Lanthanide complexes are widely employed as shift reagents in NMR spectroscopy,[1] catalysts in organic synthesis and biotechnology,[2] and probes for fluorescence/MRI sensing.[3] We recently demonstrated that lanthanide tris(β-diketonate)s and tetraphenylporphyrin complexes offered efficient extraction of unprotected amino acids under neutral pH conditions and also acted as circular dichroism (CD) probes capable of chirality sensing of the bound guests.[4,5] In these systems, the central lanthanide(III) ions were electrically neutralized by coordination from the diketonate and/or porphyrinate anions, with the additional CO_2^- group of the guest amino acids forming highly coordinated complexes.[4] Since zwitterionic amino acids are hydrophilic and bifunctional guests, more effective receptors should have multiple binding sites highly complementary to the NH_3^+ and CO_2^- sites of the guest. Thus, we designed a novel type of conjugate receptor for synergistic binding of zwitterionic amino acids in which a benzo-18-crown-6 moiety is covalently connected to the lanthanide porphyrin complex **1**–**3**. Because benzo-18-crown-6 coordinates to the NH_3^+ moiety and since lanthanide porphyrinate binds the CO_2^- moiety, these conjugates with two different kinds of binding sites within a molecule are expected to offer multiple binding of zwitterionic, chiral amino acids and sensitive CD probing of their chirality.[6]

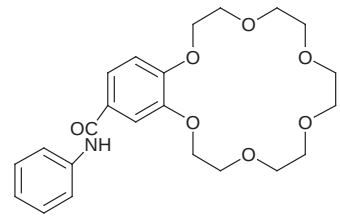
6 M = Yb



7

Conjugates **1**–**3** were prepared from lanthanide tris(acetylacetonate)s and the corresponding crowned porphyrin ligand,[7] which was derived from amino-substituted tetraphenylporphyrin and 4-chlorocarbonylbenzo-18-crown-6. Their receptor–probe abilities were characterized by liquid–liquid extraction of amino acids and subsequent CD measurements. The concentrations of the amino acids in the aqueous phases were determined, based on UV spectroscopy and/or amino acid analysis (ninhydrin colorimetry). Mixtures of lanthanide porphyrin complexes and benzo-18-crown-6 derivatives,[7,8] *i.e.* **4** + **7**, **5** + **7** or **6** + **7**, were also examined to compare the 'intermolecular' cooperativity of two different binding sites with the 'intramolecular' one.

Porphyrinatoerbium–crown ether conjugate **1** offered efficient extraction of several amino acids from neutral aqueous solution into CH_2Cl_2 solution (Fig. 1). Its extraction ability of tryptophan (Trp) (40%) is twice as high as those of **4** alone (18%) and the mixture **4** + **7** (18%). Although **4** and **7** have binding sites for CO_2^- and NH_3^+ groups respectively, the covalent connection between the two binding sites increased the extraction ability. In other words, bifunctional amino acids are believed to be cooperatively bound to the erbium center and 18-crown-6 ring of conjugate **1**. The extracted amount of Trp by conjugate **1** strongly depended on the pH of the aqueous solution, suggesting that the guest Trp was extracted in zwitterionic form: 13% (pH = 3.5) < 40% (pH = 5.7) ≃ 38% (pH = 8.1) > 28% (pH = 9.4) > 8% (pH = 10.1). When the concentration of Trp in the aqueous phase increased, the mole ratio of the extracted Trp to conjugate **1** increased and reached 0.9, suggesting 1 : 1 complexation. The organic phase was characterized using NMR spectroscopy after extraction experiments. The signals for the aliphatic protons of the extracted Trp disappeared in the presence of conjugate **1**, while those for the aromatic protons broadened but still appeared around 5.5–6.0 ppm. These observations support the suggestion that the extracted Trp locates near the erbium center and also above the porphyrin plane of conjugate **1**. This conjugate extracted a dipeptide as well as other amino acids more effectively than the mixture **4** + **7**: [extraction percentage by **1**]/[extraction percentage by **4** + **7**] = 40%/20% for tryptophanyl-glycine (Trp-Gly);

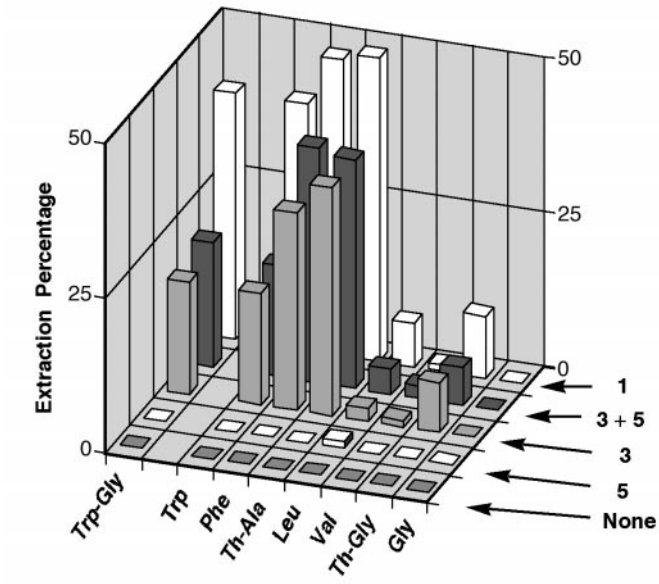


Fig. 1 Extraction of zwitterionic amino acids. Conditions: amino acid = 125 nmol, H_2O = 2.5 ml (pH = 5.9–6.2); receptor = 125 nmol, CH_2Cl_2 = 10 ml.

48%/38% for phenylalanine (Phe); 49%/37% for 3-(2-thienyl)-alanine (Th-Ala); 7%/4% for leucine (Leu); 10%/6% for (2-thienyl)glycine (Th-Gly).[9] In contrast, conjugates **2** and **3** containing gadolinium and ytterbium porphyrinates extracted Trp with comparable efficiencies to those with corresponding mixtures under the employed conditions: 39% for **2** and 34% for **5** + **7**; 14% for **3** and 10% for **6** + **7**. Thus, the nature of the lanthanide center is an important factor in designing effective conjugate receptors.

Conjugate **1** exhibited chirality-specific CD signals *via* complexation with chiral amino acids (Fig. 2). After extraction experiments with L-Trp, L-Phe, L-Th-Ala, L-Th-Gly and L-Leu guests, the resulting CH_2Cl_2 solutions gave the'reversed' S-shaped CD bands around the Soret band, while their D-isomers offered the S-shaped CD bands (Fig. 2). Their CD amplitudes ($[\theta$ at 1st $\lambda] - [\theta$ at 2nd $\lambda]/10^5$ deg cm^2 dmol^{-1}) were larger

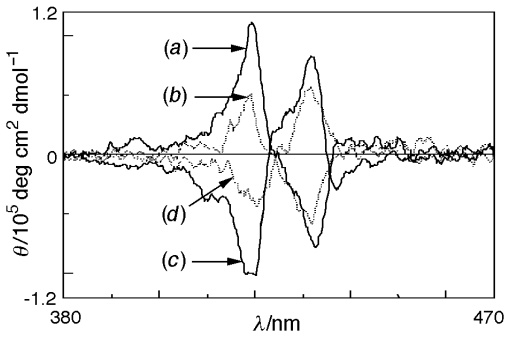

Fig. 2 CD spectra of conjugate **1** or mixture **4** + **7** in CH_2Cl_2 after shaking with an aqueous solution of L- or D-Trp. Conditions: see Fig. 1. (*a*) L-Trp·**1**, (*b*) L-Trp·**4** + **7**, (*c*) D-Trp·**1**, (*d*) D-Trp·**4** + **7**.

than those with **4** + **7**: **1** (1.9) > **4** + **7** (1.0) for L-Trp; **1** (1.8) > **4** + **7** (0.8) for L-Phe; **1** (2.3) > **4** + **7** (1.1) for L-Th-Ala; **1** (0.6) > **4** + **7** (0.5) for L-Leu; **1** (0.9) > **4** + **7** (0.4) for L-Th-Gly. Conjugate **1** was not only an effective extracting reagent of unprotected amino acids but also a sensitive CD probe for their chirality determination.

We have demonstrated that the effective cooperativity of porphyrinatoerbrium and 18-crown-6 ring promoted improved extraction of amino acids and sensitive CD probing of their chirality. A further hybridization of lanthanide complexes with receptor molecules provides promising possibilities in the development of effective sensing, transport and separation of multi-functional substrates of biological interest.

The authors are grateful to Ms M. Doe of the Analytical Center, Graduate School of Science, Osaka City University for determination of amino acid concentrations. This work was supported by a Grant-in-Aid for Scientific Research (No. 10440198) from the Ministry of Education, Science, Culture and Sports, Japan.

Diels–Alder trapping of an *o*-dinitroso intermediate in the 1-oxide/3-oxide interconversion of a 2,1,3-benzoxadiazole derivative

Muriel Sebban,[a] Régis Goumont,[a] Jean Claude Hallé,*[a] Jérome Marrot[b] and François Terrier*[a]

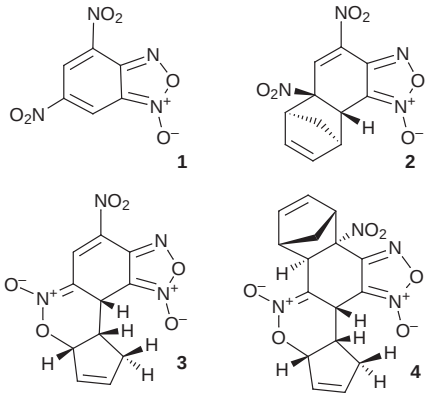
[a] *Laboratoire SIRCOB, UPRES A CNRS 8086, Bâtiment Lavoisier, Université de Versailles, 45, avenue des Etats-Unis, 78035 Versailles Cedex, France. E-mail: halle@chimie.uvsq.fr; terrier@chimie.uvsq.fr*

[b] *Institut Lavoisier, Laboratoire IREM, CNRS CO173, Université de Versailles, 45, avenue des Etats-Unis, 78035 Versailles Cedex, France*

Received (in Liverpool, UK) 16th March 1999, Accepted 21st April 1999

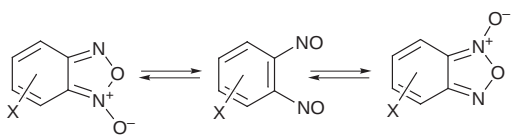
Convincing evidence is presented that the *o*-dinitroso intermediate involved in the exchange of the 1-oxide and 3-oxide tautomers of 6-nitro[2,1,3]oxadiazolo[4,5-*b*]pyridine 1-oxide 5 is the precursor of the Diels–Alder diadduct 7 isolated upon treatment of this compound with cyclohexadiene in $CHCl_3$.

The high susceptibility of the nitro-substituted 2,1,3-benzoxadiazoles to undergo covalent nucleophilic addition or substitution processes has attracted considerable attention over the two last decades, leading to numerous synthetic, analytical and biological applications.[1–8] A most significant finding has been, however, our recent discovery that the carbocyclic ring of these strongly electron-deficient heteroaromatics can also be involved in a variety of Diels–Alder type reactions.[9] As a prototype example, 4,6-dinitro-2,1,3-benzoxadiazole 1-oxide **1**



has been found to act as a dienophile in normal electron demand Diels–Alder (NEDDA) processes or as a heterodiene in inverse electron demand Diels–Alder (IEDDA) processes to give the monoadducts **2** and **3**, respectively, upon treatment with cyclopentadiene at −20 °C in $CHCl_3$. In the presence of excess cyclopentadiene at 0 °C, the IEDDA–NEDDA diadduct **4** is quantitatively formed with high stereoselectivity at the expense of **2** and **3**.[9]

Here we report our finding of another Diels–Alder reactivity pattern that we have identified in the reaction of 6-nitro[2,1,3]oxadiazolo[4,5-*b*]pyridine 1-oxide **5**[10] with cyclohexadiene. This new pattern provides convincing evidence in support of the long standing belief that the mechanism of the interconversion of the 1-oxide/3-oxide tautomers (Scheme 1) proceeds through formation of an *o*-dinitroso intermediate.[7,11,12] So far, it is only through photolysis of unsubstituted 2,1,3-benzoxadiazole and *o*-nitrophenyl azide in Ar matrices at 14 K that the existence of such an unstable species could be demonstrated by IR and UV spectroscopy.[13]



Scheme 1

Treatment of **5** with cyclohexa-1,3-diene (5 equiv.) in $CHCl_3$† affords a 2 : 1 mixture of two products which were readily separated by column chromatography and isolated as pale yellow solids. Although it has been obtained with a crystal of poor quality, the ORTEP view in Fig. 1 leaves no doubt that the major product is the diadduct **7**‡§ whose formation can only be accounted for in terms of two NEDDA processes, in which the N=O double bonds of the *o*-dinitroso intermediate **6** play the role of the dienophile contributors (Scheme 2). Such behaviour of N=O fragments is well known.[14] Based on a detailed analysis *via* COSY, HETCOR and *J* modulation experiments, the NMR data agree with the stereochemistry assigned to **7** in the solid state. The recovery of a pyridine ring on formation of **7** from **5** is supported by the disappearance in the ^{13}C NMR spectra of the

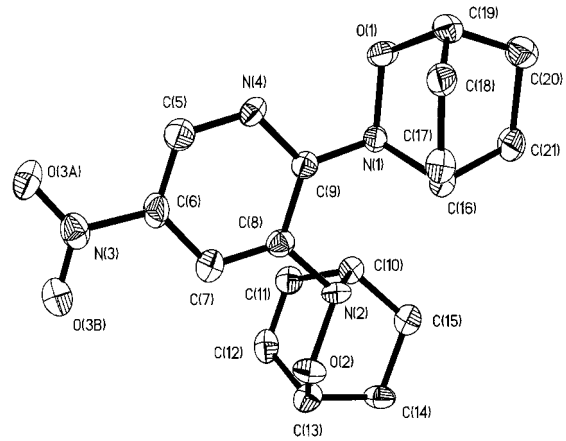


Fig. 1 ORTEP view of **7**, as derived from a partial structure solution (only one enantiomer is represented).

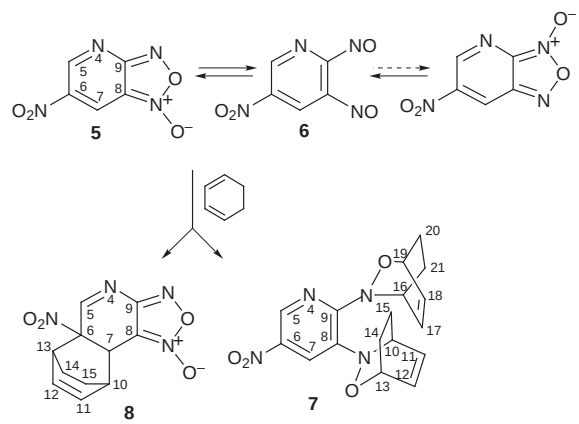
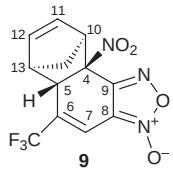


Scheme 2

resonance typical for the C_8 carbon of a 2,1,3-benzoxodiazole structure (δ_C 108.79 in **5**)[10,11] and its replacement by a resonance at δ_C 137.59 for **7**, a classical value for a pure aromatic carbon.

In view of the ^1H and ^{13}C NMR spectra also recorded in $CDCl_3$, the minor product can be formulated as the cycloadduct **8** in its racemic form. This adduct, which is not very stable in the solid state, results from a regioselective and diastereoselective NEDDA process involving the C_6–C_7 double bond of **5** as the dienophile contributor. It should be noted that the related *endo* cycloadduct **9** was recently isolated as the only product of the reaction of cyclopentadiene with 4-nitro-6-trifluoromethyl-2,1,3-benzoxadiazole.[15]



9

In the literature, many examples of 2,1,3-benzoxadiazole structures undergoing the tautomeric exchange shown in Scheme 1 have been reported,[10–12] but no firm Diels–Alder support for the transient formation of the postulated *o*-dinitroso intermediate along the reaction coordinate has been obtained so far. The isolation and characterization of the diadduct **7** *in a thermal process* is therefore of great relevance to the rearrangement shown in Scheme 1, especially because this equilibrium has been shown to be strongly shifted toward the 1-oxide tautomer in the case of the 6-nitro[2,1,3]oxadiazolo[4,5-*b*]-pyridine 1-oxide system.[10]

Notes and references

† *Synthetic procedure* for **7** and **8**: 1.3 ml of cyclohexa-1,3-diene (13.75 mmol) were added to a solution of 0.5 g of **5** (2.75 mmol) in $CHCl_3$. The solution turned rapidly orange.The mixture was maintained under stirring at room temperature for 2 d. Evaporation of $CHCl_3$ under reduced pressure gave a mixture of 7 and **8** as a red semi-solid (0.8 g). The product was purified by chromatography on silica gel using a gradient of EtOAc–pentane as eluent; **7** and **8** were obtained in a 2:1 ratio as yellow crystals.

ChemComm

Direct NMR and luminescence observation of water exchange at cationic ytterbium and europium centres

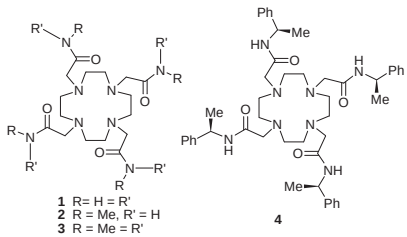
Andrei S. Batsanov, Andrew Beeby, James I. Bruce, Judith A. K. Howard, Alan M. Kenwright and David Parker*

Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE

Received (in Cambridge, UK) 22nd March 1999, Accepted 20th April 1999

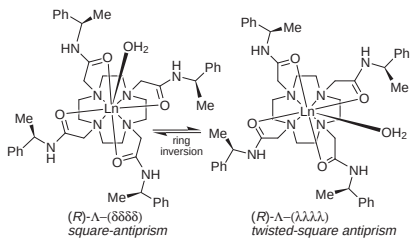
Cationic chiral Yb and Eu tetra-amide complexes, have been studied by VT NMR, luminescence and crystallography: the rate of dissociation of water is about 500 times faster at Yb than at the square antiprismatic Eu centre.

Dissociative water exchange at lanthanide ion centres has traditionally been considered to be fast, with rates of oxygen exchange of the order of 5×10^6 s^{-1} at 298 K for related nine-coordinate anionic complexes.[1] This rate is much slower for neutral[2] and cationic complexes[3] and mean water exchange rates of 5×10^4 s^{-1} occur for cationic tetra-amide complexes of gadolinium. With the europium complexes of the achiral ligands **1**–**3**, two major diastereoisomeric species exist in



solution which interconvert by cooperative arm rotation (Δ/Λ conversion) and ring inversion (δ/λ exchange). For the corresponding complexes of the enantiopure ligand **4**, arm rotation is sterically inhibited and CD and NMR studies reveal that in D_2O and CD_3OD the complex exists as a single species, with average C_4 symmetry (⩾98%). Given that the rate of water exchange has now been shown to be markedly different for two isomers of the same complex[4] (twisted square antiprismatic *vs.* square-antiprismatic, Scheme 1), we set out to examine complexes[5] of the same ligand with Eu and Yb, which exist as different, single isomeric species in solution.

The solution and solid-state structures of [Eu.**4**]$^{3+}$$(CF_3SO_3)_3$ revealed[5] a square-antiprismatic geometry about the metal centre: an (*R*) configuration at the carbon stereocentre gave rise to a left-handed (Λ) helicity with a δ configuration in each of the NCCN chelate rings. At −40 °C in CD_3CN, a resonance due to a bound water molecule was observed at δ +84.3 for [Eu.**4**]$(CF_3SO_3)_3$ (250 MHz, 10 mM complex, 80 mM H_2O) which moved to lower frequency and broadened at higher temperatures. The bound water signal could still be observed (δ_H = 60, $\omega_{1/2}$ = 750 Hz) at 295 K, while the signal for unbound water (δ *ca.* +2.5) broadened further as the temperature was raised, reaching a coalescence around 328 K,



Scheme 1

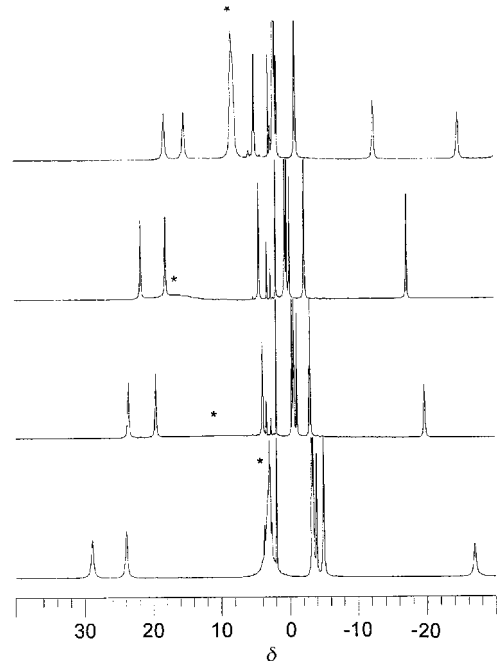


Fig. 1 Variable temperature 1H NMR spectra of [Yb.**4**(H_2O)][$CF_3SO_3)_3$ in CD_3CN (10 mM complex, 80 mM H_2O, 300 MHz) at 345, 293, 273 and 233 K, highlighting water exchange (H_2O = *).

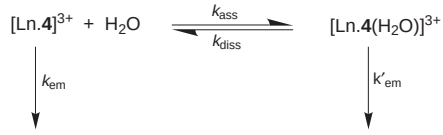
before sharpening again at temperatures in excess of 330 K. Variable temperature saturation transfer experiments at 400 MHz, allowed the rate of water exchange in the range 260–280 K to be measured. Standard ln *k vs.* 1/*T* analysis revealed that the rate at 298 K was 3600 ± 800 s^{-1}, with $\Delta G^{\ddagger}$ = 50.3 ± 2.7 kJ mol^{-1}.

For [Yb.**4**][$CF_3(SO_3)_3$], ^{1}H NMR analysis (293 K, CD_3OD, 65.3 and 300 MHz) gave shifts for the ring axial protons of δ 108.0 and −35.5 (δ 20.5/16.8 for the related 'equatorial' pair). Proton NMR chemical shifts for Yb complexes are determined primarily by the dipolar contribution and the observed shift values for the (12)ane[N_4] ring protons are entirely consistent with those obtained for tetraphosphinate complexes of 1,4,7,10-tetraazacyclododecane,[6] which exist in solution only as a *twisted* square-antiprismatic isomer (Scheme 1). The ^{1}H NMR spectra recorded in CD_3CN at −40 °C, ([Yb.**4**] = 10 mM, $[H_2O]_{tot}$ = 90 mM, 65.3 MHz) revealed a broad resonance (2H, $\omega_{1/2}$ ≈ 2800 Hz) at δ 325 consistent with an Yb-bound water molecule. On raising the temperature to 238 K, this signal broadened further ($\omega_{1/2}$ ≈ 4000 Hz) and above 240 K, the resonance was too broad to be observed. The 'unbound' water signal resonated as a relatively sharp signal at temperatures in excess of 300 K. On lowering the temperature it broadened and shifted to higher frequency, with maximal line-broadening and positive shift (δ_{H_2O} 26) around 260 K (65.6 MHz), before the signal sharpened again and resonated at δ 6 at 233 K (slow-exchange limit). An independent VT NMR study at 300 MHz (Fig. 1) gave maximal exchange-broadening and positive shift



Scheme 2

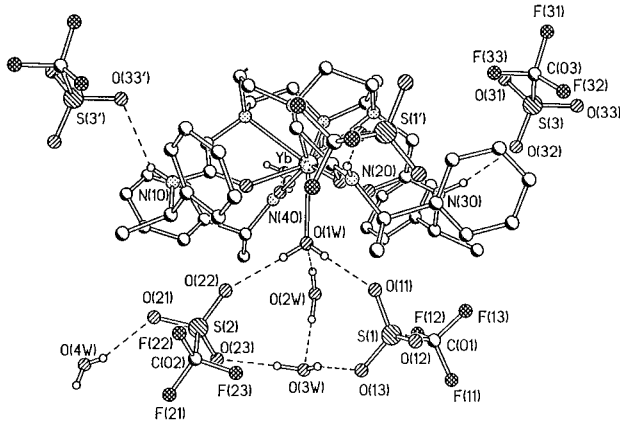


Fig. 2 View of the molecular structure of (*R*)-Λ-[Yb.**4**(H_2O)](CF_3SO_3)$_3$·3H_2O at 120 K, showing the hydrogen bonding of the inner and second sphere water molecules.

for the water signal at 283 K. Line-shape analysis for the water signal in the temperature range 293–343 K correcting for the predominant dipolar T^{-2} dependence of the chemical shift,[7] allowed the rate of water proton exchange to be measured ($\Delta\nu$ = 9.6 × 10^4 Hz at 233 K, 6.2 × 10^4 Hz at 283 K; $p^{Yb}_{H_2O}$ = 0.11, $p^{free}_{H_2O}$ = 0.89). At 298 K, the forward rate of association (Scheme 2) was 2.5 × 10^5 s^{-1}, and the rate of dissociation from ytterbium was 1.9 ± 0.7 × 10^6 s^{-1} with a free energy of activation of 34.6 ± 2.6 kJ mol^{-1}.

A single crystal X-ray diffraction analysis of (*R*)-[Yb.**4**(H_2O)]CF_3SO_3·3H_2O at 120 K revealed a nine-coordinate complex (Fig. 2)[8] with ligand Yb–N and Yb–O distances averaging 2.62 and 2.28 Å, some 0.08 Å longer than in the related europium complex.[4] The Yb–OH_2 distance of 2.44 Å was 0.01 Å longer than in the Eu analogue, but is similar to the only other Yb–water bond length reported for a nine-coordinate species.[10] The N–C–C–N and N–C–C–O torsional angles averaged +59.0 and −28.9°, consistent with a Λ(δδδδ) configuration. The twist of the N_4/O_4 planes about the C_4 axis was −39.7°, typical of a *regular* square-antiprismatic geometry at the metal centre. The selective crystallisation from water of this *minor* solution isomer at 293 K may seem surprising, but related square-antiprismatic complexes also crystallise preferentially.[9]

Luminescence from the $^2F_{5/2}$ and ^5D_o excited states of the Yb and Eu ions occurs on the micro- and milli-second timescale, respectively. The slowness of water exchange suggested that measurements of the rate constant for decay of the luminescent lanthanide excited state might allow simultaneous observation of decay from the shorter-lived nine-coordinate (Ln·OH_2) species (in which vibrational quenching to OH oscillators occurs) and from the eight-coordinate lanthanide species. The rate constant for decay of Yb luminescence in [Yb.**4**]$^{3+}$ was 1.6 × 10^5 s^{-1} at 295 K in D_2O, and a single exponential decay curve was observed. In H_2O, k_{obs} = 1.4 × 10^6 s^{-1} at 295 K, but bi-exponential decay was apparent at temperatures below 280 K. In D_2O there are no OH (or NH) oscillators available to quench the luminescence and a single exponential decay is observed: in H_2O the faster decay may be ascribed to the nine-coordinate monohydrated species, while the slower process occurs from the short-lived eight-coordinate intermediate. The rate of decay of europium emission from [Eu.**4**]$^{3+}$ was characterised by a single exponential decay profile, both in water (k_{H_2O} = 1.72 × 10^3 s^{-1}) and in dry acetonitrile (k_{MeCN} = 0.76 × 10^3 s^{-1} 293 K). The observed mono-exponential decay rate in MeCN increased as a function of added water and from a titration measuring k_{obs} as a function of added water concentration, the equilibrium constant for dissociation of water from the hydrated species was assessed to be K_d = 42 ±5 mM (298 K). Between −40 and 0 °C the rate of water exchange was sufficiently slow that independent (bi-exponential) decay was observed from the eight- and nine-coordinate species, under conditions where sufficient H_2O had been added to allow each species to be significantly populated. The proportion of the shorter-lived component (*i.e.* the species with water bound to Eu) in the bi-exponential decay increased as the temperature was lowered.

Taken together, this information is consistent with rate-limiting dissociative water exchange which occurs *ca.* 500 times faster at ambient temperature at Yb, in a twisted square-antiprismatic isomer, than at Eu in the related square-antiprismatic complex. The experiments also suggest that water (proton) exchange may be amenable to analysis by variable temperature luminescence measurements.

We thank EPSRC for support, and the Royal Society for a Leverhulme Trust Senior Research Fellowship (D. P.).

7 The T^{-2} temperature dependence of the chemical shift of the bound water resonance (2.9 Å from Yb) is an approximation, as it assumes that the contact shift (varying as T^{-1}) is not significant. Earlier work has shown that a T^{-2} dependence represents a good approximation (valid to ±10%) for the dipolar term: B. McGarvey, *J. Magn. Reson.*, 1979, **33**, 445 and references therein. The most shifted axial ring proton (3.5 Å from the Yb centre), resonating at δ 108 at 293 K (CD_3OD), showed a T^{-2} dependence of its chemical shift.

Received (in Cambridge, UK) 22nd March 1999, Accepted 28th April 1999

Two mixed-metal rhenium(I)–copper(I) and –silver(I) alkynyl complexes, $[\{\eta^2\text{-Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}\}_2\text{Cu}]\text{PF}_6$ 1 and $[\{\eta^2\text{-Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}\}_2\text{Ag}]\text{PF}_6$ 2, have been synthesized and shown to exhibit rich luminescence behaviour; the X-ray crystal structures of both complexes have also been determined.

There has been a rapidly growing interest in the chemical and physical properties of η^2-alkynyl-coordinated complexes.[1,2] Organometallic substituted alkynes $L_nMC{\equiv}CR$[3] exhibit a rich coordination chemistry with copper(I), silver(I) and gold(I) ions.[2] To the best of our knowledge, luminescence studies of π-bonded alkynyl complexes are rare[2f] despite numerous works on the luminescence behaviour of the σ-bonded counterparts have been reported.[4] With the recent reports on the successful isolation of acetylide-bridged rhenium(I) organometallics[1a,2b,e,5] and our recent efforts in incorporating metal-to-ligand charge transfer (MLCT) excited states into rhenium(I) acetylide units to make luminescent rigid-rod materials,[4d,6] we have extended our interest to utilize the luminescent alkynyl rhenium(I) complex, $\text{Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}$, to function as an η^2-ligand towards Cu^{I} and Ag^{I}. Herein are reported the synthesis, structure and luminescence behaviour of two mixed-metal rhenium(I)–copper(I) and –silver(I) alkynyl complexes, $[\{\eta^2\text{-Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}\}_2\text{Cu}]\text{PF}_6$ **1** and $[\{\eta^2\text{-Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}\}_2\text{Ag}]\text{PF}_6$ **2**.

Reaction of $\text{Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}$[6c] and $[\text{Cu(MeCN)}_4]\text{PF}_6$ in THF at room temperature in an inert atmosphere of nitrogen for 0.5 h afforded $[\{\eta^2\text{-Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}\}_2\text{Cu}]\text{PF}_6$ **1**, which was isolated as yellow crystals after recrystallization from dichloromethane–*n*-hexane. Similarly, reaction of $\text{Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}$ and $[\text{Ag(MeCN)}_4]\text{PF}_6$ in THF under similar conditions afforded $[\{\eta^2\text{-Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}\}_2\text{Ag}]\text{PF}_6$ **2** as yellow crystals. The identities of both have been confirmed by satisfactory ^{1}H NMR spectroscopy, IR, positive ESI-MS, elemental analyses,† and X-ray crystallography.‡

Figs. 1 and 2 depict perspective drawings of the complex cations of **1** and **2**, respectively, with atomic numbering. The C≡C bond lengths are in the range 1.20(1)–1.23(1) Å in **1** and 1.199(8)–1.203(8) Å in **2**, which are slightly longer than that of their precursor complex $[\text{Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}]$ of 1.199(9) Å.[6c] The bend-back angles (C–C–R) at the coordinated triple bond are 13.1(9)–18.2(9)° in **1** and 13.1(6)–14.4(6)° in **2** which are also larger than that of their precursor complex $[\text{Re(CO)}_3\text{(bpy)(C}\equiv\text{CPh)}]$ of 3.7(7)°.[6c] The interplanar angles between the MC≡C planes are 98.7 and 96.0° in the two independent molecules of **1** which is close to the expected 90° for a tetrahedrally coordinated Cu^{I} atom, and 149.0° in **2**. In addition, the bond weakening observed by IR spectroscopy of the C≡C triple bonds in **1** and **2** relative to the precursor complex (2083 cm^{-1}) further supports the π coordination mode of the alkynyl group to the d^{10} metal centres.

The electronic absorption spectra of **1** and **2** both show an intense absorption band at *ca.* 396 nm in dichloromethane solution. With reference to previous spectroscopic work on rhenium(I) diimine systems,[4d,6,7] the intense low energy absorption in the visible region is tentatively assigned as the $d_\pi(\text{Re}) \rightarrow \pi^*(\text{bpy})$ MLCT transition. The observation of the

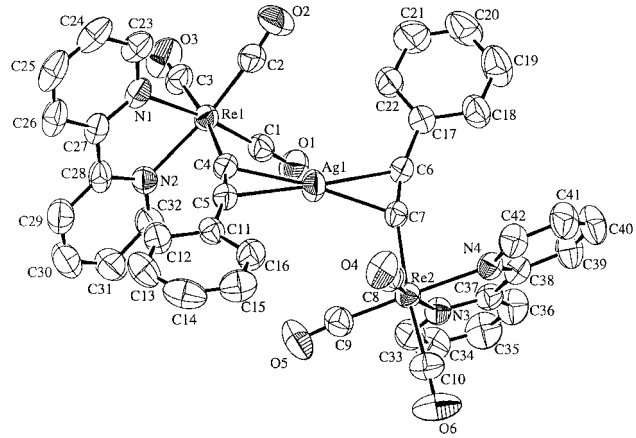

Fig. 2 Perspective drawing of the complex cation of **2** with atomic numbering. Hydrogen atoms have been omitted for clarity. Thermal ellipsoids were shown at the 40% probability level. Selected bond distances (Å) and bond angles (°): Re(1)–C(4) 2.159(6), C(11)–C(5) 1.444(8), C(4)–C(5) 1.203(8), C(4)–Ag(1) 2.257(6), C(5)–Ag(1) 2.378(6), C(6)–Ag(1) 2.382(6), C(7)–Ag(1) 2.244(6), C(6)–C(7) 1.199(8), C(17)–C(6) 1.477(8), Re(2)–C(7) 2.138(6), C(5)–C(4)–Re(1) 166.2(5), C(4)–C(5)–C(11) 166.9(6), C(6)–C(7)–Re(2) 165.9(5), C(7)–C(6)–C(17) 165.6(6).

MLCT absorption band at higher energy than that found in the related $Re(CO)_3(bpy)(C{\equiv}CPh)$ precursor, which absorbs at *ca.* 420 nm in dichloromethane, is supportive of a lower-lying $d_\pi(Re)$ orbital in **1** and **2**, resulted from the weaker π-donating ability of the acetylide ligand upon π-coordination to the d^{10} metal ions.

Excitation of **1** and **2** both in the solid state and in fluid solutions resulted in orange luminescence,† with emission lifetimes of 0.18 and 0.16 μs in dichloromethane solutions, respectively, which are attributed to the ^{3}MLCT phosphorescence. Similar to the absorption studies, the close resemblance of the MLCT emission energies of **1** and **2** is suggestive of the similar σ- and π-donating properties of the acetylide ligand upon coordination to Cu^I and Ag^I. It is also interesting that both **1** and **2** emit at higher energies than their precursor complex, *i.e.* the emission energies in CH_2Cl_2 follow the order: **1** (590 nm) ≅ **2** (600 nm) > $Re(CO)_3(bpy)(C{\equiv}CPh)$ (654 nm).[6c] The observation of a blue shift in emission energies on going from $Re(CO)_3(bpy)(C{\equiv}CPh)$ to **1** and **2** is in line with the assignment of a ^{3}MLCT [$d_\pi(Re) \rightarrow \pi^*(bpy)$] origin and disfavours the assignment of a ^{3}MLCT [$d_\pi(Re) \rightarrow \pi^*(C{\equiv}CPh)$] origin. Such a trend can be rationalized by the fact that the acetylide ligand would become a poorer electron donor upon coordination to Cu^I or Ag^I, and as a result, the energy of the Re d_π orbitals would be lowered, leading to a higher ^{3}MLCT emission energy.

Communication 9/02273B

Synthesis and molecular structure of vanadium(III) dithiolate complexes: a new class of alkene polymerization catalysts

Zofia Janas,[a] Lucjan B. Jerzykiewicz,[a] Raymond L. Richards[b] and Piotr Sobota*[a]

[a] *Faculty of Chemistry, University of Wrocław, 14 F.Joliot-Curie, 50-383 Wrocław, Poland. E-mail: plas@wchuwr.uni.wroc.pl*

[b] *Nitrogen Fixation Laboratory, John Innes Centre, Norwich Research Park, Norwich, UK NR4 7UH*

Received (in Basel, Switzerland) 3rd February 1999, Accepted 24th April 1999

The synthesis and catalytic activity in ethylene polymerization of new vanadium complexes of 2,2′-oxydiethanethiolate [$O(CH_2CH_2S)_2^{2-}$] are described; the complexes [V(μ-DIPP)$_2${$O(CH_2CH_2S)_2$}Li(MeCN)$_2$] and [V(DIPP)-{$O(CH_2CH_2S)_2$}(py)] [DIPP = ($OC_6H_3Pr^i_2$-2,6)$^-$] have been structurally characterized.

The synthetic development of well defined single-site vanadium catalysts for alkene polymerization is of extremely high industrial importance[1,2] because such catalysts are able to produce high molecular weight polymers with narrow molecular weight distribution as well as α-olefin copolymers with high α-olefin incorporation.[3,4] A recent trend has been the incorporation of sulfur-containing ligands: *e.g.* (TBP)$TiCl_2$/MAO catalyst [TBP = 2,2′-thiobis(6-*tert*-butyl-4-methylphenoxide, MAO = methylaluminoxane] was ten-fold more effective in ethylene polymerization than are metallocenes catalysts.[5,6] Moreover, it is well known that vanadium-based enzyme *nitrogenase* in which vanadium is thought to be bound to sulfur-, oxygen- and nitrogen-donor ligands is able to convert acetylene into ethylene and ethane.[7] These aspects of vanadium catalysis prompted us to prepare novel vanadium compounds with thiolate ligands such as 2,2′-oxydiethanethiolate [$O(CH_2CH_2S)_2^{2-}$] and study their reactions with alkenes, particularly their potential as precursors of new ethylene polymerization catalysts.

Studies of the oxidation state of active vanadium catalysts for ethylene polymerization by different investigators has led to the proposal that V^{III} and V^{II} represent the important oxidation states in the ethylene polymerization process.[8,9] Herein we report the synthesis, structural characterization and catalytic activity of the vanadium(III) heterodinuclear complexes [V(μ-DIPP)$_2${$O(CH_2CH_2S)_2$}Li(L)$_2$] **1**, **2** and the mononuclear complex [V(DIPP){$O(CH_2CH_2S)_2$}(py)] **3** [DIPP = (OC_6H_3-Pr^i_2-2,6)$^-$, py = C_5H_5N; L = THF **1** or MeCN **2**].

Dark pink [V(μ-DIPP)$_2${$O(CH_2CH_2S)_2$}Li(THF)$_2$] **1** was prepared by reaction of [V(μ-DIPP)$_2$(DIPP)$_2$Li(THF)][10] with an excess of $O(CH_2CH_2SH)_2$ in a mixture of hexane–THF [eqn. (1)].

$$[V(\mu\text{-DIPP})_2(DIPP)_2Li(THF)] + O(CH_2CH_2SH)_2 + L \rightarrow [V(\mu\text{-DIPP})_2\{O(CH_2CH_2S)_2\}Li(L)_2] + 2DIPPH \quad (1)$$

L = THF **1** or MeCN **2**

Recrystallization of **1** from MeCN gave new X-ray quality red crystals of [V(μ-DIPP)$_2${$O(CH_2CH_2S)_2$}Li(MeCN)$_2$] **2** [eqn. (1)]. Addition of pyridine to toluene solutions of compounds **1** and **2** breaks up the heterodinuclear structures forming the monomeric species [V(DIPP){$O(CH_2CH_2S)_2$}(py)] **3** in 85% yield (eqn. (2)].

Complex **3** can be also prepared but in lower yield (53%), by reaction of [V(DIPP)$_3$(py)$_2$][11] with 1 equiv. of $O(CH_2CH_2SH)_2$ in toluene. The temperature independent (80–293 K) magnetic moments of 2.6 and 2.7 μ_B per vanadium atom in **2** and **3** respectively, are consistent with non-interacting d^2 centres.

$$[V(\mu\text{-DIPP})_2\{O(CH_2CH_2S)_2\}Li(THF)_2] + py \rightarrow [V\{O(CH_2CH_2S)_2\}(DIPP)_3(py)] + Li(DIPP) + 2THF \quad (2)$$

3

The crystal structure of the heterodinuclear complex **2** is shown in Fig. 1.† Complex **2** contains a five-coordinate V^{III} center adopting a slightly distorted trigonal bipyramidal geometry. Two sulfur atoms from the $O(CH_2CH_2S)_2^{2-}$ ligand and an aryloxide oxygen O(21) of DIPP occupy the equatorial positions. The second aryloxide oxygen O(11) and the ether oxygen O(1) from the $O(CH_2CH_2S)_2^{2-}$ group fill the axial sites. Both aryloxide oxygen atoms are engaged in the bridging interaction to Li, inducing distortion from the ideal trigonal bipyramidal geometry. A similar double-bridged V(μ-DIPP)$_2$Li unit is present in the starting material [V(μ-DIPP)$_2$(DIPP)$_2$-Li(THF)]. The average V–S(thiolate) distance in **2** is 2.290(4) Å, within the range expected for V–S single bonds and comparable to other vanadium(III) thiolato complexes.[12–15]

The X-ray analysis of **3** reveals a mononuclear complex [V(DIPP){$O(CH_2CH_2S)_2$}(py)] with slightly distorted trigonal-bipyramidal coordination around the vanadium centre (Fig. 2).† The V–S and V–O(aryloxide) bond distances in the equatorial plane [V–S 2.2970(9), 2.2987(8) Å; V–O 1.8619(13) Å] do not differ significantly from those found in complex **2**. The V–N

Selected bond lengths (Å): V–S(1) 2.2970(9), V–S(2) 2.2987(8), V–O(1) 2.1195(14), V–O(2) 1.8619(13), V–N 2.1306(17).

Table 1 Polymerization[a] of ethylene with vanadium–$MgCl_2$–$AlEt_2Cl$ catalysts

Catalyst system	T/K	Productivity[b]/ kg(g V h)$^{-1}$	M_w/M_n	d/g cm^{-3}
1/$MgCl_2$/$AlEt_2Cl$	323	39	2.7	0.964
3/$MgCl_2$/$AlEt_2Cl$	323	20	3.8	0.961

[a] *Conditions:* $[V]_0$ = 0.02 mmol dm^{-3}, [Al] = 10 mmol dm^{-3}, Mg : V = 10, $P_{ethylene}$ = 0.6 MPa. [b] Mass in kg of polymer formed per g of vanadium atoms in 1 h.

distance is also near the values observed in the other V^{III}–pyridine complexes.[11]

Compounds **1** and **3**, in combination with $AlEt_2Cl$ and $MgCl_2$, are highly active towards ethylene polymerization.[16] Yields and polymer characterization data are listed in Table 1. The amount of polyethylene (PE) produced by the catalysts is comparable to the catalyst based on VCl_3.[17] The molecular weight distribution M_w/M_n of the PE obtained in the first catalytic system is < 3, and in the second one is > 3. These findings indicate that the polymerization process in **1**/$MgCl_2$/$AlEt_2Cl$ proceeds on a single vanadium site in a homogeneous system, however for **3**/$MgCl_2$/$AlEt_2Cl$ a heterogeneous system appears to operate. Hence, the catalytic activity of the **1**/$MgCl_2$/$AlEt_2Cl$ system is almost twice that of the **3**/$MgCl_2$/$AlEt_2Cl$ system.

To our knowledge complexes **1** and **3** represent the first examples of vanadium-thiolate catalyst precursors for ethylene polymerization. We suggest that the V{O(CH_2CH_2S)$_2$} moiety is maintained in the catalyst assembly and that the geometry of such catalytic species plays an important role in determining the reactivity. It is worth noting that vanadium catalysts are very important in ethylene–propylene rubber production.[18]

The authors thank the State Committee for Scientific Research for financial support of this work (Grant No. 3 T09A 131 15), and Dr Krzysztof Szczegot of the University of Opole for preliminary polymerization tests.

Notes and references

† *Crystal data for* **2** *and* **3**: The crystals were sealed in glass capillaries under a dinitrogen stream. Preliminary examination and data collections were carried out on a KUMA KM-4 four-circle diffractometer[19] using graphite-monochromated Mo-Kα radiation (0.71073 Å) with ω-2θ scan mode. The structures were solved by direct methods (SHELXS97)[20] and refined on F^2 by full-matrix least-squares (SHELXL97).[21] The carbon bonded H-atoms were included in calculated positions and refined using a riding model with isotropic displacement parameters equal to 1.2 U_{eq} of the attached C atom. *Crystal structure analyses*: **2**: $C_{32}H_{48}LiN_2O_3S_2V$, M = 630.72, monoclinic, space group $C2/c$, a = 27.297(5), b = 18.880(4), c = 17.444(3) Å, β = 126.76(3), U = 7203(2) Å^3, Z = 8, D_c = 1.163 Mg m^{-3}, μ = 0.422 mm^{-1}, F(000) = 2688. A total of 4086 reflections with $2\theta \leqslant 50°$ were collected, of which 3463 had $I \geqslant 2\sigma(I)$. Final residuals are R_1 = 0.0357, wR_2 = 0.1007 and GOF = 1.075 for 380 variables.

3: $C_{21}H_{30}NO_2S_2V$, M = 443.52, monoclinic, space group $P2_1/n$, a = 10.022(3), b = 12.156(4), c = 18.628(4) Å, β = 98.44(3)°, U = 2244.8(11) Å^3, Z = 4, D_c = 1.312, μ = 0.643 mm^{-1}, F(000) = 936. A total of 3526 reflections with $2\theta \leqslant 50°$ were collected, of which 3108 had $I \geqslant 2\sigma(I)$. Final residuals are R_1 = 0.0269, wR_2 = 0.0760 and GOF = 1.124 for 248 variables.

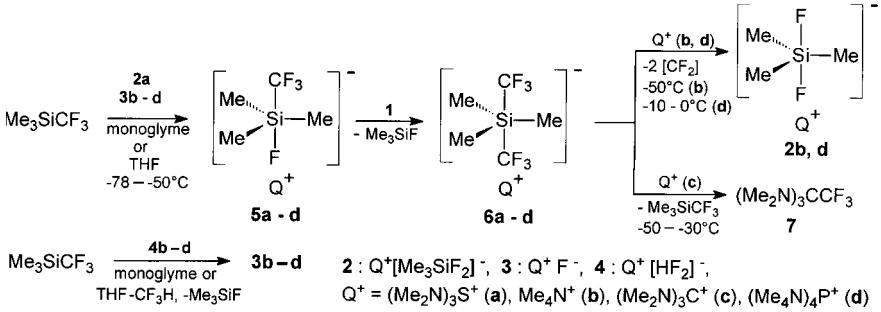
Received (in Cambridge, UK) 11th March 1999, Accepted 20th April 1999

(Trifluoromethyl)trimethylsilane, CF_3SiMe_3 reacts with $[(Me_2N)_3S]^+[Me_3SiF_2]^-$, Q^+F^- and $Q^+[HF_2]^-$ (Q^+ = Me_4N^+, $[(Me_2N)_3C]^+$, $[(Me_2N)_4P]^+$) at −70 to 50 °C to afford the first hypervalent silicon species, $[(CF_3)_2SiMe_3]^-$ with five Si–C bonds (stable in monoglyme up to −10 °C) as the main reactive species whose molecular structure was determined by X-ray crystallography.

One of the most useful reagents for anionic trifluoromethylation of different organic and organometallic electrophiles is (trifluoromethyl)trimethylsilane.[1,2] The instability of the corresponding lithium and magnesium counterparts (CF_3Li and CF_3MgX decompose even at −100 °C) and the reduced nucleophilicity of trifluoromethyl derivatives of zinc, cadmium and copper makes CF_3SiMe_3 indispensable in many cases.[3,4] For the generation of 'CF_3^-' in the presence of a catalytic[4] or stoichiometric[5] quantity of fluoride anion an intermediary hypervalent silicon species has not so far been found.[4,6a] This led to the conclusion[4] that the highly basic nature of the 'CF_3^-' anion together with the high propensity to eliminate α-fluoride renders the pentavalent CF_3 intermediate elusive. Investigation of the Me_3SiCF_3–$Me_4N^+F^-$ system in CD_3CN revealed Me_3SiF and CF_3D as the only reaction products.[4] Furthermore, if Me_3SiCF_3–$Me_4N^+F^-$ is reacted in MeCN the anion $[Me_3Si(CH_2CN)(F)]^-$ was found, but no CF_3 containing the hypervalent silicon derivative was found.[6b] It is noteworthy that the generation, structures and spectral properties and reactivities of fluorosiliconates $[R_nSiF_{5-n}]^-$ and $[R_nSiF_{6-n}]^{2-}$ (n = 1–3) have been extensively studied.[7] Despite the fact that fluorine directly bonded to hypervalent silicon has a stabilizing effect, no reports have appeared, to the best of our knowledge, describing their isolation and reliable characterization of $[(CF_3)_2SiF_3]^-$ and $[CF_3SiF_4]^-$ in the solid state.[8a] Lithium pentaphenylsiliconate was observed in solution at −80 °C.[8b] Investigation of species formed in the course of Me_3SiCF_3 interaction with fluoride ions is very important for designing selective high-yield trifluoromethylation procedures of synthetical and possible practical use.

Studying the Lewis acidic properties of $P(CF_3)_3$ we observed that a 1 : 2 : 1 mixture of $[(Me_2N)_3S]^+[Me_3SiF_2]^-$–$CF_3SiMe_3$–$P(CF_3)_3$ in THF yielded the stable acyclic phosphoranide, $[P(CF_3)_4]^-$ at −55 °C together with 5–10% $[P(CF_3)_3F]^-$ impurity.[9] However, if Me_4NF–CF_3SiMe_3(1 : 2–2.5), forming a clear solution at −60 °C in glyme was used and $P(CF_3)_3$ was added at −60 °C, analytically pure $[P(CF_3)_4]^-$ was obtained.[10] A trifluoromethylating species has been pre-generated, which we tried to elucidate by reacting CF_3SiMe_3 with a range of fluoride ion sources.

Here we report results obtained for CF_3SiMe_3 **1** reactions with $Q^+[Me_3SiF_2]^-$ **2a**,[11,12] Q^+F^-, **3b–d** and $Q^+HF_2^-$, **4b–d** [**a**: Q^+ = $(Me_2N)_3S^+$, **b**: Q^+ = Me_4N^+,[13] **c**: Q^+ = $[(Me_2N)_3C]^+$,[14] **d**: Q^+ = $[(Me_2N)_4P]^+$[15]).† When **1** was added to a suspension of **2a** or **3b–d** (2 : 1 ratio) in monoglyme at −50 °C or in THF at −78 °C, the solids were immediately dissolved to form a stable colourless solution of the siliconates, $Q^+[(CF_3)_2SiMe_3]^-$, **6a–d** in 95% yield (Scheme 1) with δ_F in the range −63.6 to −63.8, approximately 3.2–3.6 ppm downfield of the CF_3SiMe_3 resonance.‡§ After recrystallization of **6a** monitored by ^{19}F NMR spectroscopy only *one* species with δ_F −63.7 was present, namely $(Me_2N)_3S^+$ $[(CF_3)_2SiMe_3]^-$ **6a** the first isolated pentacoordinate silicon species having five Si–C binds, proven by single-crystal X-ray structural determination (Fig. 1).¶ The new compound is stable in the solid state upto 0 °C but decomposes exothermally at 0–5 °C with the formation of **2a**. The same reaction has been observed in monoglyme solution of **6b** at −30 °C with the quantitative formation of $Me_4N^+[F_2SiMe_3]^-$ **2b** proven by ^{19}F NMR and single-crystal X-ray diffraction.‖ The corresponding **6d** decomposes at −10–0 °C to give **2d**. Obviously, the size of the counter ion plays an important role in the thermal stability of $[(CF_3)_2SiMe_3]^-$.[8b] Expected reaction



Scheme 1

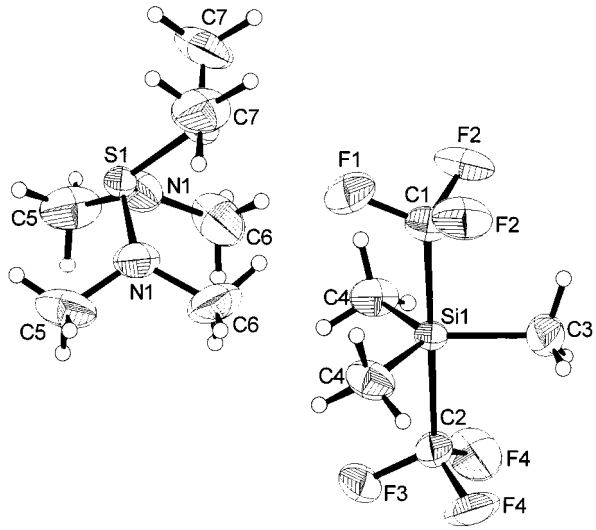


Fig. 1 Crystal structure of **6a** with thermal ellipsoids. Selected bond lengths (pm) and angles (°): Si(1)–C(1) 205.6(4), Si(1)–C(2) 206.2(4), Si(1)–C(3) 188.2(5), Si(1)–C(4) 188.6(3); C(3)–Si(1)–C(4) 120.85(12), C(3)–Si(1)–C(1) 91.0(2), C(3)–Si(1)–C(2) 89.6(2), C(1)–Si(1)–C(2) 179.40(19).

products[16] of difluorocarbene with monoglyme or THF were not detected. Addition of **1** to **3c** in THF at −80 °C afforded **6c** (δ_F −63.7) as the sole product, which upon warming to −50 °C gave slowly $(Me_2N)_3CCF_3$ **7** and **1** (Scheme 1), at −30 °C the formation of **7** proceeds much faster and was complete in 1 h along with gaseous Me_3SiF and CF_3H impurity.†† In the case of hydrogen difluorides and compound **1**, a 1 : 3 ratio has to be applied to convert **4b–d** at −80 °C into the fluorides **3b–d** under formation of CF_3H and Me_3SiF (Scheme 1) and subsequently **6b–d** are formed.

Probably the siliconates **5a–d** containing the $[(CF_3)Si(F)Me_3]^-$ anion were produced initially as intermediates releasing $[CF_3]^-$ to attack CF_3SiMe_3 yielding $[(CF_3)_2SiMe_3]^-$. So far, there is no direct spectroscopical observation of $[(CF_3)Si(F)Me_3]^-$, whereas the isoelectronic phosphorane, $(CF_3)P(F)Me_3$ could be isolated and fully characterized.[17]

The single crystal X-ray structure determination of **6a** showed almost ideal trigonal-bipyramidal geometry at silicon [C(1)–Si(1)–C(2) 179.40(19), C(3)–Si–C(1) 91.0(2) and C(3)–Si–C(4) 120.85(12)°] with a rather long[4] apical Si–C(1)F_3 bond [205.6(4)] and a considerably shorter equatorial Si–C(1)H_3 bond [188.2(5) pm] (*cf.* 187.4 pm in **2a**[12]). For the isoelectronic $(CF_3)_2PMe_3$ the same structure was found with shorter P–C distances[18] [P–CF_3 197.4(4) and P–CH_3 181.3(2) pm]. The geometry parameters of the cation $(Me_2N)_3S^+$ are similar to those investigated earlier.[12]

The use of the hypervalent trifluoromethylating silicon compounds for new carbon–carbon bond forming reactions and synthesis of trifluoromethylated phosphorus(v) derivatives is underway in our laboratories. The results of the study for CF_3SiF_3 and CF_3SiPh_3 interaction with the different fluoride anion sources including $(Et_2N)_3PF_2$ and Ph_3CF and reactions of $(Me_2N)_3CCF_3$ will be published in due course.

A. A. K. is grateful to the Deutsche Forschungsgemeinschaft for financial support. The generous gift of CF_3SiMe_3 by Bayer AG, Leverkusen (Germany) is gratefully acknowledged.

The isolated iron–molybdenum cofactor of nitrogenase binds carbon monoxide upon electrochemically accessing reduced states

Saad K. Ibrahim,[a] Kylie Vincent,[b] Carol A. Gormal,[a] Barry E. Smith,[a] Steven P. Best*[b] and Christopher J. Pickett*[a]

Received (in Cambridge, UK) 24th March 1999, Accepted 26th April 1999

The first spectroscopic evidence for the binding of a small gaseous molecule to the isolated iron molybdenum cofactor of nitrogenase (FeMoco) is presented: FTIR spectroelectrochemistry in a thin-layer cell shows that reduced FeMoco binds carbon monoxide and gives rise to ν(CO) stretches that are close to those observed during turnover of the enzyme.

The cofactor extract[1–3] in NMF was in the oxidised EPR-silent form, FeMoco^{ox}.† Cyclic voltammetry of FeMoco^{ox} at a vitreous carbon electrode is shown in Fig. 1. The primary reduction process [A in Fig. 1(a)] encompasses the one-electron reduction of the oxidised cofactor to the EPR-active (S = 3/2) FeMoco$^{semi\text{-}red}$ state, a process which involves reversible interconversion of redox isomers, as delineated earlier by Schultz *et al.*[4] The reduction of the semi-reduced state is observed as a poorly resolved irreversible process under argon or molecular nitrogen [B in Fig. 1(a)]. Whereas the primary process A is unperturbed by carbon monoxide, interaction with CO is evident by the resolution of process B into two successive reduction steps [C and D in Fig. 1(b)] and by the detection of two oxidisable species [E and F in Fig. 1(b)]. Purging the solution with argon or dinitrogen fully restores the response to that observed in the absence of CO. Importantly, an enzyme reconstitution assay[5] showed the cofactor to be fully active after exposure to CO for one hour.

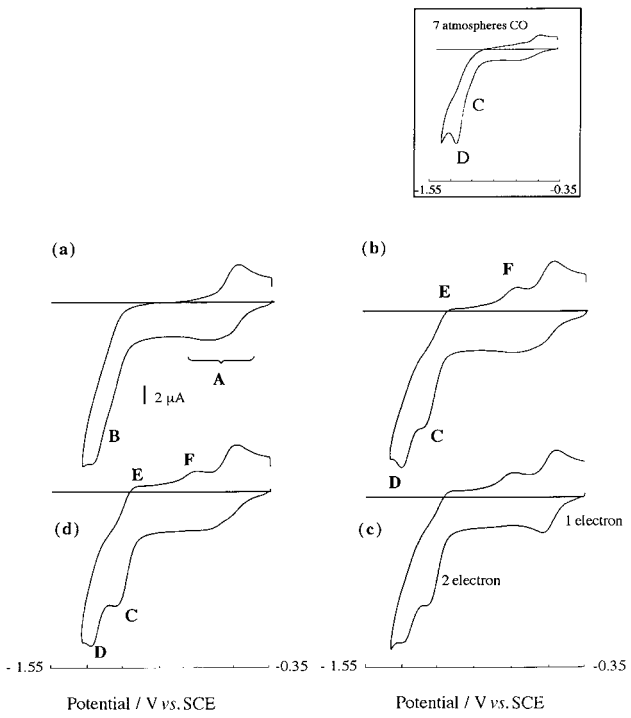

Fig. 1 (a) Cyclic voltammogram of FeMoco^{ox} (*ca.* 1.8 mM) in NMF recorded at a vitreous carbon electrode of area 0.071 cm^2 at 292 K under a dinitrogen atmosphere in a glove box operating at < 1 ppm O_2, the potential scan rate = 50 mV s^{-1}; (b) conditions as for (a) but saturated with CO at 1 atm; (c) conditions as for (b) after the addition of 1 equiv. of PhSH, the isomeric system A collapses to a single reversible one-electron process corresponding to thiolate ligation at the terminal Fe atom of the cofactor; (d) conditions as for (b) in the presence of 90 mM imidazole. Inset: cyclic voltammogram of FeMoco^{ox} recorded under CO at 720 KPa showing the increase in the height of peak D, conditions otherwise as for (b) except [FeMoco^{ox}] *ca.* 1 mM.

Variable scan-rate studies show that the intermediates detected at E and F are generated by the CO-dependent two-electron reduction process occurring at C. Process D involves further reduction and binding of CO. With increasing CO pressure, peak D increases in intensity and is shifted to more positive potentials; this is indicative of a rate-limiting interaction with CO, Fig. 1 (inset). Carbon monoxide is a powerful π-*acid* ligand, thus binding to the cofactor not unexpectedly promotes sequential two-electron transfer steps (processes C and D) *cf.* proton-coupled redox chemistry.[6]

Despite the nominal coordinatively unsaturated nature of the trigonal iron atoms of the Fe_7S_9Mo cluster in the protein and (presumably) in the isolated cofactor, neither the resting-state MoFe-protein nor the corresponding FeMoco$^{semi\text{-}red}$ state of the cofactor, interact measurably with CO. Turnover is necessary to observe MoFe-protein–CO interactions; accessing the FeMoco^{red} state is necessary to observe isolated cofactor interactions with CO, at least at pressures below 2016 kPa.

Since the cyclic voltammetry suggests that at least four electrons can be added overall to the FeMoco$^{semi\text{-}red}$ state under CO, it would not be surprising if redox chemistry associated with accessing low valent Fe and/or Mo states is involved.[7]

Direct spectroscopic evidence for the binding of carbon monoxide to reduced states of FeMoco is revealed by thin-layer FTIR spectroelectrochemistry[8] under moderate pressures (720 kPa) of CO at a highly polished vitreous carbon working electrode (2.6 mm diameter disc). Potential-dependent FTIR spectra obtained by reflectance through the thin solution layer (*ca.* 10–20 μm) are shown in Fig. 2. Two major bands develop at 1883 and 1922 cm^{-1} which we assign to terminally bound CO at reduced FeMoco states. Neither band appears under argon or dinitrogen, nor in a solution of the cofactor irreversibly damaged by exposure to air.

The band at 1883 cm^{-1} is the first to appear at high potential [compare Fig. 2(a)–(c)] and is therefore most likely associated with process C, that at 1922 cm^{-1} becomes dominant at lower potentials and is probably associated with process D [Fig. 1(b)]. Re-oxidation at E_{appl} −0.85 V *vs.* SCE selectively depletes the 1883 cm^{-1} band and gives rise to a strong new absorption at 1965 cm^{-1} and a weak band at 1999 cm^{-1} (data not shown). Re-oxidation at E_{appl} −0.45 V *vs.* SCE depletes both infrared bands. It is probable that these two oxidations are associated with processes E and F, respectively, Fig. 1(b).

Coordination of thiophenol at the terminal tetrahedral Fe atom and imidazole (Im) at the Mo atom provides a ligation environment for FeMoco akin to that of the cofactor in the

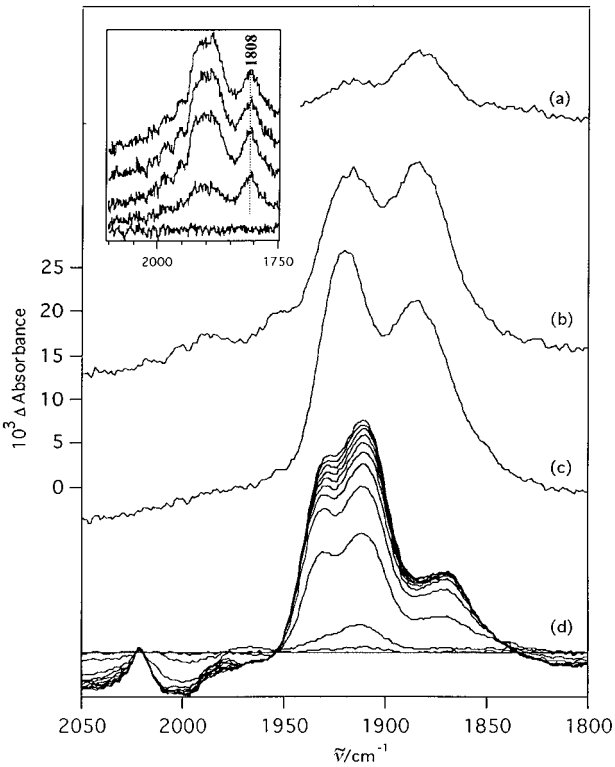

Fig. 2 Thin-layer FTIR spectroelectrochemistry of FeMoco at a highly polished vitreous carbon disc of area 0.053 cm^2 at ambient temperature. (a) Accumulated spectrum after electrolysis under CO at 720 KPa for 70 s at E_{appl} −1.05 V *vs.* SCE showing growth of bands centred on 1883 and 1922 cm^{-1}; (b) as for (a) but at E_{appl} −1.25 V *vs.* SCE; (c) as for (a) but at E_{appl} −1.45 V *vs.* SCE; (d) as for (c) showing the development of bands centred at 1870, 1910 and 1929 cm^{-1} when reduction is performed in the presence of thiophenol (*ca.* 100 mM) and imidazole (*ca.* 50 mM). Inset: development of spectra at low (pre-equibrium) concentrations of CO showing development of a band at 1808 cm^{-1}, the spectra were recorded at 12.4 s intervals.

enzyme.[1–3,9] Whereas FTIR spectra obtained in the presence of thiophenol are similar to those observed for the unmodified cofactor, the addition of imidazole has a substantial effect. This is shown by Fig. 2(d), the 1922 cm^{-1} band is split into two new bands which appear at 1910 and 1929 cm^{-1} and which develop at the same rate. This suggests that at least two CO molecules can be bound at the same cofactor molecule. Additionally, the band at 1883 cm^{-1} is shifted to 1870 cm^{-1}.

Cyclic voltammetry shows that ligation of thiophenolate collapses the redox isomerism of the FeMoco$^{ox/semi\text{-}red}$ system to that of a single reversible couple,[4] but does not otherwise perturb the voltammetry under CO [Fig. 1(c)], thus the terminal tetrahedral Fe-atom of the cofactor is unlikely to be a site at which CO binds. Imidazole does not change the form of the voltammetry under CO even at [Im] = 90 mM [Fig. 1(d)]. Evidently imidazole and CO do not compete for the same site at Mo, as is concordant with the spectroelectrochemistry.

George *et al.*[10] have recently reported that turnover of nitrogenase under CO at low partial pressure leads to the growth of a band at 1906 cm^{-1} which is replaced by an intense absorption near 1936 cm^{-1} at higher partial pressures of CO; weaker absorptions near 1958 and 1880 cm^{-1} also appear. The major bands we observe, particularly those obtained in the presence of imidazole and thiophenol, clearly fall in the spectral domain of CO interactions with the enzyme.

Hoffman and Hales[11] have proposed a model for CO interaction with the {Fe$_7$S$_9$Mo} cluster which is based on detailed isotopic EPR and ENDOR studies of the enzyme during turnover. At low [CO] they suggest the binding of CO in a bridging or semi-bridging fashion between two core Fe atoms; at high [CO] a second molecule then binds to one of these Fe atoms thereby opening the bridge and giving a species with two terminally bound CO ligands, one on each of the neighbouring Fe sites. *A priori* their data do not exclude CO binding at molybdenum nor the generation of EPR-active states produced by two- or four-electron reduction of the resting state MoFe-protein, *cf.* process C and D.

Whilst the major bands we observe for the cofactor are undoubtedly associated with terminally bound CO ligands,[12] at low [CO] a weak band at 1808 cm^{-1} precedes the growth of the 1883 and 1922 cm^{-1} absorptions, Fig. 2 (inset). This may arise from a bridging carbonyl intermediate, related to that proposed by Hoffman and Hales,[11] however a terminal CO stretch cannot be excluded.

In conclusion, direct studies of the isolated cofactor have certain advantages over studies on the whole enzyme system, notably the possibility of selectively accessing redox states; the exclusion of complications which might arise from the presence of the other metallo-sites within the MoFe- or Fe-proteins; and the opportunity to widely and systematically control both the co-ligand and the outer-sphere environment. The studies described herein take some first steps towards obtaining spectroscopic information on interactions of isolated FeMoco at redox levels not hitherto addressed, and which are complementary to studies of the whole enzyme system under turnover conditions.

We thank Glen Deacon (Monash) for providing IAB facilities, Steven Prawer for provision of machined vitreous carbon, Simon George, Graham Heath, Thierry LeGall, Ray Richards and Roger Thorneley for useful discussion. We thank the ARC and BBSRC for supporting this work and the Wilsmore Trust for funding a Visiting Fellowship (to C. J. P.).

Triscyclopenta[*cd,fg,jk*]pyrene: another congener of the externally cyclopenta-fused pyrene series

Martin Sarobe,[a] Remco W. A. Havenith[ab] and Leonardus W. Jenneskens*[a]

[a] *Debye Institute, Department of Physical Organic Chemistry, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands. E-mail: jennesk@chem.uu.nl*

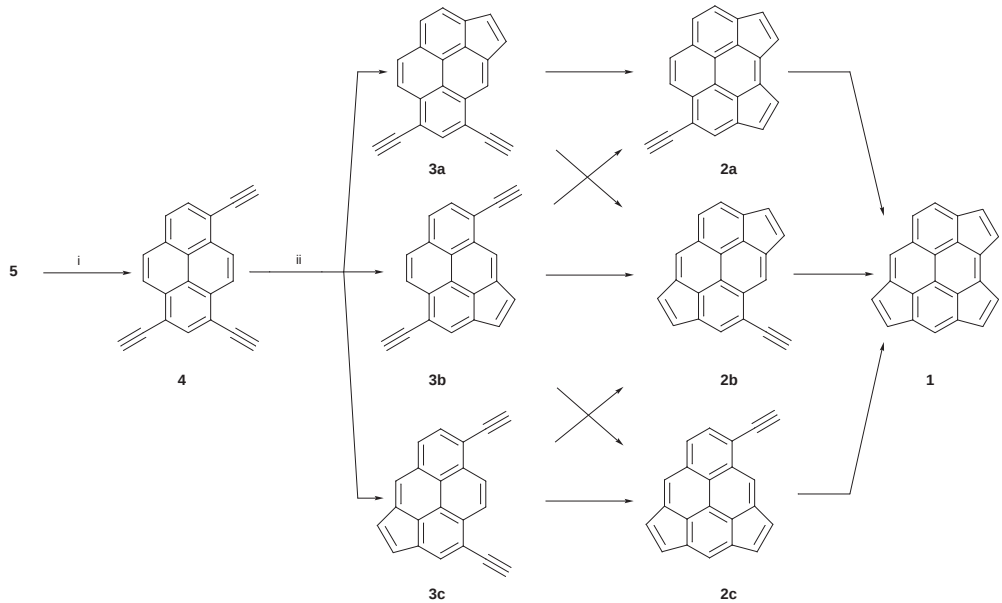
[b] *Debye Institute, Theoretical Chemistry Group, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands*

Received (in Liverpool, UK) 3rd March 1999, Accepted 23rd April 1999

Flash vacuum thermolysis of 1,3,6-tris(1-chloroethenyl)pyrene 5 between 900–950 °C gave the thermally labile triscyclopenta[*cd,fg,jk*]pyrene 1; in line with the 'conjugated circuits model' and supported by IGLO III//RHF/6-31G calculations, all hydrogen atoms of 1 are additionally shielded by 0.4–0.9 ppm (^{1}H NMR).

Flash vacuum thermolysis (FVT, 10^{-2} Torr, 1000 °C) of 1-(1-chloroethenyl)pyrene, *viz.* 'masked' 1-ethynylpyrene, quantitatively gave the ubiquitous and genotoxic combustion effluent cyclopenta[*cd*]pyrene **8** [mass recovery (MR) 90%].[1] This result supports the proposal[2] that ethynyl-substituted polycyclic aromatic hydrocarbons (E-PAH) play a pivotal role in the formation of externally cyclopenta-fused PAH (CP-PAH) effluents under high temperature conditions in the gas phase, *viz.* during combustion. Since 1-ethynylpyrene is thought to arise from C_2 and/or C_2H_2 addition to pyrene **7**,[3] we anticipated that multiple ethynyl-substituted pyrenes might be precursors for congeners of **8** containing multiple externally fused cyclopenteno units, that may represent hitherto unidentified combustion effluents. FVT of 1,6-, 1,8- and 1,3-bis(1-chloroethenyl)pyrene gave in reasonable to good yields dicyclopenta[*cd,jk*]- (**6a**), dicyclopenta[*cd,fg*]- (**6b**) and dicyclopenta[*cd,mn*]pyrene (**6c**), respectively,[4,5] which were all stable up to 1100 °C.† Subsequently, **6a–c** were indeed identified in flames as the three most abundant $C_{20}H_{10}$ CP-PAH combustion effluents.[6] Furthermore, it was shown that dicyclopenta-fusion topology markedly affects the electronic and magnetic properties of **6a-c**. Their gross ^{1}H NMR features, *i.e.* their average five- [$\delta(5)_{av}$] and six-membered ring [$\delta(6)_{av}$] ^{1}H chemical shifts, revealed that all hydrogen atoms of **6a,b** are 0.4–0.8 ppm more shielded than those of **6c** and **8** [$CDCl_3$; $\delta(5)_{av}/\delta(6)_{av}$: **6a**, 6.90/7.58, **6b**, 6.66/7.55, **6c**, 7.36/8.32 and **8**, 7.34/8.19].[4,5] These results were qualitatively rationalized using the obsolete ring perimeter model of Platt.[7] Whereas for **6a**,**b** two of the seven Kekulé resonance structures are anti-aromatic (16π-electron ring perimeter), similar anti-aromatic, ring perimeter resonance structures are unavailable for **6c** and **8**.[5,8] However Randić's conjugated circuits model,[9] which takes into account contributions of *all* possible [4*n*+2] and [4*n*] π-electron conjugated circuits, gives a better interpretation. It is readily shown that in the case of **6c** and **8** [4*n*] π-electron conjugated circuits are absent in their possible Kekulé resonance structures.

Here we report the synthesis of triscyclopenta[*cd,fg,jk*]pyrene **1** ($C_{22}H_{10}$) by FVT of 1,3,6-tris(1-chloroethenyl)pyrene **5**, *viz.* 'masked' 1,3,6-trisethynylpyrene **4** (Scheme 1),‡ and its salient spectroscopic properties. FVT (10^{-2} Torr, sublimation at 180 °C, rate 50 mg h^{-1}) of **5** (50 mg aliquots) was done at 800, 900, 950 and 1000 °C.§ In the 800 °C pyrolysate (MR 50%) the $C_{22}H_{10}$ (CP)-PAH **4** (30%),‡ the bisethynylcyclopenta[*cd*]pyrenes (**3a–c**, 20%) and traces of the ethynyldicyclopentapyrenes (**2a–c**) were identified [^{1}H NMR, GC-MS (Scheme 1)]. Surprisingly, the known $C_{20}H_{10}$, $C_{18}H_{10}$ and $C_{16}H_{10}$ (CP)-PAHs, 1,6-, 1,8- and 1,3-bisethynylpyrene (combined yield 20%),[4] 1-, 6- and 8-ethynylcyclopenta[*cd*]pyrene (combined yield 16%),[4] **6a–c** (1%),[4,5] **7** (7%) and **8** (5%),[1] respectively, were also found as side products (^{1}H NMR, GC-MS, GC-IR, HPLC). Hence, fragmentation reactions, *viz.* C_2 extrusions,[10] are competitive. At 900 °C (MR 20%) and 950 °C (MR 15%),§ instead of **4**, a novel compound (900 °C, 30% and 950 °C, 40%) was identified besides the fragmentation products



Scheme 1 *Conditions*: i, FVT (10^{-2} Torr, 800 °C); ii, FVT (10^{-2} Torr, 900 ≤ *T* < 1000 °C).

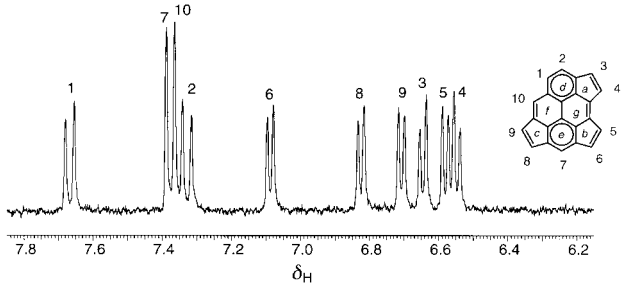


Fig. 1 ^{1}H NMR (300.13 MHz, acetone-d_6) spectrum of **1** (Table 1). See text for NICS(IGLO III//RHF/6-31G) (ref. 13) values *a–f*. (^{1}H NMR). Column chromatography (silica, *n*-hexane) of the 950 °C pyrolysate gave a pure sample (*ca.* 5 mg) that could be assigned to **1** [^{1}H, ^{13}C NMR, (HR)FAB-MS (Fig. 1)].¶ Whereas in the 950 °C pyrolysate besides **1** (40%) the $C_{20}H_{10}$ CP-PAH **6a**[4,5] (40%) is the other major product, the latter is the sole product upon FVT of **5** at 1000 °C [(MR *ca.* 10%) ^{1}H NMR, GC-MS]. In contrast with the prediction[11] that **1** represents a high temperature 'stabilomer', and the thermal stability of **6a-c**[4,5] and **8**,[1]† as well as their E-PAH precursors,[1,4] **1** and **4** are susceptible to fragmentation (C_2 extrusions[10]) under the FVT conditions.

The ^{1}H NMR chemical shifts of **1** resemble those of **6a**,**b** {Fig. 1 and Table 1 [$\delta(5)_{av}/\delta(6)_{av}$: **1** (acetone-$d_6$) 6.74/7.44, **6a** ($CDCl_3$) 6.90/7.58 and **6b** ($CDCl_3$) 6.66/7.55.[4,5]]}. This gives further credence to the applicability of the 'conjugated circuits model'.[9] Although **1** with its 17-carbon atom ring perimeter does not have any *closed shell* [4*n*] π-electron ring perimeter resonance structures, many [4*n*] (with n = 3, 4, 5) π-electron conjugated circuits can be distinguished in its available Kekulé resonance structures. Consequently, in analogy with **6a**–**b**, all its hydrogen atoms are 0.4–0.9 ppm more shielded than those of **6c** and **8** [$\delta(5)_{av}/\delta(6)_{av}$: **6c** ($CDCl_3$) 7.36/8.32[4,5] and **8** ($CDCl_3$) 7.34/8.19[1]]. This qualitative interpretation is further corroborated by *ab initio* calculations.

For **1** (C_s symmetry) a pyrene-like *ab initio* RHF/6-31G structure containing three cyclopenteno moieties with distinct sp^2–sp^2 carbon–carbon double (1.35 Å) and single (1.49 Å) bonds was obtained (Fig. 1). In addition, the IGLO III//RHF/6-31G[12] δ_H and δ_C chemical shifts of **1** were in good agreement with the experimental data (Table 1).¶ A comparison of the IGLO III//RHF/6-31G anisotropy of the diamagnetic magnetic susceptibility $\Delta\chi$ (= $\chi_{out\text{-}of\text{-}plane} - \chi_{in\text{-}plane}$)‖ of **1**, **7** and **8**, respectively, showed that **7** ($\Delta\chi$ −248.5 ppm cgs) and **8** ($\Delta\chi$ −267.2 ppm cgs) possess similar values. In contrast, $\Delta\chi$ of **1** (−206.5 ppm cgs) is substantially less negative due to changes of $\chi_{out\text{-}of\text{-}plane}$ and $\chi_{in\text{-}plane}$ (ratio $\chi_{out\text{-}of\text{-}plane}/\chi_{in\text{-}plane}$: **1**; −314.2/−107.7 = 2.9, **7**; −359.9/−92.7 = 3.9 and **8**; −333.7/−85.2 = 3.9). Hence, **1** will have a reduced ring current[12] leading to additional shielding of all hydrogen atoms. The magnetic properties of the individual rings of polycyclic **1** using the nucleus independent chemical shift criterion [NICS(I-GLO III//RHF/6-31G); 0.5 Å above each ring center[13]] reveal that the five-membered rings are anti-aromatic (*a*: 10.7, *b*: 4.8 and *c*: 5.3 ppm), the top/bottom six-membered rings are aromatic (*d*: −9.6 and *e*: −9.4 ppm) and the central ones are nearly non-aromatic [*f*: 1.3 and *g*: 0.5 ppm (Fig. 1)]. The NICS results indicate that **1**, like **7** and **8**,‖ is best represented by a Clar-type[14] structure. In going from **7** to **8** and finally **1**, the related NICS values of the five- (six-) membered rings become more positive (less negative); their anti-aromatic (aromatic) character increases (decreases).

Financial support [M. S. Basque Government (Beca de Formacion de Investigadores)], discussions with Dr J. H. van Lenthe (Utrecht University) and fruitful suggestions from a referee are acknowledged.

Notes and references

† At 1100 °C **6c** gave some **8** (16%) (ref. 4).

‡ Independent synthesis for **4**: Treatment of **5** with Na/NH_3 (l) (ref. 15) at −40 °C gave **4** (yield 40%). For **5**: Acetylation (3.5 equiv.) of **7** gave 1,3,6-trisacetylpyrene (ref. 16), which by treatment with PCl_5 (3.5 equiv. (ref. 1,4) gave **5** (overall yield 16%). Satisfactory analytical data [^{1}H, ^{13}C NMR, FT-IR, (HR)MS and/or EA] were found for **4** and **5**.

§ Only *ca.* 50% w/w of **5** sublimed into the hot zone, the remainder gave an intractable solid in the sample flask. At T ⩾ 900 °C carbonization became a competitive process. Pure **4** could not be sublimed into the hot zone; upon heating it gave an intractable solid.

Separation, isolation and characterisation of two minor isomers of the [84]fullerene C_{84}

Nikos Tagmatarchis,[a] Anthony G. Avent,[a] Kosmas Prassides,*[a] T. John S. Dennis[b] and Hisanori Shinohara*[b]

[b] *Department of Chemistry, Nagoya University, Nagoya, 464-8602, Japan*

Received (in Oxford, UK) 3rd March 1999, Accepted 19th April 1999

The first successful separation and isolation from arc-burned soot of Gd-doped composite rods of a mixture (in an abundance ratio of 3 : 2) of two minor isomers of C_{84} with molecular symmetry D_{6h} and D_{3d}, and their characterisation by ^{13}C NMR and UV-VIS-NIR absorption spectroscopy, are described.

Following the discovery and isolation in pure form of macroscopic amounts of C_{60} and C_{70}, the presence of the so-called higher fullerenes (C_n, $n > 70$) was also identified in the soot obtained by the resistive heating of graphite under an inert atmosphere. Advances in the chromatographic separation of the higher fullerenes and their endohedrally-coordinated metal complexes have allowed the quantitative isolation and characterisation of certain higher fullerenes, even in isomer-pure form.[1] Examples of these include the molecular systems C_{76}, C_{78} and C_{84}, which have all been isolated quantitatively. While C_{76} exists as a single isomer with D_2 symmetry,[2] only three of the five possible isomers of C_{78} with isolated pentagons (IPR) and symmetry C_{2v}, C_{2v}', and D_3 have been studied.[3] The situation is even more complicated for the higher fullerene C_{84}. The C_{84} molecule can exist in 24 different structural isomers obeying the 'isolated pentagon rule'. However, two of the isomers with symmetry D_2 and D_{2d} (in the ratio 2 : 1) constitute the bulk of the material and these have been isolated and characterised in isomer-pure form by ^{13}C NMR and UV-VIS-NIR absorption spectroscopy.[4] The structural properties of the pristine [84]fullerene solid ($D_2 : D_{2d} \approx 2 : 1$) have also been reported as a function of temperature[5] together with the first results of the intercalation chemistry of both isomer-pure and mixed isomer solids with potassium.[6] In addition, the two dominant isomers have been separated chemically and the structure of the D_{2d} isomer has been determined by single crystal X-ray diffraction.[7] The structural solid state properties of the isomer-pure D_2 and D_{2d} C_{84} solids also exhibit a series of structural phase transitions on cooling.[8] An attempt to identify and characterise the major and minor isomers present in the main and tail HPLC fractions of C_{84} has been already reported in the literature.[9] However, the large number of lines (one hundred and fifty four) present in the ^{13}C NMR spectra has precluded reliable identification of isomers and correct assignment of the observed lines. Here we report the first successful isolation and characterisation of [84]fullerene comprising a mixture of only two of the minor isomers with symmetry D_{6h} and D_{3d}.

Fullerenes were produced by the dc arc discharge technique and extracted with CS_2 and pyridine. In the present experiments, we have used arc-burned soot of Gd-doped (0.8 wt%) composite rods. Similar experiments employing pure or Ca-doped graphite rods did not produce similar amounts of minor isomers of C_{84}, implying a catalytic effect for the Gd atoms in the early stage of the growth of these isomers. The separation of the C_{84} isomers was achieved by the technique of recycling HPLC using a Cosmosil 5PYE column and toluene as eluent (Fig. 1). Following recycling of the sample for 135 min, we succeeded in separating a fraction of minor isomers from the two major isomers of symmetry D_2 and D_{2d}. Further recycling of the fraction of the major isomers for an additional 70 min did not reveal the presence of other isomers of C_{84}.† Theoretical calculations[10] of the stability of C_{84} isomers predict that the most stable isomers after D_2 and D_{2d} should be those with symmetry (11)C_2, (16)C_s, (19)D_{3d} and (24)D_{6h}. From the above symmetries of the minor isomers, we expect in the ^{13}C NMR spectra the appearance of 42 ($\times$2 C), 43 (41 $\times$ 2 C + 2 $\times$ 1 C), 8 (6 $\times$ 12 C + 2 $\times$ 6 C) and 5 (3 $\times$ 12 C + 2 $\times$ 24 C) lines, respectively for each of these isomers.[11]

The ^{13}C NMR spectrum of our purified sample after accumulating 200 000 scans for ten days showed 13 single distinct lines (Fig. 2) which are attributed to a mixture of the D_{6h} and D_{3d} isomers of C_{84} in the ratio 3 : 2. The observed pattern can be classified as comprising of two groups of lines whose intensity ratio is almost in the ratio 2 : 1. The group of eight intense lines can be further divided into two subgroups, one with two lines (δ 139.50, 144.78) slightly more intense, assigned to the D_{6h} isomer, and one with the remaining six lines (δ 135.23, 139.41, 139.60, 139.64, 141.34, 147.49) with slightly lower intensity, assigned to the D_{3d} isomer, in an abundance ratio of 3 : 2. The group of five less intense lines can be also divided into two subgroups; three of them have slightly higher intensity than the other two and they can be assigned to the D_{6h} isomer (δ 135.70, 138.56, 148.14). The remaining two lines (δ 136.39, 147.81) are then assigned to the D_{3d} isomer.

We also measured the UV-VIS-NIR absorption spectrum (Fig. 3) of the purified sample of the mixture of the D_{6h} and D_{3d} isomers of C_{84}. The major features of the spectra appear at 492, 578, 649, 757 and 914 nm. The absorption dip near 750 nm in the spectrum accounts for the sample being of golden yellow colour in toluene.

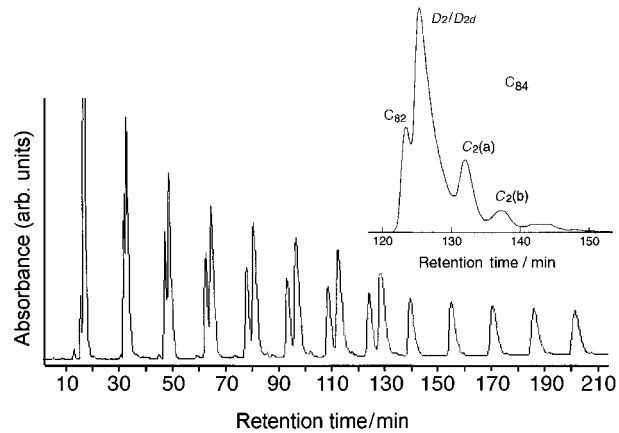

Fig. 1 HPLC profile of the second recycling phase, showing the separation of the mixture of the minor D_{6h} and D_{3d} isomers of C_{84} (second fraction with longer retention time) from its major D_2 and D_{2d} isomers (first fraction that elutes earlier). The second fraction was collected after 135 min and the first fraction was recycled for an additional 70 min. The inset shows part of an HPLC profile of the mixture obtained by using undoped graphite rods. The D_{6h} and D_{3d} isomers are absent and should have appeared between the major D_2/D_{2d} and C_2(a) isomers.

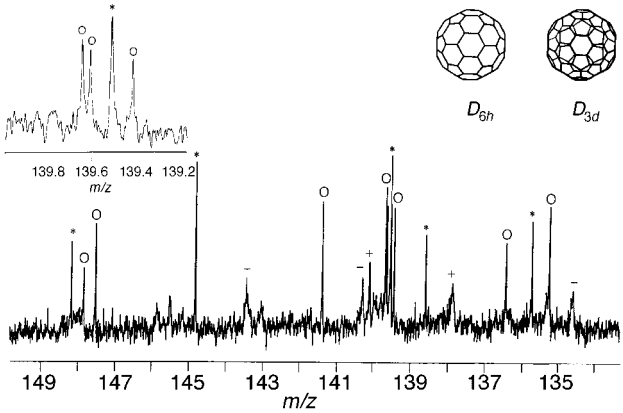

Fig. 2 ^{13}C NMR spectra [500 MHz, CS_2 solution with few drops of deuterated acetone as lock signal and $Cr(acac)_3$ as relaxant] of the purified mixture of the minor isomers D_{6h} (*) and D_{3d} (○) of C_{84}. Peaks labelled as (+) arise from the solvent (toluene) and other impurities. The region around δ139 is expanded for clarity. The inset shows the molecular structures of the two isomers.

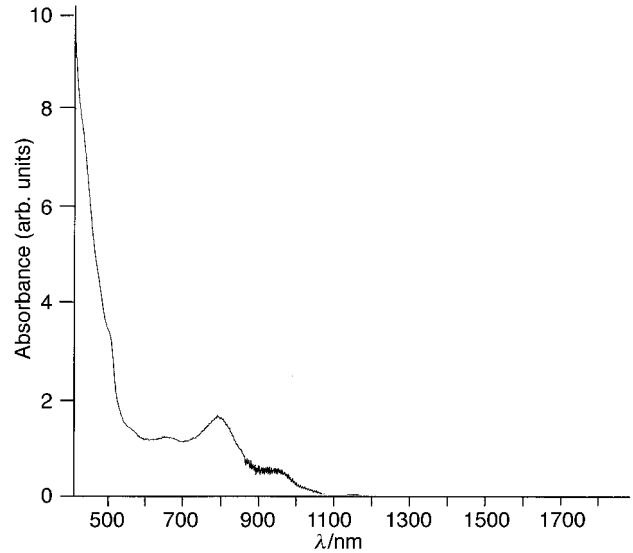

Fig. 3 UV-VIS-NIR absorption spectra of the purified mixture of the minor isomers D_{6h} and D_{3d} of C_{84}.

In conclusion, we have succeeded in separating, isolating and fully characterising by ^{13}C NMR spectroscopy a 3 : 2 mixture of the minor isomers D_{6h} and D_{3h} of the higher fullerene C_{84}.

Asymmetric dihydroxylation route to a dipeptide isostere of a protease inhibitor: enantioselective synthesis of the core unit of ritonavir

Arun K. Ghosh,* Dongwoo Shin and Packiarajan Mathivanan

Department of Chemistry, University of Illinois at Chicago, 845 West Taylor Street, Chicago, Illinois 60607, USA. E-mail: arunghos@uic.edu

Received (in Corvallis, OR, USA) 29h March 1999, Accepted 22nd April 1999

An enantioselective synthesis of the dipeptide isostere of ritonavir has been accomplished utilizing Sharpless asymmetric hydroxylation as the key step.

The utility of dipeptide isosteres in the design and synthesis of potent and selective HIV protease inhibitors has been well documented.[1] A number of peptidomimetic protease inhibitors in combination with reverse transcriptase inhibitors have now been approved for treatment of AIDS, and early indications are very promising.[2, 3] Ritonavir **1** is one such protease inhibitor which is potent, selective and clinically effective.[2a] Ritonavir consists of a unique dipeptide mimic **2** evolved from structure-based design strategies (Fig. 1).[4] Most syntheses of the ritonavir isostere start with N-protected L-amino acids and are therefore limited to natural amino acid-derived substitutents.[5] Herein we report an enantioselective synthesis of the ritonavir isostere utilizing the Sharpless' catalytic asymmetric dihydroxylation reaction as the key step.

As illustrated in Scheme 1, γ,δ-unsaturated ester **4** was prepared by addition of vinyl magnesium bromide to phenylacetaldehyde **3**, followed by Claisen rearrangement of the resulting allylic alcohol with triethyl orthoacetate in the presence of propionic acid at 145 °C.[6] Ethyl ester **4** was converted to lactone **5** utilizing Sharpless protocol.[7] Thus, ester **4** was treated with AD-mix-β and $MeSO_2NH_2$ in a mixture (1 : 1) of Bu^tOH and H_2O at 0 °C for 36 h and the resulting hydroxy ester was lactonized in the presence of a catalytic amount of AcOH in refluxing toluene for 6 h. The desired hydroxy lactone **5** was obtained in 87% yield after silica gel chromatography [$[\alpha]_D^{23}$ −58, (*c* 1.81, $CHCl_3$)]. The hydroxy lactone **5** was transformed into protected amino lactone derivative **6** in the following three steps sequence: (1) formation of the mesylate with MsCl and Et_3N in the presence of a catalytic amount of DMAP; (2) displacement of the mesylate with NaN_3 in DMF at 90 °C and (3) catalytic hydrogenation of the resulting azide over 10% Pd/C in EtOAc in the presence of Boc_2O (overall 73% yield). The benzyl side chain at C-2 in isostere **2** was installed by a stereoselective alkylation of lactone derivative **6** as described previously.[8] Thus, generation of the enolate of lactone **6** with LiHMDS in THF at −78 °C, and subsequent reaction with BnI afforded the alkylated product **7** as a single diastereomer along with a small amount (4%) of dialkylated product. Alkylated lactone **7** was separated (70% yield) by silica gel chromatography. Saponification of lactone **7** by LiOH followed by protection of the resulting hydroxy acid with TBDMSCl, imidazole in DMF afforded the TBDMS protected acid derivative **8**.[5a] Curtius rearrangement of the acid **8** with $(PhO)_2PON_3$ and Et_3N in refluxing toluene followed by addition of BnOH as described previously provided the Z-

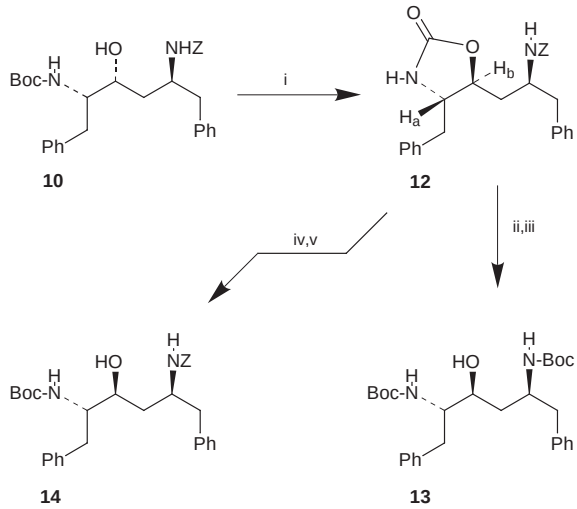
LiOH, DME, 23 °C, H_3O^+, then imidazole, TBDMSCl, DMF, 23 °C, quant. ix, $(PhO)_2PON_3$, Et_3N, PhMe, then BnOH, 130 °C, 65%; x, TBAF, THF, 23 °C, 75%.



Scheme 2 *Reagents and conditions*: i, $SOCl_2$, THF, 23 °C, 73%; ii, KOH, EtOH–H_2O (1 : 1), 70 °C; iii, THF, Boc_2O, $NaHCO_3$, 23 °C, 52%; iv, Boc_2O, Et_3N, DMAP (cat), THF, 23 °C, 93%; v, Cs_2CO_3, Pr^iOH–MeOH (6 : 1), 23 °C, 60%.

derivative **9** (overall 65% yield from **7**).[9] Removal of the silyl group by treatment with TBAF in THF at 23 °C afforded the dipeptide isostere **10** with (4*R*)-configuration. Catalytic hydrogenation of **10** over 10% Pd/C in the presence of Boc_2O and Et_3N furnished the Boc derivative **11** in 72% yield after silica gel chromatography.

In the ritonavir isostere, the (4*S*)-configuration of the hydroxy group is known to be essential for effective enzyme inhibitory properties.[2a, 5, 10] Therefore, the C-4 hydroxy group stereochemistry was inverted as depicted in Scheme 2. Reaction of **10** with $SOCl_2$ in THF at 23 °C furnished the oxazolidinone **12** (73%). The vicinal coupling constant of oxazolidinone **12** is consistent with an *anti* stereochemical relationship (J_{AB} 4.8 Hz).[11] Treatment of the oxazolidinone **12** with KOH in EtOH–H_2O (1 : 1) resulted in the cleavage of the Z group and the oxazolidinone ring. Boc protection of the free amines afforded the biologically active dipeptide mimetic **13**. Differentially protected dipeptide mimic **14** was prepared by protection of oxazolidinone **12** with Boc_2O and Et_3N in the presence of a catalytic amount of DMAP in THF followed by selective cleavage of the oxazolidinone ring by treatment with Cs_2CO_3 in Pr^iOH–MeOH (6 : 1) at 23 °C for 6 h.[12] Consistent with the previous report, dipeptide mimic **11** with (4*R*)-hydroxy configuration has shown enzyme inhibitory potency (IC_{50} value) greater than 2 mM in the assay protocol developed by Toth and Marshall.[13, 14] Inversion of the C-4 hydroxy configuration of **10** resulted in derivatives **13** and **14** with inhibitory potencies of 118 nM and 75 nM respectively. Dipeptide isostere **14** has been previously converted to ritonavir and its derivatives.[2a]

In conclusion, we have developed an enantioselective synthesis of the core unit of ritonavir by utilizing Sharpless' catalytic asymmetric dihydroxylation reaction as the key step. The present route provides access to a diverse array of protease inhibitors containing designed functionalities. Synthesis and biological evaluation of novel protease inhibitors are currently in progress.

Financial support of this project was provided by the National Institutes of Health (GM 53386). We thank Ms Hanna Cho for the protease inhibition assay.

A new combination of donor and acceptor: bis(η⁶-benzene)chromium and hexafluorobenzene form a charge-transfer stacked crystal

Catherine J. Aspley,[a] Clive Boxwell,[a] Maria L. Buil,[a] Catherine L. Higgitt,[a] Conor Long[b] and Robin N. Perutz*[a]

Received (in Oxford, UK) 3rd February 1999, Accepted 23rd April 1999

Bis(η⁶-benzene)chromium reacts with hexafluorobenzene to yield a red charge-transfer complex [Cr(η⁶-C_6H_6)$_2$•C_6F_6] which contains stacks of alternating donor and acceptor molecules with close inter- and intrastack contacts; in addition to the charge-transfer complex, formation of [Cr(η⁶-C_6H_6)$_2$]$^+$ is demonstrated by EPR and IR spectroscopy.

Non-covalent interactions have a major role in determining structures of molecular assemblies. The formation of stacks of donors alternating with acceptors can lead to special electronic and magnetic properties as in [Fe(η⁵-C_5Me_5)$_2$][TCNE] or [Fe(η⁶-$C_6Me_3H_3$)$_2$][$C_6(CN)_6$].[1,2] Stacking of aromatic rings (π-stacks) represents another motif, this time driven by quadrupolar interactions, *e.g.* in co-crystals of benzene and hexafluorobenzene.[3] Complex analogues of C_6H_6•C_6F_6 are attracting interest for their optoelectronic properties.[4,5] Bis(η⁶-benzene)chromium **1** has potential for both these types of interaction: it has featured as a donor in [Cr(η⁶-C_6H_6)$_2$][S_2O_6•2SO_2] and has been employed for crystal engineering.[6,7] Donor-acceptor (DA) complexes are also formed by **1** in [Cr(η⁶-C_6H_6)$_2$][TCNE] and [Cr(η⁶-$C_6Me_3H_3$)$_2$][TCNQ] but they are arranged in stacks of the type ⋯A_2DD⋯ or in chains.[8]

Several authors have proposed that an electron-transfer process precedes C–F bond activation of perfluoroalkanes and perfluoroarenes by transition metal complexes,[9–11] although experimental support for redox initiation is sparse. If this proposal is to be reconciled with the redox potentials, there must be either preassociation of the fluorocarbon and transition metal complex, or the products must be stabilised by rapid irreversible dissociation (*e.g.* $C_6F_6^-$ to C_6F_5 + F^-), or more likely both.[12] Crabtree *et al*. recently reported that [Fe(η⁵-C_5R_5)$_2$] (R = H or Me) associates with perfluoronaphthalene or perfluorophenanthrene in the solid state to form an irregular DA stack.[13] However, there was no optical evidence for a charge-transfer (CT) interaction. We report that **1** reacts with hexafluorobenzene to form a red CT complex in solution which crystallises as a donor–acceptor stack, and additionally that **1** undergoes one-electron oxidation by C_6F_6 to a limited extent.

When a large excess of dry hexafluorobenzene is condensed onto a freshly sublimed sample of **1** and thawed under argon, a claret-coloured solution is obtained from which crystals grow over several weeks at room temperature. The crystals have two habits, red–pink blocks and thin yellow plates, both of which are stable only in the mother liquor. An X-ray crystal structure of a red–pink crystal mounted in its mother liquor in a capillary at room temperature revealed it to be [Cr(η⁶-C_6H_6)$_2$•C_6F_6].† The structure contains face-to-face stacks of [Cr(η⁶-C_6H_6)$_2$] moieties alternating with C_6F_6 units at regular intervals of *ca*. 3.5 Å, a value similar to that in [Fe(η⁵-C_5Me_5)$_2$][TCNE].[2] The stacks lie approximately parallel to the body diagonal of the triclinic unit cell (Fig. 1) such that the benzene rings of the [Cr(η⁶-C_6H_6)$_2$] units eclipse the C_6F_6 rings in the same stack. The angle between the ring normals of the C_6F_6 and [Cr(η⁶-C_6H_6)$_2$] units is 5.9°. Each C_6F_6 lies approximately in line with one of the C_6H_6 rings in a neighbouring stack. The minimum C⋯C distance between C_6H_6 and C_6F_6 lies within a stack, while the minimum Cr⋯F distance lies between stacks (Fig. 2, Table 1). The regularly spaced DA stacks contrast with those of [Fe(η⁵-C_5Me_5)$_2$•$C_{14}F_{10}$][13] and [**1**][TCNE].[8]

We have also attempted to solve the structure of the thin yellow plates at −100 °C. Although the crystal did not diffract well, we found that the structure was little changed from that of the red–pink blocks. A compression along *b* and *c* led to a contraction of 1.9% in the minimum intrastack C⋯C distance and 3.7% in the minimum interstack Cr⋯F distance.

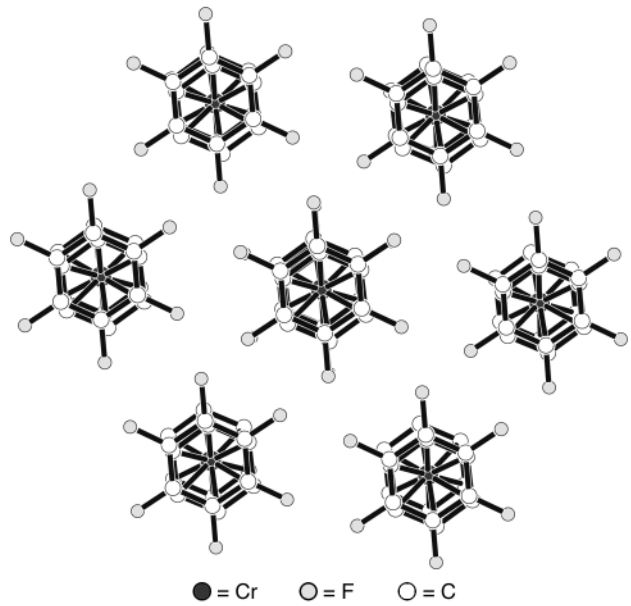

Fig. 1 Packing diagram for [Cr(η⁶-C_6H_6)$_2$•C_6F_6], viewed down the body diagonal of the triclinic cell (hydrogen atoms omitted).

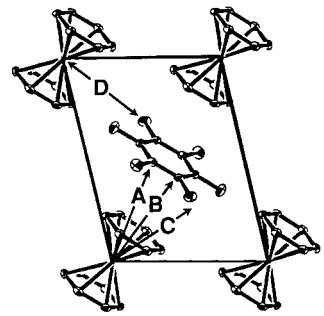

Fig. 2 ORTEP diagram (ref. 15) showing the key intra- and inter-stack spacings within the crystal structure of [Cr(η⁶-C_6H_6)$_2$•C_6F_6], viewed down the *c* axis. The hydrogen atoms are omitted for clarity. The average C–C and Cr–C bond lengths within a Cr(C_6H_6)$_2$ unit are 1.397 and 2.134 Å. For the C_6F_6 molecule, the C–C and C–F bond lengths average 1.365 and 1.341 Å.

Table 1 Minimum contact distances in the structure of [Cr(η⁶-C_6H_6)$_2$•C_6F_6]

Label[a]	Type of contact	Contact atoms	Distance/Å
A	Intrastack $C_6H_6\cdots C_6F_6$	*r*(C···C)	3.480(4)
B	Intrastack Cr···C_6F_6	*r*(Cr···C)	5.074(3)
C	Intrastack Cr···C_6F_6	*r*(Cr···F)	5.312(3)
D	Interstack Cr···C_6F_6	*r*(Cr···F)	4.490(2)

[a] labels A, B, C, D refer to Fig. 2.

When the reaction of **1** with C_6F_6 was carried out with higher concentrations of **1**, a fine yellow precipitate separated from the claret solution. A UV–VIS absorption spectrum of the solution, measured after filtering off the precipitate, showed an absorption at 503 nm and a shoulder at 390 nm.[16]‡ On freezing in liquid nitrogen, the claret solution turned to a yellow glass, but the claret colour returned on melting. The corresponding absorption maxima lie to longer wavelength (542, 414 nm) on reaction of [Cr(η⁶-1,4-$C_6H_4Me_2$)$_2$] with C_6F_6 and to shorter wavelength (424 nm)§ on reaction of **1** with C_6F_5H. These absorption bands are assigned to charge-transfer transitions of the complexes [Cr(η⁶-arene)$_2$•$C_6F_{6-n}H_n$] (n = 0, 1) which must be present in solution. Redox potentials suggest that the ground state of the complex will be close to the A•D description and the excited state close to A^+•D^-.¶

The solutions from reaction of **1** with C_6F_6 (whether dilute or more concentrated) gave a broad EPR signal at g = 1.987 consistent with formation of [Cr(η⁶-C_6H_6)$_2$]$^+$ **1**$^+$.[6] Solid-state EPR spectra of the yellow precipitate from reaction of **1** with C_6F_6 also revealed the presence of **1**$^+$ ($g_{||}$ = 2.002, $g_\perp$ = 1.983), while IR spectra showed characteristic bands of both **1** and **1**$^+$.[17] The presence of fluoride as a corresponding anion was revealed by its reaction with Me_3SiOTf yielding Me_3SiF.‖ In order to ascertain the proportion of **1** which is oxidised, we investigated the effect of addition of C_6F_6 to toluene solutions of **1**. A control sample of **1** in toluene showed only traces of **1**$^+$. On addition of 2 and 5 equiv. of C_6F_6, well-resolved resonances (A_H = 3.4 G) for **1**$^+$ were observed with intensities *ca*. 20 fold and 48 fold greater than the control, respectively. Comparison with the resonance of a standard solution of TEMPO (10^{-4} mol dm^{-3} in toluene) provided lower-limiting estimates that the solutions of **1** were 0.5 and 3.3% oxidised, respectively.** The extent of oxidation is appreciably higher than expected to arise from impurities in the hexafluorobenzene. The formation of [Cr(C_6H_6)$_2$]$^+$F$^-$ is reminiscent of the reaction of cobaltocene with perfluoroalkanes.[10]

These experiments lead to the following conclusions. (i) A donor–acceptor complex is formed between [Cr(η⁶-C_6H_6)$_2$] **1** and C_6F_6 with a long-wavelength absorption in solution, assigned to a CT transition between **1** and C_6F_6. (ii) The complex crystallises as [Cr(η⁶-C_6H_6)$_2$•C_6F_6] with a ···DADA··· stacked structure with close intra- and inter-stack contacts. The claret colour is observed in the larger crystals. The structure is probably stabilised by charge-transfer and π–π interactions. (iii) In addition to [Cr(η⁶-C_6H_6)$_2$•C_6F_6], salts including [Cr(η⁶-C_6H_6)$_2$]$^+$F— are formed in low conversion although half-wave potentials suggest that **1** is incapable of reducing C_6F_6.¶ (iv) The formation of the donor–acceptor complex and the oxidation of **1** provide support for related mechanisms for reactions of metal–hydride complexes with fluoroarenes.[11, 12]

We thank Dr T. Braun and Professors N. Connelly and W. E. Geiger for helpful discussions, the referees for helpful criticism, S. Foxon and Dr A. C. Whitwood for experimental help and the EPSRC and the European Commission for support.

Notes and references

† *Crystal data* for [Cr(η⁶-C_6H_6)$_2$•C_6F_6]: $C_{18}H_{12}CrF_6$, M = 394.28, red–pink blocks, triclinic, space group $P\bar{1}$, a = 7.3254(8), b = 9.2627(9), c = 6.6102(8) Å, α = 100.026(9), β = 112.327(8), γ = 97.532(9)°, V = 398.87(8) Å^3, Z = 1, T = 293(2) K, μ(Mo—Kα) = 0.778 mm^{-1}, F(000) = 198, 1477 reflections measured, 1401 unique (R_{int} = 0.040), 116 parameters. The crystal was mounted in a capillary in its mother liquor. The structure was solved by direct methods (SHELX) (ref. 14) and refined by full-matrix least-squares on F^2. Goodness of fit on F^2 1.083, final $R1$ [$I > 2\sigma(I)$] $R1$ = 0.0392, $wR2$ = 0.1027. CCDC 182/1238. See http://www.rsc.org/suppdata/cc/1999/1027/ for crystallographic files in .cif format.

‡ [Cr(C_6H_6)$_2$] is yellow–green with a weak band at 640 nm and an intense band at 320 nm. The corresponding cation exhibits weak bands in the near-IR region and a more intense band at 340 nm (ref. 16). The CT band of Cr(η⁶-C_6H_6)$_2$•SO_2 is observed at 540 nm (ref. 6).

§ The short-wavelength shoulder will overlap the bands of [Cr(η⁶-C_6H_6)$_2$] in C_6F_5H.

¶ The half-wave potentials of C_6F_6/$C_6F_6^-$ and [Cr(η⁶-C_6H_6)$_2$]$^+$/ [Cr(η⁶-C_6H_6)$_2$] are −2.55 and −0.68 V respectively *vs*. SCE. (ref. 18).

‖ Characterisation of the anion in the yellow precipitate was complicated by paramagnetic **1**$^+$. The precipitate was dissolved in CD_2Cl_2, Me_3SiOTf added and the volatiles condensed into an NMR tube. Me_3SiF was identified by the eight central lines of the decet at δ −157.96 (J_{HF} 7.6 Hz) in the ^{19}F NMR spectrum (ref. 19). A control experiment with C_6F_6, CD_2Cl_2 and Me_3SiOTf generated only traces of Me_3SiF.

** Complex **1** was freshly sublimed before use. Solutions in toluene (0.047 mol dm^{-3}) were made up in an argon-filled glove-box; C_6F_6 (99.9%), previously dried over molecular sieves and degassed by freeze-pump-thaw methods, was added in the box with a microsyringe. Typical impurities are C_6F_5Cl and $C_6F_5Cl_2$. Since the addition of C_6F_6 causes slight precipitation, the values of the percentage oxidation are lower limits.

Long-lived [1.1.1.1]- and [2.2.1.1]-'Isopagodane' dications: novel 4C/2e σ-bishomoaromatic dications†

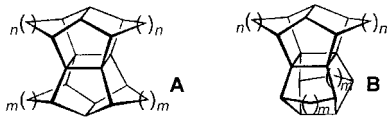
G. K. Surya Prakash,*[a] Klaus Weber,[ab] George A. Olah,*[a] Horst Prinzbach,*[b] Markus Wollenweber,[b] Markus Etzkorn,[b] Torsten Voss[b] and Rainer Herges*[c]

[a] *Donald P. and Katherine B. Loker Hydrocarbon Research Institute and Department of Chemistry, University of Southern California, Los Angeles, California 90089-1661, USA. E-mail: prakash@methyl.usc.edu*
[b] *Institut für Organische Chemie und Biochemie, Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany*
[c] *Institut für Organische Chemie, TU Braunschweig, Hagenring 30, D-38106 Braunschweig, Germany*

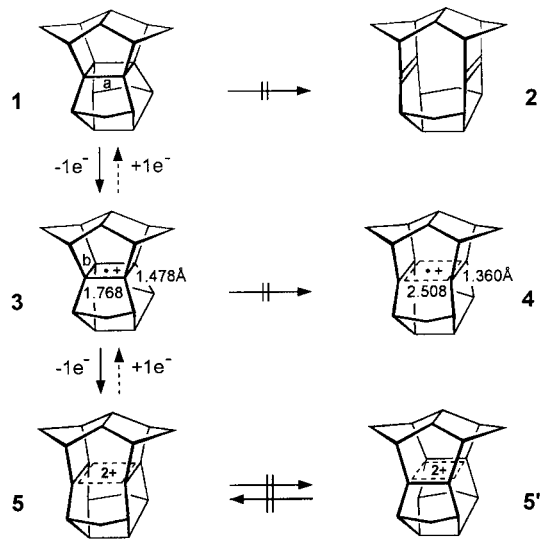
Received (in Corvallis, OR, USA) 12th February 1999, Accepted 14th April 1999

The dications generated from [1.1.1.1] and [2.2.1.1]isopagodane in SbF_5–SO_2ClF solution at −78 °C are of σ-bishomoaromatic nature (4C/2e), very similar in geometry, yet chemically different in their properties.

The [1.1.1.1]pagodane (**A**, $m = n = 1$) and functionalized derivatives have received considerable attention as intermediates in the various synthetic routes to pentagonal dodecahedranes.[1] An important theoretical aspect is linked to the central, planar, peralkylated cyclobutane ring: Two-electron oxidations had allowed the experimental verification of σ-homoaromaticity in form of the respective 4C/2e dications.[2,3] In order to gain more insight into the limiting structural and energetic prerequisites of this intriguing phenomenon—and into the intermediate 'tight' and 'extended' radical cations[4]—structural variations of the pagodane skeleton have been made by homologation[5] and 90° rotation of the two molecular 'halves' to give the isopagodanes **B**.[6]



The [1.1.1.1]- and [2.2.1.1]-isopagodanes **1** and **6** had shown rather differing behaviour upon one-electron oxidation: the radical cation of **1** (Scheme 1) was only observable in a Freon matrix (−196 °C) and was identified as a tight species (**3**, a = 1.768 Å),[7] that from **6** was persistent in fluid solution (−40 °C, CH_2Cl_2) and existed, also in the Freon matrix, in an extended configuration (**9**, a = 2.512 Å). Under cyclic voltammetry (CV) conditions only for the latter a (reversible) two-electron oxidation wave (ECE) had been recorded.[8] Apparently the iso[1.1.1.1] skeleton does not allow the expansion of tight **3** into extended **4**. Here the question is addressed whether the σ-bishomoaromatic stabilization potentially arising from two-electron oxidation of **1** and **6** would be sufficient to enforce the skeletal changes which are necessary to make the respective cyclically delocalized 4C/2e dications observable.



Scheme 1

Upon dissolution of **1** in SbF_5–SO_2ClF at −78 °C (dry ice–acetone bath) the initial dark green–blue color of the paramagnetic solution (**3**[7]) upon prolonged vortex stirring changed into the light yellow of the diamagnetic solution. The 75 MHz ^{13}C NMR spectrum[9] consisted of seven absorptions at δ_C 251.7 (s), 66.8 (d, $J_{C–H}$ 169), 66.5 (t, $J_{C–H}$ 139.6), 63.4 (d, $J_{C–H}$ 149.3), 51.2 (d, $J_{C–H}$ 163.0), 45.3 (d, $J_{C–H}$ 154.3) and 41.7 (t, $J_{C–H}$ 148.8), the 300 MHz ^1H NMR spectrum[9] of seven (two are overlapping) unresolved signals [δ_H 3.35 (br, 4H), 3.3 (br, 2H), 3.2 (br, 4H), 2.76 (br, 4H), 2.27 (br, 2H), 1.84 (br, 2H), 1.72 (br, 2H). Number and observed deshielding of carbons and protons relative to neutral **1**, in comparison with isomeric dication **15** (Fig. 1),[4] establish the C_{2v} symmetrical σ-bishomoaromatic structure **5** and exclude a rapid equilibration with degenerate **5′**. The lowering of the symmetry from D_{2d} of **1** to C_{2v} of **5** reflects distortion of the central carbon core from square to rectangular. Quenching the ion solution with cold MeOH (at −78 °C) induced two-electron reduction back to pagodane **1** (70% isolated) rather than to the much less stable diene **2** [ΔE_{rel} (**1**–**2**) = 14.68 kcal mol^{-1}, Fig. 2]. Particularly 1,4-bisaddition to give the bismethoxy ether was not observed (< 5%); in case of reference **15** the corresponding bisether had been the sole product.[2]

Exposure of **6** (Scheme 2) to similar oxidation conditions (−78 °C) produced the deep blue colour of the highly persistent extended radical cation **9**. Only after repeated vortex mixing at higher temperature (0 °C) the colour changed into pale yellow. The seven ^{13}C NMR signals of the diamagnetic solution at δ_C 238.5 (s), 67.0 (t, $J_{C–H}$ 142.9), 62.3 (d, $J_{C–H}$ 138.3), 48.0 (d, $J_{C–H}$ 148.8), 47.4 (d, $J_{C–H}$ 130.3) 43.5 (d, $J_{C–H}$ 150.2), 22.2 (t, $J_{C–H}$ 140.1) and the ^1H NMR signals (partially superimposed) at δ_H 3.26 (br, 6H), 2.88 (br, 6H), 2.66 (br, 4H), 2.08 (br d, 4H), 1.4 (br, 4H), 0.82 (br, 4H) are in line with the retention of C_{2V} symmetry in going from **6** to the σ-bishomoaromatic dication **10**. The formation of the same dication by the analogous oxidation of [2.2.1.1]isopagodadiene **7**[10] and the comparison with isomeric dication **16** (Fig. 1) provided additional confirmation. After quenching with MeOH (−78 °C) from a complex product mixture the dichlorodimethoxy- and chlorotrimethoxydienes **13** (two isomers) and **14** in the ratio ~1:2 were separated. Two-electron reduction to either **6** or **7** was not detected. A plausible explanation implies reduced *anti*-Bredt-

† Stable Carbocations, Part 309. For Part 308, see G. K. S. Prakash, V. P. Reddy, G. Rasul, J. Casanova and G. A. Olah, *J. Am. Chem. Soc.*, 1998, **120**, 13 362.

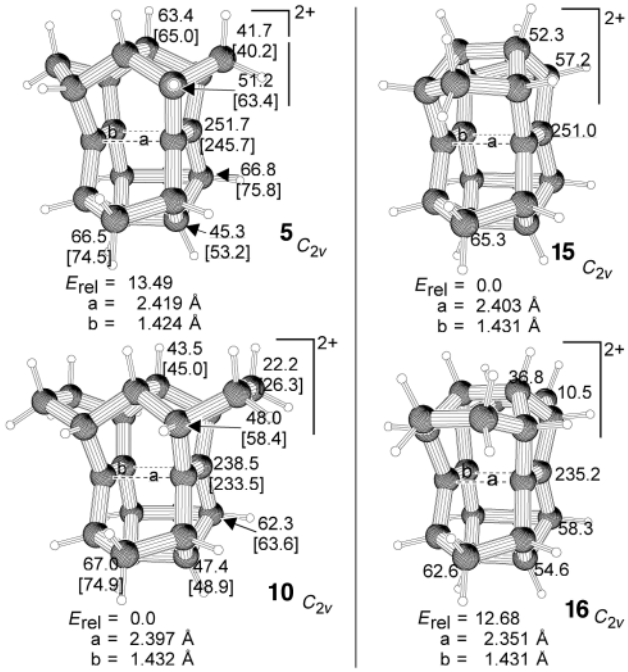


Fig. 1 B3LYP/6-31G* optimized structures, experimental and calculated (in brackets) ^{13}C NMR chemical shifts based on the DFT geometries and a GIAO B3LYP/6-31G* NMR calculation of the dications **3**, **10** (**15**, **16** as references); a and b denote DFT bond lengths; energies (E_{rel}) are given in kcal mol^{-1} and are relative to the more stable isomer.

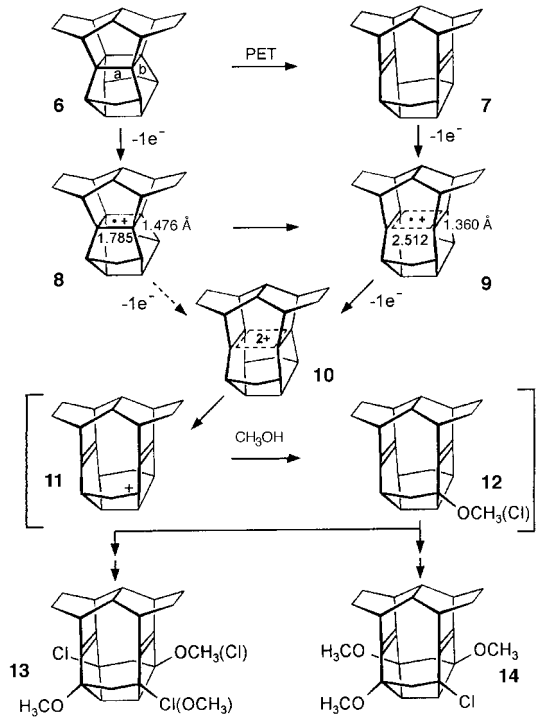

Scheme 2

protection in **10** opening up a sequence of deprotonation (*e.g.* **11**), nucleophilic addition (*e.g.* **12**) and reoxidation of the respective functionalized dienes.

GIAO[11] chemical shift calculations were performed based on the DFT calculated geometries. Calculated and observed chemical shifts agree within the error limit of the method. The ^{13}C shifts of the core carbons of **5** and **10** are very similar to those of the reference dications **15** and **16**; the ^{13}C NMR chemical shift additivity analysis[12] with total chemical shift differences of 910 and 905 ppm, respectively, amounts to more than 450 ppm deshielding per unit positive charge in both systems (*cf.* 460 ppm for **15**, 418 ppm for **16**).

According to *ab initio* calculations at the B3LYP/6-31G* level of theory[13] the dications **5** and **10** are of C_{2v} symmetry and the central C4 units have rectangular geometries very similar to the reference dications **15** and **16** (Fig. 1). As opposed to the hypersurface of the neutral species and the radical cations (tight isomers **3**, **8**; extended isomers **4**, **9**) there is only one minimum on both dicationic hypersurfaces. Evidently, σ-bishomoaromaticity provides the energy in dication **5** for the lengthening (shortening) of the a(b)-bonds by 0.651 (0.054) Å with respect to precursor **3** [by 0.857 (0.136) Å relative to **1**], in dication **10** for shortening (lengthening) by 0.115 (0.072) Å with respect to **9** [by 0.484 (0.092) Å relative to diene **7**].[14] The dications **5** and **10** (like **15** and **16**) can be viewed as frozen Woodward–Hoffmann allowed transition states of [1 + 1] cycloadditions of two ethylene radical cations with lengths of the a-bonds which are close to the mean values of the two isomers on the symmetry forbidden neutral [2+2] and radical cationic [2 + 1]cycloaddition energy hypersurfaces.

Unexpected migration of the indenyl ligand in the reaction of alkynyl(η^5-indenyl)iron complexes with phosphanes and phosphites from iron to the alkynyl group

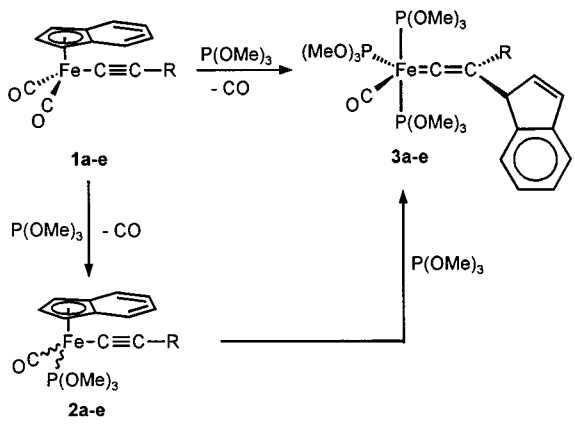
Received (in Cambridge, UK) 8th April 1999, Accepted 29th April 1999

Novel indenylvinylidene iron complexes are formed in the reaction of alkynyl(η^5-indenyl)iron complexes with phosphites and phosphanes in large excess by an intermolecular transfer of the indenyl ligand from iron to the C_β atom of the alkynyl ligand; mechanistic studies indicate that the reaction proceeds by a radical pathway.

Many associative substitution reactions of coordinatively saturated cyclopentadienyl and indenyl complexes have been documented.[1] These reactions have been interpreted as proceeding *via* an $\eta^5 \rightarrow \eta^3 \rightarrow \eta^5$ ring slippage.[2] The conversion of η^5- to isolable η^3- or even η^1-cyclopentadienyl or indenyl complexes has also been observed.[3] The cleavage of the cyclopentadienyl ligand as $[C_5H_5]^-$ from [(η^5-Cp)(CO)(NO)Re–Me] or *mer*-[(η^1-Cp)(NO)(PMe_3)$_3$Re–Me] in the reaction with PMe_3 in large excess to give ionic *trans*-[(NO)(PMe_3)$_4$Re–Me]$^+$[C_5H_5]$^-$ has also been described.[4] Finally, the loss of the indenyl ligand formally as a cation and the formation of [R_3P(Ind)]$^+$ in the reaction of [Cp(η^5-Ind)(CO)$_2$Mo]$^{2+}$ with PR_3 was recently proposed by Romão and coworkers.[5] We now report on (i) an unusual temperature-controlled product selectivity in the reaction of (alkynyl)(η^5-indenyl)iron complexes with phosphites and phosphanes, (ii) the novel transformation of (alkynyl)(η^5-indenyl)iron complexes into vinylidene complexes by reaction with PR_3, and (iii) the first evidence for the release of the indenyl ligand as a radical.

The alkynyl(dicarbonyl)(η^5-indenyl)iron complexes [(η^5-Ind)(CO)$_2$Fe–C≡CR] (R = Ph **1a**, C_6H_4Me-*p* **1b**, Me **1c**, $SiMe_3$ **1d** or C≡CBu^n **1e**) react in refluxing Bu_2O with a slight excess of $P(OMe)_3$ within a few minutes by substitution of $P(OMe)_3$ for one CO ligand to form a racemic mixture of [(η^5-Ind)(CO){$P(OMe)_3$}Fe–C≡CR] **2a**–**e**. However, when **1a**–**e** is heated in neat $P(OMe)_3$ for *ca.* 4 h at 70 °C, the complexes **2a**–**e** are formed in only minor amounts. The major products are the novel monocarbonyl-vinylidene complexes [CO{$P(OMe_3)_3$}-Fe=C=C(inden-1-yl)R] **3a**–**e** (Scheme 1).† The complexes **3a**–**e** are derived from **1a**–**e** by substitution of $P(OMe)_3$ for one CO ligand, addition of two more molecules of $P(OMe)_3$ and an unusual transfer of the indenyl group from iron to the C_β atom of the alkynyl ligand. Such a migration is without precedence. The migration is highly selective. In the reaction of **1e** with $P(OMe)_3$, in addition to **2e**, only the vinylidene complex **3e** is observed. The alternative butatrienylidene complex that would have been formed by migration of the indenyl ligand to the C_δ atom of the butadiynyl ligand could not be detected.



R = Ph (**a**), $C_6H_4CH_3$ (**b**), Me (**c**), $SiMe_3$ (**d**), C≡CBu^n (**e**)

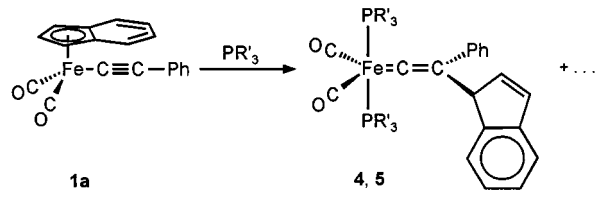
Scheme 1

The product ratio **2a**–**e**:**3a**–**e** is strongly temperature dependent. With increasing temperature it is shifted towards the substitution product **2**. On prolonged heating at 70 °C in neat $P(OMe)_3$ the alkynyl complexes **2a**–**d** are also transformed into the vinylidene complexes **3a**–**d**.

When the nucleophilicity of the alkynyl C_β atom is changed by variation of its substituent (R = Me, C_6H_4OMe-*p*, C_6H_4Me-*p*, Ph, C_6H_4Br-*p*, $SiMe_3$) the product distribution and the reaction rate are only slightly influenced. Therefore, a bimolecular mechanism *via* a nucleophilic attack of the alkynyl C_β atom at an indenyl ligand is unlikely. In contrast, the steric requirements of the P-donors considerably influence the reaction rate and the product distribution. For instance, **1a** reacts significantly more slowly with $P(OEt)_3$ than with $P(OMe)_3$. When the even bulkier $P(OPr^i)_3$ or PPh_3 are employed in the reaction with **1a** no monocarbonyl-vinylidene complex analogous to **3a**–**e** is formed but rather a dicarbonyl-vinylidene complex [$(CO)_2(PR_3)_3$Fe=C=C(inden-1-yl)Ph] (R = OPr^i **4** or Ph **5** in addition to the substitution product [(η^5-Ind)-(CO)(PR_3)Fe–C≡CPh] (Scheme 2). The latter cannot be transformed into a vinylidene complex.

Labelling studies show that the Fe/C_β migration of the indenyl ligand proceeds by an intermolecular pathway. The reaction of a 1:1 mixture of undeuterated **1a** and [(η^5-1,3-$C_9H_5D_2$)$(CO)_2$Fe–C≡C–C_6D_5] ([D_7]-**1a**) with $P(OMe)_3$ at 70 °C affords [D_0]-, [D_2]-, [D_5]- and [D_7]-**3a** in a ≈ 1:1:1:1 ratio as determined by mass spectrometry.

In the reaction of **1a** with PPh_3, complex **5** is formed independent of whether the reaction is carried out in toluene, EtOH or EtOH–H_2O (20:1). Therefore, the formation of [C_7H_9]$^+$ and [$(CO)_2(PPh_3)_2$Fe–C≡CPh]$^-$ or of [C_7H_9]$^-$ and [$(CO)_2(PPh_3)_2$Fe–C≡CPh]$^+$ as intermediates is unlikely. Since [$(CO)_2(PPh_3)_2$Fe–C≡CPh]$^-$ and [C_7H_9]$^-$ are rapidly trapped in a large excess of EtOH–H_2O as [$(CO)_2(PPh_3)_2$Fe=C=C(H)Ph] and indene, respectively, complex **5** should not be formed.



R′ = OPr^i (**4**), Ph (**5**)

Scheme 2

The most probable mechanism involves dissociation of the indenyl ligand as a radical and subsequent addition of $[C_7H_9]^{\cdot}$ to the alkynyl C_β atom of either $[(CO)(PR'_3)_3Fe–C{\equiv}CR]^{\cdot}$ or $[(CO)_2(PR'_3)_2Fe–C{\equiv}CR]^{\cdot}$. This mechanistic proposal is supported by two observations: (i) addition of the radical-scavenger galvinoxyl to the reaction mixture of **1a** and $P(OMe)_3$ efficiently inhibits the formation of **3a** but does not affect the formation of the substitution product **2a**; (ii) dimerization of the indenyl radical to give bisindenyl, $C_{14}H_{18}$, is preferentially observed when the addition of the indenyl radical to the alkynyl C_β atom is hindered by the sterically demanding mesityl (Mes) substituent. Then, only small amounts of the corresponding vinylidene complex, [CO{P(OMe)$_3$}$_3$Fe=C=C(inden-1-yl)Mes], are formed. In addition, small amounts of 1,4-bis-(mesityl)butadiyne are obtained. The butadiyne is presumably formed by decomposition of the 17-electron intermediate [CO{P(OMe)$_3$}$_3$Fe–C≡CMes].

The indenyl radical intermediates are very likely stabilized by addition to the phosphites or phosphanes which are present in the reaction mixture in a large excess. The reversible addition of radicals to PR_3 is well known.[6] The resulting phosphoranyl radical $[R_3P(Ind)]^{\cdot}$ would then act as a mediator. The assumption is supported by the following observation: when the *methyl*indenyl complex [(η^5-1-Me-Ind)(CO)$_2$Fe-C≡CPh] is treated with $P(OMe)_3$ in the presence of a mixture of $P(Ind)_3$ and $P(Ind)_2OMe$, both [CO{P(OMe)$_3$}$_3$Fe=C=C(1-Me-inden-1-yl)Ph] *and* [CO{P(OMe)$_3$}$_3$Fe=C=C(inden-1-yl)Ph] are formed in nearly equal amounts.

The results demonstrate a novel route to vinylidene complexes. Presumably, the transformation mode can also be extended to other complexes such as alkynyl(allyl) and alkynyl(fluorenyl) complexes. Based on previous results,[4,5] we initially assumed that the transformation most likely proceeds by an ionic pathway *via* either an indenyl anion or cation. However, all observations indicate a radical mechanism. Presumably, more organometallic reactions proceed by a radical mechanism than anticipated. There are some experimental hints that the proposed 17-electron intermediate is rather long-lived and can be intercepted also with other substrates. Recently, several other related 17-electron iron complexes $[(CO)_2(PR_3)_2FeX]$ (X = Br or I)[7] and [{P(CH$_2$CH$_2$PPh$_2$)$_3$}FeC≡CR][8] have been isolated and structurally characterized.

Financial support of this work by the Fonds der Chemischen Industrie is gratefully acknowledged.

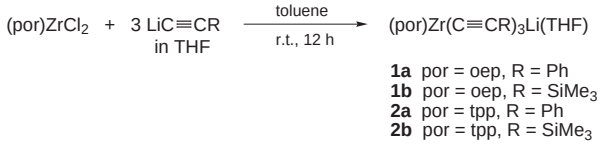
Received (in Cambridge, UK) 10th March 1999, Accepted 21st April 1999

Reaction of (por)ZrCl$_2$ [por = 2,3,7,8,12,13,17,18-octaethylporphyrinato dianion (oep) or 5,10,15,20-tetraphenylporphyrinato dianion (tpp)] with 3 equiv. of LiC≡CR (R = Ph and SiMe$_3$) produces novel alkynyl zirconium(IV) porphyrin complexes (por)Zr(η^1-C≡CR)$_3$Li(THF) in which three alkynyl ligands are coordinated to the zirconium center in a piano stool fashion and the Li$^+$ ion is bound to the pocket formed by three alkynyl ligands; treatment of (por)Zr(η^1-C≡CPh)$_3$Li(THF) with anhydrous HCl produces a C–C bond coupled product H$_2$C=CPh(C≡CPh) and HC≡CPh quantitatively.

Although early transition metal porphyrin complexes have received considerable attention in recent years,[1] the chemistry still remains in large part undeveloped. We[2] and others[3,4] have prepared organometallic zirconium porphyrin complexes and investigated their chemistry. As part of our work on organometallic zirconium porphyrin complexes, we are interested in alkynyl zirconium porphyrin complexes. Alkynyl metal complexes have been known to be involved in linear- and cyclooligomerization of terminal alkynes by various d-block[5] and f-block[6] metals. Alkynyl ligands σ-bonded to a metal center are also able to coordinate to other metal centers by using π-electrons of the C≡C groups. A variety of bridging fashions have been found in alkynyl bridged multinuclear complexes.[7] However, there are few transition metal alkynyl complexes containing three alkynyl ligands coordinated to a single metal center.[8] Here we report the synthesis and characterization of novel alkynyl zirconium porphyrin complexes. They are not only the first well-characterized alkynyl metalloporphyrin complexes[9] but also rare examples of trialkynyl transition metal complexes.

Alkynyl zirconium porphyrin complexes **1a**,**b**, **2a**,**b** were synthesized in high yields by the reactions of (por)ZrCl$_2$ with 3 equiv. of LiC≡CR.†



The ^{1}H NMR signals for the phenyl and the SiMe$_3$ protons of the alkynyl ligands coordinated to the (por)Zr moiety in **1a**–**2b** are shifted to higher field owing to the ring current of the porphyrin ligand. The diastereotopic methylene signals for the oep ligand in **1a** and **1b** indicates that the environments of the two sides of the porphyrin are different in these complexes. In addition, the significant upfield shift of the signals for one THF molecule implies that the THF molecule is located above the porphyrin ring current. The THF molecule is easily displaced by an excess of diethyl ether, as judged by NMR spectroscopy.

The structure of **1a** has been confirmed by X-ray crystallography (Fig. 1).‡ Three alkynyl groups are attached to the zirconium on one side of the (oep)Zr unit. The coordination geometry around the zirconium is best described as a 4 : 3 piano stool with the porphyrin occupying the square base. The Li$^+$ is coordinated by three C≡C bonds of the alkynyl ligands and one THF molecule in a pseudotetrahedral coordination geometry. The overall structure of **1a** is consistent with that in solution. The crystal structure of **1a** also suggests that the larger upfield shifted ^{1}H NMR signals for the THF molecule in **1a** than those in **1b** are due to the additional ring current of the three phenyl groups. The Zr–N bond distances range from 2.253(3) to 2.272(4) Å with an average value of 2.259(7) Å. The Zr atom is displaced 1.008 Å from the mean N$_4$ plane. The Zr–C bond distances in **1a** [2.305(10), 2.329(10) and 2.334(10) Å] are somewhat longer than those in (oep)Zr(CH$_2$SiMe$_3$)$_2$ [2.285(4), 2.289(4) Å],[3a] but shorter than those in (oep)ZrMe$_2$ [2.352(4), 2.334(4) Å].[3b] The Zr–C bond distances in **1a** are significantly longer than those in (C$_5$Me$_5$)$_2$Zr(C≡CPh)$_2$ [2.19(3), 2.21(3) Å],[10] which may be attributed to the large steric congestion caused by three alkynyl ligands in **1a**. However, the C≡C distances [1.210(12), 1.230(12) and 1.215(12) Å] in **1a** are similar to those in (C$_5$Me$_5$)$_2$Zr(C≡CPh)$_2$ [1.23(4) and 1.24 (4) Å]. The THF molecule is coordinated to the Li$^+$ along the Zr···Li axis (Zr···Li–O angle 175.8°) with a Li–O bond distance of 1.905(8) Å. The Zr···Li distance of 3.071(8) Å shows no direct interaction between two metal centers.

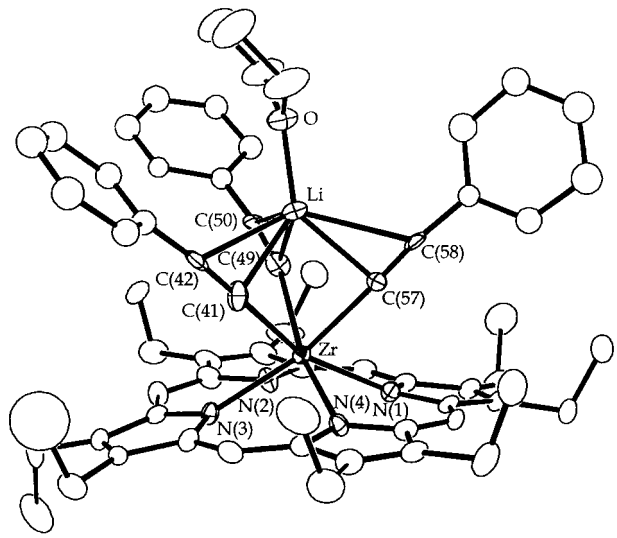


Fig. 1 Structure of (oep)Zr(η^1-C≡CPh)$_3$Li(THF) **1a**. Selected bond distances (Å) and angles (°): Zr–N(1) 2.254(4), Zr–N(2) 2.257(3), Zr–N(3) 2.272(4), Zr–N(4) 2.253(3), Zr–C(41) 2.334(10), Zr–C(49) 2.329(9), Zr–C(57) 2.305(10), Li–C(41) 2.212(12), Li–C(49) 2.240(12), Li–C(57) 2.227(12), Li–C(42) 2.611(12), Li–C(50) 2.676(12), Li–C(58) 2.590(12), C(41)–C(42) 1.210(12), C(49)–C(50) 1.230(12), C(57)–C(58) 1.215(12), Li–O 1.905(8), Zr···Li 3.071(8), C(41)–Zr–C(49) 77.2(3), C(49)–Zr–C(57) 78.3(3), C(41)–Zr–C(57) 76.8(3), Zr···Li–O 175.8.

Complexes **1a**–**2b** are highly sensitive to moisture similarly to other alkyl zirconium porphyrin complexes. Upon the addition of water, they are readily hydrolyzed to produce the corresponding acetylene HC≡CR and hydroxo-bridged dimeric zirconium porphyrins.[2b] On the other hand, treatment of **1a** with anhydrous HCl in C_6D_6 produces quantitatively a C–C bond coupled product H_2C=CPh(C≡CPh) and HC≡CPh along with (oep)$ZrCl_2$. In contrast, under the same conditions **1b** produces mainly the simple alkyne HC≡$CSiMe_3$ along with (*E*)-Me_3-SiCH=CHC≡$CSiMe_3$ as a minor product. The tpp analogs **2a** and **2b** show similar reactivities. It is not surprising that **1b** and **2b** exhibit different reactivity and regioselectivity from **1a** and **2a**. Such differences of the dimerization of terminal alkynes have been found in the literature,[5,6] which is believed to be due to the different electronic effect of the substituent on the alkyne. Negishi and coworkers reported similar reactivities of Li[$Cp_2Zr(C{\equiv}CPh)_3$] which is generated *in situ* from the reaction of Cp_2ZrCl_2 with 3 equiv. of LiC≡CPh.[11] Upon quenching Li[$Cp_2Zr(C{\equiv}CPh)_3$] with aqueous HCl, (*Z*)-PhCH=CHC≡CPh was produced as an isomerically pure compound. They proposed that C–C bond formation proceeds *via* a non-dissociative mechanism such as 1,2-migration of an alkynyl group. The mechanism of C–C bond formation in our case is still unclear, but the following observation is informative. Treatment of **1a** or **2a** with anhydrous HCl in the presence of an excess of HC≡CR (R = *p*-Tol, $SiMe_3$) produces only H_2C=CPh(C≡CPh) as a C–C bond coupled product without cross-coupled products such as H_2C=CPh(C≡CR) or H_2C=CR(C≡CPh). The result implies that C–C bond formation does not proceed *via* the dissociative pathway involving the reinsertion of free HC≡CPh into the Zr–C≡CPh, followed by protonolysis.

We have also attempted to synthesize the dialkynyl complexes (por)Zr$(C{\equiv}CR)_2$ using 2 equiv. of LiC≡CR, but the reaction afforded (por)Zr$(C{\equiv}CR)_3$Li(THF) as the major product. This is in sharp contrast to the zirconocene case in which stable dialkynyl complexes are isolated.[12] More electropositive metal centers of the Zr(por) unit compared to the Cp_2Zr moiety may account for their different reactivities.

In summary, we synthesized the novel trialkynyl zirconium porphyrin complexes (por)Zr(η^1-C≡CR)$_3$Li(THF). The porphyrin complexes show different reactivities compared to the analogous Cp_2 complex. Further studies on the mechanism of the enyne formation upon treatment of the alkynyl complexes with HCl as well as other reactivities of the alkynyl zirconium porphyrin complexes are underway. These complexes may be useful entries to a variety of bimetallic porphyrin complexes by replacing Li^+. Work along this line is also in progress.

Assembling nanosized ring-shaped synthons to an anionic layer structure based on the synergetically induced functional complementarity of their surface-sites: $Na_{21}[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{54}(H_2PO_2)_7]\cdot xH_2O$ ($x \approx 300$)

Received (in Basel, Switzerland) 25th February 1999, Accepted 19th April 1999

The reaction of an aqueous solution of sodium molybdate with hypophosphorous (phosphinic) acid acting both as reducing agent and ligand at low pH values (≈ 1) results in the formation of nanosized ring-shaped cluster units which assemble to form layers of the compound $Na_{21}[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{54}(H_2PO_2)_7]\cdot xH_2O$ 1 ($x \approx 300$); the assemblage is based on the synergetically induced functional complementarity of amphiphilic O=MoL (L = H_2O, $H_2PO_2^-$) groups and corresponds to the replacement of H_2O ligands of rings by related terminal Mo=O groups of other rings (and *vice versa*) the nucleophilicity of which is induced by coordinated $H_2PO_2^-$ ligands.

One of the great challenges of modern chemistry is to create multifunctional structures which have well defined cavities and surfaces with sites or areas of different reactivity by linking preorganized robust building blocks/synthons.[1,2] Here we report the synthesis of a related metal–oxide based electron-rich compound built up by nanosized ring-shaped cluster units using a type of crystal engineering.

If an aqueous acidified solution of Na_2MoO_4 is reduced with hypophosphorous acid (H_3PO_2) in the presence of a rather high electrolyte (salt) concentration, blue crystals of **1** precipitate after a few days.† Compound **1** was characterized by elemental analysis, thermogravimetric analysis (to determine the crystal water content), cerimetric titrations [for the determination of the (formal) number of the (28) Mo^V centres], bond valence sum (BVS) calculations (to determine the number and positions of H_2O ligands and OH groups as well as the number of Mo^V centres), [3] spectroscopic methods (IR, resonance-Raman, VIS–NIR) ‡ and single-crystal X-ray structure analysis.§

$Na_{21}[Mo^{VI}_{126}Mo^{V}_{28}O_{462}H_{14}(H_2O)_{54}(H_2PO_2)_7]\cdot xH_2O$ **1**
$\equiv Na_{21}$**1a**$\cdot xH_2O$ ($x \approx 300$)

The crystal structure of **1** (space group *Cmca*)§ shows the abundance of nanosized ring-shaped units (crystallographic site symmetry 2/*m*) which are linked through covalent Mo–O–Mo bonds to give a layered structure (Fig. 1). In the crystallographic *ac* plane, each cluster ring is surrounded by four rings such that the anionic layer structure **1a** with condensed ring-shaped units parallel to the *ac* plane results. The packing of these layers gives rise to nanosized channels (Fig. 1) with 'encapsulated' $H_2PO_2^-$ ligands, while 7 of the 14 $\{Mo_2\}$-type groups of the 'parent' layer system [with only H_2O ligands (see **2a**)] show the coordination of 7 bidentate $H_2PO_2^-$ ions (which are statistically distributed over the ring system but always with one ligand per bridge). Since the corresponding discrete (non–condensed) ring-shaped cluster with only H_2O ligands, which is known as the Na^+ salt, has the stoichiometry[4] $[\{(O)_2{=}Mo^{VI}(H_2O)(\mu_2\text{-}O)(H_2O)Mo^{VI} = (O)_2\}^{2+}{}_{14}\{Mo^{VI/V}{}_8O_{26}(\mu_3\text{-}O)_2H(H_2O)_3\text{-}Mo^{VI/V}\}^{3-}{}_{14}]^{14-}$ ($\equiv [\{Mo_2\}_{14}\{Mo_8\}_{14}\{Mo_1\}_{14}]^{14-}$) **2a**, the building-block description for the corresponding hypothetical discrete unit of **1a**, with 14 H_2O ligands replaced by 7 bidentate $H_2PO_2^-$ ligands, is $[\{(O)_2{=}Mo^{VI}(\mu_2\text{-}H_2PO_2^-)_{0.5}(\mu_2\text{-}O)(H_2O)\text{-}Mo^{VI} = (O)_2\}^{1.5+}{}_{14}\{Mo^{VI/V}ir8O_{26}(\mu_3\text{-}O)_2H(H_2O)_3\text{-}Mo^{VI/V}\}^{3-}{}_{14}]^{21-}$ **3a**.

It can be assumed that the formation of the ring system **1a** based on the reducing power of the hypophosphorous acid constitutes the initial step of the reaction considered here. This is a reasonable assumption as the characteristic spectrum of the

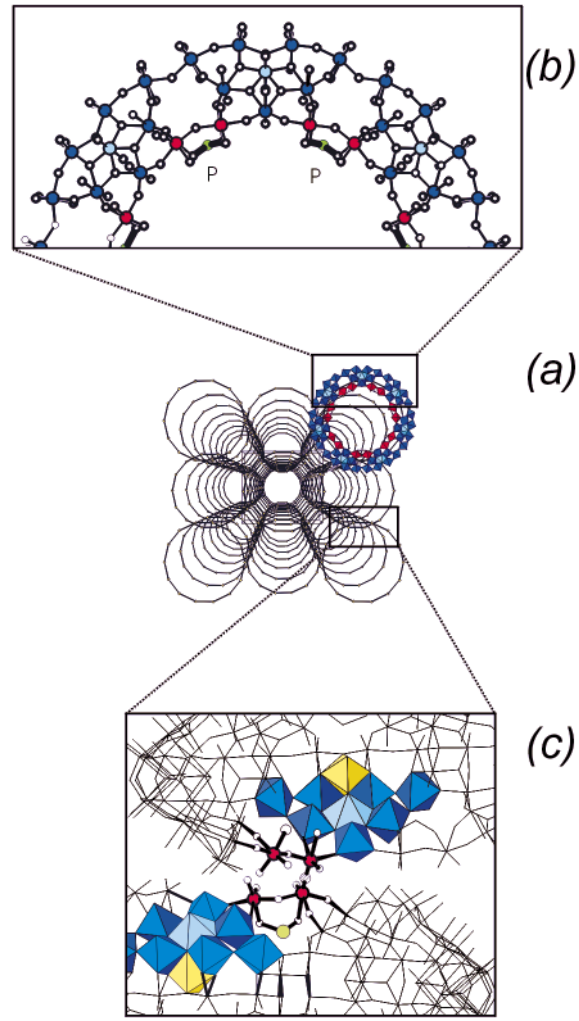

Fig. 1 (*a*) Perspective view of the cluster framework of **1** along the crystallographic *c* axis, showing the abundance of nanotubes and cavities. For clarity, only one complete ring (without the P ligands) is shown in polyhedral representation. With respect to the other rings, only the centres of the $\{Mo_1\}$ units are given and connected. (*b*) Ball-and-stick representation of the upper half of a ring segment showing the principal positions of the $H_2PO_2^-$ ligands. (*c*) Detailed view [perpendicular to (*a*) and (*b*)] of the bridging region between two cluster rings of **1** emphasizing one $\{Mo_8\}$, one $\{Mo_1\}$ unit (in polyhedral representation) as well as one $\{Mo_2\}^{2+}$ unit and one $H_2PO_2^-$ ligand (in ball-and-stick representation). The bridging (disordered) oxygen centre is depicted as a large hatched circle [colour code: $\{Mo_2\}$, red; $\{Mo_8\}$, blue (central MoO_7 pentagonal-bipyramid, light blue); $\{Mo_1\}$, yellow; P, green].

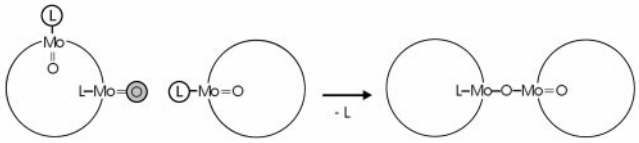

Fig. 2 Schematic presentation of the basic assembly principles of ring-shaped cluster units forming the layers of **1a** which are based on the synergetically induced functional complementarity of the $\{Mo_2\}$-type O=MoL (L = H_2O, $H_2PO_2^-$) sites of their surfaces: each precursor ring contains the corresponding virtual functional complementary O=Mo(H_2O) groups (becoming 'donors' due to the electron-donating $H_2PO_2^-$ replacing H_2O ligands and 'acceptors' without $H_2PO_2^-$ ligands).

discrete ring is observed after a few minutes, independent of the type of reducing agent used. The value accepted now for the charge of **1a** and all related compounds is in accord with the results of numerous Na analyses [4,5] and also with the analysis of the hydrogen-bond situation[5,6] in respect of the constant BVS values for the μ_3-O atoms of the equatorial (μ_3-O) · · · H · · · (μ_3-O) units.[4,5] Not only for the 'parent' system **2a** with only H_2O ligands but also for all known tetradecameric ring-shaped clusters without defects, the charge of 14− corresponds to the difference between the (formal) number of Mo^V centres and the number of protons at equatorial μ_3-O atoms.

The main difference between the discrete cluster **3a** and **1a** with the condensed clusters is that **1a** contains two $\{Mo_2\}$-type H_2O ligands less per formula unit. This is caused by the substitution of $\{Mo_2\}$-type H_2O ligands by terminal $\{Mo_2\}$-type Mo=O groups of neighbouring rings formally acting as ligands which results in the linkage of the rings (see formulae **2a** and **3a**). This means that each of the four connections of one ring unit corresponds to 0.5 H_2O molecules less per formula unit in **1a**. As the same $\{Mo_2\}$-type O=MoL group (L = H_2O, $H_2PO_2^-$) of the 'ring unit precursor' is involved in the present case, the linking procedure is based on a type of synergetically induced functional complementarity at the O=MoL sites of the cluster surfaces (see **2a** and **3a** as well as Fig. 2). In the crystal lattice the O=MoL groups are found for L = H_2O disordered in the sense that the O and L ligands can change their positions and the O=MoL group can thus act as 'donor' or 'acceptor'.

Because of the increased electron density (or the nucleophilicity/donor properties) of the considered Mo=O groups (when pointing to the outside of the ring), caused by the coordinated $H_2PO_2^-$ ligand, the related ring formally acts as a ligand due to a synergetic process resulting in the substitution of the H_2O ligand of a corresponding $\{Mo_2\}$-type Mo=O group of the adjacent ring which has no coordinated $H_2PO_2^-$ ligands (Fig. 2). In this context, it should be noted that in order to form the layer structure, not all H_2O ligands of the 14 $\{Mo_2\}$ groups have of course to be replaced by the abundant $H_2PO_2^-$ ligands.

The interesting aspects of this work are: (1) Giant robust ring-shaped building blocks can be linked together to form a well-defined layered network based on a type of crystal engineering, *i.e.* in this case based especially on the synergetically induced functional complementarity of relevant sites of the surfaces. (2) It is possible to place molecules/replace ligands at different sites of the surface of a giant cluster or within its cavity and subsequently change the properties of well defined regions of its surface (*e.g.* increase the nucleophilicity). (3) The investigation of reactions between molecules inside the cavity is in principle possible. (In this context, it is important to note that the system is metal–oxide based and electron rich, which allows activation of ligands.) The anion of the hypophosphorous acid, which is involved in each ring connection and coordinates as a bidentate ligand to the $\{Mo_2\}$ groups of **2a** by substituting two H_2O ligands of the 'parent' ring, can in principle be replaced by several other bidentate ligands, too.

We thank B. Hauptfleisch, C. Kuhlmann, F. Peters and Syed Q. N. Shah for their collaboration and Professor S. Sarkar (I.I.T. Kanpur, India) for helpful discussions. Financial support of the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Notes and references

† To a solution of $Na_2MoO_4{\cdot}2H_2O$ (3.04 g, 12.56 mmol) and NaCl (1.0 g, 17.11 mmol) in 25 mL of water which was acidified with 2.5 mL of hydrochloric acid (32%), hypophosphorous acid (0.2 mL, 50%, 1.93 mmol) was added as reducing agent. After stirring for 15 min under bubbling argon gas, the resulting solution was kept in a closed flask at room temperature. After 4 days the precipitated blue bipyramidal-shaped crystals were filtered, washed quickly with a small amount of cold water and dried at room temperature under argon. Yield: 0.38 g (16% based on Mo). (Note: the crystals should be separated out from the reaction mixture after 4 days, to avoid the coprecipitation of amorphous materials as after effect).

Received (in Liverpool, UK) 8th March 1999, Accepted 15th April 1999

Glycosidation reactions performed between glycosyl donors and acceptors covalently linked to a peptide template produced increased regio- and stereo-selectivities, which were dependent on the nature of the peptide, and which may be rationalised by simple molecular modelling.

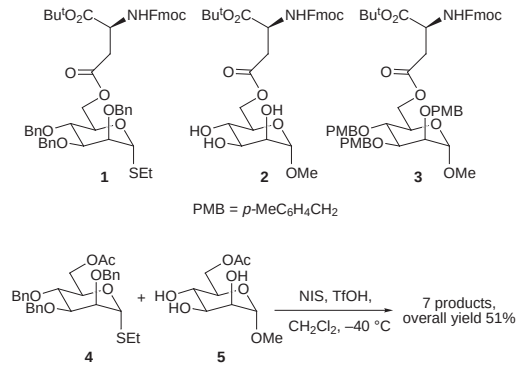
Despite an enormous effort over the course of the last hundred years, the stereo- and regio-selective construction of glycosidic bonds remains an unsolved problem. Extremely significant advances have been made since Koenigs and Knorr disclosed their classic glycosidation methodology back at the beginning of the twentieth century,[1] and numerous excellent reviews on some of the most significant methodological developments exist.[2] However the ultimate goal for the synthetic chemist is the reduction of the synthesis of oligosaccharides to an automatable solid phase process, a feat which revolutionalised the synthesis of oligonucleotides and oligopeptides. We would therefore like to disclose our preliminary investigations into a completely novel approach to the construction of glycosidic linkages. Herein our strategy is to abandon the classical philosophy of the search for a 'general glycosidation reaction', and to attempt to use combinatorial techniques to search for separate synthetic solutions to the construction of each individual glycosidic bond.

The technique of molecular tethering, first introduced to glycosidation chemistry by Stork,[3] and also used by Hindsgaul[4] and Ogawa[5] amongst others, has proven to be an excellent approach for the synthesis of β-mannoside bonds. More recently, several groups have disclosed the use of more extended tethers for the stereo- and even regio-selective construction of glycosidic linkages.[6] As a solution to the problems of glycosidic bond formation we have combined the use of tethering, which displays great promise for the construction of particular glycosidic linkages, with a combinatorial approach. In theory this will allow us to search rapidly through libraries of tethers, screening their potential to promote the formation of particular glycosidic linkages in stereo- and regio-selective fashions.

Since we required tethers in which structural diversity can be readily introduced by solid phase synthesis, our initial investigations have focussed on peptides. Ultimately this may allow us to use existing automatable methodology for solid phase peptide synthesis for oligosaccharide construction. The question therefore is: can a peptide sequence, itself readily synthesizable quantitatively in an automated manner on the solid phase, be effectively translated into an oligosaccharide sequence?

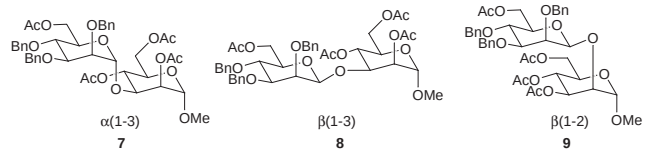
We recently disclosed[7] the synthesis of the novel glycosyl amino acids **1**, **2** and **3**, wherein the sugar moieties are linked through the free OH-6 hydroxy to the β-carboxy of a suitably protected aspartic acid residue. We now disclose the results of several glycosidation reactions undertaken after linking glycosyl donor **1** and glycosyl acceptor **2** together *via* short peptide chains.

† Detailed NMR data are available for selected products, see http://www.rsc.org/suppdata/cc/1999/1037/



Scheme 1

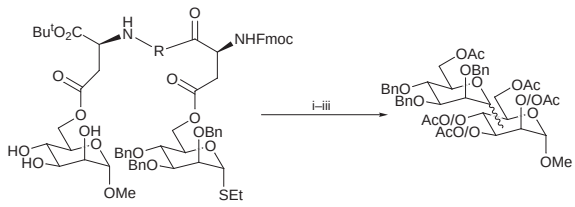
Firstly, a control reaction of the protected thioglycosyl donor **4** with the triol **5** under standard conditions was investigated, and found to proceed in moderate yield but with extremely poor selectivity (Scheme 1). Of the seven products only two were found to be disaccharides, which were identified as the α(1-3) and β(1-3) linked materials **7** and **8** respectively. Four of the



other products were found to be undesired trisaccharides, and the final material was simply the product of hydrolysis. Armed with the knowledge that the simple intermolecular reaction was particularly unselective we then undertook an investigation of several intramolecular reactions between the same acceptor and donor, when they were instead covalently linked to a peptide template.

Aspartate linked glycosyl donor **1** and acceptor **2** were elaborated to the oligopeptides **6a**–**g** using standard protecting group manipulations and EEDQ (2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline) mediated peptide coupling. Intramolecular glycosidation mediated by *N*-iodosuccinimide (NIS) and TfOH was then undertaken (Scheme 2). The resulting disaccharides were released from the peptide template by treatment with K_2CO_3 in MeOH, before complete acetylation and structural assignment. The results of this series of glycosidation reactions are summarised in Table 1.

Several points are worthy of comment. Firstly, the overall yields for the peptide templated glycosidation reactions are in all cases similar to those observed for the control reaction. Secondly, the absence of any trisaccharide products, in contrast to the control, is a clear indicator that all glycosidation is effected intramolecularly. Thirdly we were delighted to find that moderate levels of regio- and stereo-selectivity were achieved, and that the product distribution was dependent on the nature of the peptide template. It is clear that the α(1-3) **7** and



6a R = —
b R = Gly
c R = Ala
d R = Phe

		β(1-3) 56	β(1-3) 42

[a] Glycosyl donor linked *via* β ester to N-terminal aspartate, glycosyl acceptor linked *via* β ester to C-terminal asparate. [b] Minor or inseparable reaction products not identified. [c] Overall yield for cleavage from peptide backbone and subsequent acetylation.

β(1-3) **8** products dominate throughout, though the relative amount of these two isomers is variable. It would also seem that simple variation of the intermediate amino acid in the tripeptides from glycine (Gly) **6b** to alanine (Ala) **6c**, to phenylalanine (Phe) **6d** actually influences the outcome of the glycosidation reaction only slightly. However, with the use of proline (Pro) as the linking residue (**6f**) then a much higher degree of β selectivity is observed; β(1-2) linked disaccharide **9** now becomes a major product, together with the previously observed β(1-3) disaccharide **8**, and now none of the α(1-3) linked product **7** is formed. Moreover, increasing the length of the peptide by the addition of another Gly residue did not greatly alter the outcome (**6g**).

In order to begin to understand the dependence of product distribution upon peptide sequence we undertook some simple molecular modelling. Thus, a number of potential energy minima locations for a selection of these glycopeptides were probed by variation of the starting point through varying the torsional angles in the linker. This allowed us to probe a number of representative points at different relative orientations of the glycosyl acceptor ranging from the β face to the α face of the glycosyl donor. It was found that all of the modelled peptides AspGlyAsp, AspAlaAsp and AspPheAsp have minima in positions above both and α and β faces, *i.e.* there is little facial distinction, although the α face minima are typically slightly lower in energy. For example, Fig. 1(*a*) shows (hydrogen atoms omitted for clairty) the Bu^{t}AspGlyAspFmoc peptide system **6b** in which the glycosyl acceptor occupies a minimum above the α face of the glycosyl acceptor. In contrast the half chair conformation of the proline residue shown in Fig. 1(*b*) biases the AspProAsp model towards a β face energy minimum. This therefore suggests that the increased β selectivity observed for the AspProAsp peptide is a consequence of the conformation of this tether. In addition, changing identity of the intermediate amino acid from Gly to Ala or Phe changed the conformations of these minima only very slightly. This is consistent with the similar product distributions that were observed for these three peptide linkers. Finally, these simple models also provided a plausible explanation for the preponderance of (1-3)-linked disaccharide products; in all of the minimised models the 3-hydroxy of the acceptor is readily disposed to react with the anomeric centre of the donor.

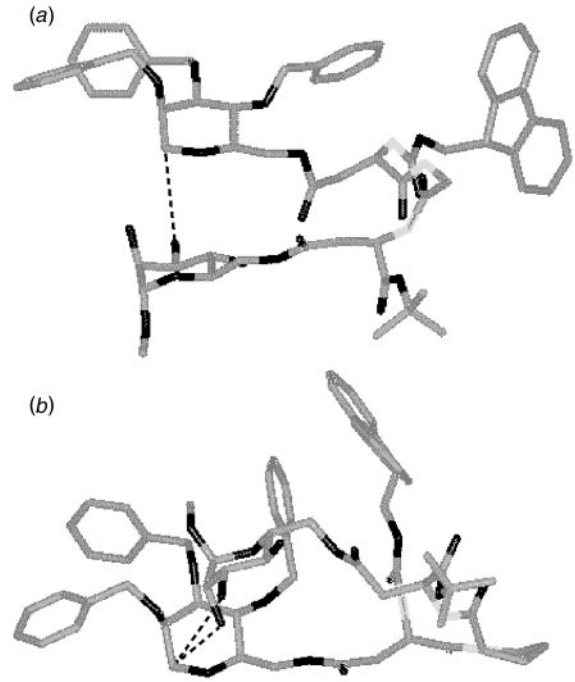

Fig. 1 Minimized structures of tripeptide-tethered systems illustrating the positions of O-2 and O-3 of the glycosyl acceptor relative to the anomeric centre of the glycosyl donor (hydrogens omitted for clarity): (*a*) Bu^{t}AspGlyAspFmoc **6b** and (*b*) Bu^{t}AspProAspFmoc **6f**.

In summary, we have successfully demonstrated for the first time that glycosidation reactions may be achieved between glycosyl donors and acceptors which are bound to a peptide template. In addition these reactions show enhanced, though at present modest, regio- and stereo-selectivities, the product distribution of which can be rationalised by simple molecular modelling. Further investigations in these areas are currently in progress and results will be published in due course.

We gratefully acknowledge financial support from the EPSRC (Quota award to R. J. T.-E.).

Biosynthesis of XR587 (streptopyrrole) in *Streptomyces rimosus* involves a novel carbon-to-nitrogen rearrangement of a proline-derived unit

Mairi E. Raggatt,[a] Thomas J. Simpson*[a] and Stephen K. Wrigley[b]

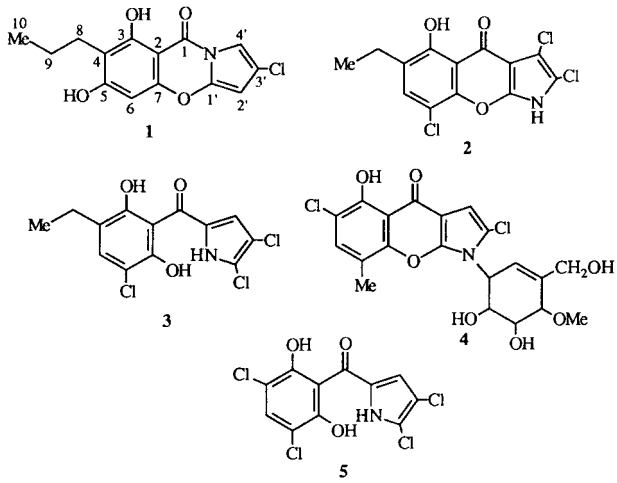
[a] *School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: tom.simpson@bristol.ac.uk*

[b] *TerraGen Discovery (UK) Ltd,† 545 Ipswich Road, Slough, Berkshire, UK SL1 4EQ*

Received (in Liverpool, UK) 7th April 1999, Accepted 22nd April 1999

Results from incorporation studies with ^{13}C-labelled acetate, propionate and proline establish a polyketide origin for the pyrrole-containing streptomycete metabolite, XR587, and are in accord with the formation of an amide bond *via* an unprecedented rearrangement of a proline-derived starter unit.

A pyrrole-containing metabolite, XR587, was isolated from a streptomycete strain (X10/78/978; NCIMB 40808) identified as *Streptomyces rimosus* during a screening programme for antibacterial agents.[1] The novel benzopyranopyrrole structure **1**



was deduced from spectroscopic studies and confirmed by X-ray crystallography. Recently, Breinholt and co-workers reported the isolation of a metabolite, streptopyrrole, from *Streptomyces armeniacus* whose structure is clearly identical to XR587.[2] Streptopyrrole was reported to display weak growth inhibitory activity against a range of fungi and bacteria.

A benzopyranopyrrole skeleton was first reported[3] for the metabolite TAN-876A **2** which is isolated along with the closely related TAN-876B **3**. The carbonyl group is, however, joined to the pyrrole unit at the β-position in **2**, and not through the nitrogen as in XR587. The pyralomycins isolated from *Microtetraspora spiralis* also contain a benzopyranopyrrole structure[4] and preliminary biosynthetic studies on the major metabolite, pyralomycin 1A **4**, indicated that the 2-ketopyrrole moiety is derived from proline although no mechanism for its formation was suggested.[5]

We initially proposed a biosynthetic pathway to XR587 in which the phenolic ring could be polyketide in origin and the pyrrole ring derived from proline. Oxidation of a propionate- (or possibly methionine-) derived methyl followed by amide formation (as indicated in Scheme 1) and subsequent oxidative modifications and chlorination would give XR587 by a pathway analogous to the biosynthesis of the mycotoxin, ochratoxin A **6**, which is formed *via* a similar polyketide linked to phenylalanine by an amide bond.[6] We now report the results of biosynthetic studies with ^{13}C-labelled precursors which show that XR587 is formed *via* two polyketide chains and a unique carbon-to-nitrogen rearrangement of proline.

The results of incorporation of [1,2-$^{13}C_2$]acetate, [1-^{13}C]propionate and [$^{13}C_5$]proline are summarised in Fig. 1 and Table 1.

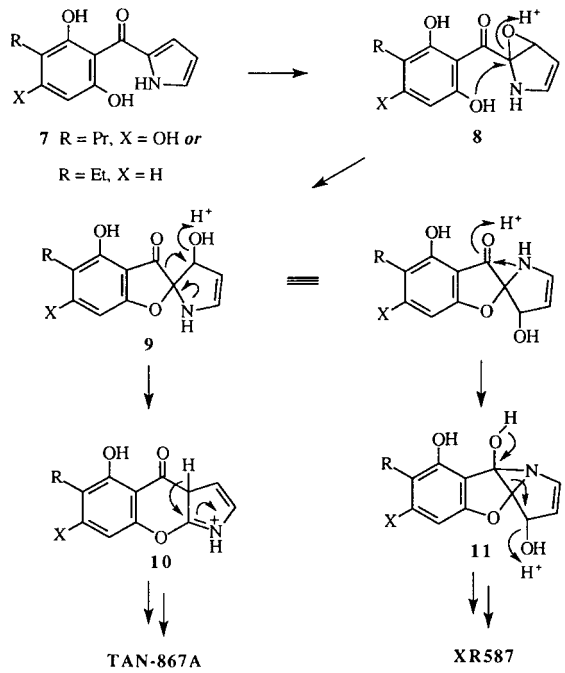


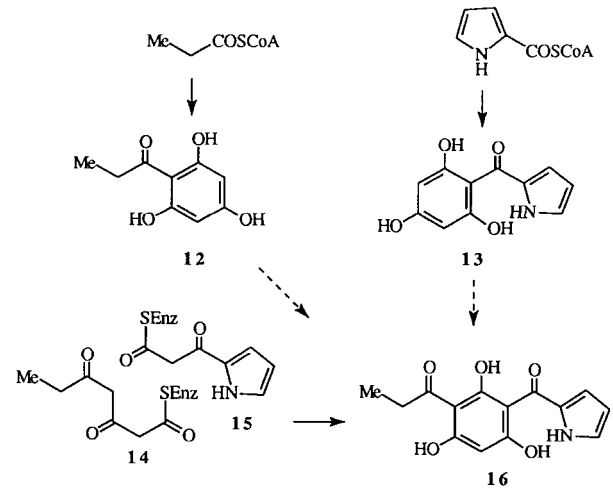
Scheme 2

The phenolic ring is derived from three intact acetate units arranged as shown in Fig. 1. The low level of labelling observed for carbons 3′ and 4′ is consistent with the derivation of the pyrrole ring from proline which itself is derived *via* α-ketoglutarate.[7] Similar low-level incorporation of acetate into the pyrrole ring of pyralomycin 1A was also observed by Kawamura *et al*.[5] An exceptionally high level of labelling from propionate (54%) was observed at C-8, and a very small amount of enrichment (< 1%) was observed at C-1. Although this low level of incorporation might have been indicative of enrichment of the C_1 pool, feeding ^{13}C-labelled methionine or formate failed to give any detectable enrichment of C-1, which implies that its derivation *via* the C_1 pool is unlikely. In fact, in several experiments, methionine was found to consistently inhibit the production of XR587. However, on feeding [$^{13}C_5$]proline, high levels of incorporation (average 5.5%) and ^{13}C–^{13}C couplings were observed at all positions in the pyrrole ring, confirming its derivation from proline. More surprisingly, the C-1 amide carbonyl was also enriched to a similar level and geminal and vicinal couplings were observed to C-1′ and C-3′ to prove that all five proline carbons are incorporated as an intact unit during the biosynthesis of XR587. Thus the original proposal for a polyketide origin for C-1 is firmly ruled out.

The pyrrolomycins, *e.g.* **5**, are pyrrole-containing metabolites of *Streptomyces fumanus* which have been shown to be derived *via* a tetraketide in which a proline-derived starter unit is extended with three acetates.[8] This, along with the reported derivation of pyralomycin 1A **4** from proline, one propionate and two acetates, and the co-occurrence of TAN-876A **2** and TAN-876B **3**, leads us to propose the pathway shown in Scheme 2 which rationalises the formation of the different benzopyranopyrrole metabolites *via* a pyrrole-polyketide intermediate **7**.

Conversion of **7** to the epoxide **8** followed by addition of the phenolic hydroxy group leads to the key spiro-intermediate **9**.‡ Subsequent loss of the hydroxy group after protonation or other activation, migration of the carbonyl bond to give the pyrrolinium intermediate **10**, and rearomatisation leads to the ketonic structure found in TAN-876A (and pyralomycins). Alternatively, addition of the pyrrolidine nitrogen to the ketonic carbonyl generates the aziridine **11** which rearranges as shown to generate the amide. To the best of our knowledge, this rearrangement of a proline-derived moiety is unprecedented.

The formation of the phenolic intermediate **7** requires comment. In the case of pyrrolomycin and pyralomycins, the corresponding intermediates may be formed from folding and condensation of a simple tetraketide intermediate which is presumably primed by the coenzyme-A thioester of pyrrole-2-carboxylate. However, the situation with XR587 is more complex. The single acetate labelling pattern observed in the phenolic ring is incompatible with a single-chain mechanism and makes the intermediacy of the phloroglucinol intermediates **12** or **13** (Scheme 3) unlikely, as there is ample precedent to suggest that the involvement of either of these symmetrical intermediates would lead to randomisation of acetate labelling of the ring.[9] Thus formation of **16** by acylation of **12** or **13** by pyrrole-2-carboxylate or propionate respectively is unlikely, and the remaining alternative requires condensation of separately formed triketide **14** and diketide **15** chains. Such two-chain mechanisms are rare but there is precedent in *e.g.* the biosynthesis of radicinin.[10]



Scheme 3

Studies to provide further evidence for this pathway, and to establish *inter alia* the exact nature of the proline-derived starter unit, reduction of C-8 and the timing of the chlorination reactions, are in progress.

The EPSRC is thanked for a studentship (M. E. R.) and Drs Inês Chicarelli-Robinson, Carole McNicholas and Sally Trew for support and advice. Dr Martin Murray is thanked for his help with NMR experiments.

Notes and references

‡ An equally feasible alternative would involve the pyrrole nitrogen in the opening of the epoxide to give an iminium species, which would then be attacked by the phenolic hydroxy group.

Pd/C(en)-catalyzed regioselective hydrogenolysis of terminal epoxides to secondary alcohols

Hironao Sajiki, Kazuyuki Hattori and Kosaku Hirota*

Laboratory of Medicinal Chemistry, Gifu Pharmaceutical University, Mitahora-higashi, Gifu 502-8585, Japan. E-mail: hirota@gifu-pu.ac.jp

Received (in Cambridge, UK) 19th March 1999, Accepted 28th April 1999

Various terminal epoxides, such as 1,2-epoxyalkanes, glycidyl ethers and glycidol, were hydrogenolyzed to give secondary alcohols with high regioselectivity using a 10% Pd/C–ethylenediamine complex as a catalyst under entirely neutral conditions.

The reductive ring-opening reaction of epoxides, in particular terminal epoxides, to the corresponding alcohols is a transformation of considerable importance in organic synthesis[1] in connection with the recent progress in the development of practical and efficient methods for epoxidation of terminal olefins.[2] This important transformation has mainly been accomplished by stoichiometric metal hydride or dissolving metal reagents,[3] and such reductive cleavage with most reducing agents generally produces a large quantity of metal sludge. Industry in particular requires high yield, high selectivity, sufficient productivity, low cost, safety, operational simplicity, and environmental consciousness among other technical factors.[2a] In this context, the general advantages associated with heterogeneous catalysts for hydrogenolysis are convenient use and easy separation, production of no sludge and low cost. From investigation of the hydrogenolyses of 1,2-epoxyalkanes, it was found that while the primary alcohol is formed in greater quantity with a Ni catalyst, the secondary alcohol is predominant with a Pd catalyst.[4,5] However, the Pd catalysts have not been practically applicable since a substantial ratio of the reverse opening primary alcohol is obtained (*ca.* 35–15%) in most cases.[4,6] Some improvements were demonstrated by the combination of Pd/C with NaOH[4,7] or ammonium formate.[6] Although these few reports provide successful results, the basic or nucleophilic conditions (NaOH or ammonia provided from ammonium formate) often restrict their use.[7] Thus, there is a need for the development of novel hydrogenation catalysts that can provide high yields and selectivity as entirely heterogeneous catalysts under neutral conditions without any nucleophilic additives. We now disclose a very practical method that overcomes these serious problems.

Recently, we introduced a carbon-supported Pd–ethylenediamine complex [Pd/C(en)] as a catalyst of choice for general chemoselective hydrogenation of reducible functionalities such as olefin, acetylene, nitro, azide, aromatic bromine or benzyl ester moieties, in the presence of *O*-Bn or *N*-*Z* protective groups.[8] During the course of our studies aimed at developing the Pd/C(en) complexes[9] as catalysts for selective hydrogenation,[8,10] we found that 10% Pd/C(en), without any nucleophilic additives, promotes the regioselective reductive ring-opening of terminal epoxides to afford the corresponding secondary alcohols with high yields and selectivity.

Hydrogenolysis of a variety of terminal epoxides in the presence of 10% Pd/C(en) (10% of the weight of the substrate, *ca.* 2 mol% as Pd metal) as catalyst in MeOH at room temperature was carried out and the results are summarized in Table 1. For example, 1,2-epoxydecane was hydrogenolyzed using 10% Pd/C(en) under 5 atm of hydrogen pressure to afford decan-2-ol as the sole product in 81% yield, whereas employment of 10% Pd/C (Aldrich) under 1 or 5 atm hydrogen pressure resulted in the formation of a mixture of decan-2-ol and decan-1-ol (82 : 18 or 84 : 16, Table 1, entries 1–3). The 10% Pd/C(en)-catalyzed hydrogenolysis proceeded with complete regioselectivity, although the completion of the reaction required

Table 1 Regioselective hydrogenolysis of terminal epoxides using 10% Pd/C(en) catalyst[a]

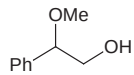
9	**1g** R = $CyCH_2OCH_2$	B	1	66	79	100	ND[f]
10	**1h** R = $HOCH_2$	B	1	22	89	100	ND[f]
11[i]	**1g** R = 4-$ClC_6H_4OCH_2$	B	1	24	89	100[j]	ND[f,j]

[a] Unless otherwise specified, the reaction was carried out using 0.5 mmol of the substrate in methanol (1 ml) with 10% Pd/C(en) (10% of the weight of the substrate) under hydrogen atmosphere (1–5 atm) for the given reaction time. [b] Isolated yield. [c] Determined by ^{1}H NMR. [d] 10% Pd/C was purchased from Aldrich Co. [e] Reaction was performed using Ishii Medium Pressure Hydrogenator CHA-E. [f] Not detectable. [g] Trace (less than 5%). [h] X = 2,3-dihydro-1,4-benzodioxan-2-yl. [i] Reaction was performed in the presence of Et_3N (1.2 equiv. *vs.* substrate) to neutralize the resulting HCl. [j] Dechlorinated product.

higher hydrogen pressure (5 atm). 1,2-Epoxyhexane, 1,2-epoxydecan-10-ol and 1,2-epoxy-4-phenylbutane were similarly hydrogenolyzed (5 atm) with 10% Pd/C(en) to give the corresponding secondary alcohols in high yields (entries 4–6). The hydrogenolysis of glycidyl ethers and glycidol gave the corresponding secondary alcohols in high yields even under 1 atm hydrogen pressure without the formation of any detectable by-products, such as primary alcohols (entries 7–11). In the case of 4-chlorophenyl glycidyl ether, non-nucleophilic Et_3N (1.2 equiv.) was added to the reaction mixture as a base, which traps HCl generated during the reaction (entry 11). In this reaction the dechlorinated product, 1-phenoxypropan-2-ol, was obtained in 89% yield as the sole product.

The 10% Pd/C(en) catalyst is stable and retains high efficiency during consecutive catalytic cycles. The catalyst could be recovered almost quantitatively following simple filtration of the catalyst, washing with MeOH and Et_2O and drying, and it could be reused at least three times without any decrease in the yield and regioselectivity of the hydrogenolyzed product. One drawback of this method is the inapplicability encountered in the hydrogenolysis of styrene oxide (**1** R = Ph). Styrene oxide was converted to a 14 : 86 mixture of phenethyl alcohol (**3** R = Ph) and 1-phenylethylene glycol monomethyl ether **4**, which may be formed *via* Pd/C(en)-catalyzed regioselective solvolysis with MeOH.[11]



4

The exact role of the ethylenediamine of the 10% Pd/C(en) complex catalyst in facilitating the regioselective hydrogenolysis of terminal epoxides remains unclear. The catalytic activity of 10% Pd/C(en) to the reductive ring-opening reaction of terminal epoxides was lower than that of 10% Pd/C. It should be noted that higher regioselectivity was observed with the less active catalyst.

As described, the present 10% Pd/C(en)-catalyzed hydrogenolysis of terminal epoxides would provide a new catalytic method for regioselective synthesis of secondary alcohols under entirely neutral and heterogeneous reaction conditions.

Received (in Cambridge, UK) 15th February 1999, Accepted 19th April 1999

Stereoselective hydrogenation reactions in the ionic liquid system 1-ethyl-3-methylimidazolium chloride–$AlCl_3$ can be performed with excellent yields and selectivities, using electropositive metals and a proton source.

The hydrogenation of aromatic compounds can be achieved by a number of methods, including high pressure catalytic hydrogenation,[1] dissolving metal reductions,[2] and ionic hydrogenations with TFA and silanes.[3] Here, we report a new, highly stereoselective method for the reduction of carbocyclic aromatic compounds in chloroaluminate(III) ionic liquids at ambient temperatures.

Room temperature ionic liquids such as [emim]Cl–$AlCl_3$ (X = 0.67)[4] ([emim]$^+$ = 1-ethyl-3-methylimidazolium cation, see Fig. 1),† have been found to be excellent solvents for a number of reactions, such as the Friedel–Crafts reaction,[5] isomerisations,[6] polymerisation of alkenes such as refinery waste gas,[7] and catalytic hydrogenation reactions.[8,9]

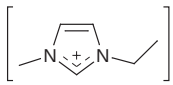

Fig. 1 Structure of the [emim]$^+$ cation.

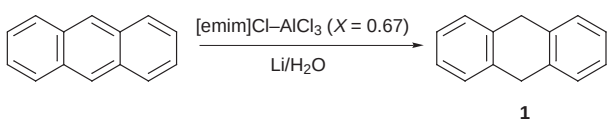
When polycyclic aromatic compounds, such as anthracene, are dissolved in solvents containing dissolved aluminium(III) chloride, deeply coloured paramagnetic solutions are formed.[10] Authors such as Olah[11] have referred to these compounds as $AlCl_3$ π-complexes, but the precise structure and bonding of these complexes has yet to be elucidated.[10] It has also been observed that carbocyclic aromatic compounds are readily protonated in the [emim]Cl–$AlCl_3$ (X = 0.67) ionic liquid.[12] It was thus envisaged that the interaction of an electropositive metal with a protonated aromatic hydrocarbon would result in reduction of that compound. A preliminary investigation led to the observation that when moist air was introduced to a deep green solution of anthracene in [emim]Cl–$AlCl_3$ (X = 0.67), containing lithium metal, the green colour faded and 9,10-dihydroanthracene **1** was formed in 98% yield (Scheme 1).



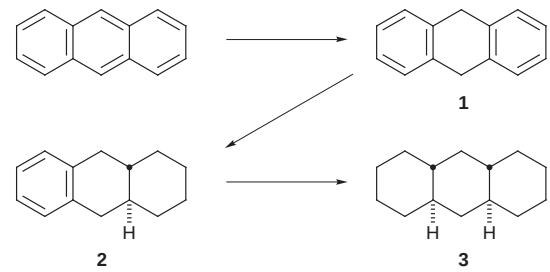
Scheme 1

Following on from this initial observation, a more detailed investigation was carried out with anthracene, pyrene and 9,10-dimethylanthracene, in order to examine the stereochemical outcome of this reaction. The results of this investigation are summarised in Table 1 and Schemes 2–4.

The partial reduction of anthracene and pyrene was achieved by using the ionic liquid [emim][HCl_2] as a proton source.[13] For complete reduction to the alicyclic products (**3** and **7**), anhydrous HCl gas was found be the most effective proton source. In general, this reaction was successful with electropositive metals (*e.g.* Na, Li, Mg, Al and Zn). The metal of choice was found to be aluminium, since the aluminium(III) chloride by-product of the reaction is precipitated and the composition of the ionic liquid remained largely unaffected. It should be noted that this reaction differs from other dissolving metal reductions, such as the Birch reduction,[2] in that products containing unconjugated double bonds are not observed.

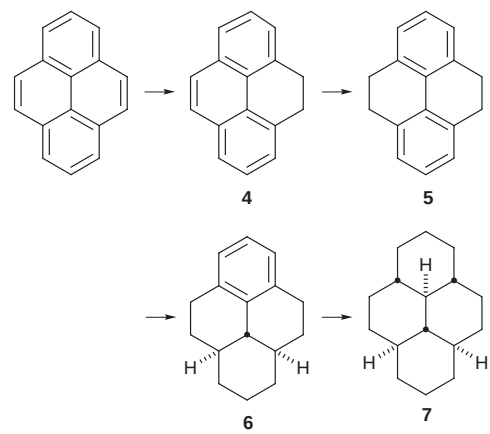
Table 1 The reduction of aromatic compounds in [emim]Cl–$AlCl_3$ (X = 0.67) at 20 °C

Substrate	Metal	H^+ source	t/h	Products (% yield)
Anthracene	Al	[emim][HCl_2] (l)	24	**1** (25), **2** (25), **3** (25)
Anthracene	Zn	excess HCl (g)	6	**3** (90)
Pyrene	Li	[emim][HCl_2] (l)	1	**4** (2), **5** (18), **6** (20), **7** (25)
Pyrene	Al	excess HCl (g)	4	**7** (84)
9,10-Dimethyl-anthracene	Al	HCl (g)	0.5	**8** (81), **9** (14)

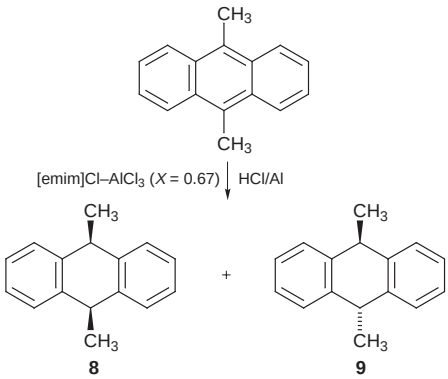


Scheme 2

The reduction of anthracene was found to proceed sequentially, as shown in Scheme 2. It should be noted that **2** and **3** are the thermodynamically most stable isomers.



Scheme 3



Scheme 4

The reduction of pyrene occurs in a similar manner to that of anthracene (see Scheme 3): the two most reactive bonds are reduced first. Again, the subsequent reduction gave rise to the thermodynamically most stable intermediate **6** and ultimately the product **7** as single diastereomers.[14] The structure of **7** was confirmed by X-ray crystallography[15] and was found to be identical to the published structure.[16]

The partial reduction of 9,10-dimethylanthracene (see Scheme 4) gave rise to two isomers (**8** and **9)** in a 6 : 1 ratio respectively. In contrast to the products from the reduction of pyrene and anthracene, the major product **8** was the *cis*-isomer and the minor product **9** was the *trans*-isomer. This difference from the behaviour of anthracene and pyrene can be explained by the enthalpies of formation of the two products **8** and **9**. The *cis*-isomer **8** is 16 kJ mol^{-1} more stable than the *trans*-isomer **9**.[17] Hence, as with the pyrene and anthracene reductions, the thermodynamic product predominates.

The reductions of simpler aromatic compounds such as benzene and naphthalene were found to behave in a more complex manner. In both these cases, the expected products [cyclohexane (2%) and decalin (15%, as a 5 : 1 *trans*- to *cis*-isomer mixture)] were obtained, but in low yields. In these two cases, polymerisation reactions occur in addition to reduction reactions. In the reduction of benzene, products such as phenylcyclohexane and bi(cyclohexyl) were detected, presumably from the Friedel–Crafts reaction between benzene and cyclohexene (a postulated intermediate in the reduction reaction): the major product was a non-volatile colourless oil—polycyclohexane—obtained in 70% yield.

In conclusion, reduction by a metal–acid combination in a chloroaluminate(III) ionic liquid provides an effective means of hydrogenating aromatic compounds in a highly selective manner. This contrasts with the catalytic hydrogenation of anthracene or pyrene, which requires high temperatures and pressures, and usually gives rise to isomeric mixtures.[1,18]

We are indebted to Unilever Research Laboratories, Port Sunlight for financial support, and the EPSRC and Royal Academy of Engineering for the award of a Clean Technology Fellowship (to K. R. S.).

Notes and references

† The composition of a tetrachloroaluminate(III) ionic liquid is best described by the apparent mole fraction of $AlCl_3$ {$X(AlCl_3)$} present. Ionic liquids with $X(AlCl_3) < 0.5$ contain an excess of Cl^- ions over $[Al_2Cl_7]^-$ ions, and are called 'basic'; those with $X(AlCl_3) > 0.5$ contain an excess of $[Al_2Cl_7]^-$ ions over Cl^-, and are called 'acidic'; melts with $X(AlCl_3) = 0.5$ are called 'neutral'.

Cyclodextrin-accelerated cleavage of phenyl esters: is it the 2-hydroxy or the 3-hydroxy that promotes the acyl transfer?

Makoto Fukudome, Yuji Okabe, De-Qi Yuan and Kahee Fujita*

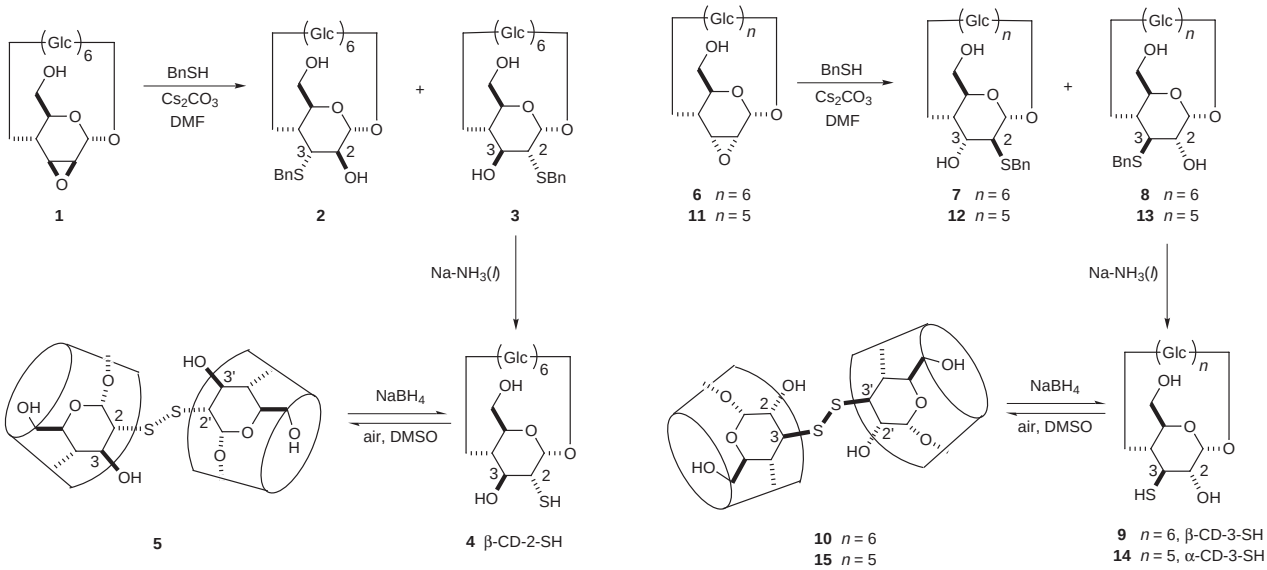
Faculty of Pharmaceutical Sciences, Nagasaki University, 1-14 Bunkyo-machi, Nagasaki 852-8521, Japan. E-mail: fujita@net.nagasaki-u.ac.jp

Received (in Cambridge, UK) 17th March 1999, Accepted 28th April 1999

Both 2- and 3-monothiocyclodextrins have been synthesized and used in probing the mechanism of cyclodextrin-mediated cleavage of phenyl esters, showing that the 3-thiols are much more effective than the 2-thiols in promoting the acyl transfer.

Cyclodextrin-accelerated cleavage of phenyl esters is among the earliest examples of enzyme mimetic reactions.[1] Acylated cyclodextrins are usually the products and are difficult to recycle during the reaction. Although this reaction is not a catalytic one, it involves a rapid and reversible pre-binding of the substrate into the cyclodextrin cavity and subsequent acyl transfer to a cyclodextrin hydroxy group in the specifically arranged complex, in the same way that natural serine proteases bind their substrates and promote the transfer of an acyl group to a serine hydroxy group in the first enzymatic step.[2] Therefore, it provides an excellent model for better understanding enzyme action and has attracted a long-standing interest.[3] Some fundamental factors such as the effect of proximity,[4] binding of the substrate in the transition state,[5,6] geometric freedom needed for the entire reaction[7] and so forth have been elucidated, and very large rate-acceleration (up to 6 million-fold[4]) and good structural selectivity or enantioselectivity[8,9] have been obtained. However, the nucleophile in this reaction still remains to be determined. It is certain that the secondary hydroxy groups are engaged in the reaction, but there is no easy way to determine whether the 2-OH or 3-OH is the one to attack the ester first. Bender[10] suggested that the reaction involves the 3-OH group based on the observation that the 3-*O*-methylated derivative causes no rate-acceleration, while Breslow[8,11] believes that the reactive hydroxy group is the 2-OH by analogy with its greater reactivity toward methylation. Computer simulation[12] supports the 2-OH mechanism. Unfortunately, not enough experimental evidence for either mechanism has been obtained. We reason that adjusting the relative reactivity of the two positions can afford some insight into the mechanism. This idea is made practicable by our recent method[13] for selectively functionalizing the secondary face without significantly altering the conformation of cyclodextrin. Replacement of the secondary hydroxy group by a SH group has an interesting influence on the catalytic behaviour of cyclodextrins. Here we describe the preliminary results, which are striking and indicative of the 3-SH being preferred to the 2-SH as the nucleophile.

The syntheses of thiocyclodextrins **4**, **9** and **14** were carried out by nucleophilic ring-opening of cyclodextrin epoxides with BnSH followed by reduction with Na–NH_3 (l) (Scheme 1). The resultant thiols were converted to the corresponding dimers for easy storage. The nucleophilic ring-opening[14] of cyclodextrin mannoepoxide **1** was believed to exclusively result in the formation of a cyclodextrin derivative with a 3-functional altrose sub-unit which slightly distorts the cyclodextrin cavity.[15] We found that, with imidazole as nucleophile, the undistorted product with an imidazolyl group at C-2 of the glucoside unit can be obtained in addition to the distorted one.[13] This abnormal reaction actually occurs with various nucleophiles including BnSH, giving the undistorted cyclodextrin derivative with a functional group at C-2 of the glucoside unit as a minor product.[16] Though in very low yield, this method does afford the undistorted C-2 functional cyclodextrins which are otherwise inaccessible at present. Reaction of **1** with BnSH in DMF gave the undistorted cyclodextrin sulfide **3** in 6% yield in addition to **2** in 77% yield. The replacement of 3-OH was easily realized by the reaction of alloepoxides **6**[13,17,18] and **11** with BnSH which afforded the undistorted cyclodextrin sulfides **8** and **13** as main products. Reduction of the sulfides **3**, **8** and **13**



Scheme 1

Table 1 Kinetic parameters of the cleavage of nitrophenyl acetates by thiocyclodextrins at pH 9.0[a]

[a] Reactions were carried out in a pH 9.0 standard buffer solution at 25 °C; the release of nitrophenols was monitored at 400 nm. Lineweaver–Burk treatment was applied to derive the k_{cat} and K_d values. [b] Determined by UV titration at 230 nm of the acidic solution of a cyclodextrin thiol with aq. NaOH. [c] Data at pH 11.7 from ref. 19.

with Na–NH_3 (l) gave the cyclodextrin thiols **4**, **9** and **14** which were further converted to the corresponding dimers **5**, **10** and **15** for storage.† The thiols were freshly regenerated with $NaBH_4$ just before use.

The free thiols show no obvious absorption above 215 nm while deprotonation of the thiol group generates a new absorption bond around 230 nm. Titrating the acidic solution of the thiols with aq. NaOH solution and following the absorption changes at 230 nm allows the determination of their pK_a values. As shown in Table 1, the three thiols **4**, **9** and **14** have pK_a values of 7.5, 7.7 and 7.7, respectively, very similar to each other. The behaviour of these thiols on cleavage of phenyl esters was investigated by following the absorption changes of the buffered aqueous solution of *m*-nitrophenyl acetate and its *p*-isomer, which are widely employed as substrates for serine protease mimics. The kinetic parameters of the thiocyclodextrin-mediated decomposition of nitrophenyl acetates at pH 9.0 are summarized in Table 1. β-CD-3-SH **9** significantly facilitates the reactions. It cleaves *p*- and *m*-nitrophenyl acetates 500 and 290 times faster than the buffer solution. Compared with β-cyclodextrin, β-CD-3-SH **9** is 62 times more effective towards *p*-nitrophenyl acetate and 3 times more effective towards the *m*-isomer. The result with β-CD-2-SH **4** is very different. This thiol shows a rate acceleration of 26 fold over the buffer solution in hydrolysing the *p*-nitrophenyl acetate, about 3 times that of β-CD. However, it hydrolyzes the *m*-isomer 3 times less effectively than β-cyclodextrin itself. As a result, β-CD-3-SH **9** is 10–20 times more effective than β-CD-2-SH **4** in promoting the acyl transfer of both substrates. Obviously the thiol group of both β-CD-2-SH **4** and β-CD-3-SH **9** is engaged in the reaction. The kinetic difference between them is most likely a reflection of their geometric specificity rather than their acidity difference since both thiols have similar pK_a values and should deprotonate almost to the same extent at pH 9.0. Only when SH is put in the right position with the correct conformation required to access the transition state can it significantly accelerate the reaction. This position appears to be C-3. Incorporation of SH at C-3 of α-cyclodextrin also gives striking results. α-CD-3-SH **14** accelerates the cleavage of *m*-nitrophenyl acetate by a factor of 4000, 25 times that of its *p*-isomer.

As suggested by the kinetic data in Table 1, the thiocyclodextrins decompose the nitrophenyl acetates in a pre-binding process, just in the same way that the native cyclodextrins do. All the thiocyclodextrins bind the ground state of *p*-nitrophenyl acetate ($1/K_d$) with a comparable strength which is not obviously different from that of native cyclodextrins. However, their transition state (TS) binding ($1/K_{TS}$) is quite different. β-CD-3-SH **9** binds the TS of *p*-nitrophenyl acetate 30 times tighter than its counterpart β-CD-2-SH **4**. Compared with the corresponding native cyclodextrins, β-CD-3-SH **9** and α-CD-3-SH **14** increase the TS binding by 64 and 33 fold, respectively, while β-CD-2-SH **4** does not significantly alter it. A similar result is also obtained in the case of *m*-nitrophenyl acetate. Replacement of one 3-OH of the cyclodextrins by SH greatly increases the TS binding of *m*-nitrophenyl acetate, whereas the replacement of one 2-OH by SH does not significantly change the binding of both ground state and TS. It is apparent that the 3-SH is preferred to the 2-SH as nucleophile in developing the transition state of the acyl transfer reaction of both substrates.

No significant conformational difference should exist between the modified cyclodextrins and the corresponding native ones except that one of the secondary hydroxy groups is replaced by SH. Though the S atom is larger than an O atom and would lead to an earlier TS for the acyl transfer, it appears that this replacement does not reverse the geometric preference of the ester cleavage for the 2- or 3-position. Thus the present research may supply a useful approach to evaluate the reactive group in the cyclodextrin-accelerated cleavage of phenyl esters.

We thank Japan Maize Products Co. Ltd. for a generous gift of cyclodextrins. D.-Q. Y. thanks the NSFC for projects 29632004 and 29772023 and the State Education Committee of China for project 380.

Dependence of the relaxivity and luminescence of gadolinium and europium amino-acid complexes on hydrogencarbonate and pH

Silvio Aime,*[a] Alessandro Barge,[a] Mauro Botta,[a] Judith A. K. Howard,[b] Ritu Kataky,[b] Mark P. Lowe,[b] Janet M. Moloney,[b] David Parker*[b] and Alvaro S. de Sousa[b]

Received (in Cambridge, UK) 22nd March 1999, Accepted 28th April 1999

Reversible binding of hydrogencarbonate to a chiral di-aqua lanthanide complex occurs in the pH range 6.5–8.5, limiting the measured relaxivity in the gadolinium complex and enhancing the metal-based emission in the europium analogue.

The behaviour of well defined lanthanide complexes is currently being explored in which the metal-based luminescence (Eu, Tb, Yb)[1] or relaxivity (Gd)[2,3] is a function of a defined biochemical parameter or set of variables, such as pH, $p(O_2)$ or anion concentration. Modulation of the luminescence or relaxivity of a given lanthanide complex may occur *via* ligand- or metal-based processes. Deprotonation of water molecules bound to the metal centre offers an effective means of reducing the relaxivity of cationic gadolinium complexes and pH-dependent behaviour has been demonstrated.[3] For luminescent complexes of europium and terbium, the removal of proximate OH oscillators increases both the lifetime and intensity of the metal-based emission,[4] as intramolecular vibrational quenching of the excited $^5D_0$ or $^5D_4$ state is significantly reduced.[5] Recent preliminary reports have suggested that the binding of hydrogencarbonate to a tri- or di-aqua metal centre may modulate the luminescence[4] (Eu, Tb) and the relaxivity[6] (Gd) of lanthanide complexes under ambient conditions. Such behaviour offers a means of studying both the concentration of HCO_3^- in solution and the pH in the ambient range *via* the H_2CO_3/HCO_3^- equilibrium (effective pK_a = 6.16, I = 0.1 mol dm^{-3}, 298 K).

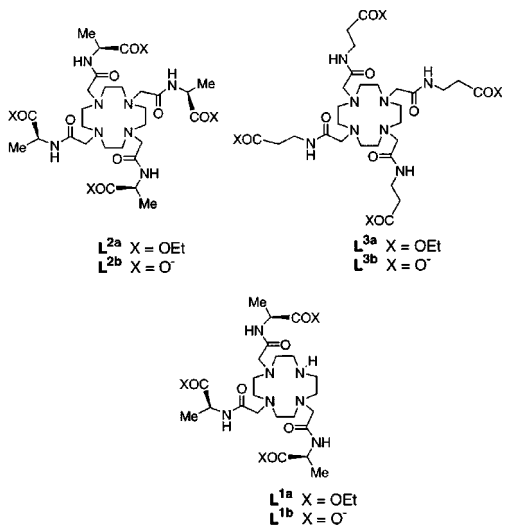
With this in mind, a heptadentate ligand L^{1a} and two model octadentate analogues L^{2a} and L^{3a} have been prepared, and the luminescence and relaxivity of their Eu and Gd complexes studied as a function of pH in the presence or absence of HCO_3^-. Reaction of (*S*)-ethyl-*N*-2-chloroethanoylalanate with 1,4,7,10-tetraazacyclododecane (MeCN, Cs_2CO_3, 65 °C, 18 h, 1% KI) yielded the tetra-ester L^{2a}, and a similar reaction with the β-alanine analogue gave L^{3a} in 55% yield, after purification by column chromatography on neutral alumina. Under milder alkylation conditions (MeCN, $NaHCO_3$, 4 Å sieves, 48 h, 20 °C), the tri-ester L^{1a} was formed and purified on silica gel (CH_2Cl_2, 0→3% Pr^i_2NH). Reaction of the anhydrous $Ln(CF_3SO_3)_3$ salt with each of these ligands in boiling dry MeCN afforded the corresponding cationic esters, and controlled hydrolysis of the ester groups (20 °C, 24 h, 0.02 M NaOH) followed by cation exchange chromatography (Dowex 50 W H^+, eluent 0.5 M aq. ammonia) yielded the carboxylic acid complexes $[LnL^{2b}]^-NH_4^+$, $[LnL^{3b}]^-NH_4^+$ and $[LnL^{1b}]$. The complex $[EuL^{2a}]^{3+}$ crystallised as the hydrated hexafluorophosphate salt from aqueous solution and the crystal structure† revealed a regular mono-capped square-antiprismatic geometry about the europium ion. The NC–CN and NC–CO torsion angles averaged −58.9 and +28.6°, respectively consistent with a Δ(λλλλ) absolute configuration, as observed previously for related tetra-amides with an *S*-configuration at the stereogenic carbon centre.[7] Europium–ligand oxygen bond lengths averaged 2.405 Å [Eu–N(av) 2.642 Å] and the Eu–OH_2 bond length was 2.429(4) Å.

The kinetic stability of the gadolinium complexes was assessed by measuring the change in the water proton relaxation rate as a function of time in 2.5 M HNO_3 at 298 K. The half-lives for dissociation under these conditions were 639 h $[GdL^{2b}]^-$, 304 h $[GdL^{3b}]^-$ and 0.2 h $[GdL^{1b}]^-$. Such high stability to acid-catalysed dissociation has been observed previously for tetra-amide Gd complexes[9] and may be compared to a value of 4.5 h for $[Gd(dota)]^-$ (dota = 1,4,7,10-tetraazacyclododecane tetracetate). The corresponding europium complexes were stable in aqueous solution at 20 °C in the pH range 3–10 for several weeks.

Variable temperature ^{17}O NMR experiments with the Gd complexes of L^{1b}, L^{2b} and L^{3b} allowed the mean lifetime for water exchange to be estimated. At 298 K and pH 7, τ_m values of 8.31, 19.0 and 1.24 μs were measured for $[GdL^{2b}]^-$, $[GdL^{3b}]^-$ and $[GdL^{1b}]$ respectively which are sufficiently slow to limit the overall relaxivity of the two q = 1 complexes[9] [eqn. (1); $\tau_m > T_{1m}$, where R^{is}_{1p} is the inner sphere contribution to the

$$R^{is}_{1p} = \frac{C_{tot}q}{55.6\,(T_{1m} + \tau_m)} \quad (1)$$

measured relaxivity, τ_m is the mean water exchange rate, q is the number of bound water molecules, C_{tot} is the complex concentration (mM) and T_{1m} is the longitudinal relaxation time of the coordinated water protons]. Thus at 20 MHz, 298 K and pH 6, the measured proton relaxivity was 2.86 mM^{-1} s^{-1} for $[GdL^{2b}]^-$, 2.31 mM^{-1} s^{-1} ($[GdL^{3b}]^-$) and 7.21 mM^{-1} s^{-1} for $[GdL^{1b}]$. The pH dependence of the relaxivity of $[GdL^{2b}]^-$ and $[GdL^{3b}]^-$ (20 MHz, 298 K) was similar. In the pH range 5–8, the overall relaxivity is dominated by the outer sphere contribution, and at lower pH successive protonation of the carboxylate groups (pH 4.5–2.5) slightly enhanced the relaxiv-



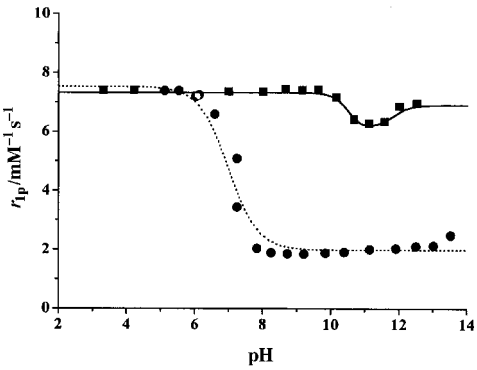


Fig. 1 pH Dependence of the relaxivity of [GdL^{1b}] (1 mM, 20 MHz, 298 K) in degassed aqueous solution (■), and in a saturated aqueous solution of $NaHCO_3$ (●). The solid and dotted lines show the fits to the experimental data.[11]

ity associated with prototropic exchange. At pH > 9, base-catalysed prototropic exchange occurs, involving the co-ordinated water molecule (pK_a = 9.3, measured potentiometrically, 298 K, I = 0.1 M NMe_4NO_3); at pH > 11, fast exchange of the amide NH protons is associated with even higher overall relaxivity values owing to an enhanced interaction with second-sphere waters, as suggested for related tetra-amide complexes.[8,11]

The relaxivity behaviour of [GdL^{1b}] differed markedly: in degassed solution (*i.e.* in the absence of dissolved CO_2 and [HCO_3^-]) the relaxivity in the pH range 2→10 was very similar to that observed for other q = 2 complexes . In aerated solution, and more clearly in a saturated aqueous solution of $NaHCO_3$, the relaxivity was very low in the pH range 8→12 (1.90 mM^{-1} s^{-1}), typical of a purely 'outer-sphere' contribution. As the pH tends towards 6, the [HCO_3^-] falls and the relaxivity increased markedly (Fig. 1).

With the corresponding europium complex, [EuL^{1b}], the rate constant for decay of the Eu luminescence was measured at pH/D = 3.80 to be 2.94 (H_2O) and 1.23 ms^{-1} (D_2O), and at a pH/D of 8.6 in the presence of a 40-fold excess of $NaHCO_3$ k_{H_2O} = 2.27, k_{D_2O} = 1.33 ms^{-1}. Such values are consistent with a reduction in the number of directly bound water molecules (q) and q values of 1.49 (pH 3.8) and 0.55 (pH 8.6) may be estimated.[5] The intensity (and lifetime) of the Eu-emission was only pH dependent in the presence of HCO_3^- and the intensity of the hypersensitive ΔJ = 2 band (λ_{em} = 618 nm) decreased by a factor of 9 as the pH fell to 6.5 (1 mM [EuL^{3b}], 40 mM $NaHCO_3$). A pH titration (Fig. 2) in a simulated background of physiological anions highlights the reduction in intensity of this band with pH. The ^{1}H NMR spectrum of [EuL^{1b}] at pD 3.8 (293 K) revealed a pattern of resonances characteristic of a square-antiprismatic coordination environment,[7,8,10] with the most shifted ring axial protons resonating at δ 24.9, 17.3, 14.8 and 12.0. At pD = 8.6, in the presence of a 40-fold excess of $NaHCO_3$, the spectrum changed dramatically and the four ring axial protons resonated at δ 11.0, 9.2, 7.7 and 6.2. In the absence of added $NaHCO_3$, no significant spectral changes occurred over the pD range 3–8.

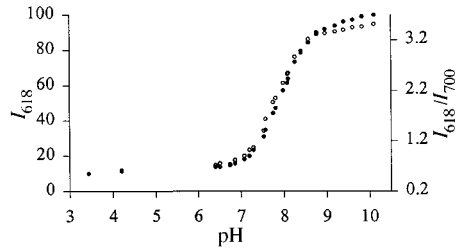

Fig. 2 pH Dependence of the europium luminescence of [EuL^{1b}] [1 mM, 298 K, 30 mM added $NaHCO_3$, 0.1 M NaCl, 2.3 mM lactate, 0.13 mM citrate, 0.9 mM hydrogenphosphate; λ_{em} = 618 nm (ΔJ = 2), and with the *ratio* of ΔJ = 2/ΔJ = 4 bands (open circles)].

