A stable monomeric ruthenium(IV) octahedral complex is synthesized with 1,2-dicyanoethylene dithiolate(2−) (mnt^{2-}) as ligand and its ligand rearranged product obtained in solution is structurally characterized as a novel bis(1,2-dicyano-2-mercaptoethylene)sulfide(2−) ($mnts^{2-}$) coordinated ruthenium(II) compound.

Over thirty years ago there was a great deal of interest in the structural and electronic properties of metal complexes with dithiolate ligands.[1] An interest in the preparation of higher oxidation state ruthenium in a coordination environment composed exclusively of sulfur donor atoms has promoted a re-examination of the use of dithiolate ligands. Tris-dithiolate complexes exhibit a variety of different structural types and reactivities.[2] Trigonal prismatic coordination is commonly observed. Some studies of ruthenium(III) and (IV) 1,1-dithiolate[3] and thiolate[4] complexes have been reported but those with 1,2-dithiolate remain scant.[5] Interestingly, to date there is no report of a tris-dithiolate ruthenium(IV) complex despite the characterization of the corresponding species for iron(IV).[6] Indeed, there is no report of ruthenium(IV) in a coordination environment composed exclusively of sulfur donors.

A facile synthetic route has been developed for $[NEt_4]_3[Ru^{III}(mnt)_3]\cdot 2MeCN$ **1**. This tris-dithiolate complex has a geometry which is the closest approximation to an octahedral arrangement of this donor atom set reported to date.[2] $[Ru^{III}(mnt)_3]^{3-}$ is readily oxidized to the deep green compound, $[NEt_4]_2[Ru^{IV}(mnt)_3]$ **2**, by addition of an equivalent amount of an oxidizing agent such as I_2, H_2O_2 or $[NH_4]_2[Ce(NO_3)_6]$.† $[Ru^{III}(mnt)_3]^{2-}$ is the first structurally characterized all sulfur coordinated ruthenium(IV) complex. This species also has an octahedral arrangement of donor atoms. $[Ru^{III}(mnt)_3]^{2-}$ decomposes in the presence of light to the compound $[NEt_4]_2[Ru^{II}(mnts)_2]\cdot 0.5H_2O$ **3**, containing a novel tridentate ligand, bis(1,2-dicyano-2-mercaptoethylene)sulfide(2−) ($mnts^{2-}$).

The X-ray structure‡ of $[Ru^{III}(mnt)_3]^{3-}$ (Fig. 1) shows a C_3 axis of symmetry with the Ru located on this axis. The average twist angle[7] is 50.2° and the S–Ru–S *trans* angle is 172.2°, only 4.9° less than the value calculated for the 'octahedral limit' with the constrained ligand bite angle.[8] This is the smallest *trans* angle deviation for transition metal tris-dithiolate complex reported so far.[2] The crystal structure of $[Ru^{IV}(mnt)_3]^{2-}$ (Fig. 2) is more distorted than $[Ru^{III}(mnt)_3]^{3-}$ but again the ruthenium atom is ligated with six sulfur atoms. Two Ru–S distances for one ligand are shorter than the other four. The twist angle is 47.1° and the average S–Ru–S *trans* angle is 169.4°, 7.0° less than the calculated 'octahedral limit.' The *trans* angle deviation is close to that reported for the iron analogue.[6] The increase in the oxidation state of ruthenium between $[Ru^{III}(mnt)_3]^{3-}$ and $[Ru^{IV}(mnt)_3]^{2-}$ is not reflected by any substantial change in the average Ru–S distance. However, the C=C distance in the ligand is shorter in $[Ru^{IV}(mnt)_3]^{2-}$, an unexpected result since formal ligand oxidation involves C–S multiple bonding and would imply the opposite trend for the C=C distance.

Both of these complexes are paramagnetic. Magnetic moments of 1.69 and 2.84 μ_B for $[Ru^{III}(mnt)_3]^{3-}$ and $[Ru^{IV}(mnt)_3]^{2-}$, respectively, correspond to their octahedral low-spin configuration. $[Ru^{IV}(mnt)_3]^{2-}$ [$E°$(IV/III) = −0.70 V, (III/II) = −1.71 V *vs.* Fc^+/Fc in CH_2Cl_2, 0.1 M $NBu^t_4PF_6$, 25 °C] is highly susceptible to reducing agents such as PhSH and gives $[Ru^{III}(mnt)_3]^{3-}$ in good yield. In dilute solution, $[Ru^{IV}(mnt)_3]^{2-}$ is both light and air sensitive. In CH_2Cl_2 or acetone, the green solution of $[Ru^{IV}(mnt)_3]^{2-}$ turns brown on Hg irradiation for 3 h and this product undergoes further decomposition on standing for one day in the presence of air. A major decomposition product is the deep purple ruthenium(II) complex, $[Ru^{II}(mnts)_2]^{2-}$, coordinated with two tridentate sulfur ligands. The unique sulfur ligands have formed from two

Selected bond lengths (Å) and angles (°): Ru–S(1) 2.341(2), Ru–S(2) 2.311(2), Ru–S(3) 2.329(2), Ru–S(4) 2.352(2), Ru–S(5) 2.318(2), Ru–S(6) 2.341(2), S(1)–C(1) 1.690(8), S(2)–C(3) 1.763(7), S(2)–C(5) 1.747(7), S(3)–C(7) 1.710(8), S(1)–Ru–S(4) 176.43(7), S(1)–Ru–S(2) 88.51(7), S(2)–Ru–S(3) 88.08(7), S(2)–Ru–S(5) 93.23(7).

mnt^{2-} ligands. Attempts to characterize the intermediate brown species structurally were unsuccessful but FAB MS data suggest an oligomeric species. It is conceivable that the complexes link by formation of disulfide bonds[9] and that the $mnts^{2-}$ ligand forms by subsequent elimination of sulfur. The structure of $[Ru^{II}(mnts)_2]^{2-}$ [$E°(III/II)$ = +0.42 V *vs.* Fc^+/Fc in CH_2Cl_2, 0.1 M $NBu^t_4PF_6$, 25 °C] is shown in Fig. 3. The trivalent sulfur atoms of the two ligands are *cis* to each other. The average Ru–S distance and S–Ru–S *trans* angle are 2.332(2) Å and 177°, respectively, with an octahedral arrangement of donors.

Received (in Cambridge, UK) 7th September 1999, Accepted 6th October 1999

Steric forces within a hexaaza bicyclic cobalt cage system cause chromophore expansions which bring about extraordinary transformations in the CoN_6 chemistry, leading to $Co^{III/II}N_6$ redox potentials close to +0.8 V (*vs.* SHE) and Co^{II} hexaamine complexes that are air and substitution stable.

Steric factors pervade chemistry and their capacity to affect isomerism, structure and reactivity in transition metal coordination chemistry is well known.[1] They have also dramatically influenced metal complex stabilities and electron transfer rates, especially for macrocyclic[2] and polycyclic cage[3] ligand systems. When the steric forces cooperate to change the intrinsic geometry or rigidity of a metal complex chromophore, its spectroscopic, redox and photophysical characteristics change in response to the new ligand field and potential energy (PE) surfaces. Recently, the incorporation of relatively high stability and stereorigidity factors with modified chromophore PE surfaces in sterically crowded, expanded cavity cage complexes has led to unusual ground and excited state properties for MN_6(M = Co^{III}, Rh^{III}, Pt^{IV}, Cr^{III}) amine type chromophores.[4]

In the pursuit of kinetically stable metal amine systems that radically transform MN_6 chemistry, a Co^{II} cage complex $[Co(Me_8tricosatrieneN_6)]^{3+}$ **1** ($Me_8tricosatrieneN_6$ = 1,5,5,9,13,13,20,20-octamethyl-3,7,11,15,18,22–hexaazabicyclo[7.7.7]tricosa-3,14,18-triene) was synthesized by an approach based on the $[Co(tame)_2]^{3+}$ {tame = ethylidynetris(methanamine)} template.[5a,c] A vigorously agitated mixture of $[Co(tame)_2]Cl_3$ (2 g) and $NaClO_4$ (9.4 g) in acetonitrile (50 ml) was treated with paraformaldehyde (5 equiv.), 2-methylpropanal (50 equiv.) and triethylamine (8 ml), quenched with HCl after stirring for 30 min at 20 °C, and chromatographed by cation exchange methods to give a bright crimson major product (15–20% yield), which was identified as the C_3 symmetric Co^{III} triimine ion **1** by its ^1H and ^{13}C NMR spectra,† and a single crystal X-ray analysis of its tetrachlorozincate salt.†‡ The cation structure has virtual C_3 symmetry in the crystal with equivalent imines as well as equivalent chiral nitrogen centres. Although the CoN_6 geometry in the structure is close to octahedral, the Co–N distances are remarkably long compared to those found in complexes with near optimal $Co^{III}N_6$ (amine, imine) dimensions.[3c,5] In particular, the average Co–N (endoimine) distance of 2.011 Å is 0.11 Å longer than the value of 1.90 Å for analogous bonds in relatively unstrained systems.[5] In spite of this exceptional expansion of the $Co^{III}N_6$ module, triimine **1** is stable to metal ion substitution and imine hydrolysis in aqueous solution from 6 M HCl to pH *ca.* 8 at 20 °C. This result contrasts with the relatively high lability found for most Co^{III} amines having mean Co–N distances ⩾2.00 Å,[3c] but is consistent with that observed for another expanded cavity cage complex[4a] with a mean§ Co^{III}–N (amine) distance of 2.023(±0.01) Å.

Scheme 1

The formal similarities between $[Co(Me_8tricosatrieneN_6)]^{3+}$ **1** and its homologue[4a] $[Co(Me_5tricosatrieneN_6)]^{3+}$ **2** are obvious, especially the identical bonding frameworks linking the nitrogen atoms of the chromophore. However, the apparent likeness between the two species is largely limited to their C_3 symmetry and solution stability (at pH ⩽ 8), and they exhibit important fundamental differences in their chromophore electron chemistry. The electronic spectrum of the octamethyl complex **1** (Cl_3 salt in H_2O) shows the first spin-allowed ligand field absorptions at λ_{max} (ε_{max}) 518 (150) and 367 (150), compared with 468 (107) and 343 nm (135 $dm^3\ mol^{-1}\ cm^{-1}$) for the corresponding bands of the pentamethyl homologue **2**,[4a] which by spectral comparison with analogous Co^{III} (amine, imine) systems[5] is thought to have a fairly optimal $Co^{III}N_6$ geometry. These results imply that the Co–N distances in **1** are much longer than those of **2**. The striking differences in the chromophore sizes and ligand field spectra of the two homologues are attributed to steric factors arising from the three additional methyl groups of $[Co(Me_8tricosatrieneN_6)]^{3+}$, which block the ligand conformation that is needed to form an optimal cavity size for Co^{III}. Reduction potentials (*vs.* SHE) of *E* +0.40 and −0.16 V for the $Co^{III/II}$ couples of **1** and **2** were determined using cyclic voltammetry in aqueous 0.1 M NaCl. It is likely that the expanded cavity of the conformation adopted by **1** to accommodate its extra methyl groups, is a good fit for Co^{II} and is probably also preferred by **2** in the Co^{II} state. This would imply that the 560 mV positive shift in the $Co^{III/II}$ potential for the larger cavity species **1** arises mainly from a destabilization of its Co^{III} state rather than a stabilization of Co^{II}. Furthermore, the difference in the $Co^{III}N_6$ sizes of **1** and **2** means that a substantial part of the destabilization energy is associated with the expansion of the chromophore.

More profound CoN_6 redox and spectral behaviour results when $[Co^{III}(Me_8tricosatrieneN_6)]^{3+}$ is reduced to the more sterically crowded saturated amine form $[Co^{II}(Me_8tricosaneN_6)]^{2+}$ **3**. These phenomena involve fundamental changes in the nature of CoN_6 (amine) chemistry and are not entirely understood at present. The Co^{II} complex **3** was first formed by stirring the trichloride salt of **1** with $NaBH_4$ (6 equiv.) in basic aqueous solution (pH 10) for 20 min at 20 °C and quenching with saturated $NaHCO_3$ solution (1 h), and then isolated as a *pink* dinitrate salt (95% yield), following cation-exchange chromatography using aqueous $LiNO_3$ as eluent and evaporation of the eluted complex solution. A *violet* tetrachlorozincate salt of **3** was also obtained by anion-exchange chromatography (Cl^- form) of the aqueous nitrate solution, addition of excess $ZnCl_2$ solution (pH 5) and concentration at 20 °C. Fig. 1 The (*a*) $\Lambda(S_6)$ and (*b*) $\Lambda(S_4R_2)$ cations of **3** in its $(NO_3)_2{\cdot}H_2O$ and $ZnCl_4$ salts. Selected bond lengths (Å) and angles (°) for (*a*) (D_3 averaged§): Co–N 2.223 (±0.020); N(12)–Co–N(16) 86.3(±0.4), Co–N–C (cap) 114.1(±0.4). For (*b*) (C_2 independent): Co–N(12) 2.135(4), Co–N(16) 2.355(4), Co–N(22) 2.206(4); N(12)–Co–N(16) 82.2(2), N(22)–Co–N(22*) 88.8(2), Co–N(22)–C(21) 116.2(3), Co–N(12)–C(11) 117.0(3), Co–N(16)–C(15) 116.7(3).

were conducted in air and the $[Co^{II}(Me_8tricosaneN_6)]^{2+}$ ion was identified by elemental microanalysis (C, H, N, Cl, Co), ^{1}H NMR† and VIS-near IR electronic spectra, and the single crystal X-ray analyses of its $(NO_3)_2$ and $ZnCl_4$ salts.†‡ The synthesis and isolation of an *air and* relatively substitution stable Co^{II} hexaamine species is an unusual development that involves new CoN_6 redox chemistry.

The ^{1}H NMR spectrum† of $[Co^{II}(Me_8tricosaneN_6)]^{2+}$ in D_2O solution at 25°C is consistent with the presence of two main species that do not interconvert on the 300 MHz ^{1}H NMR timescale. The CH_2 and CH_3 proton resonances display paramagnetic broadening and upfield δ shifts within the range −10 to −50 ppm, and are clearly in accord with two dominant species averaging D_3 (6 signals) and C_2 (15 discrete signals) symmetry in D_2O. These two forms of **3** most likely correspond to diastereoisomers of the type $\Lambda(S_6)$ and $\Lambda(S_4R_2)$, and their enantiomers $\Delta(R_6)$ and $\Delta(R_4S_2)$, where *R* or *S* defines the configuration of each of the six chiral nitrogen centres and Λ or Δ the configuration about the metal ion. The Co^{II} system appears to be stable to net ligand dissociation in the presence of anions such as Cl^-, ClO_4^-, NO_3^-, SO_4^{2-}, $CH_3CO_2^-$ and CO_3^{2-} in a variety of solvents. However, the lability of individual Co^{II}–N bonds should facilitate interconversion between the diastereoisomers within minutes. Diagrams of the two distinct Co^{II} cations found in single crystals of the *pink* $(NO_3)_2$ and *violet* $ZnCl_4$ salts of **3** are shown in Fig. 1(*a*) and (*b*), viewed down their bridgehead axes. The crystal structures clearly reveal the virtual D_3 symmetry of the $\Lambda(S_6)$ cation (*a*) and the C_2 symmetry of the $\Lambda(S_4R_2)$ cation (*b*), consistent with their being the major components in solution. Mean Co^{II}–N distances are very similar for the $\Lambda(S_6)$(2.223 Å) and $\Lambda(S_4R_2)$(2.232 Å) structures, but the latter has two short (2.135(4) Å) and two very long (2.355(4) Å) bonds. Notably, the mean distances are 0.05–0.07 Å longer than those of 2.16–2.18 Å observed for other $Co^{II}N_6$(amine) structures[6] having nearly optimal $Co^{II}N_6$ sizes. It follows from the data that these two conformations of the free ligand would prefer a larger ion than Co^{II}. Overall, the implication is that strong steric influences in the $[Co(Me_8tricosaneN_6]^{n+}$ system stabilize larger cavity conformations, which markedly expand both $Co^{II}N_6$ and $Co^{III}N_6$ centres relative to those of the formally analogous $[Co(fac\text{-}Me_5tricosaneN_6)]^{n+}$ system,[4a] which has a C_3 tris-(chair) conformation in the Co^{III} complex (**4**) and probably also in the Co^{II} state.[4a] The structures also show sizeable $Co^{II}N_6$ twist distortions away from O_h geometry about the molecular bicyclic axes, with the average§ twist angles (ϕ)¶ being 46.0(±0.8)° for the $\Lambda(S_6)$ isomer (assuming D_3 symmetry), and 46.2 and 31.5° for the two independent angles of the C_2 symmetric $\Lambda(S_4R_2)$ form. However the distortions are decidedly less than that of $[Co^{II}(NH_3)_2sar)]^{4+}$ (sar = 3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane, apically substituted) in its $(NO_3)_4$ salt structure[6c] [ϕ 29.0(±0.9)°], which accommodates an optimal Co^{II}–N mean distance of 2.170(±0.021) Å.

The expanded $Co^{II}N_6$ cores of the $[Co^{II}(Me_8tricosaneN_6)]^{2+}$ components exert substantial influences on the positions of the main ligand field bands, in the visible and near-IR absorption spectrum of **3** in aqueous solution at 25 °C. These transitions, of origin $^4T_{1g}(F) \rightarrow {}^4T_{2g}$ and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ at λ_{max} (ε) 1062 (4.8) and 498 nm (11.1 dm^3 mol^{-1} cm^{-1}), are red shifted by 150 and 35 nm (> 1500 cm^{-1}) from those of analogous cobalt(II) amine complexes[4a,6a] with relatively optimal chromophore dimensions. Although the binary composition of **3** may cause broadening, asymmetry and lower resolution, particularly for the lower intensity bands, its overall spectral profile remains similar to that of the smaller cavity analogues.[4a,6a]

Cyclic voltammetry of the $[Co^{II}(Me_8tricosaneN_6)]^{2+}$ system in aqueous 0.1 M KCl reveals unusual $Co^{III/II}$ redox behaviour. A complete interpretation requires more data for the isolated Co^{III} species,[7] but the general features account for the extraordinary air stability of the Co^{II} system, which is not oxidised by O_2 or H_2O_2. The voltammogram† is distinctly asymmetric, with the oxidation and main reduction wave peaks occurring at *ca*. +0.84 and +0.29 V(*vs*. SHE at 100 mV s^{-1}), and was reproduced using multiple and reverse scans and several different salts of **3**. The system is electrochemically irreversible but chemically reversible, and the main wave features are consistent with configurations of $[Co(Me_8tricosaneN_6)]^{3+/2+}$ that reduce at *ca*. 0.3 V and oxidise at *ca*. 0.8 V (*vs*. SHE). The system has not been completely unravelled yet but there are clearly at least two diastereoisomers of the Co^{II} complex involved, and recently a blue and an orange form of the Co^{III} complex have been characterized after coulometric oxidation (800 mV *vs*. SCE) of the Co^{II} form.[7] The Co^{III} forms appear to be conformationally interconvertible, both with D_3 symmetry and clearly very different ligand fields (λ_{max} for $^1A_{1g} \rightarrow {}^1T_{1g}$ *ca*. 600 and 480 nm.

The results in total show some astonishing changes in $Co^{II/III}$ amine spectroscopy and redox chemistry that are tied to dimensional changes in the $Co^{II/III}N_6$ chromophores, and clearly demonstrate the potential of sterically crowded expanded cavity cage systems in the development of new ML_6 chemistry.

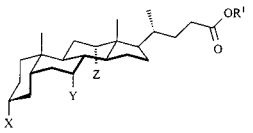
Received (in Cambridge, UK) 9th September 1999, Accepted 12th October 1999

This paper describes the first synthesis of branched bile acid oligomers.

The chemistry of dendrimers has been a dominating theme in chemical sciences in recent years. Chiral dendritic species[1] also appeared in the chemical literature shortly after the first achiral version was reported.[2] Apart from their potential applications in asymmetric catalysis and chiral recognition,[3] chiral dendritic species have been of considerable interest because of a search towards *macromolecular asymmetry*.[4] A dendrimer possesses three distinct regions, *viz.* the core, the branching units and the end groups, and the incorporation of chirality in the dendrimer can in general be achieved by choosing one or more such components to be chiral.[1b] Molecules from the natural chiral pool, *e.g.* amino acids,[1a] nucleic acids,[5] sugars[6] and tartaric acid,[4e,f] have been employed to design chiral dendrimers. Bile acids, forming another class of the naturally occurring group of chiral molecules, have been extensively used in supramolecular chemistry including the synthesis of cyclic and linear polymers.[7] Bile acids (*e.g.* **1**–**3**) offer a carboxy group and multiple



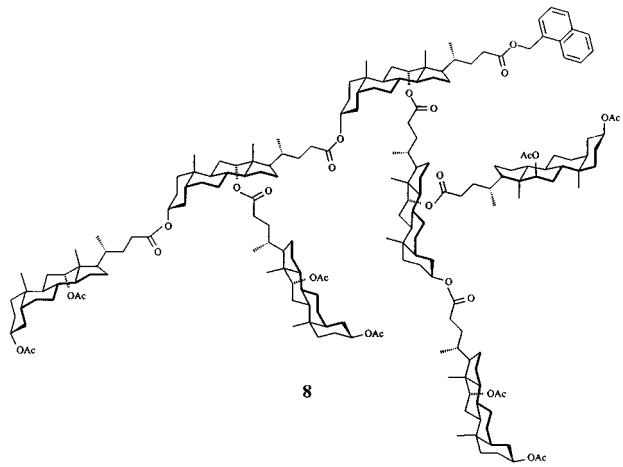
1 Lithocholic acid	X = OH, Y = Z = H, R^1 = H
2 Deoxycholic acid	X = Z = OH, Y = H, R^1 = H
3 Cholic acid	X = Y = Z = OH, R^1 = H
4 Deoxycholic acid, 3,12-diacetate	X = Z = OAc, Y = H, R^1 = H
5 1-Naphthylmethyl deoxycholate	X = Z = OH, Y = H, R^1 = 1-CH_2Np
6 Cholic acid, 3,7,12-triacetate	X = Y = Z = OAc, R^1 = H
7 1-Naphthylmethyl cholate	X = Y = Z = OH, R^1 = 1-CH_2Np

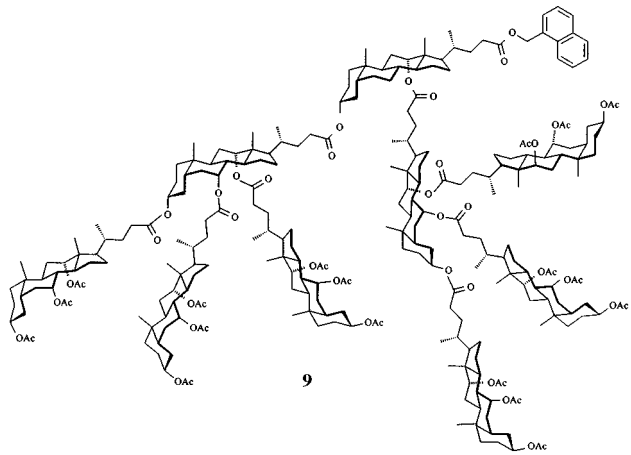
hydroxy groups (up to three) and are versatile AB_2 or AB_3 building blocks for dendritic construction. We report here the synthesis of the *first* bile acid-based chiral dendrons **8** and **9**, a heptamer and a nonamer, respectively. These relatively small oligomers of large chiral building blocks are of nanometric dimensions.

We adopted *Fréchet's* convergent strategy[8] to accomplish the synthesis of **8** and **9**. Orthogonal protection of deoxycholic acid **2** with acetate and 1-naphthylmethyl groups[9] generated steroids **4** (Ac_2O, Et_3N, DMAP, 92%) and **5** (1-naphthylmethyl chloride/DBU/DMF, 79%), respectively. In an analogous manner cholic acid **3** was converted to **6** (45%) and **7** (77%).

Steroid **4** was converted to the acid chloride, and reacted with **5**, (CaH_2, $BnEt_3N^+Cl^-$, toluene, reflux, 2 d) to generate trimer **10** (70%) which was characterized by IR, ^1H and ^{13}C NMR, UV, HPLC, elemental analysis and MALDI-TOF MS (Scheme 1). The deprotection of **10** to **11** (Pd/C, H_2), conversion to the acid chloride and subsequent reaction with **5** provided heptamer **8** in 75% yield.[10]

The use of cholic acid-based starting materials **6** and **7** led to an increase in the number of branching units, which allowed us to construct tetramer **12** in 69% yield. The deprotection of **12** to **13**, followed by its coupling with **5** generated nonamer **13** (35%).[10] One of the (many possible) conformations of **9** is shown in Fig. 1.





The mobility of these compounds on reversed-phase HPLC shows an interesting pattern (Table 1). With the increase in the oligomeric size, both the polarity (increased number of ester groups) and the lipophilicity (increased number of bile acid

Table 1 HPLC data on bile acid oligomers (25 cm C-18 column, 4.6 mm id)

Steroidal oligomers	Solvent system	Retention time/min
8 (7[a], 15[b])	30% THF–MeOH	14.5
9 (9, 27)	15% THF–MeOH	12.9
10 (3, 7)	15% THF–MeOH	17.1
12 (4, 13)	MeOH	13.8

[a] Number of bile acid moieties present. [b] Number of ester linkages.

units) increase. Experimentally, the order of elution (increasing retention time) on a C-18 column is: **12** < **9** < **10** < **8**. On silica gel TLC a different order is observed; the R_f values increase in the order: **9** < **12** < **8** < **10** (EtOAc–hexanes, 2 : 3 v/v).

The optical rotations of these dendrons are given in Table 2. The molar rotation values show a roughly linear relationship with the number of bile acid units in each dendron (or its molecular weight). This suggests the absence of chiral conformations and local micropolarity which might affect the optical rotation.

These bile acid-based dendrons are of considerable interest because of their shape and nanometric dimensions. The design of larger functionalized dendrimers using analogous repeating units is in progress in our laboratory.

Table 2 Molar and specific rotation values of dendrons in $CHCl_3$

Compound (MW)	Specific rotation	Molar rotation
8 (3116.4)	102.9	3207
9 (4413.9)	84.2	3717
10 (1450.0)	86.6	1256
11 (1309.9)	94.7	1240
12 (2098.8)	80.8	1696
13 (1958.6)	80.6	1579

Carbon nanocage structures formed by one-dimensional self-organization of gold nanoparticles

Takeo Oku* and Katsuaki Suganuma

Institute of Scientific and Industrial Research, Osaka University, Mihogaoka 8-1, Ibaraki, Osaka 567-0047, Japan. E-mail: Oku@sanken.osaka-u.ac.jp

Received (in Cambridge, UK) 15th July 1999, Accepted 25th October 1999

Carbon nanocapsules and nanotubes have been formed by one-dimensional self-organization of gold nanoparticles, caused by the adhesive force at the step edge of amorphous carbon thin films; the present result is expected to be a promising fabrication technique for self-assembling nanowires and cluster-protected quantum dots at scales beyond the limits of current photolithography.

The recent speed-up of ultra-large scale integrated circuits (ULSI) of semiconductor devices is highly dependent on the minimization of the design rule. New properties are also expected by formation of low dimensional arrays of quantum dots. The photolithography technique is used for the formation of these nanostructures, and ULSI with 0.07 μm rule will be produced in 2009.[1] However, the limit of the design rule is reported to be 0.05 μm (= 50 nm) using extreme ultraviolet lithography.[2] The establishment of nanostructure-formation technique by self-organization of nanoparticles[3–8] is worth investigation in order to overcome this lithography limit. However, self-organization has been of two- and three-dimensional type, whereas one-dimensional (1D) self-organization is required for the 'nanowiring' formation of the future ULSI devices.

The purpose of the present work is to form 1D carbon nanocage arrangements using self-organization of metal nanoparticles with a size below 10 nm. Gold colloids have been used for the formation of single electron transistors.[9,10] In the present work, gold (Au) nanoparticles were selected because of easy control of cluster size.[11] Fabrication of 1D Au nanodots and nanowires encapsulated in carbon nanocage structures was attempted by annealing the 1D self-organized nanoparticles on carbon thin films. In order to understand the self-organization mechanism, high-resolution electron microscopy (HREM)[12,13] was carried out. The present work gives a guideline for the design and synthesis of 1D self-organized nanostructures, which are expected for future nanoscale devices.

Au nanoparticles (ULVAC Ltd.) with a size of *ca.* 5 nm are selected in the present work for the 1D positioning. The surface of these nanoparticles was stabilized by α-terpineol ($C_{10}H_{18}O$) in toluene solution. The Au nanoparticle solution was dispersed on holey carbon grids with thickness *ca.* 15 nm (Oken Syoji. Co. Ltd.). After drying the specimens, they were loaded into the vacuum chamber and annealed at 400 °C for 30 min in a vacuum of *ca.* 7×10^{-4} Pa. HREM observations were performed with a 1250 kV electron microscope (ARM-1250) equipped with a top entry goniometer having a point-to-point resolution of 0.12 nm. To avoid sample damage by electron irradiation, the electron beam width for HREM observations was minimized by using a small spot size.

A low magnification image of as-prepared Au nanoparticles on amorphous carbon film is shown in Fig. 1(a). 1D ordering of Au nanoparticles with a size of 5 nm is observed over a length of 70 nm and a line profile of amorphous carbon across the row is shown. The image intensity of amorphous carbon at the lower side is 1.2 times stronger than that of the upper side as indicated by white lines in the inset to Fig. 1(a), which indicates that the step edge of the carbon thin films is *ca.* 3 nm (0.2×15 nm). The longest size of the 1D ordering was *ca.* 1.5 μm, which is dependent on the length of step edge of the carbon thin films. An enlarged HREM image of the self-organized Au nanoparticles is shown in Fig. 1(b). The image contrast of amorphous carbon in region A is brighter than that in region B, which also indicates the step edge of the carbon film as measured in Fig. 1(a). 1D positioning of Au nanoparticles with a width of *ca.* 15 nm is also observed in Fig. 1(c), which consists of two or three rows of Au nanoparticles. Reproducibility of the 1D self-organization was confirmed.

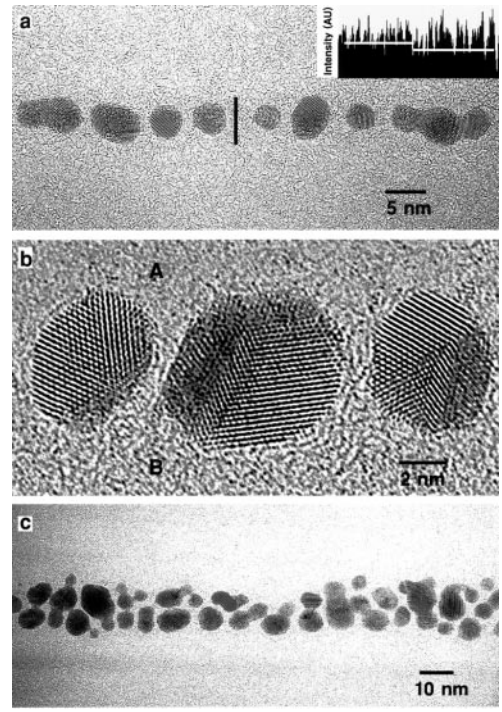

Fig. 1 (a) Low magnification image of 1D self-organized Au nanoparticles on amorphous carbon film with the intensity distribution across the interface indicated. (b) Enlarged HREM image of 1D self-organized Au nanoparticles. (c) 1D self-organization of Au nanoparticles with a width of *ca.* 15 nm.

Fig. 2 shows HREM images of annealed Au nanoparticles at 400 °C. Au nanoparticles encapsulated in carbon nanocapsules are observed in Fig. 2(a). At elevated temperatures, Au nanoparticles grow by coalescence, and the particle size is *ca.* 15 nm. The carbon nanocapsules are isolated owing to the surface diffusion of Au and C atoms and the surface tension of the nanoparticles. Amorphous carbon would be graphitized by the catalytic effect[14] of the active Au surface at low temperature of 400 °C compared to that of ordinary chemical formation of carbon nanocapsules.[15] An enlarged image of the Au nanoparticles encapsulated in carbon nanocapsules is shown in Fig. 2(b). All the Au nanoparticles are surrounded and isolated by double or triple graphite sheets, which would prevent the nanoparticles from growing and so acts as cluster protection. Au nanowires encapsulated in carbon nanotubes are often formed as shown in Fig. 2(c). An Au nanoparticle encapsulated in a

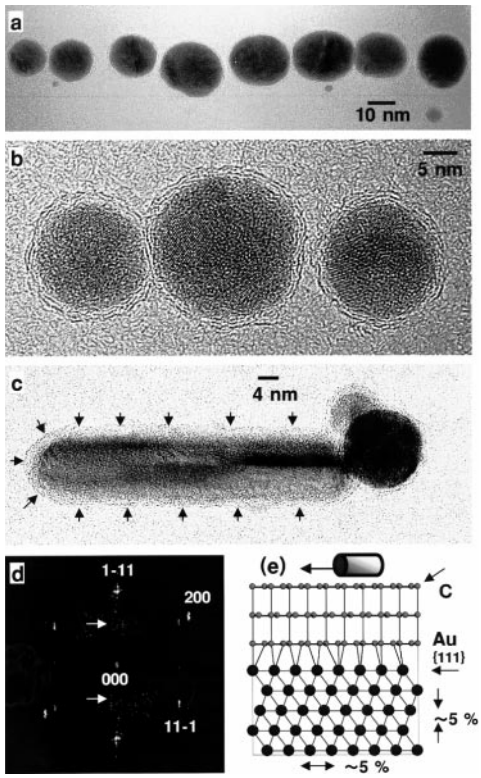

Fig. 2 (a) Low magnification image of annealed Au nanoparticles at 400 °C. (b) HREM image of Au nanoparticles encapsulated in carbon nanocapsules. (c) Au nanowire encapsulated in carbon nanotube. (d) Fourier transformed pattern of the nanotube. (e) Structural model of Au{111}/C{002} interface.

carbon nanocapsule is also observed at the tip of the nanotube. The one-dimensionality is retained after the coalescence of nanoparticles, which is a useful formation technique for protected nanowires. The maximum length of the continuous wire is *ca.* 100 nm, and the length is dependent on the nanoparticle distance. A Fourier transformed pattern of a circular cross-section of a cut Au nanotube is shown in Fig. 2(d). The diffractogram is indexed with the [011] incidence of Au. In the Fourier transform, lattice distortion is observed as indicated by the streaks of each reflection perpendicular to the growth direction of the nanowire. Some distortion is observed in all Au nanowires. The $1\bar{1}1$ reflection is expanded, which indicates reduction of lattice distance of Au{111}. The maximum difference between $1\bar{1}1$ and $11\bar{1}$ reflections is *ca.* 10%. Diffuse scattering of carbon 002 is observed as indicated by arrows, which is due to the carbon layers of the nanotube. A structure model of the $Au\{111\}/C\{002\}_{nanotube}$ interface is shown in Fig. 2(e). Lattice expansion and reduction are observed parallel and perpendicular to the growth axis, respectively. It is believed that the distortion of nanowire is due to the coalescence of nanoparticles along the growth direction at low temperatures. The maximum distortion is *ca.* 10%, which would indicate expansion and reduction of *ca.* 5%, respectively.

The formation of graphitic coatings around metal nanoparticles supported on amorphous-C films is often observed when subjected to high intensity electron beam irradiation.[16] However, a high intensity electron beam was not used here. As is evident in Fig. 1, which was obtained with a 1250 kV electron microscope, there are no graphite layers around the Au nanoparticles for the as-prepared samples. If the formation of the graphite layers around the nanoparticles is due to the effect of the electron beam, there should be carbon layers around the nanoparticles for the as-prepared samples. When a high intensity electron beam is used, an amorphous carbon matrix is also graphitized. However, an amorphous carbon matrix is observed around the carbon nanocapsules and nanotubes in Fig. 2. In addition, several micrographs for the as-prepared and annealed samples were taken under the same conditions in the present work, and formation of carbon layers around the nanoparticles was observed only for the annealed samples. These results indicate that the formation of these carbon nanocage structures is due to annealing, and that this method is effective for the homogeneous formation of carbon nanocage structures.

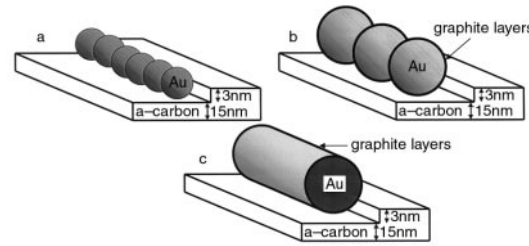

Fig. 3 Schematic illustration of (a) 1D self-organized Au nanoparticles, (b) carbon nanocapsules and (c) a carbon nanotube.

A schematic illustration of self-organized Au nanoparticles, carbon nanocapsules and a carbon nanotube is shown in Fig. 3. Adhesion due to the step edge and substrate is the main force leading to the 1D arrangement whereas 2D self-organization[6–8] of nanoparticles is due to inter-nanoparticle forces by ligands around particles. The present result indicates that the 1D arrangement is strongly dependent on the step edge of the substrate. The formation of carbon nanocapsules and nanotubes would depend on the distance between gold nanoparticles. For larger distances, carbon nanocapsules will be formed while for smaller distances, gold nanowires will be formed by the coalescence of gold nanoparticles. Although step edges are formed by a simple sample preparation technique in the present work, the step edge size can be controlled by ordinary lithography techniques such as use of an electron beam, and is expected to be a viable nanofabrication technique for future electronic devices.

We acknowledge Professors K. Hiraga and E. Aoyagi for allowing us to use the electron microscope. This work was partly supported by The Shinsedai Foundation, and Grant-in-Aid for Scientific Research, Ministry of Education, Science, Sports and Culture, Japan.

A model for pathways of radical addition to fullerenes

Kevin M. Rogers and Patrick W. Fowler*

School of Chemistry, University of Exeter, Stocker Road, Exeter, UK EX4 4QD. E-mail: p.w.fowler@exeter.ac.uk

Received (in Cambridge, UK) 14th July 1999, Accepted 18th October 1999

A sequential π-electronic model that simulates addition of large radicals to fullerenes yields pathways to the experimental structures of $C_{60}X_6$ (X = Cl, Br) and $C_{70}Cl_{10}$ and predicts structures for $C_{60}X_{12}$ and $C_{60}X_{18}$.

The fullerenes behave as giant electron-deficient alkenes[1] and possess a rich addition chemistry. Derivatives in which the addends are halogen atoms were among the first to be fully characterised: $C_{60}Cl_6$,[2] $C_{60}Br_6$,[3] $C_{60}Br_8$[3] and $C_{70}Cl_{10}$[4] have all been synthesised and their structures identified. Analogous derivatives have been made by replacing some or all of the halogen addends with aryl[5] and allyl[6] groups. Six nitro groups add to C_{60} to give a derivative that is thought to be isostructural with $C_{60}Br_6$.[7] Direct alkylation, haloalkylation and arylation *via* radical species have also been studied.[8,9] Whilst benzylation of fullerenes, for example, clearly involves radical species, often leading to relatively stable radical products,[8,9] halogenation leads directly to products with even numbers of addends and stable electronic configurations. However, it is believed that addition of halogen atoms also occurs *via* a radical mechanism.[10]

The present communication describes a simple model based on topology alone that is designed to predict the most likely sites for addition of large radicals to an extended carbon π system. Application of the model to C_{60} and C_{70}, the two fullerenes for which data exist, generates addition pathways that lead to stable addend patterns isostructural with experimentally produced compounds. The potential for generalisation of the approach when new fullerenes become available in quantity is clear.

The model is based on Hückel molecular-orbital (HMO) theory, which is often used to provide simple qualitative π-electronic information of fullerenes. The background is given in many textbooks.[11] In the simplest ('topological') approximation, Coulomb integrals α are equal for all atoms, resonance integrals β are equal for all σ-bonded pairs and all more distant interactions are neglected. Diagonalisation of the adjacency matrix gives the dimensionless eigenvalues $\lambda = (\varepsilon - \alpha)/\beta$ (where ε is an orbital energy) and their corresponding eigenvectors. One useful feature of the Hückel model is that topological coordinates of the atoms of a fullerene can be generated from the eigenvectors of its adjacency matrix.[12] The model developed here generates several π-electronic properties of fullerenes from their Hückel eigenvectors.

One property readily derived from HMO eigenvectors is p_{rs}, the π *bond order* between two atoms r and s in an extended π system. It is a sum over the partial mobile bond orders contributed by all molecular orbitals [eqn. (1)],

$$p_{rs} = \sum_j n_j c_{jr} c_{js} \quad (1)$$

where c_{jr} is the coefficient of the p_π orbital of atom r in the jth molecular orbital and n_j is the *occupation number*.

The model applied here is based on two further properties. The first, *free-valence index*, was used in early work by Coulson and coworkers on radical addition to small unsaturated hydrocarbons.[13] The free-valence index F_r, defined by Coulson,[14] measures ease of attack by species, particularly free radicals, at an atom r in a conjugated π system [eqn. (2)].

$$F_r = N_{\max} - N_r \quad (2)$$

N_r is the sum of π bond orders over all bonds joining atom r to the remainder of the π system. $N_{\max}$ is the maximum value of this sum and depends on how many other sp^2 carbons are attached to the atom in question; $N_{\max}$ is $\sqrt{m}$ for an sp^2 carbon attached to m others.[15] The second property, *spin density*, $\rho_{(\pi)r}$, measures the amount of unpaired electron density on an atomic site of a molecule in an open-shell state [eqn. (3)],

$$\rho_{(\pi)r} = \sum_j v_j (c_{jr})^2 \quad (3)$$

where v_j is the *spin number* of the jth molecular orbital. In this model, empty and full (doubly occupied) orbitals have spin number zero and the spin number may be non-integral for a partially filled, degenerate HOMO.

The two properties are used in combination to create a model for simulation of free-radical attack, specified as follows. Assume that addends are attached to a fullerene framework sequentially, in a game with two rules. Attack of the first addend on the closed-shell molecule obeys *rule* (*i*): attach to a position of maximum free valence. This produces a radical product, which is attacked in the next addition, under *rule* (*ii*): attach to an available position of maximum spin density amongst all those that will quench the radical. If steric effects are ignored, all sites are 'available', but for a bulky addend such as Cl, Br or $PhCH_2$, neighbours of sp^3 sites can be taken to be unavailable unless their occupation becomes necessary for radical quenching. It turns out that in the examples investigated here, the position of maximum free valence is never adjacent to an sp^3 site [hence the omission of the term 'available' from rule (i)], although this may not be the case for other examples.

Addition to C_{60}: following rules (i) and (ii), addition to C_{60} occurs in a straight-forward sequence. After one addition, the site of maximum spin density is at the other end of the attacked formal double bond (hexagon–hexagon edge), but the preference for *non-adjacent* attack leads to attachment at the 1,4 position of a hexagon. Successive brominations continue to make 1,4 patterns, winding around a central pentagon [Fig. 1(*a*)]. By the addition of the fifth Br atom, the pentagon in question is isolated and is effectively a cyclopentadienyl radical in the Hückel model (although in more sophisticated theory, the radical moiety would interact weakly with the rest of the cage *via* homoconjugation[16]). The only way to quench the radical at the next step is by addition within the surrounded pentagon, giving the experimental $C_{60}X_6$ (X = Cl, Br) pattern with a single sp^3–sp^3 adjacency.[2,3] This addition sequence, summarised in Fig. 1(*a*), is compatible with more sophisticated calculations and the ESR measurements on known radical additions such as benzylation,[8] where the long lifetime of the intermediate allyl and cyclopentadienyl radicals makes direct observation possible. Such radical intermediates are stabilised by the hyperconjugation and steric protection provided by the bulky organic addends.[8,9] Neither of these features is provided by atomic halogen addends; hence any radical intermediate is susceptible to rapid further addition.

Extended application of the model to C_{60} leads to incorporation of two further sets of six addends, indicating possible stability for derivatives with 12 and 18 bulky ligands. The pattern of addition in both of these further sets is identical to the first, proceeding *via* allyl and cyclopentadienyl intermediates. However, isomers are possible owing to the number of possible locations of the addends in the central pentagons. Addition

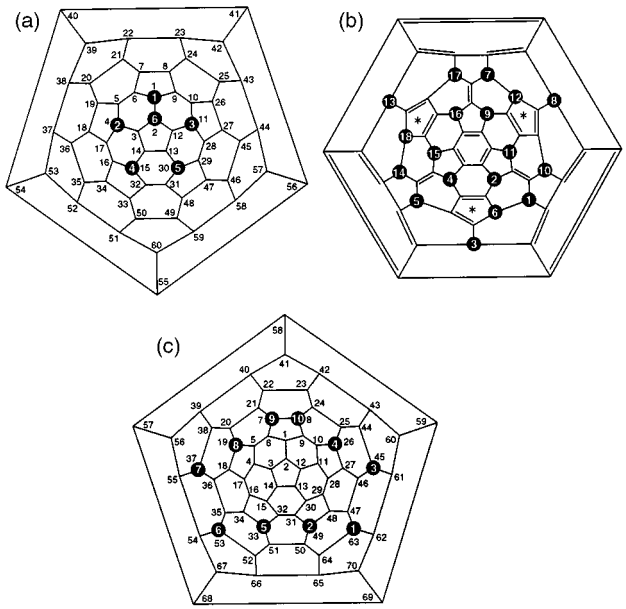

Fig. 1 Sequence of attack on C_{60} and C_{70} (in the IUPAC numbering scheme).[17] (a) The first six addends on C_{60} give the experimental structure $C_{60}X_6$ (X = Cl, Br).[2,3] (b) After 18 additions, the remaining six available sp^2 sites (outer hexagon of the Schlegel diagram) are part of an 18-atom aromatic π system. Isomers are possible since addends 6, 12 and 18 could be attached to any of the five sites in the pentagons marked with an asterisk. (c) The first ten addends on C_{70} give the experimental structure of $C_{70}Cl_{10}$.[4,18]

beyond 18 addends may be less favourable as the six remaining available (non-adjacent) sp^2 sites are part of a stable aromatic π system. The predicted order of attack by addends 7–12 and 13–18, leading to $C_{60}X_{12}$ and $C_{60}X_{18}$ respectively, is summarised in Fig. 1(*b*). Although not found for Br, these structures are plausible candidates for addition of, for example, X = Cl.

Addition to C_{70}: for C_{70} it is not necessary to invoke the bulk of the addend, as 1,4 addition is favoured electronically at every spin-quenching stage. Addition according to rules (i) and (ii) proceeds around the equator, forming a belt of 1,4 links across hexagons, which after the ninth addition can be spin-quenched by forming an sp^3–sp^3 adjacency. Addition at this position (8 in the IUPAC labelling[17]), which is the centre of maximum spin density, splits the π system into 28- and 32-atom components, each with a significant HOMO–LUMO gap. (The site that would be occupied under strict non-adjacent attack has a much lower spin density, 0.097 *cf.* 0.270.) Again, the result of alternate quenching of free valence and spin [Fig. 1(*c*)] is a known pattern, the experimental structure of $C_{70}Cl_{10}$.[4] At least within the small number of structures compatible with the ^{13}C NMR spectrum of the compound, this structure is also the one that is thermodynamically favoured over its competitors.[18]

The model presented here can be seen as essentially a kinetic one, since the rules choose the site most directly reactive towards an approaching radical, rather than necessarily the thermodynamically most stable product. The practice of predicting addition patterns by following sequences of thermodynamically stable species is common,[19] and has correctly predicted the structures of experimentally characterised derivatives. As the degree of addition to the cage increases, a combinatorially exploding number of thermodynamic calculations is needed to cover all possible patterns at each step. The model developed here is based on simple rules that lead directly from one pattern to the next in a deterministic sequence. Examples exist where semi-empirical thermodynamic energies predict no clear candidate for the most stable isomer, a case in point being $C_{60}Br_8$.[20] It is certain that in $C_{60}Br_6$ itself, some rearrangement must occur on further bromination, as its six bromine positions do not form a subset of those in either $C_{60}Br_8$ or $C_{60}Br_{24}$.[3] The present Br_6 pattern *may* in fact also be the thermodynamic result for $C_{60}Br_6$, but this is not established. A theoretical test would be a calculation of energies for all $C_{60}Br_6$ isomers. In this connection, it is worth noting that the experimental isomers of $C_{60}Br_6$ and $C_{70}Cl_{10}$ are selected uniquely from 418 470 and 19 835 545 518 possibilities[21] by the present, purely graph-theoretical model.

Geometric requirements in the ferriin oxidation of benzylic 1,2-diols

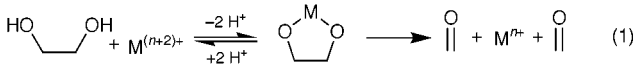
John H. Penn,* Robert C. Plants and An Liu

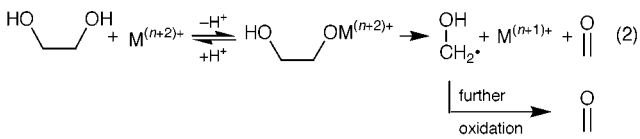
Department of Chemistry, West Virginia University, Morgantown, WV 26506-6045, USA. E-mail: jpenn2@wvu.edu

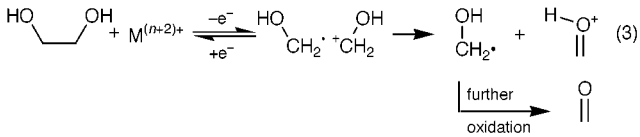
Received (in Corvallis, OR, USA) 12th July 1999, Accepted 8th October 1999

The rates of ferriin [*i.e.* tris(1,10-phenanthroline)iron(III)] oxidation of *cis*- and *trans*-1,2-diphenylcyclohexane-1,2-diol have been found to be dramatically different; *cis*-1,2-diphenylcyclohexane-1,2-diol reacts a minimum of 10^4 times faster than the corresponding *trans*-isomer; implications for the oxidation of benzylic diols by ferriin are discussed.

The oxidative cleavage of 1,2-diols by a variety of reagents has been extensively studied.[1] The mechanisms are conventionally classified into several types.[1] In the first class of oxidative cleavage of *vic*-diols [eqn. (1)], a bidentate complex between

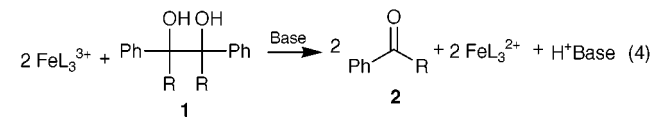






the oxidant and the glycol breaks down by an apparent six-electron process (two electrons to the oxidant).[1] The second general class of oxidative cleavage mechanisms of *vic*-diols [eqn. (2)] invokes a monodentate complex, which yields an intermediate radical *via* a one-electron process, followed by C–C fission and then further oxidation of the resulting radical.[1] A third general class of oxidative cleavage reactions for appropriately substituted *vic*-diols [eqn. (3)] is a single electron transfer to form a radical cation, that can subsequently undergo bond cleavage to form fragments similar to those formed in [eqn. (2)].[2,3]

In our laboratories, we hoped to use *vic*-diols that undergo cleavage by the general mechanism shown in [eqn. (3)] in order to determine fundamental reaction rate constants. Our initial studies demonstrated that ferriin readily oxidized tetraaryl-ethane-1,2-diols to the corresponding ketones [eqn. (4)].[4] By



applying a mechanism in which a slow rate-determining outer-sphere electron transfer was followed by rapid bond cleavage {general mechanism of [eqn. (3)]}, we reported endergonic electron transfer rate constants that were faster than expected, based upon estimates of the solution phase oxidation potential.[5] As we have varied functionality in standard structure–reactivity probes in an attempt to understand this anomalously fast electron transfer rate, we have observed non-isosbestic point behavior during a kinetics experiment on appropriately substituted compounds. This has served as an indication that the reaction mechanism is more complex than originally thought.[6]

As part of our reinvestigation of this reaction mechanism, we have studied the geometric relationship of the hydroxy groups in this oxidation reaction. Our preliminary investigation of the reactivity differences exhibited by *dl*- and *meso*-1,2-diphenyl-ethane-1,2-diol indicated to us that steric requirements existed in this reaction and that the geometry of the reacting groups might be important. The free rotation of the central C–C bond in the *dl*- and *meso*-isomers of 1,2-diphenylethane-1,2-diol does not allow for a definitive analysis of the various intramolecular interactions, which may be responsible for the observed reactivity. In order to lock the geometry of all components in place, we chose to study *cis*- and *trans*-1,2-diphenylcyclohex-ane-1,2-diol. These compounds were synthesized based on Tomboulian's method.[7] In brief, *cis*-**3** was obtained from 1,4-dibenzoylbutane in a McMurry coupling reaction with $TiCl_3/LiAlH_4$ followed by OsO_4 oxidation to give the *cis*-1,2-diphenylcyclohexane-1,2-diol in 27% yield [mp 86.5–87.5 °C (lit.,[7] 86–87 °C)]. *trans*-1,2-Diphenylcyclohex-ane-1,2-diol was obtained from reaction of cyclohexane-1,2-dione with excess (3 equiv.) of PhLi at reflux in dry THF for 20 h, followed by appropriate work-up to yield the resultant white needle-like crystals, mp 122–123 °C (lit.,[7] 121–122 °C).

Quantitative analysis of the reaction of ferriin (10 mM) with *cis*- and *trans*-**3** (5 mM) in MeCN at room temperature was accomplished by reverse-phase HPLC on a C-18 column eluted with MeCN–H_2O, using methyl benzoate as an internal standard. A base (2,6-di-*tert*-butylpyridine) was added to avoid the possible carbocation-induced rearrangement product (*i.e.* the pinacol rearrangement). *cis*-**3** reacted quantitatively (mass balance = 98.9% at 34% conversion) to form the anticipated bond cleavage product (*i.e.* 1,4-dibenzoylbutane). The error limits for this determination are ±5%, which means that a small amount of the *trans*-1,2-diphenylcyclohexane-1,2-diol could have been formed in this reaction. The data were carefully analyzed for the appearance of the *trans*-1,2-diphenyl-1,2-cyclohexanediol. Since no *trans*-diol was observed and the appearance of 1,4-dibenzoylbutane was near quantitative, we conclude that the major reaction pathway (by a factor of $> 20:1$) is oxidative cleavage of the 1,2-diol C–C bond.

In contrast, the *trans*-1,2-diphenylcyclohexane-1,2-diol did not react within a time period of two days. In fact, we were unable to see a reaction under any conditions employed by us. Therefore, we were unable to confirm that the expected oxidation product arose from this reaction. Under controlled conditions where both *cis*-**3** and *trans*-**3** were reacted in the same solution, we were able to show that a minimum reactivity difference of 10^4 exists between these isomers. Thus, there is a significant reactivity difference between *cis*-**3** and *trans*-**3** for ferriin oxidation.

This extreme reactivity difference between the two isomers required an analysis of the possible conformations of *cis*- and *trans*-**3**. These conformations are shown in Fig. 1. For *cis*-**3**, both available ring-flipped conformations have one phenyl group in the axial conformation and one phenyl group in the equatorial conformation. Thus, the energetics of these two

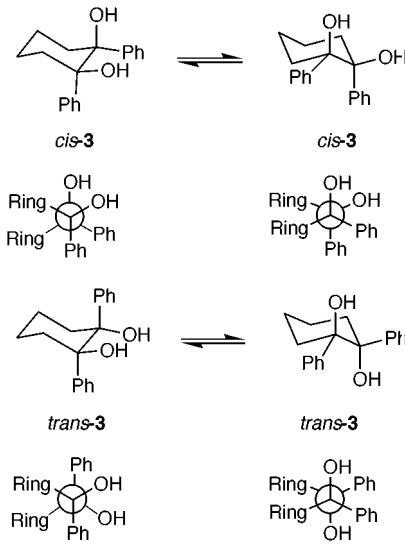


Fig. 1 Conformations of *cis*- and *trans*-1,2-diphenylcyclohexane-1,2-diol.

alternative conformations are equivalent. In contrast, *trans*-**3** does not have equivalent conformational energies. Since the phenyl group is larger than the hydroxy group,[8] one would anticipate that the conformation in which the phenyl groups are equatorial would be quite a bit more stable than the conformation in which the hydroxy groups are in the axial position. This conformational preference tends to 'lock' the cyclohexanediol into the conformation with both phenyl groups in the equatorial position in the same way that the *tert*-butyl group is said to 'lock' the conformation of substituted cyclohexanes. In this conformation, the hydroxy groups are in an *anti*-relationship to each other. This expectation is consistent with molecular mechanics calculations in which the energetic difference between the conformation in which the phenyl groups are axial and the conformation in which the phenyl groups are equatorial is 5.4 kcal mol^{-1}. From this relative arrangement of groups, we conclude that either *syn*-OH groups or an antiperiplanar phenyl–OH arrangement can lead to the observed bond cleavage reactions.

The results of this study have important implications for the ferriin oxidation of *vic*-diols. A simple outer-sphere electron transfer reaction, in which an electron is transferred from the electron donor to the ferriin molecule, cannot explain the observed reactivity differences. One would anticipate that the oxidation potentials of *cis*-**3** and *trans*-**3** would be identical, since *cis*- and *trans*-1,2-diphenylcyclohexane have identical photoelectron spectra (identical ionization potentials).[9] Our estimate of a minimum rate differential for these two compounds of 10^4 would be inconsistent with the energetic equivalence of these two reactions.

Alternatively, one could argue that electron transfer occurs in both species, but that *trans*-$\mathbf{3}^{\bullet+}$ is a stable species and does not lead ultimately to the dione, while *cis*-$\mathbf{3}^{\bullet+}$ is relatively unstable and reacts rapidly to form the dione. This argument is ruled out by two experimental results. First, there is no trace of *trans*-1,2-diphenylcyclohexane-1,2-diol in the reactions starting from the *cis*-1,2-diphenylcyclohexane-1,2-diol isomer. This argues against equilibration of *cis*-$\mathbf{3}^{\bullet+}$ and *trans*-$\mathbf{3}^{\bullet+}$. Further, preliminary experimental results in which *cis*-$\mathbf{3}^{\bullet+}$ and *trans*-$\mathbf{3}^{\bullet+}$ were generated by single electron transfer to excited state dicyanoanthracene showed similar non-reactivity for both the *cis*- and *trans*-isomers.

The reactivity differences between *cis*- and *trans*-**3** seem to preclude reaction through a general mechanism such as that shown by the general cleavage mechanism of eqn. (2). A mechanistic interpretation that there is a sufficient energetic difference for complexation of an equatorial OH group as compared to an axial OH group is, in principle, possible. Combined with evidence that the monomethyl ethers of both *meso*- and *dl*-1,2-diphenylethane-1,2-diol are unreactive in comparison[10] allows us to definitively rule out the general mechanism of eqn. (2), since two OH groups are required for the reaction.

To the best of our knowledge, such geometric requirements for the two hydroxy groups are unprecedented in the cleavage of *vic*-diols by one-electron oxidizing reagents [general oxidative cleavage mechanism shown in eqn. (2)]. We are continuing our efforts to fully understand the mechanism of this reaction in order to better understand the oxidation reaction mechanisms of one electron oxidants in reactions such as the Belousov–Zhabotinski (B–Z) reaction.[11,12]

The geometric requirements for the ferriin oxidation of aromatic 1,2-diols involve the orientation of the two OH groups in a *syn*-position or an anti-periplanar phenyl–OH arrangement. The differing reactivity of **3a** and **3b** with ferriin indicates a very unexpected and unusual non-outer sphere oxidation mechanism for this type of compound.

We gratefully acknowledge the financial support of the West Virginia University Department of Chemistry.

Melt supramolecular assembly of oligomers with regularly spaced, alternating hydrogen bonding and hydrophobic sites

Bryan Greener* and John Rose

Smith & Nephew Group Research Centre, York Science Park, Heslington, York, UK YO10 5DF. E-mail: bryan.greener@smith-nephew.com

Received (in Liverpool, UK) 18th August 1999, Accepted 18th October 1999

The melt condensation of 2,5-dihydroxybenzoic acid with dodecanedioyl dichloride resulted in oligomers with regularly spaced, multiple hydrogen bonding sites; fibres were drawn from melts at 150 °C.

Non-covalent interactions dominate the mechanisms of life. Hydrogen bonds and hydrophobic effects are frequently invoked to describe complex biochemical processes.[1] Much recent endeavour has been directed at the modelling of these exquisite interactions,[2] in the hope that such principles can be applied to industrial syntheses. It is striking that biochemical processes require the complementary interplay of both hydrophobic and hydrophilic interactions. This observation has provided inspiration in the fields of self assembly[3] and supramolecular polymer chemistry.[4] Attempts to create polymers linked only by non-covalent interactions (multiple hydrogen bonds) have achieved varying degrees of success.[4]

Replacing a single covalent bond with a non-covalent interaction of equivalent strength requires the interaction of multiple adjacent hydrogen bonding sites,[5] and it has been demonstrated that even the ordering of donor and acceptor groups at these sites can have a significant effect upon the overall interaction achieved.[6] Multiple adjacent sites have been realised, to date, by employing a limited range of nitrogen based donor/acceptor moieties.[4] To overcome the entropic barrier to the assembly of multiple non-covalent interactions systems reported thus far have clustered the interactive groups at terminal sites only,[5] thus limiting the number of hydrogen bonds that can be accommodated between adjacent molecules. With the aim of increasing the number of non-covalent interactions between adjacent molecules, here we report the synthesis and preliminary characterisation of biocompatible oligomers capable of multiple, multisite hydrogen bonding and hydrophobic interactions.[7]

The direct melt reaction of the aspirin metabolite and moth silk component,[8] 2,5-dihydroxybenzoic acid (gentisic acid) **G** with 1 equiv. of lauroyl chloride **L** produced 3-carboxy-4-hydroxyphenyl laurate **GL** in > 99% purity as determined by ^{1}H NMR spectroscopy. The specificity of this reaction was proposed to be due to the strong nucleophilicity of **G** in the 5-hydroxy position compared to the intramolecularly hydrogen bonded 2-hydroxy position. Furthermore, melt reactions involving *n* equiv. of **G** and $(n-1)$ equiv. of dodecanedioyl dichloride **D** produced a series of oligomers of average composition $\mathbf{G}_n\mathbf{D}_{n-1}$ (n = 2, 3, 4). While $\mathbf{G_2D_1}$ was a discrete compound, reaction products $\mathbf{G_3D_2}$ and $\mathbf{G_4D_3}$ were distributed over a narrow oligomeric range, as elucidated by electrospray MS and ^{1}H NMR spectroscopy. The three $\mathbf{G}_n\mathbf{D}_{n-1}$ oligomers were > 95% **G** capped (through the 5-hydroxy) as shown by ^{1}H and ^{13}C NMR spectroscopy. Reaction of 1 equiv. **G** with 1 equiv. of **D** produced **GD**, an oligomeric distribution centred around three of each subunit with random end-caps (**G** capping through the 5-hydroxy). For purposes of comparison, equivalent compounds were synthesised in an identical manner with methyl-2,5-dihydroxybenzoate **MeG** in the place of **G**; all lacked an intermolecular hydrogen bond donor.

All of the aforementioned compounds were fully soluble in THF, while only the **MeG**-based compounds were soluble in $CHCl_3$. Remarkably, **GD** dissolved a 40-fold molar excess of $CHCl_3$, resulting in liquification; phase separation occurred in the presence of excess $CHCl_3$. Comparison of the ^{13}C NMR spectra of **GD** in THF-d_8 and $CDCl_3$ showed a 5 ppm down-field shifting of inner-chain **G** carbonyl carbons (from δ_c 165.0 to 170.0) and a 1 ppm down-field shifting of terminal **G** carbonyl carbons (from δ_c 170.5 to 171.5) on moving from THF-d_8 to $CDCl_3$. This shifting was consistent with the **G** carbonyl oxygen acting as an intermolecular hydrogen bond acceptor site in terminal and inner-chain positions.[9] Infrared spectroscopic study of the oligomers was hampered by the intramolecular hydrogen bonding already present, however, **G** carbonyl absorbances (1700 cm^{-1}) were broadened due to multiple overlapping bands in contrast to the sharp discrete absorbance in **MeG**-based oligomers.

The melt behaviour of $\mathbf{G}_n\mathbf{D}_{n-1}$ oligomers was in sharp contrast to that of $\mathbf{MeG}_n\mathbf{D}_{n-1}$ oligomers in the respect that transparent, flexible, self-adherent fibres could be pulled from $\mathbf{G}_n\mathbf{D}_{n-1}$ compounds in the melt (150 °C) while $\mathbf{MeG}_n\mathbf{D}_{n-1}$ showed no such tendancy. Viscometric analysis of the oligomers was performed, in duplicate, at 150 °C and the resulting measured viscosities are shown in Table 1.[10] In general, the viscosity of **G**-based oligomers was an order of magnitude greater than that of the corresponding **MeG**-based oligomers. The significantly higher viscosities observed for **GD** than for $\mathbf{G}_n\mathbf{D}_{n-1}$ were due to a significantly broader oligomeric distribution in the former oligomers. These differences in physical properties can be attributed only to intermolecular hydrogen bonding interactions present in $\mathbf{G}_n\mathbf{D}_{n-1}$ but not $\mathbf{MeG}_n\mathbf{D}_{n-1}$.

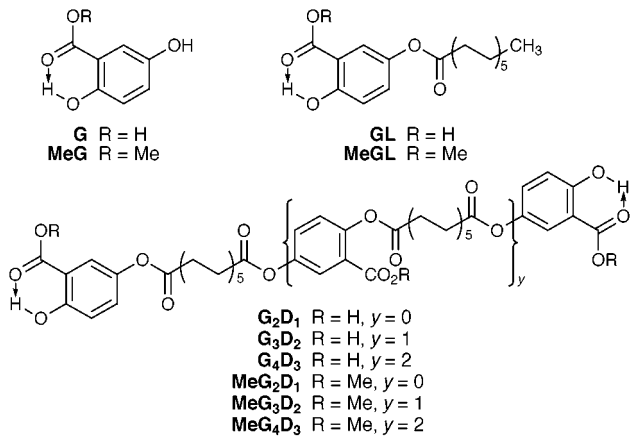

Table 1 Variation of viscosity in **G**- and **MeG**-based compounds

Oligomer	Viscosity/Pa s		Oligomer	Viscosity/Pa s	
MeGL	0.001	0.001	**GL**	0.007	0.009
$\mathbf{MeG_2D_1}$	0.007	0.010	$\mathbf{G_2D_1}$	0.148	0.066
$\mathbf{MeG_3D_2}$	0.022	0.017	$\mathbf{G_3D_2}$	0.346	0.319
$\mathbf{MeG_4D_3}$	0.030	0.017	$\mathbf{G_4D_3}$	0.820	0.771
MeGD	0.249	0.465	**GD**	2.909	3.399

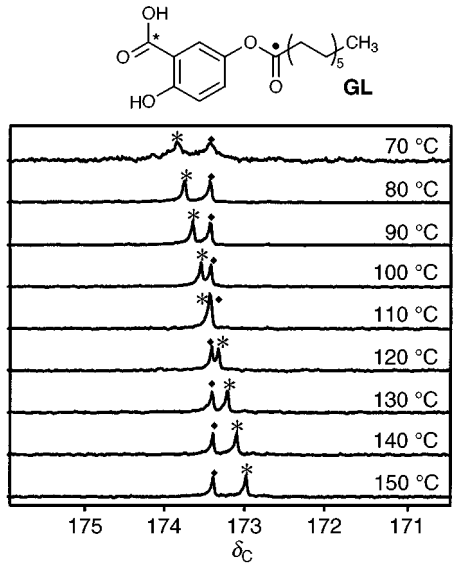

Fig. 1 ^{13}C NMR spectra (67 MHz) of neat **GL** recorded at various temperatures.

Further evidence of the intermolecular hydrogen bonding present in **GL**, in contrast to **MeGL**, was provided by a variable temperature ^{13}C NMR melt study. Neat samples of **GL** and **MeGL** were heated to temperatures in the range 70–150 °C. At each temperature the ^{13}C NMR spectrum of the sample was recorded. The result for **GL** is shown in Fig. 1. It can be seen that as the temperature was decreased the carboxylic carbonyl shifted to lower field, consistent with electronic donation to a hydrogen bond from the attached carbonyl oxygen.[9] No shifting was observed over this temperature range for **MeGL**.

The importance of hydrophobic interactions, between the alkyl chains of the oligomers, in producing the above physical effects was supported by the UV–VIS spectroscopic observations summarised in Fig. 2. It can be seen that λ_{max} did not vary widely for compounds with free 5-hydroxys, **G** and **MeG** (330–341 nm), or **MeGL** (315–318 nm), on going from THF solution to cast film (solid); 2-hydroxybenzoic acid (salicylic acid) **S** is also shown in Fig. 2 for comparison. The exception to

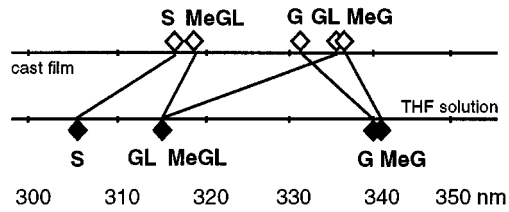

Fig. 2 Position of λ_{max} for **S**, **G**, **MeG**, **GL** and **MeGL** recorded as THF solutions and solid cast films on KBr.

this general rule was **GL**, which exhibited a 21 nm bathochromic shift on going from THF solution to cast film (solid), consistent with the effect of hydrogen bond formation in the solid state.[9] Extinction coefficients at these wavelengths were in the range 3700–7500 mol^{-1} dm^3 cm^{-1} for all compounds ($\pi\rightarrow\pi^*$ transition). In $\mathbf{G}_n\mathbf{D}_{n-1}$ and $\mathbf{MeG}_n\mathbf{D}_{n-1}$ oligomers a pair of absorbance bands were observed. The variation of these bands with formulation allowed us to deduce that the band at 313 nm was the result of a $\pi\rightarrow\pi^*$ transition in terminal **G** units (consistent with observations recorded in Fig. 2), while the band at 289 nm was the result of a $\pi\rightarrow\pi^*$ transition in inner chain **G** units.

We propose that the physical and spectroscopic observations reported herein can be accounted for by the hydrogen bonded aggregation of **G**-based subunits in a manner consistent with the previously reported crystal structure of **G**.[11] The hydrophobic compatibility of **D** with **D**, the hydrophilic, hydrogen bonded attraction of **G** with **G** and the mutual incompatibility of these two interactions promotes the hydrogen bonded aggregation of **G** moieties.

In conclusion, we have demonstrated the synthesis and preliminary characterisation of a new group of biocompatible supramolecular polymers. Further chemical and physical investigation of these systems is underway.

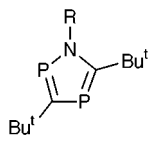
Received (in Cambridge, UK) 17th September 1999, Accepted 13th October 1999

Two different synthetic routes to the new aromatic 1,2,4-azadiphosphole ring system $P_2C_2Bu^t_2NR$ (R = Pr^i, Pr, Ph, MeC_6H_4, Bu^tCH_2 and cyclohexyl) are presented and the planar structure of $P_2C_2Bu^t_2NPh$, established by a single crystal X-ray diffraction study, is in good agreement with theoretical calculations at the B3LYP/6-311G* level on the parent $P_2C_2H_2NH$ ring.

We recently described reactions of vanadium(V), titanium(IV) and zirconium(IV) imides with phosphaalkynes (RC≡P).[1,2] Thus, $Bu^tC{\equiv}P$ reacts with $VCl_3{=}NBu^t$ or its DME adduct to afford 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene or 3-aza-1,2,4,6-tetraphosphaquadricyclane, respectively.[1] Likewise one- and two-step [2 + 2] cycloaddition reactions of $Bu^tC{\equiv}P$ with $[Zr(\eta^5\text{-}C_5H_5)_2(NC_6H_3\text{-}2,6\text{-}Me_2)]$ and $[TiCl_2(NBu^t)(py)_3]$ gave the structurally characterised complexes $[Zr(\eta^5\text{-}C_5H_5)_2(PCBu^tNC_6H_3\text{-}2,6\text{-}Me_2)]$ and $[TiCl_2(P_2C_2Bu^t_2N\text{-}Bu^t)(py)]$.[2]

We now report that minor modification of the reactions described above leads to the formation of the first examples of the previously unknown aromatic 1,2,4-azadiphosphole ring systems $P_2C_2Bu^t_2NR$. Thus heating $[TiCl_2(NPh)(py)_3]$ with $Bu^tC{\equiv}P$ at 60 °C for 56 h gave $P_2C_2Bu^t_2NPh$ **1** (31%) as a white solid after sublimation.† The analogous $P_2C_2Bu^t_2N(p\text{-tolyl})$ **2** (30%), $P_2C_2Bu^t_2NEt$ **3** (15%) and $P_2C_2Bu^t_2NPr^i$ **4** (20%) were also made by a similar route using the appropriate titanium imide precursor.



1 R = Ph
2 R = *p*-Tol
3 R = Et
4 R = Pr^i
5 R = Pr
6 R = CH_2Bu^t
7 R = Cy

In a related series of reactions, **4** was also obtained (67%) from the reaction of the vanadium imido complex $[VCl_3{=}NR]$ (R = Pr^i) with $Bu^tC{\equiv}P$ on warming the mixture from −78 °C to room temperature.‡

This route also afforded $P_2C_2Bu^t_2NPr$ **5** (55%), $P_2C_2Bu^t_2NCH_2Bu^t$ **6** (87%) and $P_2C_2Bu^t_2N$(cyclohexyl) **7** (61%). The $^{31}P\{^1H\}$ NMR spectra of all the 1,2,4-azadiphospholes **1**–**7** exhibited the characteristic AX pattern of lines whose chemical shifts, as expected, both lay in the unsaturated region.

The reaction mechanism of the vanadium imide reaction most likely involves the four-membered ring intermediate $[VCl_3(NR)P{=}CBu^t]$ (Scheme 1), which was characterised spectroscopically (R = Bu^t).§

The molecular structure of the phenyl-substituted 1,2,4-azadiphosphole **1** has been determined by a single crystal X-ray diffraction study (Fig. 1).¶ The ring is completely planar (Σ internal angles = 539.9°; Σ angles at N = 359.9° and the P(2)–N [1.715(6) Å], P(2)–C(1) [1.697(8) Å], P(1)–C(1) [1.746(8) Å], P(1)–C(2) [1.740(9) Å] and C(2)–N [1.366(10) Å] bond distances are all fully consistent with significant electron delocalisation.

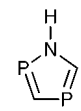
The parent hydrogen-substituted derivative $P_2C_2H_2NH$ **9** has been calculated at the B3LYP/6-3111G* level of the theory.[3] The free azadiphosphole was a real minima on the potential



9

energy surface and the five-membered ring is perfectly planar. The calculated bond lengths and bond angles, which are in good agreement with those obtained from the X-ray diffraction study on **1**, are collected in Table 1. To characterise the aromaticity of the system several criteria were investigated. According to geometric BDSHRT[4] and Bird[5] indices (BI) and NICS[6] data the 1,2,4-aza-, 1,2,4-oxa- and 1,2,4-thia-diphosphole ring systems are somewhat less aromatic than the analogous organic rings furan, pyrrole and thiophene (see Table 2).

Table 1 Theoretical and observed bond length data and bond angles of azadiphospholes **9** and **1** (ring numbering as in Fig. 1)

	Calculated bond lengths for **9**/Å	Observed bond lengths for **1**/Å	Calculated bond angles for **9** (°)	Observed bond angles for **1** (°)
N–P2	1.725	1.715(6)	P2NC2 119.4	119.6(5)
P2–C1	1.709	1.697(8)	NC2P1 117.1	113.7(6)

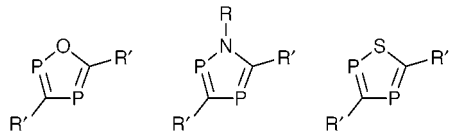
Table 2 BDSHRT, BI and NICS data for several unsaturated rings systems

Ring	BDSHRT	BI	NICS
1,2,4-Oxadiphosphole	46	37	−11.0
1,2,4-Aziadiphosphole	48	52	−12.8
1,2,4-Thiadiphosphole	53	56	−12.4
Furan	51	49	−12.3
Pyrrole	55	73	−14.7
Thiophene	57	68	−13.2

It is also interesting to compare NMR data for the 1,2,4-azadiphosphole rings with the isoelectronic series of 1,2,4-oxa-[7] and 1,2,4-thia-diphosphole[8] ring systems, $P_2C_2R'_2E$, (R′ = Bu^t, Mes; E = O, S).



As the electronegativity of the heteroatom becomes smaller, the *difference* in chemical shifts of the two unsaturated P centres decreases significantly (161, 99 and 11 ppm respectively for E = O, NR and S). The magnitude of the $^2J_{(PP')}$ cross-ring coupling constants are also dependent on the nature of the heteroatom [17.5, (E = O) 34.9 (E = NR) and 49.9 Hz (E = S)].

We anticipate that, by analogy with other unsaturated polyphosphorus ring systems,[9] the new 1,2,4-azadiphosphole ring systems will have an interesting coordination chemistry, behaving as 2e, 4e or 6e donors towards suitable transition metal centres, and this aspect is currently under investigation.[10]

We thank the Alexander von Humboldt Foundation and OTKA T014555 for financial support (for L. N.) and the Royal Society for joint funding (for J. F. N. and L. N.).

A new diastereoselective synthesis of a 1β-methylcarbapenem intermediate

Chang-Young Oh and Won-Hun Ham*

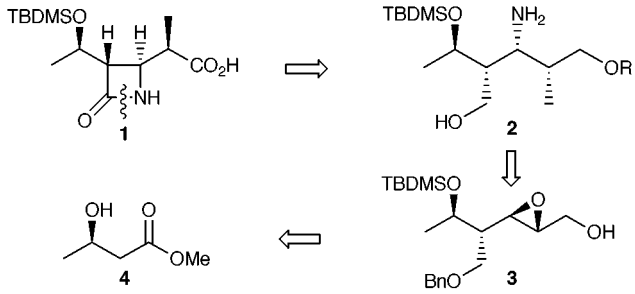
College of Pharmacy, SungKyunKwan University, Suwon 440-746, Korea. E-mail: whham@speed.skku.ac.kr

Received (in Cambridge, UK) 1st October 1999, Accepted 13th October 1999

A 1β-methylcarbapenem key intermediate is synthesized from methyl (*R*)-3-hydroxybutyrate *via* the diastereoselective alkylation and regioselective cuprate ring opening of a chiral epoxide which is readily prepared from Sharpless asymmetric epoxidation of the corresponding allylic alcohol.

The discovery that 1β-methylcarbapenem has potent and broad-spectrum antibacterial activitiy as well as enhanced metabolic and chemical stability[1] has prompted many synthetic organic chemists to develop efficient methods for the stereoselective synthesis of the key 1β-methyl intermediate **1**, and recent reviews describe impressive progress in this area.[2, 3]

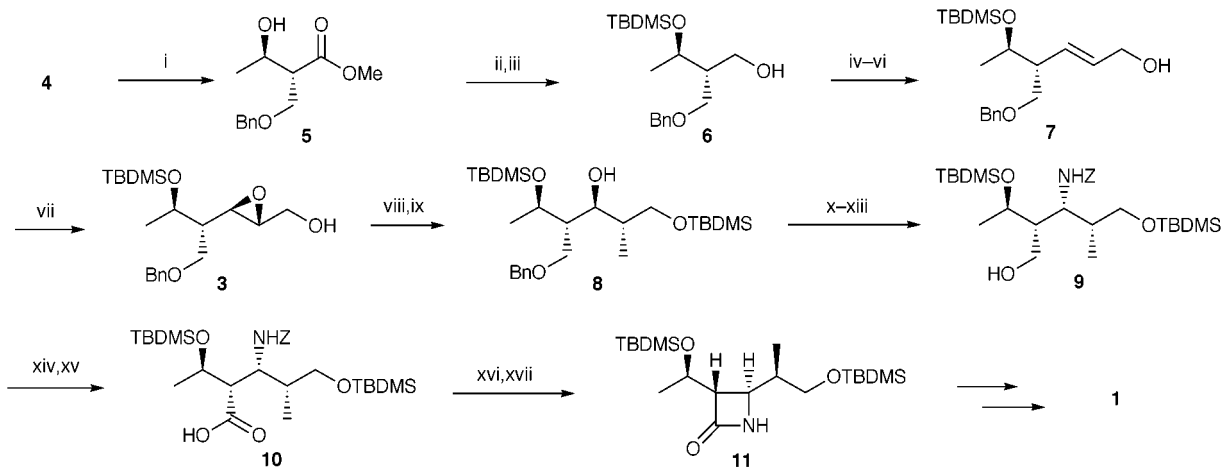
Our approach to the enantioselective synthesis of **1** relies on regioselective ring opening of chiral epoxy alcohol **3**, which is readily available from Sharpless asymmetric epoxidation of the allylic alcohol (Scheme 1). This allylic alcohol **7**, containing two stereocenters which are requisite for key intermediate **1**, could be easily obtained from diastereoselective alkylation of methyl (*R*)-3-hydroxybutyrate **4** followed by a short transformation.



Scheme 1

Thus, methyl ester **4**, available in high enantiomeric purity, was converted into the allylic alcohol **7** as shown in Scheme 2. To this end, β-hydroxy ester **4** was alkylated with benzyloxymethyl chloride (BOMCl). Generally, alkylation of the dianions of such β-hydroxy esters has been shown to yield products of high diastereomeric excess with predictable stereoselectivity, but in this case alkylation with BOMCl afforded the benzyl ether with moderate stereoselectivity (*ca.* 10::1) and low conversion yield (*ca.* 50%).[4–6] Fortunately, there was a dramatic improvement both in conversion yield and diastereomeric ratio (70% and 35:1) when we added HMPA as an additive.[7] The secondary alcohol of the resulting benzyl ether **6** was protected as an TBDMS ether in high yield and the ester was subsequently reduced to the corresponding alcohol **6** with DIBAL-H at −78 °C. Swern oxidation of **6** afforded the aldehyde, which without purification was subjected to a Horner olefination with triethyl phosphonoacetate under the conditions developed by Masamune and Roush.[8] to give the α,β-unsaturated ester with complete *E*-selectivity. Reduction of the *E*-unsaturated ester using DIBAL-H at −78 °C produced the allylic alcohol **7**. The epoxidation of this allylic alcohol under Sharpless conditions employing D-(−)-diisopropyl tartrate as stereodirecting ligand gave rise to the epoxide **3** with excellent diastereoselectivity (15:1). The stage was now set to introduce the fourth chiral center in **3** and for this we made use of the ubiquitous high order cuprate protocol; the highly regioselective opening of the epoxide with $Me_2Cu(CN)Li_2$ gave the 1,3-diol. The primary hydroxy group of the resulting diol was selectively protected as a TBDMS ether to give **8**.

The conversion of **8** to **9** was accomplished by a four step sequence. Mesylation of the secondary alcohol followed by



Scheme 2 *Reagents and conditions*: i, LDA (2 equiv.), BOMCl, HMPA, −78 °C, 70%; ii, TBDMSCl, imidazole, DMF, 90%; iii, DIBAL-H, Et_2O, −78 °C, 86%; iv, $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, −65 to −55 °C; v, $(MeO)_2POCH_2CO_2Me$, LiCl, Pr^i_2NEt, MeCN, 84% for 2 steps; vi, DIBAL-H, Et_2O, −78 °C, 95%; vii, $Ti(OPr^i)_4$, D-(−)-diisopropyl tartrate, Bu^tOOH, 76.5%; viii, $Me_2Cu(CN)Li_2$, Et_2O, −20 to 0 °C, 72.4%; ix, TBDMSCl, Et_3N, DMAP, CH_2Cl_2, 84.4%; x, MsCl, pyridine, 97.7%; xi, NaN_3, DMF, 76.4%; xii, $Pd(OH)_2$, H_2 (1 atm,), MeOH, EtOAc; xiii, $ClCO_2Bn$, $NaHCO_3$, Et_2O, 0 °C, 51% for 2 steps; xiv, $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, −65 to 55 °C; xv, $NaClO_2$, 2-methylbut-2-ene, NaH_2PO_4, H_2O, Bu^tOH, 71% for 2 steps; xvi, Pd-black, MeOH, H_2 (1 atm); xvii, $(PyS)_2$, PPh_3, MeCN, reflux, 79% for 2 steps.

sequential azide substitution, reduction of the corresponding azide under Pd/C and the protection of the amino group with $ClCO_2Bn$ afforded **9** in 41% overall yield in four steps. Unfortunately attempts, including Mitsunobu conditions, to directly convert the alcohol to amine stereospecifically were not successful. This result may be due to the steric hindrance present in **8**. Swern oxidation of **9** led to the β-amino aldehyde, which was further oxidized to the corresponding acid **10** with $NaClO_2$. Finally removal of the Z group by catalytic hydrogenation followed by cyclization using Ohno's conditions[9] furnished the known key intermediate **11**.[10–12] The physicochemical properties of **11** obtained by the present synthesis were in complete agreement with those reported in the literature {$[\alpha]_D^{27}$ −7.8755 (*c* 0.53, $CHCl_3$) [lit,[12] $[\alpha]_D^{22}$−7.8777 (*c* 1.03, $CHCl_3$)]}.

In summary, we report a new synthetic method for the 1β-methylcarbapenem key intermediate from commercially available methyl (*R*)-3-hydroxybutyrate **4**. The key features in this strategy are the diastereoselective alkylation of the dianion of the β-hydroxy ester, Sharpless asymmetric epoxidation and subsequent regioselective cuprate ring opening of the chiral epoxide.

Novel macrocycles with 1,1′-binaphthyl substituents for the recognition of saccharides

Oleksandr Rusin and Vladimír Král*

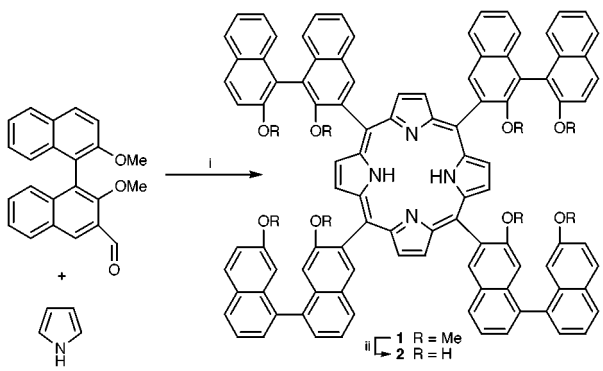
Department of Analytical Chemistry, Institute of Chemical Technology, Technická 5, 166 28 Prague 6, Czech Republic. E-mail: vladimir.kral@vscht.cz

Received (in Liverpool, UK) 6th May 1999, Accepted 18th October 1999

Novel saccharide-selective receptors 1 and 2 based on *a* porphyrin with 1,1′-binaphthyl substituents were synthesized and tested for binding of mono-, di- and tri-saccharides; *a* binding selectivity for di- and tri-saccharides was found.

Recent developments in the area of supramolecular chemistry have led to the study of carbohydrate complexation by artificial receptors.[1] The design of artificial receptors that bind selectively to sugars in aqueous or non-aqueous media is an important topic in bioorganic chemistry.[2] As a contribution to this effort we focused our attention on the preparation of a variety of macrocyclic derivatives with peripheral functionalities giving interesting recognition properties.[3–8]

Here we present the synthesis and basic properties of 1,1′-binaphthyl substituted porphyrins **1** and **2** designed as specific receptors for biologically important polyhydroxylic compounds. There are several host systems reported in the recent literature that utilized sterically organized receptors for recognition of biologically important substrates.[10–14] The design of receptors is based on multiple H-bonding, where receptor **1** is an H-bonding acceptor and receptor **2** is an H-bonding donor. The binding site of **2** contains eight acidic phenolic hydroxy groups that presumably can form hydrogen bonds with guests. The binding mode was proven by ^{1}H NMR, Raman and IR studies for methyl *O*-glucoside, where the 1,1′-binaphthyl subunit's interaction was clearly observed, indicating complex formation.[17] The synthesis of **1** (Scheme 1) was carried out according to the known methodology for the preparation of porphyrins (Rothemund protocol) by cyclotetramerization of protected 1,1′-binaphthyl-3-carbaldehyde with pyrrole.[1] TLC, HPLC and the photometric analysis of the reaction products was used to identify the major and minor porphyrinic components. The solvent was removed and the major product was isolated by column chromatography on silica gel with MeOH–CH_2Cl_2 (95 : 5) as eluent, characterized as the (*R,S*)-α,β,α,β-isomer and used for the complexation study. The structure was proved by ^{1}H NMR analysis, where characteristic signals for identical binaphthyls and singlet pyrrolic β-protons were observed, as described for the unsubstituted binaphthol–porphyrin derivative.[15] This product **1**, as a single atropoisomer, was collected in 4% yield. Product **2** was obtained by treatment of **1** with BBr_3 in dry CH_2Cl_2. The deprotected product was isolated in 80% yield.



Scheme 1 *Reagents and conditions*: i, propionic acid, reflux, 4 h, then silica gel, CH_2Cl_2–MeOH (95 : 5), 4%; ii, BBr_3 (10 equiv.), CH_2Cl, 1 day, room temp., wash with H_2O, dry, isolate on reverse phase column, MeOH, 80%.

The binaphthylic subunits of macrocycles **1** and **2** contain peripheral methoxy or hydroxy groups. These groups play an essential role in the formation of complexes with saccharides. The two host binding pockets formed by the bulky aryl substituents were specifically designed for binding of di- and tri-saccharides in a similar way as in lectins. The effect of solvent was also important. Thus the host **1** is insoluble in water whereas **2** is soluble in H_2O–MeOH (5–10% MeOH, v/v) allowing determination of binding constants for saccharides. The binding constants for both hosts were determined in DMSO at room temperature by UV–VIS titration experiments. The change in the absorbance at 427 nm was observed upon addition of the saccharide species to the hosts **1** and **2**. In this media the receptor **1** (R = OMe) displays low binding affinity for unmodified saccharides (for octyl glucopyranoside and *p*-nitrophenyl galactopyranoside strong binding was observed). The methoxy groups of the binaphthylic subunits form weak hydrogen bonds with the guests.[17] However substrates such as α- or β-D-methylglucopyranose are able to interact better with this host than unsubstituted glucose, with a remarkable selectivity for the β-anomer (Table 1). Saccharide derivatives with octyl and *p*-nitrophenyl substituents, namely octyl α-D- and octyl β-D-glucopyranoside and -galactopyranoside showed selectivity for the α-anomer and more pronounced interaction. The decisive role in these host–guest interactions apparently belongs to the hydrophobic interactions between the alkyl (or aryl) chain of the substrates and the naphthyl rings of the host **1**. A different tendency was observed for the host **2**. The receptor **2** (R = OH) easily interacts with unmodificated saccharides in

[a] The formation and UV–VIS estimation constants of sugar–receptor complexes. In a 1 cm square quartz cuvette was placed a 6.15×10^{-6} M solution of macrocycle **1** or **2** in DMSO or H_2O contained 5% of MeOH (v/v). A known amount of saccharide was added in increments (0–1000 equiv.). The absorbance changes were measured in maxima (room temperature), and data were then evaluated with the aid of the Benesi–Hildebrand equation. From the linear plot of $-1/A$ *vs.* 1/[saccharide], the intercept was estimated as K_a. Linear fits had a correlation coefficient of 0.95. The K_a was calculated for 1 : 1 complexes. The reproducibility of the K_a values was ±10% in triplicate runs.

water (with 5–10% MeOH) and DMSO and displays a significant preference for the di- and tri-saccharides over the monosaccharides. The results of the UV–VIS titration of **2** with different sugars are presented in Table 2. The tendency for preferable interaction of host **2** with di- and tri-saccharides was confirmed also by fluorescence spectroscopy (Table 2). Moreover, for monosaccharides, differences between pyranoses and furanoses were observed in both media (K_a see Table 2). Cooperation of several H-bonds in binding to particular saccharides led to higher values of binding constants. Introduction of the hydroxy groups into the porphyrin core often drastically changed their binding abilities for neutral guests.[16] The Job's plots for different series of the macrocycle–sugar interactions showed the initial formation of 1 : 1 host–guest type complexes, although in our observations, ditopic hosts **1** and **2** also formed other complexes at higher saccharide concentration. The sensitivity of **1** and **2** to the saccharides could be changed by incorporation of metal into the porphyrin core;[12] this work is now underway.

In conclusion, we have found that 1,1′-binaphthyl receptor **2** displayed effective complexation abilities for unmodificated saccharides, while **1** formed complexes with alkyl- or aryl-glycosides. The receptor **2** can serve as a successful model for efficient and selective di- and tri-saccharide binding in highly competitive media such as DMSO and H_2O, where sugar binding is easy monitored in the visible wavelength region. Due to the size of the host binaphthylic cavity above and below the porphyrin plane, trends towards stronger binding of oligosaccharides in comparison with monosaccharides were observed.

The study of the binding of saccharides with receptors based on phosphorylated analogues of compound **2** under physiological conditions is in progress.

Glaser coupling reaction in supercritical carbon dioxide

Jinheng Li and Huanfeng Jiang*

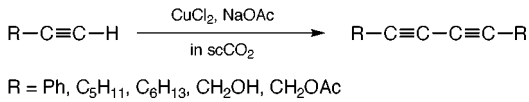
Guangzhou Institute of Chemistry, Chinese Academy of Sciences, PO Box 1122, Guangzhou 510650, China. E-mail: jhf@mail.gic.ac.cn

Received (in Cambridge, UK) 5th October 1999, Accepted 18th October 1999

It is demonstrated for the first time that Glaser coupling can be carried out smoothly in supercritical carbon dioxide using a solid base (NaOAc) instead of amines.

Considerable attention has recently been focused on using supercritical carbon dioxide ($scCO_2$) as a medium for organic reactions.[1–3] As a solvent the attractive physical and toxicological properties of $scCO_2$ have made it superior to conventional organic solvents with regard to environmental considerations.

Diacetylenes are central to many biological and polymer molecules.[4–8] Many of the most useful methods for the synthesis of diacetylenes[8–10] involve cupric salt promoted coupling reactions, Glaser first observed that terminal acetylenes underwent oxidative coupling to diacetylenes with CuCl in the presence of NH_4OH. Subsequent studies have shown that a variety of cupric salts or oxygen in the presence of cuprous salts can be employed. The oxidation has the further advantage of solvent versatility. Water, methanol, Methyl Cellosolve, acetone, pyridine, cyclohexylamine and toluene have all been used as solvents for the reaction with nearly equal success. Amines, most frequently pyridine and tetramethylenediamine, are required in almost all Cu^{II}-promoted Glaser coupling. However, amines often have unpleasant smells and flavors. The present study is the first demonstration that Glaser coupling can be carried out in the presence of $CuCl_2$ in $scCO_2$ using NaOAc instead of amines (Scheme 1).



Scheme 1

Our investigation began with an effort to optimize reaction conditions for the oxidation coupling of terminal acetylenes using $CuCl_2$ and NaOAc. Phenylacetylene was chosen as a model substrate for the optimization process (entries 1–8, Table 1). The final optimized reaction conditions for Glaser coupling in $scCO_2$ consisted of $CuCl_2$ (2 mmol), NaOAc (2 mmol), MeOH (1 ml) and CO_2 (14 MPa) at 40 °C.† Other terminal acetylenes besides phenylacetylene were employed successfully using the optimized conditions (entries 9–12, Table 1).

The coupling reaction gave low conversion and yield in pure $scCO_2$ (entry 1, Table 1), in which $CuCl_2$ and NaOAc cannot dissolve (entries 1, 4 and 7, Table 2). It has been reported that some organic or inorganic compounds, so-called 'modifiers', can be added to the supercritical fluids to increase its solvent power.[11] Our results indeed show that the presence of MeOH remarkably enhanced the rate of the reaction (entries 1 and 6, Table 1). We further examined the solubility of different reagents in different solvents in $scCO_2$ and the results were summarized in Table 2. MeOH, as modifier or co-solvent, increased the solubility of $CuCl_2$ and NaOAc in $scCO_2$ (entries 3, 6 and 8, Table 2).[2,3,11,12] Increasing the amount of MeOH to 3 ml in the reaction, decreased the rate and the yield to a small extent. It is of interest to note that if only MeOH was used as solvent, both the rate and the yield decreased and the reaction was not clean (entry 2, Table 1). These results imply that $scCO_2$ and MeOH are of the same importance to the reaction. The low viscosity of $scCO_2$ allows the products (diacetylenes) to diffuse away from $CuCl_2$ and NaOAc, while the proper amounts of MeOH makes $CuCl_2$ and NaOAc partially dissolve in $scCO_2$, although excess MeOH may affect the diffusion of the products.

The pressure of CO_2 also affected the reaction rate to some extent. Our results indicate that a higher CO_2 pressure is preferable (entries 5 and 6, Table 1).

In earlier studies, when cupric chloride or cupric acetate was added as a promoter, an organic base (pyridine) was usually added to retain $CuCl_2$ or $Cu(OAc)_2$ in solution as complexes or solvates and to catch the acid liberated during the coupling reaction. In $scCO_2$, to our surprise, the coupling took place without base with higher conversion and yield than those in the presence of pyridine (entries 3 and 4, Table 1). When NaOAc

6	NOAc	MeOH/$scCO_2$	partial
7	$CuCl_2$/NOAc	$scCO_2$	insoluble
8	$CuCl_2$/NOAc	MeOH/$scCO_2$	partial
9	$CuCl_2$/NOAc	MeOH[c]	soluble
10	Pyridine	$scCO_2$	soluble
11	$CuCl_2$/pyridine	MeOH	partial[d]

[a] The procedure for determining solubility in $scCO_2$: The desired amount of the related reagents was placed in a 25 ml stainless steel cell. The cell was sealed and filled with liquid carbon dioxide (14 MPa). The cell was then heated to 40 °C for the desired time and the solubility of the related reagents was monitored by viewing through a sapphire observation window. [b] Amounts of reagents: $CuCl_2$ = 269 mg, NaOAc = 164 mg, pyridine = 158 mg. Amounts of solvent: $scCO_2$ = 14 MPa, MeOH = 1 ml. [c] 10 ml. [d] The solubility of solid in this experiment is more than that of entry 8.

was added, the reaction gave a satisfactory result (entry 6, Table 1). It is clear that NaOAc is superior to pyridine in $scCO_2$. The results in Table 1 also show that a sufficient amount of cupric chloride is necessary for the Glaser coupling (entries 6 and 7, Table 1).

At least two reaction pathways had been proposed in earlier reports.[8a,d] One involves a radical mechanism and the other formation of a cupric complex. We used two radical traps (*N*-*tert*-butylbenzylideneamine *N*-oxide and 2-methyl-2-nitrosopropane) in the reaction, but we did not detect any radicals.

Base on the results shown in Tables 1 and 2, we could conclude several points. (i) In $scCO_2$, the presence of NaOAc plays an important role in enhancing the reaction rate. (ii) A sufficient amount of cupric chloride is necessary for the Glaser coupling. (iii) the low viscosity of $scCO_2$ favors the oxidation coupling reaction of terminal acetylenes. (iv) Addition of a correct amount of MeOH can increase the dissolution of $CuCl_2$, and enhance the rate of the reaction.

In summary, we have observed that Glaser coupling reactions can proceed smoothly in $scCO_2$ in good yields. Of particular note is the fact that this new Glaser coupling reaction is more environmentally friendly than the traditional reaction and shows potential utility in industry. The mechanism and applications of the reaction are currently under investigation in our laboratory.

We thank the National Natural Science Foundation of China for financial support (No. 29772036 and 29872039) and Dr Fanglü Huang for helpful discussion. We also thank Professor Buxing Han (Beijing Institute of Chemistry, Chinese Academy of Sciences) for providing the reaction cell.

Notes and references

† *Typical procedure*: To a mixture of $CuCl_2$ (2 mmol) and NaOAc (2 mmol) in an HF-25 autoclave, MeOH (1 ml) and alkyene (1 mmol) were added. Liquid CO_2 was then transferred into the autoclave to the desired pressure. The reaction mixture was stirred at 40 °C for 3–5 h. After the reaction, the CO_2 was vented and the surplus was extracted with Et_2O. The conversion was determined by GC using an internal standard. The product was then purified by preparative TLC on silica gel using light petroleum–EtOAc (10 : 1) as eluent.

Pyridine ring formation through the photoreaction of arenecarbothioamides with diene-conjugated carbonyl compounds†

Kazuaki Oda,* Rikiji Nakagami, Naozumi Nishizono and Minoru Machida

Faculty of Pharmaceutical Sciences, Health Sciences University of Hokkaido, Ishikari-Tobetsu, Hokkaido 061-0293, Japan. E-mail: k-oda@hoku-iryo-u.ac.jp

Received (in Cambridge, UK) 27th August 1999, Accepted 19th October 1999

Irradiation of arenecarbothioamides with hexa-2,4-dienal in benzene solution gives 2-arylpyridines in moderate yields.

Of all the naturally occurring heterocycles, the pyridine ring is one of the most well-known simple structures. Pyridine and fused-pyridine moieties are present in numerous natural products, such as the quinoline and isoquinoline alkaloids,[2] and have a vast range of potential biological activities. Therefore, many methods for pyridine ring formation have been reported.[3] In addition, in fields other than the biological one, synthetic methods for pyridine derivatives were also required and developed. Since di- and tri-heteroaromatic compounds[4] containing pyridine have received significant attention in the fields of electrical materials,[5] biologically active molecules,[6] chelating agents and metal–ligand chemistry,[7] the synthesis of arylpyridine derivatives has become increasingly important.

In the course of our systematic study of the photochemistry of the arenecarbothioamide–alkene system,[8] we found that photoreaction of arenecarbothioamides with 2-furylacrylaldehyde in benzene proceeds *via* key intermediate 4-aminobut-3-enal to give 2,3-diarylpyrrole derivatives.[9] From this pyrrole formation, utilization of a diene-conjugated carbonyl as a photochemical substrate for pyridine formation was suggested. Here we report a facile synthesis of 2-arylpyridines, 2,6-diarylpyridines and benzo-fused pyridines through the photoreaction of arenecarbothioamides with diene-conjugated carbonyl compounds.

Photoreaction of arenecarbothioamide **1** with hexa-2,4-dienal **2** was carried out in benzene using a high-pressure mercury lamp through a Pyrex filter under a nitrogen atmosphere. The results are listed in Table 1. Irradiation of benzenecarbothioamide **1a** with 0.5 equiv.[10] of **2** for 5 h exclusively gave 2-phenylpyridine **3a** (32%). Further, the photoreactions of a series of heteroaromatic thioamides **1b–f** with **2** were performed. As expected, the corresponding 2-arylpyridines **3b–f** were obtained in moderate yields.

In addition, preparation of 2,6-diarylpyridines was also examined. The photolysis of arenecarbothioamide **1** with

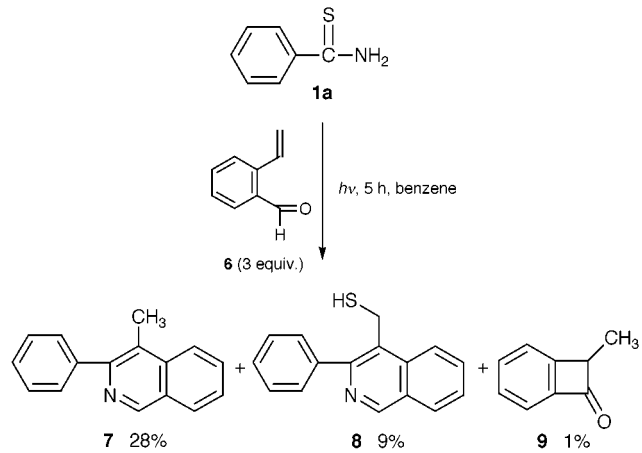
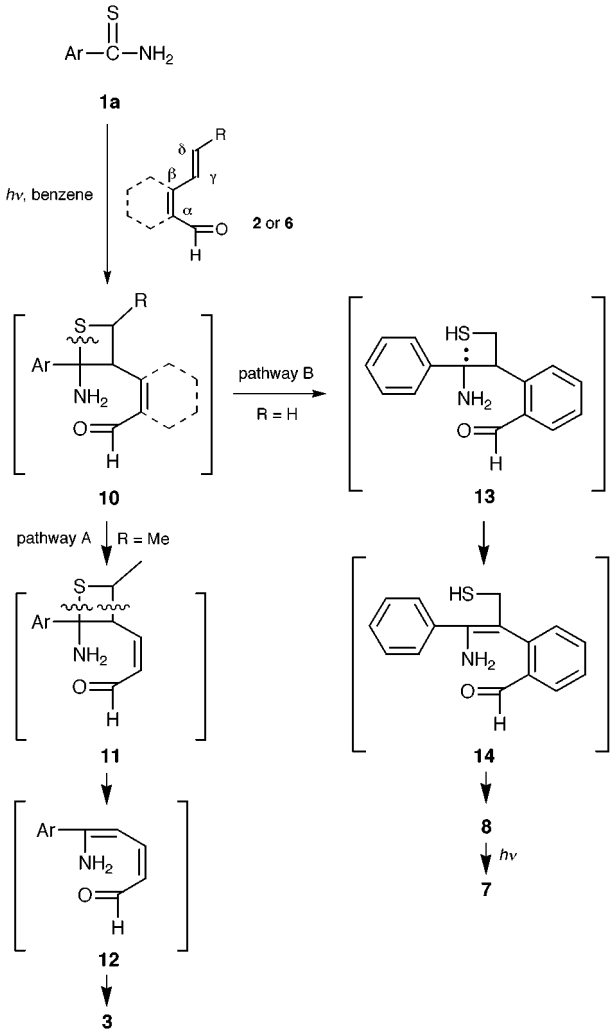
1-arylhexa-2,4-dien-1-one **4** was carried out under similar conditions to those described above. Similarly, the expected 2,6-diarylpyridines **5** were obtained in moderate yields (Table 2).

Next, as an extension of this reaction, photoreaction of **1a** with *o*-vinylbenzaldehyde **6** as the dienal equivalent was performed under similar conditions. Irradiation of **1a** with **6** for 5 h gave 4-methyl-3-phenylisoquinoline[15] **7** (28%) and (3-phenyl-4-isoquinolyl)methanethiol **8** (9%), accompanied by small amounts of **9** (Scheme 1).[16] Presumably, the isoquinoline **7** was derived from thiol derivative **8**. In fact, thiol **8** was easily converted to **7** by further irradiation.

From these experiments, the reaction seems to proceed in several steps involving initial thietane **10** formation between the thiocarbonyl and γ,δ-alkenyl moiety of **2**, leading to the key ω-aminodienal intermediate **12**,[17] which subsequently cyclizes to the pyridine derivatives **3** as shown in Scheme 2 (pathway A). However, no evidence is available at this time to suggest if this step is thermal or photochemical. In the case of *o*-vinylbenzaldehyde **6** as dienal analogue, formation of isoquinoline **7**



Scheme 1



Scheme 2

seems to proceed *via* thiol **8** which arises from the initially formed thietane **10** followed by photochemical fission of the C–S bond of the thietane ring, and then subsequent cyclization (pathway B).

In this study, the new photochemical formation of pyridine promises to have broad applications for the synthesis of aryl- and heteroaryl-pyridines. In addition, it was shown that certain dienal species and their analogues are potentially useful building blocks in photosynthesis of nitrogen-containing heterocycles. A detailed study on further synthetic application and the reaction pathway of this reaction is in progress.

This work was supported in part by a Grant-in-Aid for High Technology Research Programs from the Ministry of Education, Science, Sports and Culture of Japan.

Simultaneous modification of mesopores and extraction of template molecules from MCM-41 with trialkylchlorosilanes

Valentyn Antochshuk and Mietek Jaroniec*

Department of Chemistry, Kent State University, Kent, Ohio 44242, USA. E-mail: jaroniec@columbo.kent.edu

Received (in Bloomington, IN, USA) 29th June 1999, Accepted 13th October 1999

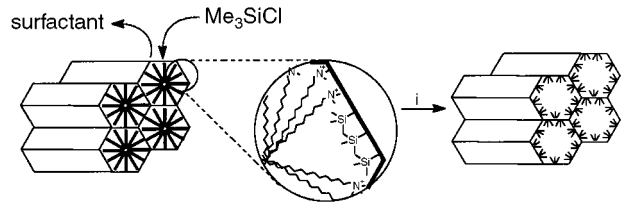
The simultaneous removal of a surfactant template and attachment of trialkylsilyl groups has been successfully achieved by treating uncalcined MCM-41 with trialkylchlorosilanes, resulting in the synthesis of mesoporous hydrophobic materials of highly uniform pore structure.

The preparation of MCM-41 materials[1] usually includes a high temperature calcination step that in fact opens mesopores as well as resulting in structure shrinkage.[2] Functionalization with silanes is often employed to achieve materials with the desired surface properties for advanced adsorption and catalytic applications[3] and to increase their stability with respect to atmospheric humidity.[4] The main drawback of the conventional modification procedure[5] lies in the necessity for template removal prior to attachment of the ligands to the MCM-41 pore walls by either calcination (which leads to structure shrinkage) or solvent/HCl extraction. Another shortcoming of this conventional modification is the low bonding density of the resulting materials, especially when larger groups are attached. So far, only a few attempts at the modification of uncalcined MCM-41 materials have been reported.[6–8] The first two reports describe the modification of somewhat different materials, *i.e.* alkyltrimethylammonium–kanemite complexes[6] and MCM-48,[7] without providing clear information about the degree of surfactant removal and the structure of the bonded layer. Another report[8] deals with a stepwise post-synthesis silylation procedure, the first step of which was intended to modify only the external surface of MCM-41, whereas two additional subsequent steps were proposed to remove the template from the mesopores *via* HCl/ETOH extraction and to attach functional groups to their walls.

The current work shows that a one-step silylation of uncalcined MCM-41 materials leads not only to external surface modification, but also to the removal of the surfactant template from the mesopores and chemical modification of their walls. The proposed one-step treatment of uncalcined MCM-41 materials with trialkylchlorosilanes allows one to achieve several goals: (i) preparation of functionalized mesoporous materials with hydrophobic surfaces; (ii) removal of surfactant molecules from the mesopores; (iii) avoiding high temperature calcination or solvent extraction procedures; and (iv) avoiding structure shrinkage during the calcination process. Templating and charge balancing surfactant molecules, which interact with the silica surface *via* van der Waals and electrostatic forces, were replaced by more strongly (chemically) interacting groups, *e.g.* trialkylsilyl groups. The method reported here could be useful in the low temperature synthesis of catalytic materials and adsorbents with a high surface coverage of attached ligands (especially when larger silanes are used) and with a high degree of pore uniformity. The one-step procedure makes extraction or calcination of as-synthesized samples a redundant and superfluous step in the preparation of modified MCM materials.

The MCM-41 sample studied was prepared by a method involving post-synthesis hydrothermal restructuring.[9] Two unmodified samples were used: MCM-41U (uncalcined 'as prepared' mesoporous material) and MCM-41C (the same sample but calcined). Both samples were subjected to modification. The uncalcined material with template molecules inside the mesopores was functionalized in a one-step process that includes simultaneous trialkylsilanization and extraction of the template. Two modified samples were prepared: MCM-41UM and MCM-41UO, with attached trimethyl- and octyldimethylchlorosilyl groups, respectively. Calcined mesoporous material was modified with the trimethyl- and octyldimethyl-chlorosilanes using a conventional modification procedure,[10] and the resulting samples were designated as MCM-41CM and MCM-41CO, respectively.

In the proposed one-step modification procedure of uncalcined samples no additional pretreatment was performed. A typical synthesis (Scheme 1) included dispersion of the mesoporous material (about 0.2 g) in 10 ml of trialkylsilane, and refluxing the mixture for 36 h. Upon addition of *ca.* 5 ml of anhydrous pyridine to the mixture, it was refluxed for a further 18 h. After cooling, the modified mesoporous material was filtered off and washed several times with small portions of EtOH, EtOH–n-heptane and finally n-heptane to remove excess modifier and pyridine as well as possible products of hydrolysis. Finally, the modified mesoporous material was dried overnight in an oven at 95–100 °C under vacuum.



Scheme 1 *Reagents and conditions*: i, $ClSiMe_2CH_2R$ [R = H or $(CH_2)_6Me$], reflux, 36 h, then pyridine, reflux, 18 h.

Modification of the silica surface with alkylsilanes, *via* chemical bonding of alkylsilyl ligands to the surface, was proved by means of ^{13}C CP-MAS (chemical shifts in the interval between 0 and 40 ppm) and ^{29}Si NMR spectroscopy (decrease in the amount of Q^3 silanols with simultaneous increase of Q^4 siloxane sites at −99 and −108 ppm, and an additional signal at 12–15 ppm which corresponds to silane molecules attached to the surface in a monomeric fashion).[10] Elemental analysis showed the presence of bonded alkylsilyl groups (appropriate ratio C : H) and the successful removal of all surfactant molecules and pyridine (complete absence of nitrogen). The concentration of immobilized ligands is shown in Table 1. A much higher amount of attached octyldimethylsilyl

Table 1. Structural features of the 'parent' MCM-41 and materials functionalized with trialkylchlorosilanes

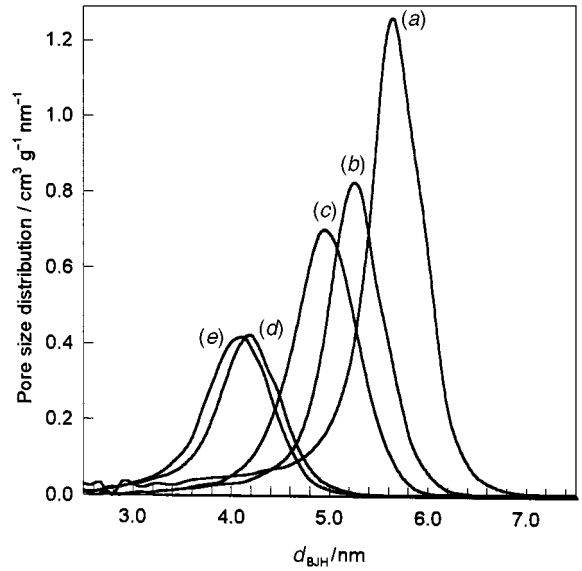

Fig. 2 Pore size distributions for (*a*) MCM-41C, (*b*) MCM-41UM, (*c*) MCM-41CM, (*d*) MCM-41UO and (*e*) MCM-41CO.

groups can be achieved in the one-step modification in comparison to the conventional procedure. The maximum number of attached groups in the one-step modification is probably limited by the size of the $SiMe_2CH_2R$ groups [where R = H or $(CH_2)_6Me$].

Adsorption studies showed opening of pores upon modification from completely filled (uncalcined as-prepared sample) to fully accessible pores of different diameter (modified samples). The pore diameter of the modified samples as well as the surface area and mesopore volume depend on the size of the attached ligands (see Table 1). Unmodified calcined sample MCM-41C has a very pronounced step in capillary condensation at $P/P_0 \sim 0.57$ (Fig. 1), which shifts gradually to lower pressure for modified samples. The size of the hysteresis loop decreases with increasing size of grafted ligands.

Thermogravimetric studies showed great similarity for the samples modified *via* the conventional and one-step procedures. A notable difference in the shape of the DTG curves for the samples with similar ligands is attributed to the presence of different conformations of the attached alkyl groups.[10] The pore diameters and pore size distributions for all samples were calculated from nitrogen adsorption data using the BJH method with the corrected form of the Kelvin equation (see Fig. 2).[11] The decrease in the pore size upon modification of the surface with trimethylchlorosilane is typically about 0.50 nm.[10,12] For the MCM-41CM and MCM-41UM samples there is a significant difference in the size of the mesopores, emphasizing the well-known effect of structure shrinkage upon calcination.[2] A similar tendency is observed for the MCM-41CO and MCM-41UO samples, but in this case the difference is smaller because of two competing factors: higher surface coverage (about 30%) and no shrinkage when uncalcined sample is used.

In conclusion, the MCM-41 mesoporous silicate can be functionalized *via* a one-step procedure using an uncalcined sample. Such a procedure greatly simplifies modification of MCM-41 and pore opening, and makes high temperature calcination or solvent extraction unnecessary. This has advantages such as higher surface coverage of grafted ligands and avoidance of the structure shrinkage. The current study shows that further investigation is needed to determine the detailed synthetic procedure required for selective polyfunctionalization of uncalcined MCM-41 or its complete modification with one reagent only.

We thank Dr A.Sayari for providing the MCM-41 sample. The donors of the Petroleum Research Fund administrated by the American Chemical Society are gratefully acknowledged for partial support of this research.

Iodine transfer cyclization mediated by DIBAL-H/THF

Arindam Chakraborty and Ilan Marek*

Department of Chemistry and Institute of Catalysis Science and Technology, Technion-Israel Institute of Technology, Technion City, Haifa 32000, Israel. E-mail: chilanm@tx.technion.ac.il

Received (in Cambridge, UK) 27th August 1999, Accepted 18th October 1999

The combination of DIBAL-H/THF in a 1:1 ratio offers a unique and useful protocol for iodine transfer cyclization *via* a radical pathway; different iodo acetals are employed to obtain the corresonding tetrahydrofuran derivatives in good to excellent yield.

The trialkyltin hydride mediated cyclization of hex-5-enyl and hex-5-ynyl halides (and related radical precursors) is one of the most powerful tools at the disposal of the synthetic chemist for the formation of carbocycles and heterocycles.[1] However, one of the inherent limitations of these tin hydride reagents is the formation of a carbon–hydrogen bond at the end of the sequence. Reagents that mediate the *non-reductive*[2] cyclization have been the focus of recent research and in this endeavour the photolytic ditin method has emerged as a remarkable general procedure due to its unique ability to promote atom transfer cyclizations[3] (or isomerizations)[4] in a *non-reductive* manner. Herein, we report our preliminary results in this area and specifically the use of DIBAL-H–THF (in a 1:1 ratio) as a reagent for iodine transfer cyclization.

During the course of a study aimed at the hydrometallation and carbometallation reactions of functionalized substrates,[5] we wanted to prepare a vinylaluminium derivative[6] in the presence of a sensitive acetal moiety and an sp^3 carbon–iodine bond. Earlier studies of Yamamoto *et al.*[7] revealed that DIBAL-H cleaves acetals regio- and stereo-selectively to the corresponding alcohols due to the complexation of one of the oxygen atoms of the acetal with the oxyphilic organoaluminium compound.[8] In order to overcome this cleavage it was necessary to decrease the Lewis acidity of the aluminium reagent. Accordingly, we felt that addition of 1 equiv. of THF per equiv. of DIBAL-H, as used by Zweifel for the hydroalumination reaction of propargylic THP ethers,[9] should prevent acetal cleavage. However, when we performed the reaction as per our plan, the chemical outcome was totally different and instead of the hydroalumination reaction, we observed an unexpected iodine transfer cyclization under mild conditions and in good overall yield, as described in Table 1.

