
Flovent™), the anti-inflammatory action of FP treats the underlying inflammatory component of asthma. FP also has an indication in an intra-nasal form for rhinitis, where it is marketed under the trademark‡ Flixonase™. It has a superior therapeutic index to beclomethasone dipropionate (BDP).

FP is known to exist in two polymorphic forms. Form 1 can be obtained by crystallization from a variety of solvents (typically acetone), and the crystal structure of form 1 has been determined previously[1] from single crystal X-ray diffraction (and also confirmed as part of our current research by structure determination from powder diffraction data using the techniques discussed below). In attempts to produce crystals of FP of controlled size and morphology for pharmaceutical applications, crystallization in a supercritical fluid medium (with EtOH or acetone as solvent) was carried out, and was found to yield a new polymorph (form 2). As form 2 was obtained only by the supercritical crystallization method, yielding polycrystalline powder samples, structural characterization of form 2 could not be carried out by single crystal X-ray diffraction. Here we report the determination of the crystal structure of form 2 of FP directly from powder X-ray diffraction data.

Although traditional techniques[2–4] for structure solution from powder diffraction data have been applied successfully in several cases, these techniques have certain intrinsic limitations[3] and organic molecular crystals represent a particularly challenging case. For this reason, there has been much recent interest in the development of new methods for solving crystal structures directly from powder diffraction data, leading *inter alia* to a new generation of 'direct-space' approaches that are particularly suited for molecular crystals. The direct-space strategy[5,6,3] is based on sampling trial crystal structures in direct space, with the 'quality' of each trial structure assessed by comparing the powder diffraction pattern calculated for the trial structure and the experimental powder diffraction pattern. In our work, this comparison is made using the profile *R*-factor R_{wp},[3,5] which considers the whole digitized intensity profile and thus implicitly takes care of peak overlap. In effect, the structure solution process involves searching a hypersurface $R_{wp}(\mathbf{X})$ to find the best structure solution (lowest R_{wp}), where $\{\mathbf{X}\}$ represents the variables that define the trial structures. In the case of one molecule in the asymmetric unit, the variables in $\{\mathbf{X}\}$ represent the position $\{x, y, z\}$, orientation $\{\theta, \phi, \psi\}$ and intramolecular geometry (specified by variable torsion angles $\{\tau_1, \tau_2, \ldots \tau_n\}$) of the molecule. In general, the bond lengths and bond angles (and any known torsion angles) are fixed in the calculation, and are taken either from standard values for the type of molecule under study or from the known geometries of similar molecules. Methods used to search *R*-factor hypersurfaces to locate the global minimum (structure solution) within direct-space structure solution strategies have included Monte Carlo,[5,7,8] simulated annealing[6,9,10] and Genetic Algorithm (GA)[11–15] techniques. Here we focus on the application of our GA method, details of which are described in ref. 12. In this approach, a population of trial structures is allowed to evolve subject to the normal rules and operations (mating, mutation and natural selection) that govern evolutionary systems.

The powder X-ray diffraction pattern of form 2 of FP was recorded at 22 °C in transmission mode on a Siemens D5000 diffractometer, using Ge-monochromated Cu-Kα_1 radiation and a linear position-sensitive detector covering 8° in 2θ. The total 2θ range was 5° to 60°, measured over 12 h in steps of 0.02°. The powder X-ray diffraction pattern was indexed by the program ITO.[16] [The lattice parameters following Rietveld refinement (see below) are: a = 23.2434(9), b = 13.9783(5), c = 7.6510(3) Å.] Systematic absences are consistent with space group $P2_12_12_1$, and density considerations suggest that there is one molecule in the asymmetric units.§

In the GA structure solution calculation (using the program GAPSS,[17,12]), all non-hydrogen atoms of the FP molecule were used (to define the asymmetric unit). The tetracyclic ring system

† Fractional coordinates for the non-hydrogen atoms in the final crystal structure of form 2 of FP are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1677/

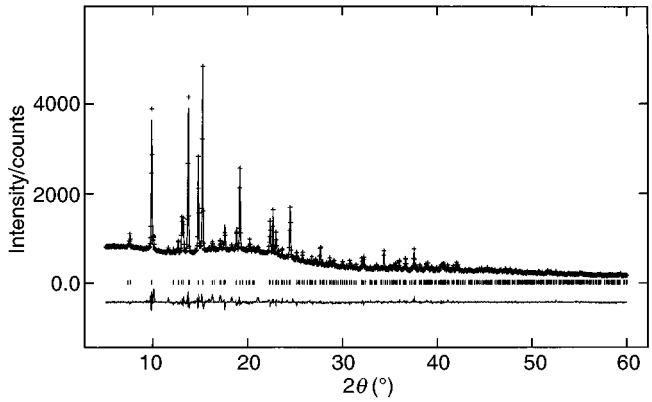

Fig. 1 Experimental (+), calculated (solid line) and difference (lower line) powder X-ray diffraction profiles for the Rietveld refinement of form 2 of FP. Reflection positions are marked. The calculated powder diffraction profile is for the final refined crystal structure, details of which are given in the supplementary material. See note †.

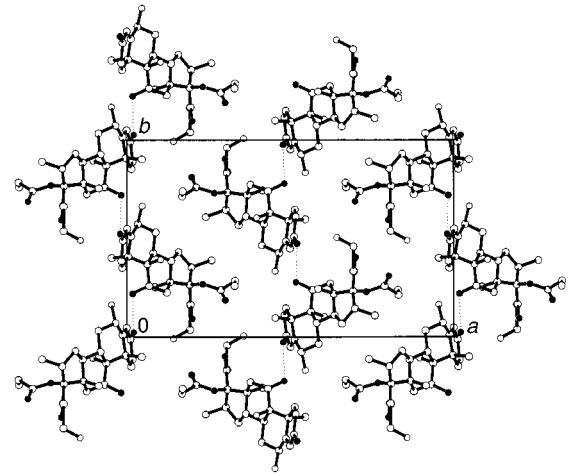

Fig. 2 Final refined crystal structure of form 2 of FP (hydrogen atoms not shown) viewed along the *c*-axis. Dashed lines indicate hydrogen bonding interactions.

was considered as a rigid unit, comprising one planar six-membered ring (designated A), two six-membered rings in chair conformation (B and C), and a five-membered ring in an envelope conformation (D). The side-groups attached to the D ring were considered as flexible units, with their conformations defined by six variable torsion angles. Thus, the GA calculation involved 12 degrees of freedom $\{x, y, z, \theta, \phi, \psi, \tau_1, \tau_2, \ldots \tau_6\}$. Bond lengths and angles were taken from known structures of other steroid molecules and from other information on standard molecular geometries.[18] The GA calculation involved the evolution of 60 generations of a population of 100 structures. In each generation, 200 offspring (involving 100 pairs of parents) and 10 mutations were considered. For mating and mutation, each of the 12 variables was considered as an independent gene. In carrying out a given mating operation between two parents to generate two offspring, the 12 variables from each parent were combined and distributed between the two offspring, with no restriction on the combination of variables allowed to pass from a given parent to a given offspring. In carrying out the mutation procedure on a selected structure, six variables were selected at random, and a new random value was assigned to each of the selected variables.

The best structure solution (lowest R_{wp} in the final generation) was taken as the starting structural model for Rietveld refinement using the GSAS program package.[19] The positions of all non-hydrogen atoms were refined, with standard geometric restraints applied to bond lengths and angles. A common isotropic displacement parameter was refined (final U_{iso} = 0.050 Å^2), and in the final stages a preferred orientation parameter was refined. The final Rietveld refinement (Fig. 1; Table 1) gave R_{wp} = 4.8% and R_p = 3.3%.

In the crystal structure of form 2 of FP (Fig. 2), the molecules form stacks along the *c*-axis with adjacent molecules related by translation. Zig-zag chains of molecules related by the 2_1 screw operation along the *b*-axis are linked by C–O–H···O=C hydrogen bonds involving the hydroxy group (C ring) and carbonyl group (A ring) of adjacent molecules (O···O, 2.8 Å; C–O···O, 110°). This structure provides interesting similarities and contrasts with the structure of form 1 of FP.[1] Both structures contain similar hydrogen-bonded chains (described above along the *b*-axis in form 2), but differ in the structural relationship between adjacent chains of this type; in form 2, adjacent chains are anti-parallel (related by a 2_1 axis), whereas in form 1, adjacent chains are parallel to each other (related by translation).

It is clear that knowledge of the structure of form 2 of FP provides a basis for understanding differences in the properties of forms 1 and 2, including those relating to pharmaceutical applications of these materials. This opportunity has arisen through the present-day ability to solve molecular crystal structures of moderate complexity directly from powder diffraction data.

We are grateful to Glaxo Wellcome plc and the EPSRC for financial support.

Received (in Oxford, UK) 14th June 1999, Accepted 23rd July 1999

The use of complexing agents to generate polynuclear precursor species containing both Al and Si allows the synthesis of thermally stable mesoporous aluminosilicates including solely tetrahedrally coordinated aluminium, in which the Si/Al ratio can be modulated down to a minimum Si/Al value of 1.06(4).

A great part of fine chemicals production is dependent on high surface Al–Si mixed oxides or zeolites which act as catalysts or serve as catalyst supports.[1–3] After the discovery of silica-based MCM-41 mesoporous derivatives,[4] a key scientific objective has been the attainment of increasing content of tetrahedral Al in the framework of materials of this type to achieve higher Brønsted acidity and thus improved catalytic activity. Different direct surfactant-assisted synthetic procedures related to that of MCM-41[5–8] or, alternatively, post-synthesis reactions[9] have been explored with this aim. Indeed, the use as principal reagent of $Al_4Si_4(OH)_8O_{12}^{4-}$ cube-like molecular polyanions (*i.e.* by incorporating the optimal Si/Al = 1 molar ratio into the precursor) led to a mesostructured material with high Al content.[5] Unfortunately, surfactant removal led to a collapse of the pore system together with partial conversion of tetrahedral Al centers into octahedral ones. In general, the best results have been obtained by reproducing the MCM-41 synthesis in the presence of an Al source. As far as we know, stable mesoporous solids prepared through surfactant-assisted procedures having the largest contents of tetrahedral Al are those reported by Luan *et al.*[6] (Si/Al = 2.5) and Borarde and Clearfield[7] (Si/Al = 2), who used $Al_2(SO_4)_3$ and $NaAlO_2$, respectively. This notwithstanding, as stated by Hamdan *et al.*,[8] the outcome of direct synthesis of Al containing MCM-41 depends strongly on the nature of the Al source used, which often leads to irreproducible results.

We report here a new direct and reproducible procedure that provides thermally stable mesoporous aluminosilicate molecular sieves in which the Al content in the framework can be modulated down to a minimum Si/Al value of 1.06(4), very close to the ideal molar ratio of 1 (compatible with the presence of mainly tetrahedrally coordinated Al centers).[10]

Aluminium rich mesoporous materials of the MCM-41 type have been synthesized using CTABr as surfactant in $TEAH_3$–water (CTABr = cetyltrimethylammonium bromide, $TEAH_3$ = triethanolamine). A typical preparation leading to the Si/Al = 1.06 mesoporous aluminosilicate can be described as follows: a mixture of TEOS (7.2 mL, 0.033 mol) and $Al(OBu^s)_3$ (8.4 mL, 0.033 mol) was added to a solution containing $TEAH_3$ (30 mL, 0.226 mol) and 1.32 g (0.03 mol) of NaOH in 2 mL of water, and heated at 190 °C for 10 min [TEOS = tetraethylorthosilicate, $Al(OBu^s)_3$ = aluminium *sec*-butoxide]. The resulting solution was cooled to 50 °C, and CTABr (6.5 g, 0.018 mol) in 180 mL of water was added while stirring. The mixture was allowed to age for 5 days at room temperature, resulting in the formation of a white solid. This was then filtered off washed with ethanol and air dried. To obtain the final mesoporous material, the as-synthesized solid, which is mesostructured, was calcined at 500 °C for 5 h under air to eliminate the surfactant. Table 1 summarises the main synthesis variables and physical data corresponding to some selected samples. All the samples were analyzed and characterized by electron probe microanalysis (EPMA), (Philips SEM-515 instrument), XRD techniques (Seifert 3000TT diffractometer using Cu-Kα radiation), TEM (Philips CM10 microscope), ^{29}Si and ^{27}Al MAS NMR (Varian Unity-300 spectrometer), and N_2 adsorption–desorption isotherms (Micromeritics ASAP2010 analyzer). Moreover, fast atom bombardment (FAB) analysis of the precursor solutions was been performed to gain insight into the role of $TEAH_3$.

EPMA analysis shows that all the samples are chemically homogeneous with a regular distribution of aluminium and silicon atoms throughout the inorganic walls. Hence, the solids can be considered as monophasic products. The Si/Al molar ratio in the final material is very close to that present in the mother-liquor, indicating that there is no preferential incorporation of aluminium or silicon into the final net.

XRD pattern resolution of mesoporous materials is poorer than for purely siliceous MCM-41 solids. This fact indicates a degree of loss of the typical hexagonal order observed for MCM-41 solids. Hence, the pore packing motif can be better described as disordered hexagonal, as confirmed by TEM micrographs (Fig. 1).

Previous ^{27}Al NMR results indicate that Al containing MCM-41 solids may include octahedrally coordinated aluminium atoms, with a degree of controversy about their extra- or intra-framework nature. Thus, on the basis on 2-D NMR data, Janicke *et al.*[11] have recently concluded that both four- and six-coordinate Al centers can coexist in the inorganic walls. In any case, it seems clear that Al atoms in octahedral environments do

not contribute to the Brønsted acidity. The ^{27}Al MAS NMR spectra of all mesostructured or mesoporous materials reported here show essentially only one resonance signal at δ *ca.* 55 (Fig. 2), which is characteristic of tetrahedral Al. The small signals at either side of the main signal are due to the spinning of the sample (side bands) as they move equally when changing the spinning frequency. A remarkable fact is that neither dealumination nor conversion from tetrahedral into octahedral aluminium occurs as a consequence of surfactant removal. ^{29}Si MAS NMR spectra for all samples show a very strong and broad signal whose center shifts from δ −113 for pure siliceous MCM-41 materials to δ −87.9 for sample 4 (Fig. 3) (see Table 1). In this last case, the displacement of the signal is in accordance with the resonance of Q^4 (4Al) and Q^3 (3Al) Si environments. The broadness of the signal may be a consequence of resonances of other minor Si environments such as Q^4 (3Al) and other Q^3 sites, similarly to results reported in ref. 5. Thus, both ^{27}Al and ^{29}Si MAS NMR results are in good accordance with the Si/Al = 1.06 molar ratio calculated from EPMA analysis.

All samples show one well defined step in their N_2 adsorption isotherms. According to previous observations, incorporation of Al leads to significant decreases in BET surface area and pore size (Table 1). Despite this, the high surface area, porosity and thermal stability characteristic of the parent mesoporous silicas, are retained even for the highest Al content [Si/Al = 1.06(4)]. An estimation of the pore wall dimensions can be made from XRD and porosity data. As shown in Table 1, the pore wall thickness increases (17.7–28.3 Å) with Al content and probably leads to the materials' high thermal stability.

A preliminary mass-spectral analysis (FAB) carried out on TEOS–Al(OBu^s)$_3$–TEAH$_3$ mixtures, prior to surfactant addition, indicates the presence of entities of different nuclearity in which triethanolamine must displace the initial alkoxide anions from the metallic coordination spheres and give rise to more hydrolysis stable complexes when water is added [TEAH$_{3-n}$-(TEASi)$_n$ (n = 1–3); Al(TEA)]. Although MS FAB analysis cannot differentiate between Si and Al in polynuclear species, taking into account the similar affinity of both Si and Al towards coordination of TEA,[12] mixed molecular precusor species can be envisaged, *e.g.* Si$_{3-n}$Al$_n$ (TEA)$_{4-n}$(TEAH)$_n$ (n = 1,2) This fact indicates that Al and Si are essentially mixed to a nearly atomic level in the precursor solution, and explains the high chemical homogeneity observed both in the mesostructured and in the final mesoporous solids.

In summary, this work demonstrates that it is possible to increase, in a continuous way, the Al content in MCM-41-like mesoporous materials up to virtually a 1/1 Si/Al molar ratio, the maximum possible for an aluminosilicate without formation of Al–O–Al links. Taking into account the ready formation of stable monomeric and polynuclear species, the role played by triethanolamine can be viewed as a 'hydrolysis retarding agent' for both Si and Al. This allows a balance between the hydrolysis and condensation reactions affecting the inorganic species and the self-assembling processes between the resulting inorganic fragments and the organic surfactant. Moreover, by leading to an intimate mixture of Al and Si in the mother-liquor, the presence of triethanolamine favours chemical homogeneity and hence the thermal stability of the resulting materials. In this context, complexing agents such as triethanolamine appear invaluable and highly promising tools for the preparation of new mesoporous materials.

Received (in Oxford, UK) 27th May 1999, Accepted 26th July 1999

Curve fitting analysis of Al K-edge XANES is employed as a novel characterization method for the quantitative estimation of tetrahedral and octahedral Al in various aluminas.

Transition aluminas, such as γ-Al_2O_3, formed by partial dehydration of aluminium hydrates have been of catalytic importance.[1] It is well established that the catalytic property of aluminas depends strongly on their local structure.[1] However, because of their poor crystallinity, accurate structures of the transition aluminas are not known except for θ-Al_2O_3, in which Al atoms are equally distributed between tetrahedral and octahedral sites of the spinel.[2] ^{27}Al MAS NMR can be used to distinguish several Al atoms with different local structures, and quantification of Al coordination has been successful for crystalline materials.[3] However, for amorphous alumina, its application to quantitative structural analysis is difficult owing to a large quadrupolar interaction.[4] A conventional tool for determining Al distribution in catalytic alumina is desirable. X-Ray absorption spectroscopy (EXAFS/XANES) is another method for investigating local structure.[5–8] In general, EXAFS is popular for quantitative structural analysis, while XANES is less so. Considering the fact that XANES can potentially reflect the local site symmetry around X-ray absorbing atoms, and that the intensity of XANES spectra is higher than EXAFS oscillations, it can be a valuable tool for quantitative analysis if a proper method of analysis is established. Recently, we have succeeded in using Ga K-edge XANES analysis for the quantification of tetrahedral/octahedral Ga atoms in gallium oxides.[7,8] In this study, Al K-edge XANES analysis is applied for the quantitative determination of tetrahedral and octahedral Al atoms in transition aluminas.

Mordenite-type aluminosilicate (JRC-Z-HM15,[9] SiO_2/Al_2O_3 = 15) containing Al atoms in the zeolite framework was supplied from the Catalysis Society of Japan. θ-Al_2O_3 was prepared by calcining γ-Al_2O_3 (JRC-ALO-4[10] supplied from the Catalysis Society of Japan) at 1273 K for 12 h. Boehmite (γ-AlO_2H) was prepared by hydrolysis of aluminium(III) triisopropoxide, followed by drying at 393 K for 12 h. A series of aluminas with various phases were prepared by calcining boehmite in air at various temperatures (673–1773 K) for 2 h. The crystal phases of these samples were confirmed by X-ray diffraction and are given in Table 1. The diffraction pattern of the alumina sample calcined at 1773 K corresponds to that of pure α-Al_2O_3 (corundum).

Al K-edge X-ray absorption spectra were measured on BL-7A at UVSOR with a ring energy of 750 MeV and a stored current of 70–220 mA in a mode of total electron yields. An YB_{66} double crystal monochromator was used, and the absolute energy scale was calibrated to a negative glitch due to the Y L_3 peak of YB_{66} at 2080.0 eV.[11] The monochromator scanning step width was 0.01°, which corresponds to *ca.* 0.3 eV at 1560 eV.

Fig. 1 shows the normalised Al K-edge XANES spectra of alumina samples together with those of model compounds containing AlO_4 tetrahedra (mordenite) and AlO_6 octahedra (corundum and boehmite). It is known in the literature that a clear distinction can be made between the XANES spectra of AlO_4 and AlO_6; a white line peak at 1566 eV is characteristic of AlO_4 compounds, while peaks at 1568 and 1572 eV are characteristic of AlO_6 compounds.[12,13] In this study, it was confirmed that a single peak at 1566 eV due to AlO_4 appeared in the spectrum of mordenite, while a peak at 1568 eV and a broad peak at *ca.* 1571–1572 eV due to AlO_6 appeared in the spectra of corundum and boehmite. In addition, the edge positions of AlO_6 compounds were *ca.* 2 eV higher than those of AlO_4 compounds. For the transition alumina samples calcined in the temperature range 673–1273 K and θ-Al_2O_3, XANES spectra exhibited three distinguishable peaks due to AlO_4 (1566 eV) and AlO_6 (1568 and 1572 eV). Clearly, the relative intensity of the 1566 and 1568 eV peaks differs from sample to sample. This observation is similar to that observed in our previous study of Ga K-edge XANES, where the relative intensity of white line peaks due to GaO_4 and GaO_6 varied with Ga distribution in the samples.

To estimate the ratio of Al atoms in tetrahedral and octahedral sites in transition aluminas, curve fitting analysis of XANES spectra[6] was carried out. Fig. 2 shows the deconvoluted spectrum of θ-Al_2O_3 as an example. Following the method in

Table 1 Parameters of deconvoluted peaks in XANES spectra of aluminium oxide

Sample (calcn. temp.[a]/K)	Crystal phase	AlO_4 tetrahedra/eV		AlO_6 octahedra/eV		Third peak/eV		AlO_4 : AlO_6 ratio[b]
		Position	Area	Position	Area	Position	Area	
θ-Al_2O_3	θ	1565.4	2.6	1567.7	2.6	1571.2	5.0	50 : 50

[a] Calcination temperature. [b] Ratio of the area of AlO_4 peak : AlO_6 peak. The analytical error is estimated to be ±4%.

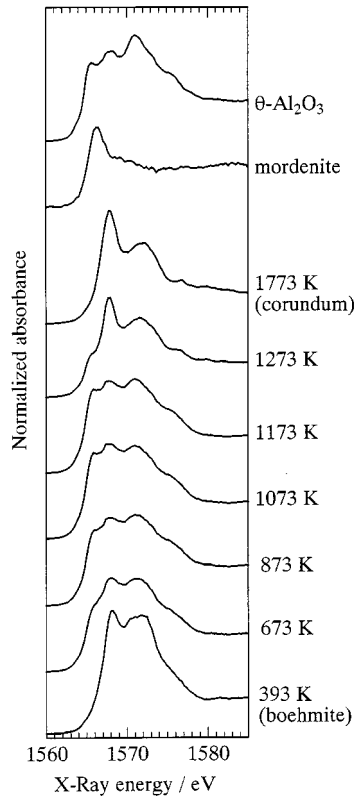

Fig. 1 Al K-edge XANES spectra of alumina samples calcined at various temperatures and of reference compounds.

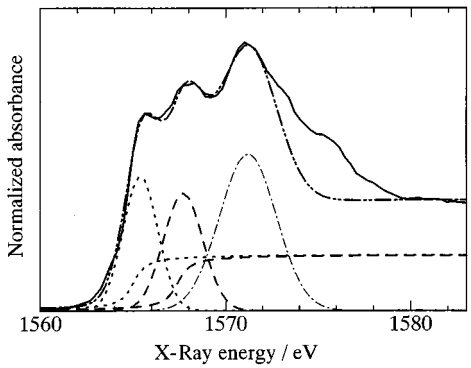

Fig. 2 Al K-edge XANES spectrum of θ-Al_2O_3 (—) and the simulated spectrum (-···-), which is composed of two sets of Gaussian and one arctangent function (dotted and broken) and a Gaussian function (-··-).

our previous study,[7,8] the analysis was performed on the assumption that absorptions due to AlO_4 (1566 eV) and AlO_6 (1568 eV) are expressed by a set of Gaussian and arctangent functions. As for the third peak (at 1572 eV), it is likely, from a comparison of the spectra of AlO_6 compounds (corundum and boehmite) that the relative intensity of the 1568 eV peak to the 1571–1572 eV peak is not constant. Considering the suggestion that this peak can include multiple scattering contributions,[14] it was not employed for the quantitative analysis in this study, and was tentatively expressed by a Gaussian function. Thus, the best parameters, *i.e.*, the exact peak energy, and the peak area of each Gaussian were determined so as to simulate the original spectra in the range 1560–1572 eV and are listed in Table 1. The positions of the first and the second Gaussian peaks were centered at 1565.5 ± 0.1 and 1567.7 ± 0.2 eV, which were almost identical to those of AlO_4 and AlO_6 model compounds, respectively, within experimental error. For θ-Al_2O_3, the ratio of the areas of the 1566 and 1568 eV peaks was determined to be 50 : 50 with an analytical error of ±4%. This value is in good agreement with that derived from X-ray diffraction analysis,[2] which suggests that the ratio of AlO_4 to AlO_6 in the samples can

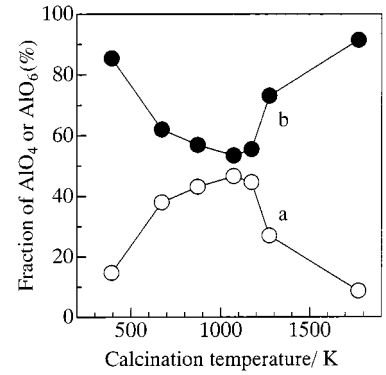

Fig. 3 Fraction of AlO_4 tetrahedra (a) and AlO_6 octahedra (b) in alumina samples as a function of calcination temperature.

be estimated quantitatively from the ratio of each Gaussian peak area.

The percentage of AlO_4 and AlO_6 was estimated by using the above method for a series of aluminas and is plotted as a function of calcination temperature (Fig. 3). The results show that the ratio of AlO_4 to AlO_6 is a function of the calcination temperature. For aluminium hydrate (boehmite), as expected, AlO_6 octahedra are predominant. As the calcination temperature is increased to 1073 K, the fraction of AlO_4 increases to a value of 47%, and then decreases at higher calcination temperatures. For the sample calcined at 1773 K, which is classified as α-Al_2O_3 (corundum), AlO_6 octahedra are again predominant. Thus, it is shown that XANES analysis is helpful for a better understanding of the effect of calcination conditions on the Al cation distribution in transition aluminas.

In conclusion, curve fitting analysis of Al K-edge XANES is shown to be a novel characterisation method for the quantitative estimation of Al coordination states (tetrahedra and octahedra) in alumina samples. This method will now be used for quantitative estimation of Al coordination states in unknown aluminium oxides.

Electrochemically controlled micropatterning of immobilised species on functionalised electrode interfaces

Charlotte S. Hadyoon,[ab] Andrew Glidle,[a] David G. Morris[b] and Jonathan M. Cooper*[a]

[b] *Department of Chemistry, University of Glasgow, Glasgow, Scotland, UK G12 8QQ*

Received (in Oxford, UK) 15th June 1999, Accepted 19th July 1999

The reactivity of an activated ester group in a suitably functionalised electrodesposited conducting polymer can be modulated electrochemically, providing a mechanism for the patterning of immobilised species at discrete electrodes.

Conducting polymer matrices have previously been used extensively for the immobilisation of active biological species including enzymes and DNA fragments,[1] as well as other ligand binding species, including *e.g.* crown ethers.[2] One advantage of the technique concerns the ability to electrodeposit the polymer matrix in specific, electronically addressable arrays, thereby providing the possibility of selective immobilisation of different species at different places within an electrode array (*i.e.* to pattern a bound species). Under these circumstances the polymer matrix must either be deposited sequentially,[3] with intervening coupling reactions, or sequentially activated,[4] for example by light passing through a photolithographic mask.

When considering the various methods that can be used for biomolecule immobilisation at a biosensor interface, reaction between a polymer-bound activated ester and a nucleophilic amine (*e.g.* a biomolecule) has a number of advantages, including minimisation of side reactions and high reaction yields. We now describe a method of promoting or inhibiting the immobilisation of such a species onto a suitably functionalised conducting polymer matrix, involving the (simple) use of an applied electrochemical potential to modulate the reactivity of an activated ester group. We demonstrate this by using electrochemistry, XPS and FTIR spectroscopy to characterise the immobilisation of two model species, hexylamine and 2-ferrocenyl ethylamine ($FcCH_2CH_2NH_2$). These complementary surface-sensitive techniques allow us to investigate both the interfacial and bulk properties of the polymer.

The activated polymer investigated in this study is derived from the pentafluorophenyl ester of 3-pyrrolylpropionic acid (PFP). Thin films of this polymer are prepared by electropolymerisation of the monomer at potentials in excess of 1.0 V (*vs.* Ag/AgCl) in MeCN.[5] Electrochemical doping and undoping of the polymer occurs at 0.75 V, a potential which is significantly higher than the 0.65 V required to dope the unactivated parent polymeric species, poly(3-pyrrolylpropionic acid). This shift in redox potential suggests that the energy levels in the conjugated polymer backbone are perturbed either by electronic distributions in the carbonyl region of the N-pendant group, or more probably by steric effects concomitant with the bulkier side group.[6] Here, we explore the possibility that changes *induced* in the distribution of electrons in the polymer backbone, brought about by electrochemical oxidative doping and undoping, could influence the reactivity of the pendant group activated ester.

Doped and undoped films of poly(PFP) were immersed in DMSO solutions containing a nucleophilic amine species and the results of the experiments, described below, indicate that the rates of both aminolysis and hydrolysis are significantly reduced when oxidatively doped poly(PFP) is exposed to nucleophile-containing solutions. To assist in evaluating the extent of aminolysis of poly(PFP), 2-ferrocenylethylamine, a redox centre containing moiety, was used as a model nucleophile, due to its characteristic electrochemical and Fe(2p) XPS spectroscopic signature. The redox peaks at *ca.* 0.42 V in the cyclic voltammograms of Fig. 1(*a*), due to the Fc/Fc^+ couple, illustrate the degree of coupling which occurs upon holding a poly(PFP) electrode in a 1 mM 2-ferrocenylethylamine solution at 0 V. When the poly(PFP) electrode is held in the 2-ferrocenylethylamine solution at 0.77 V, there is a complete absence of these redox peaks, [Fig. 1(*b*)]. Fig. 1(*c*) shows the voltammogram arising from an electrode previously held in the doped state in the $FcCH_2CH_2NH_2$ solution, after reimmersion, following undoping, in the nucleophile containing solution. These results clearly show the immobilisation of ferrocene species into the polymer matrix is inhibited by maintaining the polymer in a doped state, and furthermore, that the reactivity is restored following undoping of the polymer.

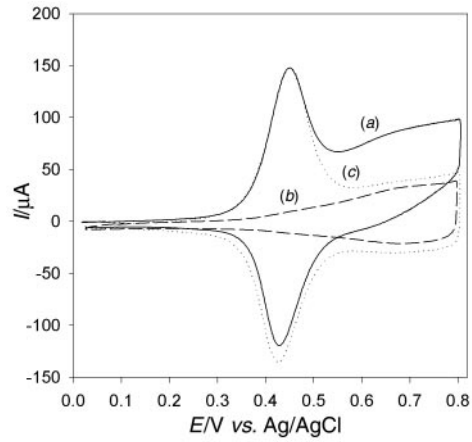

Fig. 1 Cyclic voltammagrams of poly(PFP) films in MeCN after immersion in DMSO solutions containing 1 mM $FcCH_2CH_2NH_2$ for 3 min under various conditions of electrochemical control: (*a*) electrode held at 0 V; (*b*) electrode held at 0.77 V; (*c*) electrode initially held at 0.77 V in $FcCH_2CH_2NH_2$/DMSO solution for 3 min, and then held at 0 V in same solution for 3 min. Electrode areas 1 cm^2; scan rate 20 mV s^{-1}; supporting electrolyte 0.1 M tetraethylammonium perchlorate, for both MeCN and DMSO solutions.

The RAIRS spectra of Fig. 2(*a*)–(*c*) are of a poly(PFP) film [Fig. 2(*a*)], together with poly(PFP) electrodes which have been held in $FcCH_2CH_2NH_2$ solutions at either 0 [Fig. 2(*b*)] or 0.77 V [Fig. 2(*c*)]. These confirm that for the polymer held at 0 V, the ferrocene species becomes covalently attached *via* an amide linkage (loss of the fluorophenyl ester peak at 1790 cm^{-1}, and the subsequent appearance of amide I and amide II peaks at 1650 and 1570 cm^{-1}). The small change from the as-deposited spectrum, for the doped polymer which has been immersed in the nucleophile containing solution at 0.77 V [Fig. 2(*b*)], indicates the activated ester functionality is not lost following maintenance of polymer in the oxidised state. This observation is consistent with the cyclic voltammetry of Fig. 1(*c*) corre-

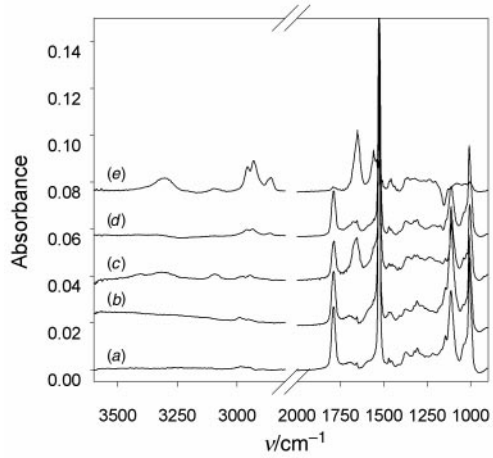

Fig. 2 RAIRS spectra for poly(PFP) films polymerised on evaporated gold electrodes, after immersion in amine containing solutions whilst holding at specified electrochemical potentials (spectra offset for clarity): (*a*) as prepared poly(PFP) film; (*b*) oxidatively doped film immersed in 1 mM $FcCH_2CH_2NH_2$/DMSO for 3 min; (*c*) undoped film immersed in 1 mM $FcCH_2CH_2NH_2$/DMSO for 3 min; (*d*) oxidatively doped film immersed in 0.5 mM hexylamine/DMSO for 3 min; (*e*) undoped film immersed in 0.5 mM hexylamine/DMSO for 3 min.

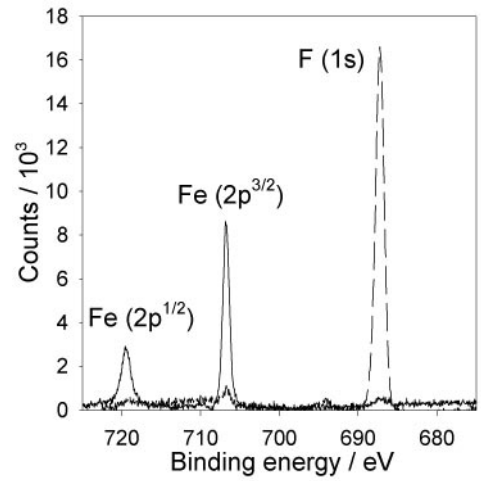

Fig. 3 F(1s) and Fe(2p) XPS spectra of poly(PFP) films after immersion in DMSO solutions containing 1 mM $FcCH_2CH_2NH_2$ and 0.1 M tetraethylammonium perchlorate for 5 min; (---) electrode held at 0.77 V; (—) electrode held at 0 V.

sponding to immobilisation of $FcCH_2CH_2NH_2$ into a previously 'inhibited' polymer film. The short reaction times used for the samples illustrated in Fig. 2 show that partial substitution is possible, if desired; however complete substitution is readily achieved simply by increasing the immersion time. Notably, coupling inhibition in the doped polymer can be maintained for >30 min.

The Fe(2p) and F(1s) XPS spectra of Fig. 3 corroborate the results of Figs. 1 and 2, and show that the amount of ferrocene in the surface layers of the film following immersion of the modified electrode at 0.77 V in the ferrocene ethylamine solution is *ca.* 5% of that found in a fully reacted film, giving a patterning selectivity of 20:1 in this unoptimised system. This low level could not directly be inferred from the lack of signal in the corresponding cyclic voltammogram (Fig. 1) since physisorbed, or partitioned, $FcCH_2CH_2NH_2$ may have exhibited poor electronic communication with the poly(PFP) matrix.

Since $FcCH_2CH_2NH_2$ is in the positively charged, oxidised state at 0.77 V, to investigate whether this coupling inhibition was a consequence of permselectivity effects in the oxidised, cationic membrane, similar potential-dependent coupling experiments were performed with the strong nucleophile, hexylamine. Hexylamine is unoxidised at these potentials (and also uncharged) and thus its permeation into the polymer is not restricted by similar permselectivity effects as may operate for $FcCH_2CH_2NH_2$. As expected, the redox voltammograms of the hexylamine-substituted poly(PFP) show the doping/undoping process now occurs at a lower potential (*ca.* 0.6 V). Figs. 2(*c*) and (*d*) show the RAIRS spectra for poly(PFP) electrodes held in either the undoped or oxidatively doped state respectively whilst immersed in hexylamine–DMSO solutions. These spectra indicate a complete reaction occurs with the undoped poly(PFP) (appearance of amide bands and C–H stretch at 2850 cm^{-1} arising from the alkyl chain) and a limited reaction for polymer films poised in the doped state. It was also noted that coupling inhibition persisted after removal of the applied potential following doping of the polymer at 0.77 V.

Furthermore, it has been found that hydrolysis in basic semi-aqueous MeCN, DMF or DMSO solutions can also be inhibited for *ca.* 30 min by electrode polarisation at 0.77 V. This extended duration compares to less than 5 min for complete hydrolysis when the electrode is held at 0 V, and, as a consequence, this technique may suitable for the nucleophilic coupling of biological species from semi-aqueous organic solvents. Furthermore, using an electrochemical assay to determine the degree of aminolysis by either $FcCH_2CH_2NH_2$ or hexylamine it has been possible to demonstrate selective patterning of $FcCH_2CH_2NH_2$ on a photolithographically fabricated microelectrode, followed by coupling of hexylamine to an adjacent (10 μm separation) polymer modified electrode (at which $FcCH_2CH_2NH_2$ coupling had previously been inhibited).

A functionalised, conjugated polymer film is physically a complex environment and the results to date do not establish a mechanism for the inhibition of these aminolysis and hydrolysis reactions, other than its independence of significant charge permselectivity control. Further mechanistic possiblities which are being investigated include: (i) changes in the bonds strengths in the activated ester group induced by electronic band changes in the conducting polymer backbone associated with doping and undoping; (ii) hindrance of nucleophile attack at the activated ester group induced by molecular conformational changes associated with doping and undoping the polymer backbone; and (iii) changes in the membrane's internal ionic strength associated with doping inhibiting the ingress of hydrophobic nucleophiles.

The authors wish to acknowledge Dr Graham Beamson (Daresbury) for assistance in the acquisition of XPS spectra, the Leverhulme Trust, EU Research Project 'BICEPS' and EPSRC for the provision of both a studentship and their funding through CCLRC of XPS facilities at RUSTI, Daresbury Laboratory, UK.

Supramolecular dendritic solubilisation of a hydrophilic dye and tuning of its optical properties

David K. Smith

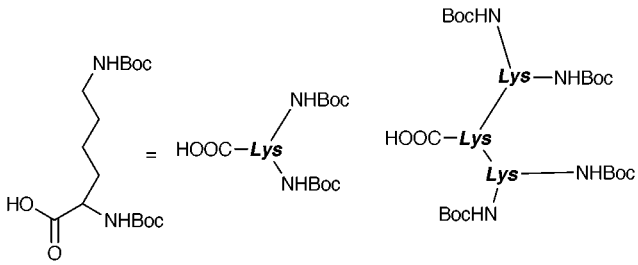
Department of Chemistry, University of York, Heslington, York, UK YO10 5DD. E-mail: dks3@york.ac.uk

Received (in Cambridge, UK) 17th May 1999, Accepted 23rd July 1999

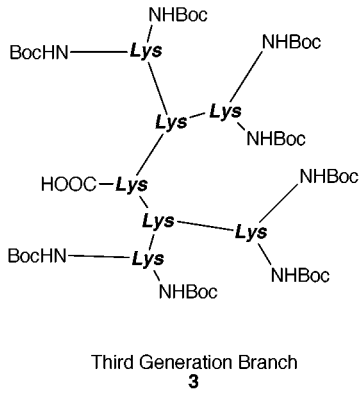
Dendritic peptides with a carboxylic acid at the focal point of the branched structure specifically solubilise a polybasic aromatic dye, the microenvironment and optical properties of which are controlled by the size (generation) of the branched peptide.

The development and investigation of the unique properties of functional dendrimers is a research area of intense current activity.[1] The preparation of dendrimers, however, requires considerable synthetic input and consequently, supramolecular dendrimer chemistry and self-assembling systems are of increasing interest.[2,3] There have been extensive investigations of the use of spherical dendrimers for the supramolecular solubilisation of dyes,[4] which are ideal optical probes of the branched environment. It has also been shown that a dendritic shell can generate a unique microenvironment deep within its branched architecture, modulating optical properties,[5] as well as behaviour such as redox chemistry, molecular recognition and catalysis.[6] Here a new approach to the supramolecular dendritic solubilisation of a hydrophilic dye is reported. Rather than using spherical dendrimers,[4] individual dendritic branches with a functional group at the focal point are used for the supramolecular encapsulation process. Furthermore, the encapsulated dye experiences a unique microenvironment,[5] with its optical properties being dendritically tuned by the extent of the branching assembled around it.

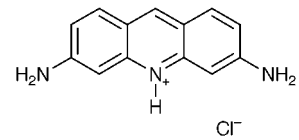
Dendritic branches **1**–**3** were constructed in a solution phase approach, starting from protected L-lysine building blocks.[7] All dendritic branches were fully characterised and monodisperse as proven by electrospray mass spectrometry and analytical gel permeation chromatography (Shodex gel). It was proposed that these dendritic branches containing a free carboxylic acid unit at the focal point should interact with molecules containing basic amine sites through the formation of a hydrogen bonded (acid–base) complex with potential proton transfer.[8] A hydrophilic dye containing amine groups, proflavine **4**, was of great interest as a putative guest. It is intensely coloured and possesses interesting luminescence properties, which assist in monitoring the uptake of the dye by the dendritic branch. Furthermore, its optical behaviour is dependent on the microenvironment in which it is located and this allows the effect of supramolecular dendritic encapsulation to be quantified.[5]



First Generation Branch **1** Second Generation Branch **2**



Third Generation Branch **3**



Proflavine hydrochloride **4**

Solid-liquid extraction (solubilisation) experiments were performed using 2 ml of a solution of dendritic branch in CH_2Cl_2 (13.0 mM) and solid proflavine **4** (20 mg). The mixture was stirred at ambient temperature for 24 h, filtered through a pad of Biobeads gel in a pipette, which was washed with additional solvent, and the resultant solution made up to 5 ml in a volumetric flask. This solution was then analysed using UV-visible and fluorescence spectroscopy to assess the degree of dye uptake.

Each of dendritic branches **1**–**3** solubilised a small but significant quantity of the solid hydrophilic proflavine dye **4** into the apolar CH_2Cl_2 solution, as was clear from UV-visible spectroscopy (Table 1), with the dye molecule exhibiting an absorption maximum around 450 nm. In CH_2Cl_2 without dendritic branch present, however, no uptake was observed and the solution remained colourless. The effect of other additives (13.0 mM) was also investigated. AcOH led to no significant uptake of the dye (a simple carboxylic acid is not effective), whilst the methyl ester of **2** also exhibited no uptake (the dendritic branch without a carboxylic acid group at the focal point is not effective). Stearic acid ($C_{17}H_{35}CO_2H$) also did not solubilise the dye (a long unbranched hydrophobic chain is not effective). It therefore seems clear that the carboxylic acid group and the dendritic branching act cooperatively, solubilis-

Table 1 UV-Visible and fluorescence spectroscopic data after proflavine uptake by the dendritic branches, **1**–**3**

	UV-Visible data		Fluorescence data	
Dendritic branch	Peak maximum/nm	Relative absorption intensity	Emission peak maximum/nm	Relative emission intensity
1	446	1.0	505	1.0
2	448	2.25	503	2.10
3	450	13.7	500.5	7.85

ing proflavine **4** into apolar CH_2Cl_2, presumably *via* the formation of supramolecular interactions between acid and amine groups within the dendritic environment.†

Furthermore, the optical properties of proflavine differ in a progressive manner: as the branched molecule becomes larger, increasing quantities of the dye are solubilised into CH_2Cl_2. This effect is particularly marked between second and third generation branches. This would be consistent with a model in which the hydrophilic dye becomes encapsulated within a branched environment, shielding it from bulk solvent and enhancing its solubility in the hydrophobic solvent phase.[4c–f]

In addition, the UV-visible absorption maximum of proflavine is dependent on the size of the dendritic branch. For branch **1**, this maximum is at 446 nm, whilst for branch **2** it absorbs at 448 nm and for branch **3** it has shifted to 450 nm. These results agree with binding studies performed by Seel and Vögtle on proflavine using an acidic endoreceptor in which the absorption maximum of proflavine shifted bathochromically on encapsulation.[9] The absorption maximum of proflavine is dependent on the protonation state of the molecule, with more highly protonated proflavine absorbing at longer wavelength.[10] It is possible that as the size of the dendritic branch increases, the degree of proton transfer from carboxylic acid to amine accompanying dendritic encapsulation increases. This would agree with theoretical studies,[11] which indicate that carboxylic acid–amine interactions are favoured in a low dielectric (*i.e.* CH_2Cl_2 solvent) whilst carboxylate–ammonium interactions (with proton transfer) are only favoured in a higher dielectric (*i.e.* that generated by the larger polypeptide dendritic branches).

Fluorescence investigations provided further insight (Table 1). On excitation at 450 nm, a proflavine emission peak was observed at 505 (**1**), 503 (**2**) and 500.5 nm (**3**). Interestingly, the relative intensities of these emissions increase less markedly than the intensities of the associated UV-visible absorptions. This would indicate that for the larger dendritic branches there is a greater degree of fluorescence quenching. This once again illustrates the dendritic microenvironment experienced by proflavine.

These results clearly show for the first time that, like their spherical dendrimer counterparts,[4c–f] individual dendritic branches with suitable functionalisation at the focal point can non-covalently solubilise a hydrophilic dye. Furthermore, the optical properties of the encapsulated dye indicate that it experiences a unique microenvironment[5a] as a consequence of supramolecular encapsulation.[5b,9] This has implications for the future design of functional branched systems, as some of the time-consuming covalent synthesis may be avoided. Investigations in this laboratory are currently targeting the synthesis of well-defined aggregates.[3] In addition, dendritic control of a wide variety of molecular function, and the application of assembled branched architectures to the problems of drug encapsulation and delivery,[12] are of considerable interest.

D. K. S. acknowledges the support of the University of York in initiating this new research programme.

Notes and references

† The complex still has low solubility, which has thus far prevented an accurate analysis of its stoichiometry, but studies are in progress with other hydrophilic dyes and in different solvents to ascertain how many branches interact with the dye, and hence fully characterise these dendritic aggregates.

Received (in Cambridge, UK) 1st July 1999, Accepted 19th July 1999

A liposome including the lipopeptide RGD-C4A2, whose surface is modified by a GRGDS-repeating peptide ligand, is found to bind to NIH3T3 cells *via* the interaction between the peptide ligand and the membrane receptor.

Liposomes have been extensively examined as potential carriers of drugs,[1] proteins[2] and DNA[3–5] for drug delivery systems (DDS), in spite of their nonspecificity of delivery due to entrapment by reticuloendothelial systems.[6] We present here a new functional liposome (RGD liposome) whose surface is modified with a high density of peptide chains. Lipopeptide **RGD-C4A2** composed of peptide and lipid parts was synthesized in advance by a method similar to that previously reported,[7,8]† and was then incorporated into the liposome bilayer membrane when the liposome was prepared using the freeze-thaw method.[9]‡ **RGD-C4A2** has a five-times repeated GRGDS sequence, which is the same as the cell adhesion sequence of fibronectin,[10] and therefore is thought to bind to the cell membrane receptor.

The peptide ligand extruded from the RGD liposome into the aqueous phase was expected to bind specifically to an anti-peptide antibody. We therefore confirmed using immunoelectron microscopy[11,12]§ that the peptide ligand was actually placed in the outer aqueous phase. Experimentally,gold colloidal particles were clearly observed on the surface of the liposome when **RGD-C4A2** was located in the liposome membrane, while they were rarely seen in the control liposome.

We applied flow cytometry to evaluate the binding between RGD liposomes and the NIH3T3 cell line (Fig. 1).¶ NIH3T3 was established from mouse fibroblasts, had normal cell-like properties, and was thought to have fibronectin receptors and bind to the present modified liposome. It is worth noting that RGD liposome/NIH3T3 [Fig. 1(*c*)] gave greater fluorescence intensity than either the NIH3T3 alone [Fig. 1(*a*)] or the control liposome/NIH3T3 [Fig. 1(*b*)]. This indicates that the RGD liposome can bind to the cells to a greater degree than the control liposome. We undertook an inhibition experiment to confirm that the peptide chain of **RGD-C4A2** participates in the binding to NIH3T3. The fluorescence intensity was actually reduced by 34.8% in the presence of the free peptide, H-Trp-(Gly-Arg-Gly-Asp-Ser)$_5$-NH$_2$ [Fig. 1(*d*)]. This strongly suggests that the binding between the RGD liposome and the NIH3T3 cell takes place *via* the interaction between the peptide chain of **RGD-C4A2** and the membrane receptor of NIH3H3.

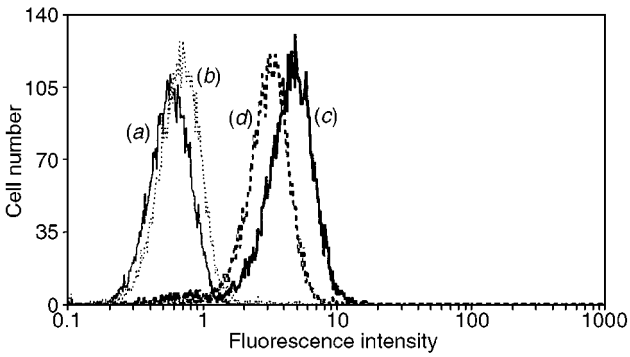

Fig. 1 Flow cytometry of (*a*) NIH3T3 only, (*b*) NIH3T3 + control liposome, (*c*) NIH3T3 + RGD-liposome and (*d*) NIH3T3 + RGD liposome + H-Trp-(Gly-Arg-Gly-Asp-Ser)$_5$-NH$_2$.

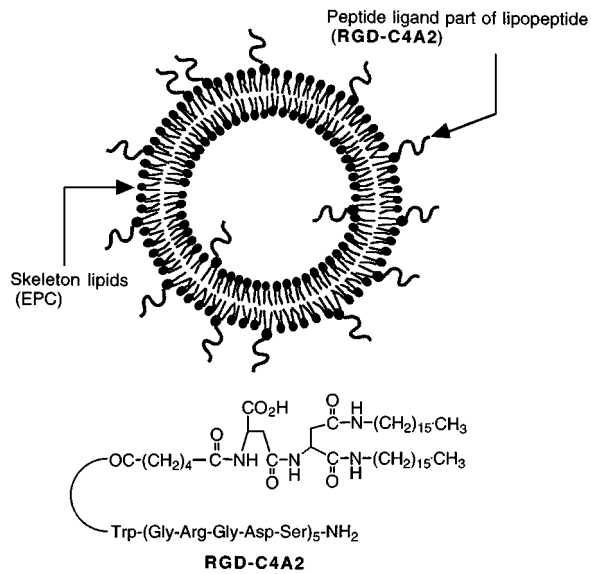

Viruses have been used as vectors in the field of gene therapy.[13] In spite of their prominent function as drug carriers, problems endangering vital functions have not yet been completely solved and thus their clinical use is still limited. Compared to viruses, however, liposomes are superior in safety and reproducibility if only the problem of specificity can be solved. Many trials have been made to give liposome the binding specificity to cells. For example, the liposome surface has been equipped with a glycolipid,[14] transferrin[15] or an antibody[16,17] as a binding anchor to cells. Among various ligand candidates, peptides seem the most appropriate for the present purpose, since information about amino acid sequences and corresponding receptors is easily available and the synthetic methods are also well established.[18] In ordinary methods such as the 'succinimide method',[16] proteins or peptides are reacted with amino groups of specific lipid molecules already incorporated into lipid bilayer membranes. However, it is very difficult to modify the surface of liposomes at high density by this ordinary method, because the reactivity is reduced owing to the steric repulsion between the liposome membrane and the protein or peptide ligand fragments. In contrast to the succinimide method, our new technique was highly efficient in incorporating the lipopeptide in the liposome membrane, *viz.* more than 90% of the added **RGD-C4A2** was introduced into the liposome.

In conclusion, we have succeeded in preparing a liposome whose surface is modified by peptide chains at high density. This liposome has been shown to bind to the membrane receptor of NIH3H3 cells using the peptide ligand on its surface. This method may open a way to wide application of liposomes for clinical use.

We thank Dr Kazunori Kawasaki, Dr Toku Kanaseki and Ms Rena Kawai of the National Institute of Bioscience and Human-Technology for assisting with the electron microscopy.

Notes and references

† *Selected data* for **RGD-C4A2**: $\delta_H(D_2O)$ 7.34–7.60 (m, 2H, Trp), 7.19 (s, 1H, Trp), 6.98–7.14 (m, 2H, Trp), 4.68–4.82 (m, 6H, CH), 4.28–4.50 (m, 10H, CH), 3.75–4.12 (m, 30H, Ser-CH_2, Gly-CH_2), 3.21 (m, 10H, Arg-$CH_2CH_2CH_2N$), 2.74–2.94 (m, 10H, Asp-CH_2), 2.04–2.34 (m, 4H, $COCH_2$), 1.54–1.98 (m, 20H, Arg-$CH_2CH_2CH_2N$), 1.36–1.54 (m, 4H, $NHCH_2CH_2$), 1.27 (s br, 52H, $2(CH_2)_{13}CH_3$), 0.88 (t, 6H, $2CH_2CH_3$, *J* 6.6); MALDI-TOFMS: calc. 3369.8 (MH^+), found: 3370. Retention time in HPLC (YMC-Pack ODS-AM, 4.6 × 250 mm, eluant: 0.08% aq. TFA–MeCN from 100 : 0 to 50 : 50 over 30 min, flow rate: 0.8 ml min^{-1}): 17.4 min.

‡ After **RGD-C4A2** was dissolved in 10 μl of 20% AcOH, 100 μl of egg phosphatidylcholine (EPC)–chloroform solution (5 μmol ml^{-1}) was added. These two separated phases became homogeneous after addition of a few drops of MeOH. The solvent was evaporated under reduced pressure to form a thin lipid film on the wall of a test tube. This film was left *in vacuo* for at least 12 h to thoroughly remove the solvent. Hank's buffer solution (pH 7.2) (1 ml) was added to the thin lipid film, which was vortexed for 5 min at room temperature and subjected to repeated (7 times) freezing (−196 °C) and thawing (70 °C). The solution was then extruded 5 times through a polycarbonate membrane (pore size: 0.1 μm).

§ An antibody against H-Cys-Trp-(Gly-Arg-Gly-Asp-Ser)$_5$-NH_2 [one cysteine residue was added to H-Trp-(Gly-Arg-Gly-Asp-Ser)$_5$-NH_2] was prepared by an ordinary method from a female New Zealand white rabbit using KLH (Keyhole Limpet, Hemocyanin)-conjugated Cys-Trp-(Gly-Arg-Gly-Asp-Ser)$_5$-NH_2. After labeling the modified liposome by the prepared primary antibodies and a secondary antibody (goat anti-rabbit IgG), the samples were negatively stained with uranyl acetate, stabilized by perpendicular carbon evaporation, and observed under a transmission electron microscope.

¶ To the lipopeptide (0.1 μmol) dissolved in 20% AcOH (10 μl) was added a chloroform solution containing EPC (1.6 μmol), cholesterol (Ch) (0.4 μmol) and *N*-(fluorescein-5-thiocarbamoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (FITC-PE) (0.02 μmol). A few drops of MeOH were added to make the solution homogeneous and the modified liposome was prepared in a similar manner as described above. After the liposome and NIH3T3 cells had been incubated at 37 °C for 30 min, the cells were washed by centrifugation (1000 rpm, 3 min) at 37 °C, twice with Dulbecco's modified Eagle's medium (DMEM) and once with CMF-PBS. The cells were then suspended in 1.0 ml of CMF-PBS containing BSA (0.1%) and sodium azide (0.1%), and the fluorescence emitted from the cells was measured on the flow cytometer.

A new family of amorphous molecular materials showing large photorefractive effect

Qing Wang, Liming Wang, Haythem Saadeh and Luping Yu*

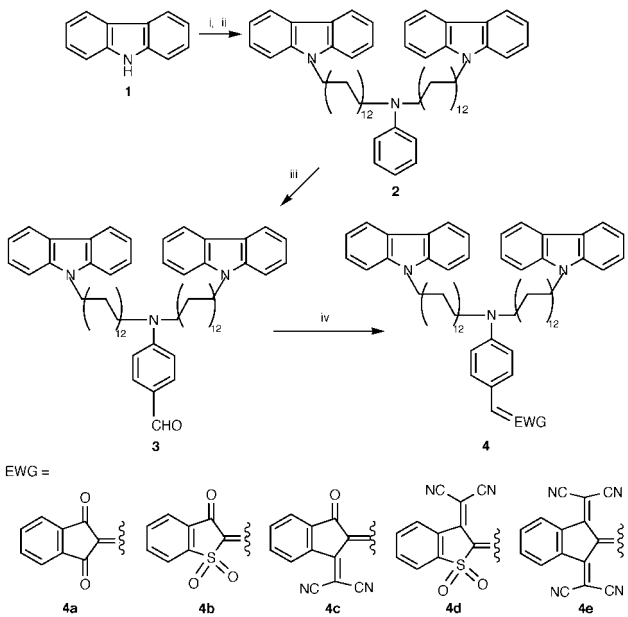
Received (in Corvallis, OR, USA) 15th June 1999, Accepted 19th July 1999

A novel series of amorphous molecular materials containing carbazole and methine dyes have been synthesized and characterized for photorefractive applications.

In recent years, functional molecular materials exhibiting nonlinear optical, electroluminescent, ferromagnetic and photoconducting properties have been sought for practical applications.[1–4] These materials possess excellent processibility, transparency and can be efficiently purified by many well-known techniques such as chromatography. The versatility of structural modification offers a unique opportunity to meet additional challenges, for example, designing multifunctional materials that could simultaneously possess several properties. Photorefractive (PR) materials are such multifunctional materials that combine photoconductivity and nonlinear optical (NLO) response to modulate the refractive index of the medium.[5] Due to their potential applications in holographic optical data storage and real-time optical processing, various classes of organic PR materials including polymers,[6–8] liquid crystals[9] and organic glasses[10,11] have been explored. Herein, we report a novel series of amorphous molecular materials based on carbazole and methine dyes, which exhibit very interesting charge-transfer complex formation and large PR responses.

The synthetic route is shown in Scheme 1, where carbazole was chosen as the photoconductive component for hole transport. Condensation of aldehyde **3** with electron withdrawing groups yielded methine dye as the NLO chromophores. The molecules synthesized (compound **4**) thus possess dual functions: photoconductivity and second-order NLO activity.



Scheme 1 *Reagents and conditions*: i, $Br(CH_2)_{12}Br$, NaH; ii, aniline, K_2CO_3; iii, $POCl_3$, DMF; iv, EWG, EtOH.

The long aliphatic chain was introduced to prevent the materials from crystallization and help resulting compounds remain amorphous at room temperature. The structures of the compounds were confirmed by microanalysis and by spectroscopic methods.[12] The thermal properties of the compounds are summarized in Table 1, which indicated the low T_g nature of the materials. These compounds were found to readily form amorphous films, as evidenced by differential scanning calorimetry (DSC), polarizing microscopy and X-ray diffraction. The amorphous films made from these compounds are very stable in an ambient atmosphere for over a year up to the present time and no crystallization phenomenon was observed even on further heating. The UV/vis spectra of compound **4** in CH_2Cl_2 display two intense bands. The one at around 347 nm can be attributed to the carbazole moiety, while the other is due to the NLO chromophore. As also shown in Table 1**,** increasing acceptor strength by replacing carbonyl groups with sulfonyl and dicyanovinyl groups results in a bathochromic shift in the corresponding chromophores. It is interesting to note that in solid UV/vis spectra, new long-wavelength absorption bands were observed in addition to the peaks from chromophore and carbazole. The intensity of these new peaks varies as a function of temperature. As the temperature increases, the absorbance decreases and finally becomes zero at around 75 °C. These new bands were assigned to the formation of charge-transfer complexes (CTC) between the carbazole and electron withdrawing groups because it was observed that when compound **2** was mixed with electron acceptors in CH_2Cl_2 solution, an intense coloration with new long-wavelength absorption peaks developed immediately. For example, CTC bands at 492 and 690 nm were observed for compounds **4b** and **4c** respectively. These new absorption bands enable us to photoexcite the materials mainly through the charge-transfer complex at a longer wavelength. It is worth mentioning that additional photosensitizers, such as 2,4,7-trinitrofluoren-9-one (TNF), are needed in most reported composite PR materials containing a carbazole moiety.[13] The system reported here shows all necessary functions for PR response in single molecules.

Photocurrent measurements indicated these materials are photoconductive and a second harmonic generation signal was observed as a function of an external field. The PR nature of these molecular materials was verified in two-beam coupling measurements. In this experiment, two coherent laser beams (*p*-polarized) intersect inside the sample to write a holographic

Table 1 The properties of carbazole containing amorphous molecules

Compound	T_g/°C[a]	T_d/°C[a]	λ_{max}/nm[b]	ε_{max}/l mol^{-1} cm^{-1}[b]
4a	9	292	491	48 900
4b	10	282	492	59 100
4c	13	211	570	49 000
4d	7	228	602	59 300
4e	6	205	628	18 300

[a] The glass transition temperature (T_g) and the decomposition temperature (T_d) were determined by DSC, 10 °C min^{-1}. [b] Measured in CH_2Cl_2.

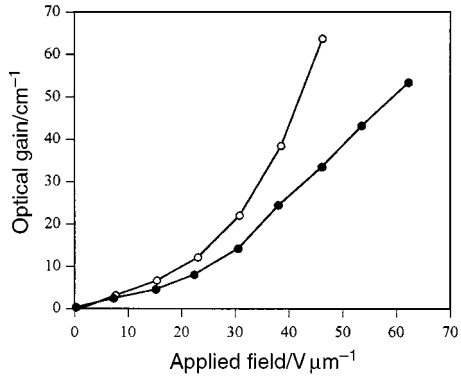


Fig. 1 Photorefractive optical gain of compound **4b** (○) and compound **4c** (●) as a function of the applied field.

grating. It is known that this grating has a non-zero phase shift with respect to the light intensity pattern. An asymmetric energy exchange between the two beams, characterized by the two-beam coupling gain coefficient Γ, can be observed.[5] A further note is that in this experiment, the normal of the sample surface needs to be tilted 52 °C to yield a projection of the grating wave vector along the poling axis. The films for PR characterization were prepared by sandwiching the melt of compounds between two glass substrates coated with indium-tin oxide. The thickness of films is about 128 μm, maintained by a polyimide spacer. Some preliminary results performed on compound **4b** and **4c** are presented in Fig. 1. Compound **4b** was measured with a He-Ne laser (632.8 nm), while compound **4c** was excited by a diode laser with a wavelength of 780 nm. As the applied field increased, the intensity of one beam increased, while that of the second beam decreased. When the electric field was turned off, the intensities returned to their original levels and no energy exchange was observed. The strong field dependence of the optical gain reflects the field dependence of both the quantum yield of photogeneration of charge carriers and the second-order NLO response. For compound **4b**, at a field of 46 V μm^{-1}, an optical gain value of 65.4 cm^{-1} was achieved. The absorption coefficient of the material was only 1.4 cm^{-1}, thus giving us a net optical gain of 64 cm^{-1}. For compound **4c,** we have obtained a PR gain of 53 cm^{-1} by applying a field of 62 V μm^{-1}, whereas the absorption coefficient was 4.3 cm^{-1}. The index grating recorded in the material was further tested by a weaker, counter-propagating probe beam (*p*-polarized) in the four wave mixing experiments. The diffraction efficiency η is calculated as the intensity ratio of the diffracted signal to the probe beam. It was observed that the diffraction efficiency also had a strong dependence on the applied field and reached 17% for compound **4b** and 9% for compound **4c** at E = 42 V μm^{-1}.

In summary, a new series of multifunctional amorphous molecules has been synthesized and characterized for photorefractive applications. Selecting different electron acceptor groups affords control not only of electrooptic effects but also of charge generating characteristics of the resulting materials. This approach opens the way for an extension of PR sensitivity to near-IR or even IR regions, which is very interesting for applications in telecommunication. Moreover, the synthetic flexibility and simplicity of this molecular system offer great possibilities for structural modifications to further improve performance or match the laser wavelength for the application desired. Extensive work based on this system is now under way.

We gratefully acknowledge the financial support of the National Science Foundation and Air Force Office of Scientific Research. This work also benefited from the support of the NSF MERSEC program at the University of Chicago.

Chemoselectivity and enantiocontrol in catalytic intramolecular metal carbene reactions of diazo acetates linked to reactive functional groups by naphthalene-1,8-dimethanol

Michael P. Doyle,* Doina G. Ene, David C. Forbes and Thomas H. Pillow

Department of Chemistry, University of Arizona, Tucson, Arizona, USA. E-mail: mdoyle@u.arizona.edu

Received (in Corvallis, OR, USA) 3rd June 1999, Accepted 14th July 1999

The use of chiral dirhodium(II) carboxamidate catalysts for metal carbene transformations of diazo acetates linked to a reactive functionality through naphthalene-1,8-dimethanol produces chemoselective and enantioselective reaction either at the remote functionality or by addition to the 1,2-position of the naphthalene ring; enantioselectivities up to 84% ee have been obtained for the Büchner reaction.

Considerable mechanistic and synthetic interest has been directed recently to the Büchner reaction.[1,2] Catalytic intramolecular cycloaddition has been pursued with vigor since dirhodium(II) catalysts were employed,[3,4] but there have been few reports that provided evaluation of the Büchner reaction in competitive processes.[5,6] Similarly, only two reports have documented enantiocontrol in this transformation from the use of chiral catalysts.[3,7] In our ongoing investigations of enantiocontrol in catalytic intramolecular metal carbene transformations, we have discovered two reacting systems that offer catalyst-controlled chemoselectivity and the highest levels of enantiocontrol yet achieved in aromatic cycloaddition reactions.

We investigated the influence of catalyst on the partitioning of the metal carbene derived from **1** between products **2** and **3**. The diazo acetate linked to a propargyl group through a naphthalene-1,8-dimethanol (**1**) was prepared by standard methods in good overall yield. Consistent with recently reported results for macrocyclic cyclopropenation,[8] treatment of **1** with $Rh_2(OAc)_4$ produced macrocyclic cyclopropene **2** in 69% isolated yield. However, the application of chiral catalysts to this system resulted not only in **2** but also in the aromatic cycloaddition product **3**. Indeed, use of $Rh_2(4R\text{-MEOX})_4$ gave **3** in 66% overall yield and in 73% ee. The norcaradiene structure for **3** was confirmed spectrally and is consistent with results obtained with a structurally analogous diazo ketone.[9] Results obtained with a representative selection of chiral catalysts are presented in Table 1.

As is evident in these data, the catalyst has a definite but, in this system, unpredictable influence on chemoselectivity. The selectivity achieved with chiral dirhodium(II) carboxamidate catalysts is not uniform. Also, since reactivity of the catalysts generally finds $CuPF_6$–**4** to be comparable to $Rh_2(S\text{-TBPRO})_4$, with both of them much more reactive than the chiral dirhodium(II) carboxamidates, chemoselectivity appears to respond here to a subtle combination of electronic and steric effects. In any case, proper choice of catalyst allows the selection of either **2** or **3**.

The competition between ylide formation and aromatic cycloaddition was also evaluated. By investigating the design potential of the naphthalene-1,8-dimethanol linker for ylide formation–[2,3]-sigmatropic rearrangement,[10] we discovered similar results to those reported in Table 1. The synthesis of **5** was accomplished in good yield. Treatment with $Rh_2(S\text{-TBPRO})_4$ caused the sole production of [2,3]-sigmatropic rearrangement (Scheme 1) product **7** in 82% yield (6% ee).[11] In contrast, use of $Rh_2(4S\text{-MEOX})_4$ gave aromatic cycloaddition product **8** exclusively in 55% isolated yield (84% ee). The use of $CuPF_6$–**4** gave a 20:80 mixture of **7** (44% ee) and **8** (76% ee).

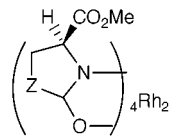
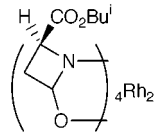
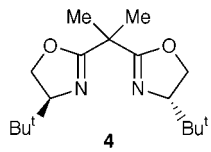
3



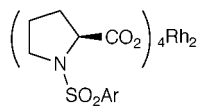
$Rh_2(4S\text{-MEOX})_4$ Z = O
$Rh_2(5S\text{-MEPY})_4$ Z = CH_2
$Rh_2(4S\text{-MPPIM})_4$ Z = $NCOCH_2CH_2Ph$



$Rh_2(4S\text{-IBAZ})_4$



4



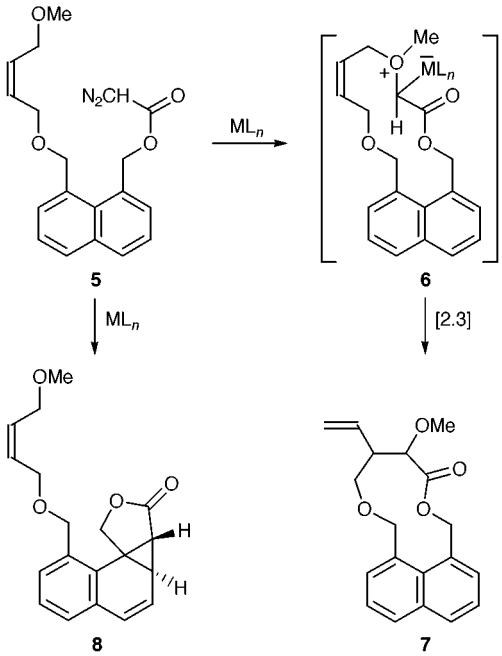
$Rh_2(S\text{-TBPRO})$
(Ar = *p*-$Bu^tC_6H_4$)

To determine the effectiveness of these catalysts for aromatic cycloaddition on the basic naphthalene system, **9** was treated with a selection of catalysts from Table 1. Aromatic cycloaddition product **10** was produced[12] in high isolated yield in each case (% **10**, % ee): $Rh_2(4R\text{-MEOX})_4$ (76% yield, 56% ee); $Rh_2(5S\text{-MEPY})_4$ (72% yield, 42% ee); $Rh_2(4S\text{-IBAZ})_4$ (87% yield, 81% ee); $Cu(MeCN)_4PF_6$–**4** (83% yield, 42% ee). Thus,

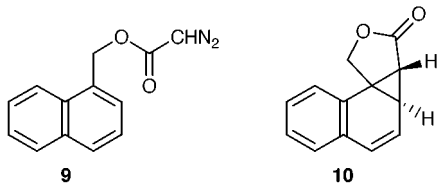
Table 1 Products from catalytic diazo decomposition of **1**[a]

Catalyst	Isolated yield (%)[b]	Relative yield (%)		Ee (%)	
		2	**3**	**2**	**3**
$Rh_2(OAc)_4$	69	100	0	—	—
$Rh_2(4R\text{-MEOX})_4$	66	0	100	—	73
$Rh_2(5S\text{-MEPY})_4$	74	54	46	62	10
$Rh_2(4S\text{-MPPIM})_4$	74	83	17	15	—
$Rh_2(4S\text{-IBAZ})_4$	74	68	32	51	65
$Cu(MeCN)_4PF_6$–**4**	72	14	86	—	59
$Rh_2(S\text{-TBPRO})_4$	72	98	2	11	—

[a] Reactions were performed in refluxing CH_2Cl_2 using 1.0 mol% catalyst. [b] Yield of **2** + **3** after chromatography.



Scheme 1



in this case, $Rh_2(4S\text{-IBAZ})_4$ is superior even to $Rh_2(MEOX)_4$ catalysts for highly enantioselective aromatic cycloaddition.

The composite of results demonstrates that the more reactive catalysts favor reactions that occur at remote functional groups rather than at the nearby naphthalene. This selectivity characterizes alkyne addition and ylide formation and should also be evident in other addition and association reactions. Furthermore, the enantiomeric excess for aromatic cycloaddition in these naphthalene systems is the highest yet reported.

We are grateful to the National Science Foundation and to the National Institutes of Health (GM-46503) for their support of this research.

A novel approach to site-specifically platinated oligonucleotides applying combinations of nucleobase protecting groups

Robert J. Heetebrij, Reynier A. Tromp, Gijs A. van der Marel, Jacques H. van Boom and Jan Reedijk*

Leiden Institute of Chemistry, Gorlaeus Laboratories, Leiden University, PO Box 9502, 2300 RA Leiden, The Netherlands. E-mail: reedijk@chem.leidenuniv.nl

Received (in Cambridge, UK) 1st June 1999, Accepted 14th July 1999

Platination of a properly protected oligonucleotide followed by deprotection represents a new method for the synthesis of site-specific platinum-modified nucleic acids; N7 platination of 2′-deoxyguanosine can be circumvented by introducing a bulky protective group at the O6 position.

Since the discovery of the cytotoxic activity of cisplatin, *cis*-$[Pt(NH_3)_2Cl_2]$, much effort has been directed towards elucidating the mechanism of action of this drug. At present it is generally accepted[1] that intracellular damage occurs by coordination of cisplatin to DNA, causing a profound spatial disturbance and destabilisation of the double-helix leading to inhibition of DNA replication. It is well-established now that the intrastrand 1,2-GG (G = guanine) crosslink is the predominant platinum–DNA adduct. Moreover, other adducts such as 1,2-AG and 1,3-GXG adducts, as well as interstrand GG crosslinks, have also been observed.[2]

The molecular mechanistic aspects of platinum antitumour drugs are commonly investigated by elucidation of the 3D structures of platinum adducts of oligonucleotides.[3] In addition, selectively platinated oligonucleotides are required in fairly large amounts for applications in new therapeutic strategies like gene modulation *via* antisense and antigene methodologies.[4] The construction of selectively platinated DNA adducts by modification of an unprotected oligonucleotide with a platinum complex is often hampered by lack of selectivity of the platination reaction. Consequently the available range of DNA–Pt crosslinks to be studied is rather limited.

One approach to overcome these problems entails the use of platinum-bound mononucleotides[5] in the synthesis of platinum adducts by automated DNA synthesis following an H-phosphonate coupling approach. However, the recovery of site-specifically platinated oligonucleotides was rather disappointing. Recently, an automated DNA synthesis based on phosphoramidite chemistry of Ru^{II} and Os^{II} modified oligonucleotides was published.[6] This methodology leads to higher yields, but has been limited to coordinatively saturated complexes covalently linked to the nucleobase *via* polypyridine ligands.

Lippert *et al.*[7] showed that coordination of M^{II}(dien) (M = Pd,Pt) towards N6′,N6′,N9-trimethyladenine solely occurs at N3. The latter finding implies that platination at the N7 position of guanosine can be prevented by the introduction of a sterically demanding protective group at the O6 position of the guanine moiety. Consequently, it was to be expected that platination would be inhibited by N2,O6 protection, while N7 platination would be allowed in the case of N2 protection.

In order to substantiate the viability of the aforementioned hypothesis, we first examined the influence of the N2 protecting group on the course of the platination (Fig. 1). To this end we compared the traditionally used[8a] diphenylacetyl (DPA) group in **1a** with the more mildly removable[8b,c] di-*n*-butylaminomethylene (DNB) group in **1b**. For reasons of solubility the platination experiments were carried out in DMF-d_7–D_2O (80:20) mixtures and using [Pt(dien)Cl]Cl.† The reaction between [Pt(dien)Cl]Cl and **1a** and **1b** at 37 °C, monitored by ^{1}H NMR (see Fig. 2), clearly reveals that N7 platination occurs. Surprisingly the 2-*N*-DNB protected guanine derivative **1b** proved to be roughly two-fold more reactive towards $[Pt(dien)]^{2+}$ than the 2-*N*-DPA protected derivative **1a**. The latter observation might be explained by electronic effects of the amidine group in **1b**, as well as by stacking of the diphenyl group in **1a**, thereby reducing the accessibility of N7. A detailed study on these effects is currently being performed.

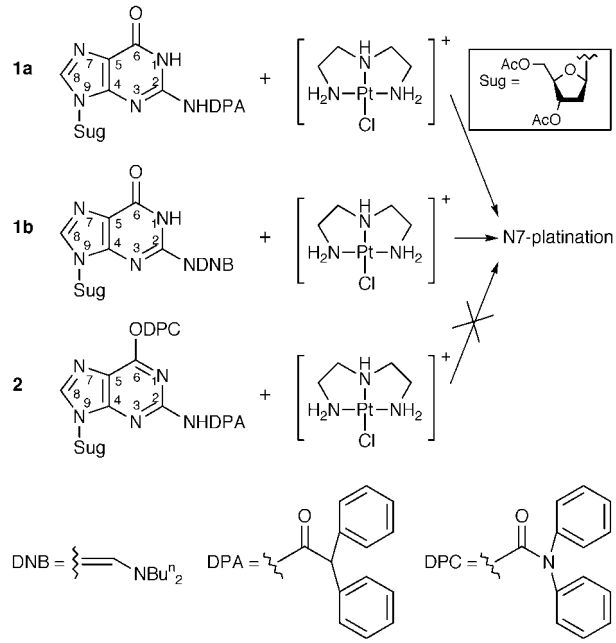

Fig. 1 Structures of 2′-deoxy-3′,5′-*O*-acetylated guanosine model compounds differing in base-protection and their (absence of) reactivity towards [Pt(dien)Cl]Cl.

The diphenylcarbamoyl (DPC) group[9] was selected to protect O6 of the guanine base giving, in combination with a diphenylacetyl (DPA) group at the N2 position, compound **2**. It can be seen in Fig. 2 that N7 platination of the N2,O6 protected derivative **2** is completely prevented.

Additional evidence for retardation of N7 platination was found by comparing the reactivity of *trans*-$[Pt(NH_3)_2Cl(DMF\text{-}d_7)]BF_4$ towards 2-*N*-(isobutyryl)-2′-deoxyguanosine (2-*N*-Bu^i-dG)‡ and 6-*O*-(diphenylcarbamoyl)-2-*N*-(diphenylacetyl)-2'-deoxyguanosine (6-*O*-DPC-2-*N*-DPA-dG). At room

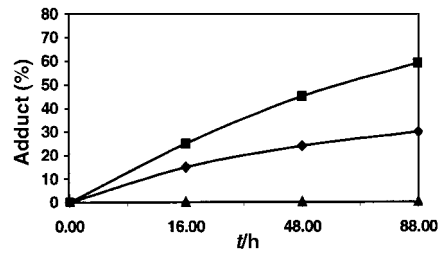

Fig. 2 Observed product formation during the reaction between [Pt(dien)Cl]Cl and (◆) **1a**, (■) **1b** and (▲) **2** in a 1:1 ratio at 4 mM concentration in DMF-d_7–D_2O (8:2 v/v) at 37 °C.

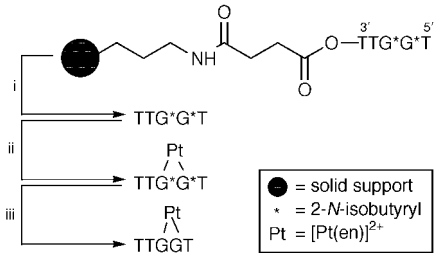

Scheme 1 *Reagents and conditions* i, NH_3–H_2O, (room temp., 15 min; ii, $[Pt(en)Cl(H_2O)]NO_3$, pH 6.0, 50 °C, 16 h; iii, NH_3–H_2O, 50 °C, 16 h.

temperature in DMF-d_7 with a slight excess of the platinum species, platination of 2-*N*-Bu^i-dG at N7, as gauged by ^{1}H NMR, went to completion within 1 h. No significant amount of platinated 6-*O*-DPC-2-*N*-DPA-dG could be observed under the same conditions. In the reaction of a 1 : 1 mixture of 2-*N*-Bu^i-dG and 6-*O*-DPC-2-*N*-DPA-dG with 1.1 equiv. of *trans*-$[Pt(NH_3)_2Cl(DMF\text{-}d_7)]BF_4$, only the downfield shifted H8 and H1′ resonances of the 2-*N*-Bu^i-dG derivative are observed, implying selective N7 platination for the 2-*N*-protected guanosine derivative in this competitive system.

The additional role of the electronic and/or steric effect of the protecting group at the exocyclic amine upon the reaction kinetics of N7 platination would allow a synergistic effect in our approach of protecting group directed selectivity enhancement.

Implementation of the latter results in the synthesis of selectively platinated oligonucleotides requires an effective platination of a N2-protected oligonucleotide. Therefore, the fully protected and immobilised pentamer d(TTGGT), having 2-*N*-Bu^i protection of the guanine bases and a β–cyanoethyl protection of the phosphate, which lacks strong competing nucleobase binding sites besides the 1,2-GG motif, was selected as a test system for maximisation of the product yield. The protected pentamer was obtained *via* routine automated DNA synthesis using controlled-pore glass (CPG) as the solid support. The platination of this immobilised pentamer by $[Pt(en)]^{2+}$ to form the 1,2-GG adduct was investigated. Platination experiments were performed under various conditions. Anion-exchange analysis on the platinated and deprotected sequence reveals that only 50–60% platinated pentanucleotide was obtained in this heterogeneous $[Pt(en)]^{2+}$/oligo-support system (data not shown). To increase the yield of platinated oligonucleotide, an alternative approach was followed (see Scheme 1) in which the oligonucleotide was cleaved from the support leaving the isobutyryl groups at the N2 position of the guanines intact.§ Subsequent platination of the base-protected pentamer by $[Pt(en)Cl(H_2O)]^+$, followed by removal of 2-*N*-Bu^i groups by aminolysis, provided a platination efficiency which was nearly quantitative. This can be attributed to both the homogeneity of this system, and loss of β-cyanoethyl phosphate protection (by the ammonia treatment) affording a negatively-charged backbone, thus allowing nucleophilic attack by the N7 and also electrostatic interaction between Pt and the target, as well as an increased hydrophilicity. Moreover, the observed stability of the [Pt(en){d(TTGGT)-N7(3),N7(4)}] adduct under prolonged ammonia exposure allows the use of more base-stable protecting groups like DPA and Bu^i at N2 within this, protective-group forced, platination strategy.

In summary, a promising new synthetic strategy utilising G building blocks with O6 protecting groups to prevent platination and G building blocks bearing amidine and acyl type N2 protection at the predetermined site for the bifunctional Pt-lesion has been presented. The general applicability of our approach to the synthesis of site-specifically platinated oligonucleotides is currently under investigation.

The authors wish to thank Professor Dr B. Lippert, Fachbereich Chemie Universität Dortmund, Germany, for scientific contributions and helpful discussions on the manuscript. This work was performed in the frame of the BIOMED project BMHA-CT97-2485. The authors wish to thank Johnson & Matthey (Reading, UK) for their generous loan of K_2PtCl_4.

Notes and references

† [Pt(dien)Cl]Cl, $[Pt(en)Cl_2]$ and *trans*-$[Pt(NH_3)_2Cl_2]$ were synthesized according to literature procedures, (ref. 10); the latter two were converted into the reactive species $[Pt(en)Cl(DMF)]NO_3$ and *trans*-$[Pt(NH_3)_2Cl(DMF\text{-}d_7)]BF_4$ by treatment with 1 equiv. of $AgNO_3$ or $AgBF_4$, respectively, in DMF and DMF-d_7. The protected mononucleosides **1a** and **1b** and 2-*N*-(isobutyryl)-2′-deoxyguanosine were synthesized according to procedures adapted from the literature (ref. 8), 6-*O*-protected nucleoside **2** was synthesized by a procedure analogous to Robbins *et al.* (ref. 9). ^{1}H and ^{195}Pt NMR measurements were performed on a Bruker WM 300 spectrometer. Internal calibration was based on the methyl groups of DMF in the case of ^{1}H NMR measurements and externally on K_2PtCl_6 for ^{195}Pt NMR measurements. Platination reactions of the protected mononucleosides and [Pt(dien)Cl]Cl were performed at a 4 mM concentration of both reactants in a DMF-d_7–D_2O mixture (80 : 20 v/v) at 37 °C. Calculations were performed by relative integration (estimated error 10%) of H8 and H1′ proton signals of both reaction products and starting materials during the reaction.

‡ Reaction of 2-*N*-(isobutyryl)-2′-deoxyguanosine at 4 mM concentration with 1.1 equiv. of *trans*-$[Pt(NH_3)_2Cl(DMF\text{-}d_7)]BF_4$ in DMF-d_7 showed a downfield shift of the H8 proton from δ 8.29 to δ 9.01 and from δ 6.30 to δ 6.38 for the H1′ proton.

§ The model oligonucleotide d(TTGGT) was assembled using an automated Gene Assembler (Pharmacia). Stepwise elongation of thymidine, immobilized by a 3′-*O*-succinyl bond to controlled pore glass (CPG), was carried out using standard synthesis protocols. The immobilised pentamer was washed thoroughly with MeCN and dried *in vacuo*. Cleavage conditions, for removal of the protected oligonucleotide from CPG matrix (*i.e.* hydrolysis of the succinyl linker) by treatment with NH_3–H_2O (25%) at room temperature, were established by analytical reversed phase HPLC (Lichrosphere® C_{18} column, starting buffer of 5% MeCN in TEAA (pH 7), 100 mM, to 75% MeCN in Et_4NOAc buffer). Deprotected species started to appear upon exposure times exceeding 20 min. For platination experiments a 1 mM stock solution of protected pentamer in H_2O was prepared and used immediately in reactions with $[Pt(en)Cl(H_2O)]NO_3$ (0.5 mM at pH 6.0). After reaction was allowed to proceed for 16 h at 50 °C, excess NH_3–H_2O (25%) was added and deprotection performed for 16 h at 50 °C, the reaction mixture was concentrated *in vacuo* and redissolved for analysis by anion exchange FPLC (APB MonoQ® HR 5/5 column, gradient from starting eluent 0.01 M NaOH to 1.2 M NaCl in 0.01 M NaOH).

Synthesis and X-ray structure of $[(THF)K(C_5H_4CH_2CH_2PPh_2)]_\infty$: a structurally characterized heavier alkali metal phosphane complex

Hans H. Karsch,* Volker W. Graf and Manfred Reisky

Anorganisch-chemisches Institut der Technischen Universität München, Lichtenbergstr. 4, D-85747 Garching, Germany. E-mail: Hans.H.Karsch@lrz.tu-muenchen.de

Received (in Cambridge, UK) 12th March 1999, Revised manuscript received 12th July, Accepted 26th July 1999

Reaction of spiro[2.4]hepta-4,6-diene with $KPPh_2$ in THF gives $K(C_5H_4CH_2CH_2PPh_2)$ 1, which crystallizes from THF and shows coordination of a neutral phosphane functionality to potassium.

Stable complexes with phosphorus to alkali metal bonds are obtained with anionic phosphane type ligands like phosphanides {*e.g.* $[KPHMes^*]_\infty$,[1] $[K_3(THF)\{PH(Mes)\}_3]_\infty$,[2] $[K(THF)P(SiMe_3)_2]$[3]}. In these complexes phosphorus is of the σ^2, λ^3-type. So far there is no example for coordination of a neutral phosphane (σ^3, λ^3) to a heavier alkali metal center (K, Rb, Cs)[4] with one remarkable exception: In $[\{(Bu^tP)_2H\}K\bullet pmdeta]_2$ (pmdeta = *N*,*N*,*N*′,*N*′,*N*″-pentamethyldiethylenetriamine), a 'secondary coordinative interaction' of the neutral phosphorus to potassium is defined, containing a long K–P interaction of 3.658 (3) Å. This phosphorus is directly attached to a neighbouring phosphanide P-atom,[5] formally introducing the negative charge on the ligand. This resembles the situation in phosphanomethanides, where a carbanion enhances the donor capacity of the adjacent neutral phosphorus atom to an extent, that a variety of phosphane complexes including very electropositive metals (alkali, alkaline earth, lanthanide metals) have successfully been synthesized.[6]

In contrast, in alkyl substituted cyclopentadienyl ligands with an additional phosphane functionality in the side chain ('anionic phosphane ligands') the negative charge is well separated from the phosphane donor functionality. Nevertheless these anionic ligands likewise bind to electropositive metal centers. Remarkable results have been obtained in the field of lanthanide chemistry.[7]

The additional phosphane functionality, in contrast to 'simple' cyclopentadienyl derivatives, provides a labile and hence reversible coordination to metal centers, thus combining coordinative 'protection' with enhanced reactivity and therefore is of great interest for catalytic reactions, particularly when combined with transition or lanthanide metal centers. Lithium derivatives[7,8*a*] have been used to transfer the anionic phosphanoalkyl cyclopentadienide moiety to these metals,[7] but derivatives of the heavier alkali metals often have advantages in salt separation from the reaction mixtures.

We report here the synthesis and the solid state structure of $[(THF)K(C_5H_4CH_2CH_2PPh_2)]_\infty$ **1**, the first molecular example exhibiting a coordinative interaction of a neutral phosphane donor with a heavier organo alkali metal center.

Phosphanoethyl substituted cyclopentadienides $\{M[C_5H_4(CH_2)_2PR_2]$, M = Li, Na,} are best prepared by reaction of the corresponding phosphanide with spiro[2.4]hepta-4,6-diene.[8] Anionic lithium and sodium compounds with R = Ph, Pr^i, Bu^t,[8] Me[7] are known, but not structurally characterized. The complex $K[C_5H_4(CH_2)_2PPh_2]$† was synthesized by reaction of spiro[2.4]hepta-4,6-diene with $KPPh_2$ in THF (Scheme 1).

Scheme 1

In the $^{31}P\{^1H\}$ NMR spectrum (dioxane-d^8) only one singlet at δ −13.27 is detected. The signal remains unchanged upon varying the temperature. This result indicates that the compound is not involved in dynamic processes but there is no indication of the actual species present in solution. In particular, the kind of ligation around potassium and the degree of association remains unknown.

The crystal structure‡ of $[(THF)K(C_5H_4CH_2CH_2PPh_2)]_\infty$ consists of polymeric zigzag chains [Fig. 1(a)] as, for example, in CpK,[9] $CpK\bullet Et_2O$,[10] $Cp^*K\bullet 2Py$[11] and $(C_5H_4SiMe_3)K$.[12]

The potassium atom is surrounded by two cyclopentadienyl rings in an η^5 fashion. The $K–Cp_{center}$ distances are 2.821(2) (intramolecular) and 2.792(2) Å ($K\text{-}Cp_{center}$ distance to the next molecule) [Fig. 1(b)], *i.e.* the 'intermolecular' distance is shorter than the 'intramolecular' one. Therefore, the ligand $CpCH_2CH_2PPh_2^-$ can be regarded a bridging rather than a chelating ligand.

These values can be compared with the $K–Cp_{center}$ distance in the coordination polymers of KCp [mean 2.816(3) Å][9] and

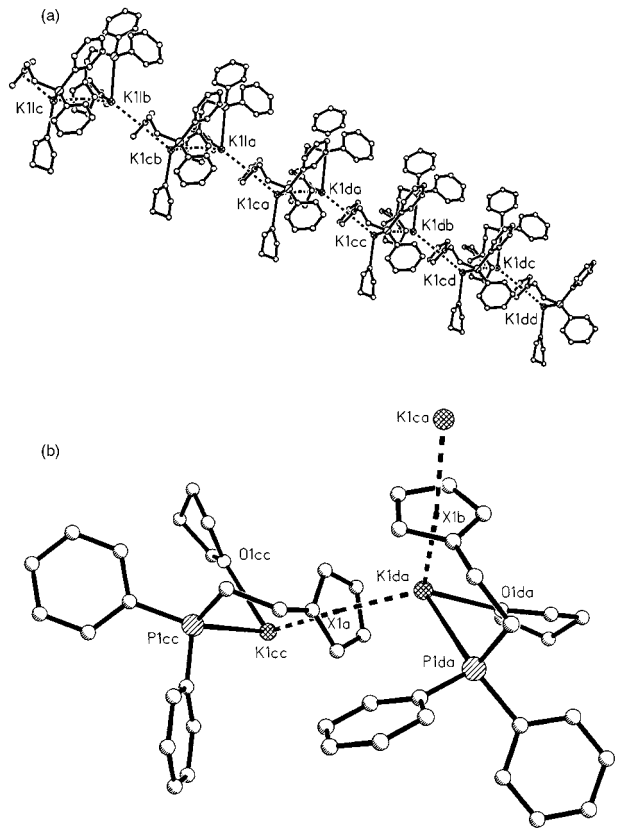

Fig. 1 Structure of $[(THF)K(C_5H_4CH_2CH_2PPh_2)]_\infty$ **1** (a) Polymer chain; (b) detail of the structure. Selected bond lengths (Å) and angles (°):K1da–P1da 3.320(2), K1da–O1da 2.708(2), K1da–X1a 2.792(2), K1da–X1b 2.821(2); P1d–K1da–O1da 88.75(4), P1d–K1da–X1a 123.90(5), O1da–K1da–X1a 109.32(4), O1da–K1da–X1b 126.7(6), K1da–X1a–K1cc 173.10(4); X: centroids of the Cp-rings.

KCp*•2Py (mean 2.79 Å).[11] An unique feature of the solid state structure is the additional P–K bond due to an intramolecular coordination of the alkyl phosphano functionality. The P–K distance of 3.320(2) Å is only slightly longer than in the phosphanide compounds $[Bu^t_2SiFK(THF)_2PC_6H_2Me_3]_2$[13] [3.230(1)], $[K_3(THF)_2\{PH(Mes)\}_3]_\infty$[2] [3.368(1), 3.397(1), 3.453(1), 3.306(2) Å], $[\{(Bu^tP)_2H\}K•pmdeta]_2$[5] [3.251(2) Å], $[KPH(2,4,6\text{-}Bu^t_3C_6H_2]_\infty$[2] [shortest distance 3.271(2), longest distance 3.357(2) Å] and $[K(THF)P(SiMe_3)_2]_\infty$[3] [3.317(7) Å], but considerably shorter (0.332 Å) than the only other K–P distance involving a neutral phosphane donor as mentioned earlier[5].

In **1** the K–Cp_{center}–K angle is 173.1(4)° and the Cp_{center}–K–Cp_{center} angle amounts to 126.7°. To complete the coordination sphere one molecule of THF is coordinated to potassium. The K–O distance of 2.708(2) Å lies in the expected range for a K–O interaction {2.781(2) in $[K(THF)P(SiMe_3)_2]_\infty$}.[3]

The first organopotassium compound with an additional potassium–phosphorus bond presented here establishes the first example of a potassium to phosphorus bond exhibiting a 'normal' bond length and involving a neutral phosphane donor and is the first structurally characterized alkali metal cyclopentadienide with a phosphanoalkyl side chain. All other known molecules with potassium phosphorus bonds contain phosphanide ligands. Particularly noteworthy is the fact that the potassium–phosphorus bond is formed even on precipitation from THF solution, *i.e.* this bonding can successfully compete with a potassium–THF interaction. As in many other K–Cp compounds a polymeric zigzag chain of alternating cyclopentadienyl groups and potassium atoms is adopted in the solid state structure of **1**.

Notes and references

† To a solution of 0.041 mol (9.1 g) $KPPh_2$ in 150 ml of THF 0.041 mol (3.59 g) spiro[2.4]hepta-4,6-diene in 20 ml of THF were added by means of a pipette. After stirring the reaction mixture for 12 h at room temperature the solvent was removed and the product was washed three times with pentane. After drying the residue, 8.9 g (68%) of a colorless solid were obtained. Decomp. 181 °C; correct elemental analysis.

Received (in Cambridge, UK) 30th June 1999, Accepted 23rd July 1999

A novel method has been developed to modify the surface properties of boron-doped CVD diamond electrodes by electron stimulated desorption (ESD) of hydrogen and oxygen from as grown diamond surfaces allowing the selective electrochemical silver deposition on the areas not irradiated with electrons.

Boron-doped CVD diamond is a very promising material in areas such as electrochemistry and electronics owing to very useful properties, such as extreme hardness, chemical inertness, very high electrical and heat conductivity and negative electron affinity (NEA) when hydrogen terminated. In this study, results are presented on the effect of the electron stimulated desorption of hydrogen and oxygen from boron-doped diamond surfaces on the electrochemical characteristics, monitored by the silver deposition on areas irradiated and not irradiated with high energy electrons in a scanning electron microscope (SEM). A correlation between changes in electron affinity and electrochemical activity is observed.

Highly conductive boron-doped diamond films were deposited on 5 mm diameter tungsten substrates from a gaseous feed of diborane and 1% methane in hydrogen using a hot filament assisted CVD reactor as described previously.[1] The boron-doped diamond surface was irradiated by an electron beam of an energy ranging from 1 to 25 keV and a current density ranging from *ca.* 93 mA cm^{-2} to 60 A cm^{-2} at a background pressure of *ca.* 10^{-6} mbar at room temperature. SEM images of treated and untreated areas after electrochemical deposition of silver on the surface of the boron-doped diamond are presented in Fig. 1. An interesting feature shown in the SEM images is the well defined dark irradiated area in contrast to the much brighter surroundings. In a XPS study, Cui *et al.*[2] reported electron beam stimulated desorption of hydrogen from single crystal diamond (111) surfaces. They showed that H-terminated diamond has a negative electron affinity (NEA) of $\chi = -1.27$ eV and that electron irradiation desorbed the terminal hydrogen as a function of time giving the diamond surface a positive electron affinity of $\chi = +0.4$ eV (less brightness in SEM images) without graphitising the surface. NEA materials such as hydrogenated diamond when irradiated with energetic electrons, exhibit very high secondary electron emission.[3] Hence, the darker feature shown on the SEM image can be attributed to lower secondary electron emission and is therefore indicative of a hydrogen depleted diamond surface. Interestingly, in the backscatter mode no shading is observed. The backscatter electrons have much higher energy than secondary electrons and so are insensitive to the energy barrier which exists at the surface. This is consistent with a surface modification involving a change in χ.

Based on the work by Cui *et al.*[2] it is proposed that the electron beam irradiation desorbs hydrogen from a well defined area with a resolution approximating that of the electron beam (*ca.* 0.5 nm) from the hydrogen terminated diamond surface. Energy dispersive X-ray spectrometry (EDX) was performed in order to estimate the oxygen concentration of the irradiated area compared to the surrounding surface. Although EDX is not highly surface sensitive, a comparison clearly indicates that the electron irradiated area, after the silver deposition process, exhibits a very low O/C ratio (O below the signal to noise level) and therefore had practically no oxygen functionalities on the surface. The O/C peak area ratio in the EDX spectrum for the area not irradiated was significantly higher with a value of *ca.* 5%. It can be concluded that the electron beam actively removes hydrogen, oxygen, and probably other impurities from the surface.

In order to study the effect of the electron beam on the electrochemical characteristics of the surface of the boron-doped diamond, silver was deposited electrochemically. Fig. 2 shows cyclic voltammograms for three consecutive potential cycles with a scan rate of 0.1 V s^{-1} for the reduction/oxidation

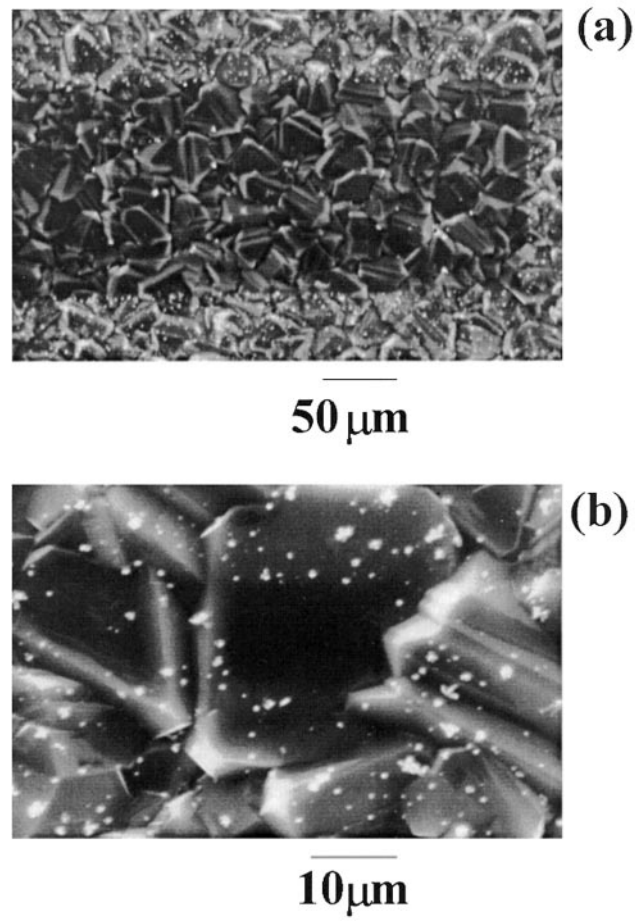

Fig. 1 SEM images of boron-doped diamond electrode surfaces after electrochemical deposition of silver from 1mM $AgNO_3$ in aqueous 0.1 M HNO_3 at a potential of $E = +0.17$ V *vs.* SCE (deposition time 3 min, irradiated with electrons of (a) an energy of 1 keV and a current density of *ca.* 93 mA cm^{-2} for 30 min and (b) an energy of 25 keV and a current density of *ca.* 60 A cm^{-2} for 5 min).

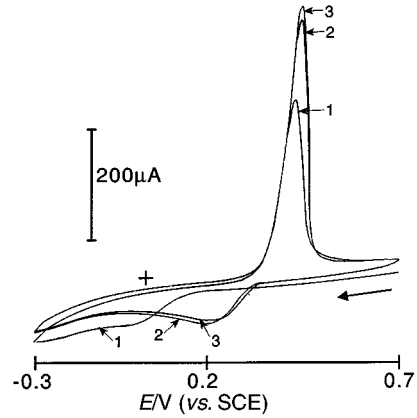

Fig. 2 Three consecutive cyclic voltammograms recorded with a scan rate of 0.1 V s^{-1} for the reduction/oxidation of 1mM $AgNO_3$ in aqueous 0.1 M HNO_3 at a 5 mm diameter boron-doped diamond electrode ('+' indicates zero current).

of 1 mM $AgNO_3$ in aqueous 0.1 M HNO_3 at the surface treated boron-doped diamond electrode. On the first forward scan starting from +0.7 V *vs.* SCE to negative potentials the nucleation process starts at *ca.* 0.0 V *vs.* SCE followed by growth at more negative potentials. On the reverse scan a characteristic stripping response is observed indicative for dissolution of the metallic silver into solution. These observations are in accord with a recent study by Vinokur *et al.*[4] A closer look at the stripping peak reveals an asymmetric tailing indicating that the dissolution is slow and not complete. The second and third scan show a reduction peak at a significantly more positive potential in agreement with silver growth on the silver nuclei already present from the previous scan. The silver remaining on the diamond surface after the stripping process could also be verified by SEM and XPS measurements.[5] This incomplete oxidation of deposits on diamond has been reported for Ag[4,5] and Pb[6,7] but is not yet fully understood.

After recording the cyclic voltammograms, silver was deposited on the electron beam treated diamond surface from a solution of 1 mM $AgNO_3$ in aqueous 0.1 M HNO_3 by applying a potential of $E = +0.17$ V *vs*. SCE [Fig. 1(a) and (b)] and of $E = -0.3$ V *vs*. SCE (not shown) for periods of 3 min. The SEM image clearly shows that there is a high density of silver deposition in the unexposed area while in the darker electron irradiated area hardly any deposition occurred. However, when the deposition potential was set to more negative potentials, silver deposition was detected also in the areas exposed to the electron beam. Fig. 1(b) shows an SEM image which reveals a dark *ca.* 200 μm^2 irradiated area on a single (100) crystallite face without any silver deposition. The selectivity of the electron induced surface modification is such that even single diamond crystallites may be patterned and partly covered with silver. Hydrogenating highly resistive non-doped diamond is known to induce p-type surface conductivity.[8] However, the diamond samples are highly boron-doped making it very conductive and therefore, it can be assumed that the observed effect is a surface effect, and not a localised change in (surface) conductivity. A possibly related patterning effect has been observed after photo-treatment and electro-deposition of copper.[9]

The present study shows that diamond surfaces can be modified selectively and with high spatial resolution using a focussed electron beam and that metallic silver can be selectively deposited on the unexposed diamond surface. It is proposed that electron irradiation desorbs hydrogen, oxygen, and impurities from the as grown diamond surface yielding a surface of more positive electron affinity and lower activity towards silver nucleation and growth. It is widely accepted that oxygen functionalities play an important role in the surface activity of diamond electrodes. The selectivity towards the metal deposition can be improved by optimising the doses of electron irradiation and hence the level of dehydrogenation. Even the surface structure can be manipulated[2] to give hydrogen rich (1×1), hydrogen poor (1×1), hydrogen poor (2×1), or hydrogen free reconstructed (2×1) by controlling the level of dehydrogenation and the electron affinity may be fine tuned between $\chi = -1.27$ eV and +0.40 eV.

In conclusion, the electron stimulated modification of diamond surfaces may offer potential benefits in a wide range of applications, such as selective metal deposition, fabrication of microelectrodes and sensors, cold cathodes, and patterned field emitters.

Received (in Cambridge, UK) 26th May 1999, Accepted 28th July 1999

Metal- and ligand-based luminescence, absorption and circular dichroism difference spectroscopy signal the extent and nature of binding of enantiopure Δ and Λ cationic lanthanide complexes to $[(CG)_6]_2$ and $[(AT)_6]_2$.

Whilst there have been many reports probing the interaction of the aqua lanthanide ions with nucleotides and DNA using NMR[1] and luminescence methods,[2] no studies have appeared in which the binding of well defined chiral lanthanide complexes has been defined. Following the characterisation of the cationic, enantiomeric lanthanide complexes of ligands (*RRR*)-MeL[1a] and (*SSS*)-MeL[1b],[3] we report herein preliminary binding studies with calf-thymus DNA and the oligonucleotides $[(CG)_6]_2$ and $[(AT)_6]_2$.† These lanthanide complexes possess complementary properties allowing their interaction with chiral polyanions to be studied, including the absorption and fluorescence emission behaviour of the phenanthridinium unit and the intensity, polarisation and lifetime of the lanthanide emission.[4]

The absorption spectrum of each complex was monitored as a function of added oligonucleotide or DNA, at pH 7.4 in low added salt (Fig. 1 and Table 1). For the complexes with $[(CG)_6]_2$ and calf thymus (CT)-DNA isosbestic points were observed at 302 and 378 nm, with pronounced hypochromism in the bands at 320 and 370 nm and a red-shift, accompanied by formation of a long wavelength tail beyond 400 nm. For complexes with $[(AT)_6]_2$, changes in intensity were much smaller and the long wavelength tail and isosbestic point at 378 nm were absent. The observed hypochromism and concomitant red shifts are often associated with intercalative binding,[5] and are consistent here with a preferred charge transfer interaction involving the more electron-rich C and G bases and the positively-charged phenanthridinium unit.

The fluorescence of the *N*-alkylphenanthridinium moiety was monitored at 408 nm, as a function of added DNA, following excitation at the isosbestic point. Quenching of fluorescence was observed, as is often found when planar aromatic fluorophores bind to DNA, arising from charge transfer-catalysed non-radiative deactivation of the singlet excited state. Quenching of the long-lived europium emission (*e.g.* at 594 nm) was also observed and mirrored the decrease in the fluorescence intensity. No significant change in the lifetime of the metal emission was observed, from its value of 0.55 ms in water in the absence of DNA,[4] ruling out any direct quenching of the metal excited state by photoinduced electron transfer from the DNA bases.

Intrinsic binding constants, *K*, and site sizes *n*′ (per mole of duplex) were estimated using the method of McGhee and von Hippel[6] (Table 1). Values obtained for the model intercalators ethidium bromide and *N*-ethylphenanthridinium iodide were measured under the same conditions. Strongest binding of the Eu complexes was observed to $[(CG)_6]_2$ with one complex bound per three base pairs on average, and the Δ isomer bound slightly more strongly than the Λ. With Δ-$[EuL^{1a}]^{4+}$, binding affinity to $[(AT)_6]_2$ was over 50 times weaker than to $[(CG)_6]_2$ (with a reduced site density, suggestive of a weaker intercalative interaction) , and in this case the Λ isomer bound more strongly ($\Delta\Delta G$ = 4 kJ mol^{-1}). The effect of increasing the salt concentration (10, 50 and 100 mM NaCl) was also examined for

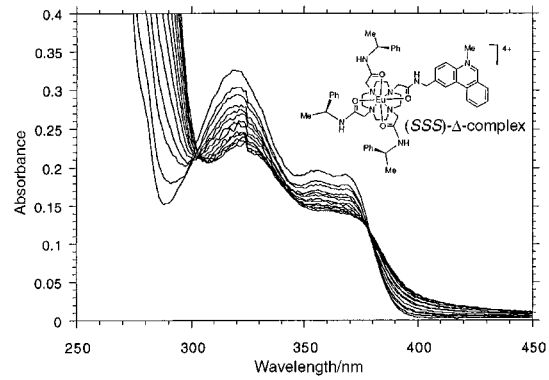

Fig. 1 UV-absorbance spectra for (*SSS*)-Δ-$[Eu(MeL^{1b})]^{4+}$ (23.6 μM) upon addition of increasing concentrations of $[CG)_6]_2$ (0–12.9 μM) in buffered aqueous solution (HEPES 10 mM, pH 7.4, NaCl 10 mM, 293 K).

Table 1 Intrinsic binding constants (*K*), site sizes (*n*′) and degree of hypochromism measured for complexes of $[(CG)_6]_2$ and $[(AT)_6]_2$ with Δ$[LnL^{1a}]^{4+}$ and Λ$[LnL^{1b}]^{4+}$ (298 K, 10 mM HEPES pH 7.4, 10 mM NaCl)

Complex	10^{-5} K^a/dm^3 mol^{-1} duplex^{-1}	n'^a/(duplex)$^{-1}$	% hypochromism at 320 (370) nm
Δ-$[EuL^{1a}]^{4+}$/$[(CG)_6)]_2$	87	3.98	35 (27)[c]
Λ-$[EuL^{1b}]^{4+}$/$[(CG)_6]_2$[b]	36	3.96	33 (28)[c]
Δ-$[EuL^{1a}]^{4+}$/$[(AT)_6]_2$	1.6	1.52	13 (10)
Λ-$[EuL^{1b}]^{4+}$/$[(AT)_6]_2$	8.0	1.82	15 (12)
N-ethylphenanthridinium iodide/$[(AT)_6]_2$	< 0.3	n.d.	11 (10)
ethidium bromide/$[(CG)_6)]_2$	31	2.26	n.a.
N-ethylphenanthridinium iodide/$[(CG)_6)]_2$	6.8	3.88	32 (10)

[a] Typically [LnL] = 10–20 μM; data from luminescence intensity changes[d] with added oligonucleotide were analysed by the method of McGhee and von Hippel;[6] an approximate analysis of the more limited CD data gave similar values. [b] In 50 mM NaCl, $K = 7.2 \times 10^5$ and $n' = 2.0$ and in 100 mM NaCl, $K = 2.8 \times 10^5$ ($n' = 1.9$). [c] Very similar spectra were observed for Δ/Λ-Eu complexes binding to calf-thymus DNA (42% CG). [d] Limiting changes in fluorescence intensity ratio (I_{free}/I_{bound}) were 55 for Δ-Eu/$[(CG)_6]_2$ and 2 for Λ-Eu/$[(AT)_6]_2$.

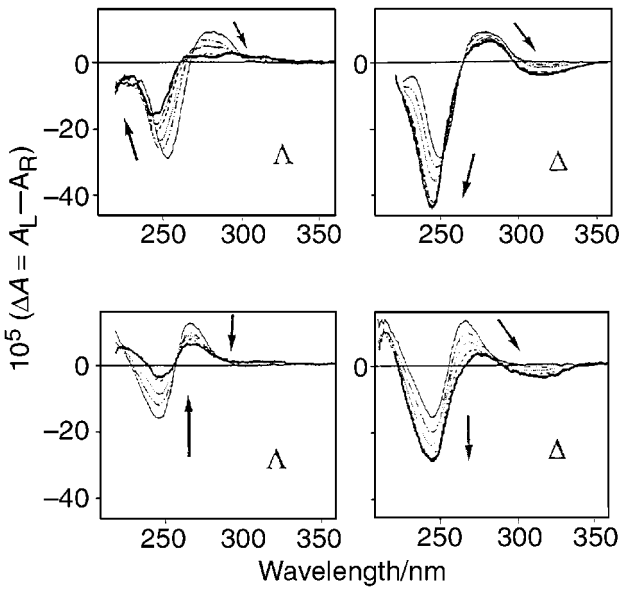

Fig. 2 Near-UV region CD spectrum of $[(CG)_6]_2$ (upper) and $[(AT)_6]_2$ (lower) in buffered aqueous. solution (10 mM HEPES, NaCl 10 mM) and in the presence of increasing ratios of Λ(0, 0.50, 0.99, 1.96, 2.91, 4.76, 7.41) and Δ-$[EuL^1]^{4+}$ (0, 0.49, 0.97, 1.92, 2.86, 3.77, 4.67) (left and right respectively). In each case, the CD spectrum of the complex itself at the same concentration has been subtracted.

Λ-$[EuL^{1b}]^{4+}$ /$[(CG)_6]_2$: only modest reductions in overall affinity were found (Table 1), ruling out the possibility of a predominantly electrostatic binding interaction.

The interaction of the europium complexes with the oligonucleotides has also been examined by circular dichroism difference spectroscopy, adding the complex to a fixed concentration of the oligonucleotide. In the near-UV region, the CD spectra of $[(CG)_6]_2$ and $[(AT)_6]_2$ show the features characteristic of *B*-DNA;[7] these gross features persisted even after addition of a substantial excess of the Eu complexes (Fig. 2) ruling out the $B \rightarrow Z$ transition which can occur in the presence of a highly charged metal complex.[2] In the 220–260 and 290–340 nm regions, the CD changes for a given oligonucleotide were markedly dependent upon the chirality of the complex, and changed in the opposite sense for each pair of diastereoisomeric complexes. In particular, in the 290–340 nm region, the observed changes for the Λ isomer titration were at least 50% less than those for the Δ isomer. Control experiments, examining CD difference spectra following addition of the tripositive C_4 symmetric parent complexes (*i.e.* lacking the phenanthridinium moiety) to $[(CG)_6]_6$ and $[(AT)_6]_2$, revealed only *very* small changes in ellipticity (< 6% of the change seen with $[EuL^{1a}]^{4+}$). The difference CD spectra obtained with $[EuL^{1a}]^{4+}$ and CT-DNA were almost identical to those obtained with $[(CG)_6]_2$.

In the visible region (Fig. 3), the CD signals arise exclusively from the phenanthridinium chromophore. For the unbound enantiomeric Eu complexes, weak, mirror image CD spectra were observed in this region. Upon binding to both $[(CG)_6]_2$ and to $[(AT)_6,]_2$, a positive induced CD at *ca.* 370 nm was observed for each enantiomer and qualitatively similar changes were noted with increasing oligo concentration. This suggests that the chirality of the oligonucleotide binding site must be similar for both $[(CG)_6]_2$ and $[(AT)_6]_2$ as the induced CD is *independent* of complex handedness.

The stoichiometry of the oligonucleotide–Eu complex binding was further investigated using the method of continuous variation, by plotting the CD intensity at a single wavelength *vs.* the mole fraction of the complex. Discontinuities at 0.5 and 0.67

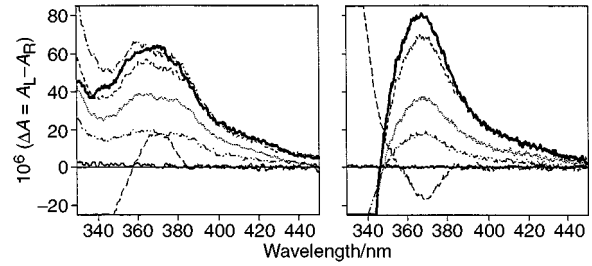

Fig. 3 Visible region CD spectra of $[(CG)_6]_2$ in the presence of increasing ratios of the Λ (left) and Δ (right) enantiomers of the Eu complex (Λ ratios shown are 0.50, 0.99, 1.96, 2.81 and 7.1; Δ: 0.49, 0.98, 1.92, 2.83), showing the long wavelength region where signals arise only from the phenanthridinium group. The CD spectrum of the complex at the same concentration has been subtracted in each case; spectra of the complexes in the absence of DNA are shown for reference (---------).

were found, consistent with stepwise formation of 1:1 and 2:1 complexes for both $[(AT)_6]_2$ and $[(CG)_6]_2$ binding.

In conclusion, the absorbance and fluorescence changes of the phenanthridinium moiety upon binding to $[(CG)_6]_2$ and CT-DNA, together with the relatively weak induced CD at 370 nm, are all consistent with a binding interaction predominantly involving intercalation. Binding to $[(AT)_6]_2$ is over 50 times weaker with Δ-$[EuL^{1a}]^{4+}$ and any intercalation is much less pronounced; the very similar spectral (CD, absorbance) changes observed with CT-DNA (42% CG) accord with this base-pair selectivity. AT-Rich sequences are believed to favour metal complex binding at the minor groove when the handedness of the complex is complementary to that of the right-handed helix.[8] Thus the stereodifferentiation observed in the interaction of the Eu complexes with $[(AT)_6]_2$ could arise from preferential minor-groove binding of the **Λ** isomer.

We thank EPSRC and the National Chiroptical Centre for support and the Royal Society for a Leverhulme Trust Senior Research Fellowship (D. P.).

Received (in Basel, Switzerland) 11th May 1999, Accepted 17th July 1999

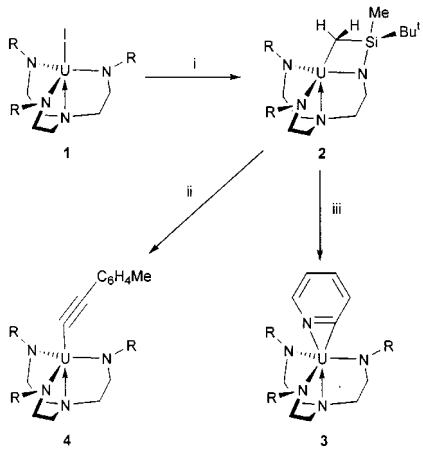
The intramolecular metalation of a β-silyl methyl group in [U{N(CH$_2$CH$_2$NSiMe$_2$Bu^t)$_3$}(CH$_2$Ph)] occurs rapidly, despite the conformational demands of the triamidoamine ligand, to produce a highly strained metallacycle (U–C *ca.* 2.75 Å); this complex reacts cleanly with a range of carbon and other acids to give, for example, an alkynyl with a bent (156°) U–C≡C unit.

Intramolecular C–H activation of ligands is relatively common among early actinide complexes, including those containing bulky alkyls,[1] amides,[2] phosphides[3] and phenoxides.[4] Molecular models suggested that triamidoamine[5] [(RNCH$_2$CH$_2$)$_3$N)]$^{3-}$ complexes of metals with large van der Waals radii would be less prone to such reactions because of conformational restrictions (*vide infra*), and might instead undergo *inter*molecular reactions with hydrocarbons. With this in mind we set out to synthesise species such as [{(RNCH$_2$CH$_2$)$_3$N}MR′] (M = U, Th; R′ = H, alkyl). While we have prepared a wide range of triamidoamine complexes containing bonds between the early actinides and other elements,[6] the synthesis of M–C σ bonds proved troublesome. For example, reactions of the uranium and thorium chlorides [{(RNCH$_2$CH$_2$)$_3$N}MCl] (R = SiMe$_3$) and related compounds with a wide variety of metal alkyls led to the formation of intractable yellow mixtures. More recently however we have shown that the bulkier triamidoamine (where R = SiMe$_2$Bu^t, henceforth NN′$_3$), forms much more synthetically useful complexes with the f elements.[7,8] Use of this ligand has allowed us to isolate an extremely reactive and structurally fascinating metallacyclic uranium complex which is an excellent starting material for the synthesis of other organometallic compounds.

Treatment of [U(NN′$_3$)I][7] **1** with a stoichiometric amount of lithium or potassium alkyl in pentane afforded brown solutions from which extremely air-sensitive orange–brown crystals of **2** were isolated by filtration and cooling to −30 °C (Scheme 1). This product was the same irrespective of the alkylating agent used, although optimum yields (71% isolated) were obtained by use of lithium neopentyl or potassium benzyl in toluene. When this latter reaction was performed in an NMR tube and monitored by ^{1}H NMR spectroscopy, smooth and quantitative conversion of **1** to **2** with co-production of toluene was observed within minutes at ambient temperature. Interestingly, the presumed intermediate species [U(NN′$_3$)CH$_2$Ph] immediately decomposed to the metallacycle **2** and was not detected. The rapidity of this reaction is quite surprising; by comparison, conversion of the titanium[9] and molybdenum[10] triamidoamines [{(Me$_3$SiNCH$_2$CH$_2$)$_3$N}TiBu^s] and [{(Me$_3$SiNCH$_2$CH$_2$)$_3$N}MoH] to their respective metallacycles occurs only slowly and at elevated temperatures. Similarly, Andersen's metallacycle [U{N(SiMe$_3$)$_2$}$_2${N(SiMe$_3$)(CH$_2$SiMe$_2$)}] is produced by thermolysis of [U{N(SiMe$_3$)$_2$}$_3$X] (X = H, Me).[2]

Single crystals of **2** were grown from a saturated solution of the pure compound in pentane and the molecular structure (Fig. 1) was determined by X-ray crystallography.† The U–C(108) distance of 2.752(11) Å is significantly longer than any other U–C σ-bond hitherto recorded; the usual range is *ca.* 2.4–2.55 Å,[12] although distances of *ca.* 2.60 Å have been measured in complexes of chelating phosphorus ylids.[13] The metallacyclic phosphide [Cp*$_2$U(CH$_2$SiMe$_2$PSiMe$_3$)][3] and amide [Cp*$_2$Th$_2$(CF$_3$SO$_3$)$_3$(NSiMe$_3$)(CH$_2$SiMe$_2$NSiMe$_3$)][14] contain M–C–Si–N rings similar to that in **2** but the M–C distances of 2.415(20) and 2.43(5) Å are well within the range observed for their acyclic counterparts. Schrock's (triamidoamine)molybdenum metallacycle[10] adopts a similar conformation to **2**, but the Mo–C bond is only *ca.* 0.08 Å longer than those in acyclic alkyls.

An important feature of the structure of **2** is the orientation of the SiMe$_2$ groups at Si(12) and Si(13) which bring one methyl group from each, C(114) and C(119), toward the otherwise open face of the uranium centre. The non-bonded U–C distances of 3.056(14) and 3.218(10) Å, respectively, are consistent with the presence of C–H→U agostic interactions.[15] The maximum deviations of any atom from the least-squares planes [U, N(12), Si(12), C(114)], [U, N(13), Si(13), C(119)] and [U, N(11), Si(11), C(108)] are 0.08, 0.05 and 0.06 Å respectively.



Scheme 1 Synthesis of complexes **2**–**4**. *Reagents and isolated yields*: i, KPh, toluene, 71%; ii, *p*-methylphenylacetylene, pentane, 80%; iii, pyridine, pentane, recrystallisation from hexamethyldisiloxane, 80%.

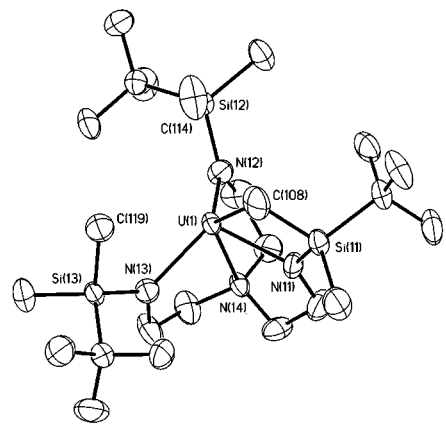


Fig. 1 Thermal ellipsoid plot of the molecular structure of **2**; hydrogen atoms omitted.

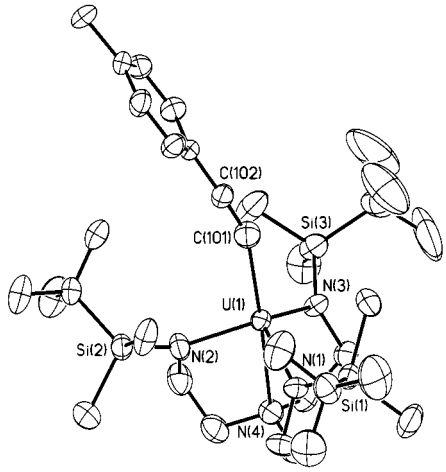

Fig. 2 Thermal ellipsoid plot of the molecular structure of **4**; hydrogen atoms omitted.

The ^{1}H NMR spectrum of **2** recorded in d_8-toluene contains a total of 22 peaks indicating that the product is chiral. Of these, 20 peaks are readily assigned to methyl and *tert*-butyl groups or diastereotopic methylene protons in the ligand backbone. Relatively broad peaks, at δ −35.34 and −52.34 are assigned to the Si–CH_2–U group on the basis of a selective deuteration study.‡ Other spectroscopic and analytical data are also in accord with the structure proposed for **2**.

The metallacycles [{$(Me_3Si)_2N$}$_2$M{$N(SiMe_3)(SiMe_2CH_2)$}] (M = U, Th) have been used extensively as starting materials for a wide range of complexes.[16] Accordingly, we have found that **2** reacts cleanly with acids HX under very mild conditions to form a range of U–X bonds with concomitant regeneration of the symmetric triamidoamine framework.

Reactions of **2** with trimethylamine hydrochloride, diethylamine and Bu^{t}OH give the complexes [(NN_3')UCl], [(NN_3')U(NEt_2)][7] and [(NN_3')U(OBu^t)][17] in essentially quantitative yields. Similarly, reaction of **2** with pyridine proceeds rapidly at room temperature to give the brown crystalline η^2-pyridyl complex **3** and *p*-methylphenylacetylene gives the yellow–green alkynyl [$(NN_3')(\eta^1$-C≡CC_6H_4Me)] **4**.

The molecular structure of **4** is shown in Fig. 2. The angle U–C(101)–C(102) of 156.4(6)° is significantly lower than the range found for the few structurally characterised non-bridging alkynyls of the f elements (170–176°).[18] Perhaps the alkynyl uranium fragment in **4** bends in order to allow for increased U–C π-overlap. We are currently investigating this and other related phenomena.

Hence, although the conformational constraints of the triamidoamine ligand do not prevent intramolecular C–H activation of the somewhat acidic β-silyl methyl groups in [U(NN'_3)R], the metallacycle **2** thus formed is an excellent starting material for the generation of a range of highly crystalline organometallic complexes of uranium.

P. S. wishes to thank EPSRC for a Project Studentship and SmithKline Beecham for a CASE award (to C. J. S.), Pfizer (UK) Ltd for a CASE award to I. J. M., Universitá degli Studi di Ferrara for support of R. B., and BNFL for both a CASE award (to P. R.) and postdoctoral fellowship (to A. J. K.). We thank EPSRC and Siemens Analytical Instruments for grants in support of the diffractometer.

Received (in Cambridge, UK) 9th July 1999, Accepted 29th July 1999

The Lewis acidities of five series of lanthanoid(III) compounds are evaluated based on their competitive dissociation observed by tandem mass spectrometry.

The reactivity of lanthanoid compounds is of considerable interest in synthetic organic chemistry and has been studied for the past two decades.[1,2] Although mass spectrometry has been used mainly for organic structure elucidation,[3] tandem mass spectrometry has been applied recently to evaluate the reactivities of organic compounds.[4] Here, we use this method for the investigation of reactivities of lanthanoid compounds.

Trivalent lanthanoid compounds such as $CeCl_3$, $Yb(OTf)_3$ and $Sc(OTf)_3$ are frequently employed as reagents or catalysts, which owing to their high Lewis acidities, interact with carbonyl or imine functionalities in organic compounds.[1,2,5–9] The intrinsic chemical properties of lanthanoid compounds, however, including their reactivity, still remains unclear. A quantitative evaluation of their Lewis acidities is essential for the development of new reagents and catalysts, as well as for a comprehensive understanding of their reactivities. Herein, we report a direct method for the evaluation of the Lewis acidities of lanthanoid compounds by the use of tandem mass spectrometry (MS).[10]

We have observed an extremely reproducible fragmentation of precursor ions derived from a series of lanthanoid(III) triflate complexes, using collision-activated decomposition (CAD) in tandem MS. Moreover, the intensity ratio of the ion due to the loss of the triflate group to that from the loss of a coordinating ligand such as hexamethylphosphoramide (Fig. 1), shows significant differences among the lanthanoid(III) compounds studied. This suggested to us that the stability of these product ions directly reflects the electronic properties of each central element a view strongly supported by recent kinetic studies using MS for thermochemical measurements.[4,11]

A total of 48 compounds consisting of three series of lanthanoid complexes, $M(OTf)_3(hmpa)_4$ (hmpa = hexamethylphosphoramide), $M(OTf)_3(tepo)_4$ (tepo = triethylphosphine oxide) and $M(OTf)_3(tmp)_4$ (tmp = trimethyl phosphate), (M = Sc, Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb or Lu) were synthesized. The tandem MS measurements were performed with four-sector (EB/EB) equipment, JMS-700T (JEOL), using Xe as the collision gas with a variable collision cell voltage of 0.5–3.0 kV. FAB with NBA as a matrix was used for ionization.

In all hmpa complexes, the fragment ion $[M(OTf)_2(hmpa)_2]^+$ is the base peak. This ion was selected as the parent ion for the CAD experiments. The FAB MS fragment ion spectrum of $[Er(OTf)_2(hmpa)_2]^+$ is shown in Fig. 2 as a representative example. In this fragment ion spectrum, we focused our attention on $[ErF(OTf)(hmpa)_2]^+$ and $[Er(OTf)_2(hmpa)]^+$, obtained by loss of OTf and hmpa, respectively. The logarithmic ratio of the ion intensities, $\ln\{[MF(OTf)(hmpa)_2]^+/[M(OTf)_2(hmpa)]^+\}$,† show significant differences with M (Fig. 3).

Upon loss of OTf, a fluoride ion remains attached to the central atom. Retention of fluoride has been ascribed to the strong affinity of Ln(III) for fluoride, and it has been previously reported that the thermal decomposition of $Ln(OTf)_3$ affords LnF_3.[12] The overall fragmentation scheme of the complexes studied involves the competitive loss of (OTf − F), and the loss of a ligand connected to the central atom such as hmpa (see Fig. 2). Any difference in the ratio of the two fragment ions reflects the electronic property of the lanthanide in terms of the affinity between the metal and oxygen or fluorine rather than any steric contribution. Observation of a discontinuity at gadolinium (Fig. 4) as a result of its electronic state also supports this theory. The properties of a given lanthanide, *i.e.* its Lewis acidity, can thus be evaluated using tandem MS.

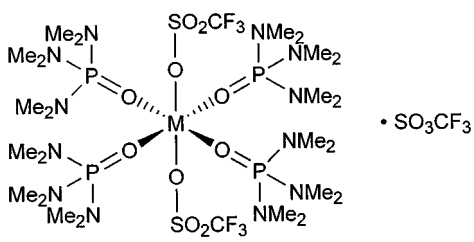

Fig. 1 Chemical structure of $M(OTf)_3(hmpa)_4$.

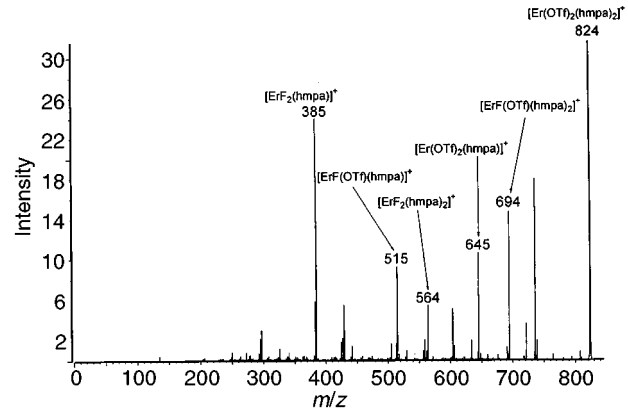

Fig. 2 MS/MS spectrum of $[Er(OTf)_2(hmpa)_2]^+$ (m/z = 824).

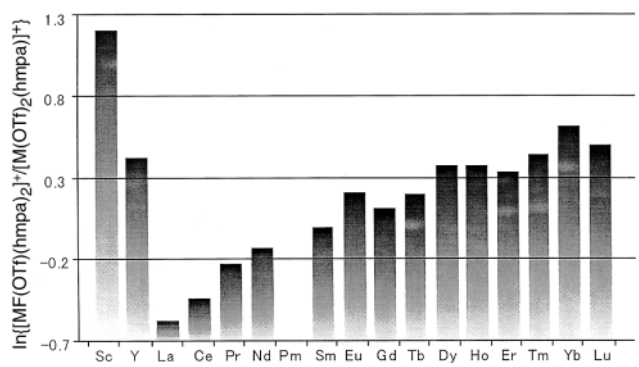

Fig. 3 MS/MS ion peak ratio, $\ln\{[MF(OTf)(hmpa)_2]^+/[M(OTf)_2(hmpa)]^+\}$.

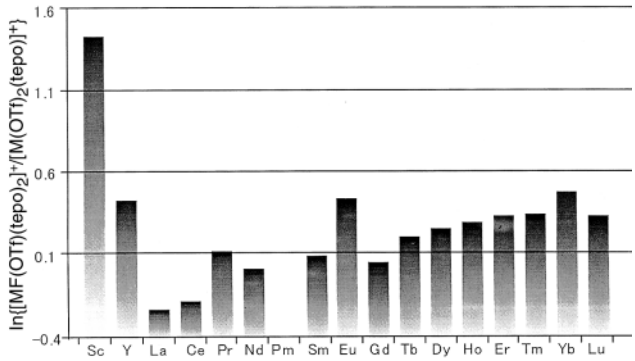

Fig. 4 MS/MS ion peak ratio, ln{[MF(OTf)(tepo)$_2$]$^+$/[M(OTf)$_2$(tepo)]$^+$}.

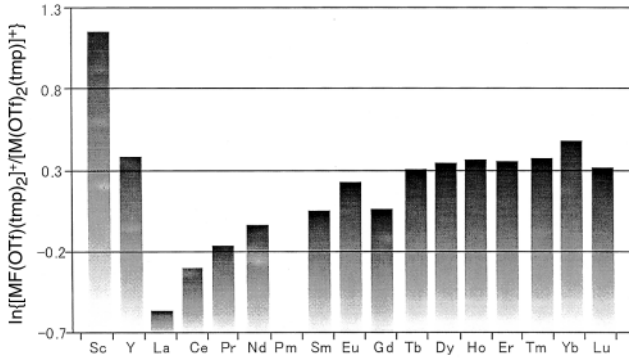

Fig. 5 MS/MS ion peak ratio, ln{[MF(OTf)(tmp)$_2$]$^+$/[M(OTf)$_2$(tmp)]$^+$}.

Two other series of rare earth complexes, M(OTf)$_3$(tepo)$_4$ and M(OTf)$_3$(tmp)$_4$, exhibit similar results. The corresponding intensity ratios for ln{[MF(OTf)(tepo)$_2$]$^+$/[M(OTf)$_2$(tepo)]$^+$} obtained from [M(OTf)$_2$(tepo)$_2$]$^+$ as the parent ion, and for ln{[MF(OTf)(tmp)$_2$]$^+$/[M(OTf)$_2$(tmp)]$^+$} from [M(OTf)$_2$(tmp)$_2$]$^+$ are illustrated in Fig. 4 and 5, respectively.

The oxophilicity of lanthanoids was also observed by the measurement of the competitive loss of OTf and tepo from [M(OTf)$_2$(tepo)$_4$]$^+$ to give [M(OTf)$_2$(tepo)$_3$]$^+$ or [M(OTf)$_2$-(tepo)$_2$]$^+$. The values of ln{[M(OTf)$_2$(tepo)$_3$]$^+$/[M(OTf)$_2$-(tepo)$_2$]$^+$} for the lanthanoid(III) metals were as follows Sc: 1.55, Y: 1.45, La: 1.40, Ce: 1.42, Pr: 1.42, Nd: 1.40, Sm: 1.43, Eu: 1.45, Gd: 1.41, Tb: 1.43, Dy: 1.46, Ho: 1.42, Er: 1.43, Tm: 1.45, Yb: 1.52, Lu: 1.42. Additionally, pure oxophilicity was estimated using [MCl$_2$(tepo)$_3$]$^+$ in which the effect of fluorine is not involved and the values of ln{[MCl$_2$(tepo)$_2$]$^+$/[MCl$_2$(tepo)]$^+$} were as follows: Sc: 2.37, Y: 1.87, La: 1.36, Ce: 1.37, Pr: 1.41, Nd: 1.49, Sm: 1.68, Eu: nd., Gd: 1.72, Tb: 1.76, Dy: 1.80, Ho: 1.84, Er: 1.87, Tm: 1.91, Yb: 2.09, Lu: 1.97.

The data presented in Figs. 3–5 and above, clearly demonstrate that Sc has the largest quotient followed by Yb.[13]† This is consistent with the exceptionally high catalytic activity of both Sc(III) and Yb(III) compounds in many Lewis acid-promoted reactions. Identical results were derived from experiments for complexes of other ligands such as dimethylsulfoxide and dimethylpropyleneurea. The high Lewis acidity of Sc(III) and Yb(III) is mainly ascribed to their small ionic radii. The higher acidity of Yb(III) relative to Lu(III) may originate from an incomplete number of electrons (thirteen) in the 4f orbital which has a tendency to become filled (f^{14}) which renders Yb(III) more electron-attractive than Lu(III). Other important observations of lanthanoid(III) behavior such as the gadolinium break and tetrad effects are also observed in these results.

In summary, using tandem mass spectrometry we have successfully evaluated the relative Lewis acidities of lanthanoid(III) compounds. The application of this methodology to other related compounds is in progress.

Notes and references

† The ratio of the rate constant k_1 (OTf loss) and k_2 (ligand loss) can be determined from the abundance of two product ions, [MF(OTf)(ligand)$_2$]$^+$ and [M(OTf)$_2$(ligand)]$^+$. Therefore, ln(k_1/k_2) gives a measure of the affinity for each central atom. See ref. 4, pp. 378–381.

‡ These facts are consistent with the data obtained from X-ray crystallographic analysis of a series of hmpa-coordinated lanthanoid triflates. The Sc and Yb complexes show relatively long P–O bond lengths towards hmpa. It is reasonable to consider that such P–O bond elongations are due to the relatively strong Lewis acidity of Sc^{3+} and Yb^{3+}.

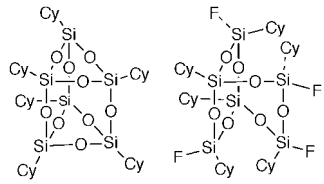
Acid-mediated cleavage and rearrangement of (c-$C_6H_{11})_6Si_6O_9$ 1 by triflic acid (TfOH) and methanesulfonic acid (MsOH) produces good yields of C_2-[(c-$C_6H_{11})_6Si_6O_8X_2$] (4a, X = OTf; 4b, X = MsO), which reacts with water, $LiNMe_2$ and LiC≡CPh to afford C_2-[(c-$C_6H_{11})_6Si_6O_8(OH)_2$] 5, C_2-[(c-$C_6H_{11})_6Si_6O_8(NMe_2)_2$] 8 and C_2-[(c-$C_6H_{11})_6Si_6O_8(CCPh)_2$] 9; silylation of 5 with $ClSiMe_2H$–Et_3N produces C_2-[(c-$C_6H_{11})_6Si_6O_8(OSiMe_2H)_2$] 6, while reaction of 5 with HBF_4·OMe_2–BF_3·OEt_2 produces C_2-[(c-$C_6H_{11})_6Si_6O_8F_2$] 7, which also reacts with $LiNMe_2$ and LiC≡CPh to afford 8 and 9.

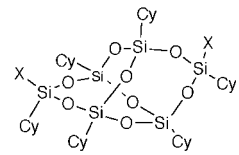
Incompletely condensed polyhedral silsesquioxanes are versatile precursors to a wide range of Si–O and Si–O–M frameworks,[1a,b] including precursors to hybrid organic–inorganic polymers.[1c] Until recently, the pool of incompletely condensed silsesquioxanes available in synthetically useful quantities was quite limited.[2] Our discovery that fully condensed $[RSiO_{3/2}]_n$ frameworks, such as (c-$C_6H_{11})_6Si_6O_9$ **1** and (c-$C_6H_{11})_8Si_8O_{12}$ **2**, can be selectively cleaved by strong acids provides access to many useful new incompletely condensed frameworks.[3] However, the synthesis of difunctional silsesquioxane frameworks with well defined structures is relatively difficult and there are strong incentives for developing practical routes to other compounds. Here, we report the syntheses of several new frameworks derived from acid-mediated cleavage and rearrangement of readily available (c-$C_6H_{11})_6Si_6O_9$ **1**.[2a,b] These difunctional frameworks have excellent potential as precursors to more elaborate Si–O frameworks because their unique C_2-symmetric $Si_6O_8X_2$ skeleton can undergo nucleophilic substitution reactions without producing complex mixtures of diastereomers.



1 **3**

Framework **1** reacts with many strong acids to afford products resulting from cleavage of both Si_3O_3 rings. When the acid is HBF_4·OMe_2–BF_3·OEt_2, cleavage of Si–O is irreversible, and the major product is a C_2-symmetric tetrafluoride (*i.e.* **3**) derived from the substitution of two framework O atoms by four F atoms with inversion of stereochemistry at all Si centers.[3a] Both Si_3O_3 rings are also cleaved upon reaction of **1** with CF_3SO_3H (TfOH) or $MeSO_3H$ (MsOH), but the products from these reactions are not $R_6Si_6O_7(OSO_2R)_4$ frameworks analogous to **3**. Instead, the reactions of **1** with TfOH and MsOH both produce difunctional $R_6Si_6O_8(OSO_2R)_2$ derivatives resulting from selective cleavage and rearrangement of the Si–O framework.

The reaction of **1** with TfOH (5 equiv., $CDCl_3$, 25 °C, 15 min) occurs quickly upon mixing to produce several new Si-containing products. The major product, which is present in *ca.* 85% yield, exhibits three resonances with equal integrated intensities in the ^{29}Si NMR spectrum (δ −60.30, −61.10 and −61.44). All three of these resonances appear upfield from the ^{29}Si resonance for **1** (δ −56.23) and significantly downfield from the region characteristic of Si_4O_4 rings in relatively unstrained, fully condensed cyclohexylsilsesquioxanes (δ −65 to −70). Similar results are observed for the reaction of **1** with MsOH (5.2 equiv., $CDCl_3$, 70 °C, 5 h).† Numerous attempts to obtain crystalline samples of these products were unsuccessful because both compounds are extremely soluble in all solvents with which they do not react. However, **4a** and **4b** are the only structures consistent with our characterization data, and the formation of these compounds seems certain based on the reaction chemistry outlined below.



4a	X =	OTf
4b		OMs

6		$OSiMe_2H$
7		F
8		NMe_2
9		CCPh

The hydrolysis of triflate-substituted silsesquioxanes can be accomplished cleanly to produce either of two stereochemical outcomes.[3b,c] Direct hydrolysis with water occurs with complete inversion of stereochemistry, while indirect hydrolysis *via* sequential treatment with aniline and aqueous HCl occurs with complete net retention of stereochemistry at Si. For **4a** and **4b**, which possess C_2-symmetric $R_6Si_6O_8X_2$ frameworks, hydrolysis with inversion or retention produces the same compound, namely disilanol **5**.‡ (Hydrolysis with inversion at one Si and retention at the other produces the enantiomer of **5**.) The structure of **5** was assigned on the basis of compelling spectroscopic data and confirmed by a single crystal X-ray diffraction study.§ As illustrated in Fig. 1, disilanol **5** crystallizes as discrete molecules with O3 and O5 located on a crystallographic C_2 axis of rotation. All bond distances and angles fall within their accepted ranges, but the Si–O–Si bond angles within the Si_4O_4 rings of **5** are more acute than those observed in the Si_4O_4 rings of **2**. In fact, the average Si–O–Si angle for **5** is only 142°, which is in the range of average Si–O–Si angles defined by **1** (133°)[4a] and **2** (149.5°).[4b] In light of the correlation between Si–O–Si bond angles and ^{29}Si chemical shifts for fully condensed polyhedral silsesquioxanes,[5] the relatively deshielded ^{29}Si resonances for **4a**, **4b** and **5** can be easily rationalized. (The ^{29}Si chemical shifts for **1** and **2** are δ −56.23 and −68.6, respectively.)

The availability of **4a**, **4b** and **5** provides access to a wide range of difunctional silsesquioxane frameworks. For example, silylation of **5** with $ClSiMe_2H$–Et_3N produces **6**, while reaction of **5** with HBF_4·OMe_2–BF_3·OEt_2[6] produces difluoride **7**. Subsequent reactions of **7** with $LiNMe_2$ and LiC≡CPh afford **8** and **9**, which can also be prepared by reacting **4a** or **4b** with $LiNMe_2$ and LiC≡CPh.¶ Although there are strong preferences for either complete retention or complete inversion of stereochemistry at Si for all of these nucleophilic substitution reactions,[4b,6,7] the stereochemical consequences are irrelevant with a C_2-symmetric $R_6Si_6O_8X_2$ framework (*vide supra*). The isolation of pure compounds is therefore relatively easy and isolated yields for all of these reactions are generally good.

The formation of **4a** and **4b** during the reactions of **1** with TfOH and MsOH requires the competitive formation of an Si_4O_4 ring under conditions where fused Si_3O_3/Si_4O_4 rings are cleaved selectively and Si–OH groups are converted into Si–OTf or Si–OMs groups. Both of these processes, as well as most

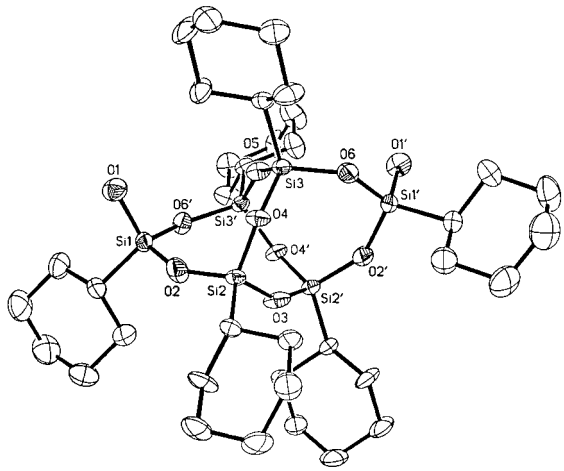

Fig. 1 ORTEP plot of **5** with thermal ellipsoids plotted at the 50% probability level. Selected distances (Å) and angles (°): Si1–O1 1.632(3), Si1–O2 1.620(2), Si1–O6′ 1.632(2), other Si–O 1.615–1.634; O1–Si1–O2 110.15(14), O1–Si1–O6′ 109.89(12), O2–Si2–O3 109.57(11), O2–Si2–O4 108.26(13), O3–Si2–O4 108.21(12), O4–Si3–O5 108.91(12), O4–Si3–O6 108.40(12), O5–Si3–O6 108.42(9), Si1–O2–Si2 147.60(16), Si2–O3–Si2′ 146.6(2), Si2–O4–Si3 133.76(14), Si3–O5–Si3′ 151.7(2), Si3–O6–Si1′ 137.57(14).

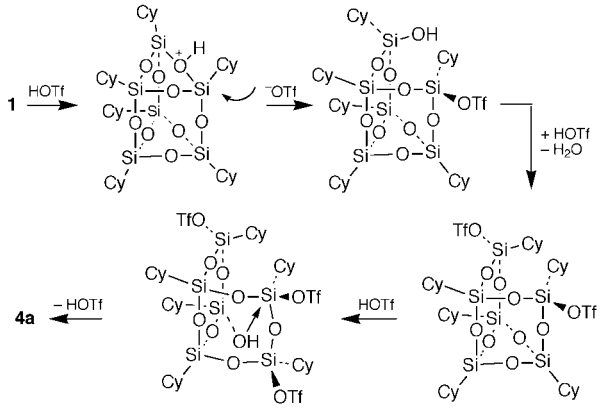

Scheme 1

nucleophilic substitution reactions of triflate-substituted silsesquioxanes, are known to occur with complete inversion of stereochemistry at Si.[4b,7] It is therefore likely that **4a** and **4b** are produced by the mechanism proposed in Scheme 1; a mechanistically similar process occurs during the reaction of **2** with TfOH.[3c] The release of ring strain in the Si–O framework is an important driving force for this process. Another important driving force is the formation of water, which is prevented from reacting with **4a** or **4b** by protonation with excess strong acid.

In conclusion, reactions of **1** with TfOH and MsOH both produce $R_6Si_6O_8(OSO_2R)_2$ derivatives resulting from selective cleavage and rearrangement of the $R_6Si_6O_9$ framework. These new compounds exhibit a rich reaction chemistry and provide access to a wide range of new Si–O frameworks.

Notes and references

† Frameworks **4a** and **4b** were prepared by reacting **1** (0.5 mM) with TfOH (5 equiv., 25 °C, 15 min) or MsOH (5.2 equiv., 50 °C, 5 h) in $CHCl_3$ (5 mL). Excess acid and water produced by the reaction were removed using an excess of 4 Å molecular sieves. Evaporation of the solvent (25 °C, 0.1 Torr) affords crude **4a** or **4b** as a pale yellow microcrystalline solid. The mass yield is practically quantitative, but the purity of **4a** and **4b** is only 80–90% as judged by ^{29}Si, ^{13}C and ^{1}H NMR spectroscopy. Both **4a** and **4b** react quickly with traces of water and are extremely soluble in all solvents with which they do not react; both compounds were used without further purification. For **4a**: $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 25 °C): δ 27.18, 26.90, 26.48, 26.27, 26.13, 26.10, 25.83, 25.69, 25.57 (CH_2), 23.05, 22.44, 22.03 (2:2:2 for CH). $^{29}Si\{^1H\}$ NMR (99 MHz, $CDCl_3$, 25 °C): δ −60.30, −61.10, −61.44 (2:2:2). MS (70 eV, 200 °C, relative intensity): *m*/*z* 1092 (M^+, 2%), 1009 {$[M - C_6H_{11}]^+$, 100%}. For **4b**: $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 25 °C): δ 39.15 (CH_3), 26.99, 26.93, 26.87, 26.83, 26.79, 26.28, 26.18, 26.03, 26.02, 25.83, 25.79, 25.63 (CH_2), 23.07, 22.33, 22.06 (2:2:2 for CH). $^{29}Si\{^1H\}$ NMR (99 MHz, $CDCl_3$, 25 °C): δ −61.43, −61.63, −61.80 (2:2:2). MS (70 eV, 200 °C, relative intensity): *m*/*z* 970 {$[M - CH_3]^+$, 28%}, 901 {$[M - C_6H_{11}]^+$, 95%}.

‡ Disilanol **5** was prepared by the hydrolysis of **4a** or **4b** in diethyl ether. The conversion of **4a**/**4b** to **5** is essentially quantitative as judged by ^{1}H, ^{13}C and ^{29}Si NMR spectroscopy; the isolated yield after recrystallization from CCl_4 is typically 40%. For **5**: ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ 2.32 (br s, SiOH, 2H), 1.73 (br m, 30H), 1.22 (br m, 30H), 0.80 (br m, 6H). $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 25 °C): δ 27.46, 27.35, 27.27, 26.75, 26.70, 26.65, 26.47, 26.45, 26.27, 26.21 (CH_2), 23.63, 22.86, 22.67 (2:2:2 for CH). $^{29}Si\{^1H\}$ NMR (99 MHz, $CDCl_3$, 25 °C): δ −55.24, −61.73, −61.94 (2:2:2). Robust and catalytically active mono- and bis-Pd-complexes of the 'Trost modular ligand'

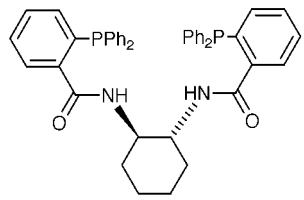
Craig P. Butts, John Crosby, Guy C. Lloyd-Jones* and Susanna C. Stephen

School of Chemistry, Cantock's Close, Bristol, UK BS8 1TS. E-mail: guy.lloyd-jones@bris.ac.uk

Received (in Cambridge, UK) 20th July 1999, Accepted 29th July 1999

A catalytically active, bimetallic Pd–allyl complex of the Trost modular ligand, for which X-ray crystallography reveals a tetradentate ('POPO') coordination mode, induces a memory effect in Pd-catalysed allylic alkylation.

Asymmetric Pd-catalysed allylic alkylation[1] has recently enjoyed much attention and has undoubtedly joined the ranks of the 'benchmark reactions' by which new chiral ligands are tested and compared. Under the appropriate conditions, the modular ligand systems of Trost,[2] *e.g.* (*R*,*R*)-**1**, have proved to be remarkably enantioselective for a range of allylic alkylations, particularly the more demanding small cyclic substrates such as **2**→**3**.[3]



(*R*,*R*)-**1**

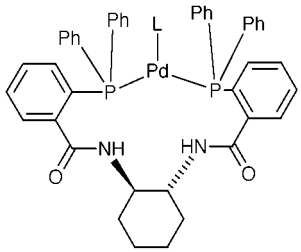
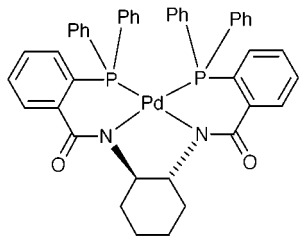
(±)-α-D-**3**



L = η^3 or η^2 ligand *etc.*

(*R*,*R*)-**4**



(*R*,*R*)-**5**

Knowledge of the mode(s) of coordination of **1** to palladium is essential in any mechanistic explanation of such high selectivities and it has generally been assumed that there is bidentate diphosphine chelation ('P,P') to Pd throughout the catalytic cycle† as in **4**.[4] However, to date, there have been no reports of the isolation or *in situ* characterisation of catalytic intermediates—which are readily converted to catalytically inert **5**.[5]

In recent investigations[6] of 'memory effects'[7] in the Pd-catalysed conversion of **2** to **3**, we suggested that a (P,L)-complexation mode (L = non-P ligand) could be responsible for the memory effect with mismatched **2** and '[**1**–Pd]'. Powerful memory effects are sometimes observed with other (P,L) ligands[6c,7c] and we noted that an amide carbonyl in **1** could act as 'L'. However, although we observed no memory effect with ligand **6**,[6a] ligands **7** and **8** are reported to give low and reversed ees (as compared to **1**) in the reaction of **2**.[4]

These latter results have in fact been taken as evidence that P,P-bidentate coordination of **1** is essential and that amide

(*R*,*R*)-**9**

carbonyl coordination (P,O) is not important in the catalytically active species.[8] Herein we describe air- and shelf-stable, catalytically active, Pd-complexes of **1**. We also show that P,O coordination of **1** can give rise to a highly active catalyst and a significant memory effect.

Non-complexed ligand **1** was crystallised from hot acetonitrile. The single crystal X-ray structure is presented in Fig. 1.‡ Notable is the latent tendency of **1** to present P and O donors on opposite faces of the elongated structure. Reaction of **1** with 1 equivalent of halide-free $[Pd(allyl)(MeCN)_2][OTf]$ in CH_2Cl_2 then evaporation gave a pale yellow powder. Combustion analysis and ES-MS§ were fully consistent with a complex of stoichiometry [Pd(allyl)(**1**)][OTf]. However, despite many attempts at crystallisation, amorphous powders were always obtained and X-ray structural analysis remained elusive. Furthermore, ^1H and ^{13}C NMR spectra (CD_2Cl_2 or 3:1 d_8-THF–CD_2Cl_2, 26 °C) were very broad and complicated. Nonetheless, all of the allyl–Pd signals disappeared rapidly on addition of a slight excess of $[NaCH(CO_2Me)_2]$ and cleanly gave allyl–$CH(CO_2Me)_2$ (> 95%, ^1H NMR).[9]

In the solid state, the mixture of complexes is air- and shelf-stable (for years) and serves as a very convenient pro-catalyst

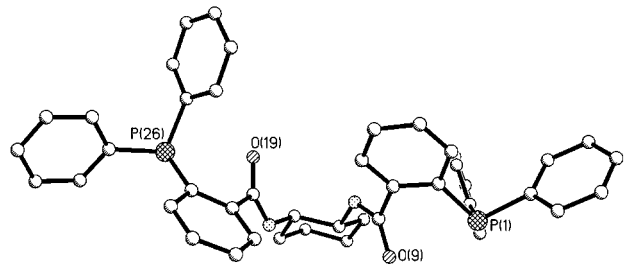

Fig. 1 The molecular structure of **1**. One and one half molecules occupy the unit cell. The half molecule and all hydrogens and solvent (MeCN) are omitted for clarity.

for asymmetric allylation of **2**.¶ Also, like the conventional 'Pd-**1**' catalysts generated *in situ* under chloride-free conditions,[6b] the pro-catalyst mixture also effects powerful kinetic resolution with (*S*)-**2** reacting over twenty-fold faster than (*R*)-**2** with $[NaCH(CO_2Me)_2]$ in THF.

When the ratio of Pd/ **1** was raised (*i.e.* ⩾1) evidence for P,O coordination was obtained. Thus, analytically pure $[Pd_2(allyl)_2(\mathbf{1})][(OTf)_2]$ **9** (mp 203 °C) was prepared as yellow–green prisms by addition of 2 equivalents of [Pd(allyl)(MeCN)$_2$][OTf] to **1** in $CHCl_3$ (99.9% yield on a 1.1 g scale). The single crystal X-ray structure of **9** which displays P,O-coordination to two Pd–allyl moieties is shown in Fig. 2.‡ This complex was also catalytically active and 2.5 mol% effected ⩾90% conversion of α-[^{2}H]-**2** to α,γ-[^{2}H]-**3** in < 60 s (22 °C, THF).‖ Importantly, the P,O complexation mode induced a moderate α-memory effect: both enantiomers of substrate giving a *ca.* 57 : 43 (±1) ratio of α-[^{2}H]-**3**/γ-[^{2}H]-**3** [83–86% isolated yield after chromatography, ^{2}H and ^{13}C NMR analysis with (+)-Eu(hfc)$_3$] and a global enantioselectivity of *ca.* 2% ee (*R*).

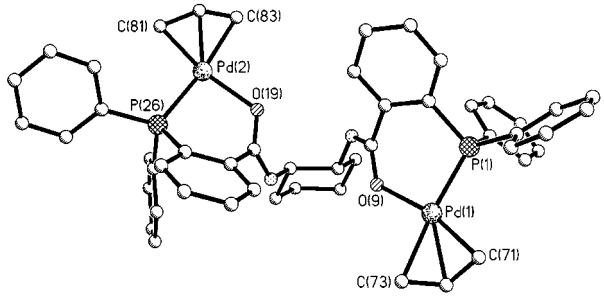

Fig. 2 The molecular structure of dication **9**. Hydrogens and triflate counter ions are omitted for clarity. Selected bond lengths (Å) and angles(°): Pd–P 2.279(2) 2.289(2), Pd–O 2.097(4), 2.109(4), Pd–C(71/81) 2.052(8)/2.086(7), Pd–C(73/83) 2.27(8)/2.191(7); P–Pd–O 89.90(11), 89.82(12), C–Pd–C 67.4(4), 69.5(3).

^{1}H, ^{13}C and ^{31}P NMR (CD_2Cl_2, 25 °C) of complex **9** indicated a single quasi-symmetrical species was present in solution (δ_P 24.8). Five unique π-allyl ^{1}H NMR signals with only one of the two allylic carbons *trans*-related to P (J_{CP} 27.3 Hz) indicated apparent allyl rotation was slow at the NMR time scale. Furthermore, the concentration independent 2.34 ppm downfield chemical shift of the N–H amide protons (δ 8.84) relative to free **1** confirmed the bis-(P,O)-complexation mode in solution. A moderate ion current corresponding to $[Pd_2(allyl)_2(\mathbf{1})]^{2+}$ (*m*/*z* 492) was observed on ES-MS analysis {a substantial proportion of the complex loses $[Pd(allyl)]^+$ and $[Pd(allyl)_2]^+$ (*m*/*z* 147 and 188) to give $[Pd(allyl)(\mathbf{1})]^+$}. When 1 equivalent of **1** was added, ^{31}P NMR and ES-MS analysis indicated complete reaction of **1** and $[Pd_2(allyl)_2(\mathbf{1})]^{2+}$ to give '$[Pd(allyl)(\mathbf{1})]^+$' suggesting a thermodynamically more favoured (P,P) binding mode in the latter species.[9]

In conclusion, reaction of **2** catalysed by the fully characterised complex **9** in which there is a bis-P,O-coordination mode (X-ray and NMR) proceeds with a significant α-memory effect in both manifolds (*R*- and *S*-**2**) and gives racemic **3**. However, with a Pd : **1** ratio of 1 : 1 a number of P,P-complexes are generated. These are active for *asymmetric* allylic alkylation with $[NaCH(CO_2Me)_2]$, effect powerful kinetic resolution and, consistent with earlier work, only demonstrate a memory effect with the mismatched enantiomer of **2**.[6a]

Generous donations from the Zeneca Strategic Research Fund and Pfizer Ltd are gratefully acknowledged. S. C. S thanks the University of Bristol for a Postgraduate Scholarship.

Notes and references

† To the best of our knowledge, published evidence for P,P-coordination of **1** is limited to the reaction of $Pd_2(dba)_3{\cdot}CHCl_3$ with **1** (**1**/Pd = 2) which gives an AB ^{31}P NMR spectrum (δ 24.9, 22.5; J_{PP} 14.6 Hz) and free **1** (δ −9) see ref. 4.

Received (in Cambridge, UK) 4th June 1999, Accepted 22nd July 1999

Triptycene and azatriptycene act as concave receptor molecules for C_{60}, resulting in the solid state organisation of C_{60} in a layered and a hexagonal pattern, respectively.

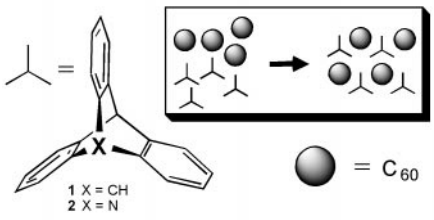
Fullerenes are of considerable interest in the design of novel materials as the strong electron acceptor properties associated with C_{60} result in intriguing optical and semiconductor phenomena.[1] The controlled organisation of C_{60} in stacks or arrays by crystal engineering and host–guest chemistry plays a decisive role in these efforts.[2,3] The solid state structures of a number of inclusion complexes and supramolecular arrays of fullerenes have been reported in recent years.[4,5] An emerging structural feature in controlling the delicate host–guest interactions is geometrical complementarity of the globular C_{60} guest and dish or saddle shaped host molecules.[2,5,6] Here we report a simple method to achieve the solid state organisation of C_{60} by inclusion crystallisation with triptycene. In addition a change in organisation, by modification at a single position in the host molecule, as shown by X-ray analysis of the inclusion complexes was observed.

We envisioned that the combination of star-shaped triptycenes, with three concave faces, and C_{60} with its convex surface might lead to self-assembly as shown in Scheme 1.

The inclusion complex of C_{60} and triptycene **1** was obtained as dark red crystals from a hot *o*-xylene solution, by slow evaporation of part of the solvent over several days. NMR, IR and chromatographic analysis established an inclusion complex of C_{60}, triptycene and *o*-xylene. X-Ray structure analysis confirmed the composition in a 1:2:2 ratio respectively. The molecular structure is shown in Fig. 1(*a*).‡

The inclusion complex has centric [monoclinic space group *P*2(1)/*c*] symmetry in the solid state. The fullerene molecules pack in an approximate hexagonal close packed sphere pattern parallel to the *bc*-plane with translation vectors 9.9958(11) (= *b*-axis) and 10.1468(11) Å [= $\frac{1}{2}$(*b*+*c*)].

The packing arrangement is shown in Fig. 2. Adjacent triptycenes stack in an antiparallel fashion generating two concave surfaces in opposite directions. Each C_{60} is capped by two molecules of **1** [Fig. 1(*a*)] and the closest distance between the two flanking arene groups of each triptycene (dihedral angle 120°) and C_{60} of approximately 3.27 Å§ is significantly shorter than those reported for calixarene and related complexes (3.51–3.62 Å).[6]



Scheme 1

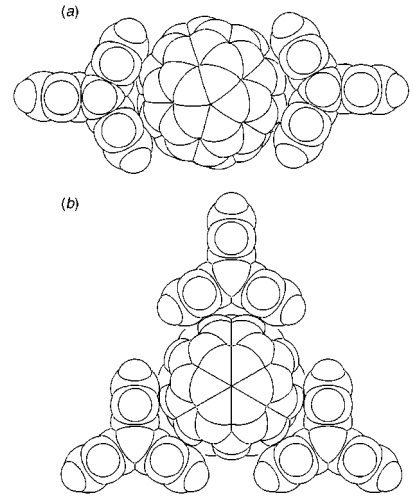


Fig. 1 (*a*) Moleculer structure of C_{60} and triptycene (**1**) (*o*-xylene omitted for clarity). (*b*) Molecular structure of C_{60} and azatriptycene (**2**).

The C_{60} molecules are arranged in sheets composed of one-dimensional strands in the *bc*-plane to achieve a close packing of spheres in the sheets. The shortest $C_{60}\cdots C_{60}$ separation of 3.08 Å¶ is close to that found in other linear strands.[2] Each sheet is separated by a double layer of antiparallel oriented triptycenes and *o*-xylenes with the latter filling voids between the

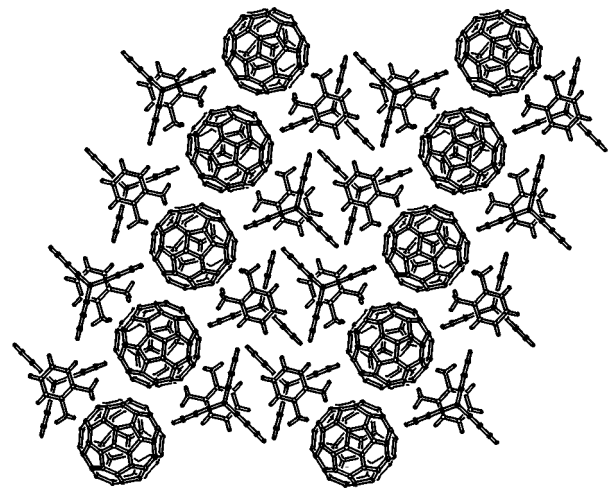

Fig. 2 Packing arrangement for the complex of C_{60}, *o*-xylene and triptycene.

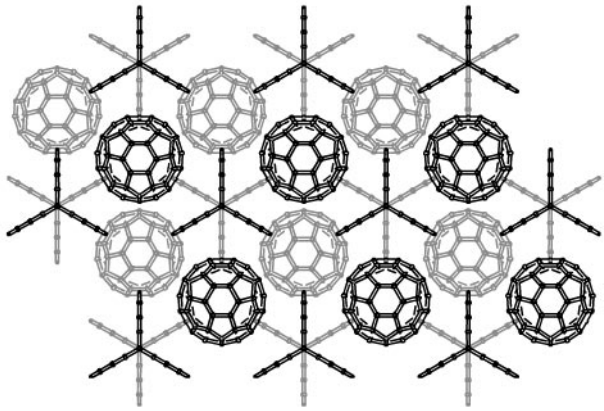

Fig. 3 Packing arrangement for the complex of C_{60} and azatriptycene.

triptycenes in this double layer. The nearest neighbour C_{60} molecules in two adjacent layers are 18.58 Å apart.

As the rigid concave triptycene has a favourable receptor shape to allow the formation of supramolecular arrays of C_{60} its molecular architecture might be suitable to change the assembly formation by modifying in the host–guest interactions. Introduction of a nitrogen atom at a bridgehead position, as is the case in azatriptycene **2**,[8] was envisioned to enhance additional electrostatic interactions in the host–guest system.

Slow evaporation of part of the solvent (*o*-xylene) from a hot solution of a 1 : 1 mixture of C_{60} and azatriptycene **2** resulted in dark red crystals of the inclusion complex suitable for X-ray analysis. The molecular structure is shown in Fig. 1(*b*).‖ The hexagonal unit cell contains two C_{60} molecules and two azatriptycenes. The fullerene molecule is rotationally disordered but as each C_{60} is flanked by three molecules of **2** [Fig. 1(*b*)], whose positions are exactly determined in the crystal lattice, and as a result of the space group symmetry, the position of each fullerene is well defined.

The C_{60} molecules assemble in the hexagonal close packing pattern with each azatriptycene embracing three C_{60} molecules and each C_{60} embraced by three azatriptycene. Capping of a C_{60} molecule by three molecules of **2** results in six concave surfaces at the periphery of this ensemble which interact with a further six fullerene molecules leading to the anticipated arrangement in each layer.

The translation period in the *ab*-packing plane amounts to 13.464(1) Å (= *a*-axis). Layers are separated by 6.349(1) Å (= 1/2 *c*-axis). The closest C–C contact between both molecular species amounts to 3.40(2) Å.

The packing arrangement is shown in Fig. 3. The azatriptycenes are arranged in one-dimensional strands parallel to the *c* axis in a head-to-tail arrangement. The C_9 carbon and the central nitrogen atom of neighbouring azatriptycenes are at a distance of 3.76 Å. Each molecule of **2** in a single strand is rotated 60° with respect to its neighbour, and as a consequence each set of three concave faces in the hexagonal arrangement in a particular layer, due to a single molecule of **2**, is rotated 60° with respect to the next layer. The hexagonal packing of the C_{60} spheres is evident if one realises that the 'pillars' of the azatriptycenes generate the voids in which a C_{60} molecule in one layer is positioned exactly between six C_{60} molecules in the two adjacent layers.

The shortest intermolecular C_{60} distance (C_{60} molecules in different layers) is approximately 2.97 Å¶ which is similar to that found in the inclusion complex of C_{60} and *p*-bromocalix-[4]arene propyl ether.[2] The centre–centre distance of the azatriptycenes in one layer is 13.464(1) Å. The remarkable propensity of triptycenes to change the self-assembly of C_{60} and the fascinating structures obtained in this way are intriguing in view of the design of new host–guest systems and materials based on fullerenes.** Studies along these lines using functionalised triptycenes are in progress.

Financial support by the Dutch National Science Foundation (NWO) is gratefully acknowledged.

Notes and references

‡ *Crystal data* for complex with **1**: $C_{60}\cdot2(C_{20}H_{14})\cdot2(C_8H_{10})$, M = 1441.54, dark red plate, space group $P2(1)/c$, a = 19.767(2), b = 9.9958(10), c = 17.661(2) Å, β = 109.882(10)°, Z = 2, V = 3281.6(6) Å^3, D_c = 1.459 g cm^{-3}, μ = 0.1 mm^{-1}, λ = 0.71073 Å, T = 150 K, θ_{max} = 25.3°. A hemisphere of reflections (11766) was scanned and averaged [R(int) = 0.15] into a unique set of 5988 reflections [2080 of which with $I > 2\sigma(I)$]. The structure was solved by direct methods (SIR97) and refined on F^2 using SHELXL97. Two sets of bond restraints were introduced in order to restrain 5-6 and 6-6 bond types. The restraints refined to 1.462(4) and 1.347(6) Å, respectively. Hydrogen atoms were introduced at calculated positions and refined riding on their carrier atoms. The displacement parameters for the C_{60} atoms display the common flat disk characteristics. Convergence was reached at R_1 = 0.0947, wR_2 = 0.261, S = 1.00, 5988 reflections, 527 parameters, 45 restraints, $-0.43 < \Delta_r < 0.64$ e Å^{-3}.

§ As a consequence of the dihedral angle of 120° in **1** and **2** the closest distance is with the C–C carbon atoms at the periphery of the (aza)-triptycenes.

¶ Based on the mean atom-to-atom diameter of C_{60} of approximately 7.07 Å (ref. 7).

‖ *Crystal data* for complex with **2**: $C_{60}\cdot C_{19}H_{13}N$, M = 975.90, dark red block, space group $P6(3)mc$ (no. 186), $a = b$ = 13.4643(11), c = 12.6983(9) Å, Z = 2, V = 1993.6(3) Å^3, D_c = 1.626 g cm^{-3}, μ = 0.1 mm^{-1}, λ = 0.71073 Å, T = 150 K, θ_{max} = 27.5°. A hemisphere of reflections (6587) was scanned and averaged (R_{int} = 0.069) into a unique set of 909 reflections [711 of which with $I > 2\sigma(I)$]. Three space groups are consistent with the observed systematic extinctions [$P6(3)mc$, P-62c and $P6(3)/mmc$]. Interpretable (partial) results (with SHELXS97 and SIR97) were obtained in both $P6(3)mc$ and its centrosymmetric counterpart $P6(3)/mmc$. In both cases it was clear that the C_{60} moiety is severely orientationally disordered. The model presented here is based on the refinement (with SHELXL97) of a restrained C_{60} 'order-model' in $P6(3)mc$. The restraint for 5-6 bonds refined to 1.480(8) Å and for 6-6 bonds to 1.290(14) Å. The unrestrained geometry of the azatriptycene is satisfactory along with the associated anisotropic displacement parameters. The anisotropic displacement parameters of the C_{60} atoms show the common flat disc shape (some non-positive definite). Hydrogen atoms were taken into account at calculated positions. Since the current refinement was stable (R_1 = 0.0861, wR_2 0.272, S = 1.05, $-0.60 < \Delta_r < 0.65$ e Å^{-3}) in the non-centrosymmetric symmetry space group description, no further attempts were made to refine a less attractive disorder model (for both moieties) required for the description in the related centrosymmetric space group. CCDC 182/1344. See http://www.rsc.org/suppdata/cc/1999/1709/ for crystallographic data in .cif format.

** The effects of C_{60}–triptycene interactions or kinetics of crystal packing on the solid state arrangement need further investigation.

Fabrication of a covalently attached self-assembly multilayer film *via* H-bonding attraction and subsequent UV-irradiation

Jinyu Chen and Weixiao Cao*

College of Chemistry and Molecular Engineering, Peking University, Beijing 100871, China. E-mail: wxcao@263.net

Received (in Cambridge, UK) 12th July 1999, Accepted 27th July 1999

A photosensitive ultrathin film has been fabricated from a diazo resin (DR) and phenol–formaldehyde resin (PR) *via* hydrogen bonding, covalent bonds are formed UV irradiation giving a covalently linked ultra-thin film; as a consequence the stability of the film towards polar solvents increases dramatically.

Recently a self-assembly technique to form ultra-thin films *via* H-bonding attraction was developed by Zhang *et al.*[1] and Stockman and Rubner.[2] However, such H-bonding attraction is very weak, which leads to the films being readily destroyed in polar solvents. In this contribution, we report a new multilayer film fabricated from a diazo-resin (DR) and phenol–formaldehyde resin (PR) formed *via* H-bonding attraction between N^+N: of DR and –OH of PR in methanol. It has been confirmed that under UV irradiation, following the decomposition of the diazonium group, that covalent bonds form in the film structure and the stability of the film towards polar solvents is substantially increased. To our knowledge, this is the first report of the formation of stable ultra-thin films from a precursor film formed *via* hydrogen bonding attraction.

DR was prepared according to the method described elsewhere.[3] PR, a polycondensation product of 4-*tert*-butylphenol and formaldehyde, ($M_w \approx 2600$, Chemical Agent Factory, Zheng-zhe City, Huinan Province, P.R. China) was used as received. The films were prepared at room temperature in the dark. A fresh quartz wafer (fused silica), which was modified with a monolayer of *N*-[3-(trimethoxysilyl)propylethylenediamine according to ref. 4, was used as substrate. The quartz wafer was first immersed in a methanol solution of polyvinylpyrrolidone (PVP) (1 mg ml^{-1}) for 5 min. After rinsing with methanol and drying, the wafer was immersed in a methanol solution of PR (1 mg ml^{-1}) for 5 min followed, after rinsing with methanol by immersion in a methanol solution of DR (0.2 mg ml^{-1}) for 5 min. The wafer was then rinsed again with methanol and air dried. In each cycle of immersion into PR and DR solutions, a bilayer of PR–DR is formed on both sides of the quartz wafer.

UV–VIS spectra were recorded on a UV–VIS spectrophotometer (Shimadzu 2100) which was used to monitor the self-assembly process of the fabrication as shown in Fig. 1. Peaks at 384 and 284 nm are assigned to the absorptions of diazonium group of DR and the phenyl group of PR. Results show that the absorbance increases uniformly in the assembly process and indicates that the step-by-step fabrication is smooth. The inset plot shows the linear relationship of the absorbance at 384 nm (or 284 nm) with the number of bilayers. Unfortunately, this multilayer film is unstable in the presence of polar solvents. For example, upon immersion of a multilayer film (14 bilayers) deposited on a quartz wafer in DMF for 10 min, most of the layer (> 90%, as calculated from the decreased absorbance at 384 nm) was destroyed. This result shows that the stability towards polar solvents of multilayer films formed *via* H-bonding attraction is poorer than for films formed by electrostatic attraction.[5,6]

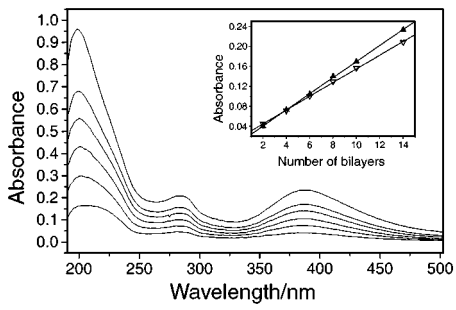

Fig. 1 UV–VIS spectra of multilayer films from PR and DR with various numbers of bilayers; bilayer number (bottom to top): 2, 4, 6, 8, 10, 14; Inset: absorbance at 384 nm (▲) and at 284 nm (▽).

It is known that DR decomposes readily under UV-irradiation or upon heating. Fig. 2 shows the photodecomposition of a 14 bilayer film under UV-irradiation (230 μW cm^{-2}). The inset of Fig. 2 drawn from the absorbance at 384 nm shows that this reaction follows first order reaction kinetics under the experimental conditions. The absorption at 284 nm (Ph–O–Ph absorption) increased with a decrease of the absorbance at 384 nm ($-N_2^+$ group absorption), which indicates the formation of the Ph–O–Ph ether bond. The conversion of the H-bond to a covalent bond (Ph–O–Ph) is shown in Scheme 1.

The stability of the film towards polar solvents increases dramatically upon exposure of the films towards UV radiation.

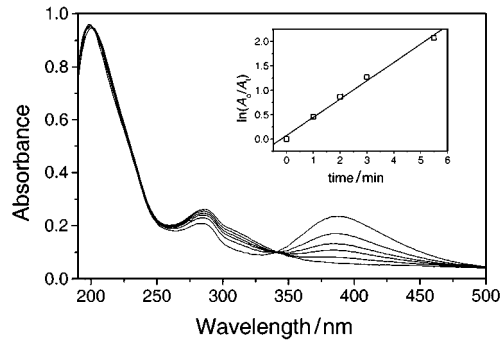

Fig. 2 UV–VIS spectra of a 14 bilayer film irradiated for different times (irradiation intensity = 230 W cm^{-2}). Irradiation time (min) 0, 1, 2, 3, 5.5, 20 min. Inset: absorbance at 384 nm.

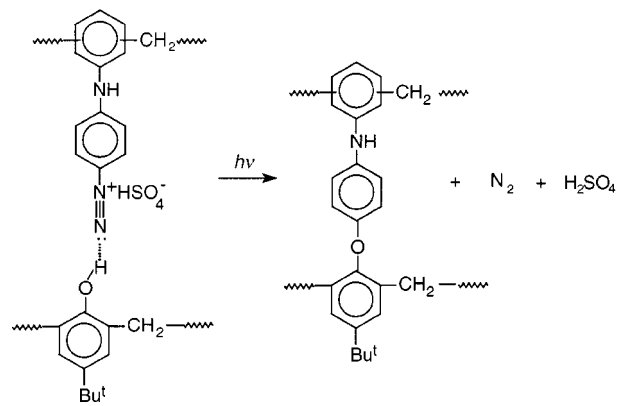

Scheme 1 The photoreaction of DR and PR in a self-assembled film.

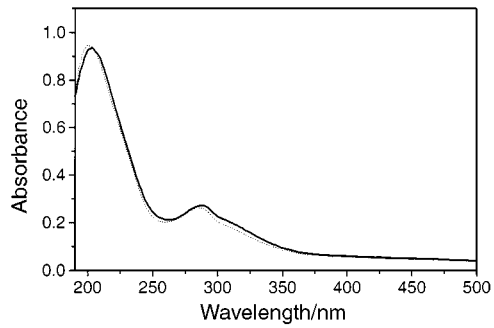

Fig. 3 UV–VIS spectra of a 14 bilayer film before (----) and after (—) etching in DMF for 10 h at 25 °C.

For example after irradiation for 20 min, the film was then immersed in DMF at 25 °C for 10 h with no decrease in absorbance (Fig. 3) being observed. This shows that the film is very stable towards polar solvents after UV irradiation.

To verify the assembly driving force is from the formation of a hydrogen bond between N^+N of DR and –OH or PR rather than NH of DR and –OH of PR, we studied PVP as an H-acceptor and DR as an H-donor in an attempt to prepare a layer-by-layer film, but this was unsuccessful. It can thus be assumed that the NH group of DR does not form a H-bond with PVP although the latter is a strong H-acceptor.

To further verify the formation of a hydrogen bond and subsequent reaction in the film upon UV irradiation, a film with 20 bilayers was fabricated on a CaF_2 wafer from DR and PR and its IR spectrum (not shown) recorded. A broad peak at 3251.0 cm^{-1} and a peak at 1371.4 cm^{-1} indicate the OH group of the PR is in an associated state. A peak at 2155.9 cm^{-1} is assigned to the stretching vibration of the diazonium group which is shifted by 11 cm^{-1} as compared with the free-molecule (2167 cm^{-1}).[5] Both observations indicate formation of an H-bond between N^+N: and OH. The film was then exposed to UV irradiation for 20 min at 230 μW cm^{-2} and the IR spectra (not shown) were recorded again. The broad peak at 3251.0 cm^{-1} was found to be weakened with both the peak at 1371.4 cm^{-1} and the absorption of the diazonium group (at 2155.9 cm^{-1}) dissappearing. This result indicates that after exposure to UV light the original H-bond has been destroyed.

In conclusion, *via* hydrogen bond attraction between the diazonium group of DR and the hydroxy group of PR and subsequent UV-irradiation, an ultra-thin film which is stable towards polar solvents was fabricated from DR and PR by a self-assembly technique.

The authors greatly appreciate the NSFC for financial support of this work.

A novel catalytic approach to the chemical detoxification of P-ester nerve agents

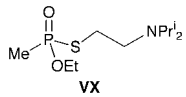
Wendy Y. Mills, Rebecca M. Kissling and Michel R. Gagné*

Department of Chemistry CB#3290, University of North Carolina, Chapel Hill, NC 27599, USA. E-mail: mgagne@unc.edu

Received (in Corvallis, OR, USA) 27th May 1999, Accepted 23rd July 1999

An effective method for the destruction of P-based nerve agent simulants using the ester interchange reaction is described; depolymerization of polycarbonate in the presence of aryl phosphinates and KOBu^t (5 mol%) leads to a net breakdown of the toxic constituents of the simulants while immobilizing each component as a polymer end group; the data suggest that application of this approach to the destruction of nerve agents such as VX may be fruitful.

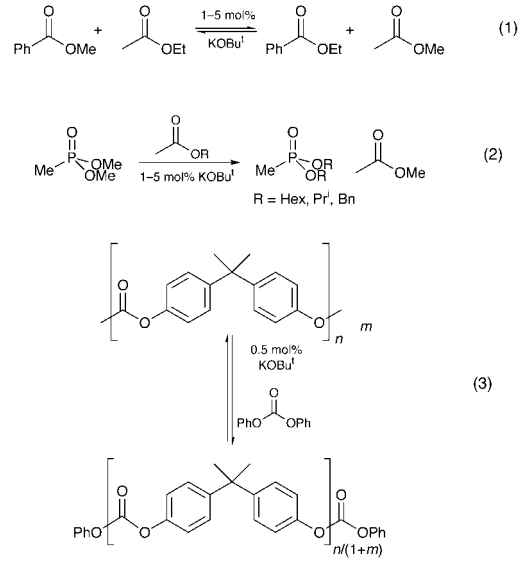
Chemical warfare agents such as VX [*S*-2-(diisopropylamino)-ethyl *O*-ethyl methylphosphonothioate] are polar organic liquids at ambient conditions.[1] Given the current stockpile of these agents (thousands of tons in the US alone), efficient and safe methods for their destruction present a scientifically challenging and important research problem. Currently, methods for their destruction rely on incineration or chemical neutralization. Each of these methods, however, have attendant disadvantages as they produce hazardous fumes or byproducts that may still be highly toxic. To address some of these issues, we have recently initiated experiments utilizing ester interchange to disassemble (*i.e.* detoxify) the key subunits of these agents, while simultaneously immobilizing them for subsequent safe disposal.



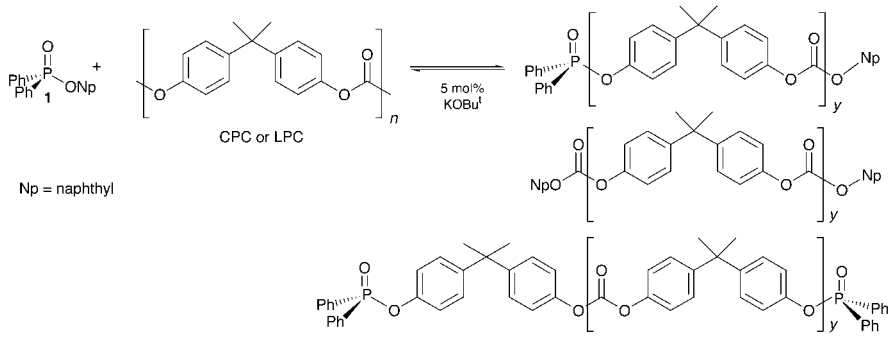
VX

We have previously reported that alkali-metal alkoxide clusters catalyze the ester interchange reaction under mild conditions and at high rates (up to 10^6 turnovers h^{-1}) [eqn. (1)].[2] As an extension of this original observation we have additionally demonstrated that (i) phosphonates are highly susceptible to ester interchange [eqn. (2)],[3] and (ii) diaryl carbonate (DAC) interchange can be used to depolymerize high molecular weight (MW) bisphenol A polycarbonate (PC) with subsequent control over polymer end groups [eqn. (3)].[4] The reaction rates for the former processes are also rapid and turnover frequencies as high as 1.5×10^6 h^{-1} have been measured. A key consideration in the successful application of this methodology is a matching of the pK_as for the two interchanging esters, *i.e.* the two ester leaving groups must be similarly competent.

Our data therefore suggest that, given a suitable interchange partner, VX should be capable of swapping its toxic amino thiolate side chain for a less toxic one. pK_a considerations indicate that thioesters (*e.g.* AcSEt) or aryl esters (*e.g.* AcOAr) should be suitable.[5] Since VX derivatives containing simple non-functionalized side chains like SEt are toxic and can be volatile, polymeric non-sulfur containing side chains might be ideal detoxification products from both a toxicity and volatility perspective. Therefore, in analogy to the depolymerization process, utilization of VX or a VX simulant as a breakdown agent for PC should effectively destroy the agent while immobilizing the toxic components as polymer end groups (Scheme 1). The additional entropic driving force associated with a polymer breakdown protocol should additionally maximize the chemical potential for P-ester destruction.



To test this hypothesis, two model VX simulants (naphthyl diphenylphosphinate **1** and phenyl diphenylphosphinate **2**) were each allowed to interchange with diphenyl carbonate (DPC) [eqn. (4)], cyclic PC (CPC)[6] and linear PC (LPC)[7] in the presence of 5 mol% KOBu^t as shown in Scheme 1. Some of the expected products from the reaction are also highlighted in Scheme 1. Under a dry argon atmosphere the desired phosphinates and carbonate were dissolved in THF and, after catalyst addition, were stirred for 30 min at room temperature. The polymer-based reactions were subsequently worked up by precipitation into a 10-fold excess of MeOH; the collected polymeric precipitates were then analyzed by GPC (Table 1) and ^{31}P NMR (*vide infra*). The amount of unreacted phosphinate in the filtrate was obtained by solvent removal and quantitative HPLC analysis (Table 1).[8] The relative amount of carbonate to phosphinate functional groups in the starting mixture was varied (10 : 1, 20 : 1 and 50 : 1) to determine its effect on simulant conversion. As expected, increasing ratios of carbonate drove the reactions forward, especially in the cases of CPC and LPC (entries 1–10). With ratios of 50 : 1, CPC and LPC reactions yielded residual amounts of **2** that were too low to accurately measure using our HPLC assay. Optimized breakdown conditions required 5 mol% of KOBu^t; lower catalyst loadings or the use of NaOBu^t or LiOBu^t gave inferior results. Most surprising were the attenuated changes in the residual phosphinate observed using DPC as the carbonate source. Longer reaction times before quenching indicated that the DPC breakdown experiments had not yet reached equilibrium (Table 1, entries 11–13). For example, quenching the reactions in entry 11 after 6 h led to 5.3% residual **1**.[9] The polymeric breakdown experiments apparently reach a final state more rapidly (< 30 min) than DPC-based protocols, as later quenching did not



Scheme 1

Table 1 HPLC and GPC analysis data[a]

Entry	Carbonate	Phosphinate	Substrate ratio[b]	Unreacted[c] (%)	M_n[d]	M_w	PDI
1	CPC	**1**	10:1	5.3	2497	3541	1.42

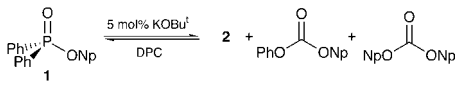
13	DPC	**1**	50:1	3.1–4.9[e]	—	—	—

[a] Catalyst loadings were at the 5 mol% level with respect to total carbonate and phosphinate functionalities; reactions were carried out in THF and were each quenched after 30 min. [b] Ratios refer to the relative quantities of carbonate and phosphinate functionalities. [c] Residual amounts of phosphinate reflect an average of at least two runs. [d] Corrections for the MW of PC utilized the universal calibration method (K_{PS} = 0.013, K_{PC} = 0.039, α_{PS} = 0.71 and α_{PC} = 0.70, see ref. 11 [e] Ranges reflect non-equilibrium ratios (see text).

affect the amount of residual **1**. While we are confident that 10:1 and possibly 20:1 polymer experiments reach a true equilibrium state,[10] we suspect that the 50:1 cases do not. Unfortunately the low phosphinate concentrations in the residues do not allow us to determine whether catalyst death occurs before a true equilibrium is reached. Clearly, low phosphinate concentrations can be achieved with these experimental conditions.



(4)

In addition to preparative protocols, *in situ* ^{31}P NMR experiments to monitor the transfer of the phosphorus-containing fragment from the simulant to the polymer were also undertaken. The naphthyl phosphinate **1** proved particularly useful in this regard as its conversion to product was readily observed by the 0.5–1 ppm upfield shift of its resonance upon substitution of an oligomeric substituent for ONp. The amount of unreacted phosphinate in these experiments closely matched those data obtained on preparative scales. ^{31}P NMR spectra of the precipitated polymers showed only a singlet shifted slightly upfield from the starting material. Spiking of these samples with either **1** or **2** confirmed that no starting material was present in the MeOH precipitate and that quantifying unreacted simulant in the filtrate is a valid protocol for assessing overall destruction.

In summary, by combining two separate methodologies, one for the synthesis of phosphonates and the other for the breakdown of polycarbonates, a potentially useful method for the destruction of toxic chemical warfare agents has been revealed. The salient features of this approach are the low levels of simulant remaining after reaction and the safe immobilization of the simulant constituents as polymer end groups.

We gratefully acknowledge the United States Army Research Office (DAAG55-98-1-0257) for funding of this research. We also wish to thank Dr D. B. Priddy Jr. at Bayer AG, Krefeld Germany, for kindly providing a generous sample of CPC.

Prochiral selectivity and deuterium kinetic isotope effect in the oxidation of benzyl alcohol catalyzed by chloroperoxidase

Enrico Baciocchi,*[a] Osvaldo Lanzalunga[b] and Laura Manduchi[a]

Received (in Liverpool, UK) 26th May 1999, Accepted 23rd July 1999

The chloroperoxidase-catalyzed oxidation of benzyl alcohol exhibits a very high prochiral selectivity, involving only the cleavage of the *pro-S* C–H bond.

The mechanistic aspects of the reactions catalyzed by chloroperoxidase (CPO), a hemoprotein isolated from the fungus *Caldariomyces fumago*, are attracting continuous interest as this enzyme is able to catalyze the H_2O_2-promoted oxidation of a large variety of organic compounds.[1] There is general consensus that in all cases the active oxidant is an iron(IV) oxo complex porphyrin IX (P) radical cation [$P^{+\cdot}$–Fe^{IV}=O], also indicated as compound I, formed by reaction of the resting enzyme with H_2O_2 [eqn. (1)].[1d,2]

$$P\text{–}Fe^{III} + H_2O_2 \rightarrow \underset{\text{Compound I}}{P^{+\cdot}\text{–}Fe^{IV}\text{=O}} + H_2O \qquad (1)$$

Here we report on a kinetic and products study of the oxidation of benzyl alcohol **1** and the enantiomeric and racemic forms of α-monodeuterated benzyl alcohol (**1**-*d*). The results obtained have shown that the process is characterized by an extremely high prochiral selectivity, providing us with useful information about the reaction mechanism.

The racemic [α-$^2H_1$]benzyl alcohol [(±)-**1**-*d*)] and the two enantiomers (*R*)- and (*S*)-[α-$^2H_1$]benzyl alcohol [(*R*)-**1**-*d* and (*S*)-**1**-*d*, respectively] were reacted with H_2O_2 in H_2O at pH 6 (0.1 M phosphate buffer), in the presence of CPO (2 nmol for 10 mmol of H_2O_2). In each case, the molar ratio between PhCDO and PhCHO produced in the reaction was measured by GC-MS and/or ^{1}H NMR, the two methods giving very similar results. The results are reported in Table 1. The kinetic parameters K_m and k_{cat} for the CPO-catalyzed oxidation of deuterated and undeuterated benzyl alcohols were obtained, as usual, by measuring the initial rates of formation of benzaldehyde at different concentrations of substrate (Lineweaver–Burk plots). These values are collected in Table 2.

Table 1 Oxidations of [α-$^2H_1$]benzyl alcohols with H_2O_2 catalyzed by CPO[a]

Substrate	Yields (%)[b]	PhCDO/PhCHO[c]
(*S*)-[α-^{2}H]benzyl alcohol	58	< 0.1
(*R*)-[α-^{2}H]benzyl alcohol	68	> 30
(±)-[α-^{2}H]benzyl alcohol	47	2.0

[a] The alcohol (0.1 ml of a solution 0.5 M in CD_3CN) and CPO (Sigma) (2 nmol) were magnetically stirred in 5 ml of 0.1 M phosphate buffer pH 6.0 at 25 °C, H_2O_2 (200 μl, 0.5 M) was then slowly added in 1 h *via* a syringe pump. After extraction with $CDCl_3$ reaction mixtures were analyzed by ^{1}H NMR, GC and GC-MS. Benzaldehyde and [α-$^2H_1$]benzaldehyde were the only products formed. [b] Yields are with respect to the starting material. Average of at least three determinations, the error is ±10%. [c] Molar ratio measured *via* GC-MS by the ratio between the corrected signal intensities of the two molecular ions at *m/z* 107 and 106. Average of at least three determinations, the error is ±10%. Similar values were obtained by ^{1}H NMR considering that the signal of the benzylic protons *ortho* to the carbonyl is due to the sum of the two products (PhCHO + PhCDO) and that of the aldehydic proton derives from PhCHO.

By looking at the data in Table 1, a very remarkable observation is that from (*S*)-**1**-*d* practically only PhCHO is produced, whereas the oxidation of its enantiomer (*R*)-**1**-*d* leads almost exclusively to PhCDO. Comparable amounts of deuterated and undeuterated benzaldehydes form instead from the racemic alcohol (±)-**1**-*d*.

These results clearly indicate that in the oxidation of (*S*)-**1**-*d* the bond broken is almost exclusively the C-D bond, whereas the oxidation of (*R*)-**1**-*d* involves almost exclusively the cleavage of the C–H bond. Thus, the ratio between the k_{cat} values for (*R*)-**1**-*d* (C–H bond cleavage) and (*S*)-**1**-*d* (C–D bond cleavage), reported in Table 2, should provide us with a lower limit for the *intrinsic* kinetic deuterium isotope effect of the reaction (k_H/k_D).[3] A value of 2.8 is obtained which is slightly smaller than those (3.3, 3.5) found in the benzylic hydroxylation of *p*-methylanisole.[1i] It therefore seems possible to suggest a similar mechanism for the two processes, *i.e.* the oxidation of benzyl alcohol catalyzed by CPO should involve the transfer of a hydrogen atom to the ferryl oxygen of the iron oxo complex (Scheme 1, path a).[5] An α-hydroxy carbon radical and the iron hydroxy complex P–Fe^{IV}–OH form. They may lead to the hydrated form of benzaldehyde directly (oxygen rebound, Scheme 1, path b) or stepwise with formation of the intermediate α-hydroxybenzyl cation (Scheme 1, path c and d). A similar sequence has also been proposed for the oxidation of benzyl alcohol catalyzed by cytochrome P-450.[6]

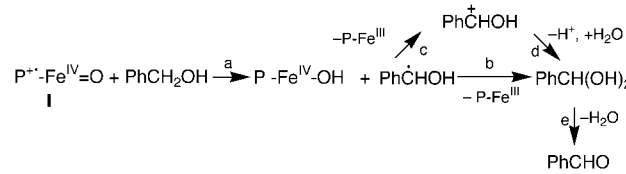
The possibility of an electron transfer mechanism facilitated by the aromatic ring seems unlikely since the value of k_H/k_D is significantly higher than that (1.8) determined in the oxidation of racemic **1**-*d* induced by the genuine one-electron oxidant $SO_4^{-\cdot}$.[7]

The data presented in Table 1 also allow some speculation concerning the orientation of the substrate in the enzyme active site. In particular, it can be suggested that the substrate binds to the enzyme orienting the C–D bond of the *S* enantiomer, and the

Table 2. Steady-state kinetic constants for the chloroperoxidase catalyzed oxidation of benzyl alcohols by H_2O_2

Substrate	K_m/mM[a]	k_{cat}/s^{-1}[a]
1	1.3 ± 0.1	17.2 ± 0.7
(*S*)-**1**-**d**	1.1 ± 0.1	6.6 ± 0.4
(*R*)-**1**-**d**	1.6 ± 0.1	18.7 ± 0.9

[a] Obtained from a Lineweaver–Burk plot. The initial rates for the formation of benzaldehyde were determined spectrophotometrically at 25 °C and pH 6 following the increase of absorbance at 280 nm.



Scheme 1

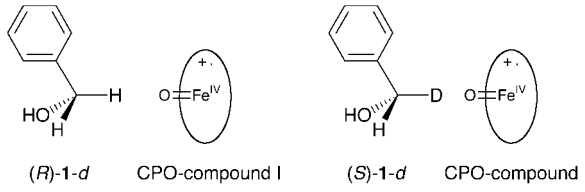


Fig. 1 Proposed orientation of (*R*)-**1**-*d* and (*S*)-**1**-*d* with respect to the iron oxo complex in the CPO active site.

C–H bond of the *R* enantiomer, towards the oxygen of the active oxidant, as illustrated in Fig. 1.

It follows that the oxidation of benzyl alcohol catalyzed by CPO should be characterized by a very high prochiral selectivity with *only* the *pro-S* hydrogen [Fig. 2(*a*)] involved in the process. An additional very interesting notation is that the same spatial orientation as that observed for the oxidation of benzyl alcohol appears to be also required in the CPO-induced oxidation of ethylbenzene, which accordingly has been reported to produce (*R*)-1-phenylethanol,[1j,8] exclusively [Fig. 2(*b*).

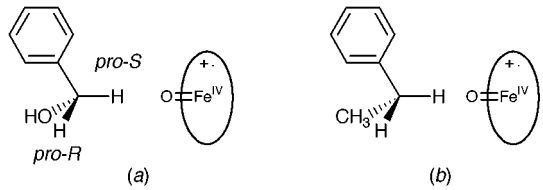

Fig. 2 Proposed orientation of (*a*) benzyl alcohol and (*b*) ethylbenzene with respect to the iron oxo complex in the CPO active site.

Thus, it would seem that in the oxidation of benzyl alcohol the OH group does not play any specific role with respect to the spatial orientation assumed by the substrate in the enzyme reacting pocket. Accordingly, the orientation appears not to change when OH is replaced by a Me group. Probably, the interaction of the aromatic ring with the side chains of Phe 103 and/or Phe 186 plays the major role in this respect. Both Phe 103 and Phe 186 are situated at the bottom of the opening of the CPO substrate-binding pocket and have been suggested to be of fundamental importance in establishing hydrophobic interactions with organic substrates.[9] Theoretical calculations to test this hypothesis are under way.

3 Actually, k^R_{cat}/k^S_{cat} is a measure of the intrinsic deuterium isotope effect only if the rate of release of the product from the enzyme–product complex is not kinetically significant. If this condition does not hold, the intrinsic deuterium isotope effect is expected to be larger than k^R_{cat}/k^S_{cat} (ref. 4).

5 However, a concerted oxygen insertion, as suggested by the use of radical probe substrates [ref. 1(*j*), (*k*)], might also be compatible with the observed intrinsic k_H/k_D values.

6 A. D. N. Vaz and M. J. Coon, *Biochemistry*, 1994, **33**, 6442. Interestingly, in this paper an intramolecular kinetic isotope effect of 2.6 was determined in the oxidation of [α-$^2H_1$]benzyl alcohol induced by purified rabbit liver cytochrome P450 2B4, using only the racemic monodeuterated benzyl alcohol. In preliminary experiments we have found significantly different values of the observed intramolecular kinetic deuterium isotope effect in the phenobarbital induced rat liver microsomal oxidation of (*R*)-**1**-*d* and (*S*)-**1**-*d* (1 and 4, respectively).

7 (±)-**1**-*d* was reacted with $SO_4^{\bullet-}$ (from $Ti^{III}/K_2S_2O_8$ or γ-radiolysis/$K_2S_2O_8$) in H_2O at pH 6 (0.1 M phosphate buffer). From the molar ratio between PhCDO and PhCHO produced in the reaction, measured by GC-MS, a k_H/k_D value of 1.8 was calculated.

8 The *pro-R* hydrogen in ethylbenzene corresponds to the *pro-S* hydrogen in benzyl alcohol.

New products in an old reaction: isomeric products from H_2 addition to Vaska's complex and its analogues

Sarah K. Hasnip,[a] Simon B. Duckett,*[a] Christopher J. Sleigh,[a] Diana R. Taylor,[b] Graham K. Barlow[b] and Mike J. Taylor[b]

[b] *BP Amoco Chemicals, BP Chemicals Limited, Salt End, Hull, UK HU12 8DS*

Received (in Cambridge, UK) 12th July 1999, Accepted 29th July 1999

***para*-Hydrogen enhanced NMR signals aid detection of minor isomers of complexes $IrH_2(L)_2(CO)Cl$ (L = PPh_3, PMe_3, PPh_2Cl and $AsPh_3$) containing magnetically inequivalent hydride ligands that are produced *via* addition across the L–Ir–L axis of $Ir(L)_2(CO)Cl$: in the case of L = PPh_3, reaction with CO and H_2 is shown to yield the substitution product $IrH_2(CO)_2(PPh_3)Cl$ which reacts further *via* HCl transfer to form $IrH(CO)(PPh_3)_2Cl_2$ and thereby enables the detection of $IrH_3(CO)_2(PPh_3)$.**

It has been shown that the addition of H_2 enriched in the *para* spin state to a transition metal centre leads to greatly enhanced hydride signals in associated ^{1}H NMR spectra.[1] This phenomenon is a powerful tool available to characterise minor reaction products such as *all-cis* $Ru(H)_2(CO)_2(PMe_3)_2$[2] and investigate hydrogenation kinetics.[3] The addition of H_2 to Vaska's complex,[4] *trans*-$Ir(CO)(PPh_3)_2Cl$ **1a**, and its analogues has been the subject of much investigation and it is currently accepted that, in general, addition proceeds exclusively over the OC–Ir–Cl axis. However, calculations by Sargent and Hall[5] revealed that H_2 addition over the OC–Ir–Cl axis rather than the P–Ir–P axis is favoured by 9.5 kJ mol^{-1} in the case of $Ir(CO)(PMe_3)_2Cl$. Furthermore, calculations indicate that increasing the π-accepting nature of the phosphine will favour H_2 addition across the P–Ir–P axis. Here, we describe studies that test this prediction by monitoring reactions of $Ir(L)_2(CO)Cl$ (L = PPh_3, PMe_3, PPh_2Cl and $AsPh_3$) with *para*-hydrogen (*p*-H_2).

It has already been shown that when a solution containing *cis*,*trans*-$IrH_2(CO)(PPh_3)_2Cl$ **2a** is examined by ^{1}H NMR spectroscopy the corresponding hydride resonances are polarised (**2a**, 0.1 mmol dm^{-3}, toluene-d_8, 343 K and 3 atm *p*-H_2).[6] Under these conditions, H_2 addition is reversible, and exchange leads to hydride signal enhancements that are 11 fold. At 298 K the hydride resonances of **2a** are unaffected by the presence of *p*-H_2 because exchange is suppressed. However, when the reaction of **1a** with *p*-H_2 is monitored by NMR spectroscopy, *in-situ*, the dihydride products are detected as they form and prior to spin population relaxation. In the corresponding ^{1}H spectrum polarised hydride resonances are detected for **2a**, and a second previously unreported species, as shown in Fig. 1(a). The enhanced resonance of this minor product is only visible when **1a** is reacting with *p*-H_2 and the associated signals decay away rapidly. Furthermore, the extra hydride resonance arises from a second order spin system with magnetically distinct hydrides.[6,7] The ^{31}P and ^{13}C chemical shifts and the multiplicities of the hydride, phosphine and carbonyl resonances of this product, located *via* a series of 2D NMR experiments, are consistent with their origin in *cis*,*cis*-$IrH_2(CO)(PPh_3)_2Cl$ **3a**. This product is formed by H_2 addition over the P–Ir–P axis of **1a**, as shown in Scheme 1.† At 295 K, the difference in hydride signal intensities of **2a** and **3a** was determined by the application of a pulse sequence involving a 90° ^{1}H pulse, a pulsed field gradient, a 100 ms delay, and a 45° ^{1}H read pulse. This procedure enables the instantaneous observation of the ratio of **2a**:**3a** by suppressing signals from pre-formed materials and suggests the ratio of **2a** to **3a** is ≈ 100 if similar enhancements are assumed for each species. There is no evidence to suggest that these two species interconvert on the NMR time scale.

