It is known that cationic side reactions catalysed by the ionic liquid itself can be avoided if a chloroethylaluminate melt is used as catalyst solvent.[5] However, with **1** the use of this melt as solvent leads to an immediate catalyst decomposition (Table 1, entry 3). At −10 °C, rapid decomposition could be avoided but the linearity of the dimer products was still low (Table 1, entry 4). Probably, even at this low temperature, $AlEtCl_2$ transfers ethyl-groups to the Ni and destroys the Ni-*X,Y* chelating system, which is known to be responsible for the desired high linearity.[1] Moreover, $AlEtCl_2$ is known to exhibit isomerisation activity[9] for converting but-1-ene rapidly into the thermodynamic distribution of butenes (*ca.* 4% but-1-ene at room temperature). While dimer selectivity was enhanced using a mixed system of the form 4-MBP/$AlCl_3$/$AlEtCl_2$ as used by Chauvin *et al.* in previous oligomerisation, dimer linearity was still unsatisfying low at 37% (Table 1, entry 5).

As an alternative way to avoid cationic side reactions, we tested **1** in buffered ionic liquids. The Lewis acidity of ionic liquids is routinely buffered by the addition of alkali metal chloride.[10] Since excess alkali metal chloride does not dissolve in the neutralised resulting ionic liquid, buffering in this manner is very efficient. Our dimerisation experiments were carried out in buffered ionic liquids with and without excess of solid alkali metal chloride. In the first case (Table 1, entry 6), almost no Ni-catalysed dimerisation was observed. Obviously, the slightly Lewis-acidic Ni-catalyst center is 'buffered' by the excess of

Table 1 Catalytic results with Ni-complex **1** in different ionic liquid systems.

General conditions: 4 g ionic liquid, 0.04 g **1**, 12 g but-1-ene, reaction time was varied to reach comparable conversions of 15–20%. [a] Turnover frequency (TOF) in mol of butene converted per mol of Ni per h. [b] Selectivity to dimer product in %. [c] Selectivity to linear dimer in the dimer fraction of the product in %. [d] The product is mainly formed by a cationic oligomerisation mechanism of the acidic ionic liquid. The calculation of a turnover frequency related to the amount of nickel catalyst would be meaningless in this case. [e] Catalyst decomposes and forms a black solid of elemental Ni. [f] No products resulting from a parallel cationic side reaction are detected. [g] Ionic liquid was buffered with excess of dry LiCl (dried for 14 days over P_2O_5 at 150 °C). The ionic liquid used for reaction contained solid excess LiCl. [h] Traces of cationic oligomers. [i] Ionic liquid was buffered with excess of dry LiCl (dried 14 days over P_2O_5 at 150 °C). Solid excess LiCl was filtered off. The ionic liquid used for reaction was a clear liquid and contained no solid excess LiCl.

solid alkali metal chloride to a non-reactive Ni-species. Without excess of solid alkali metal chloride, the extent of cationic side reaction is dominated by the chemical behaviour termed 'latent acidity'.[11,12] Even very weak bases (B:) form an $AlCl_3$ adduct in neutral buffered melts. The additional driving force for this reaction apparently results from the precipitation of the solid alkali metal chloride: $AlCl_4^- + Li^+ + B: \rightleftharpoons B:AlCl_3 + LiCl$ (s). In our experiments, the but-1-ene feedstock seems to react as such a weak base. We found that the extent of cationic side reaction correlates well with the $Al_2Cl_7^-$ content of the melt from which the buffered ionic liquid was prepared (Table 1, entries 7, 8). However, a comparison of entries 2 and 8 clearly demonstrates the efficiency of an alkali metal chloride buffer in suppressing the formation of cationic oligomers.

Alternatively, we looked for new methods to buffer acidic ionic liquids so as to avoid the precipitation of an alkali metal chloride. We found that a slightly acidic melt buffered with small amounts of weak organic bases provides a solvent which allows a selective, ligand-controlled, biphasic reaction with the Ni-catalyst **1**. The function of the base is to trap any free acidic species in the melt which may initiate cationic side reaction (Table 2).

The base has to be system-adapted to provide high solubilty in the ionic liquid in question, while at the same time being non-coordinating with respect to the catalytic active Ni-center. Possible bases are any cyclic, heterocyclic or aliphatic, aromatic or non-aromatic bases which have these properties. Specially favorable are pyrrole, *N*-methylpyrrole and chinoline (Table 1, entries 9–11).

Experiments with different pyridine derivatives as buffer are interesting in two different respects (Table 1, entries 12–14): While the pyridine-buffered but-1-ene oligomerisation shows a significantly lower activity, this is not the case for the 2-substituted pyridines. This is probably due to a stronger coordination of the unsubstituted pyridine to the active center during reaction, in contrast to the sterically more demanding pyridine derivatives. Moreover, the $S(C_8)$ selectivity clearly decreases with the steric demand of the *o*-substitutent on the pyridine. Assuming that the $S(C_8)$ can be regarded as an indicator of the efficiency of the buffering process, this is a clear sign for a considerable contribution of a sterically demanding step in the buffering process. If only superacidic protons were responsible for the observed cationic side reaction in acidic ionic liquids, these should be perfectly buffered by a strong base like 2,6-di-*tert*-butylpyridine, which is not the case. It is assumed therefore that the reaction $Al_2Cl_7^- + \text{base} \rightleftharpoons AlCl_3\text{–base} + AlCl_4^-$ plays a major role in the buffering process.

Table 2 Function of the added organic base B

$$Al_2Cl_7^- + B \rightleftharpoons B\text{-}AlCl_3 + AlCl_4^-$$

$$B\text{-}AlCl_3 + HCl \rightleftharpoons HB^+ + AlCl_4^-$$

$$Al_2Cl_7^- + HCl + B \rightleftharpoons HB^+ + 2\,AlCl_4^-$$

Overall, the buffering procedures reported here facilitate use of an ionic liquid solvent for catalyst **1**, permitting reaction to take place in biphasic reaction mode with facile catalyst separation and catalyst recycling. The high intrinsic dimer linearity of catalyst **1** is maintained, but with significant enhancement of catalyst activity over that observed in toluene solvent.

In addition, our new concept of producing a latent-acidic chloroaluminate ionic liquid, by buffering a slightly acidic melt with weak organic bases, could prove to be useful in other transition metal catalysed reactions. In contrast to the known systems,[4–7] it avoids any addition of alkylaluminium and thereby allows the use of reduction-sensitive metal complexes at higher temperatures.

We wish to thank Drs M. Jones and M. Atkins of BP Chemicals for their helpful discussions and financial support for this programme and Prof. Ken Seddon for his fruitful advice.

The elimination–addition mechanism of nucleophilic substitution at an alkylphosphonyl centre: stereospecificity, non-stereospecificity and the alkylidineoxophosphorane (phosphene) intermediate

Martin J. P. Harger* and Deborah K. Jones

Department of Chemistry, The University, Leicester, UK LE1 7RH

Received (in Liverpool, UK) 1st December 1998, Accepted 13th January 1999

The substitution reactions of $R'_2CHP(O)(NMeR^*)Cl$ (R'_2CH = fluoren-9-yl; R* = CHMePh) with secondary amines (Me_2NH, Et_2NH, Pr^iNHEt) are largely stereospecific or non-stereospecific depending on the bulk of the amine and its concentration; two elimination–additon pathways, differing in whether or not the phosphene intermediate $R'_2C{=}P(O)NMeR^*$ becomes liberated, may be responsible.

Methyleneoxophosphoranes, or phosphenes, are the phosphorus analogs of sulfenes.[1] Like other three-coordinate P^V species they generally have only a fleeting existence in solution.[2] They have been generated in some oxidation,[3] fragmentation[4] and rearrangement[5] reactions, but unlike sulfenes they have not been implicated as intermediates in nucleophilic substitution.[6] A possible exception is the conversion of the fluorenylphosphonamidic chloride **1** into the phosphonic

6

diamide **3** with Et_2NH.[7] On steric grounds (substrate and nucleophile) this should proceed very slowly, at least by the normal associative $S_N2(P)$ mechanism,[8] but in fact it proceeds quite readily.[7] It may be that in this case the acidity of the C_α–H bond in the substrate makes a dissociative elimination–addition mechanism, with a phosphene intermediate **2**, more accessible than is usual. We hoped that a stereochemical study, using a substrate related to **1**, would help to clarify the role of phosphene intermediates in nucleophilic substitution.

The phosphonamidic chloride **4** was prepared by treating fluoren-9-ylphosphonic dichloride[7] with (S)-(−)-PhMeCHNHMe (2.5 equiv.) in CH_2Cl_2 (1 : 1 v/v amine–CH_2Cl_2). Chromatography (silica gel; 1 : 6 EtOAc–light petroleum) and crystallisation afforded pure (≥99%) samples of the individual diastereoisomers of **4**: sample **A**, mp 145–147 °C; $\delta_P(CDCl_3)$ 43·0; $\delta_H(CDCl_3)$ 4.99 (d, J_{PH} 29, >CH), 1.61 (d, J_{PH} 12.5, NMe) and 0.68 (d, J_{HH} 7, CH*Me*); sample **B**, mp 103.5–104.5 °C; $\delta_P(CDCl_3)$ 43.15; $\delta_H(CDCl_3)$ 4.98 (d, J_{PH} 30, >CH), 1.62 (d, J_{PH} 13, NMe) and 1.33 (d, J_{HH} 7, CHMe).†

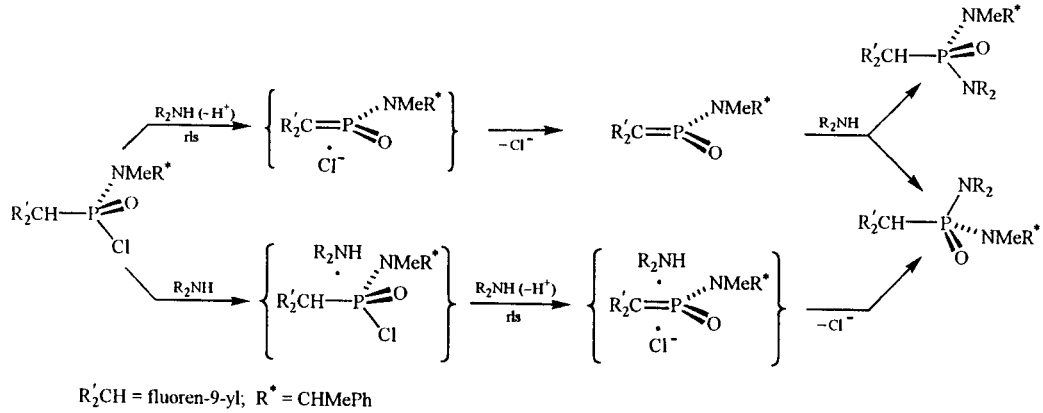
The two samples (**A** and **B**) of the substrate **4** were allowed to react with Et_2NH (large excess) as a 1.2 mol dm^{-3} solution in $CHCl_3$ at 31 °C. In both cases the phosphonic diamide **5** (R = Et), *m/z* 418 (M^+, 10%) and 253 ($M^+ - C_{13}H_9$, 100), was obtained as an unequal mixture of diastereoisomers: $\delta_P(CDCl_3)$ 34.25; $\delta_H(CDCl_3)$ 4.93 (d, J_{PH} 27, >CH), 2.18 (d, J_{PH} 9.5, NMe), 1.48 (d, J_{HH} 7, CH*Me*) and 0.80 (t, J_{HH} 7, NCH_2*Me*) (major from **A**); $\delta_P(CDCl_3)$ 34.65; $\delta_H(CDCl_3)$ 4.96 (d, J_{PH} 26, >CH), 1.82 (d, J_{PH} 9.5, NMe), 0.96 (t, J_{HH} 7, NCH_2*Me*) and 0.81 (d, J_{HH} 7, CH*Me*) (major from **B**). Monitoring the reactions by ^{31}P NMR spectroscopy showed that stereoisomerisation of the substrate was slight (≤3%) up to 50% completion (*t* = 9.5 h for **A**, 6 h for **B**) and the diastereoisomer ratio of the product did not change significantly as the reaction progressed. The observed product diastereoisomer ratios, 33 : 67 from **A** and 77 : 28 from **B**, can therefore be taken as a true indication of how the diastereoisomers of the substrate **4** react with Et_2NH.

The reactions clearly fall between the extremes of complete stereospecificity (product diastereoisomer ratios 0 : 100 and 100 : 0) and complete non-stereospecificity (ratios same; not necessarily 50 : 50). A likely explanation is that two mechanisms are operating in parallel, one stereospecific and the other non-stereospecific. The obvious candidates for these are $S_N2(P)$ and elimination–addition (EA). In the former the five-coordinate intermediate or transition state would be formed by attack of the nucleophile opposite the leaving group, resulting in inversion of configuration at phosphorus, while in the latter the trigonal three-coordinate phosphene intermediate would be susceptible to attack at either of its diastereotopic faces.

Consistent with that picture is the behaviour of **4** with other amines. Me_2NH differs little from Et_2NH in basicity but, for steric reasons, it is much more nucleophilic towards a tetrahedral P=O centre [≥100 times with $Pr^iP(O)(NEt_2)Cl$ as substrate[7]]. The $S_N2(P)$ pathway should therefore be more important with Me_2NH and increased stereospecificity was indeed observed; using 1.2 mol dm^{-3} Me_2NH in $CHCl_3$ the product **5** (R = Me) [$\delta_P(CDCl_3)$ 35.15 and 34.3] was formed with diastereoisomer ratios of 6 : 94 from **A** and 97 : 3 from **B**. Conversely, Pr^iNHEt is much less nucleophilic than Et_2NH and reduced stereospecificity was observed; with 1.2 mol dm^{-3} Pr^iNHEt the product diastereoisomer ratios were 42 : 58 and 52 : 48 [$\delta_P(CDCl_3)$ 34.3 and 34.2]. Nonetheless, there are two reasons why the competing $S_N2(P)$–EA picture seems unsustainable.

First, the reaction of the fluorenyl substrate **4** with Me_2NH is some 50 times *faster* than the corresponding reaction of the analogous isopropyl compound **6** [$\delta_P(CDCl_3)$ 58.75 and 58.45 (diastereoisomers); product $\delta_P(CDCl_3)$ 42.6 and 41.9].† We would not expect $S_N2(P)$ to be less sterically hindered when the alkyl group on phosphorus is fluorenyl rather than isopropyl, and some evidence supports that view: methanolysis of the phosphonamidic chlorides **4** and **6** under non-basic conditions (MeOH containing 0.2 mol dm^{-3} AgOTf) is 10–20 times *slower* for the fluorenyl compound ($t_{½}$ *ca.* 10 min for **6** but 3 h for **4** at 31 °C). The high reactivity of **4** with Me_2NH thus seems irreconcilable with a mechanism that is predominantly $S_N2(P)$, notwithstanding the high stereospecificity of the reaction.‡

Second, inclusion of a small amount of the strong base 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (2 equiv.; 0.07 mol dm^{-3}) increases the rate of the reaction of the fluorenyl substrate **4** with Me_2NH (1.2 mol dm^{-3}) *ca.* 100-fold but does not accelerate the reaction [$S_N2(P)$] of the isopropyl analogue **6**. Crucially, the stereochemistry of the reaction of **4** is unaffected



Scheme 1

by the presence of DBU, *i.e.* the reaction is still largely stereospecific [product **5** (R = Me) diastereoisomer ratio 97 : 3 from **B**]. The implication is clear: the stereospecific pathway, like its nonstereospecific counterpart, is base-induced and is not $S_N2(P)$.

One further observation is pertinent. When the Et_2NH concentration was reduced to 0.2 mol dm^{-3} substrate **4** gave the product **5** (R = Et) with a diastereoisomer ratio of 42 : 58 from **A** and 55 : 45 from **B**. This reduced stereospecificity implies that the stereospecific pathway is kinetically of a higher order in amine.

As a whole the results point to two EA pathways, one first order in amine and nonstereospecific, the other second order in amine and stereospecific (or practically so). In the former (Scheme 1, top pathway) the amine acts only as a base in the rate-limiting elimination step, and the resulting phosphene intermediate recombines with the chloride ion, or diffuses away and becomes free before reacting with the nucleophile. In the latter (Scheme 1, bottom pathway) there is preassociation:[9] the nucleophile is already in place when elimination occurs, the phosphene is trapped before it can diffuse away, and the nucleophile becomes attached to that face of the phosphene which is not shielded by the chloride ion.§ Of the two pathways the one involving preassociation will be more sensitive to the bulk of the amine and its concentration. As the amine changes from Me_2NH to Et_2NH to Pr^iNHEt, or the concentration of amine decreases, the contribution of the stereospecific pathway declines; the free phosphene intermediate plays an increasingly important part and the overall reaction becomes increasingly nonstereospecific.

Notes and references

† The new compounds **4** and **6** and the products derived from them were fully characterised by NMR spectroscopy (^{31}P and ^{1}H), mass spectrometry, and elemental analysis and/or accurate mass measurement.

‡ The reaction of **4** with Me_2NH is of an order > 1 in amine; this may also point to a mechanism that is not $S_N2(P)$.

§ The elimination step of the EA mechanism probably involves rapid reversible removal of the C_α proton followed by rate-limiting elimination of chloride from the conjugate base (reversible ElcB) [in the reaction of the 9-deuterio analogue of substrate **1** with Et_2NH, D/H exchange is much faster than substitution (ref. 7)]; for simplicity this detail is omitted from Scheme 1.

Role of oxygen transients in the facile scission of C–O bonds of alcohols on Zn surfaces

K. R. Harikumar and C. N. R. Rao*

Solid State and Structural Chemistry Unit and CSIR Centre of Excellence in Chemistry, Indian Institute of Science, Bangalore 560012, India. E-mail: cnrrao@sscu.iisc.ernet.in

Received (in Cambridge, UK) 19th October 1998, Accepted 23rd December 1998

The alkoxy species produced by the interaction of alcohols with Zn surfaces undergoes C–O bond scission at 150 K giving hydrocarbon species, but this transformation occurs even at 80 K when alcohol–oxygen mixtures are coadsorbed, due to the oxygen transients.

Studies of the decomposition of methanol on transition metal surfaces have shown that the methoxy species formed around 150 K, undergoes C–O bond scission on some of the surfaces at relatively high temperatures giving hydrocarbon species.[1–4] Ethanol transforms to the alkoxy species on transition metal surfaces and undergoes C–O or C–C bond scission depending on the surface.[5,6] Interaction of propan-2-ol with transition metal surfaces also produces the alkoxy species and the C–O bond scission occurs at high temperatures on some of the surfaces yielding hydrocarbon species.[5,7] We have investigated the interaction of methanol on polycrystalline as well as (0001) Zn surfaces by electron spectroscopic techniques and found that the methoxy species produced around 120 K undergoes C–O bond scission at 150 K and above, giving rise to hydrocarbon species. We show the C(1s) and O(1s) spectra of methanol on a Zn(0001) surface in Fig. 1(a) and (b) respectively to illustrate the transformations. The C(1s) features due to the methoxy and hydrocarbon species are seen at 286 and 285 eV respectively at 150 K. The O(1s) spectrum shows a feature due to the methoxy species at 532 eV which disappears above 150 K. The alkoxy species formed initially undergoes C–O bond scission on the Zn(0001) surface in the cases of both ethanol and propan-2-ol. The stability of the alkoxy species increases from methanol to propan-2-ol, the alkoxy species being formed in the latter even at 80 K. Thus, in all the three alcohols, hydrogen abstraction occurs to give the alkoxy species, followed by the scission of the C–O bond forming the hydrocarbon species at 150 K. These changes are corroborated by vibrational energy loss spectroscopy. The above transformations of alcohols (ROH, R = alkyl group) on the Zn(0001) surface can be represented as follows:

$$\mathrm{ROH(a)} \rightarrow \mathrm{RO(a)} + \mathrm{H(a)} \quad (1)$$

$$\mathrm{RO(a)} \rightarrow \mathrm{R(a)} + \mathrm{O(a)} \quad (2)$$

We were interested in examining the effect of $O^{\delta-}$ type reactive oxygen transients on the interaction of alcohols with the Zn(0001) surface, since such species are known to readily abstract hydrogen from NH_3 and other molecules.[8,9] For this purpose, we have investigated the coadsorption of a 3 : 1 mixture of methanol and oxygen on the Zn(0001) surface. Typical C(1s) and O(1s) spectra are shown in Fig. 1(c) and (d) respectively. In the C(1s) spectrum, the feature due the methoxy species at 286 eV appears at 80 K, along with a weak feature at 287 eV due to chemisorbed methanol. More importantly, a relatively intense feature due to the hydrocarbon species with a C(1s) binding energy around 285 eV also occurs at 80 K. The O(1s) spectrum shows the presence of chemisorbed methanol and the methoxy species at 80 K with O(1s) binding energies at 533.6 eV and 532 eV respectively. A feature around 530 eV due to the oxidic species emerges progressively with increasing temperature. Coadsorption of oxygen with methanol appears to give rise to the short-lived reactive $O^{\delta-}$ type of transient species which readily abstracts hydrogen from methanol even at 80 K, the OCH_3 species subsequently giving the $(CH)_x$ species through C–O bond scission. It should be noted that the coadsorption of methanol and oxygen on a Cu(110) surface only yields OCH_3 and formate[10]

Coadsorption of a 3 : 1 mixture of ethanol and oxygen on the Zn(0001) surface also results in the formation of the alkoxy and the hydrocarbon species at 80 K, with a progressive increase in the hydrocarbon species with increase in temperature. In Fig. 2(a) we show typical C(1s) spectra to illustrate the transformations. Coadsorption of a 3 : 1 mixture of propan-2-ol and oxygen on the Zn(0001) surface gives a high proportion of the hydrocarbon species at 80 K as can be seen from Fig. 2(b). It should be recalled that amongst the three alcohols studied, the proportion of the alkoxy species formed on Zn surfaces is highest in the case of propan-2-ol. Since the formation of the alkoxy species precedes the C–O bond scission, the ease of

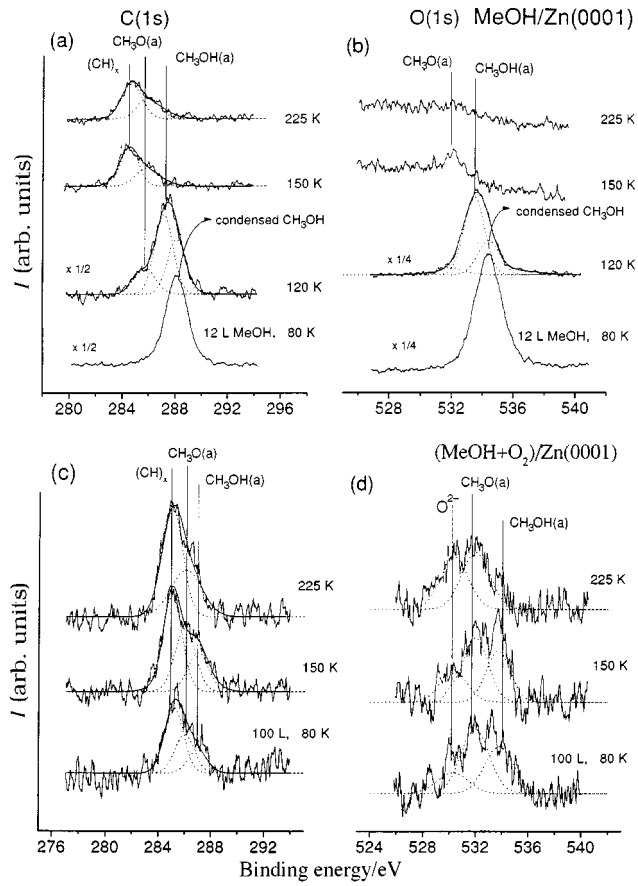

Fig. 1 (a) C(1s) and (b) O(1s) spectra of CH_3OH adsorbed on a Zn(0001) surface. CH_3OH was first adsorbed at 80 K and the surface progressively warmed to 225 K. (c) C(1s) and (d) O(1s) spectra of a 3 : 1 mixture of CH_3OH and O_2 adsorbed on Zn(0001). The mixture was adsorbed at 80 K and the surface progressively warmed to 225 K.

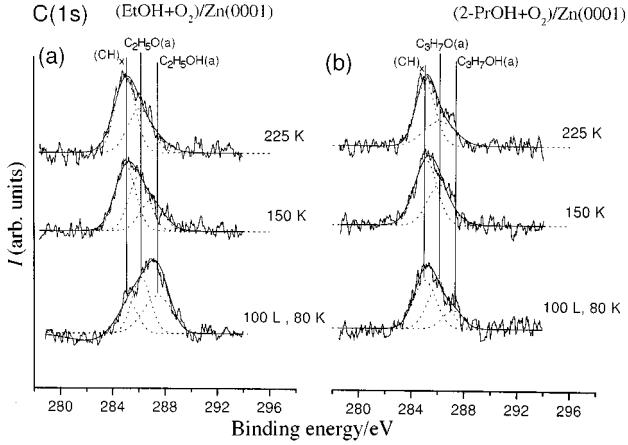

Fig. 2 C(1s) spectra of (a) of a 3 : 1 mixture of C_2H_5OH and O_2 and (b) of a 3 : 1 mixture of propan-2-ol and O_2 adsorbed on a Zn(0001) surface. The alcohol–oxygen mixture was adsorbed at 80 K and the surface progressively warmed to 225 K.

formation of the hydrocarbons will be related to the abundance of the alkoxy species. It is known that adsorption of alcohols on ZnO surfaces gives rise to alkenes, aldehydes and ketones.[11] However, in the present study on Zn surfaces, we only observe the formation of hydrocarbons.

The formation of the $(CH)_x$ type species at 80 K by the interaction of alcohol–oxygen mixtures with Zn surfaces suggests that the C–O bond scission is favoured by the oxygen transient. We represent these transformations as follows:

$$Zn + 1/2O_2 \rightarrow Zn + O^{\delta-}(a) \quad (3)$$

$$ROH + O^{\delta-}(a) \rightarrow RO(a) + OH(a) \quad (4)$$

$$RO(a) \rightarrow R(a) + O(a) \quad (5)$$

$$2OH(a) \rightarrow H_2O + O^{2-}(a) \quad (6)$$

We consider the occurrence of C–O bond scission in alcohols at as low a temperature as 80 K to be significant, considering that such scission occurs at 150 K in the absence of oxygen on the Zn(0001) surface and at much higher temperatures on other transition metal surfaces.

Is samarium diiodide an inner- or outer-sphere electron donating agent?

Rasmus J. Enemærke, Kim Daasbjerg* and Troels Skrydstrup*

Department of Chemistry, Aarhus University, Langelandsgade 140, 8000 Aarhus C, Denmark. Fax: +45 8619 6199. E-mail: kdaa@kemi.aau.dk

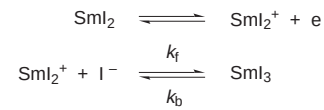
Received (in Liverpool, UK) 26th November 1998, Accepted 14th January 1999

From the measured value of $E°$ (SmI_2^+–SmI_2) in THF and using free energy plots, the electron transfer between samarium diiodide and acetophenone was shown to be clearly of inner-sphere nature; on the other hand, with benzyl bromide it is closer to an outer-sphere process.

Twenty years have almost passed since the first introduction of samarium diiodide (SmI_2) as a reagent for organic synthesis by Kagan and coworkers.[1] The rich chemistry of this polyvalent one-electron reductant has not been surpassed by any other reagent and it still continues to astound with its ability to promote an array of sequential reactions comprising of carbon radicals and anions.[2] It is surprising though that very little is known concerning the mechanistic details of the electron transfer processes (inner- or outer-sphere) taking place between Sm(II) and organic substrates.[3] In this paper, we describe the nature of the electron transfer between SmI_2 and two substrates, namely benzyl bromide and acetophenone.

Paramount for the comprehension of electron transfer processes involving SmI_2, is that the standard potential of the SmI_2^+–SmI_2 couple in THF be well defined. It is noteworthy that these fundamental measurements have not been performed even after 20 years of existence of SmI_2 in the organic chemistry community. The potential cited today by organic chemists for the Sm(III)–Sm(II) couple of −1.80 V *vs.* SCE was determined in 1948 by polarographic measurements in water,[4] which is simply not compatible with current studies.†

Hence, we set out to investigate the redox properties of SmI_2 and SmI_3 by means of cyclic voltammetry in a supporting electrolyte solution of NBu_4I (0.02 M) and NBu_4PF_6 (0.2 M) in THF.‡ Fig. 1 shows three of the voltammograms recorded for SmI_2 at different sweep rates v in the range 0.02–0.5 V s^{-1}. The peak separation increases from *ca.* 150 to 300 mV as a function of v. As the peak potentials and currents acquired in the voltammograms of SmI_2 are in good agreement with the corresponding values obtained for SmI_3, it appears that the same reaction mechanism is in play no matter which of the two compounds is the starting point for the electrochemical investigation. A working model was therefore set up, as illustrated in Scheme 1, involving a heterogeneous electron transfer step and a fast established chemical equilibrium, where SmI_2^+ coordinates strongly with I^- present in the electrolyte solution.



Scheme 1

In order to determine the standard potential (or more correctly the formal potential) $E°$ of SmI_2^+–SmI_2 from the cyclic voltammograms, the association constant ($K = k_f/k_b$) for SmI_3 is required. A rough estimate of $K \approx 10^7$ dm^3 mol^{-1} could be obtained simply by comparing conductivity measurements performed on SmI_3 and NBu_4I in THF since the association constant for NBu_4I in THF has been estimated previously.[7] However, the electrochemical measurements were carried out with substantial amounts of supporting electrolyte present in THF and K may be somewhat different in this more polar medium. Being cautious and selecting 1 and 10^4 as the limiting values of $K[I^-]$, digital simulations of the voltammograms (see Fig. 1) were carried out on the basis of the above reaction scheme.§ Simulations revealed that $K[I^-]$ is $< 10^4$ if the chemical equilibrium should be established quickly with a large k_b and without k_f exceeding the diffusion-controlled limit. The shape of the experimental cyclic voltammograms was presumably somewhat influenced by adsorption phenomena and therefore the main emphasis in the simulation procedure was to describe the reproducible development in the experimentally obtained peak potentials and currents as a function of v. This led to a value for $E°$ of −1.41 ± 0.08 V *vs.* Fc^+–Fc and for the logarithm of the standard heterogeneous rate constant $k°$ (in cm s^{-1}) of −2.20 ± 0.70. Comparing these values of $E°$ and log $k°$ with those obtained if the chemical equilibrium reaction is neglected (−1.51 V and −2.92, respectively) illustrates the importance of including follow-up or preceding reactions in electrochemical measurements.

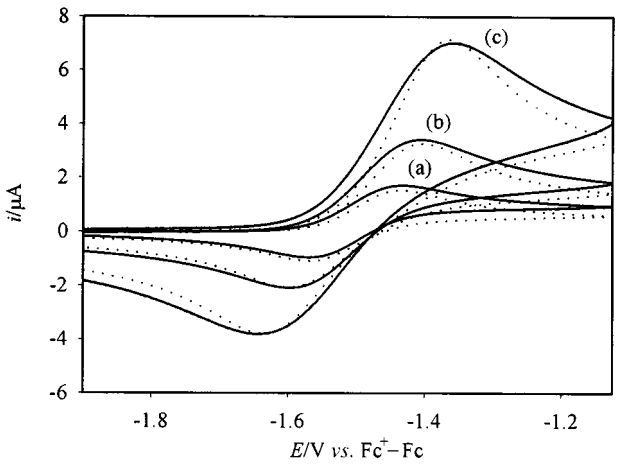


Fig. 1 Cyclic voltammograms of 2.5 mM SmI_2 recorded in THF–0.2 M NBu_4PF_6 + 0.02 M NBu_4I at a glassy carbon electrode (diameter = 1 mm) at sweep rates of (a) 0.02, (b) 0.1 and (c) 0.5 V s^{-1}. The dotted curves represent simulated curves based on the following parameters: $E°$ = −1.41 V, $k_f[I^-]$ = 1.5 × 10^5 s^{-1}, k_b = 3.8 × 10^3 s^{-1}, $k°$ = 0.0065 cm s^{-1}, D = 5.4 × 10^{-6} cm^2 s^{-1}, transfer coefficient α = 0.5 and capacitance C_d = 10^{-7} F.

The outer- or inner-sphere electron donor abilities of SmI_2 towards a given substrate can now be assessed by comparing the reactivity of SmI_2 and a corresponding outer-sphere electron donor.[8] In this way the degree of electronic interaction between SmI_2 and the substrate in the transition state can be estimated. The first reaction studied was the reduction of benzyl bromide, in which the rate-controlling step is the initial electron transfer forming the benzyl radical. As representatives of outer-sphere electron donors, four radical anions of aromatic compounds were selected having potentials $E°_A$ close to that of SmI_2^+.[8] The rate constants k_{ET} for the electron transfer reactions between the radical anions and benzyl bromide were measured¶ and depicted in free energy plots of log k_{ET} *vs.* $E°_A$ (Fig. 2). The value of k_{ET} (= 0.34 dm^3 mol^{-1} s^{-1}) corresponding to the $E°$ of SmI_2^+ = −1.41 V can be interpolated from the straight line

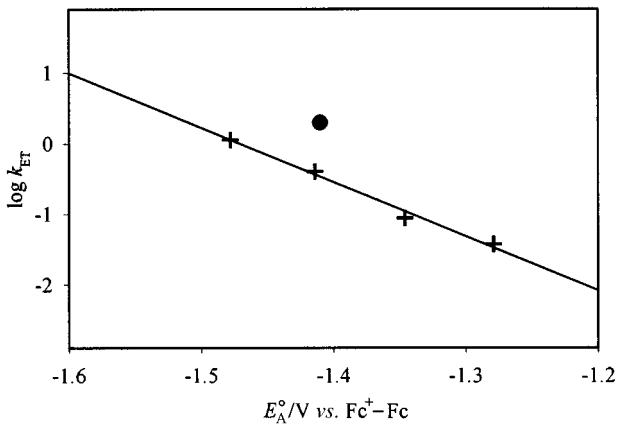

Fig. 2 Electron transfer rate constants (+) for the reaction between radical anions of aromatic compounds (2,3-dimethylanthraquinone, anthraquinone, 2,3-dimethylnaphthoquinone and 1,2-benzanthraquinone) and benzyl bromide as well as the rate constant (●) of the reaction between SmI_2 and benzyl bromide in THF–0.2 M NBu_4PF_6–0.02 M NBu_4I.

through the four points determined by linear least square analysis. Included in Fig. 2 is the rate constant k_{obs} of the reaction between SmI_2 and benzyl bromide (= 2.0 dm^3 mol^{-1} s^{-1}) with a position slightly above the line. The value of k_{obs}/k_{ET} thus obtained is 5.9 which indicates that the electron transfer process does have inner-sphere character. Nevertheless, the ratio is relatively small and it suggests that the electronic interaction between SmI_2 and benzyl bromide in the transition state amounts to only a few kcal mol^{-1}.‖

As a representative for the class of carbonyl compounds, which are involved in many SmI_2-induced electron transfer reactions, we studied the reduction of acetophenone. For SmI_2 the reaction leads to the formation of a metal-complexed ketyl radical in the rate-controlling step. However, the procedure used for measuring k_{ET} for benzyl bromide can not be employed in this case since the electron transfer from aromatic radical anions to acetophenone, forming its radical anion, involves an energetically unfavourable equilibrium reaction. Still, the rate constant for the electron transfer process between an outer-sphere donor of E° = −1.41 V and acetophenone can be estimated on the basis of the equations of Marcus and Eyring (using a collision frequency of 3×10^{11} dm^3 mol^{-1} s^{-1}).[11] The E° of acetophenone is −2.52 V as measured by cyclic voltammetry, and if the reorganization energy of the reaction is assumed to be in the range 20–30 kcal mol^{-1}, k_{ET} can be calculated as *ca.* 10^{-8} dm^3 mol^{-1} s^{-1}. The rate constant k_{obs} for the reaction between SmI_2 and acetophenone was measured¶ to be 7 dm^3 mol^{-1} s^{-1} so in this case k_{obs}/k_{ET} approaches 10^9. This is a substantial value compared with the result for benzyl bromide and the mechanism in this case clearly can be classified as an inner-sphere electron transfer process with a strong electronic interaction in the transition state.

In conclusion, we provide the E° value for the SmI_2^+–SmI_2 couple in THF, and apply it to describe the mechanism of electron transfer from SmI_2 to two organic substrates. We are currently using the above methodology to investigate the mechanism of SmI_2-based reductions of other functionalities.

Notes and references

† Shabangi and Flowers recently measured the oxidation potential of SmI_2 in THF–0.1 M NBu_4PF_6 but did not investigate the mechanism of the electrode reaction nor its thermodynamic significance (ref. 5). The peak potential was −1.33 V *vs.* Ag–$AgNO_3$ (−1.21 V *vs.* Fc^+–Fc) at a sweep rate of 0.1 V s^{-1}.

‡ The experimental set-up for the electrochemical experiments was as described in ref. 6. The working electrode was a glassy carbon disk of diameter 1 mm. All potentials were reported *vs.* the ferrocenium–ferrocene (Fc^+–Fc) redox couple, the potential of which was measured to 0.52 V *vs.* SCE in THF–0.2 M NBu_4PF_6. Experiments were carried out at 20 °C. NBu_4I was added to the cell in order to suppress any ligand-exchange of I^- by PF_6^- in either SmI_2 or SmI_3. UV-spectral investigations revealed that at least 10 mM of NBu_4I must be present in the electrolyte solution (THF–0.2 M NBu_4PF_6) for the UV-spectrum to resemble that of SmI_2 or SmI_3 in THF alone. The upper concentration limit of NBu_4I was 30 mM, set by its solubility.

§ Digisim 2.1 software (Bioanalytical Systems Inc) was used for digital simulation. The diffusion coefficients of SmI_2 and SmI_2^+, *D*, were assumed to be equal. In the experiments, variation of the NBu_4I concentration in the range 10–30 mM had no detectable effect on the position of the peak potentials. This was attributed to the small dissociation constant of NBu_4I in THF ($\approx 10^{-6}$ mol dm^{-3})[7] and the resulting low concentration of free iodide. The concentration of iodide was assumed to be reasonably constant throughout the whole scan range due to the equilibrium reaction with NBu_4I and thus included in the forward rate constant k_f in the simulations. At lower concentrations of NBu_4I the cyclic voltammetric waves were shifted in a positive direction though being complicated by ligand exchange reactions involving PF_6^- from NBu_4PF_6.

¶ The reaction kinetics was followed by UV–VIS spectroscopy using a dip-probe technique (ref. 9). The decay of SmI_2 in the presence of a substrate was detected at 560 and 620 nm. No build-up of intermediates during the reaction could be detected in the wavelength range 300–800 nm. The presence of supporting electrolyte had no influence on the reaction rate. The kinetics for benzyl bromide and acetophenone followed the same rate law described by: $d[SmI_2]/dt = -nk_{obs}[SmI_2][substrate]$, where n = 2 for benzyl bromide and n = 1 for acetophenone. k_{obs} was determined under pseudo-first-order conditions using an excess of substrate.

‖ This is true even if one takes into account that the k_{obs}/k_{ET} ratio obtained should be considered as a minimum value;[10] the self-exchange reorganisation energy of the SmI_2^+–SmI_2 couple is somewhat higher than for the aromatic radical anions as indicated by the relatively low value of k° measured by cyclic voltammetry.

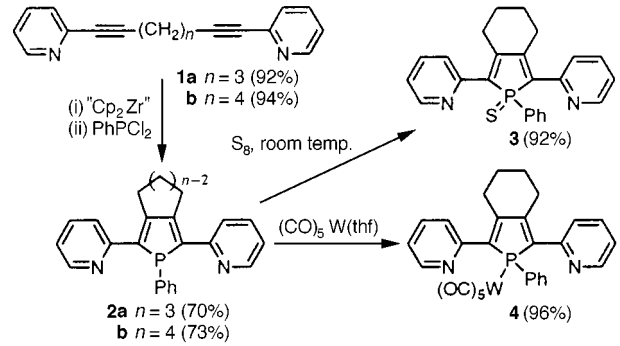
Received (in Liverpool, UK) 28th October 1998, Accepted 23rd December 1998

2,5-Di(2-pyridyl)phospholes possess an extended π-conjugated system with a charge transfer structure; high yielding chemical modifications involving the phosphorus atom allow fine tuning of the HOMO–LUMO gap.

The control of both the structure and HOMO–LUMO gap of linear π-conjugated oligomers is the focus of considerable interest. These compounds have been investigated in order to simulate the electronic and electrochemical properties of the corresponding polymers and they are now emerging as efficient molecular wires in electronics applications.[1] Group 15 and 16 heterocyclopentadienes have been widely used as building blocks for the design of well-defined linear π-conjugated oligomers.[1] However, there are only a few instances of phospholes having been used for such a purpose,[2] although they display particular properties which make them attractive synthons. Firstly, the aromaticity of phospholes is generally much lower than that of furan, pyrrole or thiophene.[3] This is a consequence of the inherent pyramidal geometry of the tricoordinate phosphorus atom which disrupts efficient orbital interaction within the five-membered ring. This property should have an impact on the molecular engineering of the HOMO–LUMO separation of linear π-conjugated systems since π-electron delocalization along the chain is favoured when the backbone features heterocycles of low resonance energy.[1a,3c] Secondly, and in contrast to thiophene or pyrrole, phospholes possess a heteroatom which retains a versatile reactivity.[3a,b] This may offer the possibility of tuning the HOMO–LUMO gap *via* chemical modifications. Recently, Mathey *et al.* prepared various α-oligophospholes (n = 2–4) and oligomers containing α-thienyl- or α-furyl-α-phospholyl links.[2a–e] X-Ray diffraction studies performed on these derivatives showed that they deviate notably from planarity. This rotational disorder prevents extended π-conjugation because the orbital overlap varies approximately with the cosine of the twist angle. A recent strategy to effect a coplanar arrangement in linear π-conjugated polymers involved constructing alternating [A-B] derivatives where the A and B units are electron-deficient and electron-rich, respectively.[4] These derivatives are considered to have a charge-transfer structure with double bond character between the A-B units. As the parent phosphole can be considered as a very electron-rich heterocyclopentadiene,[3c] we decided to investigate the preparation of derivatives based on alternating pyridine and phosphole rings with a well defined 2,5-linkage. Herein, we describe an efficient synthesis of the simplest model, namely a 2,5-di(2-pyridyl)phosphole, and we show the possibility of tuning its HOMO–LUMO gap through chemical modifications.

The target phospholes were prepared according to Fagan's method[5] which involves the reaction of zirconacyclopentadienes with dihalogenophosphines. In order to obtain the desired 2,5-substitution pattern, diynes **1a**,**b** possessing a flexible spacer were employed (Scheme 1).[6] A Sonogashira coupling of hexa-1,7-diyne with 2-bromopyridine allowed an efficient and large-scale preparation of derivatives **1a** (92%) and **1b** (94%). These compounds reacted at −78 °C with 'zirconocene'[6] *via* a regioselective ring-closing diyne coupling to give the corresponding zirconacyclopentadienes which were characterised by NMR spectroscopy. Isolation of the zirconium-containing metallacycles was not necessary; addition of 1.1 equiv. of $PhPCl_2$ to the reaction mixture at −78 °C afforded the desired phospholes **2a**,**b** in a 'one-pot' procedure. They were isolated as air-stable yellow powders after purification by chromatography (alumina) in 70 and 73% yield, respectively. Phospholes **2a**,**b** have been characterised by high resolution mass spectrometry and elemental analyses and they exhibit the expected NMR spectroscopic data. In the ^{13}C NMR spectrum, the endocyclic P–C_α carbon atoms of **2a** give a singlet, which is not unusual for phospholes,[2e,3a,b] while the other endocyclic carbon and the C_{ipso} atoms of the aromatic rings of compounds **2a**,**b** all appear as doublets with classical J_{PC} coupling constants.



Scheme 1

The crystal structure of derivative **2b** (Fig. 1) reveals that, as expected, the phosphorus atom is strongly pyramidalized [Σ(CPC angles) = 299.3°] and that the endocyclic P–C bond lengths [1.801(4) and 1.804(4) Å] approach that of a P–C single bond (1.84 Å). These data compare well with those observed for a 2,5-dialkynylphosphole[2c] [Σ(CPC angles) = 292.4°; P–C,

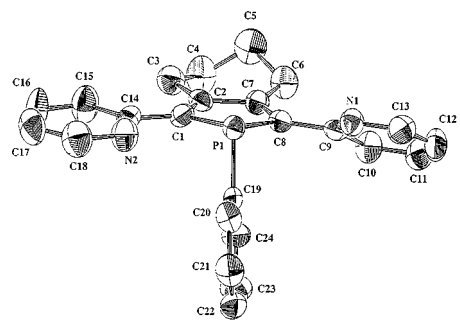


Fig. 1 ORTEP view of **2b**. Selected bond lengths (Å): P–C(1) 1.806(6), C(1)–C(2) 1.354(8), C(2)–C(7) 1.478(9), C(7)–C(8) 1.356(9), C(8)–P 1.806(6).

1.815–1.821 Å] and 1,2,5-triphenylphosphole[7] [P–C, 1.822 Å], two compounds for which it is proposed that ring delocalization is almost switched off, with the endocyclic subunit being conjugated with the C_2 and C_5 substituents.[3a,b] Of particular importance, the two bond lengths between the pyridyl rings and the slightly puckered phosphole ring [1.464(5) and 1.467(5) Å] have values that lie between those associated with single and double bonds, and the dihedral angles (25.6 and 7.0°) are relatively small, allowing an extended π-conjugation. These structural data clearly show that in 1-phenyl-2,5-di(2-pyridyl)phospholes the dienic moiety of the phosphole ring is conjugated with the two pyridine rings and not with the phosphorus atom.

The UV–VIS data for compounds **2a**,**b** and of the related 2,5-diphenylphosphole **2c** are given in Table 1. Derivative **2c** was isolated in only 10% yield according to the strategy presented in Scheme 1 starting from 1,8-diphenylocta-1,7-diyne.[6b] Interestingly, the λ_{max} observed for 2,5-pyridylphospholes **2a**,**b** are comparable, and notably longer to that of the 2,5-diphenylphosphole **2c** ($\Delta\lambda_{max}$ > 36 nm). This observation, which is in line with the conclusion drawn from the solid state structure, highlights the importance of the alternating electron-deficient/electron-rich ring structure of derivatives **2a**,**b** which favours the delocalization of the π-system.

The next question was whether chemical transformation involving the phosphorus atom, which is not involved in the π-delocalized system, would significantly modify the HOMO–LUMO gap? Treatment of phosphole **2b** with elemental sulfur and $W(CO)_5$(thf) afforded derivatives **3** and **4**, respectively, in near quantitative yields. The molecular formulae of **3** and **4** were established by multinuclear NMR spectroscopy, high resolution mass spectrometry and elemental analyses. These chemical transformations resulted in a blue shift of λ_{max} relative to phosphole **2b** (Table 1), the effect being more pronounced for the sulfide **3** ($\Delta\lambda_{max}$ = 26 nm) than for the complex **4** ($\Delta\lambda_{max}$ = 17 nm). In order to evaluate the relative contribution of geometric effects (degree of planarity) on values of λ_{max} in this series, derivative **4** was subjected to an X-ray diffraction study (Fig. 2). The structural data for complex **4**† are very similar to those observed for the free phosphole **2b**, suggesting that the coordination of the metal did not result in a dramatic steric perturbation. As observed for the free ligand, the three heteroatoms are pointing in the same direction. Note that the sum of the CPC angles is 298.7° (**2b**, 299.3°) and that the two endocyclic P–C bonds [1.818(4) and 1.824(4) Å] are slightly longer than those of **2b** [1.801(4) and 1.804(4) Å]. The twist angles between the pyridyl and the phosphole rings (11.3 and 0.0°) are smaller than those observed for the non-coordinated phosphole **2b** (25.6 and 7.0°). Since the pyridine–phosphole–pyridine moiety of **2b** is more planar when coordinated, the origin of the blue shift observed on going from **2b** to **4** is likely to be due to electronic factors. It seems reasonable to propose that both oxidation with sulfur and the coordination of the phosphorus atom decreases the electron-density of the phosphole ring, leading to a decrease in the degree of charge transfer in the π-linear conjugated pyridine–phosphole–pyridine system. As expected, this effect is more pronounced for sulfide **3** than for complex **4**.

Derivatives **2a**,**b** and **4** are air-stable in the solid state and also in THF solution for days. Preliminary stability tests by thermogravimetric analysis and differential scanning calorimetry under nitrogen show that derivative **2a** (mp 186 °C) and **2b** (mp 192 °C) are stable up to 201 and 211 °C, respectively, whereas complex **4** (mp > 204 °C) decomposes at 204 °C.

The synthesis of alternating pyridine–phosphole co-oligomers with a well-defined 2,5-linkage is under active investigation.

We thank the Conseil Régional Bretagne for financial support of this work.

Table 1 UV–VIS data in THF for compounds **2a–c**, **3** and **4**

Compound	λ_{max}/nm	log ε
2a	390	3.96
2b	395	4.02
2c	354	4.20
3	364	3.28
4	373	4.01

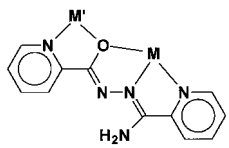
Received (in Cambridge, UK) 17th November 1998, Accepted 13th January 1999

The tetradentate ligand phaap combines a bridging alkoxide oxygen and diazine and pyridine nitrogen donors, with five critically positioned binding sites, and on reaction with $Mn(ClO_4)_2{\cdot}6H_2O$ undergoes a controlled self assembly to produce a unique trigonal bipyramidal oxygen bridged metal cluster with an exact match between the coordination requirements of the five six-coordinate metals and the donor arrangements of the six coordinated ligands.

The continued investigation of low molecular weight models for the oxygen evolving manganese complex of photosystem (II) has produced a range of homotetranuclear complexes, which have been bridged by oxygen centres and involved a variety of geometric arrangements, *e.g.* dimer of dimers, butterfly, cubane and adamantane type structures and mixed valence aggregates.[1–4] These have primarily been synthesized using strategies that utilize pre-organized macrocyclic hosts[1] or by employing self assembly reactions involving 'simple' carboxylates,[5] and substituted pyridonates.[6] The former method is a more rational approach because of the reduced tendency to form large aggregates, whereas the latter approaches often generate high nuclearity clusters that are difficult to predict in advance. There has also been a parallel increase in the number of higher nuclearity polymanganese aggregates, some of which possess manganese ions of variable oxidation state, and display single molecule magnetic behaviour.[7] However homopentanuclear Mn^{II} clusters[8] are poorly represented and their chemistry virtually unknown, while mixed oxidation state Mn_5 systems are rare ($Mn^{III}_4Mn^{II}$,[9] $Mn^{II}_4Mn^{III}$[10]). This situation can perhaps be attributed to the apparent lack of a general strategy for the synthesis of high nuclearity clusters, although several groups are attempting to overcome the problem by using *e.g.* small nuclearity clusters as 'building blocks'.[11]

We have discovered that it is possible to combine the attributes of a bridging donor (alkoxide), and terminal donors in



phaap

one 'planar' tetradentate ligand phaap which is capable of acting in a polynucleating, bridging capacity to aggregate several transition metal centres into an alkoxo-bridged cluster in an apparently controlled way. A number of square tetranuclear, homometallic (Ni^{II}, Co^{II}, Cu^{II}), and heterometallic ($Co^{II}_2Fe^{III}_2$, $Fe^{III}Cu^{II}_3$) complexes of phaap have been produced,[12] but with Mn^{II} the preferred arrangement is a pentanuclear cluster.

Reaction of phaap with $Mn(ClO_4)_2{\cdot}6H_2O$ in aqueous methanol produced an orange product (90% yield),‡ which gave orange crystals of $[Mn_5(phaap - H)_6](ClO_4)_4 \cdot 3.5MeOH{\cdot}H_2O$ **1** from ethanol suitable for structural analysis.§ A similar pentanuclear nitrate cluster complex $\{[Mn_5(phaap - H)_6](NO_3)_4{\cdot}5H_2O\}$¶ is produced by reaction of phaap with manganese(II) acetate in methanol followed by addition of $NaNO_3$.[12] The structure of the cation in **1** is unique (Fig. 1), with three pairs of almost parallel tetradentate ligands arranged around a pentanuclear, trigonal bipyramidal manganese(II) core, with each ligand filling five metal coordination sites and providing an alkoxide type bridge between adjacent pairs of pseudo-octahedral manganese atoms. The NH_2 ends of the ligands terminate at the equatorial manganese centers, and the O ends terminate at the apical centers, with each tetradentate (N_3O) ligand bridging each adjacent pair of metal centers along the six non-equatorial edges of the trigonal bipyramid. This arrangement provides an exact match between the coordination environment provided by the ligands and the coordination requirements of the five pseudo-octahedral metal centers. Within the Mn_5 core (Fig. 2) each apical metal atom is linked to an equatorial metal atom by an oxygen bridge, and each equatorial metal atom is linked to the apical pair of manganese atoms by two oxygen bridges. The equatorial manganese atoms are quite distorted, with *cis* and *trans* ligand angles as low as 70 and 140° respectively. The apical manganese centres have more normal pseudo-octahedral angles. Mn–N and Mn–O distances fall in the ranges 2.14–2.41 and 2.14–2.22 Å, respectively.

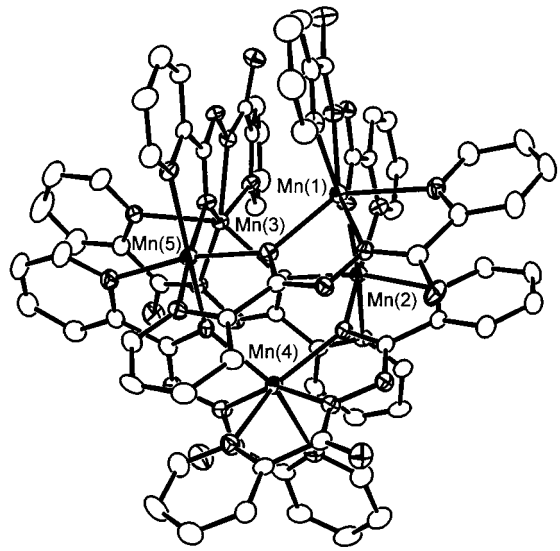


Fig. 1 Structural representation of the cation $[Mn_5(phaap - H)_6]^{4+}$ (40% probability thermal ellipsoids). Mn(1)–Mn(2) 3.9474(14), Mn(1)–Mn(5) 3.9630(12), Mn(3)–Mn(5) 3.9208(14), Mn(4)–Mn(5) 3.9059(13), Mn(2)–Mn(3) 3.9116(12), Mn(2)–Mn(4) 3.9190(13), Mn–N 2.144–2.403, Mn–O 2.140–2.218 Å.

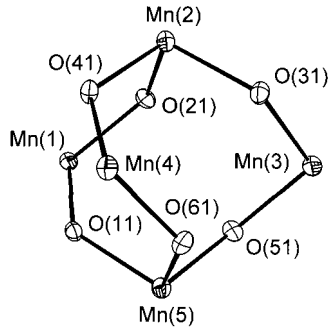

Fig. 2 Structure of the trigonal-bipyramidal core in $[Mn_5(phaap - H)_6]^{4+}$.

Adjacent Mn···Mn separations fall in the range 3.90–3.97 Å, with Mn–O–Mn angles in the range 128–131°. Within each ligand N–N distances average 1.399 Å, indicating single bond character, while average C–O and C–$N_{diazine}$ distances of 1.311 and 1.297 Å, respectively, indicate some charge delocalization within each N–C–O framework.

Variable temperature magnetic susceptibility measurements were carried out on a powdered sample of **1** in the temperature range 5–300 K.‖ Magnetic moments (per mole) drop smoothly from 13.4 μ_B at 296 K to 5.8 μ_B at 5 K, indicating the presence of antiferromagnetic coupling within the pentanuclear manganese(II) core, and the likelihood of an $S = 5/2$ ground state. This is consistent with the presence of oxygen bridges between the manganese(II) centres. An evaluation of the exchange coupling will be described elsewhere.

Electrochemical studies carried out in acetonitrile (1.0 mM, 0.1 M NEt_4ClO_4; Pt working electrode, Pt counter electrode, SSCE reference electrode) revealed three sequential, reversible, one electron waves (cyclic voltammetry; $\Delta E_p = \approx 90$ mV for each wave, and remains essentially constant from 100–1000 mV s^{-1}) in the range 0.6–1.0 V (Fig. 3), with equal current heights (coulometry at 1.1 V required 3.0 equivalents of charge for full oxidation to a brown colored solution, and with the potential set at 0.5 V after oxidation 3.0 equivalents of charge were required for full reduction to the original yellow orange colored solution) corresponding to the formation of a Mn^{II}_2-Mn^{III}_3 species. The Mn^{III} sites are assumed to be those in the equatorial plane. An irreversible wave at $E_{1/2} = 1.5$ V, similar to an irreversible wave observed in an acetonitrile solution of the zinc perchlorate complex, is associated with ligand oxidation. No EPR signal (X band) was observed for the $Mn^{II}_2Mn^{III}_3$ solution at ambient temperature, but in the UV–VIS spectrum an intense band appears at 937 nm ($\varepsilon = 720$ dm^3 mol^{-1} cm^{-1}), which is absent in the spectrum of **1**. On prolonged standing the spectrum reverts to that of the Mn^{II}_5 species.

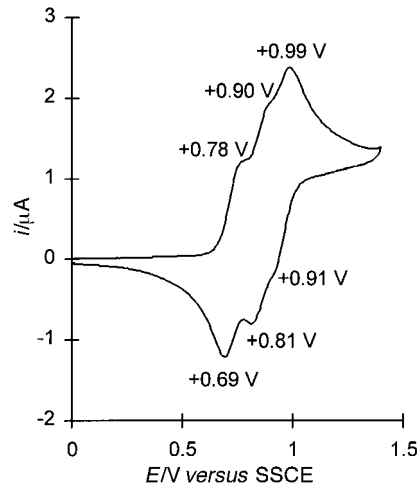

Fig. 3 Cyclic voltammetry for $[Mn_5(phaap - H)_6](ClO_4)_4$ in acetonitrile (1.0 mM, 0.1 M NEt_4ClO_4; Pt working electrode, Pt counter electrode, SSCE reference electrode; BAS CV27 Voltammograph; 100 mV s^{-1}).

The aggregation of five six-coordinate manganese(II) centres (thirty coordination positions) into an alkoxo-bridged, trigonal bipyramidal cluster by the six phaap ligands (thirty donor atoms) can be regarded as directed synthesis followed by self assembly, where the coordination site arrangement presented by the ligands matches exactly the coordination algorithm of the five metals. The fact that this geometrical arrangement seems to be unique for Mn^{II} may arise from the coordination flexibility of this metal ion due to its high spin d^5 electron configuration and zero crystal field stabilization energy.

Rationalisation of the IR stretching frequencies of Brønsted acid centres in microporous solids

Dewi W. Lewis*[a] and German Sastre[b]

[a] *Department of Chemistry, University College London, 20 Gordon St., London, UK WC1H 0AJ. E-mail: d.w.lewis@ucl.ac.uk*

Received (in Cambridge, UK) 7th December 1998, Accepted 15th January 1999

The relative position of the O–H stretching frequency of Brønsted acid sites in microporous solids is found to be correlated with the gradient norm of the electrostatic potential and, unlike previous attempts to provide a unified picture of the vibrational properties in such solids, the correlation is found for all structural and compositional variants studied to date.

Both aluminosilicate and aluminophosphate-based crystalline microporous solids can be prepared so that they possess acidic properties, rendering them suitable as solid acid catalysts. The predominant acid function in such materials is a Brønsted acid centre characterised by a protonated oxygen bridging two tetrahedrally coordinated atoms, T–O(H)–T′, where T is typically Si, Al, P. The relative acidity of different centres is typically estimated from the IR vibrational frequency of the hydroxyl bond, ν(O–H) and, more realistically, through the shift in this frequency on the sorption of small probe molecules.[1] Over the years, a number of attempts have been made to provide a rationalisation of the relative position of the stretching frequency of the Brønsted hydroxyl, ν(O–H), with the use of Sanderson electronegativity[2] being the most successful. However, this approach is found only to be valid for low concentrations of acid sites when the acid centres can be considered homogeneous and cannot, therefore, be applicable in the case of either low Si/Al zeolites,[3] or for SAPO materials, where Si-islands can form. Furthermore, the electronegativity is dependant only on composition[2] and hence differences in acidity between different structures with the same composition cannot be accounted for. Deviations are also found once acid sites are considered to be 'perturbed' as a consequence of being present in small cavities. In such cases, a $1/r^2$ relationship between the bathochromic shift observed and near neighbour oxygen distances in the same ring as the acid site has been proposed.[2] The latter observation has been taken by many authors as suggesting that the shift is proportional to the size of the cavity in which the proton vibrates and have assigned IR bands based on this assumption alone, without any consideration of the local environment not part of the immediate cavity. However, no general descriptor or rationalisation has been suggested which is consistent regardless of material structure and composition. Furthermore, there exists little theoretical evaluation of the correlations described above.

We have applied standard lattice energy minimisation and Mott–Littleton methodologies[4] to determine the equilibrium geometries of acid sites in a variety of structures and compositions of both aluminosilicates and silicoaluminophosphates and subsequently used a lattice dynamics approach to calculate the vibrational properties; the GULP code[5] was used throughout. The model consists of formally charged ions which also interact through short-range interatomic potentials (two- and three-body terms) coupled with a shell model description of polarisation; the parameters used are those of Sanders *et al.*[6] and Gale and Henson,[7] with the hydroxyl model being a modification of that derived for NaOH.[8,9] The model has been extensively demonstrated to reproduce experimental structures and also gives good agreement with experimental vibrational properties; although a -150 cm^{-1} correction for anharmonicity is required for O–H stretching frequencies.[9] The results presented here have been corrected thus unless otherwise stated.

The ability of the model to reproduce the experimentally observed vibrational properties is illustrated in Fig. 1. Not only are the relative shifts in ν(O–H) between the different structures reproduced but also the range of vibrations noted within a structure are in good agreement. Our calculations also reproduce the observed bands; for example, in SSZ-13 we calculate two bands at 3593 and 3575 cm^{-1} and in mordenite we observe two bands at 3600 and 3572 cm^{-1}, compared to 3603, 3579 and 3612, 3585 cm^{-1} respectively from experiment. Similarly, we calculate shifts to lower wavenumber with decreasing Si/Al in FAU.

Thus, together with previous studies, the data strongly suggests that this particular potential model is suitable for determining the relative positions of vibration frequencies across a broad range of microporous systems. But what properties of the structure correlate with the resulting vibrations? Do the calculated sites and geometries correlate with features such as cavity size discussed above?

We previously demonstrated that short-range interactions which manifest themselves as local geometry changes, particularly in the T–O–T′ bond angle are not adequate to identify variations in vibrational properties.[10] For example, identical T–O–T′ angles at different sites within the same structure can

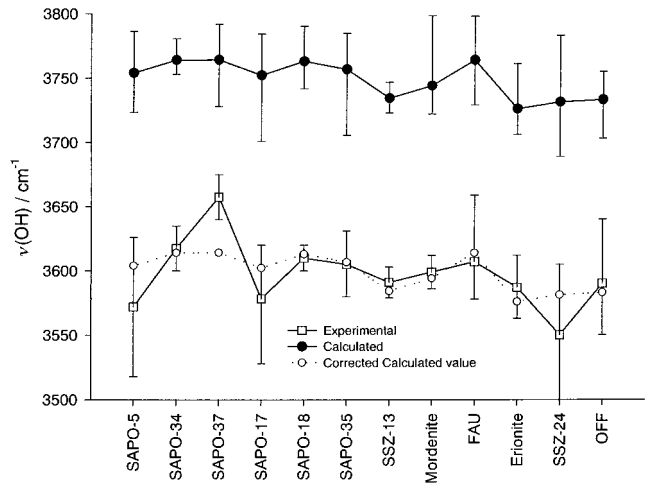

Fig. 1. Comparison of calculated (●) and experimental (□) ν(O–H) values. Shown as data points are the mean values of all noted signals; from experiment each peak position noted in published spectra has been included, whilst our calculations include all sites considered regardless of relative energy. The bars signify the minimum and maximum values found with no consideration of relative peak strength (in the case of experiment) or likely population (in the case of the calculated values). Once the anharmonicity correction term[9] of -150 cm^{-1} is applied to the calculated values (○), close agreement is found with the experimental value of ν(O–H).

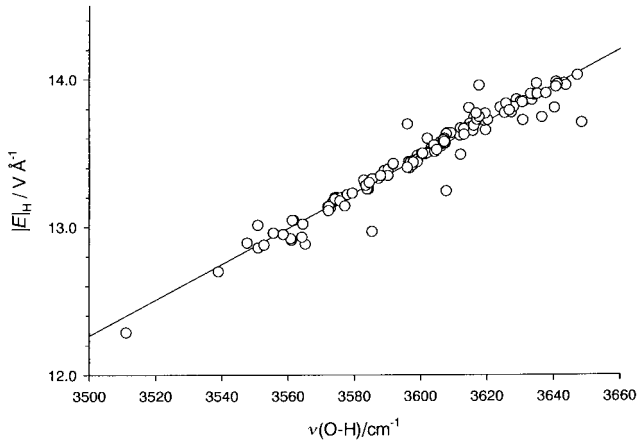

Fig. 2 Correlation of the gradient norm of the electrostatic potential at the proton ($|E|_H$) with the calculated stretching frequency (corrected for anharmonicity), ν(O–H). Acid centres considered include; isolated sites in high Si/Al aluminosilicates, sites in low Si/Al and in Si/Al = 1 aluminosilicates and isolated and island sites of SAPOs, in the structure types indicated in Fig. 1.

possess radically different values of ν(O–H). Instead, we consider (as have others) that the long-range Coulombic interactions are dominant and have previously observed a remarkable correlation between ν(O–H) and the gradient norm of the electrostatic potential at the proton, $|E|_H$, when considering the acidity of SAPOs.[10,11] Extending this idea to the range of structures now considered, it is clear from Fig. 2 that such a correlation appears quite general. We do not, however, observe a consistent correlation between ν(O–H) and the size of the cavity in which the proton is vibrating (Fig. 3) as is often claimed. Furthermore, we do not find that consideration of near neighbour O–H distances[2] can be used to identify likely shifts in

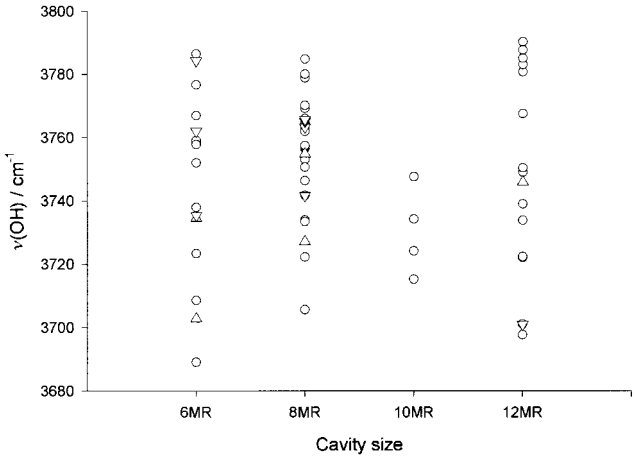

Fig. 3 Calculated vibrational frequencies and cavity size for isolated Brønsted acid sites. All data are presented as open circles whilst highlighted are the values for SAPO-17 (▽) and Offretite (△) which clearly show that cavity size alone cannot account for the relative position of ν(O–H); similar-sized cavities exhibit a wide range of values, whilst in some materials protons in large cavities have higher ν(O–H) than smaller cavities.

ν(O–H). For example, we observe a number of cases where we obtain almost identical ν(O–H) for protons vibrating within different sized cavities of the same material; in SAPO-17 we calculate that protons in both 8MR and 6MR sites vibrate at 3613–3616 cm^{-1}, whilst we also determined other sites in 6MR vibrating at a lower value of 3592 cm^{-1}.[11] In SAPO-35 we determined that three of the lowest frequency vibrations, at 3607 cm^{-1}, are present in 8MR whilst a proton in a 6MR gave a signal at 3616 cm^{-1},[11] which may have been expected to shift to lower values if the cavity size and reduction in nearest oxygen distances arguments held.[2] This apparent lack of correlation can be readily rationalised; consideration of the cavity size does not take into account the interactions between the proton and oxygens which are 'behind' the proton; and near-neighbour oxygens not directly in the same ring may be closer, and thus more influential, than those in the ring, particularly for larger cavities.

In summary therefore, we have identified that interatomic potential calculations are able to reproduce the vibrational properties of Brønsted acid sites in a wide structural and compositional range of microporous solids. We find that the relative position of ν(O–H) can be correlated with the gradient norm of the electrostatic potential at the proton, providing a direct correlation between the structure and the resulting vibration. Note, however, that simple consideration of the electrostatic potential of the framework 'hosting' the acid sites does not provide such insights; lattice relaxation is significant. Thus, we believe, these calculations can be used to verify and assign observed IR bands to specific acid sites in such structures. Furthermore, they may indeed provide a unifying rationalisation of stretching frequencies in such materials. Current work is focused on understanding further the correlation with electrostatic potential and the contribution of the electrostatic field to proton transfer.

We thank the Instituto de Tecnologia Quimica for a postdoctoral research grant (G. S.) and the Royal Society for further funding (D. W. L.). We also thank Dr J. D. Gale for many useful discussions.

Received (in Cambridge, UK) 26th November 1998, Accepted 8th January 1999

The role of the base in $RuCl_2(PPh_3)_3$-catalyzed hydrogen transfer reactions is to generate a highly active $RuH_2(PPh_3)_3$ catalyst from the dichloride *via* two consecutive alkoxide displacement–β-elimination sequences.

In 1991 we reported on a dramatic rate acceleration in the $RuCl_2(PPh_3)_3$-catalyzed transfer-hydrogenation of ketones upon addition of a catalytic amount of base.[1] The accelerating effect of the base was in the order of 10^3–10^4, and this provided a viable procedure for transfer hydrogenation. This remarkable effect was subsequently extended to other hydrogen transfer reactions,[1b] and by using it in the reversed direction, procedures for ruthenium-catalyzed Oppenauer oxidation were developed.[2] Further developments of the ruthenium-catalyzed transfer hydrogenations[3,4] into enantioselective versions have been recently realized by several groups.[5–10]

The effect of base in the iridium-catalyzed[10b–11] transfer hydrogenation has also been observed, but the role of base has remained unclear.[12] In our previous work on the use of $RuCl_2(PPh_3)_3$ **1** as a catalyst we proposed that a ruthenium alkoxide is formed with a subsequent β-elimination[13] to give a ketone and $Ru(H)Cl(PPh_3)_3$ **2**. The latter was proposed to act as the active catalyst. We have now studied the mechanism of this reaction and found that formation of a ruthenium dihydride species is responsible for the dramatic rate acceleration.

The reaction of $RuCl_2(PPh_3)_3$ **1** with isopropanol in the presence of base was studied by ^1H NMR spectroscopy with the aim of detecting complexes, which are possible active catalytic intermediates in transfer hydrogenation reactions. Treatment of $RuCl_2(PPh_3)_3$ with isopropanol and KOH at room temperature under argon gave a doublet of a triplet at δ −10.15 (J_{PH} 35.2, 42.2 Hz) and a broad singlet at δ −7.07 in an integral ratio of 3 : 1.[14] According to literature data the multiplet at δ −10.15 was assigned as $RuH_2(PPh_3)_3$ **3′**[15] and the singlet at δ −7.07 as $Ru(H_2)H_2(PPh_3)_3$.[16] Thus, the mole ratio between the complexes is 6 : 1. To further establish the assignments, reference samples of $RuH_2(PPh_3)_4$ **3**[17] and $Ru(H_2)H_2(PPh_3)_3$[16] were prepared according to literature procedures. Addition of **3** to the reaction sample increased the multiplet at δ −10.15. The doublet of triplet coupling pattern and the presence of free PPh_3 according to ^{31}P NMR clearly indicate that in solution $RuH_2(PPh_3)_4$ **3** dissociates a phosphine to give $RuH_2(PPh_3)_3$ **3′**. Also, addition of $Ru(H_2)H_2(PPh_3)_3$ to the reaction sample increased the broad singlet at δ −7.07. Furthermore, the ^{31}P NMR of the reaction sample and the reference samples established the assignments made. It is not yet clear which role $Ru(H_2)H_2(PPh_3)_3$ plays in the catalytic reaction but it is known[15a,18] that in the presence of ketones $Ru(H_2)H_2(PPh_3)_3$ easily dissociates its H_2 ligand. This will generate the active catalyst $RuH_2(PPh_3)_3$ **3′** and also lead to some 'hydrogen-leakage' in the hydrogen transfer reaction.[19]

The observation that a ruthenium dihydride complex is formed when $RuCl_2(PPh_3)_3$ reacts with isopropanol in the presence of base has interesting mechanistic implications for $RuCl_2(PPh_3)_3$-catalyzed hydrogen transfer reactions. To obtain further evidence for a dihydride species as the active catalyst, we studied the catalytic hydrogen transfer between cyclopentanol and acetone employing three different catalyst sources: $RuCl_2(PPh_3)_3$ **1**, $Ru(H)Cl(PPh_3)_3$ **2**,[20] and $RuH_2(PPh_3)_4$ **3**[17] [Fig. 1, eqn. (1)].

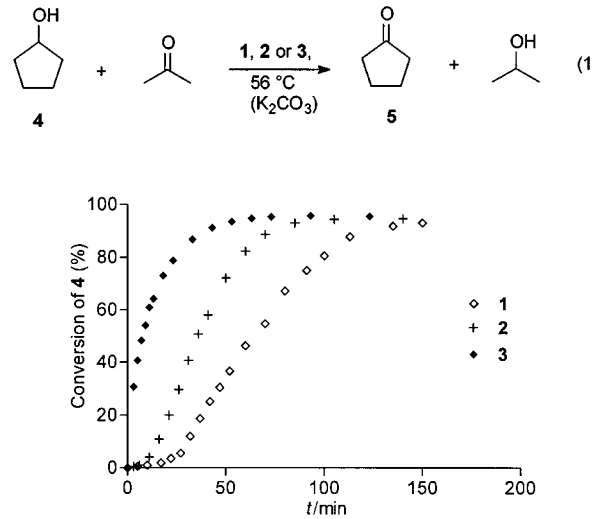

Fig. 1 Ruthenium-catalyzed hydrogen transfer from cyclopentanol to acetone with $RuCl_2(PPh_3)_3$ **1**, $Ru(H)Cl(PPh_3)_3$ **2**, or $RuH_2(PPh_3)_4$ **3** at 56 °C in the presence of K_2CO_3. In each experiment 0.2 mol% of ruthenium catalyst was employed.

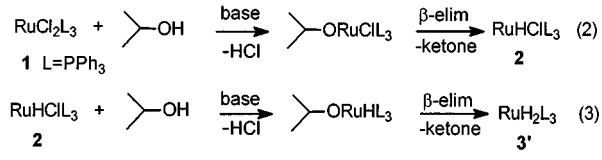
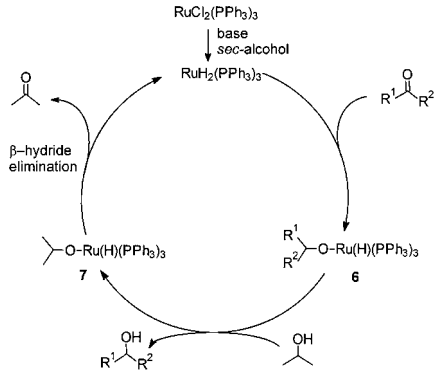
The conversion of **4** to **5** was monitored by GC. Significant differences were observed in the reaction rates for the three catalyst precursors. Thus, there were observable induction periods for the complexes **1** and **2**, with the longest induction period for **1**. For the dihydride complex **3** there was a fast initial rate, without any sign of an induction period. Catalyst **3** showed identical reactivity also in the absence of base, whereas **1** and **2** were inactive under these conditions. The longer induction period for **1** compared to **2** is explained by eqns. (2) and (3). The two chlorides in **1** are removed in two consecutive alkoxide displacement–β-elimination sequences whereas for **2** only one such sequence is requried [eqn. (3)].[21,22]



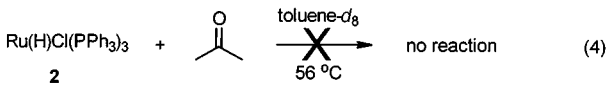
The mechanism for the ruthenium-catalyzed hydrogen transfer is depicted in Scheme 1. It is interesting that once the ruthenium dihydride has been generated the base is no longer required, which was confirmed by experiments (*vide supra*).

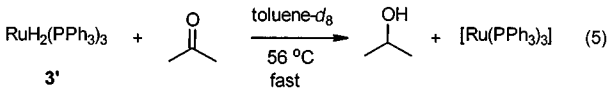
Additional support for a dihydride as the active catalyst was obtained from stoichiometric reactions of **2** and **3′** with acetone in toluene-d_8 [eqns. (4) and (5)] monitored by ^1H NMR. Thus, it was found that monohydride **2** did not react with acetone at



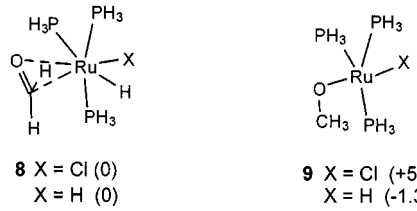
Scheme 1 Mechanism of $RuCl_2(PPh_3)_3$-catalyzed hydrogen transfer.

56 °C, whereas the dihydride **3′** (generated from **3** *in situ*) rapidly ($t_{\frac{1}{2}} \approx 5$ min) reduced acetone to isopropanol. This rules out **2** as the active catalyst. In the catalytic system (Scheme 1), where there is a large excess of alcohol, it is likely that proton transfer from isopropanol to the alkoxy group in **6** takes place. This leads to an exchange of alkoxy groups on ruthenium to give **7**. In eqn. (5) there is no excess of alcohol and a formal reductive elimination to give a Ru(0) species would predominate.





Apparently, exchange of the chloride ligand of **2** to a hydride **3′** leads to dramatic changes in the electronic structure of the ruthenium catalyst, which facilitates the hydride addition to a ketone. Preliminary theoretical calculations on the formaldehyde complex **8** and the corresponding alkoxy adduct **9** for ruthenium monohydride (X = Cl) and ruthenium dihydride (X = H) were performed at the DFT/DZ + P level of theory.[23] The calculations show that for the monohydride **8** (X = Cl) the reaction is thermodynamically unfavored by 5.3 kcal mol^{-1} (Fig. 2). This implies that the alkoxy chloride **9** (X = Cl) is unstable and will undergo facile β-elimination to give the keto compound and the hydride.[24] In the case of the dihydride complex the equilibrium is slightly shifted toward adduct **9**, the free energy difference being about 1 kcal mol^{-1}.



8 X = Cl (0)
X = H (0)

9 X = Cl (+5.3)
X = H (-1.3)

Fig. 2 Energies (kcal mol^{-1}) of structures **8** and **9** for dihydride (X = H) and monohydride (X = Cl).

In conclusion, the experimental results indicate that ruthenium dihydride $RuH_2(PPh_3)_3$ is the active catalyst in base-accelerated $RuCl_2(PPh_3)_3$-catalyzed hydrogen transfer reactions.[25] Furthermore, it is shown that the monohydride **2** is not the active catalyst. Theoretical calculations support the observation that a chlororuthenium monohydride is unreactive towards hydride addition to a keto group.

'Inverse crown ether' complexes: extension to potassium through the synthesis of $[\{[(Me_3Si)_2N]_4K_2Mg_2(O_2)\}_\infty]$, a peroxo-centred macrocycle linked into infinite chains by intermolecular $K\cdots CH_3(SiMe_2)$ interactions

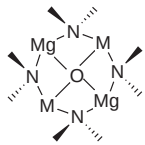
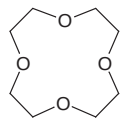
Received (in Cambridge, UK) 11th December 1998, Accepted 18th January 1999

The title compound represents the first potassium example of a novel class of amide-supported heterobimetallic macrocycle having a dicationic $(N_4K_2Mg_2)^{2+}$ octagonal ring framework surrounding a dianionic $(O_2)^{2-}$ core.

In the conventional host–guest chemistry of crown ether complexes,[1] the series of oxygen centres within the macrocyclic ligand host provide an electron-rich cavity tailor-made for the entertainment of electron-poor metal cation guests. Recently, however, we have described a remarkable new type of macrocyclic complex which conversely has a series of metal cations within its cyclic ring framework and an oxygen anion within the cavity of the ring.[2] Their generalised structural formula is depicted in **1**. Best regarded as 'inverse crown ether'



1



[12]crown-4

complexes, their ring motifs in containing four Lewis acidic metal sites can be thought of in effect as the inverse of [12]crown-4 with its four Lewis basic ligand sites. Preceding this work, the collection of [12]mercuracarborand-4 complexes developed by Hawthorne and coworkers[3] have been similarly interpreted as 'anti-crown', charge-reversed analogues of [12]crown-4, but, in this case, no oxygen anions are involved; instead the softer acid Hg centres bind anions such as Cl^-, Br^-, I^- or *closo*-$B_{10}H_{10}^{2-}$. Returning to the inverse crown ether complexes, three have been reported previously. Two are dilithium-dimagnesium amides, $[\{(Me_3Si)_2N\}_4Li_2Mg_2(O_2)_x(O)_y]$[4] **2** and $[(Me_2CCH_2CH_2CH_2Me_2CN)_4Li_2Mg_2(O)]$[2] **3**; while the third is a disodium analogue $[\{(Me_3Si)_2N\}_4Na_2Mg_2(O_2)_x(O)_y]$[2] **4**. Here, in this paper, we extend this novel class of heterobimetallic macrocyclic complex to the next member of the alkali metal family, potassium, through the synthesis and structural characterisation of the dipotassium-dimagnesium amide $[\{[(Me_3Si)_2N]_4K_2Mg_2(O_2)\}_\infty]$ **5**. Though also based on an eight-membered $(N_4M_2Mg_2)$ ring system, the crystal structure of **5** differs in two major respects from those of its lithium and sodium congeners: first, the $(N_4K_2Mg_2)$ ring is not molecular, but polymerises through intermolecular $K\bullet\bullet\bullet CH_3(SiMe_2)$ interactions; second, throughout the bulk polymer the cavities of the 2+ charged rings are filled exclusively by peroxo (O_2^{2-}) dianions, *i.e.* no oxide (O^{2-}) ions are present.

In the fortuitous preparation of the first inverse crown ether complex, we concluded that mixtures of butyllithium, dibutylmagnesium and the sterically demanding amine hexamethyldisilazane were highly efficient oxygen scavengers.[4] Thus, any oxygen contaminant available in solution would be readily sequestered by the reaction system and then precipitated in the form of the stable peroxo–oxo centred mixed-metal macrocycle **2**. With this insight we subsequently deliberately added molecular oxygen to other reaction solutions of this type. This strategy was used in the preparations of **3** and **4**. The preparation of **5** essentially mimicked that of its lighter alkali metal counterparts. Like **2**, it was initially obtained unexpectedly (in a low yield of 2%) by the reaction shown in eqn. (1): here, oxygen

$$\text{'BuK'} + Bu_2Mg + 3(Me_3Si)_2NH \xrightarrow{\text{trace of } O_2} {}^1/_x[\{(Me_3Si)_2N\}_4K_2Mg_2(O_2)] + \text{other products} \quad (1)$$

was not deliberately added to the solution; though, significantly, neither the amine reactant nor the solvents (hexane, heptane, *p*-xylene) were deoxygenated beforehand. Note also that the potassium reagent used was not pure butylpotassium, but rather the unrefined solid isolated from the metal–metal exchange reaction between butyllithium and potassium *tert*-butoxide.[5] Repeating the preparation in a Schlenk tube adapted with a calcium chloride drying tube at its inlet, gave substantially larger amounts of colourless, crystalline **5** (best yield to date, 23%).† While we attribute this improvement to the intentional introduction of atmospheric oxygen, the possibility that minute traces of moisture are involved cannot be completely dismissed. However, in a control experiment, following the same procedure carried out in eqn. (1), a stoichiometric amount of deoxygenated H_2O was additionally introduced to the reaction solution. A white solid precipitated out within a few minutes and would not redissolve on warming. The isolated solid exhibited distinct melting point characteristics from those of **5**;† even more significantly, its IR spectrum revealed the presence of a strong O–H band at 3695 cm^{-1} [characteristic of $Mg(OH)_2$] before the mull was exposed to air. Clearly this solid is not **5**.

The octagonal ring structure of **5** (Fig. 1)‡ consists of alternating nitrogen and metal atoms. Like metal atoms occupy transannular positions, and each one coordinates (side-on) to the O_2^{2-} ion in the core of the ring. These ring molecules are not discrete, but link through intermolecular $K\cdots CH_3(SiMe_2)$ interactions (one per K centre) to form one-dimensional infinite chains (Fig. 2) which propagate along the *a* direction. Selected bond lengths and bond angles are given in the legend to Fig. 1. The O–O bond length [1.583(1) Å] is close to that [1.541(9) Å] in the heptalithium-tetrarubidium mixed alkoxide peroxide $[\{(Bu^tOLi)_5(Bu^tORb)_4(Li_2O_2)\cdot 2TMEDA\}_\infty]$.[6] While the Mg centre engages this dianion in a symmetrical manner (Mg–O: mean, 2.012 Å; difference, 0.005 Å), the interaction with the K centre is lopsided (K–O: mean, 2.843 Å; difference, 0.121 Å). The extra atoms (from Me_3Si groups, see below) in the coordination sphere of the K centre may be a factor in this asymmetry. One might be inclined to explain the 100% peroxide incorporation within the ring cavity in terms of the 'soft' nature of potassium; but, the true explanation must be more profound as there is no regular pattern to the peroxide:

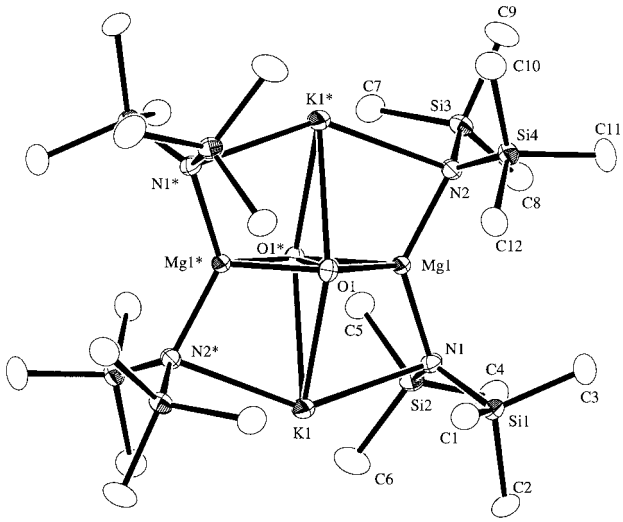


Fig. 1 Double asymmetric unit of **5**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and bond angles (°): K1–O1 2.782(1), K1–O1* 2.903(1), K1–N1 2.855(1), K1–N2* 2.804(1), Mg1–O1 2.015(1), Mg1–O1* 2.010(1), Mg1–N1 2.044(1), Mg1–N2 2.043(1), K1–N1–Mg1 83.95(3), K1*–N2–Mg1 83.11(4). * $1 - x, y, z$.

oxide ratios found in **2**, **3** and **4** (*i.e.* 72 : 28, 0 : 100, 32 : 68 respectively). Clearly, the hard/moderately hard/soft demarcation normally associated with the Li/Na/K series is not the sole factor here. Kinetic influences must also be at work. The ($N_4K_2Mg_2$) ring in **5** is essentially planar [sum of endocyclic bond angles, 1074.6 *cf.* 1073.7° for the ($N_4Na_2Mg_2$) ring in **4**]. A salient feature running through the series of inverse crown ether complexes is that the Mg atoms are always displaced towards the centre of the ring as a result of strong Mg–O bonding. The magnitude of this displacement increases with increasing size of the alkali metal partner in the ring, as evidenced by the *endo*cyclic N–Mg–N bond angles in **2** [193.3° (approximate value owing to Li/Mg substitutional disorder in crystal)], **4** (218.4°) and **5** (227.8°). Likewise, the small Li cation in **2** and **3** is pulled towards the centre of the ring through strong Li–O bonding, resulting in endocyclic N–Li–N bond angles > 180°. Conversely, the heavier alkali metal cations in **4** and **5** occupy peripheral ring sites with endocyclic N–M–N

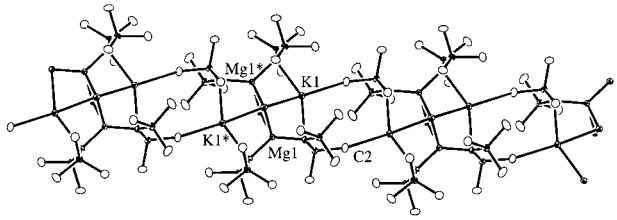

Fig. 2 View showing extended chain arrangement of **5**. Intermolecular K···$CH_3(SiMe_2)$ interactions are shown; intramolecular ones are omitted for clarity.

bond angles significantly < 180° [159.84(2)° in **4**, 142.44(3)° in **5**], reflecting longer, weaker Na–O/K–O bonding. In contrast, there is considerably less variation in the endocyclic M–N–Mg bond angles throughout the series [range: 76.58(7)–83.95(3)°]. The final feature of note in **5** is the short K···$CH_3(SiMe_2)$ contacts. Measuring 3.246(2) Å, the shortest of these are intermolecular ones (K1···C2*) which link the ($N_4K_2Mg_2$) rings together through near-linear K···C–Si units [angle, 157.29(7)°]. Interestingly, intermolecular Na···C–Si contacts of a similar length [3.275(2) Å] appear in **4**,[2] but these are normally accorded less significance when the smaller size of Na is taken into account (ionic radii: Na^+, 1.02 Å; K^+, 1.38 Å). However, the similar intermolecular contacts seen in **4** and **5** raises the question as to whether the former truly consists of discrete molecules. Intramolecular K···C–Si contacts [lengths: 3.317(2), 3.359(1) and 3.397(2) to C7, C1 and C6, respectively] also contribute to the bonding in **5**. These agostic-type interactions[7] are comparable to those in other recently reported potassium structures,[8] most pertinently in [{$(Me_3Si)_2NK$}$_2$] (shortest, 3.34 Å).[9]

We thank the EPSRC (for studentship to R. B. R.) and Monash University (for providing B. A. R. with a travel grant to allow him to work at Strathclyde).

Notes and references

† Satisfactory microanalyses have been obtained. **5** proved to be too insoluble in arene solvents for a useful, diagnostic ^{1}H NMR spectrum to be obtained. It starts to decompose at 80 °C and gradually darkens to a black solid at 140 °C. On the other hand, the white solid from the control reaction fails to melt below 300 °C and does not change colour.

‡ *Crystal data* for **5**: $C_{24}H_{72}K_2Mg_2N_4O_2Si_8$, M = 800.34, triclinic, space group $P\bar{1}$, a = 11.102(4), b = 12.907(6), c = 8.906(3) Å, α = 107.63(3), β = 100.47(3), γ = 96.34(4)°, U = 1177.3(9) Å^3, Z = 1, λ = 0.71069 Å, μ = 0.457 mm^{-1}, T = 123 K, R = 0.0229, R_w = 0.0404 for 5156 reflections with $I > 2\sigma(I)$. 5673 reflections measured with $2\theta < 55°$. Refinement on F, to convergence, with isotropic H atoms gave a maximum residual electron density of 0.323 e Å^{-3} . Program used Texsan. CCDC 182/1145. Received (in Cambridge, UK) 7th January 1999, Accepted 11th January 1999

The structure of the sex pheromone produced by the male sandfly *Lutzomyia longipalpis*, from the Jacobina region of Brazil, previously proposed tentatively as the novel homosesquiterpene 3-methyl-α-himachalene is confirmed by synthesis and biological activity; the relative stereochemistry is defined as 1*RS*,3*RS*,7*RS* by comparing the natural product with the four synthetic diastereoisomers.