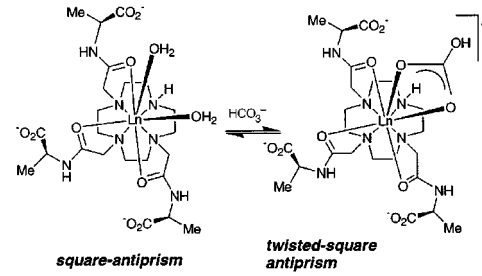

Scheme 1

Taken together the solution behaviour is consistent with reversible chelation of HCO_3^- at the lanthanide centre, displacing the bound water molecules. In the chelated ternary complex, the lanthanide ion adopts a twisted square-antiprismatic structure with a reduced helicity about the metal centre[4] (Scheme 1). The behaviour observed with these model complexes augurs well for the development of practicable relaxation and luminescent complexes that respond to pH and $pHCO_3$ changes in biological fluids under physiological conditions.

Organometallic chemistry on silicon surfaces: formation of functional monolayers bound through Si–C bonds

Jillian M. Buriak*

Department of Chemistry, 1393 Brown Laboratories, Purdue University, West Lafayette, IN 47907-1393, USA. E-mail: buriak@purdue.edu

Received (in Cambridge, UK) 5th January 1999, Accepted 8th March 1999

Silicon chips form the backbone of modern computing and yet until recently, the surface chemistry of this technologically essential material has remained relatively unexplored. As the size of devices on silicon wafers shrink (towards gigascale integration), the surface characteristics play increasingly crucial roles in the proper functioning of the device since the ratio of surface atoms/bulk escalates. While surface oxide has served thus far as the main passivation route, there is strong interest in precisely tailoring the interface properties, not only for microelectronics, but other applications including sensors, MEMS and biologically active surfaces. As a result, organometallic and organic chemistry has become essential for the synthesis of functional, modifiable monolayers, bound to non-oxidized silicon surfaces through silicon–carbon bonds. The latest approaches towards preparation of monolayers through Si–C bonds on both flat and photoluminescent porous silicon are described. Wet chemical techniques, accessible to most organometallic/organic chemists are highlighted, but recent developments using UHV conditions also receive attention.

Introduction

Silicon is clearly the most technologically important material utilized today owing to its ubiquitous role in microelectronic computing. With few exceptions, all microprocessor chips in electronic products are based upon flat, crystalline silicon wafers. In spite of several decades of intense research into the properties and potential applications of silicon, the surface chemistry of this material has only recently begun to be investigated in a systematic fashion.[1] As electronic devices on silicon become progressively smaller, the fraction of atoms residing on or near the surface becomes significant.[2] The chemical nature of these interface atoms thus plays a crucial role in the proper functioning and characteristics of the device. While native oxide on silicon has proven extremely useful in electronically passivating bulk silicon, much attention is being directed towards the synthesis of organic monolayers which can be modified upon demand for specific requirements. By tapping into the vast resources of organic and organometallic chemistry, a wide variety of functionalities can be synthesized and incorporated which will allow for fine tailoring of surface characteristics for a broad range of applications, some of which are outlined in this review. Because the surface chemistry of non-oxidized silicon is still in its infancy, several different approaches have been taken to first understand its reactivity, and then to subsequently exploit the reactivity to prepare stable, sophisticated interfaces. This review will focus exclusively on the chemistry involving formation of organic monolayers on both flat and porous silicon surfaces bound directly to the underlying bulk material through silicon–carbon bonds, some examples of which are shown in Fig. 1. Wet bench-top reactions are emphasized although recent advances utilizing ultra-high vacuum (UHV) conditions will be outlined. Capping of silica and glass surfaces with alkyl-, alkoxy- and chloro-silanes has been reviewed elsewhere.[3]

Professor Jillian Buriak was born in Toronto, Canada in 1967. She received her A. B. Degree from Harvard University in 1990 and pursued undergraduate research with Professor Andrew R. Barron. After teaching high school sciences in the Fiji Islands on a Catherine Innes Ireland Fellowship from Radcliffe College, she commenced her doctoral studies in 1991 with Professor John A. Osborn at the Université Louis Pasteur in Strasbourg, France. Upon completion of her PhD in 1995, she carried out two years of post-doctoral research with Professor M. Reza Ghadiri at The Scripps Research Institute in La Jolla, California. In 1997 she joined the faculty at Purdue University as an Assistant Professor of Inorganic Chemistry.

Flat, single crystal silicon

Single crystal silicon wafers of high purity are commercially available and relatively inexpensive due to their wide use in microelectronic applications. The most common surface orientations are Si(111) and Si(100) (*vide infra*) although other Si(*hkl*) orientations are known.[1] Upon exposure to air, single crystal silicon becomes rapidly coated with a thin, native oxide that can be removed chemically with fluoride ion or thermally under UHV conditions. Depending upon the desired electronic properties, silicon wafers are doped in a controlled fashion with electron donating (P, As, Sb: *n*-type) or withdrawing (B: *p*-type) impurities to render the intrinsic material more highly conducting.

Porous silicon

While much of the effort towards preparation of organic monolayers on silicon has been directed towards flat, single crystal surfaces, a substantial body of research has been dedicated to porous silicon functionalization.[2] Porous silicon is a potentially revolutionary variant of crystalline silicon[4] because of its tunable electro-, photo- and chemo-luminescent properties.[5] While bulk silicon is an extremely poor light emitter, porous silicon can achieve quantum efficiencies in excess of 10%, rendering it technologically important for optoelectronic applications, that is, incorporation of both optical and electronic elements into integrated circuits.[6] Because it is easily prepared through simple galvanostatic,[7] chemical (stain),[8] or photochemical[9] etches from silicon wafers ('bucket' chemistry),[5] porous silicon could be readily integrated with existing silicon-based integrated circuit (IC) manufacturing processes. Other non-silicon-based light emitting materials such as GaAs or organic light emitting compounds will require

extensive modification of the IC processes for their incorporation into silicon-based chips.

Porous silicon has a highly complex nanoscale architecture made up of one-dimensional crystalline nanowires and zero-dimensional nanocrystallites as demonstrated in Fig. 2. This material has elicited publication of over 4000 papers[10] since the discovery of its photoluminescence in 1990 which is testament not only to its technological potential, but to the fundamental interest in understanding the luminescence phenomena of nanocrystalline particles.[11] The major barrier preventing commercial applications of porous silicon is the instability of its native interface, a metastable Si–H termination (*vide infra*), and thus surface chemistry has proven to be a crucial element for the technological success of this material. The photoluminescence of porous silicon depends strongly upon the surface passivation, with certain functionalities (*i.e.* halogens)[12] resulting in complete quenching of light emission. While highly debated in the literature, it is generally accepted that quantum confinement effects, arising from recombination of entrapped electron-hole pairs (excitons) within the boundaries of nanocrystallites/nanowires with diameters of *ca.* 2 nm, are responsible.[2,5] Surface states associated with various interface species can have dramatic quenching effects if they provide sites for non-radiative recombination of the excitons.[13] The precision of organic chemistry promises to allow for fine tuning of these important interfacial effects, leading ultimately towards an understanding of the role of surface states on semiconducting nanoparticles in general. The nature of the surface bond, sterics, conjugation, and electronics of organic substituents can all be modulated at will and should provide: (i) stable porous silicon surfaces, (ii) modifiable surface characteristics, and (iii) potential to interface with organic conductor/semiconductors/LEDs and biologically relevant molecules for an array of applications.

Wet chemical functionalization strategies

For the preparation of functionalized, non-oxidized silicon interfaces, silicon–hydride terminated surfaces generally serve as an ideal starting point (Fig. 3). Si–H passivation is only metastable with respect to oxidation under ambient conditions, thus precluding long-term use in most cases. These surfaces can, however, be handled in air for tens of minutes with little degradation which renders them accessible to chemists and materials scientists wishing to use standard Schlenk and glove box techniques.[14] Silicon–hydride termination of commercial, native oxide capped flat crystal silicon wafers is carried out quickly and efficiently in under 10 min using commercially available fluoride sources. Dilute (1–2%) aqueous HF treatment of a Si(100) wafer yields the (100) dihydride $=SiH_2$ capped surface, and 40% aqueous NH_4F of a Si(111) wafer provides the atomically flat (111) monohydride ≡SiH terminated surface.[15] Porous silicon, when etched through standard procedures involving HF, is also hydride terminated but is coated with $–SiH_3$, $=SiH_2$, ≡SiH groups in a variety of different local orientations and environments owing to the porous nature of the material.[16] All the freshly etched silicon hydride terminated surfaces are chemically homogeneous (> 99% H termination) which is essential for clean reactions.

The hydride terminated surfaces are extremely useful surface precursors because the Si–H and Si–Si bonds can serve as chemical handles through which functionalization can be mediated. The body of literature involving functionalization of soluble, molecular silicon–hydride and silicon–silicon containing compounds is vast.[17] Several of these reactions for molecular compounds have been adapted and applied to surfaces, as described here. Other reactions, on the other hand, have no molecular equivalents since they utilize the underlying bulk electronic properties of the semiconducting silicon.

The chemistries of hydride terminated porous and flat, single crystal silicon surfaces are closely related and, with few exceptions, a novel reaction found to operate on one surface usually has some degree of success on the other.[18] Porous silicon is especially attractive due to its high surface area which renders analysis relatively straightforward through conventional transmission Fourier transform IR (FTIR) or diffuse reflectance IR (DRIFT) spectroscopy. As a result, routine characterization of this material is practical and facile for most chemists. Flat surfaces offer, on the other hand, a much more structurally homogeneous surface that is extremely useful for controlled reactivity studies. The general mechanistic trends for flat and porous silicon interfaces are very closely related and thus are discussed here interchangeably.

Hydrosilylation involving a radical initiator

Hydrosilylation involves insertion of an unsaturated bond into a silicon–hydride group as shown in Fig. 4. Alkyne and alkene hydrosilylation on Si–H terminated surfaces yields alkenyl and alkyl termination, respectively. The first example of hydrosilylation of non-oxidized Si–H passivated silicon was carried out by Chidsey and coworkers in 1993 on flat crystal Si(111)

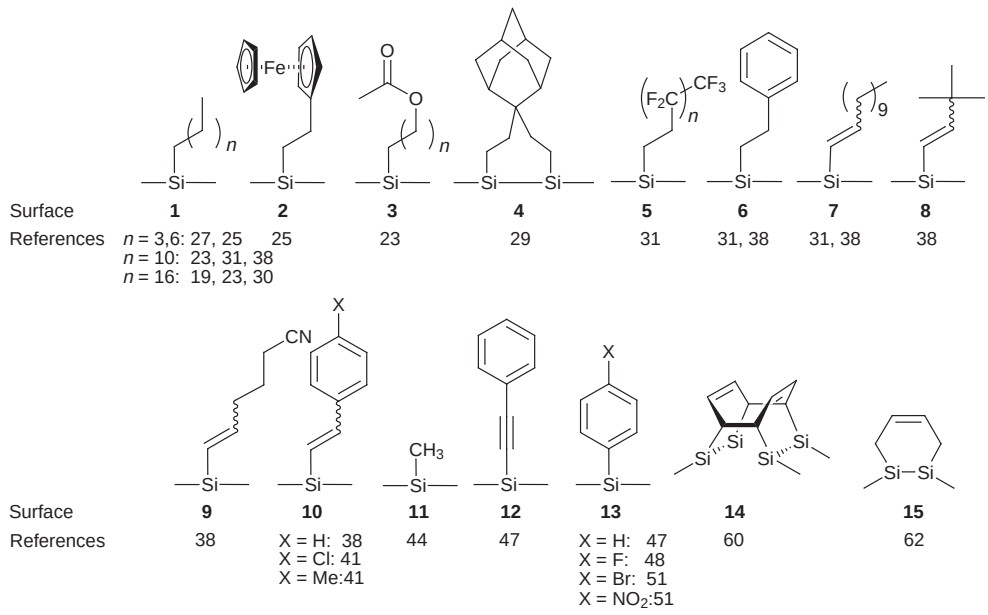

Fig. 1 Examples of organic monolayers formed on various silicon surfaces, bound through Si–C bonds.

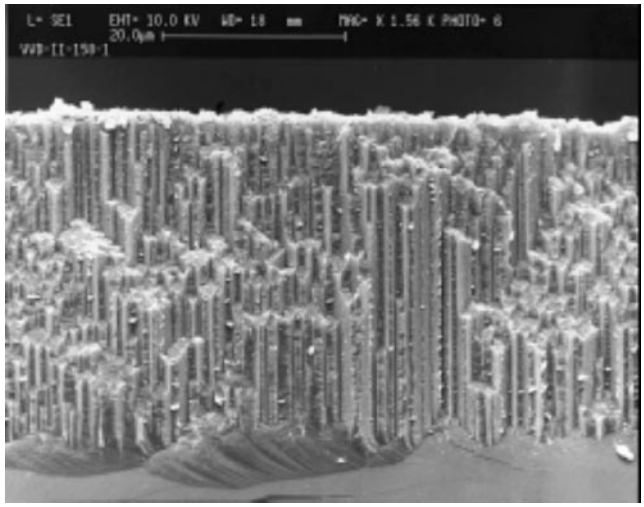

Fig. 2 Cross-sectional scanning electron micrograph (SEM) of a 30 μm thick porous silicon layer electrochemically etched on a (100) single-crystal wafer. The pores here are on the order of μm but through variation of the etching conditions, a wide range of pore sizes (from 2 nm to μm) is easily accessed. Professor M. J. Sailor is thanked for his kind permission to use this figure from ref. 2. Reproduced with permission from Wiley-VCH.

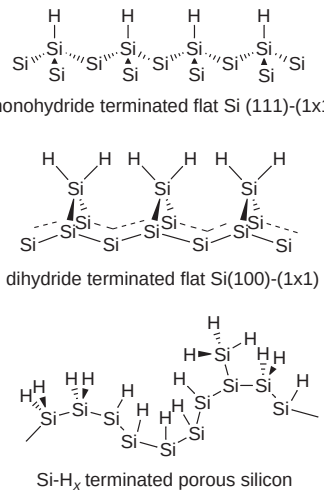

Fig. 3 The Si(111), (100) and porous silicon hydride terminated surfaces discussed here. The flat Si(111) (1 × 1) surface is capped with only one hydride to satisfy the tetravalency of the silicon atoms. The dihydride flat Si(100) (1 × 1) is shown but monohydride Si(100) (2 × 1) and mixed mono- and di-hydride Si(100) (3 × 1) surfaces are also possible.[1]

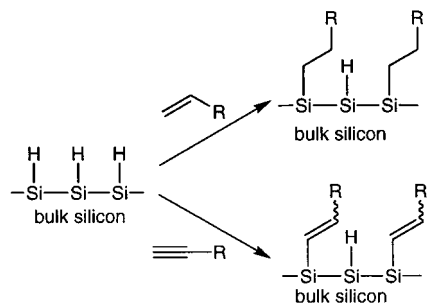

Fig. 4 Hydrosilylation of alkenes or alkynes involves insertion of the carbon–carbon unsaturated bond into the silicon–hydride bond, yielding alkyl and alkenyl terminated surfaces, respectively.

surfaces.[19] Insertion of alkenes into surface bound Si–H groups, in the presence of a diacyl peroxide radical initiator, provided high quality alkyl monolayers at 100 °C. Monolayers prepared from octadecene, yielding octadecyl groups on the surface (surface **1**, Fig. 1), are densely packed and tilted approximately 30° from the surface normal. As a result of the good coverage provided by the film, the silicon surfaces demonstrate excellent stability and withstand extended boiling in aerated chloroform, water, acid (2.5 M H_2SO_4 in 90% dioxane, v/v) and base (10% aqueous 1 M NH_4OH), and are resistant to fluoride (immersion in 48% aqueous HF). Under ambient conditions in air, little oxidation of the silicon surface is observed, indicating the usefulness of this approach for technological applications.

The authors propose a radical mechanism for monolayer formation under these conditions. The initiator, the diacyl peroxide, undergoes homolytic cleavage to form two acyloxy radicals which decompose to carbon dioxide and an alkyl radical.

$$[RC(O)O]_2 \rightarrow 2RC(O)O\cdot$$
$$RC(O)O\cdot \rightarrow R\cdot + CO_2$$

The alkyl radical can then abstract H· from a surface Si–H group to produce a silicon radical.

$$R\cdot + HSi\equiv \rightarrow RH + \cdot Si\equiv$$

Because silyl radicals are known to react extremely rapidly with olefins, formation of a silicon carbon bond is the next probable step.[20]

$$R'CH{=}CH_2 + \cdot Si\equiv \rightarrow R'(CH\cdot)CH_2Si\equiv$$

The carbon-based radical can then abstract a hydrogen atom either from a neighboring Si–H group or from the allylic position of an unreacted olefin.

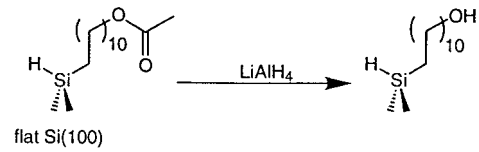
The majority of studies carried out by this group involved perhydroalkenes but the ω-Cl terminated olefin, 11-chloroundec-1-ene, produced good quality monolayers with chloride termination. As suggested by the authors, further functionalization of the surface through the chloride is possible. Hydrosilylation of the alkyne, hexadecyne, produced a good quality monolayer and as noted in a footnote,[21] may be bound to the silicon surface through a vinyl group as would be expected. The use of the bromide terminated olefin, 11-bromoundec-1-ene, however, produced a poorly organized monolayer, perhaps due to the incompatibility of the Br with the radical nature of the reaction.

Thermally induced hydrosilylation

Control experiments carried out by Chidsey and co-workers during their investigations of diacylperoxide initiated olefin hydrosilylation on Si(111) surfaces indicated that the reaction could occur in the absence of diacylperoxide initiator at higher temperatures (≥150 °C), almost certainly through homolytic Si–H cleavage.[22]

$$HSi\equiv \rightarrow \cdot H + \cdot Si\equiv$$

The silyl radical will then proceed to react with the olefin to form the silicon–carbon bond. This result was pursued by Sudhölter and coworkers on hydride terminated Si(100).[23] Working at 200 °C, a number of different olefins were examined for their propensity to form stable monolayers. 2 h contact time produced closely packed monolayers when long-chain aliphatic alkenes (12–18 C, surface **1**, Fig. 1) were used as judged by X-ray reflectivity, ATR IR spectroscopy and contact angle measurements. With ω-ester substituted alkenes, ester terminated alkyl surfaces were prepared (surface **3**, Fig. 1) and then subsequently cleaved with $LiAlH_4$ (Scheme 1) to yield the hydrophilic, hydroxy-terminated silicon surface.



Scheme 1

This reaction clearly demonstrated that alkyl monolayers on silicon are robust enough to tolerate further chemical reactions,

and can be built upon directly to produce more sophisticated surfaces. Alcohol-terminated alkenes could not be utilized directly through this method because they react with the surface through the hydroxy group, yielding ill defined monolayers. Thus traditional protecting group strategies may be viable options when preparing functional films on silicon. Recent work has demonstrated that aliphatic monolayers produced on hydride terminated Si(111) and Si(100) through this reaction are also stable up to 615 K under vacuum which indicates that organic monolayers on silicon can be thermally resistant.[24]

Thermally induced hydrosilylation of alkynes and alkenes has been applied to Si–H terminated porous silicon surfaces. Horrocks and Houlton reported that refluxing porous silicon for 18–20 h at 110–180 °C in an aliphatic alkyne or alkene yields alkyl monolayers (surface **1**, Fig. 1).[25] Alkyne hydrosilylation does not produce surface bound vinyl groups as one would expect, presumably because it undergoes two hydrosilylations. Hydrosilylation of vinyl ferrocene (surface **2**, Fig. 1) was particularly interesting since it allows for electrochemical investigations of the ethylferrocene terminated surface. While these surfaces demonstrate good stability to boiling base (75% KOH–25% EtOH, pH 12), significant photoluminescence quenching due to the thermal hydrosilylation is observed (Fig. 7, *vide infra*). Porous silicon is inherently fragile and appears to degrade under extended reflux conditions.

Photochemical hydrosilylation (UV)

It is known in the organic and organometallic literature that UV irradiation can promote hydrosilylation of unsaturated compounds[26] due to homolytic cleavage of Si–H bonds, as is the case with thermal induction. UV photoinduction, however, takes place at room temperature and thus provides a way to avoid thermal input which could be harmful to delicate or small features on a silicon chip. Minimal input of thermal energy would be preferable in any IC manufacturing process (thermal budget). Chidsey and coworkers showed in 1997 that irradiation of a hydride terminated Si(111) surface with UV light (185 and 253.7 nm) in the presence of an aliphatic alkene like pent-1-ene or octadec-1-ene (surface **1**, Fig. 1) brought about hydrosilylation in 2 h at room temperature.[27] Interestingly, these surfaces were further functionalized through a biphasic (gas/solid) photoinduced (351 nm) free radical chlorosulfonylation of the terminal methyl groups and then reacted with ethylenediamine (Scheme 2).[28] The authors propose binding of biomolecules to the amino terminus for investigation by scanning probe microscopy (SPM), sensing, and surface related assays. UV irradiation derived from a Xe UV lamp (24 h) has also been used to hydrosilylate divinyladamantane on Si(111) surfaces for use as a solid substrate for chemical vapor deposition (CVD) of diamond films (surface **4**, Fig. 1).[29]

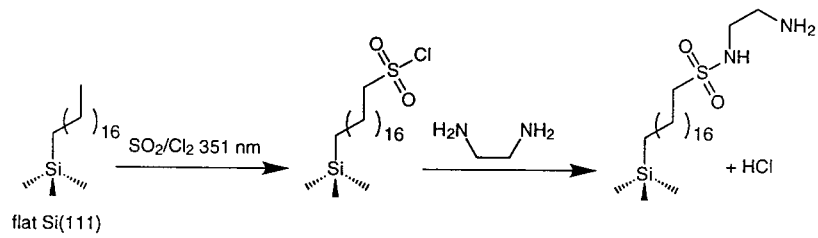
These results were followed up by Effenberger *et al.* who found that irradiation with substantially longer wavelengths, up to 385 nm, for 20–24 h were also effective in promoting alkene hydrosilylation on Si(111) surfaces (surface **1**, Fig. 1).[30] Using masking techniques, they photopatterned the surface to produce areas of differing wettabilities as visualized under a microscope.

Photochemical hydrosilylation (white light)

Recently, Stewart and Buriak demonstrated that a simple white light source could induce hydrosilylation of alkenes and unconjugated alkynes on Si–H terminated photoluminescent porous silicon surfaces at room temperature in minutes.[31] Illumination of an unfiltered tungsten ELH bulb (GE slide projector bulb) of moderate intensity (22–44 mW cm^{-2}) on a photoluminescent porous silicon sample wetted with an alkene or alkyne (surfaces **1**, **5**–**7**, Fig. 1) induces surface hydrosilylation as demonstrated schematically in Fig. 5. Because the reaction is photoinduced, photopatterning can be easily carried out with simple optical apparatus to prepare spatially defined areas of differing chemical functionalities. For instance, use of a f/75 reducing lens and a mask produced with a high quality laser printer can achieve features as small as 30 μm. Examples of larger scale photopatterning on porous silicon produced from n-type silicon crystal wafers are shown in Fig. 6. As demonstrated in Fig. 6(b)–(d) long aliphatic substituents on the surface, here dodecyl groups, can sufficiently protect the surface from boiling alkali. The remaining, unpatterned areas of Si–H termination dissolve rapidly under these conditions in what can be viewed as a lithographic process. Dodecyl terminated samples will tolerate boiling for 30 min in aerated aqueous KOH (pH 10) solution, conditions under which freshly etched (Si–H terminated) porous silicon will dissolve in seconds. These surfaces are not, however, as stable as those produced through Lewis acid mediated hydrosilylation (*vide infra*, Hydrosilylation mediated by metal complexes) which will resist several hours of contact with alkali at 100 °C. The unpatterned areas of surface Si–H groups can, instead of undergoing dissolution, hydrosilylate (white light induced) a second alkene or alkyne to produce domains of differing terminations. This provides an extremely useful method of hydrosilylating porous silicon surfaces at room temperature with simple white light illumination.

The mechanism of this reaction still remains to be determined. Monochromatic experiments indicated that the degree of incorporation increased with shorter wavelengths (450 > 550 > 650 nm) as measured by transmission FTIR. Because wavelengths as long as 400 nm will promote alkene hydrosilylation on hydride terminated Si(100) surfaces, the blue end of the white light illumination may induce homolytic Si–H cleavage to produce silicon radicals.[26] Alternatively, photogenerated holes on the photoluminescent porous silicon surface are produced upon light soaking which are subsequently attacked by alkyne or alkene nucleophiles.[32] Electron deficient alkynes (phenylacetylene, 4-methylphenylacetylene and 4-chlorophenylacetylene) require long reaction times (12 h) and are generally poorly incorporated, supporting a mechanism involving nucleophilic attack.[33] We are presently vigorously investigating this reaction through electron paramagnetic resonance (EPR) spectroscopy and chemical means in order to distinguish between surface radical reactions and potential involvement of the underlying electronic properties of the silicon nanocrystallites and nanowires which make up the porous silicon matrix.

The light mediated reaction appears very gentle and, depending upon the chemical groups incorporated, preserves most of the intrinsic photoluminescence of the porous silicon



Scheme 2

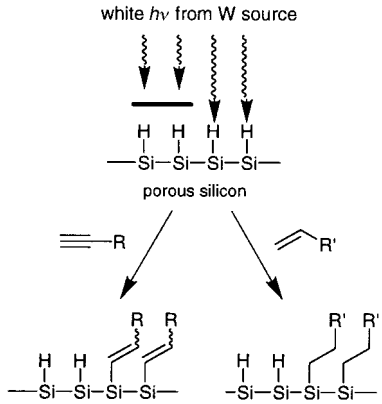


Fig. 5 Illumination of photoluminescent porous silicon samples with white light in the presence of an alkene or alkyene induces hydrosilylation, yielding alkyl and alkenyl termination, respectively. The reaction takes place at room temperature in 30–60 min, with white light of moderate intensity (22–44 mW cm^{-2}).[31] Masking techniques allow for preparation of spatially defined areas of chemical functionalities.

(Fig. 7). Dodecyl groups (surface **1**, Fig. 1), having no unsaturation, maintain 97% of the photoluminescence whereas dodecenyl termination (surface **7**, Fig. 1), bound to the surface through a vinyl group, preserves 61%. A small red shift of the photoluminescence of *ca.* 10 nm is observed. This functionalization strategy could, therefore, be important for preparation of optoelectronic porous silicon devices and sensors.

Hydrosilylation mediated by metal complexes

Because Pt(0) complexes and colloids are extremely effective catalysts for the hydrosilylation of alkenes with soluble, molecular silanes,[34] Zazzera *et al.* examined their potential on hydrogen terminated flat Si(100) surfaces.[35] Using 3,4-dichlorobutene as the olefin and platinum(0)–divinyltetramethyldisiloxane as the catalyst precursor, they observed chloride incorporation (from the Cl-containing olefin) on the surface as determined by XPS and surface mass spectrometry (TOF-SIMS) after 45 min at room temperature. *In situ* ATR IR spectroscopy indicated consumption of surface SiH_2 groups, supporting a hydrosilylation mechanism. They found, however, that the platinum complex also catalyzed oxidation of the silicon surface although this competing reaction could be reduced by minimizing trace water and utilizing a large excess of olefin.

Other workers have found that late transition metal complexes, in general, are problematic with respect to Si–H terminated porous silicon.[36] Exposure of freshly etched porous silicon to Wilkinson's catalyst, $RhCl(PPh_3)_3$, and the palladium complexes $PdCl_2(PEt_3)_2$ or $Pd(OAc)_2$/1,1,3,3-tetramethylbutyl isocyanide in the presence of alkynes,[37] resulted in blackening of the surfaces due to apparent metal deposition which thoroughly quenched the photoluminescence. Substantial oxidation was also noted even if considerable precautions were taken.

In order to avoid late transition metals and their accompanying problems of oxidation and metal deposition on porous silicon, Buriak and Allen utilized a Lewis acid to mediate hydrosilylation of alkynes and alkenes.[38] Lewis acid catalyzed or mediated hydrosilylation reactions seemed ideal for functionalization of porous silicon because of the mild reaction conditions involved and high selectivity and specificity of the corresponding solution phase reaction.[39] $AlCl_3$ is an effective catalyst for alkenes as well which suggested that Lewis acid mediated surface chemistry would not be limited to alkynes.[39b,c] Since $EtAlCl_2$ is soluble in non-polar solvents whereas $AlCl_3$ is not, it was chosen as the Lewis acid to avoid multiphasic reactions on the surface of porous silicon.[40] A wide range of alkynes and alkenes were smoothly hydrosilylated on Si–H passivated porous silicon at room temperature (surfaces **6**–**10**, Fig. 1), yielding vinyl and alkyl terminated surfaces, re-

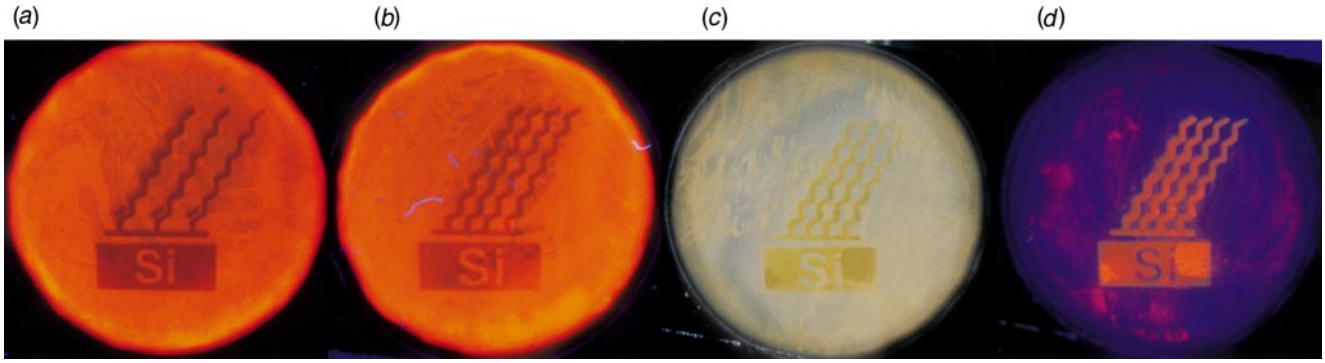

Fig. 6 Photographs of 12 mm diameter photoluminescent porous silicon samples prepared through white light promoted hydrosilylation of dodec-1-yne (surface **7**) and dodec-1-ene (surface **1**) through masking procedures.[31] (a) Surface **7** appears as the darkened, red-shifted patterned area when illuminated with a 365 nm hand-held UV lamp. The other areas of the wafer are unfunctionalized (native Si–H termination). (b) Surface **1** (ref-shifted patterned area) upon illumination with 365 nm light. (c) Sample from (b) after boiling in aerated, aqueous KOH (pH 12) solution for 15 s. The unfunctionalized porous silicon (grey area) has dissolved while the hydrosilylated surface (surface **1**, golden area) remains intact. (d) Illumination of the surface from (c) with a 365 nm hand held UV lamp. The PL of the hydrosilylated area (surface **1**) remains intact while most of the unfunctionalized PL is destroyed. This figure has been reproduced from ref. 31 with permission from Wiley-VCH.

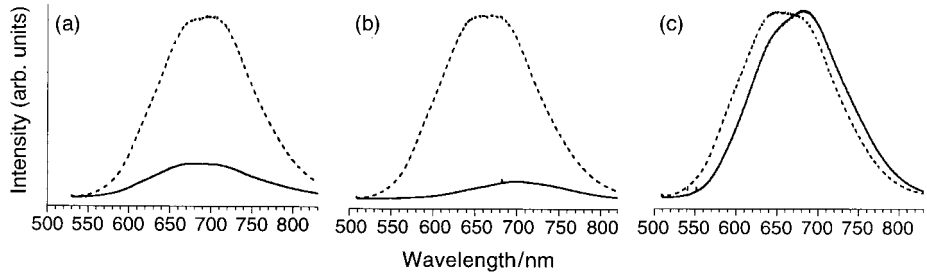

Fig. 7 Photoluminescence spectra of 1-dodecene hydrosilylation (surface **1**) on n-type porous silicon (440 nm excitation). The dotted spectrum is that of freshly etched porous silicon, and the solid that of the resulting dodecyl terminated surface. (a) Lewis acid mediated,[38] (b) thermally induced (2 h reflux in neat dodec-1-ene),[36] (c) white light promoted (60 min reaction at 22 mW cm^{-2} white light).[31]

spectively. By using an excess of $EtAlCl_2$, alkynes with coordinating functional groups (ester, hydroxy and cyano groups) could also be incorporated onto the surface. One equivalent of the Lewis acid complexes the coordinating group and the remainder mediates the hydrosilylation reaction. We have found, thus far, the reaction to be independent of silicon doping and morphology.

The effects of the reaction on photoluminescence have been studied in some detail. In all cases, at least 75% of the intrinsic photoluminescence is lost, as shown for dodec-1-ene in Fig. 7, although it can be partially restored through boiling in alkali or soaking in HF solutions.[41] Conjugated functionalities, such as styrenyl termination (surface **10**, Fig. 1), result in complete loss of photoluminescence with no possibility for recovery. Neither electron donating nor withdrawing substituents (chloro or methyl) on the conjugated styrenyl group have any effect on the photoluminescence. Sailor and Song observed similar effects for phenylacetylide termination (*vide infra*, Reactions of alkyl/aryl carbanions) in which a phenyl ring is conjugated through an alkyne linker (surface **12**, Fig. 1). These results suggest that surface states associated with the conjugated group result in efficient non-radiative recombination of the excitons produced upon irradiation with blue or UV light.

That the reaction is indeed hydrosilylation is strongly supported by the following experimental results. Consumption of Si–H groups can be clearly seen through difference FTIR spectra taken before and after the reaction with an alkyne or alkene.[36] The procedure with dodec-1-yne produces a surface bound vinyl group whose ν(C=C) of this olefin can be clearly distinguished in the transmission FTIR at 1595 cm^{-1} as shown in Fig. 8. It was proven through chemical means that this

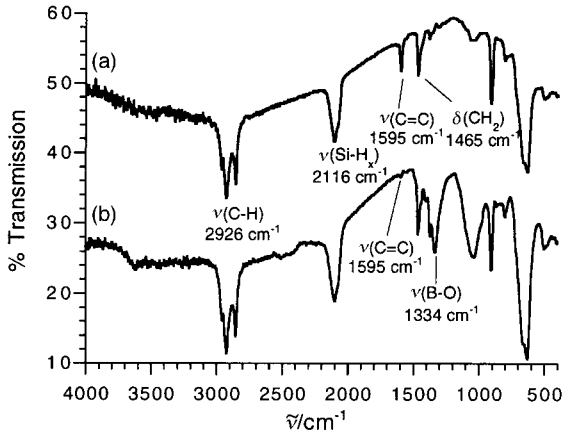

Fig. 8 FTIR (transmission mode) of monolayers prepared through: (a) hydrosilyation of dodec-1-yne mediated by $EtAlCl_2$ on porous silicon resulting in covalent attachment of a dodecenyl group (surface **7**) and (b) hydroboration of the surface-bound olefin of the dodecenyl group with 0.8 M BH_3·THF. The ν(C=C) vanishes upon hydroboration, as would be expected for an olefinic substituent. Reprinted with permission from *J. Am. Chem. Soc.* (ref. 38), Copyright 1998, American Chemical Society.

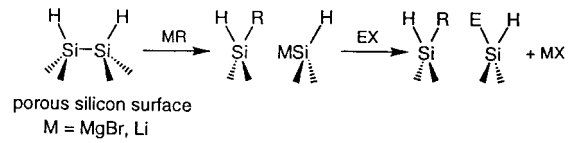
functionality is indeed a double bond. The dodecenyl terminated surface was hydroborated with excess 0.8 M BH_3·THF in THF under nitrogen followed by quenching of the surface in air and rinsing with excess THF.[42] Almost quantitative disappearance of the stretch at 1595 cm^{-1} was observed by transmission FTIR in Fig. 8(b), with concomitant appearance of a new stretch at 1334 cm^{-1} which corresponds to the B–O stretching frequency.[43] The stereochemistry of the borane addition has not been determined although it is expected that the boron atom will add preferentially to the least hindered carbon, that being the carbon β to the surface silyl group.

The hydrophobic, alkyl and alkenyl terminated surfaces are very stable under highly demanding chemical conditions. The dodecenyl functionalized surface (surface **7**, Fig. 1) will resist at least 4 h of boiling in aerated solutions of 25% EtOH–75% aqueous KOH (pH 10) with little change in the FTIR spectrum; Si–H terminated porous silicon dissolves in seconds. The surprising increase in photoluminescence of dodecyl and dodecenyl terminated porous silicon under these conditions may be due to a secondary basic etch at defect sites although this observation remains to be clarified.[41] Long term stability studies under ambient conditions are underway but preliminary results indicate that dodecenyl terminated porous silicon derived from p-type wafers is at least an order of magnitude more resistant to oxidation, as judged by FTIR spectroscopy. This route appears to be a promising, low temperature means of stabilizing porous silicon, and incorporating a broad range of chemical functionalities for preparation of 'smart', sophisticated silicon devices.

Reactions of alkyl/aryl carbanions

The use of alkyl Grignard and alkyl lithium nucleophiles on silicon surfaces was first investigated by Chazalviel, Ozanam and coworkers.[44] Silicon–methyl terminated porous silicon derived from p-type single crystal silicon (surface **11**, Fig. 1) was demonstrated to be electrochemically accessible through treatment of the native Si–H passivated surface with a methyl Grignard or methyl lithium organometallic under anodic conditions. As proposed by the authors, silicon hydride groups are consumed through a transmetallation reaction, forming silicon-methyl groups and either MgHX or LiH as by-products of the reaction. The stability of the surfaces increases an order of magnitude with respect to accelerated air oxidation at 100 °C as determined by FTIR spectroscopy. This electrochemical reaction is especially interesting since it has no obvious chemical equivalent for soluble, molecular silanes;[45] the semiconducting properties of the underlying silicon are harnessed to effect the chemistry.[46]

Song and Sailor[47] and Kim and Laibinis[48] subsequently investigated the effects of Grignard and alkyl and aryl lithium reagents without an electronic bias. The range of carbanion nucleophiles that could be bound to the surface of porous silicon through Si–C bonds was extended and detailed mechanistic studies were carried out. The mechanism proposed for silicon–carbon bond formation, shown in Scheme 3, involves attack of the weak Si–Si bond (Si–Si = 215–250 kJ mol^{-1}, Si–H = 323 kJ mol^{-1})[49] by the carbonanion nucleophile (MR). Soluble molecular disilanes react in a similar manner.



Scheme 3

The resulting silyl anion on the porous silicon surface can be further reacted with an electrophile (EX), offering the possibility to form mixed surfaces.

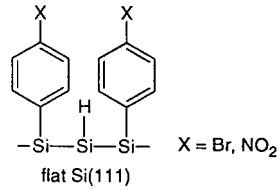
The effects of carbanion functionalization on the photoluminescence of porous silicon have also been investigated in some detail. Methyl termination, as examined by Chazalviel and coworkers,[44] has little effect on the photoluminescence intensity of p-type porous silicon. Sailor and Song observed that a conjugated alkyne (surface **12**, Fig. 1) results in irreversible quenching of the intrinsic photoluminescence that could not be recovered by rinsing with HF solutions. It was found, however, that simple phenyl[47] or 4-fluorophenyl[48] termination (surface **13**, Fig. 1) resulted in only minor quenching which points to the interesting possibility of using the surface functionalities to tune the photoluminescence and underlying optoelectronics of the material.

Alkylation of flat silicon surfaces with alkyl Grignards or lithium reagents through a two-step route has also been demonstrated by Lewis and Weinberg.[50] Chlorination of a hydride terminated flat Si(111) crystal with PCl_5 for 20–60 min

at 80–100 °C produced a chloride terminated silicon surface. Transmetallation with an organolithium or Grignard at 80 °C for 30 min to 8 days produced LiCl or MgXCl, and an alkyl group bound to the silicon surface through an Si–C linkage. Surfaces with long alkyl termination are more resistant to oxidation under ambient conditions and to boiling in aerated chloroform and water. Thermal desorption and XPS experiments indicate that ≡Si–OR linkages are not formed which provides support for the expected Si–C bond formation event.

Electrochemical diazonium reduction

Electrochemistry has also been used to produce close-packed phenyl monolayers (surface **13**, Fig. 1) on hydride terminated flat n-type Si(111) surfaces (Scheme 4).[51]



Scheme 4

Application of a negative potential of *ca.* 1 V to a dilute HF solution containing a 4-nitro- or bromo-benzene diazonium salt results in production of aryl radical and dinitrogen.

$$^{+}N{\equiv}N–Ar–X + e^{-} \rightarrow \cdot\ Ar–X + N_2\ (X = Br \text{ or } NO_2)$$

The aryl radical can then abstract a surface hydride to form silicon radicals which can react with another aryl radical to form the silicon–carbon bond.

$$\cdot\ Ar–X + {\equiv}Si–H \rightarrow {\equiv}Si\cdot + H–Ar–X$$
$${\equiv}Si\cdot + \cdot\ Ar–X \rightarrow {\equiv}Si–Ar–X$$

The covalent nature of the phenyl bonding to the surface is demonstrated by their stability to aqueous 40% HF solutions, and XPS and Rutherford backscattering (RBS) measurements. Because this reaction utilizes the electrode nature of the semiconducting silicon, no clear reaction parallels can be found for soluble, molecular silanes. One important advantage of this approach is that the process is cathodic, thus making the surface electron rich during the reaction which renders it less susceptible to nucleophilic attack by water, supressing oxidation.

Ultra high vacuum (UHV) functionalization strategies

The reactivity of clean silicon surfaces, in absence of a hydrogen monolayer, has been studied intensively by a number of groups under ultra high vacuum (UHV) conditions.[1] The activity of these surfaces is very different from that of the metastable Si–H terminated materials which provides further insight into the structures and properties of flat silicon. The thermally reconstructed Si(100) (2 × 1) surface (Fig. 9), with no

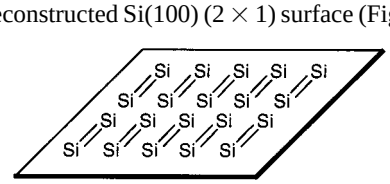


Fig. 9 Schematic diagram of the Si=Si dimers oriented on a Si(100) surface under UHV conditions.

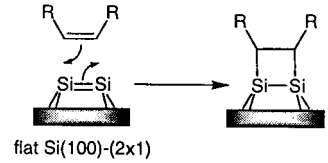
hydrogen capping, has recently been shown to be capable of a number of remarkable cycloaddition reactions that have parallels to organic reactions. The surface silicon atoms pair into dimers connected by a σ and a π bond, thus having essentially double bond character. Use of 4° miscut off-axis Si(100) single crystal wafers allows for highly rotationally oriented samples in which all the Si=Si dimers are pointed in the same direction, yielding anisotropic surfaces on a centimeter length scale. The silicon–silicon double bonds are highly reactive, and have been exploited to produce ordered monolayers through the chemistry described here.

[2 + 2] Reactions of alkynes and alkenes with reconstructed Si(100)

Early work on 'relatively simple' unsaturated hydrocarbons such as ethylene, propylene, acetylene and benzene have been shown to chemisorb on Si(100) (2 × 1) surfaces and are able to resist temperatures of up to 550–600 K.[52] It was suggested that alkenes add to clean Si(100) (2 × 1) surfaces to form a disilicon substituted aliphatic $–CH_2CH_2–$ bridge through a formal [2 + 2] cycloaddition (Scheme 5).



Scheme 5

Two new Si–C σ bonds form due to cleavage of the π bonds in the alkene and disilylene. Electron energy loss spectroscopy (EELS) suggests rehybridization of the two sp^2 carbons to sp^3 although the fate of the remaining Si–Si σ bond is still unclear.[53] Acetylene reacts in a similar [2 + 2] fashion yielding a disilicon-substituted alkene and involves a change in hybridization at the carbon from sp to sp^2 in this case.[54] Concerted [2 + 2] cycloadditions are symmetry-forbidden which suggests a low-symmetry pathway.[55]

Hamers *et al.* have recently described an elegant extension of this series of reactions involving the π bonds of organic species containing C=C bonds.[56] A wide range of complex cyclic olefins react in this manner at moderate temperatures (50–100 °C), including cyclopentene,[57] 3-pyrroline,[53] pyrrolidone,[58] norbornadiene,[53] cycloocta-1,5-diene,[59] and cyclooctatetraene.[60] The [2 + 2] addition of cyclooctatetraene (surface **15**, Fig. 1) is especially interesting since it appears to add to the surface through a double cycloaddition, leaving two alkene groups per molecule exposed through which further chemistry could be carried out.[60] Scanning tunneling microscopy (STM) images of the cyclooctatetraene functionalized surface are shown in Fig. 10, revealing the long range order of the samples and formation of only one major surface species.

Diels–Alder ([4 + 2]) reactions of dienes with reconstructed Si(100)

Konecny and Doren predicted,[61] and Bent and coworkers demonstrated experimentally,[62,63] that the double bond character of the reconstructed Si(100) (2 × 1) surface could act as a dienophile in a Diels–Alder [4 + 2] type reaction (Scheme 6).

Chemisorption of buta-1,3-diene (surface **15**, Fig. 1) or 2,3-dimethylbuta-1,3-diene onto the Si(100) (2 × 1) surface at room temperature results in an efficient Diels–Alder reaction, forming two Si–C σ bonds and one unconjugated, internal olefin. FTIR spectroscopy, thermal desorption, near edge X-ray absorption fine structure and deuterium labeling studies assisted in the determination of surface composition. A reinvestigation of the 2,3-dimethylbuta-1,3-diene reaction on Si(100) (2 × 1) by Hamers and coworkers supports the observation of a Diels–Alder [4 + 2] cycloaddition for 80% of the molecules although they note a minor (20%) [2 + 2] cycloaddition product as well.[64]

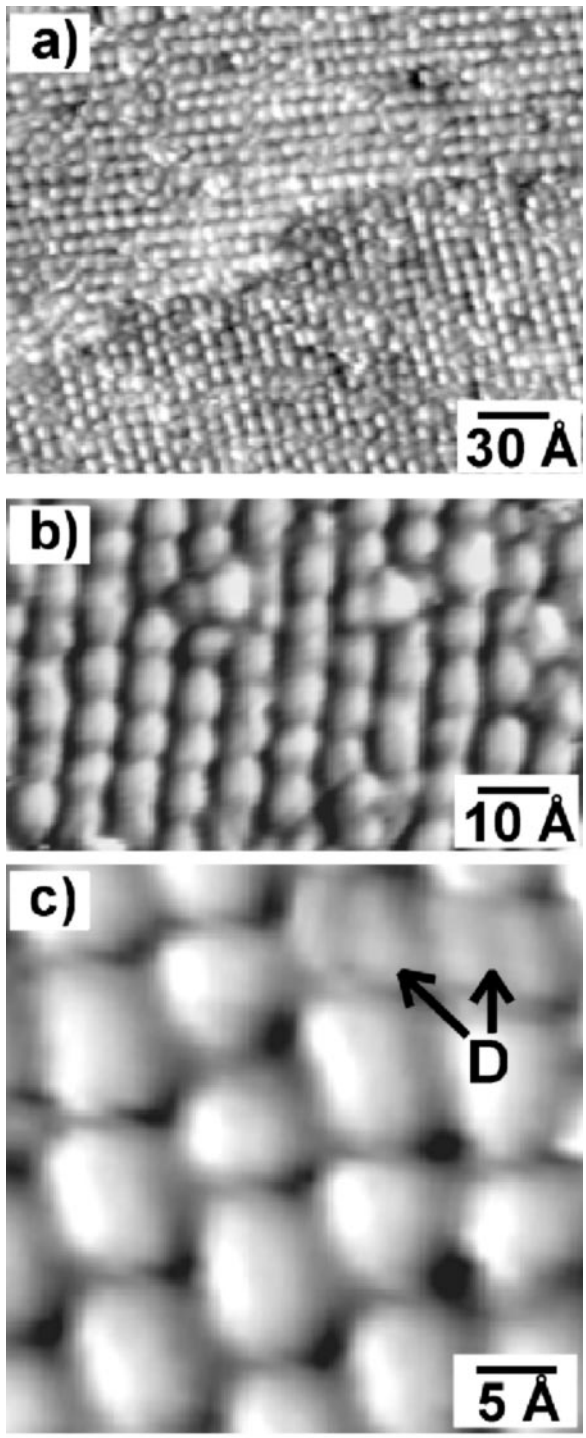


Fig. 10 Scanning tunneling microscopy (STM) images of the Si=Si dimer terminated Si(100) surface after exposure to cyclooctatetraene to form surface **15** (Fig. 1); (a) demonstrates the long range anisotropy and ordering of the surface while (b) and (c) reveal the absorption pattern of the molecules. 'D' refers to a minority species comprising < 5% of the surface features. Professor Robert J. Hamers is gratefully acknowledged for permission to reproduce this figure from ref. 60(*a*). Scheme 6

In the case of cyclohexa-1,3-diene, 55% of the surface products arise from the [4 + 2] addition, 35% the [2 + 2] and 10% and unknown product. The [4 + 2] products are predicted to be thermodynamically more stable but because surface temperature has little affect on product distributions, it is suggested that the reaction is under kinetic control.

Directions for functionalized silicon surfaces: present and future

Tunable, stabilized silicon surfaces will have a broad array of technologically important applications. Flat, non-oxidized silicon surfaces functionalized with ordered organic monolayers have obvious potential in microelectronics. Gate oxides in metal oxide semiconductor transistors (MOSFETs) may be replaced with an organic monolayer since the resistivity could be modulated through organometallic/organic synthesis.[56] Aliphatic substituents will provide obvious insulating properties but conjugated, unsaturated organic moieties could allow for fine tuning of the surface conductivity. Interfacing of silicon microelectronic circuits with neuronal networks and other biologically relevant systems is a fascinating direction that has received much attention in recent years.[65] Surface properties are crucial and thus the power of organometallic/organic chemistry on silicon could play an important role.

Functionalized, stable porous silicon surfaces have an immense variety of potential uses which partially explains the explosion of interest in this material since 1990.[2,5] Applications include use as chemical sensors,[66] microelectronics,[67] photonics,[68] optoelectronic devices[13] such as electroluminescent displays,[69] photodetectors,[13] and as a matrix for photopumped tunable lasers.[70] The biocompatability of porous silicon has been examined *in vivo* and *in vitro* within a simulated body fluid (SBF) environment.[71] Hydroxyapatite, a major constituent of bone, forms on the porous silicon surface and thus is a bioactive material with interesting applications as a biological implant.[72]

Porous silicon as a sensor is a particularly exciting application because of its high surface area which can render it more sensitive than a flat silicon chip, and the two (at least), unrelated signal transduction modes (read-out mechanisms) that are accessible. Early observations by Sailor and coworkers indicated that physisorbed molecular adsorbates such as methanol, benzene, dichloromethane (from the vapor or as a liquid)[73] or NO[74] on the native Si–H terminated porous silicon surface reversibly quench the photoluminescence. Thus quenching of the photoluminescence could serve as a visible wavelength read-out for sensing of chemical vapors or gaseous molecules in general. The second signal transduction mode for a porous silicon-based sensor involves an optical interferometric event, unrelated to the previously described photoluminescence quenching scheme.[75] Thin porous silicon films exhibit Fabry–Perot fringe patterns created by multiple reflections of white light on the air–porous silicon and porous silicon–bulk silicon interfaces. A change of the index of refraction of the porous silicon matrix, induced by absorbance of a material with a different index of refraction within the pores, will cause a shift in the fringe pattern. Oxidized porous silicon has been functionalized with a number of biologically relevant molecules such as biotin and has been shown to sense and quantify streptavidin binding.[75] Clearly, for exquisitely selective and sensitive binding, surface chemistry is of extreme importance since binding groups must be incorporated. The organometallic chemistry described here on non-oxidized silicon surfaces is highly relevant to the preparation of sensors because of the high sophistication of these surfaces and excellent stability required.

Recent work by Whitesides and coworkers has outlined a fascinating approach towards generation of small structures through soft lithography.[76] An elastomer stamp or mold is used to repeatedly and accurately pattern self-assembled monolayers

(SAMs) on surfaces, producing spatially defined arrays of chemical functionalities and interface characteristics. Recent work has demonstrated the compatability of soft lithographic techniques with standard SiO_2/Si fabrication processes.[77] At this writing, however, no results concerning utilization of soft lithography to form monolayers on non-oxidized silicon have been revealed in the literature, but with the strong technological interest in preparing small features of tunable electronic and chemical characteristics on oxide-free silicon, it is almost certainly only a matter of time.[78] Several room-temperature processes involving monolayer preparation through Si–C bonds, as described here, are under development and could be applicable to soft lithography.

Conclusions

The development of novel, organometallic reactions on non-oxidized silicon is clearly an exciting, rapidly growing field still in exploratory stages. A number of unrelated approaches have been pursued through wet chemical, electrochemical, and UHV techniques, generating preliminary trends and contributing to a better understanding of the technologically important silicon surface. The goal of exercising perfect control over the surface characteristics of silicon is a tempting one which promises both academic and commercial rewards.

21 In footnote 33 of ref. 19(*b*), the authors note that surface hydrosilylation of hexadecyne produces a small peak at 1600.8 cm^{-1} which they state suggests a surface bound vinyl group. Indeed, Lewis acid and white light mediated hydrosilylation of dodecyne on porous silicon yields a strong ν(C=C) vibration at 1595 cm^{-1} which corroborates their assumption: see refs. 31, 36 and 38.

Paper 9/00108E

Synthesis and structures of heterometallic trinuclear clusters $[CpFe(CO)_2]_2(\mu_3\text{-}S_2)W(CO)_5$ and $Cp_2Fe_2(CO)_3(\mu\text{-}CO)(\mu_3\text{-}S)W(CO)_5$ and kinetic study of migration of the $W(CO)_5$ moiety in the disulfido complex

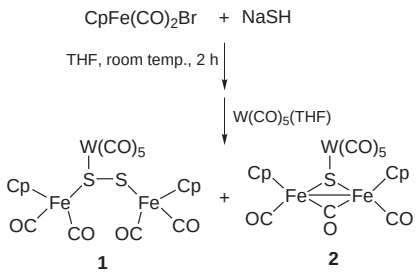
Received (in Cambridge, UK) 2nd March 1999, Accepted 4th May 1999

The reaction of $CpFe(CO)_2Br$, NaSH and $W(CO)_5(THF)$ gave two Fe_2W clusters, one with a μ_3-S_2 and the other with a μ_3-S; in the former cluster $W(CO)_5$ moiety migration on the disulfido ligand was observed by variable-temperature ^1H NMR spectroscopy.

Heterometallic cluster synthesis is widely studied aiming to find new methods of building up clusters systematically. Complexes containing sulfur ligands are often applied as building blocks for polynuclear clusters owing to the remaining coordination ability of sulfur ligands to metal moieties through their lone pairs. In addition, clusters containing a wide variety of coordination modes of sulfur ligands are fascinating from the structural point of view.[1] Simple addition of an $M(CO)_5$ moiety (M = group 6 metal) to sulfido ligands is frequently used for the synthesis of heterometallic sulfur clusters with various bridging sulfido ligands.[2] By contrast, addition of an $M(CO)_5$ moiety to disulfido ligands is rare.[3] Here, we report the synthesis of two new clusters with an Fe_2W core *via* addition of $W(CO)_5$. One of the clusters contains a new type of Fe_2W core, and migration of the $W(CO)_5$ moiety on the disulfido ligand bridging the two $CpFe(CO)_2$ moieties was observed by variable-temperature ^1H NMR spectroscopy.

Reaction of $CpFe(CO)_2Br$ with an excess of NaSH in THF at room temperature resulted in the formation of a brown solution. After 2 h, TLC indicated the disappearance of $CpFe(CO)_2Br$, but isolation and identification of the reaction product was unsuccessful. Addition of $W(CO)_5(THF)$ in THF to the reaction mixture at room temperature gave two heterometallic trinuclear clusters $[CpFe(CO)_2]_2(\mu_3\text{-}S_2)W(CO)_5$ **1** and $Cp_2Fe_2(CO)_2(\mu\text{-}CO)(\mu_3\text{-}S)W(CO)_5$ **2** in 30 and 11% yields, respectively (Scheme 1).

A crystal structure analysis of **1** (Fig. 1)† shows that two $CpFe(CO)_2$ moieties are bridged by a $\eta^1:\eta^1$-S_2 ligand, and one of the sulfur atoms in the S_2 ligand is coordinated to a $W(CO)_5$ moiety in an η^1 mode. The W atom surrounded by one S and five CO ligands adopts an octahedral geometry, and both of Fe(1) and Fe(2) atoms adopt a three-legged piano stool geometry. There are no bonds between the three metal centres. The W–S(2) bond [2.582(2) Å] is slightly longer than normal W–S dative bonds (2.522–2.57 Å)[2] encountered in clusters having a $W(CO)_5$ moiety coordinated to a bridging sulfido ligand. The Fe(1)–S(1) and Fe(2)–S(2) distances [2.292(2) and 2.307(2) Å] are similar to those of trisulfido complex $[CpFe(CO)_2]_2(\mu\text{-}S_3)$ (2.283 and 2.280 Å) and tetrasulfido complex $[CpFe(CO)_2]_2(\mu\text{-}S_4)$ (2.276 Å).[4] The S(1)–S(2) bond [2.076(2) Å] is longer than the S–S distances found in $[CpRu(PMe_3)_2]_2(\mu\text{-}S_2)^{2+}$ (1.962 Å)[5] and $[(NH_3)_5Ru]_2(\mu\text{-}S_2)^{4+}$ (2.014 Å).[6] The Fe(2)–S(2)–S(1) bond angle [116.86(7)°] is larger than that of Fe(1)–S(1)–S(2) [107.49(9)°] because of the coordination of a $W(CO)_5$ moiety to the S(2) atom. Trinuclear clusters bridged by only one disulfido ligand are rare.[4] Complex **1** is the first example of a trinuclear



Scheme 1

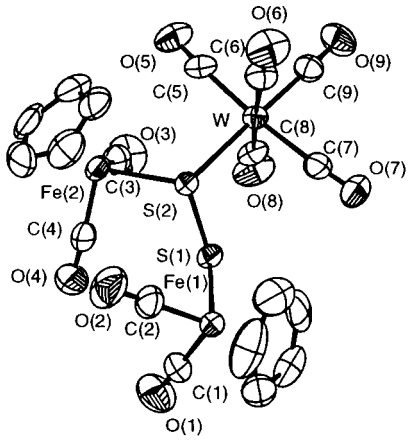


Fig. 1 ORTEP view of **1** with 50% thermal ellipsoids. Selected bond lengths (Å) and angles (°): Fe(1)–S(1) 2.292(2), Fe(2)–S(2) 2.307(2), W–S(2) 2.582(2), S(1)–S(2) 2.076(2), Fe(1)–C(1) 1.756(8), Fe(2)–C(3) 1.76(1), Fe(1)–C(2) 1.763(7), Fe(2)–C(4) 1.776(9), W–C(5) 2.026(8), W–C(6) 2.042(8), W–C(7) 2.047(8), W–C(8) 2.047(8), W–C(9) 1.974(8), Fe(1)–S(1)–S(2) 107.49(9), Fe(2)-S(2)–S(1) 109.20(9).

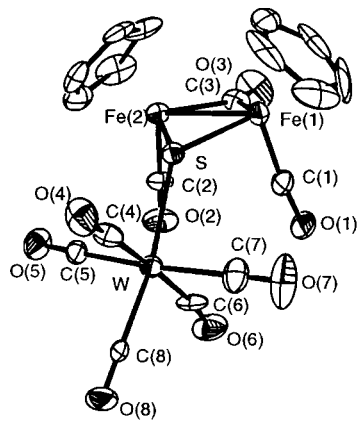

Fig. 2 ORTEP view of **2** with 30% thermal ellipsoids. Selected bond lengths (Å) and angles (°): Fe(1)–S 2.239(6), Fe(2)–S 2.228(6), W–S 2.547(6), Fe(1)–Fe(2) 2.592(4), Fe(1)–C(1) 1.75(2), Fe(2)–C(2) 1.81(2), Fe(1)–C(3) 1.94(2), Fe(2)–C(3) 1.95(3), W–C(4) 2.02(2), W–C(5) 2.02(2), W–C(6) 2.09(3), W–C(7) 2.07(2), W–C(8) 1.99(2), Fe(1)–S–Fe(2) 70.9(2).

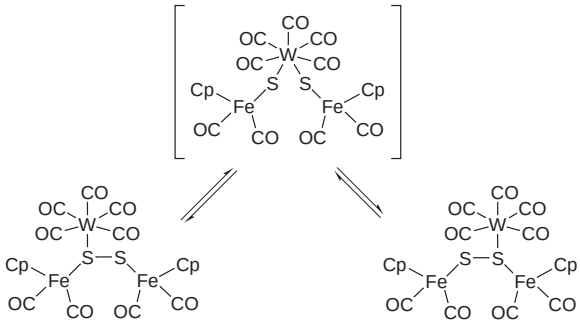

Scheme 2

cluster connected by only one disulfido ligand in an $\eta^1:\eta^1:\eta^1$ fashion.

The X-ray structure analysis of **2** (Fig. 2)† shows that two iron atoms are directly bonded to each other [Fe–Fe 2.592(4) Å] with the bond bridged by a CO ligand and a μ_3-S ligand to form an Fe(1)–S–Fe(2)–C(3) four-membered ring, and a $W(CO)_5$ moiety is coordinated to the μ_3-S ligand. Two Cp ligands are mutually *cis* and the $W(CO)_5$ moiety is at the *anti* position with respect to the two Cp ligands. The W atom has an octahedral geometry. The W–S bond [2.547(6) Å] is close in length to that of **1** suggesting a dative bond character. The Fe(1)–S and Fe(2)–S distances [2.239(6) and 2.228(6) Å] lie within the typical range for Fe–S bonds [2.18–2.26 Å].[7]

It is noteworthy that in the ^{1}H NMR spectrum of **1** at 296 K, only one broad peak for the ring protons of the Cp ligands was observed at δ 4.22. Taking account of the crystal structure of **1** in Fig. 1 in which the $W(CO)_5$ moiety is bound to only one of the two sulfur atoms, the spectrum clearly shows that the $W(CO)_5$ moiety is migrating between two sulfur atoms faster than the NMR time scale to make the two Cp ligands equivalent. At lower temperature (250 K), the signal for the Cp ligands decoalesced to two singlets at δ 3.96 and 4.17.

Abel *et al.* previously observed a 1,2-shift of a $W(CO)_5$ moiety between two sulfur atoms in $W(CO)_5(Me_3SiCH_2SSCH_2SiMe_3)$.[8] Based on the activation parameters for this reaction ($\Delta H^{\ddagger}$ = 71.6 ± 1.8 kJ mol^{-1}, $\Delta S^{\ddagger}$ = −8.7 ± 5.4 J mol^{-1} K^{-1} and $\Delta G^{\ddagger}_{298}$ = 74.2 ± 0.2 kJ mol^{-1}), they proposed an intermediate in which the lone pairs of both sulfur atoms were coordinated to the $W(CO)_5$ moiety. The activation parameters for **1** determined by complete lineshape analysis are $\Delta H^{\ddagger}$ = 75.9 ± 3.1 kJ mol^{-1}, $\Delta S^{\ddagger}$ = 55.4 ± 10.6 J mol^{-1} K^{-1} and $\Delta G^{\ddagger}_{298}$ = 59.4 ± 6.2 kJ mol^{-1}. These values are consistent with the intramolecular mechanism. However, the somewhat larger $\Delta S^{\ddagger}$ value for our system may be reasonably explained by an alternative mechanism shown in Scheme 2 involving oxidative addition of the S–S bond, where the transition state is expected to be looser than that in Abel's mechanism. Intramolecular oxidative addition of a coordinated disulfide to a W^0 center to give a seven-coordinate bis(thiolato)tungsten(II) intermediate has been proposed in $W(CO)_3(phen)(RSSR)$ complexes.[9]

Convergent synthesis of the ABCDE ring framework of ciguatoxin

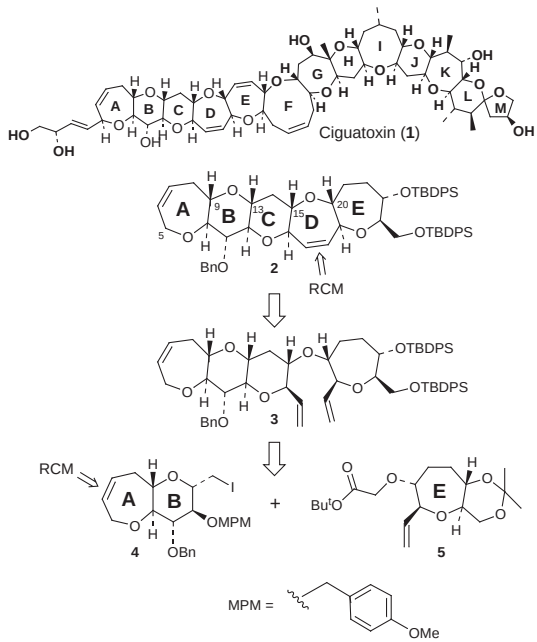
Kenji Maeda, Tohru Oishi, Hiroki Oguri and Masahiro Hirama*

Department of Chemistry, Graduate School of Science, Tohoku University, and CREST, Japan Science and Technology Corporation (JST), Sendai 980-8578, Japan. E-mail: hirama@ykbsc.chem.tohoku.ac.jp

Received (in Cambridge, UK) 19th April 1999, Accepted 4th May 1999

An alkylation–metathesis sequence is shown to be a powerful method to synthesize the ABCDE ring framework of ciguatoxin 1.

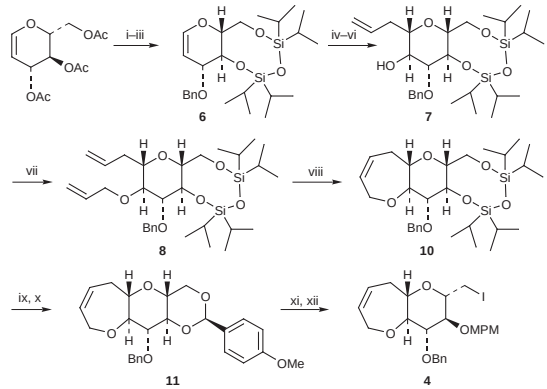
Ciguatoxin (CTX1B, **1**) is the principal toxin that causes ciguatera poisoning.[1] Its gigantic structure and unique agonist activity against the sodium channel have attracted considerable attention among synthetic organic chemists.[2] During the course of our synthetic studies directed toward **1**, we developed an efficient method of constructing *trans*-fused 6,*n*,6,6-tetracyclic ether systems (*n* = 7–10) by combining intermolecular alkylation and ring-closing metathesis (RCM) reactions.[3] We describe herein a convergent synthesis of the ABCDE ring framework **2** of **1** starting from the AB ring **4** and E-ring fragments **5**, using the described alkylation–metathesis strategy (Scheme 1).



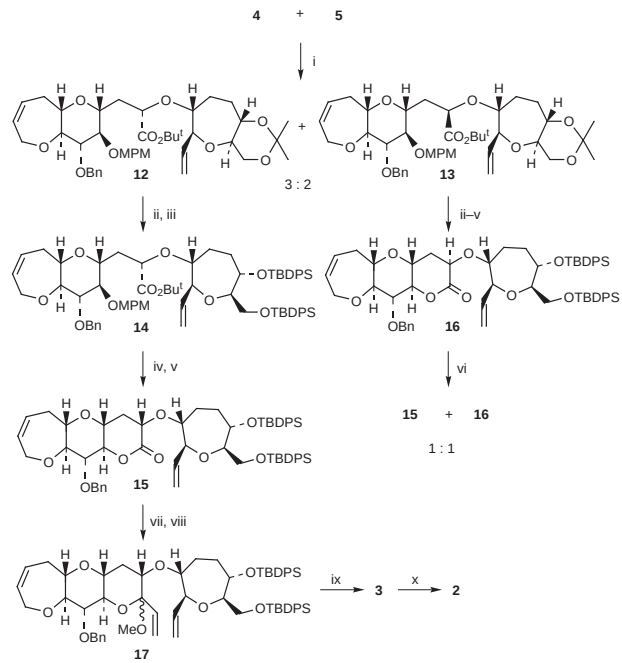
Scheme 1

The synthesis of the iodide **4** is shown in Scheme 2. Tri-*O*-acetyl-D-glucal was converted to **6** *via* methanolysis of the acetate and successive protection of the resulting triol as the tetraisopropyldisiloxanediyl (TIPDS) and benzyl ether. Epoxidation of **6** using Spilling's method[4] followed by addition of CH_2=$CHCH_2MgBr$ resulted in the formation of **7** in 53% overall yield. Allylation of the secondary alcohol of **7** gave **8**, which was subjected to RCM reaction using Grubbs' catalyst, $(PCy_3)_2Cl_2Ru$=CHPh **9**[5] to afford the 7,6-bicyclic system **10** in 94% yield.[6] The TIPDS group of **10** was removed using TBAF and the 1,3-diol was converted to the *p*-methoxybenzylidene acetal **11**. Reductive cleavage of the benzylidene acetal with DIBAL-H followed by conversion of the resulting primary alcohol to an iodide gave **4** regioselectively.[7]

Alkylation of the *tert*-butyl ester **5**, which was readily prepared from D-glucose[8] with **4** using LDA in the presence of 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidone (DMPU) gave a separable mixture of the desired diastereomer **12** and the epimer **13** in a 3 : 2 ratio in 58% combined yield (Scheme 3). When HMPA was used instead of DMPU in this alkylation



Scheme 2 *Reagents and conditions*: i, K_2CO_3 (cat.), MeOH; ii, $(TIPDS)Cl_2$, pyridine; iii, BnBr, NaH, DMF, THF, 0 °C to room temp., 63% (3 steps); iv, NBS, THF–H_2O (9 : 1); v, KHMDS, 18-crown-6, toluene, −75 to 0 °C, 4 h; vi, H_2C=$CHCH_2MgBr$, 0 °C to room temp., 53% (3 steps); vii, H_2C=$CHCH_2Br$, NaH, 0 °C to room temp., 93%; viii, **9** (cat.), CH_2Cl_2, 94%; ix, TBAF, THF; x, PPTS (cat.), *p*-$MeOC_6H_4CH(OMe)_2$, $(CH_2Cl)_2$; xi, DIBAL-H, CH_2Cl_2, −78 to −20 °C, 75% (3 steps); xii, I_2, PPh_3, imidazole, toluene, 82%.



Scheme 3 *Reagents and conditions*: i, LDA, DMPU, THF, −78 to 0 °C, 58% (based on recovery of **4**; 23%); ii, PPTS (cat.), MeOH; iii, TBDPSCl, imidazole, DMF, 71% (2 steps); iv, DDQ, $(CH_2Cl)_2$–H_2O (20 : 1), 91%; v, CSA (cat.), toluene, 80 °C, 80%; vi, imidazole, toluene, reflux, 80% (**15** : **16** = 1 : 1); vii, H_2C=$CHMgBr$, Et_2O, −78 to −60 °C, 91%; viii, CSA (cat.), $HC(OMe)_3$, CH_2Cl_2, 75%; ix, $BF_3{\cdot}OEt_2$, Et_3SiH, CH_2Cl_2, −45 °C, 96%; x, **9**, CH_2Cl_2, 40 °C, 93%.

reaction, the ratio became 1 : 1. Although further attempts to improve the diastereoselectivity and to epimerize **13** were unsuccessful at this stage, we found that the epimerization could be obtained at a later stage (*vide infra*). Acidic methanolysis of the acetonide **12** followed by protection of the resulting 1,3-diol as TBDPS ethers gave **14**. Removal of the *p*-methoxybenzyl group using DDQ followed by treatment with CSA in toluene at 80 °C gave the δ-lactone **15**. The epimeric lactone **16** was also synthesized from **13** in an analogous manner. This lactone was found to undergo epimerization by treatment with imidazole in toluene under reflux to give a separable 1 : 1 mixture of **15** and **16** in 80% yield, while stronger bases such as Bu^{t}OK and DBU caused only decomposition. Thus, the undesired epimer **13** was successfully converted into **15**. Treatment of the lactone **15** with CH_2=CHMgBr followed by conversion of the resultant hemiacetal to the corresponding methyl acetal afforded **17** as a 1 : 1 mixture of anomers. Reduction of the anomeric mixture **17**[9] with Et_3SiH in the presence of $BF_3{\cdot}OEt_2$[10] gave **3** as a single isomer in 96% yield. Finally RCM reaction of **3** with Grubbs' catalyst **9** at 40 °C in CH_2Cl_2 gave the ABCDE ring **2** in 93% yield.[11]

In conclusion, we have demonstrated that the alkylation–metathesis strategy is versatile for the convergent synthesis of the pentacyclic segment **2** of **1**. Further studies directed toward the total synthesis of **1** are currently in progress in our laboratory.

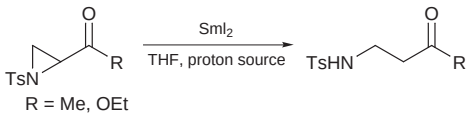
Received (in Cambridge, UK) 19th April 1999, Accepted 4th May 1999

Reaction of α-amino carbonyl compounds with SmI_2 in THF–HMPA in the presence of a proton source afforded the deamination products, where the fragmentation occurred between the nitrogen and the carbon α to the carbonyl group.

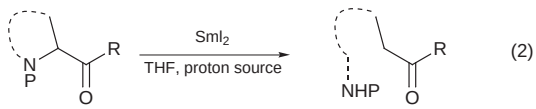
SmI_2 was firstly, introduced as a useful synthetic tool in organic synthesis by Kagan and co-workers,[1] and thereafter, this reagent rapidly became an established reagent for developing a variety of useful and unique transformations.[2] Although much effort has been devoted to studying the reductive deoxygenation of α-hydroxy or α-alkoxy carbonyl compounds employing SmI_2 as a powerful one-electron reducing reagent, its application to the deamination of α-amino carbonyl compounds has received relatively little attention. Attractive examples of the reductive deamination reaction were reported by Molander and Stengel using 2-acylaziridines and 4-acylazetidin-2-one as starting materials [eqn. (1)],[3] where the leaving amino groups were



R = Me, OEt (1)

involved in highly strained three- or four-membered rings. Similar SmI_2-promoted carbon–nitrogen bond cleavage reactions were also employed in the reductive removal of an *N*-substituted benzotriazolyl group,[4] and in the isonitrile–nitrile rearrangement.[5]

In continuation of our work on the synthesis of biologically active natural products using SmI_2,[6] we were interested in researching a general deamination reaction of α-amino carbonyl compounds [eqn. (2)], and here report our successful results

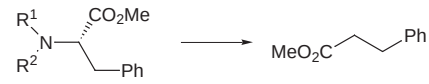


P = alkyl, acyl
R = alkyl, OR′ (2)

concerning systematic investigation of SmI_2-promoted reductive deamination.

Initially, we applied the SmI_2-promoted deamination reaction to phenylalanine derivatives,[7] and the results obtained are summarised in Table 1. Based on the results, it was concluded that reductive deamination with SmI_2 is applicable to the wide variety of amino functions including primary, secondary and tertiary amines, and also amide groups. The deamination usually took place within 30 min in the presence of a proton source, such as MeOH or pivalic acid, to give methyl dihydrocinnamate in high yields, although a relatively prolonged reaction time was required in the case of benzyl-substituted amines as leaving groups. The reductive deamination was typically carried out as follows: a solution of SmI_2 (2.5 mmol) and HMPA (2.5 mmol) in THF (12 cm^3) and a solution of proton source (MeOH or pivalic acid, 1.25 mmol) in THF (5 cm^2) were successively added dropwise to a stirred solution of an α-amino ester (0.5 mmol) in THF (10 cm^3) at 0 °C, and the resulting solution was allowed to warm to room temperature. A stream of air was bubbled through the solution, and an excess of Celite in Et_2O and saturated aqueous $NaHCO_3$ (2 cm^3) were added. The solution was filtered and the filtrate was washed with brine. The organic layer was separated, dried and evaported to give a residue, which was subjected to column chromatography on silica gel.

Table 1 Reductive deamination of phenylalanine derivatives[a]



R^1	R^2	Proton source	Reaction time	Yield (%)
H	H	MeOH	30 min	73
H	H	Pivalic acid	15 min	80
H	Me	MeOH	30 min	71
H	Bn	MeOH	2.5 h	85
Me	Me	MeOH	< 5 min	90
Bn	Bn	MeOH	4 h	93
H	Ac	MeOH	15 min	99

[a] Reaction conditions: starting material (0.5 mmol); SmI_2 (5 equiv.); HMPA (5 equiv.); proton soruce (2.5 equiv.); solvent (THF); 0 °C to room temperature.

The reactions of proline derivatives[8] (Table 2) and ethyl pipecolinate derivatives[9] (Table 3), where the leaving amino groups were involved in the cyclic systems, under the same reaction conditions as above gave the corresponding deamination products in good yields. The deamination could be applied not only to α-amino esters but also to α-amino ketones. Thus, treatment of α-acetylpiperidine derivatives[10] with SmI_2 also

Table 2 Reductive deamination of proline derivatives[a]

Starting material	Product	Proton source	Reaction time	Yield (%)
		MeOH Pivalic acid	30 min 10 min	62 73
		MeOH	1.5 h	88
		MeOH	9 h	82
		MeOH	7.5 h	99

[a] Reaction conditions: starting material (0.5 mmol); SmI_2 (5 equiv.); HMPA (5 equiv.); proton source (2.5 equiv.); solvent (THF); 0 °C to room temperature.

Table 3 Reductive deamination of 2-acetylpiperidine and ethyl pipecolinate derivatives, and a phthalimide derivative[a]

Starting material	Product	R	Reaction time	Yield (%)
		Me	1 min	87
		Bn	1 min	96
		Ac	<5 min	94
		Boc	<5 min	96
		Me	<5 min	86
		Bn	<5 min	89
		Ac	45 min	78
		—	1 min	72

[a] Reaction conditions: starting material (0.5 mmol); SmI_2 (5 equiv.); HMPA (5 equiv.); MeOH (2.5 equiv.) was used as a proton source; solvent (THF); 0 °C to room temperature.

provided the desired compounds, in high yields, in which both alkyl and acyl derivatives of amines could be used as leaving groups (Table 3). Interestingly, the reaction of *N*-(2-oxopropyl)phthalimide with SmI_2 in THF–HMPA in the presence of MeOH yielded phthalimide in 72% yield (Table 3). The products obtained were well-characterised by spectroscopic data including microanalysis, or by direct comparison with the authentic samples.

We next investigated the effect of proton sources, and found that *N*,*N*-dimethylaminoethanol (DMAE) was also effective for this reaction as well as MeOH and pivalic acid (Table 4). It should be noted that this reaction can be carried out under neutral reaction conditions in the presence of other functional groups, such as alkyl ester, alkyl ether, imide and amide groups. Moreover, this reaction proceeded in the presence or absence of HMPA, however, the presence of HMPA proved desirable in terms of yields and reaction times (Tables 2, 3 and 4). These results were in agreement with those observed in the reductive deoxygenation reactions, since HMPA was recognised to increase the rate of the reaction of SmI_2.[11]

As can be seen in Table 2, the fragmentation product bearing a primary amino function sometimes afforded the cyclisation compound. This type of conversion will provide a useful route for the synthesis of naturally occurring or biologically interesting piperidine derivatives in optically active forms. Indeed,

Table 4 Investigation of the proton sources and the effect of HMPA in reductive deamination[a]

Starting material	Product	Proton source	Reaction time	Additive	Yield (%)
		MeOH	5 h	none	65
		Pivalic acid	40 min	HMPA	82
		DMAE	45 min	HMPA	90
		MeOH	18 h	none	85
		Pivalic acid	1 h	HMPA	92
		DMAE	2 h	HMPA	78
		MeOH	36 h	none	76
		Pivalic acid	45 min	HMPA	88
		DMAE	1.5 h	HMPA	93
		MeOH	12 h	none	50
		Pivalic acid	<5 min	HMPA	86
		DMAE	10 min	HMPA	71

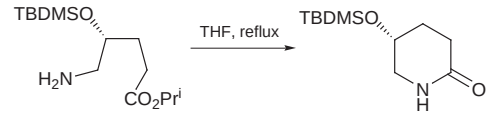

Scheme 1

heating of isopropyl δ-amino-γ-*tert*-butyldimethylsiloxyvalerate in THF for 2 days gave 5-*tert*-butyldimethylsiloxy-2-piperidone in 75% yield (Scheme 1).

In summary, we have described a general reductive deamination reaction employing SmI_2 in THF–HMPA. This reaction proceeds in relatively high yield under mild reaction conditions and seems to be applicable to the wide variety of α-amino carbonyl compounds. Utilisation of this reaction in the synthesis of natural products is under investigation. This work was supported by the Ministry of Education, Science, Sports and Culture of Japan.

Highly active supported palladium catalyst for the regioselective synthesis of 2-arylpropionic acids by carbonylation

S. Jayasree, A. Seayad and R. V. Chaudhari*

Homogeneous Catalysis Division, National Chemical Laboratory, Pune- 411 008, India. E-mail: rvc@ems.ncl.res.in

Received (in Cambridge, UK) 30th March 1999, Accepted 5th May 1999

A catalyst system consisting of supported palladium in the presence of phosphine ligands, TsOH and LiCl catalyses the carbonylation of 1-arylethanols to 2-arylpropionic acids with significantly improved activity and regioselectivity; the catalyst can be recycled with no loss in activity and selecivity.

Carbonylation of 1-arylethanols is of great interest since it provides an environmentally benign route[1] for the synthesis of anti-inflammatory drugs such as Ibuprofen, Naproxen *etc*. The importance of this route can be clearly demonstrated from the commercialisation of an Ibuprofen process at Texas in 1992 by Hoechst Celanese Corporation based on the carbonylation of 1-(4-isobutylphenyl)ethanol using a palladium complex catalyst.[2] The desired high selectivity (> 98%) for Ibuprofen was achieved only at very high pressures[3] (16–34 MPa). This homogeneous palladium catalyst system gave lower TOF† (50–100 h^{-1}) and selectivity (< 68%) at lower pressures (~ 6.8 MPa).[4] Additives such as $CuCl_2$ were reported to improve the selectivity under similar conditions.[5] In another study, a biphasic catalyst with a water soluble palladium complex[6] has been reported but in this case also, very low reaction rates (TOF = 2.3 h^{-1}) and lower Ibuprofen selectivity (70%) were observed.

Here we report, for the first time, highly active and selective supported palladium and platinum catalyst systems for the synthesis of 2-arylpropionic acids from the corresponding 1-arylethanols. Supported palladium combined with PPh_3, LiCl and TsOH provides very high TOF (3375 h^{-1}) and more importantly high selectivity (99.5%) for 2-arylpropionic acids at lower pressures (5.4 MPa). The activity as well as the selectivity was substantially higher compared to previous reports under identical conditions. The catalyst was recycled four times with no loss in activity and selectivity, attaining a total TON of 55,000. These results indicate that this new catalyst system (Pd-C/PPh_3/TsOH/LiCl) is highly efficient and provides significant improvement over the current state of the art for the synthesis of 2-arylpropionic acids.

In a typical experiment, the supported catalyst,‡ the substrate, the phosphine ligand, LiCl, TsOH, H_2O and the solvent (methyl ethyl ketone) were charged into a stirred pressure reactor and the reaction was carried out at 5.4 MPa of CO partial pressure at 115 °C under 1100 rpm for a specified time. The reaction mixture was analysed by gas chromatography§ and the products were further characterized by GC-MS and NMR.

Typical results for the carbonylation of 1-(4-isobutylphenyl)-ethanol (*p*-IBPE) using different catalysts, supports, promoters and ligands are presented in Table 1. Pt/C provided comparatively lower activity than Pd/C. Other supports such as γ-alumina and H-ZSM-5 were also useful. Different acid and halide sources were checked and were found to not significantly effect the catalytic activity. The nature of the phosphine ligand has a strong influence on the catalytic activity, as evidenced from Table 1. No reaction was observed with diphos ligands such as dppb, unlike the catalyst system reported by Ali *et al.* for the carbonylation of olefins.[7]

It was important to understand whether the reaction occurs heterogeneously or homogeneously (by soluble complexes of Pd formed *in situ*). For this purpose, liquid phase reaction samples were withdrawn during reaction and also after the end of the reaction (on cooling of the contents). The analysis of the liquid phase, after the reaction, for Pd content by atomic absorption spectroscopy showed < 0.1 ppm of Pd in solution, but the sample withdrawn under the reaction conditions showed significant leaching of Pd (1.5 ppm Pd). This indicates that the reaction is more likely to be homogeneously catalysed and the enhanced activity and selectivity is due to the combination of Pd with PPh_3 and promoters like TsOH, and LiCl. At the same time, readsorption of Pd onto the support after the reaction facilitates repeated recycling. Thus, the proposed catalyst system offers significant advantages, not only with respect to activity and selectivity, but also to catalyst recycling.

Intermediate sampling for the carbonylation of *p*-IBPE showed that the reaction proceeds through the formation of 4-isobutylstyrene and 1-(4-isobutylphenyl)ethyl chloride as the intermediates. Here the question was, which intermediate is undergoing carbonylation? To make this point clear, the carbonylation of 4-isobutylstyrene was performed in the absence of LiCl. The reaction was found to be very slow (TOF = 300 h^{-1}) with very poor Ibuprofen selectivity (65%). But in

Table 1 Carbonylation of 1-(4-isobutylphenyl)ethanol (*p*-IBPE) to give Ibuprofen using supported palladium and platinum catalysts[a]

Catalyst	Ligand	*t*/h	Conversion (%)	Selectivity (%)	TOF/h^{-1}
1% Pd/C	PPh_3	4.2	96	99.2	3375

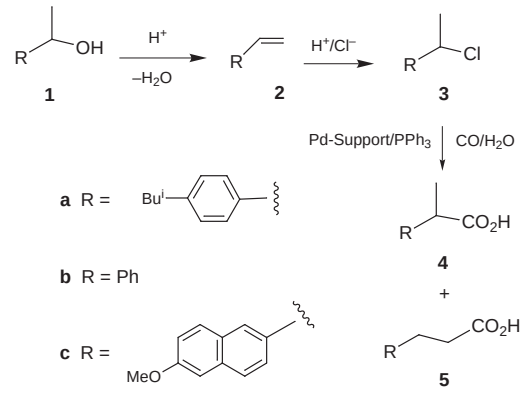
[a] *Conditions:* *p*-IBPE (14.04 mmol), catalyst (10 mg), phosphine (0.1908 mmol), TsOH (5.6052 mmol), LiCl (5.6052 mmol), H_2O (67 mmol), methyl ethyl ketone (21 ml), P_{CO} = 5.4 MPa, T = 115 °C. [b] Pd metal (2 mg). [c] HCl (5.6052 mmol) instead of TsOH and LiCl. [d] Bu_4NCl instead of LiCl.



Scheme 1

Table 2 Synthesis of 2-arylpropionic acids by carbonylation[a]

Substrate	*t*/h	Conversion (%)	Selectivity (%)	TOF/h^{-1}
1a	4.2	96	99.2	3375
2a	4	92	99.1	3400
3a	4	90	99.3	3300
1b	13	90	98	1010
2b	4.6	92	98	2900
1c	24	90	99	552

[a] *Conditions:* Substrate (14.04 mmol), catalyst (10 mg), phosphine (0.1908 mmol), TsOH (5.6052 mmol), LiCl (5.6052 mmol), H_2O (67 mmol), methyl ethyl ketone (21 ml), P_{CO} = 5.4 MPa, T = 115 °C.

the presence of LiCl the catalytic activity and Ibuprofen selectivity were the same as that of *p*-IBPE carbonylation. Under similar conditions, 1-(4-isobutylphenyl)ethyl chloride also showed the same catalytic activity and selectivity behaviour. This indicates that in the presence of LiCl, the major reaction pathway is the carbonylation of the chloro derivative, as shown in Scheme 1.

The catalyst system was also applicable for the carbonylation of various 1-arylethanols and their corresponding olefin and chloro analogues, as demonstrated in Table 2. In all cases, high TOF and 2-arylpropionic acid selectivity were achieved.

In summary, in the presence of phosphines, TsOH and LiCl, with supported palladium and platinum as the catalyst systems, the carbonylation of 1-arylethanols to 2-arylpropionic acids occurs with high activity and regioselectivity with efficient recycling of the catalyst.

Cu_2O: a catalyst for the photochemical decomposition of water?

Petra E. de Jongh,* Daniel Vanmaekelbergh and John J. Kelly

Debye Institute, Utrecht University, PO Box 80 000, 3508 TA Utrecht, The Netherlands. E-mail: pjongh@phys.uu.nl

Received (in Basel, Switzerland) 15th February 1999, Accepted 24th April 1999

The photoelectrochemical properties of polycrystalline Cu_2O electrodes are discussed with regard to the application of the oxide as a photocatalytic material for water splitting.

Recently, illuminated Cu_2O was reported to act as a stable catalyst for water splitting. Hydrogen and oxygen were evolved in a vigorously stirred suspension of Cu_2O particles, without a noticeable decrease in activity over a period of 1900 h.[1] This was very surprising since single crystalline Cu_2O is known to be photocathodically unstable.[2] The mechanism of water splitting and the precise role of the Cu_2O are still unclear.[1,3] Photocatalysis at a p-type semiconductor such as Cu_2O implies that the majority charge carriers (holes) oxidize water to oxygen, while the photogenerated minority charge carriers (electrons) reduce water to hydrogen. These reactions can be studied electrochemically; at positive potentials an anodic dark current due to oxygen evolution is expected, and at negative potentials a cathodic photocurrent accompanied by hydrogen evolution. We were already involved in research on electrodeposited polycrystalline Cu_2O layers,[4] and decided to study the photoelectrochemistry of these layers with respect to the decomposition of water.

We prepared well defined Cu_2O consisting of 0.1–1 μm crystals on a transparent, fluorine-doped tin oxide substrate by reduction of Cu^{2+} from a saturated copper(II) lactate aqueous solution. This technique has been described elsewhere.[4–8] Films were grown galvanostatically at 55 °C and pH 11 at a current density of 0.2 mA cm^{-2}. In the X-ray diffraction spectra only peaks due to Cu_2O were found. A bandgap of 1.9 eV was estimated from the optical absorption, in good agreement with literature values. Absorption at wavelengths >600 nm due to CuO was not seen. Scanning electron microscopy showed only well defined crystals. No changes in appearance or photoelectrochemical properties were found on keeping the Cu_2O layers in air for months.

The photoelectrochemical properties were investigated using a three electrode set-up with 0.5 M Na_2SO_4 as electrolyte solution. This method has the advantage that the cathodic and anodic reactions on the Cu_2O working electrode can be studied separately; they are accompanied by the reduction or oxidation of water at the platinum counter electrode. In the dark an anodic current, corresponding to the oxidation of the Cu_2O [eqn. (1)], was observed at potentials above 0.0 V *vs.* SCE (all redox potentials[9] are *vs.* SCE and at pH 7):

$$Cu_2O + 2\ OH^- + 2h^+ \rightarrow 2\ CuO + H_2O \quad E = -0.05\ V \quad (1)$$

The CuO slowly dissolves. In the presence of oxygen, a small steady state dark current was observed at negative potentials. When the solution was thoroughly purged with argon this dark current could be reduced to <1 μA cm^{-2}.

Under illumination, a large cathodic photocurrent was observed with an air-saturated solution under strong convection. This photocurrent started at a potential between 0.0 and 0.1 V, and the photocurrent spectrum was in good agreement with the Cu_2O absorption spectrum. Fig. 1(a) shows the current at −0.4 V *vs.* SCE under chopped 350 nm illumination. At low light intensities the photocurrent increased linearly with increasing photon flux; quantum efficiencies of 50% were measured for a photon flux below 5×10^{14} s^{-1} cm^{-2}. At higher light intensities

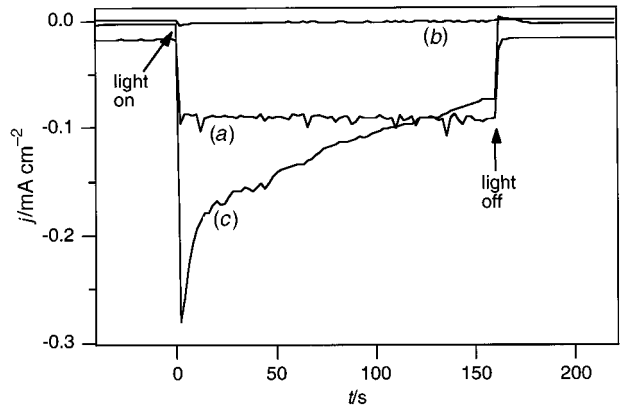

Fig. 1 Current density at −0.4 V measured on a 0.5 μm thick Cu_2O electrode illuminated with 350 nm (5×10^{15} s^{-1} cm^{-2}) in 0.5 M Na_2SO_4 solution: (a) bubbled with air, (b) bubbled with Ar and (c) bubbled with Ar and with 40 mM MV^{2+} added to the solution.

the photocurrent levels off. When the solution was carefully purged with argon, the cathodic photocurrent was very low (≈ 1 μA cm^{-2}) as is shown in Fig. 1(b). It is clear that the current observed in air-saturated solution is due to oxygen reduction, for instance *via* eqn. (2).

$$O_2 + 2\ H_2O + 2e^- \rightarrow H_2O_2 + 2\ OH^- \quad E = +0.03\ V \quad (2)$$

The hydrogen peroxide is further reduced to water. The high intensity photocurrent limit was close to the limiting current density for oxygen reduction at a platinized indium tin oxide electrode under the same hydrodynamic conditions. Obviously, the photocathodic reduction of oxygen on Cu_2O is extremely efficient. On the other hand, the reduction of water to hydrogen seems negligible. If appropriate deposition conditions were used, the Cu_2O layers, in contrast to single crystalline electrodes,[2] proved to be surprisingly stable under photocathodic conditions. The photocurrent due to oxygen reduction was constant over long periods, even when the photon flux exceeded the oxygen flux to the electrode surface. No evidence was found for the formation of copper due to the reduction of Cu_2O ($E = -0.19$ V). The small photocurrent observed in argon-purged solutions is very likely due to the reduction of traces of oxygen left in the solution.

The methylviologen (1,1-dimethyl-4,4-bipyridinium) system, $MV^{2+}/MV^{\cdot+}$ has a redox potential of −0.60 V *vs.* SCE,[10] which is close that of hydrogen. Fig. 1(c) shows a photocurrent transient for an Ar purged 0.5 M Na_2SO_4 solution containing 40 mM $[MV]Cl_2$. In the absence of oxygen, the photocurrent quantum efficiency was initially very high. However, the photocurrent decreased rapidly with time. This is likely due to the formation of a MV^0 layer on the electrode surface. The $MV^{\cdot+}$ radical cation, which is formed upon reduction of MV^{2+}, can be further reduced to MV^0; redox potentials of −1.1 to −1.3 V are reported for this reaction.[10–12] MV^0 is not soluble in aqueous solutions and is known to form blocking films on the electrode surface.[13] This is in good agreement with the observation that the photocurrent is restored as soon as air is admitted to the cell. Oxygen is known to oxidize MV^0 to MV^{2+} very effectively. Obviously the kinetics for the reduction of MV^{2+} are much more efficient than those for the reduction of water.

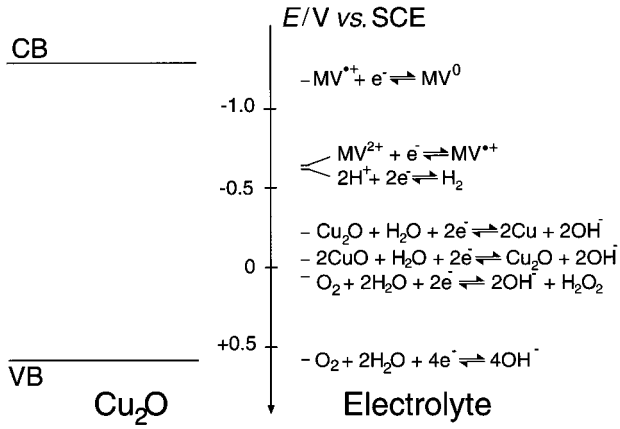

Fig. 2 Overview of the redox potentials of the relevant reactions with respect to the estimated position of the Cu_2O band edges.

It is interesting, in the light of our results, to examine the requirements that have to be met if Cu_2O is to function as a photocatalyst for water splitting. It is crucial that both the reduction and oxidation reactions of water are thermodynamically possible, and that these reactions are kinetically favourable. Fig. 2 shows the redox potentials of the relevant reactions with respect to the positions of the Cu_2O band edges.[2] To reduce water, the electron Fermi level and hence also the conduction band edge must be at an energy higher than that corresponding to the reduction potential for water, which at pH 7 is −0.65 V. The estimated position of the edge of the Cu_2O conduction band is −1.4 V.[2] This means that a large overpotential is available for the reaction. However, our measurements show that in the absence of other redox species no significant cathodic photocurrent is found in aqueous electrolyte. In the presence of oxygen or the methylviologen cation very efficient photocathodic reactions were found. The reduction of water must be kinetically highly unfavourable at our illuminated Cu_2O. To enable the oxidation of water, the Cu_2O valence band edge must be at an energy below that corresponding to the oxidation potential of water, which at pH 7 is *ca.* +0.57 V. The edge of the valence band was estimated to be at +0.6 V.[2] It is unlikely that the valence band edge lies at a much lower energy. This can be deduced from the bandgap of 2 eV and the fact that the position of the conduction band edge must be significantly more negative than −1.2 V *vs.* SCE if the photocathodic reduction of $MV^{\cdot+}$ (E = −1.2 V *vs.* SCE) is to be possible. As a consequence (almost) no overpotential is available for the oxidation of water. Furthermore, the oxidation of Cu_2O, with a redox potential of −0.05 V, is thermodynamically considerably more favourable. Our results show that the anodic current in the dark corresponds at least partly to oxidation of the oxide. Therefore, although the Cu_2O is stable under photocathodic conditions, stability under open circuit illumination is unlikely.

On the basis of these results it seems questionable if water can be split at Cu_2O *via* a normal photocatalytic reaction. However, our polycrystalline layers show long term stability under photocathodic conditions, and a surprisingly high quantum efficiency for the photocathodic reduction of both oxygen and the methylviologen cation. Therefore Cu_2O could be a promising material, not for direct photoelectrochemical water splitting, but in conjunction with a suitable redox system as a p-type photoelectrode in an electrochemical photovoltaic cell.

$[Ru\{MeC(CH_2EMe)_3\}_2](CF_3SO_3)_2$: the first homoleptic hexaseleno- and hexatelluro-ether complexes

William Levason, Simon D. Orchard and Gillian Reid*

Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ.
E-mail: gr@soton.ac.uk

Received (in Basel, Switzerland) 9th March 1999, Accepted 29th April 1999

The preparations of the first examples of homoleptic hexaseleno- and hexatelluro-ether complexes, $[Ru\{MeC(CH_2EMe)_3\}_2](CF_3SO_3)_2$ (E = Se or Te) are described; the crystal structure of the former shows both ligands binding facially to the Ru^{II} centre, with the Se-based lone pairs in the *syn* arrangement.

Recently we embarked on a comparative study of the binding characteristics of thio-, seleno- and telluro-ether ligands to transition metal centres and we have shown that to low-valent group 6 and group 7 metal centres E→M donation increases in the order S < Se << Te.[1] Despite this, multidentate telluroether ligands are very rare, and the only reported tritelluroether complex is *fac*-$[Mn(CO)_3\{MeC(CH_2TeMe)_3\}]CF_3SO_3$.[2] We have already reported the synthesis, structures and properties of a range of multidentate and macrocyclic selenoether ligand complexes, and, in light of the prediction that telluroethers will show enhanced donating abilities, we have begun to investigate the synthesis and properties of multidentate telluroethers and their complexes with the platinum group metals. There are no examples with homoleptic hexaseleno- or hexatelluro-ether coordination to octahedral metal complexes. Typically two or more of the six coordination sites are occupied by halogen co-ligands which greatly influence the metal ion properties.[3] We report here the preparation, spectroscopic and structural characterisation of the first homoleptic hexaseleno- and hexatelluro-ether complexes, $[Ru\{MeC(CH_2EMe)_3\}_2](CF_3SO_3)_2$ (E = Se or Te).

$[Ru(dmf)_6](CF_3SO_3)_3$[4] reacts with 2 mol. equiv. of $MeC(CH_2EMe)_3$ (E = Se or Te) in refluxing MeOH solution to give yellow coloured solutions containing the hexa-substituted ruthenium(II) species $[Ru\{MeC(CH_2EMe)_3\}_2](CF_3SO_3)_2$.† These species can be isolated by addition of Et_2O to the concentrated solutions and filtration. The electrospray mass spectra (MeCN) show peaks with isotope distributions consistent with the doubly charged species $[Ru\{MeC(CH_2EMe)_3\}_2]^{2+}$ (E = Se, *m/z* centred at 402; E = Te, *m/z* centred at 548). IR spectroscopy shows peaks associated with coordinated triselenoether or telluroether, as well as absorptions characteristic of the $CF_3SO_3^-$ anion. The $^{77}Se\{^1H\}$ and $^{125}Te\{^1H\}$ NMR spectra of the complexes show single resonances at δ 120 and 204, respectively. Given that pyramidal inversion at an $Ru–SeR_2$ or $Ru–TeR_2$ unit is expected to be slow,[5,6] the observation of only one resonance in each case indicates that each coordinated ligand adopts a *syn* configuration.

Repeated attempts were made to obtain single crystals of one of these compounds suitable for an X-ray crystal structure analysis. Crystals of the selenoether complex were eventually obtained by diffusion of Et_2O into a solution of the complex in $MeNO_2$. A data set collected at 150 K gave rather broad peaks and did not refine satisfactorily. Data collection was therefore repeated at a slower scan-speed on a second sample at room temperature, yielding better quality data. The crystal structure‡ shows an ordered centrosymmetric $[Ru\{MeC(CH_2SeMe)_3\}_2]^{2+}$ cation with the Ru atom occupying a crystallographic inversion centre, giving a half-cation and one $CF_3SO_3^-$ anion in the asymmetric unit. Within the cation the Ru^{II} centre is coordinated to two tridentate, facially bound selenoether ligands, to give a slightly distorted octahedral arrangement with Ru–Se 2.4808(7), 2.4701(7), 2.4781(6) Å (Fig. 1). The Se–Ru–Se angles involved in the six-membered chelate rings are very close to 90°, and the Me substituents are oriented in the propeller-like arrangement associated with the configuration. This is consistent with the *syn* configuration deduced from $^{77}Se\{^1H\}$ NMR spectroscopy. The Ru–Se distances compare with 2.396(1)–2.465(1) Å in *cis*-$\{RuCl_2([16]aneSe_4)\}$ ([16]$aneSe_4$ = 1,5,9,13-tetraselenacyclohexadecane) and 2.465(3)–2.479(3) Å in *trans*-$[RuCl(PPh_3)([16]aneSe_4)]^+$.[6]

The electronic spectrum of $[Ru\{MeC(CH_2SeMe_3\}_2](CF_3SO_3)_2$ shows two d–d transitions, $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ at 25975 and 29940 cm^{-1} respectively, as well as intense charge transfer transitions at higher energy. Analysis of the spectrum[7] leads to approximate values of 10 *Dq* and *B* of 25000 and 250 cm^{-1}, respectively. These values can be compared with $\{Ru(H_2O)_6\}^{2+}$ (17700 and 425), $[Ru(en)_3]^{2+}$ (25450 and 390)[7] and $[Ru([9]aneS_3)_2]^{2+}$ ([9]$aneS_3$ = 1,4,7-trithiacyclononane) (28400 and 290 cm^{-1}).[8] These data indicate that the selenoether tripod, like [9]$aneS_3$, is a strong field ligand with a high degree of covalent character in the Ru–Se bonds. The electronic spectrum of $[Ru\{MeC(CH_2Te-$

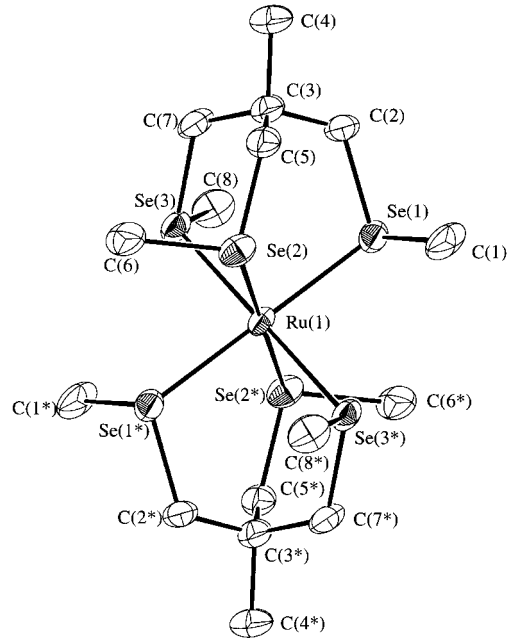

Fig. 1 View of the structure of $[Ru\{MeC(CH_2SeMe)_3\}_2]^{2+}$ with the numbering scheme adopted. H atoms are omitted for clarity, atoms marked * are related by a crystallographic inversion centre and ellipsoids are drawn at the 40% probability level. Selected bond lengths (Å) and angles (°): Ru–Se(1) 2.4808(7), Ru–Se(2) 2.4701(7), Ru–Se(3) 2.4781(6); Se(1)–Ru–Se(2) 90.18(2), Se(1)–Ru–Se(3) 89.02(2), Se(2)–Ru–Se(3) 87.56(2)°.

$Me)_3\}_2](CF_3SO_3)_2$ is less informative since the charge transfer transitions tail into the visible region and completely obscure the metal-centred transitions.

Cyclic voltammetry on $[Ru\{MeC(CH_2SeMe)_3\}_2](CF_3SO_3)_2$ (MeCN solution, 0.1 mol dm^{-3} $NBu^n_4BF_4$ supporting electrolyte) shows an irreversible reduction at −2.0 V *vs.* Fc/Fc^+ and a quasi-reversible oxidation at 1.18 V *vs.* Fc/Fc^+ which is assigned to the $Ru^{II/III}$ redox couple. This oxidation potential is considerably higher than for *trans*-$[RuCl_2([16]aneSe_4)]$ ($E_{1/2}$ = 0.32 V *vs.* Fc/Fc^+),[6] reflecting the presence of six soft Se donor atoms around the Ru^{II} centre in the former. $[Ru\{MeC(CH_2TeMe)_3\}_2](CF_3SO_3)_2$ shows no oxidative activity, only an irreversible reduction at −1.52 V *vs.* Fc/Fc^+. The relatively high potentials for these processes probably reflect the high stability of the low-spin d^6 Ru^{II} species within the strong field Se_6 or Te_6 coordination sphere, and strongly suggest that these ligands will be capable of supporting other $[ML_6]^{x+}$ species (L = Se or Te) for a wide variety of metals, thus promoting very different electronic environments at the metal centres.

We thank the University of Southampton and the EPSRC for support and Johnson Matthey plc for generous loans of $RuCl_3$.

Notes and references

† Satisfactory analytical and spectroscopic data were obtained.

‡ *Crystal data*: $C_{18}H_{36}F_6O_6RuS_2Se_6$, M = 1101.42, triclinic, space group $P\bar{1}$, a = 8.8436(5), b = 11.6692(15), c = 8.7056(8) Å, α = 107.369(9), β = 91.648(7), γ = 106.530(7), V = 815.62(14) Å^3, Z = 1, D_c = 2.242 g cm^{-3}, μ(Mo-Kα) = 73.68 cm^{-1}. Rigaku AFC7S four-circle diffractometer. Data collection at 293 K using Mo-Kα X-radiation (λ = 0.71073 Å), gave 2875 unique reflections (R_{int} = 0.0162) which were used in all calculations. The structure was solved using direct methods[9] and developed by iterative cycles of least-squares refinement[10] and difference Fourier synthesis. While the centrosymmetric cation is ordered, the $CF_3SO_3^-$ anion, which occupies a general position, shows rather high thermal parameters, particularly those associated with the F and O atoms. However, attempts to model this disorder by refining partial site occupancies were not successful, hence the atoms were refined with unit occupancies and high thermal parameters. While low temperature data collection would normally be expected to reduce the thermal motion and improve the structure quality, a data set from a different crystal collected previously at 150 K gave broad peaks and a significantly poorer fit to the data. Anisotropic thermal parameters were refined for all non-H atoms and H atoms were included in fixed, calculated positions. The weighting scheme $w^{-1} = \sigma^2(F_0) + (0.0634P)^2 + 2.2211P$, where $P = (F_0^2 + 2F_c^2)/3$, gave satisfactory agreement analyses. At final convergence, R_1 = 0.0539, wR_2 = 0.1106 (all data), R_1 = 0.0373, wR_2 = 0.1011 [$I \geqslant 2\sigma(I)$], S = 1.032 for 178 parameters. CCDC 182/1245. Received (in Cambridge, UK) 12th April 1999, Accepted 29th April 1999

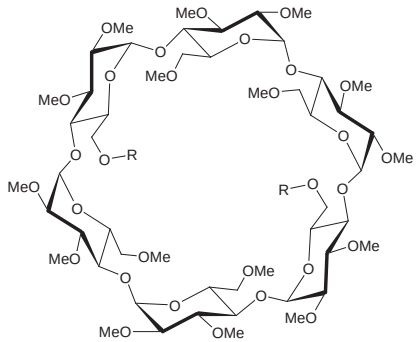
The synthesis of diphosphino α-cyclodextrins (α-CDs) and their capping by transition metals are described; one of the complexes has been tested in biphasic catalytic hydroformylation.

Multidentate ligands preorganised around a macrocyclic platform have attracted much interest in recent years in view of their ability to shape the coordination sphere of metals in a specific manner as well as to provide well defined cavities or clefts.[1] The combination of both features could lead to the development of new metal catalysts with enhanced selectivities and activities. In addition, it may be anticipated that the presence of a bulky cavity will provide protection against undesired side reactions if properly positioned with respect to the metal centre. These issues have, in some respect, been addressed by use of monosubstituted cyclodextrins (CDs) bearing a pendant catalytic site.[2–4] However, until now, no synthetic methodology has been developed for *capping* a CD with a catalytically active transition metal unit. Exact positioning of the metal at the cavity mouth appears to be essential for fully exploiting the intrinsic properties of CDs in terms of water-solubility, chirality and steric crowding. In this preliminary communication, we report on the synthesis of the first C_2-symmetrical diphosphines based on α-CD and describe how these ligands undergo efficient capping of the oligosaccharide torus with catalytically important transition metals.†

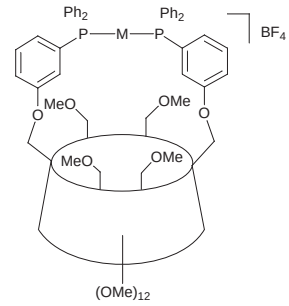


1 R = $C(C_6H_4Bu^t)_3$
2 R = H
3 R = Ms
4a R = 3-C_6H_4I
4b R = 4-C_6H_4I
5a R = 3-$C_6H_4PPh_2$
5b R = 4-$C_6H_4PPh_2$

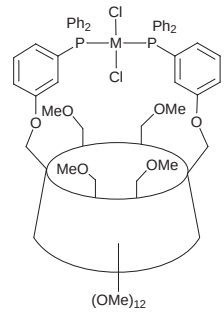
All ligands mentioned here were derived from diol **2** which was obtained in gram-scale quantities and good yield (87%) by acidic cleavage[5] of 6A,6D-di-*O*-tris(*p*-*tert*-butylphenyl)methyl-per-*O*-methyl-α-CD **1**[6] with HBF_4 (34%) in Me_3CN. Diol **2** was converted into dimesylate **3** in 90% yield. Treatment of the latter with 3-iodophenol or 4-iodophenol and K_2CO_3 in DMF afforded respectively di-iodo CDs **4a** and **4b** which on Stelzer's palladium-catalysed cross coupling[7] with diphenylphosphine gave phosphine-based ligands **5a** and **5b** in 69 and 70% overall yields, respectively.

^1H as well as ^{13}C and ^{31}P NMR spectra of diphosphines **5a**† and **5b**† clearly show the presence of the expected twofold molecular symmetry which indicates free rotational motion of the triarylphosphine fragments. For example, the ^{31}P NMR spectrum of either **5a** or **5b** consists of a single singlet respectively at δ −4.5 and −6.8.

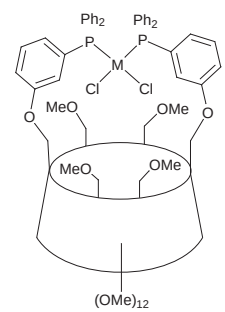
According to CPK‡ models, ligand **5a** possesses the right geometrical features to promote the formation of *trans-P,P*-chelates upon metal complexation. Evidence for the latter was given by studying the coordination of **5a** with metals prone to form linear arrangements. Thus, treatment of **5a** with $AgBF_4$ led to the C_2-symmetric complex P–Ag–P **6**. Likewise, its gold analogue **7** was cleanly obtained by reacting in CH_2Cl_2 the *in situ* prepared complex [Au(thf)(SC_4H_8)]BF_4 (SC_4H_8 = tetrahydrothiophene) with **5a** in high yield. The complex is air stable



6 M = Ag
7 M = Au



8a M = Pt
9a M = Pd



8b M = Pt
9b M = Pd

and can be subjected to chromatography on silica gel without noticeable decomposition, an unusual feature for complexes of that type. Similarly, treatment of **5a** with [$PtCl_2(PhCN)_2$] (mixture of *cis* and *trans* isomers) led to the exclusive formation of *trans-P,P*-chelate complex **8a**. However, exposure of a refluxing ethanolic solution of **8a** to sunlight produced after a week a 65:35 equilibrium mixture of **8a** and *cis* chelate **8b**. These compounds could easily be separated by column chromatography without detection of any interconversion during the separation. Molecular-weight determination using vapour phase osmometry (CH_2Cl_2) gave masses of 1890 and 1950 for **8a** and **8b**, respectively [M(calc.) = 1984]. This

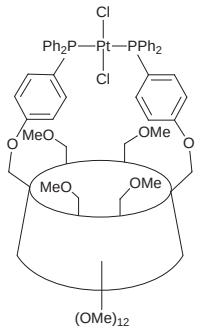
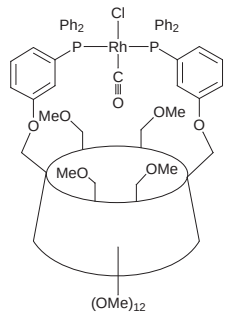
[a] In $CDCl_3$ (ext. ref.: H_3PO_4). [b] In $CDCl_3$. [c] The stereochemistry about the palladium centres was assigned empirically according to ref. 8. [d] The monomeric nature of this complex was confirmed by vapour phase osmometry.

clearly demonstrates the monomeric nature of both compounds.§ Moreover, the reaction between ligand **5a** and $[PdCl_2(PhCN)_2]$ (*cis* and *trans* isomers) afforded a rapidly interconverting 80 : 20 equilibrium mixture of *trans*-chelate **9a** and *cis*-chelate **9b** as evidenced by ^{31}P NMR spectroscopy[8] (Table 1). In addition, unlike **5a**, ligand **5b** gave with $[PtCl_2(PhCN)_2]$ both *trans* chelate **10a** and the corresponding *cis* chelate **10b** (not drawn) as a 40 : 60 mixture.¶ Their



10a



11

separation could not be achieved since they interconvert rapidly in solution. Clearly, the phosphine fragments in **5a**, less so in **5b**, are arranged on the cyclodextrin platform so as to favour *trans* chelation. Full evidence for the latter was given by the reaction of $[\{Rh(CO)_2Cl\}_2]$ in dichloromethane with **5a** which quantitatively yielded complex **11**.† The $^{31}P\{^{1}H\}$ NMR spectrum of **11** displays a single doublet [*J*(Rh–P) 127.1 Hz] in agreement with the expected *trans*-P,P stereochemistry.

Complex **11** possesses the essential features known to be important for a hydroformylation catalyst. Indeed, **11** catalyses the conversion of oct-1-ene into the corresponding aldehydes in H_2O–MeOH (conversion and chemoselectivity > 99% after 18 h).‖ Selectivity of linear to branched aldehydes (n : i) is of the order of 70 : 30, which is unexceptional for rhodium(I) bis-(phosphine) complexes. Similarly, the turn-over frequency** (70 h^{-1}) compares well with standard nonionic hydroformylation catalysts. Unfortunately, low water-solubility prevents **11** acting as a supramolecular catalyst as evidenced by the outcome of the catalytic tests which are typical of classical systems both in terms of activity and selectivity. Although **11** is only present in the methanol–water phase in the first place, transfer of the catalyst to the oct-1-ene–aldehydes phase was found to take place during the reaction.

A synthetic methodology has been designed for the preparation of highly preorganised diphosphines based on α-CD. Such ligands promote the formation of chelate complexes in which the P_2 unit rigidly holds a metal centre at the mouth of the cavity. Water-soluble analogues of the aforementioned species are expected to form inclusion complexes in water with substrates that can react catalytically *via* the metal centre. It is hoped that these combined features will improve existing hydroformylation and hydrogenation catalysts both in terms of activity and selectivity.

Notes and references

Imine allylation by allylic trimethylsilanes *via in situ* formation of *N*-tosyliminium species from carbonyl compounds and toluene-*p*-sulfonamide with $SnCl_2$ and *N*-chlorosuccinimide: regioselection and diastereoselection

Yoshiro Masuyama,* Jiro Tosa and Yasuhiko Kurusu

Department of Chemistry, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102-8554, Japan.
E-mail: y-masuya@hoffman.cc.sophia.ac.jp

Received (in Cambridge, UK) 8th April 1999, Accepted 5th May 1999

***N*-Tosyliminium species, prepared *in situ* from carbonyl compounds and $TsNH_2$ with $SnCl_2$ and *N*-chlorosuccinimide, undergo nucleophilic addition of allylic silanes (imine allylation) to produce the corresponding homoallylic amines; the imine allylation by but-2-enyltrimethylsilane with aldehydes and $TsNH_2$ leads to regio- and diastereoselection to produce *anti* 1-substituted 2-methylbut-3-enylamines.**

Lewis acid-catalysed allylations of imines or iminium species with allylic silane or tin reagents are one of the most effective methods for the introduction of an amino group into carbon skeletons.[1, 2] However, some imines and iminium species are unstable to water or heat, and their purification is difficult *via* recrystallization, distillation and chromatography. The allylation of imines or iminium species, prepared *in situ* from carbonyl compounds and amines, would therefore be a synthetically useful strategy.[3–7] We have reported that *N*-chlorosuccinimide (NCS) and $SnCl_2$ can be utilized for the aldol-type reaction of isopropenyl acetate with oxycarbenium ions derived from either aldehydes with alcohols or lactols.[8] A key step in the aldol-type reaction is probably the formation of alkoxytrichlorotins, which react with aldehydes to form oxycarbenium ions. We hoped that, using NCS–$SnCl_2$, aldehydes could be transformed into *N*-tosyliminium species with $TsNH_2$, in analogy to alcohols giving oxycarbenium ions, and that the *N*-tosyliminium species could undergo nucleophilic addition with allylic silanes (imine allylation).[9]

As a consequence of the investigation of imine allylation by allyltrimethylsilane **1** with benzaldehyde and some amines under various conditions, it was proved that starting with a solution of $SnCl_2$ (1.1 mmol), $TsNH_2$ (1 mmol) and benzaldehyde (**2**; R^1 = Ph, R^2 = H, 1 mmol) in CH_2Cl_2 (3 ml) in an ice-bath, the addition of NCS (1.1 mmol) in CH_2Cl_2 (5 ml) followed by allyltrimethylsilane (**1**, 1.5 mmol) after 2 h afforded *N*-tosyl-1-phenylbut-3-enylamine (**3**; R^1 = Ph, R^2 = H) in a 96% yield (Scheme 1). Benzylamine, benzamide, and *tert*-butyl carbamate were ineffective in the reaction under the same conditions as those used with $TsNH_2$. This allylation probably needs amines or amides bearing an acidic proton on nitrogen for the formation of the trichlorotin amide; as shown in Scheme 2, $TsNH_2$ reacts with **A**, derived from NCS and $SnCl_2$, to form **B**, which undergoes nucleophilic addition to benzaldehyde (R = Ph) to form **C** followed by **D**. The imine allylation by **1** with various carbonyl compounds and $TsNH_2$ was carried out under the same conditions as those for benzaldehyde described above. Representative results are summarized in Table 1. Any aldehyde, including aromatic aldehydes bearing either an electron-withdrawing group (entries 2 and 3) or an electron-donating group (entries 4–6), aliphatic aldehydes (entries 8–10) and an α,β-unsaturated aldehyde (entry 11) can be used in the imine allylation. In the cases of aldehydes bearing a coordinate group,

5	*c*-C_6H_{11}	15	62	9 : 91

[a] The imine allylation by **4** (1.5 mmol) was carried out with aldehydes (1 mmol), $TsNH_2$ (1 mmol), $SnCl_2$ (1.1 mmol) and NCS (1.1 mmol) in CH_2Cl_2 (3 ml) by the same method as that for the allylation by **1**. [b] Isolated yields. [c] The ratio was determined by ^1H NMR (JEOL GX-270).

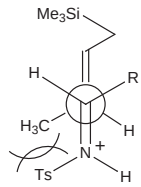

Fig. 1 Antiperiplanar transition state of **4**

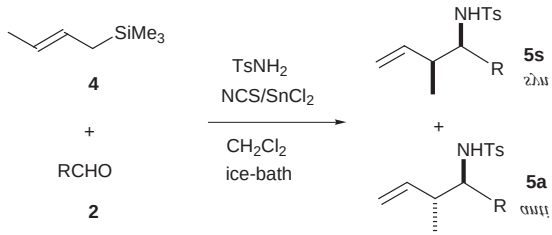

Scheme 3

3,4-methylenedioxybenzaldehyde and furan-2-carbaldehyde exhibited low yields (entries 6 and 7), and pyridine-2-carbaldehyde did not react under the given conditions. Ketones can also undergo the imine allylation to be converted into the corresponding homoallylic amines in unsatisfactory yields (entries 12–14).

The imine allylation of but-2-enyltrimethylsilane (**4**)† with some aldehydes and $TsNH_2$ under the same conditions as those of **1** caused γ-*anti*-addition to afford *anti* 1-substituted 2-methylbut-3-enylamines **5a** in good yields, as summarized in Table 2 (Scheme 3).‡ The γ-*anti*-addition probably occurs *via* an acyclic antiperiplanar transition state (**E**) between **4** and **D** (Scheme 2), due to steric hindrance between the tosyl group and the methyl group (Fig. 1).[4,9]

Notes and references

† But-2-enyltrimethylsilane (**4**; *E* : *Z* = 86 : 14) was prepared by the reaction of but-2-enyltrichlorosilane, derived from 1-chlorobut-2-ene and trichlorosilane with CuCl and Et_3N, with MeMgI (ref. 10).

‡ The stereochemistry was determined by comparison of ^1H NMR data of primary homoallylic amines (R = Ph, C_6H_{13}), which were produced by removal of the tosyl group (ref. 9), with those in the literature (ref. 11).

Highly donor-doped (110) layered perovskite materials as novel photocatalysts for overall water splitting

Hyun G. Kim, Dong W. Hwang, Jindo Kim, Young G. Kim and Jae S. Lee*

Department of Chemical Engineering and School of Environmental Engineering, Pohang University of Science and Technology, San 31 Hyoja-dong, Pohang, 790-784, Korea. E-mail: jlee@postech.ac.kr

Received (in Cambridge, UK) 12th April 1999, Accepted 6th May 1999

Highly donor-doped (110) layered perovskite materials with a generic composition of $A_mB_mO_{3m+2}$ (m = 4, 5; A = Ca, Sr, La; B = Nb, Ti) loaded with nickel have been found to be efficient photocatalysts for overall water splitting with quantum yields as high as 23% under UV irradiation.

Among various methods of solar energy conversion, photocatalytic splitting of water into H_2 and O_2 has received most attention because of its potential to obtain directly clean and high-energy containing H_2 from abundant H_2O. Since its discovery in 1972,[1] water splitting with semiconductor photocatalysts under ultraviolet (UV) irradiation has become the subject of extensive studies.[2–4] However, quantum yields (% of absorbed photons that have been actually used to generate a photoreaction product) for well known photocatalysts such as TiO_2 and $SrTiO_3$ are very low (*ca.* <1%). Recently, (100) layered perovskite materials such as $K_4Nb_6O_{17}$ and $A_4Ta_xNb_{6-x}O_{17}$ (A = K, Rb) were found by Domen and coworkers to be much more efficient, showing quantum yields of *ca.* 5%.[5,6] This greatly improved quantum yield has been attributed to the use of their interlayer spaces as reaction sites. Inoue *et al.*[7] have reported an efficient water splitting over RuO_2–$BaTi_4O_9$ with a tunnel structure. However, it is desirable to find photocatalytic materials with even higher quantum yields in order for the water splitting to become a viable method to solve both energy and environmental problems in the future.

Here, we report a group of novel photocatalysts for overall water splitting with photon yields as high as 23% under UV irradiation. The materials are a series of homologous structures based on perovskite-type slabs with a generic composition of $A_mB_mO_{3m+2}$ (m = 4, 5; A = Ca, Sr, La; B = Nb, Ti) loaded with nickel. Unlike the (100) layered perovkite-type materials reported by the Domen group, our materials have the perovskite slabs parallel to (110) relative to the perovskite structre and are highly donor-doped. These structural and electronic characteristics are believed to be responsible for the much improved quantum yields.

For the preparation of the photocatalysts, *ca.* 10 g of commercial powders of metal carbonates and oxides were mixed in a desired composition and pressed in the form of a pellet. Pellets were calcined at 1123–1173 K for 6 h in an electric furnace and sintered at 1273–1623 K for 5 h. The presence of the (110) perovskite phase in the sintered ceramics was confirmed by X-ray diffraction (XRD) analysis using Cu-Kα radiation. Particle sizes of 0.5–8 μm were obtained by pulverizing the sintered pellets in a mortar. In order to obtain photocatalysts exhibiting high activities for water splitting, it was essential to load a transition metal on our perovskite materials and nickel was found to be the most effective. Thus, perovskite powders were impregnated with an aqueous $Ni(NO_3)_2$ solution to give a Ni loading of 1 wt% which was determined to be the optimum loading that gave the highest rate of water splitting. Ni-loaded $A_mB_mO_{3m+2}$ (m = 4, 5) catalysts were reduced with dihydrogen at 973 K, and then oxidized with oxygen at 473 K. This reduction–oxidation procedure was found to be an effective method to obtain active photocatalysts based on (100) layered perovskite materials.[5,6]

The photocatalytic decomposition of water was carried out at room temperature in a closed gas circulation system using a high pressure Hg lamp (450 W) placed in an inner irradiation-type quartz reaction cell. The catalyst (1.0 g) was suspended in distilled water (350 mL) by magnetic stirring. The rates of H_2 and O_2 evolution were determined by a gas chromatograph.

Fig. 1 shows a typical time course of H_2 and O_2 gas evolution for the photocatalytic decomposition of water over Ni/$Sr_2Nb_2O_7$. Note that $Sr_2Nb_2O_7$ is the reduced formula of $Sr_4Nb_4O_{14}$, the first member of the series $A_mB_mO_{3m+2}$ with m = 4. The catalyst produces H_2 (402 μmol h^{-1}) and O_2 (198 μmol h^{-1}) in a stoichiometric ratio (H_2 : O_2 = 2 : 1). In early studies of water splitting, the simultaneous evolution of O_2 and H_2 (*overall* water splitting) had been a challenge due to the difficulty of O_2 formation and the rapid reverse reaction between the two products. Furthermore, the reaction proceeds at steady rates with no indication of catalyst deactivation for 20 h during which the mol of H_2 produced are greater than the mol of the catalyst by factors of *ca.* 50 for Ni and *ca.* 2 for Nb contained in the whole catalyst. Since two electrons are needed to produce a molecule of H_2 from water, the latter corresponds to the turnover number of 4 if all Nb atoms have participated in the water splitting. This demonstrates that *overall* water splitting on this material proceeds *catalytically*.

Table 1 summarizes results of water decomposition and catalyst characterization for a number of photocatalysts. Our (110) layered perovskite catalysts ($Ca_2Nb_2O_7$, $Sr_2Nb_2O_7$, $La_2Ti_2O_7$ and $La_4CaTi_5O_{17}$) are compared with previously known (100) layered perovskite catalysts ($K_4Nb_6O_{17}$ and $K_4Ba_2Ta_3O_{10}$) and bulk-type TiO_2 catalyst (Degussa P-25), all under the same reaction conditions. $La_4CaTi_5O_{17}$ is the second member of $A_mB_mO_{3m+2}$ with m = 5. All perovskite-type catalysts were loaded with Ni, while Pt was loaded onto TiO_2 because Pt is known to be the best modifier for TiO_2. The BET surface areas of all perovskite-type photocatalysts fabricated by sintering at 1250 °C for 5 h are 4–5 m^2 g^{-1}. The band gap energies estimated from UV–VIS diffuse reflectance spectra of all catalysts are in the UV energy region of 3.1–4.3 eV. A

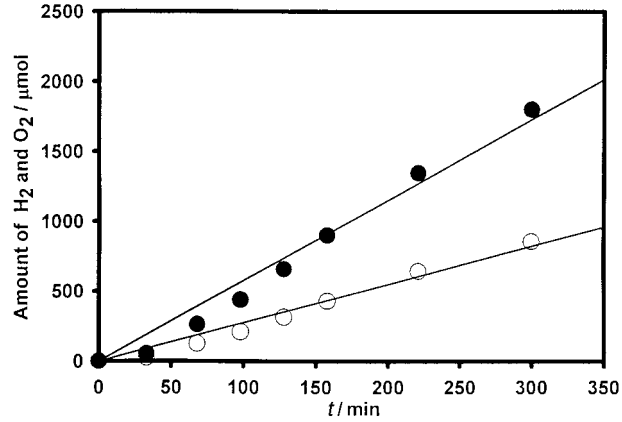

Fig. 1 Time courses of H_2 (●) and O_2 (○) evolution from distilled water over Ni (1.0 wt%)/$Sr_2Nb_2O_7$.

Table 1 Physical properties, H_2 evolution rates and quantum yields for various photocatalysts

Catalyst[a]	BET surface area/m^2 g^{-1}	Band gap/eV	Second harmonic generation	Rate of H_2 evolution/μmol h^{-1}	Quantum yield (%)
$Ca_2Nb_2O_7$	4.2	4.3	Yes	101	7 (< 288 nm)
$Sr_2Nb_2O_7$	5.1	4.1	Yes	402	23 (< 300 nm)
$La_2Ti_2O_7$	5.2	3.2	No	441	12 (< 360 nm)
$La_4CaTi_5O_{17}$	4.9	3.8	No	499	20 (< 320 nm)
TiO_2	50.0	3.1	—	0.3	< 1 (< 360 nm)
$K_4Nb_6O_{17}$	4.5	3.3	No	210	5 (< 360 nm)
$KBa_2Ta_3O_{10}$	4.2	3.5	No	150	8 (< 350 nm)

[a] All perovskite-type catalysts were loaded with Ni [1.0 wt% for (110) layered materials and 0.1 wt% for (100) layered materials] while 1.0 wt% Pt was loaded onto TiO_2.

second harmonic generation (SHG) in $Ca_2Nb_2O_7$, $La_2Ti_2O_7$ and $K_4Nb_6O_{17}$ ceramics was checked by using a fundamental wave of a pulsed Nd^{3+}:YAG laser at wavelength of 1064 nm as the incident light since $Sr_2Nb_2O_7$ is a known non-linear optical material showing SHG.[8] Although a SHG was clearly observed in $Ca_2Nb_2O_7$, $La_2Ti_2O_7$ and $K_4Nb_6O_{17}$ ceramics exhibited no SHG.

It is clear that (110) layered perovskite catalysts are, as a group, much more active than previously known (100) layered perovskite or bulk-type TiO_2 for the photocatalytic decomposition of water into H_2 and O_2 under UV irradiation. The rate of H_2 evolution over Pt/TiO_2 was a mere 0.3 μmol h^{-1}. Dramatic improvement is observed for Ni-doped (100) layered perovskites and still further for (110) layered perovskites. The quantum yield of H_2 evolution over photocatalysts was estimated by using the chemical actinometer ferrioxalate[9] [$Fe(C_2O_4)_3^{3-}$] based on known photon absorbance during the reduction of Fe^{3+} to Fe^{2+}. The quantum yield is the more meaningful parameter than the rate of H_2 evolution itself to gauge the performance of a photocatalyst because the rate is normalized against the absorbed photons. The photon flux from the UV lamp varies depending on the wavelength and, hence, the quantum yield is not necessarily proportional to the rate of H_2 production when semiconductors of different band gaps are used as catalysts. Yet, it is again clear that (110) layered perovskite materials are superior to previously known photocatalysts also in terms of the quantum yield. In fact, to the best of our knowledge, the quantum yield of 23% is the highest among reported semiconductor photocatalysts for overall water splitting. The quantum yield of 5% for $K_4Nb_6O_{17}$ is in agreement with the previous reports for the same material.[5,6]

Examination of quantum yields listed in Table 1 reveals that the superior performance of $A_mB_mO_{3m+2}$ (m = 4,5) is general and not limited to one specific composition. Probably, their structure is important for photocatalytic activity. Compounds with structures that are composed of slabs with distorted perovskite-type atomic configurations are classifed into two groups according to the geometrical relations of the slabs to the perovskite structure.[10] The slabs in (100) layered perovskites[11,12] are obtained by cutting the perovskite structure parallel to (100) and those in (110) layered perovskites[13] are parallel to (110).

As mentioned, (100) layered perovskites[5,6] or tunnel structures[7] have received attention recently since they are much more active than the generally used TiO_2 or $SrTiO_3$ for photocatalytic water splitting. The high activity of these materials has been attributed to effective utilization of interlayer space as reaction sites. We have discovered that the (110) layered perovskites of $A_mB_mO_{3m+2}$ (m = 3, 4; A = Ca, Sr, La; B = Nb, Ti) are still more active with unprecedentedly high quantum yields. These novel photocatalysts are of a layered structure and hence the contribution of interlayer space as reaction sites is expected as in (100) layered perovskite materials. Yet, we have to consider other factors to account for the further increased quantum yields.

If the TiO_2 component of $CaTiO_3$ or $SrTiO_3$ with the ideal perovskite structure is completely replaced by Nb_2O_5, the product is $Ca_2Nb_2O_7$ or $Sr_2Nb_2O_7$. The replacement of Ti^{4+} by Nb^{5+} results in excess electrons and slabs of a distorted perovskite structure of m unit cells thick in order to accommodate excess oxygen.[13] This also occurs when Ca^{2+} or Sr^{2+} is replaced by La^{3+} as in $La_2Ti_2O_7$. This structural substitution gives highly donor-doped (110) layered perovskite materials $A_4B_4O_{14}$, commonly denoted as $A_2B_2O_7$. When a part of the oxygen is lost, the next structure $A_5B_5O_{17}$ in the series is obtained as in $La_4CaTi_5O_{17}$. In the photocatalytic water splitting over a semiconductor, excited electron–hole pairs are generated when the catalyst is illuminated with light having energy equal to or greater than the band gap. The principal challenge is how to suppress the energy-wasteful recombination of the formed electron–hole pairs. Recombination is usually much more facile than the subsequent steps needed for water cleavage. In a semiconductor–liquid interface, the electron–hole pairs are separated by the electric field present in the depletion layer. It is expected that the highly donor-doped (110) perovskite would create a narrower depletion layer than undoped perovskite as is observed for metal-ion doped TiO_2.[14] Band bending would then take place on a depletion layer with a narrower width or become more drastic.[15] Finally, the increased band bending would allow more efficient charge separation and enhance the overall quantum yield of water splitting.

Nitration of cyclic vinylsilanes with acetyl nitrate: effect of silyl moiety and ring size

Govindagouda S. Patil and Gopalpur Nagendrappa*

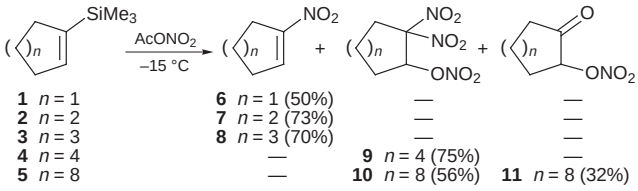
Received (in Cambridge, UK) 25th March 1999, Accepted 4th May 1999

Reaction of $AcONO_2$ with common ring vinylsilanes gives the corresponding α,β-unsaturated 1-nitrocycloalkenes, and with medium and large ring vinylsilanes it produces novel 1,1-dinitro 2-nitrates.

The reaction of $AcONO_2$ with olefins leads to a plethora of products, which include isomeric nitro acetates, nitro nitrates and nitroalkenes.[1,2] However, the desired α,β-unsaturated nitroalkenes are obtained at best as only very minor products or not at all.[3] The results have been rationalized by proposing an oxazetidine intermediate, a [2 + 2] cycloadduct of a nitryl cation with an olefin.[1] Because of the well-known propensity of vinylsilanes to undergo regiospecific electrophilic substitution,[4] we considered that they could be nitrated[5] to the synthetically versatile α,β-unsaturated nitroalkenes.[6] This has now been realized in the case of common ring vinylsilanes. However, the medium and large ring vinylsilanes give different but interesting and novel products.

The nitration procedure is very simple. The cyclic vinylsilane (2.5 mmol) in CH_2Cl_2 (2 ml) at −15 °C was treated dropwise with $AcONO_2$[7] (5 mmol). After stirring the mixture for about half an hour (the disappearance of the vinylsilanes was monitored by GC), water was added and the mixture worked up in the usual manner. The products were purified by silica gel chromatography [2% EtOAc–light petroleum (bp 60–65 °C)].

For the present study, a series of 1-trimethylsilylcycloalkenes consisting of three common rings (**1**–**3**), one medium ring (**4**) and one large ring (**5**, a 1 : 1 mixture of *cis* and *trans* isomers) was employed.[8] The three common ring vinylsilanes **1**–**3** gave, in moderate to good isolated yields, the corresponding 1-nitrocycloalkenes **6**–**8** (Scheme 1), which were identical to authentic compounds.[3,5] No other products were detected in any of these cases.



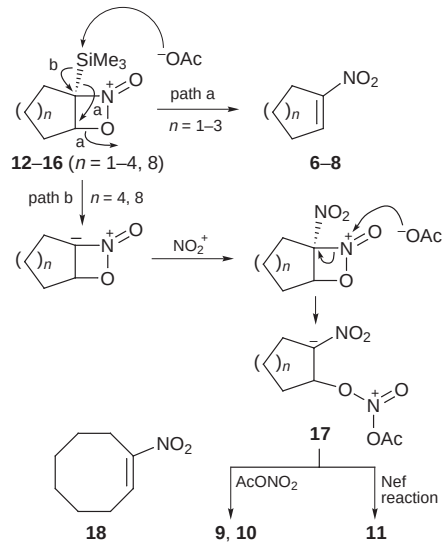
1 *n* = 1 — **6** *n* = 1 (50%) — —
2 *n* = 2 — **7** *n* = 2 (73%) — —
3 *n* = 3 — **8** *n* = 3 (70%) — —
4 *n* = 4 — — **9** *n* = 4 (75%) —
5 *n* = 8 — — **10** *n* = 8 (56%) **11** *n* = 8 (32%)

Scheme 1

1-Trimethylsilylcyclooctene **4** produced a single solid product, which was identified as 2,2-dinitrocyclooctyl nitrate **9**. 1-Trimethylsilylcyclododecene **5** (a 1 : 1 mixture of *cis* and *trans* isomers) gave a 2 : 1 mixture of the dinitro nitrate **10** and the keto nitrate **11** (Scheme 1), which were separated by repeated fractional crystallization from light petroleum (bp 60–65 °C). Compounds **9**–**11** were characterized by their spectral and elemental analysis data.[9] The expected 1-nitrocycloalkenes were not detected in either of these cases. This is in stark contrast to the results of nitration of cyclooctene, which was found to behave like the common ring cycloalkenes.[1]

The smooth conversion of the cyclic vinylsilanes **1**–**3** to the corresponding 1-nitrocycloalkenes **6**–**8** as the sole products is strikingly dissimilar to the complex results obtained in the nitration of their unsilylated analogues.[1] This clearly underlines the powerful influence of silicon in directing this transformation. The apparently different results from the medium and large ring vinylsilanes **4** and **5** can also be attributed to control by the silicon moiety.

All the results of $AcONO_2$ reaction with the cyclic vinylsilanes **1**–**5** can be rationalized by a mechanistic scheme involving the initial formation of a [2 + 2] cycloaddition intermediate **12**–**16** (Scheme 2), following the proposal of Borisenko *et al.* who based it on theoretical calculation and experimental results of $AcONO_2$ reaction with cycloalkenes.[1]



Scheme 2

In the present case, the regiospecificity is presumed to arise from the well-known β-silicon effect[4] which directs the electrophile NO_2^+ to attack the α position. Since the loss of silicon is more rapid than that of a β-proton in the β-elimination reactions of β-silicon-containing substrates, the further transformation of **12**–**16** is guided by this process. The β-elimination in **12**–**16** to the nitroolefinic products **6**–**8** occurs if silicon and the β-leaving group (C–O bond) attain the antiperiplanar geometry,[10] which is achieved when the carbocycles in **12**–**16** have the required conformation (*e.g.* cyclohexane in the chair form with α-C–$SiMe_3$ and β-C–O bonds being axial-axial *trans*). All the intermediates **12**–**16** from the vinylsilanes **1**–**5** can accommodate this conformational demand, but only those (**12**–**14**, *n* = 1–3) from the common ring vinylsilanes eventually lead to the 1-nitrocycloalkenes **6**–**8** (Scheme 2, path a). In the case of medium and large rings, the more rapid changes in their conformations and transannular interactions[10] probably diminish the life-time of the crucial conformation in which silicon and the leaving group are antiparallel to such an extent that the intermediate takes a different route to give the observed products (Scheme 2, path b).

We verified and confirmed that **9** is not formed from **4** *via* 1-nitrocyclooctene **18**. When **18**, prepared by a literature procedure,[11] was treated with $AcONO_2$ under conditions identical to those used for the nitration of **4**, the starting

nitrocycloalkene **18** was recovered intact. We presume that the formation of **10** from **5** follows a similar route.

Additional evidence for this mechanistic scheme is the fact that no 1,2-nitro acetate, 1,2-nitro nitrate or transannular products are produced from any of the cyclic vinylsilanes **1**–**5**, unlike the reported results of the nitration of cycloalkenes under similar conditions.[1]

The formation of the keto nitrate **11** is likely to be due to a Nef-type transformation[12] of a possible intermediate **17**, which can also give the dinitro nitrate.

Our work demonstrates that nitration of cyclic vinylsilanes can be accomplished, though the nature of the products is dependent on the ring size, in that the common rings give the 1-nitrocycloalkenes and rings larger than seven-membered rings will produce novel dinitro nitrates.

The authors thank the DST and the CSIR, New Delhi, for financial support of this work and a fellowship to GSP. Some of the equipment used in this work was donated by the Alexander von Humboldt Foundation, Germany.

Formation of the bidentate [$Ph_2SNC(Me)N(H)$] ligand by metal-assisted sulfimide addition to acetonitrile; X-ray crystal structure of [$Pt(Ph_2SNH)(Ph_2SNC(Me)NH)Cl]Cl{\cdot}MeCN$

Paul F. Kelly* and Alexandra M. Z. Slawin

Department of Chemistry, Loughborough University, Loughborough, Leicestershire, UK LE11 3TU. E-mail: P.F.Kelly@lboro.ac.uk

Received (in Basel, Switzerland) 4th March 1999, Accepted 1st May 1999

In contrast to similar reactions of Cu, Co and Pd species, the platinum(II) complex [$Pt(MeCN)_2Cl_2$] reacts with Ph_2SNH (ratio 1 : 2) in MeCN *via* a metal assisted addition of the sulfimide to the acetonitrile to give [$Pt(Ph_2SNH)(Ph_2SNC(Me)NH)Cl]Cl{\cdot}MeCN$, the first example of a complex of the bidentate [$Ph_2SNC(Me)N(H)$] ligand.

As part of our continuing interest in the coordination chemistry of sulfur–nitrogen species[1] we have recently reported on the reactivity of *S*,*S*′-diphenylsulfimide, Ph_2SNH **1**, towards a number of metal centres. For example, during investigations into its reactivity towards $CuCl_2$ we showed that the N-bound 2 : 1 complex, *trans*-[$CuCl_2(Ph_2SNH)_2$], forms readily *via* reaction in MeCN. Though such a product was not unexpected, it proved to be unusual in its ability to crystallise in either square-planar or pseudo-tetrahedral geometries.[2] Such isomerism appears to be unique for a neutral Cu(II) species, indicating that the ligand properties of **1** are not as simple as one might

1

imagine. This conclusion is backed up by the observation that [$Co(Ph_2SNH_2)_6]Cl_2$ exhibits strong, concerted, directed hydrogen bonding between both sets of triple N–H units on either side of the coordination octahedron and the chloride counter ions.[3] These results, backed up by the obvious potential of the sulfimides in general as functionalised ligands, prompted us to investigate the coordination chemistry of **1** further by addressing its ability to coordinate to Pt and Pd centers.

Many aspects of the latter chemistry prove to be quite straightforward;[4] thus salts of $[Pd_2X_6]^{2-}$ (X = Cl or Br) form $[PdX_3(Ph_2SNH)]^-$ or [$Pd(Ph_2SNH)_4]X_2$ depending upon reaction stoichiometry while 4 equivalents of **1** react slowly with $[PPh_4]_2[PtCl_4]$ in CH_2Cl_2 to give [$Pt(Ph_2SNH)_4]Cl_2$. There is no evidence from either X-ray crystallographic or IR spectroscopic studies that such products contain **1** as anything other than simple N-bound ligands. During such work, however, we noted that the product of the reaction of **1** with [$Pt(MeCN)_2Cl_2$] (ratio 2 : 1) in acetonitrile† generated crystalline material the IR spectrum of which was unusual in that it exhibited a very strong, broad N–H peak at 3071 cm^{-1} (of the type we have more usually seen associated with cationic sulfimide complexes) and extra bands not normally associated with the Ph_2SNH ligand (at 1540, 1249 and 807 cm^{-1}). As such data were not consistent with the simple formulation [$Pt(Ph_2SNH)_2Cl_2$] we investigated the complex by X-ray crystallography.‡

The structure obtained for **2** (which includes an acetonitrile of solvation) is shown in Fig. 1. Although two of the four coordination sites on the platinum contain expected ligands (N-bound **1** and a chloride) the other two sites are taken up by the nitrogen and sulfur atoms of a chelating [$Ph_2SNC(Me)N(H)$] ligand. Close inspection of the latter and the overall metallocycle of which it is part reveals a number of important points about the reaction and its product. First of all it is clear that during the course of the reaction one of the sulfimide units has added to an acetonitrile and completed the metallocycle by binding to the platinum through a sulfur. Within this metallocycle the S–N distance appears to be virtually identical to that in the unreacted, coordinated sulfimide ligand (1.625 *cf.* 1.618 Å) indicating that this may be best represented as a double bond. Of the two C–N bonds one, N(14)–C(13), is significantly shorter than the other (1.302 *cf.* 1.358 Å) indicating a higher bond order. Thus we can approximate the bonding within the neutral ligand to N(H)=C(Me)N=SPh_2 though as with most sulfimide systems this obviously constitutes something of an over simplification. Bond distances and angles within the coordinated unreacted sulfimide unit are not significantly different to those noted in other complexes of **1**. A point of note about the structure comes with the fact that there are significant H-bonding interactions between the two N–H bonds and the free chloride (average of the two H···Cl distances being 2.26 Å). It is possible that this is a contributory factor in the significant deviation of the N(2)–Pt–S(1) angle from linear (167.6°). In the light of this structure the unexpected IR spectrum may be explained; the strong N–H band comes about thanks to the hydrogen bonding in the system, while the other bands may be assigned to C–N stretches and deformations. The structure is also backed up by the ^1H and ^{13}C NMR data (the latter, for example, showing the CH_3–C carbons at δ 19.0 and 183.6 respectively). One final important feature of the structure comes from the fact that it constitutes the first example of a sulfimide unit binding through the sulfur atom as opposed to the nitrogen.

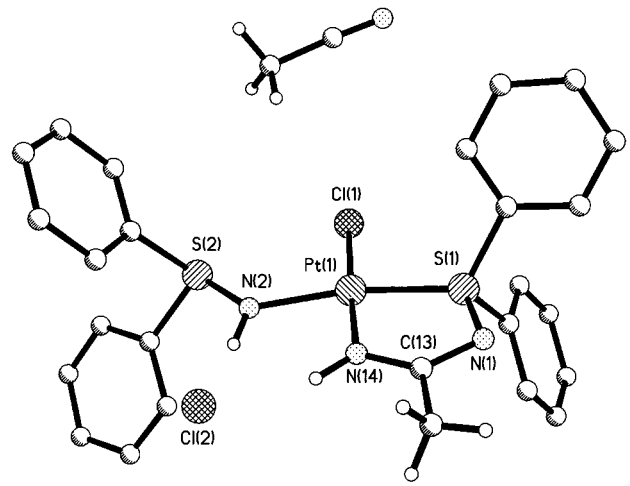

Fig. 1 X-Ray crystal structure of **2**·MeCN. Selected bond distances (Å) and angles (°): Pt–S(1) 2.1876(12), S(1)–N(1) 1.625(4), N(1)–C(13) 1.358(6), C(13)–N(14) 1.302(6), N(14)–Pt 1.989(4), Pt–Cl(1) 2.3191(14), Pt–N(2) 2.012(4), N(2)–S(2) 1.618(4); Pt–S(1)–N(1) 106.7(2), S(1)–N(1)–C(13) 110.8(3), C(13)–N(14)–Pt 119.1(3), N(2)–Pt–S(1) 167.56(14), N(2)–Pt–Cl(1) 94.36(14), Cl(1)–Pt–S(1) 97.84(5), N(2)–Pt–N(14) 87.8(2), Pt–N(2)–S(2) 127.5(3).

A number of aspects of this reaction are noteworthy. One important feature is that it can be repeated using $Pt(MeCN)_2Cl_2$ in CH_2Cl_2; in this case it is clear that coordinated MeCN ligands must be reacting as we no longer have the excess of the ligand in the form of the solvent. Additionally, it should be noted that **1** does not react with MeCN in the absence of the metal centre. Thus the solid retrieved after removal of the solvent from a solution of **1** in MeCN after stirring for 1 h at either ambient temperature, or indeed at reflux temperature, has an identical IR spectrum to the starting material. The choice of metal is also crucial; as we have already noted we have seen no evidence of this type of reaction occurring during reactions involving Co and Cu and attempts to observe analogous reactions using $Pd(MeCN)_2Cl_2$ or $[Pd(MeCN)_4][BF_4]_2$ also fail. Thus the reaction would appear to be specific to Pt, at least amongst the aforementioned metals. This brings us to the question of the reaction mechanism. It is possible that the first stage of the reaction involves coordination of one **1** ligand followed by reaction with the remaining coordinated MeCN. At present we regard this as a less likely option as it implies that coordination to the metal is activating the sulfimide towards attack by MeCN. If this were the case one might suspect that $[Pt(Ph_2SNH)_4]Cl_2$ (from **1** + $[PPh_4]_2[PtCl_4]$ in CH_2Cl_2) would be prone to reaction with this solvent; in fact it can be dissolved in boiling MeCN and, after precipitation by cooling, shows no change in its IR spectrum. In addition it should be remembered that **2** exhibits one unreacted sulfimide ligand. The other possible route involves nucleophilic addition of the sulfimide to the nitrilic carbon followed by proton transfer and coordination of the sulfur *via* loss of the remaining MeCN. This is conceptually a very simple route, the only drawback coming from the fact that it would require the sulfimide/acetonitrile addition to be faster or more efficient than simple substitution. Some justification for this comes with the observation that platinum appears to be less effective (or at least slower) at binding **1** than lighter metals. Thus while conversion of $[Pd_2X_6]^{2-}$ to $[Pd(Ph_2SNH)_4]X_2$ takes place in a matter of minutes, $[Pt(Ph_2SNH)_4]Cl_2$ only forms from $[PPh_4]_2[PtCl_4]$ over the course of many days. In addition, the $[Pt(PMe_2Ph)_2(Ph_2SNH)Cl]^+$ cation forms a solution equilibrium with $Pt(PMe_2Ph)_2Cl_2$ upon addition of Cl^-.[4] We thus favour the second of the two reaction mechanisms; this conclusion is backed up by the fact that nucleophilic addition to coordinated nitriles is well documented.[5] It should also be noted that preliminary work indicates that this reaction can be mirrored for other nitriles such as propionitrile and benzonitrile.

The metallocycle formed in this reaction is a very rare example of a transition metal based MNCNS cyclic system; indeed there would only appear to be one other example of such a unit characterised by X-ray crystallography, namely that found in $[Pt\{PhSNC(MeC_6H_4)NNC(MeC_6H_4)NSPh\}(PPh_3)]$,[6] though here it is a part of a tridentate ligand system (the X-ray structure of recently formed $[Pt\{N(H)C(Ph)N(H)S\}(dppe)]^+$ was not reported, though the species does indeed contain the cyclic PtNCNS unit[7]). In fact we can extend this further and say that with the exception of cases where X = S (the very well known and much studied dithiadiazolyls) the *only* other structure of the type *cyclo*-XNCNS to be found in a search of the Cambridge Structural Database[8] is one in which X = O.[9]

To conclude, we can say that the reaction of $Pt(MeCN)_2Cl_2$ with **1** provides an efficient, high yield route to a very rare structural system, *via* a metal-assisted activation unprecedented for a sulfimide. It is quite feasible that the neutral ligand thus formed will prove to be labile, providing an efficient route to new imine-substituted sulfimide systems; work towards this end is underway.

† A solution of $[PtCl_2(MeCN)_2]$ (61 mg, 0.18 mmol) in MeCN (20 ml) was treated with a solution of **1** (71 mg, 0.35 mmol) in the same solvent (5 ml) added over a period of 2 min with stirring. Upon continuous stirring the resulting yellow solution suddenly precipitated a pale yellow solid (time required for precipitation to start varied from experiment to experiment, ranging from < 1 to 10 min; in all cases, however, once started precipitation was very rapid). The mixture was stirred for a further 30 min then allowed to settle whereupon the solvent was decanted, the solid washed with cold MeCN (10 ml) and then Et_2O (10 ml) and dried *in vacuo* to give a pale yellow product. Yield 92 mg, 74%.

Recrystallisation from hot MeCN gave 60 mg (48% based upon original amount of Pd used) of well formed crystalline material, though the solution retained a significant yellow colour even after cooling indicating that some reaction/decomposition had occurred during the heating process, hence the lowering of yield. There was no significant difference in the IR spectra of the crude and recrystallised material. X-Ray crystallography confirmed the formulation as $[Pt(Ph_2SNH)(Ph_2SNC(Me)NH)Cl]Cl$ with no solvated MeCN present, though this X-ray data is not presented in full here. Found: C, 42.6; H, 3.3; N, 5.9%. Calc. for $C_{26}H_{25}Cl_2N_3PtS_2$: C, 44.0; H, 3.6; N, 5.9%. ^{1}H NMR ($CDCl_3$) δ 10.4 (1H, s, NH), 7.99 (8H, m, CH), 7.63 (2H, m, CH), 7.59 (4H, m, CH), 7.50 (6H, m, CH), 2.50 (3H, s, CH_3); ^{13}C NMR ($CDCl_3$) δ 183.6 (NCN), 138.2, 135.7, 134.0, 132.1, 130.0, 129.9, 128.0 (phenyl groups), 19.0 (CH_3).

A similar reaction occurred when $PtCl_2$ was dissolved in hot MeCN (effectively forming the same starting material *in situ*) and then **1** added. In this case recrystallisation gave product with one MeCN of crystallisation {*i.e.* $[Pt(Ph_2SNH)(Ph_2SNC(Me)NH)Cl]Cl\cdot MeCN$} as shown by X-ray crystallography and microanalysis (Found: C, 44.5; H, 3.9; N, 7.6%; Calc. for $C_{28}H_{28}Cl_2N_4PtS_2$: C, 44.8; H, 3.8; N, 7.5%). It is not clear why the two recrystallisations gave solvated and unsolvated materials.

IR spectroscopy confirmed that an identical product is formed if the $Pt(MeCN)_2Cl_2$ reaction is performed in CH_2Cl_2.

‡ *Crystal data* for **2**: all measurements were made on a Siemens SMART diffractometer with graphite monochromated Mo-Kα radiation. Data were collected using small slices: 12830 data collected. $C_{28}H_{28}Cl_2N_4PtS_2$, M = 750.65, monoclinic, space group $P2_1/n$, a = 13.223(1), b = 10.941(1), c = 20.912(1) Å, β = 100.302(1)°, U = 2976.5(1) Å^3, Z = 4, T = 293 K. μ(Mo-Kα) = 5.11 mm^{-1}, λ = 0.71073 Å, F(000) = 1472. R_1 = 0.0268, wR_2 = 0.0486 [$I > 2\sigma(I)$], 4267 independent reflections (4217 observed).

A versatile synthetic strategy for construction of large oligomers: binding and photophysical properties of a nine-porphyrin array

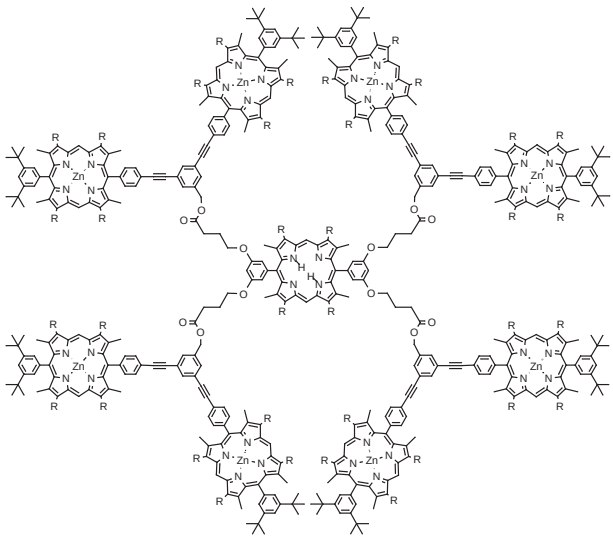
Received (in Cambridge, UK) 19th January 1999, Accepted 6th May 1999

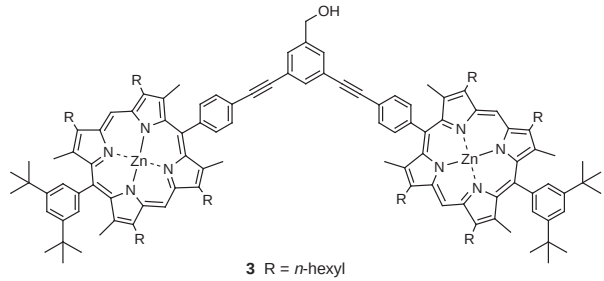
Mitsunobu coupling of a free base porphyrin tetraacid with four equivalents of a monohydroxy metalloporphyrin dimer leads to a highly non-polar dendritic nine-porphyrin array that is readily separated from more polar products resulting from incomplete coupling; photophysical measurements reveal an energy transfer process from the peripheral metalloporphyrins to the central free-base porphyrin unit.

Covalently-linked dendritic arrays of porphyrins are of interest for their photophysical and electrochemical properties, but they present a substantial synthetic challenge.[1,2] In particular, the chromatographic separation of successive generations, or of incomplete generations, becomes increasingly difficult. One solution has centred on the control of the chromatographic properties of the products, by varying the peripheral groups of the porphyrins between generations.[2] We now present a more versatile strategy based on Mitsunobu coupling of alcohols and acids to give esters.[3,4] The key feature of this approach is the simultaneous Mitsunobu couplings of a multi-acid (or multi-alcohol) central core with several peripheral components, giving only one non-polar product; any incompletely coupled products will be significantly more polar and therefore easily separated. Here, we illustrate the strategy by describing the synthesis, binding and photophysical properties of the flexible nine-porphyrin array **1**. In the following communication[5] we apply the same strategy to a mixed-metal 'star-shaped' porphyrin pentamer.



1 R = *n*-hexyl

The key to the synthesis of **1** is the availability of the appropriately-functionalised porphyrin tetra-acid **2** and porphyrin dimer **3**. In order to avoid solubility problems, all the porphyrin units in **1** have the same hydrophobic methyl and hexyl β-substitution pattern. Preparation of the porphyrin tetra-acid **2** involves condensation of aldehyde **4** with dipyrromethane **5** (generated *in situ*) followed by base hydrolysis. Recrystallisation from methanol gave pure **2**† in 21% overall yield. Unlike most other porphyrin acids, **2** is soluble in organic solvents such as THF or acetone. The synthesis of porphyrin dimer **3** has been reported previously.[2] Mitsunobu condensation of **2** with 4 equiv. of **3** in THF afforded **1**† in 69% yield as a purple solid which was easily separated from incompletely coupled side products and unreacted **2** and **3** by silica gel chromatography. Diagnostic resonances in the ^{1}H NMR spectrum of **1** are identified at $\delta -2.34$ for the inner NH protons, and at δ 5.00 for the eight benzylic protons of the peripheral units. Additional confirmation for the preparation of **1** was obtained by a peak at *m/z* = 10045 in the MALDI-TOF spectrum (M_r $C_{664}H_{846}N_{36}O_{12}Zn_8$ = 10047).



3 R = *n*-hexyl

As in the less flexible nine-porphyrin array that we reported earlier,[2] the rigid porphyrin dimer moieties in **1** can be brought together by cooperative binding to the bidentate ligand diazabicyclo[2.2.2]octane (DABCO). Titration of DABCO with **1** [Fig. 1(a)] gives a characteristic Soret maximum at 420 nm which is due to exciton coupling between the parallel porphyrin units.[6] This exciton-coupled maximum was attained with *ca.* 10 equiv. of DABCO, which is comparable to the less-flexible nine-porphyrin array we described earlier.[2] However, the present flexible system is effectively unfolded again by $< 10^4$ equiv. of DABCO, rather than the 10^6-fold excess required by the rigid system. This reflects the larger number of conformations available to the more flexible system. Exciton-

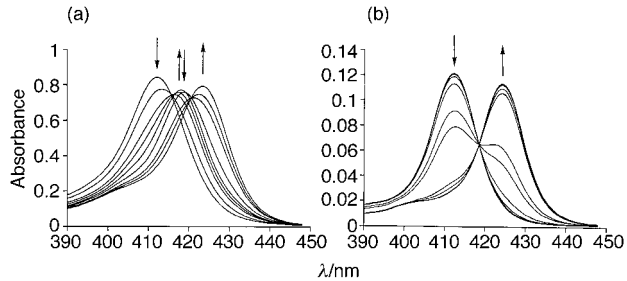


Fig. 1 UV–VIS titration (CH_2Cl_2) of DABCO (as a 2–4 × 10^{-4} M solution) *vs.* (a) **1** (number of equiv. added per nine-porphyrin array: 0, 1.1, 2.3, 4.0, 10.8, 22.7, 680, 1814, 7940) and (b) **3** (both as 2–5 × 10^{-7} M solutions).

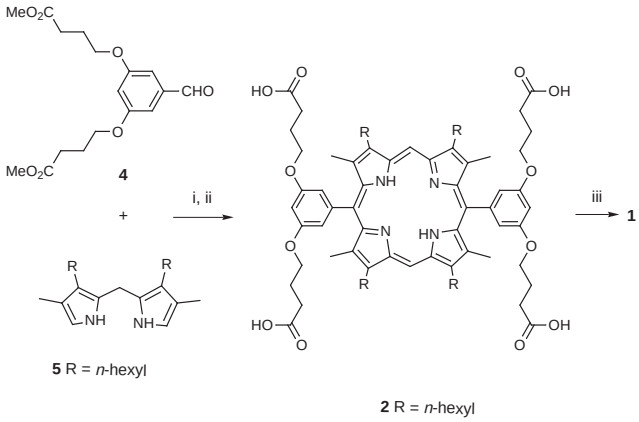

Scheme 1 *Reagents and conditions*: i, TFA (−20 °C to room temp.), DDQ; ii, Na_2CO_3 (water–THF–ethanol), reflux; iii, **3** (4 equiv.), DEAD, PPh_3.

coupled spectra are not observed when the rigid porphyrin dimer **3** is titrated with DABCO [Fig. 1(b)].

The absorption spectrum of **1** approximates a superposition of the spectra of the constituent monomeric porphyrins, suggesting a relatively weak electronic interaction between the porphyrins. The fluorescence quantum yield of **3** (Φ_f = 0.035, τ = 1.6 ns, 298K) is nearly identical to that of the monomeric porphyrin precursors, indicating the absence of quenching processes. The luminescence properties of **1** indicate that both the fluorescence quantum yield and lifetime of the singlet excited state of the Zn porphyrin units are reduced 2.5 fold at 298 K relative to a monomeric Zn porphyrin. Furthermore, excitation spectra demonstrate a parallel sensitization of the fluorescence of the free base porphyrin by the Zn porphyrin. These results show that energy is transferred[7] from the peripheral units to the core with *ca.* 60% efficiency ($k_{ET} = 9 \times 10^8\ s^{-1}$). The transferred energy is subsequently emitted by the core free base porphyrin (Φ_f = 0.10) with an efficiency nearly identical to that of a monomeric free base porphyrin. Calculations indicate that the most likely mechanism of energy transfer is the Förster type.[8] The Zn porphyrin phosphorescence of **1** is completely quenched at 77 K, probably because of an energy transfer process to the triplet excited state localised on the central free base porphyrin, the phosphorescence of which is rarely observed.

In summary, we have described a synthetic strategy in which the chromatographic properties of the desired product have been designed to differ from the strarting materials and side products. We have applied this approach to the preparation of a nine-porphyrin array (for which the photophysical properties have been presented), but clearly this methodology has the potential to be generalised for mixed metal systems[4] or to other types of dendritic structures.

We thank the EPSRC, Croucher Foundation and MURST for financial support.

Ru(II)-centred porphyrin pentamers as coordination building blocks for large porphyrin arrays

Chi Ching Mak, Nick Bampos and Jeremy K. M. Sanders*

Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: jkms@cam.ac.uk

Received (in Cambridge, UK) 19th January 1999, Accepted 6th May 1999

Ru(II)-centred porphyrin pentamers have been synthesised with Ni or Zn porphyrins at the peripheral sites; these elaborate systems have been used as building blocks for large porphyrin arrays through their coordination chemistry with bidentate and tetradentate ligands; coordination of a sterically unhindered pentamer to a free-base tetrapyridylporphyrin yields a 21 porphyrin array.

We report here the preparation of covalent Ru-centred porphyrin pentamers which can then be assembled into larger arrays by coordination to multidentate ligands.[1,2] This highly convergent and efficient approach is illustrated with the preparation of an array of 21 porphyrins that contains units in three different metallation states; it is complementary to the fully covalent[3] and photochemical[4] approaches we have reported elsewhere.

Mitsunobu condensation[5] of Ni–porphyrin **1**[6] with porphyrin tetra-acid **2** (0.25 equiv.) in THF afforded the core free-base porphyrin pentamer **3** in 58% yield as a purple solid.† This multiple Mitsunobu strategy ensures that the desired fully-coupled pentamer is the only non-polar product; it is therefore readily isolated and purified. The MALDI-TOF mass spectrum of **1** gave the anticipated MH^+ ion at *m/z* 5185. Metallation of **3** with $Ru_3(CO)_{12}$ in refluxing toluene[7] provided the Ru-centred pentamer **4** as a deep red solid in 66% yield. The lack of reactive functional groups in **3** avoids any significant Ru-mediated side reactions during metallation. The ^{1}H NMR properties and the presence of new peaks at *m/z* 5283 and 10566 in the MALDI mass spectrum corresponding to $[(M - CO)^+]$[8,9] and $[(2M - 2CO)^+]$,[9] confirmed the successful metallation. In an inverted Mitsunobu approach, the core Ru–porphyrin diol **5**[10] was esterified with 2 equiv. of the acid dimer **6**[11] to give the more rigid pentamer **7** in 21% yield. The MALDI-TOF spectrum revealed the expected peaks at *m/z* 5432 $[(M - CO)^+]$ and 10950 $[(2M - 2CO)^+]$.

The central Ru-ion dominates the coordination chemistry of pentamers **4** and **7**, with the strength of binding to N-ligands decreasing in the order Ru ≫ Zn ≫ Ni. Pyridyl ligands, such as those presented in this work, bind very tightly to ruthenium porphyrins, forming rigid well characterisable complexes.[4] However, the extremely high binding affinities make NMR and UV titrations impractical. With this in mind, addition of < 0.5 equiv. of diazabicyclo[2.2.2]octane (DABCO) to a 4–7 mM solution of **4** in $CDCl_3$ leads to exclusive Ru-coordination as shown in Fig. 1(a), where the sharp DABCO chemical shifts in the ^{1}H NMR spectrum are characteristic of the equilibrium between mono- and bi-nuclear porphyrin complexes, in slow exchange on the NMR chemical shift timescale. DABCO is a sufficiently small ligand that steric interaction between the peripheral porphyrins on the two porphyrin pentamers inhibits complete formation of a 10-porphyrin array. Titration of 0.5 equiv. of the larger bridging dipyridyl porphyrin ligand **8** with **4** results in exclusive formation of the 11-porphyrin array **4**·**8**·**4** as judged by the upfield shifts of the NH and pyridyl protons of **8** (as the 2,6-pyridyl protons of **8** shift upfield from δ 9.00 to 1.60, any 1 : 1 complex would be immediately apparent in the spectrum).

Adding a tetra-aryl ruthenium monomer to free-base tetrapyridyl porphyrin indicated that the 0.5 ppm highfield shift of the NH resonance is additive with each coordinated ruthenium monomer (free base $\delta_{NH} = -2.90$, mono-coordinated $\delta_{NH} = -3.35$, di-coordinated $\delta_{NH} = -3.87$, tri-coordinated $\delta_{NH} = -4.30$, tetra-coordinated $\delta_{NH} = -4.92$). The chemical shift of the porphyrin inner NH protons is therefore diagnostic of the number of porphyrins coordinating to the tetradentate porphyrin ligand, so that binding 4 equiv. of monomer **9** shifts the NH signal from $\delta -2.90$ to -4.91, by about 0.5 ppm per equivalent of **9** [Fig. 2(a)]. Reaction of 4 equiv. of rigid pentamer **7** with tetrapyridyl porphyrin gives rise to a high-field resonance at $\delta -4.75$ (Fig. 2(b)] suggesting the formation of a 21-porphyrin array [Fig. 1(b)]. The steric congestion associated with coordination of the more flexible pentamer **4** however, is so great that the product distribution is dominated by the coordination of only three such pentamers about the tetrapyridyl porphyrin, as is apparent by the shift of the NH protons [$\delta -4.25$, Fig. 2(c)]. Preliminary experiments with an extended analogue of tetrapyridyl porphyrin show that, four molecules of

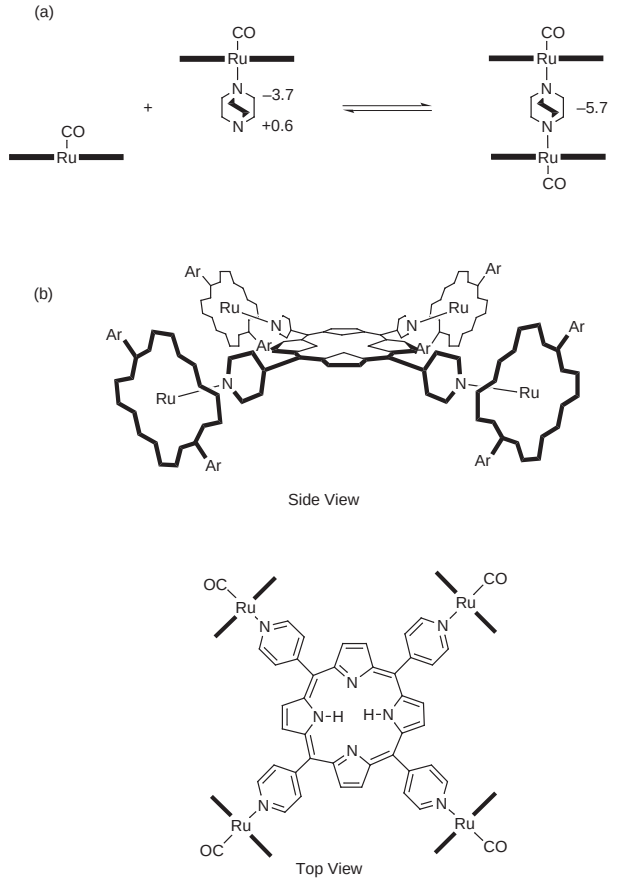

Fig. 1 (a) Equilibria and characteristic chemical shifts observed when Ru(II)–porphyrins bind DABCO; (b) cartoon representations of the assembly formed by coordination of four Ru–porphyrins to tetrapyridylporphyrin.

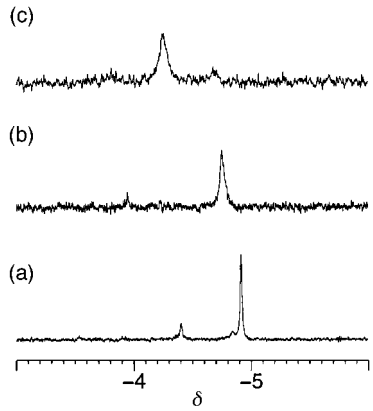

Fig. 2 Selected region of the ^{1}H NMR spectrum (500 MHz, $CDCl_3$, 300 K) showing the NH protons of tetrapyridylporphyrin in the presence of: (a) 4 equiv. of monomer **9**, (b) 4 equiv. of pentamer **7**, (c) 4 equiv. of pentamer **4**.

4 can now be accommodated if the steric constraints can be released, resulting in a NH resonance at δ *ca.* −4.90. The remote porphyrins of **4** and **7** appear to have little effect on the NH chemical shift of the coordinating pyridyl porphyrins.

In summary we have demonstrated that a combination of covalent and coordination chemistry provides a versatile approach for the assembly of very large porphyrin arrays. Elsewhere we show how photolytic removal of the Ru-bound CO ligand, followed by additional ligation can produce even more elaborate arrays.[4]

We thank the Croucher Foundation and the University of Cambridge for financial support and S. L. Darling for a sample of **8**.

Notes and references

† All new compounds gave satisfactory ^{1}H and ^{13}C NMR spectra, MALDI-TOF mass spectra and analytical values. In particular, the ^{1}H NMR spectra of pentamers gave the correct integrated intensities for the four peripheral *vs*. single core porphyrin.

Synthesis of volicitin: a novel three-component Wittig approach to chiral 17-hydroxylinolenic acid

Georg Pohnert,* Thomas Koch and Wilhelm Boland*

Max-Planck-Institut für Chemische Ökologie, Tatzendpromenade 1a, D-07745 Jena, Germany.

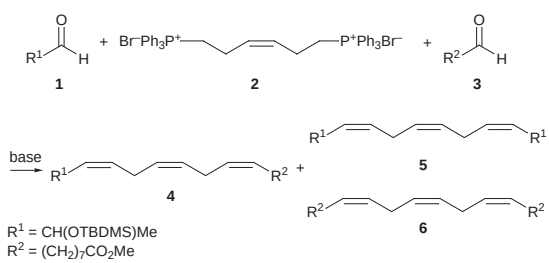
Received (in Liverpool, UK) 10th March 1999, Accepted 22nd April 1999

A short stereoselective synthesis of both enantiomers of *N*-(17-hydroxylinolenoyl)-L-glutamine (volicitin) 12, an elicitor of plant volatile biosynthesis from beet armyworm salivary secretion, is described; the protected 17-hydroxylinolenic acid 4 moiety of volicitin 12 was prepared in a one pot bis-Wittig reaction.

Plants are able to respond to herbivore damage by *de novo* biosynthesis of a characteristic blend of volatiles that attracts the natural enemies of the attacking insect.[1] Feeding on the leaf is accompanied by introduction of salivary secretions that may contain high and/or low molecular weight compounds activating the plant's defense. Established elicitors are a β-glucosidase from the regurgitant of *Pieris brassicae* caterpillars[2] and the recently identified *N*-(17-hydroxylinolenoyl)-L-glutamine (volicitin) **12** from beet armyworm oral secretion.[3] Like the microbial metabolite coronatine, which strongly induces volatile biosynthesis in plants,[4] volicitin **12** is also an amphiphilic compound that consists of a nonpolar lipid moiety joined to an amino acid by an amide linkage. First experiments with synthetic volicitin revealed that biological activity is highly dependent on the stereochemistry of the amino acid.[3] A conjugate of (±)-17-hydroxylinolenic acid and L-glutamine proved to be highly active, while the corresponding conjugate with D-glutamine was virtually inactive. The configuration of the 17-hydroxy group of the fatty acid has not been addressed to date.

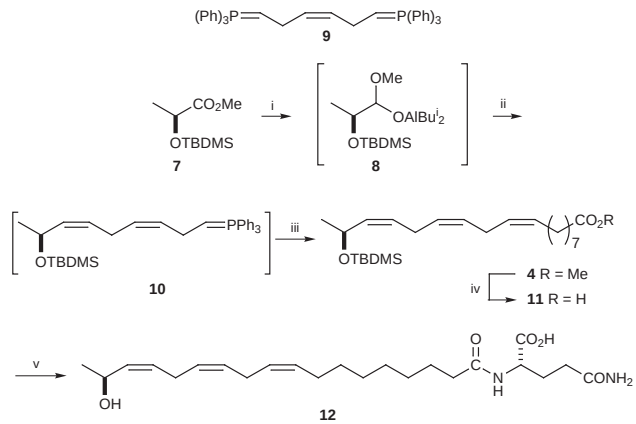
Here we report an efficient synthesis of both enantiomers of TBDMS protected 17-hydroxylinolenic acid methyl ester **4** based on a novel three component bis-Wittig approach. Subsequent deprotection and coupling with L-glutamine yielded both volicitin diastereomers (17*R*)- and (17*S*)-**12**, respectively.

According to Scheme 1, the fatty acid skeleton is readily assembled in a single operation *via* a bis-Wittig approach, based on the *Z*-hex-3-ene-1,6-diol-derived symmetric bifunctional Wittig salt **2**.[5] In order to suppress the formation of symmetric by-products **5** and **6**, resulting from statistical coupling of the three components **1**,[6] **2** and **3**, the reaction conditions were carefully optimised. While addition of a 1 : 1 mixture of the aldehydes **1** and **3** to the ylide **9** resulted in the expected statistical product ratio of **4**, **5** and **6**, successive addition of the aldehydes to **9**, in conjunction with optimised temperatures during the stepwise reaction, afforded high yields of the protected 17-hydroxylinolenic acid **4**. This result suggested



Scheme 1

different reactivity of the bis-functional ylide **9** and the monofunctional intermediates like **10**. Thus, if only 1 equiv. of aldehyde **1** was added to a cold solution (−100 °C) of the bis-ylide **9**, generated from the bis-phosphonium salt with 2.1 equiv. of KHMDS,[7] a preferential formation of the mono-ylide **10** was observed after slow warming to −20 °C. Recooling to −78 °C and addition of 1 equiv. of aldehyde **3** afforded the cross-coupled product **4** in high yield. According to GLC-MS analysis, the amount of the two symmetric products **5** and **6** was less than 20% of the product mixture. Furthermore, the amount of symmetric coupling products could be suppressed even more efficiently by using the aluminium alkoxide **8**, generated by reduction of TBDMS-protected D- or L-lactic acid methyl ester **7** with DIBAL-H at low temperature, as the first carbonyl equivalent (Scheme 2).[8]



Scheme 2 *Reagents and conditions*: i, DIBAL-H, Et_2O, −78 °C; ii, **9** [prepared from **2** in THF using 2 equiv. $KN(SiMe_3)_2$, −78 to 0 °C], −78 °C, add **8**, warm to room temp.; iii, −78 °C, **3**, warm to room temp.; iv, LiOH, THF–H_2O; v, NEt_3, THF, $ClCO_2Et$, −10 °C, then Gln, NaOH, room temp.

During warming to room temperature, the silylated aldehyde **1** is presumably slowly released from the intermediate aluminium complex **8** and reacts instantaneously with the bis-ylide **9** to give the ylide **10**. After 30 min at room temperature, the solution was recooled (−78 °C), before 1.2 equiv. of the 9-oxo ester **3** were added. Following work-up, the silylated (17*R*)- or (17*S*)-hydroxylinolenic acid **4** could be isolated in 42% overall yield.† Less than 10% of the symmetrical coupling products **5** and **6** could be detected. Use of the configurationally stable aluminium complex **8** had the additional advantage that the sensitive chiral C_3 synthon **1** reacted without racemisation under the basic Wittig conditions. Both products, (17*S*)- and (17*R*)-**4**, proved to be of >97% ee by Mosher ester analysis of the end products (17*S*)- and (17*R*)-**12** (volicitin).‡ ^{13}C NMR analysis revealed the configuration of the 9- and 15-double bonds to be of >95% *Z*.

Saponification of **4** with aqueous LiOH in THF[7] afforded TBDMS protected 17-hydroxylinolenic acid **11** in 86% yield. Coupling of **11** with glutamine was achieved using the ethyl carbonate mixed anhydride method. Acidic workup of the crude

product resulted in simultaneous deprotection, and pure volicitin **4** could be separated from excess glutamine by RP-MPLC-chromatography.§ The significance of the chiral centre for the induction of plant volatile biosynthesis is currently being evaluated. Detailed results together with information on the mode of signaling of the compound will be presented elsewhere.

The three-component Wittig reaction described here opens a new and highly versatile route to the skipped triene substructures occurring in a large variety of natural products. The central building block **2** is readily available on a multi-gram scale,[5] and one-pot product formation with good stereoselectivities allows its universal use as a building block in the synthesis of highly unsaturated fatty acids and related compounds. Like the previously introduced di-n-butyl-1-stannacyclohexa-2,5-diene[9] as a bifunctional building block for the formation of skipped dienes, the bis-Wittig approach also has universal potential, allowing the direct assembly of at least three homoconjugated double bonds from simple precursors in a single operation.

Financial support by the *Deutsche Forschungsgemeinschaft* (SPP 716) Bonn, and the *Fonds der Chemischen Industrie*, Frankfurt, is gratefully acknowledged. We thank the *BASF*, Ludwigshafen, and the *Bayer AG*, Leverkusen, for generous supplies of chemicals and solvents and Dr N. J. Oldham for proof-reading of the manuscript.

Notes and references

† Experimental procedure: A cold (−78 °C) suspension of the Wittig salt **2** (700 mg, 0.91 mmol) in dry THF (15 ml) was treated with $KN(SiMe_3)_2$ in hexane (3.8 ml of a 0.5 M solution). The solution was allowed to warm to 0 °C, stirred for 10 min and recooled (−78 °C). An ethereal solution of the aluminate **8** (2.3 ml, 0.4 M, pre-cooled to −78 °C) was added (ref. 6,8). The mixture was allowed to warm to room temperature and stirring was continued for 1 h before recooling to −78 °C. Then, a solution of **3** (203 mg in 1 ml THF) was added and the mixture was allowed again to reach room temperature. Hydrolysis with sat. NH_4Cl, extraction with Et_2O and column chromatography on SiO_2 yielded the protected ester **4** as a colourless, viscous liquid. Yield: 161 mg (42%).

‡ Both enantiomers of **12** were esterified with excess (*R*)-(−)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride in the presence of DMAP and Et_3N (ref. 10). After the reaction was complete (no starting material could be detected *via* NMR analysis) the ee of **12** was determined by integration of the isolated 17-hydroxylinolenic acid C(18)-methyl doublet [δ 1.35 for (17*S*)-**12** and δ 1.42 for (17*R*)-**12**].

Direct observation of 1,2-didehydronaphthalene in a low temperature argon matrix: consecutive photolysis of 1,2-naphthalenedicarboxylic anhydride

Tadatake Sato, Masaya Moriyama, Hiroyuki Niino and Akira Yabe*

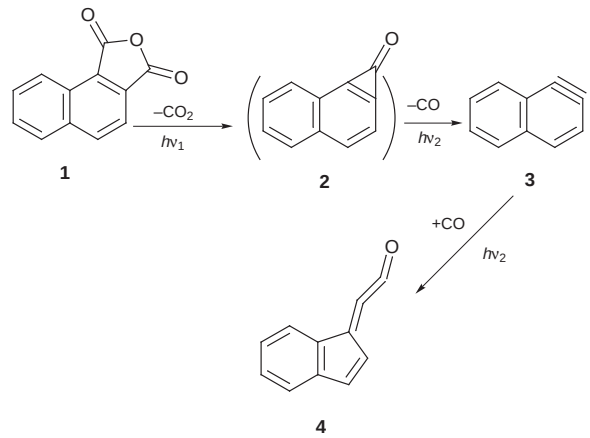
National Institute of Materials and Chemical Research (NIMC), Higashi, Tsukuba, 305-8565, Japan. E-mail: yabe@nimc.go.jp

Received (in Cambridge, UK) 23rd March 1999, Accepted 27th April 1999

1,2-Didehydronaphthalene (1-naphthyne) was produced in a low temperature argon matrix by wavelength-selective photolysis of 1,2-naphthalenedicarboxylic anhydride, which was confirmed by comparison of its FTIR spectrum with the theoretical IR spectrum calculated by density functional theory.

Arynes, benzyne and its congeners, have attracted great interest because of their ability to participate in a wide variety of organic reactions and their peculiar structures containing a strained triple bond. Among them, only the simplest member, *o*-benzyne, has been thoroughly characterized by its direct observation using matrix isolation spectroscopy.[1] Recently, its peculiar structure has been discussed on the basis of both experimental and theoretical results. The length of the triple bond in *o*-benzyne estimated by ^{13}C dipolar NMR[2] has shown that theoretical calculations, particularly calculations at the density functional theory (DFT) level, have provided reasonably accurate geometries of such an unstable species.[3] On the other hand, larger arynes, dehydrogenated polycyclic aromatic hydrocarbon molecules (PAHs), have scarcely been characterized by direct observation, although dehydrogenated and/or ionized PAHs have been recognized as important components of the interstellar medium.[4] Whereas some experimental results of ionized species are available,[5] little data on dehydrogenated PAHs have been presented: there is only one brief experimental report on 2-naphthyne.[6] Herein we wish to report the first direct observation of 1-naphthyne in a low temperature argon matrix. The FTIR spectrum of this compound is discussed on the basis of DFT calculation (B3LYP/6-31G** level).[7]

1,2-Naphthalenedicarboxylic anhydride **1** was photolyzed in an argon matrix at 11 K. During the experiment, the pressure in a sample chamber was kept under 10^{-5} Torr. Crystallites of **1** were vaporized at 50 °C and co-deposited with argon (99.9999%) onto a CsI plate.[8] It has been reported that the efficiency of photo-decomposition of anhydrides decreases as the pressure of a buffer gas increases in the gas phase and approaches zero in a condensed medium.[9] Therefore, a high intensity light is necessary to photolyze the anhydride in a cryogenic matrix.[10] Moreover, the choice of an appropriate wavelength for photolysis is quite important in order to suppress the multiple reactions proceeding simultaneously. Since the lowest transition band of matrix-isolated **1** observed was at 356 nm in its UV-VIS absorption, we used the third harmonic pulse of Nd:YAG laser (355 nm, 10 Hz, 4 mJ cm^{-2} $pulse^{-1}$) to photolyze **1**. The photolysis was followed by FTIR spectroscopy. Irradiation at 355 nm led to the diminution of the intensities of all the IR bands of **1** and concomitant growth of new IR bands ascribable to the first intermediate **2**[11] and CO_2 (2343 and 666 cm^{-1}). No IR band due to CO appeared in this photolysis. Thus it was confirmed that selective decarboxylation of **1** resulted in the formation of a $C_{10}H_6$–CO species **2**. Naphtho[*a*]cyclopropanone (in parentheses in Scheme 1) is a possible structure for **2** by analogy with the photolysis of phthalic anhydride.[1a] Indeed, the observed FTIR bands, except the C=O stretching bands, were in good agreement with the calculated vibrational bands of naphtho[*a*]cyclopropanone.[11] Meanwhile, four bands ascribed to this mode were observed at



Scheme 1

1832, 1843, 1856 and 1873 cm^{-1}, although only one band was predicted theoretically for the C=O stretching mode. Such complex IR bands have often been observed for ketenes in cryogenic matrices.[12] Thus, we tentatively assigned **2** to naphtho[*a*]cyclopropanone. This compound was stable under prolonged irradiation at 355 nm.

To photolyze **2**, a high-pressure mercury lamp (500 W) was used through a 20 cm water filter and a UV-cut off glass filter (> 290 nm) since the UV absorption edge of **2** was observed at 320 nm in the matrix. In contrast to the photolysis of **1**, compound **2** was photolyzed in a rather short time upon irradiation. New bands due to the second intermediate **3** (Table 1) and CO (2142 cm^{-1}) appeared, while the IR bands of **2** disappeared upon irradiation. In particular, since the band of CO

[a] For comparison with calculated values, integrated intensities were normalized based on the value marked by an asterisk. [b] Scaled by 0.9614.[14]

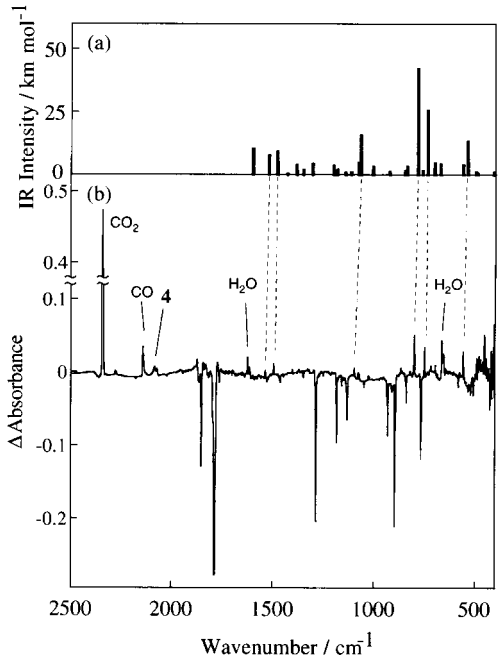

Fig. 1 (a) Theoretical IR spectrum of 1-naphthyne calculated at the B3LYP/6-31G** level. Frequencies have been scaled by a factor of 0.9614.[14] (b) Difference FTIR spectrum before and after irradiation of **1** with 95000 pulses of THG of Nd:YAG laser followed by 1.5 min with a high-pressure mercury lamp (> 290nm). Positive peaks correspond to **3** and negative peaks to **1**.

appeared with diminution of all the C=O stretching bands of **2**, it was revealed that a $C_{10}H_6$ species was formed by decarbonylation of **2**. The observed IR spectrum was compared with the theoretical IR spectrum of 1-naphthyne calculated at B3LYP/6-31G** level.[13] As shown in Fig. 1, all the predicted bands with intensities > 5 km mol^{-1} (listed in Table 1), except those at 701.6 and 1600 cm^{-1}, were observed in the experimental spectrum. The latter two bands could not be identified probably because of overlap with those of CO_2 and H_2O produced by the inevitable small leakage in the apparatus. Frequency deviations for all the bands except that observed at 452 cm^{-1} were within 20 cm^{-1}. These deviations are reasonably small at the computational level.[13] On the other hand, the relatively large deviation (62 cm^{-1} underestimated) for the band at 452 cm^{-1} can be explained as follows. The band is due to the ring deformation mode containing angular motions of the C–C≡C moiety. In the vibrational analysis of *o*-benzyne at the same computational level, the frequency of the corresponding mode was underestimated by 83 cm^{-1} from the observed frequency.[1a] Therefore, this deviation appears to be peculiar to the triple bond in arynes at the computational level. Moreover, no other IR bands ascribed to by-products formed by ring opening[15] or ring deformation[16] were observed. Thus, we conclude that the obtained $C_{10}H_6$ species can be assigned to 1-naphthyne.

Incidentally, in view of the keen debate concerning *o*-benzyne,[1] we should comment on the stretching mode of the C–C triple bond in **3**. For 1-naphthyne, the frequency and intensity of this mode were predicted as 1988 cm^{-1} and 0.0983 km mol^{-1}, respectively. Although we could observe all the bands with predicted intensity > 5 km mol^{-1}, the observation of the C≡C stretching band of 1-naphthyne was not possible under our experimental conditions.

By prolonged irradiation (> 290 nm) of **3**, new IR bands slowly appeared at 2084 and 2072 cm^{-1}. These bands could be ascribed to benzocyclopentadienylideneketene **4** according to the literature.[1a] This result shows that **3** reacts easily with CO to form **4** upon the irradiation. This reaction also occurred upon irradiation using the fourth harmonic pulse of the Nd:YAG laser (266 nm, 10 Hz, 3 mJ cm^{-2} pulse^{-1}). By contrast, 2-naphthyne[17] did not form the corresponding ketene upon irradiation at 266 nm. These results indicate differences in reactivity of the two naphthynes. The characteristics of the triple bond in arynes should be responsible for their reactivity. In the calculated geometries of these naphthynes, the lengths of triple bonds in these naphthynes were apparently different; 1.241 and 1.260 Å for 1- and 2-naphthynes, respectively.

In conclusion, we successfully produced 1-naphthyne by wavelength-selective photolysis of **1** in a low temperature argon matrix. Observed differences in reactivity of the two naphthynes is of interest from the viewpoint of their reactivity–structure profile. Further detailed study is in progress.

We are grateful to Prof. Curt Wentrup (University of Queensland, Australia) for helpful suggestions and discussions.

Perfluorotributylamine as a probe molecule for distinguishing internal and external acidic sites in zeolites by high-resolution ^{1}H MAS NMR spectroscopy

Weiping Zhang, Ding Ma, Xianchun Liu, Xiumei Liu and Xinhe Bao*

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian 116023, P R China. E-mail: xhbao@ms.dicp.ac.cn

Received (in Cambridge, UK) 14th January 1999, Accepted 4th May 1999

^{1}H MAS NMR spectra of perfluorotributylamine adsorbed on HZSM-5 zeolites loaded with or without molybdenum show that it is a promising probe molecule for distinguishing the internal and external acidic sites in zeolites as well as for determining the position of silanols and some non-framework Al species.

Molybdenum-loaded HZSM-5 zeolites are promising catalysts for the conversion of methane to benzene under non-oxidative conditions.[1–7] The acidic sites in HZSM-5 zeolites are thought to play an important role in the aromatization of the primary product, ethylene, to benzene.[2,3] Until now, it has not been easy to distinguish the internal and external acidic sites in zeolites and to obtain quantitatively the concentration of acidic sites on the external surface of zeolites, though some methods such as IR spectroscopy[8,9] have been developed for the characterization of the external acidic sites of zeolites using base molecules with different sizes. High-resolution ^{1}H MAS NMR is a direct and senstitive tool able to characterize the local environment of protons in zeolites, and different acidic sites can be distinguished by chemical shifts induced by selective adsorption of certain probe molecules.[10] Here we use ^{1}H MAS NMR spectroscopy for quantitative determination of external acidity, as well as the position of non-acidic hydroxy groups (silanols) and some non-framework Al species of the zeolites, using perfluorotributylamine [$(n\text{-}C_4F_9)_3N$] as a probe molecule. Perfluorotributylamine is a weakly basic molecule with a diameter of 0.94 nm,[11] and is much larger than the pore size of microporous zeolites such as ZSM-5 (0.55 nm) and Y (0.74 nm).

NaZSM-5 zeolite samples with controlled particle sizes were prepared by varying the duration and temperature of crystallization as well as the amount of alkali metal salt such as NaCl.[12] Fully exchanged HZSM-5 with a Si/Al ratio of 28 (determined by ^{29}Si MAS NMR, and consistent with the value of 25 obtained by inductively coupled plasma analysis) was obtained by ion exchange of NaZSM-5 with a 0.4 M aqueous solution of NH_4NO_3. A Mo-HZSM-5 sample was prepared by impregnating the above-mentioned HZSM-5 zeolites (average particle sizes 70 nm by transmission electron microscopy) with an aqueous solution of $(NH_4)_6Mo_7O_{24}$, and calcined in air at 773 K.

In order to simulate catalytic reaction conditions in an environment suitable for NMR spectroscopy, we designed and fabricated a special device for on-line treatment of zeolite samples (Fig. 1).[13] With this system, the solid samples can be heated up to *ca.* 1000 K in a vacuum for dehydration, and can be exposed to several different gases together or separately. After treatment, the sample can be filled *in situ* into a NMR rotor by a tamper, sealed with a cap from the plug rack and transferred to the spectrometer without exposure to air. In the present experiment, the zeolites were dehydrated typically at 673 K and a pressure below 10^{-2} Pa for 10–20 h. Selective adsorption of perfluorotributylamine (from Acros Organics) was performed by exposing the dehydrated sample to saturated vapor at room temperature for 30 min. After equilibration, the samples were degassed at 298 K to remove the physical adsorbates on the surface.

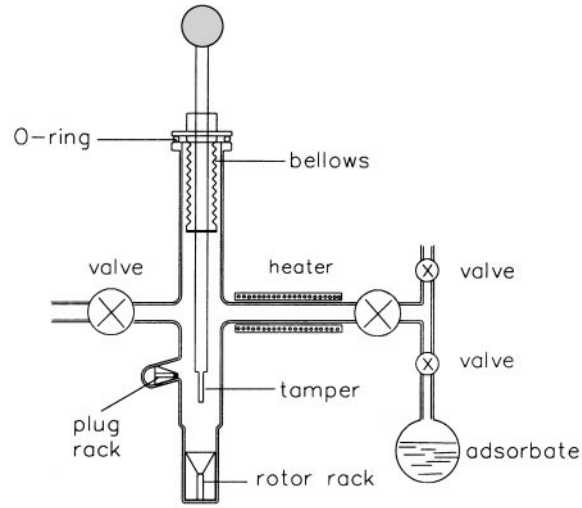

Fig. 1 Schematic diagram of the evacuating, loading and sealing apparatus of the solid samples for the solid-state MAS NMR study.

^{1}H MAS NMR spectra were recorded at 400.1 MHz on a Bruker DRX-400 spectrometer with a BBO MAS probe using 4 mm ZrO_2 rotors. The pulse width was 1 μs for a $\pi/10$ pulse, and 200 scans were accumulated with a 4 s recycle delay. Samples were spun at 8 kHz, and chemical shifts were referenced to a saturated aqueous solution of sodium 4,4-dimethyl-4-silapentanesulfonate. The Bruker software WINNMR was employed for deconvolution using fitting of Gaussian–Lorentzian lineshapes.

The upper curves in Fig. 2 show the ^{1}H MAS NMR spectra of HZSM-5 zeolite and a sample loaded with 6 wt% molybdenum before adsorption of perfluorotributylamine. At least five peaks can be clearly observed in the ^{1}H MAS NMR spectra (see the corresponding quantitatively deconvoluted spectra in Fig. 2). Besides the usually observed bridging hydroxy peak at about δ 3.9, the non-framework AlOH peak at δ 2.4 and the non-acidic silanol peak at about δ 1.7 can be identified. Moreover, a broad resonance at about δ 5.8 is also visible, which is ascribed to a second Brønsted site having an additional electrostatic interaction with the zeolite framework.[10] The narrow signal at about δ 4.9 can be assigned to an extremely small amount of water residing in the zeolite cages.[14] It is apparent from these spectra that the total ^{1}H signal intensity decreases upon loading molybdenum, and the resonances at δ 1.7 and 2.4 are preferentially reduced compared to those at δ 3.9 and 5.8. These results reveal that in the 6 wt% Mo–HZSM-5 sample prepared by impregnation, the molybdate ions preferentially react with the silanols and the non-framework AlOH groups on the surface of the zeolites. After adsorption of perfluorotributylamine, the intensity of the peak at δ 3.9 decreases, while that of the peak at about δ 5.8 ppm increases [see upper and lower curves in Fig. 2(*a*)]. This fact suggests that a portion of the bridging hydroxy groups located on the external surface of the zeolite interact with the perfluorotributylamine to form perfluorotributylaminium ions whose resonance signal

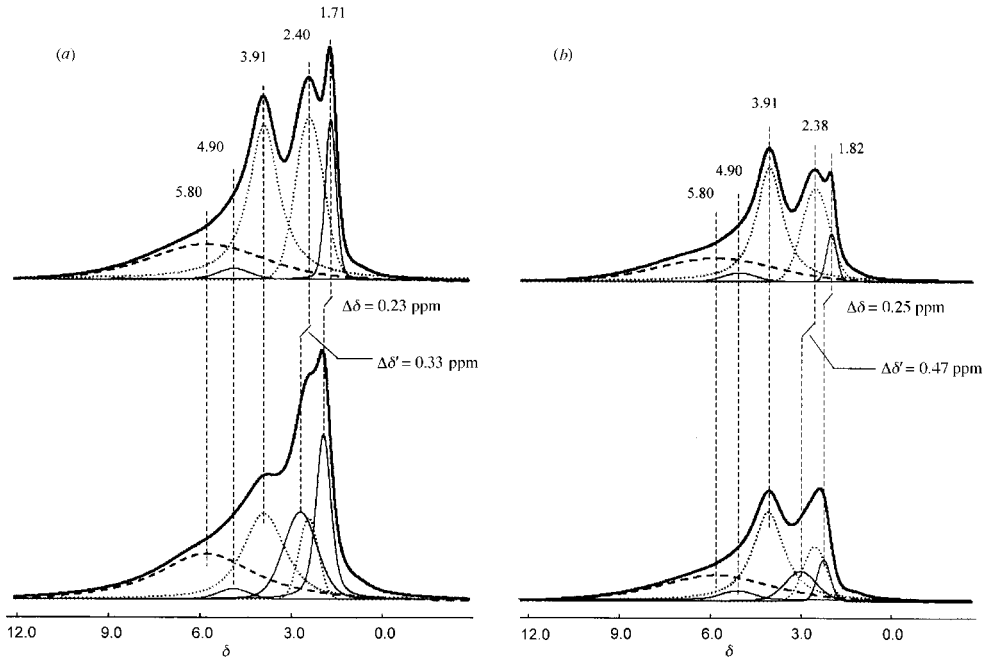

Fig. 2 ^{1}H MAS NMR spectra, with deconvolution, of (*a*) HZSM-5 zeolite and (*b*) 6 wt% Mo-HZSM-5, (top) before and (bottom) after adsorption of perfluorotributylamine, recorded at a resonance frequency of 400.1 MHz with a sample spinning rate of 8 kHz and 200 scans.

appears at about δ 6.0, while those at the internal surface are not accessible to perfluorotributylamine, so their chemical shift is unchanged. Based on these results, and after careful deconvolution of the obtained spectra, the concentration of Brønsted acid sites on the external surface of the zeolites can be calculated by (eqn. 1),

$$C_{\text{ext.surf.}} = (1 - A_1/A_2) \times 100\% \quad (1)$$

where A_1 and A_2 denote the integral area of the peak at δ 3.9 after and before adsorption of perfluorotributylamine, respectively (quantitatively deconvoluted spectra are also shown in Fig. 2). According to eqn. (1), the concentration of Brønsted acid sites on the external surface for HZSM-5 zeolites (70 nm) is 32%, while that for the 6 wt% Mo-HZSM-5 is 9%. This result, combined with the fact that the peak intensity at δ 3.9 decreases after Mo-loading clearly demonstrates that the Brønsted acidic sites on the external surface of the HZSM-5 zeolite can also react with the molybdate ions during sample preparation.

In addition, the resonance position of silanols of the samples shifts from about δ 1.7 to about δ 2.0 after adsorption of perfluorotributylamine. This low-field shift of over 0.2 ppm confirms that a weak hydrogen bond between the SiOH and the N of perfluorotributylamine is formed due to its relatively high deprotonation energy (ΔE_{DP} = 1427 kJ mol^{-1}). [15] Thus most of the silanols of the given samples are located on the external surface, and not at the lattice defects of the internal surface in the zeolites. By reasonable deconvolution, the > 0.3 ppm low-field shift of the non-framework Al resonance after adsorption of perfluorotributylamine demonstrates that some of the non-framework Al atoms exist on the external surface of the zeolites. Their concentration on the external surface can also be calculated *via* eqn. (1). Thus for HZSM-5 zeolites without Mo and with 6 wt% Mo, the concentrations are 65 and 51%, respectively. This also suggests that molybdate ions react with the non-framework AlOH groups on the external surface of the zeolites during sample preparation. From the above discussion, it is clearly demonstrated that there are at least three kinds of molybdenum species existing on the external surface of the HZSM-5 zeolite, *i.e.* Mo interacting with silanols, non-framework AlOH groups and Brønsted acidic sites on the external surface, respectively. These observations are consistent with the suggestion presented by Lunsford and co-workers[5,6] that impregnated Mo remains predominantly on the external surface of the zeolite, *via* studies comparing different preparation methods such as impregnation and solid state ion exchange. These Mo species are very likely associated with the activation of methane to form ethylene (and H_2) as the sole primary product, which aromatizes further on the Brønsted acidic sites to produce benzene and methylbenzene.[3]

In conclusion, this paper reports a feasible method for distinguishing the internal and external acidic sites in zeolites. After dehydration of the zeolites in a patented device capable of *in situ* sample pretreatments, and then adsorption of perfluorotributylamine as a probe, the Brønsted acidity distribution between the internal and external surfaces of the zeolites can be determined by ^{1}H MAS NMR spectroscopy. Meanwhile, the position of silanols and some non-framework Al species can also be identified.

We gratefully acknowledge the support of the National Natural Science Foundation of China and the Ministry of Science and Technology of China through the Climbing Project.

Received (in Cambridge, UK) 9th March 1999, Accepted 7th May 1999

Nanocrystalline semiconductors $AgGaS_2$ and $AgInS_2$ with particle sizes ranging from 5 to 12 nm are prepared by a solvothermal reaction in the temperature range 180–230 °C.

The study of nanometre sized crystallites provides an opportunity to observe the evolution of material properties with size.[1] Studies of semiconductor nanostructures with size-dependent optical and electronic properties are motivated by potential applications which include quantum-dot lasers and high-speed non-linear optical switches.[2,3] Therefore, current attention has focussed on the development of new methods for the preparation of nanocrystalline semiconductors.

I–III–VI_2 chalcopyrite semiconducting compounds such as $AgGaS_2$ and $AgInS_2$ have been shown to be useful linear and non-linear optical materials.[4,5] The band gaps and optical properties of many of these ternary sulfur containing chalcopyrites have been reported.[6,7] Considerable progress has been made in the synthesis of I–III–VI_2 semiconductor crystallites.[8,9] However, the reported preparative routes were traditional solid-state reaction methods which require high processing temperatures (800–1000 °C), long reaction times, and special apparatus. Vacancies or interstitial defects in the chalcopyrite lattice cause these compounds to have poor crystal quality and poor optical transparency.[10] As we know, different preparative methods have important effects on the resulting microstructure and physical properties of materials. Recently, various solution chemical synthesis techniques have been utilized to prepare some fascinating materials. This chemical method allows the particle size and their distribution as well as their morphology to be controlled.[11]

Herein, we report a solvothermal synthetic route to the I–III–VI_2 nanocrystalline compounds $AgGaS_2$ and $AgInS_2$ in the temperature range 180–230 °C by using AgCl, Ga (or In) and S as the reactants. The synthetic reaction was carried out in an autoclave and can be represented by eqn. (1).

$$3AgCl + 4M + 6S \xrightarrow[180–230\ °C]{\text{solvent}} 3AgMS_2 + MCl_3\ (M = Ga, In) \quad (1)$$

In this process, the coordinating solvent plays an important role in the formation of $AgGaS_2$ and $AgInS_2$.

In a typical procedure, analytical grade AgCl (1.0 g), Ga (0.648 g) or In (1.068 g), and S (0.447 g) were put into an autoclave of 50 mL capacity and then the autoclave was filled with ethylenediamine up to 85% of the total volume. The autoclave was maintained at 180–230 °C for 10 h and then allowed to cool to room temperature. The precipitates were filtered off and washed sequentially with CS_2, absolute ethanol, dilute acid, aqueous ammonia solution and distilled water, to remove the residual impurities (*e.g.* elemental sulfur and chloride). After drying in a vacuum at 70 °C for 2 h, a final dark yellow product was obtained.

The obtained samples were characterized by X-ray powder diffraction (XRD), operating on a Japan Rigaku Dmax-γA X-ray diffractometer with graphite-monochromated Cu-Kα radiation (λ = 1.5418 Å). The morphology and particle size of the final products were determined by transmission electron microscopy (TEM) images taken with a Hitachi H-800 transmission electron microscope. X-Ray photoelectron spectra (XPS) were recorded on a VGESCALAB MKII X-ray photoelectron spectrometer, using non-monochromated Mg-Kα radiation as the excitation source.

Fig. 1(a) shows the XRD pattern of an $AgGaS_2$ sample prepared by the solvothermal synthetic process. All the peaks could be indexed to the tetragonal $AgGaS_2$ phase with cell constants a = 5.7538 and c = 10.3026 Å, in agreement with reported data in the literature.[12] No characteristic peaks of other impurities such as Ga or Ag_2S, were observed. Fig. 1(b) shows the XRD pattern of an $AgInS_2$ sample. All the reflections could be indexed to the pure chalcopyrite phase $AgInS_2$ with lattice parameters a = 5.8652 and c = 11.1992 Å, in good agreement with the literature values.[13] The broadened nature of these diffraction peaks indicate that the grain sizes of the samples are on the nanometre scale. The average sizes of the particles are 6 and 10 nm, for $AgGaS_2$ and $AgInS_2$, respectively, as estimated by the Scherrer equation.

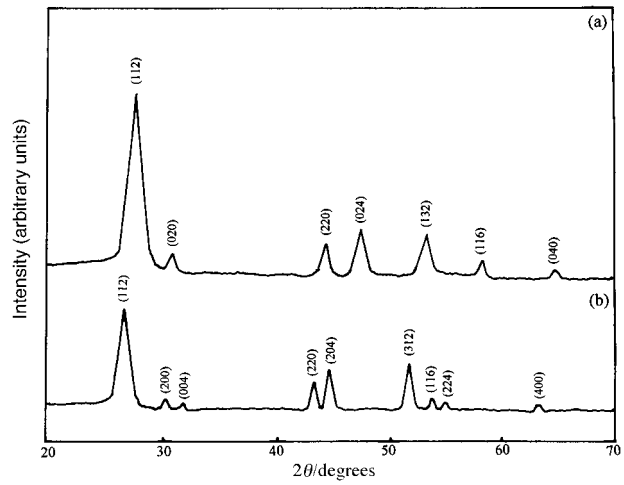

Fig. 1 XRD patterns of samples of (*a*) $AgGaS_2$ and (*b*) $AgInS_2$ prepared by solvothermal reaction.

The quality of the samples was also characterized by XPS. No obvious impurities, *e.g.* chloride ion or elemental sulfur, could be detected in the samples, indicating that the level of impurities is lower than the resolution limit of XPS (1 at%). Quantification of the XPS peaks gave Ag : Ga : S atomic ratios of 1 : 1.08 : 2.10.

Fig. 2 shows TEM images of as-prepared nanocrystalline $AgGaS_2$ and $AgInS_2$. It can be seen that the samples consist of uniform spherical particles. The diameters of the particles are in the range 5–7 and 9–12 nm, respectively, in accord with the XRD results.

It is well known that solvents can influence the reaction pathway. In our experiments, different solvents were tested and the results revealed that the coordinating ability of the solvent played an important role in the formation of nanocrystalline

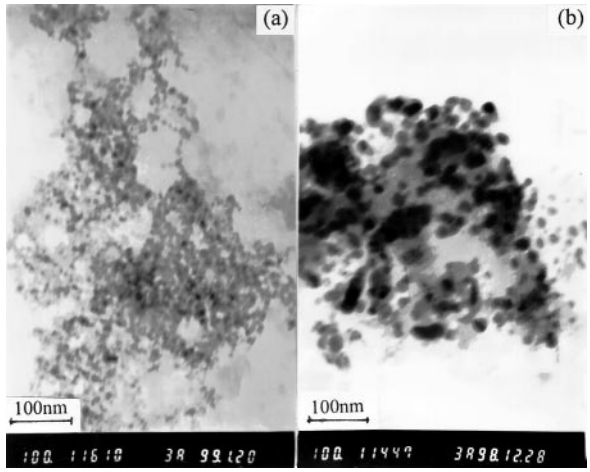

Fig. 2 TEM images of (*a*) $AgGaS_2$ and (*b*) $AgInS_2$ as in Fig. 1.