In order to test the generality of this reaction pathway we repeated this procedure with $Ir(CO)(L)_2Cl$ [L = PMe_3 **1b**, Fig. 1(*b*) and L = $AsPh_3$ **1c**]. In both these cases dihydride products corresponding to addition over the Cl–Ir–CO and L–Ir–L axes of *trans*-$IrCl(L)_2(CO)$ are detected. The spectral features of the PMe_3 products **2b** and **3b** are similar to those of their PPh_3 analogues.† However, hydride resonances for both these species are visible at 333 K for extended periods. The failure to observe **3b** with normal hydrogen suggests that while both **2b** and **3b** are accessible by H_2 addition to **1b**, both are able to reductively eliminate H_2 at 333 K, otherwise **3b** would become a significant reaction product.

When the reaction with L = $AsPh_3$ is monitored with normal hydrogen, two isomers, *cis*,*trans*-$IrH_2(CO)(AsPh_3)_2Cl$ **2c** (with hydride resonances at δ −7.11 and −18.91) and *cis*,*cis*-$IrH_2(CO)(AsPh_3)_2Cl$ **3c** (hydride δ −9.62) are detected in the ratio 1:2.85, respectively, at 295 K.† After five days the ratio became 1:0.1, this suggests that addition over the As–Ir–As

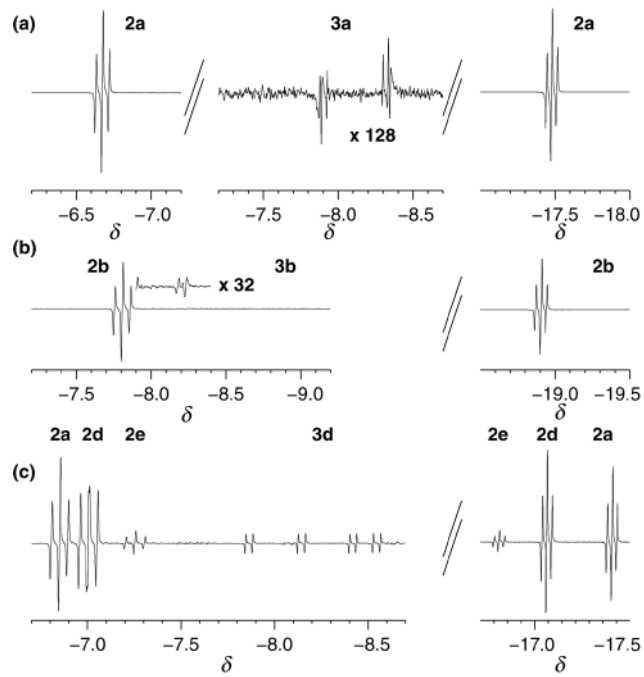

Fig. 1(a) ^{1}H NMR spectrum (400 MHz, 295 K) of a 0.1 mM solution of **1a** in benzene-d_6 under 3 atm of *p*-H_2. The weak second order resonance arises from *cis*,*cis*-$IrH_2(CO)(PPh_3)_2Cl$ **3a**. (b) ^{1}H NMR spectrum (400 MHz, 333 K) of a 0.1 mM solution of **1b** in benzene-d_6 under 3 atm of *p*-H_2 with resonances due to **2b** and **3b** indicated. (c) ^{1}H NMR spectrum (400 MHz, 333 K) of a 0.1 mM solution of **2a** in benzene-d_6 in the presence of a four-fold excess of PPh_2Cl under 3 atm of *p*-H_2 showing resonances due to **2a**, **2d**, **2e** and **3d**.

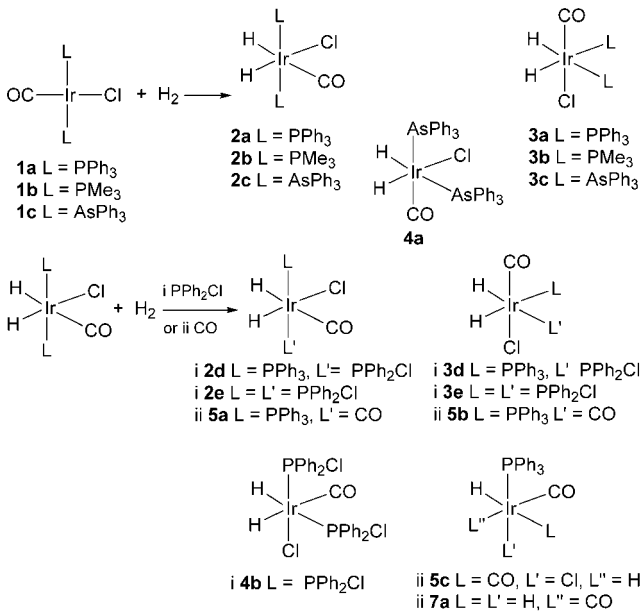

Scheme 1 Species observed in the reactions of a series of chlorocarbonylbis(phosphine)iridium(I) and dihydridochlorocarbonylbis(phosphine)-iridium-(III) complexes under *p*-H_2.

axis is kinetically preferred while addition over the OC–Ir–Cl axis leads to the thermodynamic product. Product **2c** was characterised by 2D NMR methods at 333 K where the rate of H_2 exchange is fast and the *p*-H_2 signal enhancements are long-lived.† The structure of the *cis,cis* product **3c** was confirmed by ^{13}C labelling experiments, ^1H integral measurements, and the presence of two ν(IrH) modes at 2083 and 2115 cm^{-1} in the corresponding IR spectrum.

Interestingly, a third *p*-H_2 enhanced isomer, **4a**, was detected at 338 K in the ^1H NMR spectrum that was not previously visible [Fig. 1(c)]. The chemical shifts of the hydride resonances of this product, δ −11.70 and −18.50, suggest hydride locations *trans* to CO or arsine, and *trans* to chloride, respectively. NOE measurements revealed that the hydride ligand of **4a** which resonates at δ −11.70 is close in space to a single set of *ortho*-phenyl protons (δ 7.65) while that which is *trans* to chloride is adjacent to two different sets (δ 7.65 and 7.60). **4a** therefore contains two inequivalent arsine ligands. When a ^{13}CO labelled sample was examined, the δ −11.70 signal showed a small ^1H–^{13}CO coupling of 3.4 Hz indicating that the hydride is *trans* to arsine rather than CO. In the NOE experiment, no interconversion between **2c**, **3c** and **4a** was observed which suggests that the most probable route to formation of the minor isomer **4a** is H_2 addition over the OC–Ir–As axis of the *cis* isomer of $Ir(CO)(AsPh_3)_2Cl$ (Scheme 1).

A sample containing a four-fold excess of PPh_2Cl relative to **2a** was examined to test the π-accepting role of the phosphine [Fig. 1(c)]. While this spectrum contains no resonances that can be assigned to trisphosphine species, signals corresponding to the hydride resonances of mono- and bis-phosphine exchange products (**2d**, **2e**, Scheme 1) containing *cis* hydrides and *trans* phosphines were readily assigned. Furthermore, resonances for the *cis,cis* isomers **3d** and **3e** were present in significantly higher proportions than those seen in the reaction with **1a** described above. Significantly, by virtue of the mixed phosphines, **3d** contains inequivalent hydride ligands which resonate at δ −8.13 and −8.34 with the resonances having doublet of doublet of doublet multiplicities consistent with *trans* and *cis* phosphine connections. This product is formed by H_2 addition across the P–Ir–P axis of $Ir(CO)(PPh_3)(PPh_2Cl)Cl$. Weak signals due to **4b** were also present.† Ultimately the signals of all these species disappear, and the major hydride resonances are associated with the bisphosphine carbonyl dichloride monohydride complexes **6a** and **6b**.[8] Complex **6a** is also observed in the reaction chemistry of **1a** when both CO and *p*-H_2 are present. Under these conditions, three isomers of $IrH_2(CO)_2(PPh_3)Cl$, **5a**, **5b** and **5c** and the *fac-trans* isomer of $IrH_3(CO)_2(PPh_3)$ **7a** are detected as *p*-H_2 enhanced products (Scheme 1).[9] These observations are consistent with HCl transfer from $IrH_2(CO)_2Cl(PPh_3)$ to **1a**, followed by H_2 addition to yield the dicarbonyl trihydride product.

Here we have demonstrated that H_2 addition to a series of iridium(I) carbonyl complexes based on $Ir(CO)(PPh_3)_2Cl$ involves a minor reaction pathway where addition proceeds across the P–Ir–P axis. We also show that in the presence of mixtures of CO and H_2, $IrH_2(CO)(PPh_3)_2Cl$ and the phosphine substitution product $IrH_2(CO)_2Cl(L)$ are detected in addition to HCl transfer products and a series of trihydride complexes.

Intramolecular Michael addition of benzylamine to sugar derived α,β-unsaturated ester: a new diastereoselective synthesis of a higher homologue of 1-deoxy-L-*ido*-nojirimycin

Vijaya N. Desai, Nabendu N. Saha and Dilip D. Dhavale*

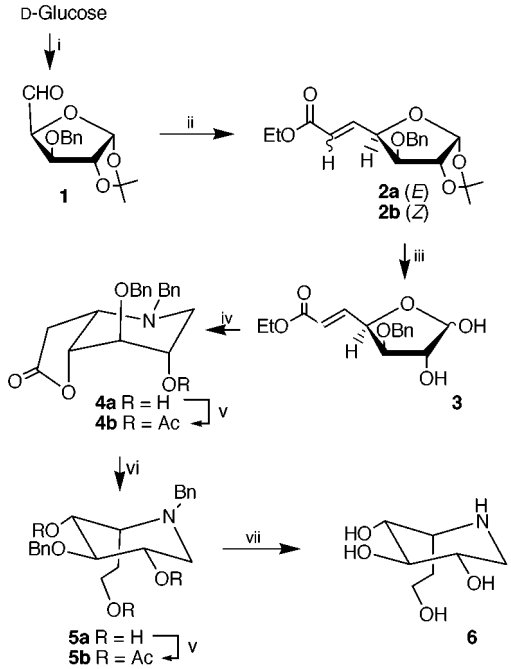
Received (in Cambridge, UK) 6th July 1999, Accepted 23rd July 1999

The diastereoselective intramolecular Michael addition of the benzylamine generated *in situ* from hemiacetal 3 leads to the lactone 4a with the required homoazasugar ring skeleton; reduction of the lactone functionality and removal of the protecting groups afford 1-deoxy-L-*ido*-homonojirimycin.

Naturally occurring polyhydroxylated piperidine alkaloids such as nojirimycin and mannonojirimycin are glycosidase inhibitors of great potential therapeutic value.[1] In order to examine the structure–activity relationship, a number of synthetic analogues of nojirimycin have been synthesised and evaluated for glycosidase inhibition in the treatment of various diseases such as diabetes, cancer, AIDS and viral infections. This includes synthesis of 6-deoxynojirimycin,[2a] 1-deoxynojirimycin,[2b] *N*-alkyl nojirimycin[2c] and *N*-linked disaccharide units.[2d] In recent years, preparation and evaluation of homoazasugars with a CH_2 homologation either at C-1 or in the C-5 side chain and nojirimycin with D and L sugar derivatives have received much attention.[3] As a part of our continuing efforts in the synthesis of nojirimycin analogues[4] we report herewith the synthesis of a one carbon higher (in the C-5 side chain) homologue of 1-deoxy-L-*ido*-nojirimycin **6**. We envisioned that the removal of the 1,2-*O*-isopropylidene in the D-glucose derived α,β unsaturated ester **2** (Scheme 1) followed by reductive amination at the anomeric carbon and concomitant intramolecular conjugate addition should lead to the homoazasugar ring skeleton. Reduction of the ester group and removal of the protecting groups should lead the target molecule. Although the intramolecular Michael addition of amines to α,β-unsaturated carbonyl compounds is widely utilized in the synthesis of polyhydroxylated pyrrolidenes and piperidine derivatives,[5] its application to the homoazasugars is highly restricted.[6]



Scheme 1 *Reagents and conditions* i, ref 8; ii, PPh_3CHCO_2Et (1.3 equiv.), MeCN, reflux, 2 h; iii, TFA–H_2O (3:2), rt, 2 h; iv, $BnNH_2$ (1.0 equiv.), $NaCNBH_3$ (2.0 equiv.), AcOH (0.2 equiv.), MeOH, −78 °C, 2 h, rt, 24 h; v, Ac_2O, pyridine, DMAP, rt, 24 h; vi, LAH (3.0 equiv.), dry THF, 0 °C to rt, 2 h; vii, 10% Pd/C, HCO_2NH_4, MeOH, reflux, 1 h.

Our synthetic route involves **2** as the starting compound, which was prepared in high yield from D-glucose. Thus, the Wittig reaction[7] of α-D-*xylo*-pentodialdose[8] **1** with PPh_3CHCO_2Et gave an isomeric mixture of **2** (*E*:*Z* = 73:27) which was separated by chromatography to afford **2a** (*E*, 64%) and **2b** (*Z*, 24%). The cleavage of acetonide group in **2a** afforded hemiacetal **3** (anomeric mixture, α:β = 7:3) with an exclusively *E* geometry at the double bond.† The one pot reaction of **3** with $BnNH_2$ (1.0 equiv.) in the presence of catalytic amounts of AcOH in MeOH followed by treatment with $NaCNBH_3$ afforded a lactone **4a** as the only isolable product (Scheme 1). Thus, the overall three step transformation presumably involves amine as the primary reaction product which undergoes concomitant intramolecular Michael addition and domino[9] lactonisation to yield diastereoselective formation of **4a** in 79% yield. The lactone **4a** was acetylated with Ac_2O in pyridine to give **4b** (78%).‡ The spectroscopic and analytical data obtained for **4a** and **4b** were in full accord with the assigned structures.§ The configuration at C-5 and conformation of **4a** and **4b** were determined from their high field ^1H NMR spectra based on the coupling constant values. The initial geometry ensures that, in the product, the substituents at C-2, C-3 and C-3, C-4 should be *trans*. The low values of $J_{3,2}$ (~6.4 Hz) and $J_{3,4}$ (~4.3 Hz) indicate that the protons at these carbons are equatorial and the substituents are axial. This suggests that the bicyclic lactones have the $^1C_4$ conformation. The small value of $J_{5,4}$ (~5.3 Hz) along with the axial orientation of the C-4 hydroxy group suggests that the C-5 substituent is equatorial with the (5*S*) configuration. This confirms that the six membered piperidine ring is *cis* fused with the lactone ring.

The diastereoselective formation of **4a** can be explained by considering the transition states **A** and **B** (Fig. 1). In general, the stereoelectronic and steric factors often play an integral role in affecting the stereochemical outcome of the intramolecular Michael addition reactions.[10] However we believe that, under the reaction conditions of borohydride reductive amination and *in situ* Michael addition, the complexation of boron with nitrogen and the C-2 and C-4 hydroxy groups determines the

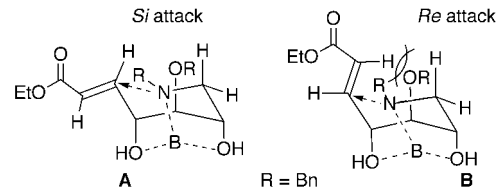


Fig. 1

amine addition.[5] Thus, the complexation of the boron with the C-2,4 hydroxy and amine groups holds the nitrogen atom in such a way that the preferred *Si* face attack at the diastereotopic β-carbon atom, as shown in transition state **A** (Fig. 1), leads to the formation of **4a**.¶ However, transition state **B** (Fig. 1), in which *Re* face attack leads to the formation of the other isomer, is destabilised due to the non-bonded interactions of the α-olefinic hydrogen with the C-1 axial hydrogen and C-3 *O*-benzyl group.

In the subsequent steps, lactone **4a** was reduced with LAH in Et_2O, and the primary alcohol **5a** (colorless solid, 84%) thus obtained was peracetylated to afford **5b** (80%).‖ In the ^{1}H NMR spectra of **5a** and **5b**, H-3 showed a double doublet with large coupling constants ($J_{2,3}$ and $J_{3,4}$ ~ 8.8 Hz).§ This indicated the axial–axial relationship of H-3 with H-2 and H-4, confirming the change in conformation of piperidine ring from $^1C_4$ to $^4C_1$. Finally, removal of the benzyl groups in **5a** was achieved in one step using HCO_2NH_4 and 10% Pd/C in MeOH to give 1-deoxy-L-*ido*-homonojirimycin **6** (90%). The ^{1}H and ^{13}C NMR spectra and analytical data are in agreement with the proposed structure with the $^4C_1$ conformation.§

In conclusion, the one pot reaction sequence of introduction of amine functionality and concomitant intramolecular conjugate addition to D-glucose derived α,β-unsaturated ester provides a unique strategy for the synthesis of homoazasugars. Easy availability of starting materials, mild reaction conditions, high diastereoselectivity and good yields make the route attractive and indicate that it could operate on a gram scale. Work is in progress to study the intermolecular Michael addition of amines to **2** and its applications to the synthesis of homoazasugars and indolizidine alkaloids.

We are thankful to AICTE, New Delhi, for the financial support, TIFR Bombay for high resolution NMR spectra and to UGC, New Delhi, for the JRF to V. N. D. We are grateful to Professor M. S. Wadia for helpful discussions.

Notes and references

† As indicated from the ^{1}H NMR spectrum, the cleavage of the acetonide group either in the isomeric mixture **2** or in **2b** (*Z*-isomer) with TFA–H_2O afforded hemiacetal **3** (α:β = 7:3) with exclusively *E* geometry. Acid catalysed $Z \rightarrow E$ isomerisation has been reported (ref. 11).

‡ Our attempts to isolate either the diastereomer or other products in pure form were unsuccessful. The ^{1}H NMR spectrum of the crude mixture indicated the presence of signals (< 10%) corresponding to an ethyl group. This could be the uncyclised open ester with (5*S*) configuration. Lactone **4a** was easily removed from the mixture by column chromatography followed by recrystallisation. The other diastereomer could not be detected even though the subsequent transformations were conducted without separation of **4a**. For example the direct acetylation of crude mixture of **4a** with Ac_2O and DMAP in pyridine gave **4b** as the only isolable product in 88% yield.

¶ This argument would be valid even if lactonisation precedes Michael addition.

‖ The direct reduction of crude mixture **4a** with LAH followed by peracetylation afforded **5b** in 68% yield.

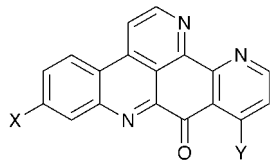
Received (in Liverpool, UK) 24th June 1999, Accepted 29th July 1999

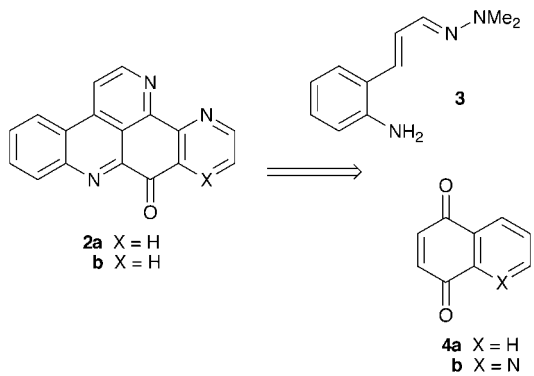
The synthesis of pyridoacridines related to the ascididemins can be performed by an intramolecular aza-Diels–Alder cycloaddition of an α,β-unsaturated hydrazone to a quinone followed by an unprecedented rearrangement to yield benzo- or pyrido-[*b*]acridine-6,11-diones.

Pyridoacridine alkaloids of marine origin, such as amphimedine and the ascididemins (**1a**–**c**),[1] have attracted much attention due to their structural novelty and cytotoxic properties.[2,3] Strategies based on Diels–Alder azacycloadditions are amongst the most conceptually simple and potentially general approaches for the synthesis of these heterocycles.[2,4] However, the practical realisation of these schemes has been hampered by the lack of suitable reactivity of 4-substituted 1-azadienes towards 1,4-quinones.[4–6]



1a X = Y = H
b X = Br, Y = H
c X = H, Y = OH

Herein we report a new approach for the synthesis of heterocycles **2a**–**b**[7,8] related to the ascididemins (**1a**–**c**) based on an intramolecular aza-Diels–Alder reaction of 1-dimethylamino-1-azadienes[9] followed by an unprecedented rearrangement which occurs under oxidative conditions. The bond connectivity achieved between azadiene **3**[4] and 1,4-naphthoquinones **4a**,**b** in the cycloaddition–rearrangement is shown in Scheme 1. This scheme is formally equivalent to an intermolecular cycloaddition of diene **3** with the corresponding 1,2-naphthoquinones.



2a X = H
b X = H

4a X = H
b X = N

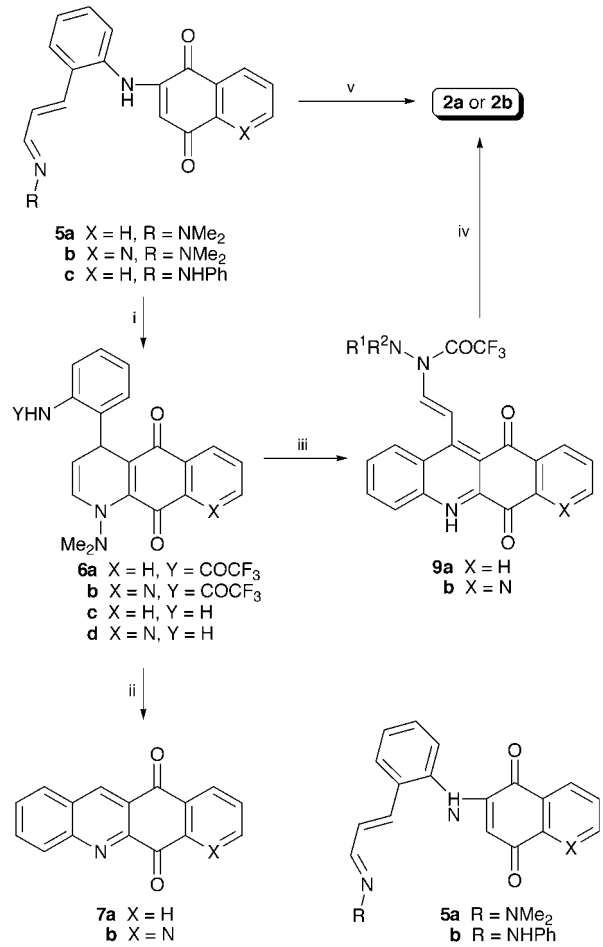
Scheme 1

† Dedicated to Professor José Elguero on the occasion of his 65th birthday.

‡ Current address: Departamento de Química Orgánica, Facultad de Química, Universidad de Granada, Spain.

The intramolecular cycloaddition of **5a**–**c** was examined as part of a projected synthesis of the alkaloid meridine[1c,10] and related compounds (Scheme 2). These aminoquinones were readily available by the addition of the aniline **3**[3] to **4a** or **4b** in MeOH at 23 °C the presence of $CeCl_3 \cdot 7H_2O$ (0.1 equiv) (70% for **4a**, 48% for **4b**).[11] On the other hand, a hydroxy group in the position 4 of quinolinequinone directs the nucleophilic attack of aniline derivatives allowing the synthesis of adducts **5d**–**e** with the opposite regioselectivity.[12]

After much experimentation, the desired cycloadditions were realised by trifluoroacetylation of the amines of **5a**,**b** (NaH, TFAA, 3 equiv. each, THF, 23 °C) followed by replacement of THF by CH_2Cl_2 and addition of excess TFA (23 °C, 1 h) to furnish quinones **6a** (45%) and **6b** (47%),[13] respectively. Under these conditions, the intermediate cycloadducts, which could not be isolated, suffer elimination of the trifluoroacetamides to form the quinone chromophores.



5a X = H, R = NMe_2
b X = N, R = NMe_2
c X = H, R = NHPh

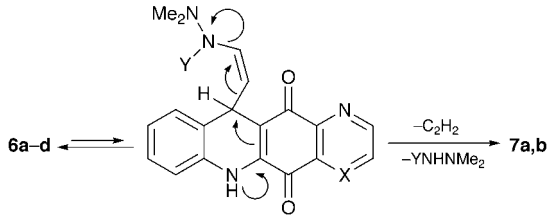
6a X = H, Y = $COCF_3$
b X = N, Y = $COCF_3$
c X = H, Y = H
d X = N, Y = H

9a X = H
b X = N

7a X = H
b X = N

5a R = NMe_2
b R = NHPh

Scheme 2



Scheme 3

Much to our surprise, **6a** was cleanly transformed into tetracycle **7a**[14] by heating with acid (1:1 10% aq HCl–1,4-dioxane, reflux; 94%). Quinone **7a** could also be obtained directly from **5a** by thermolysis (xylene, reflux; 55%) or by treatment with TFA (23 °C; 68%).[15] Under these latter conditions, heterocyclic quinone **7b** was similarly obtained from **5b** (66%).[13] Scheme 3 suggests a possible mechanism for these remarkable transformations in which the dimethylhydrazine and two carbons are lost under relatively mild conditions. Accordingly, a 6-*endo-trig* cyclization of the trifluoroacetamide (from **6a**,**b**) or the amine (*via* **6c**,**d** formed *in situ* from **5a**,**b**) onto the quinone double bond with concomitant (or subsequent) transacylation would lead to intermediates **8**, which may undergo aromatization to form a pyridine ring by a Grob-type fragmentation to give acetylene and the hydrazine derivative. The first step of this process, nucleophilic addition–elimination on a quinone, is somewhat reminiscent of the so-called mitomycin rearrangement.[16]

According to the hypothetical equilibrium of Scheme 3, oxidation of intermediate **8** could yield a precursor of tetracycles related to the ascididemins (**1**). In the event, treatment of **6a**,**b** with excess MnO_2 in CH_2Cl_2 at 23 °C smoothly led to tetracycles **9a**,**b** in quantitative yield as single isomers. The rearrangement also takes place in the presence of DDQ or CAN as the oxidants. A *trans* configuration was assigned for the alkenyl portion of these derivatives on the basis of a vicinal coupling constant of 15.5 Hz. However, the configuration around the enamine nitrogen was not rigorously assigned. Reaction of **9a**,**b** with NH_4Cl and NaOAc in EtOH under refluxing conditions gave pentacyclic **2a**[4] (93%) and **2b** (84%).[13] After examining several hydrazone and oxime derivatives,[17] we found that thermolysis of phenylhydrazone **5c** directly furnished **2a** (refluxing xylene, 40%), probably through intermediate **10a**. In fact, related tetracyclic derivative **10b** could be isolated in 54% yield by thermolysis of **5b** in xylene.

In summary, a highly concise synthesis of heterocycles **2a**,**b** has been developed based on an intramolecular aza-Diels–Alder cycloaddition followed by a novel rearrangement in which the aminoaryl formally undergoes a 1,2-shift.

This work was supported by the DGES (Project PB97-0002-C2-02). We acknowledge the Instituto Biomar, S.A., for the data in ref. 3.

Anthracene-linked calix[4]pyrroles: fluorescent chemosensors for anions

Hidekazu Miyaji,[a] Pavel Anzenbacher Jr,[a] Jonathan L. Sessler,*[a] Ellen R. Bleasdale[b] and Philip A. Gale*[b]†

[a] *Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712-1167, USA*
[b] *Department of Chemistry, University of Oxford, Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR*

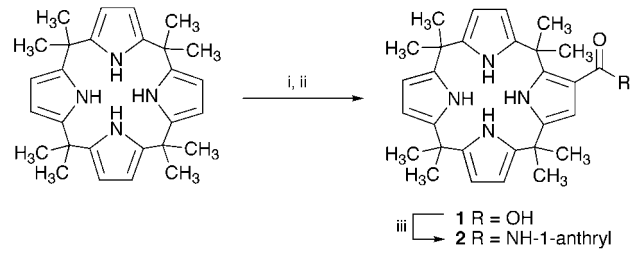
Received (in Cambridge, UK) 24th June 1999, Accepted 27th July 1999

Fluorescent anthracene–calix[4]pyrrole conjugates 2, 4 and 5 have been synthesized; these receptors can detect the presence of anions (*e.g.* F^-, Cl^-, $H_2PO_4^-$) by a significant quenching of their fluorescence.

The selective detection of guest species by redox[1] or photoactive[2] host molecules is a challenging area of supramolecular chemistry that has attracted increasing interest in the last few years. In spite of this, optical sensors for anions are still relatively rare.[3–7] We have recently discovered that calix[4]pyrroles, a class of molecule known for over a century, are effective anion binding agents in solution and in the solid state.[8–10] Our first attempt at using the calixpyrrole moiety as a sensor involved attaching redox active ferrocene moieties to the calixpyrrole skeleton *via* amide linkages and studying perturbations in the ferrocene/ferrocenium redox couple on addition of anionic guests.[11] Substantial changes occurred in the electrochemical properties of these materials but these changes were unpredictable and difficult to rationalize. We therefore decided to investigate whether calix[4]pyrrole, when combined with a fluorescent reporter group, would act as an optical sensor for anions. Here we report the synthesis a series of compounds **2**, **4** and **5** that contain a calix[4]pyrrole anion binding site linked to a fluorescent anthracene moiety.

In order to minimise the distance between the anion binding site and the fluorophore (and also provide a conjugated bond pathway between them), a new calix[4]pyrrole-monoacid precursor **1** was prepared using a modification of the procedure used previously to prepare a homologous calix[4]pyrrole ester derivative.[12] Specifically, *meso*-octamethylcalix[4]pyrrole[13] was dissolved with stirring in dry THF under an argon atmosphere, and the flask cooled to −78 °C. A solution of BuLi in hexanes (4.0 equiv.) was added dropwise to the calix[4]pyrrole solution and, after 30 min, solid CO_2 was added. The reaction was stirred for a further 3 h at −78 °C and then allowed to warm to room temperature. The solvent was removed and the residue was suspended in water. The suspension was filtered to remove unreacted *meso*-octamethylcalix[4]pyrrole and the solution was acidified with perchloric acid, whereupon calix[4]pyrrole acid **1** precipitated out as a white powder. Recrystallisation from acetone–water by slow evaporation produced colourless crystals of the mono-acid **1** in 6.8% yield. The anthracene-linked calix[4]pyrrole **2** was prepared by activation of calix[4]pyrrole acid **1** with DCC and hydroxybenzotriazole hydrate (HOBt) in DMF followed by treatment with commercially available 1-aminoanthracene. Purification by column chromatography afforded compound **2** in 34% yield (Scheme 1).

Compound **4** was prepared by coupling calixpyrrole monoacid **3**[12,14] with 1 equiv. of 1-aminoanthracene using the benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate (BOP) amide coupling reagent (1.1 equiv.) in DMF in the presence of excess Et_3N. After removal of DMF, the calixpyrrole–anthracene conjugate **4** was isolated as a yellow foam by column chromatography in 63% yield. Compound **5** was prepared in an analogous manner by coupling compound **3** with 9-aminomethylanthracene.[15] Compound **5** was isolated by column chromatography as a yellow foam in 51% yield.



Scheme 1 *Reagents and conditions*: i, BuLi (4 equiv.), THF; ii, CO_2; iii, 1-aminoanthracene, DCC, HOBt, DMF.

Initial complexation studies were conducted using ^{1}H NMR titration techniques. Aliquots of the tetrabutylammonium salts of the putative anionic guests (0.1 mol dm^{-3}) were added to a solution of compound **2**, **4** or **5** (0.01 mol dm^{-3}) in CD_3CN and the shift of the calix[4]pyrrole NH proton noted after each addition. Significant downfield shifts of the pyrrole NH protons were observed upon addition of anions, consistent with the formation of calixpyrrole–anion hydrogen bonds. In the presence of fluoride anions, the NMR spectrum broadened considerably, making a determination of the stability constant impossible by this method. However, analysis of the remaining titration data using the EQNMR[16] computer program revealed that the compounds form 1 : 1 receptor:anion complexes with chloride, dihydrogen phosphate and bromide anions. The resulting stability constants are shown in Table 1.

Fluorescence quenching experiments were carried out by addition of solutions of anions (tetrabutylammonium fluoride, chloride, bromide, dihydrogenphosphate or hydrogensulfate) to

[a] Quenching insufficient to provide an accurate stability constant value.

50 μM solutions of compounds **2**, **4** and **5** in CH_2Cl_2 or CH_3CN. Excitation and λ_{max} (emission) values for the three compounds are given in the footnote to Table 2. Significant fluorescence quenching was observed upon addition of tetrabutylammonium fluoride to compounds **2**, **4** and **5**. For example, the fluorescence spectra of compound **2** obtained as a function of added fluoride anion are shown in Fig. 1.

Quenching was also observed in varying degrees upon addition of other anions to receptors **2**, **4** and **5**. This is illustrated in Fig. 2(*a*) which shows the effects of different anions on the fluorescence of compound **2** in CH_2Cl_2. In this instance it can be seen that, on a per molar basis, the addition of fluoride anion causes the greatest fluorescence quenching, followed by the addition of dihydrogenphosphate and chloride anions. Using these quenching data and standard Scott plot analyses,[17] association constants were calculated for receptors **2**, **4** and **5** interacting with fluoride, chloride, bromide and dihydrogenphosphate anions (Table 2). In general, good agreement was observed between these K_a values and those obtained using NMR analyses. However, several of the flourescence-derived plots exhibited biphasic behaviour. This

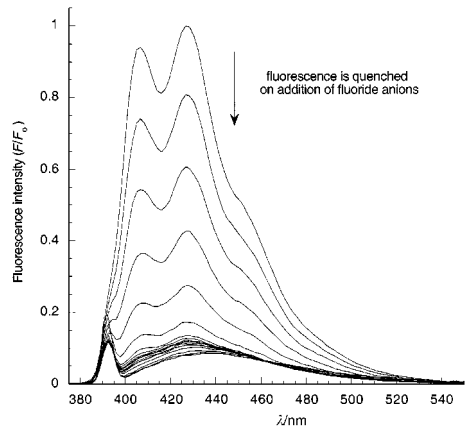

Fig. 1 Fluorescence spectra of calixpyrrole **2** in CH_2Cl_2 (0.05 mM) excited at 378 nm showing the changes induced upon the addition of increasing quantities of tetrabutylammonium fluoride.

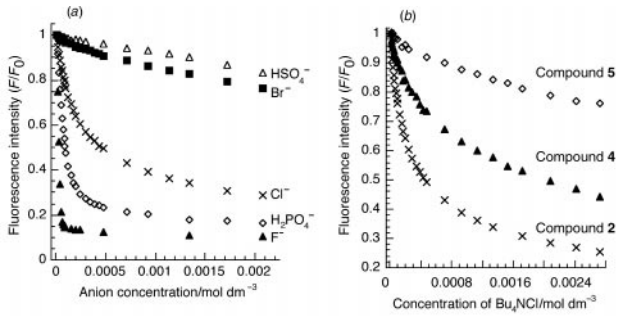

Fig. 2 (*a*) The quenching effect of various anions on compound **2** and (*b*) the fluorescence quenching effect of chloride anions on compounds **2**, **4** and **5**.

may be due to aggregation of the anthracene moieties, coordination of the anion to the amide moiety,[11] oligomerisation of dihydrogenphosphate anions[18] or heavy atom effects,[2] and is currently the topic of further investigation.

Control experiments were carried out with anthracene. At an anthracene concentration of 50 μM in CH_2Cl_2, there was no significant fluorescence quenching observed on addition of fluoride and chloride anions. On the other hand it was found that bromide and iodide acted to quench fluorescence in concentrations between 100 to 1000 mM (presumably due to the heavy atom effect).[2] No significant quenching was observed on addition of dihydrogenphosphate or hydrogensulfate anions to these control anthracene solutions.

A comparison of the quenching caused by chloride at the respective λ_{max} (emission) is shown for each of receptors **2**, **4** and **5** in Fig. 2(*b*). It can be clearly seen that chloride quenches the fluorescence of compound **2** most efficiently and compound **5** least efficiently. This trend may be related to the structure of the receptors and to their affinity for anions. The stability constants of the receptors with chloride follow the trend **2** > **4** > **5** (*cf.* Table 2). Further, the distance between the anthracene fluorophore and the anion-binding site increases in the order **2** < **4** < **5**. Finally, compound **2** has a conjugated bond pathway linking the fluorophore and anion-binding site of the calixpyrrole providing an electronic communication pathway between them, whereas compounds **4** and **5** do not. It might therefore be expected that fluorescence quenching is most efficient in compound **2** and least efficient in compound **5**.

In summary, a series of calixpyrrole–anthracene conjugate compounds have been synthesized that possess conjugated (compound **2**) and unconjugated bond pathways of different lengths (compounds **4** and **5**) between the calix[4]pyrrole anion binding site and the anthracene reporter group. The fluorescence of these receptors is quenched significantly in the presence of certain anionic guests. Compounds **2**, **4** and **5** thus represent prototypical calix[4]pyrrole based-fluorescent anion sensing agents.

Received (in Cambridge, UK) 14th June 1999, Accepted 20th July 1999

The first satisfactory application of the heterogeneous cinchona-modified Pt catalyst system for the synthesis of a C3 chiral building, namely, the highly enantioselective (up to 96.5% ee) hydrogenation of pyruvaldehyde dimethyl acetal to lactaldehyde dimethyl acetal is described.

The increasing use of chiral compounds has raised the profile of asymmetric synthesis, in particular the environmentally more friendly heterogeneous enantioselective hydrogenations.[1] One of them, the cinchona alkaloid-modified platinum catalyst system, was found to be effective in the hydrogenation of α-keto esters and keto acids.[1] The chiral hydrogenation of ethyl pyruvate provides excellent (up to 97% ee) enantioselectivity using presonicated cinchonidine–Pt/Al_2O_3 catalysts under mild hydrogen pressure.[2] In recent years new substrates have also been studied such as unsaturated carboxylic acids,[3–5] ketoamides,[6] pyruvic acid oxime,[7] ethyl nicotinate[8] and trifluoromethyl ketones.[9] Unfortunately, the optical yields in these latter cases are far from excellent.

The major thrust of our work was to widen the type of substrates in the Pt–cinchona catalyzed hydrogenations. Here, we report a new successful enantioselective ketone hydrogenation over cinchona-modified Pt/Al_2O_3 catalyst, namely, the asymmetric hydrogenation of pyruvaldehyde dimethyl acetal. This compound is a very frequently used synthon equivalent in synthetic organic chemistry for the preparation of chiral *O*-protected α-hydroxy aldehydes.[10] The enantioselective hydrogenation of the target compound and its further transformation to a valuable synthon are shown in Scheme 1.

Pyruvaldehyde dimethyl acetal itself has already been reduced to the corresponding hydroxy derivatives by rhodium complexes,[11] boranes[12] or by enzymatic methods.[13] Although each method is satisfactory, in cost or simplicity they cannot be compared to the cinchona modified Pt-catalyzed hydrogenations.

In this study two Pt/Al_2O_3 catalysts (Engelhard 4759 and 40655) were used while the modifiers [cinchonidine (CD) and cinchonine (CN)] and the substrate [Pyruvaldehyde dimethyl acetal (PDA)] were all Fluka products. The hydrogenations were performed in an atmospheric batch reactor or in a Berghof Bar 45 autoclave at 20 °C as described previously.[2] Product identification was carried out by GC-MS (HP5890 GC-HP5970MSD) and ^{1}H NMR spectroscopy (Bruker AM400), while the enantiomeric excesses (ee (%) = ($|[R] - [S]|$) × 100/($[R] + [S]$)] were monitored by chiral gas chromatography (HP 5890 GC-FID, 30 m long Lipodex-A capillary column). The ee values were reproducible to within 1%.

According to our recent observations[2] two catalysts, the well-known reference catalyst E4759 and a second 5% Pt/Al_2O_3 catalyst (E40655), which was highly efficient in the enantioselective hydrogenation of ethyl pyruvate, were tested in the hydrogenation of PDA. Taking into account the fact that in the literature many solvents have been applied, some common solvents were tested in an atmospheric system to find the most suitable medium for the hydrogenation of PDA. Although in toluene or EtOH the enantioselectivity is only moderate (up to 66% with CD and 25% with CN), using AcOH as solvent the results are comparable to those obtained with ethyl pyruvate[1,2] using both modifiers. The results obtained in AcOH including reaction rates and optical yields are summarized in Table 1.

Since the ethyl pyruvate hydrogenation produces higher optical yields under elevated hydrogen pressures the effect of hydrogen pressure on the present system was also studied. The optical yields obtained in different solvents are plotted as a function of the hydrogen pressure in Fig. 1.

According to the ee data the enantioselectivity seems to be strongly solvent dependent. It was found that the application of

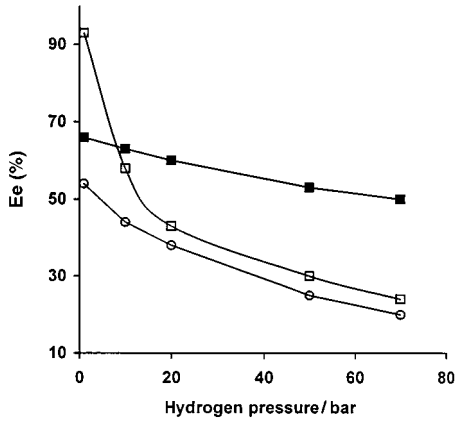

Fig. 1 Enantiomeric excess *vs.* hydrogen pressure for the enantioselective hydrogenation of pyruvaldehyde dimethyl acetal over a 5% Pt/Al_2O_3 (E4759)–cinchonidine catalyst system in different solvents at 20 °C: (□) AcOH, (■) EtOH and (○) toluene.

both CD and CN provides the best optical yields in AcOH at low hydrogen pressures. In our opinion this significant solvent dependence is a result of the weaker adsorption of PDA in the case of toluene (6π electrons *versus* 2π electrons), while using EtOH the substrate can form a semi-acetal with the solvent as pointed out for ethyl pyruvate.[1] As the data show, the increase in hydrogen pressure resulted in monotonically decreasing enantioselectivities in each solvent. However, this decrease is more pronounced in AcOH and toluene than in EtOH, for which only a slight decrease was observed.

Although E4759 provided excellent results [93% for the (*R*)-isomer], however, the other catalyst (E40655) produced even higher enantioselectivity; the highest ee obtained is 96.5% for the (*R*)-isomer. The (*S*)-isomer can be prepared in 88% optical purity in the presence of the E4759 catalyst. In this way, both enantiomers can be prepared in excellent optical purity, and no further optimization is needed. Although this work is basically of an experimental nature, the kinetic data indicate that the mechanism is most likely similar to that proposed in the case of ethyl pyruvate. The modified reactions all take place at higher rates than the nonmodified one (Table 1, compare all entries to entry 7), indicating a ligand accelerated mechanism. As a result, the highest enantioselectivity was obtained at the highest reaction rate (entry 3), however, explaining the roles of geometrical and electronic factors is not possible at this level of the study.

It should be mentioned that the above listed results were obtained on a microscale level. Taking into account the potential of the optically active product the scale up the reaction was also studied in order to isolate the hydroxy acetal. The results of the scale up experiments are also shown in Table 1 (compare entries 3, 5 and 6). After the hydrogenation was complete (see entry 6), the product mixture was poured into NaOH solution and the hydroxy acetal was extracted with Et_2O. After solvent evaporation, 2.1 g (78% yield) of the (*R*)-product was isolated. Further purification by distillation resulted in a product of 99.9% chemical (GC) and 93% optical purity [(*R*)-enantiomer]. The (*S*)-isomer can also be isolated in the same way.

The present study provides the first experimental proof that species other than α-keto acids and α-keto esters (including the cyclic ketopantolactone) can be hydrogenated with excellent optical yields over cinchona-modified platinum catalysts. Since the synthetic importance of chiral hydroxy aldehydes as useful chiral building blocks is well-known this new, environmentally friendly method for their preparation may even widen their applications.

In conclusion, the cinchona-modified Pt/Al_2O_3 catalytic system was found to be effective in the enantioselective hydrogenation of a 2-keto aldehyde derivative, providing the opportunity to still widen the practical applications and potential of this unique and important catalytic system.

Financial support (AKP97-4 2,4) is highly appreciated.

Enantioselective hydrogenation of α-keto acetals with cinchona modified Pt catalyst

Martin Studer,* Stefan Burkhardt and Hans-Ulrich Blaser

Scientific Services, Novartis Service AG., R-1055.616, CH-4002 Basel, Switzerland.

Received (in Cambridge, UK) 25th June 1999, Accepted 20th July 1999

The enantioselective hydrogenation of a variety of α-keto acetals to the corresponding α-hydroxy acetals with Pt catalysts modified with cinchonidine derivatives is described with ees up to 97% and high reaction rates, and the influence of the substrate structure, the modifier and the reaction conditions (catalyst, solvent, temperature, pressure, modifier concentration) was investigated in some detail.

Modified heterogeneous catalysts for enantioselective hydrogenation are of interest, both from a theoretical and practical point of view.[1] Up to now only two efficient catalyst systems are known with enantioselectivities of 90% or higher. Most notable are the tartrate modified Raney nickel catalysts with ees of up to 98% for β-keto esters and for β-diketones[2–4] and the cinchona modified Pt catalysts for the hydrogenation of α-keto esters with ees up to 98%.[5-7] Even though recently some progress in expanding the substrate scope of the Pt–cinchona catalysts has been reported,[8–11] only a few of the new substrates are hydrogenated with ees > 60% or are of synthetic relevance. Here we describe the enantioselective hydrogenation of α-keto acetals to the corresponding α-hydroxy acetals with cinchona modified Pt catalysts with ees up to 97% and high rates. The influence of substrate structure, the modifier and the reaction conditions (catalyst, solvent, temperature, pressure, modifier concentration) were investigated. While there are some literature reports of the enantioselective reduction of α-keto acetals,[12–15] the Pt–cinchona catalysts shows clear advantages with respect to selectivity, activity and simplicity for the synthesis of interesting chiral synthons.

The results of a rather broad variation of the α-keto acetal structure, using Pt/Al_2O_3 in presence of 10,11-dihydrocinchonide (HCd) in toluene or 9-methoxy-HCd (MeOHCd) in AcOH are summarized in Table 1. Obviously, α-keto acetals are extraordinarily suitable substrates for the cinchona modified Pt catalysts with respect to both enantioselectivity and activity. The highest ee and rate values were obtained with two pyruvaldehyde acetals (entries 1 and 2). Compared to ethyl pyruvate, the ees were slightly higher (ee up to 96% for ethyl pyruvate), and the rates somewhat lower (up to 400 mmol g^{-1} min^{-1} for ethyl pyruvate). The addition of the modifier led to a rate acceleration of the order of ten, also comparable to ethyl pyruvate. Other aliphatic and aromatic α-keto acetals with low bulkiness gave very high ees, but with significantly lower rates (entries 5,7,9–11). Significantly lower ees and very much lower rates were observed for keto acetals with more bulky R especially with larger R′ moieties. Aromatic and aliphatic ethers as well as esters and amides are tolerated and do not affect the enantioselectivity very much (entries 10–13). α-Keto ketals (entries 14,15) are hydrogenated very slowly and with negligible induction.

The effect of the modifier/solvent combination and of different Pt catalysts was studied for pyruvaldehyde dimethyl acetal and other substrates (for selected results see Table 2). The best results were always observed either with MeOHCd in AcOH or with HCd in toluene, while EtOH usually gave both lower enantioselectivities and rates. The reaction rates of the modified and the unmodified system were compared for HCd in EtOH. In most cases, ligand accelerated catalysis was observed. The best catalyst was a 5% Pt/Al_2O_3 catalyst, JMC 94 (Johnson Matthey), which in our hands also had the best performance with ethyl pyruvate. Several alumina and silica supported Pt catalysts from several catalyst manufacturers were compared; while the rates differed by a factor of up to 4, all catalysts gave ees of ⩾93% with pyruvaldehyde dimethyl acetal and MeOHCd in AcOH.

For the model reaction with pyruvaldehyde dimethyl acetal, the influence of hydrogen pressure, temperature and substrate and modifier concentration were investigated, with results similar to those obtained for ethyl pyruvate.[16,17] The most notable difference was the influence of the hydrogen pressure. In contrast to ethyl pyruvate, ees ⩾ 94% were observed at 1 bar (increasing to 96% at pressures between 2 and 140 bar), and the rate showed a half order dependence on hydrogen pressure. The substrate concentration had only a small effect on the enantioselectivity (94% at 0.4 M, 96% at 2.8 M and 80% in neat substrate at 8 M) while the rate was affected very strongly: 25 mmol g^{-1}

[a] Conditions: all hydrogenations were carried out as described in ref. 17. Typically, 1–2 g substrate, 5% Pt/Al_2O_3 (JMC type 94, 2 h pretreated with H_2 at 400 °C), 5–50 mg MeOHCd, 15–20 ml AcOH, 60 bar, 25 °C. All ees and conversions were determined by GLC (Beta-dex 110, Supelco hydrogen carrier) or by HPLC (Chiracel OD, 95% hexane and 5% Pr^iOH). All new substrates and products gave satisfactory analytical results (^{13}C, ^1H, and MS). [b] Substrate from Fluka. [c] Substrate synthesised according to literature methods. [d] Substrate synthesized from substrate in entry 1 using H^+ and EtOH. [e] Substrate synthesized from substrate in entry 1 using H^+ and BuOH. [f] Substrate synthesized from substrate in entry 6 using H^+ and MeOH. [g] Reaction in toluene using HCd. [h] Ee estimated. [i] Substrate not very pure.

Table 2 Effect of solvent, modifier structure and catalyst type (selected results)[a]

Solvent/modifier	Catalyst	Ee % (*R*)	Rate/mmol g^{-1} min^{-1}
AcOH/MeOHCd	1	96.5	41
AcOH/MeOHCd	2	96	23
AcOH/MeOHCd	3	94	12
AcOH/MeOHCd	4	93	33

Toluene/HCd	1	79	5.7
EtOH/HCd	1	61	8.4
EtOH/MeOHCd	1	35	—
EtOH/none	1	−1.1	1.3

[a] Conditions: 2 ml pyruvaldehyde dimethyl acetal, 50 mg catalyst, 5 mg modifier, 25 °C, 60 bar, 20 ml solvent. Catalyst 1 was 5% Pt/Al_2O_3, JMC 94 (Johnson Matthey), catalyst 2 was 5% Pt/Al_2O_3, E 4759 (Engelhard), catalyst 3 was 5% Pt/Al_2O_3, F 213XR/D (Degussa), catalyst 4 was 5% Pt/SiO_2, 98993 (Heräus), all 2 h pretreated with H_2 at 400 °C.

min^{-1} at 0.4 M and 119 mmol g^{-1} min^{-1} at 2.8 M, decreasing to 36 mmol g^{-1} min^{-1} at 8 M. The dependence of ee and rate on the temperature was studied between 10 and 50 °C. While the ee was almost constant (97 and 96%), the rate strongly increased between 10–30 °C. At temperatures above 30 °C, a decrease in both ee and rate was observed. Most likely, the modifier is either desorbed from the catalyst surface or hydrogenated at higher temperature. Fig. 1 shows the dependence of ee and rate on the MeOHCd concentration. Both curves had a similar shape, as was observed for ethyl pyruvate in toluene,[16] and could be modeled with a simple kinetic model assuming reversible but strong adsorption of the modifier on the Pt surface. As expected, the ee values are rather low at low modifier concentration if the reaction is run to high conversion, most likely because the modifier is hydrogenated and thereby made ineffective during the course of the reaction.

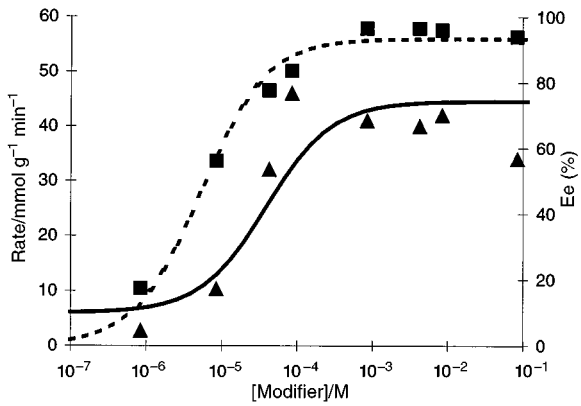

Fig. 1 Dependence of ee and rate on modifier concentration: (▲) observed rate, (—) calculated rate, (■) observed ee and (---) calculated ee. Calculated curves according to ref. 11. Pyruvaldehyde dimethyl acetal (2 ml), AcOH (18 ml), 5% Pt/Al_2O_3 (50 mg) (JMC type 94, 2 h pretreated with H_2 at 400 °C), 25 °C, 60 bar.

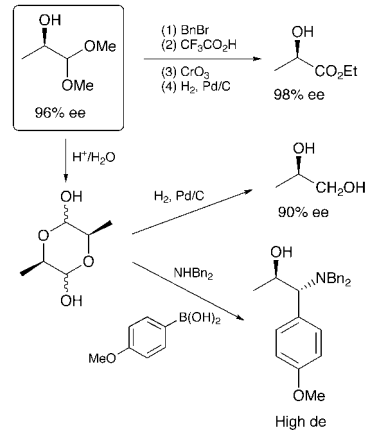
Enantiomerically enriched α-hydroxy acetals are interesting synthons and can be transformed into a variety of chiral building blocks (*e.g.* 1,2 diols, α-hydroxy acids, 1,2 amino alcohols) as shown in Scheme 1. While the oxidation to (*R*)-ethyl lactate was rather difficult and required the protection of the OH group, the reduction could be easily accomplished after hydrolysis of the acetal. No significant racemisation was observed. With a boronic acid derivative and a secondary amine, it was also possible to synthesize amino alcohols with high diastereoselectivity according to ref. 18.



Scheme 1

From all the results presented above, we conclude that the Pt–cinchona catalyzed hydrogenation of α-keto acetals is very similar to the well studied reaction of α-keto acid derivatives:[1] the most likely mode of action is that the adsorbed ketone interacts with the N_1 atom of the adsorbed cinchona modifier, probably *via* a hydrogen bridge, resulting in both a rate acceleration and the preferential addition of hydrogen from the *si* side of the keto group to produce (*R*)-α-hydroxy acetals.[17] Concerning the requirements for a suitable substrate for this chiral catalyst system we in principle confirm the postulate of Mallat *et al.*[9] that an electron-withdrawing group α to the C=O can lead to good ees. However, if we consider the results for methoxy acetone (best ee 12%), trifluoroacetophenone (56%) and the α-hydroxy acetals (97%), it is obvious that there is no clear correlation between the electronic character of the carbon α to the ketone and the enantioselectivity. The presence of either a second C=O or of a $CH(OR)_2$ group in the α-position is especially beneficial to obtain both very high ees and acceptable reaction rates. For this fact there is as yet no convincing explanation available.

We thank Professor M. Bartok for his co-operation for the back-to-back publication (see preceding article).

Received (in Cambridge, UK) 14th June 1999, Accepted 29th June 1999

Simultaneous activation of methane and carbon dioxide to aromatics (SAMCA) over sodium-modified silica supported chromium-based catalysts is reported.

In this decade, much attention has been paid to the aromatization of methane under non-oxidative conditions following the early work conducted by Bragin *et al.*[1] Effective catalysts and mechanisms have been recently reviewed.[2,3] Molybdenum oxide supported on HZSM-5 zeolite seems to be a uniquely effective catalyst system for the aromatization of methane under non-oxidative conditions.[2–6] However, understanding the interaction of methane with the surfaces greatly depends upon various observations. It appears, in general, that reduction and/or carbidation of Mo species over Mo/ZSM-5 catalyst plays a key role in the activation of methane to produce initial C_2 products, and the primary intermediates are then further oligomerized to benzene on the B-acid sites within the channels of ZSM-5 zeolite.[2,3,6] Recently, we have found that sodium-modified silica supported chromium-based catalysts exhibit considerable activity for the simultaneous activation of methane and carbon dioxide to aromatics (SAMCA). This is the first investigation, to our knowledge, to use non-zeolite supported oxide catalysts for the non-free-oxygen activation of methane to produce benzene and toluene in the presence of large amounts of carbon dioxide.

The catalysts were prepared as follows. CR18, as a typical example, is described in detail. Given amounts of Cr_2O_3 (0.35 g) and/or $(NH_4)_2Cr_2O_7$ (the molar ratio of Cr_2O_3 to $(NH_4)_2Cr_2O_7$ is 2:1) and $NaNO_3$ (0.89 g) were slurried with silica sol (42 wt% water, 45 g) for 3 h, and then dried overnight at 120 °C. Several samples with different metal loadings and different Cr(III)/Cr(VI) ratios were prepared by controlling the concentration of the sol. The resulting samples were calcined at 500 °C for 4 h and then at 800 °C for 4 h. All of the calcined catalyst samples were crushed and sieved to 26–55 mesh. The XPS spectrum in the Cr 2p region for the catalyst CR18 revealed a strong peak at a binding energy of 579.0 eV and a shoulder of this peak at a binding energy of 576.6 eV corresponding to Cr(VI) $2p_{3/2}$ and Cr(III) $2p_{3/2}$, respectively. The ratio of Cr(VI)/Cr(III) in CR18 on the basis of the XPS peak area is 5:1.

The catalytic runs were carried out at a pressure of 0.4 MPa in a fixed-bed vertical-flow stainless steel reactor mounted inside a tube furnace. The amount of the catalyst charged in the reactor was 1.0 g. The catalyst was pretreated in highly pure nitrogen (99.99%) at 840 °C for 30 min. Then, the reactant gas mixture ($CH_4:CO_2$ = 7:5) was introduced at a flow rate of 22 ml min^{-1}. When the support (SiO_2) was used as a catalyst alone, the reaction results also indicated small amounts of aromatics (yield < 0.07%, see Table 1). Isotopic trace experiments were carried out under the same conditions but at a pressure of 0.3 MPa. Pure $^{13}CO_2$ obtained from $Ba^{13}CO_3$ was pressurized to 0.3 MPa by high pressure CH_4 and CO_2 to give a CH_4/CO_2 molar ratio of 7/5. The relative partial pressure of $^{13}CO_2$ in the CO_2 mixture was calculated to be 1/3.

The products in the effluent stream were analyzed by an online GC equipped with a Hayesep Q column (TCD,H_2 as carrier) for CO, CH_4, CO_2 and C_1–C_3, 13X and 5A sieve columns (TCD, Argon as carrier) for H_2, CH_4 and CO, and a quartz capillary column coated with SE-54 (FID) for benzene and toluene. Both methane and carbon dioxide were 99.995% pure.

Operating parameters significantly influence the activity of the catalyst in the SAMCA reaction. Fig. 1(a) shows that both the aromatics yield and the selectivity are increased by increasing the reaction temperature. The yield and the selectivity of aromatics are also found to go through maxima at a contact time of 0.79 h g l^{-1}, indicating that deep oxidation may occur when the contact time is > 0.79 h g l^{-1}.

Fig. 1(b) shows the effect of the CH_4/CO_2 molar ratio on the selectivities and the yields at 840 °C. Both the selectivity and the yield of aromatics are enhanced with an increasing proportion of CH_4 in the reactant mixture, and reach a maximum at a CH_4/CO_2 molar ratio of 1.4. However, the selectivity to C_{2+} hydrocarbons essentially remains constant for CH_4/CO_2 molar ratios of > 1.1. When the molar ratio of CH_4/CO_2 is < 0.5 or > 2.5, both C_{2+} hydrocarbons and aromatics are difficult to detect. It is of note that the yields of C_{2+}

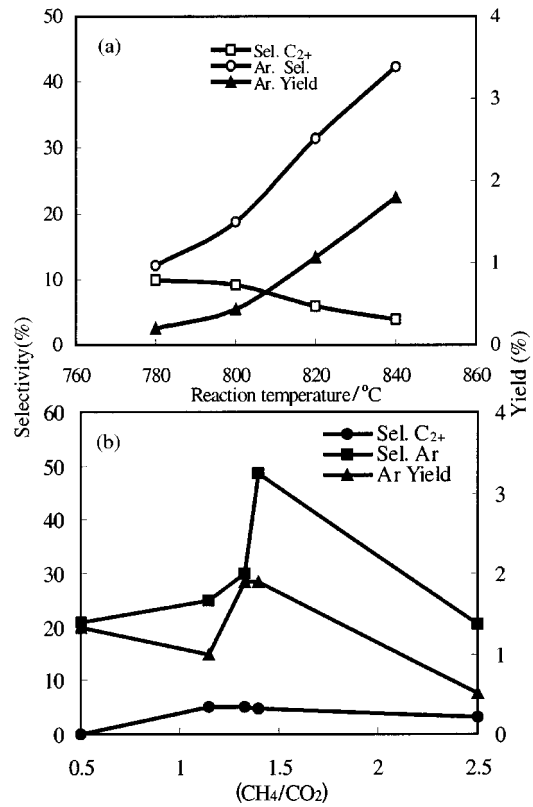

Fig. 1 Effect of operating parameters on the activity of the catalyst 5 wt% Na–7.5 wt% Cr/SiO_2 in SAMCA. (a) Effect of reaction temperature (0.4 MPa, 0.79 h g l^{-1}, CH_4/CO_2 = 7:5) and (b) effect of CH_4/CO_2 molar ratio (0.4 MPa, 0.79 h g l^{-1}, 840 °C).

Table 1 Catalytic performances of a series of chromium-based catalysts in the SAMCA reaction[a]

Catalyst	Cr (wt%)	Na (wt%)	S_{BET}/ $m^2\ g^{-1}$	$V/cm^3\ g^{-1}$	Conversion		Selectivity			Aromatics yield (%)
					CH_4	CO_2	C_2^+	Ar[b]	CO	
SiO_2	0	0	204.48	46.8	0.9	5.1	11.9	7.6	80.4	0.07
CR16	7.5	0	202.44	46.17	2.7	21.4	0.0	23.7	76.3	0.6
CR17	7.5	2	10.05	2.29	2.4	10.6	4.1	38.4	57.5	0.9
CR18	7.5	5	3.35	0.76	3.8	16.0	4.8	48.7	46.5	1.9
CR19	7.5	10	1.87	0.43	4.0	7.1	4.1	41.2	54.7	1.7
CR7[c]	11.4	2	9.80	2.11	1.4	13.5	3.6	1.8	94.6	0.03

CR10[e]	7.5	2	9.51	2.13	2.1		23.1	2.2	74.7	0.05

[a] *Reaction conditions*: 0.4 MPa, 840 °C, 20–23 ml min^{-1}, CH_4/CO_2 = 7/5. [b] Benzene + toluene. [c] Na–Cr(III)/SiO_2. [d] Na–Cr(VI)/SiO_2. [e] CH_4 feed only.

hydrocarbons and aromatics are very low when only methane is fed into the reaction mixture as demonstrated by the results for CR10 and CR15 in Table 1.

Variation of the Cr^{3+}/Cr^{6+} ratio in the preparation of the catalyst precursors has a considerable effect on the activity of the catalyst in SAMCA. The reaction results obtained from a series of chromium-based catalysts are presented in Table 1. Over the Cr_2O_3/SiO_2 catalyst (CR7 in Table 1), the dominant product is carbon monoxide (94.6%) although C_{2+} and aromatics are detectable. This situation is very similar to the results over a Cr_2O_3 catalyst reported by Asami *et al.*[7] except that they observed no aromatics.[7] However, addition of Cr^{VI} to the Cr_2O_3/SiO_2 catalyst led to significantly increased SAMCA reactivity. In particular, over the catalyst containing a 2 : 1 molar ratio of Cr^{3+} to Cr^{6+} and modified with 5 wt% sodium promoter (CR18), CH_4 conversion reaches 3.8%, while selectivity to aromatics increases to 48.7%. By comparison, when only Cr^{VI} species are present on the fresh catalyst surface (CR8), the CH_4 conversion decreases to 2.6%, and the selectivity to aromatics also decreased to 13.9%. Interestingly, when the highest selectivity to aromatics is obtained over CR18 (5 wt% Na and 2 : 1 molar ratio of Cr^{3+} to Cr^{6+}), the selectivity to CO is at a minimum, and the molar ratio of benzene to CO is *ca.* 1 : 1. In this case, small amounts of H_2 were observed at a CO/H_2 molar ratio of 3. However, after being on-stream for 6 h, the catalyst CR18 shows behavior more closely resembling that of Cr_2O_3 (CR7). Correspondingly, XPS analysis of the quenched catalyst indicates the Cr(III) $2p_{3/2}$ peak only. As proposed previously,[8–10] it is highly probable that mixing of octahedral and tetrahedral site-symmetries on the surface of the supported oxide catalyst presents catalytically active sites for the SAMCA reaction.

Asami *et al.* have proposed the reaction given by eqn. (1) to explain the formation of ethene:[7]

$$2CH_4 + 2CO_2 \rightarrow C_2H_4 + 2CO + 2H_2O \quad (1)$$

We tentatively suggest a subsequent additional step here to explain the formation of benzene for SAMCA in which the CO molecules can be obtained from either reaction (1) or the partial reduction of CO_2 in the hydrogen atmosphere.

$$2C_2H_4 + 3CO \rightarrow C_6H_6 + CO_2 + H_2O \quad (\Delta G = -183.2\ kJ\ mol^{-1}\ at\ 840\ °C) \quad (2)$$

In order to confirm whether CO_2 participates in the formation of benzene, isotopic trace experiments using $^{13}CO_2$ in CH_4 and CO_2 co-feed have been carried out under a pressure of 0.3 MPa. The $^{13}CC_5H_6$ species, which was not observed by using the normal CH_4–CO_2 mixture as the feed gas, is identified by a peak at *m/z* 79.17 in the online mass spectrum (Fig. 2), indicating that the carbon in CO_2 demonstrably takes part in the construction of the benzene ring.

Despite their low reactivity, this work has demonstrated that methane and carbon dioxide can be simultaneously activated. The reaction producing aromatics over silica supported chromium-based catalysts is accompanied by an induction period of *ca.* 20 minutes. Ethene, as the primary intermediate, is necessary for the formation of benzene, however, the definate requirement of zeolite channels as proposed based on the Mo/ZSM-5 system is questioned. This research may therefore lead to some new insights on the mechanism for the aromatization of methane.

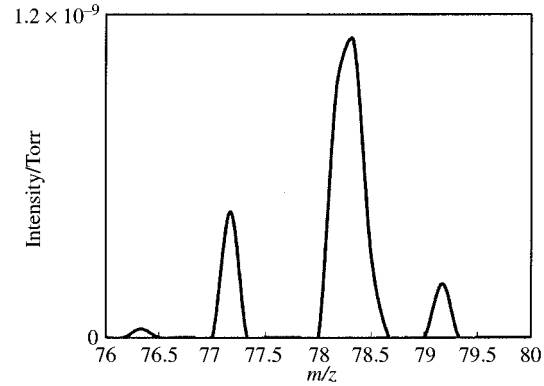

Fig. 2 MS spectra of the products formed in the SAMCA reaction with $^{13}CO_2$-labelled reactant.

Further work is in progress, not only to carry out the reaction on a larger experimental scale, but also to elucidate the nature of the mixed site-symmetry/oxidation state catalysts by XAFS analysis.

We greatly appreciate Professor Shikong Shen at Beijing Petroleum University for his helpful suggestions and discussions. We thank Drs Changchun Yu and Chunyi Li for experimental assistance.

Synthesis, structure and reactivity of the hexaphospha-titanocene, bis-(η^5-3,5-di-*tert*-butyl-1,2,4-triphosphacyclopentadienyl)titanium(II)

F. Geoffrey N. Cloke,* John R. Hanks, Peter B. Hitchcock and John F. Nixon*

School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ. E-mail: J.Nixon@sussex.ac.uk

Received (in Cambridge, UK) 7th July 1999, Accepted 26th July 1999

The novel, fully structurally characterised, 14e-titanocene [Ti(η^5-($P_3C_2Bu^t_2$)$_2$] made by (i) cocondensation of titanium vapour with the phosphaalkyne Bu^tCP (ii) reaction of Bu^tCP with [Ti(η^6-C_6H_5Me)$_2$] at −78 °C or (iii) by heating $TiCl_n$ with $n(KP_3C_2Bu^t_2)$ (n = 2, 3) in toluene at 110 °C, undergoes an unusual [2+2] cycloaddition reaction with Bu^tCP to give [Ti(η^5-$P_3C_2Bu^t_2$)(η^3-η^2-$P_4C_3Bu^t_3$)].

Despite several attempts by different workers using a variety of routes, isolation and structural characterisation of a monomeric, (non C–H activated), titanocene has failed owing to the high reactivity of the carbene-equivalent [Ti(η^5-C_5H_5)$_2$] unit. The addition of neutral ligands such as CO, N_2, PF_3, PMe_3, C_2H_4 and bulky ethynes facilitated isolation of derivatives of [Ti(η^5-C_5H_5)$_2$] and [Ti(η^5-C_5Me_5)$_2$],[1–7] however, the use of bulky substitutents on the cyclopentadienyl rings proved less successful until the very recent report of [Ti(η^5-Cp^s)$_2$] [Cp^s = $C_5Me_4(SiMe_2Bu^t)$] by Lawless and coworkers[8]

Previously[9,10] we showed that cocondensation of the phosphaalkyne Bu^tCP with transition metal vapours affords a wide variety of organometallic compounds of which those containing the di- and tri-phosphorus substituted cyclopentadienyl rings are by far the most common. We now report that cocondensation of titanium atoms with Bu^tCP yields the first example of a phosphorus substituted titanocene which has been fully characterised and its molecular structure established by a single crystal X-ray diffraction study.

Cocondensation of electron beam generated[11] titanium atoms with an excess of Bu^tCP at 77 K (i) affords the hexaphospha-titanocene complex [Ti(η^5-$P_3C_2Bu^t_2$)$_2$] **1** (*ca.* 2.5% after work up, based on titanium) (Scheme 1). **1**, which was obtained as dark-red air and moisture-sensitive crystals by sublimation (180 °C, 1 × 10^{-5} mbar) followed by recrystallisation from pentane (−20 °C)† can also be prepared, in slightly better yield (ii) by adding an excess of Bu^tCP to a pentane solution of [Ti(η^6-C_6H_5Me)$_2$] at −78 °C or in moderate (*ca.* 30%) yield (iii) by heating $TiCl_n$ with $n(KP_3C_2Bu^t_2)$[12] (n = 2, 3) in toluene at 110 °C.

A single crystal X-ray diffraction study‡ (Fig. 1) confirms the formulation of **1** and shows it to be a slightly bent, monomeric sandwich compound (angle between the planes of the two $P_3C_2Bu^t_2$ rings = 16.05°; centroid–Ti–centroid angle = 173.9°). The rings are approximately planar, with the *tert*-butyl groups staggered so as to minimize inter-ring interactions and the phosphorus atoms lying slightly above the plane containing the carbons. Although several phosphorus-containing sandwich compounds are known, the only other reported hexaphospha-metallocene structures are for Cr, Fe and Ru[13–15] although there also exists an unpublished Mn structure.[16] As expected, the metal to ring-centroid distances steadily decrease in the series [M(η^5-$P_3C_2Bu^t_2$)$_2$] (M = Ti, Cr, Mn, Fe), as the size of the metal decreases (Ti 1.942, Cr 1.815, Mn 1.710, Fe 1.687 Å). A similar trend in metal–ring distances has been observed and rationalised in the analogous metallocenes [M(η^5-C_5H_5)$_2$] (M = V, Cr, Fe).[17–20] The [M(η^5-$P_3C_2Bu^t_2$)$_2$] complexes all have slightly bent sandwich structures with centroid–metal–centroid angles of 173.5° (Cr), 173.2° (Fe), 171.0° (Mn). Since the 18e Fe and Ru compounds and the 16e Cr compound would be expected to have parallel rings, the slight distortion has been attributed to the steric effect of the *tert*-butyl groups being unable to fully intermesh. As expected, the pentaphosphametallocenes, [M(η^5-$P_3C_2Bu^t_2$)(η^5-$P_2C_3Bu^t_3$)] (M = V, Fe)[10,14] have essentially parallel rings as here the *tert*-butyl groups can fully intermesh.

Only limited structural comparisons can be made between **1** and other titanocenes because the parent titanocene is not monomeric but exists instead as various dimers.[1] Likewise, although decamethyltitanocene [Ti(η^5-C_5Me_5)$_2$] is monomeric, (in equilibrium with a C–H activated species), no structural data are available.[1] The X-ray structure of the very recently synthesised [Ti(η^5-Cp^s)$_2$] shows that the two rings are planar, staggered and exactly parallel, with the $SiMe_2Bu^t$ substituents rotated by 180° with respect to each other.[8] The metal–centroid distance [2.014(8)Å] is larger than that determined for **1** [1.942(2) Å], presumably either because of the more sterically demanding Cp^s ligand and/or the stronger bonding of the phosphorus substituted cyclopentadienyl rings.[9] The exactly parallel nature of the two Cp^s rings is also presumably due to steric factors. Although **1** has a $3d^2$ electronic configuration, it is found to be diamagnetic. At room temperature the ^1H,

M(1) and M(1)′ refer to the centroids of the two rings.

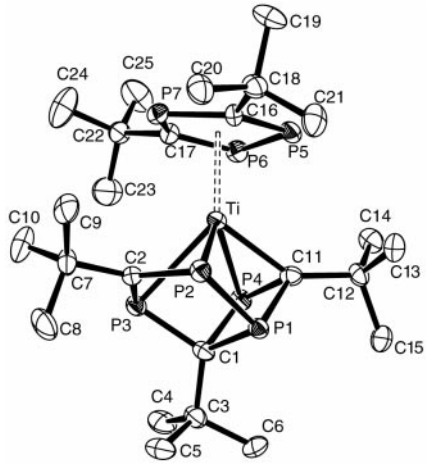

Fig. 2 Molecular structure of [Ti(η^5-$P_3C_2Bu^t_2$)(η^3-η^2-$P_4C_3{}^tBu_3$)] **2**. Selected distances (Å): Ti–M(1) 2.120(6), Ti–C(2) 2.503(6), Ti–C(11) 2.210(6), Ti–C(16) 2.465(5), Ti–C(17) 2.663(6), Ti–P(2) 2.472(2), Ti–P(3) 2.662(2), Ti–P(4) 2.577(2), Ti–P(5) 2.609(2), Ti–P(6) 2.673(3), Ti–P(7) 2.709(2), C(1)–P(1) 1.876(5), P(1)–P(2) 2.216(2), P(2)–C(2) 1.790(5), C(2)–P(3) 1.752(5), P(3)–C(1) 1.831(6), P(1)–C(11) 1.858(5), C(11)–P(4) 1.828(5), P(4)–C(1) 1.909(5). M(1) refers to the centroid of the ring P(5)C(16)P(7)C(17)P(6).

$^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra§ are all sharp (and temperature invariant over the range 185–385 K) and indicate that in solution the two $P_3C_2Bu^t_2$ rings are equivalent and that there is no inter-ring coupling. This is in contrast to the iron and ruthenium analogues which exhibit fluxional behaviour and inter-ring coupling constants of 53 Hz (Fe) and 37.4 Hz (Ru).[13,14]

Decamethyltitanocene forms dinitrogen complexes (some reversibly), and although **1** does not react with dinitrogen, it readily undergoes addition reactions with CO or ^{t}BuNC to give the 16e and 18e complexes [Ti(η^5-$P_3C_2Bu^t_2$)$_2$L] (L = CO) and [Ti(η^5-$P_3C_2Bu^t_2$)$_2$L$_2$] (L = CO, Bu^tNC) respectively, which will be reported in detail elsewhere.[21] However, with an excess of Bu^tCP the novel red–brown 14e-complex [Ti(η^5-$P_3C_2Bu^t_2$)(η^3:η^2-$P_4C_3Bu^t_3$)] **2** is formed as a result of an unusual [2+2] cycloaddition with a P=C bond of *one* of the η^5-$P_3C_2Bu^t_2$ rings of **1** (Scheme 1). No reaction is observed in an analagous experiment with Bu^tCN. The molecular structure of **2**, determined by a single crystal X-ray diffraction study,‡ is shown in Fig. 2. The titanium is attached in an η^5-fashion to the one remaining $P_3C_2Bu^t_2$ ring and η^3:η^2- ligated to the new $P_4C_3Bu^t_3$ moiety. The $^{31}P\{^1H\}$ NMR spectrum of **2** exhibits the expected seven different resonances and the ^1H NMR spectrum contains the expected five singlets.§

The mechanism of formation of **2** from **1** might involve the intermediacy of an η^1- (or less likely η^2-ligated) Bu^tCP complex and the subsequent η^5- to η^3-ring slippage of one of the $P_3C_2Bu^t_2$ facilitating a [2+2] cycloaddition with the resulting uncoordinated P=C bond leading to the product **2**. Interestingly, although **2** can be sublimed (170 °C, 1×10^{-5} mbar) with only slight decomposition to **1**, it was not isolated from the original cocondensation experiment.

To our knowledge, the only related metallocene ring addition reactions previously reported concern nickelocene and fluoroalkenes or an activated norbornadiene however no structural data are available for comparison.[22,23]

We thank Dr A. Abdul-Sada for recording the mass spectrum of **1** and the EPSRC for financial support (for J. R. H.).

Synthesis of amino-sugars using the directed dihydroxylation reaction

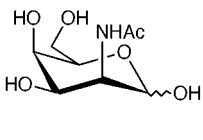
Timothy J. Donohoe,* Kevin Blades and Madeleine Helliwell†

Department of Chemistry, The University of Manchester, Oxford Road, Manchester, UK, M13 9PL. E-mail: t.j.donohoe@man.ac.uk

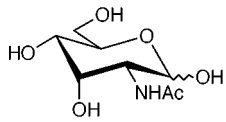
Received (in Cambridge, UK) 22nd June 1999, Accepted 29th July 1999

The synthesis of protected forms of two amino-sugars, talosamine 1 and allosamine 2, is described; the *syn, syn* stereochemistry at C-2, C-3 and C-4 was controlled by the use of a hydrogen-bonding directed dihydroxylation reaction using stoichiometric and catalytic OsO_4; proof of the relative stereochemistry of the allosamine series was obtained through an X-ray crystal structure of a protected derivative.

2-Amino-sugars are the key constituents of a variety of naturally occurring polysaccharides. We are interested in the synthesis of two of the rarer amino-sugars, talosamine and allosamine: *N*-acetyltalosamine has been isolated from both bovine and ovine cartilage,[1] whilst *N*-acetylallosamine is the repeat unit in the sugar portion of allosamidin[2] (which is an interesting chitinase inhibitor).



N-acetyl-D-talosamine
1



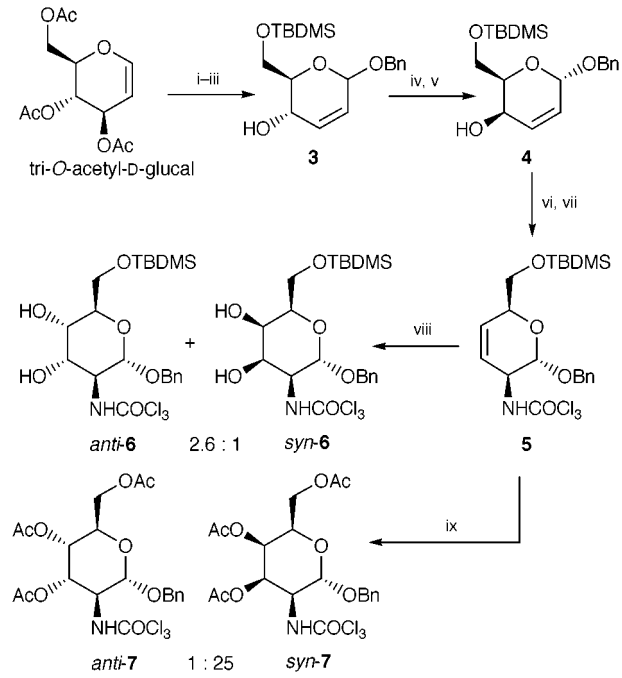
N-acetyl-D-allosamine
2

We have recently described that combination of OsO_4 with an amine (usually TMEDA) produces a reagent which dihydroxylates allylic amides: efficient hydrogen bonding between the oxidant and the allylic amide means that the stereoselectivity observed is contra-steric and therefore opposite to that obtained under standard oxidation conditions.[3] Examination of talosamine and allosamine reveals that they both have *syn,syn* stereochemistry at C2–C4 and so are ideally configured for synthesis *via* our chemistry.

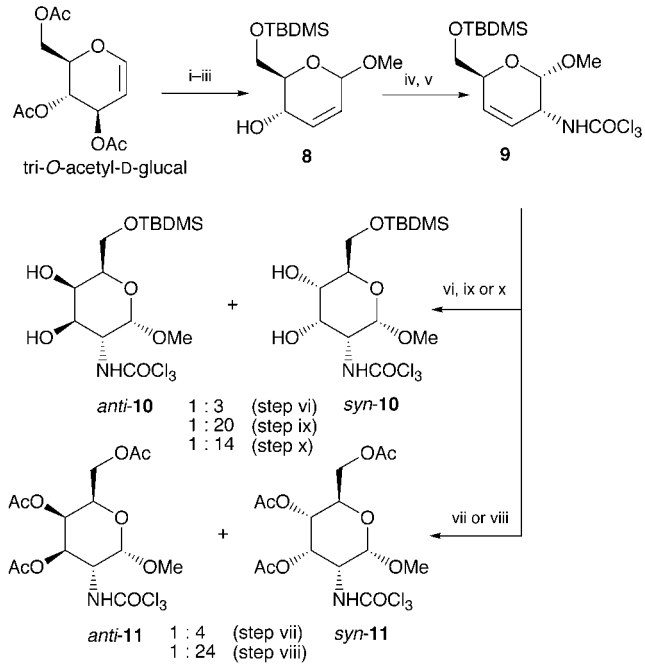
Our synthesis of *N*-acetyl talosamine began with tri-*O*-acetyl-D-glucal, which was converted into the allylic trichloroacetamide **5** using standard chemistry (Scheme 1).[4] Compounds **3**, **4** and **5** are formed as mixtures of anomers (9 : 1) and the major one was separated and is shown for clarity. The dihydroxylation of **5** was then examined under a variety of conditions to investigate ways of forming the *syn,syn* isomer which corresponds to the talosamine series. As can be observed from Scheme 1, oxidation under standard Upjohn conditons (step viii) gave predominantly the *syn,anti* isomer (this corresponds to the altrose series of amino sugars) as expected. However, use of OsO_4 and TMEDA at low temperature was successful in completely reversing the facial bias of this molecule and provides the *syn,syn* isomer with complete stereoselectivity (as measured by ^1H NMR spectroscopy, step ix) and excellent yield. The relative stereochemistry of the adducts shown in Scheme 1 was proven by correlation to a compound of known configuration (*vide infra*). Note that the products from the stoichiometric and catalytic oxidations are slightly different; the acidic work-up used with stoichiometric OsO_4 removes the TBDMS group at C-6; the resulting triol was then peracetylated with Ac_2O in order to expedite isolation.

† Author to whom correspondence regarding the crystallography should be addressed.

We then turned our attention to allosamine **2** and proceeded to prepare allylic amide **9** by a process analogous to that described earlier (Scheme 2).[5]‡ The modified conditions reported by Isobe and co-workers were crucial to success in the Overman rearrangement.[6] The oxidation of **9** (again the major anomer was isolated and is shown for clarity) proved to be most interesting. In this case the standard Upjohn reaction was moderately *syn* selective for the allosamine isomer (step vi). Unfortunately the addition of TMEDA to OsO_4 only marginally improved the *syn* selectivity of the oxidation, (step vii). Occasionally, our attempts to use TMEDA/OsO_4 for directing the dihydroxylation reaction have been frustrated by either electrostatic or steric repulsion between the substrate and the oxidant.[7] In such cases we have found that addition of a monodentate amine (quinuclidine is best) to OsO_4 can give better *syn* stereoselectivity *via* a hydrogen bonding process; this was indeed the case (step viii), and the selectivity attainable was now high enough to be synthetically useful. The reagent formed during this reaction is not as effective a hydrogen bond acceptor as OsO_4/TMEDA but can give higher levels of *syn* stereoselectivity, presumably as a consequence of its reduced steric bulk. One of the advantages of using a monodentate amine promoter in the dihydroxylation reaction is that the process can be made catalytic in osmium by using the amine as its



Scheme 1 *Reagents and conditions*: i, BnOH (1.1 equiv.), $BF_3{\cdot}OEt_2$ (0.1 equiv.), CH_2Cl_2, −20 °C room temp., 1 h, 98%; ii, K_2CO_3 (0.5 equiv.), MeOH–H_2O (4 : 1), room temp., 1 h, 93%; iii, TBDMSCl (1.1 equiv.), Et_3N (2.2 equiv.), CH_2Cl_2, room temp., 24 h, 74%; iv, PPh_3 (4.0 equiv.), $PhCO_2H$ (4.0 equiv.), DEAD (4.0 equiv.), THF, 0 °C, 2 h, 88%; v, NaOMe (0.5 equiv.), MeOH, room temp., 86%; vi, DBU (1.2 equiv.) CCl_3CN (1.3 equiv.), CH_2Cl_2, −20 °C–room temp., 97%; vii, xylene, cat. K_2CO_3, Δ, 18 h, 93%; viii, NMO (1.5 equiv.), cat. OsO_4, acetone–H_2O (4:1), room temp., 77%; ix, TMEDA (1.05 equiv.), OsO_4 (1.05 equiv.), CH_2Cl_2, −78 °C–room temp., then MeOH–HCl, then Ac_2O, 89%.



Scheme 2 *Reagents and conditions*: i, MeOH (1.1 equiv.), $BF_3{\cdot}OEt_2$ (0.5 equiv.), toluene, −20 °C–room temp., 1 h, 89%; ii, K_2CO_3 (0.5 equiv.), MeOH–H_2O (4:1), room temp., 1 h, 92%; iii, TBDMSCl (1.1 equiv.), Et_3N (2.2 equiv.), CH_2Cl_2, room temp., 24 h, 91%; iv, DBU (1.2 equiv.), CCl_3CN (1.3 equiv.), CH_2Cl_2, −20 °C–room temp., 98%; v, Ph_2O, cat. K_2CO_3, 195 °C, 3 h, 64%; vi, NMO (1.5 equiv.), cat. OsO_4, acetone–H_2O (4:1), room temp., 75%; vii, TMEDA (1.05 equiv.), OsO_4 (1.05 equiv.), CH_2Cl_2, −78 °C–room temp., then MeOH–HCl, then Ac_2O, 92%; viii, quinuclidine (1.1 equiv.), OsO_4 (1.05 equiv.), CH_2Cl_2, −78 °C–room temp., then MeOH–HCl, then Ac_2O, 90%; ix, quinuclidine *N*-oxide (2.0 equiv.), cat. OsO_4, CH_2Cl_2, room temp., 80%; x, $Me_3NO{\cdot}2H_2O$ (1.5 equiv.), cat. OsO_4, CH_2Cl_2, room temp., 87%.

corresponding *N*-oxide (with sufficient water added to allow the catalytic cycle to turn over). So, the use of quinuclidine *N*-oxide (2 equiv.)[8] and *catalytic* OsO_4 (5 mol%) with approximately 4 equiv. of water, also gave an excellent level of *syn* stereoselectivity (step ix). This novel oxidising system gave better stereoselectivity than that observed by using trimethylamine *N*-oxide as a reoxidant (step x).[9]

The relative stereochemistry of the allosamine series of compounds was proven by an X-ray crystal structure on the benzylidine protected derivative **12** (Fig. 1).§

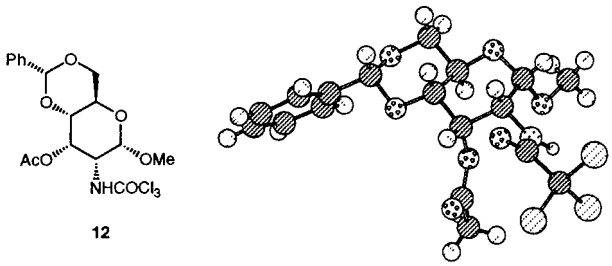


Fig. 1 X-Ray structure of **12**.

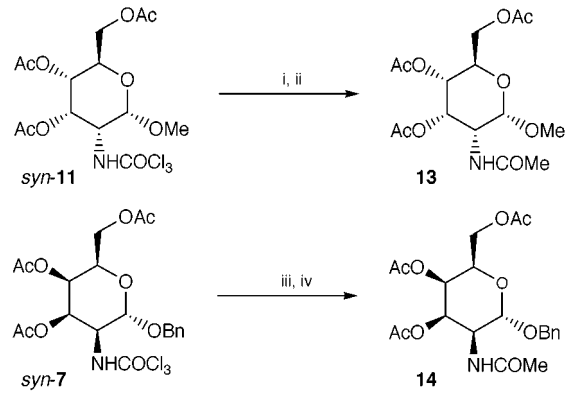
As amino-sugars frequently occur in nature as their *N*-acetyl derivatives, we removed the trichloroacetyl group and added an acetyl functionality. This was accomplished readily in a two stage, one pot process (Scheme 3).¶ Compound **14** prepared by this route is known in the literature[10] and displayed characteristics identical to those previously reported (^{1}H NMR, $[\alpha]_D$); this correlation proves the stereochemistry of the talosamine series described in Scheme 1.

To conclude, we have prepared protected forms of two naturally occurring and rare amino-sugars, talosamine and allosamine: both compounds are available in high yield and with excellent levels of stereoselectivity. These derivatives are ideally configured for further elaboration into polysaccharides and work is continuing in this direction. Moreover, we have



Scheme 3 *Reagents and conditions*: i, NaOH, EtOH, 10 min; ii, Ac_2O, cat. DMAP, pyridine, 24 h, 82%; iii, NaOH, EtOH, 10 min; iv Ac_2O, cat. DMAP, pyridine, 24 h, 86%.

introduced a novel oxidising system, using quinudidine *N*-oxide, which is capable of dihydroxylating certain allylic amides with hydrogen-bonding control‖ and which uses *catalytic* OsO_4.

We wish to thank the EPSRC (K. B.) and Zeneca Pharmaceuticals (Strategic Research Fund) for financial support.

Notes and references

‡ A similar strategy has been adopted previously for the synthesis of allosamine. However, the reported route is troubled by both a low yielding Overman rearrangement (30%) and oxidation with RuO_4 (50%).

§ *Crystal data* for $C_{18}H_{20}NO_7Cl_3$ **12**: M = 468.70, orthorhombic, a = 12.862(7), b = 27.763(6), c = 6.007(4) Å^3, T = 296 K, space group $P2_12_12_1$ (no. 19), Z = 4, μ(Cu-Kα) = 4.225 mm^{-1}, 2179 independent reflections which were used in all calculations. The final $\omega R(F^2)$ was 0.1554 (all data). $R(F)$ was 0.0499 using 1703 reflections with $I > 2\sigma(I)$. The structure was solved using direct methods and developed using difference Fourier techniques, then refined by full matrix least-squares on F^2. CCDC 182/1357.

Photodegradation of aryl sulfonamides: *N*-tosylglycine

Roger R. Hill,* Graham E. Jeffs, David R. Roberts and Sharon A. Wood

Department of Chemistry, The Open University, Milton Keynes, UK, MK7 6AA. E-mail: r.r.hill@open.ac.uk

Received (in Cambridge, UK) 2nd July 1999, Accepted 2nd August 1999

Continuing uncertainty about pathways and consequences of the photolability of aryl sulfonamides is partly resolved by the results of comprehensive product analysis in the photolysis of aqueous *N*-tosylglycine, which indicate that intramolecular electron or hydrogen transfer (according to conditions) promote the widely reported S–N cleavage and reveal the nature of subsequent and competing processes.

Aryl sulfonamides are of topical interest photochemically for two reasons: as photolabile pharmaceutical compounds[1] and as photolabile protected amines, peptides and proteins, the latter attracting continuing study[2] despite subsequent results[3] detracting from their early promise.[4] Regulatory demands for increasingly detailed stability data[5] contrast with rudimentary knowledge of the photochemistry of existing sulfonamide drugs, and prompt increasing attention to those in development. The variable and generally unsatisfactory results of attempted photodeprotections have been attributed to side reactions that can be reduced in some cases by structural modification[3] or the addition of further reagents,[6] but remain largely unknown.

In a continuing study of the photochemistry of peptide derivatives,[7,8] we have monitored products during the photolysis of aqueous *N*-tosylglycine (**1**) and, observing a high mass balance early in the reaction, are able to propose a sequence of events that both explains the product distributions and implicates processes that may direct photolytic outcomes with other aryl sulfonamides.

Photolyses were carried out under nitrogen with 10^{-2} mol dm^{-3} aqueous solutions of *N*-tosylglycine, either unadjusted (pH 3) or adjusted to pH 9 with NaOH, in quartz tubes and using a carousel surrounding a 400 W medium pressure mercury arc as previously described.[7] Products were identified by diagnostic chromatographic comparison with standards and quantified by HPLC[9] (formaldehyde and glyoxylic acid as DNP derivatives; glycine as AccQ.Tag® derivative by fluorescence detection[10]) and gas electrode analysis (CO_2 and NH_3).[7]

The data in Table 1 are consistent with the sequence of reactions in Scheme 1 (shown for 7% reaction at pH 9), which also accords collectively with several earlier observations of sulfonamide photochemistry reported separately.[3] Reaction (i) indicates a cyclic abstraction of H–C_α and reaction (ii) suggests β-homolysis of a bond known to be involved in the $\pi \rightarrow \pi^*$ state of analogous carboxamides[11] and dimerization of the comparatively stable amido-methylene radical.[7] The major route, reaction (iii), reflects the known behaviour of excited aryl sulfonamides as electron acceptors,[12] and generates an intermediate from which observed products are derived by loss of CO_2 alone [reaction (iv)] or with concomitant S–N cleavage [reaction (vi)], and, more speculatively, *via* cyclizations and hydrolysis [reactions (v) and (vii)]. Such processes would require particular orbital alignments, so product distribution would be determined largely by the conformations available in the short-lived intermediates.

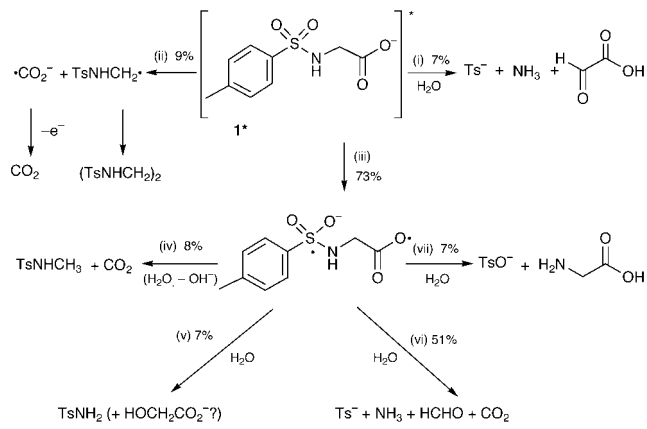
Table 1 Product distributions (mol%) in the photolysis of *N*-tosylglycine

	7% reaction[a]		20% reaction[b]	
Product	pH 3	pH 9	pH 3	pH 9
NH_3	47	49	50	49
CO_2	34	80	32	87
TsH[c]	28	68	31	62
HCHO	29	51	29	35
$OHCCO_2H$	13	7	8	4
TsOH	19	7	6	3
$H_3N^+CH_2CO_2^-$	13	—[d]	8	—
$TsNH_2$	5	7	3	5
$TsNHCH_3$	0	8	1	6
$(TsNHCH_2)_2$[e]	14	9	8	5
Mass balance[f]	80	> 90	60	60

[a] Error < ± 4. [b] Error < ± 2. [c] Standard: Li salt (98%), Sigma-Aldrich Ltd. [d] Not measured. [e] Standard tosylation of diamine, mp 161 °C (lit., 160 °C). [f] According to Scheme 1 (see text); error < ± 11 and < ± 6 at 7 and 20% reaction, respectively.

The percentage assigned to each route in Scheme 1 corresponds with the observed yield values of uniquely associated products. The accumulated values implicated for coproducts formed in more than one route [CO_2 (68%), NH_3 (58%) and TsH (58%)] are in fair agreement with those observed, and would be more so if the value for HCHO reflected some losses, directly or indirectly, by the unassigned reducing capacity available from reaction (ii). The latter would, in any case, account for loss of some material and this is incorporated in the mass balance data of Table 1. Scheme 1 is also supported by product correlations (*e.g.* TsH *vs.* NH_3, r^2 = 0.998, slope 1.1; TsH *vs.* HCHO + glyoxylic acid, r^2 = 0.984, slope = 0.9) and by the main differences in outcome when the substrate is not ionized. In that case, lower yields of principal products by reaction (iii) are consistent with the need for H-atom transfer,[13] making other pathways, including reactions (i) and (ii), slightly more competitive. The lack of $TsNHCH_3$ and the enhanced yield of TsOH may be associated with the inability to generate the sulfonyl group directly in reactions (iv) and the easier hydrolysis anticipated for the protonated intermediate in reactions (vii), respectively. While quantitation at 20% conversion is intrinsically more accurate, the scope for complication by secondary processes is increased. The data remain consistent with Scheme 1, however.

It would appear from these results that electron or hydrogen-atom transfer to the sulfonyl group will be prominent in the photochemistry of aryl sulfonamides, with β-homolysis a



Scheme 1

significant competing process. The availability of diverse pathways subsequently suggests that a search among such derivatives for photoremoveable protecting groups is unlikely to be productive and that their use for this purpose may be best pursued with cathodic deprotection strategies in mind.[14] The photochemical strategy is flawed by the capacity of the oxidized component of the charge-separated intermediates to promote highly competitive alternative degradation.

We thank Central Research, Pfizer Ltd (Sandwich) for financial support for this work and Mrs J Burrage for technical assistance.

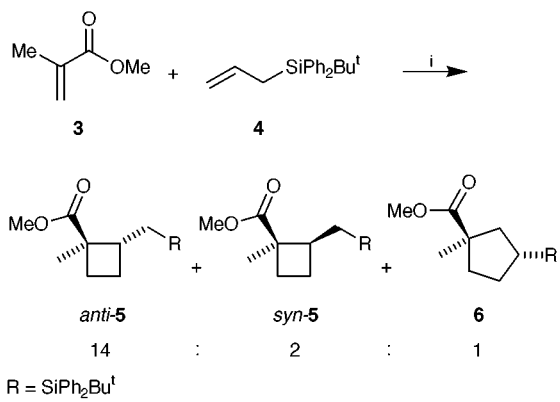
Received (in Liverpool, UK) 21st June 1999, Accepted 22nd July 1999

A stereoselective total synthesis of the monoterpenoid alcohol (±)-fragranol has been accomplished utilizing a $TiCl_4$ promoted [2 + 2] cycloaddition of allyl-*tert*-butyldiphenylsilane and methyl methacrylate as the key step.

1 **2**

The monoterpenoid alcohol fragranol **1** was isolated in 1973 by Bohlmann and co-workers from the roots of *Artemisia fragrans* Willd.[2] The diastereoisomeric grandisol **2** is a sex pheromone of the male cotton boll weevil *Anthonomus grandis* Boheman and other beetles.[3] Because of their structural features and biological activity both compounds represent important targets for novel procedures directed towards the total synthesis of four-membered ring natural products.[4] Over the past years we developed a novel synthetic methodology for the stereoselective construction of cyclobutanes by $TiCl_4$ promoted [2 + 2] cycloaddition of allylsilanes and acrylic esters.[5] We now report the stereoselective total synthesis of fragranol **1** which is the first application of this strategy to the total synthesis of a natural product.[6]

The $TiCl_4$ promoted [2 + 2] cycloaddition of allyl-*tert*-butyldiphenylsilane **4** and methyl methacrylate **3** afforded the two diastereoisomeric silylmethylcyclobutanes *anti*-**5** and *syn*-**5** along with the silylcyclopentane **6** in a total yield of 84% and a ratio of 14 : 2 : 1 (Scheme 1).‡ The structural and stereochemical assignments were based on comparison of the ^{13}C NMR data with those of our previous studies.[5a] After chromatography the major isomer *anti*-**5** was crystallized in pure form out of this mixture and structurally confirmed by X-ray crystallography (Fig. 1).§



Scheme 1 *Reagents and conditions*: i, $TiCl_4$, CH_2Cl_2, 40 °C, 4 d (84%, ratio *anti*-**5** : *syn*-**5** : **6** = 14 : 2 : 1), then crystallization from this mixture afforded selectively *anti*-**5** (67%).

† See ref. 1.

For the projected total synthesis the silyl group had to be converted into a hydroxy group. We have recently shown that by modifaction of the Fleming–Tamao oxidation[7] sterically hindered silyl groups, like triphenylsilyl, diisopropylphenylsilyl and *tert*-butyldiphenylsilyl, can be transformed to hydroxy groups.[8] Using these conditions the *tert*-butyldiphenylsilyl derivative *anti*-**5** was first converted to the *tert*-butyldifluorosilyl derivative **7** and then to the alcohol **8** (Scheme 2). The next task was to transform the hydroxymethyl group into the isopropenyl group present in the natural product. For the oxidation of the hydroxy to the formyl group we required reaction conditions which avoided an epimerization at the stereogenic center. Swern oxidation[9] and oxidation with the Dess–Martin periodinane reagent[10] provided good yields, however to a large extent with epimerization. Treatment of **8** with tetrapropylammonium perruthenate (TPAP)[11] provided a yield of 94% for the aldehydes *anti*-**9** and *syn*-**9** which were obtained in a ratio of 13 : 1.

Chemoselective addition of methyltitanium triisopropoxide[12] at the formyl group at −10 °C afforded the alcohol **10** as a 1 : 1 mixture of two diastereoisomers (Scheme 3). A further oxidation with TPAP[11] provided in 94% yield the methyl ketone **11** without epimerization at the chiral center. Wittig reaction using methylenetriphenylphosphorane gave the isopropenyl derivative **12** which was reduced to the alcohol **13** by $LiAlH_4$. Finally, a homologation of the primary alcohol was required. For this purpose the alcohol **13** was transformed to the aldehyde **14** by Swern oxidation.[9] Wittig reaction using methoxymethyltriphenylphosphonium bromide/sodium amide[13] followed by hydrolysis of the resulting enol ether afforded the homologated

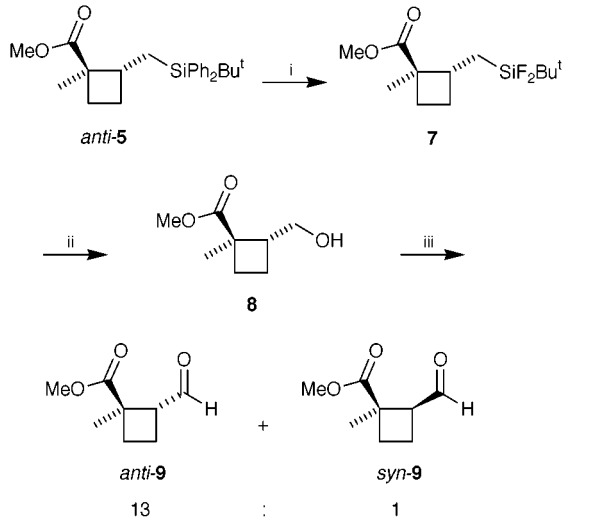
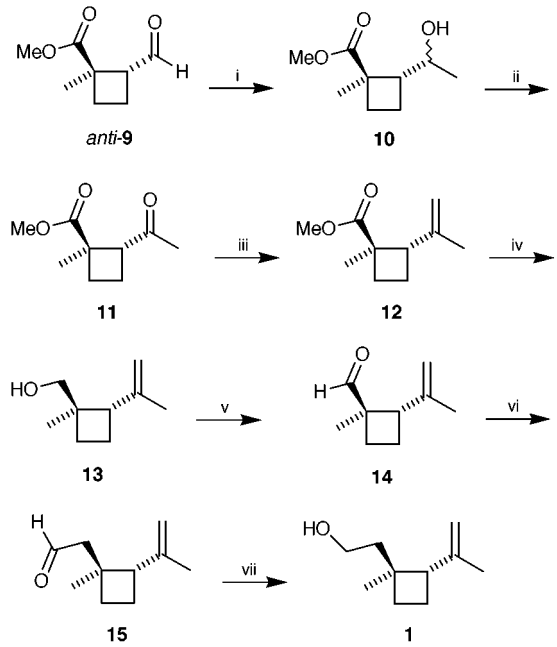


Scheme 2 *Reagents and conditions*: i, BF_3·2 HOAc, CH_2Cl_2, 40 °C, 4 h (87%); ii, H_2O_2, KF, $NaHCO_3$, THF–MeOH (1:1), 25 °C, 24 h (51%); iii, TPAP (cat.), NMO, powdered 4 Å molecular sieves, CH_2Cl_2, 0 to 25 °C, 2 h (94%, ratio *anti*-**9**:*syn*-**9** = 13:1).



Scheme 3 *Reagents and conditions*: i, $MeTi(OP^ir)_3$, CH_2Cl_2, −10 to 25 °C, 14 h (70%); ii, TPAP (cat.), NMO, powdered 4 Å molecular sieves, CH_2Cl_2, 0 to 25 °C, 2 h (94%); iii, $Ph_3P{=}CH_2$, THF, 0 to 25 °C, 2 h (65%); iv, $LiAlH_4$, THF, 0 to 25 °C, 12 h (99%); v, $(COCl)_2$, DMSO, CH_2Cl_2, Et_3N, −78 °C, 20 min (84%); vi, $MeOCH_2Ph_3P^+Br^-$, $NaNH_2$, Et_2O, −20 to 25 °C, 12 h, then TFA–H_2O (4:1), Et_2O, 25 °C, 12 h (78%); vii, $LiAlH_4$, Et_2O, 0 °C, 10 min (93%).

aldehyde **15** which on reduction with $LiAlH_4$ provided (±)-fragranol **1**. The spectral data of our synthetic fragranol (IR, ^{1}H NMR, ^{13}C NMR, MS and HRMS)¶ were in full agreement with those reported for the natural product.[2,6]

The present synthesis *via* the [2 + 2] cycloaddition of allyl-*tert*-butyldiphenylsilane **4** afforded fragranol in 11 steps and 7% overall yield based on methyl methacrylate **3**. It has been demonstrated for the first time that the Lewis acid promoted cycloaddition of allyl-*tert*-butyldiphenylsilane followed by our modified Fleming–Tamao oxidation represents a powerful new tool in natural product synthesis.

Financial support of this project was provided by the Deutsche Forschungsgemeinschaft (Kn 240/5-3) and the Fonds der Chemischen Industrie. We thank Dr John, Wacker-Chemie GmbH, Burghausen, for a generous gift of *tert*-butylchlorodiphenylsilane.

Notes and references

‡ *Synthesis* of *anti*-**5**: A solution of methyl methacrylate **3** (3.37 g, 33.7 mmol, 3.6 ml) in dry CH_2Cl_2 (30 ml) was added to a stirred solution of $TiCl_4$ (6.92 g, 36.5 mmol, 4 ml) in dry CH_2Cl_2 (50 ml) under argon at room temperature. After addition of a solution of allyl-*tert*-butyldiphenylsilane **4** (13.6 g, 48.5 mmol) in dry CH_2Cl_2 (30 ml) the reaction mixture was heated at reflux for 4 days. The mixture was hydrolyzed by addition of aq. NH_4Cl, the organic layer was separated, the aqueous layer was extracted three times with CH_2Cl_2 and the combined organic layers were dried over $MgSO_4$. Evaporation of the solvent and flash chromatography (hexane–Et_2O 20:1) of the residue on silica gel afforded a mixture of *anti*-**5**, *syn*-**5** and **6** (10.8 g, 84%, ratio 14:2:1). Crystallization out of this oil over a period of 14 days provided the cyclobutane *anti*-**5** (8.6 g, 67%) as colorless crystals, mp 65 °C; δ_H (400 MHz, $CDCl_3$) 1.04 (s, 9 H), 1.12–1.27 (m, 3 H), 1.33 (s, 3 H), 1.44 (m, 2 H), 2.10 (dt, *J* 9.0, 10.8, 1 H), 2.70 (dddd, *J* = 12.4, 10.3, 8.4, 2.1, 1 H), 3.67 (s, 3 H), 7.31–7.41 (m, 6 H), 7.63 (m, 4 H); δ_C (100 MHz, $CDCl_3$)11.43 (CH_2), 16.99 (CH_3), 18.11 (C), 25.29 (CH_2), 27.83 (3 CH_3), 28.62 (CH_2), 37.47 (CH), 46.75 (C), 51.44 (CH_3), 127.37 (2 CH), 127.52 (2 CH), 128.96 (CH), 129.00 (CH), 134.26 (C), 135.26 (C), 135.95 (2 CH), 136.04 (2 CH), 177.94 (C=O) (calc. for $C_{24}H_{32}O_2Si$: C, 75.74; H, 8.47; found: C, 75.65; H, 8.35%).

The first isolation of an alkoxy-*N*,*N*-dialkylaminodifluorosulfane from the reaction of an alcohol and DAST: an efficient synthesis of (2*S*,3*R*,6*S*)-3-fluoro-2,6-diaminopimelic acid

Andrew Sutherland and John C. Vederas*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2.
E-mail: john.vederas@ualberta.ca

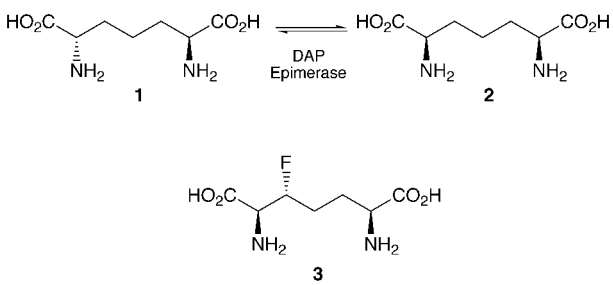
Received (in Corvallis, OR, USA) 15th June 1999, Accepted 14th July 1999

During improvement of the synthesis of (2*S*,3*R*,6*S*)-3-fluoro-2,6-diaminopimelic acid 3, a potent inhibitor of DAP epimerase, a stable alkoxy-*N*,*N*-dialkylaminodifluorosulfane 9 was isolated from the reaction of alcohol 6 with DAST

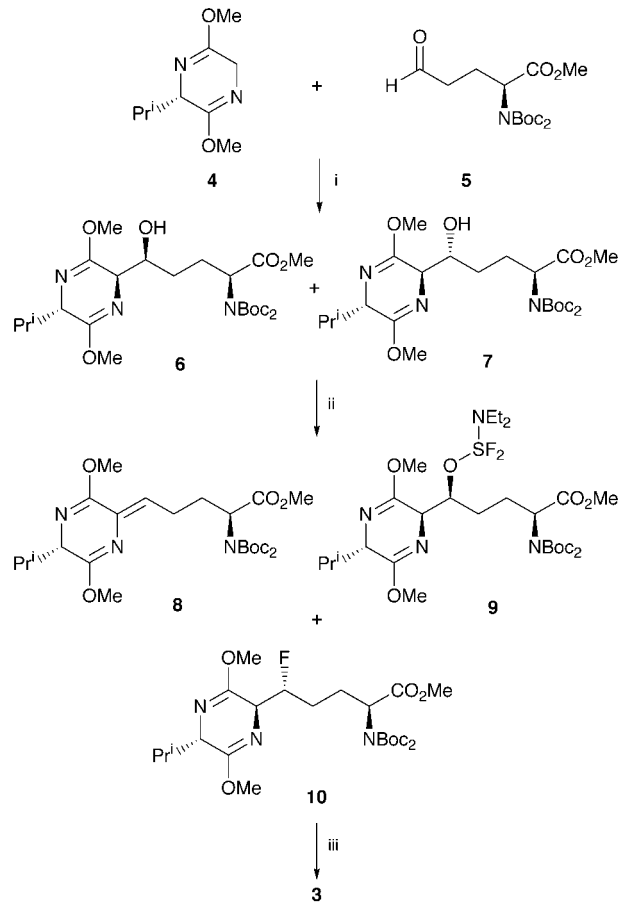
Emergence of multi-drug resistant bacteria has intensified efforts to develop new antibiotics that disrupt microbial cell wall synthesis.[1] Several studies have shown that inhibitors of the biosynthesis of diaminopimelic acid (DAP),[2] the key crosslinking amino acid in the peptidoglycan cell wall of Gram negative bacteria, possess antibiotic activity.[3] An important enzyme in this pathway, L,L-diaminopimelate epimerase, interconverts L,L-DAP **1** and *meso*-DAP **2** without the aid of any detectable metals or cofactors (Scheme 1). The mechanism has been suggested to be an unusual 'two-base' process that employs a thiolate as a general base and a thiol as a general acid.[4] We have previously shown that β-fluoro-DAP stereoisomers are potent inhibitors of DAP epimerase that can act as probes to help define substrate conformation in the enzyme active site.[5] Continued interest in the mechanism of this enzyme and recent crystallographic studies on an inactive form of this protein[4b] encouraged us to improve the synthesis[5] of pure β-fluoro-DAP isomers. We now report an efficient preparation of (2*S*,3*R*,6*S*)-3-fluoro-2,6-diaminopimelic acid **3** and the first isolation of an alkoxy-*N*,*N*-dialkylaminodifluorosulfane from the reaction of an alcohol with DAST.

The original synthesis of β-fluoro-DAP involved an aldol reaction between a Schöllkopf bis-lactim ether[6] and a glutamate semialdehyde to afford an alcohol, which was fluorinated using diethylaminosulfur trifluoride (DAST).[5] However, the reactive nature of the oxazolidinone protecting group on the glutamate semialdehyde lowered yields and made extensive purification of the intermediates obligatory. A recent synthesis[7] of *N*,*N*-di-Boc glutamate semialdehyde **5**, a versatile intermediate,[8] suggested its application to the troublesome aldol condensation. Addition of **5** to the anion of (3*S*)-3,6-dihydro-2,5-dimethoxy-3-(1-methylethyl)pyrazine **4**[6] gave a 3:1 mixture of two inseparable diastereomeric alcohols **6** and **7** in 73% yield (Scheme 2).† Treatment of **6** and **7** with freshly distilled DAST permitted isolation of only the dehydrated compound **8**, which is presumably formed by base elimination of the activated intermediate **9**. By accident we found that this dehydration could be suppressed by using DAST contaminated with water. The presence of a trace amount of water causes the release of HF and results in the stabilisation of the activated intermediate, thereby allowing the preparation of the fluoro derivative **10** as a single diastereomer in 52% yield with only trace amounts of the dehydrated product **8** (7%). In some cases carbocation rearrangements accompanying the DAST preparation of alkyl fluorides have implied a mixed S_N1 and S_N2 mechanism,[9] but formation of **10** with complete inversion of stereochemistry from alcohol **6** indicates an S_N2 reaction. Surprisingly, the modified conditions permit the isolation of alkoxy-*N*,*N*-dialkylaminodifluorosulfane **9** as a single diastereomer in 12% yield.

Compound **9** is unexpectedly stable to column chromatography and amenable to characterisation,‡ although it does decompose after several weeks at room temperature. Alkoxy-



Scheme 1



Scheme 2 *Reagents and conditions*: i, BuLi, THF, −78 °C, 73%, **6**:**7** (3:1); ii, DAST, CH_2Cl_2, −78 °C, **8** (7%), **9** (12%), **10** (52%); iii, 6 M HCl, Δ, 71%.

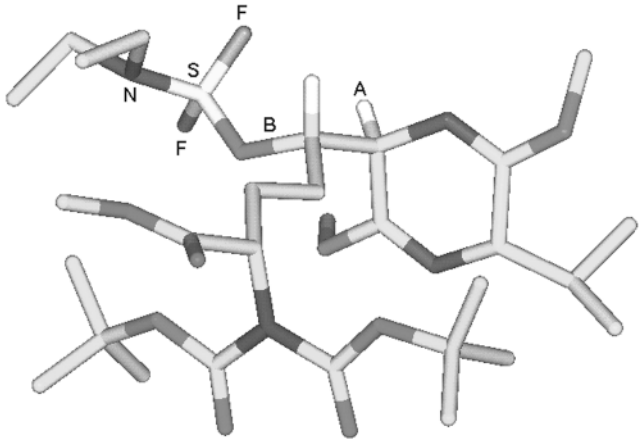


Fig. 1 A model of **9** representing a possible minimum energy conformation calculated using InsightII (MSI). Although elimination to give **8** can occur, in this geometry the orientation of hydrogen A and the cleaving bond B is disfavoured for a facile E2 process. An S_N2 reaction to cleave bond B is also sterically hindered. Only two adjacent hydrogens (white) are shown for clarity.

N,*N*-dialkylaminodifluorosulfanes are postulated as intermediates in the DAST fluorination of alcohols,[10] and the transient existence of these compounds has previously been inferred from ^{19}F NMR studies.[11] Although Markovskii *et al.* have reported the formation of analogous compounds having a perfluoroalkoxy group by reaction of polyfluoroalkyl trimethylsilyl ethers[12] with dialkylaminosulfur trifluorides, the fluoroalkyl groups obstruct elimination or substitution reactions. Preparation of **9** by reaction of an alcohol and DAST represents the first isolation of such a compound which in principle can readily undergo such decomposition. The unusual stability of **9** may be due to the steric crowding provided by nearby substituents (Fig. 1), including the two Boc groups, since DAST reactions with closely-related β-hydroxy-DAP derivatives bearing an *N*-Cbz substituted oxazolidinone[5] do not permit isolation of the corresponding intermediate.

Treatment of **9** with 1.0 equiv. of TBAF in an attempt to prepare **10** results in elimination to give **8**. Minor alcohol **7** could be recovered in quantitative yield as a single stereoisomer from the 'wet' DAST reaction of a mixture of **6** and **7**, thereby indicating that only alcohol **6** reacts to generate inverted fluoro derivative **10**. Molecular modeling of the two alcohols using InsightII (MSI) suggests that the alcohol functionality of **7** is more sterically crowded than **6**, which may account for the observed kinetic resolution. To complete the synthesis of (2*S*,3*R*,6*S*)-3-fluoro-2,6-diaminopimelic acid, the fluoro derivative **10** was hydrolysed with hydrochloric acid to give the desired β-fluoro-DAP **3** in 71% yield after cellulose chromatography. Further studies on synthesis of fluoro-DAP isomers and other DAP analogues[13] are in progress.

The synthesis of ethenyl bifunctional reagents containing a sulfone moiety and zirconium by the abnormal addition of $Cp_2Zr(H)Cl$ to internal acetylenic sulfones

Xian Huang* and De-Hui Duan

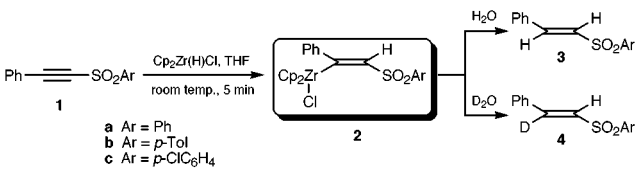
Department of Chemistry, Zhejiang University (Xixi Campus), Hangzhou Zhejiang 310028, P.R. China. E-mail: Huangx@mail.hz.zj.cn

Received (in Cambridge, UK) 9th June 1999, Accepted 27th July 1999

Ethenyl bifunctional reagents containing a sulfone moiety and zirconium are prepared by the abnormal addition of $Cp_2Zr(H)Cl$ to internal acetylenic sulfones.

Acetylenic sulfones have been used extensively in organic synthesis as activated acetylene equivalents. They can take part in cycloadditions,[1] Michael additions[2] and alkylative desulfonylation reactions.[3] Surprisingly, little attention has been paid to their hydrometalation reactions. On the other hand, *via* the hydrozirconation of alkynes, many bifunctional ethenyl reagents have been synthesized containing elements such as selenium and zirconium,[4] tellurium and zirconium,[5] silicon and zirconium,[6] tin and zirconium,[7] zinc and zirconium[8] and boron and zirconium.[9] Apparently, no efforts have been focused on the bifunctional ethenyl reagent containing sulfur and zirconium. We now report that we have successfully synthesized sulfonyl-substituted alkenylzirconocene compounds *via* the hydrozirconation of internal acetylenic sulfones. Unexpectedly, the products of *anti*-addition of $Cp_2Zr(H)Cl$ to the acetylene are observed.

Phenylacetylenic sulfones **1a**–**c** were synthesized in good yields according to the method of Suzuki.[10] Hydrozirconation of the acetylenic sulfones with 1.2 equiv. of $Cp_2Zr(H)Cl$ in THF for 5 min at room temperature gave a clear yellow solution. Unique *E*-vinyl sulfones **3a**–**c** or *E*-β-deuterovinyl sulfones **4a**–**c** were obtained respectively after hydrolysis or deuterolysis (Scheme 1 and Table 1).† The *E*-olefin geometry was verified by the coupling constant ($^3J_{HH}$ = 15.4 Hz) of the vicinal olefinic protons. In addition, the product melting points are also identical to those previously reported.[11] The olefinic proton of every deuterovinyl sulfone presents a single peak at δ 6.84, which shows that the deuterium atom must be attached to the β-position of the sulfonyl group. Thus the (*Z*)-β-sulfonylalkenylzirconocene compounds **2** are produced in the hydrozirconation reaction (Scheme 1).



Scheme 1

Table 1 Yields and melting points for **3a**–**c** and **4a**–**c**

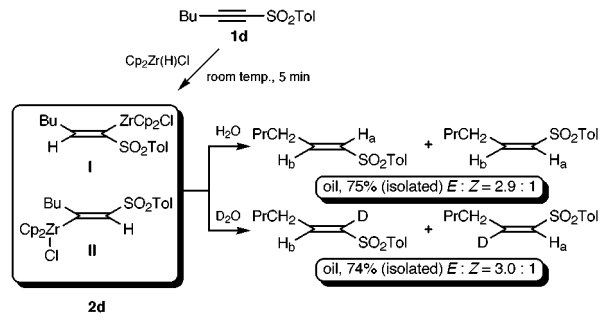
Compound	Ar	Yield (%)[a]	Mp/°C
3a	Ph	72	74.5–75.5
3b	*p*-Tol	69	126–121
3c	*p*-ClC_6H_4	70	82–84
4a	Ph	70	73.5–75
4b	*p*-Tol	73	118–120
4c	*p*-ClC_6H_4	68	82–83

[a] Yields of pure compounds.

Hex-1-ynyl *p*-tolyl sulfone was synthesized in two steps according to the method of Truce.[12] After hydrozirconation–hydrolysis, a mixture of *E* and *Z* vinyl sulfones (*E*:*Z* = 2.9:1) was obtained (Scheme 2). Its ^{1}H NMR spectrum (300 MHz) exhibits a doublet of triplets at δ 6.97 (*E*-H_b, *J* 15.1, 6.8 Hz) and multiple peaks at δ 6.20–6.32 [including *E*-H_a, (dt, *J* 15.1, 1.4 Hz) and *Z*-H_a + H_b (ABX_2 system, J_{AB} 11.1 Hz, J_{AX} 6.5 Hz)]. Further proof is also provided by the ^{1}H NMR signals for two kinds of methylenic protons [δ 2.67 (q, 0.52 H, *J* 7.7, 6.5 Hz, *Z*-CH_2) and 2.25 (dq, 1.48 H, *J* 7.4, 6.8, 1.4 Hz, *E*-CH_2)]. The proportion of the *E*:*Z* mixture was estimated *via* the integral areas of the two kinds of methylenic protons. After the parallel experiment of hydrozirconation–deuterolysis, a mixture of two regio- and stereo-isomers (*E*:*Z* = 3:1 by ^{1}H NMR) was obtained (Scheme 2). Its ^{1}H NMR spectrum exhibits a triplet at δ 6.97 (*E*-H_b), a single peak at δ 6.26 (*Z*-H_a), a triplet at δ 2.68 (*Z*-CH_2) and a quartet at δ 2.25 (*E*-CH_2). These results show that two types of alkenylzirconocene compounds **2d** (**I** and **II**) are generated in the hydrozirconation reaction.

Compounds **2** were reacted with various electrophiles (Table 2). NCS, NBS and I_2 (2.5 equiv.) reacted with **2a** to give β-halo vinyl sulfones. Using the method, we can access *Z*-β-halo vinyl sulfones, whose configurations were identified by comparisons with authoritative data.[13] Thus this approach complements the addition of sulfonyl halides to acetylenes, which provides either an *E* and *Z* mixture[13] or only the *E* isomer.[12] Carbon–carbon bond formation also occurred readily with various carbon electrophiles. Reactions with carboxylic acid chlorides afforded (*Z*)-β-sulfonyl α,β-unsaturated ketones. The cross-coupling with allyl bromide provided (*E*)-penta-1,4-dienyl sulfone. Their configurations were affirmed by H–H 2D NOSEY spectra (300 MHz). As is expected, the reaction of **2d** with BzCl afforded two isomers.

There are some regiochemical and stereochemical issues associated with the addition of $Cp_2Zr(H)Cl$ across unsymmetrical acetylenic sulfones. Based on the different substituents (Bu or Ph) on the acetylene bond, α- (major) or β-sulfonyl alkenylzirconocene compounds are obtained respectively. The different regiochemistry could be ascribable to the dissimilarity of the polarizing ability of the two groups to the C≡C triple bond and the long-distance π,π-interaction of the phenyl and bicyclopentadienyl groups.



Scheme 2

Table 2 Reaction of **2a** and **2d** with electrophiles

2	E–X	Product	Isolated yield (%)
2a	NCS		57
2a	NBS		63
2a	I_2		56
2a	BzCl[a]		65
2a	AcCl[a]		70
2a	$H_2C{=}CHCH_2Br$[b]		51
2d	BzCl[a]		45 28

[a] Reaction conditions: CuBr (0.5 equiv.), acid chlorides (1.05 equiv.), THF, 25 °C, 2 h. [b] Reaction conditions: $Pd(PPh_3)_4$ (5 mol%), allyl bromide (1.05 equiv.), 40 °C, 3 h.

In conclusion, bifunctional ethenyl reagents containing sulfone and zirconium moieties are prepared by the abnormal addition of $Cp_2Zr(H)Cl$ to internal acetylenic sulfones. The addition reactions usually generate vinyl sulfone compounds, which can be exploited for further synthetic elaboration.[14] Currently a more thorough study is being carried out in our laboratory.

Project 29772007 is supported by the National Natural Science Foundation of China; this work is also supported by the Laboratory of Organometallic Chemistry, Shanghai Instituted of Organic Chemistry, Academia Sinica.

A stereoselective synthesis of (−)-tetrahydrolipstatin

Arun K. Ghosh* and Chunfeng Liu

Department of Chemistry, University of Illinois at Chicago, 845 W. Taylor Street, Chicago, Illinois 60607, USA

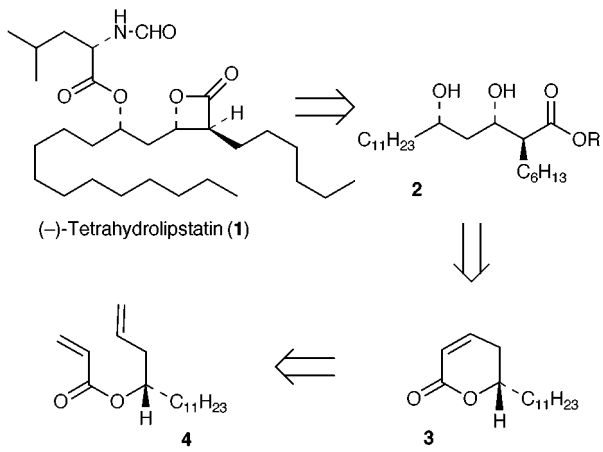
Received (in Corvallis, OR, USA) 4th June 1999, Accepted 21st July 1999

A stereoselective synthesis of (−)-tetrahydrolipstatin has been accomplished utilizing olefin metathesis of an acrylate ester as the key step.

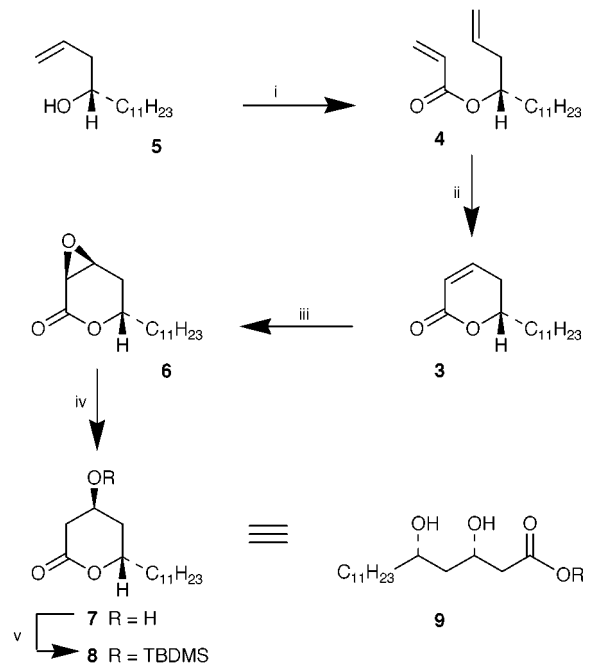
Tetrahydrolipstatin **1**, a member of the lipstatin class of β-lactone microbial agents, is a potent and irreversible inhibitor of pancreatic lipase.[1] The lipase enzyme is responsible for the digestion of fat in the diet of humans.[2] The strained β-lactone functionality of **1** is critical to its lipase inhibitory properties. The inactivation mechanism involves an irreversible acylation of the active site serine residue of pancreatic lipase by the β-lactone moiety.[3] Recent clinical studies have revealed that treatment with **1** along with diet modifications have led to sustained weight loss in humans.[4] Indeed, Hoffman-La Roche Laboratories have now introduced (−)-tetrahydrolipstatin under the trade name Xenical® as an anti-obesity agent. The important biological properties along with its unique structural features have stimulated interest in the synthesis of **1** and its structural variants.[5] Herein we report an asymmetric synthesis of (−)-tetrahydrolipstatin. The key synthetic strategy involves a stereoselective construction of a *syn*-1,3-diol synthon by olefin metathesis, stereoselective epoxidation and regioselective epoxide reduction followed by its elaboration to **1**.

As depicted in Scheme 1, we planned to construct the β-lactone ring from the corresponding β-hydroxy acid derivative **2**. The elaboration of the *syn*-1,3-diol functionality and stereoselective introduction of the C-2 alkyl chain in **2** would be achieved from the α,β-unsaturated δ-lactone **3**. The intermediate **3** would be derived from ring-closing metathesis of the corresponding acrylate ester **4**. Recently, a number of convenient syntheses of various α,β-unsaturated γ- and δ-lactones have been reported involving ring closing metathesis of acrylates utilizing Grubbs' catalyst.[6] The broad synthetic utility of Grubbs' catalyst is now well established.[7] The key starting material, homoallylic alcohol **5** was prepared in multigram quantities by Keck's enantioselective allylation of dodecanal employing a catalytic amount (10 mol%) of (*R*)-BINOL and $Ti(OPr^i)_4$ to furnish **5** in 90% yield.[8] The optical purity of the alcohol **5** [92% ee, $[\alpha]_D^{23}$ −6.3 (*c* 1.23, $CHCl_3$)] was obtained by formation of the Mosher ester and ^{19}F NMR analysis.[9] Reaction of **5** with acryloyl chloride (1.2 equiv.) and Et_3N (3 equiv.) in the presence of a catalytic amount of DMAP in CH_2Cl_2 provided the acrylate ester **4** in 91% yield after silica gel chromatography (Scheme 2). Olefin metathesis of **4** with commercially available Grubbs' catalyst (10 mol%) in the presence of $Ti(OPr^i)_4$ (0.3 equiv.) in refluxing CH_2Cl_2 (0.007 M solution) for 15 h afforded the α,β-unsaturated δ-lactone **3** in 93% yield. Consistent with our earlier report, exposure of acrylate ester **4** to Grubbs' catalyst (10 mol%) in CH_2Cl_2 for 15 h in the absence of $Ti(OPr^i)_4$ resulted in low conversion of lactone **3** (50% by ^1H NMR) with a substantial amount of unreacted starting material remaining.[6b] Epoxidation of lactone **3** was carried out with alkaline H_2O_2 in MeOH at 23 °C for 1 h. Acidification, extractive work-up followed by azeotropic removal of the water by heating in benzene furnished the epoxide **6** as a single isomer. Epoxidation of **3** proceeded stereoselectively from the less hindered β-face.[10] Exposure of epoxide **6** to PhSeSePh and $NaBH_4$ in Pr^iOH at 0 °C in the presence of AcOH resulted in regioselective reduction of the epoxide to afford the β-hydroxy-lactone **7** in 83% yield (from **3**) after silica gel chromatography.[11] Thus, the sequence of reactions involving olefin metathesis, stereoselective epoxidation and regioselective epoxide reduction constitute an effective protocol for the *syn*-1,3-diol synthon **9**. For introduction of the C-2 alkyl chain, attempted direct alkylation of the β-hydroxy-lactone **7** under a variety of reaction conditions was unsuccessful. Therefore, the elaboration of the C-2 side chain was carried out by an alternate route using Seebach's asymmetric alkylation of β-hydroxy esters.[12]

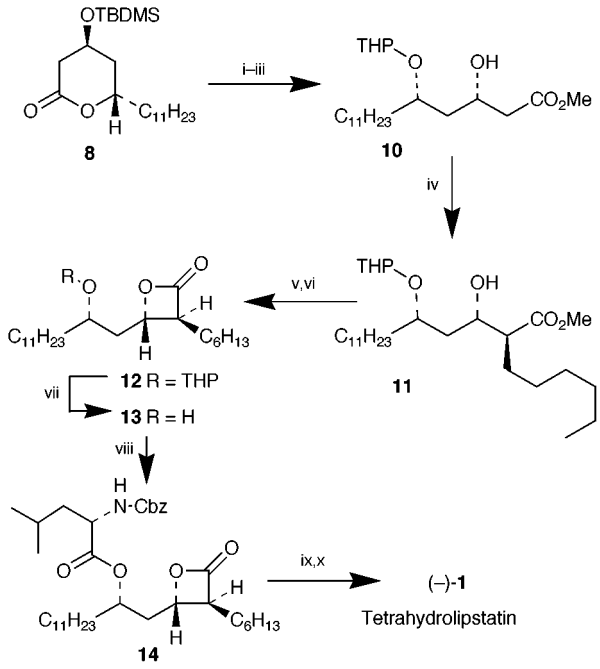
The β-hydroxy lactone **7** was first protected as a TBDMS ether **8** by treatment with TBDMSCl and Pr^i_2NEt in DMF at



Scheme 1



Scheme 2 *Reagents and conditions*: i, CH_2=CHCOCl, Et_3N, DMAP, 23 °C (91%); ii, $(PCy_3)_2Cl_2Ru$=CHPh (10 mol%), $Ti(OPr^i)_4$ (0.3 equiv.), CH_2Cl_2, 40 °C (93%); iii, aq. NaOH, H_2O_2, 23 °C; iv, PhSeSePh, $NaBH_4$, Pr^iOH, AcOH, 0 °C (83%); v, TBDMSCl, Pr^i_2NEt, DMF, 25 °C (98%).



Scheme 3 *Reagents and conditions*: i, Et_3N, MeOH, 23 °C, 12 h (75%); ii, DHP, PPTS, 8 h; iii, Bu_4NF, THF, AcOH, 25 °C, 5 h (60% from **7**); iv, LDA, HMPA, $C_6H_{13}I$, THF, −78 to 0 °C, 6 h (70% conversion, 85%); v, aq. LiOH, 25 °C, 12 h, H^+; vi, $PhSO_2Cl$, Py, 0 °C, 8 h (84% from **11**); vii, PPTS, EtOH, reflux, 3 h (90%); viii, Cbz-Leu, DCC, DMAP (95%); ix, H_2, Pd-C, 12 h; x, AcOCHO, THF, 25 °C, (87%).

23 °C for 12 h. Lactone **8** was converted to β-hydroxy ester **10** in a three step sequence involving (i) opening of the lactone ring by exposure to Et_3N in MeOH at 23 °C for 12 h, (ii) protection of the resulting δ-hydroxy methyl ester as THP ether, and (iii) removal of the TBDMS group by treatment with Bu_4NF in THF in the presence of AcOH at 23 °C for 5 h (60% from **7**). The C(2) hexyl side chain was then introduced by an asymmetric alkylation of the β-hydroxy ester **10** (Scheme 3). Thus, methyl ester **10** was treated with LDA (2.2 equiv.) in the presence of HMPA (5 equiv.) in THF at −78 °C and the reaction mixture was warmed to −50 °C for 2 h. The resulting dianion was cooled to −78 °C and reacted with hexyl iodide (2 equiv.) at −78 to 0 °C for 6 h to afford the alkylated product **11** in 85% yield (based upon 30% recovery of starting material). The removal of the THP ether group in **11** revealed excellent diastereoselectivity (ratio 22:1 by ^{13}C NMR).[13] The stereochemical course of such alkylation processes has been well-established previously.[12]

Saponification of ester **11** with aqueous LiOH followed by exposure of the resulting acid to $PhSO_2Cl$ in pyridine at 0 °C for 8 h, as described by Barbier and Schneider, afforded the β-lactone **12** in 84% yield (from **11**).[5k] The removal of the THP group by treatment with PPTS in EtOH at reflux furnished the (5*S*)-hydroxy β-lactone **13** [$[\alpha]_D^{23}$ −14.4 (*c* 1.2, $CHCl_3$)] as a single isomer. Attempted esterification with *N*-formylleucine under a variety of conditions failed to provide satisfactory results. To complete the synthesis, *N*-formylleucine was introduced by an alternate protocol as described by Uskokovic *et al.*[5g] Esterification of **13** with Cbz-leu and DCC in the presence of DMAP provided the Cbz derivative **14** in 95% yield.[14] Catalytic hydrogenation of **14** over 10% Pd-C followed by *N*-formylation of the resulting amine with formic acetic anhydride in THF at 23 °C for 1 h furnished the synthetic (−)-tetrahydrolipstatin **1** [$[\alpha]_D^{23}$ −33.8, (*c* 1.4, $CHCl_3$); lit.,[1] $[\alpha]_D^{23}$ −34.45, (*c* 1, $CHCl_3$)]. Spectral data (IR and 400 MHz ^1H NMR) for the synthetic tetrahydrolipstatin are identical to those reported for the natural product.[1]

In summary, an asymmetric synthesis of (−)-tetrahydrolipstatin has been accomplished. A number of key features of this synthesis are noteworthy; a Keck enantioselective allylation of dodecanal, olefin metathesis of an acrylate ester to an unsaturated δ-lactone, elaboration of this lactone to a *syn*-1,3-diol synthon and Seebach's asymmetric alkylation of a β-hydroxy ester.

Financial support for this work was provided by the National Institutes of Health (GM 55600).

New method for the synthesis of α-substituted tetrahydrofuran-2-methanols through diastereoselective addition of THF to aldehydes mediated by Et_3B in the presence of air

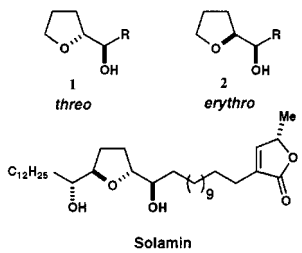
Takehiko Yoshimitsu,* Maki Tsunoda and Hiroto Nagaoka*

Meiji Pharmaceutical University, Noshio, Kiyose, Tokyo 204-8588, Japan. E-mail: takey@my-pharm.ac.jp

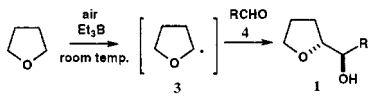
Received (in Cambridge, UK) 14th June 1999, Accepted 26th July 1999

The tetrahydrofuranyl radical, generated from THF with Et_3B in the presence of air, was found to react with aldehydes *threo*-selectively to afford α-substituted tetrahydrofuran-2-methanols, the common structural motifs of biologically active acetogenin polyketides, in moderate yields.

α-Substituted tetrahydrofuran-2-methanols **1** and **2** are common structural units present in acetogenins that possess important biological properties, such as antineoplastic and immunosuppressive activity.[1] Numerous attempts have thus been made to



elaborate these structural units,[2–4] but the direct addition of tetrahydrofuranyl synthons to aldehydes is a rare case of a carbon–carbon bond-forming reaction in the convergent synthesis of acetogenins.[5,6] The authors have accordingly established a new method for the stereoselective synthesis of **1** through the addition of tetrahydrofuranyl radical **3** generated from THF with Et_3B in the presence of air[7] to aldehydes **4**, thereby facilitating the construction of core structural motifs of acetogenins (Scheme 1). To the best of our knowledge, the



Scheme 1

radical addition of THF to aldehydes to give *threo*-α-substituted tetrahydrofuran-2-methanols **1** stereoselectively is presented in this paper for the first time.[8]

The results of the addition of THF to 4-methoxybenzaldehyde **4a**, mediated by Et_3B either in the presence or absence of air at room temperature, are listed in Table 1.†‡

The radical reaction in the presence of air, which is necessary for radical initiation,[7,9] proceeded *threo*-selectively (*ca.* 90 : 10) to afford alcohols (**1a** and **2a**) along with unchanged aldehyde **4a**. It should be emphasized that the continuous admission of air greatly enhanced the efficiency of the reaction. The chemical yield was also increased by additional amounts of reagents, but it was not significantly improved by prolonged reaction time. Its

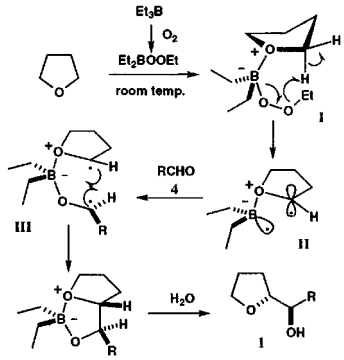
[a] Aldehydes (1.0 mmol) and 1.0 M THF solution of Et_3B (3.0 ml) were used. Air was introduced through a syringe needle with a balloon (*ca.* 10–20 ml h^{-1}). [b] Isolated yields: yields of recovered aldehydes **4** are given in parentheses. [c] Ratio determined from the ^1H NMR spectrum of the diastereomeric mixture or based on isolated yields of the corresponding acetates derived from the crude products. [d] Unreacted aldehyde **4** was not recovered. [e] Stereochemistry of the major isomer yet to be determined.



Scheme 2

inhibition by radical inhibitors such as galvinoxyl[10] clearly indicated that the reaction proceeds *via* a radical mechanism (entry 5 in Table 1). The radical reaction was also applied to representative aldehydes **4b**–**f**.

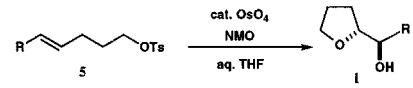
Table 2 demonstrates the general applicability of the present method to various aldehydes, though in only moderate yields.[11] The *threo*-selectivity of the addition was generally high for aromatic aldehydes, and low to moderate in the cases of aliphatic and *ortho*-substituted aromatic aldehydes (entries 4, 5 and 6 in Table 2).§ The reasons for the stereochemical outcome remain unclear but a transition state (**III**) in which boron atoms tether radical **3** to aldehydes **4** may be reasonably assumed (Scheme 2).[12]

In summary, a new method has been established for the stereoselective synthesis of *threo*-α-substituted tetrahydrofuran-2-methanols **1** by addition of tetrahydrofuranyl radical **3**, generated from THF with Et_3B in the presence of air, to aldehydes **4**. This method is quite easy to conduct and readily provides access to common structural motifs of biologically important acetogenins. It may thus be considered a superior means for the synthesis of these natural products. The mechanism of the reaction and potential applications to total synthesis of acetogenins are presently under investigation.

Notes and references

† Representative procedure: To 4-methoxybenzaldehyde **4a** (136 mg, 1.0 mmol) was added 1.0 M Et_3B in THF (3.0 ml, 3.0 mmol) at room temperature. The mixture was stirred at the same temperature with continuous bubbling of air through a syringe needle with a balloon (flow rate; 10–20 ml h^{-1}) for 12 h. The mixture was treated with AcOH and then extracted with CH_2Cl_2, and washed with sat. $NaHCO_3$. The organics were dried over $MgSO_4$. Following solvent evaporation, the residue was purified by column chromatography on silica gel (EtOAc–hexane 1:2) to afford a colorless solid consisting of α-(4-methoxyphenyl)tetrahydrofuran-2-methanols (88 mg, 42%) as a diastereomixture (**1a**:**2a** = 91:9) and unreacted aldehyde **4a** (51 mg, 37%).

‡ The relative configuration of the major adducts **1** was unambiguously determined by comparison of ^{1}H NMR spectral data with those of authentic *threo*-alcohols prepared by dihydroxylation of (*E*)-allyl tosylate **5**.



§ Satisfactory analytical (high-resolution mass) and spectral (IR, ^{1}H NMR, and MS) data were obtained for new compounds.

[Tris(*o*-iminosemiquinone)cobalt(III)]—a radical complex with an $S_t = {}^3/_2$ ground state

Cláudio Nazari Verani, Stefan Gallert, Eckhard Bill, Thomas Weyhermüller, Karl Wieghardt* and Phalguni Chaudhuri*

Max-Planck-Institut für Strahlenchemie, Stiftstraße 34-36, D-45470 Mülheim an der Ruhr, Germany. E-mail: chaudh@mpi-muelheim.mpg.de

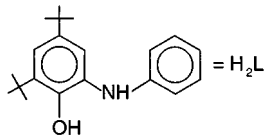
Received (in Basel, Switzerland) 11th May 1999, Accepted 2nd August 1999

Owing to their topology, three iminosemiquinone radical ligands couple in a ferromagnetic fashion, mediated by a low-spin Co(III) ion.

The realization of the widespread occurrence of radicals in enzyme catalysis has triggered considerable interest and research activity in metal–radical interactions.[1–10] Additionally, investigations relating organic radicals bound to metal ions are relevant to the field of 'molecular magnets'.[11,12]

In earlier reports[13–15] the $Ga(SQ)_3$ complex (SQ = 3,5-di-*tert*-butyl-1,2-semiquinonato) was characterized, both structurally and spectroscopically, and was found to exhibit a weak ferromagnetic exchange interaction ($J = +7.8$ cm^{-1}) between the three $S = {}^1/_2$ coordinated semiquinone ligands, mediated by a metal centre with empty d orbitals. In pursuit of our interest in coordinated radicals,[16] we now report a compound containing three *ortho*-iminosemiquinone radicals bound to a diamagnetic metal ion, low-spin Co(III), and exhibiting much stronger ferromagnetic interactions than those reported for similar systems.[17]

Treatment of anhydrous $CoCl_2$ in the presence of air with 3 equiv. of the N,O-chelating ligand H_2L in acetonitrile yielded a deep blue solution, which on addition of NEt_3 turned deep green.



The green solution was refluxed for 0.5 h, followed by stirring at room temperature for an additional 5 h. Slow evaporation of the clear solution afforded X-ray quality deep brown crystals of **1** (yield: 65%).

The most noteworthy features in the IR spectrum of **1** are the absence of both N–H and O–H modes and the appearance of two medium intense ν(CN) bands at 1588, 1577 cm^{-1} and a very strong ν(C–O) band at 1433 cm^{-1}. Optical spectra of **1** in solvents such as MeCN, THF and $CHCl_3$ consist of a series of intense bands and shoulders; in particular two extremely intense absorptions at low energies are noteworthy: λ/nm (ε/M^{-1} cm^{-1}) (MeCN) 881(2628), 668(2510); ($CHCl_3$) 902(20300), 676(16400); (THF) 910(16170), 675(13050). The intensity and its dependence on the solvent suggest that allowed electronic transitions of a CT nature dominate the spectra. The intensity of these bands decreases with time indicating the unstable nature of the radicals in solution. Cyclic voltammetric experiments exhibit four quasi-reversible one-electron redox waves for **1** in CH_2Cl_2 [0.1 M $NBu^n{}_4PF_6$]: $E^1{}_{1/2} = 0.196$, $E^2{}_{1/2} = -0.363$, $E^3{}_{1/2} = -0.933$ and $E^4{}_{1/2} = -1.320$ V *vs.* Fc^+–Fc. The first three redox potentials are associated with three ligand centred redox processes and $E^4{}_{1/2}$ must be assigned to the Co(III)–Co(II) couple.

The single crystal X-ray structure of **1** (Fig. 1)† shows that the first coordination sphere of cobalt has a C_2 axis passing through O(2)–Co(1)–N(3); the ligands have lost their aminohydrogen atoms. The structure determination unambiguously shows that cobalt is hexa-coordinated to three deprotonated ligands, each of which contains an iminosemiquinone radical anion, hence indicating a formal +3 oxidation state at the cobalt centre. Thus the distances C3–C4, C5–C6, C23–C24, C25–C26, C43–C44 and C46–C45 at 1.37 ± 0.01 Å are significantly shorter than the other C–C distances in the original phenol ring, 1.43 + 0.01 Å. Correspondingly, the imino C=N bonds at 1.345 ± 0.005 Å are shorter than the C–N bonds to the aniline rings, 1.420 ± 0.005 Å. Similar asymmetric electron density distribution in *ortho*-iminosemiquinone has been observed previously.[16*a*] Secondary structural confirmation of the intermediate reduction level of the ligand comes from the C–O bond distances, 1.304 ± 0.004(av.), which are much shorter than the 1.35 Å expected of a catechol.[18] They are in the range of those found for other first-row metal semiquinone complexes.[19] The Co–O and Co–N bond distances at 1.88 ± 0.01(av.) and 1.93 ± 0.01(av.) Å, respectively, are in accord with the low-spin description of the cobalt centre.

Magnetic data (SQUID) with $B = 1$ T for a polycrystalline sample of **1** are displayed in Fig. 2 as μ_{eff} *vs.* *T*. On lowering the temperature, μ_{eff} (3.16 μ_B at 290 K) increases monotonically approaching a maximum around 15 K with a value of 3.71 μ_B,

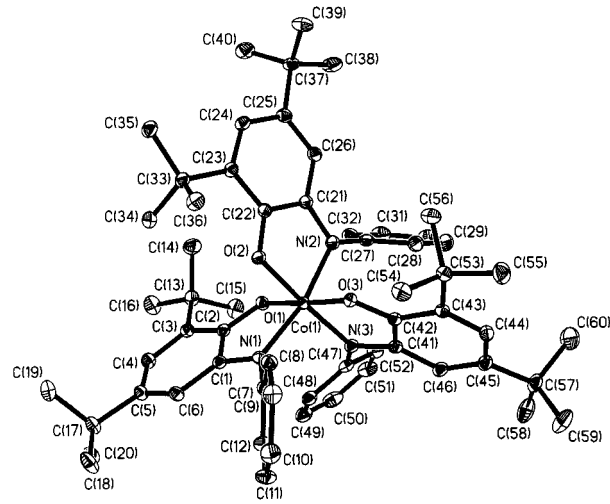


Fig. 1 Structure of the neutral complex CoL_3 **1** with selected bond lengths (Å) and angles (°): Co(1)–O(1) 1.878(1), Co(1)–N(1) 1.937(1), Co(1)–O(2) 1.896(1), Co(1)–N(2) 1.946(1), Co(1)–O(3) 1.889(1), Co(1)–N(3) 1.918(1), O(1)–C(2) 1.307(2), N(1)–C(1) 1.350(2), O(2)–C(22) 1.300(2), N(1)–C(7) 1.419(2), O(3)–C(42) 1.305(2), N(2)–C(21) 1.342(2), N(2)–C(27) 1.425(2), N(3)–C(41) 1.348(2), N(3)–C(47) 1.423(2), C(1)–C(6) 1.425(2), C(1)–C(2) 1.438(2), C(2)–C(3) 1.424(2), C(3)–C(4) 1.379(2), C(4)–C(5) 1.434(2), C(5)–C(6) 1.373(2), C(21)–C(26) 1.432(2), C(21)–C(22) 1.435(2), C(22)–C(23) 1.429(2), C(23)–C(24) 1.379(2), C(24)–C(25) 1.436(2), C(25)–C(26) 1.366(2), C(41)–C(46) 1.428(2), C(41)–C(42) 1.440(2), C(42)–C(43) 1.427(2), C(43)–C(44) 1.383(2), C(44)–C(45) 1.430(2), C(45)–C(46) 1.369(2); C(1)–N(1)–C(7) 121.2(1), C(47)–N(3)–C(41) 122.3(1), C(21)–N(2)–C(27) 119.7(1).

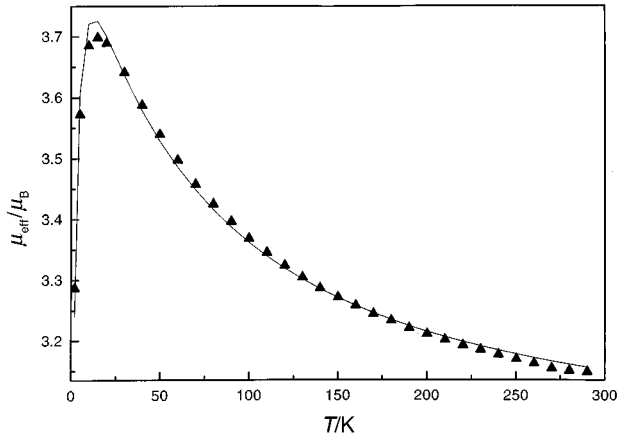

Fig. 2 A plot of μ_{eff} *vs.* T for **1**. The solid line represents the simulation of the experimental data.

which is close to the spin-only value for $S_t = 3/2$, expected as the ground state for three ferromagnetically coupled iminosemiquinone radicals. Below 15 K there is a decrease in μ_{eff}, which reaches a value of 3.30 μ_B at 2 K due to saturation effects and/or intermolecular antiferromagnetic interactions. A full-matrix diagonalization approach[20] was employed to fit the experimental data. We have found that the experimental data could not be fitted with only one 'J' as satisfactorily as with two 'J' values. Two exchange coupling constants have to be considered for the simulation based on the Hamiltonian

$$H = -2J(S_1 \bullet S_2 + S_2 \bullet S_3) - 2J_{13}(S_1 \bullet S_3)$$

with $S_1 = S_2 = S_3 = 1/2$ and the best fit shown as the solid line in Fig. 2 yields $J = J_{12} = J_{23} = +9.1$ cm^{-1}, $J_{13} = +59.5$ cm^{-1}, $g_1 = g_2 = g_3 = 2.005$ (fixed), TIP $= 100 \times 10^{-6}$ cm^3 mol^{-1} (fixed). Thus the quartet ground state is separated from the first doublet state by 27 cm^{-1} owing to the exchange interactions.

The quartet ground state is stabilized by the topology of the three magnetic orbitals of the iminosemiquinone radicals. In an idealized C_2 symmetry the three π*-magnetic orbitals are orthogonal to each other, thus rationalizing the observed ferromagnetic coupling. The superexchange mechanism is most probably mediated by the metal 3d π-orbitals. A rationale for the relative strengths of the two 'J' values might be sought in the orthogonality of the planes of the three ligands including the central cobalt in the coordination polyhedron. The dihedral angle between the two ligand planes containing O2 and O3 is 92.7°, accounting for the stronger coupling J_{13}. On the other hand, the dihedral angles between the planes containing O1 and O3 (79.4°) and between the planes containing O1 and O2 (82.8°) deviate significantly from 90°, thus rendering an appreciable antiferromagnetic contribution to the overall coupling. As a result the latter couplings, $J = J_{12} = J_{23}$, are weaker than the former one J_{13}.

The results reported here show that much larger ferromagnetic coupling can be achieved with suitably designed organic radicals by using appropriate diamagnetic acceptors. A novel tris(iminosemiquinone)metal(III) complex is described that can provide a suitable basis for further research in a systematic way, especially on the electronic properties of other metal(III)–radical complexes.

C. N. V. thanks DAAD (Bonn) for a fellowship. The experimental skill of Frau D. Schweiger is thankfully acknowledged.

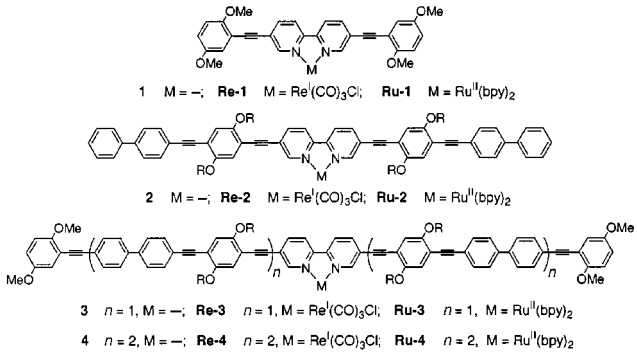
Received (in Columbia, MO, USA) 30th April 1999, Accepted 20th July 1999

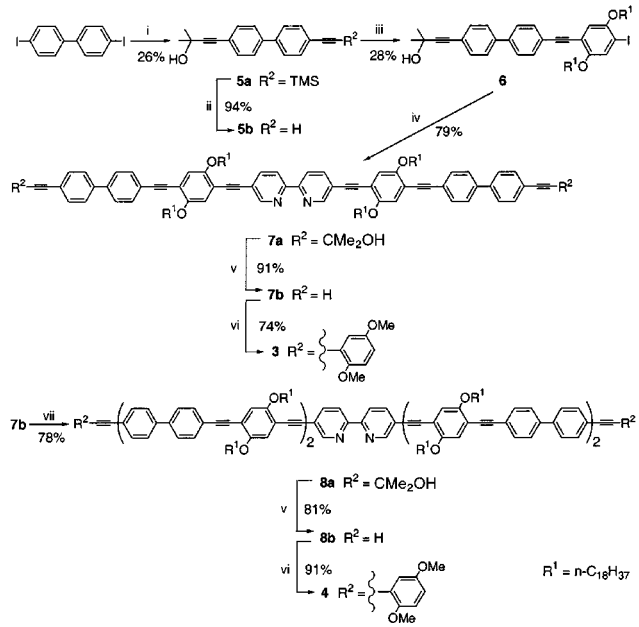
The synthesis and characterization of a series of *p*-phenyleneethynylene oligomers that contain the 2,2′-bipyridine-5,5′-diyl moiety is reported; metallation of the oligomers with $Re^{I}(CO)_5Cl$ and $Ru(bpy)_2Cl_2$ yields the corresponding $(L)Re(CO)_3Cl$ and $(L)Ru(bpy)_2^{2+}$ complexes.

π-Conjugated oligomers and polymers are of interest due to unique optical and electronic properties which enable their use as the active medium in optical, electronic, optoelectronic and chemical sensing devices.[1,2] We recently synthesized and characterized the photophysical properties of a series of π-conjugated polymers that incorporate a metal–bipyridine (bpy) chromophore directly into the backbone of a poly(phenyleneethynylene) (PPE) polymer.[3] The metal–organic polymers exhibit several interesting properties, including a decreased band-gap compared to the unmetallated polymer and a long-lived photoluminescence believed to arise from the metal-to-ligand charge transfer (MLCT) state. In an effort to better understand the optical properties of the metal–organic π-conjugated materials, we set out to prepare a series of monodisperse PPE-based metal–organic oligomers as models for the structurally related polymers.[4] Accordingly we have synthesized oligomers **1**–**4**, along with the corresponding metal complex derivatives, **Re-1**–**Re-4** and **Ru-1**–**Ru-4**. The present report describes the synthesis and optical absorption data for this new series of oligomers.



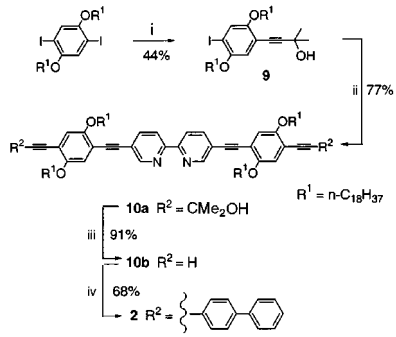
Preparation of series **1**–**4** required an iterative strategy that uses Pd-mediated (Sonogashira)[5] coupling chemistry to extend the PPE backbone outward from a 2,2′-bipyridine-5,5′-diyl 'core'. In order to implement this strategy a suitably functionalized 'monomer' unit that contains a protected terminal acetylene or a protected (or masked) aryl iodide was required. Other groups had previously reported application of the TMS group to protect terminal acetylenes and/or the 1-aryl-3,3-diethyltriazene function as a masked aryl iodide in the synthesis of mono-disperse PPE oligomers.[2a–d] The 1-aryl-3,3-diethyltriazene masking group was deemed unsuitable for our needs owing to the possibility that the bipyridyl nitrogens would react with the electrophile (MeI) that is used in the aryltriazene to aryl iodide conversion step. Although the TMS group seemed suitable for protecting the terminal acetylene, preliminary synthetic efforts aimed at preparing a monomer which contained an aryl iodide and a TMS-protected acetylene were thwarted due to the difficulty of separating the desired product from unreacted starting materials and by-products. The chromatographic separation is difficult (if not impossible) because the starting materials, the by-products and the desired product are all non-polar and therefore have similar solubility and comparable R_f values.

We finally discovered that the 2-hydroxypropan-2-yl (2-HP) protecting group[6] would allow us to readily prepare and purify multigram quantities of monomer **6** (Scheme 1), which features a protected terminal acetylene and a reactive aryl iodide.‡ Thus, in a two-step, one-pot procedure 4,4′-diiodobiphenyl was reacted with TMSC≡CH and then with 2-methylbut-3-yn-2-ol to afford **5a**. The 2-HP protecting group in **5a** allows this compound to be separated from the reaction by-products by silica chromatography. The separation is facile because the by-products have significantly higher R_f values compared to **5a** owing to the polar 2-HP protecting group. Selective removal of the TMS group from **5a** with KOH–MeOH afforded mono-protected compound **5b**. Monomer **6** was obtained by coupling **5b** with 1 equiv. of 1,4-diiodo-2,5-dioctadecyloxybenzene. Here again the polarity of the 2-HP protecting group in **6** allowed this material to be easily separated from the reaction by-products, affording the pure compound in 28% yield after chromatography.



Scheme 1 *Reagents and conditions*: i, TMSC≡CH (1 equiv.), Pd/Cu (cat.), heat, 3 h, then $HC{\equiv}CCMe_2OH$ (excess), heat, 3 h; ii, KOH, THF–MeOH; iii, 1,4-diiodo-2,5-dioctadecyloxybenzene (1 equiv.), Pd/Cu (cat.); iv, 5,5′-diethynyl-2,2′-bipyridine (0.5 equiv.), Pd/Cu (cat.); v, KOH, toluene, reflux; vi, 2-iodo-1,4-dimethoxybenzene (2 equiv.), Pd/Cu (cat.); vii, **6** (2 equiv.), Pd/Cu (cat.).

† Details of the synthesis and characterization of the oligomers is available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1749/



Scheme 2 *Reagents and conditions*: i, HC≡CCMe$_2$OH (1 equiv.), Pd/Cu (cat.); ii, 5,5′-diethynyl-2,2′-bipyridine (0.5 equiv.), Pd/Cu (cat.); iii, KOH, toluene, reflux; iv, 4-bromobiphenyl, Pd/Cu (cat.).

Once **6** was available in multigram quantities, synthesis of the desired oligomers proceeded rapidly. Thus, reaction of 2 equiv. of **6** with 5,5′-diethynyl-2,2′-bipyridine[7] produces **7a**, which is subsequently deprotected by KOH, toluene and heat to afford **7b**. Endcapping of **7b** with 2-iodo-1,4-dimethoxybenzene affords **3**, and subsequent metallation of **3** with Re(CO)$_5$Cl in toluene or Ru(bpy)$_2$(CF$_3$SO$_3$)$_2$ in THF–acetone yields **Re-3** and **Ru-3**, respectively. A further iterative sequence beginning with coupling of **7b** with 2 equiv. of **6** followed by deprotection and endcapping affords oligomer **4**.

As shown in Scheme 2, **2** was synthesized by a different approach that also relies upon the use of the 2-HP protecting group. First, 1,4-diiodo-2,5-dioctadecyloxybenzene was coupled with 1 equiv. of 2-methylbut-3-yn-2-ol to produce **9**. This compound was readily separated from unreacted starting material owing to the polar 2-HP function. Reaction of 2 equiv. of **9** with 5,5′-diethynyl-2,2′-bipyridine afforded **10a**, which was deprotected to **10b** by KOH, toluene and heat. Finally, **10b** was coupled with 4-bromobiphenyl to produce **2** which is subsequently metallated to afford **Re-2** or **Ru-2**.

Fig. 1 compares the UV-visible absorption spectra of the free oligomers with those of the corresponding (L)Re(CO)$_3$Cl and (L)Ru(bpy)$_2^{2+}$ complexes. The free oligomers all feature two absorption bands in the 300–500 nm region. The lowest energy band is assigned to the long-axis polarized π,π* (HOMO → LUMO) transition, while the second band is assigned to the short-axis polarized π,π* transition. The low energy band red-shifts considerably from **1** to **2**, but the position and bandshape of the transition remains relatively constant in **2**–**4**, indicating that the bandgap of the oligomers is defined early in the series. This observation contrasts with observations made on PPE oligomers that contain phenylene repeats (as opposed to the biphenyl and bipyridyl repeats present in **1**–**4**), in which the bandgap continues to decrease for 10 or more repeat units.[2b,d,f] This suggests that the poor electronic coupling between the non-coplanar phenyl (and pyridyl) rings in the biphenyl and bipyridyl units in **2**–**4** restricts the conjugation length.

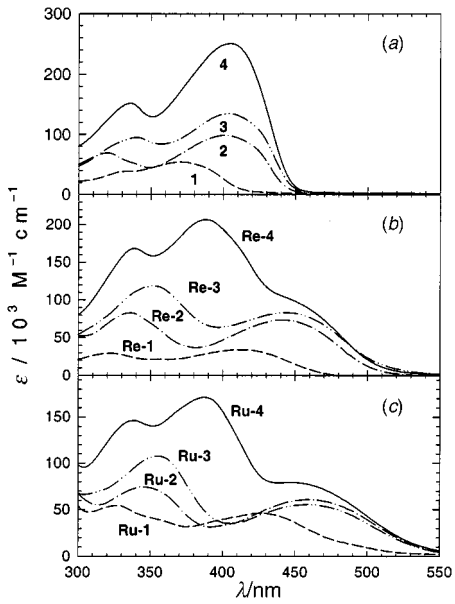


Fig. 1 Absorption spectra of oligomers: (*a*) **1**–**4** in THF solution; (*b*) **Re-1**–**Re-4** in THF solution; (*c*) **Ru-1**–**Ru-4** in CH_2Cl_2 solution.

Comparison of the spectra of **Re-1**–**Re-4** with those of the corresponding free oligomers demonstrates that metallation induces a substantial red-shift of the lowest π,π* absorption. The oscillator strength of the low energy band is large, but relatively constant throughout the series **Re-1**–**Re-4**. The low-energy band likely arises from a long-axis polarized π,π* transition localized predominantly on the chromophore defined by the bis(dioctadecyloxyphenylethynyl)-capped bipyridine segment. The transition is red-shifted because metallation forces the bipyridyl unit into a planar conformation, thereby effectively increasing the conjugation length.[4d] In addition to this effect, the electrophilic metal center likely decreases the LUMO energy and consequently decreases the HOMO–LUMO gap. An important point is that the dπ (Re) → π* (bpy-oligomer) MLCT transition, which is expected to arise in the 400–500 nm region (with $\varepsilon \approx 10^3$–10^4 M^{-1} cm^{-1}), is likely buried under the considerably more intense ligand-centered π,π* transition.

The spectra of the Ru^{II} complexes **Ru-1**–**Ru-4** are also dominated by the π,π* transitions of the ligand; in fact, these bands have approximately the same λ_{max} and ε in the Ru^{II} and Re^{I} complexes. A distinct shoulder is observed ($\lambda \approx 485$ nm, $\varepsilon \approx 8000$ M^{-1} cm^{-1}) in the spectrum of **Ru-1** which is very likely the dπ (Ru) → π* (**1**) MLCT transition. A similar MLCT band is not observed in the spectra of **Ru-2**–**Ru-4** because it is obscured by the more intense π,π* transition that occurs at a lower energy in these oligomers.

In conclusion, we have applied an iterative method to synthesize a series of mono-disperse PPE-based metal–organic oligomers. Ongoing spectroscopic and photophysical studies demonstrate that the oligomers are excellent models for structurally related bipyridine-containing poly(*p*-phenyleneethynylene) polymers.

We are grateful to the National Science Foundation (Grant No. CHE 99-01862) for support of this work.

Dideoxygenated calix[4]arene crown-6 ethers enhanced selectivity for caesium over potassium and rubidium

Richard A. Sachleben,*[a] Agathe Urvoas,[a] Jeffrey C. Bryan,[a] Tamara J. Haverlock,[a] Benjamin P. Hay[b] and Bruce A. Moyer[a]

[a] *Oak Ridge National Laboratory, PO Box 2008, MS-6119/4500S, Oak Ridge, TN 37831, USA. E-mail: sik@ornl.gov*

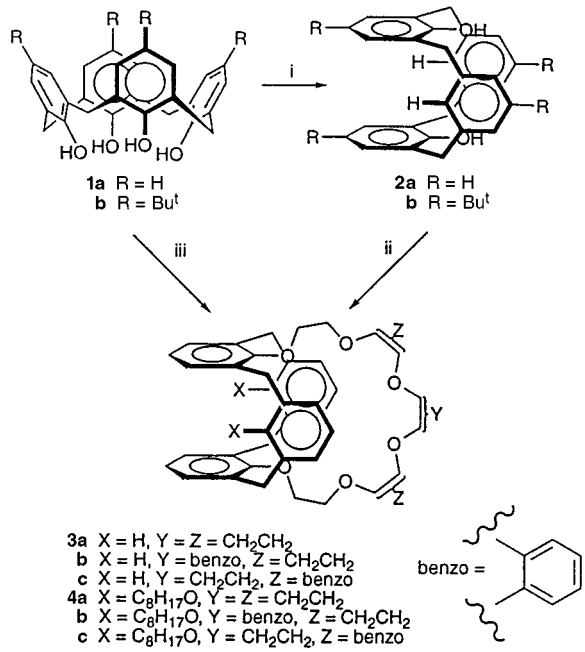
Received (in Columbia, MO, USA) 2nd December 1998, Revised 6th July 1999, Accepted 6th July 1999

Calix[4]arene crown-6 ethers derived from dideoxygenated calix[4]arene exhibit enhanced extraction selectivity for caesium over potassium; the crystal stucture of the uncomplexed calix[4]arene monobenzocrown-6 ether exists in the 1,3-alt conformation in the solid state.

Calixarenes[1] have been taking on an increasingly important role in host–guest chemistry, in large part because they can provide a well-organized platform for the attachment of pendant functional groups.[2,3] The incorporation of a calix[4]arene (**1** in Scheme 1) moiety into crown ethers[4] has been used to develop powerful, highly selective ionophores for alkali metal cations,[5,6] the properties of which are often dependent on the conformation adopted by the calixarene. Whereas diethoxycalix[4]arene crown-4 ether in the cone conformation exhibits high sodium selectivity,[7] diethoxycalix[4]arene crown-5 ether in the 1,3-alternate conformation exhibits selectivity for K^+ over Na^+ exceeding that of Valinomycin.[8] Furthermore, 1,3-alt calix[4]arene crown-6 ethers exhibit high caesium binding[9,10] with selectivities for Cs^+/Na^+ of *ca.* 10^4–10^5,[9–11] a property which has led to their study for the selective removal of caesium from nuclear fuel reprocessing wastes.[12,13] However, Cs/K selectivities are only *ca.* 80–600, which is of concern since the wastes may contain as much as 1 M K^+ in a typical matrix containing 5–7 M Na^+, but only 10^{-6}–10^{-3} M Cs.[14] Having undertaken an effort to develop extractants with improved Cs/K selectivity, we have synthesized three new calix[4]arene crown-6-ethers (**3a**–**c** in Scheme 1)† derived from di-dehydroxylated calix[4]arene **2a**,[15] which exhibit Cs^+/Rb^+ and Cs^+/K^+ selectivities significantly greater than that of comparable 1,3-dialkoxycalix[4]arene crown-6-ethers **4a**–**c**.



Scheme 1 *Reagents and conditions*: i, $(EtO)_2PHO$, CCl_4, Et_3N, toluene, 0 °C, then K, NH_3 (liquid); ii, $(TsOCH_2CH_2O\text{-}Z\text{-}O)_2Y$, Cs_2CO_3, MeCN; iii, $C_8H_{17}I$, K_2CO_3, MeCN, then $(TsOCH_2CH_2O\text{-}Z\text{-}O)_2Y$, Cs_2CO_3, MeCN.

Competitive extractions of alkali metal nitrates by the six calix[4]arenes **3a**–**3c** and **4a**–**c** were performed essentially as described previously,[14] with the organic phase consisting of 0.025 M of calixarene crown ether in 1,2-dichloroethane and the aqueous phase consisting of a mixture of alkali metal nitrates: 1.00 M $LiNO_3$, 1.00 M $NaNO_3$, 0.100 M KNO_3, 0.0020 M $RbNO_3$ and 0.0011 M $CsNO_3$. Metal ion concentrations were determined for both phases, from which distribution ratios $D_M = [M^+]_{organic}/[M^+]_{aqueous}$ were calculated directly. Caesium was analyzed by γ spectrometry, while lithium, sodium, potassium and rubidium were analyzed, subsequent to stripping of the organic phase with 1.0 mM HNO_3, by inductively coupled plasma atomic emission spectroscopy. From the data given in Table 1, it can be seen that in each case where the calixarene is changed from dioctyloxycalix[4]arene **4a**–**c** to the dihydrocalix[4]arene **3a**–**c** the extraction strength for caesium, expressed in terms of D_{Cs}, decreases by roughly an order of magnitude. However, an even larger decrease is observed for the extraction of the other alkali metals, to the point for K^+ and Rb^+ where no extraction was measured. This is despite the fact that the aqueous phase used in these experiments contained significantly higher concentrations of Li^+, Na^+, K^+ and Rb^+ than Cs^+. As a consequence, selectivity for extraction of caesium (as expressed by $S_{Cs/M} = D_{Cs}/D_M$) increases. Since only upper limits are available for the extraction of Rb^+ and K^+ by calix[4]arene crown ethers **3a**–**c**, the magnitude of the selectivity increase as compared to **4a**–**d** can only be assigned a lower limit. Even so, the observed trends provide evidence that improved extraction selectivity for Cs^+ can be obtained by appropriate modification of the calixarene portion of calix[4]-arene crown-6 ethers.

Table 1 Calix[4]arene crown-6 ethers used in this study, their distribution ratios (D_M) for the extraction of alkali metal nitrates from water to 1,2-dichloroethane at 25 °C, and the corresponding selectivities (S) for Cs^+ ions over Li^+, Na+, K^+ and Rb^+ ions [a]

Extractant	D_{Cs}	D_{Rb} ($S_{Cs/Rb}$)	D_K ($S_{Cs/K}$)	$D_{Na}/10^{-5}$ ($S_{Cs/Na}$)	$D_{Li}/10^{-5}$ ($S_{Cs/Li}$)
3a	0.403	—[b] (> 58)	—[b] (> 4200)	2.17 (23000)	1.90 (32000)
3b	0.383	—[b] (> 54)	—[b] (> 4000)	—[b] (> 150000)	—[b] (> 660000)
3c	0.116	—[b] (> 17)	—[b] (> 1200)	—[b] (> 47000)	—[b] (> 200000)
4a	3.65	0.180 (20)	0.0152 (240)	22.0 (17000)	2.98 (120000)
4b	4.04	0.214 (19)	0.0141 (290)	3.9 (100000)	0.99 (> 450000)
4c	1.61	0.178 (9.0)	0.0125 (130)	—[b] (> 640000)	0.97 (170000)

[a] All values are the average of two determinations. [b] Lower limits on measurement of distribution ratios: $D_{Li} = 5.8 \times 10^{-7}$, $D_{Na} = 2.5 \times 10^{-6}$, $D_K = 9.6 \times 10^{-5}$, $D_{Rb} = 0.0070$.

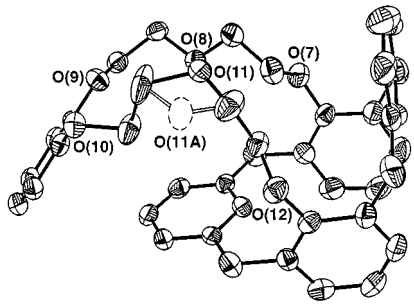


Fig. 1 ORTEP drawing (50% probability elipsoids) of **5b**. For clarity only one molecule from the asymmetric unit is displayed, hydrogen atoms are omitted, and only oxygen atoms are labeled. The minor disorder component (O11A) is represented with a dashed boundary ellipsoid.

Since previous studies have shown that the 1,3-alternate conformation is preferred for high caesium binding and selectivity[9] and that calixarenes bearing substituents smaller than ethoxy are conformationally mobile,[16] we considered the conformational preferences of these new compounds. The crystal structure of **3b** (Fig. 1)‡ reveals that this compound crystallizes with two molecules in the crystallographic asymmetric unit, with the calix[4]arene portions of both molecules clearly in the 1,3-alt conformation. The calix[4]arene crown-6-ethers **3a–c** exhibit room temperature ^{1}H NMR ($CDCl)_3$ where the Ar-CH_2-Ar resonances of the calixarene appear as a pair of doublets at $\delta \sim 4.2$ and ~ 3.7 with a coupling constant of ~ 15.5 Hz, while the intraannular proton on the deoxygenated aromatic ring is found upfield at $\delta \sim 6.0$. Grynszpan and Biali[17] interpreted the upfield shift of the corresponding proton in **2b** in terms of shielding by the two phenolic rings in the 1,3-alt conformation, whereas the positions and coupling constants of the calixarene methylenes are more consistent with the report by Ting *et al.*[15] where the 'unsubstituted phenyl rings can rotate freely'. The calixarene methylene carbon of **3b** was observed at δ 35.3, similar to the values reported to be observed for the 1,3-alternate conformers in conformationally immobile calix-[4]arenes.[18] We performed VT-NMR on **3b** in $CDCl_3$ and observed a decrease in the separation between the pair of doublets assigned to the calixarene methylene resonances, from 216 to 187 Hz ($\Delta\delta$ = 29 Hz), when the temperature was decreased from 340–220 K, consistent with rapid conformational interconversion which shows upon lowering the temperature. Conversely, in toluene-d_8, the separation between this pair of doublets decreased, from 340 to 298 Hz ($\Delta\delta$ = 42 Hz), when the temperature was *increased* from 170 to 370 K, suggesting a slow conformational interconversion which speeds up with increasing temperature. However, coalescence was not achieved even when a solution of **3b** was heated to 500 K in nitrobenzene-d_5. In $(CD_2Cl)_2$, $\Delta\delta \approx 0$ over the temperature range 240–340 K. Consequently, the solution conformation cannot be assigned to the calixarene portion of **3b** based on these results.

The results reported here have significant ramifications, not only in the effort to develop more highly selective extractants, but also in understanding the conformational and electronic factors which contribute to the remarkable ionophoric properties of calixarenes and calix[4]arene crown ethers. Efforts in this area are the subject of ongoing investigations.

This research was sponsored by the Environmental Management Science Program, Offices of Energy Research and Environmental Management, U.S. Department of Energy, under contract DE-AC05-960R22464 with Oak Ridge National Laboratory, managed by Lockheed Martin Energy Research Corporation.

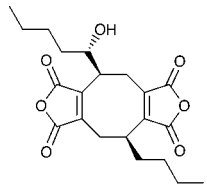
Received (in Cambridge, UK) 18th May 1999, Accepted 29th July 1999

Photochemical dimerization of 3-substituted cyclobutene-1,2-dicarboxylates followed by thermal isomerization gives regio- and stereo-selectively 3,7-*cis*-disubstituted cycloocta-1,5-diene-1,2,5,6-tetracarboxylates.

Cyclooctanoids have been attracting great interest in the fields of agricultural and pharmaceutical chemistry because of their unique structures and biological activities. For example, natural product Zopfiellin[1] was isolated very recently. Synthetic

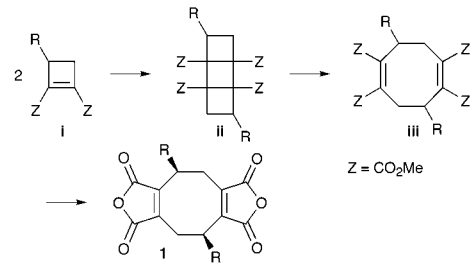


Zopfiellin

methods for cyclooctanoids have been studied over the last few decades.[2] We also reported a route to cyclooctanoids *via* bromination of tetramethyl cycloocta-1,5-diene-1,2,5,6-tetracarboxylate followed by alkylation with organocopper reagents to give rise to regio- and stereo-selectively 3,7-*cis*-disubstitution of the tetraester.[3] This method, however, was restricted to primary alkyl groups due mainly to the low reactivity of secondary and tertiary alkylcopper reagents.

Accordingly, we considered that introduction of bulky groups such as secondary, tertiary and substituted alkyls before eight-membered ring formation would be favorable. In addition, [2 + 2]cycloaddition of cyclobutene looked attractive for eight membered ring formation. Although the synthetic scheme has precedents,[4] we felt it necessary to study carefully the stereochemical and regiochemical outcome of cyclooctanoid synthesis.

Herein we demonstrate that [2 + 2]cycloaddition is widely applicable to the synthesis of eight-membered ring compounds, especially highly substituted ones, as shown in Scheme 1. Although the dimerization ring opening route is limited to symmetrical cyclooctadiene systems, we considered it important to first establish a reliable synthetic route to cyclooctanoids containing various functional groups. We envisaged that dimeric [2 + 2]cycloaddition of cyclobutene **i** would afford a mixture of tricyclo[4.2.0.0]octanes **ii** which might thermally isomerize to 3,7-*cis*-disubstituted cycloocta-1,5-diene derivative **iii**, a precursor of bisanhydride **1** closely related to Zopfiellin. After many experiments, we were pleased to find that this new synthetic route worked. Many 3,7-*cis*-disubstituted cycloocta-1,5-diene derivatives, including those substituted by secondary and tertiary alkyl groups, could be synthesized regio- and stereo-selectively by this method.



Scheme 1

Key starting materials **2** were prepared from readily available terminal olefins according to the route shown in Scheme 2.[5] Yields of **2** based on the respective olefins are summarized in Table 1. In addition to **2** with a primary alkyl group, those with a secondary or tertiary alkyl group were prepared in good to high yields. Vinyl, bromo and acetoxy groups did not interfere with the reaction (**2g**–**k**). Trimethylsilylmethyl-substituted cyclobutene **2l** was accessible, albeit in a lower yield.

Photochemical dimerization of 3-substituted cyclobutene-1,2-dicarboxylates **2** proceeded smoothly to afford isomeric mixtures of tricyclo[4.2.0.0]octanes, which upon thermal iso-

merization gave 3,7-*cis*-disubstituted cycloocta-1,5-diene-1,2,5,6-tetracarboxylates **3** as described in Scheme 3.

The results with **2a-l** are listed in Table 2. The possible regioisomer, 3,8-disubstituted cyclooctadiene **4**, was not isolated in all cases. In addition to **2a**, secondary alkyl substituted cyclobutenes **2c**, **2d** and **2e** were smoothly converted into **3c**, **3d** and **3e**, respectively.[6] *tert*-Butyl-substituted cyclooctadiene **3f** was also obtained but in 5% yield. Although **2g** (R = vinyl) gave unidentified compounds, **2h** (R = CH_2CH_2Br), **2i** (R = CH_2OAc) and **2j** (R = CH_2CH_2OAc) were transformed to cyclooctadienes **3h**, **3i** and **3j**, respectively, in moderate yields. These are potential precursors for further elaboration of side chains. The stereochemistry of **3i**[7] was proved to be 3,7-*cis* by X-ray crystallography (Fig. 1). Unexpected product **5** (13%) *in lieu* of **3k** was formed from cyclobutene **2k**. Similarly **2l** was converted into **3l**.

Regio- and stereo-selective formation of **3** is worthy of note. We consider that the dimerization of 3-substituted cyclobutene-1,2-dicarboxylates **2** would take place through diagonal aggregates due to steric repulsion to afford a single regioisomer of the bicyclo[4.2.0.0]octane tetracarboxylates which, upon heating, give thermodynamically favorable 3,7-*cis*-disubstituted cyclooctadienes **3**.

Dipropyl- and diisopropyl-substituted cyclooctadiene tetraesters **3a** and **3c** were converted into the corresponding bisanhydrides **1a**[8,9] (Fig. 2) and **1c** by alkaline hydrolysis and

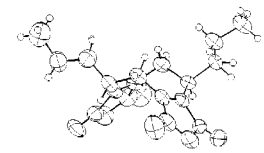

Fig. 2 X-Ray crystallography of **1a**.

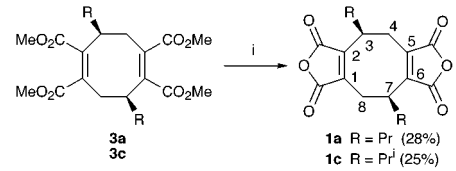

Scheme 4 *Reagents and conditions*: i, aq. NaOH,MeOH, then aq. HCl.

subsequent acidification (Scheme 4). Fungicidal activities of **1a** and **1c** were shown to be close to that of Zopfiellin.[9]

In summary, we have disclosed that facile photochemical [2 + 2]cycloaddition of 3-substituted cyclobutene-1,2-dicarboxylates followed by thermal isomerization affords regio- and stereo-selectively 3,7-*cis*-disubstituted cycloocta-1,5-diene-1,2,5,6-tetracarboxylates in moderate to good yields. Further mechanistic study of the regio- and stereo-selectivity of this new synthetic strategy is in progress.

We are grateful to the Analytical Chemistry Division of Nissan Chemical Industries Ltd. for analytical support.

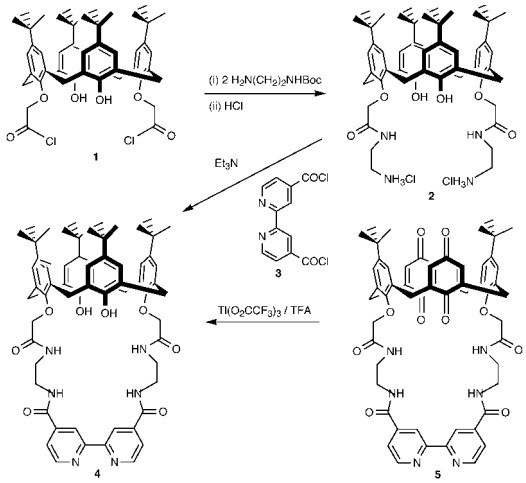
Received (in Cambridge, UK) 30th June 1999, Accepted 2nd August 1999

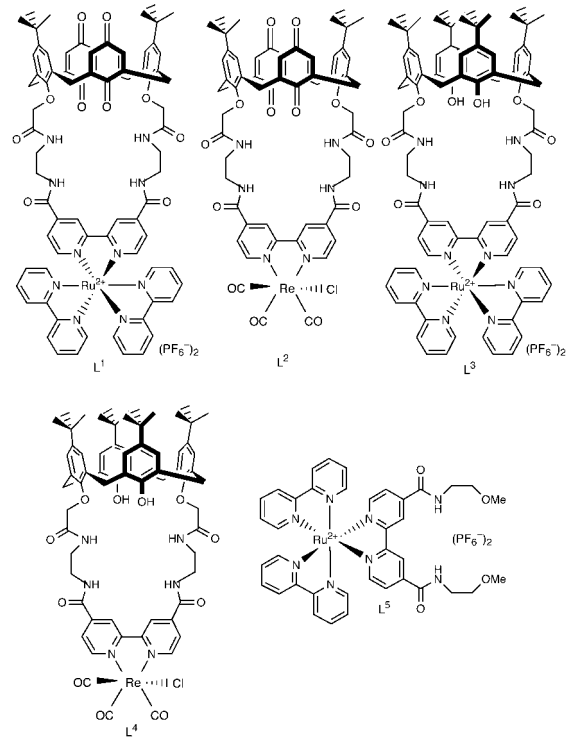
New ruthenium(II) and rhenium(I) bipyridyl calix[4]diquinone receptors have been prepared and shown to selectively bind and sense acetate anions *via* remarkable luminescent emission intensity retrieval effects.

Anionic species are well known to play numerous fundamental roles in biological and chemical processes and their detrimental effects as environmental pollutants is of growing concern.[1] In view of this there is intense current interest being shown in the design and syntheses of receptors that are proficient at detecting anions in solution.[2] By incorporating redox- and photo-active transition metal inorganic signalling probes into various acyclic, macrocyclic and calixarene ligand frameworks we have produced a series of selective spectral and electrochemical responsive reagents for anions.[2a,3] For example, using the ruthenium(II) bipyridyl luminescent reporter moiety the selective sensing of dihydrogen phosphate has been demonstrated with lower[4] and upper rim[5] ruthenium(II) bipyridyl calix[4]arene receptor systems. In an effort to construct a novel type of switchable and selective luminescent sensitive receptor for anions we report here the synthesis of new ruthenium(II) and rhenium(I) bipyridyl calix[4]diquinone receptors which selectively bind and sense acetate anions *via* remarkable emission intensity retrieval effects.

The condensation of the lower rim 1,3-bis(chlorocarbonyl) substituted *p-tert*-butylcalix[4]arene **1**[6] with 2 equiv. of mono-Boc protected 1,2-diaminoethane[7] followed by HCl gave **2** in 68% yield. The reaction of **3**[8] with **2** in the presence of Et_3N in dry CH_2Cl_2 under high dilution conditions afforded the [1 + 1] product **4** in 44% yield together with the [2 + 2] dimer in 20% yield. $Tl(O_2CCF_3)_3$ in TFA[9] was used to oxidise **4** and produce the new bipyridyl bridged calix[4]arene-diquinone **5** in 68% yield (Scheme 1). Complexation reactions with $(bipy)_2RuCl_2{\cdot}2H_2O$ followed by NH_4PF_6, and $Re(CO)_5Cl$ gave the new receptors L^1 and L^2 in 81 and 79% respective yields. Analogous high yielding complexation reactions with **4** produced the new lower rim calix[4]arene derivatives L^3 and L^4.



Scheme 1



The addition of Bu_4NOAc, Bu_4NCl and $Bu_4N(H_2PO_4)$ to DMSO-d_6 ^{1}H NMR solutions of L^1–L^4 resulted in significant perturbations of most notably the respective amide and 3,3′-bipyridyl receptor protons by up to $\Delta\delta$ = 0.95 ppm. The resulting titration curves all suggested a 1:1 receptor:anion stoichiometry. The computer program EQNMR[10] was used to determine the stability constants from the ^{1}H NMR titration data, and the results are summarised in Table 1, which includes for comparison purposes stability constant data for acyclic receptor L^5.[13] It is evident that the topological nature of a receptor's calix[4]arene/calix[4]diquinone cavity and the bipyridyl coordinated charged ruthenium(II)/neutral rhenium(I) transition metal centre have a major effect on the anion thermodynamic stability and on the selectivity preference that a particular receptor exhibits. Compared to acyclic receptor L^5, L^1–L^4 form significantly stronger anion complexes with AcO^- and Cl^-, and

Table 1 Stability constants of receptors with anions in DMSO-d_6

	K^a/M^{-1}		
Receptor	Cl^-	AcO^-	$H_2PO_4^-$
L^1	1050	9990	215
L^2	255	1790	160
L^3	840	4060	240
L^4	435	760	185
L^5	150	350	1300

[a] Errors < 10%; T = 298 K.

weaker complexes with $H_2PO_4^-$. The AcO^- > Cl^- > $H_2PO_4^-$ selectivity trend displayed by L^1–L^4 contrasts acyclic L^5 selectivity preference $H_2PO_4^-$ > AcO^- > Cl^-. It is noteworthy that the AcO^- stability constant magnitudes are significantly larger for the calix[4]diquinone-containing receptors L^1 and L^2 when compared to the calix[4] arene receptors L^3 and L^4. Electrostatic considerations can account for the neutral rhenium(I) receptors forming relatively weaker anion complexes in contrast to the charged ruthenium(II) analogues.

Preliminary absorption and emission investigations displayed in Table 2, reveal that these receptors behave like the parent $[Ru(bpy)_3]^{2+}$ and $[Re(bpy)(CO)_3Cl]$ complexes.

As expected,[11,12] the heteroleptic nature of the ruthenium receptors leads to two metal–ligand charge transfer (MLCT) transitions, Ru→bpy-macrocycle and Ru→bpy; the former lies at slightly lower energy than the Ru→bpy ones because of the presence of the electron-withdrawing carbonyl amide substituents on the bpy-macrocycle ligand. As a consequence, for L^1 and L^3 the absorption band around 450 nm is broader and the emission band is red-shifted compared to that of $Ru(bpy)_3^{2+}$. The low emission yield exhibited by L^1 is expected since it is well known that quinones efficiently quench the luminescence emission of $Ru(bpy)_3^{2+}$ *via* an oxidative (intramolecular[13] or intermolecular[14]) electron transfer mechanism. In our case an intermolecular quenching process can be ruled out because of the low receptor concentration used; thus an intramolecular quenching mechanism is operative and a rate constant of 3×10^7 s^{-1} can be calculated on the basis of the lifetimes of Ru–calix[4]arene L^3 and Ru–calix[4]diquinone L^1.

Table 2 also shows that the rhenium receptors exhibit red-shifts of the lowest energy absorption and emission bands compared to the reference $[Re(bpy)(CO)_3Cl]$ complex.[15] Again the carbonyl amide substituents on the bpy-macrocycle ligand can explain the energy decrease of the MLCT excited state involved in the absorption (^{1}MLCT) or in the emission (^{3}MLCT) process. An excited state quenching process *via* intramolecular electron transfer is also expected for the Re–calix[4]diquinone receptor L^2 since the redox properties[15] of the excited Re^I moiety are quite similar to those of the excited Ru^{II} complexes. On the basis of the luminescence lieftimes of Re–calix[4]arene L^4 and Re–calix[4]diquinone L^2 a value of 7×10^7 s^{-1} can be calculated for the rate constant of the intramolecular quenching.

The addition of Bu_4NOAc and Bu_4NCl was found to dramatically affect the luminescence spectrum of all the receptors, the only exception being an insensitive response with L^2 and Cl^- in DMSO solution. While the Ru–calix[4]arene receptor L^3 exhibits an emission decrease, the other receptors L^1, L^2 and L^4 display a marked emission retrieval upon anion addition. In particular, AcO^- addition to MeCN solutions of L^1 caused a remarkable intensity increase of up to 500% concomitant with a slight blue shift of the emission maximum (Fig. 1). A notable 60% intensity increase was observed on Cl^- addition

Table 2 Absorption and emission data of the four receptors and of the reference compounds

	Absorption[a]		Emission[a]		
Compound	λ/nm[b]	ε/dm^3 mol^{-1} cm^{-1}	λ/nm[c]	τ/ns[d]	Φ_{em}[e]/10^{-3}
$[Ru(bpy)_3]^{2+}$	452	14 000	615	180	—
L^3	472	9 300	654	510	30
L^1	475	11 000	660	30[f]	1.0
$[Re(CO)_3bpyCl]$[g]	384		615	50	—
L^4[h]	393	4 200	675	21	2.0
L^2[h]	385	4 600	685	8.5	0.5

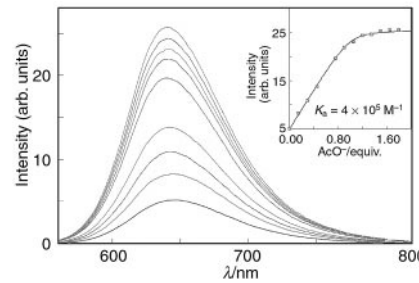

Fig. 1 Emission spectral variations upon titration of MeCN solution of L^1 (1.1×10^{-4} M) with Bu_4NOAc.

to L^1. Results obtained from Cl^- and AcO^- titrations of L^1 and L^3 in CD_3CN are consistent with a receptor–anion complex of 1:1 stoichiometry with stability constant magnitudes $>10^4$ M^{-1}, larger than the ^{1}H NMR determined values in DMSO-d_6, reflecting the less competitive CD_3CN solvent medium. The anion induced enhancement of the luminescence intensity in the case of Ru–calix[4]diquinone complex L^1 is clearly due to a significant decrease in the electron transfer rate constant, indicating that the anion binding decreases the interaction between the ruthenium(II) bipyridyl centre and the quinone moieties. In the case of Cl^- addition to Ru–calix[4]arene L^3 the intensity decrease matches the decrease in the emission lifetime (−25%) indicating that, at least in this case, anion binding favours the non-radiative decay processes.†

In summary the new ruthenium(II) and rhenium(I) bipyridyl calix[4]diquinone receptors selectively bind and optically sense AcO^- anions by overcoming intramolecular quenched luminescence and retrieving an anion induced emission.

We thank the Leverhulme Trust for a postdoctoral fellowship (V. T.) and the EPSRC for use of the mass spectrometry service at the University of Wales, Swansea.

A new stereoselective approach to the manzamine alkaloids

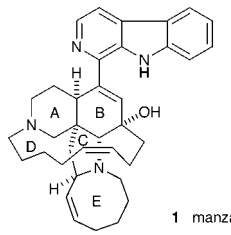
Received (in Liverpool, UK) 9th June 1999, Accepted 28th July 1999

The key step in a new, stereoselective approach to the manzamine alkaloids involves an intramolecular azomethine ylide cycloaddition reaction, which forms rings B and C simultaneously, together with three new chiral centres; this has allowed a rapid access to the core ABC ring system of manzamine A.

The manzamine and related alkaloids consist of a structurally complex polycyclic ring system, typified by manzamine A **1**.[1]

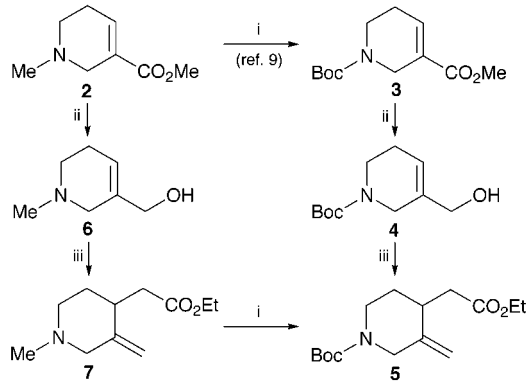


1 manzamine A

Manzamine A was the first of the family to be isolated in 1986 and, together with other manzamine alkaloids isolated from various marine sponges, has been shown to possess significant antileukemic and antibacterial properties.[1,2] The fascinating molecular structure and the promising biological activity of manzamine A has led to a number of synthetic endeavors in this area.[3] Recently the groups of Winkler[4] and Martin[5] have reported the synthesis of manzamine A, ircinol A and ircinal A. The key step in these syntheses makes use of a [2 + 2] (followed by ring expansion) or [4 + 2] cycloaddition reaction to set up ring B. Other [4 + 2] cycloaddition or cyclization strategies have been reported.[6] Our own efforts have centred on a [3 + 2] azomethine ylide cycloaddition reaction[7] to set up ring C. This approach seems ideally suited to access the manzamine alkaloids as an intramolecular cycloaddition reaction would allow, in a single step, the simultaneous formation of not only ring C but also ring B, together with all three chiral centres within ring C. Literature precedent[7,8] suggested that the azomethine ylide cycloaddition reaction would proceed to give the desired stereochemical arrangement found within the manzamine alkaloids. Herein we report a successful model study using this strategy.

The conversion of commercially-available arecoline **2** (Scheme 1) to the corresponding *N*-Boc derivative **3** has been reported by Olofson and co-workers.[9] Reduction of the ester **3** with $LiAlH_4$ gave the alcohol **4**. Use of the Johnson–Claisen rearrangement[10] with triethyl orthoacetate gave a rapid access to the piperidine **5**, containing the *exo*-methylene unit required for the key cycloaddition reaction. As an alternative route, reduction of arecoline and Johnson–Claisen rearrangement gave the corresponding *N*-methyl derivative **7**. Replacement of the *N*-Me for the *N*-Boc group in derivative **7** provided the desired compound **5**, although the yields in each step were more variable using this latter route.

The ester **5** was reduced to the corresponding alcohol **8** using $LiAlH_4$ (Scheme 2). Conversion of the alcohol **8** to the iodide



Scheme 1 *Reagents and conditions*: i, MeCH(Cl)OCOCl, PhMe, heat, then MeOH, heat, then Boc_2O, CH_2Cl_2, Et_3N, 81% from **2**, 79% from **7**; ii, $LiAlH_4$, THF, 0 °C, 95% from **3**, 99% from **2**; iii, $MeC(OEt)_3$, xylene, 2,4-dinitrophenol, heat, 71% from **4**, 39–87% from **6**.

9 was accomplished *via* the corresponding bromide. The iodide **9** was found to be a better electrophile than the bromide towards the deprotonated dithiane **10**. Addition of the dithiane gave the ester **11**, which contained the required carbon framework for rings A and B of manzamine A. Reduction of the ester **11** and oxidation gave the aldehyde **12** needed for the key cycloaddition reaction.

Our initial studies towards the formation of the ABC ring system of manzamine A have centred on the condensation of the secondary amine sarcosine ethyl ester **13** with the aldehyde **12**. Formation of the azomethine ylide (Fig. 1) and intramolecular cycloaddition leads to the generation of the pyrrolidine ring C, together with simultaneous formation of ring B. A single diastereomeric product **14** was obtained† which consisted of the

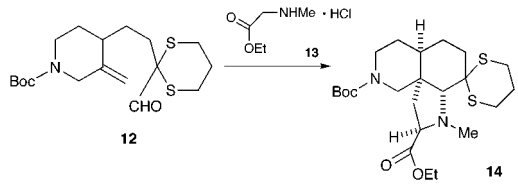

Scheme 3 *Reagents and conditions*: i, Pr^i_2NEt, PhMe, heat, 24 h, 45%.

desired ABC ring system of the manzamine alkaloids (Scheme 3). The stereochemical assignment could not be verified by NMR spectroscopy due to overlapping signals. Hydrolysis of the *N*-Boc group (TFA, CH_2Cl_2) gave rise to the corresponding secondary amine in which the peaks in the ^1H NMR spectrum were better resolved, but not to the extent required for NOE studies. The problem was solved by single crystal X-ray spectroscopic studies (Fig. 2)‡ of the *N*-Boc derivative **14**, which confirmed the structure and the relative stereochemistry of the cycloaddition product. The *cis* ring junction is favoured between rings A and B and between rings B and C. A possible ylide stereochemistry and orientation for cycloaddition is shown in Fig. 1.

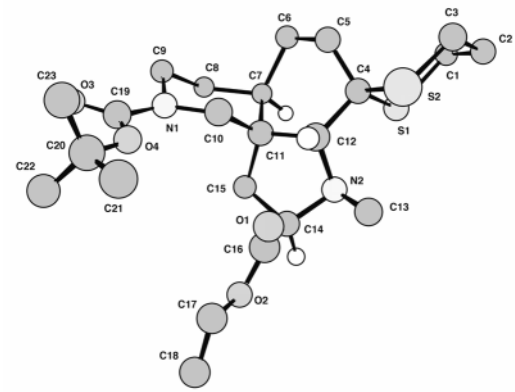

Fig. 2 X-Ray structure of the cycloadduct **14**.

In conclusion, we have demonstrated a short and efficient route to the core ABC ring system of the manzamine alkaloids. The key step is a stereocontrolled intramolecular azomethine ylide cycloaddition reaction, which sets up two new rings (rings B and C) and three new chiral centres (controlled by the existing chiral centre) in a single transformation. Further work to extend this chemistry to the preparation of more advanced intermediates of the manzamine alkaloids and to complete the total synthesis is in progress.

Self-assembly of monopyrazolylporphyrins by hydrogen bonding in solution

Chusaku Ikeda,* Noriko Nagahara, Eiko Motegi, Naoki Yoshioka and Hidenari Inoue

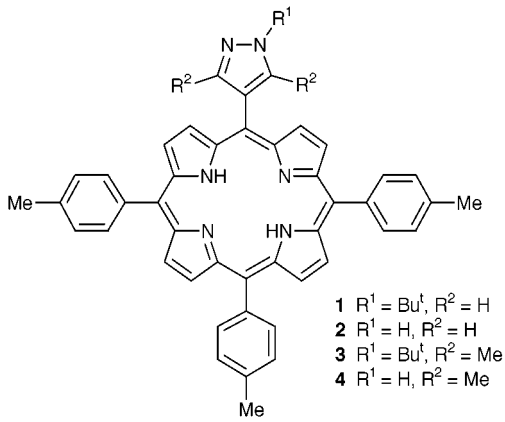
Department of Applied Chemistry, Keio University, Kohoku-ku, Yokohama 223-8522 Japan. E-mail: c05351@educ.cc.keio.ac.jp

Received (in Cambridge, UK) 7th June 1999, Accepted 28th July 1999

The self-associated structures of two noble *meso*-(monopyrazolyltritolyl)porphyrins synthesized *via* their NH-protected precursors have been studied by ^{1}H NMR, FT-IR and ESI MS measurements; *meso*-(pyrazol-4-yl)porphyrin and *meso*-(3,5-dimethylpyrazol-4-yl)porphyrin form a dimer and a tetramer, respectively, in solution due to intermolecular hydrogen bonding between pyrazole units.

In recent years there has been considerable interest in the construction of porphyrin assemblies of well-organized shape for molecular photonic devices such as artificial light harvesting systems.[1] A self-assembling strategy *via* reversible non-covalent bonding has received much attention and several attempts have been made recently to prepare supramolecular porphyrin arrays.[2–4] Hydrogen bonding is a very useful means of constructing molecular assemblies because it can fix molecules in a particular geometry by virtue of its directionality. Indeed, there are some reports in which assemblies of hydrogen bonded porphyrins have been constructed in both solution[3] and the solid state.[4] The elegance of these systems involves utilizing simple building blocks to establish a well-defined architecture. It is important to prepare novel and simple building blocks for hydrogen bonding which may realize more versatile porphyrin assemblies. In this context, five-membered diazole rings, particularly pyrazole, have been focused on because they have both hydrogen donor and acceptor sites in adjacent positions which can build up a self-complementary hydrogen-bonded assembly. It is well-known that 3,5-disubstituted pyrazoles form a dimer, a cyclic trimer and a cyclic tetramer in the solid state and/or in solution,[5] which motivated us to examine the self-association of pyrazolylporphyrins.

Here we report novel self-assembled dimers and tetramers of porphyrins having 1*H*-pyrazol-4-yl and 3,5-dimethyl-1*H*-pyrazol-4-yl groups, respectively, at the *meso*-position. Porphyrin **2** and **4** were prepared by the conventional Adler–Longo



condensation[6] *via* their pyrazole-NH protected precursors **1** (13%) and **3** (8%) followed by removal of the *tert*-butyl groups in refluxing formic acid to afford the desired porphyrins in moderate yields (81% for **2** and 85% for **4**).