Although radical processes are known in aluminium chemistry,[10] this type of iodine transfer cyclization[11] mediated by DIBAL-H has no precedent.[12] As expected for such isomerizations, we obtained two isomers for the vinyl iodides **1**, **2**, **3** and **5** in a 1:1 ratio; no trace of the β-fragmentation of the starting material into the propargylic alcohol or enol ether was observed. This behavior is characteristic of the generation of a radical since an organometallic is known to β-eliminate[13] faster than the carbocyclization reaction across a triple bond.[14] Moreover, when the reaction is performed in the presence of 40 mol% of Galvinoxyl or TEMPO, no iodine transfer is observed and only the starting material is recovered. The vinyl iodide **1** was also obtained in the same ratio and yield by isomerization following the photolytic ditin procedure.[3] It is interesting to note that variation of the concentration decreases the yield of **1**, and more specifically by changing the amount of THF with respect to DIBAL-H as described in Table 2.

The best result for cyclization was obtained using a stoichiometric ratio of DIBAL-H/THF (entries 1 and 5). In all examined cases, very little radical attack on the solvent is observed (less than 3%). Several other aluminium reagents were tested and we found that the dialkylaluminium hydrides was the best reagents for this isomerization (DIBAL-H, 80%), followed by trialkylaluminium derivatives (Me_3Al, 65%), alanate derivatives[15] [sodium bis(2-methoxyethoxy)aluminium hydride, known as Red-Al, 40%], dialkylaluminium halides (Et_2AlCl, 16%), and methylaluminoxane $[Al(CH_3)O]_n$ in only 7% yield; no isomerization was observed with activated aluminium oxide. Although the combination DIBAL-H/THF can be replaced by DIBAL-H/THP without any change in this overall isomerization, Et_3N as co-additive (instead of THF) did not lead to a good yield (26%).

Disubstituted alkynes (Table 1, entries 2 and 3) do undergo similar isomerization to provide both vinylic isomers of **2** and **3** in 1:1 ratio,whereas a secondary alkyl iodide (entry 4) gives the cyclic product as the *cis* isomer with a *Z*:*E* ratio of 13:1 in excellent yield.

Although it is tempting to speculate that the aluminium complex behaves in a similar fashion to BEt_3 in the presence of oxygen,[16] when we repeated the reaction in entry 1 (Table 1) either in a totally degassed THF and hexane solution or in the dark, we did not observe any change in the chemical outcome of this cyclization. Interestingly, during the formation of **4**, addition of benzaldehyde after the completion of the reaction yielded benzyl alcohol quantitatively, which emphasized the presence of the hydride in the reaction mixture even after the normal course of reaction.

To substantiate the generality of this newly found strategy, we examined the similar treatment of a substrate which did not have an acetal moiety. We were pleased to find that 1-iodohex-5-yne (entry 5, Table 1) produced the cyclic isomer as expected. When the alkyne is slightly activated as 6-iodo-1-trimethyl-

silylhex-1-yne, the classical hydroalumination reaction occurs to give the vinyl silane after hydrolysis.

In conclusion, the use of the combination DIBAL-H/THF provides a new and efficient method for iodine transfer cyclization for the formation of five-membered rings.[17] Synthetic applications of the present methodology[18] and investigations to understand the mechanistic rationale of the reaction are now in progress in our laboratory.

17 *Experimental procedure* for **4** (it is important to follow the order of addition of substrates for these experiments): Into a dry, argon-flushed flask kept under a static pressure of argon is placed a 1.0 molar solution of DIBAL-H (1.76 ml, 1.76 mmol) in hexane. To the cooled solution (0 °C) is added sequentially THF (127 mg, 1.76 mmol) and the iodide (467 mg, 1.76 mmol) in hexane (1 ml). The solution is stirred at 0 °C for 15 min and then allowed to attain room temperature and stirred overnight. The reaction mixture was then quenched with 1 M HCl, extracted with Et_2O and washed several times with water, dried ($MgSO_4$) and then the solvent was evaporated to provide the crude product. After purification by chromatography on silica gel (10% EtOAc in hexanes), 421 mg (90%) of the title compound was obtained.

18 All our attempts to form the six-membered ring as well as to promote the isomerization across a double bond failed.

Asymmetric amidation of saturated C–H bonds catalysed by chiral ruthenium and manganese porphyrins

Xiang-Ge Zhou, Xiao-Qi Yu, Jie-Sheng Huang and Chi-Ming Che*

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong. E-mail: cmche@hkucc.hku.hk

Received (in Cambridge, UK) 29th July 1999, Revised 2nd September 1999, Accepted 1st October 1999

Chiral ruthenium(II) and manganese(III) porphyrins catalyse the asymmetric amidation of saturated C–H bonds of ethylbenzene and ethylnaphthalenes to form the corresponding amides in up to 85% yield with 45–58% ee.

In the context of developing new protocols for asymmetric functionalisation of saturated C–H bonds, amidation *via* reactive metal–imido species is preferred over hydroxylation by reactive metal–oxo complexes because the latter usually suffers from further oxidation to give side products such as ketones. However, in contrast to the large number of investigations on the hydroxylation of saturated C–H bonds catalysed by both cytochrome P-450 and its chemical model systems such as iron and manganese porphyrins,[1] metalloporphyrin-catalysed amidations of saturated C–H bonds are rare.[2–6] Herein we describe the enantioselective amidation of saturated C–H bonds with chiral metalloporphyrin catalysts or directly by a chiral metal–imido complex (Scheme 1). Prior to this work, there was only one report on metal-mediated asymmetric amidation of saturated C–H bonds, with up to 31% ee obtained for indane,[7] despite the recent advances in metal-catalysed asymmetric aziridination of alkenes.[8]

The chiral porphyrin H_2Por* [Por* = 5,10,15,20-tetrakis(1,2,3,4,5,6,7,8-octahydro-1,4:5,8-dimethanoanthracen-9-yl)porphyrinato dianion] was synthesised by Halterman's method.[9] Its complexes with ruthenium(II) and manganese(III) ions, [Ru^{II}(Por*)(CO)(EtOH)] **1**[10] and [Mn^{III}(Por*)(OH)(MeOH)] **2**,[9,11] respectively, were prepared according to the published procedures. Both complexes were found to be effective catalysts for asymmetric amidation of saturated C–H bonds by PhI=NTs.† The results obtained for a series of substrates containing saturated C–H bonds, at a catalyst: PhI=NTs : substrate molar ratio of 1 : 100 : 500 with yields based on starting PhI=NTs, are summarised in Table 1. In each case, $TsNH_2$ was detected as a side product; the total yields of $TsNH_2$ and the amidation product were close to 100%. As can be seen from Table 1, both the yield and ee increase considerably with increasing temperature (entries 1–3; 4, 5; 8, 9), and less sterically demanding substrates could be amidated with higher ees. For example, the ee obtained for 2-ethylnaphthalene (48%, entry 13) is higher than that obtained for the more sterically demanding substrates 1-ethylnaphthalene (23%, entry 15) and indane (10%, entry 9). Mass balance studies were carried out in the case of ethylbenzene, which resulted in conversions of 14 (catalyst **1**) and 47% (actalyst **2**) for this substrate at a

3

catalyst : ethylbenzene : PhI=NTs molar ratio of 1 : 75 : 150 (CH_2Cl_2, 40 °C, 2 h), with the yields of 1-tosylamino-1-phenylethane being 84 and 76%, respectively, based on the amount of ethylbenzene consumed.

Under the same conditions, the manganese catalyst **2** exclusively afforded the amidation product in a considerably higher yield (> 70% in all the cases except entries 4 and 16) than the ruthenium catalyst **1**. The highest yield obtained was 85% for 2-ethylnaphthalene (entry 14). Increasing the amount of **2** used considerably improved the yield but only slightly enhanced the chiral induction (entries 16 and 17). Interestingly, the manganese catalyst **2** also gave higher ees than the ruthenium catalyst **1**, except for tetrahydronaphthalene. The

highest ee obtained in the catalytic amidations was 54% for 1-ethylnaphthalene (entry 17).

Efforts have been made to ascertain the active species in the ruthenium-catalysed amidation reactions. Treatment of complex **1** with 2 equiv. of PhI=NTs in CD_2Cl_2 at room temperature completely converted **1** into a bis(tosylimido)ruthenium(VI) complex, $[Ru^{VI}(Por^*)(NTs)_2]$ **3**, which was characterised by the following spectral methods. The ^1H NMR spectrum‡ of **3**, typical of a diamagnetic ruthenium porphyrin, shows *ortho*- and *meta*-proton resonances of axial tosyl groups, and the H_β resonances of the chiral porphyrinato ligand at δ 4.89, 6.19 and 8.76, respectively, with an integration ratio of 1 : 1 : 2. The UV–VIS spectrum of **3** exhibits Soret and β bands at 422 and 537 nm, respectively, both of which are red-shifted by *ca.* 8 nm when compared with the carbonyl complex **1**. All these spectral features strongly resemble those of $[Ru^{VI}(Por)(NTs)_2]$ (Por = achiral *meso*-tetraarylporphyrinato dianion).[6] Further, the positive ion electrospray mass spectrum of **3** shows a prominent cluster peak at *m/z* 1579.8 that can be attributed to the parent ion of **3**. Complex **3** constitutes the first example of a chiral imido metalloporphyrin, and, importantly, it was found to be reactive towards saturated C–H bonds, leading to an enantioselective insertion of the NTs group into these bonds.§ The results are listed in Table 2. Under identical conditions, the ees obtained for the stoichiometric amidation by complex **3** and for the catalytic amidation by **1**, except for substrates 1- and 2-ethylnaphthalene, are rather similar, suggesting that complex **3** likely functions as the active species responsible for the asymmetric amidation reactions. Notably, the amidation of 2-ethylnaphthalene by **3** gave 58% ee (entry 6), which represents the highest ee obtained in this work.

For the manganese catalysed reactions, we found that the positive ion electrospray mass spectrum of a reaction mixture of **2** and PhI=NTs in CH_2Cl_2 showed a prominent cluster peak at *m/z* 1569.1 ascribable to the fragment $[Mn(Por^*)(PhINTs)]^+$. This suggests the involvement of a manganese tosylamido reactive intermediate and suggests that different types of active species may be involved in the ruthenium and manganese catalyses. To probe the nature of the intermediates formed in the rate-limiting step during the amidation catalysed by **2**, we examined substitution effect by measuring the amidation rates (k_{rel}) of substituted ethylbenzenes *p*-YC_6H_4Et (Y = MeO, Me, F, Br) relative to that of ethylbenzene, which reveals that both electron-donating and -withdrawing substituents promote the amidation process. A dual-parameter (σ^+, $\sigma_{JJ}^\bullet$) fitting of log k_{rel}, as established by Jiang and co-workers,[12] through multiple regression gave rise to excellent linearity (Fig. 1), with ρ^+ and $\rho_{JJ}^\bullet$ values of −0.49 and 0.66, respectively, suggesting that the amidation reactions should proceed *via* a benzylic radical intermediate, which possibly resulted from H-atom abstraction from the substrates by the manganese tosylamido active intermediate.

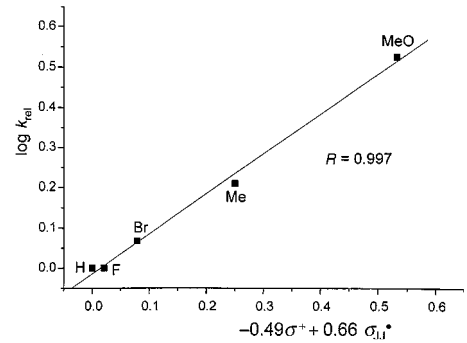

Fig. 1 Plot of log k_{rel} *vs.* (σ^+, $\sigma_{JJ}^\bullet$) for the amidation of substituted ethylbenzenes *p*-YC_6H_4Et (Y = MeO, Me, F, H, Br) by PhI=NTs catalysed by manganese catalyst **2**. The *R* value for the multiple regression is indicated.

We acknowledge support from the Hong Kong Research Grants Council and The University of Hong Kong.

Notes and references

† *General procedure* for the amidation reactions: To a Schlenk flask containing the complex (5 μmol) and molecular sieves (4 Å) (150 mg) was added a solution of substrate (2.5 mmol) in dry CH_2Cl_2 (5 ml) *via* syringe. The mixture was stirred for 10 min at room temperature under argon. PhI=NTs (0.5 mmol) was then added against a positive pressure of argon. The reaction was maintained at 40 °C for 2 h. After cooling, the molecular sieves were filtered off and washed with CH_2Cl_2. The filtrate and washings were evaporated to dryness and the organic product, purified by column chromatography, was identified by ^1H and ^{13}C NMR, and high-resolution MS, along with melting point.

‡ *Selected data* for **3**: δ_H(300 MHz, CD_2Cl_2) 8.76 (s, 8H), 7.37 (s, 4H), 6.19 (d, 4H), 4.89 (d, 4H), 3.54 (s, 8H), 2.69 (s, 8H), 1.97 (m, 8H), 1.84 (m, 14H), 1.34 (m, 24H), 1.07 (m, 8H).

§ The general procedure for the stoichiometric amidation of saturated C–H bonds by complex **3** is the same as that for the catalytic amidation by **1** and **2**, except that 0.25 mmol of **3**, formed *in situ* by treating **1** with 2 equiv. of PhI=NTs, was used instead of **1** and **2**, and no additional PhI=NTs was added.

Synthesis of an anionic tridentate phosphinoborate and its reaction chemistry with Sn(II)

Alfred A. Barney, Alan F. Heyduk and Daniel G. Nocera*

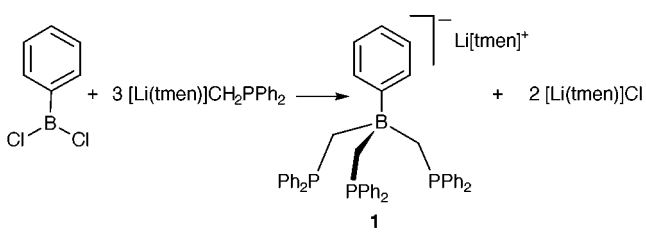
Department of Chemistry, Massachusetts Institute of Technology, 6-335, 77 Massachusetts Avenue, Cambridge, MA 02139-4307, USA. E-mail: nocera@MIT.edu

Received (in Bloomington, IN, USA) 11th August 1999, Accepted 13th October 1999

Dichlorophenylborane reacts smoothly with [Li(tmen)][CH_2PPh_2] in THF to afford, in good yields, the Li(tmen)$^+$ salt of a novel monoanionic tridentate phosphinoborate, tris(diphenylphosphinomethyl)phenylborate; reaction of the ligand with $SnCl_2$ produces tris(diphenylphosphinomethyl) phenylboratotin(II) chloride, which may be dehalogenated to give the η^3 compound, {[PhB(CH_2PPh_2)$_3$]Sn}PF_6, tris(diphenylphosphinomethyl)-phenylboratotin(II) hexafluorophosphate.

By comparison to their neutral congeners,[1] tridentate anionic phosphines are rarely found within the coordination spheres of metal ions, emerging as viable ligands only recently in the preparation of water-soluble hydrogenation catalysts.[2] In these systems, an isolated anionic charge is introduced by sulfonylation of conventional phosphine ligands remote to the ligation site. With the desire of adding new, anionic six-electron donor ligands to the palette of coordination chemistry, we turned our attention to strategies that would permit the incorporation of a negative charge within the framework of a tridentate phosphine. As amply demonstrated in pyrazoylborate chemistry[3,4] and the recent synthesis of [PhB($CH_2SR)_3$]$^-$ by Riordan and coworkers,[5] the borate bridgehead provides both the desired negative charge and a scaffold to support three ligating arms with a hybridization that sustains a *fac* conformation about a metal center. We now report the synthesis and characterization of the novel anion, tris(diphenylphosphinomethyl)phenylborate **1**. The ligand features a negative charge proximate to a highly polarizable six-electron phosphine donor set. Within the context of hard/soft treatments of acid/base properties, **1** should exhibit a propensity to associate to soft metals. Along these lines, we initially elaborate the chemistry of **1** with tin(II), reporting the X-ray characterization of tris(diphenylphosphinomethyl)phenylboratotin(II) chloride **2** and its structural changes upon replacement of the coordinating chloride with an outer sphere anion PF_6.

Addition of diphenylphosphinomethide to dichlorophenylborane yields a borate salt, which subsequently undergoes substitution of its chlorides by two additional equivalents of diphenylphosphinomethide to provide the tris(diphenylphosphinomethyl)phenylborate ligand in good yields (Scheme 1).† Work up should follow immediately after the addition is completed, as prolonged reaction times lead to lower isolated yields. The crude compound is a pale yellow solid that can be recovered in a purified form from CH_2Cl_2. The phenyl and methylene resonances of the phosphinoborate anion are readily discerned in the ^{1}H NMR spectrum at δ 6.8–7.6 and 1.07, respectively, as are the methyl and ethylene protons of the Li(tmen)$^+$ cation at δ 2.18 and 2.30.



Scheme 1

Anion **1** reacts with $SnCl_2$ in CH_2Cl_2 to give [PhB($CH_2PPh_2)_3$]SnCl **2**, which was structurally characterized.‡ This is noteworthy in view of the small number of structurally characterized tin(II) phosphine complexes. The recent classification and analysis of structural data for > 500 tin coordination compounds[6] reveals *ca.* 200 to contain divalent tin. Of these, nitrogen and oxygen are the most common non-halogen atoms found to bond with Sn(II), with poly(pyrazolyl)borates figuring prominently within this classification.[7–9] However, structurally characterized monomeric compounds containing direct ligation of phosphorus to tin are few, and only a small number of these possess tin in its divalent oxidation state.[10–15] The solution of the single crystal X-ray structure of **2** now adds to this abbreviated list.

The most striking feature of the ORTEP diagram shown in Fig. 1 is that one of the phosphine arms of the ligand coordinates the metal center only weakly. The bond distance between Sn(1) and the two phosphorus atoms P(1) and P(3) are *d*[Sn(1)–P(3)] = 2.6746(14) Å and *d*[Sn(1)–P(1)] = 2.690(2) Å, respectively. These distances are slightly longer than those found in the limited data set for Sn–P bond lengths.[10,11,15–17] In contrast, the weakly bonded phosphorus, P(2), is situated far from the metal, *d*[Sn(1)–P(2)] = 3.036(2) Å, slightly beyond the standard covalent bonding distances for tin and phosphorus.[18] This coordination of **2** is distinguished from the analogous tin(II) pyrazoylborate complex insofar as the long Sn–N bond is well within the standard covalent bonding distance for a formal Sn–N bond. Nevertheless, the distorted trigonal bipyramidal coordination geometry about the metal, as is often observed for tin(II) pyrazolylborate complexes, is completed by a Sn(1)–

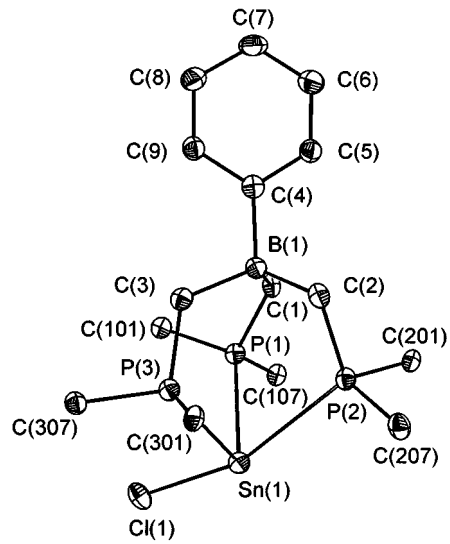


Fig. 1. ORTEP representation and labeling scheme of **2** with thermal ellipsoids drawn at the 35% probability level. Only the *ipso* carbons of the phenyl rings on phosphorus are shown for clarity.

Cl(1) bond, which is long at 2.599(2) Å, and the stereochemically active tin(II) lone pair. The intraligand P(1)–Sn(1)–P(3) bond angle of 81.76(4)° is markedly contracted relative to P–Sn–Cl angles of 87.57(4) and 95.18(5)°. Finally, the local geometry around the boron atom is approximately tetrahedral.

That all three phosphines are capable of bonding to the metal is revealed by the solution $^{31}P\{^{1}H\}$ NMR spectrum of **2**, which shows only a single broad peak, centered at δ −5.1. Similar results are observed for anionic bidentate phosphine[19] and poly(pyrazolyl)borate[7] complexes of tin(II) as well. With one coordination site of **2** occupied by chloride, the ligation of only two phosphines is consistent with the stereochemical influence exerted by the electron lone pair present on the tin(II) center. Accordingly, the removal of chloride from **2** would be expected to open a coordination site, thus allowing the dangling phosphine to strongly associate with the metal center. This contention is supported by the reaction chemistry of **2** with $TlPF_6$. Reaction of **2** with one equivalent of thallium hexafluorophosphate yields {[PhB(CH_2PPh_2)$_3$]Sn}PF_6 **3**. In contrast to **2**, the $^{31}P\{^{1}H\}$ NMR spectrum of **3** shows a single sharp resonance at δ +5.1 that is flanked by tin satellites. Coupling of three equivalent phosphorus atoms to ^{117}Sn (7.68%) and ^{119}Sn (8.59%) isotopes are clearly observed [$^{1}J(^{117/119}Sn–^{31}P)$ = 1330, 1270 Hz], consistent with the coordination of all three phosphines to the metal center.

Considering the rich coordination chemistry of the related tris(pyrazolyl)borate anion, a similarly diverse chemistry of **1** may be expected. The ligand is distinguished by its negative charge and ability of **1** to adopt four- and six-electron coordination modes about a highly polarizable metal center. The combination of these properties in a singular ligand system should find utility in the design of novel compounds and new metal-based catalytic schemes. Along these lines, the recent preparation of [PhB(CH_2PPh_2)$_3$](H)Ir(η^3-C_8H_{13}) and its reaction with H_2SiMes_2 to produce an iridium silylene[20] illustrates the unique reactivity engendered by this tridentate phosphinoborate ligand.

The National Science Foundation Grant CHE-9817851 provides generous support for this research. We thank Jonas C. Peters for useful discussions with regard to ligand design strategies.

Notes and references

† *Experimental procedures*: reactions were carried out under the nitrogen atmosphere of a dry box, which was capable of supporting a variety of standard synthetic methodologies. Solvents were freshly prepared for synthesis by their distillation from appropriate drying agents and by subsequently degassing prior to use. ^{1}H, ^{31}P and ^{11}B NMR spectra were recorded on Varian Unity 300 and Mercury 300 spectrometers. Chemical shifts for ^{1}H, ^{31}P, and ^{11}B NMR are reported in ppm *vs.* TMS, H_3PO_4 (85%) and BF_3•Et_2O, respectively.

1: [Li(tmen)]CH_2PPh_2[21] (3 g, 9.31 mmol), dissolved in 100 mL of THF, was added slowly with stirring over 1.5 h to a 25 mL THF solution of dichlorophenylborane (0.49 g, 3.1 mmol) maintained at 0 °C. The mixture was stirred an additional 30 min whereupon the solvent was removed *in vacuo* to leave an oily residue. The borate was dissolved in CH_2Cl_2 and the solution was filtered to remove LiCl. Solvent removal gave **1** as a microcrystalline solid and the product was dried *in vacuo* overnight (2.36 g, 82% yield). $C_{51}H_{57}BLiN_2P_3$; found: C, 75.5; H, 7.18; N, 3.66; P, 11.09; requires: C, 75.75; H, 7.10; N, 3.46; P, 11.49%. ^{1}H NMR (CD_3CN): δ 6.8–7.6 (m, 35H), 2.3 (s, 4H), 2.18 (s, 12H), 1.07 (br, 6H) $^{31}P\{^{1}H\}$ NMR: δ −10.2 [q, ^{2}J ($^{11}B–^{31}P$) 9.16 Hz], $^{11}B\{^{1}H\}$ NMR: δ −15.45 [q, ^{2}J ($^{31}P–^{11}B$) 9.16 Hz)].

2: a 50-mL CH_2Cl_2 solution of **1** (0.4 g, 0.5 mmol) was added to a mol equivalent of $SnCl_2$ (0.094 g) dissolved in 10 mL of CH_2Cl_2. The resulting solution was stirred overnight. A residue remained upon the vacuum evaporation of CH_2Cl_2. The product was extracted away from unreacted $SnCl_2$ with benzene, and the resulting solution was filtered and concentrated to a third of its original volume. Purified product was obtained by layering the benzene filtrate with an equal volume of pentane. Compound **2** formed over 2–3 days, after which the clear crystals were collected and dried (0.31 g, 74%). $C_{45}H_{41}BClP_3Sn$; found: C, 64.01; H, 5.03; P, 10.98; requires: C, 64.37; H, 4.92; P, 11.07%. ^{1}H NMR (C_6D_6): δ 6.7–7.8 (m, 35H), 1.9 (br, 6H); $^{31}P\{^{1}H\}$ NMR (C_6D_6): δ −5.1 (br); $^{11}B\{^{1}H\}$ NMR (C_6D_6): δ −13.23 (br).

3: the chloride ligand was removed from **2** by dissolving 0.25 g (0.30 mmol) of the compound in 50 mL of acetonitrile, followed by the addition of a mol equivalent (0.104 g) of $TlPF_6$. The reaction mixture was stirred overnight and then filtered to remove TlCl as a white solid. The filtrate was removed *in vacuo* to afford the product, which was dried *in vacuo* overnight (0.250 g, 89%). $C_{45}H_{41}BF_6P_4Sn$; found: C, 56.96; H, 4.55; P, 13.17; requires: C, 56.94; H, 4.35; P, 13.05%. ^{1}H NMR ($CDCl_3$), δ 6.7–7.8 (m, 35H), 1.9 (br, 6H); $^{31}P\{^{1}H\}$ NMR ($CDCl_3$), δ 5.1 [s, $^{1}J(^{117/119}Sn–^{31}P)$ 1331.8, 1272.8 Hz]; δ −142.9 [sept,$^{1}J(^{31}P–^{19}F)$ 708.42 Hz]; $^{11}B\{^{1}H\}$ NMR($CDCl_3$); δ –11.9 (br).

The first chiral diimido chelate complexes of molybdenum and tungsten: transition metal diimido complexes on the way to asymmetric catalysis

Eike A. Kretzschmar, Jennifer Kipke and Jörg Sundermeyer*

Fachbereich Chemie, Philipps-Universität Marburg, D-35032 Marburg, Germany.
E-mail: jsu@chemie.uni-marburg.de

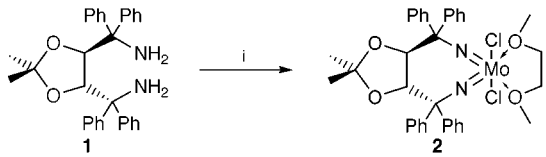
Received (in Basel, Switzerland) 13th September 1999, Accepted 25th October 1999

The first complexes [M(TADDAMINat)Cl_2(dme)] (M = Mo (2), W (4)) containing a chiral diimido ligand regime have been synthesized; 2 has been structurally characterized and used as catalyst for C–C and C–N bond formation reactions.

Transition metal imido complexes $[M^{VI}(NR)_2X_2]$ have attracted considerable attention as isolobal analogues of group 4 metallocene complexes $[cp_2M^{IV}X_2]$.[1] This may well make these diimido complexes, chelating ones in particular, promising alternatives to the well known,[2] highly efficient *ansa*-metallocenes for olefin polymerisation and other C–C or C–N coupling reactions.Although few applications of diimido complexes in catalysis are known,[3] no successful use in enantioselective transformations has been described so far.

Gibson *et al.* first reported chelating bis(arylimido) complexes, one of them revealing a solid state structure of C_2-symmetry.[4] However, this compound was found to be configurationally unstable in solution at room temperature. Here, we present the synthesis of the first chiral C_2-symmetric diimido complexes of molybdenum **2** and tungsten **4** derived from the enantiomerically pure chiral diamine **1**.

Our efforts towards the synthesis of chiral five-membered as well as seven-membered chelate complexes containing sp^2 carbon atoms in the ligand backbone failed, in accordance with the work of Siemeling *et al.*[5] In order to render the system more flexible we decided to use an entirely aliphatic backbone containing only sp^3 carbons in our chelate. The ligand TADDAMIN {(4*S*,5*S*)-2,2-dimethyl-α,α,α′,α′-tetraphenyl-1,3-dioxolan-4,5-dimethanamine} **1** reported by Seebach *et al.*[6] the amine derivative of the TADDOL family, which has proven its high efficiency in asymmetric synthesis,[7] looked very promising to us. Following the well established route for the synthesis of diimido complexes of the type $[Mo(NR)_2Cl_2(dme)]$ from Na_2MoO_4 in the presence of Me_3SiCl–Et_3N,[3] we obtained [Mo(TADDAMINat)Cl_2(dme)] **2** in 95% yield (Scheme 1).†



Scheme 1 Synthesis of molybdenum complex **2**. *Reagents and conditions*: i, Na_2MoO_4, **1**, Me_3SiCl, Et_3N, dme (Mo : **1** : Me_3SiCl : Et_3N = 1 : 1 : 20 : 20), 12 h, 85 °C.

Crystals of **2** suitable for X-ray structure determination‡ were grown from a saturated toluene solution. Each unit cell contains one solvent molecule (Fig. 1).

Group 6 metal complexes of the constraint-geometry [TADDAMINat]$^{4-}$ ligand type are isoelectronically related to the well known [TADDOLat]$^{2-}$ complexes of group 4 metals described by Seebach in ref. 9. Table 1 compares the most important structural features of the structurally characterized titanium TADDOLato complex **3**[10] with its isoelectronic TADDAMINato molybdenum counterpart **2**. Similar bonding distances and bond angles indicate comparable metal ligand π-bonding interactions and similar constraints within the isoelectronic TiO_2 and MoN_2 structural units.

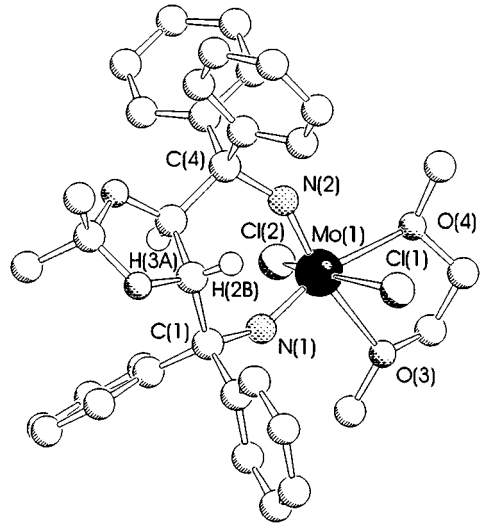


Fig. 1 The molecular structure of [Mo(TADDAMINat)Cl_2(dme)] **2** (toluene omitted for clarity). Selected bond lengths (pm) and angles (°): Mo–N(1) 173.7(2), Mo–N(2) 173.9(3), Mo–Cl(1) 240.7(1), Mo–Cl(2) 240.0(1), Mo–O(3) 236.6(2), Mo–O(4) 238.0(2), C(1)–N(1) 145.8(4), C(4)–N(2) 145.6(5); N(1)–Mo–N(2) 99.52(13), C(1)–N(1)–Mo 148.7(2), C(4)–N(2)–Mo 148.7(2), Cl(1)–Mo–Cl(2) 158.23(4), O(3)–Mo–O(4) 68.91(9).

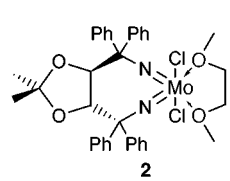
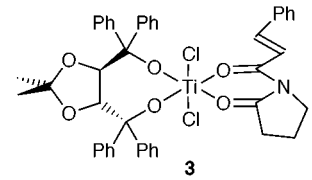
Table 1 Comparison of bond lengths (Å) and angles (°) in the molybdenum complex **2** and the titanium complex **3**





Mo≡N	1.74/1.74	Ti≡O	1.76/1.79
Mo—N—C	148.7/148.7	Ti—O—C	147.1/145.2
N—Mo—N	99.5	O—Ti—O	97.2

The analogous tungsten complex [W(TADDAMINat)-Cl_2(dme)] **4** was synthesized following a route used before in our group.[11] Reaction of WO_2Cl_2(dme), prepared *in situ* from $WOCl_4$,[12] with TADDAMIN **1** in the presence of Et_3N and TMSCl gave complex **4** as an off-white solid in 90% yield (Scheme 2).†

Since d^0 imido complexes are excellent Lewis acids, we were interested in the potential of enantiomerically pure **2** in various stereoselective reactions. Recently Leung *et al.* described the successful application of achiral group 6 organoimido com-

Scheme 2 Synthesis of tungsten complex **4**. *Reagents and conditions*: i, $WOCl_4$ (1 equiv.), $(Me_3Si)_2O$ (1 equiv.), dme, 0 °C followed by 3 h at 40 °C; ii, TMSCl (8 equiv.), Et_3N (5.6 equiv.), **1** (1 equiv.), dme, 6 d, 85 °C.

plexes in the ring opening of epoxides with $TMSN_3$.[13] Here we disclose our first results under non-optimized conditions,§ using **2** as catalyst for the kinetic resolution of racemic styrene oxide with $TMSN_3$ and the enantioselective trimethylsilylcyanation of benzaldehyde with TMSCN. Whereas the transformation of styrene oxide resulted in up to 30% ee at 100% conversion based on consumed $TMSN_3$ for the reaction of benzaldehyde with TMSCN 20% ee at 100% conversion could be obtained.[14]

As C_2-symmetric complexes of this type are of high interest for the stereoselective polymerisation of α-olefins, we currently are investigating their catalytic potential in this respect.

In conclusion, we present here the first chiral diimido complexes of molybdenum **2** and tungsten **4** and the application of **2** as a catalyst for enantioselective transformations using C–N and C–C bond forming reactions. Currently we are investigating modified ligand systems with sterically more demanding aryl substituents in order to further improve the stereodifferentiation using these complexes as a promising new class of chiral Lewis acid catalysts.

Financial support by Deutsche Forschungsgemeinschaft (SFB 260 Marburg), the Fonds der Chemischen Industrie, and the European Community (INTAS-96-I185) is gratefully acknowledged.

Stabilization of a germanium–oxygen double bond: a theoretical study

Chiu-Ling Lin, Ming-Der Su* and San-Yan Chu*

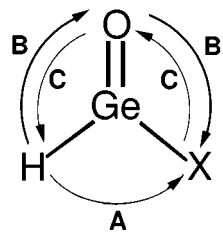
Department of Chemistry, National Tsing Hua University, Hsinchu 30043, Taiwan, ROC.
E-mail: ggs@chu1.chem.nthu.edu.tw

Received (in Cambridge, UK) 22nd September 1999, Accepted 25th October 1999

Both B3LYP and CCSD(T) computational results suggest that fluorine substitution can dramatically stabilize $F_2Ge{=}O$, with respect to FGe–OF, both from a kinetic and from a thermodynamic viewpoint.

It is generally acknowledged that intermediates with germanium doubly bonded to other elements (such as oxygen, sulfur, nitrogen *etc.*) are very unstable.[1,2] Indeed, most of our experimental knowledge of multiply bonded germanium still comes from matrix isolation studies. Therefore, the study of compounds having multiple bonds to germanium has been one of the major challenges in main group chemistry.[3,4] For instance, the first evidence for compounds containing the Ge=O moiety was reported in 1971.[5] Since then several schemes for the synthesis of germanones have been devised. Nevertheless, up to now only indirect evidence was available to suggest their transient existence.[6–9] Moreover, according to our previous study,[10] three reaction pathways for the unimolecular decomposition of HXGe=O to HX and GeO exist. These are shown in Scheme 1. The theoretical findings suggest that the most favorable dissociation path is predicted to be the 1,2-H shift route, while the 1,2-X shift path has the highest energy requirement and therefore is the least energetically favorable path. It is these intriguing theoretical results that have inspired this study. If the 1,2-X shift is the most unfavorable mechanism for the unimolecular dissociation of HXGe=O, would it be possible to extend this to synthesize and isolate compounds containing the Ge=O double bond at room temperature? What interests us particularly is to explore the possibility of designing molecular systems where $X_2Ge{=}O$ is more stable than the isomeric XGe–OX, and where relatively large barriers separate the two isomers.

HXGeO ⟶ HX + GeO



Path A:1,1-HX elimination
Path B:1,2-H shift (the most favorable)
Path C:1,2-X shift (the most unfavorable)
(X = H, F, Cl and Br)

Scheme 1

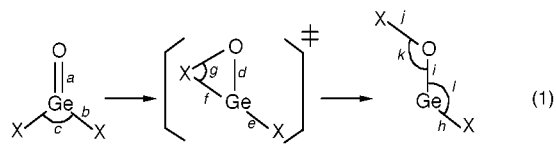
In view of the interest in isolating compounds containing a Ge=O double bond, we consider the possibility of stabilizing this moiety with various substituents. Here, we report a theoretical study concerning the effect of various substituents X (X = H, F, Cl, Br and Me) on the relative stability of $X_2Ge{=}O$ and XGe–OX isomers as well as on the transition states connecting them. See eqn. (1) in Table 1.

The geometries and energies of stationary points on the potential energy surface of eqn. (1) have been calculated using the non-localized density functional theory (DFT) in conjunction with the 6-311G* basis set, which is denoted as B3LYP/6-311G*.[11] All the stationary points have been positively identified as equilibrium structures [the number of imaginary frequency (NIMAG = 0) or transition states (NIMAG = 1)]. For better energetics, single-point calculations with B3LYP/6-311G* geometries were carried out at a higher level of theory which used coupled cluster single and double excitations including perturbative triple substitutions,[12] *i.e.* CCSD(T)/6-311++G**//B3LYP/6-311G* [hereafter designated CCSD(T)]. Unless otherwise noted, relative energies given in the text are those determined at CCSD(T) and include vibrational zero-point energy (ΔZPE) corrections determined at B3LYP/6-311G*.[13]

Some interesting points arising from the above calculations are as follows:

(1) Selected geometrical parameters of $X_2Ge{=}O$, XGe–OX, and the transition state for the reaction $X_2Ge{=}O \rightarrow$ XGe–OX [*i.e.* eqn. (1)] are listed in Table 1. It is apparent from Table 1 that halogen substitution (*i.e.* F, Cl and Br) strengthens the Ge=O double bond. In contrast, such substitutions seem to weaken the Ge–O single bond. On the other hand, methyl substitution appears to lengthen both Ge=O and Ge–O bonds slightly.

Table 1 Geometrical parameters of structures for eqn. (1) at the B3LYP/6-311G* level of theory (distances in Å, angles in degrees).



(1)

X	*a*	*b*	*c*	*d*	*e*	*f*	*g*	*h*	*i*	*j*	*k*	*l*

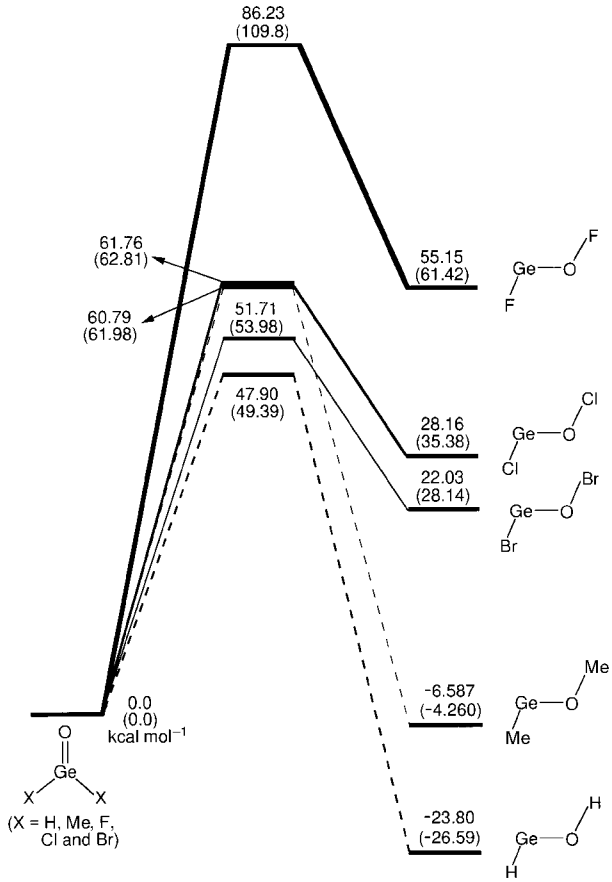

Scheme 2

(2) Scheme 2 shows the effects of various substitutions on the relative stabilities of $X_2Ge{=}O$ and XGe–OX at the B3LYP and CCSD(T) (in parentheses) levels of theory. It is worth noting that the relative stabilities of the doubly bonded and the *trans*-bent (singly bonded) species are dramatically reversed when hydrogens are replaced by electronegative substituents (such as F, Cl and Br). It is apparent from Scheme 2 that the energies of the XGe–OX molecules are much higher than those of the corresponding $X_2Ge{=}O$ by 61, 35 and 28 kcal mol^{-1} for X = F, Cl and Br, respectively. By contrast, the energies of HGe–OH and MeGe–OMe are below the energies of $H_2Ge{=}O$ and $Me_2Ge{=}O$ by 27 and 4.3 kcal mol^{-1}, respectively. Thus, the effect of dihalogen substitution is of special interest since it strongly stabilizes $X_2Ge{=}O$ relative to XGe–OX. In particular, our CCSD(T) results indicate that the endothermicity of eqn. (1) increases in the order X = Br (28 kcal mol^{-1}) < X = Cl (35 kcal mol^{-1}) < X = F (61 kcal mol^{-1}). It is therefore predicted that the more electronegative the halogen, the more stable the germanone ($X_2Ge{=}O$).

(3) The thermodynamic stability of $X_2Ge{=}O$ relative to XGe–OX may be understood in terms of the Ge–X *vs.* O–X bond energies.[14] That is to say, from eqn. (1) it is clear that a strong Ge–X bond and the weak O–X bond can overturn the large intrinsic preference of XGe–OX over $X_2Ge{=}O$.[15] Another surprising piece of evidence is that halogen substitution causes a shortening of the Ge=O double bond, as mentioned earlier. Therefore, it appears that halogen substitution strengthens the Ge=O double bond, particularly in the case of fluorine, assuming that bond energy–bond length relationships are valid. Furthermore, halogen substitution not only stabilizes the formal Ge=O double-bonded structure relative to XGe–OX, but it also raises the barrier to the $X_2Ge{=}O \rightarrow$ XGe–OX isomerizations, thus increasing the kinetic stability of the germanone molecules. For instance, as demonstrated in Scheme 2, the barrier for the isomerization of $X_2Ge{=}O$ to XGe–OX decreases in the order: X = F (110 kcal mol^{-1}) > X = Cl (63 kcal mol^{-1}) ≈ X = Me (62 kcal mol^{-1}) > X = Br (54 kcal mol^{-1}) > X = H (50 kcal mol^{-1}). In brief, fluorine is a particularly appealing possibility because of the strength of the Ge–F bonds.

(4) It should be pointed out that methyl substitution in eqn. (1) is predicted to be nearly thermoneutral, with an exothermicity of only 4.3 kcal mol^{-1}. Additionally, the barrier height for 1,2-CH_3 shift of $Me_2Ge{=}O$ is sizeable (63 kcal mol^{-1}), indicating that both $Me_2Ge{=}O$ and MeGe–OMe will have kinetic stability for such a migration reaction. This larger barrier ensures that, both isomers will be relatively stable kinetically if they were produced. Bulky substituents are generally expected to destabilize $X_2Ge{=}O$ relative to XGe–OX, owing to the steric effects.

In summary, the present work predicts that germanone $X_2Ge{=}O$ itself lies at the minimum of the potential energy surface and can be strongly stabilized in both a kinetic and a thermodynamic sense with a proper choice of substituents. For instance, the theoretical findings suggest that Ge=O double bonds can be synthesized as part of a stable compound by taking advantage of kinetic stabilization using bulky substituents as steric protection groups. Besides this, on the basis of the present theoretical results, we confidently predict that $F_2Ge{=}O$ should be very stable from both a thermodynamic and a kinetic viewpoint and should be easily observed experimentally.

We eagerly await experimental results to confirm our predictions.

We are grateful to the National Center for High-Performance Computing of Taiwan and the Computing Center at Tsing Hua University for generous amounts of computing time. We also thank the National Science Council of Taiwan for their financial support.

Received (in Bloomington, IN, USA) 3rd September 1999, Accepted 15th October 1999

The first examples of rhenacarborane complexes with nitrosyl ligands have been prepared and used to synthesise alkylidene(nitrosyl)rhenacarboranes and a novel complex in which a conjoined carboranyl–iminium group is bound to rhenium both through the η^5-C_2B_3 face of the cage and the iminium carbon atom.

Because of their high compatibility with other groups when ligating metal centres the cyclopentadienide anion and its derivatives rank among the most important ligands in organo-transition metal chemistry.[1] Formally isolobal with $[C_5H_5]^-$ the dicarbollide dianion [*nido*-7,8-$C_2B_9H_{11}]^{2-}$ and its C-substituted derivatives have been known to form metal complexes for over 30 years.[2] However, the chemistry of these species is much less extensive than that of their cyclopentadienide analogs.[3] Herein we report the first rhenacarborane carbonyl nitrosyl compound, a useful synthon for preparing other species including the first isolable complexes with alkylidene groups ligating a metal centre in an M(η^5-7,8-R_2-7,8-$C_2B_9H_9$) (R = H, alkyl, aryl) group (Scheme 1).

Treatment of Cs[Re(CO)$_3$(η^5-7,8-$C_2B_9H_{11}$)] **1**[4] in tetrahydrofuran (THF) with [NO][BF_4] gave the stable complex [Re(NO)(CO)$_2$(η^5-7,8-$C_2B_9H_{11}$)] **2a** in high yield.† A range of complexes **2b**–**2h** have been synthesized from **2a** by substitution of one or both CO ligands. In a typical reaction **2a** reacts with excess CNBu^t in THF to give yellow crystals of [Re(NO)(CNBu^t)$_2$(η^5-7,8-$C_2B_9H_{11}$)] **2g**.†

Compound **2a** was treated initially with LiPh or Li[C_6H_4Me-4] and then with [Me_3O][BF_4]. Column chromatography on silica gel of the resulting mixture gave the alkylidene complexes [Re{=C(OMe)R}(NO)(CO)(η^5-7,8-$C_2B_9H_{11}$)] (R = Ph **3a**, C_6H_4Me-4 **3b**), respectively. The $^{13}C\{^1H\}$ NMR spectrum† of **3b** displays a diagnostic resonance for the alkylidene carbon nucleus at δ 295.1 to be compared with the NMR signal for this nucleus at δ 289.2 in the isolobal cation [Re{=*C*(OMe)C_6H_4Me-4}(NO)(CO)(η-C_5H_5)]$^+$.[5] The appearance in the ^1H and $^{13}C\{^1H\}$ NMR spectra of **3b** of only one signal for the OMe group indicated that only one enantiomeric pair of molecules was formed. An X-ray crystal structure analysis‡ established the structure (Fig. 1) and showed that the OMe and NO groups are transoid to one another [ϕ(NReC(9)O(4)) 163.5°]. The Re–C(9) bond distance [2.052(9) Å] is similar to that found [1.949(6) Å] for the alkylidene ligand in [Re(=CHPh)(NO)(PPh_3)(η-C_5H_5)][PF_6].[6] We have previously observed that when alkylidene ligands are exopolyhedral substituents on a tungsten centre in a *closo*-3,1,2-WC_2B_9 tungstacarborane complex they undergo rapid and irreversible hydroboration by an adjacent B–H bond in the cage $\overline{CCBBB}$ coordinating face.[7] Thus the formation and isolation of the complexes **3** was perhaps unexpected in icosahedral metallacarborane chemistry. Grimes and coworkers[8] have recently isolated the first transition metal alkylidene complex incorporating a sub-icosahedral metallacarborane, *viz*. [RuCo{=C(OMe)Ph}(CO)$_2$(η-C_5Me_5)(η^5-2,3-Et_2-5-Cl-2,3-$C_2B_3H_2$)]. This molecule comprises a ruthenium dicarbonyl phenylmethoxyalkylidene fragment pentacoordinated by the C_2B_3 face of a *nido*-cobaltacarborane ligand.

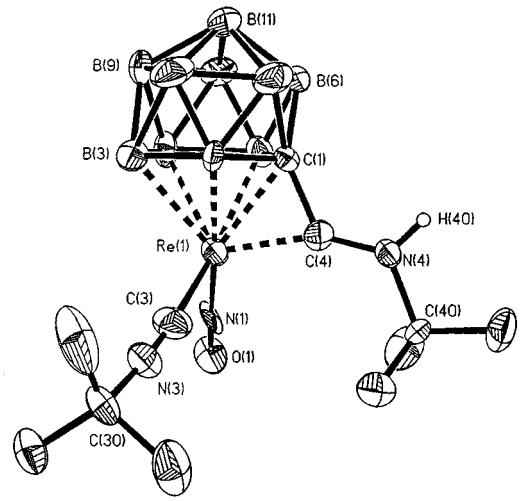

Fig. 2 Molecular structure of one of the independent molecules found in the asymmetric unit of **4** (thermal ellipsoids with 40% probability). Selected distances (Å) and angles (°): Re(1)–N(1) 1.769(11), Re(1)–C(4) 2.000(13), Re(1)–C(3) 2.02(2), C(1)–C(4) 1.49(2), N(1)–O(1) 1.206(12), C(3)–N(3) 1.14(2), C(4)–N(4) 1.29(2); N(1)–Re(1)–C(4) 111.9(5), N(1)–Re(1)–C(3) 93.0(5), C(4)–Re(1)–C(3) 101.3(5), O(1)–N(1)–Re(1) 174.1(11), N(3)–C(3)–Re(1) 173.3(14), C(3)–N(3)–C(30) 175(2), N(4)–C(4)–C(1) 127.6(12), N(4)–C(4)–Re(1) 154.7(11), C(1)–C(4)–Re(1) 76.2(7), C(4)–N(4)–C(40) 124.3(11).

protonation yields **4** (Scheme 2), formulated as a charge-compensated species. The structure was established by X-ray diffraction‡ (Fig. 2). Atom C(4) bridges the Re–C(1) connectivity [C(1)–C(4) 1.49(2), Re(1)–C(4) 2.000(13) Å]. Although the C(4)–N(4) distance [1.29(2) Å] is longer than C(3)–N(3) [1.14(2) Å] in the ligated isonitrile molecule it is somewhat shorter than that expected (1.34 Å) for a C=N double bond.[9] The NH proton is recognisable in the ^{1}H NMR spectrum† as a broad signal at δ 8.93, while in the ^{13}C{^{1}H} NMR spectrum the iminium carbon atom, which is both bound to the cage carbon vertex and to the rhenium centre (δ 218.8), can be readily distinguished from the ligating carbon atom of the classical isonitrile ligand (δ 137.7). The formation of **4** appears to be regioselective, since only one of several possible diastereomeric pairs of enantiomers was isolated. This may in part be due to the directive influence of the NO ligand and further studies with these complexes are in progress to examine this effect.

We thank the Robert A. Welch Foundation for support (Grant AA-1201).

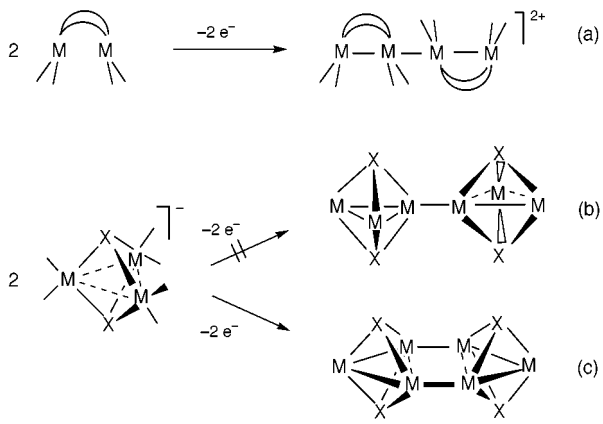
Received (in Basel, Switzerland) 20th September 1999, Accepted 25th October 1999

Oxidation of $[N(PPh_3)_2][Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6]$ with $[FeCp_2]PF_6$ gives the novel hexarhodium compound $[\{Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6\}_2]$, containing three nearly co-planar condensed metallic cycles forming a doubly-spiked square, by dimersisation of the trinuclear imidocomplex through the formation of unsupported metal–metal bonds.

Very recently we have reported a straightforward approach to tetrametallic rhodium and iridium chains by partial oxidation of appropriate dinuclear complexes.[1] After the electron abstraction, the hypothetical intermediate cations $[M^IM^{II}]^+$ promote a 'linear condensation' leading to an unsupported metal–metal bond between the two pairs of metal centres [Scheme 1(a)]. In a formal sense, the formation of this interdimer M–M bond could be related to simple C–C bond formation, assuming the similarity of the intermediate species $[M^IM^{II}]^+$ with organic radicals, for which coupling leading to dimerisation is a well known reaction. Looking for a similar condensation of triangular complexes induced by chemical oxidation one might expect doubly-spiked tetranuclear chains if a 'vertex-condensation' were operative [Scheme 1(b)]. However, other condensation schemes such as a 'bi-edge-condensation' would lead to a tetrametallic cycle [Scheme 1(c)].



Scheme 1 Possible pathways for the formation of metal chains and cycles. M = metal, X = capping ligand (NR).

We have recently reported the first tri- and tetra-nuclear organoimido rhodium clusters.[2] In the search to develop this chemistry, and looking for higher nuclearity imido clusters, we have turned our attention to the 'active M–M edge' of the trinuclear organoimido anion $[Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6]^-$. As the previously isolated salt[3] of this anion contains the redox active cation $[Rh(CO)(dppm)_2]^+$, we first prepared the new yellow compound $PPN[Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6]$ **1** by reacting $[Rh_4(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_7(cod)]_4$ with 2 mol equiv. of $[N(PPh_3)_2]Cl$ in dichloromethane and crystallization from diethyl ether.[5]

Oxidation of **1** in $CDCl_3$ with $[FeCp_2]PF_6$ (1:1 molar ratio) gives, immediately and quantitatively, an EPR silent emerald-green solution of $[\{Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6\}_2]$ **2**. The ^1H NMR spectrum is quite surprising because it shows only two new singlets, one for the aromatic protons, which are isochronous, and the other for the methyl groups. More informative is the $^{13}C\{^1H\}$ NMR spectrum, showing two carbonyl resonances (1:2 ratio) and four resonances corresponding to equivalent *p*-tolylimido ligands, which indicates that the trimetallic core capped by two *p*-tolylimido ligands is maintained in the new compound. Moreover, the resonances for *ipso*- and *ortho*-C appear as quartets by coupling with three rhodium atoms ($^3J_{RhC}$ 1.3 Hz). This green solution is obtained in a preparative scale in a similar way in dichloromethane. Red–green microcrystals of **2**[6] are isolated in high yield (> 75%) after evaporation of the solution to dryness, removal of $[FeCp_2]$ by washing the residue with hexane followed by extraction with diethyl ether {to remove $[N(PPh_3)_2]PF_6$}, and layering the extract with hexanes.

The molecular structure of **2**, determined by single crystal X-ray diffraction,[7] reveals a hexanuclear metallic core. Thus, the novel organimido rhodium cluster $[\{Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6\}_2]$ **2** consists of an almost planar tetrarhodium square with two opposite spiked edges generating a tricyclic hexametallic arrangement (Fig. 1) while four *p*-tolylimido ligands cap either side of the two metal triangles. Electron counting for **2** gives 94 valence electrons, *i.e.* two electrons less than the expected value (96 ve) for a cyclic hexametallic cluster, and two electrons over the expected counting for a doubly-spiked tetrametallic square (92 ve). The extra electron pair may be the cause of the long Rh–Rh separations for the edges connecting the fused cycles [Rh(1)···Rh(2) 3.1127(10) Å] when compared with the short Rh–Rh distances [2.7188(10) and 2.7048(9) Å] within the triangles, and the unsupported Rh–Rh bonds [Rh(1)–Rh(2′) 2.9921(9) Å] in the central square.

The formation of **2** from $[Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6]^-$ can be envisaged as a one-electron oxidation reaction leading to the neutral radical complex $[Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6]^{\cdot}$, which dimerises through the formation of two new unsupported Rh–Rh bonds. Accordingly, cyclic voltammetry measurements on **1** show an irreversible one-electron oxidation process at 0.57 V *vs.* SCE in CH_2Cl_2. However, a close inspection of this wave at fast scan rates (> 1 V s^{-1}) shows the observation of a very small reduction wave, which disappears at moderate scan rates, in accordance with a EC_{irrev} mechanism. In this case the C_{irrev} reaction ought to be the dimerisation process.

Furthermore, it is noteworthy that the major tendency of complex **1** is to undergo M–M coupling rather than C–C bond formation upon oxidation. Oxidative C–C coupling through the *para* carbon of the phenyl group in dinuclear rhodium phenyl imido/amido complexes has been reported by Sharp and coworkers,[8] and interpreted assuming that the proposed radical should be centred in the phenyl group. In our case, complex **1** shows a tunable donicity, *i.e.* it is able to coordinate metal fragments at the arene ring or at one rhodium–rhodium edge,[9] and therefore both processes, C–C coupling involving the phenyl group, and M–M coupling involving the Rh–Rh edge could *a priori* be possible. Most probably, the unpaired electron

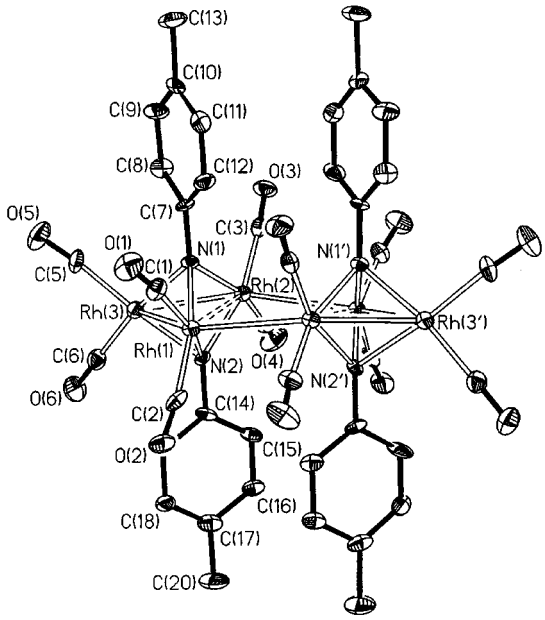


Fig. 1 Molecular diagram of $[\{Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6\}_2]$ **2**; the molecule has internal crystallographic twofold symmetry. Selected bond interatomic distances (Å) and angles (°): Rh(1)–Rh(3) 2.7188(10), Rh(1)–Rh(2′) 2.9921(9), Rh(2)–Rh(3) 2.7048(9), Rh(1)···Rh(2) 3.1127(10), Rh(1)–N(1) 2.028(6), Rh(1)–N(2) 2.069(6), Rh(2)–N(1) 2.081(6), Rh(2)–N(2) 2.041(6), Rh(3)–N(1) 2.051(7), Rh(3)–N(2) 2.063(6); Rh(2)···Rh(1)–Rh(3) 54.77(2), Rh(2)···Rh(1)–Rh(2′) 88.43(3), Rh(2′)–Rh(1)–Rh(3) 142.98(3), Rh(1)···Rh(2)–Rh(3) 55.19(2), Rh(1)···Rh(2)–Rh(1′) 90.38(3), Rh(1′)–Rh(2)–Rh(3) 144.83(3), Rh(1)–Rh(3)–Rh(2) 70.05(3), Rh(1)–N(1)–Rh(2) 98.5(3), Rh(1)–N(1)–Rh(3) 83.6(2), Rh(2)–N(1)–Rh(3) 81.8(2), Rh(1)–N(2)–Rh(2) 98.5(3), Rh(1)–N(2)–Rh(3) 82.3(2), Rh(2)–N(2)–Rh(3) 82.5(2) (primed atoms are related to their unprimed equivalent by the symmetry transformation: $y - 1, 1 + x, -z$).

in the proposed neutral radical $[Rh_3(\mu\text{-}NC_6H_4Me\text{-}p)_2(CO)_6]^{\cdot}$ is delocalized in the trimetallic core. This interpretation provides a facile explanation for the formation of the hexametallic cluster by fusion of the two edges from two trimetallic triangles leading to **2**, in which the metals present formal fractional oxidation states.

The condensation reactions induced by oxidation [Scheme 1(a) and (c)] operate selectively depending on the structure of the starting materials and products, *i.e.* tetrametallic chains ('linear condensation') result from dinuclear complexes and tetrarhodium cycles ('bi-edge condensation') from a trinuclear complex. The origin of the selectivity is probably related to the presence of the third metallic centre, which plays a non-innocent role, since the metal–metal edge in the trinuclear complexes is more accessible for a close approach of a substrate to both metals than in a dinuclear species, thus allowing the formation of the tetrametallic cycle for the former whilst vertex condensation is preferred for the latter.

The result of an electron transfer reaction on a cluster is, in general, quite unpredictable. Fragmentation, isomerisation, rearrangement and distortion of clusters are common outcomes from cluster redox reactions in addition to well documented cases where the electron loss/addition processes proceeds cleanly with M–M bond formation/cleavage.[10,11]

Clusters with fixed capping groups based on group 15 elements are versatile in undergoing oxidation and/or reduction reactions.[12] However, to the best of our knowledge, a dimerisation of clusters induced by oxidation, such as shown here, is unusual. Moreover, the chemical oxidation of polynuclear compounds of low-valent electron-rich metals with capping groups in which metal–metal bonds are not evident represents a significant challenge for the creation of higher nuclearity species by methods other than redox-condensation using mononuclear metal fragments.

The generous financial support from DGES (Projects PB95-221-C1 and PB94-1186) and a fellowship (to M. B.) are gratefully acknowledged. We also thank Dr E. Gutierrez Puebla (ICMM-CSIC) for facilities and infrastructure to carry out X-ray data collection.

Clathrate formation between halogenated species

A. Noman M. M. Rahman, Roger Bishop,* Donald C. Craig and Marcia L. Scudder

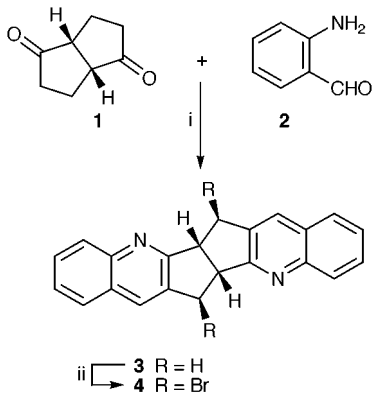
School of Chemistry, The University of New South Wales, Sydney 2052, Australia. E-mail: r.bishop@unsw.edu.au

Received (in Cambridge, UK) 10th September 1999, Accepted 19th October 1999

Analysis of X-ray crystallographic data reveals how the *exo,exo*-dibromodiquinoline derivative 4 encloses small halogenated guests as clathrate structures.

Clathrate compounds can result where molecules of a pure compound are unable to achieve efficient crystal packing by themselves.[1] This provides a strong driving force for inclusion of suitable guests but makes the design of new lattice inclusion systems a considerable synthetic challenge.[2]

Reaction of racemic bicyclo[3.3.0]octane-2,6-dione **1** and *o*-aminobenzaldehyde **2** gives the Friedländer condensation[3] product **3**† (Scheme 1). Molecules of this diquinoline derivative pack together efficiently in the solid phase and so exhibit no inclusion properties. Benzylic bromination of **3** affords the racemic dibromide **4**† which, in marked contrast, is an efficient host molecule. This change in behaviour was anticipated since its C_2 symmetry provides a favourable scissor topology[4] and since the *exo*-bromine sensor groups[4] destabilise potential aryl offset face–face attractions[5] and provide additional modes for intermolecular packing.[6]



Scheme 1 *Reagents and conditions*: i, NaOH, H_2O, MeOH, 75%; ii, NBS, CCl_4, 78%.

Crystallisation of **4** from $MeCCl_3$ gave crystals of **4**·$(MeCCl_3)_{0.5}$ whose structure‡ in space group *C*2/*c* was determined by single crystal X-ray determination. Pairs of host molecules, related by a two-fold axis, enclose each disordered guest within a molecular pen of nearly square cross-section where the aromatic faces of **4** act as the surrounding fences (Fig. 1). If these host pairs were covalently linked at the corners of this structure the result would be a cyclophane[7] but, in fact, there is not even significant intermolecular attraction. Although pens thus only result from the net outcome of all lattice attractions (see Table 1) in the clathrate it is convenient to retain this term as a descriptor. There is a planar array of pens (Fig. 2) all constructed using the same enantiomer of **4**, and the slightly offset adjacent layers of pens are built from the second enantiomer.

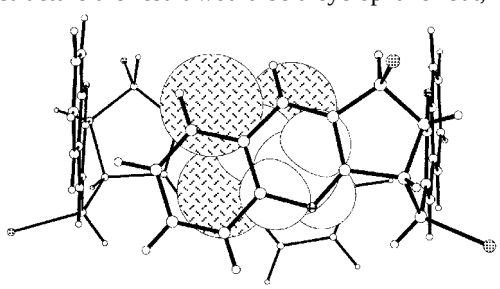


Fig. 1 Side view of the square molecular pen of **4**·$(MeCCl_3)_{0.5}$ showing the two host molecules (framework representation) acting as fences enclosing a $MeCCl_3$ guest (space-filling representation). The guest chlorine atoms are indicated by cross-hatching.

Table 1 Potential and actual supramolecular synthons operating in the clathrate structure **4**·$(MeCCl_3)_{0.5}$

Supramolecular synthon	Partners	Atoms involved	Distances/Å
Aryl offset face–face[a]	Host–host[b]	Ar···Ar	3.55
Aryl edge–face[a]	Host–host	Ar-*H*···*Ar*	Not present

Aryl-alkyl[c]	Host–guest[b]	*Ar*···H_3C[g]	3.65, 3.66
Interhalogen[e]	Guest–guest	Cl···Cl	Not present

[a] Ref. 10. [b] Within layers. [c] Ref. 5. [d] Between layers. [e] Ref. 11. [f] Ref. 12. [g] Aromatic ring centroids used. [h] Values under 4.00 Å only.

Comparatively strong intermolecular forces (such as hydroxy group hydrogen bonding) are not used in the design of host **4**. Instead, a number of relatively weak interactions such as aryl offset face–face, aryl edge–face, aryl C–H···N dimer, aryl–halogen and interhalogen attractions are available for potential combinations of **4** and $MeCCl_3$. Since it is the best overall combination of these synthons[6] (along with size, shape and conformational factors) which determines the structure, some of

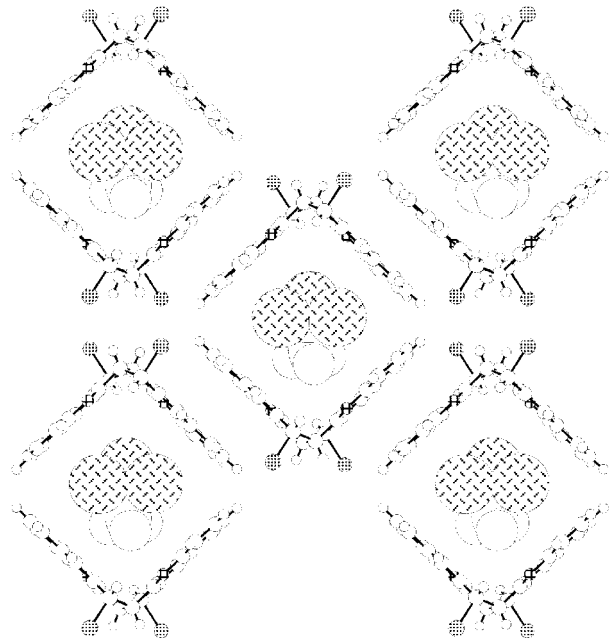

Fig. 2 Top view of part of a layer of the square molecular pens in **4**·$(MeCCl_3)_{0.5}$ showing how these are arranged in regular rows. The host bromine atoms are stippled and guest chlorine atoms cross-hatched. $MeCCl_3$ guests are shown in just one of their disorder positions.

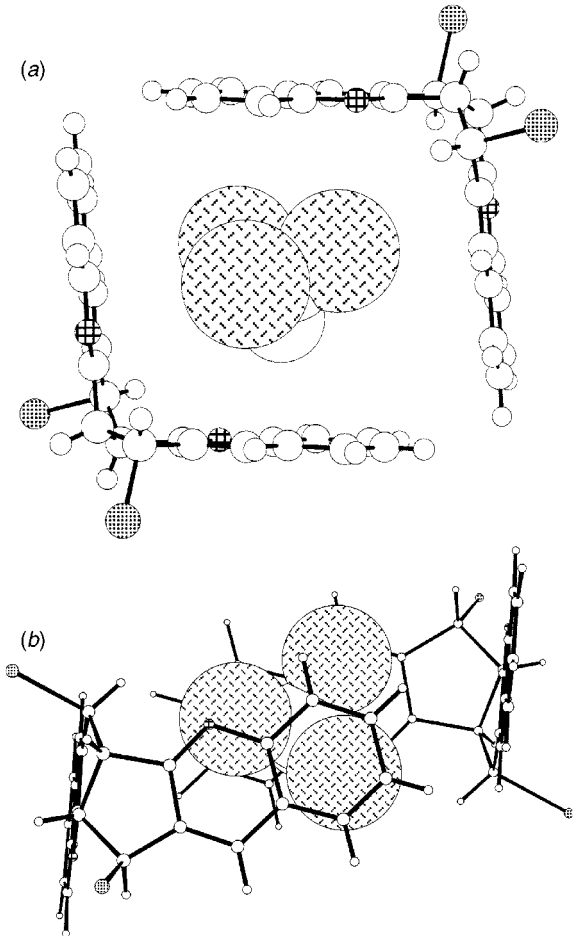

Fig. 3 (*a*) One of the two types of parallelogram-shaped molecular pens present in the clathrate structure **4**·$(CHCl_3)_{0.5}$. (*b*) Side view of the inclusion compound showing its overall parallelepiped geometry.

these turn out not to be used in **4**·$(MeCCl_3)_{0.5}$ while others (including the aryl C–H···N dimer[5]) do play a major role (Table 1).

The central bicyclic ring of the host molecule potentially allows considerable conformational mobility since, for example, the much flatter bis(*N*-oxide) derivative of **3**† has an angle of 133.4° between the normals to the two aromatic planes. It is significant that the two aromatic faces of **4** are almost orthogonal in the $MeCCl_3$ compound (97.7°). This allows maximisation of aryl–halogen and aryl–alkyl interactions between the π-deficient quinoline host and the nearly spherical electron-rich guest. Hence host **4** exhibits molecular tweezer characteristics[8,9] whereby two host molecules wrap around each $MeCCl_3$ guest.

The detailed energetic interplay changes with differing guests. Crystals of **4**·$(CHCl_3)_{0.5}$ were obtained from $CHCl_3$ solution. This structure‡ is more complex, but pairs of host molecules still enclose disordered guests in the same manner despite the changes in guest and space group ($P2_1/c$). Each molecular pen is now centrosymmetric and there are two crystallographically distinct pens (A and B) present in the lattice (angles 97.6 and 100.8° respectively). Both have a more parallelogram-like cross-section than previously (Fig. 3) and they stack alternately (-A-B-A-B-A-). Where these stacks abut, however, there is no layer formation. The pens are not parallel to each other along the stacks, but rather tilt somewhat back and forth.

The same types of intermolecular attractions operate in this second clathrate, but with different geometries. Unexpectedly, although the versatile aryl C–H···N dimer still operates between opposite enantiomers of **4**, this time it is non-centrosymmetric with two distinct *C*–H···*N* distances (3.45 and 3.49 Å). This is the first reported example of such behaviour for this motif.[5]

These preliminary results reveal the dibromide **4** to be an unusual new lattice inclusion host. The interplay of host–guest attractions results in molecular enclosure tailored to the requirements of the particular guest. The further inclusion behaviour of this host compound is under active investigation.

We gratefully acknowledge financial support from the Australian Research Council.

Notes and references

† The structures of all new compounds are based on IR, MS, ^{1}H and ^{13}C NMR spectroscopy and single crystal X-ray structural determinations.

Received (in Cambridge, UK) 5th October 1999, Accepted 20th October 1999

A series of highly efficient, chemically and thermally stable (> 310 °C) nonlinear optical chromophores were prepared through the replacement of the most reactive CN group in tricyanovinylthiophene derivatives with perfluoroaryl units.

In practice, polymer based electro-optic (E-O) devices require that nonlinear optical (NLO) polymers possess excellent E-O properties. The large E-O coefficient (r_{33}) of a polymer is generally realized by aligning the dipole moment (μ) of efficient NLO chromophores with a high external electric field at a temperature above the glass-transition temperature (T_g) of the polymer.[1] Therefore, chromophores with large molecular nonlinearity (β) are crucial to the advancement of NLO polymers, and have drawn interest in their theory-guided design and state-of-the-art synthesis.[2] Among them, a series of highly polarizable chromophores based on tricyanovinyl-substituted heteroaromatic chromophores have demonstrated very large $\beta\mu$ values.[3] Although poled E-O polymers with these chromophores incorporated either as a guest in a host polymer or as a side-chain polymer have exhibited large electro-optic coefficients (r_{33}), there are several deficiencies associated with these materials [Fig. 1(*a*)]. For instance, the α-position of the tricyanovinyl acceptor is very susceptible to attack from nucleophiles, which may easily diminish the nonlinearity of the chromophores.[4] On the other hand, the flat structures of these charge-transfer chromophores have a strong tendency to form aggregates in a polymer matrix due to intermolecular electrostatic interactions.[5] This results in lower poling efficiency and a higher light-scattering optical loss. To overcome these problems, a strategy was designed to replace the α-CN with a bulky and electron-deficient moiety which is also inherently not a good leaving group. Here, the tetrafluoropyridyldicyanovinyl (TFPD) and the heptafluorotolyldicyanovinyl (HFTD) acceptors were adapted to improve the efficiency and chemical and thermal stability of NLO chromophores. As shown in the Fig. 1(*b*), the perfluoroaryl group blocks the α-position, prevents attack from amine nucleophiles[4] and greatly improves the chemical stability of the derived chromophores. In addition, due to their electron-deficient characteristics, these perfluoroaryl groups will enhance the strength of the dicyanovinyl acceptor, and subsequently increase the β of the chromophores.[6a] Furthermore, from simple MOPAC molecular modeling, the perfluoroaryl group is twisted out of the main conjugation plane due to steric hindrance. The 3-D structure may help to prevent intermolecular electrostatic interactions among the chromophores, which in turn may enhance the poling efficiency and decrease the scattering-induced optical loss.[6]

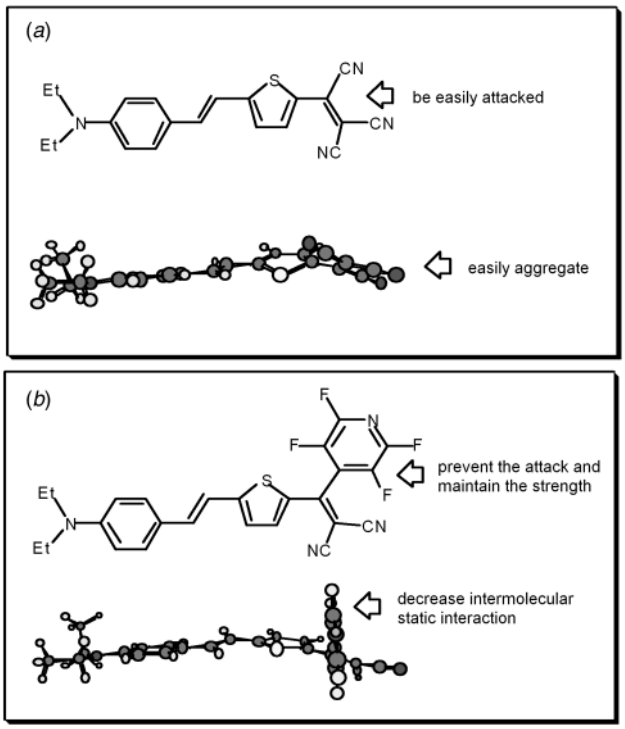

Fig. 1 Simple MOPAC modeling: (*a*) tricyanovinyl chromophore **1**; (*b*) α-perfluropyridyldicyanovinyl chromophore **1a**.

The general synthetic route for the α-perfluoroaryldicyanovinyl-containing chromophores is shown in Scheme 1. Tetrafluoropyridyllithium was prepared by the lithiation of tetrafluoropyridine with BuLi at −70 °C. Heptafluorotolyllithium was generated by the lithium–halogen exchange reaction of the heptafluoro-*p*-tolyl bromide with 2 equiv. of Bu^{t}Li at −78 °C. To the prepared perfluoroaryllithium solutions in THF at −70 °C, tricyanovinyl chromophores were added neat in one portion and the reaction mixtures were stirred at −70 °C for 1 h then warmed slowly to room temperature to give compounds **1a**–**3a** and **1b**–**3b** after purification by silica gel chromatography. All of the compounds were fully characterized by ^{1}H NMR and elemental analysis.

The chemical stability of the chromophores to a nucleophile was tested in a $CHCl_3$ solution that was saturated with a large excess of Et_2NH. The UV–VIS absorption spectra of these perfluoroaryldicyanovinyl containing chromophores showed excellent chemical stability in a nucleophilic environment (Fig. 2), unlike their tricyanovinyl analog which was almost instantaneously decolored.

The charge-transfer (CT) properties, electrochemical properties and intrinsic thermal stabilities of these chromophores are shown in Table 1. These perfluoroaryldicyanovinyl-containing chromophores have a blue-shifted CT band when compared to their corresponding tricyanovinyl counterparts. For instance, the λ_{max} valves of **1a** and **1b** in dioxane are located at 595 and 590 nm, respectively, while **1** is at 640 nm. The further deviation of the absorption band from the operating wavelengths of the lasers for telecommunication may help to decrease the absorption optical loss. However, the blue-shifted λ_{max} valves of both chromophores also indicated a decrease in strength of the new electron acceptors. This notion was supported by electrochemical measurements using cyclic voltammetry (CV).[7] The new chromophores **1a** and **1b** both

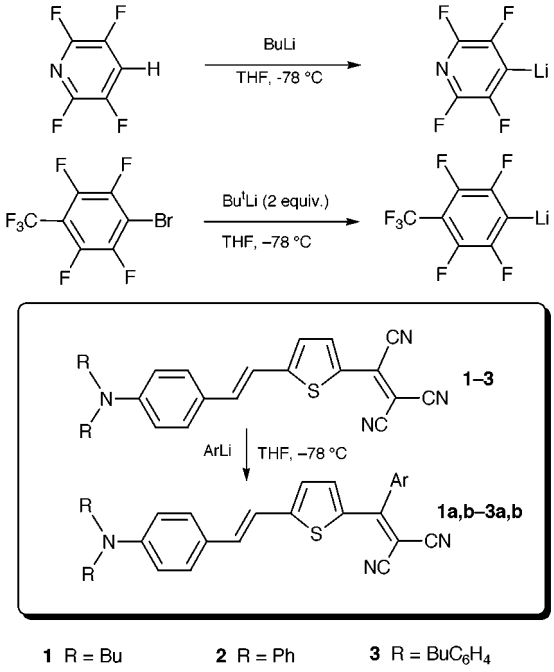

Scheme 1

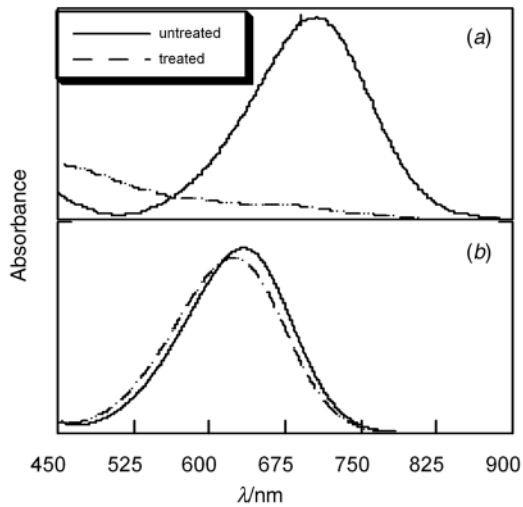

Fig. 2 Testing of the chemical stability of chromophores: a dilute solution of chromophore in $CHCl_3$ was treated with Et_2NH: (*a*) tricyanovinyl chromophore **1**; (*b*) α-perfluropyridyldicyanovinyl chromophore **1a**.

possess higher reduction potentials, at −1.02 and −1.04 V, respectively, when compared to −0.80 V for the parent compound **1**.

Thermal stability measurements using sealed pan differential scanning calorimetry (DSC) revealed that these chromophores possess excellent thermal stabilities (310–390 °C) which are much higher than that of **1** (240 °C).

Optical and E-O studies were performed on the polymers (guest–host) in which chromophores **1a** and **1b** (25 wt%) were formulated into polyquinoline (PQ-100). Optical quality thin films were spin-coated onto glass slides and indium-tin-oxide (ITO) glass substrates using a 12% w/w solution of the resin in cyclopentanone. These films were heated at 85 °C *in vacuo* for 24 h and then briefly baked on a hot stage (160 °C) under nitrogen for 20 min to remove the residual solvent. The dipole alignment of the chromophores was achieved by poling with a high electric field of 1.0 MV cm^{-1} at 200 °C. The r_{33} values of NLO polyquinoline films of **1a** and **1b** were 16 and 14 pm V^{-1} at 1.3 μm. The slight decrease in the E-O coefficients when compared to **1** may be attributed to several factors, such as the lower number density of **1a** and **1b** because of the higher molecular weights of these compounds, and the weaker electron-withdrawing ability of perfluoroaryldicyanovinyl.

Table 1 Properties of chromophores

	λ_{max}/nm[a]	E^0_{Red}/V[b]	E^0_{Ox}/V[b]	T_d/°C[c]
1	640	−0.80	0.56	240
2	601	N/A	N/A	315
3	625	N/A	N/A	315
1a	595	−1.02	0.52	320
2a	554	−0.98	0.73	390
3a	577	−1.01	0.61	360
1b	591	−1.04	0.56	310
2b	553	−1.03	0.72	340
3b	573	−1.04	0.61	370

[a] In a dilute dioxane solution. [b] In a $ClCH_2CH_2Cl$ solution of Bu_3NPF_6 (0.1 M), *vs.* Ag^+/Ag. [c] Sealed-pan DSC measurement in N_2, 20 °C min^{-1}.

The optical loss of the NLO polymer films (< 2 dB cm^{-1} measured at 1.3 μm) is much less than 6.0 dB cm^{-1} for a similar film containing a tricyanovinyl-substituted chromophore.[8] This supports our hypothesis that the 3-D structure of these perfluoroaryldicyanovinyl groups will prevent chromophores from forming aggregates.

In summary, a series of highly efficient, chemically and thermally stable (> 310 °C) nonlinear optical chromophores were prepared through the replacement of the most reactive CN group in tricyanovinylthiophene derivatives with perfluoroaryl units. The incorporation of these chromophores into high temperature polyquinoline demonstrated both high E-O properties and low optical loss.

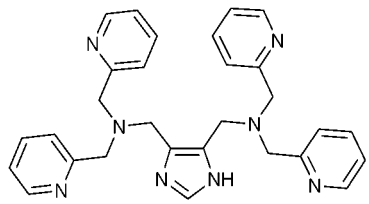
Received (in Cambridge, UK) 2nd August 1999, Accepted 25th October 1999

A novel imidazolate-bridged Cu(II)–Zn(II) heterodinuclear complex of an imidazole derivative containing two metal-binding groups has been synthesized, and its structure and properties have been clarified.

Copper–zinc superoxide dismutase (Cu, Zn-SOD) contains an imidazolate-bridged Cu–Zn heterodinuclear metal center in its active site.[1–3] This enzyme catalyzes the dismutation of highly toxic superoxide anion produced as a byproduct to dioxygen and hydrogen peroxide in a sequence of dispersion-controlled reactions.[4] Since the enzyme structure was determined by X-ray analysis,[1] the unique active site structure attracted much attention, and a number of imidazolate-bridged complexes, such as the Cu(II)-Cu(II) homodinuclear complexes by Lippard *et al.*,[5] have been reported as mimics of the metal site and provided valuable insights into the structure and properties of the SOD active site. In contrast to this, only a few imidazolate-bridged Cu(II)–Zn(II) heterodinuclear model complexes have so far been reported.[6] Because such model complexes are often constructed by self-assembly of one or two complex units by incorporating a bridging imidazolate ring, the labile nature of Cu(II) and Zn(II) complexes and dissociation of self-assembled structures made it difficult to study in detail their structures in solution and SOD functions. We here report the first imidazolate-bridged Cu(II)–Zn(II) heterodinuclear complex derived from a new imidazole derivative, Hbdpi {Hbdpi = 4,5-bis[di(2-



Hbdpi

pyridylmethyl)aminomethyl]imidazole}, which has two sets of 3N donor groups tethered to the 4 and 5 positions of the bridging imidazole ring.

Hbdpi was prepared from imidazole-4,5-dialdehyde[7] and bis(2-pyridylmethyl)amine by reductive aminomethylation using sodium cyanoborohydride in methanol, and was characterized by ^{1}H and ^{13}C NMR.‡ The heterodinuclear Cu(II)–Zn(II) complex of bdpi, $[CuZn(bdpi)(MeCN)_2](ClO_4)_3{\cdot}2MeCN$ **1**, was obtained as crystals by mixing Hbdpi and equimolar amounts of Cu(II) and Zn(II) in methanol and subsequent addition of triethylamine, and the composition of the dried sample of **1** was determined by elemental analysis, ICP, and ESI-mass spectral measurements. The corresponding Cu(II)–Cu(II) homodinuclear complex, $[Cu_2(bdpi)(MeCN)_2](ClO_4)_3{\cdot}2H_2O$ **2** was prepared in a similar manner using two equivalents of Cu(II).

The molecular structure of complex **1** was determined by X-ray analysis§ and is depicted in Fig. 1. As expected, the complex has an imidazolate-bridged dinuclear structure. In line with the previous observation,[6d] the copper and zinc sites are very similar to each other and indistinguishable, because the complex has a C_{2v}-like axis and both metal sites are statistically disordered. The metal ions are both in an approximately trigonal bipyramidal geometry with four nitrogen atoms of bdpi and a nitrogen atom of the solvent MeCN coordinated. The coordination site occupied by MeCN may be susceptible to ligand substitution, providing a possible binding site for substrate superoxide. The Cu(II)–Zn(II) distance of 6.197(2) Å in **1** is the same as that of native Cu, Zn–SOD (6.2 Å).[1]

The electronic spectrum of an acetonitrile solution of **1** (1 mM) showed two broad d–d bands at 645 and 880 nm (ε = 60 and 220 M^{-1} cm^{-1}, respectively). This spectrum is very close to that of $[Cu(tpa)Cl]PF_6$ [tpa = tris(2-pyridylmethyl)amine], indicating a trigonal bipyramidal structure at the copper site.[8] In addition, it exhibited an imidazolate-to-Cu(II) charge transfer (CT) band at 320 nm (ε = 1500 M^{-1} cm^{-1}). The intensities of the d–d and CT bands for **1** were half as strong as those observed for **2** at 645, 880 and 320 nm (ε = 110, 420 and 3000 M^{-1} cm^{-1}, respectively). The EPR spectrum of a solution of **1** (0.5 mM) in 1 : 1 MeCN–MeOH at 77 K ($g_{//}$ = 2.10, $g_{\perp}$ = 2.24 and $|A_{\perp}|$ = 12.0 mT) showed a line shape characteristic of mononuclear trigonal bipyramidal Cu(II) complexes,[9] but was very different from that of **2** having a single symmetrical derivative (g = 2.13**)**, which is similar to the spectrum of the imidazolate-bridged Cu(II)-glycylglycinate complex[10] and other imidazolate-bridged Cu(II)–Cu(II) dinuclear complexes.[11] These results as well as the ESI-mass spectrum in MeCN demonstrate that **1** in solution retains its imidazolate-bridged

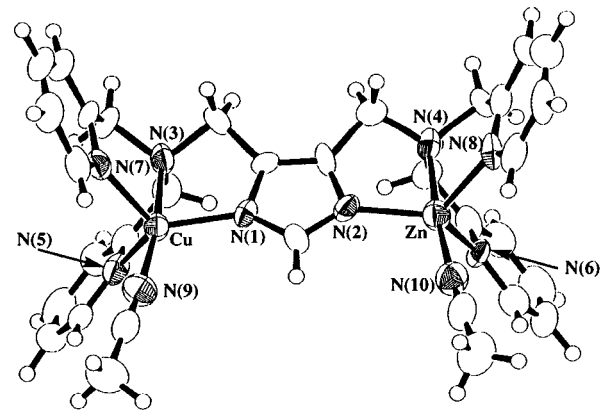


Fig. 1 X-Ray structure of complex **1** (perchlorate ions and the MeCN molecule of crystallization are omitted for clarity, and the Cu and Zn sites were so assigned that smaller R and R_w values could be obtained). Selected bonds (Å) and angles (°): Cu(1)–N(1) 2.001(7), Cu(1)–N(3) 2.104(7), Cu(1)–N(5) 2.074(7), Cu(1)–N(7) 2.105(8), Cu(1)–N((9) 2.004(9), Zn(1)–N(2) 2.005(7), Zn(1)–N(4) 2.112(7), Zn(1)–N(6) 2.076(8), Zn(1)–N(8) 2.084(7), Zn(1)–N(10) 2.023(10), N(1)–Cu–N(3) 82.5(3), N(1)–Cu(1)–N(5) 122.5(3), N(1)–Cu(1)–N(7) 118.3(3), N(3)–Cu(1)–N(9) 172.9(3), N(2)–Zn(1)–N(4) 83.0(3), N(2)–Zn(1)–N(6) 120.3(3), N(2)–Zn(1)–N(8) 120.1(3), N(4)–Zn(1)–N(10) 174.8(3).

† Present address: Department of Material and Life Science, Graduate School of Engineering, Osaka University, Suita, Osaka 565-0871, Japan.

Cu(II)–Zn(II) heterodinuclear structure and is not a 1:1 mixture of Cu(II)–Cu(II) (**2**) and Zn(II)–Zn(II) complexes. Whereas the cyclic voltammogram of **2** in MeCN exhibited two reversible redox waves at $E_{1/2}$ −0.09 and +0.19 V (*vs*. NHE), **1** showed only one reversible Cu(I)/Cu(II) redox couple at $E_{1/2}$ +0.19 V (*vs*. NHE), confirming that it has one copper ion site in the molecule. In this connection, an imidazolate-bridged asymmetric dinuclear Cu(II) complex showed one broad peak in the anodic and the cathodic wave,[12] and several mononuclear trigonal bipyramidal Cu(II) complexes of tripodal ligands containing pyridine and imidazole donors have been reported to have $E_{1/2}$ values between −0.187 and −0.290 V *vs*. NHE.[13] The positive shift of the $E_{1/2}$ values of **1** as compared with other mononuclear Cu(II) complexes may therefore be attributed to the electronic effect of the imidazolate-bound Zn(II), which could be an important factor for the efficient catalytic reaction of Cu, Zn–SOD. The SOD activities of **1** and **2** have been investigated by the cytochrome *c* assay[14] using the xanthine oxidase reaction as the source of superoxide. The IC_{50} values for **1** and **2** were determined to be 0.24 and 0.32 μM [*vs*. Cu(II) ion], respectively, which are higher than the value reported for native Cu, Zn–SOD (0.04 μM)[15] but comparable with the values of some structurally established model complexes.[6d,12,15] In addition, the IC_{50} value for $[Cu(tpa)(MeCN)](ClO_4)_2$ was determined to be 1.4 μM. The difference in IC_{50} among **1**, **2** and $[Cu(tpa)(MeCN)](ClO_4)_2$ may be ascribed to the imidazolate-bridge and zinc ion. The effect of zinc ion was recently reported for a Cu–Zn heterodinuclear complex prepared *in situ*, which was not structurally established.[16]

In conclusion, the new imidazole derivative containing two metal-binding groups incorporated Cu(II) and Zn(II) to form a heterodinuclear SOD model complex which was stable in solution, and the SOD activity measurements exhibited the effects of the imidazolate bridge and zinc ion on the SOD activity. Studies on the details of the SOD function and mechanism are now under way.

We are grateful to Prof. Wasuke Mori, Kanagawa University, for measurements of the magnetic susceptibility, Professor Hiromu Sakurai, Kyoto Pharmaceutical University, for measurements of the SOD activity and Sachiyo Nomura, Institute for Molecular Science, for ICP measurements. (Nos. 09304062 and 09045032) from the Ministry of Education, Science, Sports and Culture of Japan, to which our thanks are due.

Notes and references

‡ *Experimental:* imidazole-4,5-dialdehyde (1.0 g, 8 mmol) was dissolved in methanol (100 ml), to which bis(2-pyridylmethyl)amine (3.2 g, 16 mmol) and a small amount of acetic acid were added. Sodium cyanotrihydroborate (1.0 g, 15.5 mmol) was then added dropwise to the mixture, and after the resulting solution had been stirred for three days at room temperature, it was acidified with concentrated HCl and concentrated almost to dryness under reduced pressure. The residue was dissolved in a saturated aqueous solution of Na_2CO_3 (50 ml) and extracted with three 50 ml portions of $CHCl_3$. The combined extracts were dried over Na_2SO_4 and after removal of the solvent gave a brown oily product, which was purified by silica gel column chromatography with $CHCl_3$–MeOH as eluent to give Hbdpi (3.16 g, 80.0%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.65 (s, 4H), 3.75 (s, 8H), 7.12 (m, 4H), 7.47 (dt, 4H), 7.61 (td, 4H), 7.66 (s, 1H), 8.51 (dq, 4H). ^{13}C NMR ($CDCl_3$; 100 MHz) δ 48.2 (CH_2), 59.2 (CH_2), 121.7 (Py), 122.0 (Im), 123.2 (Py), 133.8 (Im), 136.2 (Py), 148.4 (Py), 158.9 (Py). Complex **1** was prepared by mixing Hbdpi (0.50 g, 1.0 mmol) with a MeOH solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (0.370 g, 1.0 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (0.372 g, 1.0 mmol) and adding NEt_3 (138.6 μl, 1.0 mmol). After filtration, the filtrate was allowed to evaporate slowly in the open air to give $[CuZn(bdpi)(MeCN)_2](ClO_4)_3{\cdot}2MeCN$ **1** as green crystals in 67.0% yield. Elemental analysis and ICP measurement were performed for the dried sample which lost the coordinated MeCN. The ratio of Cu(II) to Zn(II) was determined by ICP (SEIKODENKO SPS-700) with the use of the standard solutions (1000 ppm) of Cu(II) and Zn(II) obtained from Nacalai Tesque. Anal. Calc. for $[CuZn(bdpi)](ClO_4)_3{\cdot}0.25MeCN{\cdot}3H_2O$ ($C_{29.5}H_{35.75}N_{8.25}Cl_3O_{15}CuZn$): C, 36.11; H, 3.67; N, 11.78; Cu, 6.48; Zn, 6.66. Found: C, 35.88; H, 3.56; N, 11.77; Cu, 6.46; Zn, 6.65%. ESI-mass (MeCN): *m/z* 816 [$(M - ClO_4)^+$]. $[Cu_2(bdpi)(MeCN)_2](ClO_4)_3{\cdot}2H_2O$ **2** was prepared in a similar manner by using Hbdpi and 2 equiv. of $Cu(ClO_4)_2{\cdot}6H_2O$. Elemental analysis and ICP measurement were performed for the dried sample. Anal. Calc. for $[Cu_2(bdpi)](ClO_4)_3{\cdot}MeCN$ ($C_{31}H_{32}N_9O_{12}Cl_3Cu_2$): C, 38.94; H, 3.37; N, 13.18; Cu, 13.29. Found: C, 38.95; H, 3.32; N, 13.35; Cu, 13.27%. Effective magnetic moment μ_{eff} = 3.46 μ_B (300 K).

§ *Crystal data:* **1** (green): $[CuZn(bdpi)(MeCN)_2](ClO_4)_3{\cdot}2MeCN$, $C_{37}H_{41}N_{12}O_{13}Cl_3CuZn$, M = 1083.09, triclinic, space group $P\bar{1}$, a = 14.447(1), b = 14.561(1), c = 12.214(1) Å, α = 108.002(7), β = 106.920(7), γ = 89.069(7)°, V = 2330.3(4) Å^3, Z = 2, D_c = 1.508 g cm^{-3}, 5067 reflections collected, 4821 independent reflections, 3209 reflections used, 596 variables, R = 0.076, R_w = 0.110 [$I > 2.00\sigma(I)$]. The crystal was poorly diffracting. Rigaku AFC-5R four-circle automated diffractometer with graphite monochromated Cu-Kα radiation, λ = 1.54178 Å, and rotating anode generator. The structures were solved by the heavy-atom method and refined anisotropically for non-hydrogen atoms by full-matrix least-squares calculations. Hydrogen atoms for the structure were located from difference Fourier maps, and their parameters were isotropically refined. All the calculations were performed by using the teXsan crystallographic software package from the Molecular Structure Corporation. CCDC 182/1462. Selective control of sensitivity to imidazole derivatives of interference-based biosensors by use of a phase transition gel

Tetsu Tatsuma, Hiroshi Mori and Akira Fujishima

Department of Applied Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: akira_fu@fchem.chem.t.u.-tokyo.ac.jp

Received (in Cambridge, UK) 14th September 1999, Accepted 25th October 1999

Sensitivity to histidine of an interference-based biosensor coated with a phase transition gel is controlled by swelling and shrinking the gel, while that to imidazole is not changed significantly.

Interference-based biosensors are used for the detection and determination of inhibitors for biocatalysts including enzymes.[1] Inhibitors for enzymes are generally toxic and interference-based biosensors are more sensitive to a large number of toxic inhibitors. However, such sensors are essentially unselective to a specific inhibitor. For example, a sensor based on cytochrome oxidase is sensitive to cyanide, azide and H_2S[2] while a biosensor based on heme peptide (HP) is also sensitive to some inhibitors including imidazole and histidine.[3,4]

If one wishes to determine two inhibitors at the same time, two independent pieces of information have to be acquired. In response to this, an electrochemical/piezoelectric dual response biosensor was developed by modifying an electrode of a quartz crystal resonator with HP.[5] In this case, a decrease in the catalytic activity of HP (for H_2O_2 reduction) and an increase in the mass of the bound inhibitor are measured on the basis of the catalytic current and the resonance frequency, respectively. This dual transduction system is, however, not simple since both electrochemical and piezoelectric equipment must be employed. An alternative way to obtain two independent kinds of information is the use of a sensor array with some different biocatalysts. However, a two-channel electrochemical set-up and two different, but similar biocatalysts are necessary.

In the present work, a single interference-based biosensor is coated with a gel that exhibits a volume phase transition.[6] Permeability of the gel to substances can be controlled by changing an environmental factor, such as temperature. As the gel is shrunk, the permeability to some substances may be lowered, due chiefly to the reduced pore size of the polymer network. In this case, the suppression of the permeability to a large molecule should be more significant than that to a small molecule. On the basis of this effect, we intended to selectively control the sensitivity of the interference-based biosensor to inhibitors (Fig. 1). As a result, we are able to acquire two independent pieces of information, one from the sensor in the swollen state and the other from the sensor in the shrunken state.

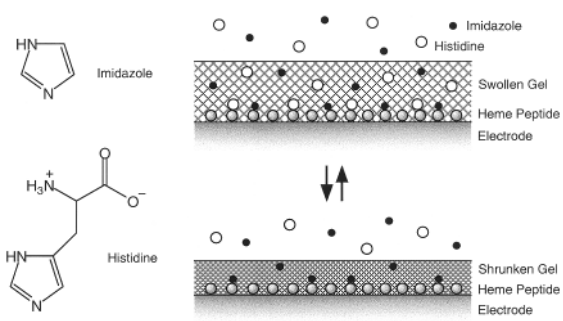

Fig. 1 Schematic depiction for the selective control of sensitivity to imidazole and histidine by shrinking and swelling the gel coated on a heme peptide-modified electrode.

This technique should also be important for the control of the apparent activity and selectivity of biocatalysts. Phase transition gels have been used to control the apparent activity of an enzyme immobilized in or on the gel.[7–14] However, to the best of our knowledge, the selective control of the apparent activity (equivalent to the sensitivity of a sensor) has not, as yet, been reported.

An indium tin oxide (ITO)-coated glass plate (area *ca.* 0.25 cm^2) was treated with a 10% toluene solution of (3-aminopropyl)triethoxysilane to introduce the amino group onto the electrode surface. The electrode was then treated with pH 7.4 phosphate buffer (0.0667 M) containing 1 g L^{-1} heme undecapeptide (HP, Sigma) and 20 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide so as to immobilize HP covalently to the electrode surface *via* amide bonding. The HP electrode thus obtained was further coated with a phase transition gel to obtain a gel–HP electrode. A 10 μL aliquot of a freshly prepared aqueous solution containing 700 mM *N*-isopropylacrylamide (NIPA), 7 mM *N*,*N*′-methylenebisacrylamide as a cross-linking agent, 0.087 mM $(NH_4)_2S_2O_8$ as a polymerization initiator, and 39 mM *N*,*N*,*N*′,*N*′-tetramethylethylenediamine as a reaction accelerator was applied to the electrode surface and was left for 5 h to obtain a gel. The gel–HP electrode thus obtained was then rinsed thoroughly with water (< 30 °C). The gel exhibited a volume phase transition at *ca.* 33 °C. It is known that NIPA-based gels are swollen at lower temperatures and shrunken at higher temperatures.[7,8,11,14] In the swollen state, the thickness of the present gel was *ca.* 1 mm while in the shrunken state, the gel was *ca.* an order of magnitude thinner.

Electrochemical measurements were performed at 25 °C (swollen gel) or 45 °C (shrunken gel) with a potentiostat LC-4C (BAS). Reference and counter electrodes were Ag/AgCl/NaCl(sat.) and a platinum wire, respectively while the electrolyte solution was 0.0133 M phosphate buffer, pH 7.4. The working electrode was polarized at +150 mV *vs.* Ag/AgCl, and a hydrogen peroxide solution was added to the electrolyte (final concentration, 10 μM), followed by the addition of an inhibitor (imidazole or histidine).

First an HP electrode not coated with the gel, was investigated. In response to the addition of hydrogen peroxide, a cathodic current was observed (1.6 nA at 25 °C and 3.9 nA at 45 °C). This is based on the electron transfer from the ITO electrode to compounds **I** and **II** of HP (oxidized forms) [eqns. (1)–(3)]

$$\text{Ferric HP} + H_2O_2 \rightarrow \text{Compound } \mathbf{I} + H_2O \quad (1)$$

$$\text{Compound } \mathbf{I} + H^+ + e^- \rightarrow \text{Compound } \mathbf{II} \quad (2)$$

$$\text{Compound } \mathbf{II} + H^+ + e^- \rightarrow \text{Ferric HP} + H_2O \quad (3)$$

Addition of imidazole or histidine suppressed the cathodic current since imidazole and histidine coordinate to the vacant coordination site of HP at which hydrogen peroxide reacts. These results have already been reported and exploited for the determination of imidazole derivatives.[3–5]

In the present paper, the response R is defined by eqn. (4)

$$R = 1 - (i/i_0) \quad (4)$$

where i_0 is the cathodic current observed after the addition of H_2O_2 (10 μM) and i is the current measured after addition of an

inhibitor (imidazole or histidine) (background current subtracted from both of the currents). In other words, the response *R* is the degree of interference. Even though the measurements were carried out at both 25 and 45 °C, relationships between the response to the inhibitor and the inhibitor concentration (Fig. 2) were similar for the HP electrode without the gel.

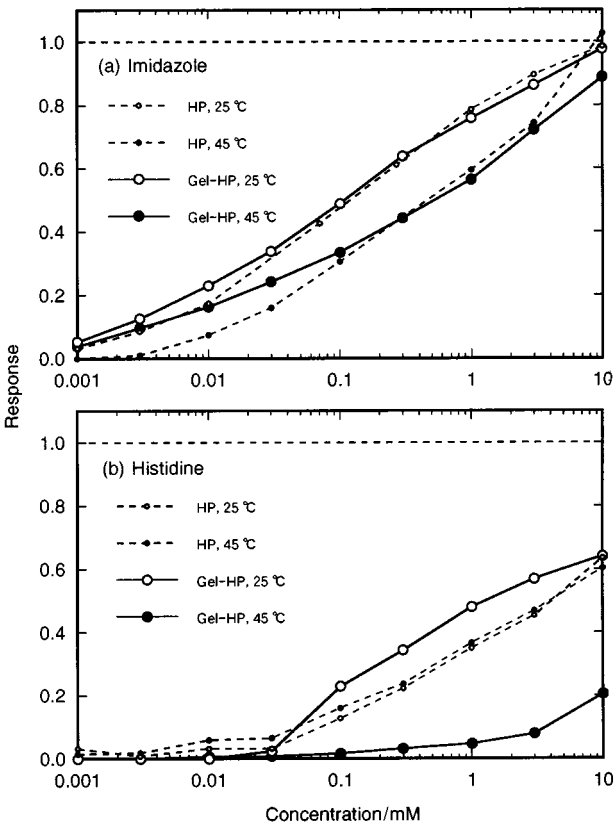

Fig. 2 Responses of the HP and gel–HP electrodes to imidazole (a) and histidine (b) at 25 °C (swollen gel) and 45 °C (shrunken gel) as a function of their concentrations.

The HP electrode coated with the phase transition gel, the gel–HP electrode, was then examined. At 25 °C, when the gel is swollen, the responses to both imidazole and histidine were almost the same as those obtained from the HP electrode without gel [Fig. 2(a) and (b)]. At 45 °C, where the gel is shrunk, while the responses of the gel–HP electrode to imidazole were similar to those of the HP electrode [Fig. 2(a)], the gel–HP electrode exhibited significantly smaller responses to histidine at 45 °C than did the HP electrode [Fig. 2(b)]. This temperature-dependent behavior was reversible for the gel–HP electrode. Additionally, the presence of both analytes (imidazole or histidine) did not interfere in the determination of each. At 45 °C, addition of histidine (final concentration, 1 mM) to 3 mM imidazole led only to a slight increase in the response, as expected from Fig. 2.

Thus, the sensitivity of the gel–HP electrode to histidine was lowered by shrinking the gel without significant changes of the sensitivity of imidazole. In other words, two independent responses can be acquired in the swollen and shrunken states. The concentration of histidine in the shrunken gel is lower than that in the solution by more than one order of magnitude. There are two possible reasons for this selective control of the sensitivity: (i) histidine (M = 155) is larger than imidazole (M = 68) so that the former permeates less effectively into the fine polymer network of the shrunken gel; and (ii) histidine, which has one positive and one negative charge at pH 7.4, should be more hydrophilic than imidazole, and hence would permeate less efficiently into the shrunken gel, which is relatively hydrophobic. In future work, we will examine the possibility of the determination of two interferants in one solution on the basis of the two responses obtained at swollen and shrunken states. Additionally, not only the size and hydrophilic/hydrophobic effects, but also electrostatic and some other effects will be exploited for the selective control of sensitivity of biosensors.

This work was supported in part by a Grant-in-Aid for Scientific Research on Priority Areas (No. 404, Molecular Synchronization for Design of New Material Systems) (No. 11167215 for T. T.) and a Grant-in-Aid for Encouragement of Young Scientists (No. 11750709 for T. T.) both from the Ministry of Education, Science, Sports and Culture of Japan.

Fluoride ion-initiated α-fluorovinylation of carbonyl compounds with α-fluorovinyldiphenylmethylsilane

Takeshi Hanamoto,* Shigeo Harada, Keiko Shindo and Michio Kondo

Department of Chemistry and Applied Chemistry, Saga University, Honjyo-machi 1, Saga 840-8502, Japan. E-mail: hanamoto@cc.saga-u.ac.jp

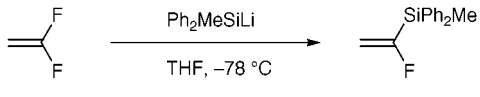
Received (in Cambridge, UK) 4th October 1999, Accepted 20th October 1999

α-Fluorovinyldiphenylmethylsilane was synthesized in one step from 1,1-difluoroethylene; the TBAF-initiated reaction of the silane with carbonyl compounds smoothly proceeded to give the corresponding α-fluoroallylic alcohols in good yields.

Fluorinated allylic alcohols have recently received much attention due to their versatility as building blocks for complex structures.[1] These alcohols should be accessible from carbonyl compounds by fluorovinylation in a straightforward way. Although the di- or tri-fluorovinylation of carbonyl compounds to afford the corresponding fluorinated allylic alcohols has been reported,[2] to the best of our knowledge, no monofluorovinylation as the simplest case has been reported so far. The reason seems to be the lack of the generation of the monofluorovinylanion species.[3] We have considered the title compound as a promising candidate for a monofluorovinylation reagent which would generate the monofluorovinyl anion species by action of the fluoride source.[4] This report describes the first preparation and reactions of the α-fluorovinyldiphenylmethylsilane **2** as a useful reagent for introducing a monofluoroethylene moiety into carbonyl compounds.[5]

Our synthetic route for the preparation of α-fluorovinyldiphenylmethylsilane is depicted in Scheme 1. Since we have recently reported the convenient preparation of α-fluorovinyldiphenylphosphine from 1,1-difluoroethylene **1**,[6] this method was applied to the preparation of the silane. As expected, the reaction of diphenylmethylsilyllithium[7] and 1,1-difluoroethylene in THF at −78 °C proceeded smoothly to give the desired product in 56% yield *in one step*.† We believe that the key to this reaction is use of chlorodiphenylmethylsilane instead of chlorophenyldimethylsilane. When the latter was employed under similar reaction conditions, the yield of the corresponding α-fluorovinylphenyldimethylsilane was low and the contaminant 1,2-diphenyl-1,1,2,2-tetramethyldisilane could not be separated from the desired α-fluorovinylphenyldimethylsilane.

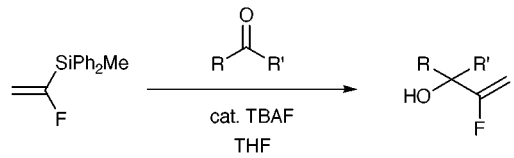
We have examined the use of α-fluorovinyldiphenylmethylsilane as a potential reagent for introducing an α-fluorovinyl group into various carbonyl compounds. The reaction of a slight excess of α-fluorovinyldiphenylmethylsilane (1.2 equiv.) and benzaldehyde in the presence of a catalytic amount of TBAF (1 M THF solution, 10 mol%) in THF gave the desired product in 34% yield. Increasing the amount of catalyst (30 mol%) did not significantly improve the yield (39%). Based on TLC analysis of the reaction mixture, we observed that the α-fluorovinyldiphenylmethylsilane was completely consumed although the benzaldehyde still remained. This finding may be explained as follows: the generated α-fluorovinylanion species decomposed to the vinylcarbene or abstracted a proton from the reaction medium due to its modest reactivity prior to its addition to benzaldehyde. On the basis of this idea, increasing the amount of the silane gave better results (1.5 equiv., 42%; 2.0 equiv., 61%). The reaction was applied to the silane and various carbonyl compounds under optimized conditions. These results are shown in Table 1. Although ketones afforded the adducts in low yields, probably due to their steric hindrance, aldehydes gave the adducts in fairly good yields. It is noteworthy that the reaction proceeded under mild conditions in contrast to the reaction of difluorovinyllithium.[8] Attempts to improve the ketone adducts at an elevated reaction temperature (55 °C) resulted in formation of a complex mixture of products.



1 **2** (56%)

Scheme 1

Table 1 Reaction of α-fluorovinyldiphenylmethylsilane with various carbonyl compounds



Entry	R	R′	Yield (%)[a]
1	Ph	H	61
2	4-$MeOC_6H_4$	H	77
3	4-PhC_6H_4	H	61
4	2-Naphthyl	H	65
5[b]	(*E*)-PhCH=CH	H	60
6[c]	$CH_3(CH_2)_9$	H	50
7	$PhCH_2CH_2$	Me	18
8	Ph	Me	13

[a] Isolated yield. [b] TBAF (20 mol%) was used. [c] TBAF was added to the reaction mixture at −70 °C.

A typical experimental procedure (Table 1, entry 2) is as follows: TBAF (1 M THF solution, 40.3 μl, 0.04 mmol, 10 mol%) was added to a mixture of α-fluorovinyldiphenylmethylsilane (97.7 mg, 0.40 mmol) and 4-methoxybenzaldehyde (24.5 μl, 0.20 mmol) dissolved in THF (1 ml) at 0 °C. The resulting mixture was stirred for 1 h at 0 °C and for 16 h at room temperature. After the usual workup, column chromatography (silica gel, hexane–EtOAc = 9:1) of the residue afforded 28.5 mg of 2-fluoro-1-(4′-methoxyphenyl)-2-propen-1-ol (77% yield).‡

In conclusion, we have demonstrated the first preparation of α-fluorovinyldiphenylmethylsilane from 1,1-difluoroethylene in one step. The generated α-fluorovinyl anion species derived from the silane by action of TBAF reacted with various carbonyl compounds to give the corresponding α-fluoroallylic alcohols in good yields. Further studies on its synthetic utility are now in progress in our laboratory.

Notes and references

† *Preparation* of **2**: To a solution of lithium wire (0.14 g, 20 mmol) in 10 ml of THF was added a catalytic amount of iodine and chlorodiphenylmethylsilane (1.03 ml, 5 mmol) at room temperature under argon. The solution was

irradiated with ultrasound for 30 min and a black–green color developed. After stirring for an additional 16 h, the solution was cooled to −78 °C. At this temperature, argon was replaced with 1,1-difluoroethylene (balloon). The mixture was stirred at −78 °C for 30 min, gradually warmed to 0 °C, and carefully quenched with saturated aqueous NH_4Cl. After the usual workup, the residue was chromatographed on silica gel (hexane as an eluent) to give the desired product (683 mg, 56%): ν_{max}(neat)/cm^{-1} 3071, 3050, 2963, 1620, 1429, 1256, 1160, 1115, 910, 881, 793, 729 and 698; δ_H($CDCl_3$) 0.72 (3H, s), 4.86 (1H, dd, *J* 3.4, 61.5), 5.48 (1H, dd, *J* 3.4, 32.7), 7.34–7.66 (10H, m); *m*/*z* 242 (0.7%, M$^+$), 201 (100), 197 (59), 181 (58), 179 (26), 164 (31), 149 (31), 139 (82), 105 (21), 91 (28) (calcd. for $C_{15}H_{15}FSi$: C, 74.34; H, 6.24. Received (in Cambridge, UK) 5th October 1999, Accepted 25th October 1999

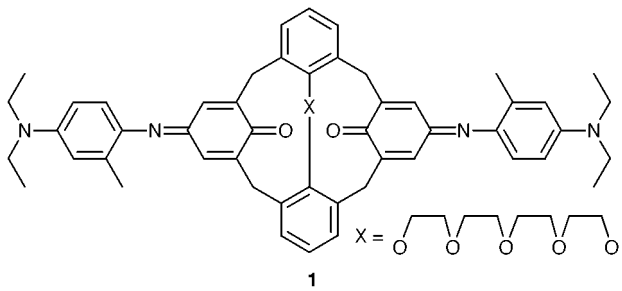
A new chromoionophore-based calix[4]crown 1 possessing an effective 'off-on-off' signalling for metal cationic inputs has been developed, the controllable signal function of which may not only be welcome for molecular information processing but also contribute to the design of new sensory materials.

The design and construction of devices miniaturized to the molecular level would not only contribute to the development of nanotechnology, but would also be of scientific interest.[1] Such progress may have important implications for biomimetic engineering.[2] Ionically-controlled optical signalling is a particularly attractive approach to switchable molecular devices for the use in information processing. In order to achieve such processing, effective ionic signal control is no doubt of importance. So far, de Silva *et al*. have reported pioneering work on developing molecular logic devices based on photo-induced electron transfer (PET) characteristics.[3] In many instances, it is of particular interest that a tailored PET system possessing two different proton binding sites forms a pH-dependant 'off-on-off' photoionic switch[4] that is a molecular emulator of an electronic device. However, the more intricate switches have only dealt with the simplest ion: H^+.[5] 'Off-on-off' switchable systems induced by ionic guests other than H^+ are as yet unknown. Thus, as an alternative approach, we have found it worthwhile to design a simplified receptor system based on competitive cation-induced 'off-on-off' colorimetric signal control:[6] it is in principle required that this system should show a colorimetric effect ('off-on' step) with the first ion, and then, if the second ion can not only bind to the system with greater affinity than the first but also induce no colorimetric effect, the second ion would release the first ion efficiently to bring about an active 'on-off' signal switch. Here we report that calix[4]crown-5[7] **1** does in fact serve as such a photoionic system.



1

The system **1** contains paired indoaniline chromophores that allow a color change to be induced when a cation becomes encapsulated within the cavity. A critical design feature of this system is the use of the crown-strapped cavity. This means that an alkali metal ion can be bound with high affinity, as it is known that calix[4]crown-5 derivatives possess high K^+ selectivity.[8] However, it occurred to us that the carbonyl groups of the chromophores, being more polar donor groups than the ethers, strongly favor Ca^{2+} over either Na^+ or K^+.[9] Indeed, we reported that a bis(ethyl acetate)-derived calix[4]arene–indoaniline conjugate efficiently encapsulated Ca^{2+} with a remarkable bathochromic absorbance shift, making it of potential use as an optical sensor for Ca^{2+} detection.[10] Taken together, if an alkali metal ion such as K^+, which is bound by the macroring crown oxygens, forms a more favorable complex with **1** than Ca^{2+}, the Ca^{2+}-induced signal response could be efficiently switched off by the cation. As a consequence, it is expected that system **1** will define a rather unique chromogenic system capable of effective 'off-on-off' signal control. As detailed below, this does indeed occur.