$AgGaS_2$. Ethylenediamine, a bidentate solvent, was selected due to its strong N-chelation ability and basicity. It can act as a bidentate ligand to form a relatively stable Ag^+ complex, which can incorporate dissolved sulfur as seen for other amine solvents.[14,15] As the temperature was increased, Ga melted and the formation of $AgGaS_2$ may be through a liquid-solution diffusion process. This route thus differs substantially from solid state reactions which require high temperature to overcome higher activation energy barriers. When pyridine, showing weaker binding and basicity, was used as solvent, keeping the other reaction conditions constant, the reaction was incomplete and the product purity was lower. A non-polar solvent, benzene, having no chelating ability or basicity, was also tried. According to XRD analysis, the reaction in benzene did not produce $AgGaS_2$, and the product was mostly unreacted AgCl and Ga. The influence of reaction temperature and time on the formation of $AgGaS_2$ were also studied. The optimum conditions for the formation of nanocrystalline $AgGaS_2$ is at a temperature of 180–230 °C for 10 h. If the temperature was lower than 150 °C, or the time was shorter than 5 h, the crystallinity of the $AgGaS_2$ was lower. If the temperature was higher than 250 °C or the time longer than 12 h, the particles were larger and the product was contaminated by carbonization of the solvent.

In summary, we have succeeded in the synthesis of nanocrystalline $AgGaS_2$ and $AgInS_2$ by solvothermal reaction. The structure and property of the solvent can strongly influence the reaction process. The method presented herein provides uniform particles with narrow size distribution which may be further enhanced by use of other solvents. This method can be readily employed to prepare other nanocrystalline I–III–VI_2 materials such as $AgMSe_2$, $CuMS_2$ (M = Ga, In). A detailed study on this synthesis method is in progress.

Financial support of this work by the National Natural Science Foundation of China is gratefully acknowledged.

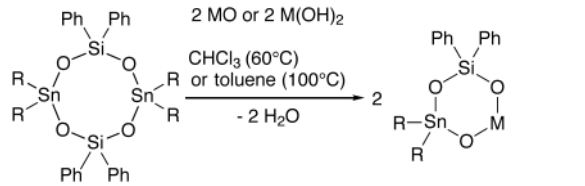
Received (in Cambridge, UK) 26th March 1999, Accepted 12th May 1999

***Umpolung* of ring strain by intramolecular Sn–N Lewis acid–Lewis base interaction is the key for the synthesis of the first organoelement oxides of the type (Ph_2SiOR_2SnOMO) [R = $(CH_2)_3NMe_2$; M = Bu^t_2Sn, Bu^t_2Ge, PhB] which hold potential as precursors to tertiary metal oxides.**

Recently, we reported the syntheses and structures of stannasiloxanes such as *cyclo*-$R_2Si(OSnBu^t_2)_2O$ (**1**, R = Bu^t; **2**, R = Ph),[1a,b] *cyclo*-$(Ph_2SiOR_2SnO)_2$ [**3**, R = Bu^t; **4**, R = $(CH_2)_3NMe_2$],[1b,c] *cyclo*-$R_2Sn(OSiPh_2)_2O$ [**5**, R = Bu^t; **6**, R = $(CH_2)_3NMe_2$],[1c,d] and of the germastannoxanes *cyclo*-$Bu^t_2Sn(OGePh_2)_2O$ **7**.[1c] Such compounds are of potential interest as molecular precursors for the synthesis by ring-opening polymerisation of inorganic polymers.[1d,2] The stannasiloxane $Bu^t_2Sn(OSiPh_2)_2O$ **5** contains a six-membered ring in solution but is the first well-defined polystannasiloxane in the solid state. The ring strain in **5** is the thermodynamic driving force for the polymerisation which however, is compensated in solution by entropy of a large number of monomers, *i.e.*, six-membered rings.[1d] In contrast, the related borasiloxane *cyclo*-PhB($OSiPh_2)_2O$ **8** is a six-membered ring both in solution and in the solid state.[2b] The reaction of the eight-membered stannasiloxane ring *cyclo*-$(Ph_2SiOBu^t_2SnO)_2$ (**3**) with 2/3 mol equivalents *cyclo*-$(Bu^t_2SnO)_3$ quantitatively provided *in situ* the six-membered stannasiloxane ring $Ph_2Si(OSnBu^t_2)_2O$ **2**. However, this reaction is also an equilibrium and removal of the solvent quantitatively yielded the starting compounds *cyclo*-$(Bu^t_2SnO)_3$ and **3**.[1b]

In contrast, the reaction of the eight-membered intramolecularly coordinated stannasiloxane ring *cyclo*-$(Ph_2SiOR_2SnO)_2$ [**4**, R = $(CH_2)_3NMe_2$] with *cyclo*-$(Bu^t_2SnO)_3$ afforded the first *cyclo*-stannasiloxane **9** containing two different substituted tin atoms (Scheme 1).§

Furthermore, the reaction of compound **4** with di-*tert*-butylgermanium dihydroxide $Bu^t_2Ge(OH)_2$ and phenylboronic acid $PhB(OH)_2$ gave the first organoelement oxides **10** and **11**, respectively, being composed of three different metals or metalloids in the same ring (Scheme 1).§



9, M = Bu^t_2Sn, R = $(CH_2)_3NMe_2$
10, M = Bu^t_2Ge, R = $(CH_2)_3NMe_2$
11, M = PhB, R = $(CH_2)_3NMe_2$

† Dedicated to Professor Dietmar Seyferth on the occasion of his 70th birthday.

‡ This work contains part of the Ph.D. thesis of N. Pieper, Dortmund University 1998, and of the intended Ph.D. thesis of J. Beckmann.

It seems that the intramolecular Sn–N coordination increases the ring strain in the eight-membered *cyclo*-stannasiloxane **6** but decreases the ring strain in the six-membered rings **9**–**11**. This means, the formation of **9**–**11** is favoured by both enthalpy and entropy.

The molecular structures¶ of compounds **10** and **11** are shown in Fig. 1 and 2, respectively. Compound **9** is isostructural with **10**. The Sn(1) atoms in **9**–**11** exhibit distorted octahedral configurations with the carbon atoms in mutual *trans* and the oxygen and nitrogen atoms in *cis* positions. The deviation from the ideal octahedral geometry is documented by the C(1)–Sn(1)–C(11) angles of 149.3(2)–152.30(2)° and the N(1)–Sn–N(2) angles of 105.4(1)–109.58(9)°. The O(1)–Sn(1)–O(3) angles fall in the range 90.30(8)–95.45(9)°. The intramolecular Sn–N distances in **9**–**11** [2.620(3)–2.764(3) Å] are shorter as compared to the Sn–N contacts in the eight-membered *cyclo*-stannasiloxane **4** [2.721(4)/2.811(4) Å].[1c] The Sn–N distances are quite different within each of the compounds **9**–**11**. This corresponds with previous observations on the intramolecularly coordinated organotin sulfide $\{[Me_2N(CH_2)_3]_2SnS\}_2$.[3]

Compared to the ^{119}Sn NMR chemical shifts in solution the ^{119}Sn MAS NMR spectra of **9**–**11** exhibit shifts of 52.9, 30.3 and 9.5/17.8 ppm‖ to low frequency which hints, especially for **10** and **11**, at a stronger Sn–N coordination in the solid state.

The synthetic concept introduced within this paper should also apply for the synthesis of organoelement oxides containing

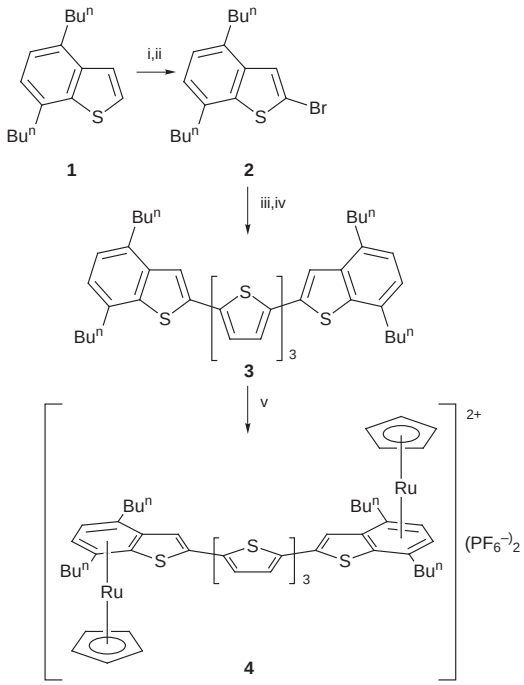
Received (in Cambridge, UK) 22nd March 1999, Accepted 4th May 1999

A novel oligothiophene metal π-complex containing the, as yet, longest α-conjugated oligothiophene as ligand is described; characterisation by X-ray and other physicochemical methods clearly reveals the influence of the metal units upon the electronic and the geometric structure.

Oligothiophenes represent ideal model compounds for the corresponding polydisperse conducting polymers[1] and novel materials used in organic transistors[2] or light emitting devices.[3] Therefore, the tailoring of the electronic properties by electronically active substituents,[4] the replacement of thiophene moieties by other heteroaromatic units,[5] and the coordination of transition metals to an oligothiophene core lead to pronounced alterations of the (electronic) properties.[6] The molecular arrangement of the oligothiophenes in the solid state may be crucial for the performance of the devices.[2] However, X-ray data for oligothiophenes have been sparse, since the growth of suited single crystals is very difficult, and the crystals often contain intrinsic disorder and defects.[5,7]

Herein we present the synthesis and characterisation of $[(CpRu)_2(\eta^6,\eta^6\text{-DB5T})](PF_6)_2$ **4**, a novel bis-ruthenium π-complex of 'benzo-capped' quinquethiophene **3**. In contrast to other examples,[6] the planar and stiff terminal benzo[*b*]thiophene units provide good stability and an optimal influence of the metal fragments onto the electronic properties.

According to Scheme 1, 4,7-di-*n*-butylbenzo[*b*]thiophene **1**[8] was reacted with Bu^nLi and bromine to yield the 2-bromo derivative **2** in 69% yield. Nickel-catalysed cross-coupling of the Grignard reagent of **2** and 5,5″-dibromoterthiophene yielded oligothiophene (DB5T) **3** (56%). The doubly ruthenated quinquethiophene $[(CpRu)_2(\eta^6,\eta^6\text{-DB5T})](PF_6)_2$ **4** was effectively formed by the reaction of **3** with two equiv. of $[CpRu(MeCN)_3]PF_6$ [9] (73% yield). The resulting metal complex **4** was purified by reprecipitation and is stable in air, is highly soluble in polar solvents such as dichloromethane, 1,2-dichloroethane, and in coordinating solvents such as acetone.†



Scheme 1 *Reagents and conditions*: i, Bu^nLi, THF, −20 °C; ii, Br_2, −20 °C; iii, Mg; iv, $Ni(dppp)Cl_2$, Et_2O, Br–T_3–Br; v, $[CpRu(MeCN)_3]PF_6$, $C_2H_4Cl_2$, reflux.

Various 2D NMR spectroscopic experiments enabled the assignment of all ^1H and ^{13}C resonances in comparison to the non-complexed quinquethiophene **3**. The $CpRu^+$-fragments are exclusively η^6-bound to the anellated benzene rings. Owing to the influence of the metal, the proton resonances of the terminal benzo[b]thiophene units are strongly shifted upfield ($\Delta\delta$: $H^{3'''',3''''}$ = −0.20, $H^{5'''',5''''}$ = −1.02, $H^{6'''',6''''}$ = −1.00 ppm). In contrast, resonances of the central terthiophene moiety are shifted downfield ($\Delta\delta$: $H^{4,4''}$ = +0.18, $H^{3,3''}$ = +0.13, $H^{3',4'}$ = +0.14 ppm). The most pronounced changes in the ^{13}C NMR spectra are evident for the benzo carbons ($\Delta\delta$: $C^{3a''''}$, $C^{3a''''}$ = −32.3, $C^{4''''}$, $C^{4''''}$ = −34.5, $C^{5''''}$, $C^{5''''}$ = −39.8, $C^{6''''}C^{6''''}$ = −42.0, $C^{7''''}$, $C^{7''''}$ = −36.2, $C^{7b'''',7b''''}$ = −30.4 ppm).

To enable comparison with the non-complexed oligothiophene DB5T **3**, the electronic properties of metal complex **4** were determined by optical measurements and by cyclic voltammetry. In the absorption spectrum metallation of the oligothiophene causes a displacement of the unstructured π–π^* transition to lower energies and a decrease of the absorption coefficient [**3**: λ_{max} (lg ε) = 436 nm (4.76); **4**: λ_{max} (lg ε) = 454 nm (4.72)]. The emission spectrum of **3** exhibits a structured band at λ_{max} = 501 nm. Owing to a strong metal ligand interaction the fluorescence of **4** at λ_{max} = 533 nm is strongly quenched. The electrochemical characterisation of **3** reveals two fully reversible oxidation waves corresponding to two one electron transfer steps ($E°_1$ = 0.39 V, $E°_2$ = 0.75 V *vs*. Fc/Fc^+). As typical for electron-rich oligothiopenes, no reduction process can be observed in the negative potential regime ($E \geq -2$ V). Owing to the electron withdrawing character of the metal fragments, oxidation of **4** is shifted to positive potentials ($E°_1$ = 0.75 V, $E°_2$ = 1.06 V *vs*. Fc/Fc^+). Additionally, in the CV of **4** a reversible two electron reduction wave arises at $E°_3$ = −1.76 V *vs*. Fc/Fc^+ which corresponds well to the values obtained for other $[CpRu(arene)]^+PF_6^-$ salts.[10] Thus, the oxidation process is located on the oligothiophene core, whereas reduction occurs at the metal fragments.

Since no splitting of the reduction wave can be seen, electron transfer to the ruthenium centers occurs at the same energy indicating none, or at best weak, interaction *via* the conjugated π system (Fig. 1).

Small ruby red crystals of the oligothiophene metal complex **4** suitable for X-ray structure determination were grown by recrystallisation from CH_2Cl_2–Et_2O.‡ Views of the molecule in Fig. 2 verify the composition of the molecule. The oligothiophene core is nearly coplanar exhibiting small interplanar angles (ring 1,2: 5.0°; ring 2,3: 9.4°). Rather unique *syn*

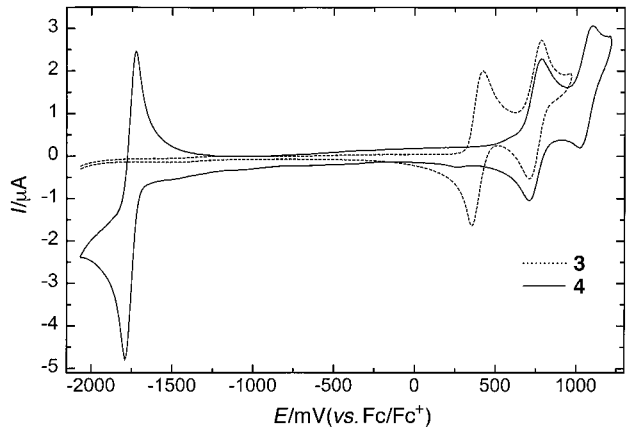


Fig. 1 Cyclic voltammograms (c = 10^{-3} mol l^{-1} substrate in CH_2Cl_2–TBAHFP (0.1 M), v = 100 mV s^{-1}; Pt disk working electrode, Pt wire counter electrode, Ag/AgCl reference electrode internally calibrated with the Fc/Fc^+-couple) of metallated oligothiophene [(CpRu)$_2$(η^6,η^6-DB5T)]$(PF_6)_2$ **4** (solid line) in comparison to the non-metallated ligand **3** (dashed line).

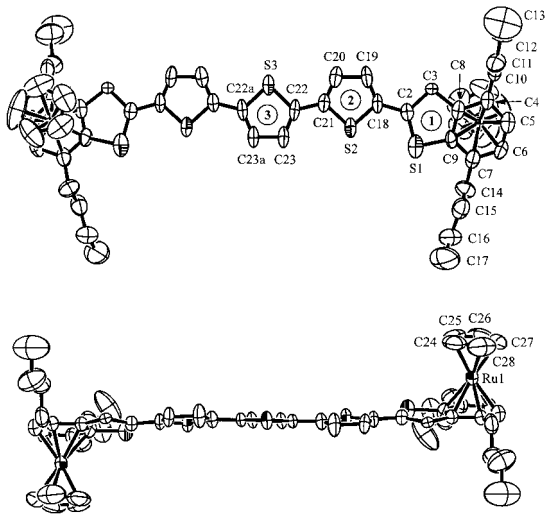

Fig. 2 ORTEP front view of oligothiophene metal complex **4** showing atomic labeling, 50% thermal ellipsoids (top). Side view of **4** (bottom). The PF_6^- counter ions have been omitted for clarity. Selected bond distances (Å): S(1)–C(2) 1.706(14), Ru(1)–C(4) 2.232(13), S(1)–C(9) 1.720(12), Ru(1)–C(5) 2.181(14), C(2)–C(3) 1.600(15), Ru(1)–C(6) 2.185(13), C(3)–C(8) 1.621(15), Ru(1)–C(7) 2.210(14), C(8)–C(9) 1.425(18), Ru(1)–C(8) 2.263(12), C(8)–C(4) 1.439(17), Ru(1)–C(9) 2.251(13), C(4)–C(5) 1.432(19), Ru(1)–C(24) 2.170(19), C(5)–C(6) 1.360(20), Ru(1)–C(25) 2.186(17), C(6)–C(7) 1.410(18), Ru(1)–C(26) 2.178(18), C(7)–C(9) 1.392(18), Ru(1)–C(27) 2.159(19), C(2)–C(18) 1.449(16), Ru(1)–C(28) 2.140 (20).

conformations of the terminal benzo[*b*]thiophene units are observed with respect to the central all *anti* terthiophene moiety which shows quite normal bond length and angles. The occurrence of *syn* conformers in coplanar arrangements has only been verified once previously in a mixed pentamer containing four thiophene and one 1,3,4-oxadiazole unit.[5] In accordance with the NMR assignments, the $CpRu^+$-fragments are η^6-coordinated to the terminal benzene rings and not η^5 to any thiophene ring. The two metal fragments are directed to opposite sides with respect to the oligothiophene plane representing one of two possible isomers.§ Simultaneously, the butyl side chains on each benzo[*b*]thiophene unit point in the opposite direction with respect to the coordinated metal. The distances Ru–C5/C6 are found to be shorter than Ru–C8/C9 indicating a transversal displacement of the metal atom by 0.07 Å from the center of the benzene ring to the ends of the molecule. This has been observed in the benzo[*b*]thiophene complex [(CpRu)(η^6-benzo[*b*]thiophene)]BF_4 and other transition-metal complexes containing fused arene ligands.[11] As a consequence, bonds C2–C3, C3–C8, and S1–C9 are longer than expected, while the corresponding bond angles are distorted.

Current efforts in our laboratory are now directed to the variation of the length of the oligothiophene ligand and variation of the transition metal.

We gratefully acknowledge a grant (Landesgraduiertenstipendium) for G. G. and Degussa AG for a generous gift of ruthenium trichloride.

Notes and references

† All new compounds had spectral (^{1}H NMR, ^{13}C NMR, UV–VIS) and microanalytical properties (C, H, S) consistent with the assigned structures.

‡ *Crystal data*: [(CpRu)$_2$(η^6,η^6-DB5T)]$(PF_6)_2$ **4**: $C_{54}H_{58}F_{12}P_2Ru_2S_5$, M = 1359.38, monoclinic, space group *I*2/*a*, a = 14.444(2), b = 16.998(3), c = 27.623(3) Å, β = 99.94(1)°, V = 6680.3(16) Å^3, Z = 2, D_c = 1.352 g cm^{-3}, crystal dimensions 0.15 × 0.27 × 0.77 mm, T = 220(2) K, μ = 0.721 cm^{-1} (analytical absorption correction). Intensity data were collected on a STOE-IPDS image-plate diffractometer [Mo-Kα radiation (λ = 0.71073 Å), graphite monochromator] in the φ rotation scan mode. 5186 unique reflections were measured and used in the refinement. The structure was solved by direct methods with the XMY93 program system.[12] The molecule is located on a crystallographic twofold axes passing through S3 and between C23 and C23a. Refinement (SHELXL93)[13] of positional and anisotropic thermal parameters for all non-hydrogen atoms converged to R = 0.0937 for 1873 reflections with $F_o \geq 4\sigma(F_o)$. The relatively poor R value is probably due to a disordered PF_6^- anion which was therefore only refined isotropically and to a high anisotropy of the terminal atoms. These effects could not be eliminated by low-temperature data collection.

§ Evidently, during the crystallization process only one possible isomer of compound **4** precipitated. The other isomer would comprise the same conformation of the oligothiophene core but with the two metal centers on the same side. Both isomers, presumably present in solution, can not be distinguished in NMR experiments.

A homobimetallic vanadium d^2–d^2 complex $(Cp_2V)_2(3\eta:4\eta\text{-}Me_3SiC{\equiv}C{-}C{=}C{-}C{\equiv}CSiMe_3)$: structure and magnetism

Received (in Cambridge, UK) 24th March 1999, Accepted 7th May 1999

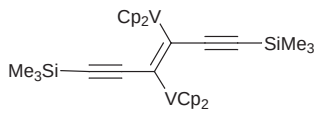
The d^2–d^2 homobimetallic complex $(Cp_2V)_2(3\eta:4\eta\text{-}Me_3SiC{\equiv}C{-}C{=}C{-}C{\equiv}CSiMe_3)$ was synthesized from $Me_3SiC{\equiv}C{-}C{\equiv}C{-}C{\equiv}CSiMe_3$ and Cp_2V and characterized by an X-ray crystal structure; magnetic moment measurements from 300 to 2 K indicated a weak antiferromagnetic *J* exchange coupling of -3.7 cm^{-1}.

The chemistry of transition metal alkynyl and related complexes continues to be an attractive focus, and among its differing chemical and physical properties, their potential non-linear optical properties are of interest.[1] Furthermore, a rich acetylenic chemistry has recently been described with group 4 transition metals in which the synthon 'Cp_2Zr' played an important part.[2] Our research group has extended this concept to group 5 with the reactive isolable vanadocene Cp_2V complex.

The remarkable oxidative addition of vanadocene Cp_2V **1** to ethynyl –C≡C– bonds was demonstrated early and a vanadocyclopropene structure was established.[3] In previous papers, we established that Cp_2V reacts with $Cp'_2Zr(C{\equiv}CPh)_2$ to give $Cp_2V(\mu\text{-}\eta^2:\eta^4\text{-}C{\equiv}C{-}C{\equiv}CPh)ZrCp'_2$, with a vanadacyclopropane moiety containing two planar tetracoordinated carbons on the butadiyne ligand[4] or with the phosphane $ArP(C{\equiv}CPh)_2$ to give the adduct $Cp_2V(PhC{=}C)P(C{\equiv}CPh)Ar$.[5] Alternatively, two Cp_2V units can be added to a diethynyl ligand RC≡C–C≡CR (R = $SiMe_3$, Ph) to give a homobimetallic V^{IV}–V^{IV} system $(Cp_2V)_2(1{-}2\eta:3{-}4\eta\text{-}RC{=}C{-}C{=}CR)$ where the Cp_2V units are in *cis* or *trans* positions depending on the nature of R.[6] As such, particular attention is given to the reactivity of Cp_2V with a triyne $Me_3SiC{\equiv}C{-}C{\equiv}C{-}C{\equiv}CSiMe_3$[7] **2**, to establish a synthetic route to an ethynyl vanadium-bridged complex.

2

Addition of a pentane solution of **1** (2 or 3 equiv.) to **2** leads to a crystalline black solid $(Cp_2V)_2(3\eta:4\eta\text{-}Me_3SiC{\equiv}C{-}C{=}C{-}C{\equiv}CSiMe_3)$ **3**,† fully characterized by an X-ray structure



3

determination (Fig. 1).‡ Surprisingly, the vanadium atom has an oxidative state of +3, instead of the expected classical V^{IV} which to our knowledge has been observed in all other cases. The main feature of **3** is the bonding mode of the two vanadocene moieties which are attached to both the internal carbon atoms of the triyne *via* a single σ-type V–C(11a) bond of length 2.165 Å which raises the vanadium oxidation state from +2 to +3. The geometrical alteration of ligand **2** is reflected by the *trans* configuration of the triyne: the nearly linear –C–C≡CSiMe$_3$ moiety [C(11a)C(12)C(13) 165.5°, C(12)C(13)Si(1) 173.2°] forms a 113.4° angle with the C(11a)C(11a′) bond. The sum of the angles around C(11a) (nearly 360°) as well as the 1.381 Å bond length of C(11)–C(11a′) (in accord with a double bond) indicate an sp^2-ethylene structure. The SiC_6Si skeleton and the vanadium atoms are in the same plane and the dihedral angle between the plane of the Cp_2V unit (obtained from the centroids of the Cp rings and the vanadium atom) and the plane of the SiC_6Si ligand is 98.66°.

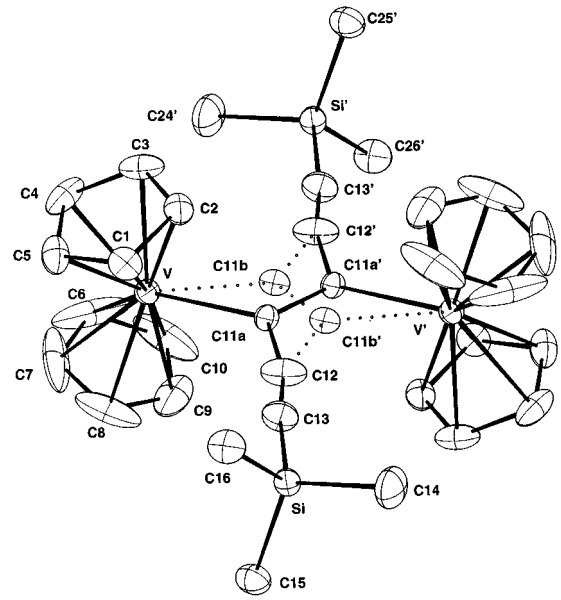


Fig. 1 Molecular structure of **3**. Selected distances (Å) and angles (°), hydrogen atoms omitted: V–C(11a) 2.165(4), C(11a)–C(11a′) 1.381(9), C(11)–C(12) 1.476(5), C(12)–C(13) 1.206(4), V···V′ 5.25, V–Cp 1.947(av.); Cp–V–Cp 147.8(av.) [Cp are the centroids of the C_5H_5 rings C(1)–C(5), C(6)–C(10)].

Variable-temperature magnetic susceptibility measurements have been carried out on the V^{III} homobimetallic d^2–d^2 species **3**.§ The effective moment μ_{eff} is 4.01 μ_B at 300 K, which is consistent with two vanadium(III) units ($\mu_{theor} = 2[\sqrt{\Sigma S(S+1)}] = 4$ for two non-interacting d^2 vanadium atoms). If the two magnetically equivalent d^2 centers are totally non-interacting, then μ_{eff} should remain constant over a large temperature range. The effective moment μ_{eff} decreases to 1.51 μ_B at 2 K. Fig. 2 shows a plot of the molar susceptibility per dimer χ_m, *vs.* *T*. The solid line represents a good fit and was considered to account for the observed dependence with an exchange interaction model, having a weak antiferromagnetism with $J = -3.7$ cm^{-1}.[8]

When 1 equiv. of **1** was treated with only 1 equiv. of **2** in pentane, tiny brown needles were obtained. Unfortunately, efforts to obtain suitable crystals for an X-ray diffraction analysis have to date failed. Elemental analysis and magnetic

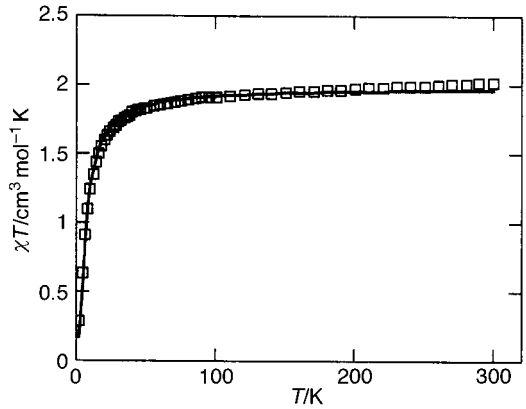

Fig. 2 Temperature dependance of molar magnetic susceptibilities per vanadium (□) of **3**; the solid line results from a least-squares theoritical fit.

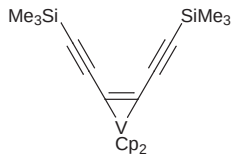
studies (μ_{eff} = 1.9 μ_B) are in agreement with a vanadium(IV) atom bound to **2**,† and a vanadocene cyclopropene structure such as $Cp_2V(3–4\eta^2\text{-}Me_3SiC{\equiv}C–C{=}C–C{\equiv}CSiMe_3)$ **4** can be suggested. Treatment of **4** in C_6D_6 with another equiv. of **1** leads



4

to **3**, as revealed by ^{1}H NMR spectroscopy (the ^{1}H NMR spectrum of paramagnetic **3** in C_6D_6 consists of an observable low field broad signal of Cp at δ 124 and a well resolved Me_3Si signal at δ 1.0. A comproportionation reaction between V^{IV} (**4**) and V^{II} (**1**) to give $2V^{III}$ (**3**) is probably operative but a mechanistic description must await further experimental evidence.

In summary, the reaction of **1** with a triyne ligand led to a homobimetallic d^2–d^2 complex. This unexpected reactivity seems to be due to the odd parity of the number of C≡C bonds in **2**.[7] It would be interesting experimentally to test other odd-yne ligands to understand the ligand/metal effects and efforts are currently being made in this direction.

Notes and references

† Satisfactory elemental analysis results were obtained for compounds **3** and **4**.

‡ *Crystallographic data* for **3**: $C_{32}H_{38}Si_2V_2$, M = 580.72, monoclinic, space group $P2_1/c$, a = 11.214(2), b = 113.778(2), c = 10.797(1) Å, β = 112.72(1)°, V = 1538.76 Å^3, Z = 4, D_c = 1.66 g cm^{-3}, μ = 6.82 cm^{-1}, $R(R_w)$ = 0.033(0.036) for 1719 unique data and 173 parameters, GOF = 1.08. Data collection was performed at *ca.* 180 K on a IPDS STOE diffractometer using graphite-monochromated Mo-Kα radiation. The structure was solved by direct methods and subsequent difference Fourier maps. A disordered distribution was observed for C(11) and the best model to fit the electronic density was to consider two positions C(11a) and C(11b) with a ratio of occupancy of 0.6/0.4. CCDC 182/1256. See http://www.rsc.org/suppdata/cc/1999/1099/ for crystallographic files in .cif format.

§ Magnetic susceptibilities were determined using a SQUID susceptometer within the temperature range 2–300 K. Using a Heisenberg Hamiltonian $H = -JS_AS_B$ with the local spin $S_A = S_B = 1$, the magnetic interaction was estimated with a model for dinuclear compounds [eqn. (1)].[9] The J and g parameters were determined by least-squares fitting. The agreement factor R [eqn. (2)] = 2.89 × 10^{-4}. The average value of the g-factor was 1.996.

$$\chi = \frac{2N\beta^2}{kT} g^2 \frac{e^x + 5e^{3x}}{1 + 3e^x + 5e^{3x}} \quad (x = J/kT) \tag{1}$$

Reversible methyl group migration between osmium and tin in reactions of osmium trimethylstannyl complexes

Clifton E. F. Rickard, Warren R. Roper,* Timothy J. Woodman and L. James Wright*

Department of Chemistry, The University of Auckland, Private Bag 92019, Auckland, New Zealand.
E-mail: w.roper@auckland.ac.nz

Received (in Cambridge, UK) 13th April 1999, Accepted 10th May 1999

Treatment of the coordinatively unsaturated osmium trimethylstannyl complex, $Os(SnMe_3)Cl(CO)(PPh_3)_2$ 1, with either pyridine (py) or sodium acetate results in methyl migration from tin to osmium, giving the structurally characterised complexes, $Os(Me)(SnClMe_2)(py)(CO)(PPh_3)_2$ 2 or $Os(Me)(SnMe_2OC[Me]O)(CO)(PPh_3)_2$ 3, respectively: the methyl migration is reversible and treatment of $Os(Me)(SnClMe_2)(py)(CO)(PPh_3)_2$ with CO gives the trimethylstannyl complex, $Os(SnMe_3)Cl(CO)_2(PPh_3)_2$.

α-Migration, as shown in eqn. (1), is an established feature of organometallic chemistry.[1] In the closely related metal silyl complex chemistry many transformations have been observed which imply the intermediacy of metal silylene complexes generated by 1,2-migration of an R group as in eqn. (2).[2] In one instance, when R = H, *reversible* 1,2-migration has been reported for a platinum silyl complex.[3] Since there is a substantial number of well characterised stannylene complexes[4] it can be envisaged that the type of interconversion represented in eqn. (3) might play a part in understanding the reactions

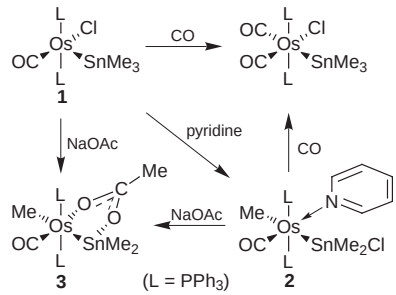
(1)

(2)

(3)

undergone by metal stannyl and metal stannylene complexes. Indeed, free, stable stannylenes have been inserted into metal–halogen bonds.[4] A further observation relevant to this idea is that $Ru[Sn(C_6H_4Me\text{-}p)_3]Cl(CO)(PPh_3)_2$ readily decomposes in solution to $Ru(C_6H_4Me\text{-}p)Cl(CO)PPh_3)_2$.[5] We describe herein new reactions undergone by the osmium trimethylstannyl complex, $Os(SnMe_3)Cl(CO)(PPh_3)_2$ **1**, in which (i) a methyl group migrates to osmium and this is accompanied by either a chloride transfer to tin forming a chlorodimethylstannyl ligand, or by formation of a bridging acetatodimethylstannyl ligand, (ii) an example of reverse migration of a methyl group from osmium to tin to reform the trimethylstannyl ligand, and (iii) the crystal structures of the two products of methyl migration to osmium, $Os(Me)(SnClMe_2)(py)(CO)(PPh_3)_2$ **2** (py = pyridine) and $Os(Me)(SnMe_2OC[Me]O)(CO)(PPh_3)_2$ **3**.

$Os(SnMe_3)Cl(CO)(PPh_3)_2$ **1**, when treated with CO, $CNC_6H_4Me\text{-}p$, or sodium dimethyldithiocarbamate, gives the expected six coordinate trimethylstannyl complexes, $Os(SnMe_3)Cl(CO)_2(PPh_3)_2$, $Os(SnMe_3)Cl(CO)(CNC_6H_4Me\text{-}p)(PPh_3)_2$, or $Os(SnMe_3)(\eta^2\text{-}S_2CNMe_2)(CO)(PPh_3)_2$.[6,7] We now report that reaction of **1** with pyridine (Scheme 1) leads not to the expected six-coordinate complex, '$Os(SnMe_3)Cl(py)(CO)(PPh_3)_2$', but rather to the colourless, methyl-migrated product, $Os(Me)(SnClMe_2)(py)(CO)(PPh_3)_2$ **2** in 64% isolated yield. That methyl group migration has occurred in the formation of **2** is revealed by the ^1H NMR spectrum which shows the osmium-bound methyl group as a triplet at δ 0.15 ($^3J_{HP}$ 6.62 Hz) (syntheses and other data for **2** and **3** are given in footnote †). This structural assignment was fully confirmed



Scheme 1

by a crystal structure determination.‡ The structure of **2** is shown in Fig. 1, along with selected bond lengths and angles. The osmium–tin bond distance of 2.6741(4) Å does not differ substantially from the corresponding distances found in other osmium stannyl complexes. The osmium–bound methyl group is found to lie *trans* to the tin atom, with the angle C–Os–Sn at 175.30(12)°. The osmium–methyl bond length of 2.249(5) Å is similar to that observed in both $Os(Me)(H)(CO)_2(PPr^i_3)_2$ [2.198(17) Å][8] and $Os(Me)(I)(CO)_2(PMe_3)_2$ [2.174(15) Å].[9] The geometry around the tin centre is quite symmetrical with the angles Os–Sn–C(3), Os–Sn–C(4) and Os–Sn–Cl(1), all close to 120°.

Remarkably, when compound **2** is treated with CO, pyridine is displaced but the compound formed is not '$Os(Me)(SnMe_2Cl)(CO)_2(PPh_3)_2$'. Instead, the trimethylstannyl complex, $Os(SnMe_3)Cl(CO)_2(PPh_3)_2$, is obtained in 80% isolated yield, where the methyl group has migrated back to the tin atom and chloride has returned to osmium. It may be significant for this

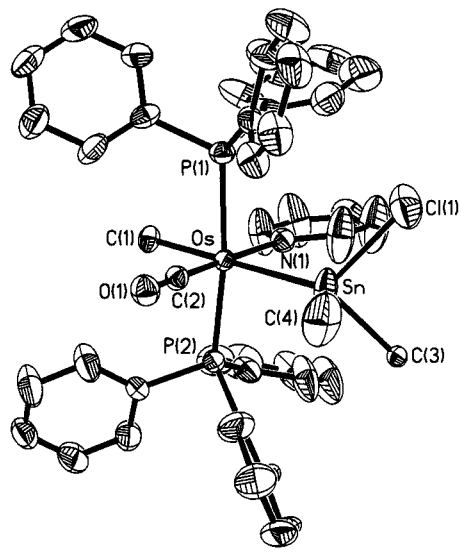


Fig. 1 Crystal structure of **2**. Selected bond lengths (Å) and angles (°): Os–Sn 2.6741(4), Os–C(1) 2.249(5), Os–N(1) 2.251(4), Sn–Cl(1) 2.422(2), Os–Sn–C(3) 123.47(11), Os–Sn–C(4) 120.9(2), Os–Sn–Cl(1) 119.17(6), C(3)–Sn–C(4) 99.5(3), C(1)–Os–Sn 175.30(12).

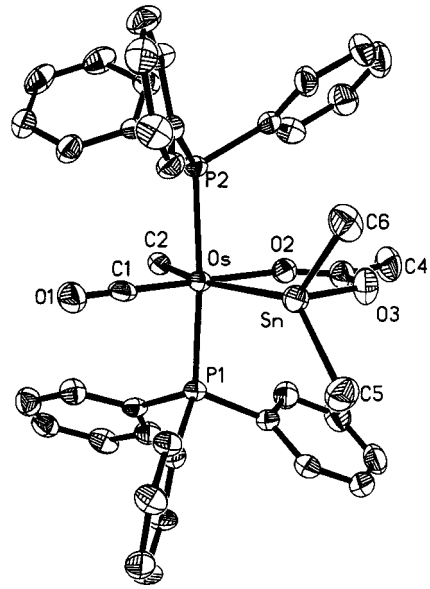

Fig. 2 Crystal structure of **3**. Selected bond lengths (Å) and angles (°): Os–Sn 2.6766(4), Os–C(2) 2.183(5), Os–O(2) 2.183(4), Sn–O(3) 2.143(4), Os–Sn–C(5) 131.22(19), Os–Sn–C(6) 129.70(18), C(5)–Sn–C(6) 98.2(3), C(2)–Os–Sn 158.77(15).

transformation that solutions of **2** are red suggesting that partial pyridine dissociation occurs to give a coordinatively unsaturated species in solution.

Treatment of **1** with sodium acetate also gives a methyl-migrated product, $\overline{Os(Me)(SnMe_2OC[Me]O)}(CO)(PPh_3)_2$ **3** (Scheme 1). The same compound is accessible from a reaction between **2** and sodium acetate. The ^{1}H NMR spectrum of **3** shows the osmium-bound methyl group as a triplet at δ 0.25 ($^3J_{HP}$ 7.12 Hz). The structure was confirmed by a crystal structure determination.‡ The molecular geometry of **3** is shown in Fig. 2, along with selected bond lengths and angles. The acetate bridges across the osmium–tin bond forming a five-membered chelate ring. The osmium–tin bond distance of 2.6766(4) Å does not differ substantially from the corresponding distances found in other osmium stannyl complexes. The osmium–methyl bond length is 2.183(5) Å, and the osmium-bound methyl group is found to lie *trans* to the tin atom, with the angle C–Os–Sn at 158.77(15)°. This considerable deviation from linearity is no doubt a consequence of the small O–Os–Sn angle required by the bridging acetate ligand. The osmium atom, the osmium-bound methyl, the carbonyl, the tin atom and the acetate ligand are all coplanar. The geometry around the tin centre is far from tetrahedral with C(5), C(6), Sn, and Os almost coplanar. The sum of the angles made by the two methyl groups and the osmium atom about tin is 359.1°, with the tin atom lying only 0.127(3) Å from the plane through C(5), C(6) and Os. The acetate oxygen, O(3), is bound to tin at a distance of 2.143(4) Å and the O(3)–Sn bond is perpendicular to the Os, Sn, C(5), C(6) plane. These structural parameters are compatible with some base-stabilised stannylene character in the bonding of the tin ligand. The tin resonance found in the ^{119}Sn NMR spectrum of **3** is a triplet signal at δ 392.94 ($^2J_{SnP}$ 119.4 Hz).

We have as yet no mechanistic information regarding these methyl group migrations. However, from the observations depicted in Scheme 1 and discussed herein, it is clear that methyl migration occurs only when a coordinatively unsaturated osmium stannyl species is accessible. It is possible that such a species is in an equilibrium of the type shown in eqn. (3).

† *Synthesis of* $Os(Me)(SnClMe_2)(py)(CO)(PPh_3)_2$ **2**: $OsHCl(CO)(PPh_3)_3$ (1.00 g, 0.960 mmol) was added directly to a solution of trimethylvinyltin (1.00 g, 5.23 mmol) in a mixture of benzene (18 mL) and toluene (18 mL) and heated to reflux under nitrogen. The mixture was then photolysed with a 1000 W tungsten/halogen lamp held 10 cm from the flask, the heat of the lamp being sufficient to maintain reflux. After 7 min the photolysis was stopped. The resulting red solution of $Os(SnMe_3)Cl(CO)(PPh_3)_2$ **1** was cooled to 0 °C in an ice bath and pyridine (2 mL) was added. The red colour changed rapidly to pale yellow. The reaction was maintained at room temperature for 30 min and then the solvent was removed *in vacuo*. Recrystallisation from dichloromethane–ethanol gave **2** as a white microcrystalline solid in 63.8% yield. ν_{max}(Nujol mull)/cm^{-1}: 1878 (CO); δ_H($CDCl_3$, 400.133 MHz, 300 K) 0.15 [t, 3H, OsCH_3, ^3J(PH) 6.62 Hz], 0.24 [s, 6H, SnCH_3, ^2J(SnH) 21.0 Hz), 6.95–7.60 (m, 35H, PPh_3 and pyridine); δ_{Sn}($CDCl_3$, 149.144 MHz, 300 K) 186.63 [t, ^2J(SnP) 110.4 Hz]. Calc. for $C_{45}H_{44}NOClP_2OsSn$: C, 52.93; H, 4.34; N, 1.37. Found: C, 53.52; H, 4.32; N, 1.26%.

Synthesis of $\overline{Os(Me)(SnMe_2OC[Me]O)}(CO)(PPh_3)_2$ **3**: to the red solution of $Os(SnMe_3)Cl(CO)(PPh_3)_2$ **1** produced as described above but cooled only to 40 °C, was added NaO_2CMe (0.080 g, 0.975 mmol) dissolved in a mixture of ethanol (10 mL) and water (5 mL). The colour of the solution changed from deep red to pale yellow over 10 s. The reaction mixture was then stirred at room temp. for 30 min. Solvent removal *in vacuo* provided a pale yellow solid which was recrystallised from dichloromethane–ethanol to give colourless microcrystals of **3** in 76.4% yield, mp 167–171 °C. ν_{max}(Nujol mull)/cm^{-1}: 1881 (CO), 1535 (O_2CMe); δ_H($CDCl_3$, 400.133 MHz, 300 K) −0.19 [s, 6H, Sn·CH_3, ^2J(SnH) 21.4 Hz], 0.25 [t, 3H, OsCH_3, ^3J(PH) 7.12 Hz], 0.71 (s, 3H, O_2CCH_3), 7.25–7.70 (m, 30H, PPh_3); δ_{Sn}($CDCl_3$, 149.144 MHz, 300) 392.94 [t, ^2J(SnP) 119.4 Hz]. Calc. for $C_{42}H_{42}O_3P_2SnOs$: C, 52.24; H, 4.38%. Found: C, 53.53; H, 4.38%.

Received (in Bloomington, IN, USA) 22nd January 1999, Accepted 29th April 1999

Amine-functionalized metalloporphyrins stably fixated on well-defined ultralarge-pore Nb-doped silicates provided excellent catalytic oxidation activity for bulky substrates.

Numerous efforts have focused on fixating enzyme-mimic metalloporphyrin catalysts to prevent self-oxidation of the active centers and to achieve easy recovery of the catalysts.[1,2] Conventional supports for metalloporphyrins include polymer resins, amorphous porous silicas, layered clays and zeolites.[2] Leaching of the porphyrins from conventional supports and steric hindrance of the catalyst due to matrix pore geometry represent major impediments to the development of effective heterogenized metalloporphyrin catalysts. To prevent distortion of the porphyrin macrocycles and to facilitate the diffusion of reactants and products in catalytic reactions, it would be ideal to employ an inorganic support with a well-defined pore structure having pore openings > 2 nm. MCM-41 silicate[3] with its unique hexagonally-packed mesoporous structure represents an attractive host for supporting the large metalloporphyrin molecules.[4,5] A highly active oxidation catalyst has been prepared by anchoring of Ru-porphyrins *via* axial nitrogen ligands to the surface of MCM-41 modified with 3-aminopropyltriethoxysilane.[4]

Our laboratory has successfully synthesized novel transition metal oxide analogs of MCM-41 (*e.g.* Nb–TMS1 and Ta–TMS1) using a covalent linkage between the amine surfactant molecules and the transition metal precursors to ensure strong interaction between the templating agents and the inorganic species during the self-assembly process.[6] In this study, we have introduced transition metal dopants into the MCM-41 silicate framework to provide distinct sites for covalent bonding with the intentionally chosen NH_2 substituents on porphyrin macrocycles. This strategy effectively fixates the porphyrins without engaging their metal centers, leaving the latter accessible as active sites for oxidation catalysis. This technique is different from previous reports, which employed MCM-41 grafted with bulky compounds for ligand bonding with porphyrins,[4] or involved encapsulation of porphyrins through hydrothermal synthesis or ion-exchange *via* hindered diffusion in MCM-41 with relatively small mesopore size (22–24 Å).[5] By directly anchoring the porphyrin molecules onto the pore walls, steric effects associated with the support structure can be minimized. The importance of active site accessibility is further illustrated in this study, which presents a first investigation on the effects of pore size and porphyrin loading on the conversion of bulky substrates during oxidation catalysis.

Nb-doped mesoporous silicates NbSil-R (where R represents the precursor Si-to-Nb atomic ratio) were synthesized by mixing an aqueous cetyltrimethylammonium bromide (CTAB) surfactant solution with a 10 wt% aqueous tetramethylammonium silicate solution, followed by the addition of niobium ethoxide.[7] To increase the pore size of Nb-doped silicates, a mixture of cationic and neutral surfactants was used in the derivation of ultralarge-pore NbSi4-R.† Both NbSi4-R and NbSil-R gels were washed with ethanol and water, filtered and calcined at 540 °C in air for 6 h for surfactant removal. To examine the effect of support microstructure on catalytic activity, an amorphous Nb-doped silica gel was synthesized by sol–gel processing of tetraethoxysilane and niobium ethoxide under acidic conditions in the absence of surfactant templating agents. Iron porphyrins were introduced to the various calcined Nb-doped silicate supports by stirring in $CHCl_3$ for 24 h at room temp. The amine-functionalized iron porphyrins, Fe(III)T_{NH_2}PPBr, were prepared using a modified literature procedure.[8]

X-Ray diffraction (XRD) patterns illustrated the hexagonally-packed pore structure of our Nb-doped mesoporous silicate samples.[7] There was negligible hysteresis in the adsorption–desorption isotherms of NbSil-5.4 and NbSi4-20, and narrow BJH (Barrett–Joyner–Halenda) pore size distributions centered at 24 and 33 Å (Table 1) were noted for these two samples, respectively. NbSil-5.4 and NbSi4-20 possessed BET (Brunauer–Emmett–Teller) surface areas of 1140 and 864 $m^2\ g^{-1}$, respectively. By contrast, the amorphous Nb-doped SiO_2 sample had a type I isotherm characteristic of microporous materials (pore size < 20 Å) and a BET surface area of 557 $m^2\ g^{-1}$.

The diffuse-reflectance UV–VIS spectrum of the supported FeT_{NH_2}PPBr catalysts showed a broad Soret absorption band at 420 nm, indicating the presence of iron porphyrins in the mesoporous matrix. The appearance of the Q band implies no distortion of the conjugated porphyrin plane[9] in the large pore

Table 1 Oxidation over supported or unsupported FeT_{NH_2}PPBr catalysts under ambient conditions[a]

Support	Nb (wt%)	Fe[b]/ mg	Surface area/ $m^2\ g^{-1}$	Pore size/Å	Substrate	Conversion[c] (%)	Selectivity			TON/mol (mol Fe)$^{-1}$	Duration/h
							Oxide	1-ol	1-one		
—	—	0.69	—	—	Cyclohexene	100	79.4	13.3	7.3	40	2
NbSil-5.4	7.72	0.75	1140	24	Cyclohexene	86	58.2	25.1	17.7	32	2
NbSi4-20	6.00	0.14	864	33	Cyclohexene	85	78.9	12.1	9.0	170	2
—	—	0.14	—	—	Cyclooctene	85	100	—	—	170	5
NbSil-5.4	7.72	0.75	1140	24	Cyclooctene	57	100	—	—	21	5
NbSil-11.4	3.64	0.36	1477	23	Cyclooctene	42	100	—	—	33	5

Nb-doped silica gel	8.60	0.36	557	< 20	Cyclooctene	14	100	—	—	11	5

[a] Reaction conditions: 1 ml substrate, 4 ml CH_2Cl_2 and 0.5 mmol iodosobenzene. [b] Total Fe content from unsupported porphyrin catalysts, or from 100 mg of supported porphyrin catalysts. [c] Conversion was determined by GC and based on moles of iodobenzene formed during the reaction in air.

opening of our mesoporous support. The mesostructure of the Nb-doped mesoporous silicates was preserved upon $FeT_{NH_2}PPBr$ loading, as indicated by XRD. In addition, the absence of XRD peaks associated with iron porphyrin crystallites demonstrated that the iron porphyrins were highly dispersed in the mesoporous matrix. N_2 adsorption–desorption analyses confirmed that the iron porphyrins were loaded within the pore channels of the Nb-doped mesoporous silicates. For example, $FeT_{NH_2}PPBr$/NbSi4-20 has a lower BET surface area (666 $m^2\ g^{-1}$), pore volume (0.89 $cm^3\ g^{-1}$) and average pore size (32 Å), compared to the unloaded NbSi4-20 support (864 $m^2\ g^{-1}$, 1.14 $cm^3\ g^{-1}$, 33 Å).

The heterogeneous metalloporphyrin catalysts were tested at ambient conditions in a 25 ml batch micro-reactor (Table 1). Epoxidation of cyclohexene over $FeT_{NH_2}PPBr$/NbSil-5.4 gave a total conversion of 86% after only 2 h. In addition to cyclohexene oxide, cyclohex-2-en-1-ol and cyclohex-2-en-1-one were found as by-products possibly *via* allylic oxidation. Allylic oxidation might be initiated by O_2, resulting in cyclohexenyl peroxyl radicals.[10] Allylic oxidation has also been observed during cyclohexene epoxidation over polymer-supported iron porphyrin catalysts, which yielded cyclohex-2-en-1-one as the main product.[11] In comparison, significantly greater selectivity to cyclohexene oxide (58.2%) was achieved with our supported catalyst. This might be attributed to faster diffusion of the cyclohexene oxide products out of the mesoporous structure, thus alleviating further oxidation. The unsupported metalloporphyrin catalysts provided a faster reaction rate and produced an even better epoxide selectivity (79.4%) since there were no steric hindrance effects associated with substrate diffusion. We found that the use of a Nb-doped silicate support with larger pores greatly facilitated substrate diffusion. When loaded with $FeT_{NH_2}PPBr$, NbSi4-20 with 33 Å pores led to significantly higher epoxide selectivity (78.9%) than NbSil-5.4 (24 Å pores, 58.2% selectivity). Cyclohexene conversions over these two supported catalysts were similar after 2 h, even though a lower $FeT_{NH_2}PPBr$ loading was employed in NbSi4-20.

We also examined cyclooctene as a substrate that is less prone to O_2 oxidation than cyclohexene. Unlike cyclohexene, the selectivity to epoxide was 100% in the oxidation of cyclooctene. The conversion after 5 h of reaction was higher for $FeT_{NH_2}PPBr$/NbSil-5.4 than for $FeT_{NH_2}PPBr$/NbSil-11.4, as the higher Nb dopant concentration of the former allowed for a greater maximum metalloporphyrin loading level (Table 1). However, TON decreased with increased metalloporphyrin loading in the NbSil-R supports, suggesting that not all the metalloporphyrin sites were accessible to the bulky substrates for epoxidation catalysis, possibly due to the pore size constraint of the support matrix (23–24 Å).

The effect of support pore size on catalytic conversion of cyclooctene was examined systematically to investigate the role of diffusional restriction in the heterogenized catalysts. Among the various systems examined, $FeT_{NH_2}PPBr$ supported on sol–gel derived amorphous Nb-doped silica showed the lowest activity after 5 h (14% conversion, TON = 11). This could be attributed to steric constraints within this microporous support. With an identical Fe loading of 0.36 mg, mesoporous NbSil-11.4 provided 3 times greater activity (42% conversion, TON = 33) than microporous Nb-doped silica gel. Using mesoporous NbSi4-20, which has a larger pore size (33 Å) than NbSil-11.4 (23 Å), 98% epoxidation of cyclooctene was achieved in < 5 h despite the lower Fe loading (0.14 mg). An excellent TON of 196 was achieved over $FeT_{NH_2}PPBr$/NbSi4-20, which was even higher than that attained by the homogeneous $FeT_{NH_2}PPBr$ system (TON = 170). For both $FeT_{NH_2}PPBr$/NbSi4-20 and unsupported $FeT_{NH_2}PPBr$, a similar catalyst loading of 0.14 mg Fe was introduced to the reactant solution. The greater TON over $FeT_{NH_2}PPBr$/NbSi4-20 suggested that highly dispersed iron porphyrins fixated within supports of sufficiently large pore dimensions would have no diffusional constraints that inhibit substrate conversion, while preventing the detrimental self-oxidation of metalloporphyrins experienced in homogeneous systems. Our studies clearly showed that the support microstructure and iron porphyrin loading were important factors governing the catalyst performance.

During the course of the oxidation reactions, no catalyst leaching was detected in our systems, as indicated by the absence of the characteristic Soret band associated with free $Fe(III)T_{NH_2}PPBr$ in the UV–VIS spectra of the reaction solutions. This confirmed that $Fe(III)T_{NH_2}PPBr$ was stably immobilized within the porous Nb-doped silicate framework *via* the N–Nb ligand interaction. We further examined catalytic performance over multiple oxidation cycles, and found no degradation in conversion over our supported catalyst systems for at least three oxidation cycles. These studies demonstrated the effectiveness of heterogenizing catalysts through strong catalyst–support interactions, which could be established easily *via* appropriate doping of the porous support. The flexibility of pore size tailoring in Nb-doped mesoporous silicates further enabled us to optimize the activity of supported iron porphyrins by providing full accessibility to the catalytic sites. Such catalyst design considerations can be applied broadly to achieve heterogenized catalysts of bulky, stereospecific enzyme and organometallic complexes for effective and efficient synthesis of fine chemicals and pharmaceuticals.

Notes and references

† Synthesis of NbSi4-R. 5 mmol of CTAB and 2.5 mmol of tetradecylamine (Acros) were first dissolved in 108 g of water. 11.4 g of tetraethoxysilane (United Chemical) were gradually added to the surfactant solution at room temp. and stirred for 30 min. A measured amount of niobium ethoxide was then introduced dropwise into the loosley-bonded silica gel. The resulting gel mixture was adjusted to pH 11 with the addition of tetraethylammonium hydroxide, and stirred for 3 h at ambient conditions before subjected to hydrothermal treatment at 120 °C for 4 days.

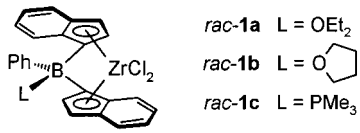
Chiral boron-bridged *ansa*-type zirconocenes can be prepared in a few simple steps; various donor molecules such as Et_2O, THF or PMe_3 undergo complexation at boron leading to catalysts having vastly different catalytic properties in Ziegler–Natta polymerization of propene; the PMe_3-containing catalyst is the most active and stereoselective (96% isotacticity).

The nature of substituents and the substitution pattern of titanocenes and zirconocenes are known to exert a pronounced influence on their activity and selectivity as catalysts in Ziegler–Natta polymerization.[1] Recently, several zirconocenes borylated at the Cp-moiety have been prepared and tested as catalysts.[2,3] None of them showed activity in the polymerization of propene, and some even failed to polymerize ethene,[3] possibly due to decomposition caused by the co-catalyst methylalumoxane (MAO) which is generally required as an activator. Here, we describe the synthesis of donor-coordinated *ansa*-type zirconocenes **1** and their use as catalysts in the

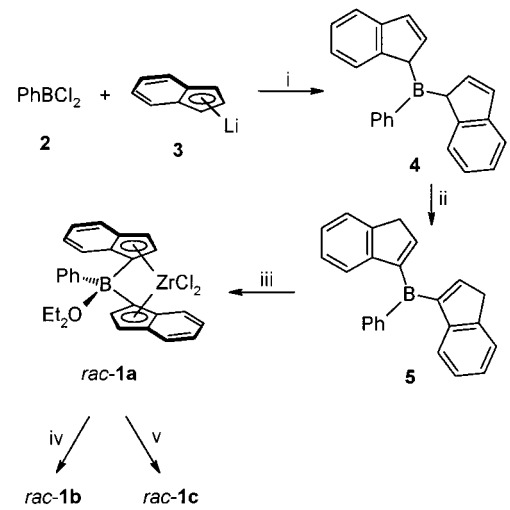


production of polypropene (PP). Significantly, it turns out that the nature of the donor ligand L determines the activity and stereoselectivity of the catalytic system, *i.e.* it can be used as a handle to control the polymerization.

The starting point for the synthesis of zirconocenes **1** was bis(1*H*-inden-1-yl)phenylborane **4**, readily accessible as a 1:1 mixture of *rac*- and *meso*-stereoisomers by the reaction of dichlorophenylborane **2** with indenyllithium **3** (Scheme 1). Although it was possible to convert **4** into the corresponding dianion by treatment with lithium bis(trimethylsilyl)amide (LiHMDS),[4] at least 20% of indenyllithium **3** was formed as an undesired side-product. This problem was solved by first isomerizing **4** into the thermodynamically more stable compound **5** in 95% yield by the action of catalytic amounts of PPr^i_3 and then effecting double deprotonation. Upon reacting $ZrCl_4$ with the intermediate dianion, a 1:1 mixture of *rac*-**1a** and *meso*-**1a** as well as non-identified side-products were formed.

Following removal of solid components, the solution was cooled to −20 °C, from which diastereomerically pure *rac*-**1a** crystallized as an orange–red solid in 12% yield. It was unambiguously characterized by ^{1}H, ^{11}B and ^{13}C NMR spectroscopy. Treatment of *rac*-**1a** with a solvent mixture of THF and CH_2Cl_2 led to the formation of *rac*-**1b** whereas the reaction with PMe_3 in toluene afforded adduct *rac*-**1c**. In both cases it was possible to obtain crystals suitable for an X-ray structural analysis (Fig. 1).† It should be mentioned that a different boron-bridged zirconocene has been described previously, but it was not possible to obtain crystals for an X-ray structural analysis, nor did it show activity towards ethene polymerization.[3] PMe_3 has been used to form adducts with other borylated metallocenes.[2c] The present C_1-symmetric compounds are structurally similar. In the case of *rac*-**1b** the angle between zirconium and the center of the two five-membered rings is 122.3(8)° (mean), which lies between that of the known Me_2C-bridged bis(indenyl)dichlorozirconium (118.2°)[5] and that of the Me_2Si-bridged analog (127.8°).[6] For *rac*-**1c** this angle was found to be 121.5(7)°, similar to that in *rac*-**1b**. Nevertheless, the Zr···B–O angle in*rac*-**1b** [120.4(6)°] is significantly smaller than the Zr···B–P angle in *rac*-**1c** [131.3(2)°].

In order to test the complexes in olefin polymerization, activation by treatment with MAO in toluene for 5 min was performed in all cases. Although compound *rac*-**1a** was found to be a fairly active catalyst (200–2600 kg PE mol[Zr]$^{-1}$ h^{-1})



Scheme 1 *Reagents and conditions*: i, Et_2O, −70 to 20 °C, 12 h (75–85%); ii, PPr^i_3 (2 mol%), Et_2O, 20 °C, 16 h (85%); iii, (*a*) LiHMDS (2.05 equiv.), Et_2O, −70 to 20 °C, 10 h; (*b*) $ZrCl_4$ (1 equiv.), toluene–Et_2O, −70 to 20 °C, 12 h; iv, THF–CH_2Cl_2 (1:1); v, PMe_3 (7 equiv.), toluene, −70 to 20 °C (21%).

[a] *Polymerization conditions*: 2 bar propene, 1 h, *ca*. 30 μmol l^{-1} [Zr].

for ethene polymerization producing high molecular weight polymer ($M_w \approx 700000$ g mol^{-1} as determined by GPC), this complex turned out to be a rather poor catalyst for the polymerization of propene. For example, using a Al/Zr ratio of 1000, activities of only 10–75 kg PP mol[Zr]$^{-1}$ h^{-1} were observed at room temperature with the production of atactic oily PP ($M_w \approx 20000$ g mol^{-1}). In contrast, the phosphine adduct *rac*-**1c** displayed remarkably high activity and stereoselectivity (Table 1). ^{13}C NMR spectra of typical PP samples obtained at various polymerization temperatures demonstrate high degrees of isotacticity, *e.g.* 96% isotacticity at room temperature.

Thus, complex *rac*-**1c** is the first boron-bridged zirconocene which catalyzes the polymerization of propene. It competes well with other *ansa*-type zirconocenes, especially with respect to isotacticity and molecular weight.[5,6] Since the ether analog *rac*-**1a** is a poor catalyst, it is obvious that the nature of the donor ligand at boron is crucial. A possible explanation is that for *rac*-**1a** excess MAO induces decomplexation of the donor ligand, thereby initiating the decomposition of the *ansa*-metallocene, whereas for *rac*-**1c** the donor ligand PMe_3 remains bonded to boron throughout the polymerization. Whatever the exact explanation may be, it is clear that the use of PMe_3 provides a handle to control activity and tacticity. It remains to be seen whether other phosphines or different donor ligands induce similar effects.

Received (in Cambridge, UK) 19th March 1999, Accepted 6th May 1999

The high density and strength of intermolecular hydrogen bonding between amine and sulfonamide units in the complex [Cu(Tstn)$_2$] [TstnH = *N*-(3-aminopropyl)-4-methylbenzenesulfonamide] give rise to energetically unfavourable coordination geometries at the copper centres in the solid state, in a manner analogous to the entatic state forced on metal active sites in metalloenzymes through secondary and tertiary protein structures.

The blue copper sites, present in several protein environments, exhibit a number of characteristics, derived from unusual electronic structures, that distinguish them from small molecule, copper(II) complexes.[1,2] These characteristics arise from distorted coordination geometries at the metal centre. The mismatch between the coordination environment supplied by the protein (determined by its amino acid sequence and hydrogen bonded structure), and that preferred by the metal centre (determined by electronic and steric effects) leads to this metastable 'entatic' or 'rack' state.[3,4] Entatic states have been modelled in small molecules by using rigid, predisposed[5] or sterically hindered ligands.[6] Although hydrogen bonded systems have been widely studied due to their potential to control solid state geometries[7] their application in imposing 'entatic states' in simple metal complexes has not been described previously.

In the system presented here we have used an unhindered ligand to engineer a high density of hydrogen bond donors and acceptors into a copper(II) complex, which lead to a large number of intermolecular interactions in the solid state. The copper(II) complex [Cu(Tstn)$_2$] exists in two crystalline forms which differ only in the disposition of intermolecular hydrogen bonds, but which have distorted copper coordination geometries that differ markedly from each other and from that seen in solution.

Reaction of TstnH, **1**, with copper acetate in boiling methanol gives a deep blue solution which, on evaporation at ambient temperature, deposits a dark blue crystalline compound, **2,** identified as [Cu(Tstn)$_2$].† If evaporation is prevented and the solution is instead left to stand at ambient temperature in a sealed vessel, it deposits a bright green crystalline compound, **3**, with the same molecular formula, [Cu(Tstn)$_2$]. In solution (DMF) the electronic and electrospray mass spectra of **2** and **3** are identical, suggesting that a single species is present. The compounds can be interconverted by dissolution in hot methanol; evaporation produces **2**, whilst crystallization on cooling and standing produces **3**, regardless of the starting complex. The marked difference in colour and in the measured solid state visible spectra, in the FTIR spectra and in the melting behaviour of the two solids led us to determine X-ray crystal structures for both to define the origin of these differences.‡

The asymmetric unit of the blue compound, **2**, contains two almost isostructural but independent [Cu(Tstn)$_2$] molecules (weighted rms deviation 1.062 Å) in which the ligands chelate the metal through deprotonated sulfonamide and amine nitrogens (Fig. 1). The coordination geometry (Table 1) at copper is highly distorted square planar (dihedral angles between the chelate planes 36.4 and 34.5° in the two independent molecules). All the amine protons form intermolecular hydrogen bonds (Table 2) to sulfonamide oxygens resulting in zigzag

Note: the N-H distances were fixed at 0.91 Å. H-bonds were assigned using the Platon program[13] to interactions of the oxygen and nitrogen atoms that were < 3.12 Å.

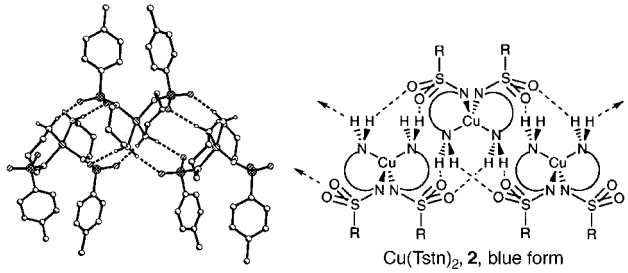

Fig. 2 Hydrogen bonded interactions in the solid state structure of **2** and a schematic representation of these interactions. Selected distances are given in Table 1.

chains of the complex extending through the structure (Fig. 2).

The asymmetric unit of the green compound, **3**, contains a single [Cu(Tstn)$_2$] molecule (Fig 3). The copper centre has a more nearly tetrahedral geometry; the dihedral angle between the two chelate planes is 58.4° and the N1–Cu–N5 chelate angles are larger, 93.3(2) and 93.7(3)°, than in **2** (average 90.9°). One of the oxygen atoms on each sulfonamide group forms two hydrogen bonds to amine protons. All of the amine protons are therefore involved in hydrogen bonds and each complex has eight S=O···H–N interactions, four as the donor and four as the acceptor. This results in the formation of a linear one dimensional hydrogen bonded polymer of [Cu(Tstn)$_2$] molecules (Fig. 4). Both **2** and **3** are very insoluble materials, dissolving only very slowly in polar solvents, reflecting the large number of intermolecular interactions. The number of hydrogen bonds that each molecule is involved in is the same in each structure. However, the mean of the O···N distances is shorter in **2** and the mean of the O···H–N angles is closer to 180°, suggesting that the hydrogen-bonded interactions are stronger than those in **3**. A survey of the CSD[8] reveals that the majority of copper(II) N_4 complexes with 1,3-diaminopropane based ligands are square planar[9] and deviation from this geometry is only observed with very bulky ligands.[6] The significant distortion toward the energetically unfavourable tetrahedral geometry observed in **2** and **3** appears to be a consequence of the system seeking the lowest free energy in the solid state *via* formation of very stable hydrogen bonding networks favoured by the ligands. This offers the intriguing possibility of controlling the electronic and magnetic properties of metal centres in the solid state using simple ligands designed to provide a matrix with unusual coordination sites for metals. Whilst such an approach is analogous to the entatic state[3] binding sites in proteins, unlike these, the unusual geometries are unlikely to be preserved in solution.

Harris for help in collecting X-ray data. Thanks to the Royal Society of Edinburgh (N. R.), the Leverhume Trust (L. C.) and Zeneca Specialties plc for funding.

Notes and references

† *Experimental procedures*: **1**: this was prepared by a modification of the method described by Kirsanov and Kirsanova.[10]

2: A solution of **1** (0.228 g, 1 mmol) in boiling methanol (10 mL) was added to a solution of copper acetate hydrate (0.1 g, 0.5 mmol) also in methanol (10 mL). Immediately a dark, ink blue solution was obtained. The solution was filtered hot then allowed to cool to room temperature. Evaporation of solvent at ambient temperature over 24 h gave dark blue crystals. These were collected by filtration, washed with methanol (3 × 5 mL), then diethyl ether (2 × 5 mL) and dried *in vacuo* (22 mg, 20% yield). Crystals suitable for X-ray diffraction were obtained by evaporation of a saturated methanol solution of the complex; mp 170 °C, decomp. 200 °C (Found: C, 46.39; H, 5.60; N, 10.60. Calc. for $C_{20}H_{30}N_4CuO_4S_2$: C, 46.36; H, 5.84; N, 10.81%); UV–VIS [λ_{max}/nm (ε dm^3 mol^{-1} cm^{-1})]: dmf, 620 (135); reflectance, 495; MS (FAB, nba) *m/z* [Cu(Tstn)$_2$]$^+$ 518.

3: This complex was prepared in an identical manner to **2**. However, instead of evaporating the dark blue solution it was left to stand in a sealed vessel at ambient temperature for 48 h giving bright green crystals. These were collected by filtration, washed with methanol (3 × 5 mL), then diethyl ether (2 × 5 mL) and dried *in vacuo* (24 mg, 22% yield). Crystals suitable for X-ray diffraction could be obtained using this method; mp (18 °C decomp.) 200 °C (Found: C, 46.36; H, 5.91; N, 10.79. Calc. for $C_{20}H_{30}N_4CuO_4S_2$: C, 46.36; H, 5.84; N, 10.81%). UV–VIS [λ_{max}/nm (ε dm^3 mol^{-1} cm^{-1})]: dmf, 620 (135); reflectance, 510. MS (FAB, nba) *m/z* [Cu(Tstn)$_2$]$^+$ 518.

‡ *Crystal data:* both structures were solved by Patterson methods (DIRDIF)[11] and refined against F^2 (SHEXL-97).[12] **2**: $C_{20}H_{30}N_4CuO_4S_2$, M = 518.14, monoclinic, space group $P2_1/c$, a = 15.019(6), b = 24.783(10), c = 12.873(8) Å, β = 101.43(4)°, U = 4696(4), Z = 8, D_c = 1.466 g cm^{-3}, T = 220(2) K, μ (Cu-K$_\alpha$) = 3.26 mm^{-1}, wR_2 = 0.1923 (8543 independent reflections), R = 0.0612 [$F > 4\sigma(F)$].

Received (in Liverpool, UK) 4th March 1999, Accepted 29th April 1999

The photocyclization of methyl-substituted α-acetamido butyrophenone derivatives is highly stereoselective and leads to 2-aminocyclobutanols with complete control of three new stereogenic centers.

The term Yang cyclization describes the formation of cyclobutanols from 1-hydroxytetramethylene biradicals which are produced *via* photochemical γ-hydrogen abstraction.[1] In the course of this reaction up to eight diastereoisomers could be formed from one chiral substrate molecule. Three subsequent steps influence the chemo- and stereoselectivity of this reaction: (i) γ-H abstraction, (ii) biradical dynamics and (iii) biradical combination *vs.* cleavage reaction. Triplet excited carbonyls give rise to triplet 1,4-biradicals and, consequently, the lifetime of these intermediates (100–1000 ns)[2] rises due to slow spin inversion processes (ISC). The γ-H abstraction proceeds most likely through a six-membered chair-like transition state.[3] Detailed mechanistic investigations have been performed by Wagner and co-workers which also included stereochemical probing.[4] During our studies on photochemical transformations of enantiomerically pure α-amino acids (N-activation mode)[5] we became interested in using Yang cyclizations as a simple tool for the synthesis of 2-aminocyclobutanols (C-activation mode). As substrates α-acetamido butyrophenone derivatives **1a**–**f** were synthesized from the corresponding amino acids by a three-step reaction protocol.[6] The photochemical behaviour of these compounds was investigated by irradiation with light λ > 320 nm in benzene solutions (Scheme 1). The *tert*-leucine derivative **1a** gave the cyclobutanol **2a** (Φ_C = 0.11 ± 0.02) and the Norrish II fragmentation product **3** (Φ_F = 0.08 ± 0.02).[7] The Yang cyclization product was isolated in 45% yield as a single diastereoisomer. The *tert*-leucine **1a** and the leucine derivative **1b**, respectively, were transformed into cyclobutanols with only one additional stereogenic center and thus solely show the influence of a given stereogenic center on a proximate radical center. In both cases, the *cis*-diastereoisomers were formed with ds > 96%.

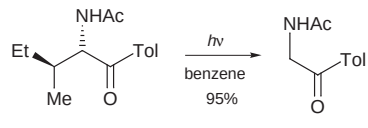
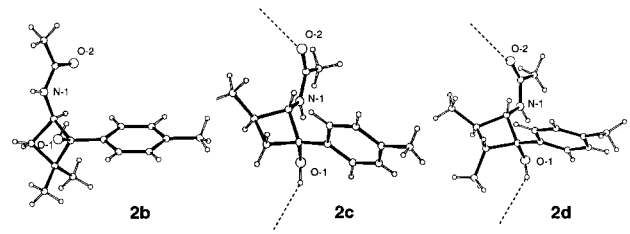
(2*R*,3*S*)-**1d** **2d**



(2*S*,3*S*)-**1d** **3**

Scheme 1 C/F = cyclization/fragmentation ratio.

Characteristic NMR shifts were observed for H-2 (δ 4.2–4.8) and the methyl groups in **2b** which showed strong anisotropic effects ($\Delta\delta$ = 0.45 ppm).[8] Additional proof came from the X-ray structure analysis for **2b** (Fig. 1).† A reasonable explanation for the high 1,2-asymmetric induction might be an intramolecular hydrogen bond at the stage of the triplet 1,4-biradical which has already been described for Yang cyclizations of α-ester-substituted ketones.[9] The valine derivative **1c** cyclized more efficiently (Φ_C = 0.19 ± 0.02) and gave the cyclobutanol **2c** in 74% yield with ds > 96%. The relative configuration was established *via* X-ray structure analysis.† Two explanations for the high 1,3-asymmetric induction are possible: selective γ-H abstraction from one of the diastereotopic methyl groups or non-selective γ-H abstraction followed by selection at the biradical stage (radical combination *vs.* cleavage and/or hydrogen back transfer). Biradical dynamics most likely were responsible for the results obtained with the isoleucine and alloisoleucine derivatives (2*S*,3*S*)-**1d** and (2*R*,3*S*)-**1d**. Whereas the (2*S*,3*S*)-isomer gave exclusively the Norrish II cleavage product **3**, (2*R*,3*S*)-**1d** cyclized efficiently to give the cyclobutanol **2d**. The latter compound again was formed diastereoisomerically pure (*i.e.* ds > 96%) with complete control of the three newly formed stereogenic centers. X-Ray structure analysis completed the configuration analysis.†

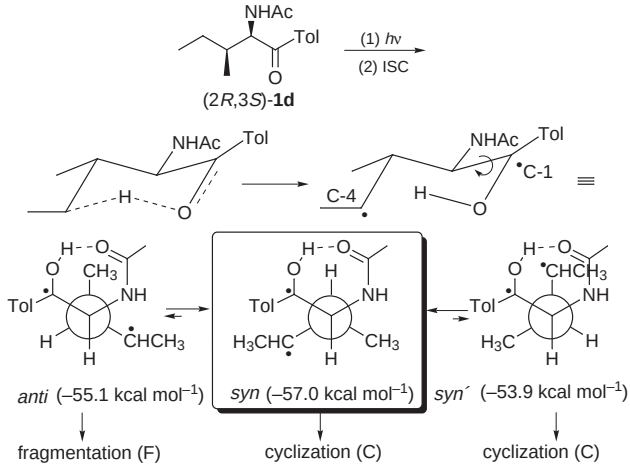


2b **2c** **2d**

Fig. 1 Crystal structures of the cyclobutanols **2b**, **2c** and **2d**.

Finally, the unbranched substrates **2e** and **2f** (from norvaline and norleucine, respectively) were investigated. Both substrates preferentially showed fragmentation and, as a minor reaction path, formation of the cyclobutanols **2e**,**f** with excellent diastereoselectivity. Thus, the radical coupling step also proceeds with high *inherent* stereoselectivity in addition to the 1,2-*induced* stereoselectivity.

In the mechanistic scenario (*vide supra*) for the Yang cyclization process *induced* and *inherent* diastereoselectivity are related to two different steps: biradical dynamics and spin inversion coupled with radical-radical combination. This relation is depicted in Scheme 2 for substrate (2*R*,3*S*)-**2d**. After hydrogen abstraction from the more reactive methylene group, equilibration of the triplet 1,4-biradical leads to three possible conformers, *anti*, *syn* and *syn*′. The energies of these species were calculated using the PM3 method. The cyclization path is not available from the *anti*-isomer, however, this structure is less favourable compared with the *syn*-isomer. Hydrogen



Scheme 2 Mechanistic scenario for the photocyclization of (2*R*,3*S*)-**1d**.

bonding stabilizes all three possible conformers and is the major contribution to the high 1,2-asymmetric induction.

The reverse is the case for (2*S*,3*S*)-**2d** and fragmentation dominates the reaction due to the more stable triplet *anti* 1,4-biradical. This theory however, does not take into account the fact that the calculated biradical minima structures are not necessarily identical with the actual ISC-reactive structures. Spin–orbit coupling, the major contribution to triplet/singlet ISC, is higher for *syn*-biradicals[10] and depends on the orientation of the p-orbitals localized at the spin-bearing carbon atoms.[11] An orthogonal orientation of these orbitals prior to C–C bond formation leads to a *trans* arrangement of the methyl at C-4 and the tolyl group at C-1 (inherent diastereoselectivity). Thus, the *induced* and *inherent* stereoselectivity of the Yang cyclization can be correlated with different selection stages of the reaction.

This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Universität zu Köln (postgraduate grant for H. H.)

Regulation of α/β-folding of a designed peptide by haem binding

Seiji Sakamoto, Ikuo Obataya, Akihiko Ueno and Hisakazu Mihara*†

Department of Bioengineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, Nagatsuta, Yokohama 226-8501, Japan. E-mail: hmihara@bio.titech.ac.jp

Received (in Cambridge, UK) 26th April 1999, Accepted 12th May 1999

A designed peptide H2α17-I bound Fe^{III}–mesoporphyrin (haem); and the haem-binding prevented the peptide forming β-sheet aggregates by facilitating the formation of an α-helix tetramer, indicating that the folding state of artificially designed peptides could be regulated by cofactor binding.

Iron porphyrins occur widely in nature as cofactors of haemproteins and display diverse functions. In addition to the wide range of iron porphyrin reactions, iron porphyrins are important factors in defining the three-dimensional (3D) structure of haemproteins, because the removal of a porphyrin cofactor from natural haemproteins caused perturbation and/or destabilization of protein 3D structures.[1–4] So far, in the field of *de novo* protein design, considerable effort has been devoted to construction of polypeptide 3D structure conjugated with porphyrin molecules *via* chelation[5–7] or covalent linkage with peptides.[8–11] However, to establish an artificial haemprotein that meets the minimal requirements for its function, it will be necessary to understand the role of porphyrin cofactors as structural elements of haemproteins. In a previous paper, we described the design of a two-α-helix peptide H2α17-L, whose binding to Fe^{III}–mesoporphyrin (haem) stabilized an α-helical structure and induced a change in the molecular-assembly of the peptide from a monomeric to a tetrameric form.[7b] These results demonstrated that the haem had a significant effect on the 3D-structure and molecular association of an artificially designed polypeptide. Here we examine the effects of amino acid disposition around the axial ligand on the haem-binding property, using novel designed peptides H2α17-I and H2α17-V. Furthermore, we found that the haem binding affected the secondary structure and molecular-association state of the peptide H2α17-I.

The design of H2α17-I and H2α17-V was based on that of the template peptide H2α17-L,[7b] which took an α-helix structure in the buffer both with and without bound haem. The amino acid sequences of H2α17-I and H2α17-V were identical to that of H2α17-L except for their hydrophobic residues (Fig. 1). In the cases of H2α17-I and H2α17-V, hydrophobic Ile and Val residues, respectively, were introduced at the 5th, 6th, 12th and 13th positions instead of the Leu residues of H2α17-L. In the designed α-helix structure, four hydrophobic residues per helix could be arranged around the His[9] to make a hydrophobic haem binding site and a haem would be deployed between the two helices. In the cases of H2α17-I and H2α17-V, however, it was predicted that the folded state of the amphiphilic α-helical sequences would be significantly destabilized by the introduction of four Ile or Val residues, which prefer a β-strand rather than an α-helix structure.[12] Additionally, when the peptide sequences were drawn as a β-sheet model, the peptide could take a kind of amphiphilic β-sheet structure. However, the haem will bind to the folded-state of an α-helical structure with higher affinity than to that of a β-structure, because the hydrophobic residues, which form the hydrophobic haem-binding site, can be arranged around the His,[9] only when the peptides take an α-helix structure. The peptides were synthesized by solid-phase method using Fmoc chemistry and purified with semi-preparative HPLC. The peptides H2α17-I and H2α17-V gave molecular ion peaks at *m/z* 4011.9 [$(M + H)^+$] (calc. 4011.7) and 3898.8 [$(M + H)^+$] (calc. 3899.0), respectively, on matrix assisted laser desorption ionization of time-of-flight mass spectrometry.

Circular dichroism (CD) studies revealed that the peptides H2α17-I and H2α17-V showed typical α-helical patterns with double negative maxima at 207 and 222 nm in trifluoroethanol (TFE), which was known to be an α-helix stabilizing solvent.[13] Upon dilution in 2.0×10^{-2} mol dm^{-3} Tris HCl buffer (pH 7.4) from TFE stock solution of H2α17-I and H2α17-V (final TFE concentration was 1.0%), the peptides showed CD spectra typical of a β-structure with a single negative maximum at 218 nm and a positive maximum at 198 nm (Fig. 2). Additionally, Fourier transform infrared (FT-IR) spectra of the peptides in cast films exhibited narrow peaks for the amide I and II bands: H2α17-I, 1630 and 1555 cm^{-1}; H2α17-V, 1627 and 1553 cm^{-1}, respectively. These wavenumbers were characteristic of a β-structure rather than an α-helix or a random structure.[14] In the absence of haem, H2α17-I and H2α17-V gave no peak on the size exclusion column, suggesting that the peptides formed β-sheet aggregates in multiple states. The formation of β-sheet aggregates was also confirmed by the binding of Congo Red dye, which stains β-sheet proteins, such as amyloid and prion proteins.[15a] Because the template peptide H2α17-L took an α-helix structure and was in a monomeric form under the same conditions, the β-conformation of the peptides in the buffer is due to the high β-propensity of the Ile and Val residues.

On the contrary to the above results, when the TFE stock solution of H2α17-I was diluted with buffer containing haem (1.0 equiv.), the peptide showed a typical α-helical pattern with

[haem] = 1.0×10^{-5} mol dm^{-3}. Inset: Plots of absorbance at the Soret band of haem as a function of concentration, peptide (●) H2α17-I and (○) H2α17-V.

double negative maxima at 208 and 222 nm in the buffer (containing 1.0% TFE) (Fig. 2). From the ellipticity at 222 nm ($[\theta]_{222}$ = −22 500 deg cm^2 dmol^{-1}), the α-helicity was estimated as 71%.[16] Size-exclusion chromatography and sedimentation equilibrium studies revealed that the peptide H2α17-I was in a tetrameric form (MW_{obs} = 18 000, 3.9-mer) after haem binding, as was observed in H2α17-L.[7b] That is, the haem binding induced a drastic alteration of the secondary structure and molecular association state from β-sheet aggregates to an α-helical tetrameric assembly. The peptide H2α17-I folded into a β-structure at acidic pH (4.0–6.0) in the presence and absence of haem. Because the pK_a of His is reported as *ca*. 6.4,[17] the pH effect is attributed to the protonation of the His side chains such that they cannot act as ligands. Therefore, we concluded that H2α17-I folded into an α-helix structure *via* haem binding through a ligation with His residues. In contrast, the peptide H2α17-V took a β-structure even in the presence of haem at pH 7.4, suggesting that H2α17-V could not bind the haem effectively. CD studies demonstrated that the secondary structure and molecular assembly of the designed peptide was regulated by the haem binding. Although the α-form (with haem) was completely denatured with 6.0 mol dm^{-3} urea (urea denaturation midpoint; $[\text{urea}]_{1/2}$ = 2.7 mol dm^{-3}, free energy of unfolding; ΔG_{H_2O} = −7.6 kJ mol^{-1}), the CD spectrum of the β-form (without haem) was not changed even with 7.0 mol dm^{-3} urea, indicating that the β-form is much more stable than the α-form. Thus, the alternation of peptide α/β folding appeared to be regulated by a kinetic mechanism rather than a thermodynamic one. Even in the absence of haem, immediately after dilution from the TFE solution, it is predicted that the peptide takes an α-helix structure,[15] although the α-helix structure is unstable and the rapid transition from the α- to the β-form follows. In the presence of haem, however, the haem binds the metastable α-form and prevents the peptide progressing to a β-form. Indeed, after formation of the β-sheet structure, the peptide could not bind the haem and the α-helix structure was not recovered by the addition of haem.

To further characterize the haem binding with the peptides, UV-VIS titration of the haem was carried out in buffer. With increasing concentration of H2α17-I an increase of the Soret band at 406 nm and a decrease of the band at 355 nm of haem were observed (Fig. 3). The UV-VIS spectrum of haem in the presence of peptide resembles those of natural cytochromes with low-spin six-coordinate iron.[7] The binding constant (K_a), determined from the absorbance change at the Soret band using a single site binding equation, was 1.0×10^7 dm^3 mol^{-1} (Fig. 3, inset), comparable to that of H2α17-L (K_a = 1.1×10^7 dm^3 mol^{-1}).[7b] On the other hand, addition of H2α17-V caused little increase of the Soret band, indicating that the peptide could not bind the haem effectively in this concentration range. The computer modeling study suggested that the side chain of the Val residue was too small to make effective van der Waals contact with the porphyrin plane, when the haem was positioned between the helices with energetically favorable side-chain torsional angles of the His ligands.[10,11] Additionally, the hydrophobicity of Val is lower than that of Ile and Leu,[18] These results revealed that the nature of amino acids at the haem binding site was important for the effective haem-binding by the two-α-helix peptides. There is enough hydrophobicity and van der Waals volume in Leu and Ile for effective haem binding in the two-α-helix form.

In conclusion, we successfully designed and synthesized the peptide H2α17-I with the unique property that the folding state was controlled by the haem-binding. The haem binding prevented the peptide from forming β-sheet aggregates by facilitating the formation of an α-helix tetramer. These findings indicate the importance of haem cofactor as a structural element of artificial haem-conjugated proteins and polypeptides. This kind of work will lead to studies to construct mini-haemproteins and elucidate their folding and application.

Decarboxylative elimination of enol triflates as a general synthesis of acetylenes

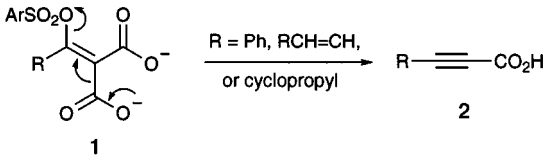
Ian Fleming* and Chandrashekar Ramarao

Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: if10000@cam.ac.uk

Received (in Liverpool, UK) 9th March 1999, Accepted 28th April 1999

Decarboxylative elimination of a range of enol triflates 11 of β-keto esters gives acetylenes 12.

We established long ago in a series of papers[1,2] that enol arenesulfonates **1** derived from acylmalonates underwent concerted decarboxylative elimination to give acetylenic acids **2** (Scheme 1), provided that the group R was cation-stabilising. Thus the reaction worked if the group R was aryl, vinyl or cyclopropyl, but not if it was alkyl or ethynyl, a severe limitation which deterred us from investigating the synthetic potential of this reaction any further. In the meantime, better leaving groups than arenesulfonate have been developed,[3] and so we have returned to this remarkably mild reaction to see if it could be made into a more general synthesis of acetylenes.

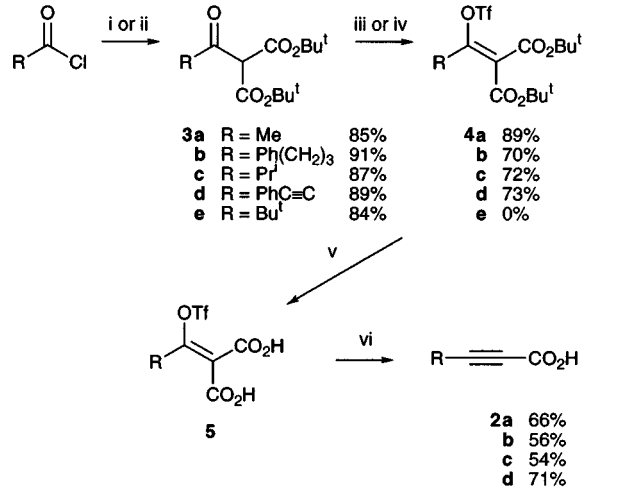


Scheme 1

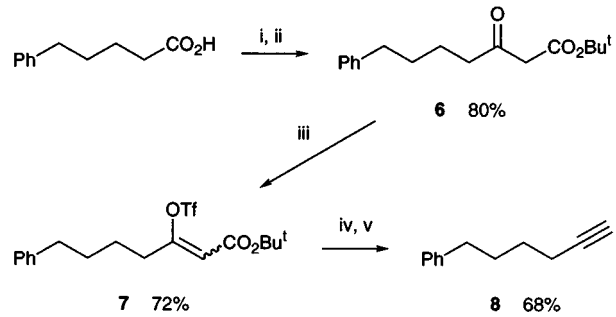
Although we know of no relevant quantitative data for elimination reactions, it is known that 1-adamantyl trifluoromethanesulfonate (triflate) undergoes S_N1 solvolysis 10^5 to 10^6 times faster than the corresponding toluene-*p*-sulfonate (tosylate),[4] and that ethyl triflate undergoes S_N2 solvolysis in AcOH 10^4 faster than ethyl tosylate.[5] We also knew that the rate of the decarboxylative elimination **1** → **2** was sensitive to how good the leaving group was, although not quite to the same extent as an S_N1 reaction. Thus the decarboxylative elimination had a ρ value for *p*-substituted benzenesulfonates of 1.16,[2] whereas the S_N1 reaction of 1-adamantyl arenesulfonates has a ρ value of 1.76.[6] Putting these facts together implied that enol triflates ought to undergo decarboxylative elimination much faster than enol arenesulfonates, and quite probably fast enough to work for those cases that had failed before. We carried out the sequence in Scheme 2 to prepare the enol triflate dicarboxylic acids **5**, and dissolved them in aqueous $NaHCO_3$. They cleanly gave the acetylenic acids **2a**–**d**, having alkyl and ethynyl groups R, showing that the main limitation in our earlier work had been overcome.

With a more general reaction now at our disposal, we investigated whether the second carboxylic acid group was necessary. It had always been possible that the second carboxylate ion, present in all our earlier reactions, had accelerated the decarboxylative elimination by a Coulombic repulsion. We prepared the enol triflate **7** (Scheme 3). On treatment with base this gave the terminal acetylene **8**, showing that the second carboxy group was unnecessary. In this case, K_2CO_3 in refluxing acetone proved to be better than aqueous $NaHCO_3$.

We also prepared a small range of acetylenes **12** and **14** with alkyl groups on both sides (Scheme 4), again with greater success using K_2CO_3 in acetone as the base. We were not successful in our efforts to prepare an enol triflate with branched alkyl groups on both sides of the intended triple bond, neither of the β-keto esters **15** giving an enol triflate, although we were successful with examples having branched chains separately on each side, as in the synthesis of the acetylenes **12c** and **14**. We



Scheme 2 *Reagents and conditions*: i, $CH_2(CO_2Bu^t)_2$, $Mg(OEt)_2$; ii, $CH_2(CO_2Bu^t)_2$, Et_3N; iii, Tf_2O, Et_3N, CH_2Cl_2, 0 °C → rt, 3 h; iv, NaH, Et_2O, 0 °C, 1 h, then Tf_2O, 0 °C, then rt, 1 h; v, TFA, rt, 30 min; vi, $NaHCO_3$, H_2O, rt, 12 h.

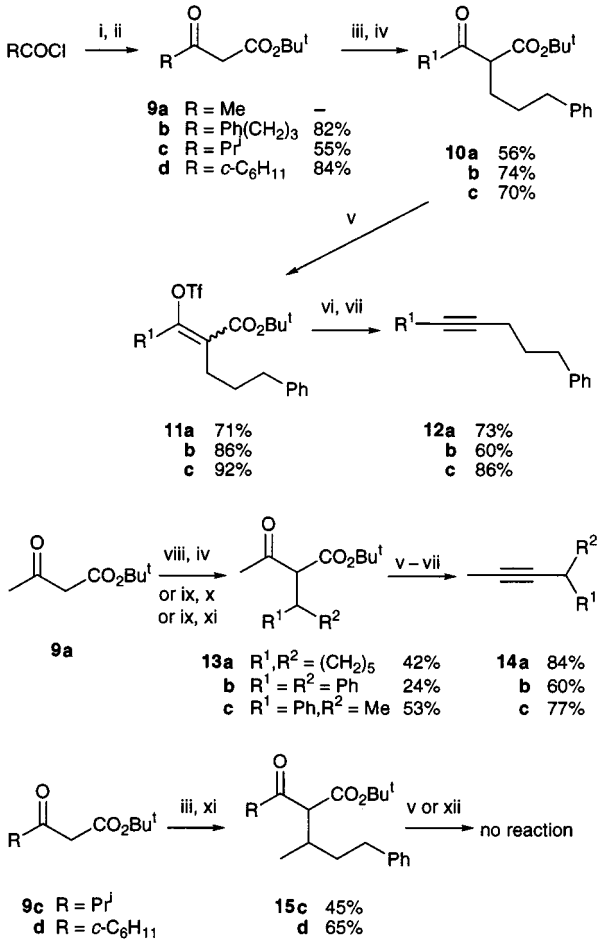


Scheme 3 *Reagents and conditions*: i, carbonyldiimidazole, THF, rt, 1 h; ii, $LiCH_2CO_2Bu^t$, −78 °C, 1 h; iii, NaH, Et_2O, 0 °C, 1 h, then Tf_2O, 0 °C → rt, 1 h; iv, TFA, rt, 30 min; v, K_2CO_3, Me_2CO, reflux, 4 h.

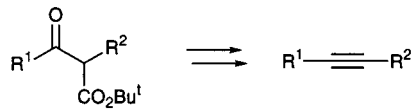
were also unable to prepare an enol triflate adjacent to a *tert*-butyl group when we treated di-*tert*-butyl pivaloylmalonate **3e** with a variety of bases and Tf_2O.

Except for these limitations, we now have a fairly general synthesis of acetylenes based on a β-keto ester system (Scheme 5), with a wide variety of methods for incorporating or attaching the groups R^1 and R^2 on each side of the ketone group,[7] some of which are illustrated by the standard but far from opitimised methods we used in Schemes 2–4. The overall transformation is similar to that achieved by Zard's intriguing reaction,[8] in which β-keto esters are treated successively with hydroxylamine and with $NaNO_2$ and iron(II) sulfate, but the pathway described here is mechanistically more straightforward, and probably less apt to give byproducts.

The following is a representative recipe for the preparation of the enol triflate and for the decarboxylative elimination. The keto-ester **13c** (7 g, 26.7 mmol) in dry Et_2O (50 cm^3) was added to a prewashed suspension of NaH (60% dispersion in mineral oil, 2.13 g, 53.4 mmol) at 0 °C and stirred for 1 h. Tf_2O (6.6 cm^3, 40.0 mmol) was added and the reaction mixture was stirred for 1 h at 0 °C and 1 h at room temperature. The mixture was cooled



Scheme 4 *Reagents and conditions*: i, Meldrum's acid, Py, CH_2Cl_2, 0 °C → rt, 3 h; ii, Bu^{t}OH, toluene, reflux, 4 h; iii, $Ph(CH_2)_2CHO$, $TiCl_4$, Py, THF, rt, 16 h; iv, H_2, Pd/C, MeOH, rt, 12 h; v, NaH, Et_2O, 0 °C, 1 h, then Tf_2O, 0 °C → rt, 2 h; vi, TFA, rt, 30 min; vii, K_2CO_3, Me_2CO, reflux, 4–5 h; viii, cyclohexanone, $TiCl_4$, Py, CH_2Cl_2, rt, 16 h; ix, PhCHO, *c*-$C_5H_{10}NH$, EtOH, 5 °C, 14 h; x, Ph_2CuLi, THF, −78 °C, 1 h; xi, Me_2CuLi, THF, −78 °C, 1 h; xii, Tf_2O and several other bases: KH, 2,6-di-*tert*-butylpyridine, *etc.*



Scheme 5

and quenched carefully with water and extracted with Et_2O (2 × 60 cm^3). The extract was washed with saturated $NaHCO_3$ (60 cm^3) and brine (60 cm^3), dried ($MgSO_4$) and evaporated under reduced pressure to give 3-*tert*-butoxycarbonyl-4-phenylpent-2-en-2-yl trifluoromethanesulfonate (8.94 g, 85%); R_f [EtOAc–light petroleum (bp 40–60 °C), 20 : 80] 0.77; ν_{max} (film)/cm^{-1} 1721 (C=O) and 1602 (Ph); δ_H(250 MHz; $CDCl_3$) 7.3–7.2 (5H, m, Ph), 3.86 (1H, q, *J* 7.3, PhC*H*), 2.1 (3H, s, *Me*C=C), 1.57 (3H, d, *J* 7.2, *Me*CH) and 1.31 (9H, s, Bu^t). The triflate was unstable and had to be used in the next step without further characterisation. The triflate (8.94 g, 22.7 mmol) was stirred in TFA (10 cm^3) for 40 min at room temperature. The excess TFA was removed under reduced pressure to give a light yellow–brown solid, which was dissolved in acetone (50 cm^3). K_2CO_3 (7.3 g, 53.4 mmol) was added and the reaction mixture refluxed for 4 h, cooled, poured into water and extracted with Et_2O. The extract was washed with dilute HCl (50 cm^3), water (50 cm^3) and brine (50 cm^3), dried ($MgSO_4$), and evaporated under reduced pressure. The residue was chromatographed [SiO_2, light petroleum (bp 40–60 °C)] to give the 4-phenylpent-2-yne[9] **14c** (2.97 g, 77% from the keto ester); R_f [EtOAc–light petroleum (bp 40–60 °C), 10 : 90] 0.85; ν_{max}(film)/cm^{-1} 1450 (Ph); δ_H(250 MHz; $CDCl_3$) 7.4–7.2 (5H, m, Ph), 3.72 (1H, m, PhC*H*), 1.88 (3 H, d, *J* 2.5, *Me*C≡C) and 1.47 (3H, d, *J* 7.2, *Me*CH); δ_C(250 MHz; $CDCl_3$) 144−, 128.4+, 126.8+, 126.4+, 82, 77.5−, 31.9+, 24.6+ and 3.6+ (+ indicates methyl or methine and − indicates methylene or quaternary carbon).

We thank Avra Laboratories, Hyderabad, for a maintenance grant (C. R.).

Sono-electrosynthesis: electrode depassivation and trapping of insoluble redox products

Richard P. Akkermans, Sarah L. Roberts and Richard G. Compton*

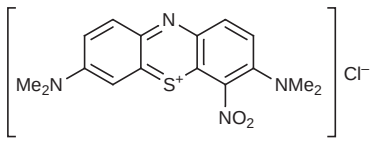
Physical and Theoretical Chemistry Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QZ. E-mail: compton@ermine.ox.ac.uk

Received (in Cambridge, UK) 16th March 1999, Accepted 7th May 1999

The electrosynthesis of water-insoluble products such as *leuco*-Methylene Green from soluble precursors can be accomplished using an emulsion formed *via* insonation so that the organic phase constantly extracts the product and simultaneously prevents the electrode passivation which would occur in aqueous solution alone.

The introduction of power ultrasound into electrochemical systems has many benefits,[1,2] including first, extremely enhanced mass transport resulting from acoustic streaming[3] or microjetting,[4] and second, electrode activation arising from cavitational erosion.[5] In addition sonication has been used to permit the electrochemical study of essentially water-insoluble organic species in aqueous solution.[6,7]

Here we report a new and general use of ultrasonically generated emulsions in electrosynthesis. Many potentially viable electrode processes are inhibited if not entirely passivated by the adsorption, precipitation or polymerisation of reaction products or intermediates on the electrode surface. This note addresses two such reactions in aqueous solution, first the two-electron reduction of Methylene Green[8–10] (MG, **1**) to *leuco*-Methylene Green, and second the oxidation of iodide to solid iodine,[11–13] both at platinum electrodes.



1

The presence of an organic phase which emulsifies under insonation is shown to lead to (i) 'clean' useful voltammetry, (ii) the extraction of reduction products and (iii) the preservation of electrode activity where in aqueous solution alone passivation would preclude useful electrosynthesis.

Experiments were conducted using a 250 ml sonovoltammetric cell at 20 °C, which incorporated a 13 mm diameter, 20 kHz titanium tipped ultrasonic horn probe (Sonics & Materials). Ultrasound power levels up to 50 W cm^{-2} were employed[14,15] and electrochemical measurements carried out using a commercial three-electrode potentiostat (Eco-Chemie, Utrecht) except that the horn probe was electrically isolated as previously reported.[16] Full descriptions of sonoelectrochemical and sonovoltammetric procedures have appeared elsewhere.[17]

Cyclic voltammograms for 0.2 and 2 mM aqueous solutions of Methylene Green in 0.1 M KCl, buffered at pH 6.5 ± 0.1 with 0.2 M KH_2PO_4, were recorded in quiescent solution. A typical 'silent' voltammogram is shown in Fig. 1. The two peaks can be attributed to the processes in eqn. (1) and (2), where *l*-MG is *leuco*-Methylene Green. The two-electron character of each wave was evidenced first by Tafel analysis and second by the observation that the reduction potentials shifted by *ca.* 30 mV per pH unit in the pH range 6 to 8 consistent with a two-electron, one proton reduction. Notice the large 'stripping' peak corresponding to the re-oxidation of the insoluble surface-bound *leuco*-Methylene Green.

$$MG_{(aq)} + H^+ + 2e^- \rightleftharpoons l\text{-}MG_{(s)} \quad E^{red}_{peak} = -0.09 \text{ V } vs. \text{ SCE} \quad (1)$$

$$MG_{(aq)} + H^+ + 2e^- \rightleftharpoons l\text{-}MG_{(aq)} \quad E^{red}_{peak} = -0.22 \text{ V } vs. \text{ SCE} \quad (2)$$

When 25 W cm^{-2} of power ultrasound is introduced into the cell the voltammetry changes markedly due to the significantly enhanced mass transport and is shown in Fig. 2. Notice first that a much larger stripping peak is seen corresponding to the greater deposition resulting from the enhanced currents flowing due to the increased mass transport. Second, whilst there is a mass-transport limited current analogous to a polarogram relating to the two-electron processes, reflecting the constant flux of material due to steady-state convection/diffusion, the wave at the more negative potential shows a progressive decrease of signal at potentials negative of *ca.* −0.23 V *vs.* SCE. This electrode passivation was also seen (i) under silent conditions and (ii) during hydrodynamic voltammetry (for example at a channel electrode) and effectively precludes the electro-

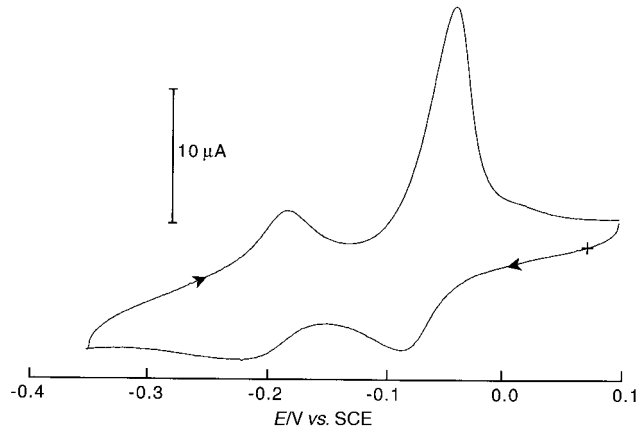


Fig. 1 'Silent' cyclic voltammogram of 0.2 mM MG in 0.1 M KCl/0.2 M $KH_2PO_{4(aq)}$ at pH 6.5. Scan rate was 10 mV s^{-1} and the working electrode was a 6 mm diameter Pt disc.

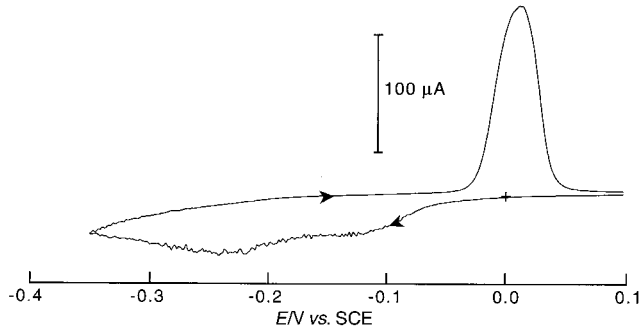

Fig. 2 Cyclic voltammogram of 0.2 mM MG in 0.1 M KCl/0.2 M $KH_2PO_{4(aq)}$ at pH 6.5. 25 W cm^{-2} ultrasound was employed at a horn-to-electrode distance of 22 mm. Scan rate was 10 mV s^{-1} and the working electrode was a 6 mm diameter Pt disc.

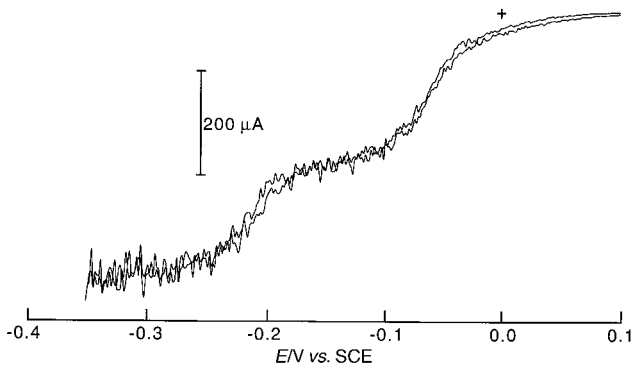

Fig. 3 Cyclic voltammogram of 2 mM MG in 0.1 M KCl/0.2 M $KH_2PO_{4(aq)}$ at pH 6.5 and 20% (v/v) toluene (emulsified). 18 W cm^{-2} ultrasound was employed at a horn-to-electrode distance of 19 mm. Scan rate was 10 mV s^{-1} and the working electrode was a 6 mm diameter Pt disc.

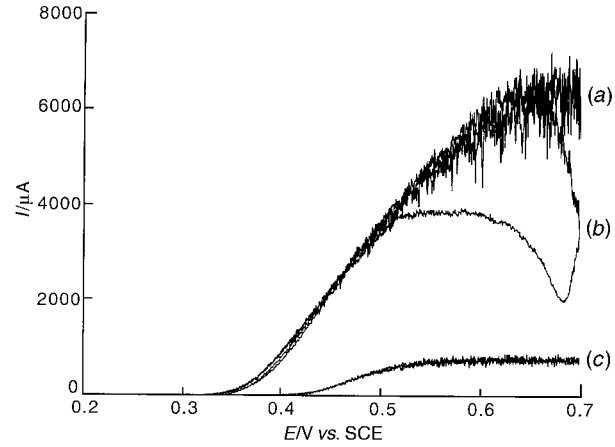

Fig. 4 Cyclic voltammograms on a 6 mm Pt disc electrode at 10 mV s^{-1} for (*a*) 1 mM and (*b*) 10 mM KI in 0.125 M H_2SO_4. 18 W cm^{-2} ultrasound was employed at a horn-to-electrode distance of 12 mm. Trace (*c*) is as for (*b*) except that 10% (v/v) of the aqueous solution was replaced with CH_2Cl_2 and emulsified.

synthetic generation of useful quantities of *leuco*-Methylene Green. However when voltammetry is conducted using a 20% (v/v) solution of toluene in water and 18 W cm^{-2} ultrasound is utilised to form an emulsion, the sonovoltammetry is very different, as shown in Fig. 3. Now, two steady-state sigmoidal reduction waves are observed with no evidence of a stripping peak on sweeps to positive potentials. Similar effects were seen using n-octane instead of toluene. We attribute this to the solubility of the reduction product in the emulsified organic phase that bathes the electrode surface. This was confirmed using a 30 min sono-electrolysis experiment during which the potential of the solution (200 ml of 2 mM MG in 0.1 M KCl/ 0.2 M KH_2PO_4 at pH 6.5 and 50 ml of toluene) was maintained at −0.35 V *vs.* SCE under ultrasound. The toluene reaction mixture was then isolated under argon, evaporated to dryness and the product dissolved in octane for UV-visible characterisation of the *leuco* base *via* the peak at 263 nm.[18]

Examination of Fig. 3 shows two roughly equal waves corresponding to the two electron reduction of Methylene Green giving respectively solid *l*-MG and aqueous phase *l*-MG. The former, of course, is rapidly removed by the emulsion. The relative sizes of the two waves reflect the amount of material that can nucleate and adsorb in the case of the first wave and the fact that the overall magnitude of the two waves taken together reflects the rate of mass transport of MG to the electrode surface. The scope for 'clean' voltammetric measurements in otherwise passivating systems in the presence of ultrasound is evident.

The oxidation of iodide at platinum electrodes is complicated by the formation of solid iodine at higher concentrations when the solubility of iodine is exceeded (1.1 mM in water at 25 °C).[19] Cyclic voltammetry of 1 and 10 mM aqueous solutions of KI in 0.125 M H_2SO_4 was performed under 19 W cm^{-2} ultrasound at a horn to electrode distance of 12 mm. This is shown in Fig. 4. At the higher concentration the voltammetry deviates from the expected steady-state behaviour and heavy electrode passivation leads to current fall-off. When 10% (25 ml) of the aqueous solution was replaced with CH_2Cl_2 and the mixture was emulsified, steady-state behaviour was achieved and is seen in Fig. 4(*c*). This was confirmed spectroscopically to be due to the dissolution of iodine from the platinum electrode.

Sonication is a convenient and effective alternative to the use of high-speed stirring and/or detergents for the promotion of emulsions for electrochemistry,[20] although the possibility of a small amount of parallel chemistry resulting from sono-decomposition of the solvents (water, toluene and dichloromethane) should be noted.

The use of the sono-emulsion technique to depassivate electrochemical systems promises much for synthetic, mechanistic and analytical studies and can be expected to considerably broaden the range of chemical systems amenable to electrochemical study.

We thank the EPSRC for a studentship for R. P. A. and for financial support (grant no. GR/L/36413) under the Analytical Sciences program.

Formation and structure of unusual [2 + 1] adducts of citronellal and oligo(hydroxy)benzenes

Bart Forier, Suzanne Toppet, Luc Van Meervelt and Wim Dehaen*

Department of Chemistry, Katholieke Universiteit Leuven, Celestijnenlaan 200F, 3001 Heverlee (Leuven), Belgium. E-mail: wim.dehaen@chem.kuleuven.ac.be

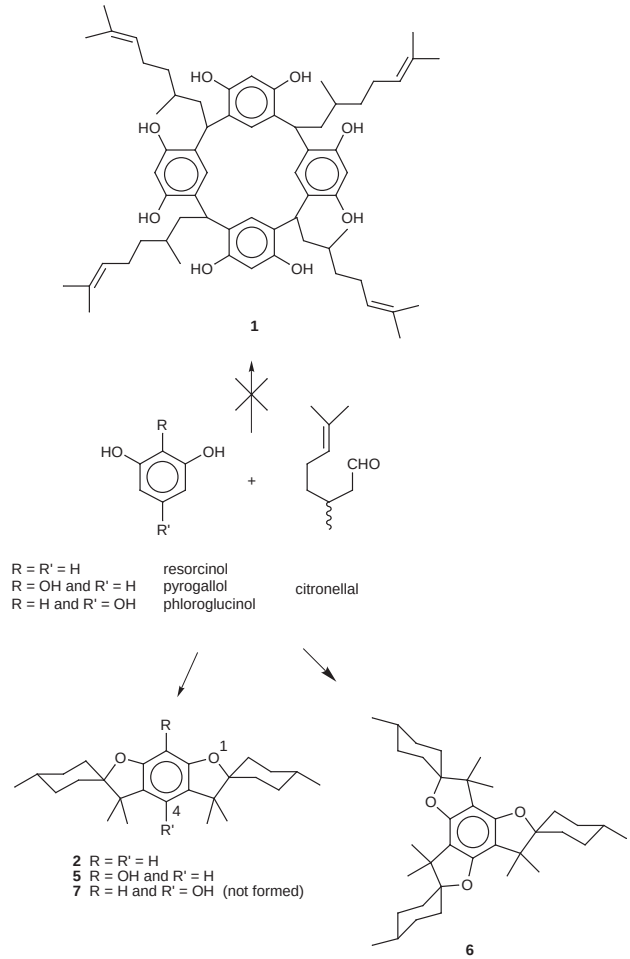
Received (in Liverpool, UK) 25th February 1999, Accepted 28th April 1999

Citronellal reacts with electron rich oligo(hydroxy)benzenes in an acid catalyzed condensation reaction to afford unusual [2 + 1] adducts which are characterized with mass and NMR spectroscopy, and X-ray crystallography.

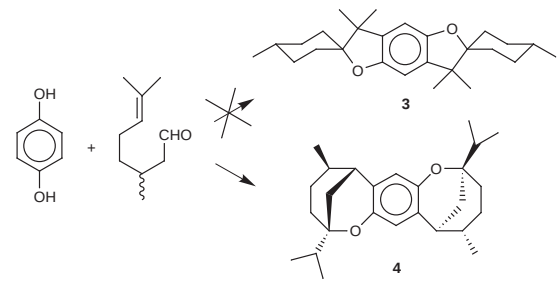
Resorcinarenes are an important class of electron rich cyclophanes, which have been used extensively as hosts for ammonium ions, amino acids, polyols and saccharides.[1] They are also the starting materials for container molecules such as cavitands and carcerands.[2] Their success is to a major extent due to their convenient one step synthesis involving the [4 + 4] acid catalyzed condensation of aldehydes and resorcinol. Both aromatic and aliphatic aldehydes can be used, and in many cases the *rccc* stereoisomer is formed preferentially.

With the goal of introducing chirality to these resorcinarenes in a simple way, we tried the acid-catalyzed condensation of citronellal with resorcinol, following literature procedures.[1] To our joy, large amounts of a white crystalline material were formed. However, the spectral data did not correspond with the desired [4 + 4] adduct **1**. This was clear by the absence of signals corresponding to phenolic hydrogens both in the ^{1}H NMR (taken at 400 MHz) and IR spectra. Moreover, the double bond had disappeared, as was clear from the shift of the methyl groups from δ 2.1 in citronellal to δ 1.1 in the product, and the disappearance of the signal of the vinyl hydrogen in the ^{1}H NMR spectrum. Notably, the product formed was not optically active, and in fact racemic citronellal was used in all subsequent reactions. Very soon it became apparent that a [2 + 1] adduct between citronellal and resorcinol, corresponding to an interesting bis(spirocyclohexane)benzodifuran **2**, had formed. The yield was 66% based on citronellal, rising to 77% when a 2 : 1 ratio of starting materials was used (Scheme 1).[3] The structure of **2** agrees with the mass spectrum (*m/z* 382). The ^{1}H NMR spectrum shows doublet absorptions (6H) at δ 0.9, and a singlet (12H) at δ 1.1 for the hydrogens of the methyl groups. A number of multiplet signals between δ 1.3 and 1.9 (total 18H) correspond to the cyclohexyl protons. Two singlets (each 1H) at δ 6.18 and 6.61 can be assigned to the aromatic H-8 and H-4 of the benzodifuran. Furthermore, in the ^{13}C NMR spectrum the aliphatic quaternary carbons are diagnostic: they show up at δ 45.7 (C-3,6 of benzodifuran) and 91.8 (C-2,7 of benzodifuran). The aromatic signals at δ 93.4 (CH-8 of benzodifuran) and 115.5 (CH-4 of benzodifuran) are within the expected values.

Although citronellal and resorcinol both are very common chemicals, we have found no earlier reference to compound **2** in the literature. To test the generality of this cyclocondensation reaction, other phenols were combined with citronellal. Phenol itself did not give a defined condensation product, but the isomeric hydroquinone gave a [2 + 1] adduct (*m/z* 382) in good yield (72%). However, careful investigation of the ^{1}H and ^{13}C NMR spectra showed that the product is not the (by now) expected benzo[1,2-*b*:4,5-*b*′]difuran **3** but a doubly bridged benzo[1,2-*b*: 4,5-*b*′]dioxocane **4** (Scheme 2). The ^{1}H NMR spectrum shows the methyl groups now all appear as doublets at δ 0.96, 0.97 and 1.10 (each 6H). A multiplet at δ 1.16 (2H) is well separated from the bulk of the aliphatic protons (14 H between δ 1.53 and 1.91). The former signal clearly corresponds to the two hydrogens at C-3,10 which undergo the shielding influence of the aromatic anisotropy. Another well-separated aliphatic signal is the doublet at δ 2.60 corresponding to the benzylic H-6,13. In the aromatic region of the spectrum, the expected singlet (2H) at δ 6.41 is found. In the ^{13}C NMR spectrum the diagnostic signals are from one aliphatic quaternary carbon (C-2,9) at δ 78.2 and one aromatic CH at δ 113.2. The product **4** is not optically active due to its centre of symmetry.



Scheme 1



Scheme 2

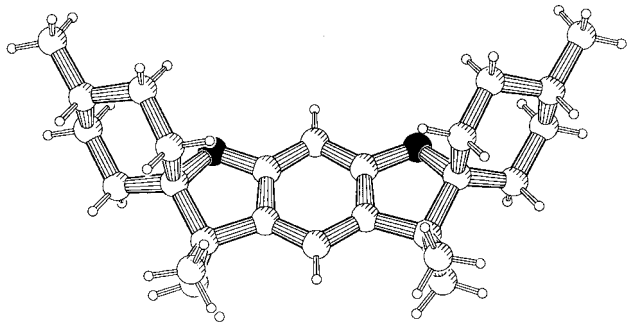


Fig. 1 X-Ray structure of **2**.

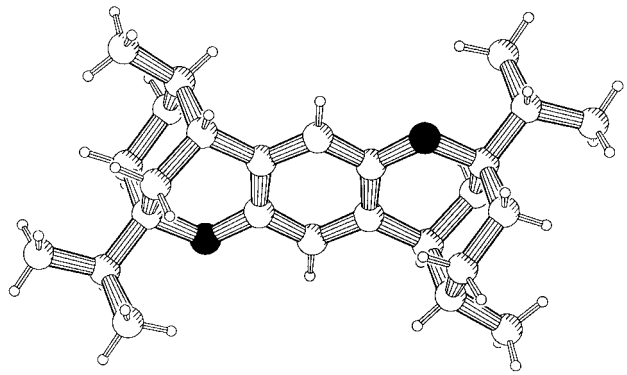

Fig. 2 X-Ray structure of **4**.

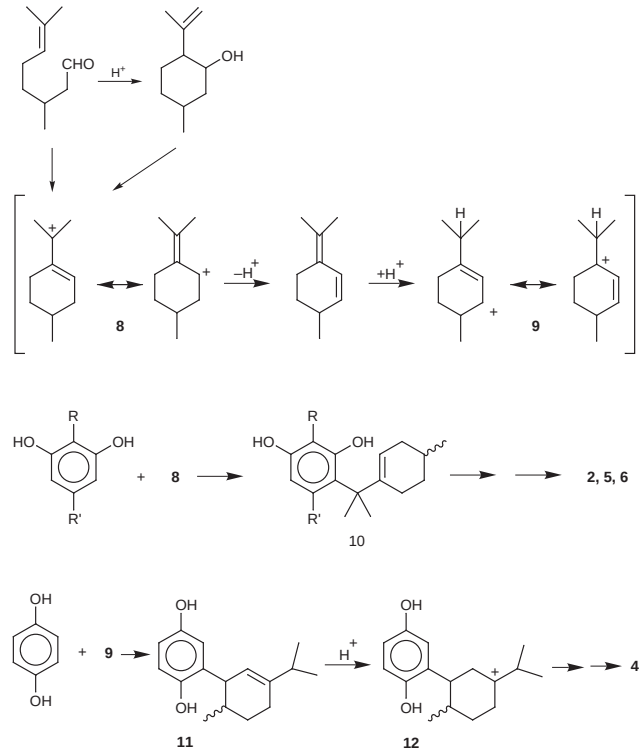

Scheme 3

Pyrogallol afforded product **5** with citronellal, having structure and yield (63%) comparable with compound **2**. The isomeric phloroglucinol gave a fair yield (33%) of an inseparable mixture of four diastereoisomers, corresponding to a [3 + 1] adduct **6** (*m/z* 534). The [2 + 1] adduct **7**, which should be theoretically possible, was not present (Scheme 1). The ^{1}H and ^{13}C NMR spectra of this mixture, which was not further investigated, showed similarity to that of the resorcinol adduct **2**.

Crystals of **2** and **4** were grown from an acetone–MeOH mixture and the molecular structures of **2** and **4** were confirmed by X-ray diffraction.[4] The molecular shape of compound **2** is determined to a large extent by the conformation of the different rings (Fig. 1). The central ring system is slightly bent: the angle between the best planes through both tetrahydrofuran rings is 14.5°. Both cyclohexane rings have a chair conformation with the methyl substituent in the equatorial position and the *gem*-dimethyl carbon in the equatorial position in order to reduce possible steric hindrance. Compound **4** possesses an internal centre of symmetry (Fig. 2). The tetrahydropyran ring has a clear envelope conformation with the isopropyl group attached in the equatorial position. The cyclohexane ring, oriented axially with respect to the previous ring, has a chair conformation with the methyl substituent in the axial position.

Citronellal is known to cyclize in acidic medium, in fact this is a way to prepare isopulegol.[5] When the condensations of resorcinol and hydroquinone were carried out with isopulegol, the adducts **2** and **4** were formed in comparable yields (75 and 76%, respectively) as for the reactions based on citronellal.

Via a number of intermediates, involving acid-catalyzed isomerizations, the stabilized cationic species **8** and **9** can form in the reaction mixture (Scheme 3). Obviously, **8** is more stable than **9** and will be preferentially formed. Resorcinol, pyrogallol and phloroglucinol are significantly more reactive than hydroquinone towards electrophilic substitution and, therefore, they can react with the stabilized cation **8** with the formation of the intermediate **10**, which after protonation will cyclize with the phenol function. It is interesting to note that even when the reactants are combined in a 1 : 1 ratio, only the [2 + 1] adduct **2** is obtained. Apparently, the intermediate [1 + 1] adduct is significantly more reactive than resorcinol itself.

Hydroquinone will only react with the less stabilized cation **9**, and the intermediate **11** will be protonated selectively with the formation of the tertiary carbenium ion **12**, and ultimately the bridged compound **4**. A similar singly bridged [2 + 1] condensation product resulting from the acid catalyzed condensation of resorcinol and 2-cyclohexenone was reported recently.[6]

We thank the Ministerie voor Wetenschapsbeleid, the F.W.O. Vlaanderen and the University for their continuing support. B. F. thanks the I.W.T for a predoctoral fellowship.

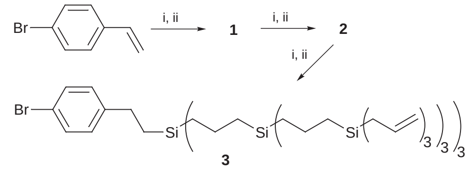
Received (in Cambridge, UK) 25th March 1999, Accepted 12th May 1999

The synthesis of a series of diphosphine ligands having phosphorus donor atoms in the core of a carbosilane dendrimer and their use in palladium catalysed allylic alkylation is described.

Dendrimers are fascinating molecules owing to their unique physical and chemical properties.[1] From the beginning catalysis has been recognised as one of their main potential applications, but so far only a few examples have appeared in the literature.[2–5] Two general strategies for the construction of dendritic catalysts can be applied: (1) multiple catalytic sites at the periphery of the dendrimer and (2) one (or more) catalytic site(s) in the core of the dendrimer.

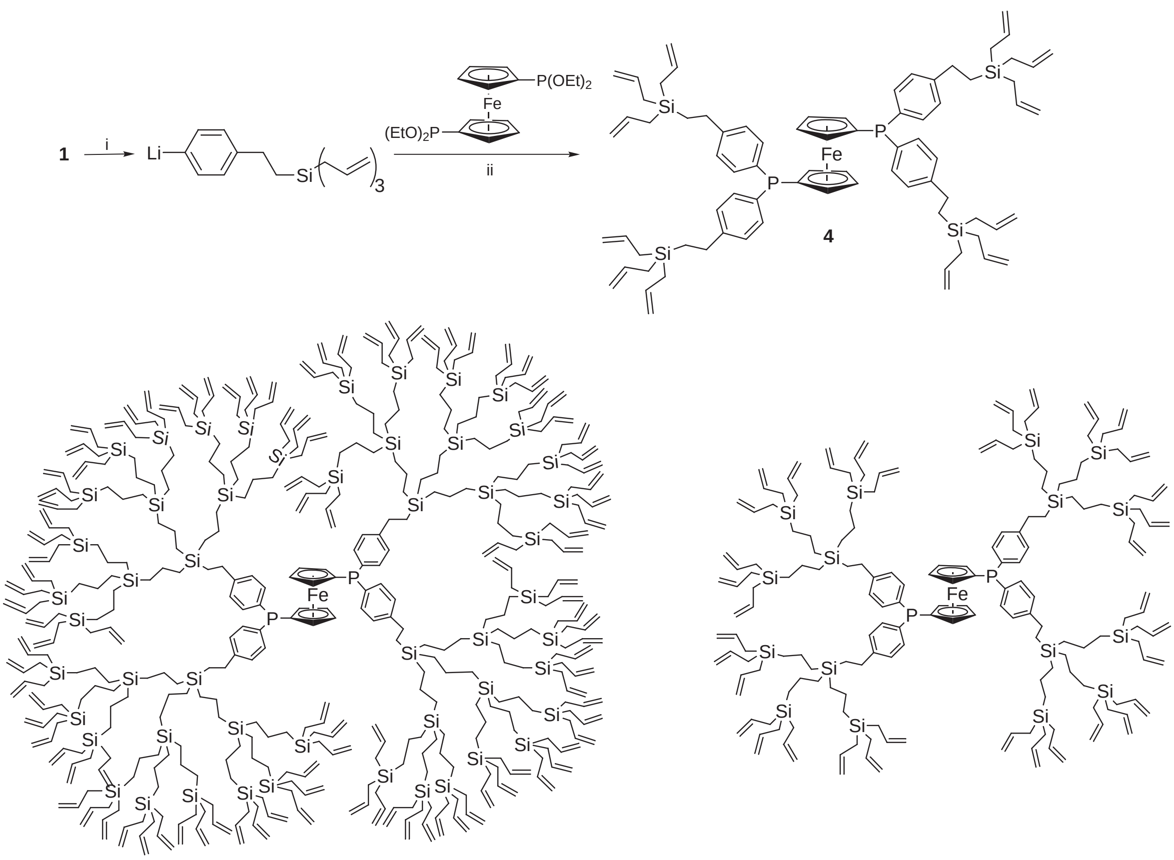
Previously, we and others have reported examples of the periphery strategy.[2,3] This approach has the major advantage that the catalyst can be removed from the product mixture *via* nanofiltration and reused.[3,4]

Recently, a number of groups reported core-functionalised dendrimers as examples of the second strategy.[5] Some of these so-called 'dendrizymes' showed that the substrate selectivity of the catalytic reaction changed with increasing generations.[6]



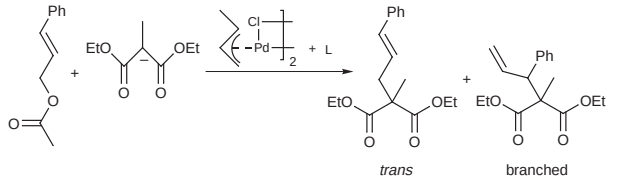
Scheme 1 *Reagents and conditions*: i, $HSiCl_3$, [Pt], rt, 2 h, 100%; ii, $BrMgCH_2CH{=}CH_2$, Et_2O, rt, 100%.

Here we describe the synthesis of carbosilane dendritic wedges using *p*-bromostyrene as starting compound. The bromide can be used to construct a new type of ligand embedded in the apolar dendrimer. The dendritic analogues of dppf [bis(diphenylphosphino)ferrocene] were synthesised as examples of such core-functionalised dendrimers. Initial experiments show that palladium complexes of these dendrimers are active catalysts in allylic alkylation reactions and a significant change in the product selectivity is observed for the largest dendrimer.



Scheme 2 *Reagents and conditions*: i, BuLi, THF, −78 °C; ii, THF, −78 °C.

Table 1 Activity and selectivity in the allylic alkylation of 3-phenylallyl acetate with diethyl 2-sodio-2-methylmalonate after 60 min[a]



L	Conversion (%)[b]	*trans* product (%)[c]
—	8	96 (±1.0)
dppf	72	90 (±0.7)
4	76	88 (±1.2)
5	58	87 (±0.8)
6	17	79 (±0.4)

[a] Conditions: 0.25 μmol $[crotyl\text{-}PdCl]_2$, 0.5 μmol **L**, 6.0 ml THF, 0.5 mmol 3-phenylallyl acetate, 1.0 mmol malonate, 0.05 mmol decane, rt. [b] All catalytic reactions reached full conversion in 24 h. [c] The selectivity of the reaction was independent of the conversion.

The carbosilane wedges **1**–**3** (Scheme 1) were prepared in a divergent manner starting from *p*-bromostyrene, using a two-step methodology.[7] These steps involve a platinum-catalysed hydrosilylation with $SiHCl_3$ followed by reaction with an excess of allylmagnesium bromide yielding wedges **1** to **3**. Under optimised reaction conditions the wedges were obtained quantitatively, purified by flash chromatography and characterised by ^1H and ^{13}C NMR spectroscopy, elemental analysis, and FAB and MALDI-TOF mass spectrometry. The bromobenzene moiety can be used to synthesise a core-functionalised dendrimer in a convergent way. After lithiation using BuLi at −78 °C, these wedges were made to react with tetraethyl ferrocene-1,1′-diylbis(phosphonite)[8] yielding the bidentate ligands **4**–**6** with molecular weights up to 8567 (Scheme 2). These compounds were purified by column chromatography and analysed by ^1H and ^{31}P NMR spectroscopy, MALDI-TOF mass spectrometry and elemental analysis.†

Palladium dichloride complexes were prepared by stirring the ligand with $Pd(MeCN)_2Cl_2$ in CH_2Cl_2 for 60 min during which the solution turned red. ^{31}P NMR spectroscopy confirmed complete complexation of the ligand in a bidentate *cis* fashion. The signal of the free ligand around δ −18 was completely replaced by a singlet around δ +32.

After it was shown that these novel core-functionalised dendrimers formed similar Pd complexes as dppf, the catalytic activity of the compounds was tested in palladium catalysed allylic alkylation. In a typical experiment, crotylpalladium chloride dimer was added to a THF solution of the ligand and the mixture was incubated for 1 h at room temperature. 3-Phenylallyl acetate, decane (internal standard) and diethyl 2-sodio-2-methylmalonate were added.‡ The reactions were followed by GC analysis of samples taken from the reaction mixture. All the Pd complexes of the dendritic phosphines were catalytically active (see Table 1), producing mainly the linear *trans* product. The *cis* product was not observed. As indicated by the similar conversion for dppf and **4**, the allyl end groups do not interfere in the catalytic reaction. As expected, the rate of the reaction decreased using the higher generation catalysts. This effect, also found by others,[5,9] is due to more difficult mass transport with increasing steric bulk of the dendritic wedges, and is most pronounced when going from generation 2 to 3.

Remarkably, the size of the dendrimers determined also the selectivity of the allylic alkylation reaction; Pd–**6** yielded significantly more of the branched product. This change in selectivity might be due to the increasing steric bulk of the dendrimer hindering the attack of the nucleophile on the Pd–allyl. The apolar microenvironment created by the carbosilane wedges could also be the reason for this observed selectivity effect. Current research is aiming at a detailed insight in the nature of the dendritic effect and extending the synthetic approach to other core functionalities.

We thank the Netherlands Foundation for Chemical Research (CW) and the Netherlands Organisation for Scientific Research (NWO) for financial support and P. G. Emmerink for experimental assistance.

Received (in Cambridge, UK) 22nd April 1999, Accepted 12th May 1999

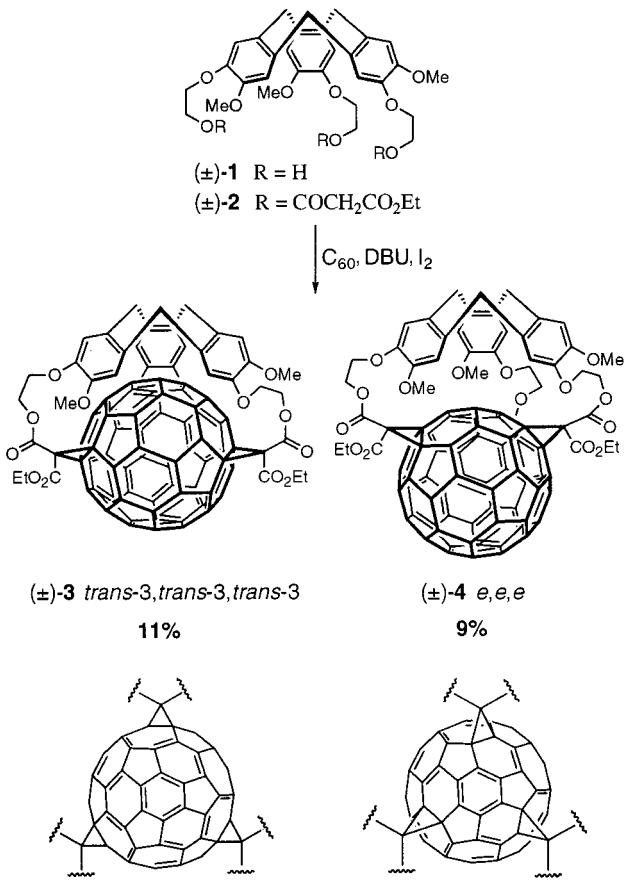
The first covalent cyclotriveratrylene (CTV)–C_{60} adducts were prepared by the tether-directed Bingel reaction, which gave the two C_3-symmetrical *trans*-3,*trans*-3,*trans*-3 and *e,e,e* tris-adducts with a high degree of regioselectivity.

The preparation of higher covalent adducts of buckminsterfullerene (C_{60}) with interesting electrochemical[1] or chiroptical properties[2] is currently under intense investigation. The tether-directed remote functionalisation method developed in the Diederich group for this purpose has proved to be very powerful because of its high regio- and stereoselectivity.[3] This methodology has been used successfully to prepare enantiomerically pure *cis*-3 bis-adducts with inherently chiral functionalisation patterns[2] or cyclophane-type crown ether[4a] and porphyrin[4b,5] conjugates with interesting redox properties, in which the second chromophore is doubly connected to the *trans*-1 positions at the two poles of the carbon sphere. Many functionalisation reactions of C_{60} leading to a variety of mono- and bis-adducts have been reported.[6] In contrast, only a few examples of tris-adducts have been described.[2a,7,8] In theory, bis-adducts of C_{60} derived from Bingel cyclopropanation reactions[9] can exist as eight different regioisomers, seven of which have been detected and isolated.[7a] The number of possible regioisomers increases to 46 in the case of tris-adducts in which three of the thirty 6-6 bonds (bonds between two six-membered rings) have been cyclopropanated.[6b] In 1994, Hirsch and co-workers reported the stepwise preparation of such tris-adducts and eventually obtained the *trans*-3,*trans*-3,*trans*-3 and *e,e,e* regioisomers together with other isomers, after tedious separation and purification.[7a]

Here we report the tether-directed regioselective synthesis of two new C_3-symmetrical tris-adducts having *trans*-3,*trans*-3,*trans*-3 and *e,e,e* structures, respectively, in one step from C_{60}. Cyclotriveratrylene (CTV) is well-suited in size and shape to interact favorably with C_{60}.[10] The affinity between these two molecules, which is reinforced by the electron donor character of CTV and the electron acceptor properties of C_{60}, has been evidenced by the formation of a crystalline complex in which C_{60} adopts a nesting position at van der Waals contact distance above the concave surface of the CTV macrocycle.[10a] These features prompted us to utilize a C_3-symmetric tris-malonate derivative of CTV, such as (±)-**2**, as a template for preparing tris-aducts of C_{60} by the tether-directed Bingel reaction (Scheme 1). The required (±)-**2** was obtained in one step by reacting the C_3-symmetrical CTV derivative (±)-**1**[11] with 3.3 equiv. of ethyl malonyl chloride (room temperature, CH_2Cl_2–pyridine). After column chromatography (SiO_2, CH_2Cl_2 → CH_2Cl_2–1% MeOH), (±)-**2** was obtained in 77% yield as a colorless solid.

The Bingel reaction of (±)-***2*** with C_{60} was carried out in the presence of 9 equiv. of DBU and 3 equiv. of I_2. After 4 h, two products (±)-**3** and (±)-**4** had formed which were separated by column chromatography (SiO_2 H, CH_2Cl_2 → CH_2Cl_2–2% MeOH) and isolated in 11 and 9% yield, respectively. FAB-MS spectra† of (±)-**3** and (±)-**4** displayed the molecular ions expected for the tris-adducts shown in Scheme 1. This is the first example of tris-adduct formation by a one-step tether-directed Bingel addition.

The C_3-symmetry of the two adducts was established using NMR spectroscopy. The ^{1}H NMR spectra of (±)-**3** and (±)-**4** display the usual features for a C_3-CTV unit, *i.e.* two singlets for the aromatic H-atoms, one singlet for the OMe groups and the characteristic AB quartet for the CH_2 bridges. This means that the adducts must themselves possess a C_3 axis that is common to the CTV and the C_{60} subnits. The ^{13}C NMR spectra (Fig. 1), showing 20 resolved peaks for the fullerene C-atoms of (±)-**3** and 18 for those of (±)-**4**, support this conclusion. Since among all the possible regioisomers only the *trans*-3,*trans*-3,*trans*-3 and *e,e,e* trist-adducts exhibit such a symmetry (the *cis*-1,*cis*-1,*cis*-1 tris-adduct cannot form for steric reasons), the structures



Scheme 1

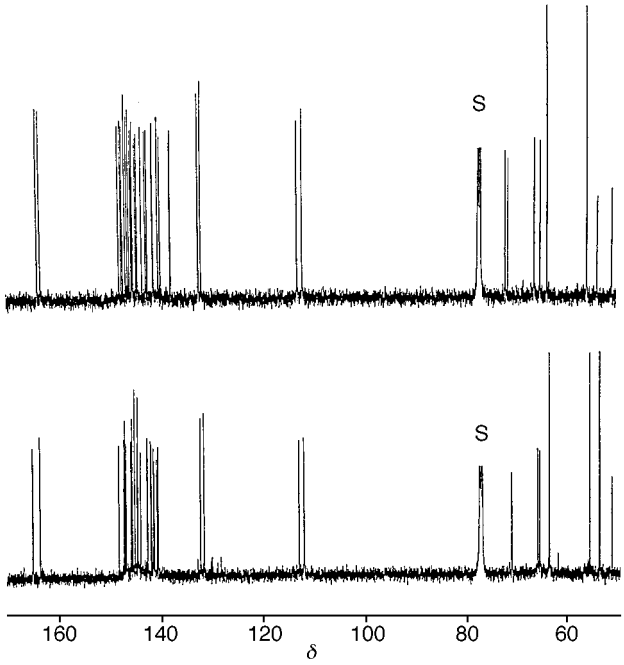


Fig. 1 ^{13}C NMR (125 MHz, $CDCl_3$) spectra of (*a*) tris-adduct (±)-**3** and (*b*) tris-adduct (±)-**4**; S stands for solvent.

of the two new tris-adducts were thus unambiguously established.

Since all attempts at transesterification to give the corresponding known tris(diethyl malonate) adducts[7a] failed, the structures of the two compounds were initially assigned with the help of UV-visible spectroscopy (CH_2Cl_2). Regioisomer (±)-**3** exhibits a cherry-red colour and (±)-**4** an orange–red colour, which are the same as those previously reported for the regioisomeric *trans*-3,*trans*-3,*trans*-3 and *e*,*e*,*e* tris(diethyl malonate) adducts, respectively.[7a] This difference is reflected in an additional absorption band at λ_{max} = 422 nm in the UV-visible spectrum of (±)-4.

The assignment of (±)-**3** and (±)-**4** as the *trans*-3,*trans*-3,*trans*-3 and *e*,*e*,*e* isomers, respectively, was further supported by a close comparison of their NMR spectra with those of analogous untethered tris-cyclopropanated C_{60} derivatives.[7a,b] The ^{13}C NMR chemical shifts of the bridgehead sp^3-C-atoms in the fullerene shell have been shown to appear at higher field in the *e*,*e*,*e* than in the *trans*-3,*trans*-3,*trans*-3 regiosomer, whereas the opposite behaviour has been observed for the methano bridge C-atom. The ^{13}C NMR resonances for the cyclopropane fragments were in fact observed at δ 71.63, 71.11 (bridgehead) and 50.61 (bridge) for (±)-**3** and at δ 70.73, 70.66 (bridgehead) and 51.07 (bridge) for (±)-**4**. The structural assignment was further corroborated by the position of the ^{1}H NMR resonance of the axial protons in the methylene bridges of the CTV fragment. For the tris-adduct (±)-**4** (δ 4.65), this signal is nearly unaffected with respect to that observed for the free CTV (±)-**2** (δ 4.74) whereas for (±)-**3**, it is significantly downfield shifted to δ 5.33. This indicates a much greater proximity of the CTV fragment to the fullerene core with its deshielding pentagon rings, which is expected for the *trans*-3,*trans*-3,*trans*-3 regioisomer, as shown in Scheme 1.

The total yield of tris-adducts is 20%, with a distribution of 55% of *trans*-3,*trans*-3,*trans*-3 and 45% of *e*,*e*,*e* regioisomer. Given the low statistical yield of 0.5% for (±)-**3** and 1% for (±)-**4** (among the 46 possible tris-adduct regioisomers), one can assume that the CTV template is largely responsible for this high degree of regioselectivity.

Since a splitting and doubling of the NMR signals is observed neither for (±)-**3** nor for (±)-**4**, one can expect the triply tethered reaction to be diastereoselective. We are currently investigating the use of optically pure C_3-CTV **2**[12] as starting material in order to confirm this diastereoselectivity, which opens new perspectives in the preparation of optically active derivatives of C_{60} and other fullerenes.

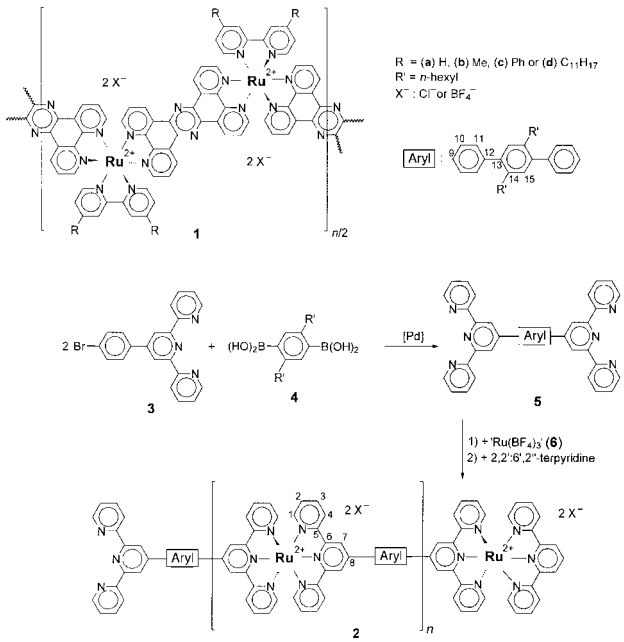
Received (in Basel, Switzerland) 1st March 1999, Accepted 1st May 1999

Well defined coordination polymers obtained *via* the conversion of 4,4″-bis(2,2′:6′,2″-terpyridine)-2′,5′-dihexyl-*p*-terphenyl and activated ruthenium(III) show intrinsic viscosities of up to [*η*] ≈ 300 mL g^{-1} and a tremendous polyelectrolyte effect in salt-free DMA solution proving both their high molecular weights and considerable chain stiffness.

Soluble ruthenium(II) coordination polymers of well defined constitution are of actual interest because of their electronic, photooptical, magnetic and catalytic properties.[1–8] Moreover, they represent important reference systems for the profound analysis of polyelectrolyte behaviour in solution which is a field of research that urgently needs appropriate model polymers. Recently, we described the first high-molecular-weight ruthenium(II) coordination polyelectrolytes **1**.[9–11] These polymers have a rigid, randomly coiled backbone and display characteristic polyelectrolyte behaviour in salt-free solutions. To further deepen the understanding of the structure–property relationship of these rather unusual coordination polyelectrolytes it is worthwhile to also make available ruthenium(II) coordination polymers which have rod-like backbones. We therefore decided to prepare polymers **2** *via* the conversion of 4,4″-bis(2,2′:6′,2″-terpyridine)-2′,5′-dihexyl-*p*-terphenyl **5** and an activated ruthenium(III) species such as **6**,[12] and thus *via* a procedure which has only been used so far for the preparation of mono- and oligonuclear ruthenium complexes (Scheme 1).

Polyelectrolytes **2** were expected to be readily soluble because of their flexible *n*-hexyl side chains[13] and to have a rod-like shape because of (i) the constitution of the bis-tridentate ligand monomers and (ii) the octahedral coordination sphere around the transition-metal atoms. The required ligand monomer **5** was prepared in almost quantitative yields and high purity *via* the Pd-catalysed condensation of 4′-(*p*-bromophenyl)-2,2′:6′,2″-terpyridine **3**[14] and 2,5-dihexylbenzene-1,4-diboronic acid **4**[15] in a heterogeneous mixture of toluene and 1 M aqueous Na_2CO_3, and its constitution was verified using ^{1}H [Fig. 1(a)] and ^{13}C NMR spectroscopy.

Prior to the polymer synthesis itself, several model studies were performed to find out the optimum reaction conditions for the conversion **5** + **6** → **2** which guarantee selective and practically quantitative formation of the $[Ru(tpy)_2]^{2+}$ motif (tpy = 2,2′:6′,2″-terpytidine). These conditions should further prevent formation of defect structures within the chains of **2** which could destroy its rod-like shape. In the course of these experiments, DMA–butan-1-ol was found to be the solvent mixture of choice for our purpose. The conversion of $RuCl_3 \cdot 3H_2O$ with $AgBF_4$–acetone, on the other hand, provided us the appropriately reactive metal monomer **6**.[12] Finally, knowledge of the chemical shifts of all absorptions of both possible chain termini of **2** is imperative for NMR end-group analysis which is a convenient method for the estimation of the



Scheme 1

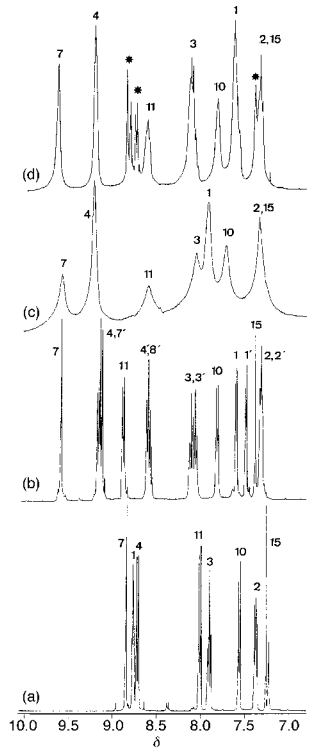


Fig. 1 400 MHz ^{1}H NMR spectra of (a) ligand monomer **5**, (b) the dinuclear model complex [(tpy)Ru(**5**)Ru(tpy)](BF$_4$)$_4$, (c) the high-molecular-weight polymer **2** and (d) a tpy-terminated low-molecular-weight polymer **2**, recorded in $CDCl_3$ (a), DMSO-d_6 (b, d) and DMA-d_9 (c), respectively, at room temperature. The signal assignment is according to the numbering specified in Scheme 1.

achieved degree of polymerisation (P_n). Therefore, the dinuclear complex [(tpy)Ru(**5**)Ru(tpy)](BF$_4$)$_4$ was prepared *via* the conversion of **5** with 2 equiv. of an activated ruthenium(III)–terpyridine complex which was obtained *via* the treatment of [Ru(tpy)Cl$_3$][16] with AgBF$_4$–acetone. The resulting dinuclear complex subsequently allowed the identification of all NMR absorptions that are caused by [Ru(tpy)$_2$]$^{2+}$ end-groups of **2** (right-hand side terminus of **2** in Scheme 1; [see Fig. 1(b) for its ^{1}H NMR spectrum]. For the tpy-termini of **2** (left-hand side terminus of **2** in Scheme 1), on the other hand, monomer **5** itself is the appropriate model compound [Fig. 1(a)]. Coordination polymers **2** were prepared under the optimised reaction conditions. For this purpose, an appropriate quantity of RuCl$_3$·3H$_2$O was first converted into the activated metal monomer **6** and subsequently heated with exactly 1 equiv. of ligand monomer **5** in butan-1-ol–DMA for 5 d. The product was precipitated in practically quantitative yields as a dark red, fibrous material which readily and completely redissolved in DMA or DMSO. Its constitution was analysed using ^{1}H and ^{13}C NMR spectroscopy. Fig. 1(c) displays a representative ^{1}H NMR spectrum of the product.

All intense absorptions clearly correspond to the inner-chain repeating units of **2**. No signals were found, on the other hand, of defect structures or of end-groups. In order to prove that such absorptions are not only covered by the broad signals of the repeating units, further polymerisations were carried out where a slight excess of either ligand monomer **5** or metal monomer **6** was used. In the latter case, 5% of tpy was added to the reaction mixture prior to work-up to produce well defined [Ru(tpy)$_2$]$^{2+}$ chain termini (Scheme 1). As expected, additional signals that correspond to the respective end-groups were observed in the NMR spectra of all these latter polymers. As an example, Fig. 1(d) displays the ^{1}H NMR spectrum of a polymer **2** prepared by using an excess of **5**.

We conclude that end-groups are reliably detectable by NMR despite the broad and intense absorptions of the polymer backbone but obviously have intensities below the limits of accuracy of the NMR method for polymers **2** prepared from an exact 1 : 1 equivalence of comonomers **5** and **6**. Moreover, formation of cyclic oligomers can be excluded because of the rod-like shape of **2**. It is evident, therefore, that very high-molecular-weight polymers were produced: considering the limits of the NMR method, we estimate average degrees of polymerisation of $P_{n(NMR)} \geqslant 30$ ($M_n \geqslant 36\,000$ g mol^{-1}) for the best products synthesized so far.

The hydrodynamic behaviour of **2** was analysed by viscosimetry to further support its high P_n and its rod-like shape. In DMA–0.02 M NH$_4$PF$_6$ solution—where intermolecular Coulomb interactions between the charged macromolecules are screened out—the high-molecular-weight samples of **2** show intrinsic viscosities of up to $[\eta] \approx 300$ mL g^{-1}. These values are *ca.* one order of magnitude higher than those reported for the randomly coiled reference polymers **1** ($[\eta] \leqslant 25$ mL g^{-1}). Moreover, a value of $[\eta] \approx 300$ mL g^{-1} is not only the highest intrinsic viscosity ever observed for a ruthenium(II) coordination polymer but also of the same order of magnitude as the intrinsic viscosities observed for purely covalent rod-like macromolecules such as poly(*p*-phenylenes)[16,17] or polyimides.[18] These results thus strongly support the high values of P_n and the rod-like shape of **2**.

In a second series of experiments, the hydrodynamic behaviour of a high- ($P_n \geqslant 30$) and a low-molecular-weight ($P_n \leqslant 10$) sample of **2** was studied in pure DMA where the intermolecular Coulomb interactions between the macromolecules are in operation. Under these conditions, the high-molecular-weight sample displays a very pronounced polyelectrolyte effect, *i.e.* a maximum in the Huggins plot of $(\eta_{sp}/c_p)_{max} \approx 2000$ mL g^{-1} at a polymer concentration of $c_P \approx 5 \times 10^{-6}$ g mL^{-1}. Nevertheless, the maximum is also clearly detectable for the low-molecular weight polymer **2** where a value of $(\eta_{sp}/c_P)max \approx 500$ mL g^{-1} is reached at a polymer concentration of $c_P \approx 5 \times 10^{-6}$ g mL^{-1}. Finally, the maximum is again less pronounced {$(\eta_{sp}/c_P)max \approx 100$ mL g^{-1}} for the high-molecular-weight but randomly coiled reference polymer **1a** and appear at a polymer concentration of $c_P \approx 7 \times 10^{-6}$ g mL^{-1}. These results highlight the tremendous influence of the chain length and in particular the shape of the macromolecules on their hydrodynamic behaviour also in solutions of low ionic strength. Comparably high-molecular-weight ($P_n \geqslant 30$) but randomly coiled reference polymers **1** reach maxima of $(\eta_{sp}/c_p)_{max} \approx 100$ mL g^{-1} at the best.

Finally, UV–VIS spectra were recorded in DMA solution of the mononuclear complex [Ru(tpy)$_2$](PF$_6$)$_2$, the dinuclear complex [(tpy)Ru(**5**)Ru(tpy)](BF$_4$)$_4$ and the high-molecular-weight polymer **2** to analyse the absorption behaviour of the [Ru(tpy)$_2$]$^{2+}$ motif as a function of the number of complexes present in one molecule. In all cases, intense absorptions are observed at wavelengths below $\lambda = 380$ nm (ligand-centered $\pi^* \leftarrow \pi$ transitions) and at wavelengths above $\lambda = 400$ nm (metal-to-ligand charge-transfer transitions). No evidence is found in these spectra that might be interpreted as the result of intramolecular electronic interaction between the metal centers in the dimeric and polymeric species. This conclusion is further supported by cyclic voltammetry performed in DMF–NBu$_4$BF$_4$ solution: half-wave potentials of $E_{1/2}^{ox} = 1.20$, 1.24 and 1.25 V are found for the metal-localized first oxidation in the case of the mononuclear complex [Ru(tpy)$_2$](PF$_6$)$_2$, the dinuclear complex [(tpy)Ru(**5**)Ru(tpy)](BF$_4$)$_4$, and the high-molecular-weight polymer **2**, respectively.

Therefore, in full agreement with previous studies on related oligomeric complexes,[19] polymer **2** can be considered as a sequence of electonically nearly independent ruthenium(II) complexes. Presently, we are analysing the spectroscopic and electrochemical behaviour of polymers **2** in more detail.

The authors are grateful to Professor M. Ballauff, Karlsruhe, for his support of this work. We would like to thank Dr W. M. Meyer and Mr C. Sieber, MPI for Polymer Research, Mainz, for skillful technical assistance (cyclic voltammetry) as well as the Deutsche Forschungsgemeinschaft for financial support of the present work.

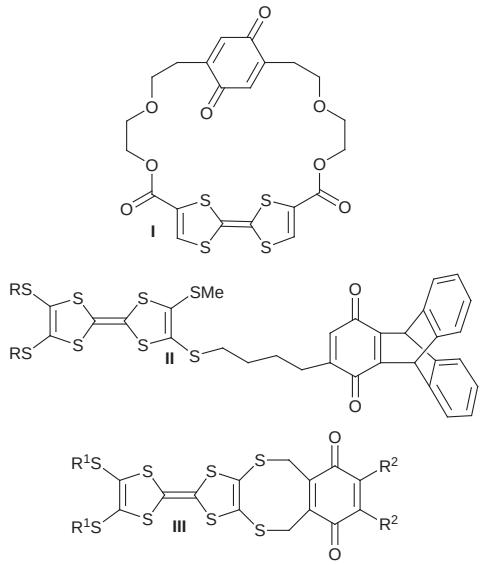
Received (in Cambridge, UK) 22nd March 1999, Accepted 6th May 1999

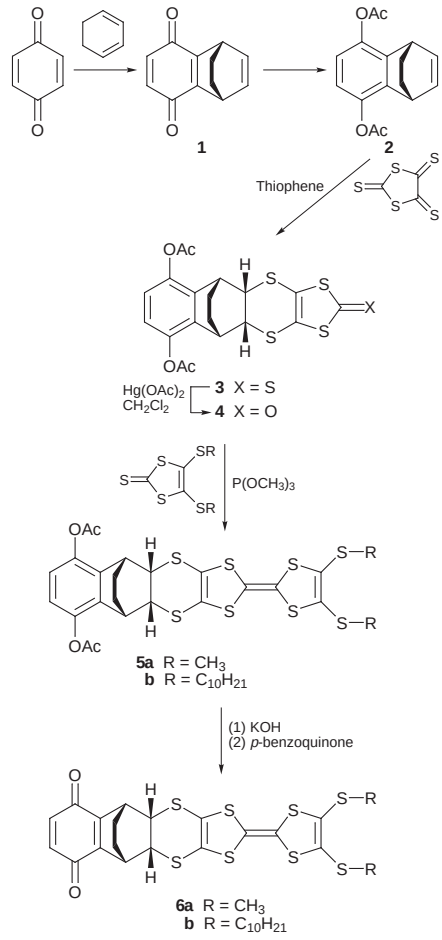
The synthesis of a novel D–A diad, involving a TTF moiety covalently linked to *p*-benzoquinone *via* a rigid spacer, shows a bent structure in the solid state which provides intrinsic through-space intramolecular charge-transfer interaction.

Since the discovery[1] of the first organic metal in 1973, much attention has been devoted to the investigation of TTF, its derivatives and analogs, as electron donor components of many charge transfer (CT) complexes and ion radical salts.[2] In order to control the stoichiometry of the D (donor) and A (acceptor) components and the degree of charge-transfer in CT complexes, which are crucial parameters in the design of 'organic metals', the concept of D–A–D and A–D–A triads was developed,[3] in which the D and A fragments are integral parts of a single molecule. Several D–TCNQ–D,[3] D–TCNAQ–D[4] and A–TTF–A[5] systems have been studied. In this context, TTF-σ-TCNQ systems have obvious appeal,[6] but have proved to be an elusive goal.[7,8] However, systems involving TTF-π-TCNQ are known.[9]



'TTF-σ-quinone' systems are known both in cyclic (**I**)[10] and non-cyclic (**II**) derivatives.[11] Recently, rigid TTF-σ-quinone derivatives (**III**) (containing two linking σ bonds) were synthesized.[12] In none of these systems, was an intramolecular CT band discernible in the UV–VIS spectrum, for different reasons.[8] Evidently, there is a need to design a molecule in which both the distance and orientation between the TTF and the quinone moieties are fixed, in order to achieve a CT interaction.

We now present the synthesis (Scheme 1), electrochemistry, X-ray structure and intramolecular charge-transfer properties of new rigid TTF-σ-Q (**6a**,**b**) molecules, involving TTF moieties chemically linked to *p*-benzoquinone by nonconjugated rigid cyclic rings, *via* two σ linkers. This type of molecule could be a potential precursor for TTF-σ-TCNQ systems. The unique bent structure of **6a** in the solid state (Fig. 1), in which the plane of the D moiety lies above the plane of the A moiety, with essentially eclipsed overlap, affords the first example of a non-cyclic system with built-in through-space σ-type interaction between the π-systems of the D and A components.[13] The synthesis of **6** involves two cycloaddition reactions[14] to afford **3** as the sole *R*,*S*,*R*,*S* stereoisomer in which the 1,3-dithiole-2-thione moiety is located opposite to the aryl ring, probably due to steric hindrance in the *S*,*R*,*R*,*S* isomer. The hydrogens on the carbons adjacent to the sulfur atoms are orientated in the same spatial direction with respect to the bent planes of the molecule. This configuration was confirmed by X-ray structure determination for the 'oxo' derivative **4**, which was generated from **3** (2 mmol). The latter reaction and the following ones



Scheme 1

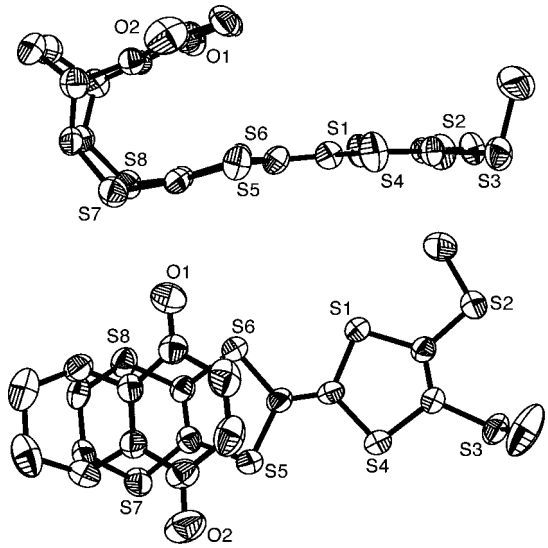


Fig. 1 ORTEP drawing of **6a** at the 50% probability level. Hydrogen atoms and the numbering of the carbon atoms have been omitted for clarity. Side-view of the molecule (above) and view in the plane of the TTF moiety (below).

which are described in Scheme 1 were performed according to known procedures.[15] Products **6a** and **6b** were separated from their reaction mixtures by silica gel column chromatography (CH_2Cl_2); both had a deep green color.

The UV–VIS spectrum of **6a** shows a broad absorption band in the 550–950 nm region, centered at *ca.* 685 nm ($\varepsilon \sim 310$), which points to a weak charge transfer interaction. The spectra were recorded at various concentrations of **6a**, and the extinction coefficient of this low energy band varied in accordance with Beer–Lambert law. Therefore, this band is assigned to an intramolecular charge-transfer interaction.

The cyclic voltammogram[16] of **6a** shows two one-electron reversible oxidation waves at $E^1_{1/2} = 0.55$ and $E^2_{1/2} = 0.825$ V, characteristic for tetraalkylthio-TTF derivatives,[2a] and two reversible reduction waves, one at −0.525 V (one-electron) and a smaller one at −1.20 V, for the reduction of the disubstituted *p*-benzoquinone moiety. (At slower scan rates a trace of an ill-defined 'third' reversible couple is observed in between the above two reduction waves, which is related to a product derived from the decomposition of the dianion.) Product **6b** affords a similar cyclic voltammogram pattern, with similar redox potentials. It is generally expected that a weak CT interaction will not affect the redox potentials pattern given by the relatively insensitive cyclic voltammetry technique.

Deep green needles of **6a**[17] were crystallized from CH_2Cl_2 by slow evaporation of the solvent. The X-ray structure (Fig. 1) verifies the bent configuration of the molecule and shows that the acceptor *p*-benzoquinone moiety is spatially located above the donor dimethylthio-TTF unit. Indeed, the intramolecular distance between the face-to-face planes of the donor and acceptor moieties is 3.29 Å, which may be compared to the plane-to-plane distances between donor and acceptor molecules in crystal packings of mixed-stacks intermolecular charge transfer of HMTSF–TCNQ[18] and ET–TCNQ[19] complexes. The apparently low degree of CT in the ground state of **6** was also confirmed by EPR measurements, which after sunlight irradiation gave rise to a photoinduced intramolecular electron transfer process, resulting in the appearance of broad signals (yet to be analyzed), with two '*g*' factors ($g_1 = 2.0050$; $g_2 = 2.0064$).

Compounds **6a** and **6b** are among the first examples of systems with inherent intramolecular through space charge transfer properties. Their synthesis opens up a way to obtain new compounds with controllable overlap between the donor and acceptor units, as well as controllable degree of charge transfer, *e.g.* by changing the strength of the acceptor moiety. Also, it is noteworthy that **6b** and its derivatives could be potential candidates for constructing Langmuir–Blodgett films and investigating their physical properties.

17 *Crystal data* for **6a**: A shiny deep green needle (0.4 × 0.15 × 0.15 mm) of $C_{20}H_{16}O_2S_8$ was used for X-ray intensity data measurements on a standard Bruker SMART CCD 1000™ diffractometer [λ(Mo-Kα) = 0.711069 Å, graphite monochromator, a scan width of 0.3° in ω and exposure time of 10 s frame^{-1}, detector–crystal distance = 4.95 cm]. A total of 1080 frames were collected and integrated with the Bruker Saint software package using a wide-frame integration algorithm. The crystal is monoclinic, space group $P2_1$, at 298 K, $a = 8.486(1)$, $b = 8.770(1)$, $c = 15.430(3)$ Å, $\beta = 98.740(3)°$, $Z = 2$, $V = 1135.0(3)$ Å^3, $F(000) = 560$, 7221 reflections were collected ($2\theta < 56.82°$), of which 4931 reflections were independent ($R_{int} = 3.18\%$) and 2823 with $F_o > 4\sigma(F_o)$. Data were corrected for absorption using SADABS program. The structure was solved by direct methods and refined by least-squares in full-matrix approximation: 273 parameters, $R1 = 4.04\%$, $wR2 = 6.20\%$, GOF = 0.796. Bruker SHELX Software package was used for all calculations and drawings. CCDC 182/1252. See http://www.rsc.org./suppdata/cc/1999/1125 for crystallographic data in .cif format.

Stereochemical course of the reduction step in the formation of 2-*C*-methylerythritol from the terpene precursor 1-deoxyxylulose in higher plants

Duilio Arigoni,*[a] José-Luis Giner,[b] Silvia Sagner,[c] Juraithip Wungsintaweekul,[c] Meinhart H. Zenk,[c] Klaus Kis,[d] Adelbert Bacher,[d] and Wolfgang Eisenreich[d]

Received (in Cambridge, UK) 19th March 1999, Accepted 4th May 1999

Feeding of 1-deoxy-D-[3-^{2}H]xylulose to leaves of the tree *Liriodendron tulipifera* affords 2-*C*-methyl-*D*-erythritol labelled specifically in the H_{Si} position of C-1.

Over the last few years evidence has been accumulated in different laboratories for the existence in eubacteria, algae and higher plants of an alternative mevalonate-independent metabolic pathway for the formation of isopentenyl pyrophosphate (IPP, **3**) and dimethylallyl pyrophosphate (DMAPP, **4**), the two universal building blocks of terpene biosynthesis (Scheme 1).[1] The first C_5 intermediate in this pathway, 1-deoxyxylulose 5-phosphate **1a**, is assembled from pyruvic acid and glyceraldehyde 3-phosphate in a decarboxylative reaction that requires the participation of thiamine pyrophosphate as a cofactor, and genes specifying for the corresponding synthase have been cloned from *Escherichia coli*[2] and from *Mentha piperita*.[3] The isolation of a NADPH-dependent reductoisomerase from *E. coli* capable of catalyzing the transformation of **1a** into 2-*C*-methylerythritol 4-phosphate **2a** has been described recently.[4] While the remaining steps of the sequence remain unknown, it has been shown that the (*E*)-methyl group of DMAPP **4** and the terminal methylene group of IPP **3** acquire label from 1-deoxy[3-^{2}H]xylulose **1b** (H• = D) in *E. coli*[5] as well as in cell cultures of *Catharanthus roseus*.[6] In addition, the specific localization of this label in the H_E position of the IPP generated in the plant system rules out DMAPP as the committed precursor of IPP along the deoxyxylulose pathway.[6] Supporting evidence for the same conclusion has been obtained in work with secretory cells from *M. piperita*.[7]

The well documented efficiency of leaves of the tree *Liriodendron tulipifera* in converting exogenous 1-deoxyxylulose **1b** into 2-*C*-methylerythritol **2b**[8] was exploited in the present study for investigating the stereochemical course of the reduction step of this transformation in a feeding experiment involving the easily accessible 1-deoxy[3-^{2}H]xylulose **1b** (H• = D).[9] For this purpose the leaf stems were immersed into a 18.5 mM solution of the precursor at room temperature and under natural daylight illumination. After two days the desired product was isolated from the biomass as described.[8] Following careful purification by HPLC on a column of Rezex Phenomenex (300 × 7.8 mm), using distilled water as eluent and a refractometer as the detecting system, the biosynthetic sample was converted into the known bis-acetonide **5**.[10]† Assignments of all the ^{1}H and ^{13}C NMR signals were obtained for an unlabeled reference specimen of **5** by two dimensional homonuclear (COSY, NOESY) and heteronuclear (HMQC) experiments. The data are summarized in Table 1 and Fig. 1. Specifically, the assignment of the ^{1}H NMR signals at δ 3.64

and 3.95 to H_{Re} and H_{Si} of C-1, respectively, is well-supported by the network of NOE interactions detailed in Fig. 1. Monodeuteration at C-1 in the sample of **5** derived from the feeding experiment was evidenced by the appearance in the proton-decoupled ^{13}C NMR spectrum of a new triplet (J_{CD} = 22.5 Hz) with an upfield shift of −313 ppb from the normal signal at δ 72.89 (Fig. 2a). Under ^{2}H-decoupling conditions this triplet collapsed to a singlet (Fig. 2b) with an intensity of 4% relative to the overall intensity of the C-1 signal. In addition, the ^{2}H NMR spectrum of the compound displayed a single signal at δ 3.96, thus ensuring that the deuterium was specifically localized in the H_{Si} position of C-1.

On the basis of this evidence the stereochemical course of the conversion **1b** → **2b** can now be depicted as in Fig. 3a (R = H). The reaction is likely to occur through the intermediacy of the corresponding phosphoric acid monoesters (R = PO_3^{2-}).[4] Comparison with the mechanistically related steps involved in the biosynthesis of valine and isoleucine[11] (*cf.* Fig. 3b) reveals a close stereochemical matching, which suggests that in each of the reactions there is a steric necessity for the migrating group and the reducing cofactor to be located on opposite faces of the planes defined by the respective hydrogen-bridged α-hydroxycarbonyl substructures.

This work was supported by grants from the Deutsche Forschungsgemeinschaft (SFB 369) and the Fonds der Chemischen Industrie. Financial support by Novartis International AG, Basel (to D. A.) is gratefully acknowledged.

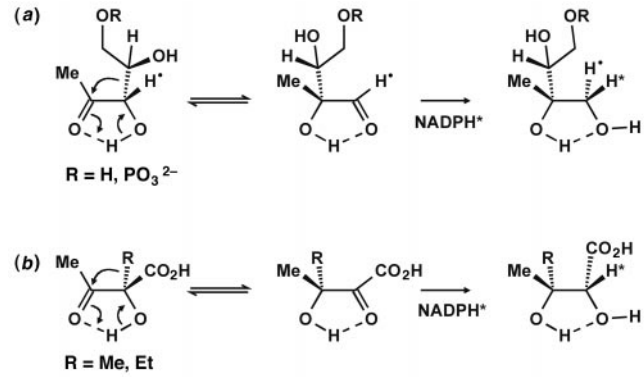

Fig. 3 (*a*) Stereochemical course of the 1-deoxyxylulose conversion into 2-*C*-methylerythritol. (*b*) stereochemical course of reductoisomerase reactions in the biosynthesis of valine (R = Me) and isoleucine (R = Et).

Notes and references

† In improvement of the original procedure a solution of 21 mg of **2b** in 8 ml of acetone was treated with 2 ml of 2.2 M $ZnCl_2 \cdot Et_2O$ in CH_2Cl_2 at room temperature for 24 h; after addition of 20 ml of $CHCl_3$ the organic phase was washed with $NaHCO_3$ (5%) and water, dried with $MgSO_2$ and concentrated to a crude oil, which was purified on a column of silica gel (0.5 × 10 cm) with hexane–EtOAc (3 : 1 v/v) as the solvent to yield pure **5** in a yield of 77%.

First total synthesis of (+)-koninginin D

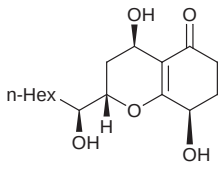
Gang Liu and Zhiqin Wang*

Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Feng Lin Lu, Shanghai 200032, China. E-mail: wangzq@pub.sioc.ac.cn

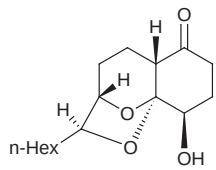
Received (in Cambridge, UK) 17th February 1999, Accepted 29th April 1999

A total synthesis of (+)-koninginin D (1) is described; the absolute configuration of the immediate antecedent of 1 is shown to have the configuration 7*R*,9*S*,10*S* by X-ray diffraction analysis.

(+)-Koninginin D, a biologically active natural product, was isolated from the culture of *Trichoderma koningii* Oudem by Ghisalberti *et al.* in 1989.[1] The structure and relative stereochemistry were determined as shown in structure **1.** Since



(+)-koninginin D **1**

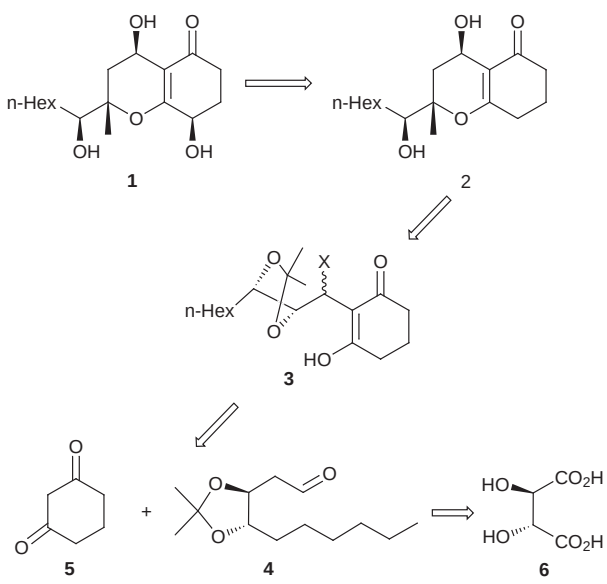


(–)-koninginin A

then four congeners of koninginin D have been isolated (koninginin A, B, C and E).[2] In 1995 Mori and Abe[3] and Xu and Zhu[4] published the total synthesis and absolute configuration of (−)-koninginin A independently. Here we report the total synthesis of (+)-koninginin D.

Mori constructed chiral centers C_9 and C_{10} of (−)-koninginin A *via* the Sharpless asymmetric dihydroxylation, while Xu used tartaric acid as the starting material to establish the two chiral vicinal hydroxy groups. Because koninginins A–E were isolated from a culture of the same species of microorganism, we suggested that (+)-koninginin D has the same absolute configuration at C_9 and C_{10} as that of (−)-koninginin A. Our retrosynthetic analysis of (+)-koninginin D is shown in Scheme 1.

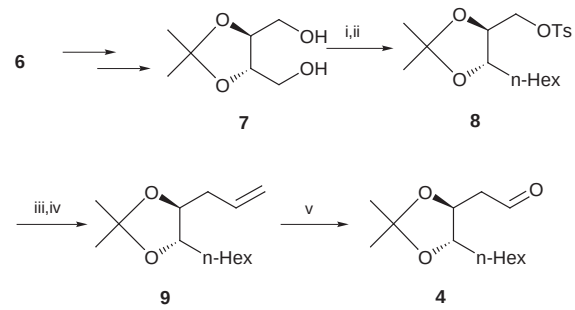
The synthesis of **4** is shown in Scheme 2. According to the known procedure[5] (+)-tartaric acid was transformed to diol **7**, which when treated with TsCl and $C_5H_{11}MgBr$ afforded monoalkylated acetonide **8** in 48.5% yield. Compound **8** was transformed to the iodo compound with NaI, which when reacted with CH_2=CHMgBr in the presence of CuI gave **9**.[6] Ozonolysis of **9** afforded **4**. The overall yield of **4** from **7** is 30% (5 steps).



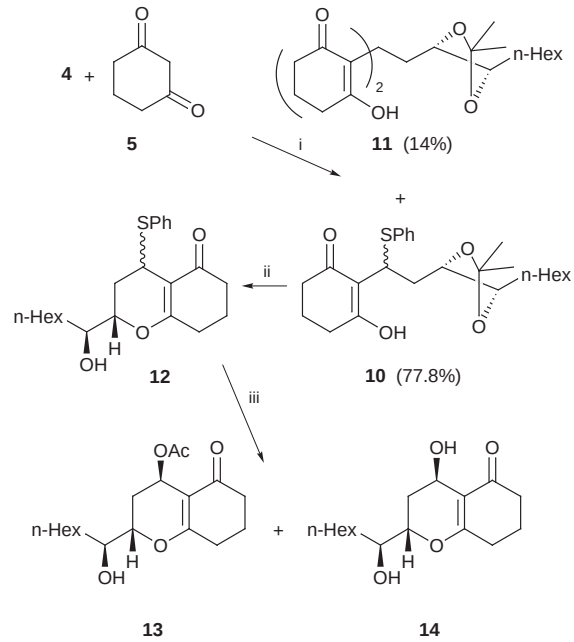
Scheme 1

The condensation of **4** and cyclohexane-1,3-dione **5** was performed by the method described by Paquette *et al.*,[7] giving **10** and a small amount of the Michael addition product **11** (Scheme 3)

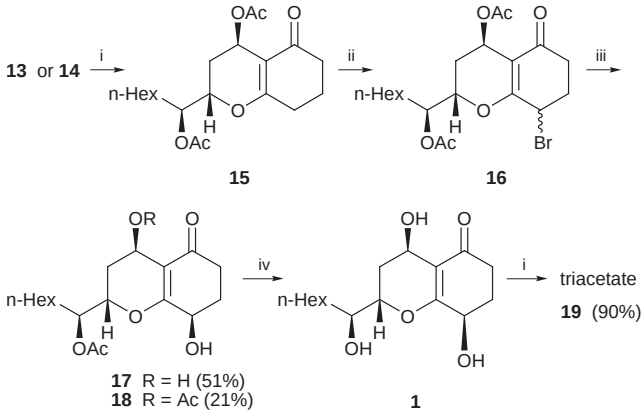
Treatment of **10** with dilute HCl in acetone resulted in deprotection and cyclization furnishing **12**. Under the reaction of $Hg(OAc)_2$ in AcOH the PhS group of **12** was replaced by an AcO group, affording **13** and a small amount of **14**. X-Ray diffraction analysis revealed that the C_7 acetoxy group of **13** is *trans* to the β-alkyl group.† Since the chiral centers C_9 and C_{10}



Scheme 2 *Reagents and conditions*: i, TsCl, CH_2Cl_2, Et_3N, rt, 6 h, 95%; ii, $C_5H_{11}MgBr$, THF, Li_2CuCl_4, −78 °C to rt, 5 h, 51%; iii, NaI, DMF, 80 °C, 2 h, 91%; iv, CH=CHMgBr, CuI, HMPA, THF, −30 to 10 °C, 20 h, 75%; v, O_3, CH_2Cl_2, MeOH, −78 °C, 91%.



Scheme 3 *Reagents and conditions*: i, PhSH, SiO_2, CH_2Cl_2, 30–35 °C; ii, 2 M HCl, acetone, rt, 24 h, 87%; iii, AcOH, $Hg(OAc)_2$, rt, 5 h, 84%.



Scheme 4 *Reagents and conditions*: i, Ac_2O, Et_3N, DMAP, rt, 2 h, 95%; ii, NBS, AlBN, CCl_4, reflux, 2 h, 69%; iii, NaI, dioxane, $CaCO_3$, H_2O, reflux, 48 h, 72%; iv, MeOH, Na_2CO_3, H_2O, rt, 1 h, 91%.

of **13** came from (+)-tartaric acid the absolute configuration of **13** can be assigned as 7*R*,9*S*,10*S*. Both of **13** and **14** treated with Ac_2O gave **15**. Attempts to introduce a hydroxy group at C_4 *via* allylic oxidation of **15** with reagents like SeO_2, $SeO_2{\cdot}SiO_2$, $Hg(OAc)_2$, $Pb(OAc)_4$ and $AcOBu^t$ failed.

Allylic bromination of **15** with NBS gave **16** in fairly good yield. Nucleophilic substitution of **16** *via* the method described by Wu [8] produced a mixture of 4β-hydroxy compounds **17** and **18**, both of which upon hydrolysis gave (+)-koninginin D **1** as a white powder, mp 140–142 °C (hot plate); $[\alpha]_D^{20}$ 171 (*c* 0.125, $CHCl_3$) [ref. mp 122–123 °C, $[\alpha]_D$ +166.9 (*c* 0.3, $CHCl_3$)] (Scheme 4). The H^1 NMR, C^{13} NMR and mass spectra of **1** and its triacetate **19** were identical with those of natural (+)-koninginin D and its triacetate, respectively.‡ The overall yield of (+)-koninginin D from tartaric acid was 4.1% (15 steps).

Communication 9/01320B

A zwitterionic carbene–plumbylene adduct

Frank Stabenow, Wolfgang Saak and Manfred Weidenbruch*

Fachbereich Chemie, Universität Oldenburg, D-26111 Oldenburg, Germany

Received (in Liverpool, UK) 13th April 1999, Accepted 28th April 1999

4,5-Dimethyl-1,3-diisopropylimidazol-2-ylidene reacts with bis(2,4,6-triisopropylphenyl)plumbylene to furnish the adduct 4 as yellow crystals; an X-ray structure analysis of 4 revealed a very long lead–carbon bond of 254.0(5) pm and a pyramidal lead centre with a bending angle of 70.5°.

Since the first isolation of thermally stable carbenes of the imidazol-2-ylidene type[1] the chemistry of this class of compounds has undergone vigorous developments, which were recently reviewed.[2] The nucleophilicity of these molecules is reflected, for example, in the formation of adducts with GeI_2,[3] $SnCl_2$,[4] and even a diarylstannylene.[5] Lead(II) derivatives of this carbene system were previously unknown. We now report on the formation and structure of the first adduct between a plumbylene and an imidazol-2-ylidene.

Compound **1** (Scheme 1) which we recently prepared[6] is the first diplumbene having a Pb=Pb double bond length and *trans*-bending angle of the sizes predicted by theoretical calculations.[7–9] Although **1** is indefinitely stable in the solid state under exclusion of light and air, it decomposes in solution to furnish predominately the plumbylene molecules **2** as a consequence of the low Pb=Pb bond dissociation energy, calculated to be merely 24 kJ mol^{-1} for the parent compound $H_2Pb{=}PbH_2$.[9] Addition of the carbene **3**[10] to a violet solution of **2** in toluene results in a spontaneous change in the colour of the solution to orange. Replacement of the toluene by *n*-hexane and cooling to −30 °C then affords compound **4** as yellow crystals in 43% yield. The adduct **4** is sensitive to light and air and the solid decomposes at room temperature. It is only stable in solution in the presence of an excess of **2**. All attempts to record NMR and electron spectra of pure **4** have failed because deposition with formation of 1,3,5-triisopropylbenzene occurs even at −70 °C in C_7D_8 solution.

Accordingly, our determination of the constitution of **4** is based solely on a low-temperature, X-ray crystallographic analysis (Fig. 1)† which, however, does reveal some interesting features. The Pb–C(carbene) bond length of 254.0(5) pm is unusually long and is probably one reason for the lability of the molecule. While the carbon atom C(1) exhibits an almost planar environment, the lead atom shows a pyramidal arrangement of its substituents as reflected by the bending angle of θ = 70.5° between the plane of the atoms C(12)–Pb–C(27) and the Pb–C(1) vector.

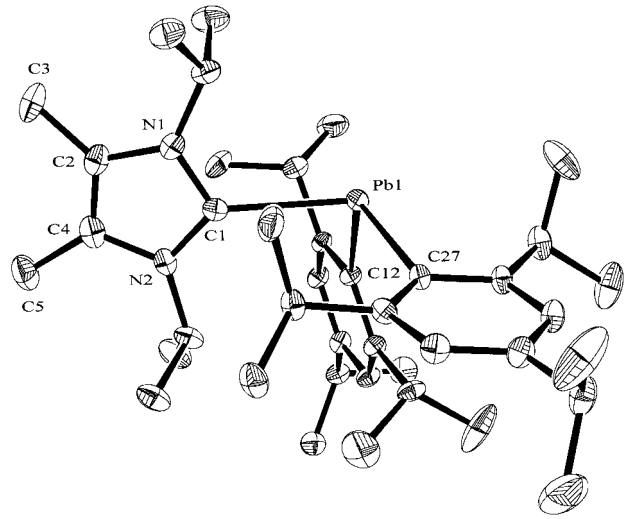

Fig. 1 Molecular structure of **4** (50% probability, hydrogen atoms omitted). Selected bond lengths (pm) and angles (°): C(1)–Pb 254.0(5), C(12)–Pb 237.6(4), C(27)–Pb 238.3(4), C(1)–N(1) 135.7(6), C(1)–N(2) 136.3(6), N(1)–C(2) 139.3(7), N(2)–C(4) 140.3(7), C(2)–C(4) 134.0(8), C(12)–Pb–C(27) 105.3(1), C(12)–Pb–C(1) 90.1(1), C(27)–Pb–C(1) 108.8(1), N(1)–C(1)–N(2) 104.6(4).

These results clearly indicate that, of the two possible electronic forms of the molecule **4** (Scheme 2) (the plumbene form **4a** and the zwitterionic form **4b**), the latter dominates. Further evidence in support of the existence of **4b** is provided by the Pb–C(*ipso*) bond lengths which are 8 pm longer than those in **1**.[6] Similarly, density functional theory calculations for the parent compound $H_2Pb{=}CH_2$, predicting a planar molecule with a Pb=C bond length of 204.5 pm,[8] are also suggestive of the loose adduct **4b** rather than a molecule with a Pb=C double bond of type **4a**. A bonding situation formally similar to that of **4b** may be present in the cyclopropylidene adduct of a diaminoplumbylene in which, however, the Pb=C bond length is 12 pm shorter such that the molecule is accordingly more stable.[11]

Although germenes and stannenes are now well-established,[12] molecules with Pb=C double bonds remain unknown. All attempts to achieve this goal by reaction of **2** and similarly constructed plumbylenes[13] with electrophilic carbenes of the cryptodiborylcarbene type[14] have been unsuccessful. This seems to indicate that diarylplumbylenes preferably participate in bond-forming reactions with nucleophilic rather than electro-

N–H activation *vs.* C–H activation: ruthenium-catalysed regioselective hydroamination of alkynes and hydroarylation of an alkene with *N*-methylaniline

Yuko Uchimaru

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305, Japan.
E-mail: y_uchimaru@home.nimc.go.jp

Received (in Cambridge, UK) 22nd March 1999, Accepted 12th May 1999

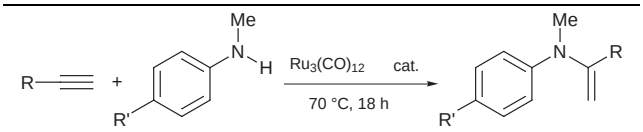
Phenylacetylene and its derivatives undergo regioselective insertion into the N–H bond of *N*-methylaniline in the presence of $Ru_3(CO)_{12}$ catalyst to afford *N*-methyl-*N*-(α-styryl)anilines in high yields, whereas styrene reacts with the *ortho* C–H bond of *N*-methylaniline giving 2-(1-phenylethyl)-*N*-methylaniline.

Transition metal complex-catalysed hydroamination of carbon–carbon double or triple bonds with non-tertiary amines is an attractive method for carbon–nitrogen bond formation. Indeed, various *intramolecular* hydroamination reactions of aminoalkenes and aminoalkynes have been reported to date.[1,2a] Although several examples of *intermolecular* reactions[2–5] have been also reported, the substrates for these reactions are usually limited to highly reactive or strained carbon unsaturated compounds.[4] We have found that ordinary alkynes undergo hydroamination with aromatic amines in the presence of a catalytic amount of $Ru_3(CO)_{12}$. This is the first example of ruthenium-catalysed *intermolecular* hydroamination. In addition, the same ruthenium complex catalyses regioselective hydroarylation reaction of an alkene with an aromatic amine *via ortho* C–H bond activation. We report here these ruthenium complex-catalysed reactions.

A mixture of phenylacetylene (**1a**, 0.25 mmol), *N*-methylaniline (**2a**, 2.5 mmol), and $Ru_3(CO)_{12}$ (0.0125 mmol Ru) was heated at 70 °C in a sealed glass tube under nitrogen. After 18 h, **1a** was completely consumed and *N*-methyl-*N*-(α-styryl)aniline (**3a**) was regioselectively formed in 85% GLC yield (based on the amount of **1a** charged) (Table 1, run 1). GLC and GC-MS analyses indicated that isomers of **3a** were less than 2% yield.† A similar result was obtained under milder conditions (50 °C, 3 d). In a separate four-fold scale reaction, **3a** was isolated in 61% yield by Kugelrohr distillation and was fully characterised by ^1H and ^{13}C NMR, IR and GC-MS analyses.‡

The catalytic activity of several transition metal complexes was also examined for the present reaction (**1a** : **2a** : catalyst = 1 : 10 : 0.05 mol ratio, 70 °C, 18 h). A ruthenium complex $[RuCl_2(CO)_3]_2$ was found to promote the reaction. However, the catalyst $Ru_3(CO)_{12}$ was more effective; 85% yield of **3a** with $Ru_3(CO)_{12}$, 69% with $[RuCl_2(CO)_3]_2$. In addition, the amine **2a** was more selectively transformed to **3a** with $Ru_3(CO)_{12}$ (96% selectivity based on the amount of **2a** consumed) than with $[RuCl_2(CO)_3]_2$ (74%). Other transition metal complexes such as $[RuCl_2(p\text{-cymene})]_2$, $RuCl_2(PPh_3)_3$, $[RuCl_2(cod)]_n$ $[CpRu(CO)_2]_2$, $Fe(CO)_5$, $Co_2(CO)_8$, $Co_4(CO)_{12}$, $PdCl_2(PPh_3)_2$ and Cp_2ZrMe_2 were ineffective. Thus, $Ru_3(CO)_{12}$ was the most effective among the complexes examined.

Table 1 Hydroamination of alkynes catalysed by $Ru_3(CO)_{12}$[a]



1 **2** **3**

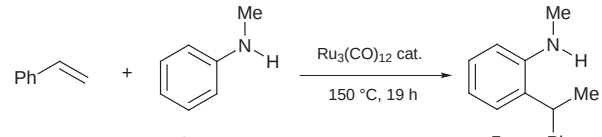
Run	1	R	2	R′	3	Yield (%)[b]
1	**1a**	Ph	**2a**	H	**3a**	85
2	**1b**	*p*-MeC_6H_4	**2a**	H	**3b**	78
3	**1c**	*p*-FC_6H_4	**2a**	H	**3c**	88
4	**1a**	Ph	**2b**	Me	**3d**	76
5	**1d**	Cyclohex-1-enyl	**2a**	H	**3e**	77

[a] **1** 0.25 mmol; **2** 2.5 mmol; $Ru_3(CO)_{12}$ 0.0125 mmol/Ru; 70 °C for 18 h. [b] GLC yields based on the charged amount of alkyne **1**.‡

Table 1 summarises the results of the reactions of alkynes **1a**–**d** with *p*-substituted *N*-methylanilines **2a**,**b**. In all cases, the corresponding enamines **3a**–**e** were obtained in high yields. The results of *p*-substituted phenylacetylenes **1a**–**c** (runs 1–3) suggest that an electron-withdrawing substituent at the *para*-position increases the yield of **3**. The tendency was more clearly observed when the reactions were carried out under the retarded reaction conditions (**1** : **2a** = 1 : 1 mol/mol, in toluene, 70 °C, 18 h); the yields of products: **3c** (26%) > **3a** (13%) > **3b** (4%).§ A conjugated enyne, 1-ethynylcyclohexene (**1d**) also underwent hydroamination with **2a** to give enamine **3e** under similar conditions (run 5).

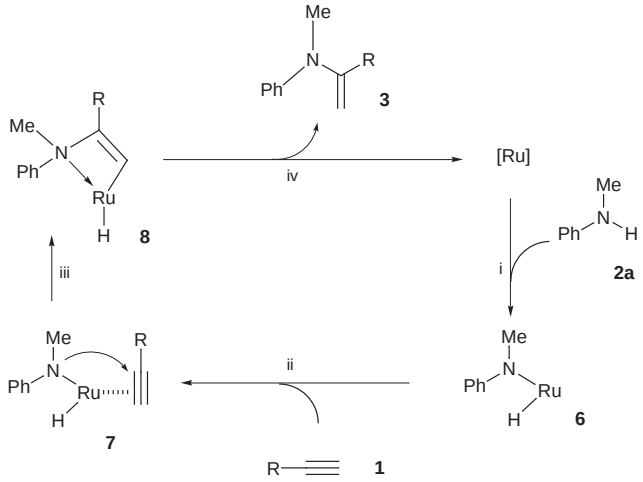
Surprisingly, when styrene (**4**) was used instead of alkynes, the reaction course was completely different. As shown in Scheme 1, the hydroarylation product, 2-(1-phenylethyl)-*N*-methylaniline (**5**), was selectively obtained in 83% yield after heating a mixture of **4** (0.25 mmol), **2a** (0.25 mmol), $Ru_3(CO)_{12}$ (0.0125 mmol Ru) and toluene (0.2 ml) at 150 °C for 19 h.‡ The hydroamination product was not detected at all. Treatment of the same mixture at 70–100 °C reaction temperature resulted in complete recovery of both starting materials **2a** and **4**. Previously a $[RhCl(PEt_3)_2]_2$–lithium amide system was reported to promote hydroarylation of norbornene with aniline.[4d] In this system, however, not only hydroarylation, but also hydroamination proceeded at the same time, and the combined yields for both reactions were not high. Therefore we believe that our present reaction is the first successful example of transition-metal complex-catalysed hydroarylation of an alkene with an aromatic amine.[6]

A plausible mechanism for hydroamination of alkyne is shown in Scheme 2, which involves (i) oxidative addition of the N–H bond of amine **2** to a coordinatively unsaturated ruthenium(0) centre giving the (amido)ruthenium hydride **6**,[7,8] (ii) coordination of alkyne **1** to the ruthenium centre to form complex **7**, followed by (iii) intramolecular nucleophilic attack of the nitrogen lone pair of **7** on the coordinated carbon–carbon triple bond,[4a,d] and (iv) reductive elimination of enamine **3** from the vinyl ruthenium species **8** to reproduce the coordinatively unsaturated ruthenium(0) centre.¶ The trend of the relative

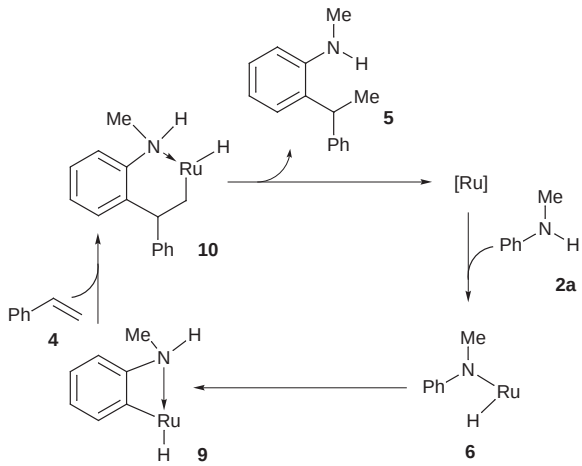


4 **2a** **5**

Scheme 1



Scheme 2



Scheme 3

reactivities of *para*-substituted phenylacetylenes **1a**–**c** toward **2a** (*vide supra*) is consistent with step (iii). On the other hand, the striking difference in the reaction course for styrene (hydroarylation) may be explained by a mechanism depicted in Scheme 3. Probably because of the lower coordination ability of the carbon–carbon double bond to the metal centre,[8] the styrene analogue of complex **7** might not be produced from the (amido)ruthenium hydride complex **6**. Instead, if *ortho* C–H bond activation[9] takes place to form complex **9**, hydroarylation product **5** could be formed *via* a ring expansion reaction of the strained four-membered ruthenacycle **9** with styrene followed by reductive elimination from the resulting six-membered ruthenacycle **10**.

To summarize, we have found the first examples of ruthenium-complex catalysed regioselective hydroamination and hydroarylation of carbon–carbon multiple bonds with *N*-methylaniline. The reaction course depends on the structure of the unsaturated substrate. Studies on other substrates and the mechanism are in progress.

Notes and references

† Trimers of **1a**, such as 1,2,4-triphenylbenzene and 1,3,5-triphenylbenzene, were detected in 5 and 2% yields, respectively.

‡ All the products in this study were known and were identified by ^{1}H and ^{13}C NMR, IR and GC-MS analyses or by comparison with authentic samples. For synthesis of authentic samples of the enamines, see J. Barluenga, F. Aznar, R. Liz and R. Rodes, *J. Chem. Soc., Perkin Trans. 1*, 1980, 2732. For an authentic sample of 2-(1-phenylethyl)-*N*-methylaniline, see M. M. Aly, M. Z. Badr, A. M. Fahmy and S. A. Mahgoub, *Acta Chim. Hung.*, 1985, **120**, 15.

§ Recoveries of the starting materials are as follows; for the reaction of **1c** (**1c** 69%, **2a** 72%), for the reaction of **1a** (**1a** 85%, **2a** 86%), for the reaction of **1b** (**1b** 94%, **2a** 96%).

¶ Since activation of an N–H bond of aniline by $Ru_3(CO)_{12}$ was reported to take place under reaction conditions similar to those in the present reaction [see ref. 7(*a*)], we propose a mechanism with the (amido)ruthenium hydride **6** involved as an intermediate [step (i)]. However, because of the relatively high coordination ability of the carbon–carbon triple bond with the metal centre, we cannot completely exclude the possibility of another mechanism which includes alkyne coordination to the Ru metal centre followed by nucleophilic attack of an amine nitrogen at the activated carbon–carbon triple bond.

Lanthanum(III) capture of 18-crown-6 in the cavity of *p*-sulfonatocalix[4]arene

Alexander Drljaca,[a] Michaele J. Hardie,[a] Julian A. Johnson,[b] Colin L. Raston[a] and Helen R. Webb[a]

[a] *Department of Chemistry, Monash University, Clayton, Melbourne, Victoria, 3168, Australia. E-mail: c.raston@sci.monash.edu.au*

[b] *CSIRO Minerals, Clayton, Melbourne, Victoria, 3168, Australia*

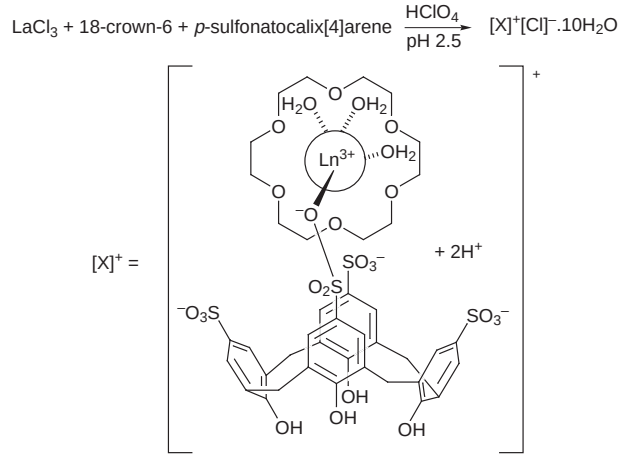
Received (in Columbia, MO, USA) 2nd March 1999, Accepted 13th April 1999

Aqueous solutions of sodium *p*-sulfonatocalix[4]arene, 18-crown-6 and lanthanum(III) trichloride at pH 2.5 afford the 'ferris wheel' type supercation: [{Ln^{3+}⊂(18-crown-6)$(OH_2)_3$}∩{(*p*-sulfonatocalix[4]arene^{4-} + 2H^+)}]$^+$ isolated as the chloride with numerous waters of crystallisation.

The coordination selectivity exhibited by calixarenes toward rare earth cations has been widely investigated because of its implications for separation science.[1] Of particular interest are the interactions with the highly charged and water-soluble sodium *p*-sulfonatocalixarenes.[2–5] These show remarkable inclusion properties for both ionic and neutral molecules (especially the smaller sized calix[4 and 5]arenes).[5–8] As crown ethers are good lanthanide complexants[9] it was anticipated that they would also be useful supramolecular synthons. Thus the species formed when combining a rare earth cation, crown ether, and sodium *p*-sulfonatocalixarene was explored. Whilst these systems may ultimately prove important for the separation of lanthanides, the assembly of such multicomponent arrays is of interest in itself.

Herein we report the results of the interaction between the cone-shaped sodium *p*-sulfonatocalix[4}arene, 18-crown-6, and lanthanum(III) chloride in aqueous media. The interplay between the two macrocycles has proved effective in stabilising, and in some cases selectively crystallising, a broad range of highly charged polynuclear aqua cations. Specifically, $[Cr_2(OH)_2(H_2O)_8]^{4+}$, $[Cr_3(OH)_4(H_2O)_{10}]^{5+}$ and $[Cr_4(OH)_6(H_2O)_{12}]^{6+}$, and $[Al_3O_4(OH)_{12}(OH)_{24}(H_2O)_{12}]^{7+}$ have been identified.[10] The main counterions are globular-like ionic capsules or superanions [{Na^+⊂(18-crown-6)$(OH_2)_2$}⊂{(*p*-sulfonatocalix[4]arene^{4-})$_2$}]$^{7-}$ (Θ^{7-}), which vary their crown ether conformation and degree of protonation with the polynuclear cation. A variety of cohesive forces are present in these solid-state ionic capsules, including hydrogen bonding, electrostatic, π-stacking, and van der Waals interactions. Additionally, the crown ether and the calixarene exhibit a complementarity of curvature, albeit after some geometric pre-organisational requirements. In the present study a new type of assembly results whereby the crown ether (containing a lanthanide and three water molecules) resides in one calixarene, as a perched structure, like a 'ferris wheel' with the rotation axis about a metal to O-centre of a sulfonate group. This supercation has a single positive charge and hence two of the sulfonate groups are protonated, as [{Ln^{3+}⊂(18-crown-6)$(OH_2)_3$} ∩ {(*p*-sulfonatocalix[4]arene^{4-} + 2H^+)}]$^+$ ([X]$^+$). It is noteworthy that the formation of an ionic capsule, Θ^{7-} or the partially protonated forms, is precluded in the present study by (i) the lanthanide ions effectively competing with sodium to form the central ionic core, demanding a different coordination environment, and/or (ii) the trivalent positive charge of the metal ion being insufficient to overcome the electrostatic repulsion between two calixarenes in the ionic capsule (at least for the pH of the solutions studied).

The complex [X]$^+$[Cl]$^-$.10H_2O crystallised from an aqueous solution of sodium *p*-sulfonatocalix[4]arene,[11,12] 18-crown-6, and lanthanum trichloride hexahydrate[12] at pH 2.5 (which was adjusted using perchloric acid) (Scheme 1).† Using small-scale reactions varying in 0.5 pH units, it was established that



Scheme 1

crystallisation occurred over a narrow pH range (2.5–3). The proposed composition of this structure is reinforced by electron microprobe results which show that lanthanum and chloride are present, and in an equivalent stoichiometric ratio.

Crystals suitable for X-ray diffraction‡ deposited over several days. They crystallised in the space group $P3_1$ with the supercation [X]$^+$, the counter ion, and ten water molecules in the asymmetric unit. Results are reported in Fig. 1 and 2. As can be

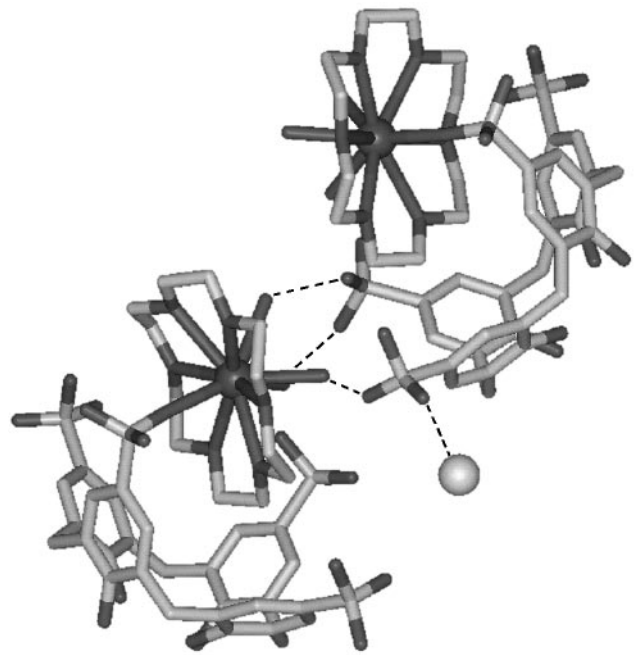


Fig. 1 Projection of two supercations [X]$^+$ in **1** showing associations between sulfonate groups and coordinated waters and sulfonate groups and chloride ions; hydrogen atoms have been removed for clarity and implied hydrogen-bonding interactions are represented by dashed lines.

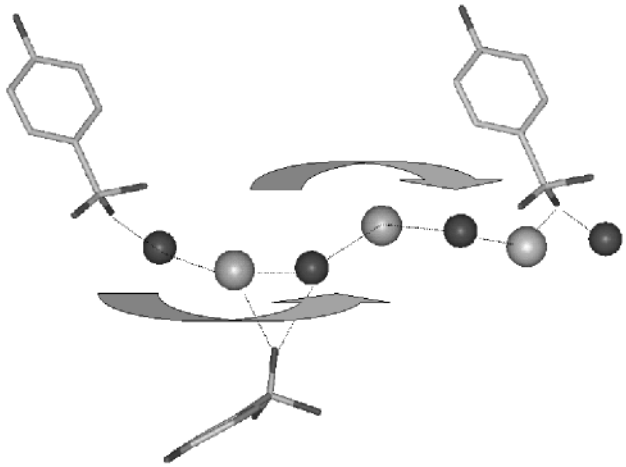

Fig. 2 Hydrogen bonded helical array of supercations, chlorides and waters of crystallisation. Only one phenyl group of each supercation is shown for clarity.

seen, the lanthanide is bound symmetrically by the six crown ether oxygen atoms [La–O = 2.654(5) to 2.733(5) Å] (Fig. 1). Assisted by the complementarity of curvature, this moiety resides in the cavity of the calixarene *via* a La–sulfonate linkage [La–O = 2.418(5) Å] and van der Waals interactions. The metal centre also has three water molecules attached at 2.557(5), 2.558(5) and 2.542(5) Å, on the opposite side to the sulfonate group relative to the plane of the crown ether, and these hydrogen bond to a single adjacent supercation (Fig. 1, O···O distances = 2.696, 2.799, 2.916 Å). The coordination environment around the lanthanide is unexceptional.[13]

Complementarity of curvature of the crown ether with that of the calixarene is achieved by the splaying of two opposite phenol groups (with torsion angles between the opposite phenol groups of 140.5 and 79.9°). In comparison the analogous angles in the ionic capsules Θ^{7-} range from 93–100°, and 46–59° respectively.[10] Due to the linkage between the metal and the calixarene, in the present structure the plane of the crown ether is rotated towards the cavity of the calixarene by 51.6° with respect to the vector of symmetrical approach. Within the crystal lattice an infinite helical array of the supercations, chloride counterions and water is formed through hydrogen bonding associations (Fig. 2).

In conclusion, using a combinatorial approach we have gained access to a novel supercation comprised of four components. By varying the pH in a systematic way, there is scope for constructing a wide range of structural types for such multicomponent systems.

Support of this research from the Australian Research Council is gratefully acknowledged.

Notes and references

† *Synthesis*: Using an excess of the metal salt, 13 mg of $LaCl_3.6H_2O$ (3.8×10^{-2} mmol), 15.5 mg of *p*-sulfonatocalix[4]arene (1.89×10^{-2} mmol) and 5 mg of 18-crown-6 (1.89×10^{-2} mmol) were dissolved in *ca.* 1 ml of water and the pH adjusted to 2.5 using a few drops of concentrated perchloric acid (65%). A yield of 13% was obtained (*ca.* 3 mg). Electron microprobe: lanthanum and chlorine are present in an equal ratio.

‡ *Crystal data* for **1**: $C_{40}H_{72}ClLaO_{35}S_4$, M_r = 1415.59; trigonal (hexagonal setting), $P3_1$, $a = b$ = 20.1097(3), c = 13.2080(3) Å, V = 4625.7 Å^3, Z = 3, μ = 0.963 mm^{-1} (no correction), 25935 data collected, 12878 unique (R_{int} = 0.044), number of parameters = 729, final GoF = 1.038, R_1 = 0.0591 [on 11332 observed data with $I > 2\sigma(I)$], wR_2 = 0.1720, (all data). Data were collected at 123(1) K on an Enraf-Nonius KappaCCD diffractometer using Mo-Kα radiation (λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-97) and refined using full-matrix least-squares on F^2 (SHELXL-97). All nonhydrogen atoms were refined anisotropically except for two disordered water positions that were refined isotropically, and all C-H hydrogens were fixed at geometrically estimated positions. Interestingly, a crystal with a corresponding unit cell [trigonal (hexagonal setting), $P3_1$, $a = b$ = 20.0838(3), c = 13.1953(2) Å] was also isolated from a solution prepared in an analogous way using lanthanum *tris*(trifluoromethanesulfonate) nonahydrate. Perchloric acid was not required to acidify the solution to *ca.* pH 2.5. Electron microprobe results indicate that lanthanum and fluorine are present, but not chlorine. CCDC 182/1251. Cyclam crystallised from $CHCl_3$–hexane gives infinite, hydrogen bonded assembled columns; in acidic aqueous media (pH 2) in the presence of sodium *p*-sulfonatocalix[4]arene and the dichromium(III) aqua ion, the superanion or ionic capsule $[[H_4(cyclam)]^{4+} \subset \{(p\text{-sulfonatocalix[4]arene}^{4-})_2\}]^{4-}$ crystallises as the salt of $[Cr_2(OH)_2(H_2O)_8]^{4+}$.

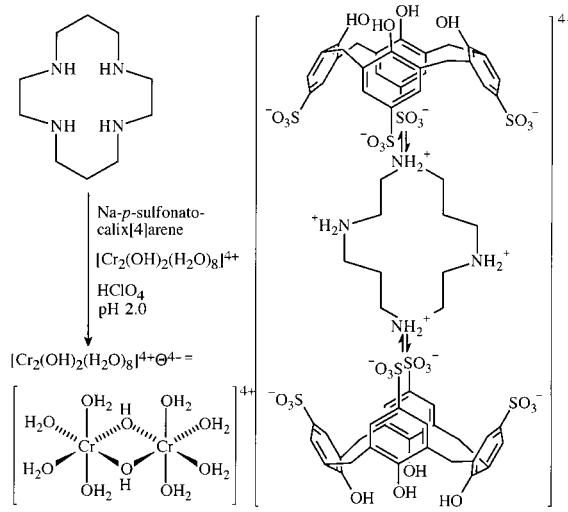
Cyclam (1,4,8,11-tetraazacyclotetradecane) is a traditional macrocyclic ligand in metal ion chemistry.[1] It can be di- or tetra-protonated at low pH to form cationic macrocycles. The tetra-protonated form $[H_4(cyclam)]^{4+}$ adopts an *exodentate* conformation[2] while the di-protonated $[H_2(cyclam)]^{2+}$ and neutral molecule adopt an *endodentate* conformation.[3,4] The neutral molecule has four nitrogen centres capable of hydrogen bonding, as donor and/or acceptor groups, and in this regard its potential in supramolecular chemistry, at least where one of the modes in intermolecular interplay involves hydrogen bonding, is yet to be realised. Both the di- and tetra-protonated forms, on the other hand, have been used as templates in crystal engineering studies, forming polymeric arrays with a variety of anions.[2,3] In exploring this chemistry we have discovered two remarkable, disparate, hydrogen bonding arrays. One of these is the crystallisation of solvent free, pure cyclam from $CHCl_3$–hexane solutions.

The other hydrogen bonding array is associated with the formation of a new ionic capsule where the $[H_4(cyclam)]^{4+}$ is shrouded by two *p*-sulfonatocalix[4]arenes, *viz* $[[H_4(cyclam)]^{4+} \subset \{(p\text{-sulfonatocalix[4]arene}^{4-})_2\}]^{4-}$ (Θ^{4-}), isolated as the salt of the dichromium(III) cation $[Cr_2(OH)_2(H_2O)_8]^{4+}$. The bowl-shaped, highly charged and water soluble *p*-sulfonatocalixarenes, usually used as their sodium salts, show remarkable inclusion properties for ionic guests and neutral molecules, for both calix[4 and 5]arenes.[5] As to the ionic capsule reported, we note that these classes of compounds have only recently been established, but with a metal crown ether complex in the centre of the capsule, $[\{Na^+ \subset (18\text{-crown-6})(OH_2)_2\} \subset \{(p\text{-sulfonatocalix[4]arene}^{4-})_2\}]^{7-}$, which is effective in crystallising, in some cases selectively, the polynuclear cations $[M_2(OH)_2(H_2O)_8]^{4+}$, $[M_3(OH)_4(H_2O)_{10}]^{5+}$ and $[M_4(OH)_6(H_2O)_{12}]^{6+}$ (M = Cr or Rh), and $[Al_{13}O_4(OH)_{12}(OH)_{24}(H_2O)_{12}]^{7+}$.[6] Ionic capsules relate to other contemporary studies on self-assembly of neutral molecular capsules,[7] as does the formation of a 1:1 crown ether to calixarene perched structure with lanthanum(III) in the crown ether, $[\{Ln^{3+} \subset (18\text{-crown-6})(OH_2)_3\} \cap \{(p\text{-sulfonatocalix[4]arene}^{4-} + 2H^+)\}]^+$.[8] The ionic capsule is without precedence, and its ability to crystallise as a dichromium(III) aqua cation suggests it has potential in forming complexes of a wide range of large cationic species, with ultimate applications in separation science. A key feature of the ionic capsules is the complementarity of curvature of the cyclam with the calixarene, albeit with some geometrical preorganisational requirements.