The IR spectra of **2** and **4** recorded in $CDCl_3$ showed strong concentration dependencies. The sharp ν(NH) at 3463 cm^{-1} assignable to pyrazole NH stretching 'free' from hydrogen bonding was weakened upon increasing the concentration, while the broad pyrazole-NH···(N) hydrogen-bonded vibration began to be observed around 3200 cm^{-1} above *ca*. 10^{-2} M. These spectral changes indicate that the formation of hydrogen bonds between pyrazole rings at higher concentrations[7] leads to the porphyrin assemblies. The ESI mass spectra using $CHCl_3$ as eluent showed a peak at *m/z* 1294.1 for **2** and *m/z* 2699.5 for **4**. These two peaks correspond to a dimer of **2** (MW = 1293.6 g mol^{-1}) and a tetramer of **4** (MW = 2699.4 g mol^{-1}), respectively. The peaks of the porphyrin oligomers almost disappeared upon addition of a protic solvent such as MeOH to the eluent, which strongly supports the suggestion that the porphyrin self-assembly is formed by intermolecular hydrogen bonding. In order to confirm the self-assembly of pyrazolylporphyrins, ^{1}H NMR dilution experiments were carried out in $CDCl_3$. In **2** and **4**, appreciable concentration dependencies were observed for the chemical shifts of the pyrazole ring protons, though the pyrazole NH peaks were too broad to be detected under the present experimental conditions.† The proton signal showing the largest concentration dependency was that nearest to the pyrazole NH group, *i.e*. the pyrazole-H3 or -H5 proton of **2** and the pyrazole 3,5-methyl protons of **4**. The magnitude of the dilution shift ($\Delta\delta$) of these protons was 0.033 ppm (downfield shift) for **2** and 0.059 ppm (upfield shift) for **4** upon dilution from 10$^{-3.7}$ to 10$^{-1.5}$ M. These dilution shifts are relatively small but apparently larger than $\Delta\delta$ in the presence of MeOH ($\Delta\delta_{max}$ = 7 × 10^{-3} ppm in $CDCl_3$–CD_3OD = 7:3) and $\Delta\delta$ observed for the corresponding NH-protected **1** and **3** ($\Delta\delta_{max}$ = 6 × 10^{-3} ppm) in $CDCl_3$. The above comparison of ^{1}H NMR spectra has revealed that the concentration depend-

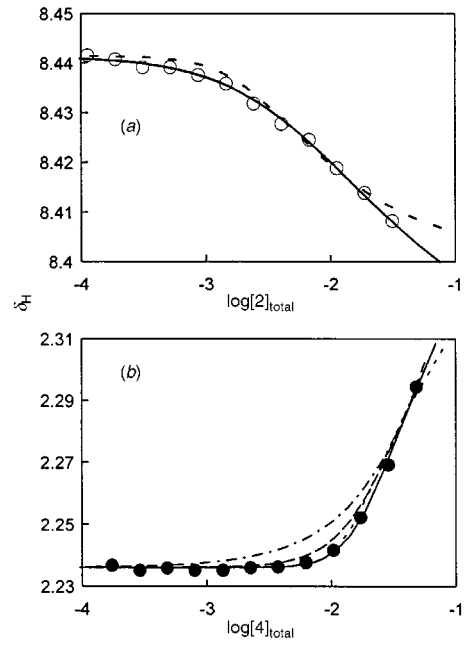


Fig. 1 Curve fitting analysis of ^{1}H NMR dilution shifts in pyrazolylporphyrins: (*a*) (○) pyrazole 3,5-H of **2**, (——) dimer model, (– – –) trimer model; (*b*) (●) pyrazole 3,5-methyl of **4**, (–·–·–·–) dimer model (– – –) trimer model, (——) tetramer model, (·····) pentamer model.

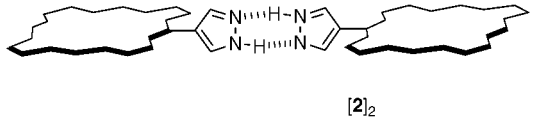
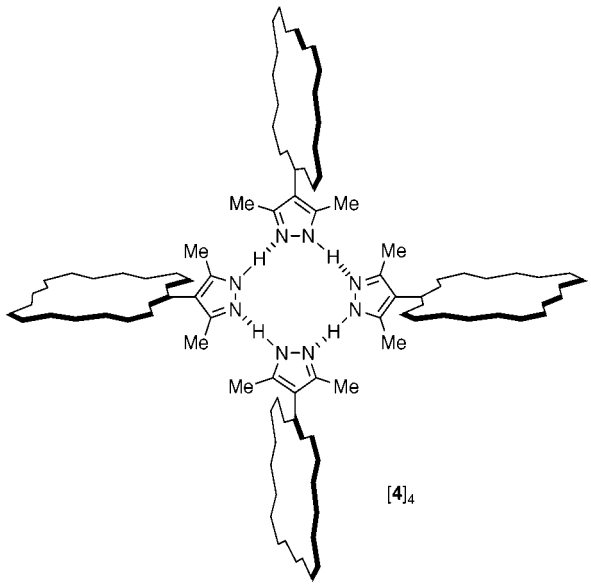
encies observed in **2** and **4** are due to the formation of hydrogen bonds between pyrazole units rather than any other type of aggregation.‡ In order to estimate the possible structure of the association, the dilution curves (at 295 K in $CDCl_3$) were fitted to the models for an equivalent *n*-merization process using nonlinear least-square fitting.[8] The dilution curve for **2** fits well the optimized dimer model throughout the concentration range, but the best-fit trimer model deviates substantially from the experimental data (Fig. 1). On the other hand, the experimental data for **4** fit the tetramer model while they do not obey the dimer, trimer or pentamer model (Fig. 1). The combined ESI MS, IR and NMR results demonstrate that **2** forms a dimer $[\mathbf{2}]_2$



$[\mathbf{2}]_2$



$[\mathbf{4}]_4$

and **4** a cyclic tetramer $[\mathbf{4}]_4$ in $CHCl_3$. There is a report that the hydrogen bonded pyrazole dimer is less stable than the trimer or tetramer.[9] However, porphyrin **2**, in which the rotational barrier of the pyrazole ring is very low,§ seems to prefer the dimer structure (based on molecular modeling), as the aryl groups at the 10 and 20 positions might cause steric hindrance in the case of a co-planer geometry of the pyrazole ring with the porphyrin plane in the trimer or tetramer model. The dimerization constant, $K_2 = 39\ M^{-1}$, obtained from the curve fitting of **2**, is roughly comparable to that in the 2-pyridone system.[10] The tetramerization constant of **4** (K_4) is estimated to be $9.3 \times 10^3\ M^{-3}$ from the curve fitting, which is much larger than that of the hydroxy analogue (*e.g.* phenol).[11] The unique associated structure of the cyclic square is expected to be an interesting building block for porphyrin architecture. Studies in the solid state as well as in solution of pyrazolyl-porphyrins with more than two pyrazole rings, and their metal complexes are currently underway.

We are grateful to Professor Taira Imamura and Mr Kenji Watabe at Hokkaido University and Mr Yutaka Takahashi, JEOL Co., for their help with the ESI mass spectrometry.

Notes and references

† This is probably due to the electronic quadrupole moment of the nitrogen atom and/or the equilibrium of hydrogen bonding. In the case of pyrazole itself the NH proton can be observed only above *ca.* 10^{-1} M in $CDCl_3$.
‡ The possibility of π–π stacking was excluded because no broadening of the ^1H NMR signals was observed.
§ The rotational barrier of the pyrazole ring in **2** is much lower than that of the *p*-tolyl group: the calculated values are *ca*. 130 and 420 kcal mol^{-1} for the 3,5-unsubstituted pyrazole and the *p*-tolyl groups, respectively (MMX force field).

Intermolecular reactions of indol-2-yl radicals: a new route to 2-substituted indoles

Andrea Fiumana and Keith Jones*

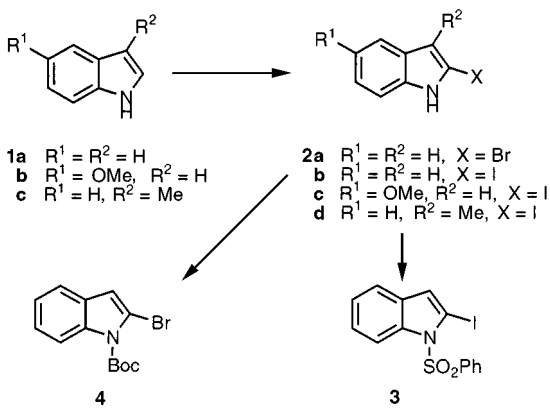
School of Applied Chemistry, Kingston University, Penrhyn Road, Kingston-upon-Thames, Surrey, UK KT1 2EE. E-mail: keith.jones@kingston.ac.uk

Received (in Liverpool, UK) 22nd June 1999, Accepted 22nd July 1999

The generation of indol-2-yl radicals and their addition to a variety of radical acceptors to prepare 2-substituted indoles is presented.

The intermolecular reaction of alkyl radicals has been extensively studied and forms a useful method for the creation of new carbon–carbon bonds under mild conditions[1] and with the potential for stereocontrol.[2] Exploration of the more reactive aryl radicals has been centred almost exclusively on their intramolecular reactions and this has provided a powerful approach to a variety of polycyclic compounds.[3] Radicals derived from heteroaromatic systems have been much less extensively explored despite the fact that heteroaromatic rings form the basis of many natural products and synthetically-derived bioactive molecules.[4] However, the literature contains only vague reference to the intermolecular reactions of aryl radicals.[5] We now disclose the results of our studies on the intermolecular reactions of radicals derived from 2-haloindoles as a method for the regiospecific formation of carbon–carbon bonds to the 2-position of indoles.

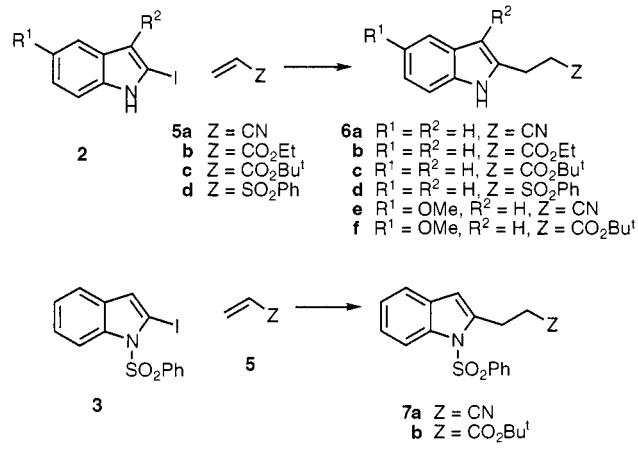
The generation of 2-lithioindoles using either an activating group attached to the indole nitrogen or the *in situ* activation of Bergman[6] and Katritzky[7] provides a method for reaction at C-2 but under extremely basic conditions. Alternatively, 2-haloindoles can be coupled with a variety of unsaturated carbon centres using palladium chemistry.[8] We have previously reported on the cyclisation reactions of radicals derived from 2-bromoindoles[9] and we wished to explore the possibility of trapping these radicals in an intermolecular sense. A range of 2-haloindole substrates were synthesised as shown in Scheme 1. Thus treatment of indole under Bergman conditions with either a brominating agent or iodinating agent gave 2-bromo- and 2-iodo-indole in 96 and 84% yields, respectively. Under similar conditions, 5-methoxyindole gave the 2-iodo derivative in 38% yield, whilst 3-methylindole gave 2-iodo-3-methylindole in 41% yield. Finally, 2-iodoindole was reacted with phenylsulfonyl chloride and base to give the *N*-phenylsulfonylindole in 95% yield, and 2-bromoindole was reacted with di-*tert*-butyl dicarbonate to give the *N*-Boc derivative in 98% yield.



Scheme 1

Initially, a range of these substrates were reacted under various conditions to explore the generation and intermolecular trapping of the indol-2-yl radical. Acrylonitrile, which is an excellent acceptor for nucelophilic alkyl radicals, was used as the trapping reagent. Reaction of either bromo- or iodo-indoles using tributyltin hydride (TBTH) at low concentration or delivered by syringe pump consistently gave reduced indole as product. The use of hexabutylditin instead of TBTH led to little or no reaction. Using a different strategy, the reaction of the 2-haloindoles with allyltributylstannane[10] was explored, but no 2-allylindoles could be detected. At this stage, the catalytic TBTH conditions developed by Stork and Sher were investigated.[11] The reaction of 2-iodoindole with tributyltin chloride and $NaCNBH_3$ in Bu^tOH using AIBN as initiator and acrylonitrile as the radical trap gave 2-(2-cyanoethyl)indole in 30% yield. Having found suitable conditions, a range of 2-haloindoles and electron-deficient alkenes were reacted together and the results are presented in Scheme 2 and Table 1.†

With the exception of 2-iodo-3-methylindole, which gave only traces of the desired adducts by GC-MS, all 2-iodoindole substrates reacted under these conditions. Acrylonitrile proved in each case to be the best radical acceptor, with an acceptable yield of 37% for the reaction with *N*-phenylsulfonyl-2-iodoindole. Modest yields were obtained for the reactions with *N*-unsubstituted indoles, illustrating this important feature of radical reactions. Acrylate esters also proved to be reasonable radical acceptors, giving the appropriate 3-indole-substituted propionates in poor to modest yields. In the simplest case of 2-iodoindole, phenyl vinyl sulfone gave the desired adduct in 25% yield, although with other iodoindoles only reduction of the indole was observed. The effect of indole substituents is interesting. The *N*-phenylsulfonyl and the 5-methoxy group seem to have little effect on the reactions with acrylonitrile and acrylate esters, but the reaction with phenyl vinyl sulfone only works in the case of an unsubstituted indole. However, the 3-methyl group on the indole seems to shut down the intermolecular radical pathway almost completely. This is



Scheme 2

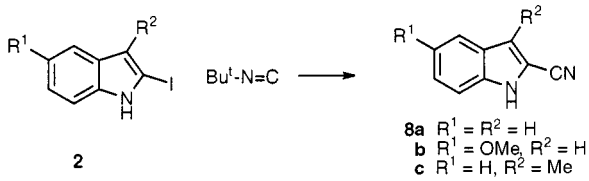
2d	**5b**		trace[b]
2d	**5c**		trace[b]

[a] No addition product could be detected by GC-MS, only the de-iodinated product was isolated. [b] No addition product could be isolated, but it was detected in very low yield by GC-MS.

presumably caused by the increase in steric hinderance close to the radical centre and must reflect the sensitive nature of these reactions to the reaction conditions and the exact radical precursor and acceptor. The balance between intermolecular addition to the alkene, intermolecular reaction with TBTH (leading to reduction) and the radical chain breaking down (leading to starting material) is clearly delicate. The critical nature of the halogen abstracted to form the indolyl radical is demonstrated by the lack of any addition product using 2-bromoindoles as radical precursors.

Having achieved some success in the reaction of indol-2-yl radicals with electron-deficient alkenes, attention was turned to the reaction with *tert*-butyl isocyanide.[12] 2-Cyanoindoles have been shown to be useful in directing radical addition to indoles[13] but their synthesis generally requires multi-step sequences or an indole ring synthesis. Using the catalytic TBTH method and *tert*-butyl isocyanide the results shown in Scheme 3 and Table 2 were obtained. 2-Iodoindole and 2-iodo-5-methoxyindole gave 37 and 40% yields of cyanoindoles, respectively, whilst 2-iodo-3-methylindole again proved to be a significantly poorer substrate. Interestingly, *N*-phenylsulfonyl-2-iodoindole gave rise to mainly reduced product along with a small amount of the de-sulfonylated 2-cyanoindole. Investigation of the reaction



Scheme 3

Table 2 Reaction of 2-iodoindoles with *tert*-butyl isocyanide

Indole	Product	Yield (%)
2b	**8a**	38
2c	**8b**	40

3	*N*-Phenylsulfonylindole	90
	2-Cyanoindole	trace

mixture by GC-MS revealed the presence of *tert*-butyl phenyl sulfone, suggesting that the *tert*-butyl radical generated is able to cleave the N–S bond. This suggests a possible radical method for desulfonylation of *N*-sulfonyl indoles but a trial reaction using *tert*-butyl bromide as the source of *tert*-butyl radicals indicated that it is necessary to generate the *tert*-butyl radicals in the vicinity of the *N*-sulfonyl group to achieve the bond cleavage, providing some evidence for a cyclic mechanism (Fig. 1).

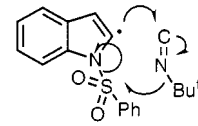

Fig. 1

In summary, we have demonstrated that, under appropriate conditions, indol-2-yl radicals can be generated from 2-iodoindoles, and they undergo addition to electron-deficient alkenes and addition of the cyano group from *tert*-butyl isocyanide in moderate yields. The fact that *N*-protection is not required for these reactions is a useful feature.

We should like to acknowledge financial support from Kingston University, and Dr John Storey for helpful discussions.

Notes and references

† *Typical procedure* for the radical additions: A mixture of 2-iodoindole (0.50 g, 2.06 mmol), Bu_3SnCl (56 μl, 0.206 mmol), $NaCN{\cdot}BH_3$ (0.259 g, 4.12 mmol), ethyl acrylate (4.46 ml, 20.6 mmol) and AIBN (0.033 g, 0.2 mmol) in degassed Bu^{t}OH (40 ml) was prepared and immediately refluxed for 5 h under nitrogen. After cooling, the Bu^{t}OH was removed under reduced pressure. The residue was dissolved in Et_2O (20 ml) and washed with 20% aq. NH_3 (3 × 20 ml), brine (3 × 20 ml), dried over $MgSO_4$ and concentrated *in vacuo*. The residue was chromatographed (3:1 CH_2Cl_2–hexane; R_f 0.45) to give a solid which was recrystallized from hexane–Et_2O to give 3-(1*H*-indol-2-yl)propionic acid ethyl ester **6b** (0.125 g, 28%) as white needles, mp 83–85 °C (lit.,[14] 84–85 °C).

Highly efficient palladium catalyst system for addition of trihydrosilanes to acetylenes and its application to thermally stable polycarbosilane synthesis

Hiroshi Yamashita* and Yuko Uchimaru

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305-8565, Japan.
E-mail: yamashita@home.nimc.go.jp

Received (in Cambridge, UK) 25th June 1999, Accepted 29th July 1999

Regio- and stereo-selective mono-, di- and tri-alkenylation of trihydrosilanes with monoynes proceeded smoothly with a Pd–PCy_3 catalyst, while the reaction of phenylsilane with 1,4-diethynylbenzene provided a thermally stable and blue light emissive polycarbosilane.

Transition metal-catalysed hydrosilylation is a versatile reaction affording useful organosilicon derivatives.[1] Addition of trihydrosilanes to acetylenes is expected to give C=C and/or Si–H bond-containing alkenylsilanes utilisable as new synthetic reagents, monomers for silicon polymers *etc.*[2] However, in our hands conventional Pt catalysts such as Speier's (H_2PtCl_6) and Karstedt's ($Pt_2(dvs)_3$, dvs = $[(H_2C{=}CH)Me_2Si]_2O$) systems have proved to be inefficient (*vide infra*).[3,4] Through a survey of group 10 metal complexes we have found that a Pd–PCy_3 system is highly active for the reaction. In addition, the catalysis affords the first successful example of polymerisation of a trihydrosilane with diynes providing polycarbosilanes with unique thermal and optical properties.[5]

Thus, when a mixture of phenylsilane (**1a**, 0.20 mmol) and oct-1-yne (**2a**, 1 equiv.) in benzene-d_6 (0.05 ml) was treated with a benzene-d_6 (0.10 ml) solution of $Pd_2(dba)_3$ (1 mol% Pd) and PCy_3 (P/Pd = 2) at room temperature for 15 min, (*E*)-2- and 1-hexylvinylsilane [**3a**(β) and **3a**(α), respectively] were formed with high linear selectivity (β : α = 94 : 6) and in good combined yields (80%) (≥98% conversion of **2a**; Scheme 1, Table 1, run 1).† The formation of the *Z* isomer of **3a**(β) and diphenylsilane (a redistribution byproduct from **1a**) was negligible according to NMR analysis. A small amount of dialkenylsilane **4a** (9%) was also formed with recovery of **1a** (8%). In contrast, previously reported $RhCl(PPh_3)_3$[3] was not effective under the present conditions [yield of **3a** = 29% (β : α = 73 : 27)]. Conventional H_2PtCl_6 and $Pt_2(dvs)_3$ catalysts also resulted in much lower yields [3% (β : α = 5 : 1) and 14% (81 : 19), respectively]. In the cases of $RhCl(PPh_3)_3$[3] and $Pt_2(dvs)_3$, unfavorable diphenylsilane formation (10 and 20%, respectively) was also observed. The Pd–PCy_3 system was very active, and only 0.01 mol% Pd effectively converted ≥98% of **2a** after heating at 60 °C for 3 h (run 2). Di- and tri-alkenylation took place cleanly by controlling the charged amount of **2a**; using 2 or 3 equiv. of **2a** respectively provided **4a** or **5a**, each in > 90% yield (runs 3 and 4). These reactions proceeded regioselectively, yielding **4a**(β_2) and **5a**(β_3) with linear alkenyl moieties as the major products.

Besides **2a**, phenylacetylene (**2b**, 1 equiv.) also readily reacted with **1a** to give the corresponding mono- and di-alkenylsilane (**3b**, 75%; **4b**, 13%) with predominant formation of the linear regioisomers (run 5). Aromatic acetylene **2b** was much more reactive than **2a**, and even 0.01 mol% Pd catalyst completed the reaction after 3 h at room temperature (run 6). Dialkenylsilane **4b** was obtained in a high yield (83%) by using 2 equiv. of **2b** (run 7). Likewise, hexylsilane (**1b**) underwent smooth mono- and di-alkenylation with **2b** (runs 8 and 9).

Instead of $Pd_2(dba)_3$–PCy_3, $PdCl_2(PCy_3)_2$ could be used as well, although the reaction was slower; the yields of **3b** and **4b** in the reaction of **1a** and **2b** were respectively 20 and ≤2 (room temp., 15 min) and 75 and 12% (40 °C, 2 h). Other Pd–trialkylphosphine catalysts were also active, albeit in lower efficiency; the yields of **3b** and **4b** (40 °C, 2 h) were 63 and 5

Scheme 2

$[PdCl_2(PBu^i{}_3)_2]$, 47 and 5 $[PdCl_2(PEt_3)_2]$ and 34 and 5% $[PdCl_2(PBu_3)_2]$. Accordingly, the Pd^0–PCy_3 system is the best catalyst among the Pd complexes examined.

Since acetylenes **2** (2 equiv.) react with **1a** cleanly, C=C–SiH–C=C linkage-containing polycarbosilanes can be readily prepared. Thus, treatment of a mixture of **1a** (0.20 mmol) and nona-1,8-diyne (**6a**, 1 equiv.) with the Pd–PCy_3 catalyst (0.1 mol% Pd) in benzene-d_6 (0.15 ml) at 40 °C for 4 h gave a new polymer (**7a**) with one Si–H bond being intact nearly quantitatively (by ^{1}H NMR, Scheme 2).‡ The molecular weight M_w (M_w/M_n) was estimated by GPC (polystyrene standards) to be 29 000 (3.1). The vinylic moieties in the C=C–SiH–C=C linkages were assigned by ^{1}H NMR to be VL × 2 (VL = vinylene) and VL + VD (VD = vinylidene) in the ratio of 88 : 12. Similarly, the use of 1,4-diethynylbenzene (**6b**) (0.1 mol% Pd cat., 40 °C, 1 h) yielded **7b** with phenylene rings (≥95% NMR yield; M_w = 49 000, M_w/M_n = 4.8; VL × 2 : VL + VD : VD × 2 = 63 : 33 : 4 for the vinylic moieties).

Polymers **7** have reactive C=C and Si–H bonds, and cross-linking between them easily proceeds to form thermally stable polymeric materials. Thus, heating a cast film of **7b** on a glass plate at 100 °C for 2 h under vacuum formed a hard film that was nearly insoluble in toluene, $CHCl_3$ and THF. The mp was > 300 °C and thermogravimetric analysis revealed considerably high T_{d_1} and T_{d_5} values (1 and 5% weight loss temperatures, 444 and 504 °C, respectively, under N_2) and a good char yield (78% at 980 °C). This suggests that **7b** is utilisable for manufacturing heat-resistant materials and/or SiC ceramics. In addition, **7b** has interesting light-emitting properties; a film of **7b** exhibited intense blue emission on irradiation with a UV lamp, and a THF solution of **7b** [λ_{max} in UV: 308 nm (ε = 2.2 × 10^4)] showed photoluminescence with λ_{max} = 445 and 466 nm (excitation at 393 nm).[6]

To summarize, the Pd–PCy_3 catalyst is demonstrated to be highly efficient for hydrosilylation of acetylenes with trihydrosilanes and applicable to the synthesis of polycarbosilanes, which are promising as new functional materials. Extension of the substrates and application of the resulting polycarbosilanes are under way.

Received (in Cambridge, UK) 19th April 1999, Accepted 29th July 1999

Porphyrin H_2TMpyP binding peptides were selected from a phage displayed pentapeptide library that was immobilized onto a solid phase and, as a result, a binding motif that binds to the porphyrin in the same way as a motif obtained by our previous combinatorial chemistry was revealed.

Two methods, combinatorial chemistry and phage display, are used to obtain novel interactions between polypeptides or proteins and desired target molecules. Combinatorial chemistry can select functional molecules from complete libraries of molecules of five or fewer amino acids.[1] On the other hand, phage display can deal with huge libraries and use cDNA libraries for a selection, so that this method is suitable for high molecular weight molecules such as proteins, although some deviation of the libraries occurs because of codon usage by the host cells.[2,3] From such properties, combinatorial chemistry has been used to obtain small functional peptides,[4] while phage display has been applied to epitope mapping of proteins or antibody selection *in vitro*.[5,6]

However, binding motifs obtained *via* the two methods do not always correspond with each other.[7] For example, Maruyama *et al.* specified two epitopes of human galectin-3 *via* a λ phage display system, but the epitopes were not similar to the motifs selected by combinatorial chemistry.[8] The discrepancy may be due to the difference of the selection procedures, *i.e.* an immobilized library and a free target are used for combinatorial chemistry, while a free library and an immobilized target have been used for phage display so far.[9] Here we have carried out a peptide selection against a porphyrin [5,10,15,20-tetrakis(*N*-methylpyridinium-4-yl)-21*H*,23*H*-porphine; H_2TMpyP] which was a small target molecule of our combinatorial chemistry study reported previously,[4] using a new phage display selection method with an immobilized library and the free target porphyrin as for the combinatorial chemistry selection.

A random pentapeptide library displayed on a phage was constructed[10] and used for peptide selection with H_2TMpyP. The library can contain up to 20^5 ($= 3.2 \times 10^6$) individual peptides with different sequences. The phage library was immobilized on nitrocellulose filters as follows, instead of immobilization of the target (the commonly used method for a selection using a phage display system).[9] The recombinant phages were incubated with an *Escherichia coli* TG1 (*supE*) fresh culture and spread on 2×YT agar plates.[11] The spread phages on the plates were transferred onto nitrocellulose filters. The filters were blocked with 1% bovine serum albumin in PBT buffer[12] for 2 min and washed with PBT buffer for 2 min. Then the filters were incubated with 10 μM H_2TMpyP in 2×SSC buffer[12] for 12 h and washed with 2×SSC for 4 min. Porphyrin binding phages on the filters were detected *via* emission of the porphyrin at 656 nm. As a result, four plaques with very strong signals, corresponding to the four phages shown in Fig. 1, were specified by the assay with H_2TMpyP from over 1×10^7 plaques. The four plaques were amplified and their phagemids were sequenced by the dideoxy method. The translated amino acid sequences of the introduced random region at the N-terminus of the pIII coat protein of the four phages were His-Ala-Ser-Tyr-Ser (HASYS), Arg-Ala-Ser-Ser-Leu (RASSL), Arg-Leu-Tyr-Val-Arg (RLYVR) and Leu-Pro-Tyr-Ala-Thr (LPYAT). Every phage displayed a peptide with aromatic amino acids or Arg on the pIII protein. Equal amounts of phage particles of the four positive phages were blotted on a nitrocellulose filter and incubated with H_2TMpyP. The HASYS phage that displayed aromatic His and Tyr was the tightest binder of all, as shown in Fig. 1, with a K_a of about 10^5 M^{-1}.

We obtained previously a porphyrin binding peptide Tyr-Ala-Gly-Tyr (YAGY) that interacted with H_2TMpyP by a sandwiching interaction from a combinatorial library.[4] Molecular modeling was carried out to anticipate the interaction between the HASYS phage and H_2TMpyP. A crystal structural study of the N-terminus domain of the pIII protein[13] suggested that the structure of an expressed peptide in a fusion protein was not influenced by the pIII coat protein and was flexible. Thus we carried out the molecular modeling of an N-terminus tridecapeptide of the pIII protein Ala-Ala-Gln-Leu-Ala-His-Ala-Ser-Tyr-Ser-Ala-Ala-Ala containing the HASYS sequence. 120 conformations of the tridecapeptide–H_2TMpyP complex were generated after a simulated annealing from 0 to 1000 K. Although the two molecules were dissociated during the annealing in about half of the conformations, H_2TMpyP was stacked in the space between the side chains of His and Tyr in all the remaining conformations. The energies of these complexes were minimized and over two thirds of the minimized structures corresponded to the structure shown in Fig. 2. As a result, a cognate sandwiching[14,15] interaction, as in the case of YAGY, was suggested to be a suitable way for the HASYS peptide to interact with H_2TMpyP. Many natural proteins use a His residue to interact with a porphyrin,[16,17] however, the imidazole ring of the His stands perpendicular to the porphyrin ring. In this case, the vertical conformation was suggested to be unstable by molecular modeling, probably because the porphyrin H_2TMpyP used as the target molecule did

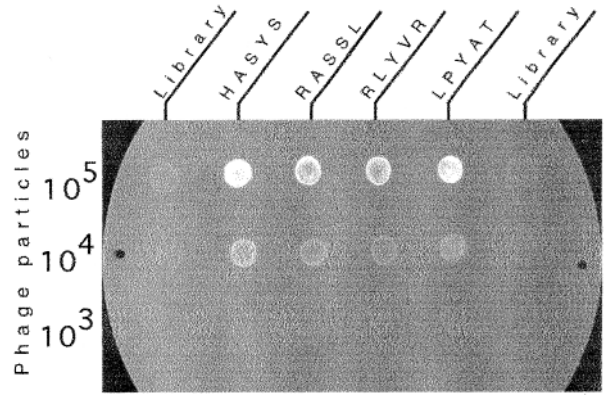

Fig. 1 Binding of the positive phages to H_2TMpyP visualized by fluorescence of the H_2TMpyP. After the selection, equal amounts of phage particles of the four positive phages (HASYS, RASSL, RLYVR, LPYAT) were blotted on a nitrocellulose filter and incubated with H_2TMpyP. Library is the phage before the selection.

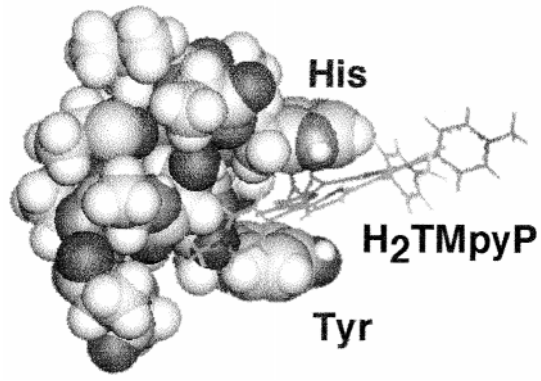

Fig. 2 Proposed structure of the HASYS–H_2TMpyP complex drawn with a molecular modeling calculation using QUANTA97/CHARMm23.2. The energy of the complex was minimized by the adopted basis set Newton–Raphson method. All calculations were performed on a Silicon Graphics Indigo2 workstation running IRIX 5.3.

not have a metal in its center. Consequently, the HASYS peptide should interact with H_2TMpyP by means of a sandwiching interaction in the same manner as the H_2TMpyP–YAGY interaction, as shown in Fig. 2. The YAGY peptide was selected from a biased combinatorial library in which two aromatic amino acids were inserted into positions *i* and *i*+3 or *i*+4.[4] The fact that the same sandwiching interaction was revealed from a completely random library suggests that the stacking between aromatic amino acids and a porphyrin is the most profitable manner for a short peptide to interact with a porphyrin.

In a few cases of selection, only with a protein as the target molecule, common motifs were revealed from the two methods, combinatorial chemistry and phage display. Bianchi *et al.* obtained a very similar consensus from a phage library and a combinatorial library for a binding motif to monoclonal immunoglobulin,[18] and many streptavidin binding phages selected from a phage library with 36 random amino acids[19] contained a similar sequence to one of the consensus sequences picked from a combinatorial pentapeptide library.[1] In both the cases, the target molecule was very large and the obtained interaction was very strong. When a small target is used, as in the present study, such a strong binding with enough energy for anchoring a phage to the target molecule cannot be expected because the available interactions are restricted. So, a high background may hinder simple and efficient selection by the normal phage display system with an immobilized small target.[8] Consequently our system, which binds free H_2TMpyP (MW 1364) to a solid support *via* the interaction between a porphyrin and a phage, is superior to a system that binds a free phage with a 10^4 times greater mass than the porphyrin by the same interaction.

In summary, we have succeeded in obtaining the same peptide motif that binds to a small target H_2TMpyP from both combinatorial chemistry and phage display with an immobilized phage library. Our results suggest that the immobilized phage display system is a promising method for identifying functional short peptides that interact with a small target.

meso-Tetraarylporphyrins as dipolarophiles in 1,3-dipolar cycloaddition reactions

Ana M. G. Silva, Augusto C. Tomé, Maria G. P. M. S. Neves, Artur M. S. Silva and José A. S. Cavaleiro*

Received (in Liverpool, UK) 21st June 1999, Accepted 21st July 1999

***meso*-Tetraarylporphyrins participate, as dipolarophiles, in 1,3-dipolar cycloaddition reactions with azomethine ylides to yield novel chlorins and isobacteriochlorins.**

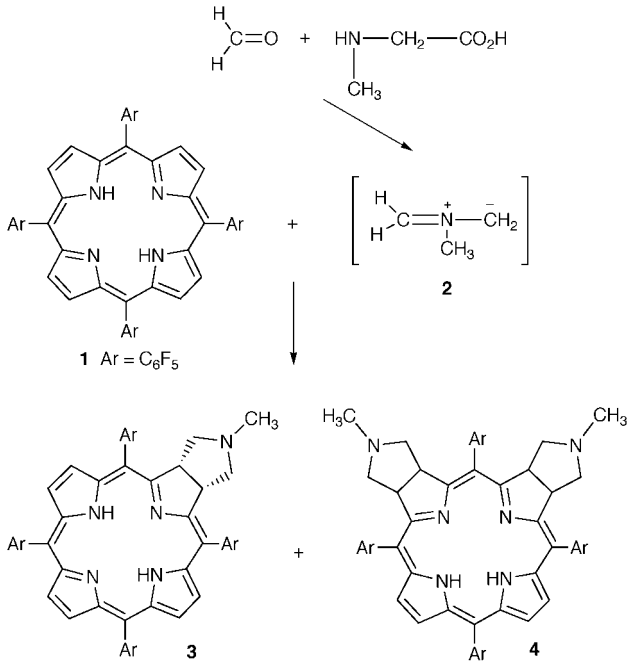
Recently we have shown that peripheral double bond(s) of the porphyrin nucleus can participate in Diels–Alder reactions.[1] The results of that work prompted us to investigate the behaviour of the porphyrins in other pericyclic reactions, namely in 1,3-dipolar cycloadditions with azomethine ylides.

A very simple approach to the generation of azomethine ylides involves the reaction of an aldehyde with an α-amino acid: the *in situ* thermal decarboxylation of the resulting imine gives the corresponding 1,3-dipole. Lately these transient species are being used extensively for the functionalization of fullerene C_{60}.[2]

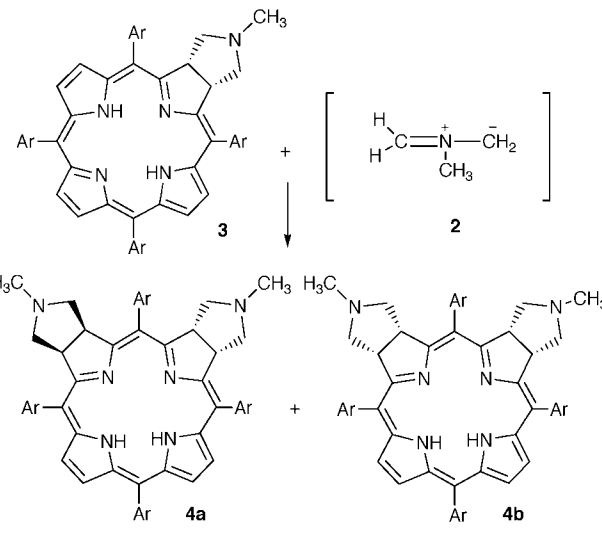
Here we report that azomethine ylides react with *meso*-tetraarylporphyrins to give, in good yields, pyrrolidine-fused chlorins and isobacteriochlorins.

Based on our previous results on the relative reactivities of the arylporphyrins in Diels–Alder reactions, we decided to use *meso*-tetrakis(pentafluorophenyl)porphyrin **1** as a dipolarophile in the reaction with azomethine ylide **2** (Scheme 1). A toluene (5 ml) solution of **1** (22 mg), *N*-methylglycine (4 mg, 2 equiv.) and paraformaldehyde (3.4 mg, 5 equiv.) was heated at reflux for 5 h under a nitrogen atmosphere. TLC of the reaction mixture showed that about half of the starting porphyrin was converted into two new products. Further portions of *N*-methylglycine (4 mg) and paraformaldehyde (3.4 mg) were then added and the resulting mixture was refluxed for another 5 h. The solvent was evaporated and the compounds were separated by column chromatography using a gradient of $CHCl_3$–light petroleum. The first fraction to be collected was the unchanged starting porphyrin (4.4 mg; 20%), then a chlorin (14.2 mg; 61%) and, finally, one isobacteriochlorin (2.8 mg; 11%) were eluted.

For the main product, the ^{1}H, ^{19}F and ^{13}C NMR and mass spectra, and its elemental analysis, are in agreement with structure **3**; also the UV-Vis spectrum of this compound is typical of a chlorin (λ_{max} = 652 nm).† The ^{1}H NMR spectrum of **3** shows, in the aliphatic region, a singlet at δ 2.21, corresponding to the N-CH_3 protons, and two multiplets at δ 2.52–2.56 and 3.11–3.16, corresponding to the methylene protons. Another multiplet at δ 5.24–5.27 was assigned to the resonance of the two β-pyrrolic protons of the reduced ring. In the aromatic region, four of the six β-pyrrolic protons appear as two doublets at δ 8.40 and 8.71 (*J* 4.9 Hz) and a singlet at δ 8.48 for the other two. The ^{19}F NMR spectrum of **3** shows two sets of equivalent pentafluorophenyl rings.‡ The mass spectrum of the minor product shows that it is a bis-adduct [$(M+H)^+$ = 1089]. On the basis of our previous results on the bis-addition of *o*-quinodimethanes to porphyrins we expected that this compound could be a bacteriochlorin. Surprisingly, its UV-Vis spectrum shows that it is an isobacteriochlorin (λ_{max} = 546 and 588 nm). In order to increase the amount of the bis-adduct, the chlorin **3** (21 mg) was treated with *N*-methylglycine and paraformaldehyde in refluxing toluene. After 40 h, and successive additions of small portions of the 1,3-dipole precursors, most of the chlorin was converted into bis-adducts (Scheme 2). Purification of the reaction mixture by preparative TLC gave several fractions. The one with higher R_f was the unchanged chlorin **3** (6.8 mg). The next two fractions (very small amounts) correspond to diasterioisomeric bacteriochlorins, on the basis of their mass [$(M+H)^+$ = 1089] and UV-Vis spectra (λ_{max} = 732 nm). The following fraction was the main product (8.3 mg); it is identical with the isobacteriochlorin previously obtained. The next fraction was also an isobacterio-



Scheme 1



Scheme 2

chlorin, but in a much smaller amount (1.2 mg) than the previous one. The last fraction (the one with lower R_f) was also obtained in small amount and was shown by MS (parent ion at *m/z* 1146) to be a 'tris-adduct'.

The formation of two isomeric isobacteriochlorins and two bacteriochlorins is not surprising since in the bis-adducts the two pyrrolidine rings can be in a '*cis*' or '*trans*' configuration. It is evident from the results of this experiment that the formation of the bis-adducts is regio- and stereo-selective, yielding mainly one of the four possible isomers. By analysis of the ^{1}H, ^{19}F, ^{13}C and 2D COSY and HETCOR NMR spectra of the two isobacteriochlorins we were able to establish their structures and configurations: the main product has structure **4a** and the minor one has structure **4b**. In the ^{1}H NMR spectra of these compounds, in addition to the expected aliphatic and aromatic proton resonances, a broad singlet appears at δ 4.12 for **4a** and at δ 4.08 for **4b**, corresponding to two protons in each case. These signals disappear after shaking with deuterium oxide and thus were assigned to the N*H* proton resonances.§ The ^{19}F NMR spectra of compounds **4a** and **4b** gave us important information for the establishment of the structure of these compounds as isobacteriochlorins. If the products were bacteriochlorins, then, due to the symmetry of the two possible diastereomers, all the pentafluorophenyl rings should be equivalent and only two signals would be expected for each group of *o*- and *m*-fluorine atoms, which is not the case. However, for the two possible diastereomers of isobacteriochlorin **4** three sets of non-equivalent pentafluorophenyl rings were expected, in the proportion 1:2:1, which is the case observed for compounds **4a** and **4b**. This fact is confirmed, in both isomers, by the integral values of the *p*-fluorine atoms (1F:2F:1F) in their ^{19}F NMR spectra. From the spectrum of compound **4b** we can conclude that: (i) the resonances attributed to the two *o*-fluorine atoms of the 5-phenyl ring are very different from each other (δ −133.32 and −137.62, 1F each), and the former have a quite different environment relative to all of the other fluorine atoms in the molecule; (ii) the phenyl rings at positions 10 and 20 are equivalent but again, in each ring, the two *o*-fluorine atoms are not equivalent (δ −136.66 and −139.73, 2F each); and (iii) the two *o*-fluorine atoms in the 15-phenyl ring are also not equivalent but have a similar environment (δ −139.26 and −139.53, 1F each). These results are only compatible with the structure of an isobacteriochlorin having a '*cis*' configuration. The ^{19}F NMR spectrum of compound **4a** shows that its structure must be more symmetrical than **4b**, since only four signals (δ−136.98, −137.16, −139.27 and −139.67) are observed for the *o*-fluorine atoms: one signal for the two *o*-F atoms in the 5-phenyl ring, two signals for the two non-equivalent *o*-F atoms in the equivalent 10- and 20-phenyl rings, and one signal for the two *o*-F atoms in the 15-phenyl ring. This spectrum is only compatible with the structure of an isobacteriochlorin having a '*trans*' configuration.

Table 1 Comparative reactivity and product yields of *meso*-tetraarylporphyrins with azomethine ylides

		Yield (%)	
meso-Aryl group	*t*/h	Monoadduct	Bis-adducts
C_6F_5	10	61	11
2,6-$C_6H_3Cl_2$	35	26	6
Ph	50	12	not observed

In order to find the effect of the substituents in the *meso*-aryl groups, we performed the same type of reaction (porphyrin, *N*-methylglycine and paraformaldehyde in refluxing toluene) with two other porphyrins. The results are presented in Table 1. It is evident from the results that the presence of electron-withdrawing atoms in the aryl groups increase the reactivity of the porphyrin towards azomethine ylides.

Work is in progress in our laboratory to extend these studies to other azomethine ylides and to other families of 1,3-dipoles.

Thanks are due to the University of Aveiro and to FCT, Portugal, for funding the Research Unit 62/94, the Praxis/2/2.1/QUI/145 Project and a Ph.D. grant (A. M. G. Silva).

Notes and references

†*Selected data* for **3**: $\lambda_{max}(CHCl_3)$/nm [log (ε/10^3 dm^3 mol^{-1} cm^{-1})] 405 (5.29), 505 (4.26), 598 (3.77), 652 (4.72); *m/z* (LSIMS) 1032 $(M + H)^+$ (calc. for $C_{47}N_{17}N_5F_{20}$: C, 54.72; N, 6.79; H, 1.66; found: C, 54.69; N, 6.49; H, 2.10%).

‡ It is important to note that, for each pentafluorophenyl group, the two *o*-F and the two *m*-F are non-equivalent (they are coupled to each other, $^4J \sim 8$ Hz). This may result from the lack of free rotation of the pentafluorophenyl groups.

§ Similar chemical shift values (δ 2.98–3.65 ppm) were reported for N*H* protons of other isobacteriochlorins (ref. 3).

The field of synthesis and physical characterization of oligomeric porphyrin arrays has been the subject of intense research in recent years. Some of these systems present unique physical and optical properties which reflect the extent of electronic interaction between the monomers in the array, and determines their potential applications in chemistry, physics, and biology. General synthetic approaches to a multitude of porphyrin arrays, including directly linked *meso-meso*, *meso*-β, and β-β compounds, oligoporphyrins with fused π-systems, and arrays bearing rigid or flexible spacers, developed by us and by others, are described. X-Ray structures of representative compounds are presented.

Introduction

Procedures for the synthesis and functionalization of monomeric porphyrin molecules have advanced to the stage that almost any porphyrin can be obtained using available methodology.[1] Many research groups have now moved to the development of syntheses of porphyrin analogues and to the construction of multiporphyrin arrays which can either mimic natural systems, or can be used as molecular-level devices for advanced technological tasks. Interest in porphyrin arrays as model systems to mimic the vital functions of photosynthetic reaction centers and antenna systems has increased significantly in recent years. Considerable work has been reported in the field of oligoporphyrins, and we will illustrate the most general approaches by discussing some recent developments to which our own group has contributed.

Porphyrin arrays are potential precursors in building electron- and energy-transfer molecular devices; they are also robust and efficient catalysts for the multielectron redox transformations of small molecules and for the oxidation of organic substrates.[2] For all of the uses mentioned above it is important that the individual molecules within an array communicate with each other, otherwise the whole will be no better than the sum of the components and the array cannot behave with enhanced effectiveness. For effective electronic communication between adjacent porphyrins, the geometry, distance, and orientation between components of rigid porphyrin arrays are usually to be considered, though, in the area of molecular recognition such rigidity is not essential.[3] The nature of the bridges between porphyrin components, the extent of steric interactions (if any), and the connectivity of the porphyrin components directly affect the photophysical properties of covalently linked systems. The present Feature Article reports on recent work carried out in our UC Davis laboratories, and places this within the context of related research from other groups.

In the first part of this Article we concentrate on methodology we have developed to use the so-called McMurry reaction for construction of dimeric porphyrin arrays. These include cofacial bisporphyrins and bischlorins, symmetrical and unsymmetrical systems linked by ethene, stilbene, styryl, and hexatriene linkages, as well as planar fully congugated systems, and directly *meso-meso* linked dimers. After that, we discuss porphyrin oligomers derived from other synthetic approaches, leading to structures containing fused π-systems, orthogonal π-systems and supramolecular arrays.

Bridged and cofacial porphyrin oligomers

It seems clear that, at least for the reaction center in bacterial photosynthesis,[4a] cofacial π–π interacting tetrapyrrole chromophores are essential for charge separation, the first step in photosynthesis. Likewise, such interactions are vital in light-harvesting systems.[4b] A simple model of the special pair in such reaction centers would be two cofacially disposed porphyrins with a *meso-meso* alkene tether possessing a *cis* orientation (*e.g.* **1**). Prior to our work, two approaches had been investigated to provide such face-to-face dimers: (1) compounds linked on one side by a rigid aromatic spacer [the PacMan porphyrins of C. K. Chang (*vide infra*)], and (2) compounds with two or more flexible strapping units. Synthetic routes to these kinds of compounds are usually laborious, requiring multiple steps, and provide only low yields of the targeted compounds. Our methodology for the synthesis of cofacial bisporphyrins is based on the low-valent titanium-induced reductive coupling [$TiCl_3(DME)_{1.5}$/Zn-Cu couple] of *meso*-formyl-metalloporphyrins, which are conveniently prepared by Vilsmeier formylation of metalloporphyrins.[5] In the McMurry reaction a mixture of both the *cis*- and the *trans*-bisporphyrins is generally produced.[6,7] That the *cis* compound (presumably the least stable geometrical isomer) is produced at all is something of a surprise; presumably the strong intramolecular face-to-face π-stacking of the metalloporphyrin pinacol intermediate results in the formation of the kinetic cofacial *cis*-dimers, which can be converted into the stable thermodynamic extended *trans*-dimers by heating (to 120 °C for several hours) or photochemically. *Cis-trans* isomerization of ethene-linked bisporphyrins is also observed in acidic conditions and occurs more readily for the metal-free compounds.[7,8] The nature of the central metal ion is a determinant of the relative amounts of the *cis*- and *trans*-bisporphyrins obtained in this reaction, since it significantly affects the extent of macrocyclic π–π stacking prior to the formation of the ethene bond. In the cofacial arrangement (Fig. 1) the two macrocycles are almost parallel, the distance between the two metal centers is 5.36 Å (for the Ni/Zn heterodimer), and substantial macrocyclic overlap occurs as a result of the π–π interaction between the two macrocycles. The ^{1}H NMR spectra of diamagnetic *cis*-bisporphyrins typically show downfield shifts for the ethylenic protons (between 9.0 and 9.5 ppm), diastereotopic methylene proton signals, and substantial upfield shifts of the *meso* protons adjacent to the ethylene bridge; this supports a similar stacking of the porphyrin units in solution as in the solid state. In contradistinction, the extended *trans*-bisporphyrins (*e.g.* **2**) display a simplified ^{1}H NMR spectrum with the ethylene protons at 7.7 ppm, and the *meso* protons at 9.5 ppm; the X-ray structure of a bis-Ni *trans*-dimer **2** is shown in Fig. 2. In the optical spectrum the Soret band of the *cis*-porphyrins typically appears blue-shifted relative to the Soret of the corresponding extended *trans*-isomers. The *cis*- and *trans*-isomers also display distinct solubility differences; the *cis*-bisporphyrins are generally more soluble in organic solvents than are the *trans*-compounds, which facilitates their chromato-

5

graphic separation. Pure metal-free *trans*-ethene-1,2-bisporphyrins have also been obtained by oxidation of the corresponding ethanebisporphyrins in refluxing acetic acid.[9] The free-base

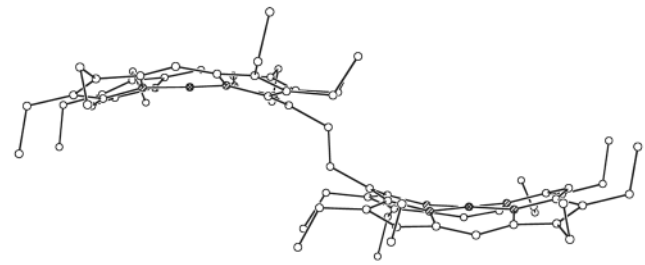

Fig. 2 Molecular structure of bis-Ni^{II} *trans*-ethene dimer **2** (hydrogen atoms not shown).

dimer can be selectively metalated to afford a series of monometallic, and homo- and hetero-bimetallic bisporphyrins.[10] The reductive coupling of *meso*-(2-formylvinyl)metalloporphyrins and metallochlorins analogously produces the corresponding dimers, linked by three conjugated carbon–carbon double bonds.[5]

Under the same reductive coupling conditions, a β-formylmetalloporphyrin produced a hydroxymethylene-bridged dimer **3** by loss of one of the formyl groups,[6] although a β-formylmetallochlorin formed the expected ethene-linked bischlorin. The crystal structure of **3** (Fig. 3) displays a skewed arrangement of the two macrocycles, the two planes of the four nitrogens form an angle of 77.3°, and the distance between the two metal centers is 8.08 Å. The reductive coupling of *meso*-formylmetallochlorins containing bulky propionate ester substituents resulted in the selective formation of the *trans*-bischlorins (such as **4**), which because of steric interactions did not significantly isomerize to the corresponding *cis*-products even upon heating in acetic acid.[11] Aerial oxidation of **4** in refluxing toluene–acetic acid led to the formation of the corresponding *trans*-bisporphyrin, as well as a porphyrin-chlorin hetero-dimer; under the same conditions bischlorin **5** selectively produced the corresponding *cis*-bisporphyrin.

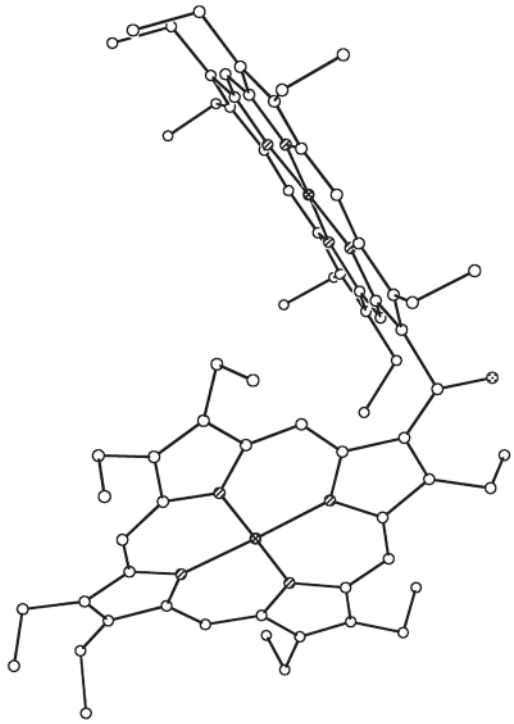

Fig. 3 Molecular structure of bis-Ni^{II} porphyrinyl alcohol **3** (hydrogen atoms not shown).

Syntheses of symmetrical cofacial bisporphyrins containing rigid aromatic bridges, such as 1,2-phenylene, biphenylene and anthracene (the so-called PacMan series), have been accomplished by stepwise condensation of aromatic dialdehydes with a 2-unsubstituted pyrrole, followed by reaction of the α-unsubstituted aromatic-linked bis(dipyrromethane) with a 1,9-diformyldipyrromethane.[12,13] Both symmetrical and unsymmetrical cofacial bisporphyrins are most conveniently prepared by initial monoprotection of the dialdehyde bridge, followed by condensation with pyrrole and an aromatic aldehyde to afford an aldehyde-protected porphyrin. This, upon deprotection and a second cyclization, produces homo- and hetero-bisporphyrins.[14,15] The syntheses of cofacial bisporphyrins bearing two amide bridges,[16] and larger host cavities with four strapping units,[17] have also been reported.

Another successful application of the McMurry methodology involves the synthesis of symmetric stilbene-linked bisporphyrins (*e.g.* **6**). The key intermediate is a stilbene-linked bis(dipyrromethane), produced by reductive dimerization of a 5-(*p*-formylphenyl)dipyrromethane, which upon MacDonald-type condensation with a 1,9-diformyldipyrromethane affords symmetric bisporphyrins such as **6**.[18,19] In yet another approach, these systems were obtained, albeit in lower yield, by reductive coupling of metalloporphyrins bearing a *meso*-(*p*-formylphenyl) substituent.[18,20] The latter methodology yielded both *cis*- and *trans*-stilbene-linked systems.

The synthesis of symmetrical bisporphyrins linked at the *meso* positions by an aryl group usually involves a stepwise

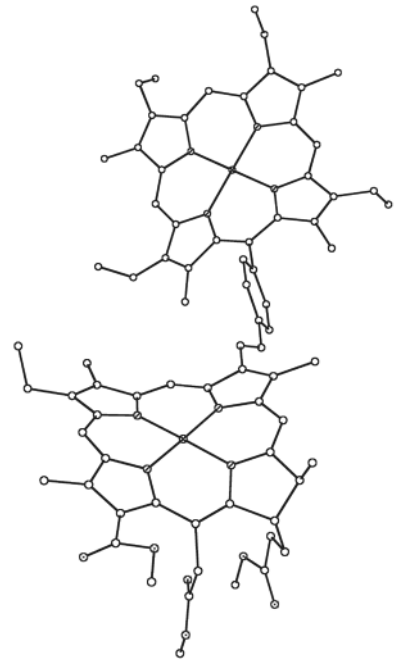

Fig. 4 Molecular structure of Ni^{II} porphyrin–Ni^{II} chlorin heterodimer **7** (hydrogen atoms not shown).

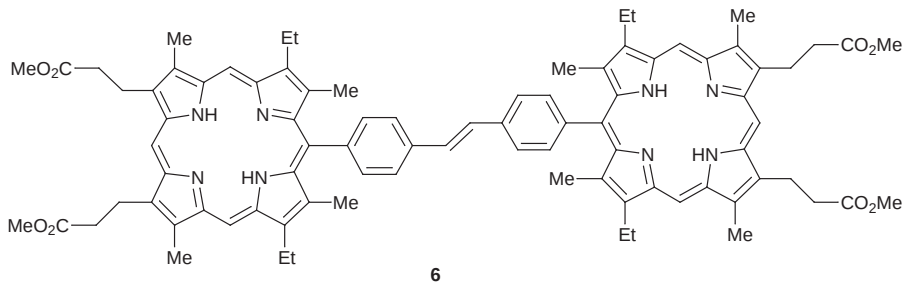
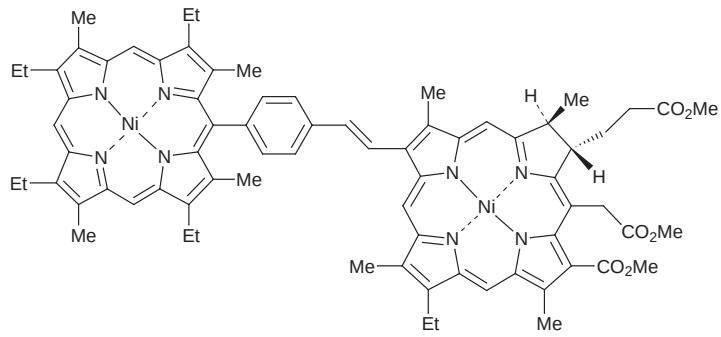


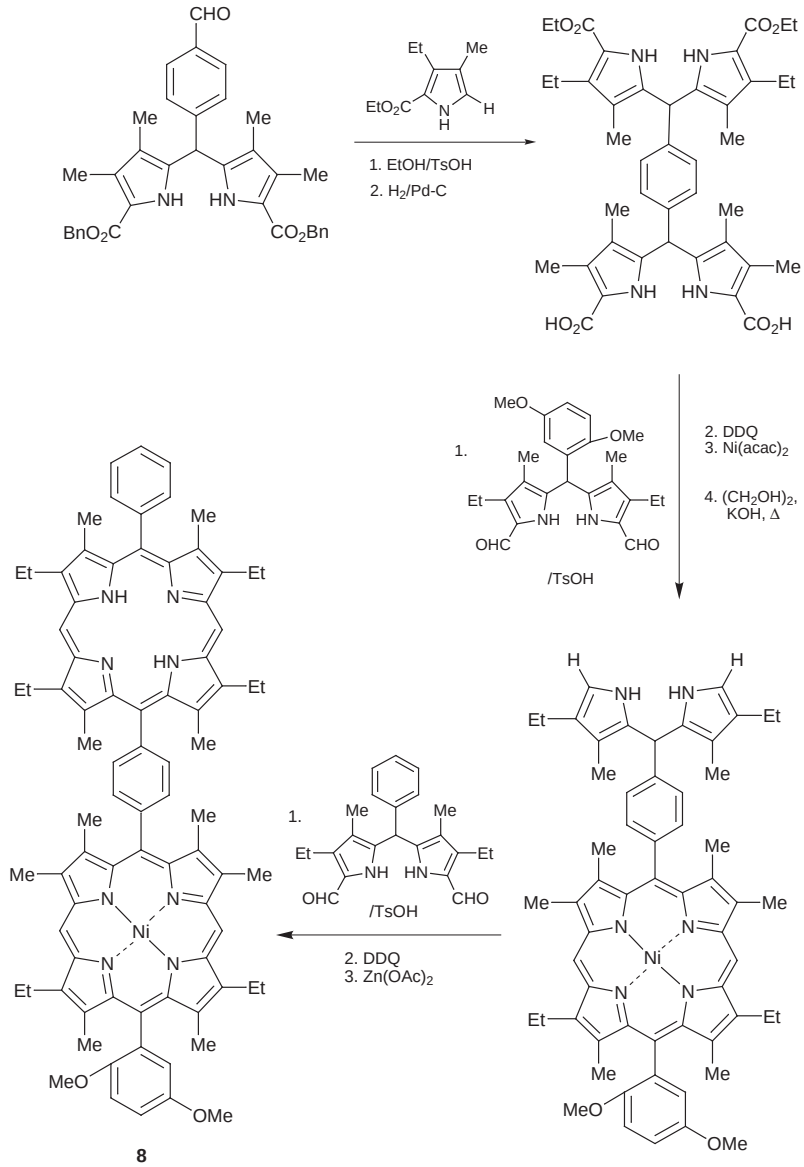
6



7

methodology, from intermediate aryl-linked α-unsubstituted bis(dipyrromethanes), which are in turn obtained from the condensation of formyl-substituted aromatic units with 2-unsubstituted pyrroles.[21,22] The preparation of symmetrical phenyl-linked bisporphyrins has also been accomplished, by acid-catalyzed condensation of a porphyrin bearing a *meso*-formylphenyl substituent with an excess of pyrrole and benzaldehyde;[23,24] in the presence of a large excess of pyrrole, a *meso*-[(*p*-formylphenyl)triphenyl]porphyrin was reported to produce a pentaporphyrin in 1% yield.[24] Unsymmetrical dimers and porphyrin-chlorin systems can be obtained from low-valent titanium-promoted heterocouplings of formyl-substituted porphyrins and chlorins, although a statistical mixture of all possible homo- and hetero-dimers is generally produced. When a 2:1 mixture of nickel(II) 3-formylchlorin-e_6 trimethyl ester and a *meso*-(*p*-formylphenyl)porphyrin was coupled under the McMurry conditions, the corresponding bisporphyrin and bischlorin were obtained in 6 and 42% yields, respectively, along with the porphyrin-chlorin dimer **7**, in 41% yield.[18] The crystal structure of **7** (Fig. 4) shows the *trans* arrangement of the two macrocycles, and a bow-shaped structure for this molecule with an angle between the two N_4 planes of 35.7°. Unsymmetrical bisporphyrins, such as **8**, linked at the *meso* positions by aromatic groups are generally synthesized as shown in Scheme 1;[18] the key intermediate is an unsymmetrical bis(dipyrromethane) bearing both benzyl and ethyl ester groups which are selectively cleaved and reacted with a dipyrromethane, in a stepwise manner. Phenyl-linked unsymmetrical dimers have been synthesized by reaction of a *meso*-(formylphenyl)porphyrin with a 2-unsubstituted pyrrole, followed by condensation with a dipyrromethane,[25] or by mixed condensation.[26] Bisporphyrins bound by several *trans*-stilbene linkages have also been synthesized from the corresponding poly(benzyl sulfone)-linked bisporphyrins *via* the Ramberg–Bäcklund reaction.[27] A β-substituted porphyrin methylphosphonium salt has been used as a building block for the synthesis of porphyrin arrays, linked by butadiene, styryl, and diethenylphenylene bridges, and consisting of up to nine porphyrin units.[28]

Other syntheses of *meso*-*meso*, *meso*-β or β-β linked porphyrin arrays take advantage of metal-mediated cross-coupling methodologies and the ease with which β- or *meso*-haloporphyrins are prepared. Alkynyl-bridged porphyrin arrays, obtained *via* the Pd^0 cross-coupling of a small set of ethynyl- and halo-porphyrin building blocks display large porphyrin–porphyrin excitonic and electronic couplings far exceeding those of other porphyrin-to-porphyrin aromatic, aliphatic or vinylic linkages.[29] *meso*-Ethynyl bridges are most efficient to conjugatively connect porphyrins. Glazer–Hay oxidative coupling of 5,15-diethynylporphyrin afforded polymeric materials absorbing in the near IR region and exhibiting strong third-order non-linear optical behavior.[30] Construction of *meso*-alkynylaryl



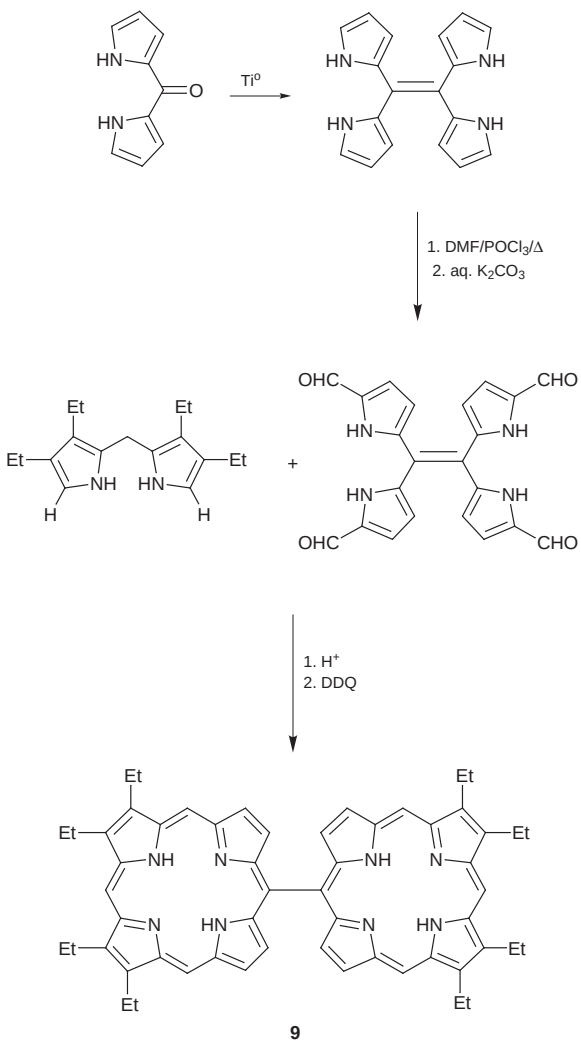
8

Scheme 1

linked oligoporphyrins relied also on a small set of (halo- and ethynyl-phenyl)porphyrin building blocks and iterative cross-coupling reactions. A variety of molecular structures have been obtained, as exemplified by the preparation of a square macrocyclic array of four mutually coplanar porphyrins from the palladium catalyzed reaction of zinc(II) 5,10-di(*p*-ethynylphenyl)-15,20-dimesitylporphyrin with 5,10-di(*p*-iodophenyl)-15,20-dimesitylporphyrin in the presence of $As(Ph)_3$.[31] Positive coupling of linear *m*-ethynylaryl functionalized porphyrins with copper(I) chloride/air in the presence of pyridine-based templates yielded butadiyne bridged dimeric or tetrameric cyclic species.[32]

Porphyrin oligomers with orthogonal π-systems

The low-valent titanium coupling reaction provides a synthetic route to directly linked *meso-meso* bisporphyrins (*e.g.* **9**). Dipyrrol-2-yl ketone smoothly undergoes reductive coupling in the presence of pyridine, affording tetra(pyrrol-2-yl)ethene, which upon tetraformylation under the Vilsmeier conditions, followed by MacDonald-type condensation with a 1,9-di-unsubstituted dipyrromethane, produced bisporphyrin **9** (Scheme 2).[33] The crystal structure of **9** (Fig. 5) shows an orthogonal arrangement of the two directly linked macrocycles; the dihedral angle between the two porphyrin planes was found to be 83.9° (crystallization from CH_2Cl_2–methanol) or 64.3° (crystallization from THF–hexane), the difference probably due to variable lattice packing. The optical spectrum of **9** exhibits a large splitting of the Soret band ($\Delta\lambda$ = 36 nm) which reveals excitonic coupling[34] indicating substantial electronic interaction between the two macrocycles, despite their orthogonal arrangement. Directly *meso-meso* linked bisporphyrins and trisporphyrins have also been obtained by reaction of a *meso*-formyl β-unsubstituted porphyrin with a 1,9-di-unsubstituted dipyrromethane,[35] and by electrochemical or Ag^I-promoted oxidative coupling of 5,15-diarylporphyrins.[36] The latter approach also produced higher oligomers, which can be separated by size exclusion chromatography. The one-electron oxidations are usually performed on the Zn^{II} complexes, which readily form the π-cation radical intermediates, and the reaction mechanism probably involves subsequent nucleophilic attack by a neutral zinc(II) porphyrin. The chemical oxidation is usually accomplished with $AgPF_6$ at room temperature, and addition of iodine was reported to accelerate the coupling reaction. The electrochemical oxidation generally uses a platinum net as the working electrode;[37] electrochemical oxidations performed on the free-base porphyrin, and on the Cu^{II}, Pd^{II} and Ni^{II} complexes regioselectively produced *meso*-β linked bisporphyrins.[38] The electrochemical oxidation of zinc(II)octaethylporphyrin in the presence of an excess of 4,4′-bipyridine led to the production of a pentaporphyrin, *via* a *meso*-tetra(4,4′-bipyridinium)porphyrin intermediate.[39]



9

Scheme 2

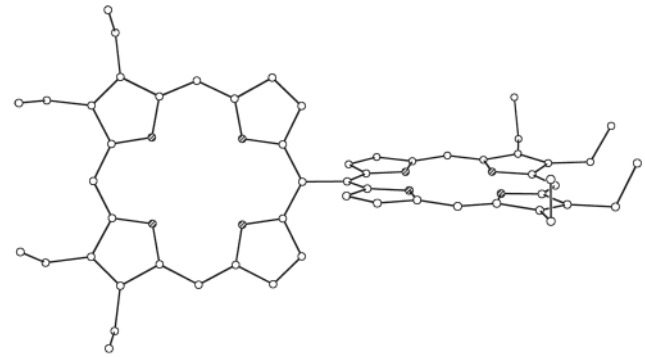


Fig. 5 Molecular structure of free-base *meso-meso* linked dimer **9** (hydrogen atoms not shown). Dihedral angle is 83.9°.

Directly *meso*-β linked porphyrin-chlorin dimers have been obtained by mixed condensation of methyl pyropheophorbide *d*, *o*-methylbenzaldehyde, and a 1,9-di-unsubstituted dipyrromethane.[40] We have developed a related synthetic route to porphyrin-chlorin dimers by stepwise condensation of a β-formylchlorin with a 2-unsubstituted pyrrole, *via* a chlorin-dipyrromethane intermediate.[41] Dimer **10** was produced from the condensation of a pyropheophorbide *a*-dipyrromethane with a 1,9-diformyldipyrromethane, whereas trimer **11** resulted from condensation of β-formylpyropheophorbide *a* with a 1,9-di-unsubstituted dipyrromethane. A dimer was also produced from the latter reaction, presumably by cleavage of the strained C_β–C_{meso} bridge at the pyropheophorbide *a*-porphodimethene oxidation step.

Porphyrin oligomers with fused π-systems

Relatively few oligoporphyrin arrays in which individual porphyrin rings are bridged by coplanar aromatic bridges have been prepared. Such rigid coplanar arrays should display pronounced electronic interactions between metal centers *via* overlap of their d(π) orbitals with the conjugated π-system of the porphyrins. The McMurry reaction, applied to chlorophyll derivatives containing an exocyclic cyclopentanone ring, produces fully conjugated bischlorins.[42] The metal-free compound **12** was obtained from the zinc complex monomer by performing the McMurry reaction in the presence of pyridine, followed by demetalation with TFA. The crystal structure of **12** (Fig. 6) shows that the molecule is essentially planar, forming an angle of 2.2° between the two planes of the N_4 atoms. These bischlorin systems show substantial hyperchromic and bathochromic shifts ($\Delta\lambda$ *ca.* 90–100 nm) of the long-wavelength absorption band in their optical spectra when compared with the precursor monomers, a result of their extended π-electronic delocalization (Fig. 7).

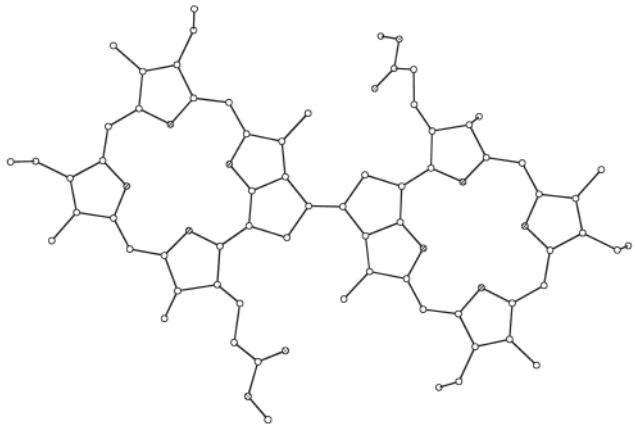

Fig. 6 Molecular structure of planar free-base bis-chlorin **12** (hydrogen atoms not shown).

Crossley and co-workers developed an approach to laterally extended oligoporphyrins sharing up to three 1,4,5,8-tetraazaanthracene units.[43] Linear and bent tris-porphyrins and a tetrakis-porphyrin were prepared by condensing porphyrin-2,3-diones and porphyrin-2,3,12,13- or -2,3,7,8-tetraones with aromatic *ortho*-diamines or 1,2,4,5-tetraamines in refluxing toluene. A bis-tetrabenzoporphyrin in which two benzoporphyrins share a fused benzene ring has been obtained by cross-condensation of pyromellitic dipotassium diimide and potassium *tert*-butylphthalimide at 320 °C.[44] Our approach to related arrays sharing a common benzene ring was based on the participation of *meso*-tetraarylporphyrins as dienophiles in Diels–Alder type reactions with highly activated dienes, such as those generated *in situ* by thermal extrusion of SO_2 from fused aromatic sulfones. Refluxing a solution of *meso*-tetraphenylporphyrin and excess ethyl 1,1-sulfolano[3,4-*c*]pyrrole-2-carboxylate in 1,2,4-trichlorobenzene gave tetraphenylchlorin **13** as an enantiomeric mixture.[45] Oxidation with DDQ and subsequent zinc(II) insertion afforded the corresponding zinc(II) 2*H*-isoindoloporphyrin. Reduction of the ester group of this porphyrin with $LiAlH_4$ produced the alcohol which, upon acid-catalyzed tetramerization and oxidation with *p*-chloranil, gave a cyclohexadiene annulated pentaporphyrin. This pentamer could be further aromatized with excess DDQ to afford a conjugated

pentaporphyrin **14**, displaying a long-wavelength absorption band at 774 nm. In order to further enhance the interporphyrin communication, we prepared a novel modular β-β′ building block, *i.e.* pyrrolo[3,4-*b*]porphyrin, by applying the [3 + 2] cycloaddition of nitroalkenes with isocyanoacetates[46] to metallo-2-nitrotetraphenylporphyrins (2-NO_2TPPs). We took advantage of the strong ability of the nitro group to activate a tetraarylporphyrin towards Michael addition and its propensity to act as leaving group. Thus, refluxing Ni(2-NO_2TPP) with methyl isocyanoacetate and two equiv. of DBU in THF–Pr^iOH led, as a result of an *in situ* transesterification reaction with Pr^iOH, to the formation of the first β-fused pyrroloporphyrin, as its isopropyl ester **15**. Fig. 8 shows the X-ray structure of pyrroloporphyrin **15**. Use of benzyl alcohol in place of Pr^iOH yielded advantageously the pyrroloporphyrin benzyl ester **16**. Reaction of Ni(2-NO_2TPP) with *tert*-butyl isocyanoacetate (in THF–Bu^tOH) gave (in addition to pyrroloporphyrin *tert*-butyl ester) naphthochlorin **17**. Attempted crystallization of **17** afforded a β-β′ naphthochlorin dimer (**18**).[47] Despite the direct β-β′ bond, the macrocycles were nearly coplanar, exhibiting an interplanar angle of 30.1° (Fig. 9). The macrocyclic overlap was limited to one pyrrolic subunit of each naphthochlorin monomer, displaying a marked similarity to the special pair in the bacterial photosynthetic reaction center. The π-radical dimerization of **17** could be promoted by benzoyl peroxide in refluxing benzene to afford **18** in higher yield. When Zn(2-NO_2TPP) was subjected to the Barton–Zard conditions

Fig. 10 Molecular structure of aggregated Zn^{II} cyclopropyl-annulated chlorin **19** (hydrogen atoms not shown).

($NCCH_2CO_2Et$, Pr^iOHTHF, DBU), no pyrroloporphyrin was formed; instead a cyclopropyl-annulated chlorin was isolated with an *endo* configuration with regard to the isocyanide group.[48] This zinc(II) chlorin self-assembled with isocyanide axially coordinated to the central zinc(II) ions, affording **19** (crystal structure shown in Fig. 10). Isolation of this cyclopropylchlorin prompted our development of a new methodology for dihydroporphyrin synthesis based on the Michael addition of active methylene compounds to 2-NO_2TPPs.[49] A Diels–Alder cycloaddition of di(2-phenylethyl) acetylenedicarboxylate with an *N*-(*tert*-butoxycarbonyl)pyrrolo[3,4-*b*]porphyrin gave, after cleavage of the Boc group and subsequent zinc(II) insertion, the

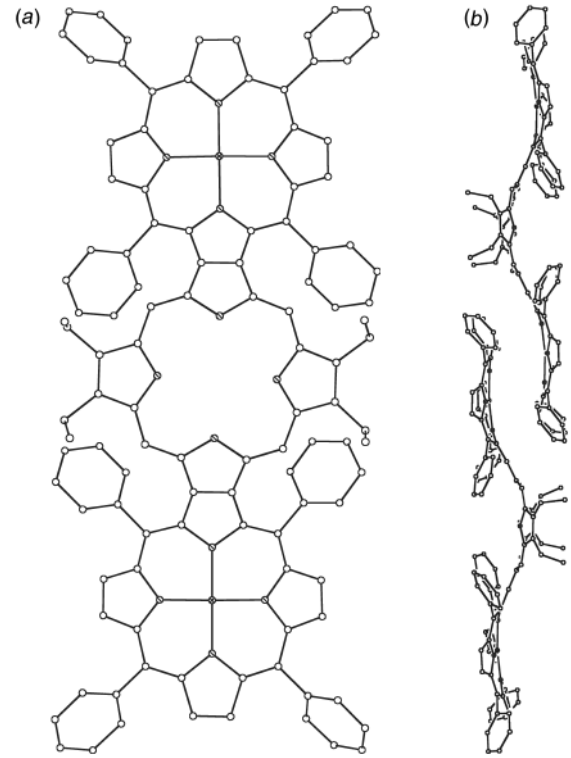

Fig. 11 Molecular structure of $[Ni^{II}][H_4^{2+}][Ni^{II}]$ fused trimer **21**·$(HCl)_2$ (hydrogen atoms not shown); (*a*) top view, (*b*) side view of two molecules illustrating the π–π interactions observed in the crystal packing.

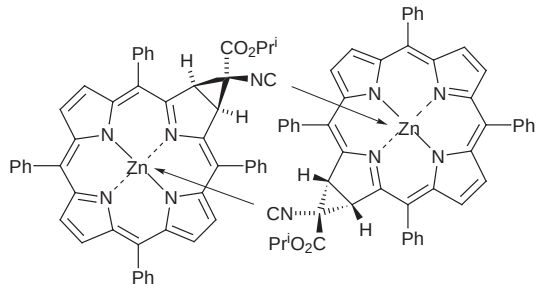
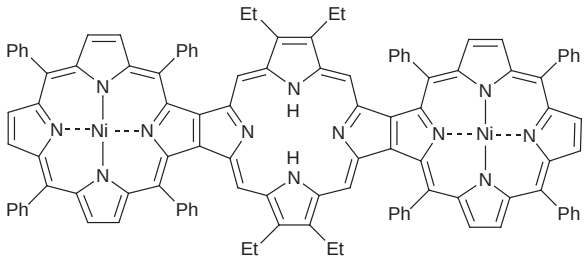
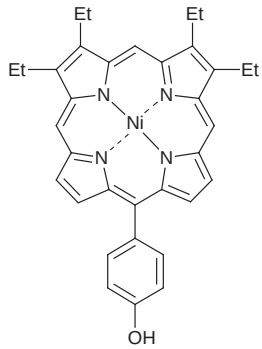
corresponding zinc(II) 7-azabicyclo[2.2.1]heptadiene porphyrin.[50] In the solid state, a non-covalent cyclic hexameric array was obtained wherein each zinc(II) porphyrin was coordinated to the fused azabicyclo group of an adjoining porphyrin unit. Hydrogenolysis of pyrroloporphyrin benzyl ester **16** using 20% palladium(II) hydroxide on carbon and cyclohexene as the hydrogen donor afforded the green di-α-unsubstituted pyrroloporphyrin **20**.[51] Under non-acidic conditions, 2,5-bis(trimethylammoniomethyl)-3,4-diethylpyrrole reacted with **20** in refluxing methanol–THF in the presence of $K_3Fe(CN)_6$/air to afford the first β-β′-directly-fused porphyrin trimer **21**.[52] This novel compound possesses a large fully-delocalized aromatic network which could possibly give rise to metallic type conduction. The molecular structure of **21**·$(HCl)_2$ was confirmed by X-ray crystallography (Fig. 11). Protonation of the central porphyrin facilitated the crystal packing by enabling intermolecular π–π stacking to occur only between terminal porphyrins, thus giving rise to independent linear rods of fused porphyrins. The porphyrin trimer has an edge-to-edge span of 27.0 Å and an intramolecular distance between metals of 16.16 Å. The most notable feature in the absorption spectra of **21** and a related β-β′ fused dimer [obtained from cross condensation of **20**, pyrrole and 2,5-bis(trimethylammoniomethyl)-3,4-diethylpyrrole] is an intense Q band at 715 nm or at 652 nm for the fused dimer, reminiscent of a bacteriochlorin (or chlorin) type visible spectrum [see optical spectrum of **21**·$(HCl)_2$ on the cover of this Issue]. Demetalation of **21** gave a stable metal-free porphyrin trimer which undergoes two reversible, spectroscopically distinct protonation steps. As shown by X-ray crystallography, protonation takes place first on the two bookend moieties to yield a green tetraprotonated species.[53] The two inner hydrogen atoms of the central porphyrin were located on the non-fused diethylpyrrolic moieties. Upon addition of excess acid a red hexaprotonated species was obtained which featured a split Soret band (429, 510 nm) and two broad Q bands (664, 820 nm). The metal free trimeric fused porphyrin shows a very intense fluorescence band with a maximum at 775 nm. The very short Stokes shift observed could lead, by analogy with the monomeric porphyrin, to the attribution of this band to the lowest π–π* transition. Such an intense band is quite rare in the 750–900 nm range, so



19



21



22

the fused trimer could be a good reference for measuring quantum yields in this spectral region.[53]

Supramolecular arrays

Spontaneous generation of higher order structures is a major goal in supramolecular chemistry, and self-assembly concepts have been widely applied to rigid polynucleating porphyrin-based ligands in order to mimic light harvesting and electron transport systems. Many photoactive supramolecular assemblies are based upon the peripheral coordination of *meso*-pyridyl groups to transition metals[54] or on their coordination to the central metal ion of a porphyrin.[55] As a recent example, a palladium mediated peripheral assembly of twenty one components [*i.e.* four di(4-pyridyl)porphyrins, four tri(4-pyridyl)porphyrins, one tetra(4-pyridyl)porphyrin and twelve $PdCl_2$ units] resulted in a nonameric square planar porphyrin array.[54] Self-assembled arrays occur through the coordination of the central metal ion by a β-functional group afforded head-to-tail dimeric,[48,56] trimeric,[57] hexameric[50] or polymeric species.[56] Other supramolecular analogues of the photosynthetic special pair have been prepared by inducing the intermolecular aggregation of two tetra(alkylammonio)porphyrins *via* binding their ammonium moieties within the cavities of four ditopic crown ethers.[58] Multiple hydrogen bonding has been employed in the construction of organized porphyrin arrays,[59] but their low kinetic stability ultimately limit their study as well as their use. In the case of double decker or triple decker metal-

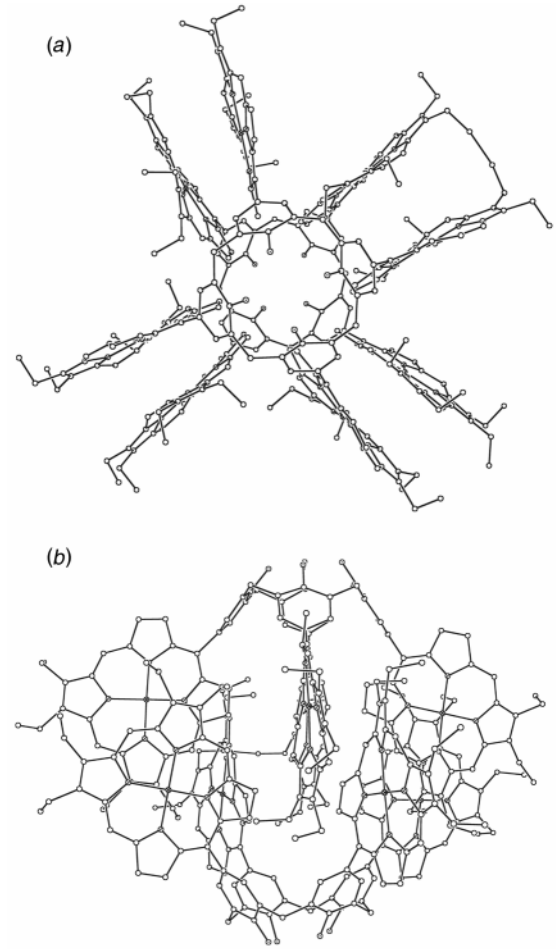


Fig. 12 Molecular structure of aggregated Ni^{II} calix[4]arenoporphyrin (**23**) dimer (hydrogen atoms not shown); (*a*) top view, (*b*) side view.

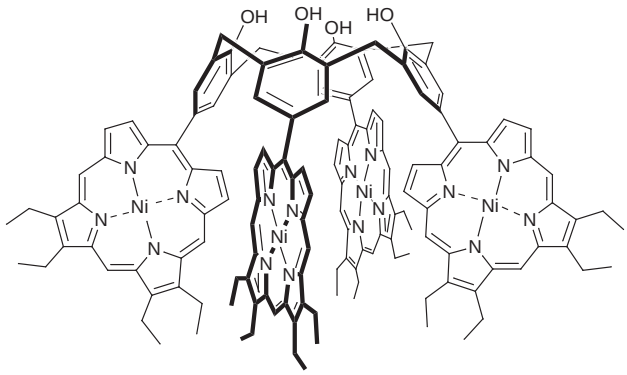
loporphyrinoids, the coordinated metal ions, usually from the lanthanide series, act as the bridging units.[60]

The design of complex three dimensional arrays *via* the use of building blocks displaying electronic and structural information enticing a covalent self-assembly process is less common. We felt that applying known macrocylization reactions to suitably functionalized porphyrinoids could lead to covalent supramolecular assemblies which are stable, both thermodynamically and kinetically. Our approach to the construction of such arrays with highly organized cavities was based on the redox reactivity of 15-substituted oxophlorins,[61] or the use of a *covalent template* strategy (since up to eight new covalent bonds could be formed in a predefined manner) based on the condensation of phenolic porphyrins into a calix[*n*]arene molecular platform.[62]

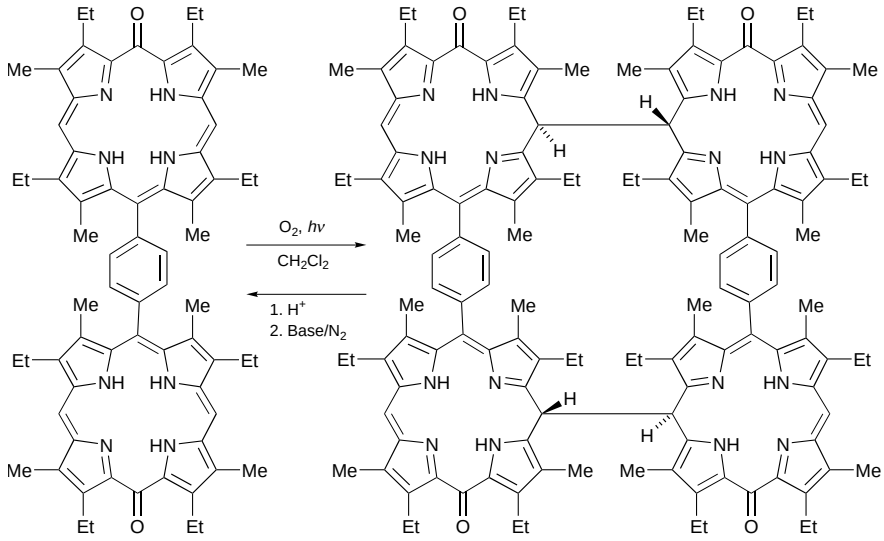
Combination of calix[4]arenes, which possess strong ion binding properties, with an organized array of pH-dependent photoactive chromophores can lead to the development of efficient sensor agents. Condensation of a *meso*-(*p*-hydroxyphenyl)porphyrin with formaldehyde under selective alkaline conditions may potentially afford calix[4], [6] or [8]arenoporphyrins. We first targeted a calix[4]arenoporphyrin and adopted the Zinke–Cornforth procedure with minor modifications. To minimize steric congestion among adjacent porphyrins and to increase the solubility of the final product, a porphyrin with unsubstituted β-positions on its upper half and β-ethyl groups on its lower half was targeted. Vilsmeier bisformylation of 5-(*p*-methoxyphenyl)dipyrromethane in refluxing CH_2Cl_2 gave the corresponding 1,9-diformyldipyrromethane, which upon acidic condensation with 2,3,7,8-tetraethyldipyrromethane afforded *p*-(12,13,17,18-tetraethylporphyrin-5-yl)anisole in moderate yield. This MacDonald-type (*i.e.* '2 + 2') condensation was successful only when the β-unsubstituted upper moiety bore the bridging formyl groups. After BBr_3 demethylation and metalation of the nitrogen core, *p*-substituted phenol **22** was obtained



23

and refluxed in dioxane in the presence of NaOH and formaldehyde, affording mono- and di-benzyl alcohol porphyrins. The crude mixture was then refluxed in diphenyl ether to give the calix[4]arenoporphyrin **23** (purified on Sephadex). The calix[4]arenoporphyrin adopted the cone conformation, a motif prevalent in calix[4]arenes which is stabilized by a cyclic array of intramolecular hydrogen bonds among OH groups. For the solid state, this was shown by X-ray diffraction studies. Figure 12 shows the interactions which exist between two neighboring molecules of calix[4]arenoporphyrin and fully explains the preferential cone conformation over other possible conformations such as the 1,2- or 1,3-alternate. It is apparent that the preference for the cone conformation is related more to a unique π-stabilized dimerization process rather than intramolecular hydrogen bonding at the phenolic head of the molecule; very strong π-stacking interactions are the key feature in the molecular recognition of two calix[4]arenoporphyrin molecules leading to a unique non-covalent cogwheeled array of eight porphyrins. Although an AB type pattern for the benzylic methylene protons characteristic of a fixed cone conformation was not clearly identified, the broad NMR signals, which were only marginally temperature dependent, attest of the persistence of such an aggregated dimeric form in solution. Functionalization of the upper rim and a decrease in hydrogen bonding could favor an aggregation network based on a 1,3-alternate conformation.

Our second strategy toward the synthesis of covalent supramolecular arrays relied on the propensity of oxophlorins (5-oxyporphyrins) to form, upon light induced aerial oxidation, fairly stable π-neutral radicals in which dimerization results in the formation of a carbon–carbon bond between two sp^3 *meso* carbons, sited opposite to the carbonyl group (*i.e.* at the 15-position).[63] In order to alter the oxidation potential, the spin distribution of the π-neutral radical, and the dimerization process, we synthesized 15-substituted oxophlorins, *via* a '2 + 2' condensation of 1,9-diformyldipyrroketones with 5-substituted (ethyl, aryl, porphyrin-5-yl, corrol-10-yl) dipyrromethanes in acid.[61] The ethyl substituent induced a steric stabilization of a novel non-aromatic, non-redox active tautomeric species of oxophlorins (*i.e.* 15-iso-oxophlorin) because the resulting loss in aromatic stabilization is largely overcome by a decrease in the steric congestion at the 15-position introduced by a sp^3 hybridized carbon atom.[61] Upon complexation with zinc(II), these 15-iso-oxophlorins formed a doubly oxo-bridged head to tail dimer, placing the two macrocycles within π–π contact. Formation of the π-neutral radical of 15-substituted oxophlorins with air occurred spontaneously in solution in the case of electron-donating substituents and led to the formation of dimeric species. The presence of two



24 **25**

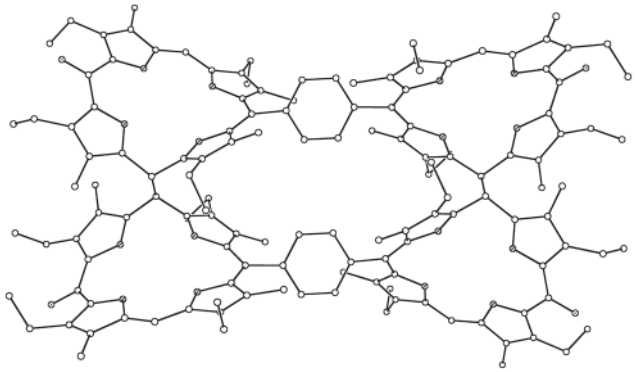

Fig. 13 Molecular structure of dimerized bis-oxophlorin **25** (hydrogen atoms not shown).

regioisomers (with regard to the orientation of the carbonyl groups) resulting from the dimerization demonstrated that 15-substituted oxophlorins dimerize at the 10,10′-positions. Although no attempts were made to separate these regioisomers, spontaneous resolution occurred during the growth of individual single crystals, as shown by the molecular structures of ethyl and phenyl 15-substituted dimers. Introduction of electron-withdrawing groups such as a pentafluorophenyl efficiently minimizes the spontaneous formation of oxophlorin π-radicals. Radical formation could be mediated with a mild oxidant such as $K_3Fe(CN)_6$ in THF, and 15-(pentafluorophenyl)oxophlorins were shown to dimerize with this kind of encouragement, in high yield.

Having established the redox activity of 15-substituted oxophlorins, we used their self-assembly to prepare various tetrameric arrays of chromophores.[61] Bis-oxophlorin **24** was prepared by condensation of 1,9-diformyldipyrroketone with a symmetrical 1,4-bis(dipyrromethan-5-yl)benzene in TFA. A daylight-induced oxidative coupling of bis-oxophlorin **24** afforded, in very high yield, a cyclic macromolecule **25** consisting of four iso-oxophlorin-like subunits arranged in a stereochemically unique *trans*,*trans*,*trans* fashion at the bridging 10,10′-positions (Fig. 13). The molecular structure of **25** showed an overall helical structure with disordered molecules of *n*-hexane fitting into the groove of the helix (not shown). The stereochemistry of the self-assembly process of the achiral components can be controlled by the insertion of a methoxy group at the 10-position of the bis-oxophlorin precursor (when prepared in MeOH–CH_2Cl_2, TsOH) resulting in a tetrameric array possessing a "stepped" structure with a *trans*,*cis*,*trans* orientation at the 10,10'-bridges. Whereas aromatic porphyrins display extremely shielded central nitrogen protons, these iso-oxophlorin species have an interrupted conjugation pathway and feature ^{1}H NMR peaks characteristic of a non-aromatic chromophore, with D_2O/Et_3N exchangeable NH peaks around 13 ppm. Addition of acid (TFA) to all these dimeric and tetrameric species reverses quantitatively the oligomerization process to form the oxophlorin dications as shown by the clean isosbestic points in spectrophotometric studies and by X-ray crystallography. Neutralization drives again the oxidative self-assembly. This overall process involves a very facile redox couple. Owing to the reversible, high yielding self-assembly behaviour of these oxophlorin species, we term this strategy *radical capture* and stress that it represents a unique approach towards the design and synthesis of covalently linked supramolecular assemblies. To further explore radical processes as a generic strategy, we turned our attention to adjacent *meso*,β-bis(methoxycarbonylmethyl)porphyrins.[64] Such porphyrins (*e.g.* **26**) when adsorbed on CH_2Cl_2-moistened silica gel gave the Dieckmann-like cyclized β-keto ester **27** which dimerized at the 20-position *via* the intermediacy of a delocalized π-radical. Any porphyrinoid system that possesses structural features which can efficiently form a stabilized π-radical (*e.g.* the carbonyl oxygen in oxophlorins, or the phenolic moiety in **27**) should undergo oxidative chemistry leading potentially to oligoporphyrin arrays.

Conclusions

It seems clear, from the work of our group and others, that past dramatic advances in the synthesis of monomeric porphyrin systems have brought us to the point where combination strategies for preparation of oligomeric porphyrin arrays are now not only possible, but are being actively exploited. When one combines the unparalleled redox, photochemical, spectroscopic, metal chelation/ligand binding, and catalytic properties of our favorite chromophore with the potential for assembling these molecules to give interactive arrays, one can only conclude that the future for research in this area is unbounded.

A quantitative UV–VIS probe of enantioselectivity in metalloporphyrin catalyzed oxygenation using aluminium model complexes

James P. Collman,* Zhong Wang, Christian Linde, Lei Fu, Louis Dang and John I. Brauman*

Received (in Bloomington, IN, USA) 24th May 1999, Accepted 29th July 1999

UV–VIS spectroscopy is used to study the selective binding of enantiomeric pairs of chiral epoxides to an αααββ binaphthyl-strapped Al porphyrin; the binding selectivity correlates to the enantioselectivity in the epoxidation of alkenes catalyzed by its Fe analog.

Catalytic asymmetric epoxidation and hydroxylation constitute appealing strategies for synthesizing optically active organic compounds.[1] Much effort has been devoted to the design and preparation of catalysts with novel chiral structures in order to generate good enantioselectivity. Although efficient methods have been developed for asymmetric epoxidation of allylic alcohols,[2] enantioselective epoxidation of unfunctionalized alkenes and hydroxylation of simple alkanes, in general, have been less successful.[3] Owing to the lack of directing functional groups, only weak non-bonding interactions can be used to induce enantioselectivity in oxygenation of unfunctionalized alkenes and alkanes. Evaluating the energy differences of these weak interactions and predicting the enantioselectivity have been virtually impossible.

A paramagnetic NMR relaxation technique was recently used to study the complexation of epoxides to a chiral Cu porphyrin,[4] and correlation was found between the favorable mode of epoxide binding and the direction of chiral induction in the epoxidation. This experiment suggested that the transition state of oxygen transfer in metalloporphyrin-catalyzed epoxidations resembles the product epoxide bound to the metalloporphyrin. However, this method provides no information on the *degree* of chiral induction (*i.e.* the enantiomeric excess of the epoxidation reaction), which is critical for evaluating the efficiency of a chiral catalyst and designing systems with improved selectivity. Herein we present the first quantitative method to probe enantioselectivity in metalloporphyrin-catalyzed oxygenations, by studying the complexation of oxygenation products to an aluminium porphyrin using UV–VIS spectroscopy. This method allows for quantitative measurement of the binding constants of a pair of epoxide or alcohol enantiomers to the Al center. The relative binding selectivity correlates to the enantioselectivity observed in Fe porphyrin catalyzed epoxidation and hydroxylation.

Porphyrins H_2–**1**, Al–**1** and Fe–**1** (Fig. 1) were synthesized by condensing the corresponding ααββ-tetrakis(*o*-aminophenyl)-porphyrin with a binaphthyl diacid chloride. The Fe complex efficiently catalyzes the epoxidation of unfunctionalized alkenes with high enantioselectivity for simple terminal alkenes.[5] The ^{1}H NMR spectrum of Al–**1** shows two sets of resonances for the protons on the two sides of the porphyrin, reflecting a five-coordinate Al center and the resulting disruption of C_2 symmetry. Reversible binding of O or N ligands to this complex gives a distinct red shift in the Q-band region of UV–VIS spectra. This is a useful feature that allows us to conduct ligand titrations and to measure the complexation constants for different ligands.[6] The UV–VIS titration with enantiomerically pure (*S*)- and (*R*)-styrene oxides† in CH_2Cl_2 shows that Al–**1** preferentially binds (*S*)-styrene oxide, which is the major enantiomer obtained in Fe–**1** catalyzed epoxidation of styrene. The binding constants of (*S*)- and (*R*)-styrene oxide to Al–**1** are K_S = 14 dm^3 mol^{-1} and K_R = 1 dm^3 mol^{-1} [eqn. (1) and (2)].‡

This suggests that the (styrene oxide)–Al–**1** complex is a good transition state analog of the Fe–**1** catalyzed epoxidation of styrene (Scheme 1), and that the factors governing the enantioselective binding of Al–**1** are also responsible for the facial selectivity in Fe–**1** catalyzed epoxidations.

It is significant that enantiopure samples are not necessary for this method because the binding constants for two enantiomers can be determined by performing a series of measurements using samples of varying enantiomeric purities.§ For example, the formal binding constants (K_{obs}) can be obtained with (1*R*,2*S*)/(1*S*,2*R*) = 50/50 (racemic), 70/30, and 90/10 mixtures of (1*R*,2*S*)- and (1*S*,2*R*)-*cis*-β-methylstyrene oxide. The binding constants for pure (1*R*,2*S*)- and (1*S*,2*R*)-isomers are calculated to be 0.22 and 0.96 dm^3 mol^{-1}, respectively. The more

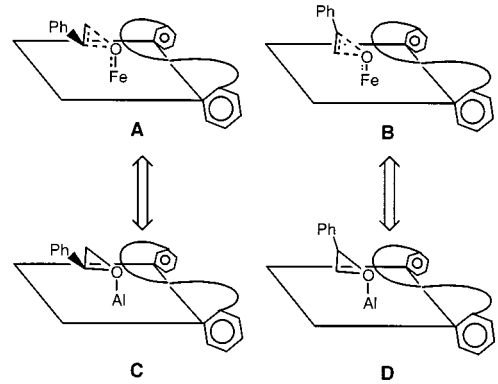

Scheme 1 Epoxide–Al–**1** complexes as epoxidation transition state analogs: **A** proposed epoxidation transition state forming (*S*)-styrene oxide (favored); **B** transition state forming (*R*)-styrene oxide (disfavored); **C** (*S*)-styrene oxide–Al–**1** complex (more stable) and **D** (*R*)-styrene oxide–Al–**1** complex (less stable). The S curve is the schematic designation of the chiral (*R*)-binaphthyl group.

Table 1 Comparison of the enantioselectivities in Al–**1** complexation and Fe–**1** catalyzed epoxidation[a]

Epoxidation product	Binding to Al–**1**		Fe–**1** catalyzed epoxidation	
	(*S*/*R*)	$\Delta\Delta G^\circ_{R-S}$/ kcal mol^{-1}	(*S*/*R*)	$\Delta\Delta G^\ddagger_{R-S}$/ kcal mol^{-1}
Styrene oxide	14.0 ± 1.7	1.56 ± 0.07	4.71 ± 0.35	0.92 ± 0.04
2-Naphthyl oxirane	4.5 ± 0.5	0.89 ± 0.06	2.43 ± 0.12	0.53 ± 0.04
cis-β-Methyl styrene oxide	4.4 ± 0.5[b]	0.88 ± 0.07	2.33 ± 0.12[b]	0.50 ± 0.04
trans-β-Methyl styrene oxide	3.2 ± 0.3[c]	0.69 ± 0.06	1.67 ± 0.08[c]	0.30 ± 0.03

[a] UV titration and epoxidation were both conducted at 298 K in CH_2Cl_2. [b] *S*/*R* = (1*S*,2*R*)/(1*R*,2*S*). [c] *S*/*R* = (1*S*,2*S*)/(1*R*,2*R*).

favorably bound enantiomer, (1*S*,2*R*)-epoxide, is again the major isomer formed in the Fe–**1** catalyzed epoxidation. The complexation constants of *cis*-β-methylstyrene oxides to Al–**1** are significantly smaller than those of styrene oxides, suggesting that steric exclusion is a major factor governing the enantiofacial selectivity in the epoxide binding. Table 1 compares the selectivities ($S/R = K_S/K_R$) of a number of epoxides obtained in ligand binding studies and Fe–**1** catalyzed epoxidations,¶ as well as the corresponding free energy differences $\Delta\Delta G^\circ$ and $\Delta\Delta G^\ddagger$, for binding and reactivity respectively. These data show that the selectivities in epoxide to Al–**1** complexation and Fe–**1** catalyzed epoxidation are in agreement, *i.e.* greater binding selectivity correlates to higher enantioselectivity in the epoxidation. A plot of $\Delta\Delta G^\ddagger$ against $\Delta\Delta G^\circ$ shows an excellent linear correlation (Fig. 2), demonstrating that the epoxide–metalloporphyrin complex can serve as a transition state model for metalloporphyrin catalyzed epoxidations.[7] The slope of *ca.* 0.6 suggests that the interaction in the epoxidation transition state is slightly less than that in the Al complex. More significantly, the quantitative correlation allows us to use Al porphyrin complexes to screen different chiral structures and substrates and predict the *degree* of enantioselectivity of epoxidation before conducting the actual reaction.

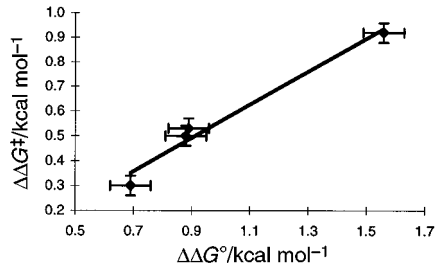

Fig. 2 Linear correlation between $\Delta\Delta G^\ddagger$ and $\Delta\Delta G^\circ$.

We have also applied this method to model the Fe porphyrin catalyzed asymmetric hydroxylation with chiral alcohol-bound Al complexes. Enantiomerically pure (*R*)- and (*S*)-*sec*-phenethyl alcohol have been used as model compounds to study ethylbenzene hydroxylation. Binding studies show that (*R*)-*sec*-phenethyl alcohol coordinates to Al–**1** more strongly than the (*S*)-alcohol by a factor of 2.1 (K_R = 16.0 dm^3 mol^{-1}, K_S = 7.4 dm^3 mol^{-1}). When we carried out the actual hydroxylation of ethylbenzene with Fe–**1** as the catalyst, we found that (*R*)-alcohol is formed preferentially, giving an enantiomeric excess of 20%. Although more data are needed to verify the correlation between the alcohol binding and hydroxylation, the qualitative agreement suggests that this UV–VIS technique can be a useful method to study the mechanism and enantioselectivity of metalloporphyrin catalyzed hydroxylation.[8,9]

In summary, we have demonstrated a UV–VIS spectroscopic method to probe the enantioselectivity in catalytic asymmetric oxygenation reactions. This technique quantifies the differential binding of enantiomers to a chiral metalloporphyrin; it not only can be used to measure the selectivity in enantiomer binding and compute the relative energy differences involved, but also can be applied to screen and predict the stereoselectivity of catalysts before carrying out the reaction. We believe the application of this technique to related fields will have a significant impact in chiral ligand design and catalyst development.

RR 04112 and RR 01614). C. L. thanks the Royal Institute of Technology, Sweden, for a research fellowship. L. D. thanks the Bing Foundation for a summer scholarship.

Notes and references

† Aluminium porphyrin catalyzed polymerization of propylene oxide and ethylene oxide has been reported (T. Aida and S. Inoue, *Macromolecules*, 1981, **14**, 1166). However, in our experiment, no polymerization of styrene oxide was observed: both Al–**1** and styrene oxide can be recovered quantitatively after the UV titration. This is probably due to the hindered porphyrin structure which substantially slows down the polymerization or oligomerization.

‡ We have attempted to use NMR titration to determine the binding constants, but we were not able to observe distinct chemical shift changes at room temperature because of the relatively small binding constants and rapid ligand exchange on the NMR time-scale.

§ In a system involving a mixture of *R*- and *S*-ligands, the formal binding constant $K_{obs} = K_R R + K_S (1\text{-}R)$ where *R* is the percentage/100 of *R* enantiomer in the mixture. The binding constants of pure *R* and *S* isomers K_R and K_S can thus be calculated from the formal binding constants of two different samples:

$K_S = (K_{obs}'R'' - K_{obs}''R')/(R''\% - R')$

$K_R = [K_{obs}'(1 - R'') - K_{obs}''(1 - R')]/(R' - R'')$

¶ Catalyst modification occurs during Fe–**1** catalyzed epoxidation, resulting in a rise of ee in the early stages of reaction.[5] We have taken the *initial* enantioselectivities of the epoxidation, which better reflect the stereoselectivity of the original Fe catalyst.

Received (in Cambridge, UK) 14th June 1999, Accepted 3rd August 1999

Non-ionically templated [Si]-MSU-1 mesoporous silicas have been prepared in weakly ionic sodium salt solutions from a non-ionic silica precursor and exhibit highly symmetric bimodal mesopore systems and demonstrate the immense flexibility of the non-ionic templating system.

Innovation in the synthesis of inorganic structures with novel and improved synthesis routes and structures is an area of intense international scientific and technological research. Ever since the disclosure of the M41S family of materials[1] in 1992, a veritable explosion of research effort has occurred in the area of macromolecular and micelle templating syntheses of mesostructured materials.[2] A considerable number of different synthesis approaches have now been developed, all of which possess strong philosophical similarities but are both chemically and mechanistically diverse.[3]

One of the major post M41S advances has been the discovery that non-ionic alkyl polyethylene oxide (PEO) surfactants and block co-polymers can template regular inorganic structures.[4–9] The N^0I^0,[4,5] $N^0/N^+X^-I^+$[6,7] and $N^0M^+I^-$[6] non-ionic templating routes appear to offer significant advantages over other assembly pathways. These include reproduction of structures reported in cationic systems[7] and novel structures, thicker pore walls and economic and environmental cost benefits of near ambient temperature, neutral pH and low cost, non-toxic and recoverable templates.

Biomimetic vesicular structures can form when the ionic strength of the non-ionic surfactant solution is raised from that of the pure aqueous solution through modification of the PEO–H_2O hydrogen bonding. To date such structures have only been exploited for inorganic phase formation through the application of diamine bolaform surfactants.[10] Here, we have simultaneously created biomimetic vesicle structures along with regular micelles from non-ionic alkyl-PEO surfactants in dilute electrolyte solutions† and thereby used these to direct the assembly of novel mesostructured silicas. We report, for the first time, the synthesis of inorganic silica structures that exhibit bimodal pore systems with pore diameters in the size range 3.0–9.0 nm.

Powder X-ray diffraction patterns (XRD) of a hydrothermally treated [Fig. 1(a)] and then calcined [Fig. 1(b)] sample synthesised in the presence of NaCl can be compared to XRD patterns of regular MSU-X materials.[5] The latter generally display single d_{100} reflections indicative of uniform worm-like mesopores with no long range periodicity. Two strong major reflections are observed in conjunction with a number of minor reflections at higher angles. An initial hypothesis was that these reflections were due to reflections from a novel two- or three-dimensional pore structure. Further analysis however modified this hypothesis and suggested a structure simultaneously possessing two distinct pore arrangements.

The formation of a novel structure type was supported by N_2 sorption isotherms (Fig. 2) which clearly display two distinct capillary condensation steps.[11] BJH model analysis of a material prepared in NaCl solution provides two pore diameter maxima at 3.4 and 5.2 nm (Table 1). Hysteresis is observed in the desorption branch which also exhibits two distinct, but less well separated, desorption steps. The suggestion is therefore, that two interconnected pore systems are present and that the desorption hysteresis suggests a three-dimensional pore structure.

Scanning electron micrographs (SEM) indicate elementary particles of *ca.* 0.5 μm that exhibit a general spherical morphology and some evidence for the formation of rounded extrusion-like particles. Secondary particles are aggregates of *ca.* 10–15 μm diameter. Confirmation of a double pore system was obtained from transmission electron micrographs (TEM) (Fig. 3). The micrographs show regions of extended lamellar-like features with low curvature, regions of highly ordered pores in hexagonal symmetry and regions of less ordered worm-like pore symmetry. This suggests that both vesicular and micellar aggregation types co-exist in these systems.

The effects on the synthesis of [Si]-MSU-1 materials in the presence of Na^+ electrolytes can be separated into two different effects. In the case of H^+ cation addition[6,7] some authors have proposed that the template becomes protonated and should thus

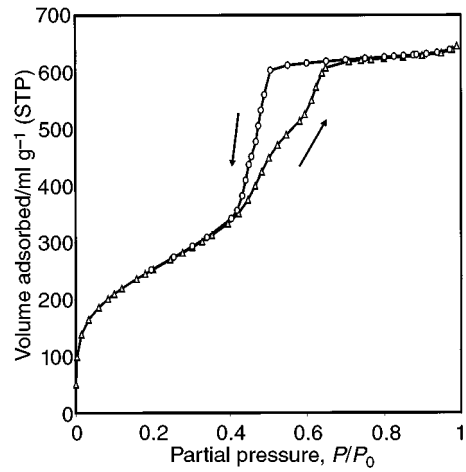

Fig. 2 Nitrogen adsorption–desorption isotherms of hydrotreated and calcined [Si]-MUS-1 prepared in the presence of NaCl.

Table 1 Properties of [Si]-MSU-1 silica samples prepared in the presence of dilute electrolytes

[Si]MSU-1 sample[a]	Electro-lyte[b]	d_{h00}[c]/nm	Pore diameter[d]/ nm	Surface area[e]/ $m^2\ g^{-1}$	Pore volume[f]/ ml g^{-1}
1	NaF	9.2, 5.3	8.7	520	1.2
2	NaCl	7.5, 5.6	5.2, 3.4	900	1.0
3	NaBr	7.9, 5.8	5.6, 3.6	810	1.1
4	NaI	8.7, 5.8	8.0	500	1.3
5	$NaSO_4$	8.5, 6.0	6.2, 3.8	880	1.2
6	$NaNO_3$	7.8, 6.0	5.8, 4.5	730	1.1
7	NaOAc	8.5, 4.9	6.7	900	1.4

[a] All samples templated with Brij 97 oleyl-EO_{10} non-ionic surfactant. [b] Sodium salts added at 5 mol% w.r.t Si. [c] ±0,1 nm [d] Pore diameters (±0.1 nm) calculated using the BJH cylinder model. (This model has recently been shown to underestimate pore diameters by up to 20%).[13] [e] Surface areas (±10 $m^2\ g^{-1}$) calculated with the BET model. [f] Pore volumes (±0.1 ml g^{-1}) calculated from $P/P_0 = 0.98$.

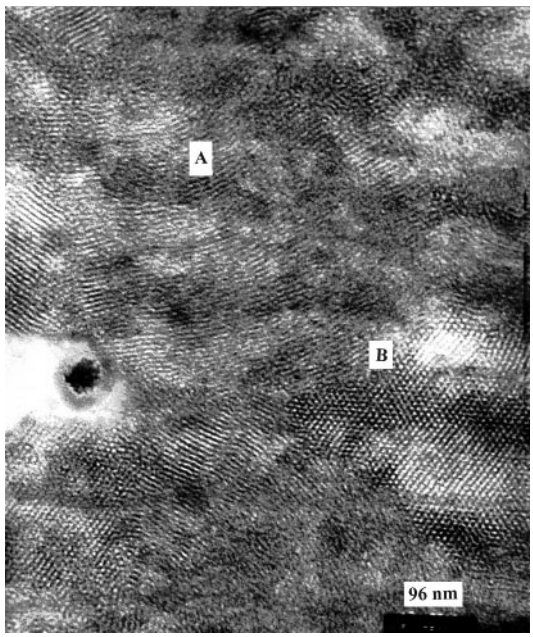

Fig. 3 Representative TEM of hydrotreated and calcined [Si]-MSU-1 prepared in the presence of NaCl showing (A) extended curved lamellar and (B) hexagonally ordered mesopores.

be labelled $N^+X^-I^+$.[7] In the system presented here, the pH of the reaction medium remains neutral and thus the assembly pathway is a true ion mediated non-ionically templated $N^0X^{+/-}I^0$ pathway. We suggest that the Na^+ cations induce the formation of vesicular systems through 'coordination' of PEO head groups, conformation extension and surface curvature decrease thereby forming vesicles. As the Na^+ concentration is 40 mol% with respect to R-PEO and each R-PEO contains 10 EO groups, only 4–8 mol% of the R-PEO surfactant will be fully Na^+ coordinated (assuming one Na^+ per one or two EO groups). Thus the remaining 96–92 mol% R-PEO surfactant will be in the normal state with regular PEO conformations forming regular micelles with greater surface curvature.

The second electrolyte effect is that of the anion which modifies not only the interaction of the tetraethyl orthosilicate (TEOS) silica precursor with the template head-group, but also the rate of hydrolysis and condensation of the TEOS. The effect of different anions in the $N^0X^{+/-}I^0$ pathway is to cause subtle changes to the final form of the mesostructures beyond the template aggregation modification caused by the cation. Fluoride addition has been previously reported[5] and remains a special case. The F^- ion possesses special chemistry that leads to very rapid TEOS condensation,[11] very small elementary particles, decreased micelle curvature and hence larger pore diameters.[5] The strong F^-/TEOS interaction appears to override any cation effects and a single pore system is formed. The other halides Cl^-, Br^- and I^- show decreasing rates of TEOS hydrolysis with increasing ionic radius. The oxy-anions SO_4^{2-}, NO_3^- and OAC^- show varying separation of the diameters of the two pore systems again with increasing ionic radius and decreasing ionisation (Table 1). ^{29}Si MAS NMR spectra indicate that anions with greater ionisation constant (*e.g.* F^-, Cl^-, SO_4^{2-}) induce more extensive hydrolysis of the TEOS and therefore more condensed and stable silica structures. Possible coordination effects by oxy-anions have not as yet been fully considered.

The results briefly outlined here provide further indications of the immense flexibility of the non-ionic alkyl-PEO templating system. They show that simple engineering of the chemistry in the synthesis medium can have profound effects on the templating mechanism and resultant porous products. This is further indication that the technological future of mesoporous materials development will lie within the PEO templating system. The exact nature of the templating system remains to be established. An investigation of the complete mechanisms through which different electrolytes (*i.e.* hard and soft cations and anions) modify the templating process is currently under investigation and will be discussed in a future contribution.

This work has been performed as part of a research contract with the New Zealand Foudnation for Science Research and Technology, contract number CO 8512.7. The author thanks Karen Reader of the Victoria University of Wellington Electron Microscopy facility for expert TEM analysis.

Notes and references

† *Experimental*: In a typical $N^0X^-I^0$ [Si]-MSU-X synthesis, a non-ionic polyethylene oxide surfactant was dissolved in distilled water at 7.5 wt%. In this study, Brij 97 (oleyl EO_{10}) surfactant was used exclusively. The temperature of the surfactant solution was raised to 40 ± 2 °C and TEOS was added under stirring to an Si: surfactant molar ratio of 8 : 1 and stirred for a predetermined time. The electrolyte, dissolved in a minimum of water was then added to the surfactant–TEOS solution at 5 mol% with respect to Si (*i.e.* 0.4 mol% w.r.t. PEO, 0.04 mol% w.r.t EO). The mixture was stirred at moderate rate, while the temperature was held at 40 ± 2 °C, over 36 h ensuring that the total aqueous volume was maintained. The white precipitate obtained was recovered by filtration, washed with distilled water and dried in air at room temperature. The dried samples were then hydrothermally treated by dispersing in distilled water and heating in a sealed polypropylene bottle at 100 °C for 72 h. The hydrothermally treated samples were recovered by filtration and dried in air at room temperature. The template was removed from the products by calcination at 600 °C in air over 4 h at a heating rate of 2 °C min^{-1}.

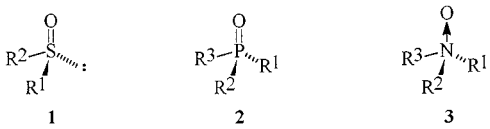
Received (in Cambridge, UK) 12th July 1999, Accepted 27th July 1999

Unsymmetrical teriary amines were oxidized with a few oxidants in the presence of bovine serum albumin to give the corresponding *N*-oxides of the highest optical purity ever reported (up to 66%) for the reaction of asymmetric oxidation of amines *via* their kinetic dynamic resolution.

During the last three decades chiral sulfoxides **1**[1] and phosphine oxides **2**[2] have found widespread application in the stereochemistry of heteroorganic compounds and especially in asymmetric synthesis. In a sharp contrast, the nitrogen analogues of **1** and **2**, *i.e.* chiral tertiary amine *N*-oxides **3**, are much



1 **2** **3**

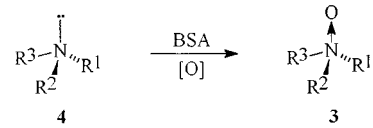
less known and without practical use in asymmetric synthesis. This results mainly from the fact that access to optically active tertiary *N*-oxides is very limited[3] in comparison to the sulfur and phosphorus analogues. Until now a few optically active tertiary *N*-oxides of high optical purity have been obtained *via* classical resolution of the corresponding racemates. At the beginning of this century Meisenheimer[4] resolved some asymmetric *N*,*N*-dialkylarylamine oxides *via* diasteromeric salts with α-bromocamphoric acid and tartaric acids. More recently, the enantiomers of *N*-methyl-*N*-phenyl-4-methylcyclohexylamine *N*-oxide[5] and *N*-methyl-*N*-neopentyl-4-methylcyclohexylamine *N*-oxide[6] were resolved using (−)-dibenzoyltartaric acid. Very recently, Toda *et al.*[7] reported nonclassical resolution of some asymmetric *N*,*N*-dialkylarylamine *N*-oxides with optically active host compounds. Simultaneously a report[8] appeared on partial resolution of the enantiomers of *N*-benzyl-*N*-methylpropynylamine *N*-oxide using the chiracal OD and chiralpark AD CPS columns.

Asymmetric oxidation of unsymmetrical tertiary amines has also been used for the preparation of optically active *N*-oxides. However, all the reported procedures gave the required oxidation products in very low optical yield. Thus, when *N*-methyl-1,2,3,4-tetrahydroquinoline was treated[9] with percamphoric acid at −70 °C in $CHCl_3$ the corresponding *N*-oxide obtained as the hydrochloride had an ee value of only 0.6%. Similar oxidation of a series of *N*-alkyl-*N*-methylanilines produced *N*-oxides with germinal optical rotation.[10] (+)-*N*-*trans*-crotyl-*N*-ethyl-*p*-toluidine *N*-oxide having an ee of 16% was derived from the parent amine by oxidation with dibenzoyl-L-pertartaric acid.[11]

As part of our program involving biologically-mediated reactions of prochiral heteroorganic substrates[12] we became interested in the asymmetric protein catalyzed oxidation of unsymmetrical tertiary amines **4** to the corresponding optically active *N*-oxides **3**.

Our interest in this oxidation results not only from the still existing need for an efficient procedure for the preparation of optically active *N*-oxides, but mainly from the fact that this conversion fulfils at least one of the conditions which characterise an ideal dynamic kinetic resolution procedure.[13] Indeed the starting material enantiomers (tertiary amines) are always in equilibrium due to a very fast pyramidal inversion on the stereogenic nitrogen atom of the substrates.

Here we report that a number of optically active *N*-oxides **3** of considerably higher enantiomeric excess than these reported until now were obtained from the direct oxidation of the corresponding amines **4** in the presence of bovine serum albumin (BSA) [eqn. (1)]. BSA, the most abundant protein in



4 **3** (1)

blood plasma, acts as a transport protein and forms adducts with various kinds of hydrophoboic compounds.[14] Effective discrimination of the substituents bonded to the nitrogen atom in amine **4** should be achievable by fixing the amine in the chiral environment of BSA, thus making asymmetric induction in the subsequent oxidation possible. Here we report that BSA can be used in catalytic amounts to afford the corresponding optically active *N*-oxides. The reactions were carried out by stirring at room temperature a heterogeneous mixture of substrate (1 mmol) and oxidant (2 mmol) in the presence of BSA (0.05 mmol; the molecular weight of the BSA was taken as 66 000) in a borate buffer solution (pH 9). (These conditions were found to afford the highest enantioselectivity in the BSA—catalyzed sulfoxidation of functionalized sulfides.[12])

The results collected in Table 1 show the oxidations always produced optically active *N*-oxides in chemical yields ranging from 10% to quantitative. It should be noted that in many cases, when chemical yields are low, a substantial amount of the starting amine was recovered during the chromatographic purification of the crude reaction products. The extent of asymmetric induction was determined by ^{1}H NMR spectroscopy using optically active *tert*-butylphenylphosphinothioic acid as a chiral solvating agent.[15] Analysis of the ee values indicates that optically active *N*-oxides of high opitcal purity (*ca.* 65%) were produced in two cases (**3d** and **3e**).

Modest enantiomeric excesses were observed in other cases. In general higher selectivity is observed with increased length of the alkyl chain of *N*-alkyl-*N*-methylbenzylamine *N*-oxides. The highest ee values in the oxidation with $NaIO_4$ were observed for *n*-butyl oxide **3d** (64.6%) and *n*-pentyl homologue **3e** (63.5%). Similar behaviour has already been observed in the BSA catalyzed sulfoxidation of sulfides with $NaIO_4$[12*a*] and dioxiranes.[12*b*] In this context it was interesting to check the influence of the nature of the oxidant on the stereochemical outcome of the oxidation of amines to *N*-oxides. As a model compound amine **4e** was selected. Analysis of the observed relationship indicates that the stereoselectivity change dramatically with MCPBA as oxidant instead of $NaIO_4$, the ees being

Table 1 The bovine serum albumin catalyzed oxidation of tertiary amines $R^1R^2R^3N$ **4** to the corresponding *N*-oxides, $R^1R^2R^3N \rightarrow O$ **3**

[a] All rotations were measured in $CHCl_3$. [b] Determined by ^1H NMR spectroscopy with *tert*-butylphenylphosphinothioic acid as a chiral solvating agent (ref. 15). [c] Substantial amount (20–30%) of the starting amine was recovered during chromatographic purification of the produced *N*-oxide. [d] Maximum value reported for this *N*-oxide is $[\alpha]_D$ +16.4 ($CHCl_3$) (ref. 7). [e] Maximum value reported for this *N*-oxide is $[\alpha]_D$ +13.0 ($CHCl_3$) (ref. 7).

4 and 63.5%, respectively. This shows the great sensitivity of this method to changes in the reaction conditions.

In conclusion we would like to stress that although our method did not always give very high stereoselectivity, it constitutes the first procedure for effective asymmetric oxidation of unsymmetrical amines to the corresponding *N*-oxides. It also constitutes the first example of a dynamic kinetic resolution procedure, which is based on the inherent ability of the substrate enantiomers to be in equilibrium under the reaction conditions. The results presented above demonstrate moreover that the use of a catalytic amount of BSA is not limited to the oxidation of prochiral organosulfur derivatives, but can be extended to substrates containing other heteroatoms. Work is in progress to extend the applicability of this dynamic kinetic resolution procedure and to determine the absolute configuration at the nitrogen stereogenic center in the formed optically active *N*-oxides by spectroscopic techniques.

Received (in Cambridge, UK) 1st July 1999, Accepted 27th July 1999

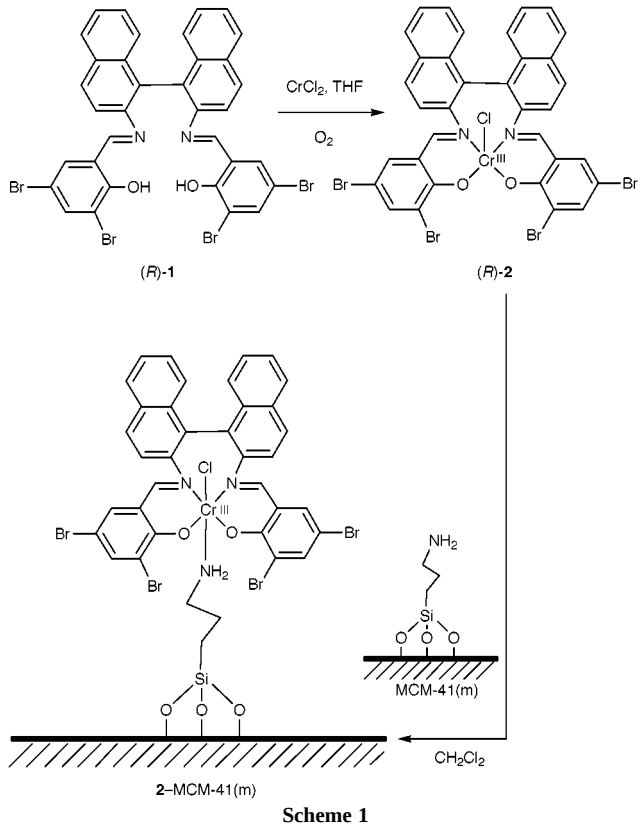
A chromium(III) binaphthyl Schiff base complex immobilised on modified MCM-41 is an effective catalyst for asymmetric epoxidation of unfunctionalised alkenes and gave significantly higher ee than the free complex.

The heterogenisation of homogeneous catalysts, which endows the homogeneous systems with attractive features such as easy product separation and catalyst recovery, constitutes a rapidly expanding research area.[1–5] Chief among various types of heterogenised catalysts are the metal complexes immobilised onto solid supports such as molecular sieves,[2,3] ion-exchange resins[4] and polymer membrance.[5] Although such immobilisation can sometimes enhance the activity of homogeneous catalysts, a common problem encountered in asymmetric catalysis is a decrease of enantioselectivity upon heterogenisation.[6] Indeed, all the heterogenised catalysts developed very recently for epoxidation of unfunctionalised alkenes exhibit considerably lower[7–10] or no higher[5,11] enantioseletivity than their homogeneous counterparts. Herein we report the alkene epoxidation with PhIO catalysed by a chromium binaphthyl Schiff base complex immobilised on MCM-41,[2] which demonstrates that the heterogenisation of a homogeneous catalyst can result in an increase of enantioselectivity for epoxidation of unfunctionalised alkenes.

The preparation of the heterogenised chromium Schiff base complex is depicted in Scheme 1.† Species **2** was characterised by IR and FAB mass spectroscopy as well as elemental analysis.‡ Based on the structures of the iron and manganese complexes,[12] the size of **2** is estimated to be 14 Å. Treatment of **2** with MCM-41(m),[13] a modified MCM-41 having a pore size of 36 Å, in CH_2Cl_2 readily led to immobilisation of **2** on the support.§ The catalyst thus obtained is designated as **2**–MCM-41(m), as indicated in Scheme 1. By varying the amount of **2** used in the immobilisation reaction, **2**–MCM-41(m) having four different contents of **2**, namely, 0.5, 0.8, 1.8 and 3.6 wt% determined on a POEMS ICP spectrometer, was obtained. The X-ray diffraction patterns of these catalysts all resemble that of MCM-41 as well as that of MCM-41(m), indicating that, after the above immobilisation treatments, the mesoporous structure of this support remains undisrupted and the molecules of **2** should be dispersed on the surface of the support. On the other hand, the FT-Raman spectrum of **2**–MCM-41(m) is similar to that of **2** if the bands belonging to MCM-41(m) are excluded. This suggests that **2** remains intact in the heterogenised catalysts.

Since the chromium centre in **2** is either five-coordinate or six-coordinate with a substitutionally labile water molecule, immobilisation of **2** onto MCM-41(m) could be readily achieved through coordination of the chromium ion to a terminal NH_2 group of the surface-bound tether *via* simple addition or ligand substitution reactions, as in the case of our recent immobilisation of ruthenium porphyrins onto the same support.[13] As might be expected, attempts to immobilise **2** onto the unmodified MCM-41, which lacks the above mentioned NH_2 groups, have failed.

The epoxidation of a series of unfunctionalised alkenes with PhIO catalysed by **2**–MCM-41(m) was carried out in toluene for 12–36 h by using 20 mg of the catalyst, 0.1 ml of substrate and 16 mg of PhIO. The reactions were monitored by GC until completion. The results are summarised in Table 1. Besides epoxides, some minor side products such as benzaldehyde or its derivatives were also detected by GC. Efforts were first directed to optimise the content of **2** in the catalysis with *p*-chlorostyrene as substrate. As is obvious from entries 1–3 and 9 in Table 1, both the yield and ee of the corresponding epoxide increase with the content of **2** until it reaches 1.8%. However, a further increase of the content of **2** results in a decrease of the yield and ee. Therefore, we used **2**–MCM-41(m) containing 1.8% of **2** for all further studies. The effect of temperature was investigated. Interestingly, a temperature decease of 20 °C led to very little change in either the yield or ee (entries 3 and 8), in contrast to the catalysis involving free **2**, in which the ee markedly increased with a decrease in temperature (entries 10 and 11). The reusability of **2**–MCM-41(m) was also examined. After the epoxidation reaction was complete, the catalyst could be recovered simply by filtration followed by washing with CH_2Cl_2. Entries 4–7 give the results obtained for reusing



Scheme 1

Table 1 Asymmetric epoxidation of alkenes with PhIO catalysed by **2**–MCM-41(m).[a] The results obtained by using free **2**[b] (entries 10, 11, 17, 18) with *p*-chlorostyrene and *cis* β-methylstyrene are also listed

[a] All reactions were performed in toluene by using 20 mg of catalyst, 0.1 ml of substrate, and 16 mg of PhIO. This gives, for example, 0.56 mol% of **2** relative to PhIO for the 1.8% content of **2**. [b] Reaction conditions: identical to those for **2**–MCM-41(m) except 1 mol% of **2** (relative to PhIO) was used. [c] The content of **2** in **2**–MCM-41(m) was determined on a POEMS ICP spectrometer. [d] Determined by GC based on the PhI formed. [e] Determined by GC with chiral column. [f] First, [g] second, [h] third, and [i] fourth reuse of **2**–MCM-41(m) containing 1.8% of **2**. After these reuses, a total of 2–3% of Cr had leached into solution. [j] Free **2** was used instead of **2**–MCM-41(m). [k] The ratio of *cis*:*trans* = 66:31. [l] *cis* Isomer. [m] The ratio of *cis*:*trans* = 91:9.

2–MCM-41(m) up to four times. Notably, this catalyst could be reused at least two times with a total turnover number of 322 (entries 3–5) without a decrease in enantioselectivity. In contrast, a recently reported Mn–MCM-41–salen catalyst suffered from a loss of enantioselectivity of 40% ee when reused for the first time.[10] Extension of the above epoxidation reaction to other substrates also gave moderate to relatively high ees at room temperature (entries 12–16). The highest ee (73%) was obtained for *cis*-β-methylstyrene (entry 16).

Surprisingly, the heterogenised **2** exhibits significantly higher enantioselectivity than free **2** under identical conditions (entry 3 *vs.* 10 or 16 *vs.* 17). For example, with *cis*-β-methylstyrene as substrate, the ee increased by as much as *ca.* 20% upon immobilisation of **2** onto MCM-41(m) (entries 16 and 17). As the support MCM-41(m) showed negligible catalytic activity toward these oxidation reactions, the increase in chiral recognition could arise from the enhanced stability of the chromium complex upon immobilisation. Alternatively, it could also result from the unique spatial environment constituted by both the chiral binaphthyl Schiff base ligand and the surface of the support. To make clear which environment, inside or outside the channels, is responsible for the enhancement of chiral induction, we immobilised **2** on another modified MCM-41 designated as MCM-41(m-in), whose external surface was passivated with Ph_2SiCl_2, thus placing the same surface-bound tether containing the terminal NH_2 groups as in MCM-41(m) inside the channels only.[14] Under the same conditions with *p*-chlorostyrene as substrate, both **2**–MCM-41(m-in) and **2**–MCM-41(m), having similar content of **2**, afforded the corresponding epoxide in almost the same yield and ee. This shows that the environment inside the channels of the support leads to the enhancement in the chiral induction.

We acknowledge support from The University of Hong Kong and the Hong Kong Research Grants Council.

Notes and references

† *Preparation* of **2**: A mixture of anhydrous chromium(II) chloride (1 mmol) and **1** (1 mmol) in THF (20 ml) was stirred under argon at room temperature for 3 h, leading to a color change from brown to green. The mixture was then left open to the air for 3 h to allow full oxidation of chromium(II) to chromium(III). After removal of the solvent, the residual solid was recrystallised from CH_2Cl_2–hexane to give the desired product as a green solid. Yield: 70%.

‡ *Spectral data* for **2**: ν_{max}(KBr)/cm^{-1}) 3443, 1603, 1507, 1430, 1302, 1207, 1160, 1072, 820, 751, 715, 688, 539; *m/z* (FAB MS) 893 (M^+), 858 ([M − Cl]$^+$) (Calc. for $C_{34}H_{18}N_2O_2Br_4CrCl\cdot 2H_2O$: C, 43.89; H, 2.37; N, 3.01. Found: C, 43.71; H, 2.58; N, 3.21%). The ^{1}H NMR spectrum of **2** is featureless due to its paramagnetism.

§ *Preparation* of **2**–*MCM-41(m)*: A mixture of **2** and MCM-41(m) (100 mg) in CH_2Cl_2 (10 ml) was stirred at room temperature for 2 h. The solid product was then collected by filtration, thoroughly washed with CH_2Cl_2, and dried under vacuum.

Enantioselective hydroxylation of benzylic C–H bonds by D_4-symmetric chiral oxoruthenium porphyrins†

Rui Zhang, Wing-Yiu Yu, Tat-Shing Lai and Chi-Ming Che*

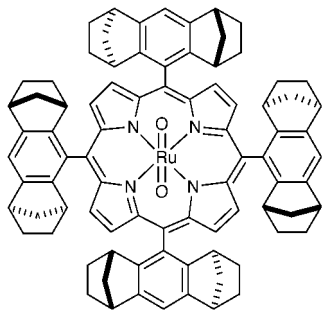
Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong. E-mail: cmche@hku.hk

Received (in Cambridge, UK) 21st May 1999, Accepted 20th July 1999

A D_4-symmetric chiral dioxoruthenium(VI) porphyrin can effect stoichiometric and catalytic enantioselective hydroxylation of benzylic C–H bonds to give enantioenriched aryl alcohols, the highest ee of 76% being attained in the catalytic oxidation of 4-ethyltoluene with 2,6-dichloropyridine *N*-oxide as terminal oxidant; the oxidations proceed *via* a rate-limiting H-atom abstraction to germinate a benzylic radical intermediate.

Despite significant advances in asymmetric alkene epoxidations,[1] the development of protocols for highly enantioselective hydroxylations of saturated C–H bonds has met with limited success. Groves and Viski first described the catalytic enantioselective benzylic C–H bond hydroxylations using a chiral iron porphyrin catalyst.[2] Recently, with the use of chiral Mn(salen) catalysts, ethylbenzene can be oxidized enantioselectively to 1-phenylethanol in 22% yield and 53% ee.[3] We herein describe a highly enantioselective benzylic C–H bond hydroxylation based on oxoruthenium complexes supported by a D_4-symmetric chiral porphyrin.

The [Ru^{II}(Por*)(CO)(EtOH)] and [Ru^{VI}(Por*)O_2] complexes {H_2Por* = 5,10,15,20-tetrakis[(1*S*,4*R*,5*R*,8*S*)-1,2,3,4,5,6,7,8-octahydro-1,4:5,8-dimethanoanthracen-9-yl]-porphyrin} were prepared by the literature methods.[4] In a



[Ru^{VI}(Por*)O_2]

degassed CH_2Cl_2 solution (containing 2% w/w pyrazole), an excess of ethylbenzene reacted with [Ru^{VI}(Por*)O_2] to afford a mixture of 1-phenylethanol (32%) and acetophenone (33%) at room temperature; the (*S*)-1-phenylethanol was obtained in 45% ee (Table 1, entry 1). This features the first well-characterized chiral oxo-metal complex capable of hydroxylating saturated C–H bonds enantioselectively. Similarly, the stoichiometric oxidations of substituted ethylbenzenes, 2-ethylnaphthalene, indane and tetrahydronaphthalene by [Ru^{VI}(Por*)O_2] also furnished enantioenriched (*S*)-alcohols, and the oxidation of 2-ethylnaphthalene registered the highest ee of 58% ee (Table 1, entry 7). In all cases, a bis-pyrazolato-ruthenium(IV) porphyrin, [Ru^{IV}(Por*)$(pz)_2$], was isolated in > 85% yield at the end of the oxidation.

† Experimental and kinetic data, including UV-vis spectral traces, dual-parameter Hammett correlation studies and representative chiral GLC chromatograms, are available from the author at the address given above.

Under pseudo-first order conditions, the ethylbenzene oxidation by [Ru^{VI}(Por*)O_2] in 1,2-dichloroethane (with 2% w/w Hpz) exhibited isosbestic UV-vis spectral changes from Ru^{VI} to Ru^{IV} porphyrin (isosbestic points at 350, 415 and 444 nm). At 313 K, the second-order rate constant (k_2) is $(7.7 \pm 0.4) \times 10^{-4}$ dm^3 mol^{-1} s^{-1}. The second-order rate constants for the oxidation of *para*-substituted ethylbenzenes had been measured, and a linear dual-parameter Hammett correlation between log k_{rel} [$k_{rel} = k_2$(4-substituted ethylbenzene)/k_2(ethylbenzene)] and the $\sigma_{JJ}^{\cdot}$ and σ_p^+ constants[5] was established: log k_{rel} = + (0.57 ± 0.04) $\sigma_{JJ}^{\cdot}$ − (0.36 ± 0.01) σ_p^+ (R = 0.99; $|\rho_{JJ}^{\cdot}/\rho^+|$ = 1.58),† consistent with a rate-limiting benzylic radical intermediate formation. The primary kinetic isotope effect (k_H/k_D) for the oxidation of ethylbenzene-d_{10} was found to be 8.9 (313 K), in accord with a rate-limiting step involving substantial C–H bond cleavage.[6]

A catalytic quantity of either [Ru^{II}(Por*)(CO)(EtOH)] or [Ru^{VI}(Por*)O_2] can effect hydroxylation of ethylbenzene using 2,6-dichloropyridine *N*-oxide (Cl_2pyNO) as terminal oxidant to produce (*S*)-1-phenylethanol in 62% yield and 72% ee at 25 °C (Table 1, entry 1). More importantly, the catalytic reactions afforded the alcohols in much higher enantioselectivity. Benzene is the solvent of choice, while the use of CH_2Cl_2 led to a lower ee of 62% (Table 1, entry 1). Likewise, other *para*-substituted ethylbenzenes were oxidized to their (*S*)-1-arylethanols in 62–76% ee and 28–72% yields under the ruthenium-catalyzed conditions (entries 2–6). Notably, the catalytic asymmetric 2-ethylnaphthalene oxidation afforded 1-naphthylethanol in 75% ee and 66% yield (Table 1, entry 7). In all cases, only alcohols and ketones were formed, and the combined alcohol and ketone yields have a mass balance of 98% of the amount of substrate consumed.

The effect of *para*-substituents on the chiral ruthenium porphyrin-catalyzed asymmetric hydroxylation of ethylbenzenes has been examined. Both electron-donating and -withdrawing substituents can promote the reaction, and the relative rate constants (log k_{rel}), established by competitive experiments, correlate linearly with the $\sigma_{JJ}^{\cdot}$ and σ_p^+ substituent constants:[5] log k_{rel} = + (0.78 ± 0.05) $\sigma_{JJ}^{\cdot}$ − (0.71 ± 0.02) σ_p^+ (R = 0.99, $|\rho_{JJ}^{\cdot}/\rho^+|$ = 1.1, Fig. 1). A primary kinetic isotope effect (k_H / k_D) of 11.2 (298 K) was found for the catalytic oxidation of ethylbenzene-d_{10}.

It is known that ruthenium porphyrin-catalyzed alkane oxidations using 2,6-dichloropyridine *N*-oxide proceed through a reactive oxoruthenium intermediate.[7] Thus, the high ee observed in the catalytic ethylbenzene hydroxylations would suggest that the chiral 'Ru=O' intermediate should preferentially abstract the *pro-S* hydrogen atom of ethylbenzene, if a hydrogen atom abstraction mechanism is operative.[2a] Because oxidation of benzyl alcohol by reactive oxoruthenium complexes involves a rate-limiting C–H bond cleavage analogous to the hydroxylation of aromatic hydrocarbons,[6d,8] the (*S*)-isomer of racemic 1-phenylethanol is expected to be more readily oxidized to acetophenone, leaving an excess of (*R*)-1-phenylethanol. However, when racemic 1-phenylethanol (1 mmol) was subjected to the ruthenium-catalyzed conditions {[Ru^{II}(Por*)(CO)(EtOH)] (0.5 μmol) and Cl_2pyNO (3 mmol) in C_6H_6}, we found that only a 4% excess of (*R*)-1-phenylethanol and 97% yield of acetophenone were produced at 42% alcohol

[a] Stoichiometric oxidation: to a degassed CH_2Cl_2 solution (2 cm^3) containing pyrazole (0.05 g) and alkane (1.0 mmol) was added $[Ru^{VI}(Por^*)O_2]$ (30 μmol) under argon; the mixture was then stirred at room temperature for 12 h. The ruthenium complex was removed by filtration through a short alumina column. After addition of 1,4-dichlorobenzene as internal standard, aliquots were analyzed by GLC for product identification and quantification. [b] Yields were based on the ruthenium oxidant used. [c] The ketone yields were calculated based on a stoichiometric ratio of oxidant-to-ketone = 2:1. [d] In C_6H_6. [e] Catalytic oxidations: a mixture of alkane (0.5 mmol), $[Ru^{II}(Por^*)(CO)(EtOH)]$ (0.5 μmol) and Cl_2pyNO (0.55 mmol) was stirred in dry and degassed C_6H_6 (5 cm^3). Aliquots were analyzed by chiral capillary GC equipped with J & W scientific Cyclodex-B or B-PM chiral column for quantification and ee determination. [f] Yields were based on the amount of alkane consumed. [g] In CH_2Cl_2.

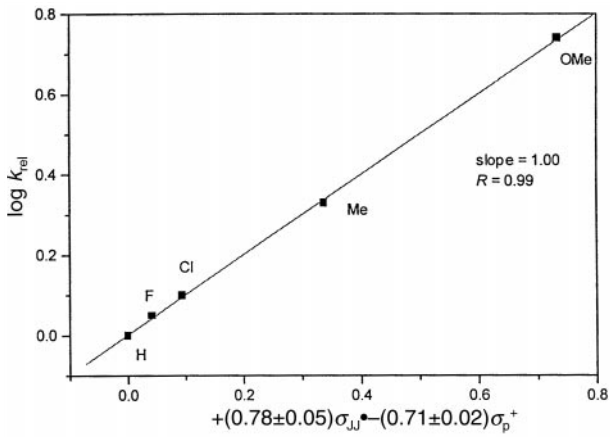

Fig. 1 Dual-parameter Hammett correlation for the ruthenium catalyzed enantioselective hydroxylation of *para*-substituted ethylbenzenes (*p*-YC_6H_4Et; Y = MeO, Me, F, Cl and H).

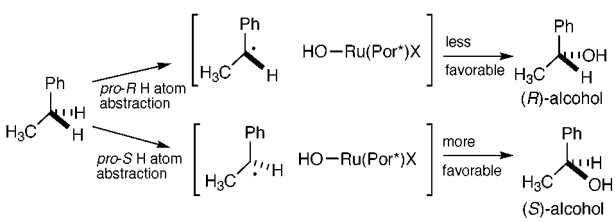

Scheme 1

consumption. The low degree of kinetic resolution for the catalytic (±)-1-phenylethanol oxidation is in constrast to the high ee of the catalytic ethylbenzene hydroxylation reactions. Assuming an oxygen rebound mechanism (Scheme 1),[9] we postulate that the production of enantioenriched alcohols may arise from the preferential collapse of the benzylic radical on the *pro-S* face *versus* the *pro-R* face at the oxygen atom rebound step, due to the good fit of the substrate into the chiral cavity.

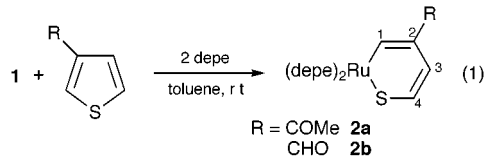
Reactions of [Ru(cod)(cot)] 1 [cod = cycloocta-1,5-diene, cot = cycloocta-1,3,5-triene] with 3-acetyl(or formyl)thiophene and 2-acetyl(or formyl) thiophene in the presence of depe [1,2-bis(diethylphosphino)ethane] lead to completely regioselective 1,2- or 1,5-insertion into the C–S bond giving the new thiaruthenacycles [Ru(SCR=CHCR′=CH)(depe)$_2$] [R = H, R′ = COMe (2a); R = H, R′ = CHO (2b); R = COMe, R′ = H (3a); R = CHO, R′ = H (3b)], respectively.

The study of coordination and reactivity of transition metal complexes with thiophene derivatives[1] is an area of increasing interest with regard to the hydrodesulfurization (HDS) reaction of fossil fuels.[2] In this sense, electron-withdrawing substituents at the 2- or 3-position of thiophene were reported to facilitate the insertion of Rh into the less congested C–S bond.[3] In addition, when small metal fragments were used, mixtures of the 1,2- and 1,5-insertion products were generally obtained.[4] We wish to report here the completely regioselective 1,2- or 1,5-insertion reactions of [Ru(cod)(cot)] **1** with thiophenes having an electron-withdrawing substituent at the 3- or 2-position, respectively, in the presence of depe.

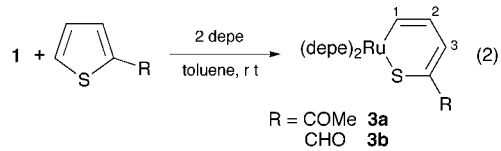
3-Acetylthiophene reacted with **1** in the presence of 2 equiv. of depe in toluene at room temperature for 12 h to give [Ru{SCH=CHC(COMe)=CH}(depe)$_2$] **2a**[5] in 72% yield, as a yellow solid [eqn. (1)].



The ^{31}P{^{1}H} NMR spectrum of **2a** shows an AMNX spin system at δ 54.8, 48.5, 45.5 and 28.8 for four different phosphorous nuclei, and the ^{1}H NMR spectrum exhibits resonances for the thiaruthenacycle protons at δ 10.73 (H^1), 6.61 (H^3) and 5.90 (H^4). 3-Formylthiophene reacted in a similar way giving [Ru{SCH=CHC(CHO)=CH}(depe)$_2$] **2b** in 68% yield [eqn. (1)]. The molecular structure of **2b** was established by X-ray structure analysis (Fig. 1).[6] The ORTEP drawing clearly shows that ring cleavage occurred at the C–S bond close to the substituent in spite of the steric repulsion. The six-membered ring defined by Ru, S, C1, C2, C3 and C4 atoms is basically planar, with no atom deviating by more than 0.1 Å from their mean plane. Furthermore, the C–C distances for C1–C2, C2–C3 and C3–C4 of 1.371(9), 1.44(1) and 1.33(1), respectively, indicate bond alternation suggesting a localized diene structure.

It is remarkable that the regioselective 1,2-insertion of the very bulky Ru(depe)$_2$ fragment takes place into the C–S bond of the 3-substituted thiophene, suggesting that the electronic effect is the major controlling factor in the selectivity of the insertion.

In contrast to the above results, **1** reacted with 2-acetylthiophene to give the 1,5-insertion product [Ru{SC(COMe)=CHCH=CH}(depe)$_2$] **3a**[7] in 84% yield, as a red solid (eqn. 2).



The ^{1}H NMR of **3a** shows resonances for the thiaruthenacycle protons at δ 8.36 (H^1), 7.98 (H^3) and 7.39 (H^2). Detailed analysis of coupling constants by homo-decoupling techniques indicated that protons H^1 and H^2 are coupled with the P nuclei (J_{H^1P} 18.0, 3.3 Hz and J_{H^2P} 12.3, 3.0 Hz) and between them ($J_{H^1H^2}$ 12.0 Hz), but H^3 only displays coupling with H^2 ($J_{H^2H^3}$ 7.5 Hz). A dtd resonance at δ 169.6 for C^1 in the ^{13}C{^{1}H} NMR spectrum of **3a** provides strong evidence for the formulation of the C–S insertion product. In addition, spectroscopic data of **3a** are comparable with those for the known thiaferracycle [Fe{SC(COMe)=CHCH=CH}(depe)$_2$] in which insertion also takes place into the C^5–S bond,[8] away from the substituent at the 2-position. 2-Formylthiophene reacted giving also the 1,5-insertion product [Ru{SC(CHO)=CHCH=CH}(depe)$_2$] **3b** in 36% yield [eqn. (2)]. Thus, the steric effect seems to be predominant in 2-substituted thiophenes. It is noteworthy that neither 2,5-dimethyl-3-acetylthiophene nor alkyl-substituted thiophenes reacted under the same reaction conditions.[9]

Reactions of **2a**, **b** and **3a** with MeI followed by treatment with NaBPh$_4$ gave exclusively the S-methylated cationic adducts [Ru(SCH$_3$CR=CHCR′=CH)(depe)$_2$][BPh$_4$] [R = H, R′ = COMe (**4a**); R = H, R′ = CHO (**4b**); R = COMe, R′ = H (**5a**)].[10] The molecular structure of **5a** has been unequivocally

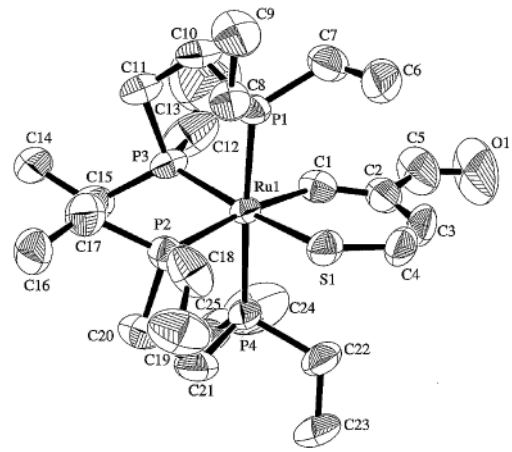


Fig. 1 An ORTEP drawing of **2b** with the numbering scheme. The hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): Ru1–C1, 2.049(6), Ru1–S1 2.427(2), C1–C2 1.371(9), C2–C3 1.44(1), C3–C4 1.33(1), C4–S1 1.715(8); S1–Ru1–C1 90.3(2), Ru1–S1–C4 110.4(3), S1–C4–C3 130.9(6), C4–C3–C2 127.4(7), C3–C2–C1 126.9(7), C2–C1–Ru1 133.4(5).

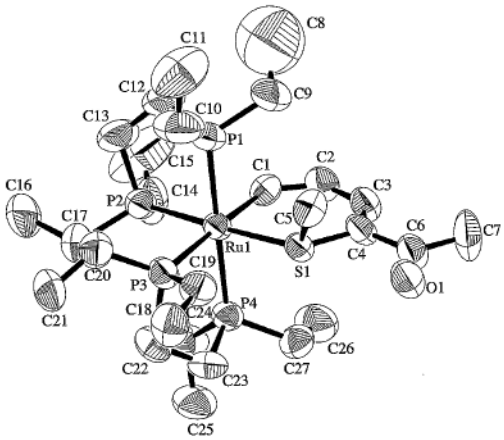

Fig. 2 An ORTEP drawing of **5a** with the numbering scheme. The tetraphenylborate anion and hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): Ru1–C1, 2.044(9), Ru1–S1 2.423(2), C1–C2 1.38(1), C2–C3 1.44(1), C3–C4, 1.37(1) C4–S1 1.739(9); S1–Ru1–C1 89.3(2), Ru1–S1–C4 115.0(3), S1–C4–C3 124.6(7), C4–C3–C2 128.9(9), C3–C2–C1 129.1(8), C2–C1–Ru1 132.8(6).

determined by single-crystal X-ray structure analysis (Fig. 2).[6]

The ORTEP drawing of **5a** also supports that 1,5-insertion takes place in the 2-substituted thiophene. The thiaruthenacycle ring in **5a** is also planar (highest deviation from the best mean plane is 0.07 Å) with a localized diene structure of the C1–C2–C3–C4 linkage.

In all cases, except for **3b**, the formation of the thiaruthenacycles was very clean and no other side-products were observed when the reactions were followed by ^{1}H and ^{31}P{^{1}H} NMR.

The present Ru-promoted C–S bond cleavage of thiophenes may be essentially interpreted by the mechanism reported by Harris and Jones.[11] Thus, thiophene coordinates to the metal through the sulfur atom, followed by attack of the metal on the adjacent carbon atom *via* donation into the C–S antibonding orbital. As previously reported for a Rh complex,[3] electron-withdrawing substituents on the thiophene facilitate the C–S bond cleavage and, in fact, that is what we observed for Ru since alkylthiophenes did not react in our system. The preferred insertion of Ru into the C–S bond close to the substitutents in **2a** and **2b** can be interpreted in terms of the large coefficient on C^2 in the LUMO of these thiophenes bearing electron-withdrawing substituents.[12]

In conclusion, for the first time, electronic effects were found to be predominant in 3-substituted thiophenes leading exclusively to 1,2-insertion of Ru into the C–S bond, whereas steric effects become much more important in 2-substituted thiophenes affording only 1,5-insertion products.

This study was partially supported by the Ministry of Education, Science, Sports, and Culture, Japan and NEDO.

TEMPO oxidations with a silica-supported catalyst

Carsten Bolm* and Thomas Fey

Institut für Organische Chemie der RWTH Aachen, Professor-Pirlet-Straße 1, D-52056 Aachen, Germany. E-mail: carsten.bolm@oc.rwth-aachen.de

Received (in Cambridge, UK) 14th July 1999, Accepted 29th July 1999

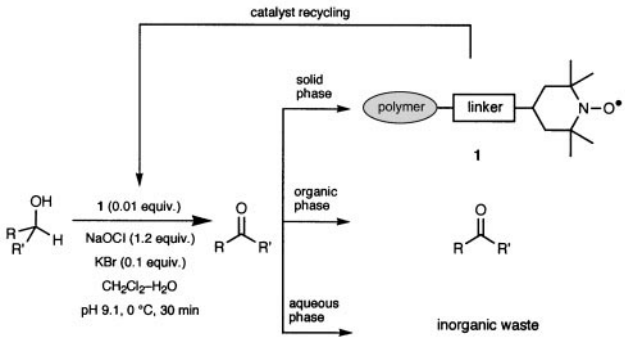
Silica-supported 1-hydroxy-2,2,6,6-tetramethylpiperidine (SG-TMP-OH) was successfully applied as a recyclable catalyst in the oxidation of various alcohols.

Aminoxyl† radicals are well-established catalysts for the oxidation of alcohols.[1] Typically, such oxidations are carried out in the presence of 1 mol% of catalyst and a stoichiometric amount of a terminal oxidant such as bleach,[2] sodium chlorite,[3] sodium bromite,[4] *tert*-butyl hypochlorite,[5] *N*-chlorosuccinimide,[6] MCPBA,[7] [bis(acetoxy)iodo]benzene,[8] or oxygen in combination with a high-valent metal salt.[9] Furthermore, electrochemical reoxidation of the catalyst is possible.[10]

Especially for large scale oxidations, the TEMPO–bleach protocol introduced by Anelli *et al.*[2] appears most useful.[11] Although usually a small quantity of the catalyst is sufficient for an efficient transformation, it is still desirable to develop improved work-up conditions which allow simple product isolation as well as catalyst separation and recycling.[12] We envisaged that both requirements could be realised by using a polymer-supported aminoxyl radical. Usually TEMPO-catalysed reactions afford the desired carbonyl compounds in high yields without the formation of significant amounts of by-product, and thus catalyst separation and product isolation could easily be accomplished by simple filtration and phase separation followed by evaporation of the organic solvent (Scheme 1).

Although several polymer-bound aminoxyl radicals have already been synthesised,[13] only a very few of them were applied as oxidation catalysts.[13*a–d*] To the best of our knowledge, none of them has been studied under the conditions mentioned above. Due to several publications concerning the application of polymer-supported oxidation reagents and catalysts,[14] and based on our own expertise in the use of heterogenised alkaloids in the Sharpless dihydroxylation reaction,[14*g*,15] we focused our attention on the attachment of the TEMPO precursor 1-hydroxy-4-oxo-2,2,6,6-tetramethylpiperidine (**2**)[16] onto silica. The synthesis of **3** (SG-TMP-OH) was accomplished by reductive amination of **2** with commercially available aminopropyl-functionalised support (Scheme 2).[17]‡ The resulting solid was carefully washed with hot MeOH using a Soxhlet extractor for several days in order to ensure complete removal of non-chemically bounded hydroxypiperidine derivatives from the surface.

SG-TMP-OH **3** was then applied as catalyst in the oxidation of various alcohols according to the Anelli protocol (Table 1).[2*a*]§ As shown by quantitative GC analysis, aldehydes and ketones were formed in high yields from the corresponding primary and secondary alcohols, respectively. Both benzylic and aliphatic substrates react equally well.

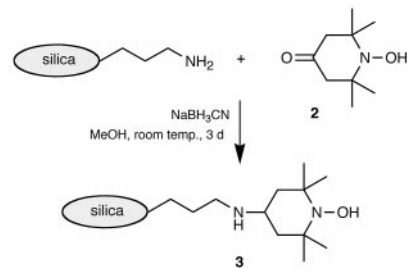


Scheme 1

In order to study the selectivity profile in the oxidation of primary and secondary alcohols, we performed competition experiments using equimolar mixtures of both. Entries 8 and 9 of Table 1 show a high selectivity towards the oxidation of the primary alcohols, which resembles the known behaviour of the unsupported TEMPO catalyst.[19] Thus, the corresponding aldehydes of nonan-1-ol and benzyl alcohol were formed in 96 and 92% yield, respectively, whereas the oxidation of the secondary alcohols nonan-2-ol and 1-phenylethanol occured in low yield only (1 and 3%, respectively). In addition, as in catalysed oxidations with TEMPO itself,[2*c*] no racemisation of optically active compounds occured (entry 10).

We finally investigated the possibility of recycling the catalyst. Therefore, the silica-bound TEMPO derivative was recovered by filtration after the reaction and reapplied in a sequence of oxidations using nonan-1-ol as substrate. The results illustrated in Fig. 1 show that even after 10 subsequent runs the catalyst activity remained high. In both substrate conversion and product yield only a minor decrease was observed, proving the high efficiency of the catalyst recovery.

In conclusion, we have demonstrated that silica-supported TEMPO is an excellent catalyst for the oxidation of alcohols, affording the corresponding carbonyl derivatives in high yields. Primary alcohols are selectively oxidised in the presence of



Scheme 2

Table 1 TEMPO oxidation of various alcohols to the corresponding aldehydes and ketones with silica-supported catalyst **3**[*a*]

Entry	Substrate	Yield (%)[*b*]
1	Benzyl alcohol	92 (75)
2	Heptan-1-ol	90
3	Octan-1-ol	88
4	Nonan-1-ol	90 (85)
5	Dodecan-1-ol	81
6	Nonan-2-ol	65
7	1-Phenylethanol	91
8	Nonan-1-ol/nonan-2-ol	96/1
9	Benzyl alcohol/1-phenylethanol	92/3
10	*(S)*-2-Methylbutan-1-ol[*c*]	60

[*a*] Oxidation experiments conducted following the protocol in note §. [*b*] Yields were determined by quantitative GC analysis using decane or dodecane as internal standard. Values in parentheses are isolated yields. [*c*] The ee of 95% remained unchanged (ref. 18).

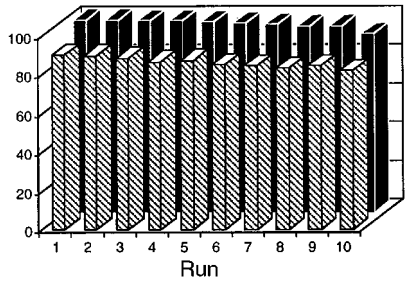


Fig. 1 Yields [hatched (%)] and conversions [black (%)] in consecutive oxidation reactions of nonan-1-ol when using silica-supported catalyst **3**.

secondary substrates. Optically active starting materials can be used without racemisation. Finally, the catalyst was shown to be stable under the reaction conditions, thus allowing it to be recycled without significant loss of activity.

This research was supported by the Katalyseverbund NRW and the Fonds der Chemischen Industrie.

Notes and references

† CAS nomenclature = nitroxyl.

‡ Aminopropyl-functionalised silica was purchased from Aldrich. According to the distributor's information the degree of functionalisation is approximately 1.0 mmol g^{-1}.

§ *General procedure* for the oxidation of alcohols with SG-TMP-OH **3** as catalyst: The reaction was performed in a glass tube with a cooling mantle. The bottom of the tube was equipped with a ceramic filter plate and a stopcock allowing easy separation of the supported catalyst from the reaction mixture by filtration. In this vessel was placed 9.2 mg of SG-TMP-OH **3** (8 μmol based on complete functionalisation; degree of functionalisation = 0.87 mmol g^{-1}). Then a CH_2Cl_2 solution (2 ml) of the alcohol (0.4 M) and decane or dodecane (0.12 M; as internal standard) was added followed by an aqueous solution (0.16 ml) of KBr (0.5 M). After the cooling of the reaction mixture to 0 °C, 2.7 ml of aq. NaOCl (diluted to a final concentration of 0.37 M and buffered by the addition of $NaHCO_3$ to a pH of 9.1) was added. Then, the reaction mixture was vigorously shaken for 30 min. After filtration, the organic phase was separated, dried over $MgSO_4$, and the product composition was analysed by means of GC [ultra-2-column (Hewlett Packard)]. The filtered solid was washed five times with water, MeOH and CH_2Cl_2 (2 ml each), air-dried, and reused as such. Preparative runs were carried out on a five-fold scale, and the reaction time was extended to 1 h. After filtration the organic layer was separated, and the aqueous phase was extracted with CH_2Cl_2 once. The combined organic phases were dried over $MgSO_4$, the solvent was removed *in vacuo*, and the crude product purified by column chromatography on silica gel with CH_2Cl_2 as eluent.

Platinum-catalyzed hydrosilylation of C_{60}: synthesis of a novel fullerene–siloxane polymer

Michael L. Miller[a] and Robert West*[b]

[a] *Department of Chemistry, Utica College, 1600 Burrstone Road, Utica, NY 13502-4892, USA*
[b] *Department of Chemistry, University of Wisconsin, 1101 University Avenue, Madison, Wisconsin 53706, USA. E-mail: west@chem.wisc.edu*

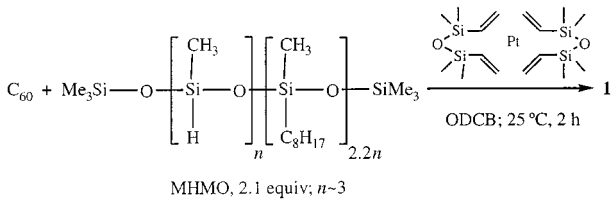
Received (in Columbia, MO, USA) 30th April 1999, Accepted 27th July 1999

The hydrosilylation of buckminsterfullerene with the oligomer poly(methylhydridomethyloctylsiloxane) produced a soluble, oxidation-resistant fullerene–siloxane copolymer, in which the siloxane oligomer is multiply attached to the C_{60} moiety by covalent Si–C bonds essentially encapsulating the fullerene cage.

With the development of a method for the preparation of macroscopic amounts of buckminsterfullerene, the chemistry of this closed shell molecule has been extensively investigated.[1,2] Finding useful chemical applications for C_{60}, however, has been met with limited success, partly due to its low solubility in common organic solvents.[3] Thus, much of the organic chemistry involving this molecule focuses on the synthesis, isolation, and characterization of its derivatives. It is hoped that some of these compounds will find useful application due to their increased solubility and unique electronic properties.

In 1991 Fagan *et al.* published the synthesis of C_{60}-η^2-bis(triphenylphosphine)platinum, the first fullerene–metal complex.[4] This landmark paper has led to further developments in fullerene–metal chemistry.[5] In addition, since platinum is the favored catalyst for hydrosilylation, it raised the possibility that C_{60} might be derivatized by R_3SiH addition reactions.[6] We report the metal catalyzed hydrosilylation of C_{60} with poly(methylhydridomethyloctylsiloxane), MHMO, and characterization of the product, an unusual fluid.[7]

The original goal of this research was to synthesize a siloxane copolymer with pendant C_{60} units. C_{60} was synthesized using a modified graphite evaporation apparatus and was purified by continuous column chromatography.[8,9] The reaction of pure C_{60} with 2.1 equiv. of MHMO ($M_w \approx 1470$; 3.1 Si–H/chain), and 0.05 equiv. of the platinum catalyst, (divinyltetramethyldisiloxane)platinum(0), afforded a shiny, black oil **1** in 83% yield (Scheme 1).† Product **1** was relatively viscous and displayed a low molecular weight, low dispersion pattern using size exclusion chromatographic analysis with an estimated molecular weight of *ca.* 4000 (Fig. 1). **1** was readily soluble in tetrahydrofuran, toluene, benzene, chloroform and carbon disulfide; slightly soluble in hydrocarbons such as hexane, cyclohexane and 3-methylpentane; and insoluble in water and alcohols. In contrast to many fullerenes and fullerene derivatives, **1** was resistant to air oxidation.[10] The IR absorption spectrum of the purified compound showed no absorption in the 2100–2300 cm^{-1} region, indicating the absence of any Si–H functionality.



Scheme 1

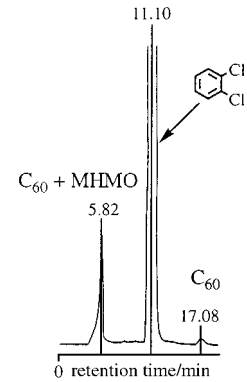


Fig. 1 GPC chromatograph of the reaction mixture after 1 h; a small amount of unreacted C_{60} is still present.

The UV–VIS spectra of the product and of unreacted C_{60} in THF are shown in Fig. 2. The strongest absorption band observed in the spectrum of unreacted C_{60} (λ = 256 nm) has completely disappeared in the absorption profile of **1**, with a coincident increase in the intensity of the band at λ = 220 nm. The intensity of the absorption at λ = 333 nm is also reduced. These changes are characteristic of a highly derivatized C_{60} moiety, where more than two π-bonds of the fullerene cage have been reduced.[11]

The ^{1}H NMR spectra of unreacted MHMO and of the product are shown in Fig. 3.‡ The upfield signals in both spectra can be unambiguously assigned to alkyl substituents, shifted by < 0.05 ppm on going from the siloxane copolymer to the product. In the ^{1}H NMR spectrum of unreacted MHMO, a characteristic Si–H resonance is found at δ 5.18. In the product this is replaced by a resonance at δ 3.99 which we attibute to hydrogen attached to the fullerene cage.[13] Integration of this signal with an internal standard suggests the incorporation of 5.9 protons per fullerene–siloxane adduct.

Analysis of the MALDI mass spectrum indicated an average parent ion mass of 3650 au. The C_{70}–siloxane adduct was also observed when a mixture of C_{60} and C_{70} was used. (Fig. 4).

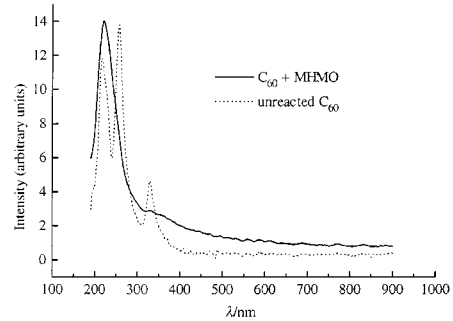

Fig. 2 UV–VIS absorption spectra of **1** (THF) and of C_{60} (toluene).

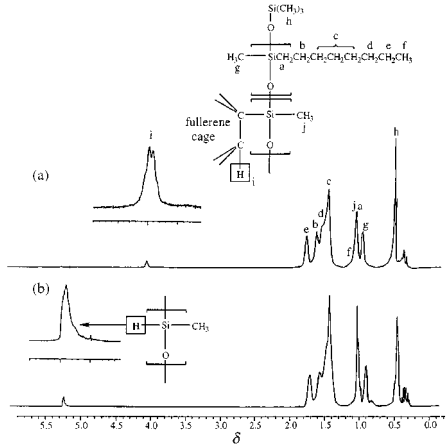

Fig. 3 ^{1}H NMR spectra (500 MHz; [$^2H_6$]benzene) with designations of H and C atoms for tentative assignment of ^{1}H and ^{13}C NMR resonances. (a) polymer **1** and (b) poly(methylhydridomethyloctylsiloxane).

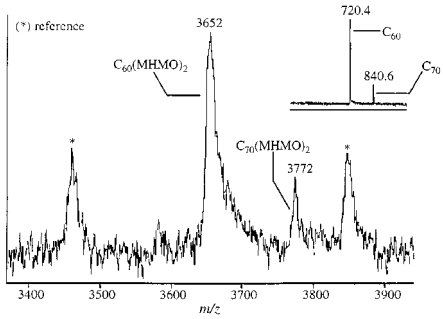

Fig. 4 MALDI mass spectrum of **1**. Inset: unreacted C_{60}/C_{70} mixture.

The analytical and spectroscopic data for **1** are inconsistent with the anticipated pendant structure. The molecular weight determination indicates that **1** is a 2:1 adduct of the siloxane copolymers with C_{60}. The lack of Si–H bonds in the product suggests that every Si–H silicon atoms in the polymer becomes attached to the fullerene cage. We propose a structure in which the C_{60} moiety is surrounded and essentially encapsulated by two siloxane molecules, both multiply attached. A hypothetical representation of the structure is shown in Fig. 5. The sharp GPC peak and unusual resistance to air oxidation are also consistent with the proposed structure of this hybrid siloxane–fullerene fluid. The fullerene ^{13}C resonances are also highly indicative of a reduced fullerene cage.

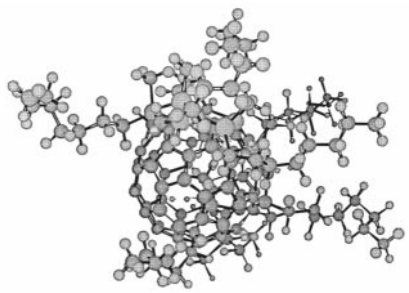

Fig. 5 A schematic representation of 'shrink-wrapped' fullerene. One of the siloxane adducts has been removed to reveal the C_{60} moiety.

The order of the addition of the platinum catalyst was found to be important.[14] If buckminsterfullerene was allowed to stir with the platinum complex before the addition of the poly(alkylhydridosiloxane), an insoluble precipitate would form; this precipitate, which we suppose to be a platinum–fullerene adduct, was unreactive towards the poly(alkylhydridosiloxane) and greatly reduced the overall yield of **1**.

This research was supported by a grant from the National Science Foundation.

Notes and references

† *Reagents and conditions*: MHMO polymer was obtained from Gelest, Inc. Chloroplatinic acid ($H_2PtCl_4·6H_2O$), Aldrich, was used without further purification and stored under argon with refrigeration. The tetramethyldivinyldisiloxane platinum(0) complex was prepared by the reaction of chloroplatinic acid and 1,1,3,3-tetramethyl-1,3-divinylsiloxane $(CH_2{=}CHSiMe_2)_2O$ (Gelest) to yield a 16 wt% platinum solution.

All experiments were carried out with Schlenk techniques under a dry argon atmosphere. All solvents were distilled immediately before use. NMR: Bruker AM-500 instrument, the solvent was used as an internal standard, with TMS as an external standard: [$^2H_6$]benzene (δ_H 7.15), CS_2 (δ_C 198), $CDCl_3$ (δ_{Si}). IR: Mattson FTIR spectrometer (KBr plates, neat). GPC analysis: Waters Associates LC system {Shodex KF-802 column; THF: flow rate, 1.0 ml min^{-1}; UV detector, (λ = 254 nm)}. UV–VIS: Perkin Lambda Array 3840 spectrometer (THF).

Synthesis of **1**: in a typical experiment, MHMO siloxane copolymer (130 mg, 0.087 mmol) was added to divinyldisiloxane Pt catalyst (2.5 mg, 0.013 mmol) dissolved in 5 ml degassed *o*-dichlorobenzene. The solution was stirred for 15 min at which point the clear, colorless mixture had become straw-yellow. A clear, purple solution of C_{60} (30 mg, 0.042 mmol) in 24 ml of benzene was added. The reaction mixture immediately darkened and became opaque. After stirring for 2.75 h at 25 °C, the mixture was loaded onto an activated silica gel column and the amber-colored fraction was collected using benzene–MeOH (9:1) solution as the mobile phase (under 7.5 psi N_2). Some black, insoluble material remained on the column head. Removal of the solvent afforded 122 mg (80%) of a dark brown oil (**1**). GPC analysis indicated that no unreacted C_{60} remained in the product. The material was then characterized as previously described. Exposure of **1** to air for several months led to no change in its spectra or its solubility.

Silylacetylene dendrimers: synthesis and characterization

Tsukasa Matsuo, Kumiko Uchida and Akira Sekiguchi*

Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki, 305–8571, Japan.
E-mail: sekiguch@staff.chem.tsukuba.ac.jp

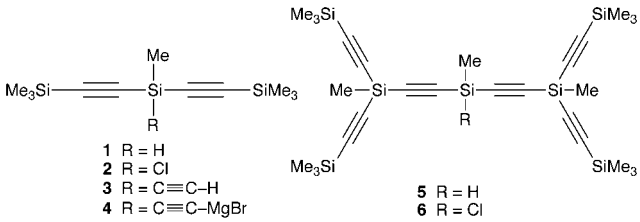
Received (in Cambridge, UK) 25th June 1999, Accepted 5th August 1999

The first silylacetylene dendrimers (1G and 2G) with alternating silicon–acetylene units [(SiC≡C)$_n$] have been synthesized and characterized by spectroscopic methods; the X-ray structure of 1G is reported.

Nanochemistry is a rapidly expanding field that is concerned with the synthesis, characterization and properties of structures of nanosize dimensions.[1] Dendrimers with a regular, three-dimensional, tree-like structure have attracted much attention as well-defined nanosize compounds. In the past 10 years, there has been increasing interest in the synthesis and properties of dendritic molecules.[2] Phenylacetylene dendrimers and related compounds are well known as a class of dendrimers containing acetylene units.[3] However, there are no published studies on dendrimers with alternating E (E = CR, SiR *etc.*) and carbon–carbon triple bonds [(EC≡C)$_n$], due to the instability of polyacetylene derivatives.[4] We report here the structurally defined nanoscale synthesis of the first silylacetylene dendrimers with alternating silicon–acetylene units [(SiC≡C)$_n$] up to the second generation with 22 silicon atoms and 21 acetylene units.

All of the previously characterized silicon-containing dendrimers, *e.g.* carbosilane dendrimers,[5] siloxane dendrimers[6] and polysilane dendrimers,[7] have been made solely by the divergent method. However, the divergent method is not suitable for silylacetylene dendrimers due to the problem of the deprotection step. Thus, we have applied a convergent method for the unprecedented synthesis of silylacetylene dendrimers.

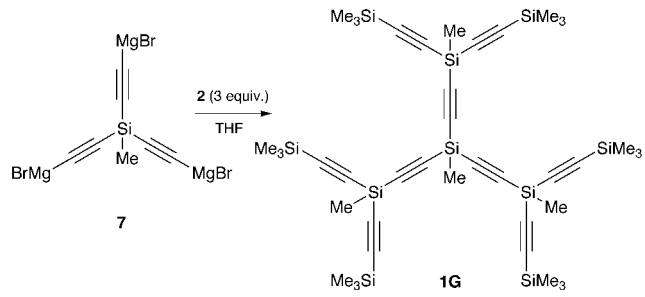
The preparation of the silylacetylene dendrimers starts with the synthesis of the chlorosilanes **2** and **6**.† First, $MeHSiCl_2$ was reacted with (trimethysilyl)ethynylmagnesium bromide in Et_2O



to give diyne **1** in 76% yield. Then, the Si–H moiety of **1** was converted to a Si–Cl moiety (**2**) using catalytic $PdCl_2$ in CCl_4 (85%). Next, **2** was reacted with ethynylmagnesium bromide to yield triyne **3** in 87% yield. After treatment of ethylmagnesium bromide with **3**, the resulting Grignard reagent **4** was added to $MeHSiCl_2$ to produce hexayne derivative **5** in 79% yield. Finally, the Si–H moiety of **5** was converted to a Si–Cl moiety (**6**) in CCl_4 using benzoyl peroxide (BPO) (52% yield).

As a core part, triyne Grignard reagent **7** was prepared from triethynylmethylsilane[8] with 3 equiv. of ethylmagnesium bromide in THF. Species **1G** was isolated as colorless crystals by the reaction of **7** with 3 equiv. of dendron **2** in THF (48% yield, Scheme 1). Crystallization from benzene afforded fine crystals of **1G** containing three molecules of benzene. However, these crystals quickly become opaque when removed from the mother liquor.

The molecular structure of **1G**·3C_6H_6 and the packing of the molecule in the crystal's unit cell are shown in Figs. 1 and 2, respectively.‡ There are three independent molecules in the unit cell, and the crystal structure possesses a crystallographic three-fold axis. Unlike previously reported dendrimers, **1G** has a nearly planar structure due to the rigid linear acetylene units, with a diameter of about 2 nm. The two molecules of **1G** lie in an alternating fashion to produce layers, in which the dendritic arms of these two molecules are arranged to give a staggered conformation through the core Si–Me bond. The benzene molecules fill spaces between the layers. The C–C triple bond



Scheme 1

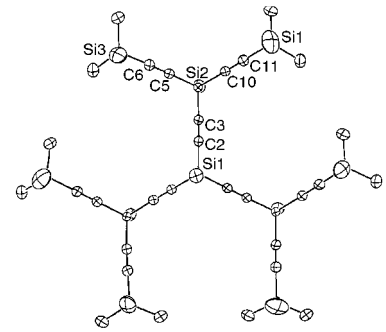


Fig. 1 Structure of **1G**·3C_6H_6 (hydrogen atoms are omitted for clarity). Selected bond distances (Å) and angles (°) are: Si1–C2 1.831(5), Si2–C3 1.835(5), Si2–C5 1.827(5), Si2–C10 1.828(5), Si3–C6 1.851(5), Si4–C11 1.849(5), C2–C3 1.205(6), C5–C6 1.208 (7), C10–C11 1.211(7); Si1–C2–C3 178.3(5), Si2–C3–C2 177.3(4), Si2–C5–C6 177.5(5), Si2–C10–C11 178.3(5), Si3–C6–C5 179.7(5), Si4–C11–C10 179.7(5).

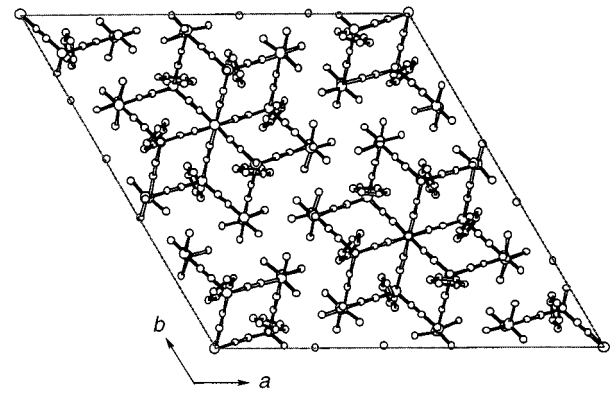

Fig. 2 Perspective view of **1G**·3C_6H_6 from the direction of the *c* axis.

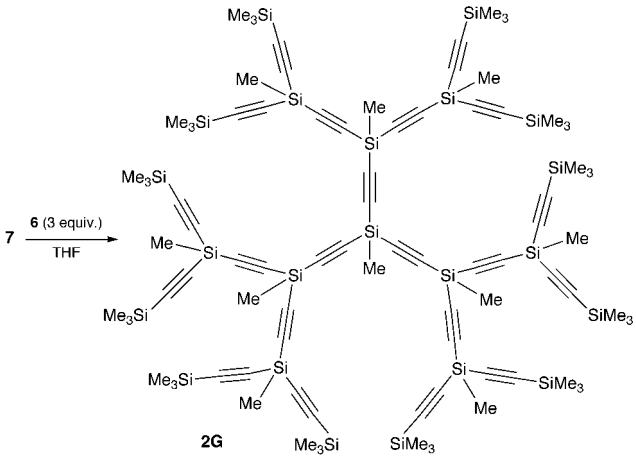

Scheme 2

lengths are 1.205(6)–1.211(7) Å [av 1.208(7) Å], and the Si–C (sp) single bond lengths are 1.827(5)–1.851(5) Å [av. 1.837(5)Å]. The bond angles of the acetylene units [Si–C(sp)–C(sp)] are almost linear {177.3(4)–179.7(5)° [av. 178.5(5)°]}.

Dendrimer **2G** was obtained as a colorless glassy solid by the reaction of **7** with 3 equiv. of dendron **6** in THF (18% yield, Scheme 2).§ The structure of **2G** was characterized by NMR spectroscopy and matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry. The MALDI-TOF mass spectrum showed an intense ion peak at 1836.8 ($M + Na^+$), in agreement with the formula $C_{88}H_{138}Si_{22} + Na^+$. In the ^{29}Si NMR spectrum, four sets of signals were observed at δ −68.3, −66.5, −66.3 and −17.4. The signal appearing at δ −17.4 is assignable to the terminal trimethylsilyl groups. The other three signals at higher field are assignable to triethynyl-substituted silicon atoms. The ^{13}C NMR showed eight resonances of sp carbon atoms; δ 108.3 (3 C) and 108.6 (3 C) for the innermost acetylene carbons, δ 107.6 (6 C) and 110.1 (6 C) for the middle acetylene carbons, and δ 106.22 (6 C), 106.23 (6 C) 117.3 (6 C), and 117.4 (6 C) for the outermost acetylene carbons. Assignments of these ^{13}C resonances were made on the basis of peak intensities. Four sets of methyl groups were also found in the ^{13}C NMR spectrum; the core SiMe at δ −0.2 (1 C), the adjacent branched SiMe at δ −0.3 (3 C), the next adjacent branched SiMe at δ 1.0 (6 C), and the peripheral $SiMe_3$ at δ −0.55 (18 C) and −0.53 (18 C). The outermost two (trimethylsilyl)ethynyl groups are diastereotopic.

The polyyne dendrimers (**1G** and **2G**) are thermally stable up to 200 °C. However, they are highly sensitive to both acidic and alkaline conditions, and the Si–C(sp) bonds are easily cleaved. In the UV-VIS spectrum of **2G**, two absorption bands are observed at 210 (ε = 28900) and 219 nm (ε = 15300), whose intensities are about three times larger than those of **1G**, at 210 (ε = 10700) and 219 nm (ε = 5200).

This work was supported by Grants-in-Aid for Scientific Research (Nos. 09239101, 10304051, 1113321, 11166209) from the Ministry of Education, Science and Culture of Japan, and TARA (Tsukuba Advanced Research Alliance) fund.

Notes and references

† A THF solution of ethylmagnesium bromide (30 ml, 24 mmol) was added to triethynylmethylsilane (0.91 g, 7.7 mmol) in THF (10 ml) to produce the Grignard reagent of the triyne. Bis(trimethylsilylethynyl)methylchlorosilane **2** (6.00 g, 25 mmol) in THF (30 ml) was added to the THF solution of the resulting Grignard reagent **7**, and the mixture was stirred overnight. Usual workup followed by Kugelrohr distillation gave **1G** as colorless crystals (180–190 °C/0.2 mmHg). Yield 48% (3.05 g), mp 115–118 °C; δ_H(300 MHz, $CDCl_3$) 0.18 (s, 54H, CH_3), 0.47 (s, 9H, CH_3), 0.52 (s, 3H, CH_3); δ_C(75.5 MHz, $CDCl_3$) −0.4 (CH_3), 0.5 (CH_3), 1.0 (CH_3), 105.5 (C), 106.9 (C), 109.4 (C), 117.0 (C); δ_{Si}(59.6 MHz, $CDCl_3$) −69.0, −67.3, −17.4 [calc. (MALDI): 850.8 ($M + Na^+$), found: 850.8].

‡ *Crystal data* for **1G**·3 C_6H_6: $C_{40}H_{66}Si_{10}\cdot 3C_6H_6$, M = 1062.17, trigonal, a = 31.061(1), c = 12.566(1) Å, V = 10499.3(3) Å^3, T = 180 K, space group = $P3$, Z = 6, ρ_{calc} = 1.008 g cm^{-3}. Diffraction data were collected on a Mac Science DIP2030K Image Plate Diffractometer employing graphite-monochromatized Mo–Kα radiation (λ = 0.71073 Å). The final R factor was 0.054 (R_w = 0.051) for 7207 reflections with $I > 3\sigma(I)$. Single crystals of **1G**·3 C_6H_6 were obtained by crystallization from benzene, mounted in a glass capilary tube and transferred to the cold gas stream of the diffractometer. The structure was solved by the direct method and refined by the full-matrix least-squares method. CCDC 182/1363. Received (in Cambridge, UK) 21st May 1999, Accepted 16th July 1999

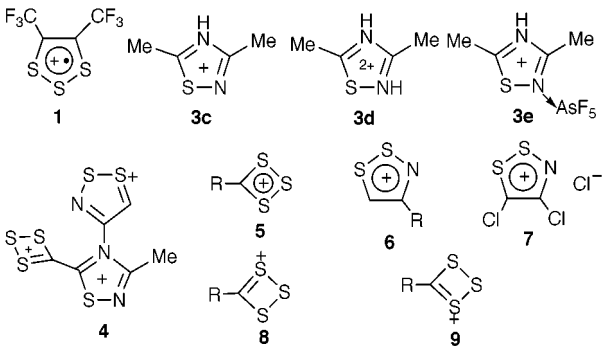
RCN (R = C_6F_5, Me) reacts with $S_n(AsF_6)_2$ (n = 4, 8) in liquid SO_2 to give the corresponding 3,5-disubstituted-1,2,4 thiadiazoles, and also, in the MeCN case, the tricyclic trication 4 containing the trithietanylium -$\overline{CSSS}^+$ and 1,2,3-dithiazolium -$\overline{CSSNCH}^+$ rings formed by the oxidation of methyl groups by sulfur homopolyatomic cations.

The isolation of stable soluble salts of the homopolyatomic cations of groups16 and 17[1] has allowed the exploration of their chemistry, leading to new classes of compounds.[2] Reactions of sulfur cations with F_3CCCCF_3 and CF_3CN gave the new radical cations $F_3C\overline{CSSSSCCF_3}^{+\cdot}$ **1** and $F_3C\overline{CNSSS}^{+\cdot}$ quantitatively,[3]



and with dicyanogen the diradical $^{+\cdot}\overline{SSSNCCNSSS}^{+\cdot}$.[4] In an attempt to probe the generality of such reactions, we found that with C_6F_5CN, **2a** and **2b** were obtained, and with MeCN, derivatives of **3a** were formed. This furnishes a new, simple, high yield synthetic route to 3,5-disubstituted 1,2,4-thiadiazoles from nitriles with relatively low ionisation energies.[5]

The reaction of an equal molar mixture of $S_4(AsF_6)_2$ and $S_8(AsF_6)_2$ with MeCN gives the AsF_6^- salt of **4**, as well as AsF_6^- salts of **3c**, **3d** and **3e**. Species **4** contains the trithietanylium ring **5**, the first example of the -$\overline{CXXX}^+$ (X = O, S, Se, and Te) heterocyclic ring system, and a 1,2,3-dithiazolium ring **6**, formed by the oxidation of the methyl groups by sulfur cations and transfer of the protons to **3a** (Scheme 1). This reaction is reminiscent of the oxidation of $ArCH_3$ to $ArCO_2H$ by strong oxidising reagents.[6] The synthesis of the chloride of **5** (R = Ph) has been claimed,[7] but no structural evidence has been reported. Fused derivatives of **6**, Herz salts, are well known,[8] and recently, the X-ray structure of **7** (Appel's salt) was determined.[9]

The structures of **2b**† and the AsF_6^- salts of **3c**,‡ **3e**§ and **4**¶ were determined by X-ray crystallography. Species **4** dimerises by weak electrostatic interactions [S(5)–N(4a) 2.946(6) Å]. The centrosymmetric dimer is shown in Fig. 1. All rings are planar, and calculated (at MPW1PW91/6-31G* level)‖ distances and

3c	3.07 (3.05)	2.75 (2.89)	12.33 (9.69)	—	14.3 (16.0)	192.9 (205.0)	164.3 (173.5)	15.5 (16.9)
3d[c]	3.50 (3.85)	3.35 (3.66)	13.21 (10.50)	12.93 (10.10)	17.0 (21.1)	196.1 (214.4)	170.9 (185.3)	15.6 (19.5)
3e[c]	3.39 (3.09)	3.24 (3.47)	12.74 (9.47)	—	15.8 (16.6)	193.7 (202.7)	169.0 (175.6)	16.3 (18.3)

[a] Chemical shifts were obtained at −70 °C in liquid SO_2, using $NH_4(AsF_6)$ (δ_H 5.80) or MeCN·AsF_5 (δ_H 2.67, δ_C 110.7) as internal standards. [b] Isotropic NMR shielding tensors were calculated at the MPW1PW91/6-311G(2DF)//MPW1PW91/3-21G* level and referenced against calculated TMS values. [c] ^{1}H and ^{13}C chemical shifts were assigned based on HMQC and HMBC experiments at −70 °C.

bond angles are in good agreement with the values derived from the X-ray structure. The structure of the observed 1,2,4-thiadiazolium ring fragment in **4** does not differ significantly from that in **3c** and **3e**. Although the $-\overline{CSSS}^+$ ring is formally related to the 6π square planar S_4^{2+} ring,[1] the cyclobutadiene dianion,[10] and 1,2-dithietes,[11] it can be represented by the valence bond structures **8** and **9**, consistent with the average Pauling bond orders of 1.35 (C–S) and 1.06 (S–S).

C_6F_5CN (3.283 g; 17.00 mmol) reacted with $S_4(AsF_6)_2$[12] (2.198 g; 4.344 mmol) in SO_2 (11.917 g) in a two-bulb Pyrex glass vessel incorporating a medium sintered-glass frit (apparatus and techniques given in ref. 12). After 3 days, insoluble S_8 (FT-Raman), OSF_2, AsF_3 (gas phase IR and ^{19}F NMR), 5.136 g of a mixture of **2a** (elemental analysis, ^{19}F NMR) and **2b** (elemental analysis, ^{19}F NMR, X-ray crystal structure, MS, IR and FT-Raman), and $S_n(AsF_6)_2$ ($n \approx 19$) (colour, EPR) were identified.**

The AsF_6^- salts of **3c**, **3e** and **4** were prepared by the reaction of MeCN (0.5108 g; 12.443 mmol) and an equal molar mixture of $S_n(AsF_6)_2$ (n = 4, 8) [prepared by the reaction of S_8 (1.0222 g; 31.878 mmol) and AsF_5 (2.6668 g; 15.694 mmol) in SO_2 (12.991 g)][3] for about 15 days under strictly anhydrous conditions.[12] The overall molar ratio of MeCN, $S_4(AsF_6)_2$ and $S_8(AsF_6)_2$ was 4:1:1. After slowly removing the solvent and washing out the most soluble products (minor), the obtained mixture contained significant amounts of white needle-like crystals of the AsF_6^- salt of **3e** and dark red brick-like crystals of the AsF_6^- salt of **4**. The mixture was dissolved in SO_2, leaving insolubles (including the AsF_6^- salt of **4** and S_8), and the obtained solubles were identified as a mixture of the AsF_6^- salts of **3c**, **3d** and **3e** by multinuclear NMR studies, here and in related studies. Observed and calculated NMR results are in reasonable agreement (Table 1). OSF_2 and AsF_3 (^{19}F NMR) and minor amounts of deprotonated species (*in situ* ^{13}C studies) were also identified. The formation of S_8 indicates that sulfur cations were reduced during the deprotonation process of the methyl groups. In a related reaction of $S_4(AsF_6)_2$ and **3a**,†† crystals of the AsF_6^- salt of **3c** were obtained and the X-ray crystal structure determined.

Hitherto the chemistry of homopolyatomic sulfur and selenium cations has been restricted to hydrogen-free compounds with the exception of a preliminary report of the reaction of E_n^{2+} (E = S, Se, n = 4, 8) with alkanes and toluene giving products that included sulfides and selenides.[13] This work suggests an extensive novel organic chemistry of homopolyatomic cations of group 16, presently under investigation.

We thank Dr Ingo Krossing for valuable advice on the theoretical calculations, Dr Larry Calhoun (UNB) for his assistance with numerous NMR experiments, Dr J. Britten (McMaster University) for X-ray data collection on species **3e** AsF_6 and **4** $(AsF_6)_3$, and NSERC for an operating grant (J. P.).

A new nonionic surfactant pathway to mesoporous molecular sieve silicas with long range framework order

Wenzhong Zhang, Brian Glomski, Thomas R. Pauly and Thomas J. Pinnavaia*

Department of Chemistry and Center for Fundamental Materials Research, Michigan State University, East Lansing, MI 48824-1322, USA. E-mail: pinnavai@cem.msu.edu

Received (in Oxford, UK) 16th June 1999, Accepted 2nd August 1999

Mesoporous molecular sieve silicas with ordered structures are formed from tetraethylorthosilicate (I^0) in a new reaction pathway based on nonionic $R(EO)_nH$ surfactants (N^0) and denoted $(N^0M^{n+})I^0$, wherein electrostatic forces are introduced into the assembly process through $-(EO)_nH$ complexation of small metal cations (M^{n+} = Li^+, Co^{2+}, Ni^{2+}, Mn^{2+} and Zn^{2+}).

The long-range structures of mesoporous molecular sieve silicas and other metal oxides are determined in part by the pathways used to assemble the polymerizable inorganic reagent at the surface of the structure-directing supramolecular micelle.[1] Assembly pathways that utilize electrostatic charge matching between ionic surfactants (S^+ or S^-) and inorganic reagents (I^+ or I^-) typically afford hexagonal, cubic or lamellar structures that minimize the electrostatic energy.[2,3] In contrast, coulombic forces are absent in pathways that exclusively utilize H bonding interactions between electrically neutral surfactants (S^0) and inorganic reagents (I^0).[4] Consequently, S^0I^0 pathways and related N^0I^0 pathways based on non-ionic polyethylene oxide surfactants,[5] afford disordered framework structures with wormhole-like channel motifs.[6]

Electrically neutral assembly pathways offer several attractive features for the preparation of mesoporous molecular sieve silicas.[4,5] For instance, assembly can be carried-out at near-neutral pH and relatively low reaction temperatures (20–65 °C). Also, recovery of the surfactant by simple solvent extraction can be achieved without sacrificing the surface areas and pore size fidelity obtained through charge matching pathways. In addition to these processing advantages, the pore branching and, especially, the complementary textural porosity associated with wormhole frameworks, can improve catalytic reactivity by facilitating access to reactive sites in the framework.[7] Nevertheless, long range order is desirable for certain electronic and photonic applications where structural periodicity can be important.[8]

In the present work we describe the synthesis of ordered silica mesostructures without sacrificing the processing advantages of neutral surfactant assembly. Our approach is based on a new pathway, denoted $(N^0M^{n+})I^0$, in which hydrogen bonds are formed between a cationic metal complex form of a nonionic (N^0) polyethylene oxide surfactant of the type $R(EO)_nH$ and the electrically neutral inorganic precursor (I^0). The complexation of small M^{n+} cations by the EO groups of N^0 brings the assembly process under electrostatic control and forms ordered mesostructures in much the same way as the recently reported acid-mediated $N^0(H^+X^-)I^+$ pathway,[9] except that strong acid conditions are avoided.

As shown by the representative X-ray powder diffraction pattern in Fig. 1A, one-dimensional hexagonal mesostructures were formed upon hydrolysis of tetraethylorthosilicate (TEOS) at 25–65 °C in the presence of Brij 56 [$C_{16}H_{33}(EO)_{10}H$], Triton X-100[$C_8H_{17}(C_6H_4)(EO)_{10}H$], and Tergitol 15-S-12 and the chloride salts of Co^{2+}, Ni^{2+}, Mn^{2+} and Zn^{2+} as structure modifiers at a reaction stoichiometry of H_2O/Si = 85, N^0/Si = 0.04–0.07 and M^{2+}/N^0 = 0.5–2.0. All of these structure-modifying cations are known to form complexes with polymeric EO units.[10] For each modifier, a hexagonal mesostructure was indicated by the presence of at least three XRD lines that could be indexed as 100, 110 and 200 reflections (*cf.*, Fig. 1A). Consequently, these one-dimensional hexagonal framework structures are analogous to MCM-41[2] and SBA-3 silicas[3] in long range order. In the absence of the metal ion salts, only wormhole structures with a single broad diffraction line were formed.

The incorporation of lithium chloride into the reaction mixtures also yielded hexagonal mesostructures. Interestingly, however, metals such as Fe^{3+}, Cr^{3+} and Rh^{3+} afforded only wormhole structures. The inability of these latter cations to induce long range electrostatic order presumably is related to their formation of polynuclear oxocations[11] under near neutral conditions of pH and the inability of these large ions to form stable complexes with the $(EO)_n$ segment of the N^0 surfactant.

Decreasing the divalent metal ion concentration in the reaction mixture to M^{2+}/N^0 values in the range 0.10–0.20 results in an ordered structure different from the one-dimensional hexagonal frameworks described above. Fig. 2 provides a representative TEM image and an electron diffraction pattern for this new structure in comparison with the hexagonal framework formed by $(N^0M^+)I^0$ assembly. The deviation from a hexagonal structure most likely is associated with a change in the surfactant packing parameter upon decreasing the average charge on the surfactant head group through metal ion complexation. Similar TEM images and electron diffraction patterns have been reported for electrostatically assembled cage–like frameworks with 3D hexagonal symmetry,[12] as well as for cubic and faulted 3D hexagonal–cubic structures.[13] The X-ray powder diffraction patterns of the products formed at lower M^{2+}/N^0 values contain only a single, well-resolved line (*cf.*, Fig. 1B), which precludes a definitive structural assignment. Nevertheless, the TEM and electron diffraction properties

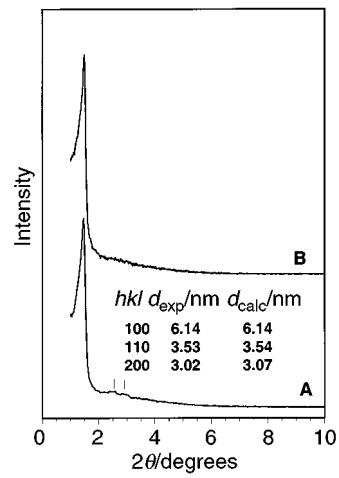

Fig. 1 XRD patterns of silica molecular sieves formed through $(N^0M^{n+})I^0$ assembly at 45 °C: (A) the product assembled at a Co^{2+}/Brij 56 ratio of 0.50; (B) the product formed at a Co^{2+}/Brij 56 ratio of 0.12. The N^0/Si ratio was 0.04 in both cases and the samples were calcined at 600 °C. Analogous patterns were obtained for solvent-extracted products.

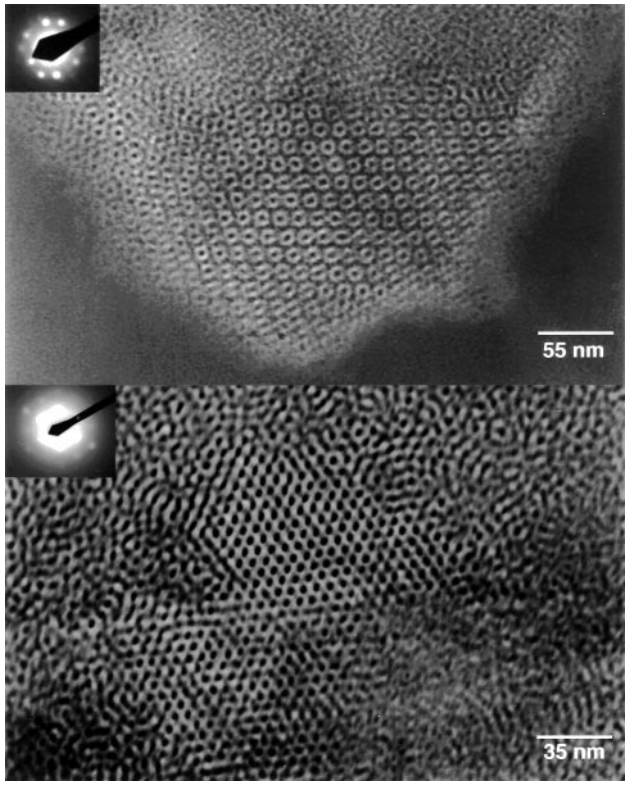

Fig. 2 TEM images and electron diffraction patterns (insets) of the silica mesostructures assembled at Co^{2+}/Brij 56 ratios of 0.50 (lower image) and 0.12 (upper image).

closely resemble the faulted 3D hexagonal–cubic structures recently observed for silica films on glass,[12] and we tentatively favor this type of 3D faulted structure.

The N^0 surfactant is easily removed from the ordered mesostructures by ethanol extraction or by calcination. Moreover, the solvent-extracted products are free of both framework metal ions and the structure-mediating metal salt. These observations are consistent with our proposed $(N^0M^{n+})I^0$ pathway, wherein hydrogen bonds are formed between the uncomplexed EO oxygen atoms of the cationic (N^0M^{n+}) complex and the silanol protons of the hydrolyzed I^0 precursor. Charge balance at the surfactant–silica interface is achieved through ion pairing with the counter anions of the metal salt. However, the anion does not play a direct structure-directing role, because the same structures are obtained regardless of the type of anion (chloride, nitrate, or acetate) used in the assembly process.

Fig. 3 shows N_2 adsorption–desorption isotherms for representative mesostructures formed in the presence of Brij 56 and Co^{2+} as the structure modifier. Pore necking in the 3D faulted structure, as suggested by the cage-like pore structure of the upper TEM image of Fig. 2, is verified by the hysteresis loop associated with the filling and emptying of the framework void space. Little or no hysteresis is observed for the one-dimensional hexagonal structure, as expected. The BET surface areas, pore volumes, and Horvath–Kawazoe pore diameters for the 3D faulted structure are 1103 $m^2\ g^{-1}$, 1.06 $cm^3\ g^{-1}$ and 6.0 nm, respectively. The corresponding values for the hexagonal mesostructures are 937 $m^2\ g^{-1}$, 0.68 $cm^3\ g^{-1}$ and 4.3 nm. These textural parameters are comparable to those for mesoporous silica molecular sieves obtained through conventional electrostatic assembly pathways. Future studies will examine the framework crosslinking and hydrothermal stability of these ordered silicas in comparison to silicas formed through other electrostatic pathways.