System **1**† was synthesized from calix[4]arene[11] *via* a set of straightforward steps involving a Williamson synthesis with 3,6,9-trioxaundecane-1,11-diyl ditosylate in the presence of a base, and condensation with 2-amino-5-(diethylamino)toluene monohydrochloride under alkaline conditions in the presence of $KMnO_4$. Based on our previous work,[10] system **1** was expected to complex Ca^{2+} with high efficiency within its cavity. Indeed, an EtOH solution of **1** showed a remarkable bathochromic shift ($\Delta\lambda$ = 112 nm) and an increase in absorption intensity upon addition of Ca^{2+}, resulting in an immediate color change from blue to green. At a [Ca^{2+}] to [**1**] ratio of 1.5:1, a new absorption band at 734 nm was observed ('off-on' switch; Fig. 1). Independent Job plot analysis[11] was consistent with the formation of a 1:1 stoichiometric complex. This then allowed an association constant (K_a) of 1.8×10^6 M^{-1} to be calculated using a nonlinear least-squares curve fitting procedure. The Ca^{2+}-induced colorimetric effect is mainly attributed to efficient ion–dipole interactions between the encapsulated Ca^{2+} and the quinone carbonyl groups of the indoaniline chromophores. In contrast, upon interaction with K^+ under similar conditions, no evidence of significant interaction between this cation and the chromophores was obtained. However, of particular interest is

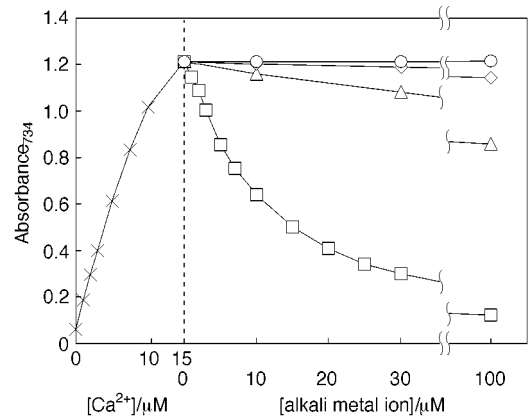


Fig. 1 Absorption intensity change at 734 nm induced by Ca^{2+} addition and subsequent alkali metal ion additions: (○) Ca^{2+}-**1** plus Li^+, (Δ) Ca^{2+}–**1** plus Na^+, (□) Ca^{2+}-**1** plus K^+ and (◇) Ca^{2+}–**1** plus Cs^+. These data were collected in EtOH at 25 °C where the concentration of receptor **1** is 10 μM.

that a competitive titration, involving adding K^+ to a solution of **1** (10 μM) and 1.5 equiv. of Ca^{2+}, exhibited significant reversed spectral changes ('on-off' switch; Fig. 1); when adding 2 equiv. of K^+ to the solution, *ca*. 70% of the absorption intensity at 734 nm was apparently diminished. This phenomenon was readily detected visually, being clearly consistent with the encapsulated Ca^{2+} being released from **1** in an almost stoichiometric reversible and competitive fashion as K^+ was added.‡

Semi-quantitative assessment of the competitive complexation process came from FAB mass spectrometric analyses. The formation of a 1 : 1 complex between **1** and Ca^{2+} was confirmed by monitoring the peaks at *m/z* 970 ($[M+Ca]^+$) and 1027 ($[M - H + Ca + SCN]^+$) using a *m*-nitrobenzyl alcohol matrix. Upon adding K^+ to the **1**–Ca^{2+} complex, the peak due to the Ca^{2+} complex was almost completely suppressed, whereas a new peak signal at *m/z* 968 ($[M-H + K]^+$) could be detected. These results are consistent with those obtained from the UV–Vis titrations and thus strongly support the notion that reversible competitive complexation takes place between Ca^{2+} and K^+ in the case of receptor **1**. We were interested to know whether or not the effective 'on-off' switch obtained in **1** can be induced by only K^+. Thus, we tested alkali metal ions other than K^+. As depicted in Fig. 1, the Ca^{2+}-induced signal was barely influenced by Li^+, Na^+ and Cs^+. The association constants (K_a) for the complexation of the alkali metal ions to **1** were calculated using a mathematical method that may be applied to competition experiments[13] and **1** was found to have peak affinity with K^+ ($K_a = 7.2 \times 10^6\ M^{-1}$); the selectivity of K^+ over Ca^{2+} was 4.0. As K^+ induced almost no color change, and can switch off the Ca^{2+}-induced optical signal with high selectivity over other alkali metal ions, an effective 'off-on-off' switch for system **1** could be achieved by making use of the combination of Ca^{2+} and K^+.

NMR studies were carried out in an effort to understand the detail of the substrate–receptor interactions. Although the ^1H NMR spectra showed that both the Ca^{2+} and K^+ complexes in CD_3OD adopt cone conformations, the binding modes are slightly different, as inferred from 2D COSY and NOESY experiments.§ These different modes in the cavity might suggest that the guest Ca^{2+} is bound by the more polar carbonyl groups of the indoanilines to induce the drastic color change, whereas K^+ interacts with the convergent crown oxygens to switch off the Ca^{2+}-induced signal more efficiently than other alkali metal ions.

In conclusion, the results described here lead us to suggest a new approach to the generation of photochemical 'off-on-off' switching systems. On a different level, the selective 'on-off' switching step described herein could prove useful in terms of generating a molecular sensor in analytical chemistry.[14] We feel that such possibilities warrant future exploration.

General acid catalysed hydrolysis of β-sultams involves nucleophilic catalysis

Nicholas J. Baxter, Andrew P. Laws, Laurent J. H. Rigoreau and Michael I. Page*

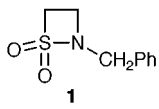
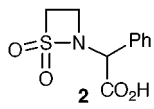
Received (in Cambridge, UK) 15th September 1999, Accepted 13th October 1999

The hydrolysis of the four-membered ring sulfonamide *N*-benzyl β-sultam is catalysed by carboxylic acids, which is attributed to specific acid–nucleophilic catalysis with the intermediate formation of a mixed anhydride which can be trapped with aniline.

Contrary to intuition, the four-membered monocyclic β-lactams are not significantly more reactive than their acyclic amide analogues. For example, the second-order rate constant for the alkaline hydrolysis of *N*,*N*-dimethylacetamide is only three times greater than that of *N*-methyl β-lactam.[1] By contrast, β-sultams undergo alkaline hydrolysis at least 10^8-fold faster than an analogous acyclic sulfonamide.[2] It is normally difficult to study the mechanism of reactions of sulfonamides because of their intrinsic stability,[3] despite their inherent interest as potential therapeutic agents.[4] The four-membered β-sultams therefore offer the opportunity to readily investigate sulfonyl transfer reactions.



1



2

The rate of hydrolysis of *N*-benzyl β-sultam **1** was measured by monitoring changes in its UV spectrum at 225–235 nm in a range of carboxylate buffers under pseudo-first-order conditions. At a constant pH, ionic strength [I = 1.0 M (KCl)] and at 30 °C, the observed first-order rate constants increase linearly with increasing concentrations of buffer, indicative of buffer catalysis. Plots of k_{obs} against the total buffer concentration yield slopes (k_{cat}) which give the total contribution to the rate law by both the concentration of the undissociated carboxylic acid and the carboxylate anion. The intercepts of these buffer plots (k_{int}) correspond to the calculated observed first-order rate constants for the specific acid catalysed hydrolysis based on the second-order rate constant (k_{H^+} = 1.52 M^{-1} s^{-1}) obtained from reactions studied in solutions of hydrochloric acid. For each series of buffers, a plot of k_{cat} against α, the fraction of the buffer present as the free base, gives intercepts, when α = 0 and 1.0, of k_{HA} and k_{A^-}, respectively, the individual second-order rate constants for catalysis by the acidic and basic buffer components. The values of k_{A^-} were indistinguishable from zero. The rate law for the hydrolysis of *N*-benzyl β-sultam in carboxylate buffers is thus given by eqn. (1).

$$k_{obs} = k_H[H^+] + k_{HA}[HA] \quad (1)$$

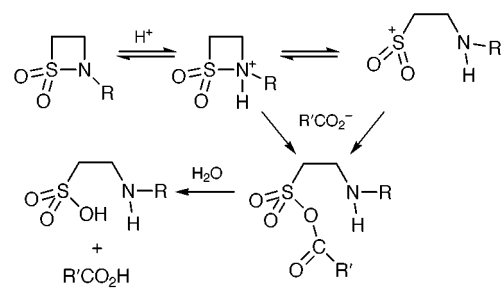
The values of the second-order rate constants k_{HA} are given in Table 1, from which it can be seen that they increase with decreasing pK_a of the carboxylic acid buffer. The observation of general acid catalysed hydrolysis is in contrast to the general base catalysis seen with the buffer catalysed hydrolysis of β-lactams of penicillins.[5] Although catalysis by acidic species other than the protonated solvent is usually referred to as 'general acid catalysis', mechanistically the reaction may proceed *via* different but kinetically equivalent processes. Mechanistic general acid catalysed hydrolysis could involve nucleophilic attack by water which is concerted with the protonation of the β-sultam by the undissociated carboxylic acid. Interestingly, there is no evidence of intramolecular general acid catalysis in the hydrolysis of *N*-carboxy(phenyl)-methyl β-sultam **2**. Alternatively, a specific acid–general based catalysed pathway could involve pre-equilibrium protonation of the β-sultam nitrogen, followed by the general base catalysed attack by water, the nucleophilicity of which is enhanced as a result of proton abstraction by the carboxylate anion.

Table 1 Second-order rate constants for the carboxylic acid catalysed hydrolysis of *N*-benzyl β-sultam at 30 °C [I = 1.0 M (KCl)]

Carboxylic acid	pK_a	k_{HA}/M^{-1} s^{-1}
$ClCH_2CO_2H$	2.70	7.61×10^{-2}
$MeOCH_2CO_2H$	3.38	2.95×10^{-2}
HCO_2H	3.67	7.53×10^{-2}
CH_3CO_2H	4.57	4.14×10^{-3}

The third and probable mechanism of buffer catalysis involved specific acid–nucleophilic catalysis (Scheme 1). The β-sultam undergoes reversible protonation, probably on nitrogen, followed by direct nucleophilic attack of the carboxylate anion to form a mixed acid anhydride intermediate which is subsequently hydrolysed. Nucleophilic catalysis in the carboxylate buffer hydrolysis of β-sultams was confirmed by trapping the mixed acid anhydride intermediate with aniline to give acetanilide. A series of high performance liquid chromatograms were obtained by injecting samples of acetate buffer (0.2 M, pH 4.83) containing aniline (0.50 M) with and without added *N*-benzyl β-sultam. In the presence of the β-sultam, a peak with a retention time corresponding to that of acetanilide was observed, whereas in the absence of the β-sultam no acetanilide is produced. These observations provide the most conclusive evidence that the carboxylate buffer catalysed hydrolysis of β-sultams is due to specific acid–nucleophilic catalysis.

The hydrolysis of *N*-benzyl β-sultam in acetate buffers showed unusual behaviour because the kinetics showed biphasic behaviour; an initial exponential burst of UV absorbance was followed by a much slower first order reaction. This was only observed for acetate buffers and the catalytic rate constants were obtained from the initial rates. The biphasic kinetics observed in the acetate buffer hydrolysis of *N*-benzyl β-sultam may be attributed to the accumulation and subsequent hydrolysis of the anhydride intermediate. The rate of decomposition of the intermediates derived from the 2-chloroacetate, 2-methoxyacetate and formate anions are greater than those for their formation because of the high nucleofugacity of these anions.



Scheme 1

As a result, the intermediates decompose faster than they are formed and normal first-order kinetics are observed.

There is convincing evidence that the protonation of sulfonamide occurs on nitrogen[6] and the general acid-catalysed hydrolysis of the β-sultam could occur by a unimolecular A-1 type process with the carboxylate anion trapping the reversibly formed electron-deficient sulfonylium ion (Scheme 1). The evidence for such a mechanism in the hydrolysis of five-membered γ-sultams is ambiguous, although most of it is consistent with a bimolecular mechanism.[7] Unimolecular ring opening has been suggested for the acid-catalysed hydrolysis of both β-lactams[8] and β-phospholactams.[9]

The Brønsted plot (not shown) for the carboxylic acid catalysed hydrolysis of *N*-benzyl β-sultam gives a good correlation between the values of log k_{HA} and the pK_a for 2-chloroacetic, 2-methoxyacetic and acetic acids with a slope of −0.67. This corresponds to a β_{nuc} of 0.33 for the specific acid–nucleophilic mechanism, indicative of an early transition state in which there has been a small amount of neutralisation of the negative charge on the carboxylate anion. Formic acid shows a positive derivation from this line which is again indicative of a nucleophilic pathway for catalysis.

The solvent isotope effect k_{H_2O}/k_{D_2O} of 1.57 for the chloroacetate buffer hydrolysis of *N*-benzyl β-sultam is compatible with the specific acid–nucleophilic process, as is the observed entropy of activation of −148 J K^{-1} mol^{-1} for the chloroacetic acid catalysed hydrolysis.

Structure and bonding in the d^4/d^3 alkyne redox pairs $[WX(CO)(MeC{\equiv}CMe)Tp']^z$ (X = F, Cl, Br and I; z = 0 and 1): halide stabilisation of electron deficient metal alkyne complexes

Ian M. Bartlett,[a] Susannah Carlton,[a] Neil G. Connelly,*[a] David J. Harding,[a] Owen D. Hayward,[a] A. Guy Orpen,*[a] Christopher D. Ray[a] and Philip H. Rieger*[b]

[a] *School of Chemistry, University of Bristol, Bristol BS8 1TS, UK. E-mail: Neil.Connelly@bristol.ac.uk*

Received (in Basel, Switzerland) 28th September 1999, Accepted 25th October 1999

X-Ray structural and EPR spectroscopic studies of the redox-related pairs $[WX(CO)(MeC{\equiv}CMe)Tp']^z$ (X = F, Cl, Br and I; z = 0 and 1) [Tp′ = hydrotris(3,5-dimethylpyrazolyl)borate] are consistent with the HOMO of the d^4 (z = 0) species being π-bonding with respect to the W–CO bond, π-antibonding with respect to the W–X bond, and δ-bonding with respect to the W–alkyne bond.

We have recently shown[1] that the oxidation of $[Cr(CO)_2(\eta\text{-}PhC{\equiv}CPh)(\eta\text{-}C_6HMe_5)]$ (d^6) to $[Cr(CO)_2(\eta\text{-}PhC{\equiv}CPh)(\eta\text{-}C_6HMe_5)][PF_6]$ (d^5), and of $[Mo(CO)_2(\eta\text{-}PhC{\equiv}CPh)Tp']$ (d^5) to $[Mo(CO)_2(\eta\text{-}PhC{\equiv}CPh)Tp'][PF_6]$ (d^4) is accompanied by structural changes consistent with stepwise removal of two electrons from the antibonding M–alkyne π⊥ orbital (of the d^6 alkyne complex). In this series, the alkyne effectively acts as an electron-sink. We now describe an unexpected and remarkable extension of this work wherein the d^4 complexes $[WX(CO)(MeC{\equiv}CMe)Tp']$ (X = F, Cl, Br and I) undergo one-electron *oxidation* affording isolable d^3 complexes $[WX(CO)(MeC{\equiv}CMe)Tp'][BF_4]$. The halide both influences the ease of oxidation and allows stabilisation of the resulting electron deficient d^3 metal alkyne complexes.

Treatment of $[W(CO)_2(MeC{\equiv}CMe)Tp'][BF_4]$ with $[NBu^n_4]X$ (X = F, Br or I) or $[N(PPh_3)_2]Cl$ in CH_2Cl_2 gives the neutral complexes $[WX(CO)(MeC{\equiv}CMe)Tp']$ **1** (X = F, Cl, Br or I[2])† in 40–60% yield. Each complex undergoes reversible one-electron oxidation, at a Pt electrode in CH_2Cl_2, followed by a second, irreversible, oxidation process at a more positive potential (Table 1). The potential for the first oxidation step, $E°'_1$′, becomes more positive and ν(CO) *increases* in energy in the order X = F < Cl < Br < I (Table 1), manifestations of the 'inverse halide order'[3] where the complex of the most electronegative halogen (X = F) has the most electron rich metal centre.

Treatment of **1** with $[Fe(\eta\text{-}C_5H_4COMe)Cp][BF_4]$ in CH_2Cl_2 gives 40–70% yields of the paramagnetic salts $[WX(CO)(MeC{\equiv}CMe)Tp'][BF_4]$ ($\mathbf{1}^+[BF_4]^-$)† which show ν(CO) shifted to very much higher energy, by 160 (X = I) to 189 cm^{-1} (X = F). In addition, the order ν(CO) = F ≈ I < Br < Cl is now more nearly that expected on the basis of inductive effects due to halogen electronegativities (except for F).

The d^3 cations in CH_2Cl_2–thf (1:2) show well resolved EPR spectra; parameters are given in Table 1 and the spectra of $\mathbf{1}^+$ (X = F), at 300 and 77 K are shown in Fig. 1. The isotropic metal coupling, $<A^W>$, decreases in the order F > Cl > Br suggesting a smaller metal contribution and larger participation of the halogens in the HOMO of **1** on descending the halogen group. The increase in $<g>$ in the series F to I suggests a smaller metal contribution and a larger heavy halogen participation in the LUMO as well.[4]

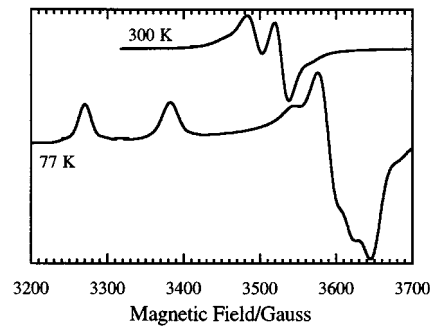

Fig. 1 EPR spectra of $[WF(CO)(MeC{\equiv}CMe)Tp']^+$ at 300 and 77 K in CH_2Cl_2–thf (1:2).

Table 1 Spectroscopic and electrochemical data for $[WX(CO)(MeC{\equiv}CMe)Tp']^z$

X	z	Electron configuration	ν(CO)/cm^{-1} (in CH_2Cl_2)	$E°'_1$/V[a]	$<g>$[b]	$<A^W>$, $<A^X>$[b,c]

Single crystal X-ray diffraction studies‡ on the two redox pairs $[WX(CO)(MeC{\equiv}CMe)Tp']^z$ (X = Cl and Br, z = 0 and 1) show the structural effects of oxidation. The gross structures of the four complexes are generally similar; that of $[WCl(CO)(MeC{\equiv}CMe)Tp']$ **1** (X = Cl) is shown in Fig. 2 as a representative example. In each case the alkyne is aligned approximately parallel to the W–CO bond. However, there are significant changes in metal–ligand bond lengths on oxidation (Table 2). Thus, for both pairs there is a significant shortening of the W–X bond (by *ca.* 0.09 Å), and a considerable lengthening of the W–C(O) bond [by 0.15–0.17 Å. consistent with the very large increase in ν(CO)]. In contrast to the shortening of the $M–C_{alkyne}$ bonds in the d^6/d^5 and d^5/d^4 pairs noted above (*ca.* 0.10–0.11 Å on oxidation), there is a very small lengthening of the $W–C_{alkyne}$ bonds (average *ca.* 0.02 Å) on oxidation of **1**.

The structural changes are consistent with the HOMO of **1** being largely d_{yz} in character but π-antibonding with respect to the W–X bond, π-bonding with respect to the W–C(O) bond, and weakly δ-bonding with respect to the W–alkyne bond (see

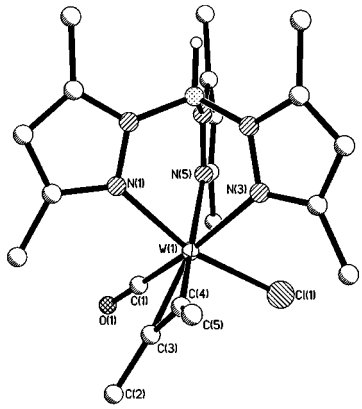

Fig. 2 Structure of [WCl(CO)(MeC≡CMe)Tp′] (hydrogen atoms omitted for clarity); important bond lengths are given in Table 2.

Table 2 Important bond lengths (Å) for [WX(CO)(MeC≡CMe)Tp′]^z

X	z	Electron configuration	W–C_{alkyne}	W–X	W–C(O)	C–O	W–N (av.)
Cl	0	d^4	2.050(6) 2.002(6)	2.429(1)	1.941(6)	1.174(6)	2.223(8)
Cl	1[a]	d^3	2.067(3) 2.035(3)	2.343(1)	2.087(3)	1.114(4)	2.179(3)

Br	1[a]	d^3	2.076(4) 2.027(4)	2.503(1)	2.118(5)	1.080(5)	2.184(6)

[a] As the $[BF_4]^-$ salt.

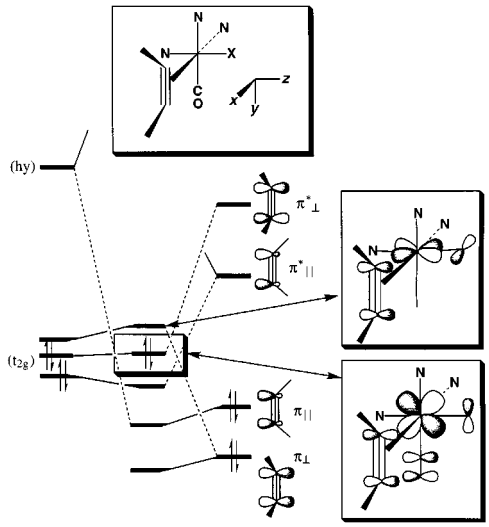

Fig. 3 Schematic diagram of the orbital interactions in d^4 [WX(CO)(MeC≡CMe)Tp′] (hy = σ-hybrid orbital).

Fig. 3). This pattern of interactions, and the magnitude of the orbital contributions to the SOMO suggested by the EPR parameters, are reproduced by EHMO calculations on **1**.

As noted above, the variations in both $E°'_1$′ and ν(CO) indicate an 'inverse halide order' for the set of complexes **1**; X = F < Cl < Br < I. The sequence of ν(CO) for **1** (Table 1) indicates strongest M–C bonding in **1** (X = F) and weakest in **1** (X = I) and by implication greatest metal π-donor ability (or electron releasing ability) in **1** (X = F). The ν(CO) data show a decreasing sensitivity of the carbonyl ligand in **1** to the effect of oxidation, in the order F > Cl > Br > I. The implication is that the contribution of the carbonyl ligand to the HOMO of **1** is greatest for X = F and least in X = I. This trend is also reproduced in EHMO calculations which show that more electronegative halogens make contributions preferentially to the lower energy molecular orbitals.

The inverse halide order has been noticed previously during electrochemical studies[5,6] or organometal halide complexes, and attributed to variation in either X-to-M p_π–d_π[7] or M-to-X d_π–d_π[3,6] donation. In most previous studies, the absence of data on the fluoride complex has hindered distinction between these two possibilities. For **1**, it is clear that the inverse halide order also encompasses the fluoride member of the series yet M–F d_π–d_π overlap is impossible. A recent study[7] revealed an inverse halide order for the series $[FeX(dppe)(\eta\text{-}C_5Me_5)]^z$ (z = 0 and 1; X = F to I) where changes in bond dissociation energies (from electrochemical studies) showed that the HOMO/SOMO is significantly M–X bonding. This, is clearly different from **1** where oxidation is accompanied by W–X bond shortening, indicating that the HOMO is W–X antibonding (at least for X = Cl and Br). The π-donation of the halides is apparently the key to their ability to stabilise electron deficient species such as $\mathbf{1}^+$. The EHMO-computed halogen atomic orbital participation in the HOMO of **1** rises in the sequence F < Cl < Br < I while the metal contribution falls monotonically.

We thank the EPSRC for Studentships (to D. J. H. and O. D. H.) and the University of Bristol for a Postgraduate Scholarship (to I. M. B.).

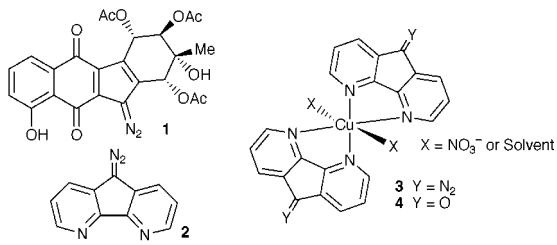
Received (in Bloomington, IN, USA) 19th August 1999, Accepted 13th October 1999

Bis(9-diazo-4,5-diazafluorene)copper(II) nitrate is an effective DNA photocleaving agent under anaerobic conditions using visible light and represents a potential model for the action of Kinamycin antitumor antibiotics.

The natural product antitumor antibiotic Kinamycin C **1**,[1,2] was recently found to contain a reactive terminal diazo group that is thought to be responsible for the DNA cleaving activity of the



molecule. Although very little is known about the details of Kinamycin's antibiotic activity, the thermal and photochemical reactivity of organic diazo compounds has been long established.[3] Recently, organic chemists have sought to mimic the function of Kinamycin C using simple synthetic diazo analogs, while monitoring biological activity through DNA cleavage assays.[4,5] Although functional, these agents are typically activated through long thermal incubations or UV photolyses, conditions that are less than ideal for medicinal uses.

In addition to their photochemical lability, the thermal decomposition of diazo groups is known to be accelerated by both oxidizing[6,7] and reducing[8] agents. Addition of Cu^{II} salts has been shown to significantly increase the thermal DNA cleaving ability of synthetic diazo compounds.[7] Notably, Kinamycin C contains a redox-active quinone unit in close proximity to the diazo group, suggesting that the antibiotic may use this functionality as an *intramolecular* redox switch to promote N_2 release. To this end, we sought to investigate the effect of binding a redox active transition metal to a diazo-containing ligand on the reactivity and DNA-photocleaving properties of the resulting complex. Ligand **2** was chosen for our initial studies because it is a simple nitrogen chelate containing an exocyclic diazo group that would direct a highly reactive carbene or radical intermediate toward potential substrates.

Compound **2** was synthesized from 4,5-diazafluorenone, using modified literature procedures.[9] The copper(II) complex **3** was synthesized by adding methanolic $Cu(NO_3)_2{\cdot}2.5H_2O$ to a solution of ligand in a 1 : 2 ratio. The full solution and solid-state characterization, as well as the X-ray crystallographic analysis, of the complex are reported elsewhere.[10]† Compound **4**, the ketonic diazo precursor complex, was prepared in an analogous manner and used as a control for DNA cleavage studies.

The effectiveness of DNA cleavage was assessed under rigorously anaerobic conditions by comparison of supercoiled (form I) DNA to the circular relaxed (form II) and linear (form III) DNA. As seen in Fig. 1(*a*), control photoreactions with DNA alone (lane 3) or 200 μM **4** (lane 4) and dark control reactions with 200 or 100 μM **3** (lane 5, 6) resulted in little or no DNA cleavage. In contrast, photoreactions of **3** using visible wavelength light resulted in significant production of linear and nicked DNA depending on the concentrations of **3** used. At a concentration of 200 μM (lane 7), no distinct bands are observable because the plasmid has been degraded into many minor fragments, resulting only in a faint streak on the gel. At concentrations of 100 (lane 8), 50 (lane 9) and 25 μM (lane 10), significant amounts of linear and nicked DNA are visible. Even at concentrations as low as 12.5 μM (lane 11), approximately half of the supercoiled plasmid has been converted to the nicked form. Discernable photocleavage by **3** is also observed at concentrations of 12.5 μM when wavelengths longer than 590 nm are used over 12 h (lane 12).‡

A comparison of efficiency between 2 equiv. of **2** and 1 equiv. of **3** was made because it is possible that both ligands of the Cu^{II} complex could react with DNA substrate. Significantly less cleavage was detected in the case of **2** alone [Fig. 1(*b*), lanes 3, 5, 7] relative to **3** (lanes 4, 6, 8) at one half the concentration, respectively. Close inspection of both gels in Fig. 1 reveals that the migration of the linear DNA product is slightly retarded relative to that of the linearized control, suggesting that the 4,5-diazafluorene moiety may be covalently bound to the DNA strand following photolysis. Evidence for alkylation of DNA by radical intermediates is well-established in the literature.[11]

In an effort to gain chemical insight into the reactivity of **3**, photolysis reactions were performed in aqueous solution in the absence and presence of calf thymus DNA and buffer. Anaerobic photolysis of **3** at $\lambda \geqslant 455$ nm in unbuffered water

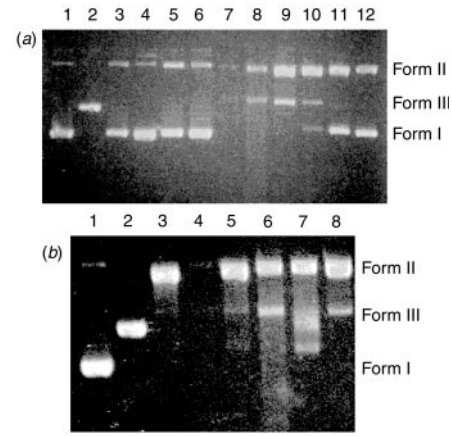


Fig. 1 Agarose gel electrophoresis of the photocleavage reaction of plasmid pUC118 (3162 bp) by **3** and related control compounds. † Experimental and spectral data for this communication are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2405/

results in the formation of new absorption feature at λ_{max} ~ 590 nm [Fig. 2(*a*), inset]. In the presence of O_2 this transition bleaches due to reaction of Cu^I with O_2 yielding reactive oxygen species (•OH or O_2^-) which oxidize the ligand generating a new absorption feature at 415 nm. Interestingly, the absorption band at 415 nm also appears in the photolysis of **2** under anaerobic buffered conditions, ruling out assignment of this feature as a Cu^{II} ligand-to-metal charge transfer transition and suggesting that it may arise from a conjugated organic species such as a dimerization product.§ Photodimerization and thermal dimerization of carbene intermediates to form ketazine and bifluorenylidene species have been documented for **2** and the related 9-diazofluorene derivatives in the presence of bulky or unreactive solvents.[3,12] However, since the absorption feature is also observed upon anaerobic photolysis of **3** and subsequent O_2 oxidation in unbuffered aqueous solution, the growth of the feature at 415 nm likely arises from oxidation of the ligand *via* either hydroxyl radicals from Cu^I/O_2 reactivity, or carboxy radicals generated by H-atom abstraction from buffer in the absence of O_2. Both of these reactive species are capable of addition reactions with aromatic frameworks to yield hydroxylated, ketonized or carboxylated ligand products.[3,7,13,14] In fact, one of the organic products detected upon extraction with $CHCl_3$ is the 4,5-diazafluorenone (λ_{max} = 390 nm). Further oxidation of this species yields the 4,5-diazafluorene-3,9-dione which has an absorption maximum at 414 nm.[13]

Anaerobic photolysis of **3** in 10 mM Tris acetate buffer at $\lambda \geqslant 455$ nm shows clean conversion to photoproduct during the first 40 min, resulting in the formation of the absorption feature at 415 nm and a broad transition at lower energies (λ_{max} ~ 590 nm). This profile indicates partial conversion to a Cu^I species and formation of oxidized ligand product [Fig. 2(*a*)].† Photolysis of **3** in the presence of calf thymus DNA (0.33 mM in bp) under identical conditions is shown in Fig. 2(*b*). The optical spectrum indicates a significantly different product distribution relative to reaction without DNA substrate. Of note is the diminished growth of the band at 415 nm indicating that the photolysis intermediate of **3** is predominantly reacting with the CT DNA substrate rather than forming dimerization products or generating potent radical oxidants. Neither simple H-atom abstraction from the deoxyribose ring nor phosphonation of diazofluorene[15] would yield products exhibiting the strong absorption band at 415 nm. Also, the prominent growth of the Cu^I band at low energy is not evident in the reaction with DNA, demonstrating that any Cu^I formed is also reoxidized in the acetate/DNA environment.

We are currently investigating the differences in reactivity of **2** and **3** toward DNA substrates. One plausible mechanism involves the binding of the copper dication to the negatively charged DNA backbone. Although the crystal structure shows two asymmetrically bound ligands and two nitrates bound tightly to the complex, conductivity studies indicate that the nitrate anions dissociate to form a 2:1 electrolyte in aqueous solution creating a labile site that permits the DNA substrate to bind to the Cu center. The mechanism for photoactivated DNA cleavage by **3** is intriguing in that excitation at 455 nm would be expected to lead directly to decomposition and N_2 release *via* the ligand centered n $\rightarrow \pi^*$ state localized on the diazo group. However, detection of photoreduced Cu^I suggests that metal–ligand redox chemistry may also play a role in activation of the diazo unit, possibly generating a diazonium cation prior to N_2 release. This is indeed supported by precedence for electrooxidative[6,7] and bimolecular photooxidative N_2 release.[16] Electrochemical studies of **3** in DMSO show a chemically reversible Cu^{2+}/Cu^+ couple at +0.094 V *vs*. SCE, while parallel studies of **2** exhibit an irreversible oxidation at +1.3 V corresponding to N_2 release.[8] From these values a Cu^+–$L^{\cdot+}$ ligand radical state would lie in the vicinity of +1.2 V above the ground state and would be accessible *via* $\lambda \geqslant 455$ nm excitation. The ability of transition metal diazo compounds to employ an additional unimolecular photoredox pathway to release N_2 and form ligand-bound, DNA-damaging radical intermediates suggests that the quinone subunit of Kinamycin C may indeed be serving as a redox source in a parallel N_2-releasing mechanism.

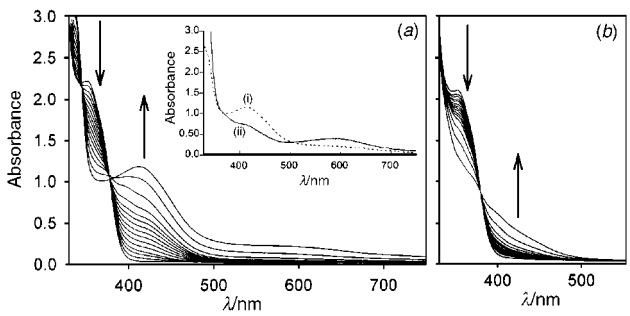

Fig. 2 Evolution of the electronic absorption spectra upon anaerobic photolyses of **3** (0.33 mM, $\lambda \geqslant 455$ nm) in the absence (*a*) and the presence (*b*) of CT DNA (0.33 mM in bp) in Tris acetate buffer (pH 7.6). Times shown are 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 16, 24 and 40 min. The spectra obtained upon anaerobic photolysis of **3** in unbuffered aqueous solution (i) prior to and (ii) following exposure to O_2 are given in the inset.

Complexes such as **3** represent the first of a new class of potent transition metal diazo DNA photocleavers that may be activated using visible light under hypoxic conditions. The ability to employ metal–ligand photoredox chemistry *via* visible region excitation may allow compounds based on this photo-triggering unit to find potential applications in structural biology and the growing field of photomedicine.

Notes and references

‡ Control experiments involving photolysis of the plasmid DNA alone at $\lambda \geqslant 590$ nm for 12 h yielded only slight nicking, comparable to that observed in Fig. 1(*a*), lane 3, confirming the activity of **3** at these wavelengths.

§ 9,9′-Bi(4,5-diazafluorenylidene) has been prepared recently and also shows a distinct band at 417 nm in CH_2Cl_2. Photolysis of **4**, the 4,5-diazafluorenone analog, resulted in no change in the absorption spectrum over a period of 3 h, indicating that the observed reactivity is derived from the diazo unit. Loss of the diazo group on photolysis in **3** has been unequivocally confirmed by N_2 bubble formation and disappearance of the asymmetric diazo stretch in the IR at 2080 cm^{-1} (ref. 10).

¶ Photolysis studies show that DNA cleavage does indeed occur under aerobic conditions as well.

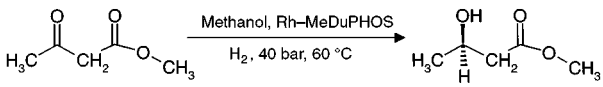
Received (in Cambridge, UK) 6th September 1999, Accepted 26th October 1999

The first heterogeneous system of Rh–MeDuPHOS, obtained by occlusion of the complex in a PDMS membrane, is reported and tested in the hydrogenation of methylacetoacetate (MAA).

Asymmetric synthesis with homogeneous chiral complexes is one of the best methods to prepare enantiopure compounds.[1] In 1991, Burk developed a set of new chiral biphosphine ligands referred to as DuPHOS [1,2-bis(phospholano)benzene] and BPE [1,2-bis(phospholano)ethane],[2] both commercially available nowadays. The Rh and Ru complexes of these ligands were found to be extremely effective in the enantioselective hydrogenation of a vast array of unsaturated substrates.[3–8] All reactions are characterized by high convenience, selectivity, catalytic productivity and activity, adaptability and durability. A major class of these substrates form the β-ketoesters. Their reduction was recently reviewed by Klabunovskii and Sheldon.[9] The authors stated that chiral metal complexes constitute the most elegant and efficient way to asymmetric hydrogenation with the broadest scope, but that facilitation of their recycling by immobilizing them, still remained an important future challenge.

We report here the first heterogenisation of Rh–MeDuPHOS, chosen as a typical representative of the class of catalysts reported by Burk *et al.*[2–8] Immobilisation was realized by occluding the catalyst in a polydimethylsiloxane membrane. This easy approach to heterogenisation was earlier applied already for several transition metal complexes.[10–12] The hydrogenation of MAA was selected as a test reaction (Scheme 1). A PDMS solution was prepared by mixing 0.075 g of crosslinker [tetrakis-(dimethylsiloxy)silane, United Chemical Technologies], 22 μl of Pt catalyst [*cis*-dichlorobis(diethyl sulfide)platinum(II), Aldrich, applied as a 2 wt% solution in toluene], 2.25 g of the vinyldimethyl terminated silicone polymer (M_n = 5350 with a polydispersity = 2.27, obtained after stripping the polymer under vacuum till constant weight, United Chemical Technologies), and 0.465 g of the silica (Hi-sil 233, pretreated at 120 °C, PPG Industries) in 11.5 g of dichloromethane (Fig. 1). The catalyst was prepared by dissolving the Rh salt [bis(cycloocta-1,5-diene)rhodium(I) trifluoromethanesulfonate, 99%, Strem] and the ligand {(−)-1,2-bis[(2*R*,5*R*)-2,5-dimethylphospholano]benzene, 99%, Strem} separately in methanol (Fig. 2). An amount of 0.0397 g of Rh salt and 0.0264 g of ligand were dissolved in 2.1 and 0.7 g of methanol, respectively. The ligand solution was then added dropwise to the Rh salt solution under constant stirring. Further stirring for 15 min turned the yellow solution into dark orange. A portion of 0.174 g of this solution, corresponding to 5 μmol



Scheme 1 Asymmetric hydrogenation of MAA.

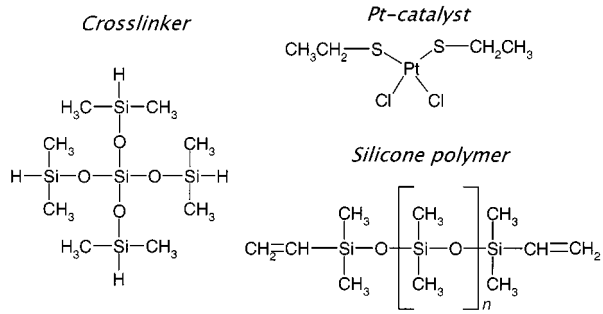


Fig. 1 PDMS constituents.

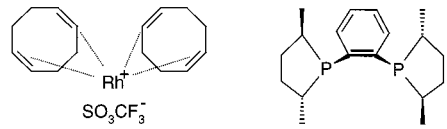

Fig. 2 Rh salt and ligand for Rh–MeDUPHOS synthesis.

of the Rh complex, was poured in a Petri dish and after removal of the methanol, 1.5 g of the PDMS solution was added. After complete dissolution of the complex in this mixture, the solvent was allowed to evaporate. Approximately 3 h later, the curing of the PDMS was finished and the resulting membrane was stored under nitrogen prior to use in the reactor. A typical TEM image of such a composite membrane is shown in Fig. 3, proving the good dispersion of the silica particles in the membrane matrix. A 20 ml reactor with magnetic stirring was used in which the membrane was clamped between two porous stainless steel disks. A volume of 18 ml of methanol was added to the reactor, together with 2 g of MAA. Reaction took place at 60 °C at a pressure of 40 bar during 24 h for the membrane reaction and 2 h for the homogeneous reference reaction. The reaction mixture was analysed with gas chromatography (Chiraldex G-TA column, Astec).

A homogeneous reaction (Table 1) was performed in order to test the activity of the prepared catalyst and its ability to reduce MAA. Even though attempts to utilize Rh–MeDuPHOS in enantioselective ketone hydrogenations were reported to be unavailing[5] and in spite of the fact that Burk *et al.* found other DuPHOS and BPE related catalysts performing better than Ru-BINAP,[3,4] we found for Rh–MeDuPHOS an activity in the MAA hydrogenation at 60 °C that was even superior to that of Ru–BINAP, a catalyst commonly used for this reaction.[9,13,14] The membrane occluded catalyst (membrane thickness 452 μm) was first tested in ethylene glycol (EG), the solvent preferentially used for the analogous Ru–BINAP/PDMS system.[15] The activity of the catalyst was lower than in the homogeneous reaction but remained constant in a second run, in which the same enantioselectivity was maintained. No reactivity was

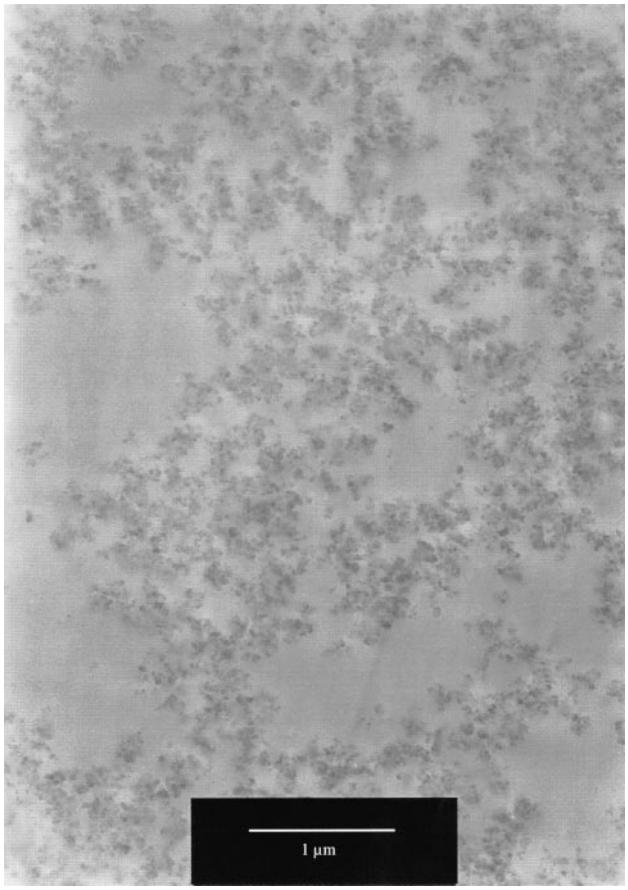

Fig. 3 TEM photograph of a PDMS membrane containing 10 wt% silica.

Table 1 Turnover frequency and enantioselectivity in the hydrogenation of MAA. (H = homogeneous reaction; 1 = first membrane reaction; 2 = second membrane reaction). All reaction selectivities were 100%. Reaction time: 2 h (for homogeneous reactions) or 24 h (for heterogeneous reactions)

Catalyst	Solvent	TOF/h^{-1}	ee(%)
Rh–MeDuPHOS (H)	MeOH	482	99
Ru–BINAP (H)	MeOH	135	90
Rh–MeDuPHOS/PDMS (1)	EG	7	93
Rh–MeDuPHOS/PDMS (2)	EG	7	93
Rh–MeDuPHOS/PDMS (1)	MeOH	28	90
Rh–MeDuPHOS/PDMS (2)	MeOH	28	90

found when only the reaction mixture from the first membrane catalysed reaction was used in another run after adding new substrate to the reactor. This proved that the reported system was a truly heterogeneous version of the catalyst. By performing the reaction in methanol, the membrane activity (thickness 578 μm) could be increased fourfold, while leaving enantioselectivity quasi-unaffected. Exactly the same results were found in a second run. This is remarkable because methanol is a good solvent for the catalyst and it was found earlier that the use of such solvents generally causes leaching of the catalyst from PDMS membranes.[11] Also the mixture of this reaction proved to be completely inactive in a subsequent run with new substrate added. The absence of Rh in all reaction mixtures was also confirmed subsequently with ICP-MS.

The reported heterogenisation allows facile recycling of this versatile catalyst and should enable the development of continuous processes. Experiments to improve the activity of the reported membrane system by optimizing the membrane properties and to expand it further to other reactions and catalysts of this class are planned. In particular, the complete absence of leaching in methanol opens interesting perspectives in this respect.

I. V. thanks the Fund of Scientific Research (F.W.O.) for a grant as a Post-Doctoral Researcher.

Confinement of dimeric sulfuric acid in a self-assembled molecular capsule: $[(H_2SO_4)_2\subset(\text{calix[5]arenesulfonic acid})_2]$

Michaele J. Hardie, Mohamed Makha and Colin L. Raston

Received (in Columbia, MO, USA) 14th September 1999, Accepted 7th October1999

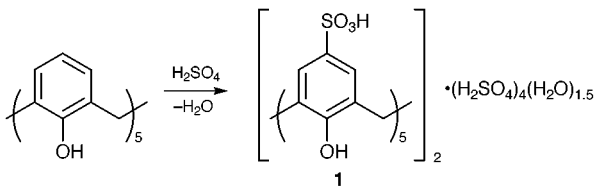
Self-assembled molecular capsules are formed on crystallisation of calix[5]arenesulfonic acid resulting from treating calix[5]arene with sulfuric acid; the calix[5]arenesulfonic acid molecules dimerise *via* hydrogen bonding through the sulfonic acid groups, shrouding two hydrogen-bonded sulfuric acid molecules as the supermolecule $[(H_2SO_4)_2]\subset\{(\text{calix[5]arenesulfonic acid})_2]$.

Highly charged water soluble sulfonated calix[4,5,6,8]arenes form a diverse range of complexes and structural types depending on the counter ion/degree of protonation.[1–13] We recently showed that *p*-sulfonatocalix[4]arenes form superanions or ionic capsules in water at low pH in which two calixarenes shroud an 18-crown-6 molecule bearing sodium and two *trans*-water molecules, or a tetra-protonated cyclam molecule, the counter ions being chromium(III) oligomeric species.[12,13] This work relates to a surge in contemporary studies on the formation of self-assembled molecular capsules using hydrogen bonding,[14–18] and the formation of other ionic capsules held together by coordination interactions.[19,20] In general, molecular/ionic capsules are of interest in building large polyhedral structures similar to those in biological systems, trapping and stabilising molecules, and for novel functions such as drug delivery, separation problems and chemical transformations.[14–20]

We now report the synthesis and structural characterisation of a molecular capsule comprised of two calix[5]arenesulfonic acid molecules which encapsulate two sulfuric acid molecules as a hitherto unknown hydrogen bonded dimer. Treatment of calix[5]arene† with sulfuric acid then cooling the brown solution to –15 °C for several weeks gave the corresponding *para*-substituted penta-sulfonic acid isolated as a mixed sulfuric acid/water adduct, (calix[5]arenesulfonic acid)-$(H_2SO_4)_4(H_2O)_{1.5}$ **1** (Scheme 1). The composition of the material was established from single crystal X-ray diffraction data collected at 123(1) K.[24] The samples appeared uniform but attempts to isolate the crystals were compounded by the extremely fragile, hygroscopic and indeed deliquescent nature of the material on removal from the mother liquor. The decomposed material can be converted to the corresponding sodium salt, as a derivative of compound **1** (yield 50%). NMR studies to ascertain the formation of the capsules in DMSO-d_6 and other solvents were inconclusive. While sulfuric acid is the reagent of choice for sulfonating calixarenes,[1–13] the formation of a sulfuric acid adduct of a calixarene, indeed a host–guest complex, is without precedence.

Details of the structure of **1** are shown in Fig. 1.‡ The compound crystallises in space group $P\bar{1}$ with one supermolecule or molecular capsule, $[(H_2SO_4)_2\subset(\text{calix[5]arenesulfonic acid})_2]$, in the unit cell and thus the capsules lie on inversion centres. In addition to the capsule the unit cell contains six sulfuric acid molecules, disordered over several positions with partial occupancies, and three water molecules of crystallisation, also disordered. The capsules and solvent molecules form a 1D hydrogen bonded network. In contrast the two symmetry equivalent encapsulated sulfuric acid molecules are fully occupied. The S–O bond lengths indicate that S–OH/S=O disorder is likely for the encapsulated sulfuric acids, with one S=O and one S–OH linkage clearly identifiable and the remaining S–O bonds similar within estimated standard deviations. There are several salient features of the capsule. The calixarenes are in the cone conformation, although two of the phenol groups disposed in the 1,3 positions in the calixarene ring are noticeably more tilted away from the principle axis of the calixarene than the other phenolic groups. The tilt angles relative to the plane defined by the five phenolic O-centres are sequentially 150.8, 113.0, 148.7, 125.5 and 123.7° (tilt angle defined as angle from arene centroid to centroid of O_5 plane at the phenolic oxygen). The most tilted phenol group is hydrogen bonded to a sulfuric acid molecule in the cavity of the calixarene, with an O··O separation of 2.92 Å. While the precision of the structure precluded location of the hydrogen atoms, the O··O distances in general are indicative of hydrogen bonding interactions.

Other features of the capsule are that it is flattened in the direction of the principle axes of the calixarenes, and that the calixarenes are slipped relative to each other (Fig. 1). This gives



1

Scheme 1

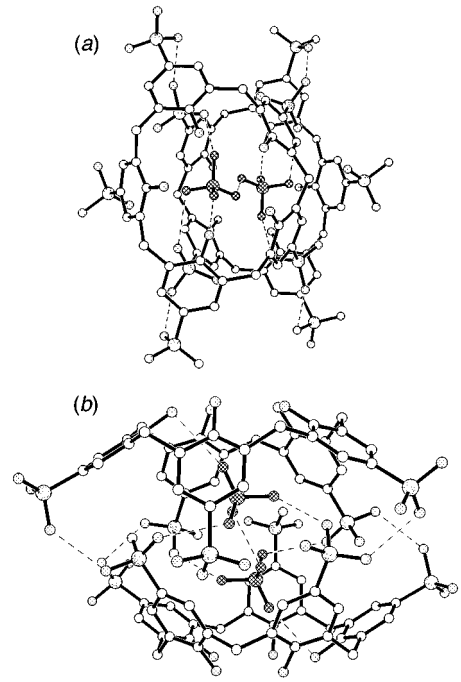


Fig. 1 Projections of the molecular capsule $[(H_2SO_4)_2\subset(\text{calix[5]arenesulfonic acid})_2]$ in the structure of **1** showing (*a*) the alignment of the calixarenes and sulfuric acid molecules in the capsule involving hydrogen bonding, and (*b*) the flattening of the molecular capsule. Hydrogen bonds are shown as dashed lines and the sulfuric acid molecules are cross-hatched.

a snug fit of the sulfuric acid dimer in the capsule, with one sulfuric acid molecule in each of the cavities of the calixarenes, and hydrogen bonding of the sulfonic acid groups of one calixarene with the other. There are four such inter-calixarene (intracapsule) hydrogen bonds (Fig. 1) at O··O separations of 2.62 and 2.64 Å, with inter-digitation of some of the sulfonic acid groups of one calixarene with those of the other calixarene. The binding of the sulfuric acid molecules is driven by four hydrogen bonding interactions per molecule, one for each of the oxygen centres of each sulfuric acid molecule. The oxygen centre residing deepest in the cavity has a hydrogen bond to one of the phenolic O-centres which is skewed furthest from the average cone conformation. Two others are to sulfonic groups of the other calixarene, at 2.39 and 2.79 Å, and this also is a manifestation of the flattened nature of the capsule. The other hydrogen bond involves an oxygen atom of its centrosymmetric related sulfuric acid molecule at an O··O distance of 2.63 Å.

The single hydrogen bond linking the sulfuric acid dimer is particular noteworthy in the context of the structure of crystalline sulfuric acid. Here there is a continuous two-dimensional puckered sheet-like array of acid molecules held together by hydrogen bonding interactions such that each oxygen in the tetrahedral arrangement of O-atoms around each sulfur forms a single hydrogen bond to another sulfuric acid molecule (O··O separation 2.62 Å).[21] Thus the present structure has two adjacent sulfuric acid molecules interacting with each other through vertices of the tetrahedra analogous to the continuous structure of sulfuric acid itself. Furthermore the S–O··O angles are similar (109.9 *cf.* 120.4° in **1**). This is also the type of hydrogen bonding in the few sulfuric acid adducts which have been structurally authenticated.[22] Alternative hydrogen bonding modes are possible including face-to-face linking of the tetrahedra. Effectively we have stabilised a dimer of a similar spatial arrangement as two adjacent sulfuric acid molecules in the continuous structure.

The structure of compound **1** is notably different from that of the corresponding Na salt where the calixarenes do not form molecular capsules.[3,9] This is in direct contrast to the only other structurally authenticated calixarenesulfonic acid, {calix[6]arenesulfonic acid}.23H_2O, which is isostructural with its corresponding Na salt, and has the calix[6]arene in a double partial cone conformation, effectively excluding the possibility of capsule formation.[23]

The results herein extend the range of molecular capsules which can be assembled using the principles of supramolecular chemistry, from the initial studies on calix[4]arene[12,13] to the larger calix[5]arene. Success here suggests that a range of species may be encapsulated, depending on interaction complementarity between the molecules and with calixarenes and between the calixarenes. It is likely that the larger calix[5]arene has greater flexibility, able to form a flattened, slipped structure, as in **1**, or an expanded structure able to encapsulate larger molecules, beyond the crown ether in the above calix[4]arene studies.[12,13]

Support of this research from the Australian Research Council is gratefully acknowledged.

† *Synthesis:* *p-tert*-Butylcalix[5]arene was prepared by the literature method (ref. 24) and debutylated by standard procedures (ref. 25). Calix[5]arene (0.25 g, 0.47 mmol) was treated with 98% sulfuric acid (3 ml) at 80 °C for 10 h, and the resulting brown solution cooled then stored at –15 °C for several weeks, whereupon colourless crystals of deliquescent (calix[5]arenesulfonic)(H_2SO_4)$_4$(H_2O)$_{1.5}$ deposited which proved difficult to isolate in an analytically pure form. δ_H(DMSO-d_6) 7.15 (s, ArH), 6.22 (s, broad, COH/SOH, shifts downfield with increasing [H_2SO_4]), 3.85 (s, $ArCH_2Ar$). For H_2SO_4: δ_H(DMSO-d_6) 12.32 (s, SOH).

‡ *Crystal data* for **1**: A prismatic crystal of dimensions 0.25 × 0.20 × 0.15 mm was mounted on a glass capillary under oil and quickly placed under a stream of cold nitrogen. The crystal lost clarity during mounting, indicating a degree of deterioration. X-Ray data were collected at 123(1) K on an Enraf-Nonius KappaCCD single crystal diffractometer with Mo-Kα radiation (λ = 0.71073 Å). Data was corrected for Lorentzian and polarisation effects, but not absorption. The structure was solved by direct methods with SHELXS-97 and refined by full-matrix least-squares on F^2 using SHELXL-97. (Calix[5]arenesulfonic acid)(H_2SO_4)$_4$(H_2O)$_{1.5}$: $C_{35}H_{49}O_{37.5}S_9$, M_r = 1358.28 g mol^{-1}, triclinic, space group $P\bar{1}$, a = 11.7770(3), b = 15.9118(4), c = 16.0580(4) Å, α = 105.459(1), β = 90.871(1), γ = 105.767(1)°, U = 2778.68(12) Å^3, Z = 2, ρ_{calc} = 1.623 g cm^{-1}, μ = 0.464 mm^{-1}, 2.6 < 2θ < 55.0, 57663 reflections measured, 12660 unique reflections (R_{int} = 0.073), 7156 observed [($I > 2\sigma(I)$], 846 parameters, 2 restraints, R_1 = 0.1267 (observed data), wR_2 = 0.4012 (all data), S = 1.384. C–H hydrogen atoms of the calixarene were fixed at geometrically estimated positions with a riding refinement. A number of the sulfuric acid molecules and the waters were disordered and given partial occupancies. Two disordered sulfuric acid groups were modelled with restrained S–O bond lengths. Received (in Cambridge, UK) 20th September 1999, Accepted 27th October 1999

The ^{1}H NMR spectrum of the fulleroid $C_{61}H_2^{6-}$ consists two high field doublets, providing experimental evidence for diamagnetic five-membered rings in C_{60}^{6-}.

Aromaticity, one of the most important and interesting concepts of organic chemistry, has undergone certain modifications since the original proposition by Hückel in 1931.[1] The theory was then devoted to single π-conjugated ring systems, later expanded to polycyclic molecules[2] and recently to non-planar molecules.[3]

The discovery of fullerenes[4] offers a new challenge in the field of aromaticity as the fullerenes are not only conjugated systems but are also spherical and therefore, no borderlines exist and numerous Kekulé structures can be assigned.[5] In the quest to understand the nature of the electronic structure of fullerenes their reduction is a method of choice as these molecules are capable of accepting a high number of electrons with only small changes in their rigid skeleton.

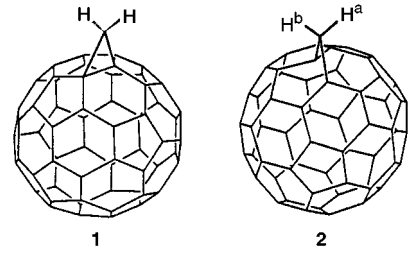
For the most abundant fullerene C_{60}, calculations,[6] as well as experimental data,[6b,7] demonstrate only a modest aromatic character. Calculations also indicate that the lowest unoccupied molecular orbital (LUMO) of C_{60} is low-lying and triply degenerate, and hence is capable of accepting six electrons,[6a,8] which is confirmed by the presence of six reduction waves in its cyclic voltometry.[9]

The magnetic ring current susceptibility of C_{60}^{6-} is expected to be very high[6a] in contrast to C_{60}, as was recently shown experimentally.[10] This is corroborated by calculations showing that the ring current of C_{60} is a result of two contributions, the diamagnetic six-membered rings (6-MRs) and the paramagnetic five-membered rings (5-MRs). These two opposite contributions cancel each other in C_{60}, leading to a low magnetic susceptibility. Moreover, calculations predict that in C_{60}^{6-} the 5-MRs will be diamagnetic, which should cause a high diamagnetic ring current in the entire system.[11]

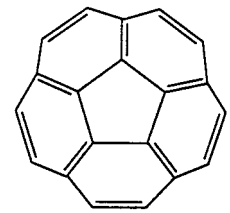
An accepted method of studying local ring currents in polycyclic arrays is by attaching a methylene bridge, where the protons of the bridge are located above the centers of the ring, and their chemical shifts can probe the magnetic character of each ring.[2]

By the addition of CH_2N_2 to C_{60} two methylene adduct isomers of $C_{61}H_2$ were prepared.[12] The two protons of the methylene can be located either both above two 6-MRs (**1**) or one above a 6-MR (H^a) and the other one above a 5-MR (H^b) (**2**). In isomer **2**, the two different protons can serve as external and localized probes for the two rings types. The ^{1}H NMR spectrum of **2** consists of two doublets, at δ 2.84 and 6.35, which are ascribed to H^a and H^b, respectively.[12a] Therefore, it can be deduced that the 6-MR is diamagnetic, and the 5-MR is paramagnetic, as predicted by calculations.[11]

Here we report the reduction of **2** to a hexaanion and the characterization of the anion by NMR.[13] The reduction was carried out, in a 5 mm NMR tube equipped with a reduction chamber on top, in THF-d_8, with excess lithium metal and in the presence of corannulene (**3**). Lithium metal reduction of fullerenes requires extreme conditions, including the use of an ultrasonic bath. However, it has previously been reported that polycyclic molecules and especially **3** could serve as 'electron shuttles' which transport electrons in etheral solution to fullerenes, and thus enable the reduction of the insoluble C_{60} under mild conditions.[10] The solution was brought into contact with the lithium metal by repeatedly inverting the tube, and formation of the anion was detected by ^{1}H, ^{13}C and ^{7}Li NMR spectroscopy.



1 **2**



3

The ^{1}H NMR spectrum of the anion (Table 1) shows two doublets at δ 1.34 and 2.74 (J = 8.93 Hz). The $\Delta\delta$ between these two peaks is significantly smaller than the difference between the peaks of the neutral molecule [$\Delta\delta$(**2**) = 3.51 ppm compared with $\Delta\delta$(**2**$^{6-}$) = 1.4 ppm].[12a] The small $\Delta\delta$ of **2**$^{6-}$ suggests a similar magnetic environment for the two protons, in contrast to the neutral molecule, and moreover, the two protons of **2**$^{6-}$ are shielded. Since they are located above the centers of the rings, it confirms that these two rings are both diamagnetic, and thus the 5-MR is forced to become diamagnetic.

The ^{13}C NMR spectrum of **2**$^{6-}$ shows an NMR band at δ 37.08 assigned to the methylene carbon, and the fullerene

Table 1 Proton and carbon chemical shifts

	δ_C	δ_H	Ref.
C_{60}	142.68		16
C_{60}^{6-}	156.7		14
$C_{61}H_2$ (**2**)	38.4 (CH_2), 135.15–149.25	2.84, 6.35	12(*a*)
$C_6H_2^{6-}$ (**2**$^{6-}$)	37.08 (CH_2), 138.07–164.68	1.34, 2.74	

skeleton NMR bands appear in the region δ 138.07–164.68. The ^{7}Li NMR spectrum shows an absorption at δ 1.93 (200 K, relative to 1 M LiCl in D_2O at 298 K). Comparison of these chemical shifts to those of C_{60}^{6-} (δ_C 156.7 and δ_{Li} 1.6)[14] shows two phenomena: (i) the reduction of **2** leads to a hexaanion, as does C_{60};[6a,8,9] (ii) the character of $\mathbf{2}^{6-}$ is 'fullerene like' and has a similar charge distribution and aromaticity to C_{60}^{6-}.

Charging of $C_{61}H_2$ not only sheds light on the magnetic properties of its hexaanion, but it also contributes to the understanding of the nature of the building blocks of C_{60} itself. These results are in a good agreement with calculation,[11] and with ^{3}He chemical shift measurement[15] of He@C_{60} and He@C_{60}^{6-} that have been previously reported.[10] While the ^{3}He served as an endohedral probe of the bulk magnetic properties, the protons in **2** serve as external and localized probes. Therefore, it can be concluded that the extra electrons of C_{60}^{6-} convert 5-MRs from paramagnetic building blocks ('anti-aromatic') to components having diamagnetic nature ('aromatic'). The change of the ring current in the 5-MRs on the one hand, and the similarity of the aromatic 6-MRs in the neutral and the charged species on the other, demonstrates and rationalizes the highly aromatic character of C_{60}^{6-}.

We thank the Research and Development Authority of the Hebrew University of Jerusalem for financial support.

13 A justification for using the fulleroid **2** as an analogous system to C_{60} is based on the small change of the ^{3}He chemical shift between ^{3}He@C_{60} and ^{3}He@$C_{61}H_2$, which is evidence that both have the same bulk magnetic properties and there is no perturbation of the C_{60} π-system in $C_{61}H_2$ (see ref. 15).

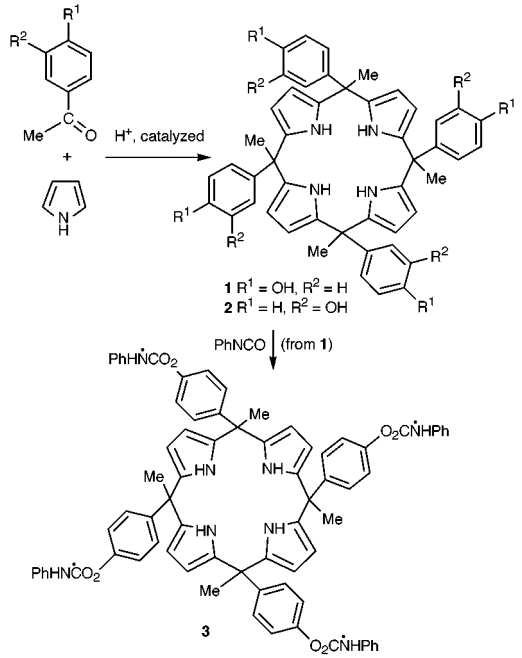
Received (in Cambridge, UK) 17th September 1999, Accepted 20th October 1999

The acid-catalyzed condensation of pyrrole with *p*- or *m*-hydroxyacetophenone led to the formation of *meso*-tetramethyltetrakis(hydroxyphenyl)calix[4]pyrroles occurring in three isomeric forms, with the cone conformer displaying topologically variable multi-site or multi-point surfaces for binding neutral or anionic substrates.

There has been a recent explosive development in the realm of molecular recognition of polar, and often uncharged, multifunctional organic molecules in which multi-point hydrogen bonds provide stabilization.[1–3] Multi-point hydrogen bonding molecules are appropriate devices for the maintenance of the function and structure of complex biomolecules.[4] Many of them are bifunctional molecules, *i.e.* amino acids[5a] and steroids,[5b,3c] all requiring bifunctional hosts which have two chemically different binding areas. The present report deals with the discovery of a class of compounds particularly appropriate to play a role in multi-point or multi-site host–guest interactions. An important factor in any artificial receptor is simplicity of synthesis, and this is the case reported here. The general synthetic procedure is shown in Scheme 1. The acid-catalyzed condensation of pyrrole with *p*- or *m*-hydroxyacetophenones led to the formation of the expected *meso*-octaalkylporphyrinogen derivatives[6,7] **1**‡ and **2**,† occurring in three isomeric forms (the cone **a**, the partial cone **b** and the 1,2 alternate conformation **c**) in a 7:2:1 ratio.



Scheme 1

The separation of the three isomers was performed either by crystallization or chromatography.†‡ The identification of the three isomers is conveniently made by ^{1}H NMR spectroscopy. Compound **1** in its cone conformation **a** is associated into dimers or trimers, the molecular complexity being determined by the guest molecule.[1–3,8] In the presence of hydrogen-binding substrates such as DMF or acetic acid, the isomer **1a** is assembled into closed two-basket cavity dimers,[1] **1a**·DMF (Fig. 1),§ or into cyclic trimeric units, **1a**·AcOH (Fig. 2),§ displaying C_3 symmetry. The trimeric cavity hosts nine molecules of AcOH, three of them being associated to the porphyrinogen moieties while the other six establish an intermolecular hydrogen bonding network with other trimers.

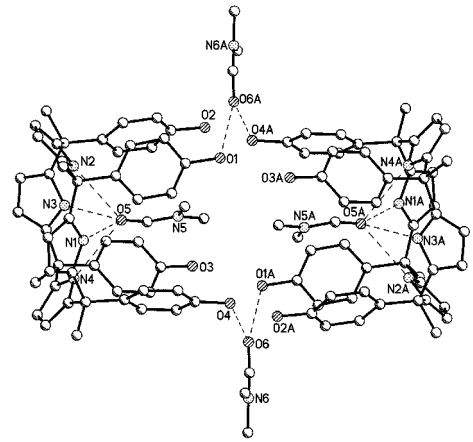


Fig. 1 A plot of **1a**·DMF linked into pairs by hydrogen bonds. Selected bond distances (Å) and angles (°): N–H···O [H···O$_{av}$ = 2.15, N···O$_{av}$ = 3.013(7), N-H···O$_{av}$ = 170.0]. Letter *A* denotes the symmetry transformation −*x*, −*y*, −*z*.¶

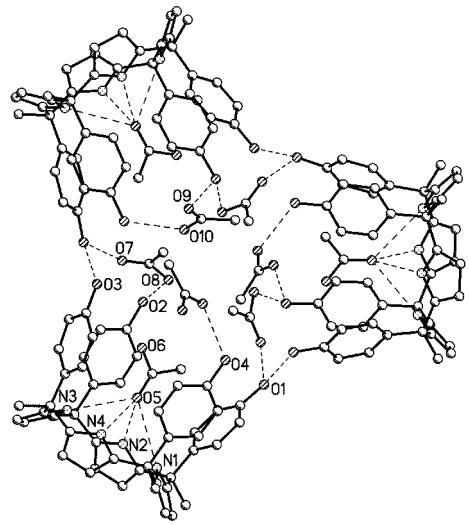

Fig. 2 A plot of **1a**·AcOH associated into trimers by hydrogen bonds and viewed down the three-fold axis. Selected bond distances (Å) and angles (°): N–H···O [H···O$_{av}$ = 2.26, N···O$_{av}$ = 3.140(5), N–H···O$_{av}$ = 174.0].¶

† Details of the synthesis and characterisation of **1**–**3** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2413/

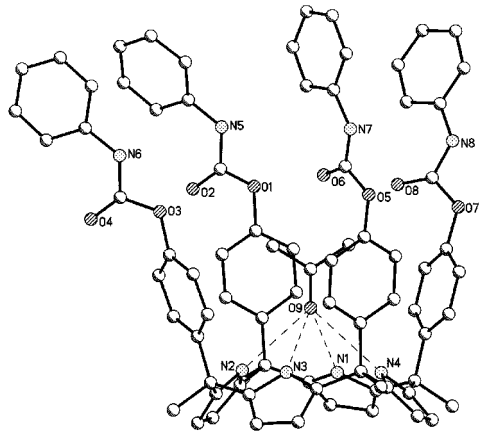

Fig. 3 A plot of **3** showing the interaction with the inner acetone. Selected bond distances (Å) and angles (°): N–H···O [H···O$_{av}$ = 2.26, N···O$_{av}$ = 3.12(1), N–H···O$_{av}$ = 168.1].¶

Therefore the overall structure of **1a**·AcOH is a tridimensional cylindrical cavity. Compound **1a** has been converted into the corresponding *N*-phenylcarbamate **3**,† which was crystallized from acetone (Fig. 3).§ The structure of **3** shows the same conformation of the monomeric unit in **1**. The guest molecules, except those bonded to the porphyrinogen moiety,[9] are loosely bonded and easily lost on gentle heating *in vacuo* or in solution, as shown by the ^{1}H NMR spectra.

Unlike other attempts,[10] our approach maintained in **1**–**3** both the OH and NH surfaces associated with the cone conformation of calix[4]arene and calix[4]pyrrole, thus, depending on the tunable spacer, being appropriate hosts of functionalizable molecules.

The overall structures of **1**–**3** deserve some additional comments concerning the calix[4]arene fragment, since the calix[4]pyrrole moieties are structurally very close to that of the well known *meso*-octaalkylporphyrinogens.[7] In our case, we are dealing in fact with an upside down flexible calix[4] unit cavity, the connectivity between the phenol groups being assured through the *p*-carbons of the phenyl substituent rather than through the *o*-carbons. In the three compounds the most significant structural parameters related to the monomeric building block are very close: (*i*) the planarity of the N_4 and O_4 set of atoms; (*ii*) the distance between the two parallel O_4 and N_4 planes [5.482(4), **1a**·DMF; 5.492(7), **1a**·AcOH; 5.53(2) Å, **3**]; (*iii*) the size of the slightly elliptical cavity, which can be roughly estimated from the opposite oxygen's distance [9.915(7) and 8.14(1), **1a**·DMF; 10.146(5) and 8.435(6), **1a**·AcOH; 10.478(9) and 8.19(1) Å, **3**]. The general synthesis outlined in Scheme 1, with an appropriate choice of acetophenone derivatives and the various conformations associated both with the porphyrinogen and the calix[4]arene moieties, will allow us to obtain topologically variable (tubes, cylinders *etc.*) multi-site or multi-point surfaces for binding neutral or anionic substrates.

‡ *Synthesis* of **1**: MeOH (10 ml) was added to a solution of *p*-hydroxyacetophenone (80.0 g, 588 mmol) and pyrrole (40 cm^3, 588 mmol) in MeOH (200 cm^3). The reaction was refluxed for 3 h and then quenched with water (700 cm^3). A yellow solid precipitated, which was collected and dissolved in Et_2O (400 cm^3). A black residue was filtered off and the solution was evaporated to dryness to give a light pink powder, which was dried *in vacuo* (10^{-7} Mbar) at 90 °C for 24 h (65.3 g, 60%). The ^{1}H NMR spectrum of this powder showed a mixture of the three isomers **1a**–**c** in a 7:2:1 ratio. Each isomer was isolated by flash chromatography (CH_2Cl_2–*n*-hexane–MeOH, 8:1.4:0.6). All the fractions were dried *in vacuo* (10^{-7} Mbar) at 90 °C for 24 h. The third fraction [R_f = 0.193 (UV)] contained the major isomer **1a**: δ_H (acetone-d_6, 400 MHz, 298 K) 8.74 (s br, 4H, NH),8.15(s br, 4H, OH), 6.76 (d, *J* 8.8, 8H, ArH), 6.65 (d, *J* 8.8, 8H, ArH), 5.94 (d, *J* 2.45, 8H, C_4H_2N), 1.8 (s, 12H, CH_3). The major isomer **1a** (30.0 g) was also isolated by crystallization of the isomeric mixture from AcOH (19.4 g, 59%); δ_H(THF-d_8, 200 MHz, 298 K) 8.35 (s br, 4H, NH), 6.90 (d, *J* 8.8, 8H, ArH), 6.56 (d, *J* 8.8, 8H, ArH), 5.63 (d, *J* 2.45, 8H, C_4H_2N), 1.88 (s, 12H, CH_3 overlapping with s, 3H, CH_3COOH). Acetic acid elimination from **1a**·AcOH was carried out by azeotropic distillation with Bu_2O. Crystals suitable for X-ray diffraction, grown from a THF–AcOH solution, contain AcOH in a **1a**:AcOH = 1:3 molar ratio. Crystals of **1a**·DMF suitable for X-ray analysis and containing DMF in a **1a**: DMF = 1:3 molar ratio were obtained from a DMF–THF solution of the isomeric mixture; δ_H(THF-d_8, 200 MHz, 298 K) 9.14 (s br, 4H, NH), 8.12 (s br, 3H, CHO), 6.69 (d, *J* 8.8, 8H, ArH), 6.48 (d, *J* 8.8, 8H, ArH), 5.90 (d, *J* 2.6, 8H, C_4H_2N),2.70 (s br, 18H, CH_3), 1.75 (s, 12H, CH_3); (THF-d_8, 200 MHz, 330 K) 9.12 (s br, 4H, NH), 7.91 (s br, 3H, CHO), 6.70 (d, *J* 8.8, 8H, ArH), 6.48 (d, *J* 8.8, 8H, ArH), 5.90 (d, *J* 2.6, 8H, C_4H_2N), 2.60 (s, 12H, CH_3), 2.25 (s br, 6H, CH_3), 1.76 (s, 12H, CH_3).

§ *Crystal data* for **1a**·DMF: $C_{48}H_{44}N_4O_4{\cdot}C_4H_8O{\cdot}3C_3H_7NO$, *M* = 1032.26, monoclinic, space group $P2_1/c$, *a* = 10.960(2), *b* = 21.081(4), *c* = 24.039(5) Å, β = 90.42(3)°, *V* = 5554.0(19) Å^3, *Z* = 4, D_{calc} = 1.235 g cm^{-3}, *F*(000) = 2208, λ(Mo-Kα) = 0.71070 Å, μ(Mo-Kα) = 0.082 mm^{-1}; crystal dimensions 0.20 × 0.13 × 0.10. Dendrimers based on cyclophosphazene units and containing chiral ferrocenyl ligands for asymmetric catalysis†

Raoul Schneider, Christoph Köllner, Immo Weber and Antonio Togni*

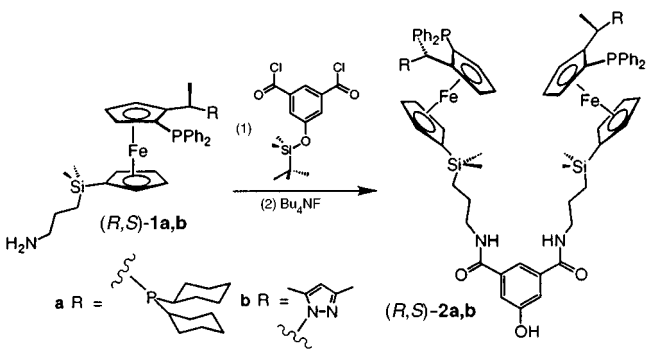
Laboratory of Inorganic Chemistry, Swiss Federal Institute of Technology, ETH Zentrum, CH-8092 Zürich, Switzerland. E mail: togni@inorg.chem.ethz.ch

Received (in Basel, Switzerland) 29th September 1999, Accepted 26th October 1999

A simple and efficient synthesis and characterization of a series of first generation dendrimers based on cyclophosphazene cores and containing up to 16 peripheral chiral ferrocenyl ligands is described.

Dendrimers,[1] highly branched three-dimensional monodisperse macromolecules, are in principle useful for applications in catalysis, but have still rarely been prepared for this purpose.[2] As an interface between heterogeneous and homogeneous catalysis, such catalysts react in homogeneous solution but may be recycled by means of nanofiltration.[3] We have previously shown that chiral ferrocenyl ligands may be successfully applied to a variety of asymmetric catalytic reactions,[4] and that these ligands could be conveniently functionalised with a view to attaching them to the periphery of dendrimers by a convergent approach.[5] It has been found that such macromolecules, when used in catalytic reactions, do not show relevant differences in terms of stereoselectivity and catalytic activity, as compared to their monomeric congeners and are completely recovered by nanofiltration.[5]

In continuation of our studies, we aimed to improve and simplify the preparation of our dendritic ligands. We report now an efficient three-step synthesis of a new family of dendrimers containing up to 16 chiral ferrocenyl ligand units with PP or PN chelating systems. The synthesis starts from compounds of type **1** and utilises cyclotriphosphazene or tetraphosphazene units as dendrimer cores. Although the N_3P_3 fragment has been used previously in pioneering work by Majoral and co-workers,[1g,h] the next larger oligomeric N_4P_4 phosphazene ring[6] has not been exploited before in dendrimer chemistry. The precursors $N_3P_3Cl_6$ and $N_4P_4Cl_8$ offer more branching points, as compared to more commonly used internal fragments, such as trisubstituted benzenes, or tetrasubstituted adamantanes, implying that, for an equal number of synthetic steps, dendrimers containing a higher number of peripheral units may be obtained. Furthermore, because of the higher internal branching, dendritic particles approaching a spherical shape may be obtained with a lower number of generations.



Scheme 1

Thus, the synthesis of the first-generation dendrimers **$G_1$12PN**, **$G_1$12PP** and **$G_1$16PP**, containing 12, 12 and 16 ferrocenyl groups, respectively, was achieved from intermediates **2** (Scheme 1), obtained by reacting **1** with 5-(*tert*-butyldimethylsiloxy)isophthaloyl dichloride followed by deprotection with Bu_4NF. A slight excess of the sodium salt of **2** was allowed to react in dioxane with $N_3P_3Cl_6$ and $N_4P_4Cl_8$, respectively, affording the desired compounds as orange powders in good yields after purification by column chromatography (Scheme 2).

All new multiple ferrocenyl ligands were characterised by NMR (^{1}H, ^{13}C and ^{31}P) and mass spectroscopy.† As expected, the ^{31}P NMR spectra of the products show one singlet for the cyclophosphazene phosphorus atoms, indicating full substitution of the central core [Fig. 1(*a*)]. The peripheral phosphorus atoms in **$G_1$12PN** display a singlet, whereas **$G_1$12PP** and **$G_1$16PP** each show one pair of doublets with a typical long range $^4J_{PP}$ coupling constant of *ca*. 40 Hz, indicating the equivalence of the ferrocenyl units. The new dendrimers were also characterised by MALDI-TOF mass spectroscopy and in all cases the molecular peak could be detected. Several in-source fragmentations at *m/z* values in good agreement with the calculated ones were observed.† Furthermore, addition of 16 equiv. of $[Rh(COD)_2]BF_4$ to **$G_1$16PP**, for example, led to the corresponding monodisperse species containing 16 equivalent and non-interacting Rh complexes, as indicated by the ABX-spin system in the ^{31}P NMR spectrum of Fig. 1(*b*), displaying $^2J_{PP}$ and $^1J_{PRh}$ coupling constants of 30 and 142 Hz. Preliminary experiments with **$G_1$12PP** and **$G_1$16PP** in the Rh-catalysed hydrogenation of dimethyl itaconate, under the conditions

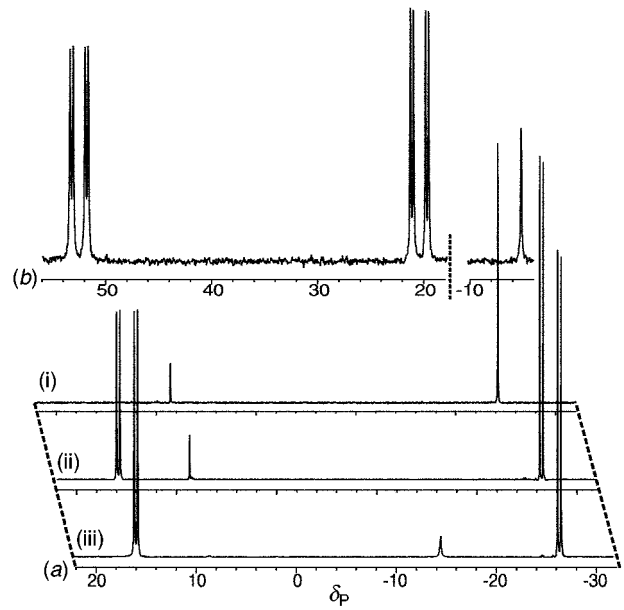


Fig. 1 ^{31}P NMR (101.202 MHz, $CDCl_3$) spectra of G1-dendrimers: (*a*) (i) **$G_1$12PN**, (ii) **$G_1$12PP** and (iii) **$G_1$16PP** and (*b*) **$G_1$16PP** + 16 equiv. of $[Rh(COD)_2]BF_4$.

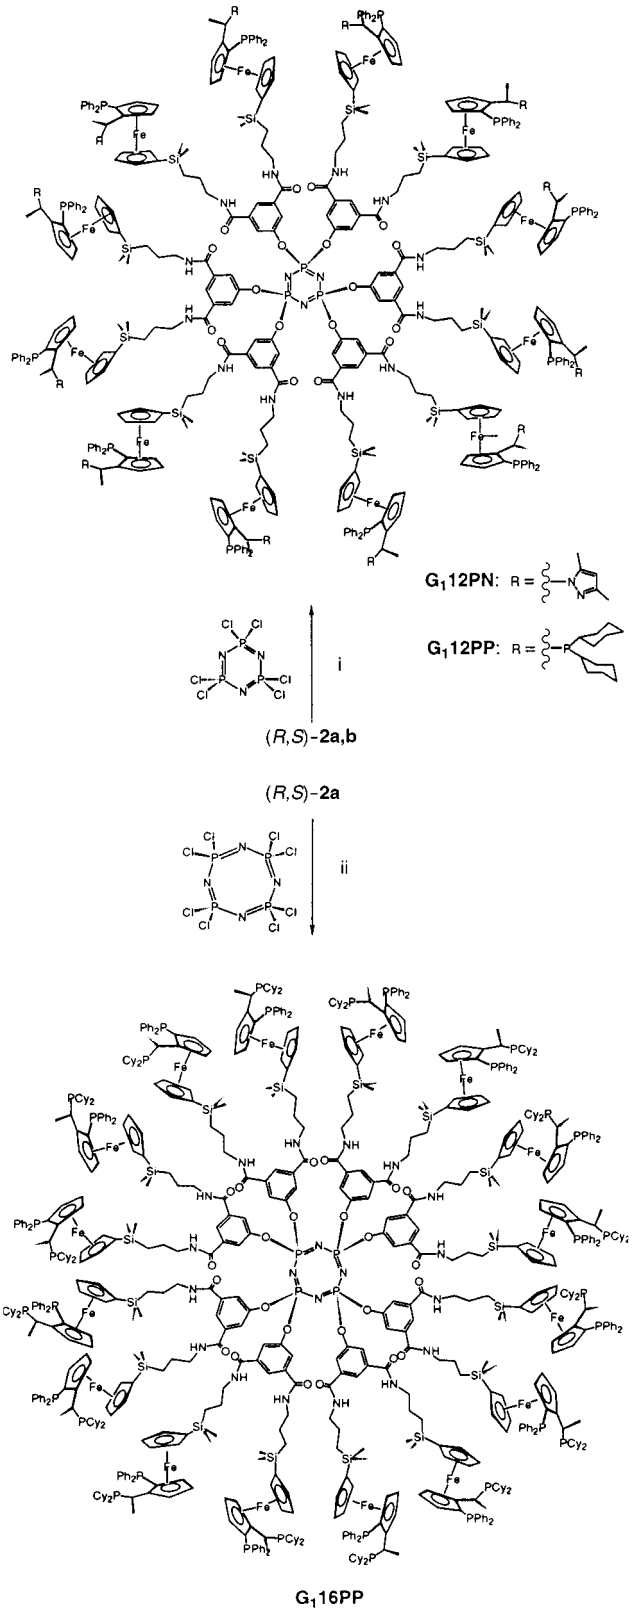
† Experimental and spectral data for (*R,S*)-**2b**, **$G_1$12PN**, **$G_1$12PP** and **$G_1$16PP** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2415/



Scheme 2 *Reagents and conditions*: i, Na, MeOH–1,4-dioxane, 60 °C, 1 h, then $N_3P_3Cl_6$, 1,4-dioxane, 16 h (**$G_1$12PN**: 54%, **$G_1$12PP**: 64,5%); ii, Na, MeOH–1,4-dioxane, 60 °C, 1 h, then $N_4P_4Cl_8$, dioxane, 16 h, 83%.

previously reported,[5] afforded the product in *ca*. 98% ee. This indicates that the dendritic structure of the catalyst, as compared to its monomeric version, is not significantly detrimental to enantioselectivity, at least up to the size of **$G_1$16PP**.

We are currently exploiting cyclophosphazenes for the preparation of dendrimers of higher generations, as well as using such dendrimers as catalysts in a continuous asymmetric hydrogenation process. The results of such investigations shall be disclosed in due course.

We are grateful to Walter Amrein (Laboratory of Organic Chemistry, ETH-Zürich) for measuring MALDI-TOF mass spectra.

New π-extended organic donor containing a stable TEMPO radical as a candidate for conducting magnetic multifunctional materials

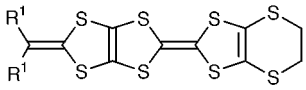
Hideki Fujiwara* and Hayao Kobayashi

Institute for Molecular Science, Myodaiji, Okazaki 444-8585, Japan. E-mail: fuji@ims.ac.jp

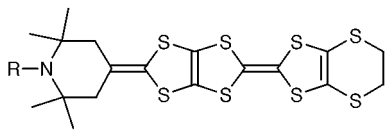
Received (in Cambridge, UK) 10th September 1999, Accepted 20th October 1999

A novel organic electron donor containing a stable TEMPO radical (TEMPOET) was synthesized and its magnetic and electrochemical properties were investigated; furthermore, the crystal structure and physical properties of the $Au(CN)_2^-$ salt of TEMPOET were clarified.

Organic molecular magnetism has become a very active field of research since the discovery of the first pure organic ferromagnet, *p*-nitrophenyl nitronyl nitroxide (β-NPNN), in 1991 and the subsequent development of several ferromagnets based on aminoxyl radicals.[1,2] On the other hand, recent studies on molecular conductors and superconductors containing magnetic transition metal anions, such as the $(ET)_2[(H_2O)Fe(C_2O_4)_3]$•PhCN salt, a series of λ-$(BETS)_2Fe_xGa_{1-x}Cl_4$ alloy salts and the κ-$(BETS)_2FeBr_4$ salt[3] [where ET is bis(ethylenedithio)-TTF and BETS is bis(ethylenedithio)tetraselenafulvalene], have stimulated interest in the interplay between conductivity and magnetism in the search for new organic conductors. Among them, several donors containing a stable aminoxyl radical have been prepared by several research groups for the development of novel organic conducting magnetic multifunctional materials and organic ferromagnetic metals.[4,5] However, no highly conducting salt has been obtained from these donors so far. From the view point of the realization of metallic conductivity, we designed a molecular structure as the fusion of a stable TEMPO radical moiety to a DTET-TTF skeleton, which is a promising building block for realizing stable metallic behavior, as reported in the cases of MeDTET



R^1 = Me, MeDTET
$2R^1$ = –$(CH_2)_4$–, CPDTET

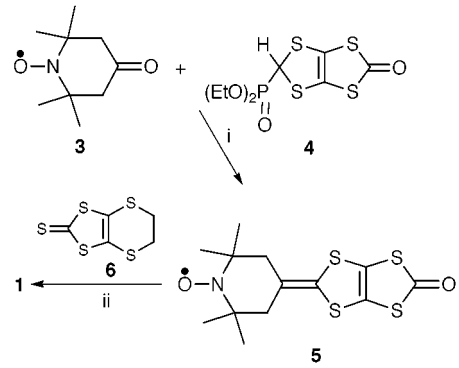


1 R = O•; TEMPOET
2 R = H

and CPDTET salts.[6,7] Here we present the synthesis, structure and physical properties of novel organic donor TEMPOET **1**. Furthermore, we report here the structure and physical properties of its $Au(CN)_2^-$ salt as the first X-ray structure analysis of a cation radical salt based on a TEMPO radical-containing donor.

TEMPOET **1** was synthesized as shown in Scheme 1. Thus, the ketone **5** was obtained in 52% yield by the Wittig–Horner reaction of **4**[8] and 4-oxo-TEMPO **3**. It was then reacted with thione **6** by a cross-coupling reaction. TEMPOET was obtained as air-stable microcrystals in 45% yield.†

As shown in Fig. 1, TEMPOET presents four waves at +0.56, +0.88, +1.17 and +1.77 V *vs.* Ag/AgCl, the first and third ones are slightly reversible, the second one is completely reversible and the fourth one irreversible. The first oxidation potential, +0.56 V, is almost the same as that of ET (+0.53 V). On the other hand, the corresponding piperidine analogue **2** showed



Scheme 1 *Reagents and conditions*: i, 0.5 M LDA (1.1 equiv.), THF, −78 °C, 15 min; ii, $P(OEt)_3$ (100 equiv.), 75 °C, 45 min.

three redox waves. Comparing the redox potentials of **1** to those of **2**, three (+0.56, +0.88 and +1.77 V) of the four potentials of **1** are almost equivalent to the three potentials of **2** (+0.55, +0.87 and +1.74 V). Therefore, the oxidation of the TEMPO radical part is considered to occur at the third oxidation process (+1.17 V), suggesting the possibility of the formation of the cation radical salts with an active TEMPO radical spin. However, the almost complete loss of reversibility of the first redox wave of **1** might indicate the existence of some further reaction in the reductive process of the cation radical state of **1** dissimilar to the case of **2**. The static magnetic susceptibility measurement of **1** showed a paramagnetic value (χ_{rt} = 1.25 × 10^{-3} emu mol^{-1}) corresponding to one S = 1/2 spin per molecule and a Curie–Weiss temperature dependence (θ = −1.00 K).

The $Au(CN)_2^-$ salt of **1** was electrochemically prepared in 1,2-dichloroethane. An X-ray structure analysis revealed that the D:A ratio of this salt is 2:3 and each TEMPOET has +1.5 valence.‡ The N–O bond length of the TEMPO radical part is 1.42(1) Å and is a little longer than that of the reported neutral TEMPO radicals (1.27–1.30 Å).[9] When a TEMPO radical is oxidized, the N–O bond length becomes shorter than the neutral one because of N^+=O double bond formation, as in the case of TEMPO•$TCNQF_4$ complex [1.195(5) Å].[10] Furthermore, judging from the bent form of the N–O bond from the C–N–C plane

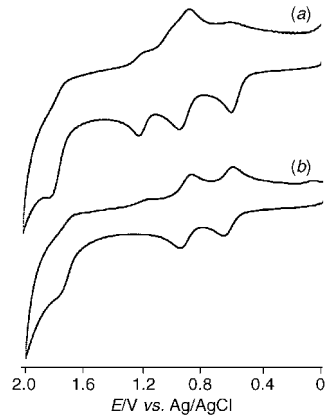


Fig. 1 Cyclic voltammograms of (*a*) **1** and (*b*) **2** in PhCN (scan rate 50 mV s^{-1}).

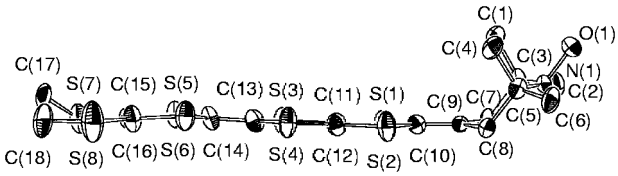

Fig. 2 Structure of the donor molecule in the $(\mathbf{1})_2[Au(CN)_2]_3$ salt.

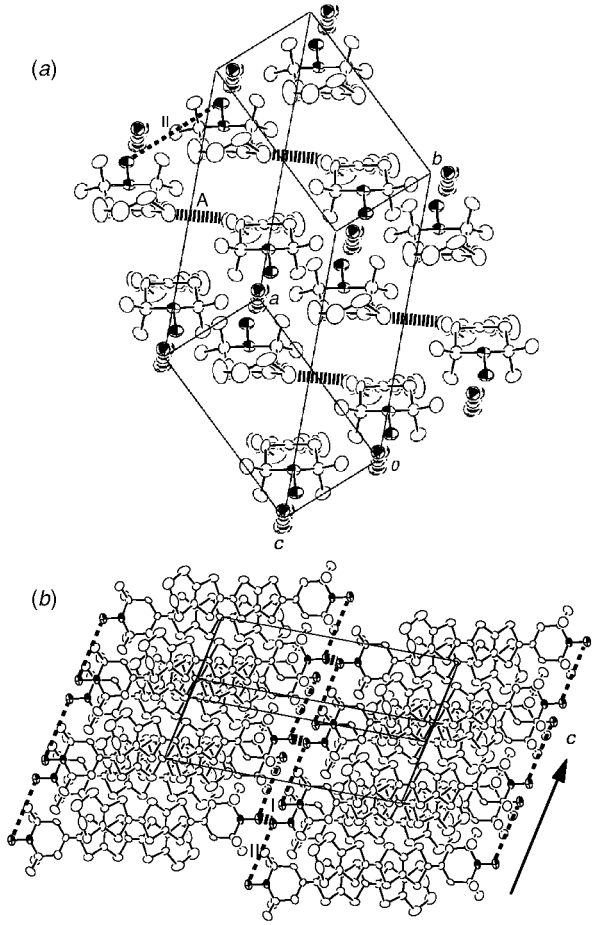

Fig. 3 Crystal structure of $(\mathbf{1})_2[Au(CN)_2]_3$ salt viewed (*a*) along the molecular long axis and (*b*) perpendicular to the molecular planes. S–S contacts: A S(1)–S(7) 3.624(5), S(3)–S(5) 3.658(5) and S(3)–S(7) 3.529(5) Å. O–O distances: I 3.24 and II 7.43 Å.

and the redox behavior of this donor discussed above, we think that the TEMPO radical part is not oxidized in this $Au(CN)_2^-$ salt. The framework of TEMPOET is almost flat except for the chair-formed TEMPO part, suggesting the oxidation of the donor part (Fig. 2). One of the $Au(CN)_2^-$ anions exists between the donor dimers, indicating no overlap of π-orbitals between dimers in the donor stack [Fig. 3(*a*)]. The dimers array along the *c*-axis with an offset of the molecular long axis (4.84 Å) and form sheet-like structure [Fig. 3(*b*)]. There is one very short O··O contact [3.24(2) Å] between the donor sheets. The room temperature electrical conductivity of this salt is low, with a value of about 10^{-3} S cm^{-1}, due to the highly oxidized state and undesirable stacking of donors. The temperature dependence of the resistivity produces semiconducting behaviour with an activation energy of 0.20 eV. The measurement of the magnetic susceptibility of this salt showed a much smaller room temperature value (9.6×10^{-4} emu mol^{-1} for a 2:3 salt) than the expected high value from the coexistence of two TEMPO radical spins and one cation radical spin in the $(\mathbf{1})_2[Au(CN)_2]_3$ salt. This result suggests the existence of intramolecular spin singlet formation and/or intermolecular strong antiferromagnetic spin configuration, which may be derived from the strong spin–spin interaction *via* the very short O–O distances between donor sheets (I). Furthermore the χT value decreases monotonically with decreasing temperature, as shown in Fig. 4. The

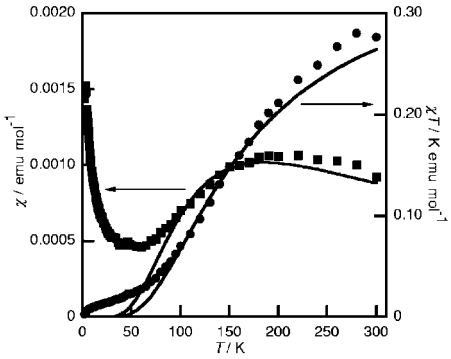

Fig. 4 χ-T (■) and χT–T (●) plots for the $(\mathbf{1})_2[Au(CN)_2]_3$ salt. Solid lines are calculated on the basis of a Bleaney–Bowers expression.

temperature dependence of the magnetic susceptibility is roughly fitted to a Bleaney–Bowers expression[11] and the singlet–triplet gap is estimated to large, with a value of $-2J$ = 206 cm^{-1}, except for the lower temperature region probably due to a small amount of paramagnetic impurities and lattice defects. This result suggests the strong antiferromagnetic interaction between two spins and an almost singlet ground state.

Dramatic effect of the porphyrinic metal on the conformation of a two-ring threaded system

Myriam Linke, Jean-Claude Chambron,* Valérie Heitz and Jean-Pierre Sauvage*

Laboratoire de Chimie Organo-Minérale, U.M.R. 7513 au C.N.R.S.,Université Louis Pasteur, Institut Le Bel, 4, rue Blaise Pascal, 67000 Strasbourg, France. E-mail: sauvage@chimie.u-strasbg.fr

Received (in Basel, Switzerland) 6th September 1999, Accepted 25th October 1999

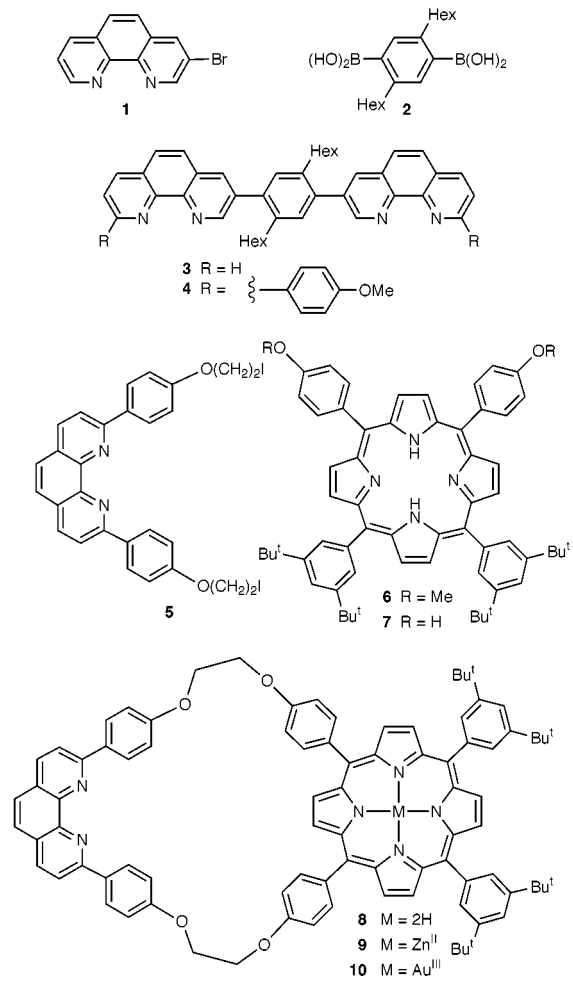
Porphyrin homodimers have been assembled by transition-metal-directed threading of porphyrin-incorporating macrocycles onto a rigid-rod bis-chelate, and the relative orientations of the porphyrins shown to be controlled by the nature of the metal that they contain.

Assemblies of naturally-occurring porphyrins or analogues held by noncovalent interactions are important components of photosynthetic systems, as light antennas, energy funnels, and electron transfer chains.[1] These facts, recently highlighted by beautiful X-ray crystal structures,[2] have stimulated the design and synthesis of multifarious porphyrin aggregates mainly based on coordination bonds, some of them showing relevant electron transfer properties.[3] In particular, the preparation and study of simple dimers of stacked porphyrins is highly significant,[4] as far as mimicking the unusual spectroscopic properties of the Special Pair of bacterial reaction centers is concerned.[5]

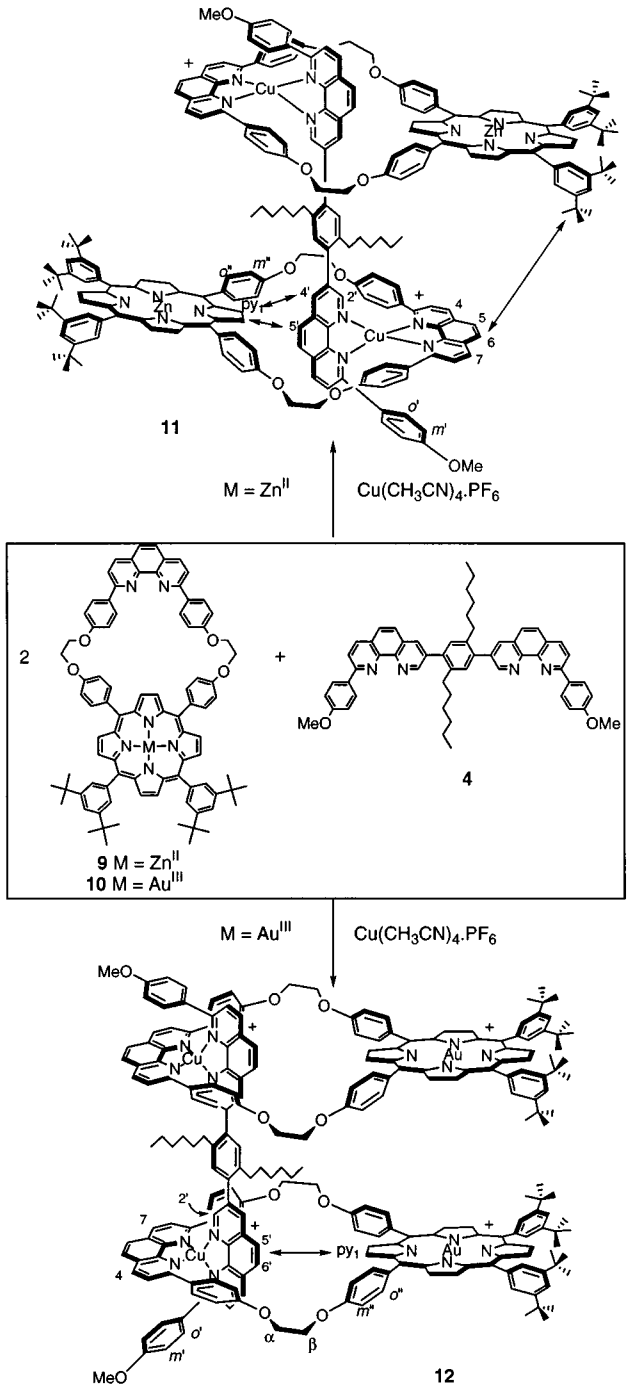
We have recently described the efficient assembly of porphyrin dimers by the transition-metal-controlled *threading* of macrocycles bearing *pendant* porphyrins and incorporating a 2,9-diphenyl-1,10-phenanthroline (dpp) chelate onto molecular threads containing two such dpp fragments.[6] Here we show that when a rod-like, phenanthroline-based bis-chelate and macrocycles *incorporating* metalloporphyrins in their backbone are used, the relative orientations of the porphyrins can be controlled by the nature of the metal that they contain.†

The bis-phenanthroline rigid-rod molecule **4** and the dpp-based macrocycles **9** and **10** incorporating a Zn^{II} and a Au^{III} porphyrin, respectively, as well as their precursors, are represented below. Suzuki coupling of 3-bromophenanthroline **1**[7] and diboronic acid **2**[8] in stoichiometric amounts [$Pd(PPh_3)_4$, aq. Na_2CO_3, EtOH–$PhCH_3$, reflux] afforded bis-phenanthroline **3** in 55% yield after chromatography.[9] This compound was further reacted with lithioanisole (3 equiv.) in THF at −5 °C.[10] After hydrolysis, MnO_2 aromatization and chromatographic separation from substitution isomers and homologues, bis-phenanthroline **4** was isolated in 32% yield. Direct precursors of macrocycle **8**, which incorporates a free-base porphyrin, are the phenanthroline derivative **5** and porphyrin **7**. This latter compound was obtained in quantitative yield by treatment of porphyrin **6**[11] with an excess of BBr_3 in CH_2Cl_2 at −78 °C. High-dilution condensation of **5** and **7** in DMF at 55 °C containing Cs_2CO_3 (5 equiv.) provided **8** in 28% yield after chromatography.[12] Insertion of Zn^{II} was carried out by reaction with $Zn(OAc)_2{\cdot}2H_2O$ (1 equiv.) in a 2:1 refluxing mixture of $CHCl_3$ and CH_3OH, to produce the Zn^{II} porphyrin-incorporating macrocycle **9** in 85% yield. The preparation of the Au^{III} porphyrin-incorporating macrocycle **10**, which could not be obtained by direct metallation of **8**, has been described elsewhere.[11]

Copper(I)-directed threading of either macrocycle **9** or **10** onto bis-phenanthroline rod **4** was carried out as follows (Scheme 1).[6,10] Equimolar amounts of $Cu(CH_3CN)_4{\cdot}PF_6$ in CH_3CN and the desired macrocycle in CH_2Cl_2 were combined under argon. Compound **4** (0.5 equiv.) in CH_2Cl_2 was subsequently transferred to the reaction mixture. After removal of the solvents under reduced pressure, the crude material was flash-chromatographed on silica gel, affording the threaded assembly. The Zn^{II} porphyrin dimer **11** was obtained in 85% yield and its Au^{III} porphyrin analogue **12** in 50% yield. Since the threading experiments proceeded more or less quantitatively, these isolated yields show that partial dethreading takes place during chromatographic purification, especially in the case of the Au^{III}porphyrin dimer **12**.



Diagnostic of macrocycle threading onto bis-phenanthroline **4** are the large upfield shifts of protons *m′* of **4** both for **11** (−1.28 ppm) and **12** (−0.98 ppm), due to ring current effects of the phenanthroline fragment included in the macrocycles on the anisyl extremities of **4**.[13] Methyl protons of these groups are also affected, albeit to a lesser extent. As expected, threading also breaks off the symmetry plane of the macrocycle, which contains the C_2 symmetry axis. The largest resulting splittings are observed for **11**. *o″* and *m″* protons of the porphyrins produce two pairs of signals, indicating that the rotation of the



Scheme 1 Cu^{I}-directed threading of macrocycle **9** or **10** onto bisphenanthroline **4**. Protons highlighted in the text are indicated, as well as intercomponent NOE effects.

corresponding phenylene groups is slow on the NMR timescale, and α and β protons of **11** clearly form two sets of diastereotopic pairs of atoms.

Despite these common features, the ^{1}H NMR spectra of the threaded complexes **11** and **12** showed dramatic differences, which could not be attributed solely to the different nature of the metal cation of the porphyrins. Upon threading, protons 2′ of **4** and (4,7) of the macrocycles are −2.54 and −0.59 ppm more shielded, respectively, when **11** is compared to **12**. 2D ^{1}H NMR ROESY experiments on **11** showed a remarkable intercomponent NOE crosspeak between the Zn^{II} porphyrin Bu^{t} groups and the pair (5,6) of protons of the phenanthroline fragment belonging to a different macrocycle, that was absent in the case of **12**. For the latter, a symmetrical correlation between py_1 of the Au^{III} porphyrins and the pairs (5′,6′) of protons of **4** could be observed, which, in the case of **11**, involved protons 4′ and 5′ instead.

All of these data suggest that, in the threaded system **11**, the Zn^{II} porphyrin components are roughly antiparallel, as shown in Scheme 1, each being tilted towards the phenanthroline chelate of the macrocycle maybe thanks to attractive interactions between the electron-rich Zn^{II} porphyrin of one macrocycle and the electron-deficient Cu^{I}-complexed phenanthroline included in the other macrocycle. The significant differences in the ^{1}H NMR spectra of **11** and **12** suggest that the Au^{III} porphyrin dimer has a conformation dramatically different from that of the Zn^{II} porphyrin dimer. The Au^{III} porphyrins being cationic, they are no longer able to stack with the Cu^{I}-complexed phenanthrolines, due to electrostatic repulsion. A likely conformation would be that represented in Scheme 1, in which the two Au^{III} porphyrins are roughly parallel. In conclusion, the threaded complexes **11** and **12** represent new members of the family of porphyrin dimers assembled with coordination bonds. The present study also shows that, by modifying the nature of the central metal in threaded porphyrin-containing systems, dramatic geometrical changes are induced.

We warmly thank J.-D. Sauer for the 400 MHz NMR spectra and R. Huber for the FAB mass spectra. We are grateful to P. Staub for the preparation of 3-bromophenanthroline. M. L. thanks the Ministère de l'Enseignement Supérieur et de la Recherche for a fellowship.

Synthesis and structure of $Li_2Al_3(HO_3PMe)_2(O_3PMe)_4Cl{\cdot}7H_2O$, an ionic, layered lithium aluminium methylphosphonate

Gary B. Hix,*† David S. Wragg, Ivor Bull, Russell E. Morris and Paul A. Wright

Department of Chemistry, University of St. Andrews, St. Andrews, Fife, UK KY16 9ST. E-mail: gbh1@st-and.ac.uk

Received (in Cambridge, UK) 20th September 1999, Accepted 20th October 1999

A new layered mixed metal methylphosphonate, which contains interlayer chloride anions, has been prepared by contacting an LDH with molten methylphosphonic acid, and its structure solved using microcrystal X-ray diffraction at a synchrotron source.

It is only recently that aluminium phosphonates have been reported in the literature.[1–8] The breakthrough was made by Maeda *et al.*, who reported the synthesis of two crystalline microporous aluminium methylphosphonates, AlMePO-β[1,2,4,7] and AlMePO-α.[3] Subsequently, two layered methylphosphonates,[7,8] several phenyl phosphonates[6,9] and a carboxymethylphosphonate[10] have been reported.

A previous attempt at using layered double hydroxides (LDHs) in the preparation of mixed metal phosphonates by Vichi and Alves[11] succeeded in introducing both phenyl- and carboxyethylphosphonate groups. The crystal structures of the materials formed were not solved, however, and there was no evidence that the anion initially present in the LDH remained in the products after intercalation of the phosphonate groups.

The overwhelming majority of aluminium phosphonates are formed by hydrothermal syntheses,[1–7,9,10] with only a few examples prepared by other methods (*e.g.* refluxing[6,9] or contacting an aluminium source with a molten phosphonic acid[8]). The title compound was synthesised by grinding the layered double hydroxide, $LiAl_2(OH)_6Cl{\cdot}H_2O$[12] with methylphosphonic acid (such that the Al:P ratio in the reaction mixture was 1 : 3·5). The mixture was placed in a sealed glass tube and heated at 110 °C (the melting point of methylphosphonic acid is 104 °C) for 5 days. Products were recovered, washed with distilled water and dried in air at 60 °C.

Inspection of the recovered sample under a microscope revealed the presence of small crystals amongst a polycrystalline phase. One of these crystals was removed from the sample and used in a single crystal determination of the structure.

The crystals were too small (max. size 20 × 20 × 10 μm) for single crystal X-ray data collection using a standard laboratory four-circle diffractometer, so diffraction data were collected at low temperature (150 K) using a Bruker AXS SMART CCD area-detector diffractometer on the high-flux single-crystal diffraction station 9.8 at CCLRC Daresbury Laboratory Synchrotron Radiation Source, Cheshire, UK.

As a result of the single crystal structure determination,† the material was found to possess a stoichiometry of $Li_2Al_3(HO_3PMe)_2(O_3PMe)_4Cl{\cdot}7H_2O$. It is believed that this is the first example of a layered phosphonate, which is charged and contains interlayer anions. Comparison of a calculated powder XRD pattern with that obtained from the bulk product shows that the bulk contains a quantity of $Al(HO_3PMe)(O_3PMe){\cdot}H_2O$ as an impurity phase.[8] This necessarily means that an accurate analysis of the composition of the material by conventional methods (*e.g.* XRF, chemical analysis) is not possible.

Single crystal structure determination† revealed that the material is layered, with the lamellae stacking in the (100) direction (Fig. 1). All three of the Al atoms in the structure are octahedrally coordinated by oxygen. The six phosphonate groups possess tetrahedral coordination about the P atom. Two of the phosphonate groups, however, are monoanionic, $[HO_3PMe]^-$, whilst the other four are di-anionic, $[O_3PMe]^{2-}$. The layers are made up from corner sharing of the equatorial positions of the Al octahedra with the four dianionic phosphonate groups. The P–C bonds of these four methylphosphonate groups are oriented perpendicular to the plane of the layers (Fig. 2).

The axial positions of the octahedral Al coordination sphere are occupied by water molecules, or oxygens shared with the two remaining protonated methylphosphonate groups. One Al

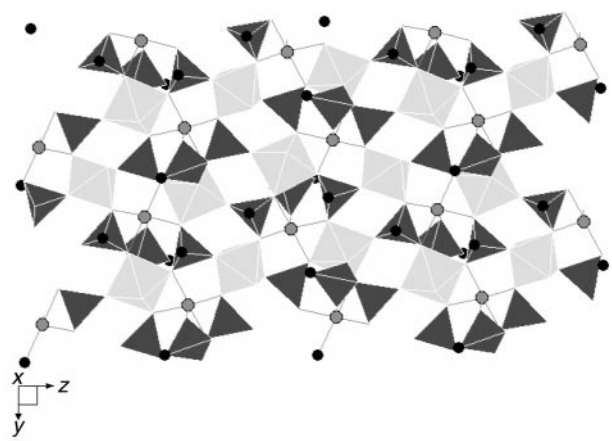

Fig. 1 A view of the layers along the (100) direction. The CPO_3 tetrahedra and the AlO_6 octahedra are shown as dark grey and light grey polyhedra respectively. Carbon atoms are shown as small black circles and lithium atoms as small grey circles. The interlayer water molecules and chlorine atoms are omitted for clarity.

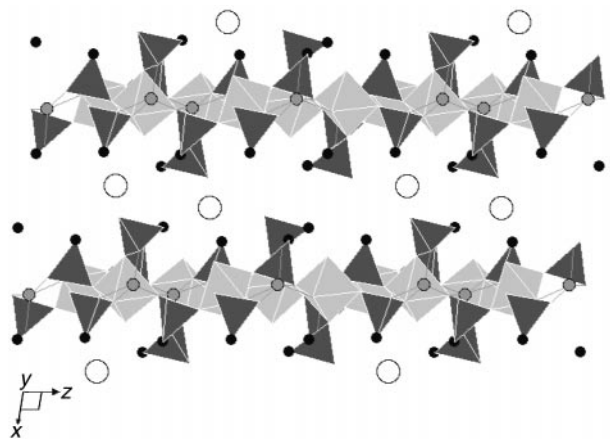

Fig. 2 Polyhedral view along the (010) direction showing the lamellae separated by interlayer chloride anions, and the different orientations adopted by the methylphosphonate groups. The CPO_3 tetrahedra and the AlO_6 octahedra are shown as dark grey and light grey polyhedra respectively. Carbon atoms are shown as small black circles, chlorine atoms as large white circles, and lithium atoms as small grey circles. The interlayer water molecules have been omitted for clarity.

† Present address: School of Chemistry, Hawthorn Building, De Montfort University, The Gateway, Leicester, UK LE1 9BH. E-mail: ghix@dmu.ac.uk

atom is coordinated by two water molecules in axial positions, whilst the other two have only one coordinated water molecule. The remaining axial positions of these two octahedra are occupied by an O from a methylphosphonate. The P–C bonds of those phosphonate groups attached to the axial positions of the Al atoms, are oriented parallel to the direction of the layers (Fig. 2). This has also been observed in another aluminium methylphosphonate, which we reported previously.[8]

The Li atoms are situated inside six-membered rings within the layers. The Li atom is coordinated by five oxygen atoms (Fig. 3), in a distorted square pyramidal environment. The axial oxygen atom is attached to the phosphonate group which is also attached to the axial position of one of the Al atoms. Bond valence calculations (using the method of Brown and Altermatt)[13] yielded values of 1.000 and 1.045 for the two Li ions, hence showing that the Li cations are in good coordination spheres.

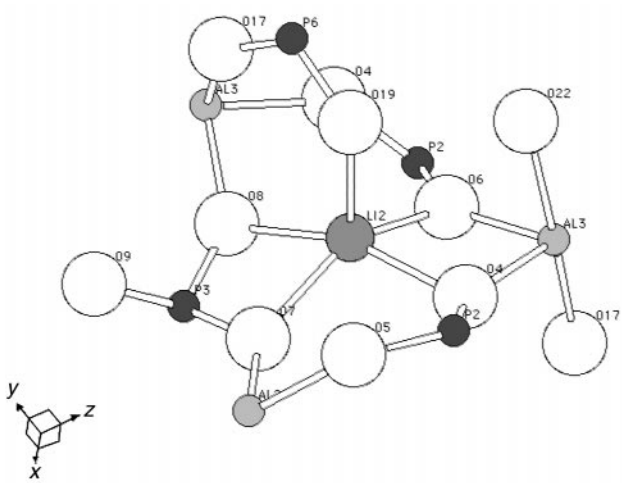

Fig. 3 Representation of the coordination about the Li ions, showing the phosphonate group bridging the Al and Li atoms.

The chloride anions are located in the interlayer region along with the three remaining water molecules. Hydrogen bonding between the interlayer species and the water molecules coordinated to the Al atoms hold the layers together.

TG experiments, carried out upon a sample of the crystals separated manually from the reaction product, show stepwise mass losses upon heating. The loss of water beginning around 90 °C and ending around 350 °C is complex, but peaks in the derivative of the weight loss curve indicating that the losses are centred at 162 and 296 °C. This can be rationalised by considering that the lower temperature event is the loss of the three water molecules in the interlayer region, and the higher temperature event is the loss of the two water molecules coordinated to each of the Al atoms. There is then a further exothermic weight loss at 550 °C of *ca*. 7.8 mass%, which is associated with decomposition of the methyl groups. The final mass loss is centred at 1100 °C and corresponds to removal of P_2O_5 from the material to leave a mixture of $AlPO_4$, Li_2O and LiCl (as shown by XRD).

The authors would like to thank Dr David Taylor and Dr Simon Teat of the SRS for their help in the X-ray data collection and the EPSRC for funding. R.E.M. would like to thank the Royal Society for provision of a Personal Research Fellowship.

Facile synthesis and conformation of 3′-*O*,4′-*C*-methyleneribonucleosides

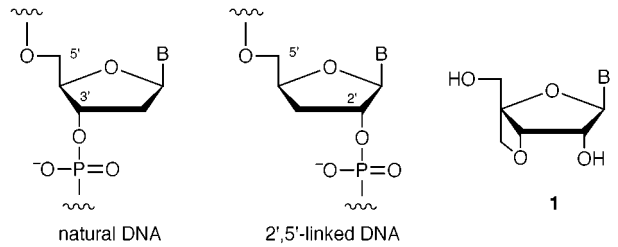
Satoshi Obika, Ken-ichiro Morio, Yoshiyuki Hari and Takeshi Imanishi*

Graduate School of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565-0871, Japan. E-mail: imanishi@phs.osaka-u.ac.jp

Received (in Cambridge, UK) 7th September 1999, Accepted 26th October 1999

Bicyclic nucleoside analogues, 3′-*O*,4′-*C*-methyleneribonucleosides 1, including thymine, cytosine, adenine and guanine nucleobases, were conveniently synthesized from D-glucose, and the ribofuranose ring of 1 was found to exist predominantly in a *S*-conformation by means of ^{1}H NMR and X-ray analysis.