Complex $[Cr_2(OH)_2(H_2O)_8]^{4+}\Theta^{4-}$ crystallised from a solution of cyclam, sodium *p*-sulfonatocalix[4]arene, and the perchlorate salt of the dichromium(III) cation, with the pH adjusted to 2 using perchloric acid (Scheme 1).† This is the only example of an ionic capsule where the charge on the superanion matches that required by the polynuclear cation, without the need to invoke some degree of protonation of the superanion, unlike for complexes involving $[\{Na^+ \subset (18\text{-crown-6})(OH_2)_2\} \subset \{(p\text{-sulfonatocalix[4]arene}^{4-})_2\}]^{7-}$, which can adjust the degree of protonation depending on the polynuclear cation.

Crystals suitable for X-ray diffraction studies of cyclam and $[Cr_2(OH)_2(H_2O)_8]^{4+}\Theta^{4-}.6(H_2O)$‡ deposited over several days. Both crystallise in $P\bar{1}$ systems with the two independent cyclams residing over centres of symmetry (Fig. 1), or the ionic capsule and cation residing over inversion centres (Fig. 2). Cyclam has been reported to have an *endodentate* conformation[4] although a detailed structure is not available.[9] Cyclam (Fig. 1) has two opposite NH groups in the plane of and directed into the centre of the macrocycle, which form intramolecular hydrogen bonds across the 1,3-diamine groups at N–H···N distances of 2.243 and 2.273 Å (corresponding N···N 2.934 and 2.948 Å) and angles at the hydrogen of 135.7 and 133.1°. These are slightly longer interactions than the intramolecular hydrogen bonding observed for $[H_2(cyclam)]^{2+}$.[3] The remaining two N–H groups are directed away from the macrocycle and form



Scheme 1

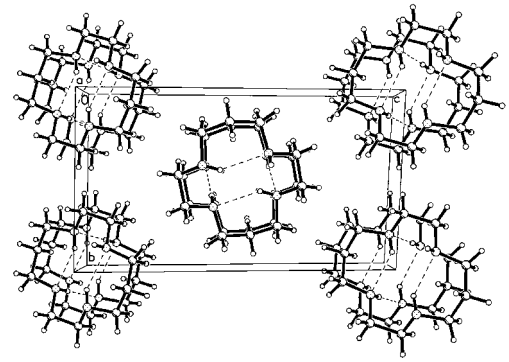


Fig. 1 Packing diagram for cyclam showing the intermolecular hydrogen bonded columnar arrays and intramolecular hydrogen bonding (hydrogen bonds indicated by dashed lines).

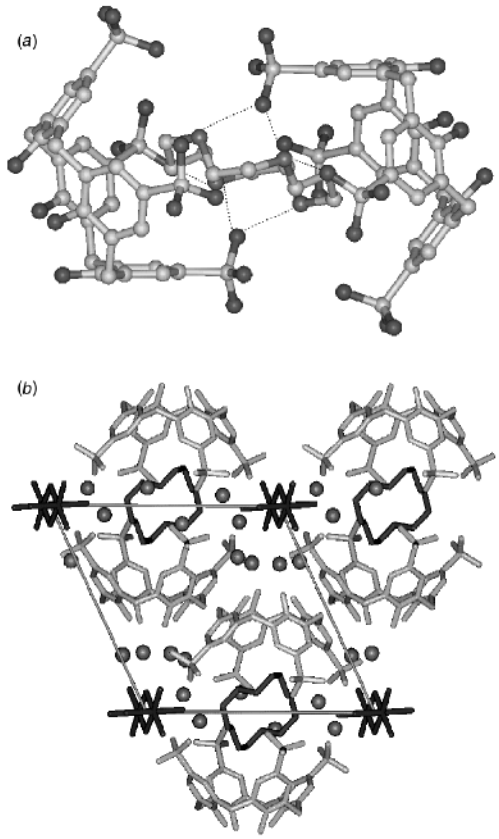

Fig. 2 Projection of (*a*) the superanion $[[H_4(cyclam)]^{4+} \subset \{(p\text{-sulfonatocalix[4]arene}^{4-})_2\}]^{4-}$ (Θ^{4-}), hydrogen atoms have been removed for clarity and implied hydrogen-bonding interactions are represented by dashed lines, and (*b*) unit cell and packing in $[Cr_2(OH)_2(H_2O)_8]^{4+}\Theta^{4-}.6(H_2O)$.

intermolecular N–H···N hydrogen bonds giving columns of cyclam held together by alternating pairs of intermolecular hydrogen bonds at N–H···N distances of 2.296 and 2.267 Å (corresponding N···N 3.155 and 3.143 Å). The intermolecular hydrogen bonds are considerably more direct than the intramolecular hydrogen bonds with N–H···N angles of 178.1 and 177.0°.

In the structure of $[Cr_2(OH)_2(H_2O)_8]^{4+}\Theta^{4-}.6(H_2O)$ the $[H_4(cyclam)]^{4+}$ is locked within the capsule by an intricate hydrogen bonded array [Fig. 2(*a*)]. Protons were not found crystallographically and the hydrogen bonding network is implied through numerous close N···O contacts ranging from 2.61 to 2.83 Å. There are close N···O contacts, in addition to those shown in Fig. 2(*a*), with a sulfonate group of another capsule and a water molecule, hence each N-centre is associated with at least two hydrogen bonds, which, along with its *exodentate* conformation,[2] is good evidence that the cyclam is the tetra-protonated species $[H_4(cyclam)]^{4+}$. The capsule itself is not as symmetrical as those containing crown ether,[6] with the two bowl cavities offset relative to each other, presumably to maximise hydrogen bonding and for geometrical complementarity between the interacting hydrophobic components of the cyclam and calixarene. The conformation of the calixarene, however, is more symmetrical than for the crown ether ionic capsules where two opposite phenol groups are splayed apart, with dihedral angles 93–100° relative to the other two, dihedral angle 46–59°.[6] In the present structure the corresponding dihedral angles are 81 and 52°. Packing of the capsules within the crystal lattice shows sulfonate to hydroxy hydrogen bonding between calixarenes of adjacent capsules (O···O separations of 2.87 and 2.90 Å) complemented by a slightly displaced π stacking of phenyl groups (centroid separation 3.62 Å, closest C···C = 3.43 Å, torsion angle between aromatic faces = 0°) [Fig. 2(*b*)]. The dichromium cations sit at the hydrophilic equator of the capsules [Fig. 2(*b*)], with close O···O contacts between the coordinated waters and sulfonate groups ranging from 2.62 to 2.77 Å. The geometry of the dichromium cation is unexceptional[6,10] and deviates from strict octahedral coordination.

Overall, we have established new supramolecular chemistry of cyclam, that of pure cyclam as a reference point in the area, and that of the capsule which gives further insight into construction of ionic capsules.

Support of this research from the Australian Research Council is gratefully acknowledged.

Notes and references

† Synthesis of $[Cr_2(OH)_2(H_2O)_8^{4+}\Theta^{4-}$: An aqueous solution of sodium *p*-sulfonatocalix[4]arene and cyclam in 2 : 1 proportions was added to an aqueous solution of $[Cr_2(OH)_2(H_2O)_8][ClO_4]_4$ and the pH of the mixture was adjusted to pH 2.0 with aqueous $HClO_4$. Pale green crystals of $[Cr_2(OH)_2(H_2O)_8]^{4+}\Theta^{4-}$ grew as a hexahydrate over several weeks. Crystals were sensitive to loss of solvent, becoming opaque on removal from mother liquor.

‡ Data were collected at 123(1) K on an Enraf-Nonius KappaCCD diffractometer with Mo-Kα radiation, λ = 0.71073 Å. Structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares on F^2 (SHELXL-97). *Crystal data* for Cyclam: $C_{10}H_{24}N_4$, M_r = 200.33, crystal size = 0.23 × 0.18 × 0.13 mm, triclinic, $P\bar{1}$, a = 4.6353(3), b = 8.5958(6), c = 15.2418(10) Å, α = 90.704(3), β = 96.743(4), γ = 99.336(4)°, V = 594.80(6) Å^3, Z = 2, μ = 0.07 mm^{-1} (no correction), $2\theta_{max}$ = 60.14°, 4366 data collected, 2989 unique (R_{int} = 0.023), 223 parameters, final GoF = 1.040, R_1 = 0.0498 [on 2198 observed data with $I > 2\sigma(I)$], wR_2 = 0.1099 (all data). All nonhydrogen atoms were refined anisotropically and all hydrogen atoms were located in the difference map and fully refined isotropically. For $[Cr_2(OH)_2(H_2O)_8^{4+}\Theta^{4-}.6(H_2O)$: $C_{33}H_{77}CrN_2O_{27}S_4$, M_r = 1114.21, crystal size = 0.18 × 0.08 × 0.04 mm, triclinic, $P\bar{1}$, a = 10.9916(3), b = 14.8774(5), c = 15.3517(6) Å, α = 63.836(1), β = 86.583(2), γ = 80.499(2)°, V = 2222.03(13) Å^3, Z = 2, μ = 0.545 mm^{-1} (no correction), $2\theta_{max}$ = 54.44°, 37347 data collected, 9727 unique (R_{int} = 0.146), 613 parameters, final GoF = 2.277, R_1 = 0.1644 [on 9727 observed data with $I > 2\sigma(I)$], wR_2 = 0.2347 (all data). All nonhydrogen atoms were refined anisotropically and C–H hydrogens were fixed at geometrically calculated positions. High residuals are a consequence of the extremely small, needle-like crystals obtained and poor data quality indicated by the high R_{int}. CCDC 182/1249. Octaphenylcyclotetrasiloxane confinement of C_{60} into double columnar arrays

Ian E. Grey,[a] Michaele J. Hardie,[b] Timothy J. Ness[b] and Colin L. Raston*[b]

[a] *CSIRO Division of Minerals, Box 312 Clayton South, Melbourne, Victoria 3169 Australia*

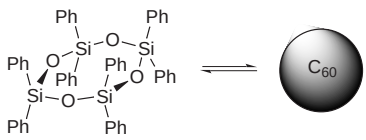
Received (in Columbia, MO, USA) 2nd March 1999, Accepted 13th April 1999

Excess octaphenylcyclotetrasiloxane [{$SiPh_2$(μ-O)}$_4$] and C_{60} in toluene affords the 1 : 1 supramolecular complex as a hemi-toluene solvate where the fullerenes are arranged in double columnar arrays shrouded by edge on, interlocking siloxanes.

Host–guest and supramolecular chemistry of the electron-deficient fullerenes has focused mainly on the use of more traditional host or receptor molecules including cyclodextrins,[1] and container molecules with hydrophobic pockets lined with aromatic rings, notably calixarenes,[2–6] resorcinarenes,[7] and cyclotriveratrylene and related molecules.[8,9] A recent development is the confinement of C_{60} and C_{70} (and other globular molecules) in complementary cavities of rigid nickel(II) macrocycles.[10] Here the interaction may be synergic with the likelihood of fullerene to metal electron density flow as well as the reverse for the unsaturated rings of the host in contact with the fullerene. However, in general, encouraging inherently weak host–guest interactions involving a fullerene is facilitated by the complementarity of curvature of the host with that of the fullerene, as is having a host with a rigid structure such that there is no pre-organisation energy requirement prior to complexation with the fullerene.[10]

In further exploring the use of rigid receptor molecules to 'recognise' fullerenes we have investigated the interplay of octaphenylcyclotetrasiloxane [{$SiPh_2$(μ-O)}$_4$] with C_{60} and find it forms a 1 : 1 complex in the solid state. In principle, the siloxane can act as a multi-divergent receptor molecule with six concave surfaces surrounding the central core. Molecular mechanics suggests that these surfaces have complementarity of curvature with that of C_{60} and that there is little pre-organisation for complexation which is associated with simple torsion along the Si–C bonds. Despite this, the isolated complex has the siloxane acting as a single receptor site with C_{60}, in one of the four cavities which is edge-on relative to the tetrasiloxane plane (**1**). This is unexpected given that the two faces above and below



1

the siloxane plane have deeper cavities. Rather a phenyl ring of one siloxane molecule is directed into one of these cavities of another siloxane. This was also found in the structure of the siloxane itself but had been overlooked,[11] and surprisingly there is no inter-siloxane molecule π-stacking. The structure is also noteworthy in that the fullerenes are aligned in double columnar arrays; this structural motif is unusual, restricted to an organometallic inclusion complex[12] and a charge transfer complex with a thiafulvalene.[13] Moreover, this is the first report of a siloxane–C_{60} host–guest complex, and C_{70} fails to form a complex under similar conditions.

Dark red crystals of the 1 : 1 complex as a toluene hemi-solvate, [{$SiPh_2$(μ-O)}$_4$]C_{60}(toluene)$_{0.5}$, were obtained by slow diffusion of Pr^iOH vapour into a toluene solution of C_{60} and excess siloxane, ratio *ca.* 1 : 10.† Many other ratios and solvents, and solvent mixtures, were unsuccessful in forming the complex. The IR of the complex showed the superposition of peaks corresponding to the three components in the lattice, as expected for weakly associated species. In solution, UV–VIS studies show very little change in the range 400 to 800 nm, unlike in other systems,[5,8,13] and there was little change in the NMR spectroscopic data. Thus the interactions in solution are inherently weak.

In the structure derived from X-ray diffraction studies,‡ a molecule of each of the supramolecular synthons and half a toluene molecule residing over a centre of inversion comprise the asymmetric unit; results are presented in Fig. 1 and 2. The side-on interaction of the fullerene with the siloxane is unsymmetrical; two of the four phenyl rings attached to the same silicon centre have the closest contacts to the fullerene at 3.70 Å. The two phenyl rings on the other silicon associated with the same edge of the siloxane are positioned such that there

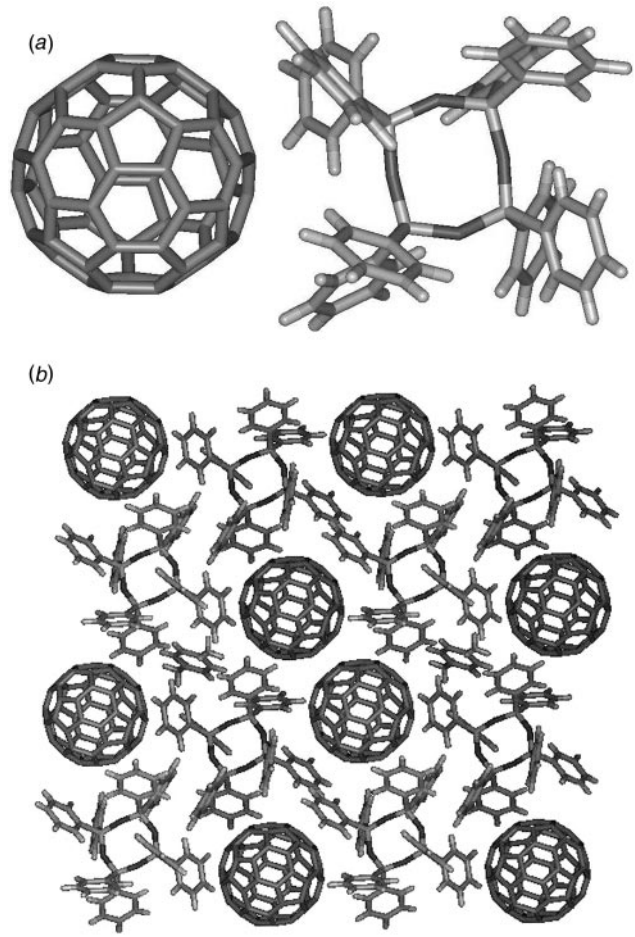


Fig. 1 The structure of [{$SiPh_2$(μ-O)}$_4$]C_{60}(toluene)$_{0.5}$ showing (*a*) the two interacting supramolecular synthons, and (*b*) the extended interplay projected down the axis, the direction of the double columnar arrays of fullerenes; the toluene molecules are disordered over centres of inversion.

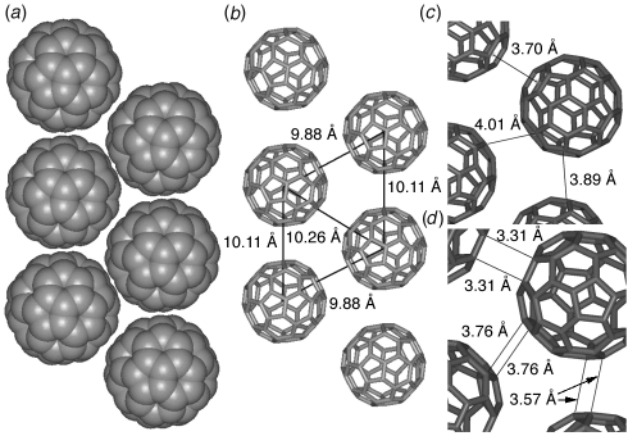

Fig. 2 The double columnar array of fullerenes in $[\{SiPh_2(\mu\text{-}O)\}_4]C_{60}(toluene)_{0.5}$ showing (*a*) space filling packing, (*b*) fullerene centroid–centroid separations, (*c*) inter-fullerene ring centroid separations, and (*d*) closest fullerene contacts.

is no π-stacking between the two components, and indeed, the protons on the phenyl rings are the atoms in immediate contact with the fullerene [Fig. 1(*a*)]. This type of C–H···C_{60} interaction has precedence in one other structure, notably that of $[C_{60} \subset (L)_2]$ (L = *p*-benzylhexahomooxacalix[3]arene).[3]

In the upper and lower cavity of the siloxane, there are either one or two phenyl rings orientated with the C–H groups towards the centre of the siloxane ring. These orientations preclude any interaction of the fullerene in the clefts. One 'upper' phenyl ring of one siloxane molecule is pointing into the 'lower cavity' of the same siloxane one unit cell away in the direction of the *a* axis [Fig. 1(*b*)]. This interlocking stacking motif is similar to that found in the crystal structures of the pure siloxane.[11] The predilection towards this type of stacking for the siloxane may be one of the factors influencing its interplay with the fullerene.

Fig. 2 shows the pairs of C_{60} columns. Analysis of the centroid-to-centroid distances of the C_{60} molecules shows that the packing is not as regular as close packing, with the positions of the C_{60} molecules in one column slightly offset, so they are closer to one of the nearest neighbours in the other column. The centroid-to-centroid distances are 10.11 Å within a column and either 9.88 or 10.26 Å between columns for the nearest neighbours. The shortest of these distances compare with the very short, dipole induced inter-fullerene distances in the single columnar arrays of C_{60} found in a calix[4]arene–C_{60} complex, *viz*. 9.8782(5) Å.[6] Within a single column of C_{60} molecules, the closest centroid to centroid approach for two C_6 rings is 3.89 Å, with the rings offset, so that the centroids are not directly opposite each other. The closest approach between C_6 ring centroids occurs between the columns at 3.70 Å. The closest C···C contact is 3.31 Å. The siloxane molecules appear to interact between columns, and with other C_{60} and toluene molecules [Fig. 1(*b*)]. With a few exceptions,[3,4,8] inter-fullerene interactions play a major role in the structures of supramolecular complexes of C_{60},[2,5–8,10,12,13] and this is further corroborated in the present structure. Establishing the ground rules for inter-fullerene interactions is important in understanding the competing interactions associated with the formation of discrete host–guest supermolecules.

This report clearly demonstrates the ability of a simple siloxane to self-assemble with C_{60}. From here there is the exciting prospect of stronger binding by incorporating extended aryl arms on the siloxane, and to extend the work to the analogous octa-aryloctasiloxanes $[\{Si(aryl)(\mu\text{-}O)\}_8]$.

The support of this work by the Australian Research Council is gratefully appreciated.

Formation of bamboo-like nanocarbon and evidence for the quasi-liquid state of nanosized metal particles at moderate temperatures

Yongdan Li,* Jiuling Chen, Yanmei Ma, Jinbao Zhao, Yongning Qin and Liu Chang

Department of Catalysis Science and Technology and State Key Lab on C1 Chemical Technology, School of Chemical Engineering, Tianjin University, Tianjin 300072, China. E-mail: ydli@tju.edu.cn

Received (in Cambridge, UK) 22nd March 1999, Accepted 12th May 1999

Carbon nano-filament formation in hydrocarbon and syngas based catalytic processes is fatal for supported metal catalysts as this leads to deactivation and crushing, and hence limitation of carbon deposition has been a major topic in catalysis.[1–5] Recently, the deliberate preparation of catalytically grown nanocarbons has been investigated because of their specific structure and potential for application in many fields.[6–8] Many nanocarbon conformations have been reported, such as tubular, coiled, helical, branched, octopus, *etc*. and have been found to be sensitive to the reaction conditions and catalyst properties.[9–14] Catalytic hydrocarbon decomposition[9–13] or arc-discharge evaporation of graphite[14–18] have been often used as preparation methods, though in the latter case, the presence of a metal is necessary as catalyst in the form of either vapor or droplets of melt. The selective preparation of a given formation is a challenge to catalysis researchers. Here, several nanocarbon conformations are shown to be formed with high morphological purity from methane on a copper–nickel–alumina catalyst, and some interesting phenomena related to the nanosized metal are reported.

A catalyst with a mol ratio Ni:Cu:Al of 75:15:10 was prepared by coprecipitation. The precipitate has a Feitknecht compound structure, which in ideal composition has formula $Ni_6Al_2CO_3(OH)_{16}\cdot 4H_2O$, However, here part of the Ni was replaced by Cu, the amount of Al was reduced, and the structure was distorted. After calcination, an NiO like phase is observed but with scattered XRD peaks. During reduction uniformly nanometer sized Ni-Cu alloy was obtained, as shown in Figs. 1 and 2. It is interesting that no structural information of other components except for NiO and Ni appeared in the XRD profiles of the oxidized and reduced state, respectively. Detailed catalyst preparation and reaction conditions have been published elsewhere.[9,10]

When this catalyst is exposed to methane–nitrogen (v/v = 1:2), at 773 K, and after the reaction rate reduced to zero, a large amount [93.5 mg C(mg Ni)$^{-1}$] of morphologically pure octopus carbon was formed. As shown in Fig. 3, the metal particles are polyhedral and are the origin of several nanocarbon fibers. When the temperature was 1023 K, and with the same feed, a large amount of hollow nanocarbon tubes are produced as shown in Fig. 4, with rare stick-shaped nanocarbon formed at the same time.

When this catalyst was exposed to methane–hydrogen (1:2, v/v) at temperatures of 1003 and 1043 K, a large amount of

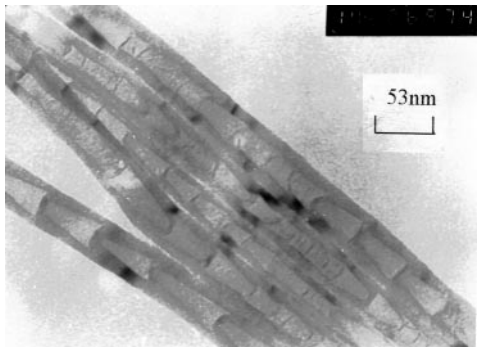

Fig. 5 Bamboo-shaped carbon grown on the catalyst in methane–hydrogen at 1043 K.

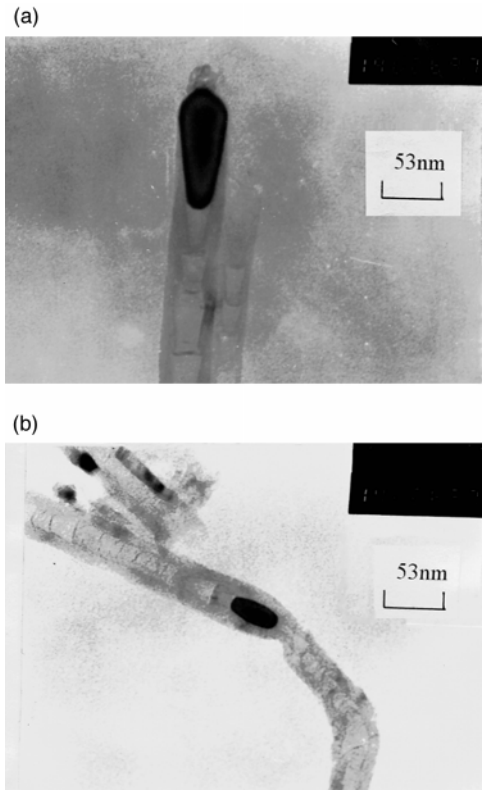

Fig. 6 Bamboo-shaped carbon grown on the catalyst in methane–hydrogen at 1003 K with encapsulated metal.

bamboo-shaped nanocarbon was obtained in a high morphology purity. The bamboo-shaped carbons formed under several conditions are shown in Figs. 5 and 6.

These conformations of carbon have been reported previously, though they were found together with other forms. Adveeva *et al.*[19] has reported octopus-shaped carbon, which was formed under nearly the same conditions as in this work. Saito[14] and Kovalevski and Safronov[20] reported separately bamboo-like carbons formed either from arc-discharge evaporation of graphite or from catalytic pyrolysis of hydrocarbons at 2223–2873 K. They attributed the formation of bamboo-like carbon to the catalytic effect of melted droplets of metal.[14,20]

Inspections of Figs. 2 and 3 show that the metal particles before reaction are irregularly shaped while after reaction at 773 K they are polyhedral, indicating recrystallization during induction of carbon formation. Micrographs in Fig. 6 show clearly that the metal, either at the tip of the carbon fiber or encapsulated inside, resembles a drop of mercury in a glass capillary, indicating that it is in a quasi-liquid state during reaction. Although no metal tip was found in Figs. 4 and 5, due to the crushing of the nanotubes before TEM observation, the carbon shows the same structure growth indicating the catalytic function of the liquid like metal. The shape of the carbon shows that it was formed by jumping of the metal tip at regular time intervals over similar distances. This can only be explained by supposing that the metal is in a quasi-liquid state with high surface energy and poor wetting ability towards graphite carbon. The highest temperature studied for these reactions was 1043 K, which is far below the melting point of the metals either in the pure or alloyed state. The melting point of nickel is 1728 K, while that of copper is 1357.5 K.[21] A Ni–Cu alloy with the same composition as the catalyst here has a melting point of 1423 K.[21] Some literature[22,23] has proposed metal carbide formation in this system, however, the temperature of Ni_3C formation is 1773–2373 K and the lowest melting temperature of a C–Ni alloy (atomic ratio 9 : 91) is 1573 K.[24] The existence of the metal in a quasi-liquid state at *ca*. 1000 K can only be attributed to the size effect of the metal at the nanometer level and the interfacial effect between nanocarbon and nanometal.

Results presented here suggest that (1) The conformation of a nanocarbon is sensitive to the reaction conditions and catalyst, and its morphological purity can be controlled. (2) The Ni–Cu/Al_2O_3 catalyst used here can catalyze nanocarbon formation both in the solid and molten state. (3) The Ni–Cu alloy undergoes recrystallization during induction of carbon formation producing pure octopus carbon in methane–nitrogen at 773 K, while a catalyst prepared under the same conditions but without doping of copper showed different behaviour.[10] (4) Ni–Cu alloy exists in the reaction system at as a quasi-liquid state at moderate temperatures owing to its nanosize and interfacial effects. (5) These phenomena may help to validate reaction mechanisms for nanocarbon formation on metals.

Cyclodimerization and Diels–Alder reaction of a spiroepoxycyclohexadienone with an *o*-quinodimethane structure

Vincent Bonnarme,[a] Martine Mondon,[a] Alain Cousson[b] and Jean-Pierre Gesson*[a]

[a] *Laboratoire de Chimie XII, Université de Poitiers et CNRS, 40 avenue du Recteur Pineau, 86022 Poitiers, France. E-mail: jean-pierre.gesson@campus.univ-poitiers.fr*

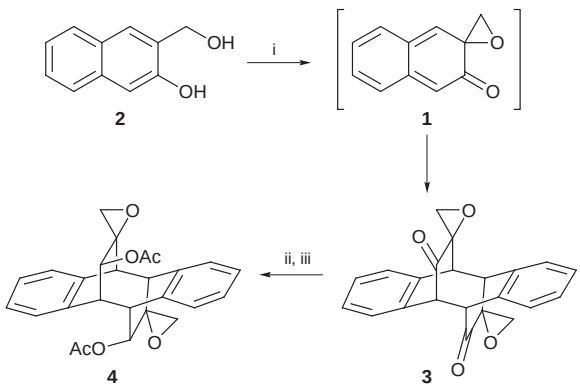
Received (in Liverpool, UK) 8th March 1999, Accepted 29th April 1999

Oxidation of 3-hydroxymethyl-2-naphthol with periodate affords a single *exo-syn* dimer arising from the intermediate *ortho* quinonoid spiroepoxycyclohexadienone; the latter can also be trapped by reactive dienophiles.

Spiroepoxycyclohexadienones are easily obtained from the corresponding 2-hydroxymethylphenols upon $NaIO_4$ oxidation.[1] Like related *ortho*-quinones, quinols and quinol acetates, these dienones easily dimerize *via* a concerted $4\pi+2\pi$ process.[2] Indeed, cycloaddition with various dienophiles (dienes, alkenes, styrenes, enol ethers and esters, enamides) readily occurs to give highly functional adducts.[3] The preparation of similar, albeit stable, dienones in the naphthalene series has been also reported from 2-hydroxymethyl-1-naphthol[4] and 1-hydroxymethyl-2-naphthol.[5]

In this respect, we became interested in the preparation of spirodienone **1** possessing a reactive *ortho*-quinomethane structure which could lead to benzo-fused bicyclo[2.2.2] adducts with dienophiles. This material was prepared from the known 3-hydroxymethyl-2-naphthol[6] **2**, easily obtained in two steps from 3-hydroxy-2-naphthoic acid (MeOH, H^+, 90%; $LiAlH_4$, 86%) (Scheme 1). Upon $NaIO_4$ oxidation (MeOH, H_2O, 20 °C), a single dimeric compound, **3**, mp 201–203 °C, was isolated in 67% yield. This material is characterized, apart from signals of aromatic and CH_2O protons, by two sharp singlets at δ 3.52 and 4.23. This is consistent with only one of the four possible symmetrical head-to-head dimers resulting from *endo* or *exo* and *syn* or *anti* (with respect to the epoxide oxygen) approaches (two of these structures have C_2 symmetry and two are *meso*). The exclusive formation of the *exo-syn* dimer was secured by an X-ray analysis of **4**† (Fig. 1) obtained after $NaBH_4$ reduction and acetylation (Scheme 1). Such orbital symmetry forbidden dimerizations (a formal $\pi^4s + \pi^4s$ process) have already been observed with *ortho*-quinonoid species, usually under irradiation.[7] For example, *in situ* generated 2-benzopyran-3-one has been reported by Bleasdale[8] to give mainly photodimer **5** in unspecified low yield,‡ and Schlosser[9] has described the spontaneous dimerization to **6** (74%) of an



Scheme 1 *Reagents and conditions*: i, $NaIO_4$ (1.1 equiv.), MeOH, 90 min, rt; ii, $NaBH_4$ (1.1 equiv.), 0 °C, 10 min ; iii, Ac_2O, Py, 12 h, rt.

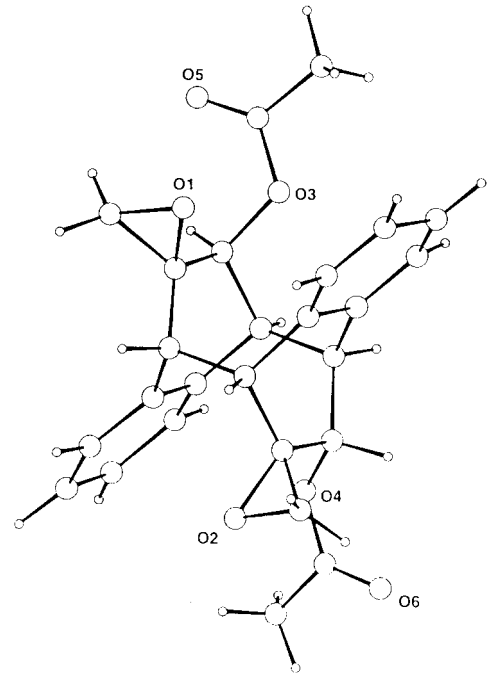


Fig. 1 Crystal structure of **4**.

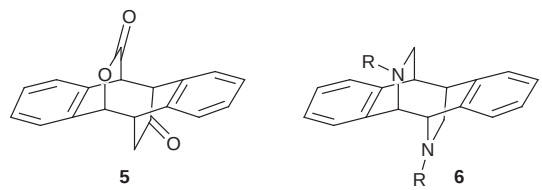
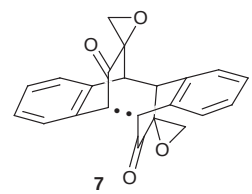
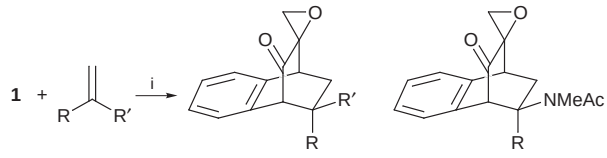




ortho-quinomethane derived from MeOH elimination of a tetrahydroquinoline. As suggested by Trahanovsky to explain the dimerization of 2,3-dimethylene-2,3-dihydrofuran,[10] **3** probably results from the intermediate diradical **7**, arising from the less hindered *exo-syn* approach of two monomers **1.**

The high facial selectivity observed in the reduction of **3** with $NaBH_4$ is also noteworthy since reduction of α,β-epoxy ketones with hydrides predominantly occurs *syn* to the oxygen epoxide.[11,12] On the other hand, Okada[13] has shown that $NaBH_4$ reduction of 2,3-benzo-fused norbornen-7-one proceeds *syn* to the phenyl ring, while *anti* reduction of 5,6-benzo-fused bicyclo[2.2.2]octan-2-one has been reported[12b] with $LiAlH_4$.



8 R = OEt, R′ = H
9a R = H, R′ NMeAc
9b R = NMeAc, R′ = H
10 R = *p*-MeOC$_6$H$_4$, R′ = H
11a R = OMe, R′ = Me
11b R = Me, R′ = OMe

9c

Scheme 2 *Reagents and conditions*: i, $NaIO_4$ (1.1 equiv.), dienophile (5 equiv.), MeOH–H_2O, 2–12 h, rt.

The π-facial selectivity of the reduction observed here is not controlled by the epoxide group, but this may be due to steric hindrance from the remote phenylene group rather than stereoelectronic control by the nearest phenyl ring.

Then, *in situ* cycloaddition of dienone **1** was attempted by carrying out the oxidation step in presence of 5 equiv. of dienophile (Scheme 2). Ethoxyethene and *N*-methyl-*N*-vinylacetamide add to **1** to give **8** (82%) and **9a–c** (70%) without notable dimer formation, unlike the less reactive 4-methoxystyrene, which gave **10** (42%) together with **3** (30%), and 2-methoxyprop-2-ene, which gave **11a** (25%), **11b** (4%) and **3** (44%). As expected, *syn-endo* cycloadition is observed in most cases, except for the enamide which exhibits low selectivity, giving *syn-exo* (**9a**), *syn-endo* (**9b**) and *anti-exo* (**9c**)§ adducts in a 2 : 1 : 1 ratio (a high *syn-exo* selectivity has been observed with enamides for a related spirocyclohexadienone[3d] and for a pyrone[14]).

In summary, oxidation of 3-hydroxymethyl-2-naphthol affords chiral dimer **3** possessing C_2 symmetry in a rigid framework, and trapping of the unstable dienone **1** is possible at room temperature with electron-rich dienophiles. Such adducts may serve as useful templates for the preparation of rigid phenethylamine derivatives[15] or of tetrahydronaphthalene derivatives after cleavage of the α,β-epoxy ketone moiety.[16]

Received (in Cambridge, UK) 15th April 1999, Accepted 13th May 1999

The structure of $[\{As_2(NCy)_4\}_2Cu_4]$ reveals a dramatic change in the metal coordination mode compared to that found in the Sb analogue $[\{Sb_2(NCy)_4\}_2Cu_4]$, resulting in the distortion of the Cu_4 core from a square-planar to a butterfly shape and providing the first illustration of ligand-selective cage modification in such heterobimetallic species; in contrast the square-planar Na_4 arrangement found in $[\{Sb_2(NCy)_4\}_2M_4]$ (M = Na, Cu, Ag) is retained in $[\{As_2(NCy)_4\}_2Na_4]$.

In recent years the synthesis of nitrogen-containing anion ligands of Groups 15 and 16 [such as isoelectronic $S(NR)_3^{2-}$ [1] and $Sb(NR)_3^{3-}$ [2]] has provided new opportunities for the assembly of molecular cages containing a broad spectrum of mixed-element compositions.[3] However, most studies of the coordination chemistry of these and related systems have involved the alkali or alkaline earth metals[3,4] and no studies have so far indicated that changing the Group 15 or 16 elements within a particular family of ligands has any major effect on the coordination behaviour or on the nature of the cage formed for a particular metal. Studies of $[\{Sb_2(NCy)_4\}_2M_4]$ (M = Li,[5] Na,[6] Cu, Ag[4a,b]) have shown that the geometries of the supported M_4 cores arise from the compromise between the predominant rigidity of the $[Sb_2(NCy)_4]^{2-}$ ligand and the bonding demands of the coordinated metal ions. These influences are responsible for the switch from a tetrahedral Li_4 core for the Li complex to essentially square-planar M_4 cores in the Na, Cu(I) and Ag(I) complexes, and for the accompanying greater involvement of the μ_2- and exocyclic-N donor centres of the $[Sb_2(NCy)_4]^{2-}$ ligand in the latter. The recent synthesis of $[\{As_2(NCy)_4\}_2Li_4]$,[7,8] a source of the $[As_2(NCy)_4]^{2-}$ ligand, provides the opportunity for assessing the impact of differing geometric demands on cage architecture for a closely related ligand. We report here the first observation of ligand-selective modification for such a heterometallic cage.

In order to provide comparison with the related Sb systems, the Na complex $[\{As(NCy)_4\}_2Na_4]$ **1** and $[\{As_2(NCy)_4\}_2Cu_4]$ **2** were prepared. Complex **1** was obtained from the reaction of $As(NMe_2)_3$ with $CyNH_2$ followed by the addition of CyNHNa. Transmetallation of **1** with CuCl gave **2** (Scheme 1).†

The low-temperature X-ray study of **1**‡ (Fig. 1) shows that the complex has a cage structure consisting of two $[As(NCy)_4]^{2-}$ anions which coordinate four Na^+ cations using a combination of their μ-N and exocyclic-N donor sites. This overall structure and the rhombic arrangement of the Na^+ cations at the centre of the cage is identical to that occurring in the Sb analogue $[\{Sb_2(NCy)_4\}_2Na_4]$[6] and in the Cu and Ag complexes $[Sb_2(NCy)_4]_2M_4$ (M = Cu, Ag).[4a,b] However, although still essentially planar and possessing similar Na···Na distances (av. 3.17 Å) the Na_4 core in **1** is significantly more distorted than that in $[\{Sb_2(NCy)_4\}_2Na_4]$ (with alternating Na···Na···Na angles of av. 99.6 and av. 80.4° *cf.* av. 93.5 and 86.4° [6]).

In view of the similarity between **1** and the analogous Sb complex $[\{Sb_2(NCy)_4\}_2Na_4]$ it was anticipated that the Cu(I) complex $[\{As_2(NCy)_4\}_2Cu_4]$ **2** would exhibit the same overall structure as $[\{Sb_2(NCy)_4\}_2Cu_4]$[2] (in which essentially the same coordination mode as that found in **1** is preserved). However, the low-temperature X-ray study of 2‡ reveals that replacement of the Na^+ cations with Cu^I results in a dramatic change in the cage architecture. Rather than the μ-N and exocyclic-N centres of the two $[As_2(NCy)_4]^{2-}$ ligands bridging the alternate Cu···Cu edges of the Cu_4 core (as occurs in the Sb analogue[2]), the N atoms of each coordinate separate Cu ions in a manner not previously observed. This change in bonding mode results in essentially linear Cu(I) geometries [N–Cu–N 175.4(2)°]. The consequence of the asymmetrical coordination of the Cu centres of **2** [exocyclic-N–Cu 1.854(4), μ-N–Cu 1.949(4) Å] is that the Cu_4 core now has a butterfly-shape (rather than planar) arrangement. The switch from a symmetrical to an asymmetrical coordination mode corresponds to a 45° rotation of the Cu_4 core, a result of which is that the As_2N_2 and Cu_4 rings are now eclipsed.

The structural pattern found in **1** and in the Sb analogue, $[\{Sb_2(NCy)_4\}_2Na_4]$, stems from the presence of essentially ionic metal–ligand interactions which favour a ligand mode that maximises the coordination number of Na^+. In complexes containing Cu^I the preference for an essentially linear geometry can be satisfied by maintaining this same coordination mode (as

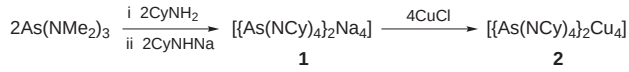

Scheme 1

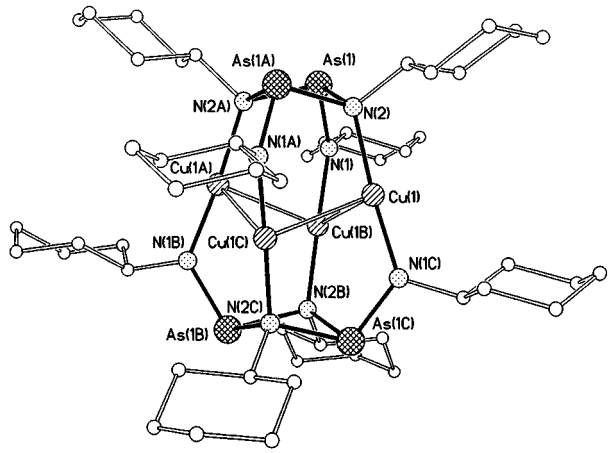

Fig. 2 The unique cage arrangement found in **2**. H-atoms have been omitted for clarity. Key bond lengths (Å) and angles (°); As(1)–N(2) 1.955(4), As(1)–N(2a) 1.949(4), As(10–N(1) 1.767(4), N(1)–Cu(1b) 1.854(4), N(2b)–Cu(1b) 1.927(4), Cu(1)···Cu(1b) 2.692(1); N(2)–As(1)–N(2a) 80.4(2), As(1)–N(2)–As(1a) 94.3(2), N(2)–As(1)–N(1) 104.3(4), N(2a)–As(1)–N(1) 104.0(2), N(1)–Cu(1b)–N(2b) 175.4(2), Cu(1b)···Cu(1)···Cu(1c) 83.4(2), dihedral angles between the As_2N planes in the As_2N_2 rings 143.2, and the Cu_3 planes of the Cu_4 core 126.0.

occurs in [{$Sb_2(NCy)_4$]$_2Cu_4$]^2). This symmetrical arrangement has the advantage that the Cu centres can increase their coordination numbers by additional weak interactions with the μ-N donor sites. However, with the more compact $[As_2(NCy)_4]^{2-}$ ligand adoption of the same mode would presumably destabilise the complex since the consequent compression of the Cu_4 core would lead to unfavourably short Cu···Cu contacts (*ca.* 2.46 Å; *cf.* 2.56 Å in Cu metal).[9] The alternative adopted in **2** gives a release from this effect since the asymmetrical ligand mode results in puckering of the Cu_4 core {with a resulting increase in Cu···Cu separation to 2.692(1);*cf.* 2.57 Å in [{$Sb_2(NCy)_4$}$_2Cu_4$]^2, but still maintains a linear Cu coordination geometry,

This study shows for the first time that geometric changes brought about by substitution of one Group 15 element for another within a particular family of poly-imido ligands can have large effects on the cage produced. This finding has important implications to the targeted design of cages with a particular structure and to the possibility of selective coordination involving ligands based on p block element frameworks.

† *Syntheses*: **1**; a mixture of [$PhCH_2Na$} (0.46 g, 4 mmol) and $CyNH_2$ (0.46 ml, 4 mmol) in a toluene (10 ml) was heated briefly to reflux, with the formation of a pale yellow precipitate. In a separate Schlenk tube, a mixture of $As(NMe_2)_3$ (2.5 ml, 4.0 mmol) and $CyNH_2$ (0.46 ml, 4 mmol) in toluene (10 ml) was briefly heated to reflux. This solution (cooled to room temperature) was added to the first, with the formation of a clear yellow solution which became orange after bringing to reflux (2 min). A small amount of solid was removed by filtration and careful reduction of the filtrate under vacuum resulted in precipitation of a small amount of white solid. Hexane (1 ml) was added and the precipitate was warmed into solution. Storage at room temp. (72 h) gave small, colourless needles of **1** (0.63 g, 54%). Final decomp. 192 °C. IR (Nujol, NaCl), ν_{max} = 1094m, 1067, 1019m, 798m, 750w. ^{1}H NMR (+25 °C, d_6-benzene, 250 MHz), δ 3.67 (m 2H, α-C–H Cy), 2.63 (m 2H, α-C–H Cy), 2.20–1.0 (m 40 H, –CH_2– Cy). Satisfactory elemental analysis (C, H, N) was obtained.

2; a mixture of **1** (1.22 g, 1.0 mmol) and CuCl (0.46 g, 4.6 mmol) in toluene (20 ml) was briefly heated to reflux then stirred (3 h). A cloudy grey–green suspension was formed which was filtered off to give a yellow filtrate. The solution was reduced under vacuum until precipitation commenced, this being warmed back into solution. Storage at room temp. (72 h) gave small, colourless needles of **2** (0.07 g, 5% first batch). Decomp. 188 °C. ^{1}H NMR (+25 °C, d_6-benzene, 250 MHz), δ 3.65 (2H, m α-C–H of Cy), 3.55 (2H, m α-C–H of Cy), 2.7–1.1 (40 H, overlapping m, –CH_2– of Cy). Satisfactory elemental analysis (C, H, N) was obtained.

‡ *Crystal data*: **1**; $C_{48}H_{88}As_4Na_4N_8$, M = 1168.90, orthorhombic, space group *Pbca*, Z = 8, a = 24.883(5), b = 37.424(8), c = 11.980(9) Å, V = 11156(9) Å^3, μ(Mo-Kα) = 2.446 mm^{-1}, T = 180(2) K. Data were collected on an Siemens-Stoe AED diffractometer and corrected for absorption using ψ-scans. Of a total of 9314 reflections collected, 6096 were independent (R_{int} = 0.068). The structure was solved by direct methods and refined by full-matrix least squares on F^2. Final $R1$ = 0.105 [$I > 2\sigma(I)$] and $wR2$ = 0.264 (all data).[10] The high R values for **1** are due to poor crystal quality. Maximum peaks in the Fourier synthesis can be assigned to a shadow image of the molecule in the crystal structure. Refinement of these peaks as As and Na positions give an occupation of 8% for the shadow image. However, in the final refinement the shadow image was omitted owing to rather high correlation factors and lack of convergence.

2; $C_{48}H_{88}As_4Cu_4N_8$, M = 1331.10, tetragonal, space group $I4_1/a$, Z = 4, a = 24.046(3), b = 24.046(3), c = 9.941(3) Å, V = 5748(2) Å^3, μ(Mo-Kα) = 3.783 mm^{-1}, T = 223(2) K. Data were collected on a Siemens P4 diffractometer and corrected for absorption using ψ-scans. Of a total of 2653 reflections collected, 2001 were independent (R_{int} = 0.044). The structure was solved by direct methods and refined by full-matrix least squares on F^2. Final $R1$ = 0.044 [$I > 2\sigma(I)$] and $wR2$ = 0.076 (all data).[10] CCDC 182/1259. Novel reagents for targeted cleavage of RNA sequences: towards a new family of inorganic pharmaceuticals

Alavattam Sreedhara, Anjali Patwardhan and J. A. Cowan*

Evans Laboratory of Chemistry, The Ohio State University, 100 West 18th Avenue, Columbus, Ohio 43210 USA

Received (in Bloomington, IN, USA) 10th February 1999, Accepted 27th April 1999

Copper kanamycin degrades cognate RNA targets at concentrations as low as picomolar levels at physiological pH and temperature, but shows no chemistry with random RNA or DNA molecules, thereby demonstrating potential for development as a novel antiviral agent.

RNA-binding ligands that selectively disrupt RNA–protein interactions are of potential therapeutic value.[1] Both the absence of a cellular repair mechanism for RNA and the structural diversity of RNA motifs make these attractive drug targets.[1,2] Aminoglycoside antibiotics have been demonstrated to inhibit protein translation by recognition of 16S rRNA,[3,4] to inhibit the binding of the HIV Rev protein to its viral RNA recognition element, the Rev response element (RRE),[5] and also to inhibit the activity of hammerhead ribozymes,[6] group I intron ribozymes,[7] and the binding of HIV Tat peptide to TAR-RNA.[8] Solution structures have been determined for RNA complexed with a variety of aminoglycosides (paromomycin, ribostomycin, neamine, gentamicin).[9] Given the cognitive qualities of these molecules, we sought to develop metal derivatives that would not only inhibit protein binding to target RNA molecules, but better, would mediate destruction of the target. Hydrolysis of RNA by metal ion complexes has attracted considerable attention, since sequence-specific agents that catalyze the destruction of mRNA represent a new therapeutic approach.[10] Typically, high concentrations of complex, reaction times of several hours to days, and extremes of temperature and pH are used.[10b,11] Recently, RNA cleavage under milder conditions has been described.[12]

Herein, we report our finding that copper complexes of the aminoglycosides neomycin B and kanamycin A (Fig. 1) exhibit efficient RNA cleavage activity at physiological pH and temperature. Acetylation protection and ^{13}C NMR studies have been reported for the reaction of Cu^{2+} and kanamycin A that support the structure shown.[13] We have isolated the blue Cu^{2+}(kanamycin) complex **1** from the reaction of 1 : 1 kanamycin A and $CuSO_4$, and also Cu^{2+}(kanamycin)$_2$ **2** and Cu^{2+}-neomycin **3** complexes from reaction mixtures of 2 : 1 kanamycin A and $CuSO_4$, and 1 : 1 neomycin B and $CuSO_4$, respectively, as previously described.[14] Complex **1** was found to be stable in aqueous solution for more than one day, however, complexes **2** and **3** were less stable and formed precipitates within 4 h. For this reason, our attention focused on **1**.

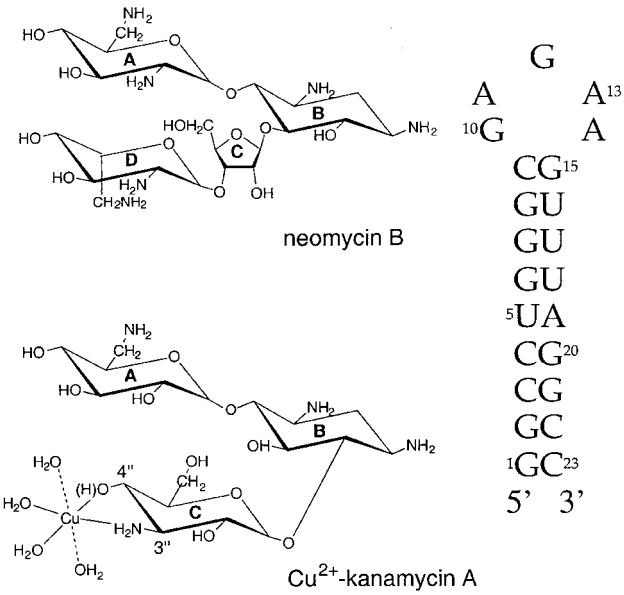

Fig. 1 Structures of the aminoglycosides used in this study (the copper complex of kanamycin A is shown), and a schematic illustration of the stem loop structure adopted by R23 (ref. 16).

A modified 23-mer RNA aptamer (hereafter termed R23) with a high binding affinity for neomycin B[15] (Fig. 1) was selected for a preliminary investigation of cleavage chemistry. The NMR solution structure of the neomycin B complex of R23 shows the aminoglycoside bound to the major groove through electrostatic and hydrogen bonding interactions with the amine and hydroxy groups of rings A and B, while the C and D sugar rings are pendant and can potentially chelate metal ions (Fig. 1).[16] Kanamycin A lacks the ribose ring C and two amine groups in ring D of neomycin B; however, neither ring contributes significantly to binding,[16] and so it is presumed that kanamycin A and neomycin B bind in a similar manner. In fact a comparison with published data indicates that rings A and B appear to form a conserved structural motif for recognition and binding to ribosomal RNA.[9]

Cleavage chemistry of **1** with either 5′-^{32}P end- or body-labeled R23 was examined in the absence and presence of the coreactants, H_2O_2 and ascorbate. R23 was incubated at 37 °C for 30 min to 1 h with various concentrations of **1**, and products were separated on a 19% denaturing polyacrylamide sequencing gel (Fig. 2). The cleavage sites were assigned by comparison with products generated by both alkaline hydrolysis and G-specific RNase T1 digestion. Data in Fig. 2(*a*) shows that cleavage of 5′-end-labeled R23 by **1** alone is not random, but rather specific cleavage sites were observed (lanes 2–4). Two sites of cleavage could be identified: one in the loop region at A^{14}/G^{15}, and the other in the stem region at C^4/U^5. This cleavage data is consistent with the NMR solution structure of R23 RNA bound to neomycin B, which shows binding of the aminoglycoside antibiotic in the loop region $A^{13}A^{14}G^{15}$, and in the stem region $U^5G^6G^7G^8$. The cleaved products co-migrate with products generated by partial alkaline hydrolysis [Fig. 2(*a*), lane 8]. Under these conditions, almost 70% cleavage of R23 is observed under hydrolytic conditions within 1 h.†

Although the hydrolysis of RNA by **1** is appreciable, addition of H_2O_2 or ascorbic acid increase the cleavage efficiency dramatically. Addition of 10 or 100 μM H_2O_2 to 30 μM R23 in the presence of as little as 50 pM **1** led to extensive cleavage—a truly catalytic multiturnover reaction with a ratio of catalyst to substrate of almost 1 : 10^6. Control experiments carried out in the absence of **1** and the presence of up to 100 μM H_2O_2 showed no background cleavage. Moreover, use of aqueous Cu^{2+} and H_2O_2 at concentrations where **1** demonstrated cleavage of R23 were ineffective for the former. Addition of 200 μM ascorbic acid to R23 treated with 20 nM **1** also showed extensive cleavage with almost 100% digestion of the parent RNA [Fig. 2(*b*], however, the relative concentrations of **1** required to effect cleavage of R23 in the presence of H_2O_2 and ascorbate indicates

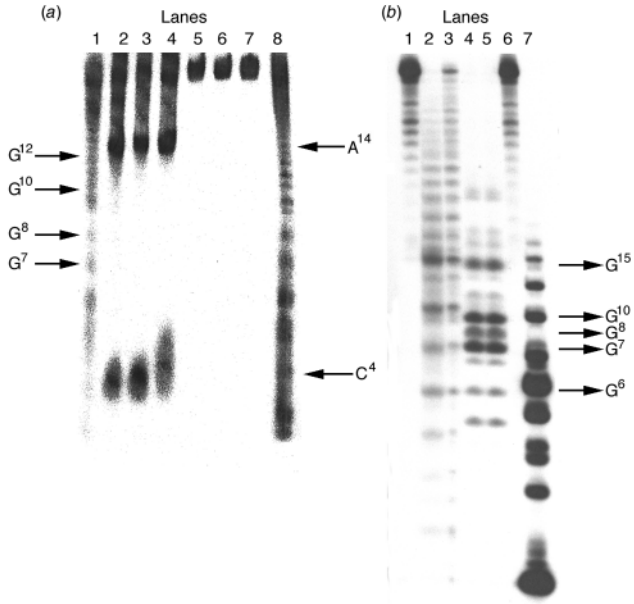

Fig. 2 (*a*) Autoradiograph of a 19% denaturing polyacrylamide electrophoretic gel for the cleavage of 5′-end-labeled R23 RNA by **1** at 37 °C for 2 h (ref. 18). Lane 1, R23 + 0.5 units RNase T 1; lane 2, R23 + 10 μM **1**; lane 3, R23 + 50 μM **1**; lane 4, R23 + 100 μM **1**; lane 5, R23; lane 6, R23 + 100 μM $CuSO_4$; lane 7, R23 + 100 μM kanamycin. Cleavage reactions were carried out in Tris-HCl (20 mM; pH 7.5) and contain *ca.* 1 μM RNA. Captions on the left indicate G-specific cleavage by RNase T1, while those on the right indicate sites giving rise to cleavage products of R23 following reaction with **1**. (*b*) Autoradiograph of a 19% denaturing polyacrylamide electrophoretic gel for the cleavage of uniformly-labeled R23 RNA by **1** at 37 °C for 1 h. Lane 1, R23; lane 2, R23 + 0.1 M NaOH; lane 3, R23 + Na_2CO_3/$NaHCO_3$ buffer; lane 4, R23 + 0.25 units RNase T 1; lane 5, R23 + 0.5 units RNase T1; lane 6, R23 + 1 μM $CuSO_4$/100 μM ascorbate; lane 7, R23 + 20 nM **1**/100 μM ascorbate. Cleavage reactions were carried out in Tris-HCl (20 mM; pH 7.5) and contain *ca.* 10 nM RNA. Captions on the right indicate G-specific cleavage by RNase T1 in lanes 4 and 5. Standard procedures for ^{32}P-labeling of R23 RNA, alkaline and RNase T1 digestion, and SDS-PAGE experiments were used (ref. 18).

that the former is more efficient in promoting oxidative damage. The products generated from ascorbate induced cleavage with **1** [Fig. 2(*b*), lane 7] were more numerous (most likely indicative of limited hydroxyl radical migration away from the copper ion), and offset relative to bands generated by backbone hydrolysis, consistent with a distinct oxidative cleavage pathway.‡ Again, control experiments show no background cleavage in the absence of **1** but in the presence of aqueous Cu^{2+} and ascorbate [Fig. 2(*b*), lane 6]. Recently we have demonstrated that **1** mediates oxidative cleavage of DNA through reactive copper-oxo or copper-hydroxo species.[14] Similarly, here we have used a spectrophotometric assay to identify formation of hydroxyl radical by use of rhodamine B.[14] The change in the λ_{552} absorbance from rhodamine was monitored in the presence of **1** (or reducing agents) alone, and with added ascorbate or H_2O_2. While **1** (or reducing agents) alone did not result in degradation of the dye, a combination of **1** with ascorbate or H_2O_2 led to a rapid decrease in λ_{552}, demonstrating that **1** is capable of producing reactive oxygen species only in the presence of reducing agents. These reactive oxygen species are capable of mediating oxidative damage to nucleic acids,[14] however, such hydroxyl radicals could not be trapped by rhodamine in the presence of a nucleic acid substrate. This indicates that the radicals formed are localized on or close to the copper ion, and are non-diffusible. Thus, the products from reaction of **1** with R23 RNA in the presence of H_2O_2 or ascorbic acid are indicative of an oxidative mechanism, mediated by a copper redox couple, with the concomitant release of hydroxyl radicals.

A primary reason for cleavage efficiency at low complex concentration arises from the high binding affinity for an R23 target site.[3,15,16] No cleavage products were observed after treating R23 with comparable concentrations of either aqueous Cu^{2+} or metal-free aminoglycoside alone (Fig. 2). To determine if cleavage by **1** was selective toward this particular structured RNA (R23), we examined the cleavage efficiency of linear oligo($A_{12\text{-}18}$) and poly(C), and double-strand poly(A).poly(U), each of which binds aminoglycosides weakly. No cleavage was detected by an FPLC assay, supporting the notion that tight binding of **1** to a target RNA is required for cleavage. Similar cleavage efficiencies for plasmid DNA were observed only at much higher complex concentrations (0.1 to 0.5 μM) as a result of the significantly lower binding affinity relative to a cognate structured RNA motif.[14] Artificial ribonucleases based on oligonucleotide-appended metal-based Lewis acidic functional groups represent an antisense approach for effective RNA cleavage.[12] Recognition of structured RNA targets[17] over linear RNA and DNA sequences by aminoglycoside antibiotics, coupled with the site-directed degradative capacity of their copper complexes, may render metalloaminoglycosides as novel and attractive therapeutic agents for the treatment of viral disease, and provide an alternative to the antisense approach. Experiments to test the antiviral activity of such complexes are in progress.

S. thanks OSU for the award of a University Postdoctoral Fellowship (1997–1998). We thank D. R. Schoenberg and K. Cunningham (Department of Pharmacology, OSU), and M. Foster (Department of Chemistry, OSU) for experimental advice and assistance with gel electrophoresis.

Notes and references

† Also consistent with efficient cleavage, under both oxidative and hydrolytic conditions, is the rapid increase in absorbance in UV–VIS spectra resulting from loss of hypochromism from interacting base pairs.
‡ Strand cleavage by a hydrolytic mechanism that is mediated through a 2′-OH leads to formation of 5′-OH and a terminal phosphate at the cleavage site. Cleavage by an oxidative path can lead to destruction of the ribose ring and base release, resulting in band positions that are offset from hydrolytic controls, as observed in Fig. 2(*b*) (lane 7).

Long-lived charge separation in a donor–acceptor dyad adsorbed in mesoporous MCM-41

Vinoda Kuchi, Anna M. Oliver, Michael N. Paddon-Row* and Russell F. Howe*

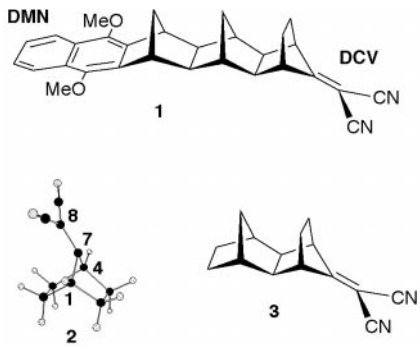
Received (in Cambridge, UK) 19th March 1999, Accepted 14th May 1999

Irradiation of a rigid donor–{6-bond-bridge}–acceptor dyad [donor = dimethoxynaphthalene (DMN); acceptor = dicyanovinyl (DCV)] occluded within the pores of mesoporous MCM-41 containing aluminium leads to the formation of the DCV radical anion of the dyad with a lifetime of days.

Photoinduced charge separation in covalently linked dyads such as **1** occurs extremely rapidly, a result of strong electronic coupling mediated by a through-bond (TB) mechanism.[1] However the lifetimes of the resulting charge-separated (CS) states are short (nanosecond scale[2]), which is also a consequence of strong TB electronic coupling. We now report that photolysis of **1**,[1b] which has been occluded within the pores of mesoporous MCM-41, leads to a charge separation in which the host material participates, the final state of which has a lifetime measured in days.



The ability of microporous zeolite hosts to stabilize organic radical cations and anions is well documented.[3] Mallouk *et al.* showed that the rates of charge recombination in a series of Ru^{II}–viologen dyads adsorbed at the external surface of several microporous zeolites were slowed by a factor of 10^5 relative to the same molecules in solution.[4] This dramatic stabilization of the charge-separated state in a molecule only partly occluded within a porous solid prompted us to begin a study of dyads totally occluded within the pores of the larger pore size (mesoporous) zeolite analog, MCM-41. The test dyad selected was **1**, which comprises a dimethoxynaphthalene (DMN) donor coupled to a dicyanovinyl (DCV) acceptor covalently linked to a rigid σ-bonded hydrocarbon bridge.

MCM-41 is a mesoporous silica containing a regular array of uniform linear one-dimensional pores with an approximately hexagonal cross section and a diameter determined by the particular surfactant molecule used in the synthesis.[5,6] Although the original preparations of MCM-41 were pure silica materials, it is also possible to incorporate aluminium into the synthesis to form mesoporous aluminosilicate zeolite analogs (hereafter designated AlMCM-41) with pores large enough to easily accommodate molecules such as **1**.[7] The pore volume of AlMCM-41 (0.22 $cm^3\ g^{-1}$) is sufficient to occlude up to 50 wt% of **1**. FTIR and ^{13}C NMR measurements on samples of AlMCM-41 (Si:Al = 15) loaded up to this level by impregnating the dehydrated AlMCM-41 with a CH_2Cl_2 solution of **1** under nitrogen showed that the molecule was adsorbed intact into the pores of the AlMCM-41.† Irradiation of loaded samples *in vacuo* at wavelengths where the DMN chromophore absorbs (below 310 nm) gave the EPR signal shown in Fig. 1(*a*). This signal grew in intensity with irradiation time for several hours, and was stable in the dark *in vacuo* for at least one day. The first derivative spectrum shows evidence of poorly resolved hyperfine splitting‡ which was enhanced by recording the second harmonic spectrum [Fig. 1(*b*)]; this shows clearly five hyperfine components. The second harmonic spectrum could be approximately simulated by assuming an isotropic hyperfine coupling with two equivalent ^{14}N nuclei and a coupling constant of 1.8 Gauss [Fig. 1(*c*)]. The actual hyperfine coupling in the observed spectra is clearly not completely isotropic; nevertheless the spectrum appears to be that expected for the DCV radical anion moiety in **1**. This identification was supported by B3LYP[8] DFT calculations of the isotropic hyperfine coupling constant for the model dicyanovinylnorbornane radical anion **2**.§ The calculated coupling constants are 1.76 and 1.34 Gauss using the 3-21G and 631G basis sets, respectively.

No EPR signal was observed when the corresponding experiment was carried out in MCM-41 containing no aluminium, *i.e.* the photoinduced formation of the radical anion of **1** appears to require the presence of aluminium on the MCM-41 framework. Conventional aluminosilicate zeolites are known to contain electron donor sites capable of transferring an electron to strong acceptors such as tetracyanoethylene.[9] Adsorption of TCNE from CH_2Cl_2 solution into dehyrated MCM-41 gave the

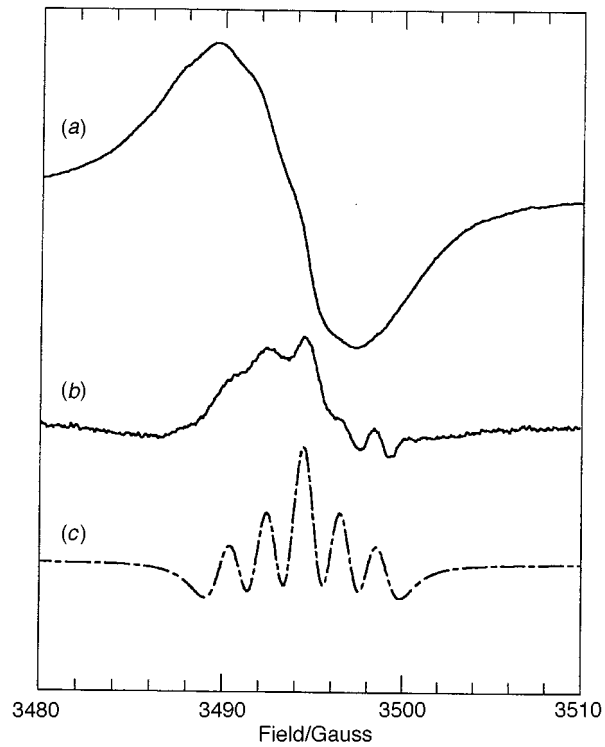


Fig. 1 (*a*) EPR spectrum of **1** in AlMCM-41 following irradiation *in vacuo* at room temperature; (*b*) second harmonic EPR spectrum; (*c*) computer simulation of (*b*) assuming isotropic hyperfine coupling to two equivalent ^{14}N nuclei of 1.8 Gauss.

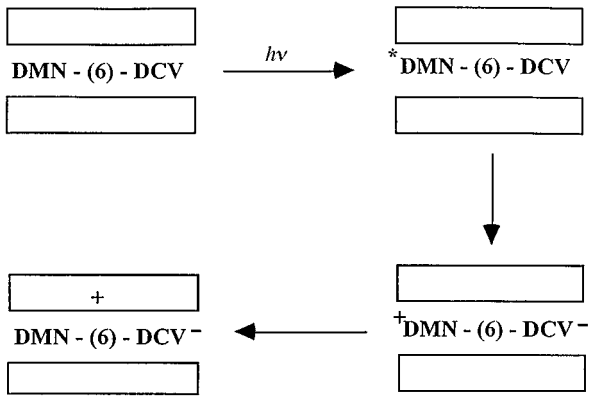

Fig. 2 Schematic of the proposed mechanism for the formation of the long-lived radical anion of **1**.

EPR spectrum of the radical anion only when the MCM-41 contained aluminium, and not with the all-silica form, confirming the role of aluminium in the framework in generating electron donor sites.

It is unlikely that the radical anion of **1** is formed in AlMCM-41 by direct electron transfer from the host, since the reduction potential of the DCV group is 1.5 V more negative than that of TCNE,[10] and the EPR signal was not observed without irradiation. This was confirmed by adsorbing the molecule **3** which contains no electron donor group into AlMCM-41; this gave no EPR signal in the dark or upon irradiation.

Our proposed explanation for the observed photoformation of the stable radical anion of **1** when it is adsorbed in AlMCM-41 (but not MCM-41 containing no aluminium) is shown schematically in Fig. 2: photoinduced intramolecular charge separation is followed immediately by hole transfer from the DMN cation radical to the MCM-41, leaving a stable DCV radical anion.

The ability of the host to stabilize the radical anion in this way clearly depends critically on the relative rates of charge recombination within the charge-separated state of the dyad and hole transfer to the host. We plan flash photolysis experiments to quantify these rates and to determine quantum yields, as has been done in solution[1] and for zeolite adsorbed species.[4] Better characterization of the electron donor (hole acceptor) sites in the AlMCM-41 host is also necessary. The many variations possible in this system (varying the Al content of the host, the pore size, the length of the hydrocarbon spacer and the redox properties of the dyad) provide intriguing opportunities to understand more fully and control electron transfer processes in heterogeneous systems.

An exciting aspect of our preliminary findings is that they offer the possibility of transducing photonic energy into truly long-lived energetic species possessing useful chemical potential. Furthermore, the generation of long-lived charge separation in mesoporous materials need not be restricted to rigid multichromophoric systems, but should occur with non-rigid systems as well. This is a very important conjecture, from the viewpoint of synthetic facility, and its validity will be tested.

We thank the Australian Research Council for support and Mr Paul Harvey for assistance and advice on the NMR studies.

Notes and references

† The adsorbed molecule gave FTIR and ^{13}C NMR spectra closely similar to those of the parent compound. Primary evidence for adsorption within the pores of MCM-41 came from observation of FTIR spectra: the ν(OH) band due to silanol groups within the pores of MCM-41 was broadened and shifted to lower frequency, indicating a weak hydrogen bonding interaction with **1**.

‡ No improvement in resolution was achieved by recording the spectrum at 77 K.

§ Geometry optimization of **2** was carried out under C_s symmetry constraint using the UB3LYP theoretical model and the 3-21G and 6-31G(d) basis sets. The UB3LYP/6-31G(d) and UB3LYP/3-21G optimized structures are nearly identical.

Highly stereocontrolled access to a tetrahydroxy long chain base using *anti*-selective additions

Makoto Shimizu,* Manabu Kawamoto and Yasuki Niwa

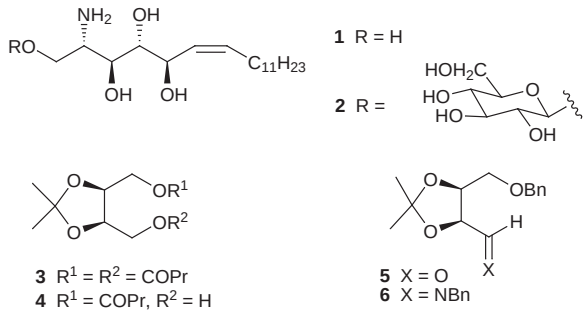
Received (in Cambridge, UK) 25th March 1999, Accepted 12th May 1999

Complete diastereostereoselection was attained for the addition of acetylide and benzyloxymethyl anions to a chiral aldehyde and an imine derived from *meso*-tartaric acid, leading to a facile synthesis of (2*S*,3*S*,4*R*,5*R*,6*Z*)-2-amino-1,3,4,5-tetrahydroxyoctadecene as its pentaacetyl derivative in enantiomerically pure form.

Increasing interest in the field of cerebrosides prompted us to investigate an easy access to this class of compounds in a highly stereocontrolled fashion.[1] In conjunction with the amino polyols which recently have attracted the interest of chemists, several 2-amino-1,3,4,5-tetrahydroxyoctadecene derivatives have been found in bovine spinal cords and human brains as well as in green and red algae.[2] Among them, (2*S*,3*S*,4*R*,5*R*,6*Z*)-2-amino-1,3,4,5-tetrahydroxyoctadecene **1**, the long-chain base

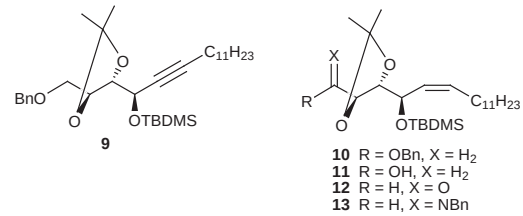


(LCB) part of a new cerebroside **2**, was isolated from the latex of *Eupohorbia characias L* and its structure has been elucidated.[3] The biological importance of such cerebrosides, especially the imparted bioactivities, makes this compound a useful target for synthesis. To the best of our knowledge, however, only two approaches to tetrahydroxy-LCB **1** have been reported; one starting from D-mannose[4a] and the other from D-glutamic acid.[4b] There still appear to be important problems of stereocontrol,[5] and we focused on the topic of stereocontrol in the addition of nucleophiles to chiral aldehydes and imines to find a solution to these problems. We have recently reported that complete *anti*-stereocontrol has been attained in an addition of nucleophiles to the chiral aldehyde derived from L-serine, leading to a short synthesis of (2*S*,3*S*,4*R*)-phytosphingosine,[6] while *syn*-selective addition of nucleophiles has also been successfully used for the synthesis of deoxybiotin.[7] In these studies, a non-chelation- or chelation-type transition state was thought to be crucial for such complete *anti*- or *syn*-stereoselection, respectively.[5–7] For the synthesis of tetrahydroxy-LCB **1**, the *anti*-stereocontrolled construction of the contiguous asymmetric carbons is likely to be difficult, as can be seen from its structure. Here we describe a new stereocontrolled approach to tetrahydroxy-LCB **1** using a tandem *anti*-selective addition of nucleophiles to the chiral aldehyde **5** and the imine **6** derived from *meso*-tartaric acid.

The chiral aldehyde **5**[8] was prepared in good overall yield in enantiomerically pure form starting from *meso*-tartaric acid using lipase-mediated desymmetrization as a crucial step. *meso*-Tartaric acid was converted into dibutyrate **3** *via* diethyl ester formation (cat. TsOH, EtOH) and acetonization (cat. TsOH, 2,2-dimethoxypropane, benzene, 94% yield for two steps) followed by reduction ($LiAlH_4$, THF, 84%) and bis-acylation (*n*-butyryl chloride, Et_3N, CH_2Cl_2, 75%). The dibutyrate **3** was treated with Lipase Amano PS in phosphate buffer–acetone at room temperature for 5 h to give the mono-ester **4** in 93% yield with > 99% ee.[9] The protection of the hydroxy functionality with an ethoxyethyl group (cat. PPTS, ethyl vinyl ether, CH_2Cl_2) was followed by hydrolysis of the ester moiety (K_2CO_3, MeOH). The benzyl etherification of the resulting ethoxyethyl ether (KHMDS, BnBr, THF) and hydrolysis of the ethoxyethyl group (cat. PPTS, PrOH) gave the alcohol, which was oxidized using the Swern oxidation to give the aldehyde **5** in enantiomerically pure form in 66% overall yield from the mono-ester **4**.†

As shown in Table 1, the *anti*-selective addition of acetylide to aldehyde **5** was conducted with triisopropoxytitanium acetylide **7** as described earlier[7,10] to give the desired adduct *anti*-**8** in 98% yield as single diastereomer (entry 1),‡ whereas modest *syn*-selectivity was observed with halomagnesium, lithium, or dichlorocerium acetylide (entries 2–5).

The *anti*-propargyl alcohol *anti*-**8** was then transformed into the imine **13** possessing the functionalities necessary for the synthesis of tetrahydroxy-LCB **1** *via* the following sequences: protection of the hydroxy group with TBDMS (TBDMSCl, imidazole, DMF, **9**: 95%); partial reduction of the triple bond



under the Lindlar conditions [H_2, Pd/$BaSO_4$, quinoline, MeOH, **10**: 99%, ($Z : E$ = > 99 : < 1)]; removal of the benzyl protecting group (Ca, liq. NH_3, **11**, 86%); Swern oxidation of the hydroxy group (oxalyl chloride, DMSO, Et_3N, CH_2Cl_2, **12**: 93%); benzylimination ($BnNH_2$, Et_2O, **13**: 100%).

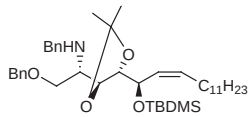
[a] Isolated yields. [b] Determined by HPLC analysis (Merck Hibar Column). [c] Preparation of this anion, see ref. 12.

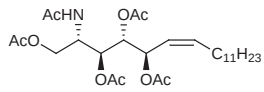
For the introduction of a hydroxymethyl moiety into the imine **13**, three types of nucleophiles were investigated for the addition reaction in terms of diastereoselectivity, in which the imine **6** was used as a model substrate, and Table 2 summarizes the results.

As shown in Table 2, lithium dithianide in THF added to the imine **6** to give *syn*-**14** (Nu = 1,3-dithiane) as the sole product, whereas reversal of the diastereoselectivity was observed in the same reaction conducted in the presence of an excess BF_3•Et_2O, giving *anti*-**14** stereospecifically (entries 1 and 2).[7] Similar trends of reversal of the diastereoselectivity were observed in the cases with the lithium acetylide and 2-furyllithium (entries 3–6). TMSCN in the presence of BF_3•Et_2O[11] also effected the predominant formation of the *anti*-adduct *anti*-**14** (Nu = CN) (entry 7). For the preparation of tetrahydroxy-LCB, the use of a hydroxymethyl anion equivalent was more preferable in terms of functional group manipulation and, therefore, benzyloxymethyllithium[12] was used for the addition in the presence of BF_3•Et_2O to give *anti*-**14** (Nu = $BnOCH_2$) as the sole product in good yield (entry 8). This high selectivity is most probably explained in terms of non-chelation (for *anti*-adduct) and chelation transition states (for *syn*-adduct).

Thus, addition of benzyloxymethyllithium to the imine **13** was conducted as in the case with **6** in the presence of BF_3•Et_2O to give, as expected, the desired *anti*-adduct **15** exclusively in



15



16

32% yield.§ Deprotection of the benzyl group was carried out with Na-NH_3, and subsequent hydrolysis with TFA followed by acetylation gave the pentaacetyl derivative **16** of tetrahydroxy-LCB **1** in 11% overall yield from **15**.¶

In conclusion, the present synthesis using a tandem *anti*-addition reaction to the chiral aldehyde and the imine realizes a rapid access to biologically important molecules in a highly stereocontrolled fashion. Since the level of the diastereoselectivity attained on the addition of nucleophiles to α-hydroxy aldehyde and imine was extremely high, this procedure may be applied to the syntheses of a variety of amino polyols of biological importance in a stereocontrolled manner.

Notes and references

† The enantiomeric purity was determined by HPLC using a chiral stationary column (Daicel OJ).

‡ To a solution of tridecyne (1.63 g, 647 mmol) in 70 ml of THF was added BuLi (1.68 M in n-hexane, 4.62 ml, 7.76 mmol) at −78 °C, and the mixture was stirred at −78 °C for 30 min. A solution of $ClTi(OPr^i)_3$ (1.0 M in n-hexane, 7.8 ml, 7.76 mmol) was added to the mixture at −78 °C and it was allowed to stand at −60 °C for 1 h. A solution of **5** (647 mg, 2.58 mmol) in THF (35 ml) was added to the resulting mixture at −78 °C, and the mixture was stirred at that temperature for 2 h. After usual work-up, the crude oil was purified by flash silica gel chromatography to give the propargyl alcohol *anti*-**8** (1.09 g, 98%) as a colorless oil.

§ To a solution of $SnCl_2$ (214 mg, 1.15 mmol) in THF (2 ml) was added a solution of LiBr (100 mg, 1.15 mmol) in THF (2 ml) and the mixture was stirred at room temperature for 30 min. A solution of $BnOCH_2Cl$ (180 mg, 1.15 mmol) in THF (2 ml) was added to the resulting mixture, to which was added BuLi (1.68 M in n-hexane, 2.74 ml, 4.61 mmol) at −78 °C, and stirred for 1 h at that temperature. BF_3•Et_2O (164 mg, 1.152 mmol) was added to the mixture and after 10 min a solution of **13** prepared *in situ* from **12** (131 mg, 0.288 mmol) and $BnNH_2$ (32.4 mg, 0.302 mmol) in THF (2 ml) was added at −78 °C, and the whole mixture was gradually warmed to 0 °C. After usual work-up, the crude oil was purified on preoperative TLC to give **15** (60.7 mg, 32%) as a colorless oil.

¶ The spectral properties are identical with the reported data (ref. 4).

Confinement and recognition of icosahedral main group cage molecules: fullerene C_{60} and *o*-, *m*-, *p*-dicarbadodecaborane(12)

Michaele J. Hardie and Colin L. Raston*

Department of Chemistry, Monash University, Clayton, Melbourne, Victoria 3168, Australia.
E-mail: c.raston@sci.monash.edu.au

Received (in Cambridge, UK) 29th January 1999, Accepted 1st March 1999

Supramolecular chemistry of icosahedral main group cage molecules, fullerene C_{60} and the carboranes *o*-, *m*- , *p*-$B_2C_{10}H_{12}$, is of interest in the purification of these molecules and in building up novel materials. The non-polarised, spherical like nature of C_{60} requires specific shape and electronic complementarity between the interacting supramolecular synthons which leads to polarisation of the fullerene, whereas for the carboranes, hydrogen bonding involving the C–H groups, including the formation of bifurcated hydrogen bonds [C–H···(N,O)$_2$], and C–H···π interactions, along with shape complementarity, facilitate the self assembly process. Insight into future prospects in this field is presented.

Background

Highly symmetrical icosahedral molecules have captured the imagination of the chemical sciences community and beyond. This is particularly the case since 1985 with the discovery of a new allotropic form of carbon now known as the family of electron deficient fullerenes for which C_{60} is the most abundant and widely studied, having a truncated icosahedral structure.[1] A plethora of organic chemistry of C_{60} resulted in the 1990s which pertains to addition reactions across the 6,6′ position ring junction of two six membered rings, in accordance with the double bonds avoiding the five membered rings of the polyhedron.[2] Exohedral metal complexes of C_{60}, the metal to fullerene binding usually associated with the same 6,6′ positions of the fullerene, are also known,[3] as are endohedral species,[4] and the electrochemical behaviour of C_{60} is remarkable showing reversible reduction to C_{60}^{6-}.[5] Then there is the supramolecular chemistry of C_{60},[6] which is a focus of this article, with advances coming mainly from our research group, and those of Atwood, Fuji, Fukazawa, Matsubara, Shinkai, Verhoeven, and Wennerstrom.

Another focus of this article is the supramolecular chemistry of the related icosahedral main group cage molecules, the carboranes, 1,2-, 1,7-, 1,12-dicarbadodecaborane(12), *viz* *o*-, *m*-, *p*-$C_2B_{10}H_{12}$ (hereafter abbreviated *o*-, *m*-, and *p*-carborane). These carboranes have a rich organometallic chemistry (direct metal–carbon bonds),[7] and a rich organic chemistry associated with replacing one or more hydrogen atoms of the C–H groups as well as the boron atoms.[8] The supramolecular chemistry of the carboranes is even less developed than that of C_{60}. This is surprising given the nexus between these cages, and that unlike C_{60}, the carboranes have been known for several decades.[9] Fullerene C_{60} and the carboranes are all remarkably thermally stable, icosahedral cages with not too dissimilar diameters of 10.0 and ≈8 Å respectively.

In embracing the principles of supramolecular chemistry for C_{60} and the carboranes, the goal is to encourage the association of two or more components (a molecular cage and a second or more supramolecular synthon) in an organised array using weak intermolecular forces, namely van der Waals, hydrogen bonding, electrostatic and labile coordination interactions.[10] Such interactions are inherently weak and some can be comparable to crystal packing and other competing forces. Gaining control over these interactions is a major challenge and underpins much of the basic aims and ideals of supramolecular chemistry.[10] Complementarity of shape of the interacting synthons is important, as is taking advantage of the electron deficient nature of C_{60} and the acidic nature of the C–H groups of the carboranes[9] in optimising interactions between the two different synthons, in effectively negating competing solvent–cage, cage–cage, and host–host interactions.

The overall chemistry of the higher fullerenes is less developed than that of C_{60} with the supramolecular chemistry limited to a few reports, and for completeness, and that given one of the host–guest complexes of C_{70} is isomorphous with that of the C_{60} analogue,[11] the supramolecular chemistry of C_{70} is also included herein.

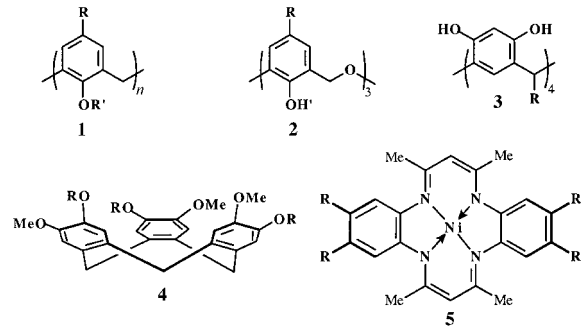
Fullerene C_{60} (and C_{70})

Fullerene C_{60} (and C_{70}) form supramolecular complexes with a variety of hydrophobic host systems including calixarenes, **1**,[5,11–28] oxacalix[3]arenes, **2**,[20,21,29] and related resorcina[4]-arenes, **3**,[30] and cyclotriveratrylene, **4,** R = Me (=

Professor C. L. Raston FRACI is an ARC Senior Research Fellow (1998) and recipient of an ARC Special Investigator Award (1998), Department of Chemistry, Monash University. He completed a Ph.D. under the guidance of Professor Allan White, and after postdoctoral studies with Professor Michael Lappert at the University of Sussex, he was appointed Lecturer at the University of Western Australia (1981) then to the Chair of Chemistry, Griffith University (1988) being awarded a D.Sc. there in 1993, and in 1995 moved to Monash University. Professor Raston received the RACI Burrows Award in 1994, and the H. G. Smith Award in 1996. Research interests cover aspects of main group, supramolecular and green chemistry, and he has published over 360 papers. In 1996 he chaired the 17th International Conference on Organometallic Chemistry, and in 1997 was President of the RACI.

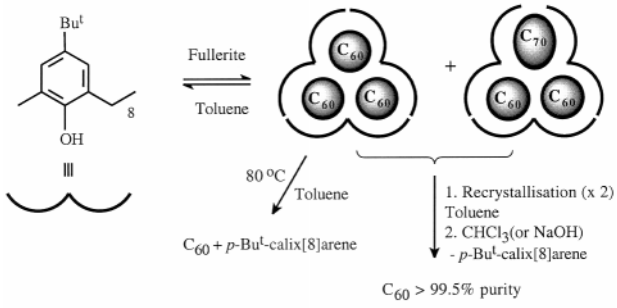
Dr M. J. Hardie is a Postdoctoral Research Fellow at Department of Chemistry, Monash University. She completed a Ph.D. at the University of Melbourne (1996) under the guidance of Assoc. Prof. Richard Robson and Dr Bernard Hoskins, and joined Prof. Raston's research group after postdoctoral studies with Dr Alison Edwards at the University of Melbourne then Prof. A. Alan Pinkerton at the University of Toledo, Ohio (1996). Research interests include supramolecular chemistry and crystallography.

CTV),[5,28,31,32] and related molecules,[33] Ni(II) macrocycles, **5**,[34] as well as complexes with γ-cyclodextrin (included a silica supported system),[35] azacrown ethers,[36] and a porphyrazine.[37] There is also complexation of C_{60} or C_{70} by hydrogen bonded hydroquinones in a super-cube,[38] and with thiafulvalenes.[6,39] We have focused on hydrophobic systems, **1**–**4**, and related saddle shaped Ni(II) macrocycles, **5**,[34] and the work encompasses the incorporation of C_{60} into mesoporous silica.[28]



Calix[6,8]arenes

In 1994 we[12] and Shinkai and coworkers[13] reported the use of *p-tert*-calix[8]arene for the retrieval of high purity C_{60} from toluene solutions of fullerite derived from carbon soot, involving the recrystallisation of the precipitate from toluene followed by decomposition of the 1 : 1 complex when added to chlorinated hydrocarbons in which the fullerene is only sparingly soluble, Scheme 1. The resulting C_{60} is > 99.5% pure



Scheme 1

whereas the initially formed precipitate contains up to 11% C_{70}. An independent study on the solid state ^{13}C NMR spectrum of the 1 : 1 complex between C_{60} and this calixarene has been reported.[18] Since the original foregoing reports, significant advances have been made in understanding the nature of the host–guest complex,[4,5,14] albeit with some conflicting reports, and in building up complex arrays based on other calixarenes, notably calix[5,6]arenes[11,21] and substituted calix[4,5,6,8]arenes,[15,16,19–28] and a resorcinarene.[30] This includes electrochemical studies, both solid state and solution, for C_{60} with calix[4,5,8]arenes and CTV.[5]

The 1 : 1 complex of C_{60} with *p-tert*-butylcalix[8]arene crystallises essentially quantitatively from toluene in the presence of *ca*. 10% excess of the calixarene. Decomposition of the complex by chloroform or dichloromethane possibly relates to the formation of a C–H···π interaction between the chlorinated solvent and aromatic rings of the calixarene taking precedence over the host–fullerene interactions. This type of interaction is found in dichloromethane inclusion complexes of calix[4]arenes.[40] Pure C_{70} does not form a complex with the same calixarene in toluene, but does so in benzene, crystallising as the 2 : 1 complex, $(C_{70})_2$(*p*-calix[8]arene).[15] Interestingly C_{70} also forms a 2 : 1 complex with *p-tert*-butylcalix[6]arene and its precipitation from toluene solutions can be used to retrieve 87% purity C_{70} from C_{60} depleted fullerite.[12]

The *p-tert*-butylcalix[8]arene–C_{60} complex has a resonant inter-fullerene molecular transition at 470 nm,[14] similar to that observed in thin films of C_{60}.[36] Formation of the complex possibly involves a monomeric 1 : 1 transient intermediate, Fig. 1, which distorts the electron cloud of the fullerene[14] resulting in micelle-like formation featuring fullerene–fullerene interactions in the interior core with the fullerenes encapsulated by the host calixarene molecules, Scheme 1. Additional ^{13}C CP MAS NMR data[41] suggest that no well ordered structure of the complex exists and a variety of modifications are possible in the solid state. Nevertheless there is a common underlying ratio of *ca*. 2 : 6[18] for two different types of *tert*-butylphenyl groups. A structure which is consistent with this ratio has each calixarene in the double cone conformation spanning two fullerenes. This double cone conformation of the calixarene would require minimal perturbation of the H-bonded phenol network relative to uncomplexed *p-tert*-butylcalix[8]arene. Determination of the number of fullerenes in the cluster comes from molecular mechanics[14] with the minimised structure for [$(C_{60})_3$(*p-tert*-butylcalix[8]arene)$_3$] shown in Fig. 1. C_{70} is complexed by *p-tert*-butylcalix[8]arene only in the presence of C_{60}, which is consistent with an aggregate of fullerenes with at least one of the C_{60} molecules replaced by C_{70}, the maximum molar incorporation of C_{70} in the complex being 15 ± 1.0%.[14] Comparison of the X-ray powder diffraction pattern of the C_{60} complex with that containing some C_{70}[41] is consistent with some isomorphous replacement of C_{60} by C_{70}. Incorporating more than one molecule of C_{70} per trimer of fullerenes, Scheme 1, may be too disruptive to the tight fullerene/calixarene meshing as suggested by molecular mechanics. Reports on the electrochemistry of the *p-tert*-butylcalix[8]arene complex have the complex breaking apart on reduction (at 400 mV more negative potential).[5] The vibrational spectrum of the complex has also been probed, using

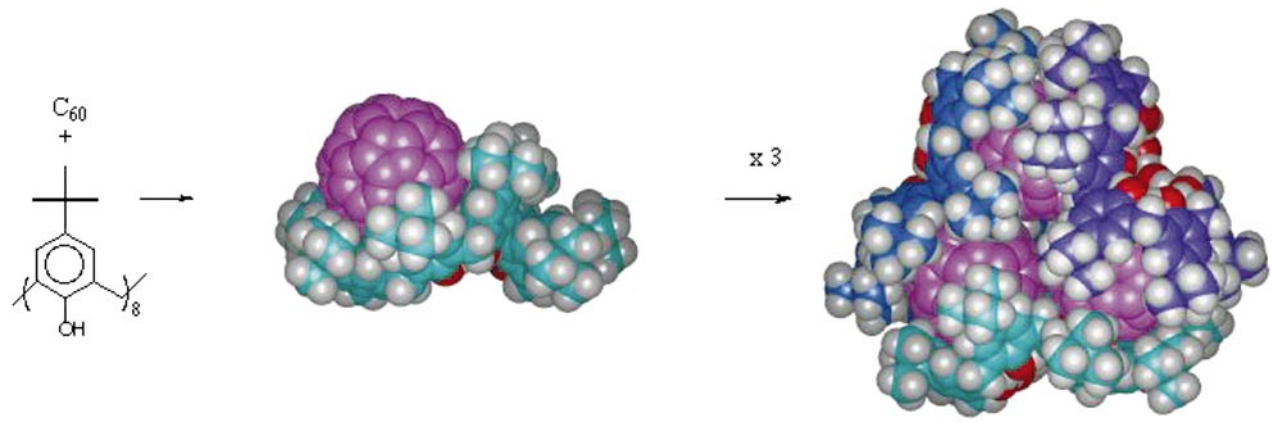


Fig. 1 Formation of the micelle like species [$(C_{60})_3$(*p-tert*-butylcalix[8]arene)$_3$] *via* a monomeric transient 1 : 1 intermediate (C_{60})(*p-tert*-butylcalix[8]-arene).[14]

Raman, IR and neutron scattering,[16] with the results consistent with the C_{60} molecules being almost isolated, suggesting any fullerene–fullerene interactions are weak. Other calix[8]arene complexes have been reported, **1** (n = 8, R = Pr^i or Et).[15]

The fullerene rich calix[6]arene complex, $(C_{60})_2$(calix[6]-arene), has been structurally authenticated[11] and as expected[6] the calixarene is in double cone conformation and associated with two fullerenes, one in each cavity as a perched structure. This arrangement resembles the jaws of a pincer acting on two adjacent spheres, and can be regarded as a building component for the three dimensional structure which has fullerene–fullerene contacts close to 10.0 Å, as well as fullerenes interacting with the aromatic rings *exo*- to the two shallow cavities, Fig. 2. Fullerene C_{70} forms the analogous 2 : 1 complex

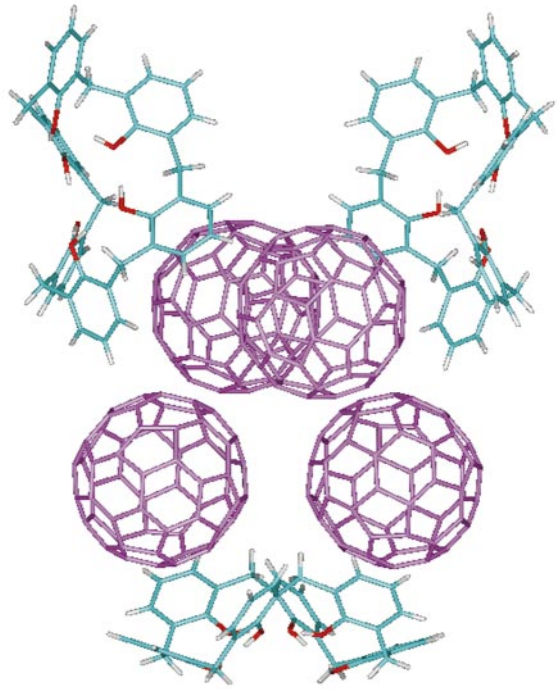

Fig. 2 Extended structure of $(C_{60})_2$(calix[6]arene) showing the double cone conformation of the calix[6]arene and interfullerene interactions.[11]

and is surprisingly isostructural with the C_{60} complex, both crystallising in space group $P4_12_12$. The principle axis of the fullerene is aligned such that the end of the fullerene close to this axis, where the curvature of the cage is similar to that of C_{60}, resides in the cavity. The double cone conformations provide further credence for the proposed structure of *p*-(C_{60})(*p*-*tert*-butylcalix[8]arene), and suggest the other 2 : 1 complexes, *p*-(C_{70})$_2$(*p*-*tert*-butylcalix[6,8]arene),[15] are also likely to have the calixarenes in the double cone conformation with a fullerene in each cavity. A calix[6]arene bearing *N*,*N*-dialkylaniline or *m*-phenylenediamine units forms complexes of C_{60} in toluene solution, with association constants of 7.9–1.1 × 10^2 dm^3 mol^{-1}.[19]

Calix[5]arenes and oxacalix[3]arenes

For the calix[6,8]arenes pre-organisation of the calixarenes *via* torsion along the C–CH_2–C moieties within the macrocycle is required for complexation with C_{60}. While both the calix-[4,5]arenes prefer the cone conformation, and are thus organised for host–guest formation, only the cavity of the calix[5]arene is large enough for binding C_{60} (but *exo*-cavity complexation is also possible—see below). The oxacalix[3]-arenes require minimal torsion for complementarity of curvature with C_{60}.[29]

Calix[5]arene itself forms a 1 : 1 complex with C_{60},[11,21] and other calix[5]arenes give either 1 : 1 or 2 : 1 complexes.[22] Molecular mechanics gives maximum overlap of the π-cloud of the calixarenes with the C_{60} where there is alignment of a C_5 axis of the fullerene with the C_5 axis of the calixarene.

p-Benzylcalix[5]arene and *p*-benzylhexahomooxacalix[3]ar-ene form 2 : 1 complexes with C_{60} from toluene solutions, as the octa-toluene solvate in the case of the calix[5]arene. In both structures the fullerene is shrouded by two staggered, *trans*-host molecules in cone conformations either with dangling benzyl groups, calix[5]arene, or edge on to the fullerene benzyl groups, oxacalix[3]arene, Fig. 3.[29] Either the benzyl groups are now

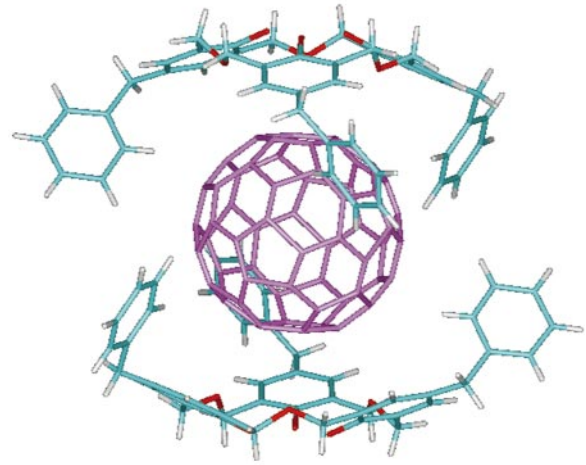

Fig. 3 The supermolecule [(C_{60})(*p*-benzylhexahomooxacalix[3]arene)$_2$].[29] The encapsulation of the fullerene by two oxacalix[3]arenes precludes the formation of extended supramolecular arrays *via* interfullerene interactions as were seen in Fig. 2.

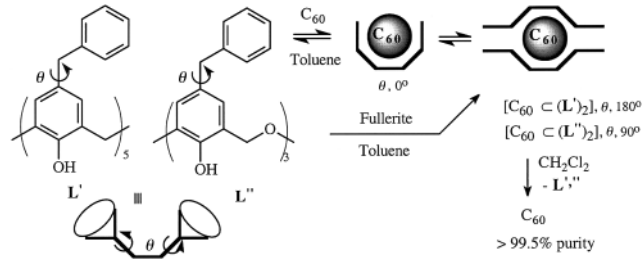
directed away from the fullerene, θ = 180°, or are such that there are C–H···fullerene interactions, θ = 90°, Scheme 2. In



Scheme 2

both C_{60} structures, the alignment of the symmetry axis of the calixarene with the same symmetry element of C_{60}, C_5 and C_3, respectively, highlights the importance of symmetry matching in designing host molecules for fullerenes. This maximises the points of contact and efficiency of π–π interactions between the two interacting moieties. The only other authenticated structure with C_{60} encapsulated by two container molecules, hence precluding interfullerene contacts, is a calix[5]arene complex with three methyl and two iodo groups (1,3 disposition) in the *p*-positions of the upper rim.[22] The synthesis of covalently linked biscalix[5]arenes capable of encapsulating C_{60} or C_{70} has also been reported with binding constants indicating that C_{70} is bound preferentially.[23]

Even a 1 : 1 mixture of calixarenes, L′ or L″, with C_{60} in toluene, Scheme 2, still gives the 2 : 1 complexes in the solid, and in both cases it is also the exclusive complex formed when treating a fullerite mixture in toluene, from which C_{60} [> 99.5% purity (HPLC)] can be readily isolated on the addition of methylene chloride and represents an effective one step purification of C_{60}.

Solution studies on complexation of L′ with C_{60} in toluene give an association constant, K_1 = 2800 ± 200 dm^3 mol^{-1} at low concentrations of the calixarene, and K_2 = 230 ± 50 dm^3 mol^{-1} at higher concentrations. This is consistent with the initial formation of the 1 : 1 complex [C_{60} ⊂ (L′)], followed by

the formation of a 2 : 1 supermolecule, [$C_{60} \subset (L')_2$], and is in agreement with densitometry studies which support the displacement of two toluene molecules from L′ in toluene and formation of 1 : 1 complex in solution, $q = 0°$, Scheme 2.[24] The K_1 values for related 1 : 1 [$C_{60} \subset$ (substituted-calix[5]arene)] complexes studied by Fukazawa and coworkers are 2120 and 76 $\pm 5 \times 10^3$ dm^3 mol^{-1} in toluene.[22] In these studies there was no report of a second equilibrium. Similar UV–VIS studies involving L″ suggest the presence of more than one species in solution, the overall 2 : 1 association constant is estimated to be *ca.* 100 dm^3 mol^{-1}. In contrast, Fuji and coworkers[20] obtained a 1 : 1 association constant of 35.6 dm^3 mol^{-1} for a related oxacalixarene (R = Bu^t, **2**; or 64 ± 5 dm^3 mol^{-1} in an independent study[21]) and C_{60} in toluene, and obtained 1 : 1 complexes rather than a 2 : 1 complex in the solid state, showing interfullerene interactions.[20] Other solution studies on oxacalix-[3]arenes and calix[5]arenes have also been reported[21,25] including the electrochemical behaviour.[5]

Calix[4]arenes and resorcina[4]arene

Shinkai and coworkers screened a wide range of calixarenes for complexation of C_{60} in toluene and found little change in the electronic spectrum for the calix[4]arenes, and thus no evidence for complexation.[21] Nevertheless, some calix[4]arenes have been shown to form stable crystalline complexes with C_{60}, including (i) *p*-phenylcalix[4]arene which has a toluene molecule in the cavity, the overall structure dominated by fullerene–fullerene and *exo*-calixarene–fullerene interactions,[42] (ii) *p*-bromocalix[4]arene propyl ether, the structure showing very close interfullerene contacts in a columnar structure, which most likely results in opposing induced dipoles from the unidirectionally aligned calixarenes,[26] and (iii) *p*-iodocalix-[4]arene benzyl ether where the fullerenes are ordered without appreciable interfullerene interactions.[27] There is also a resorcin[4]arene, R = CH_2CH_2Ph, **2**, which has a molecular capsule derived from head to head hydrogen bonding of two resorcinarenes and propan-2-ol molecules, with the fullerene arranged in columns.[30] The fourfold symmetry of calixarenes and resorcinarenes relates to complexation of octaphenylcyclotetrasiloxane, [{$SiPh_2(\mu\text{-}O)$}$_4$], with C_{60} in toluene. The 1:1 supramolecular complex is a hemi-toluene solvate where the fullerenes are arranged in double columnar arrays shrouded by edge on siloxanes, the siloxanes interlocking by one of the phenyl groups of one molecule residing in the cavity of another.[43]

Cyclotriveratrylene

Complexation of C_{60} in toluene solutions of CTV results in polymeric structures in the solid, either a fullerene rich phase $(C_{60})_{1.5}$(CTV), or a 1 : 1 phase (C_{60})(CTV).[31,32] The structures are dominated by fullerene–fullerene interactions, and each CTV has a C_{60} associated within the cavity of the CTV as a 'ball and socket' nanostructure. For $(C_{60})_{1.5}$(CTV) the fullerenes collectively comprise a two dimensional close packed array with half of the fullerenes devoid of CTV, Fig. 4.[31] Solvated host–guest species, [(CTV)(C_{60})], are formed first in solution. This results in polarisation of the fullerene promoting aggregation which is evident by a resonant interfullerene transition band as 475 nm. The substituted analogue **4**, R = allyl, with C_{60} shows only solvated host–guest species.

The incorporation of aromatic pendant arms on CTV leads to strong binding of C_{60}, that of *N*-methylpyrrole showing the highest association constant, 48 × 103 dm^3 mol^{-1} in benzene. With six benzoyl arms a 1:1 complex forms in the solid state with two host molecules surrounding one fullerene, with a second 'bare' C_{60} in the lattice.[33] The host molecule, R = benzoyl, **4**, can be used to retrieve C_{60} from fullerite.[33] A planar analogue of CTV with a central six membered ring (without the bridging methylene units of CTV) forms a 1 : 2 complex in the solid state with isolated fullerenes surrounded by four planar molecules.[44]

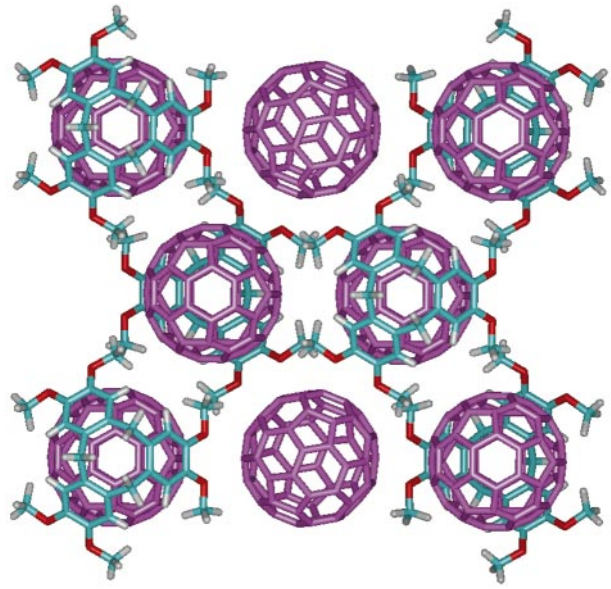


Fig. 4 Crystal packing of $(C_{60})_{1.5}(CTV)\cdot C_7H_6$.[31]

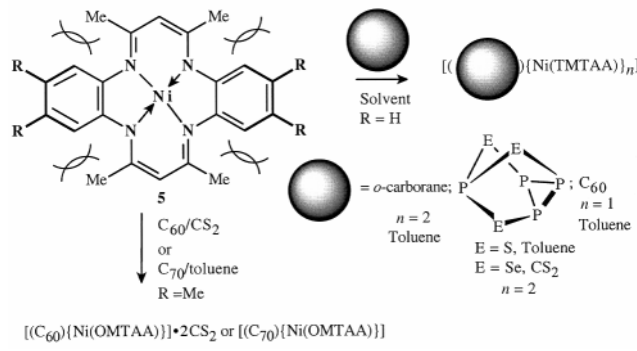
Nickel(II) macrocycles

Compound **5**, R = H, has two divergent concave surfaces in a saddle shape arrangement which arises from the otherwise unfavourable interactions between the methyl groups and the adjacent H-atoms on the aromatic rings.[34] It can act as a divergent heterotopic receptor towards C_{60}, or it can self-associate into dimeric species which in turn can act as a divergent homotopic receptor, for smaller clusters such as *o*-carborane (see below),[34] and also with the phosphorus chalcogenides P_4(S or Se)$_3$, Scheme 3.[34,45]



Scheme 3

In the structure of (C_{60})Ni(TMTAA) (TMTAA = tetramethyltetraazaannulene), Scheme 3, two host molecules shroud the fullerene such that a fullerene is in the saddle of one Ni(TMTAA) molecule with the methyl groups directed towards it and in the opposite saddle of another Ni(TMTAA) molecule, the overall host–guest contacts form a continuous zigzag array, Fig. 5, with the fullerenes forming a corrugated two dimensional sheet.[34] Cu(II) and Zn(II) TMTAA molecules similarly bind C_{60} and are isostructural with the Ni(II) analogue.[46] For R = Me, **5**, (= OMTAA) a 1 : 1 complex is formed with C_{60}, isolated as [Ni(OMTAA)C_{60}]$(CS_2)_2$. The extended supramolecular array is based on linear chains of close contact C_{60} molecules, and linear chains of π-stacked alternating molecules of C_{60} and Ni(OMTAA) with adjacent chains running in opposite directions and thus cancelling out dipole moments, Fig. 6. Surprisingly the same macrocycle forms a 1:1 complex with C_{70} which is isostructural with the C_{60} complex of Ni(TMTAA), *viz*. zigzag alternating C_{70}–Ni(OMTAA) chains with corrugated sheets of close contact C_{70} molecules.[47] In all of

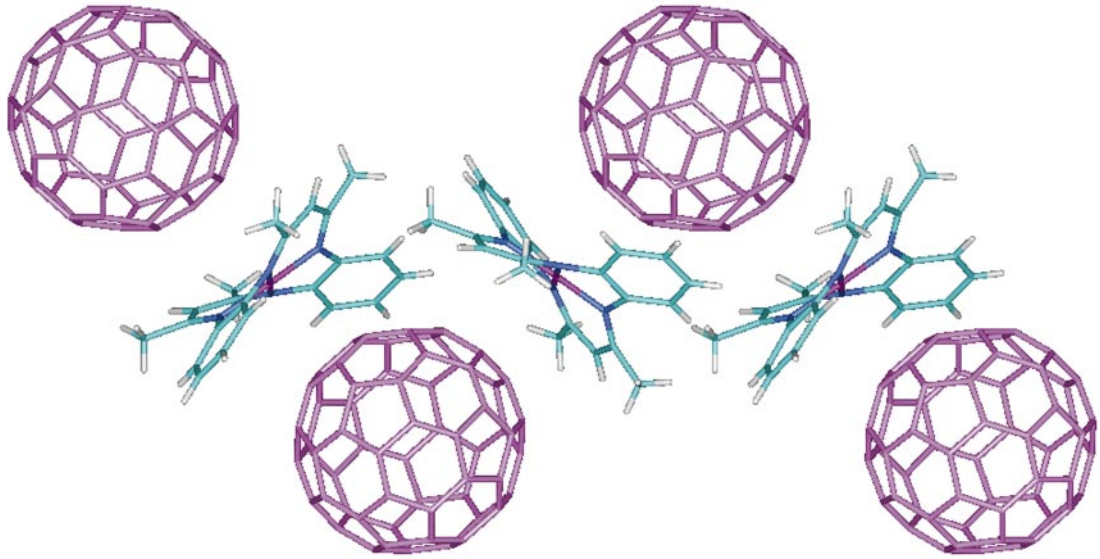


Fig. 5 The continuous zigzag array of [(C_{60}){Ni(TMTAA)}], highlighting the host–guest interactions between the C_{60} and both types of Ni(TMTAA) saddle.[34]

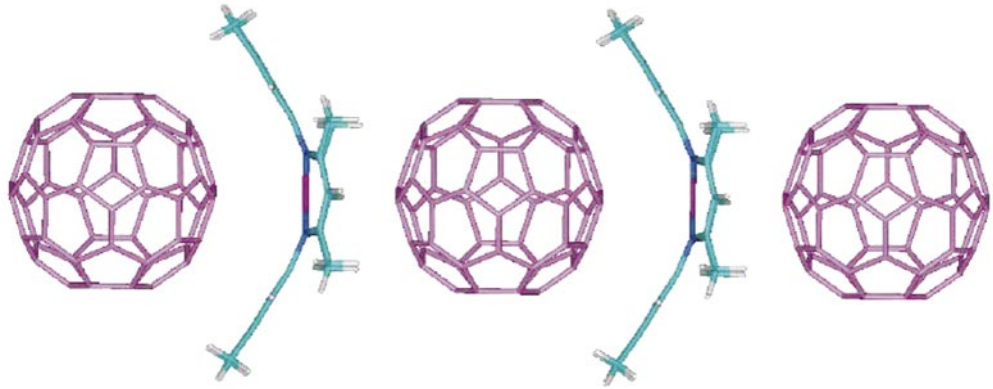

Fig. 6 The linear chains of π stacked C_{60} and Ni(OMTAA) molecules in [{Ni(OMTAA)}(C_{60})]·2CS_2.[47]

these Ni(II) macrocycle structure there are no significant contacts between the metal centres and the fullerenes. As in other systems there is evidence for the formation of 1 : 1 solvated supermolecules in solution which then go on to form micelle like species.[28,32,45] A planar Co(II) octaethylporphyrin also forms a 2 : 1 complex with C_{60} (and C_{70} and $C_{60}O$) in a 'bent metallocene' arrangement, with contacts of the metal to the fullerene in between van der Waals type interactions and a direct metal–fullerene interaction.[3] Here only one face of the macrocycle interacts with a fullerene, unlike in the C_{60} and C_{70} structures of Ni(TMTAA) and Ni(OMTAA). A silica supported zinc(II) tetraphenylporphyrin used in a HPLC column can separate metallofullerenes from C_{60} and higher fullerenes.[48]

Mesoporous silica studies

In addressing the difficulties in identifying and encouraging host–guest interactions of C_{60}, a new amorphous mesoporous silica (= $MPSiO_2$) with sufficient pore size to allow mobilisation of C_{60} was developed.[28] The material has a narrow range of pores, *ca*. 5.4 nm, which are large enough to accommodate small aggregates of fullerenes and associated host molecules, at least for small aggregates where conventional particle size analysis would be difficult. When this material is loaded with C_{60} it offers a qualitative test for supramolecular complexation of the fullerene, and the silica devoid of C_{60} is a material for uptake of preformed micelle like species ⩽5.4 nm in diameter.

Contact of magenta coloured toluene solutions of C_{60} with $MPSiO_2$ results in magenta colouration of the silica. Subsequent addition of toluene solutions of a variety of calixarenes and CTV yields brown–yellow material which shows a new broad resonant interfullerene transition band at *ca*. 450 nm. This is consistent with the formation of aggregates of C_{60}, most likely as part of micelle-like structures with the fullerene cores surrounded by host molecules in the pores of $MPSiO_2$, represented in Fig. 7. As an example, the addition of CTV

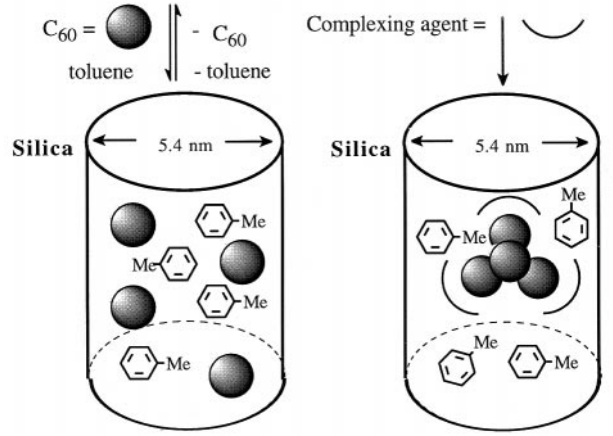

Fig. 7 Schematic representation of the formation of C_{60}–host aggregates inside the pores of mesoporous silica.

solutions to the mesoporous silica with premobilised C_{60} gives a spontaneous change in colour (magenta to brown) whereas addition of preformed solutions of C_{60} and CTV which are

brown show little mobilisation of fullerenes into the channels, and thus the micelle like species present in the solution have diameters ⩾ 5.4 nm.[28] Fullerene C_{60} has also been incorporated into molecular sieves (gas phase diffusion).[49]

Aggregation of fullerenes has been suggested in the incorporation of C_{60} into membranes,[50] and fullerene aggregates (mean diameter 10 nm) have been established in the solubilisation of C_{60} in aqueous media, with a band at 440 nm assigned to aggregate formation (*cf.* 450 nm for the above systems).[51] Aggregation of C_{60} is also prevalent in dissolution of the fullerene in a wide range of solvents, with significant reduction in its solubility.[52]

Carboranes

The C–H groups of carboranes are acidic[9] and intermolecular C–H···O,N hydrogen bonding is important in the supramolecular chemistry of carboranes, Fig. 8.[53–57] This includes

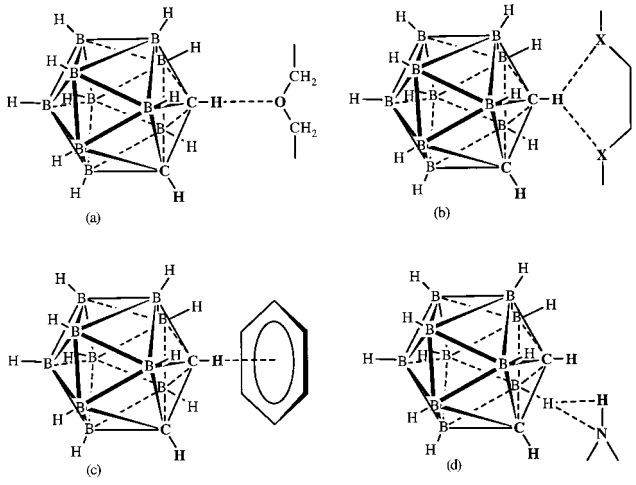

Fig. 8 Established types of interactions of carboranes (shown for the *o*-isomer): (a) classical C–H···O hydrogen bond, (b) bifurcated hydrogen bond, X = O (1,2-dimethoxylbenzene systems), N (in *o*-phenanthroline), (c) non-classical C–H···π hydrogen bond, and (d) B–H···H–N interplay.

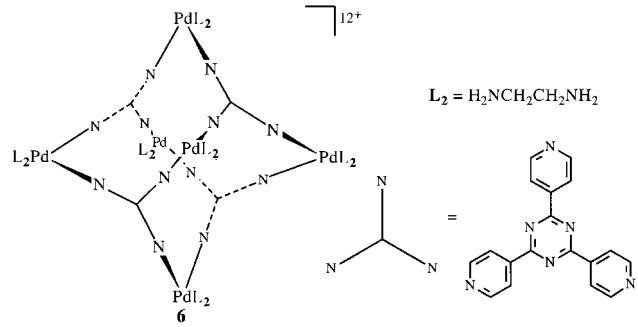
bifurcated hydrogen bonding for 1,2-di(methoxy)benzenes and *o*-phenanthroline,[56,57] Fig. 8(b). Also important are the C–H···π-aromatic ring interactions, Fig. 8(c), where the $C–H_{carborane}$ is directed towards the centroid of an aromatic ring as a Coulombic interaction between a polarised C–H bond and the basic π-electrons of an aromatic ring, and can be regarded as a non-classical hydrogen bond.[53] This is calculated to be energetically favoured by 2.74 kcal mol^{-1},[53] at the 6-31G* level, for the model system of benzene interacting with *o*-carborane. The protons on carbon of the carborane have a residual charge of +0.299 *cf.* 0.068–0.091 for the hydrogen atoms on boron. Such non-classical hydrogen bonding has precedence in dichloromethane[40] inclusion complexes of calix[4]arenes. A less common type of interaction in complexes of carboranes involves B–H···H–N interplay with amines, Fig. 8(d).[58]

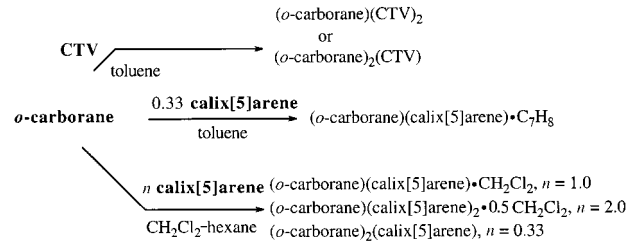
Theoretical calculations on a model system of *o*-carborane and 1,2-dimethoxybenzene give the $C–H_{carborane}···(O)_2$ interaction energetically favoured by 5.48 kcal mol^{-1}.[57] This is close to double the calculated energy of 2.74 kcal mol^{-1} for a single $C–H_{carborane}···\pi$ interaction.[53] This highlights a delicate balance between the carborane being involved in bifurcated hydrogen *versus* C–H···π bonding in the cavity of the CTV.

Host–guest chemistry

The first host–guest complexes of carboranes were the 1 : 1 complexes with α-, β- and γ-cyclodextrin, and a 2 : 1 complex for α-cyclodextrin.[59] Presumably in the 2 : 1 complex the carborane is shrouded by two host molecules, [(*o*-carborane)⊂(α-cyclodextrin)$_2$], which is related to C_{60} forming a 2:1 complex for the larger γ-cyclodextrin, noting the smaller cyclodextrins here do not form complexes with the fullerene.[35] The self-assembled ionic capsule, **6**, arising from interplay between (ethylenediamine)palladium(II)$^{2+}$ ions and four triply bridging pyridyl ligands, with the metal centres at the corners of an octahedron and the pyridyl ligands centred at the corners of a tetrahedron, has a large internal volume capable of binding four *o*-carborane molecules, presumably as a tetrahedral aggregate.[60] This encapsulation renders the carboranes water soluble, as do the cyclodextrin complexes.[59]



Other systems deal with hydrophobic host container molecules and the natures of the species formed are more substantiated with several X-ray structure determinations. These have shallow cavities and the resulting 1:1 supermolecules are at best described as perched structures. These involve calix[5]arene[56] and cyclotriveratrylene (= CTV).[53,57] Compounds prepared thus far and structurally authenticated are summarised in Scheme 4. A symmetrically tris-allyl substituted



Scheme 4

analogue of CTV with a deeper cavity forms a 1 : 1 complex with *o*-carborane,[53] but has yet to be fully characterised. These complexes have IR shifts for $\nu_{C–H}$ of the carborane to lower energy, and a shift to higher energy for $\nu_{B–H}$,[53–57] consistent with the presence of non-classical hydrogen bonding for the C–H bonds with dispersal of the extra charge on the carbons resulting in strengthening of the B–H bonds.

The calix[5]arene–*o*-carborane complexes have a common structural motif in the solid state with a 1 : 1 ball and socket nanostructure comprised of the carborane in a cone shaped calixarene.[56] The carboranes interact with the calixarene most likely *via* the non-classical C–H···π hydrogen bonding, Fig. 8(c), and in all cases the C–H vectors of the carborane are directed towards aromatic rings of the host molecule. The interplay of the supermolecules with the other components, solvent, additional calixarene or carborane builds up the supramolecular arrays. In (*o*-carborane)(calix[5]arene)·CH_2Cl_2[56] the ball-and-socket units organise into larger dimeric supermolecules with calixarene hydroxy groups facing each other, forming a hydrophilic core shown in Fig. 9.

In (*o*-carborane)(calix[5]arene)·C_7H_8[56] the (*o*-carborane)∩(calix[5]arene) supermolecules stack along the same direction. The *endo*-cavity *o*-carborane of one supermolecule has contacts to the hydroxy groups of the next (*o*-carborane)∩(calix[5]arene). The calixarene rich complex (*o*-carborane)(calix[5]arene)$_2$·0.5CH_2Cl_2[56] has a remarkable structure with both calix-

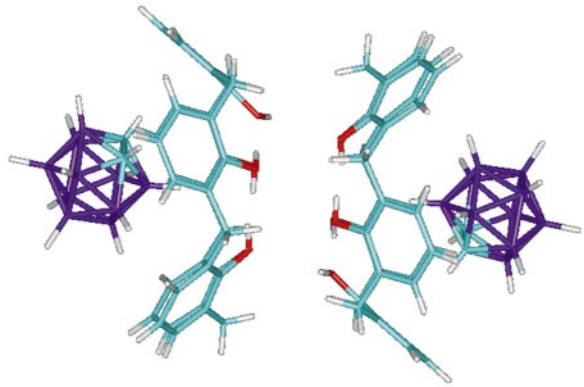


Fig. 9 The dimeric [(*o*-carborane)∩(calix[5]arene)]$_2$ nano-structure of [(calix[5]arene)(*o*-carborane)]·CH_2Cl_2. The dimer acts as a divergent receptor.[56]

[5]arene molecules acting as host molecules in quite distinct manners. One calixarene acts as a host molecule for the *o*-carborane, forming the ball-and-socket arrangement while the other acts as a secondary host for the (*o*-carborane)∩(calix-[5]arene) assembly *via* π···π interactions forming the [(*o*-carborane)∩(calix[5]arene)]∩(calix[5]arene) nano-structure illustrated in Fig. 10. The complexation of a host–guest species by a secondary host is relatively uncommon.

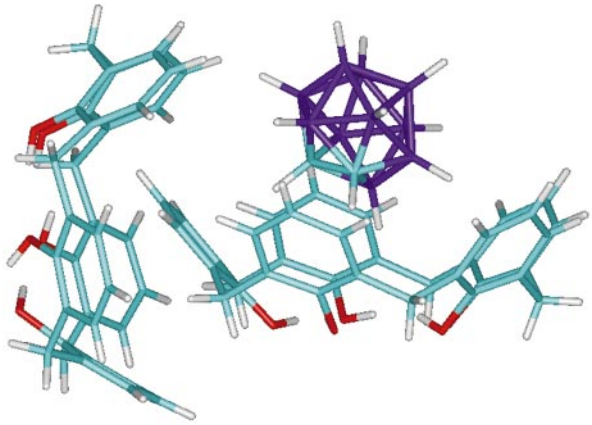

Fig. 10 The [(*o*-carborane)∩(calix[5]arene)]∩(calix[5]arene) nanostructure of [(calix[5]arene)$_2$(*o*-carborane)·0.5CH_2Cl_2].[56]

In the structure of (*o*-carborane)$_2$(calix[5]arene)[56] the carborane forms both *endo* and *exo* associations with the host calixarene, Fig. 11, with the second *o*-carborane forming a weak association with the hydroxy groups of the calixarene through one triangular face of the icosahedron. The *endo* and *exo* carboranes form pairs of cage molecules. The association of carboranes is also prevalent in the 1 : 1 complex of aza-18-crown-6 with *o*-carborane which forms an intercalation compound (see below),[55] and in the interplay between the four carboranes in the ionic capsule, **1**.[60]

In all the structures of the supermolecules [(*o*-carborane)∩(calix[5]arene)] the cage molecule is not a snug fit in the calixarene and thus while the formation of these complexes in solution is entropically driven there is some degree of torsional flexibility in the cone conformation of the calixarene to adapt to both the interactions with the cavity guest and the surroundings. Fullerene C_{60} in contrast has an excellent complementarity of curvature with calix[5]arenes in general (see above) and the calixarenes are in symmetrical conformations with little or no torsion mobility. In contrast, host–guest complexes of CTV and *o*-carborane clearly show a more snug fit of the cage species in the cavity of the host molecule, *i.e.* there is greater complementarity of curvature of the two supramolecular synthons. Surprisingly CTV also has complementarity with C_{60}[31,32] and the ability of CTV to accommodate spherical like molecules

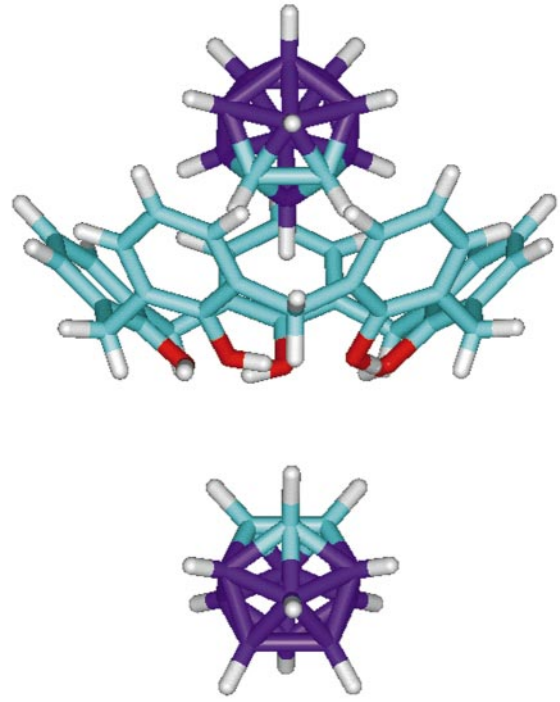

Fig. 11 The *exo* and *endo* associated *o*-carboranes of [(*o*-carborane)$_2$(calix[5]arene)].[56]

with different diameters (8 Å carborane *cf.* 10 Å C_{60}) relates to a shallower cavity of the rigid CTV relative to the diameter of the host molecule.

The structure of the 2 : 1 complex of CTV and *o*-carborane, Scheme 4, is comprised of 1 : 1 supermolecules of CTV and *o*-carborane, (*o*-carborane)∩(CTV),[53] the other CTV forming a zigzag π-stacked column with the inter-CTV contacts at the van der Waals limit. This type of association of CTV molecules is common even in inclusion complexes of CTV where the guest species are not in the cavities of the CTV molecules, the so called α-phase for CTV.[61] Thus the formation of complexes of *o*-carborane, and also C_{60}, with the guest species in the cavity of the CTV represents a major development in CTV chemistry. Non-bonded contact distances of the supermolecule (*o*-carborane)∩(CTV) show that three hydrogens of a triangular face of the icosahedron are directed towards the aromatic rings of the CTV albeit unsymmetrically, Fig. 12. This most likely arises from the energetically favoured $C–H_{carborane}\cdots\pi$ hydrogen bonds to two aromatic rings of the CTV *versus* repulsion between the B–H and the third aromatic ring of the CTV.

In (*o*-carborane)$_2$(CTV)[57] one of the carborane molecules forms three symmetry equivalent bifurcated hydrogen bonds to the methoxy groups of three equivalent CTV molecules, Fig. 8(b).[57] All three interactions originate from the same triangular face of the carborane icosahedron and, due to symmetry imposed disorder, each of the three carborane centres involved has 2/3 carbon and 1/3 boron character. A puckered hexagonal 2D hydrogen bonded network is formed, shown in Fig. 13. All CTV molecules within the grid, and indeed throughout the crystal lattice, have their bowl vertices pointing in the same direction. The second *o*-carborane molecule resides in the receptor sites forming a ball-and-socket (*o*-carborane)∩(CTV) nanostructure throughout the hydrogen bonded grid. The host–guest interplay within the supermolecule (*o*-carborane)∩(CTV) in the 2 : 1 complex is remarkably different to that found in (*o*-carborane)(CTV)$_2$. Here the alignment of the carborane within the CTV cavity is symmetrical with all carborane C–H vectors directed away from the CTV aromatic rings, Fig. 13.[57] However, the difference is consistent with the inherently weak interactions holding the supermolecule together.

^{1}H NMR spectra recorded in toluene for the 2 : 1 complex [(*o*-carborane)(CTV)$_2$] show rapid exchange processes occurring

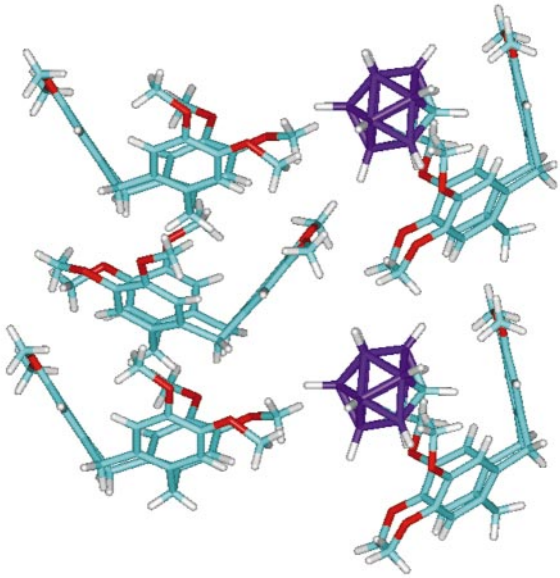

Fig. 12 Section of the crystal structure of [(*o*-carborane)(CTV)$_2$] showing the host–guest species and π stacked CTV molecules.[53]

between complexed and uncomplexed carborane. No significant changes to the ^{1}H NMR of CTV in the complexed and uncomplexed systems were evident. Variation in mole fraction of the carborane relative to CTV showed a non-linear relation with the chemical shift of the carborane C–H protons which implies that complexation is not a simple 1:1 supermolecule formation. The inability to fit the NMR data to this simple model indicates that *o*-carborane binds both *endo* and *exo* to the cavity of the CTV.

The nickel(II) macrocycle Ni(TMTAA), Scheme 3, can act as a divergent heterotopic receptor towards C_{60},[34] or it can self-associate into dimeric species which in turn can act as a divergent homotopic receptor, and this is found in the complex of *o*-carborane, and also for the phosphorus chalcogenides P_4(S or Se)$_3$.[34,46] In the solid state structure the *o*-carborane resides in the saddle of two Ni(TMTAA) molecules as bent sandwich like supermolecules with the two host molecules adjacent to each other, Fig. 14. The sandwich supermolecules form extended structures by locking together the pendant phenyl rings of one Ni(TMTAA) of one supermolecule with that of Ni(TMTAA) of another with the methyl groups all directed towards the cage. Alternatively the structures can be viewed as two associated Ni(TMTAA) molecules acting as a divergent receptor for two *o*-carboranes. The two Ni(TMTAA) moieties are at 90° to each other, and this is driven by the complementarity of curvature of the interlocking components, as well as by Ni···π-arene interactions.

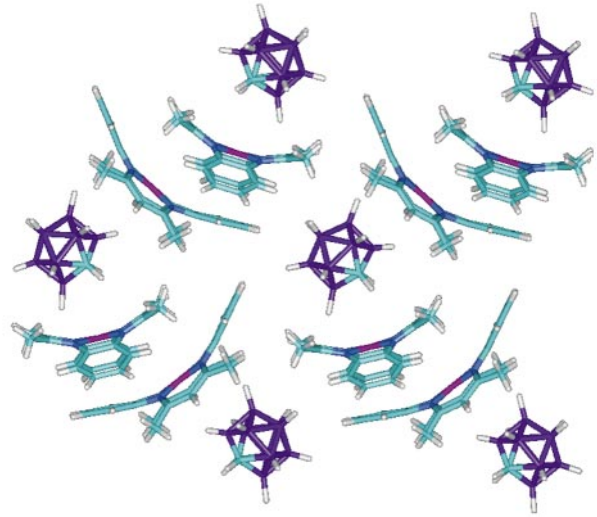

Fig. 14 Crystal stucture of [(*o*-carborane){Ni(TMTAA)}$_2$].[34]

Diaza-18-crown-6, [1,4,10,13-tetraoxa-7,16-diazacyclooctadecane] forms a 1:1 host–guest complex with *o*-carborane,[55] Scheme 5. While aza-18-crown-6, [1,4,10,13-tetraoxa-7-azacyclooctadecane] gives a 1:1 complex it is an intercalation compound with alternating layers of *o*-carboranes and crown ethers (see below). The striking difference in structure

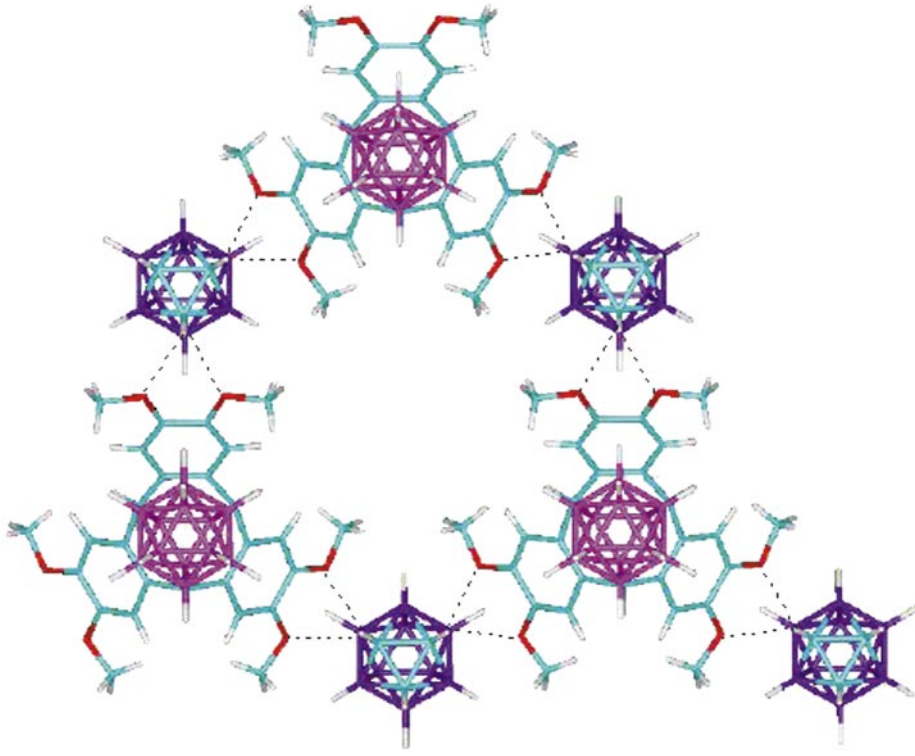

Fig. 13 Section of the crystal structure of [(*o*-carborane)$_2$(CTV)], showing the 2D hexagonal network formed through bifurcated B/C–H···O hydrogen bonds around the CTV, and guest carboranes (in pink).[57]

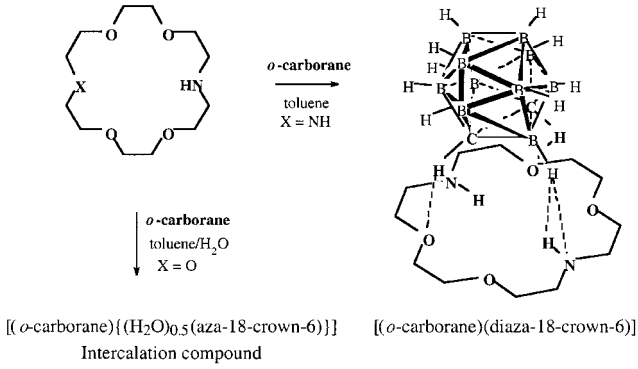

Scheme 5

between the two complexes reflects the delicate balance between weak intermolecular interactions, host–host, host–guest and guest–guest, which are within the realms of crystal packing forces.

In the supermolecules of [(*o*-carborane)∩(diaza-18-crown-6)], three H-atoms of a triangular face of the *o*-carborane polyhedron bearing the two carbon atoms reside above the diaza-18-crown-6. The two components are linked through $C–H_{carborane}\cdots O$ hydrogen bonding interactions, Fig. 8(a) coupled with B–H···H–N, Fig. 8(d), interplay. The H···H distance is close to the upper limit for unconventional dihydrogen bonds established for B–H···H–N contacts in aminoboranes.[58] The $O\cdots H_{carborane}$ distances are similar to those found in the *o*-, *m*-, and *p*-carborane adducts with HMPA.[54] A $\nu_{C–H}$ shift of the carborane of 33 cm^{-1} to lower energy and $\nu_{B–H}$ shift to higher energy of 25 cm^{-1} is observed.

Theoretical studies give the docking of the carborane with diaza-18-crown-6 to be favoured by 9.32 kcal mol^{-1}.[55] The optimised C–H···O distances at 2.471 Å compare well with experimental values at 2.49 Å, whereas optimised B–H···N and B–H···H–N at 2.924 and 2.721 Å, respectively are much longer than experimental values at 2.34 and 2.15 Å, and analogous distances in aminoboranes.[58] The reason for this is unclear. The high error in the position of the H-atom attached to nitrogen in [(*o*-carborane)∩(diaza-18-crown-6)] may be a problem, and the short B–H···H–N contacts for aminoboranes[58] arise from residual negative charge on the H-atoms attached to boron, *cf.* positive charge in [(*o*-carborane)∩(diaza-18-crown-6)].

^{1}H NMR in benzene at 25 °C for a range of concentrations of diaza-18-crown-6 (0.0–0.14 M) for a fixed *o*-carborane concentration (0.07 M) resulted in shifts in the *o*-carborane C–H resonance from δ 2.05–2.20 and the N–H resonance for diaza-18-crown-6 from δ 2.26–2.85. A near linear relationship indicate a low equilibrium constant (< 5 dm^3 mol^{-1}), eqn. (1).

$$o\text{-carborane} + \text{diaza-18-crown-6} \overset{\text{benzene}}{\rightleftharpoons} [(o\text{-carborane}) \cap (\text{diaza-18-crown-6})] \quad (1)$$

For *m*-carborane small differences in the chemical shift for C–H relative to a 1 : 1 mixture of the carborane and diaza-18-crown-6 indicate little or no complexation. Furthermore there is no complex formation in the solid state. Presumably the ability for *m*-carborane to form two C–H···O interactions within the same supermolecule while maintaining the crown conformation of the host is lost. The different binding prowess of *o*- and *m*-carborane suggests that separation of isomeric carboranes *via* selective binding is possible rather than using conventional chromatography.[9] Interestingly, ^{1}H NMR data show the corresponding *N*,*N*′-dibenzyldiaza-18-crown-6 forms a complex with *o*-carborane in benzene but attempts to isolate this complex were unsuccessful.[55]

Crystal structures of the 1 : 1 complexes of hexamethylphosphoramide (HMPA) with *o*-, *m*- and *p*-carboranes derived from toluene solutions have been reported.[54] The three complexes show extensive C–H···O hydrogen bonding and all adopt quite different supramolecular structures, commensurate with their differing arrangement of C–H sites. The *o*-isomer gives a dimeric structure, $C–H_{carborane}\cdots O$ 1.54(4)–1.60(4) Å, whereas the other isomers give polymeric structures with the HMPA O-centre bridging to two C–H groups from different carborane molecules (see below).

Tetrameric macrocycles mercuracarborand-4 and octaethylmercuracarborand-4 can also act as hosts for *closo*-$B_{12}H_{12}^{2-}$, as well as related globular borane anions *closo*-$B_{10}H_{10}^{2-}$ and *closo*-$B_{10}I_{10}^{2-}$.[7]

Extended arrays

The polymeric structures of [(*m*-, *p*-carborane)(HMPA)][54] have the O-centre of HMPA bridging to two C–H groups from different carborane molecules. Polymeric structures are also found in $(o\text{-carborane})_2$(CTV) and (C_{70})(*o*-carborane)(CTV)·1,2-dichlorobenzene.[57] Here hydrogen bonding is also prevalent, but involving bifurcated units, Fig. 8(b), rather than the classical hydrogen bond, Fig. 8(a). In the ternary system C_{70}–*o*-carborane–CTV–1,2-dichlorobenzene, each *o*-carborane interacts with two CTV molecules and in turn, each CTV is hydrogen bonded to two carboranes forming an infinite helical chain, Fig. 15. The CTV cavities are directed outwards from the helices, and each CTV complexes one C_{70} molecule. It is noteworthy that in the absence of carborane, C_{70} fails to form a complex with CTV, in contrast to C_{60} which forms two complexes, (C_{60})(CTV) and $(C_{60})_{1.5}$(CTV),[31,32] and that C_{60}

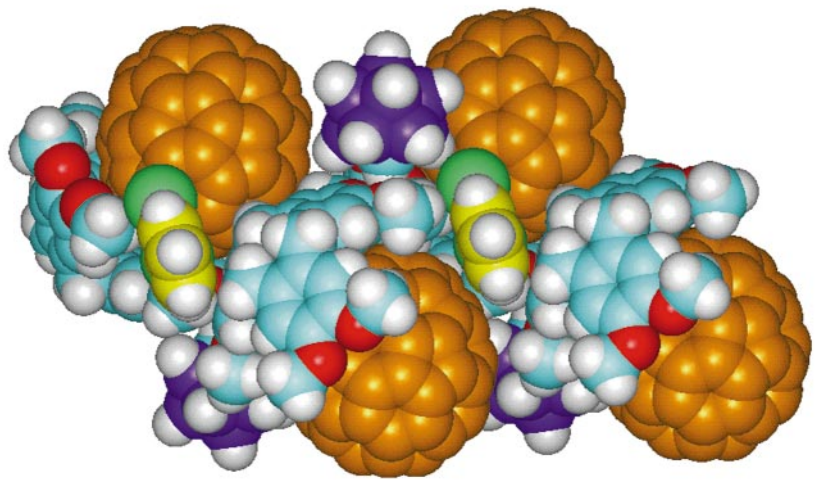

Fig. 15 Side view of a helix in [(C_{70})(*o*-carborane)(CTV)·1,2-dichlorobenzene] showing the binding of C_{70} molecules within the CTV bowls.[57]

and CTV in the presence of *o*-carborane also affords $(C_{60})_{1.5}$(CTV).

Inclusion/intercalation chemistry

Monoaza-18-crown-6 also gives a 1 : 1 complex, Scheme 5, with *o*-carborane but this is an intercalation complex, Fig. 16.[55]

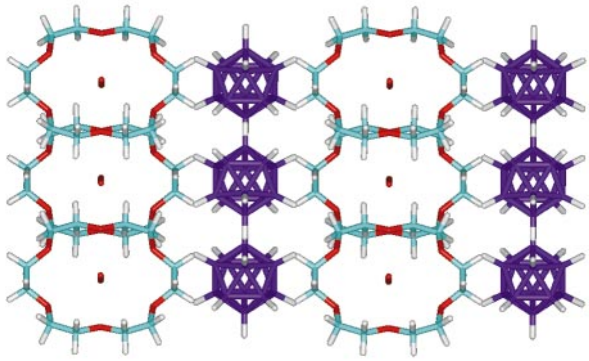

Fig. 16 Projection of [(*o*-carborane){$(H_2O)_{0.5}$⊂(aza-18-crown-6)}].[55]

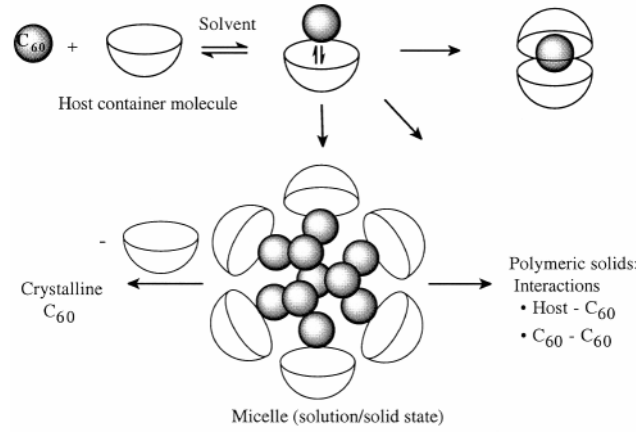
Moreover, the crown ether requires a water molecule in its cavity for the complex to form, and the isolated material has a 50% occupancy of water in the cavity, [(*o*-carborane)-{$(H_2O)_{0.5}$⊂(aza-18-crown-6)}]. ^{1}H NMR of a mixture of the *o*-carborane and crown ether suggests intimate contact of the two components in solution, but in this case host–host and guest–guest interactions are predominant in the solid state. A similar effect was observed in the absence of moisture but in this case no host–guest or intercalation complex was isolated.

Although the structure of [(*o*-carborane){$(H_2O)_{0.5}$⊂(aza-18-crown-6)}] is highly disordered, it clearly shows the absence of any close intermolecular contacts like those observed in [(*o*-carborane)∩(diaza-18-crown-6)]. The polarised clusters form a two dimensional sheet, the nearest intercarborane contacts C/B–H···H–B/C at 2.41 Å.

Future prospects

Both icosahedral C_{60} and carboranes have recently gained prominence in supramolecular chemistry, the cohesion of the supermolecules and solid state structures coming from different interactions. Solvent molecules can also play a vital role in determining the crystal packing and overall topology of the systems. Interactions involving C_{60} or carboranes with themselves, including the formation of micelle like species for C_{60}, and with solvent and other molecules has potential in assembling complex structures. Complexation of other cage molecules is even less established and the ground rules for their confinement are beginning to emerge. Foremost is the use of rigid concave host molecules with complementarity of curvature with the cage molecule; any pre-organisational energy requirements of flexible host molecules may be at the expense of host–guest complexation. Moreover, combining carboranes with container molecules capable of the bifurcated hydrogen bonding with the carborane (such as CTV) offers scope for swaying the competing energies of interaction in favour of host–guest complexes (for cage molecules other than for carborane—demonstrated for C_{70}) where the host–guest components otherwise fail to assemble.

The ability to purify C_{60} by supramolecular complexation is noteworthy. The primary process in the binding of C_{60} is the formation of a host–guest species with polarisation of the fullerene resulting in aggregation of the fullerenes. The fate of this is complete encapsulation of a single fullerene, the formation of a stable micelle-like structure (in mesoporous silica as well as in bulk solution), or the breakdown of the latter resulting in crystallisation of pure C_{60}, Scheme 6. Complexation of higher fullerenes is a synthetic goal as is the complexation of



Scheme 6

reduced fullerenes, for which the associated complexes are likely to possess unusual properties. This may be possible using the receptor macrocycle M(TMTAA) where the metal centre is easily oxidised, M^{2+}(TMTAA) → $[M^{2+n}(TMTAA)]^{n+}$, *via* electron transfer to the cage molecule. The binding of carboranes is largely through C–H···O,N hydrogen bonds, and C–H···π-cloud interaction, with some evidence for the association of the carboranes.

A major advance in supramolecular chemistry is the ability to construct large encapsulating supermolecules assembled by hydrogen bonding[62] or metal coordination chemistry.[60] These systems have very large internal voids and in principle could accommodate, and incarcerate, several fullerenes, as has been achieved for four carboranes,[60] and even larger main group cages species. Finally the supramolecular chemistry has exciting possibilities in stabilising new species, in their separation from complex mixtures, and in generating novel structures and materials.

Acknowledgments

The authors wish to acknowledge the contribution from coworkers over several years at Monash University and Griffith University, and the collaboration with Professor J. L. Atwood, University of Missouri—Columbia, and Dr R. J. Blanch, ADFA, University of NSW. Financial support from the Australian Research Council and the Department of Industry, Science and Tourism is gratefully appreciated.

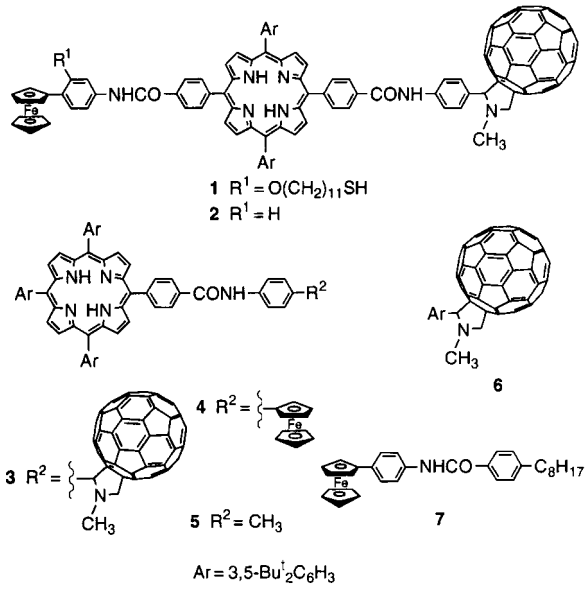
Received (in Cambridge, UK) 22nd April 1999, Accepted 27th May 1999

A self-assembled monolayer of a ferrocene–porphyrin–C_{60} triad has been prepared to mimic efficient vectorial electron transport across a photosynthetic membrane.

In photosynthesis a key process for the conversion of light to chemical energy is initial electron transfer (ET) events in the reaction center complex. The ultrafast and unidirectional multistep ET takes place along well-arranged pigments embedded in the transmembrane proteins, leading to a generation of a charge-separated state across the membrane with a quantum efficiency (Φ) of nearly 100%. There have been numerous synthetic attempts to mimic this highly efficient process. Some of them, such as triads, tetrads, and pentads, produce a long-lived, charge-separated state with a high quantum yield.[1] However, efficient conversion (overall Φ = 1–10%) of light to photocurrents or chemical products *via* the charge-separated state has been hampered, because of the difficulty of assembling the donor–acceptor linked molecules unidirectionally in artificial membranes such as lipid bilayer and Langmuir–Blodgett membranes.[2–4] Self-assembled monolayers (SAMs)[5] are an alternative and promising approach to organize the donor–acceptor molecules on electrodes owing to their uniform and well-ordered structures.[6,7] Here we report the first preparation and photoelectrochemical properties of a SAM of a ferrocene (Fc)–porphyrin (P)–C_{60} triad **1** on a gold electrode.



The synthetic route to **1** is shown in Scheme 1. Aminophenylferrocene **8** was prepared in three steps from ferrocene. Formyl-protected aniline **9** was synthesized in two steps from 4-nitrobenzaldehyde. Cross-condensation of porphyrin bis(acid chloride) **10** with **8** and **9** in benzene in the presence of pyridine, followed by acidic hydrolysis, afforded ferrocene–prophyrin **11** in 23% yield.[8] Bromide **11** was converted to thiol **12** *via* thioesterification with potassium thioacetate and subsequent base deprotection. The triad **1** was obtained by 1,3-dipolar cycloaddition using **12**, *N*-methylglycine, and C_{60} in toluene in 54% yield.[9] The reference compounds **2**–**7** were also prepared. Their structures were verified by spectroscopic analyses including ^{1}H NMR and MALDI-TOF mass spectra.†

The absorption spectrum of **2** in THF is essentially a linear combination of those of **5**, **6** and **7**, indicating no evidence for strong interaction among these chromophores. Absorption due to the porphyrin is much stronger relative to the C_{60} and the ferrocene, showing that the porphyrin is a major absorber of photons. Fluorescence spectra of **2** and **3** in THF are quenched strongly as compared with that of **5** when excited at the Soret band under the same concentration (relative intensities: 0.14 for **2**, 0.19 for **3**). In contrast, the relative fluorescence intensity of **4** *vs.* **5** (0.60) is much larger, suggesting that quenching of the excited singlet porphyrin (^{1}P*) by the attached C_{60} is a dominant deactivation pathway in **1**.

A cyclic voltammetric experiment using **1** on Au in CH_2Cl_2 containing 0.1 M Bu^nNPF_6 electrolyte with a sweep rate of 100 mV s^{-1} was performed to estimate the surface coverage. The adsorbed amount of **1** on Au was calculated from the charge of the anodic peak of the ferrocene to be 1.9×10^{-10} mol cm^{-2} (86 Å^2 molecule^{-1}), which is comparable to the porphyrin–polyalkanethiols ($0.8–2.0 \times 10^{-10}$ mol cm^{-2})[7,10] and C_{60}–polyalkanethiols ($1.3–2.0 \times 10^{-10}$ mol cm^{-2})[11,12] on gold electrodes. Assuming that the triad is packed perpendicularly to the gold surface, then the occupied area of one molecule is calculated to be *ca.* 87 Å^2 for hexagonal packing of the C_{60} moieties, which is consistent with the experimental value. Therefore, we can conclude that the triad molecules are well-packed with almost perpendicular orientation on the gold surface.

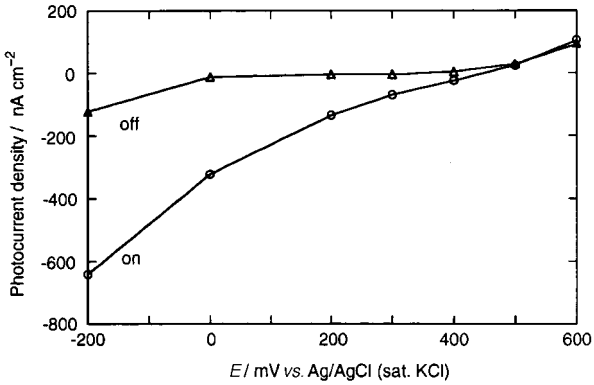

Fig. 1 Photocurrent *vs.* applied potential curves for the triad cell when the light is on (○) and off (△): λ = 438.5 nm (60 μW cm^{-2}), O_2-saturated 0.1 M Na_2SO_4 solution.

Photoelectrochemical measurements using **1** on Au in a three electrode system were carried out in an oxygen-saturated 0.1 M Na_2SO_4 solution. Fig. 1 shows current–potential curves under an illumination of 438.5 (±4.9) nm light (60 μW cm^{-2}). The SAM showed a photoelectrochemical response when the light was switched on and off. The photocurrent was reduced by argon bubbling of the solution and recovered to the initial state by successive oxygen bubbling. The results indicate that $C_{60}^{\cdot-}$ gives an electron to O_2 to produce $O_2^{\cdot-}$.[6] The intensity of the photocurrent in the present system is larger by two orders of magnitude than that of the porphyrin–polyalkanethiol systems,[10] implying that the C_{60} and ferrocene moieties are responsible for the higher efficiency. An increase in the cathodic photocurrent with an increase of the negative bias to the gold electrode demonstrates that the photocurrent flows from the gold electrode to the counter electrode through the electrolyte. The cathodic photocurrent dramatically increased as the potential applied dropped below +500 mV, which is in good agreement with the redox potential of ferrocene [+0.51 V (Fc/Fc$^{\cdot+}$)] (Fig. 1). This indicates that the photocurrent generation is controlled by the ET rate between the gold electrode and the ferrocene, similar to the porphyrin–ferrocene SAM system.[7] When methyl viologen (MV^{2+}) was employed as an electron carrier, the time profile of the photocurrent was dependent on the concentration of MV^{2+}. The initial and stable photocurrents increased with an increase of the MV^{2+} concentration under the argon- or oxygen-saturated conditions, implying that MV^{2+} also accepts an electron from $C_{60}^{\cdot-}$ to generate $MV^{\cdot+}$.

In the absorption spectra the Soret band of **1** on Au in air using the transmission mode is broad and red-shifted by 11 nm, compared with that of **2** in THF. This behavior is similar to that of the polymethylenethiol-linked porphyrin systems on gold electrodes.[7,10] This suggests increased π–π interaction among the porphyrin moieties within the SAM, which is quite consistent with the results obtained using cyclic voltammetry. The action spectrum of the cell roughly agrees with the absorption spectrum of **1** on Au, indicating that the porphyrin is the major photoactive species for photocurrent generation.

Quantum efficiency based on the number of photons absorbed by **1** on Au was calculated using the input power (60 μW cm^{-2} at 438.5 nm), the photocurrent density, and the estimated absorbance on Au (0.059). Under the optimal conditions using the oxygen-saturated solution with 30 mM MV^{2+}, we obtained a net photocurrent density of 660 nA cm^{-2} at −200 mV from the triad cell. Thus, the quantum yield is found to be 25%, which is more than two times larger than the highest value (11%) among the previous reports of photosynthetic multistep ET across artificial membranes and at monolayer-modified metal electrodes.[2–4,6,7,10,12]

The photocurrent generation may be explained as follows. On the basis of the fluorescence quenching experiments together with previously reported results,[6,13,14] photoinduced ET or charge-transfer occurs from $^1P^*$ [−0.82 V ($^1P^*/P^{\cdot+}$)] to C_{60} [−0.64 V($C_{60}/C_{60}^{\cdot-}$)] rather than from Fc to $^1P^*$. The resulting $C_{60}^{\cdot-}$ transfers an electron to diffusing electron carriers such as oxygen [−0.48 V ($O_2/O_2^{\cdot-}$)] and/or MV^{+2} [−0.62 V $MV^{+2}/MV^{\cdot+}$)], which eventually give an electron to the counter electrode. On the other hand, successive charge shift (CSH) occurs from Fc to $P^{\cdot+}$ [+1.08 V ($P/P^{\cdot+}$)], then from the gold electrode to $Fc^{\cdot+}$, resulting in the recovery of the initial state and a net vectorial electron flow from the gold electrode to the counter electrode through the monolayer and the electrolyte. There is a plausible explanation for the remarkable high efficiency in the system. We have shown that $^1P^*$ within the SAM on gold electrodes is strongly quenched by the gold electrodes.[10] This means that (i) initial photoinduced ET from $^1P^*$ to the first acceptor must compete with deactivation due to the gold electrode and (ii) the CSH to the second acceptor is much faster than charge recombination to the ground state. Utilization of C_{60} with its small reorganization energy may fully satisfy these requirements and improve the quantum yield greatly.[6,12,13,15]

In conclusion, a SAM of a ferrocene–porphyrin–C_{60} has been prepared for the first time. The high quantum yield implies that a combination of fullerenes and SAMs is promising for applications in materials science. Although our interpretation of the photocurrent generation mechanism is consistent with the results obtained by the electrochemical and photoelectrochemical measurements, further details must await photodynamical experiments in solutions and on a gold surface as well as structural studies on the monolayer.

Received (in Cambridge, UK) 26th March 1999, Accepted 12th May 1999

A chiral catalyst from the ligand 1,1′-bis(diphenylphosphino)ferrocene (dppf) anchored to the inner walls of the mesoporous support MCM-41 and co-ordinated to Pd^{II} has been shown to exhibit a degree of regioselectivity and enantiomeric excess, in the allylic amination of cinnamyl acetate, which is far superior to that of its homogeneous counterpart or that of a surface-bound analogue attached to a non-porous silica.

Stereo- and regio-selective catalysis lies at the heart of current developments in pharmaceutical, agrochemical and cognate industries.[1–3] The recognition that a small amount of a chiral catalyst may yield large quantites of a targeted chiral product has already led to the development of several ingenious methods for the design of such catalysts. These include modified metals,[4] metal oxides[5] and zeolites,[6,7] and the so-called 'ship-in-bottle' or 'tea-bag' systems.[8–10] In this work we have been able to demonstrate that a chiral ligand derived from 1,1′-bis(diphenylphosphino)ferrocene (dppf) bonded to an active metal centre (in this case Pd^{II})† and tethered, *via* a molecular link of appropriate length, to the inner walls of a mesoporous silica support (MCM-41, *ca*. 30 Å diameter) yields a degree of catalytic regioselectivity as well as an enantiomeric excess that is far superior to either the homogeneous counterpart or the cabosil-bound catalyst (Cabosil is a non-porous, high-area silica).

Our conceptual methodology was to take a homogeneous system of known catalytic behaviour and, by performing suitable modifications, to tether this catalyst within the mesopore.[11] Care is taken to ensure that all activity is confined to the internal surface of the MCM-41 channels. This is achieved by selectively deactivating the external surface of the support. We have shown previously by electron microscopy, on functionalised mesopores stained with Ru_6-based clusters, that this is a reliable and satisfactory method.[12]

Our approach to the preparation of the catalytic system is shown in Scheme 1. The mesoporous framework was first treated with Ph_2SiCl_2 under *non-diffusive conditions* to deactivate the exterior walls of the material. The interior walls of this same material were then derivatised with 3-bromopropyltrichlorosilane to give the activated MCM-41 **1**.

The ferrocenyl-based ligand, (*S*)-1-[(*R*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethyl-*N*,*N*′-dimethylethylenediamine **2**, was prepared from ferrocene by literature methods.[13,14] On

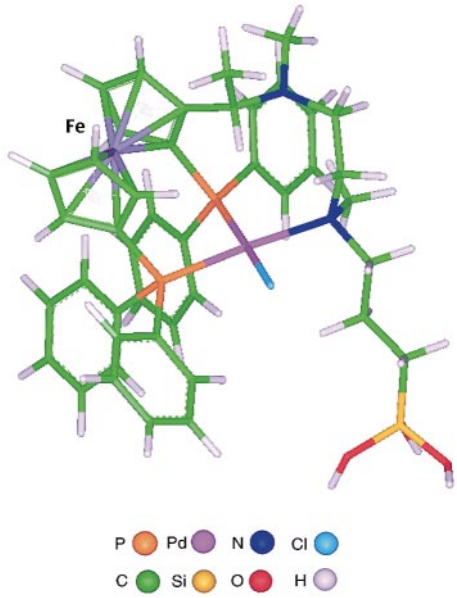

Fig. 1 Computer model of the catalytic centre inside MCM-41.

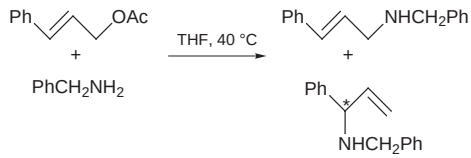
treatment of the activated MCM-41 **1** with an excess of **2** yields the chiral catalytic precursor **4** which, on reaction with $PdCl_2$–MeCN, gives the required catalyst **6**. In a separate experiment the closely related cabosil-supported catalyst **7** was prepared in a similar manner from surface-activated cabosil and **2** followed by addition of the required palladium(II) salt.

The catalyst **6** was fully characterised by a range of techniques. First, the structural integrity of the MCM-41 catalytic precursor **4** was established by MAS NMR and EXAFS spectroscopy. The presence of the tethered ferrocenyl catalysts was confirmed by comparison of the ^{13}C MAS NMR spectrum of **4** with that of the unattached precursor **2**. Apart from the additional signals arising from the propyl tethering unit the spectra were essentially the same. Examination of the ^{31}P MAS NMR of **2** and **4** showed identical chemical shift values. On incorporation of the Pd^{II} ion to yield the active catalyst **6**, significant changes in the aliphatic region of the ^{13}C MAS NMR and in the ^{31}P MAS NMR spectra were noted. Two ^{31}P resonances at δ 15.9 and 34.4 were recorded, clearly indicating two different phosphorous environments, these have been assigned as one being *trans* to a nitrogen and the other being *trans* to a chloride.[15] The change in the aliphatic region of the ^{13}C MAS NMR corresponds to changes in the methyl resonances of the amines, further corroborating the assignment of the ^{31}P spectrum. This entire arrangement was borne out by a detailed EXAFS analysis of **6**. The coordination environment of the cationic species within the mesopore is depicted in Fig. 1.

In testing our catalysts we decided to use an allylic amination reaction between cinnamyl acetate and benzylamine (Scheme 2). This reaction has two possible products: a straight chained product (which is favoured due to the retention of the delocalised π system) and a chiral branched product. The aim of the reaction is to produce the greatest possible yield of the branched product with the highest possible enantiomeric excess



Scheme 2 The catalytic reaction between cinnamyl acetate and benzylamine.

Table 1 Catalytic results

Catalyst[a]	Conversion[b] (%)	Straight chain[c] (%)	Branched (%)	ee[d] (%)
3 (*S*)	76	99+	—	—
7 (*S*)	98	98	2	43
6 (*S*)	99+	49	51	99+
6 (*R*)	99+	50	50	93

[a] Symbols in parentheses denote chirality of the directing group. [b] % Conversion is stated relative to the use of benzylamine. [c] Regio- and enantio-selectivity determined by gas chromatography on a Chiraldex G-DA column (Alltech) with γ-cyclodextrin as the active phase (20 m). *Conditions*: He pressure 12.5 psi; temperature ramped 50–180 °C at 10 °C min^{-1} and then held for the duration of the run. [d] Major stereoisomer possesses the same chirality as the catalyst. Retention time *ca.* 38 min.

(ee). Three catalysts were examined: the homogeneous {(*S*)-1-[(*R*)-1′,2-bis(diphenylphosphino)ferrocenyl]ethyl-*N*,*N*′-dimethylethylenediamine} palladium dichloride **3**, the cabosil-supported one **7** and that attached within the mesoporous material **6**. Preliminary results of the studies are listed in Table 1. With the homogeneous catalyst **3** the reaction is directed solely towards the straight chain product whilst catalyst **7** shows some of the desired regioselectivity by producing 2% of the branched product. Unfortunately the enantioselectivity of the reaction is relatively low with an ee of 43%. The use of the mesopore-confined catalyst **6** promotes a dramatic change in the regioselectivity of the reaction, producing 51% of the branched product. The enantioselectivity of the catalysis is also greatly improved relative to the cabosil-bound catalyst with the ee approaching 100%.

These results indicate that the control exercised by the MCM-41 on the activity of the ferrocenyl catalyst is considerable. The profound changes in the regio- and enantio-selectivity are clearly apparent from the data listed in Table 1. Other, related systems are currently under investigation.

Permanent blockade of *in situ*-generated acid Brønsted sites of vanadyl pyrophosphate catalysts by pyridine during the partial oxidation of toluene

Andreas Martin,* Ursula Bentrup, Bernhard Lücke and Angelika Brückner

Institut für Angewandte Chemie Berlin-Adlershof e.V., Rudower Chaussee 5 D-12484 Berlin, Germany. E-mail: a.martin@aca-berlin.de

Received (in Cambridge, UK) 6th April 1999, Accepted 20th May 1999

The permanent blockade of *in situ*-formed Brønsted-acid OH groups and an effective lowering of the catalyst acidity during the partial oxidation of toluene to benzaldehyde is demonstrated by an efficient method using a continuous dosing of pyridine to the feed that leads to drastically increased aldehyde selectivities.

Vanadium phosphates (VPO) are well known as catalysts for selective O- and N-insertion reactions of aliphatics and methylaromatics.[1,2] Recently, we have studied the ammoxidation of toluene on vanadyl pyrophosphate [$(VO)_2P_2O_7$] in detail and obtained knowledge on the formation of benzaldehyde, acting as a reaction intermediate.[3] Therefore, the idea arose to test these catalysts for the partial oxidation of toluene. However, the catalytic performance of these solids is rather poor: benzaldehyde selectivities >40% could only be reached at toluene conversions <5% and mainly carbon oxides were identified as by-products in the effluent. A number of further oxidised intermediates (cyclic anhydrides are of prime importance) that remain chemisorbed on the catalyst surface were detected by FTIR spectroscopy.[4] The reason for the rather low aldehyde selectivity can be seen in a very strong adsorption of toluene and/or intermediates on the rather acidic surface of the VPO catalyst as confirmed by *in situ*-EPR measurements carried out recently.[4] Furthermore, it is also supposed that the existence of M–OH sites could be involved in the oxidation of the aromatic nucleus, leading to total oxidation.[5]

Here, we present investigations on the partial oxidation of toluene to benzaldehyde with vanadyl pyrophosphate used as catalyst, especially on the effect of Brønsted-acid OH groups of the catalyst surface using *in situ*-FTIR spectroscopy. A procedure is proposed to block such *in situ*-generated acid OH groups by pyridine. Additionally, an effective increase of the basicity of the catalyst surface can be reached that might enhance the desorption rate of the desired aldehyde.

$(VO)_2P_2O_7$ (VPP) was generated by the usual dehydration of $VOHPO_4{\cdot}0.5H_2O$ used as precursor compound (723 K, 4 h, 10 l h^{-1} N_2). The catalytic properties were determined during the oxidation of toluene to benzaldehyde, using a fixed bed quartz-glass reactor. The catalyst (0.5 g) was applied as sieve fraction (1–1.25 mm) and mixed with an equal portion of quartz glass (1 mm) to avoid local overheating. The effluent was analysed by GC and the formation of CO/CO_2 was permanently followed by non-dispersive IR photometry. The *in situ*-FTIR investigations were carried out on a Bruker IFS 66 FTIR spectrometer using self-supporting discs with a diameter of 20 mm and a weight of 50 mg, mounted in an heated IR cell.

Fig. 1 depicts FTIR spectra of adsorbates of the partial oxidation of toluene (air– toluene = 100 : 1, 573 K) on VPP [*(a)* fresh VPP, *(b)* VPP pretreated with water vapour (4.2 mmol h^{-1} H_2O in air, 30 min) at 573 K prior to feed exposure). Beside the bands of the aromatic ring vibration (1605, 1500 cm^{-1}) and that of the adsorbed benzaldehyde (1678 cm^{-1}), the bands of cyclic anhydrides (1858, 1783 cm^{-1}) always appeared. These cyclic anhydrides can be considered as total oxidation precursors.[6] Additionally, Fig. 1 also shows FTIR spectra of air–benzaldehyde mixtures (air–benzaldehyde = 91 : 1) adsorbed at 573 K on the parent VPP sample *(c)* and on a VPP specimen pretreated with water vapour as mentioned above *(d)*. Normally, the benzaldehyde adsorption is characterised by the appearance of two vibration bands at *ca.* 1720 and 1705 cm^{-1} assigned as carbonyl stretching vibrations. In the spectrum of the water vapour pretreated sample a further carbonyl stretching band at 1685 cm^{-1} has been observed. The shift of the carbonyl band to lower wavenumbers points to a weakening of the C=O bond. This effect can be explained by a strengthening of the adsorption of the aldehyde[7] by interaction of neighbouring OH groups with the carbonyl groups probably *via* hydrogen bonding. This can also be seen in the case of the toluene–air adsorption under working conditions [Fig. 1, spectra *(a)* and *(b)*]: The carbonyl band is obviously shifted to lower wavenumbers, independent of the catalyst pretreatment, *i.e.* the water produced during the catalytic reaction causes the same effect as has been found for the water vapour pretreatment of the catalyst. This behaviour explains the findings of the recent *in situ*-EPR measurements[4] and provides a reason for the strong chemisorption of aldehyde intermediates and therefore, their subsequent oxidation in consecutive reactions.

Scheme 1 illustrates these ideas. The VPP catalyst surface consists of vanadyl dioctahedra units linked *via* V–O–P bridges with the phosphate tetrahedra of the pyrophosphate chains. A toluene molecule is chemisorbed on the Lewis sites *via* its π-electron system. An electrophilic attack on the methyl group leads to a methylene-like species, water is probably eliminated by the collaboration of bulk oxygen, which is in turn replaced by gas-phase oxygen. Thus, benzaldehyde is formed that is able to desorb, but simultaneously, the liberated water molecule can attack the neighbouring V–O–P bond, generating OH groups (V–OH and P–OH) which interact with benzaldehyde *via* hydrogen bonding and its fast desorption is markedly hindered.

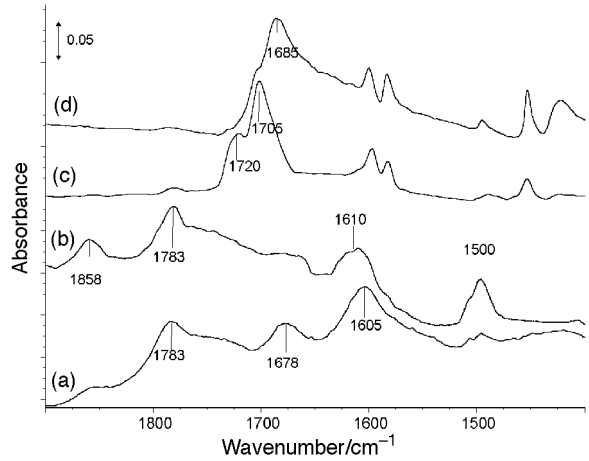

Fig. 1 FTIR spectra of adsorbates on a $(VO)_2P_2O_7$ catalyst at 673 K: (a) air–toluene flow (molar ratio = 100 : 1, 4.2 mmol toluene h^{-1}, 60 min), (b) the same air–toluene flow after water vapour pretreatment (4.2 mmol H_2O h^{-1} in air, 30 min), (c) air–benzaldehyde flow (molar ratio = 91 : 1, 2.3 mmol benzaldehyde h^{-1}, 60 min) and (d) the same air-benzaldehyde flow after water vapour pretreatment (4.2 mmol H_2O h^{-1} in air, 30 min).

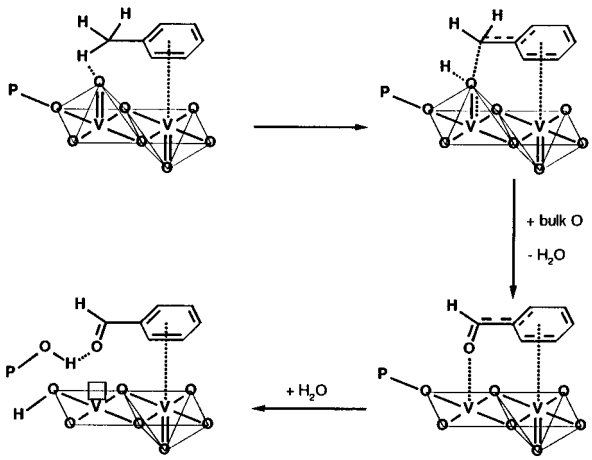

Scheme 1

The blockade or poisoning of OH groups by alkali metal cations[8] or tertiary amines[9] prior to use is already known but also *in situ*-poisoning experiments have been described. Nag *et al.*[10] observed a benzaldehyde selectivity increasing effect on MoO_x/TiO_2 catalysts at 633 K by introduction of pyridine pulses to a toluene-containing feed. This selectivity increase was accompanied by a sudden drop in the toluene conversion; acid sites (Brønsted as well as Lewis sites being necessary for toluene chemisorption) were immediately blocked. The authors concluded that the total oxidation is connected with relatively strong acid sites.

However, the idea arose to block the OH groups generated under VPP catalyst working conditions permanently. Thus, the task was to find a blocking agent that meets diverse requirements; (i) the blocking agent can be continuously dosed, (ii) it should not be involved in the catalytic reaction and (iii) sites of catalytic activity should not be covered.

Therefore, we attempted to use pyridine as an unoxidizable 'co-feed' and the FTIR spectra of Fig. 2 demonstrate the effect. Spectrum (a) shows the known spectrum if toluene and air are dosed. A continuous admixture of water vapour to such a feed causes no significant change of adsorbed species, additionally, a broad band of adsorbed water (1618 cm^{-1}) is observed as demonstrated in spectrum *(b)*. However, if a 4 wt% aqueous pyridine solution is used instead of pure water, spectrum *(c)* is obtained. This spectrum reveals the existence of pyridinium ions (Brønsted-acid sites) at 1540 cm^{-1} as well as coordinatively bound pyridine (Lewis-acid sites) at 1448 cm^{-1} but surprisingly, only low intensity bands of cyclic anhydrides and no band of adsorbed benzaldehyde are observed. One could suppose that no reaction occurred but the catalytic investigations prove the opposite. The beneficial effect of pyridine on the product desorption has also been demonstrated by *in situ*-EPR measurements. Changes of the EPR signal shape due to strong adsorption were found to be reversible by adding a 4 wt% aqueous pyridine solution to the feed, while no such effect was observed by adding water only. Fig. 3 depicts the selectivity data using a similar VPP catalyst during catalytic runs at 663 K; the toluene conversion amounts to *ca.* 12 mol%. It is clearly shown that the admixture of water vapour does not influence the selectivity but the addition of pyridine reveals a nearly threefold improvement of selectivity to benzaldehyde at constant conversion rates. Thus, pyridine is able to block the Brønsted-acid sites generated during the reaction and also to increase the surface basicity of the catalyst; otherwise, it seems unlikely that the chemisorption of toluene, occurring *via* the Lewis sites is markedly influenced.

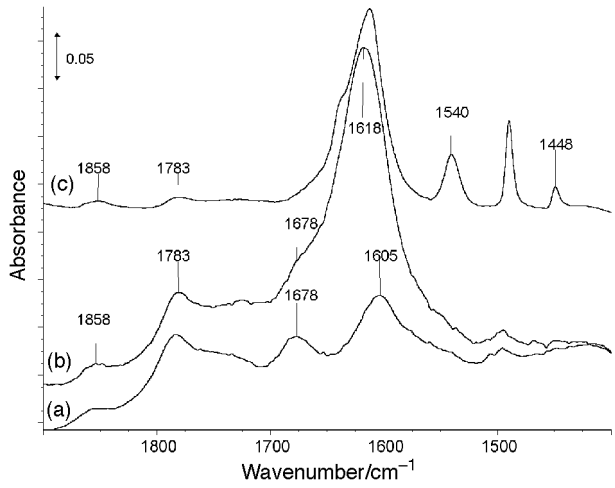

Fig. 2 FTIR spectra of intermediates of the partial oxidation of toluene on a $(VO)_2P_2O_7$ catalyst at 573 K: (a) air-toluene flow (molar ratio = 100 : 1, 4.2 mmol toluene h^{-1}, 60 min), (b) air–toluene–water vapour flow (molar ratio = 100 : 1 : 1, 4.2 mmol toluene h^{-1}, 60 min) and (c) air–toluene–water vapour (containing 4 wt% pyridine) flow (molar ratio = 100 : 1 : 1, 4.2 mmol toluene h^{-1}, 60 min).

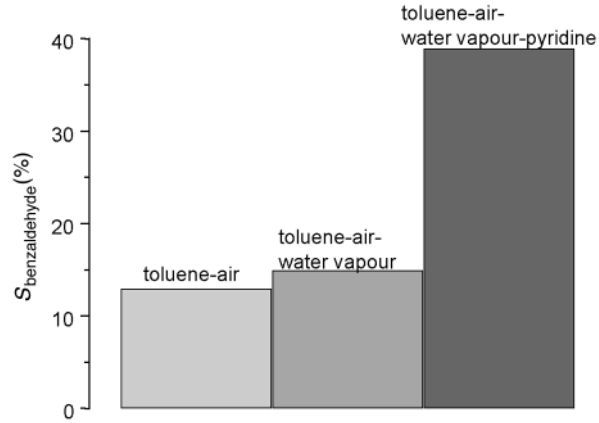

Fig. 3 Benzaldehyde selectivity of the partial oxidation of toluene over a $(VO)_2P_2O_7$ catalyst at 663 K and a *W*/*F* (total flow) = *ca.* 1 g h mol^{-1} using the following feed compositions: (a) air–toluene flow (molar ratio = 100 : 1), (b) air–toluene–water vapour flow (molar ratio = 100 : 1 : 1) and (c) air–toluene–water vapour (containing 4 wt% pyridine) flow (molar ratio = 100 : 1 : 1). Toluene conversion: 12 mmol in each case.

The demonstrated continuous tuning of the acid–base properties of the catalyst surface by a permanent blockade of *in situ*-generated OH groups, accompanied by the increase of the surface basicity of the surface results in drastically increased partial oxidation product selectivities.

The authors thank Mrs U. Wolf for experimental assistance and the Federal Ministry of Education and Research, Germany for financial support (project No. 03 C 0279 0).

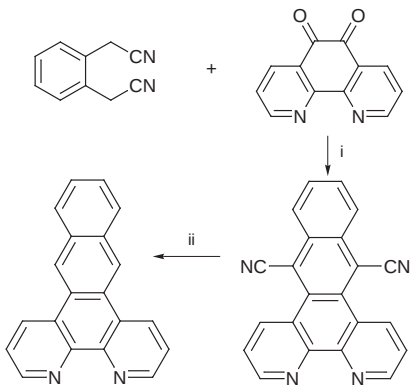
Received (in Basel, Switzerland) 3rd February 1999, Accepted 24th April 1999

New Ru(II) complexes are presented as potential luminescent sensors, fluorescent labels and DNA photoprobes.

Owing to their remarkable properties, Ru(II) polypyridyl complexes are used in several areas.[1,2,3] The chelating ligands play an important role in determining the properties of such systems.[4] In $[Ru(dppz)(bpy)_2]^{2+}$ the dppz (dipyrido[3,2-*a*:2,3-*c*]phenazine) ligand is suitable for the direct formation of a charge transfer excited state,[5] which is an important requirement for solar energy conversion. Furthermore dppz contains an extended aromatic system which can bind *via* π–π interaction to the DNA helix.[6] Along this line, two novel phenanthroline-type ligands, CN_2-np (naphtho[2,3-*f*][1,ω]phenanthroline-9,14-dicarbonitrile) and np (naphtho[2,3-*f*][1,ω]phenanthroline) have been prepared, which present some structural features similar to those of dppz. Fukui function calculations[7] indicate that, dppz, CN_2-np and, to a minor extent, np can be considered as comprising a bpy chelating subunit anchored to a remote accepting anthracene-type site (9,10-anthracenedicarbonitrile and anthracene respectively). One could therefore expect that the photophysical and electrochemical properties of $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ and $[Ru(np)(bpy)_2]^{2+}$ would be related to those of $[Ru(dppz)(bpy)_2]^{2+}$, however, we have found some new different interesting features. Since the system of $[Ru(dppz)(bpy)_2]^{2+}$ is still the subject of controversial discussion, the following results will help in the understanding of such complexes.

The CN_2-np ligand was synthesized by condensation of *o*-xylylene dicyanide and 1,10-phenanthroline-5,6-dione in basic conditions. Successive decarboxylation of CN_2-np in basic conditions gives the np ligand (Scheme 1). $[Ru(np)(bpy)_2](PF_6)_2$ was prepared by heating the np ligand with 1 equiv. of $Ru(bpy)_2Cl_2\cdot 2H_2O$ in methoxyethanol at 120 °C under argon for 15 h (yield after chromatographic plate purification: 19%). $[Ru(CN_2\text{-np})(bpy)_2](PF_6)_2$ was prepared by heating the CN_2-np ligand with 1 equiv. of $Ru(bpy)_2Cl_2\cdot 2H_2O$ in ethylene glycol for 6 min in a microwave oven (yield after chromatographic plate purification: 26%).[8]



Scheme 1 *Reagents and conditions*: i, 10% solution of NaOEt in EtOH, room temp., 36 h, yield: 90%; ii, KOH, EtOH, argon, reflux, 12 h, yield: 57%.

Electrochemical data (Table 1) show that oxidation is a reversible metal centered Ru(III)/Ru(II) process for both $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ and $[Ru(np)(bpy)_2]^{2+}$ and the $E_{1/2}$ values obtained are very similar to those reported for $[Ru(bpy)_3]^{2+}$. This suggests that CN_2-np and np are similar to bpy with respect to their coordination ability to ruthenium: the σ donating properties of the two ligands are the same as those of bpy and the back donation from the Ru(II) ion is localized on bpy orbitals having π* character and does not involve the anthracene-type fragment of the two ligands. For $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$, owing to the presence of withdrawing groups (CN), the added electron in the first reduction product and the lowest excited state are expected to be localized on CN_2-np. The first reduction wave of $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ occurs at a potential (−0.75 V in MeCN) very close to that of the free ligand (−0.79 V in DMSO, identical to that of 9,10-anthracenedicarbonitrile) and 0.27 V less negative than that of $[Ru(dppz)(bpy)_2]^{2+}$, in agreement with a stronger electron accepting character of 9,10-anthracenedicarbonitrile with respect to phenazine (Table 1). The further three monoelectronic reduction steps in $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ occur close to those of the three first reduction waves of $[Ru(bpy)_3]^{2+}$. This indicates that, after reduction of the anthracenedicarbonitrile fragment, reduction at the two chelating bpy ligands and at the bpy part of the CN_2-np ligand takes place. The last reduction step (−1.67 V) is localized on the bpy moiety of CN_2-np, since it occurs at a potential value less negative than the third reduction wave of $[Ru(bpy)_3]^{2+}$, as expected for bpy connected to an acceptor unit. The first two reduction potentials of $[Ru(np)(bpy)_2]^{2+}$ are very similar to those for $[Ru(bpy)_3]^{2+}$. The reduction potential of the free ligand np (−1.86 V) is similar to that of anthracene (−1.90 V).

Preliminary photophysical measurements show that $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ and $[Ru(np)(bpy)_2]^{2+}$ behave very differently from each other. The photophysical data are reported in Table 2 where values for $[Ru(bpy)_3]^{2+}$ and $[Ru(dppz)(bpy)_2]^{2+}$ are also listed. The photophysical properties of $[Ru(np)(bpy)_2]^{2+}$ resemble those of $[Ru(bpy)_3]^{2+}$ despite the presence of

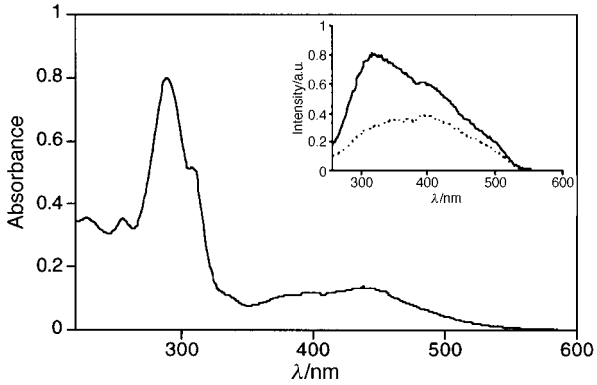

Fig. 1 Absorption spectrum of $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ in MeCN solution (1.5×10^5 M). Inset: luminescence spectra in aerated (----), and de-aerated (—), MeCN solution.

an extended π system condensed with the bpy ligand. For $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ the absorption spectrum, recorded in acetonitrile solution, shows the visible region broad bands due to absorption to different ^{1}MLCT excited states, involving both the bpy (higher energy) and the CN_2-np (lower energy) ligands (Fig. 1). It is interesting that CN_2-np shows rather low energy π–π* transitions (350–400 nm), that are also present in the complex, while the higher energy absorption bands are attributed to bpy π–π* transitions. In CH_2Cl_2 solution fluorescence of the free ligand occurs at 427 nm, while no phosphorescence emission was detected even at low temperature. We expect, however, a separation between the singlet and the triplet excited states very similar to that reported for the 9,10-anthracenedicarbonitrile,[9] and therefore a triplet state falling in the 700 nm region. The emission spectrum of $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ at room temperature in an aerated MeCN solution shows a very broad, multicomponent and weak band centered at 700 nm (Fig. 1). In deaerated solution however the maximum of this band shifts to higher energy and has two different excited state lifetimes (Table 2, and Fig. 1). Such photophysical investigation suggests the presence of two non-equilibrated charge transfer excited states; one state localized on the bpy moiety and the other lower energy state involving the anthracenedicarbonitrile unit. They appear to show different sensitivity to dioxygen, as reflected in their different lifetimes.

At low temperature the excited state lifetime (Table 2) for the lowest energy emitting state of $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ is far too long (464 μs) to be assigned to a pure ^{3}MLCT excited state. The long lived luminescence at low temperature could be attributed to a smaller degree of excited state distortion owing to the greater delocalization of the excited electron in the CN_2-np π* system as similarly reported by Meyer and coworkers[10] for a series of ruthenium complexes. However, for $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ the effect is really drastic, and in the absence of the CN groups, no effect due to delocalization is observed. Therefore the presence of a low lying triplet state centered on the CN_2-np ligand, close in energy to the lowest ^{3}MLCT excited state, should play an important role. When the solution is frozen, the ^{3}MLCT excited states move to higher energy and the intraligand (IL) state becomes the low lying excited state with a longer lifetime (Table 2). Such intraligand excited states have been previously observed in transition metal complexes.[11] The extremely long excited state lifetime is of course a very appealing property for the use of such a complex as a luminescent sensor or fluorescent label.

As mentioned above, $[Ru(np)(bpy)_2]^{2+}$ in MeCN shows emission properties similar to those of $[Ru(bpy)_3]^{2+}$. However in aqueous buffered solution an enhancement of the luminescence quantum yield in the presence of DNA, is observed as reported for $Ru(dppz)(phen)_2]^{2+}$.[12] With respect to $[Ru(dppz)(phen)_2]^{2+}$, $[Ru(np)(bpy)_2]^{2+}$ is already strongly luminescent in aqueous solution (in the absence of DNA), the quantum yield of luminescence is increased only by a factor of 2.5 ($\geqslant 10^6$ for $[Ru(dppz)(phen)_2]^{2+}$) and a simple monoexponential decay is observed in presence of increasing amounts of DNA. $[Ru(CN_2\text{-np})(bpy)_2]^{2+}$ shows, under the same conditions as above, a lowering of the absorption coefficient in the presence of DNA. In particular the bands at 350–400 nm corresponding to π–π* transitions of CN_2-np are diminished with increasing DNA concentration. This suggests binding of the anthracenedicarbonitrile unit of the ligand to the DNA helix.

This work was supported by MURST, CNR and the Swiss National Science Foundation. The authors would like to thank Professor V. Balzani for helpful discussion and Nunzio Salluce for help in some measurements.

ChemComm

A new method for the synthesis of chromium(IV) oxide at ambient pressure†

K. Ramesha and J. Gopalakrishnan*

Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore 560 012, India.
E-mail: gopal@sscu.iisc.ernet.in

Received (in Cambridge, UK) 13th April 1999, Accepted 18th May 1999

The reaction $CrO_3 + 2NH_4X \rightarrow CrO_2 + 2\ NH_3 + H_2O + X_2$ (X = Br, I), which occurs quantitatively at 120–150 °C, provides a convenient method for the synthesis of CrO_2; unlike conventional methods, the method reported here does not require the use of high pressure for the synthesis of this technologically important material.

Chromium(IV) oxide, CrO_2, is unique among the rutile-type transition metal dioxides,[1] exhibiting ferromagnetic (T_c = 395 K) and metallic properties.[2] Because of these properties, the material finds application as a magnetic recording medium in the form of tapes. In recent years, there has been a renewed interest in this material in view of the realization[3] that it is a 'half-metallic' ferromagnet [*i.e.*, the majority (spin-up) electrons are delocalized, while the minority (spin-down) electrons are localized, having a semiconductor-like gap in the density-of-states] with a nearly 100% spin polarization[4] at the Fermi energy. An important consequence of the half-metallic nature is that films of CrO_2 exhibit a low-field tunneling-type magnetoresistance[5] that appears promising for application.

Since CrO_2 is a metastable phase[2] (decomposing at > 288 °C at 1 atm pressure of O_2), all the methods reported for its synthesis require high pressures.[2] Hydrothermal decomposition of aqueous solutions of CrO_3 at elevated temperatures and pressures (typically 480 °C and 2 kbar) is a common method for the synthesis of polycrystalline CrO_2 powders.[2] Growth of single crystals[6] however require much higher temperatures (900–1300 °C) and pressures (60–65 kbar).

Considering the technological and scientific importance of CrO_2, we developed a new method for its synthesis at ambient pressure. Our method is based on the low-temperature (120–150 °C) reduction of CrO_3 by NH_4I/NH_4Br followed by annealing the solid product at temperatures below the decomposition point of CrO_2. The method crucially depends on the solid state reaction given by eqn. (1)

$$CrO_3 + 2\ NH_4X \rightarrow CrO_2 + 2\ NH_3 + X_2 + H_2O \qquad (1)$$

which occurs quantitatively between 120 and 150 °C. Here, we describe the details of synthesis of crystalline CrO_2 by this method and its characterization.

Stoichiometric quantities of CrO_3 (20 mmol) and NH_4X (X = Br, I) (40 mmol) corresponding to eqn. (1) were thoroughly mixed under CCl_4. The mixture, taken in a Pyrex glass tube connected to a vacuum line, was heated slowly *in vacuo* (*ca.* 10^{-5} Torr) under continuous pumping conditions as described earlier.[7] Copious evolution of I_2/Br_2 occurred around 120 °C. The temperature was raised to 150 °C and held at this value until the evolution of I_2/Br_2 ceased (2–3 h). The liberated I_2/Br_2 condensed in a liquid nitrogen trap provided a quantitative measure of the extent of the reduction.[7] Significantly, reaction (1) does not occur with NH_4Cl. This is consistent with the redox characteristics of Cr^{VI} which oxidizes I^- and Br^- but not Cl^- in aqueous solutions.[8]

The black solid product of reaction (1) was stable in air; it was however non-magnetic and amorphous to X-rays [Fig. 1(a)]. Pellets of this product were annealed in evacuated sealed glass tubes at various temperatures and times. We found that annealing at 195 ± 5 °C for one week yielded crystalline CrO_2 with rutile structure. The lattice parameters, a = 4.419 (1), c = 2.915 (1) Å, derived from the X-ray powder diffraction pattern [Fig. 1(b)] are in excellent agreement with the values reported for CrO_2 in the literature.[9] Determination of oxygen content by iodometric titration revealed that the product is stoichiometric ($CrO_{1.99\pm0.02}$).

Measurement of electrical resistivity and magnetic susceptibility revealed that the CrO_2 prepared here is metallic and ferromagnetic as expected. The resistivity and susceptibility data of our samples (Fig. 2) are comparable to the corresponding data reported in the literature[5] for bulk polycrystalline samples

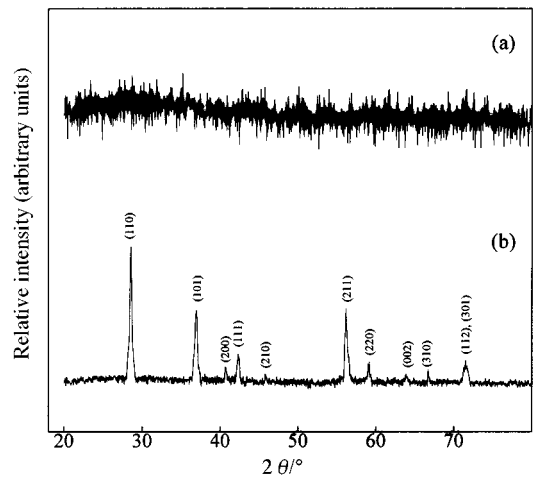

Fig. 1 Powder XRD patterns (Cu-Kα) of (a) solid product of reaction (1) with NH_4I and (b) product (a) annealed at 195 ± 5 °C for one week corresponding to crystalline CrO_2.

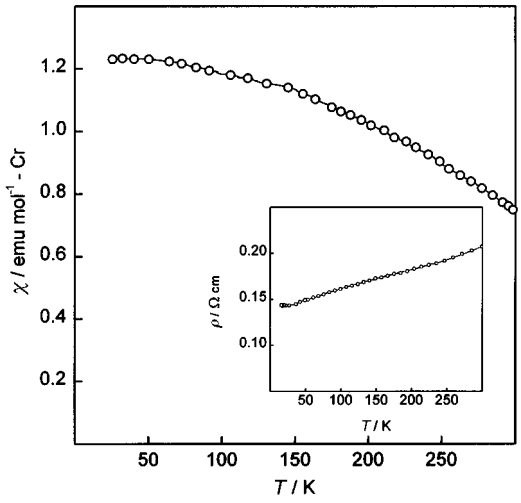

Fig. 2 Temperature dependence of magnetic susceptibility of CrO_2 measured at 0.5 T. Inset shows the temperature dependence of electrical resistivity of the same sample.

† Contribution No. 1412 from the Solid State and Structural Chemistry Unit.

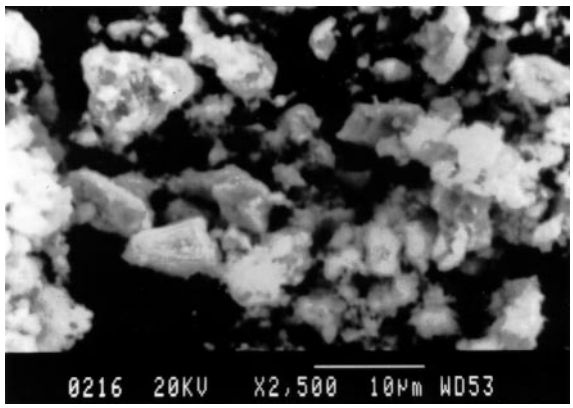

Fig. 3 SEM image of crystalline CrO_2.

as well as films of CrO_2. An SEM study showed that the samples are fairly crystalline, the particle sizes being in the range of a few μm (Fig. 3).

We believe that the key to the success of the method lies in the quantitative nature of reaction (1) which can be controlled to give an average oxidation state of Cr^{IV} in the solid state by using the required quantity of NH_4I/NH_4Br in the reaction mixture. This is in contrast to reactions between Cr^{VI} and I^-/Br^- in aqueous media, which proceed directly to give Cr^{III}; *i.e.* Cr^{VI} is not accessible as a stable species in aqueous media by redox reactions. An investigation of the X-ray morphous CrO_2 would throw light on the mechanism of reaction (1) which stabilizes Cr^{VI} in the solid state.

We can also prepare rutile-related (monoclinic) VO_2 as well as solid solutions of $Cr_{1-x}V_xO_2$ by the same method starting from V_2O_5 and V_2O_5–CrO_3 mixtures. Therefore, we believe that the method described here can be extended to the synthesis of other metastable oxides containing Cr^{IV} and/or V^{IV}, in general.

We thank the Department of Science and Technology, Government of India (Project No. SP/S1/H-17/97) for financial support. K. R. thanks the Council of Scientific and Industiral Research, New Delhi for the award of a fellowship.

Nb_2Te_3, a niobium sesquitelluride with Te_2^{2-} groups

Holger Kleinke and Wolfgang Tremel*

Institut für Anorganische Chemie und Analytische Chemie, Universität Mainz, Duesbergweg 10-14, D-55099 Mainz, FRG. E-mail: tremel@indigotrem1.chemie.uni-mainz.de

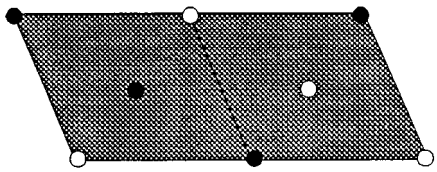
Received (in Cambridge, UK) 8th March 1999, Accepted 18th May 1999

The new binary compound Nb_2Te_3 was synthesized by reduction of $NbTe_2$ with Ga metal; different from the formally analogous Ta_2Te_3 it crystallizes in the Mo_2As_3 structure type; based on the results of band structure calculations Nb_2Te_3 is metallic with quasi one-dimensional metal electronic properties.

In spite of the spectacular progress made in fields such as supramolecular[1] or nanochemistry,[2] new binary and seemingly simple compounds still continue to be found. Typical examples are early transition metals chalcogenides: about ten new binary phases such as TaS_3,[3] Ta_6Te_5,[4] Ta_3S_2,[5] Ta_2Se,[6], Hf_3Te_2,[7] and $Ti_{11}Se_4$[8] have been reported during the past decade; all of them display a unique structure type. At first sight it may seem surprising that binaries of such simple compositions have escaped detection until recently.

Even more surprising is that these compounds challenge our basic assumptions about the chemistry of the early transition elements and our chemical understanding in general. The chemistries of Zr and Hf are considered nearly identical,[9] and the situation is similar for their Group 5 congeners, Nb and Ta. Furthermore, the opportunity for metal segregation in mixed-metal systems allows the formation of pseudobinaries such as $Nb_{1.72}Ta_{3.28}S_2$[10] which have no counterpart in the binary systems.[11] The existence and structure of none of the above compounds could be predicted *a priori* and a rationalization of their structures *a posteriori* does not give conclusive hints why the binary chalcogenides of the early transition metals display as many differences as they do, even after accounting for differences in metal–metal bond strengths.[12]

In the quest for new metal-rich early transition metal cluster compounds with interstitial atoms we have investigated reactions in the system M/A/Q (M = Nb, Ta; A = B, Ga, C, Si; Q = S, Se, Te). Nb_2Te_3 was prepared by reducing $NbTe_2$ with Ga at 1000 °C.[13] According to the results of the X-ray structure determination† Nb_2Te_3 crystallizes in the Mo_2As_3 structure type.[14] The unit cell contains eight metal atoms (two crystallographically different metal atoms per asymmetric unit) in a distorted octahedral Te coordination. The basic motif of the structure are double chains of edge-sharing $NbTe_6$ octahedra, **1**.



1

Motif **1** is a common fragment in structures derived from the NiAs or CdI_2 tye, but it is also encountered in the structures of metal oxide bronzes[15] and chalcogenides such as Nb_3Q_4[16] (Q = S, Se, Te) and Nb_2Se_3.[17] Most of these compounds have intriguing physical properties, because they represent borderline cases between metallic and non-metallic behavior.[15] Each octahedron of **1** shares one common face with the octahedron of an adjacent double chain. A view of the structure along the short axis *b* is provided in Fig. 1. A special feature of the structure is that four of the twelve octahedral voids in the unit cell remain empty; the empty holes are compressed in such a way as to give rise to the formation of Te_2 pairs with Te–Te distances of 2.915(3) Å, As a result, one third of the Te atoms are involved in Te–Te bonding. Moreover, the cations are shifted from the centers of the octahedra in such a way as to give rise to zigzag Nb–Nb chains along the *b* direction. The Nb(1) atoms are moved off their ideal positions by *ca.* 0.6 Å in the direction of one octahedral face. In this way, Nb(1)–Nb(1) chains are formed with metal–metal distances of 3.001(5) Å, which are only 5% longer than those in Nb metal. Nb(2) atoms also form chains along the *b* direction, but in these chains the Nb(2)–Nb(2) distances are, at 3.095(3) Å, considerably longer. Formally, Nb_2Te_3 may be viewed as $(Nb^{2.5+})_4(Te^{2-})_4(Te_2^{2-})$.

In contrast to the homologous Ta_2Te_3,[18] which crystallizes in a peculiar layer structure, Nb_2Te_3 adopts the Mo_2As_3 structure. The sesquiselenides Nb_2Se_3 and Ta_2Se_3 crystallize in another unique structure type,[17] whereas the corresponding sulfides are unknown. It is established that metal tellurides are distinctly different from the sulfides and selenides[19] because Te has a higher tendency to form chalcogen–chalcogen bonds;[20] still, it seemed to be a general rule that in metal chalcogenides with a metal/non-metal ratio > 2 no chalcogen–chalcogen bonds are formed. Thus, several questions need to be answered: (i) why does Nb_2Te_3 crystallize in the Mo_2As_3 structure type, *i.e.* what is the reason for the partial oxidation of Te in Nb_2Te_3? (ii) What are the electronic properties of Nb_2Te_3? (iii) Why are Nb_2Te_3 and Ta_2Te_3 structurally so different? We cannot answer the latter question; a general answer to (i) might be given in terms of 'redox competition'.[20] The lower electronegativity of Te compared to its lighter group homologues leads to a partial overlap of the metal d block and the Te centered valence band. As a result, there is an electron transfer from Te to the metal, *i.e.* Nb is reduced at the expense of Te. In order to probe the electronic structure of Nb_2Te_3 we have performed tight-binding band calculations.[21] Fig. 2 shows the t_{2g} subbands of Nb_2Te_3 along the symmetry lines corresponding to the *a*, *b* and *c* directions. The energy bands are flat along X–Γ, moderately

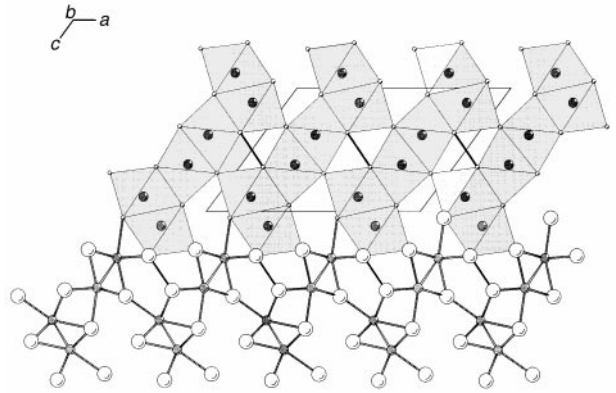


Fig. 1 View of the Nb_2Te_3 structure along *b*. Selected distances (Å): Nb(1)–Te(1) 2.883(3) (2×), Nb(1)–Te(2) 2.865(3), Nb(1)–Te(3) 2.738(3), Nb(1)–Te(3) 2.765(3) (2×) Nb(2)–Te(1) 2.904(3) (2×), Nb(2)–Te(2) 2.759(4) (2×), Nb(2)–Te(2) 2.776(3), Nb(2)–Te(3) 2.924(3), Te(1)–Te(1) 2.915(3), Nb(1)–Nb(1) 3.095(5) (2×), Nb(2)–Nb(2) 3.001(3) (2×).

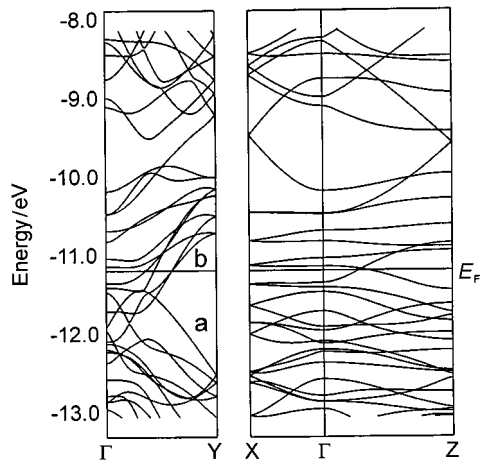

Fig. 2 Low-lying d-block bands of Nb_2Te_3: (a) along the chain direction Γ–Y; (b) along the main directions X–Γ–Z perpendicular to the chain direction. The Fermi level for Nb_2Te_3 is indicated by the horizontal bar.

disperse along Γ–Z, and highly disperse along Γ–Y. The Fermi level cuts through the middle of several steep bands; consequently, we expect metallic properties. The electronic structure may be understood in terms of the building blocks **1**, Nb_2Te_6 chains. Each of the chains **1** leads to six low-lying d block bands which originate from the t_{2g} levels of each metal. The lowest two of these bands have Nb–Nb bonding character, the two highest bands are Nb–Nb antibonding, and the remaining two bands are non-bonding with respect to the metal atoms. The unit cell of Nb_2Te_3 contains four of these chains, consequently, there must be eight bonding (labeled a in Figure 2), eight non-bonding (labeled b) and eight antibonding bands (not shown). For a $d^{2.5}$ electron count the lowest two bands of subset b are filled, and strongly anisotropic behavior is expected for Nb_2Te_3. If the bands are half-filled, a Peierls distortion may be expected. This situation is encountered for Tc_2As_3 (d^3),[22] which exhibits a superstructure of the Mo_2As_3 type and undergoes a displacive phase transition at high temperatures.

In summary, we have prepared niobium sesquitelluride, Nb_2Te_3, a new binary phase whose structure is distinctly different from those of the other known Group 5 sesquichalcogenides. It is the first early transition metal chalcogenide whose structure contains a dichalcogenide group. It is predicted to be a low-dimensional metal. For a half-filled t_{2g} subband (as observed for Tc_2As_3) a Peierls-distorted system is expected.

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are indebted to Heraeus Quarzschmelze Hanau (Dr. Höfer) for a generous gift of silica tubes.

13 In a typical reaction, 2 mmol (0.696 g) of $NbTe_2$ were reacted with 1 mmol Ga (0.070 g) at 1000 °C for 3 weeks in an evacuated quartz tube which had been dried *in vacuo* at 1000 °C before loading the starting components. The reaction products were Nb_2Te_3 and GaTe. Single crystals for the X-ray structure determination were obtained from the product mixture. Attempts to prepare single phase material from the elements or by reduction of $NbTe_2$ with Nb in the temperature range 500–1200 °C failed and lead to the formation of mixtures of $NbTe_2$ and Nb_3Te_4 instead. Similarly, attempts to grow single crystals of Nb_2Te_3 by vapor transport with halogens of TeX_4 (X = Cl, Br, I) only led to the formation of $NbTe_2/Nb_3Te_4$ mixtures.

Received (in Cambridge, UK) 9th April 1999, Accepted 19th May 1999

In the extraction of alkaline earth cations by acidic organophosphorus extractants, a correlation has been demonstrated between the effectiveness of the stereoisomers of dicyclohexano-18-crown-6 as synergists and the strain energy associated with conversion of the unbound crown ether to its complexed form.

Metal ion separations comprise an important part of numerous industrial processes and constitute an essential first step in many chemical analyses. Among metal ion separation methods, liquid–liquid extraction (LLX) has found particularly wide use, a consequence of its selectivity, physical simplicity, and ease of scale-up. The extraction of a metal ion from an aqueous phase into an organic solvent requires, among other things, that electroneutrality be maintained. For neutral extractants, this is accomplished by coextraction of anions into the organic phase:

$$M^{n+}{}_{(aq)} + n\ X^{-}{}_{(aq)} + E_{(org)} \Leftrightarrow MX_n{\cdot}E_{(org)}$$

For common inorganic anions (*e.g.* Cl^-, NO_3^-), satisfactory metal extraction requires the use of organic solvents capable of either efficiently solvating a hydrophilic anion or of dissolving high concentrations of water,[1,2] a requirement that significantly reduces the number of practical LLX solvents. This limitation can be largely overcome, however, by employing organophilic anions, in particular, the anionic form of any of a number of alkylphosphoric, carboxylic or sulfonic acid extractants. Frequently, combinations of neutral and acidic extractants exhibit synergistic properties, yielding metal ion extraction greater than the sum of that observed for the individual extractants. Strong, size-selective synergism has been reported, for example, for alkaline earth cation extraction by certain combinations of crown ethers (CE) and organophosphorus acids (HA).[3,4] Despite numerous reports describing synergistic effects,[5–7] there have been few systematic investigations of the factors governing their magnitude. As a result, guidelines for the design of synergistic systems capable of the efficient and selective extraction of a desired cation are lacking. Recently, Hay *et al.*[8,9] have shown that ligand reorganization energies calculated using molecular mechanics methods can be employed to make quantitative predictions of the relative metal ion binding affinities of a variety of ligands containing a fixed number of donor atoms but differing in conformation. In the present work, we demonstrate that these methods provide the basis of a systematic approach to the design of synergistic metal ion extraction systems.