In conclusion, we have shown that long range structural order can be introduced through complex formation of the N^0 surfactant with small metal ions at M^{n+}/N^0 ratios in the range 0.1–2.0 and near-neutral pH. In comparison, acid mediated pathways that use comparable amounts of protons rather than complexable metal ions have been shown previously to yield only wormhole structures.[14] In order to assemble ordered silica frameworks through acid mediation of EO–based nonionic surfactants, much higher H^+/N^0 ratios, typically in the range 30–600, are needed to introduce structural order.[9] The new $(N^0M^{n+})I^0$ pathway reported here offers a promising alternative approach for introducing electrostatic forces and long range structural order into the assembly process while avoiding the need for high acid concentrations. It also avoids the need for high surfactant concentrations and liquid crystal templating (casting) as a means of generating ordered frameworks.[15]

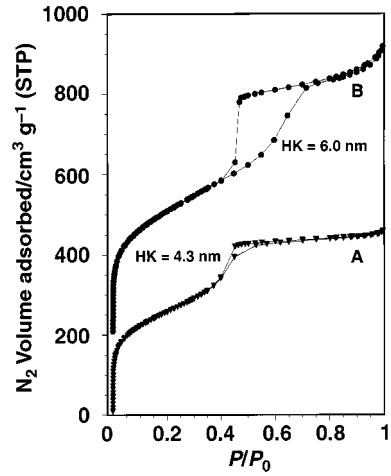

Fig. 3 N_2 adsorption–desorption isotherms for the silica mesostructures assembled at Co^{2+}/Brij 56 ratios of 0.50 (lower isotherm) and 0.12 (upper isotherm). The upper isotherm is offset by 200 $cm^3\ g^{-1}$ for clarity.

Received (in Cambridge, UK) 25th May 1999, Accepted 26th July 1999

The spectroscopy and structures of the title compounds show that the analogous species described previously were probably contaminated by OH^- at the Cl^- positions.

A recent paper in this journal reported the terphenyl gallium and indium dichlorides $\{2,6\text{-}Trip_2H_3C_6MCl_2\}_2$ (M = Ga or In; Trip = $C_6H_2Pr^i_3$-2,4,6) which were described as having halide bridged dimeric structures.[1] Unusually, the bridging metal chloride distances [Ga–μ-Cl 2.198(5) Å, In–μ-Cl 2.235(4) Å] were shorter than those to the terminal chlorides [Ga-Cl(terminal) 2.230(5) Å, In–Cl(terminal) 2.448(7) Å]. This differs from other halide bridged structures, including the related $\{2,6\text{-}Mes_2H_3C_6MCl_2\}_2$ (Mes = $C_6H_2Me_3$-2,4,6; M = Ga, In) dimers,[2] where the M–μ-Cl distances are longer than the terminal ones.[3] The M–μ-Cl bonds also differed by only 0.037 Å in spite of the different sizes of Ga and In.† Furthermore, the cell constants for these compounds resemble those reported for $\{2,6\text{-}Trip_2H_3C_6Al(Cl)_{0.68}(H)_{0.32}(\mu\text{-}OH)\}_2{\cdot}2C_6H_6$, which arose *via* contamination of the product (presumably by H_2O) during the synthesis of the halide $\{2,6\text{-}Trip_2H_3C_6AlCl_2\}_2$ from $\{2,6\text{-}Trip_2H_3C_6AlH_2\}_2$.[4] We hypothesized that the short 'Ga–Cl' and 'In–Cl' distances might be due to contamination of the μ-Cl positions by OH^-. We resolved to isolate the terphenyl metal dihalides under the rigorous exclusion of moisture, and to react these dihalide products with H_2O in order to synthesize the hydroxides deliberately.

Reaction of $2,6\text{-}Trip_2H_3C_6Li(OEt_2)$[5] and $GaCl_3$ in Et_2O gave, initially, $2,6\text{-}Trip_2H_3C_6GaCl_2(OEt_2)$ **1a** as colorless crystals‡ which were characterized by spectroscopy. Its structure probably resembles that reported for $2,6\text{-}Mes_2H_3C_6AlCl_2(OEt_2)$.[4] Recrystallization of **1a** from hot hexane yielded $2,6\text{-}Trip_2H_3C_6GaCl_2$ **1b**,‡ whose crystal structure shows that, unlike the earlier compound,[1] it is monomeric (Fig. 1).§ The Ga atom has distorted trigonal planar coordination with Ga–Cl 2.113(4) and 2.124(3) Å and Ga–C 1.930(8) Å. These are similar to those in the only other three-coordinate, monomeric aryl gallium dichloride, Mes^*GaCl_2[6] (Mes* = $C_6H_2Bu^t_3$-2,4,6) which was characterized by two groups who reported the bond distances: Ga–C 1.935(4) Å (av.), Ga–Cl 2.157(1) Å (av.); Ga–C 1.953(13) Å, Ga–Cl 2.212(4) Å.

The reaction of $2,6\text{-}Trip_2H_3C_6Li(OEt_2)$[5] with $InCl_3$ gave $\{2,6\text{-}Trip_2H_3C_6InCl_2\}_2$ **2** which was characterized by spectroscopy‡ and X-ray diffraction.§ There is ^1H NMR evidence that an Et_2O adduct of **2** (similar to **1a**) is formed, but dissociation of Et_2O is readily effected by recrystallization from hexane. It crystallizes as a centrosymmetric dimer (Fig. 2) whose structural details differ markedly from those previously reported.[1] Notably, the distance of 2.5239(7) Å is *ca.* 0.28 Å longer than the In–μ-Cl lengths 2.236(4) and 2.233(4) Å given earlier.[1] Also, the terminal In–Cl distance in **2**, 2.3341(12) Å, is *ca.* 0.11 Å shorter than the published In–Cl(terminal) distance, 2.448(7) Å. The In–C and In–Cl distances in **2** are in agreement with those in other halide bridged In compounds, *e.g.* $\{2,6\text{-}Mes_2H_3C_6InCl_2\}_2$,[2] In–μ-Cl 2.519(2), 2.514(2) Å, In–Cl(terminal) 2.344(3) Å; $\{In(CH_2CMe_3)(CH_2SiMe_3)Cl\}_2$,[3d] In–μ-Cl 2.659(3), 2.572(3) Å.

To show that the original structure of '$\{2,6\text{-}Trip_2H_3C_6GaCl_2\}_2$'[1] could have been contaminated with OH^- at the bridging positions, H_2O was added to **1b** in THF.‡ Crystals of $\{2,6\text{-}Trip_2H_3C_6GaCl(\mu\text{-}OH)\}_2{\cdot}2C_6H_6$ **3** have cell parameters which resemble those of '$\{2,6\text{-}Trip_2H_3C_6GaCl_2\}_2$'[1] and $\{2,6\text{-}Trip_2H_3C_6Al(Cl)_{0.68}(H)_{0.32}(\mu\text{-}OH)\}_2{\cdot}2C_6H_6$.[4] It has a centrosymmetric OH^- bridged structure with terminal Ga–Cl bonds (Fig. 3).§ The Ga–μ-O distances, 1.932(4) and 1.906(4) Å, are close to those in related OH^- bridged compounds, *e.g.* $\{2,4,6\text{-}(CF_3)_3H_2C_6GaCl(\mu\text{-}OH)\}_2$,[7] Ga-O 1.903(4), 1.895(4) Å; $\{Mes_2Ga(\mu\text{-}OH)\}_2{\cdot}THF$,[8] Ga–O 1.949(2) Å; $\{[(Me_3Si)_2CH]_2Ga(\mu\text{-}OH)\}_2$,[9] Ga–O 1.963(4), 1.976(4) Å. The terminal Ga–Cl and Ga–C distances, 2.1465(19) and 1.949(5) Å, in **3** are similar to those in **1b** and related compounds.

The data for **1b**, **2** and **3** lead to the following conclusions: (a) $2,6\text{-}Trip_2H_3C_6GaCl_2$ **1b** is a monomer owing to the large size of the C_6H_3Trip-2,6 ligand and the dimeric structure of the In compound **2** is due to the larger size of In which reduces steric crowding and permits association; (b) the dimeric structure of **3** results from contamination of the μ-Cl^- ligands by OH^-, and since the originally reported short 'Ga–Cl' and 'In–Cl' distances lie about halfway between those expected for bridging

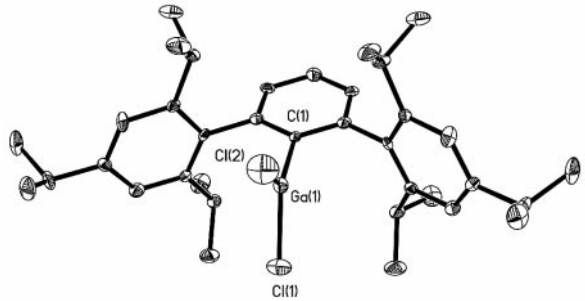

Fig. 1 Drawing of **1b** (30% probability). H atoms not shown. Selected bond lengths (Å) and angles: Ga(1)–C(1) 1.930(8), Ga(1)–Cl(1) 2.124(3), Ga(1)–Cl(2) 2.113(4); C(1)–Ga(1)–Cl(1) 124.0(3), C(1)–Ga(1)–Cl(2) 127.5(3), Cl(1)–Ga(1)-Cl(2) 108.54(14).

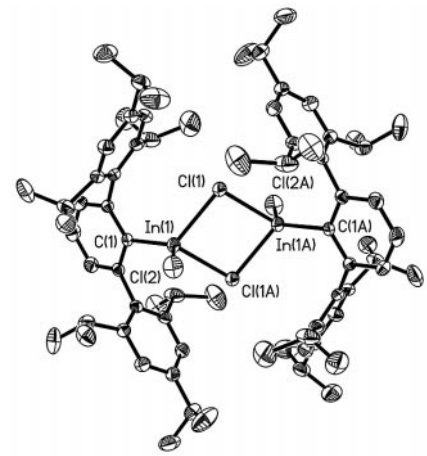

Fig. 2 Drawing of **2** (30% probability). H atoms not shown. Selected bond lengths (Å) and angles (°): In(1)–C(1) 2.145(3), In(1)–Cl(1) 2.5239(7), In(1)–Cl(2) 2.3341(12); C(1)–In(1)–Cl(2) 128.19(9), C(1)–In(1)–Cl(1) 119.01(6), Cl(2)–In(1)–Cl(1) 98.51(2), In(1)–Cl(1)–In(1A) 96.85(3).

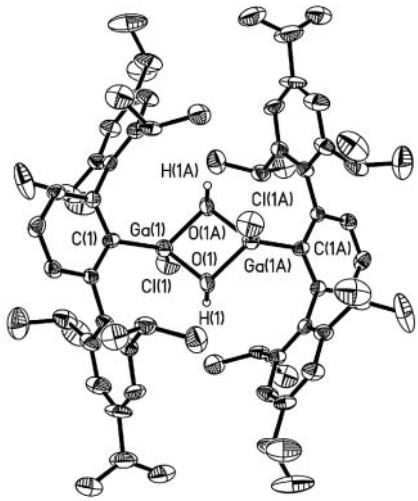

Fig. 3 Drawing of the structure of **3** (30% probability). H atoms not shown. Selected bond lengths (Å) and angles (°): Ga(1)–C(1) 1.949(5), Ga(1)–O(1) 1.932(4), Ga(1)–(O1A) 1.906(4), Ga(1)–Cl(1) 2.1465(19); C(1)–Ga(1)–Cl(1) 126.23(17), Ga(1)–O(1)–Ga(1A) 99.94(19), O(1A)–Ga(1)–Cl(1) 104.33(14).

M–OH and M–Cl (M = Ga, In) bonds, the contamination of the μ–Cl^- positions by OH^- ions is 50% which is sufficient to produce the apparent 'dimerization'; (c) the M–Cl distances in both **1b** and **2** are normal, and there is no shortening in the bridging In–Cl distance which is *ca*. 0.29 Å longer than the terminal In–Cl bond.

We note that the hydrolysis of related organogallium compounds to give Ga–OH products has been investigated in detail,[8,10] and the susceptibility of **1b** and **2** to hydrolysis agrees with these studies. The ability of OH^- ligands to occupy Cl^- sites bears some similarity to the bond stretch isomerism controversy where 'short' M–Cl (or 'long' M–O) bonds were shown to be a result of occupancy of the same site by different percentages of the O or Cl atoms rather than a new type of bonding isomerism.[11]

First example of B–C bond cleavage in the BAr_F ($B[C_6H_3(CF_3)_2\text{-}3,5]_4$) anion mediated by a transition metal species, *trans*-$[(Ph_3P)_2Pt(Me)(OEt_2)]^+$

Wayde V. Konze, Brian L. Scott and Gregory J. Kubas*

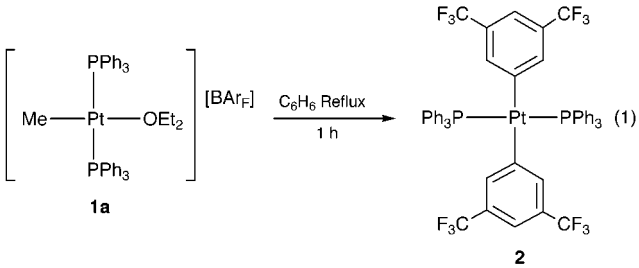
Received (in Bloomington, IN, USA) 22nd March 1999, Revised version received 26th July 1999, Accepted 28th July 1999

The first example of transition metal-mediated decomposition of the widely used BAr_F anion (BAr_F = $B[C_6H_3(CF_3)_2\text{-}3,5]_4$) has been accomplished by mild heating of the cationic platinum complex *trans*-$[(Ph_3P)_2Pt(Me)(OEt_2)]^+(BAr_F)^-$ in low-coordinating solvents to form the diarylated product *trans*-$(Ph_3P)_2Pt(Ar_F)_2$ in good yield, thus demonstrating that such non-interacting anions can react with electrophilic transition metal complexes.

The incorporation of non-coordinating, low-interacting anions for the stabilization of reactive transition metal cations has proven to be very useful for carrying out interesting bond-cleavage reactions, catalytic polymerization reactions and for stabilizing weakly coordinating ligands.[1] In order for these reactions to be successful, the anion must not coordinate to the vacant site, and must not react with the metal center. The BAr_F ($B[C_6H_3(CF_3)_2\text{-}3,5]_4$) anion has been used widely in this respect because of its ease of preparation and extremely robust character toward a variety of reactive transition metal cations.[2] Recently, however, the BAr_F anion was found to coordinate to various metal complexes in either η^3-, η^4- or η^6-fashion,[3] indicating that this anion can coordinate to suitable transition metal fragments.

Although the non-fluorinated BPh_4^- anion has been shown to be relatively reactive, displaying a marked tendency to act as a phenylating agent toward transition metal cations,[4] there have been no reported examples of arylation reactions between the BAr_F anion and transition metal centers. We herein report the first example of the reaction of the BAr_F anion with a transition metal cation in the complex *trans*-$[(Ph_3P)_2Pt(Me)(OEt_2)]^+(BAr_F)^-$ **1a**, which decomposes to form the diarylated complex *trans*-$(Ph_3P)_2Pt(Ar_F)_2$ **2** under mild conditions.

The complex *trans*-$[(Ph_3P)_2Pt(Me)(OEt_2)]^+(BAr_F)^-$ **1a** was prepared by reacting $(Ph_3P)_2Pt(Me)_2$ with $[H(OEt_2)_2]^+BAr_F^-$ in Et_2O at room temperature. Compound **1a** is stable in Et_2O solution for several weeks at −30 °C, and is stable indefinitely at −30 °C as an isolated solid. However, when **1a** was placed in benzene and allowed to stand at room temperature for 5 days, the compound *trans*-$(Ph_3P)_2Pt(Ar_F)_2$ **2** formed as colorless crystals [eqn. (1)].† The reaction was also more conveniently



1a **2** (1)

carried out by refluxing **1a** in toluene for 20 min. Complex **2** was characterized by elemental analysis, ^1H NMR and $^{31}P\{^1H\}$ NMR,† and the structure was determined by X-ray diffraction studies.‡ A characteristic feature of the ^1H NMR spectrum of **2** is the downfield shift of the Ar_F resonances and the change in relative peak heights; the BAr_F anion has peaks at δ 7.73 and 7.58 in a 2:1 ratio, while the coordinated Ar_F group in **2** exhibits peaks at δ 8.25 and 8.05 in a 1:2 ratio. The molecular structure of **2** (Fig. 1) shows that the platinum is in a square planar environment, with the bis(trifluoromethyl)phenyl groups located *trans* to each other and at an angle of 72.6° to the plane defined by Pt(1), P(1), P(1A), C(19) and C(19A).‡

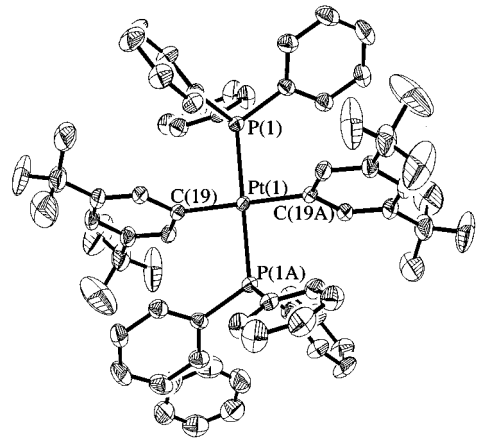


Fig. 1 Molecular structure of **2** showing the atom numbering scheme (50% probability ellipsoids). Selected bond distances (Å) and angles (°): Pt(1)–C(19) 2.083(2), Pt(1)–P(1) 2.3180(5), C(19)–Pt(1)–P(1) 91.73(6), C(19)–Pt(1)–P(1A) 88.27(6).

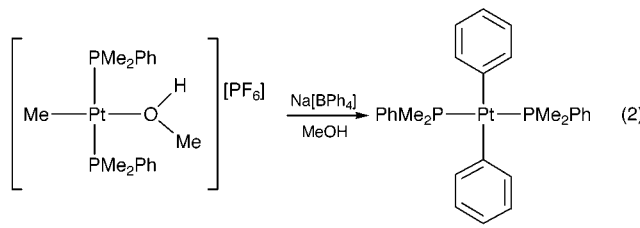
The formation of **2** entails the net transfer of two 3,5-bis(trifluoromethyl)phenyl groups from the BAr_F anion to the platinum center, constituting the first example of aryl group transfer from the BAr_F anion. Although this reaction is unprecedented for the BAr_F anion, similar reactions have been carried out with the BPh_4 anion; the metathesis reaction [eqn. (2)] of $[(PhMe_2P)_2Pt(Me)(solv)]^+$ with $NaBPh_4$ results in the



(2)

formation of the neutral bis(phenyl)platinum derivative $(PhMe_2P)_2Pt(Ph)_2$.[5] It was determined from these studies that weakly bound ligands (*e.g.*, $F_2C{=}CFH$) in place of the coordinated solvent molecules enhanced the phenylation reaction. In a separate study,[6] the mechanism of phenyl transfer from the BPh_4 anion to the dicationic platinum species $[Pt(solv)_2(L)_2]^{2+}$ (L = PMe_3, PEt_3, PPh_3; solv = H_2O, MeOH) to form $[Pt(Ph)(solv)(L)_2]^+$ was investigated. It was found that

the actual phenylating species is BPh_3, which was formed from proton-induced decomposition of the BPh_4 anion to form BPh_3 and PhH. The coordinated solvent molecules in $[Pt(solv)_2(L)_2]^{2+}$ were assumed to be acidic enough to cause the decomposition of the BPh_4 anion. It is doubtful that a similar mechanism is occurring in the decomposition of **1a**, as the coordinated Et_2O molecule does not contain acidic protons which could cause the decomposition of the BAr_F anion. Instead, this reaction most likely proceeds through an initial step that involves electrophilic attack of the platinum cation on one of the aryl groups of the BAr_F anion. The fate of the methyl ligand is not known, but no methane was evolved during the reaction.

In order to determine the effects of the ligands on the arylation reaction, both the coordinated solvent and the phosphine ligands were varied in **1a**. Complexes containing both coordinated MeCN and MeOH were prepared by dissolving **1a** in MeCN and MeOH, respectively, and precipitating out *trans*-$[(Ph_3P)_2Pt(Me)(NCMe)]^+(BAr_F)^-$ **1b** and *trans*-$[(Ph_3P)_2Pt(Me)(MeOH)]^+$ $(BAr_F)^-$ **1c** as solids.† The ^{1}H NMR spectrum of **1b** was almost identical to the known compound *trans*-$[(Ph_3P)_2Pt(Me)(NCMe)]^+(BF_4)^-$,[7] and exhibited a singlet at δ 1.157 corresponding to coordinated MeCN, which disappeared when CD_3CN was added. Complex **1c** exhibited a signal at δ 2.684 corresponding to coordinated MeOH, which disappeared when CD_3OD was added. When **1b** was refluxed in either benzene or toluene under identical conditions to that of **1a**, there was no evidence for formation of **2**. However, when **1c** was refluxed in toluene under identical conditions, **2** formed in roughly the same yield as from the reaction of **1a**. Evidently, the more weakly bound Et_2O and MeOH ligands allow the aryl group transfer to occur in order to form **2**, while the more stongly bound MeCN ligand prevents this reaction from taking place.

In order to examine the effects of the phosphine ligand on the aryl group transfer, the complexes *trans*-$[(Pr^i_3P)_2Pt(Me)(OEt_2)]^+(BAr_F)^-$ **1d** and *trans*-$[(Et_3P)_2Pt(Me)(OEt_2)]^+(BAr_F)^-$ **1e** were synthesized analogously to the preparation of **1a**. After refluxing **1d** in toluene for several hours, there was no evidence of B–C bond cleavage. However, the less sterically encumbered **1e** reacted after refluxing for 10 min in benzene. A mixture of platinum complexes formed which could not be identified, but clear crystals were obtained from benzene which were characterized by X-ray diffraction to be $B[C_6H_3(CF_3)_2\text{-}3,5]_3$ **3**, the structure of which has not been previously reported.‡ Although this reaction gave different results than the decomposition of **1a**, it still indicates that B–C cleavage takes place with this more basic, less steric phosphine. Evidently, bulky phosphines do not allow this reaction to take place, which is consistent with the transition metal cation attacking the bulky BAr_F anion.

The aryl group transfer from the BAr_F anion to the platinum metal center in *trans*-$[(Ph_3P)_2Pt(Me)(OEt_2)]^+(BAr_F)^-$ **1a** represents the first example of a transition metal-mediated decomposition of the normally non-interacting BAr_F anion and serves to alert those who use this anion to the possibility of its reactivity. The mechanism of this reaction is unclear, but we have found that the coordinated solvent must be a weak ligand (Et_2O, MeOH), the solvent for the decomposition reaction must be non-coordinating, and the phosphine ligands must not be too bulky in order for this reaction to proceed. Preliminary results indicate that analogs of **1a** containing isocyanides instead of phosphines allow similar B–C bond cleavage reactions to proceed immediately at room temperature. These results indicate that the initial step of this reaction is electrophilic attack of the platinum cation on an aryl group of the BAr_F anion, which is consistent with the fact that both a sterically accessible metal center and a weakly occupied coordination site are necessary for aryl group transfer to occur.

Notes and references

† *Experimental procedures*: **1a:** to a stirred Et_2O solution (10 mL) of $[H(OEt_2)_2]^+BAr_F^-$ (0.135 g, 0.133 mmol) at room temp. was added $(Ph_3P)_2Pt(Me)_2$ (0.100 g, 0.133 mmol) as a solid. Evolution of methane began immediately, and after 5 min the solution was clear and colorless. The volume was reduced to 3 mL, and 10 mL of hexanes was then added. The volume was reduced to *ca.* 8 mL and placed in a −30 °C freezer for 1 day to obtain a white, crystalline solid. The filtrate was decanted off, the solids were washed with 3 × 5 mL of hexanes at −30 °C and dried under vacuum to give **1a** (0.195 g, 87%). ^{1}H NMR (CD_2Cl_2, −80 °C): δ 7.73 (s, 8H, BAr_F), 7.21–7.62 (34H, Ph + BAr_F), 3.53 (br, 4H, ether CH_2), 1.16 (t, J_{HH} = 7.05 Hz, 6H, ether CH_3), 0.73 (t, J_{HP} 6.75, J_{HPt} 71.0 Hz, 3H, Pt–Me). ^{31}P{^{1}H} NMR (CD_2Cl_2, −80 °C): δ 31.3 (s, J_{PPt} 3195 Hz). Anal. Calc. for $C_{75}H_{55}BF_{24}OP_2Pt$: C, 52.44; H, 3.32. Found: C, 52.43; H, 3.59%.

1b and **1c:** complex **1a** (0.100 g, 0.0598 mmol) was dissolved in 10 mL of either MeCN (for **1b**) or MeOH (for **1c**) at room temp. and stirred for 15 min. The solvent was removed under vacuum, the oily residue was dissolved in 2 mL of CH_2Cl_2 and 15 mL of hexanes was then added. After cooling overnight at −30 °C, off-white crystals formed which were isolated by removing the filtrate and drying under vacuum to give **1b** (0.0905 g, 92%) or **1c** (0.0854 g, 90%). For **1b**: ^{1}H NMR (CD_2Cl_2, 25 °C): δ 7.53–7.75 (42H, Ph + BAr_F), 1.16 (br, 3H, MeCN), 0.28 (t, 3H, J_{HP} 7.05, J_{HPt} 78.3 Hz, Pt–Me). ^{31}P{^{1}H} NMR (CD_2Cl_2, 25 °C): δ 27.2 (s, J_{PPt} 3008 Hz). Anal. Calc. for $C_{71}H_{48}BF_{24}NP_2Pt$: C, 52.03; H, 2.95; N, 0.85. Found: C, 52.41; H, 3.04; N, 0.84%. For **1c**: ^{1}H NMR (CD_2Cl_2, 25 °C): δ 7.53–7.75 (42H, Ph + BAr_F), 2.68 (br, 3H, CH_3OH), 0.612 (t, 3H, J_{HP} 6.90, J_{HPt} 87.6 Hz, Pt–Me). ^{31}P{^{1}H} NMR (CD_2Cl_2, 25 °C): δ 32.4 (s, J_{PPt} 3114 Hz). Anal. Calc. for $C_{70}H_{49}BF_{24}OP_2Pt$: C, 51.58; H, 3.03. Found: C, 51.63; H, 3.03%.

2: complex **1a** (0.200 g, 0.120 mmol) was dissolved in toluene (5 mL) and heated to reflux for 20 min. The solution turned orange during this time. The solution was cooled, the solvent was removed under vacuum and 5 mL of MeOH was added. The mixture was cooled to −30 °C for 4 h, the white precipitate was collected on a frit, washed with cold MeOH and dried in vacuum to yield pure **2** (0.0875 g, 63%). ^{1}H NMR (CD_2Cl_2, 25 °C): δ 8.25 (s, 2H, BAr_F), 8.05 (s, 4H, BAr_F), 7.35–7.18 (30H, Ph). ^{31}P{^{1}H} NMR (CD_2Cl_2, 25 °C): δ 20.6 (s, J_{PPt} 2998 Hz). Anal. Calc. for $C_{52}H_{36}F_{12}P_2Pt$: C, 54.51; H, 3.17. Found: C, 54.47; H, 3.28%.

Extremely selective $Mg(ClO_4)_2$ mediated removal of Bpoc/Ddz moieties suitable for the solid phase peptide synthesis of thioxo peptides

Dirk Wildemann, Mario Drewello, Gunter Fischer and Mike Schutkowski*

Max-Planck Research Unit 'Enzymology of Protein Folding', Weinbergweg 22a, Halle, Germany. E-mail: schutkowski@enzyme-halle.mpg.de

Received (in Cambridge, UK) 13th July 1999, Accepted 3rd August 1999

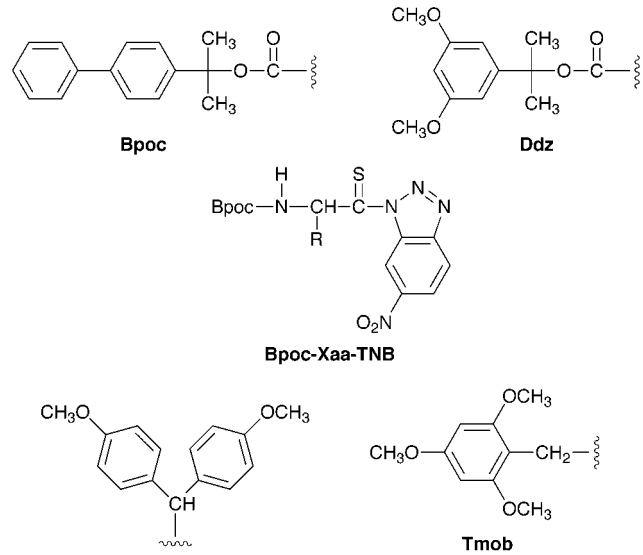
$Mg(ClO_4)_2$ in organic solvents acts as an extremely mild reagent for repetitive Bpoc/Ddz deprotection during solid phase peptide synthesis even in the presence of the acid labile thioxo amide moiety with excellent yields.

Peptide backbone modification by replacement of an amide moiety by a thioamide moiety (thioxylation)† has attracted attention in recent years for several reasons. On one hand receptor interactions of thioxylated analogues of biologically active peptides may be more selective or more potent than their parent compounds and on the other hand enhanced stability against enzymatic action could be shown for various proteolytic enzymes.[1] The introduction of a thioamide moiety is a nearly isologous substitution for an amide moiety[2] but biological studies have shown that the behavior of such modified compounds is unpredictable.[3] Nevertheless, a thioxo peptide bond provides an extraordinary backbone label for peptides and proteins introducing special spectroscopic and photochemical properties into the molecule with minimal variation of the constitution.

Regarding thioxo peptide synthesis the deprotection of the widely used side-chain protecting groups in the presence of thioxo peptide bonds is problematic because of the sensitivity of these groups toward acids. Acidolytic Boc deprotection of thioxo peptides led in most cases (depending on the sequence) to unsatisfactory yields between 10 and 65%.[4] Besides dethioxylation the thioxylated products often undergo thiazolone formation, a side reaction similar to the Edman degradation.[5]

Moreover, thioxo peptides are sensitive to the repetitive treatment with base necessary for the removal of the Fmoc protecting group, resulting in epimerized peptide derivatives. To circumvent these limitations we developed a method which can be used for both conventional peptide synthesis in the liquid phase and for solid phase peptide synthesis (SPPS) of thioxo peptides. It exclusively uses Lewis acids for both removal of the temporary 2-(biphenyl-4-yl)propan-2-yloxycarbonyl (Bpoc) or 2-(3,5-dimethoxyphenyl)propan-2-yloxycarbonyl (Ddz) protecting groups and final detachment/side-chain deprotection.

We disclosed that $SnCl_4$ is a powerful reagent for Boc deprotection in the presence of the acid-sensitive thioxo moiety.[6] In a more systematic investigation we found that Lewis acids like $Mg(ClO_4)_2$ in MeCN or $ZnCl_2$ in THF‡ are extremely mild and selective reagents for Bpoc/Ddz removal without damage of the thioxo peptide bond. This method is suitable in SPPS using extremely acid labile resins like Sieber- and Rink-amide and SASRIN® resins. The Bpoc deprotection of thioxo peptides utilising $Mg(ClO_4)_2$ in MeCN at 50 °C is fully compatible with side-chain Boc protection.[7] The thioxo moiety of Ala-Ala-Ala-Pro-ψ[CS-NH]Phe-NH-Np§ is completely stable under these conditions even after 5 weeks. We were able to synthesize the thioxylated model polyproline II helix **7** on a Sieber-amide resin using Ddz protected proline for chain elongation¶ and Bpoc-Pro-thioxo-6-nitrobenzotriazolide (Bpoc-Pro-TNB) for thioacylation‖ of resin-bound pentaproline. Detachment from the support using $ZnCl_2$-Et_2O complex in CH_2Cl_2** yielded thioxo peptide **7** in 72% yield after HPLC purification. Additionally, we synthesized bovine β-Casomorphine(1-5) amide **2** using the Fmoc strategy for preparation of the tripeptide Phe-Pro-Gly on a Sieber-amide resin, switching to Bpoc-Pro-TNB for introduction of the thioxo amide moiety and selective Bpoc-deprotection using $Mg(ClO_4)_2$ in MeCN. After acylation of the thioxo tetrapeptide with Boc-Tyr(OtBu), simultaneous Boc/OtBu-deprotection and detachment from the resin was successful using $ZnCl_2$–Et_2O complex. Moreover, we prepared the biologically active thioxo peptides endomorphine **3** and allanthoin **4** (Scheme 2) in a similar manner (Table 1).



The synthesis of the thioxo bradykinins **5** and **6** (Table 1) was successful starting from Fmoc-Arg(Boc)$_2$-SASRIN® resin and using Boc-Arg(Boc)$_2$ for final acylation of the resin-bound thioxo octapeptides. Side-chain deprotection–detachment with $ZnCl_2$–Et_2O complex yielded thioxo peptides in excellent yields and purity. The widely used Pmc/Pbf and Trt protecting groups are relatively stable against $ZnCl_2$-Et_2O complex. Therefore we preferred the trimethoxybenzyl (Tmob) and 4,4′-Dimethoxydityl (Dod) groups for side-chain protection of Gln (peptide **10**) and Asn (peptide **8**), respectively, and double Boc protection of the guanidino function of Arg to overcome these limitations. To test this method in a more sophisticated reaction we synthesized the fully protected thioxylated RNAse A fragment Boc–Lys(Boc)-Glu(OtBu)-Thr(tBu)-Ala-ψ[CS-NH]Ala-Ala-Lys(Boc)-Phe-Glu(OtBu) on SASRIN® resin and treated it with $ZnCl_2$–Et_2O complex for 10 h at room temperature. The major product corresponds to the expected thioxo peptide **9** as demonstrated by MALDI mass spectrometry. Finally, we synthesized the complete RNAse A derived thioxo S-peptide **10** using this new method. The main product (30%) of the complex mixture was **10** but in all other oligopeptides derived from incomplete couplings a thioxo moiety has been detected by the charateristic UV-band at 280 nm. This suggests that no dethioxylation had taken place. We repeated the synthesis of **10** using Fmoc-(FmocHmb)Ala and Fmoc-Asp-(2,2-dimethyl)oxazolidine-4-carboxylic acid at

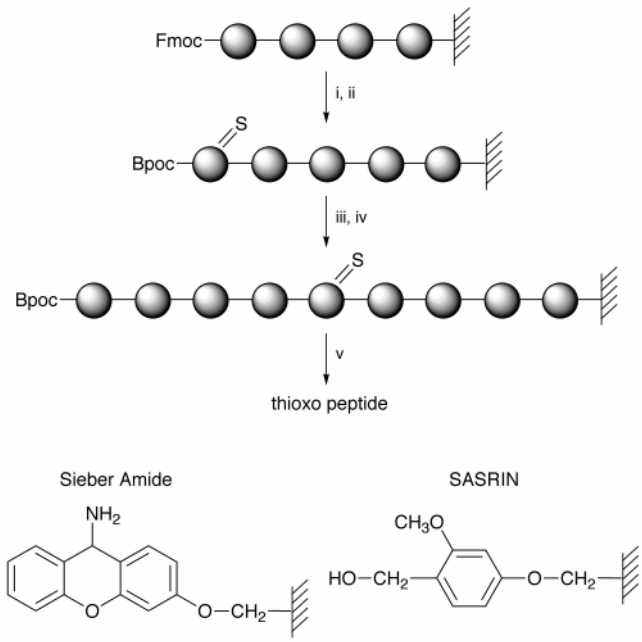

Scheme 1 *Reagents and conditions*: i, piperidine–DMF; ii, Bpoc-Xaa-TNB, DMF; iii, $Mg(ClO_4)_2$ MeCN or $ZnCl_2$/THF; iv, peptide synthesis using Bpoc for temporary protection; v, $ZnCl_2$–Et_2O complex, CH_2Cl_2.

positions 19 and 14–15, respectively, yielding **10** in 63% after final treatment with $ZnCl_2$–Et_2O complex and HPLC purification.

In conclusion, we have demonstrated that this novel deprotection scheme (Scheme 1) is an extraordinarily mild method for the SPPS of peptide derivatives containing acid and/or base sensitive functionalities. Linear thioxo peptides, which are known to be difficult to synthesize in a positionally predetermined manner, can now be prepared in good yields without epimerization.

We thank Dr A. Schierhorn and M. Kipping for mass spectroscopic measurements and Dr U. Reimer for NMR measurements. We are grateful to Thomas Schumann for atomic emission spectroscopic measurements. We gratefully acknowledge B. Hökelmann and I. Kunze for excellent technical assistance.

Notes and references

† For naming C=S the prefix 'thiono' has been frequently used in place of 'thioxo', however the IUPAC nomenclature committee recommends the use of 'thioxo'.

‡ Other Lewis acids that were investigated include ZnI_2, $Zn(AcO)_2$, $Zn(ClO_4)_2$, $MgCl_2$, $SnCl_2$, $SnBr_4$, $SnCl_4$, $Sn(AcO)_4$, $Cs(F_3CCO_2)$, $AlCl_3$ and $Ti(OPr^i)_4$. In the case of ZnI_2, $Zn(AcO)_2$, $Zn(ClO_4)_2$ and $MgCl_2$ the deprotection of Bpoc was promoted with a selectivity of at least 2000 over Boc deprotection but proceeds with sluggish kinetics. We preferred $Mg(ClO_4)_2$ due to its relative low cost, the weakly interacting counterion, its good solubility in organic solvents like MeCN, and its ease of removal.

§ Alterations of a peptide bond are represented by the ψ nomenclature system. *Pure Appl. Chem.*, 1984, **5b**, 595.

¶ The resin bound Bpoc-protected peptide derivative was treated with 10 equiv. $Mg(ClO_4)_2$ in MeCN at 50 °C for 3 h. The next acylation step in the case of SPPS was performed after extensive washing with MeCN and re-swelling in DMF. Using this method in liquid phase synthesis precipitation of the crude product with Et_2O was sufficient for removal of the deprotecting reagent.

‖ The thioxylated Bpoc-protected amino acid 6-nitrobenzotriazolides were synthesized according to a modified procedure from the literature (M. A. Shalaby, C. W. Grote and H. Rapoport, *J. Org. Chem.*, 1996, **61**, 9045).

** We preferred $ZnCl_2$–Et_2O complex for the final treatment of the resin bound thioxo peptide because of its convenient handling and because there are no difficulties with precipitation of insoluble materials complicating HPLC purification. For simultaneous detachment–side-chain deprotection we incubated the peptide resin with 2.2 M $ZnCl_2$–Et_2O complex in CH_2Cl_2 for 10 h at room temperature. After filtration the solvent was removed and the resulting slurry was re-dissolved in THF and the desired thioxo peptide was precipitated with Et_2O. Final purification using HPLC gave pure thioxo peptides. Investigation of these peptides using atomic emission spectroscopy demonstrated that the Zn^{2+} content is within the normal range (below 180 μg g^{-1}). Additionally, we were able to remove *tert*-butyl and benzyl protecting groups from the phosphate moiety in the presence of thioxo peptide bonds using this method, allowing the synthesis of side-chain phosphorylated thioxo peptides.

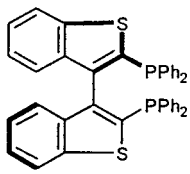
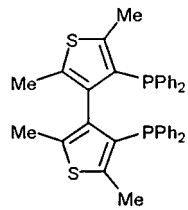
Received (in Liverpool, UK) 29th June 1999, Accepted 29th July 1999

The Heck reaction of dihydrofuran 3 with aryl triflates 4 and 6a–d and alkenyl triflate 8 in the presence of the chiral ligand (*R*)-BITIANP 1 provides the 2-substituted 2,3-dihydrofurans 5a, 7a–d and 9, respectively, with complete regioselectivity, high enantioselectivity (86–96% ee) and good yields (76–93%).

One of the main objectives in modern synthetic organic chemistry is the catalytic enantioselective formation of C–C bonds. In this respect, the Heck reaction[1]—the Pd^0 catalyzed coupling of an aryl or alkenyl halide or triflate with an alkene—is a highly versatile procedure since it tolerates several functional groups. In the years since the first enantioselective Heck reactions in 1989, published by Shibasaki[2] and Overman,[3] several novel chiral ligands have been developed which give high enantioselectivities and which have been used in natural product syntheses.[4] However, one of the problems encountered in the use of chiral ligands, especially in intermolecular Heck reactions, is the often low reactivity of the formed Pd complexes.[5] Therefore it is important to develop novel ligands and show their applicability in C–C bond formation. Here we report on the use of the new chiral ligands (*R*)-(+)-2,2′-bis(diphenylphosphino)-3,3′-bi(benzo[*b*]thiophene) [(*R*)-BITIANP] **1** and (+)-4,4′-bis(diphenylphosphino)-2,2′,5,5′-tetramethyl-3,3′-bithiophene [(+)-TMBTP] **2** in Heck reactions; ligand **1** has been employed with great success in the hydrogenation of C–C and C–O bonds,[6] whereas ligand **2** has not been used so far for enantioselective transformations.



1



2

To allow a comparison with other chiral ligands we investigated the Heck reactions of dihydrofuran **3** with the triflates **4**, **6a–d** and **8**. In principle, the Heck reaction of dihydrofuran **3** with phenyl triflate **4** leads to the two isomers **5a** and **5b** (Scheme 1). Using BINAP[7] the regioselectivity is rather low, whereas with a substituted MeO-BIPHEP[8] ligand a 22:1 ratio of **5a** and **5b** was obtained, and with chiral phosphinooxazolines[9] only **5b** is obtained.[10]

We have now shown that the Heck reaction of **3** and **4** in DMF at 90 °C using Pd_2dba_3·dba and the new chiral ligand **1** employing a Pd ligand ratio of 1:2 and 1,8-bis(dimethylamino)-naphthalene (proton sponge) as the base affords **5a** exclusively in 84% yield and 91% ee within 18 h (Table 1, entry 1).† Similar results were obtained using Pr^i_2NEt as base (entry 2); however, with THF as solvent at 70 °C the transformation was less selective and much slower. Even after 7 days the reaction was not complete (entry 3). Interestingly, (*R*)-BINAP as chiral ligand using the best conditions found for the transformation with **1** gave **5a** with a 3:1 regioselectivity and only 42% ee (entry 4). The use of the second new ligand (+)-TMBTP **2** was only marginally successful. Here the regioisomer **5b** was obtained preferentially, but with very poor ee values (entries 5–7).

In the presence of the ligand (*R*)-BITIANP **1**, other phenyl triflates **6a–d** containing either an electron-withdrawing or an electron-donating group also reacted with high regio- and enantio-selectivities (Scheme 2, Table 2). In addition alkenyl triflates could be transformed successfully; thus, the Pd catalyzed reaction of cyclohex-1-enyl triflate **8** with dihydrofuran **3** provides exclusively the dihydrofuran derivative **9** within 13 h with good yield and high enantioselectivity.

The described Heck reactions with the new chiral ligand (*R*)-BITIANP **1** have shown that this ligand has an excellent potency and may serve as a useful alternative to the ligands

The diastereoselective cycloaddition of vinyl ethers with isomünchnones

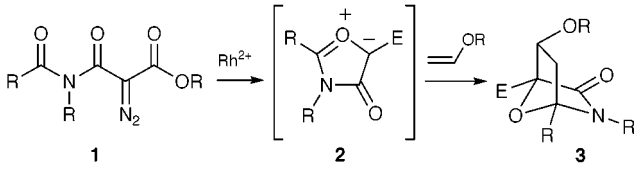
Sergey N. Savinov and David J. Austin*

Department of Chemistry, Yale University, 225 Prospect St., New Haven, CT 06520-8107 USA. E-mail: david.austin@yale.edu

Received (in Corvallis, OR, USA) 28th April 1999, Accepted 14th July 1999

Complete diastereoselective product formation in the intermolecular 1,3-dipolar cycloaddition of isomünchnones with alkyl vinyl ethers is reported.

The 1,3-dipolar cycloaddition reaction is a powerful pericyclic process, leading to the concomitant formation of two carbon–carbon bonds in a single transformation.[1] While intramolecular cycloaddition reactions have been vigorously applied to natural product synthesis,[2] the intermolecular cycloaddition reaction suffers from a lack of diastereoselectivity,[3–5] resulting in diminished synthetic utility. During our efforts to utilize this reaction in the synthesis of biomimetic probes,[6,7] we discovered that the intermolecular cycloaddition of vinyl ethers with isomünchnones proceeds with complete diastereoselectivity (Scheme 1). Here we describe this unprecedented selectivity and explore the potential of vinyl ethers as dipolarophiles.



1 **2** **3**

Scheme 1

We sought to investigate the 1,3-dipolar cycloaddition reaction as the principal component of our synthetic approach in the construction of a rigid bicyclic framework for molecular recognition. Mesoionic species such as isomünchnones (**2**) have been reported to undergo highly selective and mild pericyclic chemistry.[8,9] When formed from α-diazo imide precursors (**1**), with rhodium(II) mediated catalysis,[10,11] these 1,3-dipoles provide the possibility of a rapid and convergent construction of a heterocyclic system (**3**, E = CO_2Me) that would be well suited for the presentation of a wide variety of functional groups, in a highly dense array.

Although the isomünchnones are a well-studied class of 1,3-dipoles,[5] the selectivity of the intermolecular isomünchnone cycloaddition has primarily been explored with symmetric, electron-deficient dipolarophiles such as *N*-phenylmaleimide, tetracyanoethylene, fumarates, maleates and dimethyl acetylenedicarboxylate.[5,9] Only one example of an intermolecular isomünchnone cycloaddition with a monoactivated, electron-deficient olefin has been reported.[12] We therefore sought to explore the reactivity of various unsymmetric, monoactivated alkenes. The vinyl ethers, being a diverse and readily available set of substrates,[13] represented a good candidate functionality for this study. Treatment of α-diazo imides **4** or **5** with a catalytic amount of rhodium(II) perfluorobutyramidate [Rh_2(pfbm)$_4$], in the presence of various dipolarophiles (Table 1), led to the isolation of a single diastereomer in each case (**6**–**15**). The relative stereochemistry of compound **7** was verified by X-ray crystallographic structure analysis.[14]

For every dipolarophile evaluated, *endo* orientation of the alkoxy functionality was maintained. [15,16] Moreover, the steric properties of this substituent do not appear to influence either product yield or reaction rate. Even sterically demanding groups, such as *tert*-butyl (entry 6) and trimethylsilyl (entry 7), were accommodated with little variation in yield or rate. In order to evaluate the relative rates for β-substituted vinyl ethers, 1-methoxyoct-1-ene was tested (entries 8 and 9). When the starting *E*:*Z* ratio of the dipolarophile was 1:9, the *anti*:*syn* product distribution was 24:72 (entry 8). A starting *E*:*Z* ratio of 3:2 provided an 80:20 *anti*:*syn* product distribution (entry 9). When the *anti*:*syn* distribution of products is normalized according to the original *E*:*Z* ratio (74:26 and 72:28, in entries 8 and 9, respectively), the cycloaddition preference for the *E* isomer becomes apparent. β-Disubstituted vinyl ether (entry 10) provides the same extent of diastereoselectivity as the less sterically congested dipolarophiles. This result is remarkable, considering the high functional density of the cycloadduct (**15**) obtained *via* this cycloaddition.

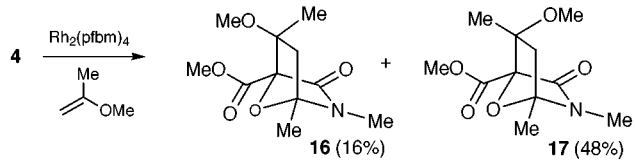
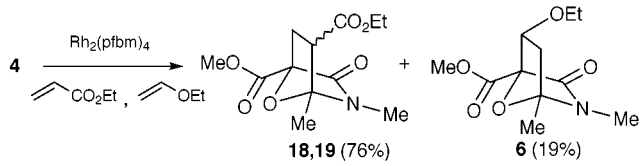
[a] 80 °C, benzene, 20 min. [b] 100 °C, benzene, 30 min. [c] 130 °C, chlorobenzene, 1 h. [d] 5 equiv. of dipolarophile with an *E*:Z ratio of 1:9 was used in this experiment. [e] 5 equiv. of dipolarophile with an E:Z ratio of 3:2 was used in this experiment. [f] Overall yield.

In order to evaluate whether our observed selectivity is steric or electronic in nature, we investigated the intermolecular cycloaddition of dipole precursor **4** with 2-methoxypropene, an *ipso*-substituted vinyl ether (Scheme 2). Interestingly, the reaction proceeded only at relatively high temperature (130 °C) and after prolonged exposure (8 h), to yield a 1:3 *exo*:*endo* ratio of the diastereomers **16** and **17**.[17] A similar reduction in rate has been reported with ketene acetals, which topologically resemble the *ipso*-substituted 2-methoxypropene.[12] Their low



16 (16%) **17** (48%)

Scheme 2

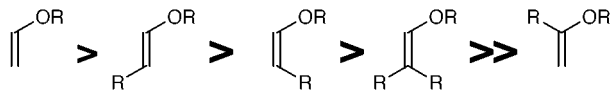


Scheme 3

reactivity was attributed to the existence of a large HOMO–LUMO gap between the dipole and dipolarophile.[12,18] The dramatic decrease in reaction rate for these disubstituted dipolarophiles, compared to the vinyl ethers described in Table 1, supports a steric involvement in diastereoselectivity. Whether this effect is purely steric or stereoelectronic in nature is ambiguous, since there still appears to be a preference for the *endo*-product (**17**).

Frontier Molecular Orbital theory has successfully rationalized both the rates and regioselectivity of most 1,3-dipolar cycloaddition reactions.[19] The fact that isomünchnones can undergo cycloaddition with both electron-rich and electron-deficient dipolarophiles is a defining feature of dipoles which readily proceed through a type II process.[1] This remarkable and useful behavior may be understood in terms of a small HOMO–LUMO energy gap.[1,5,20] We sought to further evaluate the electronic preference of isomünchnones while minimizing the steric bias on the dipolarophile. For this reason, α-diazo imide **4** was treated with $Rh_2(pfbm)_4$ in the presence of an equimolar amount of ethyl acrylate and ethyl vinyl ether at 60 °C, which resulted in a 4 : 1 mixture of cycloaddition products (Scheme 3). This comparable reactivity indicates similar FMO energetics for both electron-rich and electron-deficient dipolarophiles in the isomünchnone cycloaddition.

A pattern of diastereoselectivity for the cycloaddition of isomünchnones with vinyl ethers is apparent and appears to be controlled by the electron-donating ether functionality. Relative cycloaddition rates for these dipolarophiles are summarized in Scheme 4. Dipolarophile reactivity does not seem to be directly correlated with the extent of substitution on the alkene, but rather the placement of substitution on the alkene.



Scheme 4

In summary, we have demonstrated the diastereoselectivity of the intermolecular 1,3-dipolar cycloaddition of isomünchnones with vinyl ethers. The general nature of this diastereoselectivity is unprecedented for this class of dipoles.[5,15,20] In addition, dipolarophiles of diverse topologies have been shown to provide a synthetically feasible entry into [2.2.1] bicyclic heterocycles, in a controlled manner. Future effort in this area will include the investigation of potential stereoelectronic factors for this selective cycloaddition and expansion of the scope of vinyl ethers as dipolarophiles in the 1,3-dipolar cycloaddition reaction.

Financial support was provided by Yale Corporation. S. N. S. thanks Boehringer-Ingelheim for a summer research fellowship. The authors would like to thank Dr Susan de Gala for obtaining the crystal structure of compound **7**.

Effect of competing π-donor N-bound ligands on structure and bonding. Synthesis and structure of tungsten organoimido nitrido complexes

Caroll E. Pohl-Ferry, Joseph W. Ziller and Nancy M. Doherty*

Department of Chemistry, University of California, Irvine, CA 92697-2025, USA. E-mail: nmdohert@uci.edu

Received (in Bloomington, IN, USA) 26th July 1999, Accepted 4th August 1999

Tungsten organoimido nitrido compounds, $[W_2(N)(NR)_2Cl_5]_3$ (R = Et, C_6H_4Me-*p*), form in high yield in the reactions of $W(NR)Cl_4$ with $N(SiMe_3)_3$ and adopt structures in solution and the solid state consisting of chloro-bridged trimers of mononitrido-bridged di(organoimidotungsten) units with an unusual geometry that allows maximum π-donation from the imido and nitrido ligand set.

The nitride ion, N^{3-}, is a simple ligand that can be incorporated into a variety of environments in transition-metal compounds.[1–4] We have been interested in the nitrido ligand as a bridging group to link transition metals in new polynuclear, oligomeric and polymeric species.[5–9] To do so, it is necessary to establish control over bridging *versus* terminal structures in metallonitride compounds. Simple models of bonding suggest that competing π-donor ligands could be used to favor formation of nitrido-bridged structures. We report here, the synthesis and structure of two tungsten organoimido nitrido compounds, that support this idea. To our knowledge, these represent the first examples of *organo*imido nitrido transition-metal compounds, although compounds containing both the nitrido and parent imido (NH) ligand, especially clusters, are known,[10–15] and polynuclear haloimido nitrido complexes have been reported.[16,17]

$[W_2(N)(NEt)_2Cl_5]_3$ **1** and $[W_2(N)(NC_6H_4Me\text{-}p)_2Cl_5]_3$ **2** are isolated in high yield from the 2:1 reaction of the appropriate tungsten organoimido chloro compound with $N(SiMe_3)_3$.† ^1H NMR monitoring of the reaction indicates quantitative formation of **1** or **2** and $ClSiMe_3$ according to the stoichiometry in eqn. (1).

$$6\ W(NR)Cl_4(L) + 3\ N(SiMe_3)_3 \rightarrow [W_2(N)(NR)_2Cl_5]_3 + 9\ ClSiMe_3 + 6\ L \quad (1)$$

1 (R = Et L = none)
2 (R = C_6H_4Me-*p* L = OEt_2)

Compound **1** is a yellow air-sensitive solid while **2** is a purple air-sensitive solid. Single crystal X-ray diffraction studies indicate that **1** and **2** adopt solid state structures consisting of chlorobridged trimers of linear mononitrido-bridged ditungsten units (Figs. 1 and 2).‡ Solution studies indicate that the trimeric structure persists in dichloromethane. The ^1H NMR spectrum of **1** shows a single ethylimido signal with diastereotopic methylene protons consistent with the dissymmetry of the trimeric structure, and a molecular weight measurement of **2** confirms its trimeric nature in solution.§

The cyclic structures of **1** and **2** contain six approximately octahedral tungsten atoms each coordinated to one bridging nitrido ligand, one terminal organoimido ligand, and one terminal plus three bridging chloro ligands (Figs. 1 and 2). The $W–N_{nitrido}$ distances and $W–N_{nitrido}–W$ angles are consistent with tungsten–nitrogen double bonds in a W=N=W unit.[1,4] The $W–N_{imido}$ distances and $W–N_{imido}–C$ angles indicate tungsten–nitrogen triple bonds in an essentially linear W≡NR.[4,18] The W–Cl distances follow an understandable pattern, with $W–Cl_{terminal}$ distances (average 2.33 Å for **1**, 2.32 Å for **2**) shorter than $W–Cl_{bridging}$ distances that, in turn, vary with the *trans* ligand. Specifically, the $W–Cl_{bridging}$ distances increase on

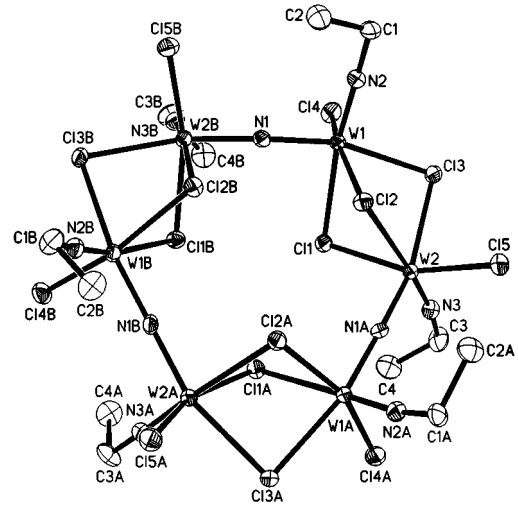

Fig. 1 Structural drawing of **1** with 50% probability thermal ellipsoids for non-hydrogen atoms. Selected bond distances (Å) and angles (°): For W=N=W, W(1)–N(1) 1.833(5), W(2B)–N(1) 1.849(5), W(1)–N(1)–W(2B) 174.5(3). For W≡NR, W(1)–N(2) 1.726(6), W(2)–N(3) 1.732(6), W(1)–N(2)–C(1) 168.6(5), W(2)–N(3)–C(3) 172.0(5). For $W–Cl_{bridging}$, W(1)–Cl(1) 2.631(2), W(1)–Cl(2) 2.443(2), W(1)–Cl(3) 2.552(2), W(2)–Cl(1) 2.452(2), W(2)–Cl(2) 2.641(2), W(2)–Cl(3) 2.546(2). For $W–Cl_{terminal}$, W(1)–Cl(4) 2.332(2), W(2)–Cl(5) 2.336(2).

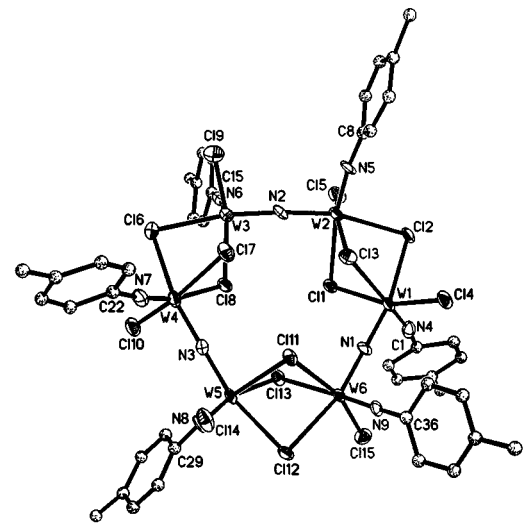

Fig. 2 Structural drawing of **2** with 50% probability thermal ellipsoids for non-hydrogen and non-carbon atoms. Selected bond distances (Å) and angles (°): For W=N=W: W(1)–N(1) 1.841(11), W(2)–N(2) 1.851(11), W(3)–N(2) 1.818(11), W(4)–N(3) 1.832(11), W(5)–N(3) 1.840(11), W(6)–N(1) 1.831(11), W(1)–N(1)–W(6) 175.3(7), W(2)–N(2)–W(3) 175.2(8), W(4)–N(3)–W(5) 175.0(8). For W≡NR: W(1)–N(4) 1.727(13), W(2)–N(5) 1.752(12), W(3)–N(6) 1.723(13), W(4)–N(7) 1.731(14), W(5)–N(8) 1.726(11), W(6)–N(9) 1.747(10), W(1)–N(4)–C(1) 167.6(10), W(2)–N(5)–C(8) 171.9(11), W(3)–N(6)–C(15) 171.0(12), W(4)–N(7)–C(22) 172.9(12), W(5)–N(8)–C(29) 176.2(10), W(6)–N(9)–C(36) 178.0(10).

going from W–Cl bonds *trans* to the terminal chloride (average 2.45 Å for **1** and **2**), to *trans* to the doubly bonded bridging nitride (average 2.55 Å for **1** and **2**), to *trans* to the triply bonded organoimido ligand (average 2.64 Å for **1**, 2.62 Å for **2**), consistent with the *trans* effects of these groups.

Of particular interest is the orientation of the two organoimido ligands in each $W_2(N)(NR)_2$ unit. The organoimido ligands are *cis* to the bridging nitrido ligand and at (RN)WW(NR) torsion angles of 105.3° for **1** and 95.2–98.9° for **2**. This nearly orthogonal orientation of the two triply bonded organoimido ligands at $W^{VI}(N)W^{VI}$ allows the complex to achieve maximum electron donation from the ligand set (each tungsten has an 18-electron count) and maximum nitrogen–tungsten π-bonding. This unusual geometry indicates that **1** and **2** may be viewed as inorganic analogs of allene with localized perpendicular π-bonds to the central atom (Fig. 3), as has also been noted for $[(\eta\text{-}C_5Me_5)W(NO)(CH_2CMe_3)](\mu\text{-}N)[(\eta\text{-}C_5Me_5)W(O)Cl]$ and $[(\eta\text{-}C_5Me_5)Mo(NO)(CH_2SiMe_3)](\mu\text{-}N)[(\eta\text{-}C_5Me_5)Mo(O)(CH_2SiMe_3)]$.[19] This is in sharp contrast with the many previously reported M=N=M compounds that are best described by delocalized three-center π-bonding.[20]

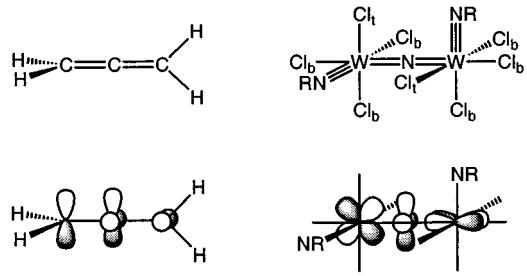

Fig. 3 Comparison of π-bonding to the central atom in allene and in the $W_2(N)(NR)_2$ unit.

Organoimido and nitrido ligands are both multiply bonding nitrogen-bound species, as terminal ligands they have similar demands for the empty π-symmetry orbitals at early transition metals, and both are capable of bridging between two or more metals. However, in a compound containing both these ligands, the nitrido should have advantages over the organoimido in a bridging position because it is sterically less demanding and a more flexible donor, able to adopt a number of different bridging structures. This is borne out by the synthesis and structures of **1** and **2**. Extension of this work to other early transition metals and the synthesis and study of 1:1:1 organoimido–nitrido–metal compounds are being explored in our laboratory.

We gratefully acknowledge support of this work by the National Science Foundation (CHE 93-21196 & 97-12775).

Notes and references

† For $[W_2(N)(NEt)_2Cl_5]_3$ **1**: a solution of $W(NEt)Cl_4$ (0.802 g, 2.17 mmol) and $N(SiMe_3)_3$ (0.250 g, 1.07 mmol) in toluene (50 mL) was stirred with heating at 90 °C under vacuum for 24 h. The solvent and volatiles were removed under reduced pressure, and the resulting solids were crystallized from dichloromethane–pentane (1:1) affording yellow crystalline **1** (0.574 g, 83%). For $[W_2(N)(NC_6H_4Me\text{-}p)_2Cl_5]_3$ **2**: a solution of $W(NC_6H_4Me\text{-}p)Cl_4\cdot Et_2O$ (2.00 g, 3.96 mmol) and $N(SiMe_3)_3$ (0.462 g, 1.98 mmol) in toluene (50 mL) was stirred with heating at 90 °C under vacuum for 24 h. The solids produced in the reaction were collected by filtration and recrystallized from dichloromethane affording purple crystalline **2** (1.32 g, 87%).

‡ *Crystal data*: for **1**: $C_{12}H_{30}Cl_{15}N_9W_6$, rhombohedral, $P\bar{3}$, a = 21.108(2), b = 21.108(2) Å, c = 16.258(3) Å, $\alpha = \beta = 90$, $\gamma = 120°$, Z = 6. Intensity data were collected at 158 K on a Siemens P4 rotating-anode diffractometer *via* a 2θ–ω scan technique in the range $2.56 < \theta < 27.50°$ using Mo-Kα radiation, λ = 0.71073 Å. All 3351 data were corrected for absorption, μ = 17.417 mm^{-1}, and for Lorentz and polarization effects. The structure was solved by direct methods (SHELXTL) and refined on F^2 by full-matrix least-squares techniques. Hydrogen atoms were included using a riding model. At convergence, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.0765$ and GOF = 1.039 for 127 variables refined against all 3123 unique data; $R1 = \Sigma||F_o| - |F_o||/\Sigma|F_o| = 0.0266$ for those 2521 data with $F_o > 4.0\sigma(F_o)$. For **2**: $C_{42}H_{42}Cl_{15}N_9W_6$, triclinic, $P\bar{1}$, a = 10.140(2), b = 15.796(2), c = 22.529(2) Å, α = 87.921(10), β = 86.200(15), γ = 78.862(14)°, Z = 2. Intensity data were collected at 158 K on a Siemens P4 rotating-anode diffractometer *via* a θ–2θ scan technique in the range $4.0 < 2\theta < 55.0°$ using Mo-Kα radiation, λ = 0.71073 Å. All 17128 data were corrected for absorption, μ = 10.33 mm^{-1}, and for Lorentz and polarization effects. The structure was solved by direct methods (SHELXTL) and refined by full-matrix least-squares techniques; the quantity minimized was $\Sigma w(F_o - F_c)^2$. Hydrogen atoms were included using a riding model. Three carbon atoms in the tolyl ring attached to N(5) are disordered and were included with two components each; four carbon atoms in the tolyl ring attached to N(6) exhibited high thermal motion, however, the probable disorder could not be fit to a reasonable model.At convergence, $R_F = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.055$, $R_{wF} = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.083$, and GOF = 2.82 for 451 variables refined against those 11817 data with $|F_o| > 6.0\sigma(|F_o|)$. Facile synthesis of well-defined water-soluble polymers *via* atom transfer radical polymerization in aqueous media at ambient temperature

X.-S. Wang, S. F. Lascelles, R. A. Jackson and S. P. Armes*

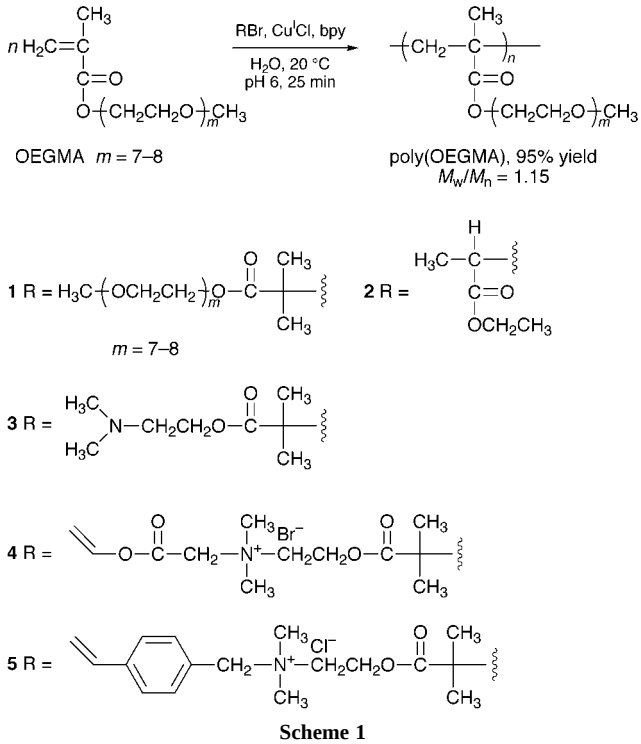
School of Chemistry, Physics and Environmental Science, University of Sussex, Falmer, Brighton, UK BN1 9QJ. E-mail: s.p.armes@sussex.ac.uk

Received (in Oxford, UK) 14th June 1999, Accepted 5th August 1999

Monomethoxy-capped oligo(ethylene oxide) methacrylate (OEGMA) is readily polymerised in aqueous media by atom transfer radical polymerisation at 20 °C using various initiators; the resulting OEGMA polymers and macromonomers were obtained in high yield (> 95%) within short reaction times and polydispersities were as low as 1.12.

Atom transfer radical polymerisation (ATRP) which is applicable to both styrenic and (meth)acrylate monomers and is remarkably tolerant of functional groups.[1,2] With regard to hydrophilic monomers, recent ATRP publications describe: (i) the polymerisation of 2-hydroxyethyl acrylate in aqueous media at 90 °C;[3] (ii) the (co)polymerisation of 2-(dimethylamino)ethyl methacrylate either in bulk or in non-aqueous media[4] and (iii) the polymerisation of sodium methacrylate at 90 °C.[5] In this latter example polymerisation was slow and incomplete: yields of only 70–80% were obtained after 21 h. Herein we describe the efficient, well-controlled polymerisation of monomethoxy-capped oligo(ethylene oxide) methacrylate (OEGMA) *via* ATRP in aqueous media at 20 °C. Excellent yields (> 95%) are obtained in short reaction times (< 0.5 h) even at 20 °C. Moreover, vinyl functional initiators can be used to prepare well-defined OEGMA macromonomers.

Our ATRP formulation was based on that described by Matyjaszewski's group.[1] The transition metal catalyst was Cu^{I}Cl and the ligand was 2,2′-bipyridine (bpy). Initiator **1** was synthesised according to a literature procedure.[5,6] A typical ATRP synthesis was carried out as follows (Scheme 1). Initiator



Scheme 1

1 (232 mg, 0.54 mmol, 1 equiv.) was dissolved in 5 ml of doubly distilled de-ionised water. To this degassed solution was added the bpy ligand (211 mg, 1.08 mmol, 2 equiv.), followed by Cu^{I}Cl (53 mg, 0.54 mmol, 1 equiv.). OEGMA monomer (9.70 g, 23 mmol, 42 equiv.) was added to this reaction mixture using a double-tipped needle and the solution was de-gassed using a nitrogen stream for 10–30 min with continuous stirring at 20 °C. The reaction solution became dark brown and much more viscous, indicating the onset of polymerisation; exotherms of 5–10 °C were typically observed. After 0.5 h, THF (50 ml) was added to the reaction solution, followed by excess $MgSO_4$ (15 g) to absorb the water. After filtration, the THF solution of poly(OEGMA) was passed through an alumina column to remove residual catalyst. THF was then removed under vacuum, yielding off-white polymers.

Molecular weight distributions were assessed using GPC (THF eluent; PMMA standards; RI detector). Polymer molecular weights, polydispersities and yields are summarised in Table 1. Conversion of OEGMA to polymer was monitored by ^{1}H NMR spectroscopy: Fig. 1(*a*) illustrates the progressive reduction of monomer vinyl signals at δ 5.4–5.8, accompanied by a concomitant increase in poly(OEGMA) signals (*e.g.* at δ 3.8–4.0). Fig. 1(*b*) shows a typical conversion *vs.* time curve derived from the NMR spectra. High conversions of monomer to polymer were obtained in short reaction times and the consumption of monomer followed first order kinetics, as expected. Narrow polydispersities (M_w/M_n < 1.12–1.30), indicative of a living polymerisation, were obtained for initiators **1**, **2** and **4**. At present we have no explanation for the somewhat higher polydispersities obtained with initiator **3**.

Overlapping peaks prevented discrimination between the NMR signals due to the oligo(ethylene oxide) initiator **1** and the OEGMA residues. However, inspection of the ^{1}H NMR spectra ($CDCl_3$ or D_2O) of the cleaned-up polymers prepared using initiators **2** and **4** confirmed the presence of the initiator, as expected. The peak integral of the NMR signal assigned to the α-proton of **2** at δ 2.1–2.2 (or to the azamethylene protons of **4** at δ 4.6) was compared to that due to the ethylene oxide protons of the OEGMA residues at δ 3.8–4.0 in order to determine the degree of polymerisation of the OEGMA chains by end-group analysis. Such calculations yielded number-average molecular weights (M_n) which were in excellent agreement with those expected from the corresponding monomer/initiator ratios (see Table 1). Moreover, in the case of initiator **4**, well-defined vinyl acetate-capped macromonomers were obtained, which are expected to be useful reactive stabilisers for poly(vinyl acetate) latex syntheses. Facile synthetic routes to such well-defined hydrophilic macromonomers are very rare in the literature, although similar selectivity has been reported by Matyjaszewski's group for the preparation of hydrophobic polystyrene-based macromonomers by ATRP utilizing a vinyl chloroacetate initiator.[7] Our attempts to prepare the analogous styrene-capped macromonomers using initiator **5** under the same conditions were not successful. High molecular weights and broad polydispersities were obtained (see Table 1), which suggests insufficient selectivity: the styrenic end-groups probably copolymerise with the OEGMA even at 20 °C.

Table 1 A summary of the molecular weights and polydispersities of various OEGMA-based polymers synthesised using ATRP in aqueous media at 20 °C. Synthesis conditions: [initiator] = 0.54–2.14 mmol; initiator : $Cu^{I}Cl$: bpy was 1 : 1 : 2 in all experiments

As far as we are aware, there have been no previous reports of rapid ATRP in aqueous media at ambient temperature. However, ATRP of hydrophobic monomers at ambient temperature is well-documented. Haddleton *et al*. described[8] the relatively slow bulk polymerisation of methyl methacrylate at 25 °C, with 92% conversion requiring a reaction time of 20 h. In contrast, Matyjaszewski and co-workers reported[9] the rapid bulk polymerisation of methyl acrylate at 22 °C. In this latter case it was shown that the choice of ligand for the Cu^{I} catalyst was critical for efficient polymerisation: much slower rates were obtained with a dialkyl-substituted bipyridine ligand than for a multifunctional ligand, hexamethylated tris[2-(dimethylamino)ethyl]amine. The same research group has also shown[10] that solvent polarity can be an important parameter in ATRP. Thus the rate of polymerisation of *n*-butyl acrylate in polar solvents such as ethylene carbonate was unexpectedly faster than that observed for bulk polymerisation, even though the monomer and initiator concentrations were significantly higher in the latter case. This observation was attributed to the mononuclear nature of the Cu^{I} catalyst. Since water is a very polar solvent, it is perhaps understandable that the ATRP of hydrophilic monomers such as OEGMA is particularly fast in aqueous media, even at room temperature. We also note that the $Cu^{I}[bpy]_2$ catalyst is more likely to be mononuclear in aqueous media, with more complex binuclear halo-bridged structures being formed in non-aqueous media.[11] One referee believes that the rapid ATRP of OEGMA described herein is due to complexation of the ethylene oxide residues to the Cu catalyst. We believe that this hypothesis is unlikely because we observe similar rates of polymerization for the ATRP of unrelated monomers such as sodium 4-vinylbenzoate.[12] The second referee pointed out that, since OEGMA is a sterically hindered monomer, its rate coefficient for termination may be anomalously low; similar observations have been recently reported for *n*-dodecyl methacrylate.[13] This would be consistent with the apparent lack of termination observed even at high conversions (see Fig. 1). This referee also suggested that the Cu–Cl bond may be more easily cleaved in water than in non-aqueous media. Thus the rate of deactivation would be reduced and faster polymerisations would ensue.

In summary, ATRP of OEGMA is facile and well-controlled under environmentally-friendly conditions; this discovery has considerable potential for commercial exploitation.

We thank the EPSRC for financial support. We also thank the referees for their comments.

Mechanism for isomerization of *n*-hexane over sulfated zirconia: role of hydrogen

Jean-Claude Duchet,*[a] Denis Guillaume,[a] Agnès Monnier,[a] Jacob van Gestel,[a] Georges Szabo,[b] Pedro Nascimento[b] and Sebastien Decker[b]

Received (in Cambridge, UK) 20th July 1999, Accepted 9th August 1999

The complex influence of hydrogen on *n*-hexane isomerization over sulfated zirconia enriched with platinum has been kinetically modelled with a simple three parameter rate equation derived from a mechanism involving Lewis sites and hydride species.

Sulfated zirconias are acidic catalysts which are able to isomerize linear alkanes at low temperature.[1,2] In practice, hydrogen is added to the isomerization unit in order to saturate the aromatics contained in the C_5–C_6 fraction and to prevent coking of the platinum enriched catalyst. Some authors attribute participation of hydrogen in isomerization *via* activation on platinum by creating either Brønsted acid sites[3,4] or hydride species accelerating the desorption of the carbenium ions.[5,6] In the literature, analysis of the influence of hydrogen has been limited to low hydrogen pressures.[6,7] Here we report the influence of hydrogen over a wide range of partial pressures (0.5–4.5 MPa) independently of the hexane pressure (0.1–0.5 MPa). Insight into the isomerization mechanism is obtained from the kinetic treatment of the data.

The catalyst was prepared as follows: zirconium hydroxide was precipitated from an aqueous solution of zirconium oxychloride by ammonium hydroxide. The dry material was sulfated with 0.5 M H_2SO_4, and then crystallised at 923 K. The sulfur content amounted to 2.0 wt%. Platinum was loaded at 0.3 wt% by impregnation with an H_2PtCl_6 solution and the final catalyst was calcined at 753 K. The catalyst was activated in the reactor at 623 K for 2 h in a dry air stream and contacted with flowing hydrogen at 423 K during 1 h. Dry *n*-hexane (0.1, 0.3 or 0.5 MPa) was vaporised in a dry hydrogen–helium mixture at 5 MPa total pressure and 423 K. The hydrogen partial pressure was varied from 0.5 to 4.5 MPa. Conversions were kept low to calculate initial rates.

The reaction was not observed without hydrogen owing to rapid deactivation. With hydrogen, the catalyst was stable for > 1 week and cracking was negligible. The distribution among isomers showed that 2-methylpentane, 3-methylpentane and 2,3-dimethylbutane were primary products formed in their thermodynamic ratio. The formation of 2,2-dimethylbutane was a consecutive reaction. The distribution was not influenced by hydrogen partial pressure.

The variation of the isomerization rate with hydrogen pressure is shown in Fig. 1. At a given hexane pressure, the rate strongly increases up to a maximum, then slowly decreases. The position of the maximum was shifted from 0.3 to 1.5 MPa pressure of hydrogen with increasing hexane pressure in the range 0.1–0.5 MPa. The reaction order with respect to *n*-hexane was slightly lower than unity at low hydrogen pressure, and reached unity beyond the maximum.

Any proposed mechanism should account for the change in reaction order for hydrogen, from positive to negative, so yielding a maximum isomerization rate. Kinetic modelling was used to infer the reaction sequence.

The maximum activity with hydrogen pressure has scarcely been reported in the literature dealing with isomerization of light alkanes over acidic catalysts. A classical metal–acid bifunctional mechanism has been developed on platinum–zeolite catalysts operating at 523 K. The detrimental effect of hydrogen was easily interpreted by the dehydrogenation step of the hydrocarbon into an alkene. However, further dehydrogenation into a diene is required to account for a positive effect at low hydrogen pressure, so yielding a maximum in the curves.[8] We found that the corresponding rate equation completely failed to fit our data in the whole range of hexane pressure. Indeed, a classical bifunctional metal–acid mechanism is improbable at 423 K. The alkene concentration is likely to be too low, and the catalyst more likely operates by an acidic mechanism. The acidity of sulfated zirconia is generally attributed to Brønsted sites[9] and accordingly, carbenium ions are formed *via* carbonium intermediates. However, reaction sequences based on this first step did not yield satisfactory rate equations. On the other hand, Lewis sites are readily created during the activation of sulfated catalysts at 923 K.[9] We propose a mechanism involving Lewis sites in which hydride abstraction from *n*-hexane (RH) on coordinatively unsaturated zirconium atoms creates carbenium ions which adsorb on Lewis basic sites (bridged oxygen atoms). The adsorbed carbenium ions are then rapidly isomerized and finally desorbed by the hydride species (Scheme 1). The isomerization step is not rate-limiting, as shown by the thermodynamic distribution of primary isomers.

This scheme is fully consistent with the poisoning effect of water adsorbed on Lewis sites. The closed sequence isomerizes

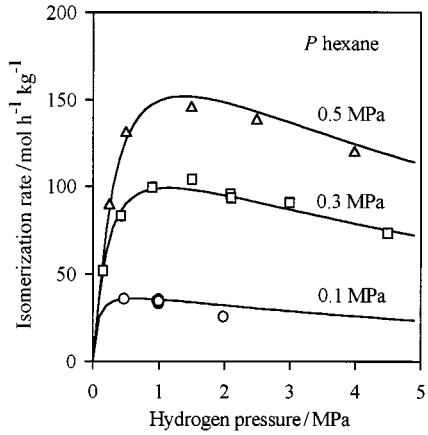

Fig. 1 Isomerization of *n*-hexane at 423 K and 5 MPa as a function of hydrogen pressure.

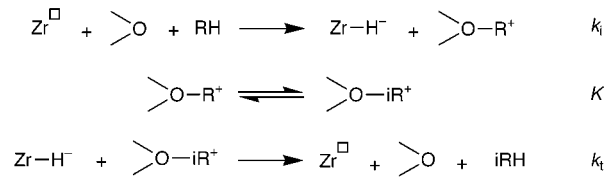
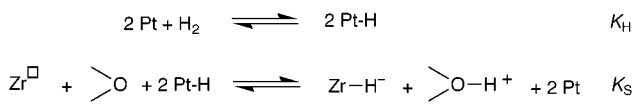


Scheme 1 Isomerization sequence.

n-hexane in the absence of hydrogen but the catalyst rapidly deactivates by coking. Hydrogen prevents this coking.

The influence of hydrogen on the isomerization rate may be rationalised by a second sequence (Scheme 2) involving platinum. Molecular hydrogen is homolytically dissociated on the metal and the hydrogen atoms migrate by spillover to the sulfated zirconia where they are converted into hydride species (Zr–H$^-$) and protons (O–H$^+$).



Scheme 2 Hydrogen sequence.

In this manner, hydrogen increases the concentration of hydride species, accelerates the desorption of carbenium ions and thus the overall rate. This explains the positive order at low hydrogen pressure, while the decrease in activity at higher hydrogen partial pressure is simply owing to a competition between protons and carbenium species.

Kinetic treatment of this sequence yielded the rate eqn. (1)

$$r = \frac{kP_{RH}}{\left\{1 + \alpha P_H + \frac{\beta P_{RH}}{\alpha P_H}\right\}^2} \quad (1)$$

with $k = Lk_i$ (L = number of adsorption sites), where $\alpha = K_H K_S$, $\beta = (k_i/(k_t)[1 + (1/K)]$, P_H = pressure of hydrogen and P_{RH} = pressure of hexane.

Besides the rate constant k, which is related to the number of sites, two parameters, α and β, characterise the catalyst. Parameter α is associated with the sequence combining the capacity of platinum to adsorb hydrogen (K_H) and the transfer of hydrogen by spillover to the coordinatively unsatured zirconium and to the oxygen sites of the sulfated zirconia (K_S). The spillover is determined by the zirconia surface. The second parameter β is representative of the strength of the sulfated zirconia sites in the isomerization sequence.

The curves on the Fig. 1 were obtained after optimisation of the kinetic parameters. The fit is very satisfactory over the whole range of hexane pressure. This model has the advantage of involving two independent parameters that can be used as a guide to improve the catalysts. For instance, the hydrogen pressure at maximum isomerization rate is inversely proportional to α. Thus, to minimise the hydrogen pressure, α should be increased, either by increasing the platinum efficiency or the spillover rate.

The above mechanism demonstrates the importance of hydrogen in isomerization. For the first time, a complete reaction sequence is proposed, that offers a very good alternative for the classical bifunctional mechanism. Such a mechanism opens perspectives in the interpretation of the influence of hydrogen on various reactions.

Efficient transfer hydrogenation of alkynes and alkenes with methanol catalysed by hydrido(methoxo)iridium(III) complexes

Kazuhide Tani,* Aika Iseki and Tsuneaki Yamagata

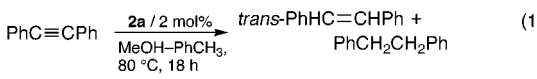
Department of Chemistry, Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka 560-8531, Japan. E-mail: tani@chem.es.osaka-u.ac.jp

Received (in Cambridge, UK) 15th July 1999, Accepted 10th August 1999

Hydrido(methoxo)iridium(III) complexes, [{Ir(H)(diphosphine)}$_2$(μ-OMe)$_2$(μ-Cl)]$^+$Cl$^-$ [diphosphine = (*R*)-BINAP **2a or = 2,2′-bis(diphenylphosphino)-1,1′-biphenyl (BPBP) **2b**] catalysed transfer hydrogenation of alkynes with methanol to give *trans*-alkenes selectively; plausible reaction pathways are also proposed.**

Catalytic transfer hydrogenation of unsaturated compounds using organic hydrogen donors such as alcohols and formic acid has widely been studied as an attractive method of reduction owing to its operational simplicity and environmentally friendly properties of the hydrogen donors.[1] Although methanol could be an exceedingly useful source of hydrogen from many viewpoints,[2] only a few reports of its use in homogeneous catalysis are available.[2,3] In addition, in contrast to the transfer hydrogenation of ketones, that of simple alkynes and alkenes by homogeneous catalysis remains relatively undeveloped.[3b,d,4] Here, we report efficient selective catalytic transfer hydrogenation of alkynes to *trans*-alkenes with soluble iridium complexes by using methanol as a hydrogen donor.

Recently we have reported that [IrCl(diphosphine)]$_2$ [diphosphine = BINAP **1a**, or 2,2′-bis(diphenylphosphino)-1,1′-biphenyl (BPBP) **1b**][5] carrying a peraryldiphosphine readily activates methanol at ambient temperature to give iridium(III) hydrido(methoxo) complexes, [{IrCl(H)(diphosphine)}$_2$(μ-Cl)(μ-OMe)$_2$]Cl [diphosphine = BINAP **2a** or BPBP **2b**].[6] In the course of the study concerning the reactivity of complexes **2** we have found that these hydrido(methoxo) complexes serve as efficient catalyst precursors for reduction of alkynes to give *trans*-alkenes using methanol as a source of hydrogen. Over-hydrogenation to alkanes was also observed. Hydrogenation proceeded in toluene–methanol (1:1, v/v) solution under fairly mild conditions at 80 °C in the presence of a catalytic amount of **2** [eqn. (1)].[7]



(1)

The results are summarized in Table 1. After 18 h with catalyst **2a**, diphenylacetylene was consumed completely to give 83% *trans*-stilbene and 17% 1,2-diphenylethane. Formation of *cis*-stilbene was not detected. When the reaction was stopped after 1 h, the conversion of diphenylacetylene was 29% and 12% *trans*-stilbene and 16.5% *cis*-stilbene were obtained, accompanied with 0.5% 1,2-diphenylethane. Reaction after 2 h gave the *trans*-alkene as the main product with 52% conversion. Although the reaction also proceeded under reflux > 36 h were required before complete consumption of diphenylacetylene. Hydrogenation of *trans*-stilbene gave 29% of 1,2-diphenylethane after 18 h, whereas hydrogenation of *cis*-stilbene gave the alkane in 39% yield, with almost all starting *cis*-stilbene being isomerised to *trans*-stilbene. Thus, *cis*-stilbene was hydrogenated faster than *trans*-stilbene and isomerisation of the *cis*-alkene to the *trans*-alkene proceeded much faster than its hydrogenation to the alkane in the presence of the iridium catalyst. The rate difference of the reduction between the *cis* and the *trans* isomers may reflect the difference of their binding constants,[8] resulting in high selectivity for the *trans*-alkene in the product. In other words, the initial hydrogenation product of diphenylacetylene should be *cis*-stilbene, which is isomerised to *trans*-stilbene by the iridium catalyst under the reaction conditions. Diphosphine complexes **1** can also be employed as the catalyst precursor for transfer hydrogenation. Interestingly, ethanol or propan-2-ol, generally more favorable sources of hydrogen,[2] were far less effective for the present transfer hydrogenation, and ketones were poor substrates. Acetophenone was hydrogenated in only 32% yield to give phenethyl alcohol with **2a** in toluene–methanol at 80 °C after 18 h. When the transfer hydrogenation was conducted in CD_3OD–toluene (1:1) using **2a** as a catalyst precursor, the deuterium contents of the olefinic as well as the methylene hydrogens of the products amounted to 100%. For the reaction performed in a CH_3OD–toluene (1:1), however, the corresponding values were 43 and 41%, respectively, as determined by 500 MHz ^{1}H NMR spectroscopy and GC–MS. Thus, during transfer hydrogenation hydrogens of both CH_3 and OH groups of methanol were incorporated in the products.

From the solid residue obtained from the catalytic reduction product of 1-phenylpropyne with methanol using complex **2a** as a catalyst precursor after removing all volatile materials *in*

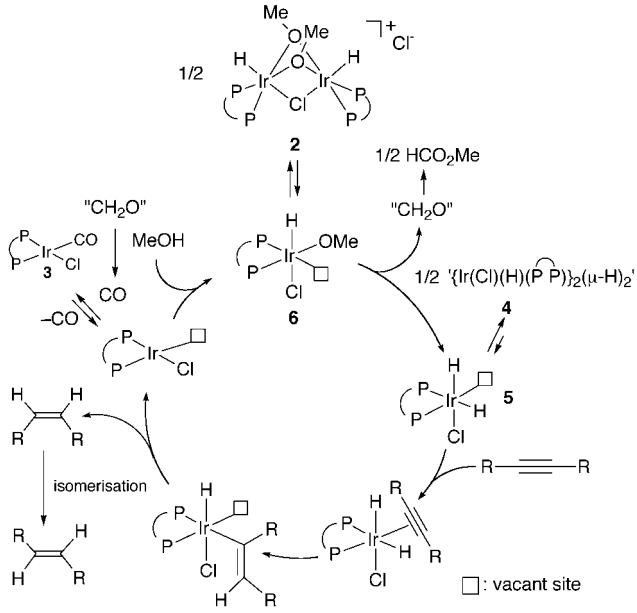
[b] Solvent: EtOH–toluene (1:1). [c] Solvent: Pr^{i}OH–toluene (1:1). [d] nd = not determined. Mixtures of dodecenes and dodecane were detected by GC–MS.



Scheme 1

vacuo, two iridium complexes, IrCl(CO)(BINAP) **3**[9] (major) and '{Ir(Cl)(H)(BINAP)}$_2$(μ-H)$_2$' **4** (minor),[10] were isolated. Although complex **3** showed comparable catalytic activity to that of **2a** for the transfer hydrogenation of diphenylacetylene, complex **4** was far less efficient. Methyl formate, the Tishchenko product of the by-product formaldehyde, was also detected by GC–MS in the reaction mixture. Based on these experimental results, we propose a plausible reaction pathway of the transfer hydrogenation of alkynes as well as alkenes and the isomerisation of alkenes catalysed by complex **2** (Scheme 1).[11] The real catalyst may be a nascent mononuclear dihydride species such as **5**, which dimerises to give the catalytically inactive dimer **4**. The possibility that coordination of alkyne to the monomeric hydrido(methoxo)complex **6** is the first step followed by hydride insertion to give a methoxo(vinyl) complex, however, can not be eliminated, though such species could not be detected by NMR of the reaction mixture of complex **2a** and diphenylacetylene.

This work was partly supported by the Grant-in Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan. BINAP was a generous gift from Takasago Perfumery Co. Ltd.

9 Complex **3**: orange powder. Anal. Calc. for $C_{45}H_{32}ClIrOP_2$: C, 61.53; H, 3.67. Found: C, 61.42; H, 3.84%; Mp > 120 °C (decomp.); MS (FAB) *m/z* 878 (M^+), 850 (M^+ − CO); IR 1986 (film, ν_{CO}), 304w cm^{-1} (Nujol, ν_{Ir-Cl}); δ_P($CDCl_3$, 121 MHz) 16.5 (d, *J* 28 Hz), 22.7 (d, *J* 28 Hz); δ_C($CDCl_3$, 75 MHz) 180.7 (dd, *J* 11, 123 Hz, *C*O). Complex **3** can be quantitatively prepared from the reaction of **1** and CO.

10 Complex **4**: yellowish orange powder, IR (Nujol) 2279 (ν_{Ir-H_t}), *ca.* 1620w br cm^{-1} (ν_{Ir-H_b}); δ_H($CDCl_3$, 300 MHz) −22.38 (dd, *J* 15, 21 Hz, Ir–H$_t$) and −11.57(tt, *J* 8, 64 Hz, Ir–H$_b$); δ_P($CDCl_3$, 121.5 MHz) 3.6 (dd, *J* 9, 10 Hz) and 5.9 (dd, *J* 9, 10 Hz); MS (FAB): group of peaks centered at *m/z* 1703 resembling the simulated pattern for (M^+ − 1) (M = $C_{88}H_{68}{}^{35}Cl_2{}^{193}Ir_2P_2$). Although complex **4** could not be isolated as a pure state, on the basis of these spectral data we tentatively propose the structure '{Ir(H)(Cl)(BINAP)}$_2$(μ-H)$_2$'. Complex **4** can also be obtained as the main product by pyrolysis of complex **2a** at 80 °C in methanol–toluene.

11 For isomerisation as well as hydrogenation of alkenes, the same dihydride **5** can also act as a catalyst. Insertion of *cis*-alkene into Ir–H and subsequent β-hydrogen elimination from the hydrido(alkyl) complex gives *trans*-alkene and **5**, or reductive elimination from the hydrido(alkyl) complex gives alkane and 'Ir(diphosphine)Cl', respectively.

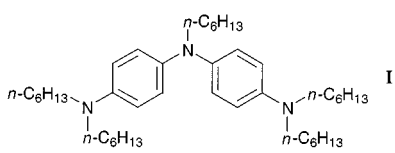
Received (in Cambridge, UK) 30th June 1999, Accepted 10th August 1999

Electroanalytical sulfide detection *via* oxidation of N^1-[4-(dihexylamino)phenyl]-N^1,N^4,N^4-trihexyl-1,4-phenylene diamine (DPTPD) deposited in form of microdroplets onto basal plane pyrolytic graphite electrodes immersed in aqueous 0.1 M $NaClO_4$ containing sulfide is proposed to be associated with two consecutive reversible one electron processes accompanied by ClO_4^- uptake, sulfide accumulation, and formation of a methylene blue derivative.

Voltammetric experiments at microdroplets of electrochemically active materials deposited on suitable types of electrode surfaces in form of an organic oil have recently been shown to result in unique electrochemical characteristics.[1,2] An organic redox system such as phenylenediamine can be made highly insoluble in aqueous media by introducing several hexyl chains into the molecular structure. With this kind of derivatisation the resulting material shows as a further useful property an extremely low tendency to crystallise or freeze into a solid glass. Surprisingly, the liquid nature of the material at room temperature remains even after oxidation and the associated uptake of anions from the solution phase to achieve charge neutrality. The material resulting from this type of redox process, a room temperature ionic liquid, is of considerable interest for electrochemical applications requiring ion accumulation and/or ion conduction.

Redox processes in microdroplets of organic oils proceed *via* exchange of anions with the surrounding solution phase and for chemically reversible processes, such as the first oxidation of tetrahexylphenylenediamine,[1] the ion exchange process has been shown to be very fast. Usually the most hydrophobic anion crosses from the aqueous into the organic liquid phase most readily. In cases in which secondary chemical processes are coupled to the redox process much more complicated conditions arise. Voltammograms become chemically irreversible and products mix with the original oil phase or escape into the aqueous solution phase. The presence of a product with a redox potential different to that of the starting material may interfere with the mass and charge transport in the microdroplet and therefore considerably change the voltammetric characteristics. The rate of the chemical follow up step is a crucial parameter which determines whether (i) the redox process can be driven to completion before reaction or (ii) the chemical step is fast and directly proceeds thereby effectively stopping any charge transport by electron hopping in the zone close to the electrode.

In the present study a novel redox system, N^1-[4-(dihexylamino)phenyl]-N^1,N^4,N^4-trihexyl-1,4-phenylenediamine (DPTPD, structure **I**) is deposited in form of microdroplets onto basal plane pyrolytic graphite electrodes, immersed in aqueous electrolyte media, and used in voltammetric experiments. A key feature of this type of molecule is its ability in the presence of sulfide to undergo a nucleophilic substitution reaction at the aromatic rings to yield phenothiazine type derivatives.[3] This type of process is known as the 'methylene blue reaction'[4] and used for the selective and highly sensitive analytical determination of traces of sulfide with *N*,*N*-dimethylphenylenediamine and a chemical oxidant, Fe^{3+}. The preliminary work described here is aimed at coupling the highly selective chemical sulfide detection method *via* the methylene blue process to the electrochemical process in the microdroplet deposit at the electrode surface.



I

DPTPD deposited onto a basal plane pyrolytic graphite electrode surface and immersed into aqueous 0.1 M $NaClO_4$ undergoes two well defined and reversible oxidation processes shown in Fig. 1. Based on the comparison of the amount of material deposited, 1.7×10^{-9} M corresponding to 0.17 mC per electron transferred, and the charge under the first and second oxidation responses (combined 0.34 ± 0.03 mC), the processes may be identified as the first and the second oxidation of DPTPD [eqn. (1) and (2)]. For this amount of deposit present on the surface of the graphite electrode the charge under the voltammetric response for the oxidation (Fig. 1) is essentially independent of the scan rate over the range of 1–100 mV s^{-1} and therefore a nearly complete conversion of the material even at moderately fast scan rate appears to be possible. However, the lack of symmetry in the observed voltammetric responses[5] suggests that mass transport effects are present and affect the shape. Voltammetric data are summarised in Table 1. The comparison of the voltammetric characteristics with results obtained for the oxidation of THPD under similar conditions[1] suggests that DPTPD is chemically much more stable in the dicationic oxidation state because of delocalisation of the

[a] Peak-to-peak separation of the voltammetric responses associated with oxidation and the reduction. [b] The half wave potential, $E_{1/2}$, corresponds to the mid-potential given by $1/2(E_p^{ox} + E_p^{red})$.

positive charge over both aromatic rings (see structure **I**). Changes in shape or width at half height, ΔE_{hh}, of the voltammetric response, may be interpreted as a measure of the interaction of redox centres in the organic oil.[6] The wider peak for the second oxidation process is consistent with a better mixing or repulsive interaction in the regular solution model[7] of the $DPTPD^{2+}$ and $DPTPD^{+}$ containing ionic liquids compared to the mixing of the $DPTPD^{+}$ containing ionic liquid and the neutral oil.

The experiment shown in Fig. 1 has been conducted with 1.7×10^{-9} mol deposit. It can be calculated, based on the geometric area of the electrode and a hypothetic density of DPTPD of 0.5 g cm^{-3}, that this amount corresponds to a layer of *ca.* 57 nm height. However, owing to the surface morphology of the basal plane pyrolytic graphite microdroplets of *ca.* 0.1 μm size are anticipated. Changing the amount of deposited material causes a corresponding change in the charge under the voltammetric signals, although for high coverages corresponding to a layer of more than *ca.* 1 μm height the time for the redox process to go to completion becomes long (several minutes).

When the concentration of the supporting electrolyte is changed or other types of anion such as nitrate are used characteristic changes in form of shifts in the reversible potential, $E_{1/2}$, following the same trend observed in earlier studies are detected. However, in the presence of SH^- ions, the voltammetric response for the oxidation of DPTPD changes dramatically. Fig. 2 shows voltammetric responses for the oxidation of a deposit of 4.2×10^{-9} mol DPTPD on a 4.9 mm diameter basal plane pyrolytic graphite electrode immersed in aqueous 0.1 M $NaClO_4$ containing 2 mM HS^-. It can be seen that the main response at $E_{1/2}$ = 0.14 V *vs.* SCE drastically changes over consecutive potential cycles. A new broad response at E_p^{ox} = *ca.* 0.3 V *vs.* SCE can be detected on the first positive scan of a multi-cycle voltammogram and a product response gradually appears at $E_{1/2}$ = *ca.* −0.1 V *vs.* SCE. Qualitatively, the rate at which the change in the voltammogram occurs depends on the concentration of sulfide present in the solution phase and the experimental conditions such as the scan rate.

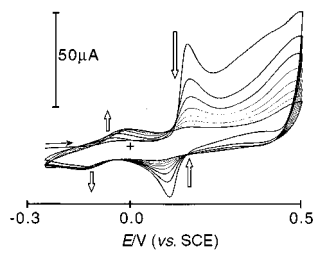

Fig. 2 Cyclic voltammograms obtained for the oxidation of 3.4×10^{-9} mol DPTPD deposited onto a 4.9 mm diameter basal plane pyrolytic graphite electrode and immersed in aqueous 0.1 M $NaClO_4$ containing 2 mM HS^- (scan rate: 20 mV s^{-1}).

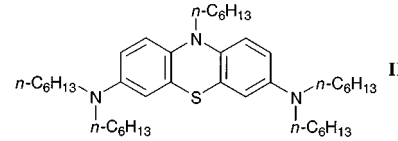
Based on the known redox chemistry of dimethylphenylenediamine[4] it is proposed that the product of the chemical reaction step in the microdroplet is a hexyl derivative of methylene blue (PHPD, structure **II**). A hypothesis for the overall mechanism of



II

this reaction, which involves DPTPD in the monocationic state, is given in eqn. (3). The voltammetric response associated with the formation of the product with $E_{1/2}$ = *ca.* −0.1 V *vs.* SCE may be proposed to result from the reversible one electron redox process given in eqn. (4). The range of organic oils giving room

$$[DPTPD^{+}ClO_4^{-}]_{oil} + HS^{-} \rightarrow [PHPD^{+}ClO_4^{-}]_{oil} + 3\ H^{+} + 4\ e^{-} \quad (3)$$

$$[PHPD^{+}ClO_4^{-}]_{oil} + e^{-} \rightleftharpoons PHPD_{oil} + ClO_4^{-} \quad (4)$$

temperature ionic liquids can be easily extended by derivatising the core redox molecule with long chain alkyl groups and chemical systems of high analytical value can be employed. The novel electroanalytical procedure based on sulfide accumulation in oil microdroplets by ion-exchange and selective detection by a chemical reaction sequence promises to combine high selectivity and sensitivity and is open to the use of combined spectroelectroanalytical techniques.

F. M. thanks the Royal Society for the award of a University Research Fellowship and New College, Oxford, for a Stipendiary Lectureship in Physical Chemistry.

Notes and references

† The redox active reagent N^1-[4-(dihexylamino)phenyl]-N^1,N^4,N^4-trihexyl-1,4-phenylenediamine (DPTPD) was prepared *via* refluxing N^1-[4-aminophenyl]-1,4-phenylenediamine (200 mg) with sodium hydride (192 mg, 8 equiv.) and hexyl bromide (1.32 g, 8 equiv.) in DMF (20 ml) at 90 °C for 12 h. The crude reaction mixture was purified by pouring into water (20 ml), extracted with ethyl acetate (3×20 ml), dried ($MgSO_4$), and the solvent removed in vacuum, and the resulting crude oil purified by chromatography over silica gel (2% Et_2O–98% hexane) to afford the title compound (142 mg) pure in 23% yield. ^1H NMR(d^8-toluene,200 MHz); 0.87 (15H, br t), 1.15 (30H, br), 1.48 (8H, br), 1.65 (2H, br), 3.10 (8H, br t), 3.55 (2H, br t), 6.61 (4H, br d), 6.95 (4H, br d); *m/z* (CI) 620 (M + 1); HRMS, calc. for $C_{42}H_{74}N_3$ 620.5883, found 620.5891.

Electrochemical experiments were conducted in a conventional three-electrode cell with a 4.9 mm diameter basal plane pyrolytic graphite working electrode, a gold wire counter electrode and a saturated calomel (SCE, Radiometer, Kopenhagen) reference electrode. A potentiostat (Autolab PGSTAT 20, Ecochemie, Netherlands) was used for cyclic voltammetric experiments. The procedure for the deposition of DPTPD microdroplets on the surface of the basal plane pyrolytic graphite electrode was based on evaporation of a solution of 0.1 mM DPTPD in acetonitrile. Solutions were degassed with argon (Pureshield, BOC) for at least 15 min prior to experiments. All studies were carried out at 20 ± 2 °C.

Intramolecular alkylation of an α-sulfinyl vinylic carbanion without loss of optical purity: a novel access to chiral cyclic vinylic sulfoxides

Naoyoshi Maezaki, Mayuko Izumi, Sachiko Yuyama, Chuzo Iwata and Tetsuaki Tanaka*

Graduate School of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565-0871, Japan. E-mail: t-tanaka@phs.osaka-u.ac.jp

Received (in Cambridge, UK) 1st July 1999, Accepted 9th August 1999

Novel cyclisation *via* intramolecular α-alkylation of vinylic sulfoxides was studied and cyclic vinylic sulfoxides of various ring sizes (5–7) were synthesised from both (*E*)- and (*Z*)-isomers without loss of optical purity.

1-Alkenyl aryl sulfoxides are deprotonated at the α-position and generate vinylic carbanion species, which react with a variety of electrophiles such as alkyl halides, epoxides, aldehydes and ketones.[1] This methodology is very useful for the synthesis of substituted vinylic sulfoxides, which can be transformed into a variety of functional groups and which also have potential use for asymmetric reactions.[2] However, research on the intermolecular reactions of α-lithio vinylic sulfoxides has revealed two problems: (i) contamination of the geometric isomer by isomerisation of its olefin moiety, and (ii) racemisation of the stereogenic center on the sulfur atom during isomerisation.[3] During the course of our research on the reaction of α-sulfinyl carbanions,[4] we have become interested in intramolecular α-alkylation of vinylic sulfoxides, which, to the best of our knowledge, has never been discussed in the literature (Scheme 1). This reaction has two advantages. (i) Not only (*E*)-isomers but also (*Z*)-isomers could be cyclised into the same product *via* rapid isomerisation; this would then provide a cyclic vinylic sulfoxide. Therefore, neither selective preparation of the geometric isomers nor their separation is required. (ii) The loss of enantiomeric excess is expected to be overcome since the intramolecular reaction is generally milder than the corresponding intermolecular version, due to the reduced decrease in the entropy of the intramolecular system.

Here we report a novel cyclisation *via* intramolecular alkylation of α-sulfinyl vinylic carbanions generated from (*E*)- and (*Z*)-isomers; this process provides cyclic vinylic sulfoxides without a subsequent loss of optical purity.

We began our study employing (*E*,*R*)-6-iodohex-1-en-1-yl *p*-tolyl sulfoxide (*E*)-**1a**. On treatment of (*E*)-**1a** with LDA (1.5 equiv.) in THF at −78 °C, rapid cyclisation proceeded to give cyclohex-1-enyl *p*-tolyl sulfoxide **2** in 82% yield; neither elimination of iodide nor the rearrangement of the double bond to the β,γ-position was observed (Table 1, entry 1). The corresponding bromide (*E*)-**1b** also afforded **2** in a comparable yield (79%) (entry 2). On the other hand, the tosylate and mesylate analogues caused the production of many products and therefore resulted in poor results (entries 3 and 4). Variation of the additive, base and solvent used did not improve the yield (entries 5–13).

Next, we examined cyclisation of ω-iodo vinylic sulfoxides (*E*)-**1e**,**f** with different chain lengths. Five- to seven-membered rings were formed in a good yield (79–82%; Table 2, entries 1–3). However, an eight-membered ring could not be formed even under highly dilute conditions (0.001 M), yielding instead many unidentified products together with the dimer **6** (22%) (entry 4). Then, we focused on the intramolecular alkylation of (*Z*)-isomers. As expected, cyclisation of (*Z*)-**1a**,**e**,**f** proceeded *via* isomerisation of their olefin geometry followed by cyclisa-

tion to give **2**–**4**, respectively, in moderate yield (64–71%; entries 5–7).

Posner reported that α-deprotonation of optical pure (*E*,*R*)-undec-1-en-1-yl *p*-tolyl sulfoxide followed by reprotonation produced no racemisation, whereas similar treatment of the corresponding (*Z*)-isomer produced racemisation (*ca.* 30% loss of optical purity).[3] Therfore, the specific rotations of the cyclised products of intramolecular alkylation from the (*E*)- and (*Z*)-isomers were compared. The cyclic vinylic sulfoxides from the (*Z*)-isomers have almost the same specific rotations as those from the corresponding (*E*)-isomers. Furthermore, the products **2** and **3** prepared from (*E*)- and (*Z*)-ω-iodo vinylic sulfoxides **1a** and **1e** were confirmed to be highly optically pure (≥96% ee) by chiral HPLC (Daisel Chiralcel OB). As we expected, racemisation did not occur appreciably during (*Z*)- to (*E*)-isomerisation with the intramolecular alkylation of α-lithio vinylic sulfoxides.

The mechanism of racemisation in the α-carbanion of the (*Z*)-vinylic sulfoxide has not been revealed. However, the results of Posners' experiments indicate that racemisation occurs during isomerisation because no racemisation occurs in the corresponding reaction of the (*E*)-isomer. This means that the intramolecular alkylation of the (*Z*)-isomer is not a stepwise reaction involving isomerisation and cyclisation. We assumed the concerted mechanism shown in Fig. 1, wherein the σ*-orbital of the internal C–X bond participates in the olefin isomerisation by accepting the carbanion extending through the sp^2 carbon and assists the isomerisation.[1c,5] This interaction with the internal electrophile would prevent the racemisation of the sulfoxide.

A typical experimental procedure is described for the reaction of 7-iodohept-1-en-1-yl tolyl sulfoxide with LDA. A solution of the iodide **1f** (43 mg, 0.12 mmol) in dry THF (2.3 ml) was added to a solution of LDA (1.5 equiv.) [prepared from Pr^i_2NH (25 μl, 0.18 mmol) and 1.58 M BuLi in hexane (115 μl, 0.18 mmol) in dry THF (2.3 ml)]. The solution was stirred at −78 °C under N_2. After 30 min, the reaction was quenched with saturated aqueous NH_4Cl and extracted with EtOAc. The extract was washed with brine prior to drying and solvent evaporation. The crude sample was purified by preparative TLC on silica gel with hexane–EtOAc (2 : 1) to give cyclohex-1-enyl *p*-tolyl sulfoxide (22 mg, 79%).

In summary, we found a ring-forming reaction *via* intramolecular alkylation of the α-lithio vinylic sulfoxides, which proceeded in moderate to good yield. Interestingly, even vinylic sulfoxides with (*Z*)-configuration were cyclised *via* rapid isomerisation; no racemisation occurred at the sulfur atoms. Further study of this method of cyclisation is currently underway.

Regioselective modification of the sugar moiety in pyrimidine nucleosides *via* a 4′,5′-dehydro-2′,3′-anhydrouridine intermediate

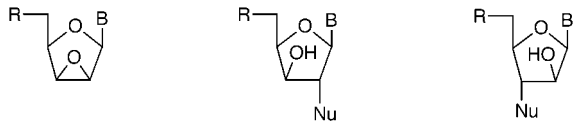
Kosaku Hirota,* Hideki Takasu, Yoshie Tsuji and Hironao Sajiki

Laboratory of Medicinal Chemistry, Gifu Pharmaceutical University, Mitahora-higashi, Gifu 502-8585, Japan. E-mail: hirota@gifu-pu.ac.jp

Received (in Cambridge, UK) 12th July 1999, Accepted 9th August 1999

3′-Substituted pyrimidine nucleoside derivatives are obtained in moderate to high yields by the reaction of 1-(2′,3′-anhydro-5′-deoxy-4′,5′-didehydro-α-L-*erythro*-pentofuranosyl)uracil with nucleophiles without the formation of the corresponding 2′-adduct.

Nucleosides modified in the sugar moiety have become important components of both chemotherapeutic agents, as potential antimetabolites,[1] and synthetic oligonucleotide probes.[2] From a synthetic point of view, it is desirable to develop a common key intermediate. 2′,3′-Anhydro-β-D-lyxo-



1 **2** **3**

furanosyl pyrimidine nucleosides **1** first synthesized by Fox *et al.*[3] are versatile building blocks, which through a nucleophilic ring-opening reaction can function as precursors of enantiomerically pure and biologically interesting pyrimidine nucleoside derivatives, and a number of reports for the application of **1** have appeared in the literature.[4] However, it is well known that the nucleophilic addition of **1** gave a mixture of 2′- and 3′-adducts (**2** and **3**) in most cases.

During our studies on the nucleophilic modification of 2′,3′-epoxy derivatives **1** and related compounds, we have discovered that the treatment of 2′,3′-epoxy-5′-iodouridine **4**[3c] with MeONa afforded 4′,5′-dehydro-5′-deoxy-3′-methoxy derivative **5a** in 96% yield as the sole product (Scheme 1). The possible reaction intermediates, 1-(2′,3′-anhydro-5′-deoxy-4′,5′-didehydro-α-L-*erythro*-pentofuranosyl)uracil **6** and 5′-iodo-3′-methoxy derivative **7**, were prepared. The epoxide **6** reacted regioselectively with MeONa to give the corresponding 3′-adduct **5a** in 80% yield *via* regiospecific nucleophilic attack of the methoxide anion at the highly reactive allylic 3′-position of **6**. On the other hand, only 2′,5′-anhydro derivative **8** was accessible from 5′-iodo-3′-methoxy derivative **7** without the formation of **5a** (Scheme 1).

We have now worked out an efficient synthetic method for the epoxide **6**, possessing contiguous enol ether and epoxide moieties in the molecule, which acts as a prominent precursor for a variety of 3′-adducts **5** and that can be incorporated into 3′-modified pyrimidine nucleosides. The synthesis of 2′,3′-anhydrouridine **6** was achieved in 92% yield by the reaction of **4** with LiHMDS (2.2 equiv.) in dry DMF (0 °C, 4 h). The efficiency of **6** as the precursor of the modified sugar moiety was demonstrated in the nucleophilic addition using various nucleophiles (Table 1). With the exception of two examples (Table 1, entries 1 and 2), which needed reflux temperatures for the completion of the reaction, all other additions were achieved at room temperature, and the yields of the 3′-adduct **5** were in the range of 52–81%. In the reaction with NaN_3 or PhSH as a comparatively soft nucleophile, 5′-adduct (**9g** or **9h**)[5] was also formed as a side product (3 or 11% yield) *via* S_N2' addition[6] together with a major product, the 3′-adduct (**5g** or **5h**).

In addition, when Et_2AlCN was used as a nucleophile, isomerized product **11** was obtained in 58% yield due to the activation of 3′-hydrogen of intermediate **10** by the strong electron-withdrawing cyano group (Scheme 2).

Next, we examined the hydroboration reaction of **5a**, aiming to convert it into the 5′-hydroxy derivatives **12** and **13**. When **5a** was refluxed with 18 equiv. of BH_3–THF in dry THF and then subsequently treated with H_2O_2–NaOH, the α-isomer **12** was obtained as the major product (53%) together with the β-isomer

Table 1 Nucleophilic addition to **6**

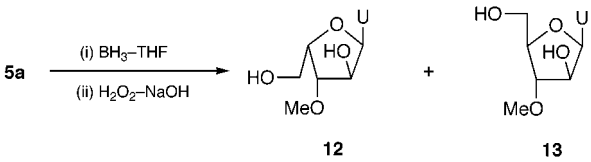

Scheme 3

13 as a minor product (17%) (Scheme 3). This isomer ratio may be interpreted by invoking the steric hindrance effects of the methoxy group at the 3′-position.

In conclusion, we have developed a regioselective method for the synthesis of 3′-substituted pyrimidine nucleoside derivatives **5**, **11**, **12** and **13** using 1-(2′,3′-anhydro-5′-deoxy-4′,5′-didehydro-α-L-*erythro*-pentofuranosyl)uracil **6** as a key intermediate without the formation of the corresponding 2′-adduct. The results presented herein provide a novel entry into a variety of sugar-modified pyrimidine nucleosides.

Preparation of mesoporous tin oxide for electrochemical applications

Fanglin Chen and Meilin Liu*

School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, GA 30332-0245, USA. E-mail: meilin.liu@mse.gatech.edu

Received (in Bloomington, IN, USA) 24th May 1999, Accepted 9th August 1999

Mesoporous tin oxide stable up to 500 °C has been prepared for the first time using both cationic and neutral surfactants.

Following the discovery of the MCM family of mesoporous silicates using the supramolecular templating approach,[1] mesoporous materials have attracted considerable attention because of their remarkably large surface areas and narrow pore size distributions, which make them ideal candidates for catalysts, molecular sieves, and as electrodes in solid-state ionic devices. A number of related synthetic strategies have been developed and a variety of materials, in terms of both composition and structure, have been prepared.[2–4]

Tin oxide is a wide-energy-gap semiconductor and has been widely used as a catalyst for oxidation of organic compounds, and for applications such as solid-state gas sensors, rechargeable Li-batteries, and optical electronic devices. The success in many of these applications relies critically on the preparation of crystalline SnO_2 with uniform nanosize pore structure. Consequently, the synthesis of thermally stable mesoporous SnO_2 is of great importance.

To date, several preparative approaches utilizing a supramolecular templating mechanism have been reported for the preparation of mesoporous tin oxide.[5–7] Upon removal of the surfactant, however, the mesoporous structures were destroyed; in other words, the preparation of mesoporous SnO_2 without the support of a surfactant has not yet been achieved. For example, upon hydrolysis of $SnCl_4$ in the presence of sodium dioctylsulfosuccinate (AOT, an anionic surfactant), Rao and Ulagappan[5] obtained a mesoporous SnO_2–AOT material with an average pore size of 3.2 nm. Attempts to remove the surfactant either by calcination at *ca.* 400 °C or by solvent extraction, however, resulted in collapse of the mesoporous structure. Similarly, upon hydrolysis of $SnCl_4$ in the presence of sodium dodecyl sulfonate (another anionic surfactant), Qi *et al.*[6] obtained mesoporous tin oxide with an average pore size of 4.1 nm. Again, the mesostructure collapsed when the surfactant was removed at 400 °C. Starting with tin isopropoxide and tetradecylamine (a neutral surfactant), Pinnavaia and coworkers[7] obtained mesoporous tin oxide with an average pore size of 5.6 nm. The mesoporous structure was stable up to 350 °C, but was destroyed upon calcination at 400 °C and the surface area was greatly reduced.

For electrochemical applications such as gas sensors, however, thermal stability of a mesoporous structure at high temperatures and without the support of a surfactant is critical for high catalytic reactivity, fast charge and mass transport, and long-term microstructural stability and durability. Thus, the objective of this study was to develop synthesis procedures for the preparation of mesoporous SnO_2, stable at high temperatures (> 400 °C), without the support of a surfactant. We have explored both neutral (S^0I^0) and electrostatic (S^+I^-) templating approaches to prepare mesoporous SnO_2.

In the neutral templating approach,† tetradecylamine (a neutral primary amine) was used as the surfactant (S^0) or structure director and tin isopropoxide as the inorganic precursor (I^0). Fig. 1 shows X-ray diffraction (XRD) patterns of the as-synthesized product and the mesostructured SnO_2 after calcination at 500 °C for 2 h. While the as-synthesized product showed a sharp diffraction peak at low angle (characteristic of a mesostructured material), the calcined sample displayed only a very broad diffraction peak. However, TEM analysis indicated that the calcined solid was indeed mesoporous; the short-range hexagonal order can be seen from the TEM images shown in Fig. 2. The average *d*-spacings of the as-synthesized and the as-calcined mesostructures are 4.8 and 3.4 nm, respectively, as calculated from the positions of the XRD peaks, which are also consistent with the pore sizes as determined from the TEM micrographs. Thermogravimetric analysis of the as-synthesized tin oxide mesoporous powder under N_2 flow indicated that the weight loss occurred between 200 and 500 °C, probably resulting from the decomposition of the surfactant and subsequent removal of the carbon residue. There was no detectable weight loss above 500 °C, indicating that the amine surfactant was completely removed from the mesoporous SnO_2 structure upon calcination at 500 °C for 2 h. Thus, we have obtained mesoporous SnO_2 (without the support of a surfactant) which is stable up to 500 °C.

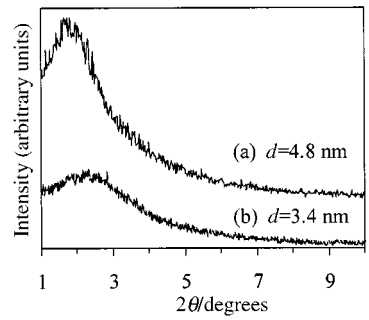

Fig. 1 XRD patterns of tin oxide synthesized *via* a neutral templating approach: (a) as-synthesized and (b) after calcination at 500 °C for 2 h.

In the electrostatic templating approach, cetyltrimethylammonium bromide (CTAB) was used as the structure director (S^+) and $[Sn(OH)_6]^{2-}$ used as the inorganic precursor (I^-).‡ This approach is similar to that employed by Suib and coworkers.[8]§ Fig. 3 shows the XRD patterns of the as-synthesized product and the mesostructured SnO_2 after calcination at 500 °C for 2 h. A sharp diffraction peak at small angle corresponding to the (100) diffraction was observed in both cases. Small peaks due to the (110) and (200) reflections are also observable before and after the removal of the surfactant.

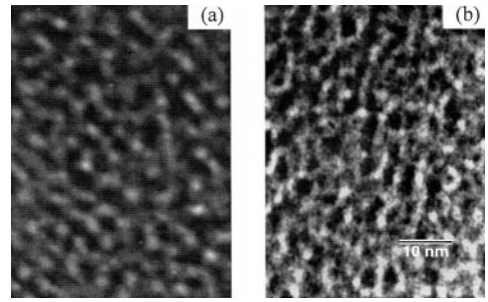

Fig. 2 Representative TEM micrographs of tin oxide synthesized *via* a neutral templating approach: (a) as-synthesized and (b) after calcination at 500 °C for 2 h.

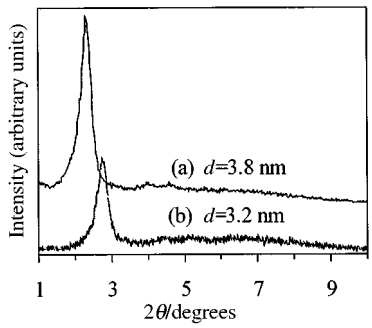

Fig. 3 XRD patterns of tin oxide synthesized *via* an electrostatic templating approach: (a) as-synthesized and (b) after calcination at 500 °C for 2 h.

The average *d*-spacings of the (100) layers in the as-synthesized and calcined SnO_2 mesostructures are 3.8 and 3.2 nm, respectively, as determined from the peak positions in the XRD patterns. Thermogravimetric analysis of the as-synthesized tin mesoporous powder under an N_2 flow showed that most of the weight loss occurred below 500 °C, implying that the surfactant could be removed from the mesoporous SnO_2 structure upon calcination at 500 °C for 2 hours. Fig. 4 shows the TEM images of the mesoporous SnO_2 before and after surfactant removal.

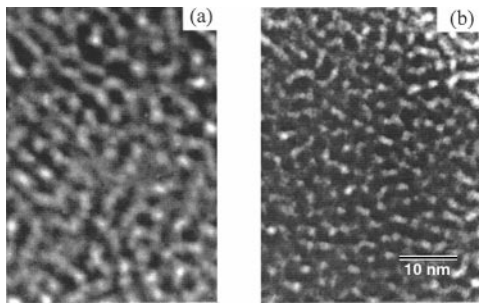

Fig. 4 Representative TEM micrographs of tin oxide synthesized *via* an electrostatic templating approach: (a) as-synthesized and (b) after calcination at 500 °C for 2 h.

In both approaches, the (100) peak shifts to slightly larger angles after removal of the surfactant, indicating that the mesostructure (and hence the pore size) contracted slightly upon surfactant removal. After calcination at 500 °C for 2 h, the BET surface area of the mesoporous SnO_2 from the neutral templating approach is *ca.* 107 $m^2\ g^{-1}$ and that from the electrostatic templating approach is *ca.* 143 $m^2\ g^{-1}$. The measured surface areas are much smaller than those for MCM-type materials (usually $> 500\ m^2\ g^{-1}$), implying that some of the pores are closed and are not accessible to BET measurement. It is clear, however, that the electrostatic templating approach is better than the neutral templating approach for the preparation of mesoporous SnO_2 with well organized structure (as revealed by XRD and TEM) and large surface area.

The major challenge in obtaining mesoporous oxides is to preserve the mesoporous structures while the surfactant is being removed. In order to avoid the collapse of the mesostructure, it is necessary to form a rigid three-dimensional inorganic framework based on Sn–O–Sn bonding before surfactant removal. In this study, it is believed that Sn–O–Sn bonds are formed during the aging process through water- or alcohol-condensation. Once a condensed 3-D mesoporous network is formed, its essential mesoporous features are likely to be preserved upon surfactant removal at 500 °C. Although there is no direct evidence to prove the formation of the Sn–O–Sn network during the aging process, we believe that this is a critical step to successful preservation of the mesoporous structure during surfactant removal. The detailed mechanism of formation of mesoporous SnO_2 structures which are stable at high temperatures is still under investigation.

Preliminary testing of a CO_2 gas sensor based on the mesoporous SnO_2 from the electrostatic templating approach showed a response time of 110 s when the gas was switched from CO_2 to air, which is seven times faster than CO_2 gas sensors based on nanosized SnO_2 powders derived from a sol–gel process (response time *ca.* 750 s[9]). Currently, the processing conditions are being further optimized to reduce the pore diameters or increase the surface area in an effort to enhance the sensitivity and speed of response of gas sensors based on mesoporous SnO_2. Further, the cycling behavior and reversible capacities of mesoporous SnO_2 used as an electrode in lithium batteries are still under investigation and will be reported in due course.

This work was supported by National Science Foundation (Award No. DMR-9357520) and by Georgia Tech Research Corporation.

Notes and references:

† 3.0 g of tin isopropoxide and 0.36 g of 1-tetradecylamine were added to 80 ml of propan-2-ol and stirred to form a homogeneous solution. This solution was kept under water-saturated air at room temp. for 48 h prior to loading to an autoclave and being kept at 80 °C for 24 h. The precipitate was then filtered off, washed with water and ethanol and then refluxed in ethanol for 10 h. The dried product was crushed into a powder and calcined at 500 °C in static air for 2 h.

‡ 10 g of $SnCl_4$ was dissolved in 30 ml distilled deionized water (DDW) and heated to 75 °C. 6.2 g of NaOH dissolved in 15 ml DDW was added to the $SnCl_4$ solution under vigorous stirring to form $Sn(OH)_4$. The pH of the solution was maintained at *ca.* 10. Then 6.7 g of CTAB was dissolved in 45 ml DDW and this solution was added to the $Sn(OH)_4$ solution. The mixture was stirred at 75 °C for 30 min and then loaded in an autoclave kept at 75 °C for 24 h. It was then aged at 90 °C for 24 h. After cooling to room temperature, the precipitate was recovered by filtration on a Buchner funnel, washed with water and dried. The as-synthesized product was then calcined in air at 500 °C for 2 h.

§ Starting from $MnCl_2$ and CTAB, Suib and coworkers[8] synthesized mesoporous manganese oxide structures which were reported to be stable up to 1000 °C. They proposed that an electrostatic interaction was established between $[Mn(OH)_6]^{4-}$ and the positively charged surfactant head group (CTA^+). Owing to the similarity between $[Sn(OH)_6]^{2-}$ and $[Mn(OH)_6]^{4-}$, it was thought that this approach was applicable to the preparation of mesoporous SnO_2.

Two-electron photoelimination reactions from edge-sharing bioctahedral dimolybdenum(III) complexes

Bradford J. Pistorio and Daniel G. Nocera*

Department of Chemistry, 6-335, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139-4307, USA. E-mail: nocera@MIT.edu

Received (in Bloomington, IN, USA) 24th May 1999, Accepted 9th August 1999

Dimolybdenum(III) edge-sharing bioctahedral (ESBO) complexes, $Mo_2X_6(dtbppm)_2$ [dtbppm = *bis*(di(4-*tert*-butylphenyl)phosphinomethane), X = Cl, Br, I], photoreact when irradiated with near-UV light, cleanly producing the corresponding quadruple metal–metal bonded complexes, $Mo_2X_4(dtbppm)_2$.

Metal complexes in electronic excited states typically exhibit one-electron oxidation–reduction chemistry. Conversely, the small molecule activation processes of most energy conversion schemes encompass multielectron transformations. This discontinuity between the intrinsic redox stoichiometries of electronic excited states and the reactions that they are targeted to thermodynamically drive has prompted us to explore conceptually new excited state reaction pathways, extending beyond the single electron. A strategy occupying our recent efforts is predicated on the chemistry of two-electron mixed-valence excited states. As one-electron mixed valence complexes promote single electron transfer reactions, a two-electron mixed valence complex can promote reactions in two-electron steps at the individual metal centers of the bimetallic core.[1] In one approach we have shown that excitation of quadruply bonded metal–metal (M^4M) dimers pairs two electrons in a d_{xy} orbital localized, for the most part, at one center of the bimetallic core with a corresponding two-electron hole at the other metal center.[2] The resultant $^+M–M:^-$ zwitterion (formally, a $M^{III}M^{I}$ intermediate for M = Mo and W) exhibits reactivity that establishes it as an excited state analog of Vaska's complex;[3] $M_2X_4(PP)_2$ (M = Mo, W; X = halide; PP = bridging phosphine) complexes undergo two-electron photoadditions of substrates to yield M^{III}_2 complexes with edge-sharing bioctahedral (ESBO) geometries.[4,5] An extensive reaction chemistry of the past decade shows these ESBO photoproducts to be inert, especially when metal–halide bonds compose the core.[6] This stability has hampered the construction of cyclic reaction schemes based on $M^{II}M^{II} \leftrightarrow M^{III}M^{III}$ photoreactivity. Accordingly, we became interested in developing the two-electron photoreduction chemistry of ESBO complexes. We now report the photoactivation of the metal–halogen bonds of the ESBO framework and subsequent two-electron photoconversion of $Mo_2X_6(PP)_2$ to $Mo_2X_4(PP)_2$.

Early efforts to investigate ESBO photochemistry were hampered by the limited solubility of $Mo_2X_6(PP)_2$ compounds in common solvents possessing moderate dielectric constants. We overcame this problem by introducing *tert*-butyl groups at the *para* position of the phenyl rings of bis(diphenyl)phosphinomethane (dppm). Reaction of $Cl_2PCH_2PCl_2$ with 12 equiv. of Bu^t-4-PhMgBr in diethyl ether at –78 °C under the N_2 atmosphere of a glove box, followed by procedures standard to a Grignard work-up, afforded bis(di-(4-*tert*-butylphenyl)-phosphinomethane) (dtbppm), which was recrystallized from acetonitrile: yield, 89%.† The introduction of the dtbppm ligand onto bimetallic cores proceeds smoothly according to literature procedures.[7] Treatment of $Mo_2(O_2CMe)_4$ with 4 equiv. of Me_3SiX and 2.2 equiv. of dtbppm in THF resulted in conversion to $Mo_2X_4(dtbppm)_2$, which was recrystallized from pentane and benzene.† Halogen oxidation of $Mo_2X_4(dtbppm)_2$ produced paramagnetic $Mo_2X_6(dtbppm)_2$ in good yields.† The electronic absorption spectra of the $Mo_2X_4(dtbppm)_2$ and $Mo_2X_6(dtbppm)_2$ complexes‡ are similar to those of their dppm counterparts,[7c,8] with only slight differences observed in absorption maxima and intensities. Fig. 1 shows the evolution of the absorption profiles for the photolysis of $Mo_2X_6(dtbppm)_2$ in THF. Each photoreaction behaves similarly. The initial spectrum, which is maintained indefinitely in the absence of light, promptly changes when THF solutions of the compound and a non-coordinating base such as 2,6-lutidine (2,6-dimethylpyridine) are irradiated with light in the blue and UV spectral regions. Well anchored isosbestic points maintained throughout the irradiation attest to a clean and quantitative photoreaction. With the appearance of the final absorption spectrum, no additional changes are observed with continued irradiation. For each photolysis reaction shown in Fig. 1, a single product is isolated with electronic absorption and $^{31}P\{^1H\}$ NMR spectra identical to those of independently prepared $Mo_2X_4(dtbppm)_2$ complexes. The photochemistry proceeds in THF only when carried out in the presence of at least a 2 equiv. excess of 2,6-lutidine (per equiv. of metal complex), though the photoconversion efficiency is independent of the concentration of base to excesses of 10^4 equiv. These results are consistent with THF acting as an *in situ* trap of

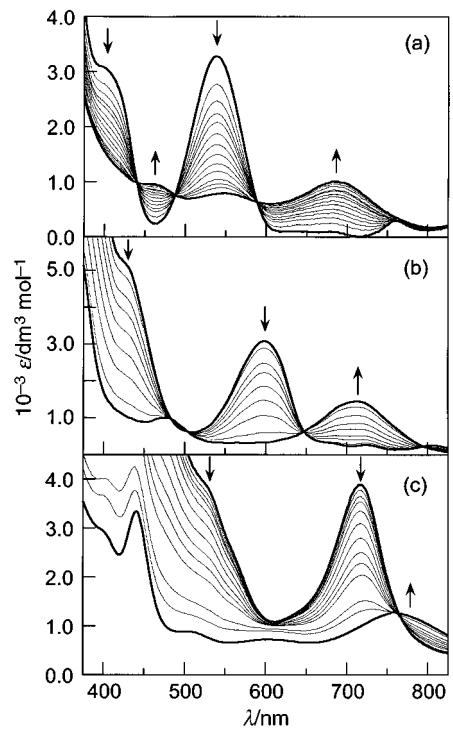

Fig. 1 The absorption profiles demonstrate the conversion of THF solutions of $Mo_2X_6(dtbppm)_2$ (*ca.* 10^{-5} M) in the presence of 20 equiv. of 2,6-lutidine at 0 °C: (a) X = Cl (λ_{exc} > 335 nm), (b) X = Br (λ_{exc} > 335 nm), and (c) X = I (λ_{exc} > 495 nm). The arrows indicate the disappearance of $Mo_2X_6(dtbppm)_2$ and appearance of $Mo_2X_4(dtbppm)_2$. Spectra were recorded over the span of 12 h for (a) and (c) and 2 h for (b).

[a] The quantum yield experiments were performed in THF at 0 °C containing 2,6-lutidine in 20 equiv. excess of $Mo_2X_6(dtbppm)_2$. The $Mo_2I_4(dtbppm)_2$ photoproduct decomposes when $\lambda_{exc} < 436$ nm.

photoeliminated X, arising from the susceptibility of the weak C_α–H bonds of THF toward atom abstraction.[9] In support of this contention, NMR spectra of photolyzed solutions exhibit a broad high frequency signal at δ 16.8 and a sharp methyl resonance at δ 2.9 of 2,6-lutidinium halide ($lutH^+X^-$); independently prepared lutidinium bromide exhibits a resonance at δ 16.3 for the acid proton and δ 2.96 for the methyl groups in $CDCl_3$. Moreover, integration of these resonances establish a stoichiometry of 2 equiv. of HX produced per equiv. of $Mo_2X_6(dtbppm)_2$ photoreagent to establish the following photoprocess of eqn. (1).

$$Mo_2X_6(dtbppm)_2 \xrightarrow[THF,\ lut]{h\nu} Mo_2X_4(dtbppm)_2 + 2\ lutH^+X^- \quad (1)$$

Table 1 lists the product appearance quantum yields (ϕ_p) for selected irradiation wavelengths. Quantum yields are high for near-UV excitation, but they decrease precipitously as λ_{exc} is moved into the visible spectral region. Moreover, the wavelength onset of this decrease red shifts along the series Cl < Br < I. A parallel shift of the near-UV absorption profiles (2900 and 5100 cm^{-1} red shift upon substitution of chloride by bromide and bromide by iodide, respectively) indicates that the action spectra are governed by the population of ligand-to-metal charge transfer states. Though no definitive assignments have been forthcoming in the absence of detailed spectroscopic investigation, computation[10] and experiment[11] identify the low-energy absorption profile of Fig. 1 to be derived largely from d and p metal-based orbitals with some halide character resulting from X p_π-mixing. The intense absorptions to higher energy are due to the Mo_2X_6 σ-framework, comprising metal in-plane π orbitals admixed with X p_σ-orbitals. Depopulation of these metal–halide σ-orbitals (and population of the correspondingly σ* orbitals) will result in significant disruption of the Mo_2X_6 equatorial framework, accounting for the high photoconversion efficiencies associated with near-UV excitation.

Photoelimination from oxidized cores of $M^{\underline{n}}M$ complexes has only previously been observed for the alkyl ligands axially coordinated to a pre-established $W^{III}{}_2L_6$ core.[12] In view of the preponderance of ESBO compounds in multiply bonded metal–metal chemistry, the photochemistry reported here provides a general framework in which to develop multielectron photoredox schemes based on $M^{\underline{n}}M$ photoreagents. Recent work in our group shows that metal–halide bonds are susceptible to photochemical activation along reaction pathways featuring two-electron mixed-valence species.[1b] Is the same M^+–$M:^-$ two-electron mixed valence zwitterion, responsible for promoting $M^{\underline{4}}M$ photoaddition reactions,[3–5] facilitating ESBO photoelimination chemistry? Alternatively, disproportionation of a photogenerated $Mo^{II}Mo^{III}$ complex could also lead to the observed photochemistry. In ongoing work, we are addressing such mechanistic issues by investigating the ESBO photochemistry with transient absorption and Raman spectroscopy, with the aim of directly establishing the precise nature of the photointermediate that leads to ESBO activation.

We are indebted to Ann M. Macintosh for her initial efforts on $Mo_2X_6(dppm)_2$ photochemistry. The National Science Foundation Grant CHE-9817851 funded this research.

α-$[NH_3(CH_2)_5NH_3]SnI_4$: a new layered perovskite structure

Jun Guan, Zhongjia Tang and Arnold M. Guloy*

Department of Chemistry and Texas Center for Superconductivity, University of Houston, Houston, Texas 77204-5641, USA. E-mail: aguloy@uh.edu

Received (in Bloomington, IN, USA) 15th February 1999, Revised manuscript received 29th June 1999, Accepted 30th July 1999

The synthesis and crystal structure of new organic–inorganic layered material, α-$[NH_3(CH_2)_5SnI_4$, is reported, which features an unprecedented <330>-terminated layered perovskite structure.

Much attention has been devoted to the synthesis and characterization of organic–inorganic multilayered perovskites owing to the tunability of their structural features.[1–5] The physical and structural properties of these compounds can be fine tuned by substituting or tailoring the organic layers or by modulating the thickness of the perovskite inorganic slabs. Applications of layered perovskite materials involve the development of functional electronic, magnetic and optoelectronic materials.[2,6,7] Several examples of conducting layered perovskites generally exhibit a trend from semiconducting to metallic behavior with increasing 'thickness' of perovskite layers (*n*).[8] This was demonstrated with the synthesis of a family of organic-based layered halide perovskites, $(C_4H_9NH_3)_2(CH_3NH_3)_{n-1}Sn_nI_{3n+1}$.

Layered perovskite structures can be derived by terminating the three dimensional cubic perovskite structure along different crystal faces.[9] Among the variety of metal oxides with layered perovskite structures, the common terminating planes are <001>, <110> and <111>. In layered organic–inorganic perovskites the ability to control the termination of perovskite sheets through the proper choice of organic cations was demonstrated by the synthesis of $[NH_2C(I)=NH_2]_2(CH_3NH_3)_{m-1}Sn_mI_{3m+2}$.[5] In contrast to the $(C_4H_9NH_3)_2(CH_3NH_3)_{n-1}Sn_nI_{3n+1}$ family, which consists of <001>-terminated perovskite layers, this structural class of Sn(II) iodides contains perovskite layers terminated along the <110> planes. Furthermore, the family of <110>-terminated Sn(II) iodide layered perovskites were found to be more conducting than their <001>-terminated analogs. This strongly suggests that termination of the perovskite layers provides an added flexibility in tuning the electronic properties of these layered materials.

Another structural element that modulates the properties of these mica-like materials is the dimensionality of the organic layers. Reducing the organic bilayers in the above mentioned perovskites into single layers may be achieved by using α,ω-substituted diamines, thereby increasing the interlayer coupling within the material.[1c,3b] Eliminating hydrophobic interactions in the organic bilayers leads to improved crystallization and mechanical strength while maintaining the two-dimensionality of the electronic structure. Herein, we report the synthesis and crystal structure of α-$[NH_3(CH_2)_5NH_3]SnI_4$ which consists of single layers of 1,5-pentanediammonium ions and an unprecedented inorganic layered perovskite.

α-$[NH_3(CH_2)_5NH_3]SnI_4$ **1** Was prepared by reacting SnI_2 (2 mmol), CH_3NH_3I (1 mmol) and $[NH_3(CH_2)_5NH_3]I_2$ (1 mmol) in concentrated HI (3 ml) solution. The HI solution of the organic and tin iodides was prepared at room temperature and heated to 120 °C. The resulting red solution was slowly cooled to 20 °C resulting in the formation of dark-red prismatic-column crystals. The dark-red air stable crystals were preserved in the mother liquor and were found to be of compound **1**. As a general precaution, all reactions were carried out under a nitrogen atmosphere and all solvents were degassed before use. The addition of CH_3NH_3I in the synthesis of **1** is crucial. Analogous reactions without CH_3NH_3I result in the formation of an orange–red polymorph, β-$[NH_3(CH_2)_5NH_3]SnI_4$, which features the commonly observed <001>-terminated $[SnI_4^{2-}]$ single perovskite sheets, as in K_2NiF_4.[10] The 'templating' role of $CH_3NH_3^+$ is presumably related to the stabilization and formation of the perovskite structure, as in $CH_3NH_3SnI_3$, and allows for its termination into layers along different crystallographic planes. Chemical analysis on several crystals of **1** confirmed the stoichiometry obtained from the structural refinement. Incorporation of CH_3NH_3I results in the formation of higher order layered perovskites $[NH_3(CH_2)_5NH_3](CH_3NH_3)_xSn_{1+x}I_{3x+1}$ (x = 1–3).[10] IR spectra recorded from thin disks of α-$[NH_3(CH_2)_5NH_3]SnI_4$, in the range 500–4000 cm^{-1}, feature characteristic IR bands (C–H at 3000–3180 and 1455 cm^{-1}, and N–H at 3430–3500 cm^{-1}) associated with 1,5-pentanediammonium ions. Measurement of the UV absorption spectra of a thin pressed disk of **1**, in the range 200–800 nm at 30 °C, shows a sharp absorption peak centered at 571 nm, in contrast to that observed at 560 nm in <001>-terminated β-$[NH_3(CH_2)_5NH_3]SnI_4$. Thermal measurements indicate that compound **1** and β-$[NH_3(CH_2)_5NH_3]SnI_4$, melt incongruently at 167 and 190 °C, respectively.

Compound **1** crystallizes in the orthorhombic space group *Pbcn*.[11] The asymmetric unit consists of three SnI_4^{2-} units (part of a layer of corner-sharing octahedra), and three $[NH_3(CH_2)_5NH_3]^{2+}$ ions. The orthorhombic crystal structure contains organic diammonium cations sandwiched between parallel corrugated sheets, $[SnI_2I_{4/2}^{2-}]$, of corner-shared tin(II) iodide octahedra. The tin layers can be built-up from $Sn^{II}I_6$ octahedra linked *via* corners into nominal zigzag chains, in the manner –*cis*–*trans*–*trans*–*cis*–*trans*–*trans*–, along the crystallographic *a*-axis. Adjacent parallel chains are further linked through their *trans*-vertices along the *b*-axis forming single corrugated $[SnI_4^{2-}]$ sheets along the *ab*-plane. The corrugated sheets are stacked along the crystallographic *c*-axis resulting in interlayer sites defined by eight terminal iodine atoms. The 1,5-pentanediammonium ions are located within the nearly orthorhombic interlayer sites forming single organic layers in contrast to the bilayers found in the monoamine compounds, $(RNH_3)_2SnI_4$. The $[SnI_4^{2-}]$ layer in compound **1** may be described as a combination of the <001> and <110> terminations and hence considered as the first member of the family of <330>-terminated layered perovskites.[9a] To our knowledge, the remarkable mixed *cis*–*trans* <330>-terminated perovskite layers is unprecedented in metal oxide and halide perovskite structures.

The unprecedented inorganic sheets feature two types of SnI_6 octahedra, namely, *trans*- and *cis*-shared, as shown in Fig. 1. The relatively long Sn–I bonds, 3.464(1) Å, in the *cis*-iodine bridges reflect the significant steric effects present in the *cis* conformation of the SnI_6 octahedra. The bond angles in both types of SnI_6 octahedra are slightly distorted from the ideal geometry as expected in low-order layered perovskite structures.[4,5,12] These bond angle distortions and the Sn–I bond distance inequalities are reflected in the 'twists' and 'buckles' of the inter-octahedral linkages and may be attributed to hydrogen-bonding and the stereochemical activity of the Sn(II) $5s^2$ lone pairs.[12]

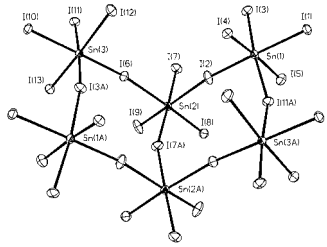

Fig. 1 ORTEP representation of the asymmetric unit of < 330 > -terminated $[SnI_4^{2-}]$ layer. Bond distances (Å): (a) around Sn(1): I(1) 3.307(1), I(2) 3.072(I), I(3) 3.116(2), I(4) 3.010(1), I(5) 3.217, I(11A) 3.217(2); (b) around Sn(2): I(2) 3.429(1), I(6) 3.464(1), I(7) 3.110(2), I(8) 2.961(1), I(9) 2.961(1), I(7A) 3.159(2); (c) around Sn(3): I(6) 3.113(1), I(10) 3.257(1), I(11) 3.154(2), I(12) 3.332(1), I(13) 2.994(1), I(3A) 3.155(2). Ellipsoids are drawn at 50% probability.

Close inspection of the organic–inorganic heterostructure in **1** reveals important characteristics. The $[NH_3(CH_3)_5NH_3]^{2+}$ ions lie between the corrugated sheets of $[SnI_4^{2-}]$ within two types of interlayer sites formed by terminal iodides of the single perovskite sheets, as shown in Fig. 2. These are sites formed between *trans*-SnI_6 octahedral units of adjacent layers, and sites formed by adjacent *cis*-SnI_6 units. In the *trans* interlayer sites, both $-NH_3$ ends of the cation are directed near the center of the 'bay' formed by four terminal iodines on each inorganic layer. The diammonium ions within the smaller *cis* interlayer sites are crowded into the 'open bay' area of these sites by close contacts with terminal iodines. The spatial environment of the different interlayer sites can be correlated with the N–N distances between the terminal nitrogen of the dications. The N–N distances are 6.10(2) and 6.65(2) Å for the dications in the *trans* sites, and 5.18(2) Å in the *cis*-sites. The N–N distances of the same diammonium ions in the interlayer sites of < 001 > -terminated β-$[NH_3(CH_2)_5NH_3]SnI_4$ range from 5.98(2) to 6.12(2) Å.[10] The variation in the observed N–N distances indicates significant differences in the conformation of the organic dications within the different interlayer sites in **1**. Moreover, steric effects present in the *cis* interlayer sites of **1** are reflected in the short N–N distances and the observed molecular shape of the diammonium ions which may be attributed to the torsional rotations around the chain backbone. Hence, formation of the unusual *cis*-SnI_6 linkage is related to a 'recognition' of the different conformations of the organic diammonium ions. The conformational differences of the cations are manifested by the differences in the C–H bands of the IR spectra of both polymorphs. The IR spectrum of the β-form features broader C–H bands (2860–3180 cm^{-1}) than those of the α-form, reflecting larger changes in the dipole moments and decreased steric restrictions on the C–H vibrations of the conformers in the β-form.[13] The thermodynamic stability and lower steric effects present in the

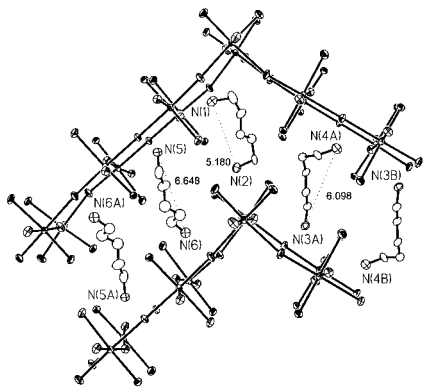

Fig. 2 ORTEP representation of the packing of 1,5-pentanediammonium ionds betwen two < 330 > -terminated $[SnI_4^{2-}]$ layers in compound **1**. Dashed lines represent distances between α- and ω-N atoms. Ellipsoids are drawn at 50% probability.

< 001 > -terminated β-form may be correlated to its higher melting point and density (ρ_β = 3.055 g cm^{-3}) compared to the < 330 > -terminated α-form (ρ_α = 3.035 g cm^{-3}). Band structure calculations on the two layered structures indicate that the < 330 > -terminated sheets have a smaller band gap than the < 100 > -terminated layer in accord with the UV absorption spectra.[4,14] The optical absorption attributed to transitions from Sn 5s and I 5p derived valence states to mainly Sn 5p conduction bands.

The control of the layer termination of the inorganic component is significantly dictated by cooperative non-covalent organic–inorganic interactions, as well as by the stereochemistry of the organic moieties. These provide additional fine variables in tuning the structure and electronic properties of layered organic–inorganic perovskites. The synthesis of **1** demonstrates the unusual structural chemistry exhibited by layered organic-based Sn(II) iodide perovskites.

This material is based in part on work supported by the Robert A. Welch Foundation, MRSEC Program of the National Science Foundation (Award Number DMR-9632667), and the State of Texas through the Texas Center for Superconductivity.

11 Single crystal X-ray analysis, using a Siemens SMART diffractometer equipped with a CCD detector was carried out at −50 °C. Monochromatized Mo-Kα radiation was used to collect a hemisphere of data. Empirical absorption correction was applied and redundant reflections were averaged. Laue photos and systematic absences unambiguously indicated the space group to be *Pbcn*. The final cell constants are: a = 30.255(2), b = 12.352(7), c = 25.6706(14) Å, V = 9593.0(5) Å^3. Other relevant crystallographic data are: M = 730.49, Z = 24, μ = 9.291 mm^{-1}, $2\theta_{max}$ = 48.40°; total data collected, 44333; independent reflections, 8381; observed reflections ($> 3\sigma_I$), 7618; total variables, 309. The final R indices, [$I > 4\sigma(I)$]: $R1$ = 0.0506, $wR2$ = 0.1282; (all data): $R1$ = 0.0691, $wR2$ = 0.1432. The structure was solved by direct methods and refined by full-matrix least-squares calculations. Thermal parameters of all non-hydrogen atoms were treated anisotropically. Five carbon sites (C3, C4, C13, C14, C15) exhibited conformational disorder and were refined based on a rotational disorder model. All hydrogen atoms were treated with a riding model (dC–H = dN–H = 0.89 Å, U_{iso} = 0.050). CCDC 182/1361.

The first bridged 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene derivatives: strained redox-active cyclophanes

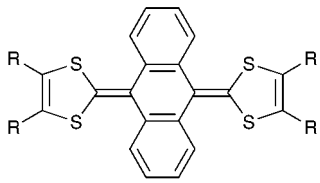
Terry Finn, Martin R. Bryce,* Andrei S. Batsanov and Judith A. K. Howard

Department of Chemistry, University of Durham, Durham, UK DH1 3LE. E-mail: m.r.bryce@durham.ac.uk

Received (in Cambridge, UK) 22nd July 1999, Accepted 16th August 1999

The reaction of anthraquinone and the dianion of bis(1,3-dithiolyl)diphosphonate reagents 2 and 3 afford the cyclophane derivatives 4 and 5, the cyclic voltammetry and X-ray crystal structures of which are reported.

There is considerable current interest in polycyclic ring systems which fold to form concave clefts[1] or saddle-like surfaces.[2] In this context the 9,10-bis(methylene)-9,10-dihydroanthracene building block has received limited attention, although crystallographic and theoretical studies have shown that bulky substituents attached to the methylene sites enforce a folding of the central anthracenediylidene ring into a boat conformation, and, hence, the molecule adopts a saddle shape.[3] Bis(1,3-dithiole) substituents placed at these methylene sites, *e.g.*

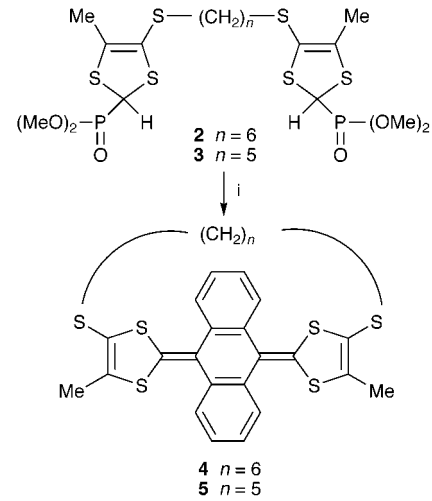


1a R = Me
b R = SMe

compound **1**,[3b] provide especially interesting electron donors with extended π-conjugation;[4] they are characterised by a single, two-electron redox wave to yield a thermodynamically stable dication at E^{ox} *ca.* +0.40 V (*vs.* Ag/AgCl) in the cyclic voltammogram (CV).[3a–c,4b,5] Methyl substituents slightly lower the oxidation potential relative to methylsufanyl substituents (*cf.* compounds **1a** and **1b**).

We have now incorporated this structural moiety into cyclophane structures,[6] and herein we report the synthesis and characterisation of the first bridged 9,10-bis(methylene)-9,10-dihydroanthracene derivatives, *viz.* compounds **4** and **5**. The synthesis of **4** and **5** was achieved by a two-fold olefination reaction, under high dilution conditions, of anthraquinone using reagents **2** and **3** (Scheme 1),[7] which were deprotonated by LDA at −78 °C, following literature precedents for other 1,3-dithiole phosphonate ester reagents.[8] Compounds **4** and **5**† were isolated as single isomers, and the *cis* configuration was confirmed by X-ray structure analysis.‡

Compound **4** gave a mixture of amber block- and needle-like crystals, which were characterised as monoclinic (α) and orthorhombic (β) polymorphs, respectively, of *cis*-**4**. Two symmetrically independent molecules in the β-**4** structure adopt very similar conformations (Fig. 1), while that of α-**4** is significantly different. In each case, the conformation of the hexamethylene bridge is rather strained and asymmetric: torsion angles around the C–C bonds range from 144 to 180° in β-**4** and from 58 to 176° in α-**4**, where two methylene groups are disordered. The bridge aggravates the U-bend of the bis(dithiolylidene)benzoquinone system: the dihedral angle between the outer S(1)C(16)C(17)S(2) and S(3)C(19)C(20)S(4) moieties is reduced from 77° in non-bridged molecule **1**[3b] to 54° in β-**4** and to only 46° in α-**4**, mostly through increased folding of both dithiole rings along the S(1)···S(2) and S(3)···S(4) vectors (24 and 13° respectively in α-**4**, 24 and 20° in β-**4**, *vs.* 17 and 8° in



2 *n* = 6
3 *n* = 5

1b). On the other hand, folding of the anthracene system along the C(9)···C(10) vector in**4** (37–40°) remains the same as in **1b** (38°).

The structure of **5** contains two independent molecules, one of which shows disorder that can be rationalised as either a varying degree of molecular bending or a rocking of the molecule as a whole. In the other (ordered) molecule (Fig. 2) the pentamethylene bridge adopts a nearly all-*trans* conformation (C–C–C–C torsion angles 164–177°) and enhances the folding of the anthracene moiety (by 43.4°) and both dithiole rings (by 29.4 and 22.6°), thus narrowing the dihedral angle between the S(1)C(16)C(17)S(2) and S(3)C(19)C(20)S(4) planes to 34.7°. The cavity is essentially empty in the solid state structures of both **4** and **5**.

The solution electrochemistry of compounds **4** and **5** was studied by cyclic voltammetry and differential pulse voltammetry. Both compounds display an irreversible two-electron oxidation wave at E^{ox} +0.69 V (compound **4**) and +0.74 V (compound **5**) [*vs.* Ag/AgCl, electrolyte $Bu_4N^+ClO_4^-$ (0.1 M),

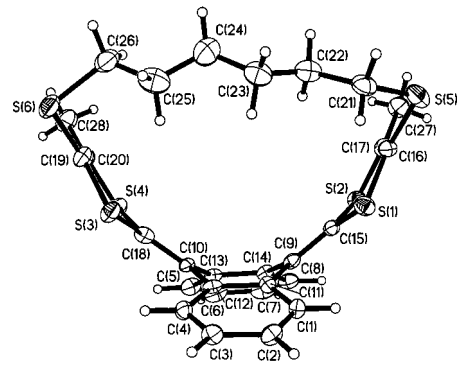

Fig. 1 Molecular structure of **4** in the β-polymorph (30% displacement ellipsoids).

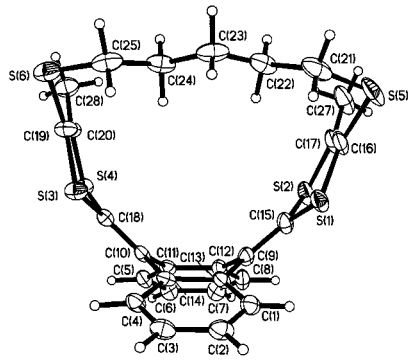

Fig. 2 Molecular structure of **5** (50% displacement ellipsoids).

MeCN, room temperature, scan rate 100 mV s^{-1}], *i.e.* the oxidation wave of the bridged systems **4** and **5** shows a significant positive shift (ΔE^{ox} *ca.* 300 mV) compared to the non-bridged analogues, *e.g.* **1**,[3b] recorded under the same conditions. This is explained by the rigidity of **4** and **5** (imparted by the bridge) restricting the conformational change which is known to accompany oxidation of the 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene system.[3a] The slightly higher oxidation potential of **5** compared to **4** (ΔE^{ox} 50 mV) is also consistent with oxidation becoming progressively harder as the strain in the system increases, as observed previously for strained tetrathiafulvalenes.[9] A second oxidation wave is observed at E^{ox} +1.0 V. Simulation of the data suggest an ECE process where dication formation is followed by a chemical reaction to form a new electroactive species, which gives rise to the oxidation wave at more positive potentials. The UV-Vis absorption spectra of **4** and **5** display a significant blue shift in the two longest wavelength bands compared to the non-bridged analogues [λ_{max} (MeCN) **1a**:[3b,8] 235, 369, 433 nm; **4**: 264, 356, 416 nm; **5**: 264, 352, 412 nm]. The further small blue shift (4 nm) for these two bands in compound **5** compared to **4** is again consistent with the more folded structure of **5**.

In summary, double olefination reactions of anthraquinone have afforded novel bridged 9,10-bis(methylene)-9,10-dihydroanthracenes, paving the way for studies on a new family of conformationally strained cyclophanes with interesting redox and structural properties.

We thank the EPSRC for funding, Dr R. Kataky for assistance with the electrochemical studies and Dr A. J. Moore for helpful discussions.

Received (in Columbia, MO, USA) 6th July 1999, Accepted 9th August 1999

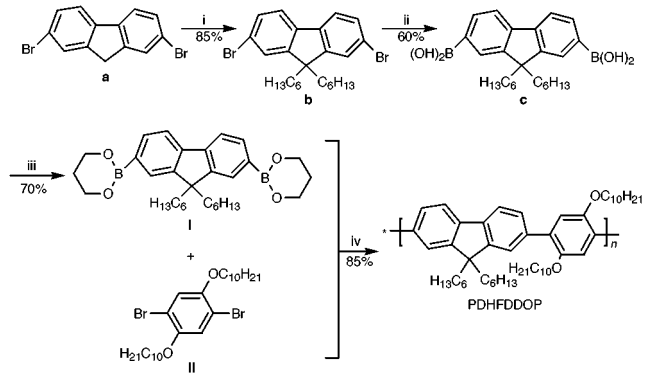
The synthesis, by the Suzuki coupling reaction, of a novel soluble blue light emitting polymer, poly{(9,9-dihexyl-2,7-fluorene–*alt*-*co*-[2,5-bis(decyloxy)-1,4-phenylene]} (PDHFDDOP) is reported. PDHFDDOP exhibits photoluminescence (PL quantum efficiency of 40% in neat films) and electroluminescence (EL) with deep blue emission.

The design and synthesis of light emitting polymers have received attention in the last decade following the discovery of EL in conjugated polymers and the development of polymer light emitting diodes (PLEDs) as a display technology.[1–4] Although the three primary colors have been demonstrated in PLEDs, only red (orange) and green PLEDs have sufficient efficiencies and lifetimes to be of commercial value.[3,4] Thus, to achieve full color polymer emissive displays, there is a need for stable blue-emitting conjugated polymers with high photoluminescence efficiency.

The first blue PLED was fabricated from poly(*para*-phenylene) (PPP),[5] which is not soluble in its conjugated form. Subsequently, soluble substituted PPPs were synthesized and high external EL quantum efficiencies were demonstrated.[6] However, low molecular weight and poor stability have limited the application of blue-emitting conjugated polymers. Blue EL has also been demonstrated in poly(*para*-phenylene vinylene) derivatives,[7] 3,4-disubstituted polythiophenes,[8] copolymers with and without non-conjugated segments,[9,10] and other structures.[11,12] Recently, the 9,9-disubstituted polyfluorenes have drawn attention as efficient blue-emitting polymers.[13–16]

We report here, the synthesis of a new blue light emitting conjugated polymer and preliminary data which characterize the emission from this polymer. As depicted in Scheme 1, poly{(9,9-dihexyl-2,7-fluorene)–*alt*-*co*-[2,5-bis(decyloxy)-1,4-phenylene]} (PDHFDDOP) comprises alternating fluorene and phenylene units. The long hydrocarbon chains at the fluorene bridge ('9') methylene and on the phenylene ring ensure the solubility of the polymer. PDHFDDOP was synthesized through the Suzuki coupling reaction.[17] The monomer 9,9-dihexylfluorene-2,7-bis(trimethylene boronate) **I**, was synthesized from 2,7-dibromofluorene **a** as starting material.† The monomer 1,4-dibromo-2,5-bis(decyloxy)benzene **II**, was prepared from hydroquinone by reaction with 1-bromodecane in a solution of NaOEt in ethanol, followed by bromination. Polymerization was performed in a refluxing toluene/aqueous potassium carbonate solution (2 M) containing 1.0–1.5 mol% of $Pd(PPh_3)_4$ under vigorous stirring for 48 h. The polymer was isolated by pouring the reaction mixture into methanol. After being purified and dried under dynamic vacuum at room temperature, the polymer was obtained as a white solid with the yield of *ca*. 85%. The structure was confirmed by NMR and elemental analysis.‡

PDHFDDOP readily dissolves in solvents, such as THF, chloroform, toluene and xylene. Uniform colorless films were prepared with thicknesses of *ca*. 750 Å on quartz and ITO coated glass substrates by spin coating from solution in toluene (3%) at a spin rate of 1500 rpm. Upon exposure to UV radiation, the films emitted intense blue fluorescence. The UV–VIS



Scheme 1 *Reagents and conditions*: i, 1-bromohexane, 50% NaOH aqueous solution, TBACl, 80 °C; ii, (1) Mg, THF, (2) $B(OMe_3)_3$, THF, −78 °C to room temp., 48 h, (3) H_2SO_4 (5% in ice); iii, Propane-1,3-diol, toluene, reflux, 3 h; iv, Toluene/aqueous potassium carbonate solution (2 M), $Pd(PPh_3)_4$, reflux, 48 h.

absorption and PL spectra obtained from the films on quartz are displayed in Fig. 1. The PL spectrum of poly(9,9-dihexyl-2,7-fluorene) (PDHF) is also given in Fig. 1 for comparison. The PL spectrum of PDHFDDOP has a maximum at 420 nm with a well defined vibronic feature at 448 nm. The emission peaks in the blue are very similar to those of PDHF. However, PDHF also emits at longer wavelengths (486, 534 nm). This longer wavelength emission is common in 9,9-disubstituted polyfluorenes and has been attributed to interchain excimer formation.[13,16] By contrast, the PL spectrum of PDHFDDOP does not include the longer wavelength components. The absolute PL efficiency of PDHFDDOP in neat films, as measured in an integrating sphere at room temperature, was found to be *ca*. 40%.

Cyclic voltammetry (CV) was performed with a polymer film on a glassy carbon disc working electrode (*ca*. 0.2 cm^2) using a platinum wire as counter electrode and a silver wire as a quasi-reference electrode (electrochemical potential *ca*. 0.01 V *vs*.

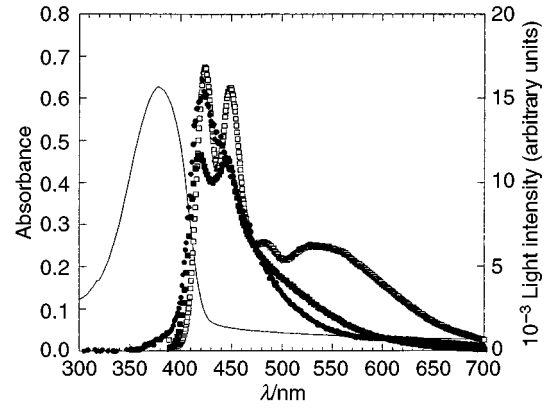


Fig. 1 Absorption (○), photoluminescence (■) and electroluminescence (●) spectra of PDHFDDOP. The photoluminescence spectrum of PDHF (□) is also given for comparison.

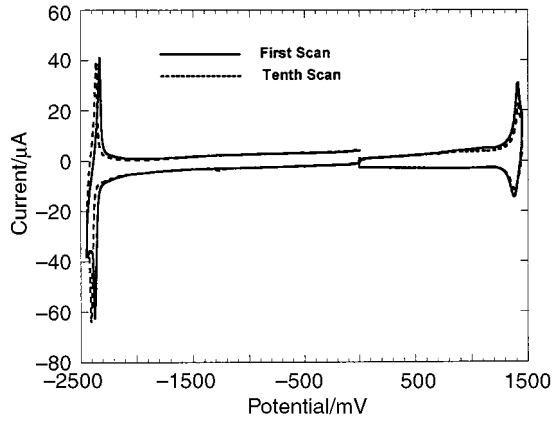

Fig. 2 Cyclic voltammograms of PDHFDDOP recorded from the first scan (——) and the tenth scan (– – – –) in a solution of $TBAPF_6$ (0.10 mol L^{-1}) in MeCN at room temp. Scan rate = 40 mV s^{-1}.

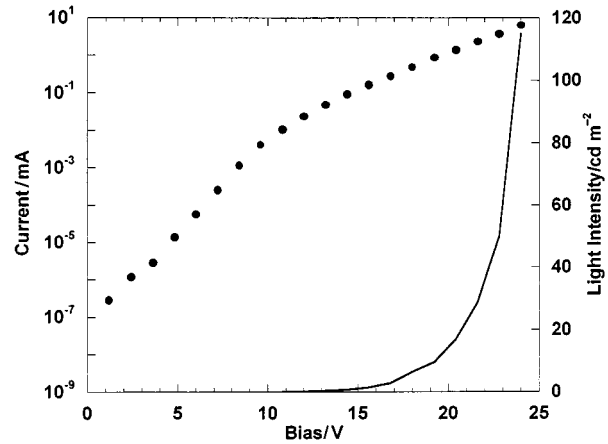

Fig. 3 Light output and *I–V* characteristics of a device in the ITO|PVK|PDHFDDOP|Ca configuration.

SCE). The data are shown in Fig. 2. Both the oxidative and the reductive reactions are reversible. The onset of reduction occurs at *ca*. −1.78 V above which the cathodic current quickly increases, and a cathodic peak appears at −2.38 V. A corresponding re-oxidation peak appears at −2.33 V. The n-doping potential, $E_{Red}^{1/2}$, is −2.36 V. For oxidation, the onset potential is *ca*. 1.22 V and an anodic peak occurs at 1.42 V with the corresponding re-reduction peak at 1.37 V. The oxidation potential, $E_{Ox}^{1/2}$, is 1.39 V. The difference between the p- and n-doping onset potentials is 3.00 V, implying that the π–π* band gap of the polymer is 3.00 eV; the same as the value determined from the onset of optical absorption. The HOMO and LUMO energy levels of the polymer were estimated from the p- and n-doping onset potentials[18] to be 5.66 and 2.62 eV, respectively. As shown in Fig. 2, after ten scans for the same polymer film, both the potentials and the current intensities of the redox peaks remain almost unchanged.

EL devices with the configuration of ITO|PVK (900 Å)|PDHFDDOP (750 Å)|Ca were fabricated, where PVK is poly(*N*-vinylcarbazole). Because of the low HOMO energy of PDHFDDOP, 5.66 eV below vacuum there is a large energy barrier for hole injection from ITO into the polymer layer. Here we use PVK as hole transporting layer. A typical device emits visible blue light at *ca*. 10 V forward bias (ITO wired positive) and reaches the brightness of 115 cd m^{-2} for a bias of 23.8 V. This gives an efficiency of 0.34 cd A^{-1} and a luminosity of 0.045 lm W^{-1}. The maximum external quantum efficiency was 0.60%. The current and light output characteristics are given in Fig. 3. The EL spectrum is displayed in Fig. 1. As noted for other polymer LED devices,[11] the HOMO level of PL (6.1 eV below vacuum) causes a large barrier for hole injection. Nevertheless, the external quantum efficiency is three times higher than that of the blue polymer LED device of 9,9-dioctylpolyfluorene, in which a polymeric triphenyldiamine is used as hole transporting layer and the thickness of the emissive polymer layer has been optimized.[14]

In summary, a new light emitting polymer, poly{(9,9-dihexyl-2,7-fluorene)–*alt*-*co*-[2,5-bis(decyloxy)-1,4-phenylene]}, has been synthesized. The polymer emits deep blue light without longer wavelength components in the emission spectrum. Relatively high PL and EL efficiences have been demonstrated. Improved EL performance, lower operating voltage and higher efficiency can be expected by further improving the hole-injection. The results demonstrate that this new polymer is a promising candidate for blue-emitting polymer LEDs.

Notes and references

† The reaction of 2,7-dibromofluorene with 1-bromohexane in 50% NaOH aqueous solution in the presence of tetrabutylammonium chloride at 80 °C afforded 2,7-dibromo-9,9-dihexylfuorene **b** as white crystals after purification by recrystallization from ethanol. 2,7-Dibromo-9,9-dihexylfuorene **b** was treated with magnesium (turnings) in THF to form the Grignard reagent. The Grignard reagent solution was slowly dropped into a sitrred solution of trimethyl borate in THF at −78 °C. The mixture was stirred at −78 °C for 2 h and then at room temperature for two days. The reaction mixture was then poured into crushed ice containing sulfuric acid (5%) while stirring. The mixture was extracted with diethyl ether and the combined extracts were evaporated to give a white solid. Recrystallization of the crude product from hexane–acetone (80 : 20) afforded pure 9,9-dihexylfuorene-2,7-diboronic acid **c** as a white solid. The diboronic acid **c** was then reacted with propane-1,3-diol in toluene under reflux to produce monomer **I**.

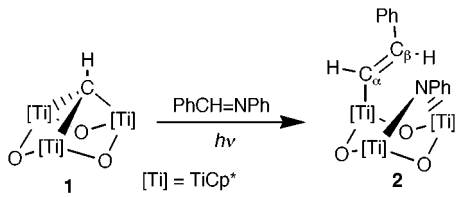
The photochemical incorporation of PhCH=NPh to the metal oxide model [{TiCp*(μ-O)}$_3$(μ$_3$-CH)] (Cp* = η^5-C_5Me_5) occurs by breaking of the C=N imine bond and formation of μ-imido and σ-alkenyl groups on the [Ti_3O_3] core; the crystal structure of the obtained product, [{TiCp*(μ-O)}$_3$(μ-NPh)(CH=CHPh)], was determined by X-ray diffraction.

Ti_3O_3(μ$_3$-CR) systems are surface models suitable for examination of both the cooperative interaction between metal centres maintained in close proximity and the chemistry of alkylidyne groups on a metallic oxide support. Recently we have described that the reactions under mild conditions of carbon monoxide and isocyanides with [{TiCp*(μ-O)}$_3$(μ$_3$-CR)] complexes proceed *via* insertion into the μ$_3$-alkylidyne units.[1] However, the incorporation of ketones follows other pathways and the experimental data support the insertion of carbonyl groups, R_2C=O, into the Ti–H bond of the *in situ* formed [{TiCp*(μ-O)}$_3$(μ-C=CH_2)(H)] intermediate to give alkoxide–vinylidene derivatives [{TiCp*(μ-O)}$_3$(μ-C=CH_2)($OCHR_2$)].[2] Here, we present the preliminary result observed from the photochemical treatment of the trinuclear titanium derivative [TiCp*(μ-O)}$_3$(μ$_3$-CH)] **1**[3] with *N*-benzylidene(phenyl)amine.

When a solution of **1** and PhCH=NPh in hexane was irradiated for 45 h the alkenylimido complex [{TiCp*(μ-O)}$_3$(CH=CHPh)(μ-NPh)] **2** (Scheme 1) was obtained in good yield.‡ The ^{1}H NMR spectrum of compound **2** shows two signals in a 2:1 ratio for the Cp* ligands in accord with C_s symmetry in solution, and supports the presence of a *trans*-styryl group ($^3J_{HH}$ 18.3 Hz).‡ This ligand is σ-bonded to the titanium atom in accord with the observation in the ^{13}C NMR spectrum of a doublet of doublets at δ 190.4 (^1J 126.0, ^2J 2.5 Hz) and a doublet of multiplets at δ 140.2 (^1J 154.4 Hz) corresponding to C_α and C_β resonances, respectively. A band of medium intensity at 1581 cm^{-1} in the IR spectrum is assigned to the alkenyl carbon–carbon double bond.



Scheme 1

An X-ray diffraction study of **2** reveals (Fig. 1)§ a *trans*-alkenyl group on one titanium atom and a phenyl imido moiety bridging the other two titanium atoms in a *syn–syn* disposition.

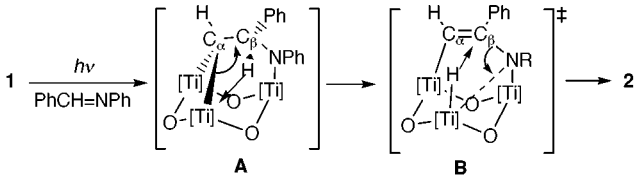
The styrene environment is planar with a Ti(2)–C(41) bond length of 2.127(9) Å, similar to those observed for Ti–C(sp^3) bonds in alkyl titanium complexes [TiCp*Me_3] (av. 2.10 Å),[4a] [{TiCp*Me}$_3$(μ-O)$_3$] (av. 2.09 Å),[4b] [{Ti_4Cp*$_4Me_2$}(μ-O)$_5$] (2.11 Å),[4c] [{TiCp*(μ-O)}$_3$(μ$_3$-CMe)] (av. 2.11 Å),[4d] [{TiCp*(μ-O)}$_3$(CH_2CH=CHMe)$_3$] (av. 2.13 Å)[4e] or Ti–C(sp^2) in alkenyl biscyclopentadienyl derivatives.[5] Within the styryl group, the C(41)–C(42) bond length [1.320(12) Å] is within the range for a C=C double bond.[6]

On the opposite side of the molecule, the Ti(1), Ti(3), N(13) and O(13) atoms form a distorted square (see Fig. 1), almost perpendicular to the Ti(1)–Ti(2)–Ti(3) and phenyl [C(51)–C(56)] planes. The N(13) atom shows a planar environment with Ti–N distances of 1.957(6) and 1.948(6) Å, close to the value of 1.91 Å (av.) found in [TiCp*(NMe_2)$_3$][7] and also to that of 1.939 Å reported in the cubane structure [{Ti_4Cp*$_4$}(μ$_3$-N)$_4$].[8] The average Ti–O bond distance (1.84 Å)[9] and Ti–ring centroid distance (2.06 Å) are comparable to those in the literature for the titanium organometallic oxides [{TiCp*(μ-O)}$_3$$X_3$] (X = Me,[4b] Cl,[10] Br[11]).

A reasonable proposal for this reaction (Scheme 2) involves imine insertion into one of the three titanium–carbon(alk-

Cp* is the centroid of the C_5Me_5 ring.

† Dedicated to Alexander von Humboldt on the occasion of his commemorative year 1999.



Scheme 2

ylidyne) bonds to generate the species **A** which was not detected. β-Hydrogen elimination[2] would then give a hydride–enamine intermediate **B** while subsequent carbon–nitrogen bond rupture, transfer of hydrogen from titanium to the β-carbon and formation of a nitrogen–titanium bond, would afford the σ-alkenyl-μ-imido complex **2**. However, we can not exclude the possibility that the conversion of **A** to **2** could occur directly by a concerted pathway.

To our knowledge, this observed behaviour is comparable only to the alkylidene/imine metathesis-like reactions reported by Rocklage and Schrock,[12] and by Cantrell and Meyer[13] for mononuclear niobium, tantalum and molybdenum alkylidene complexes. In our case the metathesis-like process occurs on the Ti_3O_3 surface with the cooperative participation of the three metal atoms and opens new perspectives in trinuclear titanium chemistry. Further studies of this process with other imines are in progress and the results will be published in due course.

Received (in Cambridge, UK) 7th June 1999, Accepted 16th August 1999

Siliceous MCM-41 and MCM-48, covalently linked with the chiral selector (*R*)-naphthylethylamine, have been evaluated as supports in chiral HPLC and show for several racemates higher separation factors than for a stationary phase based on amorphous silica.

Since the discovery of MCM-41 and MCM-48 in 1992, much research has been reported on their use in the field of catalysis, where their mesoporosity is beneficial for the conversion of large substrates.[1–3] These mesoporous molecular sieves are characterized by a high specific surface area in combination with highly ordered pores. These pores are one-dimensional in the case of MCM-41 in contrast to the three-dimensional network of MCM-48. Furthermore, the pore size of these materials can be tuned between 15 and 100 Å. In the domain of heterogeneous chiral catalysis, an extensively growing research area owing to the increasing demand for enantiomerically pure products, these mesoporous materials provide interesting supports for the development of new chiral catalysts.[4,5] Recently, in chromatographic separation techniques such as GC and HPLC, the use of non-functionalized MCM-41 has also been reported.[6,7] In chiral HPLC however, M41S materials were, up till now, not investigated in terms of their performance as supports in spite of their numerous advantages.

In this study, three chiral stationary phases (CSPs) with (*R*)-naphthylethylamine [(*R*)-NEA] as chiral selector were synthesized starting from amorphous silica, Si-MCM-41 and Si-MCM-48, respectively. MCM-41 and MCM-48 were prepared following a hydrothermal synthesis procedure.[8] They were characterized by XRD, SEM and sorption measurements. In both cases, the BET area appeared to be *ca.* 1000 $m^2\ g^{-1}$. The particle sizes of the resulting MCM-41 and MCM-48 are 5–15 μm and 0.1–0.5 μm, respectively. After silylation of the pore walls with aminopropyltriethoxysilane, these materials as well as Lichrosorb-NH_2 (Merck, 10 μm particle size), a reference for amorphous silica, were coupled with (*R*)-NEA (Fig. 1). This was done using succinic acid as a spacer molecule, according to the literature procedure.[9]

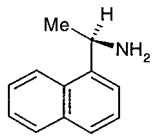

Fig. 1 Chiral selector used: (*R*)-naphthylethylamine.

Thermogravimetric analysis (TGA) revealed the amount of chiral selector on the supports: 0.06, 0.24 and 0.23 mmol (*R*)-NEA per gram of Lichrosorb-NH_2, MCM-41 and MCM-48, respectively. With the same technique, these functionalized materials were found to be thermally stable up to 130 °C. Moreover, because the selector is linked covalently, the materials are stable in all common solvents.

In order to compare the performance of the MCM-41 based CSP with the performance of the phase based on amorphous silica, two manually packed columns (10 cm) were tested in chiral HPLC experiments (Table 1) for their chiral recognition ability towards three racemates (Fig. 2). The higher separation factors achieved with MCM-41 as support are very promising. The resolution and efficiency, however, are quite poor, but can be improved by applying the slurry packing technique. Therefore in the following step, a slurry packed column of MCM-41 was tested on the same racemates (Table 2) and the study was extended to MCM-48, for which the three-dimensional pore structure might further improve the chromatographic separation.

The chiral stationary phase based on MCM-41 is characterized by 3–4 fold higher retention factors for the tested racemates than that based on amorphous silica. This is in accordance with their difference in specific area (Lichrosorb-NH_2: 300 $m^2\ g^{-1}$, MCM-41: 1000 $m^2\ g^{-1}$), leading to a higher coverage with chiral selector. This also explains the excellent separation factors achieved. An augmentation of the separation factor by 40% was obtained for DNB–NEA by using the column based on MCM-41 instead of that based on amorphous silica.

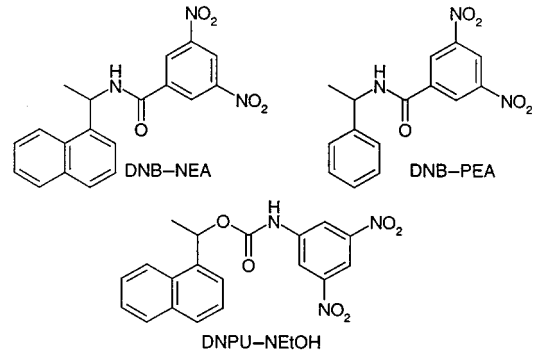

Fig. 2 Tested racemates: dinitrobenzoyl derivatives of naphthylethylamine (DNB–NEA) and phenylethylamine (DNB–PEA), dinitrophenylurethane derivative of naphthylethanol (DNPU–NEtOH).

Table 1 Chromatographic performance of manually packed Lichrosorb-NH_2 and Si-MCM-41 based CSPs[a]

	Lichrosorb-NH_2 (manually packed)					Si-MCM-41 (manually packed)				
Component	k_S	k_R	α	N	R_s	k_S	k_R	α	N	R_s
DNB–NEA	1.36	2.96	2.18	447	2.68	4.50	13.78	3.06	74	1.88

DNPU–NEtOH	1.21	1.41	1.17	—[b]	—[b]	3.30	3.97	1.20	—[b]	—[b]

[a] Mobile phase: *n*-hexane–1,2-dichloroethane–ethanol (40 : 12 : 3), flow rate: 0.6 ml min^{-1}, UV detection (254 nm), k = retention factor, α = separation factor, N = plate number, R_s = resolution. [b] Peak width determination was impossible owing to poor peak resolution.

Table 2 Chromatographic performance of slurry packed Si-MCM-41 and Si-MCM-48 based CSPs[a]

	Si-MCM-41 (slurry packed)					Si-MCM-48 (slurry packed)				
Component	k_S	k_R	α	N	R_s	k_S	k_R	α	N	R_s
DNB–NEA	3.31	10.44	3.16	136	2.50	3.48	9.11	2.62	605	4.7
DNB–PEA	3.34	6.47	1.93	117	1.32	3.47	5.92	1.71	680	2.76
DNPU–NEtOH	2.51	3.16	1.26	—[b]	—[b]	2.46	3.02	1.23	667	0.94

[a] Mobile phase: *n*-hexane–1,2-dichloroethane–ethanol (40 : 12 : 3), flow rate: 0.6 ml min^{-1}, UV detection (254 nm), k = retention factor, α = separation factor, N = plate number, R_s = resolution. [b] Peak width determination was impossible owing to poor peak resolution.

The resolution and particularly the efficiency are poor owing to the large peak widths. Peak tailing prevents accurate determination of the peak widths. Nevertheless, MCM-41 seems to be a promising support material because of the high separation factors in combination with a good analysis time (< 30 min for the strongest retained component) and very acceptable inlet pressures (100 bar). Moreover, the mobile phase used was optimized for the amorphous silica CSP, so probably further improvements can be made for the column based on MCM-41 by changing the composition of the mobile phase.

By using slurry packed columns of MCM-41 and MCM-48 based CSPs, band broadening, which is disadvantageous to the efficiency, can be reduced owing to the formation of a more uniformly packed bed. Comparing Tables 1 and 2, both the resolution and the efficiency of the separation with MCM-41 are clearly improved by use of this packing method; the efficiency of the column was doubled. The use of MCM-48 as support leads to further improvement with the efficiencies increasing by a factor of six, owing to a faster mass transfer through the three-dimensional pore system. Separations performed on this material show very good resolution and efficiency, and only slightly lower separation factors (the separation factor decreases by < 20% compared to the use of MCM-41 as support). Band broadening is substantially reduced and peak symmetry is improved. The nature of the pore system together with the smaller particle dimensions and the narrower particle size distribution can account for the successful separation with MCM-48. On both columns, based on either MCM-41 or MCM-48, a whole range of racemates are currently being tested. No loss of chromatographic performance was observed with time illustrating the stability of the materials towards repeated cycles of guest exchange.

In conclusion, the first utilization of M41S materials as supports in chiral HPLC is reported. Both MCM-41 and MCM-48 show high retention and separation factors for the tested racemates and are very promising for liquid chromatography. These results, in combination with good analysis times and very acceptable inlet pressures, make these HPLC columns successful analytical instruments. Excellent resolution and efficiency could be achieved with MCM-48. Columns based on MCM-41 show good resolution, but the efficiency should be further improved by a better control of the particle size distribution. The influence of pore size and selector loading on chromatographic performance is under current investigation for both M41S materials.

This research is done within the framework of an IUAP–PAI grant from the Federal Government. C. T. thanks the Flemish Fund of Scientific Research (F. W. O.) for a grant as aspirant research fellow. I. F. J. V. is indebted to the F.W.O. for a fellowship as postdoctoral research assistant.

Reactions of water soluble iron(II) and cobalt(II) porphyrins with nitric oxide. Implications for the reactivity of NO and biologically relevant metal centers

Leroy E. Laverman and Peter C. Ford*

Department of Chemistry, University of California, Santa Barbara, California 93106, USA.
E-mail: ford@chem.ucsb.edu

Received (in Bloomington, IN, USA) 6th April 1999, Accepted 4th August 1999

The entropies and volumes of activation ($\Delta S^{\ddagger}_{on}$ and $\Delta V^{\ddagger}_{on}$) for the fast reactions ($k_{on} > 10^9$ dm^3 mol^{-1} s^{-1}) reaction of NO with the water soluble iron(II) porphyrin complexes Fe^{II}(TPPS) [TPPS = tetrakis(4-sulfonatophenyl)porphinato] and Fe^{II}(TMPS) [TMPS = tetrakis(sulfonatomesityl)porphinato] are small and positive indicating that these reactions are dominated by the diffusion processes as is the analogous formation of the cobalt(II) complex Co^{II}(TPPS)(NO).

Nitric oxide has important and diverse roles in mammalian biology including cytotoxic immune response and intracellular signaling.[1] Under physiological conditions the principal targets for NO are metal centers, primarily iron, the best documented being the ferroheme center in soluble guanylyl cyclase (sGC).[2] NO may also have roles as an inhibitor of metalloenzymes such as catalase,[3] nitrile hydrase[4] and cytochrome oxidase,[5] as the vasodilator released from the salivary ferriheme protein of a blood sucking insect[6] and in blood pressure regulation by hemoglobin.[7] However, despite numerous rate measurements for NO reactions with ferro- and ferri-heme centers,[8] there has been little quantitative study to deduce the bimolecular mechanisms by which NO undergoes coordination to metal porphyrin centers [eqn. (1)].

$$M(por)_{aq} + NO \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} M(por)(NO)_{aq} \quad (1)$$

To address this deficiency, we have initiated studies on the temperature and hydrostatic pressure effects for the 'on' and 'off' reactions with water soluble iron(II) and iron(III) porphyrins in aqueous solutions as simple models for ferro- and ferriheme proteins {M = Fe^{II} or Fe^{III}; por = TPPS [tetrakis(4-sulfonatophenyl)porphinato anion] or TMPS [tetrakis(sulfonatomesityl)porphinato anion]}.[9] From these data, one can extract the activation parameters $\Delta H^{\ddagger}_{on}$, $\Delta S^{\ddagger}_{on}$ and $\Delta V^{\ddagger}_{on}$ in order to gain insight into the nature of the transition state(s) of the rate limiting step(s). Here we describe results for the 'on' reaction of the ferroheme complexes Fe^{II}(TPPS) **I** and Fe^{II}(TMPS) **II** in aqueous solutions and compare these to the analogous reaction for the cobalt(II) porphyrin Co^{II}(TPPS) **III**.

Fig. 1 shows the difference spectrum obtained by subtracting the absorbance spectrum of aqueous Fe^{II}(TPPS)(NO) and NO (1.7 mM) from that recorded subsequent to a 355 nm laser pulse recorded with a CCD camera (50 ns delay, 100 ns gate width).[10] This is in exact agreement with the difference between the spectra of **I** and Fe^{II}(TPPS)(NO) according to eqn. (1). The transient absorption changes decayed back to baseline and no permanent photoproducts were spectrally apparent (Fig. 1, inset).

The k_{obs} values obtained by exponential fits of these data are independent of the observation wavelength. According to relaxation kinetics, $k_{obs} = k_{on}[NO] + k_{off}$, and correspondingly plots of k_{obs} *vs.* [NO] are linear with slopes equal to k_{on} with values of (1.47 ± 0.05) × 10^9 and (1.04 ± 0.08) × 10^9 dm^3 mol^{-1} s^{-1} for **I** and **II**, respectively, in 298 K phosphate buffered (pH 7.0) aqueous solutions. The intercepts of such plots should equal k_{off}, but since equilibrium constants for Fe^{II}(por)(NO) formation ($K_1 = k_{on}/k_{off}$) are very large, k_{off} values could not be determined by extrapolation. Independent measurements in this laboratory give the upper limit estimate $k_{off} < 2$ s^{-1} for **I**.[11]

Temperature effects on the k_{on} values for **I** and **II** were evaluated from linear plots of k_{obs} *vs.* [NO] for at least six NO concentrations at each temperature. Eyring plots gave straight lines from which were extracted the values for $\Delta H^{\ddagger}_{on}$ and $\Delta S^{\ddagger}_{on}$. For **I** these were 24 ± 3 kJ mol^{-1} and 12 ± 10 J mol^{-1} K^{-1} and for **II** these were 26 ± 6 kJ mol^{-1} and 16 ± 20 J mol^{-1} K^{-1}, respectively.

Hydrostatic pressure (*P*) effects were evaluated by determining k_{on} from plots of k_{obs} *vs.* [NO] for individual *P* ranging from 0.1 to 250 MPa. Plots of ln(k_{on}) *vs. P* were linear and activation volumes were calculated according to $\Delta V^{\ddagger}_{on} = -RT[d\ln(k_{on})/dP]_T$.[12] The respective $\Delta V^{\ddagger}_{on}$ values obtained for **I** and **II** were 5.0 ± 1.0 and 2.2 ± 0.6 cm^3 mol^{-1}.

The measured rate constants k_{on} for NO binding to ferrohemes range over many orders of magnitude, from 8.3 dm^3 mol^{-1} s^{-1} for Cyt^{II} (Cyt^{II} = Fe^{II}cytochrome *c*) to 1.5 × 10^9 dm^3 mol^{-1} s^{-1} for **I** at ambient temperature.[8] Ferrohemes may be six-coordinate in the presence of an excess of strong field ligands such as pyridine or imadazole but tend to be coordinatively unsaturated otherwise. In wet toluene or dichloromethane, the model ferroheme Fe^{II}(TtButPP) {TtButPP = [(N-*tert*-butylcarbamoyl)phenyl]porphyrin} was found to bind H_2O only weakly.[13] Furthermore, ferroheme proteins tend to be five-coordinate unless a strong field ligand such as CO, O_2 or CN^- occupy an axial site, in which case the Fe^{II} is six-coordinate, although in the case of Cyt^{II} the Fe^{III} is six-coordinate with histidine and cysteine thiolate ligands in the axial site.[14] It does not appear coincidental that Cyt^{II} is extremely slow in its reaction with NO. While the exact coordination environments of **I** and **II** have not been explicitly determined in buffered aqueous media, analogy to the above and other examples clearly suggests that water is a weak field ligand for these ferrohemes which are likely to be effectively five-coordinate in solution.

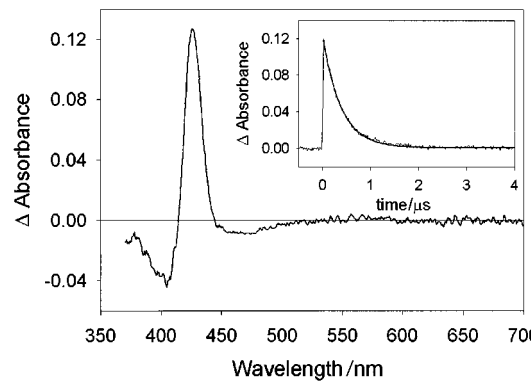

Fig. 1 The transient absorbance spectrum of aqueous Fe^{II}(TPPS)(NO) recorded 50 ns after pulsed laser excitation at 355 nm. Inset: decay of absorbance at 425 nm following a laser pulse, $k_{obs} = 2.7 \times 10^6$ s^{-1}.

Our earlier study[9] of the temperature and hydrostatic pressure effects on the rates of NO binding with the ferriheme analogs Fe^{III}(TPPS) **III** and Fe^{III}(TMPS) **IV** demonstrated very large and positive values for both $\Delta V^{\ddagger}_{on}$ and $\Delta S^{\ddagger}_{on}$. Such behaviour is a signature for a mechanism where $Fe^{III}NO$ bond formation is preceded by ligand dissociation, in this case from the hexacoordinate ferriheme complexes $Fe^{III}(por)(H_2O)_2$. In contrast, the $\Delta S^{\ddagger}_{on}$ and $\Delta V^{\ddagger}_{on}$ values determined for the iron(II) species **I** and **II** are much smaller while, correspondingly, the k_{on} values are three orders of magnitude faster.

The kinetics of ligand binding to ferrohemes have led to a proposed scheme[15] in which an encounter pair is formed before bond formation occurs, *i.e.*

$$Fe^{II}(por) + L \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} \{Fe^{II}(por) \| L\} \xrightarrow{k_a} Fe^{II}(por)(L) \qquad (2)$$

In this model, k_d is the rate constant for formation of the encounter pair by diffusion, k_{-d} is that for diffusion of the reactants apart, and k_a represents that for formation of the Fe–L bond. If the steady state approximation is made with respect to the encounter pair {Fe(por)‖ L}, then,

$$k_{on} = \frac{k_d k_a}{k_{-d} + k_a} \qquad (3)$$

and to a first approximation,

$$\Delta V^{\ddagger}_{on} = \Delta V^{\ddagger}_{d} + \Delta V^{\ddagger}_{a} - RT\left(\frac{d \ln (k_a + k_{-d})}{dP}\right)_T \qquad (4)$$

The two limiting cases are ones in which ligand binding is activation controlled or in which the reaction is diffusion controlled. In the former $k_d \gg k_a$, thus

$$\Delta V^{\ddagger}_{on} = \Delta V^{\ddagger}_{d} + \Delta V^{\ddagger}_{a} - \Delta V^{\ddagger}_{-d} \qquad (5)$$

The difference $\Delta V^{\ddagger}_{d} - \Delta V^{\ddagger}_{-d}$ is the volume difference between a contact pair and a solvent separated pair. While unknown, this can be assumed to be small when L is uncharged. The principal contributor to $\Delta V^{\ddagger}_{on}$ thus becomes $\Delta V^{\ddagger}_{a}$, which would be expected to be negative if Fe^{II}(por) is five coordinate (since this step involves bond formation).[12]

In the other limiting case, $k_a \gg k_{-d}$ and $\Delta V^{\ddagger}_{on} \cong \Delta V^{\ddagger}_{d}$. Activation volumes for diffusion limited reactions ($\Delta V^{\ddagger}_{d}$) in various solvents are generally positive owing to pressure induced increases in viscosity. In the present case, the $\Delta V^{\ddagger}_{on}$ values measured for **I** and **II** (5.0 and 2.2 $cm^3\ mol^{-1}$, respectively) are somewhat larger than expected from a diffusion limited rate in water[16] but are much smaller than found for the ferriheme analogs.[9] This suggests that k_{on} is largely dominated by the diffusional terms. Indeed the rates for reaction of NO with **I** and **II** are within an order of magnitude of the diffusion limit in water ($k_d \approx 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ at 298 K).[17]

A similar analysis of $\Delta S^{\ddagger}$ gives $\Delta S^{\ddagger}_{on} \cong \Delta S^{\ddagger}_{d}$, if $k_a \gg k_{-d}$. The activation entropy $\Delta S^{\ddagger}_{d}$ for diffusion in water is small and positive; a value of *ca.* 34 $J\ mol^{-1}\ K^{-1}$ can be calculated according to Eyring and coworkers.[18] In this context, the measured $\Delta S^{\ddagger}_{on}$ values for **I** and **II** (12 and 16 $J\ mol^{-1}\ K^{-1}$, respectively) are further argument for a diffusion dominated process.

We have also determined the temperature effects on the kinetics of the reaction of Co^{II}(TPPS) with NO to give Co^{II}(TPPS)(NO). Notably the behavior of this system is quite similar to that of the Fe^{II} analog with $k_{on} = 2.3 \pm 0.1 \times 10^9\ (dm^3\ mol^{-1}\ s^{-1})$ at 298 K, $\Delta H^{\ddagger}_{on} = 28 \pm 2\ kJ\ mol^{-1}$ and $\Delta S^{\ddagger}_{on} = 28 \pm 7\ J\ mol^{-1}\ K^{-1}$. Hence, the kinetics of the 'on' reaction for Co^{II}(TPPS) can also be concluded to be dominated by diffusion processes.

For nitric oxide to be important in intracellular signaling at the sub-μM concentrations generated *in vivo*,[19] the reactions of NO with ferroheme proteins must have very high second order rate constants in order to compete with other processes leading to NO depletion. The present study demonstrates that activation parameters for the reactions of NO with the water soluble Fe(II) porphyrin complexes **I** and **II** are consistent with the small and positive values of $\Delta V^{\ddagger}_{on}$ and $\Delta S^{\ddagger}_{on}$ expected for diffusion limited (or nearly limited) processes in solution. These results experimentally support the intuitive notion that the nearly diffusion limited rates for NO reaction with iron(II) hemes is due to vacant or extraordinarily labile coordination sites at those metal centers.

Stereoselective bromohydrin formation from β-hydroxy sulfoxides mediated by the pendant sulfoxide†‡

Sadagopan Raghavan,* M. Abdul Rasheed, Suju C. Joseph and A. Rajender

Organic Division I, Indian Institute of Chemical Technology, Hyderabad 500 007, India. E-mail: purush101@hotmail.com

Received (in Cambridge, UK) 2nd June 1999, Accepted 12th August 1999

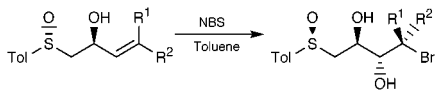
Regio- and stereo-selective bromohydrin formation promoted by a neighbouring sulfinyl moiety is disclosed.

The development of new and efficient methods for regio- and stereo-selective synthesis of biologically active compounds is an active area of research.[1] Our interest in the synthesis of polyhydroxylated sulfoxides and sulfides, *e.g.* Mannostatin A and B, has focussed initially on the stereoselective introduction of chiral centres in appropriate acyclic precursors.

It is well-known that sulfoxides may participate as neighbouring groups in a number of reactions.[2] Sulfoxide group participation in halohydrin formation from cyclic[3] and simple acyclic olefins[4] has been demonstrated, but its potential to produce highly functionalised products with stereochemical control at two adjacent centres in substituted acyclic systems remains unexplored. Here we report the formation of bromohydrins from acyclic β-hydroxy-γ,δ-unsaturated sulfoxides (Scheme 1). The unsaturated β-hydroxy sulfoxide precursors shown in Table 1 were prepared as an epimeric mixture in equimolar proportion and good yield[5] by condensing the lithium anion of (*R*)-(+)-methyl *p*-tolyl sulfoxide[6] **1** with the appropriate aldehydes[7] **2** (Scheme 2). The isomeric hydroxy sulfoxides [(R_S, S_C) and (R_S, R_C)] were separated[8] by chromatography and their configuration assigned unambiguously by comparison of coupling constants for the protons directly bonded to the carbon in the β-hydroxy sulfoxide moiety.[9]

The unsaturated β-hydroxy sulfoxides were reacted with NBS and water in toluene at ambient temperature to afford the bromohydrins in moderate to high stereoselectivity in good yield. Use of solvents like THF, MeCN and CH_2Cl_2 were not satisfactory. The sulfoxide group was envisaged to function as a pendant nucleophile and attack the intermediate bromonium ion, resulting in formation of a cyclic sulfonium salt which could then be hydrolysed by water to afford the bromohydrin (Scheme 3).[4] It is well known that hydrolysis of sulfoxonium salts proceeds with clean inversion on sulfur. Hence in effect the configuration on sulfur would get inverted.[3,10]

As Table 1 indicates, the reaction is general for a variety of γ,δ-unsaturated sulfoxides. According to the literature precedent[11] the reaction of **6a** with NBS is expected to afford **7a** as the predominant product. Contrary to the above expectation the outcome was a 1 : 1 mixture of **7a** and **8a**. The phenyl group in



Scheme 1

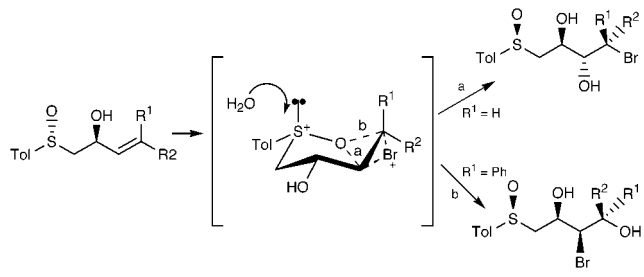

Scheme 3

† IICT Communication No. 4301.

‡ Experimental and spectral data for species described in this paper are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1845/

the sulfoxides **9a**, **9b**, **12a** and **12b** directs nucleophilic attack on the intermediate bromonium ions to C-4 to afford, regioselectively, products from 6-*endo* opening.[12] It is also apparent that the (R_S, R_C) isomers react to yield products more stereoselectively than the corresponding (R_S, S_C) isomers.

The stereochemical assignments were made by ^{13}C and ^{1}H NMR analysis of the spectra of the acetonides derived from the bromohydrins. The use of ^{13}C NMR data for acetonides of 1,3-diols and 1,2-diols for predicting their relative configurations has been reported by Rychnovsky and co-workers[13] and Dana and co-workers,[14] respectively. The coupling constants of protons on the carbon bearing the hydroxy and bromine in the six-membered ring acetonides reveal stereospecific *trans* addition to the double bond of **9** and **12**.[15] There are ample precedents for overall stereospecific *trans* addition to the double bond with respect to the olefin geometry in a similar reaction, *viz.* halolactonisation.[11] Similarly stereospecific *trans* addition to the double bond should be operative with **3** and **6** also. The sulfoxide group is known to deshield protons in which the S=O bond and the C–H bond are in a 1,3-parallel orientation.[16] The proton on C-2 of the acetonides derived from **5b**, **7b**, **8b**, **11b** and **13b** would occupy a 1,3-parallel orientation, while the proton on C-2 for the isomers **5a**, **7a**, **8a**, **11a** and **13a** would be almost orthogonal to the sulfoxide. A comparison of the chemical shifts for the protons on C-2 of the isomeric sulfoxides supports the configuration assigned to sulfur.

In conclusion, even though the product distribution often shows regio- and stereo-selectivity in a predictable way, striking anomalies are observed which underscore the influence of the sulfoxide group and its configuration on the outcome of the reaction. Experiments bearing on the mechanistic reasons for the observed stereoselectivity will be discussed in a later paper.

2-Propanephosphonic acid anhydride (T3P)-mediated segment coupling and head-to-tail cyclization of sterically hindered peptides

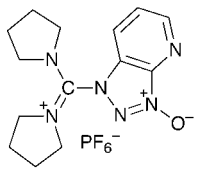
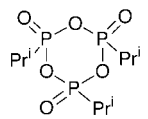
Received (in Liverpool, UK) 22nd June 1999, Accepted 3rd August 1999

In the course of comparing the effectiveness of an HOAt-derived coupling reagent (HAPyU) and a phosphonic acid-based condensation agent (T3P) by cyclization of model sequences, we found that T3P was a superior reagent with regard to conversion of the linear peptide into the stereochemically intact cyclic monomer when sterically hindered amino acids are found at the cyclization site.

Although the stepwise coupling of urethane-protected amino acids in peptide chemistry normally causes no problems with regard to loss of configuration at the reactive carboxy residue, head-to-tail cyclizations of short peptide chains having the all-L-configuration (*e.g.* penta- and hexa-peptides) or the corresponding segment condensation often remain problematic.[1c,2] For this reason, such systems represent good models for evaluating the usefulness of newly developed coupling methods. HOBt- and, more importantly, HOAt-derived coupling reagents,[3] have been evaluated and recommended as efficient tools for solving some of the most intractable problems such as reaction rate, degree of epimerization, and extent of oligomerization.[4]† Various authors have compared the efficiency of condensation reagents derived from HOBt (*e.g.* TBTU, HBTU), HOAt (*e.g.* HATU, HAPyU) and phosphoric and phosphonic acids (*e.g.* DPPA, T3P[5]) in cyclization reactions and have confirmed the superiority of the HOBt-[6] and, especially, HOAt-based reagents[4] with regard to these problems.



HAPyU



T3P

For peptide cyclization involving sterically hindered α,α-dialkyl- or *N*-methyl-amino acids at the *N*-terminal position there has been little systematic effort to uncover the important factors which influence the efficiency of the cyclization process. For loss of configuration during ordinary segment coupling it has long been known that increasing steric hindrance in the amino component correlates with increasing loss of configuration.[7] In the case of cyclization of the four possible linear precursors which lead to cyclo(Aib-Phe-D-Pro-Ala), only the isomer bearing N-terminal Ala gave the cyclopeptide in significant amount (44%).[8] The other three isomers cyclized in only trace amounts (2–3%), suggesting that factors other than steric effects at the N-terminal position are important. Although some investigators have deliberately avoided attempting cyclization at an N-Me amino acid, for example in the case of cyclosporin,[9] others have reported effective depsipeptide cyclization at N-terminal sites occupied by MeLeu (oxime ester, > 48%;[10] BOP-Cl, 87%[11]) or MeVal (acid chloride, 25%[12]). Since none of these previously reported systems involved the difficult all-L-configuration, the present study was initiated.

In the course of segment condensation studies leading to the ACP decapeptide (acyl carrier protein 74-65) one of us (P. H.) showed the effectiveness of 2-propanephosphonic acid anhydride (T3P) as a condensation reagent. This result, along with Wenger's demonstration[9] that T3P and the BOP reagent were equally effective in the cyclosporin case (65% cyclization), led to a reexamination of the T3P reagent in segment condensations and head-to-tail cyclizations of all-L-pentapeptides, especially those bearing sterically hindered amino acids at the cyclization site. Whereas comparison of HAPyU, a reagent which we had previously shown to be one of the most effective coupling reagents for peptide cyclization,[4] and T3P in ordinary [2 + 1] segment condensations in the presence of Pr^i_2NEt for the model tripeptide Z-Phe-Val-Pro-NH_2 showed far more epimerization for the T3P case (29.7 *vs.* 10.8%) along with a lower yield (58.6 *vs.* 88.8%), upon substitution of the more hindered H-Aib-NH_2 for H-Pro-NH_2 the loss of configuration for T3P, while significant, was substantially less than for HAPyU (14.6 *vs.* 41.1%) (Table 3).‡ However, under the normal conditions for HAPyU reactions, the T3P reaction was extremely slow.