The sandfly *Lutzomyia longipalpis* (Lutz and Neiva) (Diptera: Psychodidae) is the vector of the protozoan parasite *Leishmania chagasi* (Cunha and Chagas) (Kinetoplastida: Trypanosomatidae), the causative agent of visceral leishmaniasis in the New World. Male *L. longipalpis* release a sex pheromone from glands on the tergites of the abdomen[1] which is highly attractive to females.[2] The sex pheromone gland of *L. longipalpis* from Jacobina (Bahia State) in northeastern Brazil produces several compounds but only the principal volatile component is responsible for the attraction of females.[3] It was proposed, mostly on the basis of mass spectrometry of the natural product and of products of microchemical reactions, that the pheromone comprised the novel homosesquiterpene 3-methyl-α-himachelene.[4] The sex pheromones of other sympatric and allopatric populations of *L. longipalpis* are different;[5] for example, that from the Lapinha region of Brazil (Minas Gerais State) has been tentatively proposed as another novel sesquiterpene, 9-methylgermacrene-B.[6] The purpose of this work was to test the proposed structure for the Jacobina *L. longipalpis* sex pheromone by synthesis of 3-methyl-α-himachalene **1**.

The synthetic route adopted followed the intramolecular Diels–Alder methodology employed by Wenkert and Naemura[7] for α-himachalene and is described in Scheme 1. Diene **7** comprised a mixture of *E*/*Z* isomers (77 : 23–90 : 10) by ^{1}H NMR spectroscopy. The subsequent cyclisation of the keto enediene **8** in xylene under reflux gave a mixture of cyclic products, which could be separated by medium pressure liquid chromatography into enantiomeric pairs of diastereoisomers **9a**–**d**.† Final conversion to the diastereoisomeric 3-methyl-α-himachalenes **1a**–**d**‡ was achieved quantitatively using the Tebbe reagent. Assignment of structures **9a**–**d** was by correlation and two dimensional NOE spectroscopy (Fig. 1). Compounds **9a** and **9c** were designated as *cis*-fused by the ring junction protons showing a NOE to each other. The relative stereochemistry of the methyl group could be determined for **9c** by a NOE to the ring junction proton of C-1, a signal not seen for **9a**. The relative stereochemistries of the C-3 methyl group of *trans*-fused **9b** and **9d** were also elucidated by NOE experiments. A NOE was observed between the C-1 proton of **9b** and one of the C-6 methyl groups, while the *other* C-6 methyl group showed a NOE to the C-3 methyl, which therefore lies on the *opposite* face to the C-1 proton (Fig. 1). The structures of **1a**–**d** were inferred from **9a**–**d** and in comparison with NMR data for natural α-himachalene.[4] Mass spectra were obtained by GC-MS.§

Co-injection of natural product with the diastereoisomers, using high-resolution capillary GC on columns of different polarity (Table 1) gave peak enhancement only with diastereoisomer **1c**. In the case of chiral GC, only one enantiomer of **1c** enhanced the natural product peak. The ^{1}H NMR results reported,[6] although incomplete, showed good agreement with only those for structure **1c**. The mass spectrum for the natural product[6] was almost identical with that for **1c**, with greater differences from those for **1a**, **1b** and **1d**. All had a base peak at *m*/*z* 94, different from that for α-himachalene (*m*/*z* 93), which was suggested as likely when the earlier tentative structural prediction was made.[6] Bioassays¶ involving attraction of female *L. longipalpis* and conducted in a Y-tube olfactometer showed that only diastereoisomer **1c** and the natural pheromone extract were active and both showed high statistical significance. This was in agreement with the chromatographic and spectral data, giving the sex pheromone structure as (1*RS*,3*RS*,7*RS*)-3-methyl-α-himachalene, *i.e.* (1*RS*,3*RS*,7*RS*)-2-methylene-3,6,6,9-tetramethylbicyclo[5.4.0]undec-8-ene (**1c**). The *cis* stereochemistry of the natural product is analogous

¶ Virgin female sandflies were removed from larval rearing pots within 10 h after eclosion to ensure that they were unmated. They were provided with a saturated sugar solution on cotton wool and subsequently maintained for 5–6 days in Barraud cages (18 × 18 × 18 cm). Bioassays were conducted in a glass (9 mm internal diameter) Y-tube olfactometer. Zero grade air was passed (2 ml min^{-1}) through two charcoal filters into the test and control arms (10 cm long). The olfactometer was connected to the air supply by Teflon tubing. A filter paper disk (1.5 cm diameter) was inserted into the Teflon tubing at the connection with the olfactometer test and control arms. During bioassays pheromone extracts or synthetic chemicals in hexane were placed on one of the filter paper disks. Hexane in the same quantity as for the test arm was placed on the other filter paper disk. The female sandfly was introduced into the third arm (10 cm long) of the olfactometer and its response observed for 5 min. Female attraction to **1c** and extract prepared from 5–7 day old male *L. longipalpis* was highly significant (χ^2 = 6.2 × 10^{-7} and P = 1.4 × 10^{-26}, respectively). Females were not significantly attracted to **1a**, **1b** or **1d**, nor to a natural α-himachalene sample at the same levels.

Highly active Pd^{II} cyclometallated imine catalysts for the Heck reaction

Manuela Ohff, Andreas Ohff and David Milstein*

Department of Organic Chemistry, The Weizmann Institute of Science, 76100 Rehovot, Israel.
E-mail: comilst@wiccmail.weizmann.ac.il

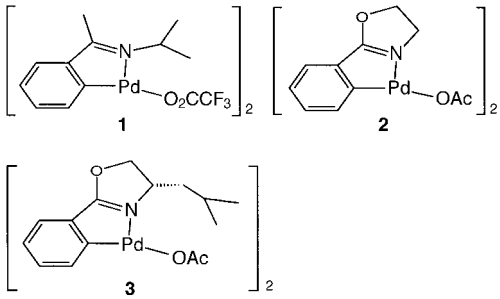
Received (in Cambridge, UK) 18th December 1998, Accepted 14th January 1999

The new cyclopalladated, phosphine-free imine complexes 1–3 are exceptional catalysts for the Heck arylation, leading to more than a million turnovers in some cases; the catalysts are very thermally and air stable and are recovered unchanged after the catalysis.

The Heck arylation of alkenes [eqn. (1)] is a useful synthetic method that is attracting much current interest.[1] Normally, palladium phosphine complexes are utilized, and the reactions

are conducted under an inert atmosphere. Recently, very efficient catalysis using palladium complexes incorporating cyclometallated phosphines,[2,3] chelating diphosphines,[4] carbene ligands[5] and dimethylglycine[6]† have been reported. We have reported that palladium complexes of tridentate PCP-type ligands are excellent catalysts, and have provided evidence which renders the traditional Pd^0/Pd^{II} cycle unlikely in that case.[6] The issue of a possible Pd^{II}/Pd^{IV} cycle in Heck catalysis is currently under debate.[4,7,8] and a new mechanism involving Pd^{IV} intermediacy in Heck catalysis has been suggested.[9]

We report here[10] that the palladium imine complexes **1**–**3** are outstanding catalysts for this reaction with turnover numbers



(TON) of more than 10^6 in some cases. These readily prepared Pd^{II} catalysts are exceedingly thermally stable and are not sensitive to oxygen. The use of phosphine free, nitrogen-based ligands in the Heck reaction is very rare and was reported for bidentate nitrogen ligands. However, low catalytic activity was observed.[11]‡

The new dimeric imine complexes **1**–**3** in which the metal center is stabilized by a five-membered ring, were readily prepared by treatment of $Pd(O_2CCF_3)_2$ or $Pd(OAc)_2$ with the corresponding imines in THF.§ Complex **1** was characterized by X-ray analysis (Fig. 1).¶ X-Ray structures of other palladated imine complexes were reported.[12]

Complexes **1**–**3** show extremely high activity in the catalytic arylation of olefins with aryl iodides and bromides (Table 1). Because of the stabilizing metallated ligand system, the complexes are very thermally stable and no degradation is observed under the reaction temperatures. These complexes are also not sensitive to oxygen and moisture and the reactions can be carried out in air, with no change in efficiencies or yield. The catalyst remains highly active after the reaction is complete, and upon addition of more substrates catalysis is resumed. At the end of the catalysis, the acetate or trifluoroacetate moieties are substituted to give the corresponding palladiumhalide complex. Conveniently, catalyst **1** can be formed *in situ* under the reaction conditions from $Pd(OAc)_2$ and the readily available imine ligand, leading to similar results.

While very high TONs and yields are observed for catalysts **1**–**3**, complex **1** exhibits higher turnover rates. Of the solvents tested, *N*-methylpyrrolidone (NMP) was found to be the best. The reaction can be carried out also in solvents of lower polarity (dioxane) or non-polar ones (mesitylene), although at lower rates. Pure solvent and starting materials should be used in the highly catalytic reactions. Both Na_2CO_3 and NEt_3 were used as bases, although the reaction was faster with the soluble amine, leading to a turnover rate of *ca.* 8×10^4 h^{-1} and 100% yield with iodobenzene and methyl acrylate.

In a typical experiment, a slight excess of the olefin is added to a solution of the aryl halide in freshly distilled NMP, followed by addition of an equimolar amount of $NaHCO_3$ or NEt_3. The catalyst is added and the mixture is stirred at 140 °C for the specified time. The reaction mixture is analyzed by gas chromatography and is worked up by addition of water and extraction of the organic phase with CH_2Cl_2. After evaporation of the volatiles, the essentially pure product is characterized by NMR and IR spectroscopy. Selected results are listed in Table 1.

As expected, the reaction outcome depends on the halide and on the olefin. With iodobenzene and methyl acrylate, essentially complete conversions are obtained with very high turnover numbers of up to 1.4×10^6, which are among the highest observed so far.‖ Methyl crotonate and styrene also react normally, while significantly lower rates are obtained with non-activated alkenes. Chlorobenzene was only marginally reactive.[13]** The observed TON of 137 100 in the case of bromobenzene is similar to the one that we reported for PCP-type ligands[6] but the reaction was slower in the latter case. As

[h] Methyl *trans*-*p*-formylcinnamate. [i] Mixture of isomers of the phenyl derivatives of the olefins. [j] Mixture of isomers, main product: 2-phenylindene.

far as we are aware, our results with the relatively inactive bromobenzene and the commonly used acrylate esters are unsurpassed.

In summary, the metallated imine palladium(II) complexes show exceedingly high catalytic activity and yields in the Heck reaction, including reactions of the non-activated bromobenzene. The activities observed are among the highest reported for the Heck reaction. The new catalyst system is very thermally and air stable. Further investigations aimed at clarification of the scope and mechanism of these reactions are in progress.

We thank Dr L. J. W. Shimon for the X-ray analysis of complex **1**. This work was supported by The Israel Science Foundation, Jerusalem, Israel, and by the MINERVA Foundation, Munich, Germany. M. O. thanks the Deutsche Forschungsgemeinschaft for a fellowship. A. O. thanks the Minerva Foundation for a fellowship. D. M. is the holder of the Israel Matz Professorial Chair of Organic Chemistry.

Notes and references

† The role of the dimethylglycine additive is unclear and stabilized palladium colloids may be involved in this case. See ref. 6.

‡ With phenanthroline ligands, only 40 TON or less were obtained. Bipyridine and bis-oxazoline ligands were inactive with methyl acrylate and resulted in very low yields and turnovers with other alkenes. See ref. 11.

‖ As far as we are aware, this is the highest TON reported for a quantitative Heck reaction. A TON of 1120000 was reported for the reaction of iodobenzene with methyl acrylate after 13 days at 95 °C, but the yield was 56%. See ref. 3.

** Catalysis with chlorobenzene was accomplished by addition of NaI and $NiBr_2$. However, the reaction was very slow, resulting in 10% yield and 190 TON after 21 h at 140 °C.

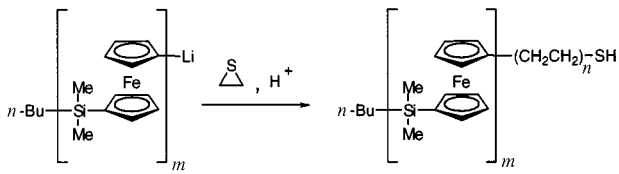
Poly(ferrocenyldimethylsilanes) (PFS) end-functionalized by ethylene sulfide form stable, electroactive layers on Au.

Interfacial electron transfer plays a fundamental role in a large number of biological and technical processes. Progress in the area of self-assembled monolayers resulted in a number of synthetic and physical developments which now allow one to perform systematic studies of surface electrochemistry of well defined molecular thin films of thiols terminated by (electroactive) ferrocene moieties, immobilized on Au.[1] Surface immobilization of redox active compounds, such as ferrocene derivatives, with a well defined structure and with a variable surface concentration of the electroactive centers offers the possibility of the control of charge transfer. We have undertaken a systematic study of thiol end-functionalized ferrocenylsilane polymers obtained by anionic polymerization.

In this contribution we describe the synthesis, molecular characterization and thin film properties of poly(ferrocenyldimethylsilane) (PFS), end-functionalized by ethylene sulfide (ES), denoted ES–PFS. This organometallic polymer has been chosen as it exhibits interesting electrochemical and other potentially useful properties owing to its unique structure which incorporates ferrocene units and Si atoms in the main chain.[2]

Poly(ferrocenyldimethylsilane) homopolymer and its thiol end-functionalized derivative were synthesized by anionic ring-opening polymerizations. The synthesis of the homopolymer has been described elsewhere.[3] ES–PFS was synthesized by treating an end-reactive living homopolymer with ethylene sulfide as shown in Scheme 1.

Molecular characterization of ES–PFS was carried out by ^{1}H NMR, GPC, FTIR and elemental analysis. GPC measurements were carried out in THF in order to determine the molar mass and its distribution. The molar mass of ES–PFS was referenced to a polystyrene calibration curve. The number average molar mass, M_n, was found to be 12.4×10^3. This value was expected from the molar ratio of monomer to initiator. The polydispersity ratio (M_w/M_n) was found to be equal to 1.11. The molar mass of the polymer was also estimated by end-group analysis using ^{1}H NMR[4] and a value of 12.3×10^3 was obtained. Thus, an excellent agreement between the molar masses according to the two techniques was found. The peak found in the ^{1}H NMR spectrum at δ 2.57 (spectrum not shown) was assigned to the methylene group next to sulfur in the end-group. The assignments of the ^{1}H NMR resonances at δ 4.00 3.80 correspond to the protons (4H) from the cyclopentadienyl rings, while the resonance at δ 0.28 corresponds to the 6H from the methyl groups attached to Si. Spectroscopic characterization of ES–PFS was undertaken by FTIR of ES–PFS in KBr pellets. The absorbances assigned to the C–H vibrations in the ferrocene rings and in the methyl, and methylene groups can be observed in the FTIR spectra. Results from elemental analysis are in a good agreement with the theoretically expected values [theoretical values (mass%): C, 59.14; H, 5.8; S, 0.97 and experimentally found values: C, 58.33; H, 5.92; S, 0.62].



Scheme 1

Thin films of ES–PFS were prepared by immersing gold substrates[5] into 0.1 and 1.0 mg ml^{-1} solutions of the polymers in toluene for 48 h to ensure maximum coverage. The samples were subsequently rinsed with toluene and dried in a nitrogen stream. The films were characterized by contact angle measurements, XPS and FTIR. Contact angles with water were measured to evaluate the wetting properties and the uniformity of the ES–PFS layers on gold. Advancing contact angles were found to be *ca.* 95° and receding contact angles *ca.* 76°, respectively, indicating a hydrophobic surface. Peaks associated with C 1s, Fe 2p (from the ferrocene ring), Si 2s (from the polymer backbone) and S 2p (from the end-function) can be distinguished in the XPS spectra of ES–PFS layers. This indicates that the polymer is immobilized on the gold surface. FTIR spectra of the monolayers taken in grazing incidence with perpendicularly polarized light confirm the presence of the end-functionalized polymer on the Au substrate. The observed vibration frequencies are in good agreement with literature data.[6]

Surface plasmon resonance spectroscopy (SPRS) experiments were carried out in order to study the adsorption kinetics of end-functionalized ES–PFS on gold in comparison with PFS, and to determine the optical thickness of the layers.[7] The formation of a thin film of ES–PFS on the gold surface results in an angular shift of the resonance angle [Fig. 1(a)] which is a function of the thickness and the refractive index. Curve 2 in Fig. 1(a) was recorded following 50 h of total sorption time. An average value of 39.8 Å was found for the limiting optical thickness of the polymer (refractive index n = 1.687) described in this study. The refractive index was determined previously by profilometry followed by ellipsometry. Measurements of the time dependence of optical reflectivity showed that a monolayer is formed with fast kinetics [Fig. 1(b)]. At between 800 and 3000 min the reflectivity remained constant. The adsorption of non-functionalized PFS on the gold surface did produce a small angular shift [Fig. 1(c)] from which an average thickness of 11.0 Å was determined. Curve 2 in Fig. 1(c) was measured following 800 min of total sorption time. The time dependence of the reflectivity showed [Fig. 1(d)] that in the case of non-functionalized polymer the adsorption rates are slower. In order to check whether the predominant process is physi- or chemisorption, the polymer films were washed after deposition using toluene. The layer formed of non-functionalized polymers

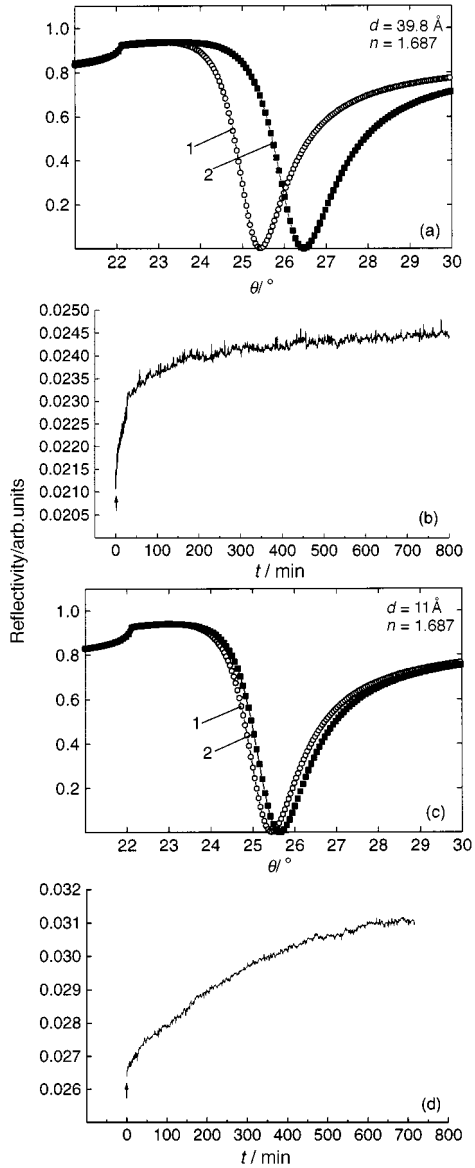


Fig. 1 (a) Angular reflectivity scans recorded in air (1) at bare Au/LaSFN9 (Berliner Glass) and (2) after immobilization of ES–PFS (c = 1.0 mg ml^{-1}) on Au/LaSFN9. (b) Time dependence of reflectivity for ES–PFS in toluene (c = 1.0 mg ml^{-1}) at an angle of incidence θ = 78° (the arrow indicates the injection of the polymer solution). (c) Angular reflectivity scans recorded in air (1) at bare Au/LaSFN9 (Berliner Glass) and (2) after adsorption of PFS (c = 1.0 mg ml^{-1}) on Au/LaSFN9. (d) Time dependence of reflectivity for PFS in toluene (c = 1.0 mg ml^{-1}) at an angle of incidence θ = 77° (the arrow indicates the injection of the polymer solution).

could be easily removed which indicated that only physisorption occurred for this polymer. The films of the end-functionalized ES–PFS were stable against washing with toluene indicating predominant chemisorption.

Atomic force microscopy (AFM) was used to image the film topography. Well defined, triangular, monoatomic terraces of Au(111) were prepared by annealing sputtered Au substrates, on glass, in a H_2 flame. Tapping mode atomic force microscopy[8] (AFM) height and phase imaging were used to characterize the morphology of ES–PFS layers on Au(111). Owing to the adsorption of the end-functionalized polymer, corresponding AFM images exhibit a globular surface structure (Fig. 2), instead of the atomically smooth terraces of bare Au(111). The contours of the underlying triangular terraces of Au(111) can still be observed on the AFM images even for the specimen showing the chemisorbed polymer film.

The electrochemical behavior of ES–PFS layers in comparison with the physisorbed PFS layers was investigated by cyclic voltammetry. The experiments were performed on layers of physisorbed, non-functionalized PFS and end-functionalized,

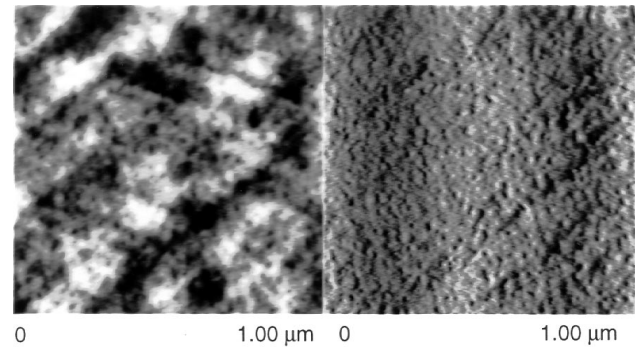

Fig. 2 Tapping mode height (left, z = 10 nm) and phase (right, z = 9°) images recorded for ES–PFS layers on Au(111).

chemisorbed films of ES–PFS before and after immersion in pure toluene for 24 h. The current observed for the end-functionalized ES–PFS showed only a small change prior to, and following immersion into toluene. This can be considered as an indication for the fact that the end-functionalized PFS forms a stable layer on gold. For the non-functionalized physisorbed PFS the change in the intensity of the current in the cyclic voltammograms prior to, and following immersion into the solvent was significant (Fig. 3).

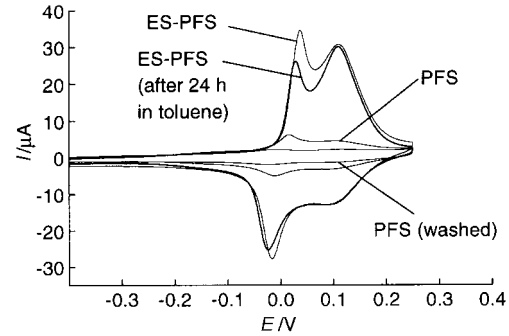

Fig. 3 Cyclic voltammograms of PFS, PFS (after 24 h in toluene), ES–PFS and ES–PFS (after 24 h in toluene) layers on gold at v = 50 mV s^{-1} scan rate (reference electrode Hg–$HgSO_4$, auxiliary electrode Pt, 0.1 M $NaClO_4$ electrolyte solution).

Further work is aimed at *in situ* studies of the electrochemical behavior of end-functionalized poly(ferrocenylsilane) layers on Au substrates by electrochemical AFM at different degrees of oxidation.

The authors would like to thank Mr H. Schönherr for his help with AFM experiments and for many helpful discussions. The contributions of Mr P. G. H. Kosters in the FTIR experiments, Mr A. H. J. van den Berg in the XPS measurements, and Mr C. J. Padberg with the GPC are acknowledged.

Determination of absolute configuration using circular dichroism: Tröger's Base revisited using vibrational circular dichroism

A. Aamouche, F. J. Devlin and P. J. Stephens*

Department of Chemistry, University of Southern California, Los Angeles, CA 90089-0482, USA.
E-mail: stephens@chem1.usc.edu

Received (in Corvallis, OR, USA) 5th November 1998, Accepted 21st December 1998

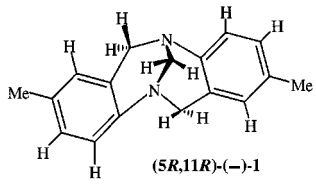
A new methodology for predicting the Vibrational Circular Dichroism (VCD) spectra of chiral molecules using Density Functional Theory (DFT) and Gauge-Invariant Atomic Orbitals (GIAOs) permits the direct determination of the absolute configuration of organic molecules in solution; application to Tröger's Base leads to the opposite absolute configuration from that deduced from electronic CD, confirming the conclusion arrived at from X-ray analysis of a diastereoisomeric salt.

Chiral molecules exhibit circular dichroism (CD).[1] The CD of enantiomers is of identical magnitude and opposite sign at all frequencies. The CD of a molecule can therefore be used to obtain its absolute configuration (AC). Application of CD to the determination of AC requires a methodology predicting the sign (or signs) of the CD for one (or more) transition of the molecule.

In practice there are two main choices to be made in utilizing CD for AC determination. First, the specific spectral region to be used must be selected. Currently, CD can be routinely measured from the mid-infrared[2] to the vacuum ultraviolet[3] encompassing both vibrational and electronic transitions. Second, the methodology to be used in predicting the CD of the transitions to be studied must be chosen. This can range from empirical correlation to *a priori ab initio* quantum mechanical calculation.

Historically, Electronic CD, measured in the near-infrared–visible–ultraviolet spectral region, has been the predominant choice of chemists.[4] Vibrational CD (VCD),[5] measured in the infrared spectral region, has been little utilized since the first measurements in the early 1970s.[6] This can be attributed primarily to the absence of a practical methodology for reliably predicting VCD intensities.

The purpose of this report is to demonstrate that recent developments in *ab initio* Density Functional Theory[7] now make practicable the prediction of VCD intensities in large organic molecules with an accuracy sufficient to permit ACs to be reliably deduced using VCD spectroscopy. The key to this advance has been the development and implementation[8] of analytical derivative techniques for calculating Atomic Axial Tensors (AATs)[9] using Gauge-Invariant Atomic Orbitals (GIAOs).[10] We report a study of the VCD spectrum of Tröger's Base **1**.



(5*R*,11*R*)-(−)-**1**

Tröger's Base was first resolved in 1944.[11] Its AC was first assigned in 1967[12] by means of the CD of electronic transitions associated with the aromatic rings. The Coupled Oscillator method[13] (also often referred to as the Exciton Coupling method[14]) was used to elucidate the AC from the CD spectrum. In 1991, on the basis of the X-ray structure of a salt of **1** with a chiral anion of known AC, it was reported that the original AC assignment was incorrect.[15]

The unpolarized absorption and CD spectra of **1** over the range 800–1700 cm^{-1} are shown in Fig. 1 and 2, together with the corresponding predicted DFT spectra. DFT calculations were carried out *via* the GAUSSIAN program[16] using the hybrid functional[17] B3PW91[18] and the 6-31G* basis set[19] (321 basis functions) as described previously.[20] All calculations use direct, analytical derivative methods. The calculations are carried out within the harmonic approximation [9] and therefore predict only fundamental transitions. The fundamentals are numbered (1 being lowest) in Fig.1(*b*) and 2(*b*). Comparison of the predicted and experimental absorption spectra (Fig. 1) leads to the assignment detailed in Fig. 1(*a*). In assigning the spectrum we allow for the overall shift of the predicted spectrum to higher frequency, due predominantly to the neglect of anharmonicity in the calculation,[21] and make use not only of frequencies but also of intensities (without the latter, assignment would be much more difficult). We note that almost all observed bands are assignable to fundamentals: only two bands are clearly observed which cannot be so assigned. This confirms the excellence of the harmonic approximation for the mid-IR spectral region. The fundamentals most easily and unambiguously assigned are those corresponding to bands which are resolved from neighboring bands and of significant intensity. The 25 fundamentals 34, 35, 38, 42–44, 50–64, 69, 70, 82 and 83 are in this category. The remaining 29 fundamentals are either unresolved and/or weak; their assignment is less definitive.

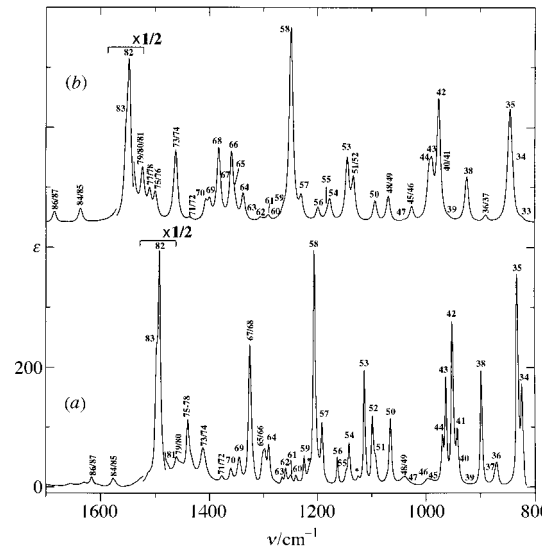


Fig. 1 Mid-IR absorption spectra of **1**: (*a*) Experimental spectrum in CCl_4 solution; 0.20 M (−)-**1**, 156 μ pathlength (800–1480 and 1525–1700 cm^{-1}); 0.10 M (−)-**1**,104 μ pathlength (1480–1525 cm^{-1}); resolution 1 cm^{-1}; (*b*) DFT/B3PW91/6-31G* spectrum; band shapes are Lorentzian (γ = 4.0 cm^{-1}). Fundamentals are numbered. Asterisks indicate bands assigned as non-fundamentals.

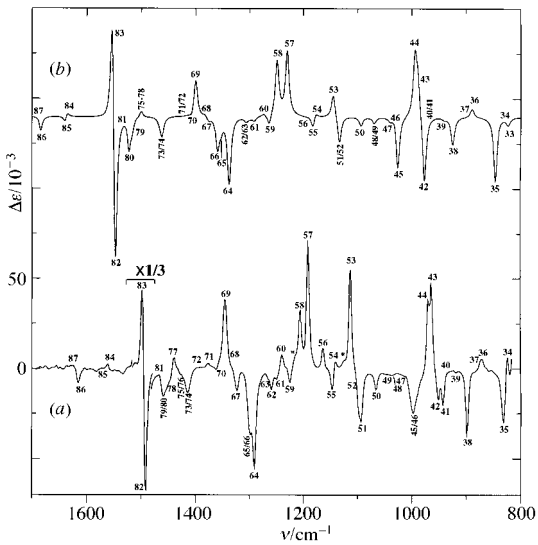

Fig. 2 Mid-IR VCD spectra of **1**: (*a*) Experimental spectrum of (−)-**1** in CCl_4 solution; concentrations and pathlengths are as in Fig. 1. Resolution 4 cm^{-1}. The spectrum is one-half of the difference in spectra of (−)-**1** and (+)-**1**. Scan time of each spectrum was 1 h. VCD was measured using a Bomem/BioTools Chiral*IR* spectrometer; (*b*) DFT/B3PW91/6-31G* spectrum of (5*R*,11*R*)-**1**; band shapes are Lorentzian (γ = 4.0 cm^{-1}). Fundamentals are numbered. Asterisks indicate bands assigned as non-fundamentals.

In Fig. 2 the experimental VCD spectrum is for the (−)-isomer of **1** and the calculated VCD spectrum is for the (5*R*,11*R*)-enantiomer. The assignment of the experimental VCD spectrum follows from the assignment of the absorption spectrum and is shown in Fig. 2(*a*). Comparison of the calculated and experimental spectra shows that predicted VCD signs and intensities are in excellent overall agreement with experimental signs and intensities. The comparison of calculated and experimental VCD signs and intensities is most straightforward for the 25 fundamentals resolved in the absorption spectrum. Of these, VCD is clearly observed for 19: fundamentals 35, 38, 42–44, 50, 53–60, 62, 64, 69, 82 and 83. In every case except for one (56) the predicted sign agrees with the experimental sign. We conclude directly that (−)-**1** has the (5*R*,11*R*) AC. This result is opposite to that arrived at from the electronic CD of **1** and consistent with the conclusion deduced by X-ray crystallography.[15]

Complete quantitative analysis of the spectra, based on the assignments shown in Fig. 1 and 2, is accomplished using Lorentzian fitting.[20] The absorption spectrum yields the frequencies and dipole strengths; the VCD spectrum yields the rotational strengths. In Fig. 3 we plot the experimental rotational strengths obtained for the 19 fundamentals resolved in the VCD spectrum against the corresponding calculated rotational strengths. In Fig. 3(*a*) and 3(*b*) the calculated rotational strengths are for the (5*R*,11*R*) and (5*S*,11*S*) enantiomers respectively. Perfect agreement of calculated and experimental rotational strengths for the correct enantiomer leads to a straight line of slope +1; comparison to the opposite enantiomer leads to a slope of −1. The plots in Fig. 3 simultaneously confirm the correctness of the identification of the (−)-isomer with the (5*R*,11*R*) AC and define the quantitative reliability of the DFT methodology.

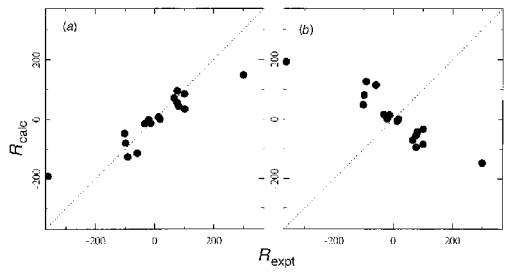

Fig. 3 Comparison of calculated and experimental rotational strengths for (*a*) (5*R*,11*R*)-**1** and (−)-**1**; (*b*) (5*S*,11*S*)-**1** and (−)-**1**. Experimental rotational strengths were obtained by Lorentzian fitting (ref. 20). The dashed line is of slope +1.

The advantages of Vibrational CD over Electronic CD are clearly exposed by this study. VCD can be measured for many transitions, in contrast to the small number of transitions generally accessible to Electronic CD measurement. The widths of vibrational transitions are much narrower than of electronic transitions, leading to more highly resolved spectra. VCD intensities depend only on ground electronic state properties and are more easily and reliably predicted than Electronic CD intensities which depend on excited electronic states in addition. The DFT/GIAO methodology for predicting VCD intensities is general and of high accuracy; it is not necessary to resort to simplified models to interpret VCD spectra. Recent developments incorporated in GAUSSIAN 98[16] have greatly enhanced the efficiency of DFT/GIAO calculations; 6-31G* calculations are now practicable for molecules possessing more than 100 atoms.

We are grateful to NIH for support (GM051972); and to Elf Aquitaine, Inc. for a post-doctoral fellowship (to A. A.).

Received (in Bristol, UK) 11th November 1998, Accepted 12th January 1999

The preparation of WC encapsulated within 2H-WS_2 inorganic fullerene-like (IF) cages by sulfidisation is described; the encapsulates were prepared from both high surface area (high S_g) and low surface area (low S_g) WC precursors; for low S_g WC, partial conversion of the carbide to the sulfide only was achieved with 2–20 IF layers obtained around carbide particles, resulting in WC/2H-WS_2 composites; the amount of conversion obtained in the case of the high S_g WC depended on the method of preparation of the precursor; total conversion to 2H-WS_2 was obtained from a precursor obtained by carburisation of small WO_3 particles, while only partial conversion was obtained in the instance of high S_g WC prepared from ball-milled low S_g WC.

Inorganic fullerene-related structures (IFs) of the form 2H-MX_2 with M = W, Mo and X = S, Se can be prepared by a variety of routes including gas–solid[1–4] and vapour phase[5] reaction between a sulfidising agent and a metal oxide, by STM induction from amorphous MoS_3 films[6] and also by chemical-transport reactions.[7] Such materials owe their fullerene-like properties to the fact that they can incorporate non-six membered moieties that result in the formation of both curved and closed multiple layered structures similar to those formed by graphitic carbon.[8] These materials have found uses in tribological applications[9] and also in nanoscale electronic devices.[10] We describe here the encapsulation of 2H-WS_2 IF material around particles of the corresponding monocarbide. This result is novel as WC is a much denser and more metallic material than the oxide or sulfide precursors previously used to synthesize IFs.

The low S_g WC used in these experiments exhibited average particle sizes of 0.3–2.5 μm and was obtained from Alfa Chemicals (99.5%). The high S_g WC was prepared by two methods. First, WC (α-form) with a surface area of 40 $m^2\ g^{-1}$ and particle diameters in the range 200–2000 Å was prepared by reacting WO_3 with a mixture of 20% CH_4–H_2 (100 ml min^{-1}), ramping the temperature from 20 to 750 °C at the rate of 1 °C min^{-1}.[11] The carburisation of this precursor was verified in the bulk by X-ray powder diffraction (XRD) using a Philips 1729 diffractometer equipped with Cu-Kα_1 radiation operated at 40 kV and 30 mA. The second high S_g sample was prepared by grinding the commercially available low S_g WC in a ball milling apparatus for 48 h. This technique also produced a precursor with particle sizes in the range 200–2000 Å. All of the sulfidisations were carried out in a standard flow reactor at a temperature of 820 °C using a mixture of forming gas (5% H_2–95% N_2) at 110 ml min^{-1} and H_2S at a flow rate of 4 ml min^{-1}. All precursors and their resulting encapsulates were characterised by electron diffraction (ED) and high resolution transmission electron microscopy (HRTEM).

In general, IFs prepared from the low S_g (*i.e.* large particle size) WC precursor materials were completely covered by the encapsulating 2H-WS_2 network which varied from between 2 and 20 2H-WS_2 layers per encapsulate. The size of the resulting encapsulates were found to be in the same range as the precursor particles (see above), although some slight expansion in size had probably occurred as a result of the conversion from the relatively dense carbide to the much bulkier sulfide [Fig. 1(a)]. For these relatively large encapsulates, there was no obvious crystallographic relationship between the hexagonal $P\bar{6}m2$ WC structure [Fig. 1(a)] and the encapsulating $P6_3/mmc$ 2H-WS_2 network [Fig. 1(a)]. In Fig. 1(b), for example, is shown a large carbide encapsulate (denoted **WC**) coated with a non-uniform 2H-WS_2 'skin', the external form of which was determined by the adventitious morphology of the precursor rather than by the encapsulate microstructure. On the surface of the encapsulate in Fig. 1(b), a small 2H-WS_2 nanotube (denoted **N**) has formed on the surface of the encapsulate that presumably originated from an asperity occurring on the surface of the unreacted WC precursor. A further point is that, regardless of the length of the sulfidisation step, the 2H-WS_2 material did not penetrate beyond a depth of *ca.* 100 Å into the WC encapsulates, except where assisted by surface irregularities of the type giving rise to the prominent feature in Fig. 1(b).

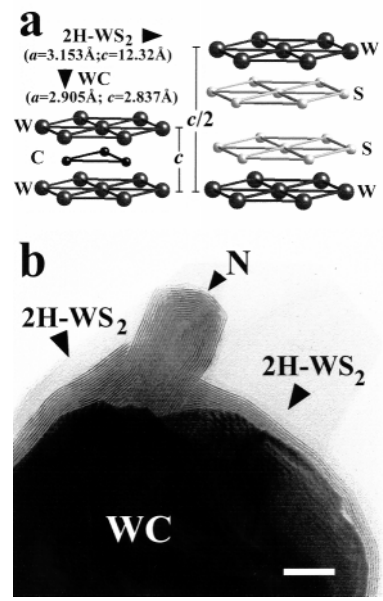

Fig. 1 (a) Schematic depictions of the hexagonal $P\bar{6}m2$ WC and $P6_3/mmc$ 2H-WS_2 structures showing the differences in *c vs.* stacking. (b) HRTEM micrograph showing 2H-WS_2 encapsulated low S_g WC particle. A small asperity in the original precursor particle has led to the formation of a small nanotube (**N**) on the surface of the encapsulate (scale bar ≈ 140 Å).

In the instance of encapsulates formed from the high S_g WC originating from carburised WO_3, near complete conversion to 2H-WS_2 IF structures was achieved. In the example shown in Fig. 2(a), a completely reacted and ellipsoidal 2H-WS_2 structure (overlapping with other IF material) is visible. A '$\bar{C}$'-shaped shard of IF material (denoted **S**) is also visible in the lower left region of the micrograph. Even in structures originating from relatively larger precursor particles than those giving rise to the structures in Fig. 2(a), fully reacted IFs were generally obtained.

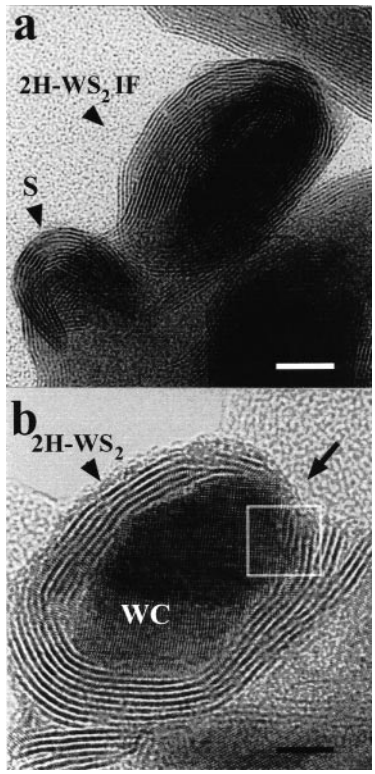

Fig. 2 (a) HRTEM micrograph showing a 2H-WS_2 IF nanoparticle originating from a high S_g precursor formed by carburisation of small WO_3 particles. A small C-shaped shard (**S**) of IF material is visible in the lower left of the micrograph (scale bar ≈ 75 Å). (b) 2H-WS_2 IF encapsulated high S_g particle formed from a ball milled WC precursor (scale bar ≈ 50 Å).

This total conversion can be explained in terms of fairly high residual oxygen content present in the carburised precursor, which may be either present in the main bulk of the WC particles as oxycarbide or on the surfaces of the carbide particles as an oxidised passivated layer.

The main difference between IF materials grown from the precursor originating from the carburised WO_3 particles and the ball-milled WC precursor is that the latter product still contained unreacted carbide. Furthermore, as with encapsulates formed from the low S_g (*i.e.* large particle size) WC precursor, the number of encapsulating shells formed around the encapsulate was limited to 2–20 regardless of the length of the sulfidisation step. In Fig. 2(b), we see a small carbide encapsulate formed from a ball milled WC particle encased in a 2H-WS_2 IF 'shell' of variable thickness up to 10 layers. Note that in the upper right region of the micrograph, a small break in the coverage is visible (arrowed) but the 2H-WS_2 coverage of most of the observed encapsulates was generally found to be complete. These smaller encapsulates yielded information with respect to the growth mechanism of the encapsulating sulfide material from the carbide. In Fig. 3(a) we see a fast Fourier transform (FFT) calculated from the WC/2H-WS_2 interface obtained from the region indicated by the superimposed square in Fig. 2(b). The main calculated reflections in the FFT can be indexed according to an [01$\bar{1}$0] projection of WC. Superimposed upon the pattern, a blurred reflection corresponding to the (0002) planes of encapsulating 2H-WS_2 is visible. Note that this reflection is aligned along the [0001] direction with respect to the carbide. In Fig. 3(b) the microstructure of the carbide (denoted **WC**) in relation to the encapsulating sulfide (denoted **2H-WS_2**) is shown. A small disordered region of carbide (denoted **DS**) is visible at the lower middle of the micrograph caused either by mechanical deformation of the carbide during the ball-milling process or by stacking faults present in the

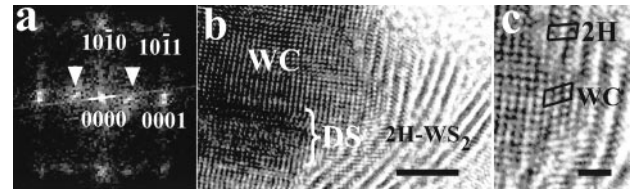

Fig. 3 (a) Calculated ED pattern, obtained from a FFT of the indicated region in Fig. 2(b) corresponding to the WC/2H-WS_2 interface. The 0002 reflections of the sulfide are arranged along [0001] with respect to the carbide. (b) HRTEM micrograph showing the WC/2H-WS_2 interface. A distorted region (**DS**) is visible in the carbide microstructure (scale bar ≈ 35 Å). (c) Enlargement of the WC/2H-WS_2 interface showing intergrowth between two layers of the distorted carbide structure (**WC**) and one layer of the sulfide (**2H**; scale bar ≈ 10 Å).

original material. In a further enlargement [Fig. 3(c)], we see that two distorted layers of the carbide (denoted **WC**) intergrow with one layer (denoted **2H**) of the sulfide. This type of growth may be important in terms of initiating the propagation of the 2H-WS_2 encapsulating material. However, we see from the lower magnification micrographs of both the low S_g and high S_g WC encapsulates [*i.e.* Fig. 1(b) and 2(b)] that the adventitious morphology of the precursor plays a more important rôle in terms of determining the overall shape of the obtained encapsulates. This is in accordance with the previous observations for WO_{3-x} oxides encapsulated within 2H-WS_2 IF materials.[12]

The consequence of encapsulation of WC inside 2H-WS_2 IF shells with respect to the composite physical properties will be to enhance considerably the structural rigidity of the resulting 2H-WS_2/WC encapsulates, which may enhance their performance in tribological applications. This would be an interesting result as WC is one of the hardest known materials. Furthermore, the inclusion of the more metallic metal carbide within the sulfide should also enhance the conductive properties of the resulting composite material.

A simple photo-affinity labeling protocol

Hong-yu Li, Ying Liu, Kan Fang, and Koji Nakanishi*

Department of Chemistry, Columbia University, New York, NY 10027, USA. E-mail: kn5@columbia.edu

Received (in Corvallis, OR, USA) 3rd December 1998, Accepted 28th December 1998

After photo-crosslinking and proteolysis of a photoaffinity labeled ligand to its receptor, the ester group incorporated in the ligand is cleaved by an amine with specific functionality, which displaces the bulk of the ligand from the peptide fragments, and facilitates subsequent tandem mass spectrometric sequencing.

With the very rapid advancement in analytical methods, the technique of photoaffinity labeling has become an increasingly central tool for investigating 3D interactions between ligands and receptors on a molecular basis.[1] Although photoaffinity labeling was introduced over thirty years ago by Westheimer,[2] the protocol remains basically unchanged. It involves synthesis of radioactive and photo-labeled ligands, incubation, photolysis, proteolysis and sequencing of radiolabeled peptide fragments by amino acid sequencer. However, in the case of membrane-bound receptors, the isolation of cross-linked peptide fragments from a sticky peptide mixture has been a particularly challenging and occasionally impossible task; nevertheless, photoaffinity labeling is the only general method to investigate such ligand–receptor interactions at a molecular level.[1]

Recently we introduced the protocol of using the bifunctional photoaffinity probe (BPP)[3] **1** coupled with tandem mass spectrometry (MS) to facilitate the often tedious photoaffinity studies dealing with membrane-bound receptors (Fig.1).

The ligand-BPP moiety which is bound to biotin through a linker is incubated with the receptor and irradiated with 350 nm light leading to site **A** photolysis and photocrosslinking. This is followed by receptor proteolysis and a second irradiation with 350 nm light, but under mildly basic conditions, upon which site

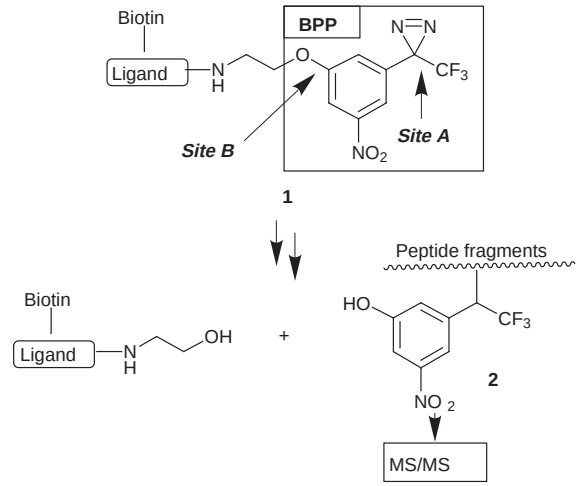

Fig. 1 Bifunctional photoaffinity probe (BPP).

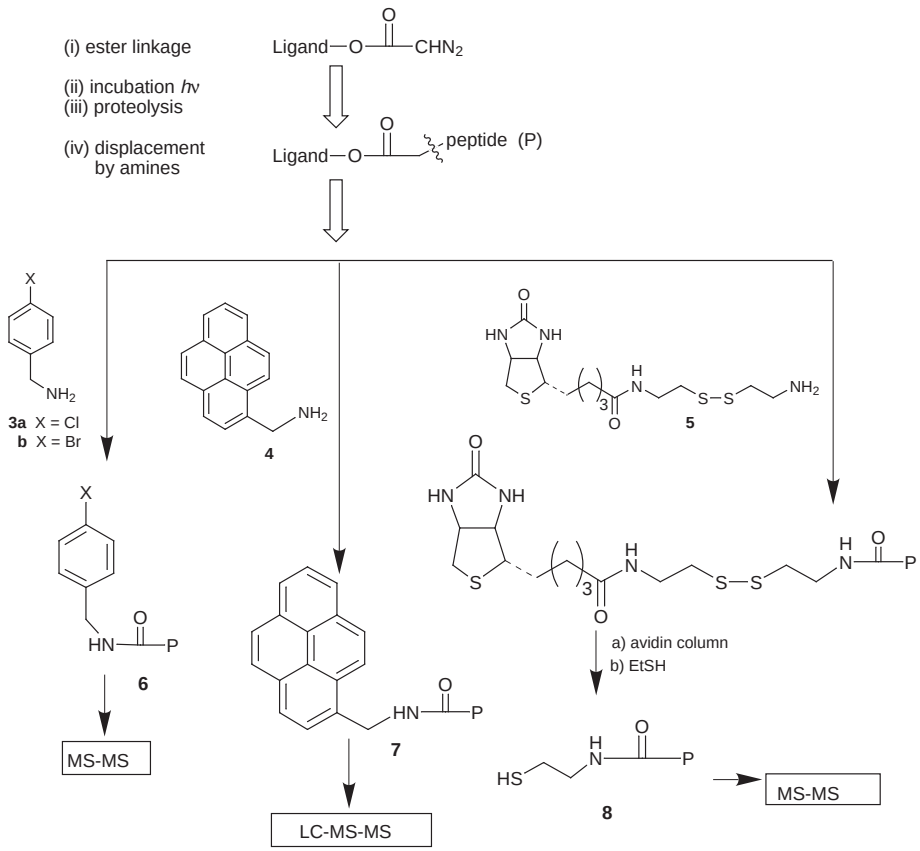

Fig. 2 General scheme of the protocol.

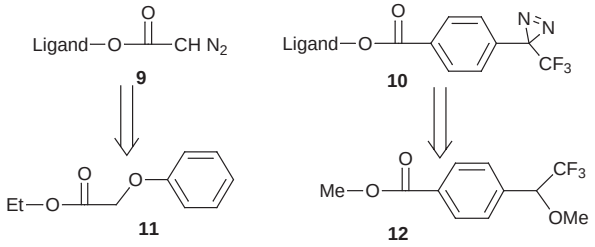

Fig. 3 Model compounds for the aminolysis reaction.

B cleavage occurs to detach the bulk of the ligand from the crosslinked peptide fragment; the ligand moiety and non-crosslinked fragments are separated from crosslinked fragment **2**, which is sequenced by tandem MS. This protocol is currently being applied to a particular ligand–receptor pair.

In the following, we introduce an alternative to further facilitate the photoaffinity crosslinking and sequencing processes. In the case of BPP, the ligand moiety was removed by a second photolysis performed under mild base conditions. In this revised protocol which does not use BPP, the ligand moiety is removed by aminolysis of a labile ester bond, as summarized in Fig. 2: (i) esterification of the hydroxy group with the appropriate photolabel, *e.g.* diazoacetate; (ii) incubation of ligand with its receptor followed by photolysis; (iii) enzymatic and/or chemical cleavage of the receptor; (iv) ester aminolysis and removal of the ligand moiety using amines **3**–**5**†‡ with functionalities for identification and/or purification purposes, *e.g.* bromine or chlorine atoms as tags for MS identification (**3**), fluorescence tag for HPLC detection (**4**), biotin tag for purification with immobilized avidin (**5**); (v) sequencing of tagged peptide fragments by tandem MS (MS/MS).[4–6]

Here, aminolysis performs the dual function of removing the undesired ligand moiety[7–9] and introducing the tag for MS sequencing, as well as purification. Namely, benzylamines **3** carry the isotopic halogen atoms[10] for facile MS identification, pyren-1-ylmethylamine **4** introduces a fluorescent tag[11] for chromatographic detection, if necessary, prior to MS, while biotinylated amine **5** with a cleavable disulfide bond is useful for separation of cross-linked peptide fragment(s) by avidin chromatography.[12,13]

A wide variety of photolabeling probes can be adapted to the protocol either directly or *via* short linkers, *e.g.* ethanolamine and glycolic acid, to modify either the ligand or the photolabile probes before linking. The aminolysis was checked with model compounds **11** and **12**, the products that might be produced from photolabeled ligands **9** and **10** (Fig. 3), respectively.

Ester **11** was converted into the amide upon treatment with 150 equiv.‡ of amines **3a**, **3b**, **4**, and **5**,§ 50° C, 1 day, in yields of 75, 61, 64 and 52%, respectively. Aminolysis of ester **11** with base **3a**, performed in the presence of four peptides Gly-Gly-Phe, Lys-Phe, Gly-Leu-Tyr and Phe-Tyr, resulted in a 62% transformation, demonstrating that peptide bonds are not affected; the sluggish aminolysis of aromatic esters was accelerated upon addition of NaCN,¶ in which case 70% of ester **12**‖ was aminolized overnight by 100 equiv. of amine **3a** in pyridine.** The disulfide bond in the biotinylated amide derived from **5** and **11** was readily cleaved by EtSH to give product **8** (P = phenoxymethyl) without biotin, suited for tandem MS analysis, in quantitative yield.††

The present simple protocol, which provides an alternative to the BPP approach, is currently being applied to an actual ligand–receptor system.

This work was supported by NIH Grant AI 100187. We are grateful to Drs Yasuhiro Itagaki and Masaru Hashimoto, and Mr Jinsong Guo, for discussions.

Notes and references

† Pyren-1-ylmethylamine hydrochloride and 4-bromobenzylamine hydrochloride are commercially available (Aldrich). The free pyren-1-ylmethylamine and 4-bromobenzylamine were obtained by passing their hydrochlorides through an ion exchange column (OH^- type). If pyren-1-ylmethylamine were brominated, the fluorophore will serve as a MS tag as well.

‡ Although the amino group in Lys in the peptide would be deactivated by protonation or hydrogen bonding, in principle, it can aminolyze the ester. Therefore, excess amine is required, which also accelerates the reaction.

§ Amine **5** was made by the coupling of cystamine and (+)-biotin 4-nitrophenyl ester.

¶ NaCN is a very mild catalyst. It is likely that the attack of cyanide anion occurs only on the ester bond without damage of the peptide fragment (ref. 14).

‖ Ester **12** was readily prepared from the photoaffinity labeling probe 4-(1-azi-2,2,2-trifluoroethyl)benzoic acid (ref. 15) by photolysis and then methylation.

** The aminolysis works in a wide spectrum of polar solvents, such as water, EtOH, MeOH, pyridine, *etc.*

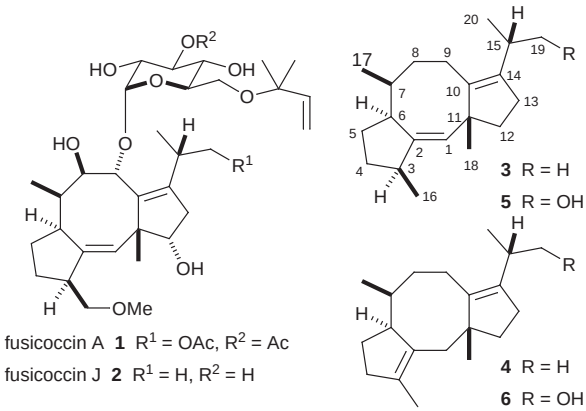
Received (in Cambridge, UK) 4th December 1998, Accepted 6th January 1999

(+)-Fusicocca-2,10(14)-diene, isolated recently by the authors, is most likely a genuine hydrocarbon intermediate in the biosynthesis of fusicoccin, as its 8β-hydroxy derivative is smoothly and efficiently converted into fusicoccin J by the fusicoccin-producing fungus, *Phomopsis (Fusicoccum) amygdali* F6.

Fusicoccin A (**1**)[1] and J (**2**)[2] and their congeners, produced by the phytopathogenic fungus *Phomopsis (Fusicoccum) amygdali*, possess potent H^+–ATPase activating activity.[3] Their



action is at the center of interest, since the fusicoccin-binding 14-3-3 proteins are regarded as key proteins in intracellular signal transductions in both plant and animal cells.[4]

Earlier studies on the fusicoccin biosynthesis have postulated fusicocca-1,10(14)-diene **3** as the hydrocarbon intermediate.[5] However, we have recently isolated fusicocca-2,10(14)-diene **4**, a double bond isomer of **3**, from *P. amygdali* F6† as a main hydrocarbon constituent.[6] This fact called our attention to the initially-forming fusicoccane hydrocarbon in the fusicoccin biosynthesis. To clarify the true hydrocarbon intermediate, feeding experiments of synthetic derivatives of both **3** and **4** have been carried out. The results reported here strongly suggest that **4**, not **3**, is the genuine hydrocarbon.

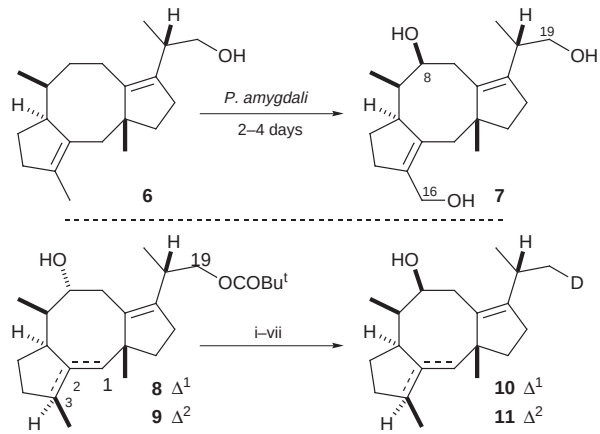
For feeding experiments of synthetic intermediary substrates, we chose hydrophilic monohydroxylated derivatives of **3** and **4**, which should have suitable solubility in the culture medium. As a preliminary study, feeding experiments (*vide infra*) using fusicocca-1,10(14)-dien-19-ol **5** and its isomer **6**[6] were carried out. Feeding of **5** showed no significant formation of the corresponding metabolites and the production of fusicoccins fell off clearly as monitored on TLC with a control mixture of metabolites, indicating that **5** seemed to perturb the biological processes. On the other hand, **6** gave a new metabolite {$[\alpha]_D^{22}$ + 35.8 (*c* 0.30, $CHCl_3$)}, whose structure was elucidated as fusicocca-2,10(14)-diene-8β,16,19-triol **7** from its spectral data (Scheme 1).‡

These results led the authors to suspect that 8β-hydroxylation at the non-allylic position occurs at an early stage of the biosynthesis. Therefore, we turned our attention to the transformations of the 8β-hydroxylated derivatives of **3** and **4**. The 8α-hydroxy-substituents of **8** and **9**[6] were epimerized by an oxidation–reduction process. Then, the 19-hydroxy group was removed by $LiEt_3BD$ reduction of the corresponding mesylate providing the deuterated compounds **10** and **11**.

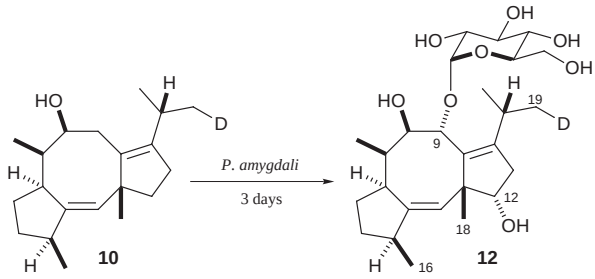
A solution of 60 mg of **10** or **11** in a small amount of EtOH was added equally (10 mg each) to six cultures of the fungus strain F6 which had been growing for 2 or 3 days at 25 °C.§ After additional cultivation for 3 days, the combined culture filtrate was extracted with EtOAc at pH 9.0.

From the feeding experiment of **10**, which has the 1,10(14)-diene system typical for fusicoccin, 50 mg of **2** and 13 mg of a new non-natural metabolite {mp 126–127 °C, $[\alpha]_D^{22}$ + 16.6 (*c* 0.41, $CHCl_3$)} were obtained. The structure of the latter was elucidated to be 16-demethoxy-6′-*O*-de-*tert*-pentenyl [19-$^2H_1$]fusicoccin J (**12**) from its spectral data (Scheme 2).

The molecular formula is $C_{26}H_{41}DO_8$; FAB MS: *m/z* 506.2844 [(M + Na)$^+$, $C_{26}H_{41}DO_8Na$ requires, 506.2840]. ^1H and ^{13}C NMR ($CDCl_3$–CD_3OD 5 : 1, +40 °C, 600 and 150 MHz, respectively) signals are fully assignable by 2D measurements. Diagnostic signals are as follows; δ_H 1.02 (2H, br d, *J* 6.8; H19, deuterated methyl), 1.09 (3H, d, *J* 7.0; H16), 1.18 (3H, s; H18), 3.18 (sextet, *J* 6.8; H15), 3.46 (dd, *J* 9.5, 9.3; H4′), 3.50 (dd, *J* 9.5, 3.8; H2′), 3.63 (ddd, *J* 9.5, 3.5, 3.3; H5′), 3.67 (dd, *J* 11.7, 3.5; H6′), 3.72 (t, *J* 6.2; H12), 3.75 (dd, *J* 9.5, 9.3; H3′), 3.77 (dd,



Scheme 1 *Reagents and conditions*: i, $(ClCO)_2$, DMSO then Et_3N, CH_2Cl_2 (Δ^1, 86%; Δ^2, 97%); ii, DIBAL-H, THF [Δ^1, 24% (**8**, 42%); Δ^2, 52% (**9**, 15%)]; iii, TBDMSCl, imidazole, CH_2Cl_2; iv, LAH, THF; v, MsCl, Py (3 steps, Δ^1, 83%; Δ^2, 73%); vi, $LiEt_3BD$, THF; vii, Bu_4NF, THF (2 steps, Δ^1, 87%; Δ^2, 86%).



Scheme 2

J 11.7, 3.3; H6′), 3.80 (d, *J* 9.9; H9), 3.92 (dd, *J* 9.9, 4.6; H8), 4.95 (d, *J* 3.8; H1′) and 5.20 (t, *J* 1.8; H1); δ_C 19.73 (C16), 21.01 (t, C19, deuterated carbon), 61.83 (C6′), 70.59 (C4′), 71.82 (C5′), 72.37 (C2′), 73.90 (C3′), 77.55 (C9), 78.62 (C8), 80.22 (C12) and 101.87 (C1′). These data clearly reveal that **12** was generated only from feeded **10**; the C9 and C12 positions were hydroxylated; α-glucosidation occurred at C9. The C16 methyl was preserved intact. The stereochemistry of the hydroxylated positions was confirmed with NOE enhancements of H9 and H12 upon irradiation of H18. The glucosidic linkage between C1′ and C9 was deduced from HMBC correlations of C9/H1′ and C1′/H9. Thus, although **12** is a fusicoccin type-glucoside, it lacks the hydroxylation of its C16-methyl group. The fusicoccin J (**2**) obtained in this feeding experiment was natural; no deuterated substance was detected by NMR spectroscopy. Identification of **12** suggests that 12α-hydroxylation of fusicoccin precedes the prenylation of its glucosyl moiety.

The result obtained from the feeding experiment using **11** was more striking and conclusive for the elucidation of the biosynthetic pathway of **2**. Fusicoccin J (**2**, 51 mg) isolated from the culture broth of this experiment was found to have a remarkable amount of the deuterated substance (**2**-*d*). Incorporation of **11** into **2**-*d* was easily recognized by ^{1}H, ^{13}C NMR ($CDCl_3$, 600 and 150 MHz, respectively) and mass spectra. The distinguishable signals between **2** and **2**-*d* are δ_H 1.04 (2H, br d, *J* 6.8; **2**-*d* H19, deuterated methyl)/1.06 (3H, d, *J* 6.8; **2**-H19) and 3.169 (sextet, *J* 6.8; **2**-*d* H15)/3.174 (septet, *J* 6.8; **2** H15); δ_C 20.44 (**2**-*d* C20)/20.47 (**2** C20), 20.98 (t, **2**-*d* C19, deuterated carbon)/21.27 (**2** C19) and 27.78 (**2**-*d* C15)/27.86 (**2** C15). In the FAB mass spectrum, the ratios of **2** $(M + H)^+$/**2**-*d* $(M + H)^+$ and **2** $(M + Na)^+$/**2**-*d* $(M + Na)^+$ are close to 1 : 1; *m/z* 581 (7.9%)/582 (7.9%) and 603 (6.3%)/604 (6.7%); FAB-MS: *m/z* 603.3513 ($C_{32}H_{52}O_9Na$ requires, 603.3509) and 604.3577 ($C_{32}H_{51}DO_9Na$ requires, 604.3572). At least 40% of fusicoccin J was derived from the feeded substrate **11**, the double bond of which had originally been located at the C2–C3 position.

Thus, these results clearly demonstrate that the C16 methyl has to be allylic for its conversion into the methoxymethyl group. Therefore **4**, actually isolated from mycelia of the fungus, is most likely the genuine hydrocarbon intermediate in the biosynthetic pathway of fusicoccin.

Our interests are currently focused on the identification of non-deuterated **11** from the fungus and on the chemical mechanism of the double bond isomerization occurring during the conversion of **11** to **2**. The transformation from **10** to **12** by the fungus can be regarded as the creation of an 'artificial fusicoccin' from a '*pseudo*-biosynthetic intermediate'. Efforts on this line are also in progress.

Notes and references

† The fungus strain F6 produces fusicoccin J as a main metabolite (*ca*. 120 μg ml^{-1}) in the culture medium indicated below.
‡ Details will be reported in a full paper.
§ The composition of the culture medium was as follows; 8.0% commercial sugar, 1.0% corn steep liquor, 0.5% peptone and 0.5% NaCl in 100 ml of deionized water .

Received (in Liverpool, UK) 10th December 1998, Accepted 15th January 1999

3-Methylthiophene can be synthesised in yields > 95 mol% from the reaction of 2-methylbutanol and CS_2 over MgO-supported potassium-promoted '$Fe_{0.95}Cr_{0.05}OOK$'; catalysts using γ-Al_2O_3 or other alkaline earth oxides as supports are less effective.

The derivatives of the sulfur-containing heterocycle thiophene have been widely used for many years as raw materials in the production of agrochemicals, dyes and pharmaceuticals.[1] As a consequence the synthesis of such compounds on an industrial scale (1000 tonnes per annum) is of significant economic importance and provides considerable incentive for research. Currently market demand is met by two heterogeneous catalytic processes involving the reaction of organic oxygenates (alcohols, carbonyls, α,β-unsaturated aldehydes) with a suitable sulfur source (CS_2 or H_2S) over γ-Al_2O_3-based catalysts at high temperatures (> 450 °C).[2,3] However, the synthesis of substituted thiophenes by standard high temperature vapour phase methods has been found to be far less efficient than the synthesis of the unsubstituted parent molecule, with yields decreasing from > 90% for thiophene to *ca.* 40–50% for 3-methylthiophene.[2,3] Here we address this problem and present initial results for catalysts based upon alkaline earth oxide-supported $Fe_{0.95}Cr_{0.05}OOK$ catalysts which give yields of 3-methylthiophene (3MT) > 95 mol% from the reaction of 2-methylbutanol and CS_2.

Catalysts were prepared by dissolution of 95 : 5 wt% Fe_2SO_4 : Cr_2SO_4 in distilled water (80 °C), with constant stirring. K_2CO_3 solution (2 : 1 K : Me^{3+}) was added, followed by the weight balance of support (85%). The mixture was evaporated to a paste, dried (120 °C, 24 h) and calcined (air, 24 h, 700 °C). Samples were then pelleted and sieved (0.6–1.0 mm), prior to testing for 3-methylthiophene synthesis in a fixed bed microreactor.[4] All reactions involved passing a reagent stream of 2-methylbutanol (2MB), CS_2 and N_2 (1 : 1.5 : 80 molar ratio) at a GHSV of 12 000 h^{-1} over 1.0 g of catalyst. Product analysis was performed by on-line GC FID analysis with a carbon balance of 98–100% for all data quoted, based upon conversion of 2MB.

Previously we have demonstrated that a mixed α-$Fe_{0.95}Cr_{0.05}OOH$ material is a highly efficient low temperature 3MT synthesis catalyst.[5,6] Further data have shown that the activity, selectivity and thermal stability of this material may be enhanced by addition of 7.5% K_2CO_3. This is postulated as being linked to the formation of mixed MOOK species (M = Fe or Cr).[6a] In addition, Stobbe *et al.*[4] have shown MgO-supported FeoOK to be an active and selective dehydrogenation catalyst. Hence we have examined the activity of MgO-supported $Fe_{0.95}Cr_{0.05}OOK$ for 3MT synthesis.

The effect of temperature on the performance of $Fe_{0.95}Cr_{0.05}OOK$/MgO for 3MT synthesis is illustrated in Fig. 1 and Table 1. Initially there is negligible 2MB conversion, however, for T > 325 °C there are dramatic increases in conversion and 3MT yield. This is initially coupled with a significant production of thiophene arising from β-methyl scission, as reflected in the concomitant increases in light fractions. However, at temperatures > 425 °C there is a plateau of activity with 3MT yields > 95 mol%, at 100 mol% conversion of 2MB. This contrasts with the data obtained for the current commercially utilised catalyst (7.5% K_2CO_3-promoted Cr_2O_3/γ-Al_2O_3), which gave a peak yield of *ca.* 78 mol% 3MT at 475 °C. In this case the selectivity of the catalyst is limited by extensive side reactions such as cracking and β-methyl fission which not only limit 3MT selectivity but are also known to have a deleterious effect on catalyst lifetime due to coke build-up.[6a]

In a further set of experiments the effect of support on the activity of the FeCrOOK phase was examined (Table 1). It is apparent that the choice of support has a marked effect on catalyst performance, with optimum activity being obtained for the MgO case. The use of alternative alkaline earth oxide supports resulted in significant decreases in overall activity and 3MT selectivity down the group. Moreover, the selectivity towards 2-methylbutene also increased with the increasing basicity of the support. Conversely, while there is minimal production of the alkene on the acidic FeCrOOK/γ-Al_2O_3, more cracking of the alcohol is observed and the peak of 3MT synthesis activity (*ca.* 95 mol%) is observed at 500 °C. Furthermore, the 3MT production increases linearly with temperature for the γ-Al_2O_3 variant with no observed plateau temperature, further hindering its industrial application.

The high activity of these materials is consistent with previous findings[5–7] and is ascribed to the presence of $Fe_{0.95}Cr_{0.05}OOK$. Attempts to characterise this phase *via* X-ray

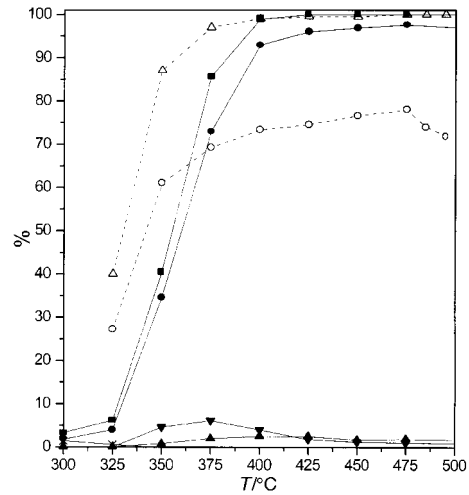

Fig. 1 3MT synthesis performance comparison of $Fe_{0.95}Cr_{0.05}OOK$/MgO and the current industrial catalyst (7.5 K_2CO_3/11% Cr_2O_3/γ-Al_2O_3). FeCrOOK/γ-Al_2O_3	220	1.60[d]	97300
Cr_2O_3/MgO	30	9.87	1200
7.5% K Cr_2O_3/MgO	30	14.58[d]	20100

[a] Normalised activity (moles of 3MT per hour per square metre surface area of catalyst). [b] Cr_2O_3. Utilisation value (normalised activity per mole of Cr_2O_3) (nominal values reflecting the effective use of Cr). [c] 7.5 K_2CO_3/11% Cr_2O_3/γ-Al_2O_3. [d] Based upon yield at 500 °C, *cf.* 475 °C for all other samples.

diffraction were unsuccessful, with only support oxide and K_2SO_4 being detected. Similarly, whilst X-ray photon spectroscopy analysis indicated the presence of Fe^{3+} as oxide/oxide hydroxide,[8] no Cr^{3+} (present at 0.3 wt%) was detected. Thus we ascribe the high selectivity to a synergistic phase formation. This premise is suggested by the lower activity of K-promoted Cr_2O_3/MgO (Tables 1, 2) and further supported by the lower intrinsic activity of Fe, *cf.* Cr for heterocycle synthesis.[6a] A comparison of normalised activities and Cr utilisation values (Table 2) supports the claim that activity is not merely due to mixed supported oxides. These findings are also consistent with the work of Stobbe *et al.*[6] who have shown FeOOK to be a specific phase of high dehydrogenation function, a feature which has been found to be of specific importance in the thiophene synthesis mechanism.[5–7]

These data briefly summarise initially findings regarding the activity of this highly promising new class of catalysts.[7] Ongoing trials are assessing their lifetime performance, regeneration characteristics and suitability for industrial application.

We are grateful for the financial support of this work by Synthetic Chemicals Ltd, now Inspec Fine Chemicals Ltd. The contribution of Mr F. P. Getton is also acknowledged.

A novel layered templated lithium zinc phosphate prepared by an unusual solution mediated technique

Torben R. Jensen*[a]† and Rita G. Hazell[b]

[a] *Chemistry Department, University of Southern Denmark, Odense University, DK-5230 Odense M, Denmark*
[b] *Chemistry Department, University of Aarhus, DK-8000 Aarhus C, Denmark*

Received (in Bristol, UK) 11th November 1998, Accepted 12th January 1999

A novel layered lithium zinc phosphate $LiZn(HPO_4)(PO_4)\cdot H_3NCH_2CH_2NH_3\cdot H_2O$ containing ethylenediamine(en), having a long nucleation time, is prepared by moderate temperature solution mediated conversion of a microporous zinc phosphate; its crystal structure is also reported.

Synthetic microporous and layered materials are of considerable interest for a wide variety of industrial and chemical applications, *e.g*. catalysis, ion exchange or intercalation.[1] These materials have expanded their range of compositions tremendously from the original zeolite type aluminium silicate minerals and now include phosphates, arsenates, vanadates, and chalcogenides.[2] Orthophosphates are possibly the fastest expanding group of inorganic materials and recently templated iron phosphates were discovered, arising from the development of new solvothermal synthesis techniques.[3]

Solvothermal synthesis using organic amine ions as templates is a common route to novel open framework materials and detailed knowledge of the synthesis mechanism, including nucleation and crystal growth, is of importance for the design of new materials.[4] The formation of a Mn substituted aluminium phosphate (Mn-AlPO-5, AFI structure) was investigated using *in situ* synchrotron radiation powder diffraction. The crystal growth followed a first order kinetic model after a nucleation period; clearly, lowering the synthesis temperature increases the nucleation time.[5] Similar main features were found for the crystallisation of a microporous oxyfluorinated gallophosphate, ULM-5.[6] Changing the composition of reactants for the ULM-5 synthesis revealed the presence of an intermediate phase; decreasing the synthesis temperature increases the time of stability of the intermediate.[6] In general microporous and layered materials are topologically metastable and convert to more dense phases upon heating dry or in water, *i.e*. approaching higher density and higher thermodynamic stability. In some cases microporous materials can transform to other microporous or layered materials upon prolonged solvothermal treatment at a constant moderate temperature. The materials prepared by such solution mediated conversion might not be attainable increasing the synthesis temperature as the system enters the stability field of other more dense phases. β-$LiZnPO_4\cdot H_2O$, a new variant of the zeolite ABW structure, was initially prepared at room temperature by solution mediated conversion of α-$LiZnPO_4\cdot H_2O$ having a nucleation period of *ca*. 3 months.[7] Variation of the composition of the reaction mixture revealed that β-$LiZnPO_4\cdot H_2O$ could be prepared with a nucleation period of several days.[7] Ambient temperature solution mediated conversion of one metastable phase to another is probably useful in a wide range of chemical compositions for discovering new materials and the method might be characterised as a *chemie douche* technique.[8] Another approach utilises slow diffusion of the reactants in a silica gel. After a nucleation period of *ca*. 3 weeks at ambient conditions crystals of new layered templated aluminium and gallium phosphates appeared.[9]

The method of solution mediated conversion is utilised in the present study preparing zinc hydrogenphosphates containing rubidium or caesium and a new layered templated lithium zinc phosphate $LiZn(HPO_4)(PO_4)\cdot H_2en\cdot H_2O$ **1**; all the materials have long nucleation time.

We have discovered a new rubidium zinc hydrogenphosphate, $Rb_2Zn_2(HPO_4)_3$ prepared at 51 °C with nucleation time of *ca*. 4.5 months [monoclinic, space group $P2_1/c$, a = 12.5880(4), b = 12.7170(8), c = 7.5827(8) Å, β = 96.100(1)°]. This material has a complex crystal structure with spiralling chains of ZnO_4 and HPO_4 tetrahedra.[10] At ambient conditions we also prepared a new layered caesium zinc hydrogenphosphate, $CsZn_{2.5}(HPO_4)_3\cdot 2H_2O$, by a solution mediated conversion after a nucleation period of *ca*. 2 months [triclinic, space group $P\bar{1}$, a = 8.3918(6), b = 9.8254(8), c = 9.9090(7) Å, α = 111.17(1), β = 111.75(1), γ = 97.56(1)°].[11]

The synthesis of **1** was performed in the system $Li/Zn/PO_4$–en–H_2O; a gel was left to stand at 21 °C in a sealed flask preventing evaporation.‡ After 1 day a microporous zinc phosphate, $Zn_2(PO_4)_2\cdot H_2en$, DAF-3,[12] formed and after *ca*. 3 months crystallisation of **1** was observed thus, DAF-3 is a metastable, intermediate phase. The material DAF-3 has only been obtained as microcrystalline powder, whereas **1** can be obtained as larger crystals. This is probably due to very different time-scales of nucleation and crystal growth for the two materials. A faster and more direct preparative route for **1** might exist but not at much higher temperatures owing to formation of more dense phases, *e.g*. δ_l-$LiZnPO_4$.[13]

The crystal structure of **1** was investigated by single crystal X-ray diffraction providing a detailed structural model including all hydrogen positions in space group $C2/c$.§ **1** is built from regular tetrahedra of PO_4, ZnO_4 and LiO_4 forming two types of chains running in the (010) direction; zigzag four ring chains of alternating PO_4 and ZnO_4 and chains of corner sharing LiO_4, each LiO_4 tetrahedron having one oxygen from crystal water. These chains are alternately connected by HPO_4 tetrahedra forming layers held together by hydrogen bonding through ethylenediamine and water. Fig. 1 shows the *ac* projection of the crystal structure of **1**. Half the H_2en ions were found across a symmetry centre and are connecting the zigzag chains. The other H_2en ions connecting LiO_4 chains in different sheets are placed across the twofold axes of the space group $C2/c$ in such a way that the individual H_2en ions do not obey this symmetry, necessitating a disordered structural model in $C2/c$ or lowering the symmetry to Cc. The refinement in Cc was unstable unless all except this dication was constrained to keep the centrosymmetric relation. In fact the least squares program, KRYSTAL,[14] has been modified to allow symmetry operations which apply to a specified number of atoms only. The two models have the same number of parameters and gave similar R-values. We therefore chose the $C2/c$ solution.

1 is the first layered material in the system M_2O–ZnO–P_2O_5–H_2O–amine, M = alkali metal, with only one other member, reported as $Na_{67}(NMe_4)_{12}Zn_8(ZnPO_4)_{96}\cdot 192H_2O$, an analogue to zeolite X.[15] The latter is partly templated by hydrated sodium ions and partly by the amine ions. A large number of alkali metal containing microporous and some layered materials have been described, *e.g*. two ABW type polymorphs of $LiZnPO_4\cdot H_2O$ denoted α and β,[7,13a] but **1** is the first compound with alkali metal–oxygen–alkali metal contact, although Zn–O–Zn linkages are known, but rare.[16] Fig. 2 shows the connectivity of

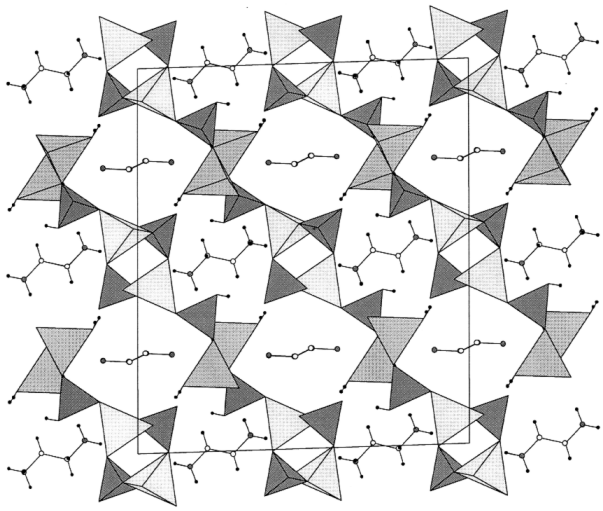

Fig. 1 The crystal structure of **1**; the *ac* projection. PO_4 (dark) and ZnO_4 (light) tetrahedra forming four-ring chains along with LiO_4 (medium dark) chains are running in the (010) direction, connected by HPO_4 tetrahedra to form layers, which are assembled by linking ethylenediamine ions. H atoms small size dark circles, C and N atoms larger medium dark circles.

‡ *Synthesis*: $LiZn(HPO_4)(PO_4){\cdot}H_2en{\cdot}H_2O$ **1** was prepared by dissolving $LiOH{\cdot}H_2O$ (1.833 g), LiCl (1.867 g) and $Zn(MeCO_2)_2{\cdot}2H_2O$ (9.639 g) in water. H_3PO_4 85% (10.022 g) and then ethylenediamine (en) (4.6 mL) were added under stirring forming a white gel with composition, 0.99 Li_2O : 1 ZnO : 0.98 P_2O_5 : 1.92 en : 43 H_2O, *c*(PO_4) *ca*. 1.7 M, pH = 4.95. A portion of this gel was left to stand at ambient conditions, *ca*. 21 °C, in a sealed bottle preventing evaporation. After *ca*. 24 h DAF-3 was formed as a microcrystalline powder [$a = b = 14.7073(8)$, $c = 8.946(1)$ Å, refined from 103 powder diffraction reflections, in accordance with ref. 12] and after *ca*. 3 months DAF-3 partly transformed to **1**.

§ *Single crystal diffraction*: A transparent, plate-like crystal of **1** was selected for data collection on a Siemens SMART diffractometer equipped with a CCD detector and graphite monochromatised Mo-Kα radiation, λ = 0.71073 Å. Approximately one hemisphere of data was collected in narrow frames covering 0.3° in ω in three sets at different φ angles using a detector to crystal distance of 40.0 mm. Data were corrected for Lorentz-polarisation effects and for absorption using an empirical method (SADABS) giving 1616 unique reflections.

Details of data collection: θ_{max} = 24.5°, T = 120(2) K, measured reflections 4108, R_{int} = 0.027, Transmission (max. min.): 0.93, 0.80. A structural model was found using direct methods and the program SIR97.[17] The program KRYSTAL was used for the structure refinement.[14] The H atom positions were found in the difference Fourier maps and thermal parameters were kept isotropic; all other atoms were refined with anisotropic temperature factors. Scattering factors of neutral atoms were applied throughout this work. The refinement converged at R = 0.027 and R_w = 0.035, with 183 parameters refined using full matrix least squares based on F^2 and a weighting scheme, $w = \{[\sigma_{cs}(F^2) + 0.03F^2]^{-2}$. Figures were prepared using the program Atoms Ver. 4.0.[18]

Crystal data for **1**: M = 343.41, monoclinic, space group *C*2/*c*, (no. 15), a = 18.068(2), b = 5.3034(6), c = 21.065(3) Å, β = 91.992(2)°, U = 2017.3(4) Å^3, Z = 8, μ = 2.794 mm^{-1}, D_c = 2.261 g cm^{-3}. Received (in Basel, Switzerland) 25th November 1998, Accepted 17th December 1998

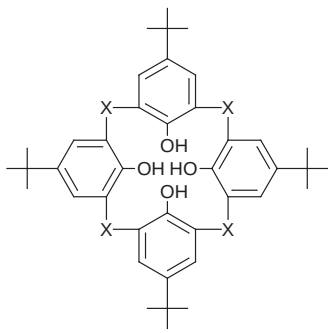
An X-ray structure determination of an antiferromagnetic copper complex of *p-tert*-butyltetrathiacalix[4]arene has shown it to contain a square, phenoxo- and sulfur-bridged cluster of four Cu(II) ions sandwiched between two fully deprotonated calixarenes, thus forming a ditopic, divergent receptor; as prepared, the complex has each cavity occupied by a molecule of dichloromethane.

Inclusion based molecular network koilates may be obtained using cavity-containing molecules, koilands 'hollow molecular units', and connector molecules.[1] So far, study of such materials has been mainly oriented towards the understanding of structural characteristics. A development which remains to be achieved is the design and preparation of functional inclusion molecular networks. Calix[4]arene[2] derivatives, *e.g.* **1**, offer particular promise in this regard, as the fusion of calixarene units by bridging through entities such as Si(IV)[3] readily enables the divergent orientation of cavities of a size and nature sufficient to accommodate a variety of guests. The fact that a number of different metals (including Ti, Nb, Al, Zn, Mg and Eu)[4] may be used similarly as bridges adds a further dimension to the possible utility of these materials.



1 X = CH_2
2 X = S

As a means of enhancing selectivity in metal ion binding, the functionalisation of calixarenes with sulfur-containing groups has been quite widely investigated.[2,5,6] In general, this has involved quite difficult synthetic chemistry but the recent discovery[7] of a facile, high-yielding pathway to the tetrathiacalix[4]arene **2**, in which thiaether sulfur has replaced the methylene groups of calix[4]arene itself, has offered considerable prospects for expansion of the applications of such molecules.[8] Oxidation of the thiaether bridges to sulfoxide[9] and sulfone[10,11] groups offers a unique way of converting **2** to a number of interesting derivatives. Here, as part of a programme to systematically evaluate the metal ion coordinating ability of these new calixarenes (Fig. 1), we report the structure of a copper derivative, $Cu_4(\mathbf{2})_2$, of **2** in which a hollow molecular

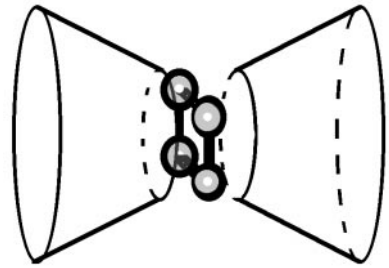


Fig. 1 Schematic representation of a hollow molecular unit obtained by fusion of two tetrathiacalix[4]arenes by four metal centres.

unit is apparent. In the case of this transition metal, coordination to the calixarene appears to involve only oxygen and sulfur donor sites, though it is anticipated that, as with the simple calixarenes, other metals may be bound through interactions with, for example, the phenyl-ring π-electrons.[12]

Upon heating a dimethylformamide (DMF) solution of compound **2**, hydrated copper acetate and Et_3N, a dark blue–black, crystalline complex was obtained.† The ^1H NMR spectrum of a solution of the complex in $CDCl_3$ at 298 K showed only a single, broad resonance, indicating that the complex was paramagnetic. Under the same conditions, an electron spin resonance could not be detected [a phenomenon known for many multinuclear Cu(II) systems,][13] but SQUID measurements of magnetic susceptibility (4–298 K; Fig. 2) could be interpreted, in the light of the structural information described below, in terms of antiferromagnetic coupling (J = 103 ± 1 cm^{-1}) of four equivalent Cu(II) ions arranged in a

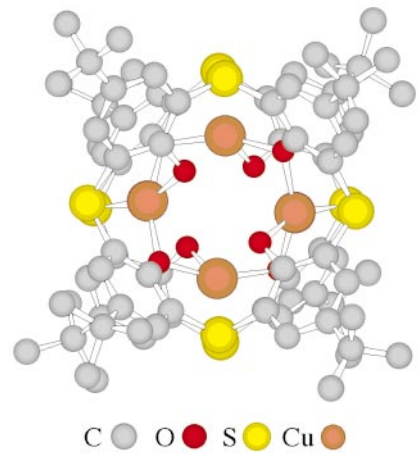

Fig. 2 A lateral view of the solid state structure of the tetranuclear copper complex possessing two cavities occupied each by one CH_2Cl_2 molecule. For clarity, H atoms are omitted.

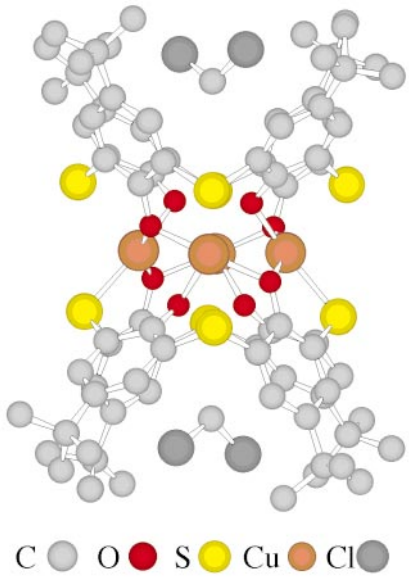

Fig. 3 Top view of the crystal structure of the tetranuclear copper complex showing the square arrangement of the metal centres and their bridging by phenoxide groups.

square. The coupling is appreciably stronger than in a previously characterised Cu_4 square array,[14] presumably as a consequence of a smaller separation between the metal atoms.

Single crystals (black tablets) of $Cu_4(\mathbf{2})_2$ suitable for X-ray crystallography were readily obtained on addition of ethanol to a solution of the complex in dichloromethane.‡ Two inequivalent $Cu_4(\mathbf{2})_2$ units are found within the unit cell but the differences between them are subtle and will be described elsewhere. In both, the Cu_4 array, sandwiched between two thiacalix entities in a 'cone' conformation similar to that of the free ligand,[8] is close to exactly square, with each copper in a six-coordinate O_4S_2 donor-atom environment. The coordination sphere is far from regular, with one Cu–O bond *ca.* 0.5 Å longer than the other three and one Cu–S bond *ca.* 0.3 Å longer than the other. Fourfold symmetry for the $Cu_4(\mathbf{2})_2$ unit is broken by the inclusion of one molecule of CH_2Cl_2 within each of the divergent cavities of this hollow molecular building block (Fig. 2 and 3). Comparison with an analogous copper complex of *p*-*tert*-butylcalix[4]arene is not possible since no such structure has been determined but it has been suggested[7] that the far better extractant activity of **2** relative to **1** may be associated with the presence of the additional sulfur-donor centres and thus it is significant that the present structure demonstrates their involvement in the coordination of Cu(II). Other structures we are in the process of refining show that this mode of binding is certainly not restricted to Cu(II).

In summary, we note that this structure is both the first known of a Cu(II) complex of any calixarene and the first known of any complex of the tetrathiacalix[4]arene **2**. It is also that of the first intentionally synthesised paramagnetic koiland (hollow molecular building block), though others have been identified.[4] The use of this hollow molecular unit in the formation of magnetic inclusion networks in the crystalline phase is under current investigation.