The crown ether dicyclohexano-18-crown-6 (DCH18C6) has five different stereoisomers,[10] each varying with respect to *cis*/*trans* isomerism at the point of ring fusion and *syn*/*anti* isomerism between cyclohexano substituents across the macrocyclic cavity. For the extraction studies, distribution ratios ($D_M = [M]_{org}/[M]_{aq}$) for Ca^{2+}, Sr^{2+} and Ba^{2+} were determined between aqueous buffers (pH ≈ 1.5–5) and toluene solutions of individual DCH18C6 stereoisomers and/or bis-*n*-octyl-, bis-2-ethylhexyl- or bis(diisobutylmethyl)-phosphoric acid [abbreviated HDOP, HDEHP and HD(DiBM)P, respectively] using standard radiometric methods. Continuous variation studies showed metal extraction to be negligible for the crown ether alone, permitting the synergistic constant to be defined simply as the ratio of the extraction constants in the presence and absence of DCH18C6 for each dialkylphosphoric acid. Acid dependency studies (Fig. 1), in which metal distribution ratios were determined as a function of pH at constant HA concentration either alone or in the presence of a stereoisomer of DCH18C6, indicated that while no significant synergistic effects are observed for Ca^{2+}, the extraction of both Sr^{2+} and Ba^{2+} is synergized by addition of DCH18C6. In nearly all cases, the magnitude of the synergistic effect was found to vary in the order:

cis-syn-cis (A) > *cis-anti-cis* (B) > *cis-trans* (E) > *trans-syn-trans* (C) ⩾ *trans-anti-trans* (D)

Slope analysis of these acid dependences, along with similar treatment of the extractant dependencies of the D_M values at constant pH and consideration of the continuous variation results, permits delineation of the equilibria describing alkaline earth cation extraction in these systems. In the absence of DCH18C6, the equilibrium expression can be written as follows:

$$K_{ex} = ([M(HA_2)_2{\cdot}nHA]_{org}[H^+]_{aq}{}^2)/([M^{2+}]_{aq}[(HA)_2]_{org}{}^{(2+n/2)})$$

where $n = 1$ for Ca^{2+} and 2 for Sr^{2+} and Ba^{2+}. For Sr^{2+} and Ba^{2+} in the presence of DCH18C6, this expression becomes:

$$K_{ex,s} = ([M(HA_2)_2{\cdot}DCH18C6]_{org}[H^+]_{aq}{}^2)/([M^{2+}]_{aq}[(HA)_2]_{org}{}^2\,[DCH18C6]_{org})$$

[The use of $(HA)_2$ to represent the alkylphosphoric acid in both sets of equilibria follows from the known dimeric state of these acids in toluene[5,11] and the absence of interaction between DCH18C6 and HA in the organic phase, confirmed by vapor pressure osmometry.] The synergistic constant, K_s, is defined as the ratio of $K_{ex,s}$ to K_{ex}, and corresponds to the organic phase reaction that leads to the formation of the final Sr^{2+} or Ba^{2+} complexes:

$$M(HA_2)_2{\cdot}2HA_{(org)} + DCH18C6_{(org)} \rightleftharpoons M(HA_2)_2{\cdot}DCH18C6_{(org)} + (HA)_{2\,(org)}$$

Fig. 2 depicts the relationship between the synergistic constants (*i.e.* the magnitude of the synergistic effect) for strontium and barium extraction and the ligand reorganization energy,[8,9] ΔU_{reorg}, for the complexation of Sr^{2+} and Ba^{2+} by the various stereoisomers of DCH18C6. The ligand reorganization energy represents the extent to which complex formation between the crown ether and a metal ion induces steric strain in the crown ether and, therefore, indicates the degree of binding site preorganization characteristic of each stereoisomer. Ligand reorganization energy is defined as the sum of two structural reorganization components: the energy required to convert the free ligand from its minimum energy conformer to one

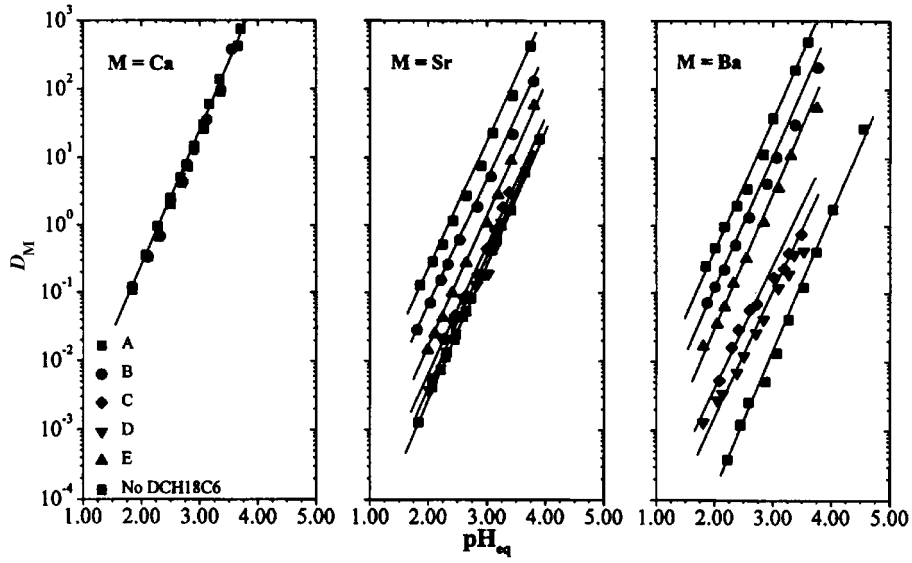

Fig 1. D_M *vs.* equilibrium pH for Ca^{2+}, Sr^{2+} and Ba^{2+} extraction by bis-*n*-octylphosphoric acid (HDOP) in toluene, both alone and in the presence of the stereoisomers of DCH18C6. Conditions: [HDOP] = 0.10 M; [DCH18C6] = 0.025 M in toluene; $[M(NO_3)_2]$ = 0.001 M; T = 23 ± 2 °C. (The least squares lines have a fixed slope of 2, consistent with the extraction equilibria.)

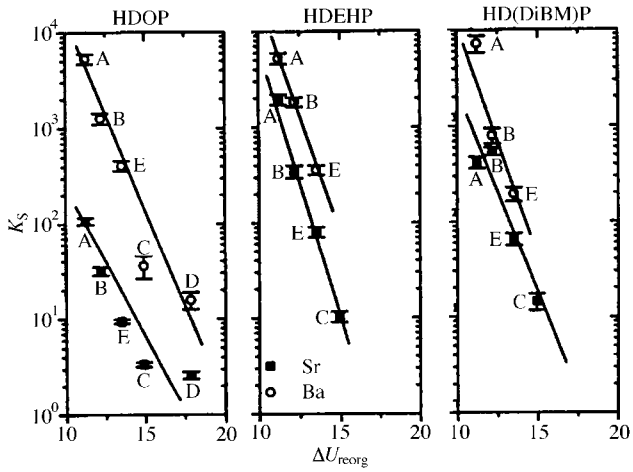

Fig 2. Relationship between the synergistic constants for Sr^{2+} and Ba^{2+} extraction and the ligand reorganization energy of the DCH18C6 stereoisomers.

predisposed for binding, ΔU_{conf}, and the energy difference between the binding conformer and the ligand conformation in the metal complex, ΔU_{comp}. Ligands highly preorganized for binding (*i.e.* 'sterically efficient' ligands) exhibit small ΔU_{reorg} values. As shown in Fig. 2, there exists an inverse linear relationship between log K_s and ΔU_{reorg}, providing strong evidence that the primary factor determining the magnitude of synergistic effects is the reorganization energy (and therefore, the metal ion binding affinity) of the neutral ligand, in this case, the various DCH18C6 stereoisomers. It appears that steric factors related to branching of the alkyl chains of the organophilic acid anion also play a role (Fig. 2), but the influence of these factors is clearly more limited.

To our knowledge, this work represents the first report of a correlation between the magnitude of a synergistic effect and ligand reorganization energies and thus, the first demonstration of the utility of molecular mechanics methods in guiding the design of synergistic metal ion separation systems. Given the widespread interest in crown ether-based separation processes and the enormous variety of both macrocyclic polyethers and organophilic acid anions available, these results are certain to have a significant impact on the development of improved systems for both analytical-scale and large-scale metal separations.

This work was performed under the auspices of the Office of Basic Energy Sciences, Division of Chemical Sciences, and the Environmental Management Sciences Program of the Offices of Science and Environmental Management, United States Department of Energy, under contract number W-31-109-ENG-38.

Formation of an organometallic coordination polymer from the reaction of silver(I) with a non-complimentary lariat ether

Paul D. Prince,[a] Peter J. Cragg[b] and Jonathan W. Steed*[a]

[a] *Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS. E-mail: jon.steed@kcl.ac.uk*

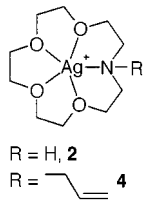
Received (in Columbia, MO, USA) 1st January 1999, Accepted 10th May 1999

The 'Ag^{I}(15-crown-5)' core moiety is a versatile supramolecular synthon, which is able to satisfy its coordination requirements using a variety of capping ligands; in the presence of the lariat ether *N*-allylaza-15-crown-5 an infinite organometallic coordination polymer is formed.

The design of supramolecular hosts for metal cations is based upon the proposition that the more complementary a host is to the guest the stronger the binding will be.[1–3] This is especially true in cases where the host is rigidly preorganised for guest complexation, as in the case of the spherands.[4] It follows from this well established fact that the majority of synthetic effort is geared towards the matching of host and guest electronic, steric and topological properties in order to maximise their mutual affinity. Clearly therefore, a successful host serves to confirm the rationality of its design. An interesting caveat of this line of reasoning is that potentially much information on host design may be gained by examination of cases in which the host is *not* complementary to the guest. In such cases the host–guest system is necessarily forced to distort in order to accommodate the conflicting requirements of each partner, with consequent diminution of affinity. The degree of distortion should furnish useful information about the tolerances on what may, and may not be termed 'complementary'.

Recently we have looked at a number of sterically and electronically non-complementary systems.[5–10] As part of these studies we reported the reaction of 'hard' oxygen donor ligands with the soft Ag^{I} cation to give complexes [Ag(L)][SbF_6] (L = 15-crown-5, **1a**; benzo-15-crown-5, **1b**).[7] In contrast to the usual linear or tetrahedral geometries of Ag^{I}[11] this results in the formation of two unusual seven-coordinate systems in which the 'Ag(15-crown-5)$^{+}$' core is capped by interactions with two oxygen atoms of the second macrocycle. The non-complementary nature of the hard base–soft acid interaction is exemplified in the long Ag–O bonding distances which ranged from 2.512(2) to 2.633(2) Å, compared with typical Ag–N_{amine} distances of *ca*. 2.2–2.4 Å.[12] Similar weak Ag–O_{ether} interactions have been noted recently in a range of β-diketonato glyme derivatives, which are of interest as CVD precursors.[13] This unsymmetrical sandwich geometry suggests that the Ag(15-crown-5)$^{+}$ core may be relatively stable and that the more loosely bound bidentate macrocycle could be readily replaced by other ligands, particularly those which are *more* complementary for the soft metal cation.

With this in mind we examined the reaction of Ag[SbF_6] with aza-15-crown-5 **2** since binding constant measurements demonstrate that Ag^{+} has a significantly greater affinity for *N*-donor ligands.[14] This reaction gave a virtually quantitative yield of a further 1:2 complex of formula [Ag(aza-15-crown-5)$_2$][SbF_6] **3**. The X-ray crystal structure of this material (Fig. 1)† proved to be approximately isomorphous with complex **1**. The key difference between the more complementary azacrown and its O-donor analogues is that in complex **3** the 'Ag(aza-15-crown-5)$^{+}$' core is capped by the nitrogen atom of a monodentate azacrown ligand, as opposed to two oxygen atoms in compounds **1**. It is likely that this is a direct result of the greater affinity of Ag^{I} for nitrogen, resulting in Ag–N distances of 2.304(2) and 2.2759(19) Å (core and cap respectively), compared to Ag–O distances in the range 2.6807(16)–2.7199(16) Å. Indeed the conformation of the capping crown ligand is entirely different because the driving force directing *two* donor atoms at the metal ion is no longer present. Interestingly this results in a significant offset to the crystal packing, which is dominated by C–H···O hydrogen bonding interactions to the non-coordinated oxygen atoms of the capping crown.[7] For compound **1a** this weak hydrogen bond results in an offset of the sandwich cation pairs giving a long crystallographic *a* axis (the direction of intermolecular chain propagation; 8.448 *vs*. 8.263 Å) and a larger monoclinic angle *β*. For compound **3** the weakly hydrogen bonded cation pairs are more directly on top of one another, reducing *β* from 101.4 to 98.8°. It is particularly noteworthy that it is the pairwise C–H···O interactions, of distances C···O 3.398(2) and 3.568(2) Å, H···O 2.58 and 2.62 Å (C–H normalised to 0.99 Å), which dominate the inter-cation packing, and not interactions to the more polar N–H moiety, which forms a long *intramolecular*



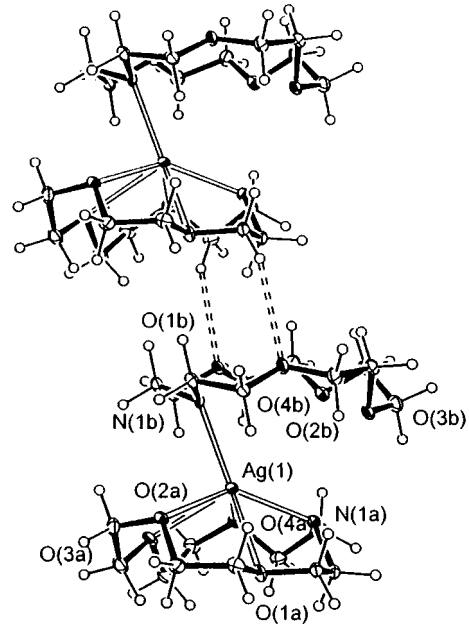


Fig. 1 Intermolecular interactions in [Ag(aza-15-crown-5$_2$][SbF_6] **3**. Selected bond distances (Å): Ag(I)–O(1A) 2.7193(15), Ag(1)–O(2A) 2.7449(16), Ag(1)–O(3A) 2.6807(16), Ag(1)–O(4A) 2.7199(16), Ag(1)–N(1A) 2.304(2), Ag(1)–N(1B) 2.2759(19).

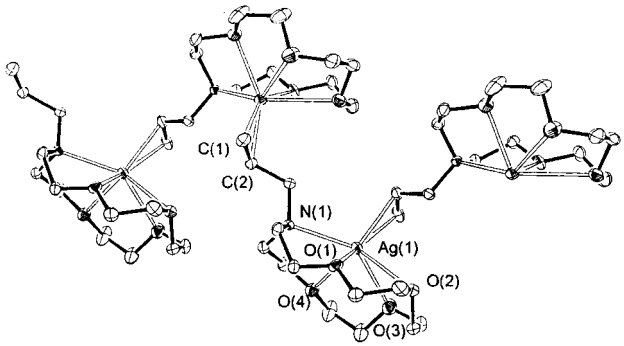

Fig. 2 The coordination polymer {[Ag(*N*-allylaza-15-crown-5)]}$_\infty$ **5**. Selected bond distances (Å): Ag(1)–C(1)′ 2.363(4), Ag(1)–C(2)′ 2.393(4), Ag(1)–O(1) 2.400(2), Ag(1)–O(2) 2.711(3), Ag(1)–O(3) 2.773(3), Ag(1)–O(4) 2.485(3), Ag(1)–N(1) 2.515(4) Å.

hydrogen bond to the distal oxygen atom of the capping azacrown, N(1A)···O(3B) 3.034(2) Å. The proton attached to N(1B) forms a bifurcated hydrogen bond to the oxygen atoms of the same crown ring, N···O 2.698(2) and 2.712(2) Å. Again, these do not affect the crystal packing because they are entirely intramolecular. The packing is however, further supported by C–H···F interactions[15–17] to the SbF_6^- anions, with shortest H···F distances 2.51–2.57 Å.

These results suggest that the interaction of derivatives of the Ag(15-crown-5)$^+$ core with further ligands with more affinity for Ag^I than etheric oxygen may prove of interest. In particular the affinity of Ag$^+$ for C-donor ligands has been well established, with the cation typically interacting with olefins and individual double bonds of arenes to form complexes such as [Ag([2.2.2]paracyclophane)]$^+$.[18] Furthermore Gokel and coworkers have noted a marked linearity between the electronic effect of the substituent on the aryl ring of the lariat and Ag$^+$ binding affinity in aryl lariat ethers[19] which is not reflected in the analogous interactions with Na$^+$ and K$^+$, which may arise from direct Ag–π interactions. Accordingly we examined the reaction of Ag[SbF_6] with the simple *N*-allyl lariat ether **4**.‡ This resulted in the formation of a polymeric complex {[Ag(allylaza-15-crown-5)][SbF_6]}$_\infty$ **5** again consisting of a substituted Ag(aza-15-crown-5)$^+$ core unit analogous to compounds **1** and **3** with a pendant allyl side arm. This side arm, while too short to wrap around and coordinate to the same Ag^I centre, is able to take the role of the second crown ether in complexes **1** and **3** resulting in an organometallic coordination polymer, with Ag–C distances of 2.363(4) and 2.393(4) Å (Fig. 2). This compares to distances of 2.49–2.68 for a range of recently reported Ag^I complexes of polyaromatic hydrocarbons[20] and typical distances of 2.40–2.60 Å[2] and confirms a full coordination interaction. Also remarkable is the Ag–N distance of 2.515(4) Å, which is *longer* than the distances from the metal cation to the two oxygen atoms nearest to the *N*-allyl moiety, Ag–O(1) 2.400(2) and Ag–O(4) 2.483(3) Å (*cf.* compounds **1** and **3**). The distal Ag–O distances are in the region of 2.74 Å. This striking difference may be rationalised by the delocalisation of the tertiary nitrogen atom lone pair onto the olefinic susbstituent,[21] and on steric grounds in which the relatively plastic coordination environment of the Ag^I ion is placing itself spatially where it may most effectively bond to the ext unit in the polymeric chain. Further evidence in support of this latter suggestion comes from the fact that the shortest Ag–O distances in **3** are to the oxygen atoms farthest away from the nitrogen atom. Again, the crystal packing is supported by C–H···F interactions to the SbF_6^- anion (shortest 2.48 Å).

We thank the EPSRC and King's College London for funding of the diffractometer system and Dr L. J. Barbour for the program X-Seed[23] used in the X-ray structure determinations. Grateful acknowledgement is also given to the EPSRC Chemical Database Service at Daresbury and to the Nuffield Foundation for the provision of computing equipment.

Received (in Cambridge, UK) 14th April 1999, Accepted 14th May 1999

Lengthening of the alkoxyl group of 4′-*n*-alkoxy-3′-nitrobiphenyl-4-carboxylic acids to C_{26} produced two types of cubic mesophases with *Im*3*m* and *Ia*3*d* symmetries, where the *Im*3*m* cubic phase is transformed into the *Ia*3*d* cubic phase at 162 °C on heating.

Optically isotropic cubic mesophases are currently attracting much interest in the field of supramolecular chemistry because of their fundamental interest in the mysterious transformation with adjacent optically anisotropic mesophases (*e.g.* lamellar, hexagonal) and because of their biological significance.[1] They can occur in a wide range of chemical systems, such as liquid crystals, biological lipid-water, and block copolymers, and their formation depends on temperature and their molecular structure and composition. Our understanding in this field is, however, far from complete.

4′-*n*-alkoxy-3′-nitrobiphenyl-4-carboxylic acids have a relatively simple molecular structure which consists of a nitrobiphenylcarboxylic acid core and a long alkoxyl tail (see Fig. 2, top). These compounds, designated as ANBC-*n* (*n* is the number of carbons in the alkoxyl groups), were first synthesized by Gray *et al*.[2] and have been investigated by several researchers;[3–6] they show a cubic phase denoted cubic D (CubD) on both heating and cooling when $n \geqslant 16$, with the temperature region of this phase becoming wider with increasing *n* (up to $n = 22$).[3,4] For the $n = 16$ and 18 homologues, the structure type of the CubD phase has been already identified as space group *Ia*3*d*,[5,6] but the structure at the molecular level is still unclear. Here, we report a homologue having a very long chain of $n = 26$ which forms two types of cubic phases, one with *Im*3*m* symmetry and the other with *Ia*3*d* symmetry, with the *Im*3*m* cubic phase transforming into the *Ia*3*d* cubic phase at 162 °C on heating. This is the first example of a thermotropic cubic–cubic phase transition in one-component systems, although two examples have been reported in lyotropic binary or ternary mixtures on varying the water content.[7–9]

The $n = 26$ homologue, ANBC-26, was prepared by three steps: first, *n*-hexacosyl bromide was prepared by a Grignard-type reaction between *n*-hexadecyl bromide and 1,10-dibromodecane, and then, according to the established method of Gray *et al*.,[2] the obtained bromide was reacted with 4′-hydroxybiphenyl-4-carboxylic acid to give 4′-*n*-hexacosyloxybiphenyl-4-carboxylic acid (ABC-26), finally, nitration of ABC-26 gave ANBC-26. The final white powder product was purified by repeated recrystallization from ethanol, and the purity was checked by elemental analysis, thin layer chromatography, ^{1}H NMR, and differential scanning calorimetry (DSC).

The DSC trace of ANBC-26 shows the following phase sequence on the first heating curve (1H): crystal 1·86 °C·crystal 2·103 °C·smectic C (SmC)·123 °C·cubic I (Cub I)·162 °C cubic II (Cub II)·194 °C· structured liquid (I_1)·200 °C·isotropic liquid (I_2), with associated entropy changes of 86, 124, 6, 0.3, 9 and 15 J mol^{-1} K^{-1}, respectively. Identification of the phase type was by both texture observation using a polarizing optical microscope and small-angle X-ray scattering (SAXS). The structure of the I_1 phase has been discussed elsewhere.[3,4] The cooling process is more complicated and has not been fully characterized; the phase sequence determined so far is I_2·198 °C I_1·192 °C·hexagonal columnar phase·189 °C·Cub II·93 °C·SmC 76 °C·crystal. On second heating (2H), the sample showed crystallization of residual glassy domains at 79 °C, but was otherwise identical with the 1H scan.

Fig. 1 shows the SAXS patterns of ANBC-26 at (a) 130.4 °C and (b) 170.4 °C, on heating, where $q = (4\pi/\lambda)\sin\theta$, $\lambda = 0.154$ nm and 2θ = scattering angle (Mac Science M18XHF X-ray generator and Huxley–Holms optics). At 130.4 °C, 11 observed peaks are arranged almost symmetrically with respect to the beam stopper (not shown here), showing the following ratios of spacings: $\sqrt{3}$:$\sqrt{4}$:$\sqrt{5}$:$\sqrt{6}$:$\sqrt{7}$:$\sqrt{8}$:$\sqrt{9}$:$\sqrt{10}$:$\sqrt{12}$:$\sqrt{13}$:$\sqrt{15}$. Since the ratios $\sqrt{7}$ and $\sqrt{15}$ are not compatible with any cubic lattices, the sequence of numbers must be doubled. Therefore, the obtained ratios are $\sqrt{6}$:$\sqrt{8}$:$\sqrt{10}$:$\sqrt{12}$:$\sqrt{14}$:$\sqrt{16}$:$\sqrt{18}$:$\sqrt{20}$:$\sqrt{24}$:$\sqrt{26}$:$\sqrt{30}$, which is characteristic of a body-centered cubic symmetry *Im*3*m*, and thus the parameter of the unit cell is $a = 20.02 \pm 0.02$ nm. The pattern abruptly changed at *ca*. 155 °C on heating, and at 170.4 °C [Fig. 1 (b)], only two peaks with a ratio of $\sqrt{6}$:$\sqrt{8}$ are seen. The pattern was very often dissymmetric with respect to the beam stopper, as shown in the inset, reflecting orientation of the Cub II domains in the glass capillary tube. Since ANBC-26 is achiral, only the space group *Ia*3*d* matches the absence of diffractions with lower indices (100), (110), (111), (200) and (210). The cell parameter is estimated as $a = 12.30 \pm 0.04$ nm. The higher-temperature Cub II phase has the same symmetry as

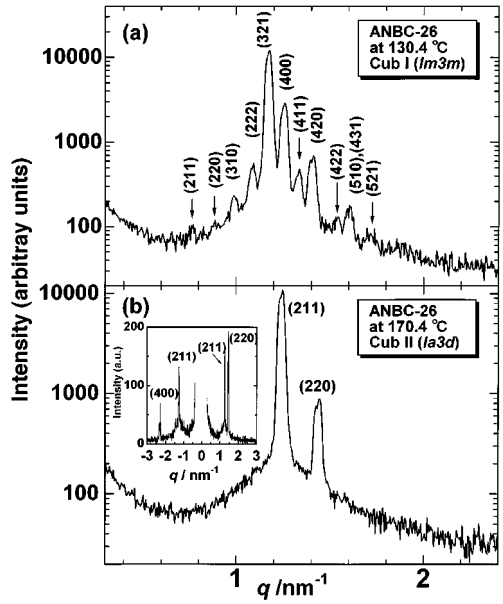

Fig. 1 SAXS patterns of ANBC-26 recorded (a) at 130.4 °C and (b) at 170.4 °C, on heating. Miller indices are also shown. In (b), the inset shows a second pattern for the same sample under the same thermal conditions.

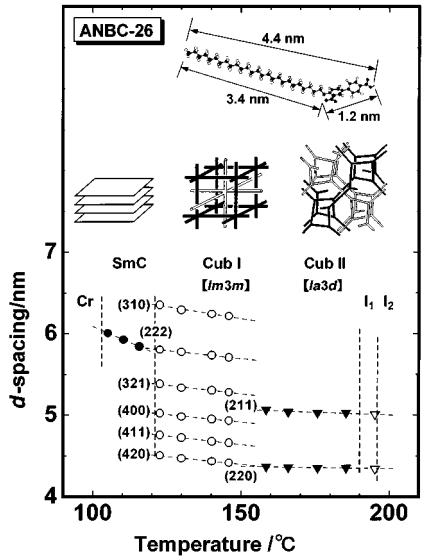

Fig. 2 Plots of *d*-spacing *vs*. temperature for ANBC-26 on heating. The molecular structure of ANBC-26 and model structures of the SmC, Cub I and Cub II phases are shown in the upper and middle part of this figure, respectively.

the CubD phase of ANBC-16[5] and −18.[6] On the other hand, the cubic phase of a 3′-cyano analogue with n = 18 (4′-*n*-octadecyloxy-3′-cyanobiphenyl-4-carboxylic acid) was identified in space group *Im*3*m*,[6] and this phase and the lower-temperature Cub I phase are of the same type.

ANBC-26 thus shows three liquid-crystalline phases, the SmC phase with a lamellar structure, and two types of cubic phases, one with *Im*3*m* symmetry and the other with *Ia*3*d* symmetry, on heating. Schematic models for these three structures are depicted in the middle part of Fig. 2. According to the models proposed for lyotropic systems by Luzzati and coworkers,[9] both cubic phases are visualized as two sets of networks of rods, which are interwoven but not connected. For the *Im*3*m* cubic phase, the rods are connected 6-by-6 at right angles so that they are directed parallel to one of three lattice axes, while in the *Ia*3*d* cubic phase, the rods are connected 3-by-3, forming two sets of helix-like networks, where each helix is linked with other four helices. In ANBC-26, the aromatic part and CO_2H group form these jointed rods, while the aliphatic chain fills out the free space between the rods.

In order to gain insight into the transformation process along the SmC–Cub I (*Im*3*m*)–Cub II (*Ia*3*d*) phase sequence, the *d*-spacings of diffraction peaks are plotted *vs*. temperature in the lower part of Fig. 2. Several interesting points are noted:

(1) The layer thickness of the SmC phase decreases as the temperature approaches the SmC–Cub I transition temperature. When the SmC layer is transformed into the SmA layer, the tilt angle of the molecular long axis against the layer normal usually reaches zero and thus the layer thickness increases. Therefore, the 'thinning' of the SmC layers may be characteristic of the SmC phase that exhibits any cubic phase at the higher temperature side.

(2) At the SmC to Cub I transition, the SmC layer thickness is equal to the (222) interplanar distance of the Cub I phase with *Im*3*m* symmetry. This suggests the existence of the so-called epitaxial relation[10] between the SmC layer planes and the (222) planes of the Cub I phase. In the *Im*3*m* cubic phase with a cell parameter a, one 6-by-6 connection point is located at (000) and the other at ($\frac{1}{2}a$,$\frac{1}{2}a$,$\frac{1}{2}a$), and the distance between them is ($\sqrt{3}$)a/2, while the (222) spacing is given by ($\sqrt{3}$)a/6. Hence, three layers should exist between the two connection points.

(3) In the Cub I phase, the diffraction of highest intensity is the (321) peak while the (211) diffraction peak is the highest in the Cub II phase; both spacings, however, show a discontinuity at the Cub I to Cub II phase transition.

(4) In the Cub I phase temperature range, the unit cell parameter a decreases with increasing temperature, showing a *negative* thermal volume expansion [$(1/a^3)(\mathrm{d}(a^3)/\mathrm{d}T) = -4 \times 10^{-2}$ K^{-1}]. This trend continues but is greatly reduced (-6×10^{-4} K^{-1}) for temperatures in the Cub II phase range. Bruce and coworkers reported a similar negative thermal volume expansion (-1.5×10^{-3} K^{-1}) for the *Ia*3*d* cubic phase of a silver(I) alkoxystilbazole complex.[11] It seems that negative thermal volume expansion is characteristic of cubic mesophases (fluid nature).

Finally, we comment on two issues. The first relates to the molecular structure characteristics of ANBC-26. A shorter alkoxyl homologue, *e.g.* ANBC-18, shows an *Ia*3*d* cubic phase, and the length of the aliphatic chain is estimated at 2.2 nm in the extended form, which is about twice the length of the aromatic core moiety (1.2 nm). For ANBC-26, the aliphatic chain length is 3.4 nm, about three times larger than the core length (see Fig. 2). The lengthening of the aliphatic chain unexpectedly produced two types of cubic phases on heating. Moreover, this lengthening also much improved the thermal stability among this series of compounds, as confirmed by thermal gravimetry.

Second, paying attention to the location of the methyl end groups in the two cubic lattices, they form curved interfaces so as to wrap the jointed rods. These interfaces are alternative sets of description for cubic phases and are denoted infinite periodic minimal surfaces (IPMS); three fundamental cubic IPMS have been reported, the Schwarz P and D and Schöen Gyroid G surfaces, which correspond to three bicontinuous cubic phases with symmetries *Im*3*m*, *Pn*3*m* and *Ia*3*d*, respectively.[12] Hyde *et al*. pointed out that three bicontinuous cubic IPMS are mathematically interrelated to each other by a Bonnet transformation *without change in curvature*.[12] This means that phase transitions between the three cubic phases should occur without heat exchange, provided that only the elastic energy of the system is taken into consideration. This may be a reason why only one type of cubic phase has been observed to date in a given thermotropic cubic system; also our observation of a very small entropy change (0.3 J mol^{-1} K^{-1}) for the Cub I–Cub II phase transition is consistent with this expectation.

In conclusion, ANBC-26 shows an interesting polymorphism, including two cubic mesophases with *Im*3*m* and *Ia*3*d* symmetries, and a structured liquid I_1 phase. We anticipate that our finding will lead to a more complete understanding of cubic molecular organization and its transformation to and from other types, especially in thermotropic liquid crystalline systems.

Synthesis of organometallic solids by protonation of $Cp^*M(CN)_3^{n-}$ (M = Rh, Ir, Ru)

Stephen M. Contakes, Michael Schmidt and Thomas B. Rauchfuss*

School of Chemical Sciences and the Frederick Seitz Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA. E-mail: rauchfuz@uiuc.edu

Received (in Bloomington, IN, USA) 16th March 1999, Accepted 18th May 1999

Protonation of aqueous acetone solutions of $[Cp^*Ir(CN)_3]^-$ produces the two-dimensional organometallic solid $(H_3O)[Cp^*Ir(CN)_3]\cdot Me_2CO$ wherein 14 Å diameter channels ($Ir_4C_8N_8O_4$) contain exchangeable solvent molecules; the analogous Ru and Rh tricyanide complexes are also susceptible to proton-induced polymerization.

The synthesis of solids based on organic[1] and metal organic subunits[2] from molecular precursors is a mature but still growing theme.[3] Organometallic solids are less well developed,[4] although the face-capping C_5R_5 ligands should be convenient for limiting the degrees of freedom in condensation processes. Molecular cages have been prepared by the reaction of *fac*-octahedral tritopic Lewis base $CpM(CN)_3^-$ with *fac*-octahedral tritopic Lewis acids Cp^*M^{2+} and $Mo(CO)_3$.[5–7] The complementary interaction of $Cp^*M(CN)_3^-$ with the pyramidal tritopic receptor[8] H_3O^+ is now shown to afford extended structures featuring two-dimensional net structures[9] (Scheme 1).

Aqueous solutions of $NEt_4[Cp^*Ir(CN)_3]$ **1** react upon mixing with protic acids (HOTf, HCl, HOTs) to produce the colorless solid $(H_3O)[Cp^*Ir(CN)_3]$ **2** in 82% isolated yield.† The yield is proportional to the stoichiometry of the acid, consistent with a cooperative process *vs.* formation of species of intermediate degrees of condensation (*e.g.* $H[Cp^*Ir(CN)_3]_2^-$). Base reverses the polymerization process, affording intact $Cp^*Ir(CN)_3^-$ [eqn. (1)].

$$\{(H_3O)[Cp^*Ir(CN)_3]\}_n \underset{H^+}{\overset{OH^-}{\rightleftharpoons}} [Cp^*Ir(CN)_3]^- \qquad (1)$$

IR measurements on **2** show two ν_{CN} bands (2156 and 2137 cm^{-1}) in the region for hydrogen bonded (or bridging) CN ligands. Compound **2** is completely insoluble in common solvents except methanol, wherein it dissociates to give free $[Cp^*Ir(CN)_3]^-$, as indicated by ^1H NMR measurements (δ 1.945, as for **1**). Conductivity measurements on 10^{-3} M MeOH solutions confirm that **2** is a 1:1 electrolyte (Λ_M of 96 Ω cm^2 mol^{-1}).

Crystals of **2** were obtained by layering an acetone solution of HOTf (10 mM) over an (10 mM) $CHCl_3$ solution of $NEt_4[Cp^*Ir(CN)_3]$ for 48 h.‡ The resulting crystals readily desolvate to give powders, even at 0 °C. The crystallographic analysis reveals a layered structure of formula $[Cp^*Ir(CN)_3]H_3O\cdot Me_2CO$. The corrugated sheets consist of $Cp^*Ir(CN)_3^-$ ions triply bridged *via* hydrogen bonds to H_3O^+ ions (Fig. 1). As in the previously described molecular boxes,[13,14] there is complementary connectivity of the Lewis base $[M(CN)_3]$ and Lewis (in this case Brønsted) acid (H_3O^+). The layers feature alternating 24- and 12-membered rings composed, respectively, of $Ir_4C_8N_8O_4$ and $Ir_2C_4N_4O_2$ atoms (ignoring H atoms). Owing to the linearity of the Ir–C–N···O linkages, the 24-membered rings are approximately octagonal and the 12 membered rings are approximately square. The 'cross window' distances in the 24-membered rings are *ca.* 14 (Ir···Ir) and *ca.* 13 Å (O···O). The 12- and 24-membered rings are eclipsed, leaving large channels that extend through the solid along the *a* axis (interlayer distance of 6.976 Å).

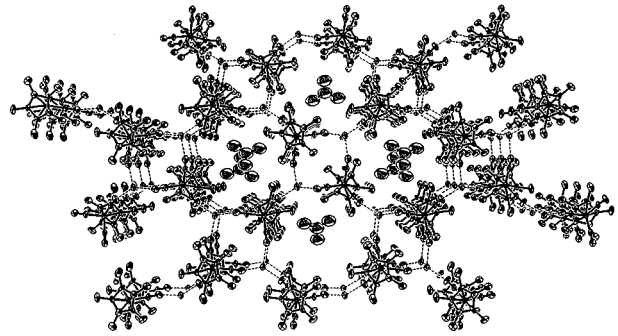

Fig. 1 Fragment of one layer of $(H_3O)[Cp^*Ir(CN)_3]\cdot Me_2CO$ viewed down the *a* axis. The acetone molecules occupy the octagonal channels (thermal ellipsoids set at the 50% probability level).

The octagonal channels in **2** are filled with acetone molecules that are subject to large thermal motion. It is thus understandable that this material easily desolvates. The lability of the solvent in **2** was examined by thermogravimetry, which confirms that acetone evolution reversibly occurs in the range 25–65 °C. Solvent *exchange* also occurs readily for *solid* **2**. To prove this point, samples of $\mathbf{2}\cdot Me_2CO$ were exposed to the *vapor* of fluoroacetone, which is virtually isosteric with acetone (Fig. 2). The TGA curves of the resultant material show an increase in the solvent weight loss from *ca.* 12% (*vs.* 12.0% theoretical) to *ca.* 15% (14.8% theoretical for $\mathbf{2}\cdot(CH_2F)MeCO$.

While the synthesis, spectroscopy, and solubility properties of $(H_3O)[Cp^*Rh(CN)_3]$ **3** are virtually identical to that of **2**, the rhodium species is significantly less stable. Thus **3** decomposes after several hours in refluxing $CHCl_3$ with evolution of HCN to produce, *inter alia*, $\{[Cp^*Rh]_7(CN)_{12}\}^{2+}$; the analogous decomposition of **2** requires 3 weeks.[6] This reaction illustrates the potential utility of the acid-catalysed condensation, somewhat analogous to the decarbonylation route used to prepare polynuclear metal carbonyls.

Hydrogen bonding interactions also play a significant role in the chemistry of $Cp^*Ru(CN)_3^{2-}$, which is of interest as a precursor to electroactive solids and cages. This species was readily prepared from the reaction of $Cp^*Ru(MeCN)_3^+$ with 3 equiv. of NaCN but it is difficult to separate the product from contaminating salts. Treatment of the crude product with HOTf (2 equiv) produced the polymer $H_2[Cp^*Ru(CN)_3]$ **4** as a white

Received (in Cambridge, UK) 28th April 1999, Accepted 24th May 1999

Three complexes {[*trans*-$Mo_2(O_2CCF_3)_2$(μ-dppa)]$_3$(μ_6-CO_3)(μ_2-X)$_3$}F [X = Cl, Br or I; dppa = *N*,*N*-bis(diphenylphosphino)amine], are reported, which are the first cyclic, hexanuclear complexes containing quadruply bonded units joined by carbonate ions.

Complexes containing metal–metal multiple bonds have already been the subject of many studies of their structures and reactivities.[1] Quadruply bonded dinuclear complexes were found to be able to dimerize to form cyclic rectangular clusters. Pairs of dinuclear molecules undergo [2 + 2] cycloaddition by loss of the δ components of the quadruple bonds with the two single bonds formed joining the triply bonded dimers together.[2] Recently tetranuclear complexes of the type $[Mo_2(DArF)_3]_2(\mu\text{-}H)_2$ (DArF = *N*,*N*′-diarylformamidinate, Ar = *p*-tolyl or *p*-anisyl) containing quadruply bonded dimolybdenum units joined by μ-hydride ions have been prepared by reaction of $Mo_2(DArF)_3Cl_2$ and $NaHBEt_3$.[3] To investigate the bonding mode of the carbonate ion in the dimolybdenum complex, we studied the reaction of [*trans*-$Mo_2(O_2CCF_3)_2(MeCN)_6][BF_4]_2$ with K_2CO_3 and *N*,*N*′-bis(diphenylphosphino)amine (dppa) in CH_2Cl_2. The reaction afforded a novel cyclic, hexanuclear complex containing quadruply bonded units joined by carbonate ions and axially bridged by chloride atoms. The synthesis and structural characterization of this complex and its bromo and iodo analogue form the subject of this report.

The chloro complex, {[*trans*-$Mo_2(O_2CCF_3)_2$(μ-dppa)]$_3$(μ_6-CO_3)(μ-Cl)$_3$}F **1** was prepared by reaction of [*trans*-$Mo_2(O_2CCF_3)_2(MeCN)_6][BF_4]_2$ with K_2CO_3 and dppa in CH_2Cl_2.† The chloride atoms in **1** are presumably obtained from the CH_2Cl_2 solvent. The transfer of chloride atoms from the CH_2Cl_2 solvent to quadruply bonded complexes has been observed during the preparation of the complexes $Mo_2Cl_3(O_2C\text{-}Me)$(etp) {etp = bis[2-(diphenylphosphino)ethyl]phenylphosphine} and $Mo_2Cl_3(O_2CMe)$(tetraphos-2) {tetraphos-2 = tris[2-(diphenylphosphino)ethyl]phosphine}.[4] Reaction of [*trans*-$Mo_2(O_2CCF_3)_2(MeCN)_6][BF_4]_2$ with dppa and K_2CO_3 in MeCN, followed by addition of ZnX_2 (X = Br or I), afforded complexes of the type [*trans*-$Mo_2(O_2CCF_3)_2$(μ-dppa)]$_3$(μ_6-CO_3)(μ_2-X)$_3$}F (X = Br, **2**; X = I, **3**).† The appearance of the F ions in **1**–**3** can be ascribed to the dissociation of the BF_4^- ions to give F^- and BF_3, which has been observed during the preparation of a linear trichromium complex $[Cr_3(dpa)_4(F)(FBF_3)](BF_4)$ [dpa$^-$ = anion of bis(2-pyridyl)-amine].[5]

Crystals of **1**–**3** are isomorphous and conform to the space group *C*2/*c* with four molecules in each unit cell.‡ Fig. 1 shows a representative ORTEP diagram for the cations of **1**–**3**. The molecule resides on a C_2 axis passing through atoms X(1), O(8), C(1) and N(2) and bisecting the Mo(3)–Mo(3a) bond. The core structure is remarkable in that three sets of quadruply bonded $Mo_2(O_2CCF_3)_2$(μ-dppa) units are joined by a carbonate group (CO_3^{2-}) and axially bridged by three halide atoms. The metal atoms in each $Mo_2(O_2CCF_3)_2$(μ-dppa) unit are bridged by a dppa ligand and two $CF_3CO_2^-$ groups which are *trans* to each other. Table 1 lists selected bond distances and angles. The Mo–Mo distances for all three complexes are very similar and are normal for Mo–Mo quadruple bonds. The Mo–X distances are relatively long, indicating only weak Mo–X interactions. The Mo–X distances, which show a strong dependence on the nature of the halogen atoms, increase from X = Cl to I. Noticeably, while the angles of Mo–X–Mo decrease from X = Cl to I, the Mo–Mo–X angles become more linear. Each molecule of the three cations can be viewed as three sets of edge-sharing bioctahedra, shown as **I** (Scheme 1), linked by adjacent $CF_3CO_2^-$ groups and dppa ligands, and quadruply bonded by

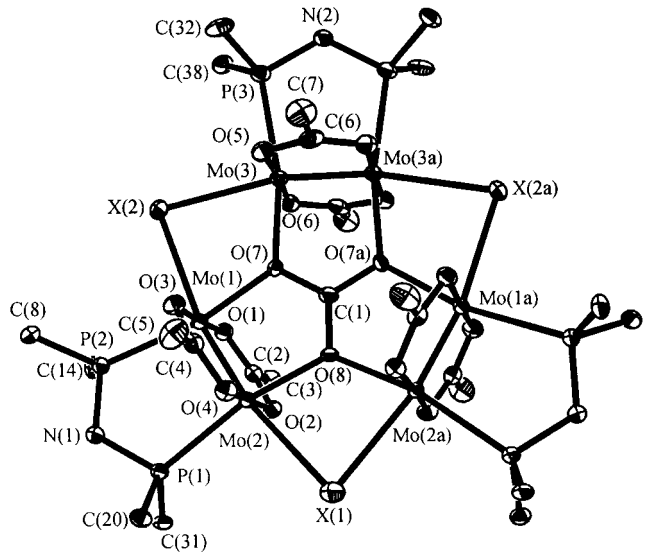

Fig. 1 A representative ORTEP drawing for complexes **1** (X = Cl), **2** (X = Br) and **3** (X = I). The F atoms of the CF_3 groups are removed and the phenyl carbon atoms are designated by their first atoms for clarity.

Table 1 Selected bond distances (Å) and angles (°) for **1** (X = Cl), **2** (X = Br) and **3** (X = I)

Scheme 1

the adjacent molybdenum atoms. The average separations of the two metal centers in **I** are 3.799, 3.790 and 3.804 Å for **1**, **2** and **3**, respectively, indicating no metal–metal interaction.

The cations of **1**–**3** show the μ_6-CO_3^{2-} (3L, 6M)[6] anions bridging the six metal centers through the three oxygen atoms of the carbonate group. Such a coordination mode of μ_6-CO_3^{2-} has been seen in the complexes $[(VO)_6(\mu_6\text{-}CO_3)(\mu\text{-}CO_3)(OH)_9]^{5-}$,[7] in which simple μ_6-bridging was seen for the carbonate ion, and in $[Na_2Nd_4L_4(CO_3)L'_4]$ {H_3L = [(*o*-$HOC_6H_4CH{=}NCH_2)_2CH$]H, L′ = tetrahydrofuran or L'_2 = 1,2-dimethoxyethane},[8] where one carbonate oxygen bridges two sodium atoms and each of the others bridges one sodium and two neodymium atoms. The carbonate coordination in **1**–**3** appears unique in bridging three pairs of multiply bonded metal atoms.

Hexametallic complexes exhibit a fascinating variety of structural patterns.[9] Aggregates are known with the six metal centers as a planar edge-bridged square, a puckered hexagon, an edge-linked bitetrahedron, an edge-bridged tetrahedron, a face-capped tetrahedron and less regular arrays.[9] No complexes of these types containing multiply bonded metal centers have been reported. The cations of complexes **1**–**3** therefore represent a unique structural type for cyclic transition-metal M_6 complexes. The six metal atoms are shifted from their mean planes in pseudo-hexagonal, planar rearrangements, shown as **II** (Scheme 1), by only 0.059, 0.049 and 0.023 Å for **1**, **2** and **3**, respectively. Complexes **1**–**3** are in marked contrast to the cyclic complex $[Mo_6O_8(OEt)_6Cl_8]$[10] which exhibits a chair configuration of metal atoms incorporating three Mo–Mo single bonds. The only trimer of quadruply bonded dimers that has been reported is the linear complex $[Mo_6(O_2CCHF_2)_{12}(bpy)$ (bpy = 2,2′-bipyridine), which comprises a central, quadruply bonded $Mo_2(O_2CCHF_2)_4$ unit whose axial ligands are two $[Mo_2(O_2CCHF_2)_2(bpy)_2](O_2CCHF_2)_2$ units.[11]

We thank the National Science Council of the Republic of China for support.

Received (in Oxford, UK) 14th April 1999, Accepted 21st May 1999

New compounds in which nickel is substituted for lithium in lithium nitride show evidence of high lithium vacancy concentrations and an ordering of these vacancies to form new structural variants.

The chemistry of transition metal ternary nitrides has recently been the subject of intense study.[1] However, the reactions of lithium nitride with the first row transition elements were first studied over fifty years ago.[2–4] A number of different compositions and structures are observed for the resulting lithium nitridometallates, some of the most common being based either on an antifluorite structure[2] or on a modification of the lithium nitride structure itself.[3] Late first row transition nitridometallates such as those formed with Co, Ni and Cu favour this latter structure type. The transition metal (M), in these compounds, partially substitutes for lithium between Li_2N planes to form $Li_{3-x}M_xN$ but the limit of substitution, *x*, is below unity. The parent binary nitride, Li_3N, is a lithium ion conductor.[5] Control of *x* has implications both structurally and in terms of the conductivity of materials. We report here the synthesis and structure of two new layered nitridonickelates.

New ternary lithium nitrides were synthesised by reaction of excess lithium nitride with nickel foil under a positive pressure of nitrogen gas. All manipulations were carried out in an argon or nitrogen-filled evacuable glove box. Lithium nitride (Li_3N) was prepared by reaction of gaseous nitrogen with cleaned lithium metal (5–6 g) dissolved in liquid sodium at 650 °C.[6] Ternary nitrides were prepared by reaction of Li_3N with a nickel foil (99.9% BDH) tube. The tube was placed inside a stainless-steel crucible, sealed in a stainless steel vessel under a positive pressure of nitrogen (*ca*. 2 atm) and heated to 750 °C for 24 h. The vessel was cooled and opened in a nitrogen filled glove box. The reaction yielded a gold coloured coating of crystalline product on the nickel foil. The air-sensitive crystals were isolated, loaded and sealed in capillaries.

Structure solution and refinement reveals two distinct products with compositions $Li_5Ni_3N_3$ and LiNiN.[7] Both compounds have structures closely related to Li_3N, with alternate layers of Li–N sheets and metal ions stacked perpendicular to the *c*-axis. The proposed structures of both compounds exhibit lithium vacancy ordering not seen in lithium nitride or the previously reported $Li_{3-x}M_xN$ compounds. Furthermore, Li ion vacancy concentrations in these lithium nitridometallates are well above the 1–2% level usually observed in Li_3N. This Li vacancy ordering enforces changes in space group with vacancy concentration and the approximate doubling of the $Li_5Ni_3N_3$ *a*-parameter relative to the Li_3N unit cell dimensions. It was almost impossible to discriminate between ordered and disordered models for the LiNiN structure by X-ray diffraction.[8]

It is useful to compare and contrast the structures of the nitridonickelates and the parent compound, Li_3N in terms of the nitrogen coordination environment. Lithium nitride, Li_3N is composed of layers of N-centred hexagonal bipyramids which stack along the *c*-axis. [Li_2N] planes (where each N is surrounded by a 'graphitic-like' hexagon of six Li atoms) are interconnected by Li atoms between layers (in the apical positions of the hexagonal bipyramids) [Fig. 1(a)].† In the nitridonickelates, Ni replaces Li in these 'apical' sites between layers additionally creating Li vacancies in the [Li_2N] planes. Hence there is an evolution of nitrogen co-ordination geometry with vacancy concentration. In $Li_5Ni_3N_3$ [Fig. (1b)] the nitrogen coordination is effectively reduced to '6 + 1' (distorted pentagonal bipyramidal). Within the Li–N planes, nitrogen is now surrounded by five lithium ions. In reality, the in-plane Li(1)–N(1) distance [2.42(4) Å] is much larger than the sum of

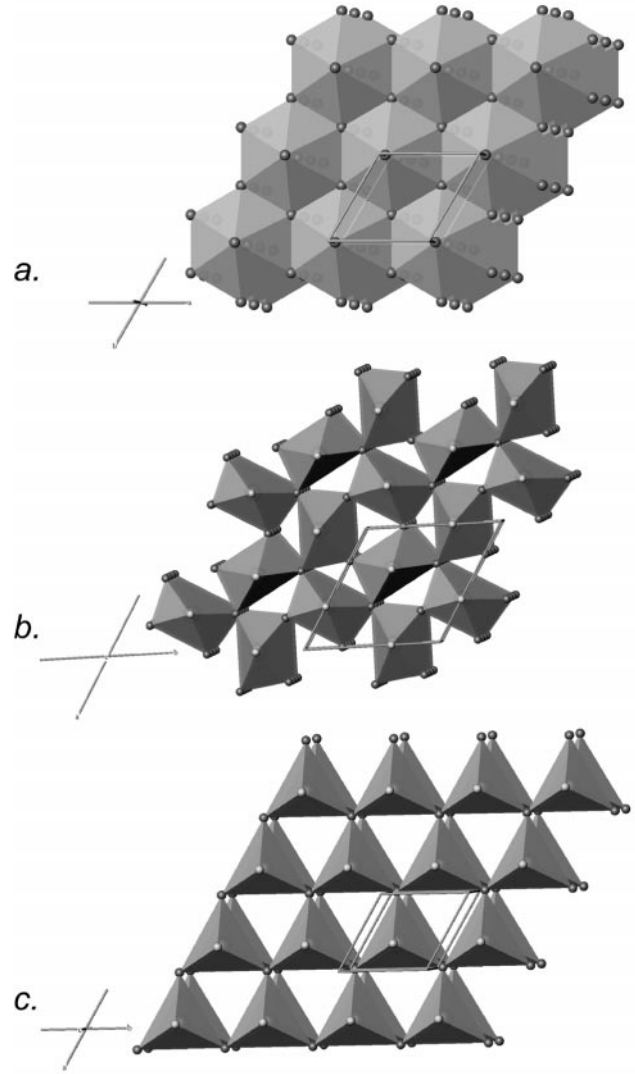

Fig. 1 Structure of (a) Li_3N, showing edge sharing of N(Li_8) polyhedra in the *ab* plane (b) $Li_5Ni_3N_3$, showing vertex sharing of N(Li_4Ni_2) polyhedra in the *ab* plane and creation of Li vacancies (c) LiNiN, showing vertex sharing of N(Li_3Ni_2) polyhedra in the *ab* plane and creation of Li vacancies.

the ionic radii[9] and the nitrogen coordination is closer to distorted octahedral than pentagonal bipyramidal. Li coordination within planes is both three- and two-fold. The N-centred polyhedra are linked by vertices both in the *ab* plane and along *c*. In the proposed structure of LiNiN [Fig. (1c)], the nitrogen coordination is reduced further to five (trigonal bipyramidal). The N coordination and the *intra*-layer linking in this compound are akin to that in the high-pressure form of Li_3N (β-Li_3N, with the Na_3As structure),[10] although the stacking of layers is altered. As in $Li_5Ni_3N_3$, the N-centred polyhedra are linked by vertices in three dimensions. The lithium coordination in the Li–N planes in LiNiN is exclusively trigonal planar as in the Li_3N parent structure. In both nitridonickelates, Li–N planes are linked *via* infinite, perpendicular N–Ni–N chains. In LiNiN, as in Li_3N, these chains are straight whereas in $Li_5Ni_3N_3$ they are slightly bent.

The Li-N bond lengths in both $Li_5Ni_3N_3$ [mean distance: 2.086(5) Å, excluding the interaction at 2.42(4) Å] and LiNiN [2.1697(6) Å] are of the same order as those observed in the parent binary nitride (2.130 Å).[11] The interplane Ni–N distances [1.777(1) Å in $Li_5Ni_3N_3$ and 1.7700(5) Å in LiNiN] are considerably shorter than the equivalent Li(2)–N distance in Li_3N (1.939 Å).[11] The Ni–N bond lengths are similar to those (Li,Ni)–N distances derived from *c*-parameters of $Li_{3-x}Ni_xN$ solid solution members[2] and are only marginally shorter than those observed in other nitridonickelate(I) species such as CaNiN (1.7904 Å)[12] and SrNiN [average: 1.81(4) Å].[13] These distances indicate the likely significant covalent (π) character of the Ni–N bond in nitridonickelates. Besides the $Li_{3-x}M_xN$ compounds, perhaps the most closely related structure to $Li_5Ni_3N_3$ and LiNiN is that of Li_4FeN_2, also a defect variant of Li_3N. In the nitridoferrate, however, metal vacancies occur *between* [Li_2N] planes (*i.e.* on iron positions) and the structure can be described by the formulation $Li_2(Fe_{0.5}\square_{0.5})N$ (where □ is a vacancy). The equivalent interplanar metal–nitrogen (Fe–N) distance in Li_4FeN_2 is 1.86(1) Å; longer than those observed in the nickel nitrides.

The nitridonickelates can be regarded as vacancy-ordered layer compounds, $Li_{3-x-y}Ni_x\square_yN$. In these examples, $x = 1$, $y = 0.333$ in $Li_5Ni_3N_3$ and $x = 1$, $y = 1$ in LiNiN. Besides affecting the nitrogen coordination environment, the other consequence of removing lithium is to increase the nickel valency and oxidation states above one become possible. $Li_5Ni_3N_3$ contains Ni^{I}/Ni^{II} ($Ni^{1.33+}$) whereas LiNiN contains exclusively divalent nickel. During the course of this study, the related nitridonickelate $Li_{5.69}Ni_{2.31}N_3$ was reported which also adopts the $P\bar{6}2m$ structure isotypic with $Li_5Ni_3N_3$.[14] In this case, $x = 0.77$, $y = 0.3333$ and Ni has an oxidation state of 1.43.

Bond valence calculations[15] performed for the nitridonickelates yielded the following values: (a) LiNiN: Li = 0.7, Ni = 1.9, N = −2.6; (b) $Li_5Ni_3N_3$: Li(1) = 0.7, Li(2) = 0.8, Ni = 1.9, N = −3.0. While the Li and N site valences compare well with Li_3N, perhaps more interesting is the magnitude of the Ni valences. These would suggest that Ni is present as predominantly Ni(II). Calculations performed on original $Li_{3-x}Ni_xN$ compositions, with (Li/Ni)–N bond lengths derived from *c*-parameters, produce similar values. In some cases, these absolute values may be artificially high since π-bonding contributions in transition metal nitrides lead to bonds shorter than anticipated from 'purely ionic' contributions. However, the inference is that regardless of the Li/Ni distribution on the interplanar site, creation of Li vacancies in the [Li_2N] plane is inevitable to maintain charge balance. There is a striking paucity of reliable structural data for the earlier reported $Li_{3-x}M_xN$ compounds. The increase in *a*-parameters with increasing *x* in these compounds suggests that substitution of transition metals for lithium *between* [Li_2N] planes also engenders structural change *within* those planes (albeit in a *disordered* manner). Neutron diffraction is a crucial tool in determining the site occupancy of light elements. Only '$Li_{2.5}Cu_{0.5}N$' has been examined by powder neutron diffraction (PND) and this compound was found to contain *ca.* 15% Li vacancies in the [Li_2N] plane (giving a refined composition $Li_{2.2}Cu_{0.5}N$).[16]

The ionic and electronic conductivity and the magnetic behaviour of $Li_{3-x}M_xN$ (M = Co, Ni) nitrides have been examined previously.[17] We are preparing $Li_{3-x-y}Ni_x\square_yN$ materials in bulk to investigate their electronic and magnetic properties. The effect of increased Li^+ ion vacancies and nickel oxidation states may have exciting implications for conductivity and magnetism in these lithium ternary nitrides.

The authors thank the EPSRC, British Telecom (S. E. S.) and the Royal Society (P. P. E.) for supporting this work and also the EPSRC for the award of an Advanced Fellowship to D. H. G.

6 Cleaned, pure lithium was added to an excess of molten sodium contained in a stainless-steel crucible at 250 °C. The cooled crucible was sealed inside a stainless-steel distillation vessel which was evacuated and filled with nitrogen gas (*ca.* 2 atm). The vessel was heated to 650 °C with the nitrogen pressure monitored using a pressure transducer. Excess Na was removed by vacuum distillation at 350 °C for 12 h.

7 *Crystal data*: $Li_5Ni_3N_3$, $M = 252.9$, hexagonal space group $P\bar{6}2m$ (no. 189), $a = 6.475(3)$, $c = 3.555(2)$ Å, $Z = 1$, $V = 129.1(3)$ Å^3, $D_c = 3.253$ g cm^{-3}, $\mu = 10.67$ mm^{-1}. 868 reflections measured at 293(2) K, 109 independent ($R_{int} = 0.0712$). Data collected on a Rigaku R-Axis II area detector diffractometer with graphite monochromated Mo-Kα radiation ($\lambda = 0.71073$ Å). The structure was solved by direct methods with SHELXS-86[a], and refined by least squares within SHELXL-93.[b] $w = 1/[\sigma^2(F_o^2) + (0.040P)^2 + 0.59P]$ where $P = (F_o^2 + 2F_c^2)/3$ $R1 = 0.0351$, $wR2 = 0.0884$.

LiNiN, $M = 79.66$, hexagonal space group $P\bar{6}m2$ (no.187) , $a = 3.758(1)$, $c = 3.540(1)$ Å, $Z = 1$, $V = 43.30(2)$ Å^3, $D_c = 3.055$ g cm^{-3}. $\mu = 10.606$ mm^{-1}, 1440 reflections measured at 297(2) K, 171 independent ($R_{int} = 0.024$). Data collected on a Stadi-4 diffractometer with Mo-Kα radiation ($\lambda = 0.71073$ Å). The structure was solved by direct methods with SHELXL-86[a] and refined by least squares within SHELXL-93.[b] $w = 1/[\sigma^2(F_o^2) + (0.0584\,P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$. $R1 = 0.0374$, $wR2 = 0.0803$. Received (in Basel, Switzerland) 20th April 1999, Accepted 18th May 1999

Stable functional complementary clusters, *i.e.* of the electrophilic and nucleophilic type, can be 'added' resulting in the planned formation of the related reaction products: the high-yield synthesis of the crystalline compounds $[Me_2NH_2]_{10}[\{(SiW_{11}O_{39})Mo_3S_4(H_2O)_3(\mu\text{-}OH)\}_2]\cdot 20H_2O$ 1 and $[Me_2NH_2]_{14}[\{(P_2W_{17}O_{61})Mo_3S_4(H_2O)_3(\mu\text{-}OH)\}_2]\cdot 25H_2O$ 2 containing the related $\{Mo_3S_4\}^{4+}$ as well as $\{W_{11}O_{39}\}^{8-}$ and $\{W_{17}O_{61}\}^{10-}$ clusters as constituents, respectively, is a good example.

The deliberate synthesis of large clusters by 'adding' or 'linking' smaller ones, which are stable in solution under certain reaction conditions, is a challenge for the inorganic chemist. The aqua ion $[Mo_3S_4(H_2O)_9]^{4+}$ can for instance be regarded as an archetypical electrophilic building block in this respect since the H_2O ligands are labile and can be easily substituted by nucleophilic cluster anions with donor functions and therefore act formally as ligands. Here, we report the deliberate high-yield synthesis of the title species and provide two examples of the potentially large class of compounds having complementary functional polyoxometalate[1] and chalcogenide clusters as constituents.[2]

In an acidic medium two electrophilic $[Mo_3S_4(H_2O)_9]^{4+}$ [3] aqua cations react with two monovacant lacunary anions $\{[SiW_{11}O_{39}]^{8-}$ [4] or $[P_2W_{17}O_{61}]^{10-}$ [5]$\}$ to yield the cluster species $[\{(SiW_{11}O_{39})Mo_3S_4(H_2O)_3(\mu\text{-}OH)\}_2]^{10-}$ **1a** and $[\{(P_2W_{17}O_{61})Mo_3S_4(H_2O)_3(\mu\text{-}OH)\}_2]^{14-}$ **2a** respectively, which were isolated as the Me_2NH_2 salts **1** and **2** in high yield.†‡ It is important to note that the structure of the reaction products of the complementary educts can be predicted by considering (a) the preferred octahedral coordination of molybdenum, (b) the easily removable H_2O ligands of the $[Mo_3S_4(H_2O)_9]^{4+}$ aqua ion, and (c) the number of oxygen atoms in the lacunary-type anions $[SiW_{11}O_{39}]^{8-}/[P_2W_{17}O_{61}]^{10-}$ acting as strong donors. Under the same conditions, other products should (preferably) not be formed.

Single crystal X-ray structure determinations have revealed that the yellow–brown diamagnetic compounds $[Me_2NH_2]_{10}[\{(SiW_{11}O_{39})Mo_3S_4(H_2O)_3(\mu\text{-}OH)\}_2]\cdot 20H_2O$ **1** and $[Me_2NH_2]_{14}[\{(P_2W_{17}O_{61})Mo_3S_4(H_2O)_3(\mu\text{-}OH)\}_2]\cdot 25H_2O$ **2** contain the discrete cluster anions **1a** and **2a**, $[Me_2NH_2]^+$ cations, and crystal water molecules in their lattices.§ Fig. 1 and 2 show perspective views of the structures of **1a** and **2a** both having a central core built up by two $\{Mo_3S_4(H_2O)_3\}^{4+}$ fragments connected through two hydroxo bridging groups which are *cis* to the μ_3-S core atoms. [Note that in $[Mo_3S_4(H_2O)_9]^{4+}$, the H_2O ligands in *cis* position to the μ_3-S atom are more acidic than the c-H_2O ligands in *trans* position;[6] the protonation of the bridging oxygen atoms clearly follows from bond valence sum (BVS) calculations.[7]]

The two nucleophilic lacunary anions, of the Keggin type $\{[SiW_{11}O_{39}]^{8-}\}$ and of the Dawson type $\{[P_2W_{17}O_{61}]^{10-}\}$, can be considered as negatively charged ligands which replace coordinated H_2O ligands of the electrophilic educt (during the reaction). In this respect the monovacant lacunary anions with four oxygen donor atoms can be regarded as inorganic equivalents of a porphyrin ligand.[1c] In agreement with our

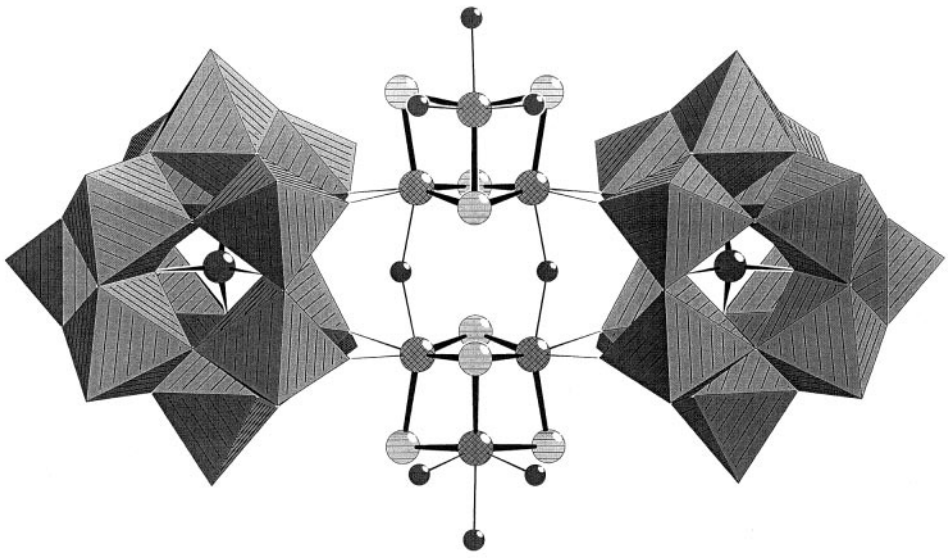

Fig. 1 Structure of the cluster anion **1a** distinguishing between the building units or constituents: $\{Mo_3S_4\}$ fragments in ball-and-stick and $\{W_9\}$ fragments in polyhedral representation.

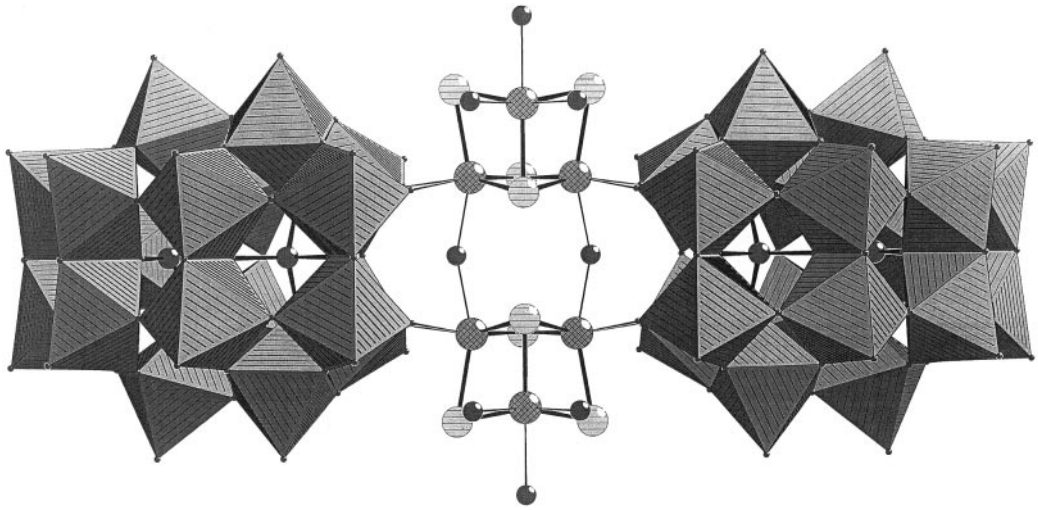

Fig. 2 Structure of the cluster anion **2a** showing the $\{Mo_3S_4\}$ and $\{W_{17}\}$ fragments as building units or constituents.

concept—the addition of stable clusters—the geometrical parameters of the constituents of the anions **1a** and **2a** are practically identical to those of the cluster educts.[8–10]

Compounds **1** and **2** are stable in air and in aqueous solutions (pH = 1–7). Heating **1** or **2** in concentrated hydrochloric acid leads to the reverse reaction, *i.e.* to the reformation of the $[Mo_3S_4(H_2O)_9]^{4+}$ cluster in quantitative yields.

The relative abundance of the different cluster constituents of **1a** and **2a** is also confirmed by the IR, Raman, UV–VIS and ^{31}P NMR spectra. The characteristic UV–VIS spectra indicate not only the presence of $\{Mo_3S_4\}^{4+}$ units possessing a d^6 electron configuration[2*a*] but also that these are almost electronically uncoupled. The characteristic vibrational spectra show bands due to the almost uncoupled vibrations of the constituents, while the ^{31}P NMR spectrum of **2a** [in a buffered aqueous solution (0.5 M $MeCO_2Na$–0.05 M $MeCO_2H$)] shows, consistent with the solid-state structure of **2**, signals in the intensity ratio 1 : 1.

We believe that the strategy of reacting appropriate stable nucleophilic and electrophilic, *i.e.* functional complementary, clusters may be of general importance for the synthesis of this type of compound.

A fluorescent molecular thermometer based on the nickel(II) high-spin/low-spin interconversion

Marianne Engeser, Luigi Fabbrizzi,* Maurizio Licchelli and Donatella Sacchi

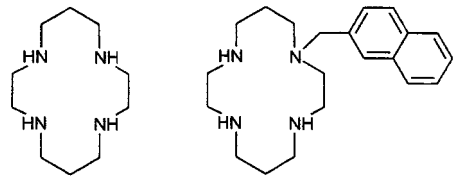
Dipartimento di Chimica Generale, Università di Pavia, via Taramelli 12, I-27100 Pavia, Italy. E-mail: fabbrizz@.unipv.it

Received (in Basel, Switzerland) 9th March 1999, Accepted 17th March 1999

The temperature of a fluid can be measured through a variation of the fluorescence emission intensity of a naphthalene fragment covalently linked to a Ni^{II} tetraaza-macrocyclic complex, which undergoes a temperature dependent spin interconversion equilibrium.

Luminescence is an easily detectable property which can be used to signal the occurrence of molecular events in real time and in real space. One of the first and most fascinating examples refers to the monitoring of the Ca^{2+} concentration inside the cell during muscle contraction by means of a specific chelating agent equipped with a fluorophore, using fluorescence microscopy as an investigating tool.[1] Since then, luminescent molecular receptors capable of sensing a variety of analytes (H^+,[2] s- and d-block metal ions,[3,4] anions,[5] amino acids)[6] have been developed. Most of them have been designed by following a two-component approach, *i.e.* by covalently linking a receptor subunit displaying selective affinity towards the envisaged substrate to a luminescent fragment.[7] Sensing is based on the occurrence of an intercomponent process (*e.g.* electron transfer) between the luminophore and the receptor, whose extent has to be distinctly different before and after recognition.

The success of the above outlined modular approach prompted us to the design of a two-component luminescent sensor of a physical rather than a chemical quantity: temperature. In the envisaged system, the luminescent fragment must be covalently linked to a bistable subunit, whose states A and B interact to a different extent with the nearby luminophore. Most importantly, the transition from A to B should be fast, reversible and controlled by temperature. We considered that the temperature dependent spin state interconversion of a transition metal centre could represent a convenient process to profit from, in order to build up a luminescent molecular thermometer. In particular, we looked at the high-spin/low-spin crossover of the Ni^{II} ion in a tetraaza coordinative environment like that offered by cyclam, **1**.[8]



1 **2**

In this connection, we prepared a series of Ni^{II} complexes with the quadridentate macrocycle **2**, in which the naphthalene fluorescent fragment has been linked to the cyclam framework through a $–CH_2–$ spacer.† Complexes of formula $Ni^{II}(\mathbf{2})X_2$ were isolated as either yellow diamagnetic or blue–violet paramagnetic solids, depending upon the nature of the anion X^-. Poorly coordinating anions (ClO_4^-, $CF_3SO_3^-$) favour the formation of the yellow low-spin complexes, which have a square-planar stereochemistry. Anions of stronger coordinating tendencies (Cl^-, NCS^-, NO_3^-) stabilize the high-spin state, occupying the two apical positions of a slightly distorted octahedron. The stereochemical feature of high- and low-spin Ni^{II} complexes of cyclam and analogues have been ascertained through X-ray diffraction studies on a number of complexes.[9]

Spin-state and stereochemistry are maintained when the $Ni^{II}(\mathbf{2})X_2$ complexes are dissolved in non-coordinating solvents. When $X^- = ClO_4^-$, $CF_3SO_3^-$, a band at 470 nm (ε = 102 and 104 $dm^3\ mol^{-1}\ cm^{-1}$, respectively), typical for a low-spin square Ni^{II} tetramine complex is observed in $CHCl_3$ solution. Such a band is absent for $X^- = Cl^-$, NCS^-, NO_3^-, the less intense d–d bands of the high-spin form at 520 nm being observed. Very interestingly for sensing purposes, the two spin states exert a different influence on the emission properties of the proximate naphthalene subunit. In particular, the emission intensity in a $CHCl_3$ solution is remarkably higher for low-spin complexes (Quantum yield, Φ = 0.019 for ClO_4^-, 0.020 for $CF_3SO_3^-$) than for high-spin complexes (Φ = 0.009 for NO_3^-, 0.005 for NCS^-, 0.007 for Cl^-). Note that Φ values of the complexes are in any case substantially lower than that observed for plain naphthalene (Φ = 0.21 in ethanol). Transition metals typically quench the emission of a luminophore through two distinct mechanisms: electron transfer (eT) and energy transfer (*via* double electron exchange, ET). In particular, when the luminescent fragment is linked to a nitrogen atom of cyclam through a $–CH_2–$ spacer, the Ni^{II} centre tends to quench fluorescence through an ET mechanism.[10] This has been confirmed in the present work by the fact that when a solution of a $Ni^{II}(\mathbf{2})X_2$ complex in the glass forming butyronitrile solvent is brought to liquid nitrogen temperature, fluorescence is not revived at all, a behaviour suggestive of the occurrence of a double electron exchange.[11]

The ET based quenching mechanism involves the circular motion of electrons between the MO levels of the photo-excited fluorophore and the partially filled d orbitals of the Ni^{II} centre. The energy sequence of the latter orbitals changes with the metal spin-state and stereochemistry and this may affect the feasibility and rate of the double electron exchange process, thus determining a different quenching efficiency. The intimate details of the quenching mechanism have not been defined at this stage of the investigation. However, it is important to note that the considered two-component system contains a control subunit capable of existing in two states of comparable stability, which affect to a different extent the emission of the nearby covalently linked fluorescent fragment.

Ni^{II} complexes of cyclam and cyclam-like macrocycles in coordinating solvents like water and MeCN give an equilibrium mixture of the high- and low-spin forms.[8] In solution, the apical sites of the octahedral complex are occupied by two solvent molecules, S. The two species interconvert according to the following equilibrium:

$$[Ni^{II}(L)S_2]^{2+} \rightleftharpoons [Ni^{II}(L)]^{2+} + 2S \qquad (1)$$

blue, high-spin octahedral — yellow, low-spin square-planar

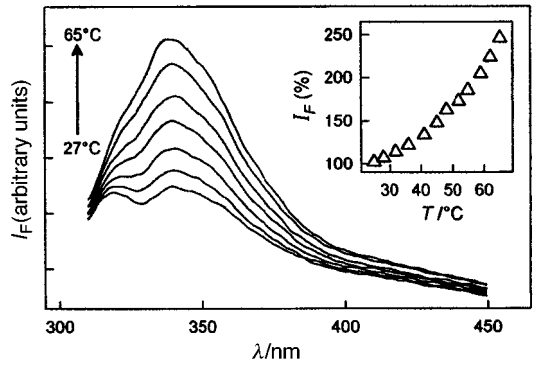


Fig. 1 Emission spectra of a 10^{-5} M MeCN solution of $[Ni^{II}(\mathbf{2})](ClO_4)_2$ recorded over the temperature range 27–65 °C (some spectra are omitted for clarity). I_F *vs.* temperature profile is shown in the inset.

The constant associated to the equilibrium (1) can be evaluated through the absorbance of the yellow form.[8] For a 10^{-3} M MeCN solution of $[Ni^{II}(\mathbf{2})](ClO_4)_2$, at 25 °C, $K = 4 \times 10^{-1}$: thus, the low-spin species is present at 30% and the high-spin species at 70%. The high-spin→low-spin conversion is typically endothermic, *i.e.* a temperature increase favours the formation of the yellow form. For a concentration $c \geqslant 10^{-3}$ M, this effect can be followed through an increase of the intensity of the d–d absorption band at 470 nm. In a very diluted concentration scale ($10^{-5} \leqslant c \leqslant 10^{-7}$ M), the temperature effect can be monitored through I_F, the intensity of the emission band of the naphthalene fragment: in particular, the temperature increase makes I_F increase appreciably.

Fig. 1 displays the emission spectra of an MeCN solution 10^{-5} M in $[Ni^{II}(\mathbf{2})](ClO_4)_2$ recorded over the temperature range 27–65 °C. The inset displays the corresponding I_F, *vs.* temperature profile. When decreasing temperature, I_F quickly decreases following the same profile. Thus, the $[NI^{II}(\mathbf{2})]^{2+}$ complex can be considered as a thermometric probe operating at the molecular level, and the I_F *vs. T* profile of the inset of Fig. 1 provides its calibration curve. Owing to the hydrophobic nature of the naphthyl substituent, $[Ni^{II}(\mathbf{2})](ClO_4)_2$ is not soluble in water even at a concenration as low as 10^{-7} M. It is soluble, however, in water–MeCN (20 : 80 v/v) and water–dioxane (50 : 50 v/v) mixtures, where it displays a similar temperature dependent emission behaviour over the temperature intervals 25–70 and 25–75 °C, respectively.

Other luminescent systems whose emission varies with temperature have been previously reported. In contrast to what is observed in the present study, in most cases a temperature increase depresses luminescence.[12] In these systems, there exists a non-emitting state, NR, slightly higher in energy than the S_1 emitting state. A temperature increase populates the NR state, which undergoes non-radiative decay, thus causing a decrease of the luminescence intensity. An increase of the emission intensity with increasing temperature was observed in the case of 'delayed fluorescence' displayed by some luminescent molecules (*e.g.* eosin).[13]

Light-emitting systems whose emission intensity varies with temperature can be used as probes for spatially and temporally resolved temperature measurement in any fluid including those of biological interest. Lipophilic fluorescent molecules displaying a decreasing emission with increasing temperature were proposed as optical thermometers of cell membranes.[14]

The two-component approach described here and the use of a metal containing a magnetically bistable subunit like $[Ni^{II}(cyclam)]^{2+}$ appears especially versatile for the construction of a fluorescent thermometer, used at a non-invasive concentration level. Thanks to the modular nature of the system, the fluorophore can be replaced at will, for instance to impart solubility in water or to provide emission in the desired wavelength interval, provided that an efficient energy transfer mechanism keeps operating.

This work has been supported by CNR (Progetto Finalizzato Biotecnologie). M. E. is grateful to the ERASMUS Bureau of the European Union for an ECTS grant.

Notes and references

† **2**: cyclam **1** (2 g, 0.01 mol) was dissolved in hot toluene (100 mL) and 2-bromomethylnaphthalene (0.442 g, 0.002 mol) dissolved in the minimum amount of toluene added. The resulting solution was refluxed for 6 h and then cooled to room temp. The ammonium salts and the excess cyclam were filtered off and the resulting clear solution washed with 5% aqueous NaOH (3×25 mL) and water (2×25 mL). After drying over $MgSO_4$, toluene was distilled off to give compound **2** as a pale yellow oil; yield 61%. MS (ESI): 341 [M + H^+]. The NMR spectrum was in accord with the proposed structure.

$[Ni(\mathbf{2})](CF_3SO_3)_2$: a solution of **2** (0.34 g, 1 mmol) in toluene (10 mL) was heated at reflux and a solution of $Ni(CF_3SO_3)_2$ (0.36 g, 1 mmol) in ethanol (10 mL) was added. After refluxing for 1 h, the solution was cooled to room temperature and concentrated at the rotary evaporator. The orange–yellow precipitate was filtered and washed with diethyl ether; yield 92%. MS (ESI): 547 [M − CF_3SO_3]. Correct elemental analysis (C, H, N). The other Ni^{II} complexes were obtained by a similar method.

Received (in Basel) 21st December 1998, Accepted 9th April 1999

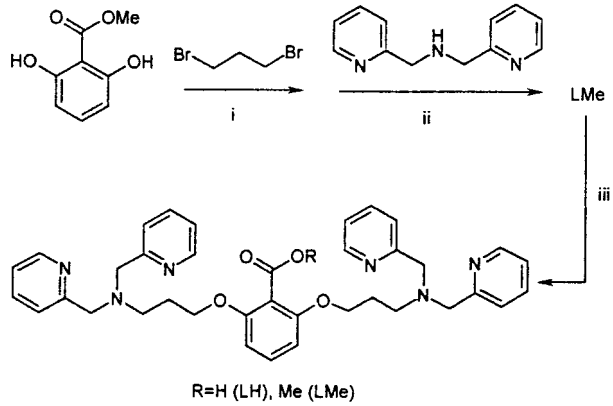
Reaction of the new polydentate ligand 2,6-bis{3-[*N*,*N*-di(2-pyridylmethyl)amino]propoxy}benzoic acid (LH) with $Fe(ClO_4)_3$ followed by addition of chloroacetic acid leads to the formation of the tetranuclear complex $[\{Fe_2OL(ClCH_2CO_2)_2\}_2](ClO_4)_4$, the crystal structure of which reveals that it consists of two $Fe^{II}_2(\mu\text{-}O)(\mu\text{-}RCO_2)_2$ cores that are linked *via* the two L ligands in a helical structure, with the carboxylate moieties of the two ligands forming a hydrogen-bonded pair at the center of the helix.

A number of Fe_2O complexes have been synthesized to model the spectroscopic and structural properties of μ-oxo-μ-carboxylato diiron sites in proteins such as soluble methane monooxygenase (sMMO), ribonucleotide reductase (RNR) and hemerythrin.[1] In many cases, such biomimetic complexes have been found to be relatively unstable.[1,2] Efforts have therefore been made to prepare framework polydentate ligands that may stabilize complexes of this type,[3] examples include ligands in which multidentate nitrogen bases that bind to metals in a capping manner are linked to alkoxo or phenoxo groups capable of bridging two metals.[4] Binucleating polydentate ligands in which nitrogen donors are linked to a carboxylate moiety should be even more relevant for the modelling of μ-oxo-μ-carboxylate diiron sites because the carboxylate bridges in these enzymes are part of the protein.[5,6] Two successful[7,8] and two unsuccessful[9,10] attempts have been reported for the preparation of dinuclear iron complexes containing similar ligands; in these ligands, the carboxylate is one of the 'peripheral' donors at the terminus of a polydentate ligand. Here we report the synthesis of a new ligand containing a potentially bridging carboxylate moiety which is a part of the spacer that links two di(picolyl)amine groups. Reaction of this ligand with an iron(III) salt followed by addition of chloroacetic acid leads to the formation of a tetranuclear complex which consists of two linked $Fe^{III}_2(\mu\text{-}O)$ dimers.

The ligand 2,6-bis{3-[*N*,*N*-di(2-pyridylmethyl)amino]-propoxy}benzoic acid (LH) has been prepared in a three-step synthesis with a general overall yield of *ca*. 60% (Scheme 1). The products LMe and LH (Scheme 1) have been identified by ^{1}H NMR spectroscopy, microanalysis and, in the case of LMe, FAB mass spectrometry. The ^{1}H NMR spectra of LMe and LH are identical except for the methyl resonance at δ 3.61 that is present in the spectrum of LMe.†

Reaction of LH with 2 equiv. of $Fe(ClO_4)_3$ in methanol leads to the formation of a green–yellow product, which has tentatively been assigned the formula $[Fe_2OL(H_2O)_2](ClO_4)_3$ **1** on the basis of UV–VIS, IR, ^{1}H NMR spectroscopy and microanalysis.‡ Addition of 10 equiv. of chloroacetic acid to a solution of **1** in ethanol results in the formation of a brown complex **2**. The UV–VIS and ^{1}H NMR spectra§ of complex **2** indicate that it contains a μ-oxo-bis-μ-carboxylate diiron core. The assignments of the ^{1}H NMR spectra of **1** and **2** are based on their similarities to the spectra of oxo-bridged diiron complexes of related ligands, *viz*. $\{PyCH_2\}_2N(CH_2)_nCO_2^-$ (n = 1,2).[11] All features in the NMR spectra of **1** and **2** appear in the range δ 0–28, indicative of relatively strong antiferromagnetic coupling between the iron atoms. There are broad features above δ 20 (PyCH_2 and *o*-Py protons), sharper peaks at δ 15–18 (*m*-Py protons), and a very sharp peak at δ *ca*. 6 (*p*-Py protons). In addition, there are sharp peaks of the spacer polymethylene chain at δ 3–9. However, the mass spectrum of **2** (*vide infra*) and the analytical data suggest that it is a tetranuclear complex (a 'dimer of dimers') rather than a simple diiron complex.

It was possible to grow crystals of **2** from a MeOH–MeCN solution. In order to confirm the proposed tetranuclear structure and to assess whether the carboxylate moiety of **2** acts as a bridge between the metals, the crystal structure of **2** was determined.¶ The molecular structure of **2** is shown in Fig. 1. The Fe–O–Fe moieties are bridged by two chloroacetates while the non-bridging facial positions are filled by two di(picolyl)-amine moieties from two molecules of L so that the two L ligands link the two diiron–μ-oxo units. The average Fe–μ–oxo distance is 1.79 Å and the average Fe–O–Fe angle is 121.8°; the intra-dimer Fe-Fe distances are 3.102(4) Å [Fe(1)–Fe(2)] and 3.138(4) Å [Fe(3)–Fe(4)] while the interdimer Fe–Fe distances vary from *ca*. 10.5 Å to 10.8 Å . Complex **2** is structurally and, to some extent, chemically related to previously structurally characterized tetranuclear *bis*-Fe_2O species[12] but there are several features of the molecular structure of **2** that render it unique. The conformation of the linking ligands is such that the whole molecule acquires a helical shape; the dihedral angle between the Fe–O–Fe planes in **2** is 42.5°. The center of the helix is held together through the central carboxylates of the two



Scheme 1 Synthetic route to LMe and LH. *Reagents and conditions*: i, Me_2CO, K_2CO_3, 72 h, 94% yield; ii, Et_3N, 96 h, 77% yield; iii, KOH–EtOH–H_2O, 12 h, 84% yield.

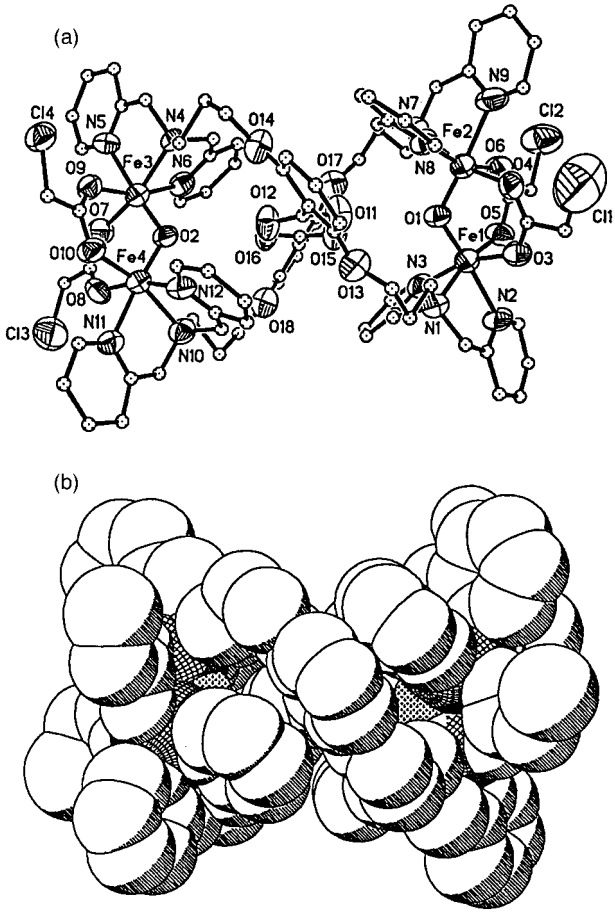


Fig. 1 (a) XP[13] and (b) space-filling drawings of the molecular structure of **2**, showing the atom labeling scheme. Thermal ellipsoids are drawn at the 20% level. Selected distances (Å) and angles (°): Fe(1)–O(1) 1.776(6), Fe(2)–O(1) 1.787(6), Fe(3)–O(2) 1.794(6), Fe(4)–O(2) 1.786(6), Fe(1)–N(1) 2.196(8), Fe(1)–N(2) 2.215(9), Fe(1)–N(3) 2.100(10), Fe(1)–O(3) 2.028(8), Fe(1)–O(5) 2.013(7), Fe(1)–O(1)-Fe(2) 121.1(4), Fe(3)–O(2)–Fe(4)122.5(4).

L ligands which form a hydrogen-bonded pair, the O(11)–O(15) and O(12)–O(16) distances are 2.61 and 2.60 Å, respectively. It is usually observed that the tertiary nitrogen atoms of di(picolyl)amines coordinate *trans* to the μ-oxo ligand in this type of diiron–oxo species but in **2**, the tertiary amines are coordinated *cis* to the oxo ligand and *trans* to one of the bridging carboxylates so that the apices by the bridging oxygens of the Fe_2O units point towards each other. It is likely that the 'girdle' that is formed by the hydrogen-bonded pair of central carboxylates prevents the two ligands from binding to the Fe_2O unit in the favoured coordination mode, instead they bind in the observed 'inverted' coordination mode.

Repeated attempts to detect the molecular ion of **2** by electrospray mass spectrometry (ESMS) have thus far proven unsuccessful. However, we do detect prominent peaks at *m/z* 952, 601 and 426; these peaks are consistent with the molecular formulation(s) $\{[Fe_4L_2(ClCH_2CO_2)_2](ClO_4)_{4-x}\}^{x+}$ (x = 2–4, respectively). Furthermore, we have prepared a number of other carboxylate derivatives of **1**. It appears that in solution, these iron–oxo carboxylate species are in equilibrium with other complexes of similar composition, the nature of which is currently under investigation. We are currently preparing a number of derivatives of LH containing other nitrogen donors and are attempting to use these ligands to synthesize structural and functional model complexes for the active sites of sMMO and RNR R2.

¶ *Crystal data*: $C_{84}H_{80}Cl_8Fe_4N_{12}O_{36.75}$, brown, crystal dimensions 0.23 × 0.21 × 0.18 mm, M = 2352.60, triclinic, space group $P\bar{1}$ (no. 2), a = 16.4575(3), b = 17.8346(2), c = 19.3790(3) Å, α = 77.521(1), β = 89.245(1), γ = 86.432(1)°, U = 5542.9(2) Å^3, Z = 2, D_c = 1.410 Mg m^{-3}, μ = 0.788 mm^{-1}, F(000) = 2404, 45710 reflections collected (1.1 < θ < 31.8°) at 293(2) K, 31848 independent reflections used in the structure refinement [$F_o > 2\sigma(F_o)$], R_1 (F) = 0.0973, wR_2 (F^2) = 0.2047, goodness-of-fit (F^2) = 0.854. Data were collected with a Siemens SMART CCD area detector, using graphite-monochromated Mo-*K*α radiation (λ = 0.71069 Å) from a Rigaku rotating anode X-ray generator. The intensity measurements were corrected for Lorentz, polarization and absorption effects. The positions of the metal atoms were found by direct methods,[13] and all the non-hydrogen atoms were located from difference Fourier syntheses. The hydrogen atoms were placed in calculated positions. A disorder in the orientations of the CH_2Cl groups of the chloroacetates containing Cl3A and Cl1A was detected and was successfully modelled; the conformations shown in Fig. 1 are favoured. The final refinement was carried out by full-matrix least-squares calculations[13] on F^2 and with anisotropic thermal parameters for all non-hydrogen atoms. CCDC 182/1215. Received (in Cambridge, UK) 30th March 1999, Accepted 18th May 1999

d^0 Transition metal-containing mesoporous molecular sieves are synthesized by the hydrolysis of tetraethyl orthosilicate in aqueous acid, in the presence of neutral or anionic low-condensed Mo(VI) or W(VI) oxo–peroxo or Re(VII) polyoxo species and a cationic surfactant; the materials have a nearly homogeneous distribution of the dopants and promising catalytic activities.

The recent discovery of mesoporous oxides offers novel possibilities for preparing transition metal-containing materials.[1] Most procedures in acidic (or basic) media require careful control of the rate of hydrolysis of the precursors, *e.g.* alkoxides. In acidic media, with $[MoO_4]^{2-}$, $[WO_4]^{2-}$, *etc.*, large iso-(or hetero-) polyoxometalates (POMs, M = Mo or W) are formed.[2–4] These POMs can be dispersed (or grafted) onto molecular sieves such as MCM-41,[5] but are not so easily inserted into pure mesoporous silica as they limit wall growth and/or lead to phase segregation. Previous work demonstrates that low-nuclearity neutral or anionic peroxo species can be prepared in 'MO_3/H_2O_2–H_2O–H_3O^+' precursor systems.[6,7]

In this work, we consider the electrostatic interaction of these peroxo species with silicate moieties (operating mode A), in the counter-ion-mediated $S^+X^-I^+$ pathway, as a means of incorporating molybdenum(VI), tungsten(VI) or rhenium(VII) into mesoporous silica. [S^+ = quaternary ammonium ion surfactant, *e.g.* cetyltrimethylammonium ($CTMA^+$); X^- = Cl^- and/or anionic oxo–peroxo species; I^+ = inorganic silicate precursor (tetraethyl orthosilicate, TEOS).[1] This procedure is compared with methods involving, or generating, polyoxometalates[8] or oxo species interacting with TEOS also in the $S^+X^-I^+$ pathway (operating mode B). The data (Table 1) show that mode A, with Mo or W oxo–peroxo species (run 1, sample A_{Mo}, wt% Mo ≈ 4.05; run 4, sample A_W, wt% W ≈ 7.55) leads to a higher M content than in the initial gel. On the other hand, with $[MeReO(O_2)_2(H_2O)]$ synthesized from '$[Me_3ReO_3]$ (denoted MTO)/H_2O_2–H_2O–H_3O^+' mixtures (run 6, sample A_{Re}, wt% Re ≈ 0.90) the rhenium content is low and a better incorporation can be obtained with aqueous $H^+[ReO_4]^-$ (run 7, sample B_{Re}, wt% Re ≈ 2.5). These results differ from those obtained with basic media (S^+I^- pathway),[1] which correspond to lower loadings of the M species (M = Mo, W or Re) incorporated into the framework of the silica matrix (see, for example, run 3, sample C_{Mo}).

The X-ray data for $(Si/M)_{initial}$ ≈ 50 are similar to those obtained for pure mesoporous silica. Samples A_{Mo}, A_W, A_{Re} and B_{Re} show higher order reflections such as (110), (200), *etc.*, which suggests that they have greater long-range order than samples B_{Mo} and B_W. Because of the relatively low metal content in these materials (Table 1), additional crystalline phases, if any, cannot be identified from the X-ray diffraction patterns, except for $(Si/Mo)_{initial} \leqslant 30$ for example, but some of them can be identified by laser Raman spectroscopy.

This method is very useful for characterizing detemplated materials with Mo or W prepared by the oxo–peroxo (mode A, Table 1) or the oxo-polyoxo route (mode B). Sensitivity to water vapour has been shown by identification of supported $H_4[SiMo_{12}O_{40}]$. (aq), while in an anhydrous atmosphere, there is no evidence for any crystalline phase or known product (*e.g.* MoO_3). Sample B_{Mo} gives a Raman spectrum corresponding to a mixture of high purity silica MCM-41 and the Keggin unit, '$SiMo_{12}$'. The Raman spectra of the W-MCM-41 prepared by the oxo–peroxo route (sample A_W) and by the polyoxo mode (sample B_W) are shown in Fig. 1. They include bands that originate from the SiO_2 matrix [*ca.* 1100, 800 (very weak) and 490 cm^{-1}] as well as from the tungsten oxo species. Bands attributed to the symmetric stretching mode of the terminal

Table 1 Metal (Mo, W or Re) content, interplanar spacing, average pore diameter, wall thickness and BET surface area (S_{BET})[a] in mesoporous silicates

Run	Operating Mode with M[b]	Si/M molar ratio: Gel	Si/M molar ratio: Calcined product	d_{100} spacing/Å	Unit cell parameter a_o/Å	Average pore diameter[c]/Å	Wall thickness[d]/Å	S_{BET}/ $m^2\ g^{-1}$
1	A_{Mo}	50	35	32	37	18	19	1072 ± 60
2	B_{Mo}	50	52	32	37	16	21	1176 ± 60
3	C_{Mo}	50	180	36	41.5	17	24.5	1037 ± 40
4	A_W	50	35	33.5	39	18	21	921 ± 60
5	B_W	50	45	33	38	16	22	897 ± 40
6	A_{Re}	50	300	31.1	36	15	21	1200 ± 60
7	B_{Re}	50	110	31.9	37	16	21	1015 ± 60

[a] These parameters refer to the calcined materials. [b]A corresponds to the oxo–peroxo route ($S^+X^-I^+$ pathway); B to the oxo or polyoxo mode ($S^+X^-I^+$ pathway); C is typical of synthesis in basic medium with $[MoO_2(acac)_2]$ as the molybdenum(VI) precursor (S^+I^- pathway). [c] Measured by BJH method (desorption). [d] Wall thickness given by the difference between a_o and the average pore diameter.

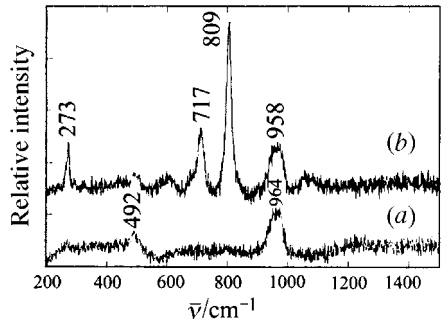

Fig. 1 Raman spectra of mesoporous tungstosilicate [W]-MCM-41; molecular sieves prepared by the oxo-peroxo route (a) and by the oxo–polyoxo mode (b).

W=O bonds are observed at 964 or 958 cm^{-1}. This assignment is still questionable:[9] terminal Si–O stretching of SiOH···OW 'defective sites' may also contribute. For sample A_W [Fig. 1(a)], no Raman bands due to crystalline WO_3 (*vide infra*) or to '$WO_3{\cdot}2H_2O$'[10] [960 (sharp), 685-662 (broad), 380 and 268 cm^{-1}] are observed. The minor Raman band at 215 cm^{-1}, associated with the W–O–W deformation mode,[11] is absent from these spectra but it must be kept in mind that W–O–W linkage can nevertheless exist, since the pore walls of M-MCM-41 resemble amorphous materials rather than crystalline molecular sieves. On the other hand, the Raman spectra of B_W materials, prepared by the aqueous method using ammonium metatungstate, $(NH_4)_6[H_2W_{12}O_{40}]$ or $Na_2[WO_4]$, at ambient temperature and calcined in air at 920 K [Fig. 1(b)], exhibit strong bands due to crystalline WO_3[10–12] at 809, 717 and 273 cm^{-1}, which are assigned to the stretching modes and to the deformation mode (δ) of the O–W–O moieties.[10] The observation of very strong Raman features due to crystalline WO_3 (sample B_W) indicates the formation of a very poorly dispersed SiO_2-supported tungsten oxide phase. Therefore, when the sample is heated, the polytungstate ions transform readily into bulk WO_3 surface species. The achievement of highly dispersed Mo, W and even Re oxo species for these silica-based materials obtained by the aqueous method is attributed to the low nuclearity of the species stabilized by H_2O_2, *e.g.* $\{MO(O_2)_2(H_2O)_2\}$, (M = Mo, W)[7] or $[MeRe(O_2)_2(H_2O)]$, or more simply by $[ReO_4]^-$.

Typical A_{Mo}, A_W, A_{Re} and B_{Re} samples exhibit a reversible, nearly hysteresis-free, type IV isotherm. Nitrogen BET surface areas (Table 1) are in the same range. Desorption hysteresis is not observed for A_{Mo}, A_W, A_{Re} and B_{Re}: a high degree of pore blocking does not occur in these samples but may do so in B_{Mo} and B_W. Mean pore sizes of *ca.* 18 Å (A_{Mo} and A_W) and 16 Å (B_{Mo} and B_W) are found by the BJH method, which is considered to underestimate the real pore size. These values are in fair agreement with TEM measurements, as is the wall thickness (19–22 Å).

X-Ray EDS experiments used to locate and quantify submicroscopic distributions of the Mo, W or Re species reveal that the Mo or W distribution in the typical $A_{Mo\ or\ W}$ solid is nearly homogeneous; the relative at %Mo[W] being 1.75[2.8] with a difference of 0.7[0.6] between maximum and minimum values.

However, B_{Mo} and B_W have a very inhomogeneous molybdenum or tungsten distribution; the average value is *ca.* 3.0 wt% (B_{Mo}) and values as high as 7.4% are also found, typical differences between maximum and minimum values being 7%. These results compare well with the other data; they indicate that there is a high dispersion or a 'quasi-homogeneous distribution' of the Mo or W sites in samples A, while in samples B there is a less ordered distribution between two (or more) phases as a consequence of phase segregation (*vide supra*).

Syntheses in acidic media would appear to be better than the basic S^+I^- pathway for the incorporation of M into mesoporous silica. The oxo–peroxo route, for Mo(VI) and W(VI), and the perrhenic acid route for Re(VII) in the $S^+X^-I^+$ mediated pathway are evidently better than synthesis with oxo–polyoxo species in acidic media for obtaining d^0 metal sites distributed throughout the bulk in spatially uniform states. Even if molybdenum(VI), tungsten(VI) and rhenium(VII) are not statistically and perfectly distributed in the hexagonal cell, high incorporation levels (Si/Mo $\simeq$ 35) never achieved before[1] can be obtained with high dispersion of the M species in the framework of the mesoporous materials. Samples A_{Mo} catalyze the oxidation of (*R*)-(+)-limonene with TBHP–decane mixtures (conversion 90%, selectivity to epoxides $\geqslant$98%). Different leaching behaviours are observed as a consequence of the different catalyst preparation methods; they are also related to the nucleophilicity of the reactants and to surface properties. Samples A_M and B_{Re} are also efficient catalysts for oct-1-ene methathesis, some of them without addition of Bu_4Sn or Ph_2SiH_2 cocatalysts. Work is in progress to control these systems better and to optimize epoxidation and metathesis results.

Notes and references

† *Preparation of samples:* A_{Mo} and A_W: MoO_3 (0.36 g, 2.5 mmol) [$WO_3{\cdot}H_2O$ (0.625 g, 2.5 mmol)] was first reacted with 15 wt% aqueous H_2O_2 (5 ml, 24.5 mmol). After 1 h stirring at 60 °C the solution, denoted A_1, was cooled to room temp. [followed by centrifugation (15 min at 2000 rpm)]. TEOS ($\approx$28 ml, 0.125 mol) was mixed with a solution of CTMACl (20 ml, 15 mmol) and 12.5 M HCl (92 ml, 1.15 mol) in H_2O ($\approx$220 ml, 17 mol); solution A_1 (Mo or W: 2.5 mmol) was then quickly added. The composition of the gel was: 1 TEOS:0.12 CTMACl:8.9 HCl:136 H_2O:0.19 H_2O_2:0.02 MoO_3. The reaction mixture was stirred (200 rpm) at ambient temperature for 1 h. The pale yellow [white] solid was isolated by filtration, washed with distilled water and dried over P_4O_{10} to give the initial sample. After efficient drying at room temperature, the powder was calcined in air (200 cm^3 min^{-1}, 1 K min^{-1}) from ambient temperature to 880–920 K (samples maintained at the final temperature for 4 h) to give sample A_{Mo} [A_W].

B_{Mo} and B_W: syntheses were adapted from methods previously described[13] for $(Si/Mo)_{initial} \approx 100$ mol/mol. To a solution of CTMACl (7.3 g, 0.02 mol) and 12.5 M HCl (8 ml, 0.1 mol) in H_2O (270 ml, 15 mol) were added precursor K_2MoO_4 (0.48 g, 2 mmol) [Na_2WO_4 (0.59 g, 2 mmol)] and TEOS (22.3 ml, 0.1 mol). The reaction mixture was stirred vigorously at ambient temperature for 24 h, then filtered, washed and treated as above for A_{Mo} and A_W.

A_{Re} and B_{Re}: MTO was prepared by a slightly modified version of the published method[14] starting from 10 g of Re_2O_7 in an overall yield of 85% after silica gel chromatography and recrystallization. $HReO_4$ was prepared from H_2O_2 (30% m/v) and metallic rhenium. A_{Re} and B_{Re} were prepared by a modification of the A_{Mo}, A_W and B_{Mo}, B_w pathways.

STM observation of 12-hydroxyoctadecanoic acid and its 4,4′-bipyridinium salt self-assembled on a graphite surface†

Pu Qian,*‡ Hiroshi Nanjo, Toshiro Yokoyama and Toshishige M. Suzuki*

Tohoku National Industrial Research Institute, 4-2-1 Nigatak, Miyagino-ku, Sendai, 983-8551 Japan.
E-mail: B.Sen@tniri.go.jp (P.Qian) and suzuki@tniri.go.jp (T.M.Suzuki)

Received (in Cambridge, UK) 15th February 1999, Accepted 17th May 1999

Self-assembled monolayers of the gelling agent, 12-hydroxyoctadecanoic acid and its 4,4′-bipyridinium salt have been observed on the solution graphite interface using scanning tunnelling microscopy (STM) and the molecular patterns are discussed wth respect to the intermolecular hydrogen bond network.

Some types of amphiphiles act as gelling agents for organic solvents.[1] Among them, 12-hydroxyoctadecanoic acid (12-HOA) has attracted extensive attention from fundamental as well as practical points of view.[2–4] A wide range of solvents can be gelled by 12-HOA and hence this reagent has been applied to the recovery of spilled oil or disposal of used kitchen oil.[1] It has been pointed out that non-covalent weak interactions are responsible in controlling the self-assembling mode and the stabilization of aggregates.[1,4,5] The presence of the hydroxyl group in 12-HOA seems particularly important to the gelling ability of 12-HOA since stearic acid does not show this property. A structural model of a 12-HOA aggregate has been proposed by Terech *et al.* on the basis of neutron and X-ray scattering investigations.[6] An infinite network of hydrogen bonds between hydroxy groups has been suggested to stabilize the plate-like building unit, which is interconnected leading to construction of a three-dimensional fibrous polymer.[6]

Scanning tunnelling microscopy (STM) has provided molecular images of self-assembled molecules at atomic resolution.[7,8] Monolayers of self-assembled amphiphiles including fatty acids have been directly observed at solution–solid interfaces by STM and the morphologies of the two dimensional crystals discussed and interpreted in terms of intra- and inter-molecular hydrogen bonds.[9–12] We have attempted to observe directly the molecular patterns of the monolayers formed with 12-HOA and stearic acid as well as their 4,4′-bipyridinium salts, to clarify the molecular interaction, especially the role of the hydrogen bond network on the molecular assembly and gel formation ability.

A warm solution (*ca.* 0.5 wt%) of racemic 12-HOA (Aldrich Co.) in octylbenzene was applied on the surface of freshly cleaved highly oriented pyrolytic graphite (HOPG). Upon cooling to room temperature (23–26 °C), the solution became a gel. We have successfully observed the STM image of a self-assembled monolayer of 12-HOA on the HOPG surface under an organic gel layer.[13] Fig. 1(a) and 2(a) show the STM images of 12-HOA and stearic acid over a scan area of 10 × 10 nm along with their possible geometries [Fig. 1(b) and 2(b)]. Edges

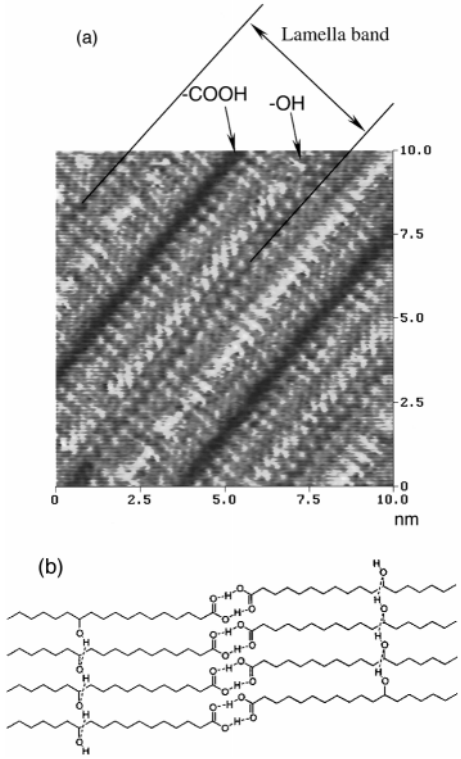

Fig. 1 (a) The STM image (10 × 10 nm) of a 12-HOA monolayer self-assembled on an HOPG surface. The image was obtained in constant current mode with a tungsten tip. Bias voltage and tunneling current were −1.47 V (tip negative) and 266 pA, respectively. (b) A possible geometry of the molecular alignment.

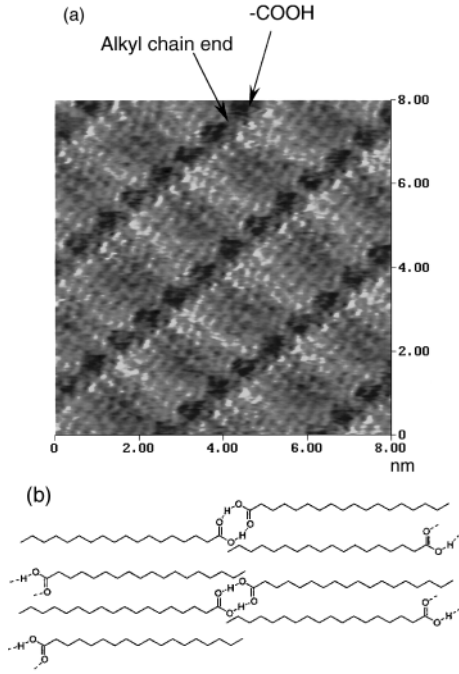

Fig. 2 (a) The STM images (8 × 8 nm) of a stearic acid monolayer self-assembled on an HOPG surface. The image was obtained in constant current mode with a tungsten tip. Bias voltage and tunneling current were −1.58 V (tip negative) and 682 pA, respectively. (b) A possible geometry of the molecular alignment.

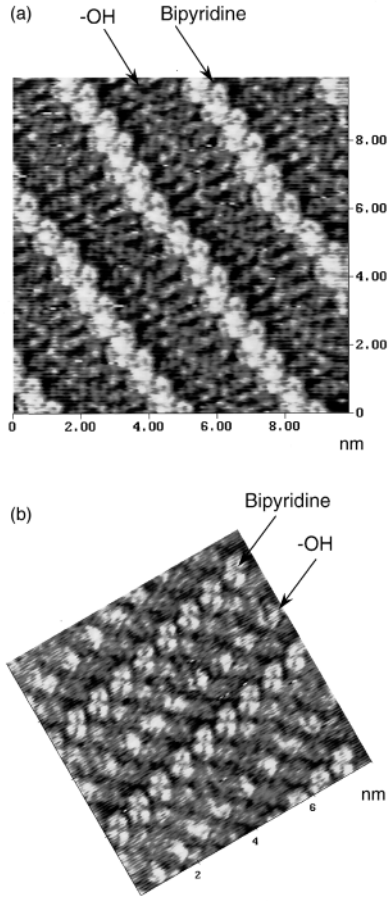

Fig. 3 The STM images of a self-assembled monolayer of 12-HOA-bpy. These two molecular orientations are mirror images. The images were obtained in constant current mode with a tungsten tip. (a) The scan area is 10 × 10 nm; bias voltage and tunneling current were 1.18 V (tip positive) and 216 pA, respectively. (b) The scan area is 8 × 8 nm; bias voltage and tunneling current were 1.41 V (tip positive) and 459 pA, respectively.

of multi-layers were not observed in any STM images indicating that the observed images are those of monolayers. Like stearic acid, 12-HOA molecules orient parallel to each other and thick dark areas are observed. The molecular axis orients perpendicularly to the dark stripes forming a centrosymmetric molecular pattern. An interdigitated geometry, in which the head groups alternately point in opposite directions has been suggested for the molecular alignment of stearic acid[9] and other saturated fatty acids[9] (Fig. 2). Thus the dark moiety has been assigned to carboxyl head groups.[9] The distance between the dark regions for stearic acid corresponds to its molecular length (*ca.* 2.5 nm) whereas that for 12-HOA is roughly double the molecular length of 12-HOA assuming that the alkyl chain is fully expanded. Therefore, the 12-HOA molecules are likely to associate in a head to head manner at carboxylic acid groups located in adjacent rows. Two brighter bands observed between thick black stripes can be attributed to the hydroxy groups on the C12 positions. The zigzag shaped dark area at the center of the image corresponds to the lamella boundary between the alkyl chain terminii. The possible molecular alignment is depicted in Fig. 1(b) where intermolecular hydrogen bonds effectively link 12-HOA molecules to form a macromolecular sheet. This molecular pattern, involving an infinite hydrogen bond network, coincides with the plate-like structure in the internal building block of 12-HOA aggregates proposed by Terech *et al.*[6]

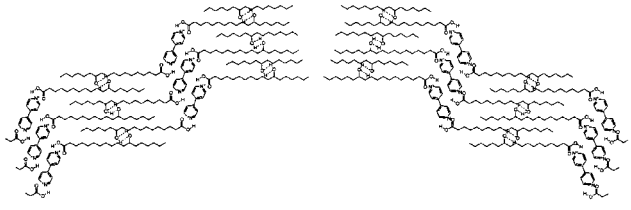

Fig. 4 Schematic representation of a possible molecular alignment for a 12-HOA–bpy monolayer.

In order to confirm our interpretation to the observed images, we have attempted to insert 4,4′-bipyridine (bpy) as a marker between carboxyl groups. A conjugated π-electron system such as bpy might be prominent in a molecular image since areas of higher electronic conductance tend to give brighter images. A mixture of 12-HOA and bpy (2:1) in octylbenzene solution formed a monolayer on HOPG, the molecular image of which is shown in Fig. 3. Remarkably bright regions corresponding to bpy moieties are now observed while the thick dark stripes disappeared. A similar phenomenon is observed in the monolayer image of bpy and stearic acid. Therefore the thick dark band in Fig. 1(a) can consistently be assigned to the region where hydrogen bonded carboxyl head groups are located. Bipyridine molecules sandwiched with 12-HOA appear to be inclined with respect to the alkyl chain at an angle of *ca.* 30°. The distance between the bpy centers is *ca.* 3.6–3.7 nm, which is much longer than that estimated from the molecular lengths of 12-HOA (2.5 nm) and bpy. When the alkyl chains in adjacent rows are associated at the hydroxyl groups as shown in Fig. 4, the observed bpy separations can be rationalized. Interestingly, enantiomeric molecular patterns are found in this system [Fig. 3(a) and 3(b)]. One plausible interpretation is that the racemate 12-HOA–bpy monolayer spontaneously segregates into different domains due to homochiral association at hydroxy groups.[12,14] Fig. 4 shows the proposed molecular arrangement of a 12-HOA–bpy monolayer in which hydroxy groups in vicinal rows are associated to form a polymeric hydrogen bond network. The infinite network of hydrogen bonds might play an important role for building up of the supramolecular assembly of aggregates. It is of note that the bpy salt of 12-HOA also shows gelling ability towards various solvents.

This research was performed as a part of Regional Consortium R&D program conducted by The New Energy and Industrial Technology Development Organization.

Efficient, general synthesis of silylketenes *via* an unusual rhodium mediated Wolff rearrangement

Stephen P. Marsden* and Wai-Kit Pang

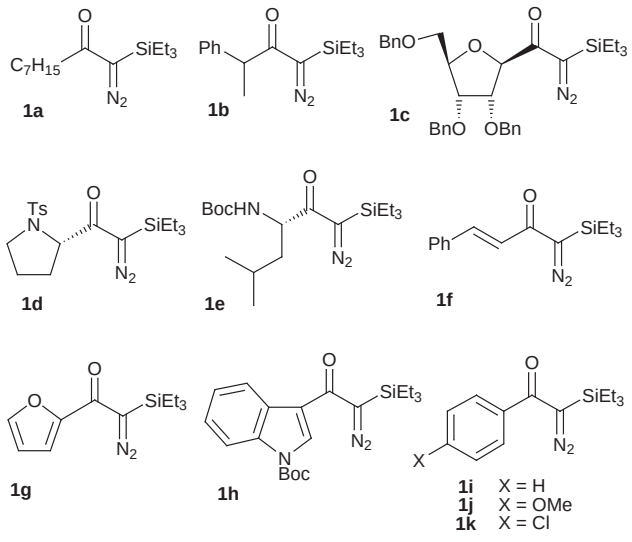
Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: s.marsden@ic.ac.uk

Received (in Liverpool, UK) 30th March 1999, Accepted 12th May1999

Silylketenes bearing a range of substituents (alkyl, alkenyl, aryl, heteroaryl) are prepared by an unusual rhodium mediated Wolff rearrangement of the corresponding silyl diazo ketones.

Silylketenes are potentially extremely versatile intermediates in organic synthesis.[1] These readily isolable ketenes exhibit extraordinary stability in comparison with their non-silylated counterparts; furthermore, whilst their reactivity shares some common modes with the parent compounds, silylketenes also display a unique and useful chemistry unavailable to their non-silylated counterparts. The development of these compounds as routine synthetic intermediates has been hampered to some extent by the paucity of methods for their preparation in terms of yield and functional group tolerance.[2] We report herein a convenient new high-yielding and general preparation of silylketenes based upon a remarkable rhodium(II) octanoate mediated Wolff rearrangement of silylated diazo ketones.

We have previously disclosed results of our investigations into the chemistry of silylated diazo esters. In particular, we have shown that these compounds undergo intramolecular C–H insertion reactions upon treatment with rhodium(II) carboxylate catalysts in refluxing benzene, giving rise to α-silyl γ-lactones[3] (by insertion into the ester group) or oxasilacyclopentanes[4] (by insertion into ethers attached to the silicon). We were therefore interested in examining the behaviour of silylated diazo ketones under similar conditions. However, upon treatment of 1-diazo-1-(triethylsilyl)nonan-2-one[5] **1a** with rhodium(II) octanoate in benzene at room temperature, a rapid and quantitative (by ^{1}H and ^{13}C NMR) conversion to heptyl(triethylsilyl)ketene **2a** occurred (Scheme 1, Table 1). The ketene could be separated from the rhodium catalyst by chromatography, but the 79% isolated yield of the ketene indicates that some decomposition occurs during purification, possibly through hydration. In order to verify the structure of the ketene, we treated the crude reaction mixture with 1.2 equiv. of $BnNH_2$ in CH_2Cl_2 at room temperature to produce the corresponding α-silyl benzylamide **3a**, which was isolated in 91% yield.



We next began to examine the functional group tolerance of this new method. As shown in Table 1, the synthesis appears to be general for a range of diazo ketones. The crude reaction mixtures were examined by ^{1}H and ^{13}C NMR to assess the purity of the ketenes prior to isolation by chromatography and/or derivitisation to the stable α-silyl benzylamides. Conversion to the silylketenes was found to be very clean in all cases, with the exception of ketenes **2e**, **2f** and **2i** which contained some minor contaminants. The isolated yields in Table 1 are lower than the observed spectroscopic purities, suggesting that some decomposition (possibly through hydration of the ketene) occurs on chromatography.

Aliphatic substituents are well tolerated (diazo ketones **1a**–**e**), including those derived from sugars (**1c**) and amino acids (**1d**,**e**). Higher temperatures were required for the decomposition of diazo ketones **1b**–**e**, possibly reflecting the increased hindrance to attack of the catalyst at the diazo carbon from the branched side-chains. The crude ketene **2e** contained unidentified contaminants which could potentially arise from interception of the intermediate carbenoid by the carbamate protecting group, or by intermolecular N–H insertion.

Alkenyl substituted diazo ketone **1f** furnished ketene **2f** after treatment with the catalyst at 80 °C. This ketene was contaminated with some minor components and was isolated pure in only 33% yield; however the 75% isolated yield of the benzylamine adduct attests to the dominance of the ketene pathway. Heteroaromatic substituents were also tolerated, with

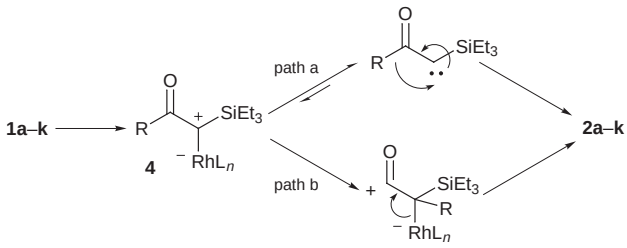
Table 1 Formation of silylketenes by Rh catalysed Wolff rearrangement

Diazo ketone	*T*/°C (*t*/min)	Ketene	Yield (%)[a]	Amide	Yield (%)[b]
1a	20 (10)	**2a**	79	**3a**	91
1b	50 (5)	**2b**	80	**3b**	—[c]
1c	50 (15)	**2c**	41	**3c**	63
1d	80 (30)	**2d**	45	**3d**	0
1e	80 (20)	**2e**	12	**3e**	27
1f	80 (10)	**2f**	33	**3f**	75
1g	60 (30)	**2g**	46	**3g**	87
1h	40 (10)	**2h**	57	**3h**	82
1j	50 (15)	**2i**	54	**3i**	47
1j	20 (5)	**2j**	54	**3j**	60
1k	60 (10)	**2k**	49	**3k**	56

[a] Figures quoted are isolated yields of pure ketene. [b] Yields of amide obtained over two steps from the diazo ketone, without isolation of the ketene. [c] No amide isolated from the reaction with $BnNH_2$.



Scheme 2

2-furyl and indol-3-yl substituted diazo ketones **1g**,**h** rearranging smoothly to the corresponding ketenes **2g**,**h**.

The electronic influence of the diazo ketone substituent upon reactivity is illustrated by the rearrangement of aryl diazo ketones **1i**–**k**. Decomposition of the phenyl-substituted diazo ketone **1i** occurred at 50 °C to give ketene **2i**. Introducing an electron-releasing *p*-methoxy group to the aromatic ring in diazo ketone **1j** allowed the rearrangement to occur at ambient temperature, while the presence of an electron-withdrawing *p*-chloro group in **1k** required the reaction to be carried out at 60 °C. This order of reactivity could be due to the differing electron density available at the diazo carbon for coordination to the rhodium catalyst, or may reflect the development of a partial positive charge on the migrating group during the rearrangement (*vide infra*). The formation of ketene **2i** was accompanied by some minor by-products which were apparent in the ^{13}C NMR spectrum. The ^{1}H NMR spectrum was not sufficiently resolved to allow an estimation of purity of the crude material, but the 54% isolated yield of the pure ketene reflects a lower limit of the efficiency of the reaction.

Alkyl,[6] aryl[6] and alkenyl[7] substituted silylketenes have previously been prepared from silylated diazo ketones by photolysis, or in a few cases by treatment with copper(I) triflate.[6b] However, the formation of silylketenes from the reaction of silylated diazo ketones with rhodium(II) octanoate is somewhat surprising, since it is a generally held view that the use of rhodium catalysts for diazo ketone decomposition suppresses Wolff rearrangement[8] with only isolated exceptions.[9] That the rhodium(II) octanoate is intimately involved in the rearrangement is supported by the fact that no ketene formation was observed in reactions carried out in the absence of catalyst. We suggest two possible explanations for this anomalous behaviour of silyl diazo ketones. The first is that the silyl group destabilises the putative carbenoid intermediate **4** by the tendency of silicon to destabilise α-positive charges,[10] and also potentially by virtue of its bulk. This leads to decomplexation of the metal (path a, Scheme 2) and subsequent Wolff rearrangement from the free carbene. However, in our studies on silyl diazoacetate decomposition we have seen significant catalyst effects upon the stereochemical outcome of insertion reactions,[3] which argues against a decomplexation of the metal catalyst in this closely related system. We therefore suggest a second mechanism for the rearrangement, based upon the ability of silicon to stabilise β-positive charge.[10] Migration of the diazo ketone substituent in the rhodium carbenoid **4** generates an acyl cation which is stabilised by the β-silyl group (path b, Scheme 2). Loss of the σ-bound rhodium species furnishes the ketene and regenerates the catalyst.

In summary a mild, efficient and functional group tolerant synthesis of silylketenes is presented, proceeding *via* an unusual rhodium mediated Wolff rearrangement. Further investigations of this process, as well as synthetic applications of the silylketenes, are now in hand.

We thank the EPSRC for a Quota studentship, the Nuffield Foundation, Pfizer Central Research and the Zeneca Strategic Research Fund for financial support, and Johnson Matthey plc for the generous loan of rhodium salts. We also thank one of the referees for bringing ref. 9 to our attention.

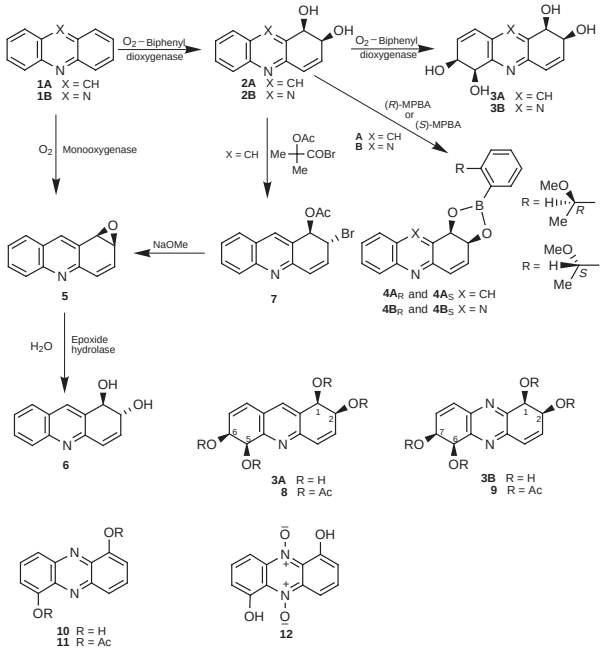
Received (in Cambridge, UK) 26th March 1999, Accepted 17th May 1999

The enhanced stability of new mono-*cis*-dihydrodiol bacterial metabolites of tricyclic azaarenes has facilitated the dioxygenase-catalysed formation and isolation of the corresponding bis-*cis*-dihydrodiols (*cis*-tetraols) and a three step chemoenzymatic route to the derived arene oxide mammalian metabolites.

Dioxygenase-catalysed oxidation of mono- and poly-cyclic arenes by bacteria occurs widely in the environment.[1–3] Dioxygenase enzymes catalyse monohydroxylation (at benzylic and allylic centres), dihydroxylation (at alkene and arene bonds), and a combination of both yielding triol bioproducts (trihydroxylation of alkyl arenes).[1–3] *cis*-Dihydrodiol bioproducts are however very poor substrates for arene dioxygenase enzymes and prior to this communication no report of remote site bis-*cis*-dihydroxylation (tetrahydroxylation) has appeared.

The biodegradation of polycyclic aromatic hydrocarbons (PAHs) in eucaryotic systems, *e.g.* plants, animals and fungi, has frequently been found to proceed *via* monooxygenase-catalysed epoxidation followed by isomerisation to phenols or epoxide hydrolase-catalysed hydrolysis to *trans*-dihydrodiols.[4,5] In a typical example the oxidation of acridine **1A** using rat liver enzymes yielded 2-hydroxyacridine and *trans*-dihydrodiol **6** *via* the arene oxide intermediate **5A** (Scheme 1).[6–8]



Scheme 1

Other studies have shown that remote site oxidation of PAHs can occur with animal liver enzymes to yield combinations of phenol, epoxide and *trans*-diol derivatives in different benzene rings.[9–12] The small quantities of metabolites, *e.g.* bis-*trans*-dihydrodiols, available from such monooxygenase-catalysed (cytochrome-P450) oxidations[9] are generally insufficient to allow rigorous structural or stereochemical analysis.

cis-Dihydrodiol metabolites resulting from oxidation at the 5,6-bond of the bicyclic azaarenes quinoline,[13] 2-chloroquinoline [14] and 2-methoxyquinoline[14] were isolated using a mutant strain (UV4) of the bacterium *Pseudomonas putida* (a source of toluene dioxygenase). These bioproducts were found to be remarkably stable in comparison with their carbocyclic analogues, *e.g.* the 1,2-*cis*-dihydrodiol of naphthalene. On this premise it was anticipated that the corresponding *cis*-dihydrodiol metabolites **2A** and **2B**, if formed from the tricyclic azaarenes acridine **1A** and phenazine **1B**, would be much more stable and consequently could prove to be valuable synthetic intermediates.

Acridine **1A** was biotransformed using a mutant strain of the bacterium *Sphingomonas yanoikuyae* B8/36 (a source of biphenyl dioxygenase, BPDO) following the reported procedure.[15] After removal of the bacterial cells the bioproducts were then extracted with EtOAc to yield a relatively polar compound (R_f 0.2, 5% MeOH in $CHCl_3$) which was identified by spectral methods (NMR, MS) and elemental microanalysis as dihydrodiol **2A**. ^{1}H NMR spectroscopy established that *cis*-dihydroxylation had occurred exclusively at the 1,2-position ($J_{1,2}$ 4.7 Hz). Reaction of *cis*-diol **2A** ($[\alpha]_D$ +72, MeOH) with (*R*)-(+)- and (*S*)-(−)-2-(1-methoxyethyl)phenylboronic acid (MPBA) yielded the boronate derivatives $\mathbf{4A}_R$ and $\mathbf{4A}_S$ respectively. ^{1}H NMR analyses of the boronates confirmed that *cis*-diol **2A** was enantiopure (> 98% ee); the absolute configuration was determined as (*1R,2S*) by application of the empirical ^{1}H NMR rule earlier established for a series of MPBA derivatives from other *cis*-dihydrodiol metabolites of PAHs [15, 16] (Table 1). The (*1R,2S*) configuration for *cis*-diol **2A**

Table 1 Yields, optical rotations and absolute configurations for metabolites **2A**, **2B**, **3A** and **3B** obtained using *S. yaniokuyae* B8/36, and derivatives **8**, **9** and **5**

Compound	Isolated yield (%)	$[\alpha]_D/10^{-1}$ deg cm^2 g^{-1} (solvent)	Absolute configuration
2A	50–55	+72 (MeOH)	1*R*,2*S*
2B	40	+102 (MeOH)	1*R*,2*S*
3A	12	+266 (Pyridine)	1*R*,2*S*,5*R*,6*S*
3B	15	+180 (MeOH)	1*R*,2*S*,6*R*,7*S*
8	95	+63 ($CHCl_3$)	1*R*,2*S*,5*R*,6*S*
9	95	+83 ($CHCl_3$)	1*R*,2*S*,6*R*,7*S*
5	55	+30 ($CHCl_3$)	1*R*,2*S*

was independently confirmed by a stereochemical correlation process involving oxidative degradation of the derived 1,2-diacetoxy-1,2,3,4-tetrahydroacridine to give (2*S*,3*S*)-(−)-dimethyl (2,3-diacetoxy)adipate of known configuration.[17]

In later biotransformation studies of acridine **1A**, total removal of water from the centrifuged culture medium at 35–40 °C under reduced pressure, followed by extraction of the semi-solid residue with EtOAc–MeOH (9:1) yielded a mixture of *cis*-diol **2A** and a more polar metabolite (R_f 0.15, 12% MeOH in $CHCl_3$) which was identified as the bis-*cis* diol **3A** (Table 1) on the basis of ^{1}H NMR (COSY, NOE) and MS data and formation of tetraacetate **8**. The chirality of the bis-*cis*-diol **3A** suggested that it was formed by initial *cis*-dihydroxylation of acridine **1A** at the 1,2-bond on the *Si*:*Si* face of the molecule followed by further *cis*-dihydroxylation at the 5,6-bond again on the *Si*:*Si* face to yield the (*1R,2S,5R,6S*) enantiomer exclusively. Confirmation that the bis-*cis*-diol **3A** had been derived from the mono-*cis*-diol **2A** was obtained by its addition as substrate to *S. yaniokuyae* B8/36. The samples of bis-*cis*-diol **3A**, isolated from metabolism of either acridine **1A** or the mono-*cis*-diol **2A**, were found to be indistinguishable.

Biotransformation of phenazine **1B** with *S. yaniokuyae* B8/36 or *Pseudomonas putida* 9816/11 (a source of naphthalene dioxygenase, NDO), and the normal extraction procedure yielded, in both cases, a mono-*cis*-dihydrodiol (R_f 0.45, 10% MeOH in $CHCl_3$, 5% yield from NDO and 40% yield from BPDO) which was identified as *cis*-1,2-dihydroxy-1,2-dihydrophenazine **2B** from ^{1}H NMR ($J_{1,2}$ 4.3 Hz) and MS analyses. Formation of MPBA derivatives $\mathbf{4B}_R$ and $\mathbf{4B}_S$ of the mono-*cis*-diol **2B** and their ^{1}H NMR analyses established that it was enantiopure (> 98% ee) and of (*1R,2S*) configuration from both bacterial mutant strains. Application of the improved extraction procedure (EtOAc–MeOH after removal of water from the centrifuged bioextracts) led to the isolation of a mixture of (*1R,2S*)-mono-*cis*-diol **2B** with a second metabolite (R_f 0.12, 15% MeOH in $CHCl_3$) from the *S. yaniokuyae* B8/36 biotransformation. This very polar bioproduct was identified as the phenazine bis-*cis*-dihydrodiol **3B** from NMR, MS and CD spectral data and formation of tetraacetate **9**; the structure was confirmed by aromatisation (thermal dehydration) and acetylation of the resulting bis-phenol **10** to yield 1,6-diacetoxyphenazine **11**.[18]

When (*1R,2S*)-mono-*cis*-diol **2B** was added as substrate to *S. yaniokuyae* the bis-*cis*-diol **3B** was isolated as the sole metabolite. The CD spectra of the bis-*cis*-diols **3A** and **3B** were found to be very similar, as anticipated. Thus the absolute configurations **(***1R,2S,5R,6S***)** and **(***1R,2S,6R,7S***)** were assigned for metabolites **3A** and **3B**, respectively**.** 1,6-Dihydroxyphenazine **10**, obtained by dehydration of the metabolite bis-*cis*-dihydrodiol **3B**, and the derived 1,6-dihydroxyphenazine 5,6-dioxide (iodinin) **12** have also been isolated from among a range of phenazine antibiotics produced as secondary metabolites in other bacterial systems.[19]

A further manifestation of the stability of the mono-*cis*-dihydrodiol **2A** became apparent from the reaction with 2-acetoxyisobutyryl bromide. It was anticipated that the resulting product, 1-acetoxy-2-bromo-1,2-dihydroacridine **7**, would aromatise spontaneously. However, compound **7** proved to be sufficiently stable to be isolated and identified by ^{1}H NMR analysis (crude yield *ca.* 80%) prior to treatment with NaOMe to yield (*1R,2S*)-(+)-1,2-epoxy-1,2-dihydroacridine (acridine 1,2-oxide, **5**). Thus the eucaryotic metabolite **5**, derived from acridine **1A**, was obtained as a single enantiomer in two steps with an overall yield of *ca.* 55% from the procaryotic metabolite **2A**. This procedure compares favourably with our earlier method for the synthesis of enantiopure acridine 1,2-oxide **5**, an eight step synthesis with an overall yield of 18%.[4,8] It also represents a significant improvement over an earlier five step method for the synthesis of enantiopure arene oxides of PAHs from the corresponding *cis*-dihydrodiols.[20]

Preliminary studies have indicated that the two-step synthetic procedure (**2A**→**7**→ **5**) used for the arene oxide synthesis is also applicable to other relatively stable *cis*-dihydrodiol metabolites of bi- and tri-cyclic azaarenes, *e.g.* the *cis*-dihydrodiols of 2-chloroquinoline (5,6- and 7,8-).[14] All arene oxide derivatives of azaarenes (*e.g.* acridine 1,2-oxide **5**) were found to hydrolyse, under aqueous conditions, to the corresponding *trans*-dihydrodiols (*e.g.* **6**) by exclusive nucleophilic attack at the allylic position.[7,8] The *cis*-dihydrodiol **2A** was also a minor hydrolysis product of arene oxide **5**.[8]

Recent studies of the bacterial metabolism of tetracyclic arene substrates, each containing two bay regions (chrysene and benzo[*b*]naphtho[2,1-*d*]thiophene), using *S. yanoikuyae* B8/36, have shown the formation of relatively unstable bis-*cis*-dihydrodiols as minor metabolites (0.3 and 3% yield, respectively).[21] Thus the new family of enantiopure arene tetraol metabolites arising from sequential *cis*-dihydroxylation on the arene *Si*:*Si* face is not confined to the linear azaarene series and more examples are anticipated.

We thank the U.S. Public Health Service grant GM29909 from the National Institute of General Medical Sciences (D. T. G.), the BBSRC (N. D. S) and the QUESTOR Centre (C. C. R. A and D. T. C.), for financial support. We also wish to acknowledge the valuable experimental assistance provided by Eric Becker and Heiko Nieke (Fachhochschule Mannheim under the EU Socrates Programme).

Synthesis of pseudo-oligosaccharides by a sequence of yne-ene cross metathesis and Diels–Alder reaction

Stephan C. Schürer and Siegfried Blechert*

Institut für Organische Chemie, Sekr. C3, Technische Universität Berlin, Straße des 17. Juni 135, D-10623 Berlin, Germany. E-mail: sibl@wap0105.chem.tu-berlin.de

Received (in Liverpool, UK) 21st April 1999, Accepted 17th May 1999

Various pseudo oligosaccharides were prepared by a combination of selective yne-ene cross metathesis and Diels–Alder reaction from readily available monosaccharide building blocks.

Oligosaccharides have been implicated as key participants in a number of biological processes including signal transduction and a wide range of recognition events.[1] Because of this tremendous biological importance, carbohydrates have aroused much interest in synthetic and medicinal chemistry.[2]

During recent years the number of applications of olefin metathesis as a very mild and competitive synthetic method[3] has been considerably increased, due to the availability of well-defined catalysts, in particular Grubbs' well-established ruthenium initiator $Cl_2(PCy_3)_2Ru{=}CHPh$ (**Ru**, Cy = cyclohexyl).[4] However, olefin metathesis has rarely been used in carbohydrate chemistry. Most applications are ring closing metatheses (RCM) for the synthesis of monosaccharide derivatives[5] and few examples exist for ring opening metathesis polymerisation (ROMP) involving carbohydrates.[6] A very recent publication describes the homodimerisation of a number of olefinated pyranosides.[7] Selective cross metatheses employing monosaccharide building blocks have not been studied, apart from some isolated examples.[8,9] Nonetheless, the selective cross coupling of monosaccharide building blocks is very intriguing since the diversity of accessible carbohydrate derivatives is much higher compared to simple homodimerisation.

A selective cross metathesis between a terminal alkyne and a terminal alkene yielding 1,3-disubstituted butadienes has been found recently in our laboratory.[9] These 1,3-dienes, formed by yne-ene cross metathesis, represent attractive starting materials for subsequent Diels–Alder reactions (Scheme 1).

However, little is known about Diels–Alder transformations of nonactivated acyclic 1,3-dienes,[10] which are regarded as poor substrates for Diels–Alder reactions. As there were no examples of Diels–Alder reactions incorporating carbohydrate-substituted 1,3-butadienes, we started investigations on yne-ene cross metatheses of monosaccharide building blocks and subsequent Diels–Alder transformations, providing an easy and very flexible access towards pseudo-oligosaccharides.

Introducing acetylated 1-*O*-allyl- and 1-*O*-propargyl-glycopyranoside as the alkene and alkyne components to yne-ene cross metathesis followed by $MeAlCl_2$-catalysed Diels–Alder reaction with methyl vinyl ketone yielded compounds **1** and **2**, respectively (Fig. 1).†

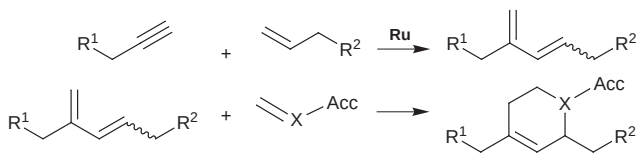
A number of allyl- and propargyl-substituted carbohydrate building blocks was then prepared and introduced to yne-ene cross metathesis followed by Diels–Alder transformation according to Scheme 2. The combination of acetylated 1-*O*-allyl- and 1-*O*-propargyl-glyco- and -galacto-pyranosides afforded pseudo-oligosaccharides **3** and **4** in high yields.‡

A problem of all cross metathesis reactions that has not been solved as yet is the formation of *E*/*Z* mixtures,[3] usually resulting in stereoisomeric mixtures after subsequent transformations. Although the described Diels–Alder reaction proceeds with excellent regioselectivity, diastereomeric mixtures are obtained, due to the incorporation of *E*/*Z* mixtures of the carbohydrate-substituted 1,3-dienes. The diastereomers refer to the relative configuration of the cyclohexene substituents. However, this disadvantage can be overcome by equilibration into the thermodynamically more stable *trans*-configuration using NaOMe in MeOH–THF with simultaneous cleavage of any acetate protective groups (Scheme 2).

This equilibration–deprotection strategy has been successfully applied to the preparation of compounds **8**–**10**, where acetyl- and benzyl-protected β-D-glyco- and β-D-galacto-pyranosides with glycosidic and nonglycosidic linkage of the respective carbohydrate residue have been employed.

In addition to the described Lewis acid catalysed Diels–Alder reactions of 1,3-dienes we focused on aza-Diels–Alder transformations, since these would provide access to biologically interesting pipecolic acid derivatives substituted by two variable carbohydrates (Scheme 3).

As dienophiles we employed *N*-trichloroethylidene toluene-*p*-sulfonamide and ethyl (4-tolylsulfonylimino)acetate. Similar



Scheme 1

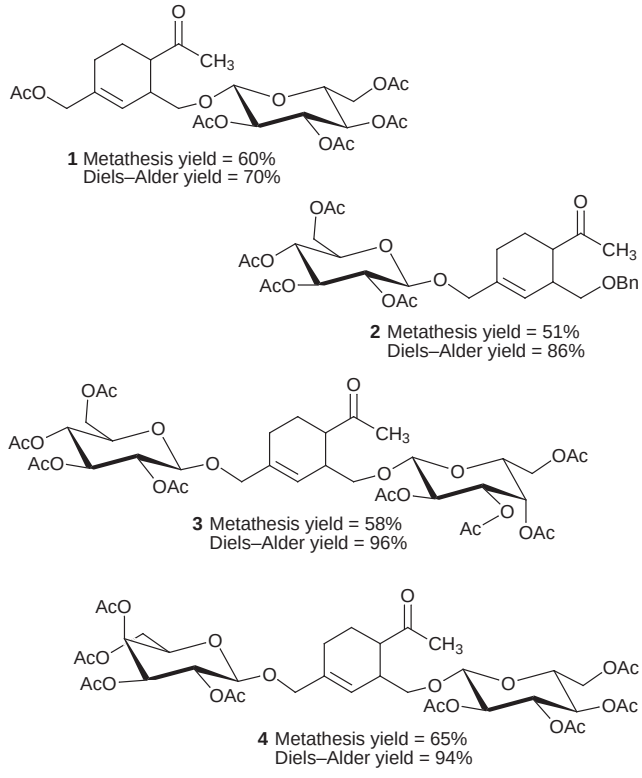


Fig. 1 Yields of **1**–**4**.

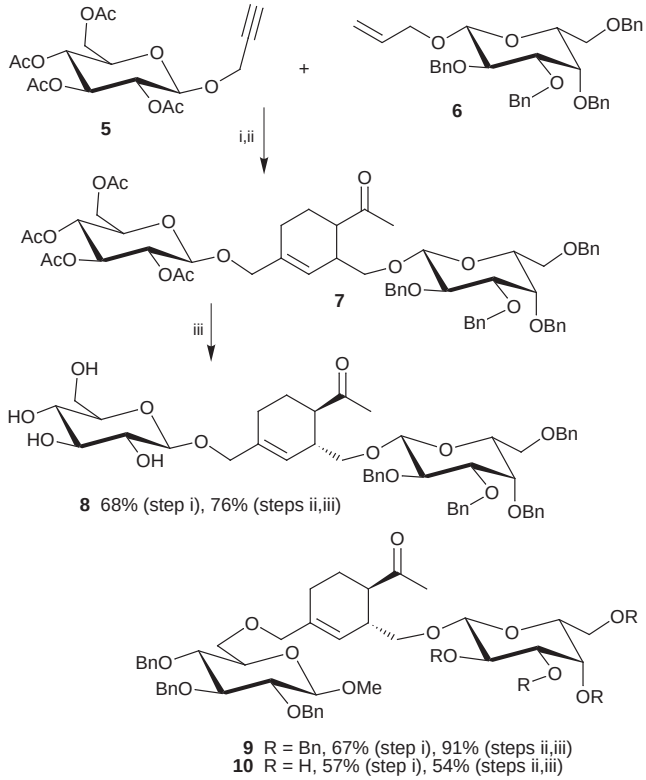
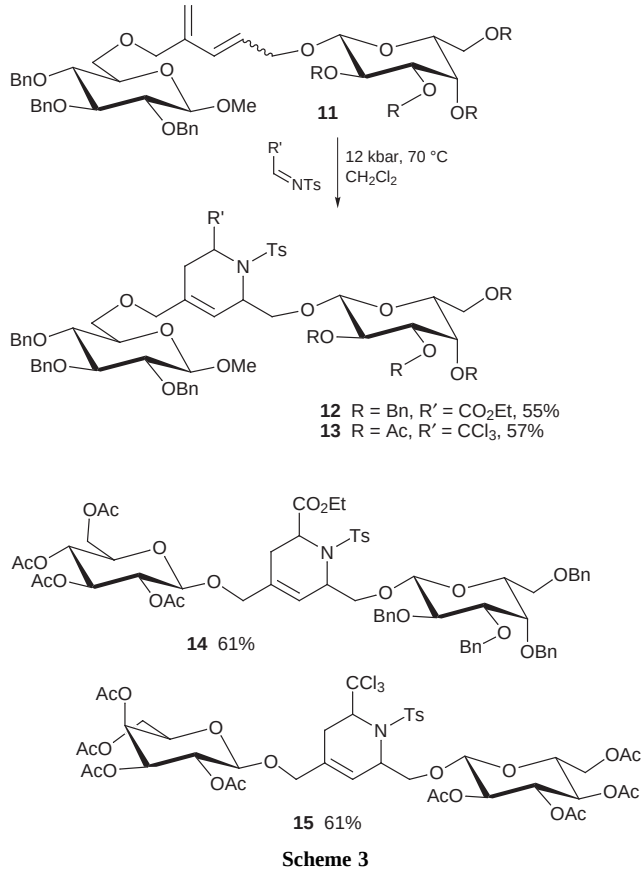


Scheme 2 *Reagents and conditions*: i, **Ru** (10%), CH_2Cl_2; ii, methyl vinyl ketone, $MeAlCl_2$, CH_2Cl_2–PhMe, −35 °C; iii, NaOMe, MeOH–THF.



Scheme 3

to the Diels–Alder reactions described above, acetyl- and benzyl-protected β-D-glyco- and β-D-galacto-pyranosides with glycosidic and nonglycosidic linkages have been introduced to aza-Diels–Alder transformations, which were found to proceed with moderate to reasonable yield and excellent regioselectivity under 12 kbar pressure at 70 °C in CH_2Cl_2 to yield pseudo-oligosaccharides **12**–**15**.

In conclusion, we have developed a general sequence of selective yne-ene cross metathesis, Diels–Alder transformation and equilibration–deprotection for the synthesis of various biologically interesting carbohydrate derivatives. The combination of different monosaccharide building blocks and dienophiles has been demonstrated and should potentially give rise to a large number of pseudo-oligosaccharides of the types presented. Further investigations to explore the scope of the described reactions are now in progress.

We are thankful to the Fonds der Chemischen Industrie for financial support and to Priv. Doz. Dr J. Jakupovic for NMR characterisation of some of the presented compounds.

Notes and references

† *Yne-ene cross metathesis*: 5 mol% of **Ru** was added to a solution of 0.5 mmol of alkyne and 1.5–2.0 equiv. of alkene in CH_2Cl_2 (0.2 M concentration). After 12 h stirring another 5 mol% of **Ru** was added. After an additional 18 h the product was purified by column chromatography.

$MeAlCl_2$-catalysed Diels–Alder reaction: To a solution of 100 μmol of 1,3-diene and 20 equiv. of methyl vinyl ketone in 3 ml of CH_2Cl_2 and 1 ml of toluene, $MeAlCl_2$ (3 equiv.) was added at −78 °C. The reaction was stirred for 24 h at −35 °C and then quenched at −78 °C by addition of 10 equiv. of Et_3N and 1 ml of MeOH, followed by filtration through silica gel, concentration, and purification by column chromatography.

Equilibration and deprotection: The cycloadducts were stirred with 0.02 M NaOMe in MeOH–THF (1 : 1, v/v) at 0.01 M concentration for 12 h and then neutralised by addition of weakly acidic ion exchange resin, followed by filtration and purification by column chromatography.

High pressure aza-Diels–Alder reaction: A solution of 100 μmol of 1,3-diene and 1.5–2.0 equiv. of dienophile (0.2 M concentration) in CH_2Cl_2 was heated in a Teflon tube to 70–75 °C under 12 kbar pressure for 40 h. The product was purified by column chromatography.

‡ All prepared pseudo-oligosaccharides have been characterised by ^1H NMR, ^{13}C NMR, FAB-MS and IR spectroscopy. Additional 2D NMR spectra (COSY, HMQC, TOCSY, HMBC) have been obtained.

Taming the coil: stabilizing a model hemoprotein fold *via* macrocyclization and peptide helix capping

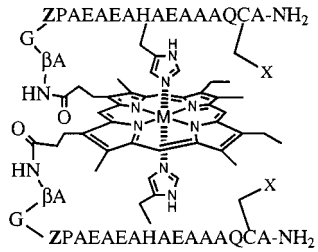
Dahui Liu, Kyung-Hoon Lee and David R. Benson*

Department of Chemistry, University of Kansas, Lawrence, KS 66045-0046, USA.
E-mail: dbenson@caco3.chem.ukans.edu

Received (in Columbia, MO, USA) 16th February 1999, Accepted 17th May 1999

An N-terminal helix capping motif combined with a C-terminal disulfide bridge stabilizes the fold of a designed hemoprotein model.

Structural stability of many proteins is enhanced by disulfide bonds[1] or by coordination of metal ions to groups of amino acid side chain ligands.[2] Induction of helicity in short peptides has also been accomplished using these and other side chain-side chain interactions.[3] Employing a related approach, we achieved moderate helix induction upon histidine (His) to iron coordination in covalent peptide–porphyrin adducts known as peptide-sandwiched mesohemes (PSMs).[4] Similar helix induction was obtained in a disulfide-dimerized peptide upon complexation of a cobalt(III) porphyrin.[5] To aid our goal of creating small hemoprotein mimics having protein-like stability, we have been exploring ways to further reduce peptide conformatioal flexibility in our designs. The successful use of aromatic side chain–porphyrin interactions in the PSMs has recently been reported.[6]



A = Ala; C = Cys; E = Glu; G = Gly; H = His; Q = Gln; P = Pro

1 X,X = S–S; Z = Asn; M = Fe^{III}
2 X = SAcm; Z = Asn; M = Fe^{III}
3 X = SAcm; Z = Gln; M = Fe^{III}
4a,b X,X = S–S; Z = Asn; M = Co^{III}

Herein we report preliminary results with **1**, in which extraordinarily high helix content is achieved through a combination of Fe–His coordination, an N-terminal helix capping motif, and macrocyclization *via* disulfide bond formation.

Lack of hydrogen bonding partners for the first and last few amino acids in a peptide helix results in fraying at each terminus.[7] Protein helices often terminate with a capping motif, which reduces the number of unsatisfied hydrogen bonding sites.[8] In the capping box motif, an amino acid with a hydrogen-bond acceptor on its side chain is situated prior to the first N-terminal helical residue. The side chain of this Ncap hydrogen bonds to the backbone amide NH of the third residue in the helix (N3), which otherwise would not have a hydrogen bonding partner other than water. The side chain of N3 (commonly glutamic acid; Glu) reciprocates by hydrogen-bonding to the backbone amide of the Ncap. The importance of side chain entropy in this end-cap motif is highlighted by the fact that asparagine (Asn) is one of the best Ncap residues in peptides while glutamine (Gln) is one of the worst.[9]

One of the most common amino acids at the first position (N1) of protein helices is proline (Pro).[10] Pro is especially useful at N1 as its backbone ϕ angle (which is ideal for residing in a helix) is fixed by its cyclic structure. Lack of a backbone amide hydrogen further works in favor of Pro at N1, as it needs no hydrogen bonding partner.

Based on the above considerations, Asn, Pro and Glu were selected as the Ncap, N1 and N3 residues in the design of **1**. The backbone torsional angles of Asn were set at the average values observed for Ncap residues in natural proteins (ϕ = −94°; ψ = 167°),[8] while the side chain torsional angles of the His residue coordinated to iron mesoporphyrin IX (MP-IX) were set at the favorable combination χ_1/χ_2 = 180°/−90°.[4,11] When His adopts this combination the peptide helix axis lies at an angle of *ca.* 30° relative to the porphyrin plane and the sulfhydryl group of a cysteine (Cys) residue located i + 7 from His is level with the porphyrin edge and just beyond it.[5] Separating Pro and His by five helical amino acids directed the α-amine of Asn toward the propionate groups of MP-IX, while the sequence β-alanine-glycine (β-Ala-Gly) nicely bridged the gap between the two. When a second peptide was incorporated on the other side of MP-IX, the two Cys residues were situated within bonding distance of one another. Fig. 1 shows a predicted energy minimized structure of **1**.[12]

The bis acetamidomethyl (Acm) protected precursor of **1** (**2**) serves to show how the disulfide linkage in **1** influences its structure and stability. We also prepared an analogue of **2** in which the Ncap Asn has been replaced by Gln (**3**) in order to determine whether Asn functions as intended in our design. Syntheses of **2** and **3** were accomplished using methods previously reported for the PSMs.[4] Brief treatment of **2** with iodine in aqueous 2,2,2-trifluoroethanol (TFE) cleanly yielded **1**.

Circular dichroism (CD) spectra of **1**–**3** are shown in Fig. 2. Using the mean residue ellipticity at 220 nm (θ_{220}) we calculate[13] that the peptides in **2** are 64% helical in aqueous solution at 8 °C (Table 1; only amino acids 4–18 are included in the calculation, as only these residues are predicted to be within the helix). In contrast, helix content in **3** is only 45% in water. The high helicity of acyclic **2** supports the choice of His placement in the peptide sequence, while the results with **3** confirm a helix-stabilizing role for the Ncap Asn. The helix stabilizing solvent TFE increases helix contents of **2** and **3** to 88 and 83%, respectively (Table 1). Finally, comparing spectra of **1** and **2** in H_2O (Fig. 2; Table 1) reveals that macrocyclization strongly increases peptide helix content as predicted. TFE

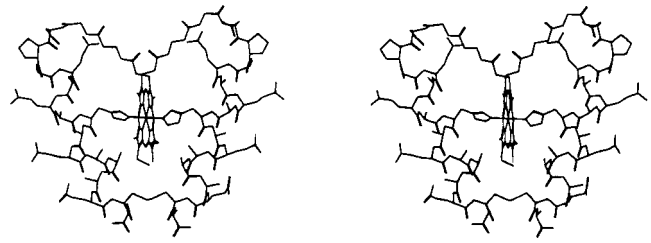


Fig. 1 Structure of one diasteromer of **1** predicted from molecular modeling studies.

Table 1 CD data for **1**–**4** in H_2O and in 3:1 (v/v) H_2O–TFE

	θ_{220}/deg cm² dmol^{-1} [a] (% Helix)[b]	
Compound	H_2O	3:1 (v/v) H_2O–TFE
1	−27 400 (94)	−30 000 (102)
2	−18 700 (64)	−25 800 (88)
3	−13 300 (45)	−24 000 (83)
4a	−25 500 (87)	−27 800 (95)
4b	−27 800 (95)	−30 100 (102)

[a] θ_{max} = −29 300 deg cm² dmol^{-1}. [b] Percent helix values are shown in parentheses.

further increases helix content in **1** from 94% to the theoretical maximum, although the relative intensities of the 208 and 220 nm bands in the two solvents suggest that TFE may cause additional changes to the structure of **1**.

The heme chromophore can contribute ellipticity in the far-UV region of CD spectra of hemoproteins and hemoprotein models.[14] Calculated helix contents reported in Table 1 must therefore be considered estimates only. Nonetheless, because the chromophore and the mode of attachment of peptide to porphyrin are the same in **1**–**3**, it is reasonable to assume that an increase in the absolute value of θ_{220} represents a proportional increase in peptide helix content.

PSMs built from MP-IX exist in two interconvertible diastereomeric forms.[4] Pavone and co-workers have reported that the two diastereomers of bis-His coordinated hemoprotein models constructed from Co^{III} deuteroporphyrin IX can be separated because His–Co^{III} bonds are exchange-inert.[15] We thus prepared and isolated the two diastereomers of the Co^{III} analogue of **1** (**4a** and **4b**). Helix contents of **4a** and **4b** are different, although both are very high. The CD Soret bands of **4a** and **4b** are of opposite sign but nearly equal intensity, whereas the Soret band of **1** is negative (Fig. 2, inset). That the helix contents of **1** and **4b** are nearly identical (and greater than **4a**) and each exhibits a negative Soret suggests that the diastereomer of **1** which corresponds to **4b** predominates at equilibrium. The diastereomer of **1** shown in Fig. 1 is the one predicted to be favored based on molecular modeling studies.

The intramolecular His ligands in **1**–**3** result in Fe–His coordination being strongly favored at neutral pH. However, because Fe–His bonds are exchange labile, at pH values near or below the pK_a of His, protonation of His competes with Fe–His coordination.[4] Protonation of His requires initial scission of the Fe–His bond, which results in conversion of heme from the low spin (S = 1/2; Soret λ_{max} = 402 nm) to the high spin (S = 5/2; Soret λ_{max} = 390 nm) form. One of our predictions with **1** was that the disulfide bridge would stabilize the folded (bis-His coordinated) form of the molecule relative to **2** by reducing the conformational freedom of its peptides in the unfolded form. We thus recorded UV/vis spectra of **1** and **2** in water as a function of pH (Fig. 3). For **2**, spectral changes are observed at pH values as high as 6. No changes were observed in UV/vis spectra of **1**, however, until pH < 5, illustrating the predicted stability enhancement of bis-His coordinated **1**.

In conclusion, we have shown that a combination of motifs commonly encountered in protein structures can provide considerable structural stabilization to hemoprotein models built from short peptides. The results illustrate the power of computer-aided *de novo* design in creating protein mimics having desired structural characteristics. Future work will be aimed at systematically investigating the influence of the Ncap, N1 and N3 residues in **1** and **2** on the stability of the folded form of each molecule. We also plan a detailed study of the three-dimensional structures of **4a** and **4b** using ^{1}H NMR, which will include an examination of how TFE influences peptide architecture.

This work was supported by NIH grant R29-GM52431.

Aerobic catalytic oxidative coupling of 2-naphthols and phenols by $VO(acac)_2$

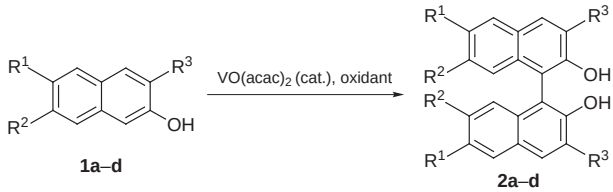
Der-Ren Hwang, Cheu-Pyeng Chen and Biing-Jiun Uang*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300, Republic of China.
E-mail: bjuang@chem.nthu.edu.tw

Received (in Cambridge, UK) 10th March 1999, Accepted 17th May 1999

In the presence of a catalytic amount of $VO(acac)_2$, oxidative coupling of 2-naphthol or phenol derivatives with molecular oxygen occurred at room temperature and selectively gave the corresponding *ortho–ortho* coupling products in moderate to high yields.

Optically active 1,1′-bi-2-naphthol and its derivatives have been widely used in enantioselective synthesis as a source of chirality.[1] There are some known methods for the oxidative coupling of 2-naphthols to give 1,1′-bi-2-naphthols using stoichiomeric amounts of oxidant,[2–4] and some methods employing catalytic oxidative coupling. These methods either use an expensive oxidant (such as AgCl) with low yield,[4c] require the preparation of a complex catalyst [such as CuCl(OH)·TMEDA, $CuSO_4(Al_2O_3)$] before the coupling reaction,[5,6] or perform the reaction at higher temperature [$CuSO_4(Al_2O_3)$, $FeCl_3$].[2a] Oxovanadium complexes were found to have specific catalytic activity towards organic syntheses especially in oxidation reactions.[7] A vast number of synthetic reactions which utilize oxovanadium(v), *i.e.* $VOCl_3$ and VOF_3, as oxidants have been documented, as exemplified by the oxidative coupling of phenols in natural product synthesis.[8] Due to the fact that $VOCl_3$ and VOF_3 are moisture sensitive, hazardous materials,[9] they are not easy to use in practice. Thus it is important to find a more convenient method for the oxidative coupling of phenols. Here we report a convenient oxidative coupling method for 2-naphthols and phenols with molecular oxygen as the oxidant in the presence of a catalytic amount (10 mol%) of $VO(acac)_2$, an inexpensive and stable catalyst (Scheme 1).[10]



1a–d **2a–d**

Scheme 1

To achieve a catalytic cycle in the vanadium mediated coupling of phenols, one has to find an oxidant which will oxidize V^{IV} to V^{V} and will not interfere with the coupling reaction during the catalytic cycle. At the outset, a system consisting of 2-naphthol **1a**, 10 mol% $VO(acac)_2$ and oxidants such as H_2O_2, Bu^tOOH and Oxone was studied. Although 2-naphthol was consumed completely in these cases, only trace amounts of the coupling product **2a** were detected. The remaining materials were intractable. Then, $NaIO_4$ and NH_4IO_4 were used as oxidants. After reaction for 24 h under similar reaction conditions, most of the starting material was recovered and there was no coupling product. Finally, when molecular oxygen was used as oxidant and the reaction was conducted in CH_2Cl_2 at room temperature for 24 h, **1a** was consumed and **2a** was obtained in 92% yield after chromatographic purification.† The coupling product was present only in trace amounts when the reaction was conducted in MeOH.

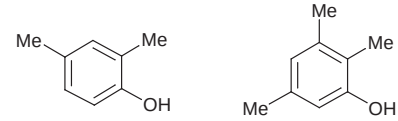
In the case of 6-bromo-2-naphthol **1b**, the coupling reaction was completed in 24 h to give **2b** in 90% yield. The reactivity of electron-donating and electron-withdrawing group substituted 2-naphthols was apparently different. Coupling of **1c** was finished within 9 h, but gave a lower yield due to the formation of some intractable materials. The coupling reaction of 3-(methoxycarbonyl)-2-naphthol **1d** was very sluggish. It gave a 35% yield of **2d** after 120 h, and 62% of **1d** was recovered (Table 1).

Table 1 Oxidative coupling of 2-naphthol and derivatives catalyzed by $VO(acac)_2$[a]

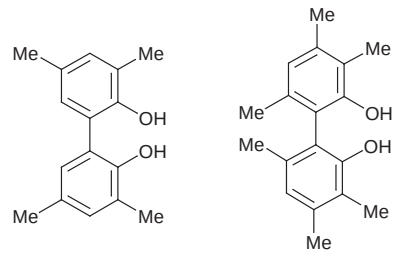
Napthol	R^1	R^2	R^3	*t*/h	Product[b]	Yield (%)
1a	H	H	H	24	**2a**	92
1b	Br	H	H	24	**2b**	90
1c	H	OMe	H	9	**2c**	76
1d	H	H	CO_2Me	120	**2d**	35

[a] The reactions were run with 10 mol% $VO(acac)_2$ in CH_2Cl_2 at room temperature under 1 atm O_2. [b] Compounds **2a–d** were identified according to data reported in ref. 6.

Coupling of phenol under similar reaction conditions was unsuccessful; there was no detectable amount of 1,1′-biphenol present. When 2,4-dimethylphenol **3a** and 2,3,5-trimethylphenol **3b** were subjected to the coupling reaction, the corresponding *ortho–ortho* coupling products **4a** and **4b** were obtained in moderate yields (Table 2). These two reactions are similar in terms of reaction rate. Prolonged reaction time did not give a better yield of coupling product. In the latter case, 28% of **3b**



3a **3b**



4a **4b**

Table 2 Oxidative coupling of alkyl substituted phenols catalyzed by $VO(acac)_2$[a]

Phenol	*t*/h	Product[b]	Yield (%)
3a	120	**4a**	66
3b	48	**4b**	62

[a] Reaction conditions were similar to those for **1a–d**. [b] **4a**,**b** were characterized according to data reported in ref. 11.

was recovered. Reaction of **3a** for 120 h gave a similar yield of **4a** but no **3a** was recovered. Instead, some intractable material was formed.

In conclusion, a facile oxidative coupling method that selectively coupled 2-naphthol or phenol derivatives to the corresponding *ortho–ortho* coupling products, 1,1′-bi-2-naphthols or 1,1′-bi-2-phenols, with molecular oxygen in the presence of a catalytic amount of $VO(acac)_2$ in moderate to high yields has been demonstrated.

We are grateful to the National Science Council, Republic of China, for support of this work.

† *Typical procedure*: A stirred mixture of 2-naphthol (144 mg, 1 mmol), and $VO(acac)_2$ (26.5 mg, 0.1 mmol) in CH_2Cl_2 (10 ml) was exposed under an atmospheric pressure of molecular oxygen at room temperature for 24 h. The mixture was then filtered through a short column of silica gel and the silica gel was washed with EtOAc (40 ml). The filtrate was concentrated and purified by column chromatography (SiO_2, hexane–EtOAc = 5:1) to afford the coupling product **2a** (131 mg, 92%, mp 215–217 °C ; lit., [4a] 216–218 °C). On a 100 mmol scale, 75–78% of the coupling product was obtained.

Received (in Cambridge, UK) 16th March 1999, Accepted 10th May 1999

The ring-opening metathesis polymerization (ROMP) of 7-*tert*-butoxybicyclo[2.2.1]hepta-2,5-diene initiated by Ru(=CHPh)$Cl_2(PCy_3)_2$ proceeds rapidly in organic solvents with almost complete consumption of initiator to form propagating ruthenium carbene species that are then converted slowly but not completely back to initiator, implying a secondary ring-closing metathesis reaction at the chain ends to form macrocycles.

The ROMP of the title monomer (7-TBONBD) initiated by $MoCl_5/Me_4Sn/Et_2O$ and $OsCl_3$ is known to give polymers containing both *anti* and *syn* units, depending on which double bond is opened in the propagation step (Scheme 1). The double bonds formed between the rings are mainly *trans* in the first case, and *cis* in the second.[1]

The ROMP of this monomer (M) has now been studied in various solvents at 20 °C, initiated by the well-defined ruthenium carbene complex[2] Ru(=CHPh)$Cl_2(PCy_3)_2$, (I), using ^{1}H, ^{13}C and ^{31}P NMR to follow the reaction. In $CDCl_3$, with $[I]_o$ = 0.0176 mol l^{-1}, $[M]_o$ = 1.016 mol l^{-1}, $[M]_o/[I]_o$ = 57.7, $t_{½}$ for the polymerization of M was about 3 min and most of the initiator was also rapidly consumed. The polymer consisted largely of *anti* units, with 34% *cis* double bonds between the rings. The consumption of M was slower in both CD_2Cl_2 ($t_{½}$ ~12 min) and C_6D_6 ($t_{½}$ ~17 min) under comparable conditions, but the *cis* content was similar. Experiments at $[M]_o/[I]_o$ = 5–10 allowed the determination of the ratio of propagation to initiation rate constants, k_p/k_i, from $[M]_o/[I]_o$ and the value of $[I]/[I]_o$ immediately after the completion of polymerization.[3] These gave k_p/k_i ~ 15, independent of solvent.

Fig. 1 is a stack plot of the carbene proton region taken at intervals over a period of 12 h for the reaction in $CDCl_3$, after the monomer had been consumed. This shows several remarkable and unexpected features, in particular (i) fine structure for the propagating species (P_n) which is not due to spin coupling, (ii) the regeneration of I at the expense of P_n, and (iii) the formation of another carbene species (X).

The positions of the three P_n lines (δ 19.38, 19.36, 19.33) were the same in a 400 MHz spectrum as in the 500 MHz spectrum. The fine structure is therefore not due to PH_α ^3J coupling nor to $H_\alpha H_\beta$ ^3J coupling. The absence of PH_α coupling is normal in ruthenium carbene complexes containing two PCy_3 ligands as in the initiator,[2] but the absence of $H_\alpha H_\beta$ coupling is very abnormal. Thus in complexes of the type [Ru]=CHR containing two PCy_3 ligands, $^3J_{\alpha\beta}$ ranges from 5.0 (R = Et) to 10.5 Hz (R = CH=CPh_2).[2,4–6] In the present case it would appear therefore that (i) rotation about the C_α–C_β bond in the propagating species is severely restricted by the interaction between the PCy_3 ligands and the enchained cyclopentene ring, (ii) the favoured conformation (**1**) has a HC–CH dihedral angle close to 90°; and (iii) the observed fine structure is due to sensitivity of the chemical shift to the *c/t* isomerism of the adjacent double bond and to the *m/r* isomerism of the adjacent dyad. The intensity pattern of the three P_n lines (31 : 39 : 30) can be interpreted in terms of similar *c/t* and *m/r* splittings (giving rise to three lines rather than four), a *cis* content of 34%, and somewhat different tacticities (*m/r* ratio) with respect to the adjacent *cis*- and *trans*-centred dyads.

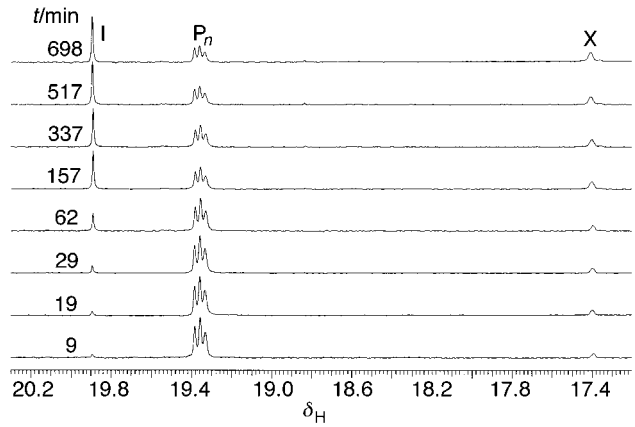

Fig. 1 Carbene proton region as a function of reaction time (t) in the 500 MHz ^{1}H NMR spectrum. Solvent $CDCl_3$: $[I]_o$ = 0.0176 mol l^{-1}, $[M]_o$ = 1.016 mol l^{-1}. P_n is the propagating species; X, see text. The intensities were referenced to the total integral of the δ 4.0–2.7 region (H-1,4 + H-7 signals). There was an overall loss of carbene proton signal of 24% during the first 700 min.

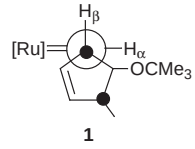
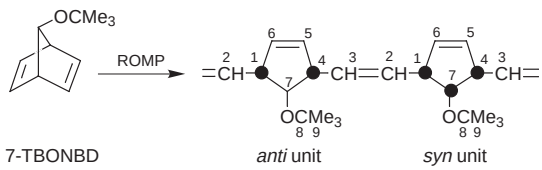
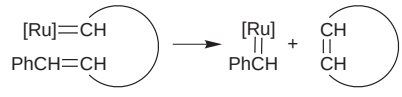


1

The regeneration of I (δ 19.89) at the expense of P_n can only occur by a ring-closing metathesis reaction in which the entire chain forms a macrocycle and the PhCH= end group re-attaches itself to the ruthenium centre (Scheme 2). When a second batch of monomer was added, [I] again fell to a very low level and slowly recovered, while [P_n] immediately rose and then again declined. However X (δ 17.40) did not fall but continued to



Scheme 1



Scheme 2

grow. The relative intensities of the three P_n lines (Fig. 1) remained unchanged during the reversion of P_n to I, indicating that the probability of ring closure is independent of the stereochemistry close to the Ru=C bond.

When a small amount of ethyl vinyl ether was added to a portion of the reaction mixture in $CDCl_3$ some time after the first addition of monomer, the peaks due to species I, P_n and X all disappeared and new carbene proton peaks appeared at δ 18.91 (2%), in the position expected for [Ru]=CH_2,[5] and δ 14.54 (98%), attributed to [Ru]=CHOEt. The P_n chains had thus been terminated to give mainly vinyl end groups. GPC measurements on polymers that had been terminated just before and some time after the second addition of monomer showed the expected increase in molecular weight after the second addition, but in both cases the distributions were broad and unimodal for the main fraction. The DP was of the same order of magnitude as $[M]_o/[I]_o$ so that back-biting at other points in the chain to yield smaller cyclic oligomers cannot be a serious competitor, probably because of the difficulty of access of the Ru=C bond to double bonds situated between two substituted rings.

GPC traces of polymers that had been made in CD_2Cl_2 and terminated (i) immediately after consumption of monomer, and (ii) later after the initiator had been regenerated, showed differences in the low molecular weight region (300–700) consistent with the presence of different proportions of linear and cyclic oligomers, but further work is needed to characterise the species associated with the observed peaks.

Regeneration of initiator was also observed for the reaction in CD_2Cl_2 and C_6D_6 except that the whole process was somewhat slower than in $CDCl_3$ and the P_n signal consisted of two lines instead of three, in the ratio 28:72 in CD_2Cl_2 (δ 19.44, 19.40 relative to initiator δ 20.02) and 24:76 in C_6D_6 (δ 19.66, 19.60 relative to initiator δ 20.31). This is consistent with the presence of four underlying structures (*c/m*, *c/r*, *t/m*, *t/r*) of which three have the same chemical shift.

When the reaction was carried out in CD_2Cl_2 in the presence of added PCy_3 ($[PCy_3]/[I]_o$ = 1.88) it was greatly retarded (factor of ~50) but followed the same general course with eventual complete consumption of M, regeneration of I, and the formation of X. This strongly suggests a mechanism in which a PCy_3 ligand must first be released from the initiator before monomer can be coordinated to the Ru centre and react by metathesis. The magnitude of the effect was consistent with a constant for the dissociation of the PCy_3 ligand from the initiator of the order of 10^{-5} mol l^{-1}.

The reaction in CD_2Cl_2 was also followed by ^{31}P NMR. The initiator gave a singlet (δ 37.24), while P_n gave four signals (δ 36.80, 36.45, 36.36, 36.10) of approximately equal intensity. After the consumption of monomer, these rose and fell respectively as for the ^{1}H NMR signals. A small peak also emerged at δ 11.52 (PCy_3), and grew in parallel with the X peak in the ^{1}H NMR spectrum. By analogy with the recent work of Grubbs [7] one may speculate that X is a monophosphine complex formed by displacement of one of the PCy_3 ligands in P_n by chelation of an oxygen atom (in the polymer chain) to the Ru centre. A number of other small peaks appeared in the ^{31}P NMR spectrum between δ 55 and 25, comparable in intensity with that at δ 11.52, one of which may be due to the PCy_3 ligand in X. The slow rate of formation of X may arise from the necessity for the C_α–C_β bond in **1** to rotate against a substantial barrier to a position where the adjacent oxygen atom comes into juxtaposition with the ruthenium centre. Conversion of P_n to X does not go to completion and is probably a slow equilibrium process [eqn. (1)].

$$P_n \rightleftharpoons X + PCy_3 \quad (1)$$

It appears that the regeneration of initiator is peculiar to the ROMP of 7-TBONBD initiated by $Ru(=CHPh)Cl_2(PCy_3)_2$. To date we have been unable to observe this phenomenon using this initiator with other monomers, *e.g.* norbornene, or this monomer with other initiators, *e.g.* $Mo(=CHCMe_3)(=NAr)(OCMe_3)_2$.

We thank Dr J. G. Hamilton for providing a sample of monomer, and Mrs C. F. Heffernan for technical assistance.

Size and shape evolution of core–shell nanocrystals

C. J. Zhong,* W. X. Zhang, F. L. Leibowitz and H. H. Eichelberger

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13902, USA. E-mail: cjzhong@binghamton.edu

Received (in Columbia, MO, USA) 20th April 1999, Accepted 19th May 1999

The findings of an investigation of temperature-manipulated size and shape evolution for pre-formed decanethiolate–encapsulated gold nanocrystals are described.

Monolayer-encapsulated metal nanoparticles are of considerable technological interest because of the potential electronic, optical, magnetic, catalytic and sensing applications emerging from the core–shell combinations.[1,2] Part of our motivation stems from the opportunities of manipulating such structural properties as interfacial building blocks towards fine-tunable electrode nanomaterials.[3] One important advance emerging from various synthetic strategies[4–16] is the two-phase method, which was first reported by Schiffrin and coworkers[4,5] and has been extensively utilized.[1,4–8] This relatively simple method, which involves transferring an aqueous tetrachloroaurate ($AuCl_4^-$) precursor into an organic phase followed by reduction in the presence of thiols (RSH), has been proven very effective for synthesizing core sizes ranging from 1.5 to 5 nm by controlling the RSH/Au ratio and reaction temperature.[4–8] Narrow-size preparation and shape control are the ultimate synthetic challenges. Relatively little is, however, known about shape control for such composite nanomaterials,[12–16] though examples have recently been demonstrated for platinum nanoparticles by manipulating precursor ratios,[14] or introducing 'shape-inducing reagent'.[15] In view of the molecular and crystal natures of such core–shell systems, size and shape are inherently a dynamic process and an evolution may occur as a result of changes in chemical potentials of the particles. Such a process is the basis of crystallography involving nucleation, dissolution and growth,[18,19] but to our knowledge has not been studied for the core–shell type systems. Here, we describe the preliminary results of an investigation of such a process of pre-formed thiolate-encapsulated gold nanoparticles by manipulating temperatures.

Thiolate-encapsulated gold nanoparticles were prepared first by the two-phase method.[4,6] Briefly for decanethiolate-encapsulated nanoparticles, after transferring an aqueous $AuCl_4^-$ by tetraoctylammonium bromide (98%) into a toluene phase, decanethiol (DT, 96%) was added at a 2:1 ratio of DT/Au, and followed by adding an excess (12 ×) of an aqueous reducing agent ($NaBH_4$, 99%). The reaction produced a dark-brown solution of the DT-encapsulated nanoparticles, which was then subjected to two types of sample handling procedures. In the first procedure, the solvent was removed by rotary evaporator (at *ca.* 50 °C) yielding a black and waxy product, DT/Au(**1**). In the second procedure, the solution was brought to *ca.* 110 °C under reduced pressure for *ca.* 30 min. Upon this treatment, the solution showed a color change from brownish to pinkish. We note here two observations for the heating treatment. First, simply heating the solution at temperatures between 50 and 110 °C did not lead to any color change. Secondly, a color change occurred under conditions of the concentration rising to *ca.* 10-fold and the temperature to 100–115 °C. A systematic study of the related factors is in progress. This treatment was performed after the formation of the encapsulated nanoparticles, a procedure different from temperature control during the synthesis.[8] After removing solvent, the gray and powdery product, DT/Au(**2**), was collected. Both **1** and **2** were subjected to subsequent cycles of suspension in ethanol and acetone and centrifugation for at least four times to ensure a complete removal of non-nanoparticle materials.

These two samples, DT/Au(**1**) and DT/Au(**2**), were first examined by transmission electron microscopy (TEM). Fig. 1 presents two representative TEM images from the two samples. For the DT/Au(**1**) sample [Fig. 1(*a*)], the result displays an average core size of *ca.* 2.0 nm with *ca.* 80% populations within the range 1.5–2.5 nm. The crystal shapes, though not clearly identifiable with the TEM resolution, appear non-uniform. These microscopic features are in good agreement with those reported previously for samples prepared under similar conditions.[8] A previous study has determined that the most likely shape for such a core size is a truncated octahedron.[12] In contrast to the results shown for the DT/Au(**1**) sample, two striking features are evident for the DT/Au(**2**) sample [Fig. 1(*b*)]. First, it displays an increased core size with a narrow distribution in which more than 90% populations are within the range 4.7–5.7 nm (average 5.2 nm). Second, a close examination of the particle shapes indicates a 'hexagon' outline for an observable percentage of the particles. Clearly, an evolution in both size and shape of the particles has occurred from DT/Au(**1**) to DT/Au(**2**) samples. While not reported for thiolate-encapsulated nanocrystals, temperature-induced changes in size and morphology, including quasimelting, coalescence and sintering of fine particles, have indeed been reported for metal or metal oxide crystals or nanocrystals.[18,19] The size and shape evolution of our encapsulated nanoparticles in the solution may involve a

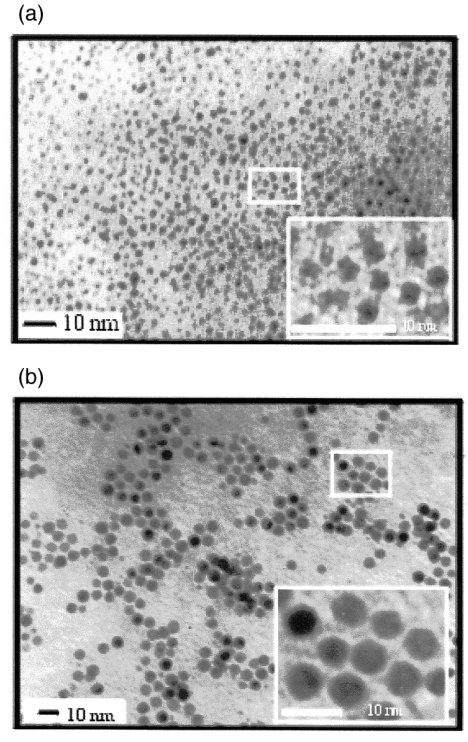

Fig. 1 TEM micrographs of two DT-encapsulated Au nanocrystal samples: (a) DT/Au(**1**) and (b) DT/Au(**2**) on carbon-coated TEM grids. The insert represents an enlarged view of the indicated area.

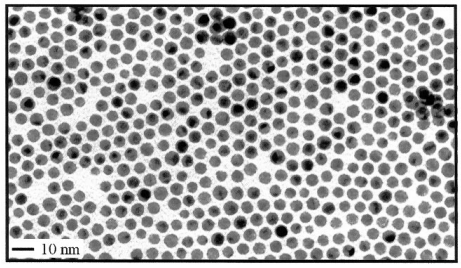

Fig. 2 TEM micrograph of the ordered domain features for DT/Au(**2**) on a carbon-coated TEM grid.

balance of the chemical potentials *via* desorption and re-adsorption of the shell components and coalescence of the cores as the driving force for the eventual size and shape.

Another remarkable feature for the evolved nanocrystals was the formation of long range order upon casting a solution of the DT/Au(**2**) sample onto a TEM grid and evaporating the solvent. As shown in Fig. 2, large domains of long range self-organizations are evident. Two-dimensional ordered arrays with a hexagon-type arrangement can also be identified. Similar long range orders have recently been reported for alkanethiolate-encapsulated gold nanoparticles that were prepared without temperature treatment, for examples, by fractionalized dodecanethiolate-encapsulated gold particles,[12] by gas-phase synthesis followed by solution-phase encapsulation,[10] and most recently by two-phase synthesized gold particles coated with quaternary ammonium ion pairs.[5] Our observation serves as an intriguing example for the long range ordering for the encapsulated nanocrystals prepared by the temperature treatment. In an excellent agreement with the notion that the encapsulating chains are likely interdigitated between opposing alkyl shells,[1,5,10,12] the determined average core–core (edge-to-edge) distance of *ca.* 1.5 nm is indeed close to the expected chain length of DT (1.4–1.5 nm).

Two sets of spectroscopic data further confirmed the observed evolution and the associated structural properties. First, the optical properties for the samples before and after the size and shape evolution were determined by measurement of adsorption in the visible region. Optically, fine particles display surface plasmon resonance bands with intensity and energy strongly dependent on size. The UV-VIS spectrum for DT/Au(**1**) in hexane displays an identifiable surface plasmon band envelope around 510 nm. The shape and position of this band is in agreement with those previously reported for similar particle sizes.[8] In contrast, the spectrum for the DT/Au(**2**) sample exhibits an increased intensity for the 520 nm band. This result, without an apparent shift in energy, is consistent with an increase in core size, a well documented phenomenon.[6,8,12]

Secondly, the structural properties of the encapsulating monolayer shells were characterized using IR spectroscopy. Two pieces of evidence emerge from the spectral similarities and differences (Fig. 3) between these two samples. First, the overall similarity in both high and low energy regions suggests the absence of major structural changes such as decomposition and transformation. Second, a close examination of the C–H stretching region provides diagnostic information about ordering properties of the alkyl chains in the shell. While bands corresponding to methyl stretching (2955 and 2872 cm^{-1}) show little change, a shift to lower wavenumbers is identified for the asymmetric and symmetric methylene stretching bands from DT/Au(**1**) (2920 and 2950 cm^{-1}) to DT/Au(**2**) (2917 and 2948 cm^{-1}). As extensively studied for both monolayers on planar[17] and on nanocrystal gold,[6,8] such a shift is diagnostic of the more crystalline nature[25] of the monolayer on larger particles. These results, combined with the optical data, confirm the evolution of the smaller-sized to larger-sized nanocrystals with the integrity of the final encapsulating shell structures maintained.

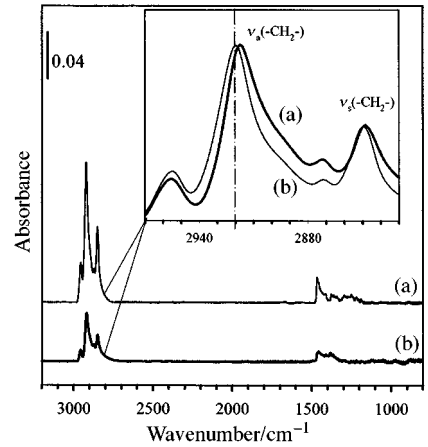

Fig. 3 FTIR spectra for (a) DT/Au(**2**) and (b) DT/Au(**1**) samples in KBr pallets. The insert represents a normalized view in the C–H stretching region.

Finally, we note that similar microscopic and spectroscopic characteristics have also been observed for samples with alkanethiolate shell components of different chain lengths.

A further systematic investigation to unravel the mechanistic aspects is in progress.

The first neutral homoleptic lanthanoid pyrazolates, including the mixed oxidation state species $[Yb_2(Bu^t_2pz)_5]$ (Bu^t_2pz = 3,5-di-*tert*-butylpyrazolate), from a simple new synthesis of pyrazolate complexes

Received (in Columbia, MO, USA) 6th April 1999, Accepted 19th May 1999

Reaction of 3,5-di-*tert*-butylpyrazole (Bu^t_2pzH) with lanthanoid metals and mercury at 220 °C in the absence of an added solvent yields $[Ln(Bu^t_2pz)_3]$ (Ln = Nd, Sm), $[Eu(Bu^t_2pz)_2]$ and $[Yb_2(Bu^t_2pz)_5]$, which is a mixed oxidation state complex with the structural arrangement $[(\eta^2\text{-}Bu^t_2pz)Yb^{II}(\mu\text{-}\eta^2:\eta^2\text{-}Bu^t_2pz)_2Yb^{III}(\eta^2\text{-}Bu^t_2pz)_2]$.

Pyrazolate coordination chemistry[1] has recently been stimulated by expansion of recognised binding modes from the long standing (i) $\mu\text{-}\eta^1:\eta^1$, (ii) η^2 and (iii) η^1 (N-bonded)[1] to (iv) $\mu_3\text{-}\eta^1:\eta^2:\eta^1$, (v) $\mu\text{-}\eta^2:\eta^2$, (vi) $\pi\text{-}\eta^1$ (C-bonded), (vii) η^3 and (viii) η^5.[2–6] In addition, a 14-year restriction of η^2 coordination to f-block elements has been removed by recent examples of η^2-bonding to d-block[7] and main group elements.[8] Although there are now a wide variety of synthetic routes to rare earth pyrazolates,[3,5,9,10] no structurally characterised neutral homoleptic pyrazolatolanthanoid(II or III) complexes, $[Ln(R_mpz)_n]$ (n = 2 or 3; R possible substituents, m = 0–3), have been prepared,[11] presumably because the large size of Ln^{n+} leads to attachment of coligands, often derived from the synthesis solvent, giving $[Ln(R_mpz)_3(L)_x]$ (*e.g.* L = dme, thf, Ph_3PO, x = 1–3)[9] or $[Ln(R_mpz)_2(L)_x]$ (*e.g.* L = dme, x = 2).[3,10] Neutral homoleptic complexes would be of major structural interest, because of the need to attain coordination saturation in the absence of coligands. We now report that both di- and tri-valent neutral homoleptic pyrazolatolanthanoid complexes $[Ln(Bu^t_2pz)_n]$ (Bu^t_2pz = 3,5-di-*tert*-butylpyrazolate, n = 2 or 3), and the novel mixed oxidation state complex $[Yb_2(Bu^t_2pz)_5]$, can be prepared by a new synthesis of pyrazolate complexes. The method has potential general applicability to pyrazolates of electropositive metals.

Reaction of 3,5-di-*tert*-butylpyrazole with an excess of lanthanoid metal and mercury under vacuum at 220 °C without added solvent, followed by extraction with toluene and crystallisation yielded $[Yb_2(Bu^t_2pz)_5]$ **1**, $[Eu(Bu^t_2pz)_2]$ **2**, $[Sm(Bu^t_2pz)_3]$ **3** and $[Nd_2(Bu^t_2pz)_6]$ **4** in satisfactory yield.† The oxidation state diversity suggests the method has considerable versatility.

$$Ln + nBu^t_2pzH \xrightarrow{Hg} [Ln(Bu^t_2pz)_n] + n/2\ H_2\ (n = 2, 2.5 \text{ or } 3)$$

The dried complexes (single crystals of **1** and **4** were toluene solvates) gave satisfactory C, H, N, Ln analyses for the above compositions. For **1**, **3** and **4**, visible/near IR absorptions characteristic[12] of the appropriate Ln^{3+} ions were observed. X-Ray structures of **1**·PhMe‡ and **4**·2PhMe‡[13] revealed a bimetallic mixed oxidation state complex and a dimeric structure $[\{Nd(\eta^2\text{-}Bu^t_2pz)_2(\mu\text{-}\eta^2:\eta^2\text{-}Bu^t_2pz)\}_2]$[13] respectively (below). Neither **2** or **3** have yet been obtained as single crystals, but divalent **2** requires a $\mu\text{-}\eta^2:\eta^2$ pyrazolate bridged dimeric or associated structure to have reasonable coordination number whilst **3** is expected to have a dimeric structure similar to **4**. However, a monomer parent ion for **3**, in contrast to the absence of metal-containing ions for **4**, does leave open the possibility of a monomeric six-coordinate structure. The ^1H NMR spectrum of **1** in d_8-THF is indicative of dissociation into separate $Yb(Bu^t_2pz)_2$ and $Yb(Bu^t_2pz)_3$ complexes owing to solvent coordination.

The molecular structure of **1** (Fig. 1),‡ determined for the toluene solvate, shows a six-coordinate Yb^{2+} ion with one terminal $\eta^2\text{-}Bu^t_2pz$ ligand linked through two $\mu\text{-}\eta^2:\eta^2\text{-}Bu^t_2pz$ groups to an eight-coordinate Yb^{3+} which has two terminal $\eta^2\text{-}Bu^t_2pz$ ligands. It is only the second complex with $\mu\text{-}\eta^2:\eta^2$-pyrazolate coordination. The oxidation states of Yb(1) and Yb(2) (Fig. 1) are clearly evident from the bond distances. Thus, terminal (ter) Yb(1)–N(12) [2.334(7) Å] is comparable with $Yb\text{–}N_{ter}$ [2.404(6) and 2.378(5) Å] of $[\{Yb(\eta^2\text{-}Bu^t_2Pz)(\mu\text{-}\eta^2:\eta^2\text{-}Bu^t_2pz)(thf)\}_2]$[3] when the difference in ionic radii (0.06 Å)[14] between six- and seven-coordinate Yb^{2+} is considered. In addition $Yb(2)\text{–}N_{ter}$ distances [2.287(7) and 2.270(7) Å] are comparable with Er–N of eight-coordinate $[Er(Bu^t_2pz)_3(thf)_2]$ [2.274(7)–2.386(8) Å, av. 2.34 Å][9c] (ionic radius Er^{3+} > Yb^{3+}

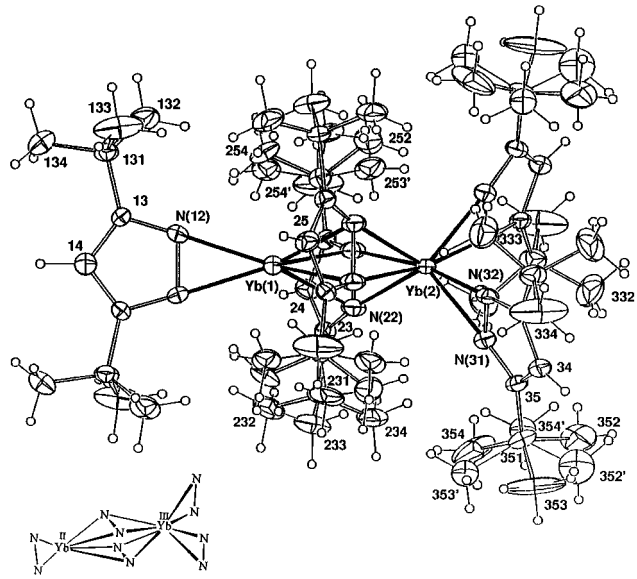

Fig. 1 Molecular projection of **1**; 20% probability ellipsoids are shown for the non-hydrogen atoms, hydrogens having arbitrary radii of 0.1 Å. Key carbon atoms are denoted by number only. [Insert: Yb(1) and Yb(2) coordination spheres]. Selected bond distances (Å) and angles (°): Yb(1)–N(12,21,22) 2.334(7), 2.534(8), 2.587(8); Yb(2)–N(21,22,31,32) 2.402(8), 2.425(8), 2.287(7), 2.270(7), N(12)–N(12*) 1.43(1), N(21)–N(22) 1.37(1), N(31)–N(32) 1.38(1); Yb(1)···C(23,24,25) 3.167(9), 3.468(10), 3.109(10); N(12)–Yb(1)–N(21,22,12*,21*,22*) 131.6(3), 145.0(3), 35.6(3), 138.7(3), 125.7(3); N(21)–Yb(1)–N(22,21*,22*) 31.1(2), 84.0(3), 76.1(3); N(22)–Yb(1)–N(22*) 85.1(3); N(21)–Yb(2)–N(22,31,32,21*,22*,31*,32*) 33.1(3), 138.5(3), 169.3(3), 89.8(3), 81.7(3), 94.0(3), 82.9(3); N(22)–Yb(2)–N(31,32,22*,31*,32*) 106.8(3), 137.2(3), 92.3(3), 120.7(3), 96.0(3), N(31)–Yb(2)–N(32,31*,32*) 35.3(3), 109.4(3), 96.7(3); N(32)–Yb(2)–N(32*) 105.4(3), Yb(1)–N(21,22)–Yb(2) 93.1(3), 91.3(3). The molecule has mirror symmetry, the mirror lying horizontal and almost normal to the page. Symmetry generated atoms are denoted by asterisks.

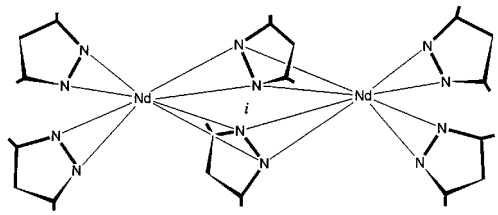

Fig. 2 Simplified representation of the structure of **4**, displaying the Nd/Bu^t_2pz connectivity.[13]

by *ca.* 0.02 Å for the same CN)[14] and with < Yb–N > (2.30$_5$ Å) of eight-coordinate [Yb(η^2-Ph_2pz)$_3$(dme)][13] (Ph_2pz = 3,5-diphenylpyrazolate). Furthermore, it can be calculated from existing lanthanoid pyrazolate structural data (*e.g.* refs. 3, 5, 9, 10) and lanthanoid ionic radii[14] that if Yb(1) were in oxidation state (III) a much shorter Yb–N_{ter} of 2.17 Å would be expected and if Yb(2) were Yb(II), a much longer < Yb–N_{ter} > of 2.44 Å would be expected. Both bridging pyrazolate groups of **1** are tilted towards divalent Yb(1) with the pyrazolate ring planes angled at 59.0(3)° to the Yb(1)···Yb(2) axis, *cf.* 90° for symmetrical bridging. Consequently, C(23) and C(25), but not the more distant (by ≥0.3 Å) C(24), of each μ-η^2:η^2-Bu^t_2pz ligand, may interact marginally with Yb(1). Subtraction of the ionic radius[14] for six-coordinate Yb^{2+} from Yb···C(23) and Yb···C(25) (Fig. 1 legend) gives 2.14 and 2.09 Å, respectively, which are near the upper limit (2.16 Å) of similarly derived values for complexes with inter- and intra-molecular π-arene···Ln coordination![15] Such interactions would enhance the coordination number of Yb(1) from the low value of six.

The connectivity of **4**[13] is shown in Fig. 2. There is no interaction of the Ln metals with toluene of crystallization in either **1** or **4**, since Ln···C(PhMe) and Ln···H(PhMe) separations lie outside the generous limits of 3.6 and 3.3 Å, respectively, for **1** and 3.7 and 3.4 Å for **4**.

1 is a rare example of a molecular compound combining lanthanoids in both II and III oxidation states and the first with pyrazolate ligands. Other examples of molecular lanthanoid(II, III) complexes include [{$Yb^{III}(C_5Me_5)_2$}$_2Yb^{II}$(μ-CCPh)$_4$],[16a] [$Yb^{III}(C_5Me_5)_2$(μ-F)$_2Yb^{II}(C_5Me_5)$]$_2$,[16b] [$Yb^{III}(C_5Me_5)_2$(μ-F)-$Yb^{II}(C_5Me_5)_2$],[16c] [$Yb^{III}Ph_2$(thf)(μ-Ph)$_3Yb^{II}$(thf)$_3$],[16d] [{$(C_5Me_4{}^iPr)_2Sm$}$_2$(μ-Cl)],[16e] and [$Sm^{III}(C_5Me_5)_2$(μ-C_5H_5)$Sm^{II}(C_5Me_5)_2$].[16f]

Structures of **1**·PhMe and **4**·2PhMe, suggest that the lanthanoid elements may prefer the newly recognised[3] μ-η^2:η^2 pyrazolate coordination mode as a means of attaining coordination saturation in [Ln($R_m$pz)$_n$] (n = 2 or 3) complexes. The range of different oxidation state products obtained from reaction (1) to this stage indicates that the method should be generally applicable for the homoleptic lanthanoid pyrazolates, and may also extend to pyrazolates of other electropositive metals, with the alkaline earths, uranium and aluminium being of particular interest. Indeed there is a near precedent for barium, where reaction of 3,5-dimethylpyrazole with Ba metal in *refluxing thf* yields the structurally uncharacterized Ba-(Me_2pz)$_2$.[17]

We are grateful to the Australian Research Council for support and for an Australian Postgraduate Award to A. G.

Notes and references

† All operations were carried out under an atmosphere of purified N_2 or Ar or under vacuum because of the extreme sensitivity of the compounds to air and moisture.

Representative syntheses: **1**: a mixture of Yb powder (2.00 g, 11.6 mmol), Bu^t_2pzH (0.52 g, 2.9 mmol) and mercury metal (two drops) was heated in a sealed tube under vacuum at 220 °C for 5 h. The dark red product was extracted with hot toluene (50 ml) yielding a dark red solution which was concentrated to 3 ml. The solution was then cooled at −20 °C for two days giving dark-red crystals of **1**·PhMe. The crystalline product was then dried at 80 °C under vacuum affording **1** (0.48 g, 67%) (Found: C, 53.00; H, 7.60; N, 11.35; Yb, 27.53. $C_{55}H_{95}N_{10}Yb_2$ requires C, 53.16; H, 7.71; N, 11.28; Yb, 27.85). IR (Nujol): ν/cm^{-1} 1560w, 1504s, 1314m, 1251s, 1227s, 1206s, 1019s, 993s, 794s. ^{1}H NMR (d_8-THF): δ 5.84 [s, 2H, H4 pz (Yb^{II})], 1.27 [s, 36H, Bu^t (Yb^{II})], −15.76 [vbr s, Bu^t (Yb^{III}) (satisfactory integration could not be obtained because of broadening)], −41.94 [s, 3H, H4, pz (Yb^{III})]. EIMS (70 eV) m/z 532 ([$Yb(Bu^t_2pz)_2$]$^+$, 9%), 180 ($Bu^t_2pzH^+$, 21). λ_{max} (PhMe)/nm (ε/dm^3 mol^{-1} cm^{-1}): 402 (351), 484sh (186), 925 (8), 945 (7), 976 (18), 981 (15).

4: a mixture of Nd powder (1.15 g, 8.0 mmol), Bu^t_2pzH (0.72 g, 4.0 mmol) and mercury metal (two drops) was heated in a sealed tube at 220 °C for 24 h. The reaction product was extracted with hot toluene (50 ml) giving a pale blue solution which was reduced in volume. Pale blue crystals of **4**·2PhMe appeared in a few hours. The product was dried at 80 °C under vacuum affording **4** (0.44 g, 48%) (Found: C, 58.07; H, 8.61; N, 12.57; Nd, 21.29. $C_{66}H_{114}N_{12}Nd_2$ requires C, 58.11; H, 8.42; N, 12.32; Nd, 21.15%). IR (Nujol): ν/cm^{-1} 1558w, 1523m, 1505s, 1414s, 1362s, 1303m, 1278w, 1253s, 1224s, 1206m, 1018s, 1006m, 980s, 808m, 796s, ^{1}H NMR (d_8-THF): δ 4.93 (s, 108H, Bu^t), 21.53 (s, 6H, H4 pz). λ_{max} (PhMe)/nm (ε/dm^3 mol^{-1} cm^{-1}): 532 (2), 578 (30), 591 (57), 744 (5). Analogous preparations gave **2** (95%) and **3** (57%).

Received (in Cambridge, UK) 24th March 1999, Accepted 19th May 1999

Naturally occuring monosaccharides D-mannose, D-galactose and D-glucose have been used for the first time as co-matrices for chiral recognition and for the determination of optical purity of the enantiomers of α-amino acid methyl ester hydrochlorides.

Mass spectrometry does not ordinarily distinguish optically active isomers. Recently, Sawada *et al.* reported the Fast Atom Bombardment (FAB) mass spectrometric estimation of the enantiomeric excess of amines and amino acid methyl esters *via* host–guest complexation using deuterated chiral crown ethers as chiral hosts.[1,2] This is an excellent method to estimate enantiomeric excess using a few micrograms of the amine, and is useful in combinatorial approaches towards the synthesis of chiral compounds. Polar chiral matrices have not so far been used as part of the mass spectral techniques for the study of chiral recognition.[3] It would be ideal if naturally occurring and readily available substrates could be used as chiral hosts for such a process. We have tested some hexoses as chiral co-matrices for gas phase chiral discrimination by Liquid Secondary Ion Mass Spectrometry (LSIMS) and found them suitable for such analyses.

Herein, we report the first observations concerning the enantioselectivity of naturally-occurring underivatized sugars D-mannose **1**, D-galactose **2** and D-glucose **3** as polar hosts towards alanine **4**, leucine **5** and phenylglycine **6** methyl esters (*R* and *S* isomers of **4**, **5** and **6**). We have also shown that this method could be used for the determination of the optical purity of **4** using the corresponding enantiomeric methyl-d_3 ester as an internal reference, employing the LSIMS technique following the enantiomer-labelled guest method of Sawada *et al.*[4–10] In the present study, we report a high degree of enantioselectivity of D-sugars towards amino acid methyl ester hydrochlorides, presumably through the host–guest complexation.

A typical LSIMS sample solution was prepared by mixing the following solutions: (i) 20 μl of a 0.5 M aqueous solution of D-mannose, (ii) 10 μl of a 0.5 M methanolic solution of D-methyl-d_3 alaninate hydrochloride, and (iii) 10 μl of a 0.5 M methanolic solution of L-methyl alaninate hydrochloride in 50 mg of glycerol (for the ee experiments, solutions of different ee were prepared by mixing appropriate quantities of 0.5 M methanolic solutions of both D- and L-methyl alaninate hydrochlorides). The above individual solution (2 μl) was loaded on to the stainless steel target of the LSIMS probe and the mass spectra were recorded.[11]

The amino acid methyl ester hydrochlorides **4**–**6** form fairly abundant adduct ions with the three monosaccharides, namely D-mannose, D-galactose and D-glucose, in the presence of glycerol as the matrix. In order to quantify the chiral discrimination parameter of the sugar we followed the enantiomer-labelled guest method recommended by Sawada *et al.*,[6] and used labelled D-amino acid methyl ester hydrochloride as the internal standard. The LSI mass spectrum of an equimolar mixture of L-methyl alaninate hydrochloride (L-**4**) and the reference D-methyl-d_3 alaninate hydrochloride (d_3-D-**4**) taken using D-mannose as a chiral co-matrix in presence of glycerol shows that the sugar forms a favourable adduct with the L-isomer [Fig. 1(*a*)]. The near absence of an isotope effect in the formation of the host–guest adduct is seen in the LSI mass spectrum of an equimolar mixture of D-methyl alaninate hydrochloride and the D-methyl-d_3 alaninate hydrochloride under identical experimental conditions [Fig. 1(*b*)]. The relative abundances of labelled D-enantiomer (*m/z* 287) and unlabelled D-enantiomer (*m/z* 284) adducts are almost identical. The existence of a chirality effect in the gas phase under LSIMS conditions is further supported by cross-chiral examination of an equimolar mixture of D-methyl alaninate hydrochloride and L-methyl-d_3 alaninate hydrochloride [Fig. 1(*c*)] wherein the

Table 1 IRIS values for α-amino acid methyl ester hydrochlorides

Substrate	IRIS value[a]		
	D-mannose	D-galactose	D-glucose
(*S*)-Ala-OMe	0.71 ± 0.03	0.71 ± 0.02	0.70 ± 0.02
(*R*)-Ala-OMe[b]	1.40 ± 0.01	—	—
(*S*)-Leu-OMe	0.75 ± 0.01	0.75 ± 0.01	0.76 ± 0.01
(*S*)-Ph-Gly-OMe	0.68 ± 0.01	0.67 ± 0.01	0.66 ± 0.01

[a] The IRIS value shown is an average of two sets of IRIS values; each is an average of 10 consecutive experiments. [b] (*S*)-Methyl-d_3 alaninate hydrochloride was used as an internal reference.

labelled L-enantiomer (L-**4**) is used as the reference. The preference of D-mannose towards the L-enantiomer is now seen as an increased abundance of the adducts corresponding to the labelled enantiomer (*m/z* 287), to the same extent as observed in Fig. 1(*a*). Again an equimolar mixture of labelled and unlabelled L-methyl alaninate hydrochloride gives adducts of almost equal abundance [Fig. 1(*d*)] showing the absence of an isotope effect.

LSI mass spectral analysis of L-methyl leucinate hydrochloride **5** and L-methyl phenylglycinate hydrochloride **6** using the corresponding d_3-labelled D-enantiomer as reference also gave similar results in the presence of all three sugars. It should be pointed out that all three monosaccharides studied have shown a preference for the L-amino acid ester hydrochloride prepared from the L-amino acids that are naturally occurring. The relative peak intensity of the diastereomeric host–guest complex ion I_R and I_S, for the *R*-enantiomer (D-amino acid) and *S*-enantiomer (L-amino acid), respectively, can be taken as a measure of the selectivity of the host sugar towards the amino acid methyl ester hydrochloride guest [eqn. (1)] as proposed by Sawada *et al.*[6]

$$I_R/I_S = \text{IRIS (abbreviation)} \quad (1)$$

The IRIS values for the amino acid esters using sugars as comatrices are given in Table 1. The utility of this approach in determining the enantiomeric excess of amino acid methyl ester hydrochlorides was tested using methyl alaninate hydrochloride as an example. Thus mixtures containing different enantiomeric excesses (ees) of methyl alaninate hydrochloride were prepared and the LSI mass spectra taken using the D-methyl-d_3 alaninate hydrochloride as the internal standard. The plot of I_{R-d_3}/I_S as a function of ee is found to give a linear plot with a correlation coefficient of 0.99 (Fig. 2), validating the idea that mass spectral techniques can be used for the determination of the optical purity of chiral compounds.

Semiempirical AM1 calculations are also supportive of the observed higher stability of protonated sugar–amino acid ester complexes of the L-amino acids studied as compared to the corresponding D-isomers. This study was performed making hydrogen bonds *via* the chiral ammonium ion hydrogens with the ring oxygen, the anomeric oxygen of the sugar, and the C_6 oxygen of the sugar. A detailed investigation of the theoretical results is in progress.

Thus the present study has shown that monosaccharides show chiral discrimination towards amino acid ester salts and that this can be observed under LSIMS conditions. In the case of the amino acid esters studied, the L-isomers form more abundant adducts with sugars than the D-isomers. By using the methyl-d_3 ester of one enantiomer as an internal standard, it is possible to determine the enantiomeric excess of the respective compound

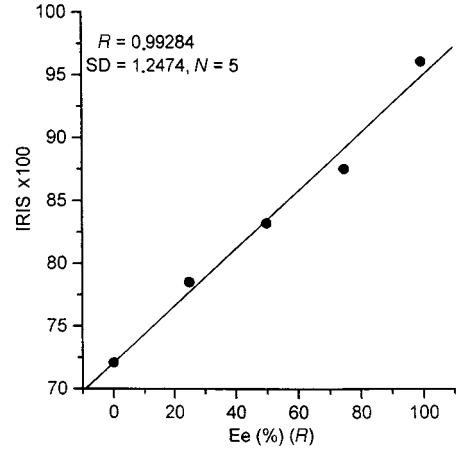

Fig. 2 A plot of IRIS values *vs.* ee for methyl alaninate hydrochlorides. Each point represents the average IRIS value optained for 10 consecutive experiments; standard deviation: < 1.0%.

by LSI mass spectrometry in the presence of a monosaccharide and glycerol. Further extension of this work to the study of other chiral compounds is in progress.

We thank the Director, IICT, for facilities and constant encouragement. A Fellowship from UGC, New Delhi, (to P. K.) is gratefully acknowledged. This work was supported in part by DST, New Delhi, India.

11 All the LSI mass spectra were recorded on an AutoSpec (Micromass, Manchester, UK) mass spectrometer using an OPUS V3.IX data system. The samples were ionized using a primary ion beam of caesium ions of 25 kV at the source temperature of 46 °C. The desorbed ions were accelerated to 8 kV. The spectra were obtained with a magnet scan rate of 3 s per decade over a mass range of *m/z* 1–400 under continuum mode. The IRIS values presented here are an average of 10 successive experiments and an averaged spectrum from each experiment is obtained *via* the accumulation of 15 consecutive scans.

Synthesis and domino reactions of 1,1-bis(hydroxymethyl)allenes

Peter Langer*

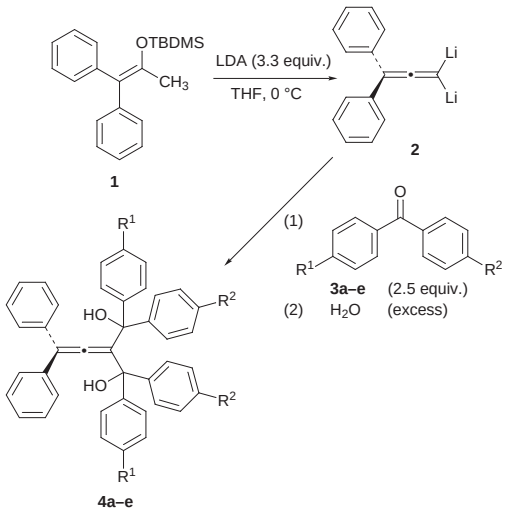
Institut für Organische Chemie der Georg-August-Universität Göttingen, Tammannstraße 2, 37077 Göttingen, Germany. E-mail: planger@uni-goettingen.de

Received (in Cambridge, UK) 15th February 1999, Accepted 12th April 1999

The reaction of dilithiated 1,1-diphenylallene with aryl ketones provides a convenient access to novel 1,1-bis(hydroxymethyl)allenes, which undergo Friedel–Crafts-type domino reactions upon treatment with TsOH.