In order to evaluate the cyclization utility of T3P, we studied the ring closure of several linear pentapeptides (model peptides **1**, **4**–**7** and thymopoietin-derived sequences **2** and **3**) by analytical HPLC using T3P and HAPyU as condensation reagents. For pentapeptide **1** optimization studies were carried out with T3P under various reaction conditions (temperature,

concentration, excess of reagent and base) and the results compared with the best results previously obtained with HAPyU. In the case of all peptides which lack a sterically demanding amino acid in the N-terminal position (Table 1), differences between T3P- and HAPyU-mediated reactions are not significant, although for the cyclization of AA(*N*-Me)AAA at 10^{-3} M concentration, regardless of reaction conditions, T3P gives a higher yield of the all-L-cyclic monomer than the corresponding HAPyU reagent (Table 1). Under the best conditions T3P led to a level of epimerization (2.2%) which is only slightly higher than that observed with HAPyU (1.6%). For the T3P case, the degree of epimerization appears to depend more on the excess of condensation reagent and concentration rather than an excess of base (Table 1). The rate of T3P-mediated cyclization is comparable to that previously observed for HAPyU; after approximately 2 min the reaction is about 90% complete in all cases. In accordance with previous results for HAPyU (J. Klose, unpublished) T3P-induced cyclization at lower temperatures leads to significantly enhanced cyclodimerization (Table 1). The cases of SP5 and (Hmb)Ala[3]-SP5 are very similar for the two activators in that comparable amounts of all-L-cyclic monomer are formed with T3P leading to somewhat less epimerization (data not shown). In all three cases significantly larger amounts of the undesired all-L-cyclodimer is formed for the HAPyU system.

Whereas for these cyclization reactions involving relatively unhindered amino acids no clear superiority of T3P can be shown, the situation is drastically different in the case of cyclization *via* peptide bond formation at a sterically hindered amino acid (Table 2). Here, HAPyU-mediated cyclization yields almost exclusively the C-terminally epimerized cyclic monomer (59–87%).§ In contrast, T3P-promoted reactions yield the desired all-L-cyclic monomer as the major product, even though the overall yield of cyclic product is not high due to the sluggishness of the reaction, which was allowed to proceed for 80 h. Even at that point cyclization was incomplete. As expected, the tendency to give the all-L-cyclic monomer is lower the more hindered is the N-terminal substituent (increasing from **4** to **7**) and formation of all-L-cyclic product fails almost completely for the sterically most demanding Tmob-residue. The differences observed with regard to C-terminal stereomutation are reminiscent of the differences seen in comparison of HBTU and HAPyU or HATU, where the former leads to extensive C-terminal epimerization.[2,4]

In summary, the data presented show that T3P is at least as effective as HAPyU in the relatively demanding cyclization of all-L-pentapeptides, and remarkably more efficient for systems having a sterically hindered amino acid, such as Aib, (*N*-Me)Ala and (*N*-Me)Phe, at the cyclization site. Whereas the HAPyU-promoted cyclization yields the C-terminally epimerized product almost exclusively, the use of T3P gives the stereo-retained cyclic monomer as the main product, albeit in rather low yield.

Table 3 [2 + 1] Segment condensation of Z-Phe-Val-Aib-NH_2[a]

Coupling reagent (equiv.)	Base (equiv.)	Residue yield[b] (%)	LD (%)[c]	Yield of LL-, LD-tripeptide[d] (%)
HATU (1)	Pri_2NEt (2)	82.9	40.3	100
HATU (1)	TMP (2)	74.6	31.0	100
HATU (1)[e]	Pri_2NEt (2)	95.2	41.5 (LL)	100
HAPyU (1.1)	Pri_2NEt (3)	82.2	41.1	100

T3P (5)[f]	DMAP (6)	54.7	11.6	4.9

[a] Test couplings were carried out by adding the base to a stirred and ice-cooled solution of Z-Phe-Val-OH, H-Aib-NH_2 and the coupling reagent (each 1 equiv., 0.125 M in DMF). The mixture was stirred at 0 °C for 1 h at room temperature overnight. Work-up was carried out as described in L. A. Carpino, D. Ionescu and A. El-Faham, *J. Org. Chem.*, 1996, **61**, 2463, Table 1, footnote *a*. [b] Calculated based on the weight of the crude product. [c] Pure LL or LD peptides were co-injected onto HPLC to determine epimerization by comparison of retention times. [d] Calculated based on integration of the LL- and LD-tripeptide peaks relative to all other HPLC peaks. [e] Z-Phe-D-Val-OH was used in this case. [f] 24 h reaction time. [g] 90 h reaction time.

A coordination polymer based on twofold interpenetrating three-dimensional four-connected nets of 4^26^38 topology, [CuSCN(bpa)] [bpa = 1,2-bis(4-pyridyl)ethane]†

Quan-Ming Wang, Guo-Cong Guo and Thomas C. W. Mak*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New territories, Hong Kong SAR, P.R. China. E-mail: tcwmak@cuhk.edu.hk

Received (in Cambridge, UK) 24th June 1999, Accepted 17th August 1999

The novel coordination polymer [CuSCN(bpa)] [bpa = 1,2-bis(4-pyridyl)ethane] consists of two interpenetrating three-dimensional four-connected frameworks of rare 4^26^38 topology, each being constructed from the cross-linkage of infinite zigzag $[(CuSCN)_2]_\infty$ chains by bpa ligands.

The construction of coordination networks with different topological characteristics has received significant recent attention.[1] One of the rational synthetic strategies is to bind symmetrically different metal centers with bi- or multi-dentate ligands. A variety of infinitely extended frameworks, in particular those involving interpenetration,[2] have been designed on the basis of the unifying concept of a net, as elaborated by Wells over two decades ago.[3] The majority of interpenetrating 3D four-connected nets are constructed of tetrahedral or square-planar nodes. From the topological point of view, these four-connected nets can be classified as (i) diamond-related nets of 6^6 topology (all tetrahedral centers); (ii) quartz-like nets of 6^48^2-b topology or NbO-like nets of 6^48^2-a topology (all square-planar centers) and (iii) PtS-like 4^28^4 nets (equal numbers of square-planar and tetrahedral centers).[2,4] Additionally, two new types of four-connected nets of 6^58 and 7^59 topologies have been recently reported in the compounds $[Cu(bpa)_2(NO_3)_2]_n$[5] [bpa = 1,2-bis(4-pyridyl)ethane] and $[\{Cu(bpethy)_2(H_2O)_2\}\{Cu(bpethy)_2(NO_3)(H_2O)\}_2](NO_3)_4\cdot bpethy\cdot 1.33H_2O$[6] [bpethy = 1,2-bis(4-pyridyl)ethyne], respectively. Furthermore, two structures of 4^26^38-a type ($SrAl_2$-like) have been found in $[Cu(AcTCNE)]\cdot Me_2CO$[7] (AcTCNE = 1,1,2,2-tetracyanopentan-4-on-1-ide) and $[Ag(sebn)_2](PF_6)$[8] (sebn = 1,10-decanedinitrile) by Carlucci *et al*.

By combining flexible organic ligands with an uncharged inorganic motif containing a bifunctional polyatomic anion of suitable length, such as CuSCN or CuN_3, we hope to generate porous 3D coordination networks that may display varying degrees of interpenetration. Interestingly, our attempt to incorporate the bpa ligand into CuSCN resulted in a non-diamond 3D coordination polymer [CuSCN(bpa)] **1**, despite the fact that most Cu(I) coordination polymers exhibit diamond structures as this d^{10} ion naturally fulfills the role of a tetrahedral node.[9] To our knowledge, the doubly interpenetrating frameworks of unusual 4^26^38 topology in the present coordination polymer is unprecedented.

The hydrothermal reaction of CuSCN and bpa in molar ratio 1:1 at 180 °C leads to the formation of red air-stable compound **1**.‡ Single crystal X-ray analysis§ has revealed that **1** contains two interpenetating 3D nets, each individual framework being constructed from the building unit shown in Fig. 1. The Cu(1) and Cu(2) atoms are each located in a severely distorted tetrahedral environment, being coordinated by two N atoms of different bpa ligands, one thiocyanato S atom and one N atom of another thiocyanate ligand, with bond angles in the range 102.9(2)–118.9(2) and 97.6(2)–117.1(1)° at Cu(1) and Cu(2), respectively.

† Dedicated to the memory of Dr James C. N. Ma (1927–1999).

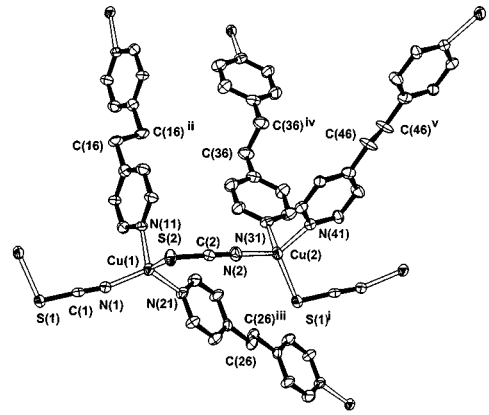

Fig. 1 The local coordination environments of Cu(I) ions in **1**; atoms are shown as 30% thermal ellipsoids. All four independent bpa ligands are located at inversion centers. Selected bond distances (Å) and angles (°): Cu(1)–N(1) 1.949(5), Cu(1)–N(21) 2.044(4), Cu(1)–N(11) 2.128(4), Cu(1)–S(2) 2.330(2), Cu(2)–N(2) 1.964(5), Cu(2)–N(41) 2.088(4), Cu(2)–N(31) 2.117(4), Cu(2)–S(1)^i 2.296(2); N(1)–Cu(1)–N(21) 118.9(2), N(1)–Cu(1)–N(11) 102.9(2), N(21)–Cu(1)–N(11) 104.8(2), N(1)–Cu(1)–S(2) 112.2(1), N(21)–Cu(1)–S(2) 108.7(1), N(11)–Cu(1)–S(2) 108.5(1), N(2)–Cu(2)–N(41) 111.1(2), N(2)–Cu(2)–N(31) 100.6(2), N(41)–Cu(2)–N(31) 97.6(2), N(2)–Cu(2)–S(1)^i, 117.1(1), N(41)–Cu(2)–S(1)^i 114.7(1), N(31)–Cu(2)–S(1)^i 113.2(1). Symmetry codes: i $x+1, y, z$; ii $-x-1, -y+1, -z+1$; iii $-x, -y, -z+1$; iv $-x, -y+1, -z+1$; v $-x+1, -y+1, -z+2$.

As shown in Fig. 2, the independent SCN^- ligands bridge Cu(1) and Cu(2) alternately to form a zigzag $[(CuSCN)_2]_\infty$ chain running parallel to the *a* direction, with bond angles Cu(1)–S(2)–C(2) 99.7(2)°, Cu(1)–N(1)–C(1) 168.1(4)° and Cu(2)–S(1)^i–C(1)^i 102.4(2)°, Cu(2)–N(2)–C(2) 167.1(4)°. Such chains are inter-connected through two bpa ligands (N21 and

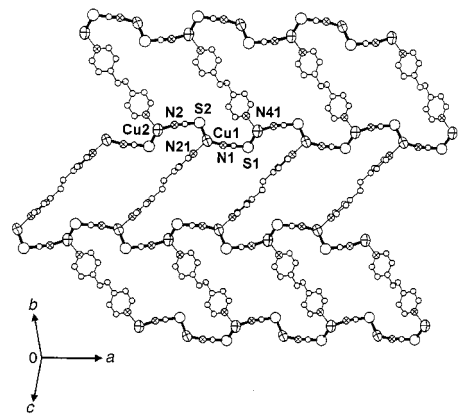

Fig. 2 A two-dimensional brick-like 6^3 network viewed along the [011] direction. Filled bonds represent $[(CuSCN)_2]_\infty$ zigzag chains running parallel to the *a* axis. The pyridyl planes of bpa N(21) and bpa N(41) make a dihedral angle of 112.7°.

N41) that bridge copper centers to generate a 2D brick-like network, which is similar to the brick-wall patterns previously reported in two-dimensional coordination compounds.[10] The pyridyl planes of bpa N21 and bpa N41 make a dihedral angle of 112.7°. Neighboring networks are further linked by the remaining bpa ligands (N11 and N31) to form a 3D framework. The dihedral angle between the pyridyl planes of bpa N11 and bpa N31 is 99.2°.

The 2D networks of 6^3 topology are stacked in an ABAB… sequence, and the mode of their linkage to build up a 3D framework is illustrated schematically in Fig. 3. It can be seen that there are three kinds of shortest circuits around every four-connected node: two 4-gons, three 6-gons and one 8-gon. Each of the resulting channels, which lie horizontally in Fig. 3, has a 10-vertex ring at its boundary. In contrast, the 6^3 nets in the $SrAl_2$-type network stack directly on top of one another so that an 8-vertex ring constitutes the boundary of each channel.[7,8]

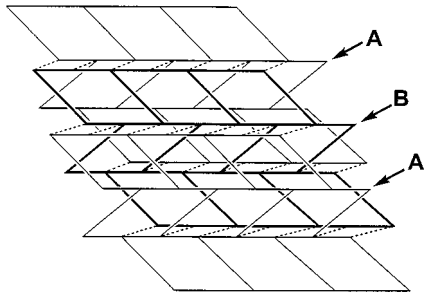

Fig. 3 Schematic representation showing the topology of a $4^2 6^3 8$ 3D network. The copper(I) ions are located at the nodes. Horizontal lines represent SCN^- ligands, inclined lines indicate bpa N(21) and N(41) ligands, and dashed lines indicate the bpa N(11) and N(31) ligands that form bridges between the 2D brick-like networks of 6^3 topology. A perspective view of a stack of three 2D networks is shown: the middle layer B (thick lines) is sandwiched between two type A layers (thin lines), and two adjacent layers are related by the translation vector ($\boldsymbol{a} + \boldsymbol{c}$).

Two 3D frameworks interpenetrate to form the crystal structure of **1**. The overall structure can alternatively be regarded as two identical 2D brick networks that interpenetrate in an inclined way, with the bridging bpa ligands (N11 and N31) occupying the voids.

The thiocyaniate ligands function as linking rods to bridge copper(I) centers to make the coordination framework of **1** a neutral one, in contrast to many common examples that are charged.[11] Several neutral Cu(I) coordination polymers have been synthesized by solution methods, for example [Cu(4,4′-bpy)Cl][12] and $[Cu_2(SCN)_2(pyz)]$ (pyz = pyrazine).[13] However, their structures are very different from **1**, as [Cu(4,4′-bpy)Cl] is built of two-fold interpenetrating 2D networks and $[Cu_2(SCN)_2(pyz)]$ has a non-interpenetrating structure. The formation of 3D frameworks depends on not only the coordination geometry at the metal centers but also the nature of the anions and the bridging ligands. In the case of **1**, the presence of four independent, centrosymmetric bpa ligands is responsible for generating the unusual framework structure.

In contrast to the extensively studied rigid ligand 4,4′-bipyridine, the flexible ligand bpa has recently attracted the interest of chemists.[5,14] The less exploited bpa ligand can adopt *gauche* and *anti* conformations, and this conformational freedom can even engender supramolecular isomerism in coordination polymers.[15] Since all four independent bpa ligands in **1** occupy $\bar{1}$ sites and exhibit the *anti* conformation, it is conceivable that other isomers may be generated in a Cu(I) system containing all *gauche* or mixed *gauche/anti* bpa ligands. Further investigation of neutral metal complexes of bpa is in progress.

Notes and references

‡ *Synthesis*: CuSCN (61 mg, 0.5 mmol), bpa (92 mg, 0.5 mmol) and 2 mL distilled water were placed in a thick-walled Pyrex tube of *ca*. 6 mL capacity, and then the mixture was frozen in liquid nitrogen. The tube was subsequently flame-sealed under vacuum and kept in a furnace at 180 °C for 24 h, and then cooled to 60 °C at 6 °C h^{-1}. From the brown powdery bulk residue, red block-like crystals of [CuSCN(bpa)] **1** were isolated in *ca.* 10% yield and washed with water. IR (KBr pellet)/cm^{-1}: 2102.9s, 2091.4s, 1605.0s, 1418.0s, 1007.6m, 825.7s, 820.7s, 761.1m, 548.1m, 535.0m. The IR spectrum of the brown powder is similar to that of **1**, except that a single peak at 2103.9 cm^{-1} appears at the position of the doublet in the spectrum of **1**. This suggests that the brown powder is a different product containing a simpler SCN^- bridging mode. Both red crystals of **1** and the brown powder are insoluble in water, MeCN and DMF.

§ *Crystal data*: [CuSCN(bpa)] **1**, $C_{13}H_{12}CuN_3S$, M = 305.86, monoclinic, space group $P2_1/c$ (no. 14), a = 10.782(2), b = 17.348(2), c = 14.084(2) Å, β = 97.405(3)°, V = 2612.4(6) Å^3, Z = 8, D_c = 1.555 Mg m^{-3}, $F(000)$ = 1248, μ(Mo-Kα) = 1.815 mm^{-1}. 11977 reflections measured, 5941 unique (R_{int} = 0.0886), final $R1$ = 0.0417, $wR2$ = 0.0759 for 2215 independent reflections [$I > 2\sigma(I)$]. Data collection was performed at 293 K on a Bruker SMART 1000 CCD diffractometer using frames of oscillation range 0.3°, with $2 < \theta < 27.5°$. CCDC 182/1379. Received (in Cambridge, UK) 15th July 1999, Accepted 19th August 1999

The intense yellow colour of the 4-nitrophenolate anion 2, in MeCN or CH_2Cl_2 solution, dissipates upon complex formation with *meso*-octamethylcalix[4]pyrrole 1; the complex may be used as a colourimetric sensor for halide anions, such as fluoride, that displace the phenolate anion thereby restoring the yellow colour, characteristic of free 4-nitrophenolate anion, to solutions containing 1, 2 and the anion in question.

The coordination chemistry of anions continues to attract increasing interest from the supramolecular chemistry community.[1–4] This is due, in no small part, to the crucial roles anions play in biological processes,[5,6] medicine,[7] catalysis[8] and molecular assembly.[9] Additionally various pollutant anions, such as pertechnetate, are believed to have deleterious effects on the environment.[10] Redox or photoactive sensor molecules have been developed that coordinate to anions and report their presence *via* changes in the physical properties of the host (such as redox potential, fluorescence or phosphorescence).[11,12] Another approach to anion detection, pioneered by Anslyn and co-workers, is the displacement assay (*i.e.* a host–anion complex that dissociates in the presence of other anions, triggering a change in the properties of the system).[13] Chemical systems that respond to the presence of anions by a colour change detectable *by eye* are extremely rare.[14] Colourimetric sensors do not require the use of a potentiostat or spectrometer to detect redox or optical perturbations and therefore have considerable advantages over other molecular sensors.[15] Here we report the formation of a new colourimetric displacement assay that is selective for halide anions over other putative anionic guest species and is extremely easy and inexpensive to make.

In 1996, we discovered that calix[4]pyrroles (*meso*-octalkylporphyrinogens), a class of molecule known for over a hundred years, can coordinate to anions such as fluoride, chloride and dihydrogen phosphate *via* the formation of pyrrole NH··· anion hydrogen bonds.[16] *meso*-Octamethylcalix[4]pyrrole **1** is particularly easy to make and can be synthesised in high yield by the acid catalysed reaction of pyrrole with acetone.[17] We decided to investigate whether the formation of a calixpyrrole–anion complex with a coloured species such as 4-nitrophenolate anion **2** would perturb the electronic properties of the anion sufficiently to produce a colour change that could be used as the basis for a colourimetric displacement assay.

2

Initial complexation studies were conducted using ^{1}H NMR titration techniques. Aliquots of tetrabutylammonium 4-nitrophenolate[18] (0.1 mol dm^{-3}) were added to a solution of compound **1** (0.01 mol dm^{-3}) in CD_2Cl_2 and the chemical shift of the calix[4]pyrrole NH proton noted after each addition. A significant downfield shift (from δ 7.0 to 10.6) of the pyrrole NH proton was observed upon the addition of 5 equiv. of tetrabutylammonium 4-nitrophenolate, consistent with the formation of calixpyrrole–phenolate hydrogen bonds. Analysis of the titration data using the EQNMR computer program[19] revealed that *meso*-octamethylcalix[4]pyrrole forms a 1:1 complex with 4-nitrophenolate with a stability constant of 290 (± 9.7) dm^3 mol^{-1}. Previous experiments showed that fluoride and chloride bind to compound **1** with stability constants of 17 200 and 350 dm^3 mol^{-1}, respectively, under the same conditions whilst the **1**·$H_2PO_4^-$ complex has a stability constant of 97 dm^3 mol^{-1}.[16] Competition experiments with fluoride, chloride and dihydrogenphosphate anions were then conducted. A CD_2Cl_2 solution of the complex **1·2** was prepared and aliquots of tetrabutylammonium salts of the anions added. After an initial addition of 0.2 equiv. of fluoride, the NH proton resonance broadened and could not be located in the NMR spectrum. Only after addition of 1.0 equiv. of fluoride did the NH resonance reappear, further shifted downfield by over 3 ppm as compared to **1·2**, indicating the formation of a calixpyrrole–fluoride complex. In contrast, tetrabutylammonium chloride and dihydrogenphosphate produced much smaller downfield shifts of 0.78 and 0.37 ppm, respectively, upon addition of 1.0 equiv. of the anion salt.

The colourimetric properties of this complex were then studied using UV/Vis spectroscopic techniques. Addition of calix[4]pyrrole **1** (5×10^{-2} mol dm^{-3}) to a solution of tetrabutylammonium 4-nitrophenolate **2** (3.6×10^{-5} mol dm^{-3}) in CH_2Cl_2 at 25 °C caused a significant decrease in intensity of the so-called '200 nm band' at 432 nm (Fig. 1).[20]

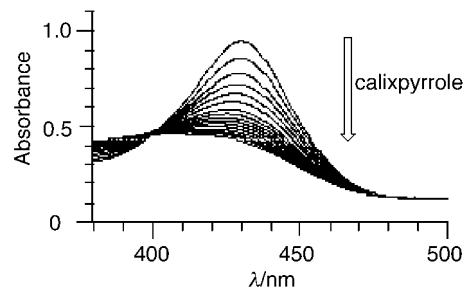

Fig. 1 Decreasing absorbance of the 4-nitrophenolate anion **2** (3.6×10^{-5} mol dm^{-3}) upon addition of calixpyrrole **1** (5×10^{-2} mol dm^{-3}) in CH_2Cl_2 at 25 °C.

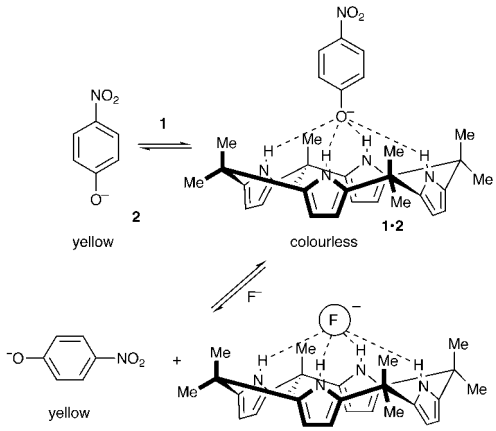
† A colour picture illustrating the dissipation and reappearance of the 4-nitrophenolate yellow colour together with NMR/UV/vis titration data are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1851/



Scheme 1

Table 1 Relative absorbance values for calixpyrrole–4-nitrophenolate solutions containing equimolar concentrations of various anions.[a] Since the signal being observed is due to liberated 4-nitrophenolate anion, the larger the relative absorbance, the stronger the binding (all anions were used as their tetrabutylammonium salts)

	F^-	Cl^-	$H_2PO_4^-$	Br^-	HSO_4^-
ΔAbsorbance[b]	0.282	0.193	0.162	0.092	0.015
Relative absorbance[c]	1.0	0.68	0.57	0.33	0.05

[a] *meso*-Octamethylcalix[4]pyrrole was added to a solution of tetrabutylammonium 4-nitrophenolate (6.0×10^{-6} mol dm^{-3}) in MeCN, affording a solution that was 5.0×10^{-4} mol dm^{-3} in calixpyrrole. Solutions of tetrabutylammonium fluoride, chloride, dihydrogenphosphate, hydrogensulfate and bromide were prepared using this stock solution such that the anion concentration was 1.6×10^{-2} mol dm^{-3} in all cases. UV/vis spectra were recorded immediately after the solutions were prepared. The data were averaged over three runs (errors < 15%). [b] Calculated by measuring the difference between 490 and 430 nm. All values are corrected relative to that measured for the calix[4]pyrrole stock solution (0.03 nm). [c] Calculated relative to **1·2** + fluoride solution, *i.e.* relative absorbance = [ΔAbsorbance (anion)/ΔAbsorbance (fluoride)].

This decrease in intensity was visible to the naked eye as a yellow-to-colourless colour change and is attributed to the formation of the calixpyrrole–phenolate complex **1·2**.† Control experiments showed that addition of pyrrole to solutions of **2** (2×10^{-1} mol dm^{-3}) under the same conditions caused no decrease in the intensity of this band.

Addition of anions to solutions of **1·2** causes the yellow colour of the 4-nitrophenolate anion to return as it is displaced from the calix[4]pyrrole anion binding site (Scheme 1). Table 1 shows the relative absorbance values for solutions of **1** (5.0×10^{-4} mol dm^{-3}) and **2** (6.0×10^{-6} mol dm^{-3}) in MeCN upon addition of various anions (solution made up to 1.6×10^{-2} mol dm^{-3}). The strongest absorbance is observed upon addition of fluoride anions followed by chloride and dihydrogenphosphate anions. This trend reflects the absolute and relative affinities of *meso*-octamethylcalix[4]pyrrole for these particular anionic guests and is illustrated in Fig. 2.

The present findings serve to illustrate that calixpyrroles, such as **1**, may be used to produce anion sensors that can report the presence of anions by means of a colour change. It may therefore be possible to incorporate analogous systems into 'dip-sticks' for anion detection in the field. We are presently working to covalently attach a variety of phenolate anions and dyes to calixpyrroles in order to produce discrete molecular hosts capable of reporting anion-binding events by colour changes. The results of this work will be reported in due course.

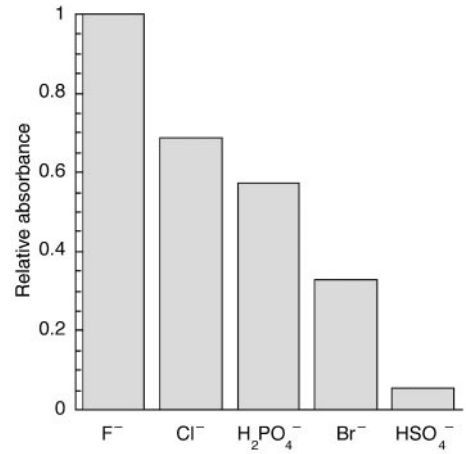


Fig. 2 Relative absorbance of solutions containing **1** (5.0×10^{-4} mol dm^{-3}), **2** (6.0×10^{-6} mol dm^{-3}) and various anions (1.6×10^{-2} mol dm^{-3}) in MeCN at 25 °C.

Received (in Basel, Switzerland) 25th June 1999, Accepted 19th August 1999

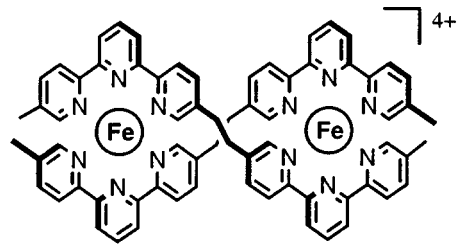
A dinuclear double helix constructed around two iron(II) bis(terpyridine) centres has been resolved by preparative column chromatography, several tens of milligrams of each enantiomer were obtained, with an excellent enantiomeric excess.

In the course of the last 30 years, coordination chemistry has afforded many examples of fascinating architectures based on metal–ligand interactions.[1] Of particular interest are double-stranded helical-type complexes, exemplified by transition-metal helical complexes[2] and molecular knots[3,4] (Fig. 1). Such compounds, with their helical topography and knotted topology, are reminiscent of more complex natural structures such as DNA[4] and proteins.[5] Interestingly, a major chemical difference between a molecular trefoil knot and a double helix is that the knot will retain its chirality even after demetallation.

Helical systems are intrinsically chiral and, in metallo-helical complexes, the coordination of the first metal centre determines the chirality of the neighboring centre.[6] If the ligand is achiral, synthesis will produce a racemic mixture containing the Δ- (right-handed) and the Λ- (left-handed) double helices. In the past few years, the challenge of isolation of the chiral forms of such systems has focussed on resolution[7] or enantioselective synthetic[8,9] techniques. Only a few examples of resolved transition-metal helical complexes[10–12] and one example of a resolved knot[13] have been reported in the literature.

In our search for new optically pure transition-metal based molecular knots, we explored the use of an iron(II) bis-(2,2′:6′,2″-terpyridine) {bis-terpy} fragment in the place of the original copper(I) bis(1,10-phenanthroline) motif. This fragment successfully yielded a racemic mixture of a diiron(II) molecular knot.[14] In order to find a more general resolution method than the diastereoselective crystallization used previously for the dicopper(I) trefoil knot,[13] for the case of the diiron(II) compound we attempted a chromatographic technique which had been recently applied to the resolution of a range of cationic mono-, di- and tri-nuclear transition metal complexes.[11,12,15] Here, we report the resolution of a dinuclear iron(II) double-stranded helix and its absolute configuration determined on the basis of an X-ray crystallographic study.

A racemic mixture of the previously described[13] dinuclear iron(II) double helix $\mathbf{1}^{4+}\cdot 2SO_4^{2-}$ (Scheme 1) was absorbed onto a column (100 × 2 cm) of SP Sephadex C-25 cation exchanger and eluted with aqueous 0.075 M sodium (−)-di-*O*,*O*′-4-toluoyl-L-tartrate. After an 'effective column length' of *ca.* 6 m (achieved by recycling using a peristaltic pump), two separate bands were collected. After isolation of the separated enantiomers as the PF_6^- salts by metathesis from the solutions of eluted bands, their molar rotations were measured in acetonitrile solution and observed to be equal in magnitude and opposite in sign.



$\mathbf{1}^{4+}$

Scheme 1

The circular dichroism (CD) spectra of the enantiomers are shown in Fig. 2. As expected, they are mirror images over the whole region of the spectrum. In the visible region, $\Delta\varepsilon$ reaches a highest absolute magnitude of *ca.* 23 $dm^3\ mol^{-1}\ cm^{-1}$, which is associated with the absorption maximum of the metal-to-ligand charge transfer (MLCT) transition at 560 nm [d_π(Fe)–π^*(terpy)].†

After two months in acetonitrile solution at room temperature, no loss of any optical activity was observed, indicating high kinetic stability of the optically pure double helix. This can

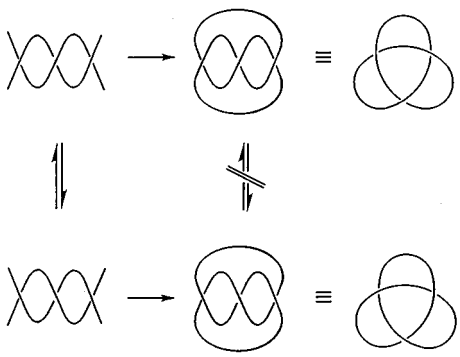


Fig. 1 From a double-stranded helix to a knot. The knotted topology makes the interconversion between both enantiomers impossible without breaking and reforming at least one chemical bond.

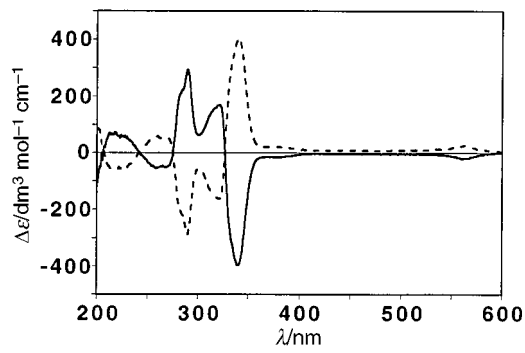

Fig. 2 Circular dichroism spectra of the enantiomers of the diiron(II) double helix in MeCN: (−)-$\mathbf{1}^{4+}\cdot 4PF_6^-$ (continuous line) and (+)-$\mathbf{1}^{4+}\cdot 4PF_6^-$ (dotted line).

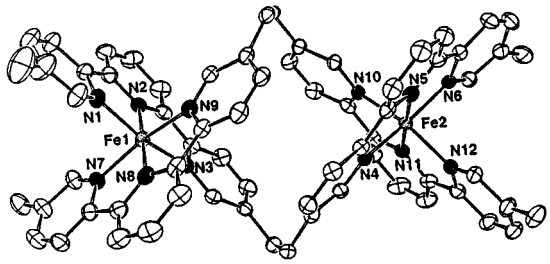

Fig. 3 Crystal structure‡ of the dextrorotatory diiron(II) double helix (+)-$\mathbf{1}^{4+}\cdot 4PF_6^-$. ORTEP representation showing the numbering scheme adopted for iron and nitrogen atoms. The solvent molecules, PF_6 anions and hydrogen atoms have been omitted and the nitrogen atoms are shown in black. Selected bond distances (Å) and angles (°) of the two pseudo-octahedral iron centres: Fe1–N1 1.990, Fe1–N2 1.899, Fe1–N3 1.992, Fe1–N7 2.008, Fe1–N8 1.869, Fe1–N9 1.981, Fe2–N4 1.963, Fe2–N5 1.872, Fe2–N6 1.976, Fe2–N10 1.981, Fe2–N11 1.902, Fe2–N12 1.966, N1–Fe1–N2 80.7, N1–Fe1–N8 99.7, N2–Fe1–N3 80.4, N2–Fe1–N7 97.4, N2–Fe1–N9 99.6, N3–Fe1–N8 99.3, N7–Fe1–N8 81.1, N8–Fe1–N9 81.9, N4–Fe2–N5 82.0, N4–Fe2–N11 99.8, N5–Fe2–N6 81.3, N5–Fe2–N10 99.7, N5–Fe2–N12 98.8, N6–Fe2–N11 97.0, N10–Fe2–N11 80.6, N11–Fe2–N12 80.9.

be compared to the mononuclear complex, $[Fe(terpy)_2]^{2+}$, which readily racemizes in solution.[16] Crystals suitable for X-ray analysis were obtained by dissolution of 14 mg of the dextrorotatory double helix (+)-$\mathbf{1}^{4+}\cdot 4PF_6^-$ in one drop of acetonitrile diluted with methanol and slow liquid diffusion of benzene. The absolute configuration of the dextrorotatory enantiomer of the double helix was determined and the X-ray crystal structure is shown in Fig. 3.

The molecule has effective D_2 symmetry, with three mutually perpendicular pseudo-twofold axes, one joining the two iron cations, another passing through the middle of the two bridges and the third being perpendicular to the others. Each ligand is twisted around the metal–metal axis in the same direction. The coordination polyhedra around each metal appeared as distorded octahedra, and it should be noted that the intramolecular Fe–Fe distance is 8.31 Å, which is larger than in the crystal obtained from a racemic mixture (7.93 Å).[14] Finally, the absolute configuration of (+)-$\mathbf{1}^{4+}\cdot 4PF_6^-$ could be determined. The two metal centres are homochiral as expected in a double-stranded helical compound where the first coordination centre induces the same chirality on the coordination of its neighbour. The *dextrorotatory* double helix corresponds to a Λ-*double helix* with the bis-terpy ligands wound in an anticlockwise fashion.

The present results demonstrate the power of the chromatographic resolution technique, although an important limitation is the requirement to have water soluble compounds. To the best of our knowledge, this is the first reported absolute configuration of an iron(II) double helix. Further developments of this work would be to achieve chromatographic resolution of the diiron(II) trefoil knot prepared recently.[14]

We thank the CNRS, the European Union and the Australian Research Council for financial support and the French Ministry of National Education for a fellowship to G. R. We are also grateful to Nathalie Kyritsakas, André De Cian and Jean Fischer for the X-ray structure.

A novel conjugated polymer containing carboxylic acid and 2-[2-(2-methoxyethoxy)ethoxy]ethoxy substituents which is soluble in both organic solvents and aqueous bases is synthesized.

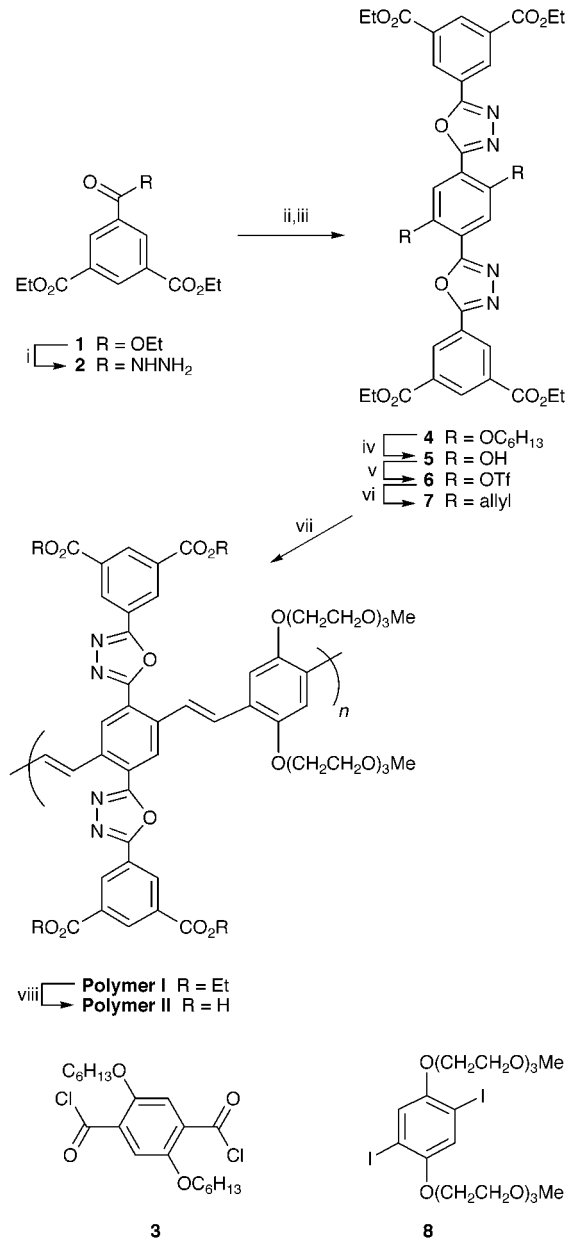
The most common driving force for the self-assembly of conjugated polymers is aromatic π–π interaction.[1,2] The resulting π–π stacking of conjugated polymers has a profound effect on the electronic and optical properties of the bulk polymers.[3,4] Controlling the self-assembly of conjugated polymers is thus of great importance for optimizing materials properties and producing novel new materials.[3–6] Conjugated polymers with polar functional groups such as hydroxy or carboxylic acid moieties may serve this purpose.[7,8] The controllable hydrogen bonding among hydroxy or carboxylic acid group allows modification of interchain interactions, thus altering the properties of the polymer. One such example is the regioregular polythiophenes with pendent carboxylic acid side chains, which have been demonstrated to be polymer chemoselective sensors.[8]

We are interested in designing hydrogen-bonded shape-persistent polymer networks. Our ultimate goal is to achieve stable, nanoporous polymer networks with controllable and uniform pore sizes. For this purpose, the polar functional groups have to be anchored in geometrically-fixed positions, rather than on flexible side chains.[7,8] Here we report the synthesis and optical properties of a water-soluble poly(phenylenevinylene) (PPV)-based polymer, shown in Scheme 1 as Polymer II. PPV, the most extensively studied electroluminescent polymer, was chosen as the polymer backbone.[9] The hydrogen-bonding anchors, isophthalic acids,[10] are covalently bonded to the PPV backbone through oxadiazole rings arranged orthogonally to the polymer backbone, a structure which assures shape persistence during self-assembly. The rigid arm and the polymer backbone are electronically cross-conjugated to enable the electronic and optical properties of the polymer backbone to change in response to the self-assembly process.

Polymer II was synthesized by the approach outlined in Scheme 1. Starting from triethyl benzene-1,3,5-tricarboxylate **1**, oxadiazole derivative **4** was synthesized in three steps. The two alkoxy groups in **4** were converted to vinyl groups (**7**) in an approach previously reported.[11] The precursor polymer (Polymer **I**) was synthesized by the Pd-catalyzed Heck coupling reaction of **7** with dihalide **8**,[12] which was synthesized by the reaction of 2,5-diiodohydroquinone with 3,6,9-trioxadecyl toluene-*p*-sulfonate.[13]

Polymer I is soluble in THF, $CHCl_3$ and CH_2Cl_2, and insoluble in DMSO, water and aqueous bases. Its weight-average molecular weight, measured by gel-permeation chromatography (GPC) at 30 °C with polystyrene as the standard, is 91 kDa with a polydispersity of 3.2. The hydrolysis of Polymer I was performed in THF with KOBu^t as the base.[14] After hydrolysis, Polymer II shows opposite solubility characteristics to that of Polymer I. For example, Polymer II is insoluble in $CHCl_3$, slightly soluble in THF, and soluble in DMSO and dilute aqueous bases such as NaOH, NH_4OH *etc*. The structures of both polymers were confirmed by spectroscopic studies and elemental analysis.

Polymer II shows unusual solubility behavior in aqueous bases. For example, Polymer II is only soluble in aqueous NaOH solutions with limited NaOH concentration (between 2 and 0.01 M). It is insoluble in solutions with NaOH concentrations that are too high (> 3 M) or too low (< 0.001 M). The decreased solubility of Polymer II in concentrated NaOH solutions may be related to the crown ether–metal ion type of bonding between ethylene oxide side chains of different polymer chains and metal ions. Such interaction results in a less soluble polymer network.



Scheme 1 *Reagents and conditions*: i, NH_2NH_2, EtOH, 52%; ii, **3**, Et_3N, $CHCl_3$, 87%; iii, $POCl_3$, 78%; iv, BBr_3, CH_2Cl_2, 93%; v, Tf_2O, pyridine, 86%; vi, tributylvinyltin, $Pd(PPh_3)_4$, 45%; vii, **8**, $Pd(OAc)_2$, P(*o*-Tol)$_3$, DMF, 90%; viii, KOBu^t. THF, quant.

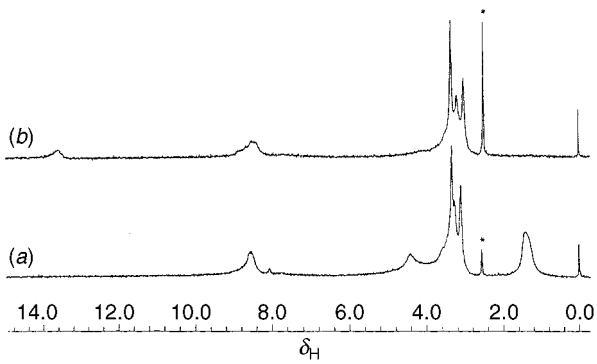


Fig. 1 ^{1}H NMR spectra of polymers (*a*) I and (*b*) II.

Fig. 1 shows the ^{1}H NMR spectra of both polymers. Before hydrolysis, Polymer I shows chemical shifts due to ester moieties at δ 4.40 and 1.5. The chemical shifts due to the ethylene oxide moieties appear between δ 3.0 and 3.7 as broad multiple peaks. The aromatic and vinyl protons are totally overlapped; only one broad peak at δ 8.6 is observed. After hydrolysis, a new peak at δ 13.5, corresponding to the carboxylic acid protons, appeared in the spectrum of Polymer II. The chemical shifts due to the ester moieties in Polymer I disappeared, indicating complete hydrolysis. Attempts to carry out the hydrolysis in acidic media such as TFA were unsuccessful.[15] It was found that, under acidic conditions, the conjugated polymer backbone was destroyed, resulting in a yellow polymer. Apparently, the acidic protons attacked the vinyl bond in the PPV backbone. The vulnerability of the vinyl bond to proton attack may be due to the partial polarization induced by the alternate electron-withdrawing and electron-donating substitution pattern of the backbones.

Polymer II also possesses good thermal stability. Differential scanning calorimetry (DSC) measurement and thermal gravimetric analysis (TGA) show that Polymer II has a decomposition temperature above 325 °C. No crosslinking process, common to the PPV backbone, is observed in the temperature range of 50–350 °C, indicating that the vinyl bonds on different polymer chains are well separated.

Fig. 2 shows the UV/Vis and fluorescence spectra of both polymers. Polymer I has two absorption peaks: *ca.* 506 nm is the absorption peak of the PPV backbone, *ca*. 310 nm can be assigned to the conjugated oxadiazole unit. After hydrolysis, the absorption of the PPV backbone is slightly blue-shifted, especially in aqueous base solutions. The maximum absorption wavelength in 1% NaOH is 484 nm.

Polymer I shows red fluorescence with an emission maximum at 615 nm. The photoluminescence quantum efficiency of Polymer I in dilute THF solutions is 3.7%. The fluorescence of Polymer II is significantly blue-shifted compared to that of Polymer I and is dependent on the choice of solvents. When a dilute DMSO solution of Polymer II was excited at 510 nm, a maximum emission at 555 nm with a shoulder at around 595 nm was observed. Polymer II in dilute NaOH solution, however, has an emission maximum at 593 nm, nearly 40 nm red-shifted compared to that of its DMSO solutions, and has a photoluminescence quantum efficiency of 4.2%.

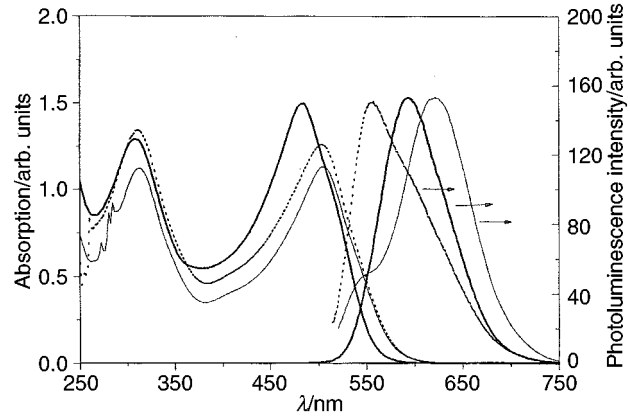

Fig. 2 Fluorescence and UV/Vis spectra of polymers I and II in solution. (*a*) I in THF, (*b*) II in 1% NaOH, (*c*) II in DMSO.

In summary, we have synthesized a novel PPV polymer containing carboxylic acid functional groups. This polymer possesses solubility in both organic solvents (DMSO) and aqueous bases (such as NaOH, NH_4OH *etc.*). The unique structure of this polymer makes it an attractive system for self-assembly studies. Its high electron affinity[11] and photoluminescence properties also warrant further study of this polymer for light-emitting diode applications, particularly as an electron-transporting layer in multilayer devices.

Received (in Cambridge, UK) 28th July 1999, Accepted 16th August 1999

The photochemical generation of silacarbonyl ylides from a silylene and carbonyl compounds and their inter- or intramolecular 1,3-dipolar cycloaddition with olefins leading to silicon heterocycles in one step was successful.

Over the past few decades the capture of a carbene with a carbonyl compound to form the corresponding carbonyl ylide has been the subject of extensive study.[1] Recently silylenes, the silicon analogues of carbenes, have attracted considerable attention in the construction of new silaheterocycles as possible new biologically active compounds and functional materials.[2] While several methods for the *in situ* generation of silylenes by photolysis have been developed,[3,4] the trapping of silylenes with aldehydes, ketones and an α-diketone leading to silaheterocycles has emerged as the result of studies on the chemical properties of silylenes.[4,5] However, specific research into the trapping of silylenes with carbonyl compounds has not been reported, nor has their application as silacarbonyl ylides in the one-step synthesis of silaheterocycles. We report herein some unprecedented examples of the 1,3-dipolar cycloaddition of photochemically generated silacarbonyl ylides, as silicon analogues of carbonyl ylides, with dipolarophiles to give silaheterocycles (Scheme 1).

The reaction of a silylene with a simple aliphatic aldehyde was investigated as an initial example. A solution of trisilane[6] **1** and acetaldehyde **2a** (100 equiv.) in hexane was irradiated at −57 °C for 40 h in a cold bath with a low pressure mercury lamp.[4] The resulting mixture was separated on a silica gel column (hexane–EtOAc = 95:5) to afford 1,4-dioxa-2-silacyclopentane **3a** in 50% yield (Scheme 2). The structure of the cycloadduct **3a** was characterized as a 1 : 2 cycloadduct of bismesitylsilylene **4** (*vide infra*) and aldehyde **2a** by spectral analysis. ^{1}H NMR observation showed that silaheterocycle **3a** was a mixture of diastereomers (*cis* : *trans* = 1 : 1), but no regioisomers such as a 1,3-dioxa-2-silacyclopentane were formed. The cycloadditions of trisilane **1** with other carbonyl compounds **2b–e** leading to 1 : 2 cycloadducts **3b–e** are summarized in Table 1.

With less bulky aldehydes such as acetaldehyde and propionaldehyde, the yields of **3** were moderate. However, when a more bulky aldehyde **2c** was employed, the yield of cycloadduct **3c** was dramatically improved to 81%. It is noteworthy that a nearly quantitative yield was observed with a non-enolizable bulky aldehyde **2d**. When acetone **2e** was employed, cycloadduct **3e** was produced in 15% isolated yield (26% by ^{1}H NMR before silica gel column separation).

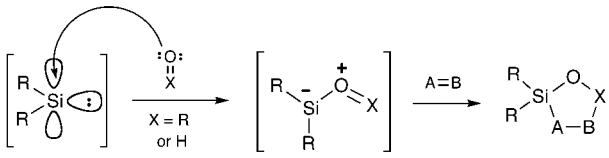
Table 1 The results of the cycloaddition reactions of silylene **4** with carbonyl compounds **2a–e** leading to 1:2 cycloadducts **3a–e**[a]

	Carbonyl compounds					
Entry		R^1	R^2	equiv.	*t*/h	Yield (%)[b]
1	**2a**	Me	H	100	40	50[c]
2	**2b**	Et	H	70	24	34[c]
3	**2c**	Pr^i	H	70	20	81[c]
4	**2d**	Bu^t	H	100	17	98[c]
5	**2e**	Me	Me	100	17	15[d]

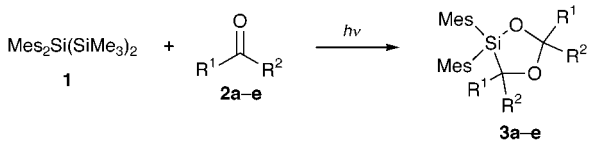
[a] Hexane solutions were irradiated at −57 °C. [b] Yield of the isolated products. [c] *cis, trans*-mixtures. [d] A large amount of enol silyl ether was detected.

The findings suggest that the silacarbonyl ylide intermediate **5** was initially generated from the silylene **4** and the carbonyl compounds **2** followed by 1,3-dipolar cycloaddition with **2** affording the cycloadduct **3**, where the aldehyde **2** plays two roles, first as a constituent of the ylide **5** and, subsequently, as a dipolarophile (Scheme 3).

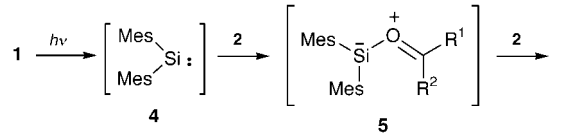
Trisilane **1** was then reacted with α,β-unsaturated aldehydes in the hope of observing intramolecular cycloaddition. Contrary to our expectation, the reaction of **1** with crotonaldehyde **7** (70 equiv.) gave the intermolecular 1:2 cycloadducts 1-oxa-2-silacyclopentane **9** and 1,3-dioxa-2-silacyclopentane **10** in 27 and 25% yields, respectively (Scheme 4). The oxasilacyclo-



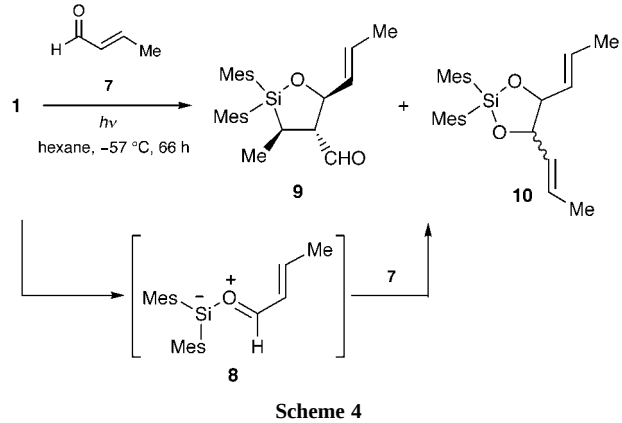
Scheme 1



Scheme 2



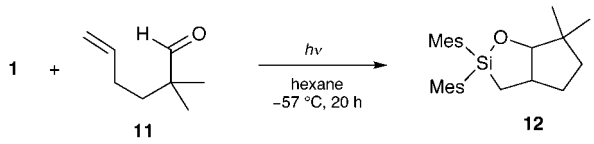
Scheme 3



Scheme 4

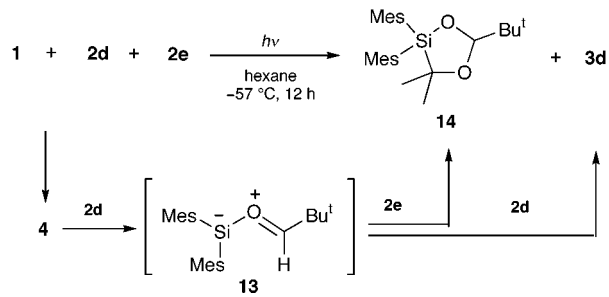
pentane structure of cycloadduct **9** was determined by spectral analysis and NOE measurement of its hydrazone derivative,[7] while product **10** had the same ring system as the 1:2 cycloadduct reported for the reaction with benzaldehyde.[8] As shown in Scheme 4, the generated silacarbonyl ylide **8** was trapped by the C=C bond of aldehyde **7** to afford **9** and by the carbonyl group of **7** to give **10**. The formation of **9** represents the first example of the cycloaddition of a silacarbonyl ylide with an olefinic dipolarophile, which strongly supports our view that this type of reaction proceeds *via* the 1,3-dipolar intermediate and not *via* a siloxirane intermediate.

Intramolecular cycloaddition was successful with a non-conjugated olefinic aldehyde leading to a silicon-atom embedded bicyclic compound. Thus, a solution of trisilane **1** and 2,2-dimethylhex-5-enal **11** (45 equiv.) in hexane was irradiated at −57 °C for 20 h to afford bicyclo[3.3.0]oxasilacyclooctane **12** in 51% yield (87% by ^{1}H NMR before SiO_2 column purification) (Scheme 5).



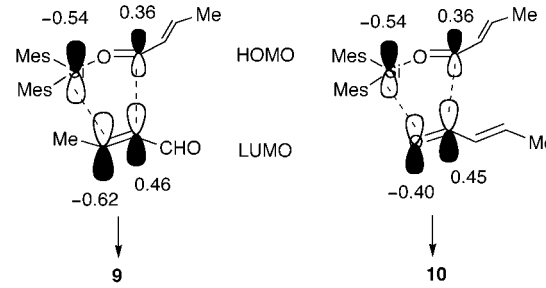
Scheme 5

Moreover, these results suggest the possibility of a three-component coupling reaction involving a silylene and two different carbonyl compounds. When a solution of trisilane **1**, pivalaldehyde **2d** (25 equiv.) and acetone **2e** (50 equiv.) in hexane was photolyzed at −57 °C for 12 h, a three-component cycloadduct **14** was successfully obtained as the major product in 37% yield along with cycloadduct **3d** in 21% yield (Scheme 6). In this three-component reaction, the 1:2 cycloadduct of silylene **4** and **2e** was not obtained at all (see entry 5, Table 1). This result implies that the generation of silacarbonyl ylide **13** from the silylene **4** and aldehyde **2d** occurred predominantly, which was followed by cycloaddition with acetone leading to **14**.



Scheme 6

Finally, the regioselectivities of the cycloadditions of silylene **4** and the aldehydes were examined by semiempirical MO calculations (PM3 method).[9] For the case of an aliphatic aldehyde such as pivalaldehyde, the orbital coefficient (−0.54) on the silicon atom is larger than that (+0.30) on the carbonyl carbon (HOMO), and the orbital coefficient (−0.64) on the carbonyl carbon of the aldehyde is larger than that (+0.47) on



Scheme 7

oxygen (LUMO).[10] The prediction of the regiochemistry of the cycloaddition by this orbital correlation was in good agreement with the structure of the isolated 1:2 cycloadduct **3d**. In the case of aldehyde **7**, the orbital coefficient on the β-carbon in the LUMO is the largest, so that cycloaddition occurs preferentially across the C=C bond of **7** leading to cycloadduct **9** as the major product (Scheme 7). However, when the difference between the orbital coefficients is small, the regioselectivity of cycloadduct **10** appears to be controlled, not by the correlation of the coefficients, but by the strong affinity between silicon and oxygen.

Thus far, we have succeeded in the photochemical generation of novel 1,3-dipoles, silacarbonyl ylides, from a silylene and various carbonyl compounds, and their inter- or intra-molecular cycloaddition leading to silicon-embedded heterocycles in one step. The inter- and intra-molecular cycloadditions with olefins, in particular, are unprecedented.

This work was partially supported by a Grant-in-Aid for Scientific Research from Ministry of Education, Science, Sports and Culture, Japan.

Triphenyleno[1,12-*bcd*:4,5-*b′c′d′*:8,9-*b″c″d″*]trithiophene: the first bowl-shaped heteroaromatic

Koichi Imamura,[a] Kazuo Takimiya,[a] Yoshio Aso[b] and Tetsuo Otsubo*[a]

[a] *Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Higashi-Hiroshima 739-8527, Japan. E-mail: otsubo@ipc.hiroshima-u.ac.jp*

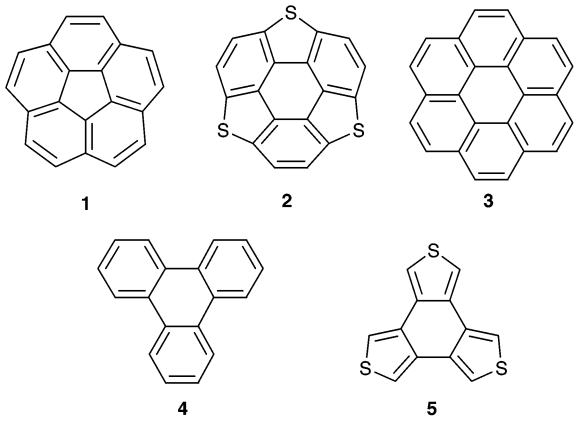
Received (in Cambridge, UK) 20th July 1999, Accepted 16th August 1999

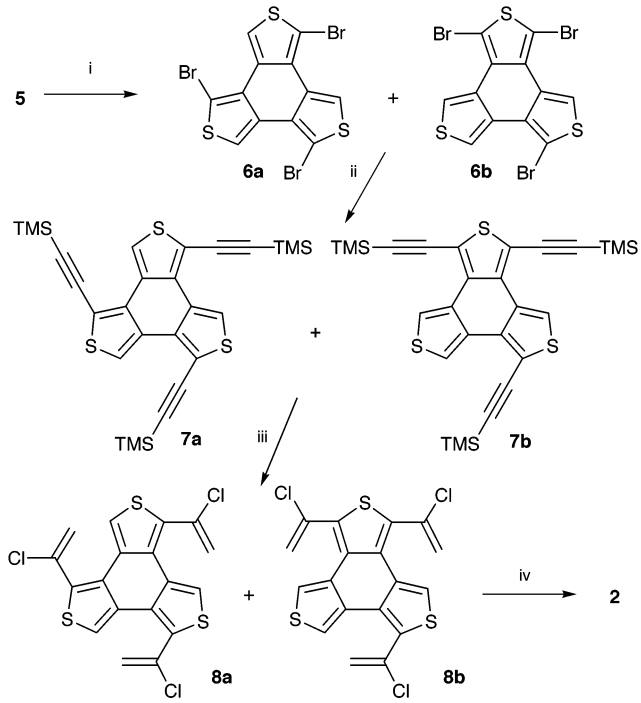
The title compound has been synthesized, and its unique bowl-shaped molecular structure and electronic spectra have been elucidated.

The discovery of buckminsterfullerene has stimulated much interest in the chemistry of bowl-shaped polycyclic aromatic hydrocarbons, such as corannulene **1**.[1–5] Such bowl-shaped



compounds can be expected to exhibit unique physicochemical properties related to the buckminsterfullerene surface. Although polycyclic heteroaromatics are of current interest for advanced materials,[6] no heteroaromatics with bowl curvature have been reported to the best of our knowledge.[7] Triphenyleno[1,12-*bcd*:4,5-*b′c′d′*:8,9-*b″c″d″*]trithiophene **2**, so far unknown, is remarkable because the electronic structure of **2** is similar to that of highly symmetrical coronene **3**. However, **2** contains severe strain in the molecular structure due to the three five-membered thiophene rings in the periphery, and accordingly, unlike planar coronene,[8] is expected to adopt a bowl-shaped structure. We now report the synthesis, molecular structure and spectroscopic properties of **2** as the first bowl-shaped heteroaromatic.

The synthesis of **2** was previously attempted by inserting sulfur bridges in the bay regions of triphenylene **4**; although the mono- and di-bridged species were successfully made, the tri-bridged species **2** was not found.[9] The difficult synthesis of **2** is presumably due to its strained structure. Our successful synthetic route is based on tribenzannulation of benzotrithiophene **5** by a flash-vacuum pyrolytic method, which was applied recently to a short access to strained aromatic systems, such as corannulene[2,4,5] and more recently to thiophene-containing heteroaromatic systems.[10] As shown in Scheme 1, **5**[11] was treated with NBS (3 equiv.) to give the tribromo derivative **6**, which was subsequently converted to the trimethylsilylethynyl derivative **7** by the Sonogashira reaction (two step yield 53%). An NMR analysis indicated that the product comprised two regioisomers **7a** and **7b** in a ratio of about 1:5. Other possible isomers which accommodate two substituent groups in the same bay region were not formed. Treatment of **7** with HCl gave the tris(chlorovinyl) compound **8**



Scheme 1 *Reagents and conditions*: i, NBS (3.0 equiv.), DMF, room temp.; ii, TMSC≡CH, $Pd(PPh_3)_4$, CuI, NEt_3, reflux; iii, conc. HCl, AcOH, 80 °C; iv, 1000 °C, 0.005 Torr, N_2 flow.

(33% yield), which was then subjected to flash vacuum pyrolysis under the conditions of 1000 °C and 0.005 Torr to afford the desired compound **2** in 35% yield.†

As shown in Fig. 1, an X-ray crystallographic analysis of **2** clearly revealed that it has the expected bowl-shaped molecular structure,‡ which is somewhat shallow compared to corannulene.[12] The crystal structure belongs to the hexagonal

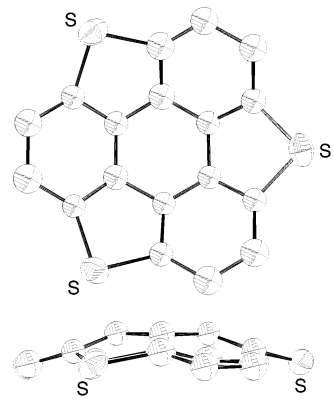


Fig. 1 Molecular structure of **2**: top view (top) and side view (bottom).

crystal system, which is very rare for the crystal structures of organic molecules. The molecules are stacked in a concave–convex fashion, unlike corannulene but like the deeper bowl-shaped aromatic hydrocarbons,[2,5] with marked intermolecular S–S contacts.

The electronic absorption spectrum of **2** in CH_2Cl_2 shows a long-wavelength vibrational α-band at λ_{max} 368 nm (log ε 3.13), which, though weak as a symmetry-forbidden transition, causes yellow coloration for **2**. In addition, there are two strong bands centered at 318 (4.42) and 245 nm (4.47), assignable to p- and β-bands, respectively. The whole absorption spectrum roughly resembles that of coronene itself,[13] supporting iso-electronic structures for both compounds. In a more detailed comparison, the respective absorption bands of **2** are somewhat blue-shifted. Coincidentally **2** demonstrates a fluorescent emission at λ_{max} 398 and 414 nm, whereas coronene fluoresces at longer wavelengths (λ_{max} 436, 456, and 482 nm).

The present work was supported by Grants-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan.

Received (in Liverpool, UK) 24th June 1999, Accepted 13th August 1999

Fluorescence titration measurements and NMR spectroscopy have identified a single molecule of Hoechst 33258 bound within the long A-tract of the dodecamer duplex d(GCAAAATTTTGC)$_2$: despite the possibility of multiple binding sites, and the apparent requirement from previous studies for the drug *N*-methylpiperazine ring to bind close to GC base pairs at the end of an A-tract (leading to an off-set asymmetric complex with this sequence), we identify a binding site that spans the central AAATTT sequence with the planar aromatic rings of the drug binding in the narrowest part of the minor groove.

The bis-benzimidazole Hoechst 33258 (H33258) binds with high affinity to the minor groove of AT rich DNA sequences.[1] Footprinting studies[2] and structural analysis of various H33258 complexes by NMR[3] and X-ray crystallography[4–6] have identified a number of key features of DNA recognition: (i) the drug binds to at least four AT base pairs, (ii) TpA steps are generally avoided, and (iii) a GC base pair is frequently accommodated at the 5′-end of the binding site. The conformation and orientation of the piperazine ring appears to account for preferential binding close to GC regions at the end of A-tracts of DNA where the wider groove has been proposed to more readily accommodate this bulky substituent.[4,5] In complexes with binding sites of only four AT base pairs (AATT)[4] the A-tract is not of sufficient length to examine this effect in detail, however, long A-tracts might enable significant site discrimination to be identified to examine the importance of the influence of the bulky *N*-methylpiperazine ring in site-specificity.

Here, we present an analysis of the interaction of H33258 with an eight AT base pair A-tract sequence within the dodecamer duplex d(GCAAAATTTTGC)$_2$ using a combination of fluorescence titration data and NMR spectroscopy to determine binding stoichiometry and site specificity within the A-tract. The sequence contains several possible high affinity sites within the A-tract (AATT, ATTT or AAAA) that could potentially complicate the analysis through multiple site occupancy with the ligand in exchange between them. Further, the A-tract is of sufficient length to accommodate two bound ligands each spanning four AT base pairs.

Fluorescence titration data were used to determine the binding stoichiometry of H33258 with the dodecamer duplex d(GCAAAATTTTGC)$_2$.[7,8] The method of continuous variation in ligand concentration (Job plot analysis) indicates a fluorescence maximum at a mole fraction of drug of 0.53, establishing a 1:1 (drug:duplex) binding stoichiometry (Fig. 1). Non-linear least-squares analysis of fractional binding saturation curves at 20 °C indicated tight binding ($\sim 10^8$ M^{-1}) in agreement with previous estimates using AATT[9] and AAATTT[7,8] containing duplexes. Despite the possibility of accommodating two drug molecules in adjacent sites, the fluorescence data indicate a single bound ligand per duplex. The fluorescence data are unlikely, however, to be able to distinguish between a number of different 1:1 binding modes in equilibrium if the ligand is bound in each case with a similar affinity.

NMR titration analysis was used to examine the possibility of multiple binding modes. In Fig. 2, the thymine methyl region of the spectrum of d(GCAAAATTTTGC)$_2$ is illustrated (1.0–2.0 ppm) for the free duplex, 0.5:1 ratio of drug:duplex and for the 1:1 complex. Addition of drug results in the four signals from the free duplex (T7, T8, T9 and T10) being replaced by a set of eight new resonances from an asymmetric 1:1 complex in which the two strands of the duplex are no longer equivalent and are in slow exchange through ligand dissociation and reassociation. We see no evidence for multiple sets of resonances that

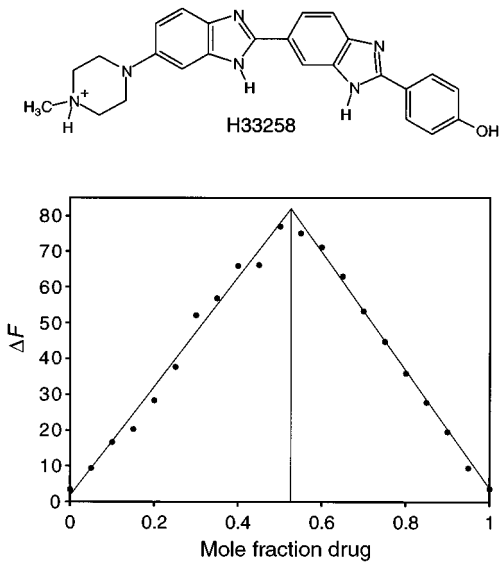

Fig. 1 Structure of H33258. Continuous variation analysis (Job plot) for binding of H33258 to d(GCAAAATTTTGC)$_2$ at pH 7.2, 100 mM NaCl and 10 mM phosphate buffer using a constant value for [ligand] + [DNA] = 0.1 μM; change in fluorescence intensity (ΔF) is plotted against mole fraction of drug. Spectra were recorded on a Perkin-Elmer Luminescence spectrometer LS 50 B at a temperature of 20 °C in 1 cm path-length polymethacrylate cuvettes using fluorescence excitation wavelengths between 330 to 360 nm and emission wavelengths from 390 to 420 nm.

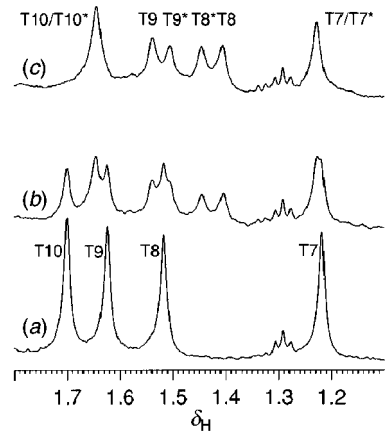

Fig. 2 ^{1}H NMR spectra (500 MHz) of the thymine methyl region (1.0–2.0 ppm) of d(GCAAAATTTTGC)$_2$: (*a*) ligand-free DNA, (*b*) drug:duplex ratio 0.5:1, and (*c*) 1:1 complex at 298 K; the two strands are distinguished by the use of asterisks, assignments are shown.

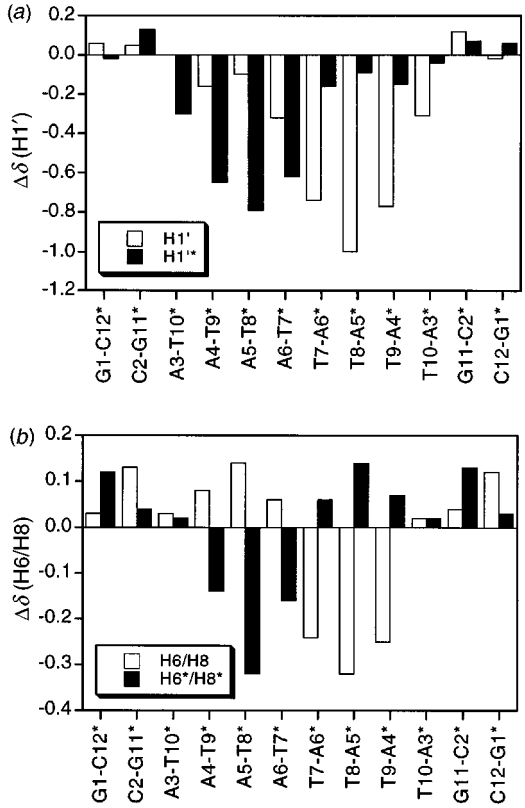

Fig. 3 Plots of drug-induced changes in ^{1}H NMR chemical shifts ($\Delta\delta = \delta_{complex} - \delta_{free}$) for (*a*) deoxyribose H1′ and (*b*) base H6/H8 for the H33258 complex with d(GCAAAATTTTGC)$_2$. The two strands of DNA read in antiparallel directions, one of which is distinguished by the use of asterisks and filled columns.

would indicate the presence of a number of slowly exchanging conformations, leading us to conclude that the drug either binds at a single high affinity site, or that the bound drug is in fast exchange between a number of overlapping sites.

To examine more closely the position of the drug within the groove we have used ^{1}H chemical shift data (assigned through 2D TOCSY and NOESY data sets) to provide an NMR 'footprint' from ligand-induced perturbations to deoxyribose H1′ and base H6/H8 resonances ($\Delta\delta = \delta_{complex} - \delta_{free}$). $\Delta\delta$ values are plotted against sequence position in Fig. 3. Many deoxyribose H1′ protons come into direct contact with the face of one or other aromatic ring of the bound ligand and experience large upfield ring current perturbations to their chemical shifts of up to 1.0 ppm. The $\Delta\delta$ values of these signals are particularly sensitive to the position of the ligand in the minor groove, with the thymine sugars showing the largest perturbations. In contrast, the effects on base H6/H8 resonances, which are located in the major groove, are smaller ($\leqslant$0.3 ppm), and probably arise from changes in base stacking interactions, but reflect the same general pattern of perturbations. The striking observation is that both sets of chemical shift perturbations suggest a highly centrosymmetric binding of the drug across the dyad axis of the duplex spanning primarily the central AAATTT sequence. The AT base pairs A3*-T10 and A3-T10* at the ends of the A-tract are relatively unperturbated by the binding interaction.

In contrast, in one X-ray structure of H33258 bound to d(CGCAAATTTGCG)$_2$,[5] containing a shorter A-tract, the drug appears to be displaced off-centre to bind across the ATTTG sequence. This binding locus is reported to accommodate the piperazine ring close to the GC base pairs at the end of the A-tract.[5] However, in a second X-ray structure with a similar AAATTT binding site the displacement is less pronounced.[6] Our data place the *N*-methylpiperazine ring within the A-tract with the bis-benzimidazole portion of the ligand binding across the AT dyad axis. Although our results seem at variance with some structural data, they do concur with some footprinting studies which also consider the interaction with longer AT tracts and which show that AATT is an unusually good binding site for H33258.[10] On a purely statistical basis, for a ligand binding site of four base pairs where there is no discrimination between sites, the central AT base pairs are expected to show the highest time-averaged site occupancy. Is a model involving fast exchange between overlapping sites consistent with the NMR data? Our preliminary analysis of intermolecular NOE data, and structural modelling, suggests that the bound ligand is restricted to a relatively small binding locus rather than shuffling between multiple (symmetrical and asymmetrical) overlapping sites. Recent studies on the binding of ammonium cations to A-tract structures,[11] together with earlier results,[12] suggest that the minor groove is at its narrowest at the centre of A_nT_n sequences. In the present context, maximising van der Waals interactions between the bound ligand and the walls of the narrowest part of the groove may be the primary determinant of A-tract site-specificity. A more detailed analysis of the structure and dynamics of this and other A-tract complexes in solution is currently in progress.

The EPSRC, the Department of Chemistry at the University of Nottingham, and the Royal Society are gratefully acknowledged for financial support. We thank John Keyte for oligonucleotide synthesis.

Received (in Cambridge, UK) 25th June 1999, Accepted 16th August 1999

A borylsilane regioselectively adds to 1,2-dienes in the presence of palladium complexes to afford high yields of alkenylboranes having allylsilane moieties, whereas a borylstannane gives a 1 : 2 telomer with 3-methylbuta-1,2-diene due to borylstannylative dimerization.

Addition reactions of metal–metal bonds to 1,2-dienes provide a straightforward route to organometallic compounds having both vinylic and allylic metal moieties, which are versatile reagents in organic synthesis.[1] Although several studies on the transition-metal-catalysed reactions of 1,2-dienes with Si–Si,[2] Sn–Sn,[3] Si–Sn,[3] Ge–Sn[4] and B–B bonds[5] have been reported, similar reactions of B–Si or B–Sn bonds have received little attention.[6,7] In the course of our investigation on the transition-metal-catalysed additions of these bonds to unsaturated organic compounds,[8,9] we have found that palladium catalysts effectively promote the reactions with 1,2-dienes, giving the corresponding adducts with extremely high regioselectivity (Scheme 1).

The following procedure is representative (Table 1, entry 1). A mixture of $Pd_2(dba)_3$ (2.5 mol%; dba = dibenzylideneacetone) and etpo as ligand [10 mol%; etpo = 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2,2,2]octane, $P(OCH_2)_3CEt$] in THF (1 ml) was heated at 80 °C for 5 min, while the color of the solution turned to green from red. To this solution were added 2-dimethylphenylsilyl-4,4,5,5-tetramethyl-2-bora-1,3-dioxacyclopentane **1** (0.33 mmol), buta-1,2-diene **2a** (1.0 mmol) and decane (30 μl; as internal standard for GC analysis), and the reaction mixture was heated at 80 °C. GC-MS analysis of the mixture indicated the complete consumption of the borylsilane **1** after 9 h and quantitative formation of a borylsilylation product **3a** (98% GC yield). It should be noted that the NMR analysis of the reaction mixture indicated the lack of formation of regioisomers like **4a**. Thus, the addition of the B–Si bond smoothly proceeded at the internal double bond of **2a**, and the boryl group was regioselectively introduced to the central carbon, leading to the exclusive formation of alkenylborane moiety. Purification of the crude product by TLC (silica gel; hexane–CH_2Cl_2 as eluent) gave analytically pure **3a** in 88% yield.†

Representative results of the reactions between **1** and various 1,2-dienes **2a–f** are summarized in Table 1. All of the products listed have exhibited satisfactory spectral data.† Under similar conditions, another monosubstituted 1,2-diene, **2b**, also underwent the borylsilylation at the internal double bond, affording **3b** in 86% yield as the sole product (entry 2). Propa-1,2-diene **2c** and sterically congested 2,4-dimethylpenta-2,3-diene **2d** effectively participated in the borylsilylation with high regioselectivity (entries 3 and 4).

The regioselectivity of the Pd–etpo-catalysed borylsilylation of 1,1-disubstituted propa-1,2-dienes was strongly influenced by the nature of substituents. For example, the reaction of 1,1-diphenylpropa-1,2-diene **2e** with **1** selectively proceeded at the terminal double bond to give **4e** in 94% yield (entry 5), whereas the borylsilylation of 3-methylbuta-1,2-diene **2f** took place at both the internal and terminal double bonds, affording a regioisomeric mixture of **3f** and **4f** with a 52 : 48 ratio (entry 6). The low regioselectivity of the latter reaction could be successfully improved by tuning the phosphorus ligands; the best result (**3f** : **4f** = 100 : 0) was achieved by using $Pd_2(dba)_3$ (2.5 mol%)–PPh_3 (10 mol%) (entry 7). The use of the $Pd_2(dba)_3$ (2.5 mol%)–PMe_3 (10 mol%) system was less effective, giving a mixture containing **3f** as major product (**3f** : **4f** = 71 : 29, entry 8).

To our surprise, the regioselectivity of this reaction completely changed when the reaction was conducted with a platinum catalyst. Thus, in the presence of a catalytic amount of $(CH_2{=}CH_2)Pt(PPh_3)_2$ (5 mol%), the B–Si bond of **1** preferentially added to the terminal double bond of **2f**, furnishing **4f** as the sole product (94% GC yield, entry 9). However, application of this catalyst to the borylsilylation of monosubstituted

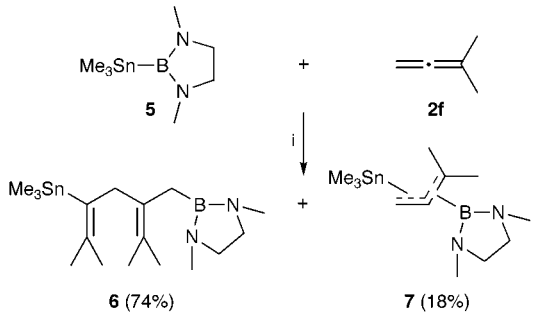
[a] Reaction conditions: borylsilane **1** (0.33 mmol), 1,2-dienes (1.0 mmol), catalyst $Pd_2(dba)_3$ (2.5 mol%)–etpo (10.0 mol%), THF (1 ml), 80 °C, 9 h unless otherwise noted. [b] ***Si*** = $SiMe_2Ph$, ***B*** = $B(OCMe_2)_2$. [c] Isolated yields based on the amount of the borylsilane **1**. Figures in parentheses are GC yields. [d] Determined by ^1H NMR spectroscopy. [e] A large excess of 1,2-diene was used. [f] $Pd_2(dba)_3$ (2.5 mol%)–PPh_3 (10.0 mol%) was used as catalyst. [g] $Pd_2(dba)_3$ (2.5 mol%)–PMe_3 (10.0 mol%) was used as catalyst. [h] Run in the presence of $(CH_2{=}CH_2)Pt(PPh_3)_2$ (5 mol%) at 80 °C for 3 h.



Scheme 2 *Reagents and conditions*: i, $Pd_2(dba)_3$ (2.5 mol%)–etpo (10 mol%), THF, 50 °C, 3 h.

1,2-dienes such as **2a** made the reaction sluggish, resulting in the formation of a mixture of many products.

The reactivities of borylsilanes in the present reaction were strongly influenced by the structure of the boryl group. For instance, $PhMe_2Si$–(BNMeCH_2CH_2NMe) failed to undergo the addition reaction with **2f** even at elevated temperatures (*e.g.* 110 °C) in the presence of the $Pd_2(dba)_3$–etpo system.

In contrast to the borylsilylation of 1,2-dienes, the B–Sn bond of borylstannane **5** underwent the palladium-catalysed addition reaction with 3-methylbuta-1,2-diene **2f**, predominantly yielding telomer **6** having both vinyl–Sn and allyl–B moieties (74% GC yield) along with an isomeric mixture of simple borylstannylation products **7** (18% GC yield) (Scheme 2). The reaction proceeded smoothly at 50 °C in the presence of the $Pd_2(dba)_3$–etpo system and was complete within 3 h. The purification of the reaction mixture by bulb-to-bulb distillation (116–118 °C/5.4×10^{-3} mmHg) afforded analytically pure **6** in 63% yield.† The structure of **6** was determined by NMR spectroscopy; its ^{119}Sn NMR spectrum displayed a signal at δ −49.6 assignable to tin attached to an alkenyl group.[3,4] In addition, the ^{13}C NMR spectrum showed a broad signal at δ 16.2 indicative of an allylic carbon bonded to boron. Further studies on the reaction mechanism are in progress.

In conclusion, the transition-metal-catalysed addition reaction of B–Si or B–Sn bonds to 1,2-dienes provides a selective and facile route to organometallic compounds containing both vinyl- and allyl-metal moieties. In view of the different reactivities of these metal moieties in electrophilic substitution, the products will find considerable synthetic applications for complex organic molecules.

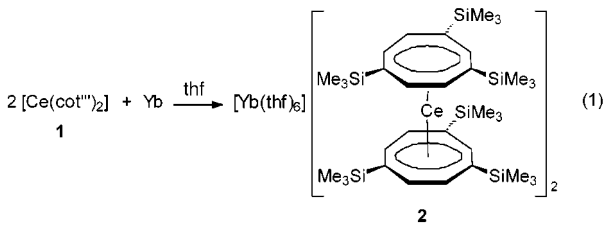
Received (in Basel, Switzerland) 18th May 1999, Accepted 15th August 1999

The first heterobimetallic organolanthanide complex containing two different rare earth elements, $[Yb(thf)_6][Ce(cot''')_2]_2$ 2 [cot''' = η^8-1,3,6-$(Me_3Si)_3C_8H_5$], has been prepared by reacting neutral $[Ce(cot''')_2]$ with Yb metal in THF; the crystal structure of 2 consists of separated $[Yb(thf)_6]^{2+}$ and $[Ce(cot''')_2]^-$ ions.

Extensive electronic structural investigations have been carried out on neutral f-element sandwich complexes of the type $M(cot)_2$ (M = lanthanide, actinide; cot = η^8-C_8H_8).[1] The electronic structure of cerocene $[Ce(cot)_2]$ has especially been the subject of much debate for many years.[2] It is now generally accepted that cerocene and its substituted derivatives are not genuine cerium(IV) organometallics. Sophisticated *ab initio* calculations as well as recent experimental data have revealed that the oxidation state of Ce in cerocene is 3+($4f^1$) and that cerocene is best formulated as a sandwich complex containing two coordinated $(cot)^{1.5-}$ ions.[3] Despite this ambiguity in the *formal* oxidation state of cerium in neutral cerocenes, these compounds should exhibit a rich redox chemistry and serve as valuable precursors for novel sandwich complexes of the lanthanide elements. While the parent cerocene is a pyrophoric material and not readily available,[4] the recently discovered polysilylated derivative $[Ce(cot''')_2]_2$ **1** [cot''' = η^8-1,3,6-$(Me_3Si)_3C_8H_5$][5] appears to be an excellent candidate for such reactivity studies. We report here the use of **1** in the preparation of the first true heterobimetallic organolanthanide complex, *i.e.* the first organolanthanide derivative containing two different lanthanide elements in a single compound.[6]

Stirring a thf solution of **1** in the presence of an excess of $HgCl_2$-activated Yb powder (< 40 mesh) at room temp. results in a gradual colour change from deep purple to bright green, while the suspended metal powder is partially consumed [eqn. (1)].



Filtration and crystallisation of the crude product from thf at −25 °C afforded the heterobimetallic ytterbium–cerium complex $[Yb(thf)_6][Ce(cot''')_2]_2$ **2** as bright green, highly air-sensitive crystals in 61% yield.‡ Obviously this product is the result of a redox reaction in which the neutral cerocene precursor **1** is reduced to the corresponding sandwich anion $[Ce(cot''')_2]^-$. The concomitant formation of Yb^{2+} is clearly evidenced by the observation of a relatively sharp ($\nu_{1/2}$ = 15 Hz) ^{171}Yb NMR signal[7] at δ 256.1. As expected, the ^{29}Si NMR spectrum exhibits two signals corresponding to the $SiMe_3$ substituents.

† Dedicated to Professor Helmut Werner on the occasion of his 65th birthday.

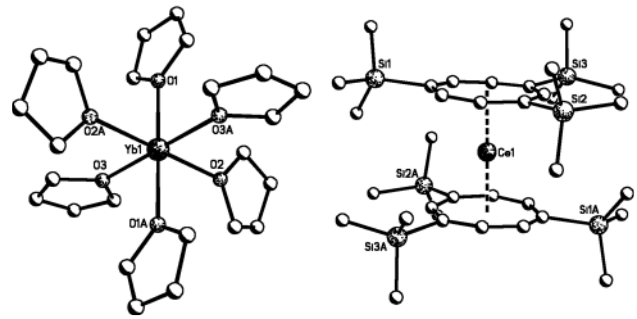


Fig. 1 Solid state structure of **1**; only the $[Yb(thf)_6]^{2+}$ cation and one of the $[Ce(cot''')_2]^-$ anions is depicted. Selected av. bond lengths (pm) and angles (°): Yb–O 237.8(5), Ce–cot_{centre} 205.3(14), Ce–C_{cot} 272(3), C–C_{cot} 141.4(11) [139.9(11)–143.6(11)], C–$SiMe_3$ 188.1(9); O–Yb–O_{cis} 87.7(2)–92.3(2,) O–Yb–O_{trans} 180, cot_{centre}–Ce–cot_{centre} 180.

X-Ray crystallography confirms the presence of the first organolanthanide complex containing two different rare earth elements in one compound (Fig. 1).§

The crystal structure of **2** consists of separated $[Yb(thf)_6]^{2+}$ cations and $[Ce(cot''')_2]^-$ anions. The mean distance between Ce and the ring centroids is 205.3(14) pm, which is in good agreement with the corresponding value in $[Li(thf)_4][Ce(cot)_2]$.[8] Quite surprisingly even the presence of six bulky trimethylsilyl substituents at the cyclooctatetraenyl rings does not lead to a significant elongation of these distances. At 237.8(5) the average Yb–O distance is practically identical to that in $[Yb(thf)_6][CPh_3]_2$ [239.0(7) pm].[9]

In the present study we have demonstrated that the readily available polysilylated cerocene derivative **1** displays an interesting redox chemistry and may thus serve as a promising precursor for the preparation of novel lanthanide organometallics.

$(NBu^n_4{}^+)_3[Re_6S_8Cl_6]^{3-\cdot}$: synthesis and luminescence of the paramagnetic, open shell member of a hexanuclear chalcohalide cluster redox system

Christophe Guilbaud,[a] André Deluzet,[a] Benoît Domercq,[a] Philippe Molinié,[a] Claude Coulon,[b] Kamal Boubekeur[a] and Patrick Batail*[a]

[a] *Institut des Matériaux Jean Rouxel, UMR 6502 CNRS-Université de Nantes, 2, rue de la Houssinière, 44322 Nantes, France. E-mail: patrick.batail@cnrs-imn.fr*

[b] *Centre de Recherche Paul Pascal, CNRS, Avenue Dr. Schweitzer, 33600 Pessac, France*

Received (in Cambridge, UK) 11th June 1999, Accepted 3rd August 1999

The chemical and electrochemical synthesis, X-ray crystal structure, magnetic characterization, absorption and luminescence spectra of $(NBu^n_4)_3[Re_6S_8Cl_6]$, the 23-electron cluster core member of the reversible redox couple $[Re_6S_8Cl_6]^{4-}$–$[Re_6S_8Cl_6]^{3-\cdot}$ is reported.

Amongst the series of molecular, hexanuclear sulfidohalide and sulfido cluster anions, $(NBu^n_4{}^+)_n[Re_6S_{4+n}Cl_{4-n}Cl_6]^{n-}$ (n = 1–4),[1,2] the latter tetra-anion stands out because of its unusual redox behaviour, characterised by a reversible one-electron oxidation process at the remarkably low potential of $E_{1/2}$ = 0.27 V *vs.* SCE in acetonitrile.[2] This is a salient feature since, within this set of isostructural and isoelectronic cluster anions, either no oxidation (n = 1) or reversible oxidation processes (n = 2,3) are observed albeit at the higher potential values of 0.99 (n = 2) and 1.04 (n = 3) V *vs.* SCE.[1] Both the low potential value, which qualifies $[Re_6S_8Cl_6]^{4-}$ as an electron donor comparable to tetrathiafulvalene (0.33 V *vs.* SCE in acetonitrile), and the reversible character of the redox process suggest that the paramagnetic 23-electron Re_6 cluster core anion might be isolated, an unprecedented opportunity in this chemistry of molecular forms of mineral clusters prepared by high temperature solid state synthesis.

Reactions of acetonitrile solutions of $(NBu^n_4)_4[Re_6S_8Cl_6]$[2] with $SOCl_2$, ferrocenium or $TCNQF_4$ afford crystalline precipitates the X-ray powder pattern of which differs from that of the starting material, and appears very similar to those of $(NBu^n_4)_3[Re_6S_7Cl_7]$[3,4] and $(NBu^n_4)_3[Re_6S_7(SH)Cl_6]$[2] simulated from the single crystal X-ray structure data. Thus, an excess of $SOCl_2$ (0.8 mL) was added under stirring at room temperature to a yellow solution of $(NBu^n_4)_4[Re_6S_8Cl_6]$ (263 mg, 0.1 mmol) in acetonitrile (30 mL), upon which the solution rapidly turned red. After 30 min, the solution was evaporated to dryness and the residual solid washed with water, ethanol and toluene, then dried under vacuum. Crystallisation in acetonitrile–ethanol (2:1) afforded red orange plate-like crystals (yield 221 mg, 93%).

Red single crystals were grown by anodic, constant low direct current oxidation (1.6 μA cm^{-2}) at a platinum wire electrode of a solution of 60 mg of $(NBu^n_4)_4[Re_6S_8Cl_6]$ dissolved in 12 mL THF–DMF (3:1). The solution slowly turned from yellow to pink red in the anodic compartment of the two-compartment electrocrystallization cell within a few days. The crystals harvested after 10 days lose THF molecules and recrystallisation of the latter in acetonitrile yielded high quality red orange stable single crystals which are identical to those obtained by the chemical route described above (Anal. for $C_{48}H_{108}Cl_6N_3Re_6S_8$. Calc.: C, 24.91; H, 4.75; N, 1.82; S, 11.08; Cl, 9.19. Found: C, 24.87; H, 4.61; N, 1.78; S, 11.13; Cl, 9.25%). In order to ensure that both the chemical and electrochemical syntheses were conducted on pristine $(NBu^n_4)_4[Re_6S_8Cl_6]$, with no $(NBu^n_4)_3[Re_6S_7Cl_7]$, the purity of the starting material has been qualified by X-ray powder pattern and elemental analysis.

The X-ray structure determination reveals that a single phase, formulated as $(NBu^n_4)_3[Re_6S_8Cl_6]$, is obtained by the two routes and is isostructural to triclinic $(NBu^n_4)_3[Re_6S_7Cl_7]$,[4] containing the closed shell, 24-electron cluster core trianion prepared by metathesis of solutions of $Cs_3[Re_6S_7Cl_7]$.[3] The asymmetric unit consists of two half-clusters located on inversion centres and three tetrabutylammonium cations in general positions. The analysis of the structure determined at room temperature indicates that the Re–Re bond lengths within the cluster core (Fig. 1) [$<d_{Re-Re}>$ = 2.600(1) Å] and the Re–(inner)μ_3-S bond lengths [$<d_{Re-S}>$ = 2.408(3) Å] are similar to those observed in the structure of $(NBu^n_4{}^+)_4[Re_6S_8Cl_6]^{4-}$, $<d_{Re-Re}>$ = 2.601(4) Å and $<d_{Re-S}>$ = 2.403(9) Å, respectively.[2] Of particular interest is the present opportunity to extend the structural correlation between the lengthening of the rhenium–μ-chloride distances with the increase of the net cluster anion charge revealed previously within the series of cluster anion forms with the same counter cation, $(NBu^n_4{}^+)_n[Re_6S_{4+n}Cl_{4-n}Cl_6]^{n-}$ [from 2.344(4), to 2.362(2), to 2.415(3) Å for n = 1, 2, 3, respectively).[1,4] Thus, $<d_{Re-Cl}>$ = 2.418(3) Å for $[Re_6S_8Cl_6]^{3-\cdot}$ is shorter than $<d_{Re-Cl}>$ = 2.451(4) Å determined for $(NBu^n_4{}^+)_4[Re_6S_8Cl_6]^{4-}$,[2] as expected.[1] This is also consistent with theoretical calculations for $[Re_6S_8X_6]^{4-}$ (X = Cl, Br, I) made available recently by Arratia-Perez *et al.*[5] which demonstrate that the pronounced halogen-based cluster HOMO has a large Re–(apical)halide antibonding character. In addition, $<d_{Re-Cl}>$ = 2.418(3) Å for $(NBu^n_4{}^+)_3[Re_6S_8Cl_6]^{3-\cdot}$ is identical to that obseved for the triclinic structure of $(NBu^n_4{}^+)_3[Re_6S_7Cl_7]^{3-}$ [$<d_{Re-Cl}>$ = 2.415(3) Å][4] and to that determined for $(NBu^n_4{}^+)_3[Re_6S_6(SH)Cl_7]^{3-}$ [$<d_{Re-Cl}>$ = 2.419(6) Å].[2]

The paramagnetic character of $(NBu^n_4{}^+)_3[Re_6S_8Cl_6]^{3-\cdot}$ is demonstrated both by (i) static magnetic susceptibility data, properly fitted to a Curie law down to low temperatures (C = 0.523 $cm^3\ mol^{-1}$) with a calculated effective magnetic moment (μ_{eff} = 2.045 μ_B) larger than the spin ½-only value (μ_{SO} = 1.73

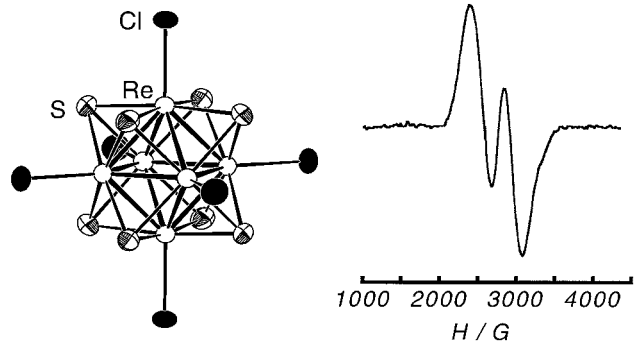

Fig. 1 Structure with thermal ellipsoids at the 50% probability level, labelling scheme and EPR spectrum of a single crystal of $(NBu^n_4)_3[Re_6S_8Cl_6]$ at 3.8 K. The two broad resonance lines with g = 2.44 and ΔH = 260 G are associated with two different orientations of the cluster in the triclinic unit cell.

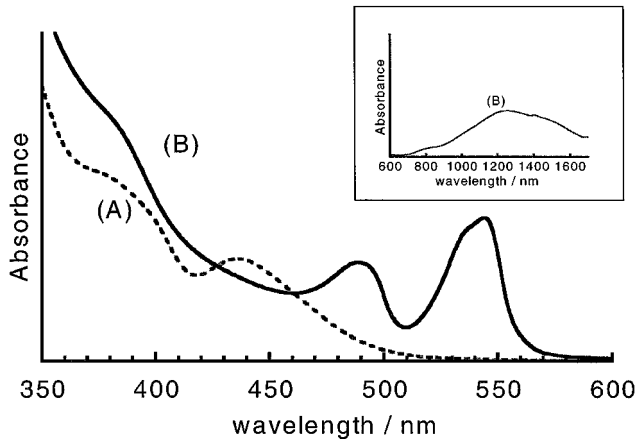

Fig. 2 Electronic absorption spectra for acetonitrile solutions ($c = 2.8 \times 10^{-4}$ M) of $(NBu^n_4)_4[Re_6S_8Cl_6]$ [(A) two poorly resolved shoulders at 335 and 380 nm and a peak of larger intensity at 436 nm ($\varepsilon_M = 8.6 \times 10^2$ dm^3 mol^{-1} cm^{-1})] and $(NBu^n_4)_3[Re_6S_8Cl_6]$ [(B), one poorly resolved shoulder (381 nm), two large peaks (489 nm, $\varepsilon_M = 8.5 \times 10^2$ dm^3 mol^{-1} cm^{-1}; 544 nm, $\varepsilon_M = 1.23 \times 10^3$ dm^3 mol^{-1} cm^{-1}) and a very wide band centred around 1250 nm (700–1750 nm, $\varepsilon_M = 4 \times 10^2$ dm^3 mol^{-1} cm^{-1})].

μ_B), a manifestation of spin–orbit coupling; and (ii) by single crystal EPR experiments ($g = 2.44$, Fig. 1). The g values for the paramagnetic hexanuclear molybdenum cluster anions $[Mo_6(X_7Q)X_6]^{2-\cdot}$ (X = Cl, Br, Q = S, Se) and $[Mo_6(Cl_6Se_2)Cl_6]^{3-\cdot}$ obtained in frozen solution at 77 K are in the range 2.05–2.23.[6,7] The higher g value observed for the present rhenium cluster is consistent with a higher spin–orbit coupling.

The UV–VIS spectrum for $(NBu^n_4{}^+)_4[Re_6S_8Cl_6]^{4-}$ in acetonitrile (Fig. 2) is essentially identical to that reported earlier by Holm and coworkers except for the absence in Fig. 2 of a weak peak at 537 nm.[2] Within the series $[Re_6S_{4+n}Cl_{4-n}Cl_6]^{n-}$, the intense absorption at 436 nm for the tetra-anion ($n = 4$) is remarkable since it is not observed for $n = 1$, 2, 3[8] and has been shown[2] to be very sensitive to the nature of the apical halide, a likely indication of ligand-to-metal charge transfer. The spectrum for acetonitrile solutions of $(NBu^n_4{}^+)_3[Re_6S_8Cl_6]^{3-\cdot}$ (Fig. 2) is strikingly different from the former. These salient differences between the spectra in Fig. 2 demonstrate that a significant change of the electronic structure of the cluster anion occurs upon the one-electron oxidation. The wide near-IR absorption band may be attributed to electronic transitions from a fully to a partially occupied metal orbital. A similar absorption band has been observed for the paramagnetic hexanuclear molybdenum clusters anions $[Mo_6(X_7Q)X_6]^{2-\cdot}$ (X = Cl, Br, Q = S, Se) and $[Mo_6(Cl_6Se_2)Cl_6]^{3-\cdot}$.[6,7]

Emission spectra for acetonitrile solutions of $[Re_6S_8Cl_6]^{4-}$ and $[Re_6S_8Cl_6]^{3-\cdot}$ are shown in Fig. 3(a) and (b), respectively, for excitations at 250 and 393 nm. As anticipated by Arratia-Pérez *et al.*,[5] the tetra-anion $[Re_6S_8Cl_6]^{4-}$ is luminescent. Altogether, the luminescence for the tetra-anion is very similar to that for the hexanuclear molybdenum(II) cluster $[Mo_6Cl_{14}]^{2-}$.[9,10] Note that the mono-, di-, and tri-anion within the chalcohalide series $[Re_6S_{4+n}Cl_{4-n}Cl_6]^{n-}$ ($n = 1$, 2, 3) do not present any such luminescence.

Strikingly, the luminescence spectra for acetonitrile solutions of $(NBu^n_4{}^+)_3[Re_6S_8Cl_6]^{3-\cdot}$ [Fig. 3(b)] exhibit emission bands which are typically more intense than those for solutions of $(NBu^n_4{}^+)_4[Re_6S_8Cl_6]^{4-}$. Time-resolved photoluminescent experiments in solution as well in the solid state are in progress in order to elucidate the nature of the excited state of the paramagnetic radical cluster anion in $(NBu^n_4{}^+)_3[Re_6S_8Cl_6]^{3-\cdot}$.

We thank P. Robin (Thomson-CSF, LCR) for assistance in optical experiments. Financial support from the CNRS, The Region Pays de Loire and the Ministry of Education (C. G. and A. D.), DGA (B. D.) is gratefully acknowledged.

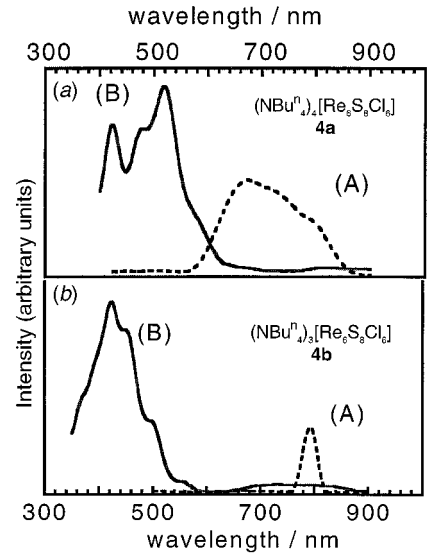

Fig. 3 (a) Luminescence spectra for an acetonitrile solution of $(NBu^n_4)_4[Re_6S_8Cl_6]$ (5×10^{-4} M) for excitations at 393 nm [(A), maximum at 660 nm] and 250 nm [(B), maxima at 418, 460 and 497 nm]. (b) Luminescence spectra for an acetonitrile solution of $(NBu^n_4)_3[Re_6S_8Cl_6]$ (1.4×10^{-4} M) for excitations at 393 nm [(A), maximum at 796 nm] and 250 nm [(B), maxima at 420, 455 and 500 nm].

Synthesis of optically active bicyclic lactone building blocks using catalytic enantioselective glyoxylate-ene reaction

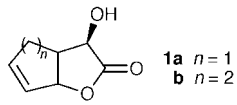
Nicholas Gathergood and Karl Anker Jørgensen*

Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. E-mail: kaj@kemi.aau.dk

Received (in Cambridge, UK) 12th July 1999, Accepted 13th August 1999

A new catalytic approach for the formation of optically active bicyclic lactones applying an enantioselective glyoxylate-ene reaction is presented; the catalytic reaction proceeds with formation of the two key stereogenic centers in good yield and with high diastereo- and enantio-selectivity.

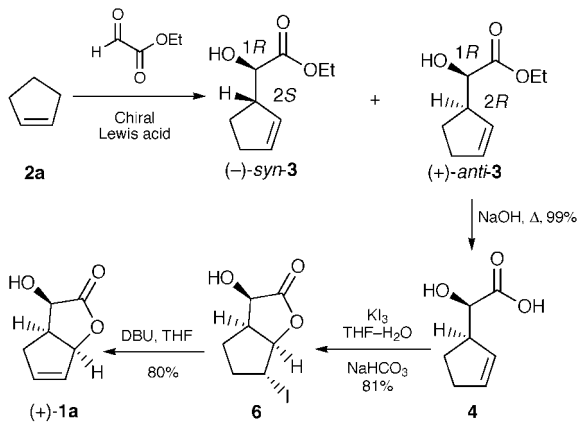
The bicyclic lactones **1** are key intermediates for the preparation of a wide range of natural products and biologically active compounds.[1] The lactone **1a** is a versatile building block for the synthesis of *e.g.* brefeldin A,[2a] carbovir,[2b] sesbanimide A and B,[2c] menovilin,[2d] aristeromycin,[2e] carbodine,[2e] carboxylic nucleosides[2f] and carbocyclic analogues of polytoxins and nikkomycines.[2g]



The synthesis of optically active **1a** has previously been accomplished by enzyme catalyzed kinetic resolution of the racemic compound prepared by the Diels–Alder reaction between glyoxylic acid and cyclopentadiene,[3] and more recently Helmchen *et al.* presented the preparation of **1a** using an asymmetric palladium-catalyzed allylic alkylation of 2-acetoxymalonates with cyclopent-2-enyl chloride.[4]

Here we present the first catalytic enantioselective ene reaction of cyclopentene **2a** with glyoxylate leading to a novel synthetic approach for the preparation of (+)-**1a** and by which the key stereogenic centres required for the synthesis of (+)-**1a** are formed in one step. The synthetic approach for (+)-**1a** is outlined in Scheme 1.

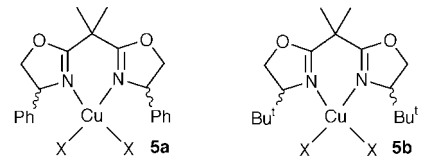
Recently, it has been shown that the bicyclic lactones **1b** can be prepared by a catalytic enantioselective hetero-Diels–Alder reaction of cyclohexadiene with glyoxylates catalyzed by C_2 bisoxazoline–copper(II) complexes followed by a rearrangement reaction.[5] Unfortunately, this methodology is not feasible for the reaction of cyclopentadiene with glyoxylates. However, the reaction of conjugated dienes with glyoxylates catalyzed by



Scheme 1

C_2 bisoxazoline–copper(II) complexes gives two products, the hetero-Diels–Alder and ene products,[5a] and recently Evans *et al.*[6] developed further the latter reaction for 1,1-disubstituted alkenes, hexene and cyclohexene with high yields and enantioselectivities.

The crucial step in the total synthesis of (+)-**1a** is the catalytic ene reaction of cyclopentene **2a** with ethyl glyoxylate. This reaction has been investigated in the presence of the C_2-symmetric bisoxazoline ligands **5a**,**b** and copper(II) salts as the



Lewis acids.† Some representative results are presented in Table 1.

The results in Table 1 show that the C_2 bisoxazoline–copper(II) complex catalyzed ene reaction of cyclopentene **2a** with ethyl glyoxylate proceed with excellent enantioselectivities for both diastereomers formed. The ligand (*S*)-**5b** gave the highest enantioinduction, with up to 98–99% ee (entries 3–5), while ligand (*R*)-**5a** gave the best diastereomeric *anti*-**3**:*syn*-**3** ratio (7.7:1) (entries 1, 6). Changing the enantiomer of the chiral ligand leads to the opposite enantiomer of *anti*-**3** (entries 1, 6), while changing the solvent to $MeNO_2$ leads to higher yield, however, a slight decrease in diastereo- and enantioselectivity (entry 7) is found. In an attempt to improve the enantioselectivity, the reaction was performed at lower temperature, but the conversion at 0 °C was very low (entry 5). An increase in the yield was achieved by increasing the catalyst loading to 25 mol%, without decreasing the diastereo- and enantio-selectivity of the products (entries 2, 6, 7). We have also investigated the enantioselective ene reactions catalyzed by (*R*)-**5a** and (*S*)-**5b** in other solvents and found that in Bu^tOMe, Et_2O and THF a lower yield of *anti*-**3** was isolated. A decrease in the diastereo- and enantio-selectivity was observed, except in Et_2O, where the *anti*-**3**:*syn*-**3** ratio was 5.1:1 with 91% ee and 89% ee

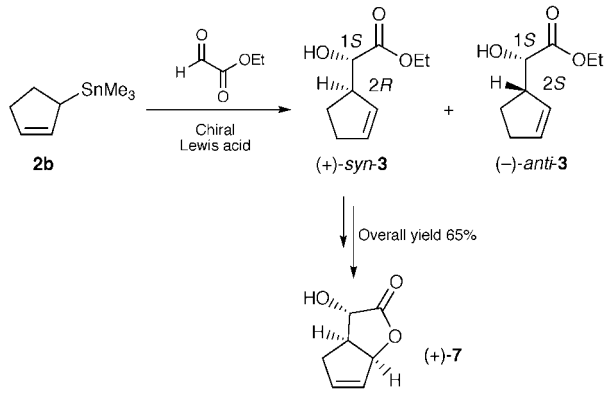

Scheme 2

for the two diastereomers, respectively. It should be noted that the absolute configuration of the ene-product *anti*-**3** is the same when using ligands (*R*)-**5a** and (*S*)-**5b** in combination with copper(II) as the Lewis acid (entries 2, 4). This phenomenon has been observed several times for these catalysts.[5,6]

From (+)-*anti*-**3** the desired bicyclic lactone (+)-**1a** can be obtained in a few steps (Scheme 1). Hydrolysis of the ester group was achieved using refluxing 3 M NaOH for 1 h giving **4** in quantitative yield. Iodolactonization of **4** using KI_3 and $NaHCO_3$ gave the iodide **6** in 81% yield. Elimination with DBU leads to (+)-**1a** in 80% yield.

By comparing the optical rotations of the bicyclic lactone **1a** to literature values[7] the absolute configuration was determined as (+)-**1a**, which leads to assignment of the absolute configuration as shown in Scheme 1.

We believed that an increase in the yield of the ene adduct could be obtained if a more active cyclopentenyl derivative was used. The allyl stannane **2b**[8] was therefore reacted with ethyl glyoxylate (Scheme 2), in the presence of C_2 bisoxazoline–copper(II) complexes; some results are presented in Table 2.

The allyl stannane **2b** was found to be more reactive than cyclopentene **2a** in the C_2 bisoxazoline–copper(II) catalyzed ene reaction with ethyl glyoxylate. At room temperature full conversion was observed in 5 min when using 2 equiv. of **2b** (entry 5). The yield for this reaction was very high, but the ee of the products was low (20% ee). When 1 equiv. of **2b** was used with 2 equiv. of ethyl glyoxylate the reaction was finished after 30 min (entry 1). The yield of the ene products *syn*-**3** and *anti*-**3** were also very good and the ee of the minor product increased to 54% ee. However the ee of the major diastereomer *syn*-**3** remained below 25% ee. By using a larger excess of ethyl glyoxylate at room temperature the ee of the major diastereomer was increased to 43% ee, with 81% ee for the minor diastereomer (entry 2). When the reaction was performed at lower temperatures (−25 and −78 °C) no improvement in the ee of the products was observed (entries 3,4). When using 1 equiv. of ethyl glyoxylate the yield was found to decrease from 98% at room temperature to 55% at −78 °C (entries 5,6). The reason for this drop in yield is attributed to the ethyl glyoxylate oligermerizing due to the extended reaction time. The ee of the major product is not dependant on the temperature of the reaction, whereas an increase from 24 to 53% ee was observed for the minor diastereomer by decreasing the temperature to −78 °C. The diastereoselectivity was also improved from 2.3:1 to 4.4:1 by reducing the temperature (entries 5,6).

The formation of (+)-*syn*-**3** in the catalytic enantioselective ene reaction using the allyl stannane **2b** as the substrate leads to a simple synthetic procedure for the formation of the other diastereomer, (+)-**7**, of (+)-**1a** in 65% overall yield as presented in Scheme 2.

In conclusion we have presented the development of highly diastereo- and enantio-selective ene reactions of cyclopentenes with ethyl glyoxylate leading to the formation of products, which in a few steps give highly attractive optically active bicyclic lactones. Work is in progress to develop this approach further.

We are indebted to The Danish National Research Foundation for financial support.

† *General procedure* for the catalytic ene reaction: A flame dried Schlenk tube was charged with ligand (*S*)-**5a** (84 mg, 0.25 mmol) and $Cu(OTf)_2$ (90 mg, 0.25 mmol) and stirred vigorously *in vacuo* for 1.5 h. Dry CH_2Cl_2 (3 ml) was added and the green suspension stirred until a clear solution formed (2 h). Freshly distilled ethyl glyoxylate (1.02 g, 10 mmol) in toluene (0.25 ml) was added at room temperature followed by the addition of cyclopentene **2a** (88 μl, 1.0 mmol) and stirred for 48 h. The reaction solution was purified by flash chromatography (25% Et_2O–hexane) to give *anti*-**3** in 48% yield (82 mg, 0.48 mmol). A small amount of the lower R_f diastereomer *syn*-**3** was isolated in 6% yield (10 mg, 0.06 mmol). *Selected data* for (+)-*anti*-**3**: $[\alpha]_D^{20}$ +1.25 (*c* 2.5, $CHCl_3$); $\delta_H(CDCl_3)$ 5.94 (ddd, *J* 5.5, 4.4, 2.2, 1H), 5.50 (ddd, *J* 6.1, 4.4, 2.2, 1H), 4.30–4.19 (m, 2H), 4.11 (dd, *J* 7.5, 4.5, 1H), 3.16–3.00 (m, 1H), 2.51 (d, *J* 7.5, 1H), 2.40–2.18 (m, 2H), 2.10–1.98 (m, 1H), 1.92–1.80 (m, 1H), 1.30 (t, *J* 7.2, 3H). $\delta_C(CDCl_3)$ 174.37, 135.02, 128.16, 73.11, 61.42, 49.89, 32.48, 25.85, 14.23; ν_{max}(film)/cm^{-1} 3496, 2941, 2852, 1732, 1446, 1368, 1259, 1197, 1159, 1097, 1027. The crystal structure of the novel title dehydrobenzoannulene reveals supramolecular organization of the hydrocarbon around the occluded solvent molecules induced by novel multiple chelating alkyne C–H···O hydrogen bonds.

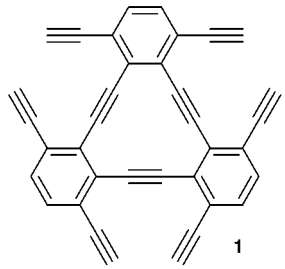
The importance of weak hydrogen bonds in the solid state has received increasing recent recognition.[1,2] Despite numerous examples of C≡C–H···Y (Y = N, O, or another electronegative atom) interactions, there appears to be no case in which two such CH bonds chelate the heteroatom. We report herein the crystal structure of 5,6,11,12,17,18-hexadehydro-1,4,7,10,13,16-hexaethynyltribenzo[*a*,*e*,*i*]cyclododecene **1**[3]



1

and the observation of THF chelation by pairs of proximal alkynyl CH bonds, the latter representing a new type of supramolecular synthon for crystal engineering.

As a subunit of, and a potential precursor to, novel carbon allotropes,[4] *e.g.* graphyne,[5] the structure of dehydrobenzoannulene **1** is of particular interest. The compound crystallizes from THF as yellow needles in the space group $R\bar{3}$ (Fig. 1). In agreement with the computed geometry,† the hydrocarbon is slightly twisted in the solid state.‡ In contrast to the hexakis(cyclohexylmethyl) derivative of **1** which adopts local C_2 symmetry in the crystal,[3] the parent compound is D_3 symmetric. The absence of substituents at the alkyne termini allows for considerable planarization, a feature already evident in the electronic spectrum of **1** which resembles most closely that of the unsubstituted tribenzodehydroannulene core which is D_{3h} symmetric.[3]

The asymmetric unit contains a third of **1** which is chelating one molecule of THF, in addition to a disordered, one sixth of THF. Pairs of nonaynes and disk-like THF clusters are generated from the asymmetric unit by a 3-fold rotoinversion axis (Fig. 2). The alkyne pairs alternate with single solvent disks to give columns along the *c*-axis (Fig. 3). In projection, the latter are arranged to form a close-packed array. Each THF disk is composed of six ordered and one disordered molecule. The disorder in the latter is required, because the site symmetry is incommensurate with the molecular symmetry of THF. Each

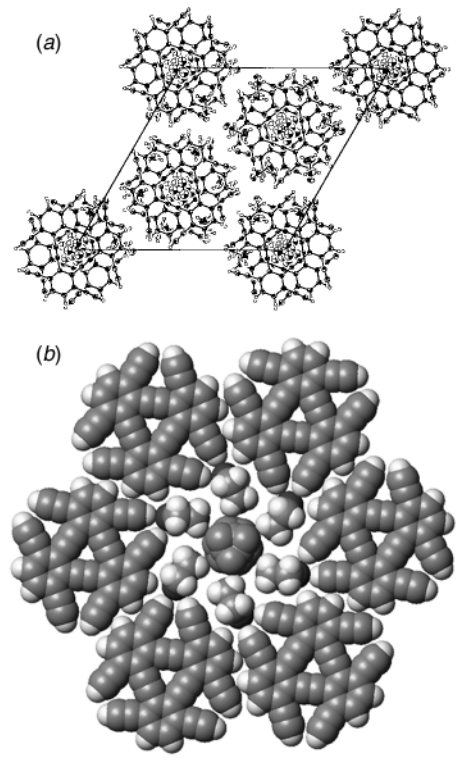

Fig. 2 (*a*) Array of **1** showing molecular packing. (*b*) Space-filling representation of a THF disk surrounded by **1**.

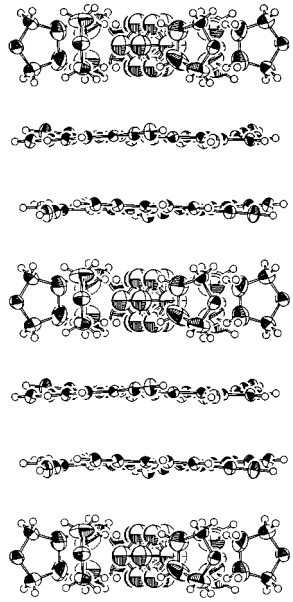

Fig. 3 Side view of a stacked column showing alternation of **1** with THF disks.

nonayne chelates three molecules of solvent in neighboring columns through two alkyne C–H···O bonds. The distances between the normalized (1.083 Å) positions of the hydrogens and the oxygen of the THF are 2.16 and 2.24 Å, respectively (C–O distances 3.22 and 3.30 Å, respectively). The corresponding respective C–H–O angles are 164.9 and 164.2°. These parameters are consistent with the assignment of these interactions as short C–H···O hydrogen bonds.[2]

Additional evidence for C–H···O hydrogen bonding was sought using infrared spectroscopy.[6] However, attempts to obtain spectra in the solid state were hampered by rapid solvent loss. In CH_2Cl_2, the alkyne CH stretching vibration was relatively unperturbed (3305 cm^{-1}) relative to that of 1,4-diethynylbenzene (3308 cm^{-1}, CCl_4).[7] However, in THF, a significant shift to lower energy (3249 cm^{-1}) was observed. Such a dramatic reduction in the CH stretching frequency is consistent with a hydrogen-bonding interaction in solution.[6]

Although examples of chelating OH···O[8] and aromatic C–H···O[9] hydrogen bonds exist, complex **1** represents the first such case for alkyne CH donors.[10]§ Furthermore, the reflection of the molecular symmetry in the organization of the solvent molecules is a stunning example of supramolecular construction in the solid state arising from weak interactions.[11] Attempts to use this property of **1** for the immobilization of a guest of appropriate symmetry are ongoing.

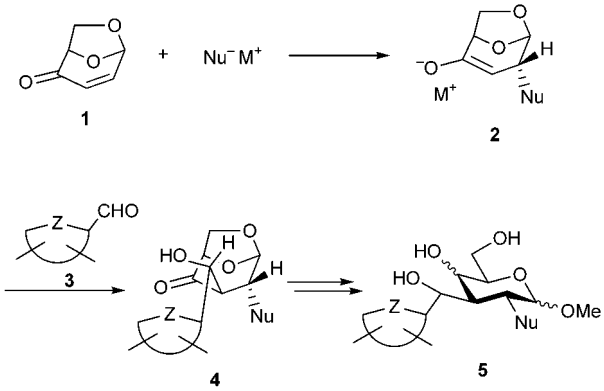
Received (in Liverpool, UK) 30th June 1999, Accepted 13th August 1999

A convergent synthesis of (1→2)- and (1→4)-*C*-linked imino disaccharides was achieved by applying Nozaki–Kishi coupling of a hydroxyproline-derived carbaldehyde with isolevoglucosenone or levoglucosenone derived enol triflates.

Carbohydrate mimetics are potentially useful tools to study cellular interactions,[1] the biosynthesis of glycoproteins, the metabolism of glycoconjugates,[2] and the mechanisms of digestion.[3] Inhibitors of the enzymes involved in these processes such as the glycosidases and the glycosyltransferases are potential anti-cancer, antiviral, and antidiabetic agents, as well as insect antifeedant agents.[4] Disaccharide mimetics such as *C*-disaccharides and dideoxyiminoalditol *C*-linked to monosaccharides have emerged as a new class of specific glycosidase inhibitors and may represent non-hydrolyzable epitopes.[5–7] Recently we disclosed an efficient and versatile approach to the syntheses of (1→3)-*C*-disaccharides and (1→3)-*C*-linked imino disaccharides **5** based on the cross-aldolisation of the aldehydes **3** with the nucleophile 1,4-adducts **2** of isolevoglucosenone **1** (Scheme 1).[8,9] We report here that (1→4)- and (1→2)-*C*-disaccharides can be prepared starting from **1** and levoglucosenone **17** with **3**, respectively.

Adduct **6** of benzyl alcohol with isolevoglucosenone was enolized, without elimination of benzylate anion, on treatment with LiHMDS in 95:5 THF–HMPA at −78 °C (Scheme 2).[9] Quenching of the corresponding lithium enolate with 2-[bis(trifluoromethylsulfonyl)amino]-5-chloropyridine provided the enol triflate **7** in 87% yield.[10] Nozaki–Kishi coupling of **7** and aldehyde **8** led to allylic alcohols **9** and **10** isolated in 62 and 17% yield, respectively.[11,12]‡ Interestingly, the reaction was accelerated by ultrasound and O_2. Under N_2 atmosphere, ultrasound shortened the reaction time from 30 to 2 h. While in the presence of a catalytic amount of O_2 (5 mol% with respect to $CrCl_2$, concentration of O_2 lower than 10%), the reaction time was reduced further to less than 1 h. Moreover, O_2 suppressed the formation of **11**, resulting from H_2O quenching of the alkenylchromium species, from 36 to less than 10%.

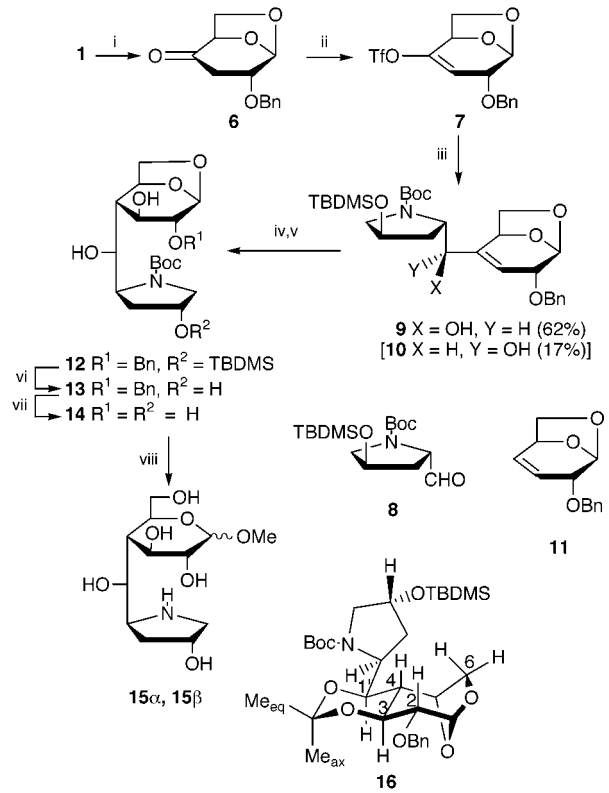


Scheme 1

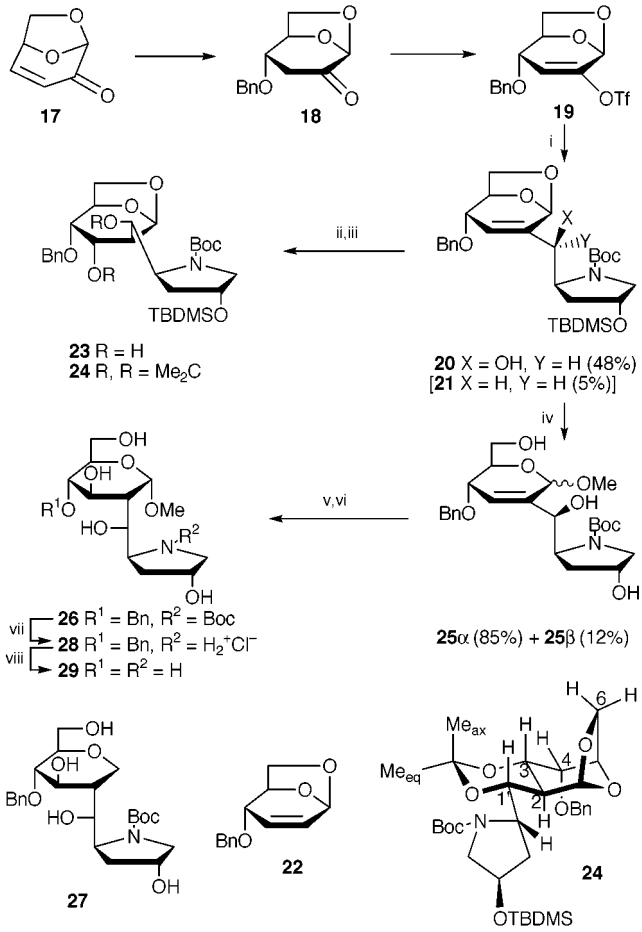
† Spectral data for **15α**, **15β** and **29** are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1873/

Hydroboration of **9** with $BH_3{\cdot}SMe_2$ in THF at 50 °C followed by H_2O_2/NaOH work-up furnished the D-glucose derivative **12** in 57% yield. Desilylation with Bu_4NF in THF gave triol **13** (97%), which was debenzylated to give tetrol **14** (94%). Treatment of **14** in refluxing MeOH saturated with gaseous HCl for 2 days produced a 2:1 mixture of **15α** and **15β** in 83% yield.

The D-*gluco* configuration of the methyl pyranosides **15α** and **15β** was determined from their ^1H NMR spectra.[13] The configuration of the hydroxymethano linker was established by converting diol **12** into the corresponding acetonide **16** [$(MeO)_2CMe_2$, acetone, TsOH, Drierite, 25 °C, 68% yield], the structure of which was established by its NOESY and ^1H NMR spectra. The coupling constants, ^3J(H-3, H-4) = 10.9 Hz, ^3J(H-4, H-1′) = 11.2 Hz and ^3J(H-2, H-3) = 7.2 Hz, show the antiperiplanar orientation between these proton pairs. Furthermore, NOEs were observed between signals attributed to H_{syn}-6, H-2, H-4, and between those attributed to Me_{axial}, H-1′, H-3. Thus, the *Re* face of aldehyde **8** is preferred for the alkenylchromium addition, which is in accord with the Felkin–Anh Model.[14]



Scheme 2 *Reagents and conditions*: i, BnOH, Et_3N, 25 °C; ii, LiHMDS, HMPA–THF, 2-[bis(trifluoromethylsulfonyl)amino]-5-chloropyridine, −78 °C, 87%; iii, **8**, $CrCl_2$, $NiCl_2$, O_2, DMF, ultrasound, 25 °C; iv, $BH_3{\cdot}SMe_2$, THF, 50 °C, v, H_2O_2, NaOH, 57% for 2 steps; vi, Bu_4NF, THF, 97%; vii, H_2, 10% Pd-C, MeOH, 25 °C, 94%; viii, MeOH, HCl, reflux, 2 days, 83%.



Scheme 3 *Reagents and conditions*: i, **8**, $CrCl_2$, $NiCl_2$, O_2, DMF, ultrasound, 25 °C; ii, $BH_3{\cdot}SMe_2$, THF, reflux; iii, H_2O_2, NaOH, 37% for 2 steps; iv, MeOH, TsOH, 25 °C; v, $BH_3{\cdot}SMe_2$, THF; vi, H_2O_2, NaOH, 46% for 2 steps; vii, MeOH, HCl, reflux, 92%; viii, H_2, 10% Pd-C, MeOH, 25 °C, 95%.

In parallel with the synthesis of (1→4)-*C*-disaccharides, (1→2)-*C*-disaccharides and analogues can be obtained starting from levoglucosenone **17** (Scheme 3). Benzyl alcohol adduct **18** was converted (as above) into triflate **19** in 90% yield.[15] In the Nozaki–Kishi coupling reaction, **19** was found to be less reactive than triflate **7**. It required activation with ultrasound and a catalytic amount of O_2 to react (best results with 5 mol% O_2 with respect to $CrCl_2$, 0.3 mol% $NiCl_2$). This led to alcohol **20** isolated in 48% yield, together with dehydroxylated product **21** (5% yield) and side product **22** (8% yield).‡ Hydroboration of **20** followed by oxidative work-up provided diol **23** in modest yield (37%). The ^{1}H NMR and NOESY spectra of acetonide **24** (obtained under the same conditions as those for **16**) showed coupling constants ^3J(H-2, H-3) = 10.7 Hz, ^3J(H-1′, H-2) = 10.7 Hz, ^3J(H-3, H-4) = 3.6 Hz, and NOEs between proton pairs H_{syn}-6/H-3, H-3/H-1′ H-3/Me_{axial} and H-1′/Me_{axial}. These establish the D-*altro* configuration of the anhydrohexose moiety and the (*R*) configuration of the hydroxymethano linker demonstrating again that the *Re* face of **8** was preferred for the nucleophilic addition.[16] Hydroboration took place from the *exo* face of the bicyclic system probably because of steric hindrance from the *endo* hydrogen at C6. The allylic acetal was readily opened by acidic methanolysis, which provided glycosides **25α** and **25β** isolated in 85 and 12% yield, respectively. Hydroboration of **25α** gave alcohol **26** (46%) and the anhydroglucitol derivative **27** (10%).[16] Under reflux in MeOH saturated with HCl, **28** was obtained in 92% yield. Hydrogenation liberated the (1→2)-*C*-linked imino disaccharide **29** (95%).

The stereoselective methods presented above should be applicable to the preparation of a large variety of (1→2)- and (1→4)-*C*-disaccharides and analogues employing the same starting materials as those for the synthesis of (1→3)-*C*-disaccharides, and thus make possible the exploration of their structure–activity relationships.[17]

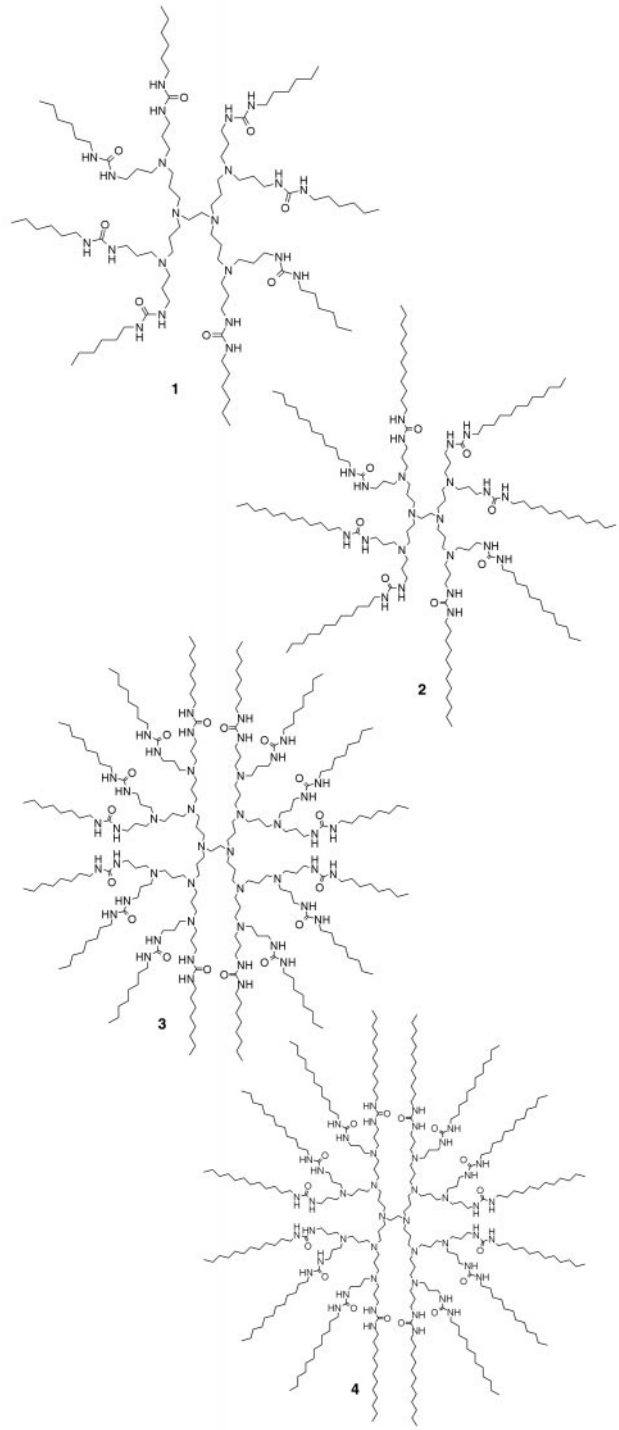
Received (in Cambridge, UK) 20th July 1999, Accepted 10th August 1999

Urea-functionalized dendrimers are prepared which show very efficient phase transfer, in particular of the diagnostically relevant anions pertechnetate, perrhenate and ATP; the extractability rates are evaluated quantitatively by tracer methods; their pH dependancy allows controlled release of guest molecules from the dendrimer host.

Due to their unique topology and unusual guest-binding behaviour, dendrimers are promising reagents for use in diagnostic imaging and therapy.[1] Commercially available compounds such as poly(aminoamide) and poly(propylenimine) dendrimers have been investigated with this application in mind. At physiological pH more than 50% of the amino groups of such dendrimers are protonated, resulting in a polycation.[2] Consequently these are capable of binding anions. We are especially interested in the efficient binding of the tetrahedral oxoanion pertechnetate as a new approach to labelling organic compounds.[3] In this context dendrimers are desired having a hydrophobic periphery in order to shield the anion from hydrophilic attack. A convenient way to obtain this is reaction of the primary amino groups with alkyl and aryl isocyanates giving lipophilic polyurea-functionalized dendrimers.[4] Urea, as hydrogen bond donating moiety, is also able to stabilize the complexed anion.[5] Knowing the interaction of dendrimers with phosphate groups in oligonucleotides,[6] DNA[7] and other guests[8] we have also investigated the binding of the nucleotides AMP, ADP and ATP with the polyurea dendrimers prepared.

We report the synthesis and complexation behaviour *via* liquid–liquid extraction of various generations of these new monodisperse urea-functionalized dendrimers. Various isocyanates (hexyl, octyl, dodecyl and phenyl isocyanate) dissolved in CH_2Cl_2 [9 mmol for second generation dendrimer-$(NH_2)_8$,[9] 17 mmol for third generation dendrimer-$(NH_2)_{16}$[9]] were slowly dropped into a solution of 1 mmol poly(propylenimine) dendrimer in 150 ml of CH_2Cl_2. After stirring for 48 h at 25 °C the solvent was partially evaporated. Upon adding 40 ml of light petroleum to the remaining solution, the urea-functionalized dendrimers were precipitated. Crude products were filtered and washed with light pertroleum. The pure compounds were isolated as colourless solids in 90% yield.§

The alkyl urea-functionalized dendrimers **1**–**4** are soluble in organic solvents like $CHCl_3$ and CH_2Cl_2, a prerequisite for studying the complexation behaviour by liquid–liquid extraction.¶ On the other hand, dendrimers having phenyl urea units at the periphery are completely insoluble in these diluents. Accordingly, we have only examined the alkyl urea dendrimers. These dendritic hosts are capable of extracting pertechnetate with remarkable efficacy (Fig. 1). As expected the extractability is enhanced with decreasing pH accompanied by a higher state of protonation. Also the increasing number of potential binding sites leads to an improvement of pertechnetate extraction (generation 3 > generation 2). Introduction of hexyl and octyl



† Part of this work was presented as a poster contribution at the Seminar 'Functional Supramolecular Systems', Frankfurt (Main), Germany, June 1999.

‡ MALDI-TOF data for **3**, and **3**·$(ATP)_5$·$(H_2O)_x$ are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/1875/

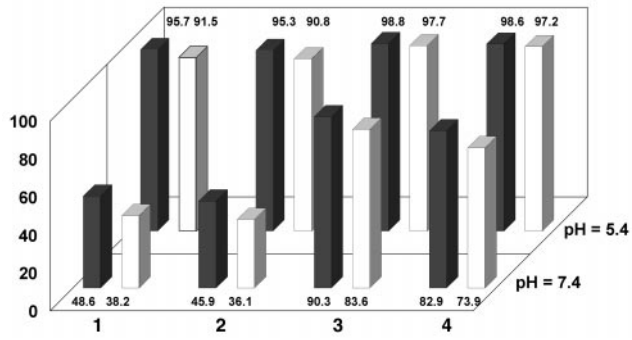


Fig. 1 Extractability of pertechnetate (grey columns) and perrhenate (white columns) with dendrimers **1**–**4**; $[KTcO_4] = [NH_4ReO_4] = 1 \times 10^{-4}$ mol dm^{-3}, pH = 5.4 (MES/NaOH buffer), pH 7.4 (HEPES/NaOH buffer), [dendrimer] $= 1 \times 10^{-3}$ mol dm^{-3} in $CHCl_3$.

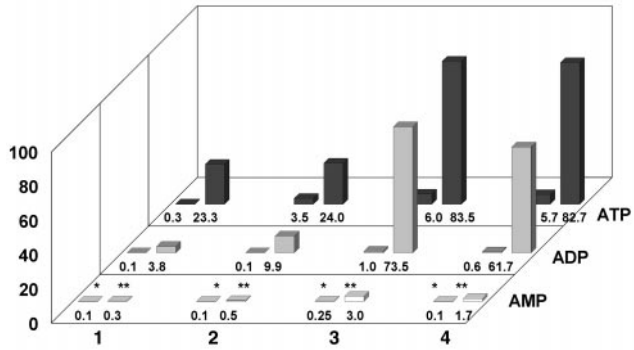

Fig. 2 Extractability of nucleotides with dendrimers **1**–**4**; [nucleotide] = 1×10^{-4} mol dm^{-3}, * = pH 7.4 (HEPES/NaOH buffer), ** = pH 5.4 (MES/NaOH buffer), [dendrimer] = 1×10^{-3} mol dm^{-3} in $CHCl_3$.

residues on the periphery of the dendrimers leads to higher distribution ratios in comparison with the dodecyl analogue. This finding is probably due to steric effects. The same trend of influence on extraction is observed for perrhenate, which is similar in size and other properties to pertechnetate. However, the efficacy is slightly decreased compared to pertechnetate extraction. This fact is also found for bimetallic cyclotriveratrylene[10] and bicyclic guanidinium hosts.[11] Differences of charge density and hydration between these two anions is probably responsible for the observed extraction behaviour.

The dendrimers investigated show also the ability to extract the highly hydrophilic nucleotide anions AMP, ADP and ATP with remarkable graduation (Fig. 2). The extraction of these anions is strongly influenced by the state of protonation and the number of binding sites in comparison to the more hydrophobic anions pertechnetate and perrhenate. The extractability of the nucleotides is enhanced with increasing number of phosphate groups, giving the order ATP > ADP > AMP. This trend meets our expectations and clearly points toward the participation of all phosphate groups in binding with the dendrimers.

As the loading capacity of the organic phase is limited, at higher concentrations of nucleotides a third phase‖ is formed during extraction. ^{31}P NMR clearly indicates that ATP is enriched in this phase. In order to obtain information about the stoichiometry of the complex extracted we utilized mass spectrometry.** Surprisingly, the MALDI-TOF mass spectrum of this complex shows one peak at *m*/*z* 6992.5, pointing to some ATP molecules being attached to the dendrimer. Considering that ATP remains hydrated†† after extraction a complex $\mathbf{3}\cdot(ATP)_5\cdot(H_2O)_x$ (with $x \approx 15$) can be postulated.

In conclusion, easily accessible urea-functionalized dendrimers are capable of binding anionic guests and transferring them to the organic phase (Table 1). The improvement of the stability of the pertechnetate complexes appears promising, and may lead to novel imaging agents. Furthermore higher generations of lipophilic dendrimers possessing anion affecting groups like (thio)ureas, amides and sulfonamides should give unusual

complexation and distribution properties for biologically relevant guests such as oligonucleotides and nucleic acids. Another concept is the use of poly (Lewis acid) hosts, recently realized for ferrocenyl dendrimers.[12]

We thank the Sächsisches Ministerium für Wissenschaft und Kunst (Project 7533-844-98/4) for support of this work.

Notes and references

§ Compounds were fully characterised by ^{1}H and ^{13}C NMR spectroscopy and MALDI-TOF mass spectrometry.

¶ Liquid–liquid extraction studies were performed at 25 ± 1 °C in 2 cm^3 microcentrifuge tubes by mechanical shaking. The phase ratio $V_{(org)}$:$V_{(w)}$ was 1:1 (0.5 cm^3 each); the shaking period was 30 min. The extraction equilibrium was achieved during this period. All samples were centrifuged after extraction. The anion concentration in both phases was determined radiometrically using β-radiation measurement of $^{99}TcO_4^-$, $^{188}ReO_4^-$ (Amersham) and ^{14}C-labelled nucleotides (NEN Life Science Products) in a liquid scintillation counter (Tricarb 2500, Canberra-Packard). The aqueous solution was adjusted using 0.05 mol dm^3 and HEPES/NaOH buffer.

‖ Extraction of ATP (2 cm^3, 5×10^{-2} mol dm^{-3}) with **3** (1 cm^3, 5×10^{-3} mol dm^{-3} in $CHCl_3$) leads to the formation of a third phase.

** For this purpose ATP (2 cm^3, 5×10^{-3} mol dm^{-3}) is extracted from aqueous solution into $CHCl_3$ using **3** (1 cm^3, 5×10^{-3} mol dm^{-3}).

†† The ATP applied has a hydration state of 7.3.

Received (in Cambridge, UK) 8th July 1999, Accepted 10th August 1999

A highly active and selective catalyst for the production of methyl propanoate *via* the methoxycarbonylation of ethene is described, based on the new zero valent palladium complex L_2Pd(dba) [where L_2 = 1,2-bis(di-*tert*-butylphosphinomethyl)benzene and dba = *trans*,*trans*-dibenzylideneacetone].

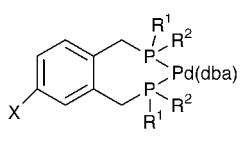
The alkoxycarbonylation of alkenes is of growing importance. Eqn. (1) shows that a range of products is accessible, from high

$$CH_3OH + CO + CH_2{=}CH_2 \longrightarrow H{-}(CH_2CH_2C(=O))_nOCH_3 \quad (1)$$

molecular weight 'polyketones', which have useful properties as engineering thermoplastics,[1] to methyl propanoate [n = 1 in eqn. (1)], a potential intermediate in the manufacture of methyl methacrylate.[2] Palladium catalysts for this transformation show a marked selectivity dependence on the nature of the phosphine ligand, with monodentate phosphines generally giving methyl propanoate and bidentate phosphines giving high molecular weight co-polymers.[3] Examples of bidentate phosphines contradicting this paradigm are rare.[4]

We report here results using catalysts based on the bidentate phosphine ligand 1,2-bis(di-*tert*-butylphosphinomethyl)benzene which offer exceptional activity, selectivity and stability as ligands for methyl propanoate production.[5] This ligand has been previously described by Shaw[6] and some of its chemistry explored by Spencer;[7] however, prior to our work little structural characterisation and no catalytic studies have been reported.

Addition of this ligand to $Pd_2(dba)_3$ (dba = *trans*,*trans*-dibenzylideneacetone) gave a complex of formula L_2Pd(dba) **1** (where L_2 = the bidentate phosphine). Treatment of this



1 $R^1 = R^2 = Bu^t$, X = H
2 $R^1 = R^2 = Bu^t$, X = NO_2
3 $R^1 = R^2 = Bu^t$, X = OMe
4 $R^1 = R^2 = Pr^i$, X = H
5 $R^1 = R^2$ = Cy, X = H
6 $R^1 = R^2$ = Ph, X = H
7 $R^1 = Bu^t$, R^2 = Cy, X = H

complex with a sulfonic acid (*e.g.* MsOH) in MeOH generates a complex capable of converting ethene, CO and MeOH to methyl propanoate at a rate of 50 000 mol of product per mol of catalyst per hour with a selectivity of 99.98%. The reaction conditions are very mild (80 °C and 10 atm combined pressure of ethene and CO).[8] In our hands catalysts based on another bidentate phosphine reported to have high activity and selectivity for methyl propanoate,[4a] namely 1,3-bis(di-*tert*-butylphosphino)propane, will typically give values of 15 000 and 98% for turnover frequency and selectivity, respectively, in these batch reactions. Under continuous operation others have reported that catalysts based on PPh_3 have only modest stability, achieving 1800 turnovers on palladium.[9] Our catalyst has now also been operated under steady state conditions for extended periods, giving total turnover numbers on palladium in excess of 100 000.

Whilst functionalisation of the aryl bridge with classical electron-releasing or -withdrawing groups (MeO and NO_2) has no significant effect on catalyst performance (presumably being too remote from the palladium centre) slight modifications of the substituents on phosphorus give dramatic results (Table 1). Thus activity is reduced by a factor of 60 on going from the *tert*-butyl substituted ligand **1** to the isopropyl analogue **4**. These numbers are lower than those reported above for the preferred catalyst system due to poor mass transfer in the laboratory glass autoclave compared to that obtained in the well-agitated metal autoclave used for more detailed characterisation of the preferred system. The selectivity of the reaction also changes with ligand structure: using the tetraphenyl analogue **6** the products are a mixture of polyketone oligomers and polymers.

There has been much published about the use of the P–Pd–P bite angle in such complexes to aid the development of structure–property relationships.[10] To this end we have undertaken a detailed study of the structure of **1**, **4**, **5** and **6**. All show the expected η^2 binding of one of the alkene groups of dba and the chelating binding of the phosphine giving a trigonal planar environment around the palladium. The measured bite angle is very constant across this series and is much larger (104 *vs.* 87°) than that reported in the only other published structure of a similar compound containing dppe as the ligand.[11] For **1** this

Table 1 Comparative catalytic results for complexes **1**–**7**[a]

Complex	Activity[b]	Selectivity[c] (%)	P–Pd–P bite angle[d] (°)	Parallel pocket angle[d] (°)
1	12 000	99.9	103.9	127.7

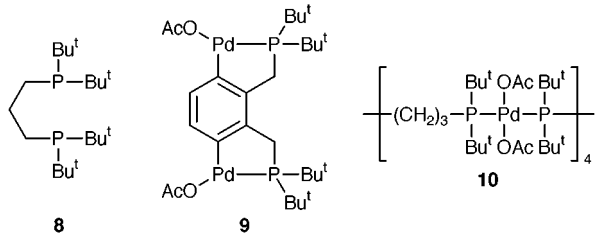
6	400	20	104.6	145.4
7	500	30		

[a] *Conditions*: reactions were carried out in an identical fashion to that described in ref. 7, except that a glass Bucchi autoclave was used, agitated by means of a magnetic follower and heated by an oil bath. [b] Activity = moles of ethene consumed per mole of palladium per hour. [c] Selectivity to methyl propanoate measured by GC (details as in ref. 7), remainder oligomers and polymers. [d] Determined by X-ray crystallography, see text.

† Current address: Strategic Projects Group, ICI Acrylics, PO Box 90, Wilton, Middlesbrough, UK TS90 8JE.

appears to be at the expense of a longer Pd–P bond (2.36 *vs.* 2.29 Å). It has been argued that the observed ligand bite angle is the result of constraints imposed by the metal and ligand; here, where we have tried to eliminate many of these, the measured parameter still appears to lack sensitivity. Analysis based on the concept of parallel pocket angle[12] does show some variation. This hints that there may indeed be an optimum steric environment, dictated by the nature of the phosphine substituents rather than the bridge length, that controls single and multiple substrate insertions prior to chain termination. These arguments will be developed in a subsequent full paper.

Recognising that the likely active species is based on divalent palladium and intrigued as to why 1,2-bis(di-*tert*-butylphosphinomethyl)benzene and 1,3-bis(di-*tet*-butylphosphino)propane **8**



8 **9** **10**

seem unusual amongst bidentate phosphines in producing highly active catalysts selective to methyl propanoate, we have also studied the coordination chemistry of these ligands with $Pd(OAc)_2$. A standard experimental procedure was adopted whereby the ligand was added as an acetone solution to $Pd(OAc)_2$ (also in acetone solution) in equimolar proportions. The reaction mixture was stirred overnight, during which time a precipitate formed. With ligand **1** the above procedure yielded a pale green solid **9**, the spectroscopic characterisation of which is consistent with a doubly orthometallated structure.[13] Recrystallisation (from CH_2Cl_2) of the yellow–green reaction product formed when ligand **8** is added to $Pd(OAc)_2$ gives the tetrameric compound **10**, the structure of which is shown in Fig.1.‡ Inspection of the salient bond lengths and angles shows that each palladium has achieved *trans* disposition of two phosphine ligands, with the relatively long Pd–P bond lengths appropriate to this geometry. Only small deviations are observed from square planar geometry around each palladium centre.

Thus the ligands which ultimately produce catalysts with high selectivity to methyl propanoate seem loath to adopt the classical bidentate chelate structure on reaction with a source of divalent palladium; this *cis* chelate structure has been observed for 1,3-bis(diphenylphosphino)propane, the archetypal ligand for the formation of ethene–CO copolymers.[14] Whilst we are not suggesting that the compounds described here are significant catalytic intermediates, it is tempting to speculate that this reluctance to adopt *cis*-chelate structures may be related to the *cis–trans* isomerisation thought to be responsible for the production of low molecular weight materials from the analogous methoxycarbonylation reaction using PPh_3 as the ligand. This selectivity is thus thought to be driven by the thermodynamic considerations which force the phosphine ligands into a *trans* geometry, isolating the growing chain from the vacant site.[3]

G. R. E. would like to thank ICI Acrylics for the support of his PhD Studentship, and Dr Mel Kilner (University of Durham) for his guidance and encouragement. The EPSRC are also acknowledged for their support in the purchase of the diffractometer.

8 Typical reaction conditions: Reactions were carried out in a mechanically stirred 2 l Hastelloy autoclave, heated by external electric jacket heaters and cooled by an internal cooling coil. The palladium complex (0.01 mmol) was dissolved in deoxygenated MeOH (300 cm^3) to which was added MsOH (0.2 mmol). The resulting solution was introduced into the autoclave which had been purged and evacuated. The solution was heated to 80 °C and then an equimolar mixture of ethene and CO was admitted to a total pressure of 10 atm from a reservoir. The reaction was maintained under these conditions for 3 h. The pressure in the reservoir was recorded to give a constant indication of reaction rate. At the end of the period the autoclave was cooled, vented carefully and the contents weighed and analysed by GC using a Perkin-Elmer Autosystem XL fitted with a semi polar CPSIL 19 column, 60 m length.

Stereospecific synthesis of chiral *N*-(ethynyl)allylglycines and their use in highly stereoselective intramolecular Pauson–Khand reactions

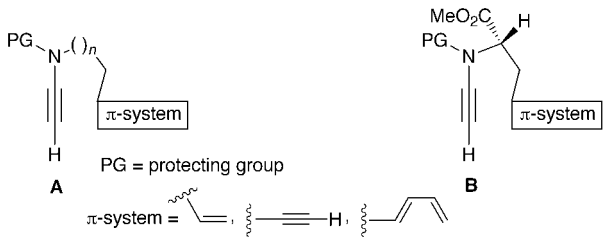
Bernhard Witulski* and Matthias Gößmann

Fachbereich Chemie, Universität Kaiserslautern, Erwin Schrödinger Straße, D-67663 Kaiserslautern, Germany. E-mail: Bernhard@chemie.uni-kl.de

Received (in Cambridge, UK) 21st July 1999, Accepted 2nd August 1999

The first synthesis of an enantiopure *N*-ethynylated allylglycine and its application in the intramolecular Pauson–Khand reaction, which leads to a novel highly functionalised proline derivative with complete control of stereoselectivity, is reported.

N-Functionalised 1-alkynylamides of type **A** are a new class of electronically tuneable acetylenes whose protecting group (PG)

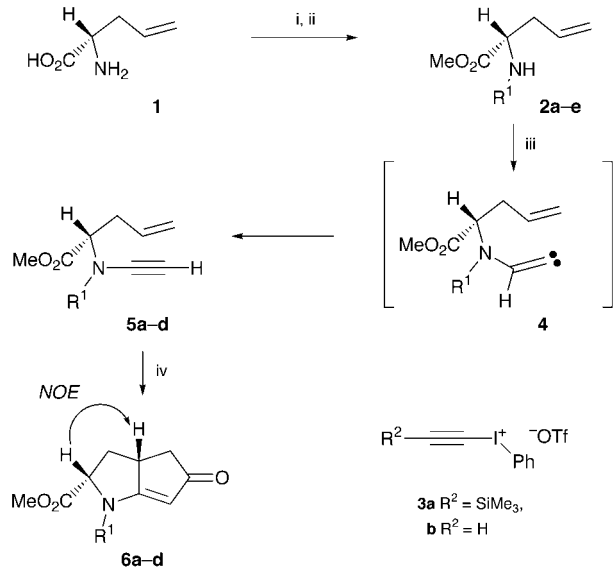


serves both in masking a secondary amine and in tuning the electron density, and hence the reactivity, of the adjacent acetylene moiety.[1] These new building blocks for organic synthesis were designed with the goal of combining the richness and diversity of the chemical reactivity of a carbon–carbon triple bond with one of the most substantial functional groups in chemistry and biology: the amino function.

Recently we described the synthesis of these novel acetylenes based on a two step sequence—ethynylation of secondary amides with trimethylsilylethynyl(phenyl)iodonium triflate[2] followed by desilylation with TBAF—and the use of the thus derived *N*-ethynylamides, whose reactivity differs significantly from those of regular ynamines,[3] in both the Pauson–Khand reaction[1] and in Rh^{I}-catalysed cyclotrimerisations.[4] Given our interest in *N*-functionalised 1-alkynylamides as versatile building blocks for nitrogen-containing heterocycles, we considered the *N*-ethynylamides **B** derived from α-amino acids as even more attractive targets, because their application in transition metal mediated cycloadditions should allow the asymmetric formation of conformationally constrained amino acids[5] and the synthesis of novel proline derivatives that are closely related to the highly potent ACE (angiotensine converting enzyme) inhibitor Ramipril.[6] Furthermore their use as alkynylogous amino acids in peptide chemistry seems to be an interesting endeavour.[7]

However, although the previously described route to *N*-functionalised 1-alkynylamides allowed some degree of functional diversity,[1,3] α-branched 1-alkynylamides could only be obtained in low yields with trimethylsilylethynyl(phenyl)iodonium triflate **3a**. Furthermore all attempts to *N*-alkynylate the α-amino acid derivatives **2a–f** with **3a** (R^2 = $SiMe_3$) failed. We assumed that the observed lack of reactivity was caused by increased steric hindrance inherent in α-branched amino acid derivatives interfering with the nucleophilic addition of the amide nitrogen to the β-carbon of the alkyne **3a** (R^2 = $SiMe_3$). The ethynyl(phenyl)iodonium triflate[8] **3b** (R^2 = H) was therefore thought to be more suitable for the intended *N*-ethynylation. Moreover its use would shorten the previously applied sequence effectively by avoiding the desilylation step and directly affording the terminal *N*-functionalised 1-alkynylamide.

With the idea of exploring the scope of the ethynylation sequence based on **3b** and developing a flexible protecting group strategy,[9] the amides **2a–f** were synthesised starting from allylglycine **1** (Scheme 1, Table 1).† Deprotonation of **2a–f** with either KHMDS in toluene or Cs_2CO_3 in DMF, followed by the addition of **3b** (1.3 equiv.) in CH_2Cl_2 at room temperature, yielded the *N*-ethynylamides **5a–d** in 70–95%.‡ A plausible mechanism for the alkyne formation embodies the *in situ* generation of the alkenylidene carbenes **4**, which immediately rearrange *via* an 1,2-H migration towards the *N*-ethynylamides **5a–d**. The observation that no 1,5-C–H insertion product was formed indicated that the migration aptitude of the hydrogen towards the carbenoid centre in **4** must have been, as anticipated,[10] significantly greater than an alternative intramolecular 1,5-C–H carbene insertion.[11] However, following



Scheme 1 *Reagents and conditions:* i, $SOCl_2$, MeOH, −10 °C, 24 h; ii, R^1Cl (for **2a–c** and **2f**) or $R^1{}_2O$ (for **2d**,**e**), Et_3N, CH_2Cl_2, 0 °C, 6–12 h, for yield of isolated **2a–f** (2 steps) see Table 1; iii, Cs_2CO_3 (1.3 equiv.), **3b** (1.3 equiv.), DMF–CH_2Cl_2, room temp., 3 h, for yield of isolated **5a–f** see Table 1; iv, $Co_2(CO)_8$ (1.1 equiv.), THF, 30 min. 0–20 °C, then NMO or Me_3NO (6 equiv.), room temp., 25 min, for yield of isolated **6a–d** see Table 1.

Table 1 Yield of isolated **2a–f**, **5a–f**, and **6a–d**†

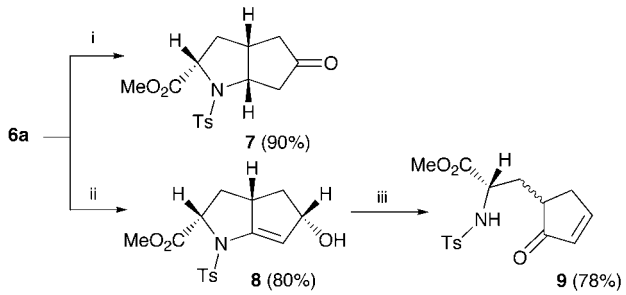
Entry	R^1	**2**	Yield (%)	**5**	Yield (%)	**6**	Yield (%) [de (%)]
1	Ts	**2a**	88	**5a**	70	**6a**	69 [> 96]
2	2-pyridyl-SO_2	**2b**	71	**5b**	78	**6b**	69 [> 95]
3	4-$NO_2C_6H_4SO_2$	**2c**	89	**5c**	95	**6c**	35 [> 97]
4	Tf	**2d**	83	**5d**	94	**6d**	60 [> 95]
5	Boc	**2e**	80	**5e**	0	—	—
6	Ac	**2f**	94	**5f**	0	—	—

this protocol the allylglycines **2e** (R^1 = Boc) and **2f** (R^1 = Ac) could not be ethynylated with **3b** (R^2 = H) and were recovered unchanged. Obviously the increase of basicity[12] and likewise the change of nucleophilicity of the potassium salts of **2e** and **2f** prevented their addition to **3b** and instead caused its decomposition presumably initiated by deprotonation.

Gratifyingly, the application of enantiomerically pure (*S*)-**2a** [ee >98%, $[\alpha]_D$ +13 (*c* 1.0, $CHCl_3$][13] in the outlined protocol afforded enantiomerically pure *N*-(ethynyl)allylglycine methyl ester (*S*)-**5a**, testifying that *N*-ethynylation proceeded without racemisation. HPLC analysis of the crude product with a chiral stationary phase (Chiralpak AD column) stated that (*S*)-**5a** [ee >98%, $[\alpha]_D$ −60 (*c* 2.0, $CHCl_3$] was obtained essentially enantiomerically pure.[14]

Having established a short and efficient route to chiral and enantiopure *N*-ethynylated allylglycines, we tested their applicability as building blocks for the synthesis of functionalised proline derivatives *via* the intramolecular Pauson–Khand reaction.[15] Although [2+2+1] cycloadditions of **6a**–**d** could be affected at 80 °C in toluene in the presence of a stoichiometric amount of $Co_2(CO)_8$, the mild amine *N*-oxide promoted protocol developed by Schreiber was most effective with respect to yield and diastereoselectivity.[16] Treatment of **5a**–**d** with $Co_2(CO)_8$ at room temperature for 25 min and subsequent addition of either NMO or Me_3NO in CH_2Cl_2 at room temperature provided the proline derivatives **6a**–**d** in yields of 69, 69, 35 and 60%, respectively. The lower yield achieved with the sulfonamide **5c** was caused by a concurrent reduction of the 4-nitrophenylsulfonyl moiety to the corresponding aniline and led to a mixture of products. Pauson–Khand reactions with **5a**–**d** proceeded with high diastereoselectivity giving almost exclusively one single diastereomer (de >95%, determined by ^{1}H-NMR, diastereomeric pure **6a**–**d** were obtained by crystallisation).§ The structural assignment of compound **6a** was based on a combination of H, H and C, H COSY experiments and the analysis of distinct NOE relationships. The use of enantiopure (*S*)-**5a** afforded the optically active (2*S*,4*R*)-**6a** [$[\alpha]_D$ +145 (*c* 2.0, $CHCl_3$)] in 69% yield.¶

Preliminary attempts to further elaborate the obtained highly functionalised proline derivatives were successful (Scheme 2). Pauson–Khand product **6a** was stereoselectively hydrogenated on Pd-C/(H_2) to the cyclopentanone **7** in 90% yield. Luche reduction of **6a** proceeded with distinctive stereoselectivity giving exclusively the allylic alcohol **8** in 80% yield. Compound **8** was obtained as colorless crystals (mp 139–140 °C, CH_2Cl_2–pentane) after column chromatography on silica gel with CH_2Cl_2 containing 0.5% Et_3N. However, the allylic alcohol **8** being extremely sensitive to traces of acid, rearranged under H^+ catalysis with ring cleavage to the cyclopentenones **9** (2:1 mixture of two diastereoisomers).



Scheme 2 *Reagents and conditions:* i, H_2 (1 atm.), (10%) Pd/C, EtOH–AcOH (1:1), room temp., 24 h; ii, $NaBH_4$ (2 equiv.), $CeCl_3 \cdot 7\ H_2O$ (1 equiv.), MeOH–CH_2Cl_2, 20 °C, 0.5 h; iii, cat. H^+, $CHCl_3$, room temp.

In conclusion, we have established a short and efficient synthesis of a first set of *N*-ethynylated amino acid derivatives and proved, for the example **2a**/**5a**, that *N*-ethynylation with the alkynyliodonium salt **3b** proceeded without detectable racemisation. Their use in the intramolecular Pauson–Khand reaction allowed the stereoselective formation of novel proline derivatives. Additional applications of *N*-alkynylated amino acids for the synthesis of conformationally constrained amino acids *via* cycloaddition strategies are part of our ongoing research.

This work was supported by the Deutsche Forschungsgemeinschaft (Wi 1696/1) and by the Fonds der Chemischen Industrie. We gratefully acknowledge the help of Dr C. Alayrac and M. Lemarié (ISMRA-Université Caen, France) with the HPLC analyses and $[\alpha]_D$ measurements. We also thank Professor Dr M. Regitz for his support.

Boronate-functionalized polypyrrole as a new fluoride sensing material

M. Nicolas, B. Fabre* and J. Simonet

Laboratoire d'Electrochimie Moléculaire et Macromoléculaire (Unité Mixte de Recherche n°6510 associée au CNRS), Université de Rennes 1, Campus de Beaulieu, 35042 Rennes Cedex, France. E-mail: fabre@univ-rennes1.fr

Received (in Cambridge, UK) 25th June 1999, Accepted 8th July 1999

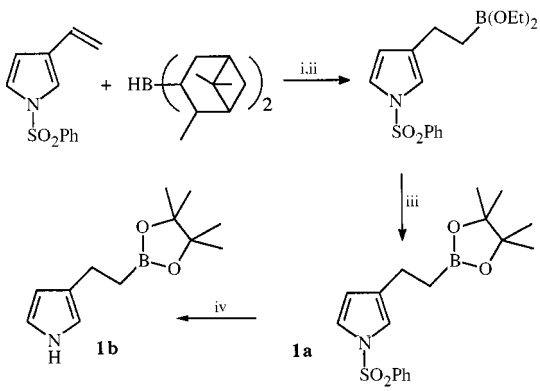
The anodic oxidation of boronate-substituted pyrrole led to a fluoride anion-responsive electroactive polymer film.

The modification of the electrochemical response of a system in the presence of a specific ion or molecule can be considered as a recognition event. In the case where such a system is deposited onto an electrode surface, this mode of recognition can be exploited for the construction of electrochemical sensors. As an example, numerous recent reports have focused on the sensing properties towards cations of some polyether or crown ether functionalized redox-active conjugated polymers.[1–7] In contrast, anion recognition by this class of polymers derivatized with a suitable receptor has been much less developed.[8,9] We have tested a novel route to anion-responsive electrodes based on a conjugated polymer substituted by a boronate group. Here, the boron-containing moiety was used as a sensing element owing to the strong interaction of this heteroatom with hard bases like fluoride giving rise to specific orbital changes from sp^2 to more stable sp^3. So, the possible electronic and/or conformational changes induced by the boron–fluoride binding could be detected from the modification of the electrochemical response of the conjugated polymer. Although numerous boronic acid-based anion and sugar receptors have been developed by Shinkai and co-workers,[10–13] their immobilization onto an electrode surface has not been investigated so far. The incorporation of boron atoms in the backbone of conjugated polymers has already been described,[14,15] but in our case we chose to attach the boronate group to the conjugated polymer by a spacer of appropriate length.

To achieve this purpose, conjugated polymer films were electrodeposited in one step onto a platinum (diameter 1 mm) electrode surface *via* the anodic oxidation in MeCN of the functionalized pyrrole. 1-(Phenylsulfonyl)-3-vinylpyrrole was synthesized in three steps from 1-(phenylsulfonyl)pyrrole using literature procedures.[16,17] Hydroboration with diisopinocampheylborane[18] (Ipc_2BH) prepared from (+)-α-pinene and borane–dimethyl sulfide complex gave the diethyl boronate derivative (Scheme 1). Treatment with pinacol gave **1a** as a colorless oil in 23% overall yield after purification by column chromatography (CH_2Cl_2). This was deprotected electrochemically at −2.45 V (*vs.* 10^{-1} M Ag^+/Ag) using pyrene as a redox mediator to give **1b** (yield 58%).†

The electropolymerization of **1b** (10^{-2} M) was carried out in thoroughly dried MeCN containing 10^{-1} M Bu_4NPF_6 as the supporting electrolyte. The doped film was potentiodynamically electroformed with an anodic limit close to the irreversible oxidation peak potential of monomer, *e.g.* 0.75 V [Fig. 1(*a*)]. Its electrochemical response in an hydroorganic medium[19] (H_2O–MeCN) showed a stable reversible redox system at −0.11 V *vs.* SCE (ΔE_p = 40 mV at 100 mV s^{-1}) corresponding to the p-doping/undoping process [Fig. 1(*b*)]. The doping level deduced from the cyclic voltammetry curve was found to be in the range 0.20–0.30 depending on the film thickness.

The addition of KF led to the decrease of this system together with the emergence of a new redox system at −0.37 V, the magnitude of which increased with F^- concentration. For a film



Scheme 1 *Reagents and conditions*: i, Ipc_2BH (1.2 equiv.), THF, −40 °C, then addition of the vinylated compound, room temp., 24 h; ii, acetaldehyde (10 equiv.), 0° C, 24 h; iii, pinacol (1 equiv.) in THF, room temp., 24 h; *iv*, pyrene (20%), reduction at −2.45 V (*vs.* Ag^+/Ag) in MeCN + 10^{-1} M Bu_4NClO_4.

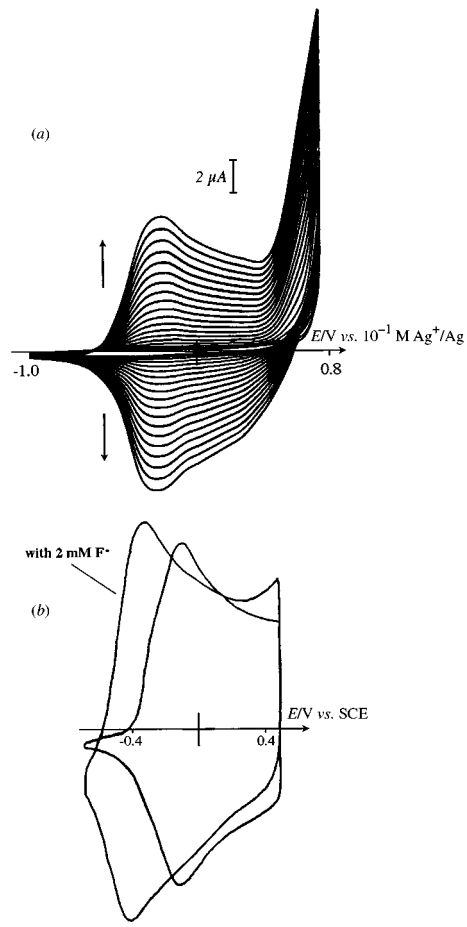


Fig. 1 (*a*) Successive cyclic voltammograms of **1b** (10^{-2} M) in MeCN + 10^{-1} M Bu_4NPF_6 (final electropolymerization charge: 70 mC cm^{-2}). (*b*) Electrochemical response of corresponding poly(**1b**) in H_2O–MeCN (1:1 v/v) + 5 × 10^{-1} M $LiClO_4$ in the absence and presence of 2 mM KF. Potential scan rate: 100 mV s^{-1}.

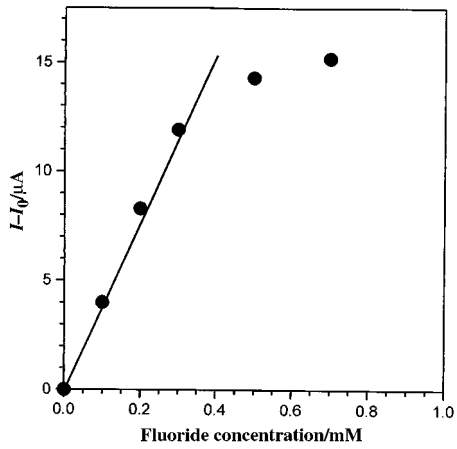

Fig. 2 Calibration curve for F^- in H_2O–MeCN (1:1 v/v) + 5×10^{-1} M $LiClO_4$ obtained with a poly(**1b**)-coated platinum (8×10^{-3} cm^2) electrode (electropolymerization charge: 280 mC cm^{-2}). I and I_o are the currents measured at −0.42 V on the voltammetric curves (100 mV s^{-1}) in the presence and absence of KF, respectively.

electropolymerized using 70 mC cm^{-2}, only the second system was observed for a large F^- concentration, *e.g.* 2 mM [Fig. 1(*b*)]. It must be pointed out that the electrochemical response of poly(**1b**) was not changed when F^- was replaced by Cl^- or Br^- up to a tested concentration of 20 mM. Moreover the interaction with F^- was specific for the boronate-containing polymer, as the voltammetric response of an unfunctionalized polymer film was found to be unmodified in the presence of this anion. Thus, all these results are consistent with a selective electrochemical recognition of F^- by poly(**1b**). The negative shift of the redox potential indicates that the F^- bound polymer was easier to oxidize. Such a result could be explained by a stabilization of F^- bound to the boron atom by the positive charges along the oxidized polymer backbone. The effect of the F^- concentration on the current intensity of the system assigned to the F^- bound polymer is shown in Fig. 2. As can be seen, an initial linear plot at low F^- concentrations (< 0.4 mM) is followed by a plateau for larger concentrations indicating that all the binding sites in the film were occupied. The slope and the linearity range of the first part were found to be dependent on the film thickness. As a matter of fact, the sensitivity to F^- was higher for thin films, as already observed for other sensory materials.[20]

Finally, this work constitutes a rare example of functionalized conducting polymer-based selective anion recognition. Some parameters, such as the film thickness, and the nature and length of the spacer arm between the monomer unit and the boron site, must be now optimized in order to obtain sensitive detection operating over a large F^- concentration range.

Drs M. Vaultier, J.-F. Pilard and G. Marchand are fully acknowledged for their help in the synthesis of monomers. The 'Région de Bretagne' is also acknowledged for a research grant to one of the authors (M. N.).

Pendant arm Schiff base complexes of aluminium as ethylene polymerisation catalysts

Paul A. Cameron, Vernon C. Gibson,* Carl Redshaw, John A. Segal, Michael D. Bruce, Andrew J. P. White and David J. Williams

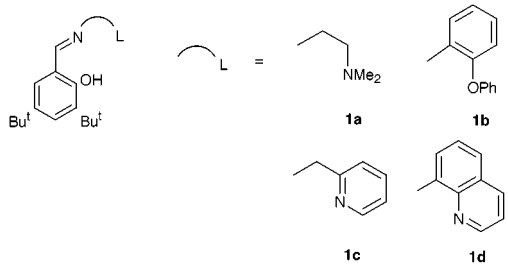
Department of Chemistry, Imperial College, South Kensington, London, UK, SW7 2AY. E-mail: v.gibson@ic.ac.uk

Received (in Cambridge, UK) 25th June 1999, Accepted 9th August 1999

The potentially tridentate Schiff base ligands [3,5-Bu^t_2-2-(HO)C_6H_2CH=NL] 1, on reaction with Me_3Al at room temperature, afford the complexes [(3,5-Bu^t_2-2-(O)C_6H_2CH=NL)$AlMe_2$] [L = $CH_2CH_2NMe_2$ 2a, (2-PhO)C_6H_4 2b, 2-$CH_2C_5H_4N$ 2c and 8-C_9H_6N (quinoline) 2d], 2a and 2c have been characterised crystallographically; further reaction of the dimethyl compounds with $B(C_6F_5)_3$ affords the cationic systems [(3,5-Bu^t_2-2-(O)C_6H_2CH=NL)-AlMe]$^+$ 3a–d of which 3a and 3b are ethylene polymerisation catalysts.

Recent reports by Coles and Jordan[1] and ourselves[2] have revealed the potential for cationic aluminium alkyls as ethylene polymerisation catalysts. The aluminium procatalysts reported thus far are bi- and tri-dentate chelates (L) of the general form [{L}$AlMe_2$], which are synthesised by the reaction of the relevant ligand system with Me_3Al. To obtain an active catalyst system, cationic species are generated on further reaction with $B(C_6F_5)_3$ in hydrocarbon or chlorocarbon solvents. The cationic aluminium alkyls so derived display low activities as ethylene polymerisation catalysts and they produce polymers of high[1] (M_w 176000–272000) or moderate[2] (M_w 13000–23000) molecular weight. In studies directed at extending the family of cationic aluminium catalysts to N,O-Schiff base chelate ligands, we first targeted bidentate chelates *e.g.* 3,5-Bu^t_2-2-(HO)C_6H_2CH=NR (R = alkyl or aryl), which led to the isolation of a range of systems of the type [(3,5-Bu^t_2-2-(O)C_6H_2CH=NR)$AlMe_2$].[3] However attempts to obtain clean alkylaluminium cations by way of reaction with $B(C_6F_5)_3$ (in toluene or dichloromethane) were unsuccessful, always leading to a mixture of species. ^{1}H NMR spectra of the product mixtures show *inter alia* the presence of high field methyl resonances that are characteristic of (ligand)$AlMe(C_6F_5)$ species[4] formed by arylation of the Al centre by the boron reagent. In view of this undesired reactivity, the investigation was extended to Schiff base chelates bearing a pendant donor arm which it was envisaged might, through coordination, lend stability to the cationic methyl product. Here we show not only that such ligands afford stable cationic alkyl species but also that these cationic alkyls are active catalysts for ethylene polymerisation. Homogeneous olefin polymerisation catalysts hitherto described which are derived from N,O-Schiff bases are limited to complexes of transition metals, namely Ti,[5,6] Zr,[6,7] Cr[8] and Ni.[9]

The Schiff base ligands **1a**–**d** (Scheme 1) are accessible in good yields (> 80%) *via* standard imine condensation procedures. Treatment of these potentially tridentate ligands with Me_3Al in toluene at room temperature readily affords the corresponding dimethyl complexes [3,5-Bu^t-2-(O)C_6H_2CH=N-L]$AlMe_2$ **2a**–**d** with concomitant elimination of methane (Scheme 2).†

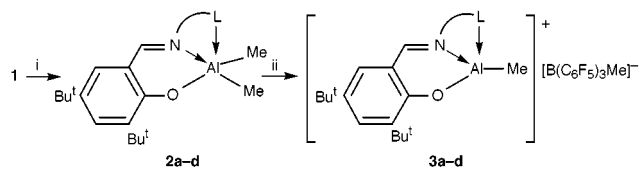


Scheme 1 Ligands **1a**–**d**.

Crystals of **2a** suitable for an X-ray structure determination‡ were grown from MeCN at room temperature. Deprotonated **1a** is seen to act as a tridentate ligand, binding to aluminium *via* the oxygen and the imino and amino nitrogen atoms [Fig. 1(a)]. The geometry at aluminium can best be described as distorted trigonal bipyramidal though with the bond to the axial amino nitrogen N(1) [2.413(5) Å] being substantially longer than that to the equatorial imino centre N(4) [1.998(4) Å]. With the exception of Al–N(1), the Al–X bonds are all clearly single in nature. These bonds, however, are noticeably longer than the corresponding linkages in the simple chelate analogues, *e.g.* {3,5-Bu^t_2-2-(O)C_6H_2CH=N(2,6-$Me_2C_6H_3$)}$AlMe_2$[3] [Al–O 1.773(3), Al–N 1.972(3), Al–Me 1.948(5), 1.959(5) Å] reflecting the presence of the additional donor in **2a** with subsequent competition for electron density. It is interesting that the aluminium atom is displaced significantly out of the equatorial plane (0.16 Å) in the direction of the ligand oxygen. The six-membered N,O chelate ring adopts a sofa conformation, the aluminium lying *ca*. 0.5 Å out of the plane of the other five atoms (which are co-planar to within 0.03 Å). The ring C=N bond has clearly retained its double bond character [N(4)–C(5) 1.294(6) Å], there being no evidence of significant delocalisation into any of the adjacent linkages. The structure of complex **2c** [Fig. 1(b)] is very similar to that of **2a**, in particular with respect to the geometry around Al, the only significant difference of note being a substantial reduction in the bond distance between the aluminium and the pyridyl nitrogen [Al–N(1) 2.254(2) Å *cf.* the dimethylamino nitrogen in **2a** [Al–N(1) 2.413(5) Å]. The remaining bond lengths and angles at aluminium do not differ significantly from those in **2a**.

The cationic complexes [(3,5-Bu^t_2-2-(O)C_6H_2CH=NL)-AlMe]$^+$ **3a**–**d** are readily generated on treatment with 1 equiv. of $[B(C_6F_5)_3]$ in CD_2Cl_2 or toluene at ambient temperature (Scheme 2) as illustrated by the ^{1}H NMR spectrum of **3a** (Fig. 2); the systems exist as free cations as opposed to the ion pairs (*i.e.* with Al···Me–B association) observed by Coles and Jordan.[1] The pendant arm is likely to stabilise the cationic aluminium centre; in its absence, as noted above, the analogous reaction with $[B(C_6F_5)_3]$ gave complicated NMR spectra corresponding to multiple products.

Complexes **2a**–**d** were combined with 1 equiv. of $B(C_6F_5)_3$ to test for ethylene polymerisation activity. Polymerisations were run with 0.25 mmol catalyst in 200 mL toluene solution under 5 bar ethylene pressure at 50 °C for 60 min. Procatalysts **2a** and



Scheme 2 *Reagents:* i. $AlMe_3$, toluene; ii, $B(C_6F_5)_3$, CD_2Cl_2 or toluene.

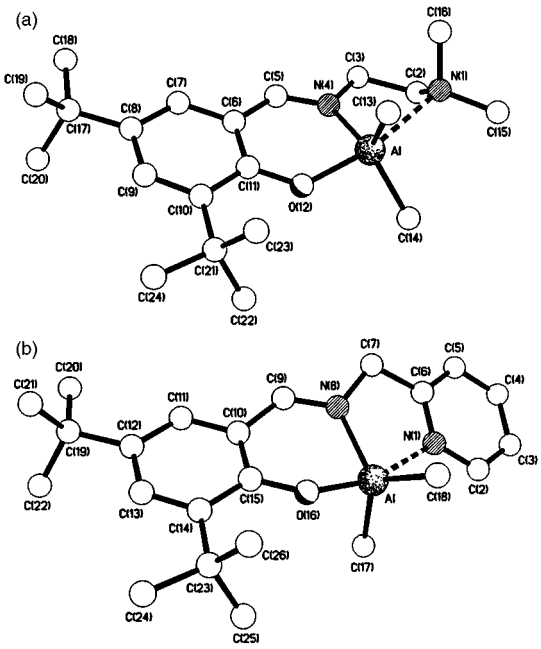


Fig. 1(a) The molecular structure of **2a**, showing the trigonal bipyramidal geometry at aluminium and the very long Al–N(amino) linkage. Selected bond lengths (Å) and angles (°): Al–N(1) 2.413(5), Al–N(4) 1.998(4), Al–O(12) 1.854(4), Al–C(13) 1.978(6), Al–C(14) 1.976(5), N(4)–C(5) 1.294(6), O(12)–Al–C(14) 96.6(2), O(12)–Al–C(13) 98.3(2), C(14)–Al–C(13) 123.7(3), O(12)–Al–N(4) 88.2(2), C(14)–Al–N(4) 116.0(2), C(13)–Al–N(4) 118.4(2), O(12)–Al–N(1) 163.0(2), C(14)–Al–N(1) 91.4(2), C(13)–Al–N(1) 89.5(2), N(4)–Al–N(1) 74.9(2). (b) Complex **2c**.

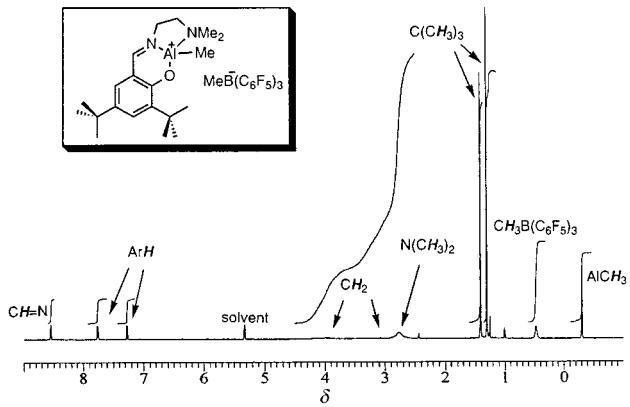

Fig. 2 ^{1}H NMR spectrum (250 MHz) of **3a**.

2b produced solid polyethylene but procatalysts **2c** and **2d** did not display any polymerisation activity. Procatalyst **2a** gave a productivity of 50 g(PE) mol^{-1} h^{-1} bar^{-1} and yielded polyethylene with M_w = 172000, M_n = 2400, whilst procatalyst **2b** gave 110 g(PE) mol^{-1} h^{-1} bar^{-1} with polymer M_w = 218000, M_n = 5200.

In contrast to our previous tridentate aluminium alkyls,[2] the present system affords higher molecular weights, as exemplified by the much higher M_w values, although the activities are similar. The results suggest that lability of the pendant donor arm, as in the cations derived from **2a**, **2b**, is an important feature of the polymerisation catalysis mechanism, providing a pathway for ethylene to approach the aluminium centre. The observation that **2c** and **2d**, which have N-heterocycles as the donor arms, did not provide active systems accords with this view as these compounds are likely to form cations with stronger donor to metal bonds (as evidenced by the significantly shorter Al–N(1) bond length in **2c** *cf.* **2a**) thereby reducing the propensity for dissociation of the coordinating arm to generate an active centre.

In summary, we have shown that Schiff base ligands are capable of stabilising cationic methylaluminium centres only when they possess an additional donor arm. We reasoned, however, that it might be possible to form cations from the analogous Schiff bases without the donor arm if a *free* donor ligand, *e.g.* THF, were added to stabilise the system. This is indeed the case, and our subsequent study of the formation of these closely related cationic species will be published elsewhere.

We thank the EPSRC for a studentship (to P. A. C.), BP-Amoco Chemicals and ICI Acrylics for financial support, and the Royal Society and the Leverhulme Trust for Fellowships (to J. A. S. and C. R.). Mr G. Audley is gratefully acknowledged for GPC measurements.

Received (in Cambridge, UK) 14th June 1999, Accepted 13th August 1999

The unique polyoxometalate compound $Na_{20}[\{Mo^{VI}O_3(H_2O)\}_{10}\{V^{IV}O(H_2O)\}_{20}\{(Mo^{VI}/Mo^{VI}_5O_{21})(H_2O)_3\}_{10}(\{Mo^{VI}O_2(H_2O)_2\}_{5/2})_2(\{NaSO_4\}_5)_2]\cdot xH_2O$ 1 ($x \approx 170$) shows remarkable structural features: *e.g.* (i) $\{Mo^{VI}/Mo^{VI}_5\}$-type pentagons as building blocks (being present in the relevant reaction medium as disposition), (ii) a 'magnetic ring-shaped band' built up by ten linked $\{V^{IV}_3\}$ triangles having common corners and (iii) two $\{NaSO_4\}_5$ rings encapsulated inside the cavity of an icosidodecahedron formed by twenty triangular and twelve pentagonal faces built up by ten Mo^{VI} and twenty V^{IV} centres, respectively.

The generation of a variety of extremely large complex molecular systems under one-pot reaction conditions requires variably linkable units as disposition in the related solution.[1,2] Knowledge of polyoxometalate systems allows for instance the generation and linking of pentagons of the type $\{Mo^{VI}/Mo^{VI}_5\}$, which contain a central pentagonal bipyramid sharing edges with five MoO_6 octahedra. Here we report on the isolation of a related aggregate which displays interesting structural features. The basic structure can be optimally described by referring to the faces of an icosidodecahedron (one of the thirteen Archimedean solids) spanned by ten Mo^{VI} and twenty V^{IV} centres.

If vanadyl sulfate is added to an acidified molybdate solution,‡ the compound $Na_{20}[\{Mo^{VI}O_3(H_2O)\}_{10}\{V^{IV}O(H_2O)\}_{20}\{(Mo^{VI}/Mo^{VI}_5O_{21})(H_2O)_3\}_{10}(\{Mo^{VI}O_2(H_2O)_2\}_{5/2})_2(\{NaSO_4\}_5)_2]\cdot xH_2O$ **1** ($x \approx 170$) precipitates in high yield in the presence of a high electrolyte concentration.§ Compound **1** was characterized by elemental analysis, thermogravimetric analysis for determination of the crystal water content, single crystal X-ray structure analysis¶ (including bond valence sum calculations mainly for a determination of the positions of the H atoms and the number of V^{IV} centres), electronic absorbtion as well as vibrational spectra, magnetic susceptibility and redox titrations [for the (additional) determination of the number of V^{IV} centres].

The anionic cluster **1a** has a nearly spherical shape with longest and shortest outer dimensions of 25 and 23 Å, respectively, and possesses a C_5-symmetry axis [Fig. 1(*b*)]. The structure of the anion **1a** can be best described with reference to a distorted icosidodecahedron formed by twenty triangular and twelve pentagonal faces built up by ten Mo^{VI} and twenty V^{IV} centres [see Fig. 1(*a*)]. Ten triangles spanned by the twenty V^{IV} centres form an unusual equatorial 'magnetic ring-shaped band'. The remaining ten triangles above and below this equatorial band, each formed by one V^{IV} (common to the above mentioned triangular faces) and two Mo^{VI} centres, complete the (distorted) icosidodecahedron. Whereas ten of the twelve pentagonal faces—each formed by one Mo^{VI} and four V^{IV} centres—are 'capped' by a $\{Mo/Mo_5\}$-type pentagonal unit [see Fig. 1(*a*) and consider that the earlier reported more symmetrical structure with I_h symmetry[6] contains twelve pentagonal units], the remaining two (top and bottom) faces, each spanned by five Mo^{VI} centres, are 'capped' in a similar way but show two significant differences: (i) the central pentagonal bipyramidally coordinated Mo^{VI} centre is missing and (ii) the (five) MoO_6 octahedra do not share common oxygen atoms (see Fig. 2). In addition, these five Mo^{VI} positions are under-occupied such that the occupancy factors add up to 2.5 per face [therefore referred to as the $\{Mo\}_{5/2}$ unit in the formula and in Fig. 1(*a*)].

Within the cluster cavity, ten sulfate groups (each attached *via* three oxygen atoms to three adjacent Mo^{VI} centres of each $\{Mo^{VI}/Mo^{VI}_5\}$ group) and ten Na^+ ions are encapsulated in a manner not previously observed. The Na^+ cations are located between adjacent sulfate groups thereby forming two novel

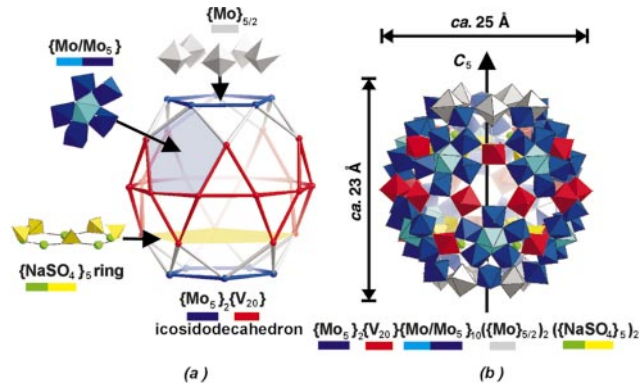

Fig. 1 (*a*) Basic framework structure of **1a** spanned by ten Mo^{VI} (blue) and twenty V^{IV} centres (red) thus forming a distorted icosidodecahedron with twenty triangles and twelve pentagons. Additional structural details shown (see text): (i) one of the $\{Mo^{VI}/Mo^{VI}_5\}$ units which cap ten of the twelve pentagonal faces (MoO_7 pentagonal bipyramid: light blue, MoO_6 octahedra: dark blue); (ii) array built up by five $MoO_4(H_2O)_2$ octahedra (see text) capping the two remaining pentagonal faces (grey); (iii) the 'magnetic ring-shaped band' formed by ten $\{V^{IV}_3\}$ triangles (red); (iv) one of the two encapsulated $\{NaSO_4\}_5$-type rings (Na atoms: green, SO_4 tetrahedra: yellow). (*b*) Polyhedral representation of the complete, nearly spherical structure of **1a** [colour code as in (*a*)].

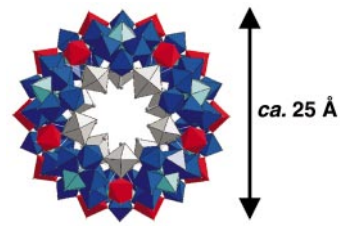

Fig. 2 Polyhedral representation of **1a** with view perpendicular to that shown in Fig. 1(*b*) (parallel to the C_5 axis).

† Disposition can be interpreted as the tendency of an object or system (here polyoxometalate solutions) to act or react in characteristic ways under certain situations (conditions); in this sense the units, such as the pentagons, which finally appear can in principle be called virtual ones.

$\{NaSO_4\}_5$ rings [Na–O(SO_3) 2.48–2.60 Å] lying above and below the equatorial ring of ten V^{IV} centres [see Fig. 1(*a*)]. Interestingly, these Na atoms possess a unique pentagonal bipyramidal coordination environment in which five of the corresponding oxygen centres belong to the cluster shell.

Although the individual metal centres all have an octahedral (or pentagonal bipyramidal) coordination geometry, the environment of some metal centres is complicated for example by disorder phenomena and can—referring to the formula—be described as follows: (i) all six Mo^{VI} centres constituting each of the ten equivalent $\{Mo^{VI}/Mo^{VI}_5\}$ groups, are surrounded by four (or five) bridging oxygen atoms; three possess a terminal oxygen atom projecting outward and a *trans*-μ_2-O atom of the tridentate sulfate ligand (see formula); two Mo centres exhibit outward projecting terminal oxygen and *trans*-OH_2 ligands; the remaining Mo centre (the type closest to the equator), possesses mainly outward projecting OH_2 ligands as well as *trans*-terminal oxygen atoms with the related disorder; (ii) all twenty V^{IV} centres have four bridging oxygen atoms but whereas the ten equatorial V^{IV} centres possess (predominantly) outward projecting OH_2 ligands and *trans*-terminal oxygen, the remaining V^{IV} centres exhibit (without the related disorder), outward projecting terminal oxygen and *trans*-OH_2 ligands; (iii) each of the five Mo^{VI} centres of the $\{Mo\}_{5/2}$ unit ($\{Mo^{VI}O_2(H_2O)_2\}_{5/2}$ part of the formula) has only two bridging (μ_2-type), and consequently four terminal ligands (two oxygen as well as two OH_2 ligands); (iv) the remaining ten Mo^{VI} centres ($\{Mo^{VI}O_3(H_2O)\}_{10}$ part of the formula) also possess disordered terminal oxygen and *trans*-OH_2 ligands; owing to the under-occupancy of the neighbouring molybdenum atoms of the $\{Mo\}_{5/2}$-type centres (occupancy factors 0.25–0.75), one or two μ_2-O atoms become terminal oxygen atoms depending on the related occupancy of the next neighbour position.

Magnetic susceptibility measurements show that χT decreases drastically from 200 to 100 K (3.4–2.3 cm^3 K mol^{-1}) indicating relatively strong antiferromagnetic exchange interactions in spite of the rather large V^{IV}–V^{IV} distances within the magnetic band (6.27–6.46 Å).

Anion **1a** is structurally similar to the inorganic superfullerene of the type $\{Mo/Mo_5\}_{12}\{Mo^V_2\}_{30}$[6] where the thirty centres (mid-points) of the $\{Mo^V\}_2$ dumb-bells span an icosidodecahedron. In this case, twelve $\{Mo^{VI}/Mo^{VI}_5\}$ pentagons cap all of the twelve faces of a distorted truncated icosahedron which is formed by the sixty atoms of the $\{Mo^V\}_2$ units. An important challenge for the future will be the apparently feasible planned synthesis of a variety of spherical clusters using the described pentagonal units.[7] In this context the encapsulation of a variety of multifunctional groups/guests as well as the integration of magnetic centres is of special interest.

Notes and references

‡ $VOSO_4 \cdot 5H_2O$ (2.53 g, 10 mmol) was added under stirring to a solution of Na_2MoO_4 (2.42 g, 10 mmol) in 16.4 ml of 1.0 M hydrochloric acid. Subsequently, NaCl (1.16 g, 19.8 mmol) (which accelerates precipitation) was added to the resulting red–brown solution which was stirred under argon for 10 min before storage under exclusion of air. The red–black rhombic crystals of **1** which precipitated after 7 days were filtered off, washed with 50 ml H_2O and dried in a nitrogen stream. Yield: 0.65 g (28.6%), based on Mo (Found: Na, 3.59; S, 1.85; V, 5.29. Calc.: Na, 3.7; S, 1.72; V 5.5%). The compound is soluble in water and the resulting red solution oxidises slowly on exposure to air.

Characteristic spectroscopic data for **1**: IR ν/cm^{-1} (KBr pellet prepared under argon, 1700–400 cm^{-1}): 1197w, 1125w, 1052w [ν(S–O)]; 968m [ν(V=O)/ν(Mo=O)]; 768s, 690(sh), 631m, 571s; Raman ν/cm^{-1} (solid, KBr dilution, λ_e = 1064 nm): 944w, 880m [ν(V=O)/ν(Mo=O)]; UV–VIS λ_{max}/nm (degassed water): 498, 677 (VO^{2+} chromophore).

§ In an earlier investigation of the Mo^{VI}/V^{VI} system[3,4] it was erroneously proposed that solutions with a relative concentration Mo^{VI}/V^{IV} = 1 yield $K_2H_6[V_3Mo_3O_{19}]\cdot 7H_2O$ at pH 4.75 and the highly soluble product $H_8[V_3Mo_3O_{19}]$ at pH < 3.1. The authors assumed that both compounds would contain Lindquist-type anions.[3,5]

¶ *Crystal data* for **1**: $H_{480}Mo_{75}Na_{30}O_{550}S_{10}V_{20}$, M = 18 508.44, monoclinic, space group *C*2/*c*, a = 47.065(2), b = 43.157(2), c = 26.946(1) Å, β = 104.26°, U = 53045(4) Å^3, Z = 4, D_c = 2.318 g cm^{-3}, μ = 2.23 mm^{-1}, F(000) = 35 920, crystal size = 0.4 × 0.2 × 0.1 mm. Crystals of **1** were removed from the mother-liquor and immediately cooled to 183(2) K on a Bruker axs SMART diffractometer (Mo-Kα, graphite monochromator). A total of 155 219 reflections (1.56 < θ < 26.99°) were collected of which 57 074 unique reflections (R_{int} = 0.069) were used. An empirical absorption correction using equivalent reflections was performed with the program SADABS. The structure was solved using the program SHELXS-97 and refined using the program SHELXL-97 to R = 0.062 for 33 490 reflections with $I > 2\sigma(I)$. SHELXS/L , SADABS from G. M. Sheldrick, University of Göttingen, 1997; structure graphics with Diamond 2.1 from K. Brandenburg, Crystal Impact GbR, 1999. Because of the disorder, not all of the Na positions could be detected as is usual in the case of the said type of compounds. An initial view of the packing of the cluster anions suggested that they are linked through the $\{Mo\}_{5/2}$ units, parallel to the approximate fivefold symmetry axis. However a closer inspection of the corresponding under-occupied Mo centres, (which would correspondingly be responsible for the linking through Mo–O–Mo bridges, reveals that the anions are (probably) not connected at all. The fact that the occupancy factors of the Mo centres of adjacent anions add up to 1.0, indicating that these positions are *alternately* occupied, suggests that a connection of the clusters is improbable. The under-occupied Mo centres (occupancy factor between 0.25 and 0.75) cannot be treated as fully occupied V atoms due to the unrealistic number of terminal ligands (three including two terminal O atoms for octahedral V) and the V analysis. Additionally, as the terminal ligands are also under-occupied, fully occupied V atoms would have an incomplete coordination sphere. Furthermore the resulting necessary linkage of the clusters—owing to the full occupancy—would significantly increase the cluster charge which is impossible considering the Na analysis.

The remainder of the anion shows nearly no disorder. Only very few atoms show a O=Mo–OH_2 ↔ O=Mo–OH_2 disorder. The bond valence sums for the ordered Mo and the V positions lie in the ranges 5.8–6.1 and 4.1–4.2, respectively. Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (fax: (+49) 7247-808-666; E-mail: crysdata@fiz karlsruhe.de) on quoting the depository No. CSD391073.

Received (in Columbia, MO, USA) 20th April 1999, Accepted 23rd July 1999

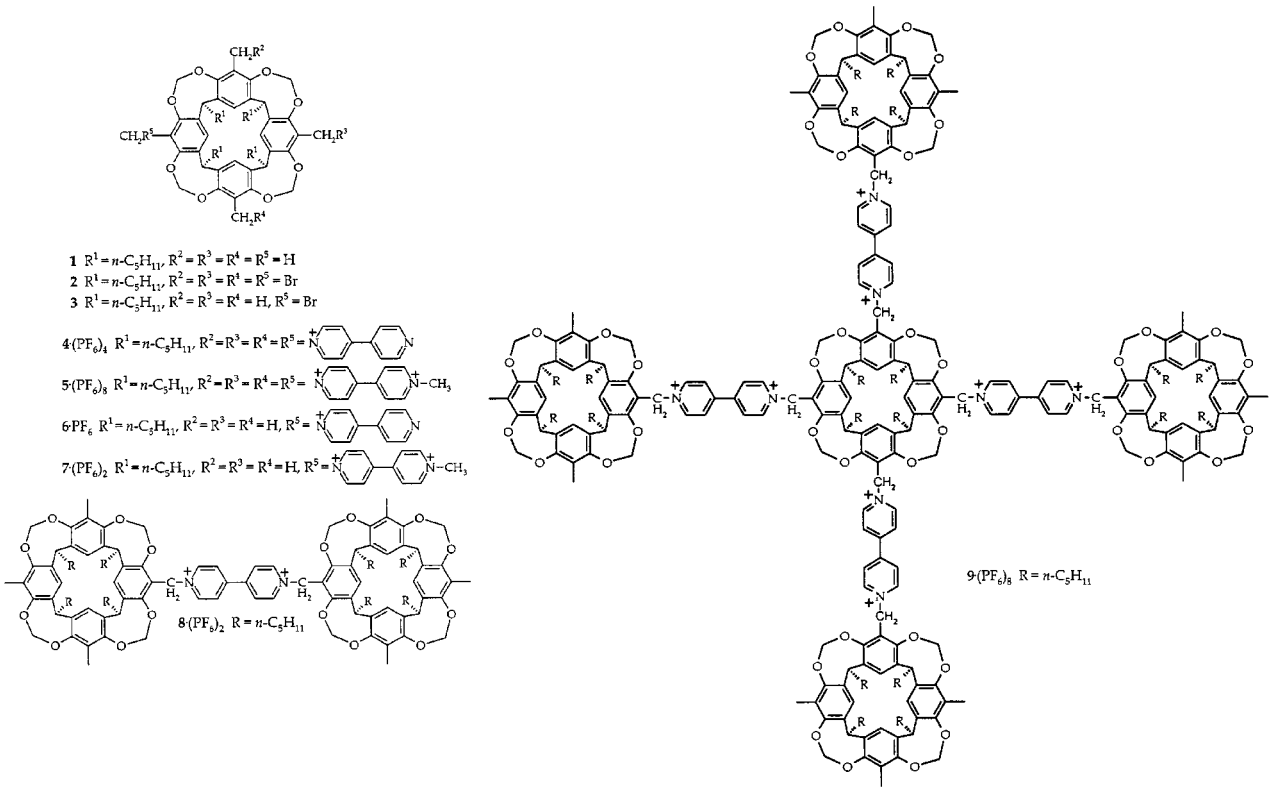
The synthesis and properties of a series of novel compounds containing one to five cavitand building blocks tethered by 4,4′-bipyridinium subunits is described.

Cavitands are bowl-shaped compounds that have attracted considerable attention in supramolecular chemistry as building blocks for the construction of carcerands, hemicarcerands, and other hosts.[1,2] Recently, Reinhoudt and co-workers reported the synthesis of tetrabromo cavitand **2** from **1**.[3] Here, we report the synthesis of the monobromo cavitand **3** and the utilization of the brominated cavitands **3** and **2** for the preparation of novel compounds containing several cavitand subunits interconnected by 4,4′-bipyridinium (bipy) tethers.

Treatment of **1** with 1 equiv. of NBS under reaction conditions similar to those used by Reinhoudt and co-workers[3] yields monobromo cavitand **3** as the main reaction product.[4] Reaction of **2** and **3** with excess 4,4′-bipyridine at 50 °C gives **4** or **6**, respectively, in high yield (> 90%).† Alkylation of these cavitands with MeI leads to the fully quaternized 4,4′-bipyridinium derivatives **5** and **7**, which were isolated as their PF_6^- salts after counterion exchange. Molecular modeling results obtained with **4**–**7** and single-crystal X-ray diffraction data for **4** suggest that both the partially and fully quaternized bipy subunits tend to orient themselves on or near the plane defined by the four benzylic carbons through which they are connected to the cavitand bowl. This is clearly evident in the X-ray crystal structure[5] of **4** (Fig. 1).

It is also possible to quaternize the free nitrogens in **4** or **6** by treatment with the monobromo cavitand **3**. Thus, reaction of **6** with 1 equiv. of **3** yields, after counterion exchange, the dimeric cavitand **8**. Similarly, the cruciform pentameric cavitand **9** was obtained by reaction of **4** with 4 equiv. of **3**.

The presence of partially or fully quaternized 4,4′-bipyridinium subunits confers redox properties to these compounds.[6] Their electrochemical behavior in MeCN solution was investigated using cyclic voltammetry. Each monoquaternized bipy residue exhibits a single one-electron reduction ($V^+ \rightarrow V$) and each diquaternized bipy subunit exhibits two consecutive one-electron reductions ($V^{2+} \rightarrow V^+$ and $V^+ \rightarrow V$). The half-wave potentials obtained in these experiments are given in Table 1. The voltammetric behavior of all the compounds having four reducible subunits reveals their non-interacting character, since only one wave is observed for each one of the reduction processes. The multi-electron character of some of these voltammetric waves may be responsible for the departure of the observed peak-to-peak potential differences from the theoretical values expected for Nernstian redox couples. The electrochemical behavior of **4** was strongly affected by precipitation of



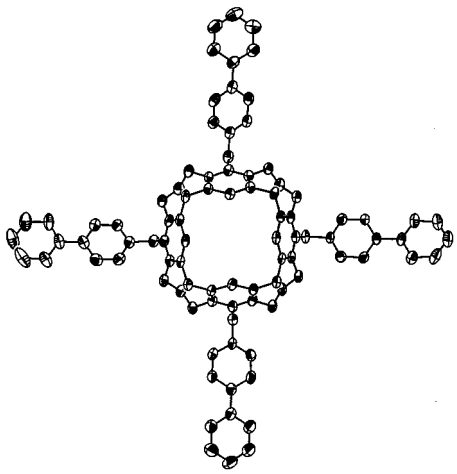


Fig. 1 X-Ray crystal structure of **4**. The four pentyl chains in the lower rim, hexafluorophosphate counterions and solvent molecules have been removed for clarity.

Table 1 Electrochemical[a] (half-wave potentials and peak-to-peak potential splittings) and spectroscopic parameters for **4**–**9**

the reduced form on the electrode surface. Compound **9** exhibited complicated voltammetric behavior that is currently under more detailed scrutiny.

Conceptually, these compounds provide an interesting example of covalent self-assembly. Notice that **9**, the largest compound reported here, has a molecular mass of 6138.6 daltons and a branching structure that is similar to that found in dendrimers. We are currently exploring bromination patterns for **1** that may result in different structures after reaction with 4,4′-bipyridine linkers.

The authors gratefully acknowledge the NSF (to A. E. K. CHM-9633434) for the support of this research work. C. P. is grateful to Xunta de Galicia for a postdoctoral fellowship and E. R. thanks the University of Miami for a Maytag graduate fellowship. K. A. wishes to acknowledge the NSF and the University of Florida for funding of the purchase of the X-ray equipment. The authors are grateful to Marielle Goḿez-Kaifer for conducting molecular modeling calculations with some of these compounds.