Notes and references

† The *p*-*tert*-butylthiacalix[4]arene **2** (270 mg, 0.37 mmol) was dissolved in DMF (8 mL) containing Et_3N (10 drops) and the resulting solution was added to a solution of $Cu(OAc)_2{\cdot}H_2O$ (150 mg, 0.75 mmol) in DMF (5 mL). EtOH (20 mL) was added to the dark brown solution and this was heated at reflux for 4 h. The reaction mixture was cooled to room temperature and filtered. The crude black solid was recrystallised twice from CH_2Cl_2–EtOH to give the product as black prisms (190 mg, 57%). MS (FAB) *m/z* 1685 (M^+ 1685, calc. 1689). Anal. Zeolite-like crystal structure of an empty microporous molecular framework

Cameron J. Kepert† and Matthew J. Rosseinsky*

Inorganic Chemistry Laboratory, Department of Chemistry, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: matthew.rosseinsky@chem.ox.ac.uk

Received (in Cambridge, UK) 15th December 1998, Accepted 7th January 1999

The rigidity of the coordination polymer framework of $Ni_2(4,4'\text{-bipy})_3(NO_3)_4$ is demonstrated quantitatively by determination of the structures of both ethanol-loaded and desolvated forms, showing only a small relaxation of the structure on guest loss.

The synthesis of extended molecular frameworks[1] robust to guest exchange[2] and linked by coordinate or hydrogen bonds has led to suggestions that such frameworks would be suitable for applications in separations and heterogeneous catalysis.[3] To date, however, there has been no direct proof by structure refinement that a completely desolvated coordination polymer can retain the same open-framework geometry (as defined by quantitative analysis of diffracted intensities) once the solvent template/guest occupying the putative void space has been removed, preventing a detailed assessment of claims for zeolite-like behaviour. Previous single crystal studies are restricted to cell dimension measurement on partly desolvated systems without structure analysis.[4] Here, we report the guest exchange chemistry and the first full crystallographic characterisation of a microporous molecular framework coordination polymer in both the solvated and completely desolvated state. Guest loss is fully reversible on a single crystal and causes no observable increase in crystal mosaicity. The refinement of data collected *in situ* on the desolvated crystal proves that the open-channel geometry is retained in the total absence of the guest, demonstrating a direct structural and chemical link with the large family of zeolite frameworks and obviating the possible problem of guest resorption on cooling present in *ex situ* studies.

Crystals of **A**, $Ni(bpy)_{3/2}(NO_3)_2{\cdot}EtOH$ (bpy = 4,4′-bipyridine), were grown and sealed in capillaries containing mother-liquor to prevent desolvation. Isomorphous salts containing water and CS_2 have recently been reported by other workers.[5,6] Our structural refinement‡ reveals the interposition of chiral bilayers of opposite handedness to form a tongue-and-groove type structure (as represented schematically in the inset of Fig. 1). The bilayers, which take the form of the 8^210 network,[7] result from the T-shaped coordination about nickel of three bpy units (Fig. 1). The pseudo-square-pyramidal nickel coordination is completed by two nitrate groups. Of the two crystallographically distinct bpy units, one links the nickel centres to form parallel chains in the *ab* plane and the other links neighbouring layers of chains along *z*. Although the layered array of coordinate bonds between Ni and bpy suggests two-dimensional interactions, closer inspection of the structure reveals C–H···O hydrogen bonds between the nitrate anions bound directly to the metal and the bpy groups of every second bilayer (Fig. 1). This interlayer interaction acts together with the Ni–bpy coordinate bonds within the bilayer to impart a three-dimensional character to the structure, which may be considered as the interpenetration of two semi-regular $6^4(6,10)^1$-type 3-D networks.[7]

The interlocking of the bilayers produces channels of dimensions 6 by 3 Å parallel to *a* which are occupied in the as-grown material by ethanol. The ethanol molecule forms a single hydrogen bond to one of four neighbouring nitrate groups coordinated to nickel. These guests are liberated slowly at room temperature (50% of the ethanol is lost within 1 h at 25 °C under dry N_2). Complete and rapid guest desorption occurs with heating to 100 °C, beyond which the empty framework material $Ni(bpy)_{3/2}(NO_3)_2$ **B** is stable to 230 °C. The desolvated phase has been shown to have microporosity by N_2 sorption measurements[5] and will take up H_2O at room temperature, with other guests including MeOH, EtOH and Pr^iOH.

The structural consequences of desorption were studied by single crystal X-ray diffraction. The evolution of the unit cell on desorption is shown in Fig. 2, as measured *in situ* by heating a crystal at 20 K h^{-1} under dry dinitrogen. With complete desolvation of the lattice at 375 K there is a 2.4% decrease in cell volume. The robust nature of the framework is reflected in the retention of similar mosaicity of the crystal upon desolvation, allowing structural refinement of the empty co-ordination polymer framework. The refined structure and flat nature of the final difference Fourier maps demonstrate that empty channels, of dimensions 6 × 3 Å, are retained on desolvation (Fig. 3). Guest loss does not involve symmetry change or channel volume collapse, unlike the extended hydrogen bonded network of $[Co(H_2O)_6]H_2(TC\text{-}TTF){\cdot}2H_2O$.[8] Quantitative assessment of

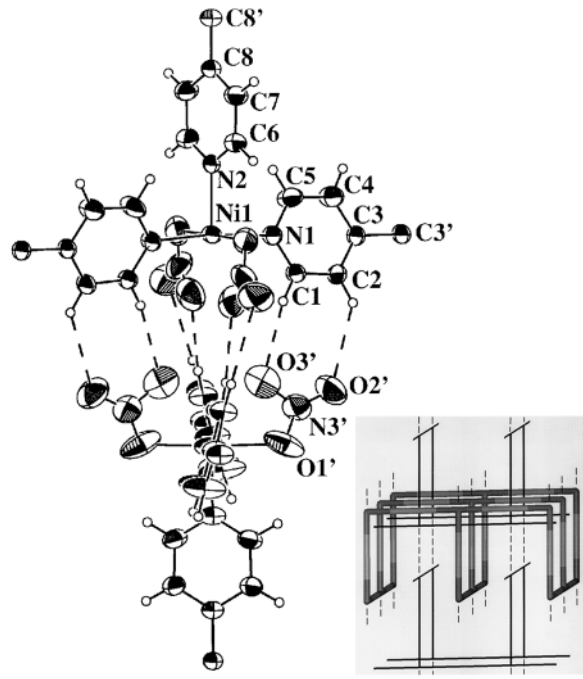

Fig. 1 The structural motif of **A** and **B**, showing labelling of all atoms in the asymmetric unit of the empty molecular framework **B** at 375 K (30% probability thermal ellipsoids). The T-shaped coordination of 4,4′-bpy about Ni gives rise to the formation of interlocking two-dimensional bilayers, as represented diagramatically in the inset. For clarity one of the interlocking bilayers is highlighted. The chains represent linear Ni(bpy) strands in the *ab* plane connected into bilayers of chains at different heights along *c* by bpy groups. The torsion angle between the two sets of chains in a bilayer relaxes upon guest loss as described in the text. Multiple hydrogen bonding interactions impart a 3D nature to the framework structure (C1···O3′ 3.536(7), H1···O3′ 2.35, C2···O2′ 3.412(7), H2···O2′ 2.76 Å). Each dashed line in the inset represents eight of the C–H···O interactions in the main figure.

the channel volume[9] reveals that it is almost unchanged: the calculated ethanol-filled volume of **A** is 808.0 Å^3 per unit cell (20.6% of crystal volume) compared to a void volume of 793.8 Å^3 (20.1%) in **B**. Removal of the ethanol atoms from the refined structure followed by treatment of the data with the SQUEEZE routine[9] suggested a cavity electron population of 24.6 e$^-$ per formula unit in **A**, agreeing well with 26 e$^-$ for one ethanol molecule. Similar analysis of the data from **B** yields a cavity population of only 0.8 e$^-$ per formula unit, demonstrating there is no significant ordered or disordered electron density in the channels. The average shift in framework atomic positions with desorption is 0.06 Å, and the observed Ni–bpy distances remain unchanged within error, as found for the T–O distances in hydrated and dehydrated Cu zeolite Y.[10] The main structural relaxation of the framework is a subtle scissor-like action of the bilayers, leading to a decrease in the bilayer torsion angle (defined in Fig. 1) from 65.5 to 63.9°. This small distortion accompanies a 2.3% decrease in *a* and a 0.9% increase in *b*. The multitude of hydrogen bonding interactions between bilayers imparts stability to the structure in the *z* direction, as evidenced by the small decrease in *c* of 1.0%.

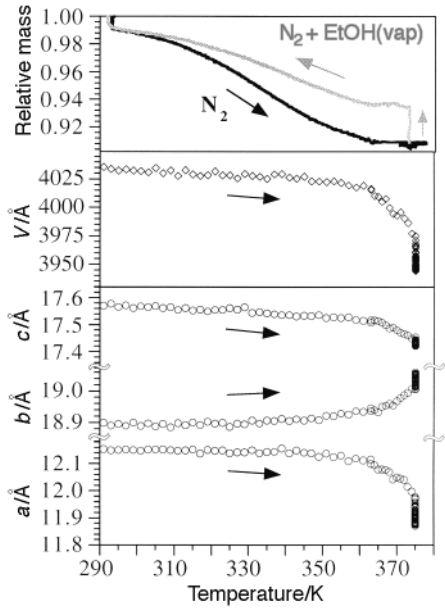

Fig. 2 Evolution of the mass, orthorhombic unit cell volume (Å^3) and axial parameters (Å) during the desorption transition **A** → **B**, as measured by thermogravimetry and single crystal X-ray diffraction. The grey curve of the TGA plot is of the sorption transition **B** → **A**, performed by cooling **B** under 5 Pa partial pressure of EtOH vapour in a stream of dry N_2.

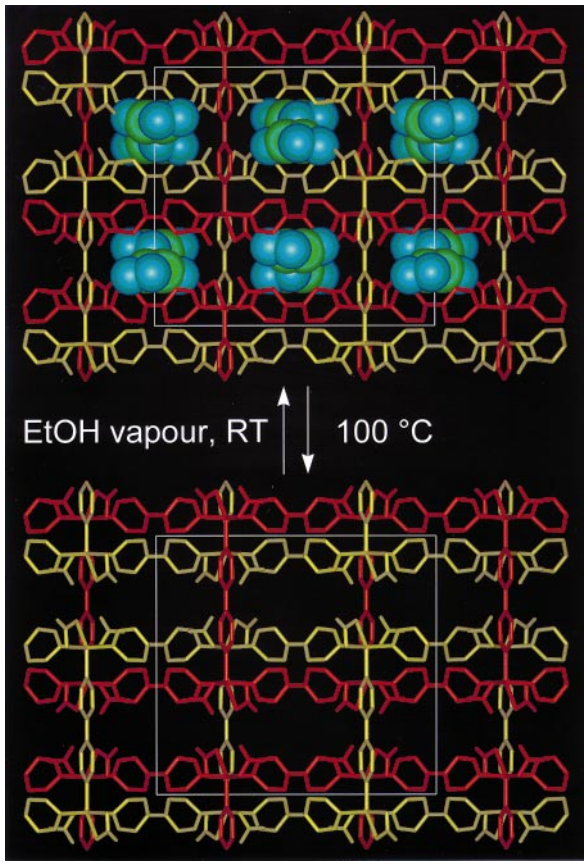

Fig. 3 Structural projections down the *a*-axis, drawn to scale, showing the complete removal of disordered ethanol molecules from **A** to form **B**. The desolvated structure, **B**, contains empty one-dimensional channels running along the *x* direction which occupy 20% of the crystal volume and have dimensions 6 × 3 Å. Adjacent bilayers are shown in yellow and red, with the C and disordered O atoms of the guest as green and blue spheres.

The present structure refinements represent the first definitive demonstration of the retention of structural integrity of a coordination polymer framework upon complete desolvation, confirming the analogy with zeolites suggested by sorption and powder diffraction measurements.

$[NHMe_3][Cu(CS_4)]$: a two-dimensional network involving an unprecedented μ_3-η^1:η^1:η^2 coordination mode of perthiocarbonate to copper(I)

Guo-Cong Guo and Thomas C. W. Mak*

Received (in Cambridge, UK) 11th December 1998, Accepted 21st December 1998

The new complex $[NHMe_3][Cu(CS_4)]$, which was obtained by solvothermal synthesis, contains a two-dimensional $^2{}_\infty[Cu(CS_4)^-]$ network consolidated by an unprecedented μ_3-η^1:η^1:η^2 coordination mode of the perthiocarbonate dianion.

The reaction of transition metal chelate polysulfides with carbon disulfide to form metal perthiocarbonates was first reported by Coucouvanis and Draganjac in 1982,[1] and up to now the few known examples in the literature include $[Ni(CS_4)_2]^{2-}$,[2] $[MoS(CS_4)_2]^{2-}$,[1,3] $[(CS_4)Mo_2S_4(CS_4)]^{2-}$,[1,3] $[(CS_4)Mo_2O_2S_2(CS_4)]^{2-}$,[3] $[Mn(CO)_3(CS_4)]_2^{2-}$,[4] $[Mn(CS_4)_2Cl]^{3-}$ [5] and $[Zn(CS_4)\{Me_2NCH_2CH_2N(Me)CH_2CH_2NMe_2\}]$.[6] These compounds are now generally synthesized by (i) the reaction of metal polysulfides with CS_2,[1,2b,3–6] (ii) the reaction of metal salts with K_2CS_4, [2a] or (iii) the oxidation of metal thiocarbonates with iodine or sulfur.[2a] Recently we employed the hydro(solvo)thermal technique to synthesize transition metal polychalcogenides using K_2E_n (E = S, Se and Te; n = 2–6) as mineralizers,[7] and herein we report the crystal structure of $[NHMe_3][Cu(CS_4)]$,† which was obtained in an analogous way.

The common coordination mode of the perthiocarbonate anion to a metal ion is bidentate, forming a nearly planar five-membered chelate ring [Fig. 1(a)], except for $[Mn(CO)_3(CS_4)]_2^{2-}$ in which each CS_4^{2-} ligand chelates to one Mn atom to form a planar five-membered ring with its perthio sulfur atom further coordinated to the other Mn atom to generate a discrete dimeric anion [Fig. 1(b)]. Single-crystal X-ray analysis has shown that the perthiocarbonate ligand in the present $[NHMe_3][Cu(CS_4)]$ complex exhibits an unprecedented μ_3-η^1:η^1:η^2 coordination mode, which bridges adjacent copper ions along the [−1 1 1] and [−1 1 −1] directions to form a two-dimensional network (Fig. 2).‡ To our knowledge, hitherto in all known metal perthiocarbonates only two terminal sulfur atoms of the CS_4^{2-} ligand bond to metal atom(s), but in $[NHMe_3][Cu(CS_4)]$ the third terminal sulfur atom has been found to be involved in metal coordination for the first time.

The anionic network $^2{}_\infty[Cu(CS_4)^-]$ can be regarded as constructed from a basic building unit, namely the centrosymmetric $Cu_2(CS_4)_2$ dimer as illustrated in Fig. 1(b). The unit cell contains two crystallographically independent dimers, which cross-link each other through interaction between the non-chelating, third terminal sulfur atom of each CS_4^{2-} ligand and an adjacent copper atom to form a puckered network as shown in Fig. 2. The network has two non-equivalent, though similar, irregular polygonal openings with wall-to-wall interatomic distances ranging from 5.4 to 10.3 Å. The crystal structure of $[NHMe_3][Cu(CS_4)]$ consists of a parallel stacking of these two-dimensional networks, with an interlayer separation of 7.83 Å, to form channels running along the [1 0 0] direction, in each of which the ordered $NHMe_3^+$ cations are arranged in a zigzag column (see corresponding figure in the Table of Contents).

Each copper atom exhibits distorted tetrahedral coordination geometry, with Cu–S bond distances in the range 2.265(1)–2.4517(9) Å that vary according to the coordination mode of the sulfur atom: S (chelate) < S (bridging) < perthio S (chelate) < perthio S (bridging). There are two kinds of nearly planar rings in the $Cu_2(CS_4)_2$ dimer, namely five-membered $CuSCS_2$ and four-membered Cu_2S_2, which make a dihedral angle of 71.2°. In β-$[Cu(S_4)]_n^{n-}$ the basic construction unit that generates a chain-like structure, namely a $Cu_2(S_4)_2$ dimer,[8] is structurally analogous to the present $Cu_2(CS_4)_2$ dimer but, unlike the CS_4^{2-} ligand, the S_4^{2-} ligand symmetrically chelates the copper atom

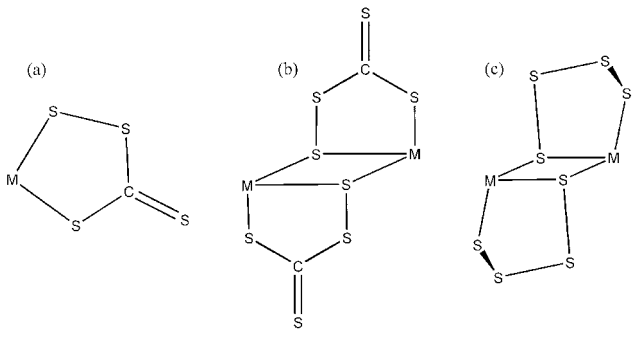

Fig. 1 Coordination modes of the perthiocarbonate dianion.

to form a puckered five-membered ring [Fig. 1(c)]. Obviously, the principal difference between the CS_4^{2-} and S_4^{2-} ligands is that the *exo* sulfur atom of a chelating CS_4^{2-} ligand is capable of binding to another metal atom, as found in the present $[Cu(CS_4)]^-$ anion. The average non-bonded Cu···Cu distance in $[NHMe_3][Cu(CS_4)]$ is 0.16 Å longer than that found in β-$[Cu(S_4)]_n^{n-}$.[8]

The CS_4^{2-} ligand in the title compound exhibits electron delocalization similar to that found in $[Mn(CS_4)_2Cl]^{3-}$,[5] $[Ni(CS_4)_2]^{2-}$ [2b] and one of the two non-equivalent anions in $K_2CS_4{\cdot}MeOH$.[9] The S–S bond distances in both delocalized and localized CS_4^{2-} ligands in transition metal complexes, with the possible exception of $[Mo_2(S)_2(\mu\text{-}S)_2(CS_4)_2]^{2-}$,[1,3] are all longer than those found in $K_2CS_4{\cdot}MeOH$; this is attributable to M–S π bonding within the MCS_3 ring that results in weakening of the S–S bond, as is the case commonly found in metal complexes containing a chelating S_4^{2-} ligand.[10] Generally, polychalcogeno complexes of d^2 and d^8 metals show a pronounced E–E bond alternation pattern within the ME_4 (E = S, Se and Te) ring whereas d^{10} metal complexes do not. Thus lengthening of the S–S bond distance in $[NHMe_3][Cu(CS_4)]$, as compared to those in $K_2CS_4{\cdot}MeOH$,[9] is consistent with additional binding of the perthio sulfur atom to the copper center. A similar case was found in $[Mn(CO)_3(CS_4)]_2^{2-}$ [4] in which the S–S bond distance is longer than that in $[Mn(CS_4)_2Cl]^{3-}$.[5]

Recently it has been pointed out that the formation of carbon–heteroatom bonds in amines, ethers and sulfides by reductive elimination can be incorporated into a number of catalytic processes,[11] and interesting speculations as to the possible significance of C–S forming processes in the biosynthesis of metalloenzymes have been proposed.[12] The identity of the perthiocarbonate dianion in the title compound is firmly established, as the measured C–S distances are in good agreement with those of known perthiocarbonate complexes. However, the formation of C–S bonds to yield CS_4^{2-} in the synthesis of $[NHMe_3][Cu(CS_4)]$ is presumably much more complex under hydrothermal conditions, causing partial degradation of the tetramethylammonium ion to yield the trimethylammonium ion while providing the source of carbon. In this context it is noted that in $[Mn(CO)_3(CS_4)]_2^{2-}$, the carbon atom of the CS_4^{2-} ligand arises from a carbonyl group in the reaction between $[(CO)_5MnMn(CO)_4Br]^-$ and S_8 in 4-methylpentan-2-one and not from the solvent.[4]

† *Synthesis*: $[NHMe_3][Cu(CS_4)]$ was prepared by reacting CuCl (37.1 mg, 0.375 mmol), K_2S_4 [7a] (232.0 mg, 1.125 mmol), NMe_4Br (115.4 mg, 0.75 mmol), and 0.4 mL EtOH in a Pyrex ampoule of *ca.* 7 mL capacity. The ampoule was flame-sealed under vacuum, heated in a furnace to 100 °C for 144 h, and then cooled to 60 °C at 6 °C h^{-1}. Dark red prismatic crystals were isolated and washed with ethanol (estimated yield *ca.*10 %). The crystals are air-stable and insoluble in water and most organic solvents.

‡ *Crystal data*: $[NHMe_3][Cu(CS_4)]$, $C_4H_{10}CuNS_4$, M = 263.91, triclinic, space group $P\bar{1}$ (no. 2), a = 9.254(1), b = 10.737(1), c = 10.887(1) Å, α = 78.62(1), β = 74.18(1), γ = 68.22(1)°, U = 960.9(2) Å^3, T = 293 K, Z = 4, D_c = 1.824 g cm^{-3}, $F(000)$ = 536, μ(Mo-Kα) = 30.72 cm^{-1}, absorption corrections applied using ABSCOR,[13] relative transmission factors in the range 0.936–1.0. A total of 3210 reflections were collected in the 2θ range 4.0–53.5° ($-11 \leqslant h \leqslant 10$, $-13 \leqslant k \leqslant 0$, $-13 \leqslant l \leqslant 13$), 3095 of which with $I > 2\sigma(I)$ were considered as observed. The structure was solved by direct methods and the $NHMe_3^+$ and CS_4^{2-} ions, which exhibit normal molecular dimensions, were readily identified. Anisotropic refinement of all non-hydrogen atoms was carried out by full-matrix least squares on F^2 using the Siemens SHELXTL (PC Version)[14] package of crystallographic software, 181 variables, $R1 = \Sigma\,||Fo| - |F_c||/\Sigma\,|F_o| = 0.0436$, $wR2 = \{\Sigma\,[w(F_o^2 - F_c^2)^2]/\Sigma\,[w(F_o^2)^2]\}^{1/2} = 0.1146$, GOF = 1.119, min., max. residual electron density +0.522, −0.754 e Å^{-3}. Received (in Basel, Switzerland) 2nd December 1998, Accepted 20th January 1999

The structure of the dipotassium complex of the dianion of *p-tert*-butylcalix[8]arene crystallised from a protogenic, coordinating solvent (ethanol–diethylcarbonate, 10 : 1) shows that the metal ions are bound above and below the cavity of the calix[8]arene, which adopts a 'pinched' conformation.

The binding of metal ions to the calixarenes and their O-pendant derivatives is an area of intense research interest, in particular with regard to selective metal ion coordination and transport.[1] The discovery that the parent calixarenes effect the transport of Group 1 metal ions in [water | organic solvent | water] liquid membrane systems stimulated great interest in this family of compounds.[2] Recent research has concentrated on metal ion binding to O-pendant derivatives of the calixarenes (mostly calix[4]arenes in which the pendant groups are generally predominant in the metal ion binding and the calixarene is used in a preorganising role), and a great deal of X-ray crystallographic structural information has been accumulated for these systems.[1] In contrast, there is a paucity of structural data for Group 1 metal ion complexes of the parent calixarenes; the only reported structures are the Cs^+ complex of the mono-anion of *p-tert*-calix[4]arene (H_4L), $Cs(H_3L)(MeCN)$, which beautifully illustrates the importance of $\pi\cdots M^+$ interactions in these systems,[3] and two Li^+ complexes of fully deprotonated *p-tert*-butylcalix[4]arene: $Li_5L(OH)(hmpa)_4$ and $Li_8L_2(hmpa)_4$ (hmpa = hexamethylphosphoramide).[4] It has been proposed that the larger calix[*n*]arenes ($n \geqslant 6$) are able to bind and transport more than one metal ion at a time, and that this may be a result of their ability to adopt 'pinched' conformations.[5] However, as yet there are no crystal structures that detail the conformation of a larger calixarene upon binding to the Group 1 metal ions, the number of metal ions that may bind, the site(s) of metal ion binding, the effects of metal ion binding upon the pattern of hydrogen-bonding within the calixarene cavity or the number and disposition of other ligands bound to the metal ions (presumably water in the ion transport systems).

In this context, we herein report the preparation and crystal structure of the dipotassium complex of the dianion of *p-tert*-butylcalix[8]arene (H_8L'). The reaction of H_8L' (0.5 mmol) with 8 equiv. of KOH or $KOBu^t$ in ethanol–diethylcarbonate (10 : 1, 100 cm^3) under a dry atmosphere yielded colourless crystals of the dipotassium salt $K_2(H_6L')(EtOH)_{4.67}\{(EtO)_2CO\}_{1.33}$ **1** upon standing for 72 h. The same product was also isolated when ethanol–dimethylcarbonate (10 : 1) was used as solvent, indicating alcohol exchange of the dialkylcarbonate under these conditions.

The molecular structure of **1** is shown in Fig. 1. The molecule of **1** lies on a crystallographic inversion centre with the K^+ ions lying above and below the cavity of the calix[8]arene and a K(1)···K(1a) distance of 4.424(2) Å. The K^+ ion is six coordinate with a distorted octahedral geometry comprising three calix[8]arene ArOH ligands in a *fac* arrangement and two ethanol ligands, and is completed by a diethylcarbonate or ethanol ligand with occupancies of 0.66 and 0.34, respectively. The calix[8]arene is doubly deprotonated and adopts a 'pinched' conformation with two ArOH groups bridging the K^+ ions at the 'pinch' (Fig. 2). There are structurally characterised precedents for the doubly bridged $K_2(\mu\text{-OAr})_2$ moiety with the deprotonated acidic phenols 2,4,6-$(CF_3)_3C_6H_2OH$ and 2,4,6-$(NO_2)_3C_6H_2OH$.[6,7] However, in **1** the bridging phenol ligands remain protonated; the free refinement of the three unique calix[8]arene ArOH protons indicates that the formally deprotonated phenol, O(3), is furthest from the K^+ ions and all three calix[8]arene ArOH protons are involved in strong intra-calix[8]arene hydrogen-bonding. There is an additional hydrogen-bond between O(3) and one of the ethanol ligands (Fig. 2), and presumably the overall hydrogen-bonding arrangement favours the observed deprotonation of O(3). The presence of protons on the bridging phenol ligands is also consistent with their greater K–O bond distances (av. 2.92 Å) compared with the terminal ligands (av. 2.73 Å) and the reported examples of the $K_2(\mu\text{-OAr})_2$ moiety (av. 2.76 Å).

The isolation of a neutral, molecular, dipotassium complex from this protogenic, coordinating solvent medium is consistent with the ion transport properties of *p-tert*-butylcalix[8]arene. It is probable that the calix[8]arene complex responsible for K^+

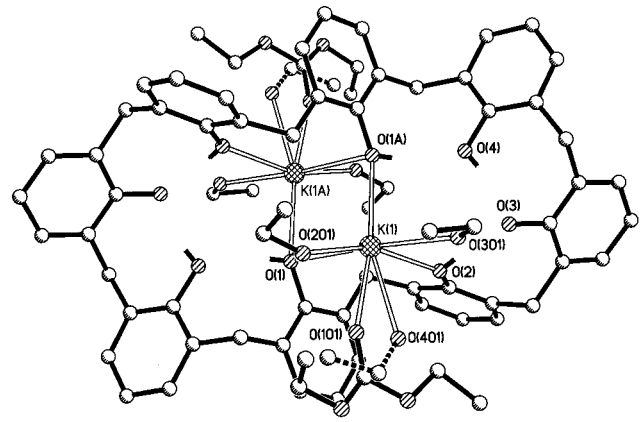

Fig. 1 Molecular structure of **1**. For clarity *tert*-butyl groups and C–H hydrogens have been omitted. Selected bond lengths (Å) and angles (°): K(1)–O(1) 2.949(2), K(1)–O(1a) 2.8963(19), K(1)–O(2) 2.7205(19), K(1)–O(101) 2.825(4), K(1)–O(201) 2.616(4), K(1)–O(301) 2.726(3); K(1)–O(401) 2.780(12); K(1)–O(1)–K(1a) 98.37(5), O(1)–K(1)–O(1a) 81.63(6), O(1)–K(1)–O(2) 97.28(6), O(1)–K(1)–O(301) 172.32(7), O(1a)–K(1)–O(101) 169.01(11), O(1a)–K(1)–O(401) 163.4(1), O(2)–K(1)–O(201) 160.68(11): symmetry operation; *a*, $-x$, $2-y$, $2-z$.

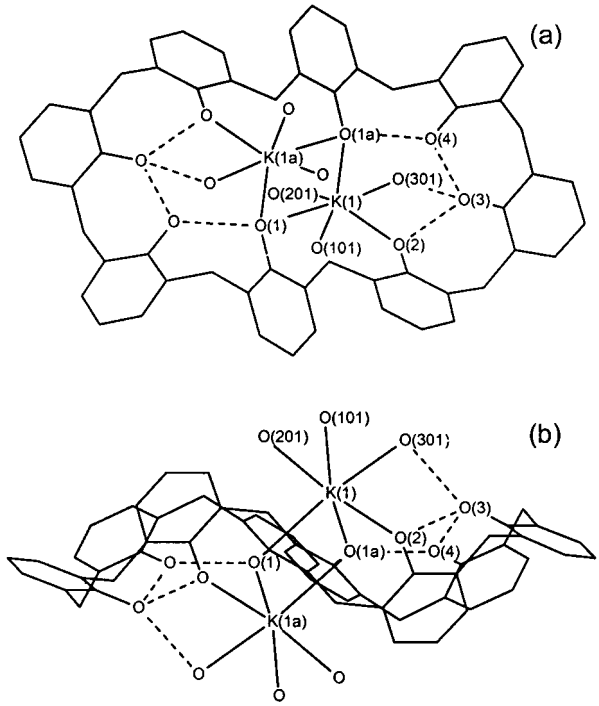

Fig. 2 Schematic representations of **1** showing the arrangement of hydrogen-bonds (O···O): (*a*) from above, (*b*) edge on. The *p*-*tert*-butyl groups are omitted for clarity and only the coordinated oxygen atom, O(101), of the partial occupancy diethylcarbonate ligand is shown. Hydrogen-bonds: O(1a)···O(4) 2.627(3), O(2)···O(3) 2.508(3), O(3)···O(4) 2.486(2), O(3)···O(301) 2.673(3), O(101)···O(201) 2.523(7) Å. (There are no other O···O interactions < 3.1 Å.)

ion transport in [water | organic solvent | water] liquid membrane systems is similar to **1** but with the ethanol and diethylcarbonate ligands replaced by water molecules. In this regard it is noteworthy that by comparison with the disposition of the ethanol molecules in **1**, these water molecules would be involved in intramolecular hydrogen-bonding to at least one of the ArOH groups of the calixarene cavity and probably also to each other, thus minimising unfavourable interactions with the organic solvent during ion transport.

Received (in Basel, Switzerland) 23rd November 1998, Accepted 16th January 1999

Proton transfer reactions between both nucleophilic sites of a dihydrido iridium complex containing the 4-*N*-methylpiperidylcyclopentadienyl ligand and their dependance with the hydrogen bonding ability of the solvent medium are studied by NMR.

Proton transfer reactions in organometallic and bioinorganic chemistry are of fundamental interest and recent reviews deal with their thermodynamic, kinetic or mechanistic aspects.[1,2] In this context, considerable attention has been focussed on the protonation or deprotonation of transition metal hydrides and on the role of dihydrogen and hydrogen-bonded complexes as possible intermediates. It is widely recognized that hydrogen bonding, in its conventional aspect,[3,4] plays a fundamental role on proton transfer reactions.[5] It may also be supposed to play a decisive role in its non-conventional aspect, *i.e.* as a weak intramolecular hydrogen–hydrogen attractive interaction between a conventional hydrogen-bond donor and a transition metal hydride.[6]

The nucleophilic character of the iridium dihydride complex [(η⁵-C_5H_5)Ir(PR_3)H_2] has been used during the past few years to prepare new cationic polyhydrides displaying in ^{1}H NMR quantum mechanical exchange couplings.[7] The recent synthesis of a piperidino-substituted cyclopentadienyl ligand[8,9] gives the opportunity to prepare an iridium dihydride containing a second nucleophilic site and convenient to study both the possibility of hydrogen bonding and the dynamics of proton transfer.

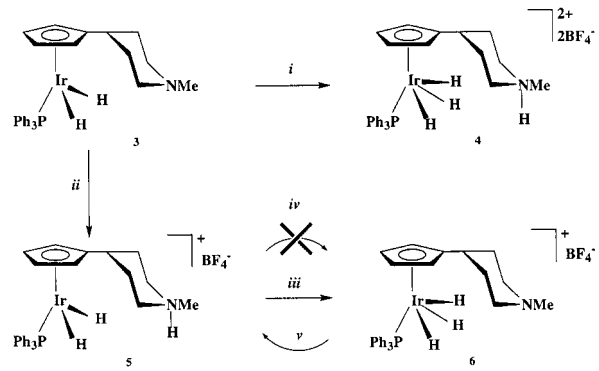
The new dihydrido iridium complex [(η⁵-C_5H_4pip)Ir(PPh_3)H_2] **3**, [pip = *N*-methylpiperidyl, $CH(CH_2)_4NMe$] has been prepared by usual methods starting from the salt Na(C_5H_4pip) recently described, and involving the intermediate preparation of the bis(ethylene) and diiodide iridium complexes [(η⁵-C_5H_4pip)Ir(C_2H_4)$_2$] **1** and [(η⁵-C_5H_4pip)Ir(PPh_3)I_2] **2**.

For the three complexes, **1**–**3**, the ^{1}H NMR spectra show respectively AA′BB′ (**1**) or AA′BB′X (**2** and **3**) patterns in the range δ 4.50–5.50 for the Cp protons, a sharp resonance at δ *ca.* 2.2 for the methyl group linked to nitrogen and second order signals in the range δ 1.2–3.0 for piperidyl ring protons. Electron saturation in **1**–**3** rules out the coordination of the piperidyl nitrogen to the metal as in the parent rhodium complex [(η⁵-C_5H_4pip)Rh(C_8H_{14})$_2$].[8]

The equivalent hydrides of **3** resonate at δ −17.52 (CD_2Cl_2, 293 K, J_{PH} 30.2 Hz) in the ^{1}H NMR and the ν_{Ir-H} vibrations appear at 2128 cm^{-1} in the IR spectrum (KBr pellet), in the terminal Ir–H region. Protonation of **3** was first carried out in the presence of 2 equiv. of $HBF_4{\cdot}Et_2O$. The reaction leads to the expected dicationic species **4** resulting from the protonation of both amino and metal dihydrido nucleophilic sites as shown in Scheme 1.

The formation of an ammonium group is revealed (^{1}H NMR) by the appearance of a new broad signal in the low-field region at δ 8.75 (CD_2Cl_2, 293 K), and by a down-field shift of the methyl resonance of the methylpiperidyl group which appears in **4** as a doublet centered at δ 2.92 ($^3J_{HH}$ 4.2 Hz). The IR spectrum exhibits new absorption bands at 2950 cm^{-1} attributed to the ν_{N-H} vibration of the ammonium group and in the ν_{Ir-H} region at 2029 cm^{-1} (KBr pellet). In the ^{31}P{^{1}H} NMR spectrum, the diprotonation of **3** is accompanied by an up-field shift of the phosphorus nucleus of the PPh_3 ligand, from δ 13.25 for the starting material to δ 7.20 for the diprotonated product **4**. The high-field ^{1}H NMR spectrum exhibits, at room temperature, a new doublet centered at δ −12.26 (CD_2Cl_2, J_{P-H} 6.6 Hz). As in the case of the cyclopentadienyl parent iridium cations [(η⁵-C_5H_5)Ir(PR_3)H_3^+],[7] this signal is highly temperature dependent and decoalesces (≈ 11.7 kcal mol^{-1}) at lower temperature into an AB_2X spin system (δ_A −12.73, δ_B −11.55) displaying large temperature dependent $J_{H_A-H_B}$ coupling constants *i.e.* 278 Hz at 183 K and 446 Hz at 203 K, attributed to quantum mechanical exchange couplings.

Acidification at room temperature of **3** in CH_2Cl_2 with slightly less than 1 equiv. of $HBF_4{\cdot}Et_2O$ gave the trihydride monocation **6** (Scheme 1) in which only the iridium hydride was protonated. This complex differs from the diprotonated product **4** mainly in that it exhibits neither the typical ammonium resonance in the low-field region of the ^{1}H NMR nor the ν_{N-H} vibration in the IR. The other spectroscopic data are somewhat similar to those observed for **4**. Typically, the ^{31}P{^{1}H} NMR spectrum exhibits a singlet at δ 7.80 (CD_2Cl_2). The ^{1}H NMR spectrum in the high-field region exhibits a broad resonance centered at δ −12,36 which decoalesces by decreasing the temperature into typical resonances for a AB_2 spin system (^{1}H{^{31}P}) characterized, as previously observed for the diprotonated derivative, by large and highly temperature dependant $J_{H_a-H_b}$ coupling constants, *i.e.* 295 Hz at 183 K, 368 Hz at 193 K, 464 Hz at 203 K and 634 Hz at 213 K. These coupling constants are slightly larger than those measured for the dication **4** at similar temperatures. According to recent observations,[10] this could suggest some degree of hydrogen-bonding interaction between the hydride ligands and the piperidyl nitrogen lone pair. This Ir(H)$_3$···N≡hydrogen-bonding interaction could also rationalize, (i) the observation in complex **6** of a slightly higher



Scheme 1 Summary of the reactions run in the NMR tube; i, $HBF_4{\cdot}Et_2O$ (2 equiv.), CD_2Cl_2, 293 K; ii, $HBF_4{\cdot}Et_2O$ (1 equiv.), CD_2Cl_2, 193 K; iii, 293 K; iv, in presence of THF or PPh_3O (10%), 293 K; v, addition of THF, 293 K.

energy barrier for the classical site to site proton exchange in the $[Ir(H)_3^+]$ group than in complex **4** and (ii) the low-field shift of the methyl resonance of the methylpiperidyl group which appears at δ 2.80 in **6** (instead of δ 2.20 and 2.92, respectively, observed for the starting material and complex **4**), although the added proton is clearly coordinated to the iridium atom.

^{1}H NMR monitoring demonstrates that the initial step of the protonation of **3** at 183 K with 1 equiv. of $HBF_4{\cdot}Et_2O$ consists in the quantitative formation of a piperidinium group observed at δ 12.3 (br) the dihydrido iridium part of the molecule being unchanged. The methyl resonance, which appears at δ 2.91 is downfield shifted, whereas the characteristic signals of the cyclopentadienyl protons and of the hydrido ligands are very similar to those observed for **3** *i.e.* two multiplets at δ 5.02 and 4.85 for the cyclopentadienyl protons and a broad doublet at δ −17.56 (J_{HP} 29.6 Hz) for the hydrides. When the reaction mixture is quickly warmed up to room temperature over a few minutes and then cooled again at 183 K, it is possible to follow by ^{1}H NMR the disappearance of the broad piperidinium resonance at δ 12.3 and of the hydride resonance at δ −17.56 and the growth of the characteristic signals of the trihydrido monocation **6**. The migration of the added proton from the piperidyl to the iridium dihydrido groups is not reversible.

When the protonation of **3** by 1 equiv. of $HBF_4{\cdot}Et_2O$ is carried out in presence of THF in the ratio THF/CD_2Cl_2 = 10/90, the initial step remains the protonation of the piperidyl group to give **5** but the migration of the added proton to give **6** is not observed. However, instead of proton transfer, ^{1}H NMR studies at various temperatures and various concentrations reveal an interesting intramolecular proton exchange process between the piperidyl amino group and iridium (Fig. 1). The coalescence was reached at 293 K (200 MHz) and ΔG^* at coalescence temperature of this purely kinetic phenomenon can be estimated[11] at 12 kcal mol^{-1}.

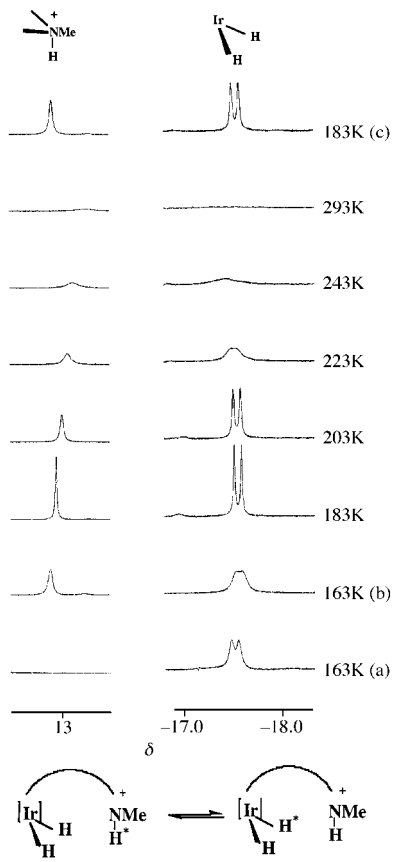


Fig. 1 Temperature dependance of the ^{1}H NMR spectra (CD_2Cl_2, 400 MHz), in the high- and low-field regions, in the presence of THF, (a) of the starting material **3** at 163 K, (b) after addition of 1 equiv. of $HBF_4{\cdot}Et_2O$ at 163 K, (c) after increasing progressively the temperature from 163 to 293 K and then cooling to 183 K.

This indicates a thermodynamic stabilization of the dihydrido piperidinium form **6** for the monoprotonated product which probably involves a weak hydrogen-bonding interaction between oxygen lone-pair of THF and the piperidinium proton. Furthermore, the observation of proton exchange with a low activation energy, involves a spatial proximity of both nucleophilic sites. This proximity could be explained by the existence of non-conventional intramolecular Ir–H···H–N hydrogen bonds such as those recently described by the groups of Crabtree[12,13] and Morris.[14]

As complementary experimental facts, it is of interest (i) that the addition of few drops of THF to a CD_2Cl_2 solution of the trihydrido cation **6** causes the immediate and total reverse transfer of the proton from the iridium hydride to the piperidyl sites to give **5** which experiences the low barrier exchange process described above and (ii) that the addition of $OPPh_3$, a weak base having a great capacity for formation of hydrogen bond,[15] to **6** causes again the total reverse transfer of the proton but the piperidinium species so obtained was stabilized to such an extent that the exchange of proton was not observed in the experimental conditions used.

In conclusion, we describe the synthesis of a new series of piperidylcyclopentadienyl iridium hydride complexes. We demonstrate that the kinetic site of protonation is the amino group of the piperidyl moiety whereas the thermodynamic one is dependent on the intermolecular hydrogen bonds present in the medium. In the absence of hydrogen bonding to solvent, the product of protonation at Ir is the thermodynamically stable one. The products of protonation at Ir and at N have similar stability in THF which allows the observation of an intramolecular proton transfer process and the product of protonation at N is the most stable in the presence of $OPPh_3$ owing to the formation of strong hydrogen bonds. This therefore further demonstrates the importance of hydrogen bonding for controlling the reactivity of hydrido organometallic complexes.

We are grateful to the CNRS for financial support of this work and to Johnson Matthey for a loan of ammonium chloroiridate. We thank Francis Lacassin for the NMR experiments.

Halide enhancement of the luminescence of $Cd_{10}S_4$ thiolate clusters

Richard D. Adams,* Bin Zhang, Catherine J. Murphy* and Lee K. Yeung

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, USA.
E-mail: Adams@psc.sc.edu; Murphy@psc.sc.edu

Received (in Bloomington, IN, USA) 3rd December 1998, Accepted 13th January 1999

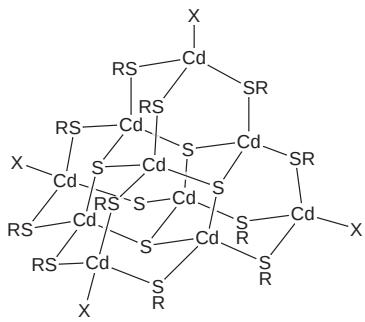
New halide-substituted cluster anions $[Cd_{10}S_4X_4(SR)_{12}]^{4-}$ (R = Ph, X = I, 2a; R = *p*-MeC_6H_4, X = I, 3a or Br, 3b) of the $[Cd_{10}S_4(SR)_{16}]^{4-}$ family have been prepared and characterized; investigations of their luminescence show that the introduction of the halide groups produces red shifts and significant enhancements in their emission intensities.

Semiconductor quantum dots are colloidal semiconductor particles, *ca.* 10–200 Å in diameter, that exhibit interesting optoelectronic properties due to quantum confinement of photogenerated electron–hole pairs.[1] Synthetic challenges in the field include narrowing the size distribution of the particles, and effective capping of surface atoms. A 'bottom-up' approach to the synthesis of well defined quantum dots begins with molecular clusters based on a semiconductor core.[1a] For CdS, one of the most studied quantum dot materials, molecular clusters having 10, 17 and 32 cadmium atoms in the core have been synthesized.[2] Here, we report the synthesis, crystallographic and spectroscopic characterization of new halide substituted molecular clusters derived from the $Cd_{10}S_4(SR)_{12}$ core. The halide ligands profoundly affect the spectral distribution and intensity of the observed photoluminescence relative to that of the parent cluster anion $[Cd_{10}S_4(SPh)_{16}]^{4-}$ **1**.

The new cluster anions $[Cd_{10}S_4X_4(SR)_{12}]^{4-}$ (R = Ph, X = I, **2a**; R = *p*-MeC_6H_4, X = I, **3a** or Br, **3b**) were synthesized by a modification of the procedure used for the synthesis of the parent $[Cd_{10}S_4(SPh)_{16}]^{4-}$.[2b]† The structures of **3a** and **3b** were determined crystallographically as their NEt_4 salts,‡ and an ORTEP diagram of **3b** is shown in Fig. 1. The cluster has S_4 symmetry and the $[Cd_{10}S_4(SR)_{12}]$ core of **3a** and **3b** is similar to those of the parent **1**.[2b]

The principal difference between **3a**,**b** and **1** is the presence of a terminally coordinated halide ligand on each of the four external cadmium atoms of the cluster.

The compounds are colorless to pale yellow, and the principal features in the UV–VIS spectra are intraligand bands at 250–300 nm.[3] The tetramethylammonium salt of the parent cluster **1** has been reported to show weak broad luminescence at *ca.* 530–550 nm in acetonitrile.[4] Under our conditions the parent cluster **1** emits broadly at *ca.* 430 nm. Interestingly, the halide clusters **2a, 3a** and **3b** show considerably more intense emission, readily visible to the naked eye under ultraviolet illumination, with apparent maxima at *ca.* 490 and 540 nm



R = Ph; X = SPh, **1** or I, **2a**
R = C_6H_4Me-*p*; X = I, **3a** or Br, **3b**

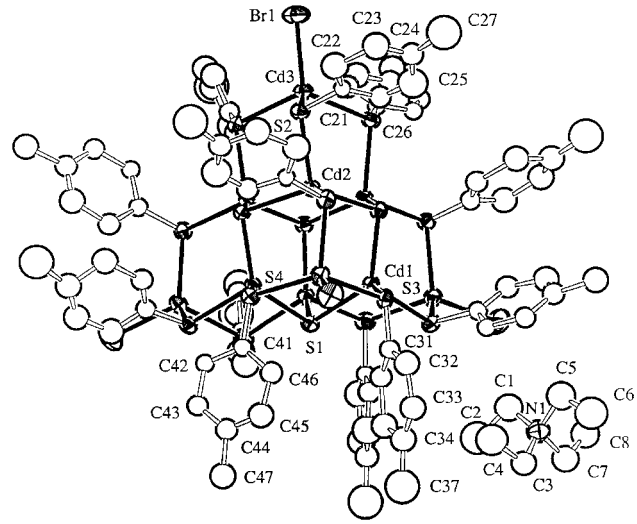


Fig. 1 An ORTEP diagram of the molecular structure of $[NEt_4]_4[Cd_{10}S_4(SC_6H_4Me\text{-}p)_{12}Br_4]$, **3b**.

(Fig. 2). For **3b**, emission spectra were also acquired on a single crystal taken from the diffractometer and was found to be identical to that taken in DMSO solution. For all compounds, the excitation spectra had maxima in the range 350–390 nm, lying in the absorption tail of the much more prominent intraligand bands.

The existence of multiple excited states, the domination of observed broad emission by a low-lying state with low oscillator strength, and the large Stokes shift have been documented in the case of a Cd_{32} cluster, and it was speculated that its *ca.* 500 nm emitting state was an intrinsic charge transfer state within the cluster.[2e] Calculations of the ground and excited states of the related Cd_4 cluster $[Cd_4(SPh)_{10}]^{2-}$ suggest that the lowest energy transition in this molecule is more localized, a

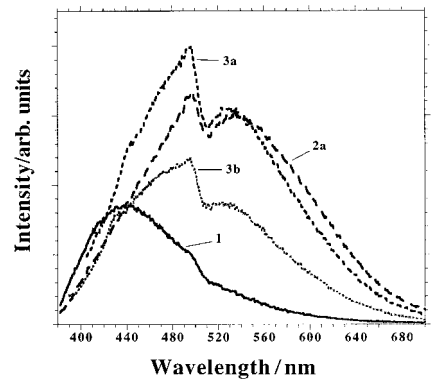

Fig. 2 Uncorrected emission spectra of 1.7×10^{-3} M **1**, 1.7×10^{-3} M **2a**, 1.6×10^{-3} M **3a** and 1.8×10^{-3} M **3b** in DMSO solution at room temperature. To ensure sample purity, single crystals of each compound, characterized by X-ray diffraction, were dissolved in DMSO and data was acquired within hours of dissolution. The excitation wavelengths employed were the maxima for each compound: 350 nm for **1**, 360 nm for **2a,** 380 nm for **3a** and 390 nm for **3b**. All other parameters were identical.

mixture of thiolate to Cd 5s ligand-to-metal charge transfer (LMCT) and intraligand charge transfer bands.[5] The sizes of Cd_{10} clusters reported here are in between these; time-resolved spectroscopy experiments are in progress to elucidate the details of the electronic structure of the halide–Cd_{10} clusters.§

Copper(I) halide clusters of the type $Cu_4X_4L_4$ also show complex emission spectra, and *ab initio* calculations have demonstrated that the two observed emissive states are likely halide-to-ligand charge transfer and 'cluster-centered' states; the cluster-centered states are a complex mixture of halide-to-metal charge transfer and metal-centered states.[6] For some of the compounds in this series, the emission spectra are insensitive to the nature of the halide, which was rationalized on the basis of competing trends in halogen electronegativities and ionization energies.[6] In these Cu_4 clusters, the electronic states of the halide are crucial to the photoluminescence of the cluster. Our results clearly demonstrate that halide ligands produce a strong enhancement in the intensity of photoluminescence from the excited states of our Cd_{10} clusters.

† *Synthesis* of $[NEt_4]_4[Cd_{10}S_4I_4(SC_6H_4Me\text{-}p)_{12}]\cdot 2H_2O$ **3a**: $Cd(NO_3)_2\cdot 4H_2O$ (0.767 g) in MeOH (15 mL) was added to a solution of *p*-thiocresol (0.943 g) and triethylamine (1.146 mL) in methanol (15 mL) at 25° C. Then NEt_4I (0.474 g) in MeOH (15 mL) was added. After all the precipitate had dissolved, the solvent was removed *in vacuo*. The residue was dissolved in acetonitrile (35 mL) and powdered sulfur (0.048 g) was added to the clear solution at 25 °C. This reaction was complete in < 2 min. Isolated yield (24% based on Cd). ^{113}Cd NMR (CD_3CN) δ 559.54 (6 Cd), 434.28 (4 Cd). Anal. Calc: C, 36.71; H, 4.46; N, 1.48. Found: C, 37.12; H, 3.90; N 1.70%. Compound **2a** was prepared similarly using benzenethiol in place of *p*-thiocresol. Compound **3b** was prepared similarly to **3a** by substituting NEt_4Br for NEt_4I. For **3b**: ^{113}Cd NMR (CD_3CN) δ 560.86 (6 Cd), 411.57 (4 Cd).

‡ The compounds $[NEt_4]_4[Cd_{10}S_4I_4(SC_6H_4Me\text{-}p)_{12}]\cdot 2H_2O$ **3a** and $[NEt_4]_4[Cd_{10}S_4Br_4(SC_6H_4CH_3)_{12}]$ **3b** both crystallize in the tetragonal crystal system: space group $P\bar{4}2_1c$. For **3a**: M = 3795.31, $a = b$ = 20.1542(8) Å, c = 18.7192(5) Å, Z = 2, 1545 reflections, R = 0.048, λ = 0.71069 Å, D_c = 1.61 g cm^{-3}, μ(Mo-Kα) = 23.71 cm^{-1}, T = 293 K. For **3b**: M = 3571.27, $a = b$ = 20.3321(6) Å, c = 18.9573(7) Å, Z = 2, 1524 reflections, R = 0.051, λ = 0.71069 Å, D_c = 1.56 g cm^{-3}, μ (Mo-Kα) = 26.84 cm^{-1}, T = 293 K. Anion **1** was also characterized crystallographically in the form of its NEt_3H salt: space group $P\bar{4}2_1c$. For $[NEt_3H][Cd_{10}S_4(SC_6H_5)_{16}]$, **1**: M = 3489.89, $a = b$ = 20.3001(3) Å, c = 18.0263(5) Å, Z = 2, 2084 reflections, R = 0.040, λ = 0.71069 Å, D_c = 1.56 g cm^{-3}, μ(Mo-Kα) = 17.27 cm^{-1}, T = 293 K. CCDC 182/1147.

§ The smallest CdS molecular cluster that has been reported to be emissive is $[Cd_4(SC_6H_4NO_2)_{10}]^{2-}$, which emits at 500 nm, albeit with a lifetime of *ca.* 200 ps or shorter; the transition has been assigned as a cluster-to-nitrobenzene charge transfer. D. I. Yoon, D. C. Selmarten, H. Lu, H.-J. Liu, C. Mottley, M. A. Ratner and J. T. Hupp, *Chem. Phys. Lett.*, 1996, **251**, 84. For the NMe_4 salt of **1** the emissive state has been assigned as metal-to-ligand charge transfer; see ref. 4*a*. Ref. 4*a* also reports very weak emission from $[Cd_4(SC_6H_5)_{10}]^{2-}$, with a wavelength maximum at *ca.* 500 nm and a lifetime of *ca.* 400 ps.

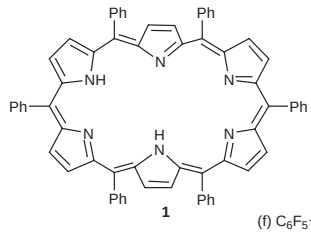
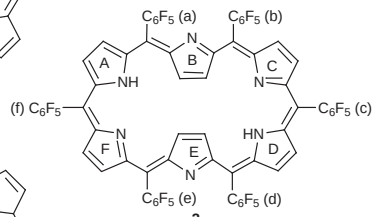
Received (in Liverpool, UK) 16th November 1998, Accepted 8th January 1999

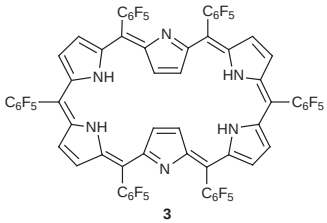
New hexapyrrolic macrocycles have been synthesized and characterized by UV–VIS, mass and NMR spectroscopy and X-ray crystallography.

In recent years there has been considerable research directed towards the synthesis and study of systems involving expanded porphyrin macrocycles. Such systems are finding applications in the fields of medicine, neutral substrate binding and anion recognition.[1]

Recent studies have shown that inverted[2] and expanded[3] porphyrins can be formed during the Rothemund synthesis of porphyrins. Very recently the synthesis of an interesting expanded porphyrin, the hexaphenylhexaphyrin **1**, has been reported.[4] The poor stability of that compound hampered its spectroscopic characterisation.







Here we report the synthesis and characterisation by spectroscopic techniques of stable *meso*-hexa(pentafluorophenyl)hexaphyrins **2** and **3**; the structure considered for **2** was also confirmed by X-ray crystallography. These new compounds were obtained during the Rothemund synthesis of *meso*-tetra(pentafluorophenyl)porphyrin under modified experimental conditions:[5] addition of pentafluorobenzaldehyde to a refluxing mixture of glacial AcOH and $PhNO_2$, followed by the dropwise addition of pyrrole. The final mixture was refluxed for 45 min, the solvents were removed by distillation, and the residue was then purified by silica gel column chromatography. The first fraction to be collected contained the expected porphyrin (15%), and a more polar bluish fraction was then eluted (*ca.* 1%). Thin layer chromatographic (TLC) analysis of this fraction revealed the presence of two main compounds with blue and violet colours: $\lambda_{max}(CH_2Cl_2)$/nm (log ε) 591 (4.95), 762 (3.82) and 568 (5.64), 712 (4.67), respectively (Fig. 1).

Both compounds show, in their mass spectra (LSIMS), the same molecular ions at *m/z* 1462, which correspond to molecules formed from six pyrroles and six pentafluorobenzaldehyde units. The fact that both compounds show the same molecular ions was an unexpected observation, since they can be interconverted by hydrogenation–dehydrogenation processes: by reacting the blue compound with DDQ in $CHCl_3$ the violet one is obtained and reduction of the violet compound with $TsNHNH_2$ gives the blue one.

Surprisingly, the ^{1}H NMR spectra of these compounds show that they have aromatic features: for the major (violet) compound, signals at δ −2.43, −1.98, 9.11 and 9.49 are observed. The analysis of this spectrum, together with the HETCOR (^{1}H/^{13}C) spectrum, revealed that the singlet (4H) at δ −2.43 correlates with the carbon resonance at δ 122.9. The very broad singlet at δ −1.98 shows no correlation with carbons and was, thus, attributed to N*H* protons. This signal became more narrow when the proton spectrum was registered at 273.1 K. Based on these spectra, and on the ^{19}F NMR spectrum (*vide infra*), the structure **2** is proposed for this macrocycle. For the blue compound the hydrogenated structure **3** is considered, based mainly on its mass and NMR spectra and its dehydrogenation to **2**. The ^{1}H NMR spectrum of the blue compound is significatively different from that of compound **2**: signals at δ 2.55 (4H, s), 4.40 (br s), 7.63 (4H, d, *J* 4.7) and 7.73 (4H, d, *J* 4.7) are observed; there are no signals at negative δ values. The signal at δ 4.40 is due to the N*H* protons since it disappears after shaking with D_2O. From the HETCOR (^{1}H/^{13}C) experiment we can observe a correlation between the singlet at δ 2.55 and the resonance at δ 119.4 while the doublets at δ 7.63 and 7.73 correlate, respectively, with the carbon resonances at δ 130.2 and 129.2. From the NMR spectra of the blue product it is obvious that there are no sp^3 carbons in this reduced compound.

The fact that both compounds show the same ion at *m/z* 1462 can be explained by a fast hydrogenation of **2** to **3** during the acquisition of the mass spectra.† This was confirmed by the use of deuterated nitrobenzyl alcohol as matrix: **2** gives a signal at *m/z* 1466, corresponding to the addition of '2D' plus the exchange of the two N*H* by N*D*; **3** gives a set of signals at *m/z* 1463–1466 corresponding to the successive exchange of the four N*H* by N*D*.

For compound **2**, the resonance at δ −2.43 corresponds to the 'inner', strongly shielded, four β-protons of the two inverted pyrrole rings (B and E). Since the N*H* protons resonate at δ −1.98 we can say that they are 'inside' the macrocycle and not in the inverted pyrrole rings. The 'outer' β-pyrrolic protons appear as two doublets (4H each) at δ 9.11 and 9.44; they correlate, in the HETCOR (^{1}H/^{13}C) spectrum, with the carbon resonances at δ 132.5 and 135.0, respectively. This last observation confirms that each pyrrole ring (A, C, D and F) has

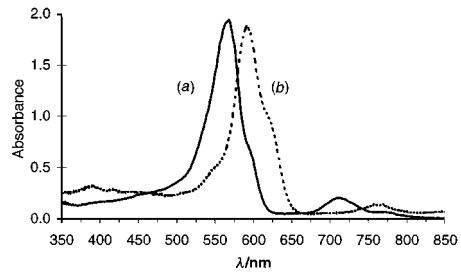


Fig. 1 Electronic spectra of compounds (*a*) **2** and (*b*) **3**.

non-equivalent β-pyrrolic carbons and protons. The resonances of all α-pyrrolic carbons (δ 156.3 for rings B, E and 149.5, 149.7 for the other rings) were determined by the connectivities found in the HMBC spectrum. The resonances of the *meso* carbons appear at δ 106.2 and 117.4, whereas those of the pentafluorophenyl rings appear as multiplets with low intensity (due to both relaxation processes and coupling with the fluorine atoms).

From the ^{19}F NMR spectrum of **2** (Table 1), by comparing the relative signal integrals, we can conclude that there are two types of pentafluorophenyl rings in a 2 : 1 ratio. This result is also compatible with the proposed structure: the two *meso*-pentafluorophenyl rings (c) and (f) are in a different environment than the other four phenyl rings.

The acidic character of the N*H* protons and the stability of *meso*-hexa(pentafluorophenyl)hexaphyrin **2** was demonstrated by the following experiments: (i) addition of several drops of a solution of NaOD (in D_2O) to a $CDCl_3$ solution of this compound, followed by a gentle shaking, led to the appearance of two signals (δ −2.43 and −5.91) in the negative region of the ^{1}H NMR spectrum; (ii) after a more vigorous shaking, only the resonance at δ −5.91 was observed for the β-H of rings B and E. This strong shielding of the 'inner' protons suggests the conversion of the macrocycle into the corresponding dianion; (iii) the neutralization of this solution allowed us to recover the *meso*-hexa(pentafluorophenyl)hexaphyrin **2**.

All the NMR results discussed here support the proposed structure **2** for this new 26π electron macrocycle. The final proof for the structure of this compound was obtained by X-ray single crystal diffraction.

The X-ray structure of **2**‡ is presented in Fig. 2. The macrocycle displays a nonplanar conformation [see Fig. 2(*b*)] with four *exo* pyrrolic rings (A, C, D and F) and two *endo* rings (B and E). π-Electron delocalization in the macrocyclic core is apparent from the observed range of bond lengths: 1.33(1)–1.39(1) Å for the N–Cα bonds and 1.39(1)–1.42(1) Å for the Cα-C*meso* bonds. On the other hand, the range found for the C–C bond lengths in the pyrrole rings suggest that these bonds have some double or single bond character: 1.36(1)–1.32(1) Å for the Cβ–Cβ bonds and 1.42(1)–1.46(1) Å for the Cα–Cβ bonds. The six pentafluorophenyl rings are tilted by 47.3(1), 43.3(1), 51.0(1), 68.4(1), 78.8(1) and 81.4(1)° relative to the least-square plane defined by the atoms of the macrocyclic core. Consequently, the average bond length between the *meso* carbons and pentafluorophenyl rings of 1.50(1) Å indicates an absence of a π interaction between those rings and the macrocyclic core.

This set of structural features is consistent with a 26π electron aromatic current ring extended over the nitrogens, the α-pyrrolic carbons and the *meso* carbons of the macrocyclic ring.

The nonplanarity of the macrocycle is due to its large dimensions [N(39)···N(45) 2.93(1), N(18)···N(24) 2.82(1), N(24)···N(39) 7.58(1) and N(18)···N(45) 7.60(1) Å] and the bulk of the *meso*-pentafluorophenyl rings. In order to minimise the steric interactions, the macrocycle looses the planarity of its core, leading an average deviation of 0.536(8) Å of the atoms belonging to the macrocyclic core from the least-squares plane defined by their atomic positions.

We thank FCT, Lisbon, for funding the Research Unit No. 62/94 and Mr Pedro Domingues (University of Aveiro) for the mass spectra.

Table 1 ^{19}F NMR chemical shifts (ppm, from TFA) observed in the spectrum of the *meso*-hexa(pentafluorophenyl)hexaphyrin **2**

	(a), (b), (d) and (e) phenyl rings	(c) and (f) phenyl rings
o-F	−136.19 (4F)	−135.63 (2F)
m-F	−162.22 (4F)	−159.61 (2F)
p-F	−151.94 (2F)	−149.08 (1F)

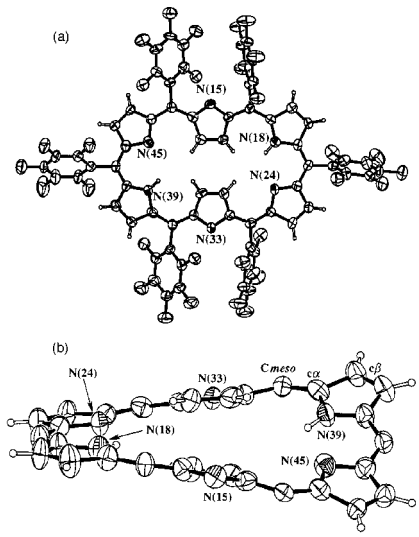

Fig. 2 (*a*) Top and (*b*) side views of **2** (thermal ellipsoids at the 40% probability level). The side view shows the nonplanarity of the macrocyclic core. In both views only the labelling scheme for nitrogen atoms is presented, and in (*b*) the phenyl rings are omitted for clarity.

Notes and references

† A similar hydrogenation process was observed during the acquisition of the mass spectrum of the *meso*-tetra(pentafluorophenyl)porphyrin.

‡ *Crystal data* for **2**: $C_{66}H_{14}F_{30}N_6$, M = 1460.83; monoclinic, space group $P2_1/c$, a = 10.911(10), b = 27.242(23), c = 19.466(21) Å, β = 90.31(1)°, V = 5786(10) Å^3, Z = 4, D_c = 1.677 g cm^{-3}, μ = 0.168 mm^{-1}. A violet needle-like crystal was mounted in a Lindmann capillary under saturated atmosphere of the mother-liquor. The X-ray data were collected with graphite monochromated Mo-Kα radiation (λ = 0.71073 Å) on a Mar-research image plate system at Reading University. The crystal was positioned at 75 mm from the plate. An exposure time of 5 min was used per 2º frame collected. Data analysis was performed with the XDS program (ref. 6). Intensities were not corrected for absorption effects. 12030 reflections collected in the range 2.0 < θ < 26.1 (*hkl* range indices: 0 ⩽ h ⩽ 11, −33 ⩽ k ⩽ 33, −19 ⩽ l ⩽ 19) were merged in the Laue symmetry group 2/*m* to 7246 unique reflections with a R_{int} = 0.0454. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 using the SHELX-97 package (ref. 7) Anisotropic parameters were used for all non-hydrogen atoms. The hydrogen atoms were included in the refinement in geometric positions with a U_{iso} = 1.2U_{eq} of the parent nitrogen atom. In agreement with ^{1}H NMR results, two geometric arrangements for two N–H protons were considered: one proton at N(39) and one at N(18) or alternatively one proton at N(24) and the other at N(45). The first arrangement was considered as correct since it gave a slightly lower R value (0.0789) than the second (0.0795). The final refinement of 920 parameters converged to R and wR values of 0.0785 and 0.2094 and GOF = 0.862 for the data with I > 2σ(I). The final R and wR values for all *hkl* data were 0.2304 and 0.2750, respectively. In the last difference Fourier map the residual electronic density was in the range of −0.341 to 0.281 e Å^{-3}. Molecular diagrams were made with ZORTEP (ref. 8). CCDC 182/1139. Crystal data are available in CIF format from the RSC web site, see: http://www.rsc.org/suppdata/cc/1999/385/

Use of 2-methyl-1-phenylpropan-2-yl hydroperoxide (MPPH) as a mechanistic probe for the heterolytic *versus* homolytic O–O bond cleavage of *tert*-alkyl hydroperoxide by iron(III) porphyrin complex

Wonwoo Nam,* Hye J. Choi, Hui J. Han, So H. Cho, Ha J. Lee and So-Yeop Han

Department of Chemistry and Center for Cell Signaling Research, Ewha Womans University, Seoul 120-750, Korea. E-mail: wwnam@mm.ewha.ac.kr

Received (in Cambridge, UK) 18th December 1998, Accepted 14th January 1999

The mechanism of the O–O bond cleavage of *tert*-alkyl hydroperoxide by iron(III) porphyrin complexes has been studied using 2-methyl-1-phenylpropan-2-yl hydroperoxide (MPPH) as a mechanistic probe; the hydroperoxide O–O bond is cleaved both heterolytically and homolytically and partitioning between the two pathways significantly depends on the reaction conditions such as the pH of the reaction solutions and the nature of porphyrin and axial ligands.

The reactions of iron(III) porphyrin complexes with alkyl hydroperoxides have been intensively studied as biomimetic models for heme-containing enzymes such as cytochromes P-450, peroxidases and catalases, with the intention of elucidating the mechanism of O–O bond activation and the structure of reactive intermediates.[1] Traylor *et al.* proposed that the O–O bond of hydroperoxides is heterolytically cleaved by the iron porphyrins, giving the formation of a high-valent iron oxo porphyrin cation radical intermediate **1** (Scheme 1, pathway A).[2] In contrast, Bruice *et al.*[3] and others[4] provided evidence that the initial step of the hydroperoxide O–O bond cleavage is homolysis, resulting in the formation of a ferryl–oxo complex, **2**, and an alkoxyl radical (Scheme 1, pathway B). Despite the intensive study for the last two decades, the nature of the O–O bond cleavage of ROOH by the iron(III) porphyrin complexes has been controversial and still remains unclear.

In recent years, 2-methyl-1-phenylpropan-2-yl hydroperoxide (MPPH) has been shown to be an excellent mechanistic probe capable of distinguishing between free alkoxyl radical chemistry and radical-free (enzyme mimetic) chemistry in non-porphyrin iron(III) complex-catalyzed oxidations of hydrocarbons by *tert*-alkyl hydroperoxides.[5] When the O–O bond of MPPH is cleaved homolytically by the iron complexes, an alkoxyl radical (MPPO·) is generated [eqn. (1)]. Then, the

$$Fe^{III} + PhCH_2CMe_2OOH \xrightarrow{\text{homolysis}} Fe^{IV}{=}O + PhCH_2CMe_2O^{\bullet} + H^+ \quad (1)$$
(MPPH) (MPPO•)

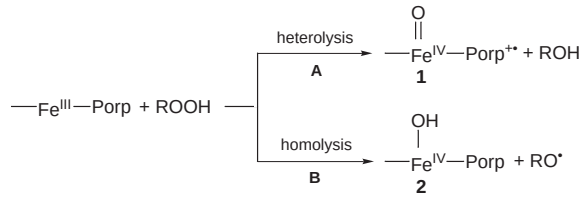
alkoxyl radical undergoes an extremely rapid β-scission, giving PhCHO and $PhCH_2OH$ [eqn. (2)].[5] In contrast, heterolytic

$$PhCH_2CMe_2O^{\bullet} \xrightarrow{-Me_2CO} PhCH_2^{\bullet} \xrightarrow{+O_2} \longrightarrow PhCHO + PhCH_2OH \quad (2)$$
(MPPO•)

reduction of MPPH by the iron complexes yields an alcohol (MPPOH) [eqn. (3)]. Therefore, the mechanism of the O–O

$$Fe^{III} + PhCH_2CMe_2OOH \xrightarrow{\text{heterolysis}} Fe^{V}{=}O + PhCH_2CMe_2OH \quad (3)$$
(MPPOH)

bond cleavage of *tert*-alkyl hydroperoxides can be determined by analyzing the products derived from the decomposition of MPPH by iron complexes. Another mechanistic probe often used to interpret the mechanism of the O–O bond cleavage of ROOH by iron(III) porphyrin complexes is to analyze the products yielded in the epoxidation of olefins such as (*Z*)-stilbene.[6] When **2** is formed *via* homolysis (Scheme 1, pathway B), **2** affords a low yield of epoxide products with a loss of stereospecificity.[7] In contrast, **1**, which is generated *via* heterolysis (Scheme 1, pathway A), is capable of epoxidizing olefins stereospecifically. We therefore studied iron(III) porphyrin complex-catalyzed olefin epoxidation reactions using the aforementioned two mechanistic probes (*i.e.* MPPH as an oxidant and (*Z*)-stilbene as a substrate), in order to clarify the mechanism of the O–O bond cleavage of *tert*-alkyl hydroperoxides by iron(III) porphyrin complexes.



Scheme 1

The catalytic epoxidation of (*Z*)-stilbene by MPPH was carried out in the presence of water-soluble iron(III) porphyrin complexes in buffered H_2O–MeOH–MeCN solutions.† Among the tested iron porphyrins (see Fig. 1), $Fe(TDFPPS)^{3-}$ showed the greatest reactivity for giving a high yield of *cis*-stilbene oxide with a trace amount of *trans*-stilbene oxide, whereas other iron porphyrins gave a small amount of *cis*-stilbene oxide (*vide infra*). Fig. 2 shows the result of product studies obtained in the (*Z*)-stilbene epoxidation by $Fe(TDFPPS)^{3-}$ and MPPH at pH 3–8. The epoxidation reaction was found to depend on the pH of the reaction solutions[8] and the yield of *cis*-stilbene oxide formed was higher at low pH values, as we have observed previously.[9] Interestingly, the amounts of *cis*-stilbene oxide and MPPOH yielded in the reactions were similar, demonstrating that the reaction of $Fe(TDFPPS)^{3-}$ and MPPH involves heterolysis of the hydroperoxide to generate $(TDFPPS)^{+\cdot}Fe^{IV}{=}O$ as a reactive intermediate responsible for the (*Z*)-stilbene epoxidation. In addition to the heterolysis of MPPH by $Fe(TDFPPS)^{3-}$,

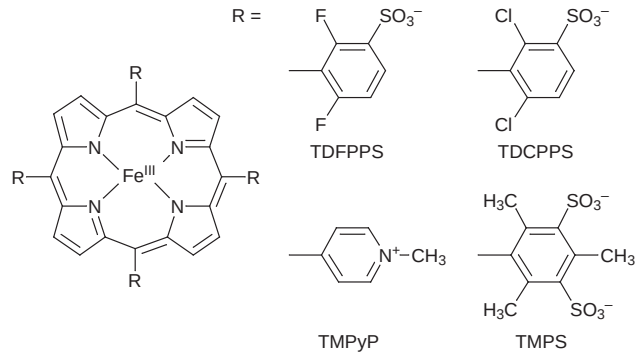


Fig. 1 Structures and abbreviated names of iron(III) porphyrin complexes used in this study.‡

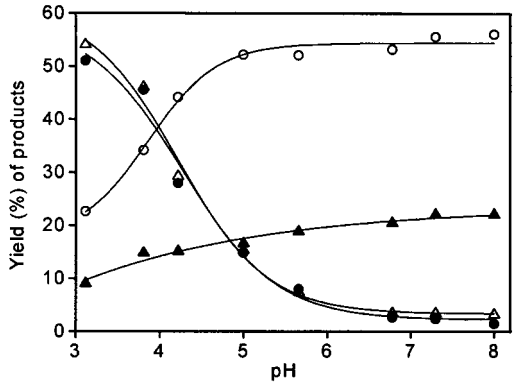

Fig. 2 Plot of the percent yield of products (●, *cis*-stilbene oxide; △, MPPOH; ▲, $PhCH_2OH$; ○, PhCHO) *vs.* pH of reaction solutions for the catalytic epoxidation of (*Z*)-stilbene by $Fe(TDFPPS)^{3-}$ and MPPH. The percent yields are calculated on the basis of MPPH used. See footnote † for detailed experimental procedures.

homolysis of MPPH took place concurrently even at low pH values, as demonstrated by the observation of the formation of PhCHO and $PhCH_2OH$ [eqn. (2)]. As the pH of the reaction solution increased, the yields of *cis*-stilbene oxide and MPPOH products decreased and the amounts of the PhCHO and $PhCH_2OH$ increased. These results indicate that the O–O bond cleavage of MPPH was shifted from heterolysis to homolysis as the pH of the reaction solutions increased.

In addition to the pH effect on hydroperoxide O–O bond cleavage, we found that there are other important factors that control the type of O–O bond cleavage of *tert*-alkyl hydroperoxides. As shown in Table 1, the O–O bond cleavage was significantly affected by the porphyrin ligands bound to iron and the general trend appeared to be that more electronegatively-substituted iron porphyrins gave a high percentage of heterolysis, whereas homolysis prevailed in the reactions with less electronegatively-substituted iron porphyrins. This result is consistent with the observation that electron-deficient iron porphyrins are effective catalysts in the epoxidation of olefins by H_2O_2 and ROOH.[10] We also found, by studying the epoxidation of (*Z*)-stilbene with $Fe(TDFPPS)^{3-}$ and MPPH in the presence of imidazoles, that there is a significant axial ligand effect on the ratio of the heterolytic and homolytic O–O bond cleavage of *tert*-alkyl hydroperoxides.[4b,11,12] Interestingly, the presence of imidazoles such as 5-chloro-1-methylimidazole and 1-phenylimidazole increased the yields of *cis*-stilbene oxide and MPPOH products, whereas 1-methylimidazole and 1,2-dimethylimidazole did not alter the ratio of heterolysis to homolysis significantly (data not shown), indicating that the nature of the axial ligand bound to iron is another important factor determining the type of the hydroperoxide O–O bond cleavage.[11–13]

In summary, we demonstrated unambiguously that the O–O bond of *tert*-alkyl hydroperoxides is cleaved both heterolytically and homolytically,[11] depending on the reaction conditions such as pH and the electronic nature of the porphyrin and axial ligands. These results rationalize the long-standing dichotomy of the interpretations for the O–O bond cleavage mechanism of ROOH by iron(III) porphyrin complexes, mainly suggested by Traylor[2] and Bruice[3] and co-workers.

Table 1 Product yields formed in the epoxidation of (*Z*)-stilbene by MPPH catalyzed by iron porphyrin complexes at pH 3.2[a]

	Yields (%)[b]			
Iron porphyrins	*cis*-Stilbene oxide	MPPOH	$PhCH_2OH$	PhCHO
$Fe(TDFPPS)^{3-}$	51	54	8	21
$Fe(TDCPPS)^{3-}$[c]	33	38	12	41
$Fe(TMPyP)^{5+}$	2	7	14	59
$Fe(TMPS)^{7-}$[c]	12	19	18	44

[a] See footnote † for detailed reaction procedures. [b] Based on MPPH used. [c] Reactions were run for 8 h.

Notes and references

† MPPH was prepared according to literature procedures[5] and the purity of MPPH was determined to be 100% by NMR. In a typical reaction, MPPH (4 mM, introduced as a 0.2 M solution in MeOH) was added to a reaction solution containing $Fe(TDFPPS)^{3-}$ (0.04 mM, introduced as 0.01 M solution in H_2O) and (*Z*)-stilbene (6 mM, introduced as 0.3 M solution in MeOH) in a solvent mixture (5 mL) of buffered H_2O (2.5 mL)–MeOH (1.0 mL)–MeCN (1.5 mL) in order to make the reaction mixture homogeneous. Reactions at pH 3 were performed in formate buffer (0.1 M), at pH 4–5 in acetate buffer (0.1 M), and at pH 6–8 in phosphate buffer (0.1 M), and the pH was adjusted by adding either HCl (3 M) or NaOH (3 M) solutions as necessary. The reaction mixture was stirred in air for 4 h at 25 °C, and then analyzed by *Orom Vintage 2000* HPLC equipped with a variable wavelength UV-200 detector. Detection was made at 215 and 254 nm.

‡ All iron(III) porphyrin complexes used in this study were obtained from Mid-Century Chemical. Abbreviations used: TDFPPS, [*meso*-tetrakis(2,6-difluoro-3-sulfonatophenyl)porphyrin; TDCPPS, *meso*-tetrakis(2,6-dichloro-3-sulfonatophenyl)porphyrin; TMPyP, *meso*-tetrakis(*N*-methylpyridin-4-ylium)porphyrin; TMPS, *meso*-tetrakis(2,5-disulfonatomesityl)-porphyrin.

Synthesis and X-ray structure of a cluster complex with facial coordination of cyclooctatetraene to a Co_2Ni triangle

Hubert Wadepohl,* Stefan Gebert, Rüdiger Merkel and Hans Pritzkow

Anorganisch-chemisches Institut der Ruprecht-Karls-Universität, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany. E-mail: bu9@ix.urz.uni-heidelberg.de

Received (in Basel, Switzerland) 4th January 1999, Accepted 16th January 1999

The reaction between $[(\eta\text{-}C_5H_5)NiCo_3(CO)_9]$ and cyclooctatetraene yields $[Co_2Ni(CO)_6(\mu_3\text{-}\eta^2:\eta^3\text{-}C_8H_8)]$ with a cyclooctatetraene ligand in the facial coordination mode to a heterometallic Co_2Ni triangle.

The facial coordination of the cyclic π-perimeters C_nH_n (n = 5–8) to a molecular metal cluster is well documented.[1–4] Examples include the complexes $[\{(\eta\text{-}C_5H_5)Rh\}_3(\mu_3\text{-}H)(\mu_3\text{-}C_5H_5)]$,[5] $[\{(CO)_3M\}_3(\mu_3\text{-}C_6H_6)]$ (M = Ru, Os),[6] $[\{(CO)_2Ru\}_3(\mu_3\text{-}SBu^t)(\mu_3\text{-}C_7H_7)]$[7] and $[\{(CO)Ni\}_3\{\mu_3\text{-}(CF_3)_2C_2\}(\mu_3\text{-}C_8H_8)]$.[8] In such complexes, the C_nH_n ligand bonds to a triangular array of three metal atoms, which may even be part of a larger cluster moiety. This coordination geometry is frequently related to the adsorption states of the corresponding hydrocarbons on atomically flat (single crystal) metal surfaces.[9] Similar adsorbates are key intermediates in the industrially enormously important catalytic hydrocarbon reforming processes.[10] Curiously, although heteronuclear cluster complexes are quite commonplace, to our knowledge only one compound has been reported with a facial coordination of a cyclic conjugated unsaturated hydrocarbon to a cluster face comprised of two different types of metal atoms, *viz.* an Ru_2Pt face in $[Ru_6Pt_3(CO)_{18}\{\mu_3\text{-}\eta^2:\eta^2\text{-}C_6H_5(CH_2)_2Ph\}(\mu_3\text{-}H)_4]$ **1**.[11] Our prime interest in such species comes from the well known fact that metal alloys and supported bimetallic clusters can have catalytic properties which may be vastly different from those of the pure metals.[12] Complexes such as **1** may be important stepping stones on the way towards an understanding of some of the factors which control how these catalysts work on the molecular level. Recently we reported on the simple one-pot synthesis of the complexes $[Co_4(CO)_6(\mu_3\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)]$ **2** and $[Co_4(CO)_6(\mu_3\text{-}C_8H_8)(\eta^4\text{-}C_8H_8)]$ **3**, starting from the binary carbonyl $[Co_4(CO)_{12}]$ and cycloheptatriene or cyclooctatetraene, respectively.[13] The products **2** and **3** provide a convenient entrance to large families of tri- and tetra-nuclear cluster complexes with facial C_7H_7 and C_8H_8 ligands.[3,13] Here, we report the synthesis and characterisation of a cluster complex containing a C_8H_8 ligand in the facial coordination mode to a Co_2Ni metal triangle. This is the first example of facial C_8H_8 coordination to a heterometallic face of a cluster, and only the second throughout the whole series $M_m(\mu_3\text{-}C_nH_n)$ (n = 5–8).

Reaction of the tetranuclear complex $[(\eta\text{-}C_5H_5)NiCo_3(CO)_9]$ **4** with an excess of cyclooctatetraene in refluxing *n*-heptane gave a dark red microcrystalline precipitate in 25% yield. The presence of a face-capping C_8H_8 ligand in this product was indicated by the NMR spectra.† However, no resonances were observed for a cyclopentadienyl ligand. The IR spectrum‡ indicated terminal and bridging carbonyl ligands; the large number of bands in the ν_{CO} region pointed to a rather low molecular symmetry. The structure of the product was eventually determined by a single crystal X-ray structure analysis.§ The molecular structure, $[M_3(CO)_6(\mu_3\text{-}C_8H_8)]$, is shown in Fig. 1, together with selected bond parameters. Unfortunately, the identity of the metal atoms M (cobalt or nickel) could not be determined unambiguously from the diffraction data.

The observed diamagnetism of the complex requires the composition of either $[Co_2Ni(CO)_6(C_8H_8)]$ or $[Ni_3(CO)_6(C_8H_8)]$. XPS analysis of a sample film deposited from solution on a gold foil gave the atomic ratio Co : Ni = 2 : 1. The isotope pattern starting with *m/z* 448 of the peak due to the molecular ion in the field desorption mass spectrum is also only consistent with the formulation $[Co_2Ni(CO)_6(\mu_3\text{-}C_8H_8)]$ **5**. The novel complex **5** is isoelectronic with its anionic tricobalt analog, $[Co_3(CO)_6(\mu_3\text{-}C_8H_8)]^-$ **6**, which was obtained in high yield by reductive degradation of **3**.[3]

The mean metal metal separation in **5** is 2.514 Å, shorter than in the tricobalt complex **6** (2.528 Å[14]). An even shorter mean metal metal distance (2.438 Å) was found in $[NiCo_2(\mu_2\text{-}CO)_3(PMe_3)_6]$, where D_{3h} symmetry is imposed on the molecule by the lattice symmetry (Co and Ni atoms are necessarily disordered).[15] This contraction of the metal triangles can be attributed to the effect of exchanging a cobalt for the smaller nickel atom. In both **5** and **6**, the lengths of the three individual metal metal bonds differ only by a maximum of 0.02 Å. In the only two structurally characterised cluster complexes with triangular Co_2Ni faces comprised of equally substituted apices disorder of the metals was found, indicating a close similarity of Co–Co and Co–Ni bonds.[15,16] For **5**, we cannot completely rule out some static disorder of the metal triangle, but there are no unusual shapes or orientations of the anisotropic displacement ellipsoids, and all the peaks in the Fourier synthesis are well defined.

The bridging C_8H_8 ligand attains an $\eta^2:\eta^3:\eta^3$ coordination mode with respect to the metal triangle. The carbocyclic ring is non-planar and approaches a chair conformation (Fig. 2). Carbon–carbon bond lengths within the $\mu_3\text{-}C_8H_8$ vary barely significantly within the range 1.396(8)–1.434(8) Å. The ligand

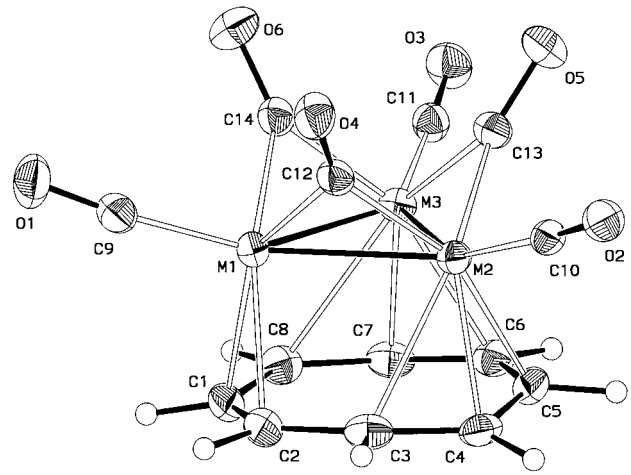

Fig. 1 Molecular structure of $[Co_2Ni(CO)_6(\mu_3\text{-}C_8H_8)]$ **5**. Selected bond lengths (Å) and angles (°): M1–M2 2.512(1), M1–M3 2.503(1), M2–M3 2.526(1), M1–C1 2.118(5), M1–C2 2.140(5), M2–C3 2.333(5), M2–C4 2.087(5), M2–C5 2.236(5), M3–C6 2.190(5), M3–C7 2.088(5), M3–C8 2.427(5), C1–C2 1.396(8), C1–C8 1.434(8), C2–C3 1.417(8), C3–C4 1.418(7), C4–C5 1.411(7), C5–C6 1.432(8), C6–C7 1.412(7), C7–C8 1.404(7), C2–C1–C8 133.2(5), C1–C2–C3 134.4(5), C2–C3–C4 136.5(5), C3–C4–C5 131.6(5), C5–C6–C7 134.8(5), C6–C7–C8 132.8(5), C7–C8–C1 136.5(5) (M = Co, Ni).

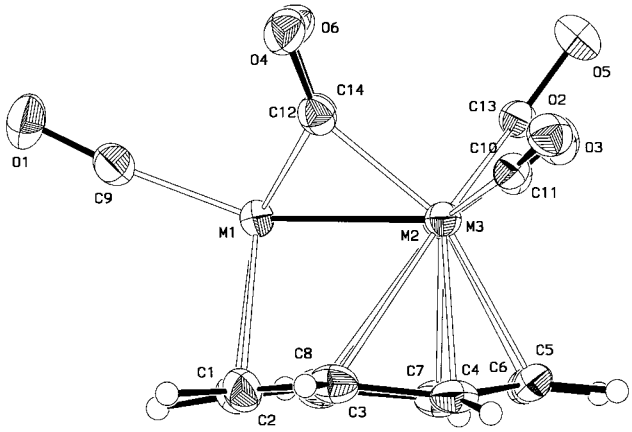

Fig. 2 Side view of **5** showing the conformation of the μ_3-C_8H_8 ring.

shell of the cluster is completed by three terminal and three edge-bridging carbonyl ligands. In solution, both the carbonyl and C_8H_8 ligands in **5** display fluxional behaviour. Only one ^{13}C NMR resonance is observed for the six carbonyl ligands, indicating a 'merry-go-round' type exchange process which involves both the terminal and bridging CO ligands. The observation of only one ^{13}C and ^1H NMR resonance for the μ_3-C_8H_8 ring is consistent with a rapid rotation of this ligand on top of the metal triangle. A high degree of fluxionality is generally characteristic for C_8H_8 ligands capping a Co_3 cluster face.[3] Evidently, the activation barrier for this process is not appreciably increased on coordination to the Co_2Ni triangle.

During the formation of **5**, the presence of [(η-C_5H_5)$Co(CO)_2$] **7** in the reaction mixture was observed by IR spectroscopy. It is therefore likely, that the reaction involves an intra- or inter-molecular transfer of the cyclopentadienyl ligand from the nickel to a cobalt atom, which then leaves the cluster in the form of **7**. Vahrenkamp and coworkers have previously noted a similar role of an intermolecular nickel-to-cobalt transfer of a cyclopentadienyl ligand during metal exchange reactions in tri- and tetra-nuclear cluster complexes.[17]

Porous platinum fibers synthesized using supercritical fluid

H. Wakayama* and Y. Fukushima

Toyota Central R&D Labs., Inc., Nagakute, Aichi, 480-1192, Japan. E-mail: e0980@mosk.tytlabs.co.jp

Received (in Cambridge, UK) 26th October 1998, Accepted 19th January 1999

Porous platinum fibers replicating both the shape and nanopore structure of activated carbon fibers have been prepared in supercritical fluid media.

Several techniques have been developed recently for fabricating nanostructured materials using templates, such as molecular[1] and surfactant arrays,[2,3] latex spheres,[4] block copolymers[5] and carbon nanotubes.[6–8] One of us has reported the synthesis of highly ordered mesoporous silica or silica–alumina using hexagonally packed aggregates of surfactants as templates.[3] In the case of porous metal, platinum black is synthesized electrochemically. Recently, Attard *et al.* have reported the production of mesoporous platinum materials.[9–11] The shape of the porous platinum materials are restricted to powders[9] or films.[10] The fabrication of such structures that can be used directly without any binders or substrates has remained an experimental challenge. The control of macroscopic shape is quite important in applying such porous materials as catalysts, electrodes, sensors and capacitors. We show here the synthesis of porous platinum fibers replicating morphologies, with both the porous structure and fibrous shape of base activated carbon fibers, using supercritical fluid as a medium. Supercritical fluids have large diffusion coefficients,[12] low viscosity and controllable solubility[13] and are expected to carry effective amounts of precursor into small spaces and to be effective media in replicating a template with porous structure such as activated carbon.