Domino reactions of alkynes have been used for the efficient synthesis of carbocycles and polycyclic aromatic hydrocarbons (PAHs).[1] Hydroxymethylalkynes have been converted into the more labile allenes and cumulenes which have then been used *in situ* for the preparation of [4]radialenes, macrocycles and 1,2-dihydrocyclobutaarenes.[2] However, only a few domino reactions using allenes as starting materials have been reported so far.[3] Herein, we report a convenient synthesis of 1,1-bis(hydroxymethyl)allenes.[4] These new difunctionalized substrates are used as starting materials in a unimolecular cationic domino reaction. In this context the first, to the best of our knowledge, Nazarov–Friedel–Crafts tandem reaction of an allene is reported which we believe represents a new type of domino process.

1,1-Diphenyl-3,3-dilithioallene **2** was generated in one pot by treatment of the TBDMS enol ether **1** with an excess of LDA in THF, a reaction recently developed by us.[5] The reaction of **2** with 2 equiv. of aryl ketones **3a**–**e** regioselectively provided the colourless bis(hydroxymethyl)allenes **4a**–**e** (Scheme 1, Table 1).† Due to the steric hindrance of the allenic phenyl groups, the sterically crowded allenes **4a**–**e** were regioselectively formed and isolated in high yields.



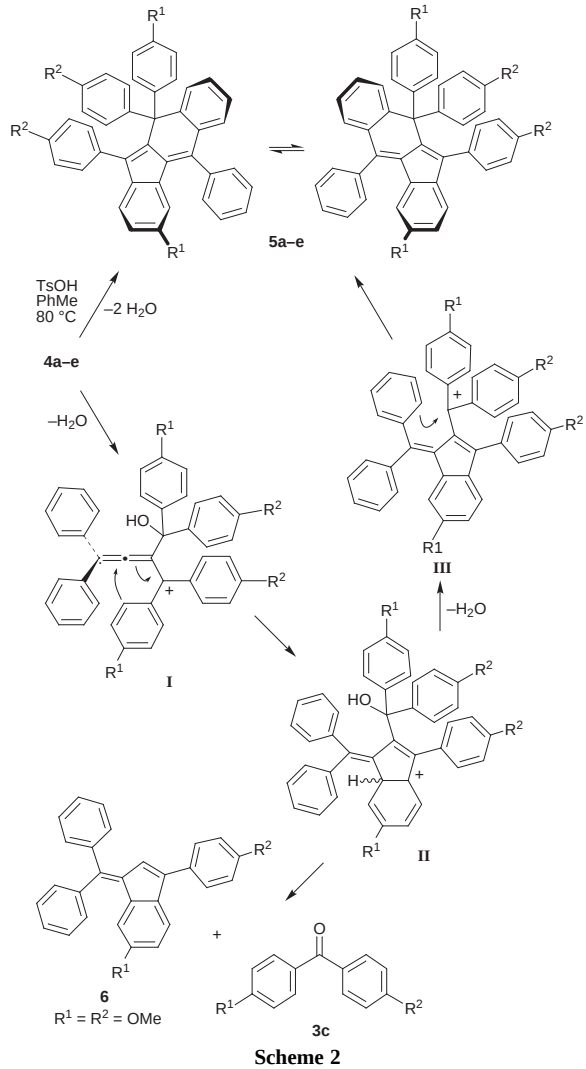
Scheme 1

Table 1 Synthesis of **4** and **5**

			Isolated yield (%)	
4/**5**	R^1	R^2	**4**	**5**
a	H	H	80	85
b	MeO	H	62	73
c	MeO	MeO	75	76
d	Me	Me	76	83
e	Cl	Cl	71	86

Treatment of allenes **4a**–**e** with TsOH in toluene resulted in elimination of 2 equiv. of water and selective formation of the orange coloured 5,10,10,11-tetraaryl-10*H*-benzo[*b*]fluorenes **5a**–**e** in very good yields (Scheme 2, Table 1).‡ In the case of allene **4b** containing two asymmetric carbon atoms, the cyclization proceeded regioselectively *via* the *p*-methoxyphenyl rather than the phenyl group to give **5b** in good yield. Pentafulvenes related to **5** have been used as intermediates in the synthesis of fullerene fragments.[6] Due to their curved structure, 10*H*-benzo[*b*]fluorenes **5a**–**e** are chiral as demonstrated by separation of the two atropic enantiomers of **5a** by HPLC using a chiral stationary phase.§

The formation of 10*H*-benzo[*b*]fluorenes **5** can be explained by a Nazarov–Friedel–Crafts domino reaction. Carbocation **I** is initially generated by dehydration (Scheme 2). The central allene carbon atom is attacked by the *ortho* carbon atom of one

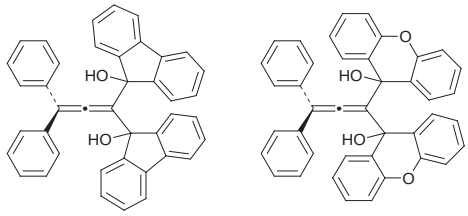


Scheme 2

of the aryl groups with formation of a five-membered ring to give intermediate **II**. Aromatization and dehydration subsequently lead to formation of the cationic intermediate **III**. The *ortho* carbon of the allene-derived phenyl group is attacked by the carbocation neighboring the ketone derived aryl groups. Aromatization finally leads to the products **5a**–**e**. The mechanism suggested is supported by the following observation: starting with the *p*-methoxyphenyl-substituted allene **4c**, the benzofulvene **6** is obtained as a minor product in 10% yield. Formation of **6** can be explained by formation of the benzofulvene moiety and subsequent elimination of bis(*p*-methoxyphenyl) ketone or, alternatively, by initial elimination of the ketone, formation of a cumulene (*vide infra*) and subsequent isomerization of the latter.

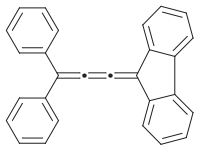
It is noteworthy that in the domino reaction leading to **5a**–**e** the allenic phenyl group became *sterically* accessible for the cationic π-cyclization only after the previous cyclization involving the rigid allene moiety had occurred. The reaction cascade thus represents a combination of cyclizations as observed for mono(hydroxymethyl)allenes[7a] and for aryl-substituted bis(hydroxymethyl)alkenes $Ar_2C{=}C[C(OH)Ar_2]_2$. The latter have been used as precursors for the generation of (hexaaryltrimethylene)methane dications.[7b]

The reaction of dilithioallene **2** with 2 equiv. of fluorenone and xanthone gave the colourless allenes **4f** and **4g** in 72 and 68% yields, respectively. As minor products, the yellow coloured cumulenes **7a** and **7b** were isolated in 10 and 14%

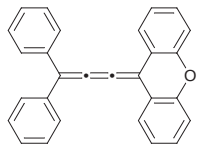


4f

4g



7a



7b

yields. Treatment of the allenes **4f** and **4g** with TsOH resulted in elimination of fluorenone or xanthone and formation of the cumulenes **7a** and **7b** in 85 and 70% yields, respectively, rather than in cyclization. Previously, formation of cumulenes has only been observed for α-unsubstituted (hydroxymethyl)-allenes.[8] In the case of **4f**, the striking difference between the course of the dehydration reactions of the allenes **4a**–**e** and **4f**–**g** can be explained by the fact that cyclization would lead to a strained unsaturated 5,5,6-ring system.[9] In addition, the anti-aromatic character of the fluoren-9-yl cation in the ground state and the rigid character of the ketone-derived subunits of **4f** and **4g** presumably direct the course of the reaction.[10]

P. L. thanks Professor A. de Meijere and Professor D. Seyferth for their support and Professor A. Mannschreck for his help with the separation of the enantiomers of **5a**. Financial support from the Fonds der Chemischen Industrie (Liebig-scholarship and funds for P. L.) is gratefully acknowledged.

† *Preparation* of **4a**. A THF solution (10 ml) of **1** (950 mg, 2.95 mmol) was added to a THF solution of LDA which was prepared by addition of BuLi (1.6 M solution in hexane) to a THF solution (30 ml) of Pr^i_2NH (3.3 equiv.) at 0 °C. The solution was stirred at 20 °C for 6 h during which time the colour of the solution became deep red. A THF solution (10 ml) of benzophenone (1.34 g, 7.38 mmol) was added at −78 °C by syringe. The temperature was allowed to rise to 20 °C within 12 h to give a deep blue solution. The mixture was poured into water (50 ml) and was extracted with Et_2O. The combined yellow coloured organic layers were dried ($MgSO_4$), filtered and the solvent removed *in vacuo*. Purification by column chromatography (Et_2O–light petroleum 1 : 5 → 1 : 1) afforded the allene **4a** (1.31 g, 80%) as a colourless solid, mp 110 °C (decomp.); δ_H($CDCl_3$, 200 MHz): 3.82 (s, 2 H, OH), 6.32 (m, 4 H, Ph), 7.10–7.40 (m, 26 H, Ph); δ_C($CDCl_3$, 50 MHz): 82.90 (C, *C*OH), 114.85, 116.11 (C, *C*=C=*C*), 126.79, 127.91, 128.04 (CH, Ph), 127.18, 127.29, 127.83 (CH, Ph), 136.56, 146.56 (C, Ph), 205.26 (C, C=*C*=C); ν_{max}(KBr)/cm^{-1} 3385 (w), 3057 (w), 1949 (m, C=C=C), 1598 (w), 1493 (m), 1447 (m), 1348 (w), 1177 (w), 1031 (m), 698 (s). *m/z* (CI, H_2O): 539 (M^{+}+1 − H_2O), 521 (M^{+}+1 − $2H_2O$), 357 (100%, $Ph_2C{=}C{=}CPh_2$ + 1). (Calc. for $C_{41}H_{32}O_2$: C, 88.46; H, 5.79. Found: C, 88.23; H, 5.75%.) All new compounds gave correct spectroscopical data and elemental analyses and/or high resolution mass data.

‡ *Preparation* of **5a**: Allene **4a** (200 mg, 0.36 mmol) and TsOH (60 mg) were heated in toluene (30 ml) at 80 °C for 2 h. The colour of the solution changed from light yellow to deep orange. The crude mixture was purified by column chromatography (Et_2O–light petroleum = 1 : 5 → 1 : 1) to give **5a** (159 mg, 85%) as orange coloured crystals, mp 176 °C (decomp.); δ_H($CDCl_3$, 200 MHz) 6.20 (d, *J* 7, 1 H, Ar), 6.56 (m, 2 H, Ar), 6.71 (d, *J* 7, 1 H, Ar), 6.11 (dd, *J* 7, *J* 1.5, 1 H, Ar), 6.41 (m, 2 H, Ar), 6.58 (m, 3 H, Ar), 6.85–7.25 (m, 18 H, Ar); δ_C($CDCl_3$, 50 MHz): 57.42 (C, *C*Ph_2), 119.89, 123.25, 124.70, 126.05, 126.23, 127.33, 127.34, 127.81, 127.99, 128.08, 128.20, 128.77, 128.99, 129.28, 130.14, 130.15, 130.37 (CH, Ar), 133.57, 133.81, 134.32, 135.51, 137.78, 139.80, 140.13, 142.24, 145.54, 145.82, 147.23 (C, Ar); ν_{max}(KBr)/cm^{-1} 3056 (m), 3024 (m), 2924 (m), 1600 (m), 1492 (m), 1448 (m), 1368 (w), 1076 (w), 1032 (w), 760 (s), 744 (s), 724 (s), 700 (s); *m/z* (FAB) 521 (100%, M^{+} + 1). (Calc. for $C_{41}H_{28}$: C, 94.58; H, 5.42. Found: C, 94.27; H, 5.50%.)

§ Conditions (a) stationary phase: tris(phenylcarbamoyl)cellulose/SiO_2; eluent: EtOH; UV detection: λ = 320 nm; polarimetric detection: λ = 436 nm; *c* = 1 mg ml^{-1} (injection of 50 μl); *P* = 63 bar; *T* = 25 °C; flow: 0.5 ml min^{-1}; t_1 = 9 min; k_1' = 0.44. The results were independently confirmed by the use of different conditions: (b) stationary phase: triacetylcellulose/SiO_2; eluent: MeOH; UV detection: λ = 278 nm; polarimetric detection: λ = 405 nm; *c* = 1 mg ml^{-1} (injection of 150 μl); *P* = 68 bar; *T* = 25 °C; flow: 1.0 ml min^{-1}; t_1 = 12.6 min; k_1' = 0.60.

Sequence dependent energy transfer from DNA to an anthryl probe: discrimination between GC and IC sequences

Challa V. Kumar* and Emma H. Asuncion

Department of Chemistry, 55 N. Eagleville Road, U-60, University of Connecticut, Storrs, CT 06269-3060, USA. E-mail: cvkumar@nucleus.chem.uconn.edu

Received (in Columbia, MO, USA) 19th January 1999, Accepted 5th May 1999

Singlet–singlet energy transfer from ionosine-cytosine sequences of DNA to an anthryl probe has been observed, but no energy transfer occurs from guanine-cytosine sequences.

Understanding the interaction of small molecules with the DNA double helix and establishing how these interactions vary with the DNA sequence is crucial for deciphering how small molecules may influence DNA structure and function.[1] Metal ions, heterocyclic cations, and natural antibiotics bind to DNA and the DNA binding studies with these ligands have been useful in cancer research.[2] Sequence dependent energy transfer from the DNA bases to *N*-ethyl-9-anthrylmethylamine hydrochloride (*N*-Et-AMAC, Fig. 1) is reported here. Upon excitation of the DNA bases, energy transfer to the anthryl chromophore (Fig. 2) has been observed from ionosine-cytosine sequences but not from guanine-cytosine sequences.

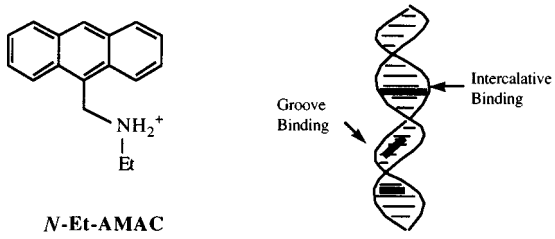

Fig. 1 Structure of the anthryl probe used for energy transfer studies with DNA, and graphical presentation of the intercalative and groove binding of organic ligands to the DNA helix.

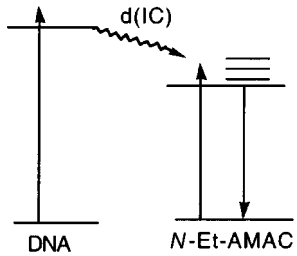

Fig. 2 Energy transfer scheme illustrating the sensitized emission from the anthryl chromophore bound to the DNA double helix.

Addition of calf thymus DNA (CT DNA) to a solution of *N*-Et-AMAC results in dramatic decreases in probe absorbance (Fig. 3). The concentration of the probe was kept constant (5 μM) while varying the DNA concentration from 0 to 400 μM. The large hypochromism (62%) accompanying the binding implies strong electronic interactions between the probe and the DNA bases.[3] No such hypochromism was observed when anthryl probes were allowed to bind to polyelectrolytes, sodium dodecylsulfate micelles, or proteins.[4] The above absorption data were used to construct Scatchard plots and a binding constant of 1.2×10^4 mol^{-1} has been estimated for *N*-Et-AMAC with CT DNA. Marginally higher binding constants have been observed with poly(dI-dC) and poly(dG-dC) (2.4×10^4 and 2.7×10^4 mol^{-1}, respectively) when compared to that with CT DNA. Additional evidence for the binding of *N*-Et-AMAC to the DNA helix was obtained from circular dichroism and from viscometric studies. Strong induced circular dichroism spectra were observed in the anthryl chromophore absorption region, when DNA was added to *N*-Et-AMAC.

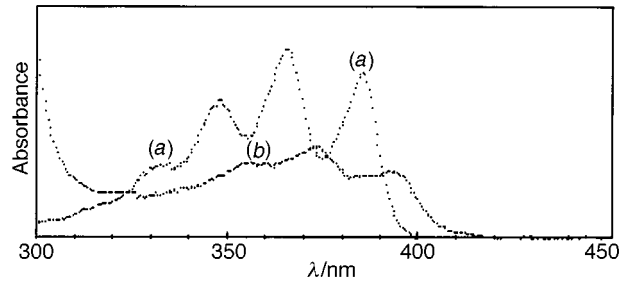

Fig. 3 Absorption spectra of *N*-Et-AMAC (9.7 μM) (*a*) in the absence and (*b*) in the presence of calf thymus DNA (400 μM). Absorbance full scale is 0.1.

The high affinity binding of *N*-Et-AMAC to the DNA helix was exploited in energy transfer studies. Singlet–singlet energy transfer from the DNA bases to 9-anthrylmethylamine hydrochloride was reported from this laboratory, previously.[3] The energy transfer from AT sequences was facile while no energy transfer was observed with GC sequences. In the case of *N*-Et-AMAC, however, energy transfer was observed from ionosine-cytosine (IC) sequences but not from guanine-cytosine (GC) sequences, providing a simple fluorescence method for discrimination between different DNA bases.

Evidence for sequence dependent singlet–singlet energy transfer was obtained from the fluorescence excitation spectra. Emission from *N*-Et-AMAC is monitored at 425 nm while varying the excitation wavelength from 260 to 410 nm (Fig. 4). Excitation in the DNA absorption region (260–300 nm) resulted in strong emission from the anthryl chromophore. Different DNA sequences were used to evaluate the dependence of

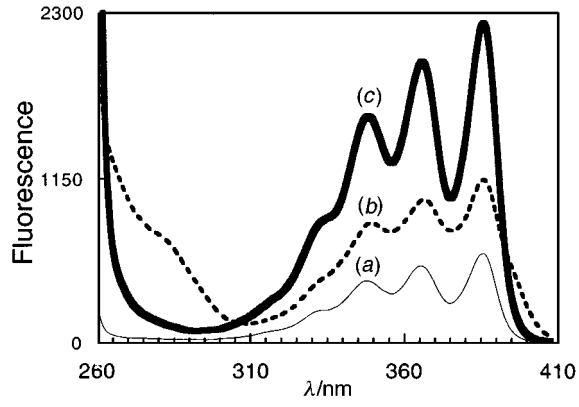

Fig. 4 Fluorescence excitation spectra of *N*-Et-AMAC (2.5 μM) in the presence of (*a*) poly(dI-dC) (99 μM) and (*b*) poly(dG-dC) (97 μM), and (*c*) in the absence of DNA.

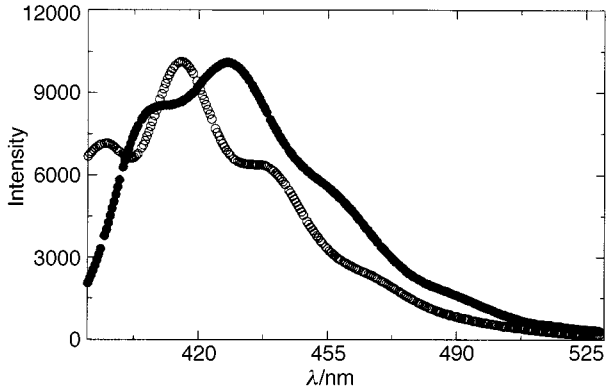

Fig. 5 Fluorescence spectra of *N*-Et-AMAC (5 μM) bound to CT DNA (54 μM) while exciting at (○) 350 and (●) 270 nm. The spectra are normalized to the same height, and no such red shifted emission was observed from *N*-Et-AMAC bound to poly(dG-dC).

energy transfer efficiencies on the DNA sequence and the curves obtained with GC and IC sequences are shown. Light absorption by the probe in the 260–320 nm region is weak, with a broad valley appearing in this window (thick line, Fig. 4). Light absorption by the DNA and subsequent energy transfer to the anthryl excited state is expected to result in sensitized anthryl emission. Accordingly, strong excitation bands in the 260–300 nm region were observed for *N*-Et-AMAC in the presence of IC sequences (dashed line). No such excitation bands appear in the spectrum of *N*-Et-AMAC when bound to poly(dG-dC) (thin line). The fluorescence spectral maxima of *N*-Et-AMAC, under these conditions, correspond to that of the probe bound to DNA (shown below), and the sensitized emission observed with poly(dI-dC) is indeed from the anthryl chromophore.

The *N*-Et-AMAC emission spectra when bound to DNA has distinct peaks at 395, 415 and 440 nm (Fig. 5, direct excitation at 360 nm), similar to those of the free chromophore, and these spectra are independent of the DNA sequence. However, when the excitation was shifted to 270 nm (into the DNA absorption region), new red-shifted emission at 405, 428, and 455 nm was observed (Fig. 5). This new emission was assigned to the chromophores bound to the DNA that are sensitized by the DNA excited states. Such red shifted emission was not observed when *N*-Et-AMAC was bound to poly(dG-dC) (270 nm excitation). These data, clearly suggest sequence dependent sensitization of anthryl fluorescence by the DNA base pairs. If the energy transfer does occur from DNA to the anthryl chromophore, then the excitation bands corresponding to the sensitizer absorption bands should appear in the excitation spectra. These are shown in Fig. 4. *N*-Et-AMAC does not have any absorption bands in the 260–320 nm region and thus, lends itself to the testing of the energy transfer hypothesis. The excitation spectra clearly indicate strong absorption in the 260–300 nm region and this absorption band is absent in the anthryl absorption spectra (bound to DNA or free). This interpretation is strengthened by the fact that the corresponding new excitation bands are absent in the presence of poly(dG-dC) and therefore, the results indicate the sequence dependence of the energy transfer process.

Exothermic energy transfer from all the DNA bases to the anthryl probe may be expected, considering the large singlet excited state energies of DNA bases (34000–35000 cm^{-1}).[5] The strong overlap of the DNA fluorescence spectra (300–400 nm) with the absorption of spectrum of *N*-Et-AMAC, and the fairly large excitation coefficients for the *N*-Et-AMAC absorption transitions suggest facile energy transfer from the DNA singlet excited states to the anthryl chromophore. Hence, the sequence dependence for energy transfer observed here is unexpected. Back energy transfer from the anthryl excited state to the DNA excited states is expected to be highly endothermic and slow. The clear dependence of the energy transfer on the DNA base sequence is suggestive of the ability of the anthryl excited state to differentiate between different DNA base pairs.

Light energy is nearly equally absorbed by all DNA base pairs in the 265–280 nm window. The excitation is known to migrate over a few base pairs along the DNA chain.[5] AT base pairs are four times less likely to trap excitation than GC pairs, and excitation localized at the GC sites is quenched efficiently at the singlet level *via* non-radiative paths, resulting in low fluorescence quantum yields.[5,6] The DNA fluorescence intensity, therefore, decreases with increased GC content of the DNA.[5] Rapid singlet–singlet energy transfer, therefore, is more likely to occur from the AT sites than from the GC sites. Energy transfer from DNA to *N*-Et-AMAC is expected to be sequence dependent and to be least efficient at GC sites. Such sequence dependence, however, was not observed with ethidium bromide (a known intercalator) and one could argue that the energy migration along the helix is slower than energy transfer to ethidium bromide, resulting in no sequence dependence. An alternative explanation for the sequence dependent energy transfer from DNA to *N*-Et-AMAC may have to do with the redox potentials of the bases. The oxidation potentials of different nucleotides are known to vary as GGG < GG < G < A < C < T.[7] One possibility is that the singlet excited states of GC base pairs are quenched by *N*-Et-AMAC by electron transfer rather than by energy trasnfer, due to the low oxidation potential of G compared to other bases.

The sequence dependence of energy transfer may arise from a combination of the excited state properties of the anthryl chromophore as well as those of the DNA bases. All DNA sequences quench the fluorescence from *N*-Et-AMAC with similar efficiencies [quenching constants for CT DNA, poly d(GC) and poly d(IC) sequences are 1.23×10^4, 1.43×10^4 and 1.24×10^4 M^{-1}, respectively). The quenching constants are nearly the same within experimental error and these data cannot account for the new excitation and emission bands presented here. Therefore, the overall sequence dependence may arise from a combination of facile energy transfer from the excited states of IC sequences and rapid electron transfer from the excited GC base pairs. While the exact mechanism of the sequence dependence for energy transfer is beyond the scope of this report, the current observations are being exploited in sequence dependent DNA cleavage studies.[8]

Evidence for unusually strong intramolecular hydrogen bonding in highly nonplanar porphyrins

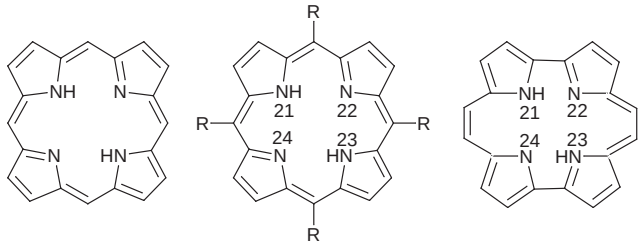
Maria S. Somma, Craig J. Medforth,* Nora Y. Nelson, Marilyn M. Olmstead, Richard G. Khoury and Kevin M. Smith

Department of Chemistry, University of California, Davis, CA 95616, USA. E-mail: medforth@indigo.ucdavis.edu

Received (in Corvallis, OR, USA) 23rd March 1999, Accepted 27th April 1999

The ^{1}H NMR spectra of the 5,10,15,20-tetraalkylporphyrins 2–4 reveal a large downfield shift of the signal for the NH protons and a reduction in the activation energy for NH tautomerism as the alkyl substituents become larger; these unusual changes can be rationalized in terms of greatly enhanced intramolecular hydrogen bonding of the NH protons as the bulkier substituents distort the macrocycle from planarity and contract the porphyrin core.

A novel and highly diagnostic feature of the ^{1}H NMR spectra of porphyrins **1** is the presence of a signal at very high field (typically δ −2 to −4) arising from the NH protons.[1,2] Herein, we describe ^{1}H NMR studies of the tetraalkylporphyrins **2**–**4** which provide the first example of a porphyrin with an NH signal far downfield of this 'fingerprint' region. We then propose a mechanism to explain this novel behavior, as well as the unusually facile tautomerism of the NH protons also observed in this porphyrin, and show that this mechanism is consistent with structural parameters determined using X-ray crystallography.



1 **2** R = C_5H_{11}; **3** R = Pr^i; **4** R = Bu^t **5**

The investigated 5,10,15,20-tetraalkylporphyrins **2**–**4** were prepared using published procedures[3] and their ^{1}H NMR spectra were recorded at a frequency of 300 MHz using $CDCl_3$ as the solvent. The ^{1}H NMR spectrum of the pentyl substituted porphyrin **2** showed a signal for the NH protons at δ −2.64, which is within the chemical shift range expected for the NH protons in porphyrins.[1,2] However, the spectrum of porphyrin **3** with more bulky isopropyl substituents showed a significant downfield shift of the NH signal to δ −1.80. In the case of porphyrin **4**, which has the even more bulky *tert*-butyl substituents, a very large downfield shift was seen for the NH signal (δ +1.58) and it was far downfield of the range expected for porphyrins.[1,2]

Large chemical shift changes in the ^{1}H NMR spectra of porphyrins are usually attributed to differences in the contribution from the porphyrin ring current effect.[1,2,4] Given the greater nonplanar distortions observed for metal complexes of tetraalkylporphyrins with larger alkyl substituents[5,6] it is plausible that the downfield shift of the NH signals is the result of a decrease in the porphyrin ring current. However, this approach is unsatisfactory because the ring current decrease determined for some cobalt(III) complexes of **4** is quite small (only about 5%).[7] Moreover, a change in the ring current would not account for the changes in the activation energies for NH tautomerism also observed in these porphyrins. For example, the activation energy for NH tautomerism in **2** measured using NMR spectroscopy ($\Delta G^{\ddagger}_{238}$ = 50 kJ mol^{-1}) was found to be similar to that measured for other nominally planar porphyrins ($\Delta G^{\ddagger}_{298}$ = 50±3 kJ mol^{-1}).[4] In addition, as with other porphyrins, the activation energy for tautomerism in **2** increased upon replacement of the inner hydrogens with deuteriums ($\Delta G^{\ddagger}_{283}$ = 60 kJ mol^{-1} in **2** *vs.* $\Delta G^{\ddagger}_{298}$ = 57±2 kJ mol^{-1} in regular porphyrins).[4] However, the activation energy for tautomerism in **3** was significantly reduced in both the dihydro ($\Delta G^{\ddagger}_{183}$ = 38 kJ mol^{-1}) and dideutero ($\Delta G^{\ddagger}_{233}$ = 50 kJ mol^{-1}) forms, and in porphyrin **4** there was no evidence of a dynamic process in either the dihydro or dideutero forms even at the lowest temperatures studied (182 K) indicating an extremely low activation energy.

In order to explain these changes in the NH chemical shifts and activation energies for NH tautomerism, we propose an alternative model in which there is also a substantial increase in intramolecular hydrogen bonding as the substituents become larger. This hydrogen bonding will produce an additional downfield shift for the NH protons, and should also lower the activation energies for tautomerism because intramolecular hydrogen bonding is analogous to the transition state for tautomerism where the hydrogens are co-shared by adjacent nitrogen atoms.[4,8] Such strong intramolecular hydrogen bonding has not previously been postulated in porphyrins, although this phenomenon has been invoked by Vogel and co-workers[9] to explain similar NMR behavior in the porphyrin isomer porphycene **5**. In porphycene, the unusual 'oblong' geometry of the macrocycle appears to provide both short N–N distances (N21–N22 2.83 Å, N21–N24 2.63 Å) and a nearly linear arrangement of a hydrogen bond between N21 and N24. In the case of porphyrins **2**–**4** it seemed likely that the increased intramolecular hydrogen bonding suggested by the NMR studies might be the result of the bulkier alkyl substituents forcing the porphyrin rings to adopt increasingly ruffled conformations, as seen for metal complexes of related tetraalkylporphyrins.[5,6] This ruffling distortion would contract the porphyrin core and shorten the distance between adjacent nitrogen atoms, thereby enhancing intramolecular hydrogen bonding.

The crystal structures of porphyrins **2**–**4** were determined† to see if they were consistent with this model. As can be seen in Fig. 1, the porphyrins with larger substituents do show increased ruffling of the macrocycle. This ruffling will maximize core contraction compared to other nonplanar distortion modes[10] and will also keep the nitrogen and hydrogen atoms in the porphyrin plane. Hence, the crystal structures show precisely the kind of nonplanar deformation expected to enhance intramolecular hydrogen bonding and produce the effects observed in the ^{1}H NMR spectra. Furthermore, the much larger effects seen in the NMR spectra of porphyrin **4** can be related to the significantly greater core contraction seen for this porphyrin (the average distance between the adjacent nitrogen atoms in **4** is only 2.71 Å *vs.* 2.89 Å in **3** and 2.91 Å in **2**). Note

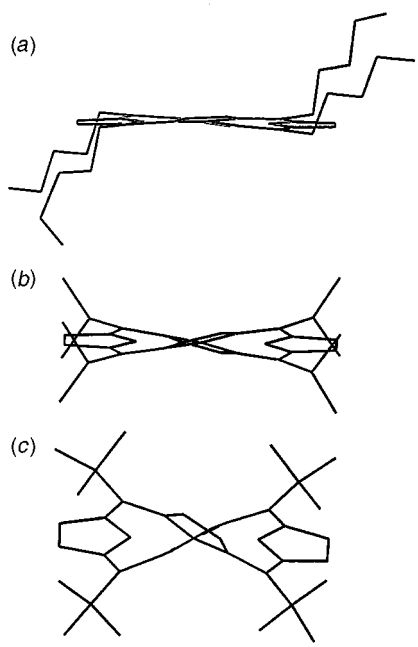


Fig. 1 Side-on views of the crystal structures of porphyrins (*a*) **2**, (*b*) **3** and (*c*) **4**. Hydrogen atoms have been omitted for clarity.

that a more detailed analysis of the pattern of hydrogen bonding within the porphyrin cores was also attempted but did not yield any definitive results. For example, the hydrogens in **4** were localized on an opposing pair of pyrrole rings and tilted towards adjacent nitrogen atoms (NH 21 towards N24 and NH 23 towards N22) possibly suggesting some additional deformation as a result of the severe core contraction. However, a review of other tetraalkylporphyrin crystal structures revealed similar NH tilting even in nominally planar systems.[3]

The studies reported here show that intramolecular hydrogen bonding in porphyrins can be strongly enhanced by a specific type of nonplanar distortion (ruffling), and also provide another example of the sometimes unexpected ways in which nonplanarity can affect the properties of porphyrins.[11] The fact that enhanced intramolecular hydrogen bonding has not previously been noted in other extremely nonplanar porphyrins is probably related to the predominantly saddle conformations[12] adopted by these molecules, where tilting of the pyrrole rings out of the porphyrin plane will disfavor intramolecular hydrogen bonding. Indeed, recent studies of such porphyrins have shown downfield shifts of the NH protons in some solvents due to increased *intermolecular* hydrogen bonding.[13] Finally, it is should be noted that this new information about hydrogen bonding in porphyrins, together with recent studies showing that even large nonplanar distortions result in only modest decreases in the porphyrin ring current effect,[7] suggests that the practice of using the chemical shift of the NH protons as an indicator of structurally induced changes in the porphyrin ring current may need to be approached with more caution.

† *Crystal data* for **2**: $C_{40}H_{54}N_4$, crystals were grown *via* slow diffusion of MeOH into a solution of **2** in THF, dimensions 0.20 × 0.38 × 0.55 mm, orthorhombic, space group $P2_12_12_1$, a = 13.416(2), b = 15.734(3), c = 16.473(2) Å, V = 3477.2(9) Å^3, Z = 4 (M = 590.87). Diffraction data were collected on a Syntex $P2_1$ diffractometer with a graphite monochromated sealed tube X-ray source [λ(Cu-Kα) = 1.54178 Å] at 130(2) K in $\theta/2\theta$ scan mode to $2\theta_{max}$ = 133.9°. Of 3466 reflections measured (+h,+k,+l), all were independent and 3229 had $I > 2\sigma$ (T_{max} = 0.77, T_{max} = 0.91, ρ_{calc} = 1.129 g cm^{-3}, μ = 0.497 mm-1). The structure was solved by direct methods and refined (based on $F2$ using all independent data) by full-matrix least-squares methods with 398 parameters (Siemens SHELXTL ver. 5.03). All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atom positions were generated by their idealized geometry and refined using a riding model, except for the hydrogen atoms bonded to the pyrrole nitrogen atoms. In this case, electron density corresponding to a hydrogen atom was present at each pyrrole ring in difference Fourier maps, so each of the nitrogens was assigned a hydrogen at 0.5 occupancy. No absorption correction was applied. The final difference map had a largest peak of 1.45 e Å^{-3} and a largest hole of −0.40 e Å^{-3}. Final R factors were $R1$ = 0.0615 (observed data) and $wR2$ = 0.166 (all data).

For **3**: $C_{32}H_{38}N_4$, crystal grown *via* slow diffusion of cyclohexane into a solution of **3** in CH_2Cl_2, dimensions 0.24 × 0.24 × 0.14 mm, orthorhombic, space group $Fdd2$, a = 20.257(4), b = 20.999(4), c = 12.373(3) Å, V = 5263(2) Å3, Z = 8 (M = 478.66). Diffraction data were collected on a Syntex $P2_1$ diffractometer with a graphite monochromated sealed tube X-ray source [λ(Cu-Kα) = 1.54178 Å] at 130(2) K in $\theta/2\theta$ scan mode to $2\theta_{max}$ = 113.0°. Of 996 reflections measured (+h,+k,+l), 920 were independent (R_{int} = 0.038), and 817 had $I > 2\sigma$ (T_{min} = 0.88, T_{max} = 0.93, ρ_{calc} = 1.203 g cm^{-3}, μ = 0.546 mm^{-1}). The structure was solved by direct methods and refined (based on F^2 using all independent data) by full matrix least-squares methods with 168 parameters (SHELXS-86, SHELXL-93). All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atom positions (except for the core pyrrolic NHs) were generated by their idealized geometry and refined using a riding model. Core hydrogen atoms, located in a difference Fourier map, were found to be localized on one opposing pair of pyrrole nitrogen atoms and were refined freely. An empirical absorption correction was applied using XABS2 (ref. 14). The final difference map had a largest peak of 0.19 e Å^{-3} and a largest hole of −0.22 e Å^{-3}. Final R factors were $R1$ = 0.0475 (observed data) and $wR2$ = 0.1272 (all data). CCDC 182/1265.

Full details of the crystal structure of **4** and related metal complexes of this porphyrin will be presented shortly (ref. 15).

NMR detection of thermal and photochemical dihydrogen addition products of mono- and tri-nuclear ruthenium complexes containing carbonyl and triphenylphosphine ligands through *para*-hydrogen induced polarisation

Christopher J. Sleigh, Simon B. Duckett,* Roger J. Mawby and John P. Lowe

Department of Chemistry, University of York, York, UK YO10 5DD. E-mail: sbd3@york.ac.uk

Received (in Cambridge, UK) 26th April 1999, Accepted 25th May 1999

Enhancement of NMR signals by *para*-hydrogen induced polarisation is shown to facilitate the detection of isomers of $Ru(CO)_2(H)_2(PPh_3)_2$ and $Ru(CO)_3(H)_2(PPh_3)$ which contain inequivalent hydride ligands, and to demonstrate that $Ru_3(CO)_9(PPh_3)_3$ adds H_2 to form $Ru_3(CO)_8(H)(\mu\text{-}H)(PPh_3)_3$, as well as undergoing fragmentation to form $Ru(CO)_3(H)_2(PPh_3)$.

We have shown that the enhanced absorption and emission signals observed in NMR spectra of complexes incorporating hydrogen nuclei derived from *para*-enriched hydrogen[1] (p-H_2) can be used to detect and characterise materials present at concentrations too low for detection by normal NMR methods.[2] In particular, using this approach we have been able to identify minor all-*cis* isomers of $Ru(CO)_2(H)_2L_2$ (L = PMe_2Ph or PMe_3) that were previously unknown.[3] Here we extend this approach by demonstrating how both $Ru(CO)_3(H)_2(PPh_3)$ **1** and $Ru(CO)_2(H)_2(PPh_3)_2$ **2** behave with p-H_2. We show that two isomers of both **1** and **2** are detectable, and demonstrate that $Ru_3(CO)_9(PPh_3)_3$ reacts with hydrogen to yield new clusters containing bridging and terminal hydride ligands and also fragments to $Ru(CO)_3(H)_2(PPh_3)$. The precursors required for these studies, $Ru(CO)_3(PPh_3)_2$, $Ru_3(CO)_9(PPh_3)_3$ and *trans*-*cis*–*cis*-$Ru(CO)_2(H)_2(PPh_3)_2$ **2a**, were prepared by standard methods.[4] These complexes were selected for study because, despite the fact that ruthenium/carbonyl/triphenylphosphine species have been implicated in catalytic cycles involving H_2, their reactivity towards H_2 is only poorly understood.[5–7]

When a benzene-d_6 solution of $Ru(CO)_3(PPh_3)_2$ under 3 atm of p-H_2 was warmed to 353 K, no change in the ^{1}H NMR spectrum of the solution was detected. However, when a similar solution, also under p-H_2 was photolysed for 2 min, an NMR spectrum recorded at 308 K contained enhanced resonances at δ −6.67 (H_a, dd, J_{PH} 15.9, J_{HH} −5.4 Hz) and δ −7.34 (H_b, dd, J_{PH} 61.6, J_{HH} −5.4 Hz) [Fig 1(a)]. The values for J_{PH} suggested that the species responsible for these resonances, **1a**, contained a single PPh_3 ligand lying *cis* to H_a and *trans* to H_b. The p-H_2 enhanced complex **1a** was further characterised by 2D NMR,[8] allowing the ^{31}P resonance to be located at δ 20.3. In order to obtain ^{13}C data, ^{13}CO-labelled $Ru(CO)_3(PPh_3)_2$ was photolysed with p-H_2. In the resulting ^{1}H NMR spectrum of ^{13}CO-labelled **1a**, the H_a resonance showed an additional doublet splitting (J_{CH} 27.8 Hz) indicative of a *trans* H–Ru–CO arrangement. Two ^{13}CO resonances were detected at δ 197.6 and 199.5 by a ^{1}H–^{13}C HMQC experiment. The data indicated that **1a** was the *mer* isomer of $Ru(CO)_3(H)_2(PPh_3)$. This complex has not previously been observed by NMR, although high pressure IR studies have indicated its existence.[6] Surprisingly, in the corresponding ^{1}H–^{31}P correlation, additional resonances corresponding to the *fac* isomer of $Ru(CO)_3(H)_2(PPh_3)$ **1b** were detected which were missed in the original ^{1}H NMR spectrum owing to coincidental overlap with the resonance due to H_a of **1a**.

A very weak hydride resonance could also be seen in the ^{1}H NMR spectra of the photolysed solutions at δ −6.35 (t, J_{PH} 23.2 Hz). This was shown to be due to the *trans*–*cis*–*cis* isomer of $Ru(CO)_2(H)_2(PPh_3)_2$ **2a** by comparison with the spectrum of an authentic sample (see above). Under normal H_2, and after prolonged photolysis, **2a** was the only detectable product.

When the solution containing $Ru(CO)_3(PPh_3)_2$ and **1a** enhanced with p-H_2 was warmed to 328 K, the hydride resonances for **1a** broadened substantially, and a second pair of polarised hydride resonances appeared at δ −6.27 (ddd, J_{PH} 26.4, 19.1, J_{HH} = −7.1 Hz) and −7.52 (ddd, J_{PH} 75.1, 33.0, J_{HH} −7.1 Hz). Resonances for two inequivalent ^{31}P nuclei, both doublets with J_{PP} 32.0 Hz, were located in the ^{1}H–^{31}P spectrum at δ 50.2 and 41.6. It was concluded that the species responsible for the new resonances was the previously undetected all-*cis* isomer of $Ru(CO)_2(H)_2(PPh_3)_2$ **2b**.

A ^{1}H–^{1}H PHIP–EXSY experiment, recorded at 308 K, contained exchange peaks that indicated that the hydride ligands of *mer*-$Ru(CO)_3(H)_2(PPh_3)$ **1a** were interchanging positions with a rate constant of 40 s^{-1}. Even at higher temperatures, however, no peaks connected the resonances of **1a** to those of **2b**, suggesting that the interchange may be intramolecular,

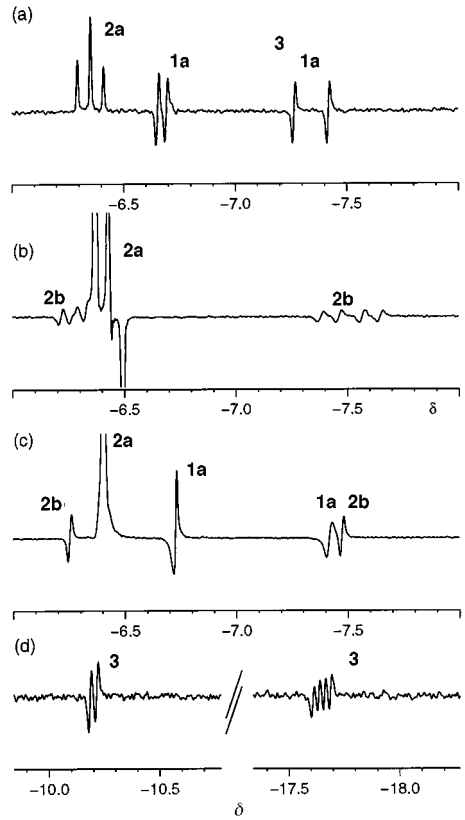

Fig 1 NMR spectra of reaction products obtained with p-H_2 in C_6D_6 showing the hydride region only. The antiphase components arise in transitions involving protons that originate from p-H_2. (a) ^{1}H spectrum of **1a** generated after UV irradiation of a sample of $Ru(CO)_3(PPh_3)_2$ at 308 K; (b) ^{1}H spectrum of **2b** at 328 K; (c) ^{1}H spectrum of a sample of **2a** warmed with p-H_2 in the presence of CO at 318 K; (d) ^{1}H spectrum of **3** generated from a sample of $Ru_3(CO)_9(PPh_3)_3$ at 308 K.

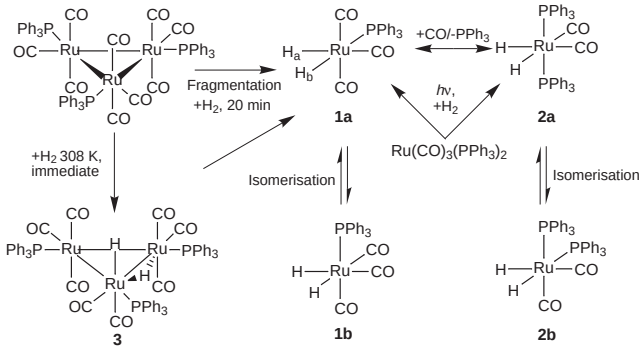

Scheme 1

perhaps a trigonal twist process similar to that reported for $Ru(CO)(H)_2(PPh_3)_3$.[9]

The interconversions between **2a**, **2b** and **1a** were further investigated using an authentic sample of **2a**. When a benzene-d_6 solution of **2a** was heated under 3 atm of *p*-H_2 to 328 K, no signals for **1a** were visible in the ^{1}H NMR spectrum, but the hydride resonances for **2b** were again observed [Fig. (1b)]. An NMR tube containing a fresh solution of **2a** was then placed under 1 atm of CO, frozen and then filled with 3 atm of *p*-H_2. When the solution was warmed to 318 K, the enhanced hydride resonances of **1a** and **2b** were observed [Fig. 1(c)]. Evidently **2a** readily undergoes replacement of PPh_3 by CO. We have recently adapted an NMR probe to allow a sample to be irradiated by UV light from a HgXe arc while NMR spectra are recorded.[10] ^{1}H NMR spectra recorded during photolysis of a benzene-d_6 solution $Ru(CO)_3(PPh_3)_2$ under 3 atm of *p*-H_2 at 292 K showed large enhanced hydride signals due to **1a** and a small non-enhanced signal due to **2a**. The signals for **1a** were not observed in the absence of UV radiation, confirming that, in this case, hydrogen exchange between **1a** and free H_2 is photochemical rather than thermal.

Many phosphine-substituted derivatives of $Ru_3(CO)_{12}$ have been characterised and studied, but the reactions of these complexes with hydrogen are less well understood.[11] We have therefore used *p*-H_2 to monitor the reaction of $Ru_3(CO)_9(PPh_3)_3$ with hydrogen. Nevinger *et al*. used a complex synthetic procedure to obtain a species believed to be $Ru_3(CO)_{11}H(\mu\text{-}H)$, whose ^{1}H NMR spectrum contained hydride resonances at δ −11.79 and 18.55.[12] We recorded the ^{1}H NMR spectrum of a benzene-d_6 solution of $Ru_3(CO)_9(PPh_3)_3$ under *p*-H_2 at 308 K, and detected enhanced resonances at δ −10.20 (dd, J_{PH} 11.2, J_{HH} −6.0 Hz) and −17.64 (ddd, J_{PH} 21.2,10.4, J_{HH} −6.0 Hz) for two mutually coupled hydrides in a species **3** [Fig. 1(d)]. The chemical shifts and couplings to phosphorus suggested that the former resonance represented a terminal hydride *cis* to a phosphine and the latter a hydride bridging two ruthenium atoms and *cis* to a phosphine ligand on each ruthenium. A 2D experiment located the resonances for the corresponding ^{31}P nuclei at δ 44.4 (coupled to both hydrides) and −17.6 (coupled only to the terminal hydride). From this evidence it appeared that **3** was the 48-electron cluster $Ru_3(CO)_8H(\mu\text{-}H)(PPh_3)_3$, with the structure shown in Scheme 1. The third ^{31}P nucleus was not detected by the 2D experiment because it is not coupled to either hydride. Complex **3**, which is comparable to both $Ru_3(CO)_{11}H(\mu\text{-}H)$ and $Os_3(CO)_{10}H(\mu\text{-}H)L$ (L = PPh_3 or CD_3CN),[13] is presumably formed by a simple substitution of CO by H_2.

After 20 min at 308 K, resonances for isomer **1a** of $Ru(CO)_3H_2(PPh_3)$ had appeared in the ^{1}H NMR spectrum of the solution. Consequently, either unreacted $Ru_3(CO)_9(PPh_3)_3$ or $Ru_3(CO)_8H(\mu\text{-}H)(PPh_3)_3$ fragment under hydrogen to yield mononuclear ruthenium complexes under relatively mild conditions. This observation is interesting, given that mixtures of $Ru_3(CO)_{12}$ and PPh_3 have been used in hydroformylation catalysis and $Ru(CO)_3(H)_2(PPh_3)$ has been implicated as an intermediate in hydroformylation.[5,7] No *para*-hydrogen enhanced products, either tri- or mono-nuclear, were detected on treating $Ru_3(CO)_{12}$ with *p*-H_2 either in the presence or the absence of UV irradiation.

Here, we have established some features of the ruthenium carbonyl/triphenylphosphine/hydrogen system, which shows some important differences from those with PMe_2Ph and PMe_3. Furthermore, we have established the feasibility of using *p*-H_2 to probe photochemical reactions, H_2 addition to clusters, and cluster fragmentations.

We are grateful to the EPSRC (C. J. S. and spectrometer), the University of York (J. P. L.), Bruker UK (spectrometer) and the Royal Society for financial support. We appreciated helpful discussions with Professor R. N. Perutz, Dr M. K. Whittlesey and Dr J. M. Lynam. A generous loan of ruthenium trichloride from Johnson Matthey is also gratefully acknowledged.

Evidence for a common Ru(P)$(NO)_2$ intermediate in photochemical and synthesis pathways involving Ru(TmTP)(NO)(ONO) and excess nitric oxide

Ivan M. Lorkovic and Peter C. Ford*

Department of Chemistry, University of California, Santa Barbara, CA 93106, USA. E-mail: ford@chem.ucsb.edu

Received (in Bloomington, IN, USA) 4th March 1999, Accepted 19th May 1999

Optical and IR spectra of the intermediate formed from the reaction of Ru(CO)(TmTP) with NO are compared with transient UV–VIS and FTIR spectra of photochemical intermediates formed from the photolysis and recovery of Ru(TmTP)(NO)(ONO) in the presence of NO; comparison reveals that the two pathways share a common intermediate, which IR spectral properties suggest to be *trans*-Ru(TmTP)$(NO)_2$.

The reaction chemistry of nitric oxide has drawn renewed attention owing to the established biological roles of NO and its interactions with metal centers in mammalian cardiovascular systems, in immunology and in various human disease states.[1–4] In this context we have been studying reactions of NO with metal porphyrin complexes,[5–7] and we and others have shown that the reaction of Ru^{II}(CO)(P) (P^{2-} = a porphyrinato dianion) with excess NO in hydrocarbon solvents forms the nitrito nitrosyl complex Ru(P)(NO)(ONO).[5,8] The other product is 1 equiv. of N_2O [eqn. (1)].[8] Other metal centers have long been known to facilitate the NO disproportionation in the presence of excess nitric oxide.[9,10]

$$Ru(P)(CO) + 4\,NO \longrightarrow Ru(P)(NO)(ONO) + N_2O \qquad (1)$$

Stopped flow kinetics studies in this laboratory with P = TmTP (tetra-*m*-tolylporphyrinate) or OEP (octaethylporphyrinate) have shown that the reaction in eqn. (1) proceeds by several steps.[6] There is a discernable intermediate **X** with a composition consistent with that of Ru(P)$(NO)_2$, and this reacts further by a pathway second order in [NO] to give Ru(P)(NO)(ONO).

$$Ru(P)(CO) + 2\,NO \rightleftharpoons \mathbf{X} + CO \qquad (2)$$

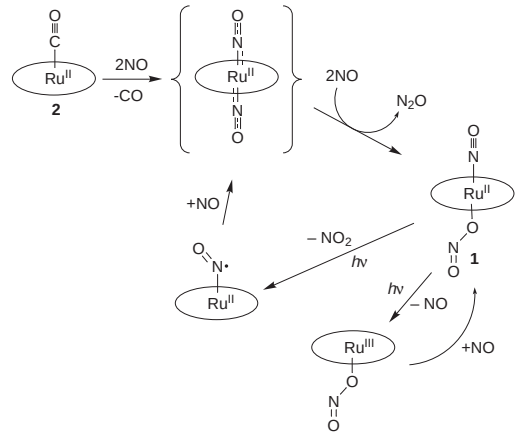
$$\mathbf{X} + 2\,NO \longrightarrow Ru(P)(NO)(ONO) + N_2O \qquad (3)$$

Parallel work in this laboratory has been concerned with the photochemistry of various Ru(P)(NO)(ONO).[11] Flash photolysis in benzene was shown to give two primary photoproducts, which were proposed to be Ru^{III}(P)(ONO) (resulting from photolabilization of NO) and Ru^{II}(P)(NO) (resulting from photolabilization of NO_2) both of which react with the excess NO to reform Ru(P)(NO)(ONO). Reformation of Ru(TmTP)(NO)(ONO) **1** from Ru^{III}(TmTP)(ONO) was shown to proceed by second order recombination with NO ($k_A = 5.5 \times 10^8$ dm^3 mol^{-1} s^{-1}). The regeneration of **1** from Ru(TmTP)(NO) **2** proved to be more circuitous; first there is a second order reaction of **2** with NO ($k_B = 4.5 \times 10^7$ dm^3 mol^{-1} s^{-1}) to form yet another transient species **Y**, then a much slower reaction of **Y** with excess NO to give **1**.[11]

On the basis of similarities in their optical spectra and reactivities, **X** and **Y** were suggested to be the same species, namely Ru(TmTP)$(NO)_2$. The OEP complex behaves similarly.[11] We present here a comparison of the UV–VIS and IR spectra of the photochemically prepared intermediate **Y** to those of **X** which was prepared by rapid mixing techniques in the thermal reaction of Ru(TmTP)(CO) plus NO. These data provide compelling evidence that the thermal and photochemical routes do indeed share a common intermediate. Also, IR analysis of the transient species of the thermal reaction confirms that N_2O production occurs during the second step of the thermal reaction, and that the isomerization of a predicted transient nitrosyl nitro species to **1** (Scheme 1) occurs too quickly to be observed by stopped flow techniques.

The optical spectral changes observed upon rapid mixing of cyclohexane solutions of NO and Ru(TmTP)(CO) are virtually identical in profile and time dependence to the changes observed using toluene as solvent.[6] In short, the carbonyl complex (Q band λ_{max} at 528 nm; $\varepsilon = 2.5 \times 10^3$ dm^3 mol^{-1} cm^{-1}) gives way, within 5 ms after mixing, to an intermediate (546 and 580 nm; 16×10^4 and 5×10^4 dm^3 mol^{-1} cm^{-1}), which reacts slowly ($k_{obs} = 0.3$ s^{-1}), in a second step, to give **1** (561 nm; 10.2×10^3 M^{-1} cm^{-1}). Furthermore the difference optical spectrum observed, after flash photolysis of a solution of **1** in cyclohexane in the presence of NO (5 mM) is indistinguishable from the difference spectrum between **X** and **1**.

Fig. 1(a) shows the IR spectral changes associated with the generation of **Y** within 1 μs after flash photolysis of **1** in cyclohexane solutions containing 5 mM NO (previously reported[11] but included here for purposes of comparison). Fig. 1(b) shows IR spectral data generated using a custom built, hand driven stopped-flow reactor to mix Ru(TmTP)(CO) with NO in a 1 mm pathlength IR cell. This difference spectrum was generated by subtracting the product spectrum generated by mixing identical concentrations of NO and Ru(TmTP)(CO) and waiting about 20 s from the initial spectrum seen immediately after mixing. The positive peaks represent the initial species formed, *i.e.* **X**, while the negative peaks can be largely attributed to the ruthenium containing product **1**, although the small peak at 2215 cm^{-1} is attributed to the formation of N_2O. Successive difference spectra show the positive and negative peaks returning to baseline as the intermediate **X** undergoes reaction with NO to form **1** and the transient spectra converge on the product spectrum. The intensities of the negative peaks in Fig. 1(a) represent *ca.* 95% of the maximum ΔA possible as determined by subtracting the product solution spectrum from



Scheme 1

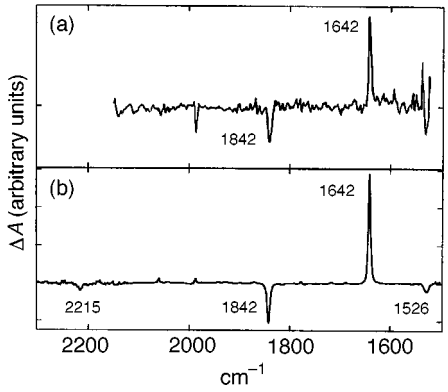


Fig. 1 (a) Long term (8–20 μs) FTIR difference spectrum observed using a step scan instrument after flash photolysis of a solution of **1** (200 μM) in cyclohexane in the presence of NO (5 mM).[11] (b) FTIR difference spectrum obtained by subtraction of the product spectrum recorded 15 s after mixing from the transient spectrum in cyclohexane recorded *ca*. 0.2 s after mixing of Ru(CO)(TmTP) (150 μM after mixing) with NO (3.9 mM) in a flow experiment. For both top and bottom spectra, the small peaks observed between 1900 and 2100 are solvent subtraction errors and correspond exactly to cyclohexane peaks.

that of pure cyclohexane. Thus, the subsequent reaction of **X** with NO has proceeded by only *ca*. 5%, and one can use the previously determined rate constant for this process to estimate the elapsed time after mixing at *ca*. 0.2 s. In this time frame, the starting material Ru(TmTP)(CO) would have reacted to completion ($k_{obs} = k_1[NO] = 3.8 \times 10^3$ s^{-1}).

It is clear from a comparison of Fig. 1(a) with 1(b) that the photolysis of **1** in the presence of NO and the reaction of Ru(CO)(TmTP) with NO generate the same intermediate, *i.e.* that **X** and **Y** are both Ru(TmTP)$(NO)_2$. There are several additional implications of these data. First, the negative peaks at 1527 and 1842 cm^{-1} show the same absorbance ratio (*ca*. 1/5) as observed for independently purified **1** in cyclohexane. This indicates that the negative peak at 1842 cm^{-1} does not overlap with a positive absorbance arising from **X**. (The small peaks visible at 1790, 1990 and 2060 cm^{-1} are due to imperfect solvent subtraction and correspond exactly to peaks in the cyclohexane spectrum). The peak at 1642 cm^{-1} is the sole characteristic absorbance of **X** with appreciable intensity between 2300 and 1500 cm^{-1}. Therefore the absorption coefficient at 1642 cm^{-1} may be estimated as 9000 dm^3 mol^{-1} cm^{-1} by intensity comparison to the negative ν_{NO} peak at 1842 cm^{-1} (3300 dm^3 mol^{-1} cm^{-1}) for **1**. The integrated intensity of the former is *ca*. 2.3 as strong as the latter.

There still remains some ambiguity with respect to the likely structure of **X**. Two possibilities would be the six coordinate dinitrosyl species implied above by the formula Ru(TmTP)$(NO)_2$ in either the *cis* or *trans* configurations. The *cis* dinitrosyl appears quite unlikely since it should show two IR active ν_{NO} bands, but only one was detected. In contrast, a linear array of two *trans* NO ligands bound to the metal in a centrosymmetric *ca*. D_{4h} point group should show a single IR band, the antisymmetric A_{2u} stretching mode of the two diatomic ligands with roughly twice the transition dipole strength of a single nitrosyl stretch. The symmetric A_{1g} stretch should not be IR active. Although ν_{NO} frequencies as low as 1600 cm^{-1} have been reported for linear or near linear metal nitrosyls,[12] the 1642 cm^{-1} remains unexpectedly low for a linear M–NO, since such bonding is commonly viewed as the result of NO^+coordination. A possible explanation would be that the two additional electrons necessary for the dinitrosyl formulation of **X** are in π* molecular orbital(s) delocalized over the five atom ONRuNO structure, thus giving a lower effective NO bond order, hence a lower ν_{NO}. The IR data are also consistent with a *trans*-Ru$(NO)_2$ structure with Ru–N–O angles less than 180° if the two NO groups are positioned in a manner to maintain a center of inversion (C_{2h} symmetry). Observation of but a single, sharp ν_{NO} band would appear to require a strong thermodynamic preference for this centrosymmetric configuration under the reaction conditions, unless there is very poor coupling between two such oscillators positioned on opposite sides of the Ru(P) plane.[13]

The difference spectrum Fig. 1(b) also shows a negative peak at 2215 cm^{-1} which decays back to baseline on the same time scale as the other negative peaks. This indicates that N_2O is formed concomitantly with **1** during the second stage in the reaction sequence in approximately the stoichiometry indicated by eqn. (3).[14] Although the final step in the mechanism described by Scheme 1 would be isomerization of an initially formed N-coordinated nitro complex to the O-bound nitrito analogue, the stopped-flow IR experiment gave no indication of intermediates between **X** and **1**. Thus, either this linkage isomerization is much faster than the trimolecular reaction of **X** with NO or this process leads to direct formation of the nitrito product.

This work was supported by the National Science Foundation (CHE-9726889) and by a Collaborative UC/Los Alamos Research (CULAR) Initiative grant from Los Alamos National Laboratory. The stopped flow spectrophotometer was purchased with an Instrumentation grant from the National Science Foundation (CHE 9522259). We thank Dr Brian Lee for intellectual contributions to this research.

13 A referee has suggested another structure for **X**, namely Ru(P)-(N(O)NO), formed by reaction of NO with the coordinated NO of Ru(P)(NO). However, this formulation for **X** would be predicted to give products for the isotopic exchange experiments where Ru(TmTP)-(NO)(ONO) was photolyzed in the presence of $^{15}N^{18}O$ different from those observed (ref. 11). Those products can indeed be explained on the basis of formation of a dinitrosyl Ru(P)$(NO)_2$ intermediate. Another argument against this formulation would be that –N(O)NO ligand would also be expected to give two strong ν_{NO} bands yet only one new band was detected in the 1500–2300 cm^{-1} region. No new bands were seen in the 1000–1500 cm^{-1} region either; however, in that region there are several windows possibly obscured by solvent interference.
14 Based on the estimated absorption coefficients for N_2O, the yield of nitrous oxide in the second stage of the reaction was *ca*. 65% that of **1**, but the small intensity of the signal at 2215 cm^{-1} as well as possible pathways for N_2O loss add to the uncertainty of this value.

Solid oxide fuel cell using Co doped La(Sr)Ga(Mg)O_3 perovskite oxide with notably high power density at intermediate temperature

Tatsumi Ishihara, Takaaki Shibayama, Miho Honda, Hiroyasu Nishiguchi and Yusaku Takita

Department of Applied Chemistry, Faculty of Engineering, Oita University, Dannoharu 700, Oita 870-1192, Japan. E-mail: isihara@cc.oita.u.ac.jp

Received (in Cambridge, UK) 12th April 1999, Accepted 19th May 1999

Power generation characteristics of fuel cells was greatly improved by using $La_{0.8}Sr_{0.2}Ga_{0.8}Mg_{0.115}Co_{0.085}O_3$ as electrolyte. In particular, the maximum power density attained a value of 1.53 and 0.50 W cm^{-2} at 1073 and 873 K, respectively, in an H_2–O_2 cell when the thickness of electrolyte was 0.18 mm.

Solid oxide fuel cells (SOFCs) represent a new and clean electric power generation system. At present, Y_2O_3 stabilized -ZrO_2 (YSZ) is commonly used as the electrolyte of solid oxide fuel cells. Since the oxide ion conductivity of YSZ is fairly low, a thin electrolyte film without gas leakage and an excessively high operating temperature (1273 K) are essential to achieve high power density. On the other hand, advantages for SOFCs such as high efficiency and increased variety of usable fuels can be obtained at decreased temperatures such as 1073 K. Furthermore, choice of the materials for cell stacking becomes wider; in particular, cheap refractory metals such as stainless steel are usable upon decreasing the operating temperature down to 900 K. Consequently, a decrease in operating temperature is of importance for the development of cheap but reliable cells.[1] It is, therefore, of great importance to develop new electrolyte materials which exhibit high oxide ion conduction over a wide oxygen partial pressure. In our previous study, oxide ion conductivity in perovskite oxides were investigated and it was found that the $LaGaO_3$-based perovskite type oxide exhibits high oxide ion conductivity,[7,8] comparable with that of CeO_2-based oxide. In particular, $LaGaO_3$ doped with Sr for La and Mg for Ga sites (LSGM) exhibits high oxide ion conductivity over a wide oxygen partial pressure.[9–12] Furthermore, it was found that doping a small amount of Co into Ga sites of $LaGaO_3$ was effective in improving the oxide ion conductivity, albeit with the appearance of a small amount of hole conductivity.[13] Although the electrical conductivity monotonously increased, the transport number of oxide ion decreased with increasing Co content. Considering the transport number and oxide ion conductivity, the optimized composition of Co doped $LaGaO_3$ was $La_{0.8}Sr_{0.2}Ga_{0.8}Mg_{0.115}Co_{0.085}O_3$ (denoted LSGMC). Power generation characteristics of SOFCs with LSGMC as electrolyte was thus studied.

All specimens used in this study were prepared by conventional solid state reaction techniques employing powders of La_2O_3, Ga_2O_3, MgO, $SrCo_3$ and CoO (99.5%, Kishida). Details of the preparation procedure can be found elsewhere.[4,13] Sintering was performed at 1773 K for 6 h in air. Platinum paste was applied on both faces of sintered sample disks followed by calcination at 1223 K for 30 min.

In our previous study, for the application of LSGM as electrolyte to SOFCs, it was found that $Sm_{0.5}Sr_{0.5}CoO_3$ and Ni were appropriate for the cathode and the anode, respectively.[12] Using the same cathode and anode in this study, LSGMC was chosen as the electrolyte to develop SOFCs operable at intermediate temperatures. The initial SOFC fabricated in this study consisted of a single planar type cell of 20 mm diameter and the anode and cathode were both of 5 mm diameter. Pure O_2 or dry air and H_2 mixed with H_2O (3 vol%) were fed to the cathode and the anode, respectively, at 100 ml min^{-1}. The power generation characteristics were measured by a four probe method and a galvanostat was used to provide the electrical load.

The temperature dependence of the maximum power density together with the open circuit potential are shown in Fig. 1. The power generation characteristics of the cells using air and pure oxygen are also compared at 1073 K (Fig. 1). Open circuit potentials were slightly smaller than the theoretical values owing to hole conduction at high oxygen partial pressure, however, they remain > 1.0 V at all temperatures for both H_2–O_2 and H_2–air cells. On the other hand, notably large power densities are exhibited at all temperatures. When O_2 is used as oxidant, maximum power densities at 1273 and 1073 K are 1.40 and 0.77 W cm^{-2}, respectively. Furthermore, even at 873 K, the maximum power density is as high as 0.19 W cm^{-2}. At present, YSZ is the most common electrolyte for SOFCs. However, the maximum power density of an H_2–O_2 cell using YSZ as the electrolyte under the same conditions is only 0.38 and 0.06 W cm^{-2} at 1293 and 1073 K, respectively. Since the ionic conductivity of YSZ at 1273 K is almost the same as that of LSGMC at 923 K, it is expected that equivalent performances would potentially be achieved at considerably lower temperatures for LSGMC. The power density of the cell was slightly decreased by changing the oxidant from O_2 to air as shown in Fig. 1, however, the maximum power density was still higher than 700 mW cm^{-2} at 1073 K. It is generally observed that the power density is greatly decreased by changing the oxidant from O_2 to air. However, in this case the decrease in the power density was not large. This may result from hole conduction in LSGMC at high oxygen partial pressure. Since an extremely large power density was exhibited for both H_2–O_2 and H_2–air cells, LSGMC is highly attractive as the electrolyte of intermediate temperature SOFCs.

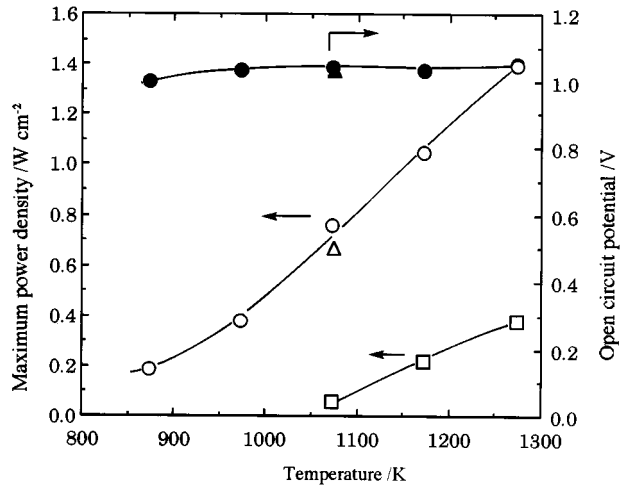

Fig. 1 Temperature dependence of electrical power generation characteristics of SOFCs containing $La_{0.8}Sr_{0.2}Ga_{0.8}Mg_{0.115}Co_{0.085}O_3$ as electrolyte. Thickness of electrolyte = 0.5 mm, $Sm_{0.5}Sr_{0.5}CoO_3$ cathode and Ni anode. (●) Open circuit potential and (○) maximum power density for an H_2–O_2 cell with LSGMC electrolyte. (△) Open circuit potential and (▲) maximum power density for an H_2–air cell with LSGMC electrolyte. (□) Maximum power density for an H_2–O_2 cell with $Zr_{0.84}Y_{0.16}O_4$ electrolyte.

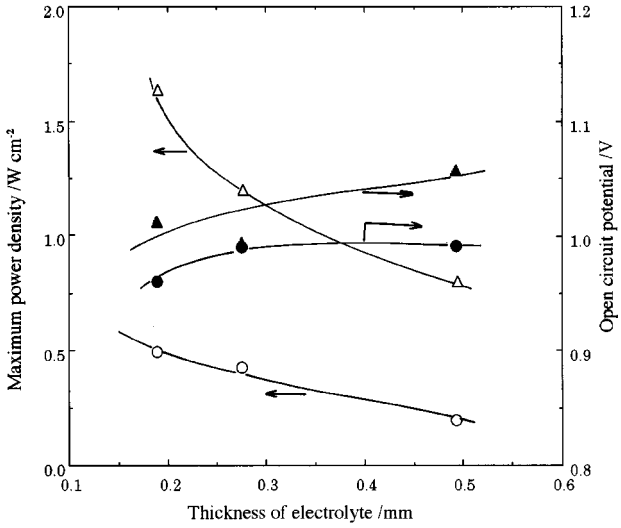

Fig. 2 Terminal voltage and power density of H_2–O_2 cells as a function of thickness of electrolyte. Ni and $Sm_{0.5}Sr_{0.5}CoO_3$ were used as anode and cathode, respectively. 873 K: (○) maximum power density and (●) open circuit potential. 1073 K: (△) maximum power density and (▲) open circuit potential.

A large part of the internal resistance of the present cell is ohmic resistance which is almost comparable to that of ionic conductivity in LSGMC. Therefore, it is reasonable to expect higher power density from a thinner LSGMC electrolyte and thus the effect of electrolyte thickness was studied. Fig. 2 shows the open circuit potential and power density of H_2–O_2 cells as a function of thickness of electrolyte. The power density of the cell monotonously increases with decreasing thickness of the electrolyte. In particular, the maximum power density reached a value of 1.53 and 0.50 W cm^{-2} at 1073 and 873 K, respectively, when the thickness of electrolyte was 0.18 mm (Fig. 2). On the other hand, the open circuit potential was decreased with decreasing thickness of the electrolyte because the contribution of hole conduction was more significant upon increasing the gradient in oxygen partial pressure. However, the open circuit potential was always > 1.0 V at 1073 K for an SOFC utilizing an LSGMC thin plate. At 0.18 mm electrolyte thickness, however, the open circuit potential was decreased to 0.94 V at 873 K, since the transport number of oxide ion was decreased. Fig. 3 shows the power generation characteristics of an LSGMC cell with 0.18 mm thick electrolyte. It is obvious that extremely large power density was attained for this cell even at 873 K. The current density at short circuited conditions at this temperature was 2.5 A cm^{-2} and furthermore, the power density at 0.7 V was as high as 352 mW cm^{-2}. This power density was comparable to that of a molten carbonate fuel cell operating at 923 K.

In light of the notably high oxide ion conductivity of LSGMC, we believe that today's SOFCs can be improved to yield higher power outputs at lower operating temperatures. The consequences of operation at low temperatures, are increased reliability of the cell with use of a reasonably priced metallic element, *e.g.* stainless steel, the removal of a requirement of an excessively thin electrolyte film and availability of more compact geometries which leads to easy maintenance and

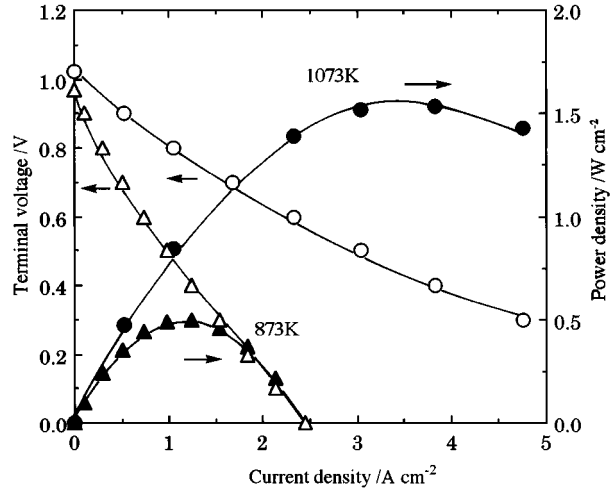

Fig. 3 Current–potential and current–power density curves of an SOFC utilizing 0.189 mm thick LSGMC at 873 and 1073 K with H_2 and O_2. (○) *I–V* curves and (●) *I–P* curves at 1073 K. (△) *I–V* curves and (▲) *I–P* curves at 873 K.

durability. These factors are major advantages arising from the use of the proposed electrolyte (LSGMC) for the next generation of power generators.

Received (in Cambridge, UK) 12th April 1999, Accepted 17th May 1999

Polyacrylamide(PAM)–semiconductor MS (M = Cd, Zn, Pb) nanocomposites with homogeneously well dispersed semiconductor nanoparticles in the polymer matrices were prepared by a novel *in situ* simultaneous polymerization–hydrolysis technique (SPH).

The synthesis and characterization of inorganic-organic polymer nanocomposites has received much intense research interest,[1] owing to their optical, electrical, catalytic and mechanical properties,[2,3] and potential applications in microelectronics.[4]

Many methods have been exploited to prepare semiconductor–polymer nanocomposites. Organization of semiconductor nanoparticles in an orderly fashion in a matrix may provide potential applications of their special properties, whereas polymers are expected to provide good mechanical and optical properties, conferring high kinetic stability on nanometer-sized semiconductor particles.

Meissner *et al.*[5] first reported a system involving dispersed semiconductor/polymer arrangements by physically embedding monograin CdS particles of *ca.* 40 μm diameter in a thin, nonconducting polyurethane membrane and various photoprocesses were examined. Later, a new method of incorporation of dispersed semiconductor CdS throughout an ionically conductive Nafion polymer membrane was developed.[6] Recently, CdS/polystyrene,[7] CdS/PS–P2VP[polystyrenes–block–poly(vinylpyridine)s],[8] PbS/S–MA(styrene–methylacrylic copolymer)[9] and PbS/E–MAA(ethylene–15% methacrylic acid copolymer) composites have been prepared in different polymer matrices using a variety of methods.[10] The multisemiconductor nanocomposite Cu_2S/CdS/ZnS was also successfully prepared in polystyrene by ion exchange.[11] Wang and Herron reported, for the first time, the synthesis of CdS/PVK(*N*-polyvinylcarbazole) polymer composite by using $Cd_{10}S_4Ph_{12}$ as precursor.[12] Currently, the use of amphiphilic block copolymer (ABC) micelles opens a doorway to utilize these materials as 'nanoreactors' for the formation of inorganic nanocrystals.[1,13] Other block copolymer system/metal sulfide nanoparticles have been prepared by addition of H_2S.[14]

Here, we report a novel *in situ* simultaneous polymerization–hydrolysis technique (SPH) for preparing polyacrylamide–semiconductor MS (M = Cd, Zn, Pb) nanocomposites in aqueous systems. The so-called SPH technique is based on the mechanism of the simultaneous polymerization of organic monomer and formation of semiconductor nanoparticles. It was found that the semiconductor nanoparticles (CdS, ZnS, PbS) were homogeneously well dispersed in the polyacrylamide matrices. The present SPH technique may provide a new route to prepare other metal sulfide–polymer hybrid nanocomposites.

In a typical procedure, the CdS–polyacrylamide (CdS–PAM) nanocomposite was prepared in an aqueous system. 0.01 mol $CdCl_2$ and 0.01 mol NH_2CSNH_2 were added to a 100 ml of 5.0 mol l^{-1} acrylamide(AM) monomer aqueous solution. Then, 0.01 g AIBN (2,2′-azobisisobutyronitrile) as radical initiator was added to the above solution. The mixture solution was put into a stainless-steel tank with a Teflon inner and heated in an oven at 140 °C for 12 h. The product obtained was washed with distilled water and absolute ethanol, dried at room temperature and ground into a powder for characterization.

The X-ray powder diffraction (XRD) pattern for the product was determined at a scanning rate of 0.02° s^{-1} in the 2θ range from 5–65°, using Japanese Rigaku Dmax γ_A-ray diffractometer with high-intensity Cu-Kα radiation (λ = 0.151478 nm) and a graphite monochromater was set at the diffracted radiation. The UV–VIS absorption spectrum was recorded with a Shimadzu UV-200 spectrophotometer. TEM images were taken with a Hitachi model H-800 transmission electron microscope, using an accelerating voltage of 200 kV.

Fig.1 shows the XRD pattern of a CdS–PAM nanocomposite obtained by the present SPH technique at 140° for 12 h. The broad peak at *ca.* 23° corresponds to the PAM phase. Cubic phase CdS nanoparticles were obtained. Not all diffraction peaks of the CdS nanoparticles can be observed in the XRD pattern of the CdS–PAM nanocomposite because of interference from the broad diffraction peaks for the PAM phase. However, the diffraction peaks for cubic CdS for $2\theta > 40°$ can clearly be seen.

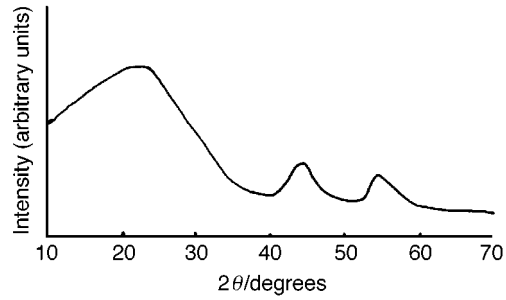

Fig. 1 The XRD pattern of a CdS–PAM nanocomposite prepared by the *in situ* simultaneous polymerization–hydrolysis technique (SPH) at 140 °C for 12 h.

The UV–VIS absorption spectrum of the CdS–PAM nanocomposite, dispersed in ethanol, was measured using pure PAM dispersed in ethanol as a reference solution.

The resulting spectrum shows λ_{max} for the CdS nanoparticles in the CdS/PAM nanocomposite at *ca.* 476 nm, *i.e.* blue-shifted relative to bulk CdS (515 nm).[15]

Fig. 2 shows a TEM image of the CdS–PAM nanocomposite powder. The image shows that the CdS nanoparticles prepared by the present SPH technique were homogeneously well dispersed in the PAM matrix. A histogram of the CdS nanoparticles (Fig. 3) shows a distribution of particle sizes in the range 2–10 nm.

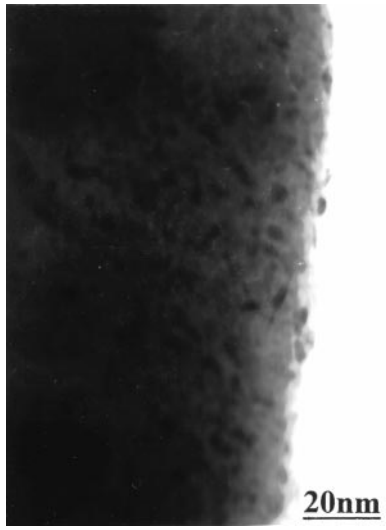

Fig. 2 TEM image of a CdS–PAM nanocomposite prepared by the *in situ* simultaneous polymerization–hydrolysis technique (SPH) at 140 °C for 12 h.

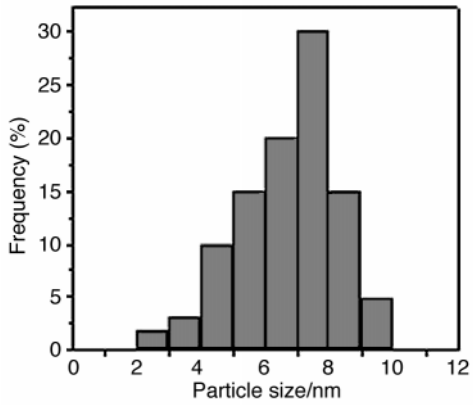

Fig. 3 Higtogram of CdS nanoparticle size in a CdS–PAM nanocomposite prepared by the present *in situ* SPH technique.

It is well known that the radical initiator AIBN decomposes at 45–65 °C, according to eqn. (1).

$$Me_2C(CN)-N=N-C(CN)Me_2 \xrightarrow{45\text{–}65\ ^\circ C} 2\ Me_2C^{\bullet}(CN) + N_2 \qquad (1)$$

The resulting radicals initiate the polymerization of the acrylamide (AM) monomer. Accompanying polymerization, CdS nanoparticles are also simultaneously formed by hydrolysis of NH_2CSNH_2 as described in eqns. (2) and (3).

$$NH_2CSNH_2 + 2H_2O \xrightarrow{Hydrolysis} 2NH_3 + CO_2 + H_2S \qquad (2)$$

$$Cd^{2+} + H_2S \longrightarrow CdS + 2H^+ \qquad (3)$$

Therefore, the obtained CdS nanoparticles can be homogeneously well dispersed in the PAM matrix. Further studies demonstrate that the average size of CdS nanoparticles in the absence of AM monomer obtained under the same preparation conditions as for the CdS–PAM nanocomposite, is *ca.* 20 nm which is larger than that of the CdS nanoparticles in the CdS–PAM nanocomposite. The reason may be that the reaction medium becomes more and more viscous as polymerization of the AM monomer proceeds, which is favorable for preventing the aggregation of initially formed CdS nanoparticles.

Fig. 4 TEM image of a ZnS–PAM nanocomposite prepared by the *in situ* simultaneous polymerization–hydrolysis technique (SPH) at 140 °C for 12 h.

We have also prepared ZnS–PAM and PbS–PAM nanocomposites *via* the present SPH technique by using $Zn(NO_3)_2$ and $Pb(NO_3)_2$ instead of $CdCl_2$. Fig. 4 shows the TEM image for the ZnS–PAM nanocomposite. It was found that the ZnS nanoparticles were also homogeneously well dispersed in the PAM matrix with a size of *ca.* 5–15 nm. The TEM image for the PbS–PAM nanocomposite indicates that the size of the PbS nanoparticles is *ca.* 10–20 nm.

In summary, CdS–PAM, ZnS–PAM and PbS–PAM nanocomposites with homogeneous dispersion of the metal sulfide nanoparticles in the polymer matrices were prepared by a novel *in situ* simultaneous polymerization–hydrolysis technique (SPH). The polymerization reaction of the AM monomer is favorable for preventing the aggregation of initially formed semiconductor nanoparticles. The present *in situ* SPH technique may provide a new route to prepare other metal sulfide semiconductor–polymer hybrid nanocomposites.

Syntheses of neutral iron, ruthenium and manganese half-sandwich vinylidene complexes. Crystal structure of $Fe(SnPh_3)(CO)(=C=CHPh)(\eta\text{-}C_5H_5)$

Harry Adams, Simon G. Broughton, Stephen J. Walters and Mark J. Winter*

Received (in Basel, Switzerland) 5th January 1999, Accepted 7th April 1999

Treatment of various anionic acyls $[M(SnPh_3)(CO)(COCH_2R)(\eta\text{-}C_5H_5)]^-$ (M = Fe, Ru) and acyls $[Mn(CO)_2(COCH_2R)(\eta\text{-}C_5H_4Me)]^-$ with MeCOCl affords acyl(oxy) carbenes $M(SnPh_3)(CO)\{=C(OCOMe)CH_2R\}(\eta\text{-}C_5H_5)$ and $[Mn(CO)_2\{=C(OCOMe)CH_2R)\eta\text{-}C_5H_4Me)]$ which formally eliminate $MeCO_2H$ to form neutral half-sandwich vinylidene complexes $M(SnPh_3)(CO)(=C=CHR)(\eta\text{-}C_5H_5)$ and complexes $Mn(CO)_2(=C=CHR)(\eta\text{-}C_5H_4Me)$.

Vinylidene complexes $L_nM(=C=CR^1R^2)$ have attracted a great deal of interest[1] over the last 15 years, partly due to the proposed intermediacy of vinylidene species in the Fischer–Tropsch process,[2] and also due to their ability to act as catalysts for alkyne polymerisation[3] and condensation[4] reactions. These complexes are prepared generally through either the rearrangement of alk-1-ynes at a metal centre, or through alkylation or protonation of the β-carbon of acetylide ligands. In the case of the Group 8 transition metals, the vast majority of these complexes are *cationic*. A very small number of neutral Group 7 and 8 half-sandwich vinylidene complexes are known.[5–7] We outline here a new method for the preparation of a class of *neutral* iron, ruthenium and manganese vinylidene complexes, the neutrality of which is expected to have important consequences for subsequent chemistry.

Recently, we reported the isolation of a number of unusually stable acyl(oxy) carbene species $M(SnPh_3)(CO)\{=C(OCOR)Ph\}(\eta\text{-}C_5H_5)$ (M = Fe, Ru; R = Me, Ph, Bu^t).[8] These are formed through the reaction of acid chlorides RCOCl with the anionic acyls $[M(SnPh_3)(CO)(COPh)(\eta\text{-}C_5H_5)]^-$. We now find that the corresponding anions $[M(SnPh_3)(CO)(COCH_2R)(\eta\text{-}C_5H_5)]^-$ **3**, **4** (Scheme 1) are available from the reactions of $LiCH_2R$ with $M(SnPh_3)(CO)_2(\eta\text{-}C_5H_5)$ **1**, **2**. These also react with MeCOCl, but while the expected acyl(oxy) carbenes $M(SnPh_3)(CO)\{=C(OCOMe)CH_2R\}(\eta\text{-}C_5H_5)$ **5** and **6** do indeed form, and are detectable by IR spectroscopy at low temperatures, the products isolated at ambient temperature are, unexpectedly, the *neutral* vinylidenes $M(SnPh_3)(CO)(=C=CHR)(\eta\text{-}C_5H_5)$ (R = H, Pr, Me, Ph) **7** and **8**.† These products correspond to the formal loss of $MeCO_2H$ from the intermediate acyl(oxy) carbenes $M(SnPh_3)(CO)\{=C(OCOMe)CH_2R\}(\eta\text{-}C_5H_5)$. The presence of protons on the carbon α to the carbene is *essential* for vinylidene formation, as is the presence of the labile acyl(oxy) substituent. We note here a previous report in which the *cationic* iron vinylidene complexes $[Fe(PPh_3)(CO)(=C=CR_2)(\eta\text{-}C_5H_5)]^+$ (R = H, Me) are prepared through loss of CF_3SO_3H from intermediate triflate-substituted carbenes of the form $[Fe(PPh_3)(CO)\{=C(OSO_2CF_3)CHR_2\}(\eta\text{-}C_5H_5)]^+$.[9]

The method for vinylidene preparation presented here is versatile in that it allows the direct preparation of rare examples of unsubstituted vinylidene complexes, as well as examples bearing methyl and phenyl substituents, in a single step from readily available starting materials. Yields are good. The method also works for different metals. For instance, the corresponding reactions of the manganese compound $Mn(CO)_3(\eta\text{-}C_5H_4Me)$ **9** (Scheme 2) afford the neutral vinylidenes $M(CO)_2(=C=CHR)(\eta\text{-}C_5H_4Me)$ (R = Pr, Ph) **10** as red oils.‡

Scheme 1

The new complexes exhibit spectroscopic data typical for vinylidene complexes. For example, the parent complex **7** (R = H)§ shows a medium strength absorption [$\nu_{CO}(CH_2Cl_2)$ 1637 cm^{-1}] in its IR spectrum. This is attributed to the C=C stretch and signals at $\delta_C(CDCl_3)$ 346.2 and 105.3 in its ^{13}C NMR spectrum due to the vinylidene α- and β-carbons respectively. The presence of a singlet for the vinylidene protons in the ^1H NMR of the complex indicates that vinylidene rotation is facile at ambient temperature.

The nature of one compound **7** (R = Ph)¶ is further illustrated by a crystallographic study (Fig. 1), carried out in order to understand the vinylidene parameters. The Fe=C bond length of 1.744(4) Å is very short, reflecting the excellent π-acceptor properties[10] of the vinylidene fragment. The C=C bond length of 1.312(5) Å is in accord for a vinylidene complex, and reflects a bond order of *ca.* two. The vinylidene fragment itself is linear [Fe–C(7)–C(8) 179.7(3)°], and shows an orientation that corresponds both with theoretical studies[10] and with previously

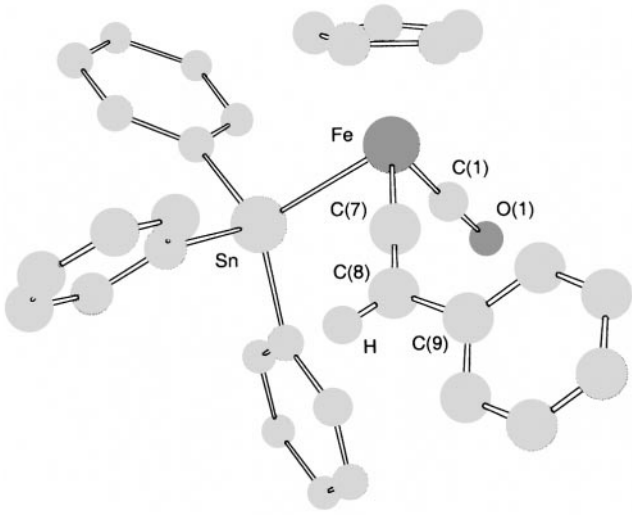

Fig. 1 Molecular structure of Fe($SnPh_3$)(CO)(=C=CHPh)(η-C_5H_5) **7** (R = Ph). Selected bond lengths (Å): Fe–C(7) 1.744(4), C(7)–C(8) 1.312(5), C(8)–C(9) 1.471(6).

reported structures of cationic iron and ruthenium vinylidene complexes.[11,12] As expected on steric grounds, the phenyl substituent occupies a position *anti* to the triphenyltin group. The vinylidene fragment does not adopt a truly horizontal conformation: the angle between the vinylidene plane and the plane defined by the centroid of the cyclopentadienyl ring, iron atom and C(7) is 73° rather than 90°. The twist is anticlockwise as viewed along C(8)–C(7)–Fe, and presumably minimizes steric interactions between the vinylidene hydrogen substituent and the triphenyltin group.

Received (in Liverpool, UK) 17th February 1999, Accepted 19th May 1999

A novel chiral stationary phase consisting of poly-L-leucine supported on porous graphitic carbon has been shown to be effective in the separation of the enantiomers of epoxides 1-5 by chiral high performance liquid chromatography.

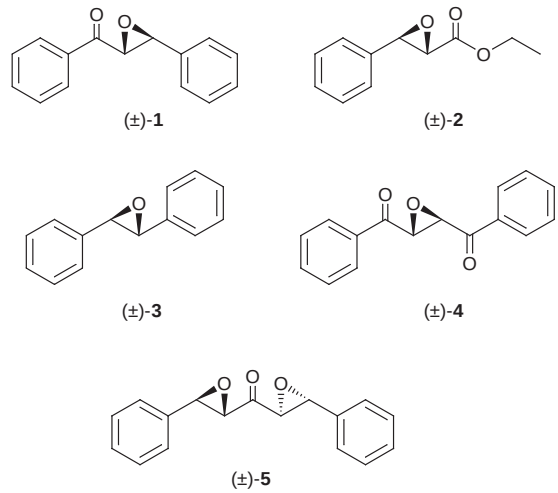
The separation of enantiomers using chiral stationary phases in high performance liquid chromatography is an important technique for both the analysis and preparation of chiral compounds.[1] The use of polysaccharide derivatives, first described by Okamoto *et al*.,[2] has been primarily responsible for the increase in accessibility of this technique. Polysaccharides, cellulose and amylose, in particular, are derivatised through the formation of carbamate residues which results in highly crystalline polymers. The recognition of chirality in analytes is attributable not only to the inherent chirality of the carbohydrate components of the polymer, but also on the substantial helical nature of the tertiary structure.[3]

Polymers are finding wide-spread use as chiral catalysts in asymmetric synthesis. For example, Julia[4] and Roberts[5] have shown that poly-L-leucine functions as an asymmetric catalyst for the epoxidation of certain α,β-unsaturated ketones. The use of polymeric α-amino acids in synthesis has been reviewed.[6] However, the basis of enantiorecognition in this system has not been conclusively determined.[7] The factors involved are no doubt similar to those responsible for the enantioselectivity of chiral stationary phases in adsorption chromatography. An understanding of the mechanism of enantiorecognition in both systems would undoubtedly enhance the development of these techniques.[8] Colonna *et al*. have suggested that enantiorecognition is attributable to hydrogen bonding between the ketone functionality and the amide NH groups of the polymer backbone.[8] More recently Roberts and co-workers discussed the chiral architecture of poly-L-leucine and suggested that the enantiorecognition was induced mainly by the amino terminus of the peptide.[9]

The remarkable selectivity generated by poly-L-leucine in the Julia–Colonna system led us to explore the use of poly-L-leucine supported on porous graphitic carbon (PLL-PGC) as a chiral stationary phase for HPLC. Poly-L-leucine with derivatised end groups has been previously described in the enantioseparation of D- and L-leucine dipeptides.[10] The separation of a racemic mixture using PLL-PGC provides evidence for the level of interaction between poly-L-leucine and the analyte.

Poly-L-leucine was synthesised by ring opening polymerisation of L-leucine *N*-carboxyanhydride, using either 1,2-diaminoethane as initiator, resulting in polymer with amino functionality at both termini of the polymer chain, or water as initiator. Molecular mass information is difficult to obtain owing to the low solubility of this crystalline polymer. However, using highly acidic solutions (1% TFA and 1% formic acid respectively) both MALDI-TOF-MS and ESI-MS spectra of poly-L-leucine produced with 1,2-diaminoethane as initiator were obtained. In MALDI-TOF-MS the observed ions range from *m/z* 647.1 to 2116.1 (DP 5 to 18). The highest mass singly charged ion observed in electrospray ionisation had *m/z* 1759.3 (DP 15).

Poly-L-leucine was adsorbed onto the surface of porous graphitic carbon through the slow evaporation of a solution in 5% TFA in EtOH. The stationary phase was subsequently slurry packed under high pressure into high performance liquid chromatography columns. Columns giving the best performance were obtained using poly-L-leucine that had been continuously extracted (Soxhlet) with DMF–EtOH (5:1) for 48 h. The epoxides **1**-**5**, all but one of which correspond to the



epoxide of an α,β-unsaturated ketone or ester, were analysed by reversed-phase HPLC. The results are given in Table 1. In all cases complete resolution of the two enantiomers was achieved. Fig. 1 shows the chromatogram recorded for the separation of the enantiomers of chalcone α,β-epoxide **1**. When racemic mixtures of **1**–**5** were eluted on an uncoated porous graphitic column, no separation of enantiomers was observed. The retention times of epoxides **1**-**5** were much greater than those observed with PLL-PGC. For example, the elution of chalcone α,β-epoxide from the uncoated column did not begin until 15 min after injection. Elution was complete after 25 min.

Table 1 HPLC data for the resolution of the enantiomers of epoxides **1**-**5** by poly-L-leucine supported on porous graphitic carbon[a]

Compound	k_1	k_2	α
1	4.35	10.68	2.56
2	4.33	5.82	1.34
3	2.05	2.42	1.18
4	5.58	12.45	2.13
5	6.47	12.30	1.90

[a] Solvent system: MeCN–H_2O (90 : 10 v/v), 0.5 cm^3 min^{-1}; column: 250 × 4.8 mm, $k = (t_R - t_0)/t_0$; k_1 = capacity factor for the first eluted peak; k_2 = capacity factor for the second eluted peak; α is the separation factor and is defined as $\alpha = k_2/k_1 = (t_{R2} - t_0)/(t_{R1} - t_0)$.

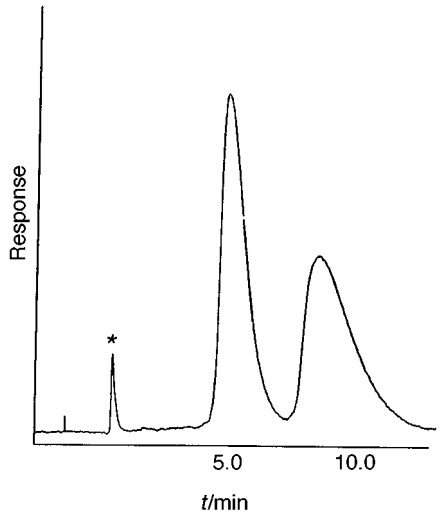


Fig. 1 Enantioseparation of epoxide **1** using PGC-PLL. Mobile phase: MeCN–H_2O (90 : 10 v/v), flow rate = 1.0 cm^3 min^{-1}; t_0 is marked with acetone (*).

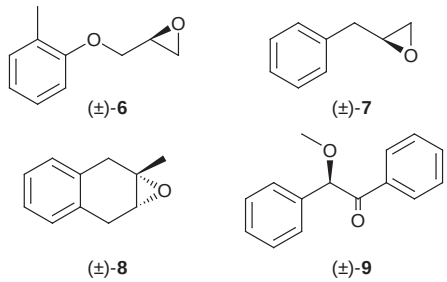
The use of poly-L-leucine as an asymmetric catalyst for epoxidation has been largely confined to α,β-unsaturated ketones. The separation of *trans*-stilbene oxide **3** suggests that the mechanism of enantiorecognition is dominated by the chirality of the epoxide and its interaction with the polymer, and not by the presence of the carbonyl group. Compounds **6**-**9** were



not separated on the PLL-PGC column. Comparison between this group and compounds **1**-**5** suggests the presence of an epoxide group with an attached phenyl or benzoyl substituent is necessary for successful separation of enantiomers. Although the number of examples is limited, these results do suggest that there is a parallel between the ability of poly-L-leucine to catalyse asymmetric epoxidation of α,β-unsaturated ketones and its ability to resolve the corresponding epoxides on PLL-PGC columns.

In summary we have demonstrated the use of a poly(amino acid)-coated porous graphitic carbon as an effective stationary phase in chiral HPLC. Poly-L-leucine has been shown to be an excellent alternative to cellulose as a stationary phase for the separation of the enantiomers of chiral epoxides. The parallel between the effectiveness of poly-L-leucine in catalysing the epoxidation of α,β-unsaturated ketones with high stereodiscrimination, and its effectiveness in resolving racemic mixtures of the same epoxides in the chiral HPLC system described above, suggests that the same factors are responsible for the stereoselectivity exhibited by both systems. It also suggests that the degree of separation of enantiomers of a given epoxide in the PLL-PGC system might be used to predict the effectiveness of poly-L-leucine as a catalyst for the epoxidation of the corresponding α,β-unsaturated ketones.

We thank Hypersil for financial support (to E. J. K.) and Professor K. R. Jennings and Dr A. Millar for electrospray ionisation mass spectrometry.

An efficient carbonylation of aryl halides catalysed by palladium complexes with phosphite ligands in supercritical carbon dioxide

Yoshihito Kayaki,[a] Yushi Noguchi,[a] Seiji Iwasa,[a] Takao Ikariya*[a] and Ryoji Noyori[b]

Received (in Cambridge, UK) 13th April 1999, Accepted 24th May 1999

The carbonylation of aryl halides catalysed by CO_2 soluble Pd complexes with trialkyl or triaryl phosphite ligands proceeds rapidly in $scCO_2$, in which the rate of the reaction is higher than those attained in solution phase reactions.

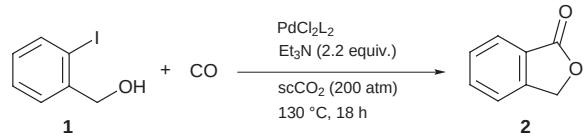
Supercritical fluids (SCFs) are attractive alternatives to organic solvents as reaction media for chemical reactions for a number of reasons. These reasons include their pressure tunable physical properties and solvent powers as well as the high miscibility of the reactant gases, efficient mass transfer, local clustering, and possible weakening of the solvation of the reactants.[1] In particular, homogeneous transition metal-catalysed reactions involving gaseous reactants in SCFs have been intensively investigated, *e.g.* hydrogenation of olefins,[1a,2] hydroformylation,[3] hydrogenation of carbon dioxide,[4] and oxidation by O_2.[2e,5] However, no discernible benefit in terms of rate was obtained by performing the reactions under supercritical conditions except for a rapid hydrogenation of supercritical carbon dioxide ($scCO_2$) with Ru complexes[4] and an olefin hydroformylation catalysed by Rh complexes.[3b,c] This report describes the first carbonylation reactions of aryl halides catalysed by CO_2 soluble Pd complexes which proceed rapidly in $scCO_2$. The rate of the reaction is higher than those attained in solution phase reactions.

We first examined the intramolecular carbonylation of 2-iodobenzyl alcohol **1**[6] catalysed by palladium complex $[PdCl_2(MeCN)_2]$ **3a** in a supercritical mixture of CO_2 and CO (P_{CO_2} = 200 atm and P_{CO_2} = 10 atm)† at 130 °C (Table 1). The reaction proceeds smoothly in the presence of 2.2 equiv. of Et_3N (**1**:Pd:Et_3N = 5000:1:11000) to give phthalide, **2** in a moderate yield, with the TON (turnover number, mol product per mol catalyst) = 2190 after 2 h. A visual inspection of the reaction mixture in the window-equipped reactor vessel confirms that all the reactants as well as the product **2** are soluble in $scCO_2$, although the catalyst **3a** is only partly soluble. The reaction was started by introducing CO_2 and then CO into the reactor containing the reactants and the catalyst at the reaction temperature (Method A). In this procedure, the reaction proceeded rapidly in the liquid phase which formed before reaching the supercritical homogeneous state. Therefore, the outcome of the reaction is at least partly due to the reaction in the liquid phase. In fact, the reaction performed in a liquid phase consisting of **1** and Et_3N without CO_2 under otherwise identical conditions (neat condition) (substrate:catalyst = 5000:1, P_{CO} = 10 atm, 130 °C, 2 h) produced **2** with a TON of 3570. Such reactions in the liquid phase can be prevented by separating the catalyst from the reactants using a small glass container (Method B, standard procedure).‡ Reactions using this standard procedure gave a TON of 120 after 2 h and 1880 after 18 h as shown in Table 1, which clearly indicates that the carbonylation proceeds in the homogeneous $scCO_2$ phase.

Encouraged by the marked catalytic activity of the less soluble catalyst precursor **3a** in $scCO_2$, we then tried to employ Pd complexes with trialkyl phosphite ligands, which are highly soluble even in nonpolar hydrocarbons.[7] The solubility test clearly demonstrated that 1×10^{-2} mmol (5.1 mg) of $[PdCl_2\{P(OEt)_3\}_2]$ **3b** were dissolved in $scCO_2$ (300 atm) at 130 °C in a 50 mL reactor vessel. The success of this strategy is shown by the greater TON attained in the reaction catalysed by **3b** under the standard conditions mentioned above compared to that with **3a**. The reaction of **1** with **3b** proceeded efficiently at 130 °C in a homogeneous single phase containing all the reactants and the catalyst to provide quantitatively the product **2** (Table 1).

The phosphite compounds are the best choice of ligand for an increase in the solubility of the Pd complex. The compound's structure and electronic properties strongly affect the outcome of the reactions, as listed in Table 1. The $scCO_2$ soluble Pd complexes with trialkyl or triphenyl phosphite ligands (**3b** and **3c**) are highly efficient catalyst precursors. The complex **3g** with PMe_3 ligands was less reactive because the strongly coordinated ligand retards slightly the reaction in $scCO_2$ as observed in conventional liquid solvents.[8] Replacement of the phenyl groups in PPh_3 with methoxy groups (**3d** and **3e**) facilitates the carbonylation due to an increase in the solubility of the Pd catalyst precursor. On the other hand, the reaction with the CO_2 insoluble PPh_3 complex **3f** proceeded rapidly almost to completion accompanied with metal deposition. One possible explanation is that the phosphorous ligand-free, CO_2 soluble Pd carbonyl species[9,10] generated might be extracted into the

Table 1 Pd complex catalysed carbonylation of 2-iodobenzyl alcohol **1** in $scCO_2$[a]



1 **2**

10	PMe_3 **3g**	CO_2 (200)	10	18	3180
11	$P(OEt)_3$ **3b**	CO_2 (200)	1	18	4650
12	$P(OEt)_3$ **3b**	CO_2 (200)	5	18	5000
13	$P(OEt)_3$ **3b**	toluene[d]	1	18	3100
14	$P(OEt)_3$ **3b**	toluene[d]	5	18	3800

[a] Reaction was conducted at 130 °C in a 50 mL reaction vessel containing 0.1 μmol of Pd catalyst (10 μl DMF solution), substrate and Et_3N (Method B). Substrate:Pd catalyst:Et_3N = 5000:1:11000. TON = product mol/catalyst mol. [b] The catalyst was not separated from the substrate (Method A). [c] Neat. [d] 50 ml.

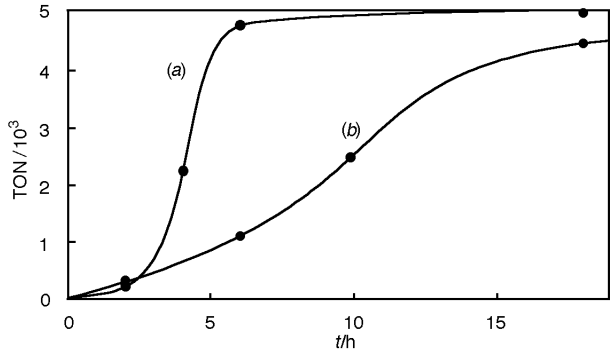

Fig. 1 Time *vs*. TON plots for the carbonylation of **1** catalysed by $[PdCl_2\{P(OEt)_3\}_2]$ **3b**, in (*a*) $scCO_2$ (standard procedure) or (*b*) toluene (substrate : catalyst = 5000 : 1, catalyst = 0.1 μmol).

$scCO_2$ phase, where the carbonyl complex effects the reaction highly efficiently and is deactivated during the later stages of the reaction because of the lack of a stabilizing ligand in the $scCO_2$ phase. In order to increase the solubility of the transition metal complexes in $scCO_2$, ligand modifications such as replacement of ligands containing aryl substituents to ligands bearing alkyl or perfluoroalkyl groups or introduction of CO_2-philic ponytails as substituents on the aryl groups have been developed previously.[4b,c,11] The use of phosphonate ligands has proved to be a practical alternative ligand modification for increasing the solubility of transition metal complexes in supercritical fluids.

The advantage of performing the carbonylation in supercritical fluids is that there is no marked effect of the CO pressure on the TON values obtained in $scCO_2$. Because of the higher diffusivity of $scCO_2$ compared to organic solvents as well as the high solubility of CO in this medium, the carbonylation even at 1 atm of CO pressure (CO : substrate = *ca*. 1.5 : 1) proceeded to near completion (TON = 4650). The yield of the product **2** (TON ~ 5000) is independent of the CO pressure over a range of 1–5 atm in $scCO_2$ (200 atm), whereas the reaction in toluene under otherwise identical conditions provided lower TON values (3100–3800) over a range of 1–5 atm of CO. The time conversion curve obtained by batch-wise experiments, illustrated in Fig. 1, as well as direct monitoring of the reaction by on-line FTIR revealed that the reaction proceeds rapidly to completion within 3–4 h after a *ca*. 2 h induction period.

The phosphonate–Pd catalyst can be applied to the intermolecular carbonylation of iodobenzene **4** and methanol (substrate : catalyst = 500 : 1) under the standard conditions in $scCO_2$ to yield methyl benzoate (TON = 260). Further optimization of the reaction is now in progress.

In conclusion, the carbonylation of aryl halides catalysed by Pd complexes with phosphonate ligands proceeds rapidly in $scCO_2$. The rate of the reaction is higher than that in the liquid phase.

Notes and references

† **SAFETY WARNING:** Operators of high-pressure equipment should take proper precautions to minimize the risk of personal injury [ref. 4(*b*)].

‡ *Standard procedure* for the carbonylation: The reactor equipped with a small vial was charged with argon gas in a desiccator. Then, a DMF (10 ml) solution of Pd catalyst (0.1 mmol) was charged in this vial, and the reactor was placed in an oven. After reaching the desired temperature of 130 °C (for *ca*. 1.5 h), a mixture of the substrate (0.5 mmol) and Et_3N (1.1 mmol) was added into the reactor (outside the vial) with a syringe through an opening against a flow of CO_2. Subsequently, CO (1–10 atm) was introduced, and then CO_2 (200 atm) was added with an HPLC pump. After stirring for 18 h, the reactor was cooled in a bath of MeOH and dry ice. The mixture of CO and CO_2 was vented, and the reactor was slowly warmed to room temperature. The yield of **2** was determined by ^{1}H NMR and GC analyses of $CDCl_3$ solutions of the products. On-line analysis was conducted by using a reactor vessel connected to the FT-IR equipment (JASCO FT/IR-610). The reaction was monitored by collecting spectra at intervals over the period of the reaction.

Control of the free radical reaction by dynamic coordination: unique reactivity of pyridylethyl-substituted tin hydrides

Seiji Suga, Takao Manabe and Jun-ichi Yoshida*

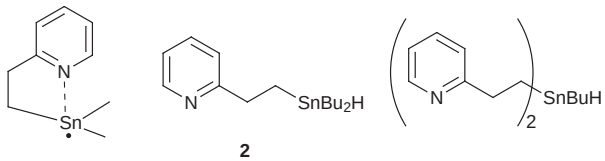
Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Kyoto 606-8501, Japan. E-mail: yoshida@sbchem.kyoto-u.ac.jp

Received (in Cambridge, UK) 11th May 1999, Accepted 26th May 1999

Tin hydrides having one or two pyridyl groups show unique reactivity in the reduction of alkyl halides under radical conditions, indicating the potential of intramolecular coordination for the control of radical reactions.

The importance of polar effects in radical reactions has attracted significant interest for many years,[1] and solvent effects[2] and anchimeric assistance[3] have been reported for various reactions involving free radicals. We report here unique reactivity of tin hydrides having pyridyl groups, suggesting the potential of intramolecular coordination for the control of radical reactions. This opens a new aspect of free radical chemistry. We also report the remarkable intermolecular effect of pyridyl groups in tin hydride reduction.

In recent work we have found the stabilization of cation radical intermediates by dynamic coordination to tin, which in turn favors the electron transfer from tetraalkylstannanes.[4] In connection with our interest in controlling chemical reactions by dynamic intramolecular coordination,[5,6] we envisioned that similar coordination might also be effective for the tin radical **1**. Thus, we synthesized tin hydrides having one or two pyridyl groups for coordination such as **2** and **3** and examined their reaction with organic halides under radical conditions (Scheme 1).[7]

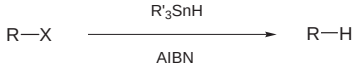


1 **2** **3**

Tin hydrides **2** and **3** were synthesized by the $LiAlH_4$ reduction of the corresponding tin halides.[4,8] The fact that the chemical shift from the ^{119}Sn NMR spectrum (in C_6D_6) of **2** (δ −88.270) is similar to that of Bu_3SnH (δ −87.210) indicated the absence of coordination of the pyridyl group to tin. This sharply contrasts to the ^{119}Sn NMR spectrum of the corresponding tin halide, which indicates the presence of a definite coordination of the pyridyl group to tin.[4]

The reduction of organic halides with **2**, however, exhibited unique features in contrast to that with Bu_3SnH (Table 1). Although primary alkyl bromides were reduced smoothly with **2**, the corresponding chlorides were unchanged under the same conditions.[9] *sec*-Alkyl chlorides and aromatic chlorides were also completely inactive towards **2** under these conditions. In the case of Bu_3SnH, however, such organic chlorides were reduced, albeit slowly. The unique reactivity of **2** seems to be ascribed to the lower reactivity of tin radical **1** towards organic halides (Scheme 2).

The reduction of alkyl bromides with **2** was completely retarded by the addition of a catalytic amount of hydroquinone



Scheme 1

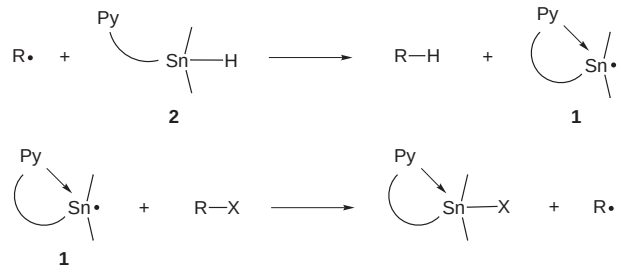
Table 1 Reduction of organic halides with tin hydrides under radical conditions[a]

	Yield of RH (%)[b]		
Organic halide	Bu_3SnH	**2**	**3**
$C_{12}H_{25}Cl$	75	0	0
$C_{12}H_{25}Br$	97	97	39
$C_{12}H_{25}I$	96	98	97
$Ph(CH_2)_3Cl$	52	0	0
$Ph(CH_2)_3Br$	100	99	56
$Ph(CH_2)_3I$	100	99	94
1-Naphthyl-Cl	12	0	0
1-Naphthyl-Br	93	90	20
1-Naphthyl-I	97	97	96
$C_8H_{17}CClHCH_3$	75	0	0

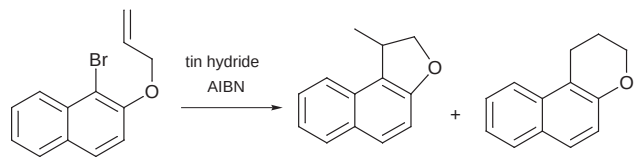
[a] Reactions were normally carried out with 0.10 mmol of organic halide, 0.12 mmol of tin hydride, and 0.01 mmol of AIBN in 0.4 ml of benzene at 60 °C for 2 h under an atmosphere of argon. [b] Determined with GC using an internal standard.

(0.1 equiv.), indicating that the reaction proceeded by a radical chain mechanism. The facile 5-*exo* cyclization[10] shown in Scheme 3 also supported a radical mechanism. The ratio of 5-*exo*/6-*endo* was similar to that observed for Bu_3SnH. The high yields of the cyclized products also demonstrates the utility of **2** for radical carbon–carbon bond formation.[11]

In order to get deeper insight into the unique reactivity of **2**, we examined the effect of the pyridyl group on the stability of the tin radical with molecular orbital calculations.[12] The geometry optimization of a model compound, 2-$PyCH_2CH_2SnMe_2$ radical, gave three structures (Fig. 1). The coordinated structures **A** and **B** are more stable than non-coordinated structure **C**, indicating that the coordination does



Scheme 2



2	93%	9 : 1
Bu_3SnH	80%	9 : 1

Scheme 3

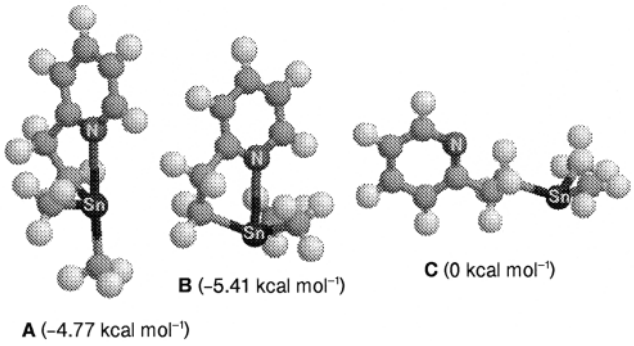


Fig. 1 Optimized structures of the 2-Py$CH_2CH_2SnMe_2$ radicals and their relative energies obtained by molecular orbital calculations (MP2/LANL2DZ).

take place at the radical. Such stabilization might decrease the reactivity of tin radicals towards organic halides,[13] although a detailed discussion should be reserved until kinetic data are available.

The reactivity of the tin hydride having two pyridyl groups, compound **3**, was also studied (Table 1). Although organic iodides were reduced smoothly with **3**, the reactions of organic bromides were much slower. Organic chlorides were almost inactive towards **3**. These data naturally imply that the second pyridyl group further decreases the reactivity of the tin radical.

It is notable that the introduction of the second pyridyl group gives us a bonus, *i.e.* easy separation and recovery of the tin halide after the reaction.[14] The tin halide derived from **3** can be completely separated by acid extraction and recovered by a follow-up base extraction, although the tin halide derived from **2** cannot be separated in a similar fashion. The easy protonation of the second pyridyl group seems to be responsible for this phenomena because the first pyridyl group should be used for coordination to the tin halide (*vide supra*).

In order to examine the effect of intermolecular coordination on the reactivity of the tin radical, we carried out the radical reduction of organic halides with Bu_3SnH in the presence of an additive such as pyridine and 2,2'-bipyridyl (Fig. 2). For the reduction of the alkyl bromide, the reaction took place smoothly even in the presence of such additives. The reduction of the alkyl chloride, however, was retarded significantly with an increase in the amount of additive. It is especially remarkable that the reaction was almost completely suppressed in the presence of 0.25 equiv. of bipyridyl. These results clearly indicate that the reactivity of tin radicals can be controlled even by intermolecular coordination.

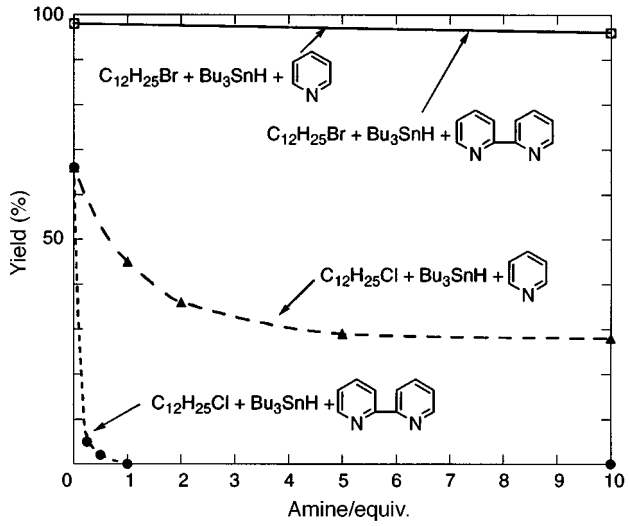

Fig. 2 Effect of pyridine and 2,2′-bipyridyl as additives on the reduction of alkyl halides by Bu_3SnH.

In summary, the results described above demonstrate the potential of dynamic coordination for the control of radical reactions. Future studies will hopefully delineate the detailed mechanistic role of the coordination.

We thank Professor Ilhyong Ryu, Osaka University, for valuable suggestions and discussions. This work was supported by a Grant-in-Aid for Scientific Research from Monbusho.

Simple synthesis of enantiomers of 6-hydroxyalkan-4-olides by stereoselective hydrogenation of methyl 4,6-dioxoalkanoates

Stefan Schulz

Institut für Organische Chemie, TU Braunschweig, Hagenring 30 D-38106 Braunschweig, Germany. E-mail: stefan.schulz@tu-bs.de

Received (in Liverpool, UK) 10th March 1999, Accepted 14th May 1999

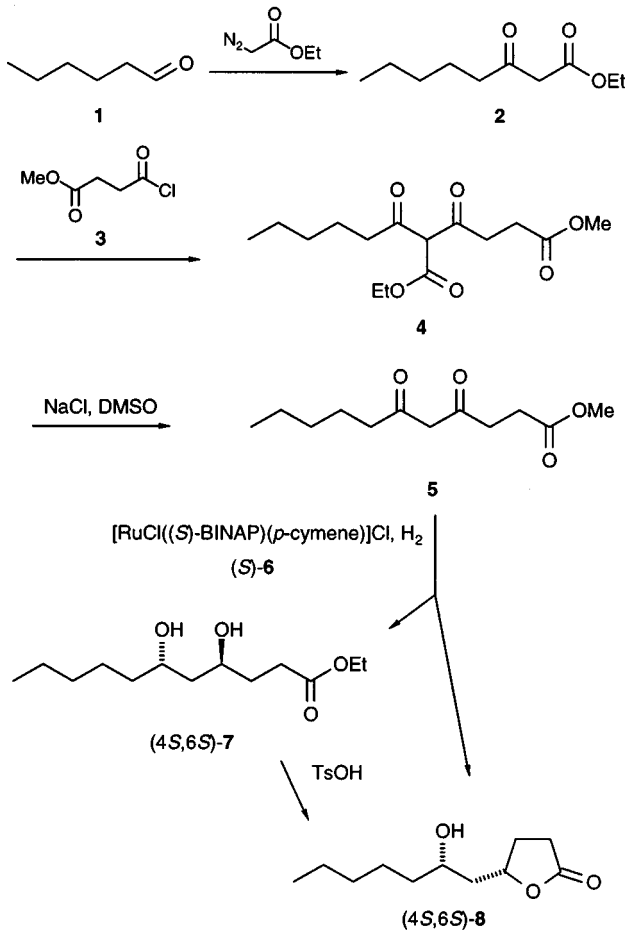
A simple method for the synthesis of (*S*,*S*)- or (*R*,*R*)-6-hydroxyalkan-4-olides, components of the pheromonal secretion of the butterfly *Idea leuconoe*, in high ee by enantioselective hydrogenation of 4,6-diketo esters with a commercial available Ru–BINAP catalyst is described.

During our studies on the pheromone system of males of the large danaine butterfly *Idea leuconoe*[1,2] we identified the previously unknown 6-hydroxyalkan-4-olides with chain-lengths between 10 and 13 carbon atoms. They seem to act synergistically with the other pheromone components and are probably involved in male–male interactions.[2] Therefore a synthesis of the pure enantiomers was needed to elucidate their absolute configuration and further investigate their ecological role.

High ee and dr of diols have been observed in Ru–BINAP catalyzed stereoselective hydrogenations of β-diketones.[3,4] We reasoned that 4,6-diketo esters might also be good substrates for such hydrogenations. Experiments with 3,5-diketo esters showed poor selectivity using the employed catalyst $[NH_2Et_2]^+$-$[\{RuCl(BINAP)\}_2(\mu\text{-}Cl)_3]^-$ between the diketo and the β-keto ester functionalities,[5] coupled with moderate enantioselectivity. In addition, the results could be interpreted as a preferred ligation of the ester group over the keto group.[5,6] On the other hand, small structural differences of the end groups are recognized by the catalyst, so that products with high dr and ee can be obtained, as has been shown by the hydrogenation of hexane-2,4-dione.[4] Therefore, the preferred reduction of the 4,6-diketo system in the presence of an ester group seemed to be possible. To the best of our knowledge, the only stable and commercially available chiral Ru–BINAP catalysts are [RuCl((*R*)-BINAP)(*p*-cymene)]Cl [(*R*)-**6**] and its (*S*)-enantiomer (Fluka). These catalysts have been regarded as ineffective below 60 °C in catalytic hydrogenations of dicarbonyl compounds.[6,7] Nevertheless, their application in the hydrogenation of allylic alcohols[8] and experience from our laboratories[9] showed that they can be effective catalysts in the reduction of β-keto esters at 80 °C and 40 bar hydrogen pressure, the upper limits of the equipment available to us. For example, hydrogenation of methyl 3-oxononanoate in the presence of (*S*)-**6** yielded methyl (*S*)-**3**-hydroxynonanoate in quantitative yield and 97.4% ee.

The major lactone in the secretion of *Idea leuconoe* is 6-hydroxyundecan-4-olide **8**. The 4,6-diketo ester required for its synthesis can be easily prepared starting from hexanal **1**. Reaction with ethyl diazoacetate yielded ethyl 3-oxooctanoate **2**,[10] which was acylated with 3-methoxycarbonylpropionyl chloride **3** (Scheme 1). Krapcho de-ethoxycarbonylation[11] of the product **4** then lead to the required precursor, methyl 4,6-dioxoundecanoate **5**. Hydrogenation at 40 bar H_2 and 80 °C in the presence of (*S*)-**6** for two days yielded a mixture of (*S*,*S*)-**8** and methyl (*S*,*S*)-4,6-dihydroxyundecanote **7**,† verified by chemical correlation as described below. The ester **7** could be smoothly transformed into (*S*,*S*)-**8** by column chromatography over silica, and subsequent treatment of the product with old $CHCl_3$ or TsOH. The dr and ee were determined by GC on a chiral phase (Lipodex E), which allowed separation of all enantiomers. The dr varied in different experiments between 95 and 99%, while the ee of the major enantiomer varied between 93 and 95%. The ee of the minor diastereomer could only be estimated to be between 0 and 20% because of the small amount isolated. Several lactones with chain lengths between C_{10} and C_{13} have been prepared with similar results by this method.

Finally, a chemical correlation was needed to see whether the stereochemical outcome of the reaction was as expected. Therefore, our synthesis of *rac*-6-hydroxydodecan-4-olide[1] was modified to obtain compounds with defined stereochemistry. Allylation of methyl 4-oxobutanoate with allyl(diisopinocampheyl)borane derived from (−)-α-pinene furnished (*S*)-hept-6-en-4-olide.[12] After ozonolysis, the labile and slowly epimerising aldehyde (*S*)-6-oxohexan-4-olide was alkylated with hexylmagnesium bromide, yielding a diastereomeric mixture of the hydroxy lactones, enriched in the (4*S*)-enantiomers. In a second experiment, *rac*-6-oxohexan-4-olide was alkylated using dihexylzinc in the presence of (1*R*,2*R*)-1,2-bis(trifluoromethylsulfonylamino)cyclohexane to yield a mixture enriched in the (6*S*)-enantiomers.[13] Gas chromatographic analysis of these mixtures and the racemate allowed unambiguous assignment of the (4*S*,6*S*)-configuration in the hydro-



Scheme 1

genation products obtained with (*S*)-**6**. The result is in accord with the enantioselective hydrogenations of β-diketones with Ru-BINAP catalysts described in the literature.[3,4] Obviously the alkyl and ester groups are clearly differentiated by the catalyst.

Work is in progress to expand the described methodology to other compounds and optimize it by using other catalysts. This method bears considerable potential for the synthesis of building blocks, because of the two stereocenters and three differentiated carbon atoms in an alkyl chain.

I thank W. Luttmer for technical assistance. Financial support from the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

Notes and references

† *Synthesis* of (4*S*,6*S*)-6-hydroxyundecan-4-olide: A stainless steel autoclave lined with Teflon and equipped with a stirring bar was charged with 200 mg of methyl 4,6-dioxoundecanoate and 5 ml of absolute MeOH. The solution was freed from air by repeatedly applying and releasing nitrogen pressure.

Approximately 10 mg of the catalyst (*S*)-**6** was added maintaining a steady flow of nitrogen to minimize contact with air. Then the autoclave was closed, a pressure of 40 atm applied, and finally heated to 80 °C for two days. When all educt was consumed (TLC control), the autoclave was cooled, the solvent removed, the product taken up in Et_2O and finally filtered over Celite. TLC control showed two spots, corresponding to **8** and **7**, which could be separated at this point by chromatography, if desired. Treatment of the crude mixture with a small amount of TsOH in CH_2Cl_2 transformed **7** into **8**. The product was then purified by chromatography over silica after removal of TsOH with saturated $NaHCO_3$ solution. Synthesis of carbocycles by insertion of 1,1-dihalo-1-lithio species into zirconacycles

Nicolas Vicart† and Richard J. Whitby*

Department of Chemistry, Southampton University, Southampton, UK SO17 1BJ. E-mail: rjw1@soton.ac.uk

Received (in Liverpool, UK) 4th March 1999, Accepted 14th May 1999

1,1-Dihalo-1-lithio species (halogenocarbenoids) undergo double insertion into the carbon–zirconium bonds of a zirconacyclopent-ane or -ene to produce, after hydrolysis, bicyclo[3.3.0]oct-anes and -enes.

The intramolecular coupling of 1,*n*-dienes and -enynes induced by the zirconocene ('Cp_2Zr') equivalent zirconocene(but-1-ene) (generated *in situ* from dibutylzirconocene[1]) is a powerful method for ring construction.[2] It is important for efficient use of the transition metal to develop elaboration methods for the zirconacycles formed as intermediates. Of particular interest is their transformation into carbocycles by replacement of zirconium with carbon. Carbonylation to form cyclopent-anones and –enones by the mechanism shown in Scheme 1 is one method.[3] We extended this to the addition of isocyanides, where the zirconocene η^2-imine complex analogous to **2** could be trapped by insertion of a variety of alkenes, alkynes, and carbonyl compounds.[4] The direct formation of five-membered carbocyclic rings from zirconacycles has also been observed in a tandem allenyl carbenoid/aldehyde addition.[5] Takahashi has formed cyclopentadiene products from zirconacyclopentadienes by 1,1-addition to propynoates and copper catalysed addition to 3-iodopropenoates, and from zirconacyclopentenes by copper catalysed addition to acyl chlorides.[6]

We have developed a range of ring expansions of five-membered zirconacycles to six-membered homologues through the insertion of carbenoids (1-lithio-1-halo species), analogous to the formation of **1** (Scheme 1).[7] Here we describe how the insertion of 1,1-dihalo-1-lithio species allows the formation of five-membered carbocycles in a fashion analogous to the formation of **2** (Scheme 1).

Our first experiments were performed using the simplest halocarbenoid, lithiodichloromethane (**6a**).[8] Negishi has reported the formation of diphenylmethane from diphenylzirconocene and $LiCHCl_2$.[9] A solution of the zirconacyclopentane **4** in THF was formed from the diene **3** by the usual method.[1] Addition of CH_2Cl_2 followed by the slow addition of LDA at −78 °C and then hydrolysis gave a mixture of the protonolysis product of **4** and the anticipated product **10a** (Scheme 2 and Table 1, entry 1). Increasing the excess of $LiCHCl_2$ gave complete reaction of the zirconacycle **4**, but afforded **10a** mixed with products in which more than one molecule of the carbenoid had been incorporated. By using the bulkier carbenoid, $LiBr_2CPr$ (**6b**), generated *in situ* by deprotonation of 1,1-dibromobutane,[8] the multiple insertion pathway was eliminated and compound **10b** was isolated as the single product in good yield (Table 1, entry 2).‡ The likely mechanism is shown in Scheme 2. Deprotonation of **5b** by LDA gave the halogenocarbenoid **6b** which adds to **4** to produce the ate-complex **7b**. A 1,2-metallate rearrangement[9,10] to afford **8b** is followed by a diotropic rearrangement[11] to give **9b**. The formation of **9b** was confirmed by quenching the reaction at −78 °C with D_2O to afford the deuterated product **11** in 71% yield (Scheme 3). It is notable that both the formation of **8b** and its rearrangement to **9b** are fast at −78 °C. For the clean synthesis of **10b** it was important to maintain the reaction temperature below −50 °C until quenching, otherwise the by-product **12** was formed. We were pleased to find that allowing the reaction mixture to warm to room temperature before quenching gave **12** (86%) as the only product. Quenching with D_2O confirmed that the metal had

been lost by this stage, and a reasonable mechanism is a β-hydride elimination process (dehydrozirconation).

Metallation of dichloromethyl methyl ether **5c** with LDA in the presence of **4** gave the methoxy-substituted cyclopentane **10c** in good yield after protonolysis (Table 1, entry 3). Attempts to insert the carbenoid derived by lithiation of dichloromethyl(trimethyl)silane failed due to self condensation[12] and only the hydrolysis product of **4** was recovered. We found that the lithium derivative **6d** of the bulkier dichloromethyl(dimethyl)phenylsilane inserted into **4** efficiently to give silane **10d** (Table 1, entry 4) on protonolysis.

To avoid self condensation of the carbenoid precursor dichloroacetonitrile **5e** we added it to a mixture of LDA and the zirconacycle **4** in THF at −95 °C.[13] The cyanide **10e** was then isolated in moderate yield on hydrolysis (Table 1, entry 5).

When zirconacyclopentene **14** was treated with 1.5 equiv. of the *in situ* generated lithium carbenoid **6b** an inseparable mixture of **16** and **17** was formed (Scheme 3, Table 2, entry 1). Both **16** and **17** were formed as single diastereoisomers (estimated >93:7 detection limits). The formation of the mixture of **16** and **17** is easily rationalised by rapid allylic rearrangement of the initially formed organozirconium species **15**, indeed an η^3-allylzirconocene representation is probably most accurate. There is little to differentiate the two ends of the allylic system so a mixture of hydrolysis products is to be expected. Hydrolysis at 20 °C gave the diene **18** as a side product (Table 2, entry 2) presumably formed by a similar mechanism to the formation of **12**. The small amount of **18** produced compared with the formation of **12** is a reflection of the greater stability towards β-hydride elimination of the η^3-allyl *cf.* η^1-tertiary alkyl bonded zirconium.

Using dichloromethyl methyl ether **5c** as the carbenoid precursor, acidic quench of the reaction gave the single regioisomeric product **19** as a separable 72:28 mixture of diastereoisomers in good yield (Table 2, entry 3). When MeOH was used during the quench, we isolated a mixture of one diastereoisomer of **19** (the major one of the preceding experiment) and one diastereoisomer of **20a** (Table 2, entry 4). Quenching with CD_3OD gave a mixture of deuterated **19** and **20b** (Table 2, entry 5). Moreover, treatment of a sample of the minor diastereoisomer of **19** in THF with MeOH in the presence of Cl_2ZrCp_2 induced its fast transformation into **20a**. Formation of **20** is then due to an acid catalyzed $S_{N'}$ substitution of the methoxy group of **19** by the alcohol, probably *via* a carbocation. We have previously observed the 1,3-transposition of an amino group and the $S_{N'}$ replacement of an amino group by a hydroxy group in similar systems.[4a]

In conclusion, we have shown that selected halogenocarbenoids insert into a zirconacyclopentane to produce the related five-membered carbocyclic rings *via* sequential 1,2-metallate, and diotropic rearrangements. The yields are good for a tandem reaction sequence in which three carbon–carbon bonds are formed. Extension of the methodology to a zirconacyclopentene was complicated by poor regio- and/or diastereo-selectivity.

We gratefully acknowledge the European Community for financial support (TMR program, contract ERB-FMIBCT 97-2839). R. J. W. thanks Pfizer Central Research for generous uncommitted financial support.

Self assembly of a diphenanthrolinylpyrene-bridged Cu^{I} trimer

Céline Bonnefous, Nathalie Bellec† and Randolph P. Thummel*

Department of Chemistry, University of Houston, Houston, Texas 77204-5641, USA. E-mail: thummel@uh.edu

Received (in Columbia, MO, USA) 26th February 1999, Accepted 27th April 1999

The ligand 1,8-di(1,10-phenanthrolin-2-yl)pyrene has been prepared and complexed with Cu^{I} such that three ligands bridge a triangular arrangement of three metals resulting in a symmetrical helical assembly with each pyrene layered between two phenanthrolines at optimum π-stacking distance.

The use of metals and appropriate bridging ligands has become a dominant theme in the construction of some interesting three dimensional arrays.[1] Cu^{I} is particularly useful in this regard since many of its diimine complexes are labile, allowing ligand interchange to occur until the most thermodynamically stable assembly has been attained.[2] This report will focus on a Cu^{I} trimer of a diphenanthrolinylpyrene ligand **3**.

The Friedel–Crafts diacetylation of pyrene affords a mixture of the 1,3-, 1,6- and 1,8-diacetyl derivatives from which the pure 1,8-isomer **1** can be isolated.[3] When this material is treated with 2 equiv. of 8-aminoquinoline-7-carbaldehyde,[4] a 93% yield of 1,8-di(1,10-phenanthrolin-2-yl)pyrene **3** was obtained (Scheme 1). Treatment of this ligand in MeCN–CH_2Cl_2 (3:4) with 1 equiv. of $[Cu(MeCN)_4]ClO_4$ afforded a crude material which upon extraction with MeCN provided a 36% yield of the complex $[(Cu\mathbf{3})_3](ClO_4)_3$.

Constable and co-workers[5] have reported a system where two 6-substituted 2,2′-bipyridines joined by a 1,3-phenylene spacer bridged two metals while Sauvage and co-workers[6] have prepared a related di-1,10-phenanthrolinyl analogue. We expected a similar 2:2 combination of metal and ligand, which would afford a complex where the bridging pyrene moieties would be held co-facial to one another. This premise appeared to be supported by the high symmetry of the ^{1}H NMR spectrum (Fig. 1).

At 300 MHz the free ligand shows eleven well resolved signals between δ 7.75 and 9.05: three AB quartets for $H_{2,3}$, $H_{3',4'}$ and $H_{5',6'}$; singlets at δ 8.59 (H_9) and 8.40 (H_4); and a typical three proton pattern for H_7, $H_{8'}$ and $H_{9'}$. The complex also shows eleven well resolved signals with some shifted substantially upfield. The electrospray mass spectrum showed two major peaks at high mass. The peak at *m/z* 622, corresponding to $[(Cu\mathbf{3})_n]^{n+}$, established the 1:1 relationship of ligand and metal while the peak at *m/z* 983, corresponding to $[(Cu\mathbf{3})_3(ClO_4)]^{2+}$, indicated the trinuclear nature of the system.

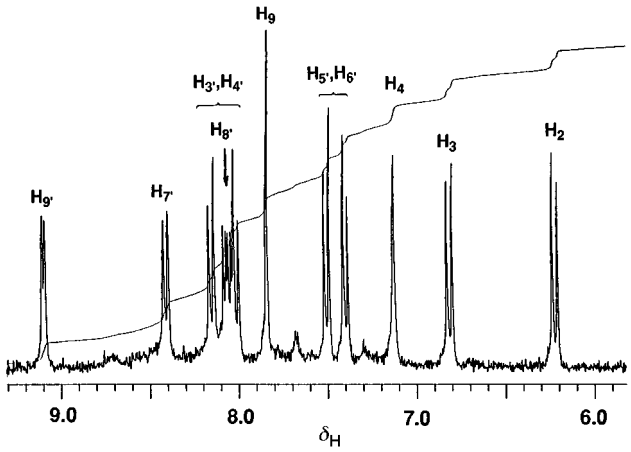

Fig. 1 300 MHz ^{1}H NMR spectrum of $[(Cu\mathbf{3})_3](ClO_4)_3$ at 25 °C in DMSO-d_6.

The structure of the complex was revealed by an X-ray analysis of a crystal grown from DMSO solution. Unfortunately the crystal quality was poor so that only a preliminary structure of the cation could be obtained. An ORTEP drawing of the cation is shown in Fig. 2 and Table 1 provides a summary of selected structural features. The geometry around copper is quite distorted. Each 1,10-phenanthroline unit binds to the metal through a short bond (1.96–1.99 Å) using the distal nitrogen N_{10}. The internal nitrogen N_1 forms a much longer bond to the metal (2.10–2.16 Å). We have seen similar bond distortions in the Cu^{I} complex of a highly twisted 2,2′-biquinoline derivative.[7] The tetrahedral geometry is also distorted. The N1–Cu–N10 chelation angles are relatively normal (80.9–81.5°) but the

Table 1 Selected geometric parameters for $[(Cu\mathbf{3})_3]^{3+}$ according to the numbering scheme in Fig. 2

Bond lengths (Å)		Bond angles (°)	
Cu1–N1	1.96 (0.0139)	N1–Cu1–N2	81.47 (0.59)
Cu1–N2	2.16 (0.0130)	N5–Cu1–N6	81.37 (0.54)
Cu1–N5	1.98 (0.0141)	N3–Cu2–N4	80.89 (0.47)
Cu1–N6	2.10 (0.0118)	N1–Cu1–N5	146.05 (0.63)
Cu–N3	2.14 (0.0113)	N1–Cu1–N6	121.94 (0.52)
Cu2–N4	1.99 (0.0108)	N2–Cu1–N5	123.12 (0.52)
		N2–Cu1–N6	96.52 (0.44)

Dihedral angles (°)			
N4–C39–C40–N3	1.65 (1.79)	Cu1–N1–C12–C4	170.65 (1.14)
N6–C51–C52–N5	2.67 (2.11)	Cu1–N2–C11–C7	168.04 (1.14)
N2–C11–C12–N1	4.59 (2.08)	Cu1–N5–C52–C44	167.98 (1.16)
N2–C10–C13–C14	59.73 (1.90)	Cu1–N6–C51–C4	168.13 (1.22)
N6–C50–C53–C54	57.75 (2.95)	Cu2–N3–C40–C32	168.63 (1.11)
N3–C29–C22–C21	58.34 (1.80)	Cu2–N4–C39–C35	170.75 (1.09)

N–Cu–N angles involving two different ligands are less regular with N1–Cu–N6 and N2–Cu–N5 being 122 and 123°, respectively, while N1–Cu–N5 is about 24° larger and N2–Cu–N6 is about 26° smaller. The planes of the two phenanthrolines are not orthogonal to one another. The extent to which the Cu lies out of the plane of the phenanthroline ring can be assessed by examining the C_a–C_b–N–Cu dihedral angle where C_a and C_b denote the two carbons common to pyridine and the central benzo-ring of phenanthroline. These angles range from 168–171°, where the ideal angle would be 180°, again indicating some distortion of tetrahedral geometry,

This cation has D_3 symmetry so that all three ligands are identical having the same helical twist about the phen–pyrene–phen bonds (57.8–59.7°). The phenanthroline rings are fairly planar with N_1–C–C–N_{10} dihedral angles of 1.7–4.6°. What is truly remarkable about the cation structure is the manner in which the aromatic rings π-stack, a pyrene being layered between two phenanthrolines to form three triple decked stacks which define a donut-shaped assembly (see Fig. 3 for stereoview). The stacking of the three rings is well organized and the average distance of any atom in a phenanthroline ring to the mean plane of the layered pyrene ring is 3.6 Å, which is approximately the optimal π-stacking distance. The increased surface area of pyrene as well as its ability to form well organized π-stacked arrays apparantly dictates the nuclearity of the complex. A similar effect for an Ag^+ trimer has recently been reported by Williams and co-workers.[8]

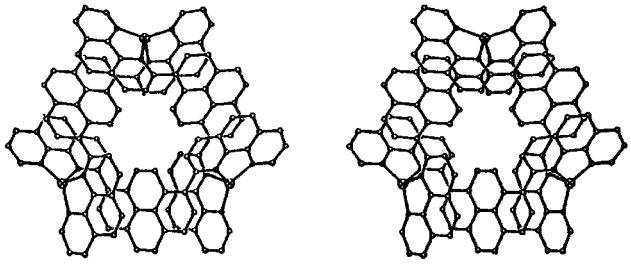

Fig. 3 Stereoview of the cation of $[(Cu\mathbf{3})_3](ClO_4)_3$.

From the stereodrawing, we notice that the hydrophobic cavity of the molecule consists of eighteen methine units. At the interior of the cavity are the C_9 and C_{10} hydrogens of the three pyrene units. On one face of the cavity are the C_3 and C_4 hydrogens of one set of three phens and on the other face are the C_3 and C_4 hydrogens of the other set of phens. The approximate diameter of the cavity is estimated to be about 3 Å by measuring the distance between opposing sets of atoms. If the van der Waals radii of the atoms are taken into account, the cavity size shrinks to about 1.8 Å. To verify that this cavity is indeed too small to accommodate a hydrophobic guest, we added Bu_2O to an NMR sample of $[(Cu\mathbf{3})_3](ClO_4)_3$ in DMSO-d_6 but no change was observed from the chemical shift values of the uncomplexed species.

Knowing the three dimensional structure, we can now more confidently assign the proton resonances in Fig. 1. The singlet for H_9 on the interior of the donut is downfield from the singlet for H_4 on the exterior. Similarly $H_{3'}$ and $H_{4'}$ are assigned as the downfield AB quartet. Due to the twist about the pyrene–phen bond, H_2 is held over the shielding region of the neighboring phen and found at higher field (δ 6.22).

To evaluate other features of the trimer, it became useful to prepare a monomeric analogue and hence the ligand 2-(pyren-1-yl)-1,10-phenanthroline **4**[9] was complexed in a 2:1 fashion with Cu^I. An NMR spectrum of the crude reaction product showed two sets of peaks in a 2:1 ratio which were attributed to conformational differences about the 2,1′-bond of ligand **4** in the complex.

The electronic absorption spectra (MeCN) of the ligands show long wavelength absorptions at 374 (log ε 4.53) for **3** and 342 nm (log ε 4.44) for **4**. The lower energy absorption of **3** is attributed to the presence of two phen substituents. The complexes show absorptions at 379 (log ε 4.76) and 473 nm (log ε 4.00) for $[(Cu\mathbf{3})_3]^{3+}$ and 346 (log ε 4.61) and 453 nm (log ε 3.50) for $[Cu(\mathbf{4})_2]^+$. The more intense, shorter wavelength band relates to the corresponding ligand absorption. The weak longer wavelength band is assigned to a characteristic metal to ligand charge transfer (MLCT) which gives the complexes their red color. The absorbance of the trimer appears at lower energy and is approximately 50% more intense than the monomer due to the 3:2 ratio of pyrene found in these two complexes.

Upon excitation into their lowest energy bands, the ligands exhibit strong pyrene-based emissions at 434 (**4**) and 450 nm (**3**). For the corresponding complexes these bands are greatly reduced in intensity possibly due to quenching by the copper center. Excitation into the MLCT bands of the complexes revealed only very weak luminescence.

The half-wave oxidation potentials for the two Cu^I complexes were determined by cyclic voltammetry and found to be virtually identical at +0.31 V (*vs.* SCE). This value compares with +0.67 V for $[Cu(dmp)_2]+$ (dmp = 2,9-dimethylphen).[10] It is noteworthy that the monomeric system is considerably more reversible than the trimer. The question of whether one or more electrons was being transferred in the oxidation of $[(Cu\mathbf{3})_3]^{3+}$ was addressed by controlled potential coulometry at 0.8 V, which indicated that only one copper in the trimer is being oxidized to Cu^{II}.

We would like to thank the Robert A. Welch Foundation and the National Science Foundation (CHE-9714998) for financial support of this work, Dr Eric van Caemelbecke for assistance with the electrochemical measurements, and Dr Jim Korp for assistance with the X-ray determination.

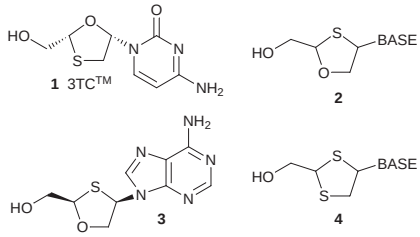
Synthesis and anti-HIV activity of 1,3-dithiolane nucleosides

Nghe Nguyen-Ba, William L. Brown, Laval Chan, Nola Lee, Livio Brasili, Dominique Lafleur and Boulos Zacharie*

BioChem Pharma Inc., 275 Armand-Frappier Blvd., Laval, Québec, Canada H7V 4A7

Received (in Corvallis, OR, USA) 3rd March 1999, Accepted 20th May 1999

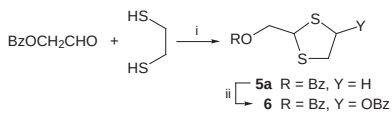
The potent activity displayed by 3′-azido-3′-deoxythymidine (AZT)[1] against human immunodeficiency virus (HIV) provides impetus for the development of novel nucleoside analogues.[2] Unfortunately, those compounds with the natural stereochemistry possess undesirable pharmacological properties[3] and are susceptible to the development of resistant stains of HIV.[3,4] In an attempt to overcome some of these detrimental side effects, the carbohydrate moiety of 2′,3′-dideoxynucleoside analogs has been replaced by other five membered rings.[3d,4] It has been demonstrated that hetero-substitution of these rings has a profound effect on the biological activity of the resulting nucleoside analogue[5] as displayed by (−)-2′-deoxy-3′-thiacytidine (3TC, Epivir) **1**.[5c,6]



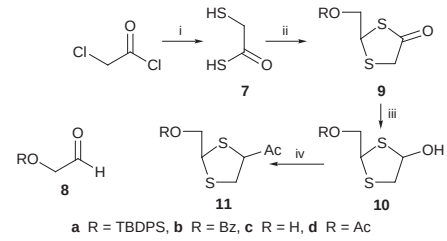
As part of an ongoing search for new anti-AIDS leads, we further explored this class of thioribonucleosides. These compounds possess improved metabolic stability to phosphorylases which cleave the glycosidic bond in nucleosides.[7] Recently, we reported the anti-HIV activity of 2,4-disubstituted 1,3-oxathiolane nucleosides **2** by transposing the sulfur and oxygen atoms of **1**.[4a] In this series, the (−)-adenine derivative **3** with the natural configuration was found to be twice as active as ddI in MT-4 cells. We further modified the oxathiolane ring by replacement of the oxygen atom of **2** with sulfur. This is exemplified by the general structure **4**. Here we report the synthesis and anti-HIV activity of this class of compounds.

The synthetic route to (±)-1,3-dithiolane compounds is based upon coupling a persilylated heterocyclic base with a dithiolane moiety **5** bearing a suitable leaving group Y at the 4-position under Vorbruggen's conditions.[8] Two approaches were considered for the preparation of the ring **5**. The first route is the introduction of a leaving group at position 4 using peroxide derivatives. For example, dithiolane **6** was prepared by treating **5a** with benzoyl peroxide in refluxing benzene (Scheme 1).[9]

The second approach offers a more general route for the synthesis of the key intermediate 1,3-dithiolane **11**† with a variety of displaceable leaving groups at C-4. Our synthetic strategy was based on the preparation of 1,3-dithiolan-4-one **9**, followed by reduction and acylation to give 4-acyloxy-1,3-dithiolane **11** (Scheme 2). Thus, reaction of freshly distilled $ClCH_2COCl$ with excess NaSH (3 equiv.) in absolute ethanol at −10 °C gave **7**[10] in quantitative yield. The crude product was



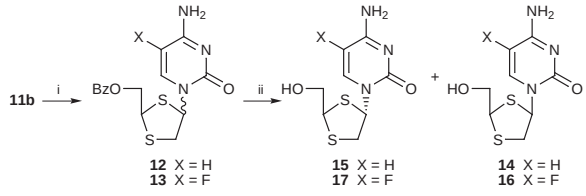
Scheme 1 *Reagents and conditions*: i, C_6H_6, TSA; ii, BzOOH, C_6H_6, heat.



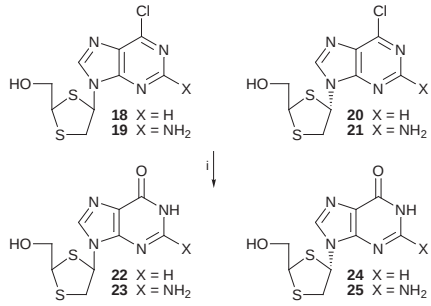
Scheme 2 *Reagents and conditions*: i, NaSH, absolute EtOH, −10 °C; ii, **8**, ZnI_2, CH_2Cl_2; iii, DIBAL-H, PhMe or BH_3·THF, $B(MeO)_3$; iv, AcOCl, Py.

immediately treated with aldehyde **8** in the presence of ZnI_2 as catalyst in CH_2Cl_2[11] to give the desired (±)-1,3-dithiolan-4-one **9** in moderate yield (50–60%). The initial synthetic procedure was based upon using the TBDPS protecting group for the hydroxy function of **9**. Reduction of **9a** with DIBAL-H (1.1 equiv.) in toluene gave thiolactol **10a** which was subsequently acylated to give the key intermediate **11a** in high yield. The silyl protecting group was later replaced by a benzoate group in order to facilitate the separation of the *cis* and *trans* nucleoside isomers. Applying the same conditions to reduce the benzoate **9b** did not result in any reduction product. However, using excess of DIBAL-H (3 equiv.) was successful and both the thiolactone and the benzoate function were reduced to give diol **10c** in 40% yield. Compound **10c** was then bis-acylated giving intermediate **11d** in high yield. Efforts were then directed to scale-up this procedure. Unfortunately, the DIBAL-H reduction proved particularly intractable. We therefore investigated other reducing agents that are selective and require little work-up. Only BH_3·THF (1.2 equiv.) catalyzed by $B(OMe)_3$ (1 equiv.) gave satisfactory results. The reduction was completed in 16 h and the product **10b** was obtained in 95% yield. This compound was then acylated to give the expected product **11b**. Following the same procedure, a number of different leaving groups (Bz, *m*-$ClC_6H_4CH_2$ and *p*-$O_2NC_6H_4CH_2$) were successfully introduced at C_4 of the sugar moiety **11**.

Compound **11b** is suitable for coupling with silylated cytosine or 5-fluorocytosine under refluxing conditions in CH_2Cl_2 and in the presence of $SnCl_4$ (Scheme 3). This gave the desired nucleoside analogue **12** or **13** as a 1 : 2 mixture of *cis* and *trans* isomers in moderate yields. Replacement of $SnCl_4$ with TMSI altered the ratio of the isomers. For example, compound **6** reacted with silylated N-acetylcytosine to give a mixture of the *cis* and *trans* nucleosides **12** in 62% yield with a slight predominance of the *cis* isomer.[9] Similar results were obtained using other leaving groups at C_4. This did not improve the yield



Scheme 3 *Reagents and conditions*: i, 2,4-Bis(trimethylsilyloxy)pyrimidine, $ClCH_2CH_2Cl$, $SnCl_4$, reflux, 16 h; ii, NH_3, MeOH.



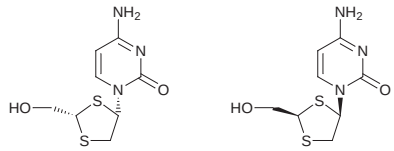
Scheme 4 *Reagents and conditions*: i, 25% aq. Me_3N–H_2O, 55–65%.

or the *cis*:*trans* ratio. The next step was the separation of the isomers **12** or **13**. This was achieved by flash chromatography on silica gel by prior acetylation of the amino group (cytosine) or by reverse chromatography HPLC after deprotection (5-fluorocytosine). The protecting groups were then removed by treatment with methanolic ammonia to give the desired nucleosides **14**–**17** in high yields. The relative stereochemistry of these products was assigned by difference NOE spectra.

Similarly, uracil, thymine, adenine and guanine derivatives were produced from **11b** using the same conditions. However, in the case of hypoxanthine and guanine analogs **22**–**25**, synthesis was undertaken by treating the corresponding 6-chloropurine or 2-amino-6-chloropurine derivatives **18**–**21** with 20 equiv. of an aqueous Me_3N solution in water (Scheme 4).

The anti-HIV activity of (±)-1,3-dithiolane nucleoside analogues was evaluated in MT-4 (human T helper) cells at concentrations up to 100 μg ml^{-1} and compared with 3TC™ (Epivir)[12] and the 5-fluoro derivative (FTC).[13] In this assay, only *cis* cytosine and 5-fluorocytosine derivatives **14** and **16** displayed inhibitory activity at ID_{50} of 9.3 and 4.8 μg ml^{-1} and were not cytotoxic at 100 μg ml^{-1}, whereas 3TC™ and FTC showed anti-HIV activity at 0.3 and 0.14 μg ml^{-1}, respectively. All the other nucleosides did not exhibit antiviral activity with no cytotoxicity up to 100 μg ml^{-1}. In contrast, *cis* and *trans* 6-chloropurine derivatives **18** and **20** showed cytotoxicity at CD_{50} of 10 μg ml^{-1}.

Described herein is a novel class of anti-HIV (±)-1,3-dithiolane nucleoside analogues. The biological results demonstrate that replacement of an oxygen atom of the oxathiolane with sulfur causes reduction in antiviral activity. It should be noted that compounds **14** and **16** are racemic. Resolution of the enantiomers may improve the activity. Therefore, enantiomeric separations of the racemic *cis* **14** was undertaken by chiral HPLC.[14] This gave the two enantiomers **26** and **27** in a



26 $[\alpha]_D^{25}$ +75 (*c* 0.10, H_2O) **27** $[\alpha]_D^{25}$ –70 (*c* 0.10, H_2O)

reasonable yield. It was found that isomer **27** possesses the natural configuration as evidenced by enzymatic resolution of the racemic mixture. Thus treatment of the mixture of the two enantiomers with cytidine deaminase converted only **27** to its corresponding uracil derivative. However, the unnatural enantiomer **26** was recovered and characterized by comparison of HPLC retention time and optical rotation with the previously isolated isomer. Both enantiomers were submitted for anti-HIV evaluation. Neither of the two compounds displayed improved antiviral activity.

We thank Drs T. Bowlin and R. Storer for reading the manuscript, Drs P. Hopewell and N. Cammack of Glaxo Group Research for testing the compounds, Ms L. Bernier and J. Dugas for technical assistance with HPLC separation of enantiomers, and Ms L. Marcil for secretarial and technical assistance.

Received (in Cambridge, UK) 26th April 1999, Accepted 24th May 1999

Palladium catalysed allylic alkylation and amination reactions have been demonstrated to proceed readily in the room temperature ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate ([bmim][BF_4]) with easy catalyst/solvent recycling and no need to generate separately the carbanion nucleophiles.

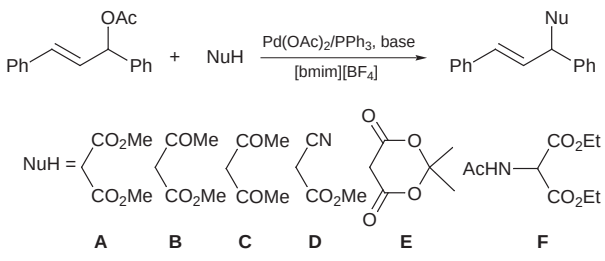
Room temperature ionic liquids consisting of 1,3-dialkylimidazolium cations and their counter ions have attracted growing interest in the last few years.[1–8] These ionic liquids offer an attractive alternative to conventional organic liquids for clean synthesis, as they are easy to recycle and possess no effective vapor pressure. As with water and perfluoro solvents, they also offer the potential for easy catalyst/product separation, owing to their limited miscibility with many common organic liquids. A few types of catalytic reactions have been carried out in these and related ionic liquids; recent examples include Friedel–Crafts reactions,[1,4] Diels–Alder reactions,[2] alkylations,[3] olefin dimerisation and oligomerisation,[5–7,9] hydrogenation,[8] Heck reaction[10] and hydroformylation.[11] We report herein the first examples of palladium catalysed allylic alkylation and amination reactions in the ionic liquid [bmim][BF_4]. [bmim][BF_4] has a liquid range down to −81 °C. It is miscible with polar compounds such as lower alcohols but immiscible with less polar compounds such as toluene and Et_2O. Many organometallic compounds have been found to display good solubility in this liquid.

Palladium(0) catalysed allylic alkylations of soft carbon nucleophiles represent a very useful tool for organic synthesis.[12] As summarised by Hegedus, the alkylation reactions are usually conducted by mixing stabilised carbanions with a substrate-catalyst mixture in THF and then heating the resultant mixture at reflux.[13] The carbanions are generated separately using bases such as NaH in dipolar solvents like THF. Catalyst and solvent recycling, which will undoubtedly be difficult with conventional solvents, has rarely been addressed for these reactions.[14] Prompted by Seddon's recent report on *in situ* generation of anions in the alkylaton of indole and 2-naphthol in [bmim][PF_6],[3] we examind the room temperature, one-pot alkylation of the active methylene compounds **A**–**F** by 1,3-diphenylallyl acetate in [bmim][BF_4] (Scheme 1). The results are presented below.

The alkylation of dimethyl malonate **A** by 3-acetoxy-1,3-diphenylprop-1-ene was investigated first. The catalyst or catalyst precursor was formed by heating $Pd(OAc)_2$ (2 mol%, based on the acetate) with PPh_3 (8 mol%) in [bmim][BF_4] at 80 °C for 20 min. The ionic liquid was then cooled to ambient temperature, and the reaction started by adding the substrates and K_2CO_3. ^{1}H NMR monitoring showed that the alkylation was complete after 5 h reaction time at ambient temperature. The initial rate was slightly lower, due perhaps to the dissolution of the substrates and base or to the formation of active Pd^0 species at the beginning of the reaction. A few variables have been identified to be important for the success of the alkylation in [bmim][BF_4] (Table 1). (i) As with allylic alkylations in molecular solvents,[13] no reaction takes place in the ionic liquid without PPh_3. (ii) The reaction rate decreases markedly when the molar ratio of PPh_3:$Pd(OAc)_2$ is less than 4:1. Thus, with 3 equiv. (relative to palladium acetate) of PPh_3, the conversion of the acetate was only 50% after 15 h reaction time and, with 1 equiv. of PPh_3, a much lower conversion of 13% was observed. (iii) The reaction is slower without initial heating of $Pd(OAc)_2$ and PPh_3 in [bmim][BF_4]. Thus, heating of $Pd(OAc)_2$ and PPh_3 with the substrates in the absence of [bmim][BF_4] followed by reaction in the ionic liquid at ambient temperature for 15 h afforded only a 68% conversion. As a base, K_2CO_3 and DBU are equally effective but, in the case of the latter, the reaction mixture is homogeneous. K_2CO_3 only partly dissolves in [bmim][BF_4] under the reaction conditions. The quantity of palladium used can be lowered to 0.2 mol% without affecting the 100% conversion for reactions carried out overnight.

Using the procedures developed for dimethyl malonate, the alkylation was extended to the active methylene compounds **B**–**F**. The results are summarised in Table 2. All the reactions were completed with 100% conversion within the time indicated when using DBU as the base. The lower yield obtained with the acetylacetone **C** was partly due to double alkylation. Alkylation of the amido malonate **F** was sluggish at room temperature, but the reaction proceeded smoothly at 50 °C to give the product with 86% isolated yield. For the reactions involving methyl acetoacetate **B** and methyl cyanoacetate **D**, the product was a 1:1 mixture of two diastereomers. Replacing DBU with K_2CO_3 resulted in lower conversions for the substrates **B**–**F** under identical conditions; the reason is not immediately clear.

Using similar procedures, we also tested the amination of 1,3-diphenylallyl acetate. The amination by pyrrolidine pro-



Scheme 1

Table 1 Palladium catalysed allylic alkylations in [bmim][BF_4] under various conditions[a]

PPh_3/$Pd(OAc)_2$	*t*/h	Conversion (%)
0	48	0
1	15	13
2	15	36
3	15	50
4	5	100
4	15	68[b]
4	15	100[c]

[a] General reaction conditions: 1.0 mmol of 3-acetoxy-1,3-diphenylprop-1-ene, 2 mol% $Pd(OAc)_2$, 1.5 mmol of dimethyl malonate and 2.0 mmol of K_2CO_3 in 1 ml of [bmim][BF_4] at ambient temperature. Before starting the reaction, $Pd(OAc)_2$ and PPh_3 were heated at 80 °C for 20 min in the ionic liquid. [b] $Pd(OAc)_2$, PPh_3 and the substrates were heated at 80 °C before introducing the base and ionic liquid at ambient temperature. [c] 0.2 mol% $Pd(OAc)_2$.

Table 2 Palladium catalysed allylations in [bmim][BF_4] with various nucleophiles[a]

NuH	Base	*t*/h	Yield (%)[b]
A	K_2CO_3	5	91
B	DBU	15	87[c]
C	DBU	15	54
D	DBU	14	88[c]
E	DBU	15	79
F	DBU	12	86[d]

[a] The reaction conditions were the same as the general reaction conditions given in Table 1, unless otherwise indicated. All the reactions completed with 100% conversion. [b] Isolated yield. [c] The product was a 1:1 mixture of two diastereomers. [d] Reaction was carried out at 50 °C.

ceeded readily to give the corresponding 1,3-diphenylallylamine with 100% conversion. Unlike the alkylations, no additional base is required in this transformation.

Catalyst separation/recycling appears to be difficult under the conditions established above, because the organic compounds and the ionic liquids form a homogeneous mixture and so catalyst separation *via* phase separation is not feasible. Further, extraction of the products with solvents of various polarity resulted in significant leaching of palladium species out of the ionic liquid. However, replacing PPh_3 with the hydrophilic phosphine P(*m*-$C_6H_4SO_3Na)_3$ led to effective recycling of the catalyst-containing ionic liquid phase; the catalyst along with the ionic liquid was reused three times without losing activity in the alkylation of dimethyl malonate. The product was extracted with toluene after each cycle of the reaction.

In summary, we have demonstrated that allylic alkylation and amination can effectively be performed in the room temperature ionic liquid [bmim][BF_4] with the additional benefit of easy catalyst/solvent recycling. Ionic liquids like this provide an ideal environment where ionic intermediates may be generated *in situ* and stabilised therein. Reactions in such media offer an attractive 'greener' alternative to the conventional processes where volatile organic solvents are frequently employed and catalyst reuse is difficult to implement.

We are indebted to the EPSRC and the University of Liverpool Graduates Association (Hong Kong) for postdoctoral research fellowships (W. C. and L. X.), and to the Leverhulme Centre for Innovative Catalysis for a LCIC studentship (C. C.).

Singlet–triplet bistability in a 1,3-phenylene-based bis(aminoxyl) diradical

Andrzej Rajca,* Kan Lu, Suchada Rajca and Charles R. Ross, II†

Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304, USA. E-mail: arajca@unlinfo.unl.edu

Received (in Columbia, MO, USA) 8th March 1999, Accepted 26th April 1999

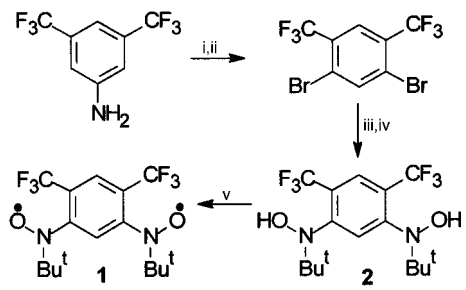
Rapid quenching of the title bis(aminoxyl) 1 in 2-methyltetrahydrofuran from ambient temperature to cryogenic temperatures (5 K or below) produces 1 in its singlet state, which slowly converts at low temperatures, with an S-shaped time-dependence, to the triplet ground state.

1,3-Phenylene-based diradicals are ubiquitous building blocks for both high-spin polyradicals and molecular magnets.[1,2] Although 1,3-phenylene is the most reliable mediator of ferromagnetic coupling in organics, it is well established that severe bond torsions in 1,3-phenylene-based diradicals may result in singlet ground states.[3–5] Therefore, different bond torsions associated with selected conformers may allow for the same diradical to be obtained in either a singlet or triplet ground state. Such a phenomenon was recently reported for a different class of organic diradicals, which have been obtained in either a singlet or triplet state, depending on the photon energy in the photochemical generation or the solvent.[6–8] However, the rate of such conformationally mediated conversion between the different spin states in diradicals was not observed.[8] Now we report the singlet and triplet ground state in a 1,3-phenylene-based diradical, 4,6-bis(trifluoromethyl)-*N*,*N*′-di-*tert*-butyl-1,3-phenylenebis(aminoxyl) **1**, with an observable rate of conversion between the low- and high-spin states.

Synthesis of **1** is outlined in Scheme 1. X-Ray crystallography, EPR, ^{1}H NMR, MS, IR and elemental analysis data confirm the structure and suggest a purity of > 95%.

X-Ray crystallography indicates that the aminoxyl moieties are twisted out of the plane of the 1,3-phenylene with torsional angles of −70 (C5–C6–N2–O2) and 49° (C3–C2–N1–O1); both oxygens point toward the trifluoromethyl groups.[9] The geometry and conformation of the trifluoromethyl groups suggests negligible radical–fluorine hyperconjugation (Fig. 1).[10]

The $\Delta m_s = 1$ region of the X-band EPR spectrum of **1** in frozen 2-MeTHF has six broad peaks consistent with a triplet state. The two inner most resonances show resolved hyperfine coupling with the two nitrogens; the center resonance, which would correspond to a monoradical impurity, is negligible. The spectral width of 0.0321 Tesla is constant in the 10–65 K range and it is of similar magnitude to that found for other 1,3-phenylene-connected bis(aminoxyl)s.[3,4,11] The $\Delta m_s = 2$ signal is also observed (Fig. 2). In the ^{1}H NMR spectrum of a 0.05 mol dm^{-3} solution of **1** in $CDCl_3$, two prominent peaks at −16 (broad) and 1.1 ppm (narrow) have a relative intensity of 36 : 1, they are assigned to the *tert*-butyl groups associated with the aminoxyl moiety and the diamagnetic impurity (presumably a hydroxyamine moiety), respectively.[12] Molecular ions in the EI MS for **1** and the dihydroxyamine **2** (Scheme 1) show a *m/z* difference corresponding to two hydrogen atoms.



Scheme 1 *Reagents and conditions*: i, Br_2, Fe, CH_2Cl_2; ii, $NaNO_2$, H_2SO_4, EtOH (45% for 2 steps); iii, Bu^{t}Li, Et_2O; iv, (Bu^{t}NO)$_2$; v, Ag_2O, $CHCl_3$ (20% for 3 steps).

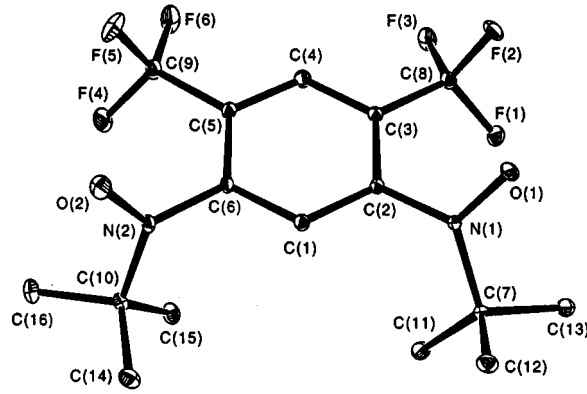

Fig. 1 Molecular structure of **1** in the solid state at 50 K; thermal ellipsoids at the 50% probability. The hydrogens are not shown.

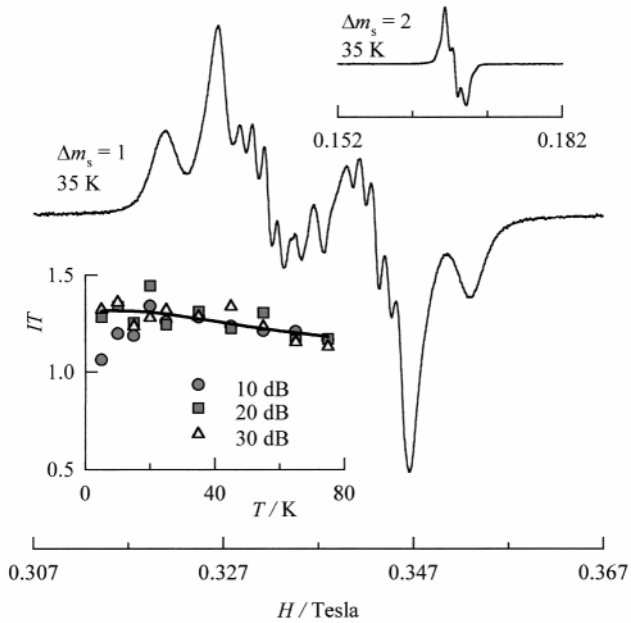

Fig. 2 The EPR spectrum of 0.001 mol dm^{-3} **1** in 2-MeTHF. Zero field splitting parameters for an $S = 1$ state are: $|D/hc| \approx 0.015$ cm^{-1} and $|E/hc| \approx 0.001$ cm^{-1}. Lower insert: plot of the product (IT) of the intensity (I) for the $\Delta m_s = 2$ resonance and the temperature (T) *vs.* T at three settings of microwave power (10, 20 and 30 dB); the 20 and 30 dB data are amplified by the consecutive factors of 3.2 ≈ $(10)^{1/2}$. The values of I are obtained by numerical double integration of the $\Delta m_s = 2$ region. The solid line corresponds to a numerical fit with the singlet–triplet energy gap corresponding to $2J/k = 80$ K (ref. 14) (J is a coupling constant from the Heisenberg Hamiltonian, $H = -2J\boldsymbol{S}_1\cdot\boldsymbol{S}_2$ with $|\boldsymbol{S}_1| = |\boldsymbol{S}_2| = 1/2$).

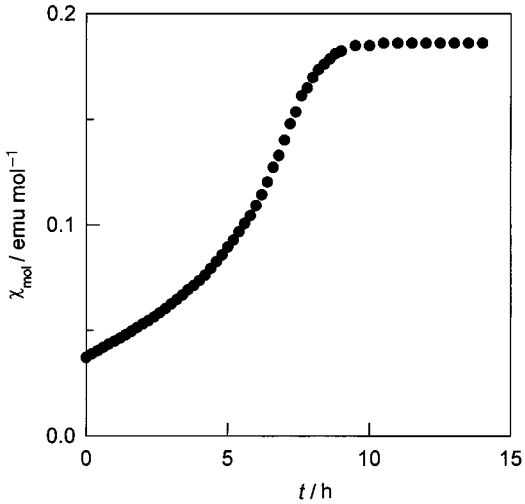

Fig. 3 Plot of molar magnetic susceptibility (χ_{mol}) *vs.* time, following rapid cooling of **1** (0.62 ± 0.07 mg) in 2-MeTHF (*ca.* 0.05 ml) from ambient temperature to 5 K. The applied magnetic field is 0.5 Tesla.

A sample of **1** in 2-MeTHF (10^{-2} mol dm^{-3}) was inserted, at a moderately rapid rate (5–10 min), into a SQUID magnetometer/susceptometer sample chamber kept at approximately 5 K. After establishing a stable temperature in the sample chamber (*ca.* 5 min), and an additional brief equilibration (2–5 min), the molar magnetic susceptibility (χ_{mol}) was measured at a constant applied magnetic field (H = 0.05–0.5 Tesla) as a function of time.[13] S-shaped plots were obtained, in which χ_{mol} increases about five times (Fig. 3).[13] The onset of a sharp rise in χ_{mol} is random and varies from several minutes to several hours. Gradual cooling of **1** in 2-MeTHF, *e.g.* temperature sweep from 290 to 5 K at 3, 5 or 10 K min^{-1}, gives the equilibrium value of χ_{mol} at 5 K. Analogous S-shaped plots are obtained at 1.8 and 2 K. The observed phenomena are solvent dependent; the time-dependence of χ_{mol} was not found for **1** in tetrahydrofuran (THF) or toluene (constant χ_{mol} *vs.* time).

Diradical **1** in 2-MeTHF was kept at 1.8 or 5 K until χ_{mol} (*vs.* time) reached a constant value, and then magnetization (M) was measured at T = 1.8 and 5 K as a function of H = 0–5 Tesla. The fit of the M *vs.* H/T data to the Brillouin functions gives S = 1, indicating a triplet ground state. Furthermore, the plateau value of χ_{mol} = 0.19 at 5 K (Fig. 3) is in good agreement with χ_{mol} = 0.20, as expected for a predominantly triplet ground state at 5 K. The plot of IT *vs.* T, where I is the intensity of the EPR signal in the Δm_S = 2 region, slightly decreases at the higher end of the 10–75 K range (Fig. 2). Therefore, the triplet ground state is slightly depopulated at higher temperatures, suggesting a small energy gap between the triplet and the excited singlet state within the same conformer (weak ferromagnetic coupling) or conversion to another conformer with different ordering of states.

One of the most straightforward rationalizations for these results is by invoking two conformers (conformational isomers) for **1** with different torsions about the C(1,3-phenylene)–N bonds.[3] The low temperature conformer has a triplet ground state, probably with a rather small (Heisenberg $2J/k$ < 100 K) singlet–triplet energy gap.[14] The high temperature conformer has a singlet ground state (at least, at low temperatures), with a non-negligible singlet–triplet energy gap. Upon rapid quenching from ambient temperature to 5 or 1.8 K, the high temperature conformer (or a large fraction of) is frozen in 2-MeTHF glass. Because the singlet–triplet thermal equilibration within the same conformer will remain very fast, the singlet ground state is predominantly populated in the 1.8–5 K range for the high temperature conformer. The observed S-shaped increase of χ_{mol} *vs.* time in the 1.8–5 K range would involve a conformational change from the high temperature to the low temperature conformer. The resultant dramatic change between the population of the singlet *vs.* triplet states is responsible for a typically five-fold increase in χ_{mol}. The S-shape and random time span for the completion of the conformational change are associated with various glassy matrix effects, *e.g.* random distribution of non-equivalent sites in the matrix.[15] A somewhat vexing problem is the preference for the singlet ground state in the high temperature conformer. This would require overcoming the entropic advantage of the triplet state (m_s degeneracy) by other sources of entropy or enthalpy, *e.g.* relatively low energy vibrational modes in the singlets or different solvation in the liquid *vs.* glassy 2-MeTHF. Unfortunately, there are no structural data for the singlet state (or states) of **1**.

Although conformational isomers were invoked in studies of some organic di- and poly-radicals, the time-dependence of the magnetic susceptibility of **1** in 2-MeTHF is unprecedented and calls for prudent interpretation of magnetic data for organic molecules, especially in glassy matrices.[6] Ultimately, a rational design of spin-bistable diradicals (or polyradicals) may provide organic analogues of metal ion based spin crossover compounds.[16]

12 The chemical shift of −17 ppm is found for protons of the Bu^t group in 2-methyl-*N*-*tert*-butylphenylaminoxyl: A. Calder, A. R. Forrester, J. W. Emsley, G. R. Luckurst and R. A. Storey, *Mol. Phys.*, 1970, **18**, 481. Treatment of **1** in $CDCl_3$ in an NMR tube with phenylhydrazine gives quantitatively dihydroxyamine **2**, as expected.

13 A Quantum Design MPMS5S SQUID instrument was used with either standard or continuous temperature control. An approximate correction for diamagnetism (χ_{dia}) for each sample was obtained from extrapolation of χ *vs.* $1/T$ (χ = total magnetic susceptibility) plots using the data in the T = 160–280 K range in the cooling mode of the MPMS5S. Typical values $\chi_{dia} \approx 4 \times 10^{-8}$ emu are an order of magnitude less than the total χ in the 5–1.8 K range.

14 The estimate of the Heisenberg coupling constant, J/k = 40 K (Fig. 2), can only be very approximate, as conformational effects may interfere with a simple two-state model.

Received (in Columbia, MO, USA) 16th March 1999, Accepted 20th May 1999

Secondary dialkylammonium ions thread through the cavity of (*RS*)-benzo-2,2′-binaphtho[26]crown-8 to create [2]pseudorotaxanes, one of which was stoppered to produce a [2]rotaxane—incorporating the chiral binaphthyl unit—that was characterised by NMR spectroscopy, mass spectrometry and X-ray crystallography.

There is currently a resurgence of interest in the employment of binaphthyl-containing macrocyclic hosts in supramolecular chemistry,[1] principally because of the potential for the chiral binaphthyl unit to associate diastereoselectively with racemic guest mixtures. However, the pioneering studies in this area took place more than a quarter of a century ago when, in 1973, Cram and his associates[2] described the synthesis of chiral binaphthyl-incorporating crown ethers, *e.g.* (*R*)-2,2′-binaphtho[20]crown-6 [(*R*)-BN20C6, Fig. 1], that exhibit enantiomeric recognition[3] of racemic *primary alkylammonium* ($R^1R^2CHNH_3^+$) ions, *e.g.* (*RS*)-α-methoxycarbonylbenzylammonium [(*RS*)-**1**$^+$], during the formation of face-to-face complexes. More recently, we discovered that crown ethers with suitably sized cavities, *e.g.* dibenzo[24]crown-8 (DB24C8), are pierced by *secondary dialkylammonium* ($R^1CH_2NH_2^+CH_2R^2$) ions, *e.g.* dibenzylammonium (**2**$^+$), producing[4] [2]pseudorotaxanes—and, ultimately, rotaxanes[5]—by means of, *inter alia*, hydrogen bonds. Here, we demonstrate that the expanded racemic binaphthol-derived crown ether (*RS*)-benzo-2,2′-binaphtho[26]crown-8 [(*RS*)-BBN26C8†] can be penetrated by $R^1CH_2NH_2^+CH_2R^2$ ions to produce (Fig. 1) [2]pseudorotaxanes.[6] This observation has resulted in the synthesis of a racemic binaphthyl-containing [2]rotaxane that has been characterised by NMR spectroscopy, mass spectrometry and X-ray crystallography.

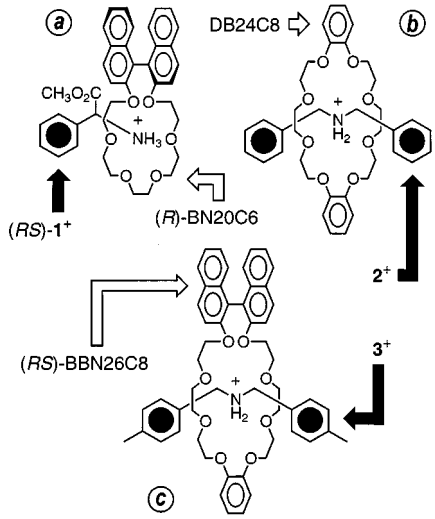

Fig. 1 Several complexes produced by the intermolecular association of crown ethers with ammonium ions. (*a*) Face-to-face complex [(*R*)-BN20C6·(*RS*)-**1**]$^+$. (*b*) [2]Pseudorotaxane [DB24C8·**2**]$^+$. (*c*) [2]Pseudorotaxane [(*RS*)-BBN26C8·**3**]$^+$.

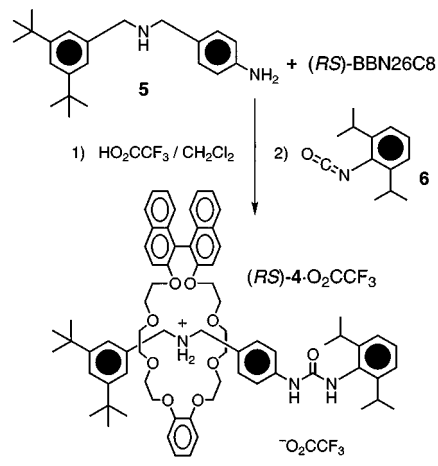
The first indication that (*RS*)-BBN26C8 forms pseudorotaxane complexes with $R^1CH_2NH_2^+CH_2R^2$ ions was provided by FAB mass spectrometry. The FAB mass spectrum of a 1:1 CH_2Cl_2 solution of (*RS*)-BBN26C8 and bis(*p*-methylbenzyl)ammonium hexafluorophosphate[4a] (**3**·PF_6) reveals a strong supramolecular ion at *m/z* 851, corresponding to [(*RS*)-BBN26C8·**3**]$^+$. Complex formation was also indicated in solution by ^{1}H NMR spectroscopy. The ^{1}H NMR spectrum [400 MHz, $CDCl_3$–CD_3CN (3:1), 300 K] of an equimolar solution of (*RS*)-BBN26C8 and **3**·PF_6 shows that, like[4] [DB24C8·**2**]$^+$, the complex [(*RS*)-BBN26C8·**3**]$^+$ exchanges slowly with its uncomplexed constituents on the NMR timescale, signals being observed for (1) [(*RS*)-BBN26C8·**3**]$^+$ itself, (2) free (*RS*)-BBN26C8 and (3) uncomplexed **3**$^+$. In other words, even though the 26-membered macroring of (*RS*)-BBN26C8 is two atoms larger than that of DB24C8, the cavity is still small enough for the relatively bulky aryl rings of the cation to have some difficulty threading. The fact that so many different species are equilibrating slowly with one another on the NMR timescale, coupled with the crown ether's C_2 symmetry, means that the signals associated with the polyether/benzylic CH_2 and aromatic CH portions of the spectrum, located at δ 2.84–4.15 and 6.53–7.80, respectively, are extremely complicated. However, the signals for the CH_3 protons in both the free and complexed states of **3**$^+$ are well separated from one another, resonating at δ 2.23 and 2.13, respectively. From an analysis of the relative intensities of these signals, an association constant (K_a) of 960 ± 100 M^{-1} was calculated for [(*RS*)-BBN26C8·**3**][PF_6] by using the single-point method.[4] Noticeably, this K_a is much lower than that obtained for the [DB24C8·**3**][PF_6] complex (1900 ± 200 M^{-1}) under identical conditions, indicating that replacing one of DB24C8's catechol units with the less preorganised binaphthol residue lowers the complex stability.‡

Next, we investigated the application of the (*RS*)-BBN26C8–$R^1CH_2NH_2^+CH_2R^2$ recognition motif to rotaxane synthesis. Gratifyingly, the [2]rotaxane (*RS*)-**4**·O_2CCF_3 was isolated§ in 42% yield when (*RS*)-BBN26C8 was reacted (Scheme 1) with



Scheme 1

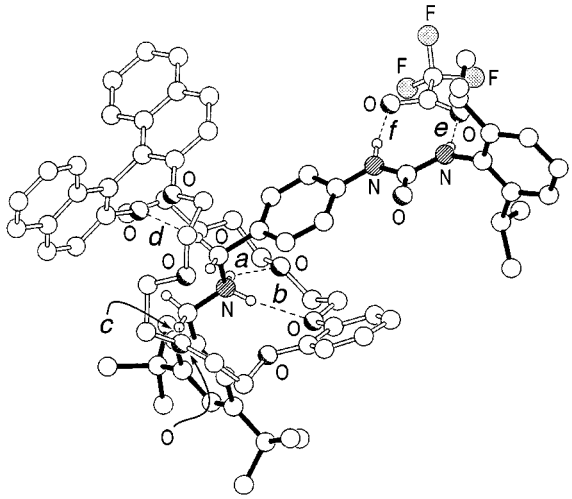


Fig. 2 X-Ray crystal structure of the (*R*)-enantiomer of [2]rotaxane (*RS*)-**4**·O_2CCF_3. Hydrogen bonding distances and angles {[X···O], [H···O] distances (Å), [X–H···O] angles (°)}: (*a*) 2.86, 2.12, 139; (*b*) 2.95, 2.08, 160; (*c*) 3.28, 2.39, 153; (*d*) 3.21, 2.29, 160; (*e*) 2.86, 2.00, 161; (*f*) 2.89, 2.00, 168.

p-aminobenzyl-*m*,*m*′-di-*tert*-butylbenzylamine (**5**), HO_2CCF_3 and *o*,*o*′-diisopropylphenyl isocyanate (**6**).[5] This interlocked compound is completely stable to column chromatography, indicating that the *m*,*m*′-di-*tert*-butylphenyl and *o*,*o*′-diisopropylphenyl termini of the rotaxane's 'dumbbell' component are sufficiently bulky to ensure that dissociation does not occur. Further evidence for the stability of the [2]rotaxane architecture is provided by the FAB mass spectrum of (*RS*)-**4**·O_2CCF_3, where the base peak, observed at *m/z* 1153, corresponds to the ion [(*RS*)-**4**]$^+$. Although the ^{1}H NMR spectrum (400 MHz, CD_3CN, 300 K) of (*RS*)-**4**·O_2CCF_3 displays numerous sets of complicated multiplets, a comparison of the integrals associated with resonances for both (*RS*)-BBN26C8 and the dumbbell component reveals that both species are present in a 1 : 1 ratio in the rotaxane. Interestingly, the peaks associated with the benzylic C$H_2NH_2^+$ protons do not lie in the 'expected' δ 4.45–4.75 range,[5] presumably as a direct consequence of the binaphthyl unit's shielding effect. In this instance, a ^{1}H–^{13}C HMQC experiment revealed that two sets of signals, ranging from δ 3.78–3.94 and 4.01–4.24, occur for these protons. The ^{13}C NMR spectrum (100 MHz, CD_3CN, 300 K) of (*RS*)-**4**·O_2CCF_3 is also intriguing and demonstrates that the crown ether is desymmetrised, *i.e.* the C_2 axis is negated, upon its incorporation into the [2]rotaxane architecture. The presence of the unsymmetrical dumbbell makes BBN26C8's two halves heterotopic and, hence, *all* of its 38 carbon atoms anisochronous. A total of 55 of the 60 ^{13}C NMR signals anticipated¶ for (*RS*)-**4**·O_2CCF_3 were observed in the spectrum (several of the heterotopic carbon atoms resonate at the same frequency).

The X-ray analysis‖ of the rotaxane (*RS*)-**4**·O_2CCF_3 reveals (Fig. 2) that the binaphthol-derived crown ether BBN26C8 encircles the dumbbell's NH_2^+ centre. Stabilisation of the [2]rotaxane architecture occurs principally *via* a combination of [N$^+$–H···O] and [C–H···O] hydrogen bonding involving the NH_2^+ centre, its adjacent CH_2 groups and the crown ether's oxygen atoms. There is also a near-parallel (5°), partial overlap between one of the BBN26C8 naphthalene rings and the *p*-toluidinyl ring of the dumbbell (mean interplanar separation 3.6 Å), indicative of a supplementary weak π–π stacking interaction. The $^-O_2CCF_3$ anion hydrogen bonds to the two urea NH groups.[5] There are no inter-[2]rotaxane interactions of note.

To summarise, we have established that $R^1CH_2NH_2^+CH_2R^2$ ions penetrate the cavity of binaphthol-derived crown ether (*RS*)-BBN26C8, generating [2]pseudorotaxanes that may be capped to form [2]rotaxanes. The preparation of these pseudorotaxanes and rotaxanes, which incorporate the chiral binaphthyl unit, augurs well for future studies on (1) the concepts of supramolecular chirality,[7] (2) the preferential recognition[3] of a chiral $R^1CH_2NH_2^+CH_2R^2$ ion over its enantiomer by either (*R*)- or (*S*)-BBN26C8 in the production of diastereoisomeric pseudorotaxanes[8] and (3) the synthesis of optically active rotaxanes.[9]

Notes and references

† (*RS*)-BBN26C8 was acquired in 42% yield by reaction of (*RS*)-1,1′-bi-2-naphthol with *o*-bis(2-{2-[2-(*p*-tolylsulfonyloxy)ethoxy]ethoxy}ethoxy)benzene (which was prepared using a method similar to that employed to obtain the corresponding *p*-derivative: M. J. Gunter, D. C. R. Hockless, M. R. Johnston, B. W. Skelton and A. H. White, *J. Am. Chem. Soc.*, 1994, **116**, 4810) in MeCN in the presence of Cs_2CO_3 and CsOTs.

‡ By the same token, Cram's group discovered (D. S. Lingenfelter, R. C. Helgeson and D. J. Cram, *J. Org. Chem.*, 1981, **46**, 393) that the binaphthol-derived crown ether BN20C6 binds RNH_3^+ ions less well than its 2,3-dihydroxynaphthalene-derived congener.

§ It should be noted that **4**·O_2CCF_3 was obtained as a racemic mixture, the rotaxane's chirality arising only by virtue of the C_2-symmetric binaphthyl unit. Here, cycloenantiomerism (C. Yamamoto, Y. Okamoto, T. Schmidt, R. Jäger and F. Vögtle, *J. Am. Chem. Soc.*, 1997, **119**, 10 547), a phenomenon that would lead to the formation of two diastereoisomeric pairs of enantiomers, does not occur, because (*RS*)-BBN26C8 has two homotopic faces by virtue of its C_2 axis of rotation.

¶ Free (*RS*)-BBN26C8, dumbbell and anion give rise to 19, 20 and two signals, respectively, in their ^{13}C NMR spectra. Thus, the ^{13}C NMR spectrum of rotaxane (*RS*)-**4**·O_2CCF_3 would be expected to exhibit a total of 41 signals if no desymmetrisation were to occur.

‖ X-Ray quality single crystals were obtained by vapour diffusion of *n*-C_5H_{12} into a CH_2Cl_2 solution of (*RS*)-**4**·O_2CCF_3. *Crystal data*: $[C_{73}H_{90}N_3O_9][O_2CCF_3]\cdot 2CH_2Cl_2$, M = 1436.4, monoclinic, $P2_1/n$ (no. 14), a = 13.281(3), b = 30.528(2), c = 21.593(2) Å, β = 96.80(1)°, V = 8694(2) Å^3, Z = 4, D_c = 1.097 g cm^{-3}, μ(Cu-Kα) = 17.2 cm^{-1}, F(000) = 3040, T = 173 K; Siemens P4 rotating anode diffractometer, ω-scans, 12673 independent reflections; structure solved by direct methods, all major occupancy non-hydrogen atoms of cations and anions refined anisotropically (non-hydrogen atoms of solvent molecules isotropically) using full-matrix least-squares, based on F^2, to give R_1 = 0.138, wR_2 = 0.342 for 5299 independent observed reflections [$|F_o| > 4\sigma(|F_o|)$, $2\theta \leqslant 120°$] and 950 parameters. Received (in Cambridge, UK) 29th April 1999, Accepted 25th May 1999

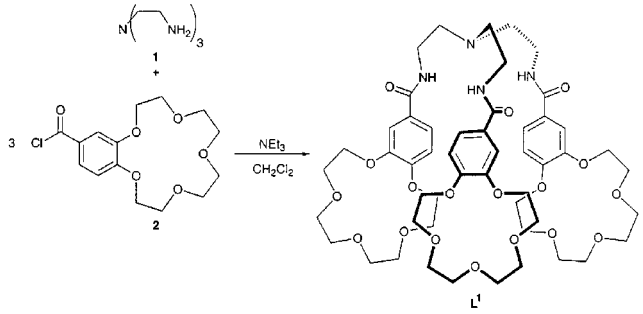
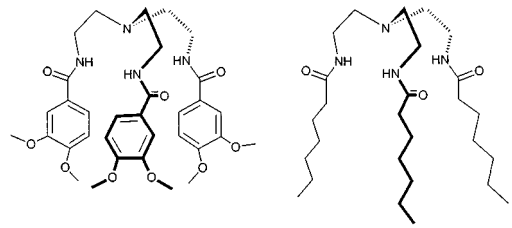
A new tripodal tris(amido benzo-15-crown-5) ligand L[1] cooperatively binds chloride, iodide and perrhenate anions *via* co-bound crown ether complexed sodium cations and efficiently extracts and transports the pertechnetate anion from simulated aqueous nuclear waste solutions *via* cooperative ion-pair binding effects.

Ion pair recognition, the simultaneous complexation of cationic and anionic guest species by multisite receptors, is a new, emerging and topical field of coordination chemistry.[1–6] These heteroditopic ligands can be designed to exhibit novel cooperative and allosteric behaviour whereby the binding of one charged guest can influence, through electrostatic and conformational effects, the subsequent coordination of the pairing ion. Such systems have potential as new selective extraction and transportation reagents for ion pair species of environmental importance. As a consequence of discharges from nuclear fuel reprocessing plants the radioactive pertechnetate anion TcO_4^- is alleged to have a detrimental effect on the environment.[7] Approaches to the removal of pertechnetate anion from waste include liquid–liquid coextraction with metal complexed crown ethers,[8] lipophilic arsonium[9] and ferrocenium[10] salts and π-transition metal–cyclotriveratrylene derivatives.[11] In order to demonstrate, to the best of our knowledge for the first time, the practical usage of ion-pair cooperativity for extraction of such a toxic anionic guest species, we report here the synthesis of a new tripodal tris(amido benzo-15-crown-5) ligand L[1] that cooperatively binds halide and perrhenate anions *via* crown ether complexation of sodium cations, and also efficiently extracts and transports the pertechnetate anion from simulated aqueous nuclear waste *via* cooperative ion-pair binding effects. The target ligand L[1] containing a tripodal tetrahedral amide hydrogen bond donor anion recognition site in combination with crown ether cation binding moieties was synthesised in 55% yield by condensation of tris(2-aminoethyl)amine (tren) **1** with 3 equiv. of 4-chlorocarbonylbenzo-15-crown-5[12] **2** in the presence of Et_3N in CH_2Cl_2 (Scheme 1). Analogous synthetic procedures using appropriate acid chlorides were used to prepare the tripodal model ligands L[2] and L[3] in 30 and 29% yield respectively.



Scheme 1



The anion binding properties of L[1]–L[3] were initially investigated by ^{1}H NMR titration studies with Cl^-, I^- and ReO_4^- in $CDCl_3$ solution. The latter two anions were chosen as I^- has approximately the same size and charge density as TcO_4^-, and ReO_4^- is an isostructural analogue. The addition of all three anions (as their Bu_4N^+ salts) to $CDCl_3$ solutions of L[1]–L[3] caused significant downfield perturbations of the respective ligand's amide protons by up to $\Delta\delta$ = 1.41 ppm, indicating anion binding is taking place in the tripodal amide vicinity of the ligand. Analysis of the resulting titration curves with the computer program EQNMR[13] suggested 1:1 complex stoichiometry in all cases and the determined stability constant values are presented in Table 1. The magnitudes of the stability constants shown in Table 1 are relatively modest, reflecting the neutrality of the ligands; all three ligands exhibit the largest stability constant with chloride. Because nuclear waste discharges typically contain high concentrations of sodium cations it was of interest to investigate the mode of binding of this particular cationic guest to L[1]. Unfortunately solubility problems prevented use of ^{13}C NMR titration techniques.† By monitoring the picrate chromophore, UV-visible spectroscopic titration experiments with sodium picrate and L[1] in 1:1 THF–CH_2Cl_2 indicated that at high concentrations of sodium cation (*i.e.* ⩾ 3 equiv.) unsurprisingly, one sodium cation is bound in each benzo-15-crown-5 moiety. However at lower concentrations, the observation of a well documented bathochromic shift of the picrate chromophore to 377 nm[14] indicated the additional presence of a 1:1 charge separated sandwich complex. Interestingly, alkali metal picrate extraction experiments with L[1] (Table 2) revealed an extraction preference for $Na^+ > K^+ > Cs^+$. In order to elucidate cooperative ion-pair binding effects

Table 1 Anion stability constant data

	K^a/M^{-1}

L[2]	75	40	40
L[3]	40	20	30

[a] Determined in $CDCl_3$ at 298 K, errors estimated to be ⩽10%. [L] = 1 × 10^{-2} M.

Table 2 Extraction of metal picrates by L^1

Picrate	Extraction[a] (%)
Na	80
K	40
Cs	15

[a] Aqueous phase: 1×10^{-4} M metal picrate; $CDCl_3$ phase: 1×10^{-3} M L^1 at 298 K.

^{1}H NMR anion titration experiments with L^1 were repeated in the presence of 1 equiv. of sodium picrate and EQNMR determined stability constant values are present in Table 3. Clearly there is a significant increase in the strength of binding for all anions in the presence of 1 equiv. of sodium cation; in the case of ReO_4^- the increase is greater than twenty-fold. This positive cooperativity may be attributed to the increased electrostatic attraction between the positively charged $L^1 \cdot Na^+$ complex and the guest anion. The complexed metal cation may also affect the spatial arrangement of the ligand and enhance the relative acidity of the ligand's amide protons, leading to stronger hydrogen bonding of the anionic guest. It is noteworthy that the anion selectivity trend displayed by L^1 is altered in the presence of sodium. With no metal cation present, L^1 binds Cl^- in preference to ReO_4^-, however on addition of sodium cation, ReO_4^- is more strongly bound (Table 3), which suggests the binding of the metal cation preorganises L^1 for tetrahedral anionic guest recognition.

Table 3 Stability constants for L^1 anion binding in the presence and absence of sodium picrate in $CDCl_3$

Anion	K/M^{-1}
Cl^-	60[a]
Cl^- ($+Na^+$)[b]	520[c]
I^-	30[a]
I^- ($+Na^+$)[b]	390[c]
ReO_4^-	40[a]
ReO_4^- ($+Na^+$)[b]	840[c]

[a] At 298 K, errors estimated to be ⩽10%. [b] Titration carried out in the presence of 1 equiv. of sodium picrate. [c] At 298 K, errors estimated to be ⩽15%.

Encouraged by these cooperative ion pair binding results, pertechnetate extraction experiments were carried out using conditions that simulated nuclear waste streams. The aqueous phase contained ammonium pertechnetate (100 ppm) and sodium nitrate (2.35 M) and the pH was adjusted to basic conditions (pH = 11) using NaOH. The organic phase consisted of CH_2Cl_2 solutions of L^1–L^3 and benzo-15-crown-5 at concentrations of 1.5×10^{-2} M for the tripodal ligands and 4.5×10^{-2} M for the crown ether. Equal volumes (2 ml) of each solution were mixed, and rapidly shaken. Inductively coupled plasma mass spectrometry (ICP-MS) and ^{99}Tc NMR were used to determine the concentrations of pertechnetate in the respective phases. L^1 extracted *ca.* 70% TcO_4^- whereas benzo-15-crown-5 achieved *ca.* 20% extraction after 5 min.‡ No increase in percentage extraction occurred after this time. Interestingly the tripodal ligands L^2 and L^3 containing no crown moieties displayed respectively less than 10 and 0% extraction of TcO_4^- even after 24 h. The distribution coefficients for TcO_4^- extraction by all the ligands are shown in Fig. 1. The distribution coefficient D for L^1 of 2.3 represents a greater than twenty-fold and ten-fold enhancement in extraction efficiency when compared to L^2 and benzo-15-crown-5, respectively. This important result suggests that a crown ether cation binding site covalently linked to a tripodal amide anion coordinating cavity creates a new efficient extraction reagent for TcO_4^- which operates *via* similar cooperative ion-pair binding effects as

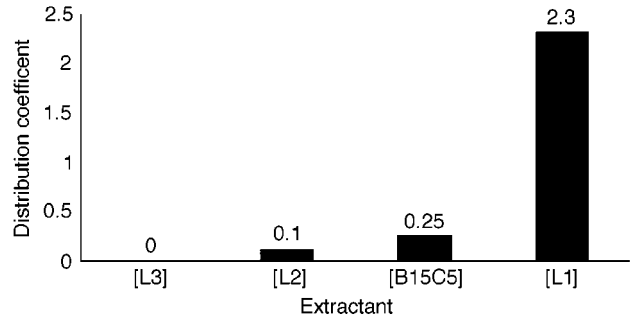

Fig. 1 Distribution coefficients for pertechnetate extraction by L^1–L^3 and benzo-15-crown-5. Organic phase: CH_2Cl_2, concentration of L^1–L^3 = 1.5×10^{-2} M, benzo-15-crown-5 = 4.5×10^{-2} M; aqueous phase: 100 ppm NH_4TcO_4, 2.35 M $NaNO_3$, pH 11, T = 298 K.

noted in the NMR titration experiments. Preliminary U-tube membrane transport investigations using the same aqueous conditions as described previously for the extraction experiments as the source of the aqueous phase revealed a six-fold increase in the rate of transport of TcO_4^- by L^1 (flux = 6.3×10^{-8} mol h^{-1}) over transport mediated by benzo-15-crown-5 (flux = 1.0×10^{-8} mol h^{-1}).

In summary, the new tripodal heteroditopic ligand L^1, by virtue of having both anion and cation recognition sites, has been demonstrated to cooperatively bind chloride, iodide and perrhentate anions *via* co-bound crown ether complexed sodium cations, and is a more efficient extraction and carrier transporting reagent for the pertechnetate anion when compared to monotopic ligands L^2, L^3 and benzo-15-crown-5.

We thank BNFL for a studentship (P. K. H.) and the EPSRC for use of the mass spectrometry service at University College, Swansea.

Notes and references

† ^{1}H NMR titration studies with L^1 and Na^+ unfortunately proved too complicated to monitor, to enable binding stoichiometries to be determined.

‡ In analogous extraction experiments at neutral pH, L^1 extracted 65% TcO_4^-.

Synthesis of primary amides by lipase-catalyzed amidation of carboxylic acids with ammonium salts in an organic solvent

Mike J. J. Litjens, Adrie J. J. Straathof,* Jaap A. Jongejan and Joseph J. Heijnen

Delft University of Technology, Kluyver Laboratory for Biotechnology, Julianalaan 67, 2628 BC Delft, The Netherlands. E-mail: straathof@stm.tudelft.nl

Received (in Liverpool, UK) 30th March 1999, Accepted 12th May 1999

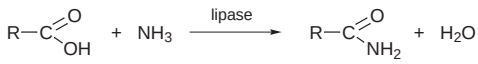
The synthesis of butyramide and oleamide, by *Candida antarctica* lipase B-catalyzed amidation of the carboxylic acids, in an organic solvent with ammonium bicarbonate or ammonium carbamate as a source of ammonia results in good yields, making prior activation of the acids unnecessary.

Primary amides are important derivatives of several types of carboxylic acids, such as fatty acids and amino acids. In addition, enantioselective amidation of chiral acids may be used as an alternative to esterification in kinetic resolution processes. However, direct reaction of carboxylic acids with ammonia requires extreme conditions (200 °C, 7 bar anhydrous ammonia).[1] This may lead to the formation of byproducts in the production of heat sensitive amides such as oleamide. A selective reaction under mild conditions is therefore desirable.

For amidation of aliphatic acids with ammonia, lipases have been considered as the catalyst, but they have been rejected because the formation of a carboxylate anion would lead to precipitation of the ammonium carboxylate rather than formation of the acyl–enzyme complex and subsequent reaction with ammonia.[2,3] For this reason amides are usually synthesized from a neutral and activated form of the acid, such as the acid chloride (which takes away the need for a catalyst) or an ester. For example, De Zoete *et al.*[2] developed a one-pot procedure for the esterification and subsequent ammoniolysis using *Candida antarctica* lipase B (CALB) to catalyze both steps. In many cases it would be attractive if such an activation step could be avoided.

A recent thermodynamic study on the hydrolysis and ammoniolysis of the ester butyl butyrate indicates that the unactivated butyric acid should react efficiently with ammonia under mild conditions in anhydrous methyl isobutyl ketone (MIBK).[4] We decided to verify these thermodynamic predictions experimentally.

Here we demonstrate that primary amides can indeed be formed in good yields under mild reaction conditions, by direct amidation of the carboxylic acids (Scheme 1). The amidation of butyric acid to form butyramide and water serves as a model reaction, using CALB as the biocatalyst. The reaction is performed in MIBK at 25 °C, and ammonium salts that partly dissolve during the course of the reaction are used as a convenient source of ammonia. The experiments were carried out in 33 ml closed glass vessels containing 25 ml dry MIBK with various butyric acid concentrations (concentrations are mentioned in Fig. 1). Immobilized CALB (15 mg) (Novozym 435, a kind gift of NOVO Nordisk, with a catalytic activity of approximately 11000 PLU g^{-1} preparation) and solid ammonium bicarbonate or ammonium carbamate (*ca.* 2.5 mmol) were added, and the suspension was stirred. Samples were taken through a septum to prevent the escape of gas during sampling, and were immediately centrifuged and analyzed for butyric acid and butyramide by GC.



Scheme 1

The experimental results are very encouraging, yields at equilibrium for the amide (after 17 days) were found to be 80–90% when using ammonium bicarbonate and 90–100% when using ammonium carbamate as the source of ammonia (Fig. 1). In addition the model predictions agree reasonably well with the experimental results. No butyramide was formed in the absence of the enzyme, thus the amidation is enzyme-catalyzed. Fig. 1 shows that the amidation proceeds better with ammonium carbamate than with ammonium bicarbonate as the source of ammonia. Model calculations show that this results from the combined effect of a higher ammonia concentration and a lower water concentration. Ammonium bicarbonate dissolves as one equivalent of ammonia, water, and carbon dioxide, whereas ammonium carbamate dissolves as two equivalents of ammonia and one equivalent of carbon dioxide. It is obvious that an increased concentration of ammonia improves the yield at equilibrium, and that an increased concentration of water, which is a coproduct of the amidation, decreases the yield at equilibrium.

With ammonium carbamate as the source of ammonia, the yields obtained in the present experiments approach the optimized yields of the two-step process by De Zoete *et al.*[2] for the synthesis of octanamide and oleamide from the carboxylic acids *via* the esters. The yield of our direct enzymatic amidation may be improved by increasing the ammonia concentration. According to the model calculations[4] the ammonia concentration is below 30 mmol l^{-1} under the experimental conditions employed. Up to 230 mmol l^{-1} of ammonia may be used by saturating the reaction medium with gaseous ammonia.[4] The removal of reaction water, for example by molecular sieves, may further improve the yield.

To estimate the productivity of CALB in our one-step procedure as compared to the two-step procedure by De Zoete *et al.*,[2] an experiment was performed with oleic acid as the substrate. The experimental conditions were similar to those mentioned for butyric acid, except that the temperature was

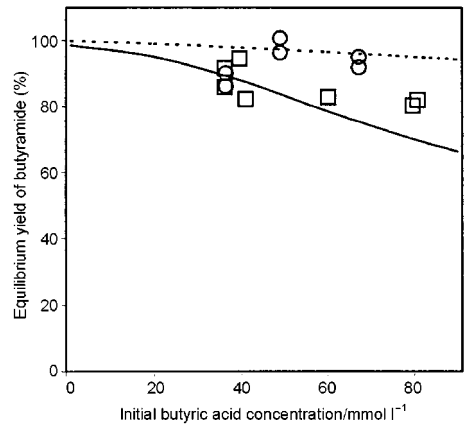


Fig. 1 Yields of butyramide at equilibrium for various initial butyric acid concentrations with solid ammonium bicarbonate (□, —) or solid ammonium carbamate (○, ···) as the source of ammonia. Markers are measured data, lines are predictions using the model presented in ref. 4.

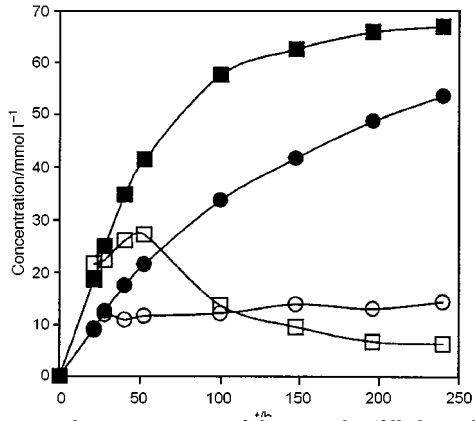

Fig. 2 Measured concentrations of butyramide (filled symbols) and dissolved butyric acid (empty symbols) for a CALB-catalyzed amidation of 70 mmol l^{-1} butyric acid in MIBK. In experiment A (□), 115 mmol l^{-1} ammonia is released gradually by dissolving ammonium carbamate. In experiment B (○), the same amount of ammonia is added in one portion.

35 °C and the enzyme concentration was 1 g l^{-1}. With 1.3 mmol ammonium carbamate as the source of ammonia, 48 mmol l^{-1} oleic acid was converted into oleamide in 95% yield in 4 days. This corresponds to a productivity of 11 mmol oleamide per gram of immobilized enzyme per day, which is more than twice the productivity calculated from the experiment by De Zoete *et al.*,[2] which was performed at 60 °C. Immobilized CALB is highly stable even at 60–80 °C.[5]

Thus, the direct amidation of aliphatic carboxylic acids with ammonia proceeds well, despite the commonly held belief that such a reaction might not be feasible. For this reason we expect that the acid is present mainly in its undissociated form, and not as the unreactive carboxylate. The ammonia concentrations that result from the dissolution of the ammonium salts are apparently sufficient for amidation of the acid, but are not so high that they cause precipitation of the acid as its ammonium salt. Model calculations[4] for butyric acid concentrations of 70 mmol l^{-1} in MIBK predict that ammonia concentrations of 115 mmol l^{-1} cause an equilibrium situation where most of the butyric acid is precipitated, and therefore not available to the enzyme. However, if the ammonia concentration is kept below 30 mmol l^{-1}, then the dissolved butyric acid concentration is much higher. For this reason it is important to add the necessary amount of ammonia gradually, for instance by adding it as slowly dissolving ammonium carbamate. The influence of a gradual addition of ammonia on the reaction rate is demonstrated by the experiments shown in Fig. 2. In a similar experimental setup as described above, 140 mmol l^{-1} butyric acid was dissolved in dry MIBK at 25 °C. In experiment A, 10 ml of this solution was diluted with 10 ml dry MIBK, and 115 mmol l^{-1} ammonia was added as 1.15 mmol solid ammonium carbamate. In experiment B 10 ml of the butyric acid solution was diluted with 10 ml MIBK that previously had been saturated with ammonia, thereby adding the same total amount of ammonia as in experiment A. Immobilized CALB (24 mg) was added to both experiments. Fig. 2 shows that the gradual addition of ammonia through dissolving ammonium carbamate (experiment A) results in higher dissolved butyric acid concentrations and therefore higher amidation rates than the instantaneous addition of the same amount of ammonia (experiment B). In this example the rate of amidation is increased by a decreased ammonia concentration.

In a recent publication Cerovsky and Kula[6] report that low yields (between 0.5 and 38%) of dipeptide amides have been obtained in the protease-catalyzed amidation of the C-terminal carboxylic group of dipeptides. The reactions were performed in MeCN with dissolved ammonium bicarbonate as the source of ammonia. This shows that the reaction described by us is also applicable to other compounds. However, the low solubility of the dipeptides in the organic medium was thought to limit the yield. For substrates of CALB such as aliphatic acids we do not expect any such limitations.

In conclusion we have demonstrated that the direct enzymatic amidation of butyric acid and oleic acid with ammonia is a feasible reaction. Using a widely applicable, commercially available and robust lipase preparation, high yields are achieved under mild reaction conditions. We intend to optimize this amidation reaction and apply it to other carboxylic acids.