In recent studies aimed at developing an effective antisense molecule, numerous oligonucleotide analogues have been synthesized with various chemical modifications of the phosphodiester backbone, sugar moiety and/or nucleobase region.[1] In these attempts, the oligonucleotide analogues containing 'non-genetic' 2′,5′-phosphodiester linkages (2′,5′-linked oligonucleotides) were found to be favorable as antisense molecules because of their RNA selective hybridization ability and

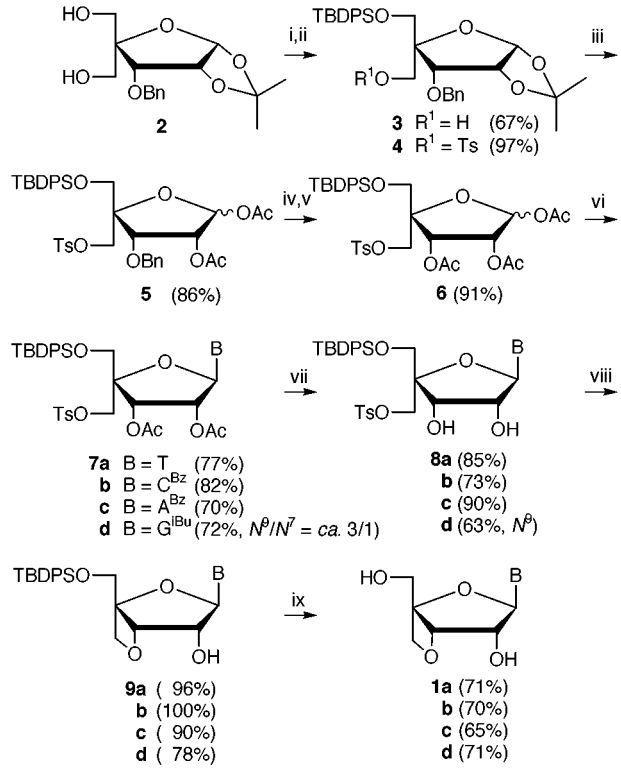


enzymatic stability.[2] Furthermore, 2-5A (2′,5′-linked oligoadenylate 5′-triphosphate) is well-known to have an important role in the interferon-mediated antiviral system in living cells,[3] and intensive studies on various 2-5A analogues have been reported.[4] However, there is only limited information available on the relationship between the sugar conformation in 2′,5′-linked oligonucleotides and their attractive properties, such as hybridization ability and antiviral activity.[5]

From the consideration that the restriction of sugar puckering in nucleosides to a proper conformation would serve as an advantageous strategy to develop a desired antisense (antigene) molecule,[6,7] we have recently accomplished the synthesis of conformationally restricted nucleoside analogues, 3′-*O*,4′-*C*-methylene-uridine and -cytidine **1** (B = U and C) by using uridine as a starting material,[8] and also demonstrated interesting properties of the 2′,5′-linked oligonucleotide analogues containing **1** (B = U and T), *e.g.* RNA selective hybridization abilities.[9]

Unfortunately, the synthetic route of **1** was not practical for purine analogues. We now report a novel and practical synthetic route to **1** bearing various nucleobases, exemplfied by synthesis of all four nucleoside analogues **1** (B = T, C^{Bz}, A^{Bz} and G^{iBu}), and also discuss their conformation.

After several attempts,† the synthesis of the target compounds **1** was performed by a coupling reaction of a 1-*O*-acetylribofuranose derivative with silylated nucleobases and a subsequent oxetane ring formation, as shown in Scheme 1. A stereoselective silylation of the diastereotopic hydroxy groups in 3-*O*-benzyl-4-hydroxymethyl-1,2-*O*-isopropylidene-α-D-ribofuranose **2**[10] gave the desired compound **3** (67%). The stereochemistry at C4 in **3** was confirmed by means of NOE measurements. A *p*-tolylsulfonylation of **3** afforded the tosylate **4** (97%), which was converted to diacetate **5** (86%) by treatment with AcOH and Ac_2O in the presence of a catalytic amount of H_2SO_4. Debenzylation and subsequant acetylation of the 3-hydroxy group in **5** gave the triacetate **6** (91%). The reaction of **6** with *O*,*O*′-bis(trimethylsilyl)thymine (T·2TMS) under Vorbrüggen's conditions[11] afforded only the β-anomer of



Scheme 1 *Reagents and conditions*: i, TBDPSCl, Et_3N, CH_2Cl_2, room temp., 14 h; ii, TsCl, Et_3N, DMAP, CH_2Cl_2, room temp., 16 h; iii, AcOH, Ac_2O, conc. H_2SO_4, room temp., 30 min; iv, 10% Pd-C/H_2, Et-OAc–$CHCl_3$, room temp., 17 h; v, Ac_2O, Py, room temp., 20 h; vi, sililated base, TMSOTf, $CH_2CH_2Cl_2$, reflux, 8–18 h; vii, K_2CO_3, room temp., 15 min; viii, NaHMDS, THF, room temp., 1h; ix, TBAF, THF, room temp., 15 min.

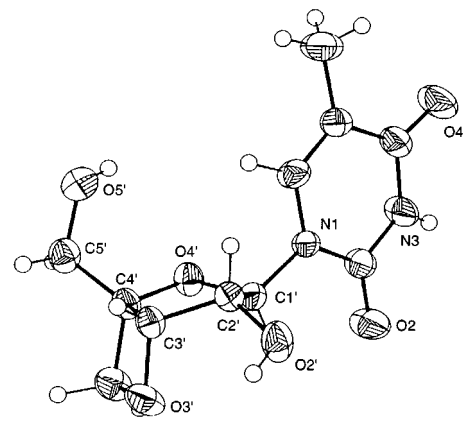


Fig. 1 ORTEP drawing of **1a**.

thymidine derivative **7a** (77%). The triacetate **6** was also coupled with silylated N^4-benzoylcytosine (C^{Bz}·2TMS), N^6-benzoyladenine (A^{Bz}·2TMS) and N^2-isobutyrylguanine (G^{iBu}·3TMS) to give the corresponding β-nucleoside derivatives **7b** (82%), **7c** (70%) and **7d** (72%),‡ respectively. Methanolysis of **7** gave diols **8** (63–90%) and then oxetane ring formation from **8** was accomplished on treatment with sodium hexamethyldisilazide in THF at room temperature, yielding only the corresponding 3′-*O*,4′-*C*-methyleneribonucleoside derivatives **9** (78–100%). The desired products **1** were obtained (65–71%) by removal of a TBDPS group in **9**. We have, thus, achieved a facile synthesis of 3′-*O*,4′-*C*-methyleneribonucleosides **1** in good yield.§

The conformational analysis of the obtained 3′-*O*,4′-*C*-methyleneribonucleosides **1** was carried out by means of ^{1}H NMR and X-ray crystallographic data. Namely, all of the bicyclic nucleoside analogues **1** show a relatively large $J_{1'2'}$ value (7.3–7.6 Hz in CD_3OD), which means that these nucleoside analogues have predominantly the *S*-conformation (*S*% = 91–96%),¶ regardless of the type of the nucleobase. Furthermore, an X-ray crystallographic analysis of **1a** shows that the sugar pucker pseudorotation phase angle (*P*) is 136.2° and the maximum out-of-plane pucker (ν_{max}) is 32.3°, characteristic of the C1′-*exo*-C2′-*endo* form (*S*-conformation) of sugar puckering.‖

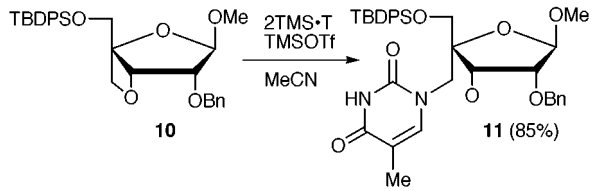
It is noteworthy and very interesting that the expressed *S*-preference of the nucleoside analogues **1** is vastly different from conformational analysis of other nucleosides possessing a 2′-OH group, *e.g.* uridine (*S*% = 52%),[8] cytidine (*S*% = 26%),[8] 3′-deoxyuridine (*S*% = 3%)[8,12] and 3′-deoxycytidine (*S*% = 0%).[8,13]

Further studies on these bicyclic nucleosides are now in progress.

A part of this work was supported by a Grant-in-Aid for Scientific Research (B), No. 09557201, from the Japan Society for the Promotion of Science. We are also grateful to the Takeda Science Foundation for financial support.

Notes and references

† As an altanative route for the synthesis of **1**, we briefly tried a coupling reaction of the oxetane derivative **10** with silylated thymine, resulting in exclusive C–O bond fission of the oxetane ring to afford only **11**.



‡ Guanosine derivative **7d** was obtained as a mixture of N^9 and N^7 regioisomers (72%, N^9/N^7 = *ca.* 1/3) which was directly converted to **8d** without separation. The N^9 and N^7 isomers of **8d** were obtained in 63 and 18% yield, respectively, after silica gel chromatography. The stereochemistry of each isomer **8d** was determined by comparison of their ^{1}H and ^{13}C NMR data.

The change in the X-ray dipole moment as a quantitative measure of the polarizing effect of the molecular environment: application to a complex of *p*-amino-*p′*-nitrobiphenyl with triphenylphosphine oxide

Yuegang Zhang and Philip Coppens*

Department of Chemistry, State University of New York at Buffalo, Buffalo, New York, 14260-3000, USA. E-mail: coppens@acsu.buffalo.edu

Received (in Columbia, MO, USA) 14th September 1999, Accepted 13th October 1999

The X-ray determined dipole moment has been used to assess the strength of the electrostatic interactions in a new complex of *p*-amino-*p'*-nitrobiphenyl, which is a suitable candidate for photo-crystallographic studies of transient species.

Prior to photo-crystallographic studies of light-induced excited molecular states, suitable candidates for such time-resolved studies must be identified.[1,2] A relatively long-lived triplet excited state of *p*-amino-*p′*-nitrobiphenyl (PANB) has been reported to exist at room temperature in solution.[3] PANB is a typical donor–acceptor molecule; upon excitation an intramolecular charge transfer occurs from the amine donor to the nitro acceptor group.[4] Correspondingly, fluorescence and time-resolved microwave measurements indicate a large increase in dipole moment (by more than 20 D) when the molecule is excited.[5] In order to increase the conversion percentage of excited state molecules upon irradiation, and/or reduce the number of photons to be absorbed by the crystal, it is highly desirable to dilute the photoactive species with photo-inert spacer molecules. In a previous study, the β-cyclodextrin complex of PANB was found to show disorder in the guest molecules, and thus to be less suitable for photo-crystallographic studies.[3]

We report here on the 90 K structure and charge density of a fully-ordered mixed crystal of PANB. We use the molecular dipole moment as determined from the X-ray diffraction data as a measure of the strength of the electrostatic forces acting on the host molecule. This analysis is based on the extensive evidence indicating a pronounced enhancement of the electrostatic moments of polar molecules in crystals.[6–8] The enhancement is directly dependent on the molecular environment, and it thus varies with crystal composition and molecular packing.

Triphenylphosphine oxide (TPPO) is a strong hydrogen acceptor. It has been shown to form high quality crystals with molecules containing donor hydrogen atoms, like the amino hydrogens of PANB.[9] As the TPPO molecule does not absorb above 300 nm,[10] its absorption does not interfere with the charge-transfer absorption of PANB, which peaks at 400 nm,[11] an essential condition for a photo-inert 'spacer' molecule. X-Ray data on a specimen grown by slow evaporation[12] were collected on a Bruker SMART 1K CCD diffractometer at 90(1) K.[13]

Hydrogen bonding between the NH_2 groups and the oxygen atoms of TPPO (Fig. 1) leads to a synthon consisting of four molecules (two each of TPPO and PANB), which is the basic unit in the crystal.[14] The square arrangement of hydrogen bonded atoms is similar to that in TPPO tetrachloropyrocatechol monohydrate, in which water molecules of crystallization are the hydrogen donors.[15] A comparable arrangement is found in bis(triphenylphosphine oxide) tris(toluene-*p*-sulfonamide) where the two P=O groups are bridged by three sets of hydrogen bonds, donated by NH_2 groups.[16] Unlike in neat PANB, the nitro groups in PANB/TPPO are involved only in weak O···H–C interactions.[17] The crystals are fully ordered and do not contain solvent molecules.

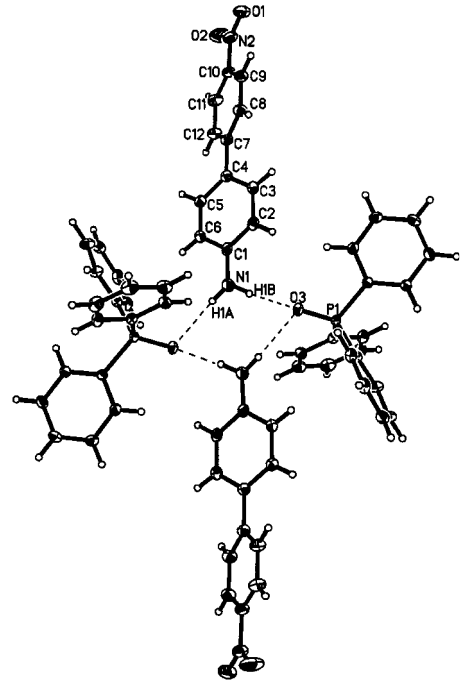

Fig. 1 Illustration of the basic packing motif in the PANB/TPPO crystal.

In the neat crystal the biphenyl group adopts a close to planar conformation (see Fig. 2),[18,19] though calculations[20] indicate the isolated molecule to be twisted by 43.3°, similar to what is found for gas-phase biphenyl.[21,22] In the current structure the inter-ring twist angle is 30.27(3)° (Fig. 2), compared with values of 40.6(2) and 42.0(1)° at 20 K for the two independent molecules in the less constraining environment of β-cyclodextrin. The concentration of PANB in PANB/TPPO is 2.64 M compared with 6.56 M in the neat crystal.

In general the dipole moment of a molecule in a polar crystal is enhanced relative to that of the isolated molecule in the gas phase. The increase in dipole moment is a quantitative measure of the polarizing field exerted on the molecules by the crystal matrix. While the isolated molecule value is calculated as 9.12 D for the configuration of the PANB molecule as observed in the neat crystal, and as 8.17 D for the twisted optimized geometry,[20] the value derived by topological analysis of the theoretical density for the periodic crystal is 23.0 D.[8] This

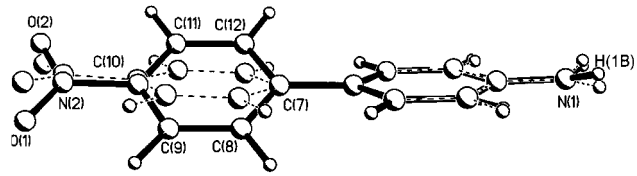

Fig. 2 The molecular structure of PANB in the TPPO complex (twisted), compared with the almost planar conformation in the neat crystal.

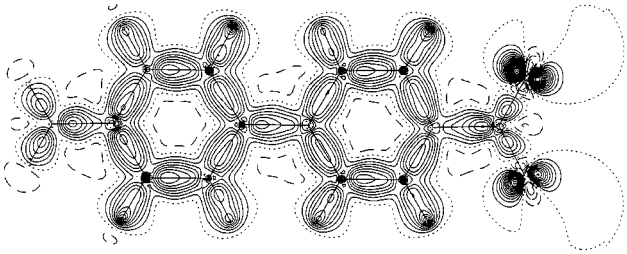

Fig. 3 Deformation density map of PANB in the PANB/TPPO crystal as calculated from the aspherical atom multipole refinement results. For illustration purposes, the two phenyl rings of the non-planar molecule have been rotated into the plane of the paper. Contours at 0.1 eÅ^{-3}. Positive contours: full lines; zero contour: dotted; negative contours: broken.

compares with an experimental X-ray result of *ca*. 40 D.[8,19] An aspherical atom refinement[23,24] of the current data shows the molecular dipole moment in the mixed crystal to be 16.8(1.6) D, much in excess of the isolated molecule values, but significantly below that in neat PANB (the static deformation density map in the least square planes of the two phenyl rings is shown in Fig. 3). The neat crystal contains sheets of parallel molecules, leading to parallel and anti-parallel (between sheets) alignment of the dipole moments such as to maximize electrostatic interactions. By comparison, the electrostatic interactions are significantly reduced in PANB/TPPO, in agreement with the relatively weak interactions of the nitro group in the complex. Since the molecular dipole moment can now be routinely obtained from good quality X-ray data, it provides a readily accessible measure of the electrostatic interactions in a crystal.

In summary, the PANB/TPPO mixed crystal is a candidate for excited state diffraction studies, given the absence of disorder and undesirable spectral overlap, and the reduced concentration of the active species. Both the experimental dipole moment and the inter-ring twist angle are intermediate between those of the isolated molecule and the neat PANB crystal. The X-ray dipole moment can be used to characterize related solids, and provides insight into factors relevant to crystal engineering.

Support of this work by the National Science Foundation (CHE9615586) and the Petroleum Research Fund of the American Chemical Society (PRF32638AC3) is gratefully acknowledged. All theoretical calculations were carried out on the SGI Origin-2000 supercomputer at the Center for Computational Research at SUNY/Buffalo, which is supported by a grant (DBI9871132) from the National Science Foundation.

Bispyrene based chiroptical molecular redox switch

Christian Westermeier, Hans-Christoph Gallmeier, Markus Komma and Jörg Daub*

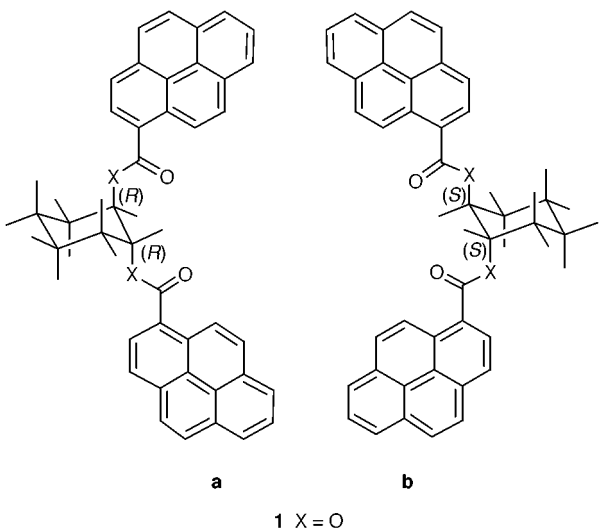
Institut für Organische Chemie der Universität Regensburg, Universitätsstraße 31, D-93040 Regensburg, Germany. E-mail: joerg.daub@chemie.uni-regensburg.de

Received (in Cambridge, UK) 14th September 1999, Accepted 28th October 1999

The chiral *trans*-cyclohexanediol bispyrene esters (1*R*,2*R*)-1a and (1*S*,2*S*)-1b are reversibly reduced to the corresponding bisradical anions $1a^{2-}$ and $1b^{2-}$ which show strong absorption bands at 510 nm exhibiting exciton-split circular dichroism (CD) with opposite signs, whereas the radical anions of the bisamides 2a and 2b failed to show split CD signals.

Molecular switches are intensively studied due to their potential applications in molecular devices and optical data storage systems.[1] In this context, much attention has been given to photochemically and electrochemically induced switching processes (photochromic and electrochromic compounds) which lead to significant optical spectra changes. Pyrene derivatives are one of the well-exploited probes for the design of fluorescent molecular switches due to their monomer–excimer emission characteristics.[2] Surprisingly, pyrene based chiroptical molecular redox switches have not received any attention. However, the use of chiroptical molecular switches based on photochromic chiral ethenes has been demonstrated recently by Feringa and co-workers.[3] Circular dichroism spectroelectrochemistry (CD spectroelectrochemistry) is a recent technique that we have introduced to study molecular switches.[4,5] Here the characteristic optical absorption and reversible redox behaviour of pyrene are integrated with the optical activity of *trans*-cyclohexanediol for the design of novel redox active chiroptical molecular switches. The redox switching between the neutral and radical ion states is monitored by both UV–VIS–NIR and circular dichroism (CD) spectroelectrochemical methods.

The requirements for the design of an efficient chiroptical molecular redoxswitch are: (i) stability of the optical active forms, (ii) chemical reversibility of the redox processes, (iii) high sensitivity of the chiroptical response and (iv) potential application in multimode switching. During the process of screening several systems we found that pyrene functionalized *trans*-1,2-substituted cyclohexanes appear to be excellent candidates for chiroptical redox switching due to intramolecular exciton coupling which leads to split CD.[6] Bis-esters **1a**,**b** and bis-amides **2a**,**b** were synthesized in the optically active forms (1*R*,2*R*)-**1a** [mp 208 °C, $[\alpha]_D^{20}$ 115.0, (*c* 0.42 in CH_2Cl_2)] and (1*S*,2*S*)-**1b** [mp 208 °C, $[\alpha]_D^{20}$ −111.6 (*c* 0.40 in CH_2Cl_2)], and (1*R*,2*R*)-**2a** [mp 379–380 °C, $[\alpha]_D^{20}$ 114.3 (*c* 0.01 in THF)] and (1*S*,2*S*)-**2b** (mp 379–380 °C, $[\alpha]_D^{20}$ −111.4 (*c* 0.012 in THF)], starting from the corresponding optically active *trans*-cyclohexane-1,2-diols and *trans*-1,2-diaminocylohexanes respectively. Compounds **1a** and **1b** show reversible reduction (Fig. 1) to the bis-radical anions in a 'one-wave-two-electron transfer' cyclic voltammogram [$E_{1/2}$(reduction) = −2120 mV (*vs.* Fc^+/Fc)] leading to the appearance of an intense absorption at 510 nm [Fig. 2(*a*)]. Formation of radical anions of both pyrene units was established by comparison with the cyclic voltammetric data of analogous model compounds.[7] Obviously, the two redox active pyrene groups in **1a** and **1b** are weakly coupled in the ground state and can be classified as Robin/Day class I systems. The stationary absorption and CD spectra of the *R*,*R* isomer **1a** are illustrated in Fig. 2. The CD spectra of **1a** and **1b** show the expected mirror-image features. CD spectroelectrochemistry of **1a** on reduction leads to a split CD with a positive sign at 504 nm [Fig. 1(*c*)]. The band formation is reversible and the process can be repeated continously. Compound (*S*,*S*)-**1b**



1 X = O
2 X = NH

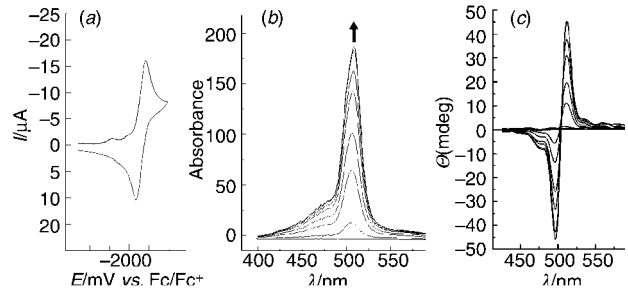


Fig. 1 (*a*) Cyclic voltammogramm of **1a** ⇄ $\mathbf{1a^{2-}}$, and (*b*) UV–VIS–NIR spectroelectrochemistry and (*c*) CD spectroelectrochemistry of **1a** ⇄ $\mathbf{1a^{2-}}$ obtained by scanning over the reduction wave at $E_{1/2}$ = −2120 mV (*vs.* Fc^+/Fc in THF, ν = 250 mV s^{-1}).

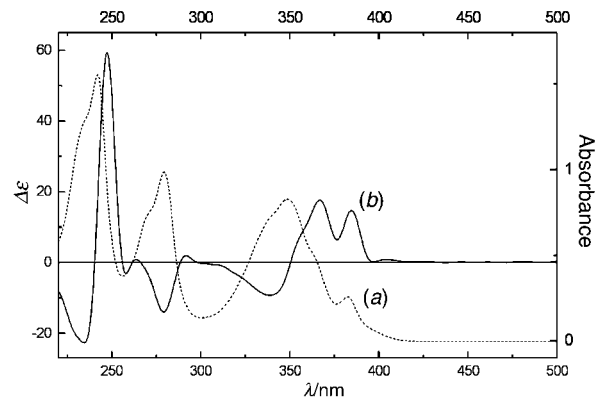

Fig. 2 (*a*) UV–VIS absorption and (*b*) CD spectra of (*R*,*R*)-**1a** (c = 10^{-5} mol dm^{-3} in THF).

behaves identically with a negative sign for the couplet at 504 nm.

It is also interesting to briefly refer on the fluorescence spectra of **1a** and **1b** since these compounds may be of interest for fluorescence-detected circular dichroism[6c] and circularly polarized luminescence. Bis-esters **1a** and **1b** show the typical pyrene emissions at 387, 409 and 432 nm and in addition an excimer emission at 517 nm ($c = 10^{-6}$ mol l^{-1}). The excimer emission depends strongly on concentration, which is characteristic of the intermolecular association of the pyrene moieties. At 10^{-4} mol l^{-1} a three-fold increase in the intensity of the excimer emission is observed.

We also investigated the redox switching behaviour of bis-amids (1*R*,2*R*)-**2a** and (1*S*,2*S*)-**2b**. Both bis-amides **2a** and **2b** are reversibly reduced to their radical anions ($E_{1/2} = -2420$ mV *vs*. Fc/Fc^+) leading to an absorption for the pyrene radical anion at 510 nm. The chiroptical behaviour of **1** and **2** is however different. Even though the neutral compounds **2a** and **2b** showed the expected mirror-image CD spectra, reduction to the radical anions does not lead to a split-CD signal around 500 nm. On reoxidation, the original CD spectrum is restored. Even though at this point the exact reason for this observation is not clear, we assume that proton transfer from the amide linkage at the radical anion stage or possible hydrogen bonding inhibits the appearance of a CD couplet.

In summary, we found that C_2-symmetric pyrene conjugated cyclohexanes **1** are well-suited as reversible chiroptical redox switches, which behave differently from bisamides **2a** and **2b**. The circular dichroism spectroelectrochemical method has been successfully employed for the monitoring of the switching behaviour. Work to apply compounds **1a** and **1b** as probes for molecular sensing is in progress. Also investigations to correlate the sign of the Cotton effects with the molecular structure of the pyrene-linked cyclohexanes are under way.

C. W. and M. K. are grateful to the Stiftung Stipendien-Fonds des Verbands der Chemischen Industrie, Frankfurt for doctoral fellowships. The authors thank Dr A. Ajayaghosh for stimulating comments, Mrs M. Lutz for synthetic work and Professor O. S. Wolfbeis for making the spectropolarimeter available.

Unambiguous characterisation of dienylimines as intermediates in Fischer indolisation of *o*-substituted *N*-trifluoroacetyl enehydrazines

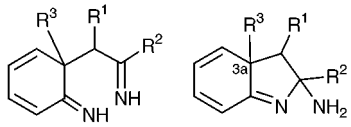
Okiko Miyata, Yasuo Kimura and Takeaki Naito*

Kobe Pharmaceutical University, Motoyamakita, Higashinada, Kobe 658-8558, Japan.
E-mail: taknaito@kobepharma-u.ac.jp

Received (in Cambridge, UK) 17th September 1999, Accepted 1st November 1999

Thermal cyclisation of *o*-substituted *N*-trifluoroacetyl enehydrazines was systematically investigated and found to proceed *via* dienylimine intermediates, which were unambiguously characterised by X-ray and spectral analysis.

The Fischer indole synthesis provides a versatile and convergent route to a wide variety of indoles.[1] Although today the key step in Fischer indolisation is regarded as a [3,3]-sigmatropic rearrangement of the enehydrazines, which is related to the Cope and Claisen rearrangements,[1,2] there have been only a few reports on the isolation and characterisation of the dearomatised dienylimine (**1** or **2**) intermediates because of



1 **2**

their instability. To the best of our knowledge, there has been only one paper[3] pertaining to the isolation of a pure dienylimine having a methyl group at the 3a-position in which the relative configurations at the 2-, 3- and 3a-positions remain to be established.

During the course of our investigation on reactivity of *N*-trifluoroacetyl enamine moieties,[4] we investigated the thermal cyclisation of *o*-substituted *N*-trifluoroacetyl enehydrazines under mild conditions and succeeded in the isolation and structure determination of the dienylimine intermediates in the Fischer indolisation. *o*-Substituted hydrazones are generally known to react more sluggishly than the *m*- and *p*-substituted analogs and sometimes give low yields of the desired indoles accompanied with side reactions.[1]

We first examined the thermal cyclisation of *N*-trifluoroacetyl enehydrazine **3a** having an *o*-methoxy group (Table 1). Previously, characterisation[1,5] of the dienylimine intermediate with a methoxy group had been attempted but found to be unsuccessful. A solution of **3a** in THF was heated at 65 °C for 10 h to give a mixture of indoline **4a** and two dienylimines **6a** in 63 and 36% yields, respectively (entry 1). Furthermore, **6a** was easily separated into two diastereomers, *cis-syn*-**6a** and *cis-anti*-**6a**, in a 5 : 1 ratio. The stereostructure of *cis-syn*-**6a** was established unambiguously by single-crystal X-ray analysis[6] (Fig. 1) and then the relative configuration of the isomeric *cis-anti*-**6a** was deduced from comparison of its ^{1}H and ^{13}C NMR spectra with those of *cis-syn*-**6a**. Therefore, we have now succeeded in the isolation and structure determination of the dienylimine intermediate in the Fischer indolisation of the *o*-methoxy enehydrazine. Additionally, the *cis-syn*-isomer was obtained as the major product.

Interestingly, the polarity of the organic solvent used influences both the product ratio of **4a** and **6a** and the reaction time (entries 2–4). In MeCN, the reaction proceeded smoothly to give a 1 : 1 mixture of **4a** and **6a** in 98% yield (entry 3). On the other hand, in non-polar hexane, **4a** was obtained as the major product in 75% yield, although prolonged reaction time was required for complete consumption of **3a** (entry 4). Heating the indoline **4a** in xylene at 138 °C afforded the corresponding indole **5a** in quantitative yield as a result of the elimination of

[a] Yields in parentheses are for the recovered starting material.

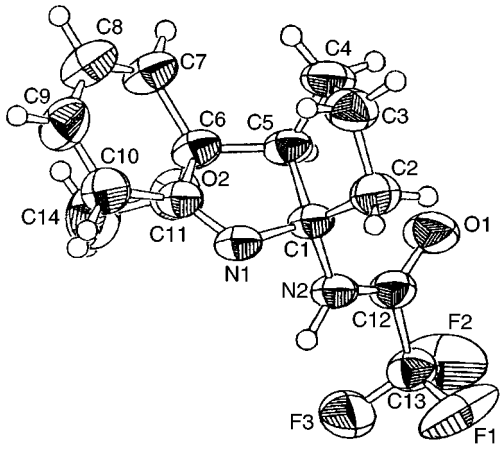

Fig. 1 ORTEP drawing of the molecule *cis-syn*-**6a** at the 50% probability level. The structure depicted is one of the independent molecules with the major component of the disordered CF_3 group.

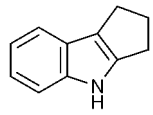
trifluoroacetamide. Under the same conditions, both *cis-syn*-**6a** and *cis-anti*-**6a** were converted into indole **7**. Reaction of cyclohexene hydrazines **3b** proceeded slowly under similar mild conditions to give 7-methoxyindole **5b** as the major product with no detection of indoline **4b** (entries 5 and 6).



7

It is well-known that Fischer indolisation of (2-methoxyphenyl)hydrazone gives 7-methoxyindole as a minor product and the abnormal 6-substituted indole as a major product, respectively. [1,7,8] On the other hand, our results indicate that the indolisation reaction of **3** proceeds preferentially at the unsubstituted position to give 7-methoxyindole as the major product. Consequently, the thermal cyclisation of **3** has provided a practical synthetic method for the 7-oxygenated indoles, which are known to be potential intermediates for the synthesis of biologically active compounds.

Next, we turned our attention to the corresponding *o*-methyl *N*-trifluoroacetyl enehydrazines **3c**,**d**. Reaction of **3d** proceeded smoothly at a high temperature (110 °C) to give **5d** with moderate regioselectivity, while **3c** afforded a mixture of **4c**, **5c**, *cis-syn*-**6c** and *cis-anti*-**6c** (entries 7, 8, 9 and 10). The *cis-syn* and *cis anti*-dienylimines **6c**,**d** were obtained as minor products. Their stereostructures were deduced from comparisons of their ^{1}H and ^{13}C NMR spectra with those of *cis-syn*-**6a**,**b** and *cis-anti*-**6a**,**b**. Brown [9] has reported that attempts to isolate a tricyclic dienylimine having a methyl group were unsuccessful. Therefore, our result is the first example of the isolation and structure determination of the tricyclic dienylimine with a methyl group.

When an electron-withdrawing group such as a chlorine or nitro group was present in the *o*-position, the indolisation occurred regioselectively at the unsubstituted position to give 7-substituted products (entries 11 and 12).

Finally, the isolation and structure determination of the dienylimines intermediates in the Fischer indolisation of *o*-methoxy and *o*-methyl enehydrazines provides good evidence for the postulated reaction mechanism, including a stereochemical rationalisation, particularly for the [3,3]-sigmatropic rearrangement step.

This work was supported in part by a Grant-in-Aid for Scientific Research (No. 09672293) from the Ministry of Education, Science, Sports and Culture, Japan and a research grant from the Science Research Promotion Fund of the Japan Private School Promotion Foundation. We thank Dr K. Aoe (Analytical Research Laboratory, Tanabe Seiyaku) for the X-ray crystallographic structure determination of **6a**.

Received (in Cambridge, UK) 31st August 1999, Accepted 22nd October 1999

The synthesis of benzo[1,2-*e*:3,4-*e′*:5,6-*e″*]tribenzo[*l*:*l′*:*l″*]-triacephenanthrylene ($C_{60}H_{30}$) has been accomplished by a triple palladium-catalysed arylation of a *syn*-trialkylated truxene.

Part of the recent outburst in the chemistry of bowl-shaped polycyclic aromatic hydrocarbons (polyarenes)[1,2] concerns their potential use as starting materials for the development of syntheses of fullerenes as alternatives to those based on the vaporisation of graphite.[2–4] Indeed, fullerenes have been formed pyrolytically in low yield from aromatic hydrocarbons such as naphthalene and corannulene.[2] Additionally, the development of practical syntheses of functionalised bowl-shaped polyarenes should allow for the construction of fullerene-like molecular cages with polycyclic aromatic substructures. Progress towards the synthesis of giant polyarenes is also of interest in the area of materials science.[5]

We have recently completed a synthesis of polyarene **1**, benzo[1,2-*e*:3,4-*e′*:5,6-*e″*]triacephenanthrylene,[6] using the palladium-catalysed intramolecular arylation reaction that we previously applied for the preparation of benzo[*e*]acephenanthrylenes and related polycyclic aromatic hydrocarbons.[7] The synthesis of **1** was carried out by the intramolecular arylation of *syn*-trialkylated truxene[8] **2** by using $Pd(OAc)_2$ as the catalyst at 130 °C in DMF (Scheme 1), while cyclisation of the *anti*-isomer of **2** had to be performed at 150 °C under otherwise identical conditions.[6]

We decided to apply this approach for the synthesis of the higher analogue **3**, benzo[1,2-*e*:3,4-*e′*:5,6-*e′*]tribenzo[*l*:*l′*:*l″*]-triacephenanthrylene. Polyarene **3** contains a decacyclene core (highlighted in boldface in **3″**) fused with three naphthyl units and possesses half of the rings of C_{60} as shown in the Schlegel diagram **3′**.

The alkylation of the lithium trianion of truxene with 2-bromomethylnaphthalene gave selectively the *anti*-isomer of **4**. Initial isomerisation to the more stable *syn*-isomer **4** failed under the standard conditions (heating with KOBu^t in Bu^{t}OH)[6] due to the insolubility of the *anti*-isomer. However, simple addition of a small amount of CH_2Cl_2 as co-solvent allowed for the almost quantitative conversion of the *anti*-isomer into **4** (75% overall yield). The preparation of the required starting material for the palladium-catalysed arylation was carried out by the alkylation of the lithium trianion of truxene with

1-bromo-2-bromomethylnaphthalene[9] to give the *anti*-stereoisomer of **5** as the major compound, which was isomerised with KOBu^t in Bu^{t}OH under refluxing conditions to give *syn*-5,10,15-tris(1-bromo-2-naphthylmethyl)truxene **5** (62%). Similarly, **6** was obtained by using 2-bromomethyl-1-methoxynaphthalene[10] as the electrophile in the alkylation reaction, followed by base-catalysed isomerization (85% overall yield). Demethylation of **6** with BBr_3 in CH_2Cl_2 at −78 °C afforded trisnaphthol **7** (83%), which was treated with Tf_2O and 2,6-lutidine in CH_2Cl_2 (−30 to 0 °C) to give tris(triflate) **8** (52%).[11]

Treatment of **5** with $Pd(OAc)_2$ (10–20 mol%) in the presence of $BnMe_3NBr$ and K_2CO_3 or NaOAc in DMF or DMA at 110–160 °C gave complex reaction mixtures of insoluble materials. However, use of higher amounts of $Pd(OAc)_2$ (100 mol%, 0.3 equiv.) led to cleaner reaction mixtures from which **3** could be isolated in 42% yield.[12]‡ Treatment of tris(triflate) **8** in the presence of $Pd(PPh_3)_2Cl_2$ (150 mol%) and excess NaOPiv in DMA (120 °C, 26 h) also led to **3**, albeit in lower yield (11%).[13]

Polyarene **3** is a highly insoluble substance and its ^{1}H NMR could only be determined in 1,1,2,2-tetrachloroethane-d_2 at 130 °C. The EI-MS of **3** was very revealing since it showed the molecular ion at *m/z* 750 as the base peak along with characteristic M^{2+} and M^{3+} peaks at 375 and 248, respectively (Fig. 1). Additionally, peaks corresponding to loss of two (*m/z* 748, 6%), four (*m/z* 746, 4%), and six hydrogens (*m/z* 744, 2%) were clearly observed in the EI-MS. No $C_{60}^{+\cdot}$ (*m/z* 720) was observed in the mass spectrum. Polyarene **1** showed a similar EI mass spectrum to that of **3** under identical conditions, with

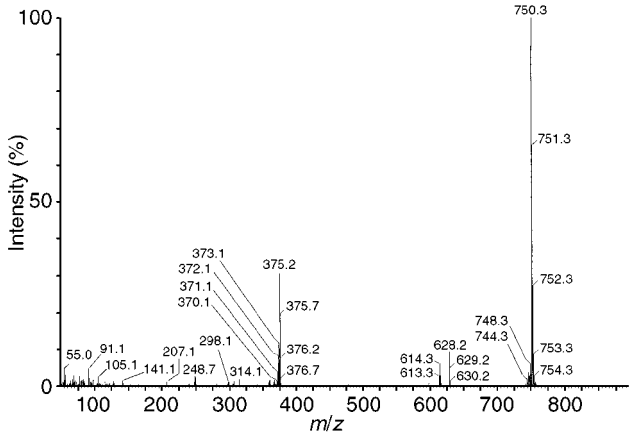

Fig. 1 EI-MS (probe temperature: 600 °C, ion source: 300 °C, 90 eV) of **3**.

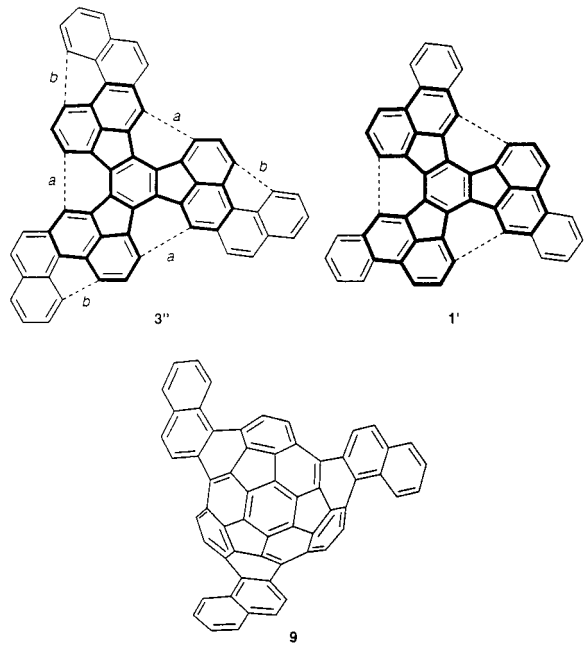

dehydrogenations presumably corresponding to that shown in **1′**.[14] This result suggests that under the conditions of the EI spectrum, **3** suffers the cyclodehydrogenations labelled *a* (**3″**).

The synthesis of **3** from **5** highlights the synthetic utility of the intramolecular C–H activation through aryl–palladium complexes.[15] Now readily available polyarene **3** could serve as the starting material for the preparation of **9** ($C_{60}H_{24}$) by a triple cyclodehydrogenation analogous to that recently carried out on decacyclene by Scott to form the fullerene fragment $C_{36}H_{12}$.[16] Additionally, bowl-shaped open fullerene **9** could be a direct precursor of C_{60} by a cascade of cyclodehydrogenation reactions.[3] Efforts along these lines are in progress.

We are grateful to the *DGES* (Project PB97-0002) for support of this research and to the *MEC* for a postdoctoral contract to B. G.-L. We acknowledge Johnson Matthey plc for a generous loan of $PdCl_2$ and Dr Maite Alonso (SIdI-UAM) for her skilled MS determinations.

Notes and references

‡ *Synthesis* of **3**: A mixture of **5** (150 mg, 0.15 mmol), $Pd(OAc)_2$ (34 mg, 0.15 mmol), $BnMe_3NBr$ (69 mg, 0.3 mmol) and K_2CO_3 (207 mg, 1.5 mmol) in DMA (8 ml) was stirred at 140 °C for 36 h. The mixture was cooled to 23 °C and the solid was filtered off and washed with CH_2Cl_2 and acetone. The solid was suspended in aqueous NaCN and stirred for 1 h. The solid was filtered off and washed with water and acetone to give **3** as a clear brown powder (47 mg, 42%): mp > 300 °C; δ_H(1,1,2,2-tetrachloroethane-d_2, 130 °C, 300 MHz) 9.26–9.01 (m, 12 H), 8.13–8.02 (m, 12 H), 7.80–7.69 (m, 6 H); *m/z* (EI) (probe temperature: 600°C, ion source: 300 °C, 90 eV) *m/z* 750 (M^+, 100%), 748 ($M^+ -2$, 6), 746 ($M^+ -4$, 4%), 744 ($M^+ -6$, 2%), 375 (M^{2+}, 30%), 248 (M^{3+}, 2%).

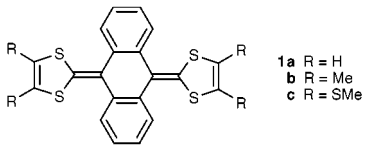
Received (in Cambridge, UK) 27th September 1999, Accepted 20th October 1999

An exocyclic diene derivative of 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene undergoes Diels–Alder reaction with naphthoquinone to provide the D–π–A diad 10.

Derivatives of the π-electron donor **1** are emerging as versatile components of organic conductors,[1] nonlinear optical materials,[2] multi-stage redox assemblies[3] and cyclophanes.[4] System **1**

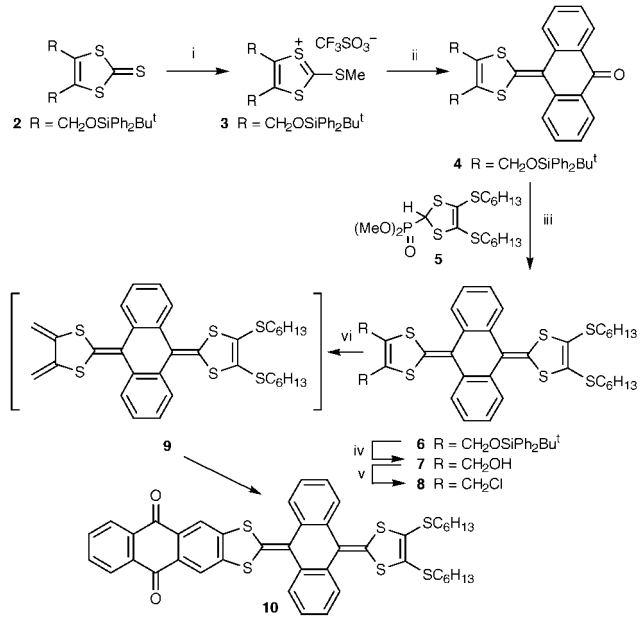


offers a unique combination of redox and structural properties, *viz.* a quasi-reversible two-electron oxidation process to yield a thermodynamically stable dication [E^{ox} +0.30 to +0.40 V (*vs.* Ag/AgCl)].[5] The neutral molecule adopts a saddle-shape; on oxidation the anthracene ring becomes aromatic and planar, with the 1,3-dithiolium cations almost orthogonal to this plane.[1b,5d]

We are developing methodology for the synthesis of new derivatives of **1**.[6] Herein we describe the first Diels–Alder reaction involving system **1**, *viz*. the reaction of the transient exocyclic diene derivative **9** with naphthoquinone to afford the aromatised adduct **10**. This study is timely in the light of interest in the Diels–Alder trapping of diene derivatives of tetrathiafulvalene[7] and 1,3-dithiole-2-one systems.[8]

Bis(chloromethyl) compound **8** is the precursor to our target diene **9** (Scheme 1). Hexylsulfanyl substituents enhance the solubility. The bis-DPTBS protected diol **2**[9] was methylated with MeOTf to afford the unstable salt **3** which was sufficiently pure for immediate reaction with the anion of anthrone, which gave ketone derivative **4** (70% yield from **2**). Horner–Wadsworth–Emmons olefination with the anion of reagent **5**[10] gave compound **6** (77% yield), which yielded the diol derivative **7** (88% yield). Reaction of a concentrated solution of diol **7** and PPh_3 in a mixture of CCl_4 and MeCN at 90 °C[11] gave the stable bis(chloromethyl) derivative **8** in 45% yield ($SOCl_2$ in CCl_4 at 20 °C gave only 10% of **8**). A mixture of **8**, KI, 18-crown-6 and 1,4-naphthoquinone was heated in toluene for 5 h, whereupon 2,3-dichloro-5,6-dicyanoquinone (DDQ) was added. After further heating the aromatised adduct **10**† was isolated (63% yield from **8**).

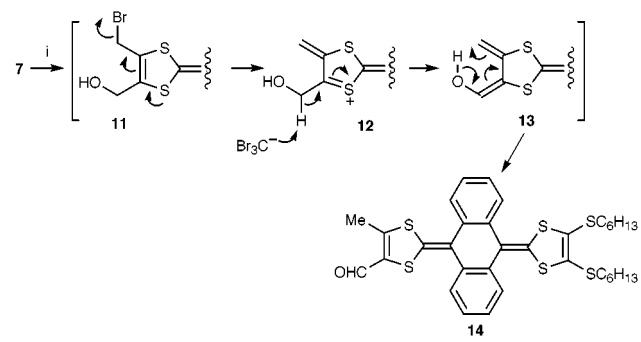
The good stability of the dichloro compound **8** contrasts with the attempted preparation of the bis(bromomethyl) derivative of **7** using conditions described[7c,9] for other 4,5-bis(bromomethyl)-1,3-dithiole systems. Reaction of diol **7** with CBr_4 and PPh_3 in THF at 0 °C gave a complex mixture of products (TLC analysis) from which the bis(bromomethyl) derivative (if present) could not be isolated; instead, the formyl derivative **14**† was obtained. The yield of **14** was optimised (61%) by using a dilute solution of **7** and CBr_4 and PPh_3 (3.0 equiv.). Formyl derivatives as byproducts during the synthesis of related



Scheme 1 *Reagents and conditions*: i, MeOTf, CH_2Cl_2, 20 °C, 1 h; ii, anthrone, pyridine–AcOH, 55 °C, 3 h, then 120 °C, 3 h; iii, **5**, LDA, −78 °C, 2 h, then add **4**, THF, −78 °C to 20 °C, 12 h; iv, Bu_4NF, THF, 20 °C, 1.5 h; v, PPh_3 (3.0 equiv.), CCl_4, (excess), MeCN, reflux, 1 h; vi, KI (3 equiv.), 18-crown-6 (3 equiv.), 1,4-naphthoquinone (4 equiv.), PhMe, 90 °C, 5 h, then DDQ (4 equiv.), 90 °C, 4 h.

4,5-bis(bromomethyl)-1,3-dithiole systems has been noted previously,[12] but no mechanism for their formation has been published.[13] A possible route is shown in Scheme 2. Loss of bromide from intermediate **11** would give **12** and hence the intermediate **13**, which could undergo an oxy-Cope type rearrangement to give **14**.

The structures of compounds **10** and **14** (Fig. 1 and 2) were confirmed by X-ray crystal structure analysis.‡ The asymmetric



Scheme 2 *Reagents and conditions*: i, PPh_3 (3.0 equiv.), CBr_4 (3.0 equiv.), CH_2Cl_2, 20 °C, 16 h.

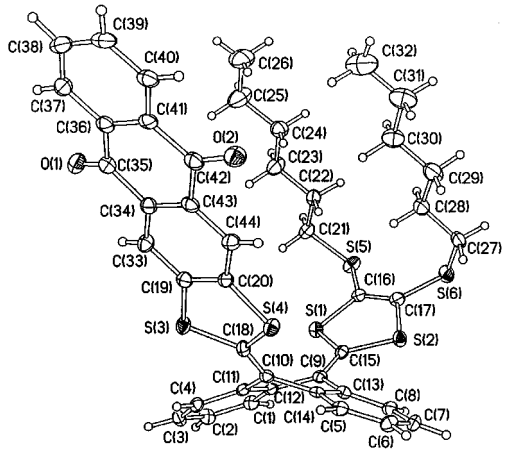


Fig. 1 Molecular structure of **10**.

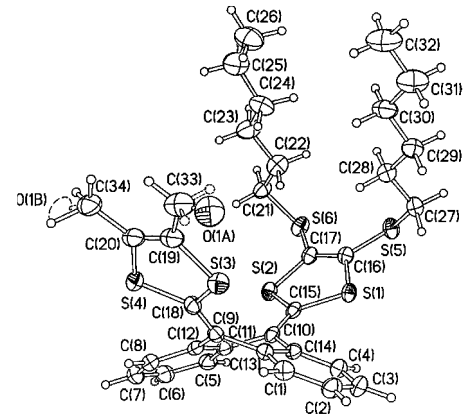

Fig. 2 Molecular structure of **14**; CH_3 and CHO substituents are evenly distributed between C(19) and C(20).

unit in the crystal of **10** contains only one independent molecule, while that of **14** comprises two molecules of similar but non-identical conformations; in one molecule, one of the *n*-hexyl chains is disordered. The anthracenediylidene system is folded along the C(9)···(10) vector by *ca.* 39° in **10** and 41° in **14** and both dithiole rings are folded inward along the S···S vectors (by 8–14°). The anthracenediylidenebis(dithiole) system is U-shaped, with an acute angle between the S(1)C(16)C(17)S(2) and S(3)C(19)C(20)S(4) planes: 83° in **10**, 82° in **14**.

The *n*-hexyl chains adopting all-*trans* conformations lie parallel to the nearly planar anthraquinone (**10**) or formylthiole (**14**) system. Such parallelism particularly highlights the packing motif characteristic for 'molecular saddles': namely, a pseudo-dimer of mutually engulfing molecules, symmetrically related *via* an inversion centre.[6b]

Cyclic voltammetry shows a quasi-reversible two-electron oxidation wave at E^{ox} +0.64 V (**10**) and E^{ox} +0.54 V (**14**). Additionally for **10** a quasi-reversible reduction wave of the AQ moiety is observed at E^{red} −0.95 V [CV data were recorded *vs.* Ag/AgCl, electrolyte $Bu_4N^+ClO_4^-$ (0.1 M), CH_2Cl_2, 20 °C, scan rate 100 mV s^{-1}].

The UV–VIS spectrum of compound **10** displays two bands characteristic of system **1**[5d,6] at 348 and 428 nm: no absorption was observed at longer wavelengths where intramolecular charge-transfer (ICT) bands would be expected. Studies aimed at photoinducing ICT in system **10**, and increasing the acceptor strength of the AQ moiety,[14] are in progress.

We thank the EPSRC and the Danish Research Academy for funding.

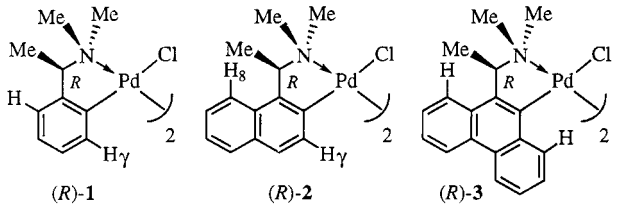
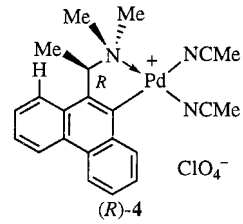
Received (in Cambridge, UK) 20th September 1999, Accepted 2nd November 1999

The novel ortho-metallated complex (*R*,*R*)-di-μ-chlorobis{9-[(1-dimethylamino)ethyl]-10-phenanthrenyl-*C*,*N*}dipalladium has been prepared and found to be a significantly better catalyst than its phenyl and naphthylamine analogues for the asymmetric Claisen rearrangement of a non-activated allyl imidate.

Over the past decade, chiral cyclopalladated-amine complexes have contributed significantly to many aspects of synthetic stereochemistry.[1] They have been frequently used as efficient resolving agents for chiral ligands, clear and reliable references for the NMR assignment of unknown absolute stereochemistry in solution, sensitive chiral shift reagents for the determination of optical purities, activators for the asymmetric carbon–carbon bond formation and as chiral templates for the synthesis of functionalized P-chiral phosphines. Surprisingly, these easily accessible square-planar organometallic complexes have not been used in any catalytic asymmetric transformations. Here, we present the systematic application of three analogous cyclopalladated-amine complexes **1**–**3** for the asymmetric Claisen rearrangement. Similar to the Diels–Alder reaction, Claisen rearrangement is an efficient and elegant method for asymmetric carbon–carbon bond formation.[2]



Both enantiomeric forms of complexes **1** and **2** are well documented. The optically active forms of the new phenanthrylamine ligand for complex **3** were obtained by optical resolution using *O*,*O*′-dibenzoyltartaric acid as the resolving agent. Thus, both the (*R*)-(+)- and (*S*)-(−)-forms of α-(9-phenanthryl)ethylamine were obtained as white solids in 60–70% yields, mp 79–81 °C, $[\alpha]_D$ ±44.0 (*c* = 0.5, CH_2Cl_2). The ortho-metallated complex (*R*)-**3** was prepared from the (*R*)-(+)-phenanthrylamine and $[Pd(MeCN)_4](ClO_4)_2$ in the presence of Et_3N followed by the treatment with an excess of NH_4Cl. The dimeric complex was obtained as pale yellow needles (60%), $[\alpha)_D$ −393 (*c* = 0.6, CH_2Cl_2). However, single crystals of (*R*)-**3** that are suitable for structural analysis could not be produced. In an effort to determine the absolute stereochemistry of the phenanthrylamine ligand, (*R*)-**3** was converted quantitatively to the perchlorate salt (*R*)-**4** by treatment of the dimeric complex with silver perchlorate in acetonitrile, $[\alpha]_D$ −198 (*c* = 0.5, CH_2Cl_2). X-Ray structural analysis of the highly crystalline cationic complex (*R*)-**4** was achieved (Fig. 1).† Similar to that observed in (*R*)-**2**,[1] the X-ray analysis of the phenanthrylamine complex reveals that the methyl group at the *R*-chiral carbon centre is located at the axial position. The geometry at palladium is distorted square planar with *cis* angles ranging between



80.2(2) and 96.4(2)°, the most acute being associated with the five-membered chelate ring which has a distinctly folded conformation with C(14) and C(15) lying 0.61 and 1.04 Å respectively out of the coordination plane. The palladium coordination distances are unexceptional, though the Pd–N bond *trans* to carbon is significantly longer than those *trans* to nitrogen. The phenanthrylene ring has a slightly twisted conformation, with deviations from planarity of up to 0.07 Å; the palladium atom lies 0.35 Å from this plane.

To compare the efficiency of the three analogous complexes on the Claisen rearrangement, an electronically non-activated allyl imidate was selected (Scheme 1). All the rearrangement processes were carried out at the optimum temperature of 20 °C in the presence of a palladium catalyst (10 mol%). Interestingly, while all three dimeric catalysts gave the corresponding amide efficiently, the cationic complex (*R*)-**4** could not catalyse the rearrangement. Apparently an electronically neutral Pd(II) species is required for this catalytic process. Furthermore, in

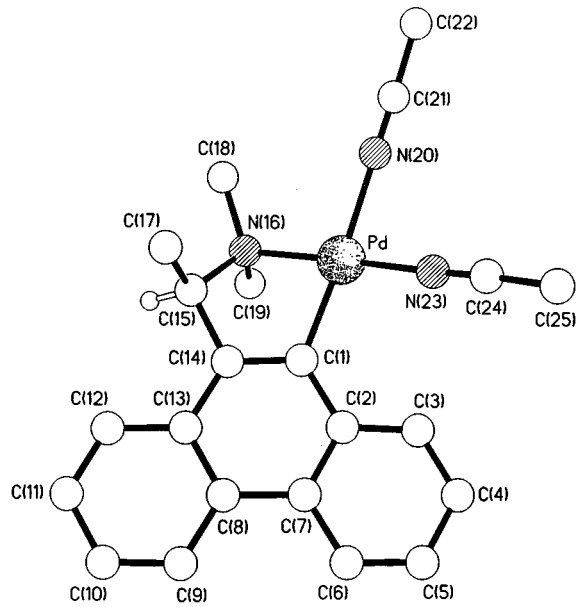


Fig. 1 Molecular structure and absolute stereochemistry of the complex cation (*R*)-**4**. Selected bond lengths (Å) and angles (°); Pd–C(1) 2.000(4), Pd–N(16) 2.062(4), Pd–N(20) 2.126(5), Pd–N(23) 2.023(4); C(1)–Pd–N(16) 80.2(2), C(1)–Pd–N(20) 176.2(2), C(1)–Pd–N(23) 96.3(2), N(16)–Pd–N(20) 96.4(2), N(16)–Pd–N(23) 172.0(2), N(20)–Pd–N(23) 86.9(2).

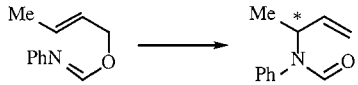
terms of stereoselectivities, it is obvious that (*R*)-**3** is the best asymmetric catalyst among the three studied. When benzene was used as the solvent, (*R*)-**3** produced the chiral amide with 79% ee.‡ Under the same reaction conditions, however, only 4% ee could be achieved by both (*R*)-**1** and (*R*)-**2**. These catalytic results are indeed in agreement with our expectations, based on the well established stereoelectronic features of complexes **1** and **2**. The five-membered organometallic ring in complex (*R*)-**1** is stereochemically non-rigid and the chiral chelate adopts both the δ and λ conformations in the solid state and these ring chiralities are inter-convertable in solution. In complex (*R*)-**2**, however, there is a strong steric inter-locking force operating between the methyl group at the chiral carbon centre and the neighbouring H(8) of the naphthylenyl ring.[1,3] Thus the δ conformation is secured in the skew organometallic ring in (*R*)-**2** and cannot be inverted into the λ form, even at elevated temperatures. Thus the stereochemistry of the naphthylamine moiety is expected to be transmit *via* the prochiral NMe groups and the H_γ proton onto the neighbouring coordination sites without any fluctuation. The X-ray analysis of (*R*)-**4** and the 2D ^{1}H ROSEY NMR studies of (*R*)-**3** and (*R*)-**4** in $CDCl_3$ confirmed that similar stereochemical inter-locking forces are operating within the palladium–phenanthrylamine chelates. In terms of electronic directing effects, it is well established that in both (*R*)-**1** and (*R*)-**2**, the Pd–Cl bonds which are located *trans* to the π-accepting aromatic carbon are stable and inert.[1,4] In contrast, the Pd–Cl bonds that are *trans* to the σ-donating nitrogen are kinetically labile. As the donor atoms in all three complexes are similar, we therefore expect that the Pd–Cl bonds in (*R*)-**3** to exhibit similar kinetic stabilities as their counterparts in (*R*)-**1** and (*R*)-**2**. Undoubtedly the labile chloro ligands in these chiral complexes provide the catalytic sites for the asymmetric Claisen rearrangements. It is noted that the stereochemical environment of the catalytic sites in (*R*)-**1** and (*R*)-**2** are controlled only by the projecting H_γ protons. However, the influence exerted by these H_γ protons is less than that of the extended aromatic ring in (*R*)-**3** as the protons are small and further away from the site. Currently we are investigating the absolute stereochemistry of the Claisen rearrangement products. In addition synthesis of analogous optically active chrysenylamine complexes and further studies of the asymmetric Claisen rearrangements involving activated allyl imidates are currently in progress.



Catalyst	Solvent	*T*/°C	Enantiomer	ee(%)
(*R*)-**1**	CH_2Cl_2	20	(−)	10

Intramolecular cyclization of 1-nitroalkenyl radicals generated by one-electron oxidation of *aci*-nitro anions with CAN: stereoselective formation of 3,4-functionalized tetrahydrofurans

Anne-Catherine Durand, Estelle Dumez, Jean Rodriguez and Jean-Pierre Dulcère

RéSo, Réactivité en Synthèse organique, UMR 6516, Faculté des Sciences et Techniques de St Jérôme, Boîte D 12, Av. Esc. Normandie-Niemen, F-13397, Marseille Cedex 20, France. E-mail: jean-pierre.dulcere@reso.u-3mrs.fr

Received (in Liverpool, UK) 28th September 1999, Accepted 28th October 1999

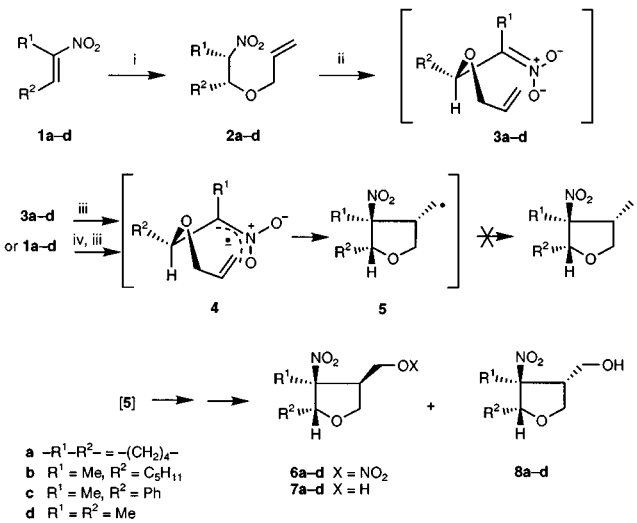
Upon one-electron oxidation by ammonium hexanitratocerate(IV) (CAN), *aci*-nitro anions 3a-d resulting from oxa-Michael addition of allylic alcohol to α,β-disubstituted nitroalkenes 1a-d undergo stereoselective radical cyclization into 3-nitro-4-nitrooxymethyltetrahydrofurans 6a-d and 3-nitro-4-hydroxymethyltetrahydrofurans 7,8a-d.

One-electron oxidation of carbanions is one of the simplest methods for generation of carbon-centered radicals. However, so-generated radicals usually afford self-condensation products,[1] and intermolecular[2] carbon–carbon bond forming reactions have only occasionally been disclosed in the literature.

Recently, ammonium hexanitratocerate(IV) (CAN) was found to be an efficient one-electron oxidant of *aci*-nitro anions to provide 1-nitroalkyl radicals which add intermolecularly to electron-rich olefins;[3] moreover, secondary 1-nitroalkenyl radicals undergo intramolecular cyclization to afford isoxazoles, provided the olefinic moiety is appropriately substituted.[4]

The failure of tertiary α-nitroalkyl radicals to cyclise, except in particular cases in which the yields of cyclized products are not satisfactory,[5] prompted us to study the reactivity of readily available α-substituted β-allyloxynitronates **3** upon oxidation with CAN.

α-Substituted β-allyloxy nitro compounds **2a**–**d**, obtained in 85–90% yield by oxa-Michael addition of allylic alcohol[6] to nitroalkenes **1a**–**d**, were reacted with NaH to afford *aci*-nitro anions **3a-d** (Scheme 1); addition of **3a**–**d** to a solution of CAN (3 equiv.) in THF at −78 °C generated radical anion intermediates **4** resulting in the stereoselective formation of *exo* nitronitrates **6a-d**† (45–60%) along with nitro alcohols **7,8a**–**d** (5–8%, **7**:**8** = 5:1).‡§ Alternatively, the same product mixture could be obtained directly from **1a-d**, in a one-pot process. According to previous reports,[4,5] reduction by solvent of alkyl radicals **5** resulting from direct 5-*exo* cyclization was not observed; indeed, a further transformation occurs, and the transformation into nitronitrates **6** which constitute the major products of the reaction could be related to a ligand transfer reaction in the presence of CAN.[7]

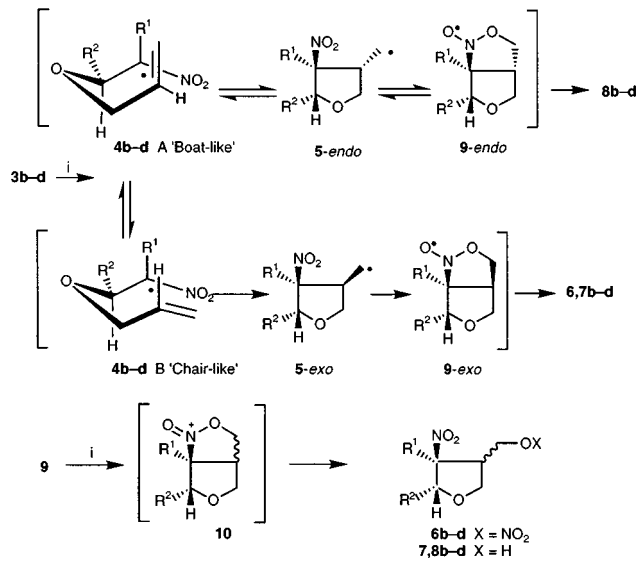


Scheme 1 *Reagents and conditions*: i, Bu^{t}OK (1.5 equiv.), Bu^{t}OH–benzene (0.5:1), then allylic alcohol, then H$^+$, 85–90%; ii, Na, H, THF; iii, CAN, THF, −78 °C, then 0.1 M $Na_2S_2O_3$, 45–60%; iv, NaH, THF, then allylic alcohol, 60% (**6a**), 58% (**6b**), 52% (**6c**), 45% (**6d**), 6% [(**7** + **8**)**a**], 7% [(**7** + **8**)**b**], 8% [(**7** + **8**)**c**], 5% [(**7** + **8**)**d**].

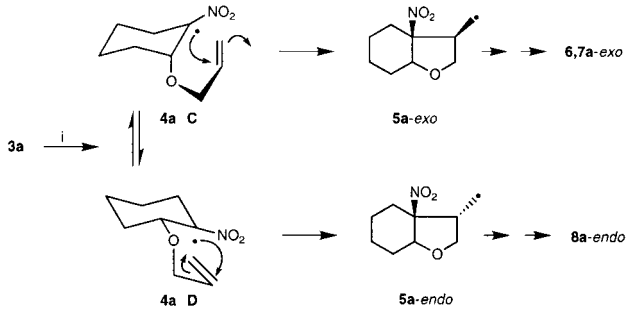
The relative *cis* stereochemistry for R^1 and R^2 in acyclic compounds **6**–**8** arises from favored conformation **B** required by allylic 1,3-strain (Scheme 2) during the intramolecular *C*-alkylation; [8] the Beckwith transition state model[9] invoked to account for these selective transformations has previously been proposed for radical cyclisations of α-nitroalkyl radicals.[10]

Moreover, the isolation of *endo* nitro alcohols **8** as minor products indicates that the observed stereochemistry is also consistent with a reversible tandem cyclisation,¶ leading to a persistent *cis*-fused bicyclic nitroxyl radical **9**-*exo*,‖ which could act as a driving force for this stereoselective cyclisation to occur; oxidation of nitroxyl radical **9** with a second molecule of CAN affords cation **10** which is then neutralized by ligand exchange with CAN[7] (Scheme 2).

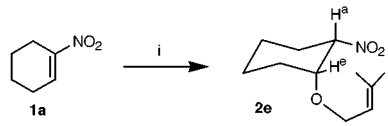
Selective formation of bicyclo compound **6a** is well-interpreted by using the '*cis*-decalin' model for cyclization of cyclohexyl radicals (Scheme 3).[11] This model predicts that *exo* product should result from conformation **C** in which the allyloxy substituent is axial, while cyclisation of **D**, with an equatorial substituent, should provide *endo* product. Indeed NMR data of 1-nitro-2-dimethylallyloxycyclohexane **2e** indicates that, even at room temperature, only the conformation with an axial dimethylallyloxy group is observed**†† (Scheme



Scheme 2 *Reagents and conditions*: i, CAN, THF, −78 °C.



Scheme 3 *Reagents and conditions*: i, CAN, THF, −78 °C.

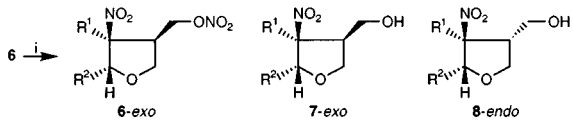


Scheme 4 *Reagents and conditions*: i, NaH, THF, then 3-methylbut-2-en-1-ol, then H^+, 12%.

4); this fact could argue for the high selectivities obtained at low temperature.

Therefore, although an intramolecular [3+2][12] cycloaddition of radical **4** could account for a totally stereoselective formation of *exo*-nitronitrates **6** through the bicyclic intermediate **9**-*exo* (Scheme 2), the proposal of a prior 5-*exo*-*trig* radical cyclization is better supported by the selectivities obtained in these transformations.

Solvolytic decomposition of nitrate esters in alkaline solution[13] accounts for the formation of nitro alcohols **7**-**8**; the isolation of *endo* nitro alcohol **8** as a minor compound could argue for the initial formation of *endo* nitro nitrate, transformation of which into **8** is quantitative under the reaction conditions, while the major *exo* nitro nitrate **6** is only partially converted into *exo* alcohol **7** (Scheme 5); indeed, when pure **6a** was reacted with NaH in 0.1 M $Na_2S_2O_3$ for 48 h, pure **7a** was isolated in 28% yield,‡‡ along with some remaining **6a**, while **8a** could not be detected by NMR. Thereby, the apparent total *exo* selectivity observed in the formation of nitro nitrates **6** should arise from the total transformation of the minor *endo* diastereomer into alcohol **8**.



Scheme 5 *Reagents and conditions*: i, NaH, THF.

In conclusion, although it has been previously believed that cyclization of α-nitroalkenyl radicals for synthetic purposes could only be useful if groups more nucleophilic than unactivated alkenes are present,[14] our results show that, in turn, α-nitroalkenyl radicals generated by one-electron oxidation of *aci*-nitro anions with CAN lead stereoselectively to bifunctionalized tetrahydrofurans bearing three contiguous stereogenic centers. Moreover, the scope of subsequent conversions of the nitro and nitrate ester groups[15] should expand the utility of this new strategy in organic synthesis.

We are grateful to Professor M. Bertrand and Dr R. Faure (Marseille), Professor W. Dolbier Jr (Gainesville) and Professor D. P. Curran (Pittsburg) for useful suggestions.

Cyclization reactions of vicinal dianions with 1,2-dielectrophiles: synthesis and properties of the first 2,3-diiminothietanes†

Peter Langer*[a] and Manfred Döring[b]

[a] *Institut für Organische Chemie der Georg-August-Universität Göttingen, Tammannstrasse 2, 37077 Göttingen, Germany. E-mail: planger@uni-goettingen.de*

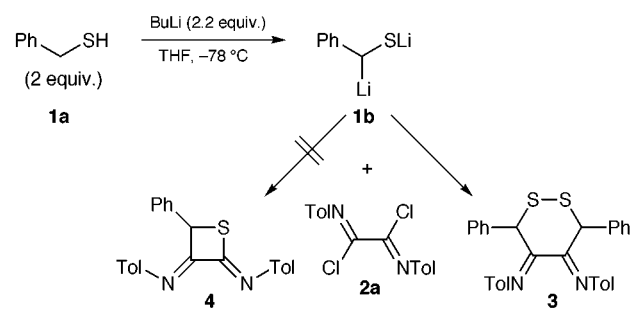
Received (in Cambridge, UK) 25th August 1999, Accepted 14th October 1999

Reaction of dilithiated ethyl thioglycolate with bis(imidoyl chloride)s of oxalic acid afforded the first 2,3-diiminothietanes, which underwent ring expansion reactions upon treatment with ethyl thioglycolate or dimethyl acetylenedicarboxylate.

Four-membered ring lactams and lactones represent pharmacologically important compounds which, due to their ring strain, readily undergo ring-expansion or -opening reactions.[1] To the best of our knowledge, azetidine-2,3-diones represent the only known heterocycles which combine the biologically significant structural features of a four-membered ring and a 1,2-dione subunit.[2] Due to their high reactivity, oxetanes and thietanes containing a 1,2-dione subunit are unknown to date. However, a few examples of the corresponding heterocyclic 1,2-diimines have been reported.[3,4] We envisaged that reaction of 1,2-dianions with oxalic acid dielectrophiles could provide a convenient synthesis of four-membered ring heterocycles containing a 1,2-dione or related subunit. Much to our surprise, until recently cyclization reactions of oxalic acid dielectrophiles with 1,1-, 1,2-, 1,3- or 1,4-dianions had not been reported.[5] This is presumably due to the fact that these reactions can suffer from several drawbacks, such as overaddition of the nucleophile, expulsion of CO or decomposition. We have recently shown that bis(imidoyl chloride)s of oxalic acid [$Cl_2C_2(NR)_2$] represent useful C_2 building blocks in cyclization reactions with 1,3-dianions.[6] Herein we report that bis(imidoyl chloride)s can be cyclized with 1,2-dianions equally successfully. To the best of our knowledge, these transformations represent the first examples of cyclization reactions of 1,2-dianions with 1,2-dielectrophiles to date.[7]

Our first aim was the preparation of 2,3-diiminothietanes by reaction of dilithiated thiols with bis(imidoyl chloride)s.[4,8] Unfortunately, treatment of bis(imidoyl chloride) **2a** with the dianion of BnSH **1b**[9a] gave a complex reaction mixture from which the cyclic disulfide **3** was isolated in low yield (Scheme 1). Formation of **3** can be explained by initial condensation of **2a** with 2 equiv. of **1b** and subsequent oxidative cyclization. The yield of **3** could be improved by the use of 2 rather than only 1 equiv. of the dianion. However, a change of the reaction conditions (slow addition of the dianion to **2a**) and of the work-up procedure (filtration under inert conditions rather than aqueous work-up) did not provide the desired product **4**. Similar disappointing results were obtained when the dianion of prop-2-enethiol was employed.

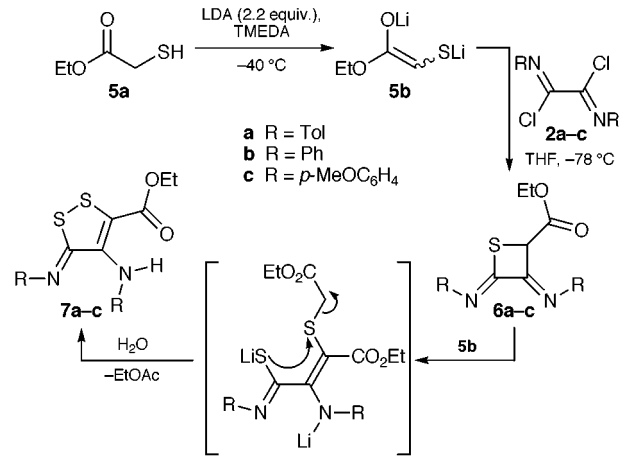


Scheme 1

Much to our satisfaction, reaction of bis(imidoyl chloride) **2a** with the dianion of ethyl thioglycolate **5b**[9b] afforded the 2,3-diiminothietane **6a** in 30% yield (Scheme 2).‡ Thietane **6a** could be readily isolated by chromatography as it represented the only Et_2O-soluble product formed in the reaction. In contrast, reaction of **5b** with oxalyl chloride or diethyl oxalate gave polymeric material under a variety of conditions. In contrast to the open-chained derivative Me(PhHN)C=CH-CO_2Et, thietane **6a** adopted a 3-iminopropionate- rather than a 3-aminocrotonate structure, presumably for electronic reasons. Variable temperature ^{1}H NMR ($CDCl_3$) showed that 2,3-diiminothietane **6a** represented a structurally mobile compound due to *E*/*Z* isomerization of the imino group at C-3.§

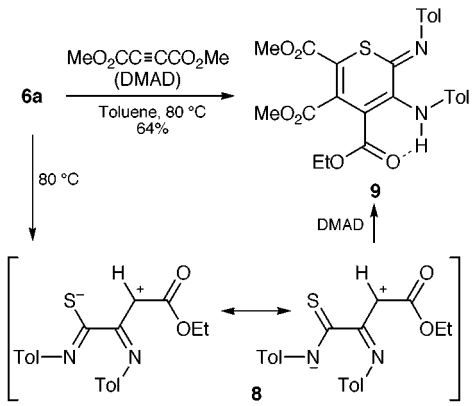
Interestingly, treatment of bis(imidoyl chloride)s **2b**,**c** with the dianion **5b** resulted in formation of the 1,2-dithioles **7b** and **7c** in 41 and 40% yields, respectively (Scheme 2).[10] The formation of the dithioles **7** can be explained by initial cyclization to give the 2,3-diiminothietanes **6**, subsequent ring opening, addition of a second equivalent of the dianion, cyclization and expulsion of EtOAc.

In order to elucidate the mechanism of the conversion of 2,3-diiminothietanes **6** into the bisthioles **7**, cycloaddition reactions of **6a** were studied. When a toluene solution of thietane **6a** and dimethyl acetylenedicarboxylate (DMAD) was stirred at 80 °C for 12 h, the yellow coloured thioimino ether **9** was isolated in 64% yield (Scheme 3). The formation of cycloadduct **9** can be explained by initial ring-opening of thietane **6a** to give the 1,4-zwitterionic intermediate **8** and subsequent regioselective cyclization of the latter with DMAD.¶ Bisthiole **7a** was isolated in 58% yield when a toluene



Scheme 2

† Dedicated to Professor A. Zeeck on the occasion of his 60th birthday.



Scheme 3

solution of **6a** and of ethyl thioglycolate **5a** was stirred for 12 h at 80 °C. This experiment suggested that intermediate **8** was not only involved in the formation of the cycloadduct **9** but also in the conversion of the 2,3-diiminothietanes **6a**–**c** into the bisthioles **7a**–**c**.

The influence of the heteroatoms of the 1,2-dianion on the regiochemistry of cyclization was next studied. No cyclization could be induced in the reaction of bis(imidoyl chloride) **2a** with the dianion of ethyl lactate, presumably due to the lower nucleophilicity of the oxygen relative to the sulfur atom. In contrast, reaction of **2a**,**b** with the dianion of ethyl hippurate **10**[11] afforded the 6-imino-6*H*-1,3-oxazines **11a**,**b** by regioselective cyclization *via* the carbon and the oxygen atom of the dianion (Scheme 4). The regioselectivity of this reaction, which was carried out under kinetic conditions, can be explained by the higher electron density at the oxygen rather than at the nitrogen atom of the dianion or, alternatively, by initial formation of a four-membered ring and subsequent ring expansion. Similar to bisthioles **7a**–**c**, oxazines **11a**,**b** represent masked 1,2,3,4-tetracarbonyl systems containing strong intramolecular hydrogen bonds (N–H···O).

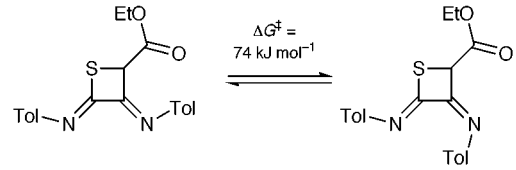
Notes and references

‡ *Preparation* of **6a**: A THF solution of LDA (2.5 equiv.) was prepared by addition of BuLi (9.4 ml, 1.6 M solution in hexane) to a THF solution (15 ml) of diisopropylamine (2.1 ml) at 0 °C. To this solution TMEDA (2.3 ml) and ethyl thioglycolate (0.54 ml) were added at −40 °C. The deep yellow solution was stirred at 0 °C for 2 h and subsequently transferred to a THF solution (80 ml) of **2a** (1.8 g) at −78 °C. The temperature was allowed to rise to ambient and the mixture was stirred for 2 h at 20 °C. The solvent was removed *in vacuo* and the residue was purified by chromatography (silica gel, Et_2O–light petroleum = 1 : 10 → 1 : 3) to give 634 mg (30%) of a yellow solid, mp 110 °C (decomp.); δ_H($CDCl_3$, 200 MHz) 0.98 (t, *J* 7, 3 H, CH_2CH_3), 2.32, 2.34 (s, 6 H, Tol-CH_3), 4.94 (m, 2 H, CH_2CH_3), 5.33 (s, 1 H, $CHCO_2Et$), 6.95–7.25 (m, 8 H, Tol); δ_C($CDCl_3$, 50 MHz) 13.62 (CH_2CH_3), 21.01, 21.18 (Tol-CH_3), 54.47 (CH, $CHCO_2Et$), 62.21 (CH_2CH_3), 121.44, 122.37, 129.75, 129.99 (CH, Tol), 136.66, 137.34 (C, Tol-C to CH_3), 142.95, 143.25 (C, Tol-C to N), 157.00 (C, CHCNTol), 158.99 (C, SCNTol), 167.39 (C, CO_2Et); ν_{max}(KBr)/cm^{-1} 2980 (w), 1738 (s), 1655 (m), 1641 (m), 1505 (s), 1268 (s), 1235 (m), 1125 (m), 1030 (m), 823 (m); *m*/*z* (CI, H_2O) 353 (M^+ + 1), 236 (M^+ + 1 − TolN=C), 203 (M^+ + 1 − TolN=C=S) (Calc. for $C_{20}H_{20}N_2O_2S$: C, 68.16; H, 5.72; N, 7.94. Found: C, 68.51; H, 5.79; N, 8.07%).

§ From 90 to 60 °C the ^1H NMR spectra exhibited only one set of signals. By cooling, broadening of the signals and coalescence (60 °C) were observed giving rise to two signals each for the CH, CH_2 and CH_3 group with the integration ratio 1 : 5. Singlets were detected for the CH groups and multiplets were detected for the CH_2 groups, both for the major and the minor component. The free energy of activation of this process ($\Delta G^‡$ = 74.0 kJ mol^{-1}) lies in the range of typical activation barriers for *E*/*Z* isomerizations of imines.



¶ To the best of our knowledge, open-chained 1,4-zwitterions related to **8** have not been reported so far. In contrast, 1,3-zwitterions have been previously discussed as intermediates in the chemistry of thietanes, see refs. 4(*a*) and 8(*c*). The mass spectrum of **6a** exhibited characteristic fragment peaks (loss of electroneutral TolN=C=S) which independently supported the existence of intermediate **8**. Cleavage of the carbon–sulfur bond of a 2-iminothietane has been observed during the thermal rearrangement of the latter to an α,β-unsaturated thioamide, see ref. 8(*b*).

Iridium PCP pincer complexes: highly active and robust catalysts for novel homogeneous aliphatic dehydrogenations

Craig M. Jensen

Department of Chemistry, University of Hawaii, Honolulu, HI 96822, USA. E-mail: jensen@gold.chem.hawaii.edu

Received (in Cambridge, UK) 5th May 1999, Accepted 17th August 1999

The PCP pincer complexes, $IrH_2\{C_6H_3(CH_2PR_2)_2\text{-}2,6\}$ (R = Bu^t, Pr^i) are extraordinarily active and robust catalysts for aliphatic dehydrogenation reactions. Their application to alkane dehydrogenation has resulted in the first efficient catalytic systems for homogeneous thermochemical alkane dehydrogenation without the use of a sacrificial hydrogen acceptor and for dehydrogenation of *n*-alkanes to α-olefins. The pincer catalysts also effect other aliphatic dehydrogenations which had not previously been accomplished *via* homogeneous catalysis including the conversion of cycloalkanes to arenes, ethylbenzene to styrene and tetrahydrofuran to furan. All of these catalytic reactions are inhibited by even traces of nitrogen. This is apparently due to the formation of the remarkably stable dinitrogen complexes: $[Ir\{C_6H_3(CH_2PR_2)_2\text{-}2,6\}]_2(\mu\text{-}N_2)$. Mechanistic studies have indicated that the high activity of the pincer catalysts may be in part due to 'agostic promotion' by phosphino aliphatic groups.

Introduction

The selective functionalization of aliphatic groups is one of the great unsolved problems of organic chemistry. The quest for methods to effect this type of transformation continues to entice chemical researchers through economic incentives and intellectual challenge. One of the most commercially tantalizing possibilities is the production of major organic feedstocks such as terminal alkenes (α-olefins) through regioselective aliphatic dehydrogenation reactions. Two decades ago, Crabtree *et al.* first reported the stoichiometric dehydrogenation of alkanes to alkenes by soluble transition metal complexes.[1] This was followed by the 1983 discovery by Baudry *et al.* of the first homogeneous catalyst for the transfer dehydrogenation of alkanes to alkenes.[2] A variety of other complexes were found during the next 12 years that operate in systems that are driven by the hydrogen transfer from alkanes to hydrogen acceptors (transfer-dehydrogenation),[3–9] photoirradiation,[5,10] and the thermal evolution of hydrogen.[11,12] The systems generally suffered from very slow reaction rates and rapid catalyst decomposition.[1–5,8,11,12] The first efficient thermochemical system for the transfer dehydrogenation of alkanes was achieved by Goldman and coworkers in 1991 using $Rh(CO)Cl(PMe_3)_2$ as catalyst under a hydrogen atmosphere.[6] Unfortunately, this system also catalyzes a 4–20 fold excess of direct (non-transfer) hydrogenation of the sacrificial alkene. It was subsequently found that closely related rhodium arsine[7] and phosphine enolate[9] complexes function as efficient catalysts under similar conditions. Notably the excess of acceptor which is consumed is significantly reduced when the reaction is catalyzed by arsine complexes.[7] While the state of the art of homogeneous alkane dehydrogenation catalysts had continuously advanced, it was apparent that the development of practical systems awaited the discovery of catalysts with greatly improved thermal stability and enhanced reactivity with alkane C–H bonds.

Hydrido complexes containing a tridentate monoanionic aryl bis(phosphino), 'PCP pincer' ligand were first prepared by Moulton and Shaw.[13] The complexes $IrClH\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$ **1a** and $RhClH\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$ **1b**, were found to possess unusually high thermal stabilities and sublime at 180–200 and 245–350 °C, respectively, without decomposition.[13] In 1979, it was observed that the intermediate resulting from the dehydrochlorination of **1b** with $NaN(SiMe_3)_2$, reacted readily with pentane, octane and cyclohexane to produce hydride complexes.[14,15] Thus it seemed that '$M\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$' (M = Ir, Rh) might have the right combination of thermal stability and high reactivity with aliphatic C–H bonds to function as practical alkane dehydrogenation catalysts. Unfortunately, '$Rh\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$' has proven to be too unstable to isolate. Attempts to utilize the complex for the catalytic transfer dehydrogenation of alkanes upon *in situ* generation from **1b** were also unsuccessful. Thus we considered alternative methods of generating a PCP pincer catalyst.

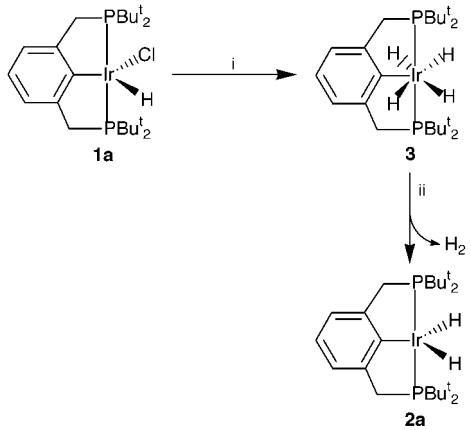
A number of dihydrido iridium bis(phosphine) complexes had been found to be catalysts for alkane dehydrogenation.[3–5,8,11] Therefore, we reasoned that the dihydrido PCP pincer complexes $MH_2\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$, (M = Ir, **2a**; Rh, **2b**) were logical catalyst candidates. As we began our exploration of the pincer catalyst in the spring of 1996, we were unaware that the groups of Goldman[16] and Leitner[17] had independently identified rhodium complexes containing very similar chelating phosphine ligands as likely candidates for advanced alkane dehydrogenation catalysts and were embarking on similar studies.

Synthesis and characterization of dihydrido pincer complexes

The dihydrido complex **2a** had not previously been synthesized and isolated. A species previously generated *in situ* and identified as **2a**[18] is actually the tetrahydride complex, $IrH_4\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$, **3a**. We have found methods whereby the dihydride complexes can be prepared and isolated in > 85% yield.[19] The iridium complex **2a** was synthesized by the two step procedure seen in Scheme 1. This reaction

Craig M. Jensen is a Professor of Chemistry at the University of Hawaii. He was born and raised in Wenatchee, Washington, USA. His undergraduate education began at the University of Washington and was completed, after a sabbatical in the Aleutian Islands, at the University of California at Santa Barbara. He obtained his PhD at the University of California at Los Angeles under the supervision of Professor H. D. Kaesz. Following a postdoctoral appointment at the University of California at San Diego, he joined the faculty at UH in 1986. In addition to pincer catalysts, his research group is developing advanced hydrogen storage materials.

sequence had previously been developed by Kaska and coworkers for the preparation of $IrH_2\{HC(C_2H_4PBu^t_2)_2\}$ from $IrClH\{HC(C_2H_4PBu^t_2)_2\}$.[20] In the first step of this procedure, the hydrido chloride complex **1a** is converted to the white tetrahydride complex **3a** through reaction with $LiBEt_3H$ under an atmosphere of H_2. Following isolation and recrystallization of **3a**, the brown dihydrido complex, **2a** is obtained quantitatively upon heating finely powdered **3** at 130 °C *in vacuo*.



Scheme 1 *Reagents and conditions*: i, $LiEt_3BH$ (1 M in THF) 1 equiv., 1 atm H_2, 25 °C, pentane; ii, 3×10^{-3} torr, 130 °C, 24 h.

An X-ray structure determination was carried out on a single crystal of **2a** in order to verify the structural composition.[19] A diagram of the determined molecular structure is presented in Fig. 1. This depiction underscores how the rigid coordination

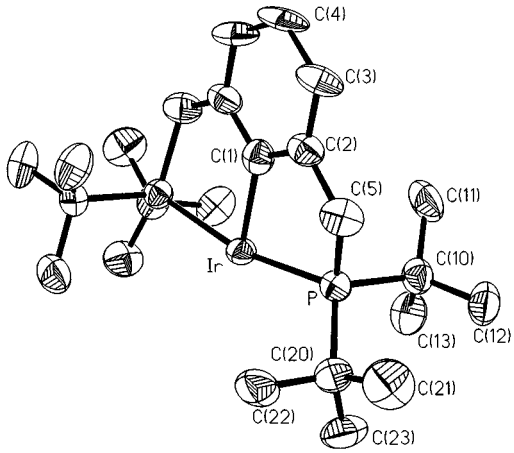


Fig. 1 Projection of $IrH_2\{C_6H_3(CH_2PBu^t_2)_2$-2,6} **2a** with the thermal ellipsoids at 50% probability. Selected bond distances (Å) and angles (°): Ir–C(1) 2.12(1), Ir–P 2.308(2), P–Ir–C(1) 82.41(6), P–Ir–P(a) 164.8(1).

framework of the PCP pincer ligand effectively restricts the access of the metal center to the P–C and C–C bonds of the ligand thus rendering the complex to be sufficiently robust to withstand high temperatures.

The synthesis of **2b** is not complicated by the formation of a tetrahydride. Thus the rhodium PCP dihydride can be prepared directly from the hydrido chloro complex. It was initially obtained among the products resulting from the treatment of **1b** with either $NaN(SiMe_3)_2$ or KH under an atmosphere of hydrogen.[15] A much cleaner reaction occurs with $LiBEt_3H$ under an atmosphere of H_2 and purified **2b** can be isolated upon recrystallization.[21]

Dehydrogenation of alkanes to alkenes

Cyclooctane

The enthalpy of dehydrogenation of cyclooctane is 23.3 kcal mol^{-1}, 5–7 kcal mol^{-1} lower than for most alkanes. This 'best case' substrate has been the conventional starting point for most studies of homogeneous catalysts for the dehydrogenation of alkanes. As mentioned above, a sacrificial hydrogen acceptor is generally required in thermochemical catalytic systems. Crabtree *et al.* found *tert*-butylethylene (tbe) to be a particularly effective acceptor in their early studies[1] and its use in these systems has become standard.

Our initial attempts to utilize the di- and tetra-hydrido pincer complexes as catalysts for the generic cyclooctane–tbe system were unsuccessful. No catalytic activity was observed when the complexes were used either directly upon generation *in situ* or in crude unpurified form. The key to the discovery of the extraordinary catalytic activity of both **2a**[19] and **3a**[21] was the recrystallization of the complexes from pentane to remove borate impurities introduced during its generation from $LiBEt_3H$. At 150 °C the dehydrogenation of cyclooctane by **2a** proceeds at a rate of 82 turnovers h^{-1} while a rate of 12 turnovers min^{-1} is observed at 200 °C. Appreciable activity (20.5 turnovers h^{-1}) is observed as low as 100 °C. Furthermore, no significant decomposition of the catalyst occurs within the time required for the complete consumption of the hydrogen acceptor. The long term maintenance of catalyst integrity contrasts with the short, *ca.* 12 h half lives which had typically been found for alkane dehydrogenation catalysts.

Prior to our studies of the pincer catalysts, only rhodium complexes had been found to exhibit high activity as alkane dehydrogenation catalysts.[6,7,9,10] Thus it is surprising that **2b** shows only very low catalytic activity. For example, a rate of only 0.8 turnovers h^{-1} was observed for the dehydrogenation of cyclooctane by **2b** at 200 °C.[21] *Ab initio* calculations have shown[22] that addition of H_2 to $Rh(PH_3)_2Ph$ is $\geqslant$ 20 kcal mol^{-1} less favorable than addition to $Ir(PH_3)_2Ph$, $Rh(PH_3)_2Cl$ or $Ir(PH_3)_2H$.[23] This suggests that addition of closely related C–H bonds to rhodium PCP pincer complexes may also be unfavorable thus accounting for the low observed catalytic activity. In support of this hypothesis, Milstein *et. al.* have recently found the alkyl rhodium pincer complexes $RhR\{C_6H_3(CH_2P^tBu_2)_2$-2,6}I (R = Pr^i, Pr^n, Et) to be exceptionally stable against intermolecular addition of the β-C–H bonds of the alkyl ligands.[24]

Nitrogen and alkene inhibition

The catalytic activity of the pincer complexes is suppressed by N_2. In order to achieve the maximum catalytic rates, reaction mixtures must be freeze–pump–thaw degassed prior to heating to remove any vestiges of N_2. This unusual N_2 inhibition of the catalytic activity is due to the formation of the surprisingly stable dinitrogen complex, $[Ir\{C_6H_3(CH_2PBu^t_2)_2$-2,6}$]_2(\mu$-$N_2)$ **4**.[25] The complex was isolated by treating a cyclohexane solution **2a** with a 15 fold excess of tbe under 1 atm of nitrogen at 80 °C. The dinitrogen complex is produced in nearly quantitative yield within 1 h. The formation of **4** is evidently initiated by the reaction of nitrogen with the intermediate resulting upon the dehydrogenation of **2a** by tbe as nearly one equivalent of *tert*-butylethane is produced in the reaction.

The molecular structure of **4** was elucidated through a single crystal X-ray structure determination[25] and is depicted in Fig. 2. The dihedral angle between the planes defined by Ir(1), P(11), P(12) and Ir(2), P(21), P(22) is 89.5°. This nearly perpendicular arrangement results in the encapsulation of the nitrogen ligand and is apparently responsible for the surprising stability of **4** and the pronounced inhibiting effect of nitrogen on the catalytic reactions.

The dehydrogenation activity of **2a** is inhibited by high concentrations of alkene. Thus the loading of hydrogen acceptor in the reaction mixture is restricted. For example, diminished rates of catalysis are found in solutions containing > 300 : 1 ratio of tbe to catalyst. In order to achieve high turnover numbers, a limited amount of tbe must be periodically added to reaction

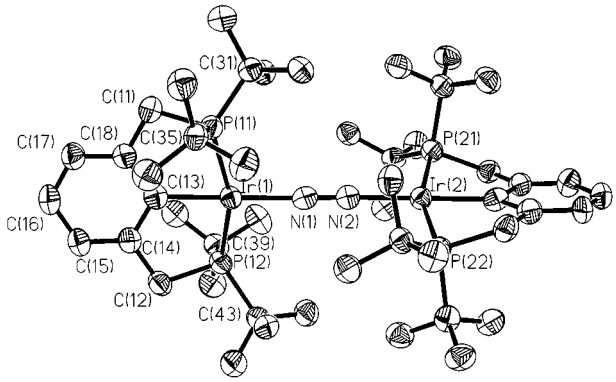

Fig. 2 Projection of [Ir{$C_6H_3(CH_2PBu^t_2)_2$-2,6}]$_2$(μ-N_2) **4** with the thermal ellipsoids at 25% probability. Selected bond distances (Å) and angles (°): Ir(1)–C(13), 2.053(12), Ir(1)–P(11) 2.312(3), Ir(1)–N(1) 2.007(11), N(1)–N(2) 1.176(13), C(13)–Ir(1)–P(11) 78.6(3), P(11)–Ir(1)–P(12) 160.22(10), Ir(1)–N(1)–N(2) 178.7(9).

mixtures. Following incremental additions of tbe, the dehydrogenation of cyclooctane is observed to again proceed at a rate of 12 turnovers min^{-1}.[21]

At higher concentrations, the cyclooctene product inhibits the catalyst and only *ca*. 10% of the cyclooctane can be dehydrogenated. Overcoming this problem of product inhibition is one of the major challenges to be met in the development of synthetically useful methods based on pincer complex catalyzed dehydrogenation reactions.

Linear alkanes

Terminal alkenes (α-olefins) are a major feedstock for the production of plastics, detergents and lubricants. Their production through the selective dehydrogenation of linear alkanes would be an attractive alternative to the present commercial processes based on hydrogen, ethylene and trialkylaluminium catalysts.[26] Several studies of alkane activation by rhodium and iridium complexes have shown that oxidative addition of primary C–H bonds is kinetically preferred despite their greater bond strength.[27] Thus it is plausible that a kinetically controlled, catalytic system based on rhodium or iridium complexes could be developed for the regioselective dehydrogenation of *n*-alkanes to terminal alkenes. An early study by Felkin *et al.* found that $IrH_5(PPr^i_3)_2$ catalyzes the transfer dehydrogenation of *n*-hexane to hex-1-ene with >90% selectivity.[3] However, only 0.3 catalytic turnovers were achieved owing to the low activity and stability of the catalyst. Other catalytic systems were found to have higher activity with *n*-alkanes but the observed product distributions were essentially thermodynamically controlled and contained little or no terminal alkene.[6,7,10] The hope of developing a system which capitalized on the kinetic preference of iridium and rhodium complexes for the activation of the terminal C–H bonds of alkanes was raised by the discovery that $RhCl(CO)(PMe_3)_2$ catalyzed a photochemical system for the efficient, regioselective carbonylation of the terminal position of *n*-alkanes.[28] In view of the high activity found for **2a** in our studies with cyclooctane, it seemed possible that its application to the dehydrogenation of *n*-alkanes might lead to the selective production of the kinetically preferred terminal alkenes.

Our initial studies of the dehydrogenation of *n*-octane with the pincer catalyst **2a** indicated that the reaction was highly selective for internal octenes over oct-1-ene.[29] However, a study of product distribution *vs*. time at 150 °C revealed a more complicated situation.[30] The data presented in Fig. 3 clearly illustrates the high kinetic selectivity of the reaction for oct-1-ene. To our knowledge this is the first catalytic system for the efficient and selective dehydrogenation of linear alkanes to terminal alkenes. It can also be seen that **2a** also functions less efficiently as an alkene isomerization catalyst. While the net

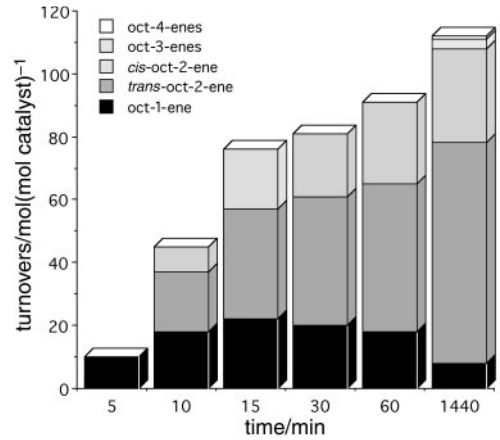

Fig. 3 Distributions of octenes produced at various times from the transfer dehydrogenation of *n*-octane catalyzed by **2a** at 150 °C.

production of octenes begins to level off within the first hour due to octene inhibition of the dehydrogenation reaction, the distribution of octenes continues to slowly shift towards the internal isomers. Although the practical utility of this system is limited by the secondary alkene isomerization reaction, modification of the system may permit production of high yields of terminal alkenes. For example, Goldman and coworkers have found that the rate of the isomerization reaction is sensitive to the steric bulk of hydrogen acceptor. Using the combination of dec-1-ene as hydrogen acceptor and **2a** as catalyst for the transfer dehydrogenation of *n*-octane, a 68% selectivity for oct-1-ene after 143 total turnovers is observed before its level begins to decline due to secondary isomerization.[30]

Acceptorless dehydrogenation of alkanes to alkenes

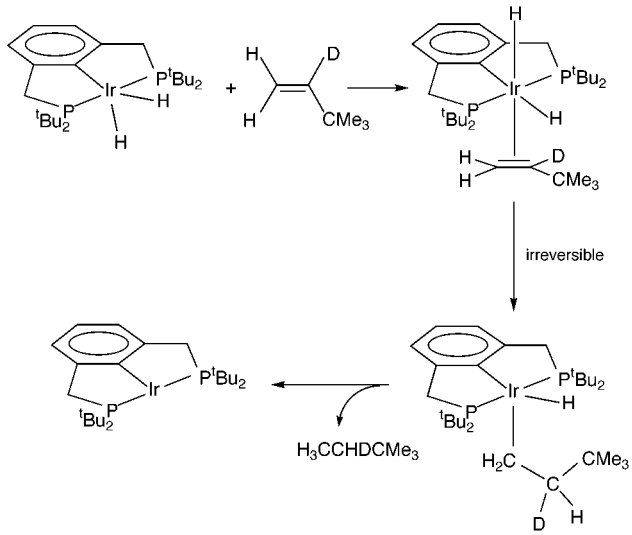
Both economical and environmental considerations preclude systems requiring a sacrificial hydrogen acceptor from consideration for the commercial production of alkenes. Thus there is great interest in the development of 'acceptorless' systems in which alkanes are transformed to alkenes upon the direct elimination of H_2. In 1990 Fujii and Saito reported the first thermochemical homogeneous catalytic systems for acceptorless dehydrogenation of alkanes.[11] In order to circumvent unfavorable equilibrium constraints, hydrogen was evolved from the refluxing systems *via* a continuous purge with an inert gas. Other systems for acceptorless alkane dehydrogenation were developed using this approach but suffered from the usual problems of very low catalytic activities (<2 turnovers h^{-1}) and catalyst instability.[11,12]

The iridium PCP pincer complexes have been found to be much more efficient catalysts for acceptorless dehydrogenation.[22,31] As a result of their high activity and long term stability at very high temperatures, the turnover numbers which can be achieved in continuously purged, open reflux systems are increased by two orders of magnitude. Recently, Liu and Goldman observed turnover numbers approaching 1000 for the acceptorless dehydrogenation of cyclodecane in experiments employing $IrH_2\{C_6H_3(CH_2PPr^i_2)_2$-2,6} **6**, the isopropyl analog of **2a,** as catalyst.[31]

Mechanistic studies

The overall mechanism of the transfer dehydrogenation of alkanes by **2a** is largely unexplored. However, the initial process in the catalytic sequence is undoubtedly the dehydrogenation of the dihydride by the hydrogen acceptor to produce the key intermediate '$Ir\{C_6H_3(CH_2PBu^t_2)_2$-2,6}'. This reaction occurs cleanly at 25 °C and has been studied in detail.[25] The dehydrogenation of **2a** in neat tbe at 25 °C gives a stoichiometric amount of *tert*-butylethane (tba) within 1 h. As seen in Scheme 2, experiments in neat $H_2C{=}CDCMe_3$ produce ex-

clusively β labeled tba. We also observed that no deuterium is scrambled into **2a** during the course of the dehydrogenation reaction. These findings lead to the conclusion that hydride migration to coordinated tbe is irreversible.



Scheme 2 Mechanism of the dehydrogenation of **2a** by $H_2C=CDCMe_3$.

Results of studies of dehydrogenation of **2a** contrast with those of our earlier study with the chloro complex $IrClH_2(P\text{-}Pr^i_3)_2$ **5**.[8] While coordination of tbe and subsequent hydride migration are also facile with **5**, the reductive elimination of tba from the resulting alkyl hydride complex requires the addition of an alkane and heating to 150 °C. The high barrier to elimination of tba in the case of **5** renders the hydride migration step reversible as demonstrated by the transfer of deuterium from $IrClD_2(PPr^i_3)_2$ (**5**-d_2) to the β position of tbe.

It is possible that an agostic interaction with a methyl C–H bond of a *tert*-butyl methyl group triggers tba elimination from the pincer complex. This hypothesis is supported by the observation of deuterium scrambling in the dideuterio complex, **2a**-d_2. The exchange between the deuteride and the methyl hydrogens of the *tert*-butyl methyl groups of the pincer ligand was apparent within 2 h of dissolving **2a**-d_2 in cyclohexane at 25 °C. In contrast, heating the dideuterio complex, **5**-d_2 in toluene solution at 150 °C for 24 h does not result in transfer of the deuterium label to isopropyl methyl groups of phosphine ligands.[32] The ability of the phosphine alkyl groups of **2a** to interact with the iridium center may eliminate the requirement of alkane association for tba elimination found for **5**.[8] Thus 'agostic promotion' by the pendent *tert*-butyl methyl groups may partially account for **2a** having much higher activity for the catalytic transfer dehydrogenation of alkanes than **5**.

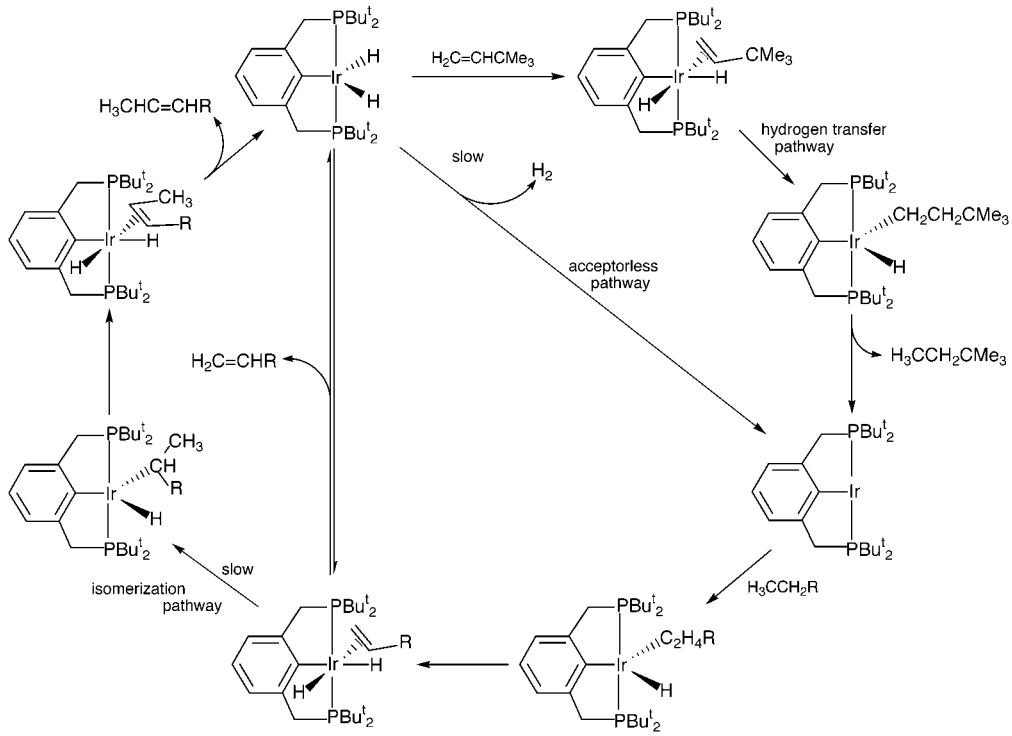
The complex which is produced upon the dehydrogenation of **2a** has been characterized by ^1H and ^{31}P NMR spectroscopy. These data confirm the presence of the pincer ligand and absence of hydride ligands. However, it remains questionable whether the product is the 14-electron species $Ir\{C_6H_3(CH_2P\text{-}Bu^t_2)_2\text{-}2,6\}$ as the spectroscopic data do not preclude the possibilities of highly fluxional agostic interactions with phosphine alkyl groups or the presence of tbe and/or solvent ligands which undergo rapid exchange with the bulk solution. As found for the rhodium analog, '$Ir\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$' is highly reactive and all attempts to isolate it as a crystalline solid gave rise to a complicated mixture of unidentified products. Similar, highly reactive intermediates have recently been reported to result from the dehydrogenation of $IrFH_2(P\text{-}Bu^t_2Ph)_2$ by ethylene.[33] The '$Ir\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$' intermediate reacts instantaneously at room temperature with N_2 to form the dinitrogen complex **4** and is trapped with ethylene by the formation of the stable complex $Ir(C_2H_4)\{C_6H_3(CH_2P\text{-}Bu^t_2)_2\text{-}2,6\}$.[30] Similar reactivity has been found for the analogous rhodium complexes $Rh\{C_6H_3(CH_2PBu^t_2)_2\text{-}2,6\}$[12] and $Rh\{CH(CH_2CH_2PBu_2)_2\text{-}2,6\}$.[34] Thus the nitrogen and alkene inhibition of the pincer catalytic dehydrogenation reactions apparently arise through this intermediate. The surprisingly low alkene affinity, which has been ascribed to crowding in the coordination sphere of the metal, accounts for the occurrence of catalytic inhibition only at high alkene concentrations.

The alkane dehydrogenation side of the catalytic cycle can be envisioned to proceed *via* a reversal of the mechanism for the hydrogenation of tbe: alkane substrate C–H oxidative addition, β-hydride elimination from the resulting alkyl group and dissociation of the product alkene to regenerate **2b**. This mechanism is complicated in the case of linear alkanes by the secondary catalytic alkene isomerization reaction. As seen in Scheme 3, the dissociation of terminal alkenes from the metal center is apparently much faster than hydride migration to the α-carbon of the coordinated alkene to produce a secondary alkyl group. This kinetic preference for the production of terminal alkenes can be ascribed to the pronounced steric constraints conferred by the pincer ligand. Goldman[30] has pointed out that the partitioning of the dehydrogenation/isomerization catalytic pathways can be viewed simply as a competition between the initial terminal alkene product and the sacrificial acceptor alkene for coordination to the dihydrido complex. This hypothesis accounts for the high concentrations of terminal alkenes which are obtained early in the dehydrogenation reaction when dec-1-ene is used as an acceptor in place of the sterically encumbered tbe.[30] The terminal alkenes do, however, eventually reassociate and follow the thermodynamically mandated isomerization pathway. The steric control of the kinetics of the isomerization process is further evidenced by the observation that the subsequent isomerization of alk-2-enes to further internalized alkenes occurs at much slower rates than the initial 1–2 isomerization.

The dehydrogenation of the dihydrido complexes in the absence of a hydrogen acceptor must occur by the direct reductive elimination of H_2 as seen in Scheme 3. Unlike the reaction with sacrificial alkenes which occurs at room temperature, the direct reductive elimination of H_2 occurs only at elevated temperatures. The sizable increase in the barrier to entering the dehydrogenation pathway results in the predominance of the isomerization pathway and thus precludes the possibility of production of significant concentrations of terminal alkenes. Even at very short reaction times, only traces of terminal alkenes are found when the catalytic dehydrogenation of linear alkanes are carried out in open reflux systems.

Dehydrogenation of cycloalkanes to arenes

The dehydrogenation of alkanes through catalytic reforming is the leading commercial method of producing arenes.[35] Platinum (often with a rhenium promoter) on alumina catalysts employed in this reaction require temperatures of 450 to 550 °C.[35] It is anticipated that homogeneous systems for the dehydrogenation of cycloalkanes to arenes would operate under milder conditions and give improved product selectivities. However, prior to our development of the pincer catalysts, only a few examples of such systems had been discovered.[36–41] Pioneering studies by Shilov and coworkers showed that K_2PtCl_4 catalyzes the reaction of H_2PtCl_6 with cycloalkanes to produce a mixture of arenes, alcohols and chlorinated species at 100–120 °C in aqueous trifluroacetic acid.[36] $Pd(OCOCF_3)_2$ has been reported to catalyze the dehydrogenation of cyclohexene to benzene[37] but reacts with cyclohexane only stoichiometrically in the presence of CF_3CO_2H to produce benzene.[38] $Ru(styrene)_2(PPh_3)_2$, $[Ir(cod)(PPh_3)_2]^+$, and $[Ir(cod)\{P(C_6H_4F\text{-}p)_3\}_2]^+$ catalyze the dehydrogenation of cyclohexene to benzene but are unreactive with cyclohexane[39] while $PdSO_4$ in the presence of



Scheme 3 Proposed mechanism for the catalytic dehydrogenation of linear alkanes by **2a**.

H_2SO_4 effects only the stoichiometric conversion of cyclohexane to benzene.[40] Crabtree *et al.* found an oxidative addition type system in which $IrH_2\{OC(O)CF_3\}(PPr^i_3)_2$ effects the dehydrogenation of alkanes to arenes at 150 °C in the presence of the hydrogen acceptor, tbe.[41] This system fails to turnover catalytically because hydrogenolysis of the phosphine P–C bonds occurs at the temperatures of 135 °C or above that are required for the release of the arenes from the intermediate complexes. Thus the development of a homogeneous system which was completely catalytic in precious metal awaited the development of catalysts such as the PCP pincer complexes that did not decompose at temperatures required to achieve arene elimination.

We have found **2a** will catalyze the transfer dehydrogenation of the six membered aliphatic ring of cyclohexane, methylcyclohexane, and decalin at temperatures as low as 150 °C.[19] The distribution of products arising after 1 h at 200 °C from solutions of the cycloalkanes containing equal loadings of the catalyst and tbe are given in Table 1. These data show that the initial dehydrogenation of cycloalkanes to cycloalkenes is much faster than the subsequent dehydrogenation of the cycloalkenes to arenes. It can also be seen that dehydrogenation reactions are sensitive to the stringent steric constraints at the iridium center. These conclusions are reinforced by the observation that the conversion of significant amounts of decalin to naphthalene occurs only after 72 h at 200 °C.

As mentioned previously, the dehydrogenation activity of **2b** is inhibited at tbe : catalyst ratios of $> 350:1$. Thus, high turnover numbers can be achieved only through periodic incremental additions of tbe. After about 10% of the saturated substrate has been consumed, product inhibition occurs and there is virtually no net increase in the amount of hydrogen that can be transferred to tbe. However, as is the case with linear alkanes, the complex also catalyzes secondary hydrogen transfer reactions. The dehydrogenation of methylcyclohexane at 200 °C provides an excellent example of this reactivity. As seen in Fig. 4, very little additional hydrogen elimination from the substrate occurs between 1 and 24 h of reaction. However, during this period the catalytic system remains active for the conversion of 2- and 3-methylcyclohexene to the thermodynamically preferred products, 1-methylcyclohexene and toluene. A similar time dependent shift in the product distribution toward the ternary alkene was observed in the dehydrogenation of methylcyclohexane to methylcyclohexenes by IrH_5-$(PPr^i_3)_2$.[4] However, the further dehydrogenation of methylcyclohexenes to toluene does not occur in this catalytic system.

Aliphatic dehydrogenation in the presence of functional groups

The catalytic dehydrogenation of aliphatic C–H bonds in the presence of functional groups is of major industrial importance. For example, the direct dehydrogenation of ethylbenzene accounts for 85% of the commercial production of styrene.[42] The reaction is carried out commercially at *ca.* 620 °C in the vapor phase over catalysts which primarily consist of iron oxide and potassium salt promoters.[42] Recently there has been considerable interest in the development of higher activity dehydrogenation catalysts which are also more selective for styrene over the degradation products, benzene and carbon.[42]

Our finding that **2a** remains catalytically active in the presence of relatively high concentrations of arenes suggested its application to the aliphatic dehydrogenation of alkyl benzenes. As seen in Table 1, **2a** will catalyze the transfer dehydrogenation of ethylbenzene to styrene.[43] However, the production of styrene ceases after only 50 turnovers. Thus it appears that the catalytic activity is inhibited by styrene at concentrations that are much lower than those observed for unfunctionalized alkenes. However, the observation of this catalytic activity was significant as it represented the first example of a homogeneous catalytic system for aliphatic dehydrogenation of a substrate containing an aromatic functionalization.

We have also investigated the reactivity of **1** with saturated ethers[43] and alcohols.[44] Surprisingly, the catalyst is not deactivated by either class of functionality. As seen in Table 1, the cyclic ether tetrahydrofuran (thf) is transfer dehydrogenated to a mixture of dihydrofurans and furan. However, pronounced product inhibition limits the reaction to < 200 turnovers. The dehydrogenation of alcohols is much more efficient and up to 80% conversion to products can be achieved. However, dehydrogenation of the aliphatic groups does not occur. Instead, much more pedestrian dehydrogenation of the alcohol functionality occurs to produce aldehydes from terminal alcohols and ketones from the internal alcohols.

Conclusions

Dihydrido iridium PCP pincer complexes have been found to be extraordinarily active and robust catalysts for aliphatic dehydrogenation reactions. This unique reactivity can be ascribed to the PCP pincer ligand which introduces a remarkable balance of electronic and steric effects such that the metal center is reactive with aliphatic C–H bonds but at the same time can not access the P–C and C–C bonds of the ligand. The resulting combination of high thermal stability and reactivity with aliphatic C–H bonds can be used to great advantage. The unusual high thermal stability of the pincer catalysts results in a two orders of magnitude improvement in the efficiency of homogeneous thermochemical systems for the dehydrogenation of alkanes without a sacrificial hydrogen acceptor. The unprecedented high reactivity of the pincer catalysts provides the basis for the first catalytic system of any kind for the selective dehydrogenation of linear alkanes to α-olefins. The combination of the pincer catalysts' high reactivity and stability has opened the door to other aliphatic dehydrogenations which had not previously been accomplished *via* homogeneous catalysis including the conversion of cycloalkanes to arenes, ethylbenzene to styrene and tetrahydrofuran to furan. These reactions represent major steps toward the development of viable methods for the selective functionalization of aliphatic groups. However, none are of practical value owing to the problems of product inhibition and/or requirement of sacrificial acceptors. Mechanistic studies have revealed the sources of these limitations and suggest possible designs for advanced catalysts. Modified PCP pincer complexes may well provide a means for the commercial production of commodity chemicals from alkanes and other abundant organic resources through catalytic aliphatic dehydrogenation reactions.