Acetone (5 ml) along with $Pt(acac)_2$ (0.5 g) (acac = acetylacetonate) was placed in a stainless steel vessel (50 ml). A stainless steel basket containing 1 g of activated carbon fibers (Touyoubou co. BW103) was then placed in the vessel. The activated carbon fibers in the cage were not in contact with the liquid acetone or the Pt precursor. The closed vessel was filled with CO_2 and kept at 423 K and 32 MPa for 2 h in an oil bath. Then, the base activated carbon was removed by oxidation using YAMATO Scientific O_2 plasma equipment (PC-103, RFG-500) at 500 W in O_2 (160 ml min^{-1}) for 8 h. The fibrous shape of the cloth was retained even after removal of the activated carbon fiber cloth.

As shown in Fig. 1(a), the sample treated with oxygen plasma shows three characteristic X-ray diffraction peaks which correspond to (111), (200) and (220) peaks for metallic platinum. No peaks due to platinum oxide were detected in the XRD pattern in the sample treated with oxygen plasma while XRD peaks from activated carbon disappear for the sample treated with oxygen plasma. The crystalline sizes of platinum metal calculated from the half widths of the (111), (200) and (220) reflections in the XRD pattern were estimated to be *ca*. 10 nm.

Thermogravimetry(TG) showed that the weight loss up to 1273 K in air flow was only 3% for the Pt-coated sample after removal of activated carbon. This confirmed that no activated carbon was present in the treated sample in O_2 plasma.

Scanning electron micrographs (SEM) (Fig. 2) showed the morphology of base activated carbon fibers (A) and Pt-coated samples after the removal of activated carbon in O_2 plasma (B–D), revealing fibrous shapes with almost the same diameter as that of activated carbon fibers. The product, the structure of which is a cast-off skin of the base activated carbon fibers, consisted of fused particles of 20–80 nm in diameter.

In the Pt coating process, the temperature and the pressure in the vessel was 423 K and 32 MPa, beyond the critical temperature (304 K) and pressure (7.38 MPa) of CO_2. The Pt precursor [$Pt(acac)_2$] at the bottom of the vessel dissolves in supercritical CO_2 and acetone and is carried into the pores of the activated carbon fiber. $Pt(acac)_2$ adsorbed on the surface of the activated carbon will react with hydroxyl units and adsorbed water molecules. During the treatment in O_2 plasma, the sample was heated to 453 K and adsorbed $Pt(acac)_2$ on the activated carbon is reduced to Pt metal. Because of the low surface concentration of Pt precursor on activated carbon, the Pt metal sintered into particles.

The BET surface area of the Pt porous fiber calculated measuring N_2 adsorption isotherms was 47 m^2 g^{-1}, larger than that found for platinum black (20–30 m^2 g^{-1}).

Recently Attard *et al.* produced mesoporous platinum powder denoted Hi-ePt of surface area 22 ± 2 m^2 g^{-1} [9] and platinum film denoted Hi-Pt of surface area 60 ± 6 m^2 g^{-1}.[10] The shapes of these Pt porous materials, however, were limited

to granules or films. Removing the base material after coating the metal precursor using supercritical fluid makes it possible to produce metallic materials with a similar shape to that of the base. The morphology of porous metal can thus be controlled through the choice of the shape of base activated carbon. Supercritical fluids can even carry precursor molecules into micropores (*ca*. 1 nm diameter) without condensation into the liquid phase. Thus, the coating process with supercritical fluids provides a new effective method for obtaining castoff skins using fine structures of base porous materials. Porous platinum structures with high surface area will show great advantages for catalytic applications and encouraging results were obtained for the synthesized porous Pt fibers as a catalyst for CO oxidation.[14]

The authors thank Ms Sasaki and Dr Inagaki for useful discussions and Mr Kadoura for taking the SEM micrographs.

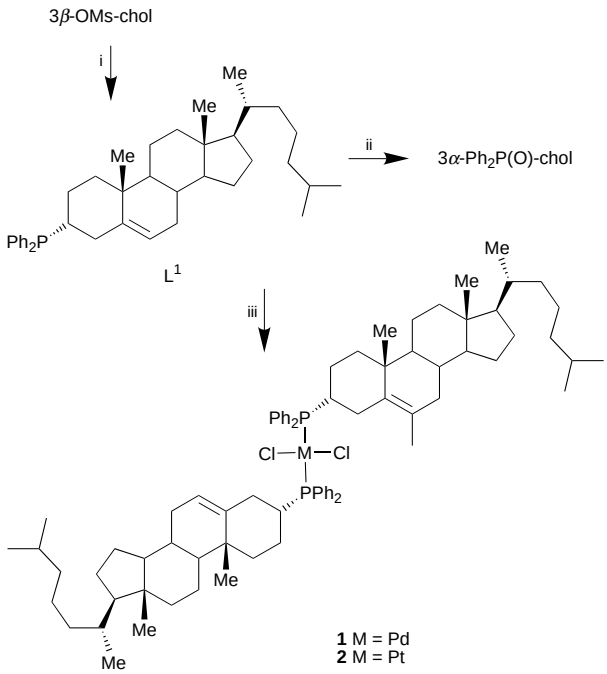
Received (in Cambridge, UK) 19th November 1998, Accepted 14th January 1999

Novel optically pure cholesteryl-phosphine ligands (3α-PPh_2chol and 3β-PMe_2chol) have been synthesized and were shown to form stable and highly soluble Pd(II) and Pt(II) complexes; as revealed by an X-ray analysis the (chol)-P···P(chol) fragment of the square planar *trans*-[PtI_2(3β-PMe_2chol)$_2$] complex adopts a staggered arrangement (V-shape).

As part of our ongoing research for new catalytic and mesomorphic molecular materials it was of interest to design multifunctional ligands based on steroidal phosphines. Surprisingly, very little work has been devoted to cholesteryl-derived phosphines[1] and it appears that no complexes have been reported until now with such hybrid ligands. The cholesteryl fragment offers many advantages in terms of chirality,[2] liquid-crystalline behaviour,[3] lipophilicity,[4] optical and molecular recognition.[5] We now report a convenient synthesis of 5-cholestene derivatives substituted at the C_3-carbon atom with phosphino groups (PPh_2 and PMe_2) and present their coordinative properties towards precious metals.†

Phosphine L^1 was prepared in 73% isolated yield‡ by reacting 5-cholestene-3β-methanesulfonate (3β-MsO-chol)[6] with Ph_2PLi as shown in Scheme 1. The ligand is characterized by a ^{31}P NMR signal at δ −18.6 and by an $[\alpha]_D^{589}$ of +15.8° (*c* = 1, CH_2Cl_2). The phosphino subunit occupies the α position of the C_3-carbon atom as unambiguously proven by a positive NOE effect of 8% found between the olefinic H-6 proton and the *ortho* P-phenyl atoms. It is noteworthy that there is no indication for the formation of the 3β substituted isomer, an observation that is in keeping with an S_N2 substitution reaction. A complete assignment of proton and carbon signals was made using NOESY, ^1H–^{13}C COSY, ^{13}C-DEPT and HMBC pulse sequences (for selected data and atom labelling see Table 1). The corresponding phosphine oxide which was readily obtained by oxidation is characterised by a ^{31}P NMR signal at δ +35.6, and a strong IR absorption band at 1187 cm^{-1} ($\nu_{P=O}$). Reaction of 2 equiv. of L^1 with [MCl_2(PhCN)$_2$] afforded quantitatively‡ the corresponding *trans*-[$MCl_2(L^1)_2$] complexes (**1** M = Pd, **2** M = Pt; Scheme 1). Both complexes are *highly* soluble in *hydrocarbons* and insoluble in protic solvents.



Scheme 1 *Reagents and conditions*: i, Ph_2PLi, THF, 25 °C, 3 d; ii, air, CH_2Cl_2; iii, [$MeCl_2$(PhCN)$_2$], CH_2Cl_2 (M = Pd, Pt).

In contrast to the reaction described above yielding exclusively a C_3-α-substituted product, we discovered that treatment in THF at −78 °C at 3β-Cl-chol with 2 equiv. of PMe_2K (prepared[7] by quantitative reduction of Me_2P–PMe_2 in decaline) gave a mixture of compounds from which 3β-PMe_2-chol (L^2) could be isolated in 47% yield (as the major compound, Scheme 2). Selected spectroscopic data for L^2 are: δ_P −41 and $[\alpha_D]^{589}$ of −33.7° (*c* = 1, CH_2Cl_2). The α-stereochemistry of L^2 could unequivocally be established using 2D proton NMR spectroscopy ($^3J_{H\text{-}3\alpha/H\text{-}4\beta}$ 11 Hz and $^3J_{H\text{-}3\alpha/H\text{-}4\alpha}$ 15 Hz) and was further confirmed by an X-ray diffraction study (*vide infra*). The 3α-PMe_2-chol isomer was also formed in this reaction (β/α ratio 7/3) but could not be obtained in a pure form. Note, the ^{31}P NMR signal of the latter isomer (δ_P −54) is considerably shifted with respect to the β form; such shielding effects have previously been observed on going from 4-methyl-$P_{axial}Me_2$-cyclohexane to its $P_{equatorial}$-isomer.[8] We also note that Me_2P–PMe_2 (δ_P −58) was detected in the reaction mixture.

The sparingly soluble complexes **3** (M = Pd) and **4** (M = Pt) were obtained in high yield by reaction of L^2 with [$MCl_2(SEt)_2]_2$. Metathesis of **4** with NaI in acetone–THF resulted in the formation of the soluble *trans*-[$PtI_2(L^2)_2$] complex **5** (Scheme 2), the molecular structure of which was determined by a single-crystal X-ray analysis¶ (Fig. 1). This study confirmed the α-stereochemistry of the cholesteryl-phosphine ligand L^2. The platinum atom is in a square-planar environment with the two P-atoms occupying *trans* positions. Interestingly, the molecule possesses a C_2-axis perpendicular to the metal plane, with the two steroidal backbones located on the same side of the coordination plane. Observing the molecule perpendicularly to the P···P axis, the two chol subunits adopt a V-shaped arrangement, as shown in Fig. 1; the relative organization of the steroidal fragments is probably controlled by van der Waals forces between cholesteryl units of neighboring molecules. In the crystallographic cell (Fig. 1) the molecules are arranged in a head-to-tail fashion, a situation which is reminiscent of that found in some chol-derivatives displaying liquid-crystalline behaviour.[3] The shortest chol–chol intermolecular distances are in the order of 2.5 Å (1 − *x*, 1 − *y*, *z*). Note, the situation found here contrasts with the solid state

structure of a related bis(cholesteryldiethylphosphinite)Pd(II) complex where no significant intermolecular interactions were observed.[2c]

In summary, chol-derived phosphines with a wide range of physical properties should now be accessible with this synthetic protocol. Further studies are in progress to elucidate the mechanism and driving force leading to the formation of the new 3β-PMe_2chol ligand. We are also continuing to explore the potential of these new ligands in three major directions: (i) formation of three-dimensional scaffoldings to generate metallomesogens, (ii) the use of these functional phosphines for Wittig olefinations and finally (iii) the study of their transition metal complexes as precursors in asymmetric catalysis.

We warmly thank Drs A. Burger (ULP) and J.-F. Biellmann (ULP-CNRS) and Prof. M. Rohmer (ULP) for fruitful discussion. The CNRS is acknowledged for partial financial support.

Transition metal-catalysed addition reactions of H–heteroatom and inter-heteroatom bonds to carbon–carbon unsaturated linkages *via* oxidative additions

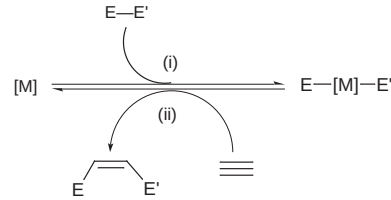
Li-Biao Han and Masato Tanaka*

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305-8565, Japan.
E-mail: mtanaka@ccmail.nimc.go.jp

Oxidative addition of inter-heteroatom bonds comprising B, Si, Ge, Sn, P, S, Se and Te with late transition metal complexes readily takes place at room temperature and triggers a variety of catalytic additions of the bonds to carbon–carbon unsaturated linkages. The new catalytic reactions are regio- and stereoselective and provide high yield syntheses of synthetically versatile heteroatom compounds.

Introduction

Transition metal complex catalysis in heteroatom chemistry is experiencing vigorous growth these days. This is partly because heteroatom-to-carbon bonds can be very reactive and versatile intermediates in synthetic organic chemistry. In addition, heteroatom compounds can exhibit biological activity. Furthermore heteroatom compounds, inclusive of polymeric ones, are useful as such or as precursors in various applications such as ceramics, heat-resistant materials, semiconductors and electroluminescent materials. Although metal complex-catalysed substitution reaction with heteroatom nucleophiles such as palladium-catalysed amination of organic halides[1] has been fairly well studied, metal complex-catalysed addition reactions of H–heteroatom and inter-heteroatom bonds (H–E, E–E′; E, E′ = heteroatom) to carbon–carbon unsaturated bonds have not been extensively explored until recently. The newly developed addition reactions generally give the products selectively in high yields under mild reaction conditions and hence are particularly attractive from the synthetic point of view. Although mechanistic details may vary depending on the heteroatom compounds used, most of the additions are overall envisioned to proceed *via* a simple sequence of events comprising (i) oxidative addition of an inter-heteroatom bond (E–E′) to a transition metal complex, (ii) insertion of an alkene or alkyne, and reductive elimination (Scheme 1). Exceptional



Scheme 1

reactions in this category that have been rather well studied include those of group 14 element compounds such as Si–H, Sn–H, Si–Si, Si–Sn, Si–CN and some of them are exploited in industry.[2] Transition metal-catalysed additions of B–H bonds, which provide a possibility to control regio-, stereo- and chemoselectivity in the hydroboration processes, have also been well studied.[3] This article focuses on the recent progress in the transition metal-catalysed additions of groups 13, 15 and 16 (B, N, P, S and Se) heteroatom compounds that are considered to proceed *via* a mechanism similar to Scheme 1. Since additions of group 14 element compounds and the catalysed hydroborations have been subjects of numerous review articles, they will not be discussed here.

Metal-catalysed additions of B–E bonds (E = B, Si, Sn, S)

In 1993, Miyaura and Suzuki reported addition reactions of diborons with alkynes (Scheme 2).[4] The addition of bis(pinacolato)diboron **1** to alkynes proceeds efficiently in the presence of a catalytic amount of $Pt(PPh_3)_4$ to afford the *cis*-bis(boryl)alk-

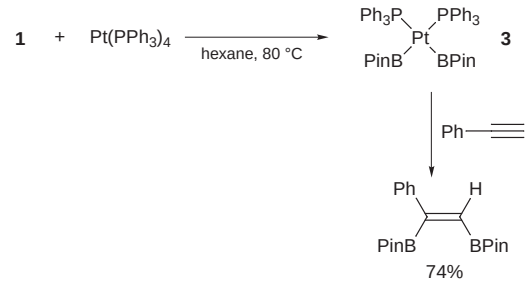
Li-Biao Han was born in Shandong, China in 1965. He finished his university education at Osaka University in 1988 and received his PhD in 1993 under the supervision of Professor N. Sonoda. After several years postdoctoral research experience, he joined the National Institute of Materials and Chemical Research in 1997.

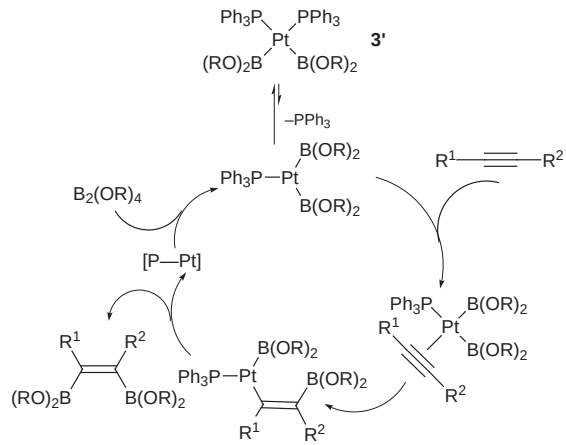
Masato Tanaka is the Director of the Department of Organic Chemistry of the National Institute of Materials and Chemical Research. He is also an Adjunct Professor of the Department of Industrial Chemistry, Science University of Tokyo. He received his PhD from Kyoto University in 1974 for his work on carbonylation and was a research associate with Professor Howard Alper at the University of Ottawa in 1977–1978. He won several awards, including the Progress Award in Synthetic Organic Chemistry (1986), a Commendation by the Minister of State for Science and Technology (1987), the Divisional Award of the Chemical Society of Japan (1994), and the Wilhelm Manchot Research Professorship (Pinguin Foundation, Germany, 1998).

enes **2** in high yields. In this diboration both terminal and internal alkynes are reactive as substrates. The reaction is accelerated in polar solvents such as DMF and MeCN, but also proceeds in non-polar solvents like hexane to give the products in good yields. $Pt(CO)_2(PPh_3)_2$ also exhibits high activity, but others such as $Pd(PPh_3)_4$ and $RhCl(PPh_3)_3$ that are efficient catalysts for hydroboration[3] are ineffective. Mechanistic studies by these authors and others have disclosed that oxidative addition of the B–B bond to the Pt complex is a key reaction that triggers the catalysis.[4–6] Indeed, $Pt(PPh_3)_4$ reacts with **1** to give a *cis* complex **3**, which reacts with an alkyne (but not with alkene) to afford the adduct (Scheme 3). Since a detailed study



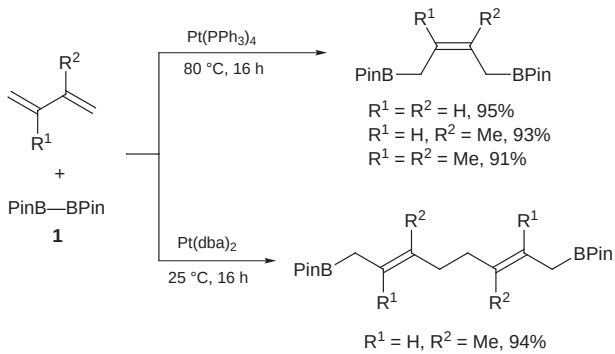
Scheme 3

on the reaction of *cis*-$Pt(BCat)_2(PPh_3)_2$ (Cat = $C_6H_4O_2$) with alkynes revealed that the addition reaction was strongly retarded by an addition of a free phosphine to the reaction mixture, dissociation of a phosphine ligand from **3′** generating three coordinate species is believed to precede the insertion of an alkyne (Scheme 4).



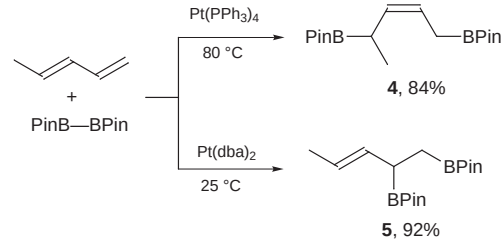
Scheme 4

1,3-Dienes also react bis(pinacolato)diboron **1** in the presence of $Pt(PPh_3)_4$ to form *Z*-1,4-adducts in high yields with excellent selectivities (Scheme 5).[7] Interestingly, when a



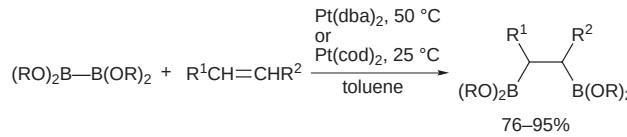
Scheme 5

phosphine-free platinum complex, $Pt(dba)_2$, is employed as catalyst, a 1:2 adduct of the diboron to the diene is obtained. Regioselectivity in the reaction of penta-1,3-diene varies depending on the platinum complex catalyst being phosphine-ligated or phosphine-free. Thus, 1,4-addition to penta-1,3-diene takes place with $Pt(PPh_3)_4$ to form **4**, whereas the same reaction with $Pt(dba)_2$ selectively affords the 1,2-addition product **5** (Scheme 6).



Scheme 6

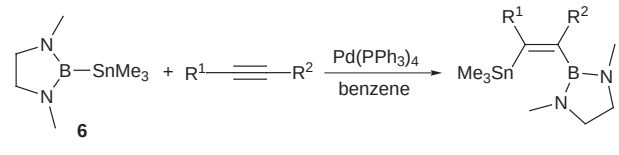
In contrast to the facile additions to alkynes, $Pt(PPh_3)_4$ does not catalyse the additions of diborons to alkenes. In 1995, Baker and co-workers briefly described that a phosphine–gold(I) complex was able to catalyse the addition of a diboron to styrenes to give desired 1,2-diboronate esters.[8] Very recently, phosphine-free platinum complexes such as $Pt(cod)_2$ and $Pt(dba)_2$ have been found to efficiently catalyse the diborations of terminal alkenes and strained cyclic alkenes to afford the addition products in high yields (Scheme 7).[9]



$(RO)_2B$ = PinB or CatB
Alkenes: ethylene, hex-1-ene, styrene, 4-methoxystyrene, 6-chlorohex-1-ene, cyclopentene, norbornene *etc.*

Scheme 7

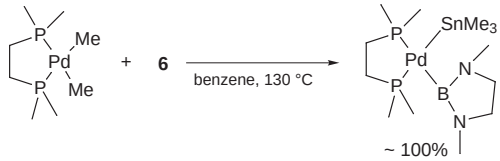
Palladium- or platinum-catalysed additions of other B–heteroatom bonds are also rapidly emerging. We have found a highly stereo- and regio-selective Pd-catalysed addition of a B–Sn reagent to alkynes, which represents the first addition reaction of a bond comprising groups 13 and 14 elements to unsaturated carbon linkages (Scheme 8).[10] The addition of **6** to



R^1 = n-C_6H_{13}, R^2 = H, 83%
R^1 = Ph, R^2 = H, 73%
R^1 = R^2 = Ph, 78%

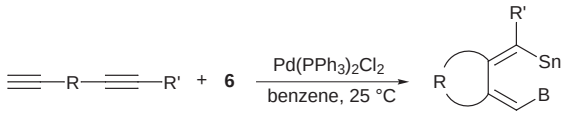
Scheme 8

terminal alkynes takes place rapidly even at room temperature to afford *cis*-adducts in high yields, although the presence of an N–B bond in the starting diboron reagent retarded the diborations of alkynes.[4] Both terminal and internal alkynes are reactive substrates. The reactions of terminal alkynes end up with the boryl group selectively attached to the terminal carbons. Mechanistic studies have substantiated that oxidative addition of the B–Sn bond of **6** to the palladium centre is involved in the catalytic cycle. In one case such an adduct was isolated and was fully characterized (Scheme 9) and the adduct proved to exhibit a high activity when employed as catalyst. Diynes also readily react with **6**; highly regio- and stereo-selective borylstannylative carbocyclization takes place to



Scheme 9

afford good yields of 1-(borylmethylidene)-2-(stannylmethylidene)cycloalkanes (Scheme 10).[11] Simple addition products to



R = $(CH_2)_3$, R' = H, 92%

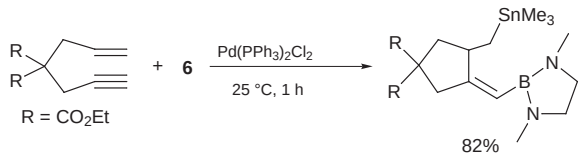
Scheme 10

the triple bonds are not found in the reaction mixture. It is surprising that even a very strained four-membered ring can be selectively formed nearly quantitatively starting with a hexa-1,5-diyne as substrate. An enyne compound also undergoes the borylstannylative carbocyclization (Scheme 11). These carbo-



R = CO_2Et

Scheme 11

cyclization reactions are very regioselective; the boryl group is selectively introduced to the more reactive unsaturated linkage, *i.e.* the terminal C≡C rather than internal one in the unsymmetrical diyne system and the C≡C rather than the C=C in the enyne system. On the basis of these experiments, the triple bond insertion to the Pd–B bond (in preference to the Pd–Sn bond) is believed to follow the oxidative addition of **6** in the catalytic cycle. The reaction of 1,3-dienes requires narrower tuning of the nature of the ligand. Triphenylphosphine–palladium complexes that were active in the reactions of alkynes, diynes, and enyne compounds are not so efficient with dienes. 4-Ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane [$P(OCH_2)_3CEt$ = etpo] proved to be the ligand of choice, the use of which results in more than 80% yields of 1,4-adducts (Scheme 12).[12]

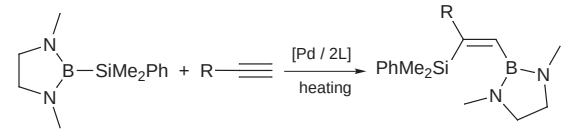
Scheme 12

In contrast to the B–Sn additions to alkynes, analogous B–Si additions are not straightforward and do not proceed efficiently under similar conditions. The $Pd_2(dba)_3$/etpo catalyst system is again the catalyst of choice but heating (typically 110 °C) is required for the reaction to take place (Scheme 13). The



Pd = $Pd_2(dba)_3$, L = $P(OCH_2)_3CEt$

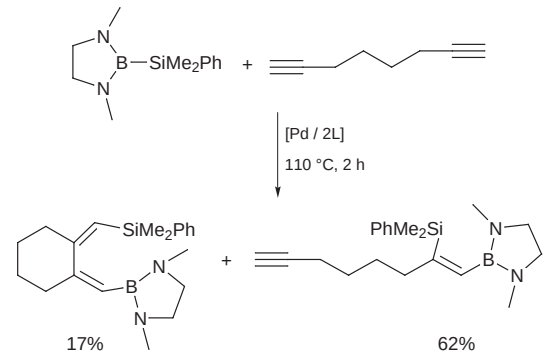
R = Ph, 97%

Scheme 13

$Pd_2(dba)_3/PMe_3$ system, which was among the better catalysts for the additions of disilanes or digermanes,[13] also exhibits respectable performance.[14] Both the regio- and stereo-selectivities of the B–Si addition to terminal alkynes are similar to those found in the B–Sn addition to give the *cis* adduct with the boryl group bound to the terminal carbon predominantly. Unlike the borylstannylative carbocyclization in which the cyclization products were exclusively produced, the reaction of octa-1,7-diyne with the silylborane is not selective but gives a mixture of a cyclization product and a simple addition product (Scheme 14) when catalysed by the $Pd_2(dba)_3$/etpo catalyst



Scheme 14

system. The palladium(0)–*tert*-alkyl isocyanide catalyst systems, which were efficient for the addition of Si–Si bonds,[15] are also active catalysts for the addition of another B–Si reagent to alkynes to produce similar *cis*-addition products (Scheme 15).[16]

Scheme 15

Successful addition of the Si–B reagent to alkenes has been achieved by using platinum complex catalysts (Scheme 16).[17] Thus, refluxing a mixture of the silylborane and 1-alkenes in dioxane in the presence of $Pt(CH_2{=}CH_2)(PPh_3)_2$ affords the adducts **7** with the boryl group bonded to the internal carbon of the double bond; note that the regioselectivity is the reverse of that found in addition reactions of terminal alkynes. Besides **7**, significant amounts of 1-boryl-1-silylalkanes **8** are also formed in the reactions of 1-alkenes.[18] Interestingly, the palladium(0)–*tert*-alkyl isocyanide complexes and $Pd(PPh_3)_4$, both of which are efficient in the Si–B and Sn–B additions to alkynes, respectively, do not show catalytic activity towards the addition to alkenes.

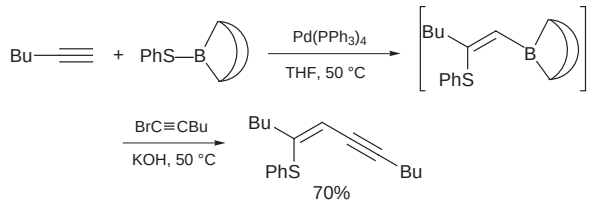
Scheme 16

The palladium-catalysed addition of B–S bonds to terminal alkynes is another example of metal catalysed B–heteroatom bond additions.[19] The reaction takes place in THF to afford the adduct in high yields and selectively with the boryl group bound to the terminal carbons, as for the B–Si and B–Sn additions. Isolation of the adducts is hampered by the very high susceptibility of the C–B bond to cleavage, but the product generated *in situ* can be used for further manipulations, *e.g*. the Suzuki–Miyaura coupling reaction, without isolation (Scheme 17). A catalytic cycle starting with the oxidative addition of the



Scheme 17

B–S bond to Pd has been proposed for this reaction, but the mechanistic detail remains to be clarified.

Metal-catalysed additions of N–H, P–H and P–Se bonds

Compared to other heteroatom compounds, only a few metal-catalysed additions of group 15 element compounds are known. Although catalytic additions of N–H bonds to unsaturated bonds are highly attractive from the practical viewpoint,[20] only limited success has been achieved.[21] Milstein and co-workers have demonstrated that aniline oxidatively adds cleanly to an electron-rich Ir^{I} complex, $[Ir(PEt_3)_2(C_2H_4)Cl]$, to produce an Ir^{III} anilido hydrido complex. Despite its low catalytic efficiency, the Ir^{III} anilido hydrido complex undergoes insertion of norbornene leading to a new complex containing a chelating aminoalkyl ligand, from which the addition product is formed through reductive elimination (Scheme 18).[22] A catalytic system generated from $[RhCl(PEt_3)_2]_2$ and LiNHPh in aniline has also been used for hydroamination of norbornene, in which a rhodium anilido complex is probably involved as key catalytic species. Another adduct arising from addition of an *ortho* C–H bond of aniline to norbornene is also formed in addition to the desired hydroamination product (Scheme 19).[23] Recently, asymmetric hydroamination of norbornene with aniline was reported by use of an Ir^{I}–binap catalyst system, albeit in low chemical yields.[24] An addition of fluoride ion to the reaction mixture enhances the catalytic activity to give 22% chemical yield and 95% ee of the *exo*-2-(phenylamino)norbornane (Scheme 20). Palladium-catalysed hydroamination of allenes has also appeared recently (Scheme 21).[25] Addition of acetic acid facilitates the reaction, but the detailed reaction mechanism remains to be clarified.

Transition metal-catalysed additions of phosphorus compounds *via* oxidative addition are still very rare. Pringle and

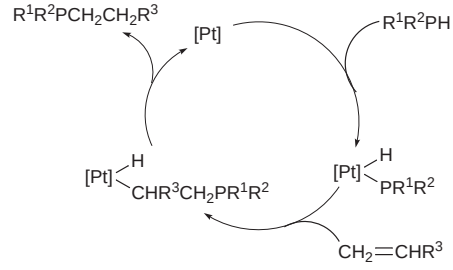
Scheme 21

coworkers have reported that PH_3 reacts with acrylonitrile in the presence of $Pt[P(CH_2CH_2CN)]_3$ to give $P(CH_2CH_2CN)_3$ (Scheme 22).[26] The reaction has been proposed to proceed *via*

Scheme 22

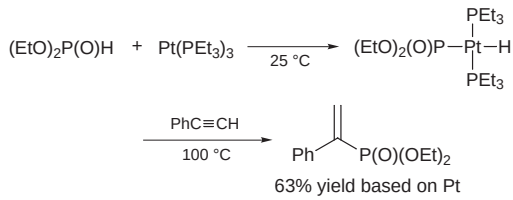
oxidative addition of the P–H bond to platinum. A recent mechanistic study has confirmed this idea, showing furthermore that the reaction is likely proceed through insertion of acrylonitrile into the Pt–P (but not Pt–H) bond, followed by a C–H reductive elimination (Scheme 23).[27]



Scheme 23

We also have found that oxidative addition of the H–P bonds of hydrogen phosphonates $[(RO)_2P(O)H]$ with Pt^0 complexes

readily takes place to afford the corresponding hydrido(phosphoryl) complex quantitatively. Heating the complex with phenylacetylene formed a vinylphosphonate (Scheme 24).[28]



Scheme 24

Accordingly, catalytic addition of hydrogen phosphonates to alkynes readily proceeds when palladium complexes are used as catalysts (hydrophosphorylation). Markovnikov adducts are normally formed in high yields and with high selectivities (Scheme 25). When oct-4-yne was employed as substrate, only

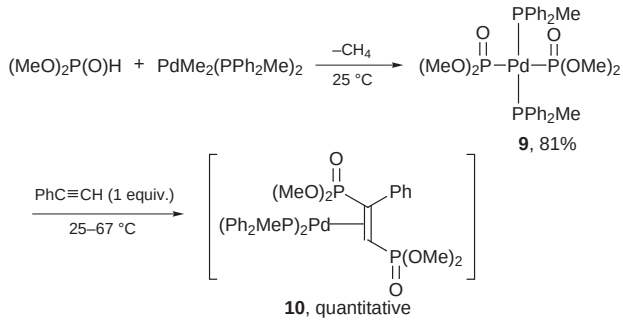
Scheme 25

the *cis*-adduct was selectively obtained. Among the complexes screened, $Pd(CH_2{=}CH_2)(PPh_3)_2$ and $PdMe_2(PPh_2Me)_2$ show highest activity. The frequently employed $Pd(PPh_3)_4$ also catalyses the addition, albeit slowly. Pd^{II} complexes such as $PdCl_2$, $Pd(OAc)_2$, $PdCl_2(PPh_3)_2$ and $PdCl_2(PhCN)_2$ are totally ineffective, presumably because of the difficulty of these precursor complexes being reduced to Pd^0 active species. When $PdMe_2(PPh_2Me)_2$ is used as precursor, Pd^0 species **10** is readily formed through the sequence shown in Scheme 26,[29] and the



Scheme 26

species **10** does catalyse the addition of $(MeO)_2P(O)H$ to phenylacetylene efficiently.

Unlike the reaction of alkynes with hydrogen phosphonates, the reactions with $Ph_2P(O)H$ in the presence of $Pd(PPh_3)_4$ catalyst proceeds under very mild conditions (hydrophosphinylation) and selectively forms *anti*-Markovnikov products through *cis*-addition (Scheme 27).[30] The P–H bond of $Ph_2P(O)H$ also undergoes oxidative addition with Pd^0 and Pt^0 complexes to afford *cis*-MH[P(O)Ph_2][PPh_2(OH)](PEt_3) (M = Pd, Pt) (Scheme 28).[30,31] Although platinum complex **11a** does not react with oct-1-yne upon heating, **11b** does react in benzene at room temperature to afford two regioisomeric alkenylpalladium species. Heating the reaction mixture at 70 °C affords the

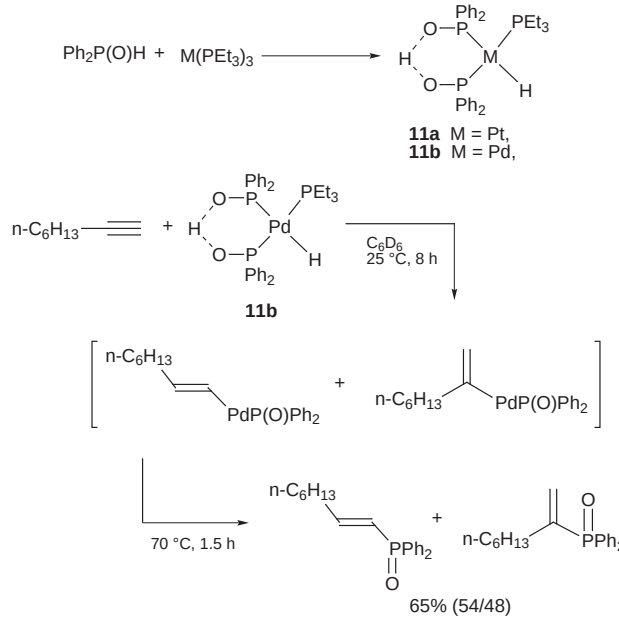
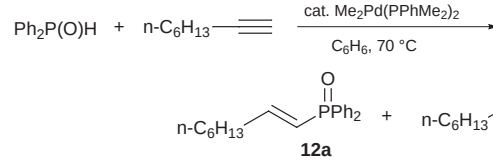
Scheme 27



Scheme 28

corresponding alkenylphosphine oxides. This result indicates that the catalysis proceeds through insertion of an alkyne into the Pd–H bond (hydropalladation) followed by reductive elimination of the alkenyl and phosphinyl ligands forming the product, which differs from the platinum-catalysed addition of PH_3 to acrylonitrile (*vide supra*).[27]

Very interestingly, the regioselectivity of the hydrophosphinylation of alkynes can be easily switched by addition of only one drop of $Ph_2P(O)OH$ to the reaction mixture (Scheme 29).[32]

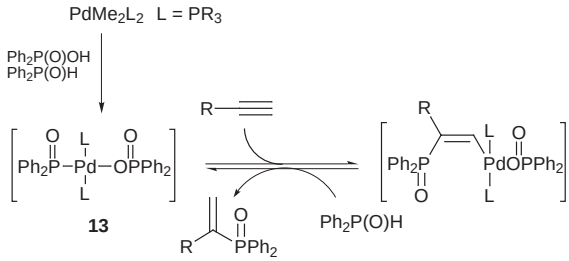


mol% $Ph_2P(O)OH$ added	% yield of **12** (**a**/**b**)
0	75 (88/12)
1	92 (21/79)
5	99 (5/95)
10	96 (4/96)

Scheme 29

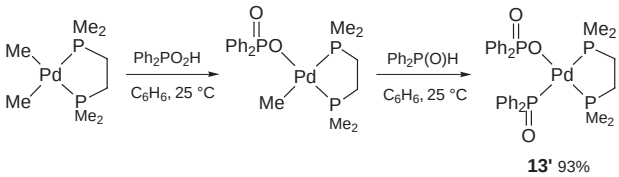
Thus, when an equimolar mixture of $Ph_2P(O)H$ and oct-1-yne in C_6D_6 was heated at 70 °C for 2 h in the presence of a catalytic quantity (5% relative to the substrate) of *cis*-$Me_2Pd(PPhMe_2)_2$, isomeric **12b** and **12a** were formed in 75% total yield with a ratio of 12:88. However, another reaction run in the presence of only 1 mol% (relative to the substrate) of $Ph_2P(O)OH$ under otherwise identical conditions resulted in 92% total yield and a **12b**/**12a** ratio of 79:21. The regioselectivity for **12b** was further improved with an increase in the quantity of $Ph_2P(O)OH$ to

achieve nearly quantitative formation of the adducts in a ratio of 95:5 in the presence of 5 mol% $Ph_2P(O)OH$. Besides the phosphinic acid, dibutyl phosphate and phosphoric acid work as well to give **12b** as the major product. However, the reversal is not observed with HMPA, acetic acid or benzoic acid. To explain the reversal we propose another reaction mechanism, in which a new palladium species **13** plays a key catalytic role (Scheme 30). Complex **13′** was indeed generated and isolated



Scheme 30

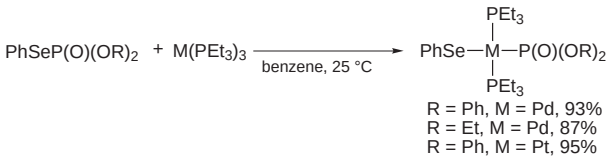
when $PdMe_2(PR_3)_2$ was treated with $Ph_2P(O)H$ and $Ph_2P(O)OH$ (Scheme 31). In addition, species **13′**, when used as



Scheme 31

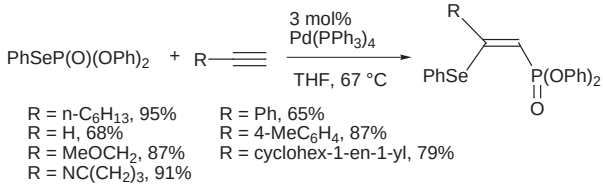
catalyst in the addition reaction of $Ph_2P(O)H$ to oct-1-yne, exhibited essentially the same activity and regioselectivity as the combination of $PdMe_2(dmpe)_2$ [dmpe = 1,2-bis(dimethylphosphino)ethane] and $Ph_2P(O)OH$.

Besides P–H bonds, oxidative additions of other P–heteroatom bonds also proceed and catalytic addition reactions can be designed. For instance, a selenophosphate readily reacts with Pd^0 and Pt^0 complexes to generate seleno(phosphoryl)metal(II) species (Scheme 32). *cis*-Additions of the selenophosphate to



Scheme 32

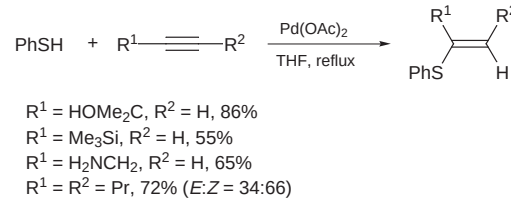
terminal alkynes also readily proceed to afford the adducts regio- and stereo-selectively with the phosphoryl group bound to the terminal carbons (Scheme 33).[33]



Scheme 33

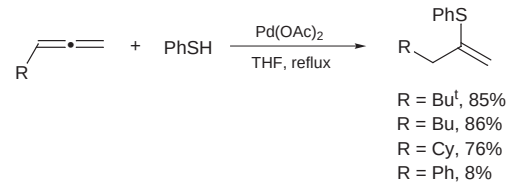
Metal-catalysed additions of chalcogen compounds

Metal-catalysed addition reactions of chalcogen reagents to carbon–carbon unsaturated bonds did not attract much attention until the pioneering work reported by Ogawa, Sonoda and their co-workers.[34] In the presence of $Pd(OAc)_2$, thiophenol and selenophenol react with terminal alkyne to produce Markovnikov *cis*-addition products in good yields with high regioselectivity (Scheme 34).[35] Allenes[36] and conjugated en-

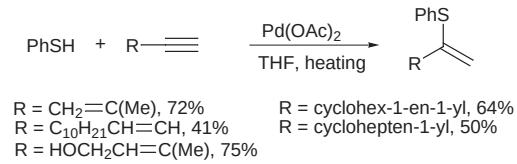


Scheme 34

ynes[37] similarly react with PhSH (Schemes 35 and 36). A very interesting thioformylation reaction also proceeds when the

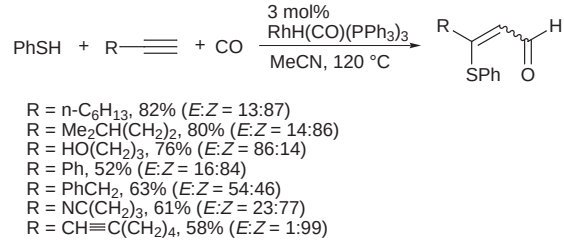


Scheme 35



Scheme 36

addition of PhSH to alkynes was carried out under a CO atmosphere in the presence of a catalytic amount of Rh^I complex (Scheme 37).[38] $Pd(OAc)_2$, which is a good catalyst for the addition of PhSH, does not exert activity towards the



Scheme 37

thioformylation reaction. The use of $Pd(PPh_3)_4$ and $PdCl_2(PPh_3)_2$ resulted in a rather complicated mixture. On the other hand, addition of chalcogen–chalcogen bonds (S–S and Se–Se) to alkynes is efficiently catalysed by $Pd(PPh_3)_4$ to give predominantly the *cis*-addition products in good yields (Scheme 38).[39] When the reaction is run under a CO atmosphere, the simple addition of the dichalcogenides is suppressed, resulting in a selective carbonylative addition to produce the *Z* products in high yields (Scheme 39). A very interesting variation is the reaction of alkynes bearing an OH group at a proper position (propargylic alcohols, for example); a novel thiolative lactonization takes place to afford the corresponding lactons in good yields (Scheme 40).[40] The metal-catalysed additions of S–S bonds are applicable to other substrates. For example, $(ArS)_2$ undergoes telomerization with isocyanides (C=NAr′) in the

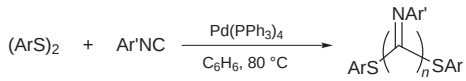
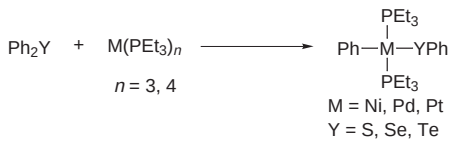
Scheme 40

presence of $Pd(PPh_3)_4$ to furnish novel telomeric products, $(ArS(C{=}NAr')_nSAr)$ (Scheme 41).[41]



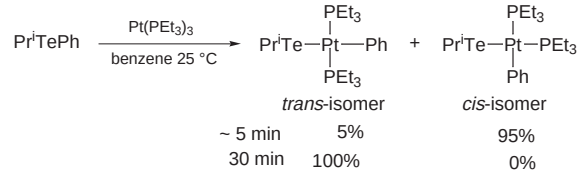
Scheme 41

Oxidative additions of S–H and S–S bonds to transition metal complexes have long been known[42] and are probably involved in the foregoing catalytic reactions. Related C–S bond scissions by metal complexes have also been extensively studied for modeling the hydrodesulfurization (HDS) process. However, similar studies on other chalcogen compounds are rare.[43] A recent systemic study on the reaction of Ph_2Y (Y = S, Se, Te) with group 10 transition metal complexes $M(PEt_3)_n$ (M = Ni, Pd, Pt; n = 3, 4) has revealed the formation of corresponding *trans*-$MPh(YPh)(PEt_3)_2$ complexes in high yields (Scheme 42).[44] However, the reaction of $PhTePr^i$ with $Pt(PEt_3)_3$ clearly



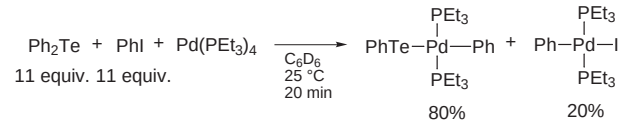
Scheme 42

suggests that *cis*-$PtPh(TePr^i)(PEt_3)_2$ is the initial product, which isomerizes rapidly to the thermodynamically more stable *trans*-form on standing (Scheme 43). The ease of the oxidative



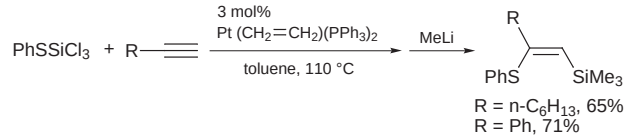
Scheme 43

addition decreases in the order of C–Te > C–Se > C–S, which is the reverse of the order of their bond strengths and has similarity to the trend found with organic halides. The C–Te bond is extremely reactive; its oxidative addition to Pd^0 is even faster than the corresponding iodide (Scheme 44)! Oxidative



Scheme 44

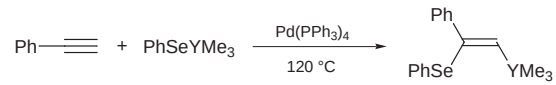
addition of chalcogenides to the palladium and platinum complexes seems quite general. In practice, chalcogenides of Si, Ge and Sn were more reactive in the oxidative addition reaction than their corresponding C–chalcogen bonds.[45] The reactivity trends were S–Si < Se–Si < Te–Si, and Si–Se < (Ge–Se) < Sn–Se, *i.e.* a heavier element bond reacted more readily. Obviously, these results have suggested new clues for the manipulations of chalcogen compounds using transition metal catalysts.[46] For example, we have found the addition of $PhSSiCl_3$ to terminal alkynes is efficiently catalysed by Pt^0 complexes to produce the *Z* adducts in high yields regioselectively with the Si moiety bound to the terminal carbons (Scheme 45).[47] Similar to the additions of $PhSeSiMe_3$ and



R = n-C_6H_{13}, 65%
R = Ph, 71%

Scheme 45

$PhSeGeMe_3$ to phenylacetylene catalysed by $Pd(PPh_3)_4$ (Scheme 46),[34] this reaction is envisioned to proceed *via*



Y = Si, 21%; Ge, 36%

Scheme 46

oxidative addition of the S–Si bond. However, there is no need to prepare starting $PhSSiCl_3$ in advance, since $PhSSiCl_3$ is generated *in situ* from $(PhS)_2$ and $(SiCl_3)_2$. In a new protocol, the same adduct can be obtained regio- and stereo-selectively in good yields, by simply heating a mixture of a disulfide, $(SiCl_3)_2$ and an alkyne in the presence of the platinum catalyst (Scheme 47). Possible byproducts coming from additions of the disulfide and/or disilane are not formed at all.

Conclusion

As described in this article, the simple combination of the classical elemental processes, oxidative addition, insertion of unsaturated compounds and reductive elimination, proves powerful for the design of new catalytic reactions in heteroatom chemistry. We believe homogeneous catalysis will find more opportunities not only in organic synthesis but in organometallic synthesis. Accumulation of knowledge concerning the chemistry of transition metal–heteroatom bonds is a pre-

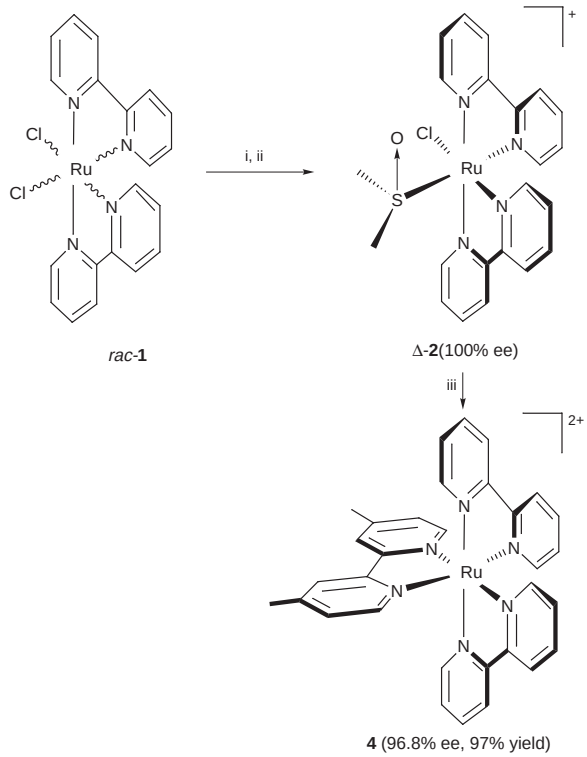
Received (in Cambridge, UK) 14th September 1998, Accepted 25th January 1999

The new chiral ruthenium bis(bpy) sulfoxide reagent, Δ-*cis*-[Ru(bpy)$_2$(dmso)Cl]PF$_6$ (100% ee following HPLC resolution) is used to prepare Δ-[Ru(bpy)$_2$(dmbpy)][PF$_6$]Cl in excellent yield (97%) with almost complete retention of absolute configuration (96.8%), as confirmed by X-ray crystallographic studies on a single enantiomer of [Ru(bpy)$_2$(dmbpy)][PF$_6$]Cl (obtained without resolution or chromatographic methods) and by analysis of the optical properties of both the precursor and product.

Optically pure octahedral ruthenium complexes have been known for many years, and are important synthetic targets.[1] Many synthetic procedures are known for their preparation but almost all of these processes rely on a resolution technique at the final stage in the preparation.[2,3] Although a diastereoselective synthesis using the so-called chiragen ligands has been reported,[4–6] the absence of a *general* asymmetric synthesis of ruthenium tris(bpy) complexes necessitates a compromise position. The preparation, and resolution of an enantiomerically pure precursor, which is stable enough to be handled, yet sufficiently reactive to allow a quantitative conversion to the desired complex, ideally with no loss of optical activity during this transformation represents such a compromise. The envisioned precursor should also comprise simple materials, that can be easily combined, then readily separated. Such methodology has been reported previously by Hua and von Zelewsky[7,8] who have developed [Ru(bpy)$_2$(py)$_2$]$^{2+}$, and by Keene and coworkers,[1,3,9] who have developed [Ru(bpy)$_2$(CO)$_2$]$^{2+}$. Both of these complexes have been resolved and subsequently applied in the synthesis of enantiomerically pure ruthenium tris(bpy) complexes in a stereoselective fashion. We have sought to add to this highly interesting work by searching for a new ruthenium complex which bears the aforementioned properties, since the availability of the widest possible range of chiral reagents permits the synthetic inorganic chemist to carefully tune the reaction conditions according to the type of product that is required. Herein we wish to report that such a precursor has been realized during the course of our research into the photochemical properties of octahedral ruthenium complexes.[10] Racemic *cis*-[Ru(bpy)$_2$Cl$_2$] **1** is converted to *cis*-[Ru(bpy)$_2$(Me$_2$SO)Cl]Cl **2** when it is heated at 85 °C in dry, deaerated Me$_2$SO for 5 h. After evaporation of the solvent, the racemic product is treated with ether and hot acetone to remove excess Me$_2$SO. The Δ- and Λ-enantiomers of **2** can be readily and completely separated by HPLC,† using a chiral stationary phase during which a counter ion exchange of Cl$^-$ to PF$_6^-$ occurs, and the enantiomers are found not to interconvert, even upon heating in Me$_2$SO for 2 h. NMR techniques allow us to confirm the sulfoxide product,‡ and IR shows that the sulfoxide is S-, not O-bonded, as demonstrated by the S-ligated sulfoxide stretching frequency at 1120 cm^{-1}.[11] It is important to note that **2**·Cl$^-$ is soluble in polar/protic solvents [much more so than Ru(bpy)$_2$Cl$_2$], but is slightly unstable upon prolonged exposure to light, slowly decomposing over several hours if left uncovered. However, the light sensitivity is not so high that completely dark conditions are required, and short exposure times do not result in any noticeable photodegradation.

Stereochemistry at the metal center is almost completely retained when resolved Δ-**2**·PF$_6$ (ee = 100%) is heated to 75 °C for 2 h with 4,4′-dimethyl-2,2′-bipyridine **3** (dmbpy) in a mixture of ethanol and acetic acid (8 : 1), affording Δ-[Ru(bpy)$_2$(dmbpy)][PF$_6$]Cl **4** in 97% yield, with an ee of 96.8% (Scheme 1). Thus, the dmso precursor reacts with near quantitative conversion, and shows almost complete stereoretention, rendering it suitable as a chiral reagent in the stereocontrolled synthesis of ruthenium tris(bpy) complexes.



Scheme 1 *Reagents and conditions*: i, DMSO, 85 °C, 5 h; ii, HPLC resolution; iii, dmbpy, EtOH–AcOH, 75 °C, 2 h.

The circular dichroism (CD) and UV–VIS spectra of both Δ-**2** and **4** are shown in Fig. 1. The main features of the CD spectra are the ligand centered bands at *ca*. 275 nm, and the MLCT bands at *ca*. 450 nm. Assignments are based on previously reported data for **1** and related ruthenium complexes.[12–14] The spectra of Δ-**2** and **4** are supported by strong, independent structural data. It should be noted that because the synthesis was stereoretentive, *no resolution procedure* was applied either in the synthesis or in the purification. The material obtained was

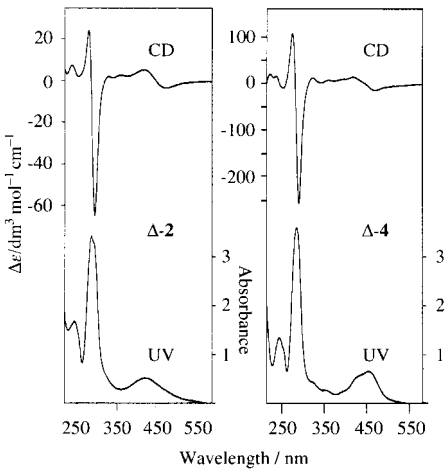


Fig. 1 CD and UV–VIS spectra of Δ-**2** and Δ-**4**.

subsequently shown to be enantiomerically pure by CD spectroscopy and HPLC. A crystal of **4** was grown from this sample using an EtOH–MeCN mixed solvent and subjected to X-ray analysis. The chirality was established as Δ using the method of Bijvoet[15] as indicated by the Flack parameter and *R* factor tests. The structure obtained is shown in Fig. 2.§ This study is therefore of high interest, as there are very few examples of the X-ray structures of enantiomerically pure ruthenium polypyridyl complexes in the literature which are accompanied by CD spectra.[3] The absolute configuration at the metal centre was also confirmed by comparison of the CD spectra and X-ray crystal structure of **4** with the previously recorded X-ray crystal structure of Λ-[Ru(dmbpy)$_2${4,4′-bis[(*R*)-(+)-α-phenylethylamido]-2,2′-bipyridine}][PF_6]$_2$ which has known stereocentres, and was therefore solved with complete certainty.[16] In **4**, the metal is in an octahedral environment with Ru–N distances ranging from 2.055(5) to 2.077(5) Å.

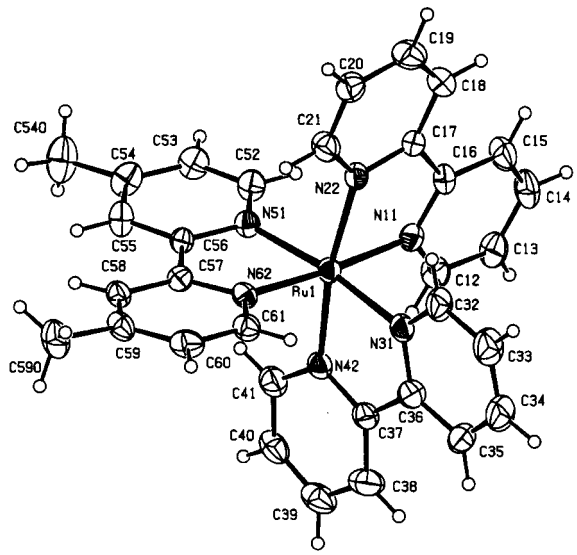

Fig. 2 ORTEP view of molecule $\mathbf{4}^{2+}$ from $\mathbf{4}\cdot 2PF_6^-$ with thermal ellipsoids at 30% probability.

In summary, *cis*-[Ru(bpy)$_2$(Me_2SO)Cl]PF_6 **2** can be prepared using very simple experimental techniques. This ruthenium bis(bpy) sulfoxide is stable (in the absence of strong light), and can be readily resolved to give the new, enantiomerically pure chiral reagent. This can be used for the synthesis of ruthenium tris(bpy) complexes with almost complete stereoretention at the metal centre, as exemplified by the preparation of **4**, which has been confirmed by CD and X-ray methods. To date, only two other complexes have been reported that can be used in this manner, and these have received a good deal of attention, demonstrating the importance of this type of reagent.[1,3,7–9] The synthesis outlined above is both simple and reliable, affording a product with a high enantiomeric excess, in near quantitative yield. This easy to handle chiral sulfoxide reagent is already beginning to prove invaluable in the synthesis of complicated, enantiomerically enriched/pure ruthenium tris(bpy) complexes (for example, the synthesis of a novel tetrakis[ruthenium tris(bipyridine)]calix[6]arene derivative with good diastereomeric purity[17]), and its use in this role will be the subject of future reports from our laboratories.

Notes and references

† HPLC was carried out using a CHIRACEL OD-R column (Diacel Chemical Industries Ltd.) (20 mm diameter × 250 mm length) with aqueous $NaPF_6$ (1 mol dm^{-3}) as the mobile phase. For a flow rate of 3 ml min^{-1}, retention times of 16.90 min for Δ-**2**, 34.6 min for Δ-**4** and 29.6 min for Λ-**4** were observed.

Received (in Liverpool, UK) 13th December 1998, Accepted 18th January 1999

The rate constants for the reaction of a cumylperoxyl radical with Bu_3SnH and $(TMS)_3SiH$ were determined at 72.5 °C to be 1600 and 66 M^{-1} s^{-1}, respectively, by using inhibited hydrocarbon oxidation methodologies.

In the last two decades, radical chain reactions have proven to be valuable in synthetic organic chemistry.[1a] The majority of such chain processes have been carried out by using Bu_3SnH or $(TMS)_3SiH$, which are the most widely used reagents under reduction conditions.[1] For a synthetically useful radical chain reaction the intermediates must be *disciplined*. The concept of discipline[2] in free radical reactions is strictly connected with the kinetic information of each individual step, although upon first consideration, the importance of the kinetic knowledge might be less apparent in planning a synthetic strategy.

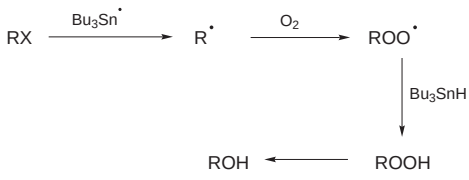
The reaction of peroxyl radicals with organic substrates is one of the most important classes of reactions in chemistry,[3] being the key step of several processes, *e.g.* autoxidation of synthetic polymers, lipid peroxidation and DNA damage. The use of alkylperoxyl radicals in synthesis is limited to a few procedures.[4,5] In one of them, the conversion of halides to alcohols has recently been approached by tin hydride reduction under aerobic conditions.[5] The reaction sequence that has been suggested is shown in Scheme 1. Examples in which the alkyl radical rearranges itself prior to the reaction with molecular oxygen are reported,[5] although in some cases the reaction is sluggish and gives undesired products.[6] Nakamura and co-workers were able to run these experiments under conditions where hydroperoxides were isolated in good yields.[7] In one case, the $(TMS)_3SiH$ mediated halide to alcohol transformation was reported to give a moderate yield.[7] In all these transformations, the reaction of a peroxyl radical with a tin or silicon hydride is crucial. Kinetic information regarding this step is not available. In their recent mechanistic studies on model DNA damage, Greenberg and co-workers[8] arbitrarily assumed the rate constants for the ROO• radical with Bu_3SnH to be 5×10^3 M^{-1} s^{-1} at 55 °C in THF. Following these considerations, the knowledge of the rate constants for the reaction of peroxyl radicals with Bu_3SnH and $(TMS)_3SiH$ turns out to be necessary for better synthetic planning as well as a reference reaction for mechanistic studies.

Herein we report the rate constants of a cumylperoxyl radical with $(TMS)_3SiH$ and Bu_3SnH which have been determined by using inhibited hydrocarbon oxidation methodologies.[9,10] In particular, two different kinetic approaches were used for the two reducing agents, depending on the presence or absence of an induction period when they are used as antioxidants. Scheme 2 shows that the initiation and propagation steps are identical for the two methods, whereas the termination steps are different.

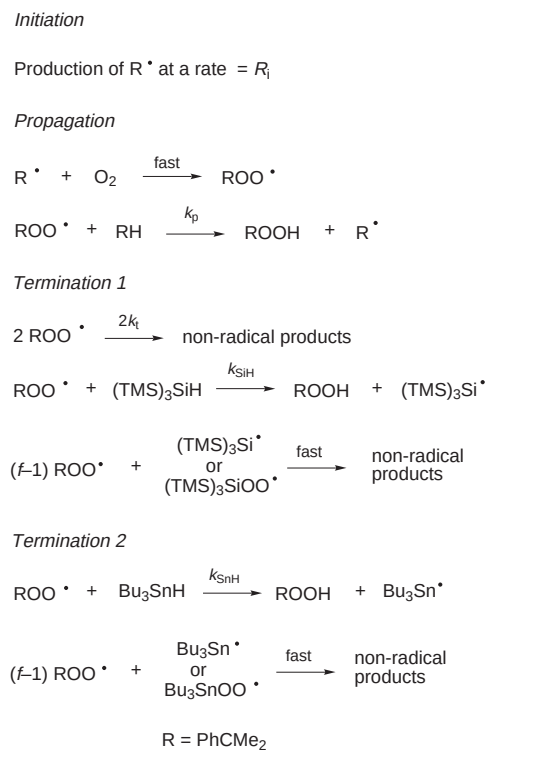
Providing that conditions can be found in which *termination 1* is applied, the rate constant for H-atom abstraction from the silane by cumylperoxyl radicals can be obtained from eqn. (1),[9]

$$\frac{(-\mathrm{d}[O_2]/\mathrm{d}t)_0}{(-\mathrm{d}[O_2]/\mathrm{d}t)} - \frac{(-\mathrm{d}[O_2]/\mathrm{d}t)}{(-\mathrm{d}[O_2]/\mathrm{d}t)_0} = \frac{fk_{SiH}[(TMS)_3SiH]_0}{(2k_tR_i)^{1/2}} \quad (1)$$

where $(-\mathrm{d}[O_2]/\mathrm{d}t)$ and $(-\mathrm{d}[O_2]/\mathrm{d}t)_0$ represent the initial rate of oxidation of cumene with or without $(TMS)_3SiH$.‡ The stoichiometric factor f, which is the number of cumylperoxyl radicals trapped by each molecule of silane, is assumed to be equal to 2.§ The inhibition of thermally initiated (0.021 M of AIBN at 345.5 K) oxidation of pure cumene by $(TMS)_3SiH$ (concentration range of 1.84×10^{-4} to 6.13×10^{-4} M) is found to be the case. Fig. 1 shows that the oxidation rate of cumene decreases upon increasing the concentration of silane without an induction period. On the other hand, Fig. 1 also shows the linear regression analysis of eqn. (1), whose slope provides $2k_{SiH}/(2k_t R_i)^{1/2}$ to be 7.1×10^2 M^{-1}. Since the rate of radical production[11]



Scheme 1



Scheme 2

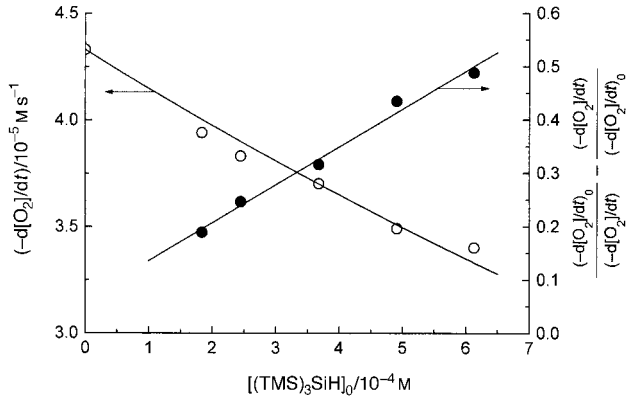


Fig. 1 Plots of (○) $-d[O_2]/dt$ and (●) $(-d[O_2]/dt)_0/(-d[O_2]/dt) - (-d[O_2]/dt)/(-d[O_2]/dt)_0$ *vs.* $[(TMS)_3SiH]$; [AIBN] = 0.021 M at 345.5 K.

and the termination for cumylperoxyl radicals[12] are $R_i = 1.09 \times 10^{-6}$ M s^{-1} and $2k_t = 3.2 \times 10^4$ M^{-1} s^{-1}, respectively, we calculated $k_{SiH} = 66.3$ M^{-1} s^{-1} at 345.5 K.

The inhibition of thermally initiated (0.0172 M of AIBN at 345.5 K) oxidations of pure cumene by Bu_3SnH (concentration range of 1.07×10^{-3} to 3.20×10^{-3} M) shows an induction period (τ). *Termination 2* in Scheme 2 describes the inhibition mechanism and the initial rate of oxidation (before exiting from the induction period), given by eqn. (2), of peroxyl radicals

$$(-d[O_2]/dt) = \frac{k_p[RH]_0 R_i}{f k_{SnH}[Bu_3SnH]_0} \quad (2)$$

trapped by each molecule of Bu_3SnH. The use of Boozer *et al.*'s induction period method,[13] of which an example is illustrated in Fig. 2 (*i.e.* suppression of the oxygen uptake by the presence of Bu_3SnH) allows the determination of the τ values. Then the stoichiometric factor f can be obtained from $f = R_i\tau/[Bu_3SnH]_0$.[9,10] All the data are summarized in Table 1. From the slope of the linear plot between $-d[O_2]/dt$ and $1/[Bu_3SnH]_0$, the

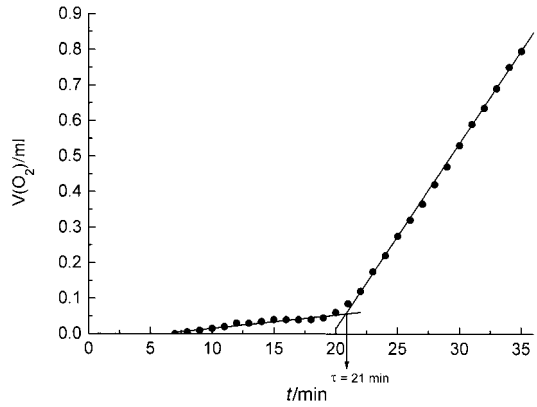

Fig. 2 Oxygen consumption during the AIBN-initiated (0.0172 M) oxidation of cumene in the presence of 2.64×10^{-3} M of Bu_3SnH at 345.5 K.

Table 1 Kinetic data for the oxidation of cumene in the presence of Bu_3SnH[a]

$(d[O_2]/dt)$[b]/M s^{-1}	$[Bu_3SnH]_0$/M	v	τ/min	f
10.94×10^{-6}	1.07×10^{-3}	11.8	10	0.52
7.01×10^{-6}	1.64×10^{-3}	7.5	15	0.51
3.15×10^{-6}	2.64×10^{-3}	3.4	21	0.44
4.67×10^{-6}	3.20×10^{-3}	5.0	20	0.35

[a] [AIBN] = 0.0172 M, $R_i = 0.89 \times 10^{-6}$ M s^{-1} at 345.5 K. [b] $d[O_2]/dt = (d[O_2]/dt)_{exp} - R_i$.

$k_p[RH]_0R_i/fk_{SnH}$ was found to be 11.6×10^{-9} s^{-1}.§ Taking $k_p = 1.3$ M^{-1} s^{-1},[12] $[RH]_0 = 7.188$ M, $R_i = 0.89 \times 10^{-6}$ M s^{-1},[11] and an average of $f = 0.46$, we calculated $k_{SnH} = 1559$ M^{-1} s^{-1} at 345.5 K.

In summary, the rate constants of 66 and 1600 M^{-1} s^{-1} at 345.5 K were obtained for the reaction of cumylperoxyl radicals with $(TMS)_3SiH$ and Bu_3SnH, respectively. Therefore, the alkylperoxyl radicals abstract a hydrogen atom from the tin hydride 24 times faster than from the silane. $(TMS)_3SiH$ is a notably less reactive hydrogen donor than Bu_3SnH, mainly due to the *ca.* 5 kcal mol^{-1} difference in bond dissociation energies.[14] For comparison, primary alkyl radicals and acyl radicals abstract hydrogen from the silane five and 16 times slower, respectively, than from the tin hydride at the same temperature and in much faster processes.[14]

Notes and references

† This relation can be used when the initial oxidation rate and the initiation rate remain essentially constant under the experimental conditions.
‡ This is possible if the reactions in *termination 1* dominate the systems and if the products of these reactions are not active towards initiation.
§ Since the chain length of oxidation [*i.e.* $\nu = (-d[O_2]/dt)_{exp}/R_i$] is less than 12, the initial rate of oxidation is corrected for oxygen absorption by the initiator, and nitrogen evolution from the initiator, *i.e.* $-d[O_2]/dt = (-d[O_2]/dt)_{exp} - R_i$, where the $(-d[O_2]/dt)_{exp}$ is the experimental initial rate of cumene oxidation.

Received (in Liverpool, UK) 10th December 1998, Accepted 19th January 1999

Thiyl radicals, generated from biologically relevant thiols under biomimetic conditions, reversibly attack the double bonds of unsaturated phospholipids containing *cis*-fatty acid residues either in lipid solutions or lipid vesicles, thus producing phospholipids containing *trans*-fatty acid residues in high yield.

Radical-based damage of biologically relevant molecules has increasingly attracted the interest of researchers from different scientific fields, from chemistry to medicine. To the best of our knowledge, reported radical processes involving membrane phospholipids are limited to lipid peroxidation,[1] and to a recently reported homolytical cleavage of lysophospholipids.[2]

In cell membranes, the *cis* configuration of unsaturated fatty acid residues regulates the self-organization of phospholipids. The enzymatic *cis–trans* isomerization[3] has recently been found to affect the lipid assembly since the *trans* arrangement resembles the structure of saturated fatty acids.[4] From a chemical perspective, the *cis* to *trans* conversion of double bonds is a thermodynamically favoured process,[5,6] which can also occur by the reversible addition of a free radical.[7] In this context, thiyl radicals are very efficient isomerizing agents.[7,8] We report herein that thiyl radicals are also able to induce the isomerization of *cis*-monounsaturated phospholipids. This process was observed using lipid solutions and, more interestingly, liposome vesicles which model the cell membrane.[9] We have shown that phospholipids containing *trans*-fatty acid residues are produced in high yield.

Dioleoyl phosphatidyl choline (DOPC) was the substrate of choice since it represents the main natural component of cell membranes.[10] It is also known that the oxidizability of this substrate is very low.[11] A first set of experiments was carried out with a *tert*-butyl alcohol solution of DOPC, since it is known that phospholipids do not aggregate in this solvent.[12] A $CHCl_3$ solution of DOPC (3 ml; 0.15 mmol of oleate contents) was evaporated in a test tube under an argon stream. Bu^{t}OH (1 ml), $HOCH_2CH_2SH$ (0.075 mmol) and AMVN (0.030 mmol) were added and the solution degassed with argon.† The reaction mixture was warmed to 54 °C and aliquots (100 μl) were processed at different times. Alternatively, Bu^{t}OH (1 ml) and $HOCH_2CH_2SH$ (0.007 mmol) were added and the solution was divided into aliquots of 100 μl in different tubes followed by saturation with N_2O prior to γ-irradiation.[13] After transesterification[14] of the phospholipids at different reaction times, the methyl oleate/methyl elaidate ratios were obtained by GC analysis. Fig. 1(*a*) and (*b*) show the time profiles of methyl elaidate (*i.e.* the *trans* isomer) formation. In all cases the conversion of the starting material to the equilibrium mixture was quantitative and in the absence of thiol the isomerization did not occur [Fig. 1(*a*) and (*b*)].

The mechanism that we conceived for this transformation includes hydrogen abstraction from the thiol, the addition of thiyl radicals to the *cis* double bond of oleic acid residues, half-rotation about the carbon–carbon bond of the radical intermediate, and ejection of the thiyl radical by β-scission (Scheme 1).[7] It is worth pointing out that the final isomeric composition is in agreement with the difference in the thermodynamic stability between methyl elaidate and methyl oleate.[7]

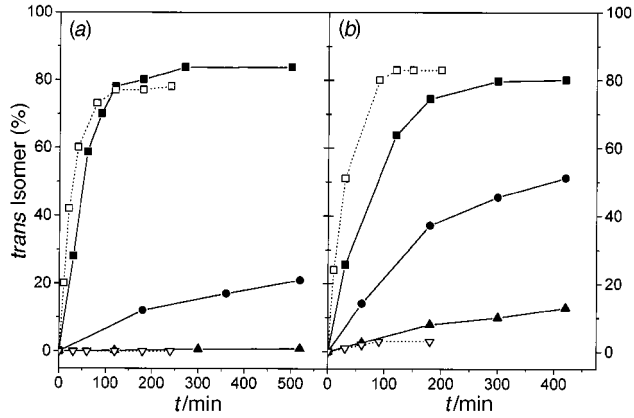

Fig. 1 Time profiles of *trans* isomer formation (*i.e.* methyl elaidate): (*a*) AMVN at 54 °C or AAPH at 37 °C: (□) DOPC with 75 mM $HOCH_2CH_2SH$ in Bu^{t}OH; (▽) DOPC without thiol in Bu^{t}OH; (■) LUVET with 75 mM $HOCH_2CH_2SH$; (●) LUVET with 75 mM of GSH; (▲) LUVET with 75 mM CySH. (*b*) γ-Radiolysis (32 Gy min^{-1}) at 22 °C: (□) DOPC with 7 mM $HOCH_2CH_2SH$ in Bu^{t}OH; (▽) DOPC without thiol in Bu^{t}OH; (■) LUVET with 7 mM $HOCH_2CH_2SH$; (●) LUVET with 7 mM GSH; (▲) LUVET with 7 mM CySH.

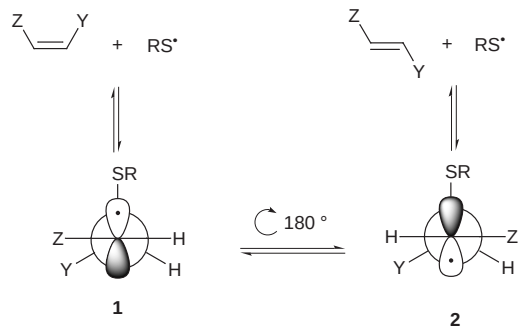
As far as the model membranes are concerned, large unilamellar vesicles (LUVET) made by the extrusion technique[15] were tested both by azo compounds and γ-irradiation using $HOCH_2CH_2SH$ or, alternatively, two other biologically-related thiols such as glutathione (GSH) and cysteine (CySH).‡

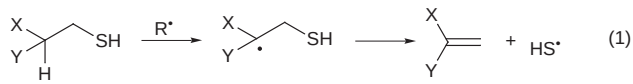
For the thermal initiation, we used the hydrophilic azo compound AAPH, by dissolving it with the thiol in the external



Scheme 1

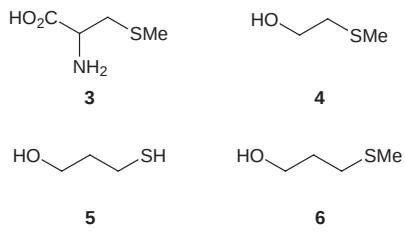
aqueous phase of the LUVET. A comparison of the time profiles given by the three different thiols is shown in Fig. 1(*a*). The isomerization is probably due to the thiyl radicals, provided that they are able to migrate into the lipophilic compartment, and attack the double bond of the phospholipids as described in Scheme 1. As a matter of fact, the isomerization rate follows the lipophilicity order of the three compounds[16] (*i.e.* $HOCH_2CH_2SH$ > GSH > CySH) and indicates that the CyS• radical is unable to induce isomerization.

For the γ-irradiation experiments the time profiles are shown in Fig. 1(*b*). The isomerization with CySH is not straightforward. In order to explain these results, we suggest that under γ-radiolysis the initial radicals,§ which are more reactive than those derived from the thermal decomposition of AAPH, can abstract either the thiol hydrogen or the β-hydrogen with respect to the SH moiety which is activated by the neighbouring groups [eqn. (1)].[17] We also suggest that the HS• radical obtained by β-



(1)

fragmentation is able to migrate into the lipophilic compartment and isomerize the double bond. The viability of eqn. (1) was confirmed by a series of control experiments. In particular, Fig. 2(*a*) shows the isomerization trends of LUVET with compounds **3** and **4** which are expected to generate MeS• radicals *via* a



reaction analogous to eqn. (1). On the other hand, using compounds **5** and **6**, isomerization occurs only with the former, the latter being inactive [Fig. 2(*a*)]. Fig. 2(*b*) shows a comparison of experiments with LUVET and $HOCH_2CH_2SH$ under two different dose rates. The higher efficiency of the *cis–trans* isomerization at a low dose rate is probably due to a decrease in competing reactions involving thiyl radicals.

In conclusion we have shown that phospholipids containing *trans*-unsaturated fatty acids are the major products of the thiyl radical attack on natural phospholipids. We have also modelled the occurrence of such a reaction in cell membranes using naturally occurring thiols. Furthermore, the role played by thiols in this process is in antithesis to their action as radioprotectors.[18] The *cis–trans* interconversion of unsaturated lipids has to be considered, together with autooxidation, when examining cellular damage caused by radical attack, since it can determine changes in barrier properties and functions of biological membranes. Therefore, accurate analyses of the cellular lipid content are required. Further work on the *cis–trans* isomerization of mono- and poly-unsaturated phospholipids and its biological implications is in progress.[19]

Notes and references

† Dioleoyl phosphatidyl choline (DOPC) as a solution in $CHCl_3$ (20 mg ml^{-1}) and the radical initiators azobis(2,4-dimethylvaleronitrile) (AMVN) and azobis(2-amidinopropane) hydrochloride (AAPH) were commercially available and used without further purification.

‡ A $CHCl_3$ solution of DOPC (3 ml; 0.15 mmol of oleate contents) was evaporated to a thin film in a test tube under an argon stream. Degassed phosphate buffer (1 ml; Na_2HPO_4 10 mM, NaCl 0.14 M, pH 7.2) was added and MLV were formed by vortex stirring for 7 min under argon atmosphere. LUVET were prepared by membrane extrusion through 100 nm polycarbonate filters with LiposoFast™ (ref. 15). To these suspensions the required amounts of thiol (0.075 mmol) and AAPH (0.030 mmol) were consecutively added. The samples were then warmed to 37 °C under argon and aliquots (100 μl) were processed at different times. For γ-irradiation experiments, LUVET were prepared as described above in which Pr^iOH (0.12-0.35 mM depending from the nature of thiol) replaced the initiator in the aqueous phase. The suspension was divided into different Pyrex test tubes, flushed for 15 min with N_2O and irradiated at different times.

§ Radiolysis of water leads to species e_{aq}^- , HO• and H•. The presence of N_2O transforms the e_{aq}^- to HO• radicals. The presence of Pr^iOH transforms the majority of the above mentioned species into Me_2C•OH radicals which are believed to further react with thiols to generate thiyl radicals (ref. 13).

Enantioselective epoxidation of *trans*-disubstituted alkenes by D_2-symmetric chiral dioxoruthenium(VI) porphyrins

Rui Zhang, Wing-Yiu Yu, Tat-Shing Lai and Chi-Ming Che*

Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong. E-mail: cmche@hkucc.hku.hk

Received (in Cambridge, UK) 10th November 1998, Accepted 4th December 1998

A series of D_2-symmetric chiral *trans*-dioxoruthenium(VI) porphyrins can effect enantioselective epoxidation of *trans*-β-methylstyrene in up to 70% ee, and 76% ee is attained for the oxidation of cinnamyl chloride; the facial selection for the *trans*-alkenes epoxidation is explained by a 'head-on approach' model.

The design of new metal catalysts for highly enantioselective epoxidation of unfunctionalized *trans*-disubstituted alkenes remains a challenge in the field of asymmetric oxidation.[1] A clue to this problem would be to prepare reactive, and yet isolable, chiral metal–oxo complexes which can act upon *trans*-alkenes to give epoxides in better enantioselectivities than the *cis*-counterparts.[2] If such complexes can be obtained, the structure–enantioselectivity relationship established by studying their stoichiometric alkene epoxidations could assist future design for better metal catalysts. Here, we show that a series of *trans*-dioxoruthenium(VI) complexes with D_2 symmetric porphyrins bifacially encumbered by four chiral threitol units (Fig. 1) can react favorably with *trans*-alkenes in exceptional %ee. Also, our findings do not reconcile with the 'side-on approach' model proposed for the oxo-metalloporphyrin-mediated alkene oxidations.

The D_2-symmetric porphyrins $H_2L^{1–3}$* and the [Ru^{II}-$L^{1–3}$*(CO)(EtOH)] precursors were prepared by the literature methods.[3] Treating the ruthenium(II) carbonyl complexes with *m*-chloroperoxybenzoic acid in dichloromethane for 5 min gave [$Ru^{VI}(L^{1–3}*)O_2$] **1a–c**, which were isolated as dark red–purple crystalline solids (80% yield). Complexes **1a–c** are diamagnetic and stable in solid and in solution for hours at room temperature. The oxidation state marker band at 1018 (**1a**), 1019 (**b**,**c**) together with an intense asymmetric O=Ru=O stretch at 818 (**1a**), 821 (**1b**), 819 cm^{-1} (**1c**) observed in their IR spectra are consistent with a Ru(VI) formulation.

At room temperature, complex **1a** in the presence of pyrazole (Hpz) oxidized styrene in a degassed benzene solution to give styrene oxide in 64% yield and 62% ee (Table 1, entry 1). The enantioselectivity was slightly improved (65% ee) when the reaction was carried out at 0 °C, and the %ee is comparable to the best reported value of 69% ee by employing the chiral Mn–porphyrin catalysts.[3] However, the other dioxoruthenium(VI) derivatives bearing *gem*-diethyl (**1b**) and *gem*-cyclopentyl groups (**1c**) at the threitol units afforded slightly lower ee of 60 and 55% respectively. A paramagnetic bis(pyrazolato)ruthenium(IV), [$Ru^{IV}(L^{1–3}*)(pz)_2$] **2** (μ_{eff} = 2.9 μ_B), was isolated by column chromatography at the end of the epoxidation reactions.[4] It is noteworthy that when styrene reacted with **1a** without Hpz; styrene oxide with only 40% ee was obtained and [$Ru^{II}(L^{1}*)(CO)$] was isolated. To account for the ee discrepancy, we propose that a ruthenium(II) species produced by further reduction of the putative Ru(IV) intermediate would racemize the chiral styrene oxide by an epoxide ring opening pathway previously suggested by Groves *et al.* (Scheme 1).[5]

More importantly, **1a** reacted with *trans*-β-methylstyrene in degassed benzene to give the *trans*-epoxide in 67% ee at room temperature, and up to 70% ee was attained when performing the reaction at 0 °C (entry 3). Notably, the oxidation of cinnamyl chloride furnished the corresponding epoxide in 76% ee and 70% yield (entry 4). Indeed, few reported metalloporphyrin-catalyzed asymmetric epoxidation systems are

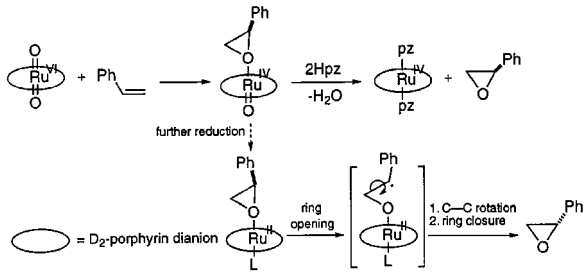
6		C_6H_6	88	20 (1*S*,2*R*)

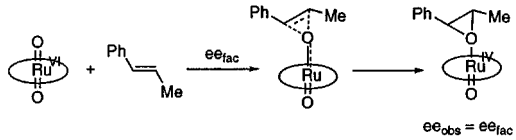
Reaction conditions: to a degassed benzene solution (1 cm^3) containing alkene (1 mmol) and pyrazole (0.3 mmol) was added the dioxoruthenium(VI) complex (0.015–0.03 mmol) under an argon atmosphere. The reaction mixture was stirred at room temperature (or otherwise noted) for 12 h, and the aliquot was analyzed by gas chromatography for product identification and quantification. [a] Yields are based on the amount of the oxidant used. [b] Enantiopurities (%ee) of the epoxides were determined by GC equipped with a chiral capillary column (J & W Scientific cyclodex-B or G-TA). Absolute configuration was determined by comparing with authentic chiral samples. [c] Benzaldehyde (27%) and phenylacetaldehyde (12%) were also detected. [d] Reaction was carried out without pyrazole.



Scheme 1

known to attain >20% ee for the *trans*-β-methylstyrene oxidation.[3,6] We had previously reported that a chiral D_4-symmetric dioxoruthenium(VI) complex can effect epoxidation of *cis*-β-methylstyrene in much higher enantioselectivity of 76% ee *vs*. 20% ee for the *trans*-isomer.[7] In this work, when *cis*-β-methylstyrene (entry 5) and 1,2-dihydronaphthalene (entry 6) reacted with **1a**, the *cis*-epoxides (>99% stereoretention) were produced in only 40 and 20% ee, respectively. Oxidation of *trans*- and *cis*-β-methylstyrene by complexes **1b** and **1c** also resulted similar *trans* preference albeit in lower enantioselectivities, for instance when **1b** was the oxidant, the *trans*- and *cis*-epoxides with 50 and 28% ee resulted respectively.

The asymmetric alkene epoxidations by **1a** also exhibit remarkable solvent dependence.[8] The *trans*-β-methylstyrene oxidation by **1a** displays clean pseudo-first-order kinetics: $-d[Ru(VI)]/dt = k_{obs}[Ru(VI)]$, where $k_{obs} = k_2[alkene]$ and k_2 is the second-order rate constant of the reaction. Upon changing solvent from benzene to dichloromethane, the k_2 value halves: 9.04×10^{-4} (C_6H_6), 4.15×10^{-4} dm^3 mol^{-1} s^{-1} (CH_2Cl_2) at 298 K. It is noted that the %ee of the *trans*-epoxide also decreases in a similar fashion: 67% ee (C_6H_6) *vs.* 32% ee (CH_2Cl_2). By contrast, no solvent effect has been observed for the analogous reactions of the D_4-chiral dioxoruthenium(VI) porphyrin. Since the alkene oxidation is highly stereospecific (Table 1, entries 3 and 5), therefore, the %ee of the epoxide should be determined only by facial selectivity at the rate-limiting association of the C=C bond with the Ru=O group (Scheme 2).[9] We suspect that polar solvent may aggregate around the threitol units through dipole–dipole interaction thereby affecting the facial approach of the alkene.



Scheme 2

In literature, *cis–trans* stereoselectivity in the metalloporphyrin-catalyzed alkene epoxidations is generally explained by the 'side-on approach'.[10] Yet, in this case, this model cannot account for the observed *trans* preference. Here, we propose a 'head-on approach' model in which the molecular plane of the C=C bond lies perpendicular to the Ru=O axis (Scheme 3). Since the *cis vs. trans* stereoselectivity should arise from the steric interaction between the incoming alkene and the porphyrin ligand, the 'head-on approach' of a *trans*-alkene molecule to oxo–metalloporphyrins can also be feasible according to previous studies.[11]

The asymmetric epoxidation of *trans*-β-methylstyrene can become catalytic using 2,6-dichloropyridine *N*-oxide (Cl_2pyNO) or O_2 as terminal oxidant. Similarly the catalytic *trans*-alkene oxidation is more enantioselective than that of the analogous *cis*-β-methylstyrene oxidation. For example, with Cl_2pyNO (0.146 mmol) as terminal oxidant and benzene as solvent, the *trans*-β-methylstyrene (1 mmol) oxidation furnished the *trans*-epoxide in 50% ee (70% yield, turnover = 70); whereas the oxidation of the *cis* analogue afforded the *cis*-epoxide in only 7% ee (70% yield, turnover = 66) under the same conditions. On the other hand, **1a** can also effect aerobic asymmetric *trans*-β-methylstyrene epoxidation in benzene (9 atm O_2, 40 h) to give the *trans*-epoxide in 59% ee (turnover = 7).

Synthesis of microporous zirconosilicates containing ZrO_6 octahedra and SiO_4 tetrahedra

Sudhakar R. Jale,* Adeola Ojo and Frank R. Fitch

BOC Gases, Technology, 100 Mountain Avenue, Murray Hill, NJ 07974, USA. E-mail: sudhakar.jale@us.gtc.boc.com

Received (in Bloomington, IN, USA) 6th November 1998, Accepted 22nd January 1999

Three novel crystalline zirconosilicate molecular sieves, analogous to elpidite, umbite and gaidonnayite minerals, containing zirconium in octahedral coordination and silicon in tetrahedral coordination are synthesized.

The isomorphous substitution of various metal ions into crystalline inorganic frameworks has been a very active area of research over the last two decades. By substituting metal ions with different oxidation states and electronegativities, it is possible to modify the acid strength and the ion-exchange capacities of zeolites.[1] Most of the isomorphous substitutions in zeolite frameworks involve the incorporation of the metal ions into tetrahedral positions. It has been shown that Ti,[2] Zr[3] and Sn[4] can form crystalline silicate materials,[5] where Si is in tetrahedral coordination and Ti, Zr or Sn is in octahedral coordination. Since these metal ions are in 4+ oxidation state and in octahedral coordination, this results in two negative charges on the framework for each of the metal ions incorporated.