We thank Dr Ulf Hanefeld for helpful discussions and for carefully reading the manuscript. A new technique for anchoring homogeneous catalysts

Robert Augustine,* Setrak Tanielyan, Stephen Anderson and Hong Yang

Center for Applied Catalysis, Chemistry Department, Seton Hall University, South Orange, NJ 07079, USA. E-mail: augustro@shu.edu

Received (in Corvallis, OR, USA) 21st April 1999, Accepted 4th May 1999

Heteropoly acids have been found to serve as anchoring agents between a support material and the metal atom of a homogeneous catalytic complex.

Interest in the ability to attach active homogeneous catalysts to an insoluble support material has been on-going for over twentyfive years.[1–5] To date, virtually every example of such supported homogeneous catalysts has involved some method for placing a ligand in or on a solid material and then using this 'heterogenized' ligand to prepare a catalytic complex. With this form of attachment, the metal atom could be removed by a ligand exchange reaction possibly with some of the product, substrate molecules or other species present in the reaction mixture. In most cases the activity and selectivity of these heterogenized complexes were lower than those observed with the corresponding homogeneous species and on attempted re-use the activity and selectivity of these heterogenized complexes were frequently lost. This approach, which requires the incorporation of the ligand onto a solid material, is particularly difficult to apply with most of the chiral ligands used in the highly efficient enantioselective homogeneous catalysts in use today.

We describe here a procedure by which a preformed homogeneous complex can be anchored to a variety of support materials, with the resulting catalyst being at least as active as the homogeneous species and capable of being re-used many times with no loss of activity or selectivity and no evidence of catalyst leaching.[6]

These heterogenized catalysts have been prepared by using a heteropoly acid such as phosphotungstic acid (PTA) as the anchoring agent to attach a complex to a support material. This is accomplished by adding a solution of the heteropoly acid (20 μmol in 2.5 ml of alcohol) with vigorous stirring to a suspension of the support material (300 mg in 10 ml of alcohol), with stirring continued for about 3 h followed by the removal of the liquid and thorough washing of the solid. This solid is then suspended in another 10 ml of degassed alcohol and a solution of the homogeneous catalyst (20 μmol in 1 ml of alcohol) is added under an inert atmosphere, with stirring, over a 30 min period. Stirring is continued for 8 to 12 h under an inert atmosphere, the liquid removed and the solid washed thoroughly until no color is observed in the wash liquid. This material can be used directly or dried for future use.

In some of our initial work with alumina supports, a slight color was sometimes imparted to the reaction mixture which, at first, was thought to indicate some leaching of the complex. However, analysis of these reaction mixtures showed that they contained not only rhodium but also tungsten and aluminum, which indicated that this loss occurred by attrition of the alumina and not by any leaching of the complex. Using EtOH in the preparation and reaction procedures successfully removed this problem.

It has been reported that Rh and Ir complexes react with a heteropoly acid to give a material in which the metal atom is attached to the heteropoly acid through the oxygen atoms on its surface.[7] Attachment of the heteropoly acid to a support such as alumina takes place by interaction of the hydroxy groups of the acid with the support.[8] The result is the attachment of the complex to the support using a heteropoly acid with bonding to the metal atom. The ^{31}P MAS NMR chemical shifts for the phosphorous atom in PTA, PTA on alumina and the Rh(DiPamp) supported on PTA–Al_2O_3 both before and after use in a hydrogenation were all identical, showing that the PTA remained intact throughout the entire preparation and reaction sequence.[9]

The data presented in Table 1 show the reaction rate and product ee for successive hydrogenations of methyl 2-acetamidoacrylate (**1**) run over a Rh(DiPamp) complex supported on PTA treated Montmorillonite K as well as the corresponding data obtained using the homogeneous catalyst. The first use of the heterogeneous catalyst was slower than that observed with the homogeneous catalyst and the product ee was also lower. However, when the first product mixture was removed from the reactor and a fresh solution of the starting material added to the heterogeneous, anchored catalyst, subsequent re-use proceeded significantly faster than the homogeneously catalyzed reaction with higher product ees observed as well. This catalyst was re-used fifteen times with no loss of activity or selectivity. Analysis of the product mixtures showed that if any rhodium was present it was there in an amount below the detection limit, which corresponded to less than 1 ppm. While we are not certain of the reason for the increase in activity after the first use of the heterogeneous catalyst, the fact that in some reactions the catalyst changed from yellow to a light gray–violet on use and back to yellow on exposure to air suggests that this activation may be the result of some partial reduction of the tungsten in the PTA.

One of the advantages of this approach to anchoring homogeneous catalysts is its apparent generality, in that this procedure can be used to anchor a variety of pre-formed active homogeneous catalysts onto a number of different supports. In Table 2 are listed the reaction rate and product ee data observed for the hydrogenation of **1** over several Rh complexes anchored to alumina along with the corresponding homogeneous catalyst data, while in Table 3 are given the data for the hydrogenation of **1** using Rh(DiPamp) anchored on different supports. We have also used these anchored homogeneous catalysts for the hydrogenation of a number of other prochiral substrates such as methyl 2-acetamidocinnamate, 2-actamidocinnamic acid, dimethyl itaconate and 2-methylhex-2-enoic acid. complex anchored to PTA treated alumina was used for successive hydrogenations of **1** and dimethyl itaconate with the reaction rate and product ee increasing after the first use in both cases. Analysis of the product mixtures from these reactions found no detectable ruthenium present.

In every instance, the reaction rates and product ee were at least equal to and frequently better than the results obtained using the corresponding homogeneous catalyst, especially when the catalysts were re-used. In some instances, even the first use of the catalyst gave superior results. Heteropoly acids other than PTA were also successful anchoring agents.

This anchoring procedure has also been applied to achiral complexes with similar results. For instance, hydrogenation of hex-1-ene over a Wilkinson's catalyst anchored to PTA treated alumina proceeded 2–3 times faster than the corresponding homogeneously catalyzed reaction, even on the first use of the heterogenized material. A Rh(dppb) complex anchored to a PTA modified alumina was used for several successive hydrogenations of hex-1-ene with a combined substrate : catalyst ratio of about 8000 : 1. An analysis of the product mixtures from these reactions found no detectable rhodium present.

This research was supported by grants CTS-9312533 and CTS-9708227 from the United States National Science Foundation and financial support from The Engelhard Corporation.

An extremely mild and stereocontrolled construction of 1,2-*cis*-α-glycosidic linkages *via* benzyl-protected glycopyranosyl diethyl phosphites

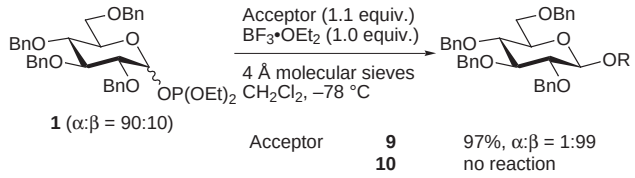
Received (in Cambridge, UK) 9th April 1999, Accepted 14th May 1999

A highly stereocontrolled 1,2-*cis*-α-glycosidation reaction under conditions mild enough for acid-labile alcohols has been developed using benzyl-protected glycopyranosyl diethyl phosphites as glycosyl donors in the presence of 2,6-di-*tert*-butylpyridinium iodide and tetrabutylammonium iodide.

Due to the rapidly recognised biological significance of the saccharide residues of carbohydrate-containing biomolecules, the rational design and development of stereocontrolled glycosidation reactions[1] are of growing importance not only in carbohydrate chemistry but also in medicinal chemistry.[2] One of the current topics in this area is the emergence of glycosyl phosphites as a new family of glycosyl donors,[3–6] the effectiveness of which has been demonstrated well by high-yield and α-selective sialylation[3a,4a,b] using sialyl phosphite as a donor and TMSOTf as a promoter. As yet another advantage of glycosyl phosphites, we recently reported that glycosidations of benzyl-protected glycopyranosyl diethyl phosphites with a variety of acceptor alcohols could be effected with the aid of $BF_3{\cdot}OEt_2$ as a promoter at −78 °C to exhibit the highest 1,2-*trans*-β-selectivity known to date for glycosidations without neighboring group participation.[7] During the course of mechanistic investigations of the reaction, we found that the glucopyranosyl phosphite **1**† could not be directly activated by $BF_3{\cdot}OEt_2$ at −78 °C. This result, together with the finding that the trimethylsilyl ether **10** derived from *O*-6-unprotected glycoside **9** did not serve as a glycosyl donor (Scheme 1),



Scheme 1

suggested that glycosidation should be effected with the aid of the BF_3–acceptor alcohol complex[8] which functioned as a proton donor to activate the phosphite group to give oxocarbenium ion and diethyl phosphite. Although TfOH is known to activate the phosphite **1** to give mainly 1,2-*trans*-β-glucosides,[4c] there has been no reported attempt to use promoters with much lower Brønsted acidity. At this stage, we envisaged that if the phosphite group could be activated using promoters such as pyridinium iodides, the glycosidation process *via* glycopyranosyl iodide coupled with Lemieux's *in situ* anomerisation method[9] might lead to the construction of 1,2-*cis*-α-glycosidic linkages under extremely mild reaction conditions.[10–12] Herein, we report a new aspect of glycosidations with benzyl-protected glycopyranosyl diethyl phosphites, wherein the combined use of 2,6-di-*tert*-butylpyridinium iodide (DTBPI)[13] as a promoter and tetrabutylammonium iodide as an additive proves to be the superior choice for allowing exceptionally high levels of 1,2-*cis*-α-selectivity, as well as glycosylations of even highly sensitive aglycones.

Since it is well-documented that glycosylations of less nucleophilic alcohols favor 1,2-*cis*-α-glycosides, we first examined glycosidation of **1** with **9** with a high reactivity in order to make an assessment as accurately as possible. After considerable experimentation, it was found that coupling of **1** (α:β = 90:10 or 75:25, 1.1 equiv.) with **9** (1.0 equiv.) in CH_2Cl_2 in the presence of DTBPI (1.2 equiv.) and pulverised 4 Å molecular sieves proceeded at room temperature for 48 h to afford the corresponding 1,2-*cis*-disaccharide in 85% yield with an α:β ratio of 92:8 (Table 1, entry 1). Since TLC and ^1H NMR analyses showed that *in situ* conversion of **1** into the α-glucopyranosyl iodide[14] proceeded to completion within 30 min irrespective of the anomeric composition of the donor, the glycosidation of the iodide *via in situ* anomerisation was presumed to be the rate-determining step. As expected, the addition of Bu_4NI (1.2 equiv.) to the above mixture facilitated the anomerisation process and shortened the reaction time to 24 h, providing the disaccharide in 84% yield with the same α-selectivity as above (entry 2).‡§

In order to clarify the scope and limitations of the present method, we then explored the glycosidation of glycosyl phosphites **1**–**8**† with a range of acceptor alcohols. The

examples highlighted in Table 1 deserve some comment. In all cases except for the exceedingly sterically hindered, unreactive *O*-4-unprotected glycoside **11** (entry 3), the present glycosidations were found to offer a high-yielding entry to 1,2-*cis*-linked glycosides and disaccharides, utilising conditions under which highly acid-sensitive alcohols such as digitoxigenin **16** and tigogenin **17** were safely glycosylated (entries 7 and 8). While glycosidations of the D-gluco- and D-galactopyranosyl donors **1** and **6** displayed high levels of α-selectivity with various alcohols of different reactivities (entries 1–8 and 13–15), that of L-fucopyranosyl donor **7** was found to exhibit less satisfactory selectivity (entries 16 and 17). However, the α-selectivity was greatly improved by switching the protective group from a benzyl group to a *p*-chlorobenzyl group (entries 18 and 19),[15] although only a small enhancement was observed with the D-glucopyranosyl donor (entry 9). According to a general trend,[10,16] protection of the *O*-6 hydroxy group as a bulky triphenylmethyl or *tert*-butyldiphenylsilyl ether gave further enhanced α-selectivities of up to 96 : 4 (entries 10 and 11). In this regard, it is also of interest that the present protocol could be advantageously extended to glycosidation with 4,6-*O*-benzylidene-protected glucopyranosyl donor **5** (entry 12).[11]

In conclusion, the present method constitutes an exceptionally mild and general procedure for the highly stereocontrolled construction of 1,2-*cis*-α-glycosidic linkages. Thus, we have now developed a stereoselective entry to either 1,2-*cis*-α-glycosides or 1,2-*trans*-β-glycosides using glycosyl phosphites as common glycosyl donors by proper choice of the reaction conditions.

This research was supported in part by a Grant-in-Aid (No.08557119) from the Ministry of Education, Science, Sports and Culture of Japan.

Notes and references

† Glycopyranosyl diethyl phosphites **1**–**8** were readily prepared from the corresponding glycopyranoses according to the reported procedure (ref. 7), the anomeric ratios of which were determined by 109 MHz ^{31}P NMR using 85% H_3PO_4 as an external standard.

‡ Typical experimental procedure: A solution of **1** (72.6 mg, 0.11 mmol) in CH_2Cl_2 (1 ml) was added to a mixture of **9** (46.4 mg, 0.1 mmol), DTBPI (38.3 mg, 0.12 mmol), Bu_4NI (44.3 mg, 0.12 mmol) and pulverised 4 Å molecular sieves (50 mg). The whole mixture was stirred at room temperature for 24 h. Standard workup followed by column chromatography (silica gel, 6 : 1 hexane–AcOEt) furnished the corresponding disaccharide (82.9 mg, 84%) as a 92:8 mixture of α- and β-anomers.

§ The combined use of 2,6-di-*tert*-butylpyridinium bromide and Bu_4NBr under otherwise identical conditions (reaction time; 48 h) provided the disaccharide with the α : β ratio of 87 : 13 in 80% yield.

syn-Diastereoselective carbonyl allylation by 1- or 3-substituted prop-2-en-1-ols with tin(II) iodide and tetrabutylammonium iodide

Yoshiro Masuyama,* Takanori Ito, Kentaro Tachi, Akihiro Ito and Yasuhiko Kurusu

Department of Chemistry, Sophia University, 7-1 Kioicho, Chiyoda-ku, Tokyo 102-8554, Japan.
E-mail: y-masuya@hoffman.cc.sophia.ac.jp

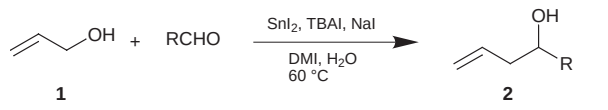
Received (in Cambridge, UK) 22nd March 1999, Accepted 17th May 1999

1-Substituted or 3-substituted prop-2-en-1-ols cause *syn*-diastereoselective carbonyl allylation with tin(II) iodide and tetrabutylammonium iodide *via* the formation of 3-substituted prop-2-enylpolyiodotins to produce *syn*-1,2-disubstituted but-3-en-1-ols.

Barbier-type carbonyl allylation is one of the most convenient methods for the introduction of allylic functions.[1] Allylic metal reagents in the allylation reaction are generated *in situ* from allylic halides, which are usually prepared from allylic alcohols in advance. Thus, it should be an important aim to generate allylic metal reagents from available and storable allylic alcohols directly. We have already reported carbonyl allylations by allylic alcohols with tin(II) chloride, which need a catalytic amount of palladium complexes such as $PdCl_2(PhCN)_2$, $Pd(PPh_3)_4$ and so on.[2] We here report that allylic alcohols serve as carbonyl allylating agents without the palladium complexes *via* the use of tin(II) iodide and tetrabutylammonium iodide (TBAI),[3] and that the carbonyl allylation by 1- or 3-substituted prop-2-en-1-ols with tin(II) iodide and TBAI exhibits *syn*-diastereoselectivity,[4] in contrast to the palladium-catalysed *anti*-diastereoselective carbonyl allylation by 3-substituted (*E*)-prop-2-en-1-ols with tin(II) chloride in 1,3-dimethylimidazolidin-2-one (DMI).[5]

Prop-2-en-1-ol (**1**) slowly caused allylation of benzaldehyde without palladium catalysts in the presence of tin(II) iodide, TBAI and NaI under the same conditions (namely at room temperature in DMI containing a small amount of H_2O) which gave the best results for the carbonyl allylation by allylic halides with tin(II) halides and tetrabutylammonium halides;[4] 15–20 °C, 166 h, 17% yield. When the temperature was raised to 60 °C, prop-2-en-1-ol (**1**) was amenable to the allylation of various aldehydes, as summarized in Table 1. Use of less than 2 equiv. of tin(II) iodide with respect to benzaldehyde lowered the yield (SnI_2 (2 mmol), 60 °C, 66 h, 61%). Tin(II) bromide slowed down the allylation of benzaldehyde (72 h, 38%), and no reaction occurred with tin(II) chloride, under the same conditions as those of the allylation with tin(II) iodide.

Table 1 Carbonyl allylation by **1** with SnI_2, TBAI and NaI[a]



R	*t*/h	Yield[b] of **2** (%)
Ph	41	77
4-MeC_6H_4	54	55
4-ClC_6H_4	45	79
$PhCH_2CH_2$	72	64
c-C_6H_{11}	62	36
C_6H_{13}	35	52
CH_2=$CH(CH_2)_8$	46	54

[a] The allylation of aldehydes (1 mmol) by prop-2-en-1-ol (2 mmol) was carried out with SnI_2 (3 mmol), TBAI (0.25 mmol) and NaI (2.5 mmol) in DMI (3 ml) and H_2O (0.1 ml) at 60 °C. [b] Isolated yields.

Diastereoselective allylation of benzaldehyde (1 mmol) by (*E*)-but-2-en-1-ol (**3**; R = Me, R′ = H, 2 mmol) was investigated with tin(II) iodide (3 mmol) and TBAI (1 mmol) at 60 °C in various solvents containing a small amount of H_2O; DMI (19 h, 74%, *syn*:*anti* = 83:17) is superior to other solvents (THF, 26 h, 74%, *syn*:*anti* = 83:17; DMF, 72 h, 18%, *syn*:*anti* = 67:33; H_2O, 72 h, 31%, *syn*:*anti* = 89:11; DMI without H_2O, 72 h, 25%, *syn*:*anti* = 71:29) for both reactivity and diastereoselectivity. The results in the diastereoselective carbonyl allylation by some 1- or 3-substituted prop-2-en-1-ols† with SnI_2, TBAI and NaI in DMI–H_2O are summarized in Table 2. Allylic alcohols bearing an aliphatic group at the α- or γ-position can be applied to the *syn*-diastereoselective carbonyl allylation. In contrast, (*E*)-cinnamyl alcohol bearing an aromatic group at the γ-position exhibits *anti*-selectivity, similar to the palladium-catalysed carbonyl allylation with tin(II) chloride.

The *syn*-diastereoselective carbonyl allylation by 1- or 3-substituted prop-2-en-1-ols, except (*E*)-cinnamyl alcohol, with tin(II) iodide and TBAI probably proceeds *via* (i) the transformation of the prop-2-en-1-ol into 1-substituted 3-iodoprop-1-ene **A**, which is then converted into 3-substituted prop-2-enylpolyiodotin **B**, and (ii) the formation of an acyclic antiperiplanar transition state **C** between 3-substituted prop-2-enylpolyiodotin **B**, in which the tin has no Lewis acidity, and an aldehyde, as shown in Scheme 1.[4]‡ The tin in (*E*)-cinnamylpolyiodotin, derived from (*E*)-cinnamyl alcohol with tin(II) iodide and TBAI, may have Lewis acidity owing to (σ–

p)π conjugation between the tin–allylic carbon σ-bond and an electron-deficient olefinic β-carbon in the (*E*)-cinnamyl group.[6] Thus, (*E*)-cinnamylpolyiodotin probably causes *anti*-addition to aldehydes *via* the formation (coordination) of chair-like six-membered cyclic transition states.[2,5]

Notes and references

† Starting allylic alcohols [prop-2-en-1-ol, (*E*)-but-2-en-1-ol, but-1-en-3-ol (*E*)-cinnamyl alcohol and (*E*)-hex-2-en-1-ol] were purchased from Tokyo Chemical Industry Co., Ltd.

‡ Allylic alcohol are known to cause α-regioselective carbonyl allylation with Me_3SiCl, NaI and H_2O–Sn (or SnI_2). (ref. 3). The tin intermediates in this reaction were assumed to be allylic (μ-iodo)ditin compounds. Since our reaction system contains an excess of iodides, triiodostannate is probably formed, preventing the formation of Sn–I–Sn bonds, and thus allylic (μ-iodo)ditin species. Thus, the thermodynamically stable γ-substituted allylic tin intermediate **B** probably causes the expected γ-addition to aldehyde to produce 1,2-disubstituted but-3-en-1-ol **4**.

FEATURE ARTICLE

The asymmetric Birch reduction and reduction–alkylation strategies for synthesis of natural products

Arthur G. Schultz

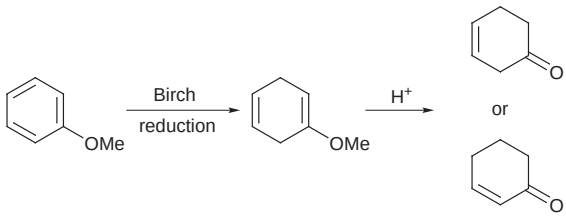
Department of Chemistry, Rensselaer Polytechnic Institute, Troy, NY 12180-3590, USA. E-mail: schula@rpi.edu

Received (in Cambridge, UK) 4th March 1999, Accepted 25th March 1999

Synthetic applications of the asymmetric Birch reduction and reduction–alkylation are reported. Synthetically useful chiral intermediates have been obtained from chiral 2-alkoxy-, 2-alkyl-, 2-aryl- and 2-trialkylsilyl-benzamides I and the pyrrolobenzodiazepine-5,11-diones II. The availability of a wide range of substituents on the precursor benzoic acid derivative, the uniformly high degree of diastereoselection in the chiral enolate alkylation step, and the opportunity for further development of stereogenic centers by way of olefin addition reactions make this method unusually versatile for the asymmetric synthesis of natural products and related materials.

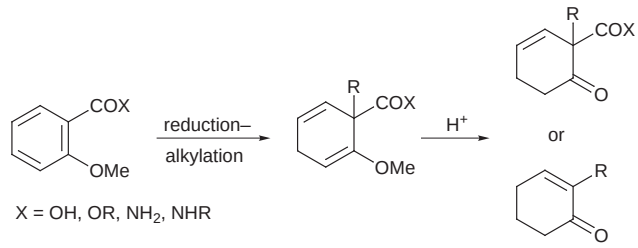
Introduction

The Birch reduction has been used by several generations of synthetic organic chemists for the conversion of readily available aromatic compounds to alicyclic synthetic intermediates.[1] Birch reductions are carried out with an alkali metal in liquid NH_3 solution usually with a co-solvent such as THF and always with an alcohol or related acid to protonate intermediate radical anions or related species. One of the most important applications of the Birch reduction is the conversion of aryl alkyl ethers to 1-alkoxycyclohexa-1,4-dienes. These extremely valuable dienol ethers provide cyclohex-3-en-1-ones by mild acid hydrolysis or cyclohex-2-en-1-ones when stronger acids are used (Scheme 1).



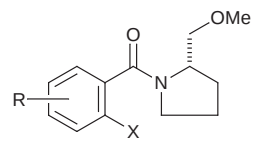
Scheme 1

The Birch reduction of derivatives of 2-methoxybenzoic acid followed by alkylation of the intermediate enolate is of even greater strategic value. The resulting chiral cyclohexa-1,4-dienes are converted to 2,2-disubstituted cyclohex-3-en-1-ones by hydrolysis of the enol ether. If the carboxylic acid is used in the reduction step, then treatment of the intermediate cyclohexa-1,4-diene with acid results in hydrolysis–decarboxylation to give 2-substituted cyclohex-2-en-1-ones (Scheme 2).

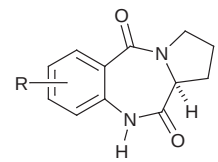


Scheme 2

Against this backdrop of prior investigation, we initiated a program directed at the development of an asymmetric version of the Birch reduction and reduction–alkylation of derivatives of benzoic acid.[2] We opted to make use of a chiral auxiliary covalently bound to the carboxylic acid group and after a brief screening of possible candidates were delighted to find that the inexpensive amino acid (*S*)-proline and its product of reduction by $LiAlH_4$, (*S*)-pyrrolidine-2-methanol, served beyond all reasonable expectation. It has been demonstrated that 2-alkoxy-, 2-alkyl-, 2-aryl- and 2-trialkylsilyl-benzamides of general structure **I** can be effectively utilized in asymmetric organic synthesis of a wide range of synthetic targets. It was necessary to develop a different protocol for the anthranilic acids; the pyrrolobenzodiazepine-5,11-diones **II**, obtained by condensation of 1 equiv. of (*S*)-proline with the corresponding isatoic anhydride, provided a remarkably flexible solution to the incorporation of nitrogen substitution on the derived cyclohexane ring.



I X = OMe, alkyl, aryl, SiR_3
R = H, OMe, alkyl, aryl



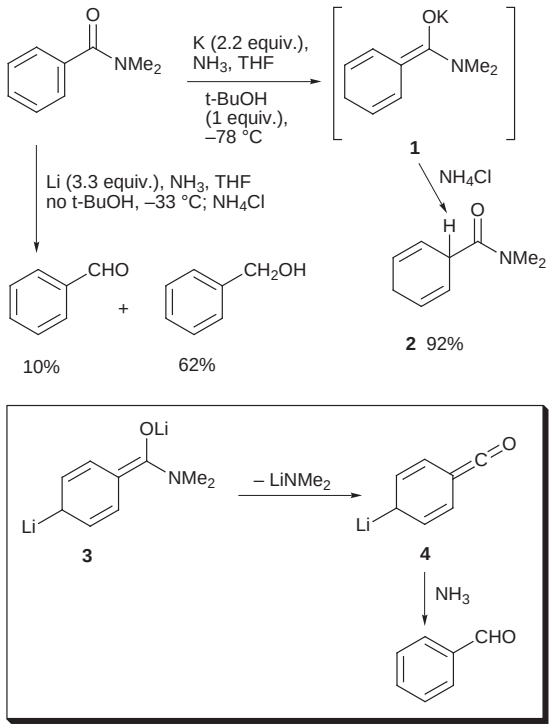
II R = H, alkyl

Much of the characterization of reactivity of **I** (X = OMe) and some of the early applications of **I** and **II** to asymmetric organic synthesis were reviewed in 1990.[3] The focus of this feature article is on recent developments with greatly expanded sets of substrates corresponding to the generalized structures **I** and **II**. Particular attention is devoted to the utilization of these substrates for the asymmetric synthesis of natural products and related materials.

Arthur Schultz is the William Weightman Walker Professor of Chemistry at Rensselaer Polytechnic Institute. He received his BS degree from the Illinois Institute of Technology and his PhD in organic chemistry from the University of Rochester under the supervision of Richard Schlessinger. From 1970 to 1972 he was a postdoctoral fellow at Columbia University with Gilbert Stork. He began his academic career at Cornell University and moved to RPI in 1978. His research interests include asymmetric organic synthesis, the development of new synthetic methods, the synthesis of natural products, and synthetic and mechanistic organic photochemistry. He is the recipient of an NIH MERIT Award 1992–2002.

Tools for asymmetric synthesis

At the outset of our studies of the reactivity of **I** and **II**, it was necessary to investigate claims that tertiary benzamides were inappropriate substrates for the Birch reduction. It had been reported that reduction of *N*,*N*-dimethylbenzamide with sodium in NH_3 in the presence of *tert*-butyl alcohol gave benzaldehyde and a benzaldehyde–ammonia adduct. We found that the competition between reduction of the amide group and the aromatic ring was strongly dependent on reaction variables, such as the alkali metal (type and quantity), the availability of a proton source more acidic than NH_3, and reaction temperature. Reduction with potassium in NH_3–THF solution at −78 °C in the presence of 1 equiv. of *tert*-butyl alcohol gave the cyclohexa-1,4-diene **2** in 92% isolated yield (Scheme 3). At the other extreme, reduction with lithium in NH_3–THF at −33 °C in the absence of *tert*-butyl alcohol gave benzaldehyde and benzyl alcohol as major reaction products.[4]



Scheme 3

Reduction of the aromatic nucleus in *N*,*N*-dimethylbenzamide occurs by an initial single electron transfer to give a radical anion. Protonation of the radical anion generates a radical and a second electron transfer gives the amide enolate **1**. Protonation of the cross-conjugated trienolate moiety in **1** occurs α to the incipient carbonyl group to give the cyclohexa-1,4-diene **2**.[1]

Amide group reduction probably occurs by the mechanism shown in Scheme 3. Two-electron transfer without protonation would give dianion **3**. Elimination of $LiNMe_2$ from **3** would give **4** (an acyl anion equivalent) and protonation of **4** at the carbonyl group would give benzaldehyde.

Because dianion formation appears to be more important when lithium rather than potassium is used, many of the Birch reductions and reduction–alkylations of **I** and **II** that have been developed utilize potassium as the reducing metal. Piperylene is added prior to the alkylation reagent to consume any remaining metal and thereby prevent reduction of the alkylation reagent. In the event that the alkylation reagent is unstable to strong bases (*e.g.* homoallylic and arylethyl halides) LiBr is added to reduce the basicity of the reaction medium.

Birch reduction of the chiral benzamide **5** generates the amide enolate **6** (Scheme 4). This enolate has been characterized by NMR spectroscopy and by an extensive examination of the effects of changes in alkali metal, solvent, reaction temperature and substituents near the reaction center on the diastereoselectivity of enolate alkylation.[5] These data have been reviewed before[3] and will not be discussed here. For this presentation it is sufficient to note that the alkylation reagent reacts with enolate **6** preferentially from the least hindered face away from the methoxymethyl group on the chiral auxiliary.

Diastereoselectivities for alkylation of enolate **6** are outstanding. Alkylation with MeI gives **7** (R = Me) as the major product diastereomer in a ratio of 260 : 1 with respect to the minor diastereomer **8**. A wide range of alkylation reagents have been examined including allylic, benzylic, homoallylic, alkoxymethyl, cyanomethyl, and arylethyl halides.

It is important to perform both the Birch reduction of **5** and the alkylation of enolate **6** at −78 °C. Enolate **6** obtained directly from **5** at low temperatures is considered to be a 'kinetic enolate'. A 'thermodynamic enolate' obtained from **6** by equilibration techniques has been shown to give an opposite sense of stereoselection on alkylation.[5] Although a comprehensive study of this modification has not been carried out, diastereoselectivities for formation of **8** were found to be greater than 99 : 1 for alkylations with MeI, EtI, and $PhCH_2Br$. Thus, it should be possible to obtain both enantiomers of a target structure by utilization of a single chiral benzamide.[6,7]

It has been demonstrated that excellent diastereoselectivities for enolate alkylation also are obtained when alkyl substituents are positioned at C(4), C(5) or C(6) of benzamide **5**.[5] Aryl[8] and methoxy[9] substituents at C(5) also are compatible, but a methyl group at C(3) leads to an inversion of the diastereoselectivity of enolate alkylation. The inverted sense of stereoselection is thought to be a result of a disruption of the internal chelation shown in enolate **6** by steric effects of the neighboring methyl substituent.[5]

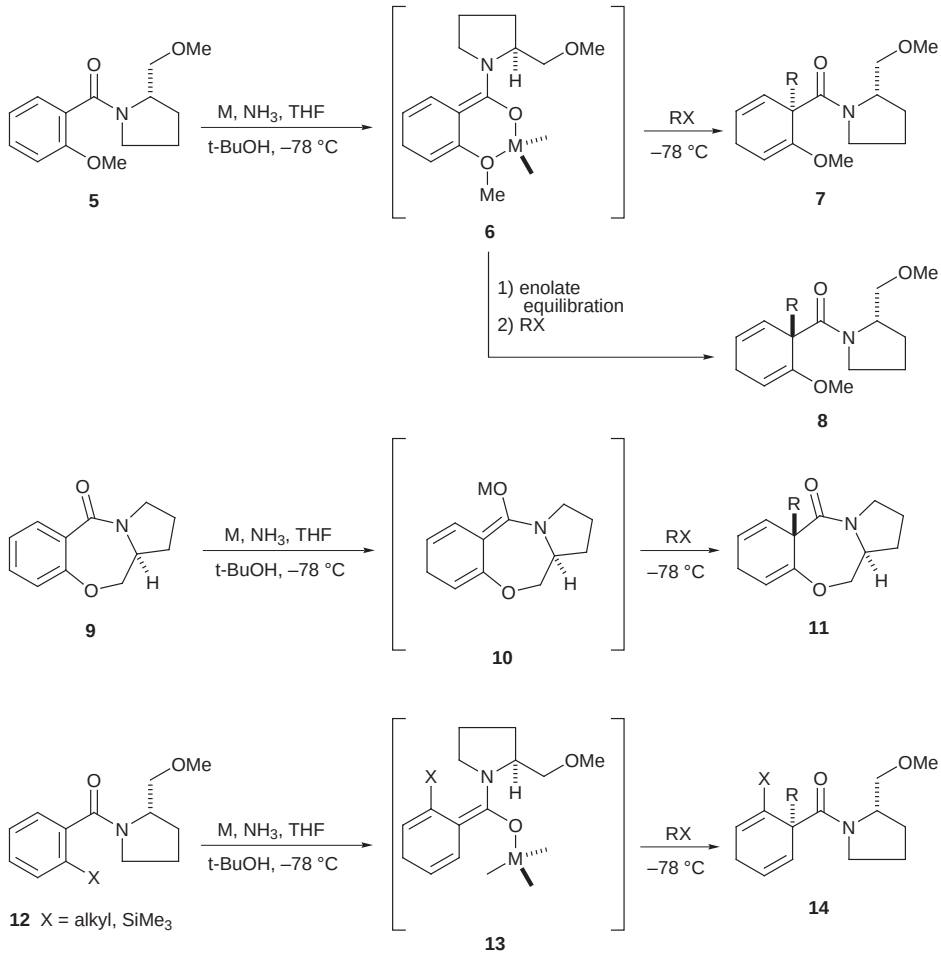
A more traveled route to the absolute configuration represented by cyclohexa-1,4-diene **8** involves Birch reduction–alkylation of benzoxazepinone **9**.[2,5] This heterocycle is best prepared by the base-induced cyclization of the amide obtained from 2-fluorobenzoyl chloride and (*S*)-pyrrolidine-2-methanol.[10] The molecular shape of enolate **10** is such that the hydrogen at the stereogenic center provides some shielding of the α-face of the enolate double bond. Thus, alkylation occurs primarily at the β-face of **10** to give **11** as the major diastereomer. The diastereoselectivity for alkylation with methyl iodide is only 85:15, but with more sterically demanding alkyl halides such as ethyl iodide, allyl bromide, 4-bromobut-1-ene *etc.*, diastereoselectivities are greater than 98 : 2.

Birch reduction–alkylation of 2-alkyl- and 2-trimethylsilylbenzamides corresponding to structure **12** has provided a very general route to cyclohexa-1,4-dienes of type **14**. Enolate **13** has been used to explain the alkylation diastereoselectivities for over twenty cases in which the substituent X is varied from a group as small as methyl to groups as large as CH_2CH_2Ph or $SiMe_3$.[11,12] As with enolate **5**, the alkylation reagent reacts preferentially from the less hindered face of enolate **13** to give **14**.

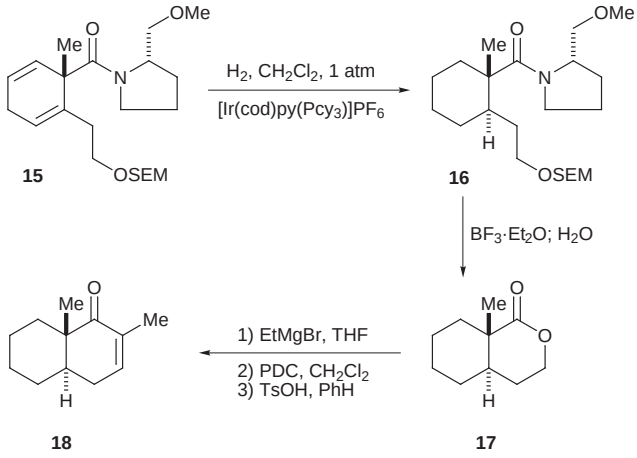
Companion reactions that serve to expand the scope of the asymmetric Birch reduction–alkylation strategy

The development of facial selective addition reactions of cyclohexa-1,4-dienes **7** and **14** has greatly extended the value of the asymmetric Birch reduction–alkylation. For example, amide directed hydrogenation[13] of **15** with the Crabtree catalyst system occurs with outstanding facial selectivity *syn* to the amide carbonyl group to give **16** (Scheme 5).[11]

The reluctance of tertiary amides to undergo hydrolysis, especially those produced in the Birch reduction–alkylation with a quaternary center next to the carbonyl group, has inspired the development of a variety of intramolecular transacylation reactions as illustrated by the cleavage of the SEM ether in **16**



Scheme 4

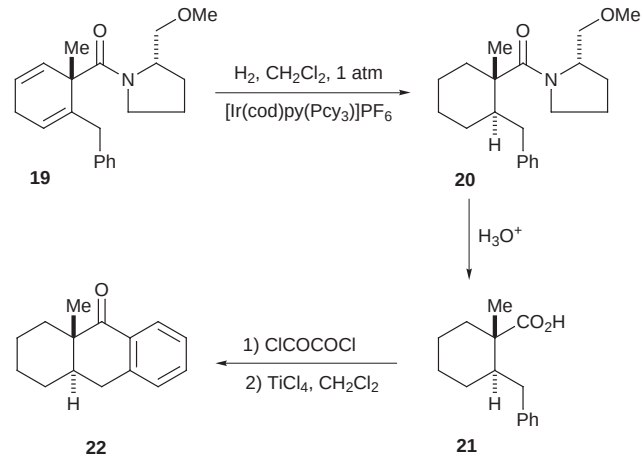


Scheme 5

and subsequent cyclization of the resulting alcohol to give lactone **17**. It is noteworthy that the chiral auxiliary can be removed at this stage by a simple partitioning of the reaction mixture between an organic solvent and aqueous acid.

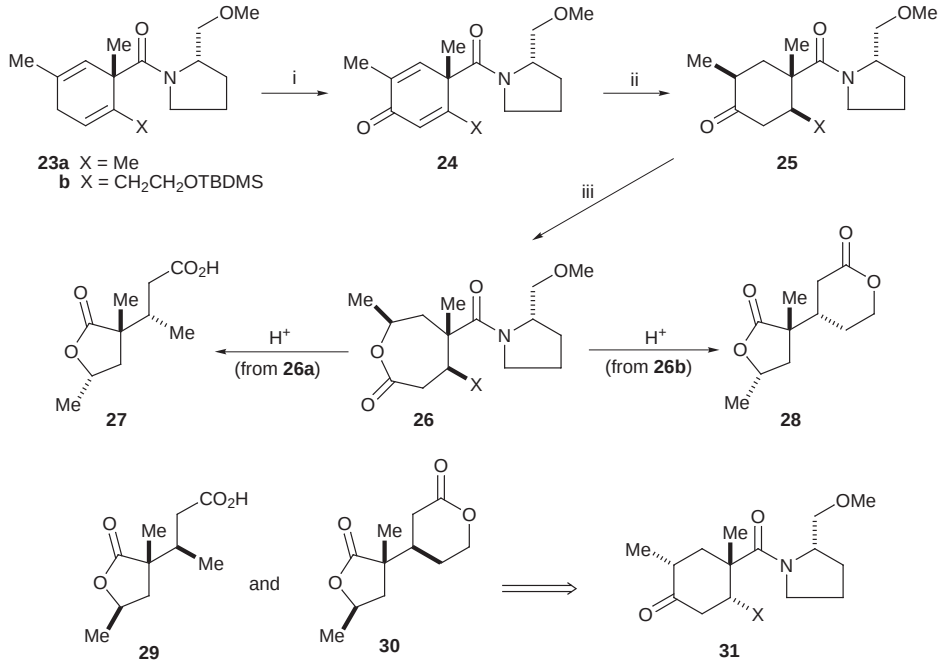
Lactone **17** was converted to the *trans* fused octalone **18** by a classical Grignard-type carboannulation. Variations of the organometallic reagent used in the conversion of **17** to **18** and modifications of the substrate and alkylation reagent utilized to produce **15** afford unusually flexible options for the preparation of annulated cyclohexanes.

An application to the asymmetric synthesis of enantiomerically pure *trans*-hexahydroanthracen-9-ones is shown in Scheme 6. It should be possible to carry out a second stereoselective reductive alkylation of the benzoyl group in **22** as was demonstrated in the related hydrofluoren-9-one and hydrophenanthren-9-one series.[14] The key to the development of synthetic strategies involving consecutive Birch reduction–alkylations will depend on sequential activations of aromatic rings toward alkali metal in ammonia reduction; carbonyl activation is illustrated by the conversion of **21** to **22** in Scheme 6.



Scheme 6

Bis-allylic oxidation of **23** and related cyclohexa-1,4-dienes provides a convenient and general preparation of cyclohexa-2,5-dien-1-ones (Scheme 7).[15] These cross-conjugated dienones are substrates for a variety of photochemical rearrangement and intramolecular cycloaddition reactions.[16] Amide-directed hydrogenations of dienones **24a** and **24b** with the homogeneous iridium catalyst afford cyclohexanones **25a** and **25b**, containing three stereogenic centers on the six-



Scheme 7 *Reagents*: i, PDC, t-BuOOH, Celite, PhH; ii, H_2, [Ir(cod)py(Pcy$_3$)]PF_6, CH_2Cl_2, 1 atm; iii, MCPBA.

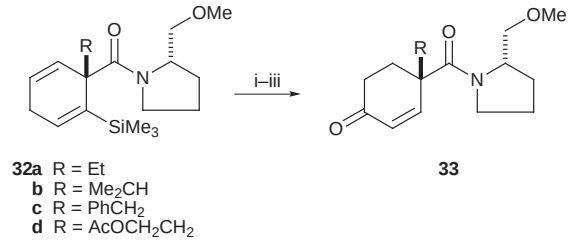
membered ring. Opposite stereoselectivity is obtained with heterogeneous catalysts such as rhodium on alumina or palladium on carbon to give cyclohexanones **31a** and **31b**.[17] X-Ray structural studies[18] demonstrate the importance of the bulky amide group in directing heterogeneous catalytic hydrogenation to the distal face of the cyclohexa-2,4-dienone ring.

We were interested in applications of the high level of stereocontrol associated with the asymmetric Birch reduction–alkylation to problems in acyclic and heterocyclic synthesis. The pivotal disconnection of the six-membered ring is accomplished by utilization of the Baeyer–Villiger oxidation (Scheme 7). Treatment of cyclohexanones **25a** and **25b** with MCPBA gave caprolactone amides **26a** and **26b** with complete regiocontrol. Acid-catalyzed transacylation gave the butyrolactone carboxylic acid **27** from **26a** and the bis-lactone **28** from **26b**; cyclohexanones **31a** and **31b** afforded the diastereomeric lactones **29** and **30**.[17]

Chiral butyrolactones of type **27** and **28** have substantial value in asymmetric synthesis because they contain readily differentiable difunctional group relationships (*e.g.* 1,5-dicarboxylic acid, 1,4-hydroxycarboxylic acid, 1,6-hydroxycarboxylic acid, 1,6-diol *etc.*) that would be difficult to assemble by existing asymmetric condensation and pericyclic processes. Applications of these chiral derivatives of glutaric acid to syntheses of indole, indoline and quinolinone alkaloids are illustrated in Schemes 16–18.

A structural requirement for the asymmetric Birch reduction–alkylation is that a substituent must be present at C(2) of the benzoyl moiety to desymmetrize the developing cyclohexa-1,4-diene ring (Scheme 4). However, for certain synthetic applications, it would be desirable to utilize benzoic acid itself. The chemistry of chiral benzamide **12** (X = $SiMe_3$) was investigated to provide access to non-racemic 4,4-disubstituted cyclohex-2-en-1-ones **33** (Scheme 8).[19] Alkylation of the enolate obtained from the Birch reduction of **12** (X = $SiMe_3$) gave cyclohexa-1,4-dienes **32a–d** with diastereoselectivities greater than 100 : 1.[20] These dienes were efficiently converted in three steps to the chiral cyclohexenones **33a–d**.

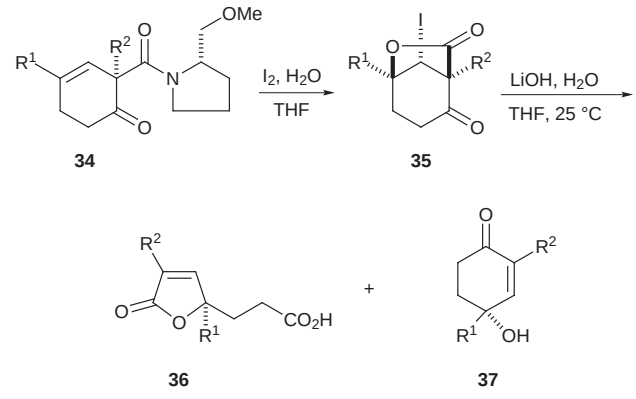
A very effective method for removal of the chiral auxiliary from cyclohexenones **34** involves treatment with I_2 in THF–H_2O to give the iodolactones **35** (Scheme 9). These highly functionalized chiral cyclohexanones have figured prominently in the asymmetric synthesis of natural products; *e.g.* Scheme 15. Furthermore, selective cleavage of the cyclohexanone ring in **35**



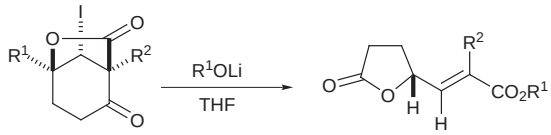
Scheme 8 *Reagents*: i, PDC, t-BuOOH; ii, H_2, Pd/C; iii, $CuCl_2$, DMF.

with LiOH under aqueous conditions affords the butenolide carboxylic acids **36**.[21] A competing fragmentation process initiated by addition of hydroxide ion to the lactone carbonyl group gives the 4-hydroxycyclohexenones **37**. Yields for formation of the butenolide **36** are in the range of 80 to 90% when relatively large groups are present at C(2). On the other hand, the 4-hydroxycyclohexenone **37** is obtained in 72% yield when R^1 = H and R^2 = Me.

A different mode of fragmentation of the lactone ring in **35** occurred to give butyrolactone **38** when anhydrous lithium alkoxides were used in place of metal hydroxides under aqueous conditions (Scheme 10). It is noteworthy that **36**, **37** and **38** (R^1 = H) are all formed without racemization. Although we are only in the early stages of development of the chemistry of iodolactones **35**, it is already clear that there is considerable potential for utilization of the butenolides derived from **35** as scaffolds for construction of carbocyclic and heterocyclic ring



Scheme 9

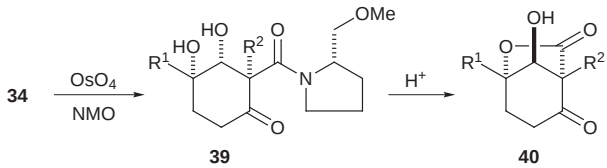


35 38

Scheme 10

systems by way of intramolecular radical and dipolar addition reactions.[21]

Cyclohexenones **34** also undergo a highly diastereoselective dihydroxylation to give *cis*-diols **39** (Scheme 11).[22] These diol amides are converted to hydroxylactones **40** by an acid-catalyzed process involving retro aldol–realdolization prior to transacylation. The enantiomers of hydroxylactones **40** are obtained from iodolactones **35** by iodide exchange with 2,2,6,6-tetramethylpiperidin-1-yloxy free radical (TEMPO) followed by reductive cleavage of the TEMPO derivative with Zn in HOAc. The enantiomeric purity of the hydroxylactones prepared by either route is 95–98% ee.



39 40

Scheme 11

Reaction of enolate **5** with excess NH_4Cl at −78 °C gave the α-protonated amide **41** as a 4 : 1 mixture of diastereomers.[5] This degree of stereoselectivity was considered to be unacceptable for applications in asymmetric organic synthesis. However, the chiral 2-substituted cyclohex-2-en-1-one **42**, obtained from **41** by enol ether hydrolysis along with double bond migration, undergoes conjugate addition reactions with Grignard reagents and related organometallic derivatives with moderate to good regio- and stereo-control.[23] Considerably more selective addition reactions of **42** occur with allyl silanes (the Sakurai reaction) and enol silyl ethers (the Mukaiyama–Michael addition).[24] Treatment of the conjugate adduct with *N*-methylhydroxylamine releases the chiral auxiliary to give a 1-methyltetrahydrobenzisoxazolin-3-one; *e.g.* **43**, 96% ee. Heterocycle **43** provides 2,3-disubstituted cyclohexanones **44** by a reduction–alkylation sequence (Scheme 12).[24]

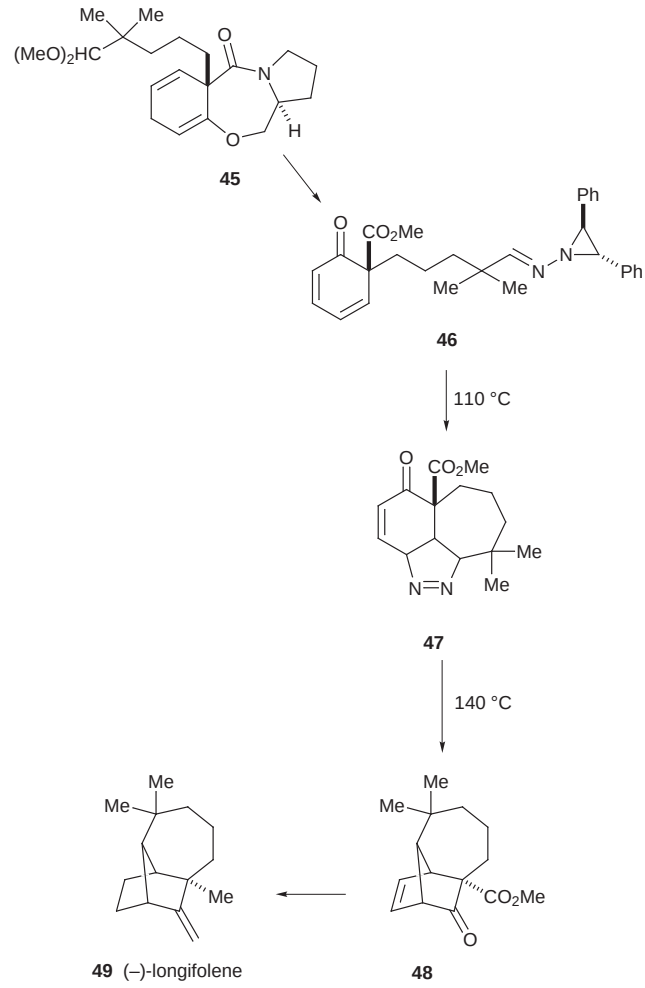
Applications to the asymmetric synthesis of natural products and related materials

What truly distinguishes the asymmetric Birch reduction–alkylation protocol from other methods for preparation of non-racemic cyclohexane derivatives is (i) the accessibility of aromatic carboxylic acids with substituents ranging from heteroatoms to alkyl and aryl groups to tethered functionality available for subsequent strategic applications, (ii) the uniformly high degree of diastereoselection in the chiral enolate alkylation step, and (iii) the opportunity for further development of stereogenic centers on the resulting chiral cyclohexa-1,4-diene ring system by facial-selective addition reactions.

The tricyclic sesquiterpene longifolene has served as a vehicle for the illustration of new strategies for organic synthesis.[25] Both enantiomers have been obtained from natural sources; (+)-longifolene occurs in several *Pinus* species and is commercially available while the rare (−)-longifolene has been found in certain liver mosses.[26] We elected to prepare (−)-longifolene **49** from the cyclohexa-1,4-diene **45**, obtained from the Birch reduction–alkylation of benzoxazepinone **9** in 96% yield with a diastereomeric excess of greater than 98% (Scheme 13).[27]



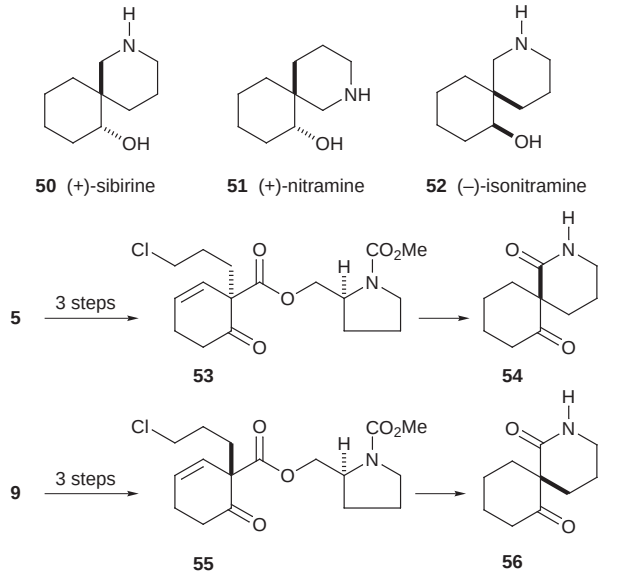
45 46 47 48

Scheme 13

Cyclohexadiene **45** was converted to **46** by what has proven to be a general method for preparation of the cyclohexa-2,4-dien-1-one ring system.[28] Fragmentation of the aziridinyl imine in **46** at 110 °C gave an intermediate diazoalkane which underwent an intramolecular 1,3-dipolar cycloaddition to give the pyrazoline **47**. At 140 °C, pyrazoline **47** expelled N_2 and rearranged to the tricyclic ketone **48**. The development of this and related bicyclizations[29] illustrated a practical synthetic equivalence of an intramolecular diene–carbene 4 + 1 cycloaddition in the cyclohexa-2,4-dien-1-one series.

The 2-azaspiro[5.5]undecane group of alkaloids occur in certain plants of the genus *Nitraria*. There has been some interest in the biological activity of these alkaloids because their structures are similar to the histrionicotoxins, a group of

1-azaspiro[5.5]undecane alkaloids found only in dendrobatid frogs.[30] The first asymmetric syntheses of (+)-sibirine **50**, (+)-nitramine **51** and (−)-isonitramine **52** from the chiral benzamide **5** and benzoxazepinone **9** established the absolute configuration of these alkaloids (Scheme 14).[31]



Scheme 14

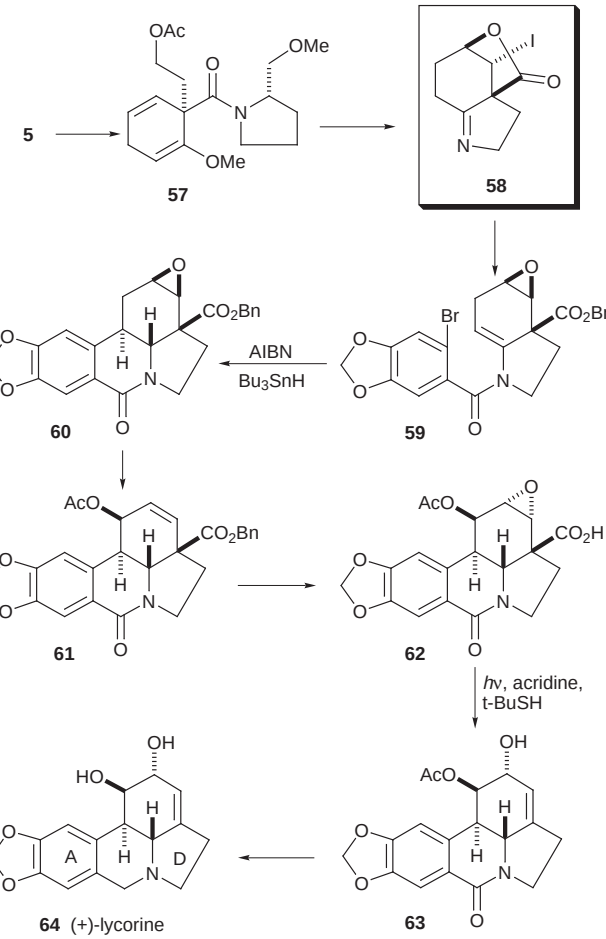
The diastereomerically related keto esters **53** and **55**, activated for removal of the chiral auxiliary, were obtained from **5** and **9**. The requisite nitrogen atom was introduced by an azide displacement of chloride and at an opportune stage of the synthesis an intramolecular aminolysis of the carboxylic ester provided the enantiomerically related keto lactams **54** and **56**. Although shorter routes to these popular synthetic targets have been reported in recent years, the conversion of **9** to (−)-isonitramine (ten steps, 50% overall yield) clearly illustrates the efficiency of the asymmetric Birch reduction–alkylation strategy for construction of the azaspiroundecane ring system.

Lycorine is the most abundant alkaloid in plants of the *Amaryllidaceae*. Several syntheses of racemic lycorine had been reported prior to our initiation of studies directed at an asymmetric synthesis of the unnatural enantiomer **64**.[32] A common theme in all of the syntheses of (±)-lycorine has been the utilization of either an intermolecular or intramolecular Diels–Alder construction of the key C-ring of the alkaloid. This six-membered ring presents a rather formidable synthetic challenge because of the four contiguous stereogenic centers, the *trans* 1,2-diol moiety, and the juxtaposition of the aromatic substituent and the carbon–carbon double bond.

The first asymmetric total synthesis of (+)-lycorine is outlined in Scheme 15. While our earlier applications of the Birch reduction–alkylation of chiral benzamide **5** were focused on target structures with a quaternary stereocenter derived from C(1) of the starting benzoic acid derivative, the synthesis of **64** demonstrates that the method also is applicable to the construction of chiral six-membered rings containing only tertiary and trigonal carbon atoms.[33]

Birch reduction–alkylation of **5** with 2-bromoethyl acetate was carried out with complete facial selectivity to give **57**. This tetrafunctional intermediate was converted to the bicyclic iodolactone **58** (> 99% ee) from which the radical cyclization substrate **59** was prepared. The key radical cyclization occurred with complete regio- and facial-selectivity and subsequent stereoselective reduction of the resulting tertiary radical gave **60** with the required *trans* BC ring fusion.[34] The allylic alcohol unit of (+)-lycorine was obtained by a photochemical radical decarboxylation, **62** → **63**.

The eburnamine–vincamine alkaloids found in plants of the dogbane family provided a useful testing ground for application

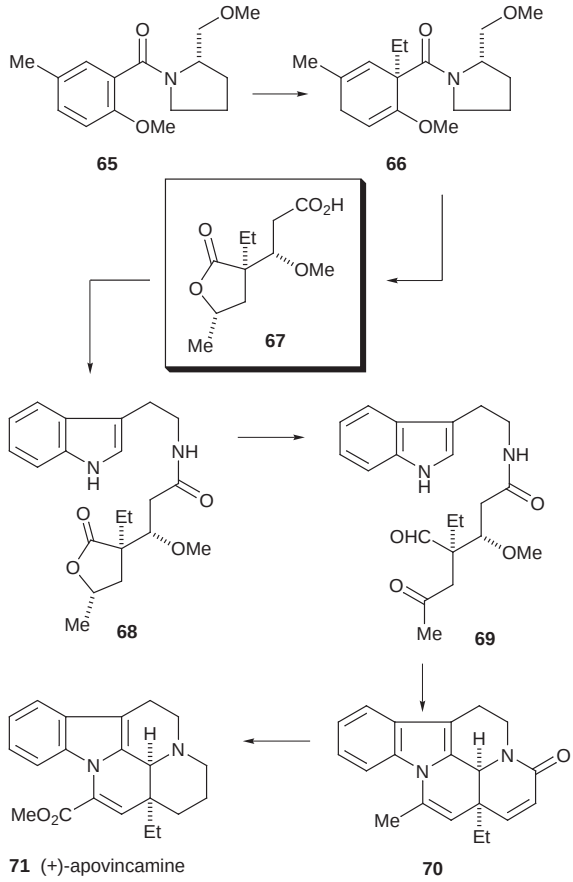


Scheme 15

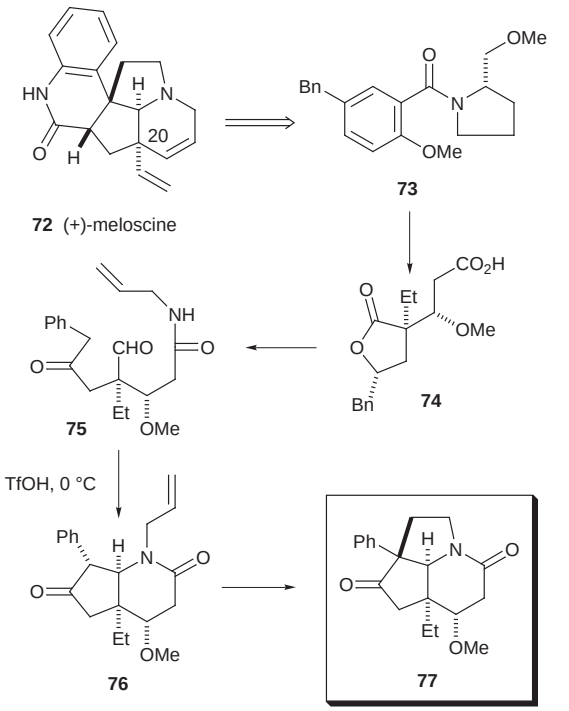
of the butyrolactone synthesis outlined in Scheme 7 to the construction of nitrogen heterocycles (Scheme 16). An asymmetric total synthesis of (+)-apovincamine **71** began with the Birch reduction–ethylation of the chiral 2-methoxy-5-methylbenzamide **65** to give **66** (diastereomer ratio > 100 : 1).[35] Tryptamine was coupled to the butyrolactone carboxylic acid **67**, and the resulting amide was converted to the keto aldehyde **69**. An acid-catalyzed cyclization of **69** followed by a base-induced elimination of MeOH provided the key *cis*-fused diene lactam **70**, which was converted to (+)-apovincamine **71** by a sequence of steps involving reduction of the ene lactam with $LiAlH_4$ and oxidation of the methyl substituent by an electrophilic dibromination.

The butyrolactone route to alkaloids was demonstrated again with a synthesis of **77**, the core structure of the *Melodinus* alkaloid (+)-meloscine **72** (Scheme 17).[36] The synthetic strategy features an early incorporation of the aromatic ring in **72** as the 5-benzyl substituent in **73**. The Mannich bicyclization of **75** provides the key *cis*-pyridin-6-one **76**, from which the remaining ring in **77** is assembled by an oxidative cleavage of the *N*-allyl group and acid-catalyzed cyclization of the resulting keto aldehyde. It is expected that (+)-meloscine **72** will be prepared from a derivative of **73** containing a modified 5-benzyl substituent. The asymmetric Birch reduction–alkylation will provide a latent vinyl group to accommodate the substitution at C(20) of **72**.[37]

The versatile cyclohexa-1,4-diene **32a** has served as an intermediate for synthesis of (−)-eburnamonine **81** and the *Aspidosperma* alkaloid (−)-aspidospermidine **84** (Scheme 18).[38] Butyrolactone carboxylic acids **78** and **82** were prepared from **32** by modification of the methodology outlined in Scheme 7. The key Pictet–Spengler-type cyclization of **79** under conditions of kinetic control gave an 18 : 1 mixture of **80** and its C(3) β-epimer in 93% yield. Subsequent hydroboration



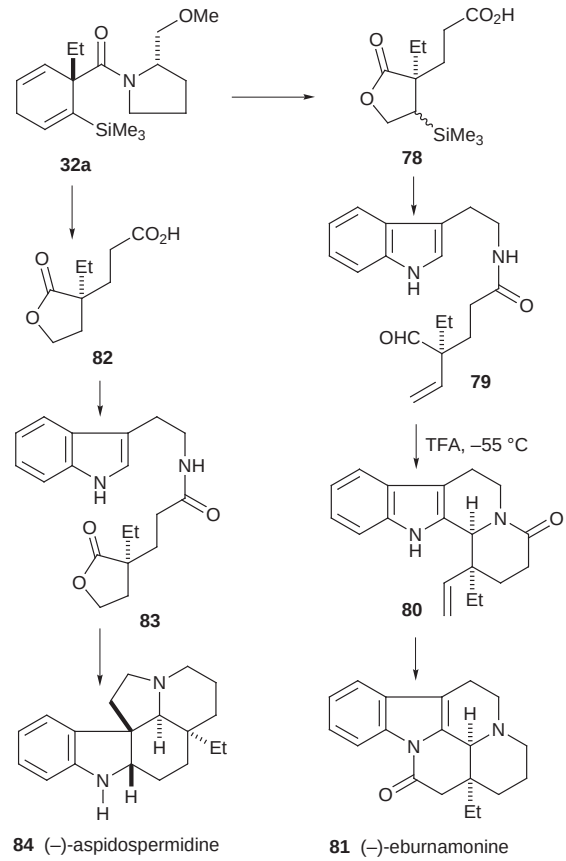
Scheme 16



Scheme 17

of **80** and oxidation of the intermediate primary alcohol gave (−)-eburnamonine **81** in a total of 12 steps from the chiral benzamide **12** (X = $SiMe_3$) and 17% overall yield.

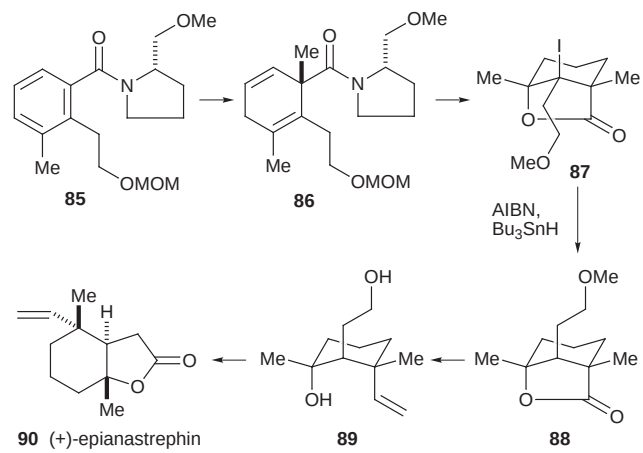
The classical Harley–Mason cyclization was utilized *en route* to (−)-aspidospermidine **84**.[39] The synthesis of **84** required 12 steps from the chiral benzamide **12** (X = $SiMe_3$) and was carried out with an overall yield of 19%.



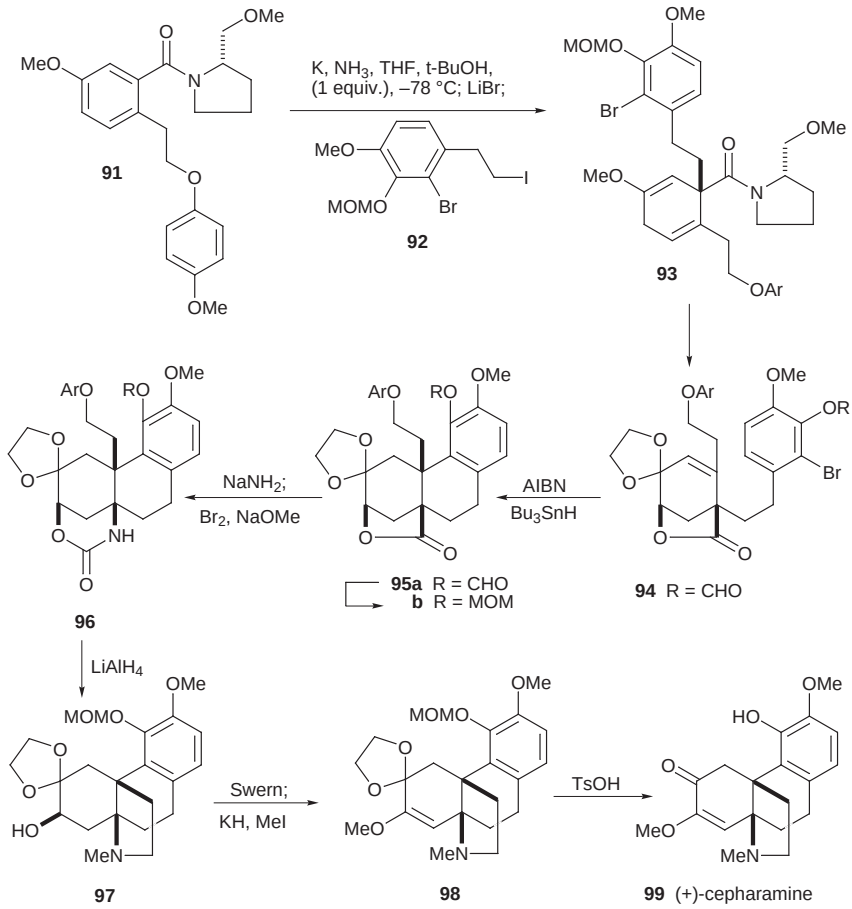
Scheme 18

Birch reduction–methylation of the 2,3-dialkyl substituted benzamide **85** (Scheme 19) provided the cyclohexa-1,4-diene **86** with diastereoselectivity comparable to that observed with the 2-alkylbenzamides illustrated in Scheme 4. Cyclohexadiene **86** was converted to iodolactone **87** and reduction of **87** with Bu_3SnH occurred with exclusive equatorial delivery of hydrogen to give the axial methoxyethyl derivative **88**. Lactone **88** was converted to the Caribbean fruit fly pheromone (+)-epianastrephin **90** (> 98% ee) in 9.5% overall yield from the chiral benzamide **85**.[40]

The hasubanan alkaloids are of pharmacological interest because of their structural resemblance to the morphine alkaloids.[41] The first asymmetric synthesis of a hasubanan alkaloid, (+)-cepharamine **99**, is shown in Scheme 20.[42] The synthesis is highly convergent as a result of the Birch reduction of **91** and alkylation with **92** to give the cyclohexa-1,4-diene **93** in 95% yield. Conversion of **93** to **94** and radical cyclization of **94** gave the hydrophenanthrene **95a**. An exchange of protecting



Scheme 19



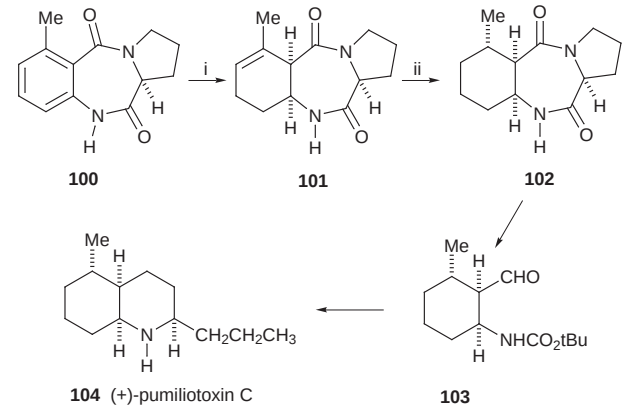
Scheme 20

group was followed by a very efficient Hofmann-type rearrangement of **95b** with internal capture of the resulting isocyanate by the neighboring OH group to give the cyclic carbamate **96**. Formation of the *cis*-fused *N*-methylpyrrolidine ring was then carried out in one experimental operation by treatment of **96** with $LiAlH_4$ in refluxing THF. Swern oxidation of **97** to the corresponding ketone followed by *O*-alkylation of the ketone enolate afforded enol ether **98**. Acid-catalyzed ketal and MOM ether hydrolysis proceeded without disruption of the enol ether to give (+)-cepharamine **99**. The synthesis of **99** required 16 steps from the chiral benzamide **91** and was carried out with an overall yield of 12%.

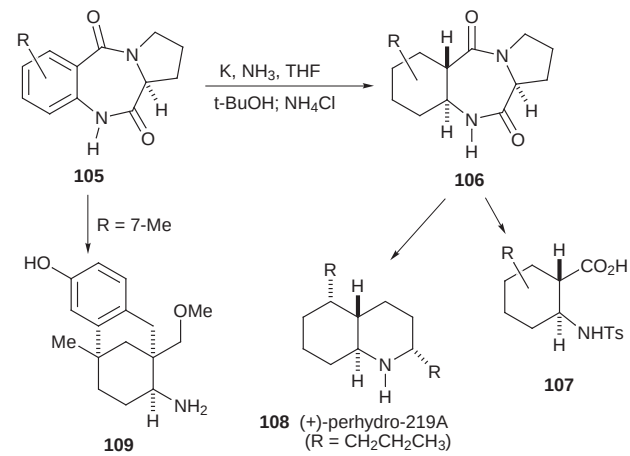
Applications of pyrrolobenzodiazepine-5,11-diones

The pyrrolobenzodiazepine-5,11-diones **II** have been utilized in asymmetric syntheses of both the *cis*- and *trans*-decahydroquinoline alkaloids (Schemes 21 and 22). For example, reduction of **100** with 4.4 equiv. of potassium in the presence of 2 equiv. of t-BuOH, followed by protonation of the resulting enolate with NH_4Cl at −78 °C gave the *cis*-fused tetrahydrobenzene derivative **101**.[43] Amide-directed hydrogenation of **101** gave the hexahydrobenzene derivative with diastereoselectivity greater than 99 : 1. Removal of the chiral auxiliary and adjustment of the oxidation state provided aldehyde **103** which was efficiently converted to the poison frog alkaloid (+)-pumiliotoxin C.

Reduction of all three of the double bonds in the pyrrolobenzodiazepine-5,11-dione **105** with excess potassium provides the corresponding *trans* fused hexahydrobenzene derivative **106** in high yield with complete stereochemical control. The preparation of (+)-perhydro-219A **108** from **106** has been reported[13] and a general method of preparation of derivatives of *trans*-2-aminocyclohexanecarboxylic acid (*e.g.* **107**) has recently appeared.[44]



Scheme 21 *Reagents*: i, K (4.4 equiv.), NH_3, THF, t-BuOH (2 equiv.); NH_4Cl; ii, H_2 $[Ir(cod)py(Pcy_3)]PF_6$



Scheme 22

The enolates obtained by reduction of two of the double bonds in **105** undergo completely stereoselective alkylation to give *cis*-fused tetrahydrobenzene derivatives in excellent yield. Structural analogues of the morphine alkaloids have been prepared by way of reduction–alkylation of **105** with *p*-alkoxybenzyl halides; *e.g.* **109**. One of these analogues has displayed high affinity for the κ-opioid receptor and anti-nociceptive studies have demonstrated that this analogue is a full κ-agonist.[45]

Conclusions and future considerations

Chiral benzamides **I** and the pyrrolobenzodiazepine-5,11-diones **II** have proven to be effective substrates for asymmetric organic synthesis. Although the scale of reaction in our studies has rarely exceeded the 50 to 60 g range, there is no reason to believe that considerably larger-scale synthesis will be impractical. Applications of the method to more complex aromatic substrates and to the potentially important domain of polymer supported synthesis are currently under study. We also are developing complementary processes that do not depend on a removable chiral auxiliary but rather utilize stereogenic centers from the chiral pool as integral stereodirectors within the substrate for Birch reduction–alkylation.[46]

2,5-Di-(*tert*-butyl)phospholyl sandwich complexes containing group 14 elements (Ge, Sn, Pb). Synthesis, molecular structure, and ring transfer chemistry of $[M(PC_4H_2Bu^t_2)_2]$ (M = Sn, Pb)

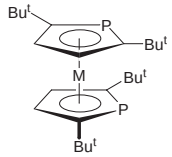
Received (in Basel, Switzerland) 12th April 1999, Accepted 26th May 1999

Structurally characterised tin and lead sandwich compounds are shown to contain aromatic phospholyl ligands which can be transferred to rhodium and iridium centres under mild conditions.

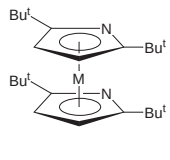
The coordination chemistry of phospholyl ligands towards transition metals is an area reaching maturity[1] and a number of recent studies have also highlighted the chemistry of alkali metal phospholides.[2] However, simple π complexes involving monophospholyl ligands and elements of the p block have yet to appear.[3] Lying somewhere between the classical ionic chemistry of the phospholide anions and covalent transition metal phospholyls, these complexes may answer some interesting questions concerning the nature of the metal–phospholyl bond and the potential for η^5–η^1 equilibria. Furthermore, it seems reasonable to assume that they will be useful reagents.[4]

We present here the synthesis of three group 14 sandwich complexes **1**–**3** containing the 2,5-di(*tert*-butyl)phospholyl ligand and the molecular structures of $[Pb(PC_4H_2Bu^t_2)_2]$ **1** and

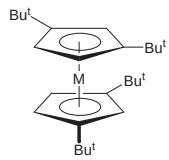


M = Pb, **1**; Sn, **2**; Ge, **3**

$[Sn(PC_4H_2Bu^t_2)_2]$ **2**. Using the 2,5-di-(*tert*-butyl)phospholyl ligand[5] diminishes the potential for electron-transfer chemistry† at the relatively redox-sensitive tin and lead centres and allows comparisons to be made with the published complexes $[M(NC_4H_2Bu^t_2)_2]$ (M = Sn **4**,[6a] Pb **5**[6b]) and $[M(C_5H_3Bu^t_2)_2]$ (M = Ge **6**, Sn **7**, Pb **8**[7a]).



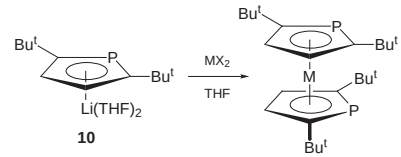
M = Sn, **4**; Pb, **5**



M = Ge, **6**; Sn, **7**; Pb, **8**

Stirring THF solutions containing $[Li(PC_4H_2Bu^t_2)(THF)_2]$ **10**[5] with MCl_2 (M = Sn, Pb) for 30 min at room temp. followed by evaporation to dryness *in vacuo*, extraction of $[M(PC_4H_2Bu^t_2)_2]$ into pentane and crystallisation at −78 °C produced air and moisture-sensitive deep (Pb, **1**) and pale (Sn, **2**) yellow cubes in *ca.* 80% yield. A similar procedure using GeI_2 gave $[Ge(PC_4H_2Bu^t_2)_2]$ **3** (50%) as a pale yellow powder.‡

X-Ray diffraction studies upon single crystals of the isostructural lead and tin compounds (Fig. 1 and 2, respectively) show two discrete molecular η^5 complexes within each unit cell.§ In each case, the Bu^t groups almost perfectly eclipse the phosphorus and CH functionalities, thus relieving nonbonding



10

M = Pb, **1**; Sn, **2**; Ge, **3**

interactions between the rings. The angles at the intersection of the planes defined by the flat phospholyl ligands (Pb: 17.3; Sn: 19.2°) predictably[1] resemble the cyclopentadienyl-derived stannocenes and plumbocenes more than the aza-analogues **4** and **5**. The tilt of 5.7° for the phospholyl ring in the related phospharuthenocene[5] suggests that these angles may simply reflect the preferred geometry of the 2,5-di-(*tert*-butyl)phospholyl ligand rather than any significant electronic drive for a bent metallocene structure. Thus, the small $^1J_{PSn}$ coupling in **2**¶ probably reflects high *s*-electron character in both the P *and* the Sn lone pair orbitals.[7b,8] The equalisation of bond lengths within the phospholyl component indicates extensive delocalisation (Table 1)[9] which is confirmed by the large intracyclic $^1J_{PC}$ coupling constants ([Pb = 51.4, Sn = 48.5 and Ge = 47.0 Hz; *cf.* $(Me_3Sn)PC_4H_2Bu^t_2$ **9**, (27.5 Hz) and the delocalised $[Li(PC_4H_2Bu^t_2)(THF)_2]$ **10** (47.0 Hz), $[Ru(C_5Me_5)(PC_4H_2Bu^t_2)]$ **11** (62.7 Hz), **12** (65.3 Hz)]. These data suggest strongly that the rings are highly aromatic.

11

Complexes **1**–**3** are hydrocarbon-soluble and may also be recovered unchanged after several days at room temperature in dichloromethane. Such solution properties suggest a significant covalent contribution to the metal–ring interaction and imply some potential as 'mild' sources of phospholyl ligands. This has been confirmed in studies of the reactivity of $[M(cod)Cl]_2$ towards warm dichoromethane solutions of **1**, which permitted clean and quantitative isolation of the new compounds $[M(cod)(PC_4H_2Bu^t_2)]$ (M = Rh, **12**, yellow; M = Ir, **13**, orange) after filtration from $PbCl_2$.

Thus, in addition to their theoretical interest, these main group complexes may be useful precursors for the synthesis of further metal phospholyl compounds.

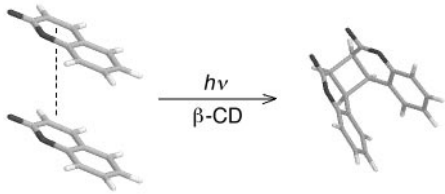
Received (in Columbia, MO, USA) 16th March 1999, Accepted 26th April 1999

From a combination of X-ray crystallography, solid-state NMR, and theoretical calculations, a model of a β-cyclodextrin (β-CD)–coumarin inclusion complex has been developed which characterizes the complex as a 2:3 β-CD–coumarin system with the coumarin molecules located in β-CD dimer 'reaction nano-tubes'; the model explains the reported yield for the coumarin photodimerization reaction carried out in powdered solids.

Several important contributions have been made to determine the mechanistic and controlling factors that produce given reaction outcomes in solid-state photochemical reactions.[1] Most such studies have focused on reactions carried out in neat crystals; however, co-crystallizing or 'host' media have been used to produce reaction outcomes not observed in neat crystals,[2] thus expanding the arsenal of the solid-state photochemist to produce a desired result. Detailed studies of such important systems at the molecular level are much less common.

β-Cyclodextrin (β-CD), a cyclic oligomer made of seven D-glucose units, is an example of one such host system in which the outcome of photochemical reactions can be modified.[3] An example system is the photodimerization of coumarin and coumarin derivatives. Upon photolysis, coumarin and its derivatives can give four structural isomers, the product ratio of which in solution is strongly influenced by the solvent polarity and the multiplicity of the excited state involved.[4] Product distributions in neat crystals and co-crystals have been found to correspond to the pre-irradiation disposition of the molecules in the crystal.[5,6] A study of the photodimerization of coumarin and coumarin derivatives in crystalline powder β-CD complexes has been reported.[7] However, these complexes were not subjected to detailed structural studies. The β-CD–coumarin complex presents an especially interesting model system for the study of intermolecular solid-state photochemical reactions in supramolecular systems. Scheme 1 illustrates the photochemical reaction in the supramolecular complex.

Not unexpectedly, room temperature X-ray crystallographic studies of the β-CD–coumarin complex[8] present a feature common to crystallographic studies of β-CD complexes: disorder. Although there is disorder of the guests at room temperature, difference Fourier maps ($F_o - F_c$) clearly reveal three general sites for coumarin molecules per cyclodextrin dimer (Fig. 1). Solid-state ^{13}C magic angle spinning NMR experiments with decoupling verified the 2:3 host:guest (H:G) ratio.[9] This finding corrects the previous characterization of this system as a 2:2 H:G system, and, as will be described below, helps to explain the previously reported 64% yield in the photodimerization reaction.[7] The disorder present was such that the coumarin orientations could not be determined unambiguously from conventional difference electron density maps. The shape of the difference electron density plots corresponding to the guest coumarins is flat and elliptical (like naphthalene), hence the general layout of the coumarins is definable.



Scheme 1

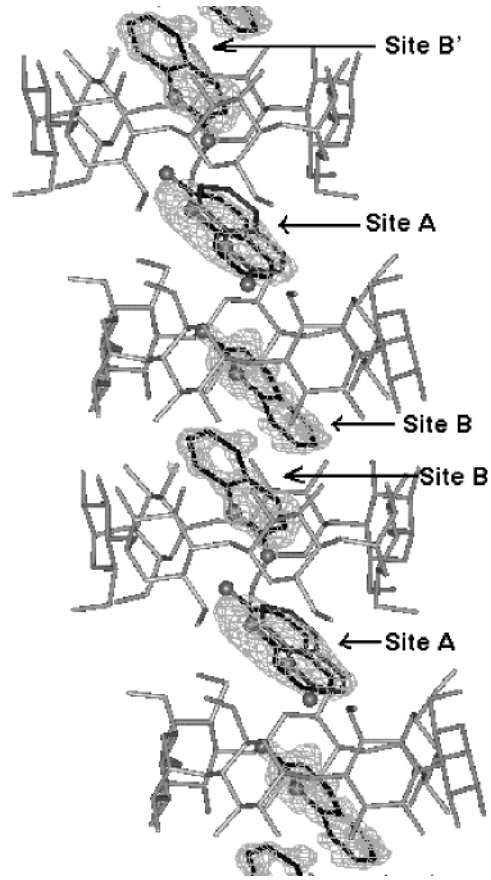


Fig. 1 Structure of the β-CD–coumarin 'reaction nano-tube' with the difference electron density ($F_o - F_c$) in the CD overlaid. CDs are in grey while coumarin molecules are shaded as follows: carbon = black; oxgen = light grey balls. Coumarin molecules at crystallographically disordered site A are shaded with black carbons for one orientation and grey carbons for the other ortientation. Waters of crystallization are omitted for clarity. The β-CD dimer stacks are roughly parallel to the crystallographic *c*-axis. See text for details. See: http://www.rsc.org/suppdata/cc/1999/1275/ for a colour version of this figure.

† Current address: Department of Structural Biology, St. Jude Children's Research Hospital, Memphis, TN 38105-2794, USA.

However, the direction of orientation (defined by which direction the carbonyl points) is not obvious. Consequently, lattice energy calculations[10] were employed to probe the most energetically favorable arrangement of coumarin orientations. The calculations indicate that an antiparallel pair of coumarin molecules in the center of the β-CD dimer (sites B and B′) is favored, while the orientation at site A must be aligned parallel with one of these two molecules. Because of space group symmetry, the orientation at site A is necessarily disordered; this coumarin sits on a crystallographic two-fold axis, but does not itself posses two-fold symmetry. The consequence is that site A's orientation is such that it could react with either site B or site B′. Either case requires some migration of the guest coumarins to bring the molecular orbitals involved closer to each other, which should be allowed in the CD's non-constraining environment.[11]

Analysis of these experiments produces an intriguing model that provides insight into the photochemical behavior of the system. The β-CD dimers pack in the crystal in a 'channel packing' motif,[12] in which the dimers stack one on top of another producing channels parallel to the *c* axis throughout the crystal allowing for interaction between guests in adjacent CD dimer cavities. The coumarin molecule at site A actually resides at the dimer-stacking interface. Even though the pair of molecules at site B is only separated by about 3.65 Å, they are antiparallel and cannot react without reorientation to give the observed *syn*-HH dimer.[13] Thus, the photodimerization likely happens between a coumarin molecule at site A and one either at site B or site B′ (depending on their respective orientations). On average, this leaves one of the three coumarin molecules per β-CD dimer unreacted, making the maximum theoretical yield 67%.

We conclude that the β-CD environment described here behaves not as a 'reaction nano-vessel', an environment where the interactions of import occur only within a single β-CD dimer, but rather as a 'reaction nano-tube', an environment where there is a considerable amount of interaction between molecules in adjacent β-CD dimers. This 'reaction nano-tube' allows for a 2:3 H:G ratio and limits the theoretical yield to 67%. In addition, the study nicely illustrates that important chemical information can be determined for complex, disordered systems by structural studies using complementary methods.

Funding for this work was provided by the NSF (CHE-9812146). We thank Dr X. C. Zeng for assistance with the theoretical calculations and for helpful discussions, and Cerestar USA, Inc. (Hammond, IN) for samples of β-CD.

8 *Crystal data* for $(C_{42}H_{70}O_{35})\bullet(C_9H_6O_2)_{1.5}\bullet 12H_2O$: M_r = 1570.38, monoclinic, space group *C2* (no. 5), a = 19.322(2), b = 24.641(3), c = 16.050(2) Å, β = 108.759(8)°, Z = 4, D_c = 1.442 g cm^{-3}, crystal size 0.5 × 0.4 × 0.1 mm, λ = Mo-Kα, T = 293(2) K. Data were collected on an automated Siemens P4 diffractometer with a sealed tube source. 6778 unique reflections (R_{int} = 0.0403) were collected to $2\theta_{max}$ = 50°. The structure was solved by molecular replacement of the β-CD coordinates from an isomorphous structure. Coumarin sites were located in difference electron density maps ($F_o - F_c$). Coumarin molecules in orientations determined from the lattice energy calculations were refined as rigid bodies. Least-squares refinement on F^2 of 835 parameters was carried out using SHELXL97 (G. M. Sheldrick, *SHELXL97, Program for the Refinement of Crystal Structures.* University of Göttingen, Germany, 1997) and converged to a final R_1 = 0.0893, wR_2 = 0.2037 and GOF = 1.239 for 3369 reflections with $F_o > 4\sigma(F_o)$. All non-hydrogen atoms were treated anisotropically except those of the coumarin molecules and low occupancy waters. Hydrogens on carbon atoms were generated geometrically and were fixed in a riding model. A final difference electron density map showed no distinct features with ρ_{max} = 0.46 and ρ_{min} = −0.33 e Å^{-3}. CCDC 182/1260. See http://www.rsc.org/suppdata/cc/1999/1275/ for crystallographic data in .cif format.
9 ^{13}C MAS spectra were obtained at 7.1 T with a standard Bloch decay pulse sequence on a sample of about 200 mg of hydrated crystalline complex. The dynamics of the guest made cross-polarization ineffective. 2048 transients were averaged, with an 80 s delay between acquisitions to allow spin relaxation. The spinning speed used was 4 kHz; at this speed, no rotational sidebands were observed. Assignments for coumarin resonances were deduced by comparison with a reference solution NMR spectrum (Aldrich). Assignments for β-CD resonances were deduced by comparison with previously published results (M. J. Gidley and S. M. Bociek, *J. Chem. Soc., Chem. Commun.*, 1986, 1223). Overlapping peaks were deconvolved to obtain integrated spectral intensities. Spectral shifts were referenced to the high frequency resonance of adamantane, and converted to a TMS scale by adding 38.56 ppm. The shifts obtained (relative to TMS), along with intensities, are as follows: δ_C 160 (3C), 154 (3C), 143 (3C), 131 (3C), 128 (3C), 124 (3C), 119 (3C), 117 (3C), 116 (3C), 104 (14C), 81 (14C), 73 (42C), 60 (14C).
10 Lattice energy calculations were performed using the CrystalPacker module in Cerius^2 (Molecular Simulations). Calculations performed were single point energy calculations with coumarin molecules located at positions from the crystallographic model. For the calculations, the orientations at site B and B′ were fixed as: an antiparallel pair, a parallel pair pointing in the +*c* direction, and a parallel pair pointing in the −*c* direction. With each of the fixed arrangements at site B, the orientation at site A was varied to each of the four orientations possible, and each time the energy was calculated. The low energy arrangements displayed an antiparallel pair at site B and B′ with site A aligned parallel to either of the molecules at site B or B′.

Received (in Cambridge, UK) 4th May 1999, Accepted 28th May 1999

Hydrogenation of cinnamaldehyde was performed in a supercritical carbon dioxide–water biphasic catalyst system, which eliminates gas–liquid–liquid mass transfer and gives better activity and selectivity.

Supercritical carbon dioxide ($scCO_2$) is considered as an ecologically benign and economically feasible reaction medium for metal catalyzed reaction.[1] It has several advantages such as nonflammability, lack of toxicity, absence of a gas–liquid phase boundary and possible simplifications in work up. This makes $scCO_2$ an alternative to conventional solvents. The physicochemical properties of $scCO_2$ can be tuned within a certain range by adjusting the pressure and temperature. Use of organometallic catalysts in $scCO_2$ is interesting, as demonstrated in some previous works.[2] Water-soluble organometallic catalysis has widened the scope of homogeneous catalysis in practice as it gives easy separation of catalyst and reactants/products, which is an important step towards the development of environmentally friendly processes.[3] Hoechst AG is operating a 300,000 tonnes per annum plant for hydroformylation of propylene using Rh and a water-soluble phosphine complex in a biphasic mode of operation. Several new concepts such as use of co-solvents[4] and surface active ligands,[5] interfacial catalysis using catalyst binding ligands,[6] supported aqueous phase catalysis,[7] and supported ethylene glycol phase catalysis[8] have emerged to improve poor reaction rates, which are due to limitations in liquid–liquid mass transfer and/or solubility of reactants. Considering the advantages of $scCO_2$ as a reaction medium and water-soluble metal complexes, there is a need to combine these two approaches to develop a truly environmentally friendly process (see Table 1). This eliminates the use of organic solvents and also gives easy catalyst/product separation and catalyst recycling. Here we demonstrate integration of biphasic catalysis and supercritical carbon dioxide using hydrogenation of an α,β-unsaturated aldehyde, cinnamaldehyde. This gives significant enhancement in the reaction rate and selectivity to cinnamyl alcohol and easy separation of the catalyst and reactants/products.

Hydrogenation of α, β-unsaturated aldehydes to give unsaturated alcohols with high selectivity is a challenging task due to several possible side reactions using heterogeneous metal supported catalysts.[9,10] However, good selectivity and activity were reported with $Ru–PPh_3$ based catalysts using homogenous and biphasic catalyst systems.[11] Table 2 summarizes the present results for hydrogenation of cinnamaldehyde using several catalyst systems.† Under the conditions used, unsaturated alcohol (UOL) and saturated aldehyde (SAL) were the main products with other very minor products. All the catalysts were reduced with H_2 for 1 h at 40 °C in order to form the active catalytic species. The catalytic chemistry for hydrogenation of α,β-unsaturated aldehydes using Ru–TPPTS [TPPTS = $P(C_6H_4SO_3Na)_3$] has already been explored well by earlier investigators.[11] In homogeneous reaction systems gas–liquid mass transfer is a key rate determining parameter. In the case of toluene solvent, 29% conversion was obtained with 92% selectivity to UOL. Homogeneous catalysis in general suffers from the major drawback of catalyst and product separation and, hence, the concept of biphasic catalysis has emerged. When this system is converted to a biphasic mode of operation keeping all parameters constant, the conversion of cinnamaldehyde drops from 29% to 11%, retaining the selectivity performance (Table 2, run 3). The important parameters such as gas–liquid–liquid mass transfer and liquid–liquid mass transfer (*i.e.* solubility of substrate in catalyst phase) are key factors in controlling the rate of reaction. In this case the substrate, cinnamaldehyde, has finite solubility in the catalyst phase, and therefore that is not a major limitation unlike hydroformylation of higher olefins in a biphasic mode of operation.[3–6] When this reaction is subjected to $scCO_2$ as medium instead of an organic solvent like toluene, the $RuCl_3–PPh_3$ catalyst system performs very poorly (run 2). It is mainly due to the very poor solubility of the phosphine ligand in $scCO_2$. Visual observation through a sapphire window confirms that solid catalyst particles are suspended in $scCO_2$. Since there is no interaction of catalyst and reactants, a poor reaction rate is observed. Presently, many researchers are working on enhancing the solubility of phosphine ligands in

Table 1 Catalysis using metal complexes

System	Type	Advantages	Disadvantages
Homogeneous	Gas–liquid	High activity and selectivity	Catalyst/product separation; gas–liquid mass transfer; organic solvent needed
Biphasic (organic–water)	Gas–liquid–liquid	High selectivity; high activity possible with water soluble substrates; easy catalyst separation and recycling	Low reaction rates for water insoluble substrates; gas–liquid–liquid mass transfer limits rate of reaction; organic solvent needed
SAPC	Gas–liquid–liquid (on solid support)	High activity and selectivity; product separation by phase separation; easy catalyst recycling	Organic solvent needed; stability of catalyst film on solid support
Biphasic (supercritical solvent–water)	Supercritical fluid–liquid	High selectivity; high activity possible with water soluble substrates; easy catalyst separation and recycling; organic solvent not needed	Poor solvating ability of many supercritical fluids
SAPC in supercritical solvent	Supercritical fluid–liquid (on solid support)	High activity and selectivity; product separation by phase separation; easy catalyst recycling; use of organic solvent is avoided	Poor solvating ability of many supercritical fluids

Table 2 Hydrogenation of cinnamaldehyde using various catalyst systems[a]

Run	Reaction type	Catalyst precursor	Ligand	Solvent system	Pressure/MPa		Conversion (%)	Selectivity (%)	
					$scCO_2$	H_2		UOL	SAL
1	Homogeneous	$RuCl_3$	PPh_3	toluene	—	40	29	92	8
2	Homogeneous	$RuCl_3$	PPh_3	$scCO_2$	140	40	1.5	89	11
3	Biphasic	$RuCl_3$	TPPTS	toluene–water	—	40	11	92	8
4	Biphasic	$RuCl_3$	TPPTS	$scCO_2$–water	140	40	38	99	0.5
5	Biphasic	$RhCl_3$	TPPTS	$scCO_2$–water	140	40	35	—	100
6	Biphasic	$Pd(OAc)_2$	TPPTS	$scCO_2$–water	140	40	22	—	100
7	SAPC	$RuCl_3$	TPPTS	toluene–water	—	40	13	93	7
8	SAPC	$RuCl_3$	TPPTS	$scCO_2$–water	140	40	44	96	4

[a] Reaction conditions: Catalyst precursor: 0.012 mmol; ligand/Ru: 8; T = 40 °C; cinnamaldehyde: 7.8 mmol; toluene (for 1,3,7): 25 cm^3; time: 2 h; water: 0.5 cm^3; silica (for 7,8): 1.5 g.

$scCO_2$ by using flourous substituents.[12] Biphasic catalytic systems such as $scCO_2$–water (runs 4–6) give much better conversion than conventional biphasic reactions (11 to 38%) and normal homogenous modes of operation (29 to 38%). This catalyst system differs from conventional gas–liquid and gas–liquid–liquid catalytic hydrogenation, since gas–liquid and gas–liquid–liquid mass transfer are completely eliminated in the case of $scCO_2$ as solvent. The concentration of hydrogen in a supercritical mixture of H_2 (85 bar) and CO_2 (120 bar) at 50 °C is 3.2 M, while the concentration of H_2 in THF under the same pressure is only 0.4 M.[13] This property of $scCO_2$ allows a reduction in viscosity and an increase in diffusion rate as compared with the liquid phase, so that transport to and from the catalyst phase is no longer a limiting factor. This causes significant rate enhancement as observed in Table 2 and might be advantageous in improving selectivity performance. $RuCl_3$ as metal precursor gives 99% selectivity towards UOL (run 4), while $RhCl_3$ and $Pd(OAc)_2$ give 100% selectivity towards SAL. Earlier investigators have already examined this feature. Supported aqueous phase catalysis (SAPC) in which the metal complex is supported on a solid surface like silica has been successfully used for biphasic reactions which have substrate solubility limitations. SAPC can also be used in $scCO_2$ as solvent and better activity and selectivity were observed when compared with toluene as solvent (12.4 to 44%). Although the application of SAPC is not particularly attractive in the case of hydrogenation of cinnamaldehyde (since it has finite solubility in the catalyst phase), it may be more attractive in the case of water insoluble substrates.

In conclusion, $scCO_2$–water was shown to be a good alternative solvent system for conventional biphasic catalytic systems. This eliminates gas–liquid–liquid mass transfer limitations due to the very high solubility of reactant gases in $scCO_2$.

We thank the Japan Society for Promotion of Science (JSPS) for financial support.

Notes and references

† Typical experimental procedure for an experiment involving the $scCO_2$–water biphasic catalytic system is as follows: $RuCl_3$ (0.012 mmol) and TPPTS (0.096 mmol) dissolved in water (0.5 cm^3) were charged to a 50 cm^3 reactor maintained at 40 °C. Hydrogen (10 bar) was introduced into the reactor and left for 1 h. Cinnamaldehyde (7.8 mmol) was introduced into the reactor after depressurizing the hydrogen. Hydrogen (40 bar) and liquid carbon dioxide were subsequently introduced into the reactor using a JASCO Model 880-PU syringe pump and compressed to the desired pressure (180 bar). The pump delivered the CO_2 at a flow rate of 3.5 ml min^{-1}. Pressure control was achieved using a JASCO Model 880-81 back pressure regulator. The reaction was started by stirring the mixture with a magnetic stirrer and continued for 2 h. After reaction, the pressure was released and the reaction mixture was analyzed *via* GC (Shimadzu GC-8A, Ucon Oil 8HB 2000 Uniport B, 6 m). Details of the experimental apparatus and procedures are described elsewhere (ref. 14).

High yields of diazabicycloalkanes and oxazabicycloalkanes containing medium and large rings from rhodium-catalysed hydroformylation reactions without the need for high dilution conditions

David J. Bergmann, Eva M. Campi, W. Roy Jackson* and Antonio F. Patti

Received (in Cambridge, UK) 6th May 1999, Accepted 1st June 1999

Rhodium-catalysed reactions of *N*-alkenyl-1,3-diaminopropanes and *N*-alkenylaminoethanols give diazabicycloalkanes and oxazabicycloalkanes containing medium or large rings in excellent yields.

We have previously reported the preparation of 1,5-diazabicyclo[4.3.0]nonane and 1,5-diazabicyclo[4.4.0]decane in high yield by rhodium-catalysed reactions of appropriate *N*-alkenyl-1,3-diaminopropanes **1** (n = 1 or 2) with H_2/CO.[1] The reactions presumably involve cyclisation of an initially formed diaminoaldehyde **2** to form an aminopropyl substituted cyclic iminium salt **3** or enamine which subsequently cyclises to give the bicyclic product **4** (Scheme 1). It has been well established that the amino function of an aminoalkene rapidly coordinates to the rhodium atom[2] and as only very low ratios of rhodium to substrate are used (typically 1:100 or greater) it seemed probable that the newly formed aldehyde function should be in close proximity to the rhodium-coordinated amino function and thus cyclisation rather than polymerisation be preferred even for medium and large ring systems. There is indirect evidence that iminium species contained in medium or large rings are susceptible to polymerisation reactions.[3] Thus the possibility that a pendant amino or hydroxy function could be used to trap any such reactive cyclic iminium species was investigated as a general route to the synthesis of bicyclic heterocycles containing medium or large rings.

A series of *N*-alkenyl-1,3-diaminopropanes **1** and *N*-alkenylaminoethanols **5** were thus reacted with H_2/CO under a range of conditions and the results are summarised in Table 1.

Excellent yields of compounds **4a** and **6a** containing a thirteen-membered ring fused to six- or five-membered heterocycles were obtained when BIPHEPHOS[4] was used as a ligand in reactions of the primary amine **1a** and the alcohol **5a** (entries 1 and 2). Use of this ligand in hydroformylation reactions has been shown to lead to almost complete regioselectivity for the terminal aldehyde.[1,4,5] The products **4a** and **6a** from these reactions showed no evidence for any compounds containing a methyl-substituted twelve-membered ring which would arise from the products of internal rather than terminal hydroformylation. Reaction of the primary amine **1b** under these conditions led to polymerisation and only a poor yield (28%) of the bicyclic compound containing a ten-membered ring was obtained when the reaction temperature was decreased to 40 °C (entry 3). A reaction of the related secondary amine **1c** however gave an excellent yield of the bicyclic product **4c** using PPh_3 as a ligand at 80 °C (entry 4). The product contained *ca.* 10% of compound arising from branched-chain aldehyde. A reaction using BIPHEPHOS with a 1:1 ratio of H_2/CO gave a complex mixture whose ^{1}H NMR spectrum suggested that some hydrogenation of the intermediate iminium species **3** and possibly the substrate **1c** had occurred. Accordingly a reaction was carried out using a 1:5 H_2/CO gas ratio as this has been shown to minimise the problems associated with substrate hydrogenation.[6] The bicycle **4c** containing a ten-membered ring was now obtained in excellent yield and with >95% regioselectivity (entry 5). The related aminoethanol **5b** behaved in an identical fashion with excellent yields (*ca.* 93%) of bicyclic compound **6b** containing a ten-membered ring being obtained (entries 6 and 7). Again the reaction involving BIPHEPHOS appeared to be virtually regiospecific.

A reaction of the primary amine **1d** using BIPHEPHOS as ligand at 80 °C gave only polymeric material but a good yield (74%) of the (6,8) bicycle **4d** was obtained when the reaction

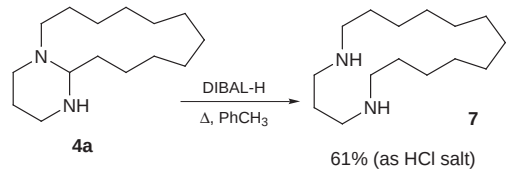
[a] Reaction conditions: Substrate (0.5–1 mmol) with substrate: $[Rh(OAc)_2]_2$:ligand = 200:1:4 in benzene (5–10 ml) for 20 h with an initial gas pressure (H_2 + CO) of 2.76 MPa (400 psi). [b] Isolated yields; products from reactions using BIPHEPHOS as ligand contained >95% of linear derived material. [c] Containing *ca.* 10% branch-chain derived product. [d] The (6,7) bicyclo compound arising from initial internal hydroformylation was the major product (38%).



Scheme 2

temperature was reduced to 50 °C (entry 8). An excellent yield (95%) of almost regiopure material was obtained from a reaction of **1e** using BIPHEPHOS with a 1:5 H_2/CO ratio (entry 9). In contrast a reaction using PPh_3 as ligand surprisingly gave the (6,7) bicyclo product arising from initial internal hydroformylation as the major product with only a small amount (14%) of the (6,8) compound **4e** (entry 10). However a reaction of the related aminoalcohol **5c** under these conditions gave an excellent yield (92%) of bicyclic products consisting mainly of **6c** together with *ca*. 10% of the methyl-substituted (5,7) compound.

The potential of the bicyclic diamines as precursors of monocyclic diamino compounds was illustrated by ring opening of the (6,13) bicyclic amine **4a** and the related (6,6) compound which was available from previous work.[1] Reactions of these compounds with DIBAL-H in toluene led to formation of 1,5-diazacycloheptadecane **7** and 1,5-diazacyclodecane respectively in good yield (*ca*. 60%) (Scheme 2).[7]

We thank the Australian Research Council for support and provision of a postgraduate award (to D. J. B.) and Johnson Matthey Pty Ltd for a loan of rhodium.

Synthesis, resolution and racemization study of helically twisted *o*-terphenyls

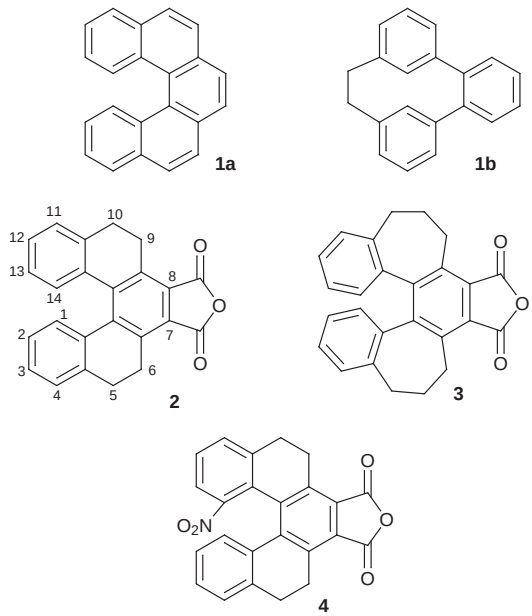
Jian Ping Gao, Xian Sheng Meng, Timothy P. Bender, Sean MacKinnon, Valerie Grand and Zhi Yuan Wang*

Department of Chemistry, Carleton University, 1125 Colonel By Drive, Ottawa, Ontario, Canada K1S 5B6. E-mail: wangw@ccs.carleton.ca

Received (in Corvallis, OR, USA) 19th February 1999, Accepted 26th May 1999

The synthesis, resolution and racemization studies of helical *o*-terphenyls, useful chiral building blocks are reported.

Understanding of the structure–chiroptics relationships of helical molecules is of theoretical and synthetic importance. Systematic distortion of helical aromatic systems by disturbance of the conjugated π-electron array,[1] from conformationally rigid helicences[2] (*e.g.* **1a**) to less rigid helically twisted



o-terphenyl (*e.g.* **1b**),[3] provides a useful way to gain knowledge about chiroptics of organic molecules. In order to gain further insight into the chiroptical properties of the helical *o*-terphenyl system, *o*-terphenyls **2**, **3** and **4**, which are structurally related to *o*-terphenyl **1b,** were chosen for study. Compounds **2**[4] and **3**[5] contain the same *o*-terphenyl moiety as **1b** but it is bridged by two ethylene or propylene units, respectively. Little is known about the resolution and chiroptical properties of bridged helical *o*-terphenyls such as **2** and **3**. Considering the similarity in π-conjugation, it occurred to us that, if resolvable and stable, optically pure bridged *o*-terphenyl derivatives would have a high optical activity as [5]helicene does. Moreover, these *o*-terphenyl derivatives are advantageously more soluble than fully aromatized helicenes and can be made on a large scale from readily available starting materials through a non-photocyclization route.[4] We recently introduced the nitro, amino and isocyanato groups into *o*-terphenyl **2** at the C-1 (*e.g.* **4**[7a]) and C-3 positions[6,7] and obtained several polymers using functionalized **2**.[7a,d,e] Therefore, resolved *o*-terphenyls **2**–**4** would be valuable building blocks for making optically active compounds and polymers. To resolve these *o*-terphenyl derivatives, chemical and chromatographic resolutions and recrystallization were attempted. Chemical resolution of **4** was achieved using brucine.[8] Since dextrorotatory [5]helicene has *P* helicity,[9] this resolved laevorotatory helical *o*-terphenyl **4** should have *M* helicity. Attempted on chemical resolution of **2** using the same route was unsuccessful, as the corresponding acid ethyl ester had no optical activity. Chromatographic separation using a chiral column was attempted for compounds **2**, **3** and **4**.[10] Racemic **4** could be readily resolved by this means. However, anhydride **2** came out as a single peak under the same chromatographic conditions using different solvent systems. Surprisingly, compound **3** gave two well-resolved peaks and the *M* enantiomer was obtained in high optical purity.

The resolved (*M*)-**4** showed very large specific optical rotations (*e.g.* −1518 at 589 nm and −7100 at 436 nm), comparable to that of (*M*)-[5]helicene (−1670 at 589 nm and −4950 at 436 nm, Table 1). Its CD spectrum [Fig. 1(*a*)] shows a strong negative band near 370 nm and a positive peak around 290 nm. In comparison with (*M*)-**4**, the resolved **3** displayed a rather low optical rotation (−55 at 589 nm). The striking difference in optical rotation between **3** and **4** is believed to be mainly due to variation in the degree of π-electron delocalization within the terphenyl moiety. Calculations have shown that optical rotations of helically twisted aromatic systems depend largely on the extended π-electron conjugation.[11] There is only a slight change in the geometry of the terphenyl moiety going from ethylene linkages in **4** to propylene linkages in **3**, as indicated by the X-ray structure analyses. The terphenyl unit in **4** is quite planar, the nitrobiphenyl unit being twisted by 37.4° and the other biphenyl being twisted by 29.1° (Fig. 2).[12] However, the biphenyl moiety in **3** has a large twist of 58°, indicating that the π-electrons of the terphenyl unit in **3** are less delocalized than those in **4**. Similarly, resolved **1b** was reported to have an optical rotation of 3210 at 365 nm and a smaller twist angle of about 47.8°. The UV-VIS spectra [Fig. 1(*b*)] of **2** and **4** display two strong peaks near 365 and 285 nm, whereas **3** had two bands centered at 330 and 270 nm. These absorption data further confirm a decrease in π-electron conjugation from **4** to **3**. Thus, the π-electron conjugation in the helically twisted *o*-terphenyl system directly relates to the strength of the optical rotation at a given wavelength. The greater the conjugation, or the smaller the twist angle is, the higher the optical rotation.

Thermal racemization studies were carried out at 49.8 °C (±0.1 °C) for (*M*)-**4**, and at 22.0 °C (±0.1 °C) for resolved **3**. The results are listed in Table 1, together with those of **1a** and **1b** for comparison. The half-life ($t_{1/2}$) of racemization at 49.8 °C was determined to be 2340 min for (*M*)-**4**, longer than that (62.7 min at 57 °C) of (*M*)-[5]helicene (**1a**).[2] Accordingly, the racemization barrier for compound (*M*)-**4** (27.7 kcal mol^{-1}) is higher than that (23.5 kcal mol^{-1}) of [5]helicene. As the lower helicenes racemize faster than higher ones,[2d,13,14] helical *o*-terphenyls having a substituent larger than hydrogen at the inner C_1-position are expected to have an increased barrier for

Table 1 Specific optical rotations and racemization half-life times ($t_{1/2}$) of resolved helical *o*-terphenyls and [5]helicene

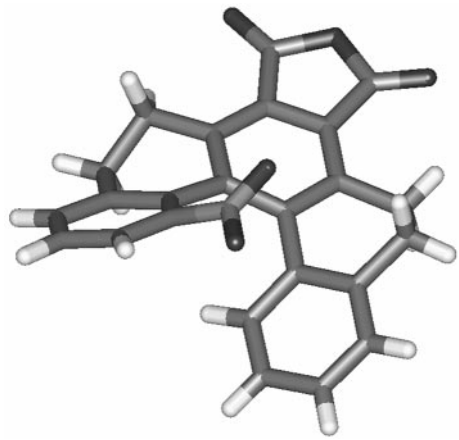

Fig. 2 Molecular geometry of **4** determined by X-ray analysis (ref. 12).

thermal racemization, which allows for effective resolution.[14] The X-ray structure of **4** shows a substantial overlapping between the nitro group and the opposite benzene ring. For compound **2**, although the terphenyl unit adopts a helical conformation and has a higher degree of π-conjugation (smaller twist angle of 32.4°) than compound **3**, the degree of overlapping between the two terminal benzene rings is probably too small to allow for resolution at ambient temperatures. Comparing compounds **2** and **3**, the former is conformationally unstable and racemizes rapidly at ambient temperatures. Owing to two extra CH_2 units, **3** has the two terminal rings overlapped to a great enough extent to allow for resolution but still easily racemizes with a half-life time of 1100 min at 22 °C. In comparison, **1b** was successfully resolved and had a racemization activation energy of about 30 kcal mol^{-1}, which is close to that (27.7 kcal mol^{-1}) of **4** and higher than that (23.5 kcal mol^{-1}) of **1a**.

In conclusion, chemical resolution of the bridged C_1-substituted helical *o*-terphenyls can be achieved. The racemization barrier depends on the degree of overlapping of the two terminal rings and optical activity relates to the degree of π-conjugation of the *o*-terphenyl moiety.

The Natural Sciences and Engineering Research Council of Canada financially supported this work. The authors would like to acknowledge Dr Gary Enright (NRC Canada) for the X-ray analysis of **4**.

8 The mixture of racemic **4** (2.96 g, 7.46 mmol) and brucine (3.30 g, 8.38 mmol) in 380 ml of absolute ethanol was heated to reflux until TLC showed no more anhydride. The reaction solution was then cooled to room temperature. On standing overnight, a crop of yellow crystals separated, which was filtered off, washed with ethanol and dried under vacuum to give 2.20 g of **4**·brucine salt: $[\alpha]_D^{22}$ = +640. Recrystallization twice of the first crop from CH_2Cl_2–EtOH raised the optical rotation to +665, which on decomposition with HCl afforded the corresponding acid esters: 1.08 g, $[\alpha]_D^{22}$ +1406 (c = 0.098, $CHCl_3$); ν_{max}(KBr)/cm^{-1} 1728, 1697(C=O); δ_H(400 MHz, $CDCl_3$) 1.43 (t, 3H), 2.66 (m, 1H), 2.81 (m, 5H), 3.01 (m, 1H), 3.19 (m, 1H), 4.44 (q, 2H), 6.69 (d, 1H), 6.90 (t, 1H), 7.21 (t, 1H), 7.30 (d, 1H), 7.33 (t, 1H), 7.47 (d, 1H), 7.59 (d, 1H); δ_C(50 MHz, $CDCl_3$) 169.4 and 169.2 (C=O, ester), 174.7 and 174.4 (C=O, acid). The mother liquor of the first crop was left open to air at room temperature for several days and the second crop precipitated out. The yellow solid was then filtered off, washed with ethanol and dried under vacuum to give 1.18 g of **4**·brucine salt ($[\alpha]_D^{22}$ −739), which upon treatment with HCl produced the acid ester: $[\alpha]_D^{22}$ −1243 (c 0.093, $CHCl_3$); ν_{max}(KBr)/cm^{-1} 1727, 1698 (C=O). Heating the acid ester ($[\alpha]_D^{22}$ −1243, *e.g.*, 150 mg) at 50 °C under vacuum (5 mmHg) for 6 h, followed by recrystallization once from hexane–CH_2Cl_2 afforded optically pure (*M*)-**4:** $[\alpha]_D^{22}$ −1518 (c 0.050, $CHCl_3$).

1,3-Thiaphosphole and 1,3-thiarsole are aromatic

Arthur J. Ashe III* and Xinggao Fang

Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055, USA. E-mail: ajashe@umich.edu

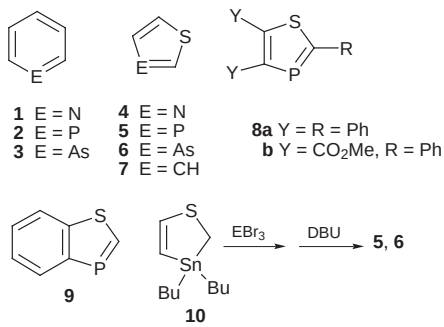
Received (in Corvallis, OR, USA) 14th May 1999, Accepted 24th May 1999

Treatment of 3,3-dibutyl-2,3-dihydro-1,3-thiastannole with either PBr_3 or $AsCl_3$ followed by DBU affords 1,3-thiaphosphole or 1,3-thiarsole, respectively.

Studies on the series pyridine (**1**), phosphabenzene (**2**) and arsabenzene (**3**) have contributed handsomely to our understanding of the concepts of aromaticity and multiple bonding between carbon and the heavier main group atoms.[1–4] 1,3-Thiazole (**4**),[5] 1,3-thiaphosphole (**5**) and 1,3-thiarsole (**6**) form a similar series of aromatic heterocycles. Heavily substituted derivatives of **5**, *e.g.* **8**[6] and **9**,[7] have been prepared although thiarsole remains unknown. A preparation of the unsubstituted heterocycles is desirable and would allow study of the intrinsic properties of the parent rings. We now report on a one step synthesis of **5** and **6** and on some properties of the compounds.

Our synthesis is analogous to the original preparation of **2** and **3**.[3] Heating 3,3-dibutyl-2,3-dihydro-1,3-thiastannole (**10**)[8] in tetraglyme with 1 equiv. of PBr_3 followed by treatment with DBU allows distillation of **5** in 10% yield (Scheme 1). Similar treatment of **10** with $AsBr_3$ followed by DBU allows distillation of **6** in 22% yield. Compounds **5** and **6** are air sensitive liquids which are most conveniently handled in dilute solutions.

The ^{1}H NMR spectra of **4**, **5** and **6** (Table 1) show very low field signals, downfield from those of thiophene (**7**). The most characteristic feature of the spectra is the particularly low field signals due to protons which are adjacent to the group 15 heteroatoms. This shift, which is also shown by the series **1**–**3**, is apparently caused by the large magnetic anisotropies of the π-bound group 15 heteratoms.[9] However the low field signals for the more remote protons H(5) of **5** and **6** are probably due to the effects of an aromatic ring current.[10] The ^{13}C NMR chemical shifts for C(2) and C(4) also occur at low field as is typical of carbon atoms which are π-bound to heavier group 15 elements.[9,11] Lastly, the ^{31}P shift of **5** (δ 211.3) is virtually identical to those of **8** and **9** which indicates **5** has a π-bound phosphorus(III).[12]



Scheme 1

The mass spectra of **4**, **5** and **6** show intense molecular ions which are the base peaks. Like **2** and **3**[3] the major daughter peaks for thiaphosphole and thiarsole are due to loss of acetylene. The loss of HCE (E = N, P, As) is rather less important for **5** and **6** than for **4**.[13]

The UV spectrum of 1,3-thiazole shows intense peaks at 208 (2550) and 233 nm (3750),[14] which have been assigned to π→π* excitations. The spectrum of **5** in hexane shows peaks at 215 (12,000), 249 (3000) and 274 nm (5000), while that of **6** shows peaks at 225 (14,000), 267 (6200) and 290 nm (9800). The progressive red shift of the corresponding bands with increasing atomic number of the heteroatoms corresponds to a smaller gap between the bonding and antibonding orbitals for the heavier heterocycles. This trend is confirmed by performing Hartree–Fock level *ab initio* molecular orbital calculations for **5**[15] and **6** with the RHF/6-31+G* basis set.[16] The optimized structural parameters of **5** listed in Table 2 do not differ significantly from those reported for the X-ray structures of the substituted derivative **8**. The calculated structures are consistent with those of planar aromatic heterocycles.

Since acid catalyzed proton isotopic exchange is the simplest aromatic substitution reaction,[17] it was of interest to examine the behavior of **5** and **6** in deuteroacids. Compound **5** is rapidly destroyed by CF_3CO_2D, but shows no H/D exchange on extended heating in CH_3CO_2D. Heating **6** with excess CH_3CO_2D–$CDCl_3$ (1:2) to 100 °C for 22 h leads to the incorporation of two deuterium atoms.[18] The rate of exchange at C(2) is 1.5 times faster than at C(4) with no detectable exchange at C(5). Under identical conditions thiophene does not show exchange[19] but the more reactive indole shows H/D exchange at C(3) at a similar rate.[20] Thus like arsabenzene,[21] 1,3-thiaarsole shows the reactivity of a highly activated aromatic ring.

We are grateful to the NSF for financial support of this work.

Table 1 Comparison of the ^{1}H and ^{13}C NMR parameters of thiophene (**7**), 1,3-thiazole (**4**), 1,3-thiaphosphole (**5**) and 1,3-thiarsole (**6**)[a,b]

First example of the atom transfer radical polymerisation of an acidic monomer: direct synthesis of methacrylic acid copolymers in aqueous media

E. J. Ashford, V. Naldi, R. O'Dell,† N. C. Billingham* and S. P. Armes*

School of Chemistry, Physics and Environmental Science, University of Sussex, Falmer, Brighton, UK BN1 9QJ. E-mail: s.p.armes@sussex.ac.uk

Received (in Oxford, UK) 11th May 1999, Accepted 1st June 1999

Sodium methacrylate is polymerised directly *via* atom transfer radical polymerisation (ATRP) in aqueous media using a poly(ethylene oxide)-based macro-initiator; the resulting poly(ethylene oxide-*block*-sodium methacrylate) copolymers were obtained in good yield and have narrow molecular weight distributions as evidenced by aqueous GPC.

Recently there has been considerable interest[1–3] in atom transfer radical polymerisation (ATRP), which allows the facile synthesis of styrenic[1,2] and (meth)acrylate[3] homopolymers and copolymers with predetermined degrees of polymerisation and narrow polydispersities. ATRP is usually performed either in bulk or in non-aqueous media and is remarkably tolerant of functional groups. For example, Matyjaszewski and co-workers demonstrated that ATRP can be carried out in the presence of ethylene carbonate, MeOH, MeCN, pyridine or PPh_3 with little or no deleterious effects.[4] More recently, Coca *et al.* have reported successful ATRP of a hydrophilic monomer, 2-hydroxyethyl acrylate, in 50% aqueous solution at 90 °C.[5]

Near-monodisperse acidic copolymers can be readily prepared *via* anionic (group transfer) polymerisation using either *tert*-butyl or benzyl methacrylate as a protected monomer for methacrylic acid.[6,7] In principle ATRP can also be used for such protected monomer syntheses, but in practice Haddleton and co-workers have reported very slow polymerisation for sterically hindered monomers such as *tert*-butyl methacrylate.[8] Moreover, in a recent review article, Patten and Matyjaszewski state that 'acrylic and methacrylic acid cannot be polymerised with currently available ATRP catalysts, because these monomers react rapidly with the metal complexes to form metal carboxylates that are inefficient deactivators and cannot be reduced to active ATRP catalysts'.[9] We report herein the successful ATRP of sodium methacrylate directly in water. Given the problems discussed above, this approach promises to be a useful and versatile route to model acidic copolymers.

Our ATRP formulation (see Scheme 1) is based on that described by Matyjaszewski's group and comprises a monofunctional poly(ethylene oxide) macro-initiator, a $Cu^{I}Br$ catalyst and 2,2′-bipyridine (bipy). This ligand was selected because it is commercially available, readily forms a water-soluble complex with Cu^{I} and, unlike the *N*-alkyl-2-pyridylmethanimine ligands reported by Haddleton and co-workers,[8,10] is not prone to hydrolytic instability. The macro-initiator was synthesised by reacting a monomethoxy-capped poly(ethylene oxide) with 2-bromoisobutyryl bromide according to Jankova *et al.*[11] An ^{1}H NMR spectrum of the purified macro-initiator is shown in Fig. 1(*a*). After several freeze-thaw and de-gassing cycles, the ATRP of sodium methacrylate was carried out at 90 °C under dry nitrogen in doubly-distilled, de-ionised water (*ca.* pH 9). The initial monomer concentration was 33 vol% based on solvent, the initiator concentration was 0.07–0.11 mol dm^{-3} (depending on the molecular weight of the target polymer) and the molar ratio of macro-initiator:$Cu^{I}Br$:bipy was 2:2:5. Polymerisations were terminated by pouring the

[a] All reactions carried out with [CuBr]:[initiator]:[bipyridine] = 2:2:5, under nitrogen at 90 °C in degassed aqueous solution. [b] Calculated using the following formula: M_n (Theory) = 108.07(Δ[Monomer]/[Initiator]*p*), where *p* = fractional conversion. [c] Aqueous GPC details: Pharmacia Biotech Superdex® 200 HR 10/30 FPLC® column; eluent: 20% MeCN (HPLC grade) + 80% (0.01 M Na_2HPO_4 + 0.05 M $NaNO_3$); flow rate = 0.5 ml min^{-1}; pH 7–8; poly(sodium styrene-4-sulfonate) standards. [d] Reaction mixture was precipitated into EtOH and dried to constant weight. [e] Control reaction: performed with 5 g monomer and 15 ml water only. [f] Control reaction: catalyst and ligand present, but no initiator. [g] Initiator is sodium bromoisobutyrate. [h] Sodium bromoisobutyrate was used as the initiator, in the presence of monomethoxy-capped poly(ethylene oxide) (1.67 mmol). [i] M_n cannot be calculated from ^{1}H NMR spectra since the end groups are not known.

reaction solution into excess EtOH in order to isolate the precipitated copolymer [the Cu^I catalyst, bipy ligand and sodium methacrylate monomer are all soluble in EtOH]. Copolymer molecular weights, polydispersities and yields are summarised in Table 1. Moderate to good yields, good control over molecular weight and narrow polydispersities (M_w/M_n < 1.30) were achieved under ATRP conditions (see entries 1–4).

A proton NMR spectrum (D_2O) of a poly(ethylene oxide-*block*-sodium methacrylate) [entry 3, Table 1] clearly shows signals arising from the macro-initiator at δ 3.15 and 3.35–3.65. In order to demonstrate genuine block copolymer formation, the isolated polymers were subjected to Soxhlet extraction with refluxing THF for 3 h (the macro-initiator is THF-soluble). The NMR spectra obtained before and after THF extraction were identical, confirming that the macro-initiator is covalently attached to the poly(sodium methacrylate) chains. The peak integrals assigned to the ethylene oxide residues can also be used to determine the block copolymer M_n by end-group analysis. These values are included in Table 1 and are in reasonably good agreement with the aqueous GPC data.

Virtually all vinyl monomers are susceptible to radical initiation if heated for prolonged periods, even in the absence of initiator. Thus it was no surprise that non-living thermally-initiated polymerisation occurred on heating an aqueous solution of sodium methacrylate to 90 °C for 21 h in the absence of any macro-initiator or catalyst; the resulting polymer had a broad molecular weight distribution and a relatively high molecular weight (see entry 5, Table 1). Similarly, heating an aqueous solution of sodium methacrylate in the presence of the Cu^IBr and bipy ligand, but in the absence of initiator (entry 6), yielded polymer of high polydispersity (M_w/M_n = 2.32) but much lower molecular weight. Here the Cu^I [or traces of Cu^{II} formed by oxidation] probably acts as a polymerisation retarder.[12] Both control experiments support the hypothesis that the macro-initiator initiates ATRP of sodium methacrylate.

Subsequent experiments confirmed that the choice of pH is critical for successful ATRP. Below pH 6, sodium methacrylate does not undergo ATRP; the bipy ligand becomes protonated and no longer solubilises the Cu^IBr catalyst. Above pH 6, controlled polymerisation is evident and the optimum pH lies between 8 and 9. It is well known that the rate of radical polymerisation of methacrylic acid in water is very sensitive to pH.[13] However, this reaction usually favours low pH, because at high pH the rate of propagation is reduced due to the build-up of anionic charge density on the polymer backbone. In the present case it appears that there is a balance between reduced propagation at high pH and competing protonation of the ligand at low pH. Furthermore, synthesis of high molecular weight poly(sodium methacrylate) by aqueous ATRP has so far proved problematic: relatively broad molecular weight distributions are obtained if target molecular weights are greater than 10000.

Choice of initiator is also important. Polymerisation of sodium methacrylate using sodium 2-bromoisobutyrate as initiator (entry 7) gave only low conversion and polydisperse polymer, with an M_n much higher than expected. To determine whether the ethylene oxide residues of the macro-initiator might be contributing to the polymerisation, we performed the same reaction in the presence of the monomethoxy-capped poly(ethylene oxide) starting material, with no improvement (entry 8). In contrast, the monomeric analogue of the macro-initiator, 2-hydroxyethyl 2-methyl-2-bromopropionate **2**, successfully initiated the polymerisation of sodium methacrylate (entry 9) to produce near-monodisperse homopolymer, but with somewhat lower monomer conversion (44%).

In summary, we have demonstrated that ATRP of sodium methacrylate works well in aqueous media. Well-defined low molecular weight poly(sodium methacrylate)-based blocks can be prepared directly, without requiring protection chemistry for the carboxylic acid residues.

We thank FMC for financial support and for permission to publish this work.

$[Ga_2Cl_4(dioxane)_2]_x$: molecular structure and reactivity of a polymeric gallium(II) halide containing two five-coordinate gallium atoms about a Ga–Ga bond

Pingrong Wei, Xiao-Wang Li and Gregory H. Robinson*

Department of Chemistry, The University of Georgia, Athens, GA 30602-2556, USA.
E-mail: robinson@SUNCHEM.uga.edu

Received (in Columbia, MO, USA) 20th April 1999, Accepted 21st May 1999

A polymeric 1,4-dioxane adduct of gallium(II) chloride, $[Ga_2Cl_4(dioxane)_2]_x$, containing two five-coordinate gallium atoms about a Ga–Ga bond [Ga–Ga 2.3825(9) Å], reacts with 1,4-dilithiotetraphenylbutadiene affording an unusual Ga(II)–tetraphenylbutadiene complex.

The first organometallic compound unambiguously shown to contain a Ga–Ga bond, $[(Me_3Si)_2HC]_2Ga–Ga[CH(SiMe_3)_2]_2$ [Ga–Ga 2.541(1) Å], isolated from reaction of $LiCH(SiMe_3)_2$ with gallium(II) bromide bis(dioxane), $Ga_2Br_4(dioxane)_2$, was reported only a decade ago.[1] In the solid state, $Ga_2Br_4(dioxane)_2$ resides in a *trans* geometry about a Ga–Ga bond of 2.395(6) Å.[2] The solid state structure of the corresponding bis(dioxane) adduct of gallium(II) chloride, $Ga_2Cl_4(dioxane)_2$, assumes a similar *trans* geometry about a comparable Ga–Ga bond of 2.406(1) Å.[3] In both $Ga_2Br_4(dioxane)_2$ and $Ga_2Cl_4(dioxane)_2$, the gallium atoms are four-coordinate tetrahedral—each bonding to two halide atoms, one dioxane adduct, and the remaining gallium atom. Herein, we report a polymeric 1,4-dioxane adduct of gallium(II) chloride, $[Ga_2Cl_4(dioxane)_2]_x$ **I**,[4] wherein both gallium atoms reside in five-coordinate trigonal bipyramidal environments about a Ga–Ga bond. The polymeric structure of **I** is interesting as it is notably different from previously reported Ga(II) halides. Moreover, **I** is shown to react with 1,4-dilithiotetraphenylbutadiene affording $[(PhC{=}CPhPhC{=}CPh)]Ga[(Cl)Li(OEt_2)_2]_2$[5] **II** (Scheme 1).

Compound **I** is significant as it represents a rare example of two five-coordinate gallium atoms about a Ga–Ga bond. Compound **II** involves cleavage of the Ga–Ga bond affording a Ga(II)–tetraphenylbutadiene complex.

From the discovery of cyclogallenes,[6–8] metalloaromatic Ga_3^{2-} ring systems, to reports of a gallyne,[9,10] a Ga_2^{2-} organometallic analog of acetylene, this laboratory has been interested in the dynamics of the Ga–Ga bond. These discoveries notwithstanding, this laboratory remained intrigued by the chemistry of the simple bis(dioxane) adducts of gallium halides, $Ga_2X_4(dioxane)_2$ (X = Cl, Br) and their well documented ability to stabilize both the Ga(II) oxidation state and the Ga–Ga bond. To this end, we sought to isolate triclinic crystals of $Ga_2Cl_4(dioxane)_2$ and explore its reactivity. To our great surprise, we obtained orthorhombic crystals of $[Ga_2Cl_4(dioxane)_2]_x$ **I** (Fig. 1).[11] It is possibly noteworthy that **I** was crystallized in our laboratory at room temperature while crystallization in the original preparation by Small and Worrall[2] took place at 0 °C. While **I** has a number of similarities with $Ga_2Cl_4(dioxane)_2$ and $Ga_2Br_4(dioxane)_2$ (*i.e.* the dioxane adducts are in the chair form), the differences are quite remarkable. Most striking about **I** is the five-coordinate, almost idealized trigonal bipyramidal coordination about both gallium atoms [O–Ga–O 179.10(10)°] while maintaining a Ga–Ga bond. It is particularly noteworthy that **I** is a rare example of a dimeric gallane consisting of two five-coordinate gallium atoms about a Ga–Ga bond. The trigonal bipyramidal coordination notwithstanding, it is also surprising that the Ga–Ga bond distance of 2.3825(9) Å in **I** is shorter than the values reported for both $Ga_2Br_4(dioxane)_2$ [2.395(6) Å] and $Ga_2Cl_4(dioxane)_2$ [2.406(1) Å]. Indeed, the Ga–Ga bond in **I** is considerably shorter than the cyclogallene Ga–Ga bond distances of 2.441(1) and 2.4187(5) Å reported for $Na_2[(Mes_2C_6H_3)Ga]_3$ and $K_2[(Mes_2C_6H_3)Ga]_3$, respectively, involving trigonal planar coordinated gallium atoms. The independent Ga–O bond distance of 2.4087(19) Å in **I** is considerably longer than the mean values of 2.03(2) and 2.027(2) Å reported for $Ga_2Br_4(dioxane)_2$ and $Ga_2Cl_4(dioxane)_2$, respectively. However, the Ga–O bond length of **I** compares well with the Ga–O(axial)

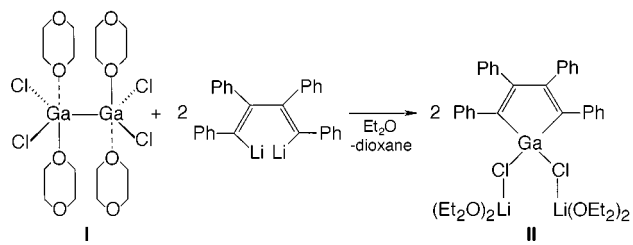

Scheme 1

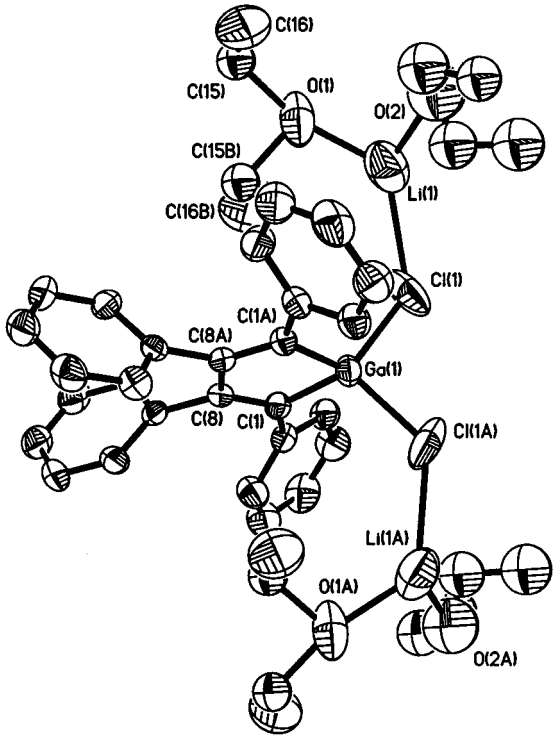

Fig. 2 Molecular structure of $[(PhC{=}CPhPhC{=}CPh)]Ga[(Cl)Li(OEt_2)_2]_2$ **II**. Bond distances (Å) and angles (°): Ga(1)–C(1a) 1.966(4), Ga(1)–C(1) 1.966(4), Ga(1)–Cl(1a) 2.2306(18), Ga(1)–Cl(1) 2.2305(18), Cl(1)–Li(1) 2.625(18), Li(1)–O(1) 2.07(2), Li(1)–O(2) 2.31(2); C(1a)–Ga(1)–C(1) 91.4(3), (1a)–Ga(1)–Cl(1a) 115.56(15), C(1)–Ga(1)–Cl(1a) 116.17(13), C(1a)–Ga(1)–Cl(1) 116.17(13), C(1)–Ga(1)–Cl(1) 115.57(15), Cl(1a)–Ga(1)–Cl(1) 102.68(14), (1)–Cl(1)–Li(1) 125.8(4). (Symmetry codes: a, $y + 1/3$, $x - 1/3$, $-z + 1.6$; b: $y + 1/3$, $x - 1/3$, $-z + 7/6$).

distances of 2.450(5) and 2.278(5) Å reported for the trigonal bipyramidal coordinated gallium atom in the azacrown ether complexation of the dimethylgallium fragment of $[(Me_2Ga)$-(diaza-18-crown-6)$[GaMe_3]_2$.[12] Also noteworthy, a view of the unit cell of **I** reveals an extended array stabilized by Cl···H(dioxane) interactions at contacts of 2.836 Å. Effectively, these interactions allow the dioxane moieties to loosely associate $Ga_2Cl_4(dioxane)_2$ units in infinite chains within the unit cell.

The tetraphenylbutadiene ligand is potentially useful in organogallium chemistry. Indeed, this ligand was utilized in the stabilization of the recently reported spirogallane anion, $[(PhC{=}CPhPhC{=}CPh)_2Ga]^-$.[13] Reaction of **I** with 1,4-dilithiotetraphenylbutadiene yields the interesting gallium(II) product **II** (Fig. 2).[11] **II** resides about a two fold mirror plane passing through the Ga(1) atom and bisecting the C(8)–C(8a) bond. The coordination about the gallium atom is distorted tetrahedral. The Ga–C bonds in **II** are a little shorter than those reported for the spirogallane. Although the mechanism which affords **II** remains unclear, Ga–Ga bond cleavage was clearly involved. Moreover, it is interesting that instead of the system eliminating LiCl, the lithium atoms, stabilized by diethyl ether, remained in the coordination sphere *via* bridging chlorine atoms [Li(1)–Cl(1)–Ga(1) bond angle is 125.8(4)°]. The Ga–Cl bond distance of 1.966(4) Å in **II** is considerably shorter than the values of 2.177(5) and 2.201(5) Å for $(Mes_2C_6H_3)_2GaCl$[14] and $[(Pr^i{}_3C_6H_2)_2C_6H_3GaCl_2]_2$,[15] respectively.

We are grateful to the National Science Foundation (G. H. R.: CHE-95-9520162) and to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this work.

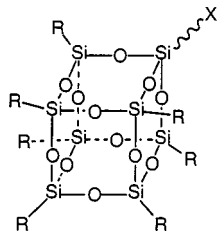
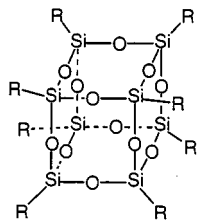
Received (in Bloomington, IN, USA) 16th February 1999, Accepted 21st May 1999

A new method is described for effecting selective monofunctionalization of $CH_2{=}CH)_8Si_8O_{12}$ 2: reaction of 2 with triflic acid (TfOH) produces $(TfOCH_2CH_2)(CH_2{=}CH)_7Si_8O_{12}$ 3, which reacts with nucleophiles (*e.g.* H_2O or 2-mercaptopyridine) to produce $(XCH_2CH_2)(CH_2{=}CH)_7Si_8O_{12}$ (4 X = OH, 5 X = SC_5H_4N); acylation of 4 with *p*-$O_2NC_6H_4COCl$ affords (*p*-$O_2NC_6H_4CO_2CH_2CH_2)(CH_2{=}CH)_7Si_8O_{12}$ 6; catalytic hydrogenation of 4 affords $(HOCH_2CH_2)Et_7Si_8O_{12}$ 7.

Polyhedral oligosilsesquioxanes (POSS) have recently attracted interest as building blocks for hybrid inorganic/organic materials.[1–5] Many families of POSS monomers are now known, but some of the most promising monomers are cube-octameric frameworks with a single polymerizable pendant group (*e.g.* **1**).[6,7] As part of a general effort to identify cost-effective ways



1 X = polymerizable pendant group



2 R = vinyl

for manufacturing POSS monomers on a large scale, we have been exploring potential methods for preparing POSS monomers from inexpensive $R_8Si_8O_{12}$ frameworks.[8–10] Here, we outline a new strategy for preparing POSS monomers from $(CH_2{=}CH)Si_8O_{12}$ **2**. This strategy, which involves addition of triflic acid (TfOH) to a C=C bond of the vinylsilsesquioxane, produces an attractive precursor for the preparation of cube-octameric POSS monomers containing seven vinyl or ethyl groups and one unique pendant group.

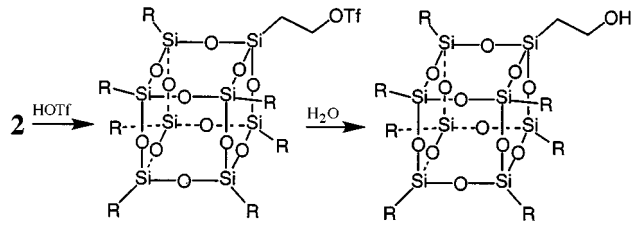
Vinylsilsesquioxane **2**, which is readily available from the hydrolytic condensation of $(CH_2{=}CH)SiCl_3$,[11,12] undergoes a wide variety of useful transformations, including free-radical addition reactions,[13] catalytic hydrogenation,[14] Diels–Alder reactions,[15] epoxidation[4] and olefin metathesis.[8] With eight potentially reactive vinyl groups, reactions of **2** often produce complicated product mixtures. Under the right conditions, however, reactions of **2** can be quite selective for the functionalization of a single vinyl group.

The reaction of **2** with TfOH† (1 equiv., CH_2Cl_2, 25 °C) occurs quickly upon mixing to afford a new silsesquioxane product in good yield (*ca.* 40–45%) (Scheme 1).‡ Based on the known reactivity of $R_8Si_8O_{12}$ frameworks toward TfOH[9,10] and the tendency of some vinylsilanes to undergo protodesilylation or rearrangement,[16] we expected to observe cleavage of Si–O–Si linkages and/or Si–C bonds. Instead, both the ^{13}C and ^{29}Si NMR spectra were consistent with a compound possessing a C_3-symmetric Si_8O_{12} framework, and the ^1H NMR spectrum exhibited an AA′BB′ coupling pattern characteristic of $R_7Si_8O_{12}(CH_2CH_2X)$ frameworks.[17] Based on the reaction stoichiometry and the ^1H chemical shift for the CH_2X group (δ 4.75, t, J 12 Hz), this compound was assigned as **3**; this assignment was confirmed by multinuclear NMR data (^{13}C, ^{29}Si, ^{19}F) and a high resolution mass spectrum. To the best of our knowledge, this is the first example of triflic acid addition to a vinylsilane.

Triflate **3** could not be isolated in pure form because it readily co-crystallizes with **2**. However, crude product mixtures containing **3** react with a variety of nucleophiles to afford substitution products that can be easily isolated as pure compounds. For example, hydrolysis of **3** (acetone or dioxane–aqueous Na_2CO_3) produces **4**, which was identified on the basis of compelling multinuclear NMR data, a high resolution mass spectrum, and a preliminary single crystal X-ray diffraction study.§ Reaction of **3** with 2-mercaptopyridine affords **5**.¶ In both cases, separation of the product from unreacted **2**, as well as small amounts of products derived from functionalization of more than one vinyl group (*vide infra*), can be accomplished by flash chromatography on SiO_2.

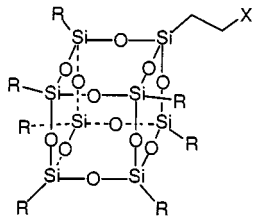
In contrast to most compounds containing $SiCH_2CH_2OH$ groups, **4** does not undergo facile base-catalyzed elimination of ethylene to produce SiOH groups. It is also resistant to acid-catalyzed dehydration. This unexpected stability, which is probably due to a strong preference for *trans*-diaxial orientation of the Si_8O_{12} framework and OH group, allows **4** to be used as a precursor to a wide range of potentially useful compounds. For example, both acylation of **4** to **6** (*p*-$O_2NC_6H_4COCl$, CH_2Cl_2–pyridine, 50 °C, 8 h) and the catalytic hydrogenation of **4** to **7** (10% Pd/C, 100 psig H_2, Et_2O, 25 °C, 20 h) occur in quantitative NMR yield.¶

Unlike TfOH-induced Si–O–Si cleavage reactions of $R_8Si_8O_{12}$, which can afford high yields of a single product at complete conversion, functionalization of POSS pendant groups is normally selective for monofunctionalization[18] only at low conversion (< 10% based on $R_8Si_8O_{12}$). At higher conversion the monofunctionalization reaction no longer enjoys a large statistical advantage and the formation of many polyfunctional products is usually observed. For the reaction of **2** with TfOH described above, the selectivity for monofunctionalization is *ca.* 85–90% as judged by multinuclear NMR spectra and EI mass spectra obtained on crude product mixtures. Under these conditions, difunctionalized products are



3 R = vinyl **4** R = vinyl

Scheme 1



5 R = vinyl; X = 

6 vinyl $O_2CC_6H_4NO_2$

7 ethyl OH

also produced in yields of *ca.* 10–15% (based on the amount of **2** consumed). Higher selectively for monofunctionalization can be achieved by performing the reaction to lower conversion, but larger amounts of unreacted **2** must be recovered and the absolute mass yield of **3** is correspondingly lower. We have not been able to separate or isolate any of the triflates derived from addition of TfOH to vinyl groups on **2**. However, hydrolysis of the crude product mixture cleanly transforms all CH_2CH_2OTf groups into CH_2CH_2OH groups and produces a mixture of alcohols that can be efficiently separated by chromatography. A full account of our efforts to control the extent of functionalization and isolate synthetically useful quantities of polyfunctional products will be reported separately.

In summary, the addition of triflic acid to vinyl groups of **2** provides the basis for a fundamentally new method for preparing functionalized silsesquioxanes. Frameworks containing seven vinyl or ethyl groups and one unique pendant group are particularly easy to prepare, but both the rich reaction chemistry of vinylsilsesquioxanes and the ease with which multiply functionalized derivatives can be isolated in synthetically useful quantities provide access to a wide range of potentially useful compounds.

These studies were supported by the Air Force Research Laboratory (Edwards AFB). We are grateful to Dr John Greaves (UCI) for obtaining high-resolution mass spectra of **3**–**7**.

Notes and references

† TfOH = CF_3SO_3H

‡ Triflic acid (TfOH, 1 equiv.) was added to a solution of **2** (188 mg, 0.297 mmol) in CH_2Cl_2. After 3 h at 25 °C, the reaction mixture was diluted with CH_2Cl_2, washed with saturated aqueous Na_2CO_3, dried over $MgSO_4$, and evaporated to afford 180 mg of a white solid. Analysis by NMR spectroscopy (^{1}H, ^{13}C, ^{29}Si) and mass spectrometry indicated that the crude product contains mainly **3** (40–45%), unreacted **2** (50%) and small amounts of products resulting from addition of TfOH to more than one vinyl group. For **3**: ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ 6.25–5.75 (m, 21H), 4.73 (t, *J* 12 Hz, 2H, CH_2OTf), 1.50 (t, *J* 12 Hz, 2H, $SiCH_2$). ^{13}C{^{1}H} NMR (125 MHz, $CDCl_3$, 25 °C): δ 137.40, 137.24, 137.03 (rel. int. 3:3:1 for CH_2), 128.39, 128.29, 128.09 (rel. int. 1:3:3 for CH), 118.5 (q, *J* 320 Hz, CF_3), 75.15 (CH_2OTf), 14.89 ($SiCH_2$). ^{29}Si{^{1}H} NMR (99 MHz, $CDCl_3$, 25 °C): δ −71.61, −80.08, −80.14 (rel. int: 1:3:4). ^{19}F{^{1}H} NMR (470.13 MHz, $CDCl_3$, 21 °C): δ −139.45. EI (70 eV, 200 °C) exact mass for M^+ (found): *m/z* 781.9020 (781.9041).

§ The hydrolysis of crude **3** was performed in wet acetone–CH_2Cl_2. Analysis (^{1}H, ^{13}C, ^{29}Si NMR) of the crude product obtained after evaporation of the solvent indicated complete conversion of $SiCH_2CH_2OTf$ to $SiCH_2CH_2OH$. Flash chromatography on silica with CH_2Cl_2 afforded **4** as a white solid, which was recrystallized from CH_2Cl_2 at −35 °C. For **4**: ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ 6.15–5.90 (m, 21H), 3.85 (t, *J* 7.2 Hz, 2H, CH_2OH), 1.18 (t, *J* 7.2 Hz, 2H, $SiCH_2$). ^{13}C{^{1}H} NMR (125 MHz, $CDCl_3$, 25 °C): δ 137.07, 137.05, 136.95 (rel. int. 3:3:1 for CH_2), 128.58, 128.56 (rel. int. 4:3 for CH), 58.48 (CH_2OH), 17.28 ($SiCH_2$). ^{29}Si{^{1}H} NMR (99 MHz, $CDCl_3$, 25 °C): δ −68.00, −80.16, −80.36 (rel. int. 1:3:4). EI (70 eV, 200 °C) exact mass for M^+ (found): *m/z* 649.9528 (649.9520).

Crystal data for **4**: $C_{16}H_{26}O_{13}Si_8$, *M* = 651.09, rhombohedral, space group $R\bar{3}$, *a* = *b* = 13.4510(8), *c* = 13.9408(12) Å, γ = 120°, *V* = 2184.4(3) Å^3, *T* = 158 K, *Z* = 3, μ = 0.426 mm^{-1}, 4488 reflections collected, 1152 independent reflections with $I > 2\sigma(I)$, R_1 = 0.0811, wR_2 = 0.2285. The CH_2CH_2OH group exhibits $\bar{3}$ disorder because the crystallographic center of inversion is located at the center of the Si_8O_{12} framework.

Tetraorganodistannoxanes: formation of a novel *cis*-ladder†

Marcus Schulte,[a] Markus Schürmann,[a] Dainis Dakternieks[b] and Klaus Jurkschat*[a]

[a] *Lehrstuhl für Anorganische Chemie II der Universität Dortmund, D-44221 Dortmund, Germany. E-mail: kjur@platon.chemie.uni-dortmund.de*

[b] *School of Biological and Chemical Sciences, Deakin University, Geelong,Vic. 3217, Australia*

Received (in Basel, Switzerland) 25th February 1999, Accepted 21st May 1999

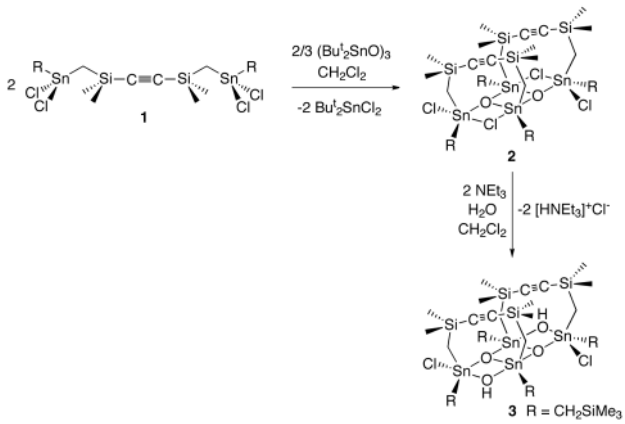
Reaction of the acetylenic-bridged ditin precursor $[Me_3SiCH_2(Cl_2)SnCH_2(Me_2)Si]_2C_2$ 1 with the oxygen source $(Bu^t_2SnO)_3$ results exclusively in formation of the dimeric tetraorganodistannoxane $\{[Me_3SiCH_2(Cl)SnCH_2(Me_2)SiC{\equiv}CSi(Me_2)CH_2Sn(Cl)CH_2SiMe_3]O\}_2$ 2 which has the hitherto unknown *cis*-configuration; this is retained during the quantitative conversion of 2 into the hydroxy-substituted analogue $\{[Me_3SiCH_2(OH)SnCH_2(Me_2)SiC{\equiv}CSi(Me_2)CH_2Sn(Cl)CH_2SiMe_3]O\}_2$ 3.

Dimeric tetraorganodistannoxanes $[R_2(X)SnOSn(X)R_2]_2$ (X = halogen, OH, R′CO_2, NCS; R, R′ = alkyl, aryl)[1–5] have been reported to be efficient homogeneous catalysts in various organic reactions such as transesterification under virtually neutral conditions,[6] highly selective acylation of alcohols,[7] urethane formation[8] and alkyl carbonate synthesis.[9]

We recently reported the syntheses and structures of tetraorganodistannoxanes $\{[R(X)SnCH_2ZCH_2Sn(X)R]O\}_n$ which contain tri- or tetra-methylene bridges between the two tin atoms. These compounds exhibit either a double ladder or a dimeric structure (n = 4; R = CH_2SiMe_3; X = Cl, OH; Z = CH_2),[10] [n = 2, 4; R = CH_2SiMe_3, CH_2CMe_3, CH_2CHMe_2; X = Cl, OAc; Z = CH_2, $(CH_2)_2$, $SiMe_2$],[11] [n = 2; R = $CH(SiMe_3)_2$; X = F; Z = CH_2].[12] Also recently reported was the first triple ladder $\{[R(Cl)Sn(CH_2)_3Sn(Cl)(CH_2)_3Sn(Cl)R]O_{1.5}\}_4$ (R = CH_2SiMe_3),[13] in this case three tin atoms are connected by trimethylene bridges.

In the double ladders $\{[R(Cl)SnCH_2ZCH_2Sn(Cl)R]O\}_4$ [R = CH_2SiMe_3; Z = CH_2, $(CH_2)_2$] the distance between the two $Sn_4Cl_4O_2$ layers is 6.04 and 7.07 Å, respectively, which is too small to contemplate any host–guest chemistry. With the goal to increase the $Sn_4Cl_4O_2$ interlayer separation, we synthesised the precursor of a double ladder containing a rigid acetylene spacer, $[Me_3SiCH_2(Cl_2)SnCH_2(Me_2)Si]_2C_2$, **1**.‡

However, reaction of **1** with $(Bu^t_2SnO)_3$ resulted in quantitative formation of the dimeric tetraorganodistannoxane **2**§ rather than the anticipated tetrameric double ladder compound (Scheme 1).



Scheme 1 Synthesis of the tetraorganodistannoxanes **2** and **3**.

† This work contains part of the intended PhD thesis of M. Schulte.

Somewhat surprisingly, the crystal structure (Fig. 1) of **2**¶ shows that both acetylenic spacer groups are on the same side of the tetraorganodistannoxane ladder core, *i.e.* **2** adopts the lower symmetry *cis*-configuration as compared to the usual *trans*-configuration.[12] The origin of this geometric disposition is not clear. Each tin atom has a distorted trigonal bipyramidal geometry. For the exocyclic tin atoms, two carbons and one oxygen occupy the equatorial positions and two chlorines occupy the axial positions, while for the endocyclic tin atoms the equatorial positions are occupied by two carbons and one oxygen and the axial positions by one oxygen and one chlorine. The shortest Sn–O bond lengths are found for the exocyclic tins [Sn(1)–O(1) 2.024(3) Å, Sn(4)–O(2) 2.018(2) Å] and the longest Sn–O bonds exist in the Sn_2O_2 ring [Sn(2)–O(2) 2.132(3) Å, Sn(3)–O(1) 2.159(3) Å]. It is worth noting that the Sn(2)–O(2) bond corresponds to the longer Sn(2)–Cl(2) bond [2.641(1) Å] whereas the Sn(3)–O(1) bond corresponds to the shorter Sn(3)–Cl(4) bond [2.512(2) Å]. The chlorine atoms Cl(1) and Cl(3) are non-bridging [Sn(2)–Cl(3) 3.490(1) Å, Sn(3)-Cl(1) 3.497(1) Å]. The torsion angles involving the bridging chlorine atoms [Sn(1)–O(1)–Sn(2)–Cl(2) 7.93(7)°,

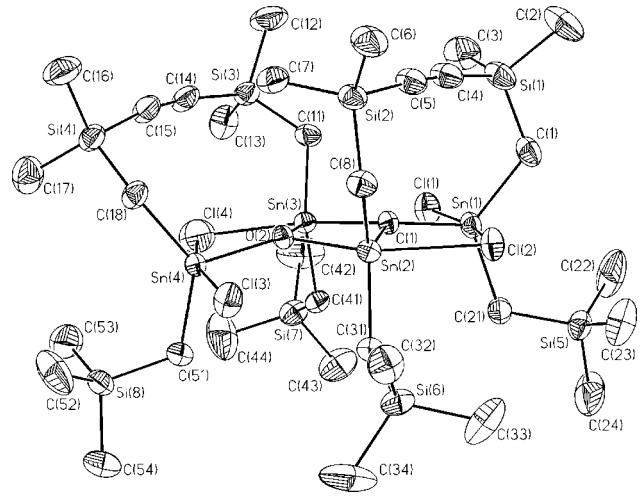


Fig. 1 Crystal structure of *cis*-$\{[Me_3SiCH_2(Cl)SnCH_2(Me_2)SiC{\equiv}CSi(Me_2)CH_2Sn(Cl)CH_2SiMe_3]O\}_2$ **2**, showing 30% probability ellipsoids. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Sn(1)–O(1) 2.024(3), Sn(1)–Cl(1) 2.453(1), Sn(1)–Cl(2) 2.740(1), Sn(2)–O(1) 2.058(3), Sn(2)–O(2) 2.132(3), Sn(2)–Cl(2) 2.641(1), Sn(2)–Cl(3) 3.490(1), Sn(3)–O(1) 2.159(3), Sn(3)–O(2) 2.049(3), Sn(3)–Cl(1) 3.497(1), Sn(3)–Cl(4) 2.512(2), Sn(4)–O(2) 2.018(2), Sn(4)–Cl(3) 2.507(1), Sn(4)–Cl(4) 2.503(2), O(1)–Sn(1)–Cl(1) 88.29(8), O(1)–Sn(1)–Cl(2) 76.28(8), O(1)–Sn(1)–C(1) 122.7(2), O(1)–Sn(1)–C(21) 112.5(2), Cl(1)–Sn(1)–Cl(2) 164.57(4), O(1)–Sn(2)–O(2) 74.4(1), O(1)–Sn(2)–Cl(2) 78.11(8), O(1)–Sn(2)–C(8) 121.0(1), O(1)–Sn(2)–C(31) 106.6(1), O(2)–Sn(2)–Cl(2) 152.36(7), O(1)–Sn(3)–O(2) 74.0(1), O(2)–Sn(3)–Cl(4) 77.72(8), O(2)–Sn(3)–C(11) 114.0(2), O(2)–Sn(3)–C(41) 108.4(1), O(1)–Sn(3)–Cl(4) 151.59(8), O(2)–Sn(4)–Cl(3) 86.29(8), O(2)–Sn(4)–Cl(4) 78.46(9), O(2)–Sn(4)–C(18) 113.7(2), O(2)–Sn(4)–C(51) 113.7(2), Cl(3)–Sn(4)–Cl(4) 163.50(6), Si(1)–C(4)–C(5) 173.7(5), Si(2)–C(5)–C(4) 176.0(5), Si(3)–C(14)–C(15) 171.8(4), Si(4)–C(15)–C(14) 169.9(4), Sn(1)–O(1)–Sn(2)–Cl(2) 7.93(7), Sn(3)–O(2)–Sn(4)–Cl(4) 6.74(8), Sn(2)–O(1)–Sn(3)–O(2) 8.0(1).

Sn(3)–O(2)–Sn(4)–Cl(4) 6.74(8)°] and the Sn_2O_2 ring [Sn(2)–O(1)–Sn(3)–O(2) 8.0(1)°] reveal a distortion from planarity which originates from ring strain in the two nine-membered Sn–O–Sn–C–Si–C≡C–Si–C rings. This ring strain is also manifested in the deviation of the Si–C≡C angles from the ideal value of 180° [Si(1)–C(4)–C(5) 173.7(5)°, Si(2)–C(5)–C(4) 176.0(5)°, Si(3)–C(14)–C(15) 171.8(4)°, Si(4)–C(15)–C(14) 169.9(4)°]. All four Sn–C–Si frameworks are bent into the same direction which results in an intramolecular stacking of the two nine-membered rings. There is no intramolecular or intermolecular interaction between two spacers [shortest intramolecular distance C(7)···C(18) 3.827(7) Å].

The dimeric nature of the material is retained in solution as was verified by molecular weight determination (calc. for **2**: M = 1334 g mol^{-1}, found in CH_2Cl_2: M = 1383 g mol^{-1}). The ^{119}Sn NMR spectrum in $CDCl_3$ contains two signals of equal integral ratio at δ −132.4 (C_2SnO_2Cl) and at δ −75.8 (C_2SnOCl_2) indicating the presence of a single isomer in solution. However, these data do not provide unambiguous information about which of the two possible isomers is present in solution.

The tetrachloro-substituted distannoxane **2** reacts almost quantitatively with triethylamine–water to give the dihydroxy-substituted distannoxane **3**.‖ Again, the *cis*-isomer of **3** is formed exclusively in the solid state‡ (Scheme 1).

In aqueous solution compound **3** does not undergo further hydrolysis. Also for **3** the dimeric structure is retained in solution as was verified by molecular weight determination (calc. for **3**: M = 1297 g mol^{-1}, found in CH_2Cl_2: M = 1349 g mol^{-1}). The ^{119}Sn NMR spectrum in $CDCl_3$ shows two signals of equal integral ratio at δ −153.1 and −152.2 revealing the presence of a single isomer only, but as stated for compound **2** it is not evident which of the two isomers is actually present.

These preliminary results reveal that the silicon containing acetylenic spacer $CH_2(Me_2)SiC{\equiv}CSi(Me_2)CH_2$ plays an essential role in controlling the structure of the distannoxane dimers **2** and **3**. Further studies on this class of compounds will focus on the catalytic activity of spacer bridged distannoxanes such as **2** and **3**.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

A cluster growth route to quantum-confined CdS nanowires

Ping Yan, Yi Xie,* Yitai Qian and Xianming Liu

Structure Research Laboratory, and Department of Chemistry, University of Science and Technology of China, Hefei, Anhui, 230026, P.R. China. E-mail: yxie@ustc.edu.cn

Received (in Cambridge, UK) 8th March 1999, Accepted 29th April 1999

Quantum-confined CdS nanowires with diameters around 4 nm and lengths ranging from 150 to 250 nm were grown for the first time from cadmium bis(diethyldithiocarbamate) $[Cd(DDTC)_2]_2$ by removal of the four thione groups with ethylenediamine (en) at 117 °C for 2 min.

Semiconductor crystallites that are small in comparison to the bulk exciton diameter show quantum confinement effects, which have been intensely studied, and a number of good reviews have mirrored this development.[1,2] Various methods for the production of II–VI and III–V nanocrystals with narrow size distributions in the desired size range of between 1 and 15 nm in diameter have been developed.[3]

Special attention has been paid to one-dimensional structures, such as nanotubes and nanowires owing to their interesting properties.[4] However the challenge of fabricating such 1D structures is substantial because technologically useful quantum wires require lateral dimensions of < *ca*. 10 nm. Such a precision level is a formidable technological challenge.[5]

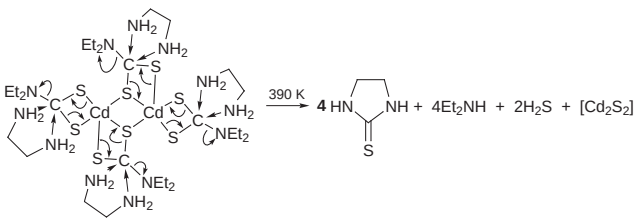
Recently very long CdTe nanowires[6] were fabricated by the molecular-beam epitaxy (MBE) growth technique, however, their diameters are much larger than 10 nm. Considering the small exciton diameter of CdS (6 nm), the preparation of quantum confined CdS nanowires (of diameter < 6 nm) is even more difficult. A promising route is deposition of semiconductors into anodic aluminium oxide membrane filters or nuclear track-etched polycarbonate membranes with small pores; the smallest semiconductor nanowire obtained by this method to date is 9 nm.[7]

Here, quantum confined CdS nanowires were successfully obtained for the first time from a cluster precursor $Cd_2(S_2CNEt_2)_4$, which can be regarded as an inorganic core $[Cd_2S_2]$ with four capping groups.[8] Nucleophilic attack by ethylenediamine at the thione carbon can lead to removal of the capping groups. This process is shown in Scheme 1 and the resulting organic product has been characterized.[9]

The inorganic Cd_2S_2 cores can then combine with each other and under appropriate chemical and physical environment, $[Cd_2S_2]$ may preferentially grow along a unique direction and result in a one-dimensional structure.

In a typical process, 1 g of $[Cd(S_2CNEt_2)]_2$, prepared by precipitation from a stoichiometric mixture of $NaS_2CN(C_2H_5)_2$ and $CdCl_2$ in water, was dissolved in 30 ml ethylenediamine in a flask, and then heated to reflux (117 °C), and maintained at this temperature for 2 min. The yellowish precipitate obtained was filtered off and washed with ethanol.

The X-ray diffraction (XRD)† pattern of the nanowires is shown in Fig. 1. All the reflections, to within experimental



Scheme 1

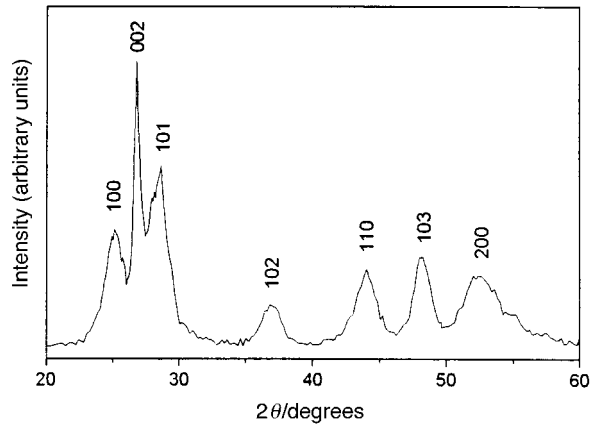


Fig. 1 XRD pattern for CdS nanowires.

error, fit that of bulk hexagonal CdS.[10] The (002) diffraction peak, the second strongest peak in bulk hexagonal CdS, is unusually narrow and strong, indicating a preferential growth along the *c* axis in the product. Using the Scherrer formula[11] on the (*hk*0) peaks (100) (110) and (200), the average diameter of the nanowires is estimated as 4.0 nm. This is confirmed by transmission electron microscopy (TEM)‡ images (Fig. 2), which reveal straight-line shapes and uniform diameters of *ca*. 4 nm and lengths ranging from 150 to 250 nm. IR spectroscopy was carried out to examine the purity of the product, and indicated the absence of both DDTC and ethylenediamine, suggesting a high degree of purity.

Fig. 3(a) shows the absorption spectrum of a sample dispersed in distilled water. The clear maximum at 455 nm is assigned to the optical transition of the first excitonic state.[2] The average particle diameter, as calculated from the maximum of the absorption curve (λ_m = 455 nm) is 3.8 nm[2] in good agreement with the TEM and XRD results. Since the onset of the absorption spectrum generally represents the larger end of

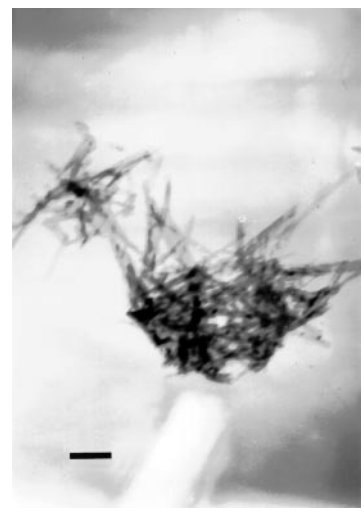

Fig. 2 TEM images of the nanowires (scale bar, 50 nm).

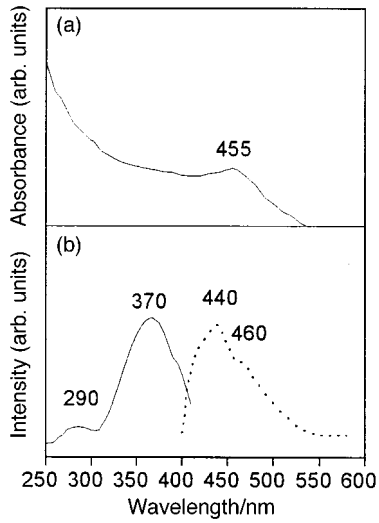

Fig. 3 (a) Absorption spectrum of a CdS sample dispersed in H_2O. (b) Excitation (solid line) and photoluminescence (dashed line) spectra of CdS nanowires. The spectra were taken in reflection geometry. The excitation wavelength for the emission spectrum was 370 nm, and the monitoring wavelength for the excitation spectrum was 440 nm.

the size distribution,[12] the position of the absorption edge (λ_e = 515 nm) shows that the lengths of the nanowires (150–250 nm) are much larger than the exciton diameter of CdS (6 nm). The large difference between sizes calculated from λ_e and λ_m, which can be related to the width of the particle size distribution, is characteristic for nanowires. The clear appearance of a blue-shift of the absorption peak relative to bulk CdS indicates that the CdS nanowires are quantum-confined. The excitation spectrum (monitoring wavelength at 440 nm) shows absorption bands at 290 and 370 nm [Fig. 3(b)]. Under photoluminescent excitation at 370 nm, the nanowires emit blue light at 440 and 460 nm [Fig. 3(b)] with a 55 nm blue shift relative to bulk CdS. These features are close to the optical absorption edge of CdS, suggesting a near band-edge emission.

When $[Cd(DDTC)_2]_2$ is thermolyzed at 250 °C for 30 min in trioctylphosphine oxide (TOPO), the morphology for most of the CdS nanocrystallites was reported to be thin plates.[13] In our experiments, other nucleophiles such as pyridine and diethylamine were also tested to remove the capping groups, however, no wire-like products were obtained. These results show that ethylenediamine plays a critical role in the formation of wire structures and probably serves as a director for the growth of the intermediate inorganic $[Cd_2S_2]$ core. Ethylenediamine has been extensively used as a template in solvothermal processes. For example, Li *et al*.[14] reported that elemental reaction of Cd and S in ethylenediamine resulted in CdS nanorods with diameters of 25–40 nm[14] although no detailed mechanism was proposed.

In summary, quantum-confined CdS nanowires with diameters of *ca*. 4 nm and lengths ranging from 150 to 250 nm have been grown for the first time from $[Cd(DDTC)_2]_2$, by removal of the four thione groups with ethylenediamine (en) at 117 °C for 2 min. Further studies may extend the method for the preparation of other quantum-confined nanowires.

Financial support from the Chinese National Foundation of Natural Science Research through the Outstanding Youth Science Fund and Huo Yingdong Foundation for Young Teachers is gratefully acknowledged. This work is also supported by the Climbing Plan from the State Science and Technology Commission of China.

Catalytic enantioselective aryl transfer: asymmetric addition of diphenylzinc to aldehydes

Carsten Bolm* and Kilian Muñiz

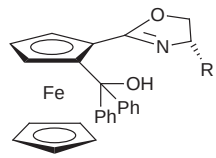
Institut für Organische Chemie der RWTH Aachen, Professor-Pirlet-Str. 1, D-52074 Aachen, Germany. E-mail: carsten.bolm@oc.rwth-aachen.de

Received (in Liverpool, UK) 17th May 1999, Accepted 26th May 1999

The asymmetric addition of diphenylzinc to aldehydes in the presence of catalytic amounts of a planar chiral ferrocene-based hydroxy oxazoline affords products with enantiomeric excesses of up to 96%.

The asymmetric addition of organozinc reagents (ZnR_2) to aldehydes is a well understood process in which the transferred moiety R is generally an alkyl group such as methyl, ethyl or isopropyl. A variety of chiral compounds catalyse this process yielding the corresponding secondary alcohols with excellent enantiomeric excesses.[1] In contrast, asymmetric transition metal catalysed C–C bond formations between aldehydes and suitable *aryl* transfer reagents are still rare.[2] In this context, Fu described the addition of diphenylzinc to 4-chlorobenzaldehyde which, in the presence of 3 mol% of a planar chiral azaferrocene, gave the product with 57% ee.[3] So far, this has been the only report on this type of arylation.[4,5] In a complementary approach, Miyaura recently described the rhodium catalysed addition of phenylboronic acid to naphthaldehyde. In the presence of an axially chiral monophosphine as ligand, an enantiomeric excess of 41% ee was obtained for the product.[6]

We have recently investigated the influence of planar chirality on asymmetric alkylation reactions catalysed by a series of ferrocenyl hydroxy oxazolines.[7–9] Within this project, the syntheses and catalytic applications of compounds **1a** and **1b** have been described.[7b] We have now employed these



1a R = Bu^t
b R = Ph

ferrocenes in asymmetric arylations by catalysed addition of diphenylzinc to aldehydes.[10] First, the reaction conditions were optimised using 4-chlorobenzaldehyde (**2**) as substrate (Table 1).

Even with as little as 3 mol% of ferrocene **1a** quantitative formation of **3** was observed, indicating the efficiency of this catalysis (Table 1, entry 1). HPLC using a chiral stationary phase revealed an enantiomeric excess of 64% for the resulting secondary alcohol. By incresing the catalyst loading to 5 and 10 mol%, the ee of **3** was raised to 82 and 88% ee, respectively (entries 2, 3). Ferrocene **1b** proved to be equally efficient and gave identical results (entry 5). Finally, the reaction temperature was lowered to −20 °C. Still, high conversion was achieved, but the increase in ee was only minor (entry 4). It is of note that the absolute configuration of the product is *R*, indicating that the face selectivity of the catalysis is unchanged with regard to the related alkylation reactions described before.[7] Such unchanged selectivity had also been reported by Fu,[3] but contrasts the findings by Soai observed in reactions with *in situ* formed diphenylzinc.[1d,5a]

[a] Isolated yield after column chromatography. [b] Determined by HPLC using a chiral stationary phase (Chiralcel OB, *n*-hexane–Pr^{i}OH = 4:1, 1.0 ml min^{-1}). [c] Determined by comparison of the optical rotation with literature values. [d] Reaction was carried out at −20 °C.

In order to guarantee a reasonable catalytic process, the catalysts loading was limited to 5 mol% and the reaction temperature was maintained at 0 °C in further studies. Under these conditions, several other aldehydes were submitted to the asymmetric arylation using ferrocene **1a** as catalyst precursor (Table 2).

Several conclusions can be drawn from these results: unsubstituted or *para*-substituted aromatic aldehydes give the highest enantioselectivities (entries 1, 2). *ortho*-Substituents at the aryl group lower the product ee of aromatic substrates (entries 3, 4). Aliphatic aldehydes give enantioselectivities up to a 75% ee as obtained for acetaldehyde (entries 5, 6). A sterically

demanding *tert*-butyl group does not allow a high ee (entry 7).

The low enantioselectivity in the arylation of 2-formylpyridine (entry 8) is due to a competitive uncatalysed nonselective reaction of diphenylzinc with the substrate itself.[11] Unlike all other arylations where a dark orange to red solution was obtained, in this case the reaction mixture turns light yellow immediately after the addition of the aldehyde. A control experiment in the absence of **1a** showed a solution of identical colour. From this reaction mixture the product alcohol was isolated in 97% yield. Thus, we assume that the arylation of this substrate is initiated by the pyridine itself leading to a product which then is able to catalyse its own formation in an non-stereoselective manner giving racemic pyridyl alcohol.[1*d*,12,13]

In order to reveal details of the nature of the active catalytic species, a catalysis with scalemic **1b** was performed: arylation of 4-chlorobenzaldehyde (**2**) in the presence of 10 mol% of **1b**, which had an enantiomeric excess of 57%, led to the formation of (*R*)-4-chlorophenyl(phenyl)methanol [(*R*)-**3**] with 48% ee. From this correlation between the enantiomeric excesses of the ferrocene and the product[13] we conclude that heterodimeric species are not involved in the catalytic conversion of the substrate. This is in accordance with our previous results for related alkylation reactions with non-enantiopure ferrocenyl oxazolines.[7–9,14]

In summary, we have described a novel catalytic system for asymmetric arylations of various differently substituted aldehydes employing diphenylzinc as organometallic aryl source.

We are grateful to the Fonds der Chemischen Industrie and to the Deutsche Forschungsgemeinschaft (DFG) within the Collaboraive Research Center (SFB) 380 ‘Asymmetric Synthesis by Chemical and Biological Methods’ for financial support.

Synthesis and α-substitution reactions of methoxime derivatives of alkene-carbon monoxide alternating copolymers

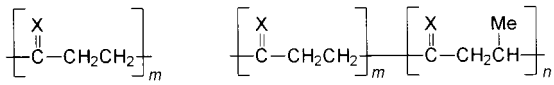
Paveena Khansawai, R. Michael Paton* and David Reed

Department of Chemistry, The University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ. E-mail: r.m.paton@ed.ac.uk

Received (in Cambridge, UK) 28th April 1999, Accepted 1st June 1999

Poly(1-methoxyiminotrimethylene) 5 and poly[(1-methoxyiminotrimethylene)-*co*-(1-methoxyimino-3-methyltrimethylene)] 6, prepared by reaction of ethene/propene–carbon monoxide alternating copolymers with methoxylamine, undergo α-substitution on treatment with BuLi followed by addition of electrophiles such as MeI.

Alternating copolymers of alkenes and carbon monoxide are proving to be useful starting materials for the preparation novel functionalised polymers.[1–5] Reaction can take place at individual ketone groups or at 1,4-dione units; for example, the ketones can be converted to their 1,3-dioxolane derivatives by acid-catalysed reaction with 1,2-diols,[4] whereas with primary amines Paal–Knorr condensation of 1,4-diones affords poly(ethylenepyrroles).[2] We have previously described[5] the conversion of ethene-carbon monoxide copolymer **1** (E-CO) and



1 X = O (E-CO)
3 X = NOH
5 X = NOMe

2 X = O (EP-CO)
4 X = NOH
6 X = NOMe

ethene/propene–carbon monoxide copolymer **2** (EP-CO) to polyketoximes **3** and **4** on treatment with hydroxylamine. We now report that reaction with methoxylamine affords the corresponding methoxime polymers **5** and **6**, and that these readily undergo base-induced reactions with electrophiles at the α-methylene group.

Reaction of E-CO or EP-CO with methoxylamine in pyridine at room temperature resulted in slow dissolution of the polymer and complete conversion of the ketone groups to their methoxime derivatives. In a typical experiment a suspension of E-CO (M_n = 1500, 100 mg) was stirred with a four-fold excess of methoxylamine hydrochloride (595 mg) in pyridine (10 ml) at room temperature for two days. The resulting homogeneous solution was poured into water (50 ml) and the product extracted into $CHCl_3$. Washing with aq. Na_2CO_3 and water, drying, and removal of the solvent afforded poly(1-methoxyiminotrimethylene) **5** as a pale yellow gum (71%), which was purified by precipitation from $CHCl_3$ by addition of MeOH. EP-CO (m = 0.99, n = 0.01)† and EP-CO (m = 0.85, n = 0.15)‡ reacted similarly, yielding poly[(1-methoxyiminotrimethylene)-*co*-(1-methoxyimino-3-methyltrimethylene)] **6**. The products were identified from their spectroscopic properties§ by comparison with the corresponding polyketoximes **3** and **4**, and with 2,5-bis(methoxyimino)hexane **7**¶ and 3,6,9-tris(methoxyimino)undecane **8**¶ which were prepared as model compounds by methoximation of hexane-2,5-dione and undecane-3,6,9-trione respectively. For polymethoxime **5** the conversion of ketone units in the polymer to methoximes is evident from the infrared spectrum in which the carbonyl absorption at 1690 cm^{-1} is replaced by a C=N peak at 1630 cm^{-1}. Furthermore in the ^{13}C NMR spectrum the carbonyl absorptions of the starting material at 208–210 ppm are absent and there are new characteristic peaks for the imino carbons at 158.57 and 158.48 ppm, similar to those found at 161–157 ppm for the *E,E-*, *E,Z-* and *Z,Z*-isomers of model dimethoxime **7** and at 161–158 ppm for trimethoxime **8**. There are also signals for the methylene carbons at 30.63, 30.50, 30.03, 29.88, 25.35, 25.07, 24.43 and 24.13 ppm, similar to those reported[5] for polyketoxime **3**. The multiplicity of peaks in this region is attributed to the presence of *syn-anti*, *syn-syn*, *anti-anti* and *anti-syn* combinations of neighbouring oximes; those at higher frequency (29–31 ppm) are assigned to the α-*anti*-carbons by comparison with literature data for methoxyimino compounds.[6] The presence of methoxy groups is shown by signals at 3.78 (^1H) and 61.10 (^{13}C) ppm. Unlike the precursor alkene–carbon monoxide copolymers (**1**, **2**) and the polyoximes (**3**, **4**) all the new polymethoximes show good solubility in a range of organic solvents, thus giving increased scope for modification reactions.

All previous modifications have involved manipulation of the carbonyl groups, either singly or as 1,4-dione or 1,4,7-trione units. Functionalisation of the backbone methylene groups has not been achieved so far, largely due to the very low solubility of these polymers in common organic solvents. The availability of the new polymethoxime derivatives described above provided the opportunity to examine the feasibility of base-induced α-substitution reactions with electrophiles, as illustrated in Scheme 1.

Preliminary experiments were carried out using the model methoximes **7** and **8** in order to establish suitable reaction conditions and also to facilitate spectroscopic identification of the polymer products. Treatment of dimethoxime **7** (1.16 mmol) in THF at −78 °C with BuLi (3.52 mmol), followed by addition of MeI (3.55 mmol) afforded, on work-up, a mixture of compounds **9** and **10** (96% combined yield). Trimethoxime **8** reacted similarly yielding a mixture of α-methylated products (62%), of which compounds **11** and **12** are representative examples. The corresponding reactions of methoximes **7** and **8** with BnBr afforded α-benzylated products **13**/**14** (24%) and *e.g.* **15**/**16** (58%) respectively. The *syn* selectivity of the lithiation process[6,7] was established by reacting dimethoxime **7** with BuLi in THF at −78 °C and quenching the resulting solution with [*O*-^2H]methanol. The isolated product was shown by NMR spectroscopy to be predominantly a mixture of mono- and dideuterio compounds **17** and **18**, together with some unreacted

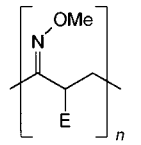
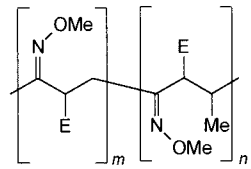
starting material. α-Deuteration at the *syn* methyl is confirmed by the presence of a peak at 1.79 ppm in the ^{2}H NMR spectrum; there is also a corresponding reduction of *ca*. 30% in the intensity of the signal for the protons of this group in the ^{1}H spectrum, with part of the singlet at 1.79 ppm in the starting material being replaced by a 1:1:1 triplet at 1.75 ppm. The analogous reaction of trimethoxime **8** resulted in 8% deuterium incorporation, representing an average of one hydrogen atom being replaced per molecule. Deuterium NMR peaks at 2.16, 2.27 and 2.44 ppm indicate isotopic substitution at several of the syn α-methylene positions, *e.g*. **19**/**20**.

Having established that directed α-substitutions could be accomplished on the model compounds the reactions of the polymethoximes were studied under similar conditions. To test the extent of anion formation a sample of EP-CO-derived polymethoxime **6** (m = 0.99, n = 0.01) was treated with BuLi (5 equiv.), excess [*O*-^{2}H]methanol added to the resulting solution, and the recovered polymer examined by NMR spectroscopy. α-Substitution in the product **21** is confirmed by



22 E = Me or H
23 E = Bn or H



21 E = D or H
24 E = Me or H
25 E = Bn or H

the presence of a peak at 2.45 ppm in the ^{2}H NMR spectrum very similar to that observed for the model compounds **19**/**20**; there is also a *ca*. 15% reduction in the intensity of the signal for the methylene protons in the ^{1}H spectrum, indicating that on average there are ~0.6 deuterium atoms per methoxime unit.

These results suggested that multiple electrophilic substitutions on the polymer backbone should be possible, and to test the feasibility of introducing alkyl substituents by this means the polymethoxime polyanions were reacted with MeI and BnBr. E-CO-derived polymethoxime **5** (100 mg) in dry THF was treated with BuLi (1.0 equiv.) at −78 °C and MeI (1.0 equiv) added to the resulting solution. After stirring for 2 h at −78 °C and warming to 0 °C the mixture was quenched with water and the product extracted into Et_2O. Drying, removal of the solvent *in vacuo* and precipitation from $CHCl_3$ solution by addition of MeOH afforded a pale yellow gum (60 mg). The NMR spectra of the product **22** were broadly similar to those observed for the polymethoxime **6** (m = 0.85, n = 0.15) previously prepared by methoximation of the alternating copolymer of carbon monoxide and 85% ethene/15% propene. The introduction of the methyl substituents was confirmed by the appearance of a new proton doublet signal at 1.00 ppm with a 6.7 Hz coupling to the adjacent backbone CH; by comparison with the oximino methyl signal the extent of reaction was estimated as 29%. In the ^{13}C NMR spectrum there are additional peaks for the ethylidene group at 16.28, 16.67 (CH_3) and 29.27, 36.00 ppm (CH). The reaction of E-CO polymethoxime **5** with BnBr proceeded similarly, yielding a yellow gum (**23**) which was purified by precipitation from $CHCl_3$ by addition of MeOH. The NMR spectra of the product showed characteristic peaks for the benzylidene group [7.1–7.3 ppm (Ph*H*); 37.52 (*C*HPh), 126.13, 128.18, 128.69 (Ph*C*H), 139.34 ppm (Ph*C*)] similar to those observed for model compounds **13**–**16**. From the proton spectrum it was estimated that there were on ~0.3 benzyl groups per methoxime unit. The corresponding reactions of BuLi / MeI and BuLi / BnBr with EP-CO-derived polymethoximes **6** (m = 0.99, n = 0.01) and **6** (m = 0.85, n = 0.15) proceeded in a similar manner to afford modified polymers **24** and **25**. On the basis of the deuterium exchange experiments it is presumed that for all the alkylated polymers the substituents are introduced *syn* to the methoximino group.

In conclusion, the conversion of the ketone groups in alkene–carbon monoxide copolymers to methoximes allows directed α-substitution reactions to be carried out on the polymer backbone. Previous modification reactions have all involved functionalisation at the carbonyl groups; the results described above therefore represent the first examples involving reaction at the alkene units. It is anticipated that a range of novel polymers will be accessible by reaction with appropriate electrophiles.

We thank BP Chemicals for the supply of the ethene/propene–carbon monoxide alternating copolymers, and the Royal Thai Government for a Scholarship (P. K.).

Exchange reaction of a decanethiol self-assembled monolayer with porphyrin disulfides observed by surface plasmon enhanced fluorescence spectroscopy

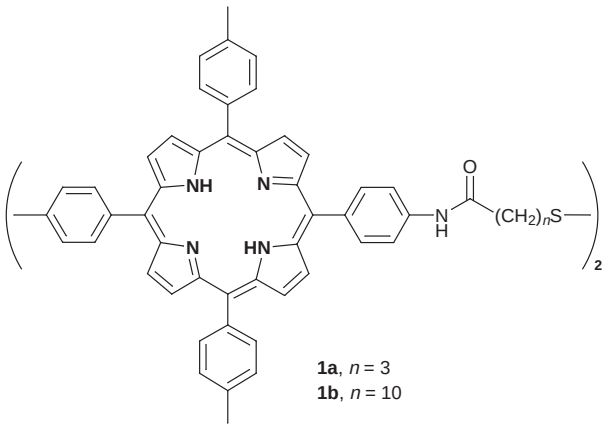
Akito Ishida* and Tetsuro Majima

The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka 8-1, Ibaraki, Osaka 567-0047, Japan. E-mail: ishida@sanken.osaka-u.ac.jp

Received (in Cambridge, UK) 27th April 1999, Accepted 8th June 1999

The treatment of a decanethiol SAM with a solution of a porphyrin disulfide gives a SAM inlaid with the porphyrin chromophores adopting J-aggregate-like partially stacked and well oriented structures by site-selective exchange reaction in the SAM.

Molecular exchange in a self-assembly monolayer (SAM) is a fundamental subject of surface science, and experimental[1–4] and theoretical[5] approaches to the reaction process have been developed. Here, we report the exchange reactions of decanethiol SAMs with porphyrin disulfides having trimethylene (**1a**) or decamethylene (**1b**) chains using surface plasmon (SP)



1a, $n = 3$
1b, $n = 10$

enhanced fluorescence spectroscopy.† SP is an effective excitation method for photo-functional molecules on a gold or silver film to give enhanced fluorescence,[6–8] and we employed p-polarization to observe the anisotropy‡ as well as other fluorescence properties.

Decanethiol SAMs were prepared by immersion of bare gold films on BK-7 right-angle prisms in a 1 mmol dm^{-3} 1,2-dichloroethane (DCE) solution of decanethiol for 5 h. The resulting decanethiol SAMs were then very carefully immersed into 50 μmol dm^{-3} DCE solutions of **1a** or **1b**, for a suitable time. After carefully washing the surface with DCE, the fluorescence properties were measured by SP excitation in air.[6] Fig. 1 shows changes in the fluorescence properties for the exchange reaction of decanethiol SAMs by **1a** and **1b**, as a function of the immersion time. The remarkable differences demonstrate that the exchange efficiency as well as the motion of the *transplanted* porphyrin chromophores in the SAM depended strongly upon the methylene chain length of **1**.

Very weak fluorescence of the porphyrin with rather large anisotropy was observed independently of the immersion time for **1a** even after a few minutes. This indicates that no exchange reaction with **1a** occurred except for fast exchange in a few minutes. It is well known that decanethiol gives a very tight and densely packed SAM on a flat gold surface. The trimethylene chains of **1a** are too short to penetrate the decanethiol SAM for interaction between the disulfide group and the surface and thus **1a** did not induce an exchange reaction.§

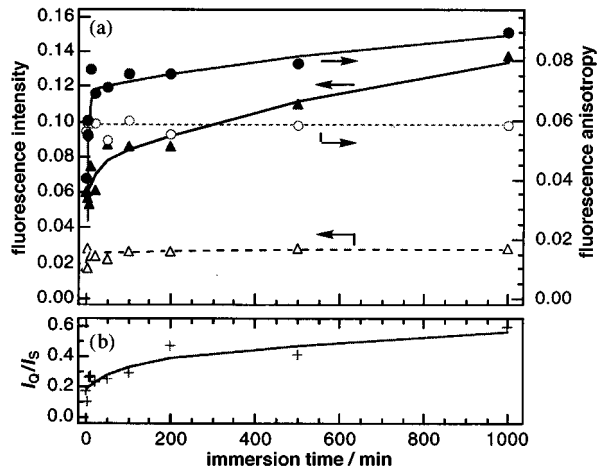


Fig. 1 Changes in the fluorescence properties for the exchange reaction; (a) anisotropy: (○) **1a**, (●) **1b** and intensity (△) **1a**, (▲) **1b**; (b) intensity ratio between the Soret and Q-bands (I_Q/I_S) of the excitation spectrum for **1b**. An almost constant I_Q/I_S value of 1.5 was observed for **1a**.

The very weak fluorescence observed for **1a** is probably attributed to the very small numbers of porphyrin-linked trimethylenethiol groups attached on the gold surface at defects in the decanethiol SAM. Because the porphyrin-linked trimethylene thiols have capped the defects, no further exchange reaction can occur.

In sharp contrast to **1a**, significant increases of fluorescence intensity and anisotropy were observed for **1b** at an initial immersion time of 50 min. These changes demonstrate effective exchange by **1b**, and the resulting porphyrin-linked decanethiols in the SAM are gradually ordered and lose their freedom of motion as the exchange reaction proceeds. The increase of the anisotropy can be rationalized by the increase of π–π stacking of the porphyrin chromophores which causes a characteristic change in the absorption spectrum. This is reflected in the SP enhanced fluorescence excitation spectra shown in Fig. 2.

The Q-bands increased strikingly with increased the immersion time.¶ It is well known that the π–π stacking of porphyrins

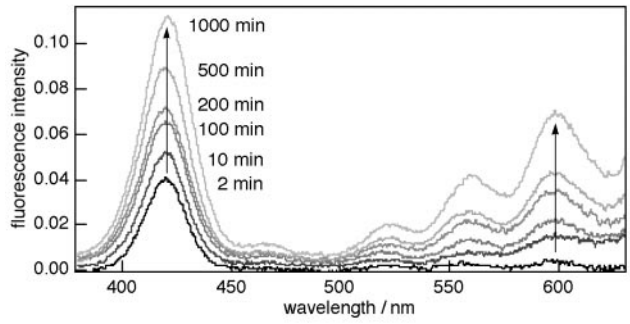

Fig. 2 Changes in the SP enhanced fluorescence excitation spectra for the exchange reaction of a decanethiol SAM with a 50 μmol dm^{-3} DCE solution of **1b** (λ_{em} = 725 nm; λ_{ex} = 425 nm).

reduces the intensity of the Soret band and that the relative ratio between the Soret and Q-bands (I_Q/I_S) increases.[9] Therefore, the changes in the excitation spectra demonstrate that the initially formed monomeric porphyrin-linked decanethiols in the SAM gradually change to a stacked structure as the exchange reaction proceeds. Because the excitation spectrum after 1000 min immersion shows maxima of the Soret bands at 420 and 470 nm, the porphyrin chromophores seem to adopt partially stacked structures similar to J-aggregates.[9] The increase of the fluorescence anisotropy is attributable to the increase of well oriented stacked structures which are more inflexible than the monomeric porphyrin chromophores.

Two possible mechanisms are presumed for the gradual stacking; (i) lateral migration of the porphyrin-linked decanethiol units exchanged at random in the SAM,‖ or (ii) site-selective exchange reaction nearby initially exchanged porphyrin-linked decanethiols. We have carried out the successive exchange reaction using a zinc complex of **1b** (**1b**–Zn) followed by **1b**. A decanethiol SAM was immersed into a 50 μmol dm^{-3} DCE solution of **1b**–Zn for 3 min and the resulting SAM showed characteristic fluorescence of the Zn–porphyrin (Fig. 3). This SAM was then immersed into a 50 μmol dm^{-3} DCE solution of **1b** for 30 s. After this treatment, the fluorescence of the Zn–porphyrin completely disappeared and was replaced by fluorescence of the free-base porphyrin (Fig. 3). This demonstrates fluorescence resonance energy transfer (FRET) from the Zn–porphyrin chromophores to the neighboring free-base porphyrin chromophores which have a lower singlet excitation energy than that of the Zn–porphyrin.** Because the efficiency of FRET is highly dependent upon the distance between the donor and acceptor, the free-base porphyrin chromophores must be exchanged nearby the Zn–porphyrin chromophores. The small numbers of initially exchanged porphyrin chromophores are likely to disturb the surrounding decanethiol SAM so leading to active sites, or act to increase the local concentration of **1b** by π–π interactions.

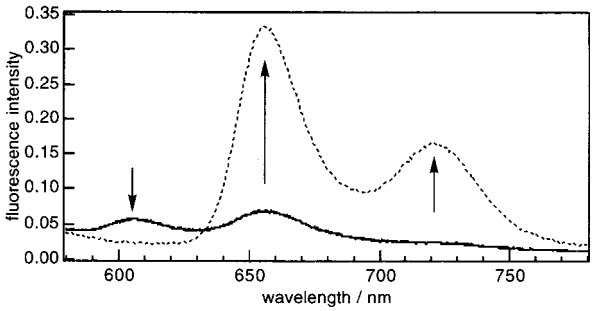

Fig. 3 The fluorescence spectra of the decanethiol SAM exchanged by a 50 μmol dm^{-3} DCE solution of **1b**–Zn for 3 min before (——) and after (- - - -) successive treatment with a 50 μmol dm^{-3} DCE solution of **1b** for 30 s (λ_{ex} = 420 nm).

We have demonstrated that the treatment of a decanethiol SAM with **1b** gives a SAM inlaid with the porphyrin chromophores adopting J-aggregate-like partially stacked and well oriented structures by site-selective exchange reaction.

M.), and Research Area of 'Fields and Reactions' in PRESTO Project of JST Corporation (A. I.), NEDO (A. I.), and the Kansai Research Foundation (A. I.).

Notes and references

† The porphyrin disulfides were synthesized and purified by reported procedures (T. Akiyama, H. Imahori and Y. Sakata, *Chem. Lett.*, 1994, 1147). A 50 nm gold film was directly evaporated on the hypotenuse face of a 15 × 15 × 15 mm BK-7 right-angle prism at a pressure of $< 6 \times 10^{-4}$ Pa, rinsed with 1,2-dichloroethane (DCE) and dried in class-100 air.

‡ The degree of polarization (r) of the β bands are calculated by the fluorescence intensities at parallel ($I_{\|}$) and perpendicular ($I_{\perp}$) polarizer configurations as $r = (I_{\|} - I_{\perp}) / (I_{\|} + 2I_{\perp})$.

§ The inefficient exchange reaction of **1a** may also be a consequence of **1a** having an odd number of methylene units. This may result in steric or kinetic barriers such as unfavorable orientation of the porphyrin chromophores of **1a** initially adsorbed in the decanethiol SAM.

¶ The fluorescence excitation spectrum of a porphyrin SAM by SP excitation shows enormous magnification of the Q-bands compared with the absorption and excitation spectra by direct photoirradiation on the surface due to the field enhancement effect which is much more considerable for the wavelength region of the Q-bands than that of the Soret-band.[6]

‖ The treatment of a bare gold surface with a mixture of **1b** and **1b**–Zn gave a SAM containing both of the chromophores in the same ratio as in the original mixture which suggests similar exchange rates for **1b** and **1b**–Zn. Consequently, we can rule out the possibility that the initially exchanged Zn–porphyrin-linked decanethiol units may be selectively forced out by added **1b** resulting in disappearance of the fluorescence.

** The changes in the fluorescence properties of the decanethiol SAM after 5 min immersion in a solution of **1b** were observed in air. After 15 h, small increases in the anisotropy and enhancement of the Q-bands were barely observed. This suggests that the lateral migrations of the porphyrin-linked decanethiols in the decanethiol SAM proceed slowly in air.

The restoration of pyrene fluorescence of a Cu^{II}–β-cyclodextrin–pyrene complex

Swadeshmukul Santra, Peng Zhang and Weihong Tan*

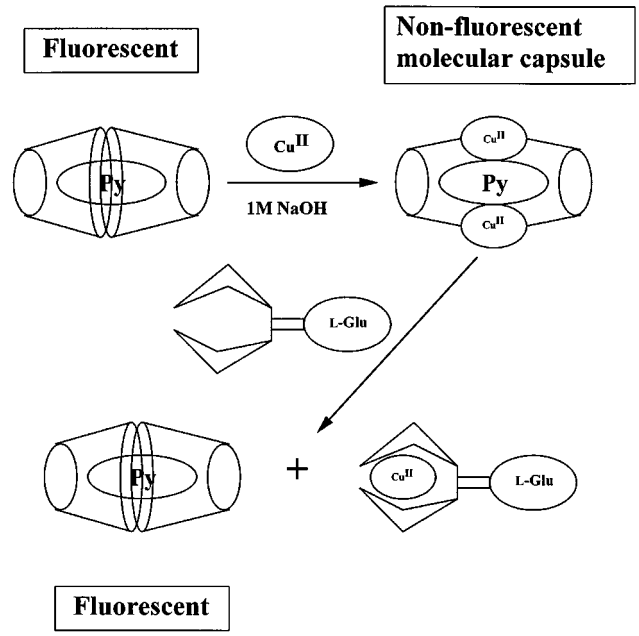
Received (in Corvallis, OR, USA) 23rd April 1999, Accepted 3rd June 1999

A new photochemical mechanism has been developed to restore the fluorescence of an interesting complex of copper ion–pyrene–cyclodextrins upon interaction with glutamate.

We describe a new photochemical mechanism to restore the fluorescence of an interesting complex of copper(II) ion–cyclodextrin–pyrene upon interaction with glutamate. This process will enable us to understand cyclodextrin (CD) based chemistry and to develop novel techniques for amino acid analysis. Cyclodextrins have been widely used in many areas including chemistry, material science and biotechnology.[1,2] They are sugar molecules having the structure of a hollow truncated cone with a hydrophobic cavity. Cyclodextrins (host) are capable of encapsulating appropriately sized fluorophores (guest) in their hydrophobic cavity by forming inclusion complexes.[1,2] These complexes can be formed based on four possible intermolecular interactions.[2] The inclusion of pyrene molecules inside the cavity of cyclodextrins has been well-studied.[3,4] Upon inclusion of a fluorophore, CDs offer a more protective microenvironment and generally enhance the luminescence of the guest molecule by shielding the excited species from quenching and non-radiative decay processes that occur in bulk solution. In general, the guest molecule loses its solvation sphere upon entering the cyclodextrin cavity, and solvent molecules are simultaneously expelled out from the cavity. On the other hand, copper(II) (Cu^{2+}) ions can (i) quench the fluorescence *via* a photo-induced electron transfer process which involves a transfer of electron from the fluorophore in the excited state to the metal ion;[5] (ii) form complexes with CDs in alkaline solutions;[6] and (iii) bind with L-glutamate,[7] a tridentate ligand. Cu^{2+}–CD complexes are capable of binding organic molecules in the cavity,[8] and Cu^{2+} can bind strongly with EDTA in alkaline media leaving free CDs in solution.[9]

Here we report a new mechanism for fluorescence enhancement based on the above-described chemical reactions taking place in aqueous media. A new Cu^{2+}–β-CD–pyrene ternary complex is prepared in which the pyrene fluorescence is quenched by the Cu^{2+} ion, as shown in Scheme 1. Cu^{2+} is weakly bound to the deprotonated secondary hydroxy groups of β-CD.[6] It is expected that strong chelating agents, such as amino acids, will bind to the Cu^{II} complex, leaving free β-CD–pyrene and resulting in fluorescence restoration. We have chosen glutamate, a major excitatory neurotransmitter in the central nervous system,[10] as an example to demonstrate the principle that the ternary complex has strong capability of binding amino acids. The restoration of the pyrene fluorescence in this study is accomplished upon the addition of glutamate.

To demonstrate the principle, we have used a fluorescence spectroscopic method to characterize the complexes synthesized at different stages of the chemical reactions shown in Scheme 1. All the experiments were done at room temperature using a Perkin-Elmer Luminescence Spectrometer [Model LS 50B, UK]. Fluorescence spectra of the solutions prepared at different stages of the process were recorded with the same pyrene concentration of 2×10^{-8} M. First, a stock solution of pyrene was prepared in cyclohexane. A calculated amount of the pyrene stock solution was added to a cuvette, and the cyclohexane was evaporated by dry nitrogen. A trace amount of pyrene was thus obtained for the preparation of experimental solutions for spectroscopic analysis. The solutions were stirred for 24 h and 12 h before and after, respectively, the addition of the required amount of solid β-CD to make its concentration in the solution 0.01 M. It was assumed that pyrene molecules were completely dissolved in all solutions. Fig. 1(*a*) and (*b*) show an almost two-fold fluorescence enhancement of the pyrene emission in β-CD [Fig. 1(*b*)] when compared to the free pyrene emission in 1 M NaOH solution [Fig. 1(*a*)]. Second, we added 0.01 M Cu^{2+} solution [$CuSO_4 \cdot 5H_2O$] to the above complex solution followed by stirring for 2 h. No precipitate of $Cu(OH)_2$ was observed and the resulting complex formed in the solution (deep blue in color) was non-fluorescent, as shown by Fig. 1(*c*). The enhanced fluorescence of pyrene complexed with β-CD was quenched by Cu^{2+} due to electron transfer. In the third step, glutamate was added to the same solution. The fluorescence spectrum of the resulting new solution is shown in Fig. 1(*d*). It is clear that the addition of glutamate to the complex solution resulted in complete restoration of pyrene fluorescence. This restoration is due to the removal of Cu^{2+} from the ternary complex. The pyrene fluorescence band is slightly distorted in Fig. 1(*d*), showing a larger full width at half maximum (FWHM). Although the vibrational structure of the pyrene fluorescence bands remained intact, their relative intensity ratios varied when compared to those of free pyrene, and pyrene encapsulated inside the β-CD cavity. The strongest vibrational peak of the pyrene fluorescence band at 374 nm became a shoulder after the complex interacted with glutamate. We also obtained excitation spectra for all the solutions at different stages of the process, as shown in the left side of Fig. 1. Overall,



Scheme 1 Proposed mechanism for the formation of a ternary Cu^{2+}–β-CD–pyrene molecular capsule and the restoration of pyrene fluorescence upon interaction with glutamate.

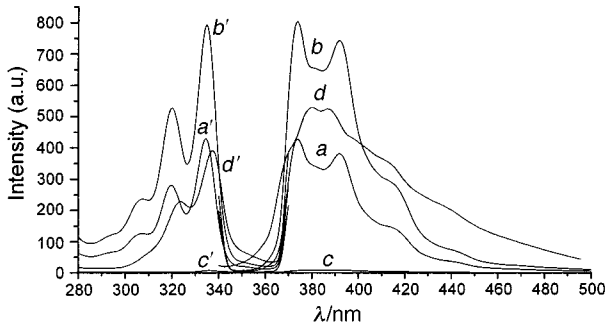


Fig. 1 Fluorescence emission spectra [λ_{exc} = 335 nm] (right) and fluorescence excitation spectra [λ_{em} = 374 nm] (left); (*a*) and (*a*′): free pyrene [*A* = 16018 au]; (*b*) and (*b*′): pyrene encapsulated in β-CD (0.01 M) cavity [*A* = 31346 au]; (*c*) and (*c*′): in the presence of 0.01 M Cu^{II} [*A* = 412 au]; (*d*) and (*d*′): after addition of 1.87 M glutamate [*A* = 30566]; [pyrene] = [2×10^{-8} M] and *A* = 392 au for the background. *A* is the uncorrected total area under the pyrene fluorescence band.

similar results to those from the fluorescence spectra were obtained. This further supports the proposed mechanisms of this series of chemical reactions. The total area under the fluorescence band for the restored emission and the emission before Cu^{2+} addition were the same. Based on the total area under each emission band as shown in Fig. 1, there is a more than 1500 times {(30566 − 392)/(412 − 392) = 1510} enhancement of fluorescence yield. This result clearly shows that there is no loss of fluorescence yield even in the solution phase, where there is a huge amount of other ionic substances. It is thus expected that an amino acid sensor, such as a glutamate sensor, developed in this manner will be highly sensitive.

One of the most important steps in this series of chemical reactions is the quenching of fluorescence by Cu^{2+}. One key question that has to be answered is how much Cu^{2+} has to be added to the complex solution in order to totally quench the pyrene fluorescence. We thus studied the effect of [Cu^{2+}] on the quenching of pyrene fluorescence. Fluorescence spectra of the complex solutions with various amounts of Cu^{2+} were taken, and the fluorescence intensity at 374 nm was used to monitor the effect of Cu^{2+} on pyrene fluorescence quenching. As shown in Fig. 2, pyrene emission decreased exponentially as the [Cu^{2+}] increased to about 0.01 M. There was no change essentially in fluorescence intensity as more Cu^{2+} was added to the solution. 0.01 M happened to be the concentration of β-CD in the complex solution. This suggests the stoichiometry of the formation of the Cu^{2+}–β-CD complex be of 1:1. Further increase of [Cu^{2+}] led to its precipitation as $Cu(OH)_2$. Based on the crystal structure of β-CD–pyrene–alcohol complex,[11] we thus propose a 2:2:1 Cu^{2+}–β-CD–pyrene molecular capsule, as shown in Scheme 1. The reaction between glutamate and the ternary complex in solution could take place in a single step (glutamate binds directly with the ternary complex) or in two steps (glutamate binds with the free Cu^{2+} ion which is in equilibrium with the ternary complex). Detailed kinetic measurements are being carried out to understand both the quenching and the restoration mechanisms.

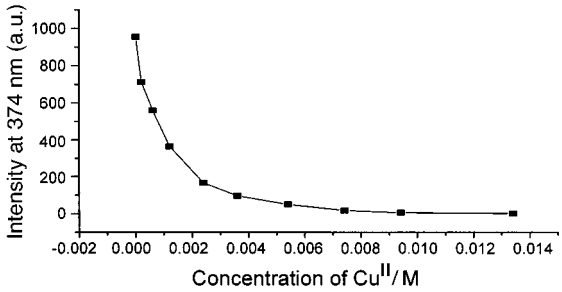

Fig. 2 Effect of copper ion concentration on the fluorescence intensity of pyrene emission in the β-CD–pyrene inclusion complex.

When different amounts of glutamate were used to restore the pyrene fluorescence, we observed a dramatic increase in fluorescence of pyrene in the complex solution. This provides an essential basis for designing a Cu^{2+}–β-CD–pyrene based bioanalysis assay for amino acids. Presently a few strategies are being pursued to take advantage of the dramatic rise of the restored fluorescence to achieve excellent detection capability. The selectivity for individual amino acid analysis could appear as a major disadvantage of this mechanism. But some of our preliminary studies have revealed that different amino acids have different binding capabilities with the copper(II) ion. We have also found that the same ternary copper(II) complex displays different sensitivity ranges for different amino acids. It is thus possible that ultrasensitive assays could be developed for glutamate and other interesting neurotransmitters. Another possible application of this photochemical mechanism could be amino acid analysis by capillary electrophoresis or HPLC using the ternary complex by either on-column or post-column reactions. We will also explore optical fiber technology to covalently bind the ternary complex for biosensor development.[12]

In conclusion, we report here for the first time the restoration of pyrene fluorescence in a Cu^{2+}–β-CD–pyrene ternary complex upon interaction with glutamate. The restoration is complete and fast. Based on Cu^{2+} concentration experiments, we have proposed a feasible molecular interaction mechanism of the complexes formed *via* a few interesting chemical reactions. The Cu^{2+}–β-CD–pyrene complex has a molecular ratio of 2:2:1. The formation of the ternary complex and the restoration of pyrene fluorescence by glutamate demonstrate the feasibility of a bioanalysis technique for the detection of glutamate and other similar ligands. The principle operates similarly to a molecular beacon (non-fluorescent probe) used for the detection of DNA sequences in the target through a hybridization process followed by the restoration of quenched fluorescence.[13] The chemistry involved in the present technique is relatively simple. Synthesis of the complex capsule can be carried out in the solution phase which should facilitate the usage of this capsule as a biosensor for *in vivo* glutamate monitoring. This inclusion system may also become a new model for multifactorial biological systems for molecular recognition and for mimicking active transport or concentration of substances.

Received (in Basel, Switzerland) 7th April 1999, Accepted 31st May 1999

Micrometer sized crystals of close packed $Au_{55}(PPh_3)_{12}Cl_6$ clusters are formed from dichloromethane solution and are investigated by transmission electron microscopy and small angle X-ray diffraction.

After a period of almost 20 years of investigation of the cluster compound $Au_{55}(PPh_3)_{12}Cl_6$ since its first synthesis we have now succeeded in making microcrystals in preparative amount. Transmission electron microscopic studies and small angle X-ray diffraction indicate a simple close packed arrangement of the spherical clusters correlating with an effective cluster distance of 2.3 nm in very good agreement with the actual cluster size of 2.1–2.2 nm.

The cluster compound $Au_{55}(PPh_3)_{12}Cl_6$ was first described in 1981.[1] In the meantime a large number of papers followed, describing its chemical and physical properties.[2–8] The compound became of extraordinary significance owing to its quantum size behavior. With respect to this property Au_{55} clusters are the most promising particles for applications in future nanoelectronics.[9]

The development of the physical and chemical characteristics of the easily available $Au_{55}(PPh_3)_{12}Cl_6$ cluster[10] was accompanied by the disadvantage of its non-crystalline nature. Thus, solid state investigations had to be performed with pellets or thin layers. Investigations of solutions suffered from their ready decomposition so that much effort has been required to reach our present knowledge of this cluster.

We have now succeeded in obtaining microcrystals of $Au_{55}(PPh_3)_{12}Cl_6$ in preparative quantities. The reason for having failed to obtain such crystalline particles previously is simply because they are too small to be distinguished directly and because long-standing electron microscopic investigations were exclusively focused on the imaging of single clusters from very dilute solutions. However, fast evaporation of the solvent from concentrated dichloromethane solutions of $Au_{55}(PPh_3)_{12}Cl_6$ results in the formation of well shaped crystals in the size range of hundreds of nanometers up to a few micrometers. Transmission electron microscopy (TEM) and small angle X-ray diffraction (SAXRD) of such microcrystals were used to establish their structure. Samples for the TEM investigations were simply prepared from a drop of a saturated solution of $Au_{55}(PPh_3)_{12}Cl_6$ in CH_2Cl_2 added onto the grid. After evaporation of the solvent the TEM images showed well shaped, mainly hexagonal, crystals (Fig. 1).