Acknowledgments

This article is dedicated to Professor Herbert D. Kaesz on the occasion of his 65th birthday. I wish to thank my collaborators and coworkers whose names appear in the list of references for their dedicated efforts and invaluable contributions to this work. The ongoing open exchange of preliminary results and ideas with Professor Alan S. Goldman of Rutgers University is gratefully acknowledged. This relationship has greatly aided our progress and enhanced the pleasure of exploring PCP pincer catalysis. I also thank Dr David Milstein of the Weizmann Institute of Science for sharing results prior to publication. Finally I thank Professor William Kaska (University of California at Santa Barbara) for my introduction to hydrido rhodium and iridium PCP pincer complexes. The financial support of this research was provided by the U.S. Department of Energy Hydrogen Program.

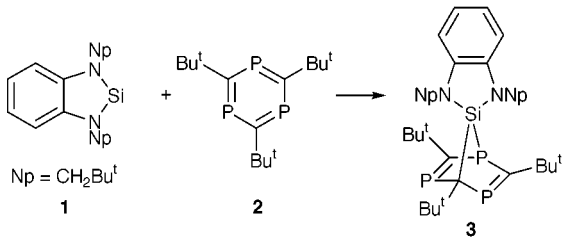
Received (in Cambridge, UK) 25th October 1999, Accepted 29th October 1999

The stable bis(amino)silylene Si[(NCH$_2$Bu^t)$_2$C$_6$H$_4$-1,2] 1 undergoes [1 + 4]-cycloaddition with 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene 2 to afford compound 3: the molecular structure of 3 is supported by NMR spectroscopic data and confirmed by a single crystal X-ray diffraction study.

Addition reactions of transient as well as stable silylenes to CX (X = N or O) multiple bonds have been well documented in recent years.[1–8] Little is known, however, about the reactions of R_2Si: species with CP multiple bonds.[9] So far, it has been shown that R_2Si: (R = Bu^t) gives a phosphasilirene[10] in a [1 + 2]-cycloaddition with the CP triple bond of a phosphaalkyne; with R_2Si: (R = mesityl), the initially formed three-membered ring undergoes subsequent insertion of another R_2Si: moiety to afford a phosphadisilacyclobutene.[11] In our studies on the reactions of the stable silylene Si[(NCH$_2$Bu^t)$_2$C$_6$H$_4$-1,2] **1** we became interested in the reaction of **1** with 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene **2**. The latter has only recently been synthesised by metal-induced cyclotrimerisation of the phosphaalkyne Bu^{t}CP[12,13] and although its structure and PE spectrum have been reported,[14] its chemistry has not been studied in depth. Binger and coworkers[15] have described the synthesis of tetraphosphabarrelene and semibulvalene derivatives by addition of different phosphaalkynes to **2**. The former products resulted from a conventional [4 + 2]-cycloaddition reaction and the latter most likely from nucleophilic attack at one of the ring C atoms, followed by ring closure.



Scheme 1

We found that treatment of the silylene **1** with triphosphabenzene **2** in benzene at room temperature afforded, after evaporation of the solvent, an orange solid which was recrystallised from toluene–hexane at −25 °C to yield the [1 + 4]-cycloaddition product **3** (pale orange crystals, mp 224–225 °C, yield 66%) (Scheme 1). Compound **3** was characterised by analytical and spectroscopic techniques,† and its structure was confirmed by a single crystal X-ray diffraction study.‡

The ^{31}P, ^{29}Si, ^{13}C and ^{1}H NMR spectroscopic data are in agreement with the proposed [1 + 4]-cycloaddition product. The ^{31}P{^{1}H} NMR spectrum exhibits the expected doublet and triplet consistent with a plane of symmetry bisecting both the triphosphabenzene and silylene moieties. The doublet at δ 320.4 is characteristic of an unsaturated P environment, while the triplet at δ −63.8 is typical of a saturated P centre. These values are similar to those of δ 324.1 and −87.0 reported recently for the tetraphosphabarrelene.[14] The ^{29}Si chemical shift of δ 3.8 is consistent with a tetravalent Si centre and the $^1J_{SiP}$ coupling of 7.1 Hz to the bridgehead P lies within the expected range.

The structure of **3** (Fig. 1) clearly reveals it to be the [1 + 4]-cycloaddition product of the silylene across the triphosphabenzene ring; the P=C bond distances of 1.68 Å and the longer P–C bond distances of 1.85 Å to the bridgehead atoms are appropriate for this formulation.

Compound **3** did not react further with **1**, using an excess of the silylene, even on heating up to 80 °C in a sealed NMR spectral tube. It was not possible to extend the reaction of **2** to the higher group 14 metal analogues of the silylene. Thus, no reaction was observed on treatment of M[(NCH$_2$Bu^t)$_2$C$_6$H$_4$-1,2] (M = Ge, Sn or Pb) with **2**, even at higher temperatures. The reactions of **2** with carbenes are currently under investigation and follow significantly different reaction pathways than that observed with the silylene.

We thank NSERC of Canada for a scholarship (for S. B. C.) and the EPSRC for a Fellowship for B. G. (with M. F. Lappert), an Advanced Fellowship (for B. G. from 1/1/2000) and for their continuing support (to J. F. N.) for phosphaorganometallic chemistry.

Shape selectivity in the adsorption of propane/propene on the all-silica DD3R

W. Zhu,* F. Kapteijn and J. A. Moulijn

Industrial Catalysis, DelftChemTech, Delft University of Technology, Julianalaan 136 2628 BL Delft, The Netherlands. E-mail: W.Zhu@tnw.tudelft.nl

Received (in Cambridge, UK) 9th August 1999, Accepted 1st November 1999

High adsorption selectivity for propene suggests that the all-silica DD3R might be effective as an adsorbent for the separation or purification of propene and propane mixtures.

Cryogenic distillation has been the dominant technology utilized for propane/propene separations for many years. Although traditional distillation is reliable and essentially unchallenged in this application, the necessary low temperatures and high pressures make it an energy-intensive separation scheme because of the small difference in their relative volatilities.[1]

A process configuration based on a hybrid adsorption/distillation system has been proposed to be an attractive commercial arrangement.[2] In order to achieve this objective, it is of utmost importance to find an effective adsorbent. Commercial zeolites (13X, 5A and 4A) and some Ag^+-substituted resins and $CuCl/\gamma$-Al_2O_3 have been investigated.[3–6] Such adsorbents show high selectivity for propene over propane.

Regeneration of zeolite-based adsorbents is difficult in applied vacuum swing adsorption (VAS) processes at temperatures as low as 298 K.[6] Increasing the operating temperature can improve this, but high temperatures can lead to propene oligomerization and possibly cracking owing to catalytic action of these materials, eventually blocking the adsorbents. In addition, these hydrophilic zeolites are sensitive to moisture.[2] Separations by adsorption *via* π-complexation are susceptible to deactivation by feed contaminants.[1]

Here, we demonstrate the selective adsorption of propene/propane on the all-silica DD3R, a highly hydrophobic and inert adsorbent, which is stable up to high temperatures.

Deca-dodecasil 3R (DD3R) is a member of the clathrasil family possessing topologically different frameworks. Gies[7] did pioneering work on the synthesis of the clathrasil DD3R. An optimum procedure for the clathrasil DD3R crystallization that ensures the phase purity of DD3R has been developed for scale-up by Den Exter *et al.*[8] The accessible pore space consists of 19-hedron cavities, connected *via* windows consisting of eight oxygen anions. Each cavity is connected to three other cavities in a hexagonal planar arrangement.[9]

The all-silica DD3R crystals had been synthesized in-house.[8] The template inside the clathrasil DD3R crystals was removed by calcination at 973 K for 6 h. The apparent density of the all-silica DD3R was 1.714 g cm^{-3} and the adsorption of N_2 indicated an accessible microporous void volume of 0.15 cm^3 g^{-1}. The crystal size was in the range of 5–10 μm as determined by SEM.

A Rupprecht & Patashnick TEOM 1500 mass analyzer with 100 mg sample size was used in an experimental set-up designed for measurement of equilibrium and transient adsorption on microporous materials.[10]

Prior to the experiments the crystals were outgassed in a helium flow of 200 cm^3 min^{-1} at 573 K for 24 h in order to remove adsorbed impurities. Helium was obtained as an ultra-high purity gas (> 99.999%). Propane and propene were 3.5 grade (> 99.95%).

The difference in the adsorption behavior between propane and propene is shown in Fig 1. The mass uptake for propane is much lower than that for propene under the same conditions. Fig. 1 also shows the mass uptake of binary mixture of propane and propene, which is the same as that of propene at the same partial pressure. This indicates that the presence of propane hardly affects the adsorption of propene.

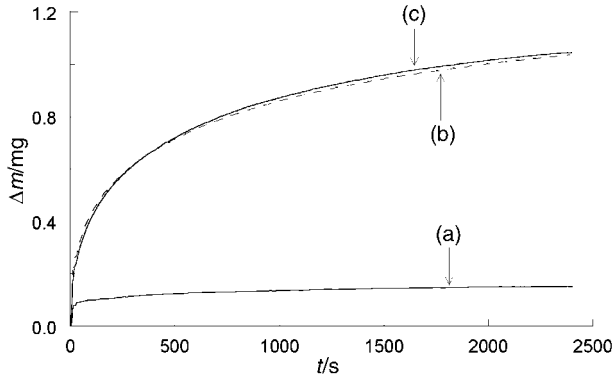

Fig. 1 Mass uptakes of single components, propane and propene, and their mixture in flowing He at a total pressure of 101.3 kPa and 373 K. A sample of 48.7 mg of the all-silica-DD3R was used in the TEOM. (a) propane (25 kPa), (b) propene (25 kPa) and (c) propane (25 kPa)–propene (25 kPa).

The critical diameter of propene (see Table 1) is significantly smaller than the free cross diameter of the 8-ring window (0.45 nm) and their molecules can enter into the 19-hedron cavities. However, the critical diameter of propane is close to 0.45 nm, so it can be expected that propane molecules are restricted from entering the 19-hedron cavities. The results shown in Fig. 1 indicate that the 8-ring window cavities are accessible to propene, while they exclude propane molecules. The small amount adsorbed for propane is attributed to adsorption at the external surface of the DD3R crystals.

Table 1 Characteristic diameters of the adsorbate molecules studied

Adsorbate	σ_s[a]/nm	σ_C[b]/nm
Propane	0.280	0.446
Propene	0.265	0.431

[a] Structural diameter defined as the diameter of the smallest cylinder that can be drawn around the molecule in its most favorable conformation through the centers of the extreme binding atoms.[11] [b] Critical diameter calculated by the summation of the structural diameter and the effective van der Waals radii of two extreme hydrogen atoms.

It takes a long time for the uptake of propene to reach the equilibrium state. This phenomenon can be interpreted in terms of the accessibility of the cavities to the adsorbate molecules. The orientation of the molecules to enter the 8-ring window and to move to the next cavity will play a role. Such a diffusion resistance can be improved by increasing the operating temperature.

The isotherms of propene on the all-silica DD3R at a temperature between 303 and 473 K are shown in Fig. 2 where closed symbols represent desorption. The isotherms were reversible over the complete pressure range investigated, resulting in the overlay of the adsorption and desorption

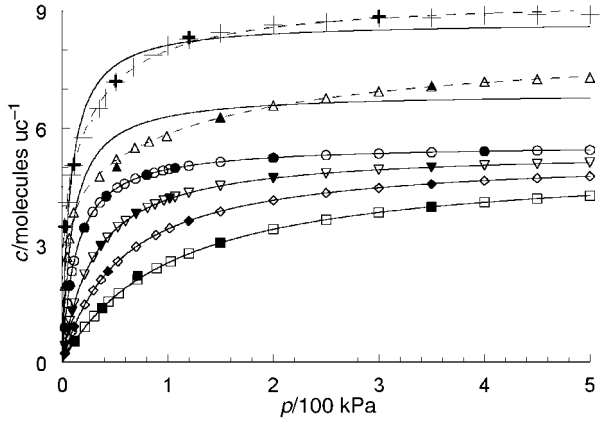

Fig. 2 Isotherms of propene on the all-silica DD3R. Open symbols adsorption data and closed symbols desorption data, solid lines Langmuir isotherm model fits and dashed lines dual-site Langmuir isotherm model fits; (+) 303 K, (▲) 338 K, (●) 373 K, (▼) 408 K,(◆) 438 K, (■) 473 K.

isotherms in Fig. 2. The isotherm data of propene are well described by the Langmuir model at high temperatures. However, deviations from the Langmuir model have been observed at 303 and 338 K and the higher-pressure range, at which the amount adsorbed exceeds six molecules per unit cell, corresponding to one molecule per cavity. These deviations from the Langmuir model are attributed to interactions between adsorbates as the number of molecules sitting inside the 19-hedron cavity exceeds one. The isotherm data at 303 and 338 K are better fitted by the dual-site Langmuir model (DSL). This DSL model takes into account implicitly interactions between adsorbates, which give rise to a pseudo-second adsorption site.

Various experimental results reveal high selectivity for propene on the all-silica DD3R. This adsorbent does not show any catalytic activity to hydrocarbons over a wide range of temperature. Furthermore, water hardly adsorbs on this material. In conclusion, the all-silica DD3R is an effective shape-selective adsorbent for the separation or purification of propane–propene mixtures. Its potential application in separation is being further investigated.

The authors are indebted to Dr J. C. Jansen for supplying the sample of the all-silica DD3R and to Mr J. H. ter Horst for preparing the graphical abstract.

Reactivity of acryloyl chloride towards the anion $[Cp_2(CO)_4Mo_2(\mu\text{-}PPhH)]^-$; synthesis of an unusual phosphaalkene

John E. Davies, Martin J. Mays,* Paul R. Raithby and Anthony D. Woods

Department of Chemistry, Lensfield Road, Cambridge, UK CB2 1EW. E-mail: mjm14@cus.cam.ac.uk

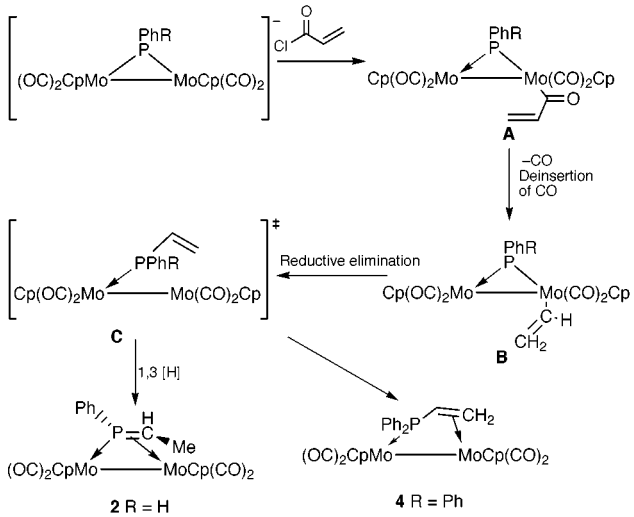
Received (in Basel, Switzerland) 25th September 1999, Accepted 1st November 1999

Deprotonation of the complex $[Cp_2(CO)_4Mo_2(\mu\text{-}PPhH)(\mu\text{-}H)]$ by Bu^{t}Li at −78 °C and subsequent addition of acryloyl chloride affords the metallophosphaalkene complex $[Cp_2(CO)_4Mo_2(\eta^1\text{-}\eta^2\text{-}PhP{=}CHMe)]$ in high yield; the complex exhibits *cis*/*trans* isomerism, both isomers having been crystallographically characterised.

Metallophosphaalkenes have been shown to be important synthons in the preparation of phosphorus-functionalised heterocycles owing to the highly polar P=C moiety present in such complexes.[1,2] A high yield route to the previously unknown dinuclear Group 6 metallophosphaalkenes is now described.

We have previously demonstrated that the anion obtained from deprotonation of $[Cp_2(CO)_4Mo_2(\mu\text{-}Ph_2)(\mu\text{-}H)]$ with Bu^{t}Li at −78 °C reacts with ECl_3 to give $[Cp_2(CO)_4Mo_2(\mu\text{-}\eta^2\text{-}PE)]$ (E = P, As, Sb)[3] and with organometallic halides to give $[Cp_2(CO)_4Mo_2\{\mu\text{-}P(R)ML_n\}(\mu\text{-}H)]$ [ML_n = $W(CO)_3Cp$, $Fe(CO)_2Cp$, $Mn(CO)_5$].[4,5] We now report that reaction of $[Cp_2(CO)_4Mo_2(\mu\text{-}PPhH)(\mu\text{-}H)]$ **1** with Bu^{t}Li and acryloyl chloride leads to the unusual metallophosphaalkene *trans*-$[Cp_2(CO)_4Mo_2(\eta^1\text{-}\eta^2\text{-}PhP{=}CHMe)]$ **2** in high (70–80%) yield rather than to the formation of a complex containing an acyl-substituted bridging phosphido group as would have been predicted on the basis of earlier work.[4] Previously only mononuclear Group 6 metal complexes containing phosphaalkenes have been characterised; these involve coordination of the ligand *via* the phosphorus atom only.[6] To the authors' knowledge there exists only one other group of complexes containing a phosphaalkene bonding in an η^1–η^2 fashion to a bimetallic fragment. These were formed in low yield by the reaction of $[Cp_2(CO)_2(\mu\text{-}CO)Fe_2(\mu\text{-}CSMe)]^+$ with $HP(SiMe_3)_2$.[7]

A possible reaction pathway for the formation of *trans*-$[Cp_2(CO)_4Mo_2(\eta^1\text{-}\eta^2\text{-}PhP{=}CHMe)]$ **2** is shown in Scheme 1. It is proposed that electrophilic attack of the acryloyl chloride on deprotonated **1** to give intermediate **A** is followed by deinsertion of CO to give **B** and reductive elimination to give **C**. A 1,3 hydrogen shift within the bridging ligand then leads to **2**. This reaction sequence is supported by the isolation and structural characterisation of $[Cp_2(CO)_4(\eta^1\text{-}\eta^2\text{-}Ph_2PCH{=}CH_2)]$ **4**, an analogue of intermediate **C**. Complex **4** is obtained by treatment of deprotonated $[Cp_2(CO)_4Mo_2(\mu\text{-}PPh_2)(\mu\text{-}H)]$ with acryloyl chloride. Presumably the final [1,3] sigmatropic shift which converts intermediate **C** into the metallophosphaalkene **2** is precluded in **4** by the absence in $[Cp_2(CO)_4Mo_2(\mu\text{-}PPh_2)]^-$ of a hydrogen atom on the bridging phosphido group. The vinyl phosphine moiety present in **4** acts as an η^1–η^2 4-electron ligand; such a mode of coordination has only previously been reported in Fe_3 and Ru_5 clusters as the result of alkyne insertion into a P–M bond.[8,9]



Scheme 1 Possible reaction pathway for formation of **2** and **4**.

Thermolysis of the *trans* isomer **2** leads to the formation of *cis*-$[Cp_2(CO)_4Mo_2(\eta^1\text{-}\eta^2\text{-}PhP{=}CHMe)]$ **3**, in which the methyl group of the phosphaalkene now lies *cis* to the PPh group and points towards a cyclopentadienyl ring.† Presumably thermolysis of **2** overcomes the barrier to rotation of the P=CHMe moiety to yield **3** as the thermodynamically favoured product.

The structures of **2** and **3** have been determined by X-ray diffraction analysis, confirming the *trans* and *cis* assignments (Fig. 1). The two molecules exhibit several significant differences.‡

Thus complex **3** shows a significantly shorter Mo–Mo bond length of 3.220(1) Å as compared to 3.240(1) Å in **2** and the P–Mo separations are both significantly shorter in the former

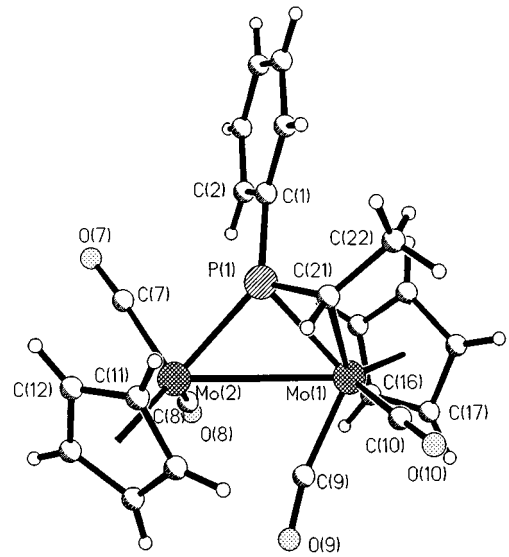


Fig. 1 Molecular structure of **2** and **3**. Selected bond lengths (Å) and angles (°): **2**: Mo(1)–Mo(2) 3.240(1), Mo(1)–P(1) 2.435(2), Mo(1)–C(21) 2.382(7), Mo(2)–P(1) 2.346(2), P(1)–C(21) 1.754(7); C(1)–P(1)–C(21) 107.3(4), P(1)–C(21)–C(22) 121.2(6), P(1)–C(21)–Mo(1) 70.3(2), P(1)–C(21)–Mo(2) 121.0(3), P(1)–Mo(1)–Mo(2) 46.19(5), C(21)–Mo(1)–Mo(2) 77.46(5), Mo(1)–C(9)–O(9) 166.6(6). **3**: Mo(1)–Mo(2) 3.220(1), Mo(1)–C(21) 2.392(3), Mo(1)–P(1) 2.418(1), Mo(2)–P(1) 2.334(1), P(1)–C(21) 1.749(3); C(1)–P(1)–C(21) 114.6(2), P(1)–C(21)–C(22) 127.4(3), P(1)–C(21)–Mo(1) 69.5(1), P(1)–Mo(1)–Mo(2) 46.27(2), C(21)–Mo(1)–Mo(2) 74.96(8), Mo(1)–C(9)–O(9) 167.2(3).

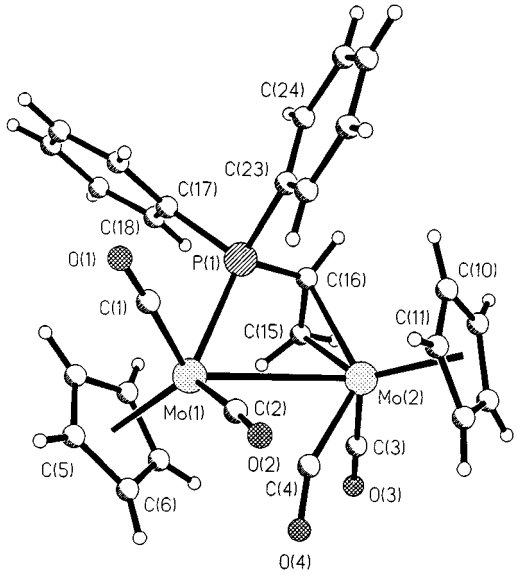

Fig. 2 Molecular structure of **4**. Selected bond lengths (Å) and angles (°): Mo(1)–Mo(2) 3.288(1), Mo(1)–P(1) 2.408(1), Mo(2)–C(16) 2.295(3), Mo(2)–C(15) 2.339(3), C(16)–C(15) 1.409(4); C(23)–P(1)–C(16) 101.9(2), P(1)–C(16)–Mo(2) 97.3(2), C(15)–C(16)–Mo(2) 74.0(2), Mo(1)–Mo(2)–C(16) 74.6(2).

complex (see Figs. 1 and 2). The P(1)–C(21)–C(22) bond angle increases from 121.2(6) to 127.4(3) on conversion of **2** to **3**.

The P=C bond lengths of 1.754(7) and 1.749(3) Å for **2** and **3**, respectively, are significantly shorter than the 1.812(9) Å recorded by Weber *et al.* for their related complex [Cp_2-$(CO)_2Fe_2\{\eta^1$–η^2-$(Cp(CO)_2Fe)P{=}CHSMe\}$].[7] However, they do fall within the range recorded by Williams *et al.* for their series of cluster-stabilised phosphaalkenes.[10] Both **2** and **3** contain a semi-bridging carbonyl group linking to the second molybdenum atom.

The molecular structure of **4** shows a Mo–Mo bond length of 3.288(1) Å, which is slightly longer than that present in **2** and **3** (Fig. 2). The C(15)–C(16) bond length of 1.409(4) Å is typical of that in other complexes containing a η^1–η^2 vinyl phosphine.[11,12]

The ^{1}H NMR spectra of **2** and **3** highlight the different environments of the vinylic proton. In **2** the proton resonates as a doublet of quartets at δ 4.14, whereas the analogous resonance in **3** occurs as a broad peak at δ 1.48; this latter value is in good agreement with that recorded by Weber *et al.* for their compound.[7]

Bimetallic Group 6 metal complexes coordinated to phosphaalkenes have not been reported previously, and an η^1–η^2 bonding mode for a phosphaalkenes is extremely rare. Additionally, the described method represents the first high yield route to metallophosphaalkenes that contain no other heteroatom substituents.

We thank the EPSRC for a quota award to A. D. W. and ICI for a CASE award to A. D. W. EPSRC support for the purchase of the Nonius Kappa CCD diffractometer is also gratefully acknowledged.

Dinuclear complexes as connectors for carboxylates. Self-assembly of a molecular box

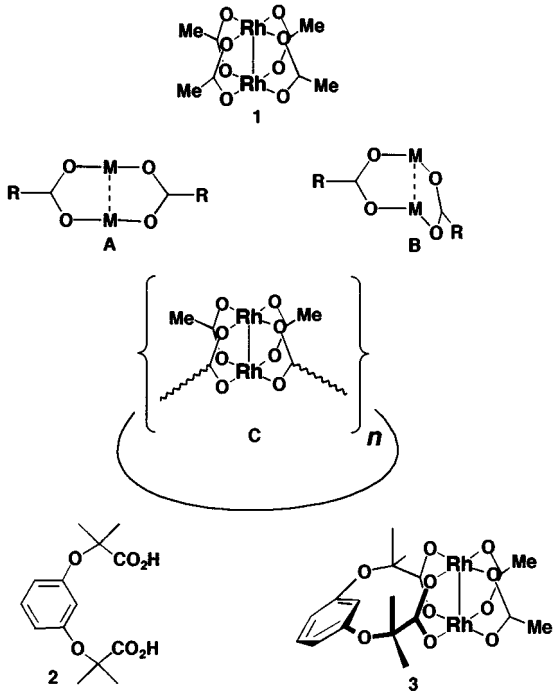
Richard P. Bonar-Law,* Thomas D. McGrath, Nirmal Singh, Jamie F. Bickley and Alexander Steiner

Department of Chemistry, University of Liverpool, Liverpool, UK L69 7ZD. E-mail: bonarlaw@liv.ac.uk

Received (in Cambridge, UK) 5th August 1999, Accepted 8th October 1999

A dinuclear complex derived from dirhodium(II) tetraacetate has been used as a corner unit for the synthesis of metallomacrocyles, including a square box with aromatic side walls.

Metal complexes are versatile building blocks in supramolecular chemistry.[1] Apart from the range of geometries available, coordination chemistry is well suited to self-assembly[2] since metal–ligand bonds are often formed cleanly and reversibly. Recent examples include one-pot syntheses of macrocycles from square-planar Pt and Pd complexes and polydentate nitrogen ligands.[3] These and related macrocylces are of particlar interest in having internal cavities large enough to accommodate other molecules.[1–3] Although metallomacrocycles are being prepared from an increasing variety of metals and ligands,[4] metal–amine coordination remains the dominant structural motif.[5] It occurred to us that a common functional group which has not been exploited for metalloassembly in solution is carboxylic acid/carboxylate.[6] One reason for this may be that two carboxylates rarely coordinate to a single metal atom in a predictable, symmetrical fashion.[7] In this respect dinuclear complexes such as $Rh_2(OAc)_4$ **1** seemed promising, since acids can be joined in well defined orientations, either in



a linear fashion, **A** (an analogue of the classical hydrogen bonded dimer) or at right-angles, **B**. Anticipating that cyclic species would have interesting properties, our initial goal was to exploit geometry **B** to connect dicarboxylic acids at right angles to give macrocycles, **C**. At the outset of our work, two small cyclic 'dimers-of-dimers' had been structurally characterised, $[Mo_2\{O_2C(CH_2)_2CO_2\}(MeCN)_6]_2[BF_4]_4$[8a] and $[Ru_2\{O_2C(CH_2)_3CO_2\}(CO)_4(PBu_3)_2]_2$.[8a] Several linear or polymeric species based on Mo_2, W_2, Ru_2 or Cu_2 cores have also been prepared recently.[9] We chose to concentrate on dirhodium compounds[10] because they are neutral, diamagnetic, kinetically stable with respect to carboxylate exchange at room temperature,[11] and most importantly for practical applications, not appreciably air or water sensitive. A very recent report[12] by Cotton and Murillo *et al.* on diacid-linked Rh_2 and Mo_2 macrocycles with formamidinate ligands $[M_2(O_2C–R–CO_2)(ArNCHNAr)_2]_n$ prompts the communication of our efforts.

The first step was to reduce the possibility of uncontrolled polymerisation by blocking substitution of a pair of *cis*-acetates in **1**. We elected to retain the basic tetracarboxylate structure, and designed dicarboxylic acid **2** to act as a substitution-inert corner ligand.[13] Heating **1** with 1 equivalent of **2** in hot *N*,*N*-dimethylaniline provided diacetate **3** in 60% yield with liberation of acetic acid, along with roughly equal amounts of unreacted **1** and a complex in which all the acetates had been replaced by two molecules of **2**. The choice of solvent was important—a polar coordinating solvent was found to be necessary to keep reactants and intermediates in solution. Heating **3** with an excess of benzoic acid displaced only the acetate groups, demonstrating the kinetic stability of the chelating dicarboxylate. In the solid state structure of **3**·2(4-*tert*-butylpyridine) (Fig. 1),† the phenyl ring of the dicarboxylate is strongly tilted, although in solution the geminal methyl groups of **3** (with or without axial ligands) appear as a sharp singlet in ^{1}H NMR spectra at room temperature, suggesting that the chelate ring is flexible.

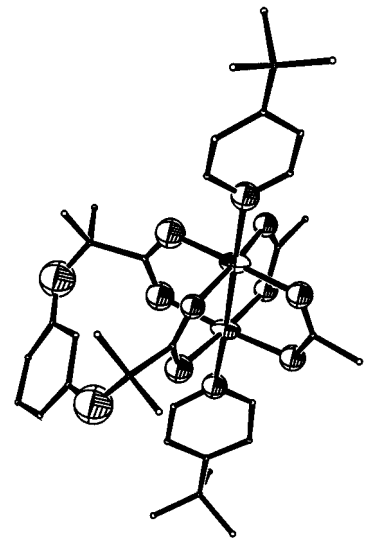


Fig. 1 Crystal structure of **3**·2(4-*tert*-butylpyridine).

Heating **3** with 1.1 equivalents of benzene-1,4-dicarboxylic acid in *N*,*N*-dimethylaniline produced a cyclic tetramer **4** in 80% yield after chromatography. The structure of **4**·8(4-*tert*-butylpyridine)·2(hexane) (Fig. 2)† shows a box 1.1 nm wide (measured between adjacent Rh_2 centres) with one pair of chelates pointing up and the other down. Like **3**, this asymmetry

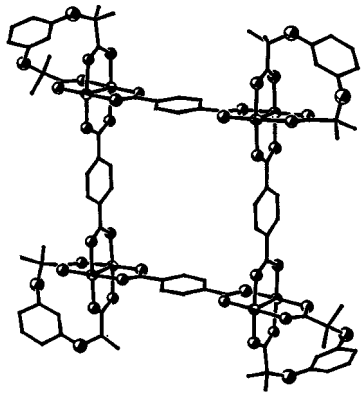

Fig. 2 Crystal structure of **4**·8(4-*tert*-butylpyridine)·2(hexane). The 4-*tert*-butylpyridine ligands and solvent molecules have been removed for clarity.

in the solid state is not evident in solution by ^{1}H NMR. In the crystal the boxes pack in two-dimensional layers, with hexane molecules between adjacent boxes, and nothing inside the macrocycles. The layers are held apart by axial pyridine ligands. The assembly of **4** was shown to be reversible: addition of excess acetic acid to the reaction mixture regenerated starting complex **3**, and subsequent heating to evaporate excess acid reformed **4**. The yield of **4** was insensitive to reactant concentration and **4** was still the main product with excess diacid, consistent with assembly under thermodynamic control.

Cyclocondensation of **3** with rigid diacids appears to be fairly general. Crystalline macrocyles have been obtained from benzene-1,3-dicarboxylic acid, naphthalene-1,4-dicarboxylic acid, naphthalene-2,6-dicarboxylic acid, biphenyl-4,4′-dicarboxylic acid and adamantane-1,3-dicarboxylic acid, among others. A characteristic feature of these species is aggregation in non-polar solvents. ^{1}H NMR spectra in chloroform are broad, but sharp in the presence of polar additives (methanol, acetone, pyridine) which can coordinate to the Lewis acidic metal centres. Monomeric dinuclear carboxylates are known to associate in the solid state *via* intermolecular metal–oxygen coordination;[14] this effect may be amplified in cyclic arrays to the extent that it becomes observable in solution.

In summary, a simple strategy for connecting carboxylic acids at right angles has been developed, illustrated by the synthesis of air- and water-stable metallomacrocyles. We are currently extending the synthetic studies, and plan to investigate the physical properties of these macrocycles, in particular inclusion chemistry and further supramolecular assembly.

We acknowledge financial support from the EPSRC, and thank Johnson Matthey PLC for generous loans of rhodium.

Notes and references

† Data were collected on a Stoe-IPDS diffractometer using graphite monochromated Mo-Kα radiation (λ = 0.71073), T = 293 K, full-matrix least squares refinements on F^2 using all data (G. M. Sheldrick, SHELX97, Crystal structure determination program, Göttingen, 1997). Non-hydrogen atoms were refined anisotropically except the methyl groups of 4-*tert*-butylpyridine ligands in **3** and all atom positions of 4-*tert*-butylpyridine ligands and the crystallographically independent hexane molecule in **4**. Hydrogen positions were set geometrically. The structure of **3** is twinned both racemically and across a pseudo mirror along c (Flack parameter = 0.42(12)). Crystals of **4** were weakly diffracting leading to poorly defined bond lengths and angles.

Crystal data: for **3**·2(4-*tert*-butylpyridine): $C_{36}H_{48}N_2O_{10}Rh_2$, M = 874.58, rhombohedral, space group $R\bar{3}$, a = 31.600(4), c = 12.700(3), U = 10983(3) Å^3, Z = 9, μ(Mo-Kα) = 0.720 mm^{-1}, 19768 reflections collected 6376 unique (R_{int} = 0.0331), $R1$ = 0.047 ($F > 4\sigma F$), $wR2$ = 0.1422 (all data). For **4**·8(4-*tert*-butylpyridine)·hexane, red plates from dichloromethane–hexane: $C_{160}H_{184}N_8O_{40}Rh_8\cdot 2(C_6H_{14})$, M = 3855.20, triclinic, space group $P\bar{1}$, a = 13.485(2), b = 19.834(3), c = 23.522(5), α = 69.66(2), β = 75.12(2), γ = 83.331(19)°, U = 5698.5(18) Å^3, Z = 1, μ(Mo-Kα) = 0.553 mm^{-1}, 31008 reflections collected, 14177 unique (R_{int} = 0.178), $R1$ = 0.056 ($F > 4\sigma F$), $wR2$ = 0.168 (all data).

Synthesis of zeolite EMT with a novel route promoted by surfactants and its benefit in catalytic performance

Jianwei Sun, Mingxing Sun, Cong Nie and Quanzhi Li*

Department of Chemistry, Fudan University, Shanghai 200433, P.R. China. E-mail: qzli@fudan.edu.cn

Received (in Cambridge, UK) 24th August 1999, Accepted 15th October 1999

Zeolite EMT with small crystal size, which was catalytically active in the alkylation of isobutane with butenes, was synthesized *via* a novel route promoted by surfactants with a low molar ratio of 18-crown-6 to Al_2O_3 and a short crystallization time.

Zeolite EMT, which is constructed by the linkage of sodalite cages through double six-rings, is the hexagonal analogue of faujasites. The two dimensional direct channel system with 12-ring aperture in EMT is unique and of great interest in catalysis and adsorption.[1–4] Pure EMT was first synthesized by Delprato and coworkers[5] using 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6) as template, which plays a key structure-directing role, in the form of the $[Na\text{-}18\text{-}crown\text{-}6]^+$ complex, during crystallization. In a traditional synthetic system, not all the 18-crown-6 molecules can participate in the templating effect because the molar ratio of 18-crown-6 to Al_2O_3 needed is higher than 0.7.[5–10] Although the ratio can be decreased to 0.4–0.5 with a low content of water,[11–12] the starting hydrogels are not easy to work with. It is well known that the solvent plays a vital role during crystallization of zeolites and other microporous materials. One of the most effective synthetic strategies is the introduction of surfactant to the solvent because it can help to change the properties of the solvent greatly. del Val *et al.*[13] demonstrated that a cationic surfactant favors the replacement of P by Si in the VPI-5 framework. Franco *et al.*[14] found that a cationic surfactant also leads to deep changes in crystal morphology, *etc.* However, these authors did not focus on the effect of surfactant on the improvement of structure-directing efficiency. Here we report a novel synthetic route to produce the EMT phase promoted by surfactant and explain its effect in detail. In addition, the catalytic properties of H-EMT were also explored for the alkylation of isobutane with butenes.

In our study, the surfactants used were dodecylbenzyldimethylammonium chloride (DBDMACl), sodium lauryl sulfate (SLS), dioctadecyldimethylammonium chloride (DODMACl), alkyl glycoside (AG, $C_{12–14}$) and polyoxyethylene (15) ether lauric monoethanolamide (POE (15) LMEA). The reaction mixture was obtained by dissolving one of the surfactants, sodium aluminate (43 wt% Al_2O_3), sodium hydroxide (96 wt%) and 18-crown-6 (99 wt%) in distilled water in turn. Finally, colloidal silica (25 wt% SiO_2, < 0.5 wt% Na_2O) was added to the mixture dropwise with stirring. The resulting hydrogel was continuously stirred for 2 h, and aged for one day at room temperature without agitation. The molar composition of the hydrogel was as follows: 10 SiO_2: 1 Al_2O_3: 2.2 Na_2O: x 18-crown-6: y surfactant: 160 H_2O. The crystallization was carried out in a PTFE-lined stainless-steel autoclave at 373 K for 3–30 days. The solid obtained was filtered off, washed thoroughly with distilled water and then dried at 353 K overnight. In order to remove the organic molecules, the as-synthesized EMT was calcined at 523 K for 2 h followed at 773 K for 5 h in air. The H-EMT was prepared by ion exchange with 2 M NH_4NO_3 solutions at 353 K (three times for 3 h each) and the following calcination at 813 K for 7 h in air.

Fig. 1 shows the XRD patterns of the products synthesized by using the surfactant alkyl glycoside (AG) with different ratios of 18-crown-6 to Al_2O_3 (x) and crystallization time (t). When x = 0.37 and t = 3 d, the three characteristic peaks of the EMT phase in the 2θ region 5–7°, which are indexed as 100, 002 and 101 reflections, can be observed. It indicates that there is a significant amount of EMT in the product, but some amorphous substance still exists [Fig. 1(a)]. The pure EMT can be obtained when t is increased to 5 d [Fig. 1(b)]. This result means that the structure-directing efficiency of 18-crown-6 molecules is improved by adding surfactant to the starting hydrogels. It was also found that the intergrowth of EMT and FAU, deduced from the increased intensity of the central peak in the 5–7° 2θ region, was produced when x was further decreased to 0.19 even if t was long enough [Fig. 1(c)]. The SEM photograph reveals that EMT crystals synthesized in the presence of AG are hexagonal plates with an average size below 2 μm [Fig. 2(a)], smaller than those synthesized without surfactant [Fig. 2(b)]. Different categories of surfactant have also been used to synthesize EMT in a more efficient manner (Table 1). This demonstrates that, no matter what kind of surfactant is used, the EMT phase can be

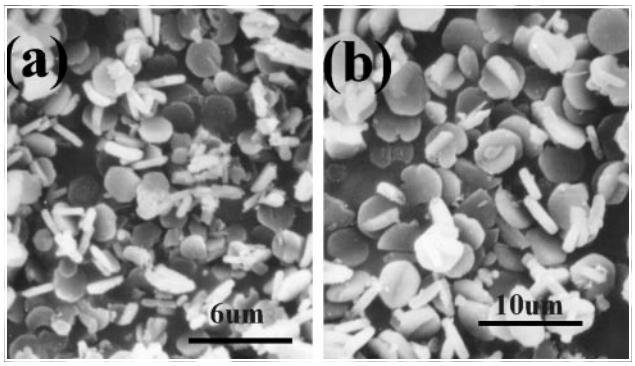

Fig. 2 SEM images of as-synthesized EMT prepared (a) with the surfactant AG (x = 0.36, y = 0.043, t = 30 d) and (b) without surfactant (x = 0.68, y = 0, t = 30 d).

Table 1 Synthesis of zeolite EMT using surfactants other than AG at x = 0.36 and t = 6 d

Surfactant	y	Product
Cationic		
DBDMACl	0.047	Amorphous
	0.102	EMT
DODMACl	0.035	EMT + Amorphous
	0.061	EMT
Anionic		
SLS	0.051	EMT
Nonionic		
POE (15) LMEA	0.017	EMT + Amorphous
	0.040	EMT

synthesized at low x and t values when the ratio of surfactant to Al_2O_3 (y) exceeds a certain level, which varies according to the surfactant.

Comparison of the ^{13}C CP MAS NMR spectra and the DTA curves of EMT synthesized with or without surfactant reveals that the surfactant molecules do not enter the channels or cages of EMT. Therefore, the surfactant must play an auxiliary role during crystallization, instead of a structure-directing role. In a synthetic system, the interaction between structure-directing agent and solvent would occur, but must not be so strong as to prevent the framework-forming species from interacting with the structure-directing molecules to form the zeolite phase.[15] In the starting hydrogel for producing EMT without surfactant, there is a balance of interactions between the water solvent, framework species and the [Na-18-crown-6]$^+$ complex. When surfactant is added to the hydrogel, the balance is upset due to the interactions between the surfactant and solvent and/or other dissolved species. Although this process is very complicated, it is clear that the interaction between the [Na-18-crown-6]$^+$ complex and the water solvent is weakened because of the interaction of surfactant with water (Scheme 1). As a result, it becomes more favorable for 18-crown-6 molecules to access the framework-forming species and direct the formation of the crystal nucleus and the following growth. On the other hand, the surface tension of the water solvent is decreased in the presence of surfactant, *i.e.* the interface energy between the newly-formed EMT phase and the solvent would be lowered, helping to shorten the crystallization time and reduce the particle size of EMT crystals produced.

For the alkylation of isobutane with butenes, the catalytic properties of H-EMT prepared by our method with AG were compared with those of H-EMT synthesized without surfactant under the same reaction conditions. It was found that the former is more selective for the main products, trimethylpentanes (TMPs), than the latter. It shows that the diffusion of bulky TMPs in small crystals is beneficial because the catalytic reaction takes place in the pores of EMT.

In conclusion, we have demonstrated a novel route to synthesize zeolite EMT by using surfactants at a low molar ratio of 18-crown-6 to Al_2O_3 and a short crystallization time. The average crystal size of the product is less than that of EMT synthesized without surfactant, which is more favorable for the alkylation of isobutane with butenes. Our route can be expanded to synthesize other types of zeolite in order to improve the templating effect, a study which is underway in our laboratory.

Financial support from the National Natural Science Foundation of China is gratefully acknowledged (Grant No. 29733070).

Getting the right answer to a key question concerning molecular wires

F. Albert Cotton,*[a] Lee M. Daniels,[a] Carlos A. Murillo*[a,b] and Xiaoping Wang[a]

[a] *Laboratory for Molecular Structure and Bonding and Department of Chemistry, Texas A&M University, PO Box 30012, College Station, TX 77842-3012, USA. E-mail: cotton@TAMU.edu*

Received (in Bloomington, IN, USA) 18th August 1999, Accepted 13th September 1999

It is shown that the $Cr_5(tpda)_4Cl_2$ molecule has alternating long and short (Cr···Cr) contacts in three compounds, including one in which an evenly spaced chain was recently claimed.

Recently, growing attention has been focused in this laboratory[1] and elsewhere[2] on *molecular compounds*[3] having linear chains of metal atoms in which there are—or may be—bonding contacts between some or all adjacent metal atoms. Even for the simplest case of only two metal atoms[4] the question of metal–metal bonding has been, and in some cases still is, problematical. Even more challenging problems arise with the more recently discovered compounds in which there are three[1a–f,2a–e] or more[1d,2f–h] metal atoms, that is with the *molecular wire* molecules, as we call them.

It is, of course, self-evident that here, as anywhere else in chemistry, a true understanding of electronic structures is possible only when the correct molecular structures are known. Thus, while it is obviously important to pursue the chemistry necessary to make molecular wire molecules, we assert that 'the key question concerning molecular wire molecules' is: how are the metal atoms spaced along the chain direction? This is a more subtle question than might have been expected.

Even for only three metal atoms, there are two possibilities, symmetrical and unsymmetrical:

M—M—M

M—M·····M

For compounds with a $Co_3(dpa)_4^{2+}$ core,† both of these structures occur and, indeed, as we recently showed,[5] the 'same' molecule, $Co_3(dpa)_4Cl_2$, may give a mixture of two types of crystals from the same solution (in which there are only symmetrical molecules[6]), one type containing symmetrical molecules and the other unsymmetrical molecules. We have also shown that there is a similar situation with $Cr_3(dpa)_4^{2+}$ species.[7]

For five metal atoms, at least three possible arrangements may be considered:

(a) M—M—M—M—M

(b) M—M·····M—M·····M

(c) M—M·····M·····M—M

We have reported the first preparation and structural characterization of the $Cr_5(tpda)_4Cl_2$ molecule,[8] and the chain of five Cr atoms was shown to have alternating Cr to Cr distances, as in pattern (b) above. Thus, to a rough approximation, there are two Cr–Cr quadruple bonds and one isolated Cr^{II} atom at the end, the latter accounting for the magnetic moment of 4.2 μ_B. We may also recall that the compound $[Cr_4(DpyF)_4Cl_2][PF_6]_2$† has the Cr atoms grouped into two Cr_2 quadruple bonds.[1d]

A recent publication[9] claims to have obtained the $Cr_5(tpda)_4Cl_2$ molecule in arrangement (a), that is, with a more or less evenly spaced arrangement of the five metal atoms. This paper also gives a lengthy discussion of the electronic structure of such an evenly-spaced Cr_5 chain. If this structure were correct it would implicate a duality of structure in Cr_5^{10+} chains similar to that for Co_3^{6+} chains, that is, sometimes evenly spaced and sometimes with alternating short and long distances.

In fact, however, this structure is incorrect and only the (b) type structure is found in each of three different crystalline forms of the $Cr_5(tpda)_4Cl_2$ molecule, namely, the one we reported,[8] the one which has just been reported in ref. 9,[9]‡ and a third‡ one that we have also characterized. The key results for all three are collected in Table 1. There is no doubt that the $Cr_5(tpda)_4Cl_2$ molecule consistently has a structure with alternating Cr–Cr distances, Cr≡Cr···C≡Cr···Cr, and the claim made[9] for evenly spaced metal atoms is erroneous.

The mistake made in the previous report of the $Cr_5(tpda)_4Cl_2$•$2Et_2O$•$4CHCl_3$ structure is obvious in Fig. 1 of ref. 9. The displacement ellipsoids of two of the inner Cr atoms look like rugby balls or American footballs. This is because at each of these positions (as well as the other three) there are two Cr atoms owing to an end-to-end disorder of the molecules:

Cr≡Cr·····Cr≡Cr·····Cr

Cr·····Cr≡Cr·····Cr≡Cr

On the other hand, when this structure is refined correctly,‡ with disordered alternately-spaced Cr_5 chains, all thermal displace-

M·$2Et_2O$·$4CHCl_3$	2.598(3)	1.872(2)	2.609(2)	1.963(3)
M·Et_2O	2.661(3)	1.862(3)	2.644(3)	1.931(3)

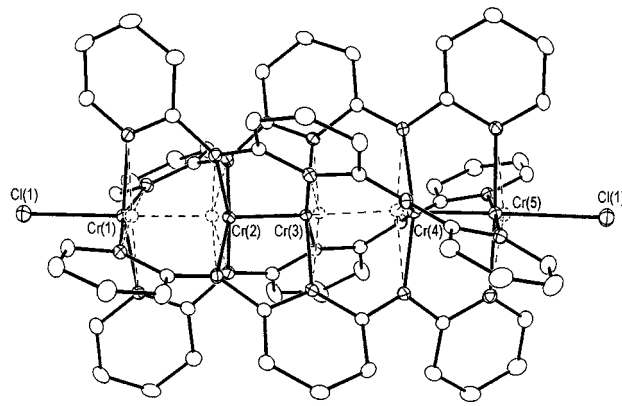

Fig. 1 The $Cr_5(tpda)_4Cl_2$ molecule as it is found in the compound $Cr_5(tpda)_4Cl_2$•$2Et_2O$•$4CHCl_3$. The four alternating Cr–Cr distances are listed in Table 1. Atoms are shown as their thermal displacement ellipsoids at the 30% probability level.

ment ellipsoids behave properly, as shown in Fig. 1, and the residuals are reduced. In the other two crystalline forms the same disorder exists and we took account of it in each of our refinements.

There was another problem with the previously reported structure. The electronic structure analysis[9] thereof led to a prediction of two unpaired electrons. This cannot be reconciled with an observed effective magnetic moment of 4.2 μ_B. This value is consistent with the correct structure, as we previously pointed out.[8] The lengthy molecular orbital analysis of the erroneous structure is also invalid.

Based on the results reported here, we would venture to say that a Cr_7 molecule of this ilk would also be expected to have strongly alternating Cr–Cr distances. However a recent report[10] shows a structure with approximately even spacing and pronounced prolate shapes for the Cr atom thermal ellipsoids.

We thank the National Science Foundation for support.

Extension of the Karplus relationship to vicinal coupling within the P–Ru–S–H moiety of the H_2S complexes *cis*-$RuX_2(P–N)(PPh_3)(SH_2)$ {X = Cl, Br; P–N = [*o*-(*N*,*N*-dimethylamino)phenyl]diphenylphosphine}

Erin S. F. Ma, Steven J. Rettig† and Brian R. James*

Department of Chemistry, University of British Columbia, Vancouver, British Columbia, V6T 1Z1, Canada. E-mail: brj@chem.ubc.ca

Received (in Bloomington, IN, USA) 10th September 1999, Accepted 28th October 1999

The Ru(II)–H_2S complexes *cis*-$RuX_2(P–N)(PPh_3)(SH_2)$ {X = Cl, Br; P–N = [*o*-(*N*,*N*-dimethylamino)phenyl]diphenylphosphine} are characterised crystallographically and by $^{31}P\{^1H\}$, ^1H and $^1H\{^{31}P\}$ NMR spectroscopies; the ^1H NMR spectra at −50 °C show three-bond coupling of only one H-atom of the coordinated H_2S to the P-atom of the P–N ligand, and this represents an extension of the Karplus relationship to vicinal coupling within a P–Ru–S–H system.

The reactions of H_2S with transition metal complexes are beginning to be explored, the systems having relevance in the biological sulfur cycle, in the formation of ores, in hydrodesulfurisation (HDS) catalysis, and in conversion of H_2S to H_2 and elemental sulfur (or organosulfur compounds).[1]

We recently reported the second structurally characterised transition metal–H_2S complex *cis*-$RuCl_2(P–N)\{P(C_6H_4Me\text{-}p)_3\}(SH_2)$ **1** {P–N = [*o*-(*N*,*N*-dimethylamino)phenyl]diphenylphosphine}, formed under ambient conditions from the reaction of the five-coordinate complex $RuCl_2(P–N)\{P(C_6H_4Me\text{-}p)_3\}$ with H_2S; unfortunately, although the formulation was unambiguous, only one H atom of the coordinated H_2S was located in the X-ray analysis.[2] We present here the X-ray structures of *cis*-$RuX_2(P–N)(PPh_3)(SH_2)$, (X = Cl **2** or Br **3**), where both H atoms of the H_2S are isotropically refined.

† Deceased October 27, 1998.

The yellow complex **2** was prepared by adding 1 atm H_2S to $RuCl_2(P–N)(PPh_3)$, formed *in situ* from $RuCl_2(PPh_3)_3$ (200 mg, 0.21 mmol) and P–N (64 mg, 0.21 mmol) in acetone (10 mL) at 50 °C.[3] This solution was stirred for 8 h at room temperature, and the resulting precipitate of **2**·Me_2CO was collected and dried *in vacuo* for 1 h (yield: 140 mg, 80%). Complex **3**·Me_2CO was prepared similarly in 72% yield using $RuBr_2(P–N)(PPh_3)$ (100 mg, 0.12 mmol) as precursor, this being isolated in 50% yield from a stirred suspension containing an excess of NaBr (1.14 g, 11 mmol), $RuCl_2(PPh_3)_3$ (420 mg, 0.44 mmol) and P–N (136 mg, 0.44 mmol) in acetone (10 mL).

Crystals of **2**·Me_2CO and **3**·C_6H_6 were obtained from saturated acetone and C_6H_6 solutions of the respective complexes left standing under 1 atm H_2S. The ORTEP plots of **2** and **3** (Fig. 1)‡ reveal pseudo-octahedral geometries with *cis* X-atoms, the coordinated H_2S ligand being *cis* to both P-atoms, and the PPh_3 ligand and the –NMe_2 being mutually *trans*. With the exception of the larger Ru–X bonds in **3**, the geometries of **1**–**3** are very similar. The S–H bond lengths (1.20, 1.30 Å in **2**, and 1.25, 1.34 Å in **3**) are generally shorter than those of gaseous H_2S (1.33 Å),[4] but other weak interactions are present and may play a role in stabilising the coordinated H_2S: H-bonding is observed within H(2)···Cl(2) (2.69 Å) and H(1)···Br(1) (2.85 Å), and both H atoms of the H_2S in **2** and **3** point towards phenyl planes. The shortest phenyl···SH distances are 2.80 Å [H(1)···C(9)] and 2.97 Å [H(2)···C(21)] within **2**, and 2.52 Å [H(1)···C(20), phenyl from P–N] and 2.59 Å

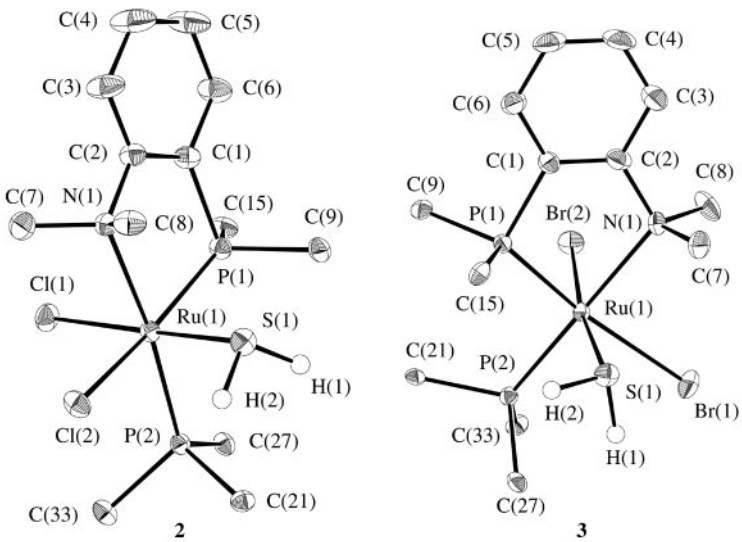

Fig. 1 The ORTEP plots of **2** and **3**. Thermal ellipsoids for non-hydrogen atoms are drawn at 33% probability (some phenyl carbons have been omitted for clarity). Selected bond lengths (Å) and angles (°): for **2**: S(1)–H(1) 1.20(3), S(1)–H(2) 1.30(3), Ru(1)–S(1) 2.3503(3), Ru(1)–P(1) 2.2712(6), Ru(1)–P(2) 2.3110(7), Ru(1)–N(1) 2.338(2), Ru(1)–Cl(1) 2.4238(6), Ru(1)–Cl(2) 2.4721(5); H(1)–S(1)–H(2) 102(2), Ru(1)–S(1)–H(1) 111(1), Ru(1)–S(1)–H(2) 103(1), Cl(1)–Ru(1)–S(1) 175.18(2), Cl(2)–Ru(1)–S(1) 82.63(2), S(1)–Ru(1)–P(1) 90.54(2), S(1)–Ru(1)–P(2) 93.76(2), S(1)–Ru(1)–N(1) 89.18(5). For **3**: S(1)–H(1) 1.25(7), S(1)–H(2) 1.34(6), Ru(1)–S(1) 2.333(1), Ru(1)–P(1) 2.262(1), Ru(1)–P(2) 2.301(1), Ru(1)–N(1) 2.372(3), Ru(1)–Br(1) 2.6343(5), Ru(1)–Br(2) 2.5540(4); H(1)–S(1)–H(2) 98(4), Ru(1)–S(1)–H(1) 101(3), Ru(1)–S(1)–H(2) 115(2), Br(1)–Ru(1)–S(1) 79.77(3), Br(2)–Ru(1)–S(1) 172.31(3), S(1)–Ru(1)–P(1) 93.87(4), S(1)–Ru(1)–P(2) 93.48(4), S(1)–Ru(1)–N(1) 89.43(9).

	2	**3**
P(1)-Ru-S-H(1)	60.79	-144.02
P(1)-Ru-S-H(2)	169.03	-39.68
P(2)-Ru-S-H(1)	-42.40	-43.97
P(2)-Ru-S-H(2)	65.84	-60.36

Fig. 3 End-on view of the solid state structures of **2** and **3**, with dihedral angles corresponding to P–Ru–S and Ru-S–H planes.

[H(2)···C(28)] within **3** (Fig. 1); related phenyl···mercapto proton interactions have been detected, for example, in $(PhMe_2P)_3Ru(\mu\text{-}SH)_3Ru(SH)(PMe_2Ph)_2$,[5] and implicated in HDS mechanisms.[6]

The $^{31}P\{^1H\}$ NMR spectra (200 MHz, 20 °C) of **2** and **3** in CD_2Cl_2 under 1 atm H_2S§ give AX patterns at δ 49.81 (*P*–N) and 43.30 (*P*Ph_3) ($^2J_{PP}$ 28.78 Hz) and δ 53.41 (*P*–N) and 44.36 (*P*Ph_3) ($^2J_{PP}$ 29.20 Hz), respectively, the coupling constants being characteristic of *cis*-P atoms.[3] Equivalent ^{1}H signals for the Ru–SH_2 resonances of **2** in solution are seen at 20 °C as a broad peak at δ *ca.* 1.0, but at −50 °C in CD_2Cl_2 (500 MHz) this peak is resolved into a doublet at δ 0.30 [H(1)] and doublet of doublets at δ 1.49 [H(2)], when the solution structure approaches that in the solid state [Fig. 2(a)]. The assignments for H(1) and H(2) are based on the observed H-bonding which would deshield the H(2) relative to H(1). The data show that H(1) and H(2) are mutually coupled ($^2J_{HH}$ = 12.3 Hz), while H(2) is coupled to a P-atom ($^3J_{HP}$ 3.50 Hz) and H(1) is not; the $^1H\{^{31}P\}$ NMR spectrum [Fig. 2(b)] shows the H(2) multiplet reduced to a doublet, and by selective ^{31}P decoupling, it was determined that H(2) is coupled to the P-atom of the P–N ligand.

The findings conform nicely to the Karplus relationship, which was initially established for vicinal coupling of protons (^3J, *H*–C–C–*H*),[7] and has been extended to *P*–C–C–*H*, *P*–O–C–*H* and *P*–S–C–*H* systems.[8] For our Ru–H_2S systems, the dihedral angles for P–Ru–S–H can be visualised by an end-on view of the Ru–S bond shown in Fig. 3. The absolute dihedral angles (ϕ) for non-coupling P and H atoms in **2** are 60.79, 42.40 and 65.84°, and these correspond to P(1)–H(1), P(2)–H(1) and P(2)–H(2) interactions, respectively, where orbital overlaps are negligible. For P(1)–H(2), ϕ is 169.03° where the $^3J_{HP}$ coupling is observed, consistent with Karplus curves that give maximum coupling when ϕ = 180°; the P(1)–Ru–S–H(2) arrangement likely results from interactions of H(2) with Cl(2) and a phenyl group of PPh_3.

Similar findings were obtained for **3**; at −50 °C H(2) appears as a doublet at δ_H 0.48 while H(1), which is H-bonded to Br(1), appears as a doublet of doublets at δ_H 1.23 ($^2J_{HH}$ 12.2, $^3J_{HP}$ 4.3 Hz). Decoupling experiments again show that H(1) is coupled to P(1), where ϕ = 144.02° (Fig. 3). The equivalence of the proton signals of the coordinated H_2S at 20 °C (for **2** and **3**) does not result from exchange with free H_2S,§ and presumably involves inversion at the S atom.

The NMR coupling through a metal centre described should be of quite general application, and provides a further structural probe for any *A*–metal–X–*B*-type system, where A and B are NMR-active nuclei, and X is an appropriate donor atom. To our knowledge, there is no corresponding example involving coordinated water.

We thank the NSERC of Canada for financial support, Johnson Matthey Ltd. and Colonial Metals Inc. for the loan of Ru, and Dr N. Burlinson of this department for assistance with the low-temperature NMR experiments.

Notes and references

‡ Crystallographic data for both structures were collected on a Rigaku/ADSC CCD area detector with graphite monochromated Mo-Kα radiation (λ = 0.71069 Å) at 180 K, solved by heavy-atom Patterson methods and expanded using Fourier techniques with the teXsan crystallographic software package of Molecular Structure Corporation. The non-hydrogen atoms were refined anisotropically; the S–H hydrogens were refined isotropically, the rest were fixed in calculated positions with C–H = 0.98 Å.

Crystal data: for $C_{41}H_{43}Cl_2NOP_2RuS$ **2**·Me_2CO: M = 831.78, yellow–brown prisms, crystal size 0.28 × 0.30 × 0.38 mm, monoclinic, space group $P2_1/n$ (no. 14), a = 14.843(2), b = 16.0292(9), c = 16.0099(8) Å, β = 95.286(2)°, V = 3792.8(5) Å^3, Z = 4, D_c = 1.46 g cm^{-3}, F(000) = 1712, μ(Mo-Kα) = 7.27 cm^{-1}, 33910 total reflections, 9547 unique (R_{int} = 0.041), 6176 observed [$I > 3\sigma(I)$], $R(R_w)$ = 0.028(0.025).

For $C_{44}H_{43}Br_2NP_2RuS$ **3**·C_6H_6: M = 940.72, orange prisms, crystal size 0.15 × 0.20 × 0.25 mm, monoclinic, space group $P2_1$ (no. 4), a = 9.667(1), b = 18.976(2), c = 11.6270(4) Å, β = 110.3292(7)°, V = 2000.0(3) Å^3, Z = 2, D_c = 1.56 g cm^{-3}, F(000) = 948, μ(Mo-Kα) = 25.61 cm^{-1}, 18513 total reflections, 5234 unique (R_{int} = 0.031), 8318 observed [$I > 3\sigma(I)$], $R(R_w)$ = 0.059(0.074). CCDC 182/1473.

§ 1 atm H_2S ensures complete formation of **2** and **3** within equilibria with the respective five-coordinate precursors;[2] the same NMR signals (together with those of the precursors)[3] are observed for solutions of the complexes in the absence of added H_2S.

Carbohydrates from glycerol: an enzymatic four-step, one-pot synthesis

Rob Schoevaart, Fred van Rantwijk and Roger A. Sheldon*

Laboratory of Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands. E-mail: r.a.sheldon@tnw.tudelft.nl

Received (in Cambridge, UK) 30th September 1999, Accepted 1st November 1999

A novel one-pot procedure, involving a cascade of four enzymatic steps, for the synthesis of carbohydrates from glycerol and an aldehyde is reported.

Dihydroxyacetone phosphate (DHAP)-dependent aldolases catalyze the highly stereoselective synthesis of a wide variety of natural and non-natural carbohydrates[1–3] *via* the aldol reaction of DHAP with an aldehyde acceptor. C–C bond formation can produce four different stereoisomers and it is possible, by an appropriate choice of aldolase, to selectively produce any one of the four possible stereoisomers. For example, the fructose-1,6-bisphosphate aldolase[4] (FruA) used in this study produces an aldol adduct with 3*S*,4*R* stereochemistry. Chemical methods for preparing DHAP are circuitous and/or require expensive reagents.[5] Known enzymatic methods require the use of expensive enzymes (kinases) and regeneration of ATP.[6,7] We reasoned that the use of a phosphatase[8,9] as the phosphorylation catalyst would enable the use of inexpensive inorganic pyrophosphate as the phosphate source.

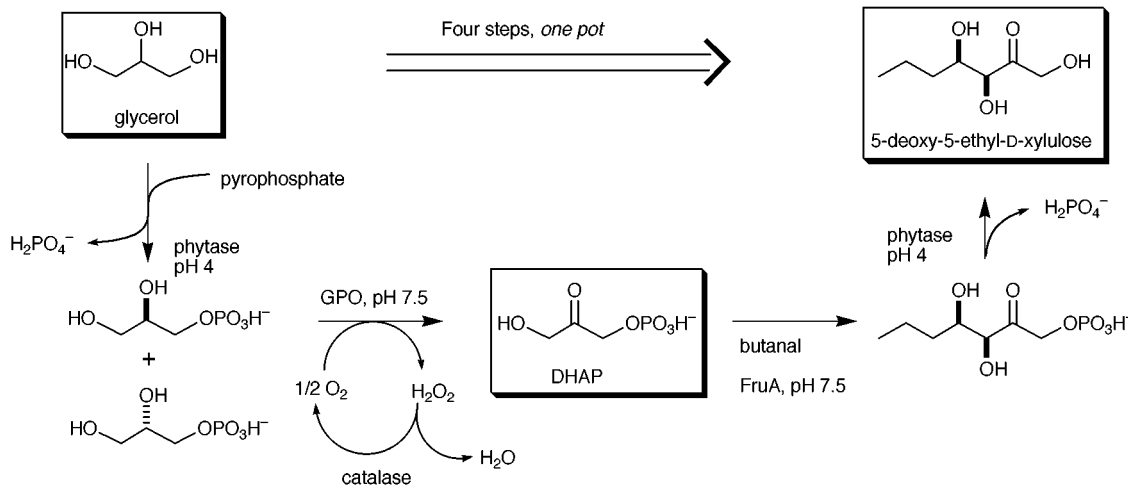
Our synthetic scheme embodies a cascade of four enzymatic steps: kinetically controlled phosphorylation of glycerol by inorganic pyrophosphate, glycerol phosphate oxidase (GPO)-catalysed aerobic oxidation of L-glycerol-3-phosphate to DHAP coupled with catalase mediated decomposition of hydrogen peroxide,[10] aldol reaction of DHAP with an aldehyde acceptor[11] and, finally, enzymatic dephosphorylation of the aldol adduct (see Scheme 1). The key to its success depends on the judicious use of pH control to switch the activities of the various enzymes on and off during the cascade.†

The phosphatase of choice was phytase[12] from *Aspergillus ficuum*, which is a cheap and readily available industrial enzyme. Its production of DL-glycerol-3-phosphate is pH dependent with a very broad optimum. For quick analysis L-glycerol-3-phosphate is detected by oxidation to DHAP and subsequent coupled assay[13] (equal amounts of the D-isomer are assumed to be formed). At pH 2 phosphorylation [glycerol > 10% (v/v)] was substantial and it decreased above pH 4 to become zero at pH 7. The yield of glycerol-3-phosphate (at pH 4) increased with increasing glycerol concentration, presumably because the competing hydrolysis of pyrophosphate and glycerol-3-phosphate is suppressed at low water concentrations. At 95% glycerol 75 mM L-glycerol-3-phosphate (corresponding to the theoretical yield of 50%) was formed according to the assay, after 24 h reaction time. ^{31}P NMR analysis confirmed that under these conditions the conversion of pyrophosphate into DL-glycerol-3-phosphate was 100%. Glycerol-2-phosphate was absent in the reaction mixture, demonstrating that phytase is completely regiospecific.

The concentration of glycerol was adjusted to 55%, because the activity of glycerol phosphate oxidase (GPO) is low in 95% glycerol. Moreover, the pH was increased to pH 7.5, which corresponds with the optimum of GPO and catalase (and that of the aldolase as well) and renders the phytase inactive, thus preventing undesirable hydrolysis. After quantitative oxidation of L-glycerol-3-phosphate to DHAP, fructose-1,6-bisphosphate aldolase (FruA) from *Staphylococcus carnosus* and butanal[14,15] were added to start the aldol addition (78% conversion after 4 h). Lowering the pH to 4 initiated the dephosphorylation of the butanal–DHAP adduct, affording 5-deoxy-5-ethyl-D-xylulose[14] in 57% yield from L-glycerol-3-phosphate. The addition of extra phosphatase for removal of the phosphate group was not necessary since phytase was still present and active.

The combination of four different enzymes and four enzymatic transformations in one pot provides an attractive procedure for performing aldol reactions with DHAP aldolases starting from the cheap, readily available glycerol and pyrophosphate. Combined with the broad substrate specificity of DHAP aldolases towards acceptor substrates, a wide variety of carbohydrates is readily accessible using this method.

Generous gifts of enzymes by Roche Diagnostics (Penzberg, Germany) are gratefully acknowledged. This work was financially supported by the Innovation Oriented Program Catalysis (IOP-catalysis).



Scheme 1

Notes and references

† Optimal conditions (per ml): phosphorylation was carried out in 95% glycerol with 150 mM pyrophosphate and 1 mg phytase at pH 4.0. After shaking at 37 °C for 24 h the pH was adjusted to 7.5 and the glycerol concentration was reduced to 55% by dilution. GPO (5 units) and catalase (50 units) were added and oxygen was applied for 3 h at room temperature. Then the mixture was shaken for 4 h with FruA (1.25 units) and butanal (100 mM). Lowering the pH to 4, stirring overnight and extraction with EtOAc afforded 5-deoxy-5-ethyl-D-xylulose (57% from L-glycerol-3-phosphate).

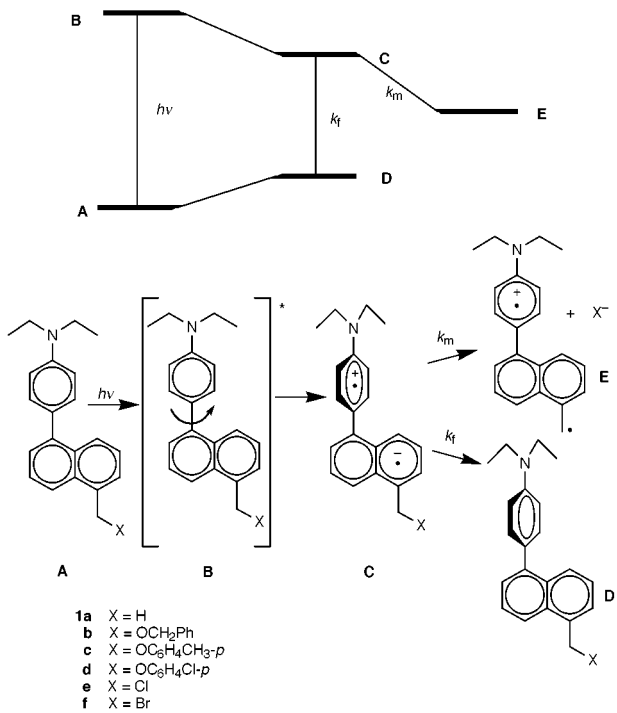
The competition between the fluorescent back-electron transfer and the exergonic fragmentation of radical anions in photogenerated intramolecular zwitterions showed that the rate of fragmentation followed the driving force of the reaction, with the notable exception of the most exergonic case.

Mesolytic cleavages[1] provide an excellent opportunity to experimentally investigate the functional dependence of the reaction rate (kinetics) on the driving force (thermodynamics) for an elementary reaction. Several theoretical and experimental studies have shown[2] that quadratic (Marcus-type) free-energy relationships may account for the main features of such fragmentation reactions. Indeed, in many instances the cleavage may be viewed as a dissociative intramolecular electron transfer, and analyzed in similar terms.[2]

To date, most of the fragmentation data have been obtained in the endergonic (or weakly exergonic) region. However, to better define the curvature of the free-energy function for the cleavage and to probe for the existence of an inverted region (similar to that found in electron-transfer reactions), data in the highly exergonic region are required. To probe such a regime, high-energy radical ions have to be generated rapidly, and once generated, they should be able to undergo fragmentation of a homolytically weak bond, giving a stable ionic fragment.[3]

Based on work of Singer[4] *et al.*, we have designed an experimental system (Scheme 1) wherein the radical ion pairs (zwitterions) are generated by an intramolecular electron-transfer from the excited state of the aminophenyl moiety to the naphthyl ring bearing a suitable leaving group in a benzylic position. The fluorescent back-electron transfer within the zwitterion competes with the fragmentation of the benzylic bond in the naphthyl radical anion, providing a sensitive handle on the dynamics of the system.



Scheme 1

UV–Visible spectra of all compounds[5] in MeCN were very similar, with the low-energy absorption band maxima at 325–330 nm. These bands was red-shifted (*ca.* 15 nm) and significantly more intense than the corresponding band of 4-bromo-*N*,*N*-diethylaniline, suggesting some charge-transfer nature of the transition (**A** → **B**). The degree of twist between the phenyl and the naphthyl moieties in **A** in solution is unknown and, therefore, the extent of the electronic coupling between the donor (aminophenyl) and the acceptor (naphthyl) could not be easily determined. The energy separation between the ground state (**A**) and the Franck–Condon state (**B**) is *ca.* 87 kcal mol^{-1}.

All compounds showed fluorescence with λ_{max} around 475 nm (**1a** has λ_{max} of 454 nm). All the fluorescence bands had identical shapes (widths) when recorded on the energy scale, but their intensity varied strongly with the nature of the substituent X (Fig. 1). The fluorescence corresponds[4] to the transition from the zwitterionic state (**C**) to the neutral state **D** (wherein the twist and solvation status is that of **C**, rather than that of the fully relaxed **A**). It is believed[4] that degree of twisting in **C** should approach 90°, but is probably somewhat less, leading to only a partial electron transfer between the donor and acceptor moieties.[6] The energy separation between **C** and **D** is *ca.* 60 kcal mol^{-1} (68 kcal mol for **1a**).

The oxidation potential of the donor part is 0.74 V *vs.* SCE, and the reduction potential of the acceptor component is −2.38 V *vs.* SCE.[7] The difference (3.12 eV) corresponds to the energy separation between the neutral state (**A**) and the zwitterionic state (**C**), assuming that the coulombic interactions (in MeCN) between the cation and the anion and the electronic coupling between them[4,6] (which depends on the twist angle) are relatively small. This approximation suggests that **B** → **C** and **D** → **A** relaxation processes (solvent and internal) correspond to *ca.* 15 and 12 kcal mol^{-1}, respectively (Scheme 1).

In the zwitterion **C** bearing a potential leaving group (**1b**–**f**) the unimolecular fragmentation reaction (k_m) of the naphthyl-centered radical anion (mesolysis) competes with the fluorescent decay (k_f). Such an additional reaction leads to a non-radiative depletion of **C**, and to the apparent change in the fluorescent life-time and the quantum yield as compared to that of the non-reactive model **1a** (Fig. 1).

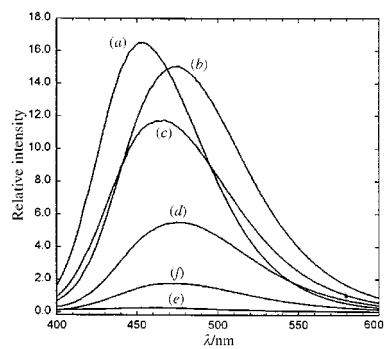


Fig. 1 Steady-state fluorescence spectra of (*a*) **1a**, (*b*) **1b**, (*c*) **1c**, (*d*) **1d** and (*e*) **1e** recorded in acetonitrile under identical experimental conditions.

Table 1 Thermodynamic and kinetic data for mesolytic fragmentation

Compound	ΔG_h(C–X)[a]/ kcal mol^{-1}	E^{ox} (X^-)[b]/ V *vs.* SCE	ΔG_m[c]/ kcal mol^{-1}	Φ_{rel}[d]	k_m[e]/s^{-1}
1a	77	−0.12	25	1.00	—

1f	53	1.28	−31	0.10	1.6×10^9

[a] Free energy of homolysis of the benzylic bond in the neutral molecule, from ref. 10. [b] Oxidation potential of the anion formed in the cleavage, from ref. 11 and 12. [c] Free energy of the mesolysis as calculated from the formula in the text. [d] Relative quantum yields for fluorescence determined in deoxygenated MeCN under argon, under identical experimental conditions for all the compounds. [e] The rate constant for radical anion fragmentation calculated as described in ref. 8.

Using the relative quantum yield data, and the fluorescence lifetime of the model compound (**1a**), values for the rate of the mesolysis (k_m) can be determined for each of the reactive compounds[8] (**1b–f**). In general, the lower the relative quantum yield for fluorescence, the faster the rate of mesolysis. The results of such calculations are collected in Table 1.

The thermodynamics of mesolytic cleavage was calculated on the basis of a simple thermodynamic cycle (Table 1).[1a,9] The free energy of mesolysis (ΔG_m) is a function of the free energy of homolysis (ΔG_h) of the scissile bond in the radical ion precursor, and the difference (ΔE) in the redox potentials of the radical ion and the ionic fragments produced. Specifically, in this case ΔE is the difference between the oxidation potential of the anion formed [$E^{ox}(X^-/X^{\cdot})$] and the reduction potential of the radical anion precursor (the reduction potential of the naphthyl moiety E^{red} = −2.38 V *vs.* SCE). Thus, $\Delta G_m = \Delta G_h - 23.06\ (E^{ox} - E^{red})$. The homolytic bond free energies are available from the literature.[10] The oxidation potentials of various ions can be obtained from thermodynamic cycles[11] or from direct measurements.[12]

The obtained data clearly show that the fragmentation rate of the radical anion correlates with the driving force for the reactions. In general, the more exergonic the reaction, the faster the cleavage of the radical anion, with the notable exception of the bromide **1f**. In this case the fragmentation reaction is five times slower than that of the less exergonic chloride (**1e**).

The sub-nanosecond lifetimes observed for these cleavage reactions are in general agreement with the reaction rates observed for other radical anion fragmentations with similar driving forces,[2b,d,13] and are, perhaps, only slightly slower than what would be expected for such exergonic processes based on other literature data.[2,13] This observation suggests that the electronic coupling does not drastically diminish the electron density in the naphthyl radical anions with the radical cation moiety in the zwitterion.[6]

The molecules studied here provide rates for the most exergonic mesolytic fragmentations studied so far. In this context, the inversion in the free-energy profile that is observed for the bromide (**1f**) suggests a possible existence of an inverted region analogous to that observed in electron-transfer reactions.[14] To the best of our knowledge this would be the first example of a reaction where bonds are broken (or made) showing such a behavior. More data are necessary before any firm conclusions can be reached, but the position of the inversion point on the free-energy plot suggests that these reactions have rather small intrinsic barriers.

According to the classical Marcus formulation,[15] the top of the parabola in the (log *k*) *vs.* ΔG plot should be located at the ΔG value equal to four times the intrinsic barrier (with the negative sign). In our case the maximum rate *at best* can be halfway between the ΔG_m values for the chloride and the bromide. Such simplified analysis suggests that the intrinsic barrier for the mesolytic cleavages of this type of radical anions is *ca.* 7 kcal mol^{-1} or less. This estimate is in very good agreement with previous observations,[2b,d,13] where the intrinsic barrier was postulated to be between 8–4 kcal mol^{-1}.

The observation of a possible inversion point on the free-energy function also suggests that the maximum rate for the cleavage reaction of radical anions is up to two magnitudes lower than what would be expected from transition state theory with a transmission coefficient of unity. Such a result would suggest that the electronic coupling between the π-system bearing the unpaired electron and the σ* orbital of the scissile bond is not very strong.

We thank the NSF and PRF for support of this research.

Notes and references

1 Mesolysis is defined as a unimolecular fragmentation of a radical ion into a radical and ion. See: (*a*) P. Maslak and J. N. Narvaez, *Angew. Chem., Int. Ed. Engl.*, 1990, **29**, 283; (*b*) P. Müller, *Pure Appl. Chem.*, 1994, 1077.

5 The reactive compounds for these studies were prepared from **1b**. Both **1a** and **1b** were synthesised following the literature procedure (ref. 4). All compounds were stable for several weeks at −10 °C under argon in the dark. Each compound was prepared and studied independently at least twice.

6 The electronic coupling between the radical cation and the radical anion in **C** (if the twist angle is less than 90°) would lead to a shift of electron density from the radical anion moiety to the radical cation site, diminishing the degree of electron transfer, and affecting somewhat the thermodynamic calculations presented here.

7 The reversible redox potentials were obtained using cyclic voltammetry on **1a**.

8 Quantum yield of the model compound (**1a**) is $Q^\circ = k_f/(k_f + k_{other})$, where k_{other} includes all non-radiative decay paths of **C**. Quantum yield of the reactive compounds (**1b–f**) is $Q = k_f/(k_f + k_{other} + k_m)$, and therefore, $k_m = (Q^\circ/Q - 1)\tau^\circ$, where τ° is the fluorescent life-time of the model [$\tau^\circ = 1/(k_f + k_{other})$ determined by time-resolved fluorescence to be 5.6 ns.

Novel chlorin–diene building block by enyne metathesis: synthesis of chlorin–fullerene dyads

Gang Zheng,[a] Thomas J. Dougherty[a] and Ravindra K. Pandey*[ab]

[a] *Chemistry Division, Photodynamic Therapy Center, Roswell Park Cancer Institute, Buffalo, NY, 14263, USA. E-mail: rpandey@sc3103.med.buffalo.edu*

Received (in Corvallis, OR, USA) 23rd August 1999, Accepted 25th October 1999

The first example demonstrating the utility of enyne metathesis in preparing a chlorin–diene system as a novel and versatile building block is discussed; Diels–Alder reaction [4 + 2] of the diene with fullerene (C_{60}) produced the chlorin–fullerene dyad, a new artificial photosynthetic model; compared to the non-fullerene analogs, the corresponding free base and Zn^{II} chlorin–C_{60} dyads showed a remarkable decrease in their fluorescence intensity, indicating a rapid quenching of the chlorin excited singlet state by the fullerene moiety.

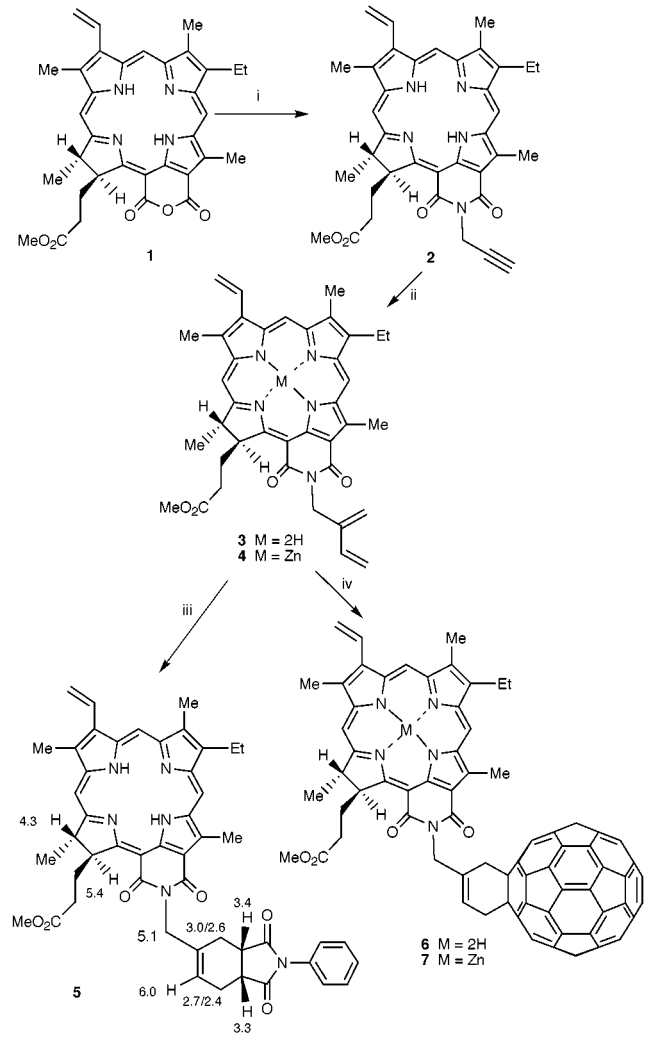
Fullerene C_{60} is one of the most widely studied molecules of the decade.[1] It has been reported as a promising new building block acting as an acceptor in artificial photosynthetic models,[2] and several porphyrin–C_{60} systems have been studied for this purpose.[3] It has been shown that C_{60} acts as an effective primary electron acceptor in a carotene–porphyrin–fullerene triad system, generating long-lived charge separated states with reasonable quantum yields.[4] Recent work by Imahori *et al.* on a C_{60}-linked Zn^{II} porphyrin system demonstrate that photoinduced electron transfer rates depend on the nature of linkages between the two chromophores.[5]

Natural chlorin pigments stand in marked contrast to symmetric porphyrin pigments due to substantially stabilized S_1 energies, a strong Qy absorption band, and unique redox reactivities. As a result, work is underway in our and various other laboratories to construct chlorin and bacteriochlorin based dimers with variable geometry and distances between the chromophores.[6] In certain fullerene-based electron and energy transfer (ET) models it has been suggested that large and spherical acceptors like C_{60} could show peculiar ET dynamics different from those shown by smaller counterparts such as benzoquinone and pyromellitic diimides, as well as by large π acceptors such as porphyrins and polycondensed aromatic compounds.[5] We believe that the synthesis of such chlorin–fullerene dyads with various spacers should provide valuable information for a deeper understanding of electron-transfer in photosynthetic reaction centers.

As a part of our research program to establish new methodologies for preparing such systems, the metathesis reaction caught our attention because of its unique ability to form C–C bonds. In recent years the applications of this approach have dramatically increased due to the availability of well-defined catalysts, in particular, Grubbs' catalyst $Cl_2(PCy_3)_2Ru{=}CHPh$ (Cy = cyclohexyl).[7] However, olefin metathesis has rarely been used in porphyrin chemistry. The only applications reported are those in which ligand metathesis has been used for preparing metalloporphyrins.[8]

Recently, Mori and co-workers reported a novel 1,3-diene synthesis from alkynes and ethylene by ruthenium-catalyzed enyne metathesis.[9] We thought it worthwhile to extend this methodology to the preparation of chlorin–fullerene conjugates *via* a sequence of enyne metathesis and Diels–Alder reactions.

For our studies, purpurin-18 methyl ester **1** was used as a starting material.[10] As shown in Scheme 1, reaction of **1** with propargylamine in toluene at 80 °C for 6 h produced propargylimide derivative **2** in 80% yield, which was used as a substrate for enyne metathesis. Treatment of the CH_2Cl_2 solution of **2** with Grubbs' catalyst (10 mol%) under ethylene gas atmosphere for 48 h at room temperature afforded the desired chlorin–diene building block **3** in 40% yield (on the basis of the starting material recovered, the yield was 100%). The structures of the intermediate chlorins **2** and **3** were confirmed by ^1H NMR and FAB mass spectometry analyses [*m/z* 616.7 and 644.6 (M + 1) respectively, exact mass calculated for compound **3** ($C_{39}H_{41}N_5O_4$): 643.3158, found: 644.3150 (M + 1)]. On comparing the resonances observed for **2** and **3**, the *N*-CH_2 protons which appeared as a singlet in diene **3** (δ 5.31, 2H) were observed as a multiplet (δ 5.29, 2H) in propargylimide **2** due to long range coupling with the acetylene proton.



Scheme 1 *Reagents and conditions*: i, $NH_2CH_2C{\equiv}CH$, toluene, 80 °C, 6 h; ii, Grubbs's catalyst, $CH_2{=}CH_2$, CH_2Cl_2, 48 h; iii, *N*-phenylaleimide, toluene, reflux, 1 h; iv, C_{60}, toluene, reflux, 2 h.

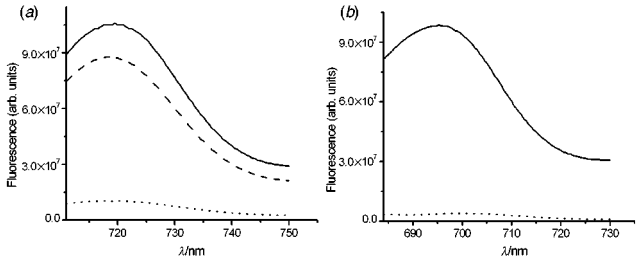


Fig. 1 (*a*) Fluorescence spectra of chlorin **3** (—), chlorin–maleimide **5** (- - -) and chlorin–C_{60} **6** (···) at 5 μmol l^{-1}. (*b*) Fluorescence spectra of Zn^{II} chlorin **4** (—) and Zn^{II} chlorin–C_{60} **7** (···) at 5 μmol l^{-1}.

To establish the reaction conditions needed to obtain chlorin–fullerene dyads, model studies were initially performed by using *N*-phenylmaleimide as dienophile, which is known to have similar reactivity to the fullerene C_{60} system.[11] As expected, reaction of free base chlorin **3** with *N*-phenylmaleimide in toluene for 1 h at 120 °C produced the corresponding Diels–Alder adduct **5** as a diastereomeric mixture (1 : 1) in 60% yield. Structural identification of **5** was performed by NMR and mass spectrometry analyses. In the ^{1}H NMR spectrum, the equal splitting of the CO_2CH_3 protons (17-$CH_2CH_2CO_2CH_3$) clearly indicated the presence of a diastereomeric mixture. Extensive spin-decoupling experiments further enabled us to assign the resonances and the coupling constants attributed to the respective protons. The chemical shift assignments of selected protons for the chlorin–*N*-phenylmalemide conjugate are shown in Scheme 1.

The reaction conditions established for the preparation of the model chlorin conjugate were then followed for the construction of the desired chlorin–fullerene conjugate. The Diels–Alder reaction of diene **3** with fullerene in refluxing toluene for 2 h afforded the chlorin–fullerene dyad **6** in 30% yield. The structure of **6** was confirmed by NMR and mass spectrometry analyses [exact mass calculated for $C_{99}H_{41}N_5O_4$: 1363.3158, found 1364.3160 (M + 1)]. In the ^{1}H NMR spectrum, the resonances of the newly formed cyclohexene ring system were observed at δ 3.98 (d, J = 5.5 Hz, 2H), 4.33 (m, 1H) and 7.22 (t, J = 5.5 Hz, 1H). The signals for the cyclohexene CH_2 (δ 4.3, see Scheme 1) and *N*-CH_2 protons appeared as multiplets, each integrating for two protons.

In our attempts to determine the effects of metallochlorins on energy/electron transfer (ET), dyad **6** was converted into the related Zn^{II} complex **7** (λ_{max} 684 nm**)** in quantitative yield following the standard methodology. The fluorescence spectra of the dyads **5**–**7** were compared with the free base diene **3** and the related Zn^{II}–**4** in CH_2Cl_2 by exciting their corresponding long wavelength absorptions (Qy band).[12] As can be seen from Fig. 1, conversion of diene **3** into the related *N*-phenylmaleimide adduct **5** had a limited effect on its fluorescence intensity. In contrast, dyads **6** and the Zn^{II} analog **7** containing the fullerene moieties showed a remarkable decrease in fluorescence, indicating a rapid quenching of the chlorin excited singlet state by C_{60}. The electronic absorption spectra of diene **3** and dyad **6** in CH_2Cl_2 and benzene indicate insignificant electronic interactions between the chromophores in the ground state. Detailed photophysical studies, such as fluorescence lifetime measurements, time-resolved transient absorption spectroscopy and the estimation of energy levels of these newly synthesized compounds, are underway. In order to determine the linkage dependence of photoinduced charge separation (CS) and subsequent charge recombination (CR), the synthesis of a series of chlorin– and bacteriochlorin–fullerene dyads with various spacers of fixed distances and geometry is currently in progress.

In conclusion, we have developed a new approach for the preparation of a versatile chlorin–diene building block **3** *via* ruthenium-catalyzed enyne metathesis. The utility of this highly reactive diene has been demonstrated by preparing new chlorin–fullerene dyads by following the [4 + 2] cycloaddition approach. The novel chlorin–diene building block has great potential for preparing not only promising models for photosynthetic reaction centers, but also for constructing a wide variety of porphyrin-based compounds of other biological significance.

The authors thank Dr S. Dutta, Molecular and Cellular Biophysics, RPCI, Buffalo, for mass spectrometry analyses. Partial support of the NMR facility by the NIH (grant CA-16056) is also acknowledged.

Electrochemical polymerization of a bis(thienyl)bithiazole osmium complex

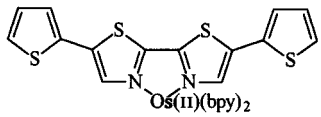
Brian J. MacLean and Peter G. Pickup*

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7. E-mail: ppickup@morgan.ucs.mun.ca

Received (in Columbia, MO, USA) 27th July 1999, Accepted 1st November 1999

A novel and easily n-doped conjugated metallopolymer has been prepared by the electrochemical polymerization of Os(bpy)$_2$[5,5′-bis(2-thienyl)-2,2′-bithiazole]$^{2+}$.

2,2′-Bithiazole is an attractive component for conjugated metallopolymers[1] because of its structural similarity to bithiophene and high π-electron density relative to bipyridine. Thus, unlike (bi)pyridine containing polymers, bithiazole based materials can be stable when p-doped and can exhibit relatively high conductivities.[2–5] An appealing approach to well defined bithiazole based metallopolymers is *via* the electrochemical polymerization of complexes of bis(thienyl)bithiazoles such as **1**. However, we have found that such complexes {Os(bpy)$_2$L^{2+}



1

and Ru(bpy)$_2$L^{2+}, where bpy = 2,2′-bipyridine and L = 5,5′-bis(2-thienyl)-2,2′-bithiazole (bthbthz), 5,5′[bis(2-thienyl)-4,4′-dimethyl-2,2′-bithiazole, or 5,5′-bis[2-(3-methoxythienyl)]-4,4′-dimethyl-2,2′-bithiazole} can not be polymerized under conventional conditions. Zhu and Swager have found that complexes of the analogous bipyridine ligand, 5,5′-bis(2-thienyl)-2,2′-bipyridine, are also resistant to electrochemical polymerization.[6,7] These authors circumvented the problem by extending the terminal thiophenes to bithiophenes, which gave polymerizable complexes.

The reason for the failure of complexes with single thiophene rings on the ligand to polymerize appears to be due to instability of the bithiophene linkages that are formed at the high potentials needed to drive the polymerization. As can be seen in Fig. 1, the oxidation of the bthbthz ligand of **1**,† does not begin until *ca.* +1.55 V *vs.* SSCE (E_{pa} = 1.68 V). This wave decreases rapidly with cycling (not shown), indicating that a passivating film is produced on the electrode. Interestingly, the Os(III/II) wave remains unchanged with extensive cycling, indicating that the passive layer contains electroactive Os centres. Indeed, a small Os(III/II) wave can still be seen when a passivated electrode is transferred to a blank electrolyte. Although the Os centres in the passivating layer can mediate the electrochemistry of Os(II) in solution, their redox potential is not high enough to mediate the oxidation/polymerization of the bthbthz ligand.

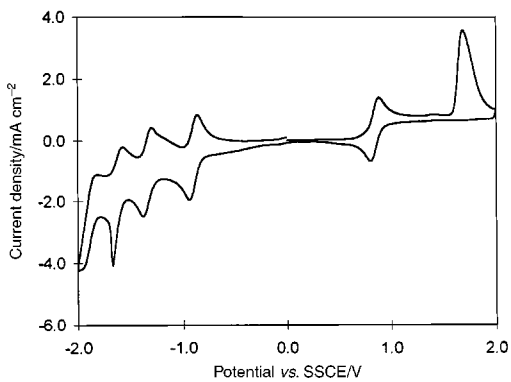


Fig. 1 Cyclic voltammetry (100 mV s^{-1}) of **1** in acetonitrile containing 0.1 mol dm^{-3} NEt$_4$ClO$_4$.

Reasoning that the passivating nature of the film formed by **1** was due to nucleophilic attack of residual water‡ on oxidized segments of the bithiophene-bithiazole backbone,[8] we added $BF_3{\cdot}OEt_2$ (Aldrich) to the acetonitrile–0.1 mol dm^{-3} NEt$_4$ClO$_4$ electrolyte solution. This reagent has been reported to be an excellent solvent system for the electrochemical synthesis of polythiophene.[9] The rationale for its use here is the deactivation of residual water by complexation with the BF_3. As shown in Fig. 2, compound **1** undergoes facile and sustained electrochemical polymerization in the $BF_3{\cdot}OEt_2$ containing electrolyte when the potential is cycled into the ligand oxidation wave at *ca.* 1.65 V. The Os(III/II) wave at a formal potential ($E^{\circ\prime}$) of +0.85 V increases monotonically with cycling of the potential into the ligand oxidation wave, and new waves appear in the region between the Os and ligand waves. The number, positions, and intensities of these new waves are somewhat variable. They are in the expected potential region for oxidation and re-reduction of a conjugated polymer backbone formed from polymerization of the bthbthz ligand at the 5-positions of the thiophene end groups, and therefore provide evidence that the complex polymerizes in this way. A deep red–purple film was observed on the electrode following the cyclic voltammetry shown in Fig. 2.

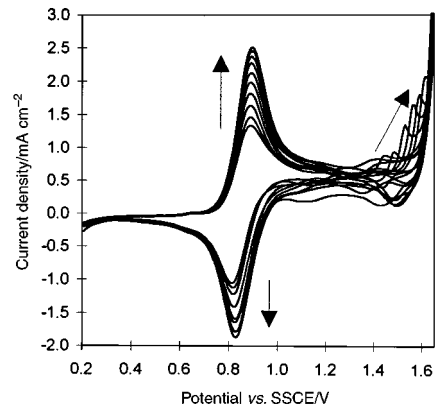

Fig. 2 Cyclic voltammetry (100 mV s^{-1}) of **1** in acetonitrile containing 0.1 mol dm^{-3} NEt$_4$ClO$_4$ and 0.45 mol dm^{-3} $BF_3{\cdot}OEt_2$. Arrows indicate changes with cycling.

Fig. 3 shows cyclic voltammograms of a poly-**1** coated electrode in the absence of **1** in solution. A reversible Os(III/II) wave appears at $E^{\circ\prime}$ = 0.865 V and a series of reduction waves are seen in the region −0.5 to −2.0 V. Based on the first three redox potentials for reduction of Os(bpy)$_3^{2+}$ (−1.26, −1.45 and −1.76 V[10]), which are for ligand based reductions,[10] the most positive reduction wave ($E^{\circ\prime}$ = −0.79 V) can be assigned to n-doping of the polymer backbone, while those at $E^{\circ\prime}$ = −1.62 and −1.85 V can be assigned to bpy based reductions. The mild potential and reversibility of the polymer based reduction, and the good stability of the n-doped form (indicated by the lack of significant decay of peak heights on multiple scans), open up the possibility of applications in molecular electronics and the

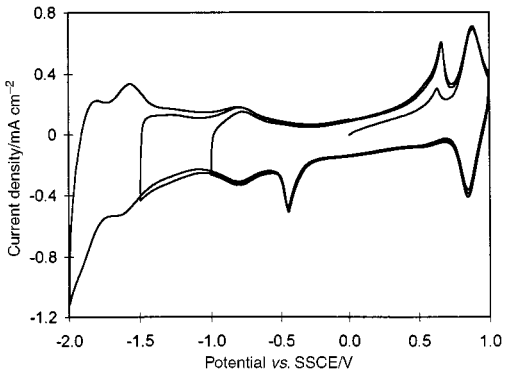

Fig. 3 Cyclic voltammetry (100 mV s^{-1}) of a poly-**1** coated Pt electrode in acetonitrile containing 0.1 mol dm^{-3} NEt_4ClO_4. Three consecutive scans to increasingly negative potentials are shown.

catalysis of reduction processes. The pre-peaks observed before the Os oxidation wave and the first reduction wave are typical of redox polymers based on bipyridine complexes.[11]

The Os(III/II) wave of poly-**1** is stable to multiple cycles extending down to −2.0 V, but decays rapidly when the potential is cycled to +2.0 V. Although no well defined polymer oxidation wave has been observed, it would appear that the polymer backbone is unstable to oxidation. Since the film remains visible on the electrode, the loss of the Os based electrochemistry implies that it is mediated by the polymer backbone. Since the backbone is not electroactive in the region of the Os(III/II) wave, electron transfer between Os sites presumably occurs *via* a superexchange interaction through the backbone.[1] Electron transport studies aimed at confirming these proposals, and establishing the influence of the metal (Os *vs.* Ru) and substituents on the polymer backbone are in progress. These studies can be expected to produce valuable guidance for the development of molecular electronics and electrocatalytic systems based on conjugated metallopolymers.

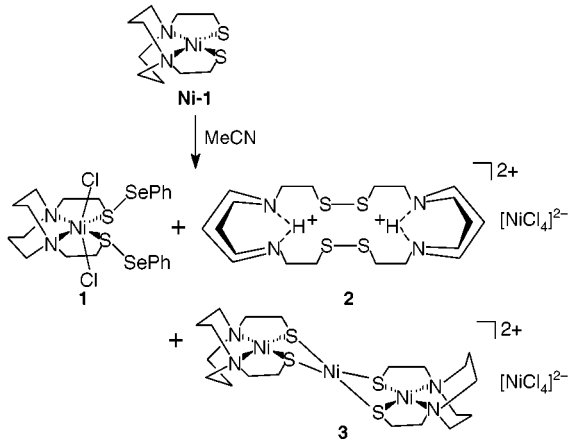
Received (in Bloomington, IN, USA) 18th May 1999, Revised manuscript received 4th August 1999, Accepted 22nd October 1999

Electrophilic addition of the PhSeCl to a nickel dithiolate yields *S,S′*-bis(phenylselenenyl-*N,N′*-bis(mercaptoethyl)-1,5-diazacyclooctane nickel(II) dichloride and a dimeric, intermolecular bis-disulfide which results from ligand oxidation.

To extend the well known S-based nucleophilicity of [*N,N′*-bis(mercaptoethyl)-1,5-diazacyclooctane]nickel(II), (bme–daco)Ni or **Ni-1**,[1] especially with regard to developing reactive ligand functionalities, we explored the reactivity of **Ni-1** with PhSeCl, Scheme 1. The desired nickel-bound selenosulfide **1**, a moiety which should be capable of subsequent oxidative addition to low-valent metals and thus of potential usefulness to the preparation of heterobimetallics, was obtained (Scheme 1). In addition the intermolecular bis-disulfide of H_2bme–daco **2** was also isolated and characterized. The latter represents the product of ligand oxidation proposed in one-electron oxidative processes of **Ni-1**,[2] concomitantly releasing Ni^{2+} which is rapidly scavenged by **Ni-1**, producing the stable trimetallic species. Its existence supports our supposition that the monomeric intramolecular disulfide of the bme–daco ligand is sterically prohibited, accounting for much of the well behaved S-oxygenation chemistry displayed by the ligand.[3]



Scheme 1 Synthetic scheme of the reaction of **Ni-1** and PhSeCl.

Compound **1** is, to our knowledge, the only example of a structurally characterized mixed RS–SeR′ ligand which is S-bound to a transition metal. Our literature and data base searches find only one other structurally characterized mixed dichalcogenide, a low yield byproduct of an organometallic reaction which is Se-bound, (PhS*Se*Ph)$Cr(CO)_5$.[4] An interesting bioinorganic reaction of selenocysteine–S-dithiolene coupling at the molybdenum site of *Desulfovibrio desulfuricans* ATCC 27774 formate dehydrogenase (FDH) has implied both Se and S binding at Mo.[5] The following report is a designed mixed dichalcogenide synthesis, doubtlessly made possible by the well known ability of nickel to facilitate the nucleophilicity of thiolate-S as well as to bind charge-neutralized sulfur, stabilizing the RS–SeR′ toward disproportionation.

On mixing MeCN solutions of orange PhSeCl with purple **Ni-1**, two different precipitates developed; a major component was green and the minor, dark red–brown.[6] The mixture was separated by extraction with CH_2Cl_2 into which the former dissolved. The latter dark solid **3** was identified as a salt of a trimetallic cation[2] (Scheme 1). The green material crystallized in two forms, compounds **1** and **2**, which were characterized by X-ray crystallography. When dissolved in MeOH under Ar, the isolated and purified compound **1**, rapidly disproportionated, producing a mixture of **2**, **3** and diphenyl diselenide (as determined by ^{1}H NMR).

The molecular structures of **1** and **2** are shown in Figs. 1 and 2. Complex **1** contains a pseudo-octahedral nickel in $N_2S_2Cl_2$ coordination; the average deviation in the NiN_2S_2 best plane is 0.096 Å. The axial chlorides are bent away from the daco framework with a Cl–Ni–Cl angle of 159.07(14)°. As is usual for six-coordinate Ni complexes containing the diazacyclooctane moiety,[7] the fused nickel diazacyclohexane rings adopt chair/chair configurations with the pendant ethylene linkages (NCH_2CH_2S) staggered with respect to each other, across the N_2S_2Ni plane.

Another open, N_2S_2 tetradentate, six-coordinate complex based on **Ni-1**,[8] the dibenzyl dibromide complex **4**, is compared to that of **1** in Table 1. Notably, in compound **4** the benzyl groups are on the same side of the N_2S_2 planes, while the phenylselenolate groups of complex **1** are in *transoid* positions. For both complexes the S–Ni–S angles are *ca*. 10° greater than that of the parent **Ni-1**, corresponding to larger S···S distances (as contrasted to 3.04 Å in **Ni-1**).[7a] The Se–S_{av} distance of 2.202(4) Å agrees well with that of Se-bound $(CO)_5Cr$(PhS-*Se*Ph) ([Se–S = 2.226(6) Å][4] and the sum of covalent radii of 2.21 Å for a Se–S single bond.[9] The Ph(PhSe)*S*→Ni dative bond presumably relaxes the typical 90° torsion angle in REE′R dichalcogenides which minimizes lone-pair repulsion. In fact the C–S–Se–CPh torsion angles are 73 and 82°.

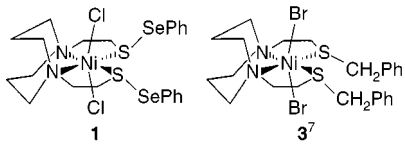
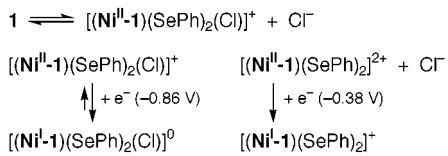
Table 1 Metrical structural data and electrochemical data



1 **3**[7]

Ni–S_{av}/Å	2.560(4)	2.493(1)
Ni–N_{av}/Å	2.120(11)	2.118(3)
S··S/Å	3.95	3.767
X–Ni–X/°	159.07(14)	162.01(2)
S–Ni–S/°	100.91(12)	98.14(3)
Ni–S–Se(C)$_{av}$/°	109.71(13)	114.91(14)
Reduction potential ($Ni^{II/I}$)/V	−0.38, −0.86	−0.67

of analogues of compound **4** and similar derivatives,[7,8,10] led to the conclusion expressed in Scheme 2. The $Ni^{II/I}$ couple at −0.38 V is the most positive observed thus far in a wide range of **Ni-1** thioether dicationic derivatives suggesting that the addition of two $SePh^+$ groups to the thiolate S achieves a charge neutralization better than that of any carbon-based electrophile. The selenosulfide derivative is less stable to reduction, consistent with weaker S–Se bonds at reduced nickel as compared to S–C bonds.[11] It is also consistent with the observed loss of the Se–S interaction in the reduction of the Mo^{VI}-selenosulfide site of FDH_H.[5] A complicated anodic region of the cyclic voltammogram was not resolved as to ligand or metal-based oxidation.[10,12]



Scheme 2 The combined results of solution conductivity measurements and electrochemical studies.

The intermolecular disulfide **2** crystallizes in a dicationic protonated form, with $NiCl_4^{2-}$ as counter ion. The bisdisulfide attains a cage conformation (C_2 symmetry) with a typical disulfide S–S average distance (2.04 Å) and a large cross cage S(3)··S(4) distance of 7.207 Å. A similar bisdisulfide was isolated as a byproduct of a N_2S_2 ligating reaction of $VOCl_2(thf)_2$.[13] The H-bonding interaction linking the two N atoms significantly shortens the N··N distance to 2.633 Å, in contrast to **Ni-1**, 2.783 Å.

Cyclic metallopeptides, cyclo[Gly-L-Cys(terpyPt^{II})]$_n$Cl$_n$†

Kentaro Tanaka,[a]‡ Kazuki Shigemori[b] and Mitsuhiko Shionoya*[a]‡

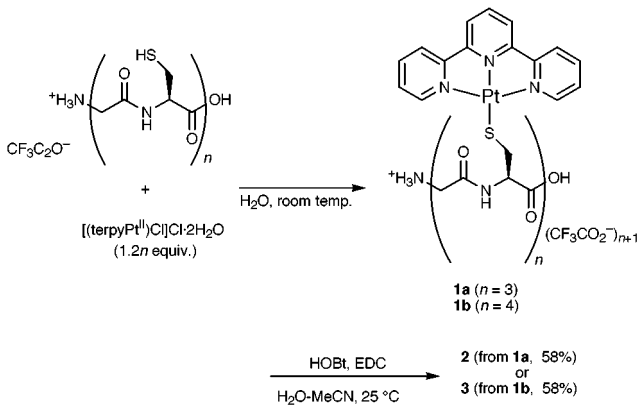
[a] *Coordination Chemistry Laboratories, Institute for Molecular Science, Myodaiji, Okazaki 444-8585, Japan*
[b] *Graduate University for Advanced Studies, Myodaiji, Okazaki 444-8585, Japan*

Received (in Columbia, MO, USA) 28th July 1999, Accepted 27th October 1999

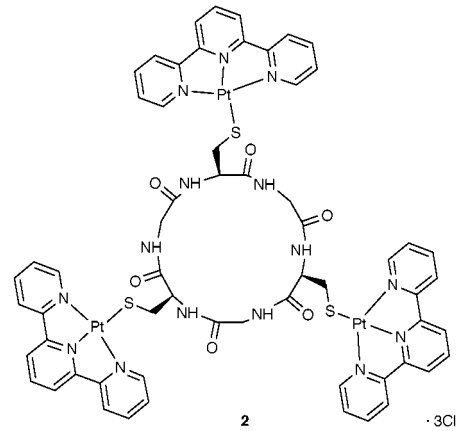
An efficient strategy for the liquid-phase synthesis of cyclic metallopeptides, cyclo[Gly-L-Cys(terpyPt^{II})]$_n$Cl$_n$ (n = 3, 4), has been developed, which could provide a powerful tool for arraying metal centers on cyclopeptide frameworks.

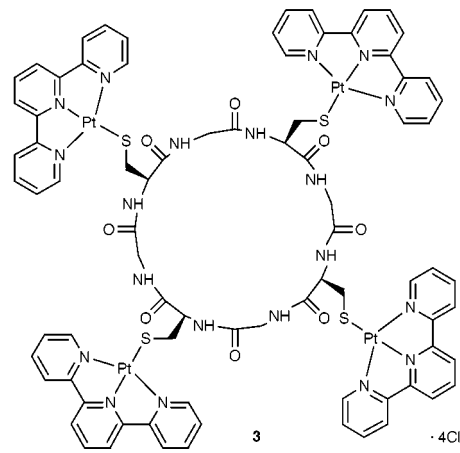
Cyclopeptides are a class of compounds with biological activity[1] and great potential as functional molecules.[2] The development of strategies for functionalizing cyclopeptides is a fundamental challenge in the emerging field of *de novo* protein design. One of the most exciting recent advances in this field is the development of a wide range of structural and functional capabilities for self-assembling nanotubes made from cyclic D,L-α-peptides and from cyclic β-peptides.[3] As another advantageous tool for the functionalization of peptides, metal binding sites have been engineered into peptides and proteins using the side chains of naturally occurring amino acids or unnatural metal binding sites incorporated at the residues, for model studies of protein folding and enzymes, biosensors and molecular architectures.[4] Our approach is based on the use of amino acids containing a metal coordinating site (*e.g.* the thiol group of Cys)§ as the components of cyclopeptides for constructing cyclopeptide–metal complex conjugates. Herein we describe an efficient strategy for the liquid-phase synthesis of cyclopeptides having a repeating Gly-L-Cys(terpyPt^{II}) sequence, cyclo[Gly-L-Cys(terpyPt^{II})]$_n$Cl$_n$, **2** (n = 3) and **3** (n = 4).§ Interest in the incorporation of a terpyPt^{II} complex onto L-Cys was initially aroused by its binding to DNA and antitumor properties.[5] In these peptides, positively charged Pt^{II} complexes are designed to align on the periphery of the macrocyclic peptide scaffold. We have found that these cyclic metallopeptides provide a novel structural motif in the receptor site for anionic guest molecules.

The synthetic route for the cyclopeptides is shown in Scheme 1. The linear peptides, H$_2$(Gly-L-Cys)$_n$OH·(CF$_3$CO$_2$) (n = 3 and 4), were prepared on a peptide synthesizer using standard Fmoc chemistry. Treatment of these peptides with 1.2n equiv. of [(terpyPt^{II})Cl]Cl·2H$_2$O in H$_2$O at room temperature afforded H$_2$[Gly-L-Cys(terpyPt^{II})]$_n$OH·(CF$_3$CO$_2$)$_{n+1}$ **1a** (n = 3) and **1b** (n = 4), in 88 and 97% yields, respectively, after purification by RP-HPLC [eluent: H$_2$O–MeCN (7:3) containing 0.1% TFA].§ The resulting linear peptides, **1a** and **1b**, were cyclized at a concentration of *ca.* 0.50 mM in H$_2$O–MeCN (7:3) at 25 °C for 48 and 72 h, respectively, in the presence of excess HOBt and EDC.§ Cyclo[Gly-L-Cys(terpyPt^{II})]$_n$Cl$_n$, **2** (n = 3) and **3** (n = 4) were obtained as red precipitates in 58% yield in both cases.[6,7] The products were highly pure even in the crude form. Whereas the ^{1}H NMR spectral patterns for the linear **1a** and **1b** were highly complicated, those for the cyclopeptides **2** and **3** were much more symmetrical and only one set of signals corresponding to a Gly-L-Cys(terpyPt^{II}) moiety was observed in each case. The electrostatic repulsion that would occur intramolecularly between the positively charged Pt^{II} complexes may complicate the solvent-dependent prefolding of the linear starting peptides, and at the same time may facilitate the intramolecular cyclization. Although the ESI MS data showed *m/z* 587 for both **2** and **3**, the rings of the cyclopeptides were clearly shown to be 18- and 24-membered, respectively, from the numbers of split lines observed in the high-resolution



Scheme 1





† Experimental and spectral data for **1a**,**b**, **2** and **3** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2475/

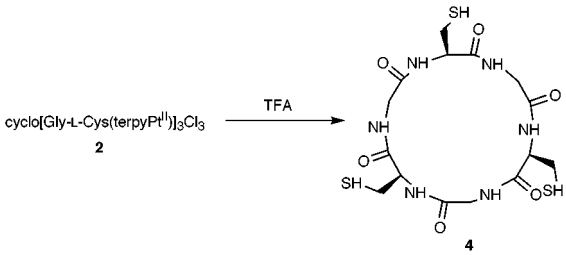

Scheme 2

spectra (Fig. 1). To the best of our knowledge, this is the first example providing an efficient strategy for the liquid-phase synthesis of cyclic metallopeptides from linear peptides bearing functional metal complexes.

The terpyPt^{II} complex moieties of **2** were readily removed by treatment with TFA to afford the corresponding cyclopeptide, cyclo[Gly-L-Cys]$_3$ **4**, as indicated by its ESI MS data (*m/z* 479 [M − H$^+$]$^-$) (Scheme 2). Consequently, terpyrPt^{II} complexes can be regarded as both protecting and promoting groups for peptide cyclization.

These cyclic metallopeptides were found to act as positively charged anion receptors.[8] In these receptors, coulombic interactions were expected primarily to contribute to the attractive force for anion binding. We have examined the binding of cyclohexapeptide **2** to benzenetricarboxylate anions (1,2,3-, 1,2,4- and 1,3,5-tricarboxylates).[9] It was clearly demonstrated from its ^{1}H NMR studies that the cyclohexapeptide **2** selectively separated benzene-1,3,5-tricarboxylate from an equimolar mixture of the three tricarboxylates to form a 1 : 1 ternary complex in neutral water at room temperature.

We have demonstrated an efficient strategy for the liquid-phase synthesis of cyclopeptides containing a repeating Gly-L-Cys(terpyPt^{II}) sequence. These results raise the intriguing possibility that this strategy will provide a powerful tool for arraying metal centers on cyclopeptide frameworks, which could lead to structural as well as functional control of multinuclear metal complexes.

Diffusion coefficients of zirconocene–borate ion pairs studied by pulsed field-gradient NMR—evidence for ion quadruples in benzene solutions

Stefan Beck,† Armin Geyer* and Hans-Herbert Brintzinger

Fakultät für Chemie, Universität Konstanz, D-78457 Konstanz, Germany. E-mail: Hans.Brintzinger@uni-konstanz.de

Received (in Oxford, UK) 11th October 1999, Accepted 5th November 1999

Diffusion coefficients for ion pairs containing zirconocene cations and fluorinated tetraphenyl- or methyltriphenylborate anions in benzene solutions are substantially smaller than those expected for monomeric species and indicate that ion quadruples are present in these solutions.