In 1990, Chapman[6] reported two titanosilicate minerals (vinogradovite and zorite) containing Ti in octahedral coordination. Subsequently, Engelhard Corporation developed microporous titanium silicate molecular sieves, described as ETS-4[7] and ETS-10,[8] which contain silicon in tetrahedral coordination and titanium in octahedral coordination. Until now, only titanosilicates have been synthesized with large pore openings. Similarly to titanium, zirconium also forms a variety of silicate minerals having zirconium in octahedral coordination. Until now, zirconosilicate minerals have been synthesized at temperatures between 300 and 700 °C and pressures of up to 700 bar.[9]

Here, for the first time, we report the synthesis of gaidonnayite and umbite zirconosilicate minerals. We have also been able to synthesize elpidite at 200 °C under autogeneous pressure. The synthesis of zirconosilicates has been carried out using sodium silicate, zirconyl chloride, potassium fluoride, sodium hydroxide, potassium hydroxide, hydrochloric acid and tetramethylammonium bromide using the gel compositions reported in Table 1. All these chemicals were obtained from Aldrich. The syntheses were carried out hydrothermally at 200 °C under static conditions. After the specified crystallization time, the product was filtered off, washed with deionized water and dried at room temperature.

The XRD patterns of all three zirconosilicates shown in Fig. 1 match well with mineral counterparts. Umbite and gaidonnayite belong to $P2_12_12_1$ and $P2_1nb$ space groups, respectively[11,12] and all three minerals have an orthorhombic unit cell. The samples calcined at 400 °C have XRD patterns identical to those of as-synthesized materials, indicating a good thermal stability. Thermogravimetric analysis of calcined and rehydrated elpidite and umbite samples showed 7 and 11 wt% loss, respectively between 35 and 300 °C. The BET surface area of zirconosilicates measured at liquid nitrogen temperature was negligible, showing that the pore size is less than the kinetic diameter of the nitrogen molecule. However, based on the structural data and the water adsorption measurements (type I isotherm), they can be classified as microporous materials. Recently, the titanium analogue of umbite also has been shown to adsorb water but not nitrogen.[10]

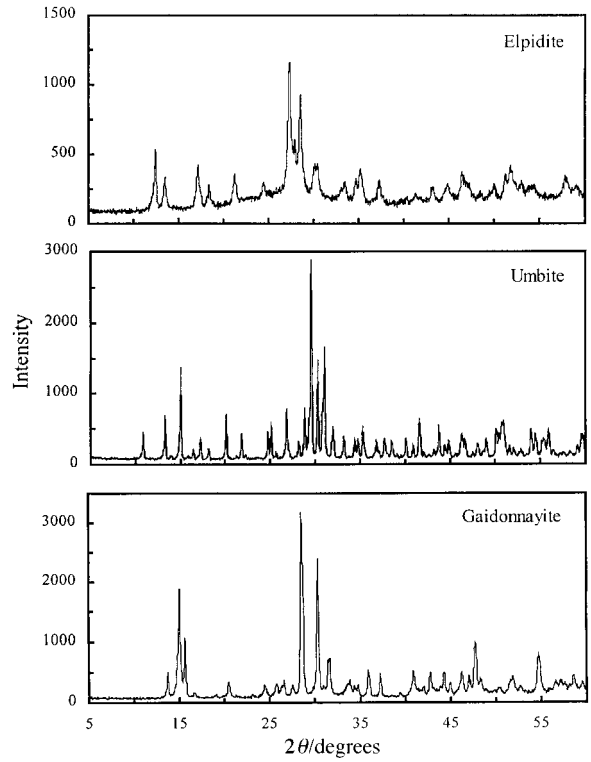

Fig. 1 The XRD patterns of zirconosilicates analogous to elpidite, gaidonnayite and umbite minerals.

Chemical analysis data of well crystalline, pure forms of zirconosilicates are summarized in Table 2. The Si/Zr ratios of elpidite, umbite and gaidonnayite are 5.1, 4.3 and 3.0, respectively. The chemical formulas of umbite[11]

Table 1 Gel composition and crystallization times in the synthesis of zirconosilicates

Compound	SiO_2	ZrO_2	K_2O	Na_2O	R_2O^a	HCl	KF	H_2O	*t*/d
Elpidite	1.0	0.17	0.10	—	—	1.59	0.33	29.8	35
Gaidonnayite	1.0	0.20	0.25	1.17	0.20	0.40	0.50	35.0	19
Umbite	1.0	0.10	0.27	0.52	—	0.20	0.53	30.8	32
Umbite	1.0	0.10	1.19	0.23	0.3	0.20	0.50	36.8	2

[a] R = Tetramethylammonium bromide.

Table 2 Chemical analysis of zirconosilicates

Compound	LOI[a] (wt%)	Si/Zr	Si/Al	Si/ (Al + Zr)	Na + K)/ (2Zr + Al)
Elpidite	10.7	5.07	59.78	4.67	0.78
Umbite	10.2	4.25	90.34	4.06	1.20
Gaidonnayite	10.3	3.06	60.52	3.06	1.02

[a] LOI = loss of ignition.

($K_2ZrSi_3O_9·H_2O$), elpidite[9] ($Na_2ZrSi_6O_{15}·3H_2O$) and gaidonnayite[12] ($K_2ZrSi_3O_9·2H_2O$) are reported in the literature. The calculated chemical formulas of umbite ($M_{2.4}ZrSi_4O_{11}$), elpidite ($M_{1.6}ZrSi_5O_{13}$) and gaidonnayite ($M_2ZrSi_3O_9$) materials synthesized in this study are slightly different from those reported in the literature.

Owing to an aluminium impurity in the source materials, there is always some aluminium in these materials. If both Al and Zr are in the framework, this ratio should be 1.0. A deviation from this value indicates that either there is an excess of alkali metal ion (possibly due to the presence of defects) or a part of these metals are not substituted into the framework. The lower ratio for elpidite is most probably due to the presence of some amorphous material.

The ion-exchange capacity of umbite was tested by refluxing in 0.5 M NaCl solution. The original sample contains 29% Na and 71% K, while the Na-exchanged sample had 81% Na and 21% K cations adding up to a (Na + K)/(2Zr + Al) ratio of 1.02. Since zirconium has two negative charges, two cations are required to balance the charge. The Si/Zr and Si/Al ratios of this sample were 3.6 and 76.6, respectively. These results confirm that at least 80% of the cations are exchangeable and most of the Zr and Al are present in the framework. Upon ignition, umbite lost about 13% of its weight as water, which is close to the value obtained by TGA.

The hydroxide concentration in the gel influences the rate of hydrolysis of the metal ions and also the rate at which the condensation of these species into the framework structures takes place. In general, an increase in the hydroxide concentration decreases the nucleation time and accelerates the crystal growth. As can be seen in Table 1, by increasing the hydroxide concentration and also by partially replacing sodium by potassium, the crystallization time of umbite was reduced from 38 to 2 days. We have been able to synthesize at least three more zirconosilicates by changing the OH^- ion concentration. However, the structures of these materials are not yet identified.

In conclusion, we have demonstrated the synthesis of microporous zirconosilicates analogous to minerals under hydrothermal conditions at temperatures significantly lower than those used previously in the literature. These zirconosilicates might be useful adsorbents for kinetic separation of smaller gaseous molecules such as water from a mixture with other components.

Side-chain alkylation of toluene with propene on caesium/nanoporous carbon catalysts

Mark G. Stevens, Melony R. Anderson and Henry C. Foley*

Center for Catalytic Sciences and Technology, Department of Chemical Engineering, University of Delaware, Colburn Laboratory, Academy Street, Newark, Delaware 19716, USA. E-mail: foley@che.udel.edu

Received (in Bloomington, IN, USA) 13th November 1998, Accepted 11th January 1999

Caesium/nanoporous carbon materials are powerful solid-base catalysts, promoting the side-chain alkylation of toluene with propene in a continuous flow reactor at conditions as mild as 150 °C and 50 psig.

When a strong base, such as Na metal, is employed as a catalyst, alkylation occurs at the benzylic hydrogen of the side chain. During the later 1950s, many researchers[1–5] explored this chemistry, most notably, Pines *et al.*[1,2,4] Recently, there has been much interest in examining novel solid-base catalysts for larger scale reactions such as side-chain alkylation of toluene with methanol[6–9] and olefins.[10,11] To date, however, there are no industrial processes that take advantage of this chemistry to produce alkylbenzenes from lower-cost toluene.[12] As early as 1964 Foster[10] had shown that graphite intercalation compounds of alkali metals readily promoted the side-chain alkylation of toluene with ethylene, but reaction was slow, required high pressure and it was not clear if the alkali metal had remained intercalated in the graphite.

In contrast to the graphite intercalation compounds of alkali metals, which exfoliate readily,[13] we have shown that Cs entrapped in nanoporous carbon is well dispersed and very strongly bound.[14] Preparing nanoporous carbon (NPC) with macropores provides for facile molecular ingress and egress to the catalytic sites.[15]

We have shown that Cs/NPC is active enough to break the C–H bond in benzene (110 kcal mol^{-1}) and to promote its condensation to biphenyl.[16] Given this result, we expected the catalyst to remove the more facile benzylic hydrogen from toluene readily, and if an olefin such as propene were present, to produce *n*-butylbenzene and isobutylbenzene. At the same time in the case of propene, cyclization and release of dihydrogen could lead to the dicyclic products 1-methylindan, 1,2,3,4-tetrahydronaphthalene and 2-methylindan.

Batch, liquid phase reactions† of toluene and propene over this nanoporous carbon catalyst containing *ca.* 10 wt% Cs produced *n*-butylbenzene, isobutylbenzene and 2-methylindan. Table 1 displays the results of several experiments carried out at 150 °C and at various conversions. The major product was isobutylbenzene. Propene was the limiting reactant in all these experiments. Once the propene was consumed, secondary reactions began to become important. As was the case in the reaction of benzene over Cs/NPC,[16] aromatic-ring coupling produced species such as bibenzyl, dimethylbiphenyls, and methyldiphenylmethanes. Additionally, cyclization of isobutylbenzene produced 2-methylindan. If 1-methylindan and 1,2,3,4-tetrahydronaphthalene were produced, they remained below our detection limits. Both side reactions should produce H_2 and GC measurements of the vapor phase over the products confirmed that H_2 indeed had been produced. Control experiments using carbon without C_2 produced no detectable reaction. At higher conversions, the catalyst achieved over nine turnovers based on the total moles of Cs, a lower limit value that confirms the catalytic nature of the reaction.

In a second set of experiments, to avoid the possible complication of Cs leaching into the liquid phase, toluene was converted to butylbenzenes in the vapor phase using a tubular flow reactor. A mixture of toluene in propene (5 mol %) was circulated over the catalyst at temperatures from 150–400 °C and 4 bar,‡ (Fig. 1, Table 2). The increase in the availability of propene reduced the toluene coupling to an undetectable level. Propene coupling, however, did occur with the excess propene in the system to form C_6 compounds such as 4-methylpentene, cyclohexane, hex-1-ene and dimethylbutenes. Above 150 °C, *ca.* 10% of the propene that reacted went to the C_6 products, indicating the potential utility of Cs/NPC as a catalyst for producing higher-molecular-weight olefin monomers. This propene coupling may also account for the decrease in activity at > 250 °C. At 350 and 400 °C the catalysts gained mass (3.6 and 6.0% of their initial mass, respectively). This suggests that deactivation arose due to the formation of propene oligomers in the pores, resulting in a loss of diffusive transport to the catalytically active sites. The sample of catalyst used at 400 °C not only gained mass, but also was coated with a hexane-soluble, waxy film.

We find that Cs/NPC yields high iso/normal butylbenzene ratios (≥10). This indicates that the predominant mechanism proceeds *via* surface anions and through the formation of the benzyl anion from the toluene substrate. Pines and Stalick[17]

Table 1 Results of batch study[a]

Conversion (%)		Toluene selectivity (%)				
Toluene	Propylene	Coupled	Isobutyl	*n*-Butyl	Indan	Turn-over
0.03	0.40	0.00	100.00	0.00	0.00	0.039
0.12	1.41	0.00	82.99	0.00	17.01	0.137
1.03	18.84	0.44	70.44	9.17	19.94	2.367
1.06	18.35	0.55	72.47	9.83	17.14	2.452
3.49	38.19	1.29	70.23	13.76	14.72	3.934
6.82	≈100.00	2.49	71.66	13.16	12.69	10.657
7.12	≈100.00	3.19	73.11	11.95	11.75	9.274

[a] Conversion of toluene and propylene and selectivity were calculated from GC of the liquid phase. Turnovers were calculated by titrating the used catalyst for Cs content with H_2SO_4. All products were identified by GCMS.

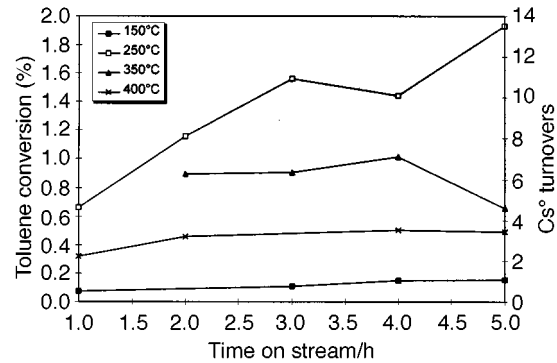

Fig. 1 Vapor-phase conversion and catalyst turnovers *versus* time on stream at 4 bar gas pressure (5% toluene in propylene) and temperature. Conversion of toluene, was calculated from GC of the liquid phase. Turnovers were calculated by titrating the used catalyst for Cs content with H_2SO_4.

Table 2 Results of gas-phase, continuous experiments[a]

		Toluene selectivity (%)				
T/°C	Propene selectivity	Isobutyl-benzene	*n*-Butyl-benzene	Methyl-indan	Tetra-hydro-naph-thalene	Catalyst weight gain (%)
150	100.0	94.7	2.6	2.7	0.0	< 0.1
250	89.4	72.3	8.2	15.8	3.6	< 0.1
350	93.0	79.8	7.6	10.7	1.9	3.6
400	93.5	85.5	9.6	5.0	0.0	6.0

[a] Propylene selectivity to alkylation products was calculated by comparing the amount of propylene converted to C_6 byproducts to the toluene conversion. Conversion and selectivity of toluene, were calculated from GC measurements of the liquid phase. Products identified by GCMS.

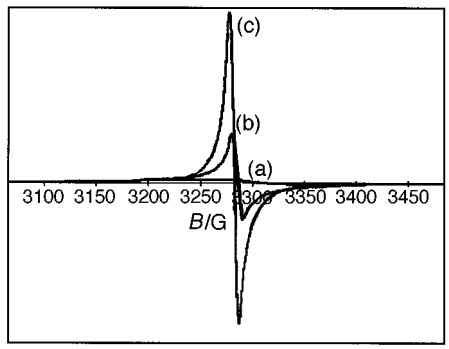

Fig. 2 EPR differential plot of: (a), carbon precursor; (b), carbon loaded with 30% Cs; (c), carbon loaded with 3% Cs.

have shown that a large normal to iso ratio is the best indicator of an anionic rather than free-radical mechanism.

That the chemistry over Cs/NPC should proceed through anions rather than radicals makes good sense based on characterization of the Cs/NPC by EPR spectroscopy. Our EPR measurements (Fig. 2) show the existence of such radical anions, and the measured g-value of 2.0026[16] indicates that the unpaired electrons are transferred from the Cs to the carbon. The EPR spectra also show that more unpaired electrons are present at low Cs levels (3 wt%) than at high loadings (30 wt%). Previously, we found that the electronic character of the material goes from strongly paramagnetic to weakly paramagnetic and diamagnetic with increased Cs content.[14] This transformation arises from spin pairing within the polyaromatic nanodomains as additional electrons are added. Based on these results, at the intermediate Cs loadings (10 wt%) used for the catalysts examined here, the material should behave as much, or more, like a Lewis base than as a radical. We conclude that radical anions, represented as $Cs_n/NPC^{n-y\cdot S}$ where $y = [1 + (-1)^{n+1}]/2$, and the corresponding spin-paired multiply charged anions (formed by addition or removal of one electron) catalyze this reaction and drive the chemistry toward isobutylbenzene formation. The same intermediate anions which produce isobutylbenzene also can react intramolecularly to form the corresponding bicyclic compounds and also through an anion mechanism.

In conclusion, we have shown the Cs/NPC materials to be powerful Lewis bases which promote the side-chain alkylation of toluene at unprecedentedly mild conditions.

Notes and references

† Batch reactions were performed in a stainless-steel, 'tubing-bomb' reactor (2.54 cm. o.d., 1.77 cm i.d. 15 cm long, capped with a valve assembly, total internal volume: 15 cm). Catalyst and toluene were loaded in an argon-atmosphere glove box. The reactor was sealed with a titanium gasket, removed from the glove box, charged with propene and placed in a fluidized sand bath maintained at the reaction temperature.

‡ A recirculating vaporizer/condenser reactor was constructed for the experiments. Propene (maintained at 4 bar with live feed) cycled through the system at 1500 sccm in the following order: bubbled through a temperature controlled (298 K) vessel containing 100 ml of toluene; the toluene rich (5 mol%) propene passed through a flow controller, a diaphragm pump and to the catalyst bed; the stream was heated to reaction temperature and flowed through the catalyst bed (1.5 g of catalyst containing 10 wt%/Cs 0.025 s/pass contact time); the reacted stream then returned to the bottom of the toluene vessel to repeat the cycle.

Received (in Cambridge, UK) 24th December 1998, Accepted 25th January 1999

Novel phosphinite–nitrogen chiral ligands synthesized from D-glucosamine furnish a high level of enantiomeric excess (up to 96% ee) in palladium-catalysed allylic alkylation.

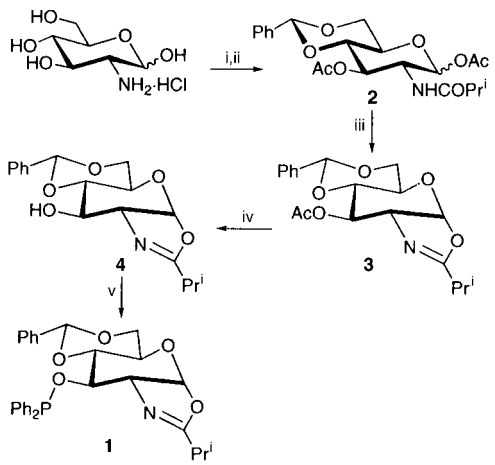
Palladium-catalysed allylic alkylation is known as a powerful synthetic tool for the construction of carbon–carbon bonds.[1] Enantioselective versions of the reaction have been explored and large enantiomeric excesses have been achieved using various C_2- and C_1-symmetric bidentate chiral ligands.[2] While they are excellent ligands, expensive chiral sources and tedious synthetic steps are sometimes needed for their synthesis. Recently carbohydrates have attracted a great deal of interest as a source of chiral ligands, because they exist widely in nature and have many chiral centres in their skeletons.[3,4] Now, we report the synthesis of novel phosphinite–nitrogen chiral ligands from commercial D-glucosamine hydrochloride (2-amino-2-deoxy-D-glucopyranoside hydrochloride), which have been less frequently used as chiral ligands,[4,5] and their application to the Pd-catalysed allylic alkylation.

First, we prepared compound **1** according to the procedures illustrated in Scheme 1. *N*-Acylation of D-glucosamine hydrochloride with $(Pr^iCO)_2O$ and NaOMe, and the protection of both 4,6- and 1,3-positions by benzylidene and acetyl groups gave D-glucopyranoside **2** in good yield. This compound could be readily converted into oxazoline derivative **3** using $SnCl_4$ without removing the benzylidene protecting group.[6] Deacetylation of the 3-position followed by treatment with Ph_2PCl and Et_3N gave phosphinite–nitrogen chiral ligand **1**. This ligand was easily oxidized by air in solution, but was relatively stable in the solid state.

Asymmetric allylic substitution of 1,3-diphenyl-3-acetoxyprop-1-ene with dimethyl malonate in the presence of *N*,*O*-bis(trimethylsilyl)acetamide (BSA) and KOAc was carried out with the palladium complex generated *in situ* by mixing chiral ligand **1** and $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$. The results are summarized in Table 1. In the presence of only 0.25 mol% Pd complex, the reaction proceeded very smoothly with high enantioselectivity. The best result was obtained when the reaction was carried out in toluene at 0 °C (entries 1–5).

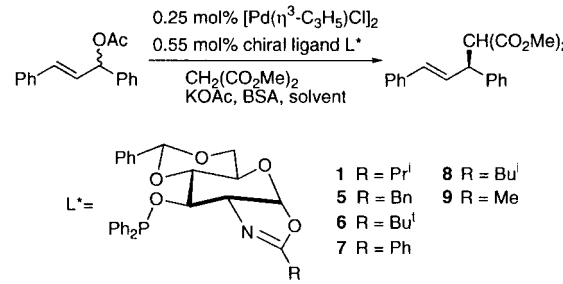
Next, we synthesized phosphinite–nitrogen ligands **5**–**9**† by the procedure described in Scheme 1 using anhydrides or acid chlorides such as BnCOCl, $(Bu^tCO)_2O$, PhCOCl, $(Bu^iCO)_2O$ and Ac_2O, and applied them to the palladium-catalysed asymmetric allylic alkylation under the previously determined optimum conditions (entries 6–10).‡ As can be seen in Table 1, a dramatic substituent effect on the enantiomeric excess was observed. The use of the ligand **5** (R = Bn) or **6** (R = Bu^t) (entries 6 and 7) gave lower enantioselectivities compared with the case of ligand **1**. On the contrary, the use of the ligand **7** (R = Ph) or **8** (R = Bu^i) increased the selectivity (entries 8 and 9). Furthermore, it was noted that the highest enantiomeric excess (96% ee) was achieved using ligand **9** (R = Me) (entry 10).

We suppose that nucleophilic attack occurs predominantly at the allyl terminus *trans* to the Pd–P bond in the π-allylpalladium complex.[8] Since the (*S*)-product was obtained as the major enantiomer, the reaction probably proceeds through *endo* intermediate **A** rather than *exo* intermediate **B**, as shown in



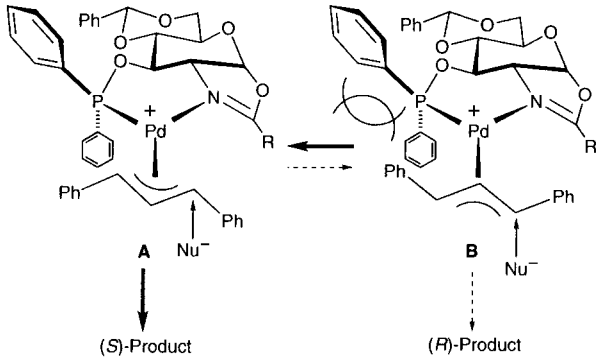
Scheme 1 *Reagents and conditions*: i, $(Pr^iCO)_2O$, MeONa, MeOH, room temp., 24 h, 82%; ii, PhCHO, $ZnCl_2$, room temp., 5 h, then Ac_2O, pyridine, room temp., 24 h, 43% (2 steps); iii, $SnCl_4$, CH_2Cl_2, room temp., 1 h, 52%; iv, K_2CO_3, MeOH, room temp., 1 h, 73%; v, Ph_2PCl, Et_3N–THF (1 : 1), cat. DMAP, room temp., 15 min, 46%.

Table 1 Palladium-catalysed asymmetric allylic alkylation with chiral ligands **1** and **5**–**9**[a]



Entry	L*	Solvent	*T*/°C	*t*/h	Ee (%)[b]
1	**1**	CH_2Cl_2	room temp.	1	85 (*S*)
2	**1**	THF	room temp.	0.5	86 (*S*)
3	**1**	toluene	room temp.	1	88 (*S*)
4	**1**	toluene	60	0.5	84 (*S*)
5	**1**	toluene	0	6	90 (*S*)
6	**5**	toluene	0	18	78 (*S*)
7	**6**	toluene	0	6	83 (*S*)
8	**7**	toluene	0	6	94 (*S*)
9	**8**	toluene	0	6	95 (*S*)
10	**9**	toluene	0	6	96 (*S*)

[a] The reaction was carried out under Ar using 1,3-diphenyl-3-acetoxyprop-1-ene (1.0 mmol), dimethyl malonate (3.0 mmol), BSA (3.0 mmol), KOAc (0.05 mmol), solvent (2.0 ml), $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (0.25 mol%) and L* (0.55 mol%). Product was isolated in quantitative yield. [b] Measured by HPLC; the absolute configuration was determined by optical rotation (ref. 7).



Scheme 2

Scheme 2. In the transition state, the steric repulsion in **A** between the phenyl group on phosphorous and the substrate appears smaller than that in **B**.

In summary, we have demonstrated that the novel chiral ligands **1** and **5**–**9** are very efficient ligands for asymmetric allylic alkylation, using only 0.25 mol% Pd complex to provide a high enantioselectivity (up to 96% ee). These ligands can be prepared in six steps using commercial D-glucosamine hydrochloride as an inexpensive natural chiral source. They are a new type of P–N ligands using only the chirality of D-glucosamine, which is communicated to the coordination sphere built with both phosphorous and nitrogen. To the best of our knowledge, this is the first example of the application of phosphinite–nitrogen chiral ligands[9] to asymmetric allylic alkylation. Application of these ligands to other asymmetric reactions is now in progress.

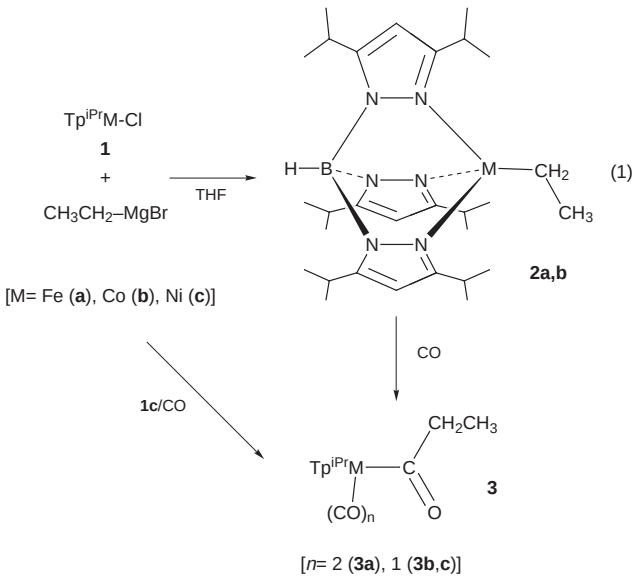
Received (in Cambridge, UK) 3rd December 1998, Accepted 27th January 1999

Coordinatively unsaturated hydrocarbyl complexes bearing β-hydrogen atoms, $Tp^{iPr}M–CH_2CH_3$ [M = Fe, Co; Tp^{iPr} = hydrotris(3,5-diisopropylpyrazolyl)borate], 14e and 15e species, respectively, are prepared; they are resistant to β-hydride elimination.

'18-Electron (EAN) rule' and 'β-hydride elimination' are usually key principles in predicting stability of organometallic compounds.[1] In a previous paper, we reported a complex which does not obey the 18e rule: the coordinatively unsaturated 14e η^1-allyliron complex supported by the Tp^{iPr} ligand [Tp^{iPr} = hydrotris(3,5-diisopropylpyrazolyl)borate], $Tp^{iPr}Fe–CH_2$-$CH{=}CH_2$.[2] Although η^3 (π)-coordination of the allyl ligand would give a 16e species, closer to the coordinatively saturated 18e configuration, X-ray crystallography of the allyliron complex revealed that the η^1 (σ)-coordination of the allyl ligand to the iron center led to the highly coordinatively unsaturated 14e species. Our communication was followed by a recent report by Parkin *et al.*, who disclosed the synthesis and unusual reactivity of the related methyliron complex, [$PhTp^{Bu^t}$]Fe–Me [$PhTp^{Bu^t}$ = PhB (3-Bu^t-pz)$_3$, pz = pyrazolyl],[3] and thus the study on the coordinatively unsaturated hydrocarbyl complexes of late transition metals has attracted increasing attention.[4] During the course of our study, we have succeeded in the synthesis and characterization of coordinatively unsaturated alkyl complexes resistant to β-hydride elimination.

Reaction of the Fe and Co chloride complexes **1** with ethylmagnesium bromide in THF afforded pale yellow (**2a**) and blue products (**2b**), respectively, after removal of the inorganic salts by filtration through a Celite pad followed by crystallization from pentane [eqn. (1)]. X-Ray crystallography of the Co



complex **2b** [Fig. 1(a)]† revealed the formation of the ethyl complex with tetrahedral coordination geometry as judged by the similar N–Co distances and N–Co–CH_2 angles [Co1–N11 2.049(6), Co1–N21 2.017(7), Co1–N31 2.025(7) Å; N11–Co1–C1 123.1(3), N21–Co1–C1 125.2(3), N31–Co1–C1 124.5(3)°]. The Co–CH_2 distance [Co1–C1 2.01(1) Å] falls in the accepted range of the Co–C σ-bond lengths. The structural parameters are comparable to those of the allyliron complex mentioned above.[2] The iron complex **2a** was also assigned to $Tp^{iPr}Fe–CH_2CH_3$ with tetrahedral structure, on the basis of its cell parameters† similar to those of **2b**, but could not be refined satisfactorily due to the low quality of the crystals. In contrast to the Co and Fe complexes, the reaction of the Ni complex **1c** afforded an intractable mixture of products from which no characterizable product could be isolated.

In order to further confirm the presence of a M–C bond in **2**, the ethyl complexes **2a**,**b** were subjected to carbonylation. Stirring a toluene solution of **2a**,**b** for 1 h under CO atmosphere (1 atm) produced **3a**,**b**, respectively. Their IR spectra containing

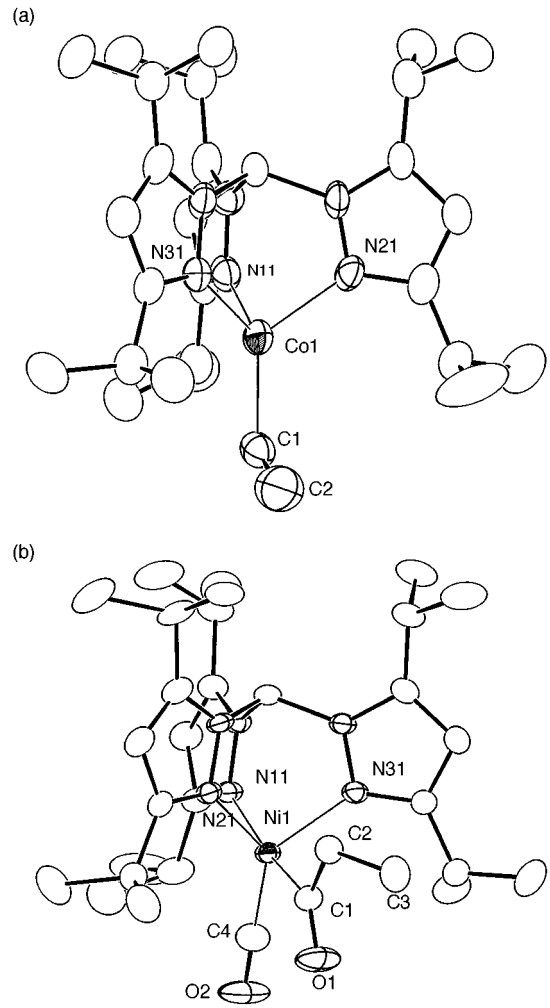


Fig. 1 Molecular structures of **2b** (a) and **3c** (b) drawn at the 30% probability level.

ν(CO) and ν(C=O) vibrations suggest formation of acyl complexes.‡ The diamagnetic iron complex **3a** was characterized on the basis of its ^{1}H and ^{13}C NMR spectra indicating the $(CO)_2Fe–C(=O)CH_2CH_3$ functional group in addition to the κ^3-Tp^{iPr} ligand, and its IR spectrum suggests the presence of two rotamers as observed for $TpFe(CO)_2–C(=O)CH_3$.[5] The assignment of the monocarbonyl structure of the cobalt complex **3b** is based on the single ν(CO) absorption. Interestingly, although the ethylnickel complex **2c** could not be isolated from the Grignard reaction mentioned above, the reaction under CO atmosphere produced the acyl complex **3c**, which was characterized spectroscopically and structurally [Fig. 1(b)].† The Ni center adopts a trigonal bipyramidal structure with the N11–Ni1–C1 axis, where the κ^3-Tp^{iPr} ligand occupies the two basal and one apical coordination sites and the acyl and CO ligands occupy the remaining apical and coordination sites, respectively, as judged by the interligand angles [N11–Ni1–C1 171.7(1) ($\approx$180°); N21–Ni1–C1 89.8(2), N31–Ni1–C1 87.7(1), C1–Ni1–C4 87.2(2), N11–Ni1–N21 85.1(1), N11–Ni1–N31 86.6(1), N11–Ni1–C4 101.1(2)° ($\approx$90°); N21–Ni1–N31 98.9(1), N21–Ni1–C4 131.0(2), N31–Ni1–C4 129.8(2)° ($\approx$120°)]. In accord with this view, the axial N–Ni distance is slightly longer than the equatorial ones [Ni1–N11 2.058(3) Å > Ni1–N21 2.018(3), Ni1–N31 2.034(3) Å]. As for the Ni(CO)–C(=O)Et part, the structure of the acyl part is normal [Ni1–C1 1.947(4), O1–C1 1.192(5) Å; Ni1–C1–O1 124.2(3), Ni1–C1–C2 115.7(3), C1–C2–C3 112.2(4)°], and the CO ligand is coordinated to the Ni center in a typical η^1-fashion [Ni1–C4 1.767(5), O2–C4 1.126(6) Å; Ni1–C4–O2 177.0(4)°]. Thus the successful characterization of the acyl complexes **3** supports the presence of the M–CH_2CH_3 functional group in the starting complexes **2**. The formation of the acyl complexes **3** *via* addition and insertion of CO molecules is in contrast to the result of carbonylation of the related iron–alkyl complex, [$PhTp^{Bu^t}$]Fe–Me, giving the Fe(I) carbonyl complex, [$PhTp^{Bu^t}$]Fe–CO.[3] The difference may arise from the highly sterically demanding $PhTp^{Bu^t}$ ligand, which would hinder formation of penta- or hexa-coordinated species leading to the acyl structure.

When the ethyl complexes **2a**,**b** were heated in heptane for 5 h at 110 °C, only small amounts of ethane [10 (**2a**) and 8% (**2b**) yields] were detected together with trace amounts of ethene by GLC analysis of the gas phase. In contrast, hydrogenolysis (2 atm; 16 h at room temperature) produced ethane in 60 (**2a**) and 91% (**2b**) yields and protonolysis with aqueous HCl afforded ethane in 66 (**2a**) and 96% (**2b**) yields. Thus complexes **2** bearing β-hydrogen atoms were found to be resistant to 'β-hydride elimination'.

The ethyl-iron and -cobalt complexes prepared in the present study are highly coordinatively unsaturated 14e (Fe: **2a**) and 15e species (Co: **2b**), respectively, which are quite sensitive to air and moisture. It is remarkable that, despite their coordinatively unsaturated electronic structures, they are resistant to β-hydride elimination and are stable at room temperature. The magnetic moments [μ = 5.0 μ_B (**2a**), 4.2 μ_B (**2b**)] close to the calculated spin only magnetic moments [4.90 (S = 2), 3.87 (S = 3/2)] and EHMO calculations indicate that the ethyl complexes **2** are high spin species and all their non-bonding d-orbitals are fully or half occupied. The stability of the ethyl complexes **2** may be interpreted in terms of the lack of a vacant coordination site (a vacant non-bonding d-orbital)[1] and the high spin electronic configurations should be a result of the tetrahedral coordination geometry regulated by the tripodal Tp^{iPr} ligand. Their electronic structure, however, should be flexible. Upon interaction with an appropriate substrate the electronic configuration may be changed so as to form a vacant coordination site and accommodate a substrate into the coordination sphere as typically exemplified by carbonylation giving the acyl complexes **3**.

We are grateful to the Ministry of Education, Science, Sports, and Culture of the Japanese Government (Grants-in-Aid for Scientific Research: No. 08102006 and 09238105) for financial support of this research.

Phthalocyanine-containing polystyrenes

Saad Makhseed, Anthony Cook and Neil B. McKeown*†

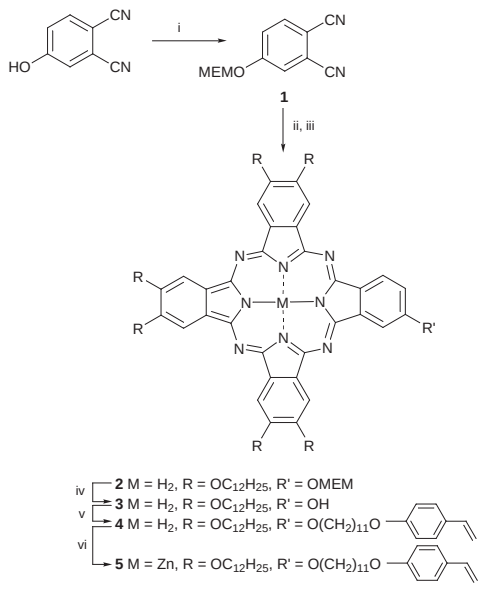
Department of Chemistry, University of Manchester, Manchester, M13 9PL UK. E-mail: neil.mckeown@man.ac.uk

Received (in Cambridge, UK) 4th January 1999

An unsymmetrical phthalocyanine derivative containing a single styrene unit, prepared using a mixed phthalonitrile cyclotetramerisation, can undergo free radical polymerisation to give well-defined polystyrenes in which the macrocyclic components aggregate even in dilute solution.

Phthalocyanine (Pc) and its derivatives possess interesting electronic, optical and catalytic behaviour.[1] There has been much interest in the synthesis of phthalocyanine-containing polymers suitable for the exploitation of Pc functionality.[2] Previously, Pc has been incorporated into intractable network polymers,[3] rigid polysiloxanes in which the silicon(IV) ion is held within the central cavity of the macrocycle,[4] main-chain liquid crystalline polymers,[5] polymers formed by the coordination of bidentate ligands with metal ion containing Pcs,[6] dendrimers which comprise a Pc ring at their core,[7] and polymers in which the Pc is a component of a side-chain attached to the polymer backbone.[8] Here we describe the synthesis of polystyrenes with Pc-containing side-chains. The widespread use of polystyrene as the substrate for polymer-supported catalysts, its excellent processability and its optical clarity make these materials attractive synthetic targets with numerous potential applications.

The synthetic route to the Pc-containing styrene monomers is given in Scheme 1. The strategy is to prepare an unsymmetrical phthalocyanine, which possesses six solubilising alkyl side-chains and a single reactive hydroxy functionality for the attachment of the styrene group, *via* a mixed cyclotetramerisation of suitable phthalonitrile precursors. In order to protect the hydroxy group during the base catalysed Pc forming reaction, 4-hydroxyphthalonitrile[9] was first reacted with methoxyethoxymethyl chloride (MEM chloride) to give **1**. The MEM moiety not only acts as a protecting group during the mixed cyclotetramerisation reaction between **1** and an excess of 4,5-bis(dodecyloxy)phthalonitrile[8] but its relative polarity, as compared to that of the dodecyloxy side-chains, also facilitates chromatographic separation of the required unsymmetrical Pc **2** from the Pc by-products.[10] Removal of the MEM group followed by the reaction of the resulting Pc **3** with 1-bromo-11-(4-vinylphenoxy)undecane[11] gives the desired Pc-containing styrene monomer **4**. Spectroscopic and elemental analysis of **4** was consistent with its proposed structure.†



Scheme 1 *Reagents and conditions*: i, MEMCl, pyridine; ii, 4,5-bis(dodecyloxy)phthalonitrile, $C_5H_{11}OLi$, $C_5H_{11}OH$, 135 °C; iii, AcOH; iv, PPTS, $C_5H_{11}OH$, 135 °C; v, 1-bromo-11-(4′-vinylphenoxy)undecane, K_2CO_3, DMF, 50 °C; vi, $Zn(OAc)_2$, $C_5H_{11}OH$, 135 °C.

The long alkyl spacing group between the styrene unit and the Pc ring is designed to minimise any detrimental steric effect on the polymerisation reaction due to the large macrocycle. Indeed, free radical polymerisation of **4** can be achieved with high conversion (> 85%) to give soluble polymers of reasonable molar mass ($M_n > 40 \times 10^3$ amu) and with relatively narrow polydispersity ($M_w/M_n \sim 1.5$) as measured by gel permeation chromatography (GPC) against commercial polystyrene standards (Table 1). The optimum conditions for polymerisation proved to be a 0.05 mmol ml^{-1} concentration of monomer **4** in benzene solution using a 5 mol% concentration of AIBN relative to **4**. Prior complexation of **4** to zinc(II), to give monomer **5**,† resulted in polymers of higher mass.

It is possible to vary the concentration of Pc functionality within the resulting materials by preparing random copolymers from styrene and Pc **4** or **5**. Interestingly, the molecular masses obtained for these copolymers were consistently higher than those of unsubstituted polystyrene obtained under the same conditions. This prompted us to perform control experiments in which styrene was polymerised with or without added unreactive metal-free octakis(dodecyloxy)-Pc (ODPc) or its zinc(II) derivative (ZnODPc). The polystyrene prepared in the presence of ODPc or ZnODPc proved to have significantly higher mass and lower polydispersity than that prepared in its absence (Table 1). This unexpected result was attributed to the Pc removing the residual oxygen which remained after conventional deoxygenation using a repeated freeze–thaw degassing process. It is well-established from various spectroscopic and electronic conductivity studies that Pcs interact strongly with molecular oxygen. Zinc(II)-containing Pcs are particularly efficient at interacting with oxygen and this may explain why monomer **5** is particularly well-suited to free radical polymerisation.

UV–VIS absorption spectra of the polymers dissolved in toluene reveal that there are strong cofacial interactions between the Pc side-chains. This is apparent from the large bathochromic shift of the primary Q-band of the Pc from 690 to 620 nm. We believe that these interactions are primarily intramolecular because even very dilute solutions show this effect, whereas solutions of monomer **4** or **5** of similar concentration display an unperturbed Q-band (Fig. 1). UV–VIS spectra of the copolymers also display the broad absorption band resulting from self-association. High resolution ^1H NMR spectroscopy clearly shows the presence of the dodecyloxy groups attached to the Pc side-chains, however the aromatic protons are indicated only by a single very broad signal centred at δ 6.9, presumably due to intramolecular association of the Pc units. NMR spectra of the copolymers show clear signals originating from the polystyrene backbone, however, only broadened resonances from the alkyl component of the Pc-containing side-chain are apparent. This

observation reinforces the evidence from UV–VIS spectroscopy that Pc self-association is a feature of the dilute solution behaviour of the copolymers even for those which possess only a small degree of Pc side-chain substitution (~0.5 mol% concentration).

Unlike the precursors and monomers **2**–**5** which form a columnar mesophase at elevated temperatures, thin films of the Pc-containing homopolymers are birefringent solids up to their decomposition temperatures (~300 °C). The copolymers are isotropic glassy solids with well-defined glass transition temperatures. Thin films of the copolymers, fabricated by spin-coating or by melt processing, are optically clear and highly coloured. The non-scattering nature of these films make them suitable for optical studies.

This work illustrates the compatibility of Pc-containing styrene monomers with free radical polymerisation to produce well-defined macromolecules. It allows the design of novel, readily processed functional materials including polymeric dyes, polymer supported Pc-catalysts, photobactericidal polymers[12] and polymers for various optical applications.

We thank Kuwait University (S. M.) and the EPSRC (A. C.) for the provision of studentships.

The first total synthesis of a type II manumycin antibiotic, (+)-TMC-1 A: the total syntheses of (−)-LL-C10037β and (+)-manumycin B

J. J. Cronjé Grové, Xudong Wei and Richard J. K. Taylor*

Department of Chemistry, University of York, Heslington, York, UK YO10 5DD. E-mail: rjkt1@york.ac.uk

Received (in Cambridge, UK) 8th January 1999, Accepted 22nd January 1999

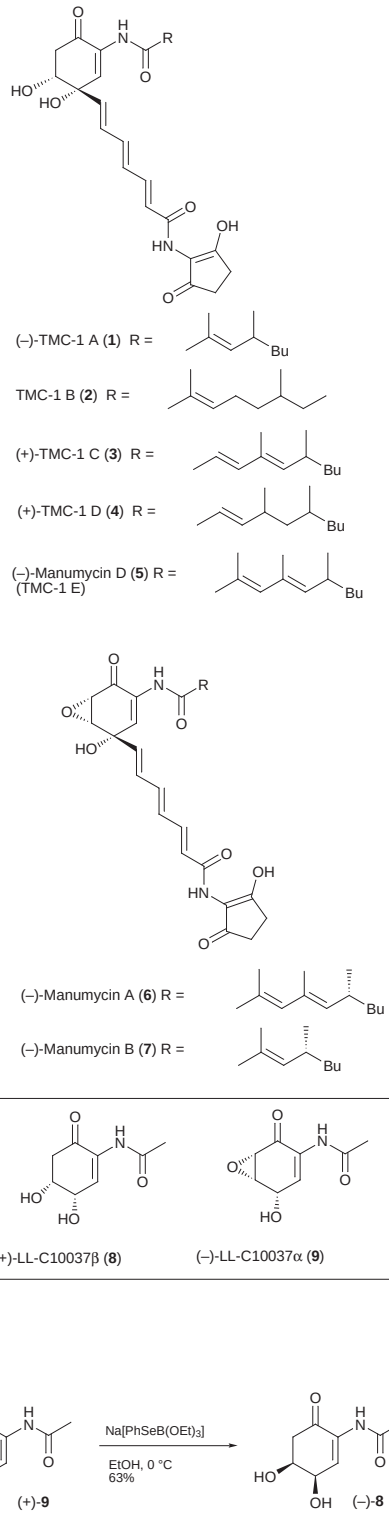
A procedure using Na[PhSeB(OEt)$_3$] is reported for conversion of the type I epoxy ketone manumycins into the type II β-hydroxyketone variants; using this procedure, (−)-LL-C10037β and (+)-TMC-1A have been prepared for the first time; the first synthesis of (+)-manumycin B, which provides full stereochemical clarification of the natural product, is also described.

The most recent additions to the manumycin family of antibiotics are the TMC-1 natural products **1**–**5** which were isolated from *streptomyces* sp. A-230 in 1996 by Kohno and co-workers and shown to be cytotoxic to a range of tumour cell lines *in vitro*.[1] This new group of compounds differ from most of the manumycin family,[2–6] *e.g.* manumycin A **6** and manumycin B **7**,† in that they possess a β-hydroxy ketone in place of the more common epoxy ketone unit. Sattler, Thiericke and Zeeck have termed[3] the β-hydroxy ketone subset, which also includes manumycin D **5**,[1,4] type II manumycins and the epoxy ketone subset type I manumycins. The same structural relationship is seen in the less complex anti-tumour natural products LL-C10037β **8** and LL-C10037α **9**.[7]

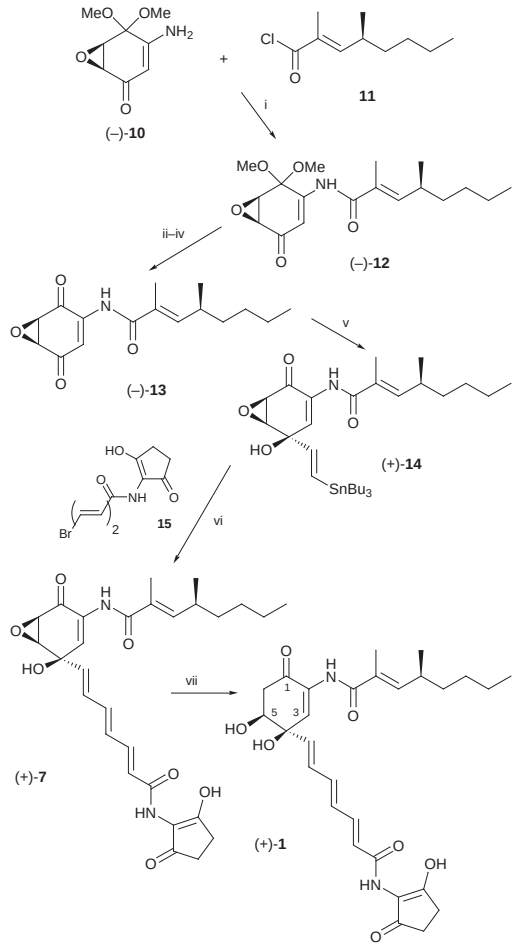
Despite their promising biological properties and interesting structures, synthetic approaches to the TMC-1 antibiotics have not been reported to date. We have recently developed a synthetic route to the type I manumycins and utilised it to prepare (+)-manumycin A[5] and other members of the family.[2,6] Regioselective reduction of the α,β-epoxy ketone group of the type I manumycins should produce the type II variants. Thus, TMC-1A **1** should be available by the reduction of manumycin B **7**.†

In order to establish the validity of this strategy, we first investigated the conversion of LL-C10037α **9** into LL-C10037β **8** as shown in Scheme 1.

The (+)-enantiomer of LL-C10037α (also known as MT 35214) was prepared using our published procedure.[6] The reagent of choice for the epoxy ketone reduction proved to be Na[PhSeB(OEt)$_3$],[8] generated *in situ* by $NaBH_4$ reduction of PhSeSePh. Model studies showed that this reagent displays exceptional tolerance towards the sensitive functional groups present within the target molecules. Treatment of (+)-**9** with a freshly prepared solution of Na[PhSeB(OEt)$_3$] in EtOH at 0 °C resulted in the formation of (−)-LL-C10037β **8**, after oxidative work-up, in an unoptimised but respectable yield of 63%.‡ Compound **8** is extremely sensitive to acid and readily undergoes dehydration–aromatisation. All spectroscopic data (IR, UV, NMR) for **8** were entirely consistent with those published[7] for the natural product. In addition, the optical rotation of (−)-**8** corresponded well to the literature data for the enantiomeric natural product {$[\alpha]_D$ −34.8 (*c* 0.9, MeOH); lit.,[7] +26.3 (*c* 0.26, MeOH)} and satisfactory HRMS data were obtained [Found: MH^+, 186.07681. $C_8H_{12}NO_4$ requires 186.07663 (1 ppm error)]. This study therefore produced the first synthesis of LL-C10037β and established the methodology for an assault on TMC-1 A. Due to the ready availability of the enantiomerically pure amine (−)-**10**, prepared utilising the Wynberg chiral phase transfer technology developed for our synthesis of (+)-manumycin A,[5,6] the (+)-enantiomer of TMC-1 A was targeted (Scheme 2).



Scheme 1



Scheme 2 *Reagents and conditions*: i, Bu^{t}OLi, THF (89%); ii, $LiEt_3BH$, THF, −78 °C (95%); iii, montmorillonite K10, CH_2Cl_2, room temp. (90%); iv, PDC, CH_2Cl_2, room temp (76%); v, (*E*)-$Bu_3SnCH{=}CHLi$, THF, −78 °C (28%); vi, [5% $PdCl_2(Ph_3P)_2$, DIBAL-H], THF–DMF, room temp. (71%); vii, Ph_2Se_2, $NaBH_4$, EtOH, 0 °C (66%).

Evans' oxazolidinone methodology was employed to prepare (*S*)-(+)-2-methylpropanal which was converted into acid chloride **11** using standard methodology.[5] Acylation of (−)-**10** in the presence of lithium *tert*-butoxide[2] afforded amide (−)-**12** in an excellent yield of 89%. Direct deprotection of the acetal was attempted but was unsuccessful due to aromatisation; amide (−)-**12** was therefore converted into the corresponding epoxy quinone (−)-**13** *via* a three step reduction–deprotection–oxidation sequence in good overall yield. The enantiomeric quinone, (+)-**13**, was obtained by Hara *et al.* by chromic acid degradation of manumycin B.[9] The NMR data and optical rotation of quinone (−)-**13** corresponded well to those of its enantiomer {*e.g.* $[\alpha]_D$ −16.5 (*c* 1.1, $CHCl_3$); lit.,[9b] +16.0 (*c* 0.2, $CHCl_3$)}.

Quinone (−)-**13** was elaborated *via* the addition of (*E*)-$Bu_3SnCH{=}CHLi$:[10] a mixture of mono- and di-adducts was obtained from which vinylstannane (+)-**14** was isolated in 28% yield after chromatography. The expected[2,5] *syn*-hydroxy epoxide structure was confirmed by the diagnostic coupling constant between H-3 and H-5 (*J* 2.7 Hz). Stille coupling between vinylstannane (+)-**14** and dienyl bromide **15**[11] proceeded efficiently (71%) to give (+)-manumycin B **7** as a bright yellow solid (mp 96–97 °C; lit.,[4] 94 °C) which displayed spectroscopic, chromatographic and polarimetric data entirely consistent with it being the enantiomer of the natural product. This is the first synthesis of manumycin B and it confirms that, as proposed,[5] it does indeed have the *syn*-hydroxy epoxide configuration illustrated (rather than the corresponding *anti*-arrangement described in the original structure elucidation[4]).

Treatment of (+)-manumycin B **7** with $Na[PhSeB(OEt)_3]$ using the reaction conditions developed in the model studies resulted in the formation of a polar, light sensitive, dark yellow solid in an isolated yield of 66%. All spectroscopic and chromatographic data proved to be consistent with the literature[1] values for the natural antibiotic, TMC-1 A [*e.g.* $\delta_C(CDCl_3$, 500 MHz) 191.8 (C-1), 132.0 (C-2), 126.2 (C-3), 73.5 (C-4), 71.8 (C-5), 40.5 (C-6); lit.,[1] ($CDCl_3$, 400 MHz) 191.8 (C-1), 132.2 (C-2), 126.0 (C-3), 73.6 (C-4), 71.9 (C-5), 40.6 (C-6)]. The optical rotation of the product {$[\alpha]_D$ +58.6 (*c* 0.5, $CHCl_3$) was consistent with it being the enantiomer of (−)-TMC-1 A **1** {lit.[1] −55.0 (*c* 0.1, $CHCl_3$)}. This study therefore confirms structure **1** for (−)-TMC-1 A and establishes the 4′*R* configuration for the side chain methyl group.

In summary, we have devised a procedure for converting the type I epoxy ketone manumycins into the type II β-hydroxy ketone variants. Using this procedure, (−)-LL-C10037β and (+)-TMC-1A have been prepared for the first time and the structures of the natural products confirmed. The first synthesis of (+)-manumycin B is also reported, thereby correcting the published stereochemical assignment and confirming the *syn*-hydroxy epoxide structure. It seems likely that manumycin B is the biosynthetic proecursor of TMC-1 A, and therefore that the chemical synthesis described above is biomimetic.

We thank the Foundation for Research Development (South Africa) and the EPSRC for research fellowships (J. J. C. G. and X. W., respectively). We are also grateful to Dr T. A. Dransfield and Miss H. Fish (University of York) for their expert assistance with mass spectrometry and NMR spectroscopy, and to Dr S.-i. Ikeda[9b] for spectra and physical data for epoxyquinone (+)-**13**.

Natural bond orbital analysis of hyperconjugative stabilization effects in the transition states of cyclohexanone reduction with $LiAlH_4$

Shuji Tomoda* and Takatoshi Senju

Department of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro, Tokyo 153-8902, Japan. E-Mail: tomoda@selen.c.u-tokyo.ac.jp

Received (in Cambridge, UK) 23rd November 1998, Accepted 22nd January 1999

Natural bond orbital (NBO) analysis of the transition states of cyclohexanone reduction with $LiAlH_4$ located at the B3LYP/6-31+G(d) level along the intrinsic reaction coordinate (IRC) strongly indicate that the antiperiplanar effect involving the incipient bond may not be important as a controlling factor of π-facial selection in carbonyl reduction.

Since Cieplak[1] proposed the theory of π-facial stereoselectivity in 1981, the direction of the antiperiplanar hyperconjugative stabilization effects (hereafter abbreviated as 'the AP effect') in the transition states of nucleophilic carbonyl addition have been the subject of intense investigation in both theoretical and experimental organic chemistry.[2] While the Felkin–Anh model[3] postulated the AP effect between the filled electron-rich incipient bond and the vacant vicinal antiperiplanar bonds, Cieplak predicted the opposite electronic property in common organic reactions, proposing exactly the reverse AP effect.[1] Herein we report the first transition state of the reduction of cyclohexanone with $LiAlH_4$ together with the natural bond orbital (NBO)[4] analysis of the AP effects along the intrinsic reaction coordinate towards the transition state.

The structures of the axial (*ax*-TS) and equatorial (*eq*-TS) transition states of cyclohexanone reduction with $LiAlH_4$ optimized at the B3LYP/6-31+G(d) level are shown in Fig. 1. The zero point vibrational energy corrected relative electronic energy was 1.36 kcal mol^{-1}, slightly favoring the *ax*-TS in agreement with experiment. Each transition state had a single imaginary vibrational frequency corresponding to the stretching vibration of the incipient bond (ν_i = 377.7 and −392.6 cm^{-1} for *ax*-TS and *eq*-TS, respectively). The incipient bond distances for $LiAlH_4$ transition states were 1.531 and 1.556 Å for *ax*- and *eq*-TS, respectively, which are far shorter than the unrealistically long incipient bonds of LiH transition states [2.739 (*ax*-TS) and 2.510 (*eq*-TS) Å; B3LYP/6-31+G(d)]. In contrast to the LiH cases, the relative earliness of *ax*- and *eq*-TS with $LiAlH_4$ in terms of the incipient bond length suggests that the latter is moderately earlier than the former. Such a trend is also seen in the bond lengths of other parts of the structures, such as the C=O, Al–H and O–Li bond distances. Thus the incipient bond for *ax*-TS may be stronger than that for *eq*-TS. The hydride approaching angles in the $LiAlH_4$ transition structures [109.8 (*ax*-TS) and 109.5° (*eq*-TS)] are greater by ~ 20° than those for the LiH cases [85.6 (*ax*-TS) and 90.3° (*eq*-TS)] The former values are similar to the average angle of nucleophile approach (107°) observed by crystallographic investigation of some crystalline ketones.[5] The torsion angles of the cyclohexanone moiety along C2–C1–C6–C5 are 44.2 and 63.8° for *ax*- and *eq*-TS, respectively. The latter is much more distorted than the LiH transition states [42.5 (*ax*-TS) and 56.5° (*eq*-TS)]. The magnitude of the torsional strain of the cyclohexanone moieties of $LiAlH_4$ transition states relative to ground-state cyclohexanone optimized at the B3LYP/6-31+G(d) level was 11.9 and 10.9 kcal mol^{-1} for *ax*-TS and *eq*-TS, respectively [single point calculation at the MP2/6-31+G(d) level]. As such, *ax*-TS is slightly (1.0 kcal mol^{-1}) more distorted than *eq*-TS, in sharp contrast to the LiH case previously reported.[6] It is therefore concluded that the torsional strain is not responsible for π-facial stereoselectivity in cyclohexanone reduction as pointed out previously by Frenking using the LiH transition states.[7]

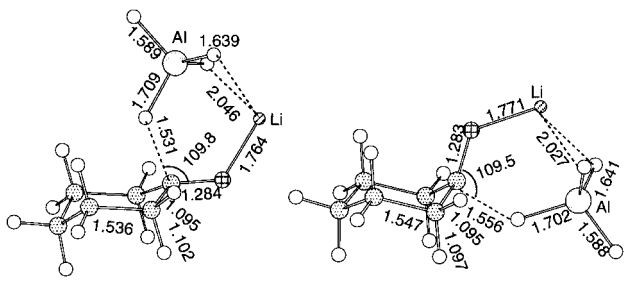

Fig. 1 Selected structural parameters for the transition states of cyclohexanone reduction with $LiAlH_4$ obtained at the B3LYP/6-31+G(d) level. Bond lengths are in Å and angles are in degrees. *E* indicates the total electronic energy.

It is expected that the magnitude of the AP effects may be initially significant, but should gradually be diminished along the IRC toward the transition state for the following two reasons. First, as the reaction proceeds, the strength of the incipient bond increases, causing some energy increase in the antibonding (σ‡*) level of the incipient bond accompanied by energy reduction of its bonding (σ‡) level. This may cause reduction of both (Cieplak and Felkin–Anh) antiperiplanar stabilization mechanisms involving the incipient bond. Secondly, as the reaction proceeds, hybridization of the carbonyl carbon (C1) changes from sp^2 to sp^3, and therefore the length of the intervening σ_{C1-C2} bond increases to cause inevitable reduction in the magnitude of the antiperiplanar hyperconjugation toward transition state. Consequently it is expected that antiperiplanar hyperconjugation mechanisms may operate effectively in the early stages and that the difference in the magnitude between the two π-faces of the carbonyl plane may be reduced steadily along the reaction coordinate toward the transition state, where it may vanish completely.

To evaluate the relative magnitude of the AP effects in the $LiAlH_4$ transition states, a natural bond orbital (NBO) program[4] combined with intrinsic reaction coordinate (IRC) calculations with GAUSSIAN 94[8] were applied at the B3LYP/6-31+G(d) level. IRC calculation clearly showed that the above structures with negative frequencies (Fig. 1) were indeed the transition states. As shown in Fig. 2, structural analysis of the reaction along the IRC indicated a steady decrease in the AP effects towards the transition states. The percentage elongation of the vicinal antiperiplanar bonds (relative to the corresponding bonds of ground-state cyclohexanone optimized at the same level) in *eq*-TS (0.33–0.14%) is always greater than that in *ax*-TS (0.13–0.05%) along the reaction coordinate. It should be noted here that elongation of the antiperiplanar bonds is reduced to almost zero (0.05%) in *ax*-TS (IRC = 0) in agreement with the above prediction. The relative magnitude of the transition state AP effects (*ax*-TS vs. *eq*-TS) as well as the marginal AP effect in *ax*-TS clearly indicate that if the AP effects were the

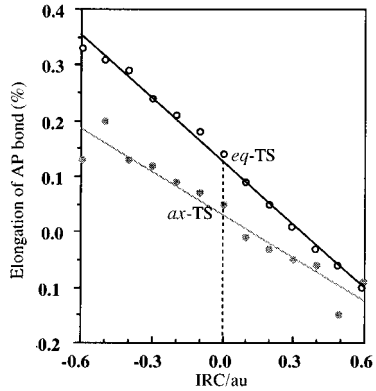

Fig. 2 Elongation of vicinal antiperiplanar bonds along the IRC for cyclohexanone reduction with $LiAlH_4$ [B3LYP/6-31+G(d)].

major mechanism of facial stereoselection in cyclohexanone reduction, stereoselectivity opposite to the experimental result must be observed, contrary to the predictions of both conventional models.[1,3]

In agreement with the above theoretical outcomes, NBO analysis along the IRC toward the transition states suggested that a small amount of electronic charge was removed from the vicinal antiperiplanar bonds all the way along the transition states [0.015–0.008 electrons for the *eq*-attack and 0.011–0.005 electrons for the *ax*-attack based on the bond population for the corresponding antiperiplanar bonds of cyclohexanone optimized at the B3LYP/6-31+G(d) level] and that they monotonously decreased along IRC as shown in Fig. 3. The small reduction in the amount of electrons in the antiperiplanar bonds clearly indicated that the Cieplak hyperconjugation effect should be greater than the Felkin–Anh hyperconjugation effect. The electron population of the incipient bond ($\sigma^{\ddagger}$) determined with natural resonance theoretical (NRT) analysis[4] was 0.696 and 0.663 for *ax*- and *eq*-TS, respectively. These values strongly suggest significantly electron-deficient incipient bonds in the transition states for cyclohexanone reduction in agreement with Cieplak's proposal.[1] Thus the greater AP effect at *eq*-TS compared with *ax*-TS as indicated by the percentage elongation of the antiperiplanar bonds (*ax*-TS = 0.05% and *eq*-TS = 0.14%) as well as by the magnitude of electron transfer (*ax*-TS = 0.005 *e* and *eq*-TS = 0.008 *e*) strongly suggests that the AP effect may not be an essential mechanism of π-facial stereoselection.

It was found that within the framework of modern molecular orbital methods operational direction of the AP effect involving an incipient bond is not necessarily consistent with a preferred direction of hydride attack, as seen in the following transition state examples of $LiAlH_4$ reduction obtained at the B3LYP/6-31+G(d) level. The 3,5-dithiacyclohexanone reduction with $LiAlH_4$, the *eq*-attack of which is preferred to the *ax*-attack,[9] shows unusual behavior of the AP effect: the C2–S3 bond in *eq*-TS is shortened (−0.11%), while the C2–H*ax* bond in *ax*-TS is elongated (+0.25%) relative to the starting ketone. The

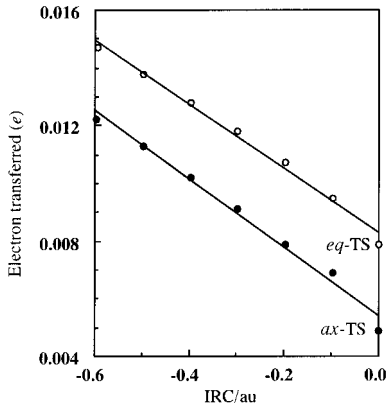

Fig. 3 Plot of the electron population moved from an antiperiplanar bond against the IRC for cyclohexanone reduction with $LiAlH_4$ [B3LYP/6-31+G(d)].

reduction in the NBO[5] electron population in the antiperiplanar bonds at C2 and C6 (−0.012 and 0.000 for *ax*- and *eq*-TS, respectively) was also consistent with this interesting trend. It is clear that the experimental stereochemistry cannot be explained in terms of the AP effect. Apparently the AP effect is more significant in *ax*-TS, although *ax*-TS is less stable by 1.39 kcal mol^{-1} than *eq*-TS.

Another intriguing case is the adamantanone system. It has long been known that adamantanone is less reactive in hydride reduction than cyclohexanone,[10] despite the theoretical observation that the AP effects are much greater in adamantanone than in cyclohexanone. The $LiAlH_4$ transition state of the parent adamantan-2-one shows more than twice (+0.34% elongation of the C–C bond) as large AP effects as those of cyclohexanone (+0.05 and +0.14% for *ax*- and *eq*-TS, respectively). While 5-methyladamantan-2-one shows only a marginal difference in percentage elongation of the vicinal antiperiplanar C–C bond between the *syn*- (+0.40%) and *anti*-TS (+0.38%) (relative to the ground-state 5-methyladamantan-2-one), 5-fluoroadamantan-2-one, which gives preferential *syn*-attack in $NaBH_4$ reduction (63 : 37),[11] shows a larger AP effect in *anti*-TS (+0.48%) than in *syn*-TS (+0.39%) relative to the ground-state 5-fluoroadamantan-2-one. In both of these cases, the *syn*-TS is more stable than the *anti*-TS by 0.12 (5-methyladamantan-2-one) and 0.23 (5-fluoroadamantan-2-one) kcal mol^{-1}. Another case which shows similar behavior is 5-azaadamantan-2-one *N*-oxide, which prefers 96% *syn*-attack upon reduction with $NaBH_4$.[12] The $LiAlH_4$ reduction transition states of this compound show elongation of the vicinal antiperiplanar bonds of +1.00% (*anti*-TS) and +0.95% (*syn*-TS) relative to the parent ketone. Virtually no difference in the magnitude of the AP effects over two carbonyl faces is evident.

The present analysis strongly suggests that the transition state effects are most likely to have minor effects on facial selection. This 'unusual' behavior may be readily understood if one considers the mechanism (the direction of the force vector on hydride nucleus) of the AP effect which operates against the incipient bond formation: the effect causes elongation of the incipient bond against the force vector on hydride directed toward bond formation with the carbonyl. We emphasize again that the difference in the magnitude of the driving force of the reaction generated over the two π-faces of the carbonyl plane through orbital interactions[13] between ketone and hydride should be the origin of π-facial stereoselectivity in cyclohexanone reduction.[14]

A new synthetic path to *peri*-naphthisoxazoles by oxidative intramolecular cyclization of some β,γ-unsaturated oximes

John C. Barnes, William M. Horspool* and George Hynd

Department of Chemistry, The University of Dundee, Dundee, Scotland, UK DD1 4HN.

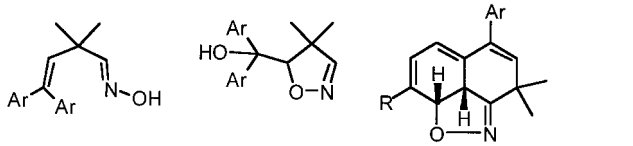
Received (in Liverpool, UK) 7th December 1998, Accepted 27th January 1999

Some β,γ-unsaturated oximes undergo an unprecedented intramolecular cycloaddition to an aryl group to afford *peri*-naphthisoxazoles when they are irradiated in the presence of $PhI(OAc)_2$ and I_2 or HgO and I_2 in benzene or by thermal reaction with NaOCl and Et_3N in CH_2Cl_2.

As part of a general study of the reactivity of β,γ-unsaturated oximes[1] we have examined their reactions in the presence of reagents known to yield free radicals. A survey of the literature on iminoxyl radicals suggests that such radicals have not been generated photochemically in solution previously. Therefore, the methodology for the generation of alkoxyl radicals was used as a model. Two methods, $PhI(OAc)_2$–I_2 in 1,2-dichloroethane[2] and HgO–I_2 in benzene[3] have been used extensively by several groups and these methods were utilised in this study. Thus we report the photochemical reactions of the β,γ-unsaturated oximes **1** with both these reagent systems.



1a Ar = Ph
b Ar = *p*-BrC_6H_4
c Ar = *p*-ClC_6H_4
d Ar = *p*-$CH_3C_6H_4$

2a Ar = Ph
b Ar = *p*-$CH_3C_6H_4$

3a Ar = Ph, R = H
b Ar = *p*-BrC_6H_4, R = Br
c Ar = *p*-ClC_6H_4, R = Cl
d Ar = *p*-$CH_3C_6H_4$, R = CH_3

The oximes **1** are readily prepared from the corresponding aldehydes. These are synthesised following the method originally reported by Zimmerman and co-workers[4] and more recently extended by Armesto *et al.*[1] Typically irradiation (λ > 280 nm) of the oxime **1a** in benzene in the presence of HgO–I_2 (3 equiv. of each) resulted in the formation of two products. The ^{13}C and ^1H NMR spectra of the more polar component showed it to be the known hydroxydihydroisoxazole **2a** (13%) previously reported by Armesto *et al.*[5]

The ^1H NMR spectrum of the less polar but major component of the mixture showed this to be considerably different from the hydroxydihydroisoxazole **2a**. The identification of this product was not easy by conventional means although the integral and the number of vinylic signals in the ^1H NMR spectrum suggested that addition to one of the aromatic rings had taken place. X-Ray diffraction† showed this product to be a *peri*-naphthisoxazole, 6-phenyl-8,8-dimethyl-10-aza-11-oxatricyclo[7.2.1^{1,9}.0^{5,12}]dodeca-2,4,6,9-tetraene **3a** (55%) (Fig. 1).

The irradiation of the oxime **1a** in 1,2-dichloroethane in the presence of $PhI(OAc)_2$–I_2 (1.2 equiv.), best carried out with a low wattage tungsten lamp, was more efficient and cleaner than in the presence of HgO–I_2, yielding only the *peri*-naphthisoxazole **3a** in 77% yield and recovered starting material. Other derivatives of the oxime behaved similarly and **1b** and **1c** were converted into the corresponding *peri*-naphthisoxazoles **3b** and **3c** in yields of 67 and 68%, respectively.

The formation of the *peri*-naphthisoxazole products from these irradiations suggests that they might arise from a conventional intramolecular 1,3-dipolar addition of a nitrile oxide to an arene. However, there appears to be no literature precedent for the addition of such a 1,3-dipole to a benzene moiety, although there are reports of additions to heteroarenes.[6] Neither are we aware of a precedent for the formation of a nitrile oxide *via* an iminoxyl radical. Thus it was important to verify whether or not the conventional route to nitrile oxides would also yield *peri*-naphthisoxazoles.

The method selected was reaction of the oxime **1b** (250 mg, 0.94 mmol) with NaOCl (0.21 ml of an 8% solution, 1.68 mmol) and Et_3N (10 mg, 0.1 mmol) in CH_2Cl_2 (10 ml).[7] The mixture was stirred at room temperature for 4 days. This indeed yields the same *peri*-naphthisoxazole **3b** obtained by the photochemical route. However, in this instance the yield is only 44% and the reaction time is much longer (4 days). Similar thermal reactivity was observed with the oxime **1d**, which gave the *peri*-naphthisoxazole **3d** in 47%. Interestingly the irradiation of oxime **1d** using either HgO–I_2 or $PhI(OAc)_2$–I_2 failed to yield a *peri*-naphthisoxazole and gave only the corresponding hydroxydihydroisoxazole **2b** in yields varying from 24–45%. Thus there appears to be a difference between the photochemical and the thermal cyclization.

It is most likely that both of the photochemical reactions involve the homolytic fission of OI bonds. There are many literature examples of hypoiodites formed from alcohols using both of the methods utilised here.[2,3] It is reasonable to assume that oximes will also yield hypoiodites and, therefore, these should also undergo OI bond fission with the formation of, in this instance, iminoxyl radicals such as **4**. The cycloaddition could involve this species with the formation of an intermediate such as **5**.

Final cycloaddition and loss of a hydrogen would yield the product. Alternatively the iminoxyl radical could lose a hydrogen to afford the nitrile oxide **6** that would then undergo cycloaddition. We have not resolved this dilemma since it is clear that the conventional path to nitrile oxides also affords the cycloadducts. The one thing that is obvious is that the paths appear to be subtly different. This is seen by the failure of **1d** to undergo the photochemical cyclization while the thermal reaction of **1d** affords **3d**. Currently experiments are in hand to try to resolve this difference.

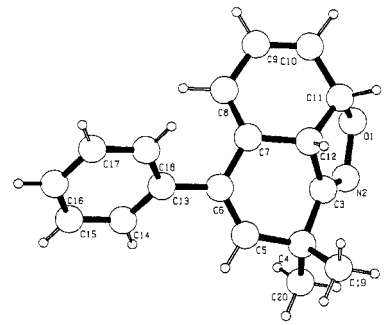


Fig. 1 X-Ray structure of **3a**.

Stereoselective construction of the tetracyclic scalarane skeleton from carvone

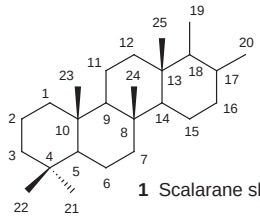
Antonio Abad,* Consuelo Agulló, Ana C. Cuñat and M. Carmen Llosá

Departamento de Química Orgánica, Universidad de Valencia, Dr. Moliner 50, 46100 Burjassot, Valencia, Spain. E-mail: antonio.abad@uv.es

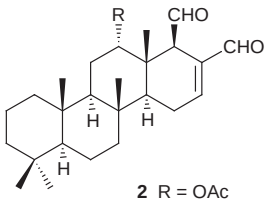
Received (in Liverpool, UK) 4th January 1999, Accepted 25th January 1999

The tetracyclic scalarane skeleton 22 has been constructed from (*S*)-(+)-carvone using two intramolecular Diels–Alder reactions as key synthetic steps.

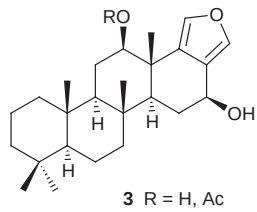
An increasing number of compounds of the relatively new family of the scalarane sesterterpenoids, which show structures based on the hypothetical scalarane skeleton **1**, have been isolated from different marine organisms.[1] These compounds



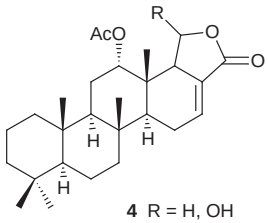
1 Scalarane skeleton



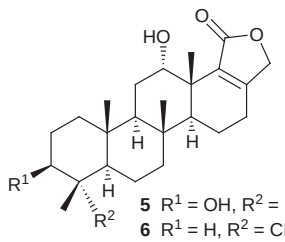
2 R = OAc



3 R = H, Ac



4 R = H, OH



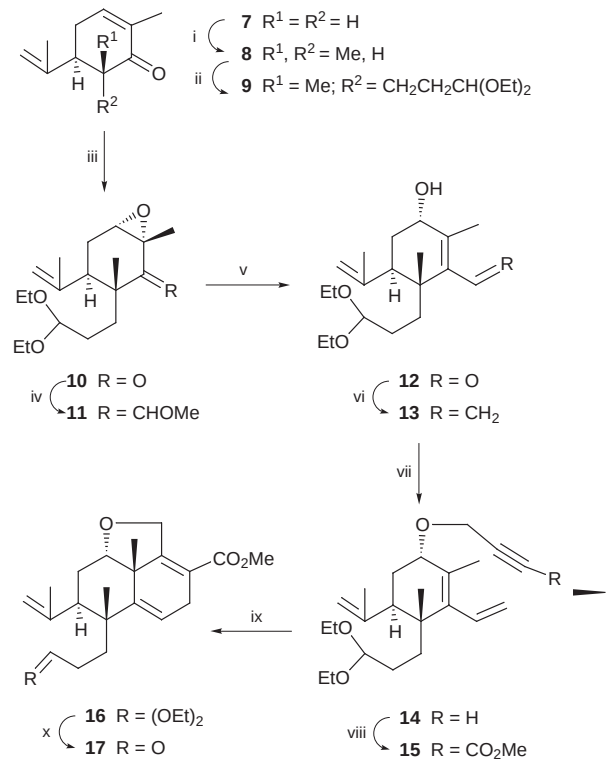
5 R^1 = OH, R^2 = Me
6 R^1 = H, R^2 = CH_2OH

seem to play an important ecological function[2] and some of them exhibit potentially useful biological activities, including antiinflammatory,[3] cytotoxic[4] and antifeedant[5] properties. Most of the members of this group of sesterterpenes possess a 1,4-dialdehyde moiety at C19–C20, either as actual aldehyde groups or latent as γ-butenolide or furan rings, as well as a C12 oxygenated function as common structural features. Recently some compounds with an additional oxygenated function at the C3 position have also been isolated.[6] Some representative compounds are scalaradial **2**, scalarafurans **3**, scalarolides **4**[4] and sesterstatins **5** and **6**.[7]

In spite of their interesting biological activities and challenging structures, this family of sesterterpenes has received little synthetic attention. To the best of our knowledge, only the synthesis of several compounds with the basic scalarane skeleton starting from manool,[8] methyl isocopalate[9] and methyl copalate,[10] as well as the total enantioselective biomimetic synthesis of scalarenedial[11] **2** (R = H) have been published. However, none of these syntheses solves the incorporation of the oxygenated function at the C12 position.

As part of our continuing interest in the synthesis of polycyclic natural products from readily available chiral building blocks,[12] we sought an efficient route to the scalarane sesterterpenes from carvone and we report herein a stereoselective general approach to the tetracyclic ABCD carbon framework. Explicitly, we describe the efficient preparation of the compound **22**, which has the scalarane skeleton and functionalisation suitable for further elaboration into some of the more representative natural scalaranes. The synthesis of **22** is effected using (*S*)-carvone as a C-ring synthon which is incorporated into the tetracyclic framework following a C→CD→ABCD ring annulation strategy, using two intramolecular Diels–Alder (IMDA) reactions as key synthetic steps.[13]

The synthesis commences with the preparation of the propargyl (prop-2-ynyl) compound **15**, precursor of the IMDA reaction that allows the construction of the CD ring subunit (Scheme 1). The known dialkylated carvone **9**, obtained in 70% overall yield from (*S*)-carvone by two consecutive alkylations with MeI and 3-iodopropanaldehyde diethyl acetal,[12a] was stereoselectively converted into the α-epoxy ketone **10** in 92% yield by treatment with alkaline H_2O_2. Treatment of **10** with the lithium derivative of methoxymethyl(diphenyl)phosphine oxide



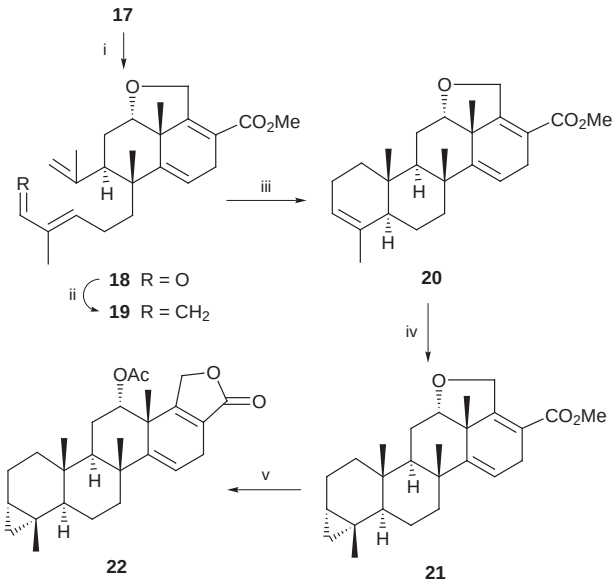
Scheme 1 *Reagents and conditions*: i, LDA, THF, −10 °C then CH_3I; ii, LDA, HMPA–THF, −78 °C then $(EtO)_2CHCH_2CH_2I$, 70% from **7**; iii, H_2O_2, NaOH, MeOH, room temp., 92%; iv, $Ph_2P(O)CH(Li)OMe$, THF, −78 °C then NaH, DMF, from 0 °C to room temp.; v, chromatography on silica gel, 77% from **10**; vi, $Ph_3P{=}CH_2$, THF, −20 °C, 85%; vii, Bu^n_4NI, $BrCH_2CCH$, 60% NaOH, room temp., 97%; viii, BuLi, THF, −78 °C then HMPA, $CNCO_2Me$, 87%; ix, toluene, 105 ºC, 99%; x, PPTS, acetone–H_2O, reflux, 87%.

in THF at low temperature afforded a mixture of crystalline β-hydroxyphosphine oxides, which were subjected to *syn* elimination by treatment with NaH in DMF at 0 °C to give a mixture of isomeric vinyl ethers **11**. Direct chromatographic purification of this mixture on silica gel resulted in chemoselective hydrolysis of the vinyl ether moiety and consecutive opening of the epoxide, providing the desired unsaturated hydroxy aldehyde **12** cleanly and efficiently (77% overall yield from epoxy ketone **10**).† Methylenation of **12** under Wittig conditions then gave dienol **13** in 85% yield, which was transformed into the propargyl ether **14** in very high yield by reaction with propargyl bromide under phase-transfer conditions. Sequential treatment of compound **14** with BuLi and methyl cyanoformate in the presence of added HMPA provided **15** in 87% yield, which underwent a smooth IMDA cycloaddition upon heating in a sealed tube at 105 °C overnight in anhydrous toluene. The reaction takes place very cleanly to give the tricyclic system **16** in nearly quantitative yield.[14]

After successfully accomplishing the synthesis of the CD ring fragment, attention was turned towards the construction of the AB rings, for which we followed a parallel route to that previously used by us for the preparation of a related system (Scheme 2).[12c] Removal of the aldehyde acetal function of **16** with PPTS in aqueous acetone afforded the aldehyde **17** in 87% yield. Wittig reaction of **17** with (α-formylethylidene)triphenylphosphorane provided the chain-extended aldehyde **18**, which by subsequent standard Wittig methylenation afforded the compound **19** in 78% overall yield. Heating a solution of this compound in toluene and a small amount of propylene oxide in a sealed tube at 185 ºC for 6 days afforded the pentacyclic compound **20**, with the expected *trans–anti–trans* fused ABC ring system of the scalarane framework, in 85% yield after column chromatography.

Completion of the synthesis of compound **22** was effected as follows. First **20** was submitted to Simmons-Smith cyclopropanation conditions to chemo- and stereoselectively cyclopropanate the ring A double bond, an indirect way of introducing the geminal dimethyl group at C-4 of the natural scalaranes. Finally, cleavage of the dihydrofuran ring of **21** occurred smoothly and cleanly by treatment with Ac_2O and zinc iodide, being accompanied by simultaneous lactonisation to give the scalarane-type compound **22**‡ in 86% overall yield for the last two steps.

The synthesis of **22** from (*S*)-(+)-carvone is thus completed in 15 synthetic operations in 17% overall yield. We believe that this compound constitutes an attractive intermediate for the synthesis of the more representative scalaranes. Work is currently in hand to further elaborate this intermediate towards scalaradial.§



Scheme 2 *Reagents and conditions*: i, Ph_3P=CMeCHO, benzene, reflux, 87%; ii, Ph_3P=CH_2, THF, −20 °C, 90%; iii, toluene, 185 °C, 85%; iv, Et_2Zn, CH_2I_2, toluene, room temp., 89%; v, ZnI_2, $(MeCO)_2O$, room temp., 96%.

Financial support from DGICYT (Grant PB95-1088) is gratefully acknowledged. Special thanks are due to Dr Roberto M. Sotelo (Programa Intercampus América Latina/España 1997 from Universidad Tecnológica Nacional de Avelladena, Argentina) for the repetition of some reactions.

Notes and references

† Alternative procedures to effect the same transformation using different mild acidic conditions also promoted hydrolysis of the acetal moiety.

Received (in Cambridge, UK) 19th November 1998, Accepted 15th January 1999

Photoinduced electron transfer between sexithiophene and fullerene derivatives in the solid phase has been studied by transient EPR spectroscopy: spin correlated radical pairs were observed having a lifetime of 10 μs and mean distance of 20 Å.

Several classes of electron donor–acceptor (D–A) systems have been investigated displaying through-bond and through-space mechanisms of photoinduced electron transfer (PET), the latter mechanism being responsible for the charge-separated state in D–A blends. Among other systems,[1] the PET process has been fully investigated in blends of thiophene polymers and oligomers and C_{60} as building blocks.[2,3]

The thiophene–C_{60} combination is particularly attractive because of the tunable donor properties of the thiophenes[4–6] (depending on their chain length and substituents) and the acceptor properties of C_{60}. PET from π-conjugated polymers and oligomers of thiophene derivatives to C_{60} have been studied mainly by photoinduced absorption (PIA) spectroscopy and light-induced electron paramagnetic resonance (LEPR).[1] Using PIA spectroscopy, it was found that the forward electron transfer is extremely fast (ps time scale), while the rate for back electron transfer can be many orders of magnitude lower.

Compounds **1**[7] and **2**[8] (Scheme 1) were prepared as described previously. Mixed films of sexithiophene/fullerene composites were prepared by dissolving the donor and acceptor mixture (1 : 1 molar ratio) in toluene in quartz tubes. After evaporating the solvent at a pressure of 10^{-1} Torr, the tubes were sealed under vacuum. The EPR experiments consisted of laser excitation followed by time-resolved direction of the signal.†

2 $R^1 = CH_2CH_2OCH_2CH_2OCH_2CH_2OCH_3$; $R^2 = H$

Scheme 1 Schematic view of possible structure of the **1**/**2** radical pair.

Field-swept spectra of **1**/**2** blends obtained at variable delay time from the laser pulse, are shown in Fig. 1(a) and (b). Within 0.5 μs from the laser pulse the signal reaches its maximum, then the spectrum intensity decays to zero within several microseconds.

The spectrum at its maximum intensity, shown in Fig. 1(c), is typical of spin correlated radical pairs.[9,10] Upon excitation and photoinduced electron transfer, the D^+A^- radical pair produced is characterized by two radicals having different g factors, g_D and g_A that interact by spin exchange and dipolar interactions, with J and D the constants that express their strength, respectively. Thorough analysis of the spectrum allows one to obtain information about the structure of the charge separated radical pair.

The basic EPR spectrum of a spin-correlated radical pair, created in a singlet or a triplet configuration, consists of four peaks arranged as two doublets with equal splittings determined by the spin–spin interaction between the radicals. Both doublets have one component emissive (e) and the other absorptive (a), reflecting the non-equilibrium populations of the four-electron

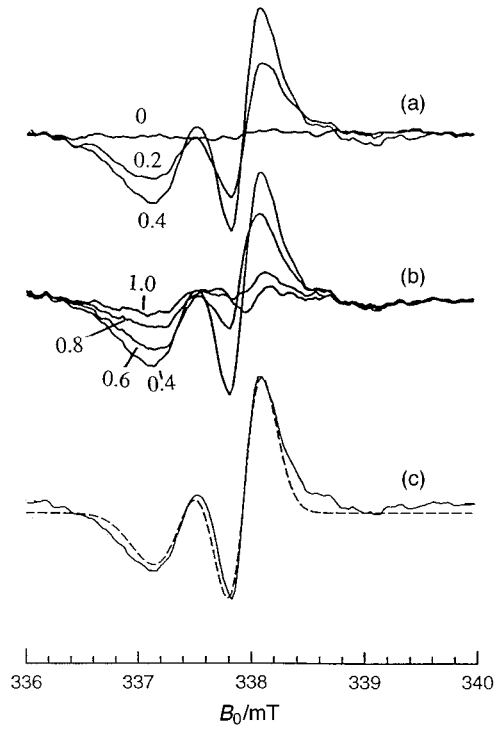

Fig. 1 Growth (a) and decay (b) of the field-swept transient EPR spectra recorded at different delay times from the laser pulse and at 120 K in **1**/**2** blends are shown. (c) Spectrum at the maximum intensity (delay time 0.4 μs, solid line) and its computer simulation (dashed line). The values of g_D = 2.0030 and g_A = 1.9998 factors were used assumed as isotropic. The value of g_A is typical of the monoanion of a C_{60} adduct.

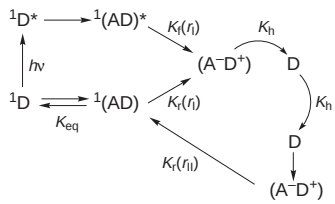
spin states. In case of hyperfine interactions with magnetic nuclei of one or both radicals of the pair, each doublet may become a more complicated multiplet. For non-oriented samples, the EPR signal has to be averaged over all the orientations of the radical pair with respect to the direction of the external field.

As shown in Fig. 1(a)–(c), the characteristic e/a/e/a pattern for a singlet born radical pair was observed in the whole time range of the experiment, extending from 0.1 to 20 μs. Simulation of the spectrum requires the knowledge of several structural parameters like the components of g_D and g_A tensors and the D and J values, although it is known that the lineshape depends most critically on the relative orientation of the principal axes of the g_D and g_A tensors and the spin–spin dipolar tensor.[10] Because of the lack of structural information on the radical pair, we have calculated the spectrum lineshape for different structural arrangements and different D and J values, and the fitting reported in Fig. 1(c) gave $D = -0.15$ mT and $J = 0.01$ mT, while principal axes of g_D and g_A, and of spin–spin dipolar tensors are assumed parallel. We have found that the spectrum lineshape is rather sensitive to the relative orientation of g and dipolar tensors, but the spread of resonant fields is scarcely affected by the above assumption. An isotropic hyperfine constant of 0.06 mT due to two equivalent hydrogen nuclei on the donor was also included.[11] In the averaging procedure over all orientations of the radical pair the stick diagram at a fixed orientation was convoluted with an envelope function in order to mimic the line broadening due to relaxation and residual unresolved hyperfine splittings. The simulated spectrum is shown in Fig. 1(c).

In order to model the structure of the pair having the charge-separated state we calculated the electron dipolar tensor for which the spin densities on the sexithiophene and on the fullerene moieties are needed. We considered for **1** the spin distribution calculated for sexithiophene,[11] while that for **2** was obtained from a HF calculation on the neutral *N*-methyl analog of **2** by taking the squares of the LUMO coefficients. The dipole–dipole interaction was calculated with the point dipole approximation, justified by the large distance between the two electrons. When the sexithiophene molecule is arranged as shown in Scheme 1, coplanar with the pyrrolidine ring, and its short in-plane axis is parallel to the z axis, the experimental value of $D = -0.15$ mT is reproduced when the centers of mass of the two molecules are 20 Å apart, a distance consistent also with the $J = 0.01$ mT value. This electron–hole (e–h) separation distance seems rather large as compared to the 10.25 Å value calculated for fullerene-doped *N*-poly(vinylcarbazole).[12] This finding supports that, in our case, a secondary radical pair is formed after e–h hopping from a more tightly bound primary pair (primary pair). It is suggested that a multistep process may occur as illustrated in Scheme 2. After the absorption of light from the donor and the exciplex formation ^{1}(AD)* the primary pair (A^-D^+) is generated by PET with the forward rate constant



Scheme 2 Schematic representation of the multistep process experienced by the electron–hole pair generated by PET. Primary pair (A^-D^+) may either recombine by rate constant $K_r(r_I)$ or may give rise by hopping of charges (K_h hopping rate constant) to a secondary pair (A^-SD^+). The latter in turn recombines with rate constant $K_r(r_{II}) < K_r(r_I)$ or transforms into subsequent pairs until it leads to radicals trapped at impurity sites.