In contrast to the case of dilute solutions, only a few single clusters could be observed. Magnification of such crystals established their monocrystalline character. The high magnification of a crystal edge in Fig. 2, thin enough for TEM, allowed the determination of more structural details.

The distance between parallel columns is 2.0–2.1 nm. Supposing a fcc arrangement of the clusters, this distance corresponds to an effective cluster distance of 2.3–2.4 nm, in good agreement with the calculated cluster diameter if van der Waals distances between the PPh_3 ligands of neighboring clusters are considered. Cluster distances of 2.3 nm could also directly be determined from the TEM image in Fig. 2. Fig. 3

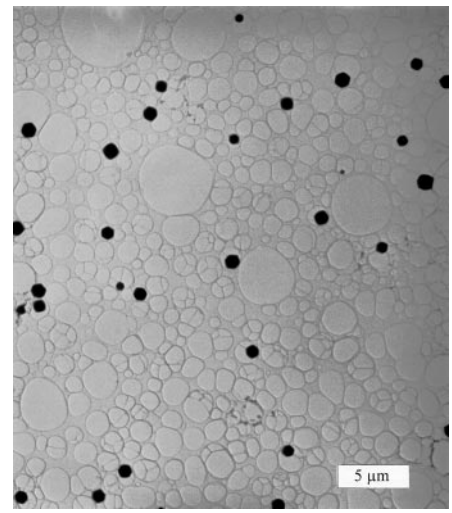

Fig. 1 Transmission electron microscopic (TEM) image of well shaped microcrystals of $Au_{55}(PPh_3)_{12}Cl_6$. Most of the crystals are *ca.* 1 μm in diameter.

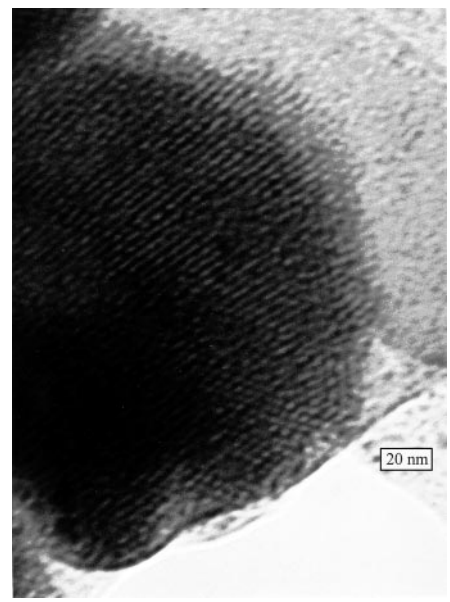

Fig. 2 High resolution TEM image of a $Au_{55}(PPh_3)_{12}Cl_6$ microcrystal. The monocrystalline particle shows cluster rows with a separation of 2.0–2.1 nm in accord with a hexagonal close-packed arrangement of the spherical clusters. The cluster distance can be determined as 2.3 nm.

† Dedicated to Professor Helmut Werner on the occasion of his 65th birthday.

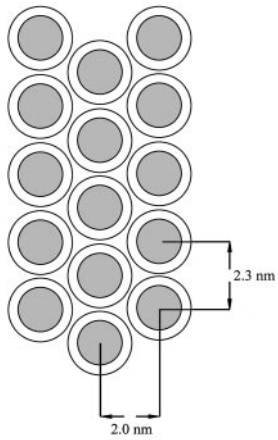

Fig. 3 Schematic view of the cluster arrangement in the microcrystals.

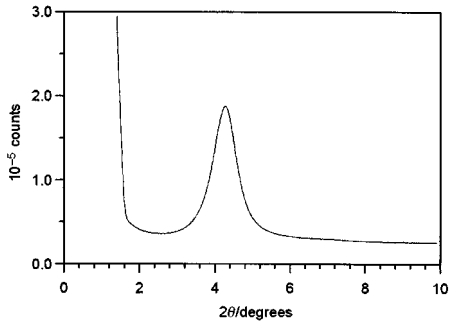

Fig. 4 Result of small angle X-ray diffraction (SAXRD) measurements on $Au_{55}(PPh_3)_{12}Cl_6$ microcrystals. The 2θ angle of 4.3° corresponds to a *d* value of 2.05 nm, in accord with the TEM results.

schematically represents the situation observed in the high resolution TEM images.

Samples for SAXRD experiments have also been prepared by fast evaporation of the solvent of concentrated dichloromethane solutions of $Au_{55}(PPh_3)_{12}Cl_6$. The black powder consisted almost exclusively of microcrystals as shown in Fig. 1. The result of the SAXRD experiments is shown in Fig. 4.

Only one strong reflection of 2θ = 4.3° is registered, corresponding to a *d*-value of 2.05 nm in accord with the average distance from TEM of 2.05 nm. This might correspond to a hexagonal close packing, if observed along the [111] direction.

Based on our knowledge of the quantum size behavior of individual clusters, the availability of nanocrystalline microcrystals now opens new routes for their use in three-dimensional single electron tunneling (SET) devices. A crystal of the size of $1 \times 1 \times 1$ μm contains *ca.* 10^8 clusters. The combination of such microcrystals by appropriate linkers is in principle possible and so could be a vehicle to a future nanotechnology.

Notes and references

‡ *Sample preparation*: the synthesis of $Au_{55}(PPh_3)_{12}Cl_6$ was carried out following ref. 10. For TEM investigations, a drop of a concentrated solution of $Au_{55}(PPh_3)_{12}Cl_6$ in dichloromethane, was added onto a carbon covered grid and dried. SAXRD measurements were performed with the powdery cluster material as synthesized.

TEM images were accomplished with a Philips FEG CM 200 microscope while for SAXRD measurements a Siemens D 5000 was used.

An open-framework iron phosphate with large voids, exhibiting spin-crossover

Amitava Choudhury,[ab] Srinivasan Natarajan[a] and C. N. R. Rao*[ab]

[a] *Chemistry and Physics of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Jakkur P.O., Bangalore 560 064, India. E-mail: cnrrao@jncasr.ac.in*

[b] *Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore 560 012, India*

Received (in Cambridge, UK) 7th May 1999, Accepted 8th June 1999

A novel iron phosphate, $[(C_4N_3H_{16})(C_4N_3H_{15})]^{5+}$-$[Fe_5F_4(H_2PO_4)(HPO_4)_3(PO_4)_3]^{5-}\cdot H_2O$, consisting of a Fe–O/F–Fe network crosslinked by PO_4 groups is shown to possess unusually large elliptical voids of 24 T atoms (T = Fe, P) and to exhibit a gradual low- to high-spin transformation.

Amongst the variety of open-framework metal phosphates investigated in recent years, those of transition metals are of particular interest not only because of the novelty in their structures, but also because of their properties of potential value. One of the important objectives in synthesizing open-framework transition metal phosphates is the possibility of obtaining new solids with novel magnetic properties. Several open-framework iron phosphates have been synthesized and characterized in recent years,[1–3] but most of them order antiferromagnetically with the exception of one, which shows ferrimagnetic behavior at low temperatures.[4] Open-framework cobalt phosphates also order antiferromagnetically.[5] We have synthesized a new iron phosphate, exhibiting spin-crossover, which is rather unusual in an oxidic material. The material also has several noteworthy structural features which include the presence of infinite Fe–O/F–Fe chains, large voids formed by 24 T atoms (T = Fe, P), crosslinking by PO_4 tetrahedra.

The new iron phosphate $[(C_4N_3H_{16})(C_4N_3H_{15})]^{5+}[Fe_5F_4(H_2PO_4)(HPO_4)_3(PO_4)_3]^{5-}\cdot H_2O$ **I**, was prepared by employing hydrothermal methods in the presence of diethylenetriamine (DETA).† The light green colored crystals of **I** belonged to the monoclinic space group $P2_1/n$ and since the asymmetric unit of **I** contains 59 non-hydrogen atoms and it is convenient to describe the structure in terms of small building blocks. The three-dimensional structure of **I** can be considered as made from layers along the [001] direction, consisting of a network of FeO_6, FeO_5F and FeO_4F_2 octahedra and PO_4 tetrahedra (Fig. 1). The framework has the formula $[Fe_5F_4(H_2PO_4)(HPO_4)_3(PO_4)_3]^{5-}$. Charge neutrality is achieved by the presence of the organic structure-directing amine (DETA) in its protonated form. There are two molecules of DETA in the unit cell, one triply protonated and the other doubly protonated. The layers are connected to each other *via* phosphate groups, completing the three-dimensional architecture (Fig. 2). This connectivity creates large elliptical voids bound by 24 T atoms (T = Fe, P) forming one-dimensional channels along the [010] direction, within which the DETA and water molecules reside. The width of the channels is 15.3 × 4.5 Å (longest and shortest atom—atom contact distances, not including van der Waals radii). To our knowledge, this is the first open-framework iron phosphate material with such large voids. The layers themselves contain pores bound by 8 T atoms (T = Fe, P) and the H_2PO_4 groups protrude into this opening rendering the pores inaccessible. Along the [100] direction, the structure has another narrow channel bound by 16 T atoms and the protruding H_2PO_4 and HPO_4 moieties occupy this channel.

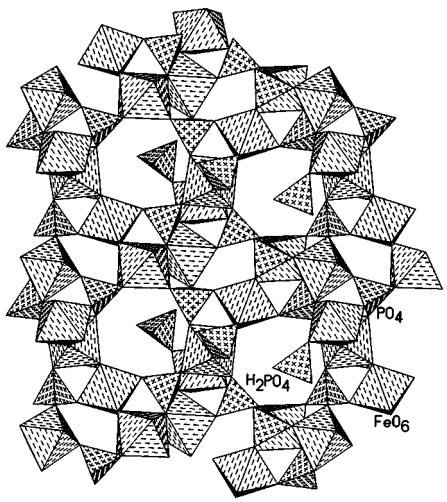

Fig. 1 Layer type arrangement in **I** along the [001] direction. Note that the H_2PO_4 moieties project into the eight-membered pores within the layers.

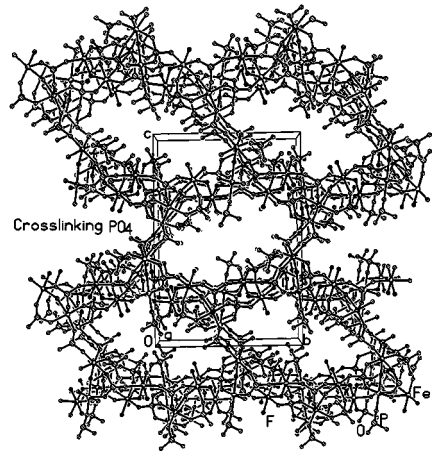

Fig. 2 Structures of **I**, showing large elliptical tunnels along the [010] direction. Note that the walls of the tunnels are composed of PO_4 tetrahedra. Amine and water molecules are not shown for clarity.

The most striking aspect of the structure of **I** is the cationic sub-network of Fe atoms. The connectivity between the various iron–oxygen(fluorine) octahedra is such that infinite Fe–O/F–Fe polymeric chains are formed as shown in Fig. 3(a). This network results from the presence of three-coordinate oxygen atoms and fluorine bridges in the structure. The Fe–O/F–Fe polymeric chains and the phosphate tetrahedra are so connected as to give rise to channels which appear as though they are decorated by PO_4 tetrahedra. This material may, thus, be considered to be an infinite iron–oxy fluoride network, $Fe_2O_{3-x}F_x$($x \leqslant 0.4$), crosslinked by the phosphate groups. Pillaring of layers in framework solids is not common, the only such material being an indium phosphate,[6] where the pillaring is by InO_6 octahedra. The crosslinking by PO_4 tetrahedra found in **I** is analogous to the pillaring in the indium phosphate.[6]

Besides its novel structural features, the iron phosphate **I** also exhibits unusual magnetic properties. Magnetic susceptibility measurements show that the magnetic moment increases gradually from 2.0 μ_B around 20 K to *ca*. 6.0 μ_B around 250 K [Fig. 3(b)]. The low-temperature moment corresponds to that of low-spin Fe^{III} ($^2T_{2g}$) and the high-temperature moment to that of

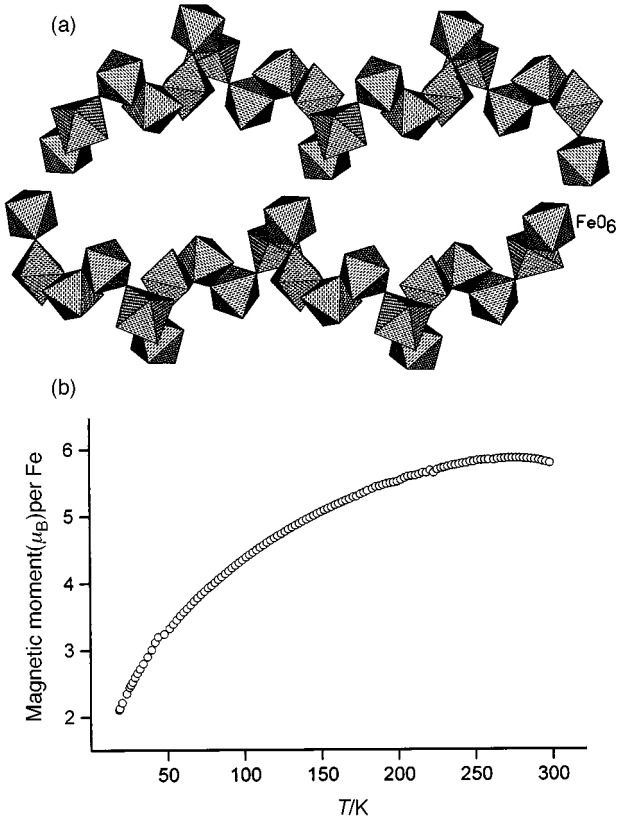

Fig. 3 Network of Fe–O/F octahedra along the [100] direction. The network shows strong anisotropy and is crosslinked by PO_4 tetrahedra (not shown). (b) Temperature variation of the magnetic moment.

high-spin Fe^{III} ($^6A_{1g}$). The variation of the magnetic moment [Fig. 3(b)] is characteristic of a gradual spin-crossover similar to that found in some iron(III) complexes.[7] Mössbauer spectra recorded at 298 and 50 K show the presence of the high- and low-spin Fe^{III} ions, respectively, with characteristic differences in the isomer shift and the quadruple splitting (δ = 0.32, 0.1 and ΔE_Q = 0.34, 1.03 mm s^{-1}). The occurrence of spin-crossover in Fe^{III} ions in an oxide material is rather unusual and suggests that the possibility of internal pressure being exerted on the Fe–O polyhedra.

In summary, the synthesis of a novel open-framework iron phosphate with interesting structure and magnetic properties has been accomplished. The presence of Fe–O/F–Fe chains and large one-dimensional channels decorated by phosphate groups are two of the novel features of the material. The occurrence of a smooth magnetic spin-crossover as a function of temperature is noteworthy in that iron(III) oxides generally have Fe^{III} in the high-spin state.

Notes and references

† The title compound was synthesized from an iron phosphate gel containing DETA as a structure-directing agent. iron(III) chloride, phosphoric acid (85 wt%), DETA, HF and water in a ratio 1:6:3:1:200 were mixed and stirred until homogeneous. The mixture was sealed in a 23 ml Teflon-lined, stainless steel autoclave (Parr, USA) and heated at 180 °C for 72 h. The resulting product, containing predominantly light green crystals, was filtered off and washed thoroughly with deionized water. A suitable single crystal (0.06 × 0.06 × 0.08) was carefully selected under a polarizing microscope. The crystal structure determination was performed on a Siemens SMART CCD diffractometer equipped with a normal focus, 2.4 kW sealed-tube X-ray source (Mo-Kα radiation, λ = 0.71073 Å) operating at 50 kV and 40 mA. A hemisphere of intensity data were collected in 1321 frames with ω scans (width of 0.30° and exposure time of 30 s per frame).

Crystal data for $[(C_4N_3H_{16})(C_4N_3H_{15})]^{5+}[Fe_5F_4(H_2PO_4)(HPO_4)_3(PO_4)_3]^{5-}\cdot H_2O$, **I**: monoclinic, space group $P2_1/n$ (no. 14), a = 9.670(1), b = 15.618(1), c = 22.563(1), β = 90.82(1)°, V = 3407.1(1) Å^3, Z = 4, M = 1254.1, μ = 1.915 mm^{-1} and D_c = 1.836(1) g cm^{-3}. A total of 13848 reflections were collected at 298 K in the θ range 1.59–23.19° and merged to give 4844 unique data (R_{int} = 0.065) of which 3635 with $I > 2\sigma(I)$ were considered to be observed. The structure was solved by direct methods with SHELXS-86[8] and difference Fourier synthesis. Final R = 0.06, R_w = 0.13 and S = 1.13 were obtained for 541 parameters. Part of the hydrogen atoms were located initially in the difference Fourier maps and for the final refinements, hydrogen atoms for both the framework as well as the amine molecules were placed geometrically and held in the riding mode. Final Fourier map minimum and maximum: −1.009 and 0.908. Full-matrix least-squares structure refinement against $|F^2|$ were carried out with SHELXTL-PLUS program package.[9]

Received (in Corvallis, OR, USA) 23rd April 1999, Accepted 1st June 1999

One-pot synthesis of 5,10,15-triphenylcorrole has been achieved by reaction of benzaldehyde with an excess of pyrrole; the triphenylphosphinocobalt complex of 5,10,15-triphenylcorrole has been structurally characterized using X-ray crystallography.

5,10,15,20-Tetraphenylporphyrin **1** is probably the most ubiquitous synthetic porphyrin and it has often been utilized to study biomimetic and/or catalytic systems.[1,2] Its success in these roles is probably due to the relatively easy synthetic approach to **1**, which is obtained by condensation of pyrrole and benzaldehyde.[3] Since the first synthetic approach reported by Rothemund,[4] a huge number of studies related to the synthetic aspects of **1** have been reported in the literature.[3] Different reaction conditions have been utilized and the reaction mechanism has been minutely discussed, but until recently[5–9] the possibility that other macrocycles might be generated from this reaction had been ignored. This aspect has now been investigated and different macrocycles have been isolated and characterized from the Rothemund reaction; these include the 'N-confused'-porphyrin **2** (NC-TPP)[5,6] and 5,10,15,20-tetraphenylsapphyrin **3** (TPS)[7] from the standard pyrrole/benzaldehyde condensation, and a *meso*-hexa(pentafluorophenyl)hexaphyrin, in low yield, from a related reaction.[8] While a study by Lindsey and Geier established the scope of the formation of NC-TPP and TPS, additional pigments were observed but in very low yield and therefore were not characterized.[9]

During our studies on the chemistry of corrole, we reported the formation of a *meso*-phenyl-β-substituted corrole from the cobalt catalyzed cyclization of a hydroxybenzylpyrrole,[10] the first intermediate in the condensation of pyrrole and benzaldehyde. This result, and knowledge that the ring-expanded sapphyrin system was also isolated,[7] caused us to suspect that 5,10,15-triphenylcorrole **4** might also be another, albeit diminutive, product of the Rothemund reaction. Two examples of *meso*-substituted corroles have since been reported in the literature;[11,12] these corroles were obtained as by-products of the expected porphyrins in the reaction of pyrrole and aldehydes. These examples further supported our hypothesis that corroles might be obtained from the condensation of pyrrole and aldehydes, but because of the low yields and the particular aldehydes used, these results cannot be generalized. Here we report that, under certain defined conditions, triphenylcorrole **4** is formed in reasonable yield from the Rothemund reaction;† cobalt was easily inserted into **4** and the corresponding triphenylphosphino complex **5** was structurally characterized.

Pyrrole and benzaldehyde (3:1 molar ratio) were reacted in refluxing AcOH for 4 h with spectrophotometric monitoring. Following work-up and chromatographic separation on alumina, triphenylcorrole **4** was obtained in 6% yield (unoptimized) as red–green crystals. The expected tetraphenylporphyrin **1** was also obtained from this reaction in yields comparable with those of **4**, indicating that under these modified conditions the ring closure to corrole is competitive with the formation of the larger porphyrin macrocycle; trace amounts of NC-TPP were also observed. [5,6] When the reaction was carried out in propionic acid[14] (for 2 h) the yields of corrole were slightly lower. The choice of reaction conditions is critical for the formation of useful amounts of **4**.

The ^{1}H NMR spectrum of **4** shows broad AB patterns for the β-pyrrolic protons because of the reduced symmetry of the corrole ring. Spectrophotometry of **4** provided the optical spectrum shown in Fig 1. The Soret band appears at 416 nm (ε 101 000), without significant shift with respect to that of **1**; three

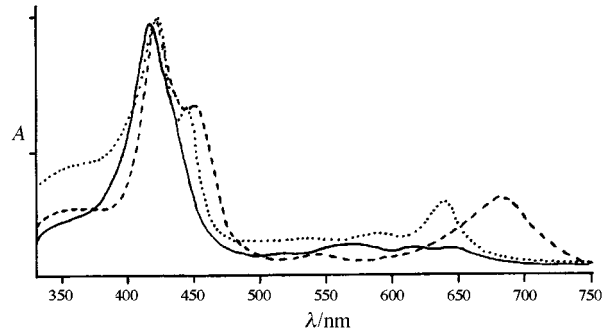

Fig. 1 Optical spectra of **4** in CH_2Cl_2 (solid line), in DMF (dotted line) and in AcOH (dashed line). Absorbances are normalized to their maxima.

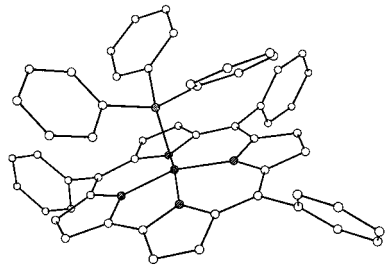

Fig. 2 Molecular structure of **5**; hydrogen atoms have been omitted for clarity.

broad Q bands are present in the 570–650 nm region. It is interesting to note that **4** is more acidic than the corresponding β-octaalkyl analogues[15] because DMF is sufficiently basic to give the corresponding monoanion derivative without addition of bases, as evidenced by the visible spectrum (Fig. 1) recorded in DMF. The same spectrum is obtained by addition of a few drops of base (NaOH 10% in water) to a methanolic solution of **4**. The monocation of **4** was formed in AcOH, as is also shown in Fig. 1. Addition of increasing amounts of H_2SO_4 to the AcOH solution of **4** led to further changes in the visible absorption spectrum; these indicated additional protonation processes which have not yet been characterized, but which do not involve disruption of the conjugated pathway (*i.e.* no removal of the Soret band). In the case of β-octaalkylcorroles[16,17] protonation at the 5-position in H_2SO_4 has been proposed on account of the disappearance of the Soret band in the electronic absorption spectrum.

The insertion of the cobalt(III) ion into **4** was performed by reaction of corrole and $Co(OAc)_2$ in refluxing MeOH in the presence of PPh_3 to give the corresponding complex **5** in 88% yield. The ^{1}H NMR spectrum of **5** is similar to that of **4**, but with more resolved resonances. The axial phosphine ligand shows three sets of resonances for the *ortho*, *meta* and *para* protons, in accord with observations in the corresponding β-octaalkylcorrole complexes,[10,18] indicating that the PPh_3 ligand does not suffer from steric interactions with the *meso*-phenyl groups.

The electronic spectrum of **5** shows a Soret band at 385 nm (ε 51 000) and a Q band centered at 561 nm (ε 11 500). Its EI mass spectrum shows an $[M - PPh_3]^+$ ion, while use of the FAB technique allowed observation of the molecular ion without loss of the axial ligand.

The structure of **5** was determined by X-ray crystallography.‡ Compound **5** was slightly non-planar with a 0.069 Å mean deviation of the macrocyclic atoms from the corrole mean plane. The conformation observed resembles the porphyrin-type dome conformation.[20] The central Co^{III} ion featured M–N bond lengths of 1.863(2), 1.891(2), 1.886(2) and 1.867(2) Å; the two shortest of these bonds involved the nitrogens adjacent to the C_α–C_α linkage. This is typical of metallocorroles and has been observed in the crystal structures of other corroles.[10,21] In **5**, the Co^{III} ion is displaced from the corrole mean plane by 0.389 Å and the Co–P bond length is 2.201(1) Å.

In conclusion, we have shown that the synthesis of **4**, even at only 6% yield, permits the corrole field to utilize and exploit a direct analogue of tetraphenylporphyrin; this should provide a starting point for further development of the comparative chemistry of this contracted macrocyclic system.

This work was supported by grants from CNR-Italy (MADESS II project no. 97.01380.PF48) and the US National Science Foundation (CHE-96-23117) and National Institutes of Health (HL-22252).

Notes and references

† After the present paper had been submitted and reviewed, a report of the synthesis of 5,10,15-tris(pentafluorophenyl)corrole from pyrrole and pentafluorobenzaldehyde appeared (ref. 13). These authors showed that using their conditions with pyrrole and benzaldehyde does not afford 5,10,15-triphenylcorrole (**4**). We thank a reviewer for informing us of the imminent publication of this article.

‡ *Crystal data* for **5**: Crystals were grown by slow diffusion of MeOH into a CH_2Cl_2 solution of **5** ($C_{55}H_{38}N_4PCo$). The selected crystal (0.28 × 0.52 × 0.54 mm) had a triclinic unit cell, space group $P\bar{1}$ and cell dimensions a = 8.5269(8), b = 13.1028(13), c = 18.161(2) Å, α = 94.284(8), β = 92.308(8), γ = 97.677(8)°, V = 2002.6(3) Å^3 and Z = 2 (FW = 844.8). Data were collected on a Siemens R3 m/V diffractometer with a sealed tube source [λ(Mo-Kα) = 0.71073 Å] at 130(2) K in ω scan mode to $2\theta_{max}$ = 55.0°. Of 9795 reflections measured (+h, ±k, ±l) all were independent and 7351 had $I > 2\sigma$ (T_{min} = 0.78, T_{max} = 0.89, ρ_{calc} = 1.40 g cm^{-3}, μ = 0.515 μ^{-1}). The structure was solved by direct methods and refined (based on F^2 using all data except for three suppressed reflections) by full-matrix least-squares methods with 550 parameters (Siemens SHELXTL ver. 5.03). Hydrogen atom positions were generated by their idealized geometry and refined using a riding model. An empirical absorption correction was applied (ref. 19). Final R factors were $R1$ = 0.041 (observed data) and $wR2$ = 0.112 (all data). CCDC 182/1277.

High separation selectivity with imperfect zeolite membranes

Elena Piera, Joaquin Coronas, Miguel Menéndez and Jesús Santamaría*

Department of Chemical and Environmental Engineering, University of Zaragoza, 50009, Zaragoza, Spain. E-mail: iqcatal@posta.unizar.es

Received (in Cambridge, UK) 16th April 1999, Accepted 8th June 1999

In spite of the presence of inter-crystalline defects, high selectivities can be obtained in the separation of gas phase mixtures with zeolite membranes.

The development and application of zeolite membranes constitutes a swiftly expanding area where the data published over a period of a few months often suffice to change the prevailing view on the status of development (population of defects, crystal orientation, *etc.*) of a specific family of zeolite membranes, or on the transport mechanism for a given separation. A well known example of the rapidly changing concepts in the field refers to the misnaming of zeolite membranes as molecular-sieving membranes. Nowadays there are numerous examples (see refs. *e.g.* 1–3) of 'reverse selectivity' membranes, *i.e.* membranes where the largest molecule is selectively separated because of preferential adsorption that leads to pore blockage.

Another widely used presumption in this area establishes that, if a high separation selectivity (a two to three-digit figure is often considered as sufficiently high) is observed, then one can claim that a 'defect-free' or 'almost defect-free' membrane has been obtained. This article deals with this perception by demonstrating that defective membranes are nevertheless capable of high separation selectivities, if tested under a suitable set of operating conditions.

The work was carried out using silicalite membranes, which are probably the most widely studied zeolite membranes. They were prepared by *in situ* hydrothermal synthesis onto stainless steel supports having 1 μm diameter pores. In order to confine the permeation area, the ends of the stainless steel porous supports (11 mm i.d., 16 mm o.d.) were soldered to non-permeable tubes of the same material and diameter.

The membranes were prepared by hydrothermal synthesis according to the directions in ref. 1, except that Aerosil 300 was used instead of Aerosil 130. The molar composition of the gel was: 21 SiO_2: 788 H_2O: 3, NaOH: 1 TPABr, (TPABr = tetrapropylammonium bromide). The gel was cloudy and thin, with a pH of 11.0. The support tube was wet with water, and then one end of the wet tube was wrapped with Teflon tape, plugged with a Teflon cap and filled with the synthesis gel. The other end was also wrapped with tape and plugged with another Teflon cap. The tube was placed vertically in a Teflon-lined autoclave, and the autoclave in a convection stove at 443 K for 8–15 h. XRD measurements (not shown) carried out on membranes synthesized using this procedure indicated that pure silicate was formed on the stainless steel support.

The separation measurements were performed with the membrane placed in a stainless steel separation module where it was sealed with silicone o-rings. The gaseous feed stream containing the desired partial pressure of TIPB (1,2,4,5-tetra-isopropylbenzene) or water and He was obtained by mixing in variable proportions two mass-flow controlled streams of He, one of which [82 cm^3(STP) min^{-1}] had been bubbled through TIPB or water saturators. The gas mixture was fed into the tube (retentate) side of the membrane, and allowed to permeate through the membrane wall. The permeate side was swept with 83 cm^3(STP) min^{-1} of carrier gas (N_2). Retentate and permeate sides were usually at atmospheric pressure.

Before running an experiment the membranes were heated to 753 K at a rate of 1 K min^{-1}, and then calcined at this temperature for 8 h, in order to remove any adsorbed species. The separation selectivities given below were calculated as the ratios of permeances, using the log (mean partial pressure) difference in the calculations. The composition of the feed stream was accurately determined by feeding it directly into the sampling loop of the on-line gas chromatography. Similarly, when steady state was reached, which often meant keeping the membrane under continuous flow for *ca.* 2 h, samples at the exit of both the permeate and retentate sides were analyzed by on-line gas chromatography.

A first series of experiments was carried out to verify the presence of inter-crystalline defects on the membrane, and to evaluate their contribution to the total permeation flux. To this end, a He steam was saturated with TIPB at a temperature of 373 K (in order to have a sufficiently high vapour pressure of TIPB), and then fed to the retentate side of the membrane. The permeation of TIPB was measured as a function of temperature and then compared to that of He when the same experiment was carried out without TIPB. Since TIPB has a kinetic diameter of 0.87 nm, higher than the average channel diameter of silicalite (0.55 nm), the TIPB flux observed can be ascribed to permeation through inter-crystalline defects.

The results of TIPB permeation experiments are shown in Fig. 1. It is interesting that at the lowest temperature tested for permeation of TIPB/He mixtures, the permeation of He is almost completley blocked by TIPB (giving a TIPB/He selectivity over 800). This is probably due to capillary condensation of TIPB in the intercrystalline voids, blocking the access of He to the zeolite membrane. For increasingly higher temperatures the access to zeolite pores was progressively freed, and the He permeance increased. It must be noted, however, that the TIPB permeance was little affected, which again agrees with the assumption that TIPB does not use the zeolite pore network, but the inter-crystalline defects. Since a relatively high permeance of TIPB [$(1.5–3.2) \times 10^{-8}$ mol m^{-2} s^{-1} Pa^{-1}] was observed throughout the temperature interval tested, it can be concluded that the silicalite membrane has a very significant concentration of inter-crystalline defects.

A more meaningful comparison can be established between water (kinetic diameter 0.265 nm) and He (kinetic diameter 0.26 nm) both of which are able to transit easily through the zeolite

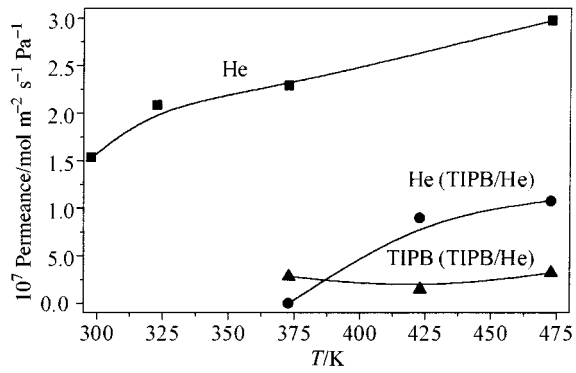

Fig. 1 He single gas permeance and He and TIPB permeances in the TIPB/He mixture as a function of temperature; partial pressure of TIPB in the feed = 1.1 kPa.

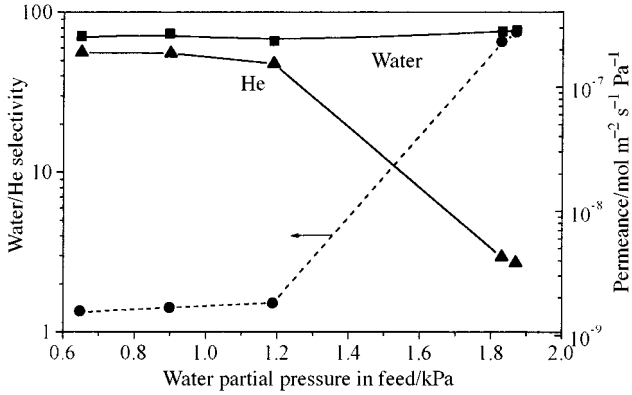

Fig. 2 He and water permeances and water/He separation selectivity in the water/He mixture as a function of the water partial pressure in the feed; temperature = 297 K.

pore network. Besides, since silicalite is an organophilic zeolite a significant interaction with water (preferential adsorption) is not expected. The experiments carried out with water–He mixtures are in general agreement with these assumptions (Fig. 2). A nearly constant value (1.3–1.5) to the water/He selectivity is obtained at water partial pressures in the feed of 1.1 kPa and lower. In spite of this low value of selectivity, it can be said that the membrane shows some water/He selectivity (about four times the Knudsen value of 0.47). This could be the result of blocking of the zeolite pores by water, which is the only condensable component present in the feed.

However, as the water partial pressure in the feed was increased to 1.9 kPa, a dramatic change takes place: the He flux is reduced by two orders of magnitude and the water/He selectivity increases markedly. This is due to blocking of most of the non-zeolite pores (*i.e.* inter-crystalline defects) by capillary condensation of water. The size of these defects can be approximately estimated by the Kelvin equation as 2.5–3 nm, much larger than the zeolite pores. In spite of these defects, a water/He selectivity of 74 is obtained at a water partial pressure in the feed of 1.9 kPa (Fig. 2).

Received (in Liverpool, UK) 28th April 1999, Accepted 3rd June 1999

Formation of 24 cooperative hydrogen bonds drives the spontaneous assembly of a rigid bifunctional trimelamine and bis(barbituric acid) to give selectively the [2 × 2] hydrogen-bonded grid, in preference to the corresponding [1 × 1] or polymeric assemblies.

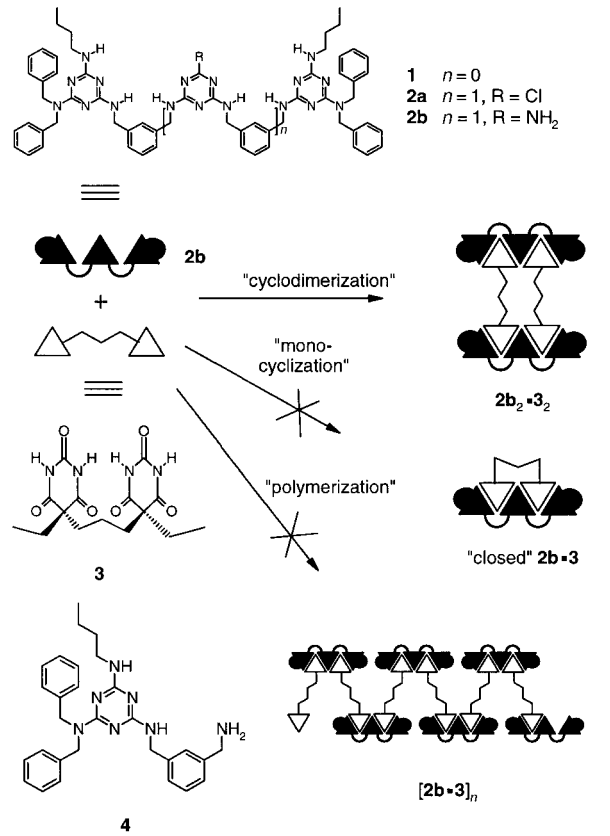
In 1992 Youinou and co-workers reported the formation of a $[Cu_4(dppn)_4](CF_3SO_3)_4$ complex in which the dppn [3,6-bis(2′-pyridyl)pyridazine] ligands are perpendicularly oriented pairwise around four Cu^+ centers thus forming a sandwich-type complex.[1] Very similar structures generally referred to as [*n* × *n*] 'metallosupramolecular grids' have been reported by Lehn and co-workers.[2–4] Information storage both on the *covalent* and on the *supramolecular* level determines the overall size [*n* × *n*] and shape (grid *vs.* helix) of the assembly.[5] We are currently investigating the self-assembly of [*n* × *m*] hydrogen-bonded grids using the melamine–barbituric acid (M•BA) binding motif.[6] The formation of six cooperative hydrogen bonds between dimelamine **1** and 5,5-diethylbarbituric acid (DEB) (K_{ass} = 7.6 × 10^4 M^{-1} in $CDCl_3$) restricts the rotations around the $C_{triazine}$–NH, the NH–CH_2, and the CH_2–C_{phenyl} bonds in **1**, giving the semi-rigid flat assembly **1**•DEB.[7] Here we describe the formation of [2 × 2] grid $\mathbf{2b}_2$•$\mathbf{3}_2$, the simplest example of this type of hydrogen-bonded assemblies.[8] The grid has been fully characterized by 2D NMR spectroscopy, MALDI-TOF mass spectrometry, and vapor pressure osmometry (VPO).

The synthesis of trimelamine **2b** starts from cyanuric chloride *via* successive reactions with Bn_2NH (1.0 equiv.) and $BuNH_2$ (1.0 equiv.), followed by refluxing in neat *m*-xylylenediamine to give **4** in 92% yield (Scheme 1). Reaction of **4** with cyanuric chloride (0.5 equiv.) and subsequent aminolysis of the corresponding chloride **2a** with excess of NH_3 gives **2b** in 85% yield.[9] Bis(barbituric acid) derivative **3** was synthesized starting with the alkylation of diethyl 2-ethylmalonate with 1,3-diiodopropane in 35% yield,[10] followed by reaction with urea (NaOEt/EtOH) in 25% yield.[11]

Assembly of **2b** and **3** can in principle lead to three different hydrogen-bonded structures (see Scheme 1), *i.e.* the [1 × 1] assembly **2b•3**, the [2 × 2] (grid) assembly $\mathbf{2b}_2$•$\mathbf{3}_2$, and the polymeric assembly $[\mathbf{2b•3}]_n$. Bis(barbituric acid) **3** was designed such that the formation of the [1 × 1] assembly, which would be preferred on entropic grounds,† is impossible. The short *n*-propyl spacer does not allow two barbituric acid moieties of one molecule of **3** to bind simultaneously to both binding sites of one molecule of **2b**. The X-ray crystal structure of free **3**‡ [see Fig. 1(*a*)] clearly confirms this picture and shows that the conformation adopted in the solid state is fully consistent with formation of the [2 × 2] grid $\mathbf{2b}_2$•$\mathbf{3}_2$ [see Fig. 1(*b*)]. Furthermore, the high extent of preorganization in the monomeric units **2b** and **3** reduces the likelihood of hydrogen-bonded polymerization ($[\mathbf{2b•3}]_n$).

Addition of 1.0 equiv. of **2b** to a suspension of **3** in $CDCl_3$ results in rapid dissolution of both components. Conclusive evidence for the formation of assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ comes from VPO measurements which give an average MW of 2500, very close to the calculated MW of 2800.§ Furthermore, MALDI-TOF mass spectrometry after Ag^+ labeling[12] shows a small but distinct signal for the Ag^+ complex of $\mathbf{2b}_2$•$\mathbf{3}_2$ (*m/z* 2924; calc. for $C_{152}H_{180}N_{44}O_{12}$•$^{109}Ag^+$ = 2924) together with that for the (open) **2b•3** (not shown) (*m/z* 1517; calc. for $C_{76}H_{90}N_{22}O_6$•$^{109}Ag^+$ = 1517). The presence of the latter is due to destruction of assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ upon addition of AgO_2CCF_3, most likely due to strong coordination of Ag^+ to the hydrogen-bonded triazine nitrogen.¶

The ^{1}H NMR spectrum of the 1:1 mixture of **2b** and **3** in $CDCl_3$ confirms the exclusive formation of the [2 × 2] grid $\mathbf{2b}_2$•$\mathbf{3}_2$. The spectrum of $\mathbf{2b}_2$•$\mathbf{3}_2$ at 60 °C [see Fig. 2(*a*)] shows a broad signal at δ14.0 (NH_{barb}), a singlet at δ 7.65 ppm (ArH) and two signals at δ 7.1 (NH_{xylyl} + ArH) and 6.76 (NH_{xylyl}). Both the NH_{butyl} and the NH_2 protons coincide with the aromatic proton signals for the four benzyl groups (δ 7.4–7.2). Furthermore, three singlets at δ 4.84, 4.62 and 4.51 (CH_2Ar) and a doublet at δ 3.33 [$NHCH_2(CH_2)_2CH_3$] are observed. At lower temperatures (< 30 °C), two signals are observed at δ 14.6 and 14.0, one broad and one sharp,‖ and a complex pattern of signals



Scheme 1 Representation of the different types of hydrogen-bonded assemblies (*i.e.* [1 × 1], [2 × 2] and [*n* × *n*]) that can be formed *via* hydrogen bond formation between trimelamine **2b** and bis(barbituric acid) **3**. Only the [2 × 2] assembly is experimentally observed.

† Address correspondence concerning crystallography to this author.

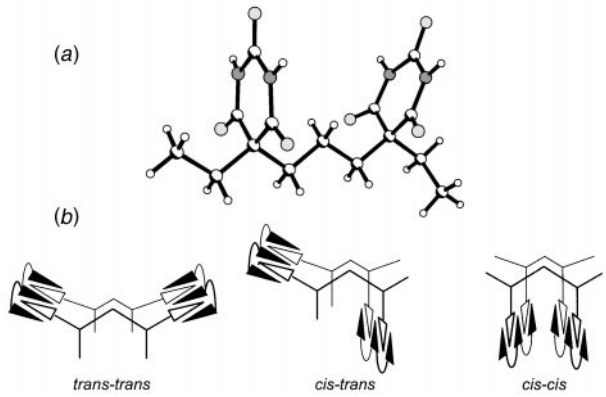


Fig. 1 (*a*) X-Ray crystal structure of **3**; white (small and large) atoms represent hydrogen and carbon atoms, grey (light and dark) atoms represent oxygen and nitrogen atoms. The barbiturate moiety [containing atom O(5)] is slightly distorted from planarity towards an envelope conformation (maximum deviation from the least-squares plane is 0.131(1) Å [for C(7)]). This distortion is most likely caused by the acceptance of intermolecular hydrogen bond formation [involving O(5) and O(6)]. (*b*) Three isomeric conformations of the [2 × 2] assembly $\mathbf{2b}_2$•$\mathbf{3}_2$.

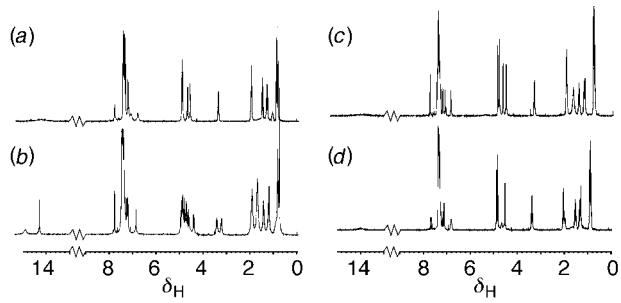

Fig. 2 ^{1}H NMR spectra (400 MHz) of (*a*) [2 × 2] assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ at 60 °C; (*b*) [2 × 2] assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ at −40 °C; (*c*) [1 × 1] assembly **2b**•DEB_2 at −40 °C; (*d*) 1:1 mixture of [2 × 2] assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ and [1 × 1] assembly **1**•DEB at 20 °C.

for the CH_2Ar protons and for the $NHCH_2(CH_2)_2CH_3$ protons is observed [see Fig. 2(*b*)]. The absence of any other signals in the δ 15–13 region clearly rules out the presence of alternative assemblies (*i.e.* [1 × 1] or polymeric) or the existence of more than one isomeric form [*trans-trans*, *cis-trans* and *cis-cis*, see Fig. 1(*b*)]. The less symmetrical *cis-trans* isomer can be ruled out based on symmetry arguments, but which of the two other isomers is the most stable one is at present unknown.

The decoalescence of the proton signals for the two heterotopic NH_{barb} protons around 30 °C clearly illustrates the much higher kinetic stability of grid $\mathbf{2b}_2$•$\mathbf{3}_2$ compared to assembly **2b**•DEB_2, which shows an averaged (broad) signal around δ 14.0 for these two protons even at −50 °C [see Fig. 2(*c*)]. The reason is that exchange of these protons in $\mathbf{2b}_2$•$\mathbf{3}_2$ involves the simultaneous cleavage of 12 hydrogen bonds, while exchange in **2b**•DEB_2 only requires six hydrogen bonds to be broken. Interestingly, the exchange between the two NH_{barb} protons in $\mathbf{2b}_2$•$\mathbf{3}_2$ is significantly faster in the presence of an equivalent amount of the two-component assembly **1**•DEB [averaged signal around δ 14.0 is observed, see Fig. 2(*d*)]. This is due to the fact that components **1** and DEB temporarily occupy the non-hydrogen bonded sites in **2b**•DEB_2 during the exchange process, thus decreasing the activition barrier for this process.[13]

Finally we studied the thermodynamic stability of $\mathbf{2b}_2$•$\mathbf{3}_2$ as compared to that of **2b**•DEB_2 and $\mathbf{1}_2$•**3**. The melting point index for hydrogen-bonded assemblies I_{T_m} = HB/(N − 1) predicts that an equimolar mixture of [1 × 2] assembly **2b**•DEB_2 (I_{T_m} = 6) and [2 × 1] assembly $\mathbf{1}_2$•**3** (I_{T_m} = 6) is thermodynamically unstable, and would rearrange to give preferentially the [2 × 2] assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ (I_{T_m} = 8) and [1 × 1] assembly **1**•DEB (I_{T_m} = 6).[14] Analysis of the ^{1}H NMR spectrum of a 1:1 mixture of **2b**•DEB_2 and $\mathbf{1}_2$•**3** clearly shows that neither one of the two assemblies is present. Diagnostic is the absence of the characteristic resonances at δ 7.0 and 4.7. This experiment confirms the assumption that the thermodynamic stability of grid $\mathbf{2b}_2$•$\mathbf{3}_2$ is significantly higher than that of **2b**•DEB_2 and $\mathbf{1}_2$•**3**. Further studies on how structural parameters influence the stability of [2 × 2] grids are currently in progress.

Notes and references

† Based on the melting point index for hydrogen-bonded assemblies I_{T_m} = HB/(N − 1) (where HB = number of H-bonds in the assembly and N = number of monomeric units in the assembly) (ref. 14), the stability of [1 × 1] assembly **2b•3** is higher (I_{T_m} = 12) than [2 × 2] assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ (I_{T_m} = 8) and the polymeric assembly [**2b•3**]$_n$ (I_{T_m} = 6).

‡ *Crystal data* for **3**: $C_{15}H_{20}N_4O_6$, M_r = 352.35, colourless, block-shaped crystal (0.2 × 0.2 × 0.3 mm), triclinic, space group $P\bar{1}$ (no. 2) with a = 6.5364(6), b = 10.8100(12), c = 11.7511(12) Å, α = 79.960(5), β = 85.799(6), γ = 88.868(6)°, V = 815.38(14) Å^3, Z = 2, D_c = 1.435 g cm^{-3}, F(000) 372, μ(Mo-Kα) = 0.1 mm^{-1}, 23889 reflections measured, 3717 independent, R_{int} = 0.0582, (1.6 < θ < 27.4°, T = 150 K, Mo-Kα radiation, graphite monochromator, λ = 0.71073 Å) on an Enraf-Nonius Kappa-CCD area detector on rotating anode. Data were collected for Lp effects but not for absorption. The structure was solved by automated direct methods (SHELXS96). Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-96) for 286 parameters. Hydrogen atoms were located on a difference Fourier map and their coordinates were included as parameters in the refinement. Refinement converged at a final w$R2$ value of 0.0898, $R1$ = 0.0317 [for 3522 reflections with $F_o > 4\sigma(F_o)$], S = 1.023. A final difference Fourier showed no residual density outside –0.24 and 0.32 e Å^{-3}. CCDC 182/1276. See http://www.rsc.org/suppdata/cc/1999/1311/ for crystallographic data in .cif format.

§ The experimentally determined average MW is slightly lower than the calculated MW, because assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ is in equilibrium with the free components **2b** and **3** (concentration dependant on association constant of the complex). Moreover, the presence of a small excess of one of the components [~5% deviation from exact 1:1 stoichiometry (w/w)] will further decrease the average MW.

¶ Destruction of assembly $\mathbf{2b}_2$•$\mathbf{3}_2$ by Ag^+ ions was confirmed independantly by ^{1}H NMR spectroscopic measurements, which show the gradual disappearance (over several hours) of the proton signals after the addition of AgO_2CCF_3.

‖ The broadness of these signals is related to the proton exchange rate with residual water present. The NH_{barb} proton bound to the *outer* melamine unit (δ 14.6) is much broader than the NH_{barb} proton bound to the *inner* melamine unit (δ 14.0), because this proton is more exposed to the solvent (breakage of 3 *vs*. 6 hydrogen bonds).

Deprotonation of low-spin mononuclear iron(III)–hydroperoxide complexes give transient blue species assigned to high-spin iron(III)–peroxide complexes

Kenneth B. Jensen, Christine J. McKenzie,* Lars Preuss Nielsen, Jens Zacho Pedersen and Henrik Molina Svendsen

Department of Chemistry, University of Southern Denmark, Odense Campus, 5230 Odense M, Denmark. E-mail: chk@chem.ou.dk

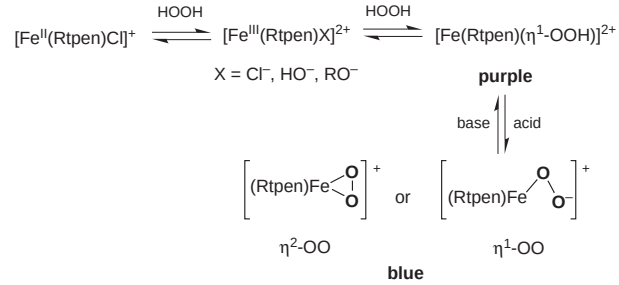
Received (in Cambridge, UK) 14th April 1999, Accepted 24th May 1999

Purple iron(III)–hydroperoxide complex ions [Fe(Rtpen)(η^1-OOH)]$^{2+}$ can be reversibly deprotonated to give transient blue species showing spectroscopic properties transient with iron(III)–peroxide complexes; a novel ferryl species is produced in MS/MS experiments with the iron(III) hydroperoxide ion.

Dioxygen activation chemistry by a single iron atom occurs in some non-heme iron enzymes[1] and the antitumor drug bleomycin (BLM).[2] The characterisation of model mononuclear non-heme Fe(III)–peroxide species is expected to aid the structural elucidation of similar species in the catalytic cycles of these non-heme iron biomolecules. In recent years several biologically relevant transient mononuclear non-heme iron(III)–hydroperoxide model systems have been identified in solution.[3–5] These species are proposed to contain end-on (η^1) hydroperoxide ligands. The only mononuclear non-heme complex proposed to contain a side-on (η^2) peroxide ligand is [Fe(edta)O_2].[6,7]

A mononuclear iron(II) complex of the pentadentate ligand *N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine (metpen) [Fe(metpen)Cl](PF_6) when treated with an excess of H_2O_2 in hydroxylic solvents generates purple solutions.[3] The UV-VIS and EPR spectra of this solution show features comparable to other reported Fe(III)–η^1-OOH systems[5] and bleomycin,[2] supporting formulation of the transient purple species as the low-spin Fe(III)–hydroperoxo compound [Fe(metpen)(η^1-OOH)]$^{2+}$. By carrying out simple ligand modifications of the parent metpen ligand we have continued this work towards the ultimate aim of solid state characterisation, and we communicate here the spectroscopic identification of new unique mononuclear Fe(III)–peroxide species obtained by deprotonation of the hydroperoxide species [Fe(Rtpen)(η^1-OOH)]$^{2+}$, where Rtpen is the generic abbreviation for the ligand series; *N*-ethyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine (ettpen) and *N*-benzyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)-ethane-1,2-diamine (bztpen).

The yellow crystalline iron(II) and iron(III) complexes [Fe(Rtpen)Cl]A and [Fe(Rtpen)Cl]$(A)_2$ (A = ClO_4 or PF_6), are prepared by the reaction of each ligand with either iron(II) or iron(III) chloride in dry methanol followed by addition of a salt of the counter anion. Crystal structures of the iron(II) compounds have been obtained. The iron(III) species are not stable in solution: their reduced counterparts and orange iron(III) compounds, formulated as [(Rtpen)ClFe(μ-O)FeCl(Rtpen)]$(A)_2$, can be isolated from aged solutions of [Fe(Rtpen)Cl]$(A)_2$. The reactions of the iron(II) and iron(III) compounds with an excess of hydrogen peroxide in hydroxylic solvents generate purple solutions which are stable for hours. There is a time lag of a few seconds before the appearance of the purple colour when the iron(II) starting materials are used. This time lag supports the notion of a rate-determining formation of an intermediate low-spin iron(III) compound (detected by EPR) before a ligand exchange reaction with deprotonated hydroperoxide. A possible reaction scheme is presented in Scheme 1. By using the iron(III) starting materials [Fe(bztpen)Cl]$(A)_2$ (A = ClO_4 or PF_6), formation of the hydroperoxide species is expedited since formation of the purple colour is, in these cases, instantaneous. The purple chromophores are proposed to be the low-spin Fe(III)–hydroperoxide complexes containing end-on bound hydroperoxide ligands, [Fe(Rtpen)(OOH)]$^{2+}$ with spectroscopic characteristics similar to those we reported[3] for [Fe(metpen)(OOH)]$^{2+}$. The addition of ammonia, triethylamine or pyridine to the purple solutions produces a transient blue colour. If the base is first added to methanolic solutions of [Fe(Rtpen)Cl]$^+$ followed by hydrogen peroxide the blue solution is generated directly. Subsequent addition of hydrochloric acid to the blue solutions regenerates the purple solution. This cycle can be repeated several times with the same solution indicating a reversible acid/base equilibrium. We assign the blue species to a novel iron(III)–peroxide compound derived from the deprotonation of the purple [Fe(Rtpen)(OOH)]$^{2+}$. The spectroscopic data obtained so far is consistent with a mononuclear high-spin iron(III) complex with either side-on (η^2) or end-on (η^1) peroxide coordination (Scheme 1).



Scheme 1

UV-VIS spectra for [Fe(ettpen)Cl]PF_6 and its proposed purple Fe(III)–hydroperoxide and blue iron(III)–peroxide derivatives are shown in Fig. 1. Similar data were obtained for the other members of the series.[8] The difference in the maxima assigned to the peroxide to iron(III) charge-transfer band in the purple and blue species is consistent with expected increased donor strength of the O_2^{2-} *vs.* O_2H^- ligand. However this simple argument is complicated by a concomitant spin change of the iron atom (see EPR results below).

Peaks assigned to both the complexes, [Fe(bztpen)(OOH)]$^+$ and [Fe(bztpen)(OO)]$^{2+}$ are observed in the ESI mass spectra of the purple solutions (Fig. 2). Consistent with the proposed acid/base equilibrium the ratio between *m/z* 511.2 and 256.1 ions increases in spectra of the blue solutions (*m/z* 511.2 is weak in Fig. 2). A prominent peak (often the most intense) at *m/z* 247.6 can be assigned to the ferryl species, [Fe(bztpen)O]$^{2+}$. Collision induced dissociation (CID) of the ion at *m/z* 256.1 produces ions at *m/z* 247.6, 239.6 and 194.6. The first two of these ions are assigned to the ferryl species [Fe(bztpen)O]$^{2+}$ and a ferrous species [Fe(bztpen)]$^{2+}$, and explained by loss of a hydroxyl and hydrosuperoxide radical, respectively, from [Fe(bztpen)(OOH)]$^{2+}$. The third peak is assigned to [Fe(bztpen − C_7H_6)]$^{2+}$. In order to determine whether or not the peaks at *m/z* 239.6 and 194.6 could be the result of the decomposition of the *m/z* 247.6

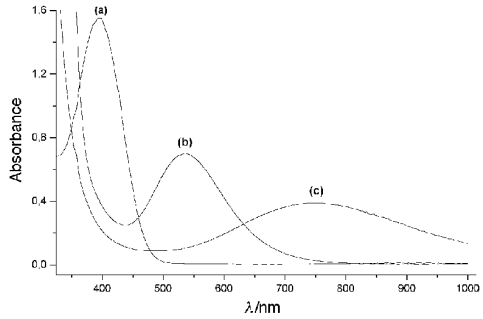


Fig. 1 UV-VIS spectra of (a) 7.5×10^{-4} M [Fe(ettpen)Cl]PF_6 in MeOH, (b) after addition of 300 equiv. of H_2O_2 and followed by (c) addition of 35 equiv. of Et_3N.

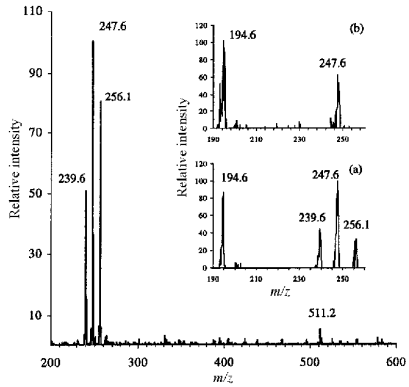

Fig. 2 The ESI mass spectrum of the purple solution generated by the reaction of [Fe(bztpen)Cl]$(ClO_4)_2$ with 100 equiv. of H_2O_2 in ethanol. Inserts show the CID spectra of the (a) *m/z* 256.1 and (b) *m/z* 247.6 ions. Assignments: *m/z* 256.1, [Fe(bztpen)(OOH)]$^{2+}$; 511.2, [Fe(bztpen)(OO)]$^{+}$; 247.6, [Fe(bztpen)O]$^{2+}$; 239.6, [Fe(bztpen)]$^{2+}$; 194.6, [Fe(bztpen − C_7H_6)]$^{2+}$.

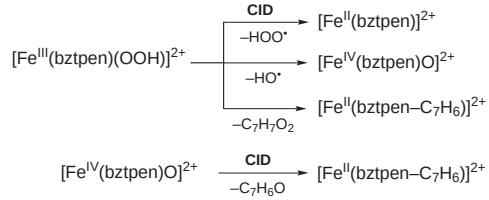
ion {[Fe(bztpen)O]$^{2+}$} as well as, or rather than the hydroperoxide ion, [Fe(bztpen)(OOH)]$^{2+}$ a second MS/MS experiment on the *m/z* 247.6 ion was performed. This resulted only in the generation of the *m/z* 194.6 ion. Loss of 106 mass units from [Fe(bztpen)O]$^{2+}$ can be ascribed to loss of the mass equivalent to benzaldehyde, and intramolecular oxo transfer from the ferryl to the dangling benzyl group seems to be a plausible explanation. The iron(II) species which is expected to remain after benzaldehyde loss, [Fe^{II}(bztpen − C_7H_6)]$^{2+}$ (= {[Fe^{IV}(bztpen)O] − C_7H_6O}$^{2+}$) fits with observation of the *m/z* 194.6 ion. In contrast, the CID spectrum obtained under similar conditions of the *m/z* 511.2 ion {[Fe(bztpen)O_2]$^{+}$} does not show any of the peaks assignable to [Fe^{IV}(bztpen)O]$^{2+}$; instead only the ligand decomposition reaction is observed. In summary reaction proceeds *via* Scheme 2.



Scheme 2

The comparative ease of O–O (and Fe–O) bond cleavage in [Fe(metpen)(OOH)]$^{2+}$ compared with [Fe(metpen)(OO)]$^{+}$ observed in the MS/MS experiments is in agreement with the expectation that hydroperoxide species are more reactive (in solution) towards the O–O bond cleavage to give highly reactive ferryl oxidants, compared to their peroxide counterparts. It is for this reason, for example, iron(III) hydroperoxide species are proposed in the DNA degradation process catalysed by bleomycin.[2]

EPR spectra of the purple solutions generated from the reaction of [Fe(bztpen)Cl]PF_6 or [Fe(bztpen)Cl]$(PF_6)_2$ with hydrogen peroxide show overlapping rhombic signals indicative of two low-spin Fe(III) species, their relative intensities depending on the amount of hydrogen peroxide added and the time lag. These results are consistent the formation of [Fe(bztpen)(η^1-OOH)]$^{2+}$ (g = 2.20, 2.16, 1.96) and its precursor, [Fe^{III}(bztpen)X]$^{2+}$, X = Cl^-, OH^- or OR^-, (g = 2.32, 2.14, 1.93) as depicted in Scheme 1. The EPR spectra of blue solutions produced by the addition of base develop new signals at g = 7.60 and 5.74 due to formation of a high-spin iron(III) species. A direct relationship between the concentration of the high-spin species in the EPR spectra and the absorbance of the 748 nm band was verified by recording EPR spectra on a series of frozen solutions in which the blue chromophore showed different concentrations. A calibration of the EPR signals was made.[9]

It is tempting to make a structural assignment of seven coordination for the high-spin blue Fe(III)–peroxide species, *i.e.* [Fe(bztpen)(η^2-OO)]$^{+}$, however other structural alternatives cannot be excluded, *e.g.* [Fe(bztpen)(η^1-OO)]$^{+}$ or six-co-ordinated iron(III) with side-on peroxide and a non-co-ordinated ligand picolyl pendant arm. The possibility that the blue species is a dinuclear μ:η^2,η^2-O_2 species analogous to the dicopper hemocyanin model of Kitajima *et al.*[10] appears to be eliminated since the expected strong antiferromagnetic coupling would cause EPR silence.

In summary, the partial spectroscopic characterisation of three biologically relevant non-heme Fe(III)(O_2H), Fe(III)(O_2) and Fe(IV)O (mass spectrometry only) motifs has been achieved. To our knowledge this is the first observation of the acid–base chemistry of non-heme Fe(III)–peroxo species.

This work was supported by a grant to C. J. M. from the Danish Natural Science research council. We are grateful to a referee for suggesting the EPR calibration and UV-VIS–EPR spectroscopy correlation experiments.

8 Purple species, λ_{max}/nm: [Fe(metpen)(OOH)]$^{2+}$, 536; [Fe(ettpen)-(OOH)]$^{2+}$, 536: blue species, λ_{max}/nm: [Fe(metpen)(OO)]$^{2+}$, 748; [Fe(ettpen)(OO)]$^{2+}$, 747.
9 The related compounds [Fe(tpen)]$(ClO_4)_3$ [tpen = *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethane-1,2-diamine and Na[Fe(edta)] (edta^{4-} = ethylendiaminetetraacetate) were used to calibrate the low-spin iron(III) and high-spin iron(III) signals, respectively. Possible differences in the rates of relaxation for the various iron compounds were eliminated by calibrating at several probe temperatures. Thus an estimation of the percentage conversion in the reactions with hydrogen peroxide was made. 100% of the iron(II) species [Fe(bztpen)Cl]$^{+}$ can be converted to the low-spin iron(III) species [Fe(bztpen)X]$^{2+}$ and [Fe(bztpen)OOH]$^{2+}$ (relative amounts depending on the H_2O_2 excess); 25% of the low-spin [Fe(bztpen)OOH]$^{2+}$ can be converted to the high-spin signal assigned to [Fe(bztpen)OO]$^{+}$. There are two factors which might be responsible for the apparent incomplete conversion: (i) All the reactions are in equilibrium (as depicted in Scheme 1) and the iron(II) species are favoured. (ii) Decomposition of all or some of the iron(III) species depicted in Scheme 1 and formation of EPR silent oxo-bridged dimers. In support of the second explanation peaks assignable to [(bztpen)Cl-Fe(μ-O)FeCl(bztpen)]$^{2+}$ (*m/z* 522) are indeed observed in ESI mass spectra of the purple and blue solutions.

Received (in Basel, Switzerland) 25th February 1999, Accepted 11th June 1999

Weak interactions between the silicon and the hydrides are responsible for the stabilization of the title complex bearing two different coordinated σ-bonds, (η^2-H_2) and (η^2-H–$SiPh_3$).

Nowadays the existence of η^2-dihydrogen or η^2-silane coordination to a metal centre is well established.[1–3] These η^2-H–X species (X = H, Si) are often considered as a representation of the arrested oxidative addition of dihydrogen or silanes to a metal center. They are thus often invoked in many catalytic reactions such as hydrogenation or hydrosilylation.[1–4] When considering the small number of complexes accommodating two σ-HX bonds, one important question is to determine the factors that promote the formation of such species. Indeed, there are only two thermally stable bis(dihydrogen) complexes[3] $[RuH_2(H_2)_2(PCy_3)_2]$ **1** and $[Tp^*RuH(H_2)_2]$, and we have recently described a new family of bis(silane) complexes $[RuH_2\{(\eta^2\text{-H–}SiR_2)_2X\}(PR'_3)_2]$ in which the disilane ligand acts as a chelate and is coordinated to the ruthenium *via* two σ-H–Si bonds.[5]

Here, we present the first structural characterization of a mixed σ-(H–H) and σ-(H–Si) complex $RuH_2(\eta^2\text{-}H_2)(\eta^2\text{-H–}SiPh_3)(PCy_3)_2$ **2** as well as theoretical studies highlighting the importance of weak formally non-bonding interactions between the silicon and the classical hydrides.

In 1994, we reported our first results concerning the reactivity of **1** toward weakly coordinating ligands such as N_2 and $HEPh_3$ (E = Si, Ge).[6] Substitution of two or one dihydrogen ligands was observed leading to $RuH_2(N_2)_2(PCy_3)_2$ and $RuH_2(\eta^2\text{-}H_2)(\eta^2\text{-H–}EPh_3)(PCy_3)_2$ respectively. The silane complex **2** was obtained by addition of 1 equiv. of $HSiPh_3$ to a pentane suspension of **1**. On the basis of NMR data and T_1 measurements, we proposed a formulation for **2** in which the two phosphine ligands were in a *trans* position, in agreement with the presence of such bulky phosphines. However, we have now succeeded in growing crystals and have obtained new information from the X-ray diffraction study. The molecular structure is shown in Fig. 1 and the principal distances and angles are listed in Table 1.‡ Two molecules are found in the asymmetric unit; however, as no significant differences are observed, we present here only the data concerning one molecule. Surprisingly, the phosphines are in a *cis* configuration with a P1–Ru–P2 angle of 109.71(5)°. The classical hydride H4 is *trans* to one phosphine with a P1–Ru–H4 angle of 166.5(14)° whereas the hydrogen H5 involved in the σ-H–Si bond is *trans* to the other phosphine with a P2–Ru–H5 angle of 170.7(11)°. The second classical hydride H3 is *trans* to the dihydrogen ligand H1–H2 with H3–Ru–H1 and H3–Ru–H2 angles of 163(2) and 168(2)°, respectively.

The (η^2-Si–H) coordination is confirmed by a significant lengthening of the Si–H5 bond: 1.72(3) Å (*ca.* 1.49 Å in free silanes). The Ru–H bond lengths vary from 1.47(4) to 1.66(2) Å with the two Ru–H distances involving the dihydrogen ligand markedly higher. The dihydrogen ligand is characterized by a H1–H2 distance of 0.82(2) Å, a value in agreement with an unstretched dihydrogen complex as highlighted by its high reactivity [addition of H_2 or N_2 results in immediate elimination of the silane and formation of the corresponding bis(dihydrogen) or bis(dinitrogen) complex]. The Si···H4 distance of 1.83(3) Å is below the limit of 2 Å normally admitted for σ-Si–H bonds. Thus the silicon is almost symmetrically bonded to H5 and H4, as can be seen from the H–Ru–Si angles of 45.9(11) and 50.2(10)°. In addition the Si···H3

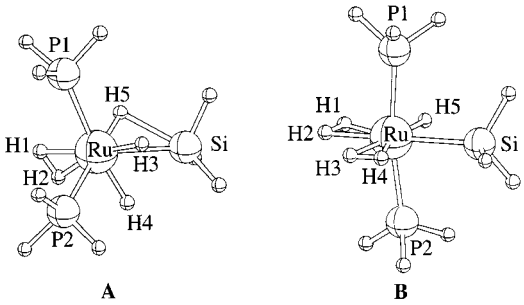

Fig. 2 The B3LYP-optimized structures of isomers **A** and **B**.

distance is 2.40(3) Å, allowing further Si···H interactions as also found by theoretical calculations. Similar interactions are also responsible for the *cis* geometry for the two PCy_3 ligands in the ruthenium complexes $RuH_2\{(\eta^2\text{-H–}SiR_2)_2X\}(PR'_3)_2$ accommodating two σ-Si–H bonds.[5b]

DFT/B3LYP calculations using a relativistic small-core pseudopotential and a [5s,5p,3d] contracted Gaussian basis for ruthenium[7] were performed on the model complex $RuH_2(\eta^2\text{-}H_2)(\eta^2\text{-H–}SiH_3)(PH_3)_2$.§ Geometry optimizations followed by vibrational frequency analyses allow identification of five singlet local minima. The structure of the most stable isomer **A** in Fig. 2 (C_1 symmetry) closely resembles that found by X-ray diffraction for **2**; we note that location of H atoms by X-ray diffraction is subject to considerable uncertainties, and that the computed P1–Ru–P2 bond angle would increase by about 7° if the PH_3 ligands were replaced by a more realistic model, such as PMe_3.[5b] Optimized geometrical parameters are listed in Table 1 for comparison. The origin of the unusual *cis* geometry for the two phosphines can be found in the presence of two attractive non-bonded interactions between the silicon atom and the two classical hydrides H3 and H4;[10] the attractive nature of these interactions is shown by the Mulliken population analysis.¶ Indeed, the calculated Si···H3 and Si···H4 distances, 2.116 and 2.071 Å, respectively, are much shorter than the sum of the van der Waals radii of silicon and hydrogen (3.3 Å). Such interactions are precluded geometrically in the four other isomers (all having *trans* phosphines). The lowest-energy of these is better described as a hydrido(silyl) complex $RuH(SiH_3)(\eta^2\text{-}H_2)_2(PH_3)_2$ (**B** in Fig. 2); it is only 8 kJ mol^{-1} above **A** [17 kJ mol^{-1} by single-point CCSD(T) calculations]. Relative B3LYP energies of the other isomers vary from 16 to 41 kJ mol^{-1}. Binding energies of the SiH_4 and H_2 ligands have been calculated from the $RuH_2(\eta^2\text{-}H_2)(PH_3)_2$ and $RuH_2(\eta^2\text{-H–}SiH_3)(PH_3)_2$ fragments.‖

As pointed out very recently by Corey and Braddock-Wilking in their impressive review on the reactions of hydrosilanes with transition-metal complexes, 'Several variations of interactions seem to occur between silanes and metals, from full oxidative addition to that of arrested addition with an interaction between a metal orbital and a Si–H sigma bond'.[2b] We have shown here how important additional Si···H interactions are; they control the coordination geometry at the metal centre. This type of bonding deserves special attention for future studies, given that it involves energies comparable to those in the 'dihydrogen bonds'** recently described by several groups,[11] and that it might well be of primary importance in catalytic silicon transformations.

Nickel nanowires of 4 nm diameter in the cavity of carbon nanotubes

Bhabendra K. Pradhan, Takashi Kyotani* and Akira Tomita

Institute for Chemical Reaction Science, Tohoku University, 2-1-1 Katahira, Aoba-Ku, Sendai 980-8577, Japan. E-mail: kyotani@icrs.tohoku.ac.jp

Received (in Cambridge, UK) 24th May 1999, Accepted 14th June 1999

Nickel nanowires of 4 nm diameter were formed in the cavity of carbon nanotubes with an inner diameter of 20 nm.

There has been an increasing interest in the fabrication of ferromagnetic metal nanowires in terms of their fundamental importance as well as potential application in magnetic recording technology. Recently, such nanowires have been often prepared by a template technique[1] that involves electrochemical deposition of metal into nanometer-wide channels of anodic aluminium oxide films,[2,3] polycarbonate track etched membranes[4,5] or nanochannel array glass.[6] The obtainable lowest diameter by such methods is restricted by the lowest attainable inner diameter of the nanochannels in the template materials. None of the nanochannels in the above host materials can easily reach an inner diameter of < 10 nm. Therefore, the template method does not allow the construction of ferromagnetic metal nanowires with a diameter of < 10 nm. Here we report a unique nickel nanowire formation by metal–organic chemical vapor deposition (MOCVD) in the cavity of carbon-coated nanochannels of anodic aluminium oxide film. The diameter of the nickel nanowires prepared by this method is uniformly 4 nm, which is much smaller than the inner diameter (*ca.* 20 nm) of the carbon-coated nanochannels.

Previously, we demonstrated that monodisperse carbon nanotubes with uniform size (length, diameter and thickness) can be prepared by the following template carbonization technique;[7,8] pyrolytic carbon deposition in the uniform and straight channels of anodic aluminium oxide film and then liberation of the carbon from the film by dissolving the template. With a similar method, but using a catalyst, Martin and coworkers prepared more highly crystallized carbon nanotubes.[9] Furthermore, by applying this template technique, we and then Martin *et al.* prepared platinum or iron-filled uniform carbon nanotubes in which the metal or metal oxide was present as nanorods or nanoparticles.[10–12] In this study, we attempted to insert nickel into carbon nanotubes. The previously described anodic oxidation[7,8] of an electropolished aluminium plate was used to prepare a porous anodic aluminium oxide film with a channel diameter of *ca.* 30 nm and the film diameter and thickness were 20 mm and *ca.* 75 μm, respectively. The film was subjected to carbon deposition by thermal decomposition of propene (1.2% in N_2) at 800 °C, which resulted in uniform coating of carbon on the channel walls. The resultant carbon-coated film was then subjected to metal–organic chemical vapor deposition (MOCVD) of nickelocene [$Ni(C_5H_5)_2$] in the following manner. Nickelocene was vaporized at 105 °C (corresponding to a vapor pressure of 0.6 kPa) and the film was exposed to the vapor with H_2 gas (50% in N_2) at a total flow rate of 100 cm^3(STP) min^{-1} at 275 °C for 0.25 or 1 h. After the MOCVD, the film was treated with 10 M NaOH solution at 150 °C in an autoclave for 6 h to dissolve the anodic aluminium oxide. Nickel/carbon nanotube composites were obtained as an insoluble fraction. The composites were observed with a transmission electron microscope (TEM; JEOL, JEM-2010) equipped with an energy dispersive X-ray spectrometer (Noran, 644G3SES).

Fig. 1(a) shows a bright field TEM image of the nickel/carbon nanotube composites prepared by MOCVD for 1 h. The image exhibits a carbon nanotube with a diameter of *ca.* 30 nm, containing a single nanowire of 500 nm in length and 4 nm in diameter. Fig. 1(b) shows the electron diffraction pattern taken from the nickel/carbon nanotube composite [Fig. 1(a)]. The pattern presents a pair of arcs from the carbon (002) reflection. In addition to the reflection from the carbon tube, two pairs of sharp diffraction spots were observed, which can be indexed as (111) and (222) reflections from fcc nickel metal. Apart from the sharp spots, there are several spots from nickel metal (220) and (331) reflections. An energy dispersive X-ray spectrum taken from this nanowire confirms the presence of nickel with no signal corresponding to oxygen. Both the diffraction pattern and elemental analyses suggest that the nanowire is pure nickel metal rather than a nickel compound. The appearance of the nickel (111) and (222) reflections not as a ring, but as a pair of symmetrical spots, indicates high orientation of the (111) planes in the nickel nanowire [Fig. 1(a)]. Judging from the positions of (111) and (222) spots, we can conclude that the (111) planes run parallel to the axis of the nickel wire. This was further confirmed by the lattice fringe image discussed below.

Fig. 2 shows a high resolution TEM image of a nanowire-containing carbon nanotube prepared under the same conditions as in Fig. 1(a). In this image, the lattice fringes of the nanowire which are located near the inner wall of the carbon nanotube are clearly observed and the lattice planes are parallel to the wire axis. The regular spacing of the observed lattice planes was 0.20 nm, which corresponds to the separation of (111) planes of fcc nickel metal. For all the nanowires we observed in this study, such preferable orientation of (111) planes was found without any clear grain boundaries. This accords with the result of the electron diffraction [Fig. 1(b)]. From these findings, we concluded that each of these nickel nanowires is a slender single crystal.

In order to examine the formation of nickel nanowire at an early stage, we carried out the MOCVD for a shorter time, *i.e.* 15 min. We observed many nickel nanowires in the cavity of carbon nanotubes as shown in Fig. 3. In some cases, short nanowires are present at an angle to the tube axis. The length of

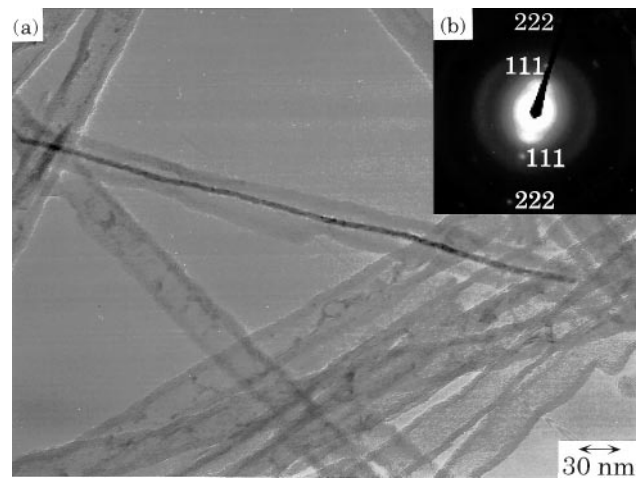

Fig. 1 (a) Low-magnification TEM image of a nickel/carbon nanotube composite prepared by MOCVD for 1 h at 275 °C. (b) Electron diffraction pattern taken from the nanowire-containing carbon nanotube (a).

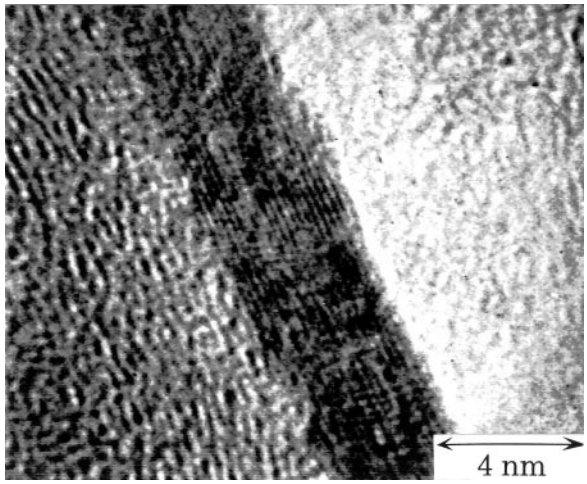

Fig. 2 High-resolution TEM image of a nickel wire near the inner wall of carbon nanotubes. The carbon nanotube/nickel nanowire composites was prepared by MOCVD for 1 h at 275 °C.

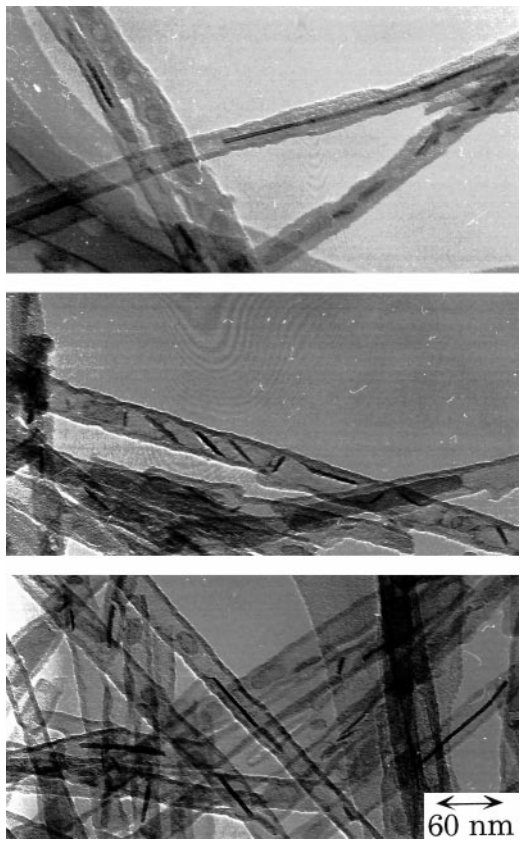

Fig. 3 Bright field TEM images at different areas for carbon tubes/nickel nanowire composites prepared by MOCVD for 15 min at 275 °C.

the nanowires varies from ten to a few hundred nm and the average length is less than that in Fig. 1(a). It was found that the nanowire diameter is rather uniform at *ca.* 4 nm irrespective of the MOCVD time period. This finding suggests preferred nanowire growth toward the direction parallel to (111) plane.

Among all the tubes we have examined with TEM, more than 50% of the tubes contained nickel nanowires with a uniform diameter of 4 nm. However, we did not observe any nanowires in the cavity of carbon nanotubes near their open ends. This implies that the growth of nickel nanowires occurred inside the carbon-coated nanochannels. Even though the nickel metal was formed in the nanochannels, the diameter of the resultant nanowires was less than the inner diameter of the nanochannels. At the present moment, we do not have a reasonable explanation for the formation of such thin nanowires, but we presume that the coated carbon plays some role in producing them.

The template method is considered to be a promising approach for the fabrication of metal nanowires of very small size.[2–6,13] In this method, the obtainable diameter of nanowires is, however, regulated by the inner diameter of the nanochannels in the template materials. To the best of our knowledge, the formation of metal nanowires with diameters smaller than that of the template has not been previously reported. Another important feature in our method is that nickel nanowires are always evident as encapsulated nanowires in the hollow interiors of uniform carbon nanotubes. Since metal-filled carbon nanotubes could have a variety of industrial applications,[14] there have been many attempts towards the production of carbon nanotubes filled with metal or metal compounds as nanowires.[15–20] However, as stated above, the diameter of the nanowires is always the same as the inner diameter of carbon nanotubes. Thus, the nanowire formation we have discovered here is a quite unique phenomenon and can provide a novel methodology for future nanofabrication technology.

This study was partly supported by the Ministry of Education, Science, Sports and Culture, Grant-in-Aid for Scientific Research on Priority Areas, No. 288 ‘Carbon Alloys’.

Development of a selective TOCSY experiment and its use in analysis of a mixture of related compounds

Gary J. Sharman*

AstraZeneca Pharmaceuticals, Silk Road Business Park, Macclesfield, Cheshire, UK SK10 2NA.
E-mail: gary.sharman@alderley.zeneca.com

Received (in Cambridge, UK) 26th March 1999, Accepted 9th June 1999

A selective TOCSY experiment based on the recently described DPFGSE selective excitation sequence has been developed: it employs gradient purging pulses which result in excellent lineshapes free of antiphase dispersive components, and has proven useful in the identification of a number of impurities in a pharmaceutical intermediate.

Recently, Stott *et al.* have described a new method of selective excitation called 'double pulsed field gradient spin echo' (DPFGSE).[1,2] The method gives exceptionally clean selective excitation. They have used this selective excitation scheme to develop a one dimensional NOE experiment, the DPFGSE-NOE, which gives excellent quality NOE spectra devoid of the subtraction artefacts normally associated with the steady state NOE difference experiment.

Using this excitation scheme, we have developed a selective TOCSY experiment.[3–5] DANTE pulses have been used instead of shaped pulses within the DPFGSE sequence [Fig 1(*a*)], due to spectrometer hardware limitations, but the quality of the selective excitation remains high. This approach has the advantage of allowing the bandwidth of the selective excitation to be easily tailored by adjusting the DANTE delay. The TOCSY transfer can be achieved by a period of spin locking following on from the selective excitation. The DIPSI[6,7] sequence was chosen in this case. However, such a sequence can result in severely distorted lineshapes.[8,5] These distortions arise because any magnetisation which is not purely single component, prior to and after the period of spin locking, results in zero quantum coherence which gives an antiphase dispersive contribution to the lineshape. Thus poorer quality spectra are obtained and interpretation is less straightforward in that direct comparison with a proton spectrum or with expected multiplet patterns is not possible. This is clearly illustrated in Fig. 2(*a*), which shows a selective TOCSY spectrum of sucrose following excitation of the anomeric proton. The triplet due to H4 and the double doublet due to H2 are both severely distorted. A z-filter, employing a variable delay list,[9,10] is one way of reducing these undesired effects, but this necessitates long acquisition times as the phase cycle must be completed for each value of the z-filter delay, of which there are typically many. In addition, even with all parameters set up optimally, this method can never remove all of the phase anomalies.[8]

A superior method for removing these zero quantum effects is provided by dephasing in an inhomogenous B_0 field, as described by Davis *et al.*[8] The method is based around a period of spin locking which is executed concurrently with a gradient pulse, before and after the mixing sequence. This method gives exceptionally clean two dimensional TOCSY spectra,[8] and a similar scheme has been used by Dalvit in a 1D TOCSY.[4] The essence of the method is that zero quantum coherence precesses during the gradient pulse. Its offset becomes spatially dependent and it is therefore dephased. The pulse sequence incorporating these purging pulses and the DIPSI mixing sequence is shown in Fig. 1(*b*). Fig. 2(*b*) shows a selective TOCSY spectrum of a sucrose test sample—the lineshape and multiplet structure is greatly improved, and compares well to the normal proton spectrum.

The excellent selectivity of the DPFGSE sequence suggested to us that this TOCSY sequence might prove useful in the analysis of low level impurities in a mixture. This type of analysis could be tackled by LC-NMR,[11] but this technique is not without its problems. Replicating chromatography at the high loading levels required for LC-NMR is not always straightforward, and lower loading levels can lead to inadequate sensitivity. Also, instrument time is a factor, with probe changes

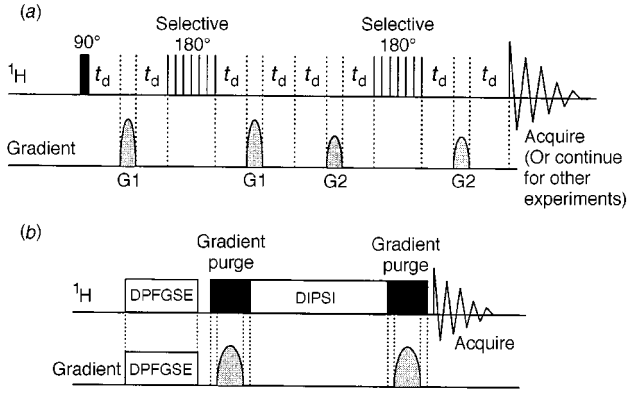

Fig. 1 (*a*) Pulse sequence for the DPFGSE selective excitation. The DANTE pulse consists of 200 π/200 pulses separated by a delay of 125 μs. (*b*) Additional pulses for the selective 1D-TOCSY experiment.

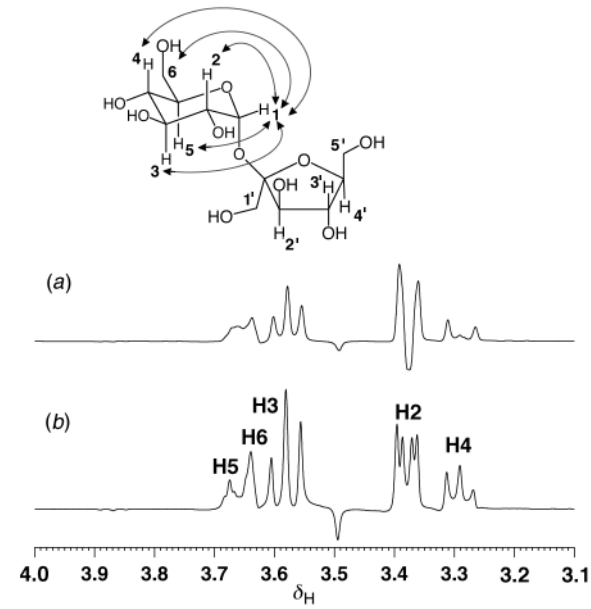

Fig. 2 (*a*) Selective TOCSY spectrum of sucrose obtained using only a period of DIPSI mixing after selective excitation. Phase distortions are apparent. (*b*) Selective TOCSY spectrum obtained using the sequence in Fig. 1(*b*), showing almost complete removal of distortions. The TOCSY mixing time was 100 ms, the purge spin lock 10 ms and the gradient pulse 9.8 ms at approximately 15 G cm^{-1} (a 100 μs delay precedes and follows the gradient).

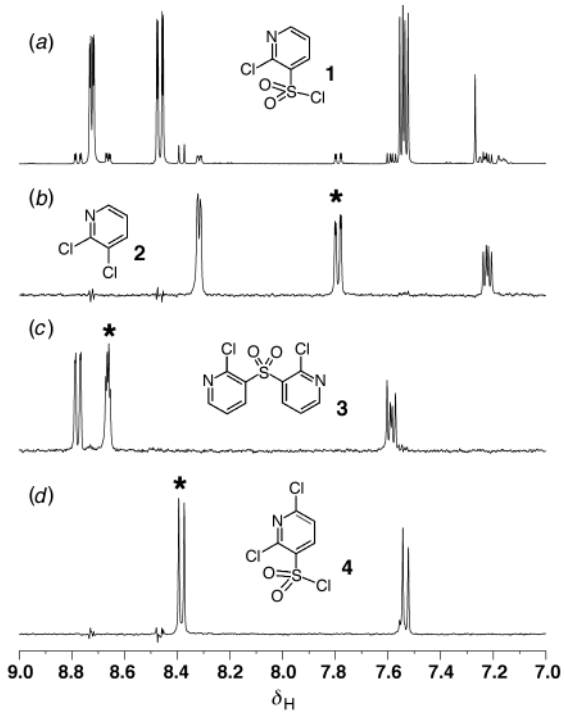

Fig. 3 (*a*) 400 MHz ^{1}H NMR spectrum of **1** in DMSO-d_6. A number of low level impurities are also apparent. (*b*)–(*d*) Selective 1D-TOCSY spectra obtained after selective excitation of the marked peaks. Each spectrum is consistent with the impurities **2**–**4**. Spectra in (*b*)–(*d*) acquired with 64 transients.

significantly increasing the time taken for analysis of a sample. Diffusion ordered spectroscopy[12,13] is perhaps a promising alternative, but this technique requires a significant difference in the diffusion coefficients of the species involved; this may well not be the case for typical impurities of related structure. The selective TOCSY experiment described above might provide another fast approach. The method would require that one impurity peak be resolved from other components. In these circumstances, a partial spectrum of the impurity could be acquired, and in the case of simple compounds consisting of one spin system, an essentially normal proton spectrum could be obtained.

This approach was tested on a sample which contained a number of impurities requiring identification. The major component in the mixture was the sulfonyl chloride **1**, but a number of other peaks were apparent in the spectrum [Fig. 3(*a*)]. Using the selective TOCSY experiment described above, the resonance at 7.8 ppm was excited, resulting in the spectrum shown in Fig. 3(*b*). This spectrum clearly shows the excellent suppression of the main component, together with a lineshape which compares favourably to that of the normal proton spectrum. The spectrum clearly represents a component in which the three aromatic protons are still present, but the relatively large chemical shift changes suggest different substituents to the main component. The spectrum is therefore consistent with that of the suspected impurity **2**. Similarly, selective excitation of the resonance at 8.65 ppm resulted in the spectrum shown in Fig. 3(*c*). As for the first impurity, the spectrum indicates a disubstituted pyridine system, but the similarity of chemical shifts to the main component suggests that these resonances are due to the dimeric sulfone **3**, another suspected impurity. Note that in this spectrum too, lineshape is good and the main component is well suppressed, despite the fact that the selectively excited proton is only 0.1 ppm from a resonance of the main component.

Finally, the resonance at 8.4 ppm was selectively excited. This gave rise to the 1D-TOCSY spectrum shown in Fig. 3(*d*). Clearly, this component exhibits only two proton resonances, indicating a tri-substituted product. It was therefore assigned to the dichloro sulfonyl chloride **4**, which was another suspected contaminant. Note that one of the two resonances in this component was completely overlapped with the main component in the normal proton spectrum. The excellent suppression of the main component, however, means that this peak can clearly be observed with its normal lineshape and doublet structure.

Overall, the three experiments took a total of 15 min to acquire. Subsequently, the sample was analysed by LC-NMR. This took several hours, including time for probe changes and setting up the chromatography. The conclusions reached were the same. Mass spectrometry also confirmed the identity of the three impurities.

The impurities in this sample were present at a level of approximately 4% w/w each. The level of suppression afforded by the selective TOCSY experiment is such that the residual peaks arising from the main component are approximately 2% of the level of each impurity. This figure suggests that the level at which impurities could be detected while retaining a useful degree of suppression of the main peak is rather lower than the 4% in this sample. It is estimated that 0.5% could be regarded as the limit of detection.

Of course, this selective TOCSY experiment will not give a complete, 'normal' spectrum of every component in every mixture; it may be that peaks are not resolved from the main component, or more complicated structures with many spin systems will not allow transfer to all parts of the molecule. However, in the case of many pharmaceutical compounds, we are looking for closely related impurities, and so a complete spectrum may not be necessary to obtain a structure. The elucidation of a different substitution pattern, or a 'missing' proton in a particular spin system, may be enough to define a structure, particularly when combined with mass spectrometry data. Also, the use of the related DPFGSE NOE experiment could allow parts of the molecule not in the same spin system to be accessed. Overall, it seems that this method, while not being a panacea for the analysis of all impurities, is nevertheless a useful technique which in this case has provided a fast answer to a real problem.

Dankasterone, a new class of cytotoxic steroid produced by a *Gymnascella* species from a marine sponge

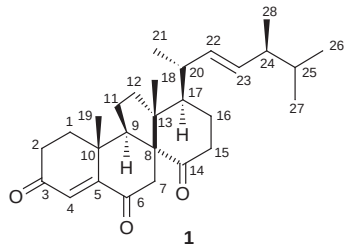
Taro Amagata, Mitsunobu Doi, Makiko Tohgo, Katsuhiko Minoura and Atsushi Numata*

Osaka University of Pharmaceutical Sciences, 4-20-1 Nasahara, Takatsuki, Osaka 569-1094, Japan. E-mail: numata@oysun01.oups.ac.jp

Received (in Cambridge, UK) 13th May 1999, Accepted 9th June 1999

Dankasterone, produced by a strain of *Gymnascella dankaliensis* from the marine sponge *Halichondria japonica*, is a novel class of steroid with significant cytotoxicity against tumour cells in culture.

In our programme devoted to the search for new antitumour metabolites from microorganisms inhabiting the marine environment, we have found a number of antitumour and cytotoxic compounds and elucidated their structures.[1,2] As part of this study, we have previously isolated the cytotoxic gymnastatins[2,3] and gymnasterones[4] from a strain of *Gymnascella dankaliensis* (Castellani) Currah OUPS-N134 originally separated from the sponge *Halichondria japonica*. Further investigation for metabolites of this fungal strain has now led to the isolation of a structurally unique and cytotoxic steroid **1**, designated dankasterone.



1

In this experiment, the fungal strain was cultivated in a medium which was prepared by replacement of glucose used for the previous experiment[2–4] by starch. The MeOH extract of the mycelium was purified by bioassay-directed fractionation employing a combination of Sephadex LH-20 and silica gel column chromatography and HPLC to afford dankasterone **1** as prisms.

Dankasterone **1** was assigned the molecular formula of $C_{28}H_{49}O_5$ as deduced from HREIMS. A close inspection of the ^{1}H and ^{13}C NMR spectral data† for **1** from DEPT and ^{1}H–^{13}C COSY experiments revealed the presence of six methyls including four secondary and two tertiary methyls, seven methylenes, five sp^3- hybridised methines, three quaternary sp^3-carbons, one disubstituted and one trisubstituted double bond, and one unconjugated and two conjugated ketones. The ^{1}H–^{1}H COSY analysis for the functional groups led to partial structures A (C-1 and C-2), B (C-9, C-11 and C-12) and C (C-15–C-17 and C-20–C-28), which were supported by HMBC correlations. The geometry of the disubstituted double bond was deduced from the coupling constants ($J_{23,24}$ 15.1 Hz) of the olefinic protons. The connection of the partial structures (A to C) and the remaining functional groups was determined on the basis of HMBC correlations. The typical correlations are as follows; H-1 and H-2 to C-3, H-4 to C-2, C-6 and C-10, H-19 to C-1, C-5, C-9 and C-10, H-7 to C-6, C-8 and C-13, H-9 to C-7, C-8, C-10 and C-14, H-15 to C-14, and H-18 to C-8, C-12, C-13 and C-17. Based on this evidence, the planar structure of **1** was elucidated.

The relative stereochemistry for **1** was established by NOESY experiments, which showed NOEs from 1-H$^\alpha$ to 9-H and 11-H$^\alpha$, 19-H to 1-H$^\beta$ and 11-H$^\beta$, 17-H to 9-H and 12-H$^\alpha$, and 18-H to 7-H$^\alpha$, 7-H$^\beta$ and 12-H$^\beta$. The relative stereostructure of **1** thus expected was cofirmed by X-ray structure analysis‡ on a single crystal of **1** (Fig. 1), which clarified the stereochemistry of the side chain. This compound is an unprecedented steroid with a 13(14→8)*abeo*-8-ergostane skeleton which is considered to have been reconstructed from ergostane through the 1,2-migration of C-13–C-14 bond to the C-8 position.

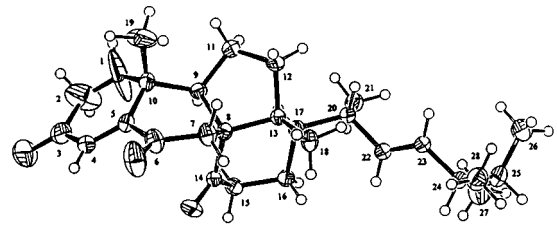


Fig. 1 X-Ray crystal structure for dankasterone **1**.

Dankasterone **1** exhibited significant cytotoxicity (ED_{50} 2.2 μg ml^{-1}) in the P-388 lymphocytic leukemia test system in cell culture. First isolation of this steroid with a unique carbon skeleton consisting of five-membered (C) and six-membered (D) rings has evoked great interest in what sort of biological activity it exhibits, compared with those of usual steroids.

Mg^0-promoted selective C–F bond cleavage of trifluoromethyl ketones: a convenient method for the synthesis of 2,2-difluoro enol silanes

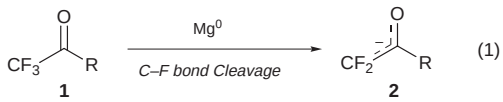
Hideki Amii, Takeshi Kobayashi, Yasushi Hatamoto and Kenji Uneyama*

Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushimanaka 3-1-1, Okayama 700-8530, Japan. E-mail: uneyamak@cc.okayama-u.ac.jp

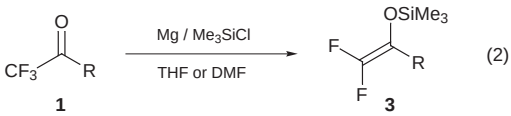
Received (in Cambridge, UK) 7th May 1999, Accepted 8th June 1999

2,2-Difluoro enol silyl ethers were readily prepared by Mg^0 promoted selective defluorination of trifluoromethyl ketones in the presence of TMSCl, which involves C–F bond cleavage.

Difluoro enol silyl ethers are synthetic equivalents of enolates of α,α-difluoro ketones and useful synthons for difluoro compounds, which provide a wide repertoire of bioactive fluorinated compounds.[1] One of the well-established methods for preparing difluoro enol silyl ethers is dehalogenation from halodifluoromethyl groups.[2] Selective defluorination of the trifluoromethyl group is a promising method for preparing difluoro compounds due to the broad and easy availability of trifluoromethylated compounds. However, there are very few successful cases of the selective demonofluorination from a trifluoromethyl group.[3–7] Recently, we have reported electroreductive methods for difluoro enol silyl ethers[8] and difluoro enamines[9] using trifluoromethyl ketones and imines as starting materials. A key feature of these methodologies is the selectivity of defluorination which derives from the higher reduction potentials of the product enols and enamines than those of the parent keto systems.[8] Here, we report the first successful Mg^0-promoted selective defluorination of trifluoromethyl ketones **1** in the presence of TMSCl by means of a process involving C–F bond cleavage [eqn. (1)],[10] which provides a highly efficient access to a variety of 2,2-difluoro enol silyl ethers.



The reaction procedure is very simple. The mixture of **1a** (6.0 mmol), TMSCl and Mg[11] (12 mmol) in 2.4 ml of anhydrous THF was stirred at 0 °C for 20 min [eqn. (2)].† After filtration, the difluoro enol silyl ether **3a** was obtained in 91% NMR yield.



Compared to previously available methods, this methodology has several advantages: (i) the starting trifluoromethylated materials are readily available directly from trifluoroacetates; (ii) Mg as a reducing agent is cheap and easy to handle; and (iii) selective formation of 2,2-difluoro enol silyl ethers is achieved in a short reaction time.

As shown in Table 1, the same procedure for the selective formation of **3** works well for a diverse group of aromatic, heteroaromatic and aliphatic ketones, and the over-reduction products were not detected.

In the cases of aromatic and heteroaromatic ketones **1a–f**, the reactions were completed within 25 min at 0 °C in THF (entries 1–6), as compared with the case of aliphatic ketones (**1g** and **1h**) which required DMF as a solvent (entries 7 and 8).[12] Also,

Table 1 Mg^0-promoted defluorinative silylation of trifluoromethyl ketones **1**[a]

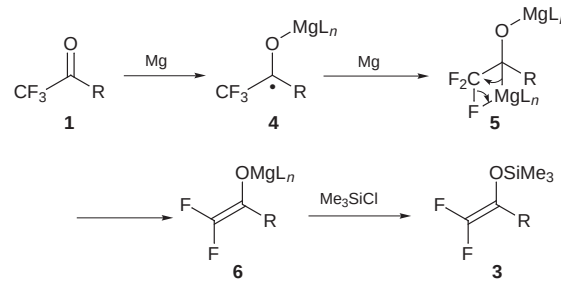
Entry	**1**	R	*T*/°C	*t*/min	Product **3**	Yield[b] (%)
1	**1a**	Ph	0	20	**3a**	91
2	**1b**	4-$MeOC_6H_4$	0	20	**3b**	89
3	**1c**	4-$CF_3C_6H_4$	0	20	**3c**	87
4	**1d**	4-ClC_6H_4	0	20	**3d**	98
5	**1e**	2-furyl	0	25	**3e**	97
6	**1f**	2-thienyl	0	25	**3f**	97
7[c]	**1g**	C_6H_{13}	0	30	**3g**	56
8[c]	**1h**	Cy	0	30	**3h**	62

[a] Unless otherwise stated, the reactions were performed on a 0.6 mmol scale in THF. [b] NMR yield, which was calculated by ^{19}F NMR integration of product **3** relative to 1,3-bis(trifluoromethyl)benzene internal standard. [c] DMF was used as solvent, and 8 equiv. of Mg was used.

aromatic and heteroaromatic ketones **1a–f** generally gave good yields, and the presence of electron-withdrawing and -donating groups had little effect on the yields. Notably, CF_3-arene and Cl-arene functionalities were compatible with the present reaction conditions; the reductive cleavage of the benzylic C–F bond[13] or aromatic C–Cl bond[14] did not occur (entries 3 and 4).

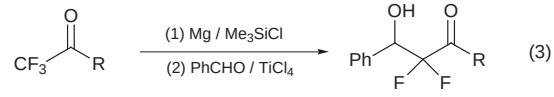
The formation of **3** can be explained by assuming the pathway pictured in Scheme 1. Initially, the intermediate ketyl species **4** is generated in the reaction of Mg^0 with a ketone **1**, which is further reduced to anion species **5** by Mg. The resultant β-fluorinated organomagnesium species **5** readily undergoes β-elimination to form **2**. In general, the cleavage of a C–F bond is not easy due to the large bond energy (*ca.* 552 kJ mol^{-1}). However, the bond breaking does occur rather easily when the CF_3 group is attached to a π-system because electron acceptance into the carbonyl group and subsequent extrusion of the fluoride ion may make large contributions to the driving force of the reaction. The reduction potential of aromatic ketones (**1a–f**) is more negative than that of aliphatic ones (**1g** and **1h**). Therefore, the difference in reactivity between aromatic ketones and aliphatic ones may derive from the tendency to form ketyl anion species **3**.

In particular, utilization of 2,2-difluoro enol silanes **3** is made in aldol reactions.[7] After simple filtration of the metal waste, the crude products **3** were used directly in the next reaction without



Scheme 1

purification due to the instability of **3**. When benzaldehyde was added to a solution of **3a** and $TiCl_4$ at −78 °C, the aldol adduct **7a** was formed [eqn. (3)] in 71% isolated yield (from **1a**).



(3)

1a R = Ph — **7a** (71%)
d R = 4-ClC$_6$H$_4$ — **d** (78%)
g R = C$_6$H$_{13}$ — **g** (38%)
h R = Cy — **h** (42%)

In conclusion, Mg^0-promoted selective defluorination of a series of trifluoromethyl ketones provides a promising route to difluoro enol silanes.

Notes and references

† *Typical procedure* for **3a**: To TMSCl (2.6 g, 24 mmol) in freshly distilled THF (24 ml) and Mg (290 mg, 12 mmol) cooled down to 0 °C under an argon atmosphere, trifluoroacetophenone (1.04 g, 6.0 mmol) was added dropwise and then stirred for an additional 20 min. After evaporation of most of the THF, hexane (20 ml) was added to the residue, and the resulting salt was filtered and the filtrate concentrated to give 1.21 g (*ca*. 0.53 mmol) of crude product (the crude product **3a** had purity > 95%).

To a solution of crude **3a** and benzaldehyde (1.27 g, 12 mmol) in CH_2Cl_2 (10 ml) cooled down to −78 °C, was added dropwise a solution of $TiCl_4$ (6 mmol) in CH_2Cl_2 (10 ml). Then the reaction mixture was quenched with aq. NH_4Cl, and the organic layer was washed with brine and dried over Mg_2SO_4. Purification of the products by chromatography on silica gel (hexane–EtOAc 5 : 1) provided **7a** (1.18 g, 71% from **1a**) as a colorless oil. *Selected data* for **7d**: 3512 cm^{-1} (ν_{OH}), 1696 cm^{-1} (ν_{CO}); δ_H($CDCl_3$, 200 MHz) 3.05 (d, *J* 3.6, 1 H), 5.35 (ddd, J_{HF} 18.6, 7.6, 3.6, 1 H), 7.2–7.5 (m, 7 H), 7.9–8.0 (m, 2 H); δ_F($CDCl_3$, 188 MHz, C_6F_6 as an internal standard) 45.2 (dd, J_{FF} 290.7, J_{HF} 18.6, 1 F), 56.9 (dd, J_{FF} 290.7, J_{HF} 7.6, 1 F).

Bis(amido)magnesium mediated aldol additions: first structural characterisation of an amidomagnesium aldolate intermediate

John F. Allan, Kenneth W. Henderson* and Alan R. Kennedy

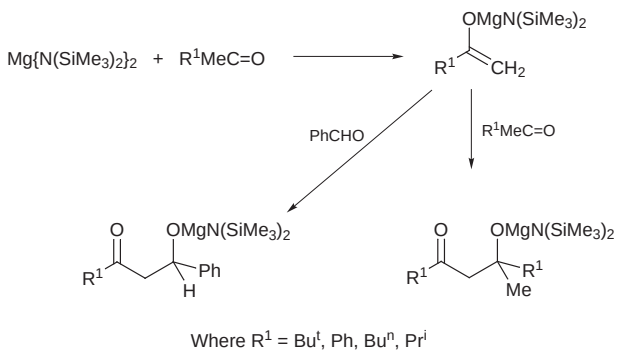
Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL. E-mail: k.w.henderson@strath.ac.uk

Received (in Basel, Switzerland) 11th May 1999, Accepted 2nd June 1999

Bis(hexamethyldisilazido)magnesium has successfully been used to mediate aldol additions of selected ketones and aldehydes in hydrocarbon media, and the structure of an intermediate amido(aldolate), [{$(Me_3Si)_2$NMg[μ-OC(Me)-$Bu^tCH_2C(Bu^t)=O$]}$_2$] 17, produced by the self-coupled reaction of pinacolone has been characterised by X-ray crystallography.

Addition of the α carbon of an aldehyde or ketone to a second carbonyl unit is known as the aldol addition and has become one of the cornerstone reactions of modern synthetic chemistry.[1] Several methods have been developed to mediate this transformation, one of the most useful being the formation of a metal enolate by abstraction of a proton α to the carbonyl using a strong base. This is most commonly achieved through the use of lithium reagents and more specifically bulky lithium amides such as lithium diisopropylamide (LDA) and lithium hexamethyldisilazide (LHMDS).[2] We are interested in exploring the utility of amidomagnesium compounds as reagents to perform similar transformations since they are less reactive, more thermally stable and, in some instances, more selective than their lithium counterparts.[3] Magnesium has previously been used to mediate aldol additions *via* transmetallation of preformed lithium enolates with magnesium halides.[2] Reactions of this type have proved problematic due to 'salt-effects'.[4] In this respect, we have recently reported the presence of Schlenk-type equilibria for Hauser bases (R_2NMgX) and halomagnesium enolates, which complicates their use.[5] In comparison, bis(amido)magnesium compounds [$(R_2N)_2Mg$] have scarcely been studied as reagents.[6] In part this is due to complications with their synthesis, leading to troublesome side reactions of *in situ* prepared complexes.[7] These experimental problems have recently been overcome and we now report the use of bis(amido)magnesium compounds as reagents.[8] Herein we exploit an ether-free preparation of the bis(amide) [Mg{$N(SiMe_3)_2$}$_2$] **1**, and examine its utility in the aldol addition reaction.

A mixture of commercially available Bu_2Mg and 2 equivalents of hexamethyldisilazane was heated to reflux in heptane solution for several hours, and slow cooling to room temperature resulted in the crystallisation of **1** in high yield.[9] Crystalline **1** was then isolated and used as a stock reagent. In turn, reactions with pinacolone **2**, acetophenone **3**, hexan-2-one **4**, 3-methylbutan-2-one **5** and cyclohexanone **6** were performed (Scheme 1), and Table 1 lists the results of the aldol addition reactions mediated by **1**.†



Scheme 1

Isolated yields from the ketone/aldehyde reactions compare favourably with lithium-mediated additions (reactions 1–5).[2] In most instances the reaction of the ketone enolates with

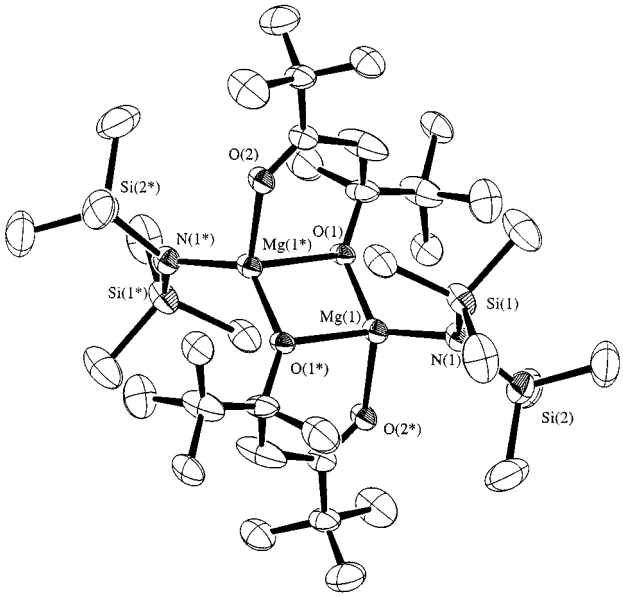

Fig. 1 Molecular structure of the major isomer of **17** with hydrogen atoms omitted for clarity. Key bond lengths (Å) and angles (°): Mg(1)–O(1) 1.9540(15), Mg(1)–O(1*) 1.9881(15), Mg(1)–N(1) 1.9920(19), Mg(1)–O(2*) 2.0619(15), O(1)–Mg(1)–O(1*) 85.90(6), O(1)–Mg(1)–N(1) 126.96(7), O(1*)–Mg(1)–N(1) 129.57(7), O(1)–Mg(1)–O(2*) 111.60(7), O(1*)–Mg(1)–O(2*) 87.18(6), N(1)–Mg(1)–O(2*) 108.51(7), C(7)–O(1)–Mg(1) 144.29(16), C(7)–O(1)–Mg(1*) 116.06(13), Mg(1)-O(1)–Mg(1*) 94.10(6), C(14)–O(2)-Mg(1*) 130.27(12).

benzaldehyde resulted in a small quantity (4–16%) of self-addition products. Significantly, this problem was overcome by adding 2 equivalents of the aldehyde to a solution of **1** before addition of the ketone. Also, no aldimine formation was detected.[10] Analogies with Corey's internal quench method for formation of silyl enol ethers are clear.[11]

It is known that ketone–ketone aldol coupling is usually less favourable than ketone–aldehyde additions. Using high temperature conditions (25–70 °C) the self-aldol reactions were found to proceed in reasonable yields (reactions 6–10).[12] The ability to perform these reactions at higher temperatures contrasts appreciably with the lithium analogues, where the aldolates commonly undergo retro-aldol reactions above −30 °C or eliminate LiOH to give enones.[2] With the systems reported here, the enone only becomes the major product after extended reflux. Furthermore, reactivity of both amide functions bonded to magnesium is suggested by reaction of 4 equivalents of **2** with **1** which yielded 55% of aldol product **12** (calculated with respect to ketone).

It should be noted that when polar donor solvents such as THF or HMPA were present, the yield of aldolate was significantly reduced (< 10% for entry 6). This is consistent with the observation that, in lithium-mediated reactions, increasing the solvent polarity increases yields of enolisation but disfavours addition. However, this effect appears to be more dramatic for magnesium, since the lithium reactions are commonly performed in THF solution. This may be a consequence of the magnesium centres being more sterically crowded than those of lithium, resulting in blocking of the incoming carbonyl.

The intermediate from the pinacolone self-coupled reaction, $[\{(Me_3Si)_2NMg[\mu\text{-}OC(Me)Bu^tCH_2C(Bu^t)=O]\}_2]$ **17**, was characterised by X-ray crystallography (Fig. 1).‡ The centrosymmetric structure is based on a *trans*-6,4,6-fused ring system in which each aldolate acts as both bridge and chelate.

Two superimposed isomers are present within the crystal lattice of **17**. The isomers differ in the conformation of the six-membered aldolate chelate rings where half-chair and twist-boat conformation are found in a ratio of 80.5(3):19.5(3). Chelate isomers are also found in aldolate derivatives of lithium,[13] zinc,[14] titanium[15] and aluminium.[16] These isomers adopt half-boat, chair, half-chair and twist boat structures, illustrating the shallow energy surface separating these conformations.

We would like to thank The Royal Society for a University Research Fellowship (K. W. H.), and Professor Robert E. Mulvey and Dr William J. Kerr for helpful discussions during the preparation of this manuscript.

Notes and references

† Base **1** (2 mmol) was suspended in 10 ml of hexane and cooled to −78 °C. Aldehyde (4 mmol) or alternatively ketone (2 mmol) was then added, followed by dropwise addition of the ketone (2 mmol). The aldehyde reactions were stirred at −78 °C for 30 min then quenched with 1 M HCl. The self-coupled reactions were warmed to room temperature and stirred for 48–72 h before quenching in 1 M HCl. Improved yields of **12** and **13** were obtained on heating the mixtures to reflux for several hours. Further improvements in yields are expected on optimising the reaction conditions.

‡ *Crystal data* for **17**: $C_{36}H_{82}Mg_2N_2O_4Si_4$, M = 768.02, T = 123(2) K, triclinic space group, $P\bar{1}$, a = 9.610(3), b = 11.381(2), c = 12.024(4) Å, α = 98.90(2), β = 104.00(2), γ = 105.996(19)°, U = 1191.5(5) Å^3, Z = 1, μ(Mo-Kα) = 0.185 mm^{-1}, D_c = 1.070 Mg m^{-3}, $2\theta_{max}$ = 56°, 6084 reflections collected, 5746 unique, (R_{int} = 0.0173) all were used in the calculations. The minor disorder component was treated isotropically with no hydrogen atoms attached. All other non-hydrogen atoms were treated anisotropically and all other hydrogens included in a riding model. The final $wR(F^2)$ was 0.1417 and conventional R was 0.0488. Programs were standard diffractometer control software and members of the SHELX family (G. M. Sheldrick, University of Göttingen, Germany). The structure was solved using direct methods and refined by full-matrix least-squares refinement on F^2. A single crystal of **17** was mounted in inert oil and transferred to the cold N_2 gas stream of the diffractometer.

Covalent and noncovalent interpenetrating planar networks in the crystal structure of {[Ni(4,4′-bipyridine)$_2$(NO$_3$)$_2$·2pyrene}$_n$

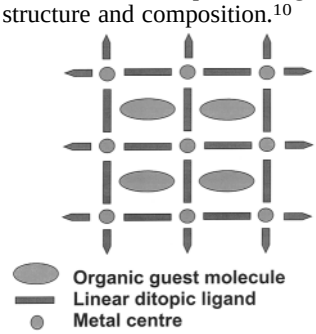
Kumar Biradha, Konstantin V. Domasevitch, Brian Moulton, Corey Seward and Michael J. Zaworotko*

Department of Chemistry, The University of Winnipeg, Winnipeg, Manitoba, R3B 2E9, Canada.
E-mail: mike.zaworotko@uwinnipeg.ca

Received (in Columbia, MO, USA) 16th February 1999, Accepted 9th June 1999

The crystal structure of {[Ni(4,4′-bipyridine)$_2$(NO$_3$)$_2$]·2pyrene}$_n$ reveals the first example of complementary, interpenetrating covalent and noncovalent 2D networks.

Crystal engineering of coordination polymer networks based upon multitopic ligands represents a growing area of coordination and supramolecular chemistry.[1,2] In this context, 2D square grid networks exemplify a particularly simple example of a predictable network. The primary reason for interest in such compounds has been their ability to afford controllable cavities that are suitable for enclathration of organic guest molecules (Scheme 1). A number of simple bifunctional spacer ligands have been examined, especially 4,4′-bipyridine (4,4′-bipy).[3–7] However, a phenomenon that mitigates against or even precludes enclathration is the filling of cavities by self-inclusion or interpenetration.[8] Interpenetrated structures have limited potential in the context of host–guest chemistry but have significant potential in terms of other bulk properties.[9] In this contribution, we report a compound that combines the above features: {[Ni(4,4′-bipy)$_2$(NO$_3$)$_2$]·2pyrene}$_n$ **1** which represents, to our knowledge, the first compound in which two very different types of 2D net interpenetrate: a square grid coordination polymer and a non-covalent planar net of pyrene molecules. A recent literature review[8] revealed that the only other example of a compound with different interpenetrating nets contains two nets of similar structure and composition.[10]



Scheme 1

A realistic motif for self-assembly of aromatic molecules is a 2D net that is sustained by edge-to-face stacking interactions. A distorted form of such a net coexists with [Ni(4,4′-bipy)$_2$(NO$_3$)$_2$] square grids in **1**. Blue crystals of **1** were grown by carefully layering a MeOH solution of Ni(NO$_3$)$_2$·6H$_2$O onto a MeOH solution of 4,4′-bipy and pyrene under ambient conditions.† The coordination networks [Fig. 1(a)] possess inner cavities of *ca*. 8 × 8 Å and stack parallel to one another with an interlayer separation of *ca*. 7.9 Å (corresponding to half the *c*-axis) and bear a close resemblance to the coordination array in [Cd(4,4′-bipy)$_2$(NO$_3$)$_2$]·2C$_6$H$_4$Br$_2$.[3] An additional factor that appears to influence the packing of the grids is weak CH···O hydrogen bonding between the 4,4′-bipy ligands and nitrate anions of the adjacent grids. C···O separations are in the range of 2.877–3.149 Å. The pyridyl rings of the 4,4′-bipy ligands are not coplanar and are twisted by 32.5–48.9°.

The pyrene nets [Fig. 1(b)] are sustained by edge-to-face interactions and contain cavities of dimensions *ca*. 6.5 × 3.5 Å. The shortest intermolecular C–C separations (3.518 Å) are similar to those reported for related compounds such as pyrene itself[11] and 1-propynylpyrene.[12] The planes of the neighboring molecules intersect at an angle of *ca*. 60° and there are no face-to-face stacking interactions between the molecules. The pyrene nets can be regarded as distorted (4,4) nets if the node is the point in space at which the vectors of the four pyrene planes intersect. An alternate interpretation is that nodes exist at the point of the edge-to-face interactions. The pyrene net could then be regarded as a distorted brick wall form of a (6,3) net.[8] It is important to note that either a (4,4) or a (6,3) planar net is complementary from a topological sense with the (4,4) coordination polymer net and ensures that the coordination

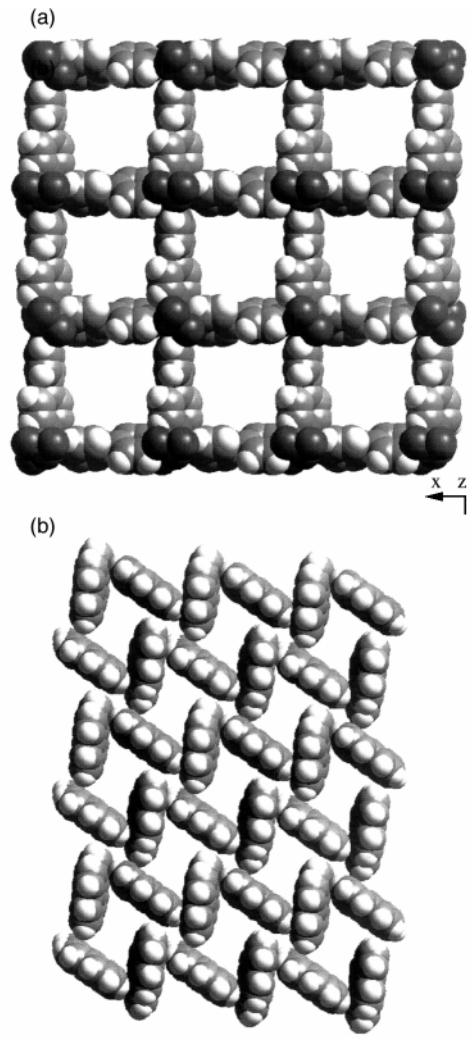


Fig. 1 (a) The square grid networks formed by [Ni(4,4′-bipy)$_2$(NO$_3$)$_2$] in **1**. Cavities have effective dimensions of *ca*. 8 × 8 Å. (b) An illustration of the pyrene (4,4) nets that exist in **1**. Cavities possess effective dimensions of *ca*. 6.5 × 3.5 Å.

polymer nets must pack in a staggered manner. Given that cavity size within the pyrene nets is complementary with the width and height of a single aromatic ring, it should be unsurprising that the pyrene nets thread orthogonally with the 4,4′-bipy ligands of the coordination polymer *via* face-to-face and edge-to-face interactions. The shortest carbon–carbon separation between the atoms of 4,4′-bipy ligands and pyrene molecules is *ca*. 3.40 Å and corresponds to face-to-face stacking (interplanar angle = 7.3°). The shortest C···O separations involving pyrene 3.20 Å may be attributed to $CH\cdots ONO_3$ hydrogen bonds. The calculated[13] volumes of the two nets are similar: 1548.5 and 1502.0 Å^3 for the covalent and noncovalent networks, respectively. This is to be expected based upon the observation that 4,4′-bipy square grids are self-complementary as they can interpenetrate in a two-fold fashion.[5] A view of the crystal packing is presented in Fig. 2.

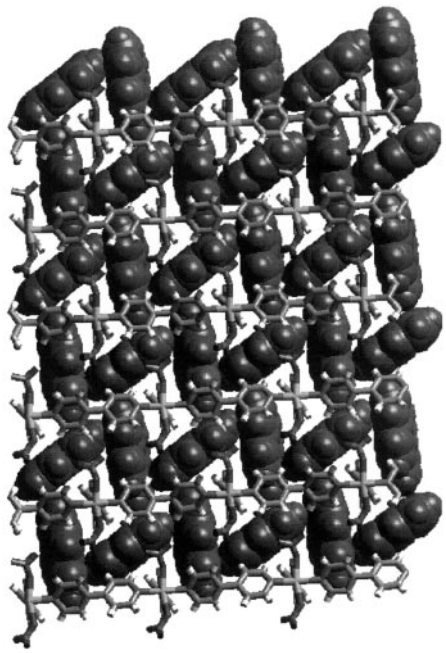

Fig. 2 A view of the crystal structure of **1** viewed down the *b*-axis. Note the stacking interactions between the pyrene molecules (space-filling mode) and square grid networks.

Interestingly, although both nets appear to be inherently centrosymmetric at first glance, the title compound crystallizes in the non-centrosymmetric space group *Pn* and is therefore polar. Pyrene molecules that lie opposite each other across the grid cavities in the *ac*-plane are clearly not related by inversion and are therefore crystallographically nonequivalent (Fig. 3). Indeed, they are not coplanar. Each set of four pyrene molecules in the *ac*-plane that surround the grid cavities adopts a bowl-like conformation and the bowls 'stack' in a parallel fashion along the *b*-axis. Additionally, the orientation of alternating pyrene molecules along the *b*-axis is slightly different, which leads to a doubling of the *b*-axis and the observed superstructure. An alternative possibility was also considered during structure refinement: random disposition of pyrene molecules in the crystal and crystallographic disorder. This artificial increase of the lattice symmetry did not afford a satisfactory refinement. Thus, the bulk polarity in **1** is a consequence of the symmetry of the supramolecular assembly of pyrene molecules.

In summary, the interpretation of the structure of **1** as interpenetrating covalent and noncovalent nets is to our knowledge unique and important in the context of understanding the structure and stoichiometry of compounds that are based upon interpenetrated covalent and noncovalent nets. **1** also illustrates how polarity in crystals can be generated from subtle packing of achiral components, as illustrated by the chiral nets of pyrenes. We are presently seeking other examples of compounds that contain complementary but chemically different nets.

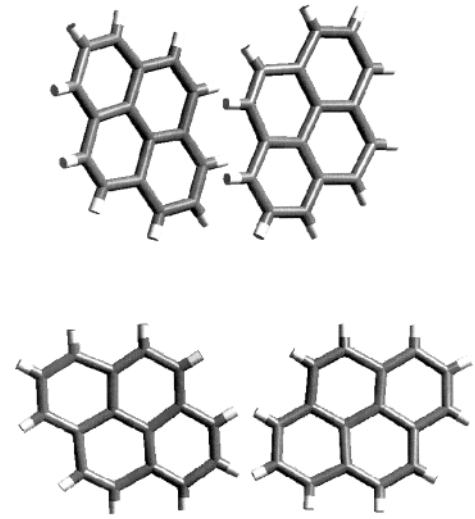

Fig. 3 An illustration of how the relative orientations of the pyrene molecules preclude a centre of inversion in **1**.

We acknowledge the generous financial support of the NSERC (Canada) in the form of a research grant (M. J. Z.).

Convergent synthesis and 'surface' functionalization of a dendritic analog of poly(ethylene glycol)

Scott M. Grayson, Manikandan Jayaraman and Jean M. J. Fréchet*

Department of Chemistry, University of California, Berkeley, CA 94720-1460, USA.
E-mail: frechet@cchem.berkeley.edu

Received (in Corvallis, OR, USA) 23rd March 1999, Accepted 21st May 1999

Aliphatic polyether dendrons exhibit easily modified surface functionality.

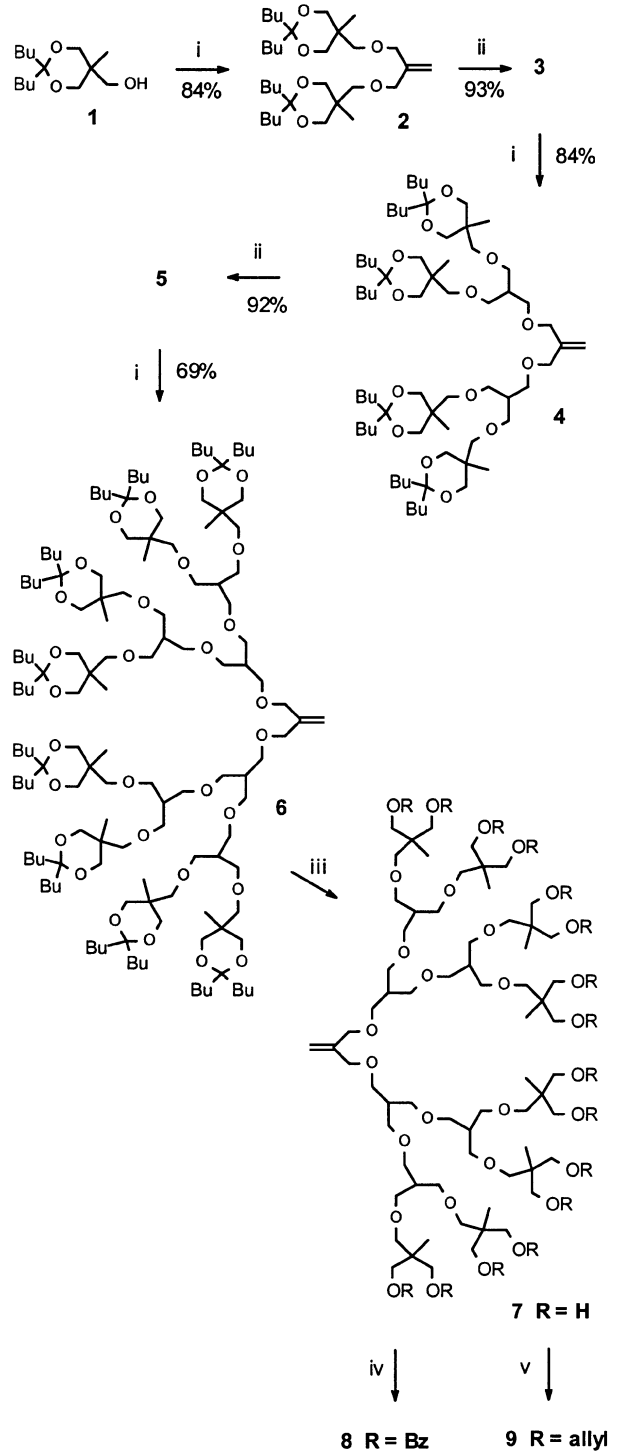
Because of its water solubility and non-ionic character, linear poly(ethylene glycol) has been utilized widely for applications ranging from surfactants to biocompatible drug solubilizers.[1] Although a variety of dendrimers have been reported to date,[2] few possess the structural features that would endow them with analogous solubility properties. An early, imaginative, divergent approach towards aliphatic polyether dendrimers reported by Hall *et al*. over a decade ago[3] has not been widely used due to synthetic complications. We have recently reported an efficient convergent route to dendrons containing an aliphatic polyether backbone and peripheral benzyl ether protecting groups.[4] Now, we report a very versatile convergent synthesis of hydroxy-terminated aliphatic polyether dendrons that may be considered dendritic analogs of poly(ethylene glycol) because of the 2 : 1 carbon : oxygen ratio in the branched repeat unit. These dendrons may prove valuable in polymer therapeutics as a result of their compact shape, high polarity, and multiple chain end functionalities.[5]

The hallmark of a successful convergent synthesis is an aptly chosen monomer that enables simple, high-yielding activation and growth steps. Our monomer, 3-chloro-2-chloromethylprop-1-ene, is well suited for high-yield Williamson coupling with two dendritic alcohols, since its symmetrical and activated allylic functionalities afford the same product regardless of displacement mechanism (S_N1, S_N2, or S_N2'). The resulting olefinic dendron can then be converted to the primary dendritic alcohol in high yield and with excellent regioselectivity *via* standard hydroboration reaction conditions. Further growth results from a repetitive cycle of coupling and activation reactions to afford larger dendrons.

Ketals were chosen as the surface protecting groups primarily because they are unaffected by the basic conditions required throughout the synthesis. While several acetals and ketals were tested, the lipophilic nature of the dibutyl ketal protecting group confers upon these dendrons excellent solubility in hexanes, thus facilitating their purification by chromatography. In addition, these protecting groups allow a facile deprotection under mildly acidic conditions, exposing terminal hydroxy functionalities that can be further modified if desired.

The synthesis of the first generation terminal moiety, [G-1]-ol, was achieved by protecting two of the hydroxy functionalities of 1,1,1-tris(hydroxymethyl)ethane with nonan-5-one in the presence of $BF_3{\cdot}OEt_2$.[6] Reaction of the [G-1]-ol, **1**, NaH, and 3-chloro-2-chloromethylprop-1-ene, in the presence of catalytic amounts of KI and 18-crown-6 afforded the second generation alkene, **2**, in 84% yield. This alkene was converted effectively to the activated primary [G-2]-ol, **3**, through hydroboration with 9-BBN,[7] followed by oxidation in alkaline H_2O_2 (92%). Repetition of the coupling and activation steps led to the preparation of higher generation dendrons up to [G-4]-ene, **6** (Scheme 1). All of the materials were purified by flash column chromatography on silica gel using EtOAc–hexane as eluent and were obtained as transparent, viscous oils.

Identification of the focal functionality by NMR and FT-IR facilitated the characterization of these dendritic compounds. In



Scheme 1 *Reagents and conditions*: i, NaH, THF, KI, 18-crown-6, $(ClCH_2)_2C{=}CH_2$; ii, 9-BBN, THF, then H_2O_2–NaOH; iii, H^+ Resin, MeOH; iv, BzCl, pyridine; v, allyl bromide, NaH, DMA–THF.

Table 1 MS and SEC data for second, third, and fourth generation dendrons

Compound	Calculated MW	FAB/MALDI MW	SEC[a] M_n	PDI
[G-2]-ene	540.8	540.7	600	1.01
[G-2]-ol	558.8	558.7	720	1.00
[G-3]-ene	1169.8	1170	1400	1.00
[G-3]-ol	1187.8	1189	1420	1.00
[G-4]-ene	2427.6	2429	2450	1.01
[G-4]-ol	2445.6	2446	2470	1.01

[a] SEC analysis was performed using THF as the eluent and was calibrated against polystyrene standards.

$CDCl_3$ the dendritic alkenes showed a singlet at δ 5.15 in the ^{1}H NMR spectrum, peaks at δ 143 and 113 in the ^{13}C NMR spectrum, and an absorbance at 1650–1660 cm^{-1} in the FT-IR spectrum, corresponding to the focal carbon–carbon double bond. The dendrons with focal hydroxy functionalities exhibited a broad absorbance at 3300–3500 cm^{-1} in the FT-IR spectrum, as well as a triplet at δ 2.7 in the ^{1}H NMR spectrum and a peak at δ 63 in the ^{13}C NMR spectrum corresponding to the adjacent methylene. The integration ratio between the peripheral acetals and the focal functionality verified both the generation of the dendron, and the retention of all protection groups.

Molecular weights of the dendritic molecules were monitored by mass spectrometry (MS) using fast atom bombardment (FAB) MS for those below 1000 Daltons, and matrix assisted laser desorption ionization time of flight (MALDI-TOF) MS for those above 1000 Daltons. In addition, the narrow signal obtained by size exclusion chromatography (SEC) further confirmed the monodisperse nature of the compounds, as expected in a convergent dendrimer synthesis (Table 1).

Deprotection of the chain-ends of the dendrons was achieved using an acid cation exchange resin. Because of the highly polar character of the resultant hydroxy-terminated dendron, and the insolubility of the polymeric catalyst, the product, **7**, could be isolated in near quantitative yield by a simple filtration of its methanol solution. At the fourth generation, these hydroxy-terminated compounds exhibited the desired water solubility regardless of the focal functionality. This was expected as previous studies of dendrimers' physical properties verified that the solubility of dendritic polymers is dominated at higher generation by the peripheral functionalities.[8]

The high reactivity of the 'surface' hydroxy functionalities was confirmed through simple modification reactions (Scheme 1). For example, reaction of the sixteen free hydroxy groups of $(OH)_{16}$[G-4]ene, **7**, with a two-fold excess of BzCl in pyridine afforded the fully esterified product, **8**. Similarly, a nucleophilic substitution reaction was performed with **7**, NaH, and a two-fold excess of allyl bromide to produce the fully allylated dendron, **9**. Both reactions appeared to be quantitative, as no partially functionalized dendrons were isolated by chromatography or observed in the MALDI-TOF MS of the crude reaction mixture.

Characterization of the surface modified dendrons was also achieved by monitoring changes in functionality. The end-deprotected dendrons exhibited a broad absorbance at 3300–3500 cm^{-1} in the FT-IR spectrum corresponding to the multiple hydroxy functionalities. Conversion of the surface groups to benzoate esters resulted in the appearance of a characteristic narrow carbonyl absorbance at 1724 cm^{-1} in the FT-IR spectrum, as well as aromatic resonances in the ^{1}H NMR,

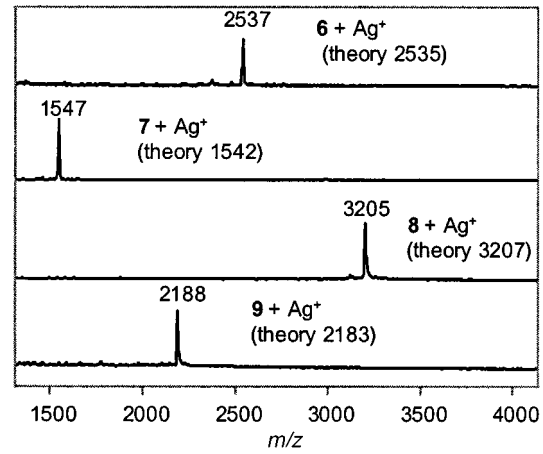


Fig. 1 MALDI-TOF MS data for the deprotection and derivatization of [G-4]-ene.

while the allyl ethers exhibited an alkene absorbance at 1646 cm^{-1} in the FT-IR spectrum as well as additional resonances for the vinyl protons (δ 5.2, 5.3, and 5.9) in the ^{1}H NMR. MALDI-TOF MS data of both functionalized dendrons exhibited a single peak with molecular weights corresponding closely to the expected values (Fig. 1.)

We believe that the unique and high yielding chemistry used in the preparation of these dendrons, as well as the flexibility of their functionalization at the focal point and at the chain ends, makes them suitable for broad use as building blocks in a variety of dendritic structures where they will complement the widely used aromatic polyethers we developed earlier.[9]

Financial support of this research by the U.S. Army Research Office (MURI program, DAAG55-97-0126) and the National Science Foundation (NSF-DMR #9816166) is gratefully acknowledged.

Exploring a chemical encoding strategy for combinatorial synthesis using Friedel–Crafts alkylation

Robin H. Scott, Colin Barnes, Ulrich Gerhard and Shankar Balasubramanian*

University Chemical Laboratory, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: sb10031@cam.ac.uk

Received (in Liverpool, UK) 29th March 1999, Accepted 14th June 1999

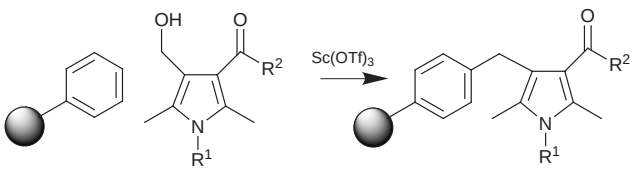
The use of scandium(III) triflate and ytterbium(III) triflate-catalysed Friedel–Crafts alkylation to insert a set of hydroxymethyl pyrrole amide tags (1b–i) on to polystyrene resins under mild conditions and the encoding of a split and mix peptide library is demonstrated.

Combinatorial approaches to molecular problem solving are the subject of great conceptual and experimental exploration. The approach is dependent on the ability to rapidly generate and screen large and diverse libraries.[1,2] The split and mix synthesis method,[3] which generates 'one-bead-one-compound' libraries, is a powerful approach, although the identification of active compounds remains a technical issue. A variety of deconvolution protocols exist,[1,4] of which the chemical tag-based encoding strategy is an inexpensive and general method that can be employed without the need for specialised equipment.[5,6] Key issues associated with chemical tagging include: the need for convenient, orthogonal chemistry for the attachment of tags to resin beads without disruption of the library molecules; the design of tags that are sufficiently robust to withstand a wide range of chemistry; and a simple cleavage and sensitive analysis strategy for decoding.

We have explored the use of Lewis acid-catalysed Friedel–Crafts alkylation to insert tags directly into the aromatic rings of polystyrene or other electron rich aromatic rings incorporated into the polymer. Friedel–Crafts chemistry has previously been used to functionalise polystyrene resins.[7,8] Having studied a variety of hydroxymethyl aromatics, the pyrrole derivative **1a** (R^1 = H, R^2 = OMe) was found to have promising reactivity with toluene (used as a resin mimic), reacting in 80% yield after 12 h at room temperature using a scandium catalyst (Scheme 1).[9] Scandium(III) triflate has particular advantages as the choice of Lewis acid since it is relatively insensitive to water, catalyses alkylations with alcohols[10] and its use has been demonstrated for solid phase chemistry.[11]

A mixture of polar and non-polar solvents was essential to retain both resin swelling and solubility of the scandium triflate. Since only small amounts of each tag need be incorporated into a bead (typically 1% of the resin capacity equating to about 0.05% of the available aromatic rings), the model solution phase reaction used 100 equiv. of toluene. Therefore in these reactions, the tags were present at relatively low concentrations. For acceptable reaction rates (completion in < 1 day), the concentration of Lewis acid required was at millimolar levels (which often equates to several equivalents compared to the tags).

Owing to the high reactivity of the pyrollic tag molecule with toluene, more stable amide derivatives were also prepared starting from the fully substituted methyl 4-formyl-1,2,5-trimethylpyrrole-3-carboxylate **2** (Scheme 2). Pyrrole ester **2** was hydrolysed to the free acid, then coupled to a variety of secondary amines. Reduction of the formyl group with $NaBH_4$ on alumina gave the corresponding alcohols **1b–i** in overall yields of 54–90% and these were found to be stable at −20 °C for at least six months. Once attached to the resin loss of the encoding tag is unlikely as the amide linkage is chemically robust, although in principle a linkage of any choice could be utilised in this methodology.



1

Scheme 1

Scandium-catalysed reaction of alcohol **1c** with toluene at room temperature was essentially complete in 2 days to give 74% of the desired product **3** and 23% of side product **4** (Table 1). Reaction of **1c** with the more reactive 1,3-dimethoxybenzene (DMB, 100 equiv.) resulted in a substantially improved reaction giving **5** in almost quantitative yield in only a few minutes. In the absence of an aromatic substrate, **1c** was shown to react slowly with itself in the presence of $ScOTf_3$ to form a dimer **4**, most likely by self-condensation and subsequent deformylation. These solution phase studies suggested that a resin containing a nucleophile more reactive than toluene would be less prone to side reactions.

The kinetics of pyrrole amide **1c** reacting with various polystyrene resins was followed by observing the loss of **1c** from the reaction mixture as compared to a control with no resin present. The observed reaction rate of amide **1c** with chloromethylpolystyrene **6** (Aldrich, 200–400 mesh) was comparable to the model studies with toluene (Table 1) under similar conditions. Reaction of **1c** with the more reactive, acetylated Wang resin **7** (Novabiochem, 200–400 mesh) gave the expected rate improvement leading to a half-life of 1.5 h as compared to 10.5 h for **6**. These reactivity studies are consistent with the observations made for the model reactions of **1c** with toluene and DMB and suggests that the resin environment does not impede the desired chemistry.

Chloromethylpolystyrene (Polymer Labs, 50–60 mesh, 1.8 mmol g^{-1}) was reacted with 3-methoxyphenol and subsequently 4-hydroxymethylphenol, to give the modified Wang resin **8**, which could be used for a library synthesis. However, some degree of cleavage of the Wang linker was observed when resin **8**, loaded with Fmoc-alanine, was treated with 10 mM

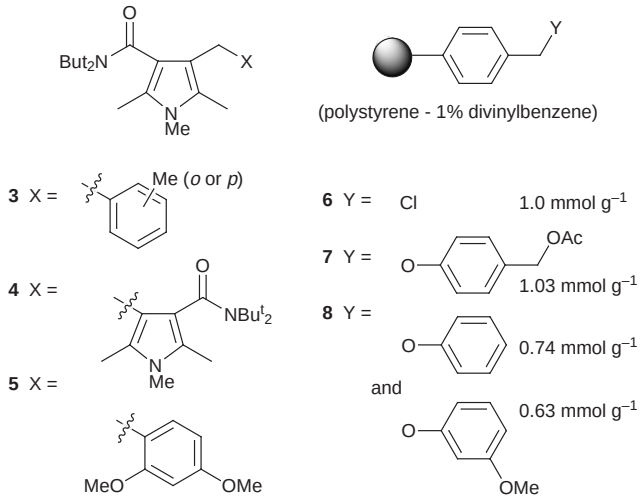
Scheme 2



scandium triflate (6.2% cleavage in 3 h). It was found that ytterbium triflate, which has similar properties to scandium triflate, [12] was more compatible with Wang resin, giving only 0.9% cleavage of the linker in 3 h.

To demonstrate that this technology can be applied to the encoding of a combinatorial library, a split and mix[3] tripeptide library (*step 1*, ala, gly, leu; *step 2*, val, met, phe; *step 3*, trp, ser, ser-lys) was synthesised on resin **8** and encoded with alcohols **1d**–**1i**. Three batches of resin **8** were coupled to an amino acid using benzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP) chemistry, the resin was capped with Ac_2O after each step and subsequently reacted with the appropriate encoding pyrroles **1d**–**i**, at 30 μmol g^{-1} of resin (approx. 300 pmol per bead, 3% compared to library loading) in 15 mM ytterbium triflate in 2 : 1 $ClCH_2CH_2Cl$–$MeNO_2$ for 16 h. The beads were then mixed and split and the Fmoc group removed ready for the next round of synthesis. The peptides, from single beads, were cleaved in TFA (95%), then the beads were subjected to hydrolysis with 5.6 M HCl to cleave the secondary amines from the encoding tags. The hydrolysate was dried *in vacuo* then reacted with dansyl chloride in the presence of Na_2CO_3 and analysed by fluorescence HPLC.

The only limitation revealed in this experiment was that no incorporation of the pyrroles was seen to beads that had incorporated methionine, presumably due to *S*-alkylation of the pyrrole tags. However, no other amino acid in the library appeared to interfere with the Friedel–Crafts encoding chemistry (notably phenylalanine and tryptophan). A number of beads were decoded and Fig. 1 shows a typical analysis of a single bead. The HPLC trace unambiguously identified the peptide from the encoding tags and the identity of the peptide was confirmed by electrospray mass spectrometry. The overall efficiency for incorporation, cleavage and detection for tags **1d**–**i** was 20 ± 10% based on a dansylated standard solution of the amines analysed under the same conditions.

Table 1 Friedel-Crafts reactions of **1c**[a]

Substrate (equiv.)	$ScOTf_3$/ mM	Reaction time/h	Unreacted **1c**[b] (%)	$t_{1/2}$/h for **1c**[c]	Yield (%)

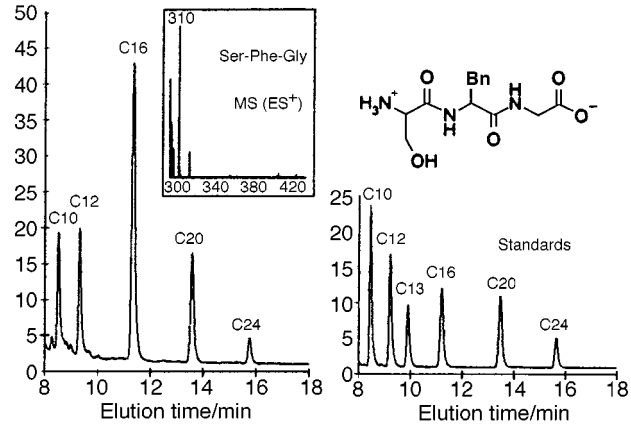

Fig. 1 Analysis of a bead: (*a*) mass spectrum of the cleaved peptide and (*b*) the HPLC trace of the cleaved tags (reverse phase, H_2O–MeCN, Novapak phenyl 1.5 × 150 mm column, excitation/emission at 340/500 nm).

These studies show that Friedel–Crafts insertion of such tags may be employed in a chemical encoding strategy. In this first instance, the methodology has been exemplified using secondary amine tags which were based on published work by the Affymax group,[5] however the pyrrole/Friedel–Crafts chemistry should also be suitable as a carrier for attachement of other tag moieties (*e.g.* MS tags) to a resin bead. In comparison with existing chemical encoding methods,[5,6] orthogonal protecting groups are not required and the tags are not randomly inserted but are directed into the resin backbone. Furthermore, it has been demonstrated that the insertion kinetics is tunable by doping the resin with electron-rich aromatics. The further application of this chemistry to the encoding of compound libraries is currently being carried out to evaluate its broader compatibility with other resins and chemistries.

We acknowledge the help of Michael Prodigalidad for the single bead analysis of peptides by mass spectrometry. We thank Zeneca Pharmaceuticals for a studentship to R. S. and the BBSRC (Grant # MOL04534). We acknowledge Chris Abell, David Hollinshead and Richard Shute for proofreading the manuscript and helpful discussions. S. B. is a Royal Society University Research Fellow.

Highly active ethylene polymerisation catalysts based on iron: an *ab initio* study

Edward A. H. Griffiths, George J. P. Britovsek, Vernon C. Gibson* and Ian R. Gould*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: v.gibson@ic.ac.uk;i.gould@ic.ac.uk

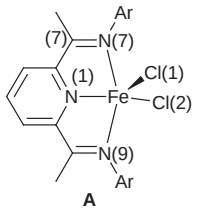
Received (in Cambridge, UK) 22nd March 1999, Accepted 4th June 1999

Full *ab initio* calculations are described on an iron-based ethylene polymerisation catalyst bearing a 2,6-bis(imino)-pyridyl ligand.

The development of non-metallocene olefin polymerisation catalysts constitutes a highly active area of academic and industrial research.[1] In particular, late transition metal polymerisation catalysts have become of interest since the discovery by Brookhart and co-workers that Ni^{II} and Pd^{II} complexes containing bulky α-diimine ligands are capable of polymerising ethylene and higher α-olefins to high molar mass polymers.[2] These systems have been the subject of several theoretical investigations.[3–5] In parallel studies, we and Brookhart and co-workers have recently reported highly active ethylene polymerisation catalysts based on iron and cobalt bearing 2,6-bis(imino)pyridyl ligands.[6,7] Here, we present the first theoretical studies on this catalyst system, having assumed the generally accepted Cossee–Arlman polymerisation mechanism.[8] The key features of the reaction pathway are shown in Scheme 1.

Optimisations† were initially performed on the bis(2,6-diisopropylphenylimino)pyridyliron dichloride complex **A** shown in Scheme 1. From the table presented in Scheme 1 it can be seen that the level of agreement between the gas-phase calculated bond parameters and the experimental data[6] is generally good. The results are also in accord with the experimental magnetic moment,[6] since quintet multiplicity (S = 2) was found to correspond to a minimum energy structure within the C_s point group. The optimised structures **1**–**4**, obtained for the first insertion step, are shown in Fig. 1; a potential energy profile is shown in Fig. 2.

For the methyl cation **1** (Fig. 1), the iron atom lies in the plane defined by the bis(imino)pyridine nitrogens (3N-plane) to within 0.04 Å. The four-coordinate geometry around the iron centre is thus best described as distorted square planar. The



A

	Experimental	Calculated
Fe–Cl(1)	2.311(2) Å	2.36 Å
Fe–Cl(2)	2.266(2) Å	2.27 Å
Fe–N(1)	2.088(4) Å	2.11 Å
Fe–N(7)	2.250(4) Å	2.23 Å
C(7)–N(7)	1.285(6) Å	1.29 Å

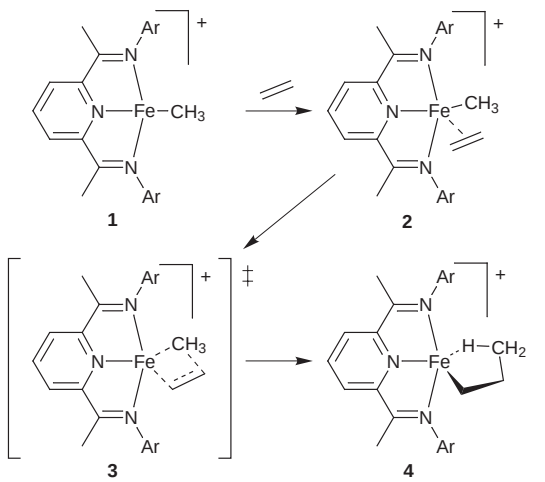
N(7)–Fe–Cl(2)	98.6(1)°	99.3°
N(1)–Fe–Cl(2)	147.9(1)°	149.1°
N(7)–Fe–N(9)	140.1(1)°	141.9°
N(1)–Fe–Cl(1)	94.62(12)°	85.4°



Scheme 1

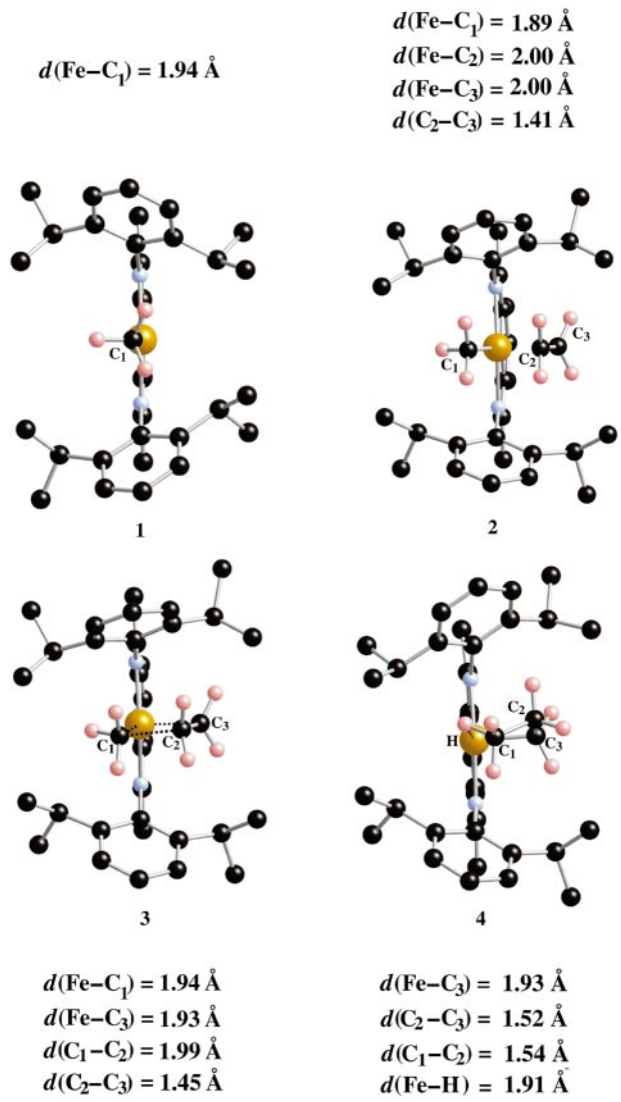


Fig. 1 The optimised structures of the reactant **1**, the ethylene π-complex **2**, the transition state **3**, and the γ-agostic product **4**. Selected atoms have been labelled. The pyridyl nitrogen is obscured by the iron atom.

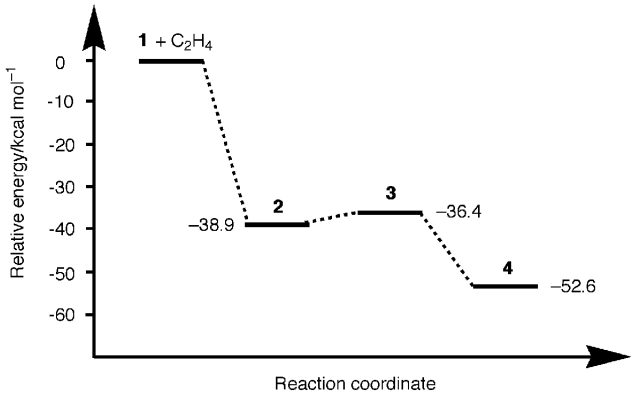

Fig. 2 Potential energy profile of ethylene insertion into the Fe–CH_3 bond of **1**.

distortion arises largely within the square plane due to the constrained nature of the ligand system, the N(imino)–Fe–N(imino) bond angle being 160.8°. Additionally, the methyl group (C_1) is bent out of the square plane by 6.4°. Compared to the dichloride (**A**), the Fe–N(imino) and Fe–N(pyridyl) distances have shortened considerably, presumably a consequence of the lower coordination number and the positively charged iron centre. The former now average 2.00 Å while the latter is 1.93 Å, the Fe–N(imino) distances vary by less than 0.01 Å in structures **1**–**4**; the Fe–C_1 distance is 1.94 Å. The 2,6-diisopropylphenyl rings have tilted relative to those in the dichloride by 9.1° and are now inclined at 70.3° to the 3N-plane.

In the structure of the ethylene π-complex **2** (Fig. 1), the methyl group has tilted further away from the 3N-plane to an inclination of 24.1° to accommodate the incoming ethylene. The geometry around the iron centre is now distorted trigonal bipyramidal with the N(pyridyl) atom, the methyl group and the complexed ethylene in the equatorial positions. The angle C_1–Fe-(midpoint of C_2–C_3) is 96.9°. The Fe–C_1 bond distance of 1.89 Å in the complex is shorter than in **1**; no rotation of the methyl group is observed. The iron atom lies at a distance of 2.00 Å to both olefinic carbons which are 1.41 Å apart. Additionally, the hydrogens of the ethylene are orientated away from the metal, consistent with partial re-hybridization of the carbon centres. The Fe–N(pyridyl) bond length shrinks slightly to 1.90 Å. In order to assist the approach of the olefin the 2,6-diisopropylphenyl rings have tilted through 18.6° away from the approach path of the incoming olefin. This tilting may protect the sterically less-hindered side of the metal centre from further coordination whilst insertion occurs. The binding energy of the ethylene is 38.9 kcal mol^{-1}.

In the transition state **3** (Fig. 1) the four centres involved, C_1–Fe–C_3–C_2, are nearly coplanar, the olefinic carbon C_2 lying only 0.08 Å above the C_1–Fe–C_3 plane. The methyl group is pulled back and is now inclined at 18.9° to the 3N-plane. Simultaneously the C_3 atom has moved from an equatorial to an apical site thus returning the geometry around the metal centre towards distorted square pyramidal with the basal site becoming vacant as the C_1–Fe bond is broken. The Fe–C_3 bond length shortens to 1.93 Å whilst the Fe–C_1 bond has elongated to 1.94 Å and the C_2–C_3 bond length has increased to 1.45 Å. The activation energy is 2.5 kcal mol^{-1}. This is a very low barrier indicating a facile insertion process.

For the insertion product **4** (Fig. 1), the carbon of the methyl group C_1 and the olefinic carbon C_2 have twisted below and above the plane containing the pyridyl nitrogen and the Fe–C_3 bond, respectively. This puckering of the propyl chain leads to a further tilting of the 2,6-diisopropylphenyl rings by 8.4° away from the propyl chain. A weak γ-agostic interaction has been formed in which the C_1–H bond length is stretched to 1.12 Å. The Fe–H distance is 1.91 Å and the Fe–N(pyridyl) distance is further shrunk to 1.82 Å. The structure is now distorted square pyramidal with the fourth basal site occupied by the agostic hydrogen of the propyl chain and C_3 occupying the apical site. The product **4** is lower in energy than **2** by 13.7 kcal mol^{-1}. Preliminary investigations have shown that the insertion of the second ethylene molecule is accompanied by a rearrangement of the propyl chain from the apical position to the in-plane site (*cf.* structure **1**).

In summary, full *ab initio* calculations have been performed on the bis(imino)pyridyliron ethylene polymerisation catalyst system, and key structures operating for the first monomer insertion within a cationic alkyl mechanism have been identified. The energetics associated with complexation and insertion are comparable with values calculated for the Ni^{II} α-diimine catalyst system, the barrier to insertion however is significantly lower.[3–5] Further studies are in progress on the propagation and termination steps for this new system.

We thank the EPSRC for a studentship (E. A. H. G.) and BP Amoco Chemicals for financial support.

Notes and references

† All *ab initio* calculations were carried out using the GAUSSIAN98 package (ref. 9). Geometry optimisations on the parent dichloride (**A**) were performed using the B3LYP, BP86 and B3P86 functionals. The B3P86 (ref. 10, 11) functional was found to give the best agreement with experiment (Scheme 1) and was thus employed to calculate the structures of the catalytic cycle. For the carbon and hydrogen atoms of the alkyl chain and the chlorine and nitrogen atoms, the 6-31G** (ref. 12) basis set was employed. For the iron atom the Ahlrichs (ref. 13) pVDZ basis set was used. The STO-3G (ref. 14) basis set was placed on all other atoms. The dichloride was calculated with C_s symmetry and quintet multiplicity (S = 2). The mirror plane contains the iron atom, the pyridyl nitrogen atom and both chlorine atoms. All structures **1**–**4** of the catalytic cycle were calculated without symmetry constraints; attempts to impose C_s symmetry led to higher energy structures. For the purpose of this study, the cationic Fe^{II} species have been assigned singlet (S = 0) multiplicities. Electronic wavefunction stability calculations reveal that **2**, **3** and **4** are all singlets. Frequency calculations were performed on all optimised structures to confirm the existence of true minimum energy structures for **1**, **2** and **4**. The first order saddle point of **3** was confirmed by the presence of a single imaginary frequency in the Hessian.

A synthetic receptor for the Cbz-L-Ala-L-Ala-OH dipeptide sequence

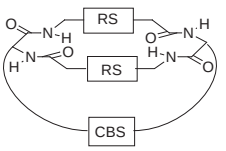
Peter D. Henley and Jeremy D. Kilburn*

Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ. E-mail: jdk1@soton.ac.uk

Received (in Liverpool, UK) 28th April 1999, Accepted 26th May 1999

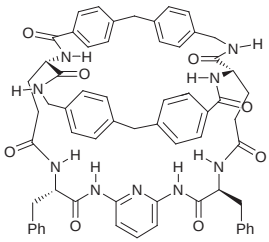
A novel bowl-shaped macrobicyclic receptor has been prepared and is a particularly strong and selective receptor for Cbz-L-Ala-L-Ala-OH ($-\Delta G_{ass}$ = 25 kJ mol^{-1} at 293 K in $CDCl_3$).

The development of synthetic receptors for biologically relevant substrates such as peptides[1] continues to be a fertile area of research. The bacterial cell wall precursor peptide L-Lys-D-Ala-D-Ala-OH represents a particularly interesting target because a selective receptor[2] for this peptide sequence might lead to mimics for the vancomycin family of antibiotics.[3] We have described several systems designed to act as receptors for peptides specifically with a free carboxylic acid terminus[1a,1e,4] and in particular we have prepared a series of receptors **1** which



CBS = carboxylate binding site
RS = rigid spacer

1

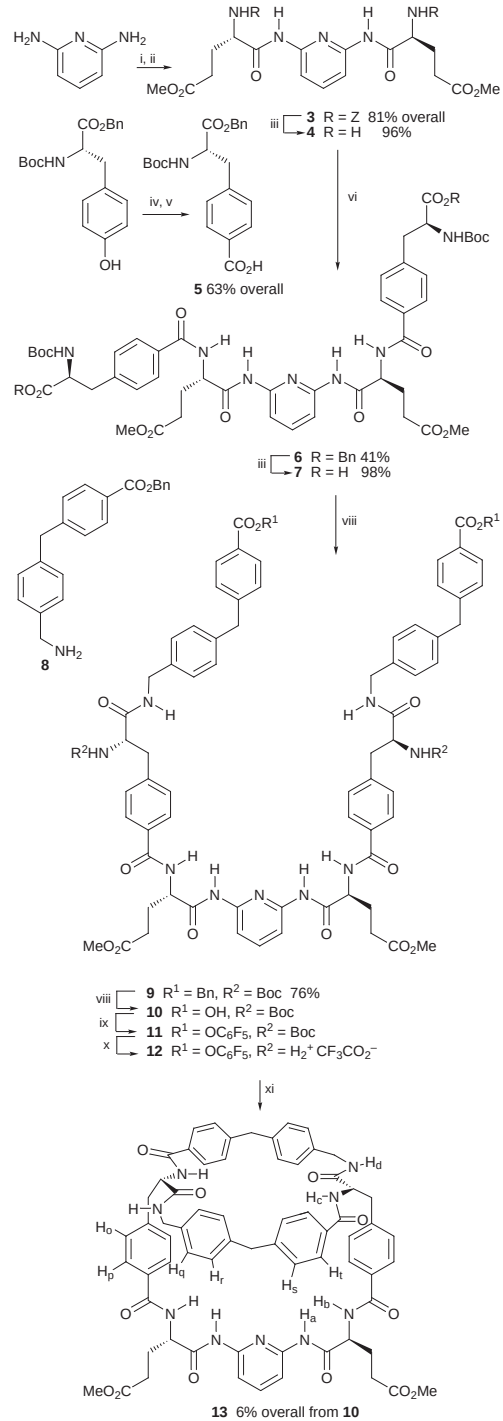


2

feature a specific binding site for the carboxylic acid terminus of peptide guests at the base of a bowl-shaped cavity.[4] Thus we have described macrobicycle **2**, which incorporates a diamidopyridine unit to serve as a carboxylic acid binding site and is an effective receptor for certain dipeptides, in particular for Cbz-β-Ala-D-Ala-OH, in chloroform solution.[4b] Despite the encouraging binding selectivities found for **2**, NMR and molecular modelling studies revealed it to be a highly flexible molecule, particularly in the portion derived from glutamic acid and phenylalanine, which links the diamidopyridine unit and the rim of the cavity. Thus **2** is far from preorganised for optimal binding of peptide guests. Here we describe a new bowl-shaped macrobicyclic receptor **13**, with increased rigidity in comparison to **2**, which has proved to be a particularly strong and selective receptor for Cbz-L-Ala-L-Ala-OH.

In order to produce a more rigid variant of our bowl-shaped receptors, we chose to link the bisarylmethane-derived rim used previously with a tyrosine derived aromatic unit, and a glutamic acid residue so that ultimately the side-chain methyl ester could be functionalised to give a water-soluble receptor.

The synthesis of macrobicycle **13** follows the strategy for the synthesis of **2** and related macrobicycles, with a double intramolecular cyclisation of a suitably activated acyclic precursor **12** as the key step (Scheme 1). Assembly of the cyclisation precursor then requires coupling together of the various amino acid building blocks around the carboxylic acid binding site, in this case diaminopyridine. Thus Cbz-L-glutamic acid γ-methyl ester was converted to the corresponding acid fluoride, using cyanuric fluoride and pyridine,[5] and coupled to diaminopyridine, which had been pretreated with *N*,*O*-bis-(trimethylsilyl)acetamide[6] to give **3** in 81% yield. Removal of the Cbz-protecting groups to yield the corresponding diamine **4** was readily achieved with Pd/C/H_2. Acid **5** was prepared by a



Scheme 1 *Reagents and conditions*: i, *N*,*O*-bis(trimethylsilyl)acetamide; ii, Cbz-L-Glu(OMe)-F, TBAF; iii, Pd, C, H_2, MeOH; iv, Tf_2O, pyridine, CH_2Cl_2; v, $Pd(OAc)_2$, $Ph_2P(CH_2)_3PPh_2$, KOAc, CO, DMSO, 65 °C, then 1 M HCl; vi, **5**, EDC, HOBT, DMAP, DMF; vii, **8**, EDC, HOBT, DMAP, DMF; viii, Pd, C, H_2, DMF; ix, F_5C_6OH, EDC, DMAP, DMF–THF (1:3 v/v); x, 10% TFA, CH_2Cl_2; xi, slow addition to a refluxing solution of Pr^i_2NEt in MeCN.

Table 1 Binding constants (K_{ass}) and free energies of complexation ($-\Delta G_{ass}$) for the 1:1 complexes formed between macrobicycle **13** and various substrates, in $CDCl_3$ at 20 °C

Entry	Substrate	K_{ass}[a]/M^{-1}	$-\Delta G_{ass}$/kJ mol^{-1}
1	Phenylacetic acid	2100 ± 100	18.6 ± 0.1
2	Cbz-L-Ala-OH	5300 ± 500	20.9 ± 0.3
3	Cbz-D-Ala-OH	800 ± 70	16.3 ± 0.3
4	Cbz-β-Ala-L-Ala-OH	2500 ± 130	19.0 ± 0.1
5	Cbz-L-Ala-L-Ala-OH	33000 ± 3200	25.3 ± 0.3
6	Cbz-D-Ala-D-Ala-OH	4500 ± 300	20.5 ± 0.2
7	Cbz-Gly-L-Ala-OH	1800 ± 150	18.3 ± 0.2
8	Cbz-Gly-D-Ala-OH	3100 ± 370	19.6 ± 0.3

[a] Errors were estimated from the quality of the fit of the experimental data to the calculated, by carrying out several titration experiments and by monitoring the shift of several protons (H_a, H_o, H_r) to obtain several estimates of K_{ass} and averaging the values obtained.

palladium catalysed carbonylation of the triflate derived from Boc-L-tyrosine benzyl ester.[7] In the presence of potassium acetate[8] and the bidentate dppp ligand,[9] the carbonylation worked well to give the desired acid **5** in 66% yield after aqueous acid work-up. Acid **5** was then coupled to diamine **4** using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) and 1-hydroxybenzotriazole hydrate (HOBT), and the resulting diester **6** was debenzylated to give the diacid **7**, which in turn was coupled with the previously described amine **8**[4b] to give the protected cyclisation precursor **9**. Debenzylation of **9** and formation of the bispentafluorophenyl ester was followed by removal of the Boc protecting groups to give the bisamine salt **12**. Slow addition of **12** to a refluxing solution of Pr^i_2NEt in MeCN gave the desired macrobicycle **13**, but in only 6% yield overall from diacid **10**, after purification by column chromatography. The yield of the final cyclised product was disappointing and in previous syntheses of related compounds[4] the analogous sequence typically yielded ~30% of macrobicycle, but in the present case the low yield is probably attributable to the greater rigidity of the precursor and of the resulting macrobicycle.

Macrocycle **13** gave a well-resolved ^1H NMR spectrum in $CDCl_3$ which could be fully assigned with the help of 2D NMR experiments. Binding studies on macrobicycle **13** were therefore carried out with a number of Cbz-protected alanine derived amino acids and dipeptides in $CDCl_3$, using a standard ^1H NMR titration experiment, monitoring the shift of various signals, and analysing the resultant binding curves (Table 1).[10] In each binding experiment a 1:1 binding stoichiometry has been assumed which was generally supported by the good fit of the measured data to the theoretical model, on analysis. In each titration experiment significant downfield shifts of the signal for NH_a were observed ($\Delta\delta$ = 0.3–0.8 ppm), consistent with a strong association between the carboxylic acid and the amidopyridine moiety. Addition of corresponding methyl esters to a solution of **13** led to no significant changes in the ^1H NMR spectrum for **13**, further confirming the importance of the carboxylic acid–amidopyridine interaction in the observed binding. The addition of all carboxylic acid substrates, with the exception of phenylacetic acid (Table 1, entries 2–8), also led to large downfield shifts of the signals for NH_c ($\Delta\delta$ = 0.4–0.9 ppm) and addition of the dipeptide substrates (entries 5–8) led to large downfield shifts of NH_d ($\Delta\delta$ = 0.1–0.5 ppm) implicating these NHs in hydrogen bonding with the respective substrates. (The signal for NH_b was obscured by the aromatic region and could not be accurately monitored.) Significant shifts in the signals for the aromatic protons were also observed. In particular, addition of substrates incorporating an L-Ala-OH moiety (entries 2, 4, 5 and 7) led to an upfield shift of ArH_p ($\Delta\delta$ = 0.1–0.2 ppm) and a downfield shift of ArH_t ($\Delta\delta$ = 0.1– 0.3 ppm), whereas addition of substrates incorporating D-Ala-OH (entries 3, 6 and 8) gave much smaller shifts of ArH_p and ArH_t, but significant upfield shifts of both ArH_q and ArH_r ($\Delta\delta$ = 0.1–0.2 ppm).

The association constants for the various guests studied indicate that the receptor, while able to bind a range of substrates, is a particularly strong receptor for Cbz-L-Ala-L-Ala-OH ($-\Delta G_{ass}$ = 25.3 kJ mol^{-1}). The receptor is very selective for this substrate as evidenced by the fact that Cbz-L-Ala-L-Ala-OH is bound > 4 kJ mol^{-1} more strongly than Cbz-D-Ala-D-Ala-OH and ~7 kJ mol^{-1} more strongly than Cbz-Gly-L-Ala-OH. The latter result is particularly notable since the difference in binding energies (~7 kJ mol^{-1}) is the consequence of replacing a single proton with a methyl group at the second residue of the dipeptide (Gly → L-Ala), and is probably a consequence of the methyl group establishing a stabilising interaction with the bisarylmethane unit in the rim of the macrobicycle—which is evidenced by the large upfield shift of the signal for the methyl group ($-\Delta\delta \approx 0.7$ ppm) on complexation with macrobicycle **13**.[11]

Thus the increased rigidity, and hence preorganisation, introduced into the structure of macrobicycle **13** has provided a stronger and considerably more selective receptor than the previously described macrobicycle **2** and, whereas the latter was a better receptor for β-alanyl-D-α-amino acid substrates, macrobicycle **13** is selective for dipeptides derived from two α-amino acids, and in particularly for the significant L-Ala-L-Ala-OH sequence.

We thank the EPSRC for a studentship for P. H. and Dr Tobias Braxmeier and Dr Herbert Röttele (Karlsruhe University) for carrying out additional NMR experiments.

10 The binding constants were calculated by fitting the data to a 1:1 binding isotherm using NMRTit HG software, kindly provided by Professor C. A. Hunter, University of Sheffield. See: A. P. Bisson, C. A. Hunter, J. C. Morales and K. Young, *Chem. Eur. J.*, 1998, **4**, 845.

11 In view of the selectivity of macrobicycle **13** for Cbz-L-Ala-L-Ala-OH over Cbz-D-Ala-D-Ala-OH (Table 1, entries 5 and 6), and for Cbz-L-Ala-OH over Cbz-D-Ala-OH (entries 2 and 3), the preference for Cbz-Gly-D-Ala-OH over Cbz-Gly-L-Ala-OH (entries 7 and 8) is somewhat surprising. The origin of this selectivity is unclear at this stage and will need to be examined in further studies.

Manganese dioxide can oxidise unactivated alcohols under *in situ* oxidation–Wittig conditions

Leonie Blackburn, Xudong Wei and Richard J. K. Taylor*

Department of Chemistry, University of York, Heslington, York, UK YO10 5DD. E-mail: rjkt1@york.ac.uk

Received (in Liverpool, UK) 18th May 1999, Accepted 3rd June 1999

The *in situ* alcohol oxidation–Wittig reaction using manganese dioxide as the oxidant has been applied to semi-activated and, for the first time, unactivated alcohols to furnish the corresponding α,β-unsaturated esters.

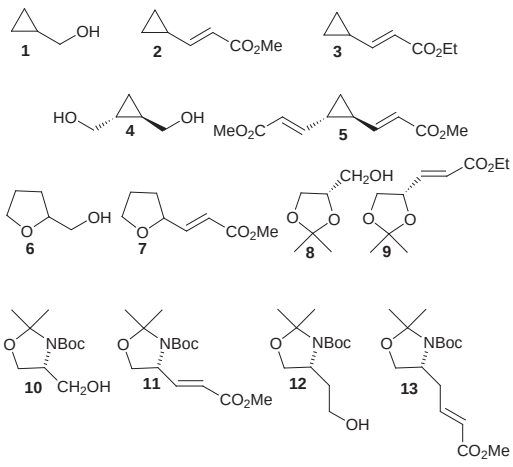
Manganese dioxide is an extremely useful oxidant in organic chemistry.[1] Oxidations using manganese dioxide are particularly easy to perform as the oxidant is heterogeneous and the reaction work-up usually involves simple filtration and evaporation of the solvent. An important use of manganese dioxide is to convert primary alcohols into the corresponding aldehydes, although the process is limited to activated systems of the allylic/benzylic type. Recently, we described the development of an *in situ* manganese dioxide oxidation–Wittig process in which activated alcohols were treated with manganese dioxide in the presence of a stabilised Wittig reagent: the resulting aldehyde was trapped as it was formed to produce the homologated α,β-unsaturated ester [eqn. (1)].[2] This procedure is particularly useful in cases where the intermediate aldehyde is difficult to isolate (*e.g.* for reasons of volatility, toxicity, liability to oligomerisation).

$$RCH_2OH \xrightarrow[Ph_3P{=}CHE]{MnO_2,\ CH_2Cl_2,\ \text{room temp.}} RCH{=}CHE \qquad (1)$$

R = vinyl, alkynyl, phenyl; E = CO_2Et, *etc.*

Coincidentally, at around the same time, Barrett *et al.* reported the combined use of the Dess–Martin periodinane and stabilised phosphoranes,[3] and Matsuda's group employed barium permanganate in a similar process.[4]†

The simplicity of the manganese dioxide procedure referred to above, coupled with the toxicity of barium permanganate and the sensitivity, and hazardous preparation, of the Dess–Martin oxidant, prompted us to attempt to extend the scope of the process (Tables 1 and 2). Initial studies concentrated on alcohols which might be classified as 'semi-activated' (Table 1).‡ Thus, as expected, cyclopropylmethanol **1** underwent smooth *in situ* oxidation–Wittig reaction giving enoates **2** and **3**, as did the corresponding diol **4** producing dienoate **5**.



Such reactions should prove useful in the synthesis of cyclopropyl-based natural products.[3a]

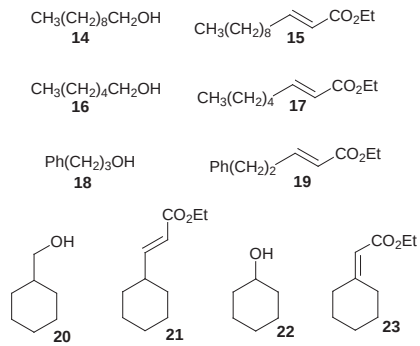
Table 1 *In situ* oxidation–Wittig reactions on 'semi-activated' alcohols[a]

Substrate	Product	Solvent	*t*/h	Yield (%)	Configuration
1	**2**	toluene	4	80	>99% *E*
1	**3**	toluene	4	86	>99% *E*
4	**5**	$CHCl_3$	18	81	>99% *E*
6	**7**	$CHCl_3$	24	66	6:1 *E*:*Z*
8	**9**	toluene	20	74	3:1 *E*:*Z*[b]
10	**11**	toluene	18	58	>95% *E*[c]
12	**13**	$CHCl_3$	20	70	>95% *E*[d]

[a] Activated MnO_2 (Aldrich, *ca.* 10 equiv.) was added in three equal portions to a mixture of the alcohol and the stabilised Wittig reagent, Ph_3PCHCO_2R (1.2 equiv.), in the specified solvent which was heated under reflux for the specified time. [b] $[\alpha]_D^{20}$ +40.5 (*c* 1, $CHCl_3$); lit.,[6] +38.3 (*c* 2, $CHCl_3$). [c] $[\alpha]_D^{20}$ −65.5 (*c* 1, $CHCl_3$); lit.,[7] −65 (*c* 4.2, CH_2Cl_2). [d] $[\alpha]_D^{20}$ −27.9 (*c* 1.15, $CHCl_3$).

In this same study (Table 1), we also investigated the oxidation of alcohols containing a proximal heteroatom which might activate the alcohol to oxidation inductively and/or by providing a coordination site for the oxidant. Encouragingly, tetrahydrofurfuryl alcohol **6** furnished the desired α,β-unsaturated ester **7** in good yield. In contrast, oxidation of this alcohol to the corresponding aldehyde is reported to be problematic and at best yields of *ca.* 50% are obtained using tetrapropylammonium perruthenate (TPAP) and 4-methylmorpholine *N*-oxide (NMO).[5] The *in situ* reaction was also successfully applied to several related enantiomerically pure primary alcohols **8**, **10** and **12**. No racemisation was observed according to polarimeteric measurements[6,7] and good yields were obtained. During the course of this study McKervey *et al.* utilised our *in situ* oxidation–Wittig methodology to convert non-racemic protected γ-amino alcohols into the corresponding α,β-unsaturated esters and ketones without loss of stereochemical integrity.[8]

In order to establish the limitations of this process we treated a completely unactivated alcohol, decanol **14**, under the *in situ* manganese dioxide–Wittig conditions.



To our amazement (Table 2), enoate **15**[9] was obtained in 80% yield after 24 h reflux in toluene.§ This result was extremely surprising given the generally accepted view that manganese dioxide is not an effective oxidant for unactivated primary alcohols.[1] We therefore studied other unactivated primary

Table 2 *In situ* oxidation–Wittig reaction on unactivated alcohols[a]

[a] Activated MnO_2 (Aldrich, *ca*. 10 equiv.) was added in three equal portions to a mixture of the alcohol and the stabilised Wittig reagent, Ph_3PCHCO_2R (1.2 equiv.), in the specified solvent which was heated under reflux for the specified time.

alcohols. Both hexanol **16** and 1-phenylpropan-3-ol **18** furnished the desired products **17** and **19**, respectively, in excellent yield. With cyclohexylmethanol **20**, the expected product **21** was obtained in reduced yield (51%); it seems likely that alkyl substitution at the β-position relative to the alcohol is responsible for the reduction in efficiency. A limitation to the process was realised when secondary alcohols were studied. As shown in Table 2, treatment of cyclohexanol **22** under the *in situ* oxidation–Wittig conditions gave only trace amounts of the desired enoate **23**. Similar results were also observed with pentan-3-ol and dihydrocholesterol, which both failed to yield the corresponding enoates. These results were not unexpected as both the oxidation of secondary alcohols and the Wittig reactions of stabilised phosphoranes with ketones are known to be difficult compared with the corresponding sequence commencing with primary alcohols.

We have carried out preliminary studies to try to rationalise these results. The most important point is that on treatment with manganese dioxide in the absence of a Wittig reagent, but under otherwise identical conditions, the primary alcohols gave only low yields of the corresponding aldehydes: for example, after reflux in toluene with manganese dioxide for 24 h, decanol gave decanal in only 12% yield, unreacted alcohol accounting for the balance of material. One possible explanation for the high conversions observed in the presence of the stabilised phosphoranes is that the primary alcohols are being converted into the corresponding aldehydes in small equilibrium quantities with the *in situ* Wittig reagent immediately trapping out the aldehyde. Alternatively it is possible that the phosphorane may be activating the oxidant or the alcohol (or the intermediate complex) to oxidation. Further mechanistic studies are in progress.¶

In summary, we have shown for the first time that unactivated primary alcohols can be efficiently oxidised using manganese dioxide under *in situ* Wittig conditions. Similar results are reported with 'semi-activated' alcohols producing a range of synthetically useful α,β-unsaturated esters.

We thank the EPSRC for a research fellowship (X. W.) and research studentship (L. B.). We are also grateful to Pfizer for additional financial support and to A. D. Campbell for carrying out the conversion of **12** into **13**.

Notes and references

† In preliminary studies, we have shown that chromium dioxide (Magtrieve™) can also be used for *in situ* oxidation–Wittig reactions.

‡ All new compounds were fully characterised spectroscopically and by HRMS.

§ Representative procedure: Activated manganese dioxide (0.3 g) was added to a stirred solution of decanol (158 mg, 1 mmol) and ethoxycarbonylmethylenetriphenylphosphorane (418 mg, 1.2 mmol) in toluene (25 ml) and the mixture was heated to reflux. Two further portions of manganese dioxide (*ca*. 0.3 g each) were added to the reaction over the first hour and then it was stirred and heated until TLC indicated that reaction was complete (*ca*. 24 h). The manganese dioxide was removed by filtration through Celite, the Celite was washed well with toluene, and the combined organic portions were concentrated *in vacuo* to *ca*. 1–2 ml. Column chromatography (light petroleum–Et_2O 5:1) gave ethyl *trans*-dodec-2-enoate (181 mg, 80%) as a colourless oil with spectroscopic data consistent with those published (ref. 9).

¶ Addition of Ph_3PO or pyridine to the manganese dioxide oxidation of decanol under toluene reflux (24 h) increases the yield from 12 to *ca*. 40%.

Received (in Cambridge, UK) 17th May 1999, Accepted 8th June 1999

Rhodium catalyzed (1–0.1 mol%) decomposition of 2-(3-diazo-2-oxopropyl)-2-methyldioxolane 1a or 2-(3-diazo-1-methyl-2-oxopropyl)-2-methyldioxolane 1b in the presence of a catalytic amount of TMSCl (10 mol%), yielded 4,7-dioxocane 3a (91%) or 3b (49%), whereas similar reaction in the absence of TMSCl caused 1,2-rearrangement to give bicyclobutanones 2a or 2b, respectively; Lewis acid-base catalysis by TMSCl of the ring-expansion of a bicyclooxonium ylide intermediate is revealed.

It is well known that metal carbene complexes (or carbenoids) react with oxygen, nitrogen or sulfur compounds to form onium ylides and some are utilized for synthetic purposes.[1] Among them, ethereal oxonium ylides, the most short-lived species,[2] have been investigated recently. Nevertheless, they are so short-lived that their application to synthesis is limited to a few examples, *e.g.* [1,2]- and [2,3]-sigmatropic rearrangement.[3,4]

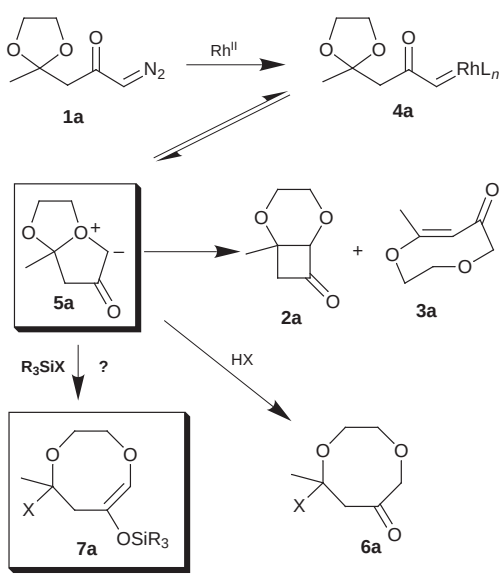
Johnson reported that a metal carbene complex generated from diazo ketone **1a** and $Rh_2(OAc)_4$ yielded [1,2]-rearrangement product **2a** as the major product (68%) and ring-expansion product **3a** in a minor amount (16%) (Scheme 1).[5] Recently, we reported that a protic nucleophile (*e.g.* MeOH, AcOH) protonates the ylide intermediate to form a bicyclic oxonium ion, suppressing the 1,2-rearrangement and facilitating three-carbon ring-expansion reactions.[6,7] In analogy to the ylide trapping method, we anticipated that a silyl cation may trap the ylide to form a silyl-substituted oxonium ion, ending up with a similar ring-expansion reaction. We report here the first evidence for Lewis acid–base catalysis by chlorosilanes of the oxonium ylides that is exerted in the three-carbon ring-expansion reaction.

In advance of the use of transition metal catalysts, we examined the stability of diazo ketone **1a** in the presence of various silyl reagents, because **1a** was suspected of decomposing in the presence of these species in the absence of the metal catalyst.[8] It was found that diazoketone **1a** decomposed only in the presence of TMSOTf.

The reaction of **1a** in the presence of $Rh_2(OAc)_4$ and various silyl reagents was performed as follows: the diazo ketone was slowly added to a solution of $Rh_2(OAc)_4$ (1 mol%) and the silyl reagent (1.0 equiv., initial concentration 0.1 mol dm^{-3}) at ambient temperature. After complete consumption of **1a**, the reaction was quenched with Et_3N and products were isolated by silica gel flash chromatography.

Choice of the silyl reagent was important. With TMSCN, the reaction did not take place, presumably because it poisoned the Rh catalyst. With TMSCl or TESCl, the expected ring-expansion product **3a** was obtained as the major product (80 or 44%, respectively). In both cases, minor products were [1,2]-rearrangement product **2a** and non-rearrangement product 2-(3-chloro-2-oxopropyl)-2-methyldioxolane.[9] In contrast, TBDMSCl (entry 4) did not give **3a**, probably because the chlorosilane was not reactive enough to capture the oxonium ylide. Again, TMSOAc gave **3a** although in low yield. Consequently, TMSCl was chosen as the most appropriate reagent, with which we examined the choice of solvent. Among those examined, benzene was the best for the production of **3** (CH_2Cl_2, 80%; benzene, 91%; THF, 68%).

Ring-expansion product **3a** seems likely to be formed by the elimination–hydrolysis of silyl ether **7** in the work-up procedure.[10] However, searching for this intermediate **7** by ^1H NMR in the reaction mixture (benzene-d_6,) was unsuccessful. Therefore, we assumed that the chlorosilane is acting as a catalyst[11]

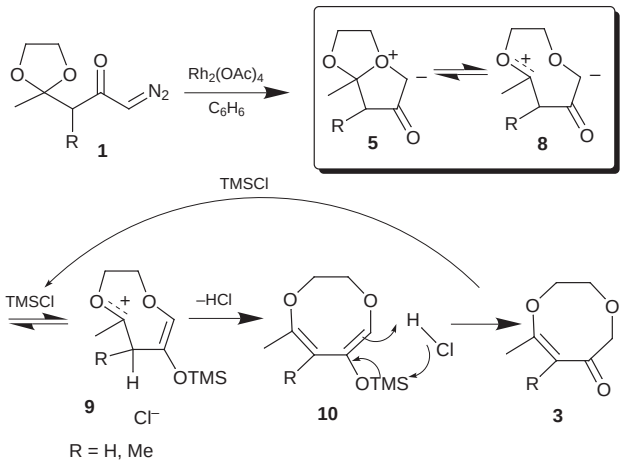


Scheme 1

Table 1 Effect of stoichiometry and concentration of TMSCl in the ring-expansion reaction

		TMSCl			
Entry[a]	Substrate	Equiv.	Init. conc./ mol dm^{-3}	Addition time/min	Products (%)
1	**1a**	—	—	—	**3a** (16), **2a** (68)[b]
2	**1a**	1.0	0.10	10	**3a** (91)
3	**1a**	0.5	0.05	10	**3a** (40), **2a** (20)
4	**1a**	0.1	0.01	10	**3a** (33), **2a** (37)
5	**1a**	0.1	0.10	10	**3a** (38), **2a** (12)
6	**1a**	0.1	0.10	120	**3a** (77)
7	**1b**	—	—	120	**2b** (58)[b]
8	**1b**	0.1	0.10	120	**3b** (27), **2b** (41)
9	**1b**	0.5	0.50	120	**3b** (42), **2b** (21)
10	**1b**	1.0	1.00	120	**3b** (49), **2b** (10)

[a] The amount of catalyst $Rh_2(OAc)_4$ was 1 mol% relative to **1** for entries 1–5, 0.1 mol% for entries 6–10. [b] Ref. 5.



Scheme 2

and investigated the stoichiometric effect of TMSCl (Table 1, entries 2–6). It is clear that, as the molar amount of TMSCl *vs.* **1a** decreases, the yield of [1,2]-rearrangement product **2a** increases (entries 2–4). However, even with a decreased amount of chlorosilane (0.1 equiv.), the catalytic role of TMSCl can be exerted effectively under the following conditions: (1) the initial concentration of TMSCl is kept at a relatively high level, *e.g.* 0.1 mol dm^{-3} (entries 2, 5, 6); (2) the amount of $Rh_2(OAc)_4$ is as low as 0.1 mol% (entry 6); (3) the diazo ketone is added as slowly as possible (entry 6). Under such conditions, the oxonium ylide is formed in very low concentration and, although very short-lived, it can react effectively with the large excess of TMSCl.

Some of these optimized conditions were also applied to methyl-substituted diazo ketone **1b** (Table 1, entries 7–10). In the absence of chlorosilane (entry 7), **2b** was formed as the sole product,[5] whereas the addition of TMSCl to the reaction mixture increased the formation of ring-expansion product **3b**. Increasing both the molar amount and initial concentration of TMSCl also improved the yield of **3b** (entries 8–10).

On the basis of the above-mentioned findings, we propose the mechanism depicted in Scheme 2. First, the treatment of diazo ketone **1** with the transition metal catalyst generates oxonium ylide **5** *via* its carbenoid **4**, both being in equilibrium[12] (see Scheme 1). Ylide **5** is in equilibrium with zwitterion **8**, which is trapped by the chlorosilane to form oxocarbenium ion **9** in preference to the [1,2]-rearrangement. Ion **9** undergoes deprotonation with counter ion Cl^- to produce diene **10**, which results in the formation of final product **3**. Relatively low yields of **3b** in comparison with **3a** may be attributable to the steric effect encountered in the deprotonation of **9** where two methyl groups must adopt a (*Z*) disposition. The double bond structure of **3** has been described as *trans*.[5] If it is *trans*, the mechanism for the double bond formation from the ylide should be a concerted one, being inconsistent with a sequential profile of the present mechanism. Therefore, we measured the X-ray crystallographic structure of **3a** (mp 67 °C) to obtain a clear insight into the mechanism.† As shown in Fig. 1, the geometry of the enone is *cis*.

To summarize, $Rh_2(OAc)_4$ catalyzed decomposition of diazo ketones **1a** and **1b** in the presence of a catalytic amount of TMSCl yielded three-carbon ring-expansion products **3a** and **3b** in better yields than in the absence of the chlorosilane, while the catalyst role of TMSCL in this sequential reaction was verified.

This hitherto unknown catalysis by chlorosilanes in the control of ethereal oxonium ylides seems promising for its utilization with other onium ylides.

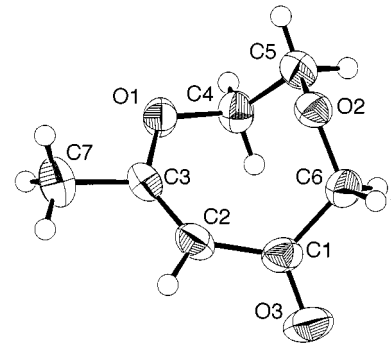


Fig. 1 Molecular structure of **3**. Selected torsion angles (°): O(1)–C(3)–C(2)–C(1) 7.9(4), C(1)–C(2)–C(3)–C(7) −175.7(2).

The authors are indebted to the skilled technical assistance of Dr Motoo Shiro, Rigaku X-Ray Research Laboratory (Tokyo), for the X-ray analysis of **3a**.

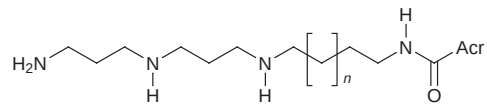
Received (in Cambridge, UK) 19th May 1999, Accepted 11th June 1999

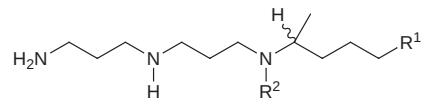
Solid-phase organic synthesis (SPOS) routes to target unsymmetrical polyamines and their acridinyl and dansyl conjugates have been developed based upon borane–pyridine complex (BAP) mediated reductive alkylation, azide reduction with triphenylphosphine, and the use of pent-4-enoyl (Pnt) as an orthogonal amine protecting group.

Polyamines and especially their unsymmetrical conjugates display a wide range of important biological activities making them useful as lead compounds for a wide range of potential therapies.[1] These medicinal chemical applications include potential anti-parasitic drugs as potent inhibitors of the enzyme trypanothione reductase[2] and cytotoxic compounds such as acridine–spermine conjugates that display significant sequence selectivity on binding to an oligonucleotide.[3] It has recently been shown that dansylated polyamines are novel glutamate (NMDA) receptor antagonists.[4] (−)-15-Deoxyspergualin, a potent immunosupressor, is a spermidine–guanidine conjugate for the treatment of corticoresistant acute renal graft rejection.[5] The regiocontrolled synthesis of unsymmetrical polyamine conjugates continues to attract the attention of bioorganic and synthetic chemists,[5–8] but these approaches often, of necessity, include a number of steps for orthogonal protecting group introduction and removal that makes the overall multistep syntheses certainly time consuming and sometimes low yielding. Furthermore, such solution-phase syntheses are simply not amenable to the rapid preparation of a wide range of conjugates for biological evaluation, and therefore attention has been turned recently to the use of solid-phase organic synthesis (SPOS) for the preparation of polyamine conjugates with the potential for compound-library design.[9–13] At the forefront of these studies are Bradley and co-workers who have addressed the synthesis of trypanothione (spermidine containing) libraries in their elegant studies of SPOS for polyamine amides and lactams.[9] Independently, Houghten and co-workers have recently used SPOS reductive alkylation to prepare diazepine derivatives and parallel SPOS borane reduction of triamides afforded large numbers of unsymmetrically substituted diethylenetriamines.[10]

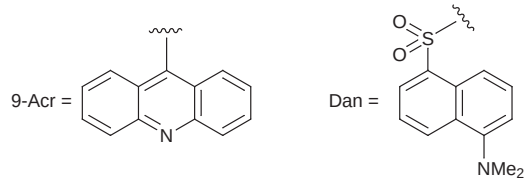
We have designed a series of unsymmetrical polyamine conjugates **1**–**5** as targets to illustrate our proof of concept that reductive alkylation is a practical approach to such substituted compounds using SPOS methodologies. The potential of this reductive alkylation route is in the ability to prepare a range of linear unsymmetrical polyamines. By design, the amine distribution along the polymethylene chain can be varied, in a controlled manner, using the sequence elaborated below. Acridin-9-ylcarbonyl thermine **1** and thermospermine **2** require reductive alkylation of an aldehyde with an amine bound to the resin. The corresponding conjugate **3**, with a regiospecific methyl substituent, requires alkylation of this resin using a methyl ketone. Azide dansyl conjugate **4** and didansylated **5** will be prepared from the same resin-bound intermediate.[13] Azide aldehyde **9** was prepared from 4-bromobutyl acetate **6**, by azide nucleophilic displacement of the halide affording **7**



1 $n = 0$
2 $n = 1$

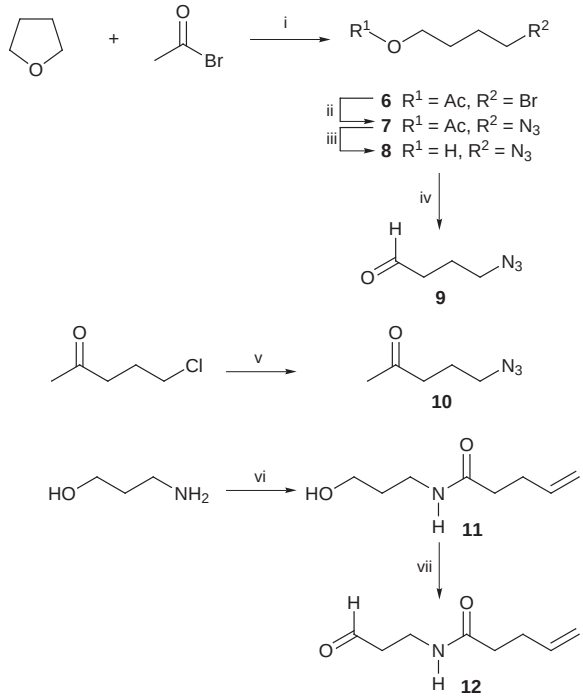


3 R^1 = NHCO-9-Acr, R^2 = H
4 $R^1 = N_3$, R^2 = Dan
5 R^1 = NHDan, R^2 = Dan

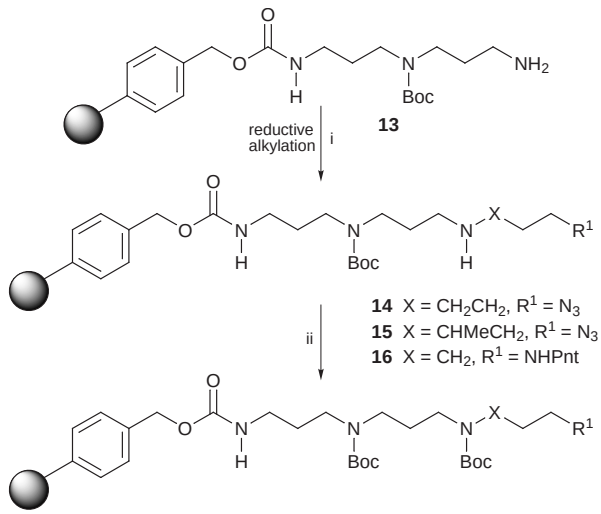


(NaN$_3$, DMSO, 25 °C, 16 h, 95%), ester saponification to azide primary alcohol **8** (2 M aq. NaOH, MeOH, 25 °C, 3 h, 85%), and then Swern oxidation of this alcohol to the desired aldehyde **9** (50%) (Scheme 1). Azide ketone **10** was prepared from the readily available 5-chloropentan-2-one (NaN$_3$, cat. NaI, DMSO, 50 °C, 18 h, 90%).[14] 3-Pent-4-enoylaminopropanal **12** was prepared from the corresponding 3-aminopropan-1-ol by *N*-acylation with the symmetrical anhydride Pnt$_2$O [15] affording amide primary alcohol **11** (CH_2Cl_2, 0 °C, 1 h, 72%) which was oxidised to the desired amide aldehyde **12** (PDC, CH_2Cl_2, 25 °C, 3 h, 76%).

Wang resin was activated under rigorously anhydrous conditions with 4-nitrophenyl chloroformate (*N*-methylmorpholine, CH_2Cl_2, 25 °C, 19 h) and then reacted with N^1-*tert*-butoxycarbonyl-N^1-(3-aminopropyl)-1,3-diaminopropane[2,6] (CH_2Cl_2, 16 h)[16] affording resin **13**. That this reaction went to completion was verified by the use of gel-phase ^{13}C NMR spectroscopy.[17] Reductive alkylation of portions of resin **13** with aldehyde **9**, ketone **10** and aldehyde **12** afforded resins **14**–**16** respectively (BAP, 3:1 DMF–EtOH, 48 h) (Scheme 2).[18] Washed and dried samples of resins **14** and **15** displayed characteristically strong IR bands (by diffuse reflectance) for the resin-bound azide functional group at 2090 cm^{-1}. Portions of these resins **14**–**16** were Boc protected (excess of Boc$_2$O, CH_2Cl_2, 2 × 12 h) on the newly formed secondary amines affording resins **17**–**19** respectively. A further portion of resin **15** was *N*-dansylated (2 equiv. dansyl chloride, 2 equiv. *N*-methylmorpholine, CH_2Cl_2, 2 × 18 h) and half of this product was cleaved from the resin (1:1 TFA–CH_2Cl_2, 25 °C, 2 h) to afford azide dansyl polyamine **4** as a white solid. The remaining half was reacted with PPh$_3$ and water (1 equiv. H$_2$O, THF, 2 ×



Scheme 1 *Reagents and conditions*: i, ZnBr, reflux; ii, NaN_3, DMSO; iii, 2 M aq. NaOH, MeOH; iv, $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2 (Swern); v, NaN_3, cat. NaI, DMSO, 50 °C; vi, Pnt_2O, CH_2Cl_2; vii, PDC, CH_2Cl_2.



Scheme 2 *Reagents and conditions*: i, aldehyde or ketone, BAP, 3:1 DMF-EtOH; ii, Boc_2O, CH_2Cl_2; iii, PPh_3, H_2O, THF; iv, I_2, 1:1 H_2O–THF.

18 h) to convert the azide into a primary amine, which has previously been reported only for solution-phase synthesis,[5,19] and this newly formed amine was then *N*-dansylated. Cleavage from the resin yielded didansylated polyamine **5** as a white solid in 35% yield over the six steps (resin loading, reductive alkylation, dansylation, azide reduction, dansylation and resin cleavage). Resins **17** and **18** were similarly reacted with PPh_3 to afford resin-bound primary amines **20** and **21** respectively.

The Pnt group has been used to protect a variety of substituted amines including amino sugars[15] in solution phase, and nucleotides in SPOS.[20] The primary amine protected by a Pnt group in resin **19** was unmasked by treatment with I_2 and water (1:1 H_2O–THF, 25 ºC, 18 h) affording resin **22**.[15,20] Resin-bound amines **20**–**22** were acylated using acridine-9-carboxylic acid activated with N^1-hydroxybenzotriazole (DMF, 2 × 15 h). The resulting acylated resins were cleaved affording targets **1**–**3** as their free bases after final purification by flash column chromatography over silica gel (eluant 8:5:1 CH_2Cl_2–MeOH-conc. aq. NH_3)† in order to remove traces of triamine starting material which had been crosslinked.

Here we report a novel reductive alkylation SPOS route to unsymmetrical polyamines and their conjugates. The feasibility of preparing unsymmetrical polyamines anchored on Wang resin as a solid support, and then selective unmasking of amines to reveal sites for conjugation, will find ready applications. Furthermore, our SPOS uses of Pnt as an amine protecting group orthogonal to Boc, and of azide reduction with PPh_3 should have wide applicability in combinatorial chemistry where libraries of amines are constructed.

We thank the Atlantic Arc for Medicinal Chemistry (GP2A), the ARC (Association pour la Recherche sur le Cancer) and the Ligue Nationale contre le Cancer for financial support of this project. We acknowledge S. Sinbandhit and M. Le Roch (Université de Rennes 1) and A. J. Geall (University of Bath) for useful discussions and their input into these studies.

Received (in Cambridge, UK) 20th April 1999, Accepted 10th June 1999

Individual single-wall carbon nanotubes (SWNTs) and bundles can be obtained over different types of supported metal catalysts by decomposition of ethylene, similar to the synthesis of multi-wall carbon nanotubes.

Until now, laser evaporation[1] and electric arc discharge techniques[2] have been used to synthesise SWNTs in high yield, but many previous reports[3–5] have shown that the catalytic decomposition of hydrocarbons could be a possible way to produce SWNTs. In the present work, we describe the synthesis of SWNTs from ethylene decomposition on supported metal catalysts, prepared by impregnation of different supports. The 3d transition metals are known for their efficient production of single- and multi-wall nanotubes.[1,2,6] For this reason, Co, Ni, Fe and mixtures of these metals are used in our catalysts, to produce individual or bundles of SWNTs. Various supported metal catalysts are prepared on different supports (alumina and silica)† and with different metals (Co, Ni, Fe) and metal mixtures (Co-Fe, Ni-Co, Co-Fe, Co-Ni-Fe) by a method already described.[7] The role of the supports involves the dispersion of the metal particles. Catalysts are prepared by impregnating the support with an EtOH solution containing the appropriate concentration (2.5 wt% of each metal) of metal salts or mixture of metals salts. After sonication (1 h) and evaporation of EtOH, the material is dried at 150 °C (12–15 h) and ground into a fine powder. The synthesis of single-wall nanotubes was carried out in a fixed-bed reactor at 1080 °C (60 min). For each synthesis, a quartz boat containing about 200 mg of catalyst was placed in the center of the reactor. The gas flows of the ethylene–nitrogen mixture used were 30 and 80 ml min^{-1}, respectively. The abundance of SWNTs is estimated from TEM observations using JEOL 200CX and Phillips CM 20 instruments for low and high resolution measurements, respectively. The TEM images show unambiguously either the presence of individual SWNTs (with some small bundles) or principally the presence of abundant bundles of SWNTs. These bundles seem to be similar to those produced by arc discharge or laser evaporation techniques with the one difference, however, that they are longer (up to several μm). All the catalysts prepared are active in the formation of SWNTs, with varying efficiency. In fact, in all cases, SWNTs have been observed, but their abundance seems to be dependent on the nature of the metal and the type of support. The synthesis of SWNTs is more efficient for the metal catalysts supported on alumina than on fumed silica. Moreover, in the case of fumed silica using the same reaction parameters, the SWNTs are coated with a thick layer of amorphous carbon. Concerning the influence of the nature of the metal, it is very difficult to discrimate among the catalysts containing a single metal. For all the metals, individual SWNTs are observed, but Co and Fe seem to be more active than Ni. In addition, some SWNT bundles are also found in these samples. For the catalysts prepared from a mixture of metals, the best activity is found for Fe-Co and Fe-Co-Ni mixtures supported on alumina. On these two catalysts, a significant amount of SWNT bundles is observed (Fig. 1). The catalysts prepared from a mixture of metals are more efficient for SWNT production than those prepared with a single metal. The bundles of SWNTs are larger and longer than those synthesised by arc discharge and the laser evaporation. Details of these SWNT bundles are shown on Fig. 2, where a large bundle of about 20–35 nm of diameter can be observed [Fig. 2(*a*)]. Moreover, the SWNT diameter can be estimated by transmission electron microscopy: Fig. 2(*a*) shows that the SWNTs in the bundles have a uniform diameter and they form crystallite-like entities organized in a two-dimensional triangular lattice, with a lattice constant *a*, about 1.0 nm, corresponding to nanotubes of 0.7 nm in diameter separated by the van der Waals intertube distances of 3.4 Å. The diameter estimated for the SWNTs is around 0.7 nm. For comparison, a lattice constant of 1.7 nm has been given for the SWNT bundles produced by laser evaporation[1] and the smallest SWNTs organised in ropes found in the synthesis by arc discharge have 1.2–0.9 nm diameter when argon is used instead of helium.[8] The estimated diameter of SWNTs in the bundle is confirmed by Fig. 2(*b*) showing the cross section of the bundles which gives the same small diameter. In fact, on the top of this picture, some graphitic layers also appear and the distance between them is equal to 3.4 Å. These data confirm the accuracy of the value of the tube diameter. The tube diameters found for the SWNT bundles are the smallest produced until now. In the case of individual SWNTs, a distribution of diameter is also observed and individual SWNT diameters range from 1.6 to 5 nm. The tubes which have the largest diameter are often double-wall nanotubes. Most of the individual SWNTs have diameters

around 1.8–2 nm. In comparison, isolated SWNTs have larger diameters than those produced by the other two techniques (around 1.4 nm). Recently, very small diameters (0.6–0.8 nm) were found for isolated SWNTs synthesised by the electric arc discharge method in the presence of argon.[8]

In the case of multi-wall carbon nanotubes (MWNT) synthesis, the influence of support on the growth mechanism is rather well-documented.[6] The mechanism depends on the interactions between the metal particles and the support. In the case of SWNTs produced by the catalytic process, Dai *et al.*[3] have proposed a growth mechanism close to that of MWNTs, because metal particles have been found trapped in the tip of SWNTs, and the diameter of the SWNTs is related to the size of the catalytic metal particle attached to their end. This fact could explain the large diameter distribution of isolated SWNTs (average diameter about 2 nm) synthesised by the catalytic decomposition of hydrocarbons compared to the ones obtained by the other techniques. In our different samples, no catalytic particles were found trapped at the end of the individual SWNTs, but the closed ends of the SWNTs are not incompatible with this proposed mechanism, where the individual SWNT could grow from a supported particle at one end and be closed at the other. This growth mechanism is strengthened by the fact that the synthesis of SWNTs can also be carried out at low temperature (750–850 °C)[5] similarly to the synthesis of multi-wall nanotubes.

In the formation of the SWNT bundles, the support does not seem to play an important role on the growth mechanism, contrary to what has previously been proposed.[4] Bundles of SWNTs were observed in all cases (on both alumina and silica) where the catalysts are composed of mixtures of metals. Possibly, the support plays a role in the dispersion of the metal on the surface, and influences the pyrolytic cracking of the hydrocarbon in certain cases, but the presence or the absence of SWNT bundles is not governed by the support. The formation of SWNT bundles increases when mixtures of metals are present. Possibly, the preparation of catalysts with mixtures of metals induces a better dispersion of the metals on the catalyst surface. Moreover, the formation of each SWNT in the bundle may not depend on a small metal particle, and the growth mechanism of SWNT bundles could be different for individual SWNTs. One of the hypotheses involves SWNT bundles grown from single bigger metal particles so that bundle formation would be linked to the nature of the metal surface. This hypothesis could also explain the presence of SWNT bundles in the samples synthesised on single metal supported catalysts. Reinforcing this hypothesis is the very small size of the SWNT diameters in the bundles compared to the diameter of isolated SWNTs (linked to the size of catalytic metal particle).

In conclusion, isolated SWNTs and SWNT bundles can be produced by catalytic decomposition of hydrocarbons. Supported catalysts containing either a single metal or a mixture of metals seem to induce the growth of isolated SWNTs or SWNT bundles, respectively. Bundles of SWNTs have been synthesised with very small and uniform diameter (around 0.7 nm), and isolated SWNTs with larger diameter (around 2 nm). In the near future, the synthesis conditions could be optimised to obtain SWNTs in large quantities, as is already the case for MWNTs obtained *via* catalytic decomposition of hydrocarbons.