4 The reaction also produced small amounts of tribromo and dibromo derivatives that we are currently trying to prepare and isolate in larger yields.
5 *Crystal data* for **4**: $C_{104}H_{112}F_{24}N_8O_{12}P_4$, M = 2245.88, triclinic, space group $P\bar{1}$, a = 17.9704(9), b = 18.3237(9), c = 19.771(1) Å, α = 67.629(1), β = 67.447(1), γ = 78.767(1)°, V = 5550.9(5) Å^3, T = 173(2) K, Z = 2. Data were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing Mo-Kα radiation (λ = 0.71073 Å). Cell parameters were refined using up to 8192 reflections. A hemisphere of data (1381 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was < 1%). Absorption corrections by integration were applied based on measured indexed crystal faces. The structure was solved by the direct methods in SHELXTL5, and refined using full-matrix least-squares. The non-H atoms were treated anisotropically, whereas the methyl hydrogen atoms were calculated in ideal positions and were riding on their respective carbon atoms. Two of the R groups on the cation are disordered. They were refined in two parts each with their site occupation factors dependently refined. All four of the hexafluorophosphates are disordered and were refined with their geometries constrained to form perfect octahedra around the P atoms. The structure consists of the macrocycle cation, four hexafluorophosphates and a variety of solvent molecules most of which are disordered or partially present in the lattice. Some of the solvents identified and included in the refinement include MeCN, acetone, EtOH, MeOH and water. Because of the large lattice volumes occupied by disordered solvents, a precise formula weight could not be used but instead an approximate formula was used to reflect all that was refined. It should be noted that the refinement provided acceptable anisotropic models for the cation and four anions while all of the solvents were treated isotropically. A total of 1688 parameters, with 248 constraints, were refined in the final cycle of refinement using 14505 reflections with $I > 2\sigma(I)$ to yield R_1 and wR_2 of 8.46 and 20.58%, respectively. Refinement was done using F^2. CCDC 182/1372. See http://www.rsc.org/suppdata/cc/1999/1887/ for crystallographic data in .cif format.

Synthesis and spectroscopic properties of a new 4-bora-3a,4a-diaza-*s*-indacene (BODIPY®) dye

Heejin Kim, Armin Burghart, Mike B. Welch, Joe Reibenspies and Kevin Burgess*

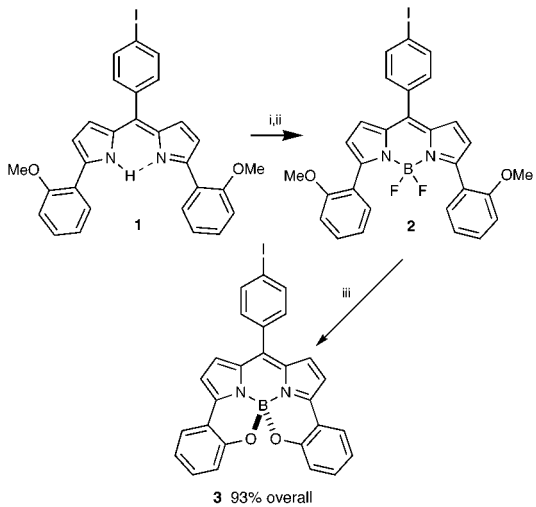
Department of Chemistry, Texas A & M University, PO Box 300012, College Station, TX 77842-3012, USA. E-mail: burgess@mail.chem.tamu.edu

Received (in Corvallis, OR, USA) 12th July 1999, Accepted 13th August 1999

The constrained dye 3 was prepared and shown to have a sharper, red-shifted, and more intense fluorescence emission than the 4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene (BODIPY®) dye 2 in which the aryl groups can rotate freely.

4,4-Difluoro-4-bora-3a,4a-diaza-*s*-indacene (BODIPY®) dyes[1] are highly fluorescent materials that have been used for several different applications.[2–5] Relatively recent efforts in our laboratories have focussed on syntheses of the new 3,5-diaryl-substituted BODIPYs of which compound **2** is typical.[6] The goal of this research was to increase the diversity of emission maxima available in the BODIPY series by introducing different substituents on the 3,5-diaryl rings. These studies were largely successful, but the 3,5-diaryl-substituted BODIPY dyes had diminished fluorescence intensities relative to similar alkyl-substituted systems. We hypothesized that this was due to dissipation of energy from an electronic excited state *via* a non-radiative process involving rotation of the aryl rings relative to the dipyrromethene core. Here we report the synthesis and investigation of the new structure **3**, work that was motivated by several considerations. First, the aryl rings in this system would not be able to spin about the aryl–pyrrole bond and this constraint could lead to enhanced fluorescence. Secondly, the ring system was completely new and might have interesting fluorescence properties. Moreover the structure should be accessible *via* demethylation of compound **1**.

A one-pot, two-step process, beginning with the dipyrromethene **1** proved to be the most convenient way to prepare compound **3** (Scheme 1).† It was isolated in high yield as a dark green solid that was stable at room temperature and to chromatography on basic alumina. The ^{11}B NMR spectrum of **2** gave a distinct triplet due to B–F coupling [δ −1.26, (t, J_{BF} = 30.6 Hz in $CDCl_3$ relative to $BF_3{\cdot}OEt_2$ external reference)], whereas the corresponding spectrum of **3** consisted of one singlet (δ −0.89).



Scheme 1 *Reagents and conditions*: i, Et_3N, PhMe; ii, $BF_3{\cdot}OEt_2$, 80 °C; iii, BBr_3, O to 25 °C.

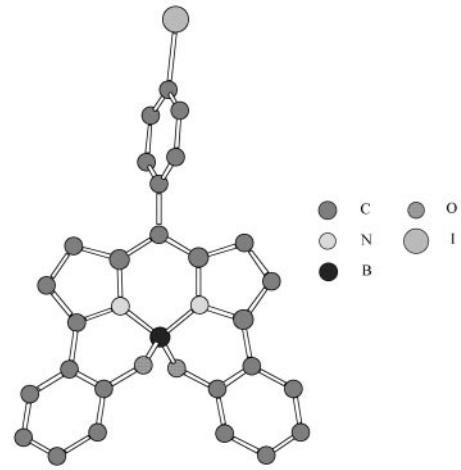


Fig. 1 Chem3D representation of **3** based on coordinates from the single crystal structure analysis.

It occurred to us that **3** is chiral, and the enantiomers of this compound might be separable at room temperature. No preparative resolution of this material has been accomplished, but HPLC analysis of pure racemic material on a Pirkle column [covalent (*S*,*S*) whelk-01 from Aldrich; Pr^{i}OH–hexanes eluant] gave two peaks. These were not baseline resolved, but they were distinct enough to indicate separation is possible.

X-Ray single crystal analysis of **3** revealed some interesting features (Fig. 1).‡ As expected, the 4-iodophenyl substituent is twisted with respect to the heterocyclic core. The tetrahedral structure of the boron in this molecule is slightly distorted. For instance, the O–B–O, N–B–N and O–B–N bond angles are 107.5, 105.5 and 115.4, respectively, showing progressively larger deviations from the perfect tetrahedral angle of 109.5°. Moreover, the torsional angles between the heterocyclic core and the 3- and 5-aryl substituents (25°) are considerably less than in the 4,4-difluoro-3,5-bis(1′-naphthyl)-BODIPY derivative (55°), whose structure was investigated recently.[7] The B–O and B–N distances are 1.47 and 1.52 Å, respectively.

Fig. 2 shows the UV absorption and fluorescence emission spectra of **2** and **3**, and some important data are presented in

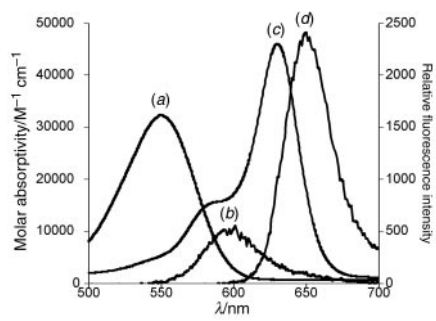

Fig. 2 Absorption (4 μM in $CHCl_3$) and fluorescence (1 μM in $CHCl_3$) spectra of **2** and **3**; (*a*) and (*b*) are absorption and fluorescence spectra of **2**; (*c*) and (*d*) are the corresponding spectra of **3**.

Table 1 Important UV and fluorescence data for **2** and **3**

	λ_{max}/nm (abs)[a]	ε/M^{-1} cm^{-1}	λ_{max}/nm (em)[a]
2	550	34 500	597
3	630	46 000	654

[a] In $CHCl_3$.

Table 1. The most striking difference between the emission spectra of **2** and **3** is that the λ_{max}(em) for the new ring system **3** is red-shifted by approximately 57 nm relative to the parent system **2**. This is probably due to extended conjugation in **3** as a result of the aryl substituents being constrained closer to planarity with the dipyrromethene nucleus. Fluorescence emission for **3** was also sharper than that of the parent BODIPY **2**; peak widths at half peak height for the emission spectra shown in Fig. 2 were 36 and 44 nm, respectively. Quantum yields for fluorescence of **2** and **3** were determined[8] in $CHCl_3$ relative to Cresyl Violet.[9] The quantum yield measured for **3** (ϕ = 0.41) is much higher than that obtained for **2** (ϕ = 0.07), validating the original premise of this work, *i.e.* that the constrained system **3** would be more fluorescent than the BODIPY system **2**.

Finally, cyclic voltammetry showed that **3** was irreversibly oxidized at a peak potential E_{pa} = +0.70 V (*vs.* ferrocene/ferrocenium at 100 mV s^{-1} in MeCN throughout), which is significantly lower than the oxidation potential of **2** (E_{pa} = +0.84 V). This implies that the rigidity of **3** allows for a more extended conjugation as compared to **2**. Both compounds are reversibly reduced at about the same potential (**3**: $E_{1/2}$ = −1.18 V, **2**: $E_{1/2}$ = −1.19 V).

In summary, the new fluorescent dye **3** gives a red-shifted, sharper fluorescence emission than the parent system **2**, and the quantum yield for its fluorescence was determined to be 5.5–6.0 times larger. It contains a unique chiral, heptacyclic core with a distorted N_2BO_2 unit. Possible applications for this new dye include studies of chiral molecular environments *via* fluorescence.

We thank Ben Lane for running the ^{11}B NMR spectra for this study, and Professor L. B.-Å. Johansson (Umeå, Sweden) for valuable discussions. Financial support for this work was provided by the NIH (HG01745) and The Robert A. Welch Foundation. A. B. thanks the Deutsche Forschungsgemeinschaft for a fellowship.

Notes and references

† *Synthesis* of **3**: Compound **2** was formed *in situ* from the corresponding dipyrromethene **1** (ref. 10) (100 mg, 0.179 mmol) in PhMe (5 ml) by addition of Et_3N (0.075 ml, 0.537 mmol), then BF_3•OEt_2 (0.113 ml, 0.896 mmol). This mixture was heated to 80 °C for 20 min to give the intermediate **2** *in situ*. The solution was cooled to 0 °C, BBr_3 (0.17 ml, 1.79 mmol) was added dropwise over 1 min, then the solution was allowed to warm to 25 °C and stirred for 5 h. The reaction mixture was filtered through Celite, concentrated and purified by column chromatography on basic alumina using 20% EtOAc–hexanes as eluant. Compound **3** was isolated as a dark green solid (90 mg, 93% yield): mp 295–296 °C; δ_H($CDCl_3$, 300 MHz) 7.89 (d, *J* 8.4, 2H), 7.77 (dd, *J* 7.8, 1.5, 2H), 7.46 (d, *J* 8.4, 2H), 7.31–7.36 (m, 2H), 7.03–7.07 (m, 2H), 7.04 (d, *J* 4.5, 2H), 6.95 (d, *J* 8.2, 2H), 6.91 (d, *J* 4.5, 2H); δ_B($CDCl_3$, 64 MHz) −0.89 (s); *m/z* (FAB) 538 (M^+); (HRMS: calc. [M^+] 538.0374, found [M^+] 538.0354).

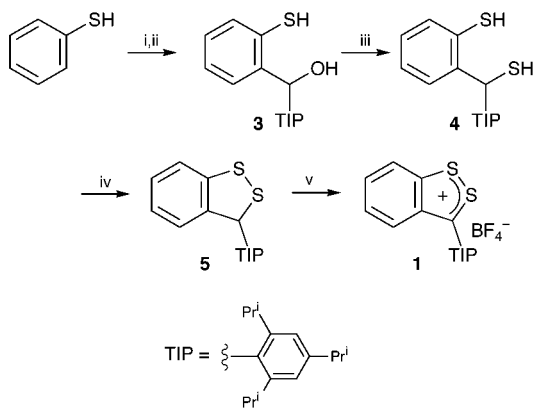
Received (in Cambridge, UK) 30th June 1999, Accepted 9th August 1999

The molecular structure of the sterically crowded 3-(2,4,6-triisopropylphenyl)-1,2-benzodithiolium cation has been determined by crystallographic studies on the BF_4^- salt and the corresponding novel 1,2-dithiolyl radical with a 7π electron framework has been isolated by one-electron reduction.

The unusual 7π electron structure of certain five-membered rings has allowed the construction of a unique reversible one-electron redox system. Recently, we reported reversible one-electron redox couples by the use of 4,7-disubstituted benzotrichalcogenoles and found by EPR spectroscopy that their radical cation salts obtained on treatment with a one-electron oxidant had unusual 7π frameworks.[1] However, to date, dithiolyl radicals with 7π electrons have so far only been obtained in solution as unstable species by electrochemical reduction or laser flash photolysis.[2] Herein we present the synthesis and structural determination by X-ray crystallographic analysis of the new sterically crowded dithiolium salt, 3-(2,4,6-triisopropylphenyl)-1,2-benzodithiolium tetrafluoroborate **1**, and the first isolation of a stable 7π radical, 3-(2,4,6-triisopropylphenyl)-1,2-benzodithiolyl **2**, by one-electron reduction. In addition, we have succeeded in the construction of a new type of one-electron redox system between **1** and **2** by means of both chemical and electrochemical methods.

3-(2,4,6-Triisopropylphenyl)-1,2-benzodithiolium tetrafluoroborate **1** was synthesized as follows (Scheme 1). We employed commercially available thiophenol as a starting material to prepare the desired cyclic disulfide compound. 2-Mercapto-2′,4′,6′-triisopropylbenzhydrol **3** was obtained in 59% yield by *ortho* lithiation[3] of thiophenol followed by the addition of 2,4,6-triisopropylbenzaldehyde, which was readily prepared by general methods.[4] Thiolation was performed upon treatment of the benzhydrol with P_2S_5 and *in situ* cyclization of the resulting dithiol **4** was carried out in the presence of I_2/Et_3N after displacement of the solvent from toluene to CH_2Cl_2. After usual work-up, the crude product was purified by column chromatography (silica gel, *n*-hexane) to give 3-(2,4,6-triisopropylphenyl)-3*H*-1,2-benzodithiole **5** quantitatively. The corresponding dithiolium salt **1** was prepared by a two-electron oxidation of dithiole **4** with 2 equiv. of $NOBF_4$ in quantitative yield.†



Scheme 1 *Reagents and conditions:* i, TMEDA (2.2 equiv.), BuLi (2.2 equiv.), cyclohexane, ii, 2,4,6-$Pr^i_3C_6H_2CHO$; iii, P_2S_5, toluene; iv, I_2, Et_3N, CH_2Cl_2; v, $NOBF_4$ (2.0 equiv.), THF–MeCN.

The structure of new dithiolium salt **1** has been fully characterized by physical and spectroscopic means, and its solid-state structure (recrystallized from benzene) was determined by single-crystal X-ray diffraction (Fig. 1).‡ In the solid state, the benzodithiolium unit is almost coplanar (the torsion angles $S_2S_1C_8C_7$ and $S_2C_3C_9C_4$ are 178.9 and −178.9°, respectively), with the 2,4,6-triisopropylbenzene ring very nearly orthogonal to the planar unit (the torsion angle $S_2C_3C_{10}C_{11}$ is 89°), which may arise from the steric repulsion between the bulky 2,6-isopropyl groups on benzene and the *ortho* proton on the benzene ring fused to the dithiolium ring. This conformation plays an important role in blocking radical dimerization, which is adopted *via* a cofacial alignment, resulting in the isolation of the corresponding radical (*vide infra*).

Cyclic voltammetry of **1** in MeCN at 20 °C under an Ar atmosphere exhibited well-defined reversible one-electron redox waves at $E_{1/2}$ = −0.51 V *vs.* Ag / 0.01 mol dm^{-3} $AgNO_3$.§ This result implies that dithiolium **1** provides a stable

neutral radical even at room temperature. The novel dithiolyl radical **2**¶ was isolated in the one-electron reduction of **1** with sodium metal in THF (Scheme 2). The structure of the first isolable dithiolyl radical **2**, a green solid, was determined by high-resolution MS and EPR spectroscopy. The EPR spectra of **2** in THF solution showed the multiple signals (g = 2.0049 G) attributable to a radical, and the a_H values were evaluated by the fitting of simulated spectra to the experiment spectrum (Fig. 2). In addition, the experimental values of the unpaired π spin density from the hyperfine splitting are in good agreement with those calculated by the simple Hückel and McLachlan's methods (Table 1). Using variable-temperature EPR spectra normalized by the Mn^{2+} on MgO standard, the intensities of the signals gradually decreased at low temperatures, but their hyperfine structure was unchanged, which suggests that the bulky substituent serves as an efficient protective group for spin-dimerization even at low temperature. Although it has not yet been possible to grow single crystals suitable for X-ray diffraction, unpaired π-electron density was delocalized over both the coplanar benzene and the five-membered heterocycle. Interestingly, the salt **2** undergoes one-electron oxidation to give **1** quantitatively by treatment with 1 equiv. of $NOBF_4$ (Scheme 2). Thus, the facile interconversion in the redox reactions of **1** and **2** has been ascribed to the unusual stabilization of the radical by the 7π electron framework.

Trichloroacetylhydrazones: new highly reactive alkylating agents

V. Atlan, L. El Kaim,* S. Lacroix and R. Morgentin

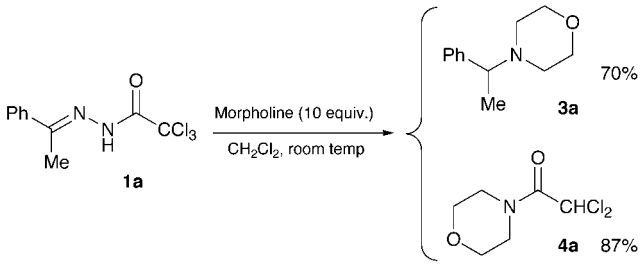
Laboratoire Réacteur et Processus, Ecole Nationale Superieure de Techniques Avancées, 75015 Paris, France. E-mail: elkaim@ensta.fr

Received (in Cambridge, UK) 22nd July 1999, Accepted 5th August 1999

The behavior of trichloroacylhydrazones as new highly reactive alkylating agents is disclosed; various secondary amines are alkylated within a few minutes at room temperature, and similar alkylating reductions were found with malonates.

Hydrazones are associated with a wealth of well-known reactions, such as the Wolf Kishner[1] and Shapiro[2] reactions and the Eischenmoser rearrangement.[3] In most of these fascinating reactions, loss of nitrogen is the driving force of the observed modifications. We recently reported a puzzling reaction of a class of poorly studied hydrazones, trichloroacetylhydrazones; when a number aldehyde derivatives were treated with K_2CO_3, clean conversion to 1,3,4-oxadiazoles was observed.[4] In order to have a better understanding of the behavior of these compounds, we decided to treat them in a different basic medium.

When hydrazone **1a** was treated with a large excess of morpholine in CH_2Cl_2, fast evolution of nitrogen was observed at room temperature along with the unexpected formation of the new alkylated amines **3a** and the dichloroacylamide **4a** (Scheme 1) as the only isolable compounds. The overall process from the carbonyl starting material is a reductive alkylation, as observed in the Leuckart reaction.[5] The reaction seems to be general, with ketone and aldehyde hydrazones **1** giving in a similar fashion the new alkylated amines **3** when treated with a large excess of amine **2** (Table 1). In most instances, the reaction was very clean and analysis of the crude product revealed that amines **3** and dichloroamides **4** were the only formed products; the pure amines **3** were most efficiently recovered through acid-base extraction and removal of the volatile secondary amine by evaporation. The poor isolated yield observed for **3f** was probably due to losses during evaporation of the morpholine. However, with aromatic ketones different behavior was observed when the morpholine was replaced by Et_2NH (or $Pr^i{}_2NH$); instead of the expected reduced compounds, formal oxidation of the ketone to the new α-amino hydrazone **5a** (or **5b**) occurred (Table 1).



Scheme 1

Under the same conditions, primary amines also gave a fast reaction with trichloroacylhydrazones, but no alkylation compounds could be recovered from the complex product mixtures.

The use of a large excess of secondary amine could be a serious drawback for the application of this chemistry to other nucleophiles. Even if the amount of amine could be lowered, at least 1 equiv. was always lost as a trap for the dichloroacyl group. A solution to this problem was eventually given by the observation that trichloroacylhydrazones were rather unreactive in ethanolic sodium ethanolate. When hydrazone **1e** was left to react in a EtONa (4 equiv.) solution in EtOH, no change was observed after 4 h at room temperature; when the same solution was refluxed for 5 h the new oxadiazole **10a** was formed in 48% yield (Scheme 2). This behavior was similar for various hydrazones tested. We then added hydrazone **1f** to a EtONa (1.2 equiv.) solution in absolute EtOH, observed after a quarter of an hour the absence of reaction, and then added to this mixture diethyl malonate (1.2 equiv.); the evolution of nitrogen was soon observed. The reaction was left at room temperature for one day, after which the usual workup gave the alkylated

Table 1 Isolated compounds after aminolysis of hydrazones **1**

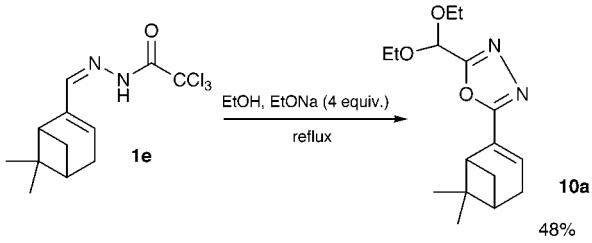
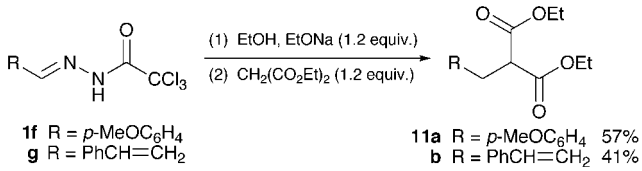


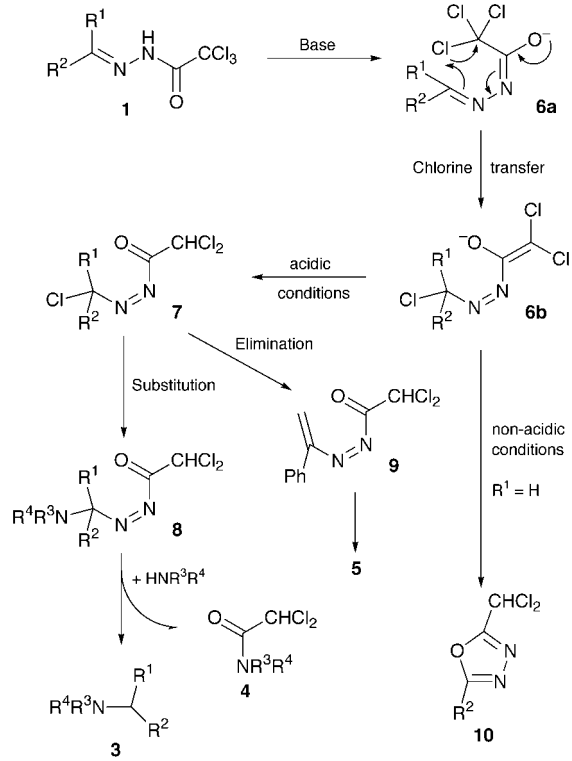
Scheme 2



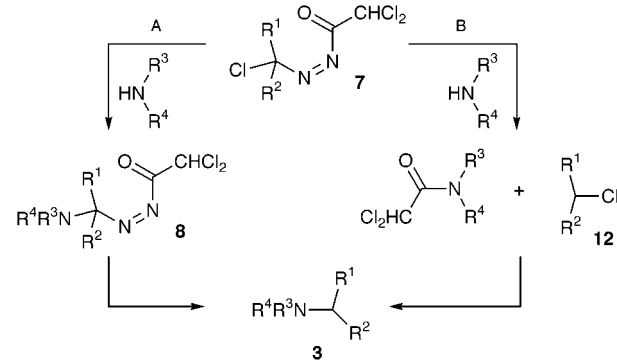
Scheme 3

malonate **11a** in 57% yield (Scheme 3). The same reaction with cinnamaldehyde hydrazone **1g** gave the new malonate **11b** in a poor 41% yield.

A reasonable mechanism for all these results is depicted in Scheme 4. The main assumption lies in a 1,5 chlorine migration from the anion. Such a migration has never been reported before but could be relevant in the results described by Yiannios *et al.* in 1968.[6] In our case the evolution of the resulting anion **6** depends on the nature of the substituted hydrazones (R = alkyl, aryl, H) and the basic conditions used in the reaction. When reprotonation of **6** is not possible (K_2CO_3, dioxane), a cyclisation to oxadiazole **10** is observed for aldehyde hydrazones giving reactive chlorides (R^1 = H, R^2 = aryl, alkenyl). When the medium is acidic enough (excess of amine and the presence of ammonium chloride salts), protonation of **6** to the α-chloroazo intermediate **7** may lead to the products through subsequent substitution and elimination reactions. With substrates sensitive to base elimination different behavior is observed: elimination of HCl from **7** (R^1 = Me, R^2 = Ph) leads



Scheme 4



Scheme 5

to azoalkenes **9** (Scheme 4) whose chemistry has been fully explored in Michael type additions or cycloadditions with nucleophiles;[7] in our case, their reaction with Et_2NH (or Pr^i_2NH) in excess gives the observed amino hydrazone **5a** (or **5b**). This elimination is best observed with poorly nucleophilic amines; indeed highest yields were obtained with Pr^i_2NH whereas the more nucleophilic morpholine led to tertiary amine **3a**.

The acidic requirements of this reaction are stressed by the experiments conducted in EtOH. The mixture of EtONa in EtOH is not acidic enough and no reaction is observed at room temperature, however the reaction starts as soon as the slightly acidic malonate is added in the mixture.[8]

The intermediacy of chloride **12** (Scheme 5, path A) was discarded in view of the sluggish reaction observed between morpholine and chlorocyclopentane in CH_2Cl_2. After 4 h at room temperature, no formation of amine **3f** was observed; hydrazone **1** under the same conditions gives amine **3f** within 10 min, revealing the highly electrophilic properties of the intermediate involved.

Trichloroacylhydrazones certainly deserve further study to fully understand the mechanism of these reactions and exploit their full potential, yet these reductive alkylations at room temperature are most noteworthy. Whatever the structure of the active alkylating agent generated under weakly basic conditions, it is much more reactive than the related chloride and can be generated from stable starting materials with weak bases. Besides their synthetic potential underlined here trichloroacylhydrazones could find useful applications in the biological field as masked alkylating species activated after interaction with a basic site of an enzyme receptor.

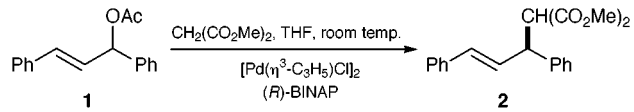
Received (in Cambridge, UK) 26th July 1999, Accepted 23rd August 1999

The enantiomeric excess of palladium-catalyzed allylic alkylations was greatly increased when Et_2Zn was used as the base to generate an anion from malonates.

Et_2Zn is a widely used nucleophilic agent. Examples include the ethylation of aldehydes,[1] 1,4-addition to α,β-unsaturated carbonyl compounds,[2] preparation of the Simmons-Smith reagent[3] and the umpolung reaction of π-allylpalladium.[4] Furthermore, Et_2Zn is known to be a weak Lewis acid to which oxygen, nitrogen and halogens can coordinate.[5] To the best of our knowledge, it has not been used as a base to generate zinc enolates. These are routinely generated *in situ* by metal–metal exchange with other metal enolates. Since the other metal coexists together with zinc in the reaction medium, it is obvious that the aggregation state is quite different from that of zinc enolates free from other metals, which may affect the stereochemical outcome of the reactions. We report here a remarkable enhancement of the enantiomeric excess (ee) in a palladium-catalyzed allylic alkylation using zinc enolates free from other metals, generated with Et_2Zn as a base.

We have chosen the reaction shown in Scheme 1 as a standard reaction to evaluate the effect of zinc enolates free from other metals.[6] Et_2Zn is known to be basic enough to form a zinc alkoxide when it is mixed with an alcohol.[7] Based on the pK_a values of alcohols and the malonate, we can expect that a hydrogen of the active methylene group of dimethyl malonate will be removed by Et_2Zn. A popular chiral ligand, (*R*)-BINAP,



1 **2**

Scheme 1

was used for the reaction and the results are listed in Table 1. A zinc enolate prepared by metal exchange from the corresponding sodium enolate showed a considerable increase in ee, although the reactivity decreased (entries 2 and 3). A significant difference in ee was not observed between the lithium enolates and the zinc enolates generated by exchange from the lithium enolates (entries 5–8). A remarkable increase in ee was observed when the zinc enolate that was directly generated with Et_2Zn was used (entry 9). These findings indicate that the aggregation state of the zinc malonate prepared with Et_2Zn is different from that prepared by metal exchange, although it is premature to present an explanation for the increase in enantioselectivity with zinc enolate free from other metals. Temperature affects the reaction rate, but not the ee, when zinc enolate free from other metals is used (entries 9–11).

The results of allylic alkylations with various nucleophiles are listed in Table 2. Zinc enolates generally gave ees greater than those with sodium enolates at room temperature. Zinc enolates generated from malonic acid derivatives again gave comparable ees at various temperatures (entries 1,2 and 10, 11), but the ee decreased markedly at higher temperature with other enolates (entries 4, 5 and 7, 8).

Remarkably high ees were observed in the alkylation of other allylic acetates **3**–**5** and **9** with the zinc malonate (Table 3). The

general tendency of zinc malonates described previously is observed in these cases. Thus, the zinc enolate gives greater ee than the sodium enolate and ees are not affected by differences in temperature.

In conclusion, we found that zinc malonates free from other metals can give high ees in allylic alkylations catalyzed by a palladium–(*R*)-BINAP complex. The present results suggest that zinc enolates free of other metals may be used to increase ees and/or chemical yields in other types of reactions involving enolates, although this application would be limited to highly acidic compounds.[9]

Received (in Cambridge, UK) 20th May 1999, Accepted 12th August 1999

The synthesis, characterisation and properties of an artificial ion channel containing a redox-active ferrocene unit are described.

During the last ten years substantial efforts have been made to mimic the action of natural ion channels[1] by the design and synthesis of model systems which would span natural (or artificial) lipid bilayers.[2–6] Generally speaking, the artificial channels consist of head groups (*e.g.* macrocyclic polyethers) to selectively capture specific cations, connected by long aliphatic chains designed to span the bilayers and often including a 'relay unit' which is sometimes another macrocyclic ether.[7] Alternative head groups include calixarenes[8,9] which, at least in one case,[9] support the concept of the 'billiard ball' effect, in essence, the charge repulsion theory of multiple ion transport.[10] In addition, synthetic proteins have been designed to mimic natural proteins, albeit with a single span rather than the multiple spans believed to exist in natural systems.[11] It is known that natural K^+ channels fall into two distinct categories.[12] The first is that of voltage-gated (K_v) channels which open and close ('gate') in response to the potential across the cell membrane. They have six trans-membrane domains, the fourth one of which has a positive charge every third residue and hence acts as the voltage sensor. The second category is that of the inward rectifier (K_{ir}) which consists of two trans-membrane domains connected by a loop which allows transport of K^+ ions in one direction only against the natural concentration gradient. This paper reports the synthesis, characterisation and properties of a one-domain artificial ion channel containing a redox-active centre (a ferrocene unit) in the middle of the channel to act as a 'filter'[10] and to influence the passage of cations by changing the oxidation state of the ferrocene during ion transport. The only redox-mediated channels of which we are aware are two C-terminus ferrocene derivatives of the *natural* peptide alamethicin which were shown to undergo dramatic changes in channel activity across lipid bilayers on *chemical* oxidation with excess ceric ion.[13]

The overall synthetic strategy, based on the inspirational work of Gokel *et. al.*,[2–5] was to link two macrocyclic units (as head groups) *via* long aliphatic chains to a central ferrocene unit which would also act as a cation relay. The resultant channel was designed to be approximately 30 Å long, the thickness of a typical biological membrane. The hydrophobic nature of the aliphatic chains was expected to promote lipid solubility and variation of the ring size in the head groups was expected to control cation selectivity. The precise synthetic sequence, shown in Scheme 1, afforded the target channel as a viscous orange oil in an overall yield of 16% from *N*-Boc-diaza-18-crown-6. Each compound in the synthetic sequence was purified by chromatography (Al_2O_3) and characterised by high resolution mass spectrometry and a combination of ^1H and ^{13}C NMR using DEPT (135).[14]

Cyclic voltammetry (CV) studies in MeCN as solvent with Bu_4NClO_4 (0.2 M) as the supporting electrolyte and using a glassy carbon working electrode gave rather curious results. A strong oxidation wave was observed at *+727* mV but the corresponding reduction wave failed to appear over a range of scan rates from 20–200 mV s^{-1} (Fig. 1).† Ferrocene amides of the type incorporated in the channel normally give a well-behaved electrochemical response[15] and the results suggest some sort of fast decomposition of the oxidised channel on the glassy carbon electrode or a rapid conformational change which inhibits the reduction process.‡ This feature of the electrochemistry is currently being investigated further. Introduction of two of the biologically important cations (Na^+ and Ca^{2+}) in increasing stoichiometric ratio from 1:1 to 1:10 ($L:M^{n+}$) produced perturbations of the oxidation wave and the results are shown in Table 1. During the initial additions of Na^+ (up to 1:3 stoichiometry) anodic shifts of various magnitudes were observed which is consistent with coordination of the Na^+ ion by the amide functions of the ferrocene unit. Addition of further equivalents of Na^+, however, produced a reversal of the shifts to slightly more cathodic values. It is difficult to rationalise this observation but one explanation may be that as the channel fills with cations, charge repulsion may reduce coordination by the

amide carbonyls, thus *reducing* the 'through bond' electron withdrawal from the ferrocene centre. With Ca^{2+}, however, the shift continued to be anodic throughout the concentration range, which may be due to the stronger coordination of the amide functions with the higher charge density Ca^{2+} ion. It should also be noted that addition of excess cations regenerated, at least in part, the reversibility of the CV wave.

An 'inside-out' patch excised from cells derived from Hamster brain§ was exposed to a solution of the synthetic channel and then tested for K^+ transport with potentials ranging from +60 to −60 mV across the membrane. The results against a control are shown in Fig. 2. Analysis of the data shows clear evidence of ion transport *promoted* by the artificial channel at both negative and positive pipette potentials. In addition, changing the potential across the patch from −60 to +60 mV results in a reduction of the transmembrane current (*i.e.* rectification) as the inside of the cell changes from negative to positive potential. For example, at −80 mV the average single channel current amplitude was −4.0 pA (equivalent to a conductance of 50 pS) whereas at +80 mV the same average current was +2.4 mA (30 pS). The results suggest the incorporation of an artificial channel with a degree of voltage control over cation transport. It is conceivable, however, that **6** is in some way activating endogenous channels within the biological membrane and hence lipid bilayer experiments are in progress to check this possibility. The details of this work will be published at a later stage but for now we report that **6**, together with several analogues, has shown similar channel activity in lipid bilayers to that reported by Gokel for non-redox-active artificial channels.[7,16,17] Thus the results obtained with the biological membrane may be viewed with more confidence as an example of an *artificial* channel with a degree of redox control over cation transport, one step nearer to the natural system.

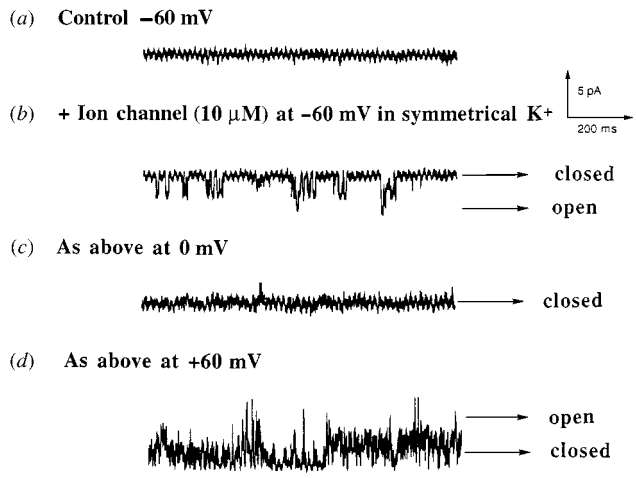

Fig. 2 Recordings of K^+ transport across an 'inside-out' patch when exposed to a solution of **6** (at 10 μM) and with a potential difference across the channel varying from −60 to +60 mV.

Welham (ULIRS, School of Pharmacy, Brunswick Sq., London WC1 1AX) for high-resolution mass spectra and to Jane Hawkes and John Cobb King's College and ULIRS for NMR spectra.

Notes and references

† The analogous cobalticenium hexafluorophosphate channel (to be reported later) gave well-behaved, fully reversible electrochemistry.
‡ Similar results were obtained using a Pt working electrode except that the current response was much lower for the same concentration.
§ Hypothalamic neurons were acutely dissociated from coronal hampster (5–15 day old) brain slices and superfused with a solution containing NaCl (140 mM) , KCl (2.5 mM), $CaCl_2$ (3 mM), glucose (3 mM) and HEPES (pH 7.4, 10 mM). Channel currents were recorded from inside-out patches using standard techniques. Fire-polished, borosilicate glass pipetttes were fabricated with a two-stage pull and filled with a solution containing: KCl (125 mM) , NaCl (10 mM), $CaCl_2$ (3 mM), glucose (3 mM) and HEPES (pH 7.4, 10 mM) which typically had resistances of 5–10 MΩ. After excision, the patches were held at indicated pipette potentials and the cell bathing solution was replaced with the above pipette solution. The artificial channel solution (in DMSO) was dissolved in the bathing solution (usually at 10 μM) and introduced to the patch at equivalent flow rates to the control. All currents were acquired using an Axoclamp 200A interfaced to a computer running pClamp6 software (Axon Instr.). Data were fitted at 1 kHz with a low-pass 8-pole Bessel filter, sampled at 4 kHz and analysed using pClamp6.

A highly active solid superacid catalyst for *n*-butane isomerization: persulfate modified Al_2O_3–ZrO_2

Y. D. Xia, W. M. Hua, Y. Tang and Z. Gao*

Department of Chemistry, Fudan University, Shanghai 200433, P.R. China

Received (in Cambridge, UK) 15th June 1999, Accepted 23rd August 1999

A new solid superacid catalyst of persulfate modified Al_2O_3–ZrO_2 has been prepared for the first time; it displays extraordinarily high catalytic activity and stability for the isomerization of *n*-butane.

In recent years, sulfated zirconia superacids have attracted increasing attention because they can give high activity at low temperature for *n*-butane isomerization, which has recently become a very important reaction in the petrochemical industry owing to growing environmental constraints and requirements for high-octane-number gasoline.[1–3] However, a rapid deactivation of this catalyst has often been observed at high temperature. In order to improve the lifetime of SO_4^{2-}/ZrO_2 catalysts for *n*-butane isomerization, the presence of hydrogen and/or addition of a small amount of Pt or Ni have been suggested.[4,5] Although Fe- and Mn-promoted sulfated zirconia are *ca.* three orders of magnitude more active than SO_4^{2-}/ZrO_2 for *n*-butane isomerization at low temperature,[6] they are deactivated quickly at 250 °C in the presence of hydrogen or at 60 °C in the presence of nitrogen.[7,8] We found that sulfated oxides of Cr–Zr, Fe–Cr–Zr and Fe–V–Zr were 2–3 times more active than sulfated Fe–Mn–Zr for *n*-butane isomerization, but these transition metal-doped sulfated zirconias also deactivated rapidly in the presence of hydrogen at high temperature.[8,9] In our previous results,[10,11] the addition of Al to sulfated zirconia significantly enhanced the activity and stability of the catalyst for *n*-butane isomerization at 250 °C in the presence of H_2. Persulfate modified zirconia is more active than sulfated zirconia for the isomerization of *n*-butane. The main problem in this research area is the durability of the catalyst during isomerization of *n*-butane. Here, we report a new solid superacid catalyst that is more active and stable for *n*-butane isomerization than any sulfated zirconia-based catalysts yet reported.

The new catalyst was prepared as follows: aqueous ammonia was added dropwise to a mixed solution of $ZrOCl_2{\cdot}8H_2O$ and $Al(NO_3)_3{\cdot}9H_2O$ until pH = 9–10. After washing the mixed hydroxide and drying at 383 K overnight it was immersed in 0.5 M ammonium persulfate solution for 30 min. The persulfated $Al(OH)_3$–$Zr(OH)_4$ was then filtered off, dried at 383 K overnight and calcined at 923 K in static air for 3 h. The new catalyst, a white solid, had a surface area of 80.8 $m^2\ g^{-1}$ and contained 3.0 mol% Al_2O_3 and 3.5 wt% sulfate. Sulfated zirconia was made for comparison in the same manner by immersing dried $Zr(OH)_4$ in 0.5 M sulfuric acid, followed by calcination at 923 K in static air for 3 h. The sulfated zirconia, also a white solid, had a surface area of 113.0 $m^2\ g^{-1}$ and contained 4.0 wt% sulfate. *n*-Butane isomerization on the catalysts was carried out at 523 K in a fixed-bed continuous flow reactor under ambient pressure with WHSV = 0.3 h^{-1} and an H_2 : butane molar ratio of 10 : 1. Before testing, each catalyst was pretreated *in situ* in dry air at 723 K for 3 h. The products were analyzed with an on-line gas chromatograph equipped with a flame ionization detector.

The major reaction product of *n*-butane isomerization at 523 K is isobutane and by-products are propane and isopentane. The selectivity to isobutane for the SO_4^{2-}/ZrO_2 and $S_2O_8^{2-}/Al_2O_3$–ZrO_2 catalysts is > 95%. Table 1 shows the variation of the conversion of *n*-butane at 523 K with time on stream for both catalysts. During the initial 1 h of reaction both catalysts are rapidly deactivated. After being on stream for 2 h the conversions of both catalysts then drop more slowly. The $S_2O_8^{2-}/Al_2O_3$–ZrO_2 catalyst reaches a steady state for *n*-butane isomerization after 2 h on stream (although it deactivates more rapidly than SO_4^{2-}/ZrO_2 during the initial 1 h of reaction), indicating that it is more stable than SO_4^{2-}/ZrO_2 for the reaction of *n*-butane isomerization. Both the initial and steady state activities of the $S_2O_8^{2-}/Al_2O_3$–ZrO_2 catalyst are much higher than those of SO_4^{2-}/ZrO_2. As compared with SO_4^{2-}/ZrO_2, $S_2O_8^{2-}/Al_2O_3$–ZrO_2 is 2.1 times more active after being on stream for 6 h.

The stability of the $S_2O_8^{2-}/Al_2O_3$–ZrO_2 catalyst has been investigated by running the reaction at 523 K continuously for 200 h. As illustrated in Fig. 1, the initial conversion on $S_2O_8^{2-}/Al_2O_3$–ZrO_2 is 51.8%, dropping to 37.8% after 2 h, and then remaining constant at *ca.* 37.4% up to 200 h without further observable deactivation. In other words, *n*-butane isomerization proceeds steadily on $S_2O_8^{2-}/Al_2O_3$–ZrO_2 at a level of 72% of its equilibrium conversion. In view of its high isomerization activity and stablity, $S_2O_8^{2-}/Al_2O_3$–ZrO_2 can be regarded as an excellent candidate for a commercial-scale *n*-butane isomerization catalyst.

After running on stream for 6 h, the amount of coke deposited on the $S_2O_8^{2-}/Al_2O_3$–ZrO_2 catalyst is 1.0 wt%, which is

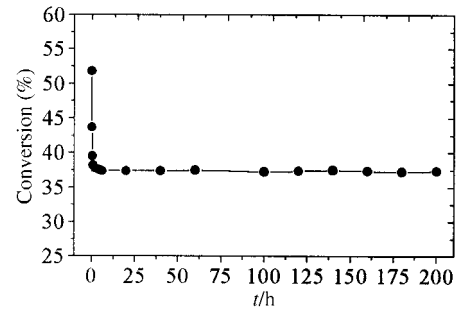

Fig. 1 Long-term test of $S_2O_8^{2-}/Al_2O_3$–ZrO_2 catalyst for *n*-butane isomerization at 523 K.

Table 1 Activities of solid superacid catalysts for *n*-butane isomerization at 523 K

	Conversion (%)							
Catalyst	2 min	10 min	60 min	120 min	180 min	240 min	300 min	360 min
SO_4^{2-}/ZrO_2	27.7	25.2	23.5	21.6	20.4	19.3	18.1	17.5
$S_2O_8^{2-}/Al_2O_3$–ZrO_2	51.8	43.7	38.2	37.8	37.7	37.7	37.4	37.3

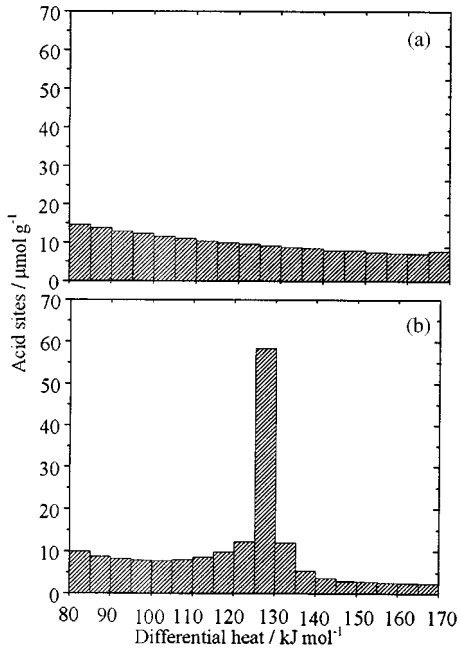

Fig. 2 Histograms of acid strength distributions for (a) SO_4^{2-}/ZrO_2 and (b) $S_2O_8^{2-}/Al_2O_3–ZrO_2$ catalysts.

slightly less than that on SO_4^{2-}/ZrO_2 (1.3 wt%). Furthermore, the amount of coke deposited on $S_2O_8^{2-}/Al_2O_3–ZrO_2$ remained almost unchanged from 6 to 200 h, showing that the initial drop in activity during 0–2 h is probably caused by catalyst coking; after this time coking and deactivation slowed down. Both catalysts can recover their activities completely after treatment in air at 723 K and can be used repeatedly, further demonstrating that the fast deactivation of the catalysts during the initial period of the reaction is mainly caused by coking.

Microcalorimetric measurements of NH_3 adsorption on SO_4^{2-}/ZrO_2 and $S_2O_8^{2-}/Al_2O_3–ZrO_2$ catalysts were conducted. The differential heat of adsorption (*i.e.* heat generated after microadsorption on the adsorption system which has already reached equilibrium) decreases with increasing NH_3 coverage, indicating a distribution of acid site strength in both catalysts. Fig. 2 shows histograms of the distribution of acid site strengths. The strengths of the acid sites on SO_4^{2-}/ZrO_2 are more evenly distributed than for $S_2O_8^{2-}/Al_2O_3–ZrO_2$. Although the total amount of acid sites with a differential adsorption heat above 80 kJ mol^{-1} for $S_2O_8^{2-}/Al_2O_3–ZrO_2$ (174.2 μmol g^{-1}) is nearly the same as that for SO_4^{2-}/ZrO_2 (178.2 μmol g^{-1}), the former posseses 2.9 times more acid sites with a differential heat between 125 and 140 kJ mol^{-1}, which have been reported in an earlier study[12] as being the effective

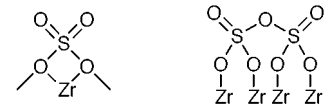

Fig. 3 Structure of active sites **I** and **II**.

active sites for *n*-butane isomerization. Hence, the abundance of sites with intermediate acid strengths on $S_2O_8^{2-}/Al_2O_3–ZrO_2$ is the main reason for its remarkable activity and stability for the *n*-butane isomerization reaction. Our recent study[11] has shown that the characteristic stretching frequency of covalent S=O bonds for persulfate modified zirconia is at 1398 cm^{-1}, which is different from that for SO_4^{2-}/ZrO_2 at 1388 cm^{-1}; we postulate that $S_2O_7^{2-}$ is responsible for this stretching frequency in agreement with earlier studies.[13,14] On the persulfate modified oxide superacid, the main structure of the active sites is **II** (Fig. 3), whereas active site **I** predominates on the sulfated oxide superacid. The difference in the structure of the active sites for each of the catalysts is probably another reason why the catalytic activity and stability of $S_2O_8^{2-}/Al_2O_3–ZrO_2$ for the isomerization of *n*-butane are much higher than those of SO_4^{2-}/ZrO_2.

Highly active Pd^{II} cyclometallated imine catalyst for the Suzuki reaction

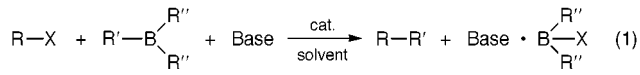
Haim Weissman and David Milstein*

Department of Organic Chemistry, The Weizmann Institute of Science, 76100 Rehovot, Israel.
E-mail: comilst@weizmann.weizmann.ac.il

Received (in Cambridge, UK) 2nd August 1999, Accepted 19th August 1999

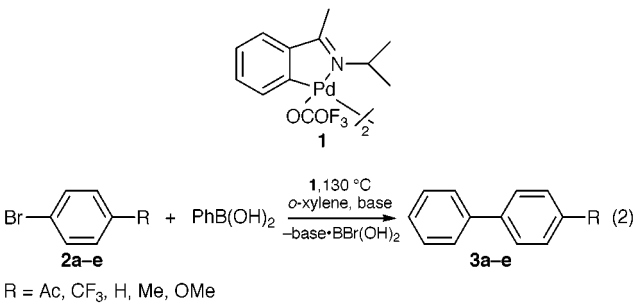
The cyclopalladated, phosphine-free imine complex 1 is an excellent catalyst for the Suzuki cross-coupling, leading to more than 10^5 turnovers with non-activated aryl bromides; the catalyst is air and thermally stable.

The Suzuki palladium-catalyzed cross-coupling reaction of organoboron compounds with organic halides or related electrophiles [eqn. (1)] represents a useful synthetic method for carbon–carbon bond formation and has attracted much current



interest.[1] Usually palladium phosphine complexes are utilized as catalysts and the reactions are conducted under inert atmosphere. Palladium–carbene complexes and other phosphine-free catalysts have been recently utilized.[2] Very efficient catalysis of the Suzuki reaction using palladium complexes incorporating cyclometallated phosphine and phosphite complexes have recently been reported.[3]

We have reported on highly active PCP-type[4] and cyclometallated imine[5] catalysts for the Heck reaction. The phosphine-free imine complexes lead to more than a million turnovers in some cases. Furthermore, the catalysts are very thermally and air stable and can be recovered after catalysis. We now find that the palladium imine catalyst **1**† is among the best known for the Suzuki reaction. It catalyzes the coupling of aryl bromides with phenylboronic acid in extremely high efficiency [eqn. (2)].



The general procedure for the coupling reaction is as follows: to a solution containing 2.5×10^{-5} mmol of catalyst **1** were added 5 mmol of 4-BrC_6H_4R (1:200000 catalyst:substrate ratio), 7.5 mmol of $PhB(OH)_2$ and 10 mmol of K_2CO_3. The mixture was heated to 130 °C with stirring in 13 ml of *o*-xylene (distilled from Na/benzophenone) under air or N_2 atmosphere. The reaction was usually over after 2 h. The reaction mixture was sampled and analyzed by GC and GC-MS techniques. Typical results are presented in Table 1.

Our catalytic system is one of the most active, especially with respect to the non-activated aryl bromides **2a**–**c**. Increasing the amount of phenylboronic acid (from 1.5 to 2 equiv. relative to the bromide) had a beneficial effect on the yield. Similar results were obtained when a nitrogen atmosphere was used. The reaction is not very sensitive to the solvent used, as similar results were obtained in dioxane.‡

In order to gain insight into the mechanism of the reaction, a competitive reaction with the five aryl bromides **2a**–**e** was performed under pseudo-first order conditions with respect to $PhB(OH)_2$. A solution containing 2.5×10^{-5} mmol of catalyst **1**, 5 mmol of each of the bromides **2a**–**e**, 0.75 mmol of $PhB(OH)_2$ and 1 mmol of K_2CO_3 was heated at 130 °C with stirring in 13 ml of *o*-xylene under air. The concentrations of the various coupling products were determined by GC. The resulting Hammett plot is exhibited in Fig. 1.

The use of σ_P^- constants results in a better fit than σ_P constants, indicating some conjugation of π-electron density with the *para* substituent in the transition state. The correlation yields a value of $\rho \approx 1$. While this electronic effect is not surprising, since electron withdrawing substituents are expected to accelerate the Ar–Br oxidative addition step, the ρ value is too low to fit a rate-determining nucleophilic aromatic substitution. For example, a ρ value of 5.2 was obtained for oxidative addition of aryl chlorides to electron rich Pd^0 complexes.[6] This indicates a subsequent rate-determining step with different electronic requirements, such as the transmetallation step. It is noteworthy that a similar value of $\rho = 1.34$ was obtained for the Heck reaction of aryl iodides involving PCP–Pd^{II} catalysts, which is unlikely to proceed by the traditional Pd^0/Pd^{II} mechanism.

Table 1 Suzuki coupling catalyzed by the imine complex **1** according to eqn. (2)

ArBr[a]	Catalyst/substrate ratio	Base (mmol)	$PhB(OH)_2$ (mmol)	Atmosphere	Yield (%)	TON (10^3)	*t*/h[b]
4-BrC_6H_4OMe	5×10^{-6}	K_2CO_3 (10)	7.5	N_2	51	102	16
	5×10^{-6}	K_2CO_3 (10)	7.5	air	57	114	16
	5×10^{-6}	K_2CO_3 (11.5)	10	air	60	120	3
	5×10^{-6}	K_3CO_4 (10)	7.5	air	68	136	22
4-BrC_6H_4Me[c]	5×10^{-6}	K_2CO_3 (10)	7.5	N_2	78	156	16
	5×10^{-6}	K_2CO_3 (10)	7.5	air	82	160	16
PhBr	5×10^{-6}	K_2CO_3 (10)	7.5	N_2	66	132	2
	5×10^{-6}	K_2CO_3 (11.5)	10	air	90	180	3
4-BrC_6H_4Ac	1×10^{-6}	K_2CO_3 (10)	7.5	air	59	590	16
	1×10^{-6}	K_2CO_3 (11.5)	10	air	84	840	16
4-$BrC_6H_4CF_3$	5×10^{-6}	K_2CO_3 (10)	7.5	N_2	93	186	16
	5×10^{-6}	K_2CO_3 (10)	7.5	air	90	180	14.5

[a] Amounts: ArBr (5 mmol) *o*-xylene (13 ml). Reaction temperature: 130 °C. [b] This is the time after which the reaction was analyzed. It might have been over at an earlier stage. [c] The same catalytic activity was observed in dioxane as a solvent.

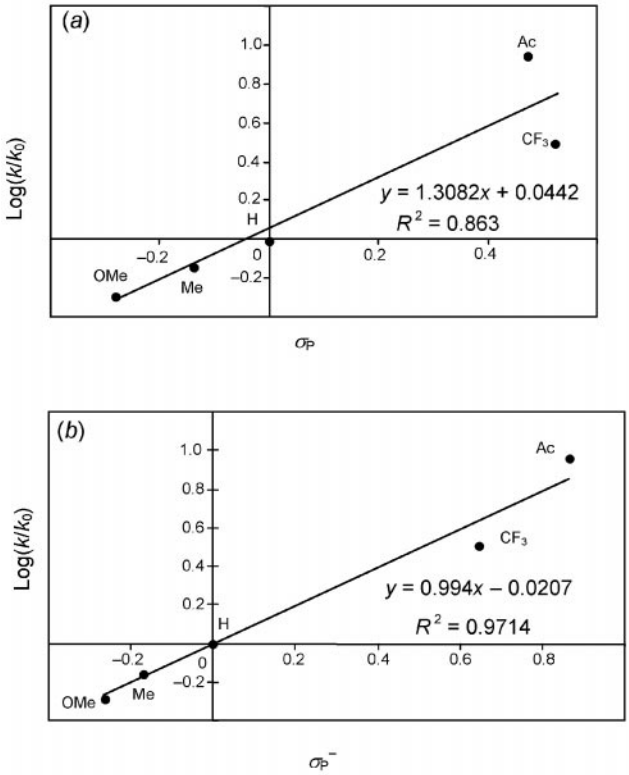


Fig. 1 Hammett correlation of the competitive reaction of aryl bromides with $PhB(OH)_2$ using (*a*) σ_P constants and (*b*) σ_P^- constants at 130 °C in *o*-oxylene.

In summary, the phosphine-free cyclopalladated imine complex **1** shows very high catalytic activity and yields in the Suzuki cross-coupling reaction of aryl bromides with phenylboronic acid. The system exhibits unprecedented turnovers with non-activated aryl bromides. The catalyst system is very thermally and air stable. Further investigations aimed at clarification of the scope and mechanism of this reaction are currently in progress.

Communication 9/06246G

An unprecedented 3D coordination network composed of two intersecting helices

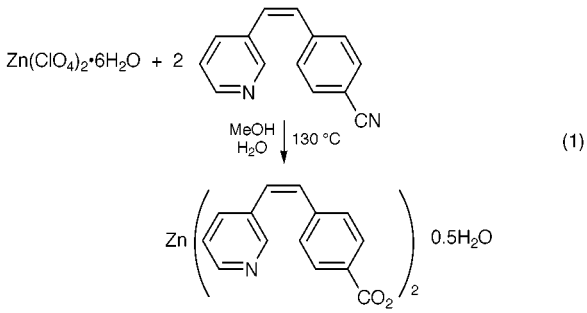
Owen R. Evans, Zhiyong Wang and Wenbin Lin*

Department of Chemistry, Brandeis University, Waltham, MA 02454, USA. E-mail: wlin@brandeis.edu

Received (in Columbia, MO, USA) 22nd June 1999, Accepted 9th August 1999

A hydro(solvo)thermal reaction between $Zn(ClO_4)_2·6H_2O$ and *Z*-3-(4-cyanostyryl)pyridine affords an unprecedented chiral 3D coordination polymer $Zn\{Z$-[4-2-(3-pyridyl)ethenyl]benzoate$\}_2·0.5H_2O$ with two intersecting six-fold helices, which shows a modest SHG activity owing to the essentially non-conjugate nature of the bridging ligand.

Chiral coordination networks are of great interest because of their potential utility in second-order nonlinear optical (NLO) applications,[1] chiral separations, and asymmetric catalysis.[2] Among many chiral structural motifs,[3] helices are of particular interest owing to their structural similarity to nucleic acids.[4] The chirality of such complexes has also shown potential in asymmetric catalysis.[2] We recently demonstrated the construction of acentric and chiral square grids using bifunctional *trans*-pyridylethenylbenzoate linking ligands.[1] In contrast, we believe that steric interactions in *cis*-pyridylethenylbenzoate will cause the pyridyl and phenyl group to significantly deviate from coplanarity. Such 'skewing' of coordination sites in the *cis*-pyridylethenylbenzoate should favor the formation of a helical structure. Herein we wish to report the synthesis and characterization of an unprecedented chiral 3D network resulting from the crosslinking of two distinct helices, $Zn\{Z$-[4-2-(3-pyridyl)ethenyl]benzoate$\}_2·0.5H_2O$, **1**.



Compound **1** was obtained in 60.5% yield by treating $Zn(ClO_4)_2·6H_2O$ and *Z*-3-(4-cyanostyryl)pyridine under hydro(solvo)thermal conditions [eqn. (1)].[5,6]† The IR spectrum of **1** shows two strong symmetric C=O stretches at 1361 and 1400 cm^{-1}, suggesting both monodentate and bidentate coordination of the carboxylate groups.[7] The formulation of **1** is supported by elemental analysis and thermogravimetric analysis results.[8]

A single crystal X-ray diffraction study of **1**‡ reveals an infinite 3D coordination polymer consisting of two distinct crosslinked helices. Compound **1** crystallizes in the chiral space group $P3_2$. The basic building block of **1** contains two crystallographically nonequivalent Zn atoms, four *Z*-[4-2-(3-pyridyl)ethenyl]benzoate (*Z*-L) ligands, and one solvated water molecule (Fig. 1).[9] The four *Z*-L ligands adopt two drastically different confirmations: the *Z*-L^1 and *Z*-L^2 ligands are similar with a dihedral angle of 47.2 and 4.75° between the phenyl and pyridyl rings, while the dihedral angles for the *Z*-L^3 and *Z*-L^4 ligands are 70.3 and 70.1°. The Zn1 center adopts a *cis*-octahedral configuration by coordinating to the carboxylate groups of *Z*-L^3 and *Z*-L^4 in a semichelating fashion and to the pyridyl nitrogen atoms of *Z*-L^1 and *Z*-L^2. In contrast, the Zn2 center adopts a tetrahedral geometry by coordinating to the carboxylate groups of *Z*-L^1 and *Z*-L^2 in a monodentate fashion and to the pyridyl nitrogen atoms of *Z*-L^3 and *Z*-L^4.

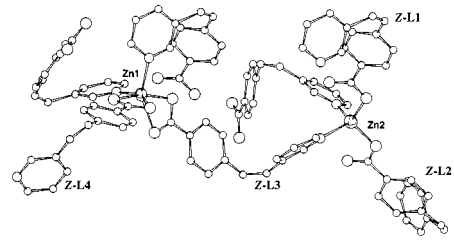


Fig. 1 Coordination geometry in **1** of Zn1 and Zn2 centers. The ellipsoids represent zinc centers, while the circles with increasing sizes represent C, N and O, respectively. Zn1–O distances: 2.084(4), 2.086(5), 2.319(5), and 2.335(5) Å; Zn2–O distances: 1.954(4) and 1.956(4) Å. The Zn–N distances range from 2.03 to 2.08 Å.

The Zn1 and Zn2 centers are bridged by *Z*-L^3 and *Z*-L^4 to form an infinite sixfold helix parallel to the *c* axis (the Zn–Zn separations are 12.15 and 12.16 Å, respectively). The helices directed by the *Z*-L^3 and *Z*-L^4 are of the right-handed screw type and will be referred to as the primary helix (Fig. 2). The primary helix has a helical period of 44.18 Å, and each helical repeat contains three Zn1 and three Zn2 centers.

Conformationally similar *Z*-L^1 and *Z*-L^2 ligands serve to link Zn1 centers of a primary helix to Zn2 centers of adjacent primary helices. Each primary helix is covalently linked to six

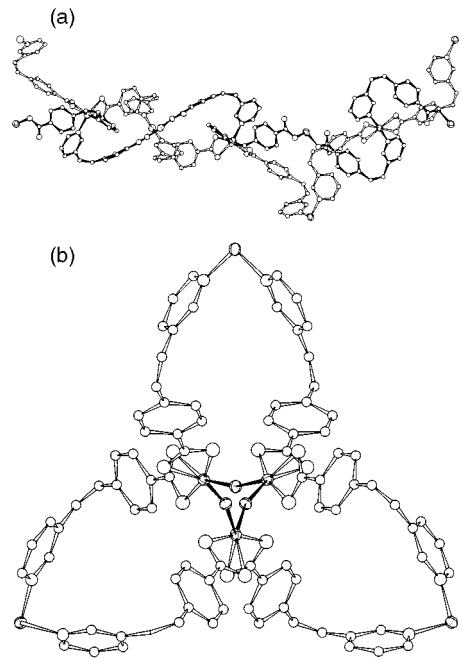

Fig. 2 A view of the cross-link between a primary helix and a secondary helix in **1** as shown down (a) the (111) face and (b) the *c* axis. The open bonds represent the primary helix,while the filled bonds represent the secondary helix. For clarity, the *Z*-L^1 and *Z*-L^2 ligands have been omitted in (b).

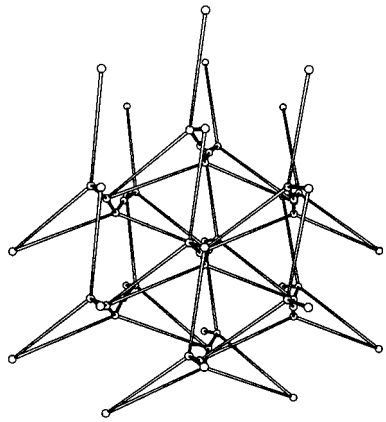

Fig. 3 A perspective view of **1** slightly away from the *c* axis showing the 3D network resulting from the crosslinking of primary helices with secondary helices. Only Zn atoms are shown. The primary helices are represented as open bonds, while the secondary helices are represented as filled bonds.

neighboring primary helices. The Zn–Zn separations (7.47 and 7.49 Å) along the *Z*-L[1] and *Z*-L[2] bridges are significantly shorter than those along the *Z*-L[3] and *Z*-L[4] bridges. More interestingly, the connectivity propagated by *Z*-L[1] and *Z*-L[2] results in the formation of a secondary sixfold helix parallel to the *c* axis [Fig. 2(b)]. The secondary helix is of the left-handed screw type and crosslinks the primary helices to afford an infinite 3D network (Fig. 3).

Many discrete helical structures[10] and infinite helical coordination polymers[11] have been synthesized over the past decade. In some of these helical structures, neighboring helices are connected to each other *via* crosslinking to form 3D networks.[12] However, the structure of **1** is unprecedented in that the 'crosslinks' (the secondary helices) in **1** also display a helical-type structure. Both Zn1 and Zn2 centers in **1** are rendered chiral *via* coordination to the carboxylate and pyridyl functionalities of the bridging ligands. Linking of chiral repeats units into a non-interpenetrated network has thus ensured the bulk chirality of **1**. Preliminary Kurtz powder second harmonic generation (SHG) measurements[13] indicated that **1** exhibits an expected modest powder SHG efficiency ($I^{2\omega}$ = 6 *vs.* α-quartz) because of the non-conjugate nature of the *Z*-L ligand. Future work is directed toward the synthesis of efficient NLO materials *via* the incorporation of highly conjugated linking ligands.

5 *Z*-3-(4-cyanostyryl)pyridine was prepared in 27% yield by a room-temperature Wittig reaction between (4-cyanobenzyl)triphenylphosphonium bromide and 3-pyridinecarboxaldehyde with NaOH as the base in dichloromethane. The product was purified by silica gel column chromatography [hexane–ethyl acetate (1 : 1)].

6 The slow hydrolysis of a cyanopyridine precursor to the desired pyridinecarboxylate ligand has been shown to be the key for the construction of polymeric coordination networks.[1b] Also see: O. R. Evans, Z. Wang, R.-G. Xiong, B. M. Foxman and W. Lin, *Inorg. Chem.*, 1999, **38**, 2969.

Macropolyhedral boron-containing cluster chemistry. The $[SB_{17}H_{19}]^-$ anion: a *nido*-ten-vertex : *arachno*-ten-vertex cluster architecture and the first single-sulfur macropolyhedral thiaborane

Received (in Cambridge, UK) 7th July 1999, Accepted 9th August 1999

Reaction of *syn*-$B_{18}H_{22}$ with metabisulfite gives a good yield of the first single-sulfur macropolyhedral thiaborane, the $[SB_{17}H_{19}]^-$ anion, which exhibits the unusual *arachno–nido* two-borons-in-common cluster fusion mode.

In the development of boron-containing cluster chemistry, the inhibiting cluster-size limit of about twelve to fourteen vertices that is a characteristic of single-cluster chemistry can be exceeded by the intimate fusion of smaller clusters to generate fused-cluster 'macropolyhedral' species. Of the known macropolyhedral species, the thiaboranes constitute very malleable molecular matrices with which to examine and extend the variety of structure available in this macropolyhedral boron-containing cluster chemistry.[1,2] However, all previously reported species have been dithiaboranes, and macropolyhedral monothiaboranes have, surprisingly, previously been lacking. Here we now report the first macropolyhedral monothiaborane, the $[SB_{17}H_{20}]^-$ anion, of *nido*-decaborano-(8′,7′:5,10)-*arachno*-6-thiadecaboranate constitution, obtained in good yield from the reaction of *anti*-$B_{18}H_{22}$ with potassium metabisulfite, $K_2S_2O_5$. Although metabisulfite and sulfite reactions have previously been used for sulfur-atom incorporation into single-cluster heteroboranes,[3] they have not previously been applied to binary boranes or to macropolyhedral species.

Four portions of $K_2S_2O_5$ (4 × 0.5 g, total 2.0 g) were added at 6 h intervals to a stirred solution of *anti*-$B_{18}H_{22}$ (0.2 g, 910 μmol) in a mixture of thf (40 cm^3) and dilute HCl (*ca*. 4 M, 30 cm^3). Stirring was continued for 2 days at ambient temperature, the mixture was filtered from the solid residue, and a solution of $[PPh_4]Cl$ (0.4 g, 1.07 mmol) in H_2O (20 cm^3) added to the filtrate. After evaporation *in vacuo*, the solid residue was extracted with CH_2Cl_2 (2 × 20 cm^3), the extract dried, filtered, and then subjected to column chromatography (silica gel, 2 cm × 20 cm) using CH_2Cl_2 as eluent. The fraction with R_F 0.22 [analytical TLC, silica G on aluminium (silufol, Kavalier, Prague), 100% CH_2Cl_2] was collected, filtered, evaporated and recrystallised from chloroform–hexane to give $[PPh_4][SB_{17}H_{20}]$ (380 mg, 656 μmol, 72%). No other chromatographically mobile products were found in significant amounts. The preparation is reproducible at the 70% level.

This product was characterised by an all-atom single-crystal X-ray diffraction analysis (Fig. 1)† allied with corroborative NMR spectroscopy.‡ The cluster architecture of the $[SB_{17}H_{20}]^-$ anion is seen to derive formally from the fusion of the structure of an [*arachno*-6-$SB_9H_{12}]^-$ anion [4] with a *nido*-$B_{10}H_{14}$ structure, with two boron atoms held in common [schematic connectivity structures **I** and **II**, unlettered vertices are BH(*exo*) units]. In accord with this, the NMR data for the two subclusters trace to the respective shielding patterns of the [*arachno*-6-$SB_9H_{12}]^-$ anion[5] and *nido*-$B_{10}H_{14}$, which have mutually distinct shielding patterns, there being a typical inversion of shielding sequence when otherwise equivalent positions in *nido* and *arachno* ten-vertex clusters are compared.[5] There are only three significant deviations from these shielding parallels: (a) for the *conjuncto* B(10) position the shielding, at $\delta(^{11}B)$ −3.0 differs substantially from either single cluster model, but is nevertheless between the positions observed for the two models (δ +10.2 and −33.8), which is expected; (b) the *nido*-decaboranyl B(8′) and B(10′) resonances at $\delta(^{11}B)$ +12.5 and −8.6, respectively, differentiate considerably from the value of +0.5 for *nido*-$B_{10}H_{14}$ itself; (c) the *nido*-decaboranyl B(5′) position adjacent to the B(10) fusion site is much more highly shielded at δ −27.8 than the equivalent position in *nido*-$B_{10}H_{14}$ itself at δ +0.5. For (b) and (c) it is probably significant here that the *nido*-decaboranyl long 'gunwale' distance, B(5)–B(8′), at 2.032(5) Å, is much longer than the other gunwale distance B(10′)–B(5′) of 1.914(7) Å at the opposite side of this sub-cluster, demonstrating markedly differential bonding induced by the constraints of the fusion to the other, *arachno*, subcluster. In *nido*-$B_{10}H_{14}$ itself this distance is 1.973(5) Å (by neutron diffraction).[6] Mechanist-

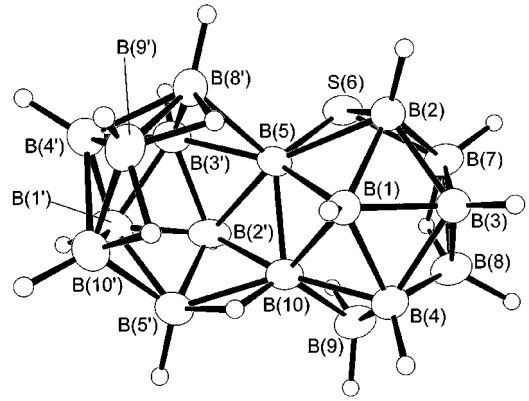

Fig. 1 Crystallographically determined molecular structure of the $[SB_{17}H_{20}]^-$ anion in $[PPh_4][SB_{17}H_{20}]$. Selected interatomic distances (in Å) are as follows: from S(6) to B(2) 1.953(3), B(5) 1.937(4) and B(7) 1.948(4), B(7)–B(8) 1.852(3), B(8)–B(9) 1.882(6), B(9)–B(10) 1.922(6), B(5)–B(10) 1.839(4), B(5)–B(8′) 2.032(5), B(8′)–B(9′) 1.778(5), B(9′)–B(10′) 1.830(7), B(10′)–B(5′) 1.914(7) and B(5′)–B(10) 1.843(5). These dimensions are for one of two independent $[SB_{17}H_{20}]^-$ anions in the unit cell; the dimensions for the other anion are within experimental deviation of these.

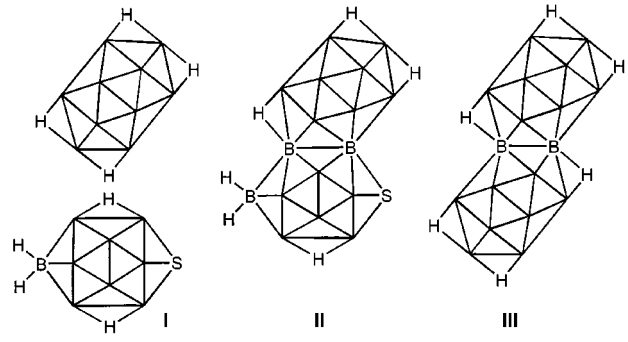

ically the conversion of *anti*-$B_{18}H_{22}$ (schematic **III**) to the $[SB_{17}H_{20}]^-$ anion (schematic **II**) has involved a net reductive replacement of $\{BH + H\}^-$ by $\{S\}^{2-}$, associated with a skeletal rearrangement. With no labelling we cannot speculate as to which of the original boron atoms of the *anti*-$B_{18}H_{22}$ skeleton is lost. In view of the great variety already exhibited by thiaborane macropolyhedral chemistry when sulfur atoms are incorporated in the cluster assemblies,[1,2] and in view of this high yield route from *anti*-$B_{18}H_{22}$, for which a variety of routes have long been known,[7] and which is also currently available commercially, the synthesis of this new $[SB_{17}H_{20}]^-$ species will constitute a very useful starting point for continued explorative investigation in macropolyhedral boron-containing cluster chemistry.

Received (in Liverpool, UK) 4th August 1999, Accepted 13th August 1999

A new oxidation catalyst containing perruthenate immobilised within MCM-41 has been prepared and used in the clean oxidation of alcohols to carbonyl compounds with molecular oxygen.

Previously, we[1] and others[2] demonstrated that tetrapropylammonium perruthenate (TPAP)[3] may serve as a convenient catalyst for the oxidation of alcohols to carbonyl derivatives by molecular oxygen. Furthermore, we discovered that when bound to a polystyrene bead the same catalytic species (RuO_4^-–polymer supported perruthenate) provided a cleaner synthetic alternative.[4] However, because of difficulties in the recycling of the PSP reagent (that may be attributed to oxidative degradation of the polystyrene support), we decided to investigate other materials as suitable supports. Here we report that on tethering this same perruthenate catalytic species within the mesoporous solid MCM-41, a remarkably clean and more efficient catalyst is produced.[5]

The mesoporous solid MCM-41 has both internal and external surfaces supporting silanol groups (SiOH) which may be suitably derivatised to immobilise a known catalytically active species (Fig. 1).[6] Treatment of this material with the appropriate amount of Ph_2SiCl_2 (using a proven methodology) effectively caps the external surface inhibiting any further reaction and yielding material **1**.[7] Further treatment of **1** with [3-(trimethoxysilyl)propylamine] yields a material with the internal $Si(CH_2)_3NH_2$ tether. After treatment with HBF_4 to give the tethered primary ammonium system $Si(CH_2)_3NH_3^+$ **2**, the required perruthenate catalyst **3** may be prepared by ion exchange with potassium perruthenate in aqueous solution.

Material **3** has been found to serve as a highly effective and clean catalyst for the oxidation of primary alcohols to aldehydes with a superior performance over that of the previously reported polymer based system (PSP). The oxidations, using our previously published protocol, produced the corresponding aldehydes in less than 3 h using 10 wt% of solid catalyst;[8] significantly, the aldehydes were free of contaminants.

Material **1** was also treated with 3-bromopropyltrichlorosilane to yield material **4** containing a propyl tether with a bromohead group. Substitution with either Me_3N or Et_3N to form the corresponding quaternary ammonium species, followed by ion exchange with potassium perruthenate, afforded the catalytic species **5** and **6** respectively. The black solid **5** was found to be an equally efficient catalyst for the oxidation reactions (Scheme 1) and **6** was found to be a more highly active recoverable and reusable catalyst for the preparation of a wide range of aldehydes (see Table 1). Optimum results were obtained when 10 wt% of the solid catalyst **6**[9] in a solution of the alcohol in toluene was employed. Maximum yields were found on heating the mixture at 80 °C for between 30 min and 3 h, in an oxygen atmosphere. The reactions were faster if a suspension of the catalyst in dry toluene was pre-saturated with oxygen. Alternatively, the reactions may be run in MeCN, CH_2Cl_2 or toluene, but in these cases a reaction time of 12 h was required for completion. Addition of up to 50 wt% of the catalyst led to complete formation of the aldehyde without any over-oxidation to the acid. Recovery and re-use of the catalyst has been investigated (3 mg of the catalyst **6**, and 30 mg of the

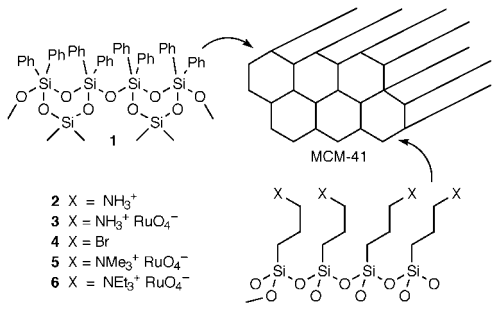

Fig. 1 Catalyst structures.

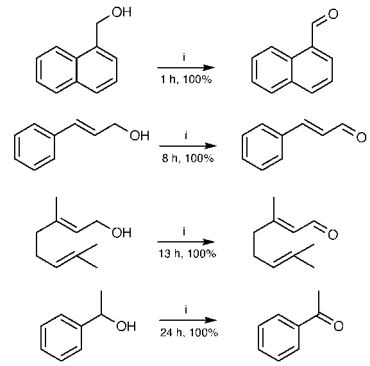
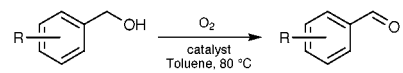


Scheme 1 *Reagents and conditions*: i, O_2, **5** (10 wt%), toluene, 80 °C, for time shown.

Table 1 Oxidation of **7** to **8**, using catalyst **6**



R	Catalyst **6** (wt%)	*t*/h	Yield (%)
H	10	0.5	quant.
4-Cl	10	1.0	quant.
4-OMe	10	2.0	quant.
3-OMe	10	3.0	quant.
2-OMe	10	2.0	quant.

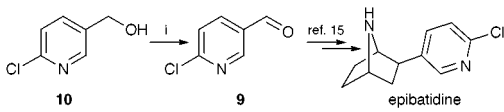
2-NO_2	10	3.0	quant.
4-F	10	1.0	quant.
3-CF_3	10	2.0	quant.
4-OBn	10	2.0	quant.

alcohol **7**). In each case, the pure aldehyde product **8** was obtained in quantitative yield, after 1 h, using oxygen in toluene as the oxidant at 80 °C, even after 12 recycle runs.[10] The catalyst **6** was efficiently used for the oxidation of allylic alcohols to the corresponding enals, and acetophenone was obtained from 1-phenylethanol. However, neither cyclohexanol nor cyclohexenol were converted to the corresponding ketones using this method. Finally, catalyst **6** was used in the preparation of aldehyde **9** from alcohol **10** on a 1 g scale, using only 25 mg of the triethylammonium catalyst **6** following the previously mentioned toluene/oxygen protocol (Scheme 2). A quantitative yield of the pure aldehyde **9** was obtained. This aldehyde was used in a ten-step linear synthesis of the potent analgesic natural product epibatidine, which employed only solid supported reagents.[11]



10 **9** epibatidine

Scheme 2 *Reagents and conditions*: i, O_2, **6** (2.5 wt%), toluene, 80 °C, 12 h.

Instead of oxygen, NMO or trimethylamine *N*-oxide (TMAO) may be used as oxidant, and although this protocol was efficient in generating the desired aldehydes in high yield, a noticeable contamination by both ruthenium and an organic impurity was found. These were probably unreduced, involatile NMO or TMAO, and a product formed by β-elimination (Hofmann elimination) of the ammonium species. Only in this experiment was the catalyst found not to be reusable.

Leaching was shown not to take place with **6** under the conditions employed. Thus, oxidation was allowed to proceed to 50% completion, and the solid catalyst was removed by filtration and stored under argon; the filtrate was then heated at 80 °C under an oxygen atmosphere and no further oxidation was observed by HPLC after 12 h. The catalyst was then re-added to the reaction mixture, the reaction was re-established and complete oxidation was observed in less than 1 h under the usual conditions.

In separate experiments designed to help elucidate the catalytically active species we have established that: (i) MCM-41 alone shows no activity; (ii) diphenylsilyl capped MCM-41 treated with potassium perruthenate (lacking the supporting tether) shows little activity and complete leaching; (iii) uncapped MCM-41 treated with potassium perruthenate (lacking the supporting tether) shows little activity and complete leaching; (iv) colloidal RuO_2 absorbed within the MCM-41 mesopores[12] shows no activity. These experiments demonstrate that a perruthenate derived species is responsible for the catalysis and not RuO_2.[13] Scanning transmission electron microscopy (STEM) revealed that coverage of the MCM-41 internal surface was uniform (also the external surface of Carbosil *vide infra*). There was no evidence for the formation of colloidal RuO_2.[14] It is worth noting that X-ray diffraction studies of the catalysts **5** and **6** indicate that long range order in the MCM-41 structure is reduced, whilst STEM showed that there are residual 'domains' of parallel mesopores. An alternative synthetic route was used to reproduce **6** without the loss of long range order by eliminating the water solvated ion exchange. However no superior performance was observed under the same reaction conditions. X-Ray diffraction also revealed that no large inorganic crystallites were formed in the catalyst preparation. We have also demonstrated that an aerogel silica tethered triethylammonium perruthenate species (preparation akin to **6**) is a good oxidation catalyst although significantly longer reaction times are needed (5 h on a 0.1 mmol scale).

In summary, we have developed a new, highly active, recoverable and re-usable heterogeneous catalytic oxidant **6** for the oxidation of alcohols to carbonyl derivatives by molecular oxygen. It may be prepared from the siliceous MCM-41 material following a reliable tethering method and ion exchange with potassium perruthenate. The immobilisation of other reagents using the improved MCM-41 support should allow us to incorporate these new solid supported reagents in our future clean chemistry programmes.[15]

8 10 wt% of the solid catalyst **3** corresponds to 0.3 wt% Ru by ICP analysis.

9 10 wt% of the solid catalyst **6** corresponds to 1.1 wt% Ru by ICP analysis.

10 *General procedure* for the oxidation of alcohols: To a solution of the alcohol (30.0 mg) in dry toluene (5 cm^3) was added MCMSP **6** (3.0 mg) and the resulting mixture heated at 80 °C, for 30 min to 3 h in an oxygen atmosphere. After cooling, filtration of the mixture followed by evaporation of the solution afforded the pure aldehyde in quantitative yield (Table 1). The solid catalytic oxidant reagent can be re-used many times (up to 12 times without loss of activity). It can be easily filtered through a polypropylene filter or through a bond elut cartridge and then washed off the surface with toluene. In addition, recovery by centrifugation was also found to be quantitative.

13 In experiments (i) and (iv), no oxidation was observed after 50 h, in toluene/oxygen at 80 °C, implying that a perruthenate derived species was responsible for the catalysis and not RuO_2. In experiments (i) and (iii), approximately 10 and 70% oxidation, respectively, to the aldehyde was observed after 3 days under the same conditions and complete leaching of potassium perruthenate was observed in both cases. The used solid material from experiments (ii) and (iii) showed no catalytic oxidative activity when reused.

meta- and *para*-Bis[zirconyl(IV)amino]cyclophanes; 1,3- or 1,4-$C_6H_4[\bar{N}(SiMe_3)]_2$ as bridging ligands†

Stephane Daniele, Peter B. Hitchcock and Michael F. Lappert*

The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ. E-mail: m.f.lappert@sussex.ac.uk

Received (in Basel, Switzerland) 17th May 1999, Accepted 17th July 1999

The structurally characterised *meta*- and *para*-dimetallacyclophanes $[R\bar{N}(C_6H_4)N(R)Zr(NMe_2)_2N(R)(C_6H_4)\bar{N}(R)Zr(NMe_2)_2]$ (R = $SiMe_3$), obtained from $[\{Zr(NMe_2)_3(\mu\text{-}NMe_2)\}_2]$ and $C_6H_4[N(H)R]_2$-1,3 or -1,4 (2 mol), are catalysts (with methylaluminoxane) for the polymerisation of ethylene.

There has been much recent interest in chelating bis(amido) ligands in the context of zirconium(IV) or titanium(IV) chemistry, in part because of their ability to catalyse the polymerisation of olefins. Examples of such catalysts have been $[Zr(LL)(CH_2Ph)_2]$ with methylaluminoxane (MAO) [LL = 2,2′-{N($C_6H_4Bu^t$-*p*)}$_2$-6,6′-Me_2-(C_6H_3)$_2$],[1] $[Ti(L'L')Me_2]$ with $B(C_6F_5)_3$ [L′L′ = N(R)$(CH_2)_3$NR, R = $C_6H_3Me_2$-2,6];[2] for a review, see ref. 3. The *ortho*-*N*,*N*′-bis(silylated)amidobenzene ligands have also been employed as chelating moieties in group 14 metal and also zirconium(IV) complexes, as exemplified by [(Sn{N($SiMe_3$)}$_2C_6H_4$-1,2)$_2$(μ-tmen)][4] and [Zr({N(SiPr^i_3)}$_2C_6H_4$-1,2)$_2$].[5]

We now draw attention to the role of the isomeric *meta*- and *para*-*N*,*N*′-disilylated bis(amido)benzene ligands in zirconium chemistry. Of particular novelty is the discovery that their bonding mode differs from that of the chelating and terminally bonding *ortho* isomer. The *N*,*N*′-bis(trimethylsilyl)-1,3- or -1,4-diamidobenzene ligands behave in a bridging fashion, giving rise to binuclear derivatives such as **1**–**4**. These are either open chain molecules (**1** or **2**) or are macrocycles (**3** or **4**).

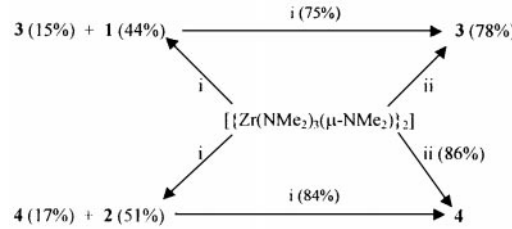
An alternative method of generating a binuclear [Cu^{II}] amido-based cyclophane from 1,4-$C_6H_4(NH_2)_2$ has been reported: by cyclocondensation of the latter with ethylenediaminetetraacetic anhydride and successive treatment with Na_2CO_3 and $CuCl_2 \cdot 2H_2O$.[6]

Treatment of $[\{Zr(NMe_2)_3(\mu\text{-}NMe_2)\}_2]$ with 1,3- or 1,4-$C_6H_4[N(H)R]_2$ (R = $SiMe_3$) (2 mol) gave (ii in Scheme 1) yellow crystals of the cyclophane **3** or **4**, respectively, while the intermediates **1** and **2** were isolated (albeit with significant proportions of **3** and **4**) (i in Scheme 1) when equimolar quantities of these reagents were used. The conversion of each acyclic compound **1** or **2** into the macrocycle **3** or **4** was evidently faster than the formation of **1** or **2**, respectively. Complexes **3** or **4** were resistant to further transamination, when an excess of the appropriate diamine was employed.



Scheme 1 Synthesis of the crystalline complexes **1**–**4**. *Reagents and conditions*: $C_6H_4[N(H)SiMe_3]_2$-1,3 or -1,4 (i, 1 mol; ii, 2 mol), PhMe, 0 °C, 20 h and then crystallisation from *n*-pentane, 4 °C.

The new, pale yellow (**3** or **4**) or colourless (**1** or **2**), highly air-sensitive, readily aromatic hydrocarbon-soluble, crystalline compounds **1**–**4** gave satisfactory microanalyses (C, H, N), as well as multinuclear NMR spectra.‡ For each complex, the ^{1}H NMR spectra displayed single sets of sharp signals, consistent with the illustrated structures, and for **3** and **4** confirmed (X-ray) for the crystalline complexes.§ A common feature as between **3** and **4** on the one hand and **1** and **2** on the other, was that the aromatic and $SiMe_3$ ^{1}H NMR signals for the former were more shielded while the converse was the case for the NMe_2 signals.

The X-ray molecular structures of complexes **3** and **4** are shown in Figs. 1 (**3**) and 2 (**4**) and selected geometric parameters

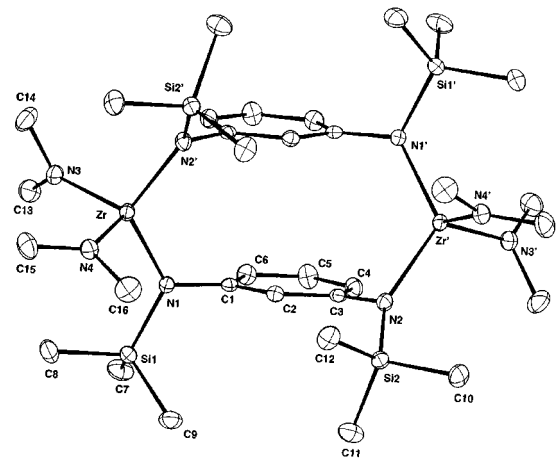


Fig. 1 The molecular structure of **3**.

† No reprints available.

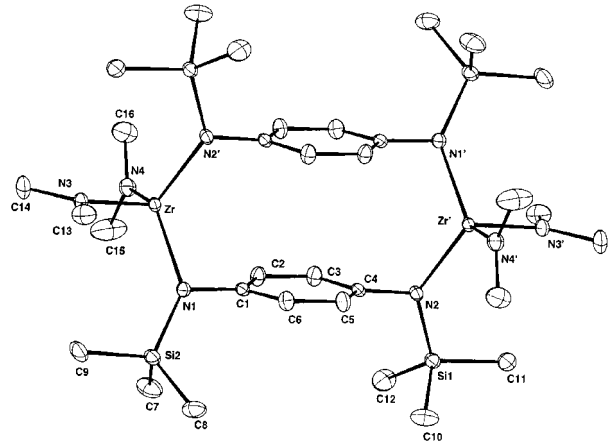

Fig. 2 The molecular structure of **4**.

are compared in Table 1. The aromatic rings are related by a crystallographic twofold axis for **3** and an inversion centre for **4**. They are parallel in both structures, the planes being separated by 3.43 (**3**) or 3.48 (**4**) Å but show a sideways displacement (**3** > **4**). The endocyclic N–Zr–N′ bond angle is somewhat wider in **4** than **3** but the converse is so for the Me_2N–Zr–N′Me_2 angle; while for each, the average endocyclic Zr–N bond length is significantly longer than the exocyclic, but both are unexceptional; for example, the average Zr–N bond lengths are 2.08 Å for [Zr({N(SiPr$^i_3$)}$_2$$C_6H_4$-1,2)$_2$],[5] and 2.06 Å for [Zr{η^5-$C_5H_4C(Me)_2C_9H_6$-η^5}$(NMe_2)_2$].[7] The sum of the angles at each nitrogen atom is close to 360°.

Each of the metallocyclophanes **3** and **4**, in the presence of MAO, was active as a catalyst for the polymerisation of ethylene, and this activity was substantially enhanced if **4** was pretreated with an excess (10 mol) of chlorotrimethylsilane to yield **5**; the polyethylenes had very high average molecular weights.¶ Complex **5** is tentatively formulated as $RN(C_6H_4)N(R)Zr(Cl)_2N(R)(C_6H_4)N(R)ZrCl_2$, an analogue of **4** (having only the terminal amido groups displaced by chloride ligands).

Compounds **1**–**4** are the first binuclear, four-coordinate zirconium(IV) amides and are also unusual in being heteroleptic. The cyclophanes **3** and **4** are of further interest in being macrocycles having both Lewis acid (Zr) and base [N(R) and C_6] sites and having parallel C_6 rings separated by distances close to that (3.35 Å) found in graphite. This ambiphilicity, as well as the catalytic properties of these compounds, are under further investigation as are comparisons of the use of these *meta*- and *para*-*N*,*N*′-bis(trimethylsilyl)bis(amido)benzene ligands in the context of complexes of other metals [for Ge^{II} and Sn^{II}, see refs. 8 and 9].

We thank the EU for the award of a Marie Curie fellowship to S. D. and to Dr M. Kristen and BASF (Ludwigshafen) for other support.

Hexahomotrioxacalix[3]arene: a scaffold for a C_3-symmetric phosphine ligand that traps a hydrido-rhodium fragment inside a molecular funnel

Cedric B. Dieleman,[a] Dominique Matt,*[a] Ion Neda,[b] Reinhard Schmutzler,[b] Anthony Harriman[c] and Reza Yaftian[d]

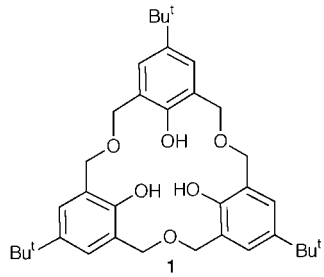
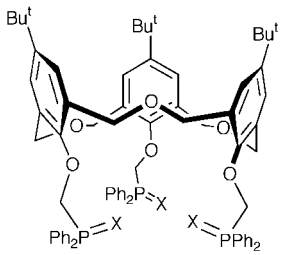
Received (in Cambridge, UK) 13th July 1999, Accepted 6th August 1999

Stereoselectivity around an H–Rh–CO fragment has been realized by reaction of the hexahomotrioxacalix[3]arene-derived triphosphine 4 with [Rh(acac)(CO)$_2$]; the resultant trigonal bipyramidal complex has the Rh–H bond directed inside the cavity.

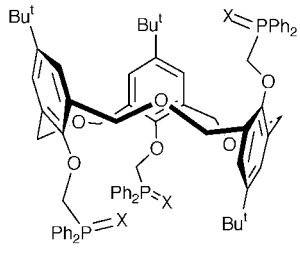
Phosphorus-bearing calixarenes have received considerable attention both for their ionophoric receptor properties and their facility for localizing reactive transition metal centres adjacent to the cavity.[1] To date, most studies have been concerned with functionalized calix[4]arenes,[2] while the corresponding hexahomotrioxacalix[3]arenes **1** remain relatively unexplored,



1



2 X = O
4 X = lone pair



3 X = O
5 X = lone pair

although such receptors have been equipped with P^{III}- or P^{V}-based binding sites.[3,4] The larger macrocyclic unit provided by **1** looks to be particularly appropriate for use as a platform on which to build C_3-symmetrical ligands able to operate as conical receptors.[5–8] We now describe the synthesis and properties of the first triphosphine ligands, and their corresponding oxides, formed by anchoring $CH_2P(O)Ph_2$ groups to the phenolic oxygen atoms of a calix[3] matrix.

Complete phosphorylation was achieved by reacting **1** with NaH and $Ph_2P(O)CH_2OTs$ in toluene at 90 °C for three days. The reaction resulted in formation of a 4:1 mixture of the (non-interconverting) phosphine oxides **2** and **3**.† Separation by column chromatography afforded pure **2** in 72% yield, but the isolated samples of **3** always contained small amounts of **2**. Consistent with a C_3-symmetrical structure, the ^{31}P NMR spectrum of **2** shows a single peak at δ_P 24.9 while the corresponding ^{1}H NMR spectrum displays a unique AB system for the $ArCH_2$ methylene groups. Compound **3** adopts a partial cone conformation as deduced from the presence of two singlets of intensity 2:1 in the ^{31}P NMR spectrum, together with three AB patterns for the $ArCH_2$ groups in the ^{1}H NMR spectrum. The phosphine oxides **2** and **3** could be reduced with $PhSiH_3$ in refluxing toluene, affording the triphosphines **4** and **5**,† respectively, in quantitative yield. The partial cone structure of **5** (Fig. 1) was confirmed by an X-ray diffraction study.‡ It should be emphasised that compounds **2**–**5** are highly soluble in alkanes.

The triphosphorylated calixarene **2** was found to be an active phase-transfer agent for rare-earth picrates (from water to CH_2Cl_2).§ Extraction experiments carried out with seven rare-earth cations (Y, La, Pr, Nd, Sm, Eu and Gd) showed the extraction percentages to be significantly higher than those obtained with conventional phosphine oxides, *e.g.* trioctylphosphine oxide, or the phosphato-calix[4]arenes reported recently by Harrowfield *et al.*[9] Interestingly, the highest selectivity was found for those elements with an ionic radius close to that of praseodymium; similar peak selectivity was observed recently with a *cone*-calix[4]arene substituted by four $CH_2P(O)Ph_2$ phosphine oxide arms tethered at the lower rim.[10] Our findings confirm previous observations showing that phosphorus-based ligands built on calixarenes may display different extraction properties than do their acyclic counterparts.[11]

Ligand **4** looks to be an ideal scaffold for the formation of C_3-symmetrical complexes. Thus, treatment of **4** with [Mo(CO)$_3$-(cycloheptatriene)] in refluxing THF afforded the colourless complex **6**† in high yield (Scheme 1). The carbonyl region of the IR spectrum displays two strong absorption bands showing the presence of an $Mo(CO)_3$ unit with local C_{3v} symmetry.[12] Tridentate *fac*-coordination of the tripod was inferred from the appearance of a singlet at δ_P 25.7 in the ^{31}P NMR spectrum. In **6**, the tripodal arms retain the metal centre beneath the cavity. Likewise, complex **7**,† formed in quantitative yield on reaction of **4** with $[Au(THF)(THT)]PF_6$ (THT = tetrahydrothiophene),

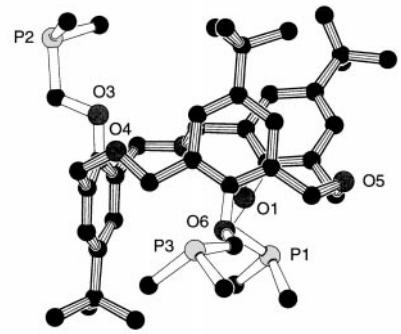


Fig. 1 PLUTON view of triphosphine **5**. For clarity, only the *ipso* carbon atoms of the PPh groups are shown.

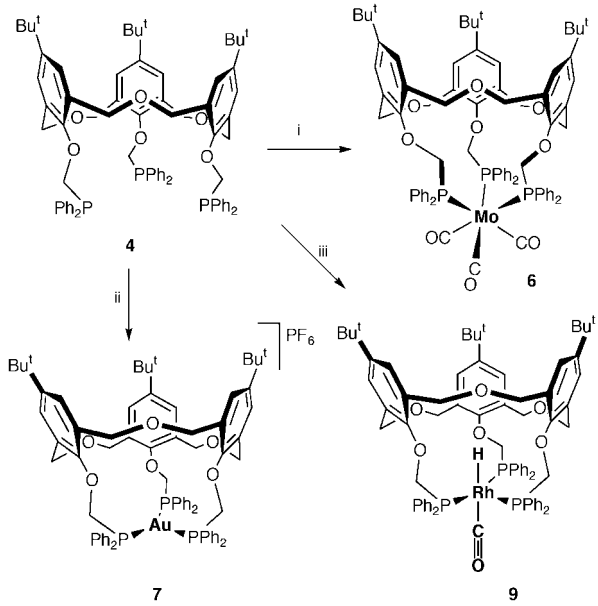

Scheme 1 *Reagents and conditions*: i, [Mo(CO)$_3$(cycloheptatriene)], THF, reflux; ii, [Au(THT)(THF)]PF$_6$, CH_2Cl_2; iii, [Rh(acac)(CO)$_2$], 20 bar H_2/CO, toluene, 70 °C.

positions a metal centre across one entrance of the cone. In this case, the trigonal AuP_3 fragment strapped across the lower rim exaggerates the conical nature of the calix[3] unit. A similar funnel-shaped silver complex **8**† (not drawn) was also obtained quantitatively from reaction with $AgBF_4$. The room temperature NMR data of both these cationic complexes are in full accord with a C_{3v} symmetrical structure. As deduced from a variable temperature NMR study made with **8,** the threefold symmetry of this complex is only virtual and corresponds in fact to an averaged structure. Indeed, the A_3X (X = Ag) pattern observed at 25 °C in the ^{31}P NMR (202.45 MHz) spectrum broadens on decreasing the temperature and eventually changes to an A_2BX system, while maintaining finite AgP coupling constants. The C_s symmetry observed at low temperature probably minimizes the strain within two of the three metallomacrocycles formed by complexation, but the exact structure of the complex is not known. Loss of C_3 symmetry at low temperature has previously been observed in a titanium-capped cone homooxacalix[3]arene, but in this case the structural modification appears to be controlled by a stereodynamic process occurring at the metal centre.[13]

A remarkable feature of triphosphine **4** concerns its ability to trap and orientate a linear H–Rh–CO fragment. Thus, treatment of a toluene solution of **4** and [Rh(acac)(CO)$_2$] with 20 bar of H_2/CO at 70 °C afforded complex **9**† in *quantitative* yield (Scheme 1). The latter species is characterized by a strong carbonyl absorption band at 1977 cm^{-1} while all NMR data are consistent with a threefold symmetry axis. The ^{31}P NMR spectrum, for example, shows a doublet at δ_P 36.4 (J_{RhP} = 153 Hz) due to the phosphorus atoms with the ^{1}H NMR spectrum displaying a quartet at δ_H −9.70 for the hydrido ligand. The small J_{PH} value (14 Hz) is in full agreement with a trigonal bipyramidal geometry. Two-dimensional ROESY (500 MHz) experiments unambiguously revealed that the hydride lies close to the methylenic Ar*CH*$_2$O groups¶ and to the PCH_2 protons. This is a clear indication that the Rh–H bond is directed inside the funnel. This particular orientation of the organometallic fragment is presumably stabilised by weak interactions between the hydride group and the phenolic oxygen atoms that also serve to enlarge the open mouth of the cavity.

As exemplified by complexes **7**–**9**, the tridentate homooxacalix[3]arene **4** facilitates formation of chelate complexes where the phosphine ligands occupy three equatorial sites. This strategy positions a transition metal centre at the bottom of a cone-shaped molecule and, in the case of Rh, leaves an axial coordination site trapped inside the cavity. It is anticipated that the preferential entrapment of Rh–H *vs*. Rh–CO will promote selective insertion reactions with appropriately sized substrates that enter the cavity.

Notes and references

† Satisfactory elemental analyses were obtained for all new compounds. *Selected data* for **2**: δ_H($CDCl_3$) 6.74 (s, 6H, *m*-ArH), 4.61 (d, $^2J_{PH}$ 3, 3H each, PCH_2O), 4.61 and 4.31 (AB q, ^2J 13, 6H each, $ArCH_2$), 1.42 (s, 27H, Bu^t); δ_P(CD_2Cl_2) 24.9. Diastereoselective Baylis–Hillman reaction of 4-oxoazetidine-2-carbaldehydes: rapid, stereocontrolled and divergent radical synthesis of highly functionalised β-lactams fused to medium rings

Benito Alcaide,* Pedro Almendros and Cristina Aragoncillo

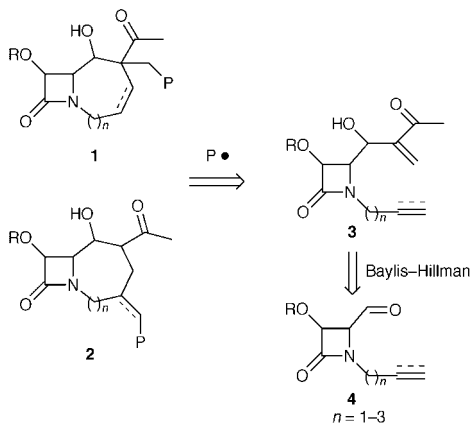
Departamento de Química Orgánica I, Facultad de Ciencias Químicas, Universidad Complutense, 28040-Madrid, Spain. E-mail: alcaideb@eucmax.sim.ucm.es

Received (in Liverpool, UK) 21st June 1999, Accepted 30th July 1999

Baylis–Hillman adducts derived from enantiopure 1-alkenyl- or alkynyl-4-oxoazetidine-2-carbaldehydes are used for the stereoselective and divergent preparation of highly functionalised β-lactams fused to medium rings through novel, chemocontrolled tandem radical addition–cyclization sequences.

The Baylis–Hillman reaction is an emerging carbon–carbon bond forming reaction for the preparation of densely functionalysed products involving an activated alkene, a carbon electrophile and a suitable catalyst (particularly a tertiary amine).[1] On the other hand, synthetic methodologies based on free radical cyclization reactions have experienced an impressive growth and are the focus of extensive studies. This wide research has been fostered by its operational simplicity, its tolerance to substrate functionalization, and the fact that it proceeds usually with high degrees of regio- and stereo-control.[2]

The increased resistance of bacteria to the commonly used β-lactam antibiotics[3] and the ever-growing new applications of these products in fields ranging from enzyme inhibition to the use of azetidin-2-ones as starting materials to develop new synthetic methodologies, has triggered a renewed interest in the construction of new systems having the azetidin-2-one ring as a common feature.[4] Our interest in the use of 4-oxoazetidine-2-carbaldehydes as substrates for intramolecular cyclization processes[5] prompted us to evaluate the combination of the Baylis–Hillman reaction with free-radical methodology as a route to unusual, chiral non-racemic bicyclic β-lactams. We report here novel, simple strategies for the stereoselective and divergent preparation of medium sized ring-fused highly functionalized bicyclic β-lactams **1** and **2** based on chemocontrolled tandem radical addition–cyclization sequences (Scheme 1). The useful and expedient approach described herein presents the opportunity to merge the rapidly expanding fields of Baylis–Hillman reaction and radical chemistry. The problems associated with the formation of medium sized rings are widely appreciated. Even the formation of seven-membered rings in the 7-*exo-trig* mode is likely to be unsuccessful in most cases (at 25 °C, $k_{7\text{-}exo} < 7 \times 10^{-1}\ s^{-1}$). Nevertheless, several authors were able to prepare seven-membered rings by radical cyclization on substrates bearing only a limited degree of freedom, including β-lactam-tethered haloalkenes or alkynes[6,7] and aryl-bridged compounds.[8]



Scheme 1

Baylis–Hillman adducts **3** were easily prepared by DABCO-mediated reaction of enantiopure 4-oxoazetidine-2-carbaldehydes **4** with methyl vinyl ketone in excellent yields and stereoselectivities (Scheme 2). Alkenyl or alkynyl aldehydes **4** were easily prepared as single *cis*-enantiomers from imines of (*R*)-2,3-*O*-isopropylidenepropanal, through Staüdinger reactions with the corresponding acid chlorides in the presence of Et_3N,[9] followed by standard transformations of the acetal moiety.[5] The Baylis–Hillman reaction using protected α-amino aldehydes has been attempted with limited success, due to partial racemisation of the chiral aldehyde by DABCO after prolongate exposure times.[10] We were pleased to find that the Baylis–Hillman reaction proceeds faster than racemization (our typical reaction time ranging from 18 h for **4a** to 72 h for **4b**) using an equimolar amount of DABCO and 10 equiv. of methyl vinyl ketone and performing the experiment in MeCN at low temperature (−20 °C).†

Subjection of any organic molecule to a high enough temperature in the gas phase results in the formation of free radicals. When the molecule contains bonds with dissociation energies from 20 to 40 kcal mol^{-1}, cleavage can be caused in the liquid phase. The dissociation energy of the $PhCH_2$–H bond is 88 kcal mol^{-1}, so the generation of the benzylic radical is an unexpected process *via* heating at usual temperatures.[11] To our

surprise, Baylis–Hillman adduct (+)-**3a**, on heating in toluene or *p*-xylene in a sealed tube at 210 °C, formed the bicyclic products **1a**, **b**, which were isolated in modest yields (37–45%).‡ Use of chlorobenzene or anisole as solvents gave unaltered starting material (+)-**3a**. When enyne (+)-**3b** was used instead of diene (+)-**3a** the reaction proceeded in the same manner, giving product (+)-**1c** in good yield (60%). Furthermore, thermal treatment of enyne (+)-**3c** with *p*-xylene gave the bicycle (+)-**1e** in reasonable yield (Scheme 2). Interestingly, the use of benzyl alcohol allowed us to obtain the hemiacetal derivative of compound **1d**. Although this latter compound was isolated in low yield (20%) this is an interesting case because three new chiral centers are generated in a highly stereoselective manner.§ All compounds **1** were obtained as single diastereomers. When a catalytic amount of hydroquinone was added, the reaction rate was considerably reduced and the product yield fell dramatically. This fact confirms that a radical reaction is involved. Also, together with compounds **1**, 1,2-diarylethanes were isolated as byproducts in all cases. These products may be formed by recombination of the initially generated benzylic radicals.

In view of the particular disposition of the 1,5- and 1,6-enyne azetidin-2-ones to undergo 5-*exo* and 6-*exo* tin promoted radical cyclization,[12] we examined the applicability of this methodology to our novel Baylis–Hillman 1,ω-enyne substrates **3b**–**3d** for the synthesis of less common bicyclic β-lactams. This approach in the synthesis of seven-membered or higher sized rings has not been hitherto applied.[13] A dramatic change in the chemoselectivity was observed when the bicyclic β-lactam (+)-**2a** was formed as the exclusive product from (+)-**3b**, in nearly quantitative yield as crude product. The tin-promoted radical reaction was also useful in the conversion of the homologous 1,4-tethered enynes (+)-**3c** and (+)-**3d** into the corresponding bicyclic systems with similar efficiency and selectivity. Compounds **2** were exclusively obtained as *Z*-isomers. In addition, PhSH reacted smoothly with β-lactams (+)-**3b** and (+)-**3c** in the presence of AIBN, in boiling benzene, to give in good yields the corresponding phenylthiovinyl derivatives as mixtures of easily separable *Z* and *E* isomers (Scheme 3). The bicyclic structure (by DEPT, HETCOR, and COSY) and the stereochemistry (by vicinal proton couplings and NOE experiments) of compounds **1** and **2** were established by NMR one- and two-dimensional techniques.

Formation of bicyclic β-lactams **1** and **2** can be explained in terms of a competition between a tandem radical Michael addition–*endo*-cyclization and a tandem radical addition–Michael addition, depending on the electronic nature of the radical promoter (Scheme 4). The more nucleophilic benzylic radical would favour formation of compounds **1**, while the more electrophilic radicals, such as PhS· and Ph_3Sn·, should promote formation of compounds **2**. The high stereoselectivity of the processes can be tentatively interpreted in terms of the allylic strain model of Giese, showing for planar substituents such as Ac good levels of 1,2-stereoinduction on α-substituted β-oxy radicals (types **5** and **6** in Scheme 4).[14]

Dendritic biomimicry: microenvironmental effects on tryptophan fluorescence†

David K. Smith* and Lars Müller

Department of Chemistry, University of York, Heslington, York, UK YO10 5DD. E-mail: dks3@york.ac.uk

Received (in Cambridge, UK) 4th August 1999, Accepted 12th August 1999

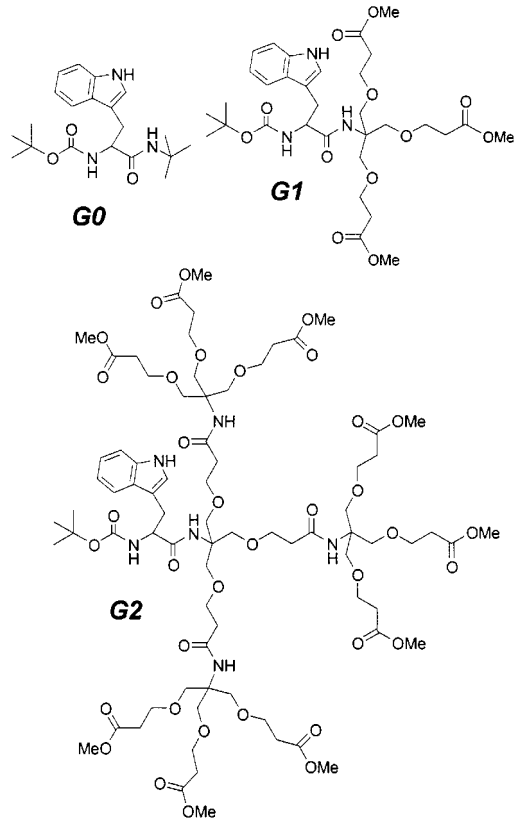
Branched tryptophan derivatives were synthesised and their optical properties investigated in a range of solvents: the steady state fluorescent emission from the indole ring sheds light on both the nature of a hydrogen bonding dendritic microenvironment and the optical behaviour of tryptophan residues in biological systems.

Tryptophan is undoubtedly the most important source of emission in proteins.[1] The wavelength of emission has proven to be very sensitive to the environmental conditions, and has consequently been extensively used as a probe of the local environment within a protein.[2] It has recently been proposed that branched macromolecules (dendrimers)[3] can mimic some aspects of protein behaviour,[4] in particular by creating unique microenvironments within their three dimensional superstructures.[5] Simple, well-understood environmental probes have been used in an attempt to yield a better understanding of this effect of dendritic encapsulation.[6] Here we target the synthesis of dendritic tryptophan derivatives containing a single tryptophan unit buried within the branched environment,[7] the emissive properties of which should respond to the environment generated by the branched shell. The results provide new information about the dendritic microenvironment, and have relevance to understanding the emissive properties of tryptophan in the protein environment, an area of intense research activity.[1]

Tryptophan derivatives **G0**, **G1** and **G2** were synthesised using a convergent coupling strategy in which *N-tert*-butoxycarbonyl-protected L-tryptophan was coupled with Bu^tNH_2 or pre-formed dendritic branches of first or second generation respectively.[8] Coupling was achieved using DCC/HOBt in CH_2Cl_2 with Et_3N as base; typical reaction times were 72 h. Products were purified by silica or gel permeation column chromatography as appropriate.†

The steady state fluorescence emission spectra of these new dendritic amino acids were measured in a range of different solvents.‡ It is well-known that environmental polarity is important in controlling the red shift of tryptophan fluorescence.[9] Firstly, compound **G0** was investigated in order to ascertain the effect of solvent on derivatives with this type of functionalisation—the emission wavelengths are provided in Table 1. Dependent on the solvent, fluorescent emission was observed between 321.5 and 343.5 nm. Attempts to correlate the data with Kamlet and Taft's π^* parameter,[10] a measure of polarity which is divorced from specific interactions such as hydrogen bonds, failed. Analysis of the data indicates that hydrogen bond acceptor solvents (THF, EtOAc and MeCN) were more red shifted than would have been expected on the basis of π^* alone, whilst hydrogen bond acceptor and donor solvents (Pr^iOH and MeOH) were shifted yet further to the red. Therefore, the hydrogen bond donor and acceptor ability of the solvent, as well as its polarity, apparently control the emission wavelength.[11] This is in stark contrast to the solvatochromic probe used by Fréchet and co-workers to investigate a dendritic microenvironment,[5a] the emission wavelength of which correlated well with π^* (polarity) alone.

As expected, therefore, the solvent plays key roles in controlling the fluorescence. The major question, however, was whether the dendritic shell would modify this behaviour, generating a unique microenvironment for the tryptophan residue. Consequently, the steady state emissive behaviour of **G1** and **G2** was investigated and compared with that of **G0** (Table 1).



The branched shell did indeed have a dramatic and progressive effect on the emission of the tryptophan residue. Fréchet and co-workers found that, in their system, the effect of the dendritic branching correlated with the solvent polarity

Table 1 Emissive wavelengths for **G0**, **G1** and **G2** measured in a range of solvents. All wavelengths are ±0.5 nm

parameter π^*, indicating that the effect of the branched shell was to moderate the polarity experienced by the solvatochromic probe. In this case, however, no correlation was observed. Rather, the magnitude of the dendritic effect was primarily dependent on the ability of the solvent to form specific interactions, in particular, hydrogen bonds. Three different types of behaviour were observed:

(i) Non-hydrogen bonding solvents: The most marked effect occurred in primarily non-hydrogen bonding solvents (cyclohexane, benzene, CH_2Cl_2) with the emission wavelength shifting bathochromically on dendritic functionalisation. In cyclohexane, for example, **G0** emitted at 321.5 nm, **G1** at 326.5 nm and **G2** at 332 nm, a remarkable total shift (dendritic effect) of 10.5 nm. This indicates that the branched shell strongly perturbs the local environment of the tryptophan residue.[5,6a] Furthermore, whilst for **G0** there was a large difference in emission wavelength between apolar cyclohexane and more polar CH_2Cl_2 (11 nm), this solvent-generated difference was much smaller for branched analogue **G2** (3.5 nm). In other words, attachment of the branched shell strongly reduces the effect of solvent polarity.

(ii) Hydrogen bond acceptor solvents: In such solvents (EtOAc, THF, MeCN), the dendritic shell had a much smaller effect on the emission wavelength (dendritic effects of between 0.5 and 1.5 nm), even though some of these solvents have polarities comparable to, or lower than, CH_2Cl_2. This provides strong supporting evidence that polarity is not the only important factor in controlling tryptophan fluorescence.

(iii) Hydrogen bond acceptor and donor solvents: In such solvents (MeOH, Pr^{i}OH) the dendritic effect is once again of smaller magnitude, but this time in the opposite direction, with the emission maximum shifted hypsochromically by around 1.5 nm after dendritic functionalisation.

It is therefore clear that the dendritic effect is much smaller in competitive solvents than in non-competitive solvents. This indicates that specific tryptophan solvation effects, such as hydrogen bonding, play a crucial role. It is proposed that, in non-competitive solvents, an intramolecular *hydrogen bond* is formed between the dendritic shell (C=O) and the N–H group of the tryptophan residue at the focal point. Such a hydrogen bond would act as a tether, holding the polar peptidic branched shell in close proximity to the tryptophan subunit, modulating the polarity of its local environment, and hence perturbing its fluorescence spectrum much more strongly.[12] In competitive solvents, the solvent is itself able to interact with the tryptophan residue, and the branched shell consequently has a much smaller effect.

Further evidence for the dendritic creation of a hydrogen bonding interaction in non-competitive solvents is provided by the downfield perturbation of the ^{1}H NMR shift (in $CDCl_3$) of the N–H proton in the indole ring. This resonance shifts from δ 8.10 for **G0** to δ 8.60 for **G1** to δ 9.45 for **G2**.

Such hydrogen bonding microenvironments have been previously postulated as being important in controlling the behaviour of dendritic receptors.[13] This report clearly illustrates the dramatic effect that such hydrogen bond interactions can have inside branched superstructures—in clear analogy with the importance of hydrogen bonds in controlling the structure and behaviour of enzymes.

In summary, dendritically modified tryptophans have been synthesised and their optical properties investigated. A remarkable dendritic effect[5] on emission wavelengths was observed. It is proposed that in non-competitive solvents, there is a *hydrogen bonding microenvironment*[13] for the encapsulated tryptophan residue, leading to enhanced dendritic effects. In addition to providing clear characterisation of this type of dendritic microenvironment, these results emphasise the potential importance of microenvironmental hydrogen bonds in controlling the fluorescence of tryptophan residues in the apolar interior of enzymes. This is significant given the wide use of tryptophan emission as a probe of protein structure.[1] Further work using these, and more deeply encapsulated, dendritic tryptophan derivatives to probe kinetic aspects of fluorescence quenching is planned. Other biologically relevant fragments will also be encapsulated in order to ascertain additional microenvironmental effects on function, and generate new, easily tuneable forms of molecular behaviour.

Liquid-phase chemistry: recent advances in soluble polymer-supported catalysts, reagents and synthesis

Paul Wentworth Jr. and Kim D. Janda*

Department of Chemistry, The Scripps Research Institute and the Skaggs Institute for Chemical Biology, 10550 N. Torrey Pines Road, La Jolla CA92037, USA. E-mail: kdjanda@scripps.edu

Received (in Cambridge, UK) 11th March 1999, Accepted 20th April 1999

Chemistry on soluble polymer-matrices, termed liquid-phase organic synthesis, is emerging as a viable alternative or adjunct to the classical solid-phase approach across the broad spectrum of polymer-supported organic chemistry. This review details the significant advances in liquid-phase synthetic methodologies, reagents, catalysts and supports that have appeared from 1997 to the present.

Introduction

Cross-linked polymer supports are now ubiquitous throughout the fields of combinatorial chemistry, organic synthesis and catalysis.[1,2] However, emerging problems associated with the heterogeneous nature of the ensuing chemistry and with 'on-bead' spectroscopic characterisation[3] has meant that soluble polymers are being developed as alternative matrices for combinatorial library production[4] and organic synthesis.[5,6] Synthetic approaches that utilise soluble polymers, termed 'liquid-phase' chemistry, couple the advantages of homogeneous solution chemistry (high reactivity, lack of diffusion phenomena and ease of analysis) with those of solid phase methods (use of excess reagents and easy isolation and purification of products). Separation of the functionalized matrix is achieved by either solvent or heat precipitation, membrane filtration or size-exclusion chromatography.

Poly(alkene oxide)s such as poly(ethylene glycol) (PEG) are amongst the most studied soluble polymers for organic synthesis,[7,8] with polyethylene oligomers[9] and poly(styrene)s[10,11] also receiving considerable attention. The wide applicability of PEG is directly linked to its broad solubility profile: soluble in DMF, dichloromethane, toluene, acetonitrile, water and methanol, but insoluble in diethyl ether, *tert*-butyl methyl ether, isopropyl alcohol[12] and cold ethanol.

In liquid-phase chemistry, where a soluble polymer is being iteratively derivatized either terminally or on side-chain residues, a balance has to be reached between loading capacity (substitution per gram of polymer) and the solubility profile of the resulting polymer derivative. As the molecular weight of the matrix is lowered, the end-groups have a proportionally greater effect on the physical properties of the polymer derivative, which can result in non-quantitative precipitation and low polymer recoveries. PEG of molecular weight 3000 to 5000 is typically utilised in liquid-phase strategies. The polymer chains can be terminated with either two hydroxy groups (dihydroxy-PEG) or with one hydroxy group and one methyl ether (monomethoxy-PEG). Lower molecular weight PEG matrices give a correspondingly higher loading per gram of support and if dihydroxy-terminated PEG is chosen the loading is double that of a monomethoxy-PEG of the same molecular weight. Throughout this review *vide infra*, the balance of loading and polymer recovery is discussed with optimal conditions being described for a number of cases.

Soluble polymer-supported synthesis

Targeted synthesis

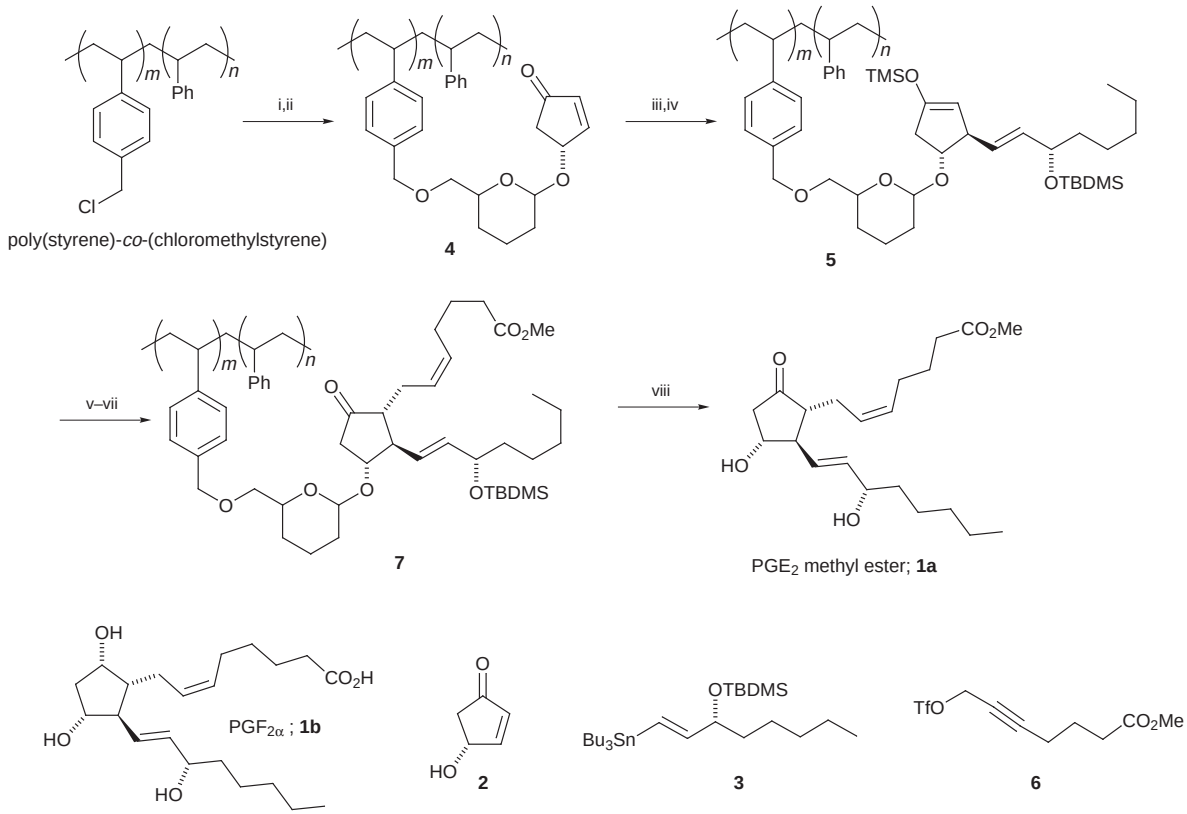
The utility of combinatorial chemistry within drug discovery is ultimately linked to the ability to rapidly construct complex molecules on polymer supports. With this in mind, a polymer-supported approach to the prostaglandin core was seen as an important benchmark in the progress of this chemistry. Chen and Janda have successfully utilised Noyori's[13] three component coupling strategy, in a 'liquid-phase' format, for the synthesis of PGE_2 methyl ester[10] **1a** and $PGF_{2\alpha}$[11] **1b** (Scheme 1).

The synthetic strategy hinged upon the choice of a soluble polymer support that could withstand extreme reaction and workup conditions. While PEG is ostensibly the polymer of choice for most facets of liquid-phase chemistry, its use in this case was contraindicated for two reasons: insolubility in THF at low temperatures and its solubility in water which precluded aqueous extraction/removal of organometallic byproducts. A non-crosslinked copolymer of styrene and chloromethylstyrene (3 mol%), previously used for peptide synthesis,[14] was prepared (0.3 mmol g^{-1} loading) and incorporated as the polymer matrix. This copolymer is soluble in THF, dichloromethane and ethyl acetate even at low temperatures, but is insoluble in methanol and water so that purification can involve both aqueous extraction and precipitation techniques.

The synthetic approach to PGE_2 methyl ester **1a** involved an initial attachment of the cyclopentanoid alcohol **2** to the soluble co-polymer *via* Ellman's tetrahydropyran linker.[15] The vinyl-

Paul Wentworth Jr. obtained both his BSc (Hons) in Chemistry and Pharmacology (1991) and PhD in Organic Chemistry (1994) from the University of Sheffield, the latter under the supervision of Professor G. Michael Blackburn. In 1994 he began postdoctoral studies involving antibody-catalysis, enzyme inhibition and combinatorial chemistry, with Professor Kim. D. Janda at The Scripps Research Institute. Since 1997, as an Assistant Professor in the Department of Chemistry at Scripps, he has pursued research into combinatorial and polymer-supported chemistry and programmable biocatalysis.

Kim D. Janda obtained his PhD in Organic Chemistry (1984) from the University of Arizona. He joined the Scripps Institute in 1985 as a postdoctoral fellow and in 1987 was promoted to the faculty, where he is currently the Ely Callaway Jr. Professor of Chemistry. His research interests include catalytic antibodies, polymer-supported methodologies, combinatorial chemistry, immunopharmacotherapy, and enzyme inhibition. He is the recipient of an Alfred P. Sloan fellowship (1993–1995), and an Arthur C. Cope Scholar award (1998). He is a co-founder of two companies: Combichem Inc. and Drug Abuse Sciences.



Scheme 1 *Reagents and conditions*: i, 6-(hydroxymethyl)-3,4-dihydro-2*H*-pyran (3 equiv.), NaH (3.3 equiv.), DMA, room temp., 24 h; ii, **2** (3.0 equiv.), PPTS (0.5 equiv.), CH_2Cl_2, 40 °C, 16 h; iii, **3** (4.2 equiv.), $Li_2CuCNMe_2$ (3.9 equiv.), THF, −78 °C, 15 min; iv, TMSCl (15 equiv.), −78 °C, 30 min; Et_3N (30 equiv.), 0 °C, 15 min; v, MeLi (3 equiv.), THF, −23 °C, 30 min; vi, **6** (6 equiv.), −78 °C, 10 min, then −23 °C, 30 min; vii, H_2, 5% Pd–$BaSO_4$, quinoline, benzene–cyclohexane (1 : 1), room temp., 48 h; viii, 48% aq. HF–THF (3 : 20, v/v), 45 °C, 6 h.

stannane ω-chain **3** was then added to **4** in the presence of $Li_2CuCNMe_2$ in THF at −78 °C. Following reaction of the intermediary enolate with TMSCl, the stable polymer-bound silyl enol ether **5** was isolated. The α-chain was then incorporated, as its respective triflate **6**, by trapping of the intermediate enolate formed following addition of MeLi to **5** in THF (−23 °C). Following partial reduction of the α-chain alkyne, the polymer-bound *Z* alkene **7** was cleaved from the support, with accompanying deprotection of the silyl ether protecting group to give **1a** in an overall yield of 37% for the eight step route. The main features to note are that the polymer recovery mass balance was > 97% and only one polymer-bound species was detected by routine NMR analysis, for each step of the synthesis.

Versatile and practical methodology for the construction of oligosaccharides of high structural complexity and in a combinatorial fashion is of tremendous interest. Solid-phase synthesis of oligosaccharides has improved dramatically over the past several years but can still suffer from problems such as decreased glycosylation rates, incomplete coupling and lowered stereoselectivities.[16] Building on an initial report by Krepinsky,[17] Dreef-Tromp and co-workers[18] utilised monomethoxy-PEG as a soluble polymer-support for their synthetic approach to heparan sulfate-like oligomers **8a**–**g**.

The PEG-supported acceptors **9** and **10** were prepared by an initial esterification of the free primary hydroxy group of the dissacharides **11** and **12** with succinic anhydride, followed by attachment to monomethoxy-PEG *via* esterification of the terminal carboxy group (Scheme 2). Subsequent glycosylations of the PEG-supported iduronic acids **9** and **10** were performed in an iterative three step cycle involving deprotection of the levulinoyl group, TMSOTf assisted coupling with disaccharide glycosyl donors as their respective trichloroacetimidates, and capping of the unreacted 4-hydroxy groups.

Optimisation studies led to excellent coupling efficiencies (> 95%) being achieved and the anomeric control (complete α-substitution) was comparable to that observed with the classical solution-phase approach. The PEG polymer support facilitated the synthetic strategy by allowing an excess of reagents to be used while ensuring that intermediates along the route could be purified by simple precipitation with high polymer recovery (> 95%). Furthermore, the extent of glycosylation could be followed routinely by ^{1}H NMR of the PEG-bound derivatives.

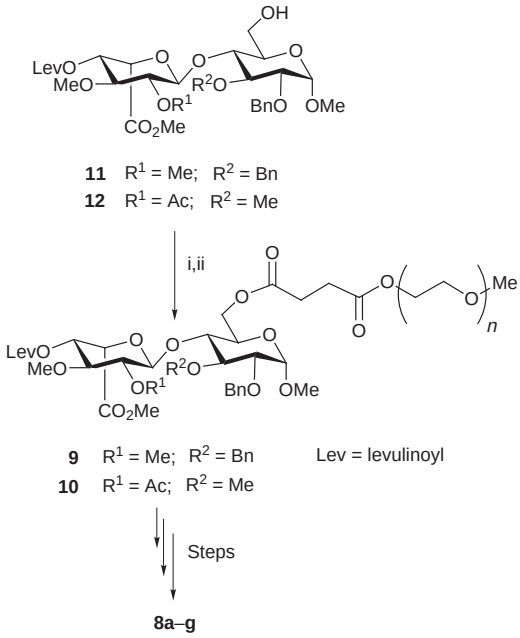
Enzyme-assisted strategies for the synthesis of oligosaccharides is recognised as a promising alternative to chemical synthesis because of high regio- and stereo-selective reactions without the need for protecting groups. An efficient methodology for the construction of carbohydrates, including oligosaccharide and sphingoglycolipids, has been developed by Nishimura and Yamada.[19,20] They synthesised a vinylic oligosaccharide monomer **13** which, when treated with acrylamide under radical polymerisation conditions, formed a water-soluble copolymer **14** (Scheme 3). This water-soluble conjugate (**14**), was then used as a primer for a regioselective sialylation reaction catalysed by rat liver βGal1→3/4GlcNAc α-2,3-sialyltransferase, in the presence of CMP-NeuAc,[21] to generate the soluble polymer-supported trisaccharide **15** in quantitative yield.

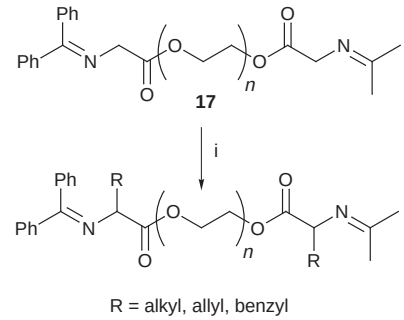


Scheme 2 *Reagents and conditions*: i, succinic anhydride, DMAP, pyridine; ii, MeO-PEG-OH, 1-(3-dimethyaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), DMAP, CH_2Cl_2.

Purification of **15** from the enzyme and excess sugar building block by gel-filtration chromatography was facilitated by the presence of the poly(acrylamide) support. Subsequent treatment of **15** with leech ceramide glycanase in the presence of an excess of ceramide as an acceptor generated the transglycosidated product GM3 (**16**) in 61% yield. Thus this polymer-supported enzyme approach afforded the glycolipid GM3 in 56% yield from the readily available precursor/monomer **13**, a remarkable improvement in both the ease of synthesis and overall yield when compared to that of chemical synthesis.[22]

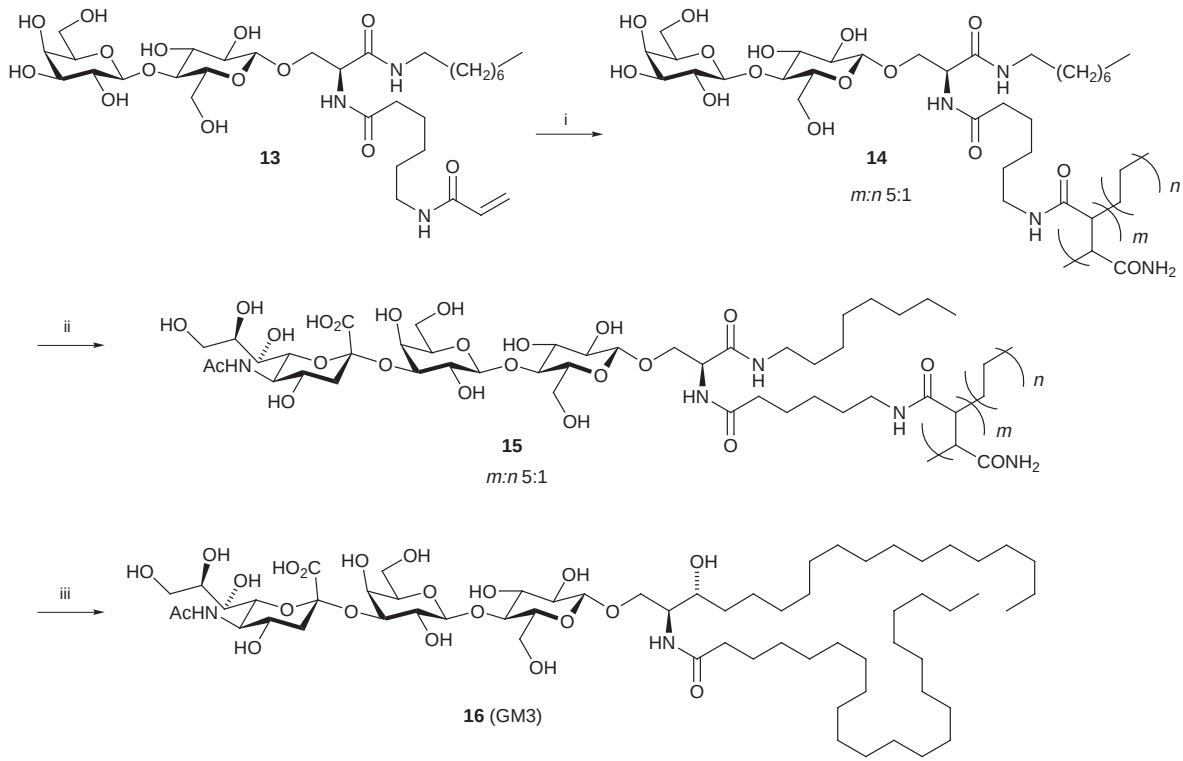
Synthetic methodology

C–C Bond formation. In addition to the extended synthetic strategies *vide supra*, exploration into chemical methodology on soluble supports continues to make significant advances. The development of efficient methods of forming carbon–carbon bonds is an important objective for any polymer-supported methodology. The reactions of stabilised carbanions with carbon centred electrophiles is one of the most common approaches in this area and Lamaty and co-workers[23] have exploited this methodology on PEG. Alkylation of the imine **17** was achieved with a range of electrophiles (RX) with K_2CO_3 as a base (Scheme 4). In the solution phase, a quaternary



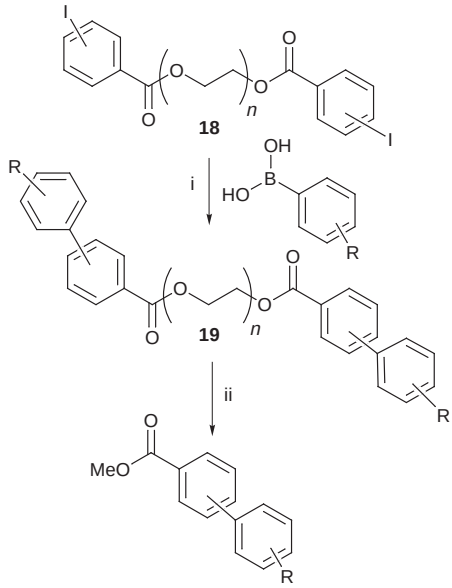
Scheme 4 *Reagents and conditions*: i, RX (2 equiv.), K_2CO_3 (4 equiv.), MeCN, reflux, 14 h (54–75%).

ammonium salt is required as a phase-transfer catalyst (PTC) to ensure complete alkylation. Interestingly the PEG support acted as a sufficiently powerful PTC under the conditions of the reaction that no ammonium salt was required. Dihydroxy-PEG_{2000} was utilised as the matrix of choice in this system which resulted in high loading capacities (1.0 mmol g^{-1}). However the authors note that the precipitation and recovery of the matrix after each reaction step was difficult and sometimes low yielding.



Scheme 3 *Reagents and conditions*: i, acrylamide (4.0 equiv.), *N,N,N'N'*- TMEDA (0.4 equiv.), ammonium peroxodisulfate (APS), 50 °C, 2 d (92%); ii, CMP-NeuAc (1.2 equiv.), α-2,3-sialyltransferase (0.3 unit), bovine serum albumin, $MnCl_2$, calf intestinal alkaline phosphate (20 unit), sodium cacodylate buffer (50 mM, pH 7.49), 37 °C, 3 d (> 99%); iii, ceramide (4 85 equiv.), ceramide glycanase (0.01 unit), Triton CF-54 (1 drop), sodium citrate buffer (50 mM, pH 6.0), 37 °C, 17 h (61%).

The biaryl subunit is an important pharmacophore in a variety of biologically active compounds. Blettner and co-workers[24] utilised the first example of a Suzuki cross-coupling reaction on PEG, in a parallel array format, to generate libraries of substituted biaryls (Scheme 5). They studied a range of



Scheme 5 *Reagents and conditions*: i, arylboronic acid (2 equiv.), $Pd(PPh_3)_4$ (0.05 equiv.), aq. Ma_2CO_3 (2 M; 2.5 equiv.), DMF, 110 °C, sealed tube, 10 h; ii, Et_3N–MeOH (1 : 4), 85 °C, sealed tube, 2 d.

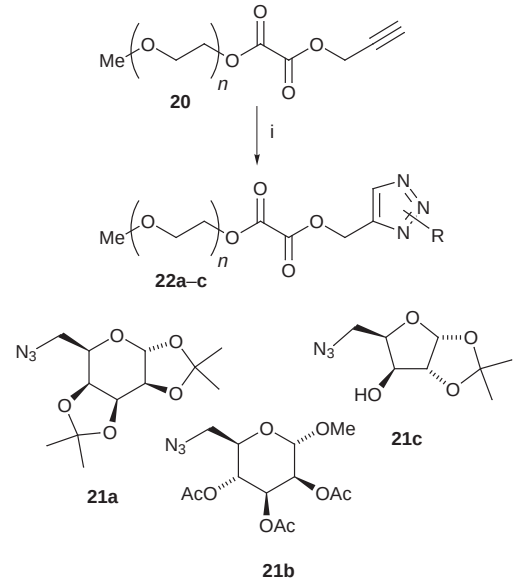
molecular weight PEGs and found that dihydroxy PEG_{6000} (0.33 mmol g^{-1}) and monomethoxy PEG_{5000} (0.2 mmol g^{-1}) supported aryl iodides **18** and biaryls **19** could be purified by precipitation, but that dihydroxy PEG_{4000} (0.5 mmol g^{-1}) derivatives had to be purified by parallel flash column filtration. Polymer recovery by precipitation ranged from 90–98%, whereas due to the polydispersity of PEG, recovery by column filtration was only variable (52–74 %).

Heterocycle formation. There is considerable precedence describing solution-phase dipolar cycloaddition reactions with alkenes and alkynes for the synthesis of aromatic and non-aromatic five-membered ring heterocycles.[25] Several examples of solid-phase cycloaddition reactions have also been reported.[26] Recently, the first example of a liquid-phase 1,3-dipolar cycloaddition reaction was reported (Scheme 6).[27]

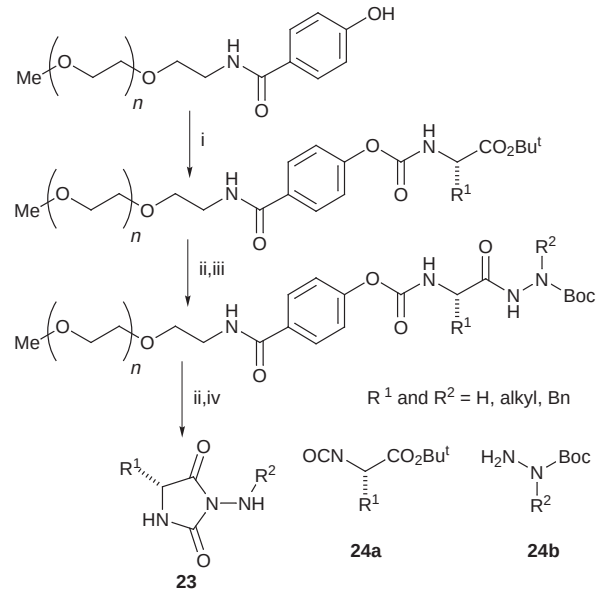
The PEG-supported alkyne **20** underwent smooth cycloaddition with a range of carbohydrate-derived primary azides **21a**–**c** to generate the regioisomeric, polymer-bound triazoles **22a**–**c** in good yields (73–86%).

The search for novel scaffolds on which molecular diversity can be constructed is an ongoing challenge throughout the field of combinatorial chemistry.[28] Janda and co-workers have synthesised a 3-aminoimidazoline-2,4-dione library[29] **23** on a monomethoxy-PEG_{5000} support (Scheme 7). The aminoimidazolinedione core is a rigid five-membered ring heterocycle with two points of diversification. The first diversity element R^1 was introduced as an amino acid isocyanate **24a**, the second as a Boc-aza-amino acid **24b**. The last step in the route involved a smooth cyclization–cleavage reaction, with maintenance of the stereochemical integrity of C-5, which furnished the scaffold **23** free in solution.

Pyrazolidine-3,5-diones **25a** are a class of heterocyclic compounds with four potential sites for diversification (Scheme 8). They are used for the treatment of arthritis but gastric irritation can limit their therapeutic application.[30] Therefore analogues are being sought that maintain the therapeutic profile but possess reduced side-effects. Janda and co-workers[12] have developed a liquid-phase approach to the synthesis of the



Scheme 6 *Reagents and conditions*: i, RN_3 (**21a**–**c**) (2 equiv.), toluene, reflux, 12 h.



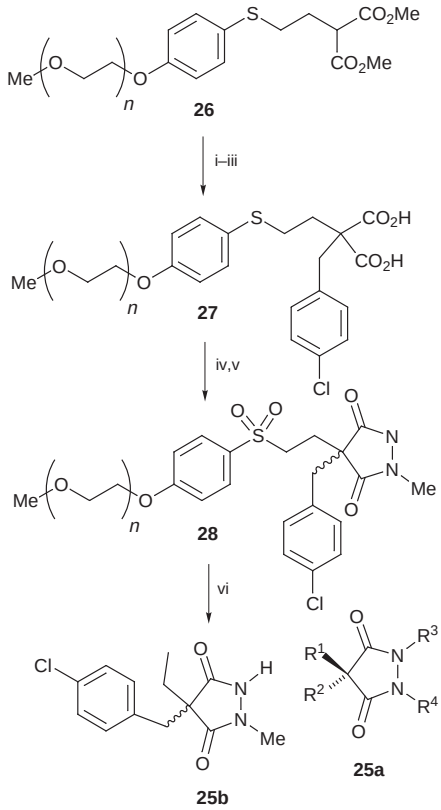
Scheme 7 *Reagents and conditions*: i, **24a**, Et_3N; ii, TFA, CH_2Cl_2; iii, **24b**, DCC; iv, dilution, Pr^i_2NEt (1.1 equiv.).

pyrazolidine-3,5-dione **25b** which involves an initial preparation of malonate **26** which is attached to PEG *via* Janda's ethyl phenyl sulfide traceless linker.[31,32] The malonate **26** was alkylated and de-esterified under standard conditions to give the polymer-supported diacid **27**. Ring closure to form the heterocyclic core was followed by oxidation of the sulfide linker and cleavage of sulfone **28** with Na–Hg amalgam to give *rac*-**25b** in excellent overall yield (61% for six steps).

Soluble polymer-supported reagents and catalysts

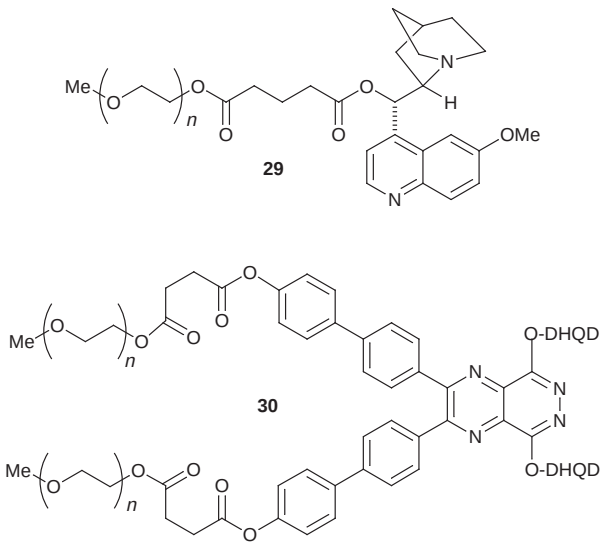
Combinatorial library construction has to date occurred almost exclusively on solid polymer supports. However, to reduce the effort involved in transferring solution-phase chemical methodology onto polymers, a notable shift towards solution-phase chemical library generation is occurring. However, to facilitate rapid library generation and purification, a whole new generation of functional polymer reagents and catalysts are being developed.[33–35]

An important application of soluble polymer-supports has been the use of PEG-supported hydroquinidine cinchona

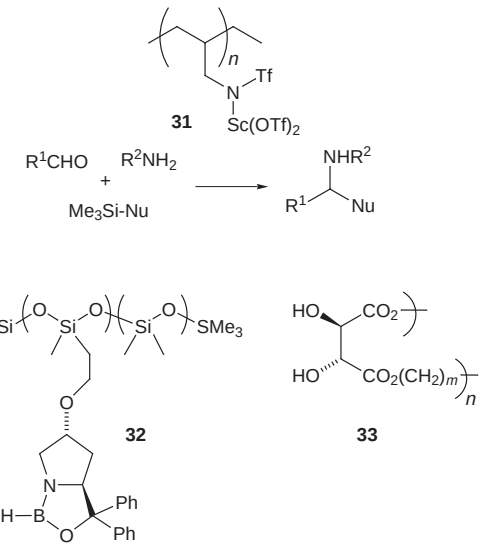


Scheme 8 *Reagents and conditions*: i, 4-chlorobenzyl chloride, Cs_2CO_3, DMF, room temp., 17 h; ii, NaOH, H_2O, room temp., 5 h; iii, Amberlite® IR-120 (plus), room temp., 1 h (94% from **26**); iv, methylhydrazine, benzotriazol-1-yloxytrispyrrolidinophosphonium (PyBOP), Pr^i_2NEt, DMF, room temp., 43 h (98%); v, $KHSO_5$, H_2O, room temp., 3 h (90%); vi, 5% Na–Hg, Na_2HPO_4, MeOH–DMF (1 : 8), room temp., 18 h, (74%).

alkaloid ligands **29** in the Sharpless asymmetric dihydroxylation reaction of olefins.[36,37] Following their seminal reports in this area, Han and Janda[38] have studied the dihydroxylation of *trans*-cinnamic acid on different polymer-supports: Merrifield and Wang resins, Tentagel and PEG. Various reaction parameters were modified: the amount of ligand/metal and reaction time. Under all conditions, the liquid-phase PEG support provided the best results and compared favourably with the dihydroxylation of a solution-bound cinnamic acid derivative. Bolm and Gerlach[39] have further improved the liquid-phase asymmetric dihydroxylation reaction, by utilising cinchona alkaloid–pyridazine–PEG conjugates **30** as ligands. This new strategy led to shortened reaction times, good yields and improved enantioselectivities (up to 99% ee).



A soluble polymer-supported scandium catalyst, poly(allylscandium triflylamide) ditriflate **31** was used for three-component condensation reactions between aldehydes, amines and silylated nucleophiles, to generate β-amino ketones, β-



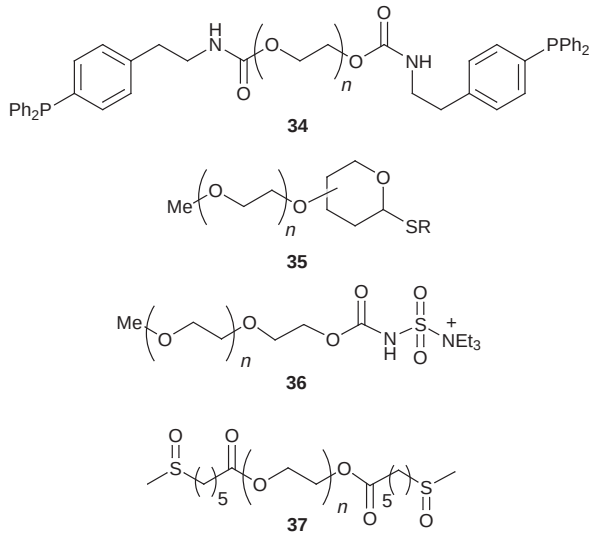
amino esters and α-amino nitriles in excellent yields.[40] The polymer-supported catalyst was recovered by precipitation in hexanes, and could be reused without loss in activity. The scandium catalyst **31** also catalysed aldimine selective reactions in the presence of aldehydes.[41] In the presence of **31**, aldimines reacted almost exclusively with silyl enolates without forming adducts with aldehydes, a common side-reaction using the more conventional $Sc(OTf)_3$ catalyst. The authors attributed this unique chemoselectivity to the stability of the aldimine–polymer–supported catalyst complex.

The recovery and reuse of polymer-supported catalysts is one of the major benefits associated with this strategy, especially when dealing with chiral catalysts which can be tremendously expensive to prepare. The commercially available copolymer of methylhydrosiloxane and dimethylsiloxane was utilised as a soluble support for Corey's chiral oxazaborolidine.[42] The reduction of a family of prochiral ketones was catalysed by polymer-adduct **32** with > 98% ee, comparable to the solution-phase oxazaborolidine counterpart. The polymer-supported catalyst, in contrast to most of the cases discussed *vide supra* is not a solid, and so was removed from the reaction mixture by size-exclusion filtration, rather than by precipitation. The strategy is compatible with automation and could see ultimate application in a continuous flow reactor system.

The linear poly(tartrate ester) **33** has been successfully applied in a liquid-phase variant of the enantioselective Sharpless epoxidation reaction.[43] The active polymer species was prepared by treating L-(+)-tartaric acid with a variety of diols under standard polycondensation conditions. However, the observed enantioselectivity for the epoxidation of *trans*-hex-2-en-1-ol was moderate (up to 79% ee), the solution-phase reaction with L-(+)-dimethyltartrate gave 98% ee showing that there exists some scope for improvement.

A number of examples of liquid-phase reagents have appeared recently. Janda and co-workers[44] synthesised a PEG-functionalized triarylphosphine **34** and showed that it is a more reactive reducing agent in the Staudinger and Mitsunobu etherification reactions than a Merrifield resin-bound counterpart. A number of PEG-matrices were studied and dihydroxy-PEG_{3400} (0.58 mmol g^{-1}) was found to be the lowest molecular weight matrix that consistently afforded excellent polymer phosphine recovery (> 97%) following precipitation from diethyl ether.

A monomethoxy-PEG-supported scialic acid glycosyl donor **35** has been utilised in a liquid-phase glycosylation reaction



with galactose analogues to give α-linked disaccharides.[45] A PEG-supported variant of the Burgess reagent **36** has been developed for application in a soluble polymer-supported approach to the cyclodehydration of β-hydroxyamides and thioamides.[46] Interestingly, the PEG-supported reagent was found to be much more stable than the solution-phase counterpart and had an extended shelf-life. Vederas and co-workers[47] have synthesised a PEG-supported sulfoxide **37** as a recyclable and odourless alternative for the Swern oxidation. The sulfoxide facilitated the oxidation of a range of alcohols in yields comparable to that of DMSO in solution. The reagent was also recyclable as the spent polymer could be smoothly and quantitatively oxidised back to **37** by treatment with sodium metaperiodate.

In a soluble-polymer strategy analogous to resin-capture,[48] Hori and Janda[49] facilitated the purification of a solution-phase library of β-amino alcohols with a monomethoxy-PEG_{5000}-supported dialkyl borane reagent **38** (Fig. 1). Simple addition of

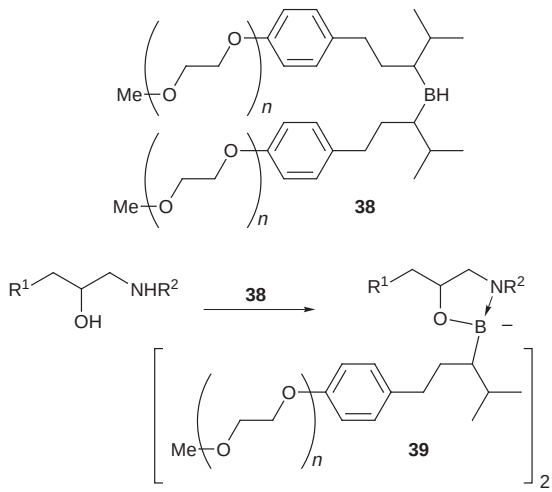


Fig. 1 Liquid-phase 'fishing-out' strategy: PEG-supported dialkylborane **38** facilitates the purification of β-amino alcohols by removal from crude reaction mixtures as polymer-supported 1,2-oxazaborolidines **39**.

38 to a crude reaction mixture containing the required product, followed by precipitation into diethyl ether, gave the polymer-supported 1,3,2-oxazaborolidine **39** from which the amino alcohol was released by acid treatment. By using this 'fishing-out' strategy amino alcohols were isolated greater than 95% pure.

Development of new soluble polymer supports

In comparison with the plethora of supports commercially available for solid-phase synthesis, there is a relative dearth of soluble polymers available to satisfy the increasing demands of liquid-phase chemistry. This reality has lead a number of groups to focus on the development of new supports possessing unique properties within the liquid-phase arena.

By incorporating a sequential normal/living free radical polymerisation strategy with bifunctional initiator **40**[50] and the styryl and vinyl monomers **41a**–**e**, Janda and co-workers[51] have generated linear block copolymer libraries (Fig. 2).

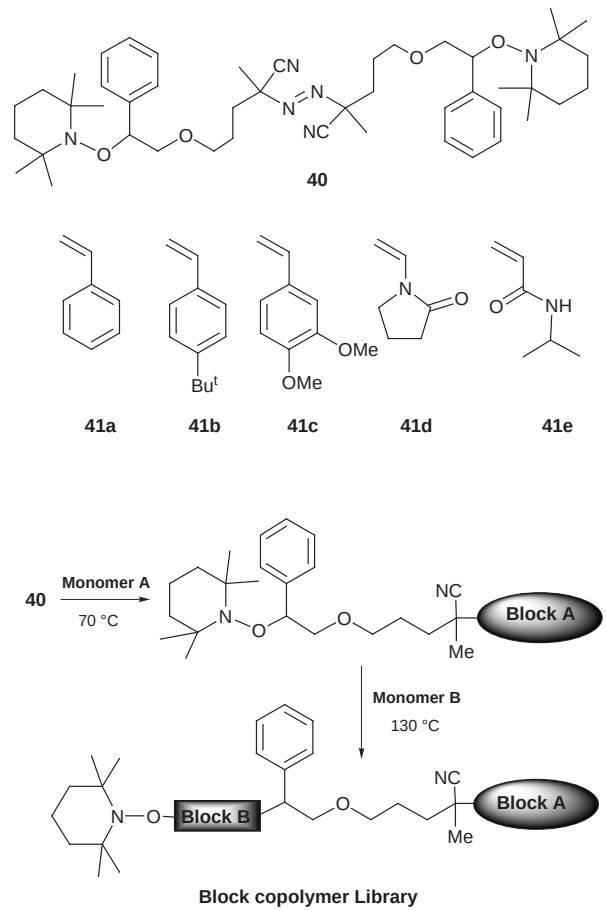

Fig. 2 Bifunctional initiator **40** and monomers **41a**–**e** utilised in a parallel format for block copolymer library generation.

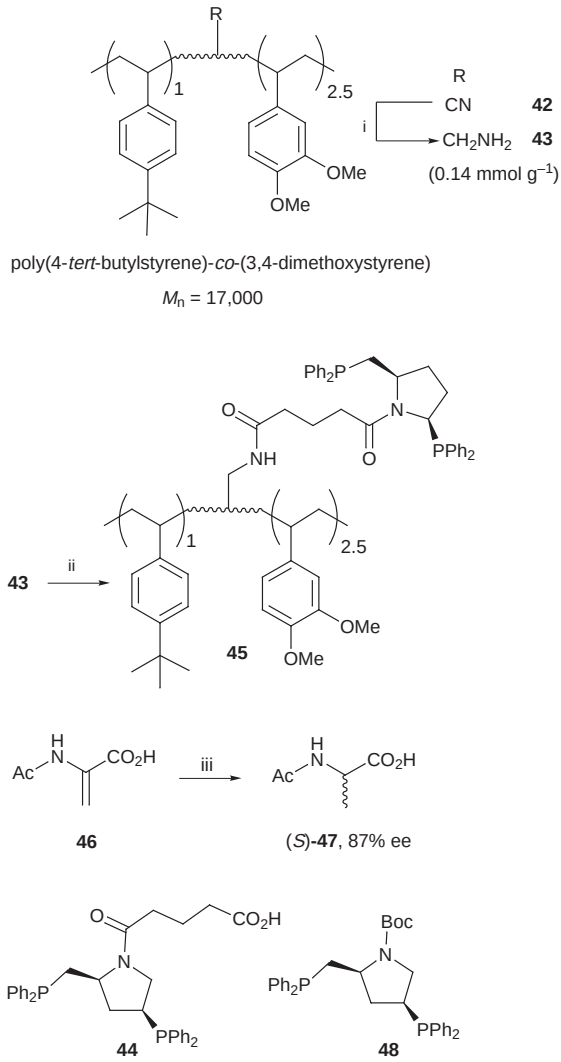
The solubility profile of each library member was then determined in a broad range of organic solvents and water. A copolymer of 4-*tert*-butylstyrene and 3,4-dimethoxystyrene **42** was found to have a solubility profile complementary to that of PEG: soluble in THF and diethyl ether, but insoluble in methanol and water, and was studied as a potential new matrix for liquid-phase chemistry (Scheme 9). The nitrile moieties, located between the two polymer chains, could be smoothly reduced with either $LiAlH_4$ or by catalytic reduction, to generate amino groups as loci for chemical derivatization.

The resulting amino groups of **43** possessed comparable reactivity to that of cyclohexylamine in solution as determined by an imine forming reaction. Derivatization of the amine groups of **43** with a diphosphine ligand **44** gave the polymer-supported chiral diphosphine **45**. The extent of derivatization and oxidation state of the phosphine ligands was routinely monitored by ^1H and ^{31}P NMR spectroscopy. Exchange of $[Rh(cod)Cl]_2$ with the diposphine **45** generated a polymer-supported rhodium(I) species which catalysed the homogeneous enantioselective hydrogenation of dehydroamino acid **46**. The observed ee, stereochemical preference, and kinetics of formation of amino acid **47**, determined by ^1H NMR spectroscopy,



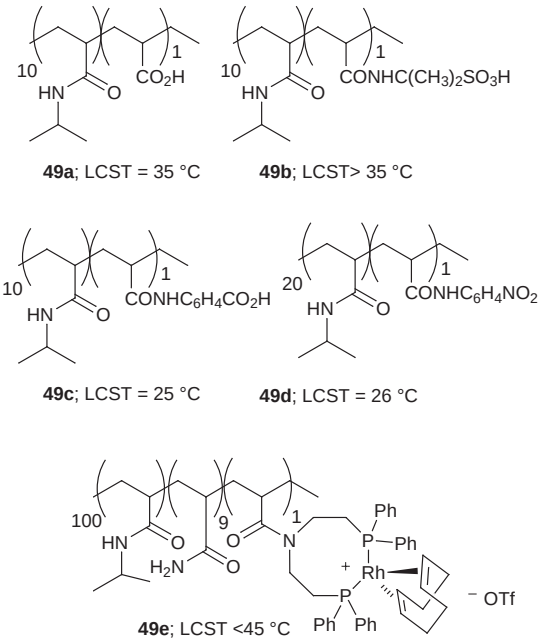
Scheme 9 *Reagents and conditions*: i, $LiAlH_4$ (76 equiv.), THF, reflux, 2 h (quant.); ii, **44** (4 equiv.), DMAP (6 equiv.), EDC (8 equiv.), THF, room temp., 4 h (quant.); iii, **45** (0.04 equiv.), $[Rh(cod)Cl]_2$ (0.02 equiv.), THF, room temp., 4 h, then **46** (1.0 equiv.), H_2 (20 psi), THF, 2 d.

were comparable to that observed with the solution-phase ligand **48**. Isolation of (*S*)-**47** was facilitated in the liquid-phase strategy as the polymer-supported catalyst was removed by simple precipitation into methanol while the solution-phase reaction required silica gel chromatography.

The block copolymer library approach shows how rapidly new linear supports can be assimilated using combinatorial chemistry methods. The only disappointing feature is the low loading capacity of the new materials (*ca.* 0.15 mmol g^{-1}), a result of the uncontrolled nature of the radical polymerisation process. However, the authors note that by increasing the initiator to monomer ratio the polymer chain length will be reduced and so the loading can be improved.

Bergbreiter and co-workers[52] have generated a number of co- and ter-polymers of *N*-isopropylacrylamides **49a–e** which are soluble in water below their lower critical solution temperature (LCST), but precipitate quantitatively at temperatures above their LCST. Thus they can be used as matrices for so-called 'smart' reagents and catalysts.

A concern when generating polymer-supported species where the functional groups are not substituted at the termini, but rather on side-chains along the polymer backbone, is that the reactivity and accessibility of these groups may not be the same as if the reaction were performed in solution. However the rate of catalytic reduction of the nitroarene groups of the poly(*N*-isopropylacrylamide) PNIPAM derivative **49d** below its LCST was equivalent to that of a solution-phase reduction of



3-acetamidonitrobenzene. The reduction of **49d** effectively ceased on heating above its LCST, showing the 'smart' nature of these polymers as substrate supports. Several PNIPAM-bound rhodium(I) catalysts were prepared including the cationic phosphine-ligated catalyst **49e**. Interestingly the rate of hydrogenation of allyl alcohol catalysed by **49e** was found to be considerably lower than that of a non-polymer bound catalyst, this was found to be caused by hydrogen bonding of the PNIPAM side-chain residues to the cationic rhodium centre. However, replacing the cationic rhodium(I) centre of **49e** with a neutral rhodium(I) core nullified this effect and the soluble-polymer supported approach was as effective as its solution-phase variant.

As discussed *vide supra* the successful use of liquid-phase supports has always been a compromise between loading and solubility profile. By comparison with solid-phase approaches this can appear to be a drawback, as a relatively large weight of polymeric material has to be utilised for a small return of product at the end. However, Cozzi and co-workers[53] have linked dendrimer chemistry to that of PEG chemistry and produced new soluble PEG-supports with expanded functional group capacity. A dihydroxy-PEG_{4600} core (0.43 mmol g^{-1}) was functionalized as a *m*-dicarboxyphenyl derivative which, following standard transformations, yielded a tetrahydroxyaryl-PEG_{4600} **50** with a loading capacity of 0.86 mmol g^{-1} (Scheme 10). This high-loading PEG-derivative was then utilised in a synthetic scheme to generate β-lactam **51**, all of the intermediates being purified by precipitation into diethyl ether with excellent polymer recovery. This shows that the solubility profile of the PEG_{4600} core has not been compromised by the higher terminal substitution. The second generation dendrimer **52** (loading of 1.73 mmol g^{-1}) was also prepared, although its solubility characteristics and utility in synthesis has yet to be demonstrated.

The past two years have seen an explosion in the utility of soluble polymers as supports in combinatorial and organic chemistry. Their unique properties which facilitate purification and easy analysis are making them increasingly useful to academics and industrialists alike and the increasing scope and removal of associated limitations of these matrices can only serve to increase their incorporation into the broad field of polymer-supported chemistry.

Received (in Oxford, UK) 30th June 1999, Accepted 23rd August 1999

The cation-exchange reaction between sodium montmorillonite and tetradecyltrimethylammonium bromide serving as a stabilizing agent in a palladium hydrosol led to the formation of alkylammonium montmorillonite with simultaneous immobilization of the palladium nanoparticles in the organoclay host; the Pd-organoclay proved to be catalytically active in olefin hydrogenation in the liquid phase.

The incorporation of Pd^{2+} ions, Pd(II) complexes or metallic Pd particles between the silicate layers of montmorillonite permits liquid-phase hydrogenation reactions with improved catalytic activity and specificity as compared with those involving supported Pd catalysts prepared by conventional impregnation routes, or with Pd(II) catalysts used in homogeneous solution. Pd(II) acetate and Pd(II) chloride have earlier been anchored to internal surface sites of montmorillonite *via* bipyridyl, diphenylphosphine and other linkages to produce interlamellar functionalized montmorillonite Pd(II) catalysts.[1,2] Reaction of ion-exchanging Na^+-montmorillonite with $[Pd(NCMe)_4]^{2+}$ and subsequent reduction of the Pd^{2+} in methanol afforded highly-dispersed metallic Pd particles in the clay galleries.[3] Ethanol is both a solvent and a reducing agent for Pd(II) acetate.[4] The preferential adsorption of ethanol from dilute hydrocarbon solutions in the interlamellar spaces of alkylammonium montmorillonite[5,6] and alumina-pillared montmorillonite[7] provided a suitable environment for *in situ* reduction of the Pd(II) acetate precursor in the interlamellar spaces of the clay host. The present work describes a new pathway for the production of organophilic Pd-montmorillonite (Pd-M) with a good control over the size of the Pd nanoparticles and the Pd content of the clay. The method involves the synthesis of a monodispersed Pd hydrosol with subsequent deposition of the Pd particles onto the clay lamellae.

The preparation of the Pd hydrosol and a systematic study relating to the control over the Pd particle size were performed under the following experimental conditions. 25–200 μL of Pd(II) acetylacetonate [$Pd(acac)_2$] solution (0.5–3 w/v% in $CHCl_3$) were added to 10 mL of tetradecyltrimethylammonium bromide (C_{14}TAB) surfactant solution [5–50 times the critical micelle concentration (cmc = 3.9 mM at 298 K in water)]. An excess of NH_2NH_2 solution (55 w/w% in water) was then introduced into the micellar system, which was left under vigorous stirring overnight to produce ultrafine Pd particles stabilized by the cationic surfactant.

The preparation of Pd-M and a systematic study concerning the control over the Pd content of the Pd-organoclay included the following experimental conditions. 50–200 mL of Pd hydrosol (stabilized with C_{14}TAB, 5–50 times the cmc) were added to 100–500 mL Na^+-montmorillonite suspension (0.1–2 w/w% in water) and the system was mixed vigorously overnight. The surfactant molecules rendered the clay surface hydrophobic, in parallel with the adsorption of the Pd particles on the silicate surface. The Pd-M material was purified by several centrifugation/redispersion cycles in ethanol and finally dried in the oven.

The proposed mechanism for the successive formation of the Pd hydrosol and the Pd-organoclay is outlined in Fig. 1. Whereas water is a poor solvent, $CHCl_3$ is a good solvent for $Pd(acac)_2$. The apparent solubility of $CHCl_3$ in water increases considerably if a sufficient quantity of C_{14}TAB surfactant is present in the aqueous phase (c > cmc). This solubilization effect allows the preparation of an aqueous colloidal solution of $Pd(acac)_2$ previously dissolved in $CHCl_3$. The UV-VIS spectra (UVIKON 930 spectrophotometer) of $Pd(acac)_2$ indicated a shift in the absorbance maximum in the micellar solution (340 nm) as compared with that in pure $CHCl_3$ solvent (327 nm). This observation may be attributed to the change in the microenvironment of $Pd(acac)_2$ upon solubilization, or to the formation of an adduct between the surfactant and the palladium salt.[8] In either case, the addition of an aqueous NH_2NH_2 solution to the $Pd(acac)_2$–$CHCl_3$–C_{14}TAB–water micellar system resulted in the formation of nanoscale Pd particles, partly sterically and partly electrostatically stabilized by the cationic surfactant molecules adsorbed on the surface of the particles (Fig. 1). The size distribution of the Pd particles in the hydrosol was determined by using a Philips C-10 transmission electron microscope (TEM) at 100 kV, assisted by the UTHSCSA Image Tool program. The present preparation method yielded spherical, monodispersed particles with a good control of size in the range 1.5–6 nm. We found that the particle size in the Pd hydrosol decreases with a decrease of the $Pd(acac)_2$ concentration and, in particular, with an increase of the C_{14}TAB concentration.

The formation of Pd-M was readily achieved by mixing the hydrosol with a dilute montmorillonite suspension. Reaction of the ion-exchanging Na^+-montmorillonite with the stabilizing (and in part with free) cationic surfactant molecules resulted in the formation of organophilic alkylammonium montmorillonite with the simultaneous release and subsequent deposition of the Pd nanoparticles onto the surface of the silicate layers (Fig. 1).

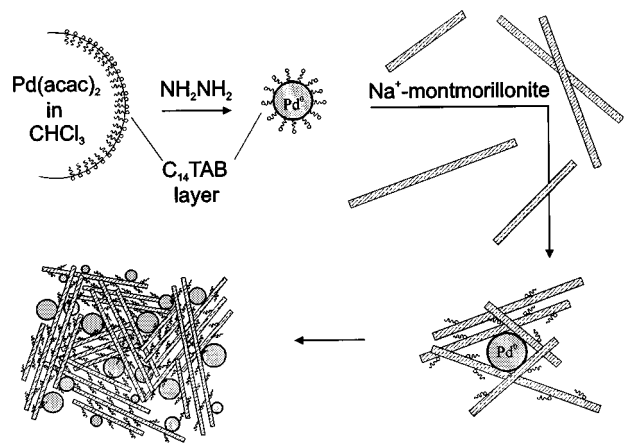

Fig. 1 Schematic illustration of the proposed mechanism for the successive formation of Pd hydrosol and Pd-organoclay in a micellar system.

Table 1 Characterization of organophilic Pd-montmorillonite catalysts

Catalyst code number	d(TEM)/nm	Pd (w/w%) (UV–VIS)	Pd (w/w%) (ICP–AES)	$10^{-3}r_i$[a] (styrene)	$10^{-3}r_i$[a] (hex-1-ene)	$10^{-3}r_i$[a] (cyclohexene)
Pd-M1	2.42	0.09	0.11	275.1	101.8	9.5
Pd-M2	3.25	1.15	1.32	34.8	26.5	5.8
Pd-M3	5.21	1.68	1.90	1.8	1.1	0.8

[a] Initial rate of hydrogenation, r_i [mL H_2 (g Pd min)$^{-1}$], in toluene.

TEM images indicated that the particles are more or less uniformly distributed on the external surface sites. The Pd contents of the Pd-M samples were determined indirectly by measuring the absorbance of the supernatant at 600 nm[9] during adsorptive removal of the Pd colloids by montmorillonite. Further, the Pd content was measured directly by inductively coupled plasma atomic emission spectroscopy at 229.7 nm[7] (ICP-AES, Jobin Yvon 24). It was established that the Pd content of the organoclay increases with decreasing solid to liquid ratio and, in particular, with decreasing surfactant concentration. X-Ray diffraction measurements on dry Pd-M samples were made with a Philips 1820 diffractometer (40 kV, 35 mA, Cu-Kα radiation) in the diffraction angle range 2θ = 1–10°. Each material gave a broad d_{001} reflection, with an interlayer spacing substantially smaller than the mean diameter of the Pd particles as determined by TEM. This finding is consistent with a disordered deposition of layer packets encapsulating the Pd particles (Fig. 1). A regular pattern of intercalation of the Pd species between the layers is unlikely.

Pd-M can be dispersed in organic solvents (ethanol, benzene, acetone, *etc*.) that are generally used in contact catalytic hydrogenation reactions in the liquid phase. Three Pd-M samples were selected for catalytic test reactions (Table 1). Toluene was used as the reaction medium: this solvent readily wets and swells the organoclay and provides access to the Pd particles for the reactant molecules. The rates of styrene, hex-1-ene and cyclohexene hydrogenation were recorded by using an automated vibration reactor at atmospheric pressure at 303 K. Typically, the reaction vessel contained 1 mL of toluene, 0.1 mL of substrate and a calculated amount of catalyst loaded with 25 μg of Pd. A Hewlett Packard GC–MS apparatus (HP 5890; HP 5970) was used for product analysis. Close correlations were found between the catalytic activity and the position of the C=C double bond of the substrate, and the catalytic activity and the degree of dispersion of the Pd particles (Table 1). For a given substrate, the initial rate of hydrogenation, r_i, increases appreciably with decreasing particle size. For a given Pd-M catalyst, r_i increases in the sequence styrene > hex-1-ene > cyclohexene. The C=C bond in conjugation with the aromatic ring displays the highest affinity toward the uptake of hydrogen, and the reactivity is higher for the terminal olefin than for the internal one. GC–MS analysis at intermediate stages indicated that the consecutive (isomerization plus hydrogenation) reactions hex-1-ene→(*trans*- and *cis*-hex-2-ene)→*n*-hexane are superimposed on the hydrogenation reaction hex-1-ene→*n*-hexane. While the simultaneous hydrogenation and isomerization of hex-1-ene were found to be fast processes, as was the hydrogenation of styrene, the rate of conversion to *n*-hexane was moderated by the appearance of the hex-2-ene isomers and the kinetic curve resembled that of cyclohexene (internal olefin).

It is anticipated that the basic principles of the present preparation method can be applied to other systems where the metallic particles are stabilized by ionic surfactants and the solid support is an oppositely charged ion exchanger. For example, if transition metal particles (M) stabilized by anionic surfactants are mixed with positively charged layered double hydroxides (LDH), organophilic M-LDH will be formed, which can be used in contact catalytic reactions in organic solvents. Experimental work on this system is currently being undertaken.

Facile α-deprotonation–electrophilic substitution of quinuclidine and DABCO

Satinder V. Kessar,* Paramjit Singh, Kamal N. Singh and Sandeep K. Singh

Department of Chemistry, Panjab University, Chandigarh-160014, India. E-mail: svkessar@panjabuniv.chd.nic.in

Received (in Cambridge, UK) 2nd July 1999, Accepted 30th July 1999

Deprotonation of BF_3 complexes of quinuclidine or DABCO by Schlosser base and subsequent reaction with electrophiles affords α-substituted products in moderate to good yields.

A number of drugs and molecules acting as chiral catalysts have a quinuclidine (**1**) framework with an appendage at a carbon atom α to the bridgehead nitrogen.[1] We envisaged a direct access to such compounds from the basic system *via* a Lewis acid promoted amine deprotonation procedure,[2] even though removal of a secondary α-proton from a piperidine ring is often problematic.[3] In the event, strong BF_3 activation in conjunction with the use of a superbase (Bu^sLi/Bu^tOK) proved to be effective for deprotonation of **1** (Scheme 1).[4,5] Subsequent reaction with electrophiles proceeded smoothly to afford a variety of products **4** in moderate to good yields (Table 1).† Barton's *N*-oxide approach is the only other route available for similar elaboration of the quinuclidine framework.[6] Our method

avoids separate *N*-oxide formation–deoxygenation steps and the overall yields for the two procedures are comparable.

The Lewis acid activation method was also explored to obtain a quinuclidine with an α-attached sulfur atom, which with its various oxidation states can provide novel bidentate ligands. On reaction of **1** with diphenyl disulfide under standard conditions the disubstituted compound **5** was obtained as the major product (52%). However, it could be cleanly reduced to the desired monosubstituted compound **6** with lithium naphthalenide in THF.[8] Finally, this methodology was extended to α-deprotonation–electrophilic substitution of DABCO (**7**) (Scheme 2).‡ This readily available diazabicyclooctane has also been used extensively to modify organic reactions.[9] However, few reports of the synthesis and use of DABCO analogs of natural and synthetic quinuclidine compounds have appeared in the literature and their potential, as ligands and drugs, has remained largely unexplored.[10]

Notes and references

† All compounds were characterised by ^1H NMR and ^{13}C NMR spectroscopy and mass spectrometry. Mps of known compounds corresponded with literature values. *Selected data* for **4f** (*threo*): mp 104–105 °C (hexane); $\delta_H(CDCl_3$, 300 MHz) 1.13–1.33 (m, 2H), 1.38–1.55 (m, 4H) (C-3H, C-5H, C-7H), 1.75 (br s, 1H, C-4H), 2.73–2.89 (m, 2H), 2.93–2.99 (m, 2H), 3.05–3.15 (m, 1H) (C-2H, C-6H, C-8H), 4.52–4.55 (d, *J* 9.7, 1H, C-9H), 7.43–7.49 (m, 2H, ArH), 7.54–7.57 (d, *J* 8.6, 1H, ArH), 7.81–7.84 (m, 4H, ArH); $\delta_C(CDCl_3)$ 21.5 (CH), 25.8 (CH_2), 26.8 (CH_2), 29.4 (CH_2), 41.4 (CH_2), 49.6 (CH_2), 62.6 (CH), 74.7 (CH), 125.0 (CH), 125.7 (CH), 125.9 (CH), 126.5 (CH), 127.7 (CH), 127.9 (CH), 128.0 (CH and Cq), 133.2 (Cq), 138.7 (Cq); *m*/*z* 268 (M^+ + 1, 11.9%), 267 (M^+, 54.7), 250 (11.2), 158 (12.0), 141 (14.4), 129 (28.9), 111 (57.2), 82 (100) (Calc. for $C_{18}H_{21}NO$, 267.1623. Found 267.1628). For **6**: mp 65–66 °C (hexane); $\delta_H(CDCl_3$, 300 MHz) 1.25 (br s, 1H), 1.31–1.38 (m, 1H), 1.51–1.54 (m, 3H), 1.82 (br s, 1H), 2.02–2.10 (m, 1H) (C-3H, C-4H, C-5H, C-7H), 2.69–2.78 (m, 1H), 2.99–3.11 (m, 2H), 3.49–3.59 (m, 1H) (C-6H, C-8H), 4.50–4.56 (t, *J* 8.6, 1H, C-2H), 7.14–7.17 (d, *J* 7.1, 1H, ArH), 7.22–7.27 (t, *J* 7 Hz, 2H, ArH), 7.41–7.44 (d, *J* 7.4, 2H, ArH); $\delta_C(CDCl_3)$ 22.7 (CH), 25.5 (CH_2), 26.8 (CH_2), 34.5 (CH_2), 40.8 (CH_2), 48.6 (CH_2), 65.8 (CH), 126.0 (CH), 128.7 (2CH), 129.2 (2CH), 136.9 (Cq); *m*/*z* 220 (M^+ + 1, 14.8%), 219 (M^+, 100), 218 (17.9), 186 (30.7), 142 (31.5), 110 (80.0), 98 (79.0), 82 (25.8) (Calc. for $C_{13}H_{17}NS$, 219.1081. Found 219.1083).

‡ *Conditions* for α-deprotonation–electrophile reaction of DABCO: To a solution of Bu^tOK (2.2 mmol) and Bu^sLi (2.2 mmol) in THF (6 ml) at −78 °C was added slowly *via* a cannula a solution of DABCO–BF_3 complex (1.0 mmol) in THF (4 ml) under a nitrogen atmosphere. After stirring for 2 h, a solution of the electrophile (2.2 mmol) in THF (2 ml) was added dropwise. The temperature was maintained at −78 °C for 30 min and then allowed to rise to −30 °C over a period of 30 min. The reaction mixture was quenched with 10% HCl (5 ml) and worked up.

Origin of diastereoselectivity in the addition of allylsilane to chiral acyclic mixed acetals

Kavita Manju and Sanjay Trehan*

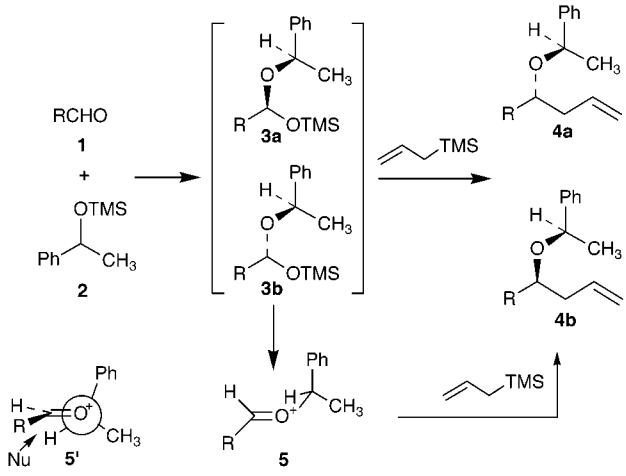
Received (in Cambridge, UK) 9th June 1999, Accepted 12th August 1999

Addition of allylsilane to chiral acyclic mixed acetals has been found to proceed *via* an S_N1 mechanism and a model has been proposed to explain the observed diastereoselectivity.

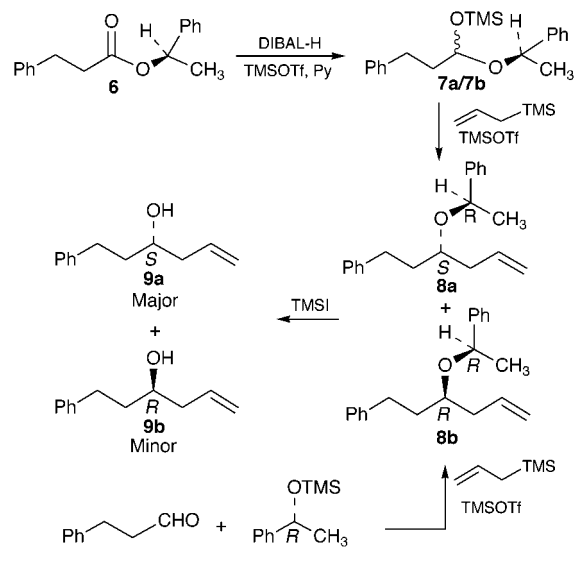
Over the last couple of decades great strides have been made in the Lewis acid catalysed reaction of chiral acetals with silyl nucleophiles. Chiral cyclic acetals have been studied in detail and the mechanism as well as the diastereofacial selectivity of their reaction is now well-established.[1] Despite the fact that chiral mixed acyclic acetals prepared *in situ* give homoallylic ethers in high diastereoselectivity,[2] an understanding of the origin of the diastereoselectivity is lacking. In order to comprehend the origin of the diastereoselectivity one needs to first establish the mechanism (S_N1 or S_N2) because there is support for both type of mechanisms in the literature.†[3] If the reaction proceeds *via* an S_N2 mechanism, then the origin of the diastereoselectivity should lie in the diastereoselective formation of a silyl acetal intermediate which would undergo allylation in a stereospecific manner (Scheme 1). In such a case the diastereomeric ratio of the silyl acetal (**3a**:**3b**) and homoallylic ether (**4a**:**4b**) should be the same. Alternatively, if the reaction proceeds *via* an S_N1 mechanism, a common oxocarbenium ion **5** will be formed from both the silyl acetal intermediates. The diastereoselectivity in this case will be determined by the extent of 1,3-induction[4] and will be independent of the ratio of the silyl acetals (**3a**:**3b**) (Scheme 1). Houk has proposed a theoretical model for the nucleophilic addition on this type of oxocarbenium ion by invoking a weak 1,3-allylic interaction and has shown reaction occurring from the most stable conformation **5′** giving **4b** as the major product.[5] Herein, we report our results which establish the mechanism and the diastereoselectivity of this reaction.

Chiral ester **6** prepared from (*R*)-1-phenethyl alcohol and hydrocinnamic acid was treated with 1 equiv. of DIBAL-H and the intermediate was treated with TMSOTf and pyridine[6] to give acetal **7a**/**7b** as a mixture of diastereomers in the ratio of 54:46 (Scheme 2).‡ This mixture of acetals was treated with 0.1 equiv. of TMSOTf and 1.5 equiv. of allyltrimethylsilane in toluene at −78 °C to give homoallylic ether **8a**/**8b** in 79% yield. The diastereomeric ratio was found to be 82:18 from its ^{1}H NMR, which was vastly different from its precursor acetals. Identical diastereoselectivity was also obtained when hydrocinnamaldehyde was treated with the trimethylsilyl ether of (*R*)-1-phenethyl alcohol and allyltrimethylsilane in the presence of TMSOTf in toluene at −78 °C. These two experiments suggests an S_N1 mechanism whether the mixed acetal is prepared *in situ* or is isolated before allylation.

The configuration of the newly created chiral centre was established to be *S* from the optical rotation of the corresponding homoallylic alcohol **9a**/**9b** {$[\alpha]_D$ −12.6 (*c* 1, $CHCl_3$); lit.[7] +16.9 (*c* 1, $CHCl_3$) for the *R* isomer with 80% ee} obtained by treatment of **8a**/**8b** with iodotrimethylsilane.[8] Thus the major diastereomer formed is (*S*,*R*)-**8a**, just as reported in earlier work,[2] and not (*R*,*R*)-**8b** as as identified mistakenly by Houk as the major product obtained by Mukaiyama[2b] and Seebach[2c] while applying his model.[5] Since the Houk model is not applicable to the system under investigation an alternate model is desirable. The reaction of the oxocarbenium ion intermediate is expected to be exothermic in nature, therefore in the absence of any polar group in the chiral centre, the ground state conformation of the oxocarbenium ion should be important in determining the diastereoselectivity.[9] In order to establish the importance of steric or stereoelectronic effects on the conformational preferences of the oxocarbenium ion intermediate leading to the product, various silyl ethers with R groups of increasing steric bulk were synthesised and used in the allylation reaction.[10] The results are summarised in Table 1. The configuration of the products was assigned as done earlier except when silyl ethers with isopropyl groups were used, because they could not be prepared in reasonable optical purity. In these cases the configuration was established by correlation of their ^{1}H NMR with that of **8**.

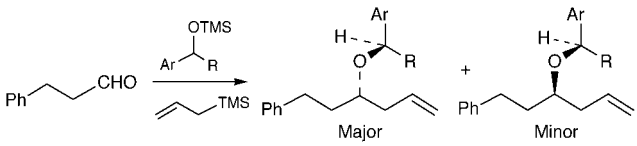


Scheme 1



Scheme 2

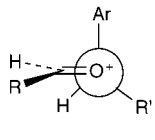
Table 1 Reaction of hydrocinnamaldehyde with various silyl ethers and allylsilane[ab]



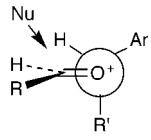
Entry	Ar	R	Diastereomer ratio[c]	Yield (%)
1	Ph	Me	82:18 (4.5:1)	89
2	Ph	Et	85:15 (5.7:1)	82
3	Ph	Pr^i	86:14 (6.1:1)[d]	85
4	*o*-Tolyl	Me	88:12 (7.3:1)	82
5	*o*-Tolyl	Et	93:07 (13.3:1)	88
6	*o*-Tolyl	Pr^i	91:09 (10.1:1)[d]	80

[a] All reactions were carried out in toluene at −78 °C under nitrogen atmosphere. [b] Enantiomeric excess of silyl ethers used in entries 1, 2, 4 and 5 were 94, 89, 90 and 81% respectively (ref. 11) and (±)-silyl ethers were used in entries 3 and 6. [c] Diastereomeric ratio was determined *via* ^{1}H NMR. [d] Configuration was established by correlation of ^{1}H NMR with that of **8**.

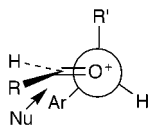
If steric effects were important, then one would expect a decrease in diastereoselectivity with a decrease in the steric difference between the medium and large groups. However, the opposite trend was observed and generally diastereoselectivity increased as the size of the alkyl group increased in the two series studied (Table 1, entries 1–3 and 4–6). This suggests that stereoelectronic effects stabilise certain select conformations of the oxocarbenium ion leading to the product. In the absence of any electrostatic effects,[12] the important stereoelectronic interactions between the three groups of the chiral centre and the C=O bond which can restrict the conformational mobility of the chiral centre are σ*–π* and π–π* (hyperconjugation).[13,14] However, conformation **10** obtained using the σ*–π* interaction[10] is similar to Houk's model[5] and therefore does not appear to be important. Therefore hyperconjugation between the substituents of the chiral centre and the oxocarbenium ion appears to be the predominant stereoelectronic interaction.



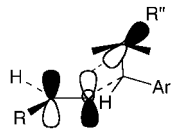
10



11a



11b



12

We suggest that the reaction proceeds through a conformation where the alkyl group occupies the *anti* position. In conformations **11a** and **11b** besides normal α–β C–C hyperconjugative stabilisation of the oxocarbenium ion there is an additional stabilisation due to bonding between the β–γ substituents, as depicted in **12**.[14c] This stabilisation is greater for a C–C bond than for a C–H bond.[14c] Therefore ethyl or isopropyl groups should stabilise conformations **11a** and **11b** more than a methyl group over other conformations. This additional stabilisation is missing for bonding between the chiral carbon and aryl groups or hydrogen.§¶‖

We conclude that C–C hyperconjugative stabilisation of the oxocarbenium ion restricts the conformation of the chiral centre to **11a** and **11b** leading to major and minor diastereomers. The observed diastereoselectivity is due to the differential interaction of the nucleophile with the hydrogen in **11a** and the aryl groups in **11b**. Accordingly higher diastereoselectivity is observed for the *o*-tolyl series.

We thank CSIR for financial support. K. M. also thanks U. G. C. for senior research fellowship.

Notes and references

† Mukaiyama has proposed an S_N2 mechanism for the allylation of chiral mixed acyclic acetals [ref. 2(*b*)].

‡ No attempt was made to assign the configuration of the newly generated acetal chiral centre in the major and minor isomer.

§ Since C(sp^3)–C(sp^2) is a stronger bond therefore C(sp^3)–C(sp^2) hyperconjugation may not be as important as C(sp^3)–C(sp^3) hyperconjugation.

¶ The silyl ether of 1-deutero-1-phenylethyl alcohol gave product in an 86:14 ratio (compare Table 1, entry 1). The increase in diastereoselectivity indicates that the C–H or C–D bond stabilises the oxocabenium ion by inductive effects and not by hyperconjugation (ref. 15).

‖ Linderman has also invoked hyperconjugative stabilisation of the oxocarbenium ion intermediate by R_3Si in diastereoselective Mukaiyama-type aldol reactions of silyl-substituted mixed acyclic acetals (ref. 16). We thank one of the referees for bringing this reference to our notice.

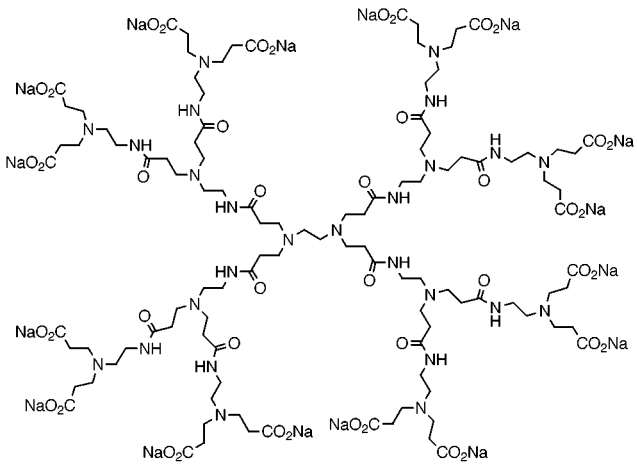
Received (in Cambridge, UK) 12th July 1999, Accepted 25th August 1999

Crystallization of $CaCO_3$ in the presence of poly(amidoamine) (PAMAM) dendrimer containing carboxylate groups at the external surface resulted in the formation of spherical vaterite crystals whereas rhombohedral calcite crystals were formed in the absence of additive.

In nature, biological organisms produce polymer–inorganic hybrids which have superior mechanical properties as compared to synthetic hybrids.[1] Small amounts of acidic-rich proteins play a major role in forming such hybrids by influencing mineral crystal nucleation and growth.[2] On the basis of specific interactions, 'matrix' proteins or other macromolecules affect crystal morphology by inhibiting the growth of particular crystal faces. The processes and materials that control such crystal growth are of great interest in the field of material chemistry, in particular in the construction of composite materials analogous to those produced by nature. Crystallization of inorganics in the presence of various synthetic polymers has been investigated as a model of biomineralization. Synthetic anionic polypeptide analogues and anionic non-peptide polymers have also been found to be potent inhibitors or habit modifiers of inorganic crystallization.[3–5] Studies of inorganic crystallization in the presence of soluble polymers, modeled on biogenic proteins, have shown that the selectivity for certain crystal faces appears to be highly dependent on the secondary structure of the macromolecules. For example, poly-L-aspartate, with a predominantly β-sheet conformation, produces more argonite than poly-L-glutamate, which has a random conformation.[3]

Poly(amidoamine) (PAMAM) dendrimers with carboxylate groups at the external surface, denoted half-generation or G = *n*.5 dendrimers have been proposed as mimics of anionic micelles or proteins.[6] The starburst structures are disklike shapes in the early generations, whereas the surface branch cell becomes substantially more rigid and the structures are spherical for later generations.[7] Owing to their unique and well defined secondary structures, anionic starburst dendrimers should be good candidates for studying inorganic crystallization. Although the interaction of the negative surface of the dendrimers with metal ions has been extensively examined,[8] the effect of dendrimers on inorganic crystallization in aqueous solution has not been reported. Here we studied crystallization of $CaCO_3$ in the presence of anionic PAMAM dendrimers and found that the anionic starburst dendrimer was a habit modifier which affected the crystal morphology upon crystallization. We used calcium carbonate ($CaCO_3$) as the inorganic phase, since its crystals are easily characterized, and since the morphology of $CaCO_3$ has been shown to be subject to control in biomineralization processes.[9]

The precipitation of $CaCO_3$ in the presence and the absence of the PAMAM dendrimer (G = 1.5) was carried out under the same conditions as used by Cölfen *et al.*[10] to prevent heterogeneous nucleation at the glass walls.† $CaCO_3$ crystal formation occurring after addition of the reactants was readily



PAMAM dendrimer (G = 1.5)

observed from a sudden increase in the turbidity of the solution. This solution was then kept at 25 °C under N_2 for 4 days with gentle stirring. Owing to the complexation of the dendrimer with calcium ions, the saturated concentration of calcium ions in the presence of PAMAM dendrimer (G = 1.5) was 1.3 times higher than that in the absence of the additive. The crystalline $CaCO_3$ was washed with water to remove contaminating dendrimers that were not involved in the crystals. The yields of the crystalline products in the absence and presence of the dendrimer were 51 and 61%, respectively. The dendrimer content in the crystalline $CaCO_3$ was 33 wt% as determined by elemental analysis. These results indicate that the anionic dendrimer was bound to the crystalline $CaCO_3$.

The precipitation of $CaCO_3$ in the presence of the Na salt of poly(acrylic acid) (PAA) (M_n = 5100) was also carried out under the same conditions as above. The concentration of calcium ions in the presence of the Na salt of PAA was twice that in the absence of the additive before a sudden increase in the turbidity of the solution was observed. In the presence of the Na salt of PAA, the formation of crystalline $CaCO_3$ was prevented and amorphous $CaCO_3$ was collected after incubation at 25 °C under N_2 for 4 days. This indicates that PAA acts as an inhibitor for crystal formation.[11]

The crystal phase of $CaCO_3$ obtained in the presence of the PAMAM dendrimer was characterized by FTIR analysis.[12] Bands at 877 and 746 cm^{-1} indicated the formation of vaterite while bands at 874 and 712 cm^{-1} characteristic of calcite were scarcely observable.

By contrast, according to IR spectroscopy, the crystal phase of $CaCO_3$ obtained in the absence of dendrimer was calcite. The IR spectrum of $CaCO_3$ obtained in the presence of the Na salt of PAA suggested an amorphous character. Crystal phases $CaCO_3$ were further confirmed by XRD; in the presence of dendrimer,

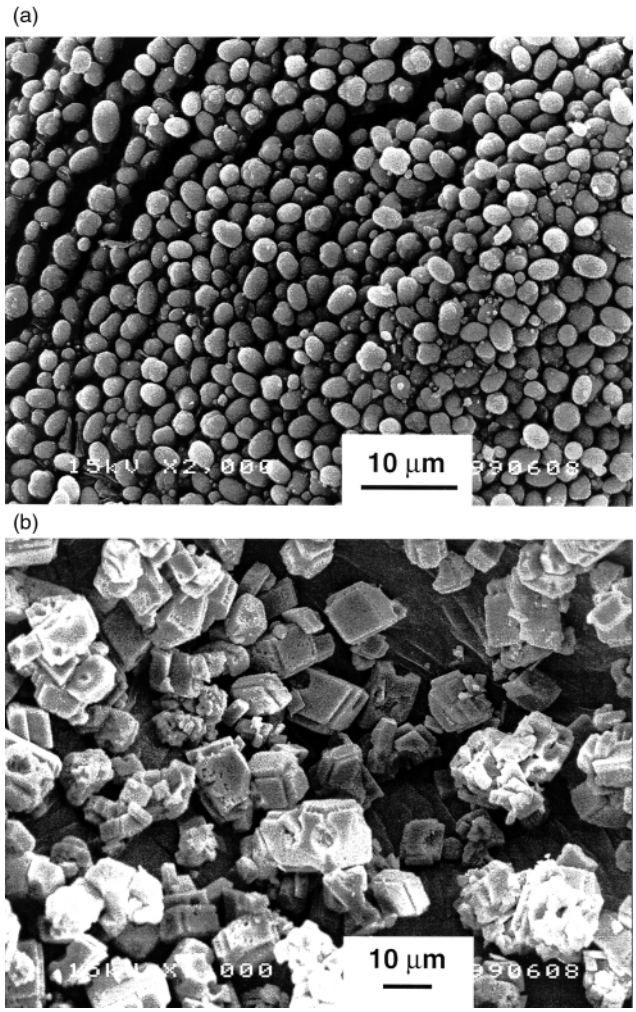


Fig. 1 Scanning electron micrographs of calcium carbonate in the presence (a) and the absence (b) of PAMAM dendrimer (G = 1.5).

the precipitate consisted entirely of vaterite (> 99%) while in the absence of dendrimer, the reflections were characteristic for calcite.

SEM observations showed that the vaterite particles were spherical [Fig. 1(a)] with an average particle diameter of 1–2 μm. SEM also showed that calcite crystals obtained in the absence of the polymer were rhombohedral [Fig. 1(b)]. Vaterite transforms readily and irreversibly into thermodynamically more stable forms when in contact with water and complete phase transformation into the thermodynamically stable calcite form occurs within 80 h and usually much faster under the conditions described above.[10] It is well known that vaterite transforms into the stable calcite form *via* a solvent-mediated process.[13] Stable spherical vaterite crystals have already been reported in the presence of various divalent cations,[14] a surfactant [bis(2-ethylhexyl)sodium sulfonate (AOT)],[15] and double-hydrophilic block copolymers.[10] We speculate that the vaterite surface is stabilized by the carboxylate-terminated dendrimer in aqueous solution to prevent phase transformation. If the Ca–O bonds to a polymer ligand are easily dissociated by water, then the polymer is thought not to be occluded in the $CaCO_3$ crystal, and solvent-mediated vaterite–calcite transformation would occur. Strong Ca–O bonds are thus required to alter the obtained polymorph of $CaCO_3$.‡ In the presence of the PAMAM dendrimer, further washing of the vaterite crystal with water did not change the crystal morphology. Although a template mechanism involving dendrimers appears to be of a complex nature since simultaneous $CaCO_3$ nucleation and interaction with the polymer is expected, the complexation properties of PAMAM dendrimers may be a major factor in the mineralization of calcium ions.

In conclusion, we present the first example of crystallization of $CaCO_3$ in the presence of an anionic starburst dendrimer. Whereas a linear poly(carboxylic acid), PAA, acts as an inhibitor for crystal formation, the dendrimer was a habit modifier and affected the crystal morphology upon $CaCO_3$ crystallization. The complexes of anionic starburst dendrimers with calcium ions are considerably stronger for higher generations than for lower generations. Investigations are now underway on crystallization of $CaCO_3$ in the presence of anionic starburst dendrimers of even higher generations.

Notes and references

† PAMAM dendrimer (G = 1.5) (16 surface carboxylate groups) was purchased from Aldrich. $CaCO_3$ crystallization was carried out as follows. A solution of 1.56×10^{-1} mmol of the dendrimer (corresponding to 2.50 mmol of $-CO_2Na$) in 300 ml distilled water was adjusted to pH 8.5 with NH_3 (aq). Then 0.5 M $CaCl_2$ aqueous solution (adjusted to pH 8.5) and 0.5 M $(NH_4)_2CO_3$ aqueous solution (adjusted to pH 10.2) were injected *via* syringe into the reaction mixture at 25 °C under N_2 with stirring. After a sudden increase in the turbidity of the solution, this solution was then kept at 25 °C under N_2 for 4 days with gentle stirring. $CaCO_3$ crystallization in the absence of the dendrimer was carried out using a 300 ml aqueous solution containing 2.50 mmol of NaCl instead of the dendrimer solution.
‡ Stoichiometric exchanges of alkali-metal ions with divalent cations such as Ca^{2+} have been reported for anionic PAMAM dendrimers.[6]

An $Al_{12}R_8^-$ cluster as an intermediate on the way from aluminium(I) compounds to aluminium metal†

Andreas Purath, Ralf Köppe and Hansgeorg Schnöckel*

Institut für Anorganische Chemie, Universität Karlsruhe (TH), Engesserstr. Geb. 30.45, D-76128 Karlsruhe, Germany. E-mail: hg@achpc9.chemie.uni-karlsruhe.de

Received (in Basel, Switzerland) 26th May 1999, Accepted 19th August 1999

A new Al_{12} cluster resembling a small section of the aluminium lattice has been prepared by the reaction of AlCl solution with $LiN(SiMe_3)_2$.

Metastable aluminium monohalide solutions generated *via* condensation of high temperature AlX molecules[1] have proved to be potential precursors for the synthesis of aluminium atom clusters. Besides Al_4Cp_4*[2] as the first example, recently an Al_{77} cluster[3] was prepared which is the largest metal atom cluster characterised by X-ray structure determination to date. In order to understand the formation of the Al_{77} cluster that may be viewed as one of the final steps in the reaction pathway to the bulk metal, we attempted to isolate smaller intermediates. Very recently we were able to characterise an $Al_7R_6^-$ species with a unique D_{3d} structure containing a 'naked' Al atom 'sandwiched' by two Al_3R_3 ring systems.[4] Here we report the cluster anion $Al_{12}R_8^-$ [R = $N(SiMe_3)_2$] which may be the next step on the way to the Al_{77} cluster.

Black crystals of $Li(OEt_2)_3^+[Al_{12}\{N(SiMe_3)_2\}_8]^-$ **1** were formed after heating an $LiN(SiMe_3)_2$–AlCl solution (toluene–diethyl ether) to *ca.* 60 °C and subsequently storing at room temperature for 10 days (Scheme 1)‡.

$$29\ AlCl + 26\ LiN(SiMe_3)_2 \longrightarrow 24\ LiCl + 2\ Li^+[Al_{12}\{N(SiMe_3)_2\}_8] + 5\ [Al\{N(SiMe_3)_2\}_2]Cl$$

1

Scheme 1

In comparison to the Al_{12} cluster, the Al_7 cluster [4] is formed by the same reaction under milder conditions (24 h at 20 °C and several weeks at −25 °C).

The structural result of the X-ray structure determination of **1** is shown in Fig. 1.§ The structure of the $Al_{12}[N(SiMe_3)_2]_8^-$ anion is similar to that of a neutral $In_{12}R_8$ cluster compound (R = $SiBu^t_3$) published recently by Wiberg *et al.*[5] The EPR spectrum of a solid sample of **1** confirmed the radical character of the anion. Like the In_{12} cluster, the anion of **1** can be regarded as a section of the metal lattice as indicated in Fig. 2.