$K_f(r_I)$, where r_I is the distance of closest approach between donor and acceptor molecules. Then, the primary (e–h) state evolves in time either by recombining to the neutral ^{1}(AD) state with backward rate constant $K_r(r_I)$ or it transforms into a secondary (A^-SD^+) pair where the active role of spacer neutral molecules (S) is to increase the e–h distance. In our case the primary pair eludes observation, since its lifetime must be < 100 ns, as shown by the signal growth in Fig. 1. In the secondary pair the dipolar and exchange interactions as well as the recombination rate constant $K_r(r_{II})$ are reduced and its lifetime falls into the ms domain. Further hopping of charges within the material eventually leads to radicals trapped at impurity sites, providing probably the light-induced EPR signals observed under continuous illumination.[13]

The phenomenon described in this work seems to be peculiar to the specific sexithiophene **1**. In fact, attempts to reproduce the same results with other methylsulfanyl-sexithiophenes[14] were unsuccessful.

In conclusion, we have shown that in blends of sexithiophene **1** with fullerene derivatives **2**, radical pairs are generated by PET that evolve in the ms domain as detected by transient EPR spectra. The resulting charge separated states are much longer than for covalently linked dyads[14] and this suggests that, analogously to other systems,[1] the blends presented here might be well suited for use in photovoltaic and optoelectronic systems.

Notes and references

† The sample was irradiated by a Lambda Physik LPX 100 XeCl excimer laser ($\lambda = 308$ nm, ≈ 10 mJ pulse^{-1}) which fed a Coumarin 47 dye laser with emitting light at 450 nm (pulse duration ≈ 20 ns). A modified Bruker ER 200D X-band (9.5 GHz) EPR spectrometer was used equipped with a fast microwave preamplifier and a broad band (10 kHz–6.5 MHz) video amplifier, whose upper frequency value limits the time resolution of the experimental to *ca.* 150 ns. The time-dependent EPR signal was digitized in a transient recorder (LeCroy 9450 digital oscilloscope) at a maximum acquisition rate of 400 megasamples s^{-1}. Typical two-dimensional (2D) EPR spectra have been recorded by collecting the time profile of the signal at different settings of the resonant magnetic field through the spectrum.

Methyl exchange on silicon during the addition of methylmagnesium iodide to a cyanohydrin *O*-silyl ether

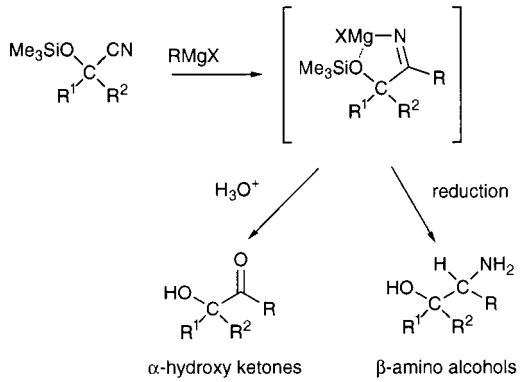
Cécile Arbez-Gindre, Valérie Berl and Jean-Pierre Lepoittevin*

Laboratoire de Dermatochimie, Université Louis Pasteur, Clinique Dermatologique, CHU, F-67091 Strasbourg, France. E-mail: jplepoit@chimie.u-strasbg.fr

Received (in Cambridge, UK) 16th December 1998, Accepted 20th January 1999

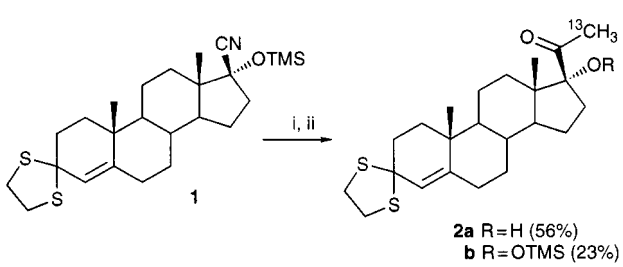
Reaction of [^{13}C]methylmagnesium iodide (99 atom% ^{13}C) with cyanohydrin *O*-trimethylsilyl ether 1, followed by acidic hydrolysis, led to the formation of a methyl ketone derivative 2a that was only partially labelled (60 ± 5 atom% ^{13}C); this loss of labelling occurred through a methyl exchange reaction on silicon as shown by the presence on intermediate 2b of [^{13}C]methyl groups on silicon (30 atom% ^{13}C).

The addition of Grignard reagents to cyanohydrin *O*-silyl ethers is a highly efficient method for synthesising α-hydroxy ketones[1,2] or β-amino alcohols[1,3] (Scheme 1). This reaction which has found numerous applications in the synthesis of natural products,[4–6] provides easy access to type **2** α-hydroxy ketones from cyanohydrin *O*-trimethylsilyl ether **1**.



Scheme 1

During studies of the allergenic potential of corticosteroids[7,8] and their interactions with skin proteins by ^{13}C NMR spectroscopy, we were interested in the synthesis of the [21-^{13}C] intermediate **2**. Addition of 2.2 equiv. of [^{13}C]methylmagnesium iodide (99 atom% ^{13}C) to **1** in toluene–Et_2O (4 : 1) at 60 °C for 26 h, followed by acidic hydrolysis, gave a mixture of **2a** and **2b** (Scheme 2) with a combined yield of 79%. However, ^{1}H NMR analysis of these products gave surprising results. In addition to the expected doublet at δ 2.25 (J_{C-H} = 128 Hz) which confirmed the formation of a [^{13}C]methyl ketone, a singlet at δ 2.25 was seen accounting for 40 ± 5% of the ^{1}H integration and due to the presence of [^{12}C]methyl ketone. Moreover, in addition to the expected singlet at δ 0.1, and characteristic of methyl groups on silicon (compound **2b**), we observed a doublet (J_{C-H} = 118 Hz) which is consistent with the presence of [^{13}C]methyl groups on silicon.



Scheme 2 *Reagents and conditions*: i, $^{13}CH_3MgI$, Et_2O, toluene, 26 h, 55–60 °C; ii, HCl 10%, acetone, THF, 14 h, room temp.

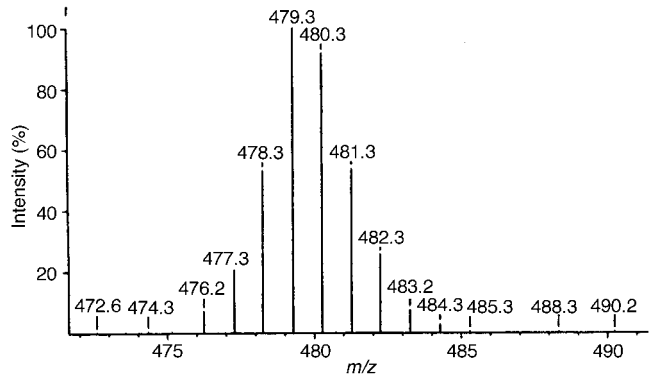


Fig. 1 Mass spectrum of compound **2b** (molecular peak).

This clearly indicates that the 21-methyl position was only partially labelled (60 ± 5 atom% ^{13}C) and that some methyl groups on silicon were also partially labelled (30 atom% ^{13}C). A mass spectrum of compound **2b** (electronic impact, Fig. 1) confirmed this finding and showed an almost statistical distribution of [^{13}C]methyl groups on the molecule.[9]

Addition of Grignard reagents to nitriles proceeds *via* rapid nitrogen complexation, followed by a slow addition of the alkyl group, to form an intermediate imine.[10–12] The presence of 30 atom% ^{13}C on the silyl group indicated that 0.9 equiv. of methyl had been exchanged. If this process occurred before the addition reaction on the nitrile, this would lead to a 1.3 : 0.9 mixture of ^{13}C/^{12}C on the Grignard and therefore to 60 atom% ^{13}C labelling of the methyl ketone.

Thus, our finding could support the idea of a methyl exchange reaction occurring before the Grignard reagent addition on the nitrile, even if we do not know the effect of a potential complexation of methyl magnesium iodide with trimethylsilyl ether on this exchange process.

Radical cation Diels–Alder reaction between indoles and exocyclic 1,3-dienes with incorporated intentional cleaving points

Thomas Peglow,[a] Siegfried Blechert*[a] and Eberhard Steckhan[b]

[a] *Institut für Organische Chemie der Technischen Universität Berlin, Strasse des 17. Juni 124, 10623 Berlin, Germany. E-mail: sibl@wap0105.chem.tu-berlin.de*

[b] *Kekulé-Institut für Organische Chemie und Biochemie der Universität, Gerhard-Domagk-Strasse 1, 53121 Bonn, Germany*

Received (in Liverpool, UK) 4th January 1999, Accepted 27th January 1999

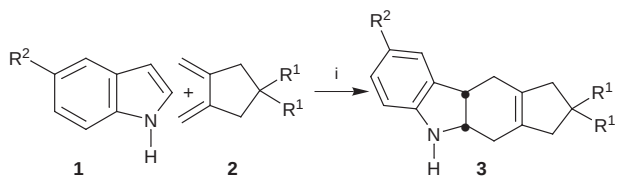
A photoinduced electron transfer catalyzed radical cation Diels–Alder reaction between exocyclic dienes, containing an N–O or N–N bond as an intentional cleaving point in the ring moiety, and indoles yields, after cleavage of the N–O or N–N bond, highly functionalized tetrahydrocarbazole derivatives, products of a formal Diels–Alder reaction between indole and open chain 1,3-dienes.

The indole skeleton is a fundamental structural unit of numerous alkaloids and biologically active compounds.[1] Since indole could prove to be an appropriate starting material for further alkaloid synthesis if suitable chemistry can be developed from this parent skeleton, attempts have been made to use the 2,3-double bond of indole in Diels–Alder cycloaddition reactions. However, the electron-rich indole shows only a low tendency to act as a dienophile. Its use mainly has been limited to Diels–Alder reactions with inverse electron demand under application of electron-poor heterodienes such as tetrazine derivatives or tetrachlorothiophene 1,1-dioxide.[2] In bimolecular Diels–Alder reactions with normal electron demand, indole can act as a dienophile if electron-withdrawing groups are present in the 1- and 3-position, but long reaction times and high temperatures are necessary.[3]

In contrast, we demonstrated the very efficient application of electron-rich indole in radical cation Diels–Alder reactions with electron-rich dienes under mild reaction conditions using photoinduced electron transfer (PET).[4,5] However, so far only a few, mainly unfunctionalized simple *endo*- and *exo*-cyclic dienes, *e.g.* cyclohexa-1,3-diene[4] and 1,2-dimethylidenecyclohexane derivatives[5] have been employed, leading to carbocyclic ring-anellated and bridged tetrahydrocarbazole derivatives, respectively. Open-chain 1,3-dienes without a rigid s-*cis*-conformation of the double bonds failed to undergo this PET-catalyzed cycloaddition reaction.

In order to broaden the synthetic scope of this reaction, we focused our investigations on the application of readily accessible functionalized exocyclic dienes, especially those which contain an intentional cleavage point in the ring moiety, thus representing the equivalents of open-chain 1,3-dienes. The rapid construction of multi-functionalized carbazoles according to this approach should be of interest with respect to indole alkaloid synthesis. In the following, our preliminary results are reported.

We started our studies with the five-membered exocyclic diene **2**[6] as a representative functionalized diene (Scheme 1).



Scheme 1 *Reagents and conditions:* i, 5 mol% photosensitizer, CH_2Cl_2, $\lambda \geqslant 345$ nm, 1000 W, 20 ° C, 1.5 h.

Due to the ease of preparation of a wide variety of these exocyclic dienes *via* an enyne cyclisation reaction,[7] these compounds are promising starting materials for the anticipated carbazole synthesis. Indeed, irradiation of diene **2**, indoles **1** and catalytic amounts of the photosensitizer triphenylpyrylium tetrafluoroborate (TPP) or tris(4-methoxyphenyl)pyrylium tetrafluoroborate (TAP) at $\lambda \geqslant 345$ nm gave good yields of Diels–Alder products **3**. Only the *cis*-fused tetrahydrocarbazoles were obtained (Scheme 1, Table 1, entries 1 and 2).

Encouraged by these results, we turned our interest to exocyclic dienes with an intentional cleavage point in the ring moiety. As potentially ring-cleavable groups we selected the N–O and N–N bonds in compounds **5** and **10** (Schemes 2 and 3). For the rapid synthesis of the hydroxylamine-derived exocyclic dienes **5** we developed a tandem-reaction initiated by a palladium-mediated allylic amination of **4** and followed by a Heck reaction (Scheme 2). The phenyl group attached to the diene moiety was chosen to stabilize the intermediate **7** and should control the regiochemistry of the anticipated cycloaddition reaction with these asymmetrical dienes (Scheme 3).[5]

Irradiation at $\lambda \geqslant 345$nm of dienes **5**, indoles **1** and catalytic amounts of either TPP or TAP gave good to moderate yields of Diels–Alder products **8** and **9** under complete regiocontrol (Scheme 3, Table 1, entries 3–9). The somewhat lower yields obtained with dienes **5** as compared to the five-membered diene **2** might be rationalized by an increased steric demand of these phenyl substituted dienes **5**. As above, in all cases the bridge is *cis*-configured, but, due to the stereogenic carbon bearing the phenyl group, 1:1 mixtures of diastereomers were obtained. An

Table 1 Reaction of dienes **2**, **5** and **10** with indoles **1**

Entry	Diene	R^1	Indole	R^2	Cycloadduct (% yield)	Photo-sensitizer
1	**2**	CO_2Et	**1b**	CO_2Me	**3a** (61)	TPP

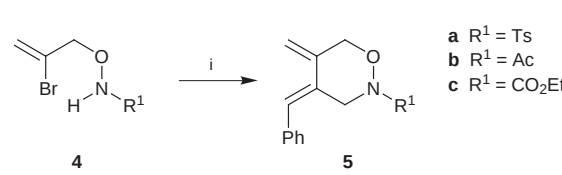
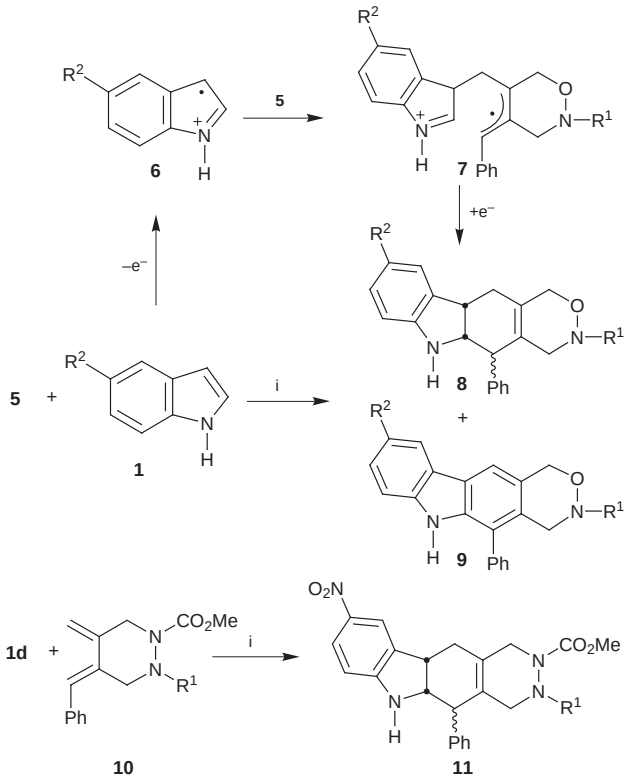
11	**10b**	COPh	**1d**	NO_2	**11b** (60)	TAP



Scheme 2 *Reagents and conditions:* i, $PhCH{=}CHCH_2OCO_2Me$ (1 equiv.), K_2CO_3 (2 equiv.), 5 mol% $Pd(OAc)_2$, 30 mol% PPh_3, MeCN, 20 °C, 2 h, then heated to 80 °C, 16 h, 60–70%.

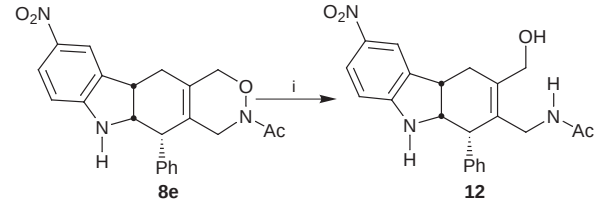


Scheme 3 *Reagents and conditions:* i, 5 mol% photosensitizer, CH_2Cl_2, $\lambda \geqslant 345$ nm, 1000 W, 20 ° C, 1.5 h.

exception is the diastereoselective (> 20 : 1) formation of **8a**, where the hydrogens at the bridge are *cis* relative to the phenyl group, probably owing to a selective aromatization of the other diastereomer giving **9**. Except for reactions with indole **1d**, this aromatization is a major follow-up reaction when TAP is used as sensitizer, but it can be completely suppressed when switching to TPP (except for indole **1a**, see Table 1, entry 3). A further feature of this reaction is the strong dependence of the yields upon the difference between the electronic character of the starting materials: the smaller the difference of the HOMO energies of the starting materials (decreasing from **1a** to **1c**/**d** in reaction with dienes **2** and **5**) the higher the obtained yield of the cycloadduct (see Table 1, entries 1–7).[8]

Variation of the electron-withdrawing group attached to the hydroxylamine component showed no effect on the cycloaddition reaction (Table 1, entries 7–9) and the yields obtained with the hydrazide-derived dienes **10**[9] are comparable to those received with the hydroxylamine derivatives **5** (Scheme 3, Table 1, entries 10 and 11). This was quite surprising because hitherto the incorporation of carbamate and amide groups in the diene was crucial to PET catalyzed reactions with indoles.[10]

As expected, the weak N–O bond of the cycloadducts is easily reductively cleaved with sodium amalgam[11] giving tetrahydrocarbazole **12** in almost quantitative yield (Scheme 4). The nitro group on the indole skeleton remained unchanged under these reaction conditions.Thus, in only four steps a highly functionalized tetrahydrocarbazole derivative is obtained in



Scheme 4 *Reagents and conditions:* i, Na_2HPO_4 (4.7 equiv.), 15× by weight Na(Hg), EtOH, 0 → 20 °C, 20 h, 94%.

reasonable yield for further synthesis. Further experiments to explore the synthetic potential of this PET-catalyzed cycloaddition reaction are being continued in our laboratories.

TEMPO-modified graphite felt electrodes: attempted enantioselective oxidation of *rac*-1-phenylethanol in the presence of (−)-sparteine

E. M. Belgsir[a] and H. J. Schäfer*[b]

Received (in Liverpool, UK) 15th December 1998, Accepted 22nd January 1999

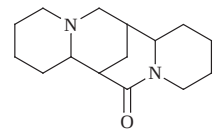
At a TEMPO-modified graphite felt electrode (TMGFE) *rac*-1-phenylethanol 2 is not enantioselectively oxidised in the presence of (−)-sparteine 1, but instead 1 is dehydrogenated to its iminium salt; 2 is oxidised in solution by the oxoammonium salt 6 in the absence of 1, but not on the TMGFE in the range 0–1.0 V *vs.* Ag/AgNO$_3$.

Oxoammonium[1] salts, generated by oxidation of aminoxyl radicals by chemical oxidants or at the anode, have been successfully used for the selective oxidation of alcohols. Of particular interest in this connection was the invention of TEMPO-modified graphite felt electrodes (TMGFE).[2–7] In the presence of (−)-sparteine **1**, it was reported that a TMGFE can oxidise enantioselectively (*S*)-1-phenylethanol (*S*-**2**) in *rac*-**2** leaving 46.2% of **2** as the (*R*)-isomer with 99.6% ee.[7] We failed to reproduce these very interesting results and therefore studied this conversion by cyclic voltammetry and controlled potential electrolysis.[8]

Fig. 1 shows voltammograms recorded at the TMGFE in 0.2 M $NaClO_4$ MeCN solution.[9] The charge, Q_P, involved during oxidation of TEMPO and reduction of $TEMPO^+$ is equal and stable within 30 cycles. Deconvolution and integration of these peaks permits evaluation of the concentration, $C_{NO\cdot}$, of the active aminoxyl radicals at the electrode.[10] It was found that $C_{NO\cdot}$ never exceeds 1 μmol cm^{-3} ($0.4 < C_{NO\cdot} < 0.6$ μmol cm^{-3}).[11] By potential controlled coulometry a density of 0.43 μmol cm^{-3} of active radicals was found, which is consistent with the results obtained *via* cyclic voltammetry.

Electrolysis in a divided cell (Nafion® 117 membrane) under previously reported conditions[7] (10 mmol of **1**, 10 mmol of *rac*-**2** and 5 mmol of tetraline **3** used as standard in 25 ml of 0.2 M $NaClO_4$ MeCN solution) afforded after consumption of 752.6 C, which is sufficient to oxidise about 80% of (*S*)-**2**, no acetophenone **4**, but **2** was almost quantitatively recovered (96%). However, 78% of **1** was oxidized, presumably into the corresponding iminium salt. It has been reported[12–14] that tertiary amines can be dehydrogenated to iminium salts by oxoammonium salts.

With a five-fold lower concentration of *rac*-**2**, **1** and **3** under otherwise the same conditions, the current decreased to 5% after consumption of 64 C. GC of the crude product gave 0.03 mmol of α-tetralol and 0.01 mmol of α-tetralone from **3** and 0.11 mmol of aphylline[15] **5** from **1**, which corresponds to more



Aphylline **5**

than 80% of the experimental quantity of electricity. The amount of iminium salt of **1** is difficult to evaluate, but it corresponds approximately to the missing quantity of electricity. Compound **4** could not be detected. In an undivided cell no conversion of **2** was found in the presence of **1** at oxidation potentials ranging from 0.53 to 1.10 V *vs.* Ag/AgNO$_3$.

These results led us to investigate the electrochemical behaviour of **1** by cyclic voltammetry (Fig. 2). As expected, **1** is oxidized both on graphite felt and on TMGFE. Under potentiodynamic conditions the TMGFE are inactive towards the *rac*-**2** oxidation between 0 and 0.8 V *vs.* Ag/AgNO$_3$ (Fig. 3), but at 1.0 V *vs.* Ag/AgNO$_3$ an oxidation wave starts even in the absence of the chiral base. It is well known that secondary alcohols are readily oxidised by oxoammonium salts in solution.

This is also found with 4-acetylamino-2,2,6,6-tetramethyl-1-oxopiperidinium **6** as a tetrafluoroborate salt. Species **6** was selected for the homogeneous oxidation because of its similar structure to the immobilized aminoxyl radical, which is also substituted with an amide group at C-4. In the absence of **1** with 1 mmol of *rac*-**2** and 1 mmol of **6** (tetrafluoroborate salt) in 5 ml of MeCN, 50% acetophenone **4** was obtained after 10 min. When **6** (2 mmol) was added to a mixture of *rac*-**2** (2 mmol) and **1** (2 mmol) in 5 ml of MeCN the solution turned immediately to an orange colour, however no *rac*-**2** was converted. The orange

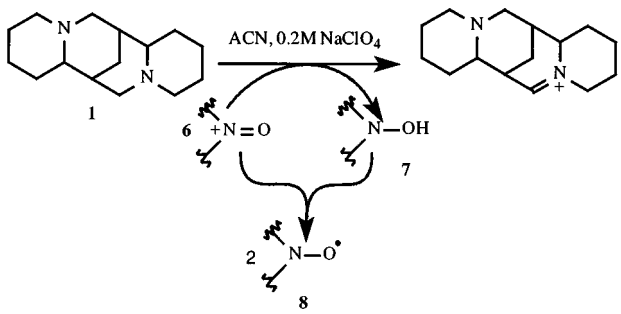

Scheme 1

colour is due to the formation of the radical *via* a fast symproportionation[1] (Scheme 1).

The results above demonstrate that the TMGFEs are not active below 0.8 V *vs.* $Ag/AgNO_3$ towards *rac*-**2** oxidation, which is easily oxidised in solution by **6**, whereby 4-acetamido-2,2,6,6-tetramethyl-1-hydroxypiperidine **7** is formed as a reduction product of **6**. The difference in these two processes is that in homogeneous oxidation **8** is regenerated *via* a base catalysed symproportionation of **6** and **7**, whilst at the TMGFE the immobilised **7** has to be oxidized.

In the absence of a base, the inactivity of the TMGFE towards the oxidation of *rac*-**2** could be due to a slow oxidation of immobilised **7**. Therefore we investigated the electrochemical behaviour of **7** by cyclic voltammetry (Fig. 4). In an unstirred solution, the CV exhibits during the first cycle a very weak oxidation of **7** into **6**, which is reduced during the negative sweep at 0.32 V *vs.* $Ag/AgNO_3$ into **8**. The current of **7** amounts to only 0.5% of that of **8** at the same concentration. In the presence of lutidine **9**, the current increases about twenty-fold, however it is still only 10% of that of **8** at the same concentration. The role of the added base appears to be connected with the regeneration of the active oxidant immobilised onto the electrode,[16] because we demonstrated that in solution **6** can oxidise *rac*-1-phenylethanol without any organic or mineral base.

The TMGFE is thus active for alcohol oxidation, but only in the presence of an electrochemically inert base which can be used in acetonitrile. (−)-Sparteine as base appears to be unsatisfactory, because it is oxidized by **6** prior to the alcohol.

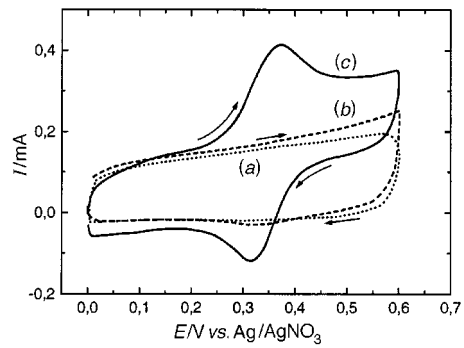

Fig. 4 Voltammograms of a graphite rod electrode recorded in 0.2 M $NaClO_4$–MeCN solution at 10 mV s^{-1} (*a*) in supporting electrolyte only, (*b*) in the presence of 0.2 mmol of **7** and (*c*) in the presence of both 0.2 mmol of **7** and 0.2 mmol of lutidine **9**.

8 The preparation of TEMPO-modified graphite felt electrodes (TMGFE) was carried out following a previously described procedure (ref. 2–7). The graphite felt electrodes (Le Carbone Lorraine, VG 4000) were refluxed in MeOH for 4 h, dried and dipped in a 0.25% polyacrylic acid (PAA, Aldrich)–methanol (Merck) solution and then carefully dried. Subsequently, the coated electrodes were treated with 4 equiv. of 4-amino-2,2,6,6-tetramethylpiperidin-1-oxyl [with respect to the amount of carboxylic acid (evaluated by weight) at the electrode] in the presence of 4.8 equiv. of DCC (ACROS) in DMF (ACROS) at room temperature for 80–90 h. Thereafter the electrodes were crosslinked with 3.3 equiv. of 1,6-diaminohexane (Fluka) in the presence of DCC for 80 h and were subsequently alkylated (CH_2N_2 or Me_2SO_4 or Et_2SO_4). Following this procedure, no difference was found between the electrodes alkylated in ethereal Et_2O or Me_2SO_4 or Et_2SO_4. If alkylation is carried out before the amide linkage formation, the concentration, $C_{NO\cdot}$, of the active aminoxyl radical decreases but the electrochemical behaviour is similar to that observed with the other electrodes. Increasing PAA thickness did not increase significantly $C_{NO\cdot}$ and did not improve the activity of the electrode even if the reaction time of each preparative step was increased proportionally. Amide linkage formation was also carried out before the coating procedure but the resulting film was very unstable.
Electrochemical measurements and electrolyses were performed in a 0.2 M $NaClO_4$ (ACROS)–MeCN (Merck) solution (dried on molecular sieves 3Å) using a HEKA PG28 generator-potentiostat. Chromatographic analyses were carried out using a Shimadzu chromatograph equipped with a capillary column [HP5 (Hewlett Packard) or FS Hydrodex β-PM (Macherey Nagel)]. *rac*-1-Phenylethanol, acetophenone, tetraline and (−)-sparteine were purchased from Aldrich. The work-up of the electrolyses solution consisted of evaporating the MeCN, then the residue was dissolved in EtOAc, filtered and subjected to chromatography.
9 Conversely to the results reported by Osa *et al.* (ref. 2), no large difference was observed between the peak potentials when the PAA on the electrode was crosslinked and methylated or untreated.
10 $C_{NO\cdot} = Q_P/nFV$, where n is the number of electrons, F is the Faraday equivalent and V the volume of the graphite felt electrode.
11 According to Osa and co-workers, the density evaluated by titration was 50 times higher (24 μmol cm^{-3}) and seems to be very stable from one article to the other (ref. 3–7). However, the quantity of electricity estimated from their voltammogram (ref. 5) is equal to 33.6 mC and corresponds to 0.7 μmol cm^{-3}.

Novel zwitterionic complexes of Ti(IV) *via* reaction of Lewis acids $M(C_6F_5)_3$ (M = B, Al) with a titanium diene complex (η^5-$C_5Me_4SiMe_2N^tBu$)Ti(1,3-pentadiene)

Alan H. Cowley,* Gregory S. Hair, Brian G. McBurnett and Richard A. Jones*

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712, USA. E-mail: cowley@mail.utexas.edu

Received (in Columbia, MO, USA) 2nd December 1998, Accepted 21st January 1999

The reaction of (η^5-$C_5Me_4SiMe_2N^tBu$)Ti(1,3-pentadiene) with $B(C_6F_5)_3$ or $Al(C_6F_5)_3$ in 1:1 mole ratio in hexane solution at room temperature results in the formation of titanium borate or aluminate zwitterions which both feature stabilisation of the Ti(IV) centre by two agostic Ti···H–C interactions.

It has been demonstrated recently that Cp_2Zr(butadiene) reacts readily with $B(C_6F_5)_3$ to afford a zirconium borate zwitterion (**1**) that is an active catalyst for α-olefin polymerization.[1] An important structural facet of this zwitterion is the presence of a weak dative interaction between an *ortho*-fluorine of one of the BC_6F_5 groups and an otherwise vacant coordination site on zirconium.[2] We report here (i) the first structurally characterised example of a new type of titanium borate zwitterion that does not involve intramolecular F→metal stabilisation,† and (ii) the first example of an analogous titanium aluminate zwitterion. In addition, both complexes feature stabilisation of the Ti(IV) metal centre by two agostic C–H···Ti interactions.

It has been reported[3] that, when treated with $B(C_6F_5)_3$, the bridged monocyclopentadienyl titanium diene complex (η^5-$C_5Me_4SiMe_2N^tBu$)Ti(1,3-pentadiene) **2** forms an active olefin polymerization catalyst. We have found that the reaction of **2** with an equimolar quantity of $B(C_6F_5)_3$ in hexane at 25 °C affords a virtually quantitative yield of a dark green crystalline solid (mp 156–157 °C) with an empirical composition (η^5-$C_5Me_4SiMe_2N^tBu$)Ti(1,3-pentadiene)·$B(C_6F_5)_3$ **3**.‡ An X-ray diffraction study of **3** (Fig. 1)§ revealed a zwitterionic structure in which the $B(C_6F_5)_3$ group is bound to the terminal $–CH_2$ carbon atom (C(1)) of the original pentadiene ligand. The C(2)–C(3) and C(3)–C(4) bond distances and the C(2)–C(3)–C(4) bond angle of the coordinated diene are similar to those reported by Erker *et al.*[1] for **1** hence the C(2)–C(3)–C(4) moiety can be regarded as being η^3-attached to the metal. However, the metal–C(2)–C(1) bond angle in **3** is considerably more acute (74.08(10)°) than the corresponding bond angle in **1** such that the Ti–C(1)–B fragment is almost linear (Ti–C(1)–B = 174.1(1)°), the Ti–C(1) distance is short (2.360(2) Å), and the C(1)–B distance is longer in **3** (1.705(3) Å) than in **1** (1.633(9) Å). Collectively, the foregoing structural features strongly suggested the presence of agostic C–H···Ti interactions for the CH_2 hydrogens of C(1). This surmise was confirmed in the later stages of refinement of the X-ray structure. Both hydrogen atoms attached to C(1) were located and refined with isotropic thermal parameters and show relatively short Ti···H distances (Ti–H(1A) = 2.20(2); Ti–H(1B) = 2.27(2) Å). Further support for the existence of the proposed agostic interactions stemmed from the observation of a C–H stretching frequency at 2669 cm^{-1} in the IR spectrum (Nujol mull). ^1H, ^{13}C, and ^{11}B NMR spectroscopic data¶ are also consistent with the X-ray analysis, thus implying that the solid state structure persists in solution. The ^{11}B chemical shift for **2** (δ −8.4) falls in the region observed for four-coordinate boron.[4] Three additional points are worth noting regarding the NMR data. Firstly, a two-dimensional ^1H–^{13}C study (at 500 and 125 MHz) revealed that the N–^{t}Bu and *Me*CHCHCHCH$_2$ signals overlap at δ −1.05. Secondly, the carbon attached to boron, C(1), is not observed in the ^{13}C NMR spectrum, and finally there is a ≈1.0 ppm difference in the ^1H chemical shifts for the C(1) methylene protons. The primary cause of this difference in chemical shifts is probably the existence of the chiral centre at titanium. However, other possible contributors include (i) the influence of the ring current from the tetramethylcyclopentadienyl group and (ii) only one H atom may be agostic in solution.

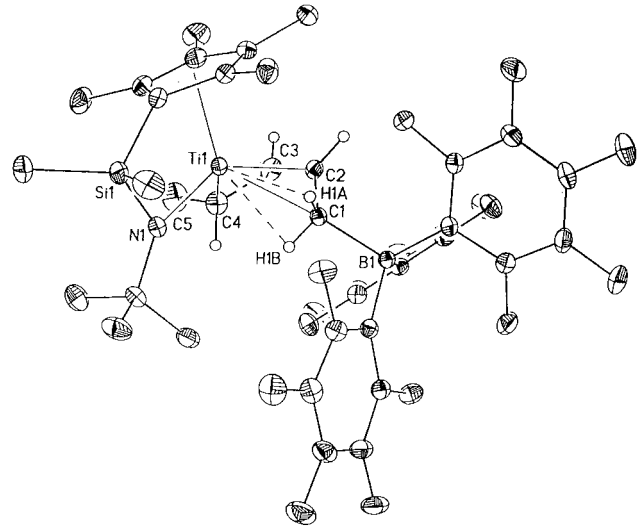

Fig. 1 X-Ray crystal structure of **3**. Selected bond distances (Å) and angles (°) for **3** (the corresponding values for **4** are shown in parentheses with Al(1) replacing B(1)): Ti(1)–C(1) 2.360(2) (2.355(2)), Ti(1)–C(2) 2.282(2) (2.261(3)), Ti(1)–C(3) 2.327(2) (2.344(3)), Ti(1)–C(4) 2.233(2) (2.271(3)), Ti(1)–H(1A) 2.20(2) (2.27(3)), Ti(1)–H(1B) 2.27(2) (2.45(3)), C(1)–B(1) 1.706(3) (2.052(3)), C(1)–C(2) 1.494(3) (1.479(5)), C(2)–C(3) 1.382(3) (1.386(5)), C(3)–C(4) 1.413(3) (1.416(5)), C(4)–C(5) 1.505(3) (1.512(5)), B(1)–C(1)–C(2) 116.8(2) (108.3(2)), C(1)–C(2)–C(3) 125.8(2) (126.6(3)), C(2)–C(3)–C(4) 125.8(2) (125.4(3)), C(3)–C(4)–C(5) 121.9(2) (120.3(3)). Thermal ellipsoids are drawn at the 30% level.

The reaction of **2** with $Al(C_6F_5)_3$ in hexane solution at 25 °C afforded high yields of **4**, the aluminium analogue of **3**.‡ To our knowledge, this represents the first example of a titanium aluminate zwitterion of this type. Structural authentication was provided by an X-ray crystallographic study§ which demonstrated that the geometry of **4** is very similar to that of **3** (Fig. 2). Two agostic Ti–H–C interactions are present with Ti–H(1A) and Ti–H(1B) distances of 2.27(3) and 2.45(3) Å, respectively. As in the case of **3**, NMR spectroscopic data indicate that the solution and solid state structures are very similar. The only significant difference in the ^1H and ^{13}C NMR spectra for **3** and **4** is that in the latter there is no overlap of the N–^{t}Bu and diene methyl ^1H resonances.

We are grateful to the National Science Foundation and the Robert A. Welch Foundation for financial support.

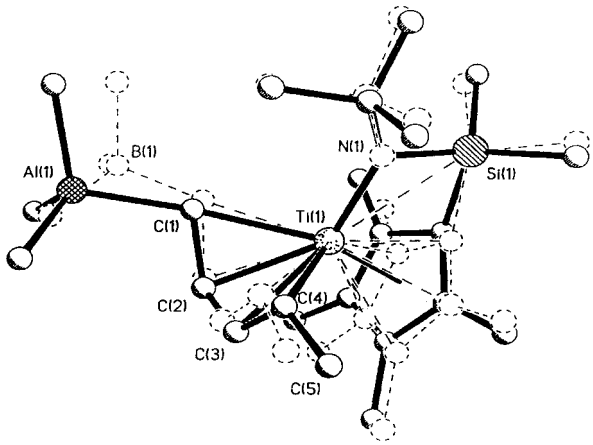

Fig. 2 Comparison of the ball-and-stick structures of **3** and **4**.

Notes and references

† A referee has suggested that the structural differences between the title compounds and the zirconium borate zwitterion (**1**) may be due to the greater electron deficiency at titanium.

‡ *Experimental procedures*: **3**: all manipulations were performed under an atmosphere of dry nitrogen or under vacuum using a Vacuum Atmospheres drybox or standard Schlenk techniques. All solvents were dried prior to use. A solution of $B(C_6F_5)_3$ (1.06 g, 2.07 mmol) in hexane (75 ml) was added to a solution of **2** (0.754 g, 2.06 mmol) in hexane at 25 °C with stirring. A dark green precipitate of **3** formed immediately and was collected and dried under vacuum. X-Ray quality crystals of **3** were grown by slow cooling of concentrated hexane solutions from 50 °C to room temperature. Isolated yield: 1.43 g, 80%; ^{1}H NMR assay indicated that the reaction is essentially quantitative. (Found: C, 52.02; H, 4.19; Ti, 5.45. Calc. for $C_{38}H_{35}BF_{15}NSiTi$: C, 52.02; H, 4.02; Ti 5.46%). Compound **4** was prepared in a similar fashion to that described for **3**.

§ *Crystal data*: **3**, $C_{38}H_{35}BF_{15}NSiTi$, M = 877.47, triclinic, space group $P\bar{1}$, a = 10.243(1), b = 11.376(1), c = 16.419(2) Å, α = 78.67(1), β = 79.45(1), γ = 84.85(1)°, U = 1841.3(3) Å^3, Z = 2, μ = 3.72 cm^{-1}, D_c = 1.583 Mg m^{-3}, F(000) = 892, λ = 0.71073 Å, T = 183 K. Data for **3** and **4** were collected on a Siemens P4 diffractometer. Of a total of 9281 collected reflections, 8284 were unique. The structure was solved by direct methods. The hydrogens on the coordinated diene were located; the remaining hydrogens were placed in calculated positions (C–H, 0.96 Å). Refinement was by full matrix least squares on F^2 with anisotropic displacement parameters for the non-located H atoms. Final R indices [$I > 2\sigma(I)$], $R1$ = 0.0410, $wR2$ = 0.1092.

3-Ethynylcyclopropene: a highly suspicious crystal structure

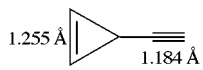
Steven S. Wesolowski, Jason M. Gonzales, Paul v. R. Schleyer and Henry F. Schaefer III*

Center for Computational Quantum Chemistry, University of Georgia, Athens, Georgia 30602-2525, USA. E-mail: hfsiii@arches.uga.edu

Received (in Corvallis, OR, USA) 7th December 1998, Accepted 25th January 1999

High level *ab initio* structures for 3-ethynylcyclopropene contain a typical cyclopropene C=C double bond of 1.296 Å, in sharp contrast to a recent X-ray structure in which the C=C double bond (1.255(2) Å) is purported to be the shortest yet observed among all hydrocarbons.

Baldridge *et al.* recently reported an X-ray crystal structure for 3-ethynylcyclopropene **1** in which the 'curiously short' 1.255 Å double bond is 'the shortest crystallographically observed C=C double bond known in any hydrocarbon.'[1] Their computed geometry at the spin restricted Hartree–Fock (RHF) level gave a double bond length of 1.27 Å, and inclusion of correlation effects *via* density functional theory† increased their best theoretical estimate to 1.28 Å, 0.03 Å longer than the experimentally inferred value. This discrepancy was not resolved. The authors suggested that the 'deviation could come from difficulties in approximating the orbital arrangement in **1**',[1] *i.e.* that their theoretical levels might not be definitive. Given this disturbing structural difference coupled with reassurances that crystal packing effects and high angle refinement procedures should have only a 'very small effect' in the X-ray structure,[1b] we investigated the structure of **1** using high level coupled cluster techniques.



1

We optimized‡ the C_s structure of **1** using the coupled cluster singles and doubles method[8] with a perturbative triples correction [CCSD(T)][9,10] within a TZ2P + f basis set.§ For wavefunction expansions dominated by a single reference determinant, the CCSD(T) approach within a suitable basis set is well known to accurately reproduce structural parameters. At the level chosen, bond lengths between heavy (non-hydrogen) atoms within closed shell molecules are typically in error relative to gas phase experimental values by less than 0.008 Å.[16,17]

Comparison of the TZ2P + f/CCSD(T) and X-ray structures (Fig. 1) reveals a substantial difference in the double bond length and a smaller difference in the triple bond length of the ethynyl group. The *ab initio* double and triple bonds are respectively 0.041 and 0.027 Å longer than those of their X-ray counterparts. Indeed, the only structural parameters in good agreement are the single bond linkage of the ethynyl group and the majority of bond angles. The exceptional similarity of our TZ2P + f/CCSD(T) double and triple bonds to microwave values for the related fragment molecules in Fig. 2 (cyclopropene,[18] propyne,[19] and acetylene[18]) supports the study of substituent effects by Baldridge *et al.* in suggesting that there are no strong adjacent orbital interactions affecting either of these bonds in **1**. Indeed, the X-ray C=C cyclopropene distance in 3-vinylcyclopropene is 1.279 Å (0.024 Å longer than the X-ray distance in **1**).[20]

At every correlated level employed (Table 1) the double bond is more than 0.035 Å longer than experiment. Although the X-ray structure r_α is inherently different from the theoretical equilibrium geometry r_e, differences of this magnitude seem unlikely. Appreciable bond contraction is observed upon increasing the DZP basis to TZ2P with both the MP2 and CCSD(T) methods, and the convergence of these bonds with respect to the basis set was examined further at the MP2 level. However, additional polarization functions [TZ2P + f and TZ2P(f,d)] or even upgrading the basis set on carbon to quadruple-ζ quality (cc-pVQZ/TZ) has only a small effect

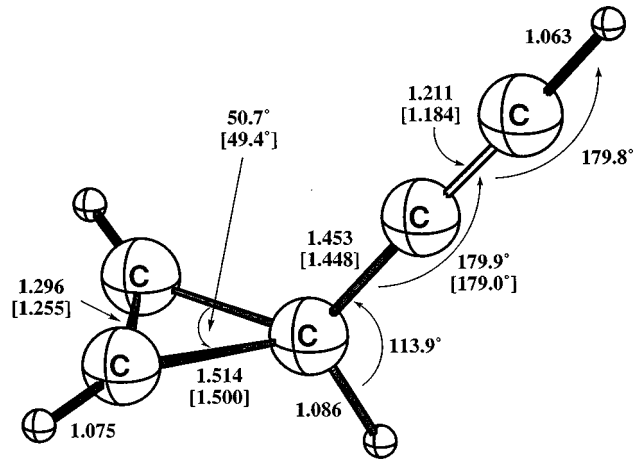


Fig. 1 The structure of 3-ethynylcyclopropene **1** optimized at the TZ2P + f/CCSD(T) level of theory. Bond lengths are in Å and bond angles are in degrees. Experimental bond lengths and angles are given in brackets.

Experiment	**1.255(2)**	**1.184(2)**

(< 0.006 Å) on these bonds, and a similar conclusion for CCSD(T) structures is expected.

Clearly, a high level theoretical equilibrium structure has been obtained which has no extraordinary features and differs dramatically from the X-ray geometry. What is the reason for this disagreement? Our computational reexamination at higher levels than employed earlier[1] increase, rather than decrease, the discrepancies with experiment. Hence, it seems unlikely that the theoretical predictions are incorrect. Solid state effects were considered by the experimentalists, but discounted.[1] Are inaccuracies in the X-ray structure possible? A referee (an expert crystallographer) reexamined the X-ray data in detail, but could find 'neither reasonable nor unreasonable problems with the original work.' Hence, no plausible explanation for the differences exist at present. Further insights will largely hinge on the availability of experimental gas phase data and future solutions of X-ray and neutron diffraction structures for related 3-substituted cyclopropenes.

Mulliken Graduate Fellowship. The authors thank Dr Holger Bettinger, Dr T. Daniel Crawford and Professor John F. Stanton for insightful discussions concerning this research.

Notes and references

† Estimate based on results using the B3PW91 hybrid functional within DZ(2df,2p) and 8s6p3d basis sets. See ref.1.

‡ Methods used in this work include spin restricted Hartree–Fock (RHF), second order Møller–Plesset perturbation theory (MP2), density funnctional theory (DFT), CCSD and CCSD(T). No orbitals are frozen or deleted in the coupled cluster and MP2 procedures. The DFT functionals used are B3LYP, BHLYP and B3PW91 composed of permutations of the correlation functionals of Lee *et al.* (LYP)[2] and Perdew and Wang (PW91)[3] with the exchange functionals of Becke: (B3)[4] and (BH).[5] Stationary point structures are completely optimized within the C_s symmetry constraints using analytic gradient techniques until residual Cartesian coordinate gradients are less than 10^{-6} au. SCF quadratic force constants were determined *via* analytic second derivatives to establish stationary structures as minima. All computations were carried out using the ACESII[6] and Gaussian94[7] program packages.

§ Five basis sets are employed throughout this study. The smallest is a double-ς plus polarization (DZP) basis consisting of the standard Huzinaga–Dunning[11,12] set of contracted Gaussian functions with sets of five d-type and three p-type polarization functions from Dunning's correlation-consistent double-ς (cc-pVDZ) basis sets[13] added to the carbon and hydrogen atoms, respectively. A TZ2P basis set was formed from the Huzinaga–Dunning[11,14] sp sets augmented with two sets of polarization functions from Dunning's cc-pVTZ sets[13,15] (two sets of five d-type functions on C and two sets of p functions on H), and the TZ2P + f and TZ2P (f,d) basis sets include further sets of seven f-type functions (α = 0.761) on C plus a set of five d-type functions (α = 1.057) on H. The cc-pVQZ/TZ set contains Dunning's[13] cc-pVQZ and cc-pVTZ functions centered on the carbon and hydrogen atoms, respectively. The DZP, TZ2P, TZ2P + f, TZ2P (f,d), and cc-pVQZ/TZ basis sets contain 95, 156, 191, 211 and 331 contracted Gaussian functions, respectively.

Metallomesogens presenting blue phases in a glassy state and in metallomesogen/nematic mixtures

Julio Buey,[a] Pablo Espinet,*[a] Heinz-S. Kitzerow*[b] and Jochen Strauss[b]

[a] *Departamento de Química Inorgánica, Facultad de Ciencias, Universidad de Valladolid, E-47005 Valladolid, Spain. E-mail: espinet@qi.uva.es*

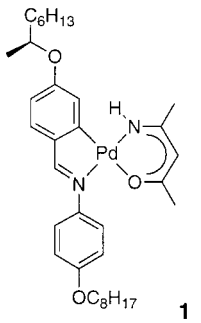
[b] *Department of Chemistry, University of Paderborn, Warburger Str. 100, 33098 Paderborn, Germany*

Received (in Cambridge, UK) 13th January 1999, Accepted 3rd February 1999

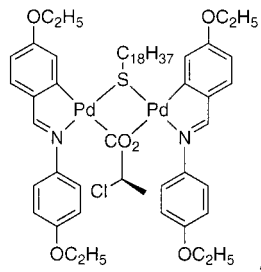
Two palladium complexes are described with very high helical twisting power and producing blue phases, in one case preserved in a glassy state for several days.

Blue phases (BPs)[1] have been the subject of intensive studies during the last decade in the field of chiral liquid crystals because of their anomalous physical and structural features such as Bragg reflections in the visible wavelength, and the occurrence of liquid single crystals (liquid crystal droplets with the shape of solid crystals).[2] These phases are sometimes observed in a narrow range of temperature, typically 2–3 °C, between the cholesteric (N*) and the isotropic (I) phases, in compounds with very small pitch (*p*). Up to three different phases can be observed at zero field,[3] labelled as BPI (body centered cubic structure), BPII (simple cubic structure) and BPIII (structure still under discussion).[4] Although many organic mesogens displaying BPs are known, the first example of a metallomesogen[5] displaying a blue phase has been reported only recently.[6,7] Here we describe two structural types of metallomesogen leading to blue phases. For one of them the BP is preserved in a glassy state for several days. These compounds have been found in the same family of orthometallated compounds that yielded the first ferroelectric[8] and the first cholesteric metallomesogen.[9]

The new chiral complexes **1** and **2** were prepared as described



1



2

elsewhere for similar compounds.[9,10] Their mesogenic properties were studied by optical microscopy and differential scanning calorimetry (DSC) at 5 °C min^{-1}, and the pitch (*p*) and handedness of the cholesteric helix were determined using the modified Grandjean–Cano method.[11] All these data are summarized in Table 1. It should be noted that the complexes display both cholesteric and blue phases in their pure state, but their high viscosity prevents a good alignment of the samples as well as the growing of well shaped BP single crystals to be studied by the Kossel method.[12] For these reasons Cano and Kossel experiments were performed on mixtures of the compounds with the nematic host ZLI-1275 (Merck). The ability of the chiral compounds to induce helical phases on mixing with the nematic host is represented either by the helical twisting power $htp = 1/pc$ (c = concentration of the dopant), or by the molecular twisting power, $mtp = M/px_mr$,[13] where M is the molecular weight, p the pitch, x_m the weight fraction of the chiral dopant and ρ the mass density of the cholesteric solution. The latter quantity is particularly suitable to characterize the twisting power of a molecule.

The mononuclear complex **1** exhibits monotropic BPII and BPI phases at reasonably low temperatures, as well as a very strong selective reflection. The appearance of these phases is in agreement with the estimated pitch of pure **1** ($\approx$ 350 nm). Due to the high viscosity and the low transition temperatures of the material, both phases are retained in a glassy state at room temperature. Thus in contrast to the usual problems, for studying BPs, which require sophisticated temperature control, glassy samples of **1** can be observed, handled, and even stored for days very easily. Kossel experiments could only be carried out on mixtures of **1** and ZLI-1275. For one of the mixtures (62.6 wt% of **1**, deep blue selective reflection at r.t.), three different Kossel diagrams were observed at 47 °C. The first one (Fig. 1a) shows the main ring corresponding to a BPII crystal viewed in its [100] orientation; the second (Fig. 1b) a BPI crystal in the [110] orientation; and the third (Fig. 1c) is the sum of both diagrams, suggesting the coexistence of BPI and BPII crystals in the sample. In order to increase the selective reflection wavelength for the BPII modification, a more dilute mixture was prepared (52.6 wt% of **1**, green selective reflection at r.t.), but in this case only the BPI modification was observed (Fig. 1d).

Moreover, **1** has good solubility in the nematic host, very high *htp* (*i.e.* very low pitch), and a *p* value almost invariant with temperature (17.43 wt% of **1**, Fig. 2). The value of its molecular twisting power is as high as for most chiral dopants used in commercial applications, but still one order of magnitude below the highest value reported for calamitic chiral dopants (DL21 : 28300 m^2 mol^{-1}).[14]

The dinuclear compound **2** also displays a monotropic BPI phase, in the range 98–94 °C, appearing under the microscope

Table 1 Phase transition data and characterisation of the helix for complexes **1** and **2**

Complex	Transition[a]	T/°C	ΔH/kJ mol^{-1}	p^d/μm	htp^d/(mm wt%)$^{-1}$	mtp^d/m^2 mol^{-1}	Handedness
(*S*)-**1**	C–I	85.4	36.5	1.9–2.9	20–30	1500–2400	Right
	I–BPII–BPI–N*[b]	46.1	−0.3[c]

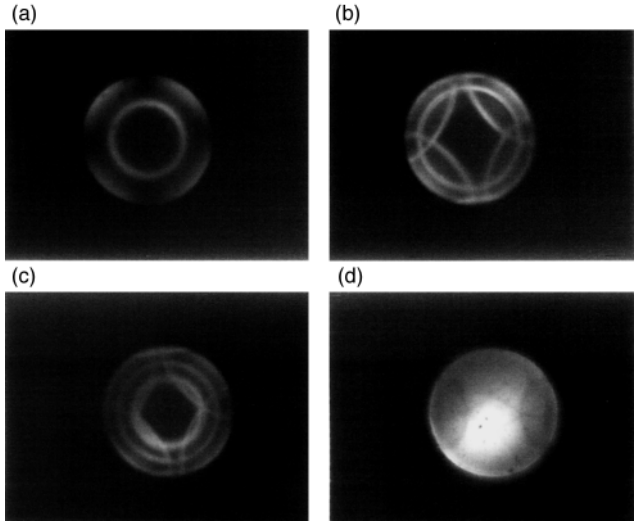

Fig. 1 Kossel diagrams of mixtures of 62.6 wt% of **1** in ZLI-1275 at 47 °C (a–c), and 52.06 wt% at 47 °C (d).

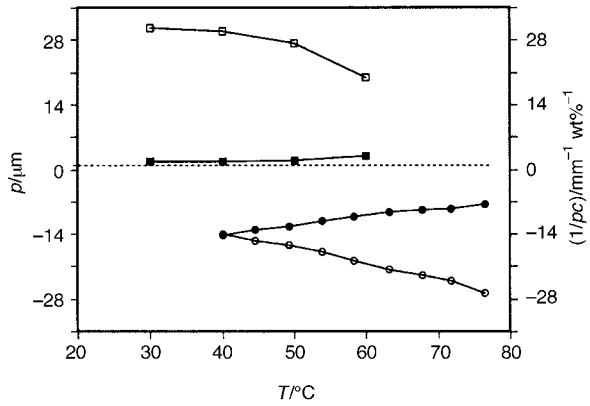

Fig. 2 Temperature dependence of the cholesteric pitch p (■, **1**; ●, **2**) and the helical twisting power $1/pc$ (□. **1**; ○, **2**) in mixtures of 17.43 wt% of **1** in ZLI-1275, or 5.01 wt% of **2** in ZLI-1275.

in its platelet texture. At the lower temperature, some crystallization occurs. Complex **2** gave rather high and temperature-dependent p values (measured on a 5.01 wt% mixture with ZLI-1275, the amount of **2** being limited by its low solubility), leading to estimated p values for pure **2** ranging from ≈350 nm at 76 °C to ≈700 nm at 40 °C. As previously reported for related systems,[9] this strong temperature dependence of p is possibly associated with the occurrence of two conformers in a temperature-dependent thermodynamic equilibrium.[15]

In summary, the mononuclear complex **1** shows a very low p value which is almost temperature independent, and a good solubility in a nematic matrix. Its enantiomer is easily available using the enantiomeric alcohol. These properties are very good for its application as chiral dopant.[16] Furthermore, the glassy state of **1** allows the stabilization of a blue phase for several days. Further studies on these fascinating materials are in progress.

Selective C_α–C_β bond cleavage by water in allenylidene and alkenylvinylidene ruthenium complexes

Claudio Bianchini,* Maurizio Peruzzini,* Fabrizio Zanobini, Carlos Lopez, Isaac de los Rios and Antonio Romerosa

Istituto per lo Studio della Stereochimica ed Energetica dei Composti di Coordinazione, ISSECC, CNR, Via J. Nardi, 39 - 50132 Firenze, Italy. E-mail: bianchin@fi.cnr.it; peruz@fi.cnr.it

Received (in Basel, Switzerland) 4th January 1999, Accepted 27th January 1999

The Ru(II) complex *mer,trans*-[(PNP)RuCl$_2$(PPh$_3$)] [PNP = MeCH$_2$CH$_2$N(CH$_2$CH$_2$PPh$_2$)$_2$] reacts in refluxing THF with propargyl alcohols HC≡CCRR′OH (R = R′ = Me, Ph; R = Me, R′ = Ph) yielding either the allenylidene complex *fac,cis*-[(PNP)RuCl$_2${C=C=CPh$_2$}] or the alkenylvinylidene derivatives *fac,cis*-[(PNP)RuCl$_2${C=C(H)C(R)=CH$_2$}] (R = Me, Ph); treatment of all these complexes in CH$_2$Cl$_2$ or THF with water results in the formation of the ruthenium carbonyl *fac,cis*-[(PNP)RuCl$_2$(CO)] and free alkenes H$_2$C=CRR′ (R = R′ = Me, Ph; R = Me, R′ = Ph) *via* regioselective C_α–C_β bond cleavage.

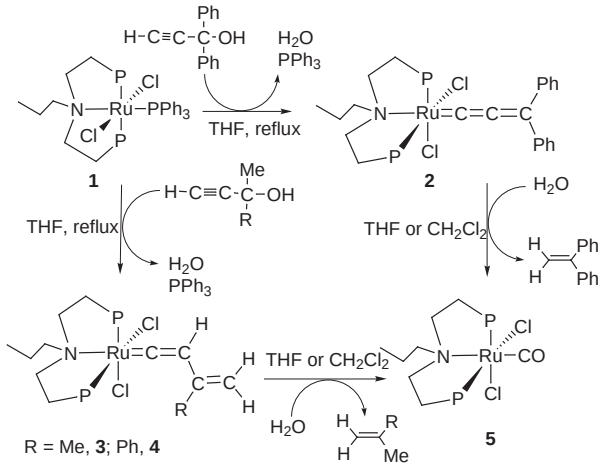
Understanding and rationalizing the reactivity of transition metal complexes containing allenylidene ligands, M=C=C=CR$_2$, is a topic of much current interest in organometallic chemistry.[1–3] Sound motivations arise from the increasing applications of allenylidene complexes, especially of ruthenium derivatives, to various catalytic reactions involving C–C bond formation.[4]

As a general trend, nucleophiles may attack either the C_α or C_γ carbon atom in allenylidene ligands affording Fischer-type carbenes or alkynyl compounds, respectively.[5] The addition of water has been found to take place selectively at C_α to give unsaturated hydroxycarbenes.[6] At least in one case, however, there was the suspicion that water might be able to cleave a C–C bond in an allenylidene ligand but no experimental evidence was reported supporting this hypothesis.[7] The question regarding the hydrolytic C–C bond cleavage in allenylidenes and homologous ligands is not of trivial importance given the wide use of their metal complexes as catalyst precursors in a variety of homogeneous processes, especially in reactions where new C–C bonds are formed.[4,8] For this reason, we decided to investigate the reactions of both allenylidene and alkenylvinylidene complexes with water. Ruthenium was the metal of choice as it is known to effectively stabilize cumulene complexes and it also constitutes the essential ingredient in many C–C bond forming reactions.[4,8]

Following the well known Selegue's synthetic protocol,[9] the neutral allenylidene complex *fac,cis*-[(PNP)RuCl$_2$-{C=C=CPh$_2$}] **2** was obtained in 78% yield by refluxing *mer,trans*-[(PNP)Ru(Cl)$_2$(PPh$_3$)] **1**[10] and 1,1-diphenylprop-2-yn-1-ol in THF (Scheme 1).†

Complex **2**[11] was authenticated by means of standard spectroscopic techniques as well as a single-crystal X-ray analysis (Fig. 1).‡ The crystallographic study confirmed the *fac* stereochemistry of the PNP ligand and the *trans* disposition of the diphenylallenylidene ligand and the nitrogen donor atom.[12]

While π-alkyne coordination (**A**) and alkyne to vinylidene tautomerization (**B**) are common steps to any propargyl alcohol activation, the eventual dehydration process of the hydroxyvinylidene intermediate may occur with different regioselectivity (Scheme 2). Either allenylidene (**C**) or alkenylvinylidene derivatives may indeed form depending on the presence of hydrogens on the carbon atom proximal to the OH group. If there are no hydrogens, the allenylidene products are stable,



Scheme 1

otherwise they may tautomerize to alkenylvinylidenes (**E**). Alternatively, the alkenylvinylidene ligand may form *via* direct elimination of water from the hydroxyvinylidene intermediate (**D**).[13]

Within this mechanistic picture, it was not surprising to find that **1** reacts with either 1,1-dimethyl- or 1-methyl,1-phenylpropyn-1-ol yielding the alkenylvinylidenes *fac,cis*-[(PNP)RuCl$_2${C=C(H)C(R)=CH$_2$}] (R = Me, **3**; Ph, **4**).[11]‡ It was surprising instead to discover that both the allenylidene

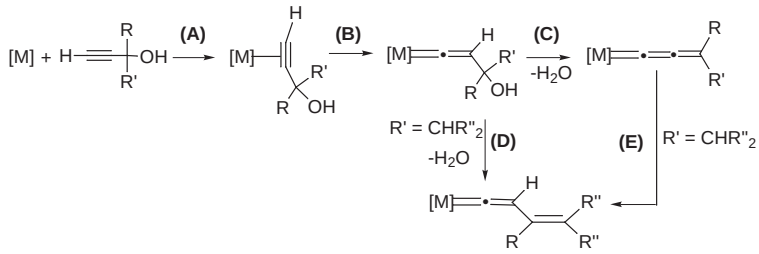

Scheme 2

complex **2** and the alkenylvinylidenes **3** and **4** are transformed by water (5 equiv.) into the known carbonyl derivative *fac*,*cis*-[(PNP)$RuCl_2$(CO)] (**5**)[14] and the corresponding free alkene $H_2C{=}CRR'$ (R = R′ = Ph; R = Me or Ph, R′ = Me). The quantitative formation of 1 equiv. of alkene was shown by GC–MS analysis and NMR spectroscopy (^{1}H, ^{13}C) on both reaction mixtures and samples isolated by TLC. The hydrolysis reactions are quite fast at reflux temperature in either THF or CH_2Cl_2 but take place also at room temperature. When D_2O was employed in the place of H_2O, the alkene was found to regioselectively incorporate two *gem* deuterium atoms ($D_2C{=}CRR'$) indicating that both terminal hydrogens come from water. Finally, the selective incorporation of ^{18}O in the carbonyl complex **5**-^{18}O, $\nu(C^{18}O)$ 1899 cm^{-1}, was observed when the hydrolysis reactions were carried out with $H_2{}^{18}O$ confirming that the C_α–C_β bond scission in either allenylidene or alkenylvinylidene ligand was brought about by water and not by adventitious oxygen.[15]

In conclusion, for the first time it has been shown that both allenylidene and alkenylvinylidene ruthenium complexes, dissolved in organic solvents, may react with water producing CO ligands and free alkene *via* regioselective cleavage of the C_α–C_β bond. The hydrolysis of metal vinylidenes has recently been reported to give carbonyl species and the saturated hydrocarbon derived from the homologation of the vinylidene substituent.[15] From allenylidene and alkenylvinylidene complexes, unsaturated hydrocarbons are selectively formed, which may open the door to the alternative synthesis of high-added value alkenes or alkenes selectively deuterated at the unsubstituted end.

Ethylene polymerization over chromium complexes grafted onto MCM-41 materials

R. Ramachandra Rao, Bert M. Weckhuysen* and Robert A. Schoonheydt

Centrum voor Oppervlaktechemie en Katalyse, Departement Interfasechemie, K.U. Leuven, Kardinaal Mercierlaan 92, 3001 Heverlee, Belgium. E-mail: Bert.Weckhuysen@agr.kuleuven.ac.be

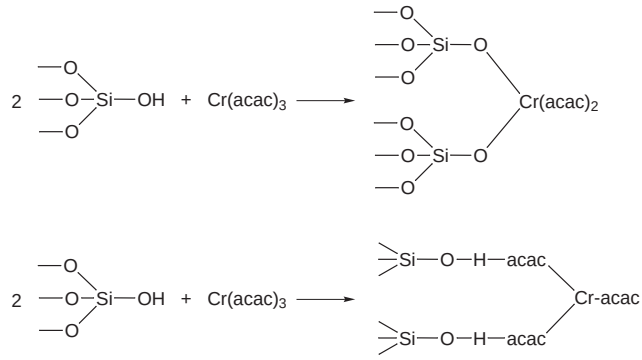
Received (in Bristol, UK) 9th November 1998, Accepted 1st February 1999

Chromium acetylacetonate [$Cr(acac)_3$] complexes have been grafted onto the surface of Al-MCM-41 materials and were characterised by combined DRS–EPR spectroscopies and TGA; these materials were found to be active for the polymerisation of ethylene.

The recent discovery of the M41S family of mesoporous crystalline solids with sharply distributed pore diameters in the range 2–10 nm has greatly increased the range of supports for preparing heterogeneous catalysts.[1] Among them, MCM-41 is the most studied. It possesses a hexagonally arranged array of uniform pores. Brönsted acidity may be generated in MCM-41 by isomorphous substitution of Al^{3+} for Si^{4+}.[2–4] Recently, transition metal complexes encapsulated in mesoporous molecular sieves have been shown to exhibit high catalytic activity in oxidation reactions. Examples are $[Mn(bipy)_2]^{2+}$ complexes in the oxidation of styrene[5*a*] and Schiff base complexes in the aerial oxidation of alkylaromatics.[5*b*] Supported chromium oxides, in particular Cr/SiO_2 and $Cr/Ti/SiO_2$, are industrially very important catalysts for the production of high-density polyethylene (HDPE) and linear low-density polyethylene (LLDPE).[6] Based on the pore size of the mesoporous solids, it was our view that the MCM-41 material should be an excellent support for grafting chromium complexes. Here, we report on the characterisation and catalytic activity of well defined $Cr(acac)_3$ complexes grafted onto MCM-41 materials. The goal of this study is two-fold: (1) to characterise chromium complexes grafted onto MCM-41 by spectroscopic methods and (2) to obtain novel and catalytically active materials for ethylene polymerisation.

Al-MCM-41 was prepared at 100 °C in a Teflon autoclave for 24 h.[7] The gel composition of the starting material was $1Al_2O_3 : 31SiO_2 : 2.2(HDTMABr)_2O : 3.16(TEA)_2O : 1.89 Na_2O : 795H_2O$ (HDTMABr = hexadecyltrimethylammonium bromide, TEA = tetraethylammonium). This material after drying at 60 °C and calcination at 500 °C, was used for impregnation with a solution of $Cr(acac)_3$ in methanol under an N_2 atmosphere. The final product after calcination contained 1.5 wt% Cr and had a Si/Al ratio of 27.

The XRD patterns of calcined Al-MCM-41 and calcined Cr(acac)–Al-MCM-41 are identical to those previously reported for MCM-41 materials,[1–5] and confirm the hexagonal mesoporous structure. The *d*-spacings of Al-MCM-41 and Cr(acac)–Al-MCM-41 were 3.71 and 3.84 nm, respectively, while the surface area and pore volume of the Al-MCM-41 catalyst were 860 $m^2\ g^{-1}$ and 1.8 ml g^{-1}, respectively. TG analysis of the Cr(acac)–Al-MCM-41 catalyst showed two weight losses at 230 and 330 °C; *i.e.* acac ligands were removed in two stages. Thus, the supported Cr-complex is stable up to 200 °C in oxygen. In the first stage one ligand is removed as acetylacetone with the aid of the surface protons of MCM-41. In the second stage, the ligands which are not interacting with framework oxygens are removed by oxidation or pyrolysis. The amount of acac molecules per chromium atom was found to be 2.65, which suggests that there are two types of complexes present on the surface: one which has only two acac ligands, and a second with three acac ligands which has partial H-bonding with framework oxygen atoms (Scheme 1).



Scheme 1

The as-synthesized $Cr(acac)_n$–Al-MCM-41 (with $n = 2$ or 3) material has been characterised by combined DRS–EPR spectroscopies to study the coordination environment of Cr. Diffuse reflectance spectra are shown in Fig. 1. At room temperature, three absorption bands at 327, 389 and 562 nm are observed, which are typical for Cr^{3+}.[8] EPR reveals an intense signal with $g_{eff} \approx 4$, and zero field parameters D and $E \neq 0$ (Fig. 2). This is indicative for a strongly distorted Cr^{3+} complex.[9] During calcination in O_2, the intensity of the DRS band at 562 nm decreases with increasing calcination temperature. At 500 °C, two new DRS bands at 280 and 370 nm became apparent. These bands are charge transfer transitions of Cr^{6+}.[8] A fraction of Cr^{3+} could not be oxidised to $Cr^{6+/5+}$, which suggests that small clusters of Cr_2O_3 were formed on the catalyst surface. This has been confirmed by EPR spectroscopy. Indeed, the EPR spectra have a characteristic broad signal around $g = 2$ of clustered Cr^{3+} in pseudo-octahedral coordination.[9] In addition, small amounts of Cr^{5+} with $g_{\|} = 1.910$ and $g_{\perp} = 1.978$ have been detected.

Ethylene polymerization was carried out over calcined $Cr(acac)_n$–Al-MCM-41 in a quartz flow cell at 100 °C with 2 bar of pure ethylene. DRS and EPR spectra were recorded at regular time intervals in order to monitor the chromium

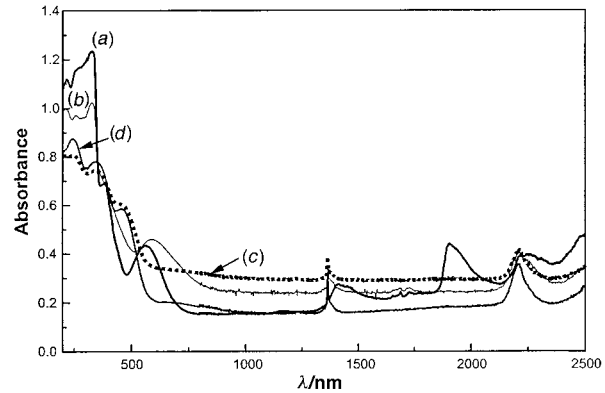


Fig. 1 Diffuse reflectance spectra of the $Cr(acac)_n$–Al-MCM-41 material after heating in O_2 at (*a*) 20, (*b*) 200, (*c*) 400 and (*d*) 500 °C.

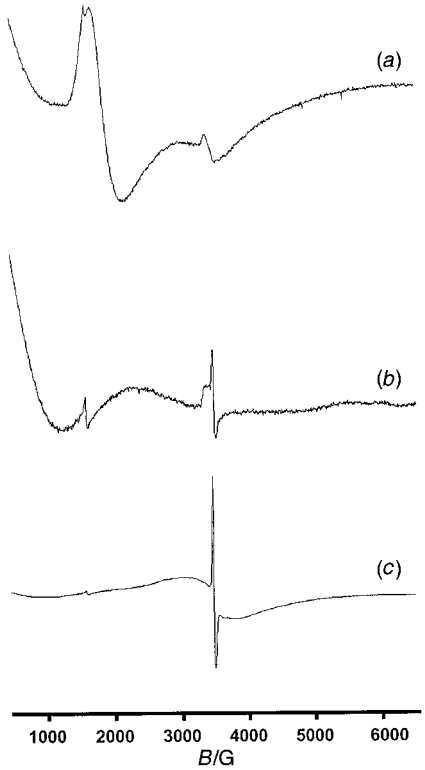

Fig. 2 Electron paramagnetic resonance spectra of Cr(acac)$_n$–Al-MCM-41 material after heating in O_2 at (*a*) 20, (*b*) 500 °C and (*c*) after 120 min reaction of ethylene at 100 °C.

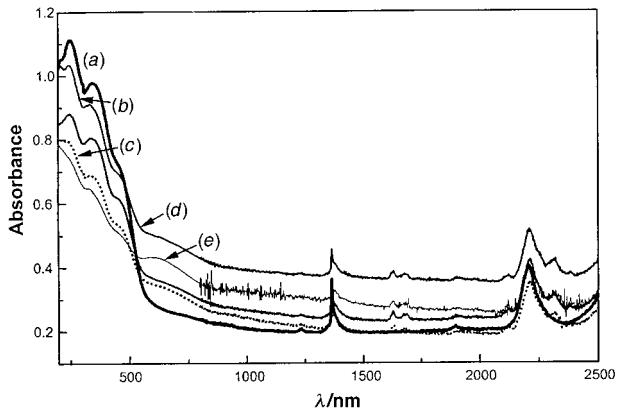

Fig. 3 Diffuse reflectance spectra of the Cr(acac)$_n$–Al-MCM-41 exposed to ethylene at 100 °C as a function of the reaction time: (*a*) 10, (*b*) 15, (*c*) 30, (*d*) 45 and (*e*) 120 min.

oxidation state during the reaction. $Cr^{6+/5+}$ is readily reducible upon interaction with ethylene, and the corresponding DRS spectra are shown in Fig. 3. After 2 h of reaction, a broad and ill defined absorption band is observed with maximum around 600 nm. This maximum is indicative for the formation of Cr^{3+}.[8] This observation has been confirmed by EPR spectroscopy. Indeed, the corresponding EPR spectrum [Fig. 2(*c*)] is dominated by a broad $g = 2$ signal, due to Cr^{3+}, and a sharp axial signal typical for Cr^{5+}.[9] In addition, new features in the NIR region of the DRS spectra were observed (Fig. 3). To further investigate this behaviour, a detailed FTIR study was performed for the catalytic materials exposed to ethylene. A band at *ca.* 1476 cm^{-1} was observed, due to the CH_2 bending mode of polyethylene.[10]

Ethylene polymerisation over Cr(acac)$_n$–Al-MCM-41 materials was then further studied at 100 °C for 2 h in a catalytic reactor, in which the ethylene consumption is reflected by a pressure decrease in the reactor system. Typical results are shown in Fig. 4. It is clear that, depending on the initial ethylene

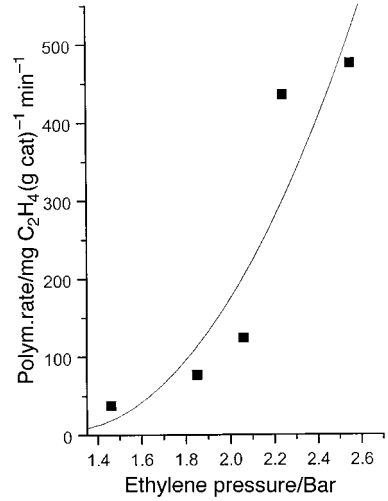

Fig. 4 Polymerization rate over Cr(acac)$_n$–Al-MCM-41 catalyst as a function of the initial ethylene pressure at 100 °C.

pressure, high polymerization rates between 50 and 500 mg ethylene (g catalyst)$^{-1}$ min^{-1} were obtained. After reaction the catalyst was dispersed in the polyethylene formed during reaction, and the formation of polyethylene was confirmed *via* FTIR spectroscopy.

Summarising, the present study demonstrates that Cr(acac)$_3$ complexes can be grafted onto Al-MCM-41 materials. It results in a novel catalytic system, which is able to polymerise ethylene at relatively low pressures. Further research has to be directed towards the influence of the pore diameter of MCM-41 on the polymer characteristics.

The facile synthesis of 1,2,3-trisubstituted pyrroles from the reaction of chlorocarbenes with 1-azabuta-1,3-dienes

Yuri N. Romashin,[a] Michael T. H. Liu*[a] and Roland Bonneau[b]

Received (in Corvallis, OR, USA) 4th December 1998, Accepted 4th January 1999

1,2,3-Trisubstituted pyrroles have been synthesized in good yield from the reaction of chlorocarbenes with 1-azabuta-1,3-dienes.

Carbenes and metal carbenoids are useful intermediates in the synthesis of nitrogen-containing heterocyclic compounds of biological importance. Most of the work has been devoted to the reactions of carbenes and metal carbenoids with azomethines that result in aziridines, pyrrolidines, oxazolidines and β-lactams.[1,2] The literature has only two examples where pyrroles appeared as the end product.[3,4] Introducing dimethyl acetylenedicarboxylate to a reaction mixture of *N*-benzylideneaniline and dichlorocarbene, generated by alkaline hydrolysis of $CHCl_3$, results in the formation of a pyrrole derivative in low yield.[3] Thermolysis of chromium carbene complexes with 1-azabuta-1,3-dienes leads to the formation of 1,2,3-trisubstituted pyrroles in good yield.[4] However, no pyrroles could be detected in the reaction of dichlorocarbene with 1-azabuta-1,3-dienes, where dichloroaziridines were isolated in high yield.[3,5] Pyrroles represent an important major class of heterocycles. Their prominence encourages the continuing evolution of new synthetic methods.[6] Our experiments produced a facile one-step synthesis of 1,2,3-trisubstituted pyrroles based on the reaction of arylchlorocarbenes with a variety of 1-azabuta-1,3-dienes under photolytic or thermal conditions.

We propose that the reaction of singlet carbene such as arylchlorocarbene with 1-azabuta-1,3-dienes goes through an azomethine ylide[3] **4** *via* a reaction between the vacant 2p-orbital of the carbene and the nitrogen non-bonding electron pair (Scheme 1). The formed ylide then undergoes intramolecular ring-closure to form a dihydropyrrole **5**, followed by HCl elimination to produce pyrroles.

The arylchlorocarbenes **2** were generated from arylchlorodiazirines **1**[7] by photolysis or thermolysis. We prepared the 1-azabuta-1,3-dienes **3** (R^1 = Me, Bn; R^2 = Me, Ph) from cinnamaldehyde or crotonaldehyde and methyl or benzyl amines. We purified them by distillation under reduced pressure. The chlorocarbenes **2** react rapidly with 1-azabuta-1,3-dienes **3** to presumably yield dihydropyrroles **5**. In all cases, the elimination of HCl from **5** to give pyrroles **6** is instantaneous since no trace of **5** could be found. Yields and melting points of pyrroles **6** are presented in Table 1 and their spectral data[8] compare well with those previously reported for **6a**,**d**.[2,6,9] The yields of pyrroles **6** obtained from photolysis (30–55%) and thermolysis (40–65%) are comparable.†

[a] Only the mp for **6d** has been reported: lit., 117–118 °C (ref. 6).

Photolyses were carried out by irradiation (350 nm) of solutions of the chlorodiazirines **1** (1 mmol) and 1-azabuta-1,3-dienes **3** (2.5 mmol) in hexane (50 ml) at 25 °C for 24 h. For the thermolysis reactions solutions of chlorodiazirines **1** (1 mmol) and the 1-azabuta-1,3-dienes **3** (2.5 mmol) were refluxed in absolute benzene (10 ml) for 3 h. After workup, the pyrroles **6** were purified by column chromatography on silica gel with hexane–Et_2O (10 : 1) as eluent, followed by crystallization from Pr^iOH–hexane (1 : 3).

M. T. H. Liu wishes to thank the NSERC of Canada for generous financial support.

A new type of supramolecular entanglement in the silver(I) coordination polymer $[Ag_2(bpethy)_5](BF_4)_2$ [bpethy = 1,2-bis(4-pyridyl)ethyne]

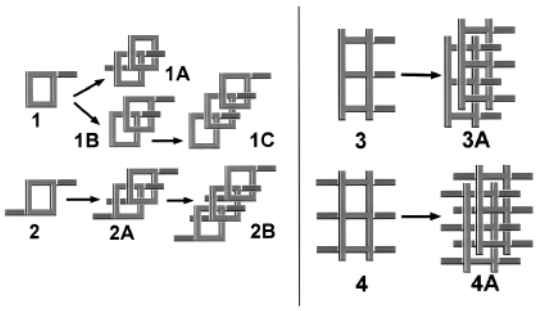
Lucia Carlucci, Gianfranco Ciani* and Davide M. Proserpio

Dipartimento di Chimica Strutturale e Stereochimica Inorganica and Centro CNR, Via G. Venezian 21, 20133 Milano, Italy. E-mail: davide@csmtbo.mi.cnr.it

Received (in Basel, Switzerland) 21st December 1998, Accepted 27th January 1999

The polymeric compound $[Ag_2(bpethy)_5](BF_4)_2$, obtained from $AgBF_4$ and 1,2-bis(4-pyridyl)ethyne (bpethy) in molar ratio 1:3, contains infinite molecular ladder motifs with monodentate ligands as sidearms on both sides, that are threaded through the squares of adjacent polymeric units in a mutual relationship, to give infinite 'polythreaded' bidimensional layers.

Two topical areas in metal-directed supramolecular chemistry,[1] that have attracted much interest in recent times, deal, respectively, with (*i*) the construction of fascinating interwoven/intertwined molecular arrays, such as catenanes, rotaxanes, knots and helicates,[2] and (*ii*) the crystal engineering of polymeric networks,[3] which are often interpenetrated.[4] Though these two fields are characterized by different objectives, the self-assembly of extended coordination frames has recently produced noteworthy examples of structural motifs typical of the former area involved in polymeric systems, such as polyrotaxanes,[5] polypseudo-rotaxanes,[6] and polycatenated molecular ladders[7] and multiple layers.[8] The stimulating current developments in the supramolecular chemistry of intertwined organic systems have revealed a variety of novel structural motifs that might have a parallel relevance also in coordination chemistry. New possible molecular modules are, for example, self-complementary units, represented by rings (or polygons) bearing one sidearm (see **1** in Scheme 1), which can self-assemble *via* non-covalent bonds to give supramolecular oligomeric or polymeric species, with the sidearm of each unit threaded through the ring of the lateral unit (see **1A**, **1B** and **1C**). Systems like these, called 'supramolecular daisy chains', have been recently discussed in the presentation of a plerotopic organic monomer that gives an array of the **1A** type.[9] A variation of the previous motif **1** can be the addition of a second sidearm, as in **2**, that can oligomerize or polymerize *via* a mutual threading involving adjacent units, as in **2A** and **2B**. On passing from finite to infinite molecular modules one can imagine the extension of rings **1** and **2** into polymeric ladder species (such as **3** and **4**, respectively). Indeed, different examples of molecular ladders have been described within coordination polymers,[7,10] including a species like **4** (called a molecular 'railroad').[11] Supramolecular assembling of **3** and **4** with identical adjacent motifs can produce, *inter alia*, two-dimensional entanglements characterized by 'polythreading' (as in **3A**) or 'mutual polythreading' (as in **4A**). We report here the characterization of an example of a type **4A** supramolecular entanglement in a coordination polymer obtained from the self-assembly of $AgBF_4$ and 1,2-bis(4-pyridyl)ethyne (bpethy). Many reactions with different silver salts in varied conditions have been carried out, but only linear $[Ag(bpethy)]^+$ polymers were isolated using metal-to-ligand molar ratios up to 1:2. We have therefore attempted reactions with a higher excess of the ligand, and from $AgBF_4$ and bpethy in molar ratio 1:3 in $MeCN–Et_2O$ we have obtained a derivative characterized by single crystal X-ray analysis as the novel species $[Ag_2(bpethy)_5](BF_4)_2$.†



Scheme 1

The structure is comprised of ladder-like polymeric units, shown in Fig. 1, bearing, as extensions of each rung (C), two additional monodentate dangling bpethy molecules (A), that are folded in opposite directions on the two sides of the ladder. The Ag···Ag distances are 13.93 Å along the siderails and 14.48 Å within the rungs.

The coordination geometry at the silver centres (see Fig. 1, top) is flattened tetrahedral. The two rows of lateral arms form dihedral angles with the ladder plane of *ca.* 137°, resulting in a stretched zigzag shaped section (see Fig. 1, bottom). In contrast, the related 'railroad' polymer of $[Ni_2(4,4'\text{-bpy})_5(H_2O)_4](ClO_4)_4\cdot 3(4,4'\text{-bpy})\cdot 4H_2O$ is flat,[11] because the Ni^{2+} centres are octahedral and all the 4,4′-bipyridyl groups lie almost coplanar. The square grids, in this species, are smaller (11.39 × 11.34 Å).

All the ladders of $[Ag_2(bpethy)_5](BF_4)_2$ run in the same direction, [−1 0 1], and are closely disposed on layers. The ladder planes are stacked parallel at a distance of 3.51 Å and display an inclination of *ca.* 22° with respect to the average plane of the layer (see Fig. 2, top). The most interesting

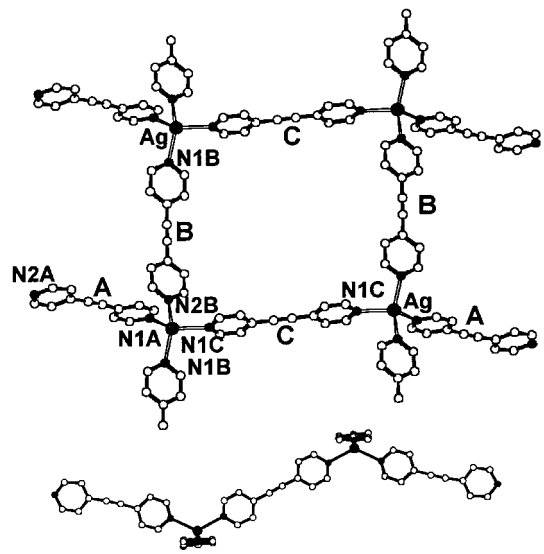


Fig. 1 Two views of a single molecular ladder motif. The top view shows the three types of bpethy ligands (A, B and C, the latter lying on inversion centres). The Ag–N bond lengths are in the range 2.300(2)–2.424(2) Å; two of the N–Ag–N angles are significantly larger [N1B–Ag–N2B 139.92(8), N1A–Ag–N1C 125.00(9)°] than the other four [in the range 95.52(8)–103.01(8)°].

structural feature, however, consists of the fact that the terminal bpethy ligands of each ladder are threaded into the squares of the adjacent ladders, in a mutual relationship. The length of the ligands is such that the threading involves not only the first but also the second nearest neighbouring ladders. Each square is therefore penetrated by four bpethy molecules, two entering by one side and two by the opposite one, as shown in Fig. 2 and 3, thus resulting in a supramolecular entanglement originated by five polymeric units. The aromatic rings of all the threaded molecules are parallel to those of the ligands of the ladder rungs. An extended system of stacked rings is thus formed, with π–π interactions [plane separation 3.5–3.6(1) Å, lateral offset 1.9–3.0(1) Å] that stabilize the whole entanglement.[12] An additional stabilization can be attributed to weak attractive CH–π interactions,[13] involving H atoms of the terminal (A) and of the rung ligands (C), that point toward the centres of the rings and of the C≡C moieties of the siderail ligands (B) (H···bar distances and C–H···bar angles: 2.66–2.79 Å, 144–168°, with bar = the baricentre of the π system). The schematic representation of the 'mutual polythreading' in this species given in Fig. 2 (bottom) shows that two adjacent ladders are displaced by *ca.* 1/4 of the polymer period along the direction of extension. The sequence of the ladders in a layer is therefore of the *ABCDABCD* type. The entangled layers stack along the crystallographic ***b*** axis, leaving interlayer voids that are occupied by the BF_4^- anions.

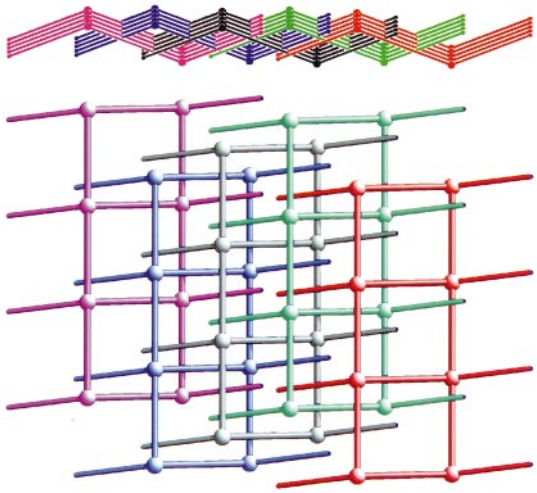

Fig. 2 Two schematic views of the entangled ladders: approximately down the direction of propagation (top), and down the perpendicular to the polythreaded layer, showing the relative displacement of the adjacent ladders (bottom).

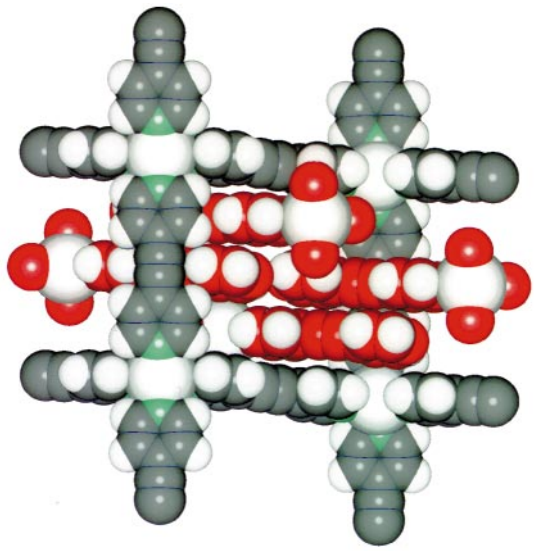

Fig. 3 Sphere packing representation of a square unit of the ladders, showing the four threading bpethy molecules (with the non-hydrogen atoms in red).

A variety of appealing interpenetrated frameworks has been recently described in coordination polymer chemistry.[4] While interpenetration requires breaking of links to separate the individual nets, other types of polymeric supramolecular architectures can be, in principle, disentangled by simply unthreading the components. These species are much less known, at present, and include examples such as infinite double-helices,[6] a clothlike warp-and-weft sheet structure,[14] and bilayer species interdigitated in a gear-like (or tongue and groove) fashion.[15] The fascinating 'polythreaded' structure here described belongs to this class of polymers and can be considered a model of a new type of infinite entanglement, that can be extended to other systems.

Phospha-alkyne hydro-osmiation: synthesis of $[Os\{\kappa^1P,\kappa^1P'\text{-}P{=}CRP(=CHR)\}Cl(CO)(PPh_3)_2]$ (R = CMe_3)

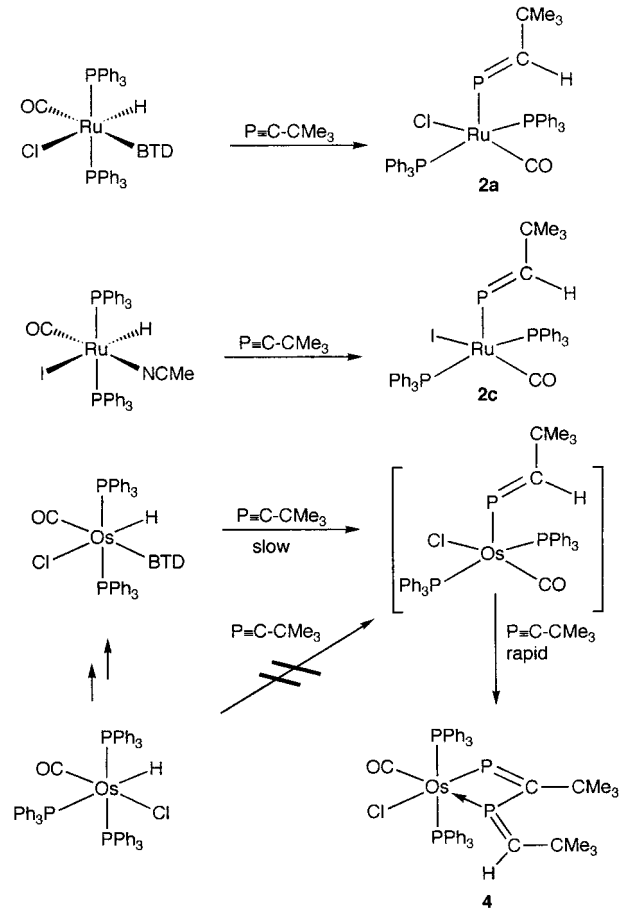
Received (in Cambridge, UK) 8th January 1999, Accepted 20th January 1999

The reaction of $[OsHCl(CO)(PPh_3)_2(BTD)]$ (BTD = 2,1,3-benzothiadiazole) with P≡$CCMe_3$ provides the novel complex $[Os\{\kappa^1P,\kappa^1P'\text{-}P{=}CRP(=CHR)Cl(CO)(PPh_3)_2]$ (R = CMe_3) which features both phospha-alkenyl and phospha-alkene donors within the same metallacycle.