Electron deficient metallocene alkyl cations of group 4 metals, in combination with weakly coordinating anions are considered to be reactive species in homogeneous olefin polymerization catalysis.[1] Particularly well defined in this regard, in several instances even by solid-state structures,[2,3a] are zirconocene ion pairs which contain the fluorinated borate anions $B(C_6F_5)_4^-$ or $MeB(C_6F_5)_3^-$; these are obtained by reaction of a dimethyl zirconocene complex with a triorganylammonium or triphenylcarbenium salt of $B(C_6F_5)_4^-$ or with $B(C_6F_5)_3$, respectively.[4] The binding of the anion to the cationic center in these contact-ion pairs is of importance for the activity of a catalyst system, since the anion A^- has to be displaced by the olefin substrate to initiate the catalytic cycle. Exchange of these anions between zirconocene coordination sites as well as their displacement by entities such as a Lewis base, $AlMe_3$ or another dimethyl zirconocene complex have been studied in considerable detail.[1–3] Rather little is known, however, about the structures of these ion pairs in solution, especially with regard to the extent to which they form dissociated, associated or aggregated ion pairs in the non-polar solvents commonly used for homogeneous olefin polymerizations. In order to clarify this point, we have determined the size of these catalytically active species in solution by measuring their translational diffusion coefficients D_t by NMR methods.

The LED (longitudinal eddy current delay) experiment measures the intensity of a spin–echo amplitude as a consequence of the change in spatial position of a molecule during the time interval between two pulsed field gradients.[5] The changing signal intensity (I) with incremented gradient strength G is related to the translational diffusion coefficient D_t by the Stejskal–Tanner equation $I = I_0\exp\{-(\gamma\delta G)^2\,[\Delta - (\delta/3)]\,D_t\}$,[6] where γ is the gyromagnetic ratio, δ the gradient duration and Δ the interval between the pulsed field gradients. The method works also for complexes and salts.[7] For approximatively spherical particles which are significantly larger than the solvent molecules, the Stokes–Einstein equation $D_t = kT/(6\pi\eta r)$, where k = Boltzmann constant, T = absolute temperature and η = viscosity of the solvent, is used to relate the translational self-diffusion coefficient D_t to the radius r of the dissolved particle. For molecules with van der Waals radii $r_W <$ 5 Å, the Stokes–Einstein factor of 6 has to be changed to a value of 4.[8] We find this so-called perfect slip condition to hold for dilute benzene solutions of the bis(cyclopentadienyl) dimethylzirconium compounds shown in Scheme 1 (Table 1). The diffusion coefficients of these neutral, monomeric zirconocene complexes decrease linearly with increasing molecular size: The inverse diffusion coefficients of these species correlate with their calculated van der Waal's radii r_W with deviations of $< 10\%$ (Fig. 1).

Rather unexpected results, however, pertain to a number of ion pairs derived from compounds **1** and **5**: While the D_t value obtained for the methylborate ion pair **5A** deviates only slightly from the calibration provided by compounds **1**–**5**, the experimentally determined D_t value of ion pair **1A** amounts to only *ca.* 80% of the expected value. These deviations from expectation are even more pronounced for the ion pairs **1B** and **5B**, which contain the more weakly coordinating $B(C_6F_5)_4^-$ anion and are, hence, presumably more polar. The D_t value obtained for ion pair **1B** in particular (5.1×10^{-10} m^2 s^{-1}), yields an apparent particle volume of 1260 Å^3, which corresponds to just twice the expected volume of this ion pair.

Even though a number of caveats have to be heeded—a pronounced anisotropic molecular shape, a change from perfect slip (SE factor 4) to perfect stick conditions (SE factor 6) or an increased solvent shell might contribute to the observed decrease of D_t—we propose that ion pair **1B** is present in these solutions predominantly in form of its dimer, *i.e.* of an ion quadruple (Scheme 2). This contention is supported by the observation that **1B** has practically the same diffusion coefficient as the related ion pair $[(C_5H_5)_2ZrMe(\mu\text{-}Me)MeZr(C_5H_5)_2]^+\,B(C_6F_5)_4^-$ **1C**, for which a binuclear structure has been independently established.[3a,9]

From the theory of ion solutions in organic solvents it is indeed to be expected that ion quadruples are present in benzene solutions of ion pairs such as **1B** at the concentrations considered here,[10] which are close to the limiting concentrations at which these ion pairs begin to form separate phases. In accord with these theoretical considerations, the degrees of ion quadruple formation, indicated by the deviations of D_t from the values expected for monomeric species, are higher for the more polar ion pairs **1B** and **5B** than for the presumably partly covalent ion pairs **1A** and **5A** and higher for ion pairs **1A** and **1B**, which contain the rather small $(C_5H_5)_2ZrMe^+$ cation, than for their more voluminous analogues **5A** and **5B**, respectively.

More detailed data on degrees of aggregation and their dependence on the nature of the zirconocene cation and its counter anion will clearly be needed for a full description of

reaction systems of this type. From the data presented here it is already clear, however, that the hitherto entirely neglected formation of ion quadruples will have to be taken into account for an analysis of exchange reactions between anions and other ligands in zirconocene-based catalyst systems.

Anodic and cathodic electrografting of alkynes on porous silicon†

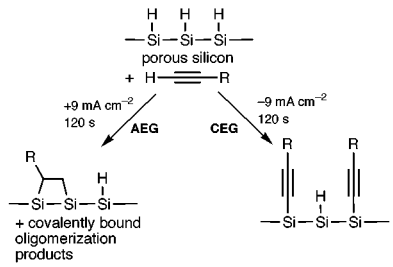
Edward G. Robins, Michael P. Stewart and Jillian M. Buriak*

Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393 USA. E-mail: buriak@purdue.edu

Received (in Bloomington, IN, USA) 18th August 1999, Accepted 25th October 1999

A versatile electrochemical grafting reaction connects conjugated molecules to porous silicon surfaces with either a positive or negative bias.

Porous silicon, an interconnected network of silicon nanowires and nanocrystallites,[1] is terminated by metastable silicon–hydride groups (Si–H_x) and Si–Si bonds. There are now a number of techniques utilized for chemical modification of these species on the surface of porous silicon.[2–6] Using the Si surface as a semiconducting electrode, several workers have reported electrochemical Si–C bond formation by direct grafting, an approach with few parallels to soluble, molecular silane chemistry.[7–9] Herein we report a system for electrochemically grafting terminal alkynes to porous silicon which gives two distinct surface derivatizations, depending on the polarity of the surface bias. *Cathodic* electrografting (CEG) directly attaches alkynes to the surface, whereas *anodic* electrografting (AEG) yields an alkyl surface.



FTIR analysis of phenylacetylene CEG (surface **1**, Fig. SM3†) reveals Si–H_x stretches which are broadened and decreased in integrated intensity compared to unmodified porous silicon. The absence of a ν(≡CH) mode around 3300 cm^{-1} and an observed sharp silylated alkyne ν(C≡C) at 2159 cm^{-1} is consistent with a Si–alkynyl surface and not simple physisorption. For instance, the ν(C≡C) of 1-phenyl-2-(trimethylsilyl)acetylene appears at 2160 cm^{-1} while that of phenylacetylene is observed at 2110 cm^{-1}. Similarly, CEG of dodec-1-yne (surface **2**, Fig. SM1†) shows a ν(C≡C) at 2176 cm^{-1}, which is identical to the silylated molecular analogue 1-trimethylsilyldodec-1-yne at 2176 cm^{-1}; underivitized dodec-1-yne appears at 2120 cm^{-1}. Fig. 1(*a*) shows the pentynyl terminated surface (surface **3**) with the ν(C≡C) at 2179 cm^{-1}. This surface was hydroborated with a 0.5 M THF solution of disiamylborane[10] to verify the presence of the silylated triple bond. The appearance of a broad band at 1580 cm^{-1} and the concomitant consumption of the ν(C≡C) is indicative of a silylated, borylated double bond, which was verified by hydroboration of 1-trimethylsilyldodec-1-yne and subsequent FTIR analysis [ν(C=C) at 1584 cm^{-1}].

Covalent electrografting of alkynes also appears to occur when an anodic potential is applied, although AEG surfaces show complete reduction of all unsaturated bonds. The C≡C triple bond is not observed, with only a weak vibration corresponding to a hydrosilylated double bond mode (1600 cm^{-1}) in the FTIR spectra. In contrast to CEG, AEG of dodec-1-yne [surface **8**, Fig. 1(*b*)] has features relating only to aliphatic C–H bonds. In the spectrum of phenylacetylene AEG (surface **9**, Fig. SM8†), ring breathing modes at 1599, 1493 and 1446 cm^{-1} compare closely with polystyrene films and differ from those observed for the conjugated CEG surface **1** at 1596, 1489 and 1443 cm^{-1}. Boiling of the surfaces functionalized through AEG for 30 min in $CHCl_3$ results in no change in the FTIR spectrum, suggesting covalent bonding as opposed to physisorption. Based on the coincidence of the ring modes and the saturation of the C≡C bonds, we conclude that doubly hydrosilylated (bis-silylation) or possibly oligomeric material decorates the porous silicon surface (*vide infra*).

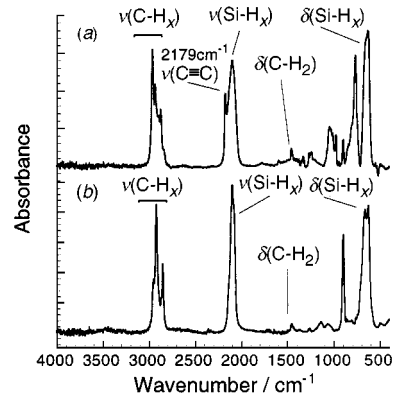


Fig. 1 Transmission FTIR of derivatized porous silicon: (*a*) CEG of pent-1-yne (surface **3**). (*b*) AEG of dodec-1-yne (surface **8**).

Photoluminescence (PL) spectra of CEG samples show varying intensities depending on the surface type (Fig. 2). Surfaces **2**–**4** (alkynyl groups) retain between *ca.* 5–15% of the light emission, with a small red shift of *ca.* 10 nm relative to freshly prepared porous silicon (λ_{max} = 663 nm). The phenethynyl surface **1** and other arynyl terminated surfaces (surfaces **5** and **6**) show no light emission whatsoever, as has been observed by Song and Sailor previously.[5a] Similarly, diphenylphosphinoethynyl surface **7** exhibits complete PL quenching as well. AEG samples have more intense PL, with *ca.*

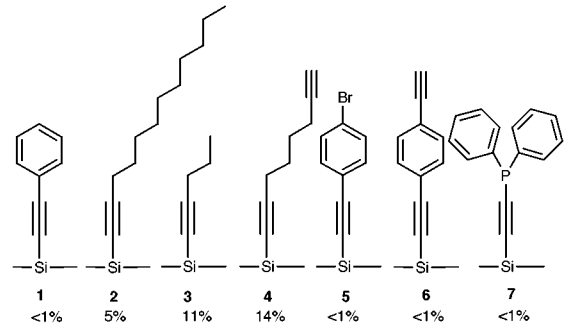

Fig. 2 Representative surfaces prepared by CEG of alkynes to porous silicon. The bold numbers refer to the numbering system in the text, and the % values represent the % photoluminescence (PL) remaining after functionalization through CEG.

† Electronic supplementary information (ESI) available. Further details concerning preparation of porous silicon and CEG, PL studies, and FTIR spectra for all surfaces reported here (**1**–**10**) and for the product of hydroboration of 1-trimethylsilyldodec-1-yne (http://www.rsc.org/suppdata/cc/1999/2479/

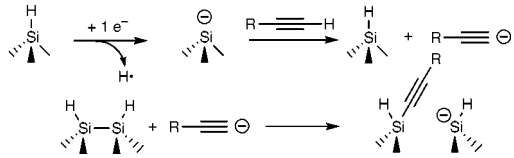

Fig. 3 Proposed mechanism for the CEG of alkynes to porous silicon. Cathodic reduction of a surface Si–H group forms the active silyl anion which initiates the reaction.

20% remaining for the alkyl protected surface **9** as compared to the freshly etched hydride terminated surface.

Stability tests using boiling aqueous NaOH solution (pH 10) demonstrate the chemical resistance of AEG and CEG samples compared to unfunctionalized porous silicon. Unmodified surfaces are destroyed under such conditions in *ca.* 180 s,[3c] whilst the CEG functionalized samples remain essentially unchanged after 10 min except for an increase in the ν(Si–O) mode at 1050 cm^{-1}. Extended treatment with ethanolic HF solution also results in no change in FTIR spectra. The combined stability with respect to both HF and alkaline treatment is known only for Si systems with covalently attached organic layers.[2b–d,11]

We believe the CEG reaction proceeds *via* a silyl anion intermediate formed by reduction of surface Si–H bonds in a space charge layer (Fig. 3) to yield either H$^{\bullet}$ or, 1/2 H_2. The silyl anion species has been previously inferred for the mechanism of alkyl halide grafting.[8,12] The subsequent *in situ* generation of a carbanion from deprotonation of the weakly acidic alkyne leads directly to nucleophilic Si–Si bond attack, as observed by previous workers.[5,6,8] The silyl anion is quenched in the presence of a proton source (0.1 M HCl in diethyl ether), leading to no incorporation of alkyne. Other weakly acidic moieties can be grafted *via* this CEG reaction, such as dodecane-1-thiol (surface **10**, Fig. SM11†), presumably through a similar deprotonation step and subsequent attack of Si–Si bonds by an RS^- species. Minor incorporation of butyl groups (2956, 2923 and 2872 cm^{-1}), which may be due to tenacious physisorption or electrochemical decomposition of the NBu_4PF_6 electrolyte,[13] is observed in all CEG reactions. The butyl groups are not removed after 30 min in boiling chloroform.

Given the observations noted in FTIR of surfaces **8** and **9** (*vide supra*), it is likely that a surface-initiated cationic hydrosilylation mechanism[12,14] is responsible for the Si–C bond formation in AEG reactions (Fig. 4). Positive charges are stabilized in the depletion layer at the semiconductor–electrolyte interface,[15] which are attacked by alkyne monomers. This can then be the starting point for a successive hydrosilylation or cationic polymerization reaction.[16]

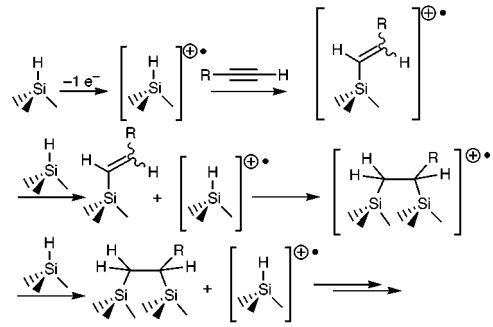

Fig. 4 Proposed mechanism for the AEG of alkynes to porous silicon. Anodic oxidation of a surface Si–H group results in formation of the active cationic silyl species.

In conclusion, a technique in which alkylation and alkynylation of porous silicon surfaces can be accomplished through CEG and AEG is reported. Future work concerns the further elucidation of the mechanisms *via* investigations using new electrolyte systems and alkynes, and the application of new experimental apparatus.

Molecular imprinting with an organometallic transition state analogue

Kurt Polborn and Kay Severin*

Institut für Anorganische Chemie, Ludwig-Maximilians-Universität, D-81377 München, Germany. E-mail: kse@cup.uni-muenchen.de

Received (in Basel, Switzerland) 3rd October 1999, Accepted 3rd November 1999

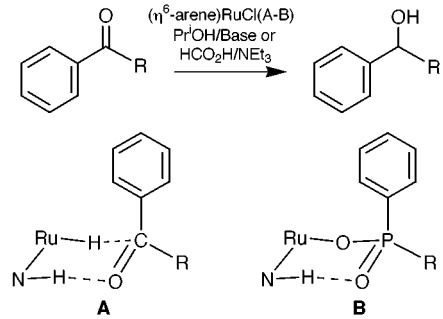
The microenvironment, and thus the activity and selectivity of an immobilised ruthenium catalyst, was modified in a controlled way using a transition state analogue as the catalyst precursor in combination with an imprinting technique.

Molecular recognition between enzymes and substrates, as well as subsequent catalytic transformation, is largely controlled by precisely positioned functional groups within cavities formed by the protein. The implementation of such cavities into artificial, biomimetic catalysts is one of the major challenges in this field. Current approaches are often based on organic host molecules (*e.g.* cyclodextrins) covalently attached to catalytically active groups but the synthetic effort required for the construction of such systems is generally substantial.[1] Alternatively, materials with cavities of molecular dimensions can be obtained by imprinting techniques.[2] Here, polymeric materials are generated in the presence of template molecules, removal of which creates cavities with complementary shapes. Several groups have tried to utilise this technology for the synthesis of catalytically active polymers using transition state analogues as templates but the observed activities were generally modest.[2] Recently, a very nice example of a synthetic esterase which shows a rate enhancement of 10^2 was reported by Wulff *et al.*[3] Nevertheless these values are several orders of magnitude lower than those observed for natural enzymes. Our goal is to produce *highly active* and *selective* enzyme mimics by combining the power of organometallic catalysts with the methodology of molecular imprinting.[4] Preliminary results are reported below.

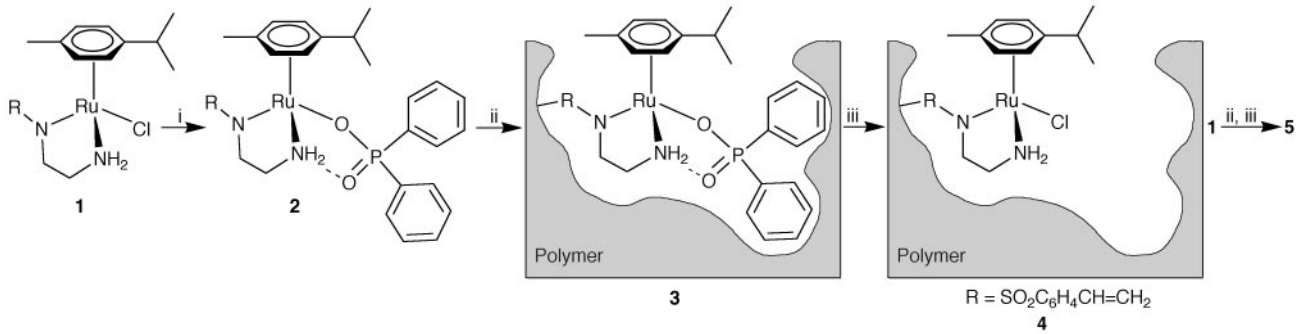
The transfer hydrogenation of aromatic ketones catalysed by ruthenium half-sandwich complexes has recently received much attention since with certain chiral amine-based ligands excellent enantioselectivities were obtained.[5] In these reactions propan-2-ol or formic acid serves as the hydrogen source (Scheme 1). In accordance with all experimental results a six-membered cyclic transition structure **A** was suggested for transformations of this kind.[5b] To imitate this structure with a coordinatively fixed pseudo-substrate we propose phosphinato complexes of the general formula **B** as organometallic transition state analogues (TSA). Our strategy for using such a TSA for the generation of an immobilised catalyst with a form-selective cavity in proximity to the catalytic centre is summarised in Scheme 2. A ruthenium complex **1** with a styrene side chain is synthesised from $[(\eta^6\text{-cymene})RuCl_2]_2$ and the respective amine ligand[6] in the presence of NaOMe (Ru:ligand:base = 1:2:2). The chloride ligand is then substituted with a diphenylphosphinato ligand to give complex **2** in good yield. The anticipated structure with a monodentate phosphinato ligand which shows a hydrogen bond to the amine group of the coligand was confirmed by the results of a single crystal X-ray analysis (Fig. 1).† To the best of our knowledge this complex represents the first structurally characterised organometallic TSA.[7] Complex **2** is copolymerised with ethylene glycol dimethacrylate (Ru:EGDMA = 1:99) in the presence of a porogen (chloroform) to give the highly crosslinked jet porous polymer **3**.[8] To initiate the reaction we employed 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) (V-70) which allows the polymerisation to be carried out under very mild conditions.[9]

The polymer was ground and wet-sieved to obtain uniform particle sizes of between 25 and 100 μm. The phosphinato ligand was selectively cleaved off using a solution of $BnNEt_3Cl$ in methanol (0.1 M) to give polymer **4** containing a ruthenium chloro complex.[10] The polymer was finally washed with methanol and dried *in vacuo*. To determine the influence of the cavity generated this way we made the polymer **5** using complex **1** instead of the TSA **2** following an otherwise identical protocol.

When tested for their ability to catalyse the reduction of benzophenone both polymers displayed a high activity indicating good incorporation and accessibility of the ruthenium



Scheme 1 Transfer hydrogenation of aromatic ketones catalysed by ruthenium half-sandwich complexes (A–B represents an anionic chelate ligand). The proposed transition structure **A** is mimicked by the phosphinato complex **B**.



Scheme 2 *Reagents and conditions*: i, AgO_2PPh_2, CH_2Cl_2, room temp., 96 h; ii, EGDMA, $CHCl_3$ (Ru:$CHCl_3$:EGDMA = 1:100:99), V-70 (1.5%), 35 °C, 20 h; then 65 °C, 4 h; iii, $[BnNEt_3]Cl$ in MeOH (0.1 M).

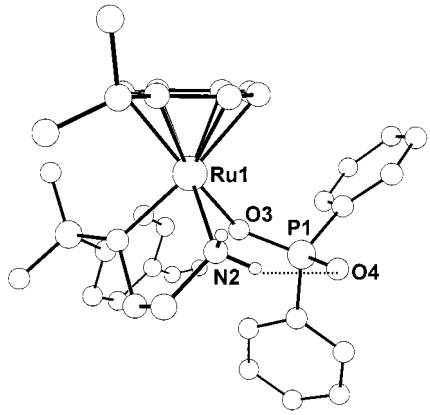


Fig. 1 The molecular structure of **2** in the crystal (most hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°): Ru(1)–N(2) 2.135(3), Ru(1)–O(3) 2.155(3), P(1)–O(4) 1.499(3), P(1)–O(3) 1.518(3), N(2)–O(4) 2.972(3); N(2)–Ru(1)–O(3) 82.81(12), O(4)–P(1)–O(3) 116.5(2), P(1)–O(3)–Ru(1) 131.9(2).

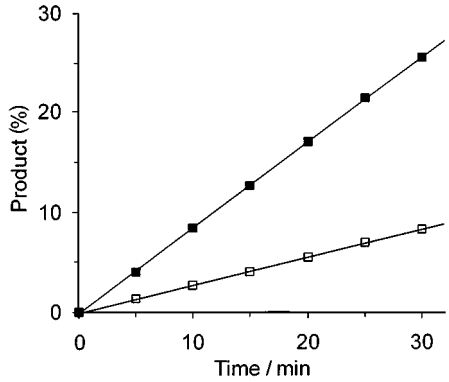

Fig. 2 Product formation as a function of time for reactions carried out at 70 °C with 500 μl of azeotropic HCO_2H/NEt_3, 500 μl of MeCN, 100 μmol of benzophenone and 1 μmol of catalyst **4** (■) or catalyst **5** (□), respectively. To calculate the amount of catalyst, a quantitative incorporation of complex **1** and **2** into the polymer was assumed. Every 5 min a sample of 100 μl was removed from the reaction vessel, quenched with $MeCN/MeCO_2H$ (3:1), filtered and analysed by capillary GC. The data represent averaged values from two independent experiments; the errors are < 0.2 %.

complexes. To quantify the activity the initial turnover frequencies (TOF) were determined. The experiments revealed that the molecularly imprinted polymer (MIP) **4** was significantly more active than polymer **5** [TOF(**4**) = 51.4 h^{-1}, TOF(**5**) = 16.5 h^{-1}, Fig. 2]. The rate enhancement of greater than a factor of three is remarkable considering that both polymers contain the same amount of ruthenium complexes having an identical first coordination sphere.

The MIP-catalyst **4** was also expected to display an increased selectivity for benzophenone, the substrate which was imitated during the polymerisation process by the pseudo-substrate diphenylphosphinate. We therefore performed a series of competition experiments with equimolar amounts of benzophenone and a cosubstrate, chosen to differ in size, shape and reactivity. The selectivity was determined comparing the initial rates of product formation (Table 1). In all cases catalyst **4** showed a substantially higher specificity for benzophenone than the control catalyst **5**. The relative increase in selectivity was slightly larger for aliphatic ketones (entries 1–3) as compared to aromatic ketones (entries 4–6).

These results show that the activity and selectivity of an immobilised catalyst can be enhanced using organometallic TSAs as templates in combination with an imprinting technique. Currently we are trying to apply this methodology to other catalytic transformations including enantioselective reactions. Further results will be reported in due course.

Table 1 Substrate-selectivity of the MIP-catalyst **4** and the control polymer **5**

		Selectivity[b]	
Entry[a]	Cosubstrate	**4**	**5**
1	2-Norbornanone	4.3	2.2
2	2-Adamantanone	4.9	2.5
3	Cyclohexyl methyl ketone	14.2	7.4
4	Acetophenone	2.8	1.8
5	α-Tetralone	3.8	2.2
6	Phenyl isopropyl ketone	20.6	13.8

[a] The reactions were carried out with 50 μmol of benzophenone, 50 μmol of the cosubstrate and 1 μmol of the respective catalyst. [b] The selectivity was calculated by dividing the initial rate of diphenylmethanol formation by the initial rate of product formation for the reduction of the cosubstrate. For norborneol the sum of isomers was used.

K. S. thanks Professor Dr W. Beck for his generous support and B. Grosch and E. Karaghiosoff for technical assistance. Financial funding from the Bayerischer Habilitations-Förderpreis (K. S.) is gratefully acknowledged.

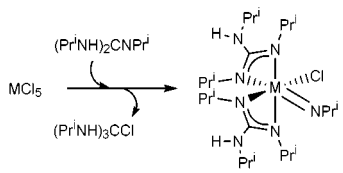
Received (in Bloomington, IN, USA) 27th August 1999, Accepted 15th October 1999

***N,N′,N″*–tri(isopropyl)guanidinate complexes of M(v) (M = Nb, Ta) bearing imido ligands represent unique examples of monoanionic and dianionic guanidinate complexes of these metals; single crystal X-ray analyses for two of the latter species, {[μ-(NPr^i)$_3$C]$_2$TaMe(NPr^i)}(Mg$_2$Cl$_2$)·4C$_6$D$_6$ and {(μ-η^2:η^2 (Pr^{i}N)$_3$C)Ta(NPr^i)Cl}$_2$, exhibit unusual bonding modes involving all of the nitrogen centers of the ligand.**

Guanidinate anions have received surprisingly limited attention as supporting ligands for metal complexes in comparison with isoelectronic amidinate species.[1] This omission is particularly conspicuous with electrophilic main group and early transition metals where amidinate complexes have displayed an exceptionally rich and varied organometallic and inorganic chemistry.[2,3] Guanidinates should certainly possess the same versatility and flexibility in coordination properties that have been exhibited by amidinates. Moreover, the presence of a third nitrogen center, which can bear either one or two organic substituents provides an additional coordination site within the ligand and the added capability of yielding dianionic species. This aspect offers bonding motifs that are not possible for the related amidinate systems.

Employing *N,N′,N″*-trialkylguanidines as ligands requires the development of fundamental ideas regarding the introduction of guanidinate anions and dianions into a metal coordination sphere, the definition of features that favor different binding modes of the ligand, and investigation of the general reactivity characteristics of these complexes. Reported preparative routes to trialkylguanidiante complexes include the elimination of HX (X = Cl, Br) from halo metal complexes,[4] elimination of H_2 from metal hydrides,[5] elimination of alkane from a metal alkyl,[6] and elimination of amine from a metal amido complex.[7,8] Examples of a dianionic guanidinate complexes include [(OC)$_3$Fe{μ-η^2(RN)$_2$CNR}Fe(CO)$_3$] (R = Pr^i or Cy),[9] (cod)Pt[C(NPh)$_3$][10] and the main group species, Li$_2$[C(NPh)$_3$],[11] Li$_2$[C(NBu^t)$_3$],[12] and Sb[(Pr^{i}N)$_2$CNHPr^i][(Pr^{i}N)$_3$C].[8] We wish to expand upon the procedures for introducing guanidinate ligands and to find general methods for the generation of dianionic guanidinate ligands.

The room temp. reaction of MCl_5 (M = Ta, Nb) with *N,N′,N″*-tri(isopropyl)guanidine lead to direct formation of MCl(NPr^i)[(NPr^i)$_2$C(NHPr^i)]$_2$ (M = Ta **1**; M = Nb **2**) after separation of guanidinium hydrochloride from the reaction mixture [eqn. (1)].† Reproducible yields in the range 30–40%



(1)

can be obtained from this procedure using spectroscopically (^{1}H, ^{13}C NMR) and analytically pure tri(isopropyl)guanidine. On the basis of these observations it seems clear that the imido function must arise from cleavage of the parent guanidine, the mechanism of this transformation is currently under investigation.[13,14] In contrast, reaction of M(NMe$_2$)$_5$ with guanidine yields only [(Pr^{i}N)$_3$C]M(NMe$_2$)$_3$ a species which possessed a single dianionic guanidinate ligand.[8]

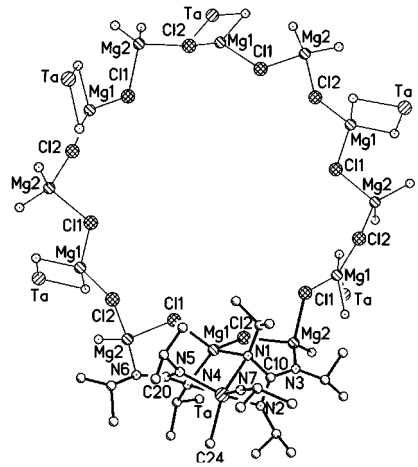


Fig. 1 Molecular structure of **3** showing a labeled asymmetric unit and the aggregation described in the text. Within the asymmetric unit, hydrogen atoms and benzene molecules of crystallization have been omitted for clarity. All atoms atoms have been refined anisotropically.

With only one equivalent of MeMgX (X = Cl, Br), complex **1** only undergoes halogen exchange. However, employing two equivalents or more readily generated alkyl complex **3**.[15] Owing to the likelihood that our synthetic procedure had generated a dianionic guanidinate ligand we performed an X-ray analysis of **3** with the results shown in Fig. 1.‡ Complex **3** exhibits a Ta center in a pseudo-octahedral environment with two dianionic chelating bidentate guanidinate ligands, one Me group and an imido function. The two guanidinate ligands span axial/equatorial sites and the bonding features within the {[(NPr^i)$_3$C]$_2$TaMe(NPr^i)}$^{2-}$ fragment are reminiscent of the reported bis(amidinate)Nb(O)Cl and the bis(guanidinate) complexes **1** and **2**.†[16] Charge balance for this fragment and completion of the asymmetric unit is provided by an (Mg$_2$Cl$_2$)$^{2+}$ cation which is coordinated to the guanidinate ligands.

Both guanidinate ligands form planar cycles with the Ta(v) center and exhibit similar bonding parameters. Within the guanidinate CN_3 cores the central C is planar as are the N atoms [N(2), N(5)] that coordinate exclusively to Ta. The C=N bond appears to be localized between these three coordinate N atoms with the longest C–N bonds observed for the four coordinate N centers [N(1), N(4)] which interact with one of the Mg^{2+} cations. The isopropyl imido linkage is similar to that observed in **1** and **2** and in **4** reported below. The *trans* influence of the imido ligand is manifest in the elongation of Ta–N(4) bond relative to Ta–N(1) [2.486(7) *cf.* 2.365(7) Å].

The two Mg centers within the asymmetric unit possess different coordination environments with Mg(1) being coordinated to the two *cis*-oriented N atoms [N(1), N(4)], and to Cl(1) and Cl(2) to give a pseudo-tetrahedral coordination sphere while Mg(2) is coordinated only to N(6) and Cl(1) within the asymmetric unit. Bridging interactions of Mg(2) to N(3) and

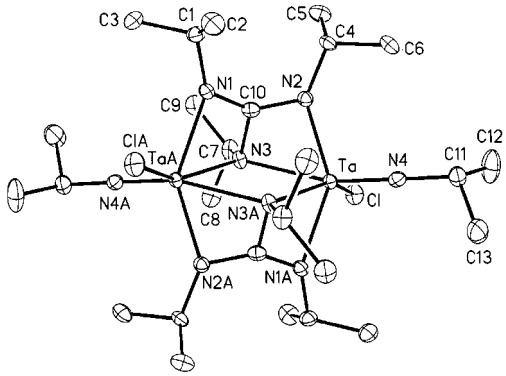

Fig. 2 Molecular structure of **4**. Hydrogen atoms have been omitted for clarity.

Cl(2) of an adjacent unit complete the coordination sphere of this center and result in a supramolecular aggregation of these subunits. This assemblage of complexes propagated through the bridging interactions of Mg(2) generates a macrocyclic ring of six subunits with a diameter of 12.1 Å which is colinear with a crystallographic 6 axis as shown in Fig. 1. The void space left in the center of this cyclic arrangement is occupied in this case with four benzene molecules of crystallization.

The ^{1}H and ^{13}C NMR spectra of **3** provide a probe of the solution behavior of this species. Based on the similarity of these spectra to those of complexes **1** and **2**, it appears that the intermolecular interactions exhibited by the observed static structure of **3** are not maintained in solution.

Reaction of metal halides with a lithium guanidinate, Li{(Pr^iN)$_2$CN(H)Pr^i}, offers an alternative metathetical route for introduction of guanidinate anions. From the reaction between *in situ* generated monolithium guanidinate and $TaCl_5$, complex **4** was isolated.† The complexity of the NMR spectra for this reproducibly obtained product prompted us to investigate **4** by X-ray crystallography. The results are summarized in Fig. 2.‡

Complex **4** is a dinuclear species possessing two bridging dianionic tri(isopropyl)guanidinate ligands each exhibiting a previously unknown chelating bridging coordination mode in which two of the nitrogen atoms [N(1), N(2)] bond to one Ta center and the third [N(3)] bridges the two metal centers. The coordination geometry of each Ta center can be described as distorted octahedral with the overall geometry of **4** being an edge-sharing bioctahedral polyhedron. An inversion center relates the two halves of the molecule. The individual Ta centers are in geometries reminiscent of the other bis(guanidinate) complexes reported herein. For example, within the asymmetric unit the metrical parameters of the guanidinate ligand are similar to those observed in **3**, *i.e.* the ligand spans axial equatorial sites with a bite angle [N(2)–Ta–N(3)] of 60.83(16)º. The central C atom of the guanidinate CN_3 core is planar. Furthermore N(1) and N(2) exhibit very similar geometric parameters and are nearly planar [Σ N(1) = Σ N(2) = 357º]. In contrast, the bridging N atom [N(3)] is distorted tetrahedral with the six defining angles ranging from 81.7(3) to 125.5(3)º (av. = 107º). The C=N double bond of the dianionic ligand appears to be delocalized between C(10)–N(1) and C(10)–N(2) as reflected by bond distances. As in **1**–**3**, the Ta coordination sphere is completed by an isopropyl imido function and a chloride ligand [Cl(1)] remaining from the starting material.

The mechanism of formation for **4** is still under scrutiny. Attempts to employ the dianionic form of tri(isopropyl)guanidinate, in what would appear to be a more direct pathway to **4**, also yield **4** but in a lower yield.

In the case of **4**, both ^{1}H and ^{13}C NMR data confirm that the observed structure remains intact upon dissolution in organic solvents. For example each of the isopropyl CH_3 signals appears as a distinct doublet. While the isopropyl(imido) function appears to exhibit equivalent methyl groups in the ^{1}H NMR, these CH_3 groups are distinguishable in the ^{13}C NMR spectra.

Our continuing efforts are directed toward the further development of these complexes and of guanidinate ligands with the specific goals of understanding the details that dictate the formation of mono- *vs.* dianionic ligands. Furthermore, we are interested in understanding the features that govern the intra- and inter-molecular interactions exhibited by these ligands.

This work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC).

Direct synthesis of acetylene from methane by direct current pulse discharge

Shigeru Kado,* Yasushi Sekine and Kaoru Fujimoto

Department of Applied Chemistry, School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: tt97208@mail.ecc.u-tokyo.ac.jp

Received (in Cambridge, UK) 25th September 1999, Accepted 1st November 1999

In non-catalytic direct conversion of methane to acetylene by using direct current pulse discharge under conditions of ambient temperature and atmospheric pressure, the selectivity of acetylene from methane was >95% at methane conversion ranging from 16 to 52%; coexisting oxygen was very effective in removing deposited carbon and stabilized the state of discharge.

Methane, which is a major constituent of natural gas, is so stable that high reaction temperatures such as 1273 K or higher are required for its pyrolysis to ethylene or acetylene.[1] Although high reaction temperature is favorable for high conversion, higher temperature promotes the consecutive decomposition of the products to carbon.[1,2] Recently, direct conversion of methane to higher hydrocarbons using plasma technology has been studied to improve the selectivity and yield of the desired products.[3–8] For example, in microwave plasma reaction, acetylene was produced with a selectivity of >90% from methane at as low a reaction pressure as 4.5 kPa.[6] The plasma catalytic conversion of methane by using dc corona discharge was also found to produce acetylene with high selectivity and yield under atmospheric pressure in the temperature range 343–773 K. The nature of the catalyst surface in contact with the plasma was very important for homogeneous activation of methane and NaY zeolite gave the highest yields of C_2 hydrocarbons. The highest yield of C_2 hydrocarbons (32%) was obtained in a hydrogen-containing plasma at a flow rate of 10 cm^3 min^{-1}.[7] In this study, dc pulse discharge was applied to non-catalytic direct conversion of methane at ambient temperature and under atmospheric pressure to prepare C_2 hydrocarbons selectively, with high methane conversion.

A flow type reaction apparatus which was composed of a Pyrex glass tube of 4.0 mm internal diameter was used as the reactor. Reactant gas which was premixed at a given ratio was fed at a constant flow rate. Stainless steel electrodes of 2 mm diameter were inserted from each end of the reactor as shown in Fig. 1 and the distance between the electrodes was 1.5 mm. A dc pulse discharge was initiated by supplying a negative high voltage with a dc power generator. The wave signal was observed by a digital oscilloscope and the pulse duration was *ca.* 10 ms. All the reactions were conducted at atmospheric pressure and ambient temperature without any catalyst and all products were analyzed by gas chromatography. Product selectivity was defined as follows; selectivity (%) = yield of the product (Carbon mmol)/sum of all the products (Carbon mmol) × 100.

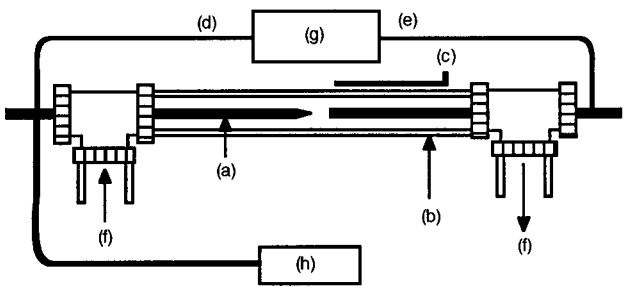

Fig. 1 Schematic diagram of the reactor. (a) 2.0 mm diameter stainless steel electrode, (b) 4.6 mm internal diameter quartz tube, (c) thermocouple, (d) negative high voltage, (e) ground, (f) direction of the flow gas, (g) direct current high voltage power supply, (h) digital oscilloscope.

Upon dc pulse discharge, methane was activated readily to form acetylene with a selectivity of >90% in the absence of catalyst. Fig. 2 shows methane conversion, yield of C_2 hydrocarbons and selectivity of acetylene, ethylene and ethane *vs.* supplied power. While methane conversion increased up to 52% by the increasing power supply, acetylene selectivity was very stable at *ca.* 95%. Applying a discharge for methane activation thus led to the selective formation of acetylene with high C_2 yield and stable selectivity, not observed in conventional homogenous gas phase reactions. Other hydrocarbon products such as prop-1-yne and buta-1,3-diyne were at <1%. Some carbon deposition occurred on both electrodes and the reactor wall during the reaction and eventually resulted in unstable discharge and sometimes in cessation.

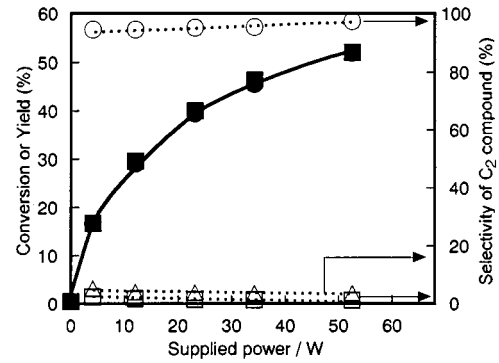

Fig. 2 Effect of supplied power on conversion and selectivity. Reaction conditions: pure methane, 10 cm^3 min^{-1} (NTP) flow rate, ambient temperature, 0.1 MPa, 1.5 mm electrode distance, (■) methane conv., (●) C_2 yield, (○) acetylene selectivity, (△) ethylene selectivity, (□) ethane selectivity.

In order to prevent carbon deposition during discharge, O_2 and Ar were added to give a resultant feed gas composition CH_4–O_2–Ar = 5 : 1 : 4. Reaction results under a flow of 10 cm^3 min^{-1} at normal temperature and pressure (NTP) and 25 W power supply are given in Table 1. Carbon monoxide was produced as well as carbon dioxide (selectivity <1% to CO_2), in addition to C_2 compounds. Comparing results with those of the reaction with pure methane, there was little difference in C_2 yield, which indicates that the increased methane conversion was essentially due to the carbon monoxide formed. Additionally, the composition of C_2 compounds was not much affected. In the reaction using pure methane, the C_2 yield was 40.6% and the amount of acetylene in the C_2 products was 94.4%, while the reaction in the presence of O_2 gave 91% acetylene selectivity in terms of non-CO/CO_2 carbon products with yields of C_2 compounds and CO of 38 and 20%, respectively. These results suggest that the precursor of the deposited carbon is converted to carbon monoxide by reaction with oxygen. Also the reaction in the presence of O_2 led to stable discharge.

The effect of total flow rate (from 3 to 225 cm^3 min^{-1} in the presence of O_2) with a supplied power of *ca.* 25 W is also shown in Table 1. Methane and oxygen conversion was remarkably

Table 1 Effect of coexisting oxygen and total flow rate[a]

Feed gas	Flow rate (NTP)/ $cm^3\ min^{-1}$	Conv. (%)		Yield (%)		Selectivity (%)	
		CH_4	O_2	C_2	CO	C_2H_2	CO
CH_4	10	40.6	—	39.9	—	94.4	—
CH_4–O_2–Ar (5:1:4)	3	83.9	100.0	49.6	33.8	56.2	40.3
CH_4–O_2–Ar (5:1:4)	10	58.9	69.9	38.1	20.2	58.9	33.8
CH_4–O_2–Ar (5:1:4)	225	6.8	9.7	4.9	1.9	62.3	27.9

[a] *Reaction conditions*: ambient temperature, 0.1 MPa, 1.5 mm electrode distance, 25 W supplied power.

affected by the total flow rate. At 3 $cm^3\ min^{-1}$ total flow rate, oxygen conversion reached 100% and methane conversion was 84%. On the other hand, the selectivity towards acetylene was scarcely affected while the C_2 yield increased to *ca*. 50%. The selectivity to carbon monoxide increased slightly as the total flow rate was decreased. If carbon monoxide was formed by a chain reaction, its selectivity should increase more drastically with decreasing flow rate. Thus, the behavior of carbon monoxide selectivity to the total flow rate indicated that carbon monoxide formation was separate from C_2 compound formation and derived from a coke precursor.

We also attempted to stabilize the discharge by using hydrogen as the coexisting gas, since using oxygen caused the formation of carbon monoxide which decreased the selectivity to C_2 compounds. The reaction results were much the same as for pure methane, and H_2 did not stabilize discharge as well as O_2. However, dilution of methane by hydrogen such that $CH_4:H_2 = 1:4$ was effective for stabilization of the discharge.

Table 2 shows methane conversion, C_2 yield and selectivities to each C_2 compound at various H_2 concentrations from 0 to 90%. Up to 50% hydrogen concentration, a marked effect of H_2 was not observed. However as the hydrogen concentration was increased, methane conversion and C_2 yield increased from 44% (pure methane) to 57% ($CH_4:H_2 = 1:2$). At 80% hydrogen concentration, methane conversion and acetylene selectivity decreased slightly, and selectivity towards ethane and ethylene increased. At conditions of > 80% hydrogen concentration, the excessive concentration of hydrogen interfered with electron attack on methane, leading to drastic reduction in methane conversion and to an increase in ethane selectivity.

Table 2 Effect of hydrogen concentration on conversion and selectivity[a]

H_2 concentration (%)	CH_4 conv. (%)	C_2 yield (%)	Selectivity (%)		
			C_2H_6	C_2H_4	C_2H_2
0	44.3	44.2	0.6	2.8	94.6
50	46.3	46.2	1.1	4.4	94.2
67	57.4	57.1	1.2	5.7	92.7
80	47.0	46.6	2.9	8.1	88.2
90	11.8	11.4	17.7	15.2	63.7

[a] *Reaction conditions*: 10 $cm^3\ min^{-1}$ (NTP) flow rate, ambient temperature, 0.1 MPa, 1.5 mm electrode distance, 4 mA dc.

In conclusion, when a dc pulse discharge was applied for methane activation, acetylene was produced directly and selectively. Oxygen removed deposited carbon by oxidation to form carbon monoxide, and stabilized the state of discharge. Dilution of methane with hydrogen up to 80% also stabilized the state of discharge without changing the product selectivity. We assume that the formation of acetylene is *via* dimerisation of CH radicals which form by dc discharge, and that the high selectivity to acetylene is a characteristic feature of short range pulse discharge.

Received (in Columbia, MO, USA) 7th June 1999, Accepted 7th October 1999

The interaction between the two viologen acceptors in a TEMPO-labeled Ru(II) bisviologen photosynthetic model system assembly has been investigated using EPR spectroscopy; the results are consistent with no viologen–viologen spin exchange in water at temperatures above 5 °C, although upon crystallization (≤2 °C) strong spin exchange is observed; the strong spin exchange interaction results in a single broad line at temperatures below 1 °C, unlike the three broad lines measured for free TEMPO upon solvent freezing; this evidence for the TEMPO-labeled complex indicates that there is no interaction of the two viologen acceptors in the supramolecular Ru(II) bis-viologen structure in solution, thus making it indeed a viable model for the photosynthetic reaction center.

A remarkable feature of the photosynthetic reaction center (RC) lies in its utilization of only one of the two nearly identical electron transfer (ET) pathways available from the excited state of the special pair to the Q_A and Q_B quinone acceptors.[1] A large number of covalently linked diads and triads of varying geometry and rigidity possessing excited state electron donors and electron acceptors have been explored as RC model assemblies.[2] These systems are generally aimed at solar energy conversion, and are therefore designed to attain a long lifetime of the charge separated state formed upon photoexcitation. Such *D–A, *D–A_1–A_2, and D–*D–A (*D = photoexcited donor, D = donor, A, A_1, A_2 = acceptors) structures are schematically shown in Fig. 1(a),[3] where in many cases *D is a Ru(II) diimine complex.[4] Although these supramolecular donor/acceptor systems have proven useful in the investigation of long-lived charge separation, only a few can be utilized in the modeling of the dual ET pathways found in the reaction center.[5] Such systems possess two chemically identical acceptors tethered to the donor, A–*D–A [Fig. 1(b)], thus providing a bifurcated pathway for the photoinduced electron transfer. One previously reported A–*D–A supramolecular assembly is of particular importance owing to the similarity in the spatial arrangement of the donor and acceptors compared to that in the RC. This system is of the type $[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{4+}$ (dmbpy = 4,4′-dimethyl-2,2′-bipyridine), where the structure of ligand di-V^{2+}-bpy in the complex is shown in Fig. 2(a) and possesses two linked 4,4′-dialkyl viologens.[6] A crucial criteria for the investigation of the charge transfer processes in this supramolecular complex is the assessment of the interaction between the two viologens, since a RC model system should not possess electron exchange between the two acceptors.

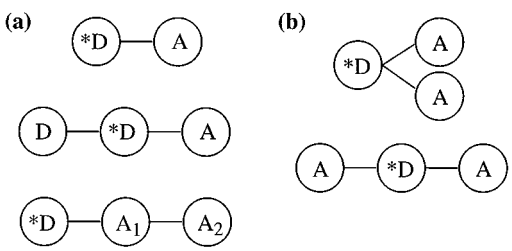

Fig. 1 Schematic representation of donor/acceptor (D/A) asseblies aimed at (a) long charge-separated states and (b) bifurcated ET pathway.

To investigate the interaction between the two viologens in the $[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{4+}$ complex we have synthesized the Ru(II) complex with a bis-TEMPO (TEMPO = 2,2′,6,6′-tetramethylpiperidine *N*-oxide) labeled ligand, di-(TEMPO-V^{2+})-bpy, shown in Fig. 2(b). The CW-EPR spectral features of the nitroxide radical in each TEMPO moiety are highly sensitive to dynamics, motion and distance from other radicals. This work presents EPR evidence against the interaction of the two acceptors in the $[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{6+}$ model complex.

The synthesis and characterization of [Ru(dmbpy)(di-TEMPO)-V^{2+})-bipy)]$^{6+}$ is given as ESI data.† Elemental analysis is consistent with the expected structure. Transient absorption measurements were conducted on an instrumental setup previously described.[7] The EPR instrument has been previously reported.[8]

As expected from the molar absorption coefficients of the Ru(II)–diimine MLCT (metal-to-ligand charge transfer) transitions and the TEMPO absorption in the visible region, the electronic absorption spectrum of the $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ complex is nearly identical to that of

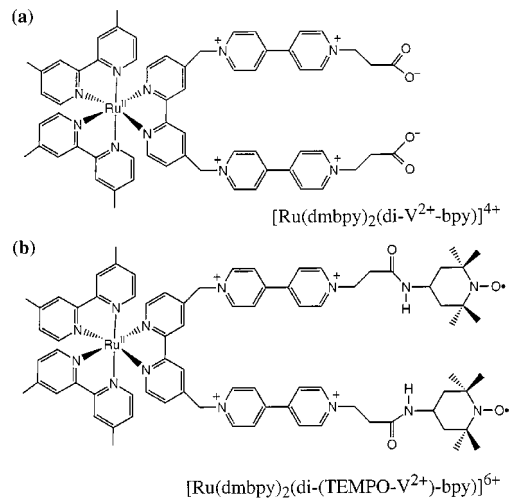

Fig. 2 Molecular structures of the photosynthetic model complex (a) $[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{6+}$ and (b) the bis-TEMPO labeled analog $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$.

Table 1 Comparison of the EPR fit parameters for doubly- and singly-TEMPO labeled complexes at 25 °C†

	τ_c/ps	g_{xx}	g_{yy}	g_{zz}	A_{xx}/G	A_{yy}/G	A_{zz}/G
$[Ru^{II}(phen)_2(TEMPO\text{-}phen)]^{2+}$ [a]	80	2.0097	2.0063	2.0035	6.8	7.5	37.3
$[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$	50	2.0090	2.0060	2.0030	7.0	7.0	36.5

[a] TEMPO-phen = 4-$(CH)_2OC(O)$N-(TEMPO)-1,10-phenanthroline, data from ref. 6.

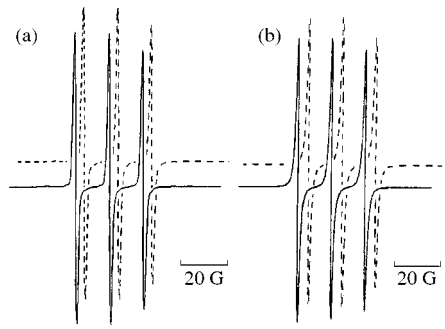

Fig. 3 EPR spectra (——) of 1×10^{-4} M $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ in water at (a) 30 and (b) 5 °C, with their respective computed spectra (– – – –).

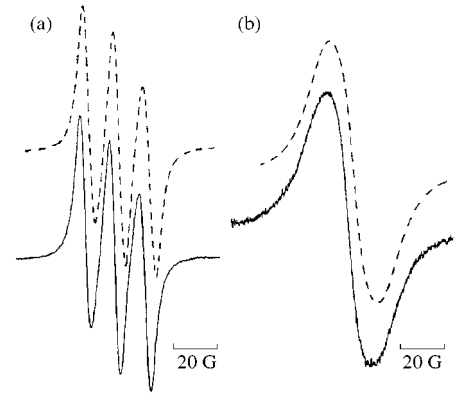

Fig. 4 EPR spectra (——) of 1×10^{-4} M $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ in water at (a) 1 and (b) −3 °C, with their respective computed spectra (– – – –).

$[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{4+}$. Both complexes are non-emissive in deoxygenated aqueous solution and possess similar excited state charge transfer characteristics. In the model complex $[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{4+}$, visible excitation leads to fast ET from the Ru(II) metal center to one of the viologens with risetime of *ca.* 1–2 ps (λ_{exc} = 450 nm, FWHM *ca.* 200 fs).[9] A typical lifetime of the charge separated state, τ_{CS}, of *ca.* 250 ± 20 ns was determined from fits of the monoexponential decay of photoexcited solutions of 5.0×10^{-5} M $[Ru^{II}(dmbpy)_2(di\text{-}V^{2+}\text{-}bpy)]^{4+}$ (λ_{exc} = 532 nm, FWHM *ca.* 4 ns), where the transient absorption of $MV^{\cdot+}$ was monitored at 610 nm. To ensure that the TEMPO-labeling of the complex did not lead to different ET dynamics, the same experiments were performed on $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$, which indicate that within experimental error the risetime and lifetime of the charge separated state are identical. Furthermore, reduction of the TEMPO radicals in $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ complexes was not observed by UV-VIS absorption and HPLC measurements.

Solution CW-EPR measurements of $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ in water were conducted at temperatures ranging from 5 to 30 °C. Selected spectra (5 and 30 °C) are shown in Fig. 3 along with the simulation traces for each experiment.† Throughout this temperature range no spectral broadening was observed at low concentration (< 1 mM), indicative of no interaction between the two TEMPO units within each complex. The solution spectra collected for 1.0×10^{-4} M $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ are similar to those measured for singly TEMPO-labeled Ru(II) complexes. The correlation time for motion, *g*-values, and isotropic hyperfine coupling constants for $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ and a related singly labeled Ru(II) complex are listed in Table 1 from which it is clear that all the parameters for both the singly- and doubly-TEMPO labeled complexes are nearly identical, indicating that the presence of the second TEMPO in the molecule does not affect the motion or magnetic features. In addition, for $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ the correlation time for motion, τ_c, increases as the temperature is lowered, consistent with slower motion at lower temperatures.

Cooling the sample below 2 °C results in the formation of red crystals, prior to solvent freezing at *ca.* 0 °C. The EPR spectra of $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ at 1 °C and −3 °C are shown in Fig. 4. For free TEMPO and most of its derivatives, lowering the temperature below the freezing of the solvent point results in broadening of all three individual lines without the occurrence of exchange broadening, which appears as a single broad line.[10] The observed spectra shown in Fig. 4 are consistent with increased exchange frequency, W_{ex}, as the temperature is lowered with W_{ex} values of 1.0×10^8 and 2.7×10^8 s^{-1} at 1 and −3 °C, respectively. The increased spin exchange between the two viologen units of $[Ru^{II}(dmbpy)_2(di\text{-}(TEMPO\text{-}V^{2+})\text{-}bpy)]^{6+}$ is only observed upon the formation of crystals (below 2 °C), but not when free in solution. It may be concluded from these observations that only in the crystalline form are the two viologen chains able to interact with each other or with TEMPO units of neighboring complexes within the close-packed lattice.

Synthesis and characterisation of a framework microporous stannosilicate

Z. Lin, J. Rocha* and A. Valente

Department of Chemistry, University of Aveiro, 3810 Aveiro, Portugal. E-mail: ROCHA@DQ.UA.PT

Received (in Cambridge, UK) 11th October 1999, Accepted 5th November 1999

The synthesis and structural characterisation of AV-6, a microporous framework stannosilicate with the structure of the mineral umbite, are reported.

Presently, the synthesis of inorganic microporous framework solids possessing structures which consist of interlinked octahedra and tetrahedra is raising considerable interest. We have been particularly concerned with the chemistry of microporous titanium silicates containing tetracoordinated Si^{4+} and Ti^{4+} usually in octahedral coordination.[1,2]

Several minerals containing SnO_6 and SiO_4 polyhedra are known and a few (dense) stannosilicate phases have been crystallised from high-temperature conditions.[3] Two microporous and a layered stannosilicate have been reported by Corcoran and Vaughan.[3] Subsequently, Dyer and Jáfar reported the synthesis of a third microporous stannosilicate.[4] The structure of all these materials is, however, unknown. Here, we report the synthesis of a synthetic stannosilicate (AV-6, Aveiro microporous solid no. 6) which possesses the structure of the rare mineral umbite ($K_2ZrSi_3O_9{\cdot}H_2O$).[2,5]

In a typical AV-6 synthesis an alkaline solution was prepared by dissolving 3.47 g of precipitated silica (BDH), 7.60 g KOH (85%, Aldrich) and 2.45 g KF (Aldrich) in 17.33 g H_2O. 5.84 g $SnCl_4{\cdot}5H_2O$ (98%, Riedel-deHaën) were added to the alkaline solution and stirred thoroughly. This gel, with a molar composition 4.82 K_2O:3.54 SiO_2:1.00 SnO_2:64 H_2O, was transferred to a Teflon-lined autoclave and treated at 230 °C for three days under autogenous pressure without agitation. The crystalline product was filtered off, washed at room temperature with distilled water and dried at 70 °C overnight, the final product being an off-white microcrystalline powder (crystallite size 0.2–0.3 μm). Chemical analysis (EDS) gave Si/Sn and K/Sn molar ratios of 2.8–3.1 (different crystal clusters) and 2.0–2.1, respectively.

AV-6 samples were characterised by chemical analysis (EDS), powder X-ray diffraction (XRD), scanning electron microscopy (SEM), ^{29}Si and ^{119}Sn solid state NMR spectroscopy, thermogravimetry and adsorption measurements (water and nitrogen).

In the structure of umbite and AV-6 (Fig. 1) the M octahedra $(Zr,Sn)O_6$, and the T tetrahedra, SiO_4, form a three-dimensional MT-condensed framework.[5] The M octahedra are coordinated by six T. In addition to the M–O–T bonds these tetrahedra also form T–O–T links with each other. Among all the known silicates and their T analogues, the umbite structure seems to be the first to display such a MT-condensed framework.

Fig. 2 shows the experimental and simulated powder XRD patterns of AV-6. The unit cell parameters have been calculated assuming an orthorhombic unit cell, space group $P2_12_12_1$ with cell dimensions a = 10.103, b = 13.132, c = 7.154 Å, and are similar to those reported for synthetic umbite with some Ti for Zr substitution (Zr/Ti = 0.5) (a = 10.063, b = 13.135, c = 7.139 Å).[2] Powder XRD shows that the framework of AV-6 is stable up to *ca.* 700 °C.

The AV-6 ^{29}Si solid-state NMR spectrum with magic-angle spinning (MAS) (Fig. 3) displays three sharp peaks at δ −84.6, −85.5 and −86.7 in 0.74:1:0.98 intensity ratios. Previously reported framework stannosilicates give resonances in the range δ −78 to −92.[3,4] The crystal structure of umbite indicates the presence of three unique Si sites with equal populations.[5] The

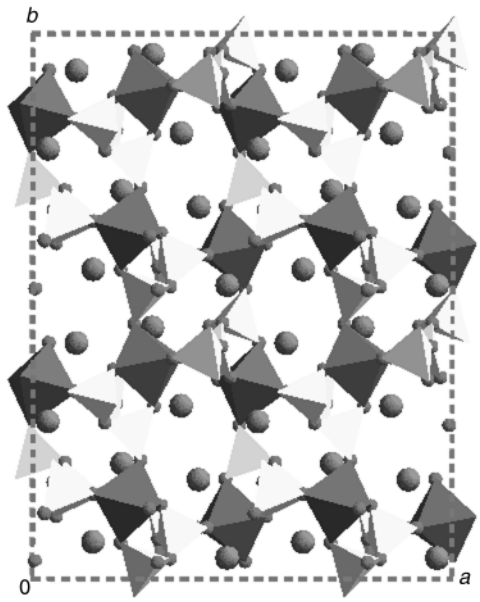

Fig. 1 Polyhedral representations of the umbite (and AV-6) structure viewed along [001]. For clarity, the water molecules are omitted.

fact that the relative population of one of the Si sites in AV-6 is slightly smaller than unity is, at present, not entirely understood. The use of NMR relaxation delays from 30 s up to 180 s did not show any difference in the relative intensities of the peaks. The ^{29}Si MAS spectrum recorded with cross-polarisation and the MAS spectrum are similar, showing only slight differences in peak intensities. Moreover, samples from different syntheses always displayed the same type of spectrum.

The ^{119}Sn MAS MNR spectrum of AV-6 (not shown) displays a single peak at δ − 709 (relative to tetramethyltin) with a full-width at half-maximum of 200 Hz. The framework stannosilicates reported by Corcoran and Vaughan which contain octahedral Sn(IV) give ^{119}Sn MAS MNR signals at δ *ca.* −706 and −708.[3]

The total AV-6 mass loss (ascertained by thermogravimetry) between 30 and 650 °C is *ca.* 5.3% while in synthetic umbite

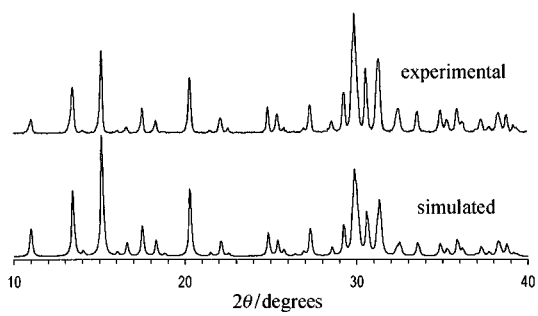

Fig. 2 Experimental and simulated powder XRD patterns of AV-6.

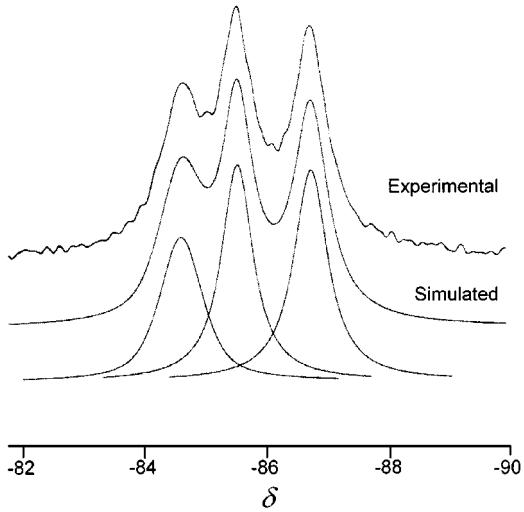

Fig. 3 Experimental and simulated ^{29}Si MAS NMR spectra of AV-6 recorded at 79.5 MHz on a Bruker MSL 400P. Chemical shifts are quoted in ppm from $SiMe_4$.

(AM-2) it is *ca*. 5.0%. This water loss is reversible. It was not possible to record a nitrogen adsorption isotherm of AV-6 probably because its pores are small. The water isotherms are of type I with maximum uptakes of *ca.* 3.34 mmol g^{-1} at P/P_0 = 0.4.

In conclusion, we report the successful synthesis and structural characterisation of AV-6, a stannosilicate which possesses the structure of the rare mineral umbite. This is the first report of a framework microporous stannosilicate with a known structure.

A new Na^+ sensor based on intramolecular fluorescence energy transfer derived from calix[4]arene

Takashi Jin

Section of Intelligent Materials and Devices, Research Institute for Electronic Science, Hokkaido University, Sapporo 060-0812, Japan. E-mail: jin@imd.es.hokudai.ac.jp

Received (in Liverpool, UK) 14th September 1999, Accepted 1st November 1999

A new calix[4]arene having pyrene (as a donor) and anthroyloxy (as an acceptor) moieties at the lower rim has been synthesized as a fluorescent Na^+ sensor based on intramolecular energy transfer.

Calixarenes have been shown to be useful building blocks in the design of fluorescent ion sensors for detecting metal ions and anions.[1–8] There are several designs of calixarene-based fluorescent ion sensor in which ion complexation can be monitored by intramolecular pyrene excimer formation,[1,2] intramolecular fluorescence quenching[3] and photoinduced electron transfer.[6–8] The objective of this work is to apply fluorescence energy transfer to the metal ion sensing system based on calixarenes. An advantage of the metal ion sensing system using fluorescence energy transfer is that a variety of fluorophore pairs can be chosen for the design of fluorescent ion sensors. Herein we report a new Na^+ sensor, based on intramolecular fluorescence energy transfer, derived from calix[4]arene.

Fluorescence energy transfer is the transfer of the excited state energy from a donor (d) to an acceptor (a). This transfer occurs as a result of transition dipole–dipole interactions between a d–a pair.[9] Thus, if a d–a pair is introduced to the appropriate sites of ionophoric calixarenes,[10] it is expected that the ion complexed by the calixarenes can be monitored by the change in the yield of fluorescence energy transfer between the d–a pair. In view of this, we have introduced pyrene (as a donor) and anthroyloxy (as an acceptor) moieties to the terminal positions of the ion binding sites (RCO-)[10] of ionophoric calix[4]arenes.

Fluorescent calix[4]arene **3** was prepared in three steps from the parent calix[4]arene. *p-tert*-Butylcalix[4]arene was dialkylated using 2 equiv. ethyl bromoacetate and 2 equiv. of K_2CO_3 in THF. The remaining two phenolic groups were functionalized firstly with 1.5 equiv. 1-pyrenemethyl iodoacetate and 2 equiv. K_2CO_3, and then with 1.5 equiv. *p*-(9-anthroyloxy)phenacyl bromide and 2 equiv. K_2CO_3 in THF. Mono-fluorophore calix[4]arenes **1** and **2** were prepared by the reaction of the tris-ethoxycarbonylmethyl ether[11] of *p-tert*-butylcalix[4]arene with the fluorescent reagents described above. All compounds were identified by ^1H NMR and field desorption mass spectroscopy.† The ^1H NMR measurements of the $ArCH_2Ar$ protons confirmed that the calixarenes **1**–**3** have rigid cone conformations in $CDCl_3$ solution.

Energy transfer from a donor to an acceptor depends on the extent of overlap of the fluorescence spectrum of the donor and the absorption spectrum of the acceptor.[9] Fig. 1 shows the fluorescence spectrum of **1** and the absorption spectrum of **2** in THF. The fluorescence spectrum of **1** is characterized by the pyrene monomer emission (*ca.* 385 nm). The absorption spectrum of **2** results from the absorption of the anthroyloxy group (λ_{max} 363 nm). Thus, the overlap between the emission of **1** and the absorption of **2** suggests that intramolecular fluorescence energy transfer from the pyrene to the anthroyloxy group can take place in **3**.

To verify the intramolecular energy transfer from the pyrene to the anthroyloxy group in **3**, we measured the fluorescence spectra of **1**, **2** and **3** at identical concentrations of 5.0 μmol

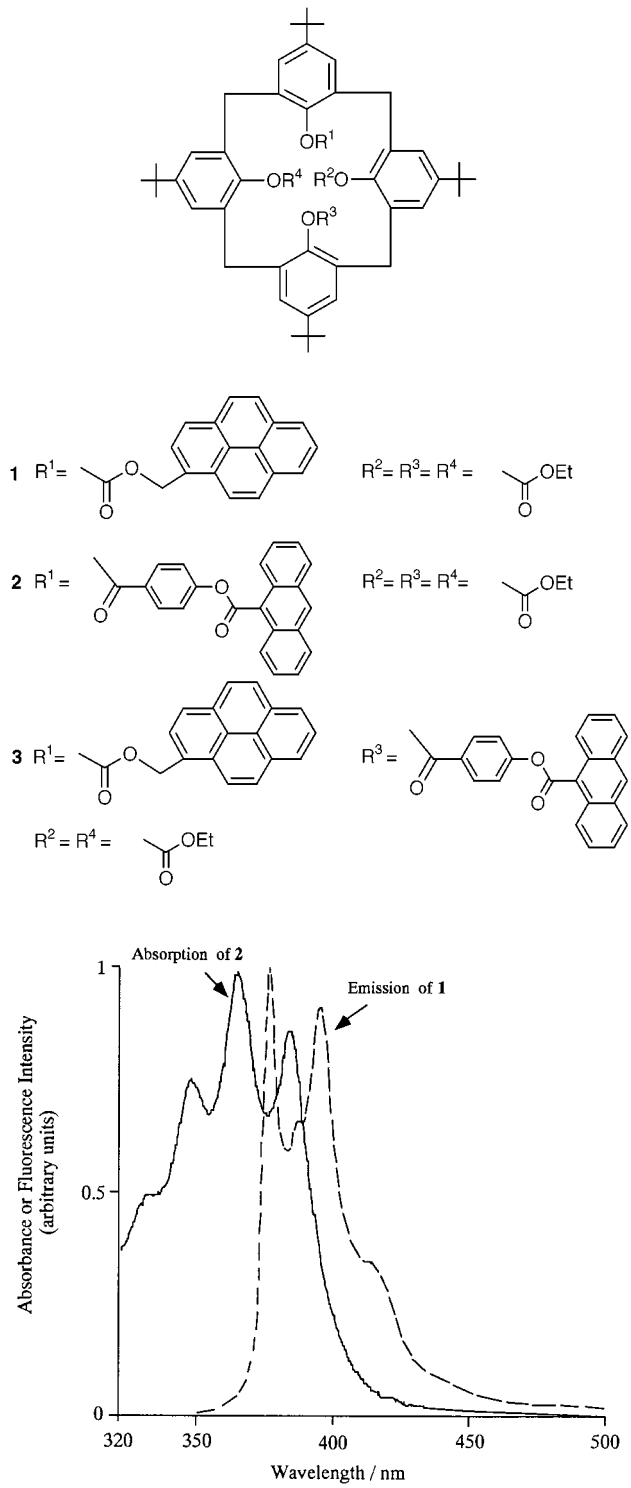

Fig. 1 Spectral overlap between the fluorescence spectrum of **1** and the absorption spectrum of **2**.

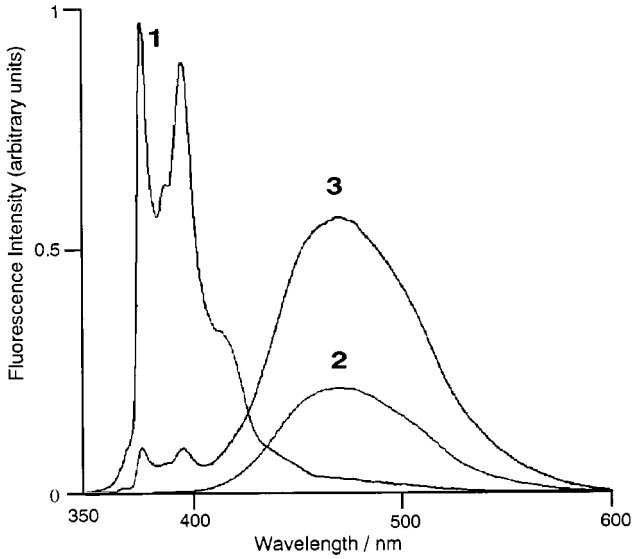

Fig. 2 Fluorescence spectra (ex. 330 nm) of **1**, **2** and **3** in THF at 25 °C.

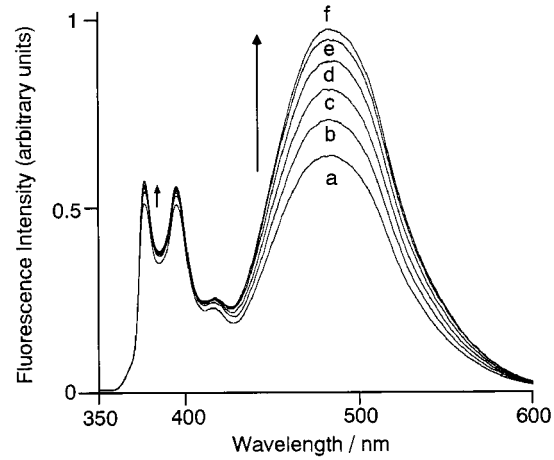

Fig. 3 Na^+ titration of the fluorescence spectra of **3** (5.0 μmol dm^{-3}) in MeOH–THF (15:1 v/v) at 25 °C: a, [NaSCN] = 0; b, [NaSCN] = 5.8; c, [NaSCN] = 17.4; d, [NaSCN] = 46.3; e, [NaSCN] = 104; f, [NaSCN] = 218 μmol dm^{-3}.

dm^{-3} (Fig. 2). At this concentration, **1** shows only the pyrene monomer emission; the intermolecular excimer emission is negligible. The fluorescence spectrum of **2** shows a broad, structureless band (λ_{max} 480 nm), which does not have an anthracene monomer-like structure.[12] It is well known that the 9-anthroyloxy group affords a large Stokes' shift of the broad emission which is a consequence of an excited-state rotation of the carboxyl group into the plane of the anthracene ring.[12] If energy transfer takes place in **3**, the emission of the anthroyloxy group (as an acceptor) should be enhanced compared with that of **2**, and the emission of the pyrene monomer (as a donor) should be depressed compared with that of **1**. As expected, the emission intensity of the anthroyloxy group of **3** increased by a factor of *ca.* 2.5 compared with **2**, while the emission intensity of the pyrene monomer of **3** decreased by a factor of *ca.* 10 compared with that of **1**. It should be noted that the emission of the anthroyloxy group of **3** has its maximum at the same wavelength (λ_{max} 480 nm) as that due to this group in **2**. This provides evidence that the anthroyloxy group is not forming an intramolecular exciplex with the pyrene in **3**.

The effects of addition of NaSCN to **1** and **2** were first examined in MeOH–THF (15:1 v/v) solution. The emissions of **1** and **2** were only slightly affected by the presence of Na^+ ions. The emission of the pyrene monomer of **1** (5.0 μmol dm^{-3}) at 385 nm was enhanced by a factor of 8% in the presence of excess amounts of NaSCN (454 μmol dm^{-3}). In the case of **2** (5.0 μmol dm^{-3}), the emission of the anthroyloxy group at 480 nm was depressed by a factor of 3% under the same NaSCN concentration. The fluorescence responses of these calix[4]arenes toward Na^+ ions are very poor and they have no potential as Na^+ sensors. In contrast, the fluorescence spectra of **3** showed a significant change in the presence of Na^+ and K^+ ions. Fig. 3 shows Na^+ titrations of the fluorescence spectra of **3** in MeOH–THF (15:1 v/v). When NaSCN was added to the solution of **3**, the fluorescence intensity of the anthroyloxy group increased significantly compared with that of the pyrene monomer. Such a fluorescence change was also observed in the case of KSCN. In contrast, the addition of other alkali metal ions such as Li^+, Rb^+ and Cs^+ did not cause fluorescence changes at concentrations as high as 50 mmol dm^{-3}. From the Na^+ titration data, the dissociation constant of the Na^+–**3** complex was determined to be 15 μmol dm^{-3}.‡ The Na^+/K^+ selectivity evaluated from the dissociation constants was found to be *ca.* 59. For Li^+, Rb^+ and Cs^+, the affinities were too low to be determined accurately and the dissociation constants were estimated to be greater than 100 mmol dm^{-3}.

In conclusion, we have synthesized a first example of a Na^+ sensor based on fluorescence energy transfer. The next step of this investigation will be the synthesis of a fluorescent calix[4]arene-based Na^+ sensor which can be excited by visible light along the same design principles. From the standpoint of the practical application of fluorescent ion sensors, the visible-light excitation is desirable to avoid a breaching of fluorescent dyes introduced to sensor compounds. We believe that a variety of donor–acceptor fluorophore pairs can be used for the design of calixarene sensors based on fluorescence energy transfer.

We thank Mr E. Yamada for the measurement of ^1H NMR spectra.

Notes and references

† *Selected data* for **3**: ^1H NMR (400 MHz, $CDCl_3$), δ 0.98 (s, 18H, CMe_3), 1.08 (t, 6H, CH_2CH_3), 1.17 and 1.19 (s, 9H, CMe_3), 3.14, 3.26, 4.85 and 5.02 (d, 2H, $ArCH_2Ar$, *J* 13.0 Hz), 4.05 (m, 4H, CH_2CH_3), 4.73 (s, 4H, OCH_2O), 5.09 (s, 2H, OCH_2OCH_2Py), 5.83 (s, 2H, CH_2COPh), 5.87 (s, 2H, CH_2Py), 6.62 and 6.69 (d, 2H each, ArH, *J* 2.4 Hz), 6.86 and 6.95 (s, 2H, ArH), 7.45–8.62 (m, 18H, anthracene and pyrene); field desorption mass spectrum, *m/z* 1431 (M^+).

‡ Since the absorption spectrum of **3** did not change upon addition of Na^+ and K^+ ions, a simple relationship between the intensity change (ΔF) in the anthroyloxy emission after complexation with metal ions and the concentration ([M^+]) of the metal ion can be derived as follows: $1/\Delta F = c + cK_d/[M^+]$, where K_d and *c* represent the dissociation constants of the metal ion complexes and a constant including terms of the quantum yields of free and complexing species, respectively.

Received (in Cambridge, UK) 30th July 1999, Accepted 4th November 1999

In contrast to the solid-state structures of the individual compounds, arene-perfluoroarene face-to-face stacking and C–H···F–C in-plane interactions dominate the solid-state structure of 1:1 co-crystals of 1,4-bis(phenylethynyl)-tetrafluorobenzene 1b and 1,4-bis(pentafluorophenylethynyl)-benzene 1c, with this supramolecular aggregation leading to the stabilisation of a nematic liquid crystalline phase.

Non-covalent interactions between aromatic units play a significant role in determining the structures and properties of molecular assemblies in biology, chemistry and materials science.[1] In the past ten years, arene–arene interactions have been employed widely in supramolecular chemistry[2] and are critical to the packing of organic molecules in crystals and in crystal engineering for the design of functional materials.[3] The stability and phase behaviour of many liquid crystals have also been reported to arise from such interactions.[4] Arene–perfluoroarene interactions are a special case which have been studied extensively since 1960 when Patrick and Prosser reported[5] that benzene (mp 5.5 °C) and hexafluorobenzene (mp 4 °C) form a 1:1 complex with a melting point of 24 °C. Although the exact nature of these face-to-face interactions is still a subject of study, they may be dominated by electrostatic forces and the large but opposite in sign quadrupole moments of C_6H_6 and C_6F_6.[6] While our work was in progress, Coates and Grubbs *et al.* reported the use of arene–perfluoroarene interactions in buta-1,3-diynes and stilbene derivatives to induce crystal packing suitable for topochemical polymerisation or dimerisation in the solid-state.[7] Herein, we present our results on the liquid crystal (LC) phase behaviour of a series of 1,4-bis(phenylethynyl)benzenes containing 0, 4, 10 or 14 fluorine atoms, namely 1,4-bis(phenylethynyl)benzene **1a**, 1,4-bis(phenylethynyl)tetrafluorobenzene **1b**, 1,4-bis(pentafluorophenylethynyl)benzene **1c** and 1,4-bis(pentafluorophenylethynyl)tetrafluorobenzene **1d**, and the single crystal structure and LC properties of 1:1 co-crystals‡ of **1b**·**1c**. These compounds were prepared by Pd/Cu catalysed cross-coupling reactions of appropriate terminal alkynes and iodoarenes as part of a larger study in our laboratories on the structure, linear and non-linear optical properties, and LC phase behaviour of conjugated rigid-rod systems.[8]

In contrast to the single crystal structures of **1a**–**d**, in which there is no evidence of any type of arene–arene interaction, 1:1 co-crystals‡ of **1b**·**1c** show two such interactions (Fig. 1). Thus, there is clear π-stacking of *all* arene and perfluoroarene moieties along the *b* axis [Fig. 1(*c*)] with the lateral slippage typical of such systems being about one C–C bond length [Fig. 1(*a*)]. As all molecules lie on inversion centres, the stacking is regular rather than alternating (*i.e.* the spacing between all molecules along *b* is equal). The perpendicular separation between mean planes in a stack is 3.337 Å. The intermolecular C–H···F–C interactions[7] shown dashed in Fig. 1(*b*) are 2.500–2.574 Å§ (sum of van der Waals radii = 2.67 Å) with C–F···H and C–H···F angles of 120–160°, the molecules thereby forming sheets which are very close to planar. We have not yet been able to grow single co-crystals of **1a**·**1d** suitable for X-ray diffraction; the sample discussed below was prepared by dissolving equimolar quantities of the two components in $CHCl_3$ and removing the solvent *in vacuo*.

Table 1 lists the axial ratio and the phase transitions detected on heating for compounds **1a**–**d**, and for the two mixed formulations. Surprisingly, molecules with an axial ratio as low as 4.1 (or 4.0 in the case of one of the co-crystals) are capable of forming liquid crystalline phases. Furthermore, the co-crystallized materials exhibit a greater liquid crystalline range and a higher temperature to obtain a fully isotropic fluid,

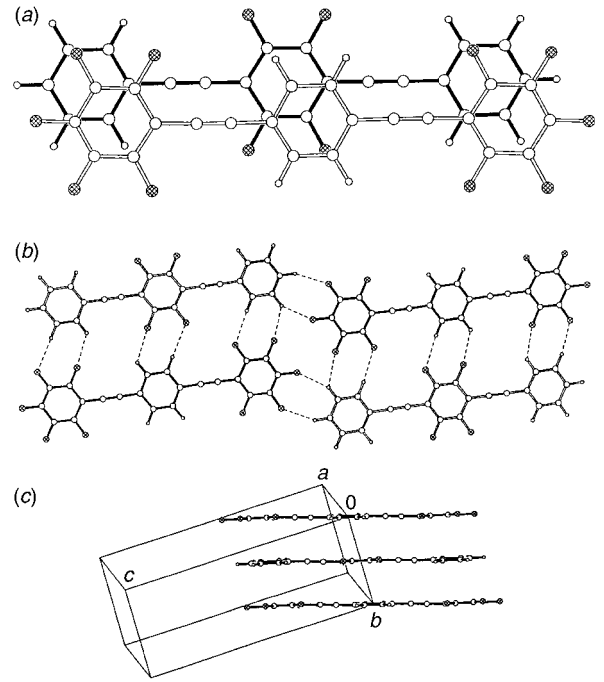

Fig. 1(*a*) Overlap diagram viewed perpendicular to the central C_6 ring of the two molecules in **1b**·**1c**, drawn in parallel projection without perspective, **1b** with solid bonds and **1c** with hollow bonds. Distances between ring centroids in adjacent molecules are 3.770 Å (central rings) and 3.750 and 3.789 Å (outer rings) with these inter-centroid vectors inclined on average 25.7° to the plane normals. Twists about the C–C≡C–C linkage in **1b**·**1c** are only 3.9° (**1b**) and 3.0° (**1c**) whereas in crystals of the individual components **1b** and **1c** these angles are 16.7 and 9.7° respectively. (*b*) A view showing the 'in-plane' intermolecular H···F contacts of 2.500–2.574 Å. (*c*) A packing diagram showing the stacking along the *b* axis.

† Preliminary results were presented at the NATO ASI Summer School on 'Crystal Engineering: The Design and Application of Functional Solids', Digby, Nova Scotia, September 1996, the RSC Dalton Division Symposium on 'Molecules to Materials', London, March 1998, and the 1998 National Congress of the RSC, Durham, April 1998.

Table 1 Axial ratio (*L/D*) and phase transitions[a]

Compound	*L/D*	Transitions on heating/°C

Co-crystal (1:1) of **1b·1c**	—	K 189.3 N 199.0 I
Two-component system (*ca.* 1:1) of **1a·1d**	—	K 178.5 S_B 196.2 bi N/I[c] 231.5 I

[a] Transition temperatures were determined by DSC and phases were assigned on the basis of the textures observed by transmitted polarised light microscopy. [b] N/I denotes that the nematic phase exists over a very narrow temperature range, and is observed only transiently by microscopy. The crystal-to-nematic and nematic-to-isotropic transition temperatures lie unresolvably close together. A single DSC endotherm is observed, and its onset temperature is quoted. [c] bi N/I denotes that the sample forms a two-phase (biphasic) mixture of both nematic and isotropic material. The subsequent clearing point refers to the nematic regions only.

compared to either of their respective constituents. These results are interesting for three reasons.

First, it is well known[9] that mixing two mesogenic species can lead to a reduction in melting point and so expand the temperature range of liquid crystallinity exhibited by either constituent; often a simple eutectic phase diagram is obtained. Here, however, we have two cases where liquid crystallinity is promoted by mixing compounds that, on their own, show no or only transient tendency to form a LC phase when heated. Also, as noted, it is not just the melting point that is lowered; the clearing points of these mixtures are raised above the temperature needed to render the respective constituents isotropic. Both observations suggest the possibility of intermolecular association in the liquid crystalline phase.

Second, it has been demonstrated previously for unsubstituted tolan oligomers, which have an approximately uniform charge distribution along the length of each molecule, that an axial ratio of 4.45 is barely sufficient to stabilize liquid crystallinity at ambient pressure.[10] The monotropically nematic compound **1a** illustrates this point. When molecules lack the necessary shape anisotropy, they can nevertheless form a liquid crystalline phase if there are sufficiently strong and anisotropic 'soft' interactions between them.[11] In some systems, intermolecular attractions can lead to the assembly of supramolecular aggregates[12] which then promote liquid crystalline order. For example, strong hydrogen bonding between benzoic acids and pyridines can lead to the formation of supramolecular mesogenic structures.[13] Our results suggest that aggregation may play a role in the present case, but that it is probably not due to strong hydrogen bonding.

Third, the fully fluorinated compound **1d** does not exhibit liquid crystallinity, but **1c**, which has the same axial ratio but contains both fluorinated and non-fluorinated phenyl residues, is transiently nematic. We also note that the liquid crystalline two-component systems contain both fluorinated and non-fluorinated phenyls. These observations suggest that arene–perfluoroarene stacking interactions, as observed in the solid-state for **1b·1c**, are the cause of the proposed aggregation in the LC phases.[14] The fact that nematic phases are formed, requiring rod-like or nearly rod-like structures, suggests that it is unlikely that large flat sheets persist at the temperatures of the phase transitions that we observe. Thus, although C–H···F–C interactions in two dimensions may play a role in LC phase behaviour, a one dimensional model based on face-to-face quadrupolar interactions between fluoroarene and arene units is preferred at this time.

Studies examining the phase behaviour of a full range of compositions of these compounds are in progress.

7-Oxabicyclo[2.2.1]heptadiene derivatives: reactivity towards Brønsted acids

Alain Maggiani, Arlette Tubul and Pierre Brun*

Laboratoire de Synthèse Organique Sélective, GCOPL, ESA 6114, Université de la Méditerranée, Faculté des Sciences de Luminy, 163 Avenue de Luminy, case 901, F-13288 Marseille Cedex 9, France.
E-mail: brun@chimlum.univ-mrs.fr

Received (in Liverpool, UK) 22nd October 1999, Accepted 4th November 1999

7-Oxabicyclo[2.2.1]heptadiene derivatives can be converted to phenols, fulvenes and/or the products from a retro-Diels–Alder-like reaction by treatment with Brønsted acids; the outcome of the reaction depends on the experimental conditions and the nature of the Brønsted acid used.

During the course of our investigations we have synthesised a large variety of arylphenols. These compounds are easily obtained *via* Diels–Alder reaction between arylfurans and dimethyl acetylenedicarboxylate (DMAD).[1] However, in most cases a mixture of the phenolic and the oxabicyclic derivatives is obtained. The proportions of the two species depend on the nature and the position of the substituent on the phenyl group. 7-Oxabicyclo[2.2.1]heptadiene derivatives are often used in organic synthesis as synthons for natural product elaboration.[2,3] We have shown previously that dimethyl 1-aryl-7-oxabicyclo-[2.2.1]heptadiene-2,3-dicarboxylates **1** can be converted to phenols **2** or to 6-hydroxyfulvenes **3** by reaction with Lewis acids.[4] Depending on the acid used, **2** or **3** can be formed in a totally selective and quantitative way (Scheme 1). Never in the past have such high yields and such a selectivity been described.[5–8] We report here the results obtained when **1** is reacted with Brønsted acids.

As with Lewis acids, depending on the nature of the Brønsted acid, phenols **2** and/or hydroxyfulvenes **3** are formed. However, another reaction was observed: a retro-Diels–Alder like reaction (retro-DA) leading to **4** and DMAD **5** (Scheme 2).

Our results are reported in Table 1. These results were obtained using 1-(2-chlorophenyl)-7-oxabicyclo[2.2.1]hepta-diene-2,3-dicarboxylate as a model compound, but similar results were observed with **1** for R = *p*-nitro or *p*-acyl.

In the presence of gaseous HCl or with glacial AcOH (entries 4, 6–9) the retro-DA reaction is totally regioselective and is the only process observed. In AcOH, the conversion rate increases with the temperature. However, the retro-DA reaction is not a purely thermal one, as exemplified by the absence of conversion when **1** is heated at reflux in a $CHCl_3$–CCl_4 mixture (entry 10).

When mineral aqueous acids are used (HCl or H_2SO_4) the results depend on the experimental conditions and particularly on the solvent and temperature (entries 1–3, 5). In Et_2O, at room temperature, only the phenol **2** is formed. In CH_2Cl_2, with H_2SO_4, only tars are formed starting from compound **1**. With aqueous HCl, under heating, the reaction is not selective and the

10	None	$CHCl_3$–CCl_4	reflux	48	100			

[a] *Reagents and conditions*: i, aq. HCl or H_2SO_4, Et_2O, room temp.; ii, aq. HCl, CH_2Cl_2, reflux; iii, anhydrous HCl, Et_2O or CH_2Cl_2, room temp. (or AcOH, reflux.) [b] The indicated yields are based on pure isolate compounds. [c] Ref. 9.

retro-DA process is observed along with the formation of **2** and **3**. The ratio of the different compounds depends on the temperature, and the yield of the retro-DA reaction increases with the temperature (entries 1, 2) while the yield of fulvene **3** decreases. It must be noted that the formation of the fulvene **3** and the retro-DA reaction are totally regioselective processes: only the 6-hydroxyfulven **3** and the 2-arylfurane **4** are formed, without any traces of another regioisomers.

With Lewis acids, **2** and **3** can be obtained selectively as unique compounds. Similarly with gaseous HCl or AcOH, the retro-DA-like reaction is the only one observed. Although we have no evidence for the mechanism of that reaction, we have observed, by thin layer chromatography, that an intermediate compound is formed during the reaction with gaseous HCl. This compound could not be isolated as it is rapidly converted to arylfuran and DMAD. This suggest that the retro-DA-like process could occur by chlorination (or acetoxylation in the case of AcOH) of the starting compound followed by subsequent rearrangements.

Our results show the great reactivity of 7-oxabicyclo-[2.2.1]heptadiene derivatives towards Brønsted acids. This was also demonstrated with Lewis acids. However, although with Lewis acids it is possible to synthesise phenols and/or 6-hydroxyfulvenes, we have shown that with Brønsted acids it is also possible to observe a quantitative and totally regioselective retro-Diels–Alder like reaction in AcOH or with gaseous HCl. Although, in our case, the retro-DA products are the same as the ones used for preparing the starting compound **1**, our observations may be applied to other 7-oxabicyclo-[2.2.1]heptadiene derivatives and thus could be very useful, as interest in retro-Diels–Alder reactions as a tool in organic synthesis is increasing.[10]

Synthesis and photochromic properties of helically locked 1,2-dithienylethenes

Liviu Dinescu and Zhi Yuan Wang*

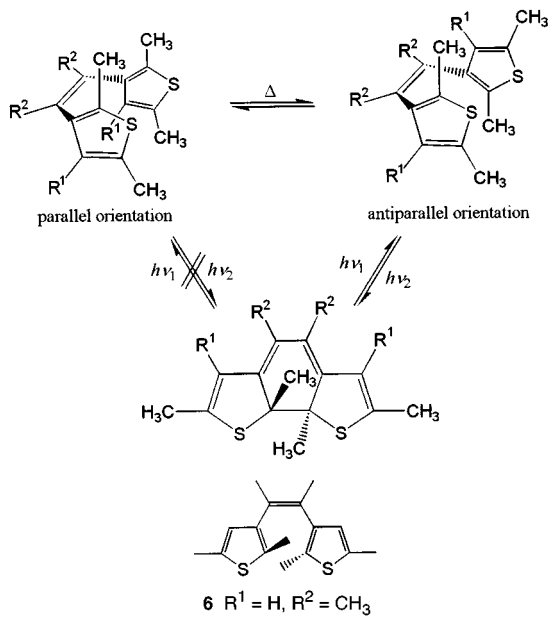
Department of Chemistry, Carleton University, 1125 Colonel By Drive, Ottawa, Ontario, Canada K1S 5B6. E-mail: wangw@ccs.carleton.ca

Received (in Corvallis, OR, USA) 17th August 1999, Accepted 2nd November 1999

The synthesis of a new family of 1,2-diarylethenes, helically locked 1,2-dithienylethenes, is reported, along with their photochromic properties in solution and as polymeric films.

In recent years a considerable effort has been made towards 1,2-diarylethenes, a class of photochromic compounds known to undergo a reversible ring closing and opening upon irradiation at two different wavelengths. Properties such as thermal stability in isomeric forms, easy preparation and good resistance to repetitive photoisomerization cycles make diarylethenes potential materials for optical data storage.[1] In order to avoid a competing *trans–cis* photoisomerization, the aryl moieties are bound to the double bond of a cycloalkene.[2] To date, all the reported photochromic 1,2-diarylethenes have a five-membered cycloalkene, which can be considered as derivatives of maleic anhydride, maleimide and perfluorocyclopentene. Recently, Feringa *et al.* succeeded in synthesizing a series of 1,2-dithienylethenes based on the cyclopentene moiety and showed that one compound was suitable for multiple photoisomerization cycles.[2]

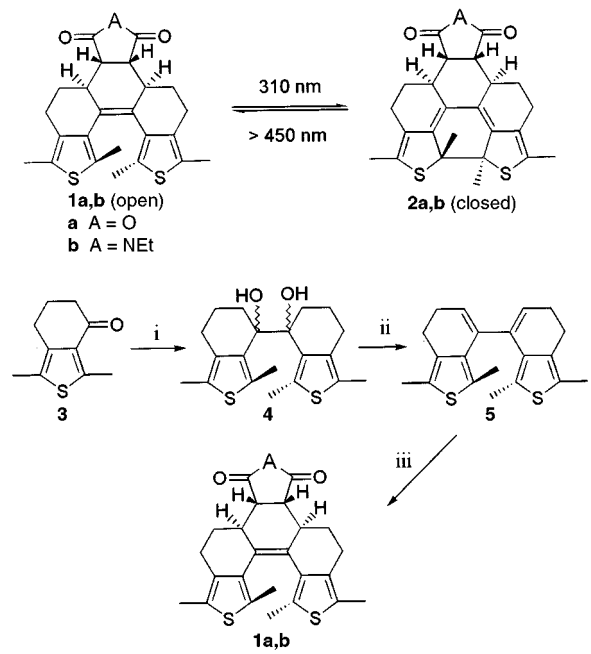
One of features of known 1,2-dithienylethenes is that the aryl rings are able to rotate around the alkene–aryl single bond. As a result, the molecules are distributed between two equally populated conformational states resulting from the parallel and antiparallel orientations of the aryl rings.[3] According to the Woodward–Hoffman rule, photocyclization of a hexa-1,3,5-triene system is allowed only in conrotatory mode. In addition to this, the photocyclization reaction of 1,2-diarylethylenes is restricted to proceed only for molecules that are in the antiparallel orientation (Scheme 1). ^{1}H NMR studies have shown that the full interconversion of the two conformers occurs at temperatures exceeding 40 °C, which is above the temperature limit ideal for most practical applications.[3] Hence, it would be of fundamental interest to design and study a rigid dithienylethene system, in which the two thiophene rings are 'frozen' or locked in an antiparallel orientation suitable for efficient cyclization. Such a system can be realized by connecting the R^1 and R^2 groups of the 1,2-dithienylethenes shown in Scheme 1. Herein we report a new class of photochromic compounds: helical 1,2-dithienylethenes **1a**,**b** (Scheme 2) that are built on the rigid frame of $\Delta^{4a(b)}$-dodecahydrophenanthrene. The multi-ring locked structure and the overlapping methyl substituents give rise to a molecular helicity in these compounds, which allows the thiophene rings to adopt an almost an antiparallel orientation. The increase in the molecular rigidity might also provide a stabilizing effect on the isomers **2a**,**b**.



Scheme 1

As shown in Scheme 2, our synthetic approach to these compounds began with commercially available 2,5-dimethylthiophene (Aldrich), which was converted into cyclic ketone **3** using a known method.[4] The McMurry–Mukaiyama coupling[5] of **3** with $TiCl_4$ and Zn in THF gave pinacol **4** in 95% yield. Without further purification, pinacol **4** was dehydrated using $POCl_3$ in pyridine to give the diene **5** in 84% yield. The subsequent steps involved the Diels-Alder reactions of **5** with maleic anhydride or *N*-ethylmaleimide to produce the racemic *endo* adducts **1a**,**b**.

Molecular mechanics calculations indicated that dithienylethenes **1a**,**b** are highly unsymmetrical. Due to the *cis*-fusion of the anhydride and imide moieties, the preferred conformations of **1a**,**b** do not exhibit any C_2 and mirror symmetry elements, as evidenced by the NMR spectral data of **1a**,**b**.[6] The NOESY and COSY NMR data recorded for **1b** were consistent with an *endo* configuration.[7]



Scheme 2 *Reagents and conditions*: i, $TiCl_4$, Zn, THF, 25 °C; ii, $POCl_3$, pyridine, 120 °C; iii, dienophile, xylene, reflux.

At first, the photocyclization of dithienylethenes **1** was examined in solution (Scheme 2). Solutions of **1a** and **1b** in oxygen-free benzene (1×10^{-4} M) were irradiated at wavelengths corresponding to the absorption bands of the open (λ = 310 nm) and closed isomers (λ > 450 nm). Upon irradiation with UV light (λ = 310 nm, Hg medium pressure lamp), the solutions turned from clear to yellow, as illustrated by the absorption change shown in Fig. 1(*a*). Alternatively, irradiation of the yellow solutions with white light (tungsten lamp) caused the decoloration of the solutions as the closed isomers **2a**,**b** were converted back to **1a**,**b**. The thermal stability of the closed isomers was found to be comparable with that of the closed isomer derived from *cis*-2,3-bis(2,5-dimethyl-3-thienyl)but-2-ene (**6**, R^1 = H, R^2 = CH_3, Scheme 1), a non-helical analogue reported by Irie.[8] A deoxygenated solution of **2b** in benzene was kept at 60 °C for 15 h and no visible change in the UV–VIS absorption spectrum was found.

Previous experiments conducted with diarylethenes in the crystalline state have shown that the photochemical ring closing proceeded reversibly and unrestricted.[9] Thus, it was useful to monitor the photochromic behavior of diarylethenes **1a** and **1b** in an amorphous polymeric film. A polycarbonate film containing **1a** or **1b** was irradiated at 310 and > 450 nm, respectively. The photocyclization proceeded readily at ambient temperature, as evidenced by the absorption maximum (λ = 450 nm) of the closed isomer [Fig. 1(*b*)]. Similar to the results of the solution experiment, irradiation of the polycarbonate film containing **2a** or **2b** with white light led to the recovery of **1a** or **1b**, respectively. Therefore, in contrast to some non-helical 1,2-dithienylethenes,[10] the complete switch between **1** and **2** in solution and in the solid polymer film can conceivably be attributed to molecular rigidity (*i.e.* locked rings) and helical conformation (*i.e.* antiparallel orientation) of compound **1**.

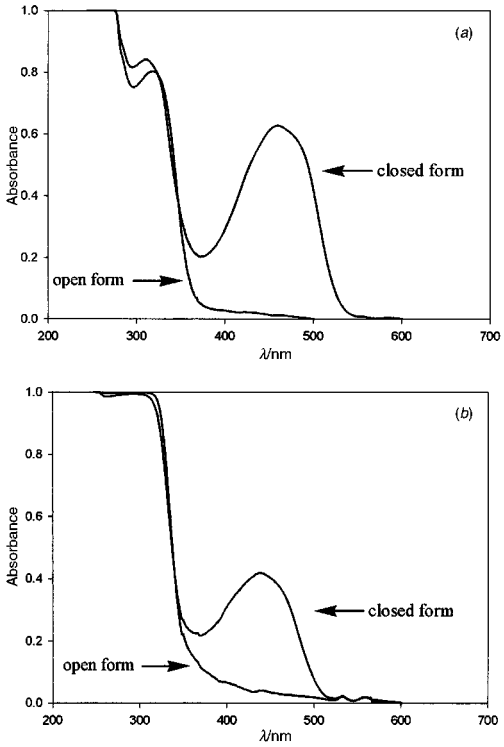


Fig. 1 UV–Visible absorption spectra of (*a*) **1b** in benzene (1×10^{-4} M) in the dark and after irradiation at 310 nm; (*b*) **1b** in polycarbonate film (6.8×10^{-2} mg per mg polymer) in the dark and after irradiation at 310 nm.

The fatigue resistance properties can be determined by the number of colour change cycles over which the color intensity of the photochromic medium decreases to 80% of that of the first cycle.[3] Accordingly, it was found that the fatigue resistance for dithienylethenes **1a**,**b** in benzene in air is about four cycles. A similar cycle number was recorded for **6** (Scheme 1),[8] which has a similar chromophore core (absorption peak corresponding to the closed isomer is 431 nm in benzene). When oxygen was removed from the benzene solution, more than ten switching cycles could be easily achieved without a noticeable decrease in the photochromic intensity.

In conclusion, we have demonstrated a new series of 1,2-dithienylethenes that display distinct photochroism at 310 and 450 nm at ambient temperatures.

The Natural Sciences and Engineering Research Council financially supported this work.

Catalytic dehydrogenation of a mixture of C_{10}–C_{14} *n*-paraffins to linear C_{10}–C_{14} monolefins in a supercritical phase

Wei Wei, Yuhan Sun* and Bing Zhong

State Key Laboratory of Coal Conversion, Institute of Coal Chemistry, Chinese Academy of Sciences, Taiyuan 030001, P.R. China. E-mail: sklcc@public.ty.sx.cu

Received (in Cambridge, UK) 16th August 1999, Accepted 10th November 1999

The catalytic dehydrogenation of a mixture of C_{10}–C_{14} *n*-paraffins (*n*-alkanes) to linear C_{10}-C_{14} monolefins (alkenes) over a commercial Pt-Sn/γ-Al_2O_3 catalyst was observed to be two to three times higher in a supercritical phase of the reactant themselves than in the gas phase; this indicated that the thermodynamic equilibrium was strongly shifted under supercritical conditions.

The preparation of linear C_{10}-C_{14} monolefins (alkenes) from a mixture of C_{10}–C_{14} *n*-paraffins (alkanes) by catalytic dehydrogenation is an important process in the production of synthetic detergents and surface-active agents.[1] Because of equilibrium limitations and deep dehydrogenation of monolefins, the present industrial process at most reaches *ca.* 12% conversion with 92% selectivity. Neither conversion nor selectivity have been significantly enhanced although the catalysts used have been highly improved. A new technique is thus required to improve the process.

Supercritical fluids (SCFs), which are fluids above their critical temperatures and pressures, have been used for extraction and separation since their discovery 170 years ago by Baron Charles Cagniard de la Tour.[2] In recent years, much interest has been generated in supercritical reactions[3] and some comprehensive reviews appeared.[4,5] Generally, supercritical fluids not only enhance the reaction rate, but also shift chemical equilibria, and hence significantly improve the performance of heterogeneous catalysis as a result of the enhancement of the physicochemical properties of the fluid near the critical state.[6,7] The supercritical catalytic dehydrogenation of a mixture of C_{10}–C_{14} *n*-paraffins to a mixture of linear C_{10}-C_{14} monolefins was thus investigated for improvement in conversion and selectivity.[8]

The feedstock composition of the C_{10}–C_{14} *n*-paraffin mixture is given in Table 1. The dehydrogenation of C_{10}–C_{14} *n*-paraffins to linear C_{10}–C_{14} monolefins was carried out over commercial Pt-Sn/γ-Al_2O_3 catalyst (DEH-7 supplied by UOP) at supercritical conditions for the C_{10}–C_{14} *n*–paraffin mixture in a downflow fixed bed reactor with inner diameter of 1.4 cm. The products were determined by the UOP analysis methods in which the conversion is represented by bromine value, the diolefin content by diolefin number, and the aromatics were determined by UV spectrometry.[9] Typical data are shown in Fig. 1 and Table 2.

Table 1 Feedstock composition of the *n*-C_{10}–C_{14} paraffin mixture

Component	C_{10}	C_{11}	C_{12}	C_{13}	C_{14}
Composition (wt%)	8.76	32.42	36.12	22.45	0.23

Fig. 1 indicated that the pressure strongly influenced the performance of the reactions. When the reaction pressure was below the critical pressure (region A) of the reactant, the reaction conversion was low. At reaction pressures of > 2.5 MPa (region C), the conversion of the reactants was slightly higher than the calculated equilibrium conversions, which might be due to the higher solubility of the products in the higher density supercritical phase relative to the gas phase. Only when both the pressure and temperature of the reaction system approached critical conditions for the C_{10}–C_{14} *n*-paraffin mixture, was conversion greatly increased and highly exceeded the equilibrium conversion. This fact indicated that the equilibrium is strongly shifted under supercritical conditions for the reactants, which might be due to either the high solubility of the products in supercritical fluids[10] or quick desorption of monolefins from the catalyst surface.[11,12] Table 2 shows that the diolefin content in the supercritical phase was relatively lower than that in the gas phase, and aromatics were scarcely observed in the supercritical phase (*cf.* 0.9–1.5% in the gas phase). These results can be attributed to the fast desorption of the main products (*i.e.* monolefins) from the surface of the catalyst, which prevents deep dehydrogenation of the main products to diolefins and aromatics,[11] so leading to a high selectivity of linear C_{10}–C_{14} monolefins (> 98%).

Unlike the present industrial processes in which a large amount of hydrogen is used (typically mol ratio H_2 : alkanes =

8:1) to avoid severe coke formation, supercritical dehydrogenation could be carried out without hydrogen (see Table 2 and Fig. 2). Fig. 2 indicates that both the activity and the selectivity scarcely decreased over 100 h in the absence of hydrogen in the supercritical phase of a mixture of C_{10}–C_{14} *n*-paraffins. Moreover, TG–DTA illustrated a reduction of coke formation over the catalysts used in the supercritical phase. This is as expected if the formation of carbonaceous species on the surface of the catalyst is suppressed by supercritical fluids.[13,14] Indeed, a partial pressure of hydrogen was detrimental on the performance of the supercritical phase, possibly owing to a change of supercritical conditions in the presence of hydrogen. The mechanism of the process is currently under investigation.

The above results indicate that reaction in a supercritical phase leads to a substantial improvement in both conversion and selectivity as well as the reduction of coke formation in the catalytic dehydrogenation of a mixture of C_{10}–C_{14} *n*-paraffins to linear C_{10}–C_{14} monolefins.

Through-space ^{13}C–^{19}F coupling can reveal conformations of modified BODIPY dyes†

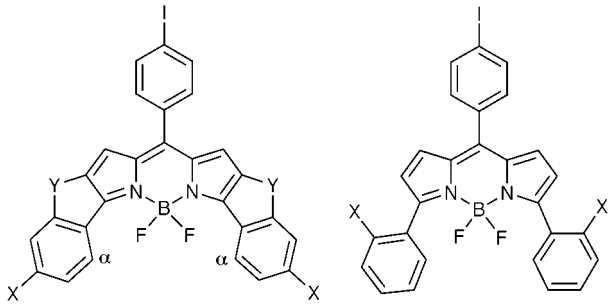
Jiong Chen, Joe Reibenspies, Agnes Derecskei-Kovacs and Kevin Burgess*

Department of Chemistry, Texas A & M University, PO Box 30012, College Station, TX 77842-3012, USA. E-mail: burgess@chemvx.tamu.edu

Received (in Corvallis, OR, USA) 13th September 1999, Accepted 27th October 1999

The fact that only compounds 1a, 1b and 2a in the series 1–3 show long-range ^{13}C–^{19}F coupling can be used to draw conclusions regarding the structures of these molecules.

Through-space coupling between carbon and fluorine atoms that are forced together through geometric constraints is a well-known phenomenon,[1–3] but it is not often used as a tool to gauge molecular conformations.[4–6] Here we describe such an application as applied to 3,5-diaryl-4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene (BODIPY®) dyes **1**–**3**.[7]



1a X = OMe, Y = CH_2CH_2
b X = H, Y = CH_2CH_2
2a X = H, Y = S
b X = H, Y = O

3a X = H
b X = OMe

Briefly, the circumstances that led to this study were as follows. Our group is attempting to prepare new fluorescent dyes for biotechnological applications.[8,9] An important part of these studies is to refine the fluorescence properties of the target dyes by relating them to molecular structure. As part of our investigations to determine molecular structure we observed that a through-space ^{13}C–^{19}F coupling[10] is observed only for compounds **1a**, **1b** and **2a** in this series, and this parameter can be correlated with their molecular conformation. These compounds show a triplet in their $^{13}C\{^1H\}$ spectra (**1a** δ 130.1, t, J = 11.0 Hz; **1b** δ 128.4, t, J = 11.2; **2a** δ = 126.7, t, J = 5.2 Hz). APT and HETCOR experiments[11] established that the carbons responsible for these triplets were the ones marked **α** (henceforth referred to as C^α). A combination of two decoupling experiments was performed on **1a** to prove that this splitting was due to coupling with the two fluorine atoms. First, a ^{13}C NMR spectrum was recorded without any decoupling, and the C^α appeared as a doublet of triplets (J = 164 and 11 Hz). A proton-coupled, fluorine-decoupled ^{13}C NMR spectrum of the same sample was then recorded, and the carbon of interest appeared as a doublet (J = 164 Hz). These experiments indicate that the triplet arises from coupling of the C^α to the two fluorine atoms.

A comparison of spectral data for compounds **1** and **2** is shown in Table 1. The ^{19}F and ^{11}B NMR chemical shifts for these dyes decrease in the order **1** > **2a** > **2b**, and the same trend was also observed in the ^1H NMR spectra of these materials. The observed C–F coupling constants in this series decrease in the same order. These observations imply that the factors that govern the ^{19}F chemical shifts also impact C–F coupling constants in this series.

Table 1 Selected spectroscopic data for **1**–**2**

	Chemical shift (δ/ppm)[a]		
Compound	^1H[b]	^{19}F[c]	^{11}B[d]
1a	8.78	−137.5	9.29
1b	8.82	−137.3	3.98
2a[e]	8.75	−147.0	—
2b	8.24	−150.6	0.41

[a] In $CDCl_3$. [b] For C^α–*H* or the corresponding C–*H*, at 300 MHz relative to a deuterium lock. [c] At 282 MHz relative to $CFCl_3$ as external reference. [d] At 64 MHz relative to $BF_3{\cdot}OEt_2$ as external reference. [e] ^{11}B NMR data could not be obtained for this compound since it is relatively insoluble in the common organic solvents used for NMR studies.

It is unlikely that C^α is coupled to the fluorine atoms *via* covalent bonds in the aromatic system, for several reasons. First, if it were to occur, the observed value of 11 Hz would be an exceptionally large *J*-parameter for a five-bond coupling. Second, other carbons in compounds **1** and **2a** would most probably be affected in the same way if that coupling mechanism was operative, especially those that are less than five bonds away. Finally, similar five-bond coupling might then also be observed for compound **2b** and **3**, but they were not.

A single crystal, X-ray diffraction analysis was performed on compound **1a** to gain more insight into the nature of the C^α–F interactions.‡ Molecule **1a** crystallizes in a bow-shaped conformation making the two fluorine atoms inequivalent (even though they are equivalent in the ambient solution phase ^{19}F NMR spectrum of this compound, Fig. 1). Moreover, there are four C^α–F distances since the BF_2 entity does not reside at a

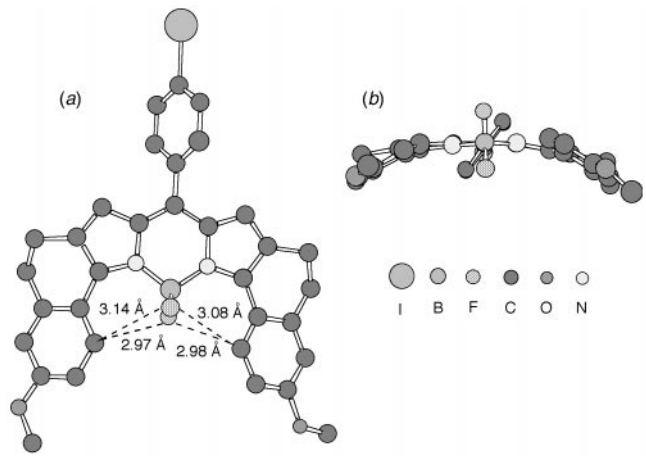


Fig. 1 Chem3D representations of **1a** from X-ray crystallographic data: (*a*) top view showing C^α–F distances; (*b*) side view illustrating curvature of the molecule.

† Spectral data for **1a,b** and **2a,b** and colour versions of Fig. 1 and 2 are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2501/

position that is exactly equidistant to both aromatic rings in the crystal structure. The four C^{α}–F distances are similar; they vary between 2.97(1) and 3.14(1) Å, and average to 3.04(8) Å. More variance was observed for the C^{α}–*H*··*F* distances. Electron density maps were used to locate the protons in this molecule, and their positions were refined (though of course, not to the same degree of accuracy as the heavier atoms). Nevertheless, the shorter C^{α}–*H*··*F* distance is no less than 2.29(1) Å, the longer one is no more than 2.75(1) Å, and the average value was measured as 2.5(2) Å. Comparison of the average C–F distance {3.04(8) Å} with the sum of the van der Waals radii for carbon and fluorine (3.19 Å)[12] implies that an interaction between these atoms is likely. Similarly, the average C^{α}–*H*··*F* distance {2.5(2) Å} is less than the sum of the van der Waals radii for hydrogen and fluorine (2.62 Å).

It appeared from the solid state structural analyses, outlined above, that the C^{α}–F interaction observed in the ^{13}C NMR spectra of compounds **1** is due to a close interaction of these atoms, through space. Crystallographic data was not obtained for compounds **2**, but a series of calculations was performed to establish why the interaction was observed for **2a** but not **2b**. Briefly, these were performed in the Cerius2 collection of programs (Molecular Simulations, Inc.). Preliminary optimizations were performed *via* molecular mechanics using the Universal Force Field (designed to accommodate all the atoms in the periodic table).[13–15] Final geometry optimizations were obtained at the semi-empirical level using the AM1 method within MOPAC.[16,17] Throughout these calculations, the iodine atoms in the real molecules were substituted by chlorine atoms in the virtual compounds.

Calculations on the Cl-for-I analog of compound **1a** gave a minimized structure obtained having the same curved conformation observed from the X-ray diffraction study (Fig. 1). Moreover, all the bond parameters were similar (data not shown). This result indicated that the AM1 calculations were reliable for this molecular type.

Simulated structures of the Cl-for-I analogs of compounds **2** are shown in Fig. 2. Comparison of Fig. 1 and 2 shows that the latter are essentially planar: they do not have the bow-shaped structure that compound **1a** has. Distances between the F- and C^{α}-atoms increase in the order **1a** < **2a** < **2b**. They are no longer within the sum of the van der Waals radii for carbon and fluorine for compound **2b**.

These structural studies clarify why the trend on the F-to-C^{α} coupling constants should be as observed. The ethylene bridges of compound **1a** force the benzene rings inwards towards the fluorine atoms, giving an exceptionally close interaction between the C^{α} and F atoms. Conversely, the S and O atoms in compounds **2** pull the benzene rings outward, giving a relatively open structure. However, this effect is less important for **2a** than for **2b** for two related reasons that expand the five-membered rings containing the sulfur atoms. First, the atomic size of sulfur is greater than that of oxygen. Second, C–S bond lengths are longer than for C–O bonds (typically 1.75 Å for sp^2 C–S bond *vs*. 1.34 Å for sp^2 C–O bond).

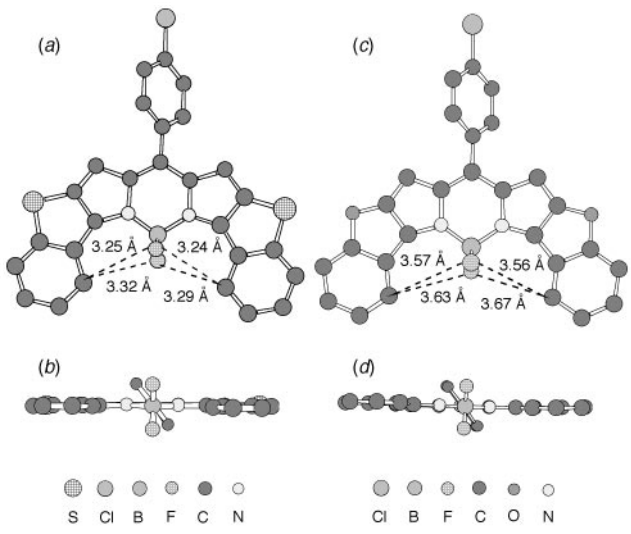

Fig. 2 Chem3D representations of the Cl-for-I analogs from AM1 calculations: (*a*) top view of **2a** showing C^{α}–F distances; (*b*) side view of **2a**; (*c*) top view of **2b** showing C^{α}–F distances; (*d*) side view of **2b**.

It is surprising that couplings between the C^{α}–*H*··*F* atoms were not observed for compounds **1** and **2a**. It appears that the C^{α}–*H*··*F* coupling is too small to be observed conveniently in the proton NMR spectra of these compounds. However, the C^{α}–H resonance for compound **1a** was broader than other aromatic protons in this molecule (2.7 Hz at half-peak-height) and sharpened in a $^1H\{^{19}F\}$ experiment (2.1 Hz at half-peak-height).

There are two possible rationales for the coupling observed between the C^{α}–F atoms in compounds **1** and **2a**. One is a thermodynamically favorable H-bonding interaction between the aromatic hydrogen and the fluorine atoms. Similar interactions have been proposed before.[18–20] However, we believe that the coupling is really a consequence of crowding within the bay area that contains the BF_2 entity in these molecules. Whatever the origin of these effects, it's clear from the data presented here that they can be used as a tool to access molecular structure.

We thank Ben Lane for running the ^{11}B NMR spectra for this study, and Steve Silber for assistance with the decoupled NMR spectra. Financial support for this work was provided by the NIH (HG01745) and The Robert A. Welch Foundation.