In order to understand the formation of the negatively charged Al_{12} cluster in contrast to the neutral In_{12} molecule preliminary DFT calculations[6] were performed for the species $In_{12}H_8$, $In_{12}H_8^-$, $Al_{12}H_8$ and $Al_{12}H_8^-$. The bonding situation for the In_{12} and Al_{12} cluster compounds is comparable in the following sense: addition of a single electron mostly influences the two apical Al3–Al5 bonds. This is evident by inspection of Table 1 which lists the calculated Al–Al distances of the model compounds $Al_{12}H_8$ and $Al_{12}H_8^-$. The discrepancies with respect to the observed distances in **1** disappear if NH_2 ligands are applied in place of H, *e.g.* for $Al_{12}(NH_2)_8^-$.[7] However, to obtain a complete insight into the electronic structure, extensive calculations including incorporation of $N(SiMe_3)_2$ ligands and without any symmetry restrictions have to be performed.

Calculations for the In_{12} compounds revealed similar trends and the $In_{12}R_8^-$ anion should be also a stable species. However,

† Dedicated to Professor Nils Wiberg on the occasion of his 65th birthday.

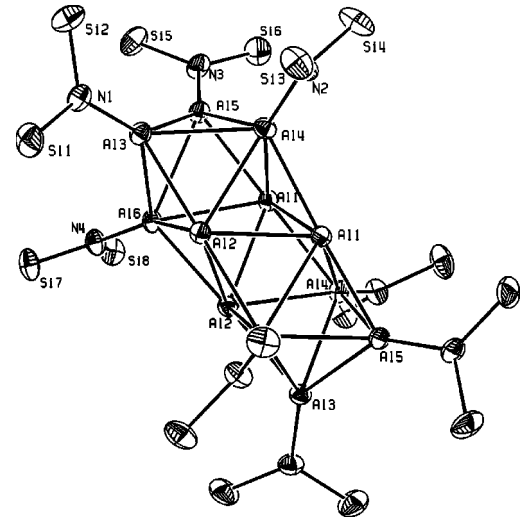

Fig. 1 Molecular structure of **1** (50% probability thermal ellipsoids; methyl groups are omitted for clarity). Selected distances (pm): Al–Al (see Table 1), Al–N 184.8 (av.), N–Si 174.4 (av.).

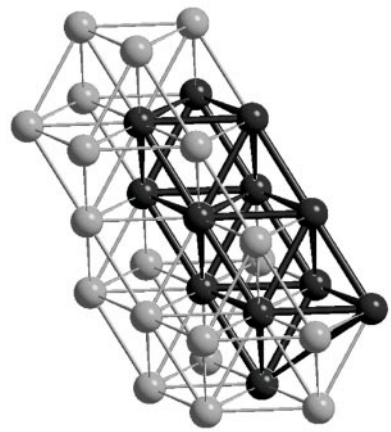

Fig. 2 Section of the aluminium metal lattice (ccp); an Al_{12} unit is accentuated.

Table 1 Selected Al–Al bond lengths for $Al_{12}[N(SiMe_3)_2]_8^-$ **1** (experimentally determined) as well as $Al_{12}(NH_2)_8^-$ (S_4), $Al_{12}H_8^-$ (D_{2d}) and $Al_{12}H_8$ (D_{2d}) (calculated)

d/pm	$Al_{12}[N(SiMe_3)_2]_8^-$	$Al_{12}(NH_2)_8^-$	$Al_{12}H_8^-$	$Al_{12}H_8$
Al1–Al5	259.8	259.4	254.3	251.4
Al2–Al6′	268.2	266.1	270.0	272.4
Al3–Al5	254.2	253.3	263.5	278.3
Al3–Al6	279.9	275.2	269.2	267.9
Al1–Al1′	263.0	273.3	271.6	270.2
Al1-Al4'	278.8	273.9	277.3	279.9

the higher electron affinity of Al^+ relative to In^+ may be the reason for its higher tendency to achieve a lower oxidation state (between 1 and 0): the average oxidation state of the Al atoms in $Al_{12}R_8^-$ is +0.58 while a value of +0.66 is found for In in $In_{12}R_8$.

20 triangular faces are present in **1** as also found in the well known Al_{12} species $Al_{12}R_{12}^{2-}$ (R = Bu^i) with icosahedral symmetry.[8] Such a related *closo* $Al_{12}R_{12}^{2-}$ anion may be one of the primary intermediates during the formation of **1**. If 2 R^- groups are removed from such an intermediate, an $Al_{12}R_{10}$ species will be formed which is similar to the distorted icosahedral $Al_{12}(AlBr_2)_{10}$ that we have published recently.[9]

$$Al_{12}R_{12}^{2-} \xrightarrow{-2R^-} Al_{12}R_{10} \xrightarrow{+2e^-,\,-2R^-} Al_{12}R_8 \xrightarrow{+e^-} Al_{12}R_8^-$$

Scheme 2

Further reduction to $Al_{12}R_{10}^{2-}$ and dissociation of two additional R^- ligands would lead to an $Al_{12}R_8$ molecule or the corresponding anion observed here. Since similar cluster compounds are obtained for In and Al, the proposed mechanism may represent the general pathway during reduction processes leading to the bulk metal. Therefore, intermediates similar to **1** can also be expected for other metals. However, the size of the metal atoms must be compatible with the size of the ligands, *i.e.* the large supersilyl ($SiBu^t_3$) ligands are suitable for protecting the large In_{12} cluster whereas the smaller $N(SiMe_2)_2$ groups match the smaller Al_{12} cluster.

Owing to the radical character of **1**, further physical measurements are underway in order to obtain more detailed information about the electronic structure of this Al_{12} cluster compound which is an example of a metal atom cluster in the sense first stated by Cotton;[10] *i.e.* an assembly of metal atoms which are essentially connected by direct bonds. The presence of metal–metal bonds has been a primary reason for the increasing interest in metal cluster chemistry over the last two decades. However, while most ligand stabilised clusters published so far do not fulfil the original criterion of Cotton, **1** is a archetypal metal atom cluster since four or six Al atoms are directly bonded to each Al atom. Furthermore, in **1** the number of ligands is smaller than the number of metal atoms and no bridging ligands are present. In our opinion these latter two criteria should be fulfilled in order to regard a compound as a genuine metal atom cluster.

We acknowledge the financial support of the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We also thank Bernd Pilawa for recording EPR spectra.

Notes and references

‡ *General considerations*: all experiments were carried out under dry argon in a glovebox (Mbraun MB 150-GI) or under dry nitrogen using standard Schlenk techniques. Solvents were dried over potassium and degassed prior to use. EPR spectra were recorded on a BRUKER ESP 300 E.

Synthesis: 8.6 ml cold (−78 °C) AlCl solution (0.29 M, toluene–Et_2O) (2.5 mmol) was added dropwise to 500 mg (3.0 mmol) solid $LiN(SiMe_3)_2$. The reaction mixture was then heated quickly to 60 °C and stored for 2 h at this temperature. Subsequently, the dark brown solution was separated from solid LiCl. Storing at room temp. gave black crystals of **1** after 10 days. Yield in crystalline form: 11 mg (0.006 mmol) 28%; EPR (solid) $g_\perp$ = 2.015 ($\Delta B_{1/2}$ = 38.9 G), $g_\parallel$ = 2.23 (weak).

§ *Crystal data*: $C_{60}H_{152}Al_{12}LiN_8O_3Si_{16}$ **1**, M = 1836.2, monoclinic, space group $P2/n$, Z = 2, a = 20.893(2), b = 13.0123(10), c = 21.455(2) Å, β = 98.134(11)°, V = 5774.5(9) Å^3, μ(Mo-Kα) = 0.30 mm^{-1}, T = 213(1) K, 31005 reflections collected/10283 (R_{int} = 0.0600) independent/6348 with $I > 2\sigma(I)$. The structure was solved by direct methods and refined by full-matrix least squares on F^2 to final values of $R1[F > 4\sigma(F)]$ = 0.0553 and $wR2$ = 16.83 (all data). The diethyl ether molecules co-ordinated to the Li atom are strongly disordered. In treatment of this disorder we disregarded occupancies for hydrogen atoms. CCDC 182/1389. 7 For the radical anion $Al_{12}(NH_2)_8^-$ most of the calculated Al–Al distances are very close to those of **1**. A complete accordance with the experimentally determined structural data can not be expected since the NH_2 ligand is different from the $N(SiMe_3)_2$ group for the following reasons. (a) The N atom in the NH_2 group is pyramidally coordinated whereas a planar surrounding is observed for the $N(SiMe_3)_2$ groups. (b) The orientation of the NR_2 groups towards the Al_{12} core should be different for both amide groups for steric reasons and therefore a different interaction of the lone pair of the N atom with the Al_{12} core can be expected. In order to save computing time a symmetry restriction (S_4) was applied for the $Al_{12}(NH_2)_8$ species. The electron affinity for the process $Al_{12}(NH_2)_8 \rightarrow Al_{12}(NH_2)_8^-$ has been calculated to be exothermic by −145 kJ mol^{-1}.

Synthesis and structure of a thiolate-bridged nickel–iron complex: towards a mimic of the active site of NiFe-hydrogenase

Sian C. Davies, David J. Evans,* David L. Hughes, Steven Longhurst and J. Roger Sanders

Department of Biological Chemistry, John Innes Centre, Norwich Research Park, Colney, Norwich, UK NR4 7UH. E-mail: dave.evans@bbsrc.ac.uk

Received (in Cambridge, UK) 2nd July 1999, Accepted 24th August 1999

The reaction, under carbon monoxide, of $[Fe(NS_3)(CO)]^-$ [NS_3 = $N(CH_2CH_2S)_3^{3-}$] with $[NiCl_2(dppe)]$ gives the structurally characterised dinuclear thiolate-bridged complex $[\{Fe(NS_3)(CO)_2\text{-}S,S'\}NiCl(dppe)]$, which has structural features similar to those of the active site of NiFe-hydrogenase.

Hydrogenases catalyse the reversible reduction of protons to dihydrogen. The NiFe-hydrogenase from *Desulfovibrio gigas*, as aerobically isolated in the inactive form, has been characterised recently by X-ray crystallography.[1,2] This indicates that the active site is most likely a dinuclear thiolate-bridged nickel–iron complex in which the nickel atom is coordinated by four cysteinate-sulfur atoms, two of which bridge to a six-coordinate iron atom. In the aerobically isolated crystals there is an additional bridging feature, probably oxo or hydroxo, which is unlikely to be present in the active form of the enzyme.[2,3] The other ligands to iron, as shown by crystallography and spectroscopy,[2] are, unusually for biology, two cyanides and one carbon monoxide. There are no examples in the chemical literature of synthetic analogues with bis(thiolate-bridged) nickel to iron with carbon monoxide bound to the iron atom, although $[\{NiL\text{-}S\}Fe(CO)_4]$ [H_2L = *N*,*N*′-bis(ethanethiol)-1,5-diazacyclooctane][4] and $[\{NiL'\text{-}S,S'\}Fe(NO)_2]$ (H_2L' = *N*,*N*′-diethyl-3,7-diazanonane-1,9-dithiolate)[5] have one or other of these features. In this work we have employed the complex $[Fe(NS_3)(CO)]^-$[6] as a chelate ligand to nickel to prepare a bis(thiolate-bridged) nickel–iron complex which has both of these structural features and has similarities to the active site of NiFe-hydrogenase.

The reaction, under a CO atmosphere, of $[NiCl_2(dppe)]$ with $[NEt_4][Fe(NS_3)(CO)]$ gives the dinuclear complex $[\{Fe(NS_3)(CO)_2\text{-}S,S'\}NiCl(dppe)]$ **1**,† the structure of which is shown in Fig. 1.‡ The iron atom is octahedrally coordinated, with two of the thiolate ligand arms also bridging to the nickel atom. The Ni is five-coordinate in a square pyramidal pattern in which the Ni atom is displaced 0.307(2) Å from the base plane towards the chloride ligand in the apical site. The normals to the S_3C 'equatorial' plane about the Fe atom and the P_2S_2 base plane about the Ni atom are inclined at 19.4(1)°. The NS_3 ligand arrangement is different from those reported previously[6,7] in trigonal bipyramidal complexes of iron and vanadium, where there is approximate threefold symmetry in the ligand. Here, the three thiolate sulfur atoms are arranged meridionally about the Fe and the pair of mutually *trans* thiolate arms of the ligand are essentially mirror images (with opposite S–C–C–N torsion angles). The carbonyl ligands are opposite the amino nitrogen atom and one of the bridging sulfur atoms.

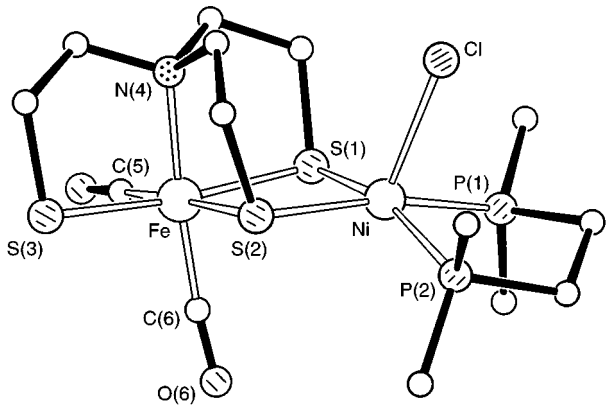

Fig. 1 A molecule of $[\{Fe(NS_3)(CO)_2\text{-}S,S'\}NiCl(dppe)]$ **1** showing the principal atoms. The phenyl groups of the dppe ligand have been omitted for clarity. Selected distances (Å) and angles (°): Fe–S(1) 2.281(3), Fe–S(2) 2.331(3), Fe–S(3) 2.306(3), Fe–N(4) 2.031(8), Fe–C(5) 1.783(12), Fe–C(6) 1.741(10), Ni···Fe 3.308(2), Ni–S(1) 2.247(3), Ni–S(2) 2.255(3), Ni–P(1) 2.164(3), Ni–P(2) 2.196(3), Ni–Cl 2.508(3); S(1)–Fe–S(2) 85.2(1), S(1)–Ni–S(2) 87.8(1), Fe–S(1)–Ni 93.9(1), Fe–S(2)–Ni 92.3(1).

Complex **1** is a good structural analogue of the proposed active site of NiFe-hydrogenase, Fig 2. The core of **1** is dinuclear with nickel bound to iron by a bis(thiolate-bridge) and the iron atom binds two carbon monoxides. The Ni···Fe distance of 3.308 Å is similar to those found for other thiolate-bridged nickel complexes (2.80–3.76 Å[4,5,8–10]) but is longer than the Ni···Fe distance, 2.9 Å, in the as isolated, inactive NiFe-hydrogenase.[1,2] However, recent theoretical calculations predict that in the active states of the enzyme the Ni···Fe distance is > 2.9 Å.[3]

The C–O stretching frequencies in the IR spectrum of **1** are at 1944 and 2000 cm^{-1}. The 1944 cm^{-1} feature is assigned to the axial CO and appears at a similar position to the axial CO stretch in the trinuclear complexes $[M\{Fe(NS_3)(CO)\text{-}S,S'\}_2]$ [M = Fe (1937 cm^{-1});[6] Co (1937 cm^{-1});[11] Ni (1934 cm^{-1})[11]] and to the CO band (1947 cm^{-1}) for the inactive form of *D. gigas* NiFe-hydrogenase.[2] Mössbauer parameters at 77 K (rel. natural Fe at 298 K) are: isomer shift (IS) 0.07 mm s^{-1} and quadrupole splitting (QS) 0.56 mm s^{-1}, consistent with octahedral low-spin iron(II). When the synthesis is performed under dinitrogen or argon, rather than CO, a complex **2**, probably a mono-CO complex, is formed with a carbonyl stretch at 1903 cm^{-1} and Mössbauer parameters of IS 0.23 mm s^{-1} and QS 0.40 mm s^{-1}. When an acetonitrile solution of **2** is stirred under a CO atmosphere it is converted to the dicarbonyl complex **1**.

The potential catalytic properties of the complex **1** will be investigated in the future.

We thank the Biotechnology and Biological Sciences Research Council for funding and The John Innes Foundation for a Studentship (S. L.). Professor R. L. Richards, John Innes Centre, is thanked for valued discussions.

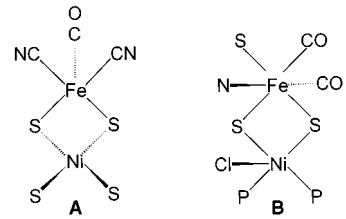

Fig. 2 A schematic comparison of the proposed enzyme active site (**A**) and the core of complex **1** (**B**).

Notes and references

† Under an atmosphere of carbon monoxide, to a stirred suspension of [$NiCl_2$(dppe)] (0.79 g , 1.5 mmol) in MeCN (100 cm^3) was added a solution of [NEt_4][Fe(NS_3)(CO)] in MeCN (20 cm^3). Dissolution was complete after 30 min. On standing overnight a dark brown, crystalline product was obtained, which was collected by filtration, washed with diethyl ether and dried (0.99 g, 83%). Found: C, 50.8; H, 4.3; N, 2.2; Fe, 6.2; Ni, 7.5. $C_{34}H_{36}ClFeNNiO_2P_2S_3$ requires: C, 51.1; H, 4.5; N, 1.8; Fe, 7.0; Ni, 7.4%. λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}) (CH_2Cl_2) 325 (18831), 494 (2614).

‡ *Crystal data:* $C_{34}H_{36}ClFeNNiO_2P_2S_3$, M = 798.8, triclinic, space group $P\bar{1}$ (no. 2), a = 11.5630(11), b = 12.068(2), c = 12.348(2) Å, α = 91.563(13), β = 91.289(10), γ = 92.839(10)°, V = 1719.9(4) Å^3. Z = 2, D_c = 1.54 g cm^{-3}, F(000) = 824, T = 293 K, μ(Mo-Kα) = 1.36 mm^{-1}, λ(Mo-Kα) = 0.71069 Å. 4782 Unique reflections were measured to θ_{max} 23° (2254 with $I > 2\sigma_I$). Structure determined by direct methods in SHELXS,[12] refined with all data, on F^2, in SHELXL[13] to wR_2 = 0.151; for the 'observed' data, R_1 = 0.058.

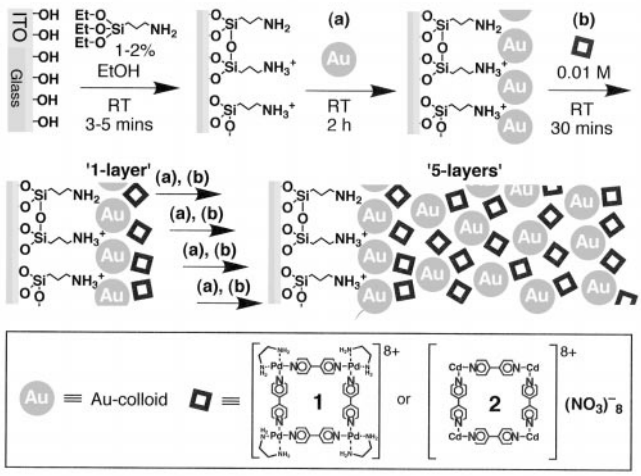
New sensing interfaces have been constructed by the non-covalent crosslinking of 12 nm Au colloids with 'molecular square' transition-metal complexes.

The development of methodologies that take advantage of supramolecular, microenvironmental or quantum effects in order to assemble highly ordered structures displaying sensoric, electronic or photoelectrochemical activites is being extensively studied.[1] Colloidal nanoparticles have been used for the organization of complex assemblies such as patterned surfaces,[2] 'strings'[3] and, in particular, multilayer architectures.[4] These nanoparticles may be passive structural elements, or may contribute to the functionality of the assembly with electronic, optical or catalytic properties.[5] We have recently reported[6] on layered superstructures of citrate-coated Au nanoparticles (12 ± 1 nm) that are crosslinked by oligocationic bipyridinium-containing receptor molecules. These assemblies are stabilized by electrostatic interactions between the negatively charged nanoparticles and the positively charged crosslinkers,[7] and exhibit three-dimensional conductivity, allowing the electrochemical sensing of a series of π-donor substrates.

Recently, a new class of water-soluble transition-metal complexes with cyclophane-like structures was developed[8] by Fujita and Stang. This series of 'molecular square' compounds, consisting of bipyridine units linked by metal ions (*e.g.* Pd^{2+} or Pt^{2+}) was examined as a general methodology for the preparation of new molecular cavities for host–guest interactions.[9] A series of square Re(I) complexes was employed for the sensing of anions by following the enhanced luminescence of the complex upon the encapsulation of an analyte.[10] Complexation results in a change of the intramolecular electron transfer quenching energetics. These molecular square complexes bear positive charges and so were anticipated to crosslink Au nanoparticles to yield novel superstructure architectures. Here, we wish to report on the organization, characterization and sensing properties of Au nanoparticle layered superstructures crosslinked by 'square-type' metal complexes.

Superstructures of Au nanoparticles were constructed on indium-doped tin oxide (ITO) conductive glass, as outlined in Scheme 1. The cleaned surface was first functionalized with 3-aminopropyltriethoxysilane to give a positively charged amine surface, which was treated with a citrate-stabilized Au colloid (12 ± 1 nm).[11] The resulting Au-colloid layer was then treated with the 'Pd-square' $[(en)Pd(4,4'\text{-bipy})]_4(NO_3)_8$ (**1**)[8a] or the 'Cd-square' $[Cd(4,4'\text{-bipy})]_4(NO_3)_8$ (**2**) to give a first receptor layer. By stepwise treatments of the superstructure with the Au-nanoparticle solution and the crosslinking component, interfaces of a controllable number of layers were generated. The resulting crosslinked Au–nanoparticle superstructures are very stable as a consequence of multi-site ion pairing, and the particles can only be removed from the ITO surface by physical scratching. The structures of the Au arrays were probed by three methods: Fig. 1(a) shows the absorbance spectrum of the array upon the stepwise assembly of layers. While the typical plasmon absorbance associated with gold nanoparticles (λ = 518 nm) is present, the growth of layers results in the appearance of an additional absorbance band at λ *ca.* 650 nm, similar to the absorbance changes experienced by an Au-colloid solution upon the formation of large (of the order of 1 μm) aggregates, and is attributed to interparticle plasmon coupling.[12] Fig. 1(b) shows cyclic voltammograms of the Au-nanoparticle surfaces in assemblies containing 1–5 layers of **1**-crosslinked Au nanoparticles. The Au surface area of the assembly increases almost linearly with the growth of the number of layers. From the diameter of the particles (12 ± 1 nm) the surface area of a single particle can be obtained, and by coulometric analysis of the Au reduction wave, the Au particle density is estimated to be 0.2×10^{11} particles $\times$ cm^{-2} per layer. The formation of the assembly of **1** and **2** and the nanoparticles is supported by XPS measurements. For a five-layer assembly, the Au : Pd ratio is *ca.* 30 : 1. This ratio is very similar to that observed for a three-layer assembly. Since the formation of the array is evident from the increase of the plasmon absorbance and cyclic voltammogram of the array, these results indicate



Scheme 1 The stepwise assembly of the three-dimensional array of the Palladium–bipyridine 'square' and Au nanoparticles on a conductive ITO support.

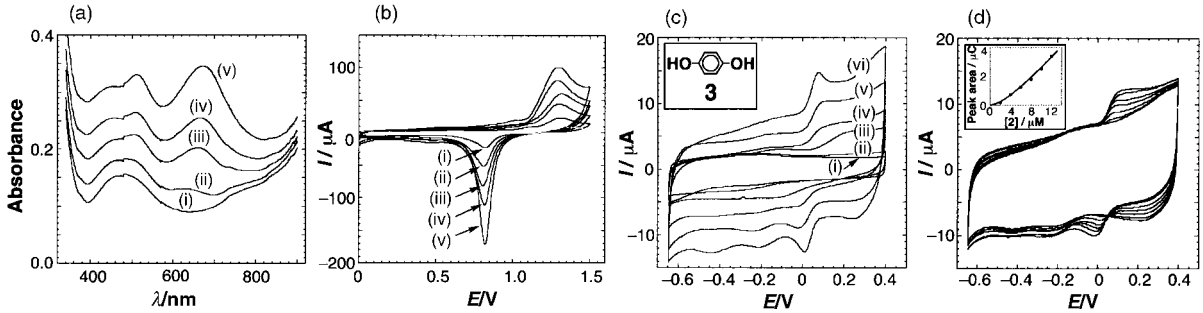


Fig. 1 (a) Absorbance spectra of the **1**–Au-colloid superstructure: (i) one Au layer, (ii) two Au layers, (iii) three Au layers, (iv) four Au layers and (v) five Au layers. (b) Cyclic voltammograms of the layered **1**-crosslinked Au-colloid assemblies corresponding to the electrochemical oxidation and reduction of the particle surface. (i)–(v) Correspond to 1–5 layers of Au particles. Experiments were carried out in 1.0 M H_2SO_4, scan rate 50 mV s^{-1}. (c) Cyclic voltammograms of the **1**-crosslinked Au-colloid arrays in the presence of hydroquinone **3** (1×10 M^{-5}). (i) ITO electrode modified only with a layer of Au colloid (ii)–(vi) 1–5 Au nanoparticle layers. All data were recorded under argon in 0.1 M phosphate buffer solution, pH = 7.2, scan rate 100 mV s^{-1}. (d) Cyclic voltammograms of a layered **1**–Au-nanoparticle array (five layers) in 0.1 M phosphate buffer (pH = 7.2) containing *p*-hydroquinone at concentrations of 0.2×10^{-6}, 0.4×10^{-6}, 0.6×10^{-6}, 0.8×10^{-6}, 1.0×10^{-6} and 1.2×10^{-6} M. Inset: Calibration curve corresponding to the electrochemical sensing of **3**. Data for (c) and (d) were recorded under argon, scan rate 100 mV s^{-1}.

that the analysis reflects the composition of the top layer of the assembly. As XPS measurements reveal a small Si signal, corresponding to the substrate surface, we estimate that *ca.* 15% of the surface is made up of unmodified domains. For the Cd^{2+}-square **2**–Au nanoparticle superstructure, the Au : Cd ratio was found to be *ca.* 100 : 1.

The crosslinker $[(en)Pd(4,4'\text{-bipy})]_4^{8+}$ **1** acts as a π-acceptor receptor for the complexation of π-donor substrates such as dialkoxybenzene derivatives.[13] Fig. 1(*c*) shows cyclic voltammograms of ITO electrodes modified with various numbers of Au-particle and **1** layers in the presence of *p*-hydroquinone **3** at a bulk concentration of 1×10^{-5} M. At this concentration no electrochemical response for **3** is observed at the electrode modified by a single Au-nanoparticle layer. Similarly, interaction of **3** (1×10^{-5} M) with an *N*,*N*′-diaminoethyl-4,4′-bipyridinium crosslinked Au-particle array (five layers)[4b] does not yield any noticeable electrochemical response. These observations indicate that neither the increased surface area of the electrode nor non-specific interactions of **3** with the polycationic–Au-nanoparticle assembly are the origin for the electrical response of **3**. Fig. 1(c) shows that the electrical response of **3** is enhanced as the number of layers is increased. Binding of **3** to the receptor units increases its local concentration at the electrode surface, and allows its electrochemical sensing by the three-dimensional conductive Au array. A further aspect to note is the decrease in the peak-to-peak separation of the redox wave of **3** as the number of layers is increased. This suggests improved interfacial electron transfer kinetics as the particle density of the assembly increases, presumably owing to enhanced conductivity.

Fig. 1(d) shows the electrical response of a five-layer Au-nanoparticle superstructure in the presence of different concentrations of **3**. Fig. 1(d) (inset) shows the derived calibration curve, corresponding to the coulometric assay of the electrochemical responses of **3** at different bulk concentrations. After electrochemical sensing of **3**, the analyte can be washed off by immersion of the electrode in a buffer solution, regenerating the sensing interface.

In conclusion, we have applied polycationic metal complexes as crosslinking 'molecular squares' for assembling three-dimensional conductive arrays of Au nanoparticles. The resulting superstructures act as functional interfaces for the concentration of π-donor analytes enabling their electrochemical sensing.

This research is supported by the Israel Science Foundation founded by The Israel Academy of Sciences and Humanities. We thank Dr Hagai Cohen for the XPS measurements. A. N. S. acknowledges a postdoctoral fellowship from the Royal Society (London, UK).

Efficient photocatalytic decomposition of water with the novel layered tantalate $RbNdTa_2O_7$

Masato Machida,* Jun-ichi Yabunaka and Tsuyoshi Kijima

Department of Applied Chemistry, Faculty of Engineering, Miyazaki University, 1-1 Gakuen Kibanadai Nishi, Miyazaki 889-2192, Japan. E-mail: machida@material.chem.miyazaki-u.ac.jp

Received (in Cambridge, UK) 30th June 1999, Accepted 23rd August 1999

Under UV irradiation, $RbNdTa_2O_7$, the first example of an active photocatalyst containing partially occupied 4f levels, demonstrated efficient evolution of stoichiometric H_2/O_2 mixtures from pure water even in the absence of loaded metal catalysts.

A variety of mixed metal oxides containing TiO_6, NbO_6 or TaO_6 octahedral units have been extensively studied as photocatalysts. Representative catalysts reported so far include $SrTiO_3$[1,2] $Na_2Ti_6O_{13}$,[3] $BaTi_4O_9$,[4] $K_2Ti_4O_9$,[5] $K_4Nb_6O_{17}$,[6] $K_2La_2Ti_3O_{10}$[7] and $K_3Ta_3Si_2O_{13}$,[8] which show potential activities for the decomposition of pure water. We have especially noted the use of layered materials because of the possibility of modifying the chemical composition as well as microstructure by means of ion-exchange or intercalation, which is useful for designing photocatalysts based on semiconducting metal oxide sheets.[9] The present work has been directed towards the synthesis of novel layered perovskite tantalates $RbLnTa_2O_7$ (Ln = La, Pr, Nd or Sm), and evaluation of their photochemical activity for the decomposition of pure water. We report here the highly efficient evolution of stoichiometric H_2/O_2 mixtures over $RbNdTa_2O_7$ even in the absence of sacrificial agents and loaded metal catalysts.

The $RbLnTa_2O_7$ samples with various lanthanoids were prepared according to the procedure reported by Toda and Sato[10] for $RbLaTa_2O_7$. Calculated amounts of powdered carbonates or oxides (Rb_2CO_3, Ln_2O_3, Pr_6O_{11}, CeO_2 and Ta_2O_5, Rare Metallic Co. Ltd., Japan) were mixed together and calcined at 1100 °C for 10 h in air. The crystal structure of the products were identified by use of a powder X-ray diffractometer (XRD, Shimadzu XD-D1) equipped with Cu-Kα radiation (30 kV, 20 mA). Diffuse reflectance spectra were recorded with a UV–VIS spectrometer (Jasco V-550). Photocatalytic H_2 evolution from water was conducted in an inner irradiation quartz cell, which was connected to a closed circulation system. The powder sample of the tantalate (0.2 g) was suspended in distilled water (200 cm^3) in the cell by use of a magnetic stirrer. The reaction mixture was deaerated by evacuation and then flushed with Ar gas (20 kPa). The reaction was carried out by irradiating the mixture with light from a 400 W high-pressure Hg lamp. Gas evolved during irradiation was analyzed by an on-line gas chromatograph (Hitachi, TCD, Ar carrier, MS-5A and Porapak-Q columns). Evolution of H_2 and O_2 only was detected.

X-Ray diffraction patterns of the La sample (Ln = La) consisted of single phase of layered perovskite, $RbLaTa_2O_7$, and all the reflections were indexed based on a tetragonal lattice (*P*4/*mmm*, a = 0.3885 nm, c = 1.112 nm) as reported previously.[10] Similar patterns were also obtained for Ln = Pr, Nd and Sm, and were free from reflections due to the starting materials or other impurities. By contrast, the systems containing Ln = Ce, Eu, or heavier lanthanoids consisted of mixtures of other lanthanoid tantalates, such as $EuTaO_4$ and $TbTa_3O_9$, and unreacted oxides. For Ln = Ce, the reduction of Ce^{4+} to Ce^{3+} required to compensate the charge neutrality in $RbCeTa_2O_7$ did not take place during calcination in air, while the product in the other systems appear to be dependent on the ionic radius of Ln^{3+}. It is well known that the structural stability of perovskite-type oxides (ABO_3) can be easily estimated by calculating the tolerance factor defined as $t = (r_A + r_O)/\sqrt{2}(r_B + r_O)$, where r_A, r_B and r_O are the radii of the respective ions, *i.e.*, t would be unity for an ideal cubic structure.[11] In the present system, the value of t decreases from 0.920 for Ln = La with decreasing ionic radii of Ln^{3+} and no layered perovskite was produced at $t < 0.90$ (Ln = Ce, Eu and heavier lanthoids). Therefore, the geometrical arrangement of the perovskite unit (Ln–Ta–O) governs the structural stability even in a layered structure.

Fig. 1 shows the UV–VIS diffuse reflectance spectrum of $RbLnTa_2O_7$. The La sample showed a clear absorption edge at *ca.* 300 nm and the corresponding band gap energy was *ca.* 3.8 eV, quite close to that of Ta_2O_5. This can be explained by the reported band structure of the perovskite tantalate, where oxygen 2p and Ta s and p orbitals form the valence band and a high-lying antibonding band, respectively, whereas 5d states of the Ta occupy the wide intermediate gap.[12] Therefore, the band gap is likely to occur between the top of the oxygen 2p band and the bottom of the Ta 5d(t_{2g}) band. The position of the absorption edge was more or less red-shifted in the other three samples (Ln = Pr, Nd and Sm). Besides the band gap transition, these samples showed several sharp absorptions in the visible region (> 350 nm). As indicated in Fig. 1, the positions of these absorptions are in accord with the internal 4f transitions observed in corresponding Ln(III) complexes, which give rise to narrow absorption bands quite unlike band gap transitions.[13] The localized 4f levels in the present tantalate systems are

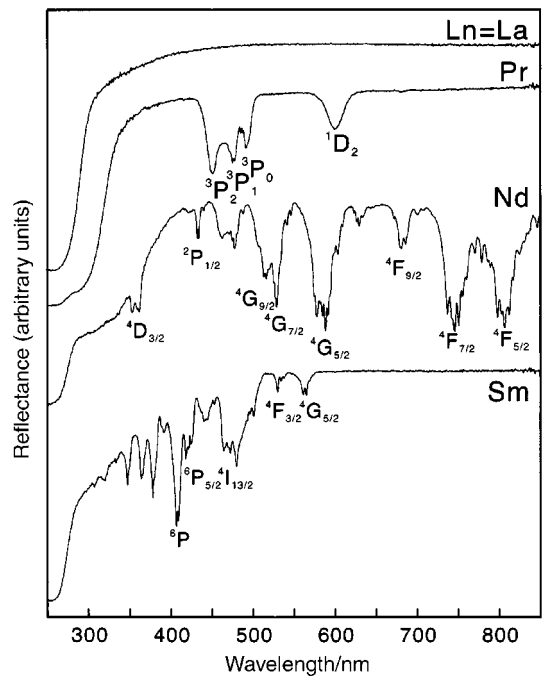

Fig. 1 UV-VIS diffuse reflectance spectra of $RbLnTa_2O_7$. Symbols for each absorptions show the excited states of isolated Ln 4f. The ground states are: La, $^1S_0$; Pr, $^3H_4$; Nd, $^4I_{9/2}$; Sm, $^6H_{5/2}$.

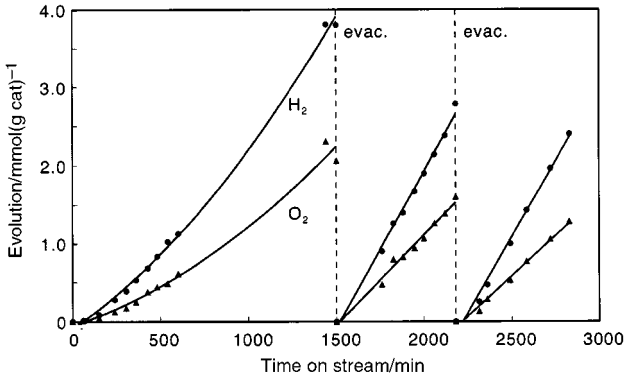

Fig. 2 Gas evolution from distilled water over $RbNdTa_2O_7$ under irradiation of UV light from 400 W high-pressure Hg lamp. Catalyst, 0.2 g, H_2O, 200 cm^3. The rate of gas evolution over $RbLnTa_2O_7$ is summarized in Table 1.

Table 1 Rates of gas evolution over $RbLnTa_2O_7$

	Evolution rate/ μmol h^{-1} (g cat)$^{-1}$	
Catalyst	H_2	O_2
$RbLaTa_2O_7$	6.0	2.8
$RbPrTa_2O_7$	4.2	Trace
$RbNdTa_2O_7$	234.8	126.4
$RbSmTa_2O_7$	53.2	28.7
0.1wt% Pt/P25	< 3	0

considered to lie within the band gap. However, it should be noted that several absorptions overlapping the onset of the absorption edge in the Nd and Sm systems are not ascribable to internal transitions. In particular, a much broader absorption in the range 300–400 nm suggests possible charge-transfer transitions between Ln 4f and other bands.

The four as-prepared layered tantalates were applied to the photocatalytic decomposition of pure water in the absence of sacrificial agents. Fig. 2 shows the time course of gas evolution over $RbNdTa_2O_7$ while rate data of all the tantalate samples are given in Table 1. The $RbLnTa_2O_7$ samples, with the exception of the Ln = Pr case, gave stoichiometric evolution of H_2 and O_2. Interestingly, the rate of gas evolution was found to be strongly dependent on Ln^{3+} and was at a maximum for the Nd system. In this case, the rate of H_2 and O_2 evolution in the first run increased initially with progress of the reaction, but then became constant at 234.8 and 126.4 μmol h^{-1} (g cat.)$^{-1}$, respectively, after 10 h. A plausible reason for the upwardly deviating gas evolution in the initial stage is CO_2 adsorption onto the as-prepared samples, since structural change of the tantalate was unobservable by XRD. After evacuating the system, almost the same rate was reproduced in the second and third runs. The total amount of H_2 and O_2 evolved during these runs reached 6.32 and 3.25 mol (mol cat.)$^{-1}$, respectively, suggesting that the reaction proceeded stoichiometrically and catalytically. A Degussa P25 catalyst loaded with 0.1wt% Pt as well as Ta_2O_5 were also applied to the reaction as reference samples; only H_2 was evolved over these catalysts at the rate of < 3 μmol h^{-1} (g cat.)$^{-1}$, two orders of magnitude less than that for $RbNdTa_2O_7$. The prominent feature of the Nd system is the efficient formation of stoichiometric H_2/O_2 mixtures even without loading of metal catalysts such as Pt, Ni, and Cu. This is in complete contrast to conventional photocatalysts, such as TiO_2, which require the assistance of such metal catalysts to bring about water splitting. Reported photocatalysts that can decompose pure water in the absence of metal catalysts are $K_4Nb_6O_{17}$,[6] $K_2La_2Ti_3O_{10}$,[7] $K_3T_3Si_2O_{13}$[8] and ZrO_2.[14] However, the rate of H_2/O_2 evolution over $RbNdTa_2O_7$ is much higher compared to these reported catalysts. Furthermore, a most promising advantage of the present layered tantalates is the wide variety of possible structural modifications that can be made by means of ion exchange, intercalation and/or pillaring. In particular, the preparation of pillared layered structures capable of creating nanocomposites between different metal oxides in porous framework is expected to be a useful strategy for the development of excellent photocatalysts, which cannot be achieved for other semiconducting oxide systems.

The reason for the high photocatalytic activity for $RbNdTa_2O_7$ is not clear at this stage. To our knowledge, however, $RbNdTa_2O_7$ is the first example of a photocatalyst containing partially occupied 4f levels. It should be noted that the sequence of the activity, Nd > Sm ≫ La ≈ Pr (Fig. 2), is well reflected by the different shape of absorption edge (Fig. 1) which is possibly influenced by charge-transfer transitions. This is considered to largely be a consequence of the partially occupied Ln 4f levels, which form localized states within the band gap of the Ta–O sublattice. This may imply that excitation of Ln 4f electrons plays a key role in the photocatalysis of the present layered perovskite tantalates.

The one of the authors (M. M.) thanks Tokuyama Science Foundation for financial support.

[b] *X-ray Structural Laboratory, Department of Chemistry, University of Wisconsin, 1101 University Avenue, Madison, WI 53706, USA*

Received (in Bloomington, IN, USA) 7th July 1999, Accepted 13th August 1999

The solid-state structures of iron porphyrin hydroxamate complexes reveal an unusual monodentate η¹-O binding mode; the bidentate η²-O,O binding of the tropolonate anion results in an apical displacement of iron of 0.80 Å from the 24-atom mean porphyrin plane.

Hydroxamic acids are ubiquitous in biology.[1] Hydroxamate groups are present in a large number of siderophores, and the hydroxamic acid functional group is a constituent of certain antibiotics, antifungal agents, tumor inhibitors, and even some food additives.[1,2] The troponoid functional group is present in a number of alkaloids and antibiotics.[3] The tropolone group has been used as a model for the antimitotics colchicine (Col) and trimethylcolchicine (Tmca), and it has been shown that some Ru and Pt complexes of Col and Tmca exhibit antitumor activity comparable to that of cisplatin.[4] The coordination chemistry of hydroxamic acids and their derivatives has been reviewed,[1,5] and the hydroxamate functional group behaves as a typical chelating (bidentate, η²) ligand towards metals in their complexes. Hydroxamic acids can be viewed as valence isoelectronic analogs of NONOates (diazeniumdiolates),[6] in which the C–H(X) group has been replaced with the valence isoelectronic N atom.

We recently reported that the Cupferron anion ($Ph[N_2O_2]^-$, an NONOate) binds in a bidentate mode to iron(III) porphyrins.[7] Surprisingly, there have been very few reports on the interactions of hydroxamic acids (or hydroxamates) with synthetic metalloporphyrins[8] or natural heme biomolecules,[9] and there has been no report on the interaction of tropolone with metalloporphyrins. Thus, we sought to determine the nature of binding of typically bidentate hydroxamates (with non-equivalent O-donor atoms, NO *vs*. CO) and the tropolonate anion (with equivalent O-donor atoms) with the metal center in metalloporphyrins. The ligands were selected to include an acyclic hydroxamic acid where the O-donor atoms could exist in *cis* or *trans* conformations, a cyclic hydroxamic acid with the O-donor atoms locked in the *cis* conformation, and tropolone where the O-donor atoms are locked in the *cis* form. We are now pleased to report our preliminary results on (i) the unambiguous determination of an unusual η¹ interaction of hydroxamates with iron(III) porphyrins, and (ii) the remarkable structural consequence of η² binding of the tropolone anion with an iron(III) porphyrin.

Benzohydroxamic acid (4 equiv.) was reacted with $[Fe(oep)]_2(\mu\text{-}O)$ (0.050 g, 0.042 mmol) in toluene at 70 °C for 1.5 h. Upon cooling, black microcrystals precipitated which were collected by filtration and dried to give [Fe(oep)(ONHCOPh)]·HONHCOPh (**1**·HONHCOPh) in 52% isolated yield.†‡ The molecular structure of **1**·HONHCOPh [Fig. 1(a)] reveals an unusual η¹-O binding mode for this acyclic hydroxamate ligand, which displays moderate hydrogen-bonding[10] [N(5A)–O(2C) 2.750(5) Å, O(1A)–O(1C) 2.673(5) Å] to a second hydroxamic acid molecule.§ The average Fe–N(por) bond length is 2.052 Å and is in the range typical of five-coordinate iron(III) high-spin porphyrins,[11] and the Fe atom is pulled out by 0.48 Å from the 24-atom porphyrin plane. Unexpectedly, the reaction of a stirred suspension of [Fe(tpivpp)Cl] in THF (in the presence of a small amount of pyridine) with a 1:1 mixture of excess benzohydroxamic acid and NaH at room temperature for 1.5 h results, after crystallization in air, in the formation of the previously reported $[Fe(tpivpp)(NO_2)(py)]$ in 25% isolated yield which we identified by X-ray crystallography. This known compound was previously obtained from the reaction of $[Fe(tpivpp)(NO_2)_2]^-$ with pyridine.[12] The net formation of $[Fe(tpivpp)(NO_2)(py)]$

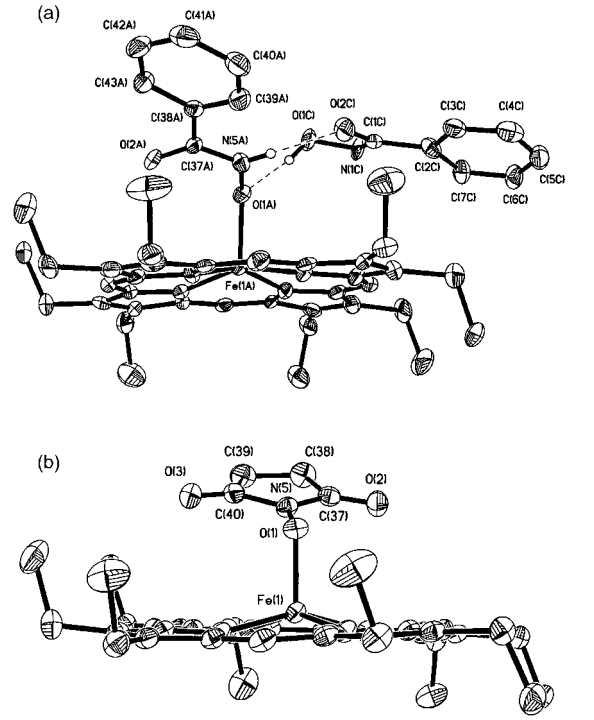

Fig. 1 (a) Molecular structure of one of the two independent molecules of **1**·HONHCOPh. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°) (the data for the second independent molecule are shown in square brackets): Fe(1A)–N(por) 2.049(4)–2.057(4) [2.043(4)–2.056(4)], Fe(1A)–O(1A) 1.927(4) [1.923(3)], O(1A)–N(5A) 1.377(5) [1.363(5)], N(5A)–C(37A) 1.341(6) [1.333(6)], C(37A)–O(2A) 1.235(6) [1.237(6)], O(1C)–O(1A) 2.673(5) [2.876(5)], O(2C)–N(5A) 2.750(5) [2.739(6)], O(1C)–N(1C) 1.402(5) [1.389(5)], N(1C)–C(1C) 1.309(6) [1.321(7)], C(1C)–O(2C) 1.251(6) [1.242(6)]; Fe(1A)–O(1A)–N(5A) 111.0(3) [108.3(3)], O(1A)–N(5A)–C(37A) 118.8(4) [121.3(5)]. (b) Molecular structure of **2**. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Fe(1)–N(por) 2.055(2)–2.065(2), Fe(1)–O(1) 1.9163(14), O(1)–N(5) 1.367(2); Fe(1)–O(1)–N(5) 115.32(11).

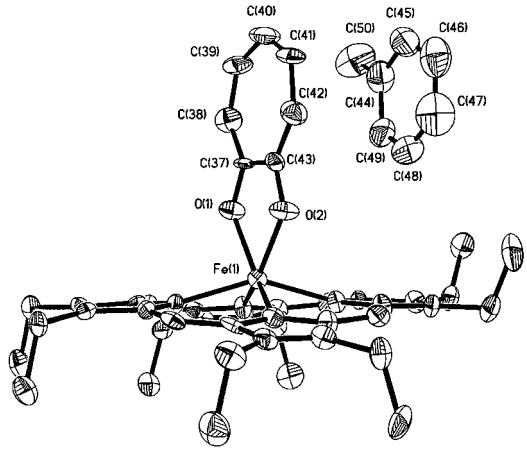

Fig. 2 Molecular structure of **3**·C_6H_5Me. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Fe–N(por) 2.088(7)–2.161(9), Fe(1)–O(1) 2.064(6), Fe(1)–O(2) 2.067(6), O(1)–C(37) 1.256(9), O(2)–C(43) 1.261(11), C(37)–C(43) 1.486(12), C(39)–C(40) 1.37(2), C(40)–C(41) 1.39(2); Fe(1)–O(1)–C(37) 120.5(6), O(1)–C(37)–C(43) 113.2(8), C(37)–C(43)–O(2) 112.3(8), C(43)–O(2)–Fe(1) 120.7(6).

from benzohydroxamic acid is remarkable and, to the best of our knowledge, is the first report of a hydroxamate effectively donating its 'NO' group to a metal center.¶

The related reaction of *N*-hydroxysuccinimide $HONC_4H_4O_2$ (4 equiv.) with $[Fe(oep)]_2(\mu\text{-}O)$ (0.060 g, 0.050 mmol) in hot toluene gave, after work-up, $[Fe(oep)(\eta^1\text{-}ONC_4H_4O_2)]$ **2** in 78% isolated yield.†‖ The molecular structure is shown in Fig. 1(b), and the η^1-O binding mode of the hydroxamate ligand is also revealed, this time with no additional hydrogen-bonding interactions that stabilize this binding mode. The carbonyl O atoms do not interact with the metal center, with (carbonyl)O-to-Fe distances of 3.85 Å [O(3)] and 3.79 Å [O(2)]. The Fe atom is apically displaced by 0.44 Å from the 24-atom porphyrin plane towards the axial ligand.

We then employed tropolone in these reactions in order to obtain an η^2-O,O binding mode of the axial ligand. The reaction of tropolone with $[Fe(oep)]_2(\mu\text{-}O)$ in hot toluene gave, after work-up, dark purple microcrystals of $[Fe(oep)(\eta^2\text{-}OC_7H_5\text{-}O)]$·toluene (**3**·$C_6H_5Me$) in 86% isolated yield.†** The molecular structure of **3**·C_6H_5Me is shown in Fig. 2. The most noticeable features of the structure are (i) the tropolonate ligand is bound to the iron center in a bidentate mode, with essentially equivalent Fe–O distances and an O–Fe–O bite angle of 73.1(2)°,†† (ii) the tropolone plane is nearly coincident with a (por)N–Fe–N(por) plane containing diagonal porphyrin nitrogens, (iii) the toluene molecule is coplanar with the tropolone ligand and is in close proximity (*ca.* 3.5 Å) to it, and most importantly (iv) the Fe atom is apically displaced by 0.80 Å from the 24-atom plane** of the porphyrin towards the tropolone ligand! To the best of our knowledge, this is the *largest* reported mean displacement of an Fe atom from a porphyrin plane. In comparison, related displacements of 0.69, 0.60 and 0.61 Å have been observed for $[Fe\{t(p\text{-}OMe)pp\}\{\eta^2\text{-}ONN(Ph)O\}]$,[7] $[Fe(tpp)(\eta^2\text{-}O_2NO)]$,[15] and $[Fe(tpivpp)(\eta^2\text{-}O_2NO)]$,[16] respectively.

The research results discussed in this publication were made possible by the OCAST award for project number HN97-088 from the Oklahoma Center for the Advancement of Science and Technology (USA). M. A. K. and D. R. P. thank the National Science Foundation (CHE-9310384 and CHE-9310428) and the respective universities for funds for the purchase of the X-ray instrumentation. We thank Dr Scheidt for providing us with a preprint of ref. 11 prior to publication.

Notes and references

† All three compounds give satisfactory elemental analyses (±0.4%) for C, H and N: tpivpp = picket fence porphyrinato dianion. Crystal data were collected on Bruker (Siemens) P4 diffractometers with Mo-Kα radiation (λ = 0.71073 Å). The structures were solved using the SHELXTL system and refined by full-matrix least squares on F^2 using all reflections. The X-ray structural study of **1**·HONHCOPh was performed at the University of Wisconsin using a SMART/CCD system, and the studies for **2**·C_6H_5Me and **3**·C_6H_5Me were performed at the University of Oklahoma.

‡ *Data for* **1**·HONHCOPh: IR (KBr, cm^{-1}): ν_{CO} = 1632s br; also 2965m, 2929w, 2870w, 1575s, 1515w, 1469s, 1451s, 1373m, 1312m, 1269m, 1216w, 1147s, 1111w, 1056m, 1016s, 982m, 958s, 916w, 894m, 841m, 795w, 748w, 731w, 697s, 677w. Iridium(III) bis-terpyridine complexes displaying long-lived pH sensitive luminescence

Matteo Licini and J. A. Gareth Williams*

Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE.
E-mail: J.A.G.Williams@durham.ac.uk

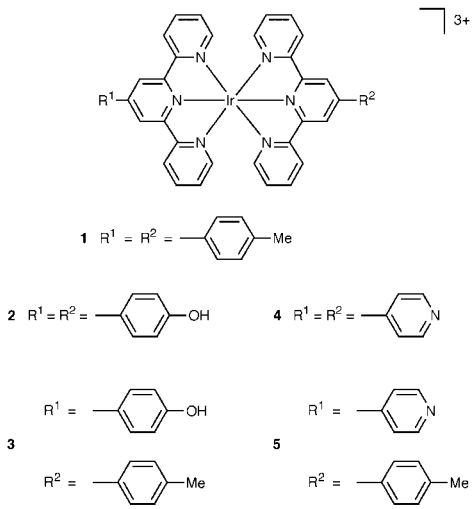
Received (in Cambridge, UK) 30th July 1999, Accepted 27th August 1999

A bis-terpyridine complex of iridium(III) incorporating a pendent pyridyl group displays long-lived emission at pH 7 in air-equilibrated aqueous solution, but both the lifetime and intensity are reduced by a factor of > 8 upon protonation of the pyridyl nitrogen; structurally similar complexes with pendent phenolic groups are only weakly emissive and their ground-state absorption spectra show a new, low-energy band (λ = 468 nm) upon deprotonation.

Molecular luminescent sensors that are able to signal the presence of molecules or ions in aqueous solution are of current interest because of their application to the analysis of biological or environmental samples.[1] Luminescent metal complexes are under investigation for such applications owing in part to the long-lived emission which some of them display, allowing discrimination from the shorter-lived background fluorescence often present in such samples.[2] Although systems based on certain lanthanide(III) ions show promise,[2,3] there are few complexes of transition metal ions with suitably long luminescence lifetimes under ambient conditions. The photophysical properties of polypyridyl ruthenium(II) complexes continue to attract a great deal of attention; sensors for pH incorporating a $Ru(bpy)_3^{2+}$ reporter have been described[4] and a study of a range of derivatives of $Ru(bpy)_3^{2+}$ bearing pyridyl and phenolic substituents has revealed pH-sensitive MLCT emission.[5] Similarly, a bis-terpyridine ruthenium(II) complex incorporating a pendent terpyridyl group displayed enhanced luminescence upon protonation, the lifetime increasing from 4 to 80 ns.[6] Short lifetimes of this magnitude are typical and seriously limit the utility of such ruthenium complexes in applications where longer lifetimes are desirable.

Recent work on bis-terpyridine complexes of iridium(III), such as **1**, has highlighted the very different photophysical properties compared to the Ru(II) analogues.[7,8] Intense ligand-centred emission has been observed in solution (τ > 1 μs under ambient conditions). We have now prepared complexes **2**–**5** in which the terpyridine ligands bear pendent protonatable (pyridyl) or deprotonatable (phenolic) groups. The ligands used here, 4′-tolyl-2,2′:6′,2″-terpyridine (ttpy), 4′-(4-pyridyl)-2,2′:6′,2″-terpyridine (qtpy) and 4′-(4-hydroxyphenyl)-2,2′:6′,2″-terpyridine (tpy-OH), were prepared using established methods.[9a–c] Complexes **3** and **5** were prepared *via* the intermediacy of (ttpy)$IrCl_3$, itself obtained by reaction of $IrCl_3 \cdot 3H_2O$ with 1 equiv. of ttpy in refluxing ethanol. Subsequent reaction with 1 equiv. of tpy-OH or qtpy in ethylene glycol at 200 °C for 1 h led to **3** and **5** respectively after chromatographic separation on silica. The symmetric complex **4** was prepared by a related route involving reaction of (qtpy)$IrCl_3$ with qtpy, whilst complex **2** could be obtained by the direct reaction of $IrCl_3 \cdot 3H_2O$ with 2 equiv. of tpy-OH in refluxing ethylene glycol.†

The ground-state absorption spectra of all four complexes in aqueous solution at pH 6 (NO_3^- salts) showed strong absorption bands (ε 10^4–10^5 dm^3 mol^{-1} cm^{-1}) in the region 250–400 nm. In the case of the pyridyl-appended complexes **4** and **5**, which are pale yellow, no significant change in the absorption spectrum was observed upon protonation. This is consistent with predominantly ligand-centred transitions (as proposed tentatively for the parent complex **1**[8]), rather than MLCT transitions: the latter would be expected to show a significant red-shift upon protonation, as the π-acceptor ability of the ligand is enhanced [*e.g.* for the Ru(II) and Fe(II) analogues of **4**, a red-shift of the MLCT absorption of 14 and 25 nm, respectively, has been reported upon protonation[10]]. On the other hand, the phenolic-substituted complexes **2** and **3**, also pale yellow at pH 6, became deep orange upon increasing the pH to 10 and a new, well defined band appeared in the absorption spectrum centred at 468 nm (Fig. 1). A somewhat similar colour change was seen for the free ligand itself but, in this case, arises from the tailing of a band centred below 400 nm into the visible region. The appearance of the long-wavelength band in the present instance must reflect the efficacy of the tripositive iridium centre in promoting delocalisation of the negative charge of the phenolate over the entire ligand framework, imparting some quinone character to the ligand and an associated ligand-centred transition of low energy.[11] From the change in absorbance as a function of pH, the ground-state



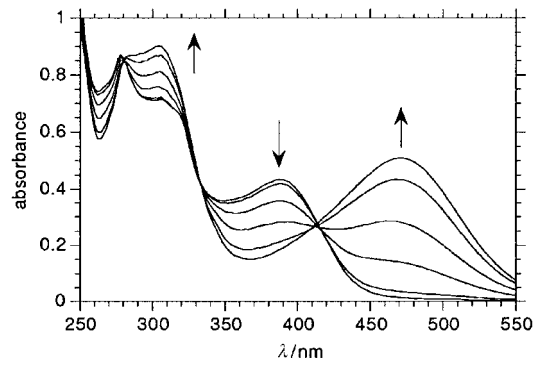


Fig. 1 Room temperature absorption spectra of complex **2** in aqueous solution at pH 5.3, 6.7, 7.6, 8.3, 9.0, 10.1. The arrows indicate the changes in the spectrum which occur as the pH is increased (addition of KOH).

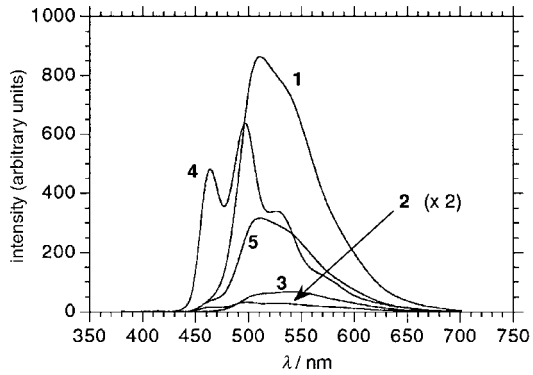

Fig. 2 Room temperature luminescence spectra of air-equilibrated, isoabsorbant aqueous solutions of **1**–**5** at pH 6.0, λ_{ex} = 364 nm.

pK_a of the complex was found to be 8.1. This is considerably more acidic than phenol itself (pK_a 10.0), which is a further indication of the stabilisation of the negative charge which may occur in the complex.

Room temperature luminescence spectra of air-equilibrated aqueous solutions of the complexes are shown in Fig. 2. Whereas the well resolved bands and emission maxima of complex **4** (and, to a somewhat lesser extent, **2**) resemble those of the unsubstituted bis-terpyridine complex, $Ir(terpy)_2^{3+}$,[7,8] the spectra of complexes **3** and **5** are more similar to the tolyl-substituted complex **1**. The sensitive dependence of the emission profile on the presence of 4′-substituents has been noted previously and discussed in terms of a greater delocalisation of the LC excited state over the 4′-aryl substituents.[8] Thus, it appears that the tolyl group must be more effective in this role than either the phenol or pyridyl substituents, or that the dihedral angle between the tolyl and terpy fragments in the excited state is more favourable for such delocalisation than for the other ligands. The phenol-appended complex **2** was only weakly emissive and found to be completely quenched upon deprotonation of the phenol. For the mixed ligand complex **3**, the emission was considerably more intense and only modestly reduced (by a factor of 1.6) over the pH range 6–10; the residual emission at high pH in this complex is thus likely to be due to the tolyl-terpyridine ligand only.

The effect of protonation on the luminescence of complex **5** is striking. Although no significant change in the spectral profile of **5** was observed (again supporting the assignment of the transitions as predominantly ligand-centred), the intensity of the emission was reduced by *ca.* 8-fold on lowering the pH from 7 to 2 (Fig. 3). Significantly, the lifetime was also reduced by a comparable factor, from 4.7 μs at pH 7 to 0.48 μs at pH 2 (caption to Fig. 3). It is well established that the mixing of d–π* charge transfer excited states into emissive π–π* ligand-centred states can promote deactivation and thereby shorten the observed lifetimes.[7] Protonation of complex **5** will lower the energy of the MLCT excited states, as noted above, leading to increased mixing with the emissive LC state and hence to the shorter lifetimes and reduced intensities which are observed. The pK_a of the excited state was found to be 4.1, significantly lower than the value of 5.25 for pyridine itself. This may be ascribed in part to electrostatic effects: protonation of the pendent pyridine increases the overall charge from +3 to +4, and also to the presence of the electron-withdrawing metal–terpyridyl unit on the 4-position of the pendent pyridine, which will serve to reduce the basicity of the uncoordinated nitrogen. Complex **4** also showed a reduction in lifetime and intensity over the same pH range, but by a smaller factor (τ = 1.1 μs at pH 7, τ = 0.34 μs at pH 2, in air-equilibrated aqueous solution).

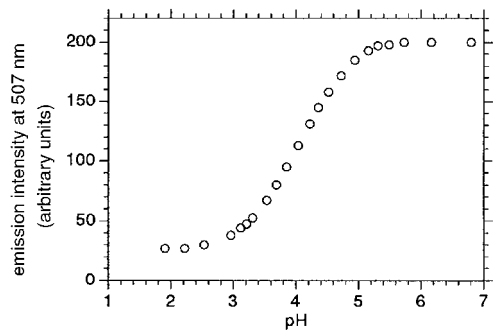

Fig. 3 Effect of pH on the emission intensity of complex **5** (monitored at 507 nm) in air-equilibrated aqueous solution, λ_{ex} = 360 nm. At the pH extremes, monoexponential decay of emission was observed and the following lifetimes were obtained: pH 6.2, τ = 4.7 μs; pH 2.0, τ = 0.48 μs. The corresponding values in degassed solution were 11.1 and 0.60 μs, respectively.

In summary, the iridium complexes described, especially complex **5**, constitute potential new sensory systems for pH, where changes in lifetime as well as intensity may be used to characterise the pH dependence, and which may be amenable to time-resolved detection methods.

We thank Dr A. Beeby for assistance with time-resolved spectroscopy and Drs L. Flamigni, F. Barigelletti, J.-P. Collin and J.-P. Sauvage, with whom the foundatory work for these studies was carried out.[8] Financial support from the University of Durham is gratefully acknowledged.

Notes and references

† The identity and purity of the complexes were confirmed by high-resolution NMR spectroscopy and electrospray ionisation mass spectrometry. *Selected spectroscopic data*: complex **4**: ^{1}H NMR (300 MHz, D_2O, NO_3^- salt): δ 9.50 (4H, s, H$^{3'}$), 9.21 (4H, d, ^3J 6.3 Hz, H^m), 8.97 (4H, d, ^3J 8.4 Hz, H^3), 8.64 (4H, d, ^3J 6.3 Hz, H^o), 8.42 (4H, dd, ^3J 8.4, 7.8 Hz, H^4), 8.02 (4H, d, ^3J 5.4 Hz, H^6), 7.71 (4H, dd, ^3J 7.8, 5.4 Hz, H^5); (H^o and H^m denote protons *ortho* and *meta* to the nitrogen of the pendent pyridine). ESMS (+) (PF_6^- salt): *m/z* 479 $[M^{3+} + PF_6^-]^{2+}$, 407 $[M^{3+} + e^-]^{2+}$, 271 $[M]^{3+}$, where M denotes cation **4**, mass 813. Interpretation of the NMR data of the mixed ligand complexes **3** and **5** was facilitated by the spectra of **1**, **2** and **4**, and was fully consistent with the structures shown.

11 Ward and coworkers have reported on the appearance of a similar band (albeit at higher energy) accompanying the deprotonation of a phenol-appended ruthenium trisbipyridine complex,[5] which only appeared when the substitution pattern was such as to provide a direct pathway of conjugation from the phenol-OH to a metal-coordinated nitrogen, as is also possible in the terpyridyl ligand described here. The lower energy of the band in the present instance probably reflects the higher positive charge on Ir(III) compared to Ru(II).

New supramolecular packing motifs: π-stacked rods encased in triply-helical hydrogen bonded amide strands

Matthew P. Lightfoot, Francis S. Mair,* Robin G. Pritchard and John E. Warren

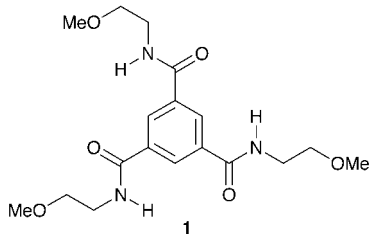
Department of Chemistry, UMIST, PO Box 88, Manchester UKM60 1QD. E-mail: frank.mair@umist.ac.uk

Received (in Cambridge, UK) 30th June 1999, Accepted 18th August 1999

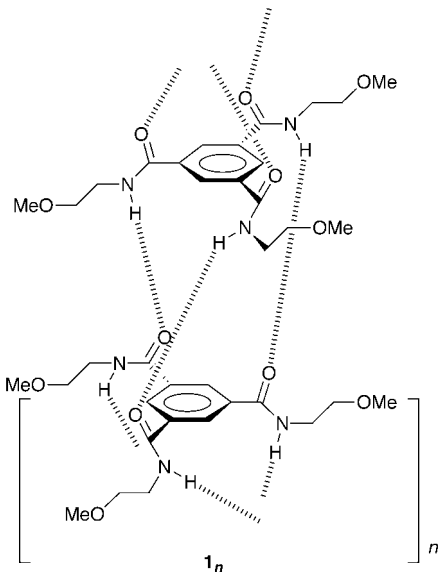
The structure of *N,N′,N″*-tris(2-methoxyethyl)benzene-1,3,5-tricarboxamide consists of aryl rings self-assembled using a novel conjunction of organizational motifs into a π-stack surrounded by a triple helical network of hydrogen bonds, in a manner suggestive of a new mode of organization for some columnar liquid crystals.

Central to the goal of crystal engineering is the discovery of molecular building blocks that can assemble in a pre-determined fashion to generate structural components[1] such as sheets,[2] ribbons,[3] tubes[4] and rods.[5] Often the hydrogen bond is used as a method of linking self-complementary molecules into such supramolecular components,[6] just as it is often used by Nature in defining protein structure. During the course of studies directed at the characterisation of alternative linking units, such as alkali metals, we synthesised† the triamide *N,N′,N″*-tris(2-methoxyethyl)benzene-1,3,5-tricarboxamide **1**. Here we report its remarkable crystal structure,‡ composed of infinite π-stacked rods supported by a triple helical network of hydrogen bonds (**1**$_n$).

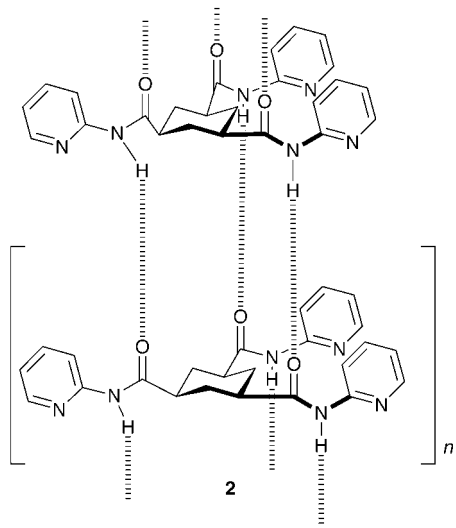
The only similar structure in the literature was reported by Hamilton and co-workers in 1995.[7] A cyclohexyl unit was used as the scaffold for three amide functions, all of which pointed in the same direction, approximately perpendicular to the average plane of the ring, so as to generate a perfectly self-complementary building unit held by three C=O–HN hydrogen bonds. The mode of its self-organization is depicted in **2**.



1



1$_n$



2

Our supramolecular rod **1** differs from **2** in two important and related respects: the use of an aromatic central scaffold, as opposed to a saturated cyclohexyl ring, and the disposition of the three amide bonds, which are partially tilted in **1** and perpendicular to the ring in **2**.

The central aromatic framework in **1** allows for a further self-assembly mechanism, additional to the three hydrogen bonds, through π-stacking. There is one molecule of **1** in the asymmetric unit (Fig. 1). The stack is generated by the crystallographic 2_1 screw axis leading to an inter-ring plane separation of $b/2$, as prescribed by the $P2_1$ space group.‡ The inter-ring centroid distance is therefore 3.62 Å. This is compatible with computed distances in the π-facial arrangement of the gas-phase benzene dimer (3.60 Å),[8] and, inter-

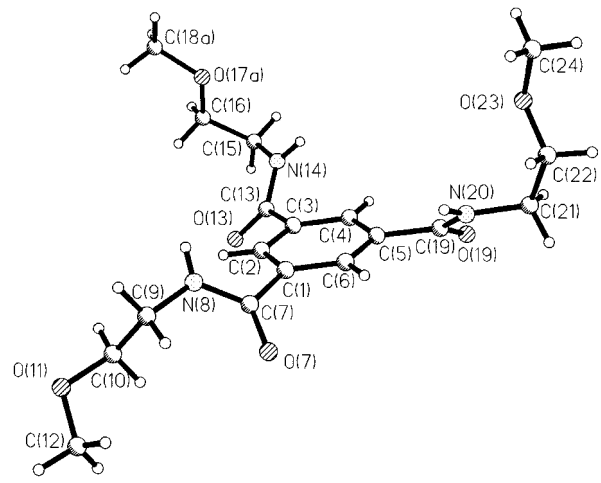


Fig. 1 Molecular structure of **1**. Minor contributor to two-fold disorder in one sidearm is omitted for clarity.

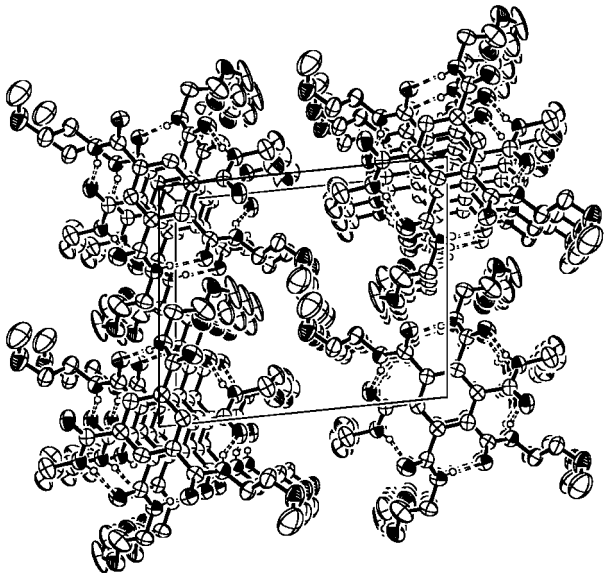

Fig. 2 Packing diagram of **1**, viewed along the *b*-axis. Non-amide hydrogen atoms and minor contributor to side-arm disorder omitted for clarity.

estingly, is similar to distances inferred from sharp peaks seen in X-ray diffraction patterns of discotic liquid crystalline phases based on aromatic cores.[9]

One such mesophase is composed of molecular cores similar to **1**, but extended using intramolecularly hydrogen bonded bipyridine units.[10] Others are more similar still, being identical to **1** but for longer alkyl chains on each amide function. Thermotropic mesophases are formed by such triamides with pentyl to octadecyl groups.[11] Furthermore, highly viscoelastic phases were formed by these species in organic solvents.[12] The methyl variant was crystallised as a model compound: in *N*,*N*′*N*″-trimethylbenzene-1,3,5-tricarboxamide, only a single amide is involved in the third dimension, the other two amides (approximately coplanar with the aryl ring) being involved in generating sheet morphology.[12] The slightly longer alkyl groups of **1** appear to make this mode of organization less favourable. The columnar structure exhibited by **1** may offer a better clue as to the nature of the novel mesophases[11] and lyotropism[12] observed. However, the particular type of primitive rectangular column packing exhibited by **1** (Fig. 2) has not previously been characterised in studies of columnar liquid crystals.[9]

Aromatic amides prefer coplanarity of the carbonyl with the aryl for conjugative reasons, as exemplified in the almost totally planar *N*,*N*′,*N*″-tris(6-methyl-2-pyridyl)benzene-1,3,5-tricarboxamide.[13] In **2** the amides are virtually perpendicular to the ring,[7] while in **1** the conflict between the demands of conjugation and the demands of intermolecular hydrogen bonding result in partial tilting, so that in place of the three vertical strands in **2**, a triple helical network of hydrogen bonds, as shown in Fig. 3, arises. These pack in the polar $P2_1$ space group with parallel alignment, such that spontaneous generation and resolution of supramolecular chirality has occurred from achiral solutions of **1**. The mean planes of the three amide units make angles of 36.8, 42.4 and 45.5° with the aryl mean plane. All therefore point their dipoles at approximately 60° from the column axis, and are helically wrapped around that axis with a pitch of 21.7 Å. The O–N distances are 2.94, 2.95, and 3.01 Å, in the normal range for amide N(H)–O interactions.

Our attempts to probe the structural effect of replacement of the amide hydrogen with alkali metals continue.

We thank the EPSRC for supporting this research and the referees for their useful comments.

† *Experimental data* for **1**: Methoxyethylamine (18.35 ml, 0.21 mol) was added to a solution of benzene-1,3,5-tricarbonyl trichloride (18.79 g, 0.07 mol) and Et_3N (29.59 ml, 0.21 mol) in Et_2O (350 ml) at 0 ºC. The solution was stirred at room temperature for 20 h. The resultant yellow powder was filtered and dissolved in $CHCl_3$ and then washed with 2 M HCl (aq.) (2 × 50 ml). Solvent removal and recrystallisation from hot EtOH produced colourless needles in a yield of 56%. A second crop of crystals was obtained giving a combined yield of 78%. Satisfactory C, H and N analyses were obtained.

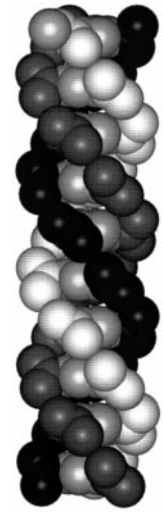

Fig. 3 Diagram of **1** showing triple-helical hydrogen bonding network. Each O, C, N(H)–O helical strand is a different shade of grey. Hydrogen atoms and methoxyalkyl side-arms omitted for clarity.

‡ *Crystal data* for **1**: $C_{18}H_{25}N_3O_6$, M = 379.41, monoclinic, space group $P2_1$, a = 10.776(3), b = 7.241(3), c = 13.028(3) Å, β = 95.84(3)º, U = 1011.4(6) Å^3, Z = 2, D_c = 1.246 Mg m^{-3}, μ = 0.094 mm^{-1}, (Mo-Kα, λ = 0.71069 Å), F(000) = 404, T = 393 K. Rigaku AFC6S diffractometer, crystal size 0.2 × 0.3 × 0.2 mm, θmax 25.02º, 1944 reflections measured, 1944 unique. Final $R_w = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma(wF_o^2)^2]^{1/2}$ = 0.1629 for all data, conventional R = 0.0636 for 1337 observed reflections. Data was of insufficient quality to determine absolute configuration. Disorder on one side chain was modelled to occupancies of 78:22%. Only the major contributor is shown. CCDC 182/1381. Progress towards viridin: synthesis of the pentacyclic furanosteroid ring system *via o*-benzoquinonoid cycloadditions

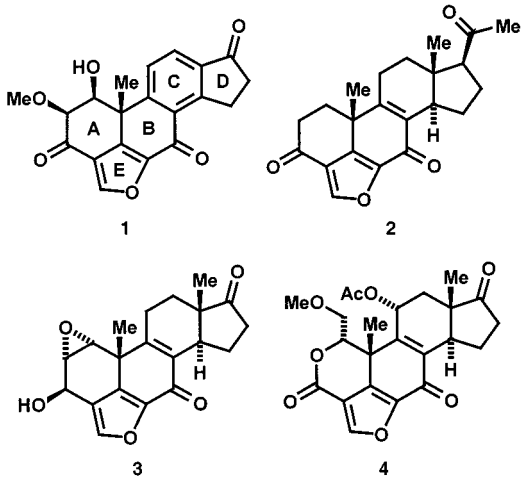
Fabio E. S. Souza[a] and Russell Rodrigo*[b]

[a] *Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1*
[b] *Department of Chemistry, Wilfrid Laurier University, Waterloo, Ontario, Canada N2L 3C5. E-mail: rrodrigo@wlu.ca*

Received (in Corvallis, OR, USA) 8th July 1999, Accepted 17th August 1999

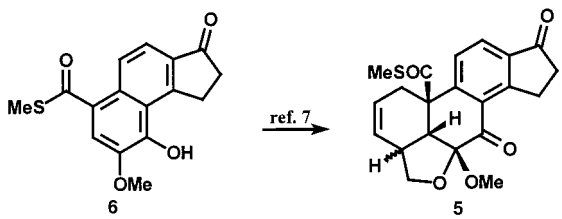
The pentacyclic ring system of viridin is synthesised in nine steps from 4-methylguaicol by means of successive cycloadditions involving *o*-benzoquinonoid intermediates generated *in situ*.

The viridin family of pentacyclic furanosteroidal antibiotics[1] isolated from various species of fungi possess several unusual structural features. Viridin **1** contains an aromatic ring C, a



highly oxygenated ring A and a furan ring in a 'triterpenoid' location, betraying its biogenetic origins from lanosterol. Virone **2**, wortmannolone **3**[2] and wortmannin **4**[3] have an additional 'angular' methyl group at C-13 and *trans* C/D ring fusion. Viridin has powerful species specific anti-fungal activity, and wortmannin has attracted some attention as an anti-inflammatory agent and, more recently, as a potent inhibitor of phosphatidylinositol 3-kinase in neutrophils of the guinea pig.[4]

Apart from a long and low yielding conversion[5] of hydrocortisone to wortmannin no synthesis of any of these compounds has been achieved, but two other studies in this area have been reported.[6] Our recent explorations in the use of *o*-benzoquinonoid intermediates for natural product synthesis had led to the preparation[7] of the pentacyclic system **5** of viridin from benzindanone **6** and penta-2,4-dienol in one step (Scheme 1). However, we were unable to selectively reduce the C-10 thiol ester of **5** to the desired methyl group and even worse, an attempt at prior installation of the methyl group as in the model

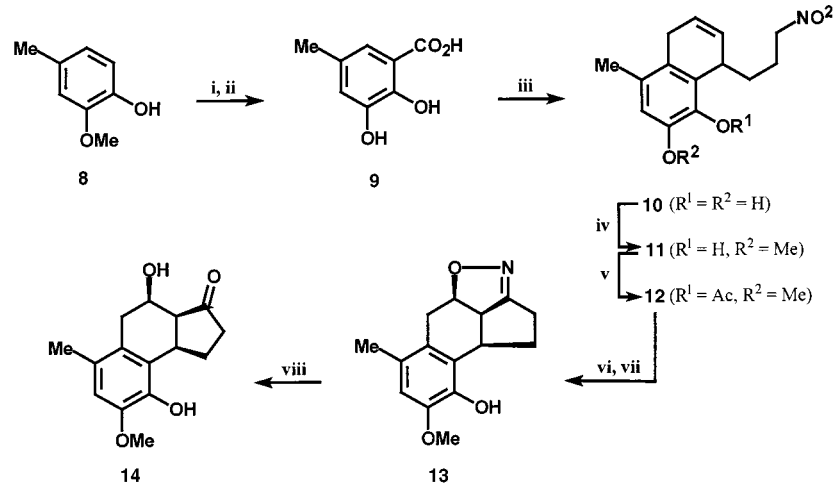


Scheme 1

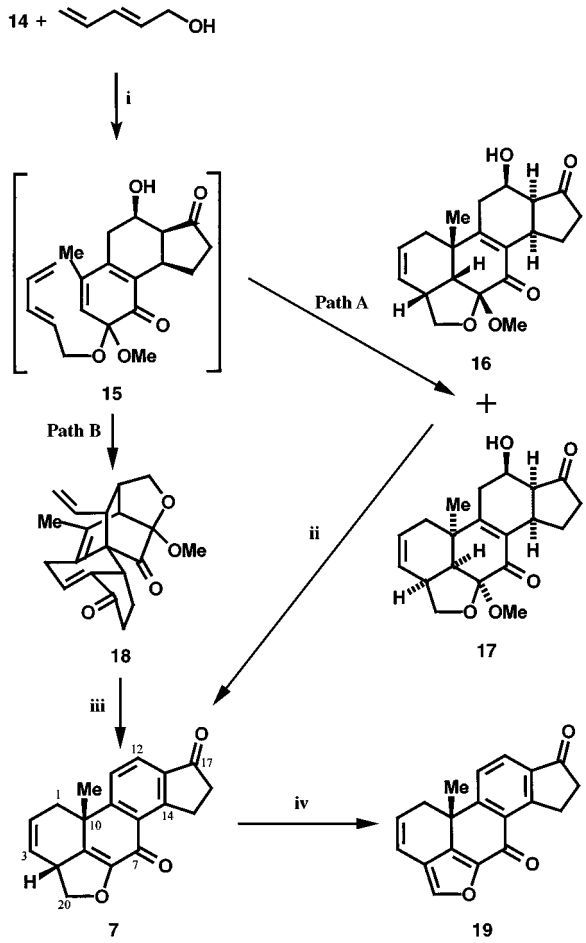
substrate 2-methoxy-4-methylnaphthol resulted in failure of the intramolecular Diels–Alder (IMDA) reaction with the pentadienol under the usual oxidative conditions. We now report that the problems associated with the incorporation of the C-10 methyl group have been overcome and the first synthesis of the desired pentacycle **7** has been achieved in nine steps from 4-methylguaicol **8**.

The acid **9** was conveniently prepared on a multi-gram scale from **8** by Kolbe–Schmitt carboxylation[8,9] followed by BBr_3 demethylation (72% overall). This methylcatechol containing the carbon skeleton of ring B will serve as a linchpin for the attachment of rings CD and AE in two separate annulations employing novel *o*-benzoquinonoid protocols recently developed in our laboratory. When treated with an excess of 1-nitrohepta-4,6-diene[10] in the presence of bis(trifluoroacetoxy)iodobenzene (BTIB) it underwent a sequence of reactions (oxidation to the *o*-quinone, regiospecific Diels–Alder cycloaddition, decarboxylation of the β-keto acid adduct and rearomatisation) to provide the dihydronaphthalene **10** in 86% yield. This remarkable 'one-pot' process, in which the evanescent carboxy group of **9** plays a key role,[11] is the equivalent of a regiospecific cycloaddition of the 5,6-benzyne derived from 4-methylcatechol. Methylation of **10** with Me_3OBF_4 is both selective and quantitative. The methyl ether **11** was acetylated and subjected to the intramolecular nitrile oxide cycloaddition[12] by treatment with *p*-chlorophenyl isocyanate and Et_3N to produce the isoxazoline **13** after hydrolytic work-up with aqueous base. Catalytic hydrogenolysis (10% Pd/C, boric acid) then generated the benzindanone **14**, representing the BCD rings of viridin, as a single diastereomer[13] (52% overall, Scheme 2).

Rings A and E were now attached to the benzene ring of **14** by our *o*-benzoquinone monoketal procedure.[7] Treatment of **14** with BTIB in the presence of excess penta-2,4-dienol produced the monoketal **15** which reacted *in situ* by both possible IMDA pathways to produce a 1:1 mixture of two inseparable *endo*-adducts, pentacycles **16** and **17** (path A, quinonoid double bond as dienophile), and bridged adduct **18** (path B, quinonoid ring as diene). The assignments of relative stereochemistry to **16** and **17** are based on our previous experience[7,14] with the IMDA reactions of *o*-quinone monoketals, and the *endo* stereochemistry of the adducts is confirmed by the fact that both lose MeOH very readily to form the dienone unit of ring B. *Exo* adducts of this type do not eliminate MeOH.[14] The stereochemical issue with **18** was decided on the assumption that one face of **15** is more crowded than the other because of the *cis* CD ring fusion of this compound; the reaction is therefore presumed to occur at the less congested face of the diene unit of **15**. We are endeavouring to confirm this assignment by an X-ray crystal structure. Bridged adduct **18** was easily separated from the mixture of two diastereomeric pentacycles and when subjected to the Cope rearrangement in refluxing tetrachloroethane provided the target **7** in 65% yield. The diastereomers **16** and **17** when treated with TsOH in benzene with exposure to air provided the same compound (**7**) by dehydration and spontaneous aromatisation of ring C.



Scheme 2 *Reagents and conditions:* i, K_2CO_3, CO_2 (800 psi), 200 °C, 4 h; ii, BBr_3, CH_2Cl_2, −78 °C to room temp. (72%, two steps); iii, 1-nitrohepta-4,6-diene (5 equiv.), BTIB, THF (86%); iv, K_2CO_3, Me_3OBF_4, CH_2Cl_2 (100%); v, Ac_2O, pyridine; vi, *p*-ClC_6H_4NCO, Et_3N, C_6H_6, room temp., 36 h; vii, NaOH, H_2O–THF (84%, three steps); viii, H_2, Pd/C, H_3BO_3, MeOH–THF–H_2O (100%).



Scheme 3 *Reactions and conditions:* i, BTIB, THF (path A: 33%, path B: 31%); ii, TsOH, C_6H_6, 45 °C, 4 h (50%); iii, $Cl_2CHCHCl_2$, reflux, 48 h (65%); iv, *p*-chloranil, xylenes, reflux, 36 h (60%).

The nine-step sequence described above is not only the first synthesis of the ring system of viridin, but it also makes **7** available in sufficient quantity (19% overall, Scheme 3) to enable a comprehensive investigation for installation of the oxygen substituents in ring A, by derivatisation of the C_2–C_3 alkene, to be undertaken. Dehydrogenation of the dihydrofuran is facile and can be effected at any convenient stage; in fact, the conversion **7** → **19** has already been achieved in 60% yield. The benzindanone **14** offers possibilities for modification into the C/D non-aromatic analogues (*e.g.* **2**, **3** and **4**). Many obvious problems remain before any of these antibiotics can be synthesised, but we regard this short and flexible route to the pentacyclic system[15] as an important first step on the way to members of the viridin family.

We thank the Natural Sciences and Engineering Research Council of Canada for support of this work.

[c] *Dipartimento di Chimica, Università di Sassari, Via Vienna 2, 07100 Sassari, Italy. E-mail: grepioni@ssmain.uniss.it*

Received (in Basel, Switzerland) 21st June 1999, Accepted 15th August 1999

Single crystals of the anhydrous polymorphic modification of the organometallic zwitterion [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)$] can only be obtained by seeding the solution with *seeds* prepared after stepwise dehydration and consequent phase transition at 506 K of the hydrated material [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)]\cdot 3H_2O$.

The control of crystallisation processes is of great interest both in crystal engineering,[1] where molecular materials with predefined organisation of the component molecules or ions are sought, and in the study of polymorphism,[2] where different polymorphs of the same substance may show different physical properties.

Here we report that single crystals of the elusive anhydrous polymorphic modification of the neutral zwitterion [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)$], **ZW**, can be obtained by *seeding* the starting solution† with 'seeds' prepared by stepwise dehydration and subsequent phase transition of the hydrated species [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)]\cdot 3H_2O$, **ZW**$\cdot 3H_2O$. This hydrate is the only product of the crystallisation from a aqueous solution of [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)$] obtained from the organometallic cationic diacid $[Co^{III}(\eta^5$-$C_5H_4CO_2H)_2]^+$.[3] Both **ZW** and **ZW**$\cdot 3H_2O$ have been structurally characterised by single crystal‡ and powder diffraction while the conversion of the initial product **ZW**$\cdot 3H_2O$ into anhydrous **ZW** has been monitored by thermogravimetry.

The most relevant features of **ZW**$\cdot 3H_2O$ and **ZW** can be summarised as follows.

(i) In contrast to the related dicarboxylic acid [$Fe^{II}(\eta^5$-$C_5H_4CO_2H)_2$] and the parent cation $[Co^{III}(\eta^5$-$C_5CO_2H)_2]^+$,[4] in crystalline **ZW**$\cdot 3H_2O$ there are no O–H···O hydrogen bonds between the $-CO_2H$/–COO groups, while C–H···$O_{(CO_2/CO_2H)}$ hydrogen bonded 'dimers' (D) are formed as shown in Fig. 1(a).

(ii) The dimeric units are linked in chains *via* a further, almost symmetric, bifurcated C–H···$O_{(CO_2/CO_2H)}$ hydrogen bond (C) between two adjacent C–H groups of a cyclopentadienyl ring and one O-atom lone-pair resulting in the formation of 'pipelines' through the crystal.

(iii) The pipelines are occupied by three water molecules per formula unit [Fig. 1(b)]. Two molecules are linked *via* O–H···O hydrogen bonds to the $-CO_2$/$-CO_2H$ groups on the walls of the channels and provide links between zwitterion stacks, whilst the central molecule interacts solely with the neighbouring water molecules.

(iv) Thermogravimetric analysis (TGA)§ shows that **ZW**$\cdot 3H_2O$ releases one water molecule at 378 K (Fig. 2). Powder diffraction‡ shows that the crystal structure remains almost unchanged. This first dehydration is reversible and the crystal is rehydrated in *ca.* 24 h at room temperature in the air. The remaining two water molecules are lost together at *ca.* 506 K. The second loss of water is immediately followed by a phase transition to a different crystalline form as revealed by powder diffraction.

(v) Most remarkably, crystallisation from an *aqueous* solution of the powder obtained from TGA at 506 K in the presence of *seeds* (a small portion of the *same* powder) leads to formation of single crystals of the species **ZW**. The structure of **ZW** is based on a one-dimensional network of O–H···O bonded zwitterion molecules (Fig. 3). Comparison of the calculated and

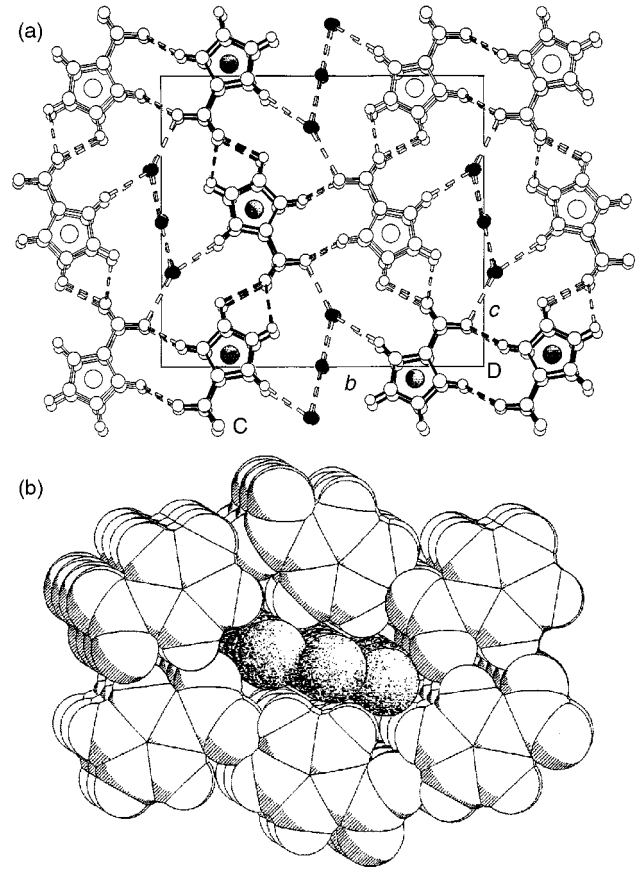

Fig. 1 (a) The zwitterions [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)$] pile up along the *a*-axis with the $-CO_2(H)$ groups pointing inward along the channels and forming O–H···O hydrogen bonds with two rows of water molecules. The organometallic units interact solely by means of C–H···O hydrogen bonds. Note how the 'dimers' (motif D) are linked in chains *via* bifurcated C–H···O hydrogen bonds; filled atom spheres represent the water oxygens. (*b*) Space filling representation of the channel in [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)]\cdot 3H_2O$, **ZW**$\cdot 3H_2O$, showing the three water molecules (dotted shading) occupying the channel. Relevant O···O distances (Å) are $O_{CO_2/CO_2H}\cdots O_{water}$ 2.758, 2780; $O_{water}\cdots O_{water}$ 2.823, 2838(2) Å.

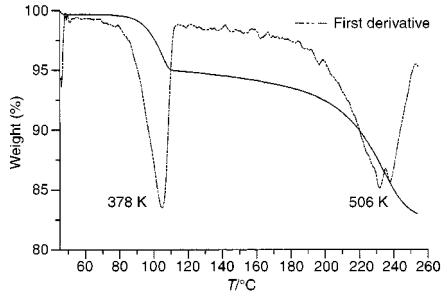

Fig. 2 TGA plot of the dehydration process. Note how the first water molecule is lost at 378 K, while the other two water molecules are released at 506 K. This second loss of water is followed by a phase transition.

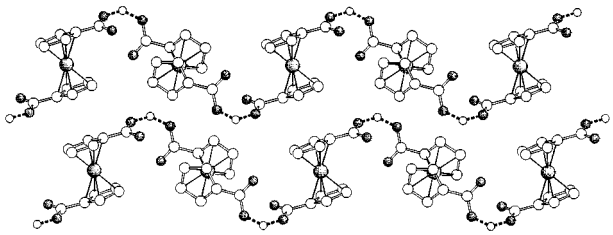

Fig. 3 Chains of O–H···O bonded zwitterions [$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)$] in the anhydrous crystalline phase **ZW** crystallised *via* seeding of the solution obtained from the dehydrated powder; O···O 2.456(2) Å.

measured powder spectra of **ZW** confirms that the powder obtained at 506 K and the single crystals precipitated at room temperature after seeding possess the same structure. Importantly, crystallisation of the original solution mentioned in point (i), in the presence of seeds of **ZW**, also leads to isolation of the anhydrous crystalline material **ZW**, while, in the *absence* of seeds, the hydrated species **ZW**·$3H_2O$ is obtained.

Crystalline **ZW**·$3H_2O$ can be seen as a pseudo-polymorphic modification of **ZW**. The anhydrous form appears to be thermodynamically less stable and can only be obtained by dehydration of **ZW**·$3H_2O$ or *via* seeding of the solution, *i.e.* very likely under kinetic control.

It is worth stressing that the C–H···O bonds between zwitterions and the O–H···O bonds between zwitterion and water molecules along the walls of the channels are sufficient to keep the crystal together up to *ca.* 500 K. To the best of our knowledge, **ZW**·$3H_2O$ is the first case of an organometallic nanoporous material[5] with channels formed *via* C–H···O hydrogen bonds, with two structural water molecules acting as O–H···O bridges along the channels. Potential applications of nanoporous compounds are in catalysis, molecular sieves, molecule storage, ion exchange and solid sensors.[6]

The characterisation of **ZW** shows, *inter alia*, that single crystals of elusive polymorphic modifications can be obtained by controlling the crystallisation process *via* seeding, a crystallisation technique exploited also in organometallic solid state chemistry.[7] Clearly, the possibility of obtaining microcrystalline seeds by *non-solution* techniques (*dehydration* but also *grinding*[8]) is fascinating and opens up potentially useful alternative routes for the engineering of molecular materials.

We thank MURST (project Supramolecular Devices) and the University of Bologna (project Innovative Materials) for financial support.

Notes and references

† The starting material, **ZW**·$3H_2O$, is obtained from an aqueous solution of the salt {[$Co^{III}(\eta^5$-$C_5H_4CO_2H)(\eta^5$-$C_5H_4CO_2)$]·[$Co^{III}(\eta^5$-$C_5H_4CO_2H)_2$]}$^+$-[PF_6]$^-$ (0.3 mmol, 0.209 g, 20 ml water) after extraction of [$Co^{III}(\eta^5$-$C_5H_4CO_2H)_2$]$^+$[PF_6]$^-$ with nitromethane (70 ml in total).[3] Evaporation of the aqueous solution yielded yellow, sword-like, crystals of **ZW**·$3H_2O$ (0.099 g). Correspondence between the structure determined by single-crystal X-ray diffraction (see below) and the bulk material was confirmed by powder diffraction measurements.

‡ *Crystal data*: **ZW**·$3H_2O$: monoclinic, space group $P2_1/n$, a = 6.707(3), b = 14.997(4), c = 13.453(4) Å, β = 99.84(1)°, Z = 4, V = 1333(8) Å^3, μ = 1.316 mm^{-1}, θ range 3–25°, T = 223(2) K, 2230 independent reflections, $R1$ [$I > 2\sigma(I)$] 0.0851, wR^2 (all data, F^2) 0.2467.

ZW: monoclinic, space group $C2/c$, a = 7.403(2), b = 10.964(8), c = 12.293(3) Å, β = 94.30(3)°, Z = 4, V = 995.0(8) Å^3, μ = 1.722 mm^{-1}, θ range 3–25°, T = 273(2) K, 863 independent reflections, $R1$ [$I > 2\sigma(I)$] 0.0362, wR^2 (all data, F^2) 0.0996. The SHELXL97[9a] package was used for structure solution and refinement based on F^2. SCHAKAL97[9b] was used for all graphical representations. Diffraction data on **ZW**·$3H_2O$ have been collected on three different crystal specimens to investigate the small disorder affecting the inner O-atom occupying the centre of the channel (site occupancies between 0.80 and 1.00). CCDC 182/1386. See http://www.rsc.org/suppdata/cc/1999/1949/ for crystallographic files in .cif format. Powder diffractograms of **ZW**·$3H_2O$ calculated on the basis of the single crystal structure, measured at room temperature, measured after the first dehydration at 378 K, and measured after phase transition upon complete removal of the three water molecules, and a comparison between this latter diffractogram and the calculated spectrum of **ZW** are available as supplementary material upon request to the authors.

§ TGA was carried out on a Perkin-Elmer TGA-7 instrument in open Al pans under N_2 atmosphere. The loss in weight at the two temperatures (see Fig. 2) corresponds to one and two water molecules per **ZW** molar unit, respectively.

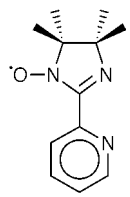
Received (in Oxford, UK) 15th June 1999, Accepted 26th August 1999

Reacting hexacyanochromate(III) with a mononuclear Ni(II) complex chelated by two bidentate organic radicals leads to a pentanuclear complex with three different kinds of paramagnetic species interacting ferromagnetically and stabilising a high spin $S = 9$ ground state.

The metal–radical approach has been successful to design one of the first one-dimensional ferrimagnetic chains that order ferromagnetically at low temperature; nitronyl nitroxyde organic radicals have been used as bis-monodentate ligands for Mn(hfac)$_2$ to do so.[1] Using the same approach, it was possible to stabilise a hexanuclear ring containing six *cis*-Mn(hfac)$_2$ entities connected by the phenyl nitronyl nitroxide radical and leading to a ground state $S = 12$.[2] Recently, Rey and coworkers reported the preparation of a bidimensionnal honeycomb like network that orders ferromagnetically at $T_C = 1.4$ K by using the bis-bidentate imidazolato nitronyl nitroxide radical as a bridging ligand for Mn(II) metal ions.[3] Inoue and Iwamura prepared another honeycomb network using a triradical molecule to connect Mn(hfac)$_2$ complexes.[4] The first extended system containing three different paramagnnetic species was reported by Kahn and coworkers.[5]

On the other hand, one of us has developed a step-by-step approach using $[Cr(CN)_6]^{3-}$ as a template to assemble mononuclear Ni(II) and Mn(II) complexes bearing pentadentate ligands as blocking chelates. Two high spin molecules, $Cr^{III}Ni^{II}_6$ and $Cr^{III}Mn^{II}_6$, possessing spin ground states $S = 15/2$ and 27/2, respectively, were thus designed.[6,7]



IM2-py

By combining these two approaches, we have designed a polynuclear molecule using a new mononuclear Ni(II) complex bearing two pyridine imino nitroxide bidentate ligands IM2-py [IM2-py = 2-(2-pyridyl)-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazolyl-1-oxy][8] acting simultanesouly (i) as bulky chelates to preclude the formation of an extended network and (ii) as an extra shell of paramagnetic species to enhance the value of the spin ground state. The nature of the different components [Cr(CN)$_6$, Ni(II), IM2-py] has been chosen to realise ferromagnetic interaction between the paramagnetic species in order to stabilise the highest spin state as the ground state.

A solution of the free radical IM2-Py (2×10^{-3} mol) in 30 ml of acetonitrile was added dropwise to 20 ml of acetonitrile containing [Ni(H$_2$O)$_6$](ClO$_4$)$_2$ (1×10^{-3} mol). A precipitate appeared immediately which was filtered off, washed with acetonitrile and dried under vacuum.† Elemental analysis indicated the formula [Ni(IM2-py)$_2$(H$_2$O)$_2$](ClO$_4$)$_2$.‡ The second step consisted in reacting [NBu$_4$]$_3$[Cr(CN)$_6$] with the Ni(II) complex in water to give a bright red precipitate immediately. The best yield was obtained for a Ni : Cr stoichiometric ratio of 3 : 2. Elemental analysis§ and thermogravimetric analysis fit well with the presence of two Cr(CN)$_6$ for three Ni(IM2-py)$_2$ and seven water molecules which corresponds to the formula [Cr(CN)$_6$]$_2$[Ni(IM2-py)$_2$]$_3$·7H$_2$O. The IR spectrum of the new species presents all the features expected for the organic radical as well as two bands at 2160 and 2128 cm^{-1} corresponding to the elongation asymmetric vibrations of bridged[6] and non-bridged cyanides, respectively. The new compound is soluble in most common solvents but is insoluble in water as expected for a neutral species. Unfortunately, crystals suitable for X-rays analysis were not obtained. However, the UV–VIS spectrum (MeOH, $c = 3 \times 10^{-2}$ mol l^{-1}) presents a band assigned to the $^3T_{2g} \leftarrow {}^3A_{2g}$ transition of the Ni(II) chromophores ($E = 11\,363$ cm^{-1}, $\varepsilon = 35.9$ l mol^{-1} cm^{-1}) which is shifted to higher energy in comparison to that of the mononuclear [Ni(IM2-py)$_2$(H$_2$O)$_2$]$^{2+}$ complex ($E = 10\,416$ cm^{-1}, $\varepsilon = 45$ l mol^{-1} cm^{-1}). Since the nitrogen end of the cyanide induces a stronger crystal field than water,[12] we deduce that the observed solubility is not due to some decomposition of an extended network in solution but to the fact that the compound is composed of soluble discrete polynuclear species retaining the same structure (presence of bridging cyanides) in solution as found in the solid state. The structure proposed is that of a pentanuclear complex where three *cis*-Ni(IM2-py)$_2$ molecules act as bridges for two Cr(CN)$_6^{3-}$ entities as depicted in Fig. 1. This structure¶ is actually based on that of the pentanuclear complex [Fe(CN)$_6$]$_2$[Ni(bpm)$_2$]$_3$·7H$_2$O [bpm = bis(1-pyrazolyl)methane] described recently by Murray and coworkers.[13]

In order to check our assumption on the structure and to investigate the nature of the ground state, we carried out

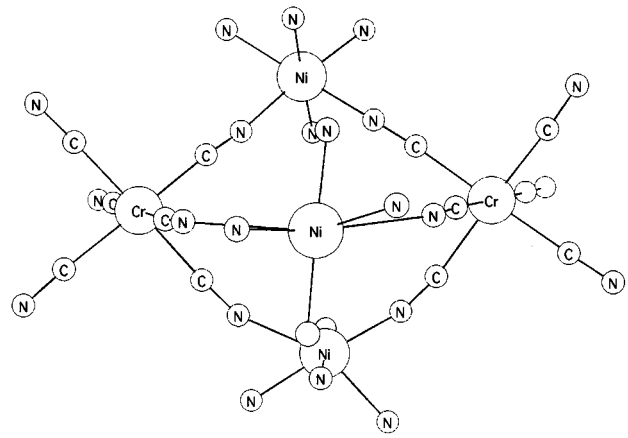


Fig. 1 Proposed model for the structure of the pentanuclear complex. Only the first coordination sphere of the nickel atoms is represented.

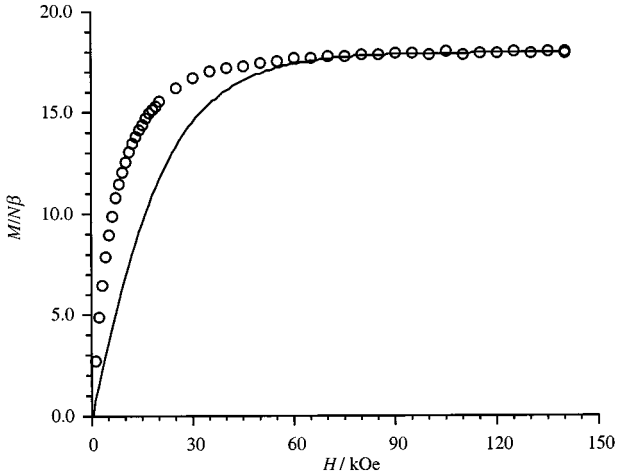

Fig. 2 *M vs.* H plot at T = 2.2 K (○) experimental, (——) sum of the calculated Brillouin functions for two S = 3/2 (Cr^{III}, g_{Cr} = 1.98), three S = 1 (Ni^{II}, g_{Ni} = 2.07) and six S = 1/2 (radical, g_{Rad} = 2.00).

magnetisation measurements on a powdered sample. The magnetisation *vs.* field plot (Fig. 2) (T = 2.2 K, H = 0–140 kOe) shows that the value at saturation (18.1 μ_B) corresponds to the expected value for ferromagnetic interaction between Cr(III) and Ni(II) on the one hand and between Ni(II) and the organic radicals on the other. Susceptibility *vs.* temperature measurements were carried with an applied field H = 2 kOe in the temperature range 300–30 K and at H = 30 Oe below 30 K to avoid saturation. On cooling, $\chi_M T$ increases and reaches a maximum at T = 6.5 K, then decreases (Fig. 3). The $\chi_M T$ value at the maximum (42 $cm^3\ mol^{-1}$ K) is very close to that expected for an S = 9 ground state (45 $cm^3\ mol^{-1}$ K for an average g value of 2) which corresponds to the parallel alignment of the local spins of the eleven paramagnetic species. In order to extract the exchange coupling parameters from the experimental data, a home-made routine was used to perform a calculation‖ of $\chi_M T$ as a function of temperature for different values of J_{CrNi} and J_{NiRad} by setting the local g values to g_{Cr} = 1.98, g_{Ni} = 2.07 and g_{Rad} = 2.00. The calculated curves for J_{NiRad} = 150 K (105 cm^{-1}) and J_{CrNi} = 9, 11, 13, 15 and 17 K are shown in the inset of Fig. 3. The best agreement between the experimental and the calculated data is obtained, in the temperature range 300–8 K, for J_{CrNi} = 13 K (9 cm^{-1}) and J_{NiRad} = 150 K (105 cm^{-1}). It is possible at this level to introduce a parameter θ that takes into account the decrease of $\chi_M T$ at low temperature as due to antiferromagnetic intermolecular interactions,** a very good agreement is obtained with θ = −0.45 K (Fig. 3). The sign and the values of the exchange coupling parameters are in the same range as have already been found for $CrNi_6$ (J_{CrNi} = 15 cm^{-1})[6] and $Ni(hfac)_2(IM2\text{-}py)$ (J_{NiRad} = 128 cm^{-1}).[9]

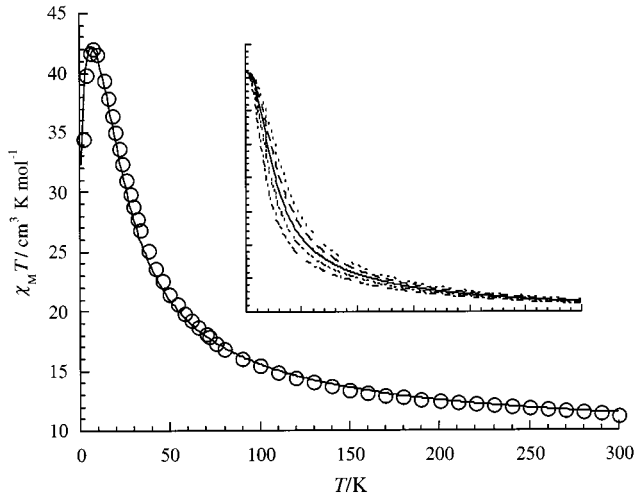

Fig. 3 $\chi_M T$ *vs.* T plot (○) experimental, (——) calculated for J_{CrNi} = 150 K and J_{NiRad} = 13 K. Inset: calculated $\chi_M T$ *vs.* T curves.

We are currently working on this combined strategy to design new high-spin molecules using bidentate organic radicals not only as a peripheral paramagnetic shell but also as bridging ligands.

This work has been supported by the European Marie Curie Research Training Grant, proposal Nr ERB4001GT965355.

Notes and references

† **CAUTION**: perchlorate salts should be used in small quantities and handled with care; explosion may occur.

‡ Anal. Found (calc.) for $C_{24}H_{36}N_6Cl_2O_{12}Ni$: C, 39.80(39.48); H, 5.02(4.97); N, 11.62(11.51); Cl, 9.85(9.71); Ni, 7.80(8.03)%. The IM2-py radical is assumed to act as a bidentate ligand *via* its two nitrogen atoms as has already been observed for $Ni(hfac)_2(IM2\text{-}py)$[9] and $Cu(hfac)_2(IM2\text{-}py)$.[10] This is reasonable since the imino nitrogen atom is a much better Lewis base than the oxygen atom of the nitroxide group. The preferred isomer of this complex is *cis* because steric hindrance between the bulky ligands preclude their presence in the same plane as is the case for $Ni(bipy)_2Cl_2$.[11]

§ Anal. Found (calc.) for $C_{84}H_{110}N_{30}O_{13}Ni_3Cr_2$: C, 49.85(49.74); H, 5.32(5.46); N = 20.86(20.71); Ni, 8.57(8.68); Cr, 4.97(5.12)%.

¶ Corey–Pauling–Koltun (CPK) molecular models were used to demonstrate the absence of any steric hindrance between the ligands' methyl groups in the proposed structure.

‖ The quantity $\chi_M T$ is related to the fluctuation of the magnetisation M, which is calculated from the energy eigenvalues and spin eigenfunctions. The eigensystem solution has been achieved by diagonalising the energy matrix. For our compound the number of microstates is given by $(2S_{Cr} + 1)^2 \times (2S_{NI} + 1)^3 \times (2S_{Rad} + 1)^6$ = 27 648. However, the matrices are built from the spin function basis in the M_S sub-spaces, where M_S is the z-component of the spin quantum number S. In this case, the size of the largest matrix that must be diagonalised which corresponds to the M_S = 0 subspace is 4390 × 4390.

** ac Susceptibility measurements which were performed down to 100 mK show the absence of long-range magnetic order, a behaviour different from the ferromagnetic order found for Murray's pentanuclear complex $[Fe(CN)_6]_2[Ni(bpm)_2]_3 \cdot 7H_2O$. The decrease of $\chi_M T$ may be due to a zero-field splitting effect and not to intermolecular antiferromagnetic interacion. Unfortunately, zero-field splitting could not be included owing to prohibitive calculation times.

Received (in Basel, Switzerland) 25th June 1999, Accepted 2nd August 1999

An electrochemical cell [$Cu_{(+)}$|MeCN + H_4L|$Pt_{(-)}$] (H_4L = title ligand), yielded powdery $[Cu_2(L)(H_2O)]_n$ and crystalline $Cu_3(H_2L)(L)\cdot 2H_2O$; the crystal structure of the latter shows an unusual helicate with an isosceles triangle core assembled by two μ-phenoxo bridges [Cu···Cu 3.413(3) and 3.858(3) Å], in which tetracoordinated Cu ions are in tetrahedrally distorted square planar environments.

The coordinating ability of compartmental ligands has been the subject of research owing to the interesting optical, magnetic and structural properties of polynuclear complexes.[1,2] Furthermore, there is much interest in the development of new polydentate ligands that can organise supermolecules upon complexation to two or more metal ions.[3]

We have recently reported some mono- and bi-nuclear Cu(II) complexes with asymmetrical Schiff bases.[4] This work has been extended to the direct electrochemical synthesis of polynuclear Cu(II) complexes with the title ligand, H_4L (prepared by condensation of 2,3-dihydroxybenzaldehyde and 1,4-diaminobutane in a 2:1 molar ratio) as a simple and efficient procedure to obtain them.

The electrochemical method [in this case summarised as: $Cu_{(+)}$|MeCN + H_4L|$Pt_{(-)}$] has been widely used by us.[5,6] An MeCN solution of H_4L (0.20 g) was electrolysed (V = 6.8 V) for a given time (3.25 h) according to the reaction $Cu_{(s)} + H_4L \rightarrow Cu(H_2L) + H_{2(g)}$. Anodic copper dissolved in the reaction mixture (0.066 g), whilst hydrogen evolved at the Pt cathode. An insoluble product was isolated which was analytically and spectroscopically identified† as $Cu_2(L)(H_2O)$ **1** (yield: 58%). The resulting solution was slowly evaporated and small crystals, suitable for X-ray diffraction studies,‡ were identified as $Cu_3(H_2L)(L)\cdot 2H_2O$, **2**·$2H_2O$ (yield 25%).

A single-crystal diffraction analysis of **2**·$2H_2O$ revealed an asymmetric unit containing half a molecule, with the central Cu(2) ion lying on a twofold axis. The neutral trinuclear complex is formed by two molecules of the coordinated ligand, one tetraanionic, L^{4-}, the other dianionic, H_2L^{2-}, and two water molecules linked by hydrogen bonds to the outer phenolic atoms of H_2L^{2-}, O(11) and O(11A). The molecular structure along with the atomic numbering scheme for the asymmetric unit is shown in Fig. 1. All atoms generated by the symmetry operation related to the twofold axis ($-x$, y, 0.5 $-$ z) have been labelled with an A.

The three Cu(II) ions are held together by two μ-phenoxo bridges, through O(20) and O(20A) of L^{4-}. The Cu(2)···Cu(1) distances, 3.413(3) Å, are similar to those found for other trinuclear copper complex which also contain alkoxo bridges between the central and terminal Cu(II) ions, but here they show a more planar geometry.[7] The longer Cu(1)···Cu(1A) distance, 3.858(3) Å, seems to be imposed by the spatial arrangement of both ligands and the three metal centres form an isosceles triangle arrangement.

These Cu···Cu separations are similar to those found for some copper(II) proteins such as oxyhaemocyanin from *Plimulus polyphemus*[8] (3.6 Å) which contain N-donor atoms and oxo-bridges. Furthermore, the trinuclear site of oxidised ascorbate oxidase from green zucchini[9,10] is also approximately isosceles triangular; two such sites are present with intermetallic distances in the range 3.66–3.90 Å.

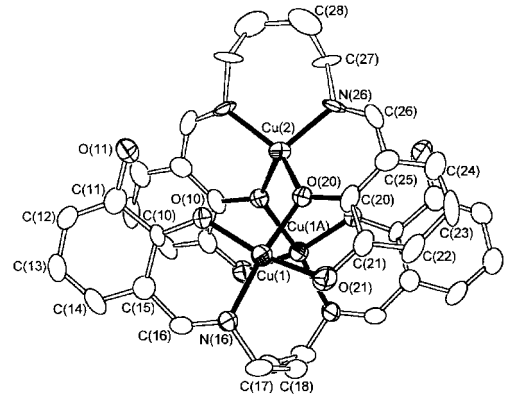

Fig. 1 ORTEP plot for **2**, showing the numbering scheme of the asymmetric unit. H-atoms and disordered atoms have been omitted for clarity. Significant distances (Å): Cu(1)–O(10) 1.872(8), Cu(1)–O(21) 1.900(8), Cu(1)–N(16) 1.950(10), Cu(1)–O(20) 1.976(8), Cu(2)–O(20) 1.905(9). Angles (°) around Cu(1) 84.0(4)–161.2(4), around Cu(2) 94.4(5)–139.0(4).

The central Cu(2) ion lies within the N_2O_2 inner compartment of L^{4-}. This donor set is usually quasi-planar in homo- and hetero-binuclear complexes containing very related ligands, but with a $(CH_2)_2$ or $(CH_2)_3$ chain. [11,12] However, in the present case with a $(CH_2)_4$ chain it is very severe tetrahedrally distorted. The longer $(CH_2)_4$ is more flexible and allows the ligand to twist and so achieve additional coordination to Cu(1) and Cu(1A) by means of both outer O_2 donor sets [O(20) and O(20A), acting as μ-phenoxo bridges], instead of a more typical binucleating fashion ($N_2O_2 + O_4$) for this type of ligand. Thus, L^{4-} is clearly behaving as a helicand with three metal-binding domains ($O_2 + N_2O_2 + O_2$). The helical arrangement is shown schematically in Fig. 2.

The absence of spacers other than the $(CH_2)_4$ between these donor sets, and the pronounced twist observed probably causes uncertainty in the atomic positions of the methylene chain. This may result in the observed disorder of its atoms, which are found in two different positions [C(27) and C(27′); C(28) and C(28′); with *ca.* 60 and 40% occupation factors, respectively]. In spite of this unusual ligand behaviour, the inner N_2O_2 compartment of L^{4-} still retains a suitable environment to effectively coordinate a copper(II) ion with usual bond lengths, but not in an ideally planar arrangement.

As Cu(1) and Cu(1A) do not satisfy their co-ordination numbers with co-ordination only to L^{4-}, the other ligand unit H_2L^{2-} must complete these. This ligand is bisbidentate and binucleating, by use of the double NO donor set of its inner

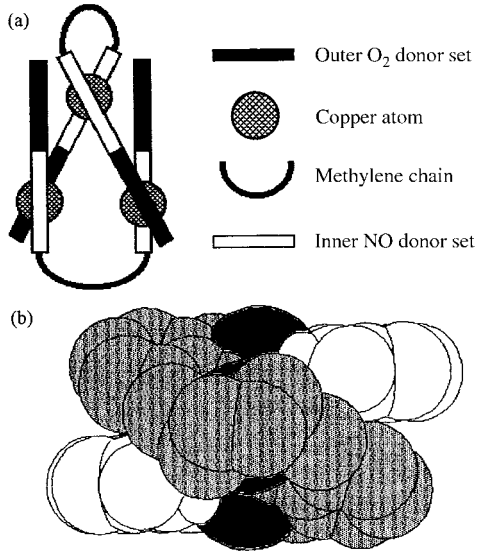

Fig. 2 (a) A scheme showing the helical arrangement for **2** and (b) a space-filling model of **2**, showing the helicand behaviour of L^{4-} (grey) and H_2L^{2-} (white) surrounding the three metal centes (black).

compartment. Thus, the NO_3 environment of Cu(1) and Cu(1A) is achieved through the O-atoms of L^{4-} [O(20) and O(21)], and the inner O(10) and N(16) atoms of H_2L^{2-} complete the coordination sphere leading to a slightly distorted square-planar coordination environment. The distortion appears to be caused by the steric hindrance between both ligand units and the twist of L^{4-} (Fig. 2). The other two potential donor oxygen atoms, O(11) and O(11A), remain protonated and are uncoordinated, but are linked by hydrogen interactions to solvated water molecules.

The bisbidentate bonding fashion observed for H_2L^{2-} (ON + NO), has been previously reported for other acyclic imines with similar[13] (but not helicand) and different donor atom sets (N_2 + N_2 but helicand).[3] However, H_2L^{2-} is not as twisted as L^{4-}, and adopts a nearly 'stepped-like' conformation, so that the two aromatic ring planes are almost parallel and fairly well separated. Overall, an unusual [4 + 4 + 4] bishelical arrangement is formed by three metal centres and two ligand units (Fig. 2).

This complex differs from usual bishelical structures, in which both helixes are similar or virtually so and the metal environments are seldom planar but more usually tetra- or octahedral.[3] Probably, the reasons for such an unusual arrangement can be found in the type of ligand used. It was previously reported that related ligands containing $(CH_2)_2$ and $(CH_2)_3$ chains could coordinate in both compartments (N_2O_2 + O_4) to Cu(II) ions.[11] The behaviour in the present system can be regarded as potentially compartmental, binucleating and leading to essentially square-planar coordination. L^{4-} acts as a trinucleating (O_2 + N_2O_2 + O_2) ligand while H_2L^{2-} is binucleating (ON + NO). Thus, the more flexible $(CH_2)_4$ chain ligand can coordinate two (NO + NO) and even three (O_2 + N_2O_2 + O_2) metal centres. Each moiety of L^{4-} is binucleating (O_2 + ON) but the flexible $(CH_2)_4$ chain allows the ligand to fold and so contain a metal centre in its inner compartment, in what can even be considered as O_2 + ON + NO + O_2 ligating behaviour.

Thus, both ligand units with their repeated metal-binding domains and a very flexible $(CH_2)_4$ chain spacer, lead to a bishelical arrangement. Perhaps, since there is no spacer between the inner NO and the outer O_2 donor sets of each moiety, both units cannot behave in the same way, as there would be a high steric hindrance between them (Fig. 2).

The assembling behaviour of this potentially N_2O_4 donor Schiff base is also unusual, as the majority of molecular threads giving rise to helicates incorporate at least one pyridine-type nitrogen donor.[3] The L^4 unit is unusual in that O-atoms predominantly coordinate and despite the presence of a long spacer it is bound to three close metal centres.

Although both ligand units show diverse behaviour, all the Cu–N and Cu–O distances are very similar in both cases, *ca.* 1.95 and 1.90 Å, respectively, which are within the usual range for copper ions coordinated to Schiff bases. Only the Cu(1)–O(20) distance [1.976(8) Å] is slightly longer than those usually found in the literature.[14] This is probably because O(20) is acting as a μ-bridge between Cu(2) and Cu(1).

Further studies are in progress; for example, magnetic data show a significant dependence with structure. EPR data for **2**·$2H_2O$ indicate a strucural change at *ca.* 100 K, probably related to the $(CH_2)_4$ moiety and its disorder.

We would like to thank Xunta de Galicia (Spain) for financial support (XUGA 20901B97).

Simple silica-particle template synthesis of mesoporous carbons

Sangjin Han and Taeghwan Hyeon*

School of Chemical Engineering and Institute of Chemical Processes, Seoul National University, Seoul 151-742, Korea. E-mail: thyeon@plaza.snu.ac.kr

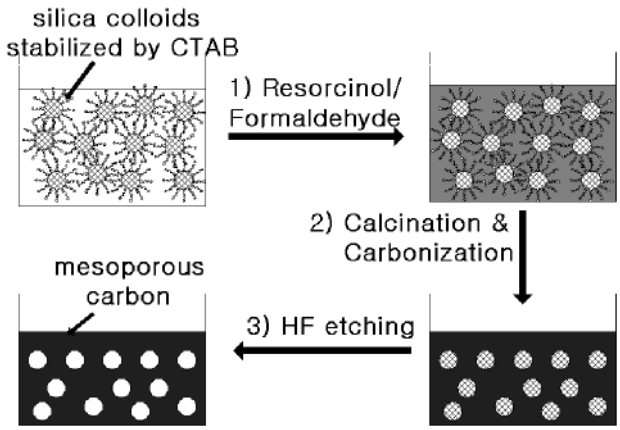
Received (in Cambridge, UK) 20th July 1999, Accepted 27th August 1999

A simple preparative method for mesoporous carbons with high pore volumes using surfactant stabilized silica particles as templates is reported.

The synthesis of mesoporous M41S silica materials by Mobil researchers has stimulated explosive research on the preparation of inorganic porous materials through template approaches.[1] A large variety of mesoporous inorganic materials have been prepared using various types of organic templates including surfactant self-assemblies and block copolymers.[2] Uniform sized polymer latex spheres and emulsions have also been utilized to produce mesoporous inorganic materials with larger pores of >10 nm.[3]

Porous carbons have been extensively used as adsorbents in many separation and purification processes.[4] These porous carbons are generally microporous and the production of mesoporous carbons is extremely important for their applications in the separation and adsorption of bulky organic materials. Inorganic templates have been used to tune the pore size of carbon materials.[5] Recently, we have developed a new synthetic method to generate porous carbon materials with pores of >50 nm using commercial silica sol as a template.[6] Here, we report the fabrication of mesoporous carbon with narrow pore size distribution and high pore volume through surfactant stabilized silica particles as templates.

In previous work, we simply added carbon precursor, resorcinol and formaldehyde (RF) into Ludox HS-40 silica sol solution.[6] The resulting RF–silica composite was carbonized and etched with HF solution to obtain carbon materials with pores ranging in size from 10 to 60 nm [Fig. 1(a), dashed line]. The average particle size of HS-40 silica sol was reported to be 12 nm, and obviously the aggregates of silica particles are acting as templates. In order to obtain a more uniform pore size distribution, isolated silica particles stabilized by surfactant were applied as templates. The overall synthetic procedure is shown in Scheme 1. In a typical synthesis, 5 g of cetyltrimethylammonium bromide (CTAB) was added to 100 mL of an aqueous Ludox HS-40 silica sol solution (40 wt% silica with average particle size of 12 nm), and the mixture was stirred for 20 min at 50 °C, resulting in a muddy slurry. The stabilized silica particles were then collected by filtration under vacuum, and washed with double-distilled water to remove un-adsorbed surfactant. Resorcinol–formaldehyde gel (RF gel) was used as a carbon precursor.[7] A solution of 1 resorcinol: 2 formaldehyde: 0.014 Na_2CO_3 (catalyst): 5.62 H_2O with pH 7.3 was added dropwise under mild suction to be infiltrated into the CTAB-stabilized silica particles. The resulting yellow RF–silica composite was aged at 85 °C for three days to obtain a red RF gel–silica composite. The composite was carbonized at 850 °C for 3 h under nitrogen to yield a silica–carbon composite. To remove the silica template, the carbon–silica composite was stirred in 48 wt% aqueous HF solution for 12 h. The BET surface area was found to be 1512 $m^2\ g^{-1}$. The N_2 adsorption isotherm shown in the inset of Fig. 1(a) (continuous line) exhibited type IV behavior (hysteresis at high relative pressure), indicating the presence of mesopores. The BJH (Barrett–Joyner–Halenda) cumulative pore volume (corresponding to pores >2 nm) was extremely high (3.6 $cm^3\ g^{-1}$). The pore size distribution of the carbon material was narrow with an average pore size of 12 nm along with a shoulder around 15 nm [continuous line in Fig. 1(a)]. The overall pore size distribution is similar to the reported particle size distribution of Ludox HS-



Scheme 1 Synthetic strategy for uniform mesoporous carbons. 1) gelation of resorcinol and formaldehyde (RF) in the presence of CTAB-stabilized silica particles; 2) carbonization of RF gel–silica composite at 850 °C to obtain carbon–silica composite; HF etching of silica templates to obtain mesoporous carbons.

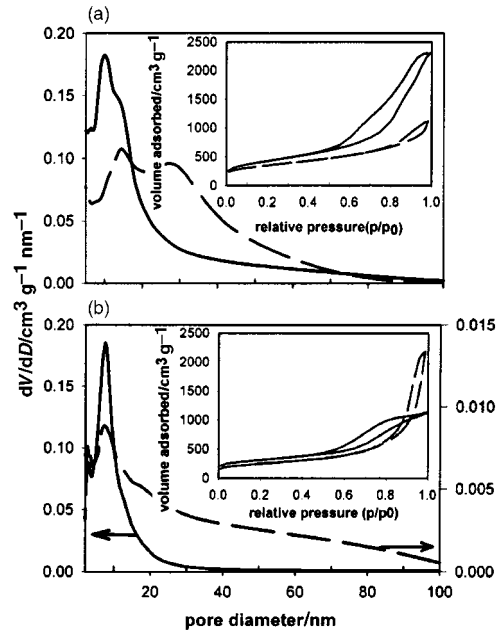


Fig. 1 The pore size distributions calculated from the adsorption branch of the nitrogen isotherm by the BJH method and the corresponding N_2 adsorption and desorption isotherms (insets) of mesoporous carbons. (a) (—) carbon prepared with CTAB-stabilized Ludox HS-40 silica sols as template and (----) carbon prepared with Ludox HS-40 silica sol aggregates as template. (b) (—) carbon prepared with CTAB-stabilized Ludox SM-30 silica sols as template and (----) carbon prepared with Ludox SM-30 silica sol aggregates as template. The isotherms were collected at 77 K on a Micrometrics ASAP2000 Gas Adsorption Analyzer after the carbon materials were degassed at 200 °C at 10 μTorr for 5 h.

30 silica sol (30 wt% silica).[8] By contrast, a carbon xerogel derived from the sol–gel polymerization of resorcinol–formaldehyde (RF) at pH 8 without silica templates was nearly nonporous. These results clearly demonstrate that the stabilized silica particles are acting as a true template for the formation of mesopores.

We have also produced carbon material using CTAB-stabilized Ludox SM-30 silica (30 wt% of silica with average particle size of 8 nm) particles as templates. The resulting carbon material revealed a very narrow pore size distribution centered at 8 nm [Fig. 1(b), continuous line]. The pore volume of the carbon material was high (1.69 $cm^3\ g^{-1}$) and the BET surface area of the material was found to be 1089 $m^2\ g^{-1}$. Carbon materials produced through SM-30 silica sol without a surfactant stabilization exhibited a relatively broad pore size distribution ranging from 8 to 100 nm [Fig. 1(b), dashed line]. Our present results demonstrate that uniform mesoporous carbons with pore size around 10 nm and very high pore volume can be easily fabricated by using surfactant-stabilized silica sol particles as templates.

Synthesis of the porphyrin-fused porphyrin, [2]porphyracene

Ken-ichi Sugiura,* Takuya Matsumoto, Satoshi Ohkouchi, Yasuhisa Naitoh, Tomoji Kawai, Yoshio Takai, Kantaro Ushiroda and Yoshiteru Sakata*

The Institute of Scientific and Industrial Research (ISIR), Osaka University, 8-1 Mihogaoka, Ibaraki, Japan. E-mail: sakata@sanken.osaka-u.ac.jp

Received (in Cambridge, UK) 27th July 1999, Accepted 24th August 1999

A novel porphyrin-fused porphyrin is formed by an oligomerization reaction of a (porphyrinato)nickel complex with $TeCl_4$; the isolated compound, [2]porphyracene, was characterized by spectroscopic methods and direct observation using scanning tunnelling microscopy; the excitation energy value of 13460 cm^{-1} (743 nm) is the lowest value reported for porphyrin dimers.

Porphyrins hold a unique position among organic compounds since they have a small HOMO–LUMO gap and can incorporate almost all types of metal ions in the central cavity.[1] Reflecting these characteristics, porphyrins are present not only in various biological systems, but are applied in many advanced materials. Recently much efforts has been focused on the expansion, contraction, isomerization and modification of the porphyrin chromophore to lead to more elaborated functions.[2–7]

In the course of our synthetic study on chalcogen substituted porphyrins for advanced materials,[8] we serendipitously discovered a novel reaction between [5,15-bis(3,5-di-*tert*-butylphenyl)porphyrinato]nickel **2** with tellurium(IV) tetrachloride ($TeCl_4$) to give a highly conjugated porphyrin-fused porphyrin. Here we report the new expanded porphyrin **1a**, denoted [2]porphyracene (porphyrin + acene; the number [2] implies the number of porphyrin nuclei) since this condensation manner is an acene type.

To prepare **3** which has a $TeCl_3$ group at a *meso*-position, the reaction of **2** with 1 equiv. of $TeCl_4$ in dry CH_2Cl_2 at room temperature[9] was carried out. The obtained reaction mixture was analyzed by matrix assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry and was found to give a series of peaks from M^+ = 1483 up to 6000 with equal mass spacings of *ca.* 744. This indicates clearly, contrary to the initial expectation, the formation of oligomeric products of **2**, from the dimer to the octamer. Separation of the dimer fraction from higher oligomers was successfully achieved using gel permeation liquid chromatography. The dimer fraction was further separated into three components **A**, **B** and **C** having M^+ = 1483, 1716 and 1949, respectively, using silica-gel flash chromatography. In a typical reaction, 48.3 mg of **1** and 8.8 mg of $TeCl_4$ gave 15.0 mg of **A**, 1.0 mg of **B**, 0.7 mg of **C**, and 20.0 mg of higher oligomers. The ^{1}H NMR spectrum of the main product **A** is different from those of porphyrin dimers directly connected at *meso–meso* or *meso*-β positions.[6] On the basis of detailed ^{1}H NMR analysis including truncated driven differential nuclear Overhauser effect measurements and MALDI-TOF mass spectra, the structure of **A** was assigned to be **1a** (Fig. 1) where the two porphyrin rings are fused at β- and *meso*-positions. The structures of **B** and **C** were assigned to be **1b** and **1c**, respectively, in a similar manner.

To confirm the structural assignment, we performed a direct observation of **1a** using scanning tunnelling microscopy (STM) (Fig. 2).† The STM image of **1a** adsorbed on a Cu(100) surface shows four lobes arranged in a parallelogram which are attributable to 3,5-di-*tert*-butylphenyl groups which are STM active substituents.[10] The size of the parallelogram is 13 × 9 Å which is consistent with the molecular size of **1a** estimated by a preliminary molecular geometry calculation [15.5 × 8.8 Å; Fig. 2(c)].

Aromatic protons of **1a** (H^b, H^c, H^d, H^e, H^f and H^{meso}) were upfield shifted by 0.18–0.67 ppm compared with the corre-

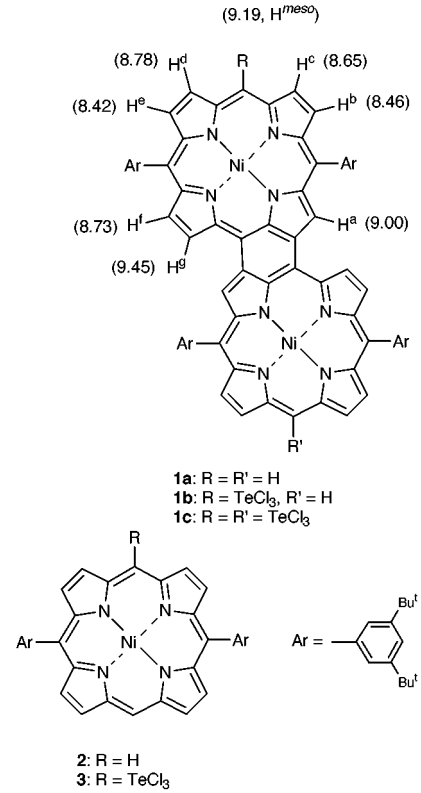

Fig. 1 Compounds **1**–**3** along with ^{1}H NMR assignments for **1a**.

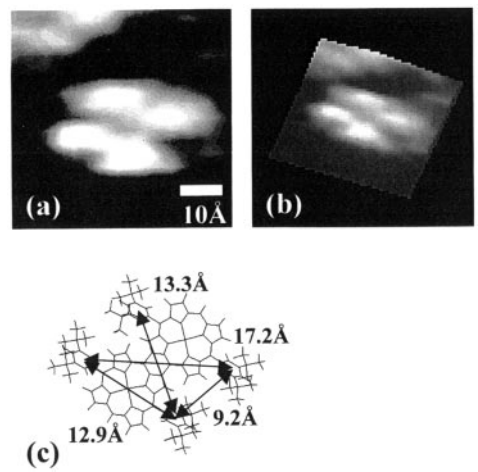

Fig. 2 STM image of **1a**: (a) top view, (b) perspective view, (c) molecular geometry of **1a**. The image shows a four-lobed pattern in a parallelogram arangement. The observed size of the parallelogram is 13 × 9 Å.

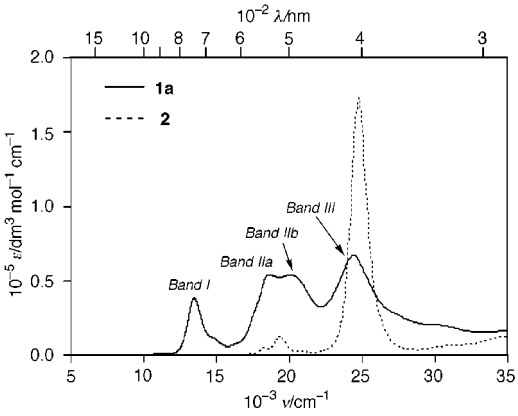

Fig. 3 Absorption spectra of [2]porphyracene **1a** (solid line) and **2** (dotted line) in $CHCl_3$.

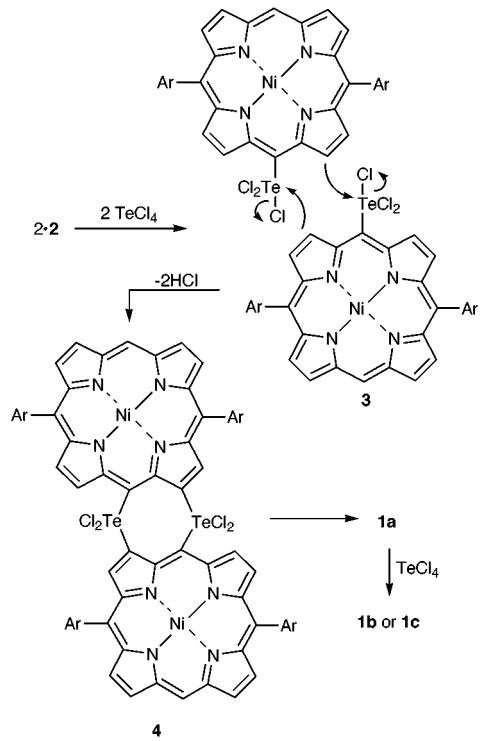
sponding protons of **2** indicating the electron donating nature of the fused porphyrin ring. On the other hand, aromatic protons H^a and H^g showed downfield shifts of 0.09 and 0.34 ppm, respectively, owing to the ring current effect of the adjacent macrocycle and the compression effect from the sterically crowded protons.

The electronic spectra of **1a** and **2** are shown in Fig. 3. The spectrum of **1a** is essentially composed of three bands, band I, Q-band-like bands IIa and IIb and Soret-band-like band III. Reflecting the highly conjugated structure, band I appeared at 13460 cm^{-1} (743 nm) *i.e.* at a much longer wavelength than those of a porphyrin dimer connected by an acetylene linkage reported by Therien and coworkers (λ_{max} 14640 cm^{-1}; 683 nm)[2] or fused dimers reported by Crossley and Burn (λ_{max} 14180 cm^{-1}; 705 nm)[4] and by Smith and coworkers (λ_{max} 15340 cm^{-1}; 652 nm).[5] The other absorption bands of **1a**, bands IIa, IIb and III, were at quite similar wavelengths to those of **2**, although the intensity of band III was decreased and those of bands IIa and IIb were increased. These phenomena suggest a lowering of the symmetry and new π-electronic system for [2]porphyracene.

Considering that reported oxidative oligomerization of porphyrins take place at *meso–meso* and/or *meso*-β positions to form a single connection,[6] it is unprecedented that the present edge-fused oligomerization reaction of the nickel porphyrin complex takes place to give a double connection. Since the corresponding free base of **2** did not give oligomeric products, increased reactivity of the nickel porphyrin **2** at its β-positions may be responsible for the reaction.[6e] As shown in Scheme 1, the dimerization reaction of **2** probably takes place through a cyclic intermediate **4**,[11] which has not, so far, been detected. The final detelluration reaction is similar to that of bis(aryl)tellurium dichloride to give aryl coupling products.[9] The isolation of **1b** and **1c** suggests that these are the intermediates of [4]porphyracene and higher oligomers.



Scheme 1 A proposed reaction mechanism for dimerization.

In conclusion, a novel and highly conjugated [2]porphyracene has been isolated. In addition to the expanded π-system of the porphyrin, [2]porphyracene has two central cavities for homo- or hetero-metallation. These characteristics will allow us to use porphyracene for the preparation of advanced materials. We are currently investigating detailed properties of [*n*]porphyracenes including characterization of higher oligomers.

This work was supported in part by a Grant-in-Aid for Scientific Research on Priority Area (#11136222 "Metal-assembled Complexes" to K-i.S and #10146103 "Creation of Characteristic Delocalized Electronic Systems" to Y. S.) from the Ministry of Education, Science, Sports and Culture, Japan. We appreciate the technical assistance provided by the Materials Analysis Center of ISIR, Osaka University.

Notes and references

† The STM image was observed with a home-made ultrahigh vacuum apparatus. An atomically clean single crystal Cu(100) surface was used as the substrate onto which **1a** was sublimed. Details of STM experiments will be published elsewhere.

Received (in Basel, Switzerland) 7th July 1999, Accepted 19th August 1999

The anionic mixed-metal cluster $[Ru_3Ir(CO)_{13}]^-$ 1, found to be catalytically active in the carbonylation of methanol, reacts with methanol at 70 °C to give, with O–H activation of the substrate, the cluster anion $[HRu_3Ir(CO)_{12}(OMe)]^-$ 2, which upon prolonged reaction loses formaldehyde to give the cluster anion $[H_2Ru_3Ir(CO)_{12}]^-$ 3; both anions 2 and 3 crystallise together as the double-salt $[N(PPh_3)_2]_2[HRu_3Ir(CO)_{12}(OMe)][H_2Ru_3Ir(CO)_{12}]$ the single-crystal X-ray structure analysis of which reveals a butterfly Ru_3Ir skeleton for 2 and a tetrahedral Ru_3Ir skeleton for 3.

Mixed-metal clusters have received steadily increasing attention over the last three decades owing to their inherent catalytic potential.[1] The presence of different metals in the same complex may have synergistic effects in the catalytic activity.[2] Recently we reported a series of Ru_3Ir and Os_3Ir mixed-metal clusters which show reasonable catalytic activity in the carbonylation of methanol to give acetic acid.[3,4] The cluster anions $[Ru_3Ir(CO)_{13}]^-$ **1** and $[Os_3Ir(CO)_{13}]^-$ **4**, used as catalyst precursors in this process, are however unstable under the reaction conditions, which has been confirmed by the isolation of the fragmentation products $Ir_4(CO)_{12}$ and $[N(PPh_3)_2][M(CO)_3I_3]$ (M = Ru, Os).[4] In this context we were interested in the behaviour of these anionic clusters towards reagents participating in the catalytic process, especially in the reaction with methanol.

The anion $[Ru_3Ir(CO)_{13}]^-$ **1** (as its $[N(PPh_3)_2]^+$ salt) reacts with methanol at 70 °C within 2 h to give the anionic cluster $[HRu_3Ir(CO)_{12}(OMe)]^-$ **2** [eqn. (1)], as indicated by a colour change of the solution from red to orange. The formation of **2** involves O–H activation of the methanol molecule, which is split into μ-H and μ-OMe ligands, replacing a carbonyl group of the starting compound. Anion **2** can be isolated as the $[N(PPh_3)_2]^+$ salt by extraction with diethyl ether after evaporation of the reaction solution to dryness, washing of the residue with hexane–dichloromethane (5:1) and recrystallisation from ethanol–pentane (1:3) at −18 °C.‡

$$\underset{\mathbf{1}}{[Ru_3Ir(CO)_{13}]^-} + MeOH \rightarrow \underset{\mathbf{2}}{[HRu_3Ir(CO)_{12}(OMe)]^-} + CO \quad (1)$$

Upon prolonged reaction (48 h) in methanol, especially at higher temperature (90 °C), anion **2** is transformed into the anion $[H_2Ru_3Ir(CO)_{12}]^-$ **3** with liberation of formaldehyde [eqn. (2)]. The formation of formaldehyde is evidenced by the ^1H NMR spectrum of the reaction mixture, which shows the signal for HCHO at δ 9.75 as well as a signal at δ 5.31 attributed to the formaldehyde trimer trioxane (by comparison with an authentic sample).

$$\underset{\mathbf{2}}{[HRu_3Ir(CO)_{12}(OMe)]^-} \rightarrow \underset{\mathbf{3}}{[H_2Ru_3Ir(CO)_{12}]^-} + HCHO \quad (2)$$

If the thermal reaction of **1** with methanol at 90 °C is stopped half-way (after 12 h), both anions **2** and **3** are present in the solution, and the double-salt $[N(PPh_3)_2]_2[HRu_3Ir(CO)_{12}(OMe)][H_2Ru_3Ir(CO)_{12}]$ can be isolated by crystallisation of the reaction residues from a 4:1 mixture of diethyl ether and hexane.

A suitable crystal§ of this double-salt revealed the molecular structure of both anions **2** and **3** (Fig. 1 and 2), disordered over the same position. Three of the four metal positions are occupied by metal atoms of both anions **2** and **3**, whereas one ruthenium atom splits into Ru(1) for anion **2** and Ru(1a) for anion **3**, the refinement of the occupancy factors giving a 1:1 ratio. In contrast to anion **2**, anion **3** is already known,[3] its structure in the double-salt being very similar to that we found in the salt $[N(PPh_3)_2][H_2Ru_3Ir(CO)_{12}]$.[3]

In anion **2**, the dihedral angle Ru(1)–Ir(1)–Ru(3)–Ru(2), that is to say the spreading of the wing tips is relatively small (82.9°) compared to those in other chalcogen- or halogen-bridged clusters, such as $HRu_3Co(CO)_{12}(\mu\text{-}SMe_2)$ (96.1°)[5] or $HRu_3Ir(CO)_{12}(\mu\text{-}Cl)$ (89.3°).[6] A similar dihedral angle as in **2** has been observed in the hydroxy-bridged osmium cluster cation $[H_4Os_4(CO)_{12}(\mu\text{-}OH)]^+$ (82.3°).[7] As a result of the small dihedral angle, the distance between the wing tip metal atoms Ru(1) and Ru(2) is only 3.3536(2) Å. The hydride-bridged edge Ru(1)–Ru(3), at 3.095(5) Å, is significantly longer than all the other metal–metal bonds. The wing tips are bridged asymmetrically by the methoxy group, the Ru–O bond distances being 2.02(2) and 2.16 (2) Å, respectively. This is well in line with the bond lengths found in other methoxy-bridged clusters, such as $HOs_3Pt_2(CO)_{10}(\mu_5\text{-}C)(\mu\text{-}OMe)(PCy_3)_2$[8] or $Os_3(CO)_{10}(\mu$-

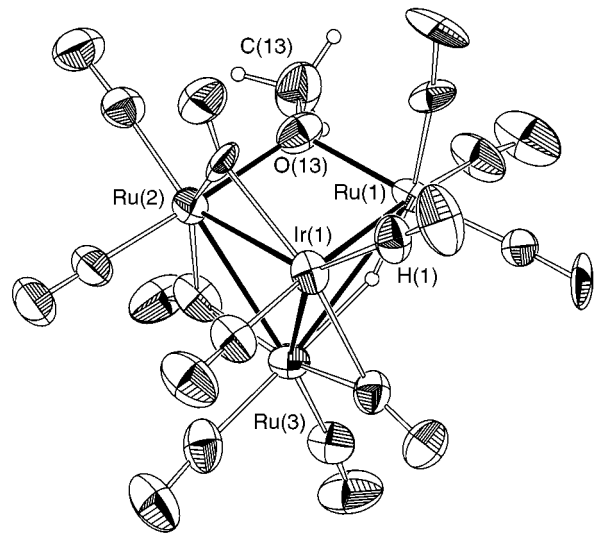

Fig. 1 Molecular structure of $[HRu_3Ir(CO)_{12}(OMe)]^-$ **2** showing the atom numbering scheme. Selected bond distances (Å) and angles (°): Ir(1)–Ru(1) 2.854(2), Ir(1)–Ru(2) 2.758(1), Ir(1)–Ru(3) 2.737(1), Ru(1)–Ru(3) 3.095(5), Ru(2)–Ru(3) 2.797(1), Ru(1)–H(1) 1.47(1), Ru(3)–H(1) 1.77(1), Ru(1)–O(13) 2.02(2), Ru(2)–O(13) 2.16(2), O(13)–C(13) 1.39(3), Ru(1)–O(13)–C(13) 119.3(16), Ru(2)–O(13)–C(13) 125.7(16).

† Present address: Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF.

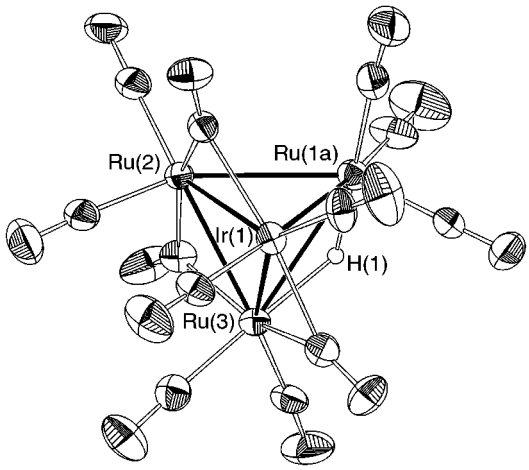

Fig. 2 Molecular structure of $[H_2Ru_3Ir(CO)_{12}]^-$ **3** showing the atom numbering scheme. Selected bond distances (Å): Ir(1)–Ru(1A) 2.689(6), Ru(1A)–Ru(2) 2.878(4), Ru(1A)–Ru(3) 2.866(6), Ru(3)–H(1) 1.77(1), Ru(1A)–H(1) 1.37(1). The second hydride ligand spanning Ru(1A)–Ru(2), only having an occupancy factor of 50%, could not be located in the double-salt, but was found in $[N(PPh_3)_2][H_2Ru_3Ir(CO)_{12}]$.[3]

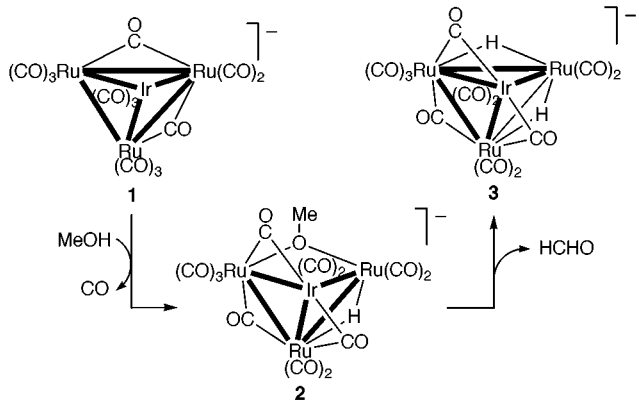

Scheme 1

$OMe)_2$.[9] The methyl group sticks out of the Ru(1)–Ru(2)–O(13) plane with an angle of 13.7°, in accordance with observations for $Os_3(CO)_{10}(\mu\text{-}OMe)_2$.[9] Anion **2** is consistent with the effective atomic number rule which requires an electron count of 62 valence electrons for butterfly clusters.

The reaction sequence involving the cluster anions **1**, **2** and **3** and the oxidation of methanol to formaldehyde is very interesting (Scheme 1). Anion **1** contains a closed tetrahedral Ru_3Ir metal framework, which is opened by the reaction with methanol to give anion **2** containing a butterfly Ru_3Ir skeleton, the wing tips of which are bridged by the methoxy ligand. The elimination of formaldehyde in going from **2** to **3** implies the reclosing of the butterfly Ru_3Ir skeleton to a closed metal tetrahedron.

We are grateful to the BASF AG (Germany) for financial support of this work. We also thank the Johnson Matthey Technology Centre (United Kingdom) for a generous loan of ruthenium trichloride hydrate.

§ *Crystallographic data* for $[N(PPh_3)_2]_2[HRu_3Ir(CO)_{12}(OMe)][H_2Ru_3Ir(CO)_{12}]$, $C_{117}H_{66}N_2Ir_2O_{25}P_4Ru_6$, M = 1387.18, monoclinic, space group $P2_1/c$, a = 14.966(1), b = 19.743(1), c = 17.07781) Å, β = 98.541(10)°, V = 4989.8(7) $Å^3$, Z = 2, D_c = 1.846 g cm^{-3}, μ(Mo-Kα) = 3.675 mm^{-1}, 38776 reflections measured ($2\theta_{max}$ = 52.08°), 5302 observed data [$I > 2\sigma(I)$] used in the refinement, $R1$ = 0.0588, $wR2$ = 0.1501 ($R1$ = 0.1042, $wR2$ = 0.1674 for all data). Intensity data were collected at 293(2) K on a Stoe Imaging Plate Diffractometer system (IPDS) equipped with a one-circle goniometer using Mo-Kα graphite-monochromated radiation (λ = 0.71073 Å). 200 exposures (3 min per exposure) were obtained at an image plate distance of 70 mm with $0 < \varphi < 200°$ with the crystal oscillating through 1° in φ. The structure was solved by direct methods (SHELXS-97[10]) and refined using weighted full-matrix least squares on F^2 (SHELXL-97[11]). A high disorder was found in the double-salt resulting in refined occupancies of 0.5 for Ru(1), Ru(1a) and the corresponding CO ligands. The methoxy group which is coordinated to Ru(1) and Ru(2) also has an occupancy of 0.5. Despite an empirical absorption correction being applied using DIFABS[12] (T_{min} = 0.168, T_{max} = 0.640), a large peak of electron density near one of the ruthenium atoms remained, which may be due to the disorder.

From porphyrin sponges to porphyrin sieves: a unique crystalline lattice of aquazinc tetra(4-carboxyphenyl)porphyrin with nanosized channels

Yael Diskin-Posner and Israel Goldberg*

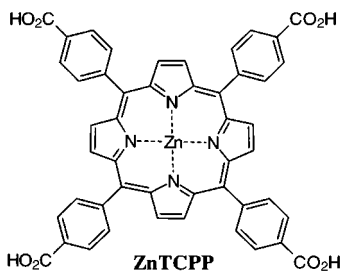
School of Chemistry, Sackler Faculty of Exact Sciences, Tel-Aviv University, 69978 Ramat-Aviv, Tel-Aviv, Israel. E-mail: goldberg@post.tau.ac.il

Received (in Cambridge, UK) 27th July 1999, Accepted 25th August 1999

A unique supramolecular solid assembly with very wide channels has been formulated with aquazinc tetra(4-carboxyphenyl)porphyrin building blocks; the open porphyrin lattice is sustained by characteristic stacking interactions and multiple hydrogen bonding, it comprises only about 39% of the crystal volume, and preserves its crystallinity up to about 360 K.

A remarkable effort has been directed in recent years towards the design, by noncovalent *supramolecular* synthesis, of new molecular solids with structural and functional similarity to the inorganic zeolites.[1,2] We have also launched an extensive research program in this area, utilizing porphyrin metallomacrocycles as building blocks. The latter readily form expansible clathrates with guest components of versatile size and shape, in which the architecture of the porphyrin lattice is, however, strongly conserved.[3] Indeed, the vast majority of these structures consist of offset-stacked porphyrin layers with an average interlayer distance of 4.5 Å, the layered arrangement of the roughly flat porphyrin species representing a fundamental property of the porphyrin–porphyrin interaction.[3–5] We anticipated that the transformation from materials with variable interporphyrin voids ('sponges') to materials with fixed-size tubular cavities ('sieves') can be achieved by incorporation of a suitable molecular recognition algorithm in the porphyrin building blocks.[4] Here we report on a novel porphyrin-sieve type structure with rather large channels, the crystal lattice of which consists of a single component, aquazinc tetra(4-carboxyphenyl)porphyrin (aqua-ZnTCPP), and occupies only 39% of the crystal volume. The architecture of this structure is determined entirely by interporphyrin hydrogen bonding and stacking interactions, without resorting to external auxiliaries. The only other known example of a porphyrin-based lattice with wide open channels consists of heterogeneous assemblies of porphyrins *via* transition metal bridges.[2] The interiors of the channels in both crystals are partly filled with a small number of disordered molecules of nitrobenzene, which acts as a template.

We have shown previously that molecules of ZnTCPP may self-assemble through self-complementary hydrogen bonding in different ways to yield hollow network architectures.[4d,e] This includes formation of two-dimensional arrays with large interporphyrin voids (16 × 21 Å)† through $(CO_2H)_2$ hydrogen bonding between the terminal carboxylic functions of adjacent porphyrins.[4d] However, the latter were found to mutually interlock into one another to fill the interporphyrin voids, as commonly observed for other systems with large intermolecular spacing.[6] More recently, two-dimensional patterns with considerably smaller cavities (8.5 × 11.0 Å)† have also been constructed, by utilizing potassium or sodium 18-crown-6 as template.[4e] These networks do not interpenetrate as the interporphyrin voids are conveniently accommodated by the macrocyclic template.



ZnTCPP

From the above observations it has become clear that in order to prevent interpenetration in the former case and to yield network structures with larger pores, it is essential to use sizeable solubilizing and templating agents with a low tendency to interact with the ZnTCPP lattice. After numerous trials, the following experimental procedure based on slow diffusion gave successful results. First, tetra(4-aminophenyl)porphyrin was dissolved in nitrobenzene, and this solution was placed at the bottom of a glass tube. This porphyrin derivative bears four amino groups which on one hand represent non-complementary binding sites for self-assembly, and on the other hand are weaker proton donors than the carboxylic function (and therefore have little chance to interact with the ZnTCPP). A second layer of ethylene glycol was placed above this solution. Then, a third layer of ZnTCPP dissolved in MeOH was placed on top. In such a manner, the ZnTCPP was allowed to diffuse slowly from the MeOH phase into the bottom layer. At saturation after several days, a phase separation occurred at the bottom solution yielding tiny needle-shaped crystals of ZnTCPP and an amorphous solid containing the tetraaminoporphyrin. The presence of the tetraaminoporphyrin in the bottom solution is essential in order to drive the ZnTCPP into the nitrobenzene layer (ZnTCPP is otherwise insoluble in nitrobenzene) and thus facilitate its self-organization *via* $(CO_2H)_2$ hydrogen bonding [Fig. 1(*a*)] around the nitrobenzene template (see below).

Fig. 1 illustrates the fascinating porphyrin sieve structure which characterizes the emerged crystals.‡ It consists of open very efficiently hydrogen-bonded networks of aqua-ZnTCPP, which stack in an offset manner along the normal direction. Four porphyrin units and eight hydrogen bonds [at OH···O distances of 2.611(4) Å] encircle any given pore within the network. The perpendicular distance between adjacent layers is 4.68 Å. The porphyrin core is slightly inclined (by 18°) with respect to plane of the network, as a result of which the van der Waals width of the open channel propagating through the crystal at its narrowest point is reduced from 16 Å[4d,e] to about 15 Å. In spite of the fact that the aqua-ZnTCPP lattice occupies only about 39% (after accounting for the van der Waals radii of all the atoms including hydrogens) of the crystal volume,[7] the presence of neither tetraaminoporphyrin nor of other species in the interporphyrin channels could be identified from the diffraction data. NMR experiments do indicate however that the crystals contain nitrobenzene solvent with an approximate 1 : 4 porphyrin : solvent ratio (which slowly reduces with time).§ The randomly distributed residual electron density peaks found in the channels did not exceed 0.85 e $Å^{-3}$, suggesting only partial occupancy of the channels (the very loose crystal packing is reflected also in relatively large atomic thermal displacement parameters) and a significant disorder of the solvent molecules even at 115 K. Nevertheless, the structure refinement based on

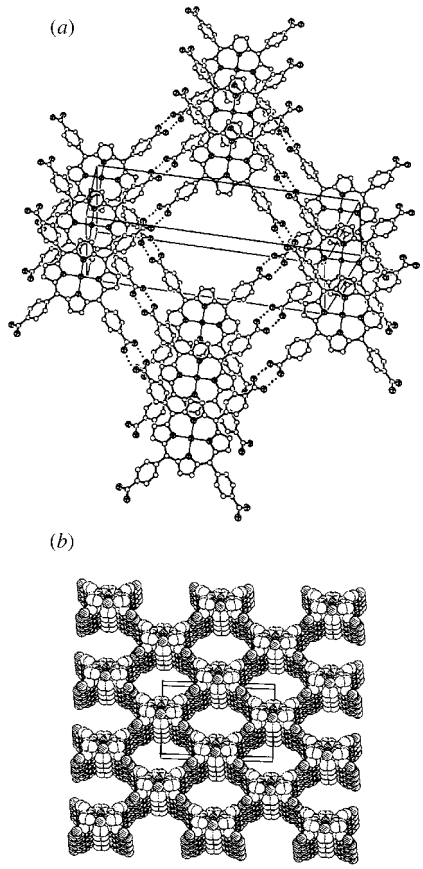


Fig. 1 (*a*) Ortep illustration of the crystal lattice, projected approximately on the plane of the porphyrin layers, showing their offset-stacked organization (the axial water bound to zinc is omitted for clarity). (*b*) Space-filling (CPK) representation of the open structure, viewed approximately down the channels which propagate along the *c*-axis of the crystal lattice. It shows best the space proportions between porphyrin lattice and the 1.5 nm wide open channels (the latter being partly occupied by disordered nitrobenzene solvent).

the ZnTCPP lattice alone converged at a relatively low (for such 'hollow' systems) *R*1 value of 13.9%. These surprising observations led us to conduct independent full-set measurements on three different crystals, but all provided identical results. Crystals of this material do deteriorate slowly when left in an open air, but are quite stable when covered with a very thin layer of light oil. Their structure and morphology does not change upon heating or cooling (apart from natural thermal expansion or contraction) within the temperature range of 115–360 K, as indicated by repeated measurements of the crystal data on the same crystal at various temperatures in this range. Despite the solvent disorder, the experimental data monitored by a CCD detector were sensitive enough to allow at this stage the location of all the hydrogen atoms on the porphyrin framework in difference Fourier maps. As the contribution of the disordered solvent to the diffraction pattern could not be rigorously included in the crystallographic calculations, it was subtracted in the next stage by the Squeeze/Bypass procedure.[8] The resulting refinement of the aqua-ZnTCPP lattice converged with reasonable precision at a considerably lower *R*1 value of 7.1%, without affecting to any significant extent the porphyrin structure. The combination of the above findings confirm with a high degree of certainty the correctness of this unique structure.

This study demonstrates that hydrogen bonding interactions combined with dominant molecular shape features (van Waals forces) can be very effective in formulations of nanoporous materials from porphyrin building blocks which recognize each other through multiple molecular recognition sites, in the presence of a suitable template. The enthalpies of such interactions when considered alone are relatively small, 20–33 kJ mol^{-1} for hydrogen bonds in the carboxylic acid dimers,[9] and $\leq$46 kJ mol^{-1} for π–π stacking between two partially overlapping zinc porphyrin moieties.[5] However, their cooperative effect (each ZnTCPP is involved in eight hydrogen bonds and is sandwiched between two adjacent porphyrins) approaches the strength of a covalent bond, and appears to be adequate to stabilize the observed molecular sieve structure even with only partial occupation of the 1.5 nm wide channels by solvent. Thus, although the porphyrin lattice occupies only 39% of the crystal volume, it forms an ordered and relatively stable solid. The preset study, along with the previous observations,[4d,e] also shows the ability of the ZnTCPP system to self-assemble into different supramolecular architectures (pseudo-polymorphism), and emphasizes the significance of the templating agent in inducing the preferred organization.

This research was supported in part by the Israel Science Foundation founded by the Israel Academy of Sciences. The assistance of Dr A. Rudi with the NMR measurements is gratefully acknowledged.

Notes and references

† Dimensions of interporphyrin voids refer throughout this paper to distances between van der Waals surfaces of the porphyrin framework.

‡ *Crystal data* for aqua-ZnTCPP: $C_{48}H_{28}N_4O_8Zn{\cdot}H_2O{\cdot}\ 4(C_6H_5NO_2)$,§ M_r = 1364.6, monoclinic, space group *C*2/*m*, a = 19.622(1), b = 29.649(1), c = 7.513(1) Å, β = 99.24(1)°, V = 4314.2(6) Å^3, Z = 2, ρc. = 1.050 g cm^{-3}, μ(MoKα) = 0.34 mm^{-1}, T = 115 K, 6103 measured reflections (one hemisphere), 3629 unique reflections, R_{int} = 0.039. The diffraction data of the poorly diffracting crystals were collected on a KappaCCD diffractometer system, using Mo-Kα (λ = 0.7107 Å) radiation and 0.5° ϕ and ω scans. Final R1 = 0.139 for 2329 reflections with $F > 4\sigma(F)$, R1 = 0.194, wR2 = 0.381 and GoF = 1.379 for all 3629 data. All hydrogen atoms of the porphyrin framework were located on difference Fourier maps; their positions were slightly adjusted to conform to standard bond lengths and angles. The porphyrin complex (with five-coordinate zinc ion) is located on, and disordered about, the inversion center. Only very diffused residual electron density was observed in the channel voids. It corresponds to a highly disordered nitrobenzene solvent, the structure of which could not thus be modeled. After subtraction of the disordered and diffused solvent contribution to the diffraction pattern (see text) (ref. 7, 8), final R1 = 0.071 for 2096 reflections with $F > 4\sigma(F)$, R1 = 0.112, wR2 = 0.198 and GoF = 0.985 for all 3629 data. CCDC 182/1391. See http://www.rsc.org/suppdata/cc/1999/1961/ for crystallograpic data in .cif format.

§ Content of the disordered solvent species in the analysed crystals was assessed by ^{1}H NMR (DMSO, 500MHz): δ 8.80 (8H, s, β-pyrrole of ZnTCPP), 8.25 (8H, d, nitrophenol), 7.85 (4H, t, nitrophenol), 7.70 (8H, t, nitrophenol).

Allylsilylation and stannylation of 1,2-diketones using bifunctional allylsilane–allylstannane reagents *via* photoinduced electron transfer reaction

Akio Takuwa,* Hiroyuki Saito and Yutaka Nishigaichi

Received (in Cambridge, UK) 16th August 1999, Accepted 31st August 1999

Bifunctional allylsilane–allylstannane and allylstannane–allylstannane reagents react photochemically with 1,2-diketones to give α-ketohomoallyl alcohols having an allylsilane moiety and α-ketohomoally alcohols having an allylstannane moiety respectively in excellent yields, and the remaining allylstannane moiety further reacts effectively with another diketone in the presence of $Mg(ClO_4)_2$ to afford a bis-α-ketohomoallyl alcohol.

The addition of allylsilane[1] and allylstannane[2] with various carbonyl compounds has been widely used as one of the most useful procedures for C–C bond formation. The process generally requires promoters such as Lewis acids which activate the electrophilic function of carbonyl compounds towards nucleophilic attack by the allylmetal reagents.[1–3] On the other hand, light-promoted addition *via* photoinduced electron transfer (PET) from allylstannane[4] and allylsilane[5] to the photoexcited carbonyl compounds has recently attracted considerable interest from both synthetic and mechanistic viewpoints. In these photoadditions, allylstannanes are good electron donors compared with the corresponding allylsilanes. For example, we found that the reaction of allylstannanes with benzophenones gave homoallylic alcohols *via* PET,[4] whereas allylsilanes behaved as an ordinary alkene to produce oxetanes and hydrogen abstraction products[6] without PET reaction. This observation prompted us to examine the photoadditon reactions of bifuntional allylsilane–allylstannane reagent **1** and allylstannane–allylstannane reagent **2** with 1,2-diketones. We expected that the differences in the reactivity of allylstannane and allylsilane would permit their differentiation in the bifunctional reagents under photochemical conditions.

Irradiation (> 400 nm) of the absorption band of benzil **3a** (0.02 mol dm^{-3}) in a N_2-purged MeCN–benzene (5 : 1 v/v) solution containing 3-tributylstannyl-2-[(trimethylsilyl)methyl-]propene[7] **1** (0.03 mmol dm^{-3}) for 3 h at ambient temperature (Scheme 1) afforded an α-ketohomoallyl alcohol having an allylsilane moiety (**4a**). The 1 : 1 adduct **4a** was isolated in 90% yield by preparative TLC (silica gel, hexane–Et_2O, 4 : 1 v/v) and the structure was determined from its spectral properties and elemental analysis.† The allylsilane unit in the product **4a** does not react further with benzil even under prolonged irradiation or even under irradiation in the presence of $Mg(ClO_4)_2$ (*vide infra*).

The bifunctional allylsilane–allylstannane reagent **1** also reacted photochemically with other diketones **3** to produce the corresponding α-ketohomoallyl alcohols containing allylsilane moieties in moderate to good yields (Table 1, entries 1–4).

On the other hand, the light promoted reaction of **3** with 3-triphenylstannyl-2-[(triphenylstannyl)methyl]propene[8] **2** afforded two types of addition products, an α-ketohomoallyl alcohol with an allylstannane moiety **5** (1 : 1 adduct) and a bis-α-ketohomoallyl alcohol **6** (1 : 2 adduct), depending on the ratio of

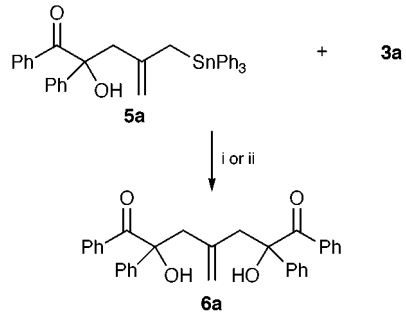
5	**2**	**3a**	1.5 : 1	3	**5a** (96)	**6a** (0)
6	**2**	**3a**	1.5 : 1	3[c]	**5a** (86)	**6a** (8)
7	**2**	**3a**	0.5 : 1	12	**5a** (25)	**6a** (56)[d]
8	**2**	**3a**	0.5 : 1	3[c]	**5a** (4)	**6a** (90)[d]
9	**2**	**3b**	1.5 : 1	3	**5b** (98)	**6b** (0)
10	**2**	**3b**	0.5 : 1	12	**5b** (14)	**6b** (67)[d]
11	**2**	**3c**	1.5 : 1	3	**5c** (98)	**6c** (0)
12	**2**	**3c**	0.5 : 1	12	**5c** (17)	**6c** (71)[d]
13	**2**	**3c**	0.5 : 1	3[c]	**5c** (< 1)	**6c** (91)[d]
14	**2**	**3e**	1.5 : 1	3	**5e** (61)	**6e** (0)

[a] Isolated yields. [b] A small amount of butylated product, 1,2-diaryl-2-hydroxyhexan-1-one, was also produced. [c] Irradiation was carried out in the presence of 5 equiv. of $Mg(ClO_4)_2$. [d] Diastereomer ratio was 1 : 1.



Scheme 2 *Reagents and conditions*: i, *hν* (> 400 nm), MeCN-benzene (4 : 1, v/v); ii, *hν* (> 400 nm), $Mg(ClO_4)_2$, MeCN-benzene (4 : 1, v/v).

the bifunctional reagent **2** to the 1,2-diketones (Table 1). Thus irradiation of benzil in the presence of a 1.5-fold molar excess of the reagent **2** for 3 h produced the 1 : 1 adduct **5a** in very high yield (96%),‡ while irradiation in the presence of 0.5 equiv. of **2** gave both **5a** and 1 : 2 adduct **6a**, where the ratio of **5a** : **6a** gradually decreased with increasing irradiation time; these two adducts were isolated respectively in 25 and 56% yield after irradiation for 12 h (entry 7). These results show that the addition reactions proceed stepwise. Other diketones **3** also gave the 1 : 1 adduct **5** and/or the 1 : 2 adduct **6** in good yields, depending on the ratio of the substrates and the reagent as shown in Table 1.

The present allylsilylation and stannylation may be initiated by PET from the bifunctional reagents to the photoexcited diketones to generate the organometalic radical cation (**1**$^{\bullet+}$ or **2**$^{\bullet+}$)-ketyl radical anion (**3**$^{\bullet-}$) pair. The selective cleavage of the Sn–C(allyl) bond of the radical cation **1**$^{\bullet+}$ produces β-[(trimethylsilyl)methyl]allyl radical because of the Si–C bond being stronger than the Sn-C bond.[9] The resulting allyl radical couples with **3**$^{\bullet-}$ to give allylsilylated product **4**. In the case of the reaction using allylstannane–allylstannane reagent **2**, the β-[(triphenylstannyl)methyl]allyl radical formed by the fragmentation of **2**$^{\bullet+}$ couples with the ketyl radical **3**$^{\bullet-}$ to yield the allylstannylated product **5**.

Next we examined the subsequent addition step from 1 : 1 adduct **5** to 1 : 2 adduct **6**. Irradiation of an MeCN–benzene solution containing benzil (0.01 mmol dm^{-3}) and isolated **5a** (0.01 mmol dm^{-3}) for 3 h gave the 1 : 2 adduct **6a** in 55% yield (Scheme 2).

Interestingly, when the irradiation was carried out in the presence of 5 equiv. of $Mg(ClO4)_2$ under otherwise identical conditions, the yield of **6a** increased to 90%. These results suggest that the second addition reaction also proceeds *via* PET and Mg^{2+} accelerates the PET reaction, probably due to the higher reducing ability of the Mg^{2+}–benzil complex compared to that of uncomplexed benzil.[10] Therefore, the photochemical reaction of the bifunctional reagent **2** with 1,2-diketones in the presence of $Mg(ClO_4)_2$ was examined. The 1 : 2 adduct **6** was obtained in very high yield (> 90%) from the reaction with 0.5 equiv. of **2** in the presence of $Mg(ClO_4)_2$ (entries 8 and 13). Even in the reaction of benzil with an excess amount of **2** a small amount (8%) of **6** was also produced in the presence of the metal salt (entry 6). These results show that the first step of the PET reaction is faster than the second one and that Mg^{2+} should catalyze the present PET reaction.

In conclusion, the light-promoted addition reaction of bifunctional allylmetal reagents to 1,2-diketones yielded α-ketohomoallyl alcohols bearing allylsilane or allylstannane groups in high yields *via* single electron transfer reaction. These products are unlikely to be obtained from well known Lewis acid-promoted reactions, as they have both nucleophilic (allylmetal group) and electrophilic (carbonyl) functions in the same molecule which are sensitive to Lewis acids.[11] In addition, bis-α-ketohomoallyl alcohols were effectively produced by stepwise photoinduced electron transfer reaction between allylstannane–allylstannane reagent and 1,2-diketones. More detailed studies on the bifunctional reagents under photochemical conditions and the intramolecular cyclization reaction of the resulting α-ketohomoallyl alcohols are in progress in our laboratory.

Received (in Cambridge, UK) 13th August 1999, Accepted 23rd August 1999

A simple controlling mechanism assuming reasonable activation energies for the reaction steps is used to simulate temperature compensation of the period length of the large amplitude sustained pH oscillations observed experimentally in a H_2O_2–$S_2O_3^{2-}$–SO_3^{2-}–H^+ aqueous flow reaction system under optimized conditions.

The period length of the rhythm in many biological clocks is largely unaffected by temperature changes which occur in a certain physiological range.[1–3] This behavior is called temperature compensation, and it is very important for the correct timing of numerous periodic processes (for example, light and dark periods in photoperiodic responses) that whould be, by and large, independent of environmental factors such as, for example, temperature. Such behavior is in contrast to that observed in chemical oscillators where an increase in temperature leads generally to a significant increase in the frequency,[4–6] since all the composite reactions accelerate as expected from the Van't Hoff's rule. An old unanswered question is whether temperature compensation is confined to circadian and ultradian rhythms, or whether homogeneous chemical oscillators may be able to act similarly.[7]

According to recent theoretical considerations, temperature compensation can be obtained in simple oscillator models, such as the Brusselator,[7] the Oregonator,[8] or the Goodwin model.[9] The theory states that temperature compensation in a reaction kinetic network requires an appropriate balance in activation energy-weighted rate constant sensitivities between opposing processes. In order to find experimental evidence for the theory, we have studied the temperature sensitivity of several pH oscillators[10] and found that a recently designed H_2O_2–$S_2O_3^{2-}$–SO_3^{2-}–H^+ system[11] exhibited temperature compensation under certain conditions.

In our experiments, we used a water-jacketed cylindrical-shaped glass vessel with a liquid volume of 12.5 ml as a continuous-flow stirred tank reactor (CSTR). The CSTR was equipped with a Horiba electrode to measure the pH and the temperature inside the reactor. The time–pH data were collected by a computer through a pH meter and an A/D converter with a sampling rate of 1 Hz. A 1.0 cm long Teflon-covered stirrer bar was used to ensure uniform mixing. Two input solutions were prepared daily: one contained 0.0270 M H_2O_2, the other contained all the remaining components, such as 0.010 M $Na_2S_2O_3$, 0.0040 M Na_2SO_3 and 5.0×10^{-4} M H_2SO_4, together. The input solutions were kept from air to avoid any effect of O_2 and CO_2. The reactor was fed with these solutions by means of an EYELA peristaltic pump. The mixing ratio was 1.0 : 1.0, so the input concentrations in the combined feed were half of those in the input solutions.

Our first task was to determine the temperature range where regular pH oscillations were exhibited. Shown in Fig. 1 is a state diagram spanned in the normalized flow rate (k_0)–T plane. The range of oscillations is rather narrow at low k_0 values. It is shifted to the higher temperatures and widens significantly as k_0 increases. At $k_0 = 4.0 \times 10^{-3}$ s^{-1} the range is as wide as 10 °C.

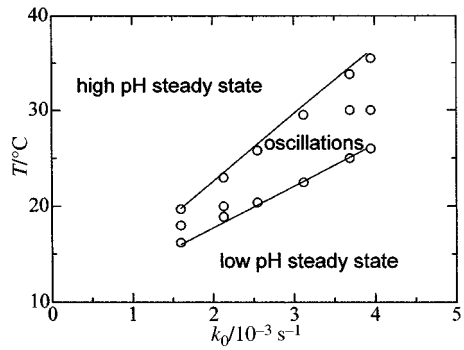

Fig. 1 Measured state diagram in the k_0–T plane. Input concentrations: $[H_2O_2]_0 = 0.0135$, $[S_2O_3^{2-}]_0 = 0.0050$, $[SO_3^{2-}]_0 = 0.0020$, $[H^+]_0 = 5.0 \times 10^{-4}$ M. k_0 is the reciprocal residence time in the CSTR.

Above and below the oscillatory region a high pH steady state (pH 8–9) and a low pH steady state (pH 4–5.5) exist, respectively. Inside the oscillatory region, the amplitudes were found to decrease gradually with increasing temperature as the upper border was approached. Transition to the low pH steady state with decreasing temperature was sharp. The system behavior became chaotic at low flow rates.[11] Here we attempted to avoid such behavior so we kept the flow rate relatively high.

Secondly, we studied the period length of the sustained oscillations as a function of temperature in the disclosed range. An average period length was calculated in minutes for each temperature on the basis of a long run containing at least 20 periods. Reproducibility of the period length was within 6%. As shown in Fig. 2, period length turned out to be remarkably constant throughout the temperature range of oscillations at a fixed flow rate and input concentrations. Some significant deviation from the average period was measured along the borders of the oscillatory region. The pH amplitude and the waveform were altered by temperature changes. The most striking effect was that the high pH stage of a period appeared

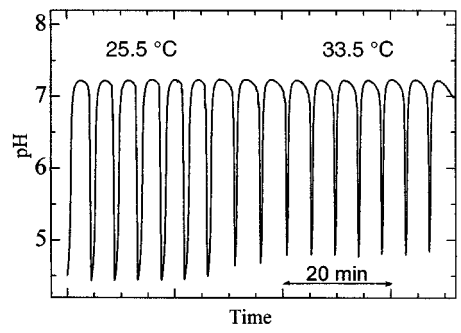

Fig. 2 Measured temperature compensation. Average period lengths at 25.5 and 33.5 °C are 4.45 and 4.41 min, respectively. Input concentratons as in Fig. 1, $k_0 = 3.60 \times 10^{-3}$ s^{-1}.

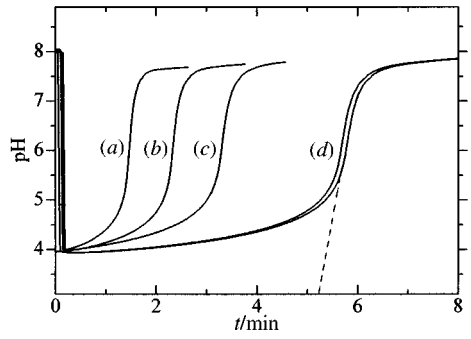

Fig. 3 Measured time–pH traces at (*a*) 36.0, (*b*) 30.0 (*c*) 26.0 and (*d*) 20.0 °C in a closed system. Double curve (*d*) shows the reproducibility. Initial concentrations: $[H_2O_2]_0$ = 0.0135, $[S_2O_3^{2-}]_0$ = 0.0050, $[H^+]_0$ = 5.0 × 10^{-4}, $[SO_3^{2-}]_0$ = 0.0020 M. Dashed line shows how the induction time was determined for the estimation of an apparent activation energy.

to be longer, and the low pH stage become shorter, with increasing temperature. As a result the average period length remained constant (Fig. 2). At k_0 = 3.90 × 10^{-3} s^{-1}, we measured the following average periods at different temperatures: 3.52 min (26.0 °C), 3.54 min (28.6 °C), 3.63 min (31.7 °C), and 3.40 min (35.8 °C). We can conclude that in the range 26.0–35.8 °C, complete temperature compensation has been achieved. Similar behavior was measured in the case of other fixed k_0 values inside the oscillatory region, but the period length decreased with increasing flow rate. On the other hand, however, it is surprising that the dynamical behavior exhibited extreme temperature sensitivity under other experimental conditions. For example, at $[H_2O_2)_0$ = 0.0070, $[S_2O_3^{2-}]_0$ = 0.0050, $[SO_3^{2-}]_0$ = 0.020, $[H^+]_0$ = 0.0010 M, and k_0 = 5.56 × 10^{-4} s^{-1} an interesting period doubling route from large amplitude regular oscillations through alternating small and large amplitudes (P2) to chaos could be observed as the temperature gradually changed from 25.0 through 24.0 to 22.0 °C, respectively.

We studied the effect of temperature on the kinetics in a closed reactor where no oscillations take place. Typical pH–time curves are presented in Fig. 3 where a sudden drop followed by an S-shaped increase in the pH is seen. An apparent activation energy, characteristic of the overall reaction rate, E_a = 67.0 kJ mol^{-1} could be determined by extrapolating the steepest section of the increasing part of the pH–time curves to the time axis and plotting the logarithm of the reciprocal intercept against 1/*T*. Such a value of E_a suggests a usual temperature dependence indicating that the temperature compensation of the oscillatory frequency found in the CSTR does not result from an unusually small temperature sensitivity of the system. A special control mechanism must instead be responsible for the behavior.

We carried out numerical simulations on the basis of the mechanism[11] shown in Scheme 1 to see whether it could be responsible for the temperature compensation. Mass action kinetics laws for steps (1)–(7) were taken into account. Two sets of estimated rate constant values were assigned for 26 and 36 °C (Table 1) and were used to simulate oscillations with a semi-implicit Runge Kutta method. Activation energies of the composite reactions were chosen to fall into a chemically reasonable range (25–92 kJ mol). The calculated periods are

$H_2O_2 + S_2O_3^{2-} \rightleftharpoons HOS_2O_3^- + OH^-$ (1/−1)
$H_2O_2 + HOS_2O_3^- \rightarrow 2HSO_3^- + H^+$ (2)
$S_2O_3^{2-} + S_2O_3 \rightarrow S_4O_6^{2-}$ (3)
$H_2O \rightleftharpoons H^+ + OH^-$ (4/−4)
$H_2O_2 + HSO_3^- \rightarrow SO_4^{2-} + H_2O + H^+$ (5)
$H_2O_2 + HSO_3^- + H^+ \rightarrow SO_4^{2-} + H_2O + 2H^+$ (5′)
$HSO_3^- \rightleftharpoons H^+ + SO_3^{2-}$ (6/−6)
$HOS_2O_3^- + H^+ \rightleftharpoons S_2O_3 + H_2O$ (7/−7)

Scheme 1

Table 1 Estimated activation energies and rate constants for 26 and 36 °C

Step	E_i/kJ mol^{-1}	k_i^{26}	k_i^{36}	Units
(1)	56.8	0.030	0.063	M^{-1} s^{-1}

(5′)	34.2	1.6 × 10^7	2.5 × 10^7	M^{-2} s^{-1}
(6)	75.1	3.0 × 10^3	8.0 × 10^3	s^{-1}
(−6)	25.8	5.0 × 10^{10}	7.0 × 10^{10}	M^{-1} s^{-1}
(7)	25.8	1.5 × 10^3	2.1 × 10^3	M^{-1} s^{-1}
(−7)	67.1	0.025	0.060	s^{-1}

almost the same for both sets of rate constants. Calculated oscillations at °C are preceded by an hour long induction period. Calculations were carried out with k_0 = 3.9 × 10^{-3} s^{-1}. Both the calculated amplitudes and waveforms resemble their experimental counterparts. Low and high pH steady states could also be reproduced with simulations.

Differences in activation energies of the composite reactions seem to be important for temperature compensation by this mechanism. The length of the neutral region (pH *ca.* 7) of a period is determined by the time required for the consumption of SO_3^{2-}. since SO_3^{2-} is produced in steps (2) (92.2 kJ mol^{-1} and (6) (75.1 kJ mol^{-1}) with high activation energies and consumed in steps (−6) (25.8 kJ mol^{-1}), (5) (31.0 kJ mol^{-1}) and (5′) (34.2 kJ mol^{-1}) with low activation energies, its production rate increases more rapidly with temperature than its consumption rate, causing an increase in its average lifetime. As a result, the length of the neutral stage increases with temperature. At the same time, the length of the low pH stage decreases with increasing temperature, as expected from the curves in Fig. 3. The two opposite changes compensate each other under certain conditions leading to constant periods at different temperatures.

In conclusion, a simple chemical system is presented which exhibits temperature compensation in its oscillatory frequency in a CSTR. We found that a mechanism proposed earlier[11] can account for such behavior. We suspect that temperature compensation may be found in other pH oscillators with similar mechanism. It remains to be seen whether pH oscillators with such behavior can provide any reasonable guide to the control mechanism of biological clocks. However, the reversibility of some composite processes may be a common feature of chemical and biological temperature compensation.

Financial support was obtained from the Hungarian Science Foundation (OTKA 25076) and from the Japan Society for Promotion of Science.

Received (in Cambridge, UK) 24th June 1999, Accepted 31st August 1999

Aluminium-incorporated SBA mesoporous materials have been obtained for the first time by direct synthesis; the resulting materials retain the hexagonal order and physical properties of purely siliceous SBA-15 and present higher catalytic activities in the cumene cracking reaction than AlMCM-41 materials.

Mesoporous molecular sieves, MCM-41, have attracted much interest because of their potential application in reactions or separations involving bulky molecules.[1,2] The synthesis and catalytic applications of AlMCM-41 have been reported by various authors.[3–8] The crucial problem is that AlMCM-41 has poor hydrothermal stability, either in steam or in hot water.[7,9] This becomes a serious limitation to the application of these new materials. Recently, Zhao *et al.*[10] reported the synthesis of a novel mesoporous silica denoted SBA-15 using an organic copolymer to organize the structure of a polymerizing silica precursor template. This material has a more regular structure and thicker walls than MCM-41, resulting in much higher stability. The aluminium-containing SBA-15 was also obtained by post-synthesis.[11,12] Here, we report a direct synthesis of aluminium-incorporated SBA mesoporous molecular sieves using a triblock copolymer as template. The physical properties and catalytic activities of the resulting materials were also studied.

The aluminium-containing SBA mesoporous solid was prepared as follows: 9 mL of tetraethyl orthosilicate (TEOS) and a calculated amount of aluminium tri-*tert*-butoxide, to obtain a given Si/Al ratio (10 or 20), were added to 10 mL of aqueous HCl at pH 1.5. This solution was stirred for > 3 h and then added to a second solution containing 4 g triblock poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) ($EO_{20}PO_{70}EO_{20}$, Aldrich) in 150 mL of aqueous HCl at pH 1.5 at 313 K. The mixture was stirred for another 1 h and allowed to react at 313 or 373 K for 48 h. The solid obtained was filtered off, dried at 373 K, and finally calcined in air flow (9 L h^{-1}) at a heating rate of 24 K h^{-1} up to 823 K and then maintained at this temperature for 4 h. The sample of SBA-15 was prepared according to the literature.[10] The samples studied are denoted AlSBAX(T_s) where X and T_s represent the Si/Al ratio and the synthesis temperature, respectively.

Table 1 gives the preparation conditions and textural properties of the resulting aluminium-incorporated mesoporous molecular sieves, together with the data of SBA-15 for comparison. The textural properties of AlSBA are similar to those of SBA-15. Fig. 1 shows the N_2 adsorption–desorption isotherm and pore size distribution of the AlSBA10(373) sample. The isotherm shows a clear H1-type hysteresis loop at high relative pressure, suggesting that AlSBA has very regular mesoporous channels despite their large pore size, which was also proved by its narrow gaussian pore size distribution. The BET surface areas and mesopore volumes of AlSBA determined by nitrogen adsorption–desorption at 77 K are in the range 689–1022 m^2 g^{-1} and 0.63–1.53 cm^3 g^{-1}, respectively. The calculated pore diameters by the BJH method are in the range of 3.6–7.4 nm, depending on the preparation temperature (T_s).

Table 1 Preparation and properties of AlSBA samples

Sample	Si/Al (in gel)	T_s/K	Synthesis pH	S_{BET}/ m^2 g^{-1}	Pore diameter/ nm	V_p/cm^3 g^{-1}
AlSBA10(373)	10	373	1.5	1004	7.4	1.53
AlSBA20(373)	20	373	1.5	1022	7.4	1.40
AlSBA10(313)	10	313	1.5	689	4.0	0.64
AlSBA20(313)	20	313	1.5	788	3.6	0.63
SBA-15(373)	—	373	< 0	901	6.5	1.20
SBA-15(313)	—	313	< 0	762	4.4	0.67

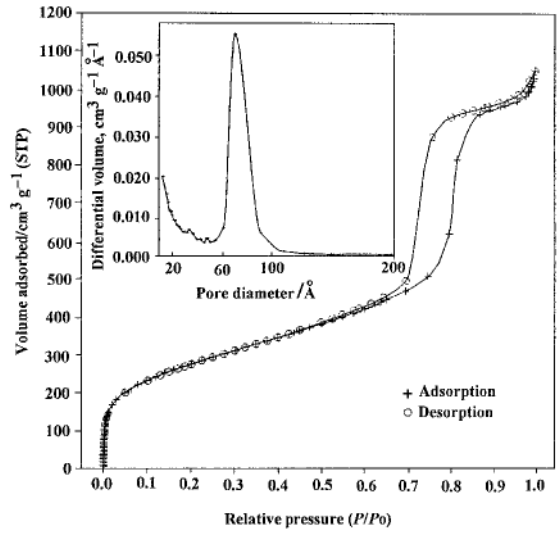

Fig. 1 N_2 adsorption–desorption isotherms of AlSBA10(373) at 77 K. The insert shows the BJH pore size distribution calculated from the desorption branch of the isotherm.

Transmission electron microscopy images show well ordered hexagonal arrays of 1D mesoporous channels and confirm that the AlSBA samples have a 2D *P6mm* hexagonal structure as does SBA-15.[11] Fig. 2 shows the TEM images of the AlSBA10(373) sample. The distance between two consecutive centres of hexagonal pores estimated from the TEM image is *ca.* 10 nm. The average thickness of the wall is *ca.* 3 nm, which is much larger than for MCM-41, and the pore diameter is around 7 nm, in agreement with the N_2 adsorption measurements.

Fig. 3(a) shows the ^{27}Al MAS NMR spectrum of the AlSBA10(373) sample. It exhibits signals at δ 52 from four-coordinate Al, at δ 38 from five-coordinate Al and at δ 0 from six-coordinate Al. This proves that a large amount of aluminium is incorporated in the framework of this sample, though some non-framework aluminium is still present. Such non-framework

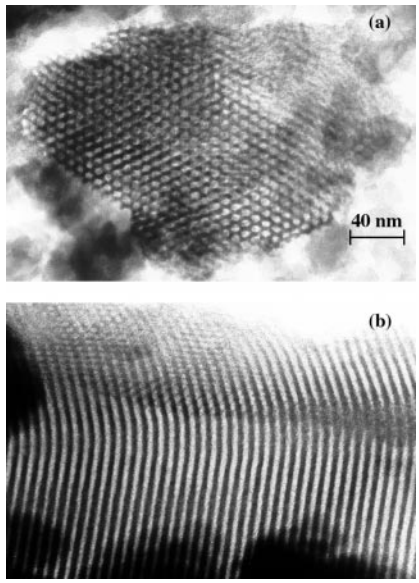

Fig. 2 TEM images of AlSBA10(373): (a) in the direction of the pore axis and (b) in the direction perpendicular to the pore axis.

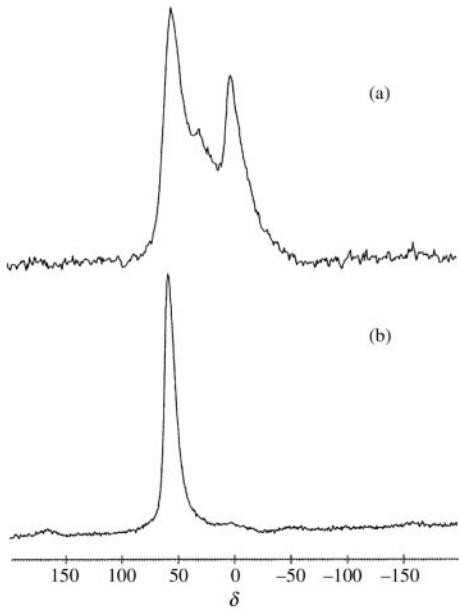

Fig. 3 ^{27}Al MAS NMR spectra of the AlSBA10(373) sample before (a) and after NH_4Cl washing (b).

aluminium was eliminated by washing the solid in NH_4Cl solution [Fig. 3(b)].

The stability of AlSBA samples following various treatments was also studied. XRD patterns of the AlSBA10(373) sample after calcination at 1073 K, steaming at 823 K and treatment in solution at different pH (Fig. 4) exhibit one very intense line and two weak lines, which are similar to those of the parent sample, indicating that the hexagonal structure of the AlSBA was not affected by these treatments. Compared with the same treatments on Al-MCM-41,[9] it can be concluded that the stabilities of AlSBA samples are much higher.

The catalytic activities of AlSBA samples towards the cumene cracking reaction have been investigated. The reaction was performed in a continuous-flow fixed-bed microreactor system with helium (25 mL min^{-1}) as carrier gas. The catalyst load for the tests was 100 mg and was preheated at 573 K for 3 h before reaction. A stream of cumene vapor in helium (25 mL min^{-1}) was generated using a saturator at room temperature. The steady state activities are given in Table 2. All samples have considerable activity in spite of their different textural properties, and the catalytic activity depends strongly on the Si/Al ratio. The activity towards cumene cracking of AlSBA

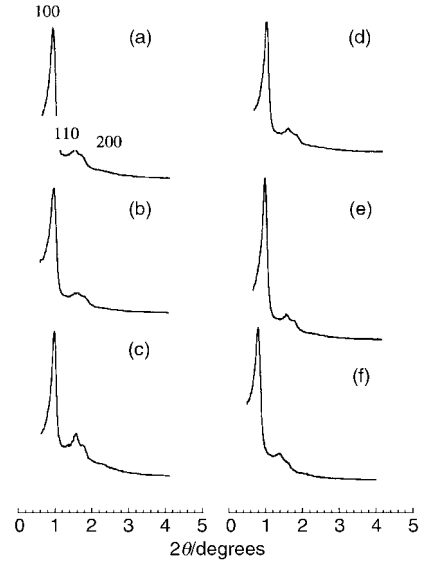

Fig. 4 XRD patterns of the initial AlSBA10(373) sample (a) and after a variety of treatments: (b) calcination at 1073 K; (c) steaming at 823 K; (d) in pH = 2 solution; (e) in pH = 7 solution and (f) in pH = 11 solution.

Table 2 Activities for cumene cracking reaction

	Conversion (%)		
Catalyst	473 K	523 K	573 K
AlSBA10(373)	12.6	43.2	87.0
AlSBA20(373)	2.5	17.1	56.0
AlSBA10(313)	12.8	34.8	86.5
AlSBA20(313)	9.4	27.7	75.8
SBA-15(373)	0	0	0
AlPSMCM5 (Si/Al = 5)[13]	—	—	50.0

molecular sieves is much higher than that of AlMCM-41[13] or AlSBA-15 prepared by post synthesis.[12] The only products of the cracking are benzene and propene, indicating that the active sites of this kind of material are of the Brönsted type. Currently we are performing two dimensional ^{27}Al solid state NMR (HETCOR) experiments to identify and establish the framework location of aluminium in these solids. Ammonia chemisorption and temperature-programmed desorption (TPD) and ^{1}H NMR at 4 K are being used to quantify the strength of the acidic sites.

Received (in Cambridge, UK) 13th July 1999, Accepted 3rd September 1999

CdS/CdSe core/sheath nanowires with diameters of 7.7/0.75 nm were prepared by treating CdS nanowires with selenium in tributylphosphine (TBP) at 100 °C for 24 h and were characterized by X-ray powder diffraction, transmission electron microscopy, high resolution TEM, UV–VIS absorption spectra, photoluminescence spectra and X-ray photoelectron spectroscopy.

Nanowires are of both fundamental and technological interest especially in the field of conductance quantization[1] and nanodevices.[2] Hybrid one-dimensional structures in axial or radial directions are essential to realize nanodevices. To date, both axial heterojunctions[3] and radial core/sheath structures[4] have been reported. Recently, routes to zero-dimensional core/shell II–VI semiconductors have been rapidly developed: core/shell semiconductors of CdS/$Cd(OH)_2$,[5] CdSe/ZnS,[6,7] CdSe/ZnSe,[8,9] CdS/HgS/CdS[10] and CdSe/CdS[11–13] are examples. These systems normally show decreased fluorescence lifetimes, higher stability and electronic accessibility in comparison with organic capped derivatives and are, in some cases, superior to existing fluorophores when applied as biological labels.[14] However, to our knowledge, core/sheath nanowires of II–VI semiconductors have not, as yet, been reported.

We have succeeded in preparing quantum confined CdS nanowires (4×200 nm)[15] using cadmium dithiocarbamate as a precursor,[16] and it is possible to prepare CdS/CdSe core/sheath nanowires by treatment of CdS nanowires. Since phosphine chalcogenides such as TBPSe,[12] Et_3PTe[17a] and TOPSe[18] have been widely used as chalcogen sources in the synthesis of II–VI nanocrystals we attempted to grow a CdSe sheath with Se in TBP. Here the reaction is described as a substitution-type process [eqn. (1)] considering the substantial difference between the solubility products of CdS ($K_{sp} = 1.4 \times 10^{-19}$) and CdSe ($K_{sp} = 1.4 \times 10^{-35}$). The detailed mechanism may involve chemical transportation of selenium by TBP [eqn. (2)] similarly to that of Te by R_3P.[17]

$$\mathrm{CdS + Se} \xrightarrow{\text{TBP, 100 °C, 12 h}} \mathrm{CdSe + S} \quad (1)$$

$$\mathrm{TBP + Se} \rightleftharpoons \mathrm{TBPSe} \quad (2)$$

The CdS nanowires were synthesized by using a modification of our previous method:[15] cadmium diethyldithiocarbamate $[Cd(Et_2NCS_2)_2]_2$ (1 g) was dissolved in ethylenediamine (en) (30 ml) and heated in a Teflon-lined autoclave at 80 °C for 12 h, then the yellow CdS nanowires were filtered off and washed with ethanol. After being dried in vacuum at room temperature for 2 h, CdS nanowires (0.576 g, 4 mmol) and selenium (0.016 g, 0.2 mmol) were ultrasonically dispersed in 20 ml TBP, transferred to a Teflon-lined autoclave, kept at 100 °C for 24 h, and then cooled to room temperature naturally. The product was filtered off, washed with ethanol, and dried in vacuum at room temperature for 2 h.

The black selenium powder disappeared and the yellow CdS nanowires turned red, the characteristic color of CdSe. X-Ray photoelectron spectroscopy (XPS)† was used to measure the composition of the core/sheath nanowires, the signal was fitted by Gaussians according to the literature[12] and gave a S/Se ratio of 93 : 7, consistent with the molar ratio of reactants added.

Fig. 1 shows the X-ray powder diffraction (XRD)‡ patterns for CdS and CdS/CdSe core/sheath nanowires, respectively. The (002) peak is much stronger and narrower than the other peaks for both nanowires, indicating that both were elongated along the *c*-axis and the shape was well preserved in the conversion reaction. According to the Scherrer formula, the average diameter is 6.5 nm for the CdS nanowires and 8.0 nm for the CdS/CdSe core/sheath nanowires. The reflection peaks of the core/sheath nanowires shifted only little from those characteristic of pure CdS to CdSe. The X-ray data may be consistent with both a core/shell structure[12] and a solid solution, so transmission electron microscopy (TEM) and high resolution TEM was carried out to confirm the former structure.

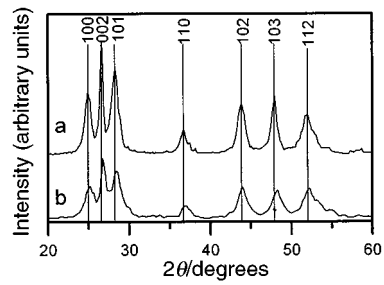

Fig. 1 XRD patterns of (a) CdS/CdSe core/sheath nanowires and (b) CdS nanowires.

TEM§ images of CdS and CdS/CdSe samples both show monodispersed wire-like shapes [Fig. 2(a) and (b)]. The average diameter is 6.7 nm for CdS nanowires and 8.5 nm for the core/sheath nanowires, which are consistent with the diameters estimated by the Scherrer formula. The retention of morphology unambiguously indicates a successful CdSe sheath growth since the likelihood for separately formed CdSe nanocrystals to be wire-like is very low. Further evidence for the core/sheath structure is from image contrast observations: CdS/CdSe core/sheath nanowires show much more contrast than the CdS nanowires owing to the stronger electron scattering power of selenium.

The size of the CdS/CdSe core/sheath nanowires is so small that only high resolution TEM (HRTEM) images give direct evidence of their formation. Fig. 2(c) and 2(d) show typical HRTEM¶ images for CdS and CdS/CdSe core/sheath nanowires respectively. The core/sheath nanowires consist of a 0.75 nm sheath and a 7.7 nm core, which is only a little larger than CdS only nanowires (6.9 nm) and in good agreement with the size estimated by the Scherrer formula. The sheath is thicker than expected from the Se to S ratio (7:93), one explanation is that the sheath is a compositionally graded interface between pure CdS and pure CdSe.

The UV–VIS absorption spectra of the CdS nanowires and CdS/CdSe core/sheath nanowires dispersed in water are shown in Fig. 3(a) and (b), respectively. There is little difference in the profile of the two spectra and an absorption peak at 472 nm is

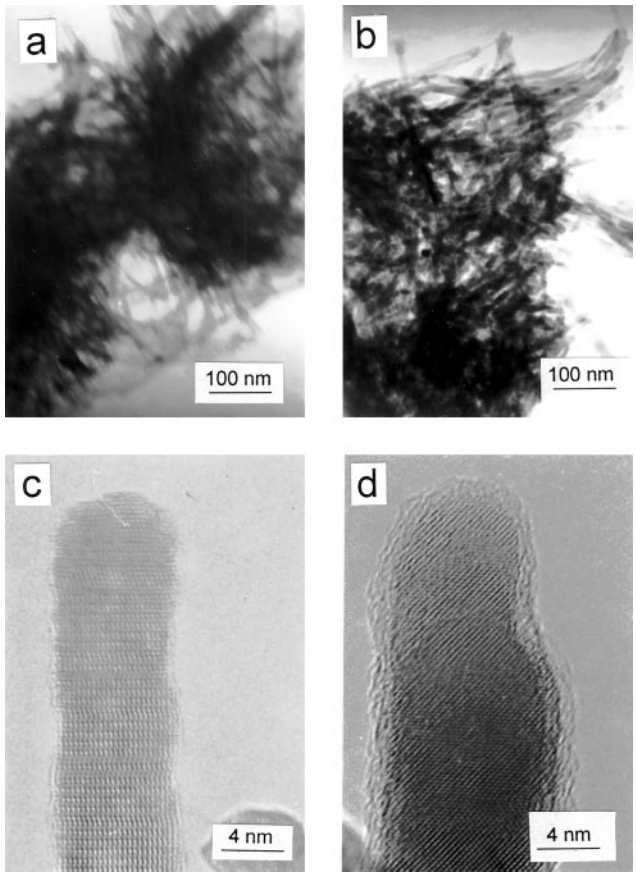

Fig. 2 TEM images of (a) CdS nanowires and (b) CdS/CdSe core/sheath nanowires along with HRTEM images of (c) CdS nanowires and (d) CdS/CdSe core/sheath nanowires.

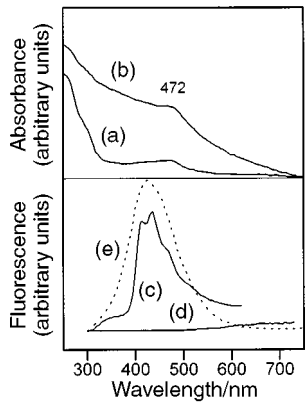

Fig. 3 Absorption spectra of (a) CdS nanowires and (b) CdS/CdSe core/sheath nanowires along with fluorescence emission spectra (excited at 250 nm) of (c) CdS nanowires, (d) CdS/CdSe core/sheath nanowires and (e) CdS/CdSe core/sheath nanowires dispersed in 1 M $CdSO_4$ solution.

common to both. This is consistent with a report that the major component of a core/shell particle dominates the absorption spectra.[9] By contrast, the photoluminescence (PL) spectra for the CdS-only and CdS/CdSe core/sheath nanowires are totally different [Fig. 3(c) and (d)] with the sheath completely quenching the fluorescence of CdS nanowires as found in the CdS/CdSe core/shell system.[11] When excess cadmium cations ($CdSO_4$) were added to a dispersion of the CdS/CdSe nanowires in water, the fluorescence was restored to virtually the previous level [Fig. 3(e)]. Accumulation of Cd^{2+} at the surface may destroy sites where radiationless recombination of charge carriers can occur.[5]

In summary, CdS/CdSe core/sheath nanowires with diameters of 7.7/0.75 nm were prepared from CdS nanowires and this method may be modified to prepare other core/sheath nanowires.

Financial support from the Chinese National Foundation of Natural Science Research through the Outstanding Youth Fund and Huo Yingdong Foundation for Young Teachers are gratefully acknowledged.