We have recently described the facile hydroruthenation of phospha-alkynes by the ruthenium complexes $[RuHCl(CA)(PPh_3)_3]$ (A = O **1a**, S **1b**).[1] The phospha-alkenyl complexes $[Ru(P{=}CHCMe_3)Cl(CA)(PPh_3)_2]$ (A = O **2a**, S **2b**) which results are remarkable for a number of reasons. Firstly, the metal centre is coordinatively unsaturated, as a result of a non-linear Ru–P–C phospha-alkenyl spine. Secondly, the phospha-alkenyl ligand is unusually simple, in that it lacks the previously requisite kinetic or thermodynamic stabilisation conferred by bulky or π-dative substituents.[2] Finally but perhaps most significantly, the phospha-alkenyl ligand serves as a versatile precursor for the preparation of a range of novel complexes of otherwise inaccessible organophosphorus ligands including the unusual phospha-alkenes $XP{=}CHCMe_3$ (X = H, Me, ClHg, $AuPPh_3$, HgPh).[3] The successful synthesis and synthetic utility of the complexes **2a** and **2b** immediately raises the question of the generality of the phospha-alkyne hydrometallation strategy. Encouragingly, Nixon and coworkers have recently reported the hydrozirconation of a *coordinated* phospha-alkyne by the Schwarz' reagent to provide a synthetically useful P-zirconated phospha-alkene complex $[ZrPt(\mu\text{-}PCHCMe_3)Cl(dppe)(\eta\text{-}C_5H_5)_2]$.[4] Furthermore the hydrostannylation of phospha-alkynes has now been reported, although in this case the process lacks the regioselectivity offered by the two transition metal systems.[5] Herein we report the hydro-osmiation of a phospha-alkyne, leading to a novel osmacycle which includes both phospha-alkene and phospha-alkenyl donor components.

In contrast to the ruthenium complexes **2a** and **2b**, treating $[OsHCl(CO)(PPh_3)_3]$ **1c** with an excess of P≡$CCMe_3$ fails to result in any appreciable reaction. We have encountered a similar lack of reactivity of **1c** towards alkynes and attributed this to the lack of phosphine lability under mild conditions. However, prior conversion of **1c** to the more labile complex $[OsHCl(CO)(PPh_3)_2(BTD)]$ **3a** (BTD = 2,1,3-benzothiadiazole) provides a reagent capable of alkyne hydro-osmiation under ambient conditions providing convenient access to the complexes $[Os(CH{=}CHR)Cl(CO)(PPh_3)_2(BTD)]$.[6] It is noteworthy that whilst the analogous ruthenium complex $[RuHCl(CO)(PPh_3)_2(BTD)]$ **3b**[7] also hydrometallates alkynes to provide coordinatively saturated σ-alkenyl complexes $[Ru(CH{=}CHR)Cl(CO)(PPh_3)_2(BTD)]$,[8] we find that treating **3b** with an excess of P≡$CCMe_3$ results in the exclusive formation of *coordinatively unsaturated* **2a** with no indication of BTD coordination. In a similar manner the acetonitrile complex $[RuHI(CO)(NCMe)(PPh_3)_2]$ reacts with P≡$CCMe_3$ to provide the new phospha-alkenyl complex $[Ru(P{=}CHCMe_3)I(CO)(PPh_3)_2]$ **2c** which despite being coordinatively unsaturated, fails to recoordinate the liberated acetonitrile ligand (Scheme 1). The formulation of **2c** follows unambiguously from spectroscopic and microanalytical data,† amongst which the ^{31}P NMR data are particularly informative. The phospha-alkenyl ligand gives rise to a triplet resonance at δ 462.7 [$J(P_2P)$ 13.1 Hz] due to coupling to the two chemically equivalent phosphine phosphorus nuclei. This resonance is shifted slightly to higher field of that for **2a** [δ 450.4, $J(P_2P)$ 10.0 Hz]. Whilst **2a** is air stable both as a solid and in solution, solutions of the more electron rich complex **2c** are rapidly decomposed by air.

The reaction of **3a** with P≡$CCMe_3$ was then investigated and surprisingly *ultimately* found not to provide the analogous phospha-alkenyl complex $[Os(P{=}CHCMe_3)Cl(CO)(PPh_3)_2]$. Rather, the product **4** obtained after 18 h at room temperature was found to incorporate two equivalents of phospha-alkyne. Even when the reaction was performed with a deficiency of phospha-alkyne, no species other than **3a** and **4** could be spectroscopically observed to accumulate during the course of the reaction. In the absence of crystals suitable for an X-ray diffraction study, the complex **4** is formulated as the metallacyclic phospha-alkenyl–phospha-alkene complex



Scheme 1

$[Os\{\kappa^1P,\kappa^1P'\text{-}P{=}C(CMe_3)P(=CHCMe_3)\}Cl(CO)(PPh_3)_2]$ on the basis of spectroscopic, micro-analytical and FABMS data.† Characteristic data pertaining to the '$OsCl(CO)(PPh_3)_2$' unit are unremarkable, with interest focusing on those associated with the novel metallacycle: Two Bu^t chemical environments follow from the appearance of two singlet resonances in the ^{1}H NMR spectrum (δ 0.90, 0.70) in addition to a doublet resonance at δ 6.83 [^2J(PH) 12.6 Hz] corresponding to the vinylic (neopentylidene) proton. The ^{31}P NMR spectrum consists of three resonances: the two phosphine ligands give rise to a double-doublet resonance [δ −1.35, J(PP) 12, 18 Hz] confirming their mutually *trans* disposition, straddling the molecular symmetry plane; the phospha-alkenyl resonance appears as a slightly broadened singlet at δ 578.9 whilst the phospha-alkene phosphorus nucleus is manifest as an apparent triplet at δ 111.9 [J(PP) 19 Hz], indicating that the net coupling between the two phosphorus nuclei of the metallacycle is negligible. Only one isomer is formed with respect to the osmium stereochemistry, and since our recent structural studies of various σ-P phospha-alkene complexes suggest a moderate π-acidity,[3] it seems reasonable that it is the isomer shown (phospha-alkene *trans* to π-basic chloride) which is formed.

The metallacycle in **4** is unique in possessing both phospha-alkenyl and phospha-alkene ligating groups, although other metallacyclic phospha-alkenyl complexes have been reported, *viz*. $[Os\{P{=}C(CF_3)O\}(CO)_2(PPh_3)_2]$,[9] $[Rh\{P{=}C(CMe_3)\text{-}C{=}CH_2\}Cl(PPr^i_3)_2]$,[10] and the λ^5-phospha-alkenyl complex $[Ru\{P(=O){=}C(CMe_3)C(=O)\}(CNCMe_3)_2(PPh_3)_2]$,[11] (spectroscopic data of which support our formulation). The route by which **4** is formed presumably involves a slow insertion of one equivalent of $P{\equiv}CCMe_3$ into the osmium hydride bond to provide transiently the phospha-alkenyl complex $[Os(P{=}CHCMe_3)Cl(CO)(PPh_3)_2]$, followed by a rapid insertion of a second equivalent of phospha-alkyne into the Os–P bond and subsequent metallacyclisation. It is therefore noteworthy that treating the ruthenium complexes **2a** or **2c** with an excess of phospha-alkyne fails to result in any discernible reaction. Thus our very modest attempt to generalise what appears a simple reaction, phospha-alkyne hydrometallation, has highlighted the diversity of reactivity available to phospha-alkynes through coordinative activation by transition metals.

A. F. H. gratefully acknowledges the Leverhulme Trust and the Royal Society for the award of a Senior Research Fellowship. Osmium and ruthenium salts were generously provided by Johnson Matthey Chemicals Ltd.

Selective synthesis of 1-stanna-2-boraferrocenes: novel bidentate Lewis acids *via* an unexpected rearrangement reaction

Frieder Jäkle, Alan J. Lough and Ian Manners*

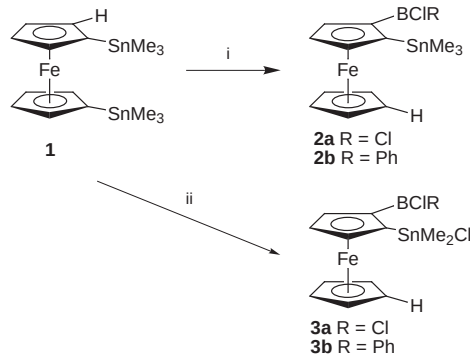
Department of Chemistry, University of Toronto, 80 St. George Street, Toronto, Ontario, Canada M5S 3H6. E-mail: imanners@alchemy.chem.utoronto.ca

Received (in Bloomington, IN, USA) 25th November 1998, Accepted 22nd January 1999

Ferrocene based bidentate Lewis acids of the general formula 1,2-fc(BR_2)(SnR_3) are obtained in one step from 1,1′-distannaferrocenes and chloroboranes *via* an unexpected rearrangement reaction.

Bidentate Lewis acids have attracted increasing attention owing to their potential in selective anion recognition,[1] self-assembly with Lewis bases,[2] as catalysts in acid catalyzed organic transformations[3] and as cocatalysts in Ziegler–Natta olefin polymerization.[4] Systems with two different acidic centers are still very rare although they might give rise to very specific binding properties.[5–7] In particular, the combination of Lewis acidic tin(IV) and boron centers permits fine-tuning of the Lewis acidity by well known selective substituent exchange reactions at either of the metal centers. As part of our general interest in the area of tin- and boron-substituted ferrocene derivatives, here, we report on a selective, one step synthesis of ferrocene based bidentate Lewis acids from readily available 1,1′-disubstituted stannaferrocenes.[8,9]

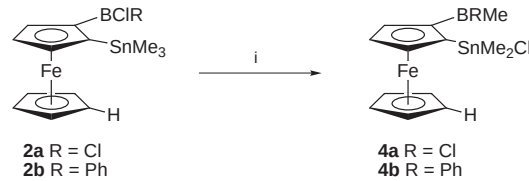
When 1,1′-bis[trimethylstannyl]ferrocene **1**[10] was treated with 1 equiv. of BCl_3 or $PhBCl_2$ in hexanes at −78 °C and the reaction mixture was allowed to slowly warm to 0 °C, the 1-stanna-2-boraferrocenes **2a** and **2b** were obtained as red oils after removal of all volatile material in high vacuum (Scheme 1). During the course of this reaction, one of the stannyl groups is replaced by a boryl substituent, which is accompanied by an unexpected rearrangement reaction. The boryl group in **2a** and **2b** is found exclusively *ortho* to the remaining stannyl substituent whereas the proton has transferred to the other Cp ring leaving an unsubstituted Cp ligand in **2a** and **2b**.† The reactions were conveniently followed by ^{1}H, ^{11}B and ^{119}Sn NMR spectroscopy.‡ The ^{11}B NMR spectra of **2a** and **2b** display a broad signal (**2a**: δ 51.1, **2b**: δ 57.2) in the expected range for aryldichloroboranes and diarylchloroboranes, respectively. In the ^{119}Sn NMR spectra of **2a** and **2b** a singlet (**2a**: δ −5.1, **2b** δ −9.9) is found at a similar chemical shift as observed for the starting material **1** (δ −6.3) indicating that a trimethylstannyl moiety is still attached to the ferrocene core. The most striking feature in the ^{1}H NMR spectra is a singlet with the intensity of five protons in the region typical of unsubstituted ferrocene Cp rings (**2a**: δ 3.92, **2b**: δ 3.93). The NMR signals for the methyl protons are particularly useful to monitor the substitution pattern on tin and boron, because of coupling between the ^{117}Sn and ^{119}Sn nuclei and adjacent methyl groups. For **2a** and **2b** one singlet with tin satellites is found [**2a**: δ 0.28, (9H), **2b**: δ 0.18, (9H)].



Scheme 1 *Reagents and conditions*: i, $RBCl_2$, hexanes, −78 °C to room temp.; ii, 2 $RBCl_2$, hexanes, −78 °C to room temp.

In order to investigate whether a second tin-boron exchange can take place, **1** was reacted with 2 equiv. of the haloboranes. If a similar reaction path as described for the formation of **2** is followed, either the formation of a 1,2-diboraferrocene or a rearranged 1,1′-diboraferrocene would be expected (Scheme 1). However, a ligand exchange on the remaining tin center to form **3a** and **3b** (73 and 53% isolated yield after recrystallization from hexanes at −55 °C, respectively) took place and no spectroscopic evidence for the formation of bisborylated ferrocenes was found.‡§ The ^{11}B NMR spectra of **3a** and **3b** show broad singlets (**3a**: δ 49.8, **3b**: δ 56.6) in the same range as observed for **2a** and **2b**. However, the exchange of a methyl for a chloro substituent on tin is evidenced by a pronounced high field shift in the ^{119}Sn NMR spectra (**3a**: δ 102.1, **3b**: δ 85.9). The planar chirality of **3a** and **3b** leads to two different signals in the ^{1}H NMR spectra for the methyl groups on tin [**3a**: δ 0.69, (3H), δ 0.52, (3H), **3b**: δ 0.82, (3H), δ 0.66 (3H)]. It is significant to note that **3b** was also detected as a byproduct in the 1 : 1 reaction between **1** and $PhBCl_2$ accompanied by a small amount of unreacted **1** accounting for a relatively low yield of **2b** in comparsion to **2a** (estimated yields based on ^{1}H NMR spectroscopy for **2a**: 95%, **2b**: 50%). By contrast, **3a** is only formed if **1** is reacted with an excess of BCl_3.

To remove any traces of Me_3SnCl or Me_2SnCl_2 from crude **2a** and **2b**, both compounds were kept at 50 °C for 3 h in high vacuum. Surprisingly, this led to another very selective rearrangement reaction giving almost exclusively **4a** and **4b**, which are obtained in good isolated yields by recrystallization from hexanes (Scheme 2). In both compounds a chloro substituent on boron has exchanged with a methyl group on the tin center.



Scheme 2 *Conditions*: i, 50 °C in high vacuum, 3 h.

The ^{11}B NMR spectra of **4a** and **4b** display a broad singlet (**4a**: δ 61.5, **4b** δ 67.5) which is shifted by about 10 ppm to lower field in comparison to **2a**,**b** and **3a**,**b**. On the other hand, the ^{119}Sn NMR spectrum of **4a** and **4b** (**4a** δ 89.8, **4b** δ 95.3) shows a singlet at a similar chemical shift as for **3a** and **3b**. Three singlets are observed for the methyl groups in the ^{1}H NMR spectra of **4a** and **4b**, but only two of them display tin satellites.§ The NMR spectroscopic data therefore clearly confirm a rearranged structure in comparison to **1** and the proposed substituent exchange reactions between **2**, **3** and **4**.

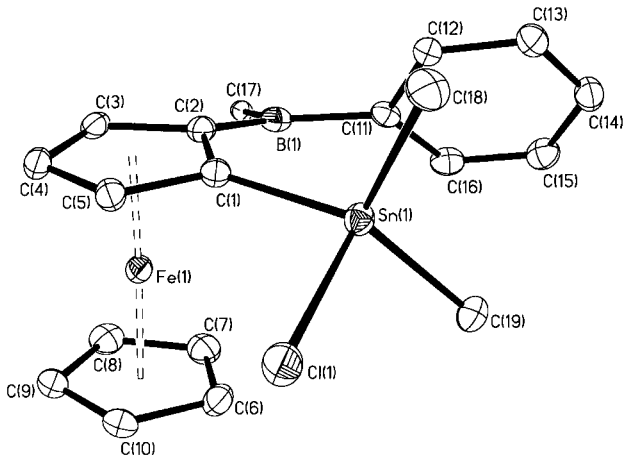


Fig. 1 Molecular structure (ORTEP drawing) of **4b**. Selected bond lengths (Å): Sn(1)–C(1) 2.121(4), Sn(1)–C(18) 2.130(4), Sn(1)–C(19) 2.121(4), Sn(1)–Cl(1) 2.404(1), B(1)–C(2) 1.536(6), B(1)–C(11) 1.571(5), B(1)–C(17) 1.623(5).

In order to further confirm the assigned rearranged structures and to distinguish unambiguously between a 1,2-substituted and a 1,3-substituted ferrocene moiety, a single crystal X-ray diffraction study of compound **4b** was undertaken.¶ Dark red crystals of **4b** were obtained from hexanes at −30 °C. A racemic mixture of both of the two possible enantiomers due to the planar chirality in **4b** is found in the single crystal used for X-ray crystallography. The structure (Fig. 1) confirmed that the proposed rearrangement reactions (see Schemes 1 and 2) had taken place. No interaction between the tin bound chlorine atom and the Lewis acidic boron center is evident. However, the boron atom is bent towards the iron atom as observed previously in the crystal structure of dibromoborylferrocene [**4b**: α^* = 12.2(3)°, $FcBBr_2$: α^* = 17.7, 18.9°; α^* = 180° − centroid (C1–C5)–C(2)–B angle] suggesting some iron–boron interaction.[11] A smaller degree of iron–boron interaction in **4b** in comparison to $FcBBr_2$ is reflected in a significantly longer B–C(Cp) bond length [**4b**: 1.536(6) Å, $FcBBr_2$: 1.474(9), 1.482(8) Å] and a longer Fe–B distance [**4b**: 3.087(5) Å, $FcBBr_2$: 2.840 Å]. The tin atom is only slightly bent away from the Cp plane [**4b**: α^* = 2.7(2)°, α^* = 180° − centroid(C1–C5)–C(1)–Sn angle].

In summary, reaction of **1** with haloboranes provides a mild, simple one step synthesis of novel bidentate ferrocene based Lewis acids. In contrast, the direct borylation of ferrocene with BCl_3 requires extended reaction times at elevated temperature.[12] The reaction sequence involves an interesting substituent rearrangement from one Cp ring to the other. Currently, we are investigating mechanistic details of the observed rearrangement reactions, the use of 1-stanna-2-boraferrocenes as bidentate Lewis acids in selective anion recognition including the effect of their planar chirality[13] and their potential as precursors for other 1,2-substituted ferrocenes.

A novel eight-membered Cu_4I_4 ring supported by sulfur atoms of an $M(mnt)_2$ moiety: syntheses and crystal structures of $(NBu^n_4)_2[M(mnt)_2Cu_4I_4]$ (M = Ni, Pd, Pt; mnt = 1,2-dicyano-1,2-ethylenedithiolato) with doubly-bridged one-dimensional chain structures

Received (in Cambridge, UK) 14th December 1998, Accepted 29th January 1999

Crystal structure analyses of the title compounds revealed that they have almost the same structure with a novel eight-membered Cu_4I_4 ring supported by an $M(mnt)_2$ moiety, two cyano groups out of the four of which coordinate to two copper(I) ions in neighboring molecules, resulting in the formation of a unique doubly-bridged one-dimensional chain structure.

There is considerable growing interest in copper(I) coordination polymer chemistry due to a variety of fascinating multi-dimensional structures and the possibility for developing new functional materials.[1] Molecules having cyano groups sometimes can be good bridging ligands since their moderate coordination abilities to copper(I) ions make it possible to obtain single crystals suitable for X-ray analyses.[2] In order to add functionality to copper(I) polymers, we chose $[M(mnt)_2]^{n-}$ (M = Ni, Pd, Pt; mnt = 1,2-dicyano-1,2-ethylenedithiolato; n = 1, 2) as bridging ligands for copper(I) ions. Conducting and magnetic properties of compounds containing $[M(mnt)_2]^{n-}$ moieties have been extensively studied.[3] However, mixed metal coordination compounds containing a $M(mnt)_2$ moiety are rare. A series of compounds with μ-bridging silver(I) ions, $[Ag(PR_3)_2]_2M(mnt)_2$,[4] is the only known example so far to our knowledge.[5] Here, we report the syntheses and structures of new mixed metal coordination polymer compounds, $(NBu^n_4)_2[M(mnt)_2Cu_4I_4]$ (M = Ni **1**, Pd **2**, Pt **3**), which represent the first examples of $M(mnt)_2$ functioning as a bridging ligand. They have novel eight-membered Cu_4I_4 rings supported by sulfur atoms of $M(mnt)_2$.

Reddish black crystals of **1**–**3** were prepared by reaction of CuI and $(NBu^n_4)_2[M(mnt)_2]$[6] in THF at room temperature followed by diffusion with diethyl ether.† Single crystal X-ray structure analyses of **1**–**3**‡ showed that all three compounds have essentially the same structure. Fig. 1 displays an ORTEP drawing of the molecular structure of **1** with the atom numbering scheme. The $Ni(mnt)_2$ moiety retains its original planar structure and there is no significant change in Ni–S bond lengths compared to those of the parent compound. One side of the $Ni(mnt)_2$ moiety is covered by an eight-membered ring of Cu_4I_4 with copper atoms being close to the mnt sulfur atoms (Cu–S 2.35 Å av.). Each copper atom is located almost directly above the corresponding sulfur atom, and not between two sulfur atoms like for the bridging mode observed in $[Ag(PR_3)_2]_2M(mnt)_2$ compounds.[4] Within the eight-membered ring, copper and iodine atoms are connected alternately with Cu–I distances ranging from 2.517(3) to 2.643(1) Å. This eight-membered ring is considered to be a new isomeric form of the Cu_4X_4 arrangement with cubane- and step-like conformations having been reported previously for $[Cu_4X_4L_n]$ complexes.[7] The molecule has a C_2 symmetry axis lying normal to the $Ni(mnt)_2$ plane through the Ni atom. There are two independent copper atoms, Cu(1) and Cu(2): the former has a distorted tetrahedral coordination with two I, one S and one N atom while

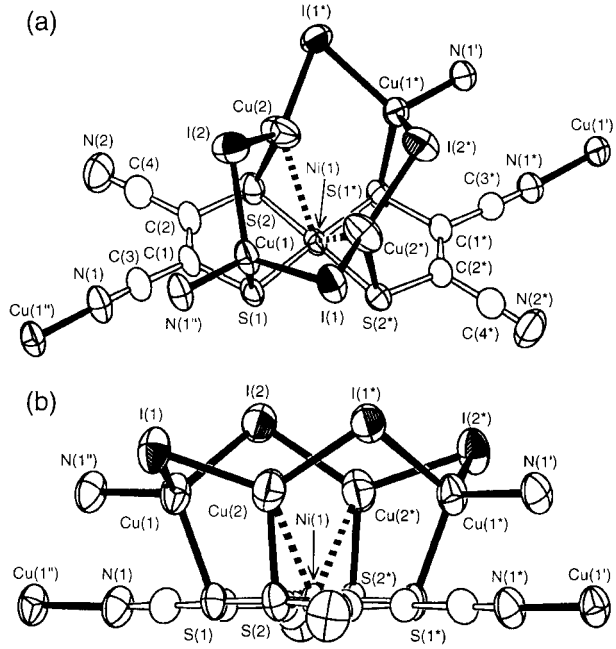

Fig. 1 (a) Top and (b) side views of ORTEP drawings of the $[Ni(mnt)_2Cu_4I_4]^{2-}$ dianion in **1**.

the latter§ shows a distorted trigonal planar coordination with two I and one S atom. It should be noted that the Ni(1)···Cu(2) distance of 2.887(4) Å is shorter than the sum of the van der Waals radii, indicating a weak interaction.

The nitrogen atom coordinating to the Cu(1) atom is from the cyano group in the neighboring molecule. This means that two cyano groups out of four in a molecular unit of **1** coordinate to two Cu(1) atoms in neighboring molecules, resulting in the formation of a doubly-bridged one-dimensional chain structure as shown in Fig. 2. This is the first example in which a $Ni(mnt)_2$ moiety acts as a bridging ligand in a coordination polymer. The chains run parallel along the *c*-axis direction, being separated from each other by bulky $NBu^n_4{}^+$ cations as shown in Fig. 3. A pressed pellet of **1** after exposure to iodine vapor for seven days gave an electrical conductivity of 1.6×10^{-3} S cm^{-1} at room

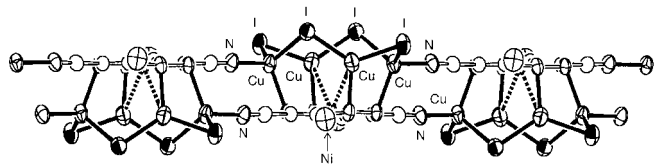

Fig. 2 View of the doubly-bridged anionic polymer $\{[Ni(mnt)_2Cu_4I_4]^{2-}\}_\infty$ in **1**.

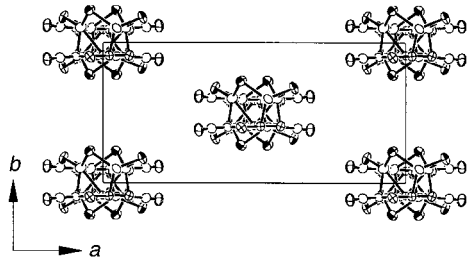

Fig. 3 Molecular packing of **1** viewed from the *c*-axis direction. The $NBu^n{}_4^+$ cations are omitted for clarity.

temperature, while the undoped material is an insulator. In spite of the polymeric structure in the solid state, **1** is soluble in THF. A ^{13}C NMR spectrum measured in d_8-THF shows two peaks at δ 115.4 and 126.0 which are shifted from those observed for $Ni(mnt)_2^{2-}$ (δ 118.1 and 125.4). These shifts indicate the presence of a slightly modified $Ni(mnt)_2^{2-}$ framework, probably $[Ni(mnt)_2Cu_4I_4]^{2-}$, in solution. The Cu–S bonds in **1** are expected to be strong enough to be maintained in THF solution whereas Cu–N(cyano) bonds are expected to dissociate. The weakness of the Cu–N(cyano) bond is exemplified by the observation of uncoordinated cyano groups in the crystal structure.

The structures of **2** and **3** are almost the same as that of **1**. The main differences are the M···Cu(2) distances which are 2.947(2) and 2.856(4) Å for Pd(1)···Cu(2) and Pt(1)···Cu(2), respectively. These distances are also shorter than the sum of the van der Waals radii, indicating weak interactions between these metal atoms. The consistency of the framework in changing the center metal atom indicates that the Cu–S interaction is dominant in determining the framework of their molecular units. Effects of changing cations as well as changing halogens on the molecular framework and the conductivity are under investigation.

In summary, we have characterized novel mixed metal compounds **1**–**3**, which have an eight-membered Cu_4I_4 ring supported by an $M(mnt)_2$ moiety. Two cyano groups out of four in the $M(mnt)_2$ moiety coordinate to two Cu(I) ions in neighboring molecules, resulting in the formation of a unique doubly-bridged one-dimensional chain structure. This is the first example showing that the $M(mnt)_2$ moiety acts as a bridging ligand for metal ions.

Notes and references

† *Procedure* for **1**: a suspension of $(NBu^n{}_4)_2[Ni(mnt)_2]$ (41.2 mg, 0.05 mmol) and CuI (38 mg, 0.2 mmol) in THF (15 ml) was stirred for 24 h at room temp. The resultant solution was filtered and the filtrate was poured into a glass tube. The same amount of ether was added slowly and the tube was sealed. After standing for one week at room temp. reddish black crystals of $(NBu^n{}_4)_2[Ni(mnt)_2Cu_4I_4]$ **1** were obtained (14.7 mg, 18.5%). Similar methods were used for the preparation of **2** and **3**. Reddish black crystals of $(NBu^n{}_4)_2[Pd(mnt)_2Cu_4I_4]$ **2**, (20.1 mg, 24.6%) and $(NBu^n{}_4)_2[Pt(mnt)_2Cu_4I_4]$ **3**, (21.7 mg, 25.2%) were obtained.

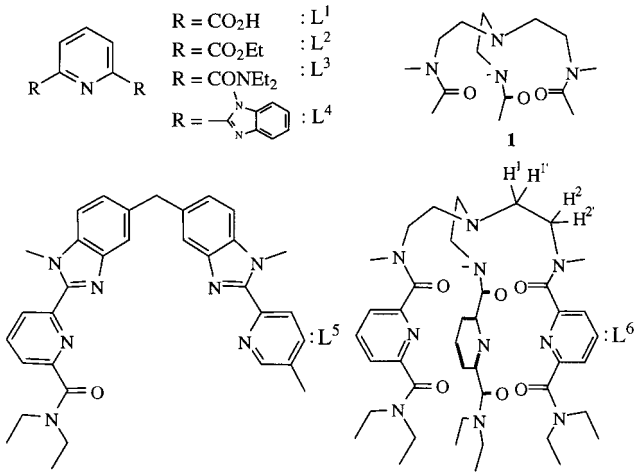
Received (in Basel, Switzerland) 15th December 1998, Accepted 20th January 1999

The protonated tripodal podand $[L^6 + H]^+$ forms stable and organized monometallic podates $[Ln(L^6 + H)]^{4+}$ where Ln^{III} is facially nine-coordinated by three wrapped unsymmetrical tridentate binding units. An unusual trifurcated hydrogen bond assists the organisation of the covalent tripod.

Symmetrical tridentate binding units containing a central pyridine ring L[1–4] are promising receptors for the design of triple helical nine-coordinate lanthanide(III) building blocks $[Ln(L^1 - 2H)_3]^{3-}$ and $[Ln(L^i)_3]^{3+}$ (i = 2–4) with pre-



determined physico-chemical properties.[1] Good structural and electronic control has also been demonstrated for unsymmetrical tridentate ligands whose facial orientation in the final C_3-symmetrical complexes is provided by a non-covalent tripod in the heterobimetallic d–f triple-stranded helicates (HHH)-$[LnM(L^5)_3]^{5+}$ (M = Fe^{II}, Co^{II}, Zn^{II}).[1,2] Surprisingly, covalent tripods which are systematically used for organizing unsymmetrical bidentate binding units around octahedral d-block metal ions in monometallic[3] and polymetallic[4] podates have rarely been involved in the related arrangement of tridentate binding units around tricapped trigonal prismatic f-block ions.[5–7] Here, we report the preparation and complexation properties of the new podand L^6 which is designed to encapsulate nine-coordinate lanthanide ions into a tricapped trigonal prismatic geometry.

The podand L^6 is obtained in one step (yield 84%) from the condensation of tris[2-(*N*-methylaminoethyl)]amine (Me-tren)[8] with an excess of 6-(*N*,*N*-diethylcarbamoyl)pyridine-2-carboxylic acylchloride.[2] Potentiometric titration of L^6 with trifluoromethanesulfonic acid in water–acetonitrile (95 : 5) in the pH range 7.0–2.0 (0.1 M $NaClO_4$) reveals a single pK_a = 4.66(1) which is attributed to the protonation of the apical nitrogen atom of the Me-tren tripod by comparison with pK_a = 5.19(2) found for the model compound **1** in the same conditions. When this titration is monitored by ^{1}H NMR in $(CD_3)_2SO$, the methylene protons $H^{1,1'}$ and $H^{2,2'}$ undergo the expected downfield shifts [$\Delta\delta(H^{1,1'})$ = 0.9 ppm, $\Delta\delta(H^{2,2'})$ = 0.3 ppm] resulting from the protonation of the apical nitrogen atom.[9] However, pK_a($[L^6 + H]^+$) and pK_a($[\mathbf{1} + H]^+$) are six orders of magnitude lower than that of the triethylammonium cation (pK_a = 11.01) which strongly suggests that the protonated apical nitrogen adopts an *endo* conformation stabilized by an intramolecular trifurcated hydrogen bond with the surrounding oxygen atoms of the side arms as previously described for protonated cryptands[10] and tris(2-hydroxyethyl)amine podands.[11] The severely reduced hydrophilicity of the resulting clipped conformation accounts for the drastic destabilization of the protonated form in polar media.[10,11]

ESMS titrations of L^6 in acetonitrile with $Ln(ClO_4)_3{\cdot}xH_2O$ (Ln = Sm–Lu; x = 6–9) show the exclusive formation of the 1 : 1 complexes $[LnL^6]^{3+}$ while signals corresponding to $[LnL^6]^{3+}$ and $[Ln(L^6)_2]^{3+}$ are detected for large Ln^{III} ions (Ln = La–Pr). This qualitative speciation is confirmed by spectrophotometric data obtained in the same conditions and fitted to eqn. (1) for Ln = Sm–Lu and eqns. (1) and (2) for Ln = La–Nd (Table 1). The formation of 1 : 2 complexes $[Ln(L^6)_2]^{3+}$ in acetonitrile is limited to light Ln^{III} (Ln = La–Pr) as a result of their larger ionic radii which make them more accessible in $[LnL^6]^{3+}$ for further complexation, as previously reported for hexadentate podands with twelve-coordinated Ln^{III}.[12]

$$Ln^{3+} + L^6 \leftrightarrow [LnL^6]^{3+} \quad \log(\beta_{11}) \quad (1)$$

$$Ln^{3+} + 2L^6 \leftrightarrow [Ln(L^6)_2]^{3+} \quad \log(\beta_{12}) \quad (2)$$

$$Ln^{3+} + [L^6 + H]^+ \leftrightarrow [Ln(L^6 + H)]^{4+} \quad \log(\beta_{11}^H) \quad (3)$$

No clear size-discriminating effect is observed for $\log(\beta_{11})$, but the stability constants are large enough to ensure the quantitative formation of $[LnL^6]^{3+}$ in solution for ligand concentrations > 1 mM and a stoichiometric ratio $Ln : L^6$ = 1. This is confirmed by ^{1}H and ^{13}C NMR spectra (0.05 M in CD_3CN at 298 K) which indicate that $[LnL^6]^{3+}$ (Ln = Ce–Lu) exist as inert and compact C_3-symmetrical complexes. Spectrophotometric titrations of $[L^6 + H]^+$ by $Ln(ClO_4)_3$ in acetonitrile can be fitted to eqn. (3) and give $\log(\beta_{11}^H)$ = 6.7(2), 6.4(2) and 6.4(5) for Ln = Sm, Y and Lu, respectively. The only marginal decrease of $\log(\beta_{11}^H)$ compared to $\log(\beta_{11})$ points to a remarkable preorganization of the protonated podand in $[L^6 + H]^+$ which essentially overcomes the increased electrostatic

Table 1 Selected thermodynamic formation constants of $[Ln(L^6)_i]^{3+}$ (i = 1,2) in acetonitrile at 298 K

Ln	$\log(\beta_{11})$	$\log(\beta_{12})$	Ln	$\log(\beta_{11})$

repulsion occurring upon complexation to Ln^{3+}. X-Ray quality prisms of $[Eu(L^6 + H)](CF_3SO_3)_3(PF_6)\cdot 0.5MeCN$ **2** can be grown from a solution containing a mixture of triflate and hexafluorophosphate anions. The crystal structure of **2** confirms the presence of a protonated cationic podate $[Eu(L^6 + H)]^{4+}$ located on a crystallographic threefold axis passing through N1, H01 and Eu.†

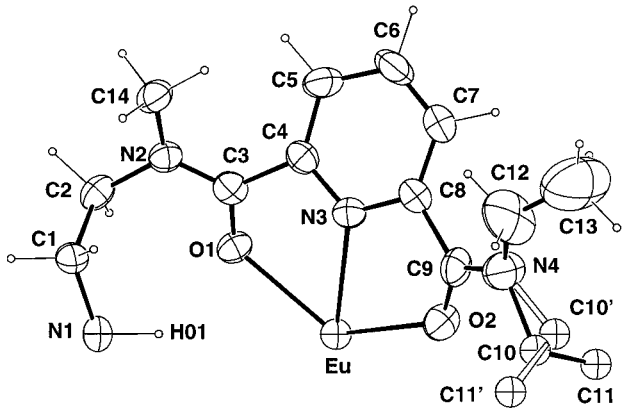

Fig. 1 Atomic numbering scheme of the cation $[Eu(L^6 + H)]^{4+}$ in **2**. Ellipsoids are represented at 40% probability level. The disordered ethyl group [C(10), C(11)] is represented with arbitrary fixed U_{iso} (0.04 Å^2) for clarity. Selected bond and contact distances (Å) and angles (°) in **2**: Eu–O(1) 2.404(8), Eu–N(3) 2.568(7), Eu–O(2) 2.395(7), N(1)···H(01) 1.10(1), N(1)···O(1) 3.02(1), O(1)···H(01) 2.167(8), O(1)–Eu–N(3) 63.5(3), O(1)–Eu–O(2) 125.5(2), N(3)–Eu–O(2) 62.4(4), N(1)–H(01)···O(1) 131.8(4).

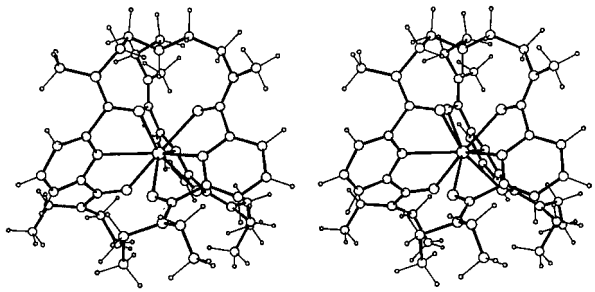

Fig. 2 ORTEP stereoview of the cation $[Eu(L^6 + H)]^{4+}$ perpendicular to the threefold axis.

The three tridentate binding units of the podand are tricoordinated to Eu^{III} whose coordination sphere is best described as a slightly distorted tricapped trigonal prismatic site in which the six oxygen atoms of the carboxamide units occupy the vertices of the prism and the three pyridine nitrogen atoms cap the rectangular faces. The Eu atom lies almost in the equatorial plane defined by the threefold symmetry related nitrogen atoms N(1), N(1′), N(1″) [deviation 0.0281(1) Å], but is significantly closer to the lower oxygen tripod [1.649(1) Å from {O(2), O(2′), O(2″)} and 1.780(1) Å from {O(1), O(1′), O(1″)}]. The Eu–N and Eu–O distances are standard[7] and the triple-helical podate adopts a conical shape which is exemplified by the larger non-bonded O···O distances observed between the oxygen atoms of the lower tripod {O(2), O(2′), O(2″)} [O(2)···O(2′) 3.01 Å, O(1)···O(1′) 2.80 Å] and which strongly contrasts with the cylindrical arrangement of the helical strands found in $[Eu(L^3)_3]^{3+}$.[7] The remarkable trifurcated hydrogen bond observed between atom N(1) (*endo* conformation) and atoms O(1), O(1′) and O(1″)[13] provides three fused and helically twisted seven-membered rings [N(1)–C(1)–C(2)–N(2)–C(3)–O(1)–H(01)] which contribute to the rigidity and the compact arrangement of the tripod. The podate $[Eu(L^6 + H)]^{4+}$ can be thus described as two helical fractions (*i.e.* the covalent tripod and the coordinated strands) which are put on top of each other. The two helical domains display opposite helicity leading to an irregular conical amphiverse *PM* (or *MP*) helix.[14]

Protonation of the apical *endo* nitrogen atoms associated with intramolecular hydrogen bonds is thought to play a crucial role in the stability, rigidity and organization of the final podate as similarly suggested by Shanzer and coworkers for lateral interstrand hydrogen bonding in related podates with d-block metal ions.[4] Preliminary photophysical studies in the solid state and in solution confirm that the C_3-symmetrical structure of the cation $[Eu(L^6 + H)]^{4+}$ is maintained in acetonitrile in agreement with paramagnetic NMR data. The high-resolution emission spectra of $[Eu(L^6 + H)]^{4+}$ display only two components for the $^5D_0 \rightarrow {}^7F_1$ transition[2,7] and three components for the transition $^5D_0 \rightarrow {}^7F_2$ which are diagnostic for a C_3-symmetrical arrangement of the donor atoms around Eu^{III}. The luminescence quantum yield of $[Eu(L^6 + H)]^{4+}$ in acetonitrile is small ($\Phi_{abs} = 1.5 \times 10^{-4}$) as a result of inefficient ligand-centered $^1\pi\pi^* \rightarrow {}^3\pi\pi^*$ intersystem crossing, but the edifice displays a good resistance toward hydrolysis: addition of 10 M water in acetonitrile has only a minor effect on the emission spectrum of $[Eu(L^6 + H)]^{4+}$ and its associated $Eu(^5D_0)$ lifetime [1.96(3) ms in absence of water and 1.29(5) ms with 10 M water], while a drastic quenching of the luminescence was observed for $[Eu(L^3)_3]^{3+}$ after the addition of 1 M water.[7] A comparison between the quenching efficiencies of H_2O *vs.* D_2O using the empirical Horrocks' equation[15] allows one to estimate $q = 0.2 \pm 0.5$ water molecule coordinated to Eu^{III} in acetonitrile containing 10 M of water. Such a small number can be accounted for by second sphere interactions. We conclude that a combination of the podand effect with secondary weak intramolecular interactions allows a precise control of facial nine-coordinate trigonal prismatic site around Ln^{III}, thus offering promising possibilities for the development of pre-organized anchors in heteropolymetallic lanthanide-containing supramolecular complexes.

Bidirectional asymmetric allylboration and the synthesis of C_2 symmetric 3-methylenepentane-1,5-diols

Anthony G. M. Barrett,* D. Christopher Braddock and Pieter D. de Koning

Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY. E-mail: m.stow@ic.ac.uk

Received (in Liverpool, UK) 16th October 1998, Accepted 27th January 1999

The double allylboration of aldehydes using 1,3-bis(diisopinocampheylboryl)-2-methylenepropane under Brown's salt-free conditions provides C_2 symmetric 3-methylenepentane-1,5-diols in excellent enantiomeric excess.

C_2 Symmetric 3-methylenepentane-1,5-diols **1** are versatile synthetic intermediates[1] and a number of procedures have been reported for their synthesis.[2,3] Most of these methods entail the

1 **2**

double addition of an aldehyde to the 2-methylpropene dianion, or a synthetic equivalent. However, the reported syntheses are neither diastereo- nor enantio-selective as only 1 : 1 mixtures of the C_2 **1** and *meso* **2** diastereomers were obtained. As an extension of the Brown asymmetric allylboration reaction,[4] we were interested in preparing the enantiomeric bis(diisopinocampheylborane)s (*S,S*)- and (*R,R*)-**4** and investigating their double allylboration reactions. In this regard, we were encouraged by a report detailing the use of 1,3-bis(dipropylboryl)-2-methylenepropane in double allylboration reactions, affording 1 : 1 mixtures of the desired 3-methylenepentane-1,5-diols **1** (racemic) and **2** (*meso*).[3]

Treatment of an ethereal suspension of 1,3-dilithio-2-methylenepropane, prepared from 2-methylpropene **3**, Bu^{n}Li and TMEDA in hexane,[5] with 2 equiv. of the commercially available (1*S*)-(+)-*B*-chlorodiisopinocampheylborane (DIP-Cl™) afforded the corresponding bis(diisopinocampheylborane) (*S,S*)-**4** (Scheme 1). The corresponding enantiomeric borane (*R,R*)-**4** was prepared from (1*R*)-(−)-DIP-Cl™.† *In situ* reaction with benzaldehyde followed by an alkaline H_2O_2 work-up gave an inseparable mixture of 3-methylene-1,5-diphenylpentane-1,5-diols **1** and **2** (R = Ph) (60%), which were readily separated from the accompanying product of mono-allylboration, 3-methyl-1-phenylbut-3-en-1-ol (**5**) (R = Ph) (30%) (Scheme 1). The diastereomeric ratio (dr) of the mixture of diols **1** and **2** (R = Ph) was estimated to be 8 : 2 (by ^{1}H NMR spectroscopy), in favour of the desired C_2 symmetric isomer **1**.

While this was a promising result, the moderate dr of the C_2 symmetric diol **1** as well as the significant amount of alcohol **5** formed necessitated changes to the reaction conditions. Reasoning that alcohol **5** arose from 3-lithio-2-methylpropene as a result of incomplete dianion formation,[5,6] the 1,3-dilithio-2-methylenepropane was isolated by filtration (35–50%) prior to the addition of the DIP-Cl™. The subsequent allylboration reaction was conducted under Brown's 'salt-free' conditions[7] in order to improve the selectivity. Gratifyingly, these modifications afforded the desired product **1** (R = Ph) with excellent diastereo- and enantio-selectivity (see Table 1, entry 1), and reduced the yield of the alcohol by-product **5** to less than 5%.

A range of aldehydes were allowed to react with both enantiomers of reagent **4**‡ to afford the corresponding C_2 symmetric 3-methylenepentane-1,5-diols **1** in moderate yields (Table 1)§ but with excellent diastereoselectivities (> 80% de)

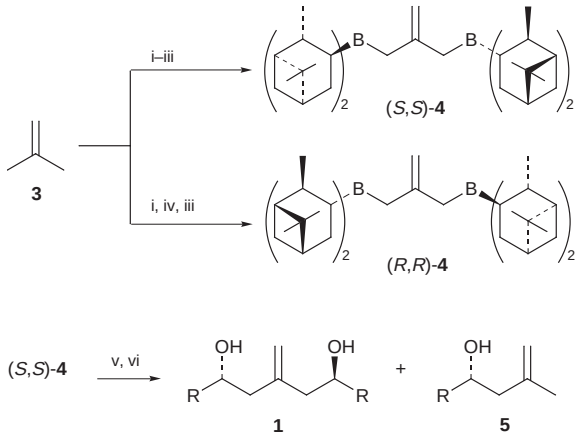
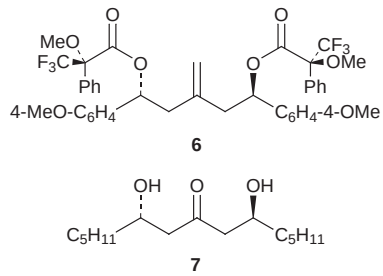
[a] The diastereomeric ratio (dr) is the ratio **1** : **2**. Both the dr and the ee are estimated from the corresponding bis-Mosher esters (ref. 8). [b] The stereochemical descriptor refers to the central 3-methylenepentanediol entity.



Scheme 1 *Reagents and conditions*: i, Bu^{n}Li, TMEDA, hexane; ii, (+)-DIP-Cl™, Et_2O; iii, pentane, filtration; iv, (−)-DIP-Cl™, Et_2O; v, RCHO, Et_2O or THF, −78 °C; vi, 30% H_2O_2, 4 mol dm^{-3} NaOH, 20 °C.

and enantioselectivities (> 95% ee).¶ Both pivaldehyde and 2-nitrobenzaldehyde failed to provide the corresponding adducts **1** presumably on account of steric congestion (Table 1, entries 13 and 14). In the case of the homochiral aldehydes (Table 1, entries 10, 11 and 12) substantial reagent control of the selectivity was observed, with largely a single isomer being isolated in both the mismatched (entry 10) and matched (entry 11) cases.

The absolute stereochemical course of the reaction was determined by an X-ray crystallographic analysis of the bis-(*S*)-(−)-Mosher ester **6**.‖ This study unequivocally established both the relative and absolute stereochemistry of the diol and, by implication, all of the other diols in Table 1. Additional confirmation of the absolute stereochemistry was obtained from a comparison of the optical rotation of dihydroxy ketone **7**



{$[\alpha]_D^{25}$ +45.8, (*c* 0.2 in $CHCl_3$)}, obtained *via* ozonolysis of diol **1** (R = C_5H_{11}) (97%), with that previously reported for the antipode {$[\alpha]_D^{25}$ −40.4, (*c* 0.2 in $CHCl_3$)}.[9]

This study further demonstrates the utility of pinene-derived compounds in asymmetric synthesis. The direct conversion of aldehydes into highly enantiomerically enriched C_2 symmetric 3-methylenepentane-1,5-diols **1** *via* an experimentally simple procedure should be of considerable application in organic synthesis.

We thank Parke Davis Warner Lambert for generous support of this programme of research, Glaxo Wellcome Research Ltd. for the generous research endowment (to A. G. M. B.), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College and the EPSRC.

Notes and references

† A solution of the salt-free bis(diisopinocampheylborane) **4** in Et_2O was found to be stable for up to 3 days at room temperature under an argon atmosphere. After this time the reagent deteriorated markedly as evidenced by substantially reduced yields.

‡ In a typical procedure a solution of (1*S*)-(+)-*B*-chlorodiisopinocampheylborane (5.4 g; 16.8 mmol) in dry Et_2O (20 ml) was added to a vigorously stirred suspension of 1,3-dilithio-2-methylenepropane·2(TMEDA) (2.3 g; 7.7 mmol) in dry Et_2O (20 ml) at 0 °C and the mixture was stirred at 20 °C for 3 h under argon. The Et_2O was removed *in vacuo* and the residue was dissolved in dry pentane (50 ml) and filtered under argon. The residual salts were washed with a further portion of dry pentane (50 ml). The combined pentane extracts were evaporated under reduced pressure and the resulting oil was dissolved in dry Et_2O (50 ml) under argon and cooled to −78 °C. 4-Methoxybenzaldehyde (2.5 ml; 20.5 mmol) was added and the resulting solution was stirred for 3 h at −78 °C. H_2O_2 (30%; 4 ml; 32 mmol) and aqueous NaOH (4 mol dm^{-3}; 8 ml; 32 mmol) were added simultaneously and the mixture was stirred for 18 h at 20 °C. Water (20 ml) was added and the mixture was extracted with Et_2O (3 × 20 ml). The ethereal extracts were dried and concentrated to give a clear residue, which was chromatographed (EtOAc–hexanes, 2 : 3) to give (1*R*,5*R*)-1,5-bis(4-methoxyphenyl)-3-methylenepentane-1,5-diol (1.377 g; 55%) as a white solid.

§ The reported yields are relative to the amount of 1,3-dilithio-2-methylenepropane. All new compounds were fully characterised by spectroscopic data, combustion analysis and HRMS.

¶ Diastereoselectivites and enantioselectivities were determined by preparation of the corresponding bis-Mosher esters (ref. 8) and ^{1}H NMR analysis.

‖ Full details of the X-ray crystallographic study will be reported elsewhere.

Anion pillaring of layered silver coordination networks

George K. H. Shimizu,*† Gary D. Enright, Chris I. Ratcliffe and John A. Ripmeester

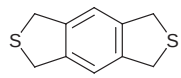
Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, K1A 0R6, Canada. E-mail: gshimizu@ucalgary.ca

Received (in Columbia, MO, USA) 5th October 1998, Accepted 29th January 1999

Silver *p*-toluenesulfonate and the dithia ligand, 1 form a layered framework where the sulfonate anion serves to 'pillar' the network, as in clay-like solids, allowing for inclusion of benzene.

The generation of microporous metal-organic networks, patterned after naturally occurring solids, is a burgeoning field of research.[1,2] Relative to their wholly inorganic cousins, these 'mineralomimetic'[3] coordination networks offer the promise of greater functionality, inherent to the incorporation of organic moieties, generally at the cost of the thermal or chemical stability of the framework.

Clays are a family of layered compounds, many of which have reactive sites in the interlayer space suitable for acid catalysis and anion exchange. A common strategy to enhance the efficacy of clays is to 'pillar' the interlayer region with a large ion, thereby offering greater access to the interlayer.[4] We recently reported the self-assembly of $AgBF_4$ and the dithia ligand, **1**, to yield an infinite layered network, structurally



1

analogous to an anionic clay, which swells to different degrees depending on the solvent.[5] As part of our ongoing study of how closely this family resembles clay-like materials, we present a new complex, formed between **1** and silver *p*-toluenesulfonate, AgOTs. This complex maintains the previously observed lamellar motif but also incorporates a coordinating anion to 'pillar' the interlayer region and allow for selective inclusion of benzene.

AgOTs in MeCN was added to a MeCN solution of **1** in a 1 : 1 molar ratio. Diffusion of benzene into this solution gave colourless, plate-like crystals of $\{Ag(\mathbf{1})OTs\cdot 0.5C_6H_6\}_\infty$, **2**, suitable for an X-ray analysis.‡ The structure of **2** (Fig. 1), reveals the formation of an infinite two-dimensional array consisting of cationic Ag(**1**) layers reinforced by a coordinating *p*-toluenesulfonate anion. The geometry at the metal centre is a distorted trigonal monopyramid comprised of three thioether donors, where the Ag–S angles sum to 355°, and a sulfonate oxygen (Ag–S1 = 2.5347(6) Å, Ag–S2a = 2.6077(7) Å, Ag–S2b = 2.5739(6) Å, Ag–O3 = 2.574(2) Å). Each molecule of **1** is asymmetrically ligated to three different silver ions (Fig. 2). That is, the sulfur donor on one side of the ligand coordinates to two silver ions while the sulfur atom on the other side of the ligand bonds to only one, consistent with the $Ag(\mathbf{1})BF_4$ complexes.[5] However, in contrast to the BF_4^- complex, the Ag(**1**) network in **2** does not form perfectly flat layers. In complex **2**, a corrugated motif is adopted (Fig. 2), as necessitated by the distorted trigonal geometry at the Ag^I centre. The dihedral angle formed by the central benzene rings of adjacent molecules of **1** is 48.50(9)°. In **2**, ligand **1** is observed solely in the *anti* conformation, with respect to the orientation of the sulfur donors in the slightly puckered pentagonal rings.

The toluenesulfonate anion is coordinated to the silver ions and orients itself at an angle of 24.2(1)° to the mean lamellar plane. The interlayer distance in **2** is 11.230(1) Å (*cf.* 10.085(1) Å in the BF_4 salt), defined as the perpendicular distance between Ag^I ions. Thus, the anion serves as a pillar to prop the lamellae apart and allow for inclusion of 0.5 molecules of benzene per asymmetric unit. This structure is analogous to that of a pillared anionic clay. The crystals readily lose the benzene upon standing but DSC/TGA reveals the desolvated network to be thermally stable to 190 °C, similar to the BF_4^- complexes.[5]

The ligand–ligand separation, measured perpendicular to the plane of the central benzene ring in **2**, is 3.940(1) Å. The maximum breadth of the *p*-toluenesulfonate ion, taken as the spherical diameter of the SO_3 group, was calculated as 4.92 Å.[6] Although the average spherical diameter of the anion is larger than the inter-ligand distance, the anions are not aligned directly adjacent to each other. For comparison, in the complex, $\{Ag(\mathbf{1})(MeCN)_2(BF_4)\}_\infty$, the inter-ligand distance[5] is 3.826(1) Å and the ionic diameter of a BF_4 ion is 4.79 Å.[6] Thus, in **2**, the lamellae have expanded to incorporate a slightly larger anion.

Interestingly, if one compares the metal centres in this structure with the two previously observed $Ag(\mathbf{1})(solv)BF_4$ (solv = $(MeCN)_2$ or PhCN) structures, one observes a different

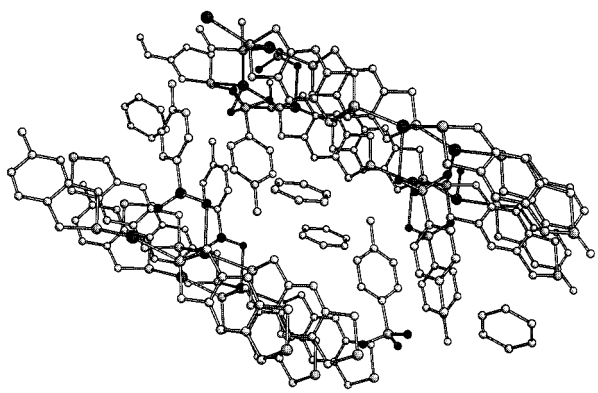


Fig. 1 View of the lamellar network formed by the complex, $\{Ag(\mathbf{1})OTs\cdot 0.5C_6H_6\}_\infty$, showing the 'pillaring' effect of the OTs anions and the inclusion of benzene in the resultant void space.

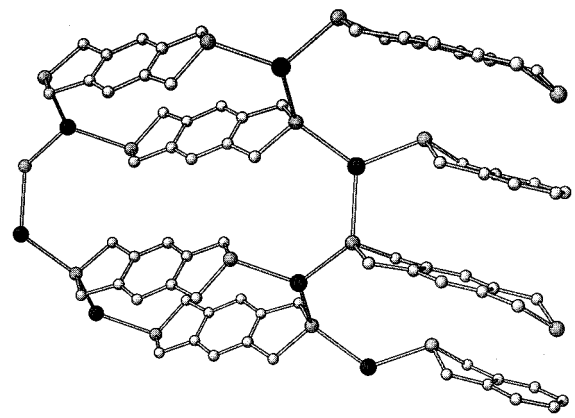

Fig. 2 View of the corrugated structure of the cationic Ag(**1**) layers and the distorted trigonal geometry at Ag^I.

coordination geometry in each case, a distorted trigonal monopyramid in the present case, and trigonal bipyramidal and near perfect trigonal monopyramidal for the MeCN and PhCN adducts of the $AgBF_4$ compounds, respectively. However, in each case, the overall motif adopted is that of a layered network. Silver(I) is well known to have a particularly pliant coordination sphere, as illustrated by these and other examples.[7] A number of studies exist where completely different structures are observed with silver(I) and a given ligand by varying the anion.[8] The tendency of the Ag(**1**)X system, where X is a monovalent anion, to adopt lamellar networks represents the manifestation of a structural constraint built into the dithia ligand, **1**, and the operation of a 'Lamellar Chelate Effect'.[5]

An attempt was made to generate compound **2** *via* anion exchange from the compound $\{Ag(\mathbf{1})(MeCN)_2BF_4\}_\infty$. The BF_4 salt was stirred, as a heterogeneous suspension, in a 0.1 M aqueous solution of sodium *p*-toluenesulfonate for 30 minutes. The solid was filtered off, washed with copious amounts of water, and analyzed by solid-state ^{13}C CP MAS NMR. The spectrum revealed a *ca.* 20% exchange of OTs for BF_4. This process was repeated twice more with the same solution resulting in a *ca.* 40% exchange. A likely scenario, consistent with clay-like behaviour, is that exchange occurs primarily around the periphery of the layered structure thus rendering the core sites inaccessible. Experiments in which exchanges with successively larger anions, also incorporating catalytic amounts of 'swelling' solvents, are in progress.

As a control, the monothia derivative of **1** was synthesized and complexation with silver(I) was studied. Without the enhanced stability provided by the layer formation, neither the AgOTs nor $AgBF_4$ salts formed stable complexes; in fact, the $AgBF_4$ salt underwent immediate photolysis and decomposition.

6 A value for the ionic volumes was calculated using Moldraw software. A qualitative value of the ionic diameter was determined by assuming a spherical ion and doubling the value of the radius from $V = \frac{4}{3}\pi r^3$. To obtain the spherical radius of the SO_3 group of the *p*-toluenesulfonate, an SO_4 group was employed.

7 Moore and coworkers have recently performed a comprehensive search of the Cambridge Structural Database to quantify occurrences of metal ion geometries, see D. Venkataraman, Y. Du, S. R. Wilson, P. Zhang, K. Hirsch and J. S. Moore, *J. Chem. Educ.*, 1997, **74**, 915. Their results, available at http://sulfur.scs.uiuc.edu, indicate that silver(I) may adopt anywhere from a two- to six-coordinate geometry but that three- and four-coordinate geometries are most common.

Novel supported catalyst for hydrodesulfurization reaction

Maria Wojciechowska,* Mariusz Pietrowski and Sławomir Łomnicki

A. Mickiewicz University, Faculty of Chemistry, 60-780 Poznań, ul. Grunwaldzka 6, Poland.
E-mail: emawoj@main.amu.edu.pl

Received (in Cambridge, UK) 18th September 1998, Accepted 20th January 1999

Thanks to a combination of the high activity of ruthenium and unique properties of a new support, magnesium fluoride, a system highly active in the hydrodesulfurization reaction was obtained.

The petrochemical industry faces a difficult problem of satisfying increasingly restrictive standards for fuels. In particular this problem concerns the reduction of the content of sulfur, nitrogen and aromatic components in the fuels produced, which can be achieved by application of various hydrotreatment processes of crude fuels (HDS, HDN, HDM, HYD and HYC). The sulfided catalysts applied at present, containing molybdenum, cobalt, nickel and tungsten supported on alumina will not be able to comply with future standards of fuel quality. Thus it is necessary to prepare new catalysts for hydrotreatment, which apart from high activity, should be characterized by high HDS selectivity.

In 1981, Pecoraro and Chianelli[1] showed that among transition metal sulfide catalysts, ruthenium systems were the most active. Further studies revealed the dependence of activity of sulfided ruthenium catalysts and the support used. For example Ru supported on alumina[2,3] was found to have different HDS properties than Ru supported on carbon.[4]

The present results concern thiophene HDS activity at atmospheric pressure. Thiophene was introduced into the reactor by bubbling a stream of pure hydrogen at a rate of 15 $cm^3\ min^{-1}$ through a thiophene saturator, maintained in an ice bath at 0 °C. The concentration of thiophene in the feed steam (total flow rate 20 $cm^3\ min^{-1}$) was maintained at *ca.* 2.5×10^{-4} mol l^{-1} by adjusting the H_2 flow rate through the saturator. The gas mixtures were analyzed by on-line gas chromatography.

The Ru/MgF_2 catalysts were prepared by conventional impregnation with $Ru_3(CO)_{12}$, surface area of the support = 40 $m^2\ g^{-1}$. Magnesium fluoride was obtained from the reaction of $MgCO_3$ with a 1 : 1 aqueous solution of HF.[5] The precipitate was then dried at 110 °C for 24 h and calcined in air at 400 °C for 4 h. The specific properties of magnesium fluoride: hardness, resistance to calcination in oxygen and well developed porous structure enable its application as an active support and owing to the absence of lattice oxygen anions, opens up great possibilities for the study of the structure and texture of the catalyst[5,6] as well as reaction mechanisms.[7,8] Additionally the presence of anions of higher electronegativity than oxygen anions leads to the expectation of the appearance of strong interactions between the support and the supported active phase.

The Ru/MgF_2 system containing 1.61% weight of ruthenium was found to be more active than similar samples supported on alumina or silica (Fig. 1). All samples were pretreated in two ways: S, sulfidation in 10% H_2S–H_2 and (ii) OS, calcination in air followed by sulfidation in 10% H_2S–H_2.

As can be seen in Fig. 1, preliminary calcination in air distinctly increases the activity of the samples (apart from those supported on silica). This effect can be explained by much easier sulfidation of calcined samples, which proceeds by the exchange of surface oxygen ions of RuO_2 clusters by sulfur atoms.

Fig. 2 presents the product distribution of thiophene HDS over Ru/MgF_2 and Ru/Al_2O_3. The selectivity of hydrogenation

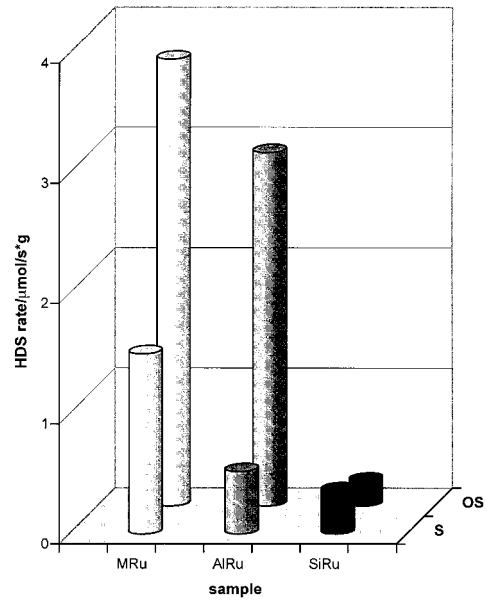

Fig. 1 Comparision of the HDS activity over Ru/MgF_2 (MRu), Ru/Al_2O_3 (AlRu) and Ru/SiO_2 (SiRu) catalysts at 400 °C. S, sulfided in 10% H_2S–H_2, 400 °C, 2 h; OS, calcined in air at 400 °C, 4 h, sulfided in 10% H_2S–H_2; 400 °C, 2 h. The rate of HDS of thiophene is given by HDS rate = *FXC/W*, where *F* is the total flow rate of feed, *X* the fractional conversion, *C* the concentration of thiophene in the feed and *W* the catalyst weight.

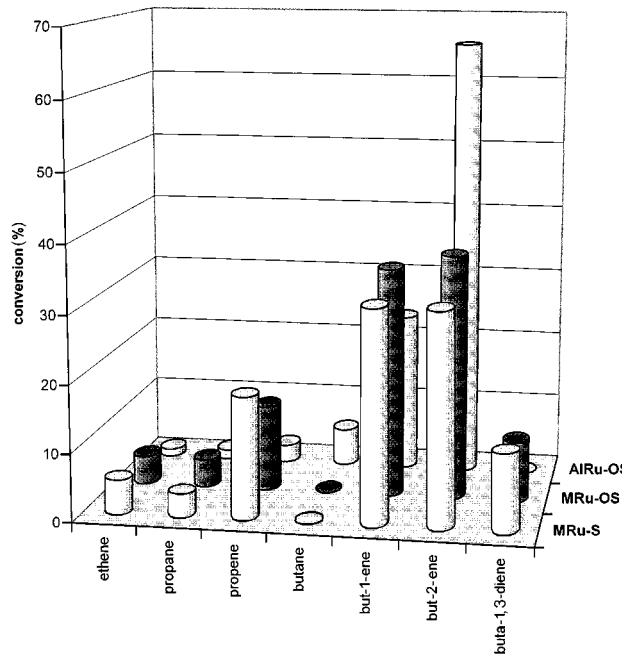

Fig. 2 Product distribution of thiophene HDS over Ru/MgF_2 (MRu) and Ru/Al_2O_3 (AlRu) catalysts. S, sulfided in 10% H_2S–H_2, 400 °C, 2 h; OS, calcined in air at 400 °C, 4 h, sulfided in 10% H_2S–H_2, 400 °C, 2 h.

Table 1 Selectivity of hydrogenation and isomerization

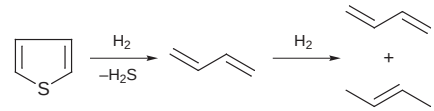
Sample	S_{hyd}	S_{iso}
MRu-S	0.00	1.00
MRu-OS	0.00	0.94
AlRu-OS	0.06	0.36

(S_{hyd}) is defined as the ratio of the formation rates of butane *vs.* butenes, whereas the ratio of but-1-ene *vs.* but-2-enes represents the selectivity of isomerization (S_{iso}).

From the above data the conclusion can be made that Ru/MgF_2 catalysts are very selective systems in the HDS process, much less hydrogenation occurs simultaneously with hydrodesulfurization (Table 1) in comparison with Ru/Al_2O_3. This, together with very high HDS activity is a clear advantage of Ru/MgF_2 catalysts compared with other ruthenium systems supported on different supports.

Since the work of Ledoux *at al.*[9] and Qusro and Massoth,[10] which found a distinct correlation between the HDS activity of thiophene and dibenzothiophene, the results of the HDS reaction for thiophene can be a model example for general conclusions of the hydrodesulfurization activity of the Ru/MgF_2 system.

The lack of tetrahydrothiophene in the reaction products together with the presence of buta-1,3-diene suggests the reaction pathway shown in Scheme 1.[11]



Scheme 1

The catalytic tests for model catalytic reactions of the described samples show a correlation between the thiophene HDS activity and the number of medium strength acidic sites.

Received (in Liverpool, UK) 16th December 1998, Accepted 26th January 1999

$C_{120}OS$ has been synthesised by thermal reaction of $C_{120}O$ and sulfur, isolated by HPLC, and characterised by MALDI-TOF-MS, LT-FAB-MS, XPS, Raman, UV-VIS, IR and ^{13}C-NMR spectroscopy; all data are consistent with a molecule of C_s symmetry with the fullerene cages linked by furan- and thiophene-like bridging units.

Following thermal reactions of the $C_{60}/C_{60}O/C_{60}O_2$ system in the solid state, various dimeric fullerene derivatives, *e.g.* $C_{120}O$,[1,2] $C_{120}O_2$ [3,4] and C_{119},[5] have been isolated and characterised. Since ethers and thioethers exhibit similar chemical behavior, we reasoned that it should be possible to synthesise sulfur analogues of the mono- and dimeric [60]fullerene oxides. Several efforts to prepare them in toluene or *o*-dichlorobenzene (ODCB) solutions using typical sulfur-transferring reagents such as Lawesson's reagent,[6] titanocene pentasulfide[7] or sulfur activated with $AlCl_3$, failed. Therefore, we performed the thermolysis of a 1 : 1 (wt%) mixture of solid $C_{120}O$[1,2] and elemental sulfur for 24 h at 230 °C under Ar at atmospheric pressure. The result was the well-known decay of $C_{120}O$ into C_{60} (*ca.* 5–10% with respect to the total amount of fullerene) as well as the production of $C_{120}OS$ (up to 70%). $C_{120}OS$ was also produced by direct heating of $C_{60}/C_{60}O$ mixtures with sulfur, but with lower yields. The product mixtures were dissolved in ODCB and analysed by high-performance liquid chromatography (HPLC)† and matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS). $C_{120}OS$, purified by two-stage HPLC, is a stable, dark brown solid, and its solubility in ODCB is *ca.* 1 mg ml^{-1}

As in the case of the oxides of [60]fullerene dimers,[1,3,4] negative-ion matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS) was used to detect the molecular anion radical, $M^{-\bullet}$, of $C_{120}OS$ (M_r 1489.38) at *m/z* 1489 (Fig. 1).‡ The fragment ions at *m/z* 720, 736 and 752, respectively, can be assigned to C_{60}, $C_{60}O$ and $C_{60}S$. Unfortunately, the observed molecular weight is also consistent with the formula $C_{120}O_3$, and the weak signal at *m/z* 752 may be interpreted as $C_{60}O_2$. The low abundance of ^{34}S (4.2%) and the experimental error in the measurement of the isotopic pattern did not allow us to distinguish between $C_{120}O_3$, $C_{120}OS$ or even C_{124}. Therefore, high-resolution negative-ion low-temperature fast-atom bombardment mass spectrometry (HR-LT-FAB-MS)[8,9] was used to obtain exact masses for $C_{120}OS$ isotopomers, confirming $C_{120}OS$ as the molecular formula.§ The results were: $^{12}C_{120}OS$, *m/z* 1487.9748 (calc. 1487.9670, error +5.2 ppm); $^{12}C_{119}{}^{13}COS$, *m/z* 1488.9764 (calc. 1488.9703, +4.1 ppm); $^{12}C_{118}{}^{13}C_2OS$, *m/z* 1489.9811 (calc. 1489.9737, +5.0 ppm).

Direct confirmation of the presence of sulfur in $C_{120}OS$ was obtained by X-ray photoelectron spectroscopy (XPS).¶ Sulfur was detected *via* the binding energies of 2p electrons which were measured as 163.2 eV ($S_{2p}{}^{3/2}$) and 164.4 eV ($S_{2p}{}^{1/2}$) and are consistent with a thioether moiety and not an S–O linkage (binding energy for sulfoxides: *ca.* 168 eV[10]).

Because of the low solubility of $C_{120}OS$ in ODCB, a sample was prepared for NMR studies with enrichment to *ca.* 7% ^{13}C.[4] The 125 MHz ^{13}C-NMR spectrum exhibited in the sp^3 region four signals with equal integrals and in the sp^2 region 54 resolved signals for 56 distinguishable sp^2 carbons, *i.e.* two pairs of carbons were coincident, giving two peaks with integral 2.‖ This spectrum is consistent with a dimer structure having two-fold symmetry and no carbon atom lying on a symmetry element. The four distinguishable sp^3 sites (eight carbon atoms) led us to a plausible structure which is homologous with the B isomer of $C_{120}O_2$.[3,4,11] The replacement of an oxygen atom in one of the furanoid bridges in C_{2v} $C_{120}O_2$(B) with sulfur results in a structure of C_s symmetry, denoted here as *syn*-**1** (stereo image in Fig. 2).** A total of six possible C_s isomers with *syn* or *anti* bridges (O, S atoms on the same or opposite sides of the cyclobutane bridging unit) were modeled with HyperChem 4.5 using the semi-empirical AM1 and PM3 methods. The *syn*-**1**

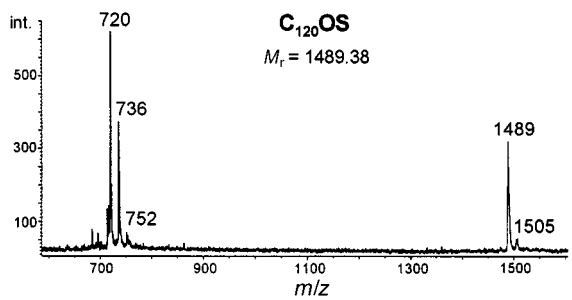

Fig. 1 The MALDI-TOF mass spectrum of $C_{120}OS$ in a 9-nitroanthracene matrix (negative-ion reflector mode) shows the molecular anion radical $M^{-\bullet}$ at *m/z* 1489 and fragment ions at *m/z* 720, 736 and 752.

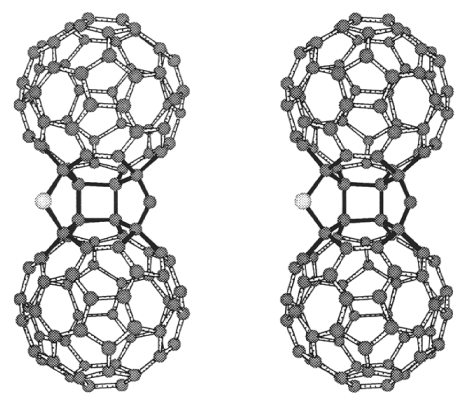

Fig. 2 Stereo pair for the lowest-energy structure of $C_{120}OS$ with C_s symmetry (denoted *syn*-**1**); furan, cyclobutane and thiophene bridges are attached to the 6,6, 5,6 and 6,6 junctions, respectively.

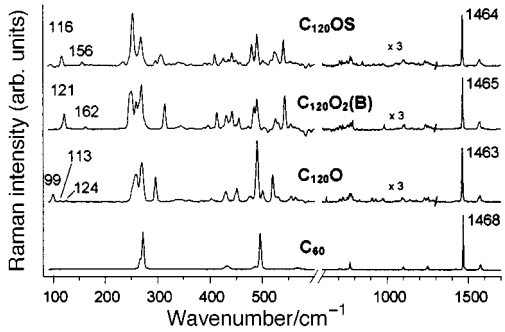

Fig. 3 FT-Raman spectra of solid C_{60}, $C_{120}O$, $C_{120}O_2$(B) and $C_{120}OS$. The region below 200 cm^{-1} is associated with 'rigid-body' cage–cage vibrations.

structure, with 6,6-5,6-6,6 junctions in each cage for the furan–cyclobutane–thiophene bridges (so-called *hph* junctions[11]), has the lowest energy and no double bonds within the pentagons. The next low-energy structure, *syn*-**2** with *php* junctions is 64 kcal mol^{-1} higher in energy. The *syn*-**1** structure can be readily formed from $C_{120}O$, which has 6,6 (*h*) furan junctions, by addition of a sulfur atom to the 6,6 junction next to the C–C bridging bond in one cage (in our nomenclature the so-called *cis*-**1** *anti* junction[4]) followed by the formation of C–S–C and C–C inter-cage bonds to the corresponding *cis*-1 6,6 junction in the opposite fullerene cage.

It has been shown that low-frequency vibrational modes in fullerene dimers are very sensitive to the details of the bridging structure.[4,12] The Raman spectra of C_{60}, $C_{120}O$, $C_{120}O_2$ and $C_{120}OS$ have been obtained under comparable conditions in the solid state (Fig. 3).†† The Raman spectra of $C_{120}OS$ and $C_{120}O_2$(B) are very similar in the range 100–600 cm^{-1}, but differ significantly from the spectrum of $C_{120}O$. In particular, two cage–cage vibrations were observed at 116 and 156 cm^{-1} for $C_{120}OS$ and at 121 and 162 cm^{-1} for $C_{120}O_2$(B), while three bands were found at 99, 113 and 124 cm^{-1} for $C_{120}O$. These results imply that $C_{120}OS$ and $C_{120}O_2$(B) have very similar bridging units and provide strong support for the NMR-consistent structure of $C_{120}OS$ with C_s symmetry (Fig. 2). The C–S–C bridge in $C_{120}OS$ has longer bonds and weaker force constants compared to the C–O–C bridge, and this is expected to result in lower cage–cage vibration frequencies in $C_{120}OS$ compared with $C_{120}O_2$(B), in agreement with the observed spectra.

The FTIR spectrum of $C_{120}OS$ (KBr micropellet) is also quite similar to that of $C_{120}O_2$(B) with bands at 1646, 1459, 1424, 1257, 1189, 1102, 1006, 965, 884, 790, 764, 549, 526 and 471 cm^{-1}. Finally, the UV-VIS spectrum of $C_{120}OS$ in n-hexane resembles that of $C_{120}O_2$(B) with peaks at 222, 274, 284 and 312 nm and weak bands at 422, 430, 464 and 486 nm.

In conclusion, $C_{120}OS$ is the first sulfur-containing dimeric [60]fullerene derivative to be synthesised and characterised by spectroscopic methods. All data are consistent with the lowest-energy modeled structure in which two fullerene cages are linked *via* furan and thiophene bridging rings with a *cis*-**1** configuration of 6,6 junctions. This structure is homologous to the lowest-energy dimeric oxide $C_{120}O_2$(B).

S. G., S. L., A. G. and W. K. thank the Deutsche Forschungsgemeinschaft for financial support (S. L.: Sonderforschungsbereich 551 'Kohlenstoff aus der Gasphase: Elementarreaktionen, Strukturen, Werkstoffe'). The authors are especially indebted to Professor M. Grunze and C. Yan for the XPS spectrum. The technical assistance of Mrs M. Schickedanz (HPLC), Mrs R. Alberts and Mrs A. Krupp (preparation of $C_{120}O$) is gratefully acknowledged.

Notes and references

† $C_{120}OS$ was separated from C_{60} and $C_{120}O$ using a 250 × 4.6 mm Cosmosil Buckyprep column (elution with 9 : 1 toluene–n-hexane, flow rate 1 ml min^{-1}, detection at 340 nm). Elution times for C_{60}, $C_{120}O$ and $C_{120}OS$ were 8.9, 16.1 and 19.2 min, respectively.

‡ MALDI-TOF mass spectra were acquired in the negative-ion reflector mode with a Bruker Biflex instrument (Bruker-Franzen Analytik, Bremen, Germany) using 10 mg ml^{-1} 9-nitroanthracene in acetone as matrix.

§ Negative-ion LT-FAB-MS was performed with a JMS-700 instrument (JEOL, Tokyo, Japan). Solid $C_{120}OS$ was dissolved in 3 μl 1-chloronaphthalene containing 10% 3-nitrobenzyl alcohol and then cooled in liquid nitrogen.[8] High-resolution measurements were made with narrow scans of the accelerating voltage. Internal mass calibration was achieved using $[(H_2SO_4)_nHSO_4]^-$ cluster ions generated from concentrated sulfuric acid. This technique was found to yield hydride adduct formation of about one third of the total molecular ion intensity superimposing the isotopic peaks and shifting the *m/z* values systematically to the high mass side (*ca.* 3 ppm).[9]

¶ XPS was obtained with an LH-12 XP spectrometer (Leybold Heraeus, Hanau, Germany). A polycrystalline gold target was placed in a concentrated solution of $C_{120}OS$ for 40 h under argon atmosphere, rinsed with ODCB and toluene and finally dried under an argon gas flow.

‖ ^{13}C-NMR measurements were performed at 125.76 MHz with a Bruker AM-500 spectrometer using standard Fourier transform techniques and a 5 mm ^{1}H/^{13}C dual probehead (Bruker Analytik GmbH, Rheinstetten, Germany). The sample contained *ca.* 0.3 mg $C_{120}OS$ (7% ^{13}C) in 0.28 ml ODCB-d_4 (saturated solution) with *ca.* 17 mM $Cr(acac)_3$ added. Parameters: temperature 20 °C, rf pulse width 5.9 μs (70° flip angle), repetition time 2.0 s, 151200 transients in 84 h). Chemical shifts for sp^2 carbons (except where noted each resonance represents two carbons): δ (ppm rel. TMS) 152.10, 149.24, 149.09, 148.65, 148.35, 148.21, 147.90, 147.63, 147.29, 146.93, 146.82, 146.54, 146.45, 146.28, 146.09, 145.81, 145.75, 145.60, 145.33, 145.27, 145.15, 145.08, 145.04, 144.97, 144.94, 144.74, 144.72, 144.61, 144.60, 144.50 (4C), 144.39, 144.37, 144.34, 144.23, 144.05, 143.89, 143.76, 143.74, 143.65, 142.93 (4C), 142.47, 142.37, 142.19, 142.18, 141.93, 141.85, 141.17, 141.15, 140.50, 139.83, 138.55, 138.06, 137.38, 134.31; sp^3: 92.40, 80.24, 72.44, 67.38.

** Theoretically, there are putative $C_{120}O_3$ structures with C_s symmetry, *e.g.* four epoxy derivatives of $C_{120}O_2$(B), but these would exhibit 5 or 6 sp^3 carbon signals and an sp^2 pattern inconsistent with the observed spectrum.

π-Mediated rearrangements and 1,2-H shifts of indanylcarbenes

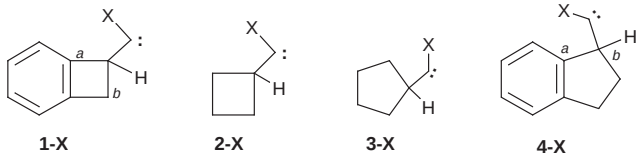
Robert A. Moss,* Wei Ma and Ronald R. Sauers*

Department of Chemistry, Rutgers University, New Brunswick, New Jersey 08903, USA.
E-mail: moss@rutchem.rutgers.edu

Received (in Corvallis, OR, USA) 15th December 1998, Accepted 29th January 1999

Absolute rate constants determined for 1,2-C and 1,2-H migrations of cyclobutyl-, cyclopentyl-, benzocyclobutenyl- and benzocyclopentenyl-(chloro)- or -(acetoxy)-carbenes reveal that 'phenyl' carbon migrations are preferred to alternative 1,2-C shifts due to π-electronic effects.

The 1,2-C migration of 'phenyl' carbon *a* is strongly preferred to that of 'benzyl' carbon *b* in benzocyclobutenylcarbenes **1-Cl**, **1-F** and **1-OAc**, whilst the 1,2-H shift is virtually non-



1-X **2-X** **3-X** **4-X**

X = Cl, OAc, or F (for **1**)

competitive.[1] The 1,2-C shift specificity is attributable to mediation by the phenyl π-system.[1] Given the somewhat unusual nature of cyclobutylcarbenes,[2] such as **2-Cl**[3] and **2-OAc**,[4] where relief of strain may drive the 1,2-C shift ring expansion, we now extend our studies to cyclopentylcarbenes **3-Cl** and **3-OAc**, as well as their benzo derivatives, the indanylcarbenes **4-Cl** and **4-OAc**. The results imply that, despite dominant reassertion of the 1,2-H shift with carbenes **3-X** and **4-X**, π-assisted 1,2-C_a migrations remain favored over unassisted C_b shifts.

All carbenes were generated from appropriate diazirine precursors. 3-Chloro-3-cyclopentyldiazirine (λ_{max} 348, 364 nm, pentane) was prepared in 35% yield by NaOCl oxidation[5] of cyclopentanecarboximidamide·HCl,[6] whereas 3-acetoxy-3-cyclopentyldiazirine (13%, λ_{max} 342, 354 nm, pentane) was obtained from a 'modified' Graham oxidation (LiOAc, NaOCl)[4] of the same amidine.† For the indanyl precursors, indan-1-one was converted (40%) to 1-cyanoindane[7] with tosylmethyl isocyanide and NaOEt in DME. The cyanoindane gave 58% of indane-1-carboximidamide·HCl upon reaction with $MeClAlNH_2$ (toluene, 80 °C, 30 h),[8] and the amidine was oxidized to 3-chloro-3-(indan-1-yl)diazirine (30%, λ_{max} 330, 346, 360 nm, pentane) with NaOCl,[5] or to the analogous acetoxydiazirine (9%, 338, 352 nm, pentane) with LiOAc/NaOCl.[4]† All diazirines were purified by chromatography on silica gel and characterized by NMR and UV spectroscopy.

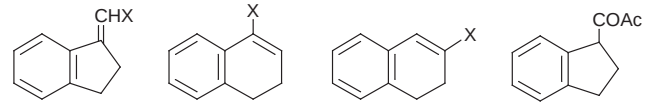
Carbenes **3-X** and **4-X** were generated by photolysis (λ > 320 nm, 25 °C) and by thermolysis (78 °C) of pentane solutions of the diazirines (A = 0.5–0.7 at λ_{max}). Products were identified by GC-MS, and confirmed by comparisons with independently synthesized samples, or were isolated and characterized by NMR and GC-MS. All new products gave acceptable elemental analyses or high resolution MS molecular ions. All major products (> 5%) were characterized.

From **3-Cl**, we obtained only 1,2-H shift product **5**, which was synthesized from cyclopentanone and Ph_3P=CHCl. Carbene **3-OAc** gave enol acetate **6** by 1,2-H shift, and dione **7** by

5 **6** **7**

1,2-Ac migration[4,9] in ratios of 1.17 : 1 (*hν*) or 1.23 : 1 (78 °C); no 1,2-C shift product was observed. Authentic **6** was readily obtained by reaction of cyclopentanecarbaldehyde with Ac_2O,[10] whilst **7** was prepared from the same starting material *via* conversion to *E*/*Z*-1-cyclopentylpropene with Ph_3P=CHMe, followed by oxidation with $KMnO_4$.[11]

Indan-1-yl(chloro)carbene (**4-Cl**) produced H-shift products (*E*/*Z*)-**8-Cl**, as well as the isomeric 1,2-C shift products



8-X **9-X** **10-X** **11**

1-chloroindene (**9-Cl**, *via* C_a migration) and 2-chloroindene (**10-Cl**, *via* C_b migration). The GC product distribution (**8-Cl** : **9-Cl** : **10-Cl**) was 8.2 : 1.0 : 0.03 (*hν*) or 10.0 : 1.0 : 0.03 (78 °C). Authentic chloroindenes were prepared by reactions of α-tetralone (for **9-Cl**) or β-tetralone (for **10-Cl**) with PCl_5 in benzene.[12] Alkenes **8-Cl** (*E*/*Z* ~ 5) were synthesized in 60% yield by NaOH-induced elimination of HCl from 1-dichloromethylindane, itself prepared by reaction of photogenerated **4-Cl** with HCl in pentane.

From acetoxyindanylcarbene, **4-OAc**, we obtained H-shift products (*Z*/*E*)-**8-OAc**, C-shift products **9-OAc** (*via* C_a migration) and **10-OAc** (*via* C_b migration), and the acetyl migration product, dione **11**. The **8-OAc** : **9-OAc** : **10-OAc**: **11** product distributions were 9.0 : 1.0 : 0.29 : 5.3 (*hν*) and 10.3 : 1.0 : 0.24 : 5.2 (78 °C). Authentic samples of **8-OAc**, **9-OAc** and **10-OAc** were synthesized by reactions of indane-1-carbaldehyde, α-tetralone or β-tetralone, respectively, with Ac_2O;[10] whilst dione **11** was identified by its GC-MS and associated cracking pattern.

Absolute rate constants (reproducibility ~ ±15%) for the carbenic rearrangements were determined at 25 °C by laser flash photolysis (LFP)[9] of pentane solutions of the appropriate diazirines (A_{max} = 0.5–0.7 at λ_{max}) at 351 nm, using the pyridine ylide method.[4,9,13] Growth of the carbene–pyridine ylide was monitored at 390 nm. Details of this methodology, as applied to the carbenic rearrangements, have been described.[4,9]

The absolute rate constants determined for the aggregate rearrangements of carbenes **3-Cl**, **3-OAc**, **4-Cl** and **4-OAc** were (where appropriate) partitioned into k_H, k_C and k_{Ac}, in accord with the product distributions given above. In the case of **4-Cl**, the product distribution is likely biased by rearrangement directly from the excited diazirine,[1,3a,14] so that we partitioned the aggregate rate constant using the 78 °C thermolysis product distribution. Excited state diazirine rearrangements are not expected in the acetoxycarbene series.[4,15] The partitioned rate constants appear in Table 1, together with related data for carbenes **1-Cl** and **1-OAc**,[1] **2-Cl**[3] and **2-OAc**,[4] Me_2CHCCl[16] and $Me_2CHCOAc$.[4] The **2-Cl** rate constants are corrected for excited diazirine contributions,[3] whereas the 78 °C thermal product distribution is given for **1-Cl**.[1]

The most immediate observation from Table 1 is the dominance of the 1,2-H shift in the chemistry of the five-membered ring carbenes. In the absence of strain relief to drive the ring expansion, as in cyclobutylcarbenes **2-OAc** and **2-Cl**,

Table 1 Absolute rate constants of carbenic rearrangements

	Rate constants/s^{-1}			
Carbene	1,2-H	1,2-C_a	1,2-C_b	1,2-Ac
Me_2CHCCl[a]	$>10^8$			
$Me_2CHCOAc$[b]	4.0×10^6			4.0×10^6
2-Cl[c]	1.2×10^7	5.6×10^7	[d]	
2-OAc[b]	1.3×10^4	3.2×10^4	[d]	4.0×10^5
3-Cl[e]	2.2×10^7			
3-OAc[e]	2.9×10^6			2.4×10^6
1-Cl[f,g]	(1.0)	(92)	(7.0)	
1-OAc[f]		8.5×10^6	$< 8.5 \times 10^4$	
4-Cl[e]	1.4×10^7	1.5×10^6	4.5×10^4	
4-OAc[e]	1.4×10^5	1.6×10^4	4.7×10^3	8.5×10^4

[a] Ref. 16. [b] Ref. 4. [c] Ref. 3*a*. [d] $C_b = C_a$. [e] This work. [f] Ref. 1. [g] Only the 78 °C product distribution is available; cf. ref. 1.

where k_C exceeds k_H by factors of 2.5–4.7,‡ the 1,2-H shift is preferred. In cyclopentylcarbenes[17] **3-Cl** and **3-OAc**, it is preferred by a factor of at least 50.§

More to the point, the π-mediation effects, detected in the benzocyclobutenylcarbenes **1-X**,[1] also appear to operate with benzocyclopentenylcarbenes **4-X**, where phenyl carbon (C_a) migrations exceed C_b shifts by factors of 33 (X = Cl) or 3.4 (X = OAc). Importantly, the C_a migrations are *accelerated* by the benzo units whatever the outcome of the k_H *vs*. k_C competition; comparisons of **1-OAc** to **2-OAc**, **4-Cl** to **3-Cl** and **4-OAc** to **3-OAc** reveal significant $k_C(a)$ enhancements.