One step synthesis of [7]metacyclophanediyne complexes from bis(propargyldicobalt) dication equivalents

Richard Guo and James R. Green*

Chemistry and Biochemistry, School of Physical Sciences, University of Windsor, Windsor, Ontario, Canada N9B 3P4. E-mail: jgreen@uwindsor.ca

Received (in Covallis, OR, USA) 1st October 1999, Accepted 4th November 1999

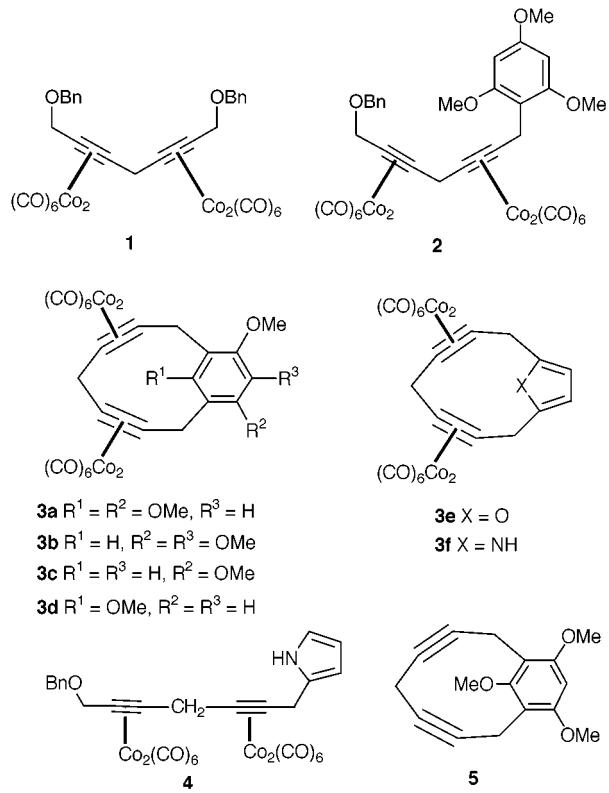
The $BF_3{\cdot}OEt_2$ mediated addition reactions of electron-rich arenes to 1,3-dialkoxyhepta-2,5-diyne(dodecacarbonyl)-tetracobalt complex 1 directly afford [7]metacyclophanediyne(dodecacarbonyl)tetracobalt complexes.

The chemistry of small cyclophanes has been the focus of much attention, due to their structural and electronic properties, and their ability to include either metal ions or neutral or charged organic molecules.[1–3] Syntheses of these classes of compounds, however, are rarely straightforward. Access to the smaller [*n*]metacyclophanes ($n \leqslant 8$), for example, is most often accomplished by rearrangement of propellanes or spirocycloalkadienones, intramolecular Diels–Alder reactions of dienynes, or extrusion reactions of sulfoxides.[1,2] Direct intermolecular cycloaddition approaches towards these systems have not been efficient ones.[4]

The use of hexacarbonyldicobalt alkyne complexes has become important in organic synthesis.[5–7] Among the noteworthy features of these complexes is their ability to serve as protected versions of alkynes that would be severely or prohibitively strained.[8] This property has seen application as a tactic in the chemistry of cyclohexynes and cycloheptynes,[9] Bergman cyclization precursors,[10] and other polyacetylenic macrocycles.[11]

We have begun a program on the investigation of the chemistry of dodecacarbonyltetracobalt complexes of hepta-2,5-diynyl 1,7-diethers **1** and closely related compounds as latent 1,4-diynes, dienes, or enynes, based on the known ability of hexacarbonyldicobalt complexes of propargyl alcohols and their derivatives to form cations readily.[5] The diether complex **1** underwent ready reaction with electron-rich arenes in the presence of $BF_3{\cdot}OEt_2$, but did not stop cleanly at the monoarylation products. When **1** was subjected to equimolar amounts of $BF_3{\cdot}OEt_2$ and 1,3,5-trimethoxybenzene at 0 °C (at 10^{-2} M each in CH_2Cl_2), only a 24% yield of **2** could be isolated. The predominant product (26%) proved to be [7]metacyclophanediyne complex **3a**, stemming from two substitution reactions by trimethoxybenzene on **1**. The yields of **3a** realized could be improved considerably by increasing the amounts of both $BF_3{\cdot}OEt_2$ and trimethoxybenzene to 2 equiv; **3a** was then obtained in 92% yield after 5 h at 0 °C.†

Other electron-rich benzenes also gave [7]metacyclophanediyne complexes under analogous conditions (Table 1). 1,2,3-Trimethoxybenzene gave **3b** in a more modest yield (34%), while 1,3-dimethoxybenzene gave two separable cyclophanes, **3c** and **3d**, in 78% combined yield (63% **3c** + 15% **3d**). Among heterocycles tested, furan gave [7](2,5)furanocyclophane complex **3e** in 30% yield. Pyrrole, unlike the other electron rich arenes, afforded monocondensation product **4** as the only tractable product in 51% yield. Subsequent addition of **4** to excess $BF_3{\cdot}OEt_2$ (4 equiv.) at 0 °C in CH_2Cl_2 (24 h, 10^{-2}M) then gave [7](2,5)pyrrolophane **3f** in 40% yield. Thiophene proved insufficiently reactive to give any condensation product with **1**. Conducting the reactions at lower concentration (10^{-3} M) increased the necessary reaction time considerably (3 d at 0 °C), but gave some improvement in the yields of **3c** (68% **3c** + 15% **3d**) and **3e** (43%). The yield of **3b** was actually inferior (19%) at the lower concentration.



The ^{1}H NMR spectra of these [7]metacyclophanediyne complexes possessed characteristics that fell into two distinctly different groups. Those which contained a methoxy function between the two termini of the bridge (**3a** and **3d**) revealed highly diastereotopic methylene groups; the bispropargylic methylene function of **3a**, for example, gave resonances at δ 4.99 and 4.31, whereas the benzylic methylene function gave resonances at δ 4.34 and 4.09. The other cyclophanediyne complexes (**3b**, **3c**, **3e**, **3f**) showed methylene groups whose protons were isochronous.

The number of alkyne containing cyclophanes is relatively modest,[11,12] and dominated by cases where the alkyne function serves simply as a spacer,[13] but there is much interest in the demonstrated coordinating ability of the alkyne function of

Table 1 Additions between diyne complexes **1** or **4** with arenes

Diyne	Nucleophile	Product (% yield)
1	1,3,5-trimethoxybenzene	**3a** (92)
1	1,2,3-trimethoxybenzene	**3b** (34)
1	1,3-dimethoxybenzene[a]	**3c** (68)
		3d (15)
1	Furan[a]	**3e** (43)
1	Pyrrole	**4** (51)
4	—	**3f** (40)

[a] Conducted at [**1**] = 10^{-3} M.

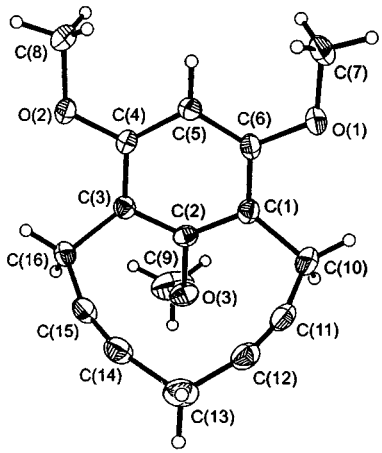


Fig. 1 ORTEP drawing of **5** (30% probability). H atoms not shown. Selected bond lengths (Å) and angles (°): C(1)–C(2) 1.398(3), C(14)–C(15) 1.186(3), C(13)–C(14)–C(15) 164.0(2), C(14)–C(15)–C(16) 162.9(2), C(12)–C(14) 106.1(2), C(2)–C(3)–C(16) 117.2(2).

cyclic polyynes.[14] As a result, we deemed it of interest to determine whether or not decomplexation of **3** could be accomplished. In fact, attempted removal of the hexacarbonyldicobalt units from **3a** by the usual reagents [Me_3NO, $(NH_4)_2Ce(NO_3)_6$, $CuCl_2$, $FeCl_3$] resulted in complete destruction of the cyclophanediyne unit. On the other hand, stirring complex **3a** in a pyridine–Et_2O solvent mixture (1:1, in air) over a 10 d period resulted in the formation of **5** in 56% yield. The ^{1}H NMR spectrum of **5** also showed the presence of diastereotopic methylene groups; the resonances for the benzylic hydrogen atoms appeared at δ 3.48 and 3.41, while the bispropargylic hydrogen atoms gave resonances at δ 2.92 and 2.61. Compound **5** gave crystals suitable for X-ray diffraction, which revealed the structure represented in Fig. 1.‡ It is apparent that there is strain in this molecule, which is reflected in several ways. Among the most notable of these are the bond angles at the alkynyl carbon atoms, which have been bent to 164 (at C-11 and C-15) and 163° (at C-12 and C-14). The arene ring also shows these effects, as the benzylic carbon atoms are pulled out of the plane of the C-1, C-3, C-4, C-6 arene ring carbons by 32.9° (β), and the benzene ring itself deviates slightly from planar at both C-2 (α = 11.2°) and at C-5 (γ = 5.5°) (Fig. 2). Nevertheless, compound **5** has good thermal stability. The structural data also suggest strongly that the diastereotopic methylene groups in **3a**, **3d** and **5** are consequences of the ring inversion represented in Fig. 2 at the slow exchange limit (Fig. 2, shown for **5**). The singlets observed for **3b**, **3c**, **3e** and **3f** stem from molecules at the fast exchange limit of the analogous inversion process.[15]

The [7]metacyclophanediyne **5** is the smallest [*n*]metacyclophane containing a triple bond reported to date. Nevertheless, a small number of reported metacyclophanes have larger deformation angles (α, β, γ),[16] and a number alkynes with smaller bond angles also exist.[17] These data suggest that smaller alkyne containing [*n*]metacyclophanes may be accessible.

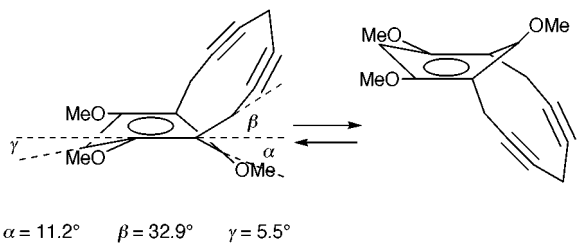

Fig. 2 Distortion angles and fluxional process for **5**.

We are grateful to NSERC (Canada) for support of this research. We wish to thank Professor Doug Stephan and Professor Stephen Loeb (WINMOL) for the crystallographic structural work on **5**.

Notes and references

† The use of the theoretically required 1 equiv. of 1,3,5-trimethoxybenzene with 2 equiv. of BF_3-OEt_2 afforded **3a** in 86% yield.

Received (in Cambridge, UK) 20th August 1999, Accepted 10th November 1999

The reaction of $[Cp^*_2TiCl_2]$ with equimolar amounts of magnesium in the presence of $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ yields the first early transition metal η^3-enyne complex $[Cp^*_2Ti\{\eta^3\text{-}Me_3SiC_3{=}C(C{\equiv}CSiMe_3)SiMe_3\}]$ 1 which is suggested to be an intermediate in early transition metal catalysed oligomerization reactions of alk-1-ynes.

Some years ago we found that $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ is cleaved[1a] by the $[Cp_2TiCl_2]$–Mg system in THF to give the dimeric titanium(III) complex $[\{Cp_2Ti(C{\equiv}CSiMe_3)\}_2]$,[1] and, that in the presence of the $[Cp^*_2TiCl_2]$–Mg system with an excess of Mg, the paramagnetic $[\{Cp^*_2Ti(C{\equiv}CSiMe_3)_2\}\{MgCl(THF)\}]$ tweezer-type compound was obtained.[2a] We have also described that when the diacetylide $[Cp^*_2Ti(C{\equiv}CSiMe_3)_2]$ is irradiated by UV light it undergoes the reverse reaction, with a coupling of the acetylides to give the titanacyclopropene complex $[Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2–C{\equiv}CSiMe_3)]$.[3a] This complex also forms from the above mentioned reduction of $[Cp^*_2TiCl_2]$ in the presence of $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ with an equimolar amount of Mg.[3b]

Here, we report the synthesis and the structure of the paramagnetic d^1 complex $[Cp^*_2Ti\{\eta^3\text{-}Me_3SiC_3{=}C(C{\equiv}CSiMe_3)SiMe_3\}]$ **1** which arises from the $[Cp^*_2TiCl_2]$–Mg–$Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ system using the molar ratios indicated in eqn. (1).

(1)

1

Compound **1** is thus the third product, in addition to the above-mentioned titanacyclopropene and the tweezer complex, which has been obtained from this system under different stoichiometric conditions. The structure of the paramagnetic complex **1** was verified by elemental analysis, EPR, IR‡ and crystallography.

An X-ray crystal structure analysis of **1**§ (Fig. 1) revealed that a bent permethyltitanocene binds an unusual carbyl, 1,4,6-tris-(trimethylsilyl)hex-3-ene-1,5-diyne-3-yl, in an η^3-mode. The Ti–C2, Ti–C3 and C2–C3 distances are consistent with a η^2-bonded triple bond and the Ti–C1 distance with a Ti–C σ bond. The alkenyl double bond is slightly elongated and the remote triple bond does not differ from the analogous bond in $[Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2–C{\equiv}CSiMe_3)]$.[3a] The entire ligand moiety is nearly planar with the sums of the valence angles around the atoms C1 and C18 both being 360° and the silylalkynyl group is almost linear. The bite angle Cp1–Ti–Cp2 of nearly 140° (Cp = centroid of cyclopentadienyl ring) and the dihedral angle between the least-squares planes of the cyclopentadienyl rings of *ca*. 41° do not indicate a significant steric hindrance imposed by the hex-3-ene-1,5-diyne-3-yl ligand.

The solution EPR spectrum of **1** consists of a single line at $g = 1.991$ ($\Delta H = 1.7$ G). The absence of low-intensity satellites due to the interaction of d^1 electron with ^{49}Ti and ^{47}Ti isotopes (I_N = 7/2 and 5/2, respectively) indicates that the unpaired electron is largely delocalized over the hex-3-ene-1,5-diyne-3-yl ligand. EPR measurements of the reacting mixtures showed the following succession of formed paramagnetic species: $[Cp^*_2TiCl]$, $[\{Cp^*_2Ti(C{\equiv}CSiMe_3)_2\}\{MgCl(THF)\}]$ and **1**.

Similar 1,4-substituted η^3-butenyne ligands coordinated to transition metals are known for *e.g.* Ru,[4a–d] Os,[4e] W[4f] and Fe,[4g,h] and their molecular parameters are essentially similar to those of the hex-3-ene-1,5-diyne-3-yl ligand in **1**. However, none of the known η^3-butenyne complexes is paramagnetic. Thus, compound **1** is the first early transition metal η^3-enyne complex and also the first paramagnetic complex of this type. While the above η^3-butenyne complexes are in many cases suggested to be intermediates in the catalysed dimerisations of alk-1-ynes, in early transition metal-based systems such intermediates like **1** have not yet been observed.[2b,5] Additionally, no such complex has been formed previously by cleavage of the central C–C single bond in a 1,3-butadiyne unit and coupling of the formed acetylide fragment with another buta-1,3-diyne.

The mechanism for the formation of complex **1** is yet not clear. On the basis of the starting materials $\{[Cp^*_2TiCl_2]$, Mg, $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3\}$, the intermediacy of $[Cp^*_2TiCl]$ and

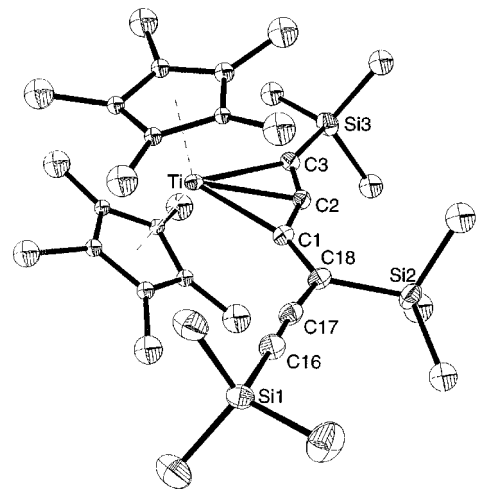

Fig. 1 Crystal structure of **1** with 30% probability level thermal ellipsoids. Hydrogen atoms and disordered groups are omitted for clarity. Selected bond lengths (Å) and angles (°): Ti–C2 2.302(4), Ti–C3 2.471(4), C2–C3 1.250(5), Ti–Cl 2.234(4), C1–C2 1.386(5), C1–C18 1.362(5), C16–C17 1.211(5), C17–C18 1.429(5); Si1–C16–C17 177.3(4), C16–C17–C18 173.2(4).

isolated products of this system {[{$Cp^*_2Ti(C{\equiv}CSiMe_3)_2$}{MgCl(THF)}], [$Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2{-}C{\equiv}CSiMe_3)$] as well as other compounds which can reasonably be expected in the reaction mixture {*e.g.* [$Cp^*_2Ti(C{\equiv}CSiMe_3)_2$], [$Cp^*_2Ti(C{\equiv}CSiMe_3)$] and [$Mg(C{\equiv}CSiMe_3)Cl(THF)_n$] a variety of reaction pathways are possible.

In analogous zirconocene chemistry, Negishi and coworkers showed that [Cp_2ZrCl_2] reacts with 3 equiv. of the acetylides LiC≡CR to yield, after hydrolysis, the enynes RCH=CH–C≡CR.[6] The mechanism of their formation suggested the presence of the 'ate' intermediates [{$Cp_2Zr(C{\equiv}CR)_3$}Li] and [{$Cp_2Zr(C{\equiv}CR)(\eta^2\text{-}RC_2{-}C{\equiv}CR)$}Li] which, however, were not isolated. Very recently this mechanism has been supported by Choukroun and Cassoux who succeeded in isolating and determining the crystal structure of the 'ate' complex [{$Cp_2Zr(C{\equiv}CPh)(\eta^2\text{-}PhC_2{-}C{\equiv}CPh)$}Li], generated from the reaction of [Cp_2ZrCl_2] with 3 equiv. of LiC≡CR.[7]

By taking into account these results one could assume that the isolated products, the titanacyclopropene [$Cp^*_2Ti(\eta^2\text{-}Me_3SiC_2{-}C{\equiv}CSiMe_3)$][3] or, alternatively, the tweezer compound [{$Cp^*_2Ti(C{\equiv}CSiMe_3)_2$}{MgCl(THF)}],[2] react with [$Cp^*_2Ti{-}C{\equiv}CSiMe_3$] or [$ClMg{-}C{\equiv}CSiMe_3$], resulting in the 'ate' complex [$Cp^*_2Ti(C{\equiv}CSiMe_3)(\eta^2\text{-}Me_3SiC_2{-}C{\equiv}CSiMe_3)]^-[Y]^+$ {$[Y]^+ = [Cp^*_2Ti]^+$ or $[MgCl]^+$}, both being similar to what has been discussed by Negishi and coworkers as non-isolable intermediates and to species which have recently been characterized by Choukroun and Cassoux. Since titanium is much less electropositive than zirconium and provides a considerably smaller coordination sphere, the diyne is inserted into the Ti–C acetylide bond (inter- or intra-molecularly) and complex **1** is formed.

Received (in Basel, Switzerland) 29th September 1999, Accepted 9th November 1999

The novel copper(I) ethylene complex [$Bu^t_2P(NSiMe_3)_2$-κ^2N]Cu(η^2-C_2H_4) and its norbornene analogue have been synthesized and characterized and their solid state structures determined.

Copper(I) olefin complexes play an important role in biochemistry and modern organic chemistry. Copper-catalyzed addition of carbanions to α,β-unsaturated carbonyls and copper-catalyzed cyclopropanation of alkenes by α-carbonyl diazoalkanes involve copper olefin complexes as catalytically active species or resting states.[1–4] Ethylene, the smallest plant hormone, binds tightly to the copper receptor site ETR 1,[5,6] participating in a variety of stress responses and developmental processes.[7] Thompson *et al.* synthesized and characterized the first stable copper(I) ethylene complex, [HB(3,5-Me_2-1,2-$HC_3N_2)_3$-κ^3N]Cu(η^2-C_2H_4), in 1983.[8] Nevertheless, the stability of the ethylene/receptor complex is much higher than that of any reported artificial copper ethylene complex.[5,6,9]

Owing to the notorious lability of ethylene coordination in known copper(I) complexes, only one extrapolated ^{13}C NMR chemical shift relative to free ethylene ($\Delta\delta$ = 31.1)[10] and no $^1J_{CH}$ coupling constant for copper(I) coordinated ethylene could be determined. Obviously, such data are highly relevant for an understanding of the copper(I)–ethylene bond.

Here, we report a remarkably stable copper(I) ethylene complex **1**, which is easily accessible by utilizing a tailor-made sterically demanding and electron-rich iminophosphanamide, first described by Scherer and Schieder more than 30 years ago,[11] as a co-ligand, generated by *in situ* deprotonation (Scheme 1).[12]

The stability of **1** in the solid state and in solution is unprecedented. Colorless crystals of **1** can be dried at 10^{-3} mbar at ambient temperature without decomposition. Complex **1** melts at 108 °C to a colorless liquid which only slowly decomposes at that temperature. Protonated **1** could be observed in the gas phase (CI + MS, 2-methylpropane). No free ethylene is detected by ^1H NMR spectroscopy upon dissolving **1** in C_6D_6, $CDCl_3$ or toluene-d_8 in an argon atmosphere. The presence of additional ethylene leads to separate broad signals of free and of coordinated C_2H_4, indicating associative olefin exchange.

The C–C distance of ethylene in **1** is 1.362(6) Å, which does not differ significantly from the corresponding distance in free ethylene [1.3369(16) Å].[13] The sp^2-character of the C_2H_4 carbons is in accordance with a $^1J_{CH}$ coupling constant of 158 Hz, which is even larger than in free ethylene (156 Hz).[14]

The ^1H NMR resonance of the ethylene protons at δ 3.48 (C_6D_6, 298 K; for free ethylene δ 5.24 under the same conditions) is shifted by 0.5 ppm to higher field than the most upfield copper(I) ethylene signal (δ 4.0) reported so far.[15] The ^{13}C NMR signal is detected at δ 73.0 with an upfield shift of 50 ppm compared to free ethylene. Lower temperatures and aromatic solvents lead to an upfield shift of the ethylene protons (δ 3.35, toluene-d_8, 233 K; δ 3.63, $CDCl_3$, 223 K).

The norbornene complex [$Bu^t_2P(NSiMe_3)_2$-κ^2N]Cu(η^2-C_7H_{10}) **2** could be obtained in a similar way.† Its solid state geometry, structurally analogous to **1**, is shown in Fig. 2.

Unlike **1**, complex **2** allows determination of the rotational barrier of the olefin ligand as $\Delta G^{\ddagger}$ = 41.5 ± 2.0 kJ mol^{-1} (VT $^{13}C\{^1H\}$NMR) through coalescence of the signals of both the diastereotopic $C(CH_3)_3$ and $C(CH_3)_3$ carbons.

The high basicity of the anionic iminophosphanamide σ- and π-donor ligand and the small bite angle N–Cu–N of 77.80(9)° in the four-membered neutral chelate ring system seem to be responsible for the unprecedented stability and unusual spectral properties of **1**. The high HOMO and the low LUMO energy of a d^{10}-ML_2 fragment with a small bite angle[16] lead to increased π-back bonding towards the olefin and a strong olefin-to-metal dative bond, thus causing an increased ethylene ligand dissociation energy compared to other neutral and, even more so, cationic copper(I) units. Formation of stable dinuclear olefin-free copper(I) complexes with nearly linear N–Cu–N fragments and concomitant weak d^{10}–d^{10} interaction as known from other systems[8] is hampered by the sterically demanding iminophosphanimide ligand system with its $SiMe_3$ groups bent towards the olefin side (P–N–Si ≈ 150°).

Complex **1** catalyzes cyclopropanation of styrene with α-carbonyl diazoalkanes at room temperature. The extremely high

Selected bond lengths (Å) and angles (°): P–N(1) 1.599(5), Si(1)–N(1) 1.704(9), Cu–N(1) 2.031(7), Cu–C(2) 2.026(23), C(21)–C(22) 1.377(20); P–N(1)–Si(1) 149.4(1.5), N(1)–P–N(2) 104.7(3), P–N(1)–Cu 89.0(4), N(1)–Cu–N(2) 77.1(1).

solubility of **1** even in alkanes and its NMR active nuclei (^{1}H, ^{13}C, ^{29}Si and especially ^{31}P) now offer an ideal chance to investigate mechanistic aspects of organometallic copper(I) chemistry, especially of copper(I)-catalyzed cyclopropanation.

Support of this work by a PhD stipend of the Fonds der Chemischen Industrie for B. F. S. is gratefully acknowledged.

Notes and references

† *Synthesis* of **1**: 13 ml 1.6 M Bu^{n}Li in hexane (21 mmol) were added to 5.78 g (18.0 mmol) Bu$^t_2$P[N(SiMe$_3$)]NH(SiMe$_3$)[11] in 20 ml of hexane under an argon atmosphere, and the solution was refluxed for 1 min,[12] then added to a suspension of 4.97 g (24 mmol) CuBrSMe$_2$ in 20 ml of hexane at −78 °C and stirred while warming to ambient temperature. Ethylene (99.7%) was bubbled into the black suspension for 2 min. The suspension was filtered through Celite under an ethylene atmosphere. From the slightly yellow solution crude **1** was crystallized at −78 °C. Recrystallization yielded 3.21 g (7.8 mmol, 43.4%) of **1**; crystallization from the collected organic phases yielded another batch of 2.80 g (6.6 mmol, 36.7%) (purity >97% **1**). Addition of norbornene has no effect on the coalescence temperatures, ruling out associative mechanisms for the observed degenerate rearrangement.

‡ Data were collected on a Bruker SMART CCD instrument and the structure solutions were performed using SHELXTL V5.10,[17] respectively. Intensities were corrected for Lorentz and polarization effects, an empirical absorption correction was applied using SADABS[18] based on the Laue symmetry of the reciprocal space.

Solid-phase synthesis of a putative heptapeptide intermediate in vancomycin biosynthesis

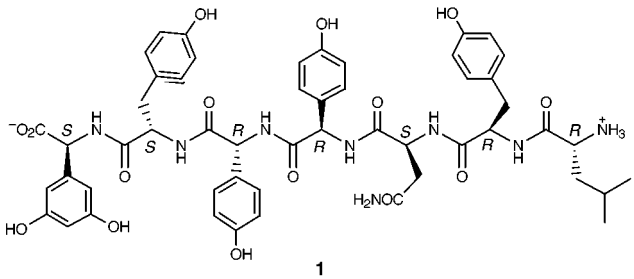
Ernst Freund and John A. Robinson*

Institute of Organic Chemistry, University of Zurich, Winterthurerstrasse 190, 8057 Zurich, Switzerland. E-mail: robinson@oci.unizh.ch

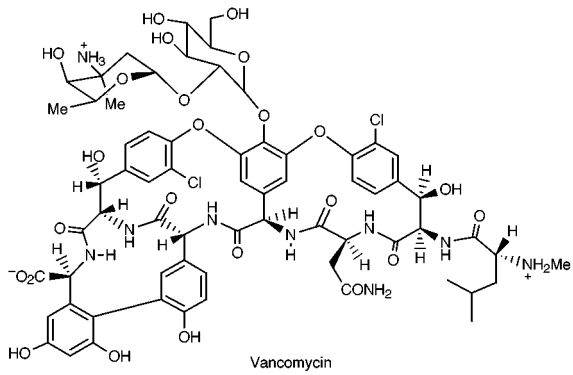
Received (in Liverpool, UK) 1st October 1999, Accepted 1st November 1999

The solid-phase synthesis was completed of the heptapeptide D-Leu-D-Tyr-L-Asn-Hpg-Hpg-L-Tyr-Dhpg, a putative intermediate in vancomycin biosynthesis, where Dhpg = (*S*)-3,5-dihydroxyphenylglycine and Hpg = (*R*)-4-hydroxyphenylglycine, using 2-chlorotrityl resin, benzyl side-chain protecting groups for the aromatic residues, and Alloc chemistry for chain elongation; the heptapeptide was obtained in 16% yield with the correct relative and absolute configuration.

Important progress has been made recently in elucidating the biosynthetic pathway to glycopeptide antibiotics of the vancomycin family. The nucleotide sequence of a gene cluster from the chloroeremomycin-producing microorganism revealed a large number of open reading frames encoding putative peptide synthetases, halogenases, hydroxylases and P450-like cytochromes, amongst many others.[1,2] Similar genes have also been cloned and sequenced from the balhimycin producer,[3] and disruption of a P450-like gene in this organism has provided the first confirmation of its role in the biosynthesis of the glycopeptide antibiotic, as well as indicating a likely role in a phenol coupling reaction.[4] Presently, however, the sequence of steps in glycopeptide antibiotic biosynthesis is largely unknown. Since most, if not all, the biosynthetic genes are now available for study, progress in this area should be facilitated by access to putative biosynthetic intermediates. We report here a convenient solid-phase synthesis of the heptapeptide **1**, which



1

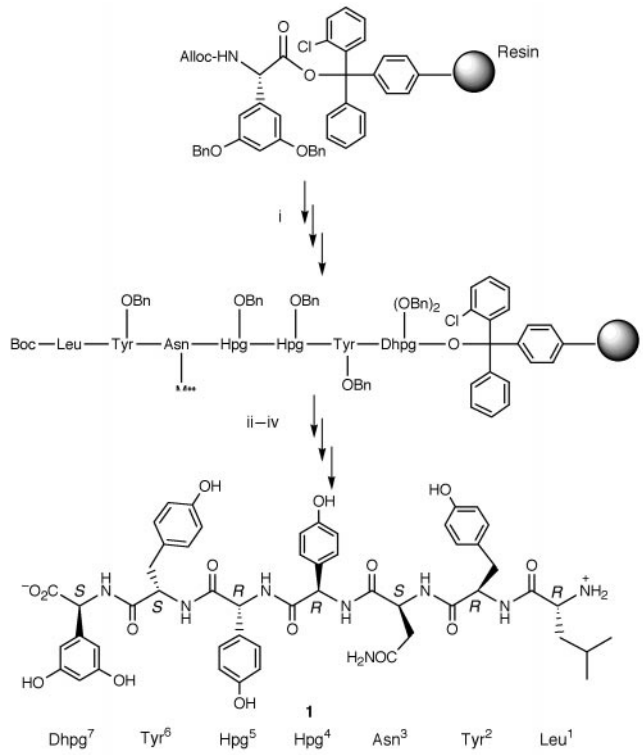


Vancomycin

may be considered[5] a possible product of the vancomycin peptide synthetase, and hence a potential substrate of downstream enzymes such as the halogenases, hydroxylases, or those catalyzing phenol coupling reactions.

A major concern in planning the solid-phase synthesis of **1** was the sensitivity of several amino acids to epimerization during chain assembly and/or subsequent deprotection steps, when using standard Fmoc or tBoc chemistry. We chose, therefore, to investigate Alloc chemistry for chain elongation, since deprotection of the N-terminus at each step of chain assembly can be performed under almost neutral conditions.[6] The amino acids (*R*)-4-hydroxyphenylglycine (Hpg) and (*S*)-3,5-dihydroxyphenylglycine (Dhpg) were synthesized by standard methods,[5] and protected on N^{α} with the Alloc group, and in the aromatic side chains with benzyl ethers. For the synthesis of **1**, (*S*)-Alloc-Dhpg$(OBn)_2$-OH was first coupled to 2-chlorotrityl chloride resin[7] in CH_2Cl_2 with NMM† as base. The peptide chain was then elaborated using for each coupling HATU/HOAt (4 equiv.) and the required amino acid derivative (4 equiv.) in DMF. For Alloc removal,[8] $Pd(PPh_3)_4$ and $PhSiH_3$ were used, as outlined in Scheme 1.

Upon completion of the solid-phase synthesis, the protected heptapeptide was first cleaved from the resin, and the N-terminal Boc and side-chain protecting groups were then



Scheme 1 *Reagents and conditions*: i, for coupling (*R*)-Alloc-Hpg(OBn)-OH, (*R*)- and (*S*)-Alloc-Tyr(OBn)-OH, L-Alloc-Asn(Mtt)-OH, or D-Boc-Leu-OH (4 equiv.), HATU and HOAt (each 4 equiv.), NMM, DMF, and for Alloc deprotection $Pd(PPh_3)_4$ (0.5 equiv.) and $PhSiH_3$ (30 equiv.) in CH_2Cl_2; ii, CF_3CH_2OH–AcOH–CH_2Cl_2 (1 : 1 : 3); iii, TFA–CH_2Cl_2 (1 : 1) + 5% Pr^i_3SiH, 0 °C, 2 h; iv, TFA, thioanisole (3 : 1), 20 °C, 3 h.

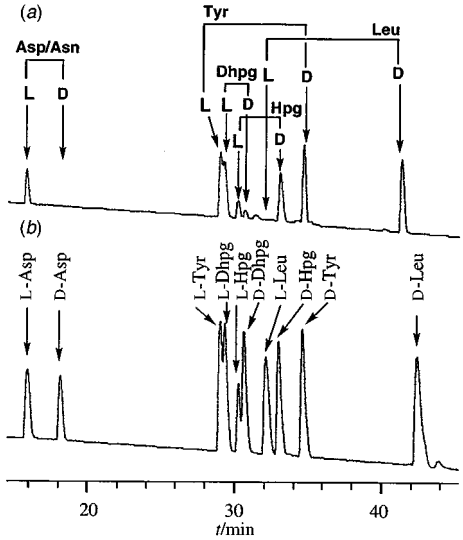


Fig. 1 HPLC chromatograms (Waters C_{18} column, 5 μm, 100 Å, 3.9 × 100 mm, flow rate: 1 ml min^{-1}, gradient, 5–100% MeCN in 0.1 M ammonium acetate buffer pH 7.4, over 130 min) showing (*a*) derivatives formed by reaction of *N*α-(2,4-dinitro-5-fluorophenyl)-L-valinamide with the amino acid hydrolysate of peptide **1** (the identities of the peaks are indicated) and (*b*) the standards prepared by reacting each optically pure amino acid with the same reagent (the identity of each peak was confirmed by MS and ^{1}H NMR spectroscopy).

removed in two steps (Scheme 1). Analysis of the crude product by HPLC revealed three main products in a ratio of *ca.* 6:2:1. The predominant product was identified by spectroscopic data as the required heptapeptide,‡ which was isolated by preparative HPLC (Vydac C_{18} 218TP1010, 10 μm, 300 Å, 10 × 250 mm, flow rate: 5 ml min^{-1}, gradient 10–40% MeCN in water + 0.1% TFA over 25 min) in *ca.* 16% overall yield. Due to difficulty in their purification, the minor products were not investigated in detail, although their mass spectra indicated the same mass as for **1**. Model studies (not described here) indicated that in particular the Hpg residues are susceptible to partial epimerization during the solid-phase synthesis.

In order to prove that the main product of the synthesis has the desired configuration, it was hydrolysed with 6 M HCl at 115 °C, under Ar, in the presence of phenol. The amino acids were immediately reacted with the modified Marfey's reagent *N*α-(2,4-dinitro-5-fluorophenyl)-L-valinamide[9] and analyzed by HPLC. Conditions were used that allowed the resolution on a C_{18} reversed phase column of a mixture of D- and L-Asp, D- and L-Tyr, D- and L-Leu, D- and L-Hpg and D- and L-Dhpg (see Fig. 1), each as a derivative with the modified chiral Marfey's reagent. In this way, the amino acid hydrolysate was seen to consist of L-Asp and D-Leu, of D- and L-Tyr, and predominantly of L- (rather than D-) Dhpg and D- (rather than L-) Hpg. This corresponds to the expected constitution of the heptapeptide **1**.

The solid-phase synthesis reported here allows the convenient preparation of **1** in multi-milligram amounts, as required for enzymatic studies of vancomycin biosynthesis. The method also appears amenable to parallel synthesis methods, that might allow the production of small combinatorial libraries of related peptides as tools to study the substrate specificities of these enzymes.

The authors thank the Swiss National Science Foundation for financial support.

Carbonylation of methanol in supercritical CO_2 catalysed by a supported rhodium complex

Rebecca J. Sowden, Murielle F. Sellin, Nicola De Blasio and David J. Cole-Hamilton*

School of Chemistry, University of St. Andrews, St. Andrews, Fife, Scotland, UK KY16 9ST. E-mail: djc@st-and.ac.uk

Received (in Basel, Switzerland) 16th August 1999, Accepted 27th October 1999

A rhodium complex supported on polyvinylpyrrolidone catalyses the carbonylation of methanol to methyl ethanoate and ethanoic acid in supercritical CO_2 at rates up to *ca.* 50% those in liquid solution but with minimal catalyst leaching.

The rhodium catalysed carbonylation of methanol is an important commercial application of homogeneous catalysis in which the product can be separated from the catalyst by distillation.[1] Since this separation is carried out separately from the reaction, not all of the catalyst can be employed in the desired reaction at any one time.[1] There is, therefore, an interest in developing truly continuous processes.

One possibility would be to use a supported catalyst and to flow the reagents over it. However, in the liquid phase, catalyst leaching from the support is always a problem, although a demonstration reactor has been commissioned in which the catalyst is $[RhI_2(CO)_2]^-$ attached to an ion exchange resin. Catalyst does leach, but the dissolved catalyst is collected on a downstream bed of the resin which is recycled to the reactor.[2]

We have recently reported studies of a catalyst consisting of $[RhI_2(CO)_2]^-$ supported on polyvinylpyrrolidone (PVP).[3,4] In the liquid phase, we showed that the rate constant for the homogeneous reaction was only 2.2 times that for the heterogeneous reaction but that significant leaching of Rh occurs.[3] In the gas phase, after activation, stable activity was observed over long periods, there was no leaching, but the overall methanol consumption rate is low because of the low concentration of methanol that can be attained in the gas phase.[4]

We reasoned that supercritical CO_2 might be an ideal vector for this reaction since it dissolves large quantities of methanol and methyl iodide, is totally miscible with CO, has gas-like diffusion properties and is a poor solvent for ionic species such as $[RhI_2(CO)_2]^-$ so that leaching should be minimised. We now report preliminary results from a study of this system.

Rhodium supported on PVP was prepared as described previously[3] and tested for its activity in the bulk liquid phase. The result (Table 1, run A1) is broadly consistent with our previous results, as is the extent of rhodium leaching.[3]

The catalysts were then used for reactions in $scCO_2$. The catalyst was loaded into an autoclave with a sapphire bottom (for observation purposes). Degassed methanol and MeI were injected into the autoclave against a stream of CO_2, the autoclave sealed, pressurised to 40 bar with CO and then CO_2 added from a cooled head HPLC pump. The amount of CO_2 was varied to control the final reaction pressure which was achieved at the reaction temperature (150 °C). Observation of the catalyst shows that it changes from red to pale yellow at the onset of the reaction as indicated by a decrease in the slope of the *p vs. T* curve, which occurred between 100 and 140 °C. At the end of the reaction, the autoclave was cooled to 0 °C then to −80 °C and vented. The liquid product was removed for analysis and the autoclave recharged with methanol, MeI, CO and CO_2. We have shown, through observations on mixtures of CO_2, MeI, methanol and CO, in the absence of the catalyst, that the mixture with the same composition as that used for experiments B and C is monophasic above 130 °C. Replacing the methanol in this mixture with ethanoic acid raises the temperature at which it becomes monophasic to 150 °C, whilst a mixture in which the methanol is replaced by methyl acetate, (1.2 cm^3), ethanoic acid (0.4 cm^3) and water (0.4 cm^3) also becomes monophasic at 150 °C.

The results of a series of runs using the same sample of catalyst are shown in Table 1 (B1–6) and Fig. 1. The rate of methanol carbonylation was *ca.* 23% that in liquid methanol, despite the fact that the concentrations of methanol and iodomethane were reduced by a factor of *ca.* 25.† Interestingly, and reproducibly, the rate increased for the second run (58% of the rate in the liquid phase) and then levelled off at a lower level for subsequent runs, despite the fact that significant amounts of Rh were leached from the support. Run B6 was carried out in the absence of added MeI; carbonylation activity was still observed at a rate similar to that observed in the previous reaction (B5). In other experiments, we have shown that the activity drops off on subsequent runs in the absence of MeI and that, if MeI is omitted from the first run in a series, no activity is observed. These results suggest that the catalyst support takes up MeI and that the rate increases as the MeI content reaches saturation either because the concentration of MeI in the supercritical phase is increased, or because the rhodium on the surface reacts with surface bound MeI (see below). When MeI is omitted from the reaction mixture, the MeI adsorbed in the surface is then used, before or after desorption, as the promoter. (Fig. 2).

In experiments B1–6, the liquid products spend significant amounts of time (up to 4 h) on the catalyst during the cooling

Table 1 Yields of carbonylation products and extent of rhodium leaching during the carbonylation of methanol catalysed by a supported rhodium catalyst under various conditions[a]

Run	MeI added/ cm^3	MeOAc yield (%)	HOAc yield (%)	Turnover frequency[b]/ h^{-1}	Rh leached (%)
A1[c]	0.8	2.6	50.4	870	52.2
B1	0.3	17.0	2.2	197	12.2[d]
B2	0.3	42.2	6.9	504	11.3[d]
B3	0.3	22.8	3.4	269	6.8[d]
B4	0.3	27.0	5.6	335	3.9[d]
B5	0.3	24.5	10.5	361	12.1[d]
B6	0	33.5	4.2	383	12.4[d]
C1	0.3	20.8	1.1	178	< 0.08[e]
C2	0.3	37.5	1.3	315	0.08
C3	0.3	30.1	4.8	283	< 0.15[e]
C4	0.3	21.8	3.5	205	< 0.3[e]
C5	0.3	28.4	2.7	252	< 0.3[e]

[a] Catalyst was rhodium on polyvinylpyrrolidone (0.17 g; B, 0.82% Rh; C, 1.04% Rh); MeOH (1.5 cm^3, 1.8 cm^3 if no MeI added); CO (40 bar at ambient temperature); $CO_{2(l)}$ (12 cm^3, 12.7 g); 150 °C; p_{150} = 200 bar, 3 h. In repetitive experiments, we have found the reproducibility is ±10%; [b] Mol of product (mol of Rh)$^{-1}$ h^{-1}. [c] Liquid phase reaction: catalyst (0.17 g, 0.82% Rh); MeOH (4.2 cm^3); CO (40 bar at ambient temperature), 150 °C, 5 h. [d] From analysis of the solution recovered after each run. Analysis of the solid catalyst after the six runs indicated 39.2% of the rhodium had leached. This is less than the total of the solution figures because some of the solution and hence part of the leached rhodium remained in the autoclave after removing the condensed liquid by syringe at the end of each run. Yields of HOAc and MeOAc might be slightly overestimated for runs B2–B6 as a result of this. [e] From analysis of the solution collected in the second autoclave, detection limits for the particular experiment are shown; these correspond to < 0.3 ppm in the analyte.

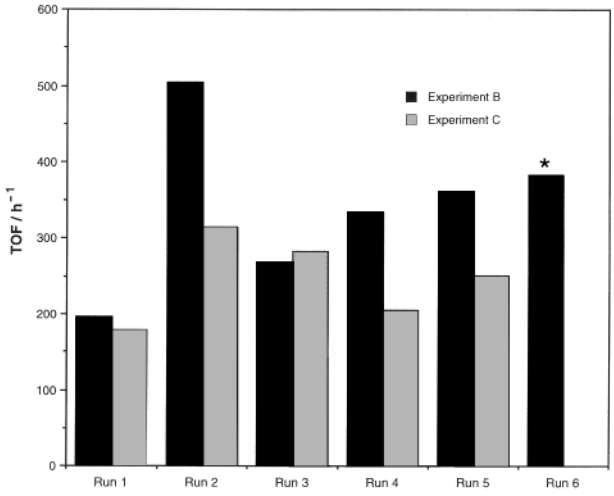

Fig. 1 Plot of turnover frequency/h^{-1} for repetitive catalytic reactions. The same catalyst was reused for all runs in a series, but different samples were used for runs B and C. For runs B, the products were condensed onto the catalyst and removed by syringe; for runs C, the products were flushed from the autoclave using $scCO_2$. The asterisk means that iodomethane was not added for this run.

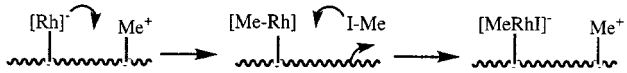

Fig. 2 Possible mechanism of reaction of the catalyst with surface bound methyl groups and remethylation of the surface.

and venting process and we surmised that the observed catalyst leaching might occur during this period of contact between the catalyst and the liquid products. To investigate the leaching under supercritical conditions, we carried out the reaction in the same way except that at the end of the reaction the stirrer was stopped and, in a process similar to that introduced by Leitner and co-workers[5] for the separation of products from homogeneous catalysts after reactions in $scCO_2$, fresh $scCO_2$ was passed into the bottom of the autoclave at the reaction temperature and pressure to flush the product solution into a second autoclave held at 40 bar and −80 °C. During this process, the CO_2 and CO were vented through an ethanol trap. The catalyst remaining in the first autoclave was reused five times (Table 1, Fig. 1, runs C1–5). The liquid product collected in the second autoclave (up to 1.2 cm^3) was analysed for the organic products by GLC and for rhodium content by atomic absorption. This series of experiments was carried out with a slightly higher catalyst loading than that for experiments B1–5, so the apparent yields are lower.‡ These lower apparent yields may arise because some solution was always left on the catalyst in the B series of experiments because the product solution was removed by syringe. This means that the starting solution for all the B series experiments, except B1, contained some product. In the C series experiments, all the product apart from that adsorbed on the support (see below) was removed by the venting process.

None of the solutions recovered after the supercritical venting process (series C) contained detectable rhodium (< 0.3% of Rh charged), apart from C2, which contained 0.08% of the rhodium charged,§ suggesting that leaching has been minimised. To confirm this, we analysed the catalyst before and after use (Table 2). The mass of the catalyst recovered was higher than that loaded, and the total rhodium content had dropped slightly (12%, although the precision of the analyses is such that this may not be significant) (see Table 2), confirming that rhodium leaching is greatly reduced when the reaction is carried out and the products are recovered in the supercritical phase.

In order to understand the increase in weight of the catalyst, we heated a sample of the recovered catalyst to constant weight in a closed system and analysed the gas phase. MeI and $MeCO_2H$ were detected by GLC and the weight loss was 22%,

Table 2 Analysis of supported catalyst used in experiments C1–5 after various treatments

	Mass of catalyst/mg	Rh content (%)	Total Rh (10^{-5} mol)
Charged[a]	170	1.04	1.7 ± 0.1
Recovered[b]	205	0.74	1.5 ± 0.1
Heated[c]	27		
Recovered[d]	21		
Expected[e]	22.4		

[a] To the reactor at the start of the series C experiments. [b] From the reactor after experiment C5. [c] Sample of catalyst taken for heating to 200 °C. [d] After heating to 200 °C, MeI and $MeCO_2H$ were released; weight loss by TGA = 13.7%. [e] If all the mass gained during the catalytic experiment were from adsorption of MeI and $MeCO_2H$.

cf. 17% if all the weight gained during the catalysis were lost. In a similar experiment carried out using thermal gravimetric analysis (TGA), the weight loss in a transient process starting at 33 °C and complete by 70 °C was 13.7%. TGA was also carried out on samples of the catalyst support washed with MeI and with ethanoic acid separately. For MeI, the transient process had an onset temperature of *ca.* 30 °C and was complete at 99 °C, whilst for ethanoic acid, onset was at 22 °C and the loss was complete at 70 °C. In all the TGA experiments, substantial further weight loss occurred above 250 °C, probably from decomposition of the polymer support. The observation that MeI is held on the catalyst (even after storing for several days) supports our suggestion[4] that it interacts with the support.

The rates obtained in the supercritical experiments are of the same order of magnitude as those obtained in the liquid phase reactions, despite the lower concentrations of methanol and MeI in the supercritical reactions. Turnover frequencies in the gas phase reactions are comparable with those obtained in the supercritical phase (up to 595 h^{-1}, at 190 °C in the gas phase compared with up to 504 h^{-1} at 150 °C for the supercritical phase reactions). However, the gas phase reactions were carried out at a higher temperature, and the concentration of methanol achievable is very much less (1 cm^3 in 9.8 dm^3, as opposed to 1.5 cm^3 in 50 cm^3 for the supercritical reactions). Rhodium leaching is a severe problem for the bulk liquid phase reactions,[3] but is very much reduced for the reactions carried out in the supercritical or gas[4] phases.

We conclude that methanol carbonylation in the supercritical phase has the potential to overcome the problems of liquid phase (catalyst leaching) and gas phase (low methanol throughput) reactions using the same supported catalyst.

We thank the EEC for a Fellowship (M. F. S.) and support under a TMR programme and for support under the ERASMUS programme (N. De B).

Notes and references

† The supercritical reactor has a volume of 50 cm^3, whilst the liquid phase reactions were carried out in a liquid volume of 5 cm^3.

‡ Using this catalyst for an experiment under the conditions of experiment B1, we obtained a turnover frequency of 176 ± 13 h^{-1}, within experimental error the same as that obtained with the batch of catalyst used for the B experiments (197 ± 20 h^{-1}).

§ In this experiment, all of the recovered solution was used for the atomic absorption analysis, improving the detection limit for this analysis. The amount detected is at this detection limit (0.5 ppm in the analysed sample).

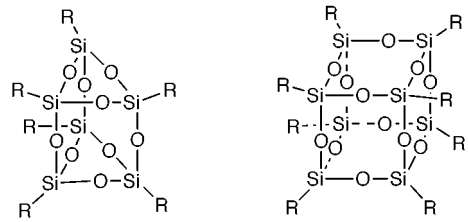
Received (in Bloomington, IN, USA) 10th September 1999, Accepted 3rd November 1999

Readily available $(RMe_2SiO)_6Si_6O_9$ (3 R = Me, 5 R = CH=CH_2); reacts cleanly with aqueous NEt_4OH in THF to afford *endo*-C_{2h}-$(RMe_2SiO)_6Si_6O_7(OH)_4$ (7 R = Me, 9 R = CH=CH_2); exhaustive silylation of 7 with $(CH_2{=}CH)Me_2SiCl/NEt_3$ affords *endo*-C_{2h}-$(Me_3SiO)_6Si_6O_7[OSiMe_2(CH{=}CH_2)]_4$ (10).

Discrete polyhedral clusters containing silicon and oxygen are attractive building blocks for the preparation of Si/O/M frameworks, inorganic solids and hybrid inorganic–organic materials.[1–10] Two broad families of polyhedral Si/O clusters exist: (1) polyhedral silsesquioxanes (*e.g.* **1** and **2**), which are



1 R = c-C_6H_{11}
3 R = $OSiMe_3$
5 R = $OSiMe_2(CH{=}CH_2)$

2 R = c-C_6H_{11}
4 R = $OSiMe_3$

usually obtained from hydrolytic condensation reactions of trifunctional organosilicon monomers ($RSiX_3$);[11] and (2) spherosilicates (*e.g.* **3** and **4**), which are most often prepared by silylation of silicate solutions.[12–15] Both families have enormous potential as precursors to advanced materials if cost-effective methods can be devised to produce appropriately functionalized Si/O frameworks on a large scale.

Over the past three years, we have developed highly selective methods for effecting the partial hydrolysis of fully condensed polyhedral silsesquioxanes with structures **1** and **2**.[16–20] These methods provide access to a variety of functionalized silsesquioxanes, but they are generally not useful for the modification of spherosilicates. Here, we report the first highly selective procedure for effecting partial hydrolysis of a spherosilicate framework. This procedure produces a C_{2h}-symmetric tetrasilanol *via* base-catalyzed hydrolysis of both Si_3O_3 rings in [$(Me_3SiO)_6Si_6O_9$] **3**, which is readily available from $Si(OEt)_4$, NEt_4OH and Me_3SiCl.[14,15] Subsequent reaction of this tetrasilanol with $(CH_2{=}CH)Me_2SiCl$ affords the corresponding tetrasilylated product. Implications of these results for the development of incompletely condensed Si/O frameworks as precursors to hybrid inorganic–organic materials[1] and as ligands for transition-metal catalysts[3,21–23] are discussed.

The reaction of **3** with 35% aqueous NEt_4OH in THF occurs rapidly upon mixing at −40 to −25 °C to produce a new silicate cluster in quantitative NMR yield.† As illustrated in Fig. 1 (top spectrum), this cluster exhibits two sets of ^{29}Si NMR resonances with relative integrated intensities of 2:1. One set appears at δ *ca.*12 and is assignable to TMSO (*i.e.*, 'M') groups. The second set of ^{29}Si resonances appears at δ *ca.* −100 to −110 and is assignable to framework silicate (*i.e.* 'Q') groups in two different environments. The smaller resonance at δ −109.27 is characteristic of ^{29}Si nuclei in fully condensed spherosilicates with relatively unstrained Si_nO_n rings. (For comparison, the ^{29}Si NMR resonance for **4** is at δ −108.95.[24]) The larger resonance at δ −100.12 is slightly upfield from the resonance for **3** (δ −99.31) and *ca.* 10 ppm downfield from the resonance for **4**. Although this resonance is in the range expected for fully condensed spherosilicates with Si_3O_3 rings, it is also consistent with $(SiO)_3Si(OH)$ groups in relatively unstrained Si_nO_n rings.[25–27] On the basis of these data—as well as ^1H and ^{13}C NMR data, electrospray mass spectrometry data† and structure/^{29}Si chemical shift correlations observed for structurally similar cyclohexyl-substituted silsesquioxanes (*i.e.* **1**, **2** and **6**)[20]—the product obtained from the reaction of **3** with NEt_4OH must be a C_{2h}-symmetric tetrasilanol derived from cleavage of both Si_3O_3 rings. Structures **7** and **8** are equally consistent with most of our data, but structure **7** is much more likely for two reasons: (1) the ^1H NMR chemical shift for the SiOH groups is strongly deshielded (*ca.* 7 ppm), consistent with extensive intramolecular hydrogen bonding,[20,28,29] and (2) the NEt_4OH-catalyzed hydrolysis of Si–O–Si linkages in both **1** and **2** are known to proceed with complete retention of stereochemistry at Si.[19,20] A structurally similar tetrasilanol (*i.e.* **9**) is also obtained from the reaction of **5** with aqueous NEt_4OH.

Tetrasilanols **7** and **9** are stable at 25 °C and soluble in many common organic solvents, including hydrocarbons, diethyl ether, chlorocarbons and acetone. They are also soluble in most of the polar solvents used as nonsolvents for the crystallization of polyhedral silsesquioxanes and spherosilicates (*e.g.* MeCN and MeOH). Both **7** and **9** separate from solution as colorless waxes rather than microcrystalline solids. Neither compound has been successfully crystallized, but it is clear from Fig. 1 (as well as ^1H and ^{13}C NMR spectra of crude reaction mixtures) that the crude product obtained after an aqueous work-up is quite pure.

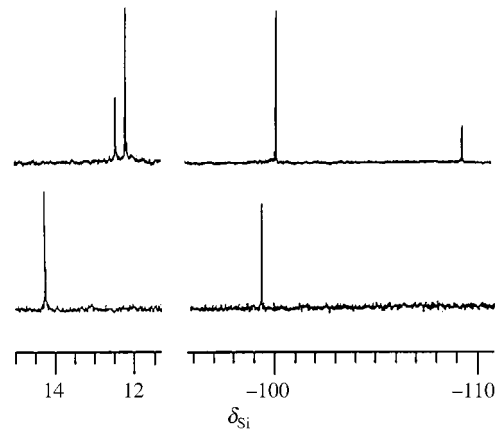


Fig. 1 ^{29}Si {^1H} NMR (99.3 MHz, $CDCl_3$, 25 °C) spectra from the reaction of $(Me_3SiO)_6Si_6O_9$ **3** with 35% aqueous NEt_4OH in THF at −40 to −25 °C. The lower spectrum is for pure **3**. The upper spectrum is for crude *endo*-C_{2h}-$(Me_3SiO)_6Si_6O_7(OH)_4$ **7** obtained after an aqueous work-up.

	R′	R
6	H	c-C_6H_{11}
7	H	$OSiMe_3$
9	H	$OSiMe_2(CH{=}CH_2)$
10	$OSiMe_2(CH{=}CH_2)$	$OSiMe_3$

8 R = $OSiMe_3$

Although the chemistry of C_{2h}-symmetric $R_6Si_6O_7(OH)_4$ frameworks[20,28,29] is largely undeveloped, these tetrasilanols offer interesting possibilities as building blocks for more elaborate Si/O and Si/O/M frameworks. For example, the reaction of **7** with $(CH_2{=}CH)Me_2SiCl$ and NEt_3 produces **10** in essentially quantitative yield after an aqueous work-up.‡ This compound is also obtained as a highly soluble waxy solid that resists crystallization. As expected, both ^{29}Si NMR resonances for the framework silicate groups appear at δ *ca.* −110 and the diastereotopic Me groups on the four chemically equivalent $(CH_2{=}CH)Me_2SiO$ groups appear as two resonances with equal intensities in both the ^{1}H and ^{13}C NMR spectra.

The results described here represent an important advance in the chemistry of spherosilicates, and they have major implications for many emerging applications for discrete Si/O clusters. From the standpoint of developing cost-effective methods for producing functionalized Si/O frameworks for use in hybrid inorganic–organic materials and incompletely condensed Si/O frameworks for use as ligands for transition metal catalysts, the ability to produce appropriately functionalized compounds from spherosilicates is attractive because many spherosilicates—including **3** and **4**—can be obtained in high yield from either silica or $Si(OEt)_4$. More importantly, the recognition that **3** can be partially hydrolyzed in high yield at high conversion offers a strategy for preparing functionalized spherosilicates that does not rely on inherently unselective pendant group modifications. If similarly selective methods can be devised for effecting partial hydrolysis of other spherosilicates (*e.g.* **4**), many of the applications being developed for polyhedral silsesquioxanes with one or two well defined functional groups can be extended to spherosilicates.

These studies were supported by Hybrid Plastics (Fountain Valley, CA) under an Advanced Technologies Program grant from the National Institute of Standards and Technology and the Air Force Research Laboratory (Edwards AFB).

Notes and references

† *Reaction* of **3** with NEt_4OH: aqueous NEt_4OH (35%, 82.3 μL, 0.20 mmol) was added to a solution of **3** (170 mg, 0.20 mmol) in THF (4 mL) at −40 °C. The resulting mixture was stirred between −40 and −25 °C for 40 min then neutralized with dilute aqueous HCl. Extraction with Et_2O, washing with brine, drying over $MgSO_4$ and evaporation of the volatiles gave **7** (175 mg, 99%) as a waxy colorless solid. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C) δ 6.53 (br s, 4H), 0.14 (s, 54H). ^{13}C{^{1}H} NMR (125.8 MHz, $CDCl_3$, 25 °C) δ 1.24, 1.28 (1:2). ^{29}Si{^{1}H} NMR (99.3 MHz, $CDCl_3$, 25 °C) δ 12.44, 12.19 (2:4 for $SiMe_3$), −100.12 (4 Si, O_3SiOH), −109.27 (2 Si, O_4Si). MS (ESI, 100% MeOH): *m/z* 905.4 ($[M + Na]^+$, 100%); 921.3 ($[M + K]^+$, 12%).

‡ *Reaction* of **7** with $(CH_2{=}CH)Me_2SiCl$: a solution of **3** (175 mg, 0.20 mmol) in Et_2O was added to a solution of $(CH_2{=}CH)Me_2SiCl$ (122 μL, 0.88 mmol) and NEt_3 (139 μL, 1.00 mmol) in Et_2O solution (5 mL). The mixture was stirred at room temp. for 4 h and then concentrated under reduced pressure. Extraction of the residue with hexane, filtration and evaporation under high vacuum gave spectroscopically pure **10** (226 mg, 92%) as a waxy white solid. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C) δ 0.13 (s, 54H), 0.14 (s, 12H), 0.18 (s, 12H), 5.75 (dd, ^2J 20, ^3J 4 Hz, 4H), 5.93 (dd, ^3J 15, ^3J 4 Hz, 4H), 6.13 (dd, ^2J 20, ^3J 15 Hz, 4H). ^{13}C{^{1}H} NMR (125.8 MHz, $CDCl_3$, 25 °C) δ 0.11, 1.52 (1:1 for $SiMe_aMe_b$), 1.62 ($SiMe_3$), 132.00 (SiCH), 138.79 (=CH_2). ^{29}Si NMR (99.3 MHz, $CDCl_3$, 25 °C) δ 11.24, 10.17 (1:2 for $SiMe_3$), −1.35 [$SiMe_2(CH{=}CH_2)$], −108.31 [4 Si, $O_3SiOSiMe_2(CH{=}CH_2)$], −108.70 (2 Si, O_4Si). MS (ESI, 100% MeOH): *m/z* 1241.6 ($[M + Na]^+$, 100% for [M + 2]); 1257.5 ($[M + K]^+$, 8% for [M + 2]). Anal. Calc. (found) for $C_{34}H_{90}O_{17}Si_{16}$: C, 33.46 (33.26); H, 7.43 (7.40)%.

CAN induced double ether ring formation: synthesis of *trans*- and *cis*-fused tricyclic ethers from 3-oxabicyclo[3.1.0]hexyl sulfides

Yoshiji Takemoto,*[a] Syun-ichirou Furuse,[b] Hiroki Hayase,[b] Tomoki Echigo,[b] Chuzo Iwata,[b] Tetsuaki Tanaka[b] and Toshiro Ibuka[a]

[a] *Graduate School of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan. E-mail: takemoto@pharm.kyoto-u.ac.jp*

[b] *Graduate School of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-oka, Suita, Osaka 565-0871, Japan*

Received (in Cambridge, UK) 8th October 1999, Accepted 11th November 1999

CAN oxidation of 3-oxabicyclo[3.1.0]hexy sulfides 4 and 5 possessing two hydroxy groups in the C-2 and C-4 side chains promoted a double ether ring formation along with a cleavage of the most substituted cyclopropyl bond to give tricyclic ketal adducts 8 and 10, which were converted to *trans*- and *cis*-fused tricyclic ethers 9 and 11 with high or moderate stereoselectivity by a TMSOTf-mediated trialkylsilane reduction.

Recently, a number of biologically active polyether toxins, such as the brevetoxins, ciguatoxins and halichondrins, have been isolated from marine organisms. The structural complexity and biological activities of these molecules have attracted the attention of synthetic chemists, and many new methods for the synthesis of cyclic ethers have been developed over the last few years.[1] Because these natural products have a unique ladder-like polycyclic molecular framework consisting of contiguous *trans*- and/or *cis*-fused polyether rings ranging in size from five- to nine-membered rings, several new synthetic methods have been aimed at the rapid construction of bi-, tri- and tetra-cyclic systems, including iterative strategies.[2]

We have already reported that the ceric(IV) ammonium nitrate (CAN) oxidation of cyclopropyl sulfides bearing a hydroxy group in a side chain promotes a S_N2-type nucleophilic substitution by the hydroxy group along with cleavage of the more substituted cyclopropyl carbon–carbon bond, giving rise to tetrahydrofuran and tetrahydropyran rings with perfect regio- and stereo-selectivity.[3] Our own interest in cyclic ether synthesis has recently been directed to a tandem synthesis of the polycyclic systems, using CAN induced double ether ring formation (**3** → **2**) and a Lewis acid-mediated trialkylsilane reduction (**2** → **1**), as shown in Scheme 1. We now report a stereoselective formation of the *trans*- and *cis*-fused tricyclic ether ring systems **1** containing five- and six-membered rings starting from 2α,4α- and 2β,4β-disubstituted 3-oxabicyclo-[3.1.0]hexyl sulfides **3**.

The several model compounds **4a**–**c** and **5b**–**c**, which possess different stereochemistry at C-2 and C-4, were synthesized to examine the applicability of the CAN-induced double ether ring formation (Table 1). Upon treatment of **4b** with CAN (8 equiv.) in dry MeOH in the presence of MS 3A at room temperature,[3] the *trans*-fused 6-6-5 tricyclic ketal **8b**† was obtained in 68% yield, and no other stereoisomers were detected (entry 2). Similarly, **4c** readily cyclized to the *cis*-fused 6-6-5 tricyclic ketal **8c**‡ in 62% yield under the same conditions (entry 3). In contrast to the *cis*-2,4-disubstituted diols **4b** and **4c**, the *trans*-2,4-disubstituted adduct **4a** gave no cyclized adducts. Indeed, only the bicyclic ketals **6** and **7** which were generated by an intermolecular nucleophilic substitution of a nitrate or methoxy group, were produced in 24 and 25% yields, respectively (entry 1). Although the different reactivity of **4a** compared with **4b** and **4c** is not clear at this stage, it is assumed that, in the case of **4a**, solvent and nitrate were introduced predominantly because the hydroxy group of the C-4 side chain, which is oriented axially in a preferred conformation (A), cannot attack the cyclopropyl carbon (C-5) from the proper back-side direction. In any event, these results demonstrate that the oxidative nucleophilic substitution by a hydroxy group to the cyclopropyl sulfides always occurs with perfect regio- and stereo-selectivity and that the sterically defined alignment of the nucleophile and fissile cyclopropyl bond is important for the ether ring formation.

Furthermore, both of the 6-6-5 triyclic ketals **8b** and **8c** were easily converted into the corresponding 6-6-5 tricyclic ethers **9b** and **9c** in good yields by known methods.[4] Specifically, the treatment of **8b** and **8c** with TMSOTf and Et_3SiH in CH_2Cl_2 at −78 °C resulted in stereoselective reduction, giving rise to the *trans-syn-cis*- and *cis-syn-cis*-fused 6-6-5 tricyclic products **9b**† and **9c**‡ as single isomers, respectively (entries 2 and 3). Finally, this method was applied to **5b** and **5c**, which possess two three-carbon side chains, with the aim of constructing a 6-6-6 tricyclic system. The same treatment of *cis*-2,4-disubstituted diols **5b** and **5c** as for **4a**–**c** gave the desired *trans-syn-trans*- and *cis-syn-trans*-fused 6-6-6 tricyclic ethers **11A**/**11B**[5] and **11C**† as the only products, respectively (entries 4 and 5).‡

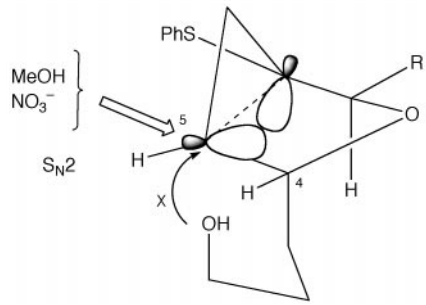

Fig. 1 Intermolecular nucleophilic ring-opening of **4a**.

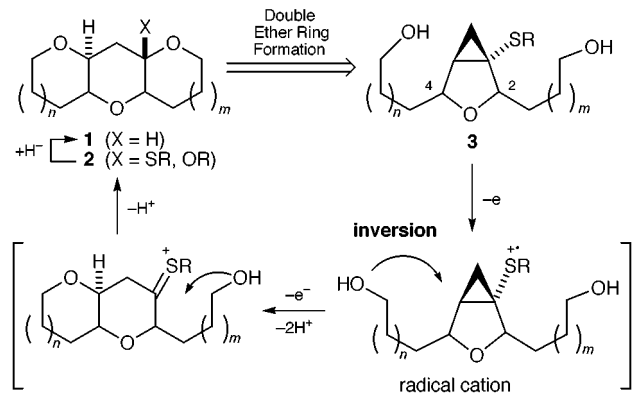
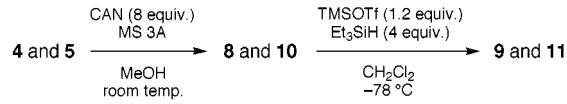


Scheme 1

Table 1 Tricyclic ether formation from bicyclic sulfides **4a**,**b** and **5b**,**c**



Entry	Substrate	Cyclic acetals (% yield)	Cyclic ethers (% yield)
1	 **4a**	 **6** X = OMe (24) **7** X = ONO_2 (25)	–
2	 **4b**	 **8b** (68)	 **9b** (68)
3	 **4c**	 **8c** (62)	 **9c** (67)
4	 **5b**	 **10A/10B**[a] (60)	 **11A** (α-H) **11B** (β-H) (79)[b]
5	 **5c**	 **10C** (70)	 **11C** (88)

[a] **10A**:**10B** = 3:1. The ratio was calculated from isolated yields, but their stereochemistry could not be determined. [b] **11A**:**11B** = 3:1. The ratio was deduced from ^{1}H NMR analysis.

Since these tricyclic ether ring systems are frequently encountered constituents in polycyclic natural toxins, this method should be a versatile tool for the asymmetric synthesis of these biologically active natural products. More efficient synthesis of the starting bicyclic sulfides and further application to more advanced chiral fragments are under way in these laboratories.

This study was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan.

Notes and references

† Stereochemical assignments of these compounds were confirmed by NOE studies.

‡ Because the same treatment of the diastereomerically pure product **10A** also provided **11A** and **11B** with the same ratio (**11A**:**11B** = *ca.* 3:1), it appears that the stereochemistry of these diastereomers has no effect on the silane reduction.

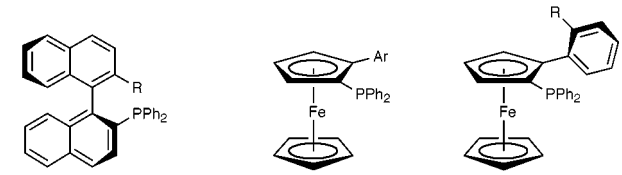
Received (in Liverpool, UK) 9th November 1999, Accepted 11th November 1999

A new family of monophosphine ferrocene ligands (MOPF) has been synthesised in two steps from an optically pure ferrocenyl sulfoxide and the first preliminary studies employing these ligands in asymmetric hydrosilylation of styrene are presented.

During the last decades only very few efficient chiral monophosphine ligands have been developed, in which the only Lewis base is the phosphorus atom. The fact that bisphosphine ligands form more rigid and stable complexes with metals, as compared to those with monophosphines, has probably stimulated the more abundant research in the former type. However, recently it has become increasingly clear that there is a need for efficient chiral monophosphine ligands for use in those reactions where the usual C_2-symmetric bisphosphines (*e.g.* BINAP) fail.[1]



1 (*S*)-H-MOP R = H, (*S*)-MeO-MOP R = OMe

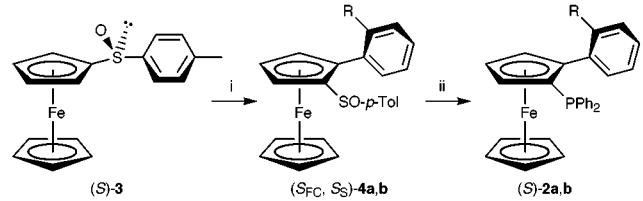
2 (*S*)-aryl-**MO**no**P**hosphino**F**errocene [(*S*)-MOPF]]

(*S*)-**2a** R = H, (*S*)-**2b** R = OMe

One of the few efficient types of monophosphine ligands discovered to date is Hayashi's MOP ligands **1**.[1a,2] Here we disclose a new family of arylMOnoPhosphinoFerrocene ligands **2** (herafter abbreviated MOPF), which show some resemblance to the MOP ligands, but are simpler to modify in a rational manner.[3]

We also present the first catalytic reactions employing these new ligands. In terms of enantioselectivity, the results are very encouraging and we believe that they can be further improved by simple variation of the aryl unit.

During the initial phase of this project we searched for a simple procedure to obtain a suitable building block for this new family of ligands. Recently, great progress has been achieved within the field of Directed *ortho*-Metallation (D*o*M) of ferrocenes.[4] However, the enantioselective *ortho*-lithiation of *e.g.* diphenylphosphinoferrocene, which in principle would allow us to synthesise these ligands in a single step, has met with only limited success.[5] On the other hand, Kagan *et al.*[4a,6] and Robinson *et al.*[4b] have recently described highly selective *ortho*-lithiation procedures of optically pure ferrocenyl sulfoxides. As the sulfoxide can be removed from the ferrocene by treatment with Bu^{t}Li we chose this compound as a starting material for the synthesis of the MOPF ligands. The synthesis of the first two members of the MOPF family is shown in Scheme 1. After diastereoselective *ortho*-lithiation of the sulfoxide (*S*)-**3**[4a] and lithium–zinc exchange, the aryl scaffold is introduced by a Negishi coupling giving **4**. The selective removal of the sulfoxide is accomplished with Bu^{t}Li and the lithiated ferrocene is then captured with $ClPPh_2$ giving the ligands (*S*)-**2a,b**.



(*S*)-**3** (S_{FC}, S_S)-**4a,b** (*S*)-**2a,b**

Scheme 1 *Reagents and conditions*: i, LDA (1.2 equiv.), THF, −78 °C, 20 min, then $ZnCl_2$ (1 equiv.) −78 °C, 1 h, then Pd_2dba_3 (2 mol%), $P(fur)_3$ (8 mol%), aryl iodide, (1.5 equiv.), (R = H) room temp., 96 h, 67%, (R = OMe) reflux, 72 h, 54%; ii, (2 equiv.) Bu^{t}Li, THF, −78 °C, 5 min; then $ClPPh_2$, (3.5 equiv.) room temp., 3 h, (R = H) 67%, (R = OMe) 76%.

The potential and efficiency of the MOPF ligands is exemplified in the asymmetric hydrosilylation of styrene.[7] This transformation belongs to the class of reactions where *e.g.* BINAP gives only poor results.[1a] However, using the most simple phenyl-MOPF ligand **2a** the reaction proceeds nicely with up to 70% ee (Table 1, entries 1 and 2). Introducing a simple methoxy substituent on the aryl group interferes slightly with the selectivity of the reaction and it is observed that the addition of benzene as solvent improves the enantioselectivity from 60 to 64% (entries 3 and 4). Currently, we have no information on the catalytically active species in this reaction, but it is noteworthy that a similar but more pronounced behaviour has been observed in the hydrosilylation of styrene using H-MOP (91% ee) and MeO-MOP (14% ee) as ligands.[8] Moreover the sense of induction in the reactions using the (*S*)-MOPF or the (*S*)-H-MOP ligands is the same. The rationalisation of these observations, however, must await further study.

In summary, a short and efficient synthesis of two members of a novel family of monodentate phosphine ferrocene ligands (MOPF) has been carried out. The simple procedure developed paves the way for the preparation of an array of structurally varied aryl-MOPF ligands. The preliminary catalytic reactions employing these ligands have given encouraging results and we

Pioda and A. Togni, *Tetrahedron: Asymmetry*, 1999, **9**, 3903; T. Okada, T. Morimoto and K. Achiwa, *Chem. Lett.*, 1990, 999.

8 This selectivity has been shown to be substrate dependent. MeO-MOP generally gave better results than H-MOP using non-styrene-type substrates such as *e.g.* oct-1-ene (up to 96% ee) [ref. 2(*b*)]. We are currently investigating the MOPF ligands to see whether they display similar behaviour.

9 *A representative hydrosilylation–oxidation procedure*: To a flame dried Schlenk tube was added $[ClPd(C_3H_5)]_2$ (6.2 mg, 0.017 mmol) and **2b** (30 mg, 0.067 mmol) under N_2. The solids were dried on the vacuum line for 1 h before styrene (0.378 ml, 3.3 mmol) and 2 ml of benzene were added *via* syringe. After another 30 min the silane (0.404 ml, 4 mmol) was added *via* syringe and the solution was left with stirring for 72 h. An aliquot of the reaction was used for NMR and it showed that the reaction was completed. The crude reaction mixture was slowly added to a suspension of KF (3.9 g, 67 mmol) in 30 ml of MeOH and the resulting solution was stirred for 30 min. The solvent was evaporated *in vacuo* and the resulting solid was suspended in 40 ml of DMF. Finally 4 ml H_2O_2 (35%) was added at room temperature and the reaction was heated to 60 °C for 1 h before quenching with 30 ml saturated $Na_2S_2O_3$ (aq). After aqueous workup and extraction the product was purified by flash column chromatography (15% EtOAc in pentane) giving **6** as a colorless oil in 41% yield (167 mg) and 64% ee detected by HLPC using a Chiralcel OD-H column (10% Pr^iOH–90% hexane, 0.5 ml min^{-1}). $[\alpha]_D^{rt}$ –36 (*c* 1.065, $CHCl_3$). Spectroscopic data were in accordance with those from a commercial sample.

10 During the course of our investigation we became aware of a paper from another group synthesising related benzene chromium tricarbonyl complexes. This prompted us to report our findings at this early stage. See: S. C. Nelson and M. A. Hilfiker, *Org. Lett.*, 1999, **1**, 1379.

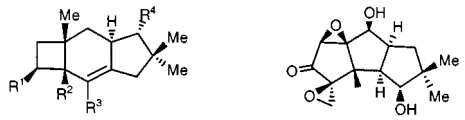
Received (in Cambridge, UK) 13th October 1999, Accepted 9th November 1999

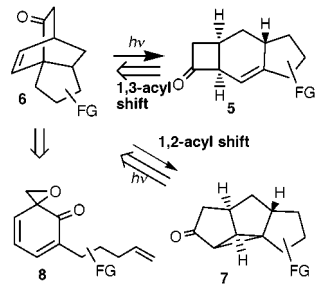
A novel, stereoselective synthesis of sterpuranes and coriolin *via* modulation of the photochemical reactivity of a tricyclic system having a β,γ-enone chromophore, which was assembled *via* intramolecular $\pi^{4s} + \pi^{2s}$ cycloaddition of 1-oxaspiro[2.5]octa-5,7-dien-4-ones, is presented.

The fungal metabolites **1**–**3** and coriolin **4** are natural products of the sterpurane[1] and triquinane[2] families of sesquiterpenes, respectively, which are biogenetically derived from humulene



cyclization cascades.[1f] Coriolin[3] and other triquinanes have witnessed a high level of sustained interest which has led to the development of several new and elegant methods for the construction of tricyclopentanoids.[3–5] However, sterpuranes have elicited only modest interest[6] despite their unique structure, which contains a cyclobutane ring fused to a hydrindane system, and their role in silver leaf disease[1] and phytotoxicity.[6e] There are only a few methods for the synthesis of sterpuranes and most of these generate the carbocyclic framework in an iterative fashion wherein the cyclobutane ring is formed *via* intermolecular $\pi^{2s} + \pi^{2s}$ photocycloaddition.[6b–f] The elegant routes devised by Okamura[6g] and Krause,[6h] although efficiently generating the framework, begin with a precursor containing a cyclobutane ring. In continuation[7] of our efforts to develop new methods for the synthesis of natural products derived from humulene cyclization cascades, we contemplated a novel and general strategy to create the tricyclic sterpurane framework in a single stereoselective sequence which does not rely upon $\pi^{2s} + \pi^{2s}$ photocycloaddition for the formation of the cyclobutane ring. Remarkably, this strategy also provides a new route to linearly fused triquinanes from the same precursor *via* modulation of the chemical reactivity in the excited state.

The cornerstone of our strategy is the recognition of the structural and functional relationship between the sterpurane framework and the tricyclic system **6** containing a β,γ-enone chromophore. It was envisaged that a 1,3-acyl shift[8] in **6** upon singlet excitation would readily furnish the sterpurane framework **5** in such a fashion as to create all three rings in the correct relative stereochemical orientation and the double bond at the desired position, in a single step (Scheme 1). It was further thought that the key tricyclic precursor **6** might be synthesized *via* intramolecular $\pi^{4s} + \pi^{2s}$ cycloaddition of 1-oxaspiro-[2.5]octa-5,7-dien-4-ones of type **8** and further manipulation of the resulting adduct. In addition, we also visualized that triplet sensitized 1,2-migration[8,9] of the acyl group in **6** would lead to the tetracyclic system **7** (Scheme 1), which upon cleavage of the



Scheme 1

cyclopropane ring might lead to linearly fused *cis*:*anti*:*cis*-:triquinanes. We report herein our exploratory results leading to a novel and general entry to sterpuranes and a formal total synthesis of coriolin from a common precursor.

Towards our objective, the key precursor **10** was prepared from aldehyde **9a**, which was obtained from alcohol **9b**.[10] Thus, the addition of Grignard reagent prepared from 4-bromobutene to aldehyde **9a** and subsequent oxidation of the resulting alcohol, followed by alkylation and removal of the acetonide protection, readily furnished the desired precursor **10**. Oxidation of **10** with $NaIO_4$ in MeCN–H_2O at 0 °C smoothly furnished the adduct **12** (Scheme 2) in excellent yield (71%). The adduct **12** is formed as a result of *in situ* generation of **11** during the oxidation and subsequent intramolecular Diels–Alder reaction. The structure and stereochemistry of the adduct were deduced from its high field ^{1}H NMR, COSY and NOE spectra. † The orientation of the oxirane ring is suggested on the basis of the general tendency of cyclohexa-2,4-dienones during addition.[7,11] It should be mentioned that there are only a few

methods[12] for the preparation of bicyclo[2.2.2]octenones of type **12** annulated through bridgeheads.

The reduction of **12** with zinc and NH_4Cl in aqueous MeOH gave the β-keto alcohol **13a** [as a *syn*:*anti* mixture, ^{1}H NMR (300 MHz)] which was oxidized with Jones' reagent, and the resulting β-keto acid **13b** was subjected to decarboxylation to furnish the tricyclic system **13c** in good yield. Protection of the carbonyl group at the ethano bridge as a ketal and subsequent reduction of the resulting keto ketal with $NaBH_4$ in THF–MeOH–H_2O followed by deprotection of the ketal group efficiently gave the desired chromophoric system **14**. The stereochemical orientation of the hydroxy group is suggested from the down field signal of the C*H*OH proton (δ 4.06, br s) which was further confirmed *via* its transformation to the known triquinane **17** (*vide infra*).

Towards the synthesis of sterpuranes, a solution of **14** in dry benzene was irradiated with a mercury vapour lamp (125 W, Applied Photophysics) for about 30 min, upon which a clean reaction occurred (TLC, IR). Removal of the solvent followed by chromatography gave the tricyclic compound **15** in good yield (55%)‡ as a result of 1,3-acyl shift (Scheme 3). The structure of the photo-product **15** was clearly revealed from its spectral data.§

On the other hand, the triplet sensitized irradiation of **14** in acetone (sensitizer as well as solvent) in a Pyrex immersion well under nitrogen furnished the tetracyclic compound **16** in good isolated yield (78%) [83% conversion, unchanged starting material was recovered] whose structure was deduced from spectral data¶ and comparison with the spectral features of its precursor.[13] Cleavage of the peripheral cyclopropane bond with Bu_3SnH–AIBN[14] in refluxing benzene gave triquinane **17** (mp 117–118 °C) (Scheme 3), which has already been elaborated to coriolin.[15] The physical and spectral characteristics of **17** compared well with the reported data.[15] Thus, the formal synthesis of coriolin was complete.

In summary, we have described a novel and stereoselective method for the synthesis of sterpuranes which has wide synthetic potential, and a formal total synthesis of (±)-coriolin employing the intramolecular $\pi^{4s} + \pi^{2s}$ cycloaddition of 1-oxaspiro[2.5]octa-5,7-dien-4-one and sigmatropic shifts in excited states. This method, in turn, also provides a new and efficient avenue to annulated bicyclo[2.2.2]octenones of type **12**–**14** which are not readily accessible otherwise.

We thank RSIC, I.I.T. Bombay, for the use of high field NMR and mass spectral facilities. Financial support from BRNS is gratefully acknowledged. S.Q. Alam is grateful to I.I.T. Bombay for a Teaching Assistantship.

Received (in Cambridge, UK) 8th October 1999, Accepted 10th November 1999

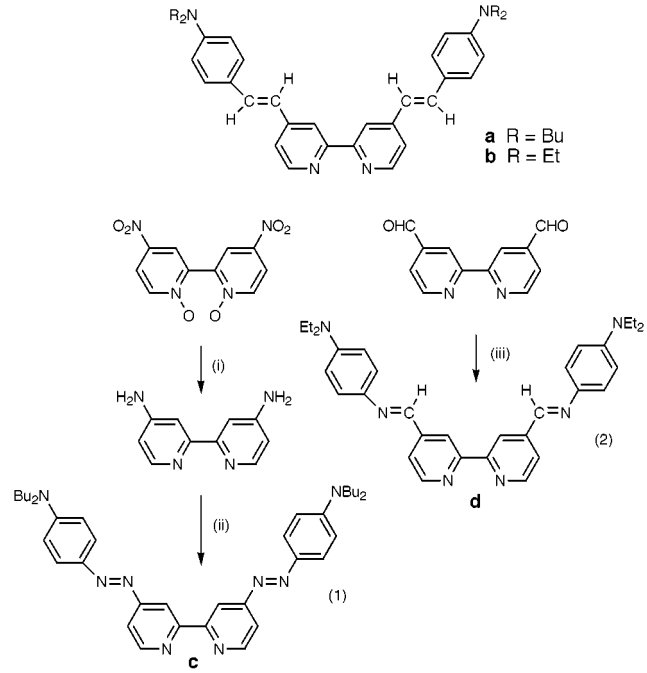
The synthesis and optical properties of 4,4′-bis(dialkylaminophenylazo)-2,2′-bipyridine and 4,4′-bis(dialkylaminophenylimino)-2,2′-bipyridine ligands are described; the corresponding dipolar bipyridyl zinc dichloride complexes have been prepared and their second order nonlinear optical properties determined by electric field-induced second harmonic generation (EFISH) at 1.34 μm.

Poled polymers containing second order nonlinear (NLO) molecules are particularly promising for electrooptic device applications. Usually, dipolar chromophores have to be aligned by using electric field poling near the glass transition temperature (T_g) of the polymer.[1] Besides this approach, which requires high temperature treatment, new mild optical poling techniques have been developed recently. The so-called 'photo-assisted electrical' poling[2] and the 'all optical' poling[3] can be used at room temperature for the macroscopic noncentrosymmetric organisation of dipolar and octupolar chromophores, respectively. These methods require the presence of chromophores featuring a photoisomerisable moiety and use the 'flexibility' of the molecule to break the centrosymmetry of the material.

We have previously reported that metalloorganic complexes containing π-donor substituted 4,4′-alkenyl-2,2′-bipyridyl ligands[4] such as **a** and **b** (Scheme 1), show large dipolar or octupolar microscopic nonlinearities.[5] As the C=C double bond is known to be poorly photoisomerisable as compared, for example, to the N=N double bond,[6] we sought to design new potentially photoisomerisable bipyridines by introducing nitrogen atoms into the transmitter. Herein we report the synthesis and characterisation of new bipyridines bearing azo- as well as imino-linked donor groups. We also describe the preparation of the corresponding dipolar zinc(II) complexes; the influence of the nature of the π-bridge on the linear and nonlinear properties of these complexes is also reported.

The synthesis of the azo-containing bipyridyl ligand **c** was readily accomplished in two steps from 4,4′-dinitro-2,2′-bipyridine-1,1′-dioxide[7] [Scheme 1, eqn. (1)]: 4,4′-diamino-2,2′-bipyridine was first prepared in quantitative yield by using hydrazine hydrate in the presence of Pd/C.[8] This mild and efficient method contrasts favourably with the well-known but poorly yielding (20%) procedure using Fe/AcOH as the reducing agent.[9] Finally, the diazotation of 4,4′-diamino-2,2′-bipyridine with sodium nitrite and subsequent coupling with *N*,*N*-dibutylaniline afforded derivative **c**, which was isolated (yield 25%) as dark red microcrystals after chromatographic workup. Imino-containing bipyridine **d** was synthesised in excellent yield (95%) by a Schiff base condensation reaction between *N*,*N*-diethyl-1,4-phenylenediamine and 4,4′-diformyl-2,2′-bipyridine[10] [Scheme 1, eqn. (2)]. Attempts to isolate the 'reverse' imino-bipyridine from the reaction of 4,4′-diamino-2,2′-bipyridine and diethylaminobenzaldehyde failed, confirming the already observed deactivation of the amino and carbonyl functions in the presence of acceptor and donor groups, respectively.[11] Ligands **c** and **d** were characterised by ^{1}H NMR and high resolution mass spectrometry. Their optical spectra and those of the related aminostyryl derivatives **a** and **b** are displayed in Fig. 1. Most importantly, a large bathochromic shift of the ICT band is observed on exchanging the C=C bond for an N=N ($\Delta\lambda_{max}$ = 71 nm) or N=C ($\Delta\lambda_{max}$ = 36 nm) bond. This effect has been already described for other chromophores: Ulman *et al.*[12] reported a bathochromic shift of 40 nm between 4-dimethylamino-4′-dimethylsulfonylazobenzene and the corresponding stilbene derivative, while Whitall *et al.* described a 20 nm shift between an imino-benzene and the corresponding stilbene ruthenium complex.[11a] In the latter case the shift was accompanied by a strong decrease of the molar extinction coefficient ε, an hypsochromic effect which is not observed in our case.

Tetrahedral zinc complexes **1a**–**d** (Scheme 2) were readily prepared upon room temperature treatment of the ligands **a**–**d** with $ZnCl_2$ in dichloromethane.[5a] In their UV-vis spectra (Fig. 1, Table 1), a red-shift of the intense ILCT (intraligand charge-transfer) band is observed ($\Delta\lambda_{max}$ = 45–60 nm), as expected from the inductive acceptor strength of the Lewis acid.[13] As in the free ligand, λ_{max} is sensitive to the nature of the X=Y transmitter and follows the order N=N > N=C > C=C.



Scheme 1 (i) Pd/C (10%), $N_2H_4{\cdot}H_2O$, EtOH, reflux, 8 h, 100%; (ii) $NaNO_2$, $Bu_2NC_6H_5$ in THF, 0–5 °C, 2 h, 25%; (iii) $Et_2NC_6H_4NH_2$, $MgSO_4$, THF, reflux, 12 h, 95%.

Table 1 Linear and nonlinear data for the free ligands and their $ZnCl_2$ complexes

Ligand	λ_{max}[a]/nm	ε/mol^{-1} cm^{-1}	Complex	λ_{max}[a]/nm	ε/mol^{-1} cm^{-1}	$\mu\beta$[b]/10^{-48} esu[c]	$\mu\beta_0$[b]/10^{-48} esu[c]
a	397	57000	**1a**	455	62000	1420	660
b	401	65000	**1b**	459	62000	1830	850
c	471	63000	**1c**	516	63000	2160	700
d	433	52000	**1d**	491	55000	1610	620

[a] Solution in CH_2Cl_2. [b] Solution in $CHCl_3$; the precision of the measurement is about 10%. [c] Correlation between esu and SI units: β(SI) = 4.172 × 10^{-10} β (esu).

The molecular hyperpolarisabilities $\mu\beta$ of **1a**–**d** were measured in chloroform using electric field-induced second harmonic generation (EFISH) at 1340 nm, and the nonresonant $\mu\beta_0$ values were calculated using the two-level model (Table 1).[14] The results show that these complexes have good nonlinear optical activities, which are sensitive to the nature of both the transmitter and donor groups. For a given bridge, such as in **1a** and **1b**, dibutylaminophenyl is more efficient than the diethylaminophenyl group, a variation already observed for octupolar complexes.[5d] For a given donor, a slight increase in $\mu\beta$ is also observed on replacing CH by N. However, comparison of the zero-frequency $\mu\beta_0$ values reveals that the increase in nonlinearity seems to be mainly due to resonant enhancement.

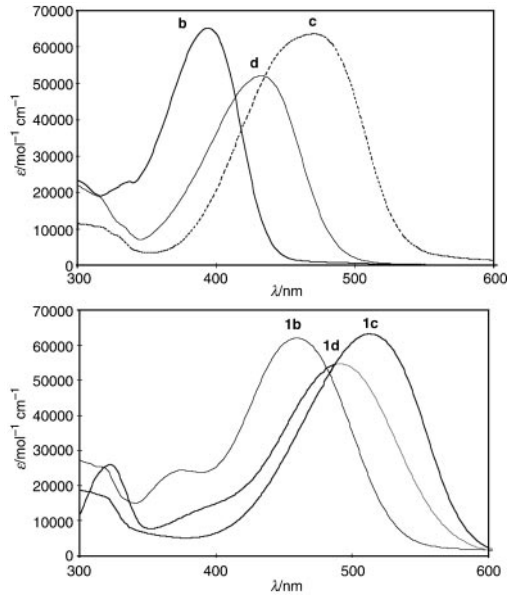

Fig. 1 UV-Vis spectra of the free bipyridine ligands (top) and related complexes (bottom).

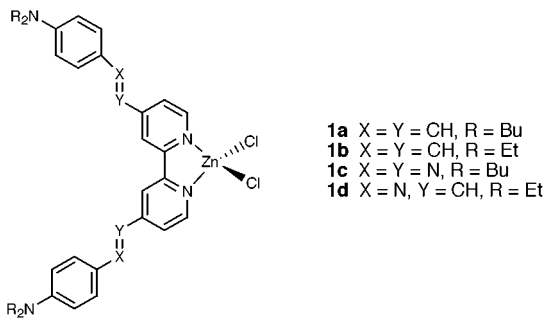

Scheme 2 (L-L)$ZnCl_2$ complexes.

In conclusion we have described the synthesis of new bipyridyl ligands bearing imino and azo substituents. The NLO activity of the chromophore **1c**, which contains the most suitable photoisomerisable azo ligand, can be favourably compared with that of the prototypical azo dye DR1 (λ_{max} = 480 nm, $\mu\beta_0$ = 450 × 10^{-48} esu).[15] Research is now in progress to study the photoassisted electrical poling of such dipoles in polymer films. Finally, these ligands provide access to D_3 octupolar complexes which will be promising candidates for the 'all optical' poling method.

We thank the CNRS (Programme Matériaux), the CNET and the Conseil Régional de Bretagne for financial support.

First asymmetric desymmetrisation of a centrosymmetric molecule: CBS reduction of a 2-pyridone [4 + 4]-photodimer derivative

Alan C. Spivey,*[a] Benjamin I. Andrews,[a] Alan D. Brown[b] and Christopher S. Frampton[c]

[a] *Department of Chemistry, University of Sheffield, Brook Hill, Sheffield, UK S3 7HF. E-mail: a.c.spivey@sheffield.ac.uk*

Received (in Liverpool, UK) 6th October 1999, Accepted 25th October 1999

The *B*-Me-(*S*)-CBS catalysed borane reduction of centrosymmetric bis-*N*-Boc tetrahydro photodimer 3 has been achieved with virtually complete enantiotopic group selectivity (>97% ee) and in good yield (76%).

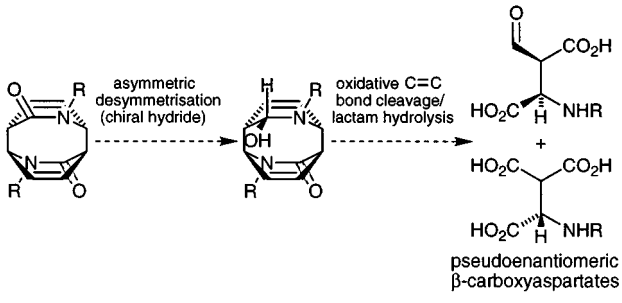
The exploitation of latent molecular symmetry to expedite synthesis is an attractive strategy in organic chemistry.[1] An exemplary tactic in this regard is the asymmetric desymmetrisation of *meso* intermediates,[2,3] *i.e.* compounds containing more than one stereocentre but which are achiral by virtue of overall molecular symmetry. This approach can provide access to enantiomerically pure compounds, often with a high degree of molecular complexity, in relatively few synthetic steps. The enantiotopic group differentiation can be achieved by either enzymatic[4] or synthetic[5] means.

However, to the best of our knowledge, this strategy has only been employed with *meso* compounds containing a mirror plane. We were intrigued by the possibility of asymmetric desymmetrisation of *meso* compounds containing a centre of symmetry, *i.e.* centrosymmetric compounds. Of particular interest to us was the prospect of desymmetrising centrosymmetric [4 + 4]-photodimer derivatives of 2-pyridone[6] as the key step in a conceptually new route to functionalised amino acids. Here we describe enantiotopic amide carbonyl group differentiation using 'chiral' hydride (Scheme 1).

Despite the plethora of literature pertaining to asymmetric carbonyl reduction by chiral hydride reagents,[7] the only work reported on amidic compounds has been the desymmetrisation of *meso* imides.[8] For example, Speckamp has described the catalytic asymmetric reduction of cyclic *meso* imides using the Corey–Bakshi–Shibata (CBS) method in 68–94% ee.[8]

For the CBS reduction of [4 + 4]-photodimers of 2-pyridone to be successful, we anticipated that 'activation' of the amide carbonyl groups towards reduction would be necessary and envisaged that *N*-Boc derivatisation would serve this purpose.[9] Furthermore, we decided to work initially on a saturated tetrahydro photodimer derivative so as to allow the optimisation of the CBS reduction without the potential complications of competing hydroboration.[10]

Irradiation (350 nm) of an aqueous solution of 2-pyridone **1** (20 g in 50 ml) in a Rayonet reactor over 5 days caused [4 + 4]-photodimer **2** to precipitate from solution as white crystals (10.4 g, 52%).[11] Treatment with BuLi/Boc_2O in THF gave the bis-*N*-Boc derivative, and subsequent bis-hydrogenation using Adams' catalyst[11] furnished the bis-*N*-Boc tetrahydro photodimer **3** in excellent yield (Scheme 2).

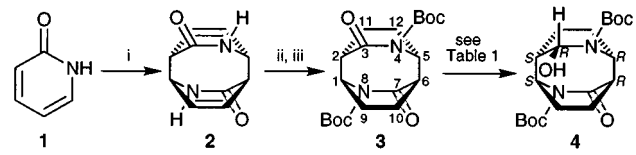


Scheme 1

Uncatalysed reaction of the bis-*N*-Boc tetrahydro photodimer **3** with $BH_3{\cdot}SMe_2$ was found to be slow, affording the racemic monolactamol† (±)-**4** in 16% yield after 22 h (entry 1, Table 1). Examination of the single crystal X-ray structure of this racemic monolactamol (±)-**4**‡ revealed it to have been formed by 'axial' attack of hydride at C3§ (this was expected as 'equatorial' attack of hydride at C3 is blocked by the C9, C10 ethylene bridge).

Using *B*-Me-(*S*)-CBS·BH_3 complex synthesised from (*S*)-proline,[12]¶ a systematic investigation of the asymmetric reduction of bis-*N*-Boc tetrahydro photodimer **3** was undertaken (Table 1).

Initial attempts at the asymmetric reduction in CH_2Cl_2 gave poor conversions and moderate ees, presumably due to the low catalyst loading and competing uncatalysed reduction by excess $BH_3{\cdot}SMe_2$ (entries 2, 3). A stoichiometric amount of catalyst and a 1:1 ratio of catalyst to borane gave significantly improved yields and ees (entries 4–6). Finally, performing the reaction at higher concentrations in $CHCl_3$ allowed for sub-stoichiometric amounts of catalyst to be used, producing the bis-*N*-Boc



Scheme 2 *Reagents and conditions*: i, hν = 350 nm, H_2O (52%); ii, BuLi (2.5 equiv.), Boc_2O (4 equiv.), THF (98%); iii, H_2 (3 bar), PtO_2 (0.2 equiv.), EtOAc (100%).

Table 1 Optimisation of the *B*-Me-(*S*)-CBS·BH_3 catalysed asymmetric reduction of bis-*N*-Boc tetrahydro photodimer **3**

					Monolactamol **4**	
Entry[a]	*B*-Me-(*S*)-CBS·BH_3/ equiv.	$BH_3{\cdot}SMe_2$/ equiv.	*t*/h	Solvent (ml)	Yield[b] (%)	Ee[c] (%)
1	0	1.2	22	CH_2Cl_2 (10)	16	0
2	0.2	1.2	22	CH_2Cl_2 (10)	34	66
3	0.2	1.2	6	CH_2Cl_2 (10)	16	64
4	1	1	6	CH_2Cl_2 (10)	41	86
5	1	1	14	CH_2Cl_2 (10)	57	94

8	0.5	0.5	22	$CHCl_3$ (1)	76	97

[a] All reactions were performed on a 100 mg scale. [b] Isolated yield after column chromatography; the mass balance consists of photodimer **3** and lesser amounts of over-reduced products. [c] Determined by chiral HPLC [Column: Chiralcel OD (25 × 0.46 cm), eluting with 99.2:0.8 hexane–Pr^iOH, 1.0 ml min^{-1}, 40 °C, UV detection at 225 nm].

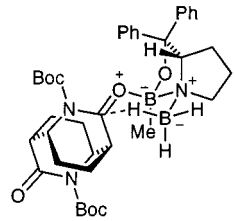

Fig. 1 Predicted transition state for the *B*-Me-(*S*)-CBS·BH_3 reduction of the bis-*N*-Boc tetrahydro-dimer **3** (NB. the larger *N*-Boc substituent is oriented equatorially and the smaller alkyl substituent is oriented axially in the chair transition state).

tetrahydro monolactamol in 76% yield and 97% ee (entries 7 and 8).

Based on the model proposed by Corey,[10] and corroborated by Speckamp for his imide reductions,[8] we predicted that the *B*-Me-(*S*)-CBS catalyst would deliver hydride selectively to the *Si*-face of the photodimer (Fig. 1).

To confirm this prediction we grew X-ray quality crystals of the enantiomerically pure monolactamol (+)-**4** {from entry 8, $[\alpha]_D$ +8.0, $[\alpha]_{365}$ +90.2 (*c* 0.5 $CHCl_3$)} and performed a single crystal X-ray structure determination using Cu-Kα irradiation.‖ This established the absolute configuration of monolactamol (+)-**4** as being (1*S*,2*S*,3*R*,5*R*,6*R*) as expected (Fig. 2, and as depicted in Scheme 2).

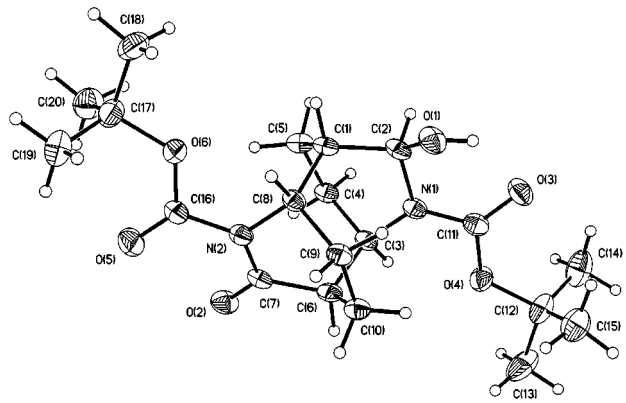

Fig. 2 ORTEP (50% probability ellipsoids) of the enantiomerically pure monolactamol (+)-**4**.‖

In conclusion, we have demonstrated that *B*-Me-(*S*)-CBS catalysed borane reduction of a bis-*N*-Boc tetrahydro photodimer can be achieved with virtually complete enantiotopic group selectivity (97% ee) and in good yield (76%). This provides efficient access to an enantiomerically pure product containing five chiral centres and represents the first asymmetric desymmetrisation of a centrosymmetric compound. It is also the first example of the asymmetric reduction of a *meso* diamide, and as such represents a significant extension of the scope and versatility of the CBS reduction process.

We are currently investigating the utility of related asymmetric desymmetrisations of unsaturated and more highly functionalised [4 + 4]-photodimer derivatives of 2-pyridone for the preparation of enantiomerically pure β-carboxyaspartic acid derivatives.

We thank the EPSRC and Pfizer for provision of a CASE studentship, and also the Nuffield Foundation and The Royal Society Equipment Fund for financial support of this work.

Notes and references

† We use the term lactamol in preference to cyclic hemiaminal (*cf.* lactone → lactol *vs.* lactam → lactamol).

‡ The single crystal X-ray structure for racemic monolactamol (±)-**4** is topologically superimposable on that of the enantiomerically pure compound (+)-**4**.‖

§ 'Axial' attack refers to the trajectory of hydride attack which results in an axial hydrogen in the 'double boat' structure of the photodimer product.

¶ The quality of the catalyst was confirmed by performing the asymmetric reduction of acetophenone to (*R*)-1-phenylethan-1-ol (ref. 13) in quantative yield and 95% ee using *B*-Me-(*S*)-CBS·BH_3 (0.1 equiv.), BH_3·SMe_2 (1.2 equiv.), CH_2Cl_2, room temp., 1 h.

Selective binding of substrates using sodium salts of linked C_3 symmetric aryl oxides

Maarten B. Dinger and Michael J. Scott*

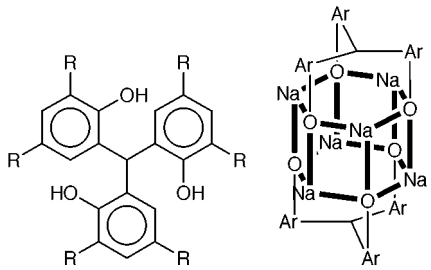
Department of Chemistry, University of Florida, PO Box 117200, Gainesville, FL 32611-7200, USA. E-mail: mjscott@chem.ufl.edu

Received (in Columbia, MO, USA) 14th September 1999, Accepted 3rd November 1999

Tris(3,5-dialkyl-2-hydroxyphenyl)methanes (*tert*-butyl, *tert*-pentyl) react with three equivalents of sodium hydride to give hexanuclear dimers; these bulky aggregates have six well-defined coordination 'pockets' which demonstrate selectivity toward a variety of ketones.

The design of molecules for the selective recognition of substrates has been an extremely active and growing area of research over the last number of years.[1] The utility of metal coordination chemistry, particularly aluminium, in a steric environment to give Lewis acidic selective reagents is clear, and a considerable body of work, largely pioneered Yamamoto,[2] regarding their use for a wide range of selective organic functional group transformations has been published.[3] Less developed work, using lithium phenolates[4] and zirconium naptholates,[5] amongst others, towards similar purposes have also been reported.

During our investigations[6] of the alkali metal salts of tris(3,5-dialkyl-2-hydroxyphenyl)methanes **1**,[7] it was clear from X-ray structure determinations that the sodium salts **2** are hexanuclear aggregates, with six coordinated solvent molecules (THF) residing in identical binding sites; somewhat surprisingly, this Na_6O_6 core had been structurally characterized only once previously.[8] From an examination of the structures, it was evident that the solvate molecules binding the metal atoms reside in a sterically crowded environment, offering the opportunity to prepare metal clusters capable of facilitating selective binding of a range of substrates. Herein we communicate our findings regarding these novel systems.



The reaction of tris(3,5-di-*tert*-butyl-2-hydroxyphenyl)methane **1a** with sodium hydride in Et_2O generates the dimeric, hexanuclear sodium salt **2a** in almost quantitative yield (^{1}H NMR).† When the bulkier tris(3,5-di-*tert*-pentyl-2-hydroxyphenyl)methane **1b** is used, refluxing THF is required for cluster formation. Examination of the crystal structures of the THF adducts of **2a** and **2b** reveals the solvent molecules reside in 'pockets' created by the aromatic rings and their aliphatic substituents. Complete removal of the coordinated solvent molecules can be readily achieved by evacuation with gentle warming.

The electrophilic nature of the coordinatively unsaturated sodiums is witnessed by their propensity to interact with very poor donor molecules. The solid state structure of the CH_2Cl_2 adduct of **2b** (Fig. 1)‡ reveals that all six sodium atoms are associated by a solvent molecule with an Na···Cl distance of 2.891(1) Å. Furthermore, the aromatic rings are canted slightly to allow for weak *ipso*-interactions with the sodiums [Na···C(3) 2.771(3) Å]. The sodium atoms clearly adopt extremely distorted tetrahedral geometries, exemplified with a minimum angle for O(1′)–Na–O(1) of only 93.21(7)°. When crystallized solely from Et_2O,[6] the cluster is forced to distort even more dramatically to allow for the binding of Et_2O molecules to only two of the six sodium atoms, and in the absence of a donor molecule, the average distance of the remaining four metal centers to the *ipso*-carbon of the aryl ring decreases to 2.676(5) Å.

Accordingly, addition of 6 equiv. of a variety of oxygen donor substances of suitable size and shape (THF, acetone, benzaldehyde, acetophenone, *trans*-cinnamaldehyde or cyclohexyl methyl ketone) to **2a** in Et_2O readily yields the corresponding adducts.§ In contrast, bulkier substrates, such as 2,5-dimethyltetrahydrofuran and 2,2,4,4-tetramethylpentan-3-one, fail to bind. Aromatic substrates immediately impart a color change upon coordination to **2a** or **2b**, with a distinctive absorption maxima evident in the visible region, providing a convenient avenue to rapidly screen binding affinities of new substrates. Et_2O and α,α,α-trimethylacetophenone bind only very poorly, and are readily displaced upon addition of more suitable molecules. Thus, addition of an equimolar mix of α,α,α-trimethylacetophenone and acetophenone to **2a** allows for complete separation of the two ketones by evaporation of the

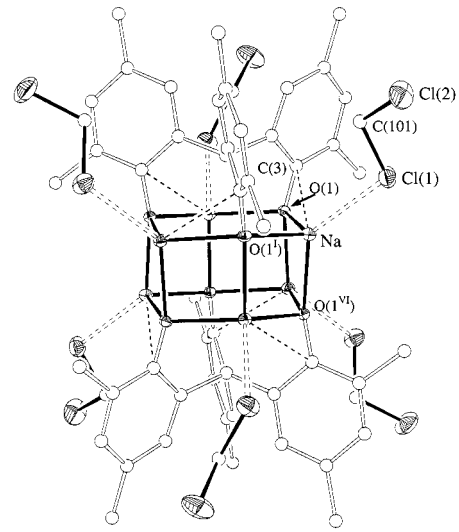


Fig. 1 Structure of **2b**·8.6CH_2Cl_2 (30% probability ellipsoids for Na, O and Cl). The molecule crystallizes on an S_6 symmetry position. Selected bond lengths (Å) and angles (°): Na···Cl(1) 2.89(1); Na···C(3) 2.771(3); Na–O(1) 2.326(2); Na–O(1) 2.280(2); Na–O(1^{VI}) 2.246(2); O(1)–Na–O(1^I) 112.88(9); O(1)–Na–O(1^{VI}) 93.21(7); O(1^I)–Na–O(1^{VI}) 94.47(7); O(1)–Na–Cl(1) 118.92(6); O(1^I)–Na–Cl(1) 103.91(6); O(1^{VI})–Na–Cl(1) 131.19(6)°. *tert*-Pentyl groups, hydrogen atoms, and additional CH_2Cl_2 solvate molecules have been omitted for clarity.

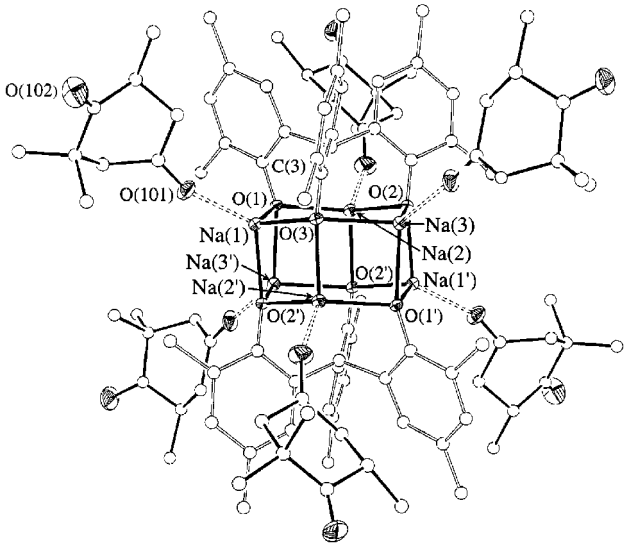

Fig. 2 Structure of **2b**·$6C_9H_{14}O_2$·$0.4Et_2O$ (30% probability ellipsoids for Na and O). Selected bond lengths (Å) and angles (°): Na(1)···O(101) 2.257(3); Na(1)–O(1) 2.362(2); Na(1)–O(3) 2.297(2); Na(1)–O(2′) 2.272(2); Na(1)···C(3) 2.748(3); O(1)–Na(1)–O(3) 116.82(8); O(1)–Na(1)–O(2′) 93.49(7); O(3)–Na(1)–O(2′) 96.27(8); O(1)–Na(1)–O(101) 116.67(9); O(3)–Na(1)–O(101) 109.54(9); O(2′)–Na(1)–O(101) 122.15(9). The *tert*-pentyl groups, hydrogen atoms and Et_2O solvate have been omitted for clarity.

solvent, and subsequent washing of the residue with pentane, in which the acetophenone adduct of **2a** is insoluble. In solution, ^{1}H NMR investigations demonstrate that only acetophenone binds in this mixture and a spectrum identical to an authentic sample of **2a**·$6C_8H_8O$ is observed.

Commercial 2,6-dimethylcyclohexanone is a thermodynamic mixture of isomers,[9] which we determined by GC to be in the ratio of 81:19 for *cis*:*trans*. When this ketone is added to **2a** so that at least 6 equiv. of the *trans* isomer are present, following workup, GC and NMR analyses reveals that the ratio of isomers now clearly favors the *trans* by 1:5. This selectivity further highlights the relative rigidity and discrete size of the 'pockets', since the two isomers differ only subtly in size and shape. To demonstrate the utility of this separation, 6 equiv. of 2,4-dinitrophenylhydrazine were added to the dimethylcyclohexanone coordinated cluster, and after work-up and recrystallization, exclusively the *trans*-isomer of the corresponding hydrazone was obtained in 73% yield.

Finally, when 2,2,6-trimethylcyclohexane-1,4-dione, a diketone that features both sterically and non-sterically crowded carbonyl functionalities, is added to **2b**, only the non-bulky end was found to bind the sodium metal (Fig. 2).¶ The ketone is obviously a much better donor than CH_2Cl_2 and maintains an average Na···O=C contact of 2.271(3) Å, a distance indistinguishable from the sodium–aryl oxide bonds. Despite the superior donor abilities of the carbonyl moiety in comparison to CH_2Cl_2, the Na–*ipso*-carbon interactions persist in this complex, with an average length of 2.749(3) Å. This system demonstrates the possibility for sterically protecting multifunctional group containing compounds, with the more reactive groups rendered inert, whilst chemistry at the less reactive sites is undertaken. The present compound, unfortunately, is only sparingly soluble, hindering reactivity studies.

In summary, we have synthesized coordinatively unsaturated sodium salts of bulky triaryloxymethanes, wherein the vacant coordination sites reside in discretely sized 'pockets'. The compounds have been successfully used to selectively bind only molecules that possess a size and shape compatible with the 'pocket'. In addition to simple chemical separations, this selectivity may have utility for the protection of reactive functional groups in chemical reactions.

Notes and references

† *General procedure* for synthesis of **2a**: Tris(3,5-di-*tert*-butyl-2-hydroxyphenyl)methane was dissolved in anhydrous Et_2O (20 ml) and dry NaH (0.03 g, excess) added. The resulting mixture was stirred at room temperature for 17 h. The excess NaH was filtered off, to leave a solution of **2a**, which was sufficiently pure for further reactions. **2b**: Tris(3,5-di-*tert*-pentyl-2-hydroxyphenyl)methane was dissolved in THF (15 ml), and excess NaH added. The milky solution was refluxed under nitrogen for 1 h. The solvent was evaporated under vacuum, and the resulting dry residue was heated to 60 °C under vacuum for 3 h, to remove coordinated THF. The residue was dissolved in Et_2O, and the excess NaH filtered off, leaving a solution of **2b** which was sufficiently pure for further reactions.

‡ *Crystal data* for **2b**·$8.6CH_2Cl_2$: $C_{106.6}H_{163.2}O_6Na_6Cl_{17.2}$, M = 2288.45, a = 14.423(2) , c = 50.468(8) Å, V = 9092(2) Å^3, rhombohedral, space group $R\bar{3}$ Z = 3, T = 173 K, final $R1$ = 0.0681 [for 3138 data $I \geq 2\sigma(I)$], $wR2$ = 0.1928 (all 3568 reflections), GoF (on F^2) = 1.098.

§ General procedure for synthesis of adducts: To an Et_2O solution of crude **2a** or **2b** was added 6 equiv. of aldehyde or ketone. The Et_2O was then slowly allowed to evaporate under a dry atmosphere, to give a crystalline residue. The crystals were then thoroughly washed with pentane producing the corresponding adduct.

¶ *Crystal data* for **2b**·$6C_9H_{14}O_2$·$0.4Et_2O$: $C_{153.6}H_{234}O_{18.4}Na_6$, M = 2519.13, a = 19.911(1), b = 15.528(1), c = 24.873(2) Å, β = 91.051(1)°, V = 7688.8(9) Å^3, monoclinic, space group $P2_1/n$, Z = 2, T = 173 K, final $R1$ = 0.0746 [for 9656 data $I \geq 2\sigma(I)$], $wR2$ = 0.2395 (all 15676 reflections), GoF (on F^2) = 1.029. Both structures were solved using the direct methods option of SHELXS. Full-matrix least-squares refinements based on F^2 were subsequently performed using SHELXL-97. (ref. 10). All non-hydrogen atoms, with the exception of a disordered CH_2Cl_2 in **2b**·$8.6CH_2Cl_2$ and a disordered Et_2O molecule in **2b**·$6C_9H_{14}O_2$·$0.4Et_2O$, were assigned anisotropic temperature factors, with corresponding hydrogen atoms included in calculated positions. A β-galactoside phosphoramide mustard prodrug for use in conjunction with gene-directed enzyme prodrug therapy

Ajit K. Ghosh, Saeed Khan and David Farquhar*

Department of Experimental Therapeutics, The University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030, USA. E-mail: dfarquha@mdanderson.org

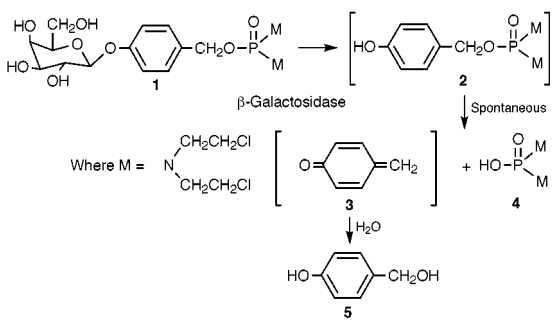
Received (in Corvallis, OR, USA) 22nd September 1999, Accepted 2nd November 1999

4-(β-D-Galactopyranosyl)benzyl *N,N,N′,N′*-tetrakis(2-chloroethyl)phosphorodiamidate 1 was facilely biotransformed to the alkylating antitumor agent, *N,N,N′,N′*-tetrakis(2-chloroethyl) phosphorodiamidic acid, 4, when incubated with *E. coli* β-galactosidase, and therefore has potential for use in conjunction with gene-directed enzyme prodrug therapy.

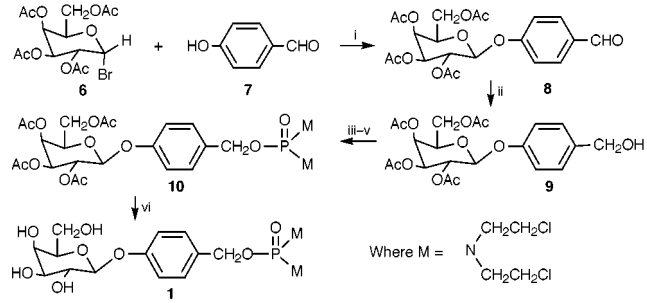
Gene-directed enzyme prodrug therapy (GDEPT) has found increasing application in cancer therapy. In this approach, a foreign gene is introduced into the target tumor, usually with the aid of a viral or liposomal vector.[1–3] When the gene is expressed, it encodes for an enzyme that can convert a nontoxic prodrug to a cytotoxic product. Most GDEPT approaches reported to date have used ganciclovir and fluorocytosine as prodrugs, with HSV thymidine kinase (HSV tk-) and cytosine deaminase (CD), respectively, as the activating enzymes. Although promising results have been described with both prodrug/enzyme combinations, a limitation of HSV tk- and CD as drug-activating enzymes is that they only accept as substrates compounds that closely resemble the natural substrates. In an effort to broaden the scope of the GDEPT approach, we investigated the potential of *E. coli* β-galactosidase as a drug-activating enzyme. Because of its permissive nature, β-galactosidase can cleave a wide structural variety of β-galactosides. Here we describe the preparation of 4-(β-D-galactopyranosyl)benzyl-*N,N,N′,N′*-tetrakis(2-chloroethyl) phosphorodiamidate **1**, a prodrug of the antitumor alkylating phosphoramide mustard *N,N,N′,N′*-tetrakis(2-chloroethyl)phosphorodiamidic acid, **4**.