Crystal structure of $[Me_3Sb–SbMe_2]_2[(MeSbBr_3)_2]$, a trimethylstibine adduct of the dimethylstibenium ion or a stibinostibonium salt?

Henrik Althaus, Hans J. Breunig* and Enno Lork

University of Bremen, FB 02, PO Box 334440, D28334 Bremen, Germany. E-mail: breunig@chemie.uni-bremen.de

Received (in Basel, Switzerland) 19th July 1999, Accepted 30th August 1999

Scrambling reactions of dimethylantimony bromide in absence of solvent give the ionic complex $[Me_3Sb–SbMe_2]_2$-$[(MeSbBr_3)_2]$, with cations consisting of pyramidal Me_3Sb bound to bent Me_2Sb units through short (282 pm) Sb–Sb bonds and dimeric anions adopting the geometry of edge sharing tetragonal pyramids where methyl groups are in apical *trans* positions.

In contrast to the rich chemistry of phosphenium cations[1] very little is known of stibenium cations, R_2Sb^+ or of Lewis acid base adducts of the type $[B{\rightarrow}SbR_2]^+$. The diphenylstibenium cation, Ph_2Sb^+ was reported as a product of the electrochemical oxidation of $Ph_2Sb–SbPh_2$ in tetrahydrofuran (thf).[2] Pioneering work in the field of adducts was done by Summers and Sisler and others,[3–6] who studied reactions of trialkyls of phosphorus, arsenic or antimony with organohalo-phosphines, -arsines, or -stibines and reported the formation of 'arsinophosphonium salts' and related compounds of the type $[R_3EER_2]X$ (E = P, As, Sb; X = Cl, Br, I). These ionic species were characterized by measurement of their conductance in nitromethane. Recently an X-ray crystal structure analysis of an adduct was carried out on the ionic complex $[Me_2Sb–SbMe_2–SbMe_2][Me_2SbBr_2]$ obtained by reaction of Me_2SbBr with $Me_2Sb–SbMe_2$.[7] The chemical properties of the cation of this complex correspond to an adduct of tetramethyldistibine coordinated on the dimethylstibenium ion, Me_2Sb^+, the latter being formed together with $Me_2SbBr_2^-$ by transfer of Br^- from one Me_2SbBr molecule to another. However neither the distibine nor the dimethylstibenium unit could be distinguished in the crystal structure. The geometrical data of the cation correspond instead to the stibonium ion, $[R_2R'_2Sb]^+$ (R = Me, R′ = Me_2Sb).[7]

We have now investigated reactions with transfer of bromide between Me_2SbBr and $MeSbBr_2$ in presence of Me_3Sb as donor and report here the formation and the X-ray crystal structure determination of a novel ionic complex $[Me_3Sb–SbMe_2]_2$-$[(MeSbBr_3)_2]$ **1**. The cation of **1** is a trimethylstibine adduct of the dimethylstibenium ion and with view on isolobal relations between Me_2Sb^+ and CH_2 or Me_3Sb and Me_3P it can be considered as an analogue of phosphorus ylides. The alternative description as stibonium ion $[R_3R'Sb]^+$ (R = Me, R′ = Me_2Sb) is useful to underline the close relation with $[R_2R'_2Sb]^+$[7] and $[R_4Sb]^+$[8] in a family of stibonium ions, where now only the members $[RR'_3Sb]^+$ and $[R'_4Sb]^+$ are still unknown. Also the relation between **1** and tetramethyldistibine is intriguing. In fact, **1** might also be envisaged as a quaternization product of $Me_2SbSbMe_2$, which is not accessible by other methods. In contrast to tetraalkyldiphosphines which are easily quaternized by reactions with methylating agents such as methyl iodide, the analogous reactions of diarsines or distibines lead to fission of the (weaker) As–As or Sb–Sb bonds.[14] The anion of **1** is a dimer of methyltribromoantimonate(III). It is a novel example of a known type of 'ate' complexes of antimony(III). Several related aryl compounds[9–12] and one alkyl derivative[13] have been reported.

Crystals of **1** were grown in 80% yield in an attempt to crystallize dimethylantimony bromide by cooling the melt to −28 °C for several weeks. The formation of **1** can be explained by stepwise reactions according to eqn. (1) and (2). First the irreversible formation of the components Me_3Sb and $MeSbBr_2$ according to eqn. (1) may occur, which is a known reaction.[14] The following possible steps are summarized in eqn. (2). They include the transfer of bromide from Me_2SbBr to $MeSbBr_2$ and the coordination of Me_3Sb on the cation. The dimethylantimony bromide used as starting material should be of very high purity. It is best prepared by the reaction of tetramethyldistibine with bromine.[14]

$$2\ Me_2SbBr \longrightarrow Me_3Sb + MeSbBr_2 \quad (1)$$

$$2\ Me_2SbBr + 2\ Me_3Sb + 2\ MeSbBr_2 \rightleftharpoons \underset{\mathbf{1}}{[Me_3Sb\text{-}SbMe_2]_2[MeSbBr_3]_2} \quad (2)$$

In contrast to other organometallic compounds with Sb–Sb bonds such as the yellow or red distibines or cyclostibines, crystals of **1** are colourless. They are slightly soluble in non-polar organic solvents. ^1H NMR spectra in C_6D_6 show however that on dissolution the components Me_2SbBr, Me_3Sb and $MeSbBr_2$ are formed in the reverse of reaction (2). Later Me_3SbBr_2 and reduced methylantimony species are formed irreversibly.[15]

The crystal structure of **1** was determined by single crystal X-ray structure analysis. The structure of the cation is shown in Fig. 1. Fig. 2 shows the arrangement and the interactions between the ions. The cation consists of a pyramidal trimethylantimony unit bonded to a bent dimethylantimony unit through an antimony–antimony bond. The Sb–Sb bond length of **1** [282.05(12) pm] lies in the normal range of Sb–Sb single bond lengths as found in $Me_2Sb–SbMe_2$ [283.8(1)],[16] $(PhSb)_6$ [283.6–283.9(1)],[17] $[Me_2Sb–SbMe_2–SbMe_2][Me_2SbBr_2]$ [282.03(4)],[7] $Me_3Sb–Sb(Me)I_2$ [285.9(1)][18] and $Me_3Sb–SbI_3\cdot$thf [284.3(1) pm].[19] The C–Sb bond lengths to the onium centre of **1** [Sb(2)–C 210.6(11)–212.1(11)] are shorter than in the Me_2Sb group [Sb(1)–C 214.9(10), 216.5(12)] but longer than in $[Me_4Sb]I$ [Sb–C 204.3(2), 207.0(1) pm].[20] The C–Sb–C bond angles in the Me_3Sb unit in **1** are wide [103.1(5)–104.4(5)°] compared to uncoordinated Me_3Sb (94, 98°)[21] or the angles in solid $Me_2Sb–SbMe_2$ [C–Sb–C

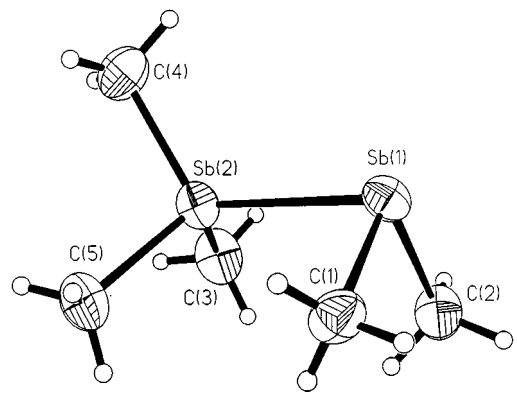

Fig. 1 The molecular structure of the cation $[Me_3Sb–SbMe_2]^+$ of **1**. Distances (pm) and angles (°): Sb(1)–Sb(2) 282.05(12), Sb(1)–C 214.9(10), 216.5(12), Sb(2)–C 210.6(11)–211.1(12); C(1)–Sb(1)–Sb(2) 91.0(4), C(2)–Sb(1)–Sb(2) 91.3(3), C(1)–Sb(1)–C(2) 94.3(5), C–Sb(2)–C 103.7(6), 103.1(5), 104.4(5), C(2)–Sb(1)–Sb(2)–C(3) 23.09(1), C(1)–Sb(1)–Sb(2)–C(5) 0.82(1).

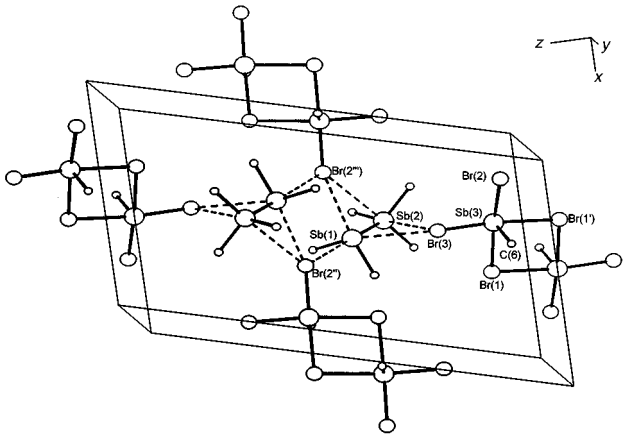

Fig. 2 Crystal structure of **1** with intermolecular interactions. Distances (pm) and angle (°): Sb(3)–C(6) 212.1(11), Sb(3)–Br(3) 263.24(16), Sb(3)–Br(2) 273.04(13), Sb(3)–Br(1) 289.17(13), Sb(3)–Br(1′) 302.72(16); Sb(1)···Br(2″) 354.3(21), Sb(1)···Br(2‴) 373.2(9), Sb(1)···Br(3) 383.0(23), Sb(2)···Br(2‴) 384.2(28), Sb(2)···Br(3) 391.2(4); Sb(2)–Sb(1)···Br(2″) 170.92(1).

88.6(5)–100.7(5)°, C–Sb–Sb [94.3(4)–94.4(4)°][16] but they lie in the range of C–Sb–C angles of the other complexes of Me_3Sb, *cf.* $Me_3Sb{\rightarrow}SbI_2Me$ [C–Sb–C, 101.3(3)–106.1(4)],[18] $Me_3Sb{-}SbI_3{\cdot}thf$ [102.9(5)–105.6(5)].[19] The widening of the angles on complexation may indicate a transition from the p^3 configuration of the free Me_3Sb to the sp^3 hybridisation in the adducts. The bond angles around the antimony atom of the Me_2Sb unit lie between 91.0(4) and 94.3(5)° corresponding to the p^3 configuration. In terms of the VSEPR model the angles at Sb(1) would reflect the stereochemical activity of the lone pair at antimony.

The loss of colour going from $Me_2Sb{-}SbMe_2$ (yellow melt and solution, red crystals) to $Me_3Sb{-}SbMe_2^+$ may result from the different orbitals forming the antimony–antimony bonds of the respective species.

The almost rectangular angles of $Me_2Sb{-}SbMe_2$ suggest that the Sb–Sb bond is formed by overlap of two 5p orbitals. In contrast, in the case of **1** the overlap of a sp^3 orbital at the four-coordinate antimony atom and a p-orbital at the three-coordinate Sb should be more effective resulting in the stabilization of the HOMO, a Sb–Sb σ-orbital and an increase in energy of the LUMO, a Sb–Sb σ*-orbital. HOMO–LUMO transitions lie in the visible region in the case of $Me_2SbSbMe_2$ but shift to the UV region of the spectra for **1**. The structure of the anions is composed of two tetragonal pyramids around the antimony atoms sharing an edge of the square base. The methyl groups are in apical positions, *trans* to each other. This type of structure is usual for organo halogeno antimonates.[9–13] It is also of interest to consider the interactions between the cation and the anion of **1**. There are three interionic Sb···Br contacts with distances shorter than the sum of van der Waals radii of Sb and Br (410 pm). The closest intermolecular contact [354.3(21) pm] exists between Sb(1) of the dimethylantimony unit and Br(2‴), one of the terminal bromine atoms of the anion. The Sb–Sb···Br angle is close to linearity. It is easy to assume that a prolongation of the dative Sb–Sb bond and a shortening of the Sb(1)···Br(2‴), contact leads to Me_2SbBr, the starting material.

Br(2‴) and Br(3) are in bridging positions above the Sb–Sb bond with contact distances of 373.2(9), 384.2(28) pm and 383.0(23); 391.2(4) pm, respectively. It is very likely that this interaction not only stabilizes the cation but also controls the unusual ecliptic conformation of the cation.

The origin of the second relaxation process in the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ single-molecule magnets: 'Jahn–Teller isomerism' in the $[Mn_{12}O_{12}]$ core

Received (in Bloomington, IN, USA) 6th August 1999, Accepted 27th August 1999

The origin of the second, faster relaxation process in Mn_{12} molecules has been identified as a different relative orientation of the Jahn–Teller elongation axes of the Mn^{III} ions, which we have termed 'Jahn–Teller isomerism'.

Single-molecule magnets are of great current interest because they represent nanoscale magnetic particles of a sharply defined size that offer, amongst other things, the potential of access to the ultimate high-density information storage devices.[1–3] They also provide excellent examples of species exhibiting quantum tunnelling of magnetization.[4–6] Out-of-phase ac magnetic susceptibility signals (χ_M'') and magnetization hysteresis loops are characteristic of SMMs, whose properties result from a large spin (S) ground state and negative magnetic anisotropy. The first SMM reported was $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]$ **1**; ($8Mn^{III}$, $4Mn^{IV}$), with S = 10 and a zero-field splitting parameter (D) of -0.5 cm^{-1}, and Friedman *et al.*[4] subsequently reported steps on its magnetization hysteresis plots indicative of quantum tunnelling. Since then, variation of the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ carboxylate group and/or solvent molecules of crystallization have been shown to have significant effects on the hysteresis plots and the quantum tunnelling behaviour.[2,7,8]

An interesting observation is the presence often of two different χ_M'' signals for a given complex, which we have assigned as due to two polymorphs in the sample with slightly different environments about the Mn_{12} molecules.[7,8] For $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]$ **2**, the **2**·$HO_2CC_6H_4Me$-4 (space group $C2/c$) and **2**·$3H_2O$ ($I2/a$) forms have χ_M'' peaks in the 2–4 and 4–7 K ranges, respectively.[8] The *precise* molecular origin of the differing magnetic behaviour has not been clear, however, but we herein report this as due to the existence of isomeric forms of the $[Mn_{12}O_{12}]$ core involving different relative orientations of Mn^{III} Jahn–Teller distortion axes. We have termed this new effect 'Jahn–Teller isomerism'.

The complexes $[Mn_{12}O_{12}(O_2CCH_2Bu^t)_{16}(H_2O)_4]$ **3** and $[Mn_{12}O_{12}(O_2CC_6H_4F\text{-}2)_{16}(H_2O)_4]$ **4** were prepared as described elsewhere.[7a] The χ_M'' *vs.* T behaviour of **4** (Fig. 1) shows that it is a mixture of the 'low-temperature' (LT) and 'high-temperature' (HT) species in an approximate 12 : 1 ratio, with peaks in the 2–3 and 4–6 K ranges, respectively. Complex **3** shows an essentially identical plot.[8b] The structure of **3**·CH_2Cl_2·CH_3NO_2† appears typical of this class of molecule but closer examination [Fig. 2(a)] reveals that one Mn^{III} Jahn–Teller (JT) elongation axis is abnormally oriented, equatorially rather than axially. As a result, the JT axis contains an oxide ion, O(18), a situation which is highly unusual; JT elongation axes usually orient as to avoid the strong Mn^{III}–O^{2-} bonds, normally the shortest bonds about the metal. The usually observed JT orientations are as in the HT molecule **2**·$3H_2O$ [Fig. 2(b)] *i.e.* all axial. In contrast, close examination of the structure of **2**·$HO_2CC_6H_4Me$-4 shows that this LT form of **2** also has an abnormally oriented JT axis, whereas **1** and other Mn_{12} species with HT χ_M'' peaks show the normal JT orientation. Thus, we conclude that the abnormal orientation of a Mn^{III} JT axis is the

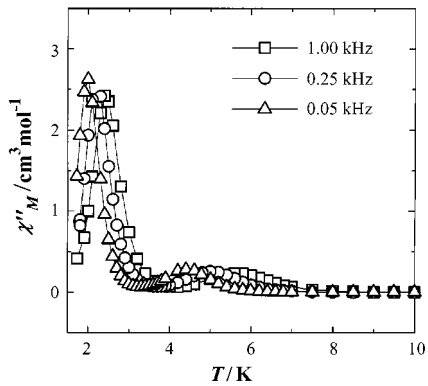

Fig. 1 Plot of the out-of-phase (χ_M'') *vs.* T behaviour of **4** at the indicated ac oscillation frequencies.

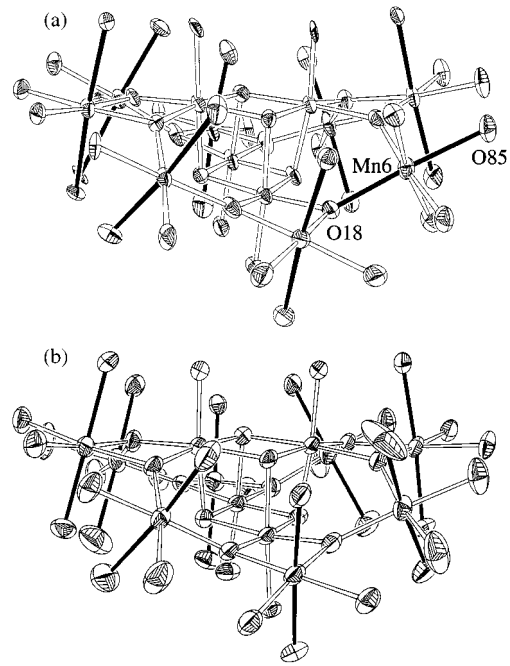

Fig. 2 The core of complex **3** emphasizing the abnormal Jahn–Teller orientation (a), and the core of **2**·$3H_2O$ showing the normal orientation (b). For **3**: Mn(6)–O(18) 2.073(7) Å, Mn(6)–O(85) 2.160(8) Å, other bonds to Mn(6) 1.873(8)–1.969(8) Å, other Mn^{III}–O^{2-} bonds 1.845(7)–1.919(7) Å.

origin of the LT χ_M'' peak.‡ This will alter the orientation of the singly occupied d_{z^2} orbital, and the influence on the relaxation rate could thus be due to a change in (i) the ground state *S* value, (ii) the separations to low-lying excited states, (iii) the molecular *D* value, or (iv) a combination of these. Further work is in progress to address this point.

The different temperatures for the LT and HT χ_M'' peaks correspond to faster and slower relaxation rates, respectively. The two separate processes were quantified for complex **4** by using the ac χ_M'' *vs. T* data to obtain Arrhenius plots; additional data on the LT process were obtained at 1.05 and 1.10 K using a Faraday magnetometer with a ^{3}He dilution refrigerator. The plots and obtained parameters are shown in Fig. 3. The HT process has an activation energy (*U*) of 65.2 K, similar to that of **1** (60–64 K),[1b,9] whereas the LT form has a much smaller *U* of 31.9 K. Similar Arrhenius data were found for complex **3**.

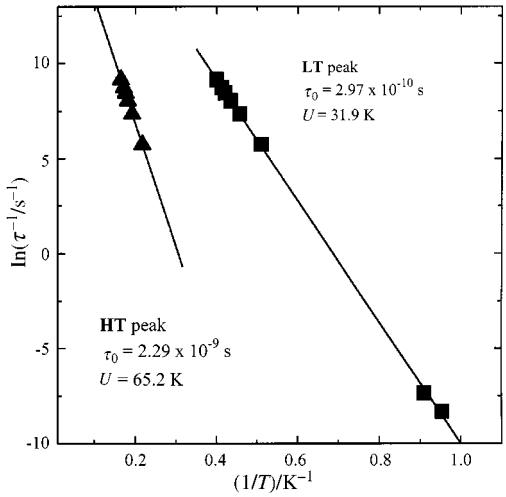

Fig. 3 Plots of the natural logarithm of the magnetization relaxation rates *vs.* 1/*T* for complex **4**: *U* is the activation energy and τ_o is the pre-exponential of the Arrhenius equation.

In summary, the LT χ_M'' *vs. T* responses of some Mn_{12} species are a result of their containing an abnormally oriented JT axis. This represents a type of isomerism not seen before and which can be defined as two or more non-equivalent forms differing in the relative orientation of one (or more) JT axes. We offer the term 'Jahn–Teller isomerism' for this new effect.

The work was supported by the National Science Foundation.

Notes and references

† *Crystal data* for **3**·CH_2Cl_2·CH_3NO_2: $C_{98}H_{189}Cl_2Mn_{12}NO_{50}$, M = 2911.71, triclinic, $P\bar{1}$, a = 16.422(2), b = 27.434(3), c = 15.814(2) Å, α = 101.78(1), β = 101.79(1), γ = 76.90(1)°, Z = 2, U = 6699 Å^3, μ(Mo-Kα) = 11.630 mm^{-1}, D_c = 1.44 g cm^{-3}, T = −174 °C. The structure was solved by direct methods (SHELXTL) and refined (on *F*) using 10 081 reflections with $F > 2.33\sigma(F)$ to $R(R_w)$ values of 0.0725 (0.0563). CCDC 182/1395. See http: //www.rsc.org/suppdata/cc/1999/1973/ for crystallographic files in .cif format.

‡ Fresh samples of **3**·CH_2Cl_2·CH_3NO_2 show essentially only the LT peak. With time at room temperature, solvent molecules of crystallization are slowly lost (confirmed by elemental analysis), and the LT/HT ratio decreases. Thus, the LT form is the structurally characterised form and the relative amount of HT form increases with solvent loss. Full details will be reported in the full paper.

ChemComm

An amidine-functionalized cobalt(III) cage complex: synthesis, structure and properties

Patricia M. Angus,*[ab] Alan M. Sargeson*[ab] and Anthony C. Willis*[a]

[a] *Research School of Chemistry, Australian National University, Canberra ACT 0200 Australia. E-mail: sargeson@rsc.anu.edu.au*

[b] *Department of Chemistry, Faculty of Science, Australian National University, Canberra ACT 0200, Australia*

Received (in Cambridge, UK) 5th August 1999, Accepted 31st August 1999

The template synthesis, structure and properties of an unusual tricyclic amidine-functionalized triaza-trithia cobalt(III) cage complex are described.

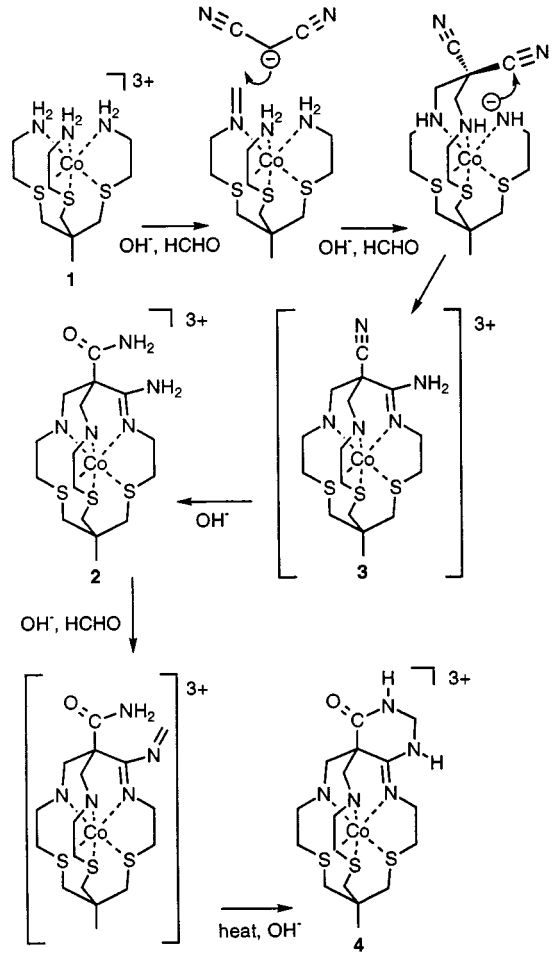
Functionalized cages have been prepared previously by condensing the templates $[Co(sen)]^{3+}$ [sen = 4,4′,4″-ethylidynetris(3-azabutan-1-amine)] and $[Co(ten)]^{3+}$ [ten = 4,4′,4″-ethylidynetris(3-thiabutan-1-amine)] with methanal and a carbon acid containing either an aldehyde, a ketone or an ester functional group. In the first two instances, condensation between the functional group and a coordinated amine resulted in the formation of a cage complex with an imine incorporated in the ligand framework whereas an amide-functionalized cage resulted when an ester was used.[1–3] Malononitrile (pK_a = 11)[4] is used here as a bifunctional carbon acid to form amidine-functionalized cobalt(III) cage complexes with three nitrogen and three sulfur donor atoms, the first example of a cage complex incorporating that functional group. The condensation of a coordinated amine with a pendant nitrile to form a coordinated amidine has not previously been applied to cage synthesis. These functionalized cage complexes are important because variations in functional groups and substituents, as well as in donor atoms, modulate substantially the physical properties of these complexes.[2,6,7]

Two red cage complexes were isolated by ion-exchange chromatography from the reaction of $[Co(ten)]Cl(ClO_4)_2$[2,8] and malononitrile in aqueous methanal at pH 10.† The first red species was assigned as an N_3S_3 amidine cage with an amide group as an apical substituent {$[Co(Me,H_2NCO\text{-}7\text{-amino}\ N_3S_3sar\text{-}6\text{-ene})]^{3+}$} (Scheme 1, **2**) using ^1H and ^{13}C NMR spectra recorded in DMSO-d_6 and microanalytical data; the same molecule was then prepared using 2-cyanoacetamide instead of malononitrile as the carbon acid.[9] The ^{13}C NMR spectrum of the second species showed that it contained two sp^2 functional groups (δ 162, 164), one of which might have been an amidine but the other could not be identified with certainty. Its surprising structure was revealed by an X-ray crystallographic analysis of the perchlorate salt and is shown in Fig. 1.‡ The ^1H and ^{13}C NMR spectra and the microanalysis of the whole fraction were consistent with this structure.§

The X-ray analysis established that the cobalt(III) ion was fully encapsulated in a pseudo-octahedral environment and that an amidine functional group was incorporated into the cage framework. The conformation of the strand containing the amidine functional group was *ob* while that of the other strands was characteristically *lel*.[10] The carbon–nitrogen bond lengths in the amidine group {C(2)–N(1) 1.915, C(2)–N(5) 1.318 Å} are comparable with those reported for other secondary amidines chelated to cobalt(III) and so is the cobalt(III)–amidine nitrogen bond length (1.915 Å).[5] An unusual feature of this cage is the structure of the cap. The amidine and amide functional groups have been cross-linked with a methylene group to form a near-planar diazine heterocycle fused to the cap as a subsidiary feature which is surprisingly stable to hydrolysis.

A mechanism for the formation of the cage complex is described in Scheme 1. The initial product (not detected) has to be an amidine cage with a nitrile substituent at the apex (Scheme 1, **3**). Clearly the nitrile group undergoes rapid intermolecular hydrolysis to give the amidine cage complex with an apical amide substituent (Scheme 1, **2**). This degree of activation of a remote functional group towards intermolecular attack is unusual. In amide cage complexes of cobalt(III), in which the cage ligand is deprotonated and bonded at the amide nitrogen, nitrile substituents are inert.[3] Similarly in monodentate cobalt(III) complexes of ligands containing a remote nitrile group and coordinated through nitrile, amide or amidine groups, no intermolecular hydrolysis of the remote functional group has been observed under basic conditions.[11] Here, the facile hydrolysis of the apical nitrile group reflects the attachment of this section of the neutral cage ligand to cobalt(III) through *three* chelate rings, thus maximizing its activation by the metal ion.

In the final stage of the synthesis methanal has added to the *exo*-nitrogen of the amidine in aqueous base and the resulting



Scheme 1

imine is attacked by the neighbouring deprotonated amide so that the groups were cross-linked to complete the heterocyclic ring. Aldehydes readily and reversibly add to amidines,[12] and this was doubtless facilitated in the present case by the increased acidity of the amidine coordinated to cobalt(III).[5] Such cross-linking between nitrogenous functional groups is a well known reaction when proteins and peptides are treated with aqueous methanal and a variety of functional groups may be connected in this way.[13] The heterocyclic cage was also synthesized directly from the amide-substituted amidine cage (**2**) and aqueous methanal but only at 60 °C or higher. At ambient temperature only a dimeric species was detected, formed by intramolecular cross-linking between two amidine functional groups. In the original synthesis the heat necessary for intramolecular cross-linking was produced by polymerization of malononitrile in aqueous base, a rapid, exothermic reaction which occurred in parallel with cage formation.

In the electronic spectrum of the heterocyclic amidine cage complex, bands arising from the d–d transitions were found at 496 and 363 (shoulder) nm (ε = 720 and 815 dm^3 mol^{-1} cm^{-1}, respectively). These were intermediate in energy and intensity between those of triamine and amide-functionalized N_3S_3 cage complexes.[2,7b] The UV region of the spectrum contained two intense bands at 288 and 210 nm (ε = 140 00 and 20 000 dm^3 mol^{-1} cm^{-1}, respectively). These are attributed to S→Co charge transfer bands. These low-spin Co$^{III/II}$ molecules should display rapid electron transfer characteristics and the chemistry in general points to useful paths for tying other functional groups and sensors to the cage complex.

This work was supported by the Australian Research Council. We thank the Microanalytical Section of the Research School of Chemistry (ANU) for the analyses.

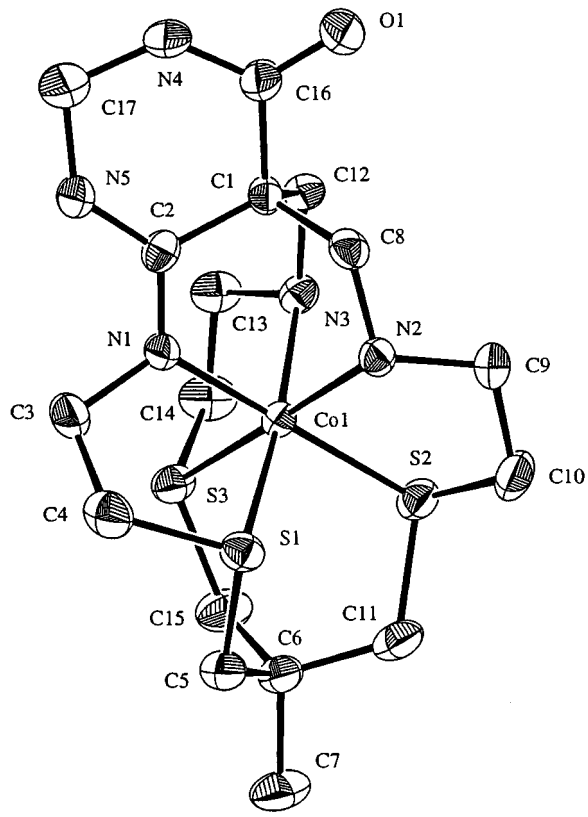


Fig. 1 ORTEP plot of the tricyclic amidine-functionalized N_3S_3 cage complex cation (the hydrogens attached to carbon and nitrogen atoms have been omitted for clarity).

Notes and references

† [Co(ten)]Cl(ClO$_4$)$_2$ (1.0 g) and malononitrile (5 mL) were dissolved in aqueous methanal (38%, 30 mL) in a 750 mL beaker in a fumehood and gradually treated with Na_2CO_3 (0.5 g). There was considerable effervescence and the solution became quite hot. After 30 min the reaction was quenched with acetic acid to pH 5 and water (200 mL) was added. The mixture was extracted with chloroform to remove excess polymeric material, then the aqueous phase was filtered and absorbed on Dowex 50W-X2 cation exchange resin. The column was washed with water then eluted with 2 M HCl which removed some Co^{II} species, ten·3HCl and some non-encapsulated by-products. Elution with 3 M HCl removed a large tripositive red band which was evaporated to dryness, dissolved in water (300 mL) and chromatographed on SP-Sepahadex cation exchange resin. The column was eluted with 0.1 M K_2SO_4 solution which separated trace amounts of the addition products then two red bands which were collected and desalted separately by chromatography on Dowex and elution with 3 M HCl followed by rotary evaporation. The first complex was recrystallized as the chloride–tetrachlorozincate salt {7-amino-8-carboxamide-1-methyl-3,13,16-trithia-6,10,19-triazabicyclo[6.6.6]icosa-6-enecobalt(III) chloride-tetrachlorozincate hydrate}, 0.22 g, 17% yield {^{1}H NMR (δ, DMSO-d^6): 1.30 (3H), CH_3; 2.50–4.05, complex methylene envelope; 7.35, 7.51, amine NH; 7.66, 7.83, amide NH_2; 8.12, 8,64, amidine NH_2}. The second complex (Scheme 1, **4**) was crystallized from aqueous sodium perchlorate solution with ethanol (0.20 g, 14% yield). **CAUTION**: perchlorate salts are potentially explosive and should only be handled in small quantities.

Strong ferromagnetic coupling in the K_2NiF_4-structured oxide $La_{0.8}Sr_{1.2}Mn_{0.6}Rh_{0.4}O_4$

P. D. Battle,* J. C. Burley, E. J. Cussen, G. C. Hardy, M. A. Hayward, L. D. Noailles and M. J. Rosseinsky*

Received (in Oxford, UK) 9th August 1999, Accepted 3rd September 1999

Substitution of diamagnetic Rh^{III} into the antiferromagnet $LaSrMnO_4$ produces the first example of a K_2NiF_4 ($n = 1$ Ruddlesden–Popper) oxide with strong ferromagnetic interactions—in 50 kG at 5 K the magnetisation of $La_{0.8}Sr_{1.2}Mn_{0.6}Rh_{0.4}O_4$ is close to saturation at 2.50 μ_B per Mn cation; the bulk magnetisation stems from the alignment by the magnetic field of ferromagnetic (Mn/Rh)O_2 sheets which are not magnetically ordered along [001] in zero applied field.

There has been a resurgence of interest in ferromagnetic oxides owing to the strong coupling between spin ordering and charge transport found in the $La_{1-x}Sr_xMnO_3$ perovskites which display colossal magnetoresistance (MR).[1] This suppression of the zero-field resistance in an applied field can be as large as $100\Delta\rho/\rho(H = 0) = 99.9\%$ in fields of over 50 kG, but achieving significant MR in the low fields required for information storage applications has proved a difficult barrier for the current generation of materials. Increasing attention[2] is now being paid to the intrinsically layered $n = 2$ members of the Ruddlesden–Popper (RP) $A_{n+1}B_nO_{3n+1}$ series, for example $La_{1.8}Sr_{1.2}Mn_2O_7$,[3] which display MR in fields as low as 3 kG owing to the small barrier to the field aligning the magnetisation between the perovskite blocks in the layer stacking sequence. Ferromagnetism has not yet been demonstrated in the two-dimensional $Sr_{1+x}La_{1-x}MnO_4$ $n = 1$ member of the RP series, with the Sr_2MnO_4[4] and $LaSrMnO_4$ end-members being antiferromagnets while the $Mn^{III/IV}$ solid solutions are spin glasses.[5] Here, we demonstrate that substitution of formally diamagnetic Rh^{III} into $Sr_{1.2}La_{0.8}MnO_4$ produces a material with short-range spin ordering in zero field which achieves a moment of 2.50 μ_B per manganese in a 50 kG field.

Preliminary investigation of the Sr–La–Rh–Mn–O phase field at the $n = 1$ RP composition under air and N_2 atmospheres indicated that our initial target composition $LaSrMn_{0.6}Rh_{0.4}O_4$ was strongly polyphasic, with $La_2O_3/La(OH)_3$ impurities showing that a higher Sr/La ratio, and thus metal oxidation state, was required for phase purity. This is consistent with the reported failure to prepare $SrLaRhO_4$[6] in contrast with $Sr_{1.2}La_{0.8}RhO_4$. $Sr_{1.2}La_{0.8}Mn_{0.6}Rh_{0.4}O_4$ was therefore prepared by reaction of Rh_2O_3, MnO_2, $SrCO_3$ and La_2O_3 at 1000, 1200 and 1250 °C for 24 h each, followed by 4 further days at 1250 °C, all firings being performed in air. This produced a material of 99.5% $n = 1$ RP phase with $a = 3.88761(6)$, $c = 12.5176(2)$ Å. The only impurity visible to X-ray powder diffraction is 0.5% by mass La_2O_3, a diamagnetic material which will not interfere with magnetic measurements.

Magnetisation *vs.* temperature measurements† made in an applied field of 100 G suggest (Fig. 1) complex magnetism with the possibility of magnetic long range order. Hysteresis is apparent between the ZFC and FC data below an anomaly in M/H at 180 K, and below 35 K both the ZFC and FC magnetisations rise sharply, with the ZFC showing a maximum at 13.5 K. Data collected in a field of 1000 G showed similar features although the ZFC magnetisation continued to rise down to 5 K. The $M(H)$ magnetisation isotherm at 5 K (Fig. 2) indicates strong ferromagnetic coupling, with a moment approaching saturation at 2.50 μ_B per Mn at 5 K; the magnetisation remains a non-linear function of field to temperatures in excess of 100 K although saturation is clearly not reached in 50 kG. Neutron powder diffraction data† (D2B, ILL) are consistent with the idea of a phase exhibiting strong ferromagnetic coupling but without the long-range magnetic order suggested by the magnetometry experiments. Rietveld-refinement[7] of data collected at both 290 and 1.7 K proceeded smoothly (at 290 K, $R_{wpr} = 5.35\%$, $\chi^2 = 2.4$; at 1.7 K, $R_{wpr} = 5.14\%$, $\chi^2 = 1.6$) within a model which considered only nuclear scattering from the $La_{0.8}Sr_{1.2}Mn_{0.6}Rh_{0.4}O_4$ composition, thus

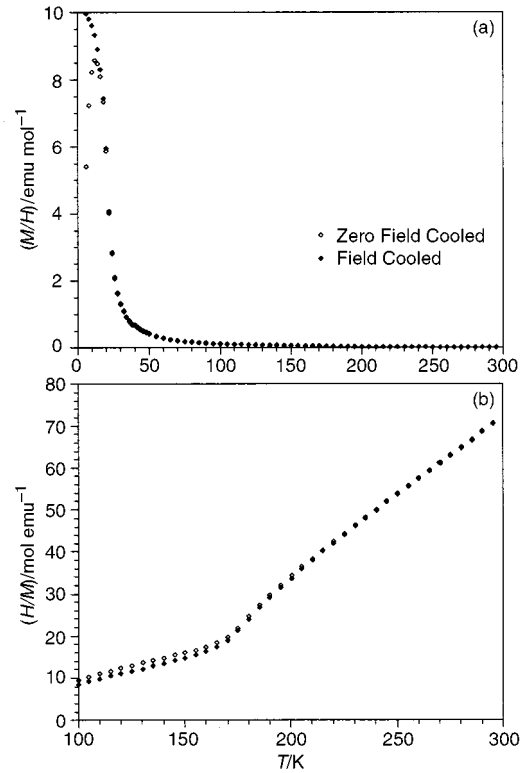

Fig. 1 (a) Molar magnetic susceptibility (M/H) and (b) inverse susceptibility (H/M) of $Sr_{1.2}La_{0.8}Mn_{0.6}Rh_{0.4}O_4$ measured in a field of 100 G: field cooled (FC) and zero-field cooled (ZFC) data are shown as filled and empty symbols, respectively.

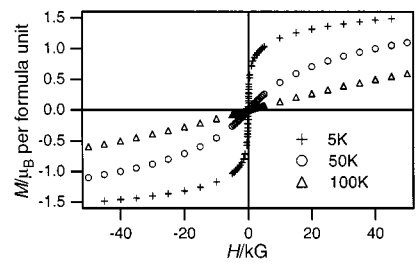

Fig. 2 Magnetisation per formula unit as a function of field and temperature for FC $Sr_{1.2}La_{0.8}Mn_{0.6}Rh_{0.4}O_4$. At 5 K, $H_{M=0} = 72 \pm 5$ G, $M_{H=0} = 0.15 \pm 0.02$ μ_B.

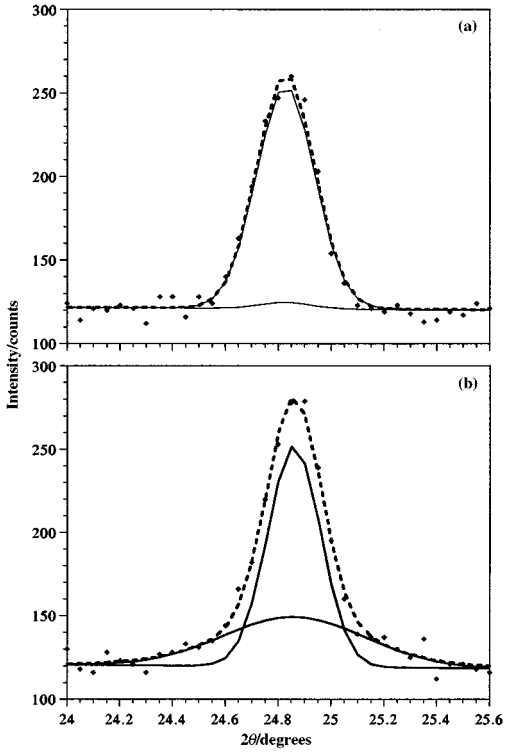

Fig. 3 Neutron powder diffraction measurements on $Sr_{1.2}La_{0.8}Mn_{0.6}Rh_{0.4}O_4$ at (*a*) 290 K and (*b*) 1.7 K, showing the two component fit (solid lines) to the 101 reflection: the extra broad diffuse scattering observed at 1.7 K is suggestive of magnetic short range ordering within the 2D layers.

conclusively demonstrating the absence of magnetic long-range order. Close inspection of the low-angle 002 and 101 reflections (which are sensitive to magnetic scattering owing to the angular dependence of the form factor) shows that the latter (Fig. 3), but not the former, develops weak but well defined broad, extra scattering at low temperature. The profile of the 101 reflection at 290 K can be fitted by two pseudo-Voigt functions in the ratio 0.966 : 0.034; the principal peak has a negligible Lorentzian component. At 1.7 K the ratio is 0.584 : 0.416; the stronger component is again essentially Gaussian but the weaker, broader component has a significant Lorentzian contribution. The growth in the latter component of the 101, but not the 002, is consistent with ferromagnetic correlations developing within but not between the two-dimensional $(Mn/Rh)O_2$ sheets.

The oxidation state of the Rh substituent at the electronically active B site is not directly defined by our measurements, but consideration of the established oxide chemistries of Mn and Rh leads to the assumption that Rh is present solely as Rh^{III} (low spin t_{2g}^6), resulting in a mean Mn oxidation state of + 3.33. The measured value of the magnetisation as it approaches saturation is a significant but reduced fraction of that (3.66 μ_B per Mn) to be expected from a fully aligned array of Mn cations in this oxidation state; the cause of the difference has yet to be determined. The presence of a transition at 180 K restricts the temperature range which can be analysed using the Curie–Weiss law and the enforced proximity to a phase transition will limit the validity and accuracy of the value of 5.54 μ_B per Mn derived for the effective magnetic moment in 100 G by fitting in the range $250 \leq T/K \leq 300$; comparisons with calculated values are therefore nonsensical. The ferromagnetic Weiss constant of +106 K is however consistent with the lower temperature magnetisation and neutron scattering measurements.

Substitution of diamagnetic low-spin Rh^{III} has a surprising effect on the magnetism of manganates having the K_2NiF_4 structure. Although the presence of both Mn^{III} and Mn^{IV} allows ferromagnetic double and super exchange, and the same oxidation state (3.33) produces ferromagnetism in the $n = \infty$ Mn-only perovskites,[8] in the pure 2D manganate series, oxidation of the antiferromagnet $La_{1-x}Sr_{1+x}MnO_4$ beyond the +3.2 oxidation state results in the suppression of antiferromagnetic ordering but not in the onset of ferromagnetism:[9] $La_{0.7}Sr_{1.3}MnO_4$ is a canonical spin-glass showing the classical FC/ZFC magnetisation divergence. The substitution of Rh on the B sites clearly enhances ferromagnetic Mn–Mn coupling in $Sr_{1.2}La_{0.8}Mn_{0.6}Rh_{0.4}O_4$, at least within the $(Mn/Rh)O_2$ layers perpendicular to [001]. One interpretation of the currently available data is that each individual $(Mn/Rh)O_2$ sheet develops a spontaneous magnetisation when 2D magnetic ordering occurs at 180 K, with the resultant magnetic moments being aligned by an applied field; saturation is approached in 50 kG at 5 K, and 100 G has a significant effect below 35 K. However, the magnetic consequences of ferromagnetic $n = \infty$ intergrowths in RP phases are well known[10] and further measurements are necessary before firm conclusions can be drawn. Increasing the Mn concentration further above the 2D square site percolation limit of 0.5 and optimisation of the mean metal oxidation state are important future improvements on this new recipe for generating ferromagnetic interactions in 2D manganates.

We acknowledge funding from the UK EPSRC.

An improved vinylalumination procedure replacing HMPA with NMO for the hydroalumination of α-acetylenic esters and ketones

P. Veeraraghavan Ramachandran,* M. Venkat Ram Reddy and Michael T. Rudd

H. C. Brown and R. B. Wetherill Laboratories of Chemistry, Purdue University, West Lafayette, Indiana 47907-1393, USA. E-mail: chandran@purdue.edu

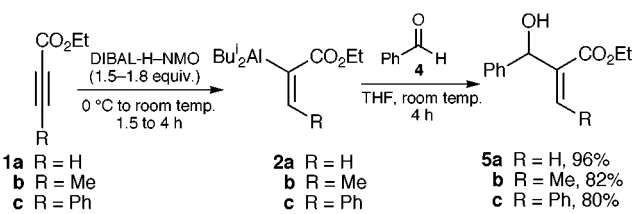
Received (in Corvallis, OR, USA) 15th July 1999, Accepted 20th August 1999

Replacing carcinogenic HMPA with NMO, a higher yielding, enviornmentally benign procedure for the vinylalumination of carbonyl compounds with [α-(ethoxycarbonyl)-vinyl]diisobutylaluminium and its β-methyl or -phenyl analogs, as well as [α-(acetyl)vinyl]diisobutylaluminium has been developed.

Vinylalumination,[1] a carbon–carbon bond forming reaction of vinylaluminium derivatives with electrophiles, provides Morita–Baylis–Hillman[2] type products without the reaction's limitations. For example, (i) the electrophiles are not limited to reactive carbonyls and imines, (ii) the reaction times are considerably shorter, and (iii) β-substitution of the vinyl moiety is readily accommodated.

Although known for over a decade, the lack of extensive utilization of this potentially useful reaction may be due to the presence of a carcinogenic material, HMPA,[3] as the complexing agent with DIBAL-H for the hydroalumination of propiolates. Several possible replacements for HMPA, such as 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidone (DMPU),[4a] 1,3-dimethylimidazolidin-2-one (DMEU or DMI),[4b] and quinuclidine *N*-oxide (QNO)[4c] have been reported in the literature. Since DMPU and DMI might undergo reduction with DIBAL-H and QNO is not economical, we studied a series of other amine oxides as complexing agents. Although mixtures of DIBAL-H and aromatic amine oxides, such as pyridine and picoline *N*-oxides, did not provide the required hydroalumination product, aliphatic trialkylamine oxides, such as trimethylamine *N*-oxide and NMO, were found to be suitable complexing agents for the hydroalumination of propargylic esters and ketones. Our study with the relatively inexpensive NMO revealed it to be an excellent HMPA alternative for vinylaluminations, improving the reaction conditions and providing superior yields of the products. We also noticed that Lewis acid catalysis[1d] and low reaction temperatures[1d] are not essential for reactions with the β-methyl and -phenyl substituted reagents.

The addition of DIBAL-H to a suspension of NMO in THF provided a clear solution. The reaction of ethyl propiolate **1a** in THF with 1.5 equiv. DIBAL-H–NMO in hexanes at 0 °C provided the [α-(ethoxycarbonyl)vinyl]diisobutylaluminium **2a**. Benzaldehyde **4** (1.2 equiv.) was added to this reagent at 0 °C and warmed to room temperature. The reaction was complete within 4 h. Hydrolysis using 1.0 *M* HCl, followed by chromatography, provided 96% yield of the product **5a** (Scheme 1). Earlier procedures employing HMPA utilized 2 equiv. of the aldehyde.[1] We observed that the hydrolysis was much more facile when compared to the reactions using HMPA.[1] The reaction provided high yields of the products with all of the aldehydes, *viz.* butyraldehyde **6**, isobutyraldehyde **8**, pivalaldehyde **10** and fluoral **12**.



Scheme 1

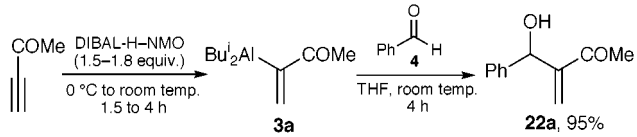
The corresponding β-substituted vinylaluminium reagent, [α-(ethoxycarbonyl)-β-methylvinyl]diisobutylaluminium **2b**, reacted with **4** smoothly to provide ethyl (*Z*)-1-hydroxy-1-phenylbut-2-enoate **5b** in 82% yield (Scheme 1). The β-phenylvinyldiisobutylaluminium reagent **2c** yielded 80% of the corresponding *Z* product **5c**. The stereochemistry of the alkenes (^{1}H NMR) is exclusively *Z*.[1e] In contrast to the earlier reported procedure involving HMPA,[1d] neither of these reactions require Lewis acid catalysis or low temperatures (−78 °C).

The reaction of acetophenone **14** with **2a** was sluggish. We worked up the reaction after 2 d and obtained only 12% yield of the product **15a** along with 25% of recovered **14** and a mixture of unidentified products. Addition of 10% of a Lewis acid, such as $BF_3{\cdot}Et_2O$, provided a small amount of the product with most of the ketone recovered. Upon the addition of 1 equiv. of $BF_3{\cdot}Et_2O$, the reaction was complete within 4 h, and work up provided a 74% yield of **15a** (Table 1, entry 12). Butan-2-one **16** reacted similarly, in the presence of 1 equiv. of $BF_3{\cdot}Et_2O$, providing the product in 75% yield (Table 1, entry 15). Reagents **2b** and **2c** gave similar results with these ketones.

An activated ketone, such as 2,2,2-trifluoroacetophenone **18**, reacted similar to an aldehyde, without Lewis acid, and the product **19a** was obtained in 95% yield (Table 1, entry 18). We then examined the reaction of **2a** with ethyl pyruvate **20**, and obtained the corresponding product alcohol in 95% yield (Table 1, entry 19).

The procedure was then extended to α-acetylvinyldiisobutylaluminium **3a**, prepared *via* the hydroalumination of but-3-yn-2-one with DIBAL-H–NMO complex (Scheme 2). A 23–31% yield of products from benzaldehyde and butyraldehyde for a reaction of **3a** prepared with DIBAL-H–HMPA was reported by Tsuda.[1a] Replacement of HMPA with NMO provided a 36% yield of **22a**. However, utilization of 2 equiv. of the reagent improved the yield to 95% (Scheme 2). We used these modified conditions for the reaction of the same series of aldehydes (**4**, **6**, **8**, **10**, **12**) with **3a** and the products were obtained in 72–95% yield. However, ketones did not react with **3a**. All of the results are summarized in Table 1.

In conclusion, we have described a significantly improved procedure for the vinylalumination of a variety of carbonyl compounds with [α-(ethoxycarbonyl)vinyl]- and (α-acetylvinyl)diisobutylaluminium. Replacement of carcinogenic HMPA with readily available NMO in the hydroalumination step makes this procedure environmentally benign. The work up is simpler and the yields of the products are considerably higher in most cases. We have also shown that Lewis acid catalysis and low reaction temperatures are not essential for reactions with



Scheme 2

Table 1 Vinylalumination of aldehydes and ketones[a]

	Reagent			R^2COR^3			Product

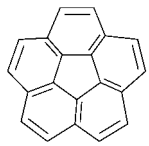
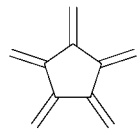
Received (in Cambridge, UK) 2nd August 1999, Accepted 31st August 1999

Persilyl-substituted [5]radialene 3 was reacted with lithium metal in THF to yield dark red crystals of the tetralithium salt of tetraanion 4 with a novel ten-center, fourteen π-electron system stabilized by silyl groups.

Polyanions with extended π-electron systems have attracted considerable interest owing to their unique structures and electronic properties.[1,2] However, polyanions of polycyclic hydrocarbons have only rarely been observed and they are one of the most attractive synthetic targets. Corannulene **1** having a



1

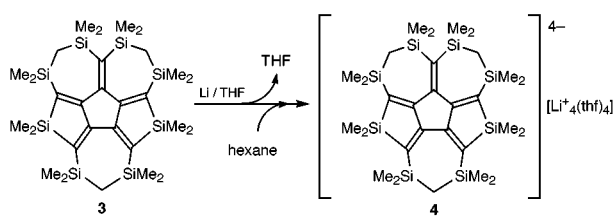


2

twenty π-electron system has a doubly-degenerate, low-lying LUMO that can accept up to four electrons to form corannulene tetraanion.[3] Scott *et al.* reported on the interesting dimer structure of the tetralithium salt of corannulene tetraanion and its derivatives in solution.[4] [5]Radialene **2** with a cross-conjugated ten π-electron system possesses a central unit of corannulene. However, to the best of our knowledge, there have been no studies on the anion species of [5]radialene derivatives. Herein, we report the first successful isolation, characterization and molecular structure of the tetralithium salt of the [5]radialene tetraanion derivative with a novel ten-center, fourteen π-electron system stabilized by silyl groups.

Reduction of **3**[5] with excess lithium metal in dry, oxygen free THF at room temperature led to the formation of a dark red solution of the tetraanion of **3** (Scheme 1). Crystallization from hexane afforded air- and moisture-sensitive dark red crystals of the tetralithium salt **4**.†

The molecular structure of **4** was determined by X-ray diffraction, as shown in Fig. 1.‡ The tetralithium salt (**4**) is monomeric and forms contact ion pairs (CIPs) in the crystals. One THF molecule is coordinated to each lithium ion. All four lithium ions are bonded to four quaternary carbon atoms of the [5]radialene π-skeleton as well as to the oxygen atoms of THF. Li1 and Li2 are located above and below the adjacent seven-membered rings (denoted **A** for the C1–C5–C10–Si7–CH_2-Si8-C6 ring and **B** for the C1–C2–C7–Si2–CH_2–Si1–C6 ring, respectively), whereas Li3 is located below the isolated seven-membered ring (denoted **C** for the C4–C3–C8–Si4–CH_2-Si5-C9 ring). The remaining Li4 is situated above one of the two



3 4

Scheme 1

silacyclopentadiene rings (denoted **D** for the C2–C3–C8–Si3–C7 ring and **E** for the C5–C4–C9–Si6–C10 ring, respectively). The distances between lithium and carbon atoms range from 2.10(1) to 2.44(2) Å (av. 2.23 Å). The two seven-membered rings **A** and **B** have highly twisted conformations about the C1–C6 bond, whereas the other seven-membered ring **C** and the two five-membered rings **D** and **E** are almost coplanar.

A comparison of the structural parameters of neutral molecule **3**[5] and tetraanion **4** is quite interesting. The ten carbon atoms (C1–C10) which constitute the π-electron system of the skeleton of **4** are almost coplanar as a consequence of the delocalization of the negative charge. The C1–C6 distance in **4** [1.523(8) Å] is considerably elongated by 0.148 Å relative to that of **3** [1.375(4) Å]. The C3–C8 and C4–C9 distances in **4** are also elongated by 0.143 and 0.066 Å, compared with those of **3** [1.363(4) Å]. The C2-C7 and C5-C10 distances in **4** are also stretched by 0.059 and 0.044 Å, relative to those of **3** [1.362(4) and 1.363(4) Å]. By contrast, the C3–C4 distance in **4** [1.377(8) Å] is remarkably shortened by 0.106 Å with respect to that of **3** [1.483(4) Å]. The C1–C2 and C1–C5 distances in **4** are shortened by 0.056 and 0.044 Å compared with those in **3** [1.506(4) and 1.485(4) Å]. These structural features are reflected by the LUMO and next LUMO of **3** (Fig. 2).[6] That is, in the LUMO of **3**, the exocyclic bonds are all antibonding, whereas the endocyclic bonds are all bonding. In the next LUMO of **3**, the exocyclic bonds, and C2–C3 and C4–C5 bonds are antibonding, while the C1–C2, C1–C5 and C3–C4 bonds are bonding.

The central five-membered ring (C1–C2–C3–C4–C5) of **4** has an almost planar structure, as determined by the sum of the bond angles (539.9°). However, this five-membered ring does not form an equilateral pentagon, as observed in the dilithium salt of hexasilylfulvene dianion with a six-center, eight π-

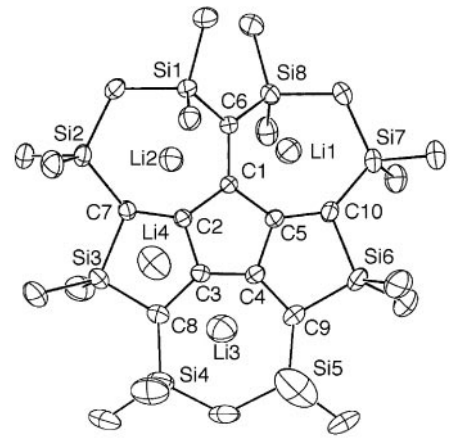


Fig. 1 Structure of **4** (THF and hydrogen atoms are omitted for the clarity). Selected bond distances (Å) are: C1–C2 1.450(7), C1–C5 1.441(8), C1–C6 1.523(8), C2–C3 1.484(8), C2–C7 1.421(8), C3–C4 1.377(8), C3–C8 1.506(8), C4–C5 1.526(8), C4–C9 1.429(8), C5–C10 1.407(8), C6–Si1 1.824(6), C6–Si8 1.815(6), C7–Si2 1.830(6), C7–Si3 1.898(6), C8–Si3 1.823(7), C8–Si4 1.798(7), C9–Si5 1.812(7), C9–Si6 1.829(7), C10–Si6 1.876(6), C10–Si7 1.841(6).

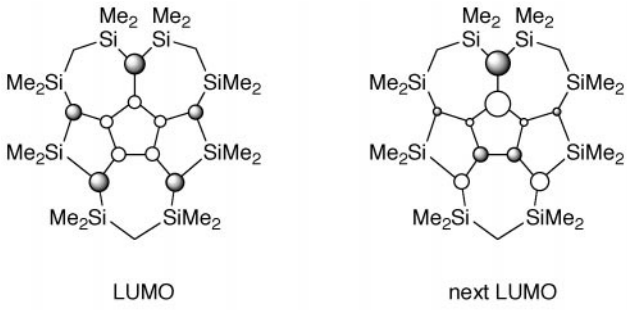

Fig. 2 Schematic representation of LUMO and next LUMO of **3** calculated by PM3.

electron system,[7] and the tetralithium salt of octasilyltrimethylenecyclopentene tetraanion with an eight-center, twelve π-electron system.[2] This suggests that the [5]radialene tetraanion **4** has no aromatic character resulting from the cyclopentadienide ion. The bond lengths of the Si–C (quaternary carbons) bonds of **4** (av. 1.835 Å) are shorter than those of **3** (av. 1.873 Å) due to delocalization of the negative charge onto the silicon centers by pπ–σ* conjugation.

The NMR data of **4** in toluene-d_8 indicate formation of highly symmetric CIPs with C_2 groups symmetry, the C1–C6 bond being a two-fold axis. The four methyls of two $SiMe_2$ groups and the two hydrogen atoms of CH_2 for rings **A** and **B** are magnetically nonequivalent, due to the fixed five- and seven-membered rings. On the other hand, the two hydrogen atoms of CH_2 for ring **C** are magnetically equivalent. Thus, the ^{1}H NMR spectrum of **4** in toluene-d_8 reveals the presence of eight signals for the methyl groups, two doublets for the ring **A** and **B** methylene groups with a geminal coupling constant of 13.2 Hz, and one singlet for the ring **C** methylene group. In the ^{29}Si NMR spectrum, four signals are observed at δ −20.1, −16.7, −15.0, and 18.5, which are shifted to higher field in comparison to those of **3** (δ −12.0, −10.0, −8.4 and 30.9). The ^{13}C NMR spectrum shows six signals for quaternary carbon atoms at δ 15.1, 40.8, 81.0, 93.1, 131.8 and 178.9. The signal appearing at δ 15.1 is assignable to the C6 carbon atom, which is considerably up-field shifted relative to that of **3** (δ 164.7) by $\Delta\delta$ −149.6 ppm. The other exocyclic carbons (C7, C8, C9 and C10) are also shifted to higher field by the four electron reduction (δ 40.8 and 81.0 for **4**; δ 163.2 and 172.0 for **3**). Apparently, the negative charge is largely delocalized over the five exocyclic carbon atoms in the π-skeleton of **4** and is stabilized by the eight silyl groups. Interestingly, the ^{6}Li NMR spectrum of **4** displays only one signal at δ −0.18. This indicates that the four Li^+ ions of **4** are not fixed to the π-skeleton, but are fluxional; the four Li^+ ions are migrating over the π-skeleton of [5]radialene on the NMR time scale.[8]

This work was supported by a Grant-in-Aid for Scientific Research (Nos. 09239101, 10304051, 1113321, 11166209) from the Ministry of Education, Science and Culture of Japan, and TARA (Tsukuba Advanced Research Alliance) fund.

Notes and references

† The crystals of **3** (21 mg, 0.033 mmol) and lithium metal (30 mg, 4.3 mmol) were placed in a reaction tube with a magnetic stirrer. After degassing the tube, dry oxygen-free THF (0.8 ml) was introduced by vacuum transfer and stirred at room temperature to give a dark red solution of **4** within 1 h. After the solvent was removed *in vacuo*, degassed hexane was introduced by vacuum transfer. After the lithium metal had been removed from the tube, the solution was cooled to afford dark red crystals of **4** quantitatively; δ_H(300 MHz, C_7D_8) −0.15 (d, *J* 13.2, 2H, CH_2), −0.11 (s, 6H, CH_3), 0.14 (s, 2H, CH_2), 0.28 (s, 6H, CH_3), 0.30 (s, 6H, CH_3), 0.33 (s, 6H, CH_3), 0.35 (s, 6H, CH_3), 0.36 (s, 6H, CH_3), 0.49 (s, 6H, CH_3), 0.54 (d, *J* 13.2, 2H, CH_2), 0.62 (s, 6H, CH_3), 1.35 (br s, 16H, THF), 3.52 (br s, 16H, THF); δ_C(75.5 MHz, C_7D_8) 2.8 (CH_3), 5.6 (CH_3), 6.0 (CH_3), 6.6 (CH_3), 7.0 (CH_3), 7.3 (CH_3), 7.5 (CH_3), 7.7 (CH_3), 15.1 (C), 15.9 (CH_2), 16.5 (CH_2), 25.4 (THF), 40.8 (C), 66.6 (THF), 81.0 (C), 93.1 (C), 131.8 (C), 178.9 (C); δ_{Si}(59.6 MHz, C_7D_8) −20.1, −16.7, −15.0, 18.5; δ_{Li}(44.2 MHz, C_7D_8) −0.18.

‡ *Crystal data* for **4**: $C_{45}H_{86}Li_4O_4Si_8$, *M* = 943.63, monoclinic, *a* = 48.328(3), *b* = 13.470(1), *c* = 21.676(1) Å, β 115.003(3)°, *V* = 12788(1) Å^3, *T* = 180 K, space group *C*2/*c*, *Z* = 8, ρ_{calc} = 0.981 g cm^{-3}. Diffraction data were collected on a MacScience DIP2030K Image Plate Diffractometer employing graphite-monochromatized Mo–Kα radiation (λ = 0.71070 Å). The final *R* factor was 0.0775 (R_w = 0.2358) for 6138 reflections with $I > 3\sigma(I)$. Single crystals of **4** were obtained by crystallization from hexane, mounted in a glass capillary tube and transferred to the cold gas stream of the diffractometer. The structure was solved by the direct method and refined by the full-matrix least-squares method using SHELXL-97 program. Some of the carbon atoms of the THF molecules have elongated thermal ellipsoids due to disorder. CCDC 182/1394. 8 As the temperature was lowered, the ^{6}Li NMR signal broadened and eventually yielded two very sharp signals at δ −0.55 and 0.08 with the same intensity at 187 K. This can be explained by assuming that the two Li^+ ions (Li1 and Li2) are fixed to the seven-membered rings (**A** and **B**), whereas the other two Li^+ ions (Li3 and Li4) are still fluxional over two five-membered rings (**D** and **E**) and one seven-membered ring (**C**). Since the latter three rings are almost coplanar, the fluxional behavior of the two Li^+ ions (Li3 and Li4) is not hindered even at 187 K. The possibility of producing a solvent-separated ion pair (SSIP) in toluene-d_8 is unlikely. The ^{6}Li NMR in THF-d_8 gave broad and complex signals.

Enantioselective electrocatalytic oxidation of racemic amines using a chiral 1-azaspiro[5.5]undecane *N*-oxyl radical

Yoshitomo Kashiwagi,*[a] Futoshi Kurashima,[a] Chikara Kikuchi,[a] Jun-ichi Anzai,[a] Tetsuo Osa[a] and James M. Bobbitt[b]

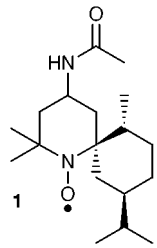
Received (in Cambridge, UK) 21st July 1999, Accepted 23rd August 1999

A preparative electrocatalytic oxidation of racemic amines, which contain a chiral centre α to the amino group, on (6*S*, 7*R*, 10*R*)-4-acetylamino-2,2,7-trimethyl-10-isopropyl-1-azaspiro[5.5]undecane *N*-oxyl yielded mixtures of carbonyl compounds (54.3–66.1%) and amines (33.9–45.7%) after 5 h of electrolysis, in which the current efficiency, turnover number, enantiopurity of the remaining (*R*)-isomers and *S* values were 90.7–94.8%, 21.7–26.5, 62–78% and 4.7–5.8, respectively.

Optically active amines are some of the most important chiral intermediates in organic synthesis. They have been prepared by many methods, including optical resolution of their racemates, usually by preferential crystallization.[1] Several enantioselective chemical oxidations for optical resolution of the racemates using chiral aminoxyl radicals have been reported, but these works were mainly carried out with secondary alcohols as the racemate.[2–4] On the other hand, 2,2,6,6-tetramethylpiperidin-1-yloxyl is known to be an effective redox mediator for the electrooxidation of amines to nitriles and carbonyl compounds.[5–7] Here we report the first efficient, enantioselective electrocatalytic oxidation of a number of racemic amines using (6*S*, 7*R*, 10*R*)-4-acetylamino-2,2,7-trimethyl-10-isopropyl-1-azaspiro[5.5]undecane *N*-oxyl **1**[3] as a chiral 1-azaspiro-[5.5]undecane *N*-oxyl radical.



The cyclic voltammetry† of **1** was carried out in a MeCN solution containing 0.1 M $NaClO_4$ as supporting electrolyte. Fig. 1 shows the cyclic voltammogram (CV) of **1**, in which a reversible redox couple was observed. This redox couple corresponds to one-electron oxidation of the oxoammonium ion. Similar electrochemical behavior has been reported by Bobbitt *et al.*[3] The redox potential and peak split between the anodic and cathodic peak potentials were +0.62 V (*vs.* Ag/AgCl) and 70 mV, respectively. These values are comparable to those for TEMPO derivatives.[8] In addition, the diffusion coefficient of **1** was estimated to be 1.3×10^{-5} cm^2 s^{-1} based on a plot of the peak current *vs.* the square root of scan rate in the cyclic voltammetry.[9] These observations suggest a possible use of **1** as catalyst in the electrocatalytic oxidation of amines.

The enantioselective oxidation of a chiral amine on **1** was investigated using (*R*)-(+)- and (*S*)-(−)-1-phenylethylamine [(*R*)-PEA and (*S*)-PEA] as substrates. The CVs of 0.1 M (*R*)-PEA and (*S*)-PEA in the presence of 0.8 M 2,6-lutidine as deprotonating agent are shown in Fig. 1. The anodic peak current for (*S*)-PEA was significantly enhanced in comparison with the blank voltammogram (**1** itself) and a small cathodic peak was observed on the reverse scan, showing that (*S*)-PEA was efficiently oxidized electrocatalytically. In contrast to the CV for (*S*)-PEA, the anodic peak current for (*R*)-PEA increased only slightly. These results clearly show that the electrocatalytic oxidation of (*S*)-PEA on **1** occurred in preference to that of (*R*)-PEA.

Preparative potential-controlled electrolysis was performed on a graphite felt electrode (Nippon Kynol Inc., $5 \times 5 \times 5$ mm) in MeCN–H_2O (4:1) solution, using an 'H type divided cell separated by a cationic exchange membrane (Nafion 117). The anolyte contained 0.05 mmol of **1**, 1 mmol of substrate, 0.5 mmol of tetralin as a chromatographic standard, 4 mmol of 2,6-lutidine and 0.5 mmol of $NaClO_4$ in a total volume of 5 ml. The catholyte was 5 ml of MeCN–H_2O (4:1) solution containing 0.5 mmol of $NaClO_4$. The electrolysis was carried out at +0.8 V *vs.* Ag/AgCl under an argon atmosphere. During electrolysis, aliquots of anolyte were analyzed occasionally by HPLC.‡ The consumption of racemic 1-phenylethylamine and formation of acetophenone are plotted against electrolysis time in Fig. 2. 1-Phenylethylamine was probably oxidized to the corresponding imine, the expected oxidation intermediate, which can be easily hydrolyzed to acetophenone; imine was not actually detected. After 5 h of electrolysis, the (*R*)- and (*S*)-forms of 1-phenylethylamine were oxidized to acetophenone in 45.9 and 92.4% yield, respectively. The current efficiency and turnover number (given by ratio of mole of product ×2/mol of **1**) were 91.5% and 26.2, respectively, at 5 h of electrolysis. The remaining (*R*)-PEA and (*S*)-PEA equalled 56.1 and 7.6%, respectively. Thus, the ee of the unreacted amine was 78%. The efficiency of the resolution is characterized by the selectivity factor, *S* (= k_s/k_R).[9] The *S* value of this reaction was 5.3.

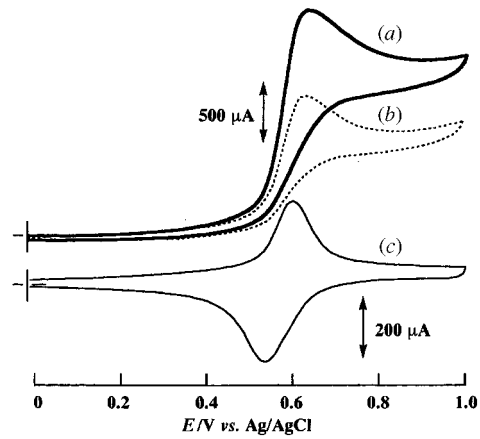


Fig. 1 Cyclic voltammograms of 0.01 M **1** in 0.1 M $NaClO_4$/MeCN at the scan rate of 50 mV s^{-1}: (*a*) in the presence of 0.1 M (*S*)-PEA and 0.2 M 2,6-lutidine, (*b*) in the presence of 0.1 M (*R*)-PEA and 0.2 M 2,6-lutidine, and (*c*) blank.

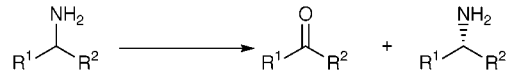
Table 1 Electrocatalytic oxidation of racemic secondary amines by **1**



R^1	R^2	Amine	Charge/C	Efficiency[a] (%)	Ee (%)	Conversion (%)	*S*	TON[b]
Ph	Me	R	137.9	91.5	78	65.4	5.3	26.2
p-Tol	Me	R	134.6	94.8	75	66.1	4.7	26.5
1-Naphthyl	Me	R	115.5	90.7	62	54.3	5.8	21.7
2-Naphthyl	Me	R	124.8	92.3	66	59.7	4.9	23.9

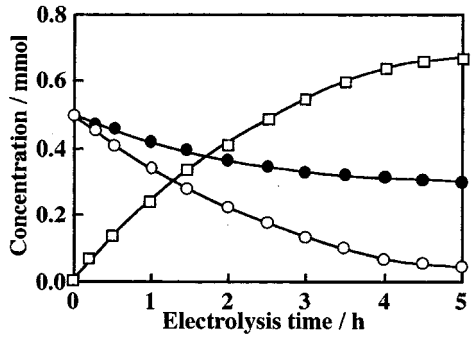

Fig. 2 Macroelectrolysis of racemic PEA by **1** in the presence of 2,6-lutidine: (●) (*R*)-PEA, (○) (*S*)-PEA and (□) acetophenone.

The results from the enantioselective oxidation reactions of a variety of racemic amines are shown in Table 1. In the electrocatalytic oxidation of the racemic amines such as 1-(1-naphthyl)ethylamine, 1-(2-naphthyl)ethylamine and 1-(*p*-tolyl)ethylamine, which contain a chiral centre α to the amino group, the (*S*)-isomers were oxidized in preference to the (*R*)-isomers. After 5 h of electrolysis, the racemic amines were oxidized to the corresponding ketones in 90.7–94.8% current efficiency, 54.3–66.1% yield and 100% selectivity. The turnover numbers based on **1** are larger than 21. The enantiopurity of the remaining (*R*)-isomers and *S* values were 62–78% and 4.7–5.8, respectively. On the contrary, the electrooxidation of 2-phenylpropylamine, which has a chiral centre β to the amino group, was not enantioselective. After 5 h of electrolysis, it was oxidized to the corresponding aldehyde in 96.1% current efficiency, 95.8% yield and 100% selectivity. The turnover numbers based on **1** is 38.3. These facts mean that an α-hydrogen in a chiral centre adjacent to the amino group is necessary to attain an enantioselective oxidation in the present system. The enantioselective oxidation with **1** is applicable to the optical resolution of racemic secondary amines.

This work was supported in part by Grants-in-Aid for Scientific Research on Priority Areas (No. 11119208: 'Innovative Synthetic Reactions') and for Encouragement Research (No. 10771266) from the Ministry of Education, Science, Sports and Culture of Japan.

Notes and references

† A glassy carbon disk electrode (3 mm diameter) and a platinum wire were employed as working electrode and counter electrode, respectively. The anode potentials were referred to Ag/AgCl (saturated AgCl and Me_2EtNCl in MeCN). Cyclic potential sweeps were generated by a Hokuto Denko Model HABF-501 potentiostat/galvanostat. Cyclic voltammograms were recorded on a Graphtec Model WX1200 X-Y recorder. All electrochemical measurements were carried out at room temperature (*ca.* 20 °C).

‡ The HPLC analysis was carried out using Daisel CHIRALCELL-OD column (46 mm $\phi \times 250$ mm). The column temperature was kept constant at 40 °C. The analytes were eluted by Pr^iOH–*n*-hexane (2:33) at 0.7 ml min^{-1} flow rate, and detected by UV absorption at 254 nm.

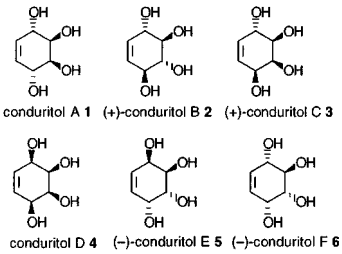
Received (in Cambridge, UK) 7th July 1999, Accepted 31st August 1999

Six possible diastereomers of conduritols have been synthesized diastereoselectively in an integrated manner starting from a single chiral precursor, which served as a synthetic equivalent of chiral *cis*-1,4-dihydroxycyclohexa-2,5-diene.

Although only two conduritols, A **1** and F **6**, occur in Nature, four other possible diastereomers, conduritols B **2**, C **3**, D **4** and E **5**, are known[1]. Since they are useful for the preparation of

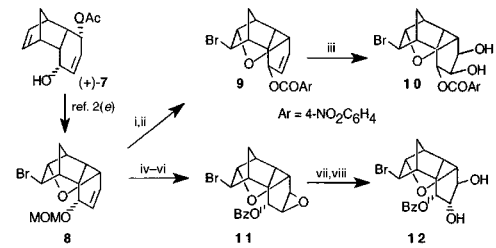


physiologically active cyclitols and their derivatives, a considerable number of syntheses have been reported to date.[2] The majority of syntheses, however, are limited to preparation of particular members of conduritols and there has been no precedent which is capable of producing all six conduritols diastereoselectively from a single precursor in an integrated manner. As we have developed an efficient preparation[3] of the tricyclic monoacetate **7** serving as a synthetic equivalent of chiral *cis*-1,4-dihydroxycyclohexa-2,5-diene in both enantiomeric forms by lipase-mediated asymmetric desymmetrization of a *meso* precursor, we examined diastereocontrolled preparation of all six conduritols on the basis of inherent steric and chemical functionalities comprised in this chiral building block.[4] We report herein the first integrated synthesis of conduritols A–F **1**–**6** starting from the single chiral compound (+)-**7** using a methoxymethyl (MOM) ether as the common protecting group.

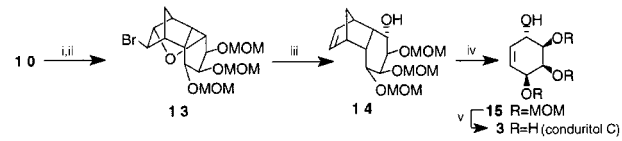
The acetate[3] **7** was first transformed into the bromo ether **8** in three steps[2e] to discriminate one of two olefin functionalities and to block the secondary hydroxy functionality in the molecule. On acid-catalyzed removal of the MOM protecting group, followed by the Mitsunobu reaction,[5], **8** afforded the *exo*-benzoate **9**, mp 135–136 °C, $[\alpha]_D^{28}$ −260.1 (*c* 1.02, $CHCl_3$), whose dihydroxylation occurred from the convex face to furnish the *exo-cis*-diol **10**, $[\alpha]_D^{30}$ −66.6 (*c* 0.96, $CHCl_3$), diastereoselectively. On the other hand, **8** was transformed into the single *trans*-diol **12**, $[\alpha]_D^{26}$ −60.5 (*c* 1.18, $CHCl_3$), through the *exo*-epoxide **11**, mp 93–94 °C, $[\alpha]_D^{28}$ +0.9 (*c* 1.02, $CHCl_3$), on sequential MOM deprotection, benzoylation, convex face selective epoxidation and acid treatments. In the latter conversion, the epoxide **11** was cleaved diastereo- and regioselectively by the participation[6] of the benzoate functionality in the presence of a Lewis acid to give a mixture of two regioisomeric benzoates, which, however, converged on the single isomer **12** on stirring with TsOH in CH_2Cl_2 (Scheme 1).

Utilizing the *cis*-diol **10**, (+)-conduritol C **3** was first prepared. On alkaline methanolysis followed by MOM protection, **10** gave the tri-MOM ether **13**, $[\alpha]_D^{29}$ −101.4 (*c* 1.05, $CHCl_3$), whose bromo ether linkage was reductively cleaved with zinc in the presence of acetic acid[2e] to regenerate the olefin and the hydroxy functionalities to give rise to the tricyclic alcohol **14**, $[\alpha]_D^{31}$ +14.4 (*c* 1.02, $CHCl_3$). Thermolysis of **14** was carried out at this stage in refluxing Ph_2O in the presence of $NaHCO_3$[7] to give the cyclohexenol **15**, $[\alpha]_D^{28}$ +123.5 (*c* 0.54, $CHCl_3$), by retro-Diels–Alder reaction. When the carbonate was absent, the yield of **15** was diminished considerably. Stirring **15** with saturated methanolic HCl at room temperature[8] induced smooth MOM deprotection to give (+)-conduritol C **3**, mp 129–130 °C, $[\alpha]_D^{30}$ +209.1 (*c* 0.62, H_2O) [lit.,[2f] mp 128–129 °C, $[\alpha]_D^{20}$ +215 (*c* 2.01, H_2O)]. As shown below, under these acid-catalyzed conditions, the MOM protecting group of the other conduritols was neatly removed to afford the corresponding conduritols after removal of low volatiles under reduced pressure followed by washing the residue with an appropriate solvent (Scheme 2).

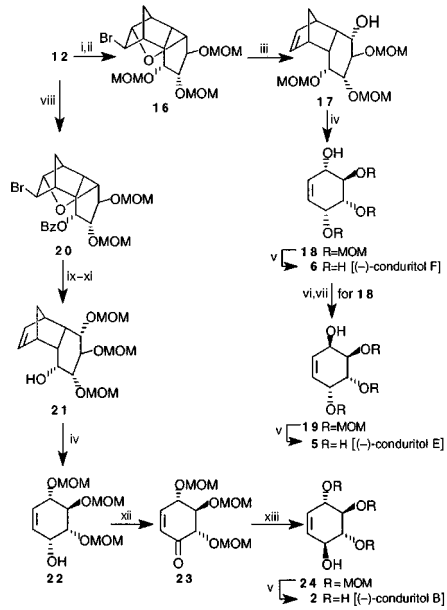
The *trans*-diol **12** was served as the precursor for the synthesis of three conduritols, (+)-B **2**, (−)-E **5** and (−)-F **6**. Thus, **12** was first transformed into the tri-MOM ether **16**, $[\alpha]_D^{30}$ −78.0 (*c* 1.15, $CHCl_3$), by sequential debenzoylation and MOM protection. Reductive cleavage of **16**, followed by thermolysis of the resulting **17**, $[\alpha]_D^{31}$ −80.8 (*c* 0.94, $CHCl_3$), afforded the cyclohexenol **18**, $[\alpha]_D^{27}$ +55.5 (*c* 0.79, $CHCl_3$), which gave (−)-conduritol F **6**, mp 129–130 °C, $[\alpha]_D^{28}$ −70.2 (*c* 0.15, MeOH) [lit.[2g] for (+)-enantiomer: mp 128–130 °C, $[\alpha]_D^{23}$ +75.1 (*c* 0.33, MeOH)], on MOM deprotection. The alcohol **18**, on the other hand, was first treated with 4-nitrobenzoic acid[9] under Mitsunobu conditions[5] to give the epimeric alcohol **19**, $[\alpha]_D^{30}$ −106.6 (*c* 1.07, $CHCl_3$), after alkaline methanolysis, which on MOM-deprotection, afforded (−)-conduritol E **5**, mp 191–192 °C, $[\alpha]_D^{29}$ −330.3 (*c* 0.18, H_2O) [lit.[2g] for (+)-enantiomer: mp 192–194 °C, $[\alpha]_D^{30}$ +327 (*c* 0.22, H_2O)].



Scheme 1 *Reagents and conditions*: i, conc. HCl–MeOH–THF (91%); ii, 4-$NO_2C_6H_4CO_2H$, DIAD, PPh_3, THF (86%); iii, OsO_4 (cat.), NMO, aq. THF (97%); iv, conc. HCl–MeOH–THF (91%);. v, BzCl, pyridine, DMAP (cat.), CH_2Cl_2 (99%); vi, MCPBA, CH_2Cl_2 (91%); vii, $BF_3{\cdot}OEt_2$, toluene (100%); viii, TsOH (cat.), CH_2Cl_2, room temp., 3 d (76%).



Scheme 2 *Reagents and conditions*: i, NaOMe, MeOH; ii, MOMCl, Pr^i_2NEt, CH_2Cl_2 (89%); iii, Zn, AcOH, MeOH (85%); iv, $NaHCO_3$, Ph_2O, reflux, 30 min (84%); v, sat. HCl–MeOH (93%).



Scheme 3 *Reagents and conditions*: i, NaOMe, MeOH; ii, MOM-Cl, Pr^i_2NEt, $(CH_2Cl)_2$ (92%); iii, Zn, AcOH, MeOH (91%); iv, $NaHCO_3$, Ph_2O, reflux, 30 min (77% for **18**; 96% for **22**); v, sat. HCl–MeOH (100% for **2**, **5**, **6**); vi, 4-$NO_2C_6H_4CO_2H$, DIAD, PPh_3, THF (74%); vii, K_2CO_3, MeOH (94%); viii, MOMCl, Pr^i_2NEt, CH_2Cl_2 (97%); ix, Zn, AcOH, MeOH (99%); x, MOMCl, Pr^i_2NEt, CH_2Cl_2 (82%); xi, K_2CO_3, MeOH (94%); xii, PCC, CH_2Cl_2 (94%); xiii, $NaBH_4$–$CeCl_3$ (93%).

On the other hand, the *trans*-diol **12** was first transformed into the di-MOM ether **20**, $[\alpha]_D^{30}$ −73.6 (*c* 1.01, $CHCl_3$), which was further transformed into the tricyclic alcohol **21**, $[\alpha]_D^{31}$ −8.0 (*c* 1.04, $CHCl_3$), by sequential reductive cleavage, MOM protection and debenzoylation. Themolysis of **21** afforded the cyclohexenol **22**, $[\alpha]_D^{28}$ +24.5 (*c* 1.01, $CHCl_3$), which was epimerized to **24**, $[\alpha]_D^{29}$ +142.1 (*c* 1.03, $CHCl_3$), *via* the cyclohexenone **23**, $[\alpha]_D^{30}$ +41.4 (*c* 1.05, $CHCl_3$), by oxidation followed by diastereoselective 1,2-reduction in the presence of cerium(III) chloride.[10] Compound **24** afforded (+)-conduritol B **2**, mp 174–175 °C, $[\alpha]_D^{28}$ +153.5 (*c* 0.31, MeOH) [lit.[2c] mp 174–175 °C, $[\alpha]_D^{20}$ −179 (*c* 1.2, MeOH)], on MOM deprotection (Scheme 3).

Although enantiocontrol is not required for the construction of the two remaining conduritols, A **1** and D **4**, having *meso* structures, the same intermediate **8** was used as the starting material to demonstrate the potential of our building block. Thus, **8** was first transformed into the tri-MOM ether **25**, $[\alpha]_D^{26}$ −33.0 (*c* 1.01, $CHCl_3$), which was then converted to the cyclohexenol **27**, $[\alpha]_D^{25}$ −8.7 (*c* 1.11, $CHCl_3$), by sequential MOM protection, reductive cleavage and thermolysis. Compound **27** afforded conduritol A **1**, mp 141–142 °C (lit.,[2a] mp 140–141 °C), on MOM deprotection.

Compound **8**, on the other hand, was first transformed into the dibenzyl ether **28**, mp 91–92 °C, $[\alpha]_D^{29}$ −63.1 (*c* 1.32, $CHCl_3$), which, on sequential reductive cleavage and thermolysis, gave the cyclohexenol **29**, $[\alpha]_D^{27}$ +12.8 (*c* 1.05, $CHCl_3$). On sequential diastereoselective dihydroxylation, MOM protection, debenzylation and thiocarbonylation, **29** furnished the *meso* cyclohexane **30**. Refluxing **30** with trimethyl phosphite[11,12] allowed smooth dethiocarbodioxylation to give the cyclohexene **31** which afforded conduritol D **4**[2b] on MOM deprotection (Scheme 4).

In conclusion, the present synthesis provides the first integrated route to all possible conduritol diastereomers with complete diastereocontrol starting from a single chiral building block by using MOM ether as the common protecting group.

Synthesis of soluble combinatorial libraries of crown ether-ester analogues *via* the cyclodepolymerisation of linear polyesters

Pathavuth Monvisade, Philip Hodge* and Clare L. Ruddick

Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL. E-mail: philip.hodge@man.ac.uk

Received (in Cambridge, UK) 14th July 1999, Accepted 23rd August 1999

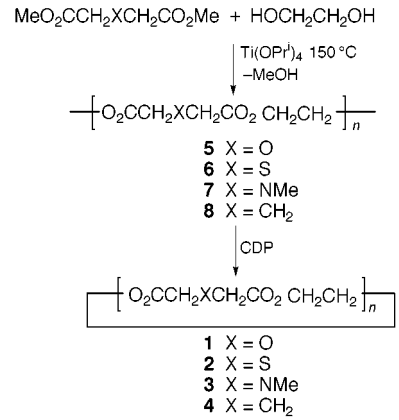
Cyclodepolymerisation of functional linear polyesters gives macrocycles which, on equilibration *via* transesterification, give soluble combinatorial libraries of crown ether-ester analogues, one consisting of 30 different 18- or 27-membered rings and another consisting of 29 different 24- or 36-membered rings.

Combinatorial chemistry has great potential to assist in solving a wide variety of chemical problems.[1,2] Most frequently to date it has involved the synthesis of combinatorial libraries on insoluble polymer supports and the target molecules have been peptides[3] or potential pharmaceuticals.[4] There are, however, other synthetic approaches and other targets of interest, for example, the synthesis of libraries in solution[5] and the synthesis of libraries to assist in the optimisation of recognition properties.[6]

Cyclic oligomers can often be prepared efficiently by the cyclodepolymerisation (CDP) of condensation polymers.[7,8] CDP involves treating a dilute solution, typically *ca.* 2% w/v, of an appropriate polymer with a catalyst that brings about the cleavage and reformation of the polymer linkages. At low concentrations the formation of cyclics is much more likely than the formation of chains. Thus, treating linear polyesters in dilute solution with a transesterification catalyst affords cyclic oligoesters in excellent yields.[7] Crown ethers are an important class of compounds, many of which can recognise cations, and we now report that CDP can be used to synthesise soluble libraries of crown ether-ester analogues made up of 18-membered and 27-membered rings containing all the combinations of the moieties in cyclics **1**–**4** and of 24- and 36-membered rings made up of all the combinations of the moieties in cyclics **13** and **14**. Although in the 18-membered ring family the binding of cations is expected to be achieved mainly *via* the ether, thioether or *tertiary* amine moieties,[9] as the rings become larger binding may also be achieved through the ester carbonyl groups. The natural ionophore valinomycin, for example, a depsipeptide which has a 36-membered ring, binds K^+ with high selectivity using the carbonyl groups of six ester linkages.[10]

Polymers **5**–**8** were synthesised by standard procedures from the appropriate dimethyl ester, ethylene glycol, and a catalytic amount of titanium isopropoxide (Scheme 1). The yields and the molecular weight data of the products are summarised in the Table. Treatment of 2% w/v solutions of each individual polymer in chlorobenzene with 2 mol% of di-*n*-butyltin oxide at 183 °C brought about CDP and the formation of the expected series of cyclic oligomers.[11] Although the reactions were substantially complete in 24 h, they were nevertheless carried out for 7 days to ensure that equilibrium was reached. It is evident from the results, summarised in Table 1, that the cyclic fractions from polymers **5**–**8**, generally isolated by passing the crude product down a short column of alumina, consisted of 61–80% of the 18-membered ring dimers (**1**–**4**; $n = 2$), and 14–18% of the 27-membered ring trimers (**1**–**4**; $n = 3$). Larger cyclic oligomers were also present[11] but only the dimers and trimers were considered to be present in sufficient amounts to be useful in the present project. It is clear that none of the functionalities involved caused the formation of, say, a particular cyclic trimer to be much more heavily favoured than any other. Thus, the various motifs present were expected to 'mix' well in combinatorial experiments.

When an equimolar mixture of the cyclics from each of the three polymers **5**, **6** and **8**, as a 2% w/v solution in chlorobenzene, was treated with 3 mol% of di-*n*-butyltin oxide

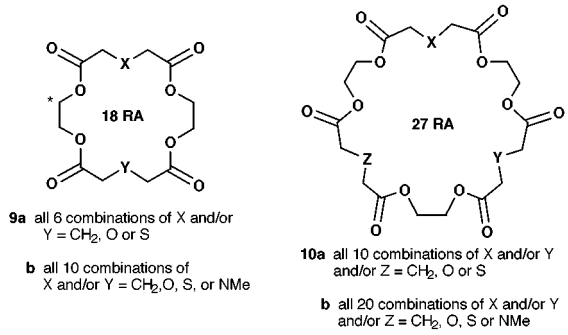


Scheme 1

Table 1 Properties of polymers and the composition of the CDP products

Starting polymer	Yield (%)	$\overline{M}_n$[a]	$\overline{M}_w$[a]	Yield of cyclic oligomers (%)	Composition of CDP product (%)[b]		
					Cyclic dimer	Cyclic trimer	Other cyclics
5	92	1 500	2 300	53	74	17	9
6	56	3 000	4 300	70	66	18	16
7	54	19 200	28 700	69	80	14	6
8	74	14 300	25 400	94	61	17	22
11	81	1 700	2 200	71	51	21	14
12	83	2 900	4 300	61	48	19	31

[a] By GPC relative to polystyrene standards. [b] By GPC on a column specifically designed to analyse oligomers. The materials unaccounted for were either linear oligomers or polymer.



9a all 6 combinations of X and/or Y = CH_2, O or S

b all 10 combinations of X and/or Y = CH_2,O, S, or NMe

10a all 10 combinations of X and/or Y and/or Z = CH_2, O or S

b all 20 combinations of X and/or Y and/or Z = CH_2, O, S or NMe

at 183 °C for 7 days, equilibration was achieved through transesterification and the product contained all the six expected combinations of the cyclic 'dimers' **9a** (75% by weight by GPC analysis) and all the ten expected combinations of the cyclic 'trimers' **10a** (15% by weight). Similar mixtures could be prepared directly by mixing the polymers **5**, **6** and **8** and subjecting them to CDP. The positive-ion chemical ionisation mass spectrum of the equilibrated products showed major signals for every expected combination. The relative sizes of the signals in mass spectra do not accurately reflect the proportions of the various species present, but by ^{13}C NMR spectroscopy it was shown that the amounts of all the cyclic 'dimers' were the same within a factor of 2, the most useful signal being that asterisked in **9**. The position of this signal is sensitive to the type of groups at both X and Y. This region of the ^{13}C NMR spectrum is shown in Fig. 1. There is no reason to doubt that the cyclic 'trimers' **10a** were also all present in comparable amounts. A mixture of the four polymers **5**–**8** was equilibrated similarly. The positive-ion chemical ionization mass spectrum of the product showed significant signals for all 10 combinations of 'dimers' **9b** and all 20 combinations of 'trimers' **10b**.

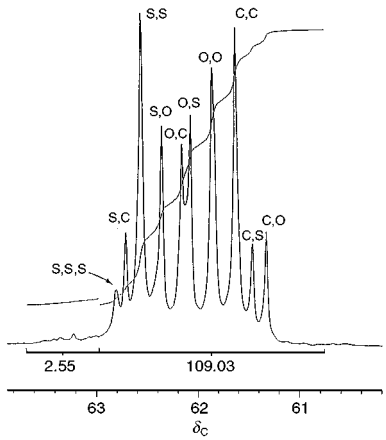


Fig. 1 Part of the ^{13}C NMR spectrum of the mixture obtained by equilibrating cyclic oligomers **1**, **2**, and **4**. The part of the spectrum shown is due to the asterisked carbon atoms in **9**. Assignments were made on the basis of studies of the NMR spectra of the pure cyclic dimers and combinatorial mixtures prepared from just two types of cyclic oligomers.

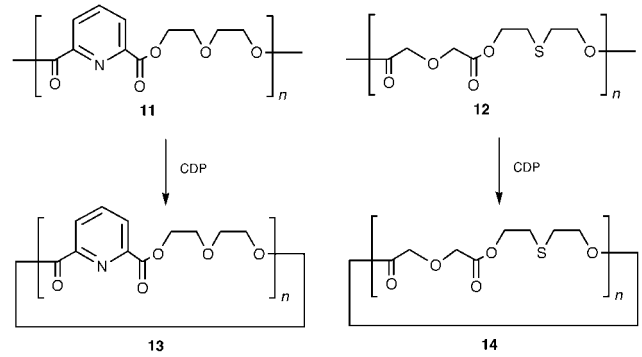
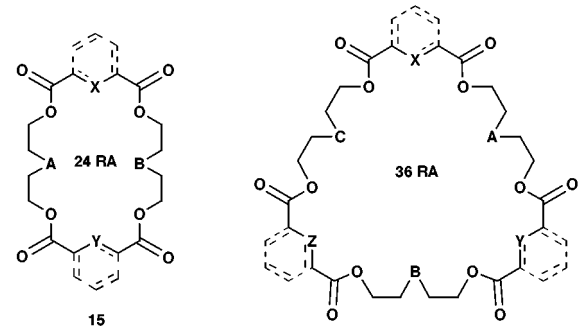
Polymers **11** and **12** were similarly prepared, characterised and subjected to CDP (Scheme 2, Table 1). In these cases the proportions of the cyclic dimers (24-membered rings) and trimers (36-membered rings) were *ca.* 2.:1 by weight. Equilibration of the cyclics from the two polymers gave solutions containing, as judged by positive-ion chemical ionisation and MALDI-TOF mass spectrometry, libraries of all nine combinations of the 24-membered rings (**15**) and all 20 combinations of the 36-membered rings (**16**). In this system the total number of possible combinations is enhanced because there is a choice in both the diacid and diol segments of the macrocycles, and, in some 'trimers', a choice in the sequence of the segments which results in isomer formation.



Scheme 2



All 9 combinations of X and/or Y = O or pyridine and A and/or B = O or S

All 20 combinations of X and/or Y and/or Z = O or pyridine and A and/or B and/or C = O or S

Research related to the above has been carried out by Sanders' group.[12–14] They have prepared macrocyclic esters directly from monomers and equilibrated *pairs* of families of the macrocycles. In their work most of the building blocks were rigid,[12–14] and, unlike in the present study, not all pairs of rings 'mixed' well.[13] Successful mixing could, however, be achieved by including ephedrine derivatives, which are relatively flexible, in the equilibrating system.[14]

Having shown that libraries of cyclic recognition systems can be prepared *via* CDP of polyesters, work is currently in hand to prepare other types of soluble libraries by CDP and to develop methods for screening the various soluble libraries.

We thank the Thai Government for a PhD Studentship for P. M. and the EPSRC ROPA Scheme for financial support.

Concerning kinetic resolution by the Sharpless asymmetric dihydroxylation reaction

Hamish S. Christie, David P. G. Hamon* and Kellie L. Tuck

Chemistry Department, University of Adelaide, S.A. 5005, Australia. E-mail: dhamon@chemistry.adelaide.edu.au

Received (in Cambridge, UK) 6th August 1999, Accepted 31st August 1999

The transition state for the product-determining step in the Sharpless asymmetric dihydroxlation reaction is not product-like, and effective kinetic resolution can occur when one face of a chiral alkene is hindered.

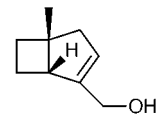
Sharpless asymmetric dihydroxlation (AD)[1] and asymmetric epoxidation (AE)[2] reactions have proved to be very effective means whereby asymmetry can be introduced into molecules starting from prochiral alkenes and allylic alcohols respectively. The AE reaction has also proved useful for effecting kinetic resolution of chiral allylic alcohols. However, with only a few exceptions, the AD reaction has not been effective for carrying out kinetic resolutions and the reasons for this are not well understood.[1]

It is known[3] that the AD reaction of 1-phenylcyclohexene proceeds with high asymmetric induction. Therefore, reaction of these reagents with 1-phenyl-4-*tert*-butylcyclohexene **1** would also be expected to proceed with high asymmetric induction but two diastereomeric products should result. For instance with AD-mix-β the enantioenriched diastereomers **2** and **3** should form (Scheme 1). If these molecules exist predominantly in the expected chair conformers, the diastereomer **2** has the phenyl group in an equatorial position whereas the phenyl group in the other diastereomer **3** has an axial orientation. The diastereomer **3** will be several kJ mol^{-1} higher in energy than the diastereomer **2**.[4] Therefore, if the transition state (TS) for the product-determining step in the AD reaction is product-like, there would be a considerable difference in the rate of formation of these two diastereomers, and an effective kinetic resolution should be possible.

The AD reaction on the alkene **1** was performed following Sharpless's recommended procedure[5] for tri-substituted alkenes (AD-mix-β, $MsNH_2$, Bu^tOH–H_2O, 0 °C). Equal quantities of the diols **2** and **3**,[6] eluting in that order, were obtained, in 84% yield after 'flash' silica gel chromatography. The enantiomeric purity of each diol was determined by the use of NMR chiral shift reagent experiments. The diol **2** from the AD reaction had > 99% ee[7] and the diol **3** had > 95% ee.[8] The racemic diols were obtained using the Sharpless method with quinuclidine as ligand to give the racemic diols in a ratio of ~ 4.5 : 1.

The kinetic resolution was also studied under the normal conditions for the AD reaction and the relative rates for the enantiomers (*E*) were determined following a literature procedure[9] which is related to the relationship derived by Kagan.[10] The percentage conversion of the racemic substrate was followed by NMR spectroscopy. The remaining alkene was separated from the diols **2** and **3**. The ee of the remaining alkene **1** was determined by conversion, using the achiral dihydroxylation reaction, into the same diols **2** and **3**. The enantiopurity of the major diol was then determined as already described. In two separate experiments, conducted at 0 °C, the reactions were stopped at 15 and 94% conversion respectively. The ee for the remaining alkene, for the former reaction, was determined as ~ 4% and, for the latter, as ~ 86%. This computes to an *E* of ~ 2 in each case. This value of *E* is too small for effective kinetic resolution. Clearly the TS of the product-determining step is not product-like.

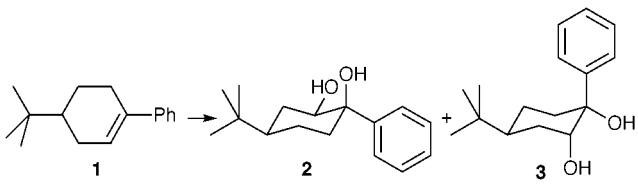
It can be reasoned that, if the product-determining step in the AD reaction is reactant-like and if the alkene is highly enantiofacially directing, then a kinetic resolution should be effective when there is considerable difference in the ease of approach to the two faces of a chiral alkene.[11] Such an effect has been demonstrated[12] recently for one molecule, which displays axial chirality. Recently we completed[13] an asymmetric synthesis of grandisol in which the key step is the kinetic resolution of the primary allylic alcohol **4** by a Sharpless AE reaction. The



4

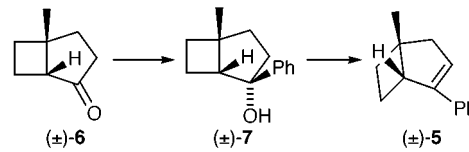
key feature in that resolution is that the molecule presents both an open convex face and a more-hindered, concave face to the reagents. The reaction proceeds to give products of attack on one face only, the convex face. This system appeared suitable to pursue the study of the kinetic resolution by the AD reaction. Indeed, the alkene **5** appears ideal for this study. Control of product formation in the Sharpless AD reaction should be determined mainly by the enantiofacial selectivity of the styrene moiety. The concave face of this molecule is hindered, so there should be a considerable difference in the rate of reaction of the enantiomers of this molecule and kinetic resolution should be effective.

Reaction of the bicycloketone **6**[14] with PhMgBr and Et_2O at 0 °C gave, in 88% yield, a single racemic alcohol, mp 56–58 °C, presumed to be the diastereomer **7** (Scheme 2). Dehydration of this alcohol (CH_2Cl_2, Et_3N, MsCl, 0 °C) gave as an oil the alkene **5** (81%).[15] A kinetic resolution of this substrate was examined in two separate experiments with 26 and 50% oxidant respectively. However, because the alkene **5** is somewhat unstable, in each case the ees for both the diol (presumed to be enantiomer **8**, based on the application of Sharpless' mnemonic) and the recovered alkene **5** were determined, after separation, in the following way. The diol **8** was converted to the mono Mosher ester derivative [(+)-MTPA, CH_2Cl_2, DCC, DMAP] and the ee determined.[16] The alkene was converted to the same diol (presumed to be mainly **9**) by the achiral dihydroxylation



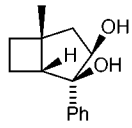
1 **2** **3**

Scheme 1

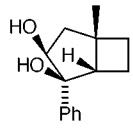


(±)-**6** (±)-**7** (±)-**5**

Scheme 2



8



9

reaction (quinuclidine ligand) and this diol was converted to the mono Mosher ester derivative from which the ee was obtained. The ees for the diols in the two reactions were 88 and 80%, and for the alkenes they were 52 and 80%, respectively. The enantiomeric ratios for these two reactions calculate to E = 26 and 21, respectively (the same within experimental error), which translates to an effective kinetic resolution (> 95% ee at 60% conversion).

In conclusion, we find that the reaction of 1-phenyl-4-*tert*-butylcyclohexene with AD-mix-β gives the two diastereomers **2** and **3** in very high enantiopurity. However, the rate difference between formation of the two enantiomers is only small ($E \sim 2$) and kinetic resolution is ineffective. We also find that the reaction of the alkene **5** with AD-mix-β gives an effective kinetic resolution ($E > 20$) and only one diastereomeric diol is formed. These results are consistent with an early, rather than a late, transition state for the product-determining step in the Sharpless AD reaction.

Asymmetric transformation (deracemisation) of an atropisomeric bisheterocyclic amine†

Michael P. Coogan,*[a] David E. Hibbs[b]‡ and Emma Smart[a]

[a] *Department of Chemistry, University of Durham, Science Laboratories, South Road, Durham, UK DH1 3LE. E-mail: m.p.coogan@durham.ac.uk*

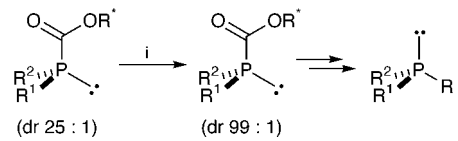
[b] *Department of Chemistry, University of Wales, Cardiff, Park Place, Cardiff, UK CF1 3TB*

Received (in Liverpool, UK) 21st June 1999, Accepted 11th August 1999

Heating (±)-6,8,14,17-tetrahydro-7*H*-[1,2,5]triazepino[3,2-*b*:7,1-*b*′]diquinazoline-14,17-dione 1 with (+)-CSA gives (−)-1 with >90% ee *via* a crystallisation-induced asymmetric transformation, the first non-racemic example of a C_2 symmetric bisheterocycle which is atropisomeric by virtue of retarded rotation around an N–N bond.

The efficacy of substituted 1,1′-binaphthyls as ligands for metals in catalytic asymmetric reactions has prompted interest in other aspects of atropisomerism: recently hindered aryl amides[2a] and novel binaphthyl ligands and analogues[2b] have been the focus of interest. One system which displays hindered rotation due largely to an electronic rather than steric barrier is the N–N bond of peracylhydrazines.[3] Atkinson *et al.*[4] have shown that the N–N bond in 3-diacylaminoquinazolin-4-ones is a chiral axis when the acyl groups are different and, by analogy, N–N linked biquinazolinones would be expected to display atropisomerism (axial chirality). However, although a range of 3,3′-biquinazoline-4,4′-diones have been prepared,[5] the issue of chirality was not addressed. A stereostable chiral axis in such compounds could lead to the design of novel ligands for metals in catalytic asymmetric reactions. Having verified the presence of chirality it was hoped that, rather than resolution of enantiomers, a deracemisation reaction (asymmetric transformation, AT)[1] could be developed. Vedejs and co-workers have obtained diastereomerically pure materials by AT at the stereogenic but stereolabile heteroatoms of chiral organoboron[6a] and organophosphorus[6b] compounds. Notably, Vedejs and Donde[6b] achieved crystallisation-induced AT at a stereogenic phosphorus utilising an alkoxycarbonylphosphine to both introduce a chiral auxiliary, and lower the barrier to inversion, allowing racemisation at around the melting point (Scheme 1). In the work described here a high barrier to rotation (racemisation) coexists with high crystallinity, and the electronic nature of the barrier is exploited, allowing it to be moderated *via* protonation.

2,2′-Bis(bromomethyl)-3,3′-biquinazoline-4,4′-dione **2** was prepared in two steps from **3**[5] in 58% yield *via* the unstable bisbromoacetate **4** (Scheme 2). The bromomethylene protons of **2** are observed as an AB system [δ 4.43, 4.32 (J 12.0 Hz)] indicating chirality (slow rotation around the N–N bond on the NMR time scale). VT NMR showed line broadening above 60 °C, however even at 135 °C free rotation was not observed around the N–N bond (non-coalescence) which indicates a *minimum* barrier to rotation in the order of 85 kJ mol^{-1}.

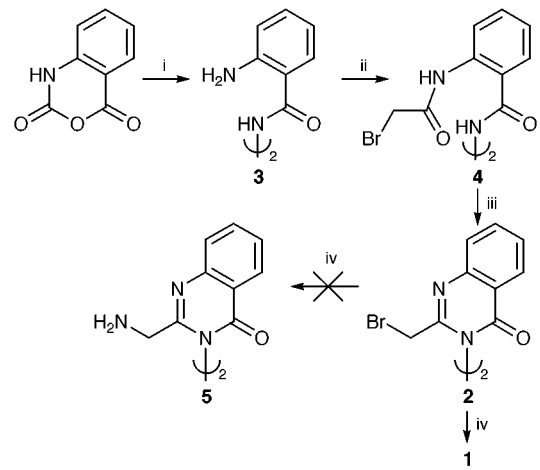


Scheme 1 *Conditions*: i, crystalline state, 50 °C, 22 h.

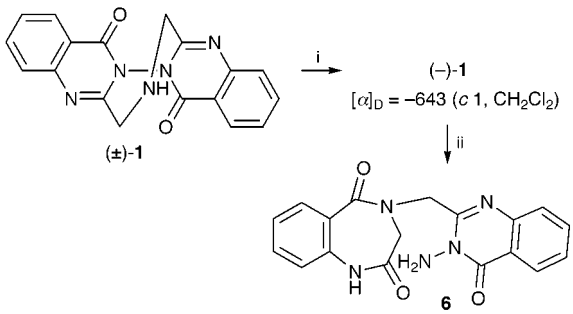
† See ref. 1.

‡ Corresponding author for crystallography.

Treatment of a solution of **2** in THF with aqueous NH_3 gave 6,8,14,17-tetrahydro-7*H*-[1,2,5]triazepino[3,2-*b*:7,1-*b*′]diquinazoline-14,17-dione **1** [*m/z* 331 (100%)]§ in 74% yield; none of the anticipated diamine **5** was detected. In amine **1** the diastereotopic protons in each methylene unit [δ 4.00, 3.93 (J 13.2 Hz)] confirmed that rotation around the N–N bond was slow on the NMR time scale; again in VT NMR experiments coalescence was not observed at 135 °C, indicating a minimum barrier to rotation of 85 kJ mol^{-1}. No separation of ^{1}H NMR signals was observed in the presence of acetylmandelic acid[7] or tartaric acid. However, in the presence of 2 equiv. of (+)-CSA, two sets of AB pattens were observed [δ 4.89, 4.75, 4.70 and 4.68 (J 14.4 Hz for all signals)] equating to the two diastereoisomeric salts. To investigate possible AT, a sample of **1** and 2 equiv. of (+)-CSA was suspended in toluene and heated at reflux for 16 h, then evaporated and analysed by ^{1}H NMR. Astonishingly, only one set of diastereotopic protons was observed (δ 4.89, 4.70), along with decomposition products. Base washing gave **1** identical with authentic material which on treatment with CSA displayed only one set of methylene signals, implying that the sample was essentially a single enantiomer. To ascertain whether this phenomenon was due to selective decomposition or AT, optimisation experiments were undertaken in various solvents at a range of temperatures and concentrations. Optimum conditions were heating **1** at reflux with benzene containing (+)-CSA (2 equiv.) for 40 h, which gave an apparent diastereoisomer ratio of >10:1 (judged by NMR) with negligible decomposition. The recovered **1** after base washing accounted for 82% of the starting material, which is incompatible with a selective decomposition of one enantiomer, and had specific rotation $[\alpha]_D$ −643 (c 0.1, CH_2Cl_2) (Scheme 3), raised by a single recrystallisation to −688 (c 0.011, CH_2Cl_2), at which point (+)-CSA as an NMR shift



Scheme 2 *Reagents and conditions*: i, $H_2NNH_2{\cdot}H_2O$ (0.5 equiv.), EtOH, reflux, 16 h, 84%; ii, $BrCH_2COBr$, Et_3N, DMF, 0 °C; iii, TsOH (10 mol%), PhMe, reflux (Dean and Stark), 58% for 2 steps; iv, 35% aq. NH_3 (100 equiv.), THF, 74%.



Scheme 3 *Reagents and conditions*: i, (+)-CSA (2 equiv.), PhH (3.8 ml mol^{-1}), reflux, 40 h; ii, HBr, EtOH–H_2O or $CoSO_4$, EtOH–H_2O.

reagent indicated that the material was enantiopure (> 98% ee).

The use of a paucity of a 'poor' solvent is essential; a *solution* of **1** with 2 equiv. of CSA (1,2-dichloroethane) at 83 °C (*vs.* 80 °C for benzene) for 40 h gave only the racemic material and, on prolonged heating (72 h), decomposition. Two samples of **1** (0.1 mmol) plus 2 equiv. of CSA heated at reflux for 16 h in 10 ml (entirely dissolved) and 1 ml (two phase) of benzene gave diastereoisomer ratios 1 : 1 and 3 : 1, respectively. The use of higher temperatures was detrimental: 2 h at 135 °C led to complete decomposition. These data are indicative of a crystallisation induced AT [see ref. 1(*c*) for a full explanation of the principles involved] rather than the formation of a thermodynamically favourable salt. The racemisation process would appear to be acid catalysed: a solution of (−)-**1** and CSA showed appreciable racemisation (diastereoisomer ratio 4 : 1) after 1 week at room temperature, whereas a solution of the free base showed minimal racemisation after 14 days, and the rate of racemisation of **1** even at 110 °C was slow ($t_{1/2}$ > 24 h at 110 °C). The crystalline material retained its original ee during the same period. It is unlikely that protonation of the secondary amine will assist rotation around the N–N bond, thus it is proposed that protonation of the quinazolinone 1-(imine) nitrogens (hence the requirement for CSA, a strong acid) and the resultant amidinium ion resonance to N-3 reduces the barrier to rotation around the N–N bond. Attempts to grow crystals containing heavy atoms suitable for the determination of absolute configuration with HBr or aqueous $CoSO_4$ led not to the respective salt/complex but to the rearranged hydrolysis product **6** (Scheme 3) as determined by single crystal diffraction.¶ This facile hydrolysis is atypical of biquinazolinones.

We thank Dr Alan Kenwright, Ian McKeag and Catherine Heffernan for VT NMR studies and Dr P. G. Steel for helpful discussions and the generous donation of materials.

Chromium bis(phosphoranimine) complexes; bridging chromium carbenes with no CO or Cp supporting ligands†

Aparna Kasani, Robert McDonald and Ronald G. Cavell*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2.
E-mail: Ron.Cavell@ualberta.ca

Received (in Bloomington, IN, USA) 29th June 1999, Accepted 27th August 1999

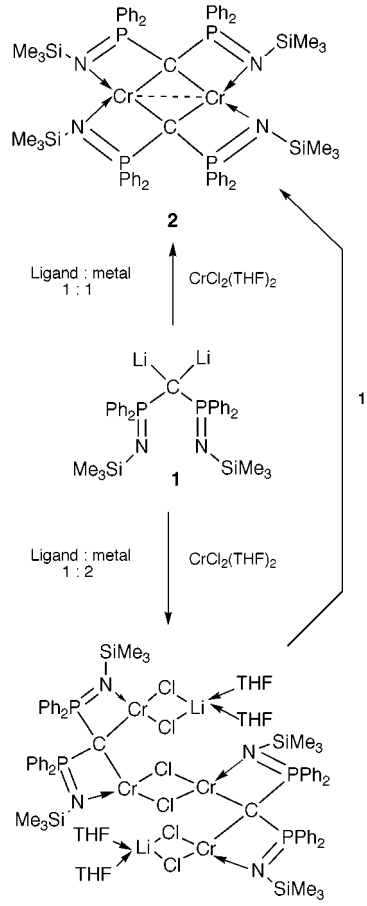
Novel dimeric and tetrametallic Cr(II) bridging carbene complexes supported by bis(phosphinimine) ligands are described.

Many carbene complexes have been synthesized since the first report by Fischer;[1] these extremely useful compounds have found widespread applications in organic synthesis and catalysis.[2–5] Chromium carbene chemistry is dominated by low-valent derivatives stabilized in general by carbonyl ligands.[6] High valent chromium carbene derivatives are rare[7–9] in contrast to the heavier group 6 metals, molybdenum and tungsten, which provide numerous examples of carbonyl-free carbene complexes.[3,4,10] Only three carbonyl-free chromium carbene complexes have been structurally characterized[11–13] although several attempts to make such chromium systems have been reported.[13–15] Here, we describe the synthesis and structure of a novel dimeric and tetrametallic carbene bridged chromium complexes obtained by a new route; the preliminary dilithiation of bis(iminophosphorano)methane[16,17] followed by the simple metathetical reaction of this salt with a metal halide. Using this and related routes we have recently prepared Ti and Zr carbene complexes.[18,19] The Cr complex described herein represents the first example of a bridging chromium carbene which is devoid of the usual carbonyl or cyclopentadienyl supporting ligands and it also represents the first example of a chromium carbene complex which contains two phosphorus substituents on the carbene carbon atom. In addition the partially substituted tetrachromium complex was also isolated and characterized.

Chromium dichloride (as the THF adduct) reacted with $Li_2\{C(Ph_2P{=}NSiMe_3)_2\}$ **1**[16,17] with elimination of 2 moles of LiCl to give $[Cr\{\mu_2\text{-}C(Ph_2P{=}NSiMe_3)_2\text{-}\kappa^4C,C',N,N'\}]_2$ **2**‡ as a paramagnetic, red, air-sensitive crystalline solid (Scheme 1). A small quantity of a green complex was also isolated from the 1:1 reaction which proved to be the partially substituted tetranuclear complex $[Cr_2(\mu\text{-}Cl)_2\{\mu_2\text{-}C(Ph_2P{=}NSiMe_3)_2\text{-}\kappa^4C,C',N,N'\}(LiCl)(THF)_2]_2$ **3**. The latter was prepared in good yield by the reaction of 0.5 molar equivalent of the ligand with the metal precursor.§ The room temperature magnetic moments for **2** and **3**, respectively, were 2.76 μ_B (for the dimer) and 6.28 μ_B (for the tetrachromium unit). The magnetic moments of **2** and **3** are too low to account for the total number of unpaired electrons for Cr(II) which suggests interaction between the metals. The Cr–Cr bond distances in **2** and **3** however are not indicative of strong metal–metal interactions.[20]

The molecular structure of $[Cr\{\mu_2\text{-}C(Ph_2P{=}NSiMe_3)_2\text{-}\kappa^4C,C',N,N'\}]_2$ **2**¶ (Fig. 1)[21] shows the complex to be a dimer with two independent molecules in the asymmetric unit. The basic framework of **2** consists a central square plane of two chromium atoms bridged by two carbene centers to form a planar Cr_2C_2 four membered, ring. The ligand backbone forms four fused, four-membered rings which are assembled from the bridging carbene carbon, the metal, the phosphorus and the imine nitrogen atoms. These four Cr, N, P, C rings arrange themselves above and below the central Cr_2C_2 plane to create a saddle-like structure in which the geometry around each Cr is approximately tetrahedral. Each of the iminophosphorane nitrogen units coordinate to the metal so that the ligand adopts a $\mu_2\text{-}\kappa^4$ coordination. The two planar four-membered metallocyclic rings in **2** which are subtended around a specific carbene center [Cr(1), N(1), P(1), C(1) and Cr(2), N(2), P(2), C(1)] and [Cr(1), N(3), P(3), C(2) and N(4), P(4), C(2), Cr(2)] make respective dihedral angles of 46.8(1) and 44.8(2)°. The two different molecules in **2** have slightly different Cr–Cr distances averaging 2.573(2) Å.

The molecular structure of the tetranuclear chromium complex $[Cr_2(\mu\text{-}Cl)_2\{\mu_2\text{-}C(Ph_2P{=}SiMe_3)_2\text{-}\kappa^4C,C',N,N'\}(LiCl)(THF)_2]_2$ **3** has been determined and substantiates the arrangement shown in Scheme 1 but is not illustrated here (see electronic supplementary information). This complex also contains carbene centers bridging two chromium atoms [Cr(1), Cr(2)] but in this case there are two types of Cr centers. One type forms a central Cr_2Cl_2 unit with a chlorine bridged Cr–Cr



Scheme 1

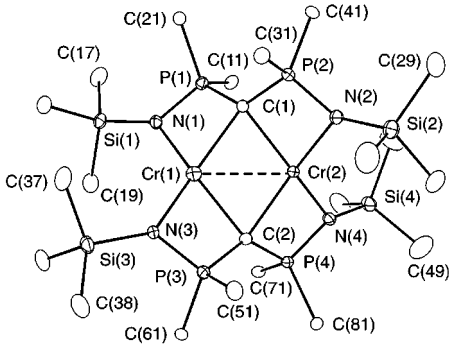

Fig. 1 An ORTEP[21] view of one of the crystallographically independent molecules of **2** showing the atom labelling scheme. The hydrogen atoms and phenyl carbon atoms except for *ipso*-C have been removed for clarity and the remaining atoms are represented by Gaussian ellipsoids at the 20% probability level. Selected interatomic distances (Å) and angles (°) for molecule A: Cr(1)–C(1) 2.148(5), Cr(2)–C(1) 2.137(5), Cr(1)–C(2) 2.150(5), Cr(2)–C(2) 2.128(5), Cr(1)–N(1) 2.103(5), Cr(1)–N(3) 2.093(5), Cr(2)–N(2) 2.091(4), Cr(2)–N(4) 2.081(4), Cr(1)–Cr(2) 2.569(1), N(1)–P(1) 1.605(5), P(1)–C(1) 1.702(6), P(2)–C(1) 1.724(6), P(2)–N(2) 1.603(5); Cr(1)–C(1)–Cr(2) 73.7(2), N(1)–Cr(1)–C(1) 76.2(2), N(2)–Cr(2)–C(1) 77.0(2), C(1)–Cr(1)–C(2) 105.7(2), P(1)–C(1)–P(2) 132.0(3), N(1)–P(1)–C(1) 105.0(3).

distance of 3.508(1) Å. Each of these Cr atoms is then also bound to a bridging carbene unit connecting it to another chromium and the distance between these carbon bridged Cr atoms is 2.9425(8) Å. The second type of Cr atom is connected to a solvated Li center *via* two chloride bridges. Imine nitrogens complete the roughly tetrahedral coordination about the Cr. There are two four-membered rings subtended from each carbene center and the dihedral angle between these two planar four-membered rings is 60.97(9)°. Both Cr–Cr distances in **3** are longer than those in **2**. The Cr–Cr distances in **2** fall in between the alkyl bridging distances in $[\{Cp^*Cr(\mu Me)\}_2(\mu\text{-}CH_2)]$ [2.394(1) Å)][12] and $[Cp^*Cr(\mu\text{-}CHSiMe_3)]_2$ [2.687(4) Å].[11] The Cr–C distances in **2** [2.137(5) Å] and in **3** [2.170(3) Å] are slightly longer than those in the aforementioned Cr(III) alkylidene complexes, 2.042(8)[12] and 2.013(12) Å[11] respectively. As expected for neutral amine coordination, the Cr–N distances in **2** and **3** are longer than observed for Cr-amide complexes.[22]

The bond distances within the bicyclic framework of both **2** and **3** are also considerably altered relative to corresponding values in free bisiminophosphoranomethane ligands;[23,24] the P=N bond distances are slightly elongated and the endocyclic P–C bond distances are significantly shorter but the exocyclic P–C bond distances are not affected. These factors suggest that there is a delocalization of π-electron density within each of the two four membered rings. The P–C–P bond angles [av. 131.7(3)° in **2** and 131.4(2) in **3**)] are significantly expanded compared to the corresponding values in $MeCH\{Ph_2P{=}N(C_6H_4Me\text{-}p)\}_2$ [112.39(19)°][23] as well as in $H_2C\{Cy_2P{=}NSiMe_3\}_2$ [117.41(12)°].[24]

Thus we have prepared and structurally characterized a novel dimeric and tetranuclear chromium carbene complexes **2** and **3** wherein the bridging carbene is supported by phosphinimines**.** Access to such complexes is straightforward given the availability of the new dilithium salt. Reactivity studies of these new carbene complexes are presently being pursued.

We thank the Natural Sciences and Engineering Research Council of Canada, NOVA Chemicals Ltd. and the University of Alberta for financial support.

Notes and references

‡ *Preparation of* **2**: all experimental manipulations were performed under rigorously anaerobic conditions using Schlenk techniques or an argon-filled glovebox. The dilithium salt $Li_2C(Ph_2P{=}NSiMe_3)_2$ **1**,[16] (0.32 g, 0.56 mmol) was added to a stirred suspension of $CrCl_2(THF)_2$ (0.15 g, 0.56 mmol) in THF (10 ml) at room temp. The reaction mixture turned green and then red. The mixture was stirred at room temp. for 2 days. The solvent was then evaporated and the residue was extracted with 8 ml of diethyl ether and filtered to remove LiCl. The diethyl ether solution was reduced to one-half volume, and the red crystalline product, which deposited at room temp. over a period of two days, was filtered off and dried under vacuum. Yield: 0.19 g, 55.6%, μ_{eff} = 2.76 μ_B.

§ *Preparation of* **3**: anaerobic techniques were used. To a stirred suspension of $CrCl_2(THF)_2$ (0.20 g, 0.75 mmol) in THF (10 ml), the dilithium salt $Li_2C(Ph_2P{=}NSiMe_3)_2$ **1**,[16] (0.21 g, 0.37 mmol) was added at room temp. The reaction mixture turned green and was stirred at room temp. for 1 day. The solvent was then evaporated and the residue was extracted with 15 ml of diethyl ether and filtered to remove LiCl. The diethyl ether solution was reduced to one-half volume 1 ml of THF was added, and the solution cooled at −15 °C for 3 days to give a green crystalline product which was filtered off and dried under vacuum. Yield: 0.21 g, 61.1%. μ_{eff} = 6.28 μ_B.

¶ *Crystal data* for **2**: monoclinic, $P2_1/n$ (a non-standard setting of $P2_1/c$, no. 14), a = 22.1588(9), b = 26.7524(12), c = 23.2798(11) Å, β = 96.410(1)°, V = 13714.0(11) Å^3, Z = 4, μ = 0.522 mm^{-1}. The structure was solved by direct methods and refined by full-matrix least squares procedures: R_1 = 0.0774 and 0.1512, (wR_2 = 0.2099 and 0.2480) for 12700 reflections with $F_o^2 \geqslant 2\sigma(F_o^2)$ and all data, respectively. $[NBnMe_3]_2[Fe_2Cu_4(SePr^i)_8Cl_2]$ and $[NBnMe_3]_2[Fe_3Cu(SePr^i)_6Cl_3]$, novel heterometallic chalcogenolate complexes with dodecahedral and octahedral selenium cages

Jörg Lackmann, Ralf Hauptmann, Stefan Weißgräber and Gerald Henkel*

Gerhard-Mercator-Universität Duisburg, Lotharstr.1, Institut für Synthesechemie, D-47048 Duisburg, Germany. E-mail: biohenkel@uni-duisburg.de

Received (in Basel, Switzerland) 25th June 1999, Accepted 17th August 1999

$[Fe_2Cu_4(SePr^i)_8Cl_2]^{2-}$, an unprecedented hexanuclear mixed iron–copper–selenolate cage complex containing a dodecahedral selenium framework and $[Fe_3Cu(SePr^i)_6Cl_3]^{2-}$, a related tetranuclear complex anion with an octahedral selenium arrangement, are described.

The chemistry of transition-metal chalcogenolate complexes continues to attract widespread attention owing to their role as synthetic analogues for the active sites of various metalloproteins such as alcohol dehydrogenase, ferredoxins, blue copper proteins or nitrogenases.[1,2] In a broader context, they display a large variety of stoichiometries and structures which have no parallels in other species. In contrast to the large number of homometallic bi- and poly-nuclear chalcogenolate complexes known so far, complexes containing different kinds of metal atoms are comparatively rare. They include $[Au_3Cu_3(SCH_2CH_2S)_4]^{2-}$,[3] $[Au_4Cu_2(SCH_2CH_2S)_4]^{2-}$,[3] $[Au_2Ag_2(SCH_2CH_2S)_4]^{2-}$,[3] $[Cu_6In_3(SEt)_{16}]^-$,[4] $[Eu_2M_2(SPh)_8(py)_6]$ (M = Cd, Hg),[5] $[Eu_2Zn_2(SPh)_8(thf)_6]$,[5] $[CuIn(ER)_4(PPh_3)_2]$ (E = S, Se)[6] and $[(PPh_3)_2Cu_2M(EC_6H_4Me)_6]$.[7,8] (M = Mo, W; E = S, Se)

Recently, we synthesized novel heterometallic thiolate complexes by reacting homometallic thiolate precursors with simple copper halides. The octanuclear complex anion $[Mn_4Cu_4S(SPr^i)_{12}]^{2-}$[9] is accessible by reaction of $[Mn_2(SPr^i)_6]^{2-}$[10] with CuCl. The mixed sulfide–thiolate compound contains a central Cu_4Mn_4 metal cube defined by interpenetrating copper and manganese tetrahedra which is stabilised by an interstitial sulfide ion and edge-bridging thiolate groups. In the case of $[Fe_3Cu(SPr^i)_6Cl_3]^{2-}$,[11] $[Fe_2(SPr^i)_6]^{2-}$ was used as the thiolate precursor. The mixed iron–copper complex has a truncated adamantane-type structure which can be derived from the structure of the parent homometallic complex of the general formula $[Fe_4(SR)_6X_4]^{2-}$ (X = Cl, Br, I, ER)[12] by replacement of a $\{FeX\}^+$ unit by Cu^+. Following this methodical approach, the chemistry of selenolate precursors under similar reaction conditions has also been investigated. In this paper, the complex anions $[Fe_3Cu(SePr^i)_6Cl_3]^{2-}$ **2** and $[Fe_2Cu_4(SePr^i)_8Cl_2]^{2-}$ **4** are described, which represent the first structurally characterized selenolate complexes containing different transition metals ions.

Both complex anions are formed in the reaction of $[NBnMe_3]_2[Fe_2(SePr^i)_6]$ with $FeCl_2$ and CuCl in acetonitrile simultaneously and were isolated as their corresponding $[NBnMe_3]^+$ salts **1** and **3** in form of light brown (**1**) or red (**3**) solids.† The structures of **1** and **3** were determined by X-ray crystallography.‡

Crystals of **1** are composed of isolated complex anions **2** and $[NBnMe_3]^+$ counter cations. They are isotypic with the corresponding sulfur derivative $[NBnMe_3]_2[Fe_3Cu(SPr^i)_6Cl_3]$ whose structural properties have already been discussed.[11] The structure of **2** is depicted in Fig. 1.

The Fe_3Cu framework of **2** is a trigonal pyramid with edges completely bridged by selenolate groups. The iron and three selenium atoms, Se(4), Se(5) and Se(6), define a compressed trigonal prism with homoatomic triangular and heteroatomic prismatic faces. The copper atom does not reside exactly within the triangular selenium face, but is shifted by 0.067 Å towards the Fe atoms (mean Cu–Fe 3.351 Å). The mean Fe–Fe and Se–Se distances within the Fe_3Se_3 prism are 4.051 and 4.066 Å, respectively, whereas the Fe–Se distances are much smaller (mean value 2.471 Å).

The complete set of selenium atoms are arranged in a distorted octahedral fashion. With edge lengths of 4.322 Å the triangle Se(1)–Se(2)–Se(3) is significantly larger than the opposite one [Se(4)–Se(5)–Se(6), mean edge length 4.066 Å]. The first triangle is neither capped by a $\{FeCl\}^+$ unit nor centered by Cu^+. The triangles Se(1)–Se(3)–Se(4), Se(1)–Se(2)–Se(5) and Se(2)–Se(3)–Se(6) are capped by $\{FeCl\}^+$ units, achieving an idealised C_3 symmetry of **2**. Each iron atom has a distorted pseudo-tetrahedral $FeSe_3Cl$ coordination with selenium atoms in metal bridging positions and a terminal chloride ligand. The average Fe–Se distance of 2.471 Å is very close to the value of 2.463 Å found in $[Fe_2(SePr^i)_6]^{2-}$.[13]

The complete anionic entity **2** can also be considered as being composed of the complex anion $[Fe_3(SePr^i)_6Cl_3]^{3-}$ and a Cu^+ cation which is probably needed to stabilise the structure.

Trigonal-planar $CuSe_3$ as well as pseudo-tetrahedral $FeSe_3Cl$ coordination sites related to those observed in **2** are also characteristic constituents of the hexanuclear complex anion **4** (Fig. 2).

In contrast to **2** which contains an octahedral selenium framework, the selenium atoms in **4** define a triangulated dodecahedron. This dodecahedron [Fig. 3(a)] is composed of two interpenetrating tetrahedra, a compressed one consisting of Se(1), Se(4), Se(7) and Se(8) (atom type A) and an elongated one consisting of Se(2), Se(3), Se(5) and Se(6) (atom type B). The Cu atoms occupy one of the two tetrahedral sets of four triangular faces of the dodecahedron which are defined by one B and two A type selenium atoms. One half of the four triangular faces defined by one A and two B type selenium atoms are capped by $\{FeCl\}^+$ units.

From another point of view, the Cu atoms bridge the four short edges of the compressed tetrahedral substructure defined

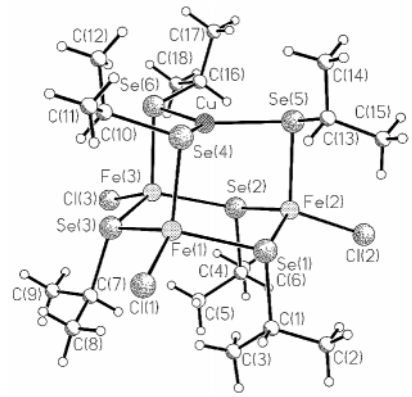

Fig. 1 $[Fe_3Cu(SePr^i)_6Cl_3]^{2-}$: molecular structure with atomic labels.

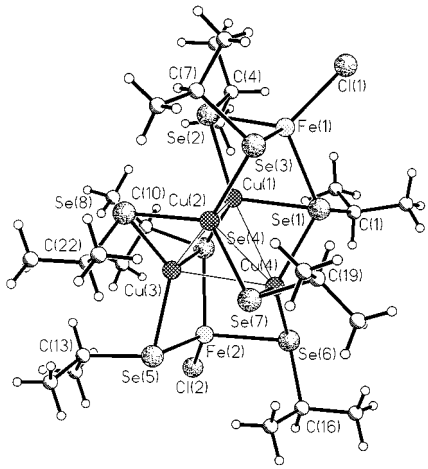

Fig. 2 $[Fe_2Cu_4(SePr^i)_8Cl_2]^{2-}$: molecular structure with atomic labels.

by the four A type selenium atoms and form an additional bond each to a B type selenium atom of the elongated tetrahedral substructure.

The Cu–Cu distances range from 2.656(6) to 2.988(8) Å, whereas the Fe(1)–Cu(1) and Fe(2)–Cu(2) distances are 2.748(7) and 2.853(8) Å, respectively. The mean Fe–Se distance is 2.469 Å. This value is very close to the values of 2.471 Å found in **2** and 2.463 Å found in $[Fe_2(SePr^i)_6]^{2-}$.[13]

The remarkable condensation principle observed here, for the first time, leads to two novel μ_3-selenolate bridges which connect two different metal types (Cu_2Fe). In addition, four heterometallic μ-selenolate bridges (CuFe) are also present. The two Cl^- ions are non-bridging in nature and expand the ligand spheres of the Fe atoms towards slightly distorted $FeSe_3Cl$ tetrahedra.

The complex anion **4** can formally be expanded by introducing two further $\{FeCl\}^+$ groups capping the remaining two triangular faces defined by one A and two B type selenium atoms [Se(2), Se(3), Se(8) and Se(5), Se(6), Se(7)]. The structure of the corresponding hypothetical electroneutral $[Fe_4Cu_4(SePr^i)_8Cl_4]$ molecule is shown in Fig. 3(b) (the additional $\{FeCl\}^+$ groups are drawn with open bonds). This complex contains two $\{Fe_2(\mu\text{-}SePr^i)_2(SePr^i)_2Cl_2\}$ subunits whose structural properties are very similar to those observed in the binuclear complexes of general formula $[Fe_2(\mu\text{-}SR)_2(SR)_4]^{2-}$ (R = Me, Et, Pr^i, *c*-C_6H_{11}, Bu^t).[14] These subunits are linked with the central Cu_4 tetrahedron *via* selenolate bridges. Further expansion of the metal–selenium cage by adding Cu^+ ions or $\{FeCl\}^+$ subunits to the metal-free triangular faces of the selenium dodecahedron defined by one A and two B type atoms is not possible owing to strong repulsions.

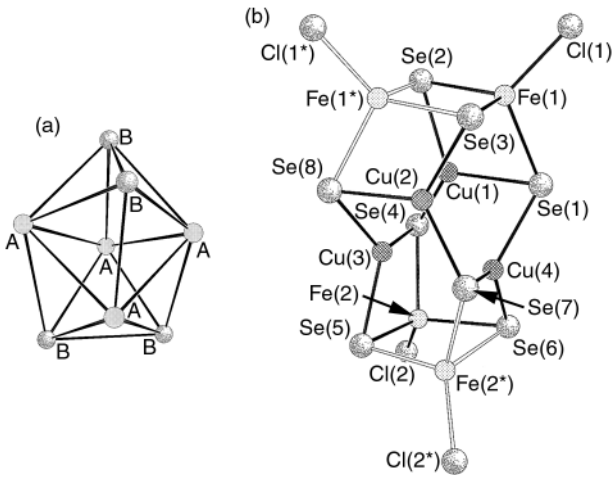

Fig. 3 (a) The triangulated Se_8 dodecahedron of $[Fe_2Cu_4(SePr^i)_8Cl_2]^{2-}$ showing the tetrahedral substructures defined by A and B type selenium atoms. (b) Structure of the hypothetical complex $[Fe_4Cu_4(SePr^i)_8Cl_4]$ (alkyl groups omitted, additional atoms marked with asterisk).

In summary, we have prepared and structurally characterised the first mixed-metal iron–copper–selenolate complexes containing octahedral (**2**) and novel triangulated dodecahedral (**4**) selenium frameworks.

Financial support from the Deutsche Forschungsgemeinschaft (DFG), from the Bundesminister für Bildung, Wissenschaft und Forschung (BMBF) and from the Fonds der Chemischen Industrie is gratefully acknowledged.

Notes and references

To a solution of $[NBnMe_3]_2[Fe_2(SePr^i)_6]$ (2.86 g, 2.5 mmol) in MeCN (40 ml) was added 0.32 g of $FeCl_2$ (2.5 mmol) followed by addition of 0.25 g of CuCl (2.5 mmol) under stirring. The solution changed from black–brown to orange–brown, the suspension was stirred for 24 h, and the black residue was filtered off. The filtrate was reduced in volume (*ca.* 20 ml). Dark red platelets of **1** and light brown columns of **2** were obtained in a 9:1 molar ratio after diffusion of *ca.* 20 ml of diethyl ether into the solution.

Received (in Cambridge, UK) 2nd July 1999, Accepted 3rd September 1999

Reaction of dialkylphosphonates with zirconium salts in acidic aqueous media provides a facile route to crystalline hybrid zirconium phosphonate materials.

Since the first synthesis of a layered zirconium phosphonate,[1] many other layered materials involving different metals [M(IV) or M(II)] have been synthesised. Some of these materials may have practical applications as supported catalysts,[2] protonic conductors[3] and molecular sieves.[4] These materials which possess a well ordered structure, are synthesised by reaction of a phosphonic acid with a metal(IV) or a metal(II) source in water or sometimes with an organic co-solvent. In order to increase the crystallinity of these materials, the addition of a mineralising agent (HF) or the use of hydrothermal conditions[5] can be employed.

Phosphonic acids, which form the necessary precursor to synthesise metal phosphonate materials, are generally obtained by reaction of a phosphonate with either a hydrogen halide (HCl, HBr) in aqueous medium or by using the method of McKenna *et al.*[6] These phosphonates are easily obtained by the Arbusov reaction[7] or by a palladium or nickel assisted phosphonation when aromatic phosphonates are required.[8] It is worth noting that, unlike dialkylphosphonates, the purification of phosphonic acids can not be readily achieved using chromatographic or distillation methods. Owing to their strong polarity and the formation of strong intermolecular hydrogen bonds.

With the aim of avoiding the prior synthesis of phosphonic acids, we report here an easy method to synthesise hybrid metal phosphonate materials by using phosphonates instead of phosphonic acids as precursors.

In a preliminary result (entry 1, Table 1) zirconium bis(methylphosphonate) **5** was obtained in quantitative yield from the reaction of dimethyl methylphosphonate **1** with zirconyl chloride **4** in an acidic aqueous solution (9 M HCl) under reflux for 24 h . This first result indicates that methyl phosphonic acid, which is progressively produced *in situ* by hydrolysis of phosphonate **1**, reacts immediately with zirconyl chloride **4** to yield **5** in quantitative yield.† Analyses of material **5** (microanalyses, XRD powder diffraction pattern, IR), as synthesised from phosphonate **1** or from phosphonic acid **2** (Alberti's method) are identical.‡ It is interesting that the microanalysis of material **5** does not show any increase in carbon content that might come from the phosphonate function. This observation indicates that the hybrid material does not contain any product resulting from monohydrolysis of phosphonate **1**.

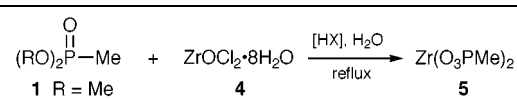
Taking into account this interesting result, the influence of experimental conditions on crystallinity of **5** has been studied. Powder XRD patterns and surface area data (BET) were used to obtain information about the degree of crystallinity of the materials. In particular, BET analysis is an interesting indicator of the crystallinity and granulometry of resulting materials. In a previous study, concerning zirconium bis(methylphosphonate) **5**, a direct relationship between the crystallinity and specific area was demonstrated (greater crystallinity leads to a smaller surface area).[9]

The use of HBr (entry 2, Table 1) instead of HCl (entry 1) affords after refluxing for 24 h, a poorly crystalline sample of material **5** (S_{BET} = 378.1 m^2 g^{-1}). This observation may be explained by the well known difference in the affinity of chloride and bromide ions for Zr(IV) (Cl > Br).[10] Furthermore, bromide is a better nucleophile than chloride and this property enhances the kinetics of the hydrolysis of phosphonate to phosphonic acid. Both factors, *i.e.* the greater affinity of HCl towards Zr and the slower hydrolysis of phosphonate by use of HCl, contribute to a decrease in the rate of reaction between phosphonic acid and Zr(IV), leading to more crystalline hybrid materials.

In order to compare the influence of the substrate (phosphonate or phosphonic acid), on the crystallinity of the resulting material, **5** was synthesised from both precursors dimethyl methylphosphonate **1** (entry 1) and methylphosphonic acid **2** (entry 3) under identical experimental conditions. The materials obtained from both experiments exhibit the same characteristics (IR, microanalyses) with the exception of their specific area. The use of phosphonate **1** leads to a slightly more crystalline material (S_{BET} = 96.6 m^2 g^{-1}) compared to the material obtained from the corresponding phosphonic acid **2** (S_{BET} = 119.0 m^2 g^{-1}).

Using diethyl methylphosphonate **3** (entry 4) in a 24 h reflux experiment leads to a sample of **5** that is less crystalline compared to that prepared using dimethyl methylphosphonate **1** (entry 1). From these results it appears that dimethylphosphonate is the best choice when short refluxing times are required.

Table 1 Reaction of phosphonates **1**–**3** or phosphonic acid **2** with zirconyl chloride **4** leading to compound **5**



Entry	Substrate	[HX]/M	*t*/h	Mole ratio **1**, **2** or **3**/Zr	S_{BET} (**5**)/m^2 g^{-1}
1	**1**	9[a]	24	3	96.6
2	**1**	9[b]	24	3	378.1
3	**2**	9[a]	24	3	119.0
4	**3**	9[a]	24	3	249.2
5	**1**	12.2[a]	24	3	86.0
6	**1**	12.2[a]	24	1.66	38.4
7	**2**	12.2[a]	24	1.66	26.0
8	**1**	12.2[a]	112	1.66	27.6
9	**1**	9[a]	112	1.66	28.8
10	**1**	3[a]	112	1.66	62.3
11	**1**	0[c]	112	1.66	203.4

[a] HCl. [b] HBr. [c] Water was used as solvent.

Since it is often the aim to synthesise hybrid materials possessing functionalised pendant organic groups (chiral molecules[11] or ligands), it is worth considering the effect of using an excess of metal salt, in order to avoid the loss of costly organic substrate. By using an excess of zirconyl chloride we observed that the phosphonate/Zr ratio has a great influence on the crystallinity of the resulting material. Indeed, a slight excess of zirconyl chloride (1.2 equiv.) yields a more crystalline sample of material **5** (entry 6, S_{BET} = 38.4 $m^2\ g^{-1}$) when compared to the use of an excess of phosphonate (entry 5, S_{BET} = 86.0 $m^2\ g^{-1}$). By using the same excess of zirconyl chloride, it appears that the use of phosphonic acid leads to a material **5** with a slightly better crystallinity (entry 7, S_{BET} = 26.0 $m^2\ g^{-1}$) compared to the use of dimethyl methylphosphonate **1** (entry 6, S_{BET} = 38.4 $m^2\ g^{-1}$).

Finally the effect of HCl concentration upon the crystallinity of **5** was investigated. When **5** was synthesised by using a high concentration of HCl (> 9 M) the same surface areas (S_{BET} = 28 $m^2\ g^{-1}$) were obtained (entry 8 and 9) while the use of a 3 M HCl solution (entry 10) yields a less crystalline material (S_{BET} = 62 $m^2\ g^{-1}$). In absence of acid (entry 11) the same material **5** was isolated in quantitative yield and characterised by IR, microanalysis and XRD powder pattern. However, BET analysis (203.4 $m^2\ g^{-1}$) indicated a poorly crystalline material. Despite the pH of the solution in this experiment being clearly acidic (pH = 1) owing to zirconyl chloride, the concentration of HCl was low (0.3 M) compared to experiments carried out in 9 M HCl. The synthesis of hybrid materials using a very low concentration of HCl could be useful when precursors are sensitive to strong acidic solutions such as when ether or cyano functions are used.

Fig. 1 shows some powder X-ray diffractograms for materials **5**, which corroborate the results obtained by BET measurement.

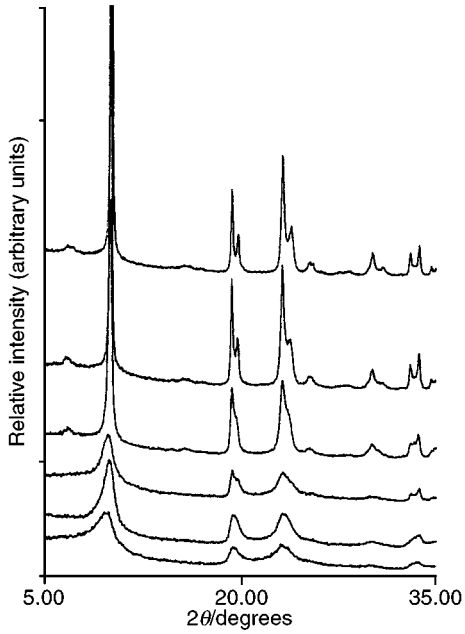


Fig. 1 Powder X-Ray diffractograms for material **5** corresponding to experiments detailed in Table 1: (a) entry 5, (b) entry 13, (c) entry 6, (d) entry 7, (e) entry 11, (f) entry 8. Corresponding BET surface areas ($m^2\ g^{-1}$: (a) 249.2, (b) 203.4, (c) 86.0, (d) 38.4, (e) 28.8, (f) 26.0.

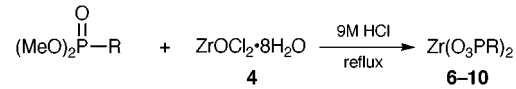
This new method is compatible with the use of other phosphonates. Materials **6** and **7** (Table 2) prepared by this method are identical to those prepared previously by other synthetic routes. In the case of compound **7**, a pillared structure was obtained. In addition, novel materials **8**–**10**, have been synthesised by using this method and were fully characterised.

The access to new zirconium phosphonate materials shows the advantage of using a phosphonate directly rather than a phosphonic acid. Thus the number of steps to produce the necessary organic substrate is reduced and its purification can be more easily accomplished. Furthermore, very slight differences, in terms of crystallinity, have been observed between this new method and that using phosphonic acid. It has also been demonstrated that this new method is suitable for the use of different phosphonates and diphosphonates to give either layered or pillared structures.

Table 2 Synthesis of layered zirconium phosphonates **6**–**10**



Entry	R	Product	Interlayer distance/Å
1	CH_2CO_2H[a]	**6**[a]	11.1 (Lit.[12] 11.1)
2[c]	$CH_2C_6H_4CH_2$	**7**[d]	10.9 (Lit.[13] 10.8)
3	CH_2Ph	**8**[b]	15.8
4	Et	**9**[b]	10.8
5	CCl_3	**10**[b]	11.5

[a] Ethyl dimethylphosphonoacetate was used as substrate but hydrolysis of the ester function leads to carboxylic functionalities in the interlayer space. [b] n = 2. [c] Dimethyl α,α′-*p*-xylenediphosphonate was used and a pillared structure was obtained. [d] n = 1.

We would like to thank Monique Duyme (UMR-CNRS 6506) for BET measurements.

Synthesis and reaction of 1,4-acetal-bridged 2,3,5,6-tetramethylidene-bicyclo[2.2.0]hexane: the first Diels–Alder route to Dewar benzenes

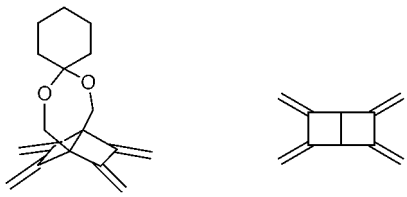
Masakazu Ohkita, Takanori Suzuki and Takashi Tsuji*

Division of Chemistry, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan. E-mail: tsuji@sci.hokudai.ac.jp

Received (in Cambridge, UK) 2nd August 1999, Accepted 3rd September 1999

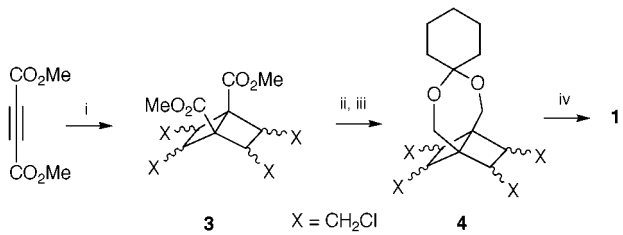
The 1,4-acetal-bridged derivative of hitherto unknown 2,3,5,6-tetramethylidenebicyclo[2.2.0]hexane, which produces the Dewar benzene skeleton through two successive Diels–Alder reactions with dienophiles, has been synthesized in four steps from dimethyl acetylenedicarboxylate and 1,4-dichlorobut-2-ene.

In the course of our studies on the chemistry of highly strained cyclophanes generated from the corresponding Dewar derivatives,[1] we were interested in developing a new general method for the preparation of Dewar benzenes,[2] especially a versatile one that is applicable to the synthesis of Dewar isomers of polyacenes.[3] An intriguing possibility is the application of hitherto unknown 2,3,5,6-tetramethylidenebicyclo[2.2.0]hexane skeleton **2**[4] because its two successive Diels–Alder reactions with dienophiles formally produce a Dewar benzene structure and subsequent dehydrogenation of the two six-membered rings thus formed would give the corresponding 9,10-Dewar anthracene skeleton. We designed a 1,4-acetal-bridged derivative **1** to prevent an undesired aromatization of the Dewar benzene product under the thermal cycloaddition conditions. Here we report an efficient synthesis of **1** and its Diels–Alder reaction with dienophiles, which represents the first preparation of a Dewar benzene structure by a Diels–Alder reaction.



1 **2**

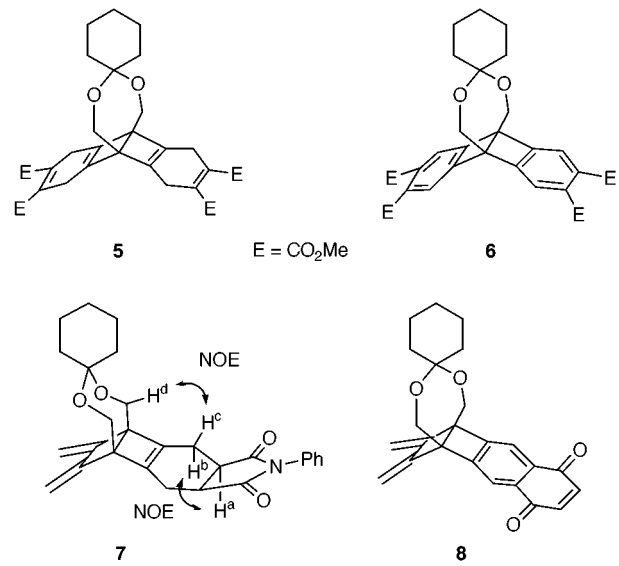
The synthesis of **1** is simple and straightforward (Scheme 1).† Thus, irradiation of dimethyl acetylenedicarboxylate (DMAD) in 1,4-dichlorobut-2-ene with a high-pressure mercury lamp at 12 °C afforded a mixture of bicyclo[2.2.0]hexane derivatives **3** in 32% yield. $LiAlH_4$ reduction of the esters **3** followed by treatment of the resultant diols with 1,1-dimethoxycyclohexane under the influence of a catalytic amount of TsOH provided cyclohexylidene acetal **4** in 48% yield. Quadruple dehydrochlorination of **4** with *t*-BuOK in the presence of 18-crown-6 at room temperature afforded desired **1** in 78% yield as a colorless oil. Compound **1** is prone to polymerization, as has been observed in other bisdiene systems,[5] but shows adequate stability to allow its chromatographic purification and spectroscopic characterization.‡



3 X = CH_2Cl **4**

Scheme 1 *Reagents and conditions*: i, *hν*, 1,4-dichlorobut-2-ene, 12 °C, 32%; ii, $LiAlH_4$, Et_2O, 90%; iii, 1,1-dimethoxycyclohexane, TsOH, benzene, 40%; iv, *t*-BuOK, 18-crown-6, THF, room temp., 78%.

Reaction of **1** with DMAD proceeded smoothly in benzene at 65 °C to afford 1:2 adduct **5** in 65% yield. The structure of **5** was confirmed by X-ray structural analysis (Fig. 1), which clearly indicates a Dewar benzene structure along with nearly flat cyclohexa-1,4-diene rings and a seven-membered acetal ring adopting a twist conformation in the solid state.§ Dehydrogenation of **5** to 9,10-Dewar anthracene derivative **6** was accomplished (87% yield) with activated MnO_2 in benzene at room temperature. Reaction of **1** with *N*-phenylmaleimide (65 °C,



5 E = CO_2Me **6**

7 **8**

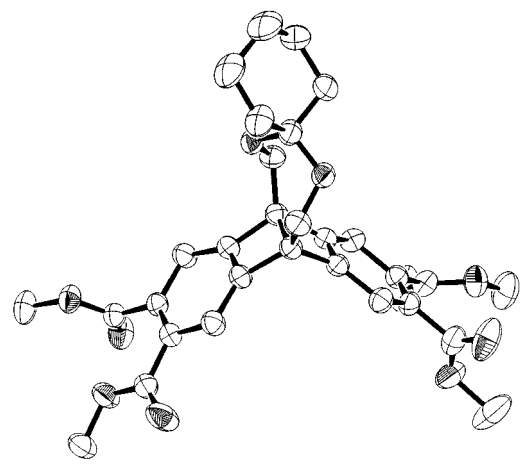


Fig. 1 Molecular structure of **5**. Hydrogen atoms are omitted for clarity.

4 h) gave **7** in 75% yield as a major product, whose stereochemistry was determined by examining the NOESY spectrum; H^c which is *trans* to H^a exhibits a NOE with H^d. The formation of **7** may be most reasonably explained by the *exo*-orientation approach of the dienophile from the *endo*-face of **1**. Reaction of **1** with benzo-1,4-quinone (65 °C, 44 h) followed by successive treatment of the adduct with DDQ in acetonitrile and activated MnO_2 in benzene afforded **8**, a possible precursor for cyclic polyacenequinone derivatives, in 55% yield.

In summary, we have successfully developed a novel Diels–Alder route to Dewar benzenes as well as Dewar polyacenes by introducing **1** as a new bisdiene molecule. Further elaboration and an application of the present method to the syntheses of novel cyclophanes as well as polyacenes are the subjects of our ongoing study.

This work was supported in part by a Grant-in-Aid for Scientific Research (No. 09640620) from the Ministry of Education, Science, Sports, and Culture of Japan. We thank Professor Tamotsu Inabe (Hokkaido University) for the use of X-ray analytical facilities.

Selective adsorption of oligonucleotides on switchable self-assembled monolayers

Börje Sellergren,*[a] Frank Auer[a] and Thomas Arnebrant[b]

[a] *Department of Inorganic Chemistry and Analytical Chemistry, Johannes Gutenberg University, Mainz, Duesbergweg 10-14, 55099 Mainz, Germany. E-mail: borje@ak-unger.chemie.uni-mainz.de*

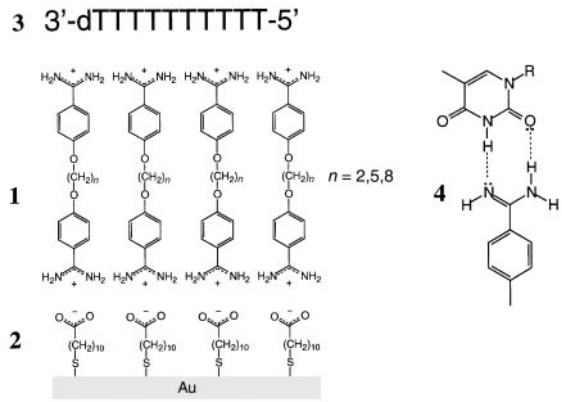
Received (in Cambridge, UK) 28th June 1999, Accepted 31st August 1999

Short oligonucleotides adsorb rapidly and selectively on pH-switchable self-assembled layers of bisbenzamidines on modified gold substrates.

Today's methods of gene analysis require rapid detection of specific DNA or RNA base sequences present in small amounts in complex mixtures.[1] These commonly make use of pre-synthesized probe oligonucleotides or oligonucleotide analogues[2] capable of hybridizing specifically to the sequence of interest.[3] Different techniques for detection of the hybridization reaction are available. These can rely on either the use of labeled probes,[3] *e.g.* radioactive, fluorescent and chemiluminescent, or the use of unlabeled probes where the probe usually is covalently bound to a surface and the hybridization reaction is detected microgravimetrically,[2,4] optically[5,6] or electrochemically.[7] The chemical modification of the probe required in these techniques may cause problems such as *e.g.* slow or nonspecific hybridization reactions and, in the case of sensors, may prevent their reuse.

Techniques for reversible attachment of the probe to the surface would be attractive in this regard. We report here a system for base-selective and reversible adsorption of nucleic acids to a surface reflected in layer thickness changes that can be detected optically.

The system is based on α,ω-bis(4-amidinophenoxy)alkanes **1**



that we previously showed form stable ordered pH-switchable layers on gold or modified gold substrates.[8,9] In view of the DNA binding properties of the bisbenzamidines[10,11] we decided to investigate whether the amidine layers exhibit selectivity for oligonucleotides enriched in one particular base or whether the system can be used to detect DNA hybridization. First we compared the adsorption of a 10-mer of deoxythymidylic acid (T10) **3** using three bisbenzamidines with different alkyl chain lengths (Table 1). The bisbenzamidines gave rapid increases in layer thickness where, for the longer amidines, the final thickness approached the molecular length corresponding to an extended conformation of the amphiphile.[9] A marked increase in the layer thickness was thereafter produced upon addition of the oligonucleotide. The change in thickness increased with the molecular length of the bisbenzamidine. It is known that bisbenzamidines interact with and may precipitate nucleic acids,[12] suggesting that the film formation is related to the different solubilities of the amidine–nucleic acid pairs. However, no visible precipitation was observed in the experiments and the changes in film thickness observed with SiO_2 surfaces under otherwise identical conditions were negligible. This was also the case when performing the experiment on the bare MUA SAM, leaving out the amidine. A preadsorbed amidine layer is thus necessary for the additional DNA layer buildup.

It is seen in Fig. 1 that the bands characteristic for the amidines are present in the IR absorption spectra of the SAM modified with **1** (n = 5). The position and intensities of the bands corresponding to N–H and O–H stretching vibrations (at *ca*. 3159 and 3355 cm^{-1}) show that the amidine groups are involved in hydrogen bonding, presumably with the SAM carboxylic acid head groups.[9] A comparison of the intensities of the bands corresponding to the C–H out-of-plane bending vibration (840 cm^{-1}, weak) and the ring C=C stretching vibration (1611 cm^{-1}, strong) further shows that this amidine prefers an orientation with the phenyl groups oriented nearly perpendicular to the surface.[9] After adsorption of the oligonucleotide additional bands appeared. The main change was the appearance of bands assigned to the phosphate groups at 1000–1270 cm^{-1}, the increase in intensity and broadening of the band corresponding to the N–H and O–H stretching to lower frequencies and the reduced intensity of the ring C=C stretching vibration parallel to an increase in intensity of the C–H out-of-plane vibration. These observations indicate further extensive hydrogen bonding in the adsorbed DNA layer as well as a

Table 1 Layer thicknesses upon consecutive addition of bisbenzamidines and a 10-mer DNA oligonucleotide to a self-assembled monolayer (SAM) of mercaptoundecanoic acid (MUA) on gold[a]

	Layer thickness/Å			
DNA oligo-nucleotide[b]	**1** (n = 5)		**1** (n = 8)	
	amidine[c]	DNA[d]	amidine[c]	DNA[d]
T10[e]	13 ± 1	14 ± 2	23 ± 1	33 ± 3
C10	12 ± 0	2 ± 1	24 ± 2	3 ± 3
G10	14 ± 1	11 ± 1	24 ± 3	2 ± 1
A10	14 ± 1	1 ± 1	25 ± 5	12 ± 1

[a] The substrates were then immersed in a quartz ellipsometric cuvette containing 5 ml sodium borate buffer (0.01 M, pH 8.7, prepared from boric acid) thermostatted to 25 °C and equipped with a small magnetic stirrer and a pH electrode. Adsorption of compounds were then monitored *in situ* by null ellipsometry (ref. 8,9) assuming a film refractive index of 1.45. The reported values were determined when the change in the polariser angle had levelled off. After one experiment the surfaces were restored by adjusting the pH to 2–3 with 0.1 M HCl followed by rinsing with water. [b] 10-mer DNA oligonucleotides of deoxythymidylic acid (T10), deoxycytidylic acid (C10), deoxyguanylic acid (G10) and deoxyadenylic acid (A10). [c] Increase in layer thickness *ca*. 200 s after addition of **1** (n = 5) or **1** (n = 8) (100 μl of a 2.5 mM stock solution). [d] Increase in layer thickness 200–300 s after addition of the oligonucleotide (5 μl of a 0.5 mg ml^{-1} stock solution) to the solution described in note *c*. The spread of the thickness values from duplicate runs has been indicated. [e] Using **1** (n = 2) the layer thickness of **1** was 11 ±1 Å and of T10 was 5 ±1 Å.

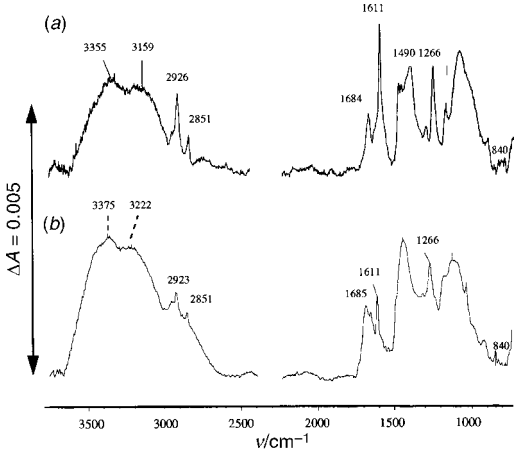


Fig. 1 Baseline corrected IR reflection absorption spectra of SAMs of MUA modified with (*a*) **1** (*n* = 5) and (*b*) **1** (*n* = 5) and a 15-mer random sequence DNA oligonucleotide.

change in the average tilt angle of the phenyl groups, the latter effect possibly due to adsorption of additional randomly ordered amidine molecules or an induced disorder of the SAM.

Table 1 shows the estimated final layer thicknesses upon addition of **1** (*n* = 5) or **1** (*n* = 8) in a first step and a 10-mer oligonucleotide in a second step. A striking difference in DNA base selectivity is seen when comparing the two amidines. Compound **1** (*n* = 5) binds preferentially T10 and G10 whereas **1** (*n* = 8) shows affinity for T10 and A10. Thus exchanging **1** (*n* = 5) with **1** (*n* = 8) in the second layer changes the base preference from G10 to A10. It should be noted that Brønsted basic head groups in close-packed monolayers, due to electrostatic effects, may be significantly less basic than the corresponding base in solution.[13,14] At the pH of the experiment, a proportion of the amidine groups may thus be uncharged. These groups may offer complementary binding sites for thymine resulting in the binding motif **4** similar to the one proposed to occur in a Langmuir–Blodgett film of guanidine and thymine functionalized amphiphiles at the air water interface,[15] or between thymine and amidine in complexes between ds-DNA and bisbenzamidines.[10]

In order to investigate whether the consecutive addition protocol could be used to detect DNA hybridizations, we used a 10-mer probe[4] with a sequence complementary to the *Eco*R1 binding site of single stranded M13 phage DNAs (7249 base pairs). In order to test the selectivity, four 10-mer oligonucleotides with a varying number of mismatches were used. As seen in Fig. 2 the adsorption of the probe sequence (DNA 1) gave an

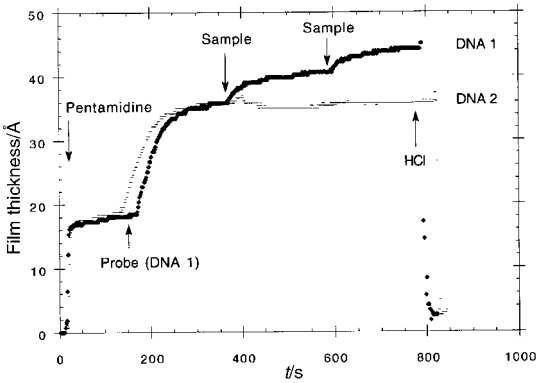

Fig. 2 Film thickness, estimated by *in situ* ellipsometry, *versus* time after the consecutive addition of **1** (*n* = 5), a 10-mer DNA probe (5 μl of a 0.5 mg ml^{-1} stock solution) and a sample oligonucleotide (2 × 5 μl of a 0.5 mg ml^{-1} stock solution) to a SAM of MUA on gold, as described in Table 1. The following DNA sequences were used with the number of antiparallel mismatches given in parantheses. Probe sequence: DNA 1: 3′-dTGCTTAAGGG-5′ (4); sample sequences: DNA 2: 3′-dCCCTTAAGCA-5′ (0); DNA 3: 3′-dCCCTGAAGCA-5′ (1); DNA 4: 3′-dAGCCGTACCC-5′ (7). The changes in layer thickness caused by the sample oligonucleotides were as follows: DNA 1: +9 Å; DNA 2: 0 Å; DNA 3: +3 Å; DNA 4: +9 Å. The spread of the thickness values from duplicate runs was less than 2 Å.

increase in film thickness of *ca.* 17 Å. Subsequent additions of the probe, as sample sequence, resulted in an additional 9 Å increase in film thickness. Adding instead a fully complementary sample sequence (DNA 2) resulted in no change or a slight decrease in layer thickness. A more pronounced decrease in the layer thickness was observed when adding a larger amount of DNA 2. Thus adding five times more DNA 2 resulted in a decrease in layer thickness of about 5 Å. The larger the number of mismatches, the larger the increase in film thickness caused by the sample sequence.

Additional control experiments were performed. The probe layer thickness depended on the sequences of the probe. For instance whereas sequences 1 and 4 (in Fig. 2) gave an increase in thickness of about 16 Å, sequences 2 and 3 resulted in an increase of about 10 Å. However, in the hybridization test, probe sequences giving similar thicknesses responded in accordance with the number of mismatches in the chain. Thus when adding sequence 1 to a surface saturated with DNA 2, 3 or 4, an additional increase in thickness of 1, 5 and 7 Å respectively was observed. Finally, regardless of the order of addition of the oligonucleotides the same end thickness was observed. This indicates a reversible adsorption process with a rapid exchange of adsorbates. As in the case of the adsorption of homo-oligonucleotides the molecular basis for the observed thickness changes remains obscure. The behaviour contrasts with what is commonly observed in hybridzation reactions using probes covalently bound to the surface.[2,4,6] In these cases, hybridization results in an increase in layer thickness. It is likely that rigid rod like double stranded DNA adsorbs more weakly or in a more compact conformation to the surface than more flexible single stranded DNA. The latter may more easily adjust its conformation to maximize the attractive interactions with the surface amidine groups.

The above results show that self-assembled monolayers of bisbenzamidines can be used for base selective binding of nucleic acids. Our future studies will show whether the system can be extended to polynucleotides and complex PCR products. Alternatively the protocol may be useful in studies of drug–DNA or protein–DNA interactions.

Copper(II), in the parts per million range, modulates photochemical and photosensitizing properties of tolmetin *via* electron transfer with a triplet carbanion

S. Sortino,*[ab] J. C. Scaiano,[b] G. De Guidi[a] and L. L. Costanzo[a]

[a] *Dipartimento di Scienze Chimiche, Università di Catania, Viale Andrea Doria 8 I-95125 Catania, Italy. E-mail: ssortino@dipchi.unict.it*

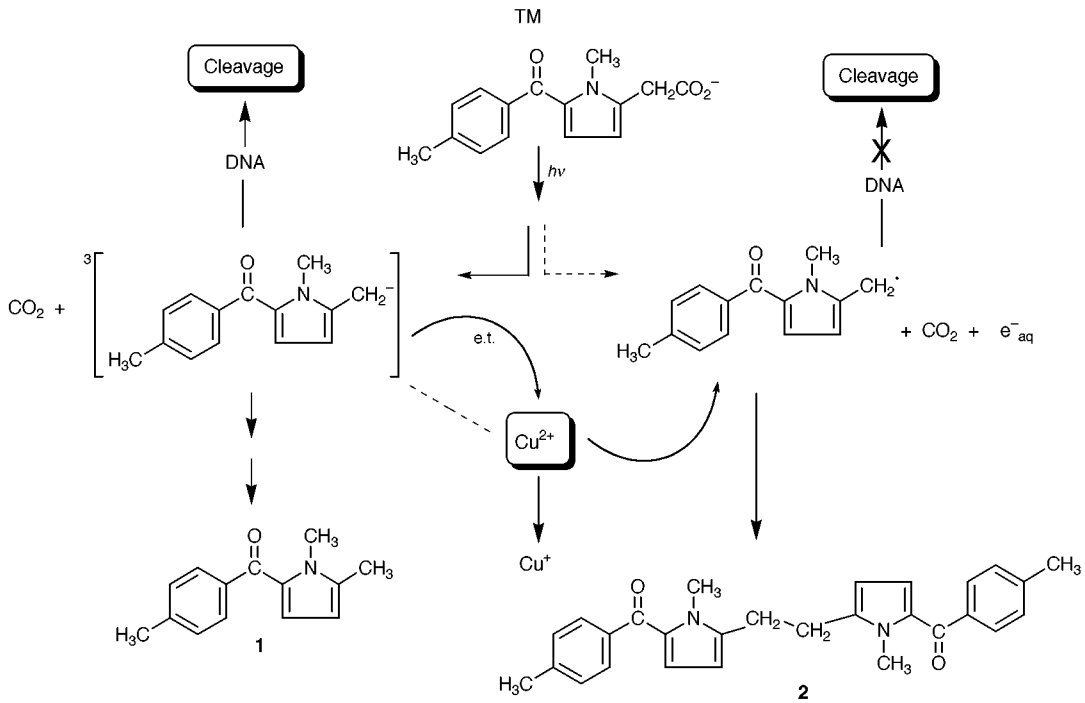
Received (in Cambridge, UK) 4th August 1999, Accepted 31st August 1999

Copper(II), at very low levels of concentration, modulates the distribution of tolmetin stable photoproducts as well as inhibits the DNA cleavage photoinduced by the drug, *via* a highly efficient electron transfer process with the main transient species generated in the tolmetin photolysis.

Tolmetin, 2-[5-(*p*-toluoyl)-1-methylpyrrol-2-yl]acetic acid (TM), is a non-steroidal anti-inflammatory drug (NSAID) and is known to induce toxic effects on biosubstrates which can be associated with light exposure.[1–3] Like other NSAIDs,[4,5] a photodecarboxylation reaction is believed to be responsible for the TM photoinduced damage.[3] In light of this, the problem of finding suitable bio-compatible devices which may control drug photodegradation and, as a consequence, exert a photoprotective action towards the photoinduced damage, is receiving growing attention. Our previous work pointed out that the use of metal ions at very low concentrations may represent a valid tool in inhibiting toxic effects photoinduced by drugs,[6–9] as well as a potential strategy for modulating the photochemical pathways involved in drug photodegradation. Furthemore, patents concerning copper(II) compounds with antioxidant activity have been registered.[10–12] Despite encouraging experimental results, the role played by the metal ions in this field is still unclear and complex. On the basis of these considerations we proposed to elucidate the role of copper(II) in the photochemistry of TM and on its photosensitizing activity towards DNA by combining steady-state and time-resolved techniques. Recent studies on the transient photochemistry of this drug have pointed out that TM photodecarboxylation is triggered by a short-lived excited triplet state involving a triplet carbanion as the key intermediate in the photodecomposition.[13,14] Stable photoproduct **1** is formed. A minor pathway, consisting of a photoionization process followed by fast decarboxylation and formation of a dimeric species such as stable photoproduct **2**, was also noticed (Scheme 1).

The results of the HPLC analysis of a nitrogen saturated, irradiated TM solution at pH 7.4 led to the photoproduct distribution shown in Fig. 1. As shown, addition of copper(II) in the micromolar range does not influence the photodegradation efficiency of the starting compound but provokes remarkable changes in the distribution of the two photoproducts. It can be seen that the reduction of the photoproduct **1** is accompanied by a corresponding increase in the amount of photoproduct **2**.

Since the photodegradation quantum yield is unaffected by the metal ion, the behavior observed accounts for the reaction between copper(II) and the transient intermediates formed in the TM photolysis. Inasmuch as the increase of the percentage of the photoproduct **2** has to involve an increase in the pyrrolyl radical concentration, we can hypothesize that an electron transfer from the triplet carbanion to copper(II), leading to the formation of the pyrrolyl radical and copper(I), may explain the observed behavior. This hypothesis is confirmed by monitoring



Scheme 1

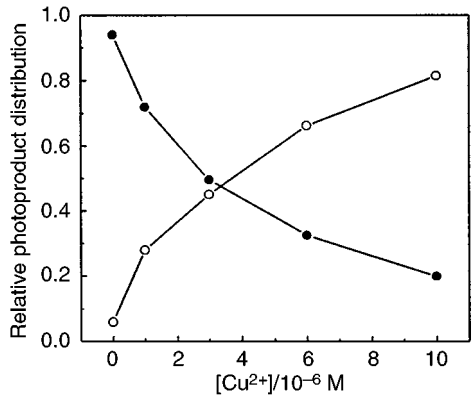


Fig. 1 Relative distribution of TM photoproducts at various copper(II) concentrations: (●) **1** and (○) **2**.

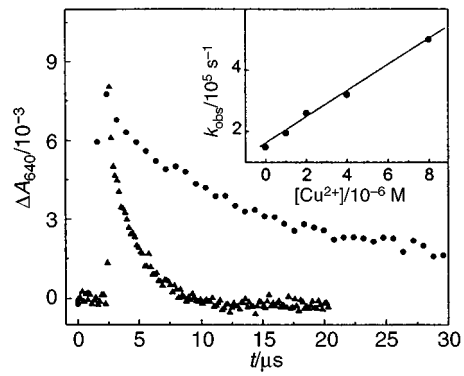

Fig. 2 Kinetic decay of the TM triplet carbanion (●) in the absence and (▲) in the presence of Cu^{2+} (7×10^{-6} M). Inset: plot for the quenching of the triplet carbanion by Cu^{2+}.

the triplet carbanion decay at 640 nm using nanosecond laser flash photolysis techniques. As showed in Fig. 2, this transient species is quenched by addition of copper(II) and a bimolecular quenching constant of $4.5–10^{10}$ M^{-1} s^{-1} (inset in Fig. 2) is obtained.

This value is higher than the diffusion-controlled rate and indicates a strong electrostatic interaction between the two reactants, due to their opposite charges.

These data are in good agreement to those obtained from steady state experiments. Indeed, the fraction of carbanion quenched by a certain concentration of copper(II) fits well both the percentage decrease of the photoproduct **1** and the increase of the photoproduct **2**. Further confirmation that the quenching mechanism occurs through an electron transfer reaction is provided by the high amount of copper(I) detected after TM irradiation in N_2O saturated solution.† Addition of sodium bathocuproinedisulfonate (BCDS) under N_2O atmosphere turns the irradiated solution red, which shows the characteristic absorption of the copper(I)–BCDS complex at 484 nm.[15]

Low concentrations of copper(II) were also used in DNA photocleavage experiments. As shown in Table 1, the metal ion inhibits markedly the amount of DNA damage photoinduced by TM.

Since the main transient intermediate produced in these experimental conditions is always the triplet carbanion, we believe that an electron transfer between this species and DNA nucleobases can trigger the photoinduced damage. The hypothesis is supported by formation of reduction products of DNA nucleobases observed in experiments performed using single nucleosides. These results can be rationalized on the basis of the influence of the metal ion on the TM photoproduct distribution. Due to the intermolecular electron transfer with cupric ions, the active DNA photocleaver triplet carbanion is converted into a pyrrolyl radical. Given its chemical structure, this species is highly stable, is inefficient for abstraction of hydrogen from the DNA backbone, and the only method of decay is a self-reaction to generate the photoproduct **2**.

Table 1 TM photoinduced DNA cleavage in anaerobic conditions in the presence of different amounts of Cu^{2+}

Cleavage (%)	$[Cu^{2+}]/10^{-7}$ M
67 ± 7	0.0
55 ± 6	1.0
42 ± 5	5.0
30 ± 4	10.0

The overall results, summarized in Scheme 1, provide a clear example in which an oligoelement such as copper(II) interacts efficiently at very low concentration with the intermediate of a photochemical reaction. This process modulates remarkably the distribution of the stable photoproducts and inhibits considerably DNA drug photoinduced damage by turning a species very highly reactive towards the biosubstrate into an unreactive one.

Functional analysis of phenylalanine 365 in hopene synthase, a conserved amino acid in the families of squalene and oxidosqualene cyclases†

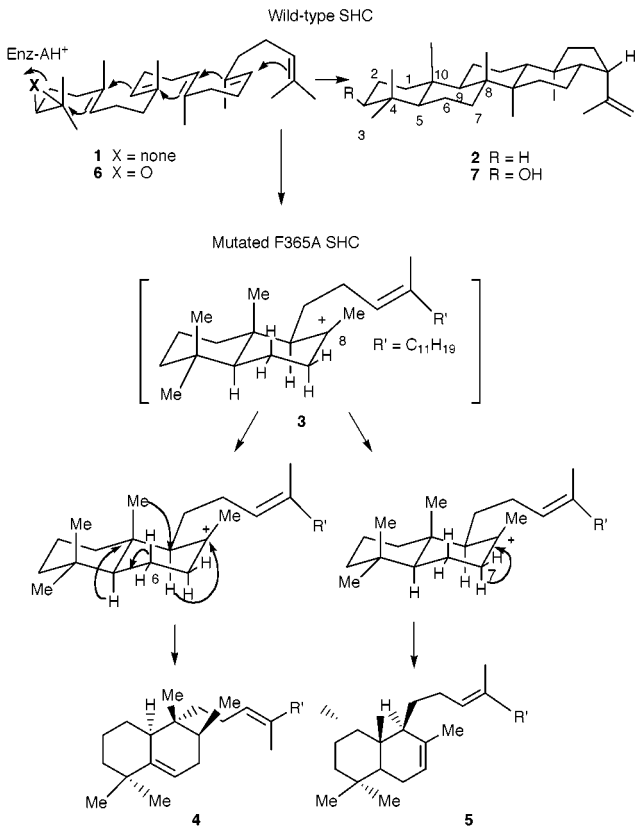
Tsutomu Hoshino* and Tsutomu Sato

Department of Applied Biological Chemistry, Faculty of Agriculture, and Graduate School of Science and Technology, Niigata University, Ikarashi, Niigata 950-2181, Japan. E-mail: hoshitsu@agr.niigata-u.ac.jp

Received (in Cambridge, UK) 9th July 1999, Accepted 3rd September 1999

Two bicyclic products were accumulated by the mutant F365A, showing the amino acid residue is located close to the transient C-8 carbocation intermediate in the active site cavity; the mutants of F365Y and F365W significantly accelerated the cyclization reaction at low temperatures.

The cyclization of squalene **1** into the pentacyclic triterpene hopene **2**, mediated by the prokaryotic squalene-hopene cyclase (SHC), is one of the most sophisticated biochemical reactions (Scheme 1).[1] Oxidosqualene also undergoes the polyolefin cyclization by eukaryotic cyclases, in a similar manner to **1**.[1] Recent investigations on the molecular biology of the two cyclases[2] and on the substrate analogues[1,3] have encouraged mechanistic studies on the polycyclization reactions. The acyclic molecule **1** is believed to be folded into an all pre-chair conformation inside the enzyme cavity,[1] but the involvement of a ring expansion process has recently been disclosed with respect to the D-ring formation.[4a,b] Such a ring expansion reaction also occurs in C-ring formation by lanosterol synthase.[4c,d] An X-ray crystal structure of the SHC from *Alicyclobacillus acidocaldarius* has been reported and a reaction mechanism proposed.[5] However, site-directed mutagenesis experiments are required to verify the catalytic functions of the residues of the presumed active center. To date, only a few essential components of these active sites have been demonstrated by point mutation experiments.[4b,6] The polycyclization cascade has been proposed to proceed by the stabilization of discrete carbocation intermediates *via* cation–π interaction with aromatic amino acid residues of the cyclases,[7] but no kinetic evidence has been reported. In a series of point mutation experiments conducted by us, Phe365, which is conserved among all the known prokaryotic SHCs and eukaryotic cyclases,[2,5,6c] has been identified as having a stabilizing function for the transient C-8 carbocation intermediate. We show here kinetic data of the mutated SHCs of F365Y and F365W.



Scheme 1

Cell-free homogenates of the *E. coli* clone encoding the mutated F365A SHC, prepared from 8 L culture, were incubated with **1** (105 mg) at pH 6.0 and 55 °C for 16 h. The GC analysis showed the presence of two major products (**4** and **5**), a little of **2** and recovered **1** in the reaction mixture. Separation on a SiO_2 column using hexane as an eluent afforded **4** (27.8 mg), **5** (25.1 mg), **2** (3.0 mg) and **1** (32.4 mg). Analyses of the 2D NMR spectra revealed that the structures of **4** and **5** had a 6/6-fused bicyclic skeleton.[8] Formation of **4** and **5** suggested that the sequential cyclization reactions are quenched at the bicyclic stage of the putative intermediate **3**. A series of 1,2-shifts of hydrides and a methyl group in an antiparallel fashion could trigger the deprotonation at C-6 to produce **4**, while a deprotonation at C-7 could give rise to **5** (Scheme 1). These findings indicate that the F365 residue is critical to the completion of the polycyclization and that the π-electron of this side chain may stabilize the transient C-8 carbocation. There were no detectable amounts of mono- or tri-cyclic products, further suggesting that the F365 residue is close to the C-8 cation in the enzyme cavity, but not near the mono- and tricyclic intermediary carbocations, which is consistent with the recent suggestion inferred from X-ray analysis.[5]

To validate the proposed role of the cation–π interaction, the mutants F365Y and F365W were constructed based on the idea that the higher electron density of the π–electrons, the faster cyclization reaction. Fig. 1 depicts the specific activities of these mutants against incubation temperatures. The mutant F365Y completed the polycyclization to the final product **2** without any intermediate being observed, differing from F365A, and exhibited a remarkable increase in the reaction rate at low temperatures (10–50 °C); the F365Y produced **2** even at a temperature as low as 10 °C, a temperature at which the wild-type SHC has no significant activity. The activation energy (E_{act}), estimated from the Arrhenius plots,[9] was greatly reduced; *e.g.* 37.0 kJ mol^{-1} for the F365Y compared with 50.1 kJ mol^{-1} for the wild-type. The higher electron density of the tyrosine residue apparently gives rise to a faster cyclization reaction. The K_m values of the wild-type and F365Y were determined from the Lineweaver–Burk plots to be 16.9 ± 0.6 (30–60 °C) and 502 ± 12 μM (10–50 °C), respectively, suggesting that the substrate affinity for F365Y was greatly decreased. An unusual profile was found between activities and temperatures (Fig. 1). Three

† Spectroscopic data for **4** and **5**, Arrhenius plots for **1** and **6** and CD spectra for the relevant SHCs are available from the RSC web site, see http://www.rsc.org/suppdata/cc/1999/2005/

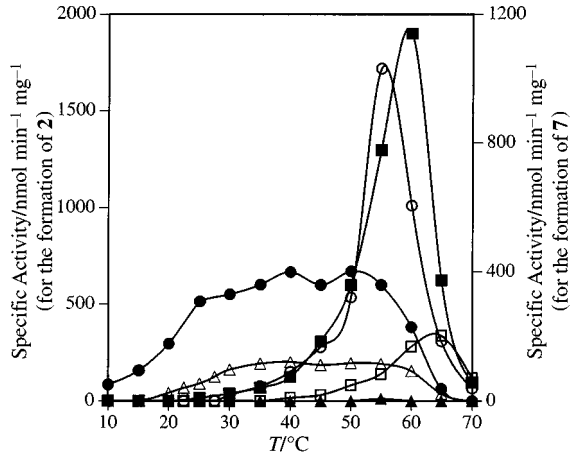


Fig. 1 Specific activities for the formations of **2** (closed symbols) and **7** (open symbols) against incubation temperatures are given for the wild-type SHC (■, □), the mutants of F365Y(●, ○) and F365W (▲, △). One mg of **1** or **6** was incubated with 5 μg of the homogeneously purified SHCs for 60 min at pH 6.0.

distinctive phases were observed: at 10–25°C, the activities were increased; at 30–50 °C, a steady state was reached; at 55–70 °C, the activities decreased due to irreversible thermal denaturation.[10] The enzyme activity of the F365W was negligible (Fig. 1) despite the higher electron density of the indole ring, which may result from the significantly decreased binding of **1** to the catalytic site. The CD spectra of the three mutants were superimposable on that of the wild-type. However, significant local change may be indeed likely and this may have no visible effect on the overall CD spectra.

(3*S*)-2,3-Oxidosqualene **6** also undergoes the cyclization by SHC to form 3β-hydroxyhopene **7**.[3b,6c,11] Compound **6** was incubated as another enzymic test to obtain further evidence for the cation–π interaction. F365Y had a remarkably enhanced activity, 5-fold higher than the wild-type, and showed a bell-shaped curve (Fig. 1).[10] As expected, F365W also had higher activity than the wild-type at temperatures below 50 °C, but exhibited an unusual profile analogous to that of **1** with the F365Y.[10] No intermediate products were detected in the reaction mixtures of **6** by either F365Y and F365W, whereas the 3-hydroxy derivatives corresponding to bicyclic intermediates were accumulated by the F365A without completion of the polycyclization, further supporting the idea that the residue at 365 must be an aromatic amino acid. The values of E_{act}[9] with **6** were 53.6, 49.9 and 42.8 kJ mol^{-1}, respectively, for the wild-type, the F365Y and the F365W mutants, which is in good agreement with the cation–π interaction concept. The enhanced K_m values for these mutants were also observed with **6**; the K_m of the F365W was largest.[11]

The faster cyclization reactions at lower temperatures with the Tyr and the Trp mutants suggest that the cation–π interaction is likely to occur for the squalene cyclization cascade. The bulky aromatic substituents make the active site region less compact. A somewhat loosely packed protein structure may be more flexible at low temperatures leading to high catalytic activity, as is found for psychrophilic enzymes.[12a] More detailed studies are required to gain greater insight into the kinetics of these mutants.[10]

The previously unknown **4** and the known products **5** (γ-polypodatetraene),[13] which have a 6/6-fused bicyclic skeleton, were produced by the site-directed mutant of F365A due to the lack of π-electrons, suggesting that the major function of Phe365 would be assigned for stabilization of the C-8 carbocation intermediate possibly *via* a cation–π interaction.

8 Analyses of NMR data (H-H COSY 45, HOHAHA, NOESY, DEPT, HMQC and HMBC) unequivocally supported the structures proposed for **4** and **5**.
9 The temperatures for the Arrhenius plots for **1** were in the range of 30–60 and 10–25 °C for the wild-type and for the F365Y, respectively, while in the case of **6** they were 40–60, 30–50 and 20–30 °C, respectively, for the wild-type, the F365Y and the F365W.
10 Our working hypothesis for the interpretation of this unusual behaviour is as follows. Reversible denaturation[12b] may gradually occur from 30 to 50 °C, and the denaturation may be attributable to the more enhanced susceptibility of the mutants to the exothermic high energy, which is released by the cyclization reaction,[5] because the geometrical change occurred at the active site region (significantly increased K_m). As for the F365Y, temperature dependency for the reaction is different between **1** and **6**. This may be closely related to the increased degree of K_m, leading to the unusual profile for **1** (K_m = 502 μM, more sensitive to higher temperatures), but to a bell-shape for **6** (K_m = 182 μM, less sensitive). If the denaturation could not occur, the k_{cat} of **1** may have been significantly increased at 30–50 °C. This idea may also be true for the case of **6** by the F365W (K_m = 357 μM).[11] The denaturation process was confirmed to be reversible; the F365Y was exposed at 40 °C for 60 min and then incubated with **1** at 20 °C, but showed the same activity as that without such treatment. To validate our hypothesis, further evidence is required.
11 Kinetic data for the reactions of **6**, measured at 40 °C and for 60 min, are as follows: k_{cat} 1.4, 12.2 and 17.2 min^{-1}, and K_m 0.72, 181.8 and 357.2 μM, respectively, for the wild-type, F365Y and F365W. The more bulky the substituents, the larger the values of K_m. The k_{cat}s and K_ms of the wild-type for the reactions of **1** and **6** at 60 °C are as follows: 288.5 min^{-1} and 16.7 μM for **1**; 23.6 min^{-1} and 0.84 μM for **6**.[6c]

Hydrogen bonding and cooperativity effects on the assembly of alkyl- and perfluoroalkyl-sulfonyl naphthols: F···F non-bonded interactions†

Janusz Kowalik,* Donald VanDerveer, Caroline Clower and Laren M. Tolbert

School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400, USA. E-mail: janusz.kowalik@chemistry.gatech.edu.

Received (in Corvallis, OR, USA) 16th July 1999, Accepted 24th August 1999

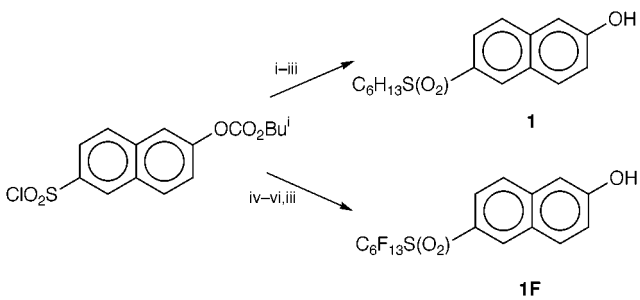
Important differences in the crystal packing of 6-perfluorohexylsulfonyl-2-naphthol (1F) including π–π stacking aromatic interactions and F···F non-bonded contacts, in contrast to its nonfluorinated analog (1), appear to translate into differences between their photophysical properties both in the solid state and in solution.

Photoacid generators produce acids upon irradiation. They are important in the field of polymeric photosensitive systems, as initiators for polymerizations,[1] for crosslinking of oligomers and polymers,[2] for polymer degradation,[3], and for conversion of acid-sensitive functional groups attached to the polymers.[4]. Especially important technological applications involve manufacturing of photoresists and UV curing materials.[5] A drawback to common (ionic) photoacid generators is that once incorporated, they usually remain within the polymeric structure, degrading the long-term stability of the polymers.

A less widely explored approach lies with generators that produce acids only for the duration of the photochemical event, thus allowing for a better control of the ensuing chemistry. Our interest in photoacids stems from the observation that hydroxy aromatics, weakly acidic in the ground state, become strong acids upon photoexcitation.[6] We have established that naphthol derivatives strategically substituted with electron-withdrawing substituents yield significantly stronger acids ('enhanced photoacids') in the excited state.[7] The electron withdrawing efficiency of substituents[8] seems to have a similar effect on the ionization in the excited state, rendering systems substituted with functionalities of large positive Hammett constant (σ_p) values better photoacids (proton donors).

Since the σ_p value for the pentafluoroethylsulphonyl group is 1.08,[9] *versus* 0.66[10] for the cyano functionality, we synthesized and tested the 6-perfluorohexylsulfonyl-2-naphthol (**1F**), and its nonfluorinated analog (**1**) for comparison. Scheme 1 illustrates our synthetic approach.

The 6-(isobutoxycarbonyloxy)naphthalene-2-sulfonyl chloride, a starting material for both reaction avenues leading to **1** and **1F**, was obtained in a two-step process involving masking of the hydroxy group in 6-hydroxynaphthalene-2-sulfonic acid by allowing it to react with isobutyl chloroformate under Schotten–Baumann conditions,[11] followed by a reaction with $POCl_3$.[12] Reduction of the acid chloride with zinc metal yielded the corresponding zinc salt of the sulfinic acid, which was alkylated without isolation of the sulfinic acid with *n*-hexyl bromide, using a modified procedure of Mal.[13] The hydroxy group protection in the obtained sulfone was then removed by hydrolysis with LiOH in THF–water to yield **1**. Since heteroatom alkylations with perfluoroalkyl iodides proceed *via* a radical-ion chain mechanism,[14] an alternative procedure was developed for the synthesis of **1F**. Reduction of the sulfonyl chloride with PPh_3[15] yielded the corresponding thiol, which then reacted smoothly with perfluorohexyl iodide to provide the aryl perfluorohexyl thioether. Oxidation with MCPBA and subsequent deprotection of the hydroxy functionality led to sulfone **1F**.



Scheme 1 *Reagents and conditions*: i, Zn, NaOH, H_2O–dioxane; ii, $C_6H_{13}Br$, DBU, DMF; iii, LiOH, 50% H_2O–THF; iv, PPh_3, PhH; v, NaOEt, $C_6F_{13}I$, DMF; vi, MCPBA, EtOAc, reflux.

† Atomic numbering schemes and stereoviews for **1** and **1F** are available from the RSC web site, See http://www.rsc.org/suppdata/cc/1999/2007/

Preliminary studies of the emission spectroscopy of **1** and **1F** in aqueous–organic solutions showed considerable differences in the relative intensities of the fluorescence.[16] Emission of the perfluoroalkyl analog was quenched by 40 × in MeOH (Fig. 1).

Similar effects were observed qualitatively in the solid state, using 366 nm radiation from a hand-held laboratory UV-VIS lamp to produce a bright fluorescence of the nonfluorinated sulfone, in contrast with a very low intensity fluorescence of the perfluoroalkyl analog. It was shown, that intermolecular π–π interactions effectively quenched the solid state fluorescence, the degree of fluorescence quenching can be used as an indicator of intermolecular π–π interactions.[17]

Recent reports from Tung's laboratory indicate that perfluoroalkyl esters of naphthalenecarboxylic acid form aggregates of unknown structure in aqueous organic solvents, leading to formation of excimers upon excitation, and chemical dimerizations as a consequence.[18] Hydrophobic attraction as well as other forces, such as hydrogen bonding,[19] are powerful

tools in forming supramolecular assemblies both in solution and in the solid state. Molecular recognition leading to aggregation and nucleation may as a result become productive in generating crystals.[20] Although the dynamics of these systems remains complex, one might assume that the forces that play a role in molecular recognition in self-organized systems in solution would be reflected in the crystal. Following this assumption we determined the crystal and molecular structures of **1**‡ and **1F**§ (see Fig. 2).

X-Ray analysis reveals that both **1** and **1F** crystallize in monoclinic unit cells, containing four molecules of **1**, and eight molecules of **1F**. The common motif present in both structures is an infinite, intermolecular, linear network of hydrogen bonds OH···OS(O)–. It passes through the crystals in the direction of the *b* axis, making the molecular arrangement supramolecular in nature. Distances are typically 2.78 Å.[21] The differences in the crystal packing are substantial. In the case of **1F** there is a distinct segregation of the well-ordered perfluoroalkane chains from the aromatic rings. The perfluorohexyl chains are nearly parallel. There is a pronounced proximity between the fluorine atom attached to the α carbon (*vs.* sulfonyl group) and the terminal CF_3 group of the next molecule. The distance between the corresponding fluorine atoms is 2.85 Å, which positions them within the range of a non-bonded interaction (van der Waals radius for fluorine is 1.47 Å).[22] We believe that the strong electron withdrawing character of the sulfonyl moiety renders the α fluorine atoms more positive than the terminal ones, effecting a dipolar interaction. This interaction along with the electrostatic repulsion between the π-electrons of the aromatic rings and the fluorine atoms,[23] substantially contribute to the crystal architecture of **1F**. The naphthol rings in **1F** partially overlap in layers 3.52 Å apart. This value relates well with 3.5 Å (interplanar distance in graphite)[24] and is still smaller than 3.81 Å, where the electronic interaction between the aromatic chromophores was found to exist.[25] The attractive π–π interaction is believed to be another element stabilizing the crystal structure of **1F**. By contrast, the planes of the aromatic rings that are positioned parallel to each other in the crystal of **1** are separated by 7.7 Å and are interdigitated with the alkyl chains. There is no interactive proximity between the hexyl chains, and the aromatic chromophores are removed beyond the limit of electron interactions between them.

In summary, three cooperative attractive interactions present in **1F** produce a crystal lattice where a strong chromophore interaction seems to effectively deactivate fluorescence in the solid state. In contrast, the more intense fluorescence of the non-fluorinated analog is attributed to the absence of that interaction. We therefore conclude that similar behavior in solution supports the notion that extensive aggregation of **1F** in MeOH and in water–organic solvent systems is caused by the same attractive interactions as those present in the solid state.

Support of this research from the NSF, grant no. CHE 9727157, is gratefully acknowledged.

The first [2,3]-sigmatropic rearrangement of allylic nitro compounds

Estelle Dumez, Jean Rodriguez and Jean-Pierre Dulcère

RéSo, Réactivité en Synthèse organique, UMR 6516, Faculté des Sciences et Techniques de St Jéróme, Boîte D12, Av. Esc. Normandie-Niemen, F-13397, Marseille Cedex 20, France. E-mail: jean-pierre.dulcere@reso.u-3mrs.fr

Received (in Cambridge, UK) 19th July 1999, Accepted 23rd August 1999

Allylic nitro compounds 1a–d undergo [2,3]-sigmatropic rearrangement in refluxing 1,2,4-trichlorobenzene, to afford rearranged alcohols 3a–d and carbonyl compounds 4a–d; the heating, under the same conditions, of a mixture of nitroalkenes 7a–c, propargyl alcohols or amine 8 and Bu^{t}OK promotes a one-pot formation of allylic alcohols 3a–c.

The influence of zwitterionic moities such as sulfoxides or amine oxides at the 3-position of hexa-1,5-dienes has been investigated and some interesting results showed that acceleration of either [3,3]- or [2,3]- sigmatropic rearrangement could be observed.[1a] Unlike for these substituents, it has been shown that allylic nitro compounds do not participate in [2,3]-sigmatropic rearrangements under thermolysis at 110 °C in toluene.[1b]

We have recently described the facile preparation of allylic nitro compounds **1a**–**d** by Bu^{t}OK-promoted oxa- and aza-Michael addition–intramolecular carbocyclization of prop-2-ynyl alcohols or amines with α,β-disubstituted nitroalkenes.[2]

Here we report on our initial investigations of the first thermal conversion of these valuable substrates into allylic alcohols and the corresponding α,β-unsaturated carbonyl derivatives.

Heating a solution of nitro olefines **1a**–**d** in trichlorobenzene at 214 °C induces a rapid [2,3]-rearrangement providing nitrite intermediates which undergo homolytic fission of the O–NO bond. Subsequent disproportionation of the resulting alkoxyl radical thus derived gives rise to alcohols **3** (12–15%) and carbonyl compounds **4**[3] (13–18%) according to a well-known process[4] (Scheme 1).

The transient formation of alkyl nitrites was established by the isolation of **2a**† (10%) along with **3a** (13%) and **4a** (7%). A selective suprafacial [2,3]-sigmatropic rearrangement leading to **2d** accounts for the stereochemistry of **3d**.‡ Indeed, the homolytic fission does not alter the configuration of the functional carbon center.

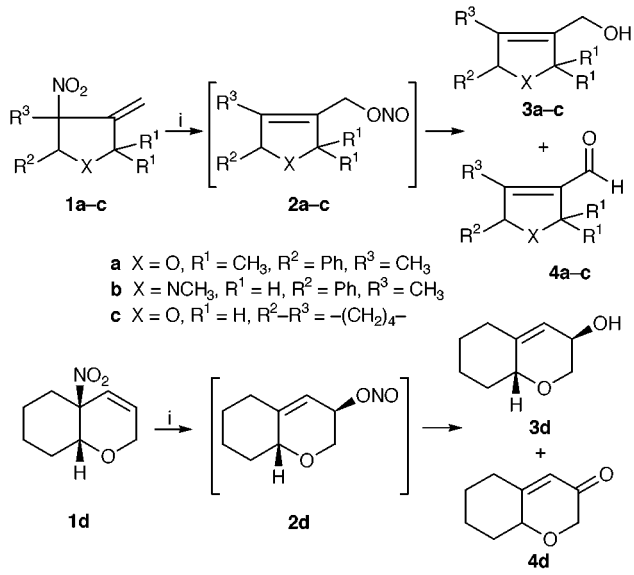
Because of their higher degree of unsaturation, we also decided to study under the same reaction conditions the behaviour of easily accessible allenyl nitro compound **1e**.[5] Interestingly, **1e** under thermolysis at 214 °C undergoes [2,3]-sigmatropic rearrangement and cleanly affords keto oxime **5**§ (23%), along with trace amounts of acetyl dihydrofuran **6** (Scheme 2).

Extensive studies[6] of either thermally or photochemically induced transformations of alkyl nitrites resulted in the observation that only photochemically generated 'activated' alkoxyl radical intermediates could lead to oximes by hydrogen-atom transfer reactions. Indeed, although thermally induced transformations afford carbonyl derivatives according to either disproportionation or acid catalysis, vapour-phase pyrolysis of nitrites with apropriate structures follows identical pathways and leads to identical products than photolysis.

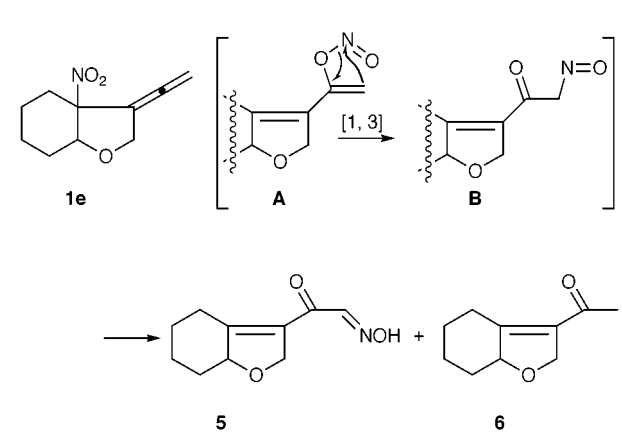
Thus, formation of oxime **5**, which formally results from incorporation of nitric oxide after homolytic scission, could be explained by a [1,3]-sigmatropic rearrangement of the vinyl nitrite unit in **A**. Although isolated in small amounts, the formation of acetyl dihydrofuran **6** could support the occurrence of an early homolytic fission stage.

In order to increase the efficiency of the overall process, we adapted our procedure previously developed for the preparation of allylic nitro compounds[2] through a domino reaction initiated by Michael addition of propargylic alcohols or amine **8** to nitroalkenes. We therefore discovered that exchanging THF for refluxing trichlorobenzene resulted in a one-pot formation of rearranged alcohols (8–13%), directly from nitroalkenes **7a**–**c** and propargylic alcohols or amine **8**. Interestingly, the formation of the corresponding aldehydes could not be detected under the reaction conditions, probably due to the rapid consumption of the nitrite intermediate in the presence of a strong base such as Bu^{t}OK¶ (Scheme 3).

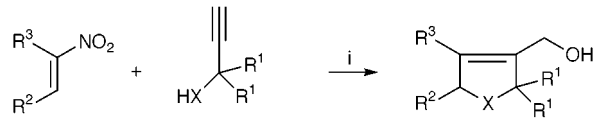
Similarly, the one-pot conversion of nitroalkene **7c** in the presence of chlorobutynol **9** and Bu^{t}OK afforded keto oxime **5** in 10% yield (Scheme 4).



Scheme 1 *Reagents and conditions*: i, 1,2,4-trichlorobenzene, 214 °C, 20–45 min (25–30%).

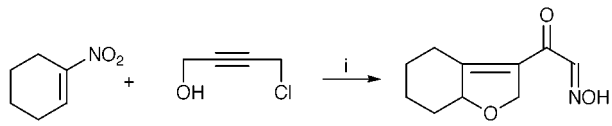


Scheme 2 *Reagents and conditions*: i, 1,2,4-trichlorobenzene, 214 °C, 5 min (**5**: 23%, **6**: trace).



7a–c **8** **3a–c**

Scheme 3 *Reagents and conditions*: i, **8** (X = NMe, O) (1.5 equiv.), 1,2,4-trichlorobenzene, Bu^{t}OK (1.2 equiv.), room temp., 5 min, then 214 °C, 45 min (8–13%).



7c **9** **5**

Scheme 4 *Reagents and conditions*: i, **9** (1.5 equiv.), 1,2,4-trichlorobenzene, Bu^{t}OK (1.2 equiv.), room temp., 5 min, then 214 °C, 2 min (10%).

In conclusion, the Bu^{t}OK/thermally induced one-pot reaction of nitroalkenes with alkynyl alcohols constitutes a new four-step domino reaction which involves [2,3]-sigmatropic rearrangement of allyl and allenyl nitro compounds and provides a new route to elaborated 2,5-dihydro-furans or -pyrroles.

We are grateful to Dr S. Zard (Ecole Polytechnique, Palaiseau), for useful suggestions.