The anticipated mechanism of activation of **1** is shown in Scheme 1. Under neutral aqueous conditions, the prodrug is expected to be stable and non-reactive. In the presence of β-galactosidase, however, it should be cleaved to the corresponding phenol **2**. This intermediate should undergo spontaneous 1,6-elimination to release the cytotoxic mustard **4** and quinone methide **3**. The latter should have only a transient existence before being converted to 4-hydroxybenzyl alcohol **5**.

Compound **1** was prepared as shown in Scheme **2**. 2,3,4,6-Tetra-*O*-acetyl-α-D-galactopyranosyl bromide **6** was reacted with 4-hydroxybenzaldehyde **7** in the presence of freshly prepared anhydrous Ag_2O (2 equiv.) in MeCN at room



Scheme 1



Scheme 2 *Reagents and conditions*: i, Ag_2O, MeCN; ii, $NaBH_4$, $CHCl_3$–Pr^iOH; iii, PCl_3, Et_3N; iv, $HN(CH_2CH_2Cl)_2$; v, *tert*-butyl hydroperoxide; vi, NaOMe, MeOH.

temperature for 8 h to give **8** (73% yield). Reduction of **8** with $NaBH_4$ in anhydrous $CHCl_3$–Pr^iOH (4 : 1) gave the corresponding benzyl alcohol **9** in 72% yield. Compound **9** was reacted successively with PCl_3 (1 equiv.) and bis(2-chloroethyl)amine (2 equiv.), and the intermediate phosphoramidite was oxidized *in situ* with *tert*-butyl hydroperoxide to afford **10**† as a white solid (47% yield) after purification over silica gel. Compound **10** was converted to the free galactoside **1**‡ in 87% yield by treatment with NaOMe in anhydrous MeOH.

The stability and enzyme activation of 1 was then investigated. A solution of **1** (10^{-4} M) in 0.05 M phosphate buffer, pH 7.4, was incubated at 37 °C in the absence or presence of *E. coli* β-galactosidase (2 units per μmole of **1**). At selected time intervals, 100 μl aliquots were withdrawn and analyzed by HPLC.§ In the absence of enzyme, the peak intensity of **1** decreased with a half life of 9.4 h. In presence of enzyme, the half-life was reduced to 7.6 min. A new peak, chromatographically identical to 4-hydroxybenzyl alcohol, appeared soon after incubation started and progressively increased with time. Since the phosphoramide mustard **4**, does not contain a strong chromophore, it was not evident in the reaction mixture using a UV detector. To establish the formation of **4**, the incubation mixture was further analyzed by LC/MS.¶ The peak suspected to be 4-hydroxybenzyl alcohol gave rise to a molecular ion of mass 107. This is consistent with the hydroxytropylium ion formed by rearrangement of the 4-hydroxybenzyl cation ion derived from **7**. Another peak, not evident when the mixture was analyzed using a UV detector, gave rise to a four-chlorine molecular ion cluster with *m/z* 345 characteristic of the free mustard **4**. These findings strongly support the rationale inherent in the design of **1**. Biological studies of this compound are in progress and will be reported in the future.

In summary, 4-(β-D-galactopyranosyl)benzyloxy *N,N,N′,N′*-tetrakis(2-chloroethyl) phosphorodiamidate **1** was prepared and shown to be converted to the free phosphoramide **4** in the presence of β-galactosidase. Compounds such as **1** might have good potential in conjunction with GDEPT to increase antitumor selectivity in cancer chemotherapy. The synthesis of other β-galactoside anticancer prodrugs are in progress.

This research was supported by NIH grant CA 71527.

Stereoselective synthesis of chiral coordination polymers with partial control of the rigid main chain topology

Jianbo Chen and Frederick M. MacDonnell*

Department of Chemistry and Biochemistry, University of Texas at Arlington, Arlington, TX 76019, USA. E-mail: macdonn@uta.edu

Received (in Bloomington, IN, USA) 12th August 1999, Accepted 3rd November 1999

The condensation polymerization between the appropriate enantiomers of [Ru(1,10-phenanthroline-5,6-dione)$_2$(bpy)]$^{2+}$ 1 and [Ru(1,10-phenanthroline-5,6-diamine)$_2$(bpy)]$^{2+}$ 2 in *meta*-cresol gave the homochiral coordination polymers Δ-3 and Λ-3 as well as the *meso* polymer, ΔΛ-3, which exhibit rigid, ribbon-like structures with different main chain topologies.

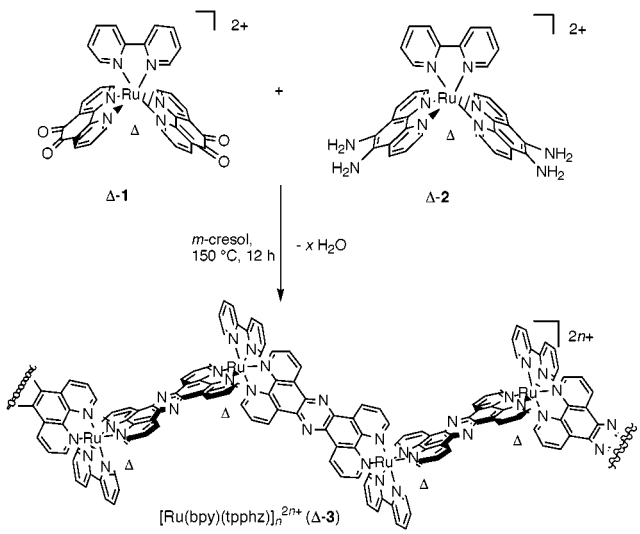
Ruthenium(II) polypyridine complexes have been incorporated into oligomers, dendrimers and polymers because they combine considerable thermal and chemical stability with advantageous catalytic, luminescent and redox properties.[1] Recently, through the work of the groups of Lehn[2] and Tor[3] and ourselves,[4] it has been shown that substitutionally inert, enantiopure derivatives of [Ru(bpy)$_3$]$^{2+}$ and]Ru(phen)$_3$]$^{2+}$ are robust chiral synthons for the synthesis of oligomeric and dendritic polynuclear assemblies. The use of enantiopure monomers permits stereospecific synthesis of a particular diastereomer (in most cases) and allows detailed study of the properties and topology of individual isomers.[5]

Rehahn and coworkers have shown that coordination polymers of the type [Ru(bpy)(tpphz)]$_n^{2n+}$ (tpphz = tetrapyrido[3,2-*a*:2′,3′-c:3″,2″,-h:2‴,3‴-j]phenazine) can be synthesized with P_n ranging from 11 to 30.[6] These polymers have a conformationally rigid main chain and high overall charge, yet remain readily soluble and easily characterized by NMR. Owing to the synthetic approach, however, the absolute stereochemistry at each ruthenium site is random which also significantly affects the main-chain topology.

We have developed a stereospecific syntheses of this polymer as shown in Scheme 1. Chiral monomers Δ-**1**[PF$_6$]$_2$ and Λ-**1**[PF$_6$]$_2$ are prepared from oxidation of Δ- and Λ-[Ru(phen)$_2$(bpy)][PF$_6$]$_2$, respectively, and are converted to Δ-**2**[PF$_6$]$_2$ and Λ-**2**[PF$_6$]$_2$,† as described for related compounds in the literature.[7] By using comonomers, it is possible to prepare three isomeric condensation polymers:‡ the enantiomorphic homochiral polymers Λ-**3** and Δ-**3** and the alternating Δ–Λ 'copolymer', ΔΛ-**3**, which is a *meso* structure. This, to the best of our knowledge, is the first example of a soluble, chiral coordination polymer in which the chirality is centered at the metal sites.§

The absorption and ^{1}H NMR spectra for all three isomers are indistinguishable and match that observed for polymer assembled from racemic monomers. All three are also luminescent at room temperature in MeCN with an emission maximum (λ_{em} = 675 nm) comparable to related multinuclear compounds.[8] Rehahn and coworkers had noted that the presence of diastereomers in their 'racemic' polymers apparently did not complicate the NMR spectrum, presumably owing to the large distance (12.7 Å) between stereocenters.[6] Our results here and with dendritic assemblies bridged by tpphz ligands confirm this hypothesis. End-group analysis of the ^{1}H NMR spectrum give a minimum P_n of 13–15 for all three isomers of **3** which corresponds to M_n of *ca.* 12 000–14 000 (as the PF_6^- salt). *meta*-Cresol was the only solvent that gave a reasonable degree of polymerization with common solvents (H_2O, MeCN, EtOH) yielding only oligomers (P_n = 3–5). Similar solvent effects had been reported in the synthesis of organic ladder polymers.[8]

The stereochemistry of the monomers is retained despite the harsh polymerization conditions, as determined by CD. The CD of the polymers, Δ-**3**, Λ-**3** and ΔΛ-**3**, are displayed in Fig. 1 where the $\Delta\varepsilon$ is reported on a per mole repeating unit. As found with related tpphz bridged dimers, tetramers, hexamers and decamers,[4] the chromophores are not significantly electronically coupled and the CD intensity in the visible region is close to that calculated on a per chromophore basis. The enantiomorphic Δ-**3** and Λ-**3** exhibit strong Cotton effects and show the expected mirror image relationship. The ΔΛ-**3** (*meso*) polymer is achiral and not expected to show any CD however a small Cotton effect is observed. We have observed a side reaction in our studies of related ruthenium dimers, tetramers, hexamers and decamers[4] which is most likely responsible for the observed CD. Coordinated phendione can undergo a two electron–two proton reduction with coordinated phendiamine to yield a coordinated catechol and phendiimine, respectively. The phendiimine is able to further react with coordinated phendiamine to form a tpphz bridge with expulsion of NH_3. The net



Scheme 1 *Reagents and conditions: meta*-cresol, 150 °C, 12 h, N_2 atm.

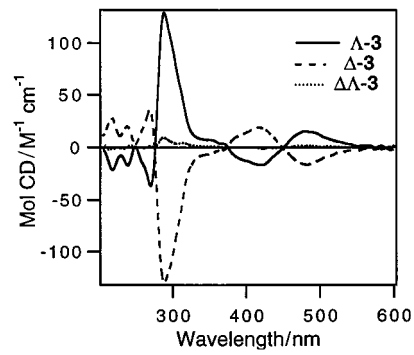


Fig. 1 CD of Λ-**3**, Δ-**3** and ΔΛ(*meso*)-**3** in MeCN.

result here would be the occasional incorporation (*ca.* 7%) of adjacent monomers **2** into the polymer and formation of chain terminating catechol species. Several lines of evidence support this. The sign of the CD found in the *meso* polymer always corresponds to the sign of the **2** monomer used in the reaction. Ammonia, in the form of ammonium ion, is observed to appear in the NMR of model complexes prepared from monomers in a NMR tube experiment in CD_3CN. Oligomers of **3** can be formed upon reaction of **2** with *para*-tetrachloroquinone. It is also possible that the observed CD is due to end-group effects, however, we note that the redox reaction described above would likely enrich the end-groups with the catechol terminated product which would likely give a CD of the opposite sign.

Rehahn and coworkers observed that the topology of the rigid, ribbon-like main chain will be dependent on the absolute configuration of the individual ruthenium centers.[6] In our system it is possible to control this variable, however, this alone does not permit complete topochemical control of the resulting polymer chain. Four 'locked' torsional isomers are possible for this polymer, two for the *meso* and two for the homochiral structures. Every four-metal unit can exhibit a form of *syn* and *anti* stereochemistry of which the torsional angle (Θ for Ru_1–Ru_2–Ru_3–Ru_4) is dependent on the chirality of the individual metal centers. Newman projections for the *meso* (Fig. 2, left) and homochiral (Fig. 2, right) polymers viewed down the Ru_2–Ru_3 axis (with the intervening tpphz parallel with the horizontal axis) show the orientation of the remaining chelate rings (bpy or bridging tpphz) on the front and back rutheniums. If the polymer chain is oriented such that the link to the front Ru_1 comes in at the b quadrant, we can denote each isomer by which quadrants the entering (Ru_1–Ru_2: dark arrow) and leaving (Ru_3–Ru_4: gray arrow) tpphz ligands are in (quadrants labeled in Fig. 2). For the *meso* polymer, only the *syn*-(b,b)-isomer and the *anti*-(b,d)-isomer are allowed, which have torsional angles (Θ) of 0 and 180°, respectively. The descriptors, *syn* and *anti*, are determined relative to the horizontal tpphz plane. Importantly, the homochiral polymers have different torsional angles for the *syn*-(b,a)-isomer (Θ = 72°) and *anti*-(b,c)-isomer (Θ = 108°) which will dramatically affect the overall main chain configuration. The torsional angles were determined from molecular modeling of related dendrimer systems in conjunction with crystallographic data for Λ-$[Ru(phen)_3][PF_6]_2$[10] and the dimer ΔΛ-$[(bpy)_2Ru(tpphz)Ru(bpy)_2][NO_3]_4$.[11]

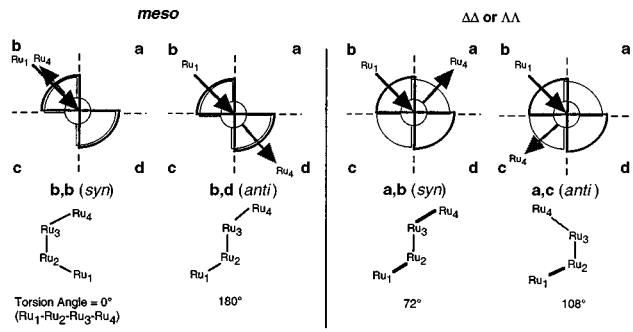

Fig. 2 Newman projections and torsional angle data for the various torsional isomers of the polymer **3**.

From the above considerations, we can predict that the *meso* polymer has a zigzag structure containing only b,b and b,d-isomers (excepting redox related defects as described above) and therefore a structure in which all the Ru atoms are approximately coplanar. On the other hand, the homochiral polymers will form random coil structures owing to the presence of only b,c- and b,a-isomers. Currently, the use of enantiopure monomers only permits partial control of the main chain topology, however steric bulk has been used with some success to favor the more expanded chain structures (in racemic polymers)[6c] and may be useful here to further direct the stereochemical outcome of this reaction.

In conclusion, we have developed a new route to coordination polymers containing chiral ruthenium trisdiimine complexes in the main chain backbone which we can use to partially control the topology of the rigid polymer main-chain. Together these results show that it is possible to exert considerable control over both the local and global polymer stereochemistry. Ultimately materials such as these may be useful in a variety of chiral technologies including chiral sensing, catalysis and separations.

We thank the Robert A. Welch Foundation (Grant Y-1301) for financial support and the National Science Foundation (CHE-9601771) for the purchase of a 500 MHz NMR spectrometer.

The synthesis and single crystal structure of an amino acid intercalated layered niobium phosphate: $[(NbOPO_4)_4{\bullet}(H_3NCH_2CO_2H)_2][H_2PO_4][OH, F]$

Xiqu Wang, Lumei Liu, Heidi Cheng and Allan J. Jacobson*

Received (in Bloomington, IN, USA) 7th September 1999, Accepted 3rd November 1999

Niobium phosphate containing interlayer glycinium phosphate has been synthesized hydrothermally and its structure determined from single crystal X-ray diffraction data.

The structure of anhydrous niobium phosphate $NbOPO_4$ contains layers of NbO_6 distorted octahedra connected in their equatorial planes by PO_4 tetrahedra *via* sharing of corners.[1] Adjacent layers are connected through corner-sharing the remaining unshared oxygen atoms in the NbO_6 octahedra. Niobium phosphate forms a series of hydrates with composition $NbOPO_4{\bullet}nH_2O$ that have been characterized by powder diffraction and infrared spectroscopy.[2–5] No single crystal structural data are available but the hydrates most probably contain layers similar to those found in the anhydrous phase with the bridging oxygen atoms replaced by H_2O molecules to give layers of composition $NbO(H_2O)PO_4$. The presence of the interlayer coordinated water molecules permits intercalation of various types of amines and alcohols between the formally electroneutral layers. The coordination intercalation chemistry is similar to that first observed in $VOPO_4{\bullet}2H_2O$.[4,6] The niobium phosphate layers are stable at high temperature, with respect to radiation damage and in most organic environments. Consequently they are suitable hosts for building composite materials.[7]

We are interested in direct incorporation of organic templates into layered compounds by using hydrothermal synthesis. Here, we report an unusual compound resulting from these studies, $[(NbOPO_4)_4{\bullet}(H_3NCH_2CO_2H)_2][H_2PO_4][OH,F]$ **1** and, to the best of our knowledge, the first single crystal structure of a $NbOPO_4$ intercalation compound.

In a typical synthesis of compound **1**, a solution was prepared by dissolving 0.1 g glycine, 0.12 ml phosphoric acid and 28 mg NH_4HF_2 in 2.1 ml H_2O. The solution (pH = 2.5) was then sealed together with 20 mg niobium metal in a Teflon bag in air. The bag was subsequently sealed in a steel reaction vessel filled with water to about 60% volume, and heated at 165 ºC for 38 h. After cooling to room temperature for 3 h, the products were filtered off, washed with water, and dried in air. Colorless square-like plates of **1** with rather uniform sizes of *ca.* 0.1 × 0.1 × 0.01 mm were recovered together with residual niobium metal. The solution pH was 2.7 at the end of the reaction. Incorporation of glycine into the structure was confirmed by the crystal structure refinement† and the IR spectrum.‡

The crystal structure of **1** consists of $NbOPO_4$ layers bridged by the carboxylic groups of the glycinium $H_3NCH_2CO_2H$ cations with H_2PO_4, F and OH anions located in the interlayer spaces. The layers are structurally equivalent to those of $NbOPO_4$, and are formed from alternating NbO_6 octahedra and PO_4 tetrahedra interconnected through Nb–O–P bonds. The four equatorial oxygen atoms of each NbO_6 octahedron with Nb–O bond lengths of 2.028–2.033 Å are shared by four phosphate tetrahedra. The two apical positions of the NbO_6 octahedron are completed by a terminal Nb=O bond of 1.708 and a weak Nb–O bond (2.219 Å) to an oxygen atom of the interlayer glycinium cation (Fig. 1). The layers are parallel to the (100) plane and stacked in ABAB… sequences. Neighboring layers are shifted relative to each other along [010] by exactly 0.5*b* and along [001] by *ca.* 0.43*c*. The shifts are

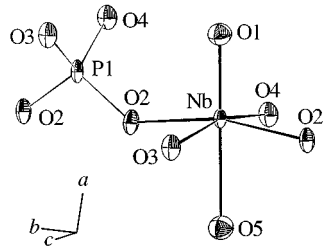

Fig. 1 Coordination environments of the Nb and P atoms in the layers. Thermal ellipsoids are drawn at the 50% probability level. Bond lengths (Å): Nb–O(1) 1.708(5), Nb–O(4) 2.028(4), Nb–O(2) 2.029(3)(×2), Nb–O(3) 2.033(4), Nb–O(5) 2.219(5), P(1)–O(4) 1.535(4), P(1)–O(3) 1.536(4), P(1)–O(2) 1.539(3)(×2).

required by the glycinium cations that bridge neighboring layers through Nb–O–C–O–Nb bonds (Fig. 2). While the oxygen atoms of the glycinium cations are ordered, the C–C–N chain is disordered randomly over four symmetry equivalent positions inside the large interlayer cavities. Although the two oxygen atoms of the carboxyl group are symmetry equivalent, there are two C–O bond lengths, 1.35 and 1.41 Å. The latter corresponds to C–OH–Nb bonds and confirms the protonation of the glycine molecule as expected from the highly acidic synthesis conditions. Because of the C–O–Nb bonding, the C–O distances are longer than those typically found in isolated glycine molecules. The charge balancing $(H_2PO_4)^-$ anions are disordered and were located from difference maps, but not unambiguously, at two

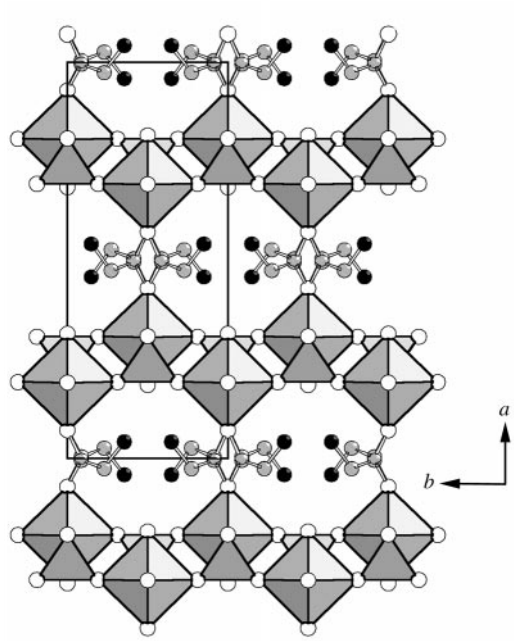

Fig. 2 Projection of the structure along [001]. Open, hatched and solid circles represent O, C and N atoms, respectively. The $H_3NCH_2CO_2H$ cations are disordered randomly over four orientations. The disordered interlayer anions are omitted for clarity.

non-equivalent positions in the interlayer cavities. Both positions can be included in the refinements as rigid groups with a fixed occupancy of 6.3% in agreement with the electron microprobe analysis§ that gave the atomic ratios: Nb : P : F = 4 : 5.0 : 0.4. The charge balancing F^- and probably also OH^- anions could not be located because of electron density overlapping caused by the disorder. Thermogravimetric analysis measured in air up to 900 ºC shows two continuous weight loss stages separated by *ca.* 300 ºC. The total observed weight loss of 17.8% agrees well with the given formula assuming the residue to be $Nb_4P_5O_{22.3}F_{0.4}$ (calc. 17.7%).

The structure of **1** is closely related to the structure model proposed for $NaNb_2(OH)_2(PO_4)_3 \cdot nH_2O$ based on powder X-ray diffraction data. In the model, neighboring niobyl phosphate layers are bridged by PO_4 tetrahedra.[6] There are several precedents for $NbOPO_4$ intercalation compounds in which the layers are bridged by anionic groups. $(VOSO_4)_2 \cdot H_2SO_4$ is generally considered to be the archetype but there are several other examples.[8,9] Compound **1** is unusual because the bridging carboxylate group is cationic and consequently the interlayer charge is compensated for by interlayer anions. All of the other examples in this family contain interlayer cations. $[(NbOPO_4)_4 \cdot (H_3NCH_2CO_2H)_2][H_2PO_4][OH,F]$ is a rare example of a layered inorganic anion exchanger and is analogous to the hydrotalcites.

In summary, we have synthesized single crystals of a novel layered niobium phosphate containing glycinium cross-linking adjacent $NbOPO_4$ layers. Our preliminary data also show that layered niobium phosphates incorporating other organic species can also be obtained in single crystal form through hydrothermal reactions.

Selective extraction of strontium with supercritical fluid carbon dioxide

Chien M. Wai,*[a] Yurii Kulyako,[b] Hwa-Kwang Yak,[a] Xiaoyuan Chen[a] and Suh-Jane Lee[a]

[a] *Department of Chemistry, University of Idaho, Moscow, ID 83844, USA. E-mail: cwai@uidaho.edu*
[b] *Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia*

Received (in Columbia, MO, USA) 3rd June 1999, Accepted 9th November 1999

Strontium (Sr^{2+}) can be selectively extracted from aqueous solutions into supercritical fluid CO_2 at 60 °C and 100 atm with dicyclohexano-18-crown-6 (DC18C6) using $CF_3(CF_2)_6CO_2^-$ ($PFOA^-$) or $CF_3(CF_2)_6CF_2SO_3^-$ ($PFOSA^-$) as a counter anion; at a mole ratio of Sr^{2+} : DC18C6 : $PFOA^-$ = 1:10:50, the extraction of Sr (5.6×10^{-5} M) from water at pH 3 is near quantitative whereas Ca^{2+} and Mg^{2+} at equal concentration are only extracted to a level of 7 and 1%, respectively; $PFOSA^-$ is an effective counter anion for selective extraction of Sr^{2+} from 1.3 M HNO_3 with DC18C6 in supercritical CO_2.

Research in selective transport of metal ions in supercritical (sc)-CO_2 is of considerable current interest because of its potential applications in a variety of chemical processes which may be carried out in this environmentally friendly solvent.[1,2] Selective extraction of alkali metal and alkaline earth metal ions from aqueous solutions to organic solvents with crown ethers is well established in the literature. Extraction of these hard metal ions with crown ethers in $scCO_2$ is expected to be difficult because of limited solubilities of the resulting metal complexes in CO_2.[3] It is known that fluorinated metal chelates are CO_2-philic.[4] Thus, fluorination of ligands is one method of increasing solubility of metal complexes in CO_2. This approach requires the design and synthesis of specific fluorinated macrocyclic compounds. Another method is to extract crown ether-metal complexes as ion-pairs into $scCO_2$ utilizing fluorinated counteranions. We report for the first time the successful extraction of Sr^{2+} from aqueous media into $scCO_2$ utilizing a macrocyclic compound and a fluorinated counter anion.

It is known that 18-membered crown ethers with cavity diameters in the range 2.6–2.8 Å are the most suitable hosts for Sr^{2+} (2.2 Å).[5] For example, ^{90}Sr can be selectively extracted from nitric acid solutions with dicyclohexano-18-crown-6 (DC18C6) dissolved in a paraffinic or halogenated solvent, where nitrate serves as the counter anion.[6] This macrocyclic system is currently being evaluated for removing ^{90}Sr ($t_{\frac{1}{2}}$ = 30 years), a major uranium fission product, from the high level acidic nuclear wastes stored at the Idaho DOE site. However, disposal of organic liquid wastes generated from any solvent extraction process is a problem of environmental concern today because of changing government regulations. Supercritical fluid extraction provides several advantages over conventional solvent extraction including minimization of waste generation, allowing rapid separation of extracted metal complexes, and enhancement of transport speed due to high diffusivity of the supercritical fluid.

The high-pressure apparatus for supercritical fluid extraction of aqueous systems has been described previously.[7] A measured amount of DC18C6 and a fluorinated counter anion, both dissolved in chloroform, was loaded into a 10 mL stainless steel extraction vessel and evaporated to dryness on a water bath at 60 °C with flowing nitrogen gas. 5 mL of an aqueous solution containing a mixture of Sr^{2+}, Ca^{2+} and Mg^{2+} at 5.6×10^{-5} M each were then added to the vessel. The vessel was pressurized with CO_2 and heated to the desired temperature. After 20 min of static extraction, the exit valve was opened and the system was flushed with $scCO_2$ for 20 min. The aqueous solution before and after extraction was analyzed by an ICP/AES instrument for metal contents.

DC18C6 is quite soluble in $scCO_2$, with a solubility estimated to be $> 10^{-2}$ mol L^{-1} at 60 °C and 100 atm, according to our experiments. Direct extraction of Sr^{2+} (5.6×10^{-5} M) with an excess of DC18C6 (5.4×10^{-4} M) in supercritical CO_2 showed virtually no detectable extraction of Sr^{2+} from water (Table 1) or from a 1.3 M nitric acid solution (Table 2). With the addition of a fluorinated carboxylic acid such as pentadecafluoro-*n*-octanoic acid (HPFOA), extraction of Sr^{2+} from water with DC18C6 in $scCO_2$ became significant. The pH of water in equilibrium with $scCO_2$ under the experimental conditions should be *ca*. 2.9 according to a previous study.[8] Because of the inductive effect of the fluorinated group in HPFOA, the pK_a value of this perfluorinated acid is *ca.* 1. Therefore, HPFOA is expected to exist as the anionic form $PFOA^-$ under the specified experimental conditions of this water/$scCO_2$ system. With a concentration of $Sr^{2+} = 5.6 \times 10^{-5}$ M and a mol ratio of Sr^{2+}: DC18C6 : $PFOA^-$ = 1 : 5 : 10, *ca.* 36% of the Sr^{2+} was removed from the water after 20 min of static extraction

Table 1 Extraction of Sr^{2+}, Ca^{2+} and Mg^{2+} from water by sc fluid CO_2 containing DC18C6 and perfluorinated counter anion $PFOA^-$ or $PFOSA^-$ at 60 °C and 100 atm[a]

Mol ratio			Extraction (%)		
Sr^{2+} : DC18C6 : HPFOA			Sr^{2+}	Ca^{2+}	Mg^{2+}
1	10	0	1	0	0
1	0	10	4 ± 1	1 ± 1	1 ± 1

		KPFOSA			
1	10	10	97 ± 2	8 ± 2	2 ± 1

[a] The aqueous solution contained a mixture of Sr^{2+}, Ca^{2+} and Mg^{2+} with a concentration of 5.6×10^{-5} M each; pH of water under equilibrium with $scCO_2$ = 2.9; 20 min static followed by 20 min dynamic flushing at a flow rate of 2 mL min^{-1}. HPFOA = $CF_3(CF_2)_6CO_2H$; NEt_4PFOSA = $NEt_4[CF_3(CF_2)_6CF_2SO_3]$; KPFOSA = $CF_3(CF_2)_6CF_2SO_3K$.

Table 2 Extraction of Sr^{2+}, Ca^{2+} and Mg^{2+} from 1.3 M HNO_3 by $scCO_2$ containing DC18C6 and HPFOA or PFOSA salt at 35 °C and 200 atm[a]

Mol ratio			Extraction (%)		
Sr^{2+} : DC18C6 : HPFOA			Sr^{2+}	Ca^{2+}	Mg^{2+}
1	10	0	1	0	0
1	10	50	18 ± 2	2 ± 1	1 ± 1
		KPFOSA			
1	10	50	60 ± 3	8 ± 2	2 ± 1
1	20	50	76 ± 3	8 ± 2	1 ± 1
		NEt_4PFOSA			
1	10	50	61 ± 3	7 ± 2	2 ± 1

[a] The acid solution contained a mixture of Sr^{2+}, Ca^{2+} and Mg^{2+} with a concentration of 5.6×10^{-5} M each; 20 min static followed by 20 min dynamic flushing at a flow rate of 2 mL min^{-1}.

followed by 20 min of dynamic flushing at 60 °C and 100 atm. The percentage extraction of Ca^{2+} and Mg^{2+} (at equal concentration as Sr^{2+}) under the same conditions was negligible (3% or less). By doubling the concentration of DC18C6 (*i.e.* at a mol ratio of Sr^{2+}: DC18C6 : $PFOA^-$ = 1:10:10), *ca.* 52% of the Sr^{2+} in the water phase was removed at 60 °C and 100 atm. Assuming the percentage Sr extraction from water represents equilibrium partition, we may estimate the distribution coefficient D_{Sr} (concentration of Sr in the CO_2 phase over that in the aqueous phase) from the extraction data using the relationship $D_{Sr} = (C_i - C_f)/C_f$, where C_i and C_f are the concentration of Sr in water before and after the extraction, respectively. The D_{Sr} value appears to double (from 0.56 to 1.08) when the Sr^{2+}: DC18C6 : $PFOA^-$ ratio is increased from 1:5:10 to 1:10:10, suggesting the stoichiometry of Sr to DC18C6 in the complex is most likely 1:1. In the absence of DC18C6, extraction of Sr^{2+} was negligible at 60 °C and 100 atm (Sr^{2+}: $PFOA^-$ = 1:10). Pressure has a minor effect on Sr^{2+} extraction. At 60 °C and 300 atm, the percentage extraction of Sr^{2+} was increased to 58% at a mol ratio of Sr^{2+}: DC18C6: $PFOA^-$ = 1:10:10.

The extraction of Sr^{2+} showed a strong dependence on $PFOA^-$ concentration. With a mol ratio of Sr^{2+}: DC18C6:$PFOA^-$ = 1:10:50, nearly quantitative extraction (98%) of Sr^{2+} from water into $scCO_2$ was observed at 60 °C and 100 atm. Under these conditions, Ca^{2+} and Mg^{2+} were extracted at 7 and 1%, respectively. Selective transport of Sr^{2+} in the presence of Ca^{2+} and Mg^{2+} from an aqueous solution to the $scCO_2$ phase apparently can be achieved using DC18C6 and $PFOA^-$ according to the results shown in Table 1. Based on the extraction data, we also estimated the variation of D_{Sr} with respect to the HPFOA concentration. Values of D_{Sr} increase from 1.1 to *ca.* 49 when the concentration of the HPFOA is increased by a factor of five. This suggests that the Sr^{2+}–crown complex extracted into the supercritical fluid probably involves 2 $PFOA^-$. Accurate measurement of *D* values in supercritical fluids requires a different experimental design. The preliminary results obtained from this supercritical fluid extraction study appear consistent with the charge neutralization requirement and the general concept of crown ether extraction.

The rate of extraction of Sr^{2+} from aqueous phase into $scCO_2$ with DC18C6 and HPFOA is reasonably fast. At 60 °C, 100 atm and with a Sr^{2+}: DC18C6:$PFOA^-$ ratio of 1:10:10 in water, the supercritical fluid extraction of Sr was found to be 11, 49, 52 and 51, for 5, 11, 19 and 30 min of static extraction, respectively. The dynamic flushing time for these experiments was fixed at 20 min. Under the specified experimental conditions, 20 min of static extraction appear sufficient to reach equilibrium.

When perfluoro-1-octanesulfonic acid tetraethylammonium salt, NEt_4 PFOSA, was used instead of HPFOA, the extraction efficiency for Sr^{2+} from water became higher but the selectivity for Sr^{2+} over Ca^{2+} and Mg^{2+} was reduced. At a Sr^{2+}: DC18C6:NEt_4PFOSA ratio of 1:10:10, the percentage extraction of Sr^{2+}, Ca^{2+} and Mg^{2+} were 99, 66, and 2%, respectively. If the potassium salt KPFOSA was used in the extraction instead of the NEt_4^+ salt, selective extraction of Sr^{2+} was observed. For KPFOSA, the extraction of Sr^{2+}, Ca^{2+} and Mg^{2+} were 97, 8 and 2%, respectively (Table 1). The cause of the unusual Ca^{2+} extraction from water with NEt_4PFOSA and DC18C6 in supercritical CO_2 is not known.

Selective extraction of Sr^{2+} by $scCO_2$ with DC18C6 and a fluorinated counter anion was also observed in 1.3 M HNO_3 (Table 2). The extraction of Sr^{2+} in the acid solution with a Sr^{2+}:DC18C6:KPFOSA ratio of 1:10:50 was 60% whereas Ca^{2+} and Mg^{2+} were extracted at a level of *ca.* 8 and 2%, respectively. The extraction efficiency of Sr^{2+} increased to 76% when the crown ether concentration was doubled (Table 2). NEt_4PFOSA did not show unusual Ca^{2+} extraction from the acid solution when it was used with DC18C6 in $scCO_2$. The fluorinated carboxylic acid HPFOA is less effective than the fluorinated sulfonic acid for Sr^{2+} extraction in the acid solution. In general, a high selectivity of extracting Sr^{2+} over Ca^{2+} and Mg^{2+} was observed in all the acid solution experiments. It should be pointed out that the high level acidic nuclear wastes stored at the Idaho DOE site is in 1.3 M HNO_3.

The experimental results obtained from this study suggest that Sr^{2+} in water or in 1.3 M nitric acid can be selectively extracted as ion-pairs with DC18C6 and a fluorinated counter anion in supercritical fluid CO_2. Utilizing the same principle of synergism, other alkali metal and alkaline earth metal ions probably can also be extracted in supercritical CO_2 with proper selection of macrocyclic hosts and perfluorinated counter anions. The possibility of extracting and transporting alkali metals and alkaline earth metals selectively in supercritical CO_2 suggests a number of potential applications including removal of major fission products ^{137}Cs and ^{90}Sr from aqueous or acidic nuclear wastes and phase transfer catalysis for specific reactions in supercritical CO_2.

The authors wish to express their gratitude to the DOE-EMSP Program and to NRC-Nuclear Waste Management Program for financial support.

Oxy-Cope rearrangements of fluorinated divinylcyclohexanols: a modular method for the construction of selectively fluorinated cyclic ketones

Gianluca Dimartino,[a] Thomas Gelbrich,[b] Michael B. Hursthouse,[b] Mark E. Light,[b] Jonathan M. Percy*[a] and Neil S. Spencer[a]

Received (in Liverpool, UK) 25th October 1999, Accepted 10th November 1999

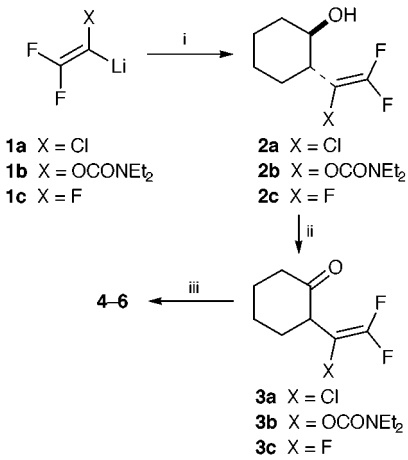
Oxy-Cope rearrangements of fluorinated divinylcyclohexanols afford access to cyclodecenones containing from two to five fluorine atoms.

The oxy-Cope rearrangement has become a tool of awesome transformative power;[1,2] ring systems can be constructed and interconverted with ease, opening routes to highly complex and densely functionalised polycyclic molecular architecture. However, oxy-Cope rearrangements of fluorinated substrates have remained uncharted territory.[3] The effect of fluorine atom substituents upon the thermodynamic parameters of simple Cope rearrangement systems is well known, thanks to the extensive and rigorous efforts of Dolbier.[4] Terminal fluorine atom substituents lower the enthalpy of activation, while the entropy of activation usually increases; overall, the rearrangement reaction in which the CF_2 centre rehybridises from sp^2 to sp^3 is favoured.

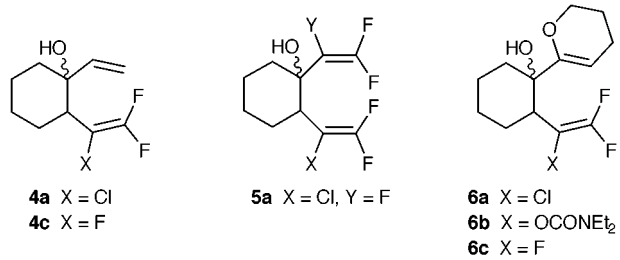
Cyclic (especially medium to large ring) difluoro ketones have a relatively unexplored chemistry because there are few rational routes for their synthesis. More highly fluorinated cyclic ketones show interesting keto/enol tautomerisation[5] behaviour that is quite different from that of acylic congeners,[6] an important class of compounds with well-defined and useful hydration behaviour.[7] Routes to conformationally-restricted difluoro ketones may therefore be of interest and there is also potential for novel transannular interactions and reactions.[8] We therefore decided to examine the oxy-Cope rearrangement as a possible novel strategy for the construction of medium to large rings with controllable patterns of selective fluorination.

We chose the divinyl cyclohexanol/cyclodecenone system, studied originally by Marvell and Whalley,[9] as our starting point and followed their synthetic strategy. Cyclohexene oxide was opened with metallated fluoroalkenes **1a**,[10a] **1b**[10b] and **1c**[10c] to afford alcohols **2a–c** in 69, 64 and 76% isolated yields. Swern oxidation of each followed to afford the corresponding ketones **3a** (83%), **3b** (52%) and **3c** (72%). We were happy to note that these β,γ-unsaturated species, which are presumably destabilised by the vinylic CF_2 centre, did not isomerise and could be purified by column chromatography (Scheme 1).

Next, we added vinylmetals, with the intention of demonstrating that a degree of flexibility was possible in precursor construction. Vinyllithium reacted smoothly with **3a** and **3c** to afford dienols **4a** and **4c** in 78 and 68% yields respectively. When the metallated fluoroalkene derived from HFC-134a **1c** was added to **3a**, a mixture of diastereoisomeric dienols **5a** with distinct ^{19}F NMR spectra were obtained (2.3:1 mixture, 57%). Finally lithiodihydropyran was added to **3a–c** to afford **6a–c**, completing a preliminary range of representative species. The three latter dienols in particular could not be purified because of decomposition during column chromatography, but crude material could be obtained directly from the addition reaction with satisfactory ^1H and ^{19}F NMR spectra. In general, we were not able to free any of the preceding dienols completely from trace amounts of hydrocarbon impurities so they were taken on without being characterised fully.



Scheme 1 *Reagents and conditions*: i, cyclohexene oxide, $BF_3{\cdot}OEt_2$, THF, −78 °C; ii, DMSO, $(COCl)_2$, −78 °C, then Et_3N; iii, alkenylmetal, THF, −78 °C (see text).



We chose to investigate the neutral oxy-Cope in anticipation of problems arising from the high nucleophilicity of potassium alkoxides and enolates, the potential for fluoride ion loss, and the known high electrophilicity of perhaloalkenes. The rearrangements were initiated by heating small samples of the dienols in dry xylene in sealed (Ace) tubes at progressively higher temperatures until appropriate ^{19}F NMR spectral changes were observed, or ^1H NMR changes in the case of **10**. No attempt was made at this stage to measure rate constants or determine activation parameters but we did run a number of substrates at 150 °C to allow some qualitative comparisons to be made (Table 1) with **10**.

Substrates **4a**, **5a** and **6a** all reacted smoothly at 150 °C in short reaction times; however, **10** failed to react at all in one week at that temperature and only underwent a slow conversion at 225 °C in xylene. Of the three series of compounds, the chlorinated congeners appeared to be more reactive than the fluorinated or oxygenated counterparts.[11] The relatively low temperatures of the rearrangements are most encouraging and suggest that a rather general method of fluoro ketone synthesis may be available.[12] Structural assignment was made by ^1H

Table 1 Rearrangement conditions and outcomes for fluorinated dienols

Dienol	T^a/°C	t^b/h	Product	Yield[c] (%)
4a	125	8	**7a**	67
4a	150	3	**7a**	58
4c	125	46	**7c**	72
5a	150	1.75	**8a**	73

NMR COSY and GOESY experiments.[13] By ^{19}F NMR, we were able to detect only products with a single double bond configuration, assumed *trans* with respect to the mutual location of the ring bonds. Unambiguous proof of alkene configuration was then obtained in the case of **9a** when single crystals[14] were grown and subjected to analysis by X-ray diffraction (Fig. 1). Also, the $^3J_{H\text{-}F}$ couplings across the alkene bond in **7c** (33.7 Hz) and **9c** (32.4 Hz) were entirely consistent with this arrangement.

We have therefore shown that oxy-Cope systems can be assembled rapidly, and that fluorinated cyclodecenones and more complex species can be developed from simple fluoroalkene building blocks. Work to define the scope and kinetic parameters of oxy-Cope rearrangement systems that contain fluorinated vinylic components is in progress.

Fig. 1 The molecular structure of **9a**. The *cis*-ring junction and *trans*-ring bonds can be seen clearly.

We thank the Engineering and Physical Sciences Research Council of Great Britain for a Project Studentship (to G. D.) under the ROPA Scheme.

Asymmetric synthesis of 2,3-disubstituted oxepanes *via* acetalization–cyclization of an enantioenriched functionalized allylsilane with aldehydes

Michinori Suginome, Taisuke Iwanami and Yoshihiko Ito*

Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Kyoto 606-8501, Japan. E-mail: yoshi@sbchem.kyoto-u.ac.jp

Received (in Cambridge, UK) 28th October 1999, Accepted 12th November 1999

According to the protocol for the acetalization–intramolecular allylsilane cyclization, a new enantioenriched allylsilane, (*R*)-(*E*)-7-(dimethylphenylsilyl)undec-5-en-1-ol, in the presence of a variety of aldehydes provided enantioenriched *trans*-2,3-disubstituted oxepanes stereoselectively.

Allylsilanes bearing hydroxylated alkyl groups have been utilized for the efficient synthesis of cyclic ethers *via* an acetal formation with aldehydes, followed by an intramolecular cyclization of the allylsilane with an oxonium ion generated from the acetal in the presence of an acid catalyst.[1,2] Moreover, an asymmetric version of the acetalization–intramolecular allylsilane cyclization (AIAC) protocol was recently established by us with use of enantioenriched allylsilanes, which were synthesized *via* a highly stereoselective intramolecular bis-silylation of enantioenriched allylic alcohols.[3] Although the AIAC protocol was successfully applied to the stereoselective synthesis of five- and six-membered cyclic ethers, attempt at the seven-membered ring formation has never been reported. In the light of the synthetic importance of the oxepane derivatives, it is highly desirable to develop a new methodology for the stereoselective construction of oxepanes. Herein, we report stereoselective synthesis of enantioenriched seven-membered cyclic ethers through the AIAC protocol by use of a new enantioenriched allylsilane **1**, which was readily available from δ-valerolactone in a multigram scale.[4]

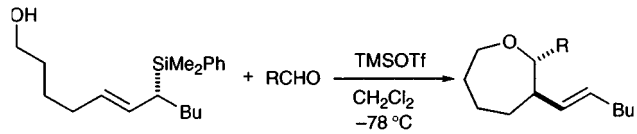
Reaction of δ-valerolactone with 1-lithiohex-1-yne followed by THP protection (THP = tetrahydropyranyl) of the resulting hydroxy group provided the ynone **2** (Scheme 1). Ruthenium-catalyzed enantioselective reduction of the carbonyl group afforded the propargyl alcohol **3** with high optical purity.[5] After the conversion of **3** to the corresponding allylic alcohol **4**, the enantiomeric excess was determined to be 97.1%. Compound **4** was then subjected to our protocol for the synthesis of enantioenriched allylsilanes.[6] The palladium-catalyzed intramolecular bis-silylation of the disilanyl ether **5** and subsequent treatment with BuLi followed by THP deprotection with PPTS afforded the enantioenriched allylsilane (*R*)-**1** with a hydroxybutyl chain.[7] The enantiomeric purity of 96.3% ee was confirmed by chiral HPLC analysis after the appropriate derivatization.[3] Note that the procedure was efficient enough to enable us to prepare (*R*)-**1** on a 10 g scale without difficulty.

With the enantioenriched allylsilane (*R*)-**1** in hand, the AIAC reaction with acetaldehyde was examined in the presence of TMSOTf (2 equiv.). Under essentially the same conditions that we reported previously for the six-membered ring formation, the cyclization took place to give the seven-membered cyclic ether **6a** in 63% yield (Table 1, entry 1).

It is noteworthy that only the *trans*-2,3-disubstituted seven-membered ring ether with *E* olefin geometry was selectively produced.[8] The enantiomeric excess of **6a** was determined to be not less than 92%; finding the chiral GC or HPLC conditions for the complete separation of the enantiomers **6a** proved difficult. Also, the cyclizations with some aliphatic aldehydes proceeded with a good level of chirality transfer (> 96%) (entries 2–4).[9,10] As observed for the reaction of acetaldehyde, only the *trans*-*E*-oxepanes **6b**–**d** were selectively obtained in the cyclization. The amount of the TMSOTf could be reduced to 1.1 equiv. without a decrease in the yield or stereoselectivity (entry 3).

Reaction with benzaldehyde also proceeded in good yield with high stereoselectivity (entry 5). A trace amount (2%) of *cis*-oxepane was detected by ^{1}H NMR, however, the enantiomeric excess of the *trans*-oxepane **6e** was found to be 95.6%. This high stereoselectivity in the seven-membered ring formation with benzaldehyde is in sharp contrast with the correspond-

Table 1 Synthesis of enantioenriched 2,3-disubstituted oxepanes through cyclization of (*R*)-**1** (96.3% ee) with aldehydes[a]



(*R*)-**1** (96.3% ee) **6**

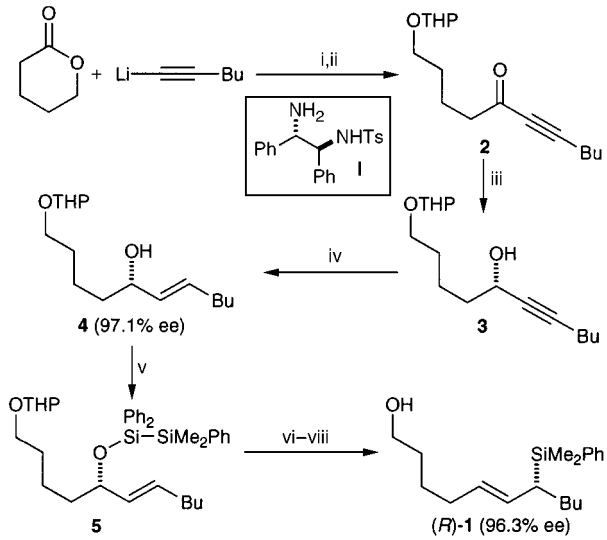
[a] The reactions were carried out at −78 °C in CH_2Cl_2 for 2 h in the presence of TMSOTf (2.0 equiv.) unless otherwise noted. [b] Isolated yields. [c] Determined by ^{1}H NMR. [d] Determined by chiral HPLC unless otherwise noted (ref. 9). [e] (Ee of the product **6**)/[ee of (*R*)-**1**]. [f] Determined by chiral GC (Chrompack Cyclodextrine-β-236M-19) with incomplete separation of signals for enantiomers. [g] Use of 1.1 equiv. of TMSOTf.



Scheme 1 *Reagents and conditions*: i, THF, 0 °C; ii, DHP, TsOH, CH_2Cl_2, room temp.; iii, **I**, $[RuCl_2(p\text{-cymene})]_2$ (cat), KOH, Pr^iOH, room temp., 41% for 3 steps; iv, Red-Al, THF, 0 °C to reflux, 95%; v, $ClPh_2SiSiMe_2Ph$, Et_3N, DMAP (cat), THF, room temp., 87%; vi, $Pd(acac)_2$, $Bu^tCH_2CMe_2NC$, toluene, reflux; vii, BuLi, THF, 0 °C; viii, PPTS, EtOH, 60 °C, 72% for 3 steps.

ing non-stereoselective six-membered ring formation, where all four possible diastereomers were formed. Reaction of **1** with *p*-tolualdehyde also gave *trans*-*E*-oxepane **6f** stereoselectively (entry 6). Interestingly, benzaldehydes bearing electron-donating or -withdrawing substituents at the *p*-positions presented contrasting results in the reactions with **1**. Thus, *p*-nitrobenzaldehyde successfully afforded the corresponding oxepane **6g** of 91% ee with slightly lower diastereoselectivity (entry 7), while no reaction occurred with *p*-anisaldehyde.

In summary, a new and highly stereoselective synthesis of oxepanes has been developed on the basis of the stereoselective preparation of the enantioenriched allylsilane. The success in the practical synthesis of **1** may lead to the synthesis of related functionalized allylsilanes, which can be used as enantioenriched building blocks in organic synthesis.

We thank the Ministry of Education, Science, Sports, and Culture, Japan for a Grant-in-Aid for Scientific Research (11650873).

7 The absolute configuration (*R*) was assigned by analogy with previous reports. See ref. 5 and 6. *Selected data* for (*R*)-**1**: $\delta_H(CDCl_3)$ 0.24 (s, 3H), 0.25 (s, 3H), 0.82 (t, *J* 6.9, 3H), 1.04–1.68 (m, 13H), 1.97–2.05 (m, 2H), 3.62 (t, *J* 6.6, 2H), 5.10–5.25 (m, 2H), 7.31–7.37 (m, 3H), 7.43–7.51 (m, 2H); $\delta_C(CDCl_3)$ −5.1, −4.5, 13.9, 22.3, 26.0, 28.5, 31.4, 32.4, 32.5, 62.9, 127.6, 128.5, 128.8, 131.5, 134.1, 138.4; ν_{max}(neat)/cm^{-1} 3356, 2968, 2940, 2864, 1432, 1250, 1114 (calc. for $C_{19}H_{32}OSi$ 304.2222, found 304.2221); $[\alpha]_D^{20}$ −8.38 (*c* 3.1, benzene).

8 The *trans* stereochemistry in the seven-membered ring was determined on the basis of the ^1H NMR coupling constant between the 2- and 3-protons in the ring. Compound **6a** exhibited a coupling constant of 9.6 Hz, whereas that for *trans*- and *cis*-2-(phenylsulfonylmethyl)-3-(phenylmethyl)oxepane were reported as 8.5 and 2.6 Hz, respectively. See: P. L. López-Tudanca, K. Jones and P. Brownbridge, *Tetrahedron Lett.*, 1991, **32**, 2261.

9 The enantiomeric excesses of **6**, except for **6a**, were determined after derivatization to the corresponding 2-substituted 3-oxepanecarboxylic acid by RuO_2-catalyzed oxidative C=C bond cleavage in the presence of $NaIO_4$ (CCl_4, MeCN, H_2O). The 3,5-dinitrophenylanilides were subjected to chiral HPLC with Sumichiral OA columns indicated below [compound, column, solvent (a ratio of hexanes–1,2-dichloroethane–ethanol)]: (**6b**, OA-4400, 50:15:1); (**6c**, OA-4500 × 3, 15:15:1); (**6d**, OA-4400, 15:5:1); (**6e**, OA-4900, 15:5:1); (**6f**, OA-4500, 15:5:1); (**6g**, OA-4600, 15:5:1). The absolute configurations were assigned by analogy with the stereochemical outcome for the six-membered ring formation reported previously. See ref. 3.

10 The slight decrease in the enantiomeric excesses may be attributed to a minor contribution of '*syn* attack' of the electrophiles on the allylsilane moieties during the cyclization in addition to the normal '*anti* attack'. For a discussion on the '*anti*' *vs.* '*syn*' attack in the reaction of allylsilanes with electrohiles, see: M. J. C. Bucke, I. Fleming and S. Gil, *Tetrahedron Lett.*, 1992, **33**, 4479.

Received (in Cambridge, UK) 14th October 1999, Accepted 19th November 1999

Synthesis and characterization of new periodic mesoporous organosilicas, PMOs, containing benzene and thiophene groups 'within' the channel walls, is presented.

Since the first report of surfactant-templated mesoporous silica by Kresge *et al.*,[1] the area of periodic mesoporous materials has exploded. This is due to the promising properties and applications of materials with ordered arrangements of pores in a new length scale in chemistry, including size exclusion chemistry and chromatography, catalysis, sensors and host materials for polymers, organic and inorganic substances.[2,3]

Recently, a new class of materials, periodic mesoporous organosilicas (PMOs), have been reported.[4–7] These materials are unique compared to first generation periodic mesoporous silica materials since the channel walls contain both organic and inorganic substances. This marriage of organic chemistry with inorganic materials chemistry offers fascinating new possibilities and applications. Some important advantages of integrated organic–inorganic channel walls (smart channels) that were not possible with first generation materials include the following. (i) Organic moieties are homogeneously dispersed *'inside'* the channel walls with a maximum loading of 100%, not achievable with organics 'hanging' in the channels with a maximum loading before collapse of 25%. (ii) Bridge bonded organics *'inside'* the channel walls do not block the pores from chemistry. (iii) 'Soft' organics *'integrated within'* the channel walls should impart interesting mechanical properties to the 'hard' inorganics not seen before. (iv) The organic precursors are easily varied to produce a wide range of materials with potentially interesting electronic, optical, charge-transport and magnetic properties.

The preparation of these materials involves the catalyzed hydrolysis of bis(trialkoxysilyl) organic precursors in the presence of a surfactant template. The presence of the organic moiety greatly influences the nature of the hydrolysis reaction and a number of new factors become important in the synthesis of these materials. Most notably, we were concerned with the stability of the Si–C bond under the hydrolysis conditions and the degree of order in the resulting product. Certain materials, such as the bis-silylated ethylene, methylene and ethane precursors show great stability to strongly acidic or basic conditions. This is confirmed by ^{29}Si NMR, which shows virtually no cleavage even under harsh conditions.[7] In more complicated bridging organic precursors, however, aqueous hydrolysis often results in significant cleavage, as well as a decrease in the degree of order in the material.

The synthesis of the precursors utilized bis-metallated organic intermediates, which reacted with chlorotriethoxysilane prepared from the partial alcoholysis of silicon tetrachloride.[8] Precursors that we synthesized include 1,4-bis(triethoxysilyl)benzene **1**,[9] 2,5-bis(triethoxysilyl)thiophene **2**,[9] 1,1′-bis-(triethoxysilyl)ferrocene **3**,[10,11] bis(triethoxysilyl)bithiophene **4**,[9] and bis(triethoxysilyl)acetylene **5** (Fig. 1).[12] Thiophene and ferrocene PMOs may have interesting electrochemical applications. PMOs with unsaturated organic groups such as benzene offer the possibility of 'chemistry *of* the channels', or act as '*ligand* channels' for metal complexes and organometallics in catalytic applications.

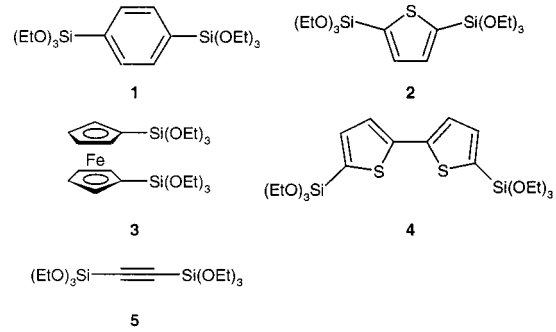

Fig. 1 Structures of the PMO precursors.

When the strongly basic conditions utilized for the synthesis of ethylene-bridged mesoporous silica[4] were applied to the benzene **1** and thiophene **2** precursors, white powders were obtained almost immediately [1.0 Si : 114 H_2O : 15.0 NH_3 (aq) (35 wt%) : 0.12 CTABr]. The powders were aged at 80 °C for two days. ^{29}Si CP MAS NMR showed that almost all the organic moieties had been cleaved from the silica. When a similar experiment was performed under acidic conditions using the thiophene precursor, ^{29}Si CP MAS NMR showed characteristic signals attributed to $Si(OSi)_4$ (Q_4 δ −112), $(HO)Si(OSi)_3$ (Q_3 δ −103) and $(HO)_2Si(OSi)_2$ (Q_2 δ −92), which clearly indicate that a proportion of the Si–C bonds had been cleaved, as well as signals which showed the presence of the organic moieties; $CSi(OSi)_3$ (T_3 δ −84), $CSi(OSi)_2(OH)$ (T_2 δ −76) and $CSi(OSi)(OH)_2$ (T_1 δ −66) [Fig. 2(a)]. ^{13}C CP MAS NMR showed that indeed the benzene and thiophene organic moieties were intact. The PXRD pattern showed very good structural order in the hexagonal phase. Most of the surfactant template could be removed by extracting into an MeOH–HCl mixture at room temp. for 2–3 days and the structural integrity of the material was maintained, as shown by PXRD and TEM studies.

To decrease the amount of cleavage of Si–C bonds in the benzene and thiophene PMOs, a decreased concentration of acid was used to catalyze the hydrolysis, as well as allowing the

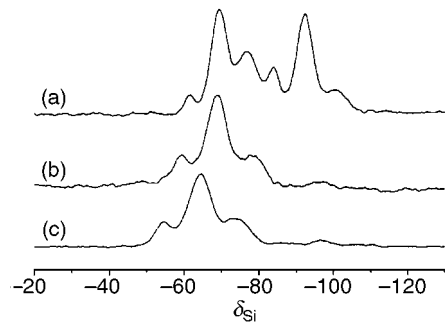

Fig. 2 ^{29}Si CP MAS NMR spectra of periodic organosilica materials. Thiophene bridged PMO prepared in (a) strong acid and (b) under the optimized procedure. (c) Benzene bridged PMO prepared under the optimized procedure.

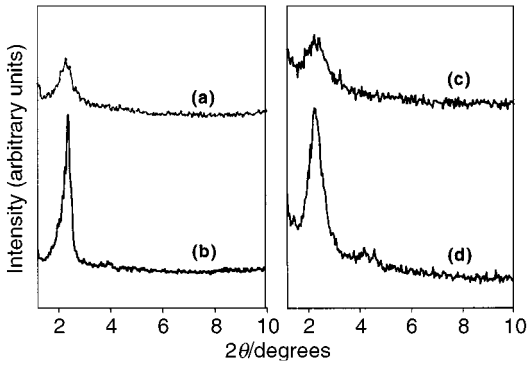

Fig. 3 PXRD of periodic mesoporous organosilica materials with a comparable degree of Si–C bond cleavage. Benzene bridged PMO prepared in (a) dilute acid and (b) under the optimized procedure. Thiophene bridged PMO prepared in (c) dilute acid and (d) under the optimized procedure.

powder to age at room temp. instead of 80 °C. NMR studies confirmed that under milder conditions, the amount of cleavage decreased. However, PXRD indicated that the degree of order of the material was diminishing with decreased acid concentration [Fig. 3(a,c)]. This is presumably due to the decreased charge concentration on the silicate species. This reduces the coulombic attraction between surfactant and silicate species that contributes to the 'surfactant templating' mechanism.[13] Also, under very dilute acidic conditions, the yield of the powder product decreased considerably as did the degree of polymerization as observed by ^{29}Si NMR. This decreased yield may be due to the formation of low molecular weight soluble silicates.

To obtain a satisfactorily ordered PMO containing benzene or thiophene in an aqueous synthesis medium, a different approach to hydrolytic polycondensation needed to be considered. The following procedure for the bis-silylated thiophene PMO gives a satisfactory sample and is representative of the approach. Cetylpyridinium chloride (CPCl) followed by 2,5-bis(triethoxysilyl)thiophene was added to an acidic aqueous solution and stirred moderately at room temp. briefly. After the resulting mixture was neutralized with portionwise addition of solid $NaHCO_3$, NH_4F (0.1 mol%) was added and the slurry allowed to stand at room temp. for two days.[14] After filtering and washing with copious amounts of water, a white powder was obtained. The material thus obtained showed only a small amount of Si–C bond cleavage [Fig. 2(b,c)] and the PXRD showed a good hexagonal mesoporous organosilica (100) reflection [Fig. 3(b,d)]. TEM also showed the presence of the expected crystalline mesoporosity (Fig. 4).[15,16] NMR did not show the presence of triethoxysilyl moieties, suggesting the hydrolysis is essentially complete.

The other precursors proved to be more challenging. For example, the bis(triethoxysilyl)ferrocene precursor **3** showed partial cleavage of the Si–C bond and a lower degree of order.

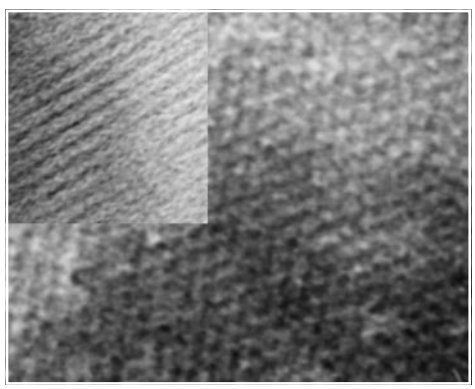

Fig. 4 TEM of hexagonal mesoporous benzene silica. Images perpendicular and parallel (inset) to the channel axis confirm the hexagonal structure of the PMO. Extensive TEM lattice imaging studies of large areas of the sample show that the PMO phase always dominates over any amorphous organosilicate xerogel phase.

NMR studies showed that a significant amount of ferrocene remained intact in the silica framework, and thus shows promise for further study. The acetylene precursor **4** had a particularly labile Si–C bond and was difficult to control under aqueous conditions. The attempt to place the bithiophene moiety **5** within the walls of the channels resulted in a material with poorer order.

The preparation of various hybrid 'organic–inorganic' walled periodic mesoporous silicas is currently being optimized.

PMOs with organic functionality *'inside'* the channel walls are a new class of materials with much promise for a wide variety of applications. PMOs are distinct from organosilica xerogels that have been previously reported. Organosilica xerogels have a *'random distribution of polydispersed mesopores'*. This is to be contrasted with PMOs that have *'crystalline mesoporosity'* and *'Angstrom precise pore dimensions'*, both considered necessary prerequisites for size selective applications.

This work was supported by the National Sciences and Engineering Research Council of Canada (NSERC). We thank NSERC for a post-graduate scholarship (M. J. M., 1995–99) and an undergraduate summer research scholarship (C. Y.-I., 1999).

14 The following procedure for the synthesis of mesoporous benzenesilica is representative: bis(triethoxysilyl)benzene (0.96 g, 2.4 mmol) was added to a homogeneous solution of water (4.88 g, 0.27 mol), HCl (36%, 0.81 g, 8.1 mmol), and CPCl (0.11 g, 0.3 mmol) at *ca.* 32 °C, and the solution was stirred moderately for 15 min. The resulting mixture was neutralized with portionwise addition of $NaHCO_3$ prior to adding NH_4F (0.1 mg, 2.7 μmol) and aging at room temp. for two days. The powder was filtered and washed with copious amounts of water.
15 The possibility that a mixture of amorphous organosilica and periodic mesoporous organosilica resulting from hydrolytic cleavage of the Si–C bond could give rise to the observed PXRD and NMR was addressed by examining large areas of the powder by TEM. The results of an extensive TEM study show that the PMO phase dominates over any amorphous organosilicate xerogel phase. Therefore the PMOs are responsible for both the solid state NMR and PXRD data reported here. Polarisation optical microscopy and micro-Raman spectroscopy confirm this proposal and show bridge bonded organics homogeneously dispersed throughout the PMO.[7]
16 Surfactant-free mesoporous benzenesilica shows a Type IV nitrogen adsorption isotherm at 77 K. Calculated BET suface area = 1365 m^2 g^{-1}, pore volume = 0.67 cm^3 g^{-1}, pore diameter = 2 nm, which together with PXRD–TEM d_{100} = 3.8–3.2 nm provides a channel wall thickness ≈ 2 nm.

Reductive coupling of alkynes to give ruthenium and osmium clusters of the type $[M_3(1,3\text{-diene})(\mu_3\text{-X})(CO)_8]$ containing $\mu\text{-}\eta^2,\eta^2$- or η^4-1,3-diene

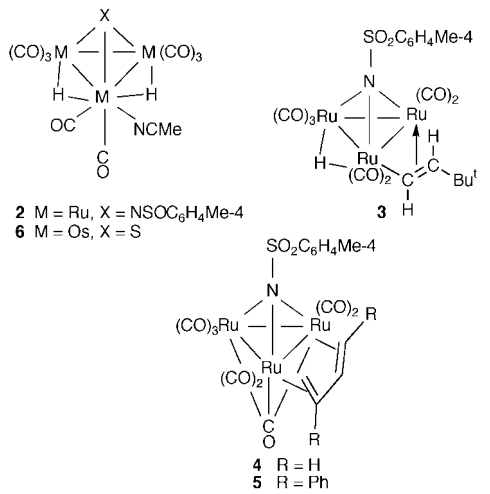
Received (in Basel, Switzerland) 29th October 1999, Accepted 12th November 1999

Replacement of a CO ligand by MeCN in the capped clusters $[M_3(\mu\text{-H})_2(\mu_3\text{-X})(CO)_9]$ (M = Ru, X = $NSO_2C_6H_4Me$-4 or M = Os, X = S) allows reductive coupling of alkynes (RC≡CH, R = H or Ph) to give regioselectively the 1,3-diene clusters $[M_3(C_4H_4R_2)(\mu_3\text{-X})(CO)_8]$, with the diene $\mu\text{-}\eta^2,\eta^2$-coordinated for ruthenium and η^4 for osmium.

Hydrido clusters usually react with alkynes to give $\mu\text{-}\sigma,\eta^2$-alkenyl containing clusters.[1–3] Dihydrido clusters either give hydrido–alkenyl compounds[1,2] or exceptionally dialkenyl compounds by double insertion.[3] Two organyl ligands formed by double insertion could couple to give new organic ligands. More commonly both hydride ligands are delivered to the same organic function leading to simple hydrogenation, for example alkyne to alkene. We now report 1,3-diene-containing clusters formed by double insertion of alkyne into M–H bonds, followed by alkenyl–alkenyl coupling. Reductive coupling of alkynes to give 1,3-dienes is not very common[4] and an alkenyl–alkenyl coupling mechanism has not been established previously, although alkenyl coupling with other organic ligands has been implicated in Fischer–Tropsch synthesis.[5] Our approach was to displace CO by more labile MeCN in strongly capped Os_3 and Ru_3 clusters with two basal hydrido bridges, thereby creating a reactive basal plane of metal atoms within a robust cluster.

The cluster $[Ru_3(\mu\text{-H})_2(\mu_3\text{-NR})(CO)_9]$ (R = $SO_2C_6H_4Me$-4) **1**[6] was treated with $Me_3NO{\cdot}2H_2O$ and MeCN to form $[Ru_3(\mu\text{-H})_2(\mu_3\text{-NR})(CO)_8(MeCN)]$ **2** with the MeCN ligand *cis* to the capping atom N; two sharp hydride ^{1}H NMR doublets observed at −25 °C are exchange-broadened at 20 °C. Treatment of **2** with $Bu^tC{\equiv}CH$ gives the mono-insertion product $[Ru_3(\mu\text{-H})(\mu\text{-}trans\text{-CH=CHBu}^t)(\mu_3\text{-NR})(CO)_8]$ **3**† reversibly. Compound **3** liberates $Bu^tCH{=}CH_2$ and $[Ru_3(\mu_3\text{-NR})(CO)_{10}]$ on treatment with CO at room temperature. In contrast, the less bulky alkynes RC≡CH (R = Ph or H) both react with **2** to give mixtures from which we could isolate two compounds, $[Ru_3(\mu\text{-}\eta^2,\eta^2\text{-}C_4H_4R_2)(\mu_3\text{-NR})(CO)_9]$ **4** (R = H) (7%) and **5** (R = Ph) (17%).



2 M = Ru, X = $NSOC_6H_4Me$-4
6 M = Os, X = S

3

4 R = H
5 R = Ph

Spectra† show that **4** and **5** are very similar and ^{1}H NMR spectra for **5** confirm head-to-tail coupling of phenylacetylene to give the *trans*-1,3-diphenylbutadiene ligand. The single-crystal structure of **4** (Fig. 1)‡ shows the presence of μ_3-NR, μ_3-CO and $\mu\text{-}\eta^2,\eta^2$-*s*-*cis*-butadiene. While $\mu\text{-}\eta^2,\eta^2$-*s*-*cis*-1,3-diene is known in several cases,[7] $\mu\text{-}\eta^2,\eta^2$-*s*-*trans*-butadiene,[8] $\mu\text{-}\eta^1,\eta^3$-*s*-*cis*-butadiene[9] and $\mu\text{-}\eta^1,\eta^4$-*s*-*cis*-1,3-diene[10] are also known. The cluster $[Os_3(CO)_{10}(\mu\text{-}C_4H_6)]$ contains $\mu\text{-}\eta^2,\eta^2$-*s*-*trans*-butadiene.[11]

Intermediate alkenyl complexes were not observed in the formation of **4** and **5**, although the formation of **3** suggests that they are involved. The Os analogue of **2** only reacts with alkynes to give clusters related to **3**, without diene formation. However, the cluster $[Os_3(\mu\text{-H})_2(\mu_3\text{-S})(CO)_8(MeCN)]$ **6**, formed as for **2**, was treated with PhC≡CH in refluxing THF for 24 h to give various insertion products: $[Os_3(\mu\text{-H})(\mu\text{-PhC=CH}_2)(\mu_3\text{-S})(CO)_8]$ **7** (23%), $[Os_3(\mu\text{-H})(\mu\text{-CH=CHPh})(\mu_3\text{-S})(CO)_8]$ **8** (11%), $[Os_3(\mu\text{-PhC}_2H_2)_2(\mu_3\text{-S})(CO)_7]$ **9** (17%) and $[Os_3(\eta^4\text{-PhCH=CHCPh=CH}_2)(\mu_3\text{-S})(CO)_8]$ **10** (12%). The isomeric mono-insertion products **7** and **8** were shown by ^{1}H NMR to be non-interconverting regioisomers. The di-insertion product **9** exists as a mixture of isomers (^{1}H NMR evidence) with both $CPh{=}CH_2$ and CH=CHPh ligands present. The 1,3-diphenylbutadiene complex **10** from treatment of **6** with PhC≡CH is also formed by treating the dialkenyl cluster **9** with CO. ^{1}H NMR data for **10** confirm head-to-tail alkyne coupling but there are very different chemical shifts for the four vinylic hydrogen atoms in **10** compared with those for **5** (δ 1.55, 2.43, 3.58 and 6.79 for **10** *cf.* δ 2.98, 4.72, 5.53 and 5.82 for **5**).

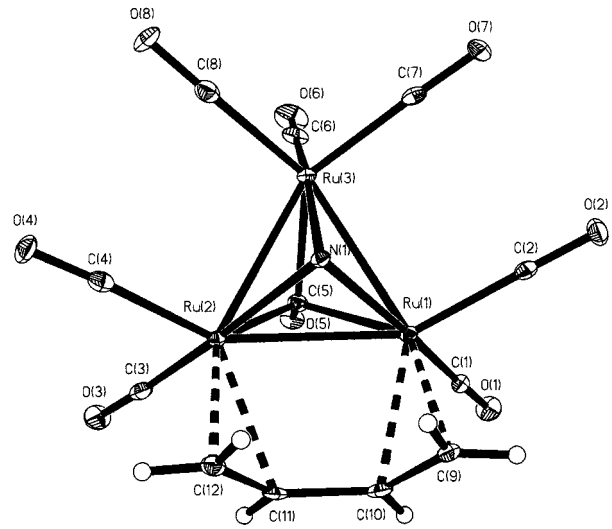


Fig. 1 Thermal ellipsoid drawing (30% probability) of $[Ru_3(\mu\text{-}\eta^2,\eta^2\text{-}C_4H_6)(\mu_3\text{-}NSO_2C_6H_4Me\text{-}4)(CO)_8]$ **4** with the tosyl group omitted. Selected lengths (Å) and angles (°): Ru(1)–Ru(2) 2.7560(3), Ru(1)–Ru(3) 2.7416(4), Ru(2)–Ru(3) 2.7554(3), Ru(1)–C(9) 2.258(3), Ru(1)–C(10) 2.304(3), Ru(2)–C(11) 2.338(3), Ru(2)–C(12) 2.246(3), C(9)–C(10) 1.393(5), C(10)–C(11) 1.461(4), C(11)–C(12) 1.393(5); C(9)–C(10)–C(11) 127.5(3), C(10)–C(11)–C(12) 127.6(3).

Furthermore there is no IR evidence for μ_3-CO in **10**. A single-crystal structure determination (Fig. 2)‡ confirms that **10** has a different structure from that of **4** or **5**. Indeed there is no μ_3-CO in **10**, but instead the two CO ligands at Os(1) are semibridging to Os(2) and Os(3) respectively. More importantly the 1,3-diene is η^4-co-ordinated to Os(1) rather than bridging as in **4**.

The formation of 1,3-diene-containing clusters from simple alkynes is unique. The mono-insertion compounds $[M_3(\mu\text{-H})(\mu\text{-alkenyl})(\mu_3\text{-X})(CO)_8]$ appear to be more reactive towards further alkyne insertion into the second M–H bond than towards reductive elimination of alkene. This almost certainly results from the ligands being along separate M–M edges and indicates that hydrogenation reactions induced by clusters could be very different from those catalysed by mononuclear compounds. The formation of μ-η^2,η^2-diene for Ru and η^4-diene for Os may reflect different alkenyl–alkenyl coupling mechanisms. We are attempting to establish the structures of the isomeric dialkenyl compounds and the geometric details of the alkenyl–alkenyl coupling.

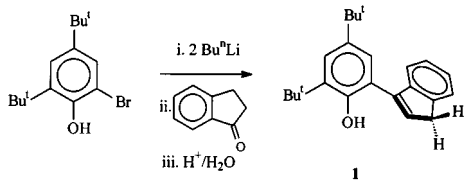
Received (in Bloomington, IN, USA) 6th August 1999, Accepted 22nd October 1999

Three distinct bonding modes for the ligand 2-(indenyl)-4,6-di-*tert*-butylphenoxide at early d-block metal centers have been identified

The use of constrained geometry cyclopentadienyl ligation has had a considerable impact on early transition metal chemistry in recent years.[1] As part of our work on novel *ortho*-substituted aryloxide ligation[2] we have synthesized the compound 2-(inden-3-yl)-4,6-di-*tert*-butylphenol **1** (Scheme 1).[3] Unlike previously reported ligands of this type, chelation of **1** to a metal center *via* deprotonation will generate an inherently chiral environment. Here we report on our initial forays into the chemistry of this ligand, which demonstrate three distinct bonding modes to transition metal centers.



Scheme 1

Compound **1** is obtained in gram quantities *via* the synthetic route shown in Scheme 1. When **1** is added to the compound [$CpTiCl_3$] in the presence of excess pyridine the simple aryloxide [$Cp_2Ti(OC_6H_2Bu^t_2$-4,6-Ind-2)Cl_2] **2** is obtained.† The solid state structure of **2** (Fig. 1) shows the *ortho*-inden-3-yl group to be unbound with a Ti–O–C angle of 158.7(1)°.‡ Surprisingly, addition of LiMe to **2** produces the corresponding dimethyl derivative **3** (Scheme 2) with no deprotonation of the inden-3-yl ligand being observed. At ambient temperatures the potentially diastereotopic methylene protons in the *ortho*-inden-3-yl groups of both **1** and **2** appear as broad singlets in the ^{1}H NMR spectra owing to inden-3-yl rotation on the NMR timescale. At lower temperatures these signals broaden and resolve into the AB pattern expected for the static structure. Similarly both Ti–*Me* groups in **3** appear as one broad singlet in

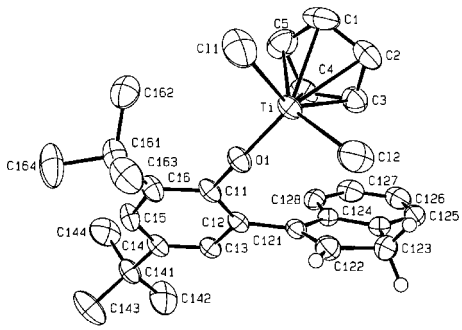


Fig. 1 Molecular structure of **2** showing the atomic numbering scheme. Selected interatomic distances (Å) and angles (°): Ti–O(1) 1.785(2), Ti–Cl(1) 2.2581(8), Ti–Cl(2) 2.2554(8); Cl–Ti–Cl 100.24(4), Cp–Ti–O(1) 118.1(1), Ti–O(1)–C(11) 158.7(1).

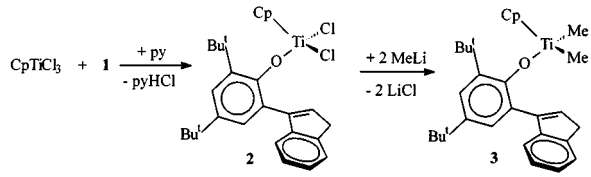
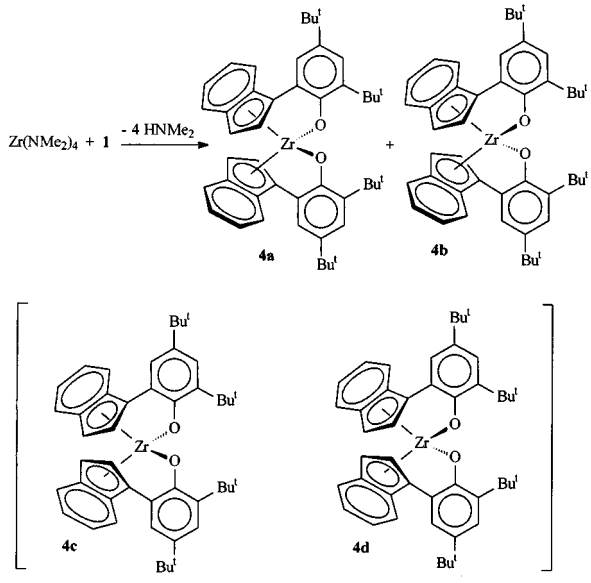


Scheme 2

both the ^{1}H and ^{13}C NMR spectra at ambient temperatures but appear as two well resolved resonances at lower temperatures. Variable temperature NMR studies of **2** and **3** in toluene-d_8 allow the barrier to inden-3-yl rotation (enantiomer interconversion) to be estimated at 13.9(5) kcal mol^{-1} (at 20 °C) and 13.4(5) kcal mol^{-1} (at −5 °C), respectively. These barriers are significantly lower than that measured for corresponding 2-(1-naphthyl)phenoxides.[2c]

Addition of **1** to the zirconium precursor [$Zr(NMe_2)_4$][4] leads to the complex [$Zr\{(OC_6H_3Bu^t_2$-4,6-(η^5-Ind)$\}_2$] **4**. In solution **4** is shown by NMR to exist as a mixture of two isomers (Scheme 3). Recrystallization from benzene–pentane generates crystals of **4a** shown (Fig. 2) to contain a crystallographic C_2 axis of symmetry. It can be seen that in the solid state both indenyl rings are η^5-bound to the same zirconium metal center, Zr–O–C angle = 128.4(2)°. In $CDCl_3$ solution **4a** undergoes slow (days at room temperature) conversion to a 50 : 50 mixture of **4a** : **4b**. In both **4a** and **4b** the aryloxide groups are equivalent (NMR) ruling out their formulation as the two alternative isomers **4c** and **4d** that contain no symmetry elements (Scheme 3).

Treatment of the compound [$Ta(NMe_2)_5$][5] with **1** initially produces the substitution compound **5** (Scheme 4) with elimination of one equivalent of $HNMe_2$. Upon theromolysis



Scheme 3

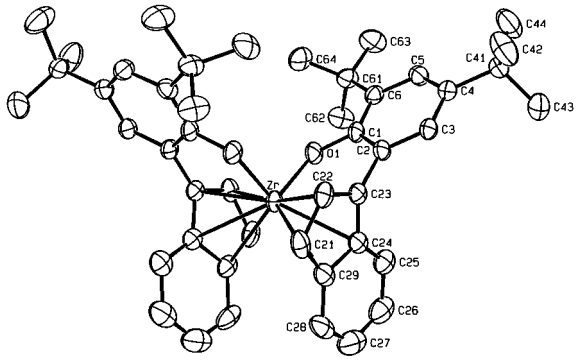


Fig. 2 Molecular structure of **4a** showing the atomic numbering scheme. Selected interatomic distances (Å) and angles (°): Zr–O(1) 2.015(2), Zr–C(23) 2.487(3), Zr–C(22) 2.500(3), Zr–C(21) 2.532(3), Zr–C(24) 2.568(3), Zr–C(29) 2.640(3), O(1)–Zr-O(1) 97.6(1), Zr–O(1)–C(1) 128.4(2).

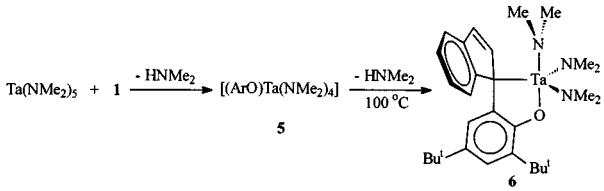

Scheme 4

(100 °C) in C_6D_6, a further equivalent of $HNMe_2$ is lost from **5** with formation of **6** (Scheme 4). The solid state structure of **6** (Fig. 3) shows the ligand to be chelated to the metal *via* an η^1-indenyl interaction, Ta–O–C angle = 122.7(6)°. The metal is attached to the *ipso* carbon atom yielding a five-membered metallacycle ring. The coordination environment about the Ta metal center in **6** is best described as tbp, with an axial oxygen atom. In the ambient temperature ^{1}H NMR spectrum of **6** a single broad resonance is observed for the Ta–N*Me*$_2$ protons. At lower temperatures this signal splits out into four singlets in the ratio of 2:2:1:1. We interpret the two larger signals as being due to the two, non-equivalent equatorial Ta–NMe_2 groups undergoing rapid rotation. The remaining signals are due to the unique axial Ta–NMe_2 group that is undergoing restricted rotation on the NMR timescale. Presumably the higher barrier to rotation of the axial group is due to the presence of the η^1-indenyl ring (Fig. 3).

We thank the National Science Foundation (Grant CHE-9700269) for financial support of this research.

A highly efficient synthesis of triisopropylsilyldifluorobromopropyne yields a versatile *gem*-difluoromethylene building block

ZhiGang Wang and Gerald B. Hammond*

Department of Chemistry and Biochemistry, The University of Massachusetts Dartmouth, North Dartmouth, Massachusetts 02747, USA. E-mail: ghammond@umassd.edu

Received (in Corvallis, OR, USA) 23rd September 1999, Accepted 8th November 1999

Triisopropylsilyldifluorobromopropyne, readily prepared in excellent yield from the reaction of lithium triisopropylsilylacetylide with CF_2Br_2, provides a convenient entry into a functionalized CF_2 synthon.

The *gem*-difluoromethylene unit is a key structural motif in many fluorine containing compounds of biological and pharmaceutical significance. For this reason, it is an important synthetic target.[1] Two complementary approaches to such important unit exist. These are (i) substitution of a carbonyl or an active methylene group by fluorine;[2] and (ii) use of small *gem*-difluoromethylene-containing building blocks.[3] When it comes to fluorinate complex molecules, the latter approach is preferred because of the reactivity, thermal instability, hazards and cost associated with electrophilic and nucleophilic fluorinating agents. The two most frequently used *gem*-difluoromethylene synthons, $(EtO)_2P(O)CF_2Br$ and $EtOC(O)CF_2Br$, were developed in the late 70s and early 80s by Burton[4] and Fried,[5] respectively. Stimulated by our earlier work in the synthesis of fluorinated phosphonates,[6] we sought a new generation of difluorinated building blocks from inexpensive industrial fluorine feedstock such as CF_2Br_2 (not included in the list of CFCs to be phased out). Our initial target, triisopropylsilyldifluoropropyne **1** (Fig 1), is a highly functionalized three-carbon backbone that contains a propargyl silane moiety. This feature should facilitate multiple synthetic conversions containing the *gem*-difluoromethylene unit.

A literature search revealed that difluoropropargyl substrates, without exception, have been prepared in disappointingly low yields.[7] The low yields obtained have probably contributed to the lack of use of the difluoropropargyl building block in the literature. To our satisfaction, **1** was very efficiently assembled in one step (92% GC-MS, 81% isolated) by the reaction of CF_2Br_2 with lithium triisopropylsilylacetylide. This reaction has been carried out on 5, 16 and 50 g scales and the results have shown excellent reproducibility.[8] We attributed the success of this reaction to the presence of the TIPS group, which possesses remarkably different properties compared to other alkylsilyl groups.[9] Chiefly, the presence of TIPS enhances the stability of the triisopropylsilyldifluoropropyne anion intermediate.[10] Although the reaction mechanism is still unclear, our experimental observation of a typical 5–10 min induction period supports the difluorocarbene based ionic chain path proposed by Wakselman and co-workers.[7a] With a highly efficient preparation of **1** in hand, we explored the synthesis of various *gem*-difluoromethylene-containing compounds. Preliminary results, summarized in Scheme 1,[11] unveiled a highly versatile building block.

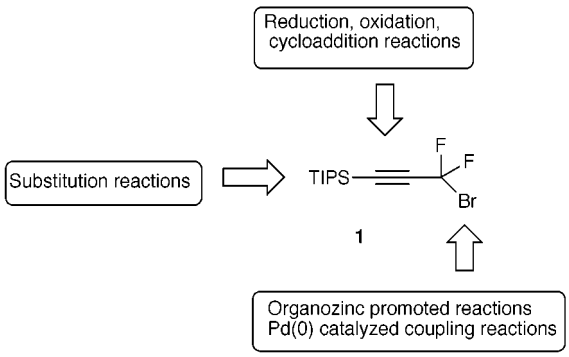

Fig. 1 Building block potential of **1**.

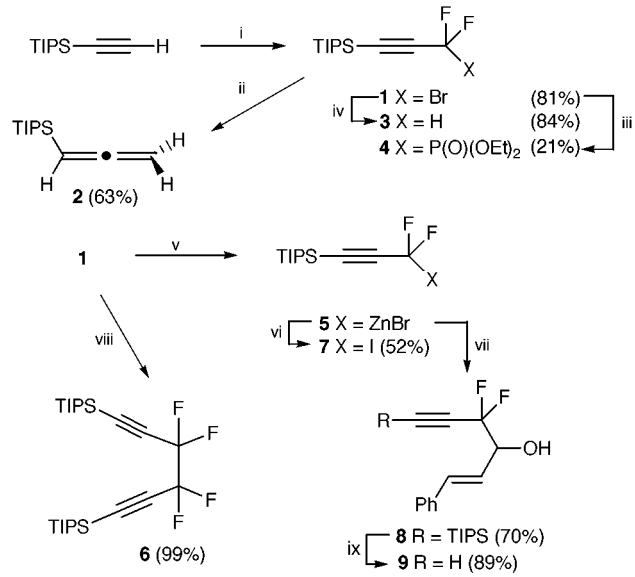
Reduction with $LiAlH_4$ gave allene **2**, whereas nucleophilic substitution with $MP(O)(OEt)_2$ afforded difluoropropyne **3** and difluoropropargyl phosphonate **4**, although the latter was obtained in low yield. Because compound **4** is a potential precursor for isosteric and isoelectronic phosphate mimics of enzyme inhibitors,[12] an optimization of this reaction is in progress. Using ultrasound, **1** reacted rapidly with zinc dust yielding the alkynyl organozinc reagent **5** *in situ*. This organozinc intermediate is a useful synthetic building block as can be seen in the Reformatsky-type reactions shown at the bottom of Scheme 1. Addition of Zn to **1** produced dimer **6** in nearly quantitative yield. Compound **6** is a potential intermediate in the synthesis of CF_2CF_2-containing bioactive molecules.[13] If **5** is quenched with powdered iodine, it produces difluoroiodopropyne **7**, another important *gem*-difluoromethylene synthon.[14] Addition of *trans*-cinnamaldehyde to **5** afforded difluoro alcohol **8** in 70% yield. When needed, the TIPS-protecting group can be easily removed, as demonstrated by the conversion of **8** to **9** under mild conditions, and in excellent yield. The latter result will allow an easy entry to the preparation of propargylic, and possibly allylic, α,α-difluorocarbonyl compounds, after oxidation of the alcohol and hydrogenation of the triple bond.



Scheme 1 *Reagents and conditions*: i, BuLi, CF_2Br_2, THF, −20 °C to room temp.; ii, $LiAlH_4$ (0.6 equiv.), THF, −80 °C; iii, NaN $(TMS)_2$, $HP(O)(OEt)_2$ (1.0 equiv.), THF, −10 °C; iv, $HP(O)(OEt)_2$, BuLi (1.5 equiv.), −10 °C; v, Zn (1.2 equiv.),THF, room temp., ultrasound; vi, I_2 (1 equiv.), 0 °C; vii, *trans*-cinnamaldehyde, 20 h, room temp.; viii, **1** (1.0 equiv.), Zn (2.0 equiv.), room temp.; ix, TBAF (1.0 equiv., 1 M in THF), −80 °C.

Other synthetic modifications of **1** and the preparation of a monofluorinated counterpart to **1** are under investigation.

The generous support of the National Science Foundation (CHE-9711062), Petroleum Research Fund (PRF#32595-B1) and the Camille and Henry Dreyfus Foundation (TH-96-012) is gratefully appreciated.

8 Under Ar atmosphere, a solution of triisopropylsilylacetylene (36 g, 0.2 mol) in THF (300 ml) was cooled to −20 °C. BuLi (125 ml, 1.6 M solution in hexane) was added *via* syringe and the resulting solution was stirred for 30 min before CF_2Br_2 (62 g, 1.5 equiv.) was added. The solution was allowed to warm to room temperature and stirred for 9 h. After solvent removal, NH_4Cl (120 ml) was added and the oily layer was extracted with Et_2O (3 × 100 ml). Standard work-up gave the crude product as a viscous orange oil (92% yield by GC−MS) which was purified by distillation (bp 51–52 °C/0.1 mmHg) to yield **1** (49.9 g, 81%); δ_H(300 MHz, $CDCl_3$) 1.11 (s, TIPS protons); δ_C(75 MHz, $CDCl_3$) 100.61 (t, $^1J_{CF}$ 290), 97.16 (t, $^2J_{CF}$ 36.5), 95.1 (t, $^3J_{CF}$ 4.7), 18.01, 11.28; δ_F −32.60 (s, 2F); *m/z* (GC-MS) 312 (M^+ + 1, 4), 310 (M^+ − 1, 4), 269 (14), 267 (14), 143 (27), 77 (100) (calc. for $C_{12}H_{21}SiF_2Br$: C, 46.33; H, 6.75. Found: C, 46.91; H, 6.83%). The triisopropylsilylacetylene starting material, purchased from GFS Co., contained diisopropylpropenylsilylacetylene (11%) and diisopropylpropylsilylacetylene (14%). Fractional distillation did not remove these impurities. The GC-MS analysis of **1** shows all three components were alkylated and their ratios perfectly match that of the starting material. The calculated C% and H% were based on the formula of triisopropylsilyldifluorobromopropyne. If the two impurities are removed from the calculation, the values found for C% and H% are 46.84 and 6.67%, respectively.

A curiously short carbon–carbon double bond?

Jack D. Dunitz

Organic Chemistry Laboratory, Swiss Federal Institute of Technology, ETH-Zentrum, CH-8092 Zurich, Switzerland. E-mail: dunitz@org.chem.ethz.ch

Received (in Corvallis, OR, USA) 20th September 1999, Accepted 9th November 1999

The discrepancy between the 'curiously short' carbon–carbon double bond distance in 3-ethynylcyclopropene, as measured experimentally by X-ray analysis [1.255(2) Å], compared with the value derived from high level *ab initio* calculations (*ca.* 1.28 Å), is largely due to neglect of corrections for molecular motion in the crystal.

The carbon–carbon double bond length in 3-ethynylcyclopropene has been described as 'curiously short' because the value 1.255(2) Å estimated from a low-temperature (120 K) X-ray crystallographic study was 'the shortest C=C double bond known in any hydrocarbon' and markedly shorter than that obtained from high-level theoretical calculations, *ca.* 1.28 Å.[1] On the basis of further, more extensive calculations, Wesolowski *et al.*[2] confirmed the validity of the discrepancy, obtaining values between 1.269 and 1.323 Å for the double bond length at different levels of theory. This apparent discordance between computational theory and experimental measurement has attracted considerable attention[3] but it probably has a simple explanation.

In 1956 Cruickshank[4] noted that rotational oscillations of molecules in crystals cause the apparent atomic positions to be slightly displaced from the true positions towards the rotation axis. This is because X-ray analysis locates the centroids of atomic distributions that are undergoing vibrations, and separations computed from these positions cannot be interpreted directly as interatomic distances.[5] Crystal structure analysis provides not only mean atomic positions but also anisotropic displacement parameters (ADPs or U_{ij} tensor components) from which principal axes and eigenvalues of the molecular libration tensor $\boldsymbol{L}$ and of the translation tensor $\boldsymbol{T}$ can be estimated together with components of a tensor $\boldsymbol{S}$ that allows for the quadratic correlation between librational and translational motion.[6,7] From the principal axis directions and mean-square librational amplitudes (eigenvectors and eigenvalues of $\boldsymbol{L}$) approximate corrections for the shrinkage effect of the librational motion can be applied. Such corrections can easily amount to 0.025 Å.[4] In the work described in ref. 1 these corrections were not applied.

There is a problem. The ***TLS*** analysis can be applied only to the ADPs of the heavy atoms, here carbon. Because of the low X-ray scattering power of hydrogen atoms, their motions are usually approximated by isotropic displacement parameters and their contributions to the ***TLS*** analysis need to be omitted. If the five carbon atoms in the C_5H_4 molecule were exactly coplanar, the least-squares fitting of the experimental U_{ij} tensor components to the components of $\boldsymbol{L}$ would lead to a singular matrix. Indeed, the five atoms are not coplanar, but the maximum deviation from the best plane is only 0.58 Å. Moreover, as Professor H. B. Bürgi has informed us, a singular matrix also results from the condition that the atoms in the molecule lie on two mutually perpendicular lines,[8] a condition that is closely satisfied in the carbon skeleton of the C_5H_4 molecule. In addition, with only $5 \times 6 = 30$ 'observables' to be fitted to 20 tensor components, any estimate of $\boldsymbol{L}$ and hence of the shrinkage corrections must necessarily be imprecise. Nevertheless, in keeping with the low melting point (179 K), the U_{ij} values obtained in the X-ray analysis at 120 K[9] are comparable to those obtained in many room temperature analyses and are indicative of possibly large librational motions of the molecules.

Analysis of the experimental ADPs of 3-ethynylcyclopropene with the computer program THMA[10] leads to a mean-square librational amplitude of 150 deg^2 about an axis nearly orthogonal (71°) to the double bond. The resulting correction to the double bond distance is +0.022 Å, leading to a corrected bond distance of 1.278 Å, much closer to the theoretical estimates. Because of problems mentioned above, the ***TLS*** analysis cannot be expected to yield an accurate correction for the effect of molecular libration. Indeed, correlation coefficients among tensor components are close to unity, in accord with the expected near singularity in the least-squares matrix. However, even if the values of $\boldsymbol{T}$, $\boldsymbol{L}$ and $\boldsymbol{S}$ given by the analysis are not uniquely determined, they represent a possible assignment among the various molecular motions that fits the experimental U_{ij} values and is also physically reasonable. Thus, the THMA analysis indicates that neglect of thermal motion is the main source of the discrepancy between the X-ray distance and the theoretical estimates.[11]

It cannot be stressed too strongly that molecular dimensions obtained by X-ray crystal structure analysis in general may be considerably in error unless corrected for the effect of molecular libration. This is apart from and in addition to any error introduced because of the inadequacy of the free-atom scattering factors for low-order reflections.

I am grateful to Professor Roland Boese for kindly providing the atomic coordinates and U_{ij} values, and for his continued interest, and to Dr W. Bernd Schweizer for running the THMA program.

9 We thank Professor Roland Boese for kindly making these available to us.
10 A FORTRAN program by the late Professor K. N. Trueblood for analysis of ADPs; available from Dr W. B. Schweizer, Organic Chemistry Laboratory, ETH-Zentrum, 8092 Zurich, Switzerland (schweizer@org.chem.ethz.ch) or Professor E. M. Maverick, Chemistry Department, UCLA, Los Angeles CA 90024, USA (maverick@chem.ucla.edu).
11 The ***TLS*** analysis leads to positive corrections to all the carbon–carbon bond distances in the molecule. Indeed, on the basis of Fig. 1 of ref. 2, the uncorrected experimental bond lengths all tend to be shorter than the best theoretical estimates.

Design, synthesis and self-association behavior of water soluble self complementary facial amphiphiles

Lyle Isaacs,*[a] Dariusz Witt[b]† and James C. Fettinger[a]

[a] *Department of Chemistry and Biochemistry, University of Maryland, College Park, MD 20742, USA. E-mail: li8@umail.umd.edu*

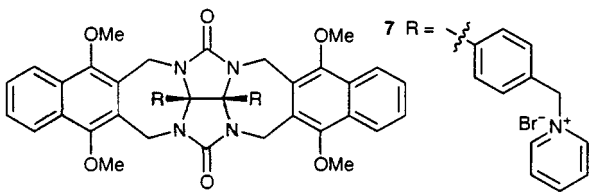
[b] *Chemical Faculty, Technical University of Gdansk, Narutowicza St. 11/12, 80-952 Gdansk, Poland*

Received (in Corvallis, OR, USA) 14th September 1999, Accepted 30th October 1999

Self-complementary facially amphiphilic derivatives of glycoluril are useful building blocks for hydrophobic self-assembly in water; we describe the design, synthesis and characterization of six dimeric self-assembled structures with values of K_S up to 1840 M^{-1} in pD 7.4 buffered D_2O.

Nature employs the hydrophobically driven self-assembly of amphiphilic molecules such as phospholipids, polypeptides and oligonucleotides to form functional structures like cell membranes, α-helical coiled coils that regulate transcription, DNA and viral capsids.[1] Ultimately, chemists would like to prepare synthetic structures that are as structurally and functionally complex as these natural systems. In efforts toward this goal some chemists have focused on the preparation of amphiphiles with novel geometries and studied their aggregation behavior in water.[2] Others are trying to deduce the rules governing the use of highly directional interactions like hydrogen bonds and metal–ligand interactions in non-polar solvents ($CHCl_3$).[3] The use of the hydrophobic effect to form designed self-assembled structures in water has received less attention.‡ Here we describe our initial efforts toward the use of self-complementary facial amphiphiles **1**–**6** as building blocks for self-assembly in water. Our goal is to develop the hydrophobic effect as a strong, directional, and predictable non-covalent interaction in water much as hydrogen bonds are now used routinely in chloroform.

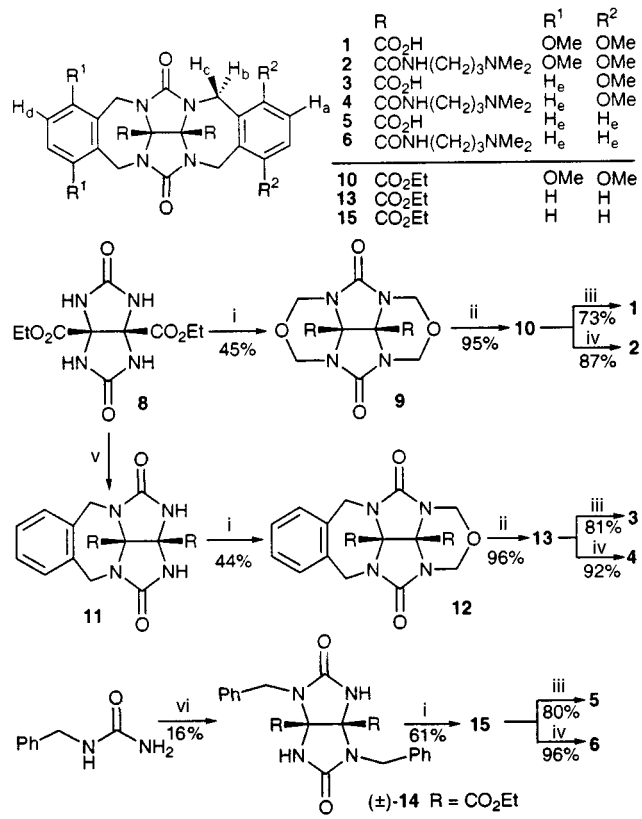
Our design of **1**–**6** was based on the observation of Nolte that water soluble glycoluril derivative **7** aggregated in water to give cigar shaped aggregates with dimensions on the order of 1 μM. This result was attributed to the interaction of the water solubilizing groups with the hydrophobic cavity of another molecule of **7**.[4] We reasoned that if we replaced the hydrophobic aromatic solubilizing groups with strictly hydrophilic carboxylate groups, we would be able to eliminate their secondary hydrophobic interactions and form well-defined dimeric structures. We decided, therefore, to use derivatives of glycoluril as building blocks for our studies since: (i) well-established synthetic precedents were available, (ii) we could impart solubility in neutral water by attaching carboxylates or ammonium groups to the convex face of the molecule, and (iii) the glycoluril subunits lead to curvature that creates a cleft-like geometry that allows dimerization.[5,6]



Scheme 1 outlines the synthetic procedures used to prepare **1**—**6**.[4–6]§ The self-complementary facial amphiphiles **1**–**6** all have good solubility in pD 7.4 buffered D_2O (> 5 mM). We synthesized **1** and **2** to allow us to test the influence of the charge on the convex face of the molecule on its self-association constant (K_S). Compounds **3**–**6** were synthesized in order to assess the influence of methoxy substituents on K_S and to investigate possible orientational preferences in **3**·**3** and **4**·**4**.

We obtained single crystals of **15** by slow evaporation of a benzene solution. Fig. 1 shows an ORTEP plot of the structure of **15** in the crystal.¶ The important features of this structure are: (i) the disposition of the ethyl ester groups on a single face of the molecule (facially amphiphilic), (ii) the formation of a hydrophobic cleft, at least in the solid state, due to the *anti* conformation of the xylylene units with respect to the ethoxycarbonyl substituents on the convex face,[7] and (iii) the distance between the centers of the phenyl rings of 6.35 Å is suitable for the complexation of an aromatic ring. The solvating benzene ring partially fills the cleft of **15** by interacting with the xylylene wall in an edge-to-face type manner (Fig. 1).

We performed dilution experiments to investigate the self-association behavior of **1**–**6**[8] In these experiments, ^1H NMR spectra were obtained at a series of concentrations and changes



Scheme 1 *Reagents and conditions*: i, TFA, $(CH_2O)_n$, reflux; ii, TFA, Ac_2O, $C_6H_4(OMe)_2$, reflux; iii, MeOH, H_2O, LiOH, 60–65 °C; iv, $H_2N(CH_2)_3NMe_2$, 70–90 °C; v, DMSO, Bu^tOK, $C_6H_4(CH_2Cl)_2$; vi, PhH, TFA, $(EtO_2CCO)_2$, reflux.

† On sabbatical leave from the Technical University of Gdansk.

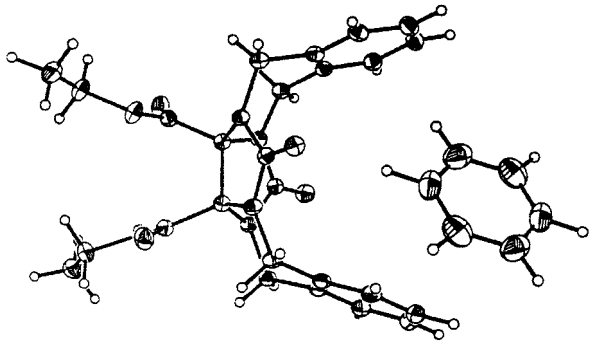


Fig. 1 Crystal structure of **15**·$(C_6H_6)_{0.25}$ with 30% probability ellipsoids.

that occurred in the chemical shifts of the different protons were monitored. The shifts in the ^{1}H NMR resonances were then fitted to the theoretical equation governing self-association of two molecules.[8]‖ For example, when the concentration of **2** is 0.2 mM, the resonance for H_a (Scheme 1) is broadened and appears at δ 6.45, which is close to the chemical shift observed for this proton in $CDCl_3$ (δ 6.73). At a concentration of 5 mM, H_a resonates at δ 5.78, indicating more extensive dimerization at that concentration. The upfield direction of this shift suggests that the H_a protons are proximal to an aromatic ring in the complex. In these experiments, we observe a single broadened resonance for each set of protons in the monomer and the dimer. This observation indicates that the monomer and dimer are in the fast exchange regime on the NMR time scale.

Table 1 summarizes the results of our studies. The values of K_S reported are the results of duplicate dilution experiments at a series of at least seven different concentrations and are averaged over all of the protons undergoing significant complexation induced shifts (> 0.1 ppm). Evaluation of each of these different protons gave similar values of K_S. Based on the values of K_S and $\Delta\delta$ we are able to draw the following conclusions. First, in all three cases—compare **1** with **2**, **3** with **4**, and **5** with **6**—the carboxylic acid and the amine derivatives have approximately equal self-association constants. This result indicates that the charged groups on the convex face of the amphiphile are merely solubilizing groups and do not alter the dimerization process. Second, compounds with greater numbers of methoxy substituents have higher self-association constants. Compounds **5** and **6** undergo no concentration dependant changes in chemical shift up to 5 mM, indicating that self-association does not occur at these concentrations. We rationalize the differences in K_S by the increase in the amount of hydrophobic surface area in **1** and **2**.[9] Third, we suggest that dimers **3**·**3** and **4**·**4** are oriented such that each dimethoxyphenyl ring is complexed in the cavity of the second molecule. We base this suggestion** on the higher values of $\Delta\delta$ for H_a and lower values of $\Delta\delta$ for H_d or **3** and **4** when compared to the $\Delta\delta$ for H_a of **1** and **2** (Table 1). Those protons that are complexed within the hydrophobic cavity experience the anisotropic effect of two phenyl rings, whereas those that are on the outside of the cavity only feel the effect of one phenyl ring. This type of selectivity could allow the orientation of several components in larger self-assembled structures.

We have shown that facially amphiphilic derivatives of glycoluril containing water solubilizing carboxylate or ammonium groups can be used as a platform for the study of hydrophobic self-assembly in water. Self-complementary facial amphiphiles **1**–**4** self-associate in aqueous solution to give dimers. The self-association constant and the orientation of the molecules in the dimeric complex are influenced by the number of methoxy groups in the monomer. Ongoing investigations are directed toward the design and synthesis of compounds with more solubilizing groups and larger amounts of hydrophobic surface area that dimerize with higher values of K_S and reduced exchange rates, as well as the covalent connection of several molecules of **6** to allow for self-assembly rather than simple dimerization.

Table 1 Thermodynamic data and induced chemical shift changes for the self-association of **1**–**6**

Compound	K_S[a]/M^{-1}	$\Delta\delta$[b] H_a	H_d	H_e	$\Delta G°$/ kcal mol^{-1}
1	1840	1.22	[c]		−4.5
2	1530	1.41	[c]		−4.3
3	140	1.48	0.61	0.12	−2.9
4	130	1.79	0.73	0.37	−2.9
5	[d]	[d]	[cd]	[d]	[d]
6	[d]	[d]	[cd]	[d]	[d]

[a] The error in the determination of K_S is ≈15%; the corresponding error in $\Delta G°$ is ≈0.1 kcal mol^{-1}. All dilution experiments were performed in 100 mM phosphate buffered D_2O (pD = 7.4) at 25 °C. [b] Based on the calculated values of the chemical shift for the dimer and the monomer. [c] H_a and H_d are symmetry equivalent. [d] The observed changes in chemical shift up to 5 mM are negligible.

We thank the University of Maryland and the donors of the Petroleum Research Fund (PRF 33946-G4) for financial support of this work.

Received (in Liverpool, UK) 14th October 1999, Accepted 8th November 1999

A novel, recyclable polymer-supported amine *N*-oxide has been prepared and shown to be a good promoter of the Pauson–Khand reaction under mild conditions, affording good to excellent yields of cyclopentenones.

The field of solid phase chemistry, as applied to organic synthesis, has grown exponentially in recent years.[1] Immobilising either reagents or substrates on a polymeric support provides two complementary methods which both offer significant advantages over traditional solution phase methods. The use of polymer supported reagents[2] affords a clean approach to solution phase chemistry, whereby a reagent may be removed by filtration, aiding facile product purification. Alternatively, by establishing the substrate molecule on solid phase, excess reagents may be used to drive the reaction to completion, with the work-up procedures remaining as simple washing and filtration steps. Furthermore, this approach is highly compatible with the preparation of combinatorial libraries.

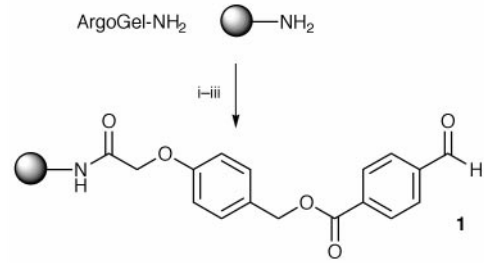
In recent years, the preparation of libraries of small organic molecules on solid phase has emerged as a powerful strategy in the drug discovery process.[3] However, these combinatorial methods are not only limited to drug discovery; recently they have also been applied to the discovery of novel compounds for a variety of purposes, most notably in the search for new asymmetric catalysts and reagents.[4] In this regard, based on our drive to further develop our chiral *N*-oxide mediated asymmetric versions[5] of the Pauson–Khand (P–K) reaction,[6] we envisioned that preparing an amine *N*-oxide on solid phase would provide a convenient polymer-supported promoter for this cobalt-mediated annulation process. More importantly, a controlled and adaptable synthetic strategy, which allowed for the incorporation of functional diversity, would also permit the preparation of libraries of chiral amine *N*-oxides. In turn, these mild oxidants could be used to further refine our methodology for inducing asymmetry in the P–K cyclisation process. Herein, we report our initial studies in this area, specifically, the preparation of an amine *N*-oxide on solid phase, and demonstrate the efficiency of this species as the first such supported promoter of the P–K reaction.

To initiate our studies, we needed to develop a flexible synthesis of solid supported tertiary amines and the corresponding *N*-oxides. We chose to generate tertiary amines *via* reductive amination of solid supported aldehydes which are, in turn, attached to the support *via* an acid labile, carboxylic acid releasing linker. Thus, ArgoGel-NH_2[7] was functionalised with the hydroxymethylphenoxyacetic acid linker in a two step process, followed by attachment of 4-formylbenzoic acid to the linker *via* standard esterification conditions (Scheme 1) to give **1**.

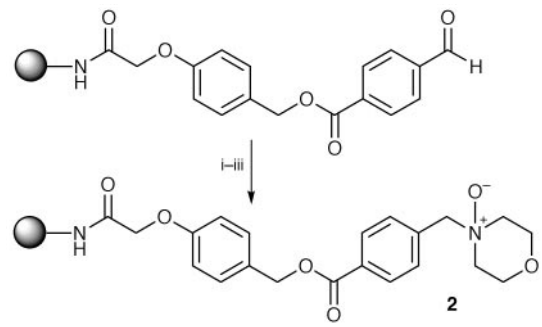
The supported aldehyde **1** was then aminated with morpholine, catalysed by acetic acid, and the intermediate reduced with acetoxyborohydride to give the tertiary amine (Scheme 2). At this stage, following TFA cleavage from the support, the amine product was analysed by NMR; clean reductive amination had occurred under the reaction conditions shown. It should also be noted that, in the initial amination stage, the use of less equivalents of amine, more acid, or shorter reaction times all ultimately led to large quantities of by-products derived from carbonyl reduction.

The supported amine was then oxidised using the *N*-sulfonyl oxaziridine reported by Davis,[8] cleanly furnishing the desired *N*-oxide **2** (Scheme 2). Following cleavage of the *N*-oxide from a known amount of resin the overall yield for this five step process was calculated† to be 51%.‡

Having established a flexible approach to the solid phase *N*-oxide **2**, its use as a promoter in the P–K reaction was then evaluated by reacting a series of cobalt complexes with norbornene. To our delight, all reactions were complete in under 30 min at room temperature, cleanly affording cyclopentenones **3** in good to excellent yields (Table 1).§ Additionally, a significant practical advantage over the more traditional P–K protocols was found in that, on reaction work-up, the oxidised cobalt residues remained bound to the resin, allowing the cyclopentenone products to be isolated in > 95% purity simply by filtration and removal of the solvent *in vacuo*. In due course, a variety of alkene substrates were also examined. These reactions also proceeded rapidly and in good yield (Table 2) with even the normally less reactive alkenes, 2,5-dihydrofuran

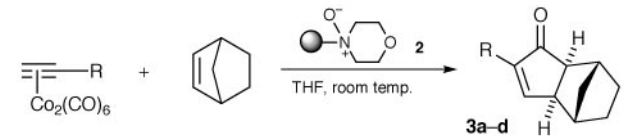


Scheme 1 *Reagents and conditions*: i, 4-formylphenoxyacetic acid, HATU, Pr^i_2NEt, DMF, room temp., 2 h; ii, Bu_4NBH_4, CH_2Cl_2, room temp., 16 h; iii, 4-formylbenzoic acid, diisopropylcarbodiimide, DMAP, DMF, room temp., 16 h.



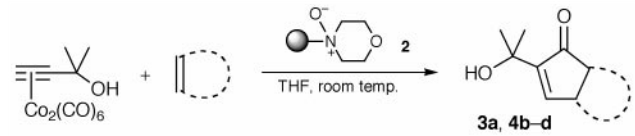
Scheme 2 *Reagents and conditions*: i, morpholine (10 equiv.), AcOH (1 equiv.), CH_2Cl_2, room temp., 7 h; ii, Bu_4NBH_4 (10 equiv.), AcOH (20 equiv.), CH_2Cl_2, room temp., 16 h; iii, *N*-(phenylsulfonyl)phenyloxaziridine (4 equiv.), CH_2Cl_2, room temp., 3 h.

Table 1 Solid phase *N*-oxide promoted P-K reactions



R	*t*/min	Product	Yield (%)
$Me_2(OH)C$	30	**3a**	91
Ph	15	**3b**	99
Me_3Si	15	**3c**	59
Bu^t	30	**3d**	74

Table 2 P–K reactions with a selection of alkenes



Alkene	*t*/min	Product	Yield (%)
Norbornene	30	**3a**	91
Norbornadiene	30	**4b**	95
2,5-Dihydrofuran	30	**4c**	79
Cyclopentene	30	**4d**	51

and cyclopentene, efficiently affording the desired products **4c** and **4d.**¶

In all cases, the bound cobalt residues could be subsequently removed from the resin by washing with a 2:1 mixture of THF and 1 M HCl, the amine then being regenerated from its hydrochloride salt by washing with a 10% solution of Pr^i_2NEt in DMF. This facile recovery of the amine opens up the possibility for recycling the polymer supported *N*-oxide by simply re-treating the resin with the Davis reagent. Indeed, this was shown to be the case. As illustrated by the reaction between the dimethylpropargyl alcohol complex and norbornene with recycled supported *N*-oxide **2**, the excellent yield and short reaction time is maintained through five cycles, demonstrating the durability of the tethered amine (Table 3).

In conclusion, we have achieved the synthesis of an amine *N*-oxide on solid phase and found it to be a highly efficient and re-usable promoter of the Pauson–Khand reaction, affording cyclopentenones in high purity without the need for column chromatography. Furthermore, due to the nature of the synthetic route, this methodology allows for a diverse set of *N*-oxides to be leveraged on solid phase. The application of this methodology to the preparation of a library of chiral *N*-oxides and the use of other resins, to allow higher loading for the polymer supported reagent, is currently under investigation and will be reported in due course.

We thank Glaxo Wellcome and the EPSRC for generous support (Industrial CASE Award, D. M. L.). We also thank the

Notes and references

† The cleaved *N*-oxide was analysed by ^{1}H NMR using *p*-nitrophenol as an internal standard.

‡ To the best of our knowledge, only one other polymeric *N*-oxide, poly(vinylpyridine *N*-oxide), has been described. Besides practical concerns, this material has the disadvantage of being less adaptable and, in turn, less utilisable as a basis for the generation of a library of supported *N*-oxides (ref. 9).

§ Representative experimental procedure: Amine *N*-oxide resin **2** (1.12 g, 0.447 mmol) was swelled in THF (15 ml) for 10 min. Norbornene (35 mg, 0.372 mmol) and hexacarbonyl(2-methylbut-3-yn-2-ol)dicobalt (24.3 mg, 0.066 mmol) were added sequentially and the reaction shaken at room temperature for 30 min. The solvent was drained and the resin washed with THF (10 × 2 ml) and CH_2Cl_2 (10 × 2 ml). The combined filtrates were then evaporated *in vacuo* to afford **3a** as a white crystalline solid (12.3 mg, 91% yield). The product was >95% pure as indicated by ^{1}H NMR analysis.

¶ Cyclopentenones **4c** and **4d** required purification by column chromatography.