Other themes may be discerned in Table 1. Anticipated decreases in both k_H and k_C are observed as consequences of replacing carbenic Cl by OAc 'spectator' substituents.[4] These decreases are common to isopropyl-, cycloalkyl- and benzocycloalkenyl-carbenes. Additionally, k_{Ac} is slowed ⩾28 times in the benzocycloalkenylcarbenes **1-OAc** and **4-OAc**, relative to Pr^iCOAc or **3-OAc**, which may well reflect stabilization of the former carbenes' vacant p orbitals by the same homo-π donation[1] that is central to the π-mediation of their C_a migrations. (The ten-fold decrease in k_{Ac} of **2-OAc**, relative to Pr^iCOAc, is attributable to enhanced electron donation by the cyclobutyl moiety.[3c,4])

We conclude that π-mediation of carbenic 1,2-C migrations is not an isolated occurrence, but may occur generally in appropriate systems.

This paper is dedicated to the memory of Professor Robert R. Squires. We thank Ms Dina Merrer and Mr Shunqi Yan for assistance with the LFP experiments. We are grateful to the National Science Foundation for financial support.

Notes and references

† Both chloro and acetoxy diazirines are produced, but are separable by silica chromatography with 1:2 CH_2Cl_2–pentane.

‡ Additionally, 1,2-H migration is disfavored in cyclobutylcarbenes due to the unfavorable imposition of δ+ on the cyclobutyl carbon during hydride migration (ref. 4).

§ The experimental results are mirrored by calculations at the B3LYP/6-311 + G(d,p)//MP2/6-31G(d) level with ZPE corrections (GAUSIAN 94, Revision B.1) which give E_a for the 1,2-H and 1,2-C shifts of **2-Cl** as 6.0 and 5.6 kcal mol^{-1}, modestly favoring 1,2-C migration, as compared to E_a = 1.9 and 8.1 kcal mol^{-1} for the analogous reactions of **3-Cl**, where 1,2-H migration is strongly preferred.

An unexpected intermolecular chiral biaryl coupling reaction induced by a hypervalent iodine(III) reagent: synthesis of potential precursor for ellagitannin

Mitsuhiro Arisawa, Saori Utsumi, Makiko Nakajima, Namakkal G. Ramesh, Hirofumi Tohma and Yasuyuki Kita*

Graduate School of Pharmaceutical Sciences, Osaka University, 1-6, Yamada-oka, Suita, Osaka 565-0871, Japan. E-mail: kita@phs.osaka-u.ac.jp

Received (in Cambridge, UK) 11th December 1998, Accepted 28th January 1999

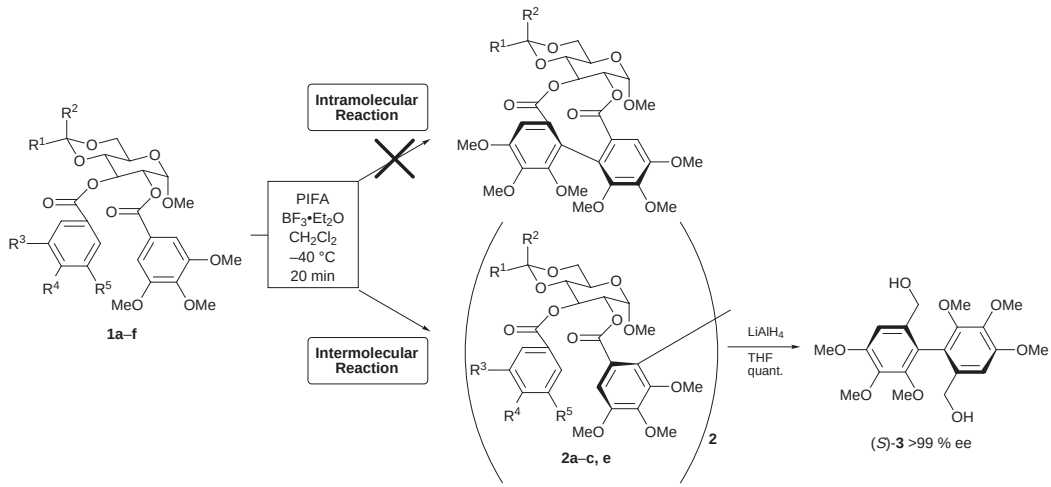
A novel phenyliodine(III) bis(trifluoroacetate) (PIFA)-induced intermolecular chiral biaryl coupling reaction has been accomplished using α-D-glucose derivatives as chiral templates.

Chiral biaryl compounds serve as important building blocks in the synthesis of natural products including ellagitannins, which have diverse pharmacological activities, such as inhibition of HIV reverse transcriptase,[1] DNA topoisomerase I mediated relaxation[2] and antioxidant activity.[3] In addition they are also used as chiral catalysts in asymmetric reactions.[4] Although several kinds of asymmetric biaryl coupling reactions leading to ellagitannin have been reported,[5] most of them involve the use of heavy metal reagents, such as $Pb(OAc)_4$, CuCN and Cu–pyridine, affording the products in moderate yields.

In recent years, use of hypervalent iodine(III) reagents has gained importance as a non- or low-toxic alternative to heavy metal reagents, to perform a variety of organic transformations. In continuation of our research on the use of hypervalent iodine(III) reagents in organic synthesis, we reported efficient nucleophilic substitution reactions on electron-rich aromatic compounds using a variety of nucleophiles such as N_3,[6] OAc, β-dicarbonyl compounds,[7] SCN and SPh.[8] Very recently, a hypervalent iodine(III)-induced intramolecular biaryl coupling reaction of phenol ether derivatives leading to dibenzo heterocyclic compounds has been reported by us.[9] The facile nature of this reaction prompted us to explore the possibility of using chiral templates in the above coupling reaction with a view to obtaining optically active biaryl compounds. Here we report the first example of an asymmetric intermolecular biaryl coupling reaction induced by phenyliodine(III) bis(trifluoroacetate) (PIFA) with α-D-glucose derivatives as the chiral auxiliary.

Our strategy to obtain the chiral biaryl compounds involves the following three step sequence: (a) synthesis of substituted aroyl derivatives of chiral diols, (b) biaryl coupling reaction using hypervalent iodine(III) reagent and (c) removal of the chiral auxiliary. Accordingly, aroyl derivatives of diols derived from glucose, menthane-3,8-diol, pinane-2,3-diol and hydrobenzoin have been synthesized and their biaryl coupling reaction examined using PIFA. Interestingly, except for the glucose-derived diol derivatives, none of the others were found to participate in the coupling reaction. Thus, the 1,2-diaroyl derivatives (**1a**, **b**)† of protected α-D-glucose underwent a smooth coupling reaction in the presence of PIFA–BF_3•Et_2O, unexpectedly in an intermolecular fashion, to afford the dimers (**2a**, **b**)† in good yields and with high diastereoselectivity

Table 1 Novel chiral biaryl coupling reaction using PIFA



Run	Substrate	R^1	R^2	R^3	R^4	R^5	Yield (%)[a]	De (%)
1	**1a**	Me	Ph	OMe	OMe	OMe	79 (90)	> 99
2	**1b**	Ph	H	OMe	OMe	OMe	44 (68)	> 99
3	**1c**	Me	Ph	OEt	OEt	OEt	37 (59)	> 99
4	**1d**	Me	Ph	OMe	H	OMe	0[b]	—
5	**1e**	Me	Ph	H	OMe	OMe	30 (38)	> 99
6	**1f**	Me	Ph	H	H	H	0[b]	—

[a] Yields in parenthesis indicate the conversion yields based upon the consumed starting material. [b] Complex mixture.

(Table 1). It is quite surprising that the reaction proceeds in an intermolecular fashion and not in the expected intramolecular way. Even more surprising is that only the aromatic ring attached to the C-2 carbon of the sugar moiety underwent the coupling reaction, while the aromatic ring on the C-3 carbon of the sugar remained intact. However, it has been observed that the substituent on the C-3 aromatic ring exerts a great influence on this biaryl coupling reaction. High yields of the products were obtained in the case where the aromatic ring on the C-3 carbon of the sugar was substituted with three methoxy groups at the 3', 4' and 5' positions. Bulkier substituents on the C-3 aromatic ring reduce the yield of the desired product, while no reaction was observed at all with the unsubstituted one. Noteworthy is that only the α-D-glucopyranoside derivative is effective in bringing about this coupling reaction. No coupling reaction took place with the diaroyl derivatives of methyl-β-D-glucopyranoside. Substituted diaroyl derivatives derived from other carbohydrate molecules such as galactose or mannose proved unsuccessful for this reaction. Furthermore, the choice of the Lewis acid used to activate PIFA seems to be critical. Among tested Lewis acids such as BF_3•Et_2O, BF_3•Bu_2O, BCl_3, $ZnBr_2$, $TiCl_4$, $SnCl_4$, Et_2AlCl, $FeCl_3$, $MgCl_2$, $Sn(OTf)_3$ and TMSOTf, only BF_3•Et_2O was found to be an efficient activator in the present case.

In order to obtain the chiral biaryl compound, the coupled adducts (**2a**–**c**, **e**) were treated with $LiAlH_4$. In all cases, the optically active biphenyl compound (**3**) was obtained in quantitative yield, with the regeneration of the chiral sugar auxiliary, which can be used for successive reactions. The optical purity of **3** was determined by HPLC to be >99%, according to the procedure of Meyers.[5d,10]

A plausible explanation for this unexpected intermolecular coupling reaction could be that the sugar moiety and the trimethoxybenzoyl group present at the C-3 carbon of the sugar have a spacial interaction, thereby favorably positioning the aromatic ring on the C-2 carbon to couple with another like molecule.

In summary, we have encountered an unexpected intermolecular biaryl coupling reaction induced by PIFA. The reaction proceeds in high yields and with remarkable diastereoselectivity. The importance of chiral biaryl compounds in organic synthesis as well as in biological sciences, coupled with the use of a hypervalent iodine(III) reagent as a low-toxic reagent, render this method attractive for the synthesis of optically active biphenyl compounds. Detailed investigation of this interesting reaction is in progress.

Notes and references

† *Preparation of* **1a**: A solution of methyl-4,6-*O*-(1′-methylbenzylidene)-α-D-glucopyranoside (ref. 11) (2.22 g, 7.5 mmol), DMAP (183 mg, 1.5 mmol), DCC (3.25 g, 15.75 mmol) and 3,4,5-trimethoxybenzoic acid (3.18 g, 15.0 mmol) in CH_2Cl_2 (125 ml) was stirred at room temperature for 12 h. The precipitate was filtered and the mother liquor was subjected to column chromatography (*n*-hexane–AcOEt = 3 : 2), giving **1a** (4.68 g, 6.83 mmol, 91.0 %) as colorless needles. Mixed benzoates **1c**–**f** were synthesized from methyl-4,6-*O*-(1′-methylbenzylidene)-2-(3′,4′,5′-trimethoxybenzoyl)-α-D-glucopyranoside, which in turn was regioselectively prepared from methyl-4,6-*O*-(1′-methylbenzylidene)-α-D-glucopyranoside using 1-(benzoyloxy)-benzotriazole (ref. 12).

Preparation of **2a**: To a stirred solution of **1a** (34.2 mg, 0.050 mmol) in CH_2Cl_2 (0.50 ml) was added a solution of PIFA (21.5 mg, 0.050 mmol) and BF_3•Et_2O (0.013 ml, 0.100 mmol) in CH_2Cl_2 (0.50 ml) at −40 °C under nitrogen atmosphere, and the reaction was stirred at the same temperature for 20 min. The reaction was quenched by the addition of saturated $NaHCO_3$, extracted with CH_2Cl_2, washed with brine, dried over Na_2SO_4 and evaporated. After column chromatography (*n*-hexane–AcOEt = 1 : 1), **2a** (27.0 mg, 0.0197 mmol, 79%) and **1a** (4.0 mg, 12%) were obtained as colorless needles. *Selected data* for **2a**: mp 168.0–170.0 °C (from Et_2O); δ_H(500 MHz, $CDCl_3$) 1.47 (6H, s), 3.32 (6H, s), 3.45 (6H, s), 3.57–3.63 (4H, m), 3.80 (6H, s), 3.82 (6H, s), 3.91 (6H, s), 3.92 (12H, s), 3.96–4.06 (4H, m), 4.64 (2H, dd, *J* 9.77, 3.66), 4.75 (2H, d, *J* 3.66), 5.86 (2H, dd, *J* 9.77, 9.77), 7.20 (2H, s), 7.33 (4H, s), 7.33–7.37 (10H, m); δ_C(75.0 MHz, $CDCl_3$) 31.78, 55.13, 55.65, 56.25, 60.39, 60.82, 60.95, 62.99, 63.73, 70.10, 72.32, 73.01, 97.50, 102.15, 107.06, 109.31, 124.56, 124.54, 125.14, 126.59, 128.13, 128.83, 140.29, 142.65, 145.51, 150.87, 152.03, 153.09, 165.22, 165.41; IR ν_{max}(KBr)/cm^{-1} 1728, 1338, 1223 cm^{-1}; *m/z* (FAB) 1366 (M^+); HRMS (FAB): calc. for $C_{70}H_{78}O_{28}Na$ 1389.4578, found 1389.4561. Anal. calc. for $C_{70}H_{78}O_{28}$: C, 61.49; H, 5.75. Found: C, 61.09; H, 5.73.

Received (in Cambridge, UK) 24th December 1998, Accepted 2nd February 1999

The synthesis, structural characterisation and catalytic activity in *tert*-butanol dehydration of microporous titanoniobosilicate ETNbS-10 are reported.

ETS-10 is a novel microporous framework titanosilicate consisting of 'TiO_2' rods, which run in two orthogonal directions, surrounded by tetrahedral silicate units.[1–3] The pore structure consists of 12-rings, 7-rings, 5-rings and 3-rings and has a three-dimensional wide-pore channel system whose minimum diameter is defined by 12-ring apertures. In an attempt to improve the acid characteristics of ETS-10, silicon has been isomorphously substituted by boron, aluminium and gallium.[4–6] A vanadosilicate with the structure of ETS-10 has also been reported.[7] We now wish to report the synthesis, structural characterisation and catalytic activity in the dehydration of *tert*-butanol, of niobium-substituted ETS-10.

ETNbS-10 materials with Nb/Ti molar ratios (ICP) of 0.12, 0.38 and 0.47 were prepared using a modification of the ETS-10 synthesis. An alkaline solution was made by mixing 10.00 g sodium silicate (Na_2O 8% m/m, SiO_2 27% m/m, Merck), 15.03 g H_2O, 0.80 g NaOH (Merck), 0.96 KF (Aldrich), 0.38 g KCl (Panreac), 1.02 g NaCl (Aldrich) 4.63 g $TiCl_3$ (15% m/m solution of $TiCl_3$ in 10% m/m HCl, Merck) and 1.50 g $Nb(HC_2O_4)_5$ (Niobium Products). 0.10 g seed of ETS-10 was added to the resulting gel. This gel, with a composition 5.6 Na_2O : 2.4 K_2O : 10.0 SiO_2 : TiO_2 : 0.30 Nb_2O_5 : 266 H_2O, was autoclaved under autogeneous pressure for 3 days at 230 °C. The crystalline product was filtered, washed with distilled water and dried at ambient temperature, the final product being an off-white microcrystalline (2–3.5 μm) powder. The samples were characterised by powder X-ray diffraction (XRD), high-resolution and scanning electron microscopies (HREM and SEM, respectively), infrared (TFIR) and Raman spectroscopies, ^{29}Si and ^{93}Nb solid state NMR.

The ETNbS-10 samples with Nb/Ti 0.12 and 0.38 are essentially pure. SEM and powder XRD reveal that the sample with Nb/Ti 0.47 also contains some quartz (< 10%) and, in addition, a small amount of an unknown niobosilicate. The HREM images of this sample (not shown) and ETS-10[2,3] are very similar. The powder XRD patterns of ETS-10 and ETNbS-10 samples (not shown) are virtually identical and show no significant shift in any reflection. This is to be expected because Ti(IV) and Nb(V) have very similar ionic radii.

The total mass losses between 30 and 700 °C of ETNbS-10 (*ca.* 11%, Nb/Ti 0.12) and ETS-10 (*ca.* 12.5%) are similar. Nitrogen adsorption isotherms of ETNbS-10 and ETS-10 materials are of type I with maximum uptakes of *ca.* 0.11 and 0,12 g/g, respectively. However, due to the presence of quartz and niobosilicate dense impurities the maximum uptake of ETNbS-10 with Ti/Nb 0.47 is much smaller (*ca.* 0.06 g/g).

Fig. 1(a) shows the ^{29}Si magic-angle spinning (MAS) NMR spectra of ETS-10 and ETNbS-10 (Ti/Nb 0.47). In ETS-10 there are two types of silicon chemical environments, Si(3Si, 1Ti) and Si(4Si, 0Ti), which give the two groups of resonances at δ −94 to −97 and δ *ca.* −103.7, respectively.[3] the spectrum reveals a further crystallograpic splitting of the Si(3Si, 1Ti) site. ETNbS-10 gives a ^{29}Si MAS NMR spectrum similar to that of ETS-10. However, all resonances broaden considerably and, in particular the ETS-10 peak at δ −103.7, shifts slightly to low frequency. Due to this broadening, the ETS-10 line splitting at δ *ca.* −96.5 is no longer resolved. This seems to indicate the framework insertion of Nb because studies on Al-substituted ETS-10 have shown that the broadening of the ^{29}Si MAS NMR resonances is due to lattice distortion upon Al incorporation.[6] However, in ETNbS-10 Nb is likely to replace Ti and not Si. We note in passing that ETS-10 and an ETS-10 sample impregnated with niobium give very similar ^{29}Si MAS NMR spectra.

The central-transition ^{93}Nb MAS NMR spectrum [Fig. 1(b)] of ETNbS-10 contains a broad (full-width-at-half-maximum, FWHM, *ca.* 240 ppm) asymmetric resonance at δ *ca.* 100 relative to solid Nb_2O_5. This is consistent with niobium being present in distorted octaedral coordination.[8]

Raman spectra (Fig. 2) provide perhaps the best evidence for the isomorphous substitution of Ti by Nb in the ETS-10 framework. ETS-10 gives a main strong and sharp band at *ca.* 735 cm^{-1}, assigned to the TiO_6 octahedra. As the samples Nb content increases this peak shifts slightly and broadens and, simultaneously, a band grows at *ca.* 664 cm^{-1}. The latter is typical of NbO_6 octahedra in microporous niobosilicates: titanoniobosilicate synthetic analogues of the mineral nenadkevichite give a similar band at 668 cm^{-1},[8] while a recently reported niobosilicate (AM-11) gives a band at 687 cm^{-1}.[9] The FTIR spectrum of ETS-10 (not shown) displays bands at 446, 550 and 746 cm^{-1}, associated with the TiO_6 octahedra. As the Nb content of the samples increases the intensity of these bands decreases, while a new band at 918 cm^{-1} is seen. This is a

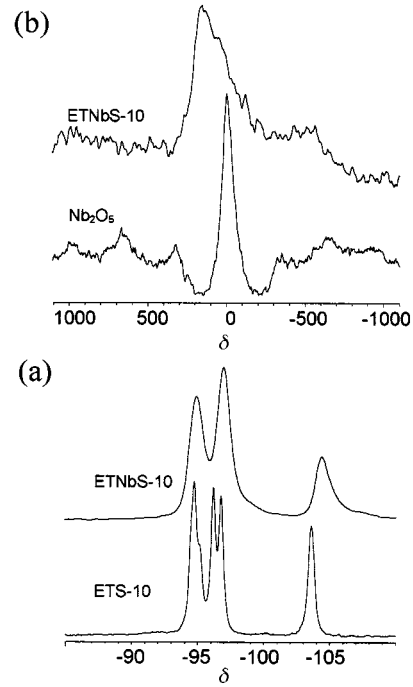

Fig. 1 (a) ^{29}Si MAS NMR spectra of ETS-10 and ETNbS-10 (Nb/Ti 0.47). (b) ^{93}Nb MAS NMR spectra of Nb_2O_5 and ETNbS-10 (Nb/Ti 0.47). The ^{29}Si and ^{93}Nb spectra were recorded at 79.5 and 97.84 MHz on a Bruker MSL 400P spectrometer using spinning rates of 5 and 32 kHz, respectively.

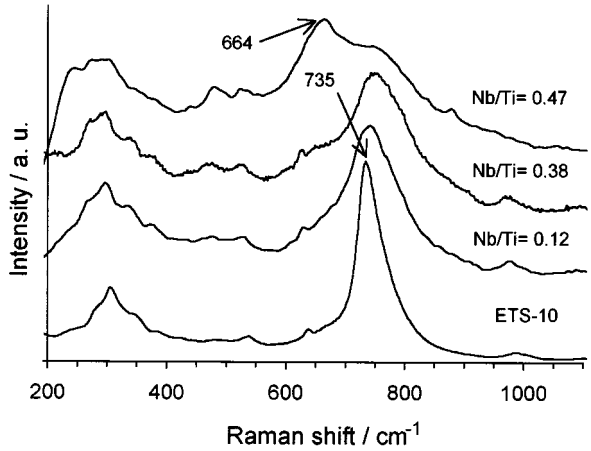

Fig. 2 Stokes-shifted Raman spectra of ETS-10 and ETNbS-10 materials (the Nb/Ti ratios are depicted). The spectra were measured using a Renishaw imaging microscope model 2000.

further indication that Nb replaces Ti in the ETS-10 framework.

A preliminary characterisation of the acid–base properties of ETNbS-10 was performed by means of *tert*-butanol dehydration. The main product of this catalytic process is isobutene an essential ingredient in methyl *tert*-butyl ether (MTBE) synthesis. The product distributions for ETNbS-10 and (for comparison) ETS-10 are given in Table 1. It is apparent that the former dehydrates *tert*-butanol to isobutene with remarkably high activity and selectivity. This finding coupled with the large pore volume of this material point to its potential in catalysis. These results are in accord with a recent study on *tert*-butanol dehydration over AM-6, ETS-10 and Al-substituted ETS-10 which has shown that the basic sites are responsible for the excellent catalytic performance of the materials.[10]

Table 1 A comparison between the catalytic performance of the ETS-10 and ETNbS-10 materials under identical reaction conditions[a]

	ETS-10	Ti/Nb = 0.12	Ti/Nb = 0.47
Conversion	44.0	71.2	99.7
Isobutene	43.56	65.0	95.0
C_5–C_9	0.44	6.2	4.7

Improvement of hydrothermal stability of MCM-41 mesoporous molecular sieve

Debasish Das, Chou-Mei Tsai and Soofin Cheng*

Department of Chemistry, National Taiwan University, Taipei 106, Taiwan. E-mail: chem1031@ccms.ntu.edu.tw

Received (in Cambridge, UK) 17th December 1998, Accepted 25th January 1999

Addition of cations such as tetraalkylammonium or sodium ions to the synthesis gel results in considerable improvement of the hydrothermal stability of mesoporous molecular sieve MCM-41.

The recent development of the mesoporous molecular sieve MCM-41 by the workers of Mobil[1,2] has attracted much attention because of the potential of these materials for use as catalysts or catalyst supports. The structure of MCM-41 consists of a hexagonal array of one-dimensional channels of uniform mesopores with pore diameter in the range 15–100 Å, depending on the nature of the template and synthesis conditions. The presence of these very large uniform pores opens up the possibilities for shape-selective conversions of bulky molecules such as those encountered in the manufacture of fine chemicals and pharmaceuticals.[3]

The main drawback of MCM-41 molecular sieve for practical applications is its rather low hydrothermal stability. The hexagonal arranged silica framework is stable when surfactant template molecules are present. However, the calcined samples, which have no templates in the pores, have very poor structural stability, especially in hot water. By contrast, the crystal structure of pure silica MCM-41 was found to be retained up to 850 °C[4] or in a 100% steam flow under atmospheric pressure at 500 °C.[5] Nevertheless, the structure of MCM-41 collapses if it is placed in hot water or aqueous solution for an extended period of time. Partial substitution of Si by other atoms like Ti or Al was reported to improve the thermal and hydrothermal stability to some extent.[6] It was also reported that improved hydrothermal stability could be achieved by adjusting the gel pH several times during the hydrothermal crystallization process.[7] However, this pH adjustment is a tedious process and the high pressure crystallization reaction has to be interrupted repeatedly. Here, we report that significant improvement in the hydrothermal stability of MCM-41 can be achieved by simply adding different tetraalkylammonium (TAA^+) or sodium ions to the synthesis gel and without the necessity of multiple pH adjustment steps.

The hydrothermal crystallization procedure described earlier[8] was slightly modified to obtain MCM-41 samples. The synthesis gel was prepared by adding sodium silicate solution (*ca.* 3.7% NaOH, *ca.* 7.0% SiO_2), to a clear solution containing cetyltrimethylammonium bromide (CTMABr, 99+%) and tetraalkylammonium (TAA^+) or sodium bromide salts. After stirring the mixture for *ca.* 10 min at room temp., a measured amount of 1.10 M sulfuric acid (p.a. grade) was added to the gel and the pH value was adjusted to *ca.* 9.5–10. The molar ratio of the final gel composition is $SiO_2 : 0.48CTMA^+ : (0–0.96)TAA^+ : 0.39Na_2O : 0.29H_2SO_4 : 50–110H_2O$. The gel mixture was stirred for 2 h at room temp. and then transferred into polypropylene bottles and statically heated at 100 °C for 4 days under autogenerated pressure. The final solid material obtained was filtered off, washed until free of Br^- ions, dried and calcined at 560 °C.

The hydrothermal stability of the synthesized samples was investigated by mixing *ca.* 0.2 g of the calcined sample with 20 g deionised water and heating in a closed bottle at 100 °C under static conditions for different time periods. After hydrothermal treatment, the samples were filtered, washed with deionised water and dried at 70 °C overnight. The hydrothermal stability was monitored by following the peak intensities of the X-ray diffraction patterns recorded on a Scintag X1 diffractometer using Cu-Kα radiation (λ = 0.154 nm). Nitrogen adsorption/desorption isotherms at liquid N_2 temperature were measured using a Micromeritics ASAP 2100 system. Prior to the experiments, samples were outgassed at 300 °C for *ca.* 6–8 h under vacuum (10^{-3} Torr). Mesopore size distribution was calculated from the desorption branch of the isotherm by the BJH (Barrett–Joyner–Halenda) method using the Halsey equation. ^{29}Si MAS NMR spectra were acquired at 59.62 MHz with 30° pulse duration of 2.0 ms, 60 s recycle delay using a Bruker MSL-300 spectrometer.

The effect of added TAA^+ cation concentration was studied by using tetrapropylammonium cation. It was found that with TPA^+/surfactant molar ratios up to 2.0, the MCM-41 structure could be obtained. Further increase in TPA^+ concentration results in either poorly crystalline or amorphous material. Highly ordered MCM-41 samples were obtained at TPA^+/surfactant ratios of 0.6–1.4. XRD patterns of the samples showed a very intense (100) diffraction peak and three additional higher order peaks with lower intensities. This suggests that these samples have a high degree of long range ordering of the structure and well formed hexagonal pore arrays. The specific surface area, A_{BET}, as determined from the linear part of the BET equation (p/p_o = 0.05–0.3), shows that these samples have a very high surface area of *ca.* 1000 $m^2\ g^{-1}$. All the samples show typical type IV adsorption isotherms of cylindrical mesopores with a sharp inflection at $p/p_0 \approx 0.3$. Pore size distribution curves show a remarkably narrow pore size distribution with a pore size of *ca.* 27 Å. The pore wall thickness as estimated from the difference of the X-ray unit cell parameter (a_o) and the peak pore diameter was found to be *ca.* 18–19 Å for the calcined samples.

The XRD patterns of the water-treated samples show that all the samples synthesized with the addition of TPA^+ are quite stable to hydrothermal treatment at 100 °C for 4 days. The intensity of the (100) peak remains very strong although the other higher order peaks become smaller. The slight shift of the (100) peak position towards higher 2θ values indicates the contraction of the pores due to an increase in pore wall thickness.

The effect of addition of cations other than TPA^+ is shown in Fig. 1 and the physical properties of the MCM-41 samples prepared with different cations are also listed in Table 1. A cation/surfactant molar ratio of 1.4 was used in the synthesis. It can be seen that highly ordered MCM-41 materials were also obtained with TMA^+, TEA^+ and even Na^+ ions. The BET surface areas, A_{BET}, of these samples are in the range 1010–1070 $m^2\ g^{-1}$. Mesopore size distribution analysis showed a very narrow distribution with a peak pore diameter of *ca.* 27 Å. By contrast, earlier workers reported that without any pH adjustment steps, addition of salts like sodium chloride resulted in poorly ordered MCM-41 samples.[7]

The MCM-41 crystalline structures were well retained after hydrothermal treatment of the calcined samples at 100 °C for 4 days (Fig. 1). Only slight decreases of the (100) peak intensity and the long-range structural ordering were observed. The surface area and pore volume of the water-treated samples were

[a] The pore size distribution was too broad and irregular to determine the peak diameter.

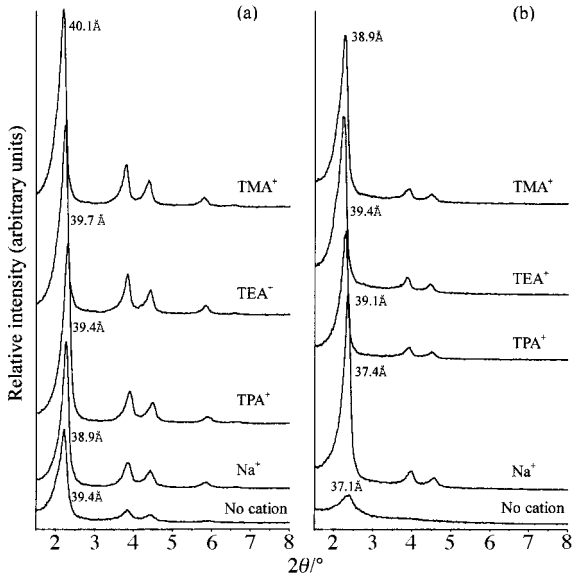

Fig. 1 XRD patterns of the MCM-41 samples prepared with the addition of different cations; (a) calcined samples and (b) after hydrothermal treatment at 100 °C for 4 days.

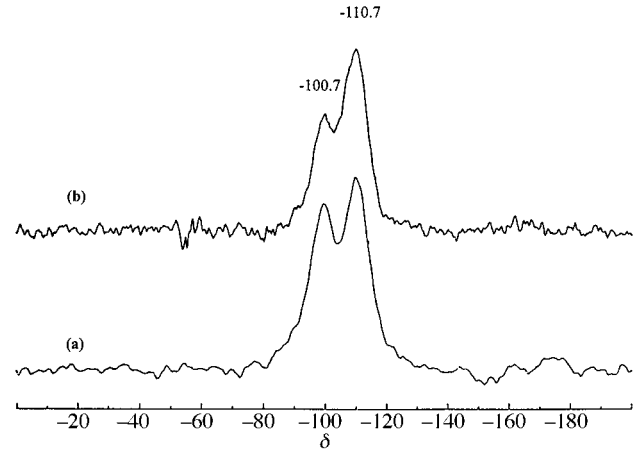

Fig. 2 ^{29}Si MAS NMR spectra of MCM-41 samples prepared (a) without additional cations and (b) with TPA^+ ions.

slightly lower than those of the calcined samples. From the nature of the adsorption isotherms and the pore size distribution curves, the pore size distribution was slightly broadened for TAA^+ and Na^+ modified samples after water treatment, but the mesoporous structure was unaltered. Also, the peak pore diameter shifts slightly towards lower values due to increased pore wall thickness. By contrast, for a sample prepared without addition of TAA^+ or extra Na^+ ions, the hexagonal pattern almost disappeared after hydrothermal treatment. The mesopore area of the unmodified sample decreases drastically after hydrothermal treatment, indicating severe disintegration of the mesostructure. It is also noted here that samples prepared without additional cations have similar pore wall thickness to those prepared by adding different cations. Hence, the increased hydrothermal stability is not related to the pore wall thickness as reported earlier.[9]

It appears that during the formation of the surfactant–silicate mesostructure, the electrostatic interaction between the cationic surfactant micelles and the surrounding silicate anions is altered by the presence of the additional cations. ^{29}Si MAS NMR spectra of the samples prepared with and without TPA^+ are shown in Fig. 2. It can be seen that the Q_4/Q_3 ratio in the as-synthesized samples was much higher for that prepared in the presence of TPA^+. The higher Q_4/Q_3 ratio indicates that there is increased condensation between the silanol groups during the formation of the mesostructure.

These results suggest that MCM-41 type mesoporous materials with a high degree of hydrothermal stability can be directly obtained without tedious pH adjustment steps by adding additional cations in the synthesis gel. Although the exact roles of these additional cations are still not clear, their presence seems to facilitate increased condensation of the silanol groups during the formation of the mesostructure. The highly condensed silica wall is considered to have better structural stability under hydrothermal treatment conditions.

Diels–Alder reactions of dienylboron compounds with unactivated dienophiles: an application of boron tethering for substituted cyclohexenol synthesis

Robert A. Batey,* Avinash N. Thadani and Alan J. Lough†

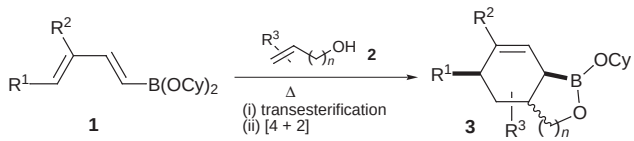
Received (in Corvallis, OR, USA) 7th December 1998, Accepted 27th January 1999

An efficient tethered intramolecular Diels–Alder reaction of 1,3-dienylboronates with various allyl and homoallyl alcohols under thermal conditions is described.

The use of Diels–Alder reactions is one of the most commonly encountered strategies for the formation of six-membered rings, particularly in natural product synthesis.[1,2] The reaction has been further augmented by using synthetic equivalents of either the diene or dienophile.[1] For instance, alkenylboron dienophiles have been used as synthetic equivalents to enols.[3–5] 1,3-Dienylboronates are versatile synthetic equivalents for hetero-subsituted dienes, since the allylboronate cycloadducts can be transformed to desirable substituted cyclohexene derivatives.[6] However, a major impediment to the use of 1,3-dienylboronate dienes in Diels–Alder reactions is the need for activated dienophile partners (*e.g*. *N*-phenylmaleimide or methylacrylate). Narasaka has demonstrated that phenylboronic acid can be used to create a temporary O–B–O tether between a diene and dienophile containing free hydroxy groups.[7] Inspired by Narasaka's work, we reasoned that tethering[8–10] *via* a C–B–O connection would enable the reaction of 1,3-dienylboron compounds with dienophiles containing hydroxy groups, such as allylic and homoallylic alcohols (*vide infra*). Here we report the first examples of Diels–Alder reactions of 1,3-dienylboron compounds with unactivated dienophiles.

Tethering of dienylboronate precursors **1** to a dienophilic component **2** allows *in situ* formation of mixed boronic esters, followed by intramolecular Diels–Alder reaction to the allylboracycles **3** (Scheme 1). Oxidation of the C–B bond in the adducts **3**, with retention of stereochemistry, leads to the formation of cyclohexenols, which are valuable precursors in natural porduct synthesis. Overall, **1** acts as a masked 1-hydroxydiene equivalent in the Diels–Alder reaction. In comparison to existing silicon-tethered Diels–Alder methodology, this approach uses the more readily synthesized dienylboronates as precursors. The use of a C–B–O rather than an O–B–O tether[7] is important, since in most cases O–B–O tethers are not applicable.

The dienylboronates **1** are formed *via* standard hydroboration methodology from the corresponding enynes. Thus, hydroboration of **4** and **7** with dicyclohexylborane afforded the corresponding dicyclohexyl(dienyl)boranes. The boron–cyclohexyl bonds were then preferentially oxidized with $Me_3N(O)$ to afford the desired dienylboronate (Table 1 and 2) without concomitant oxidation of the boron–diene bond.[6a,11] Since dienylboronates are subject to disproportionation, they were generally used *in situ* without purification. Thermal Diels–Alder reaction was conducted in the presence of an appropriate dienophile, in a degassed toluene solution, with 5 mol% of 2,6-di-*tert*-butyl-4-methylphenol (BHT) as a free radical inhibitor, using a sealed tube and a heating bath of the appropriate temperature. Oxidation with $Me_3N(O)$ or basic H_2O_2 then afforded racemic cyclohexene diols **5** and **6** in good yields (Tables 1 and 2).



Scheme 1

The constraining effects of the tether both accelerate the rate of cycloaddition, and control the regio- and stereoselectivity of the reaction. We have not been able to isolate cycloadducts in those cases where the initial tethering step cannot occur. For instance, no cycloaddition reaction was observed between ethane-1,2-diyl dienyl boronates and cinnamyl alcohol, allyl alcohol or methyl cinnamyl ether, even after prolonged heating at 220 °C.

Table 1 Tethered Diels–Alder reactions of **4**

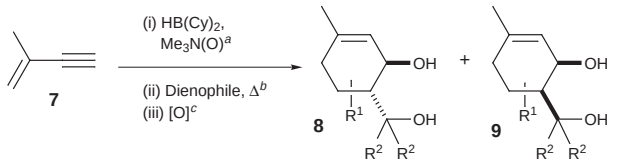
Table 2 Tethered Diels–Alder reactions of **7**



Entry	Dienophile	*T*/°C	*t*/h	Yield (%)[d]	Dr (**5** : **6**)[e]
1		190	1	81	55 : 45
2		190	6	65	75 : 25
3		150	0.5	62	75 : 25

[a] 1 equiv. $HB(Cy)_2$, THF, 0 °C to room temp., 1 h; 2 equiv. $Me_3N(O)$, THF, 0 °C to room temp., 2 h. [b] [Boronate] = *ca.* 0.3 M, $PhCH_3$, 5 mol% BHT. [c] 5 equiv. $Me_3N(O)$, C_6H_6, 80 °C, 24 h or 3 equiv. NaOH/3 equiv. H_2O_2, THF–H_2O, 2 h. [d] Yields are for chromatographically purified material and are calculated from **7**. [e] The diastereomeric ratios (**8** : **9**) are based upon NMR analysis of the crude products.

Although the tethered reactions are completely regioselective, they occur with varying diastereoselectivity depending on the substituents present on the dienophile. The presence of an activating electron-withdrawing group on the dienophile results in faster reactions (Table 1, entries 5 and 7). In comparison to the reaction using allyl alcohol (Table 1, entry 1), reaction with activated *E*-allylic alcohols favours the formation of the *trans*-substituted compounds **5** (Table 1, entries 5 and 8). This is expected, since the activating phenyl or ester groups are *endo* with respect to the diene in the transition state. The use of a longer tethering chain as exemplified by homoallyl alcohol (Table 1, entry 4) results in longer reaction times compared to allyl alcohol (Table 1, entry 1), but again favours the *trans*-substituted adduct **5**. Conversely, the presence of a *gem*-dimethyl group in the tethering chain results in shorter reaction times, because of the Thorpe–Ingold effect (Table 1, entries 3 and 6). The stereochemistry of compound **5** (Table 1, entry 5)[12] and compound **6** (Table 1, entry 9)[13] were confirmed by single crystal X-ray analysis. In the latter case the dienylboronate is delivered to the same face of the cyclohexenol ring as the hydroxy group.

Dienylboronates derived from **7** were also used as Diels–Alder precursors (Table 2). The yields are slightly lower in these cases due to the greater propensity of the dienylboronate towards polymerization. One of the enantiomers of compound **8** (Table 2, entry 1) has been used as an intermediate in the synthesis of *ent*-Δ^1-tetrahydrocannabinol.[14]

In summary, we have demonstrated a new dienylboronate tethered Diels–Alder reaction, one of the few methods allowing the use of unactivated dienophiles. The effect of the substituents on the dienophile and the length of tether on the efficacy and diastereoselectivity of the reaction was investigated. The ready availability of various enynes as precursors and the synthetic flexibility of the C–B bond in the cycloadducts is anticipated to provide access to a variety of functionalized cyclohexene derivatives.

Atom-transfer reactions catalyzed by methyltrioxorhenium(VII)—mechanisms and applications

James H. Espenson

Ames Laboratory and Department of Chemistry, Iowa State University, Ames, IA 50011, USA. E-mail: espenson@ameslab.gov

Received (in Cambridge, UK) 25th November 1998, Accepted 23rd December 1998

Methyltrioxorhenium activates hydrogen peroxide by an electrophilic mechanism, transferring a single oxygen atom to many substrates without the intervention of free-radical intermediates. The reactions proceed without by-products, unlike those of most chemical (stoichiometric) oxidizing agents. In separate chemistry, the rhenium catalyst brings about the transfer of oxygen atoms between a pair of closed-shell molecules.

Introduction

This review focuses on the catalytic chemistry of the compound methyltrioxorhenium, CH_3ReO_3, abbreviated as MTO. With but eight atoms, the small MTO molecule functions as a versatile catalyst for a considerable breadth of reactions. The essence of its chemistry is the transfer of an oxygen atom from one species to another. The oxygen source is often hydrogen peroxide; molecular oxygen is not activated. Oxygen transfer between two other substrates, as in $X + YO \rightarrow XO + Y$, is a separate process catalyzed by MTO.

Our research has been directed toward two aspects of the catalytic chemistry: gaining an understanding of the mechanisms by which different MTO reactions occur and using that understanding to predict and carry out other useful transformations. These two outlooks reinforce one another. The solubility of MTO in aqueous and most organic media adds to its versatility; the solvent can be chosen to meet requirements of the substrates, to facilitate product isolation, to enable kinetics studies, or as a matter of convenience. MTO is air-stable also, which enhances its general usefulness in catalytic systems; on the other hand, with but rare exception it does not catalyze autoxidation reactions.

The MTO molecule is isoelectronic and isostructural with the dangerously explosive permanganic acid, $HMnO_4$. MTO is rather more like perrhenic acid, $HReO_4$ or $HO–ReO_3$, in that both are quite mild oxidants. Indeed, with one known exception, the catalytic chemistry of MTO does not involve its redox reactivity; the rhenium atom remains in oxidation state VII. An exception, to be dealt with in due course, involves the intermediacy of the rhenium(v) compound $CH_3ReO_2{\cdot}L_2$, with L = solvent or incidental ligand. Let us note at the outset that the methyl group of MTO, or an aspect it confers on the system, is somehow essential. The isoelectronic perrhenic acid does not catalyze the reactions presented here, likely because ReO_4^- is anionic.

This review divides the reactions of MTO and its derivatives into these groups: (1) interactions with hydrogen peroxide, (2) O-atom transfer from hydrogen peroxide, leading to simple and complex transformations, (3) reactions proceeding by C–H activation, (4) non-oxidative rearrangement and coupling reactions, (5) the use of bromide ions as a co-catalyst, and (6) extensions to some nitrene and carbene chemistry.

The MTO catalyst

MTO remains the premier member of a now-sizable family of compounds $R–ReO_3$ in which the organic group R may be alkyl, vinyl, aralkyl, allyl, alkynyl, or cyclopentadienyl. MTO shows the greatest thermal stability (T_{dec} > 300 °C) of any member of the series, aside perhaps from $(\eta^5\text{-}C_5Me_5)ReO_3$, a catalytically-inactive compound with an 18e electronic configuration. The preparative aspects and the structural chemistry of MTO and numerous derivatives have been thoroughly reviewed recently,[1] and thus need be dealt with only cursorily here. MTO has the expected $\psi\text{-}T_d$ structure of a four-coordinate compound of a d^0 metal center.[2] Coordination compounds, such as MTO·L and $MTO{\cdot}L_2$, where L is an anionic or uncharged Lewis base, have been characterized.[3–5] They have five- and six-coordinate structures. MTO–ligand systems are highly labile, and the ^1H NMR signals for the methyl protons of MTO and MTO·L coalesce to a singlet owing to the lability of the system on the NMR timescale. At 298 K in acetonitrile, the first binding constant of pyridine to MTO is 200 L mol^{-1} whereas that of the better donor 4-picoline is 730 L mol^{-1} and that of the sterically encumbered 2,6-di-*tert*-butyl-4-methylpyridine is < 1 L mol^{-1}.[6] Under the conditions studied, binding of a second pyridine in solution was not detected.

MTO is not prone to decomposition in solvents containing water by pathways involving acid. If this appears remarkable, then it is useful to recall that this feature is common to many

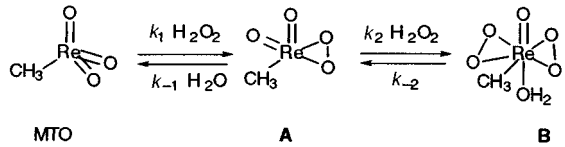
James Espenson was born in Los Angeles, California and attended school there and in its environs. He entered the California Institute of Technology, obtaining his B.S. degree in 1958. He enrolled for graduate study in the University of Wisconsin and wrote his PhD thesis under the supervision of Edward L. King in 1962. Following that he was a postdoctoral associate at Stanford University with Henry Taube during 1962–63. He was appointed Instructor of Chemistry at Iowa State University in 1963 and jointly Assistant Chemist at the Ames Laboratory of the (then) US Atomic Energy Commission. Promotions followed in due course: to Assistant Professor (1965), Associate Professor (1967), Professor (1971). He was named Distinguished Professor in 1988, and continues to hold a joint appointment at the Ames Laboratory, where he is Program Director.

Espenson has been named the John A. Wilkinson teaching award winner, Fellow of the Alfred P. Sloan foundation, Fellow of the Japan Society for the Promotion of Science, and Fellow of the American Association of the Advancement of Science. He is the author of more than 300 research publications and of the book Chemical Kinetics and Reaction Mechanisms *(2nd edn., 1995).*

other methyl–metal compounds and ions. Solutions of $HgCH_3^+$, $TlCH_3^{2+}$, $CH_3AuOH_2^{2+}$, to cite a few heavy metal derivatives, are stable toward strong acid.[7] Certain methylated first-row metals are also stable in strongly acidic solutions, such as $CH_3Co(dmgH)_2{\cdot}L$ and its relatives, including methylcobalamin. This aspect suggests, correctly, that MTO might be stabilized during catalytic turnovers by the addition of acid in semi-aqueous and aqueous media, and by the use of aprotic solvents in other instances. It is rarely useful to insist upon dry solvents for MTO-catalyzed reactions, especially since the family of reactions for which MTO is most often used, activation of hydrogen peroxide, forms water as a stoichiometric product.

Peroxorhenium compounds—structure, equilibrium, kinetics

Key to the activation of hydrogen peroxide is its interaction with MTO, yielding an equilibrium mixture of two peroxorhenium compounds, denoted **A** and **B**, both η^2-peroxo complexes of rhenium(VII). The existence of the η^2–peroxo groups comes as no surprise. This is the prevalent mode of coordination between peroxide and many d^0-metal centers.[8] The structural formulas of **A** and **B** are shown in Scheme 1.



Scheme 1

The structure of the diperoxo complex **B** has been determined crystallographically. Rhenium adopts the structure of a pentagonal bipyramid, with axial oxo (167 pm) and aqua (225 pm) groups. In the equatorial positions are the methyl group (213 pm) and the four peroxo oxygens (191 pm).[9] The water molecule is also coordinated to **B** in solution; its ^1H signal can be seen below −55 °C in d_8-THF.[9,10] No such signal was found for **A**, however, implying the absence of a coordinated water molecule or its exceptional lability.[10]

Both **A** and **B** have been detected by their methyl resonances in the ^1H and ^{13}C NMR spectra, and by their optical signals. Of these, the easier to locate is **B**, since it more readily builds to appreciable concentrations. The binding of peroxide to rhenium is cooperative, as will be explained two paragraphs hence. As a consequence, except for particular concentrations of hydrogen peroxide, **A** does not rise to levels comparable to those of MTO and **B** at equilibrium, although the NMR and optical signals of **A** can easily be seen if the peroxide concentration is not so high as to favor **B** exclusively. Because the reactions between MTO and hydrogen peroxide are equilibrium processes, it is not permitted to evaluate properties of **B**, such as its absorption spectrum, by dissolving the isolated solid. Certain erroneous values, such as absorption coefficients, have been reported as a result. Partial dissociation of **B** will occur, depending on the concentration of total rhenium and peroxide. Instead, one must obtain the spectrum of **B** by determinations in solutions containing some excess of peroxide, or by extrapolation from the least-squares fitting of the mathematical expression relating absorbance and the individual molar absorptivities:

$$\bar{\varepsilon} = \frac{\text{Absorbance}}{b[\text{Re}]_T} = \frac{\varepsilon_{\text{MTO}} + \varepsilon_{\mathbf{A}}K_1[H_2O_2] + \varepsilon_{\mathbf{B}}K_1K_2[H_2O_2]^2}{1 + K_1[H_2O_2] + K_1K_2[H_2O_2]^2}$$

That is not to say that the equilibria in Scheme 1 are instantaneously established. In fact, the four rate constants defined therein have been evaluated under different conditions of solvent and temperature. One such experiment showing time-resolved spectral changes accompanying this reaction is shown on the cover.[11]

These steps play an important role in governing the rate of catalytic turnovers. Table 1 summarizes the values of the equilibrium and rate constants for the two reaction steps in aqueous solution[12] and in acetonitrile, and Table 2 presents the molar absorptivities and chemical shifts of compounds **A** and **B**.[13]

Table 1 Equilibrium and rate constants at 298 K for the formation of the peroxorhenium compounds **A** and **B** in aqueous solution and in acetonitrile containing 2.6% water

	K	k_f/L mol^{-1} s^{-1}	k_r/s^{-1}
Step 1:	16.1 (aq.)	80 (aq.)	10 (aq.)
	209 (AN)	0.81 (AN)	3.9×10^{-3} (AN)
	261 (MeOH)		
Step 2:	132 (aq.)	5.2 (aq.)	4×10^{-2} (aq.)
	660 (AN)	4.5×10^{-2} (AN)	6.8×10^{-5} (AN)
	814 (MeOH)		

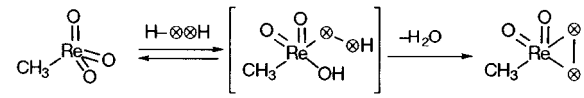
Table 2 Values of molar absorptivities and chemical shifts for MTO, **A**, and **B**

			NMR: δ	
	Compound	λ_{max} (log ε)	^1H	^{13}C
	MTO	206 (3.78)	2.1[d]	19.09[e]
		228 (3.56)[a,b]		
	A	320 (2.85)[c]	2.4[d]	
	B	360 (3.08)[c]	2.7[d]	31[f]

[a] In aqueous solution. [b] Ref 55. [c] In CH_3CN. [d] In THF; Ref 13. [e] In $CDCl_3$ at 28 °C; Ref 56. [f] In D_2O at 20 °C; Ref 9.

The unusual features of the data in Table 1 are these: (1) the second peroxide has a larger binding constant than the first, that is to say, they show cooperativity; (2) the step with the greater driving force is the slower. Both of these trends also hold in other solvents. Cooperativity is perhaps the consequence of an increasing Re–O bond order as the number of oxo groups decreases; **B** is favored as a consequence. The slowness of the second binding step compared to the first may reflect both the increased crowding of the coordination positions and the decreased electrophilic character of rhenium once the first peroxide has been added. In organic solvents the binding constants are generally larger than in water, and the rate constants smaller; indeed, the step represented by k_2 often poses a significant kinetic barrier to product formation by the path in which **B** is the intermediate.

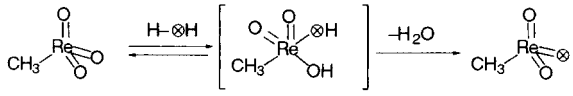
Activation parameters have been reported for the first step. The values in aqueous solution for k_1 are: $\Delta H_1^{\ddagger}$ = 24.5 kJ mol^{-1}, $\Delta S_1^{\ddagger}$ = −212 J K^{-1} mol^{-1}, $\Delta V_1^{\ddagger}$ = −10.6 cm^3 mol^{-1}.[14] These values have been interpreted according to Scheme 2.



Scheme 2

Exchange of oxygen atoms between water and hydrogen peroxide is forbiddingly slow.[15] The same is true for peroxo-rhenium complexes: the oxo and peroxo oxygens remain distinct. Oxygen atoms are, however, rapidly exchanged between MTO and water. At first this seems anomalous, in that the Re=O bonds are short and robust. However a process analogous to that just shown for peroxide easily provides a pathway for facile exchange (Scheme 3).

These reactions are the prelude to the activation of H_2O_2 by MTO. In all of this, there is no indication that organic hydroperoxides associate with MTO or are activated by it.



Scheme 3

Evidently the formation of the η^1-O_2^{2-} structure is crucial. Over very long times, MTO does decompose in the presence of alkyl hydroperoxides, such as Bu^{t}OOH and Am^{t}OOH. These reactions occur by radical pathways involving RO$^\bullet$ and ROO$^\bullet$ intermediates, among others.[16] They stand alone as examples of single-electron reactivity of MTO.

Catalyst deactivation

The decomposition of MTO is strongly accelerated by increases in the concentration of hydroxide ions. Even in strongly acidic media, pH < 3, the rate law shows a pH-dependence that implicates a first-order kinetic dependence on [OH$^-$].[17] The full

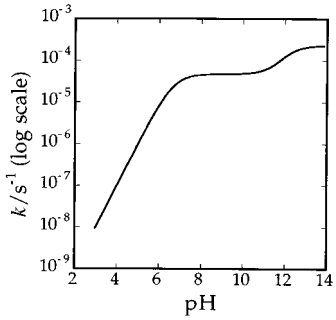


Fig. 1 The pH–rate profile for the decomposition of MTO with numerical values referring to 298 K. The reaction is strongly base-catalyzed, with two plateaus corresponding to the stepwise acid ionization of MTO_{aq}.

rate–pH profile, shown in Fig. 1, is consistent with this net reaction showing the evolution of methane:

$$CH_3ReO_3 + H_2O = CH_4 + ReO_4^- + H^+$$

The two plateaus seen in the pH profile correspond to the successive acid ionization reactions of MTO_{aq}, corresponding to $CH_3ReO_3(OH)^-$ and $CH_3ReO_3(OH)_2^{2-}$. The respective equilibrium constants, expressed as pK_a values, lie in the ranges 6.7–7.5 and 11.7–11.9 at 298 K.[10,17,18] The rate equation for the reaction at pH $< \approx 6$ is $v = k$[MTO][OH$^-$], with $k = 8.6 \times 10^2$ L mol^{-1} s^{-1} at 298 K ($\Delta H^\ddagger = 15.9$ kJ mol^{-1}).[17]

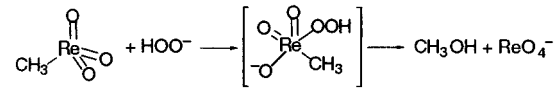
These reactions are slow enough that they tend not to cause difficulty in catalysis, although their instability toward base generally precludes the use of an alkaline medium. As will be shown, the decomposition of MTO in the presence of hydrogen peroxide occurs more rapidly and usually comprises the greater problem. Irreversible decomposition of MTO in peroxide-containing solutions forms methanol primarily, according to these net reactions:[10]

$$CH_3ReO_3 + H_2O_2 = CH_3OH + ReO_4^- + H^+$$

The rate law can be written

$$\frac{d[ReO_4^-]}{dt} = k\frac{[CH_3ReO_3][H_2O_2]}{[H^+]}$$

from which one infers that the reaction can be represented by any of these bimolecular partners: **A** + OH$^-$ ($k_{298} = 3.1 \times 10^9$ L mol^{-1} s^{-1}), $CH_3ReO_3 + HO_2^-$ ($k_{298} = 2.0 \times 10^8$ L mol^{-1} s^{-1}), or, improbably, $CH_3ReO_3(OH)^- + H_2O_2$. The first two are in principle resolvable by isotopic labeling, but oxygen exchange between H_2O and ReO_4^- occurs too rapidly to permit a definitive experiment. [19] Because HO_2^- is a more potent nucleophile than OH$^-$, it seems likely that their reactions with MTO are analogous. We therefore describe the reaction as shown below.



Concurrently, oxygen is evolved as a consequence of the MTO-catalyzed decomposition of hydrogen peroxide ($2H_2O_2 \rightarrow 2H_2O + O_2$), which we infer takes place from **B**:[10,13]

$$CH_3Re(O)(\eta^2\text{-}O_2)_2 \rightarrow CH_3ReO_3 + O_2$$

Photochemical deactivation

Irradiation of **B** by light filtered so as to allow only $\lambda > 400$ nm, to prevent direct photolysis of hydrogen peroxide itself, leads to the slow fading of its yellow color. In acetonitrile this process gives a quantitative yield of perrhenic acid and principally methyl hydroperoxide.[13] The main photoreaction is:

$$CH_3Re(O)(\eta^2 - O_2)_2 + H_2O \xrightarrow{h\nu} ReO_4^- + CH_3OOH + H^+$$

A small concentration of methanol was formed as well; the higher the concentration of hydrogen peroxide, the lower the yield of methanol. In methylene chloride and THF at higher energies, with monochromatic light between 365 and 248 nm, $^3O_2$ was formed.[20] The conclusion was reached that the coupling of initially formed oxygen atoms, ^3O, was responsible.

Peroxide activation by MTO: reaction kinetics

Hydrogen peroxide will oxidize certain electron-rich substrates, but the reactions are generally rather slow without the MTO catalyst. In a few cases both the uncatalyzed and the MTO-catalyzed rate constants have been determined. The catalytic enhancements for MTO often amount to a factor of 10^5–10^6. Many other substrates, ones that seem not to react with hydrogen peroxide, do so quite successfully once MTO has been added. In this section certain aspects of the chemical kinetics will be presented, and the subject of the chemical mechanisms will be taken up in the next section.

The reaction scheme is simply described: **A** and **B** separately react with substrate **X**, converting it to the product **XO**. In so doing, **A** is converted to MTO and **B** to **A**. The respective rate constants are designated k_3 for **A** and k_4 for **B**. These steps couple with those in Scheme 1, which enter as kinetic or sometimes equilibrium reactions depending on the various values pertaining to a given substrate and solvent, and to the concentrations employed. The analysis of the kinetic data has many features in common with that for enzyme-catalyzed reactions and the Michaelis–Menten formalism. This approximation has been termed the 'improved steady-state' method.[21] To illustrate the difference between it and the ordinary steady-state treatment, we show a simple case, the conversion of starting material S to product P *via* intermediate I. The expressions for the reaction rates are:

Reaction Scheme

$$S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} I \xrightarrow{k_2} P$$

Steady-state

$$v = \frac{d[P]}{dt} = \frac{k_1k_2[S]}{k_{-1} + k_2}$$

Improved steady-state

$$v = \frac{d[P]}{dt} = \frac{k_1k_2[S]}{k_{-1} + k_2 + k_1[S]}$$

The improved steady-state mathematics affords the advantage that the intermediate need not be maintained at a small fraction of the concentration of S, as it must in the ss formalism. That E·S may attain a concentration comparable to E is a vital

feature of the Michaelis–Menten equation in that it provides a model to account for the experimentally observed phenomenon that the reaction rates rise initially with [S] and then tend toward a plateau. This effect, known as saturation kinetics, is not found in the ss analysis.[22]

For MTO it is also not valid to adopt the ss model in that it would require that [**A**] and [**B**] always << [MTO]. The improved ss treatment gives this result:

$$-\frac{d[X]}{dt} = \frac{k_1k_3[Re]_T[H_2O_2][X] + \frac{k_1k_2k_4[Re]_T[X][H_2O_2]^2}{k_4[X]+k_{-2}}}{k_{-1}+k_3[X]+k_1[H_2O_2]+\frac{k_1k_2[H_2O_2]^2}{k_4[X]+k_{-2}}}$$

This equation appears to be more formidable than it really is. With the rate constants k_1, k_{-1}, k_2, and k_{-2} known from studies of the MTO–H_2O_2 reactions in the absence of substrate, only k_3 and k_4 remain as unknowns.

Under certain conditions this form simplifies. The parameters involved may be ones the experimenter can control to some extent, such as concentrations, but the parameter list also includes rate constants that will, of course, differ relatively among substrates, often by a large amount. Thus the conditions needed for simplification need to be scrutinized individually for different substrates and concentration ranges. Two of the useful simplifications are these:

(a) at the relatively low concentrations of hydrogen peroxide, such that **B** is not significant,

$$-\frac{d[X]}{dt} = \frac{k_1k_3[Re]_T[H_2O_2][X]}{k_{-1}+k_3[X]+k_1[H_2O_2]}$$

This form has been useful at times mostly because **A** and **B** usually (but not always) are quite comparable in their reactivity (*i.e.*, k_3 and k_4 are of the same magnitude, as illustrated later).

(b) at quite high peroxide concentrations, where **B** is the only significant form,

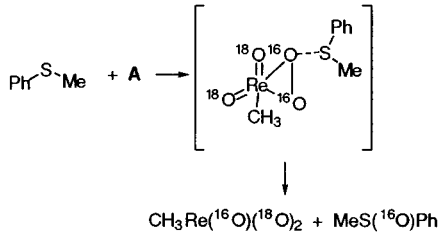
$$-\frac{d[X]}{dt} = k_4[X][Re]_T$$

This approach has proved useful when the parameters permit its application. One test, but not the only one, is that the reaction rates are peroxide-independent when this form applies.

This is an outline of the kinetics analysis. The reader is referred to the referenced publications for further detail.[23] In the balance of this review, rate constants will be given without further explanation as to their origin.

Peroxide activation by MTO: isotopic tracer

Isotopic labeling was carried out to define the source of the oxygen atom transferred to the substrate. It consisted of the use of MTO and water labeled with oxygen-18 (recall that this pair rapidly exchanges) and hydrogen peroxide labeled with oxygen-16. GC–MS determinations showed that only PhS(^{16}O)Me was formed, implying that the catalytic reaction transfers a peroxo oxygen to the substrate. As **A** (shown here) or **B** reacts, we have Scheme 4.



Scheme 4

As the cycle repeats, $CH_3Re(^{16}O)(^{18}O)_2$ continues to revert to $CH_3Re(^{18}O)_3$ by exchange with water. The repeated recycling with $H_2{}^{16,16}O_2$ generates **A** and **B** with $^{16,16}O_2{}^{2-}$ groups that then transfer oxygen-16. The necessary control experiments were carried out to verify that this was a valid experiment.[23]

Peroxide activation by MTO: reactivity of different substrates

In order to present and discuss the structure–reactivity relationships, it is desirable first to examine the relative magnitudes of k_3 and k_4. Values of these rate constants for selected substrates are presented in Table 3. These are by no means all of the data,

Table 3 Comparisons of the rate constants k_3 for **A** and k_4 for **B** in their reactions with different substrates

Substrate	k_3/L mol^{-1} s^{-1} [a]	k_4/k_3 [a]	Ref.
PhSMe	2.65×10^3	0.36	23
Ph_2S	1.18×10^2	0.27	23
PPh_3	7.3×10^5	3.0	57
$P(C_6F_5)_3$	1.30×10^3	2.7	57
trans-PhCH=CHOMe	14.2	0.90	24
trans-PhCH=CHMe	0.51	0.43	24
Cl^-	5.6×10^{-2}	2.3	12
Br^-	3.5×10^2	0.49	42
	0.19	0.58	58
	10.2	2.1	59
	$k_3 \approx 0$ $k_4 = 7.6 \times 10^{-3}$	>>1	28

[a] The solvent is 1:1 acetonitrile–water at pH 1 except for the halide ions in aqueous solution at pH 0 and the allylic alcohol where 4:1 acetonitrile–water was used.

but they are representative of the substrates. Save for the special case of the allylic alcohol to which we return in a later section, the numerical values presented make the case quite emphatically: k_3 and k_4 are of the same magnitude. Sometimes the one is a little larger, sometimes the other. A factor of three in either direction encompasses all of the variations. The similarity of the values for a given substrate is particularly striking in that the rate constants themselves span a factor of 10^8. The proof we have advanced for the comparable reactivity has been verified repeatedly; it rests on the quantitative interpretation of the kinetic effects of the concentrations of hydrogen peroxide and substrate. This demonstration has included epoxidation reactions.[24] This method has been commented on and accepted by others.[25] Despite this, certain statements and diagrams persist in identifying **A** as inactive and **B** as the only active form of the catalyst; see, for example, Fig. 1 in a 1996 reference.[20]

The inductive effect of substituents within a family of related substrates allows one to probe the electron demand in the transition state. Several such results are summarized in Table 4. In every case, the rate increases with electron-donating substituents on an aryl group and *vice versa*. These effects are regular, but mild. The four reactions in the series have Hammett reaction constants in the range −0.63 to −1.19. Each of them displays the trend that electron-donating substituents increase the rate of reaction with **A**, and *vice versa*. In keeping with that, it is instructive to examine the kinetic effects of substituting methyl groups on the double bond of aliphatic alkenes. Table 5 presents a subset of the data, which clearly show that the more alkyl groups on the double bond, the greater the reaction rate. Because of the substituent effects, and supported by the isotopic labeling, we propose a transition state for this reaction in which the nucleophilic reagent **X** (including electron-rich alkenes) attacks a peroxo-oxygen of the rhenium catalyst.

Table 4 Effect of substituents on the aryl group of different substrates on the relative rate constants (k_3/k_{3H}) for the reactions with **A**

Substituent:	4-MeO	4-Me	3-Me	H	4-F	4-Cl	4-Br	4-CF_3	4-NH_3^+	4-NO_2

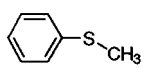
[a] Relative to k_{3H} = 18.4 L mol^{-1} s^{-1} at 25.0 °C in methanol; ρ = −1.19.[60] [b] Relative to k_{3H} = 2.65 × 10^3 L mol^{-1} s^{-1} in 1 : 1 acetonitrile–water at pH 1 and 25.0 °C; ρ = −0.98.[23] [c] Relative to k_{3H} = 7.3 × 10^5 L mol^{-1} s^{-1} in 1 : 1 acetonitrile–water at pH 1 and 25.0 °C; ρ = −0.63.[57] [d] Relative to k_{3H} = 1.1 × 10^{-1} L mol^{-1} s^{-1} in 1 : 1 acetonitrile–water at pH 1 and 25.0 °C; ρ = −0.93.[24]

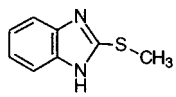
Table 5 Kinetic effects on k_4/L mol^{-1} s^{-1} at 298 K in two solvents for epoxidation reactions arising from the substitution of alkyl groups on the double bond.[61]

Structural formula	No. Alkyl groups	MeOD	CH_3CN-H_2O
	1	0.013	0.098
	2	0.048	0.25
	3	0.26	3.92
	4	1.33	8.93

In keeping with those results, it is instructive to examine the k_3 values themselves for different types of nucleophilic reagents **X**. The most reactive group are the phosphines, the least the alkenes. A display of these values is presented in Fig. 2. The rate constants span eight orders of magnitude, roughly 10^6–10^{-2} L mol^{-1} s^{-1}. An inspection of the entries in this figure confirm that this is a general trend.

A further manifestation of these effects is seen in a different variation of the substituent effects. Substitution of electronegative substituents into the molecule greatly reduces its reactivity. For example, compare these rate constants:[23]





When successive oxidation steps are found, as with this conversion: $R_2S \rightarrow R_2SO \rightarrow R_2SO_2$ for which the successive rate constants are in an approximate 35 : 1 ratio.[26] Likewise, once a 1,3-diene has been converted to the epoxide (preferentially, at the more alkylated double bond) there is little tendency to form the di-epoxide.

From these various approaches, it is possible to argue that the role of MTO is to polarize the normally nucleophilic peroxide anion to the extent that it can itself be attacked by nucleophiles. Other high-valent metal complexes from such elements as Mo(VI), W(VI), Os(VIII), Cr(VI), and V(V), often oxo species themselves and possessed of a d^0 electron configuration, can activate peroxide by a similar mechanism.[27]

This brings us to the rather special case of allylic alcohols, represented by the last entry to Table 3. A comparison of these rate constants at first suggests the same effect, save that the electronegative hydroxy group gives rise to a remarkably small kinetic deceleration by comparison with other examples. But the allylic alcohols constitute the seemingly unique instance

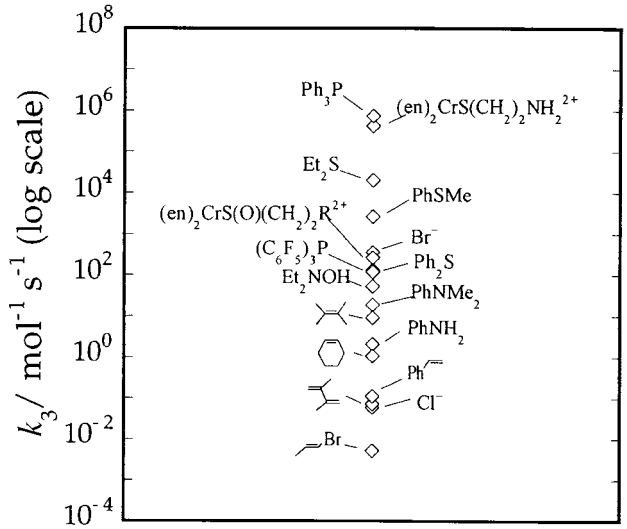


Fig. 2 A display of selected compounds showing the value of each rate constant k_3 at 298 K. Note that the reactivity spans a factor of ≈10^8; note that the axis has a logarithmic scale.

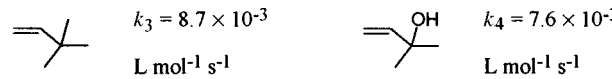
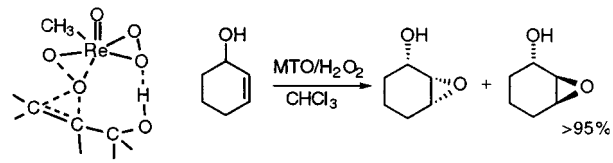
(see Table 3) in which k_3 is negligible compared with k_4, implying a special mechanism open only to catalyst **B**.[28]



We suggest that these findings manifest the overriding importance of hydrogen bonding in this transition state, a point of view reinforced by data on stereoselectivity in the same system.[28b] We have concluded that the transition state features hydrogen bonding to a *different* peroxo group than that transferring the oxygen atom. This transition state is depicted below, along with one reaction showing that diasteroselectivity can consequently be realized with allyl alcohols.



Peroxide activation by MTO: comparisons to dimethyldioxirane 

Aside from the obvious structural analogy between **A**, **B**, and DMDO, the similarities in reactivity are notable. To cite just a

few points, DMDO reacts *stoichiometrically* with many of the same substrates that **A** and **B** do, such as *N,N*-dimethylanilines,[29] alkenes,[30,31] and thioethers.[32] Beyond that, the correlation between the rate constant k_4 for **B** and that for DMDO is striking. Fig. 3 presents on a log–log scale the one set of values against another. The slopes of these lines are 0.84 for aliphatic alkenes and 1.18 for styrenes. Were it not for this, no reason would arise to question the previously given explanation that catalysis by MTO arises from the ability of Re(VII) to polarize the coordinated peroxide anion. But surely the saturated carbon center of DMDO is incapable of activating its peroxide group in the same fashion. The remarkable correlations between the MTO and DMDO reactions require that attributes common to both reagents be sought. Features such as bond and angle strain are, qualitatively, common to both groups of peroxides. The final accounting for the electronic structures remains to be made, and speculation at this point is unnecessary.

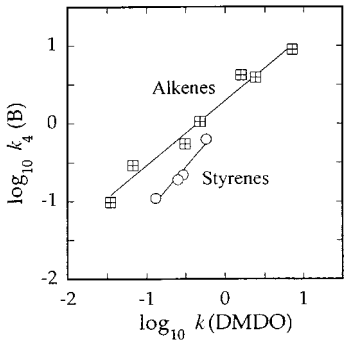


Fig. 3 The rate constants for the epoxidation of styrenes and of aliphatic alkenes by two reagents, dimethyldioxirane and the diperoxorhenium complex **B**, are shown as a linear free-energy correlation. The slopes of the lines are 1.18 (R = 0.982) and 0.84 (R = 0.987).

Peroxide activation by MTO: stabilization of epoxides

Some of the reactions that can follow epoxide formation are deleterious, the most notorious of which is loss of epoxides to acid-catalyzed ring-opening. Generally, but not universally, this is considered an undesirable event. The addition of acid to the solutions, in an effort to stabilize the catalyst, is not allowed. The acidity of the water molecule coordinated to **B**, which has been given as pK_A = 3.8,[9] provides a built-in method for loss of the epoxide. If one attempts to circumvent this effect by the use of a Brønsted base or a buffer, then the inherent base-sensitivity of **B** (especially) immediately prevails, and the catalytic reaction ceases.[10,17,18] A Lewis base such as pyridine serves to stabilize the catalyst against decomposition at the same time eliminating the acidity of the medium and thus preserving the epoxide.[33,34] Representative values of the equilibrium constants (L mol^{-1}) at 298 K for binding Lewis bases to MTO are as shown here for nitrogen bases in acetonitrile[6] and for the phosphorus derivatives in benzene.[35]

(*p*-Tol)$_3$P	2.0
3-NCC$_5$H$_4$N	7.2
(*p*-Tol)$_3$PO	5.3×10^1
C$_5$H$_5$N	2.0×10^2
C$_5$H$_5$NO	2.1×10^2
4-MeC$_5$H$_4$N	7.3×10^2

Coordination of a Lewis base to MTO evidently prevents its being attacked by HOO$^-$, which is the most serious pathway for its loss. [10] The coordination is not so tight, however, as to preclude the necessary formation of the peroxorhenium compounds. A further helpful effect of the Lewis base, if it is also a Brønsted base, is to accelerate the conversion of MTO to **A** and to **B**, which greatly reduces the time the system needs to maintain its integrity. If the epoxide-stabilizing reagent is, for example, a pyridine, then it will be oxidized concomitantly. For example, for α-methyl styrene in acetonitrile at 296 K, the competing reaction rates are: [6]

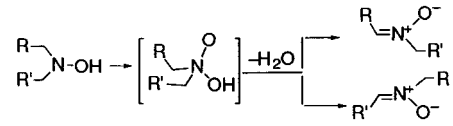
$v_i^{Py-NO} = k[MTO]_0[Py]_0 \quad k = 0.42 \pm 0.01$ L mol^{-1} s^{-1}
$v_i^{Epox} = k[MTO]_0[\alpha\text{-MeSty}]_0 \quad k = 0.22 \pm 0.04$ L mol^{-1} s^{-1}

The development of methods to prevent catalyst deactivation continues to be an active area, owing to the importance of transforming alkenes to epoxides, and the last work still remains incomplete.

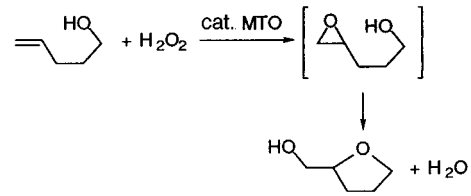
Peroxide activation by MTO: reactions with steps subsequent to O-atom addition

Certain other reactions that follow oxygen-atom transfer from **A** or **B** to the substrate are an inherent part of the process. Here are some examples:

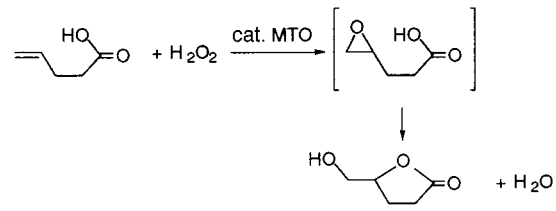
Secondary hydroxylamines yield an intermediate that is converted to the final nitrone product in a rapid elimination reaction following the first step:



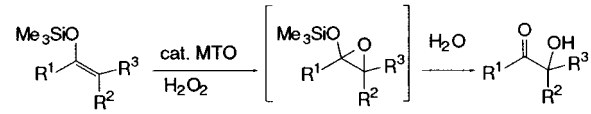
4-Hydroxyalkenes, following epoxide formation undergo cyclization to form substituted tetrahydrofurans;[36] with related molecules the cyclization rates are seen to fall in the expected order favoring these ring sizes 5 > > 6 > 3 > 7 > 8:[37]



δ,γ-Unsaturated hydroxycarboxlyic acids, again following epoxidation, yield hydroxy lactones:[38]

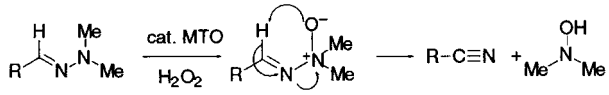


Silyl enol ethers provide a convenient an efficient route to α-hydroxy ketones by way of an epoxide; the product yields are generally ≥95%:[39]



Particularly useful is the MTO-catalyzed oxidation of *N,N*-dimethylhydrazones derived from aldehydes which produces nitriles in > 90% yield.[40] This reaction begins in the usual manner, with the transfer of an oxygen atom from **A** or **B** to the more basic (amine) nitrogen. Following that, a Cope-type elimination reaction[41] yields the nitrile and dimethylhydrox-

ylamine. The latter is independently oxidized to the nitrone, $CH_3N(=CH_2)O$, as described previously.

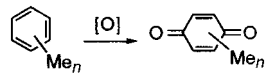


During the course of these studies we have developed a particular solvent formulation that preserves the catalyst quite well. It consists of a mixture of acetonitrile, acetic acid, and pyridine (94.5 : 5 : 0.5). The role of pyridine is to accelerate the cycling of MTO and its peroxides, as in Scheme 1, with acetic acid preventing the mixture from becoming so basic that the catalyst is irreversibly deactivated.

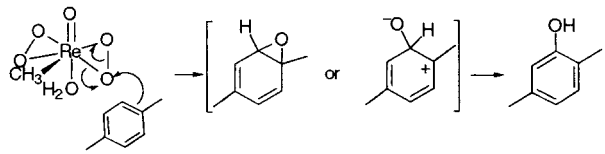
Peroxide activation by MTO: reactions involving the breaking of C–H bonds

In every one of the reactions presented to this point, an oxygen atom was transferred from a peroxorhenium complex to an electron-rich atom or center. In contrast, arenes and secondary alcohols are oxidized by a different mechanism.

MTO–hydrogen peroxide converts methyl arenes to quinones, yielding preferentially the *para* isomer:



These tend to be sluggish reactions. A higher level of MTO is employed, typically 10% of the arene, and a temperature of 57 °C in glacial acetic. The yields are high, but the conversions not, since the catalyst is gradually deactivated. *o*-, *m*-, and *p*-Dimethylbenenes gave the quinones in 12–15% conversion after 3.5 h; 1,2,4-trimethylbenzene gave 75% conversion in 4 h, along with 33% of the hydroquinone. The data are scant, but a plausible mechanism for the first and most difficult step, phenol formation, is as given in Scheme 5.

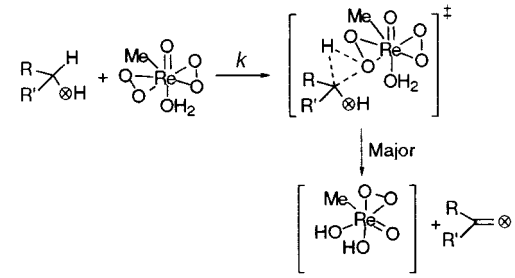


Scheme 5

The oxidation of secondary alcohols by hydrogen peroxide is also catalyzed by MTO; again the reaction faces a substantial kinetic barrier. Representative rate constants at 298 K for the reaction between **B** and the alcohols are 1.02×10^{-4} L mol^{-1} s^{-1} for 4-methyl-α-methylbenzyl alcohol and 4.9×10^{-5} L mol^{-1} s^{-1} for 4-chloro-α-methylbenzyl alcohol. There was a kinetic isotope effect of 3.2 for the α C–H bond of 1-phenylethanol (1,2,2,2-D_4). When the same alcohol was labeled with ^{18}O, 80% of the oxygen was retained in the ketone. Tests for the possible intervention of a free radical intermediate were carried out; the evidence was entirely negative. A mechanism featuring hydride abstraction is proposed, the first time for the H_2O_2/MTO system (Scheme 6)

Peroxide activation by MTO: bromide ions as co-catalyst

The ability of the MTO/H_2O_2 system to oxidize Br^- to BrO^- (ref. 42) (see Table 3) affords a means of developing a different oxidizing species in solution, one capable of adopting a different mechanism. Actually, the useful species is Br_2, not BrO^-/HOBr, since the reaction between HOBr and Br^- is



Scheme 6

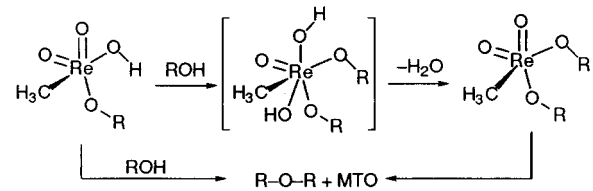
exceptionally rapid.[43] This approach offers two advantages: it opens a new mechanism in place of oxygen-atom transfer and accomplishes what amounts to a bromine reaction without using any substantial concentration of that element, obviating waste disposal costs for bromide solutions.

Sec-phenylethanol, for example, is oxidized by MTO/H_2O_2 42-times more rapidly when a catalytic concentration of bromide is present (1.1 mM HBr and 200 mM alcohol) as compared to the same reaction in its absence. The reason is that Br_2 carries out hydride abstraction, which **A** and **B** do not.[44] The sequence is the following:

MTO-catalyzed reactions not involving hydrogen peroxide

Rearrangement reactions of a single substrate

Alcohols to ethers. MTO is the first transition metal complex in trace quantity to catalyze the direct formation of ethers from alcohols. These reactions occur in various aprotic solvents (benzene, toluene, dichloromethane, acetone, *etc.*) and in the alcohols themselves. Aromatic alcohols react best; for example benzyl alcohol is converted in 30% yield to the ether; the conversion is 36%, the balance being comprised of 3% PhCHO and 3% $PhCH_3$. This required 2 d at room temperature; after that time none of the catalyst remained. The intermediates characterized and inferred for the reaction of MTO with hydrogen peroxide and for its exchange with water indicate the following mechanism (Scheme 7) from which the ether can be formed by reductive elimination.[45]

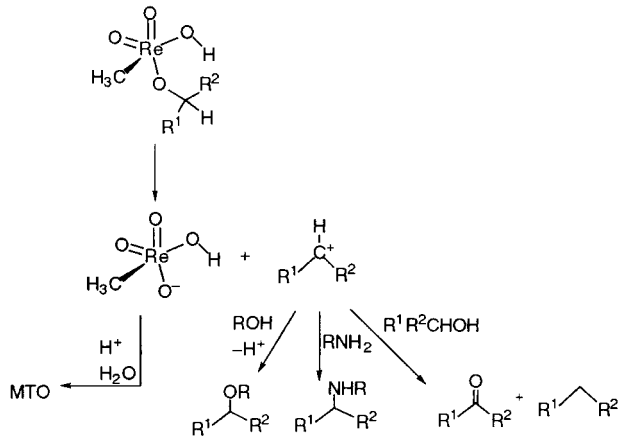


Scheme 7

We noted that (a) no reaction occurred with alcohols containing an electron-withdrawing group at the *para* position such as NO_2, Br, and Cl, (b) an olefin was formed from 2,2-dimethyl-1-phenylpropan-1-ol, and (c) alcohols underwent disproportionation catalyzed by MTO. It seems that these reactions occur through a carbocation intermediate (Scheme 8).

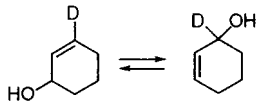
This scheme further reports that MTO catalyzes the reactions between amines, aryl and alkyl, and alcohols, leading to amine products.[45]

1,3-Transposition of allylic alcohols.[46] MTO catalyzes the approach to equilibrium in reactions such as those shown in Table 6. Yields of the isomerized alcohol are often less than

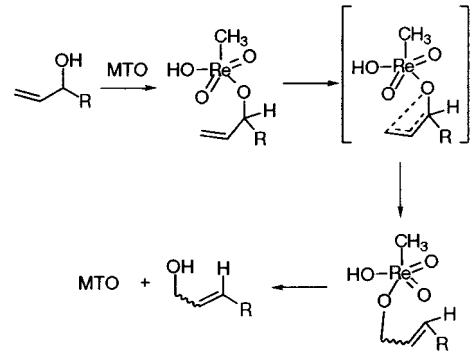


Scheme 8

100%, due to the reverse reaction. This equilibrium was confirmed by the use of deuterium labeling; the isotopomers of 2-cyclohexen-1-ol are interconverted by this degenerate reaction:

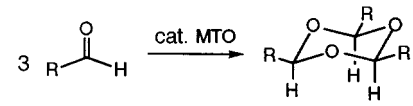


The equilibrium constant was found to be 1.20 ± 0.02 in benzene at ~23 °C, demonstrating an appreciable equilibrium isotope effect. The reaction is sharply inhibited by traces of water. The use of $CH_3Re(^{18}O)_3$ resulted in no incorporation of oxygen-18 into the alcohol product. Because of that we must discard a mechanism related to that presented for ether formation. A mechanism to account for the various lines of evidence, including the inhibition of water that competes with the allyl alcohol and leads to the dead-end species $CH_3Re(O)_2(OH)_2$, is depicted in Scheme 9.



Scheme 9

MTO-catalyzed cyclotrimerization of aldehydes. This reaction yields 1,3,5-trioxanes:



This reaction was carried out successfully for nineteen anhydrous aldehydes.[47] The stereochemistry was established by NMR and by X-ray crystallography in one instance; oxygen-18 labeling of MTO showed that just one of the three oxygen atoms in the product derived from MTO. Yields are generally high, >90%. Although many trioxanes can be isolated at room temperature, several of the reactions need to be carried out at −30 °C, lest the products revert to the parent aldehyde. Indeed, all of the trimeric products revert to the aldehyde thermally. The mechanism has not been established, but the structures shown for several of the reactions are suggestive of a sequence in which an adduct with four-membered ring, derived from the interaction of MTO and one aldehyde, is further homologated (Scheme 10).

Table 6 Equilibrium reactions for the 1,3-transposition of allylic alcohols.[62]

Substrate	Product	Time	% Product at equilibrium
		5 d	63
		10 h	98

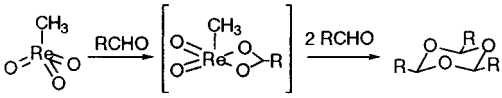
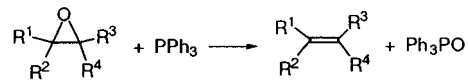


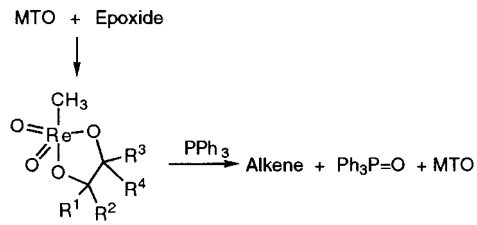
Scheme 10

Atom transfer reactions not involving hydrogen peroxide

The reactions referred to in this section are of the general form YO + X → Y + XO. One example is the reaction between epoxides and triphenylphosphine. Without MTO no reaction occurs despite its spontaneity ($\Delta G° \approx -230$ kJ mol^{-1}). The catalyst causes this general transformation:[48]



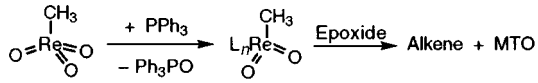
The reaction gives high yields (≥79%) in benzene at room temperature, seems to be quite general, and proceeds with preservation of the relative stereochemistry about the C–C bond of the epoxide. Two distinctly different, plausible mechanisms can be suggested from other results. In the first, the epoxide and MTO form a dialkoxyl (glycolato) rhenium complex. This reaction has been well established independently.[49] Following that the phosphine abstracts an oxygen, leading to the products and the regeneration of the catalyst (Scheme 11).



Scheme 11

A certain level of support for this scheme is afforded by the determination that the independently-prepared dialkoxylrhenium complex reacts with triphenylphosphine in the required manner.

The second plausible explanation starts with the reaction between triphenylphosphine and MTO. Methyldioxorhenium(V) is formed; the Re(V) is coordinated by phosphine (L) to an extent dependent on their concentrations; a compound in which Re(VII) is present in the molecular unit has been characterized: $CH_3Re(O)_2L_2 \cdot MTO$.[50] This species is known to abstract an oxygen atom from substrates that have a bond to oxygen weaker than that present in MTO, 465 kJ for MTO(aq) = CH_3ReO_2(aq) + O(aq).[51] Based on these ideas, this alternative reaction scheme can be proposed, in which L represents phosphines or other ligands coordinated to Re(V) (Scheme 12).



Scheme 12

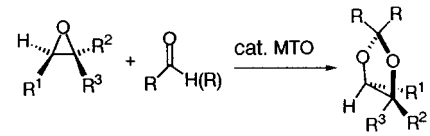
It would be premature at this stage to decide between the two. Several related transformations have also been found. Thus MTO is an effective catalyst, when accompanied by triphenylphosphine, for converting tertiary amine oxides [*e.g.*, Ar-N(O)Me_2 and C_5H_5NO] to amines, triphenylphosphine oxide being formed concomitantly. These reactions were studied in benzene, but there is no reason to believe other solvents would not serve as well.[48]

Sulfoxides are converted into sulfides in high yield (65–77%) by the same procedure. Reactions have been carried out in benzene at room temperature for aryl and alkyl sulfoxides.[48] On the other hand, attempts to excise an oxygen atom from a sulfone have failed. Among other factors, one notes that sulfoxides have an S–O bond enthalpy of ≈330 kJ mol^{-1}, whereas for sulfones this is ≈440 kJ mol^{-1}.

The bond enthalpies along the series Ar_3EO (E = P, As, Sb) are such that oxygen is preferentially bound to phosphorus. Uncatalyzed oxygen exchange is not significant. With MTO catalytic reactions occur, converting ArAs(Sb)O and Ar_3P to ArAs(Sb) and Ar_3PO. The involvement of the Re(V) complex, CH_3ReO_2 or its ligated derivatives, seems likely.

Coupling reactions using the MTO catalytic template

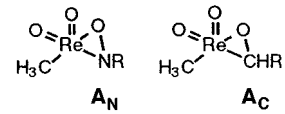
Ketones and aldehydes do not react with epoxides in the absence of MTO. With the MTO catalyst, 1,3-dioxolanes are formed, often but not invariably in high yields from reactions carried out for two days in chloroform.[52] The net equation is shown below.



The reaction proceeds in two steps: in the first, as described in the preceding section, a dialkoxylrhenium complex is formed, and then attacked by the carbonyl compound. Each step proceeds with inversion of configuration, the resultant being that the dioxolane retains the structure of the parent epoxide.

Carbene and nitrene transfer reactions

As one examines the structures of **A** and **B**, it is natural to inquire whether one (both?) of the oxygen atoms of the coordinated peroxide might be replaced with isoelectronic nitrene (NR) or carbene (CR_2) equivalents. Taking **A** for



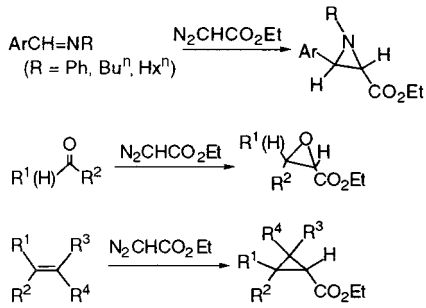
example, might the intermediates $\mathbf{A_N}$ or $\mathbf{A_C}$ be made? And, if successful, would these species transfer a group (presumably the less electronegative nitrene or carbene fragment) to a suitable substrate? Attempts to prepare $\mathbf{A_N}$ by the reactions of MTO with hydroxylamines, this being the example from isoelectronic substitutions in Scheme 1, have met with no success. Not only that, but such mixtures showed no evidence of catalytic activity toward substrates that react with MTO/H_2O_2.

We consequently turned to organic azides and diazoalkanes as sources of the putative NR and CR_2 groups for incorporation into an active form of MTO. A certain level of success has been realized, as represented by the subsequent MTO-catalyzed conversions, when ethyl diazoacetate was used. Aryl imines were transformed to aziridines, carbonyl compounds to epoxides, and alkenes to epoxides (Scheme 13)[53,54]

The model in terms of an $\mathbf{A_C}$-like carbene donor holds some appeal, but attempts to identify such species have not been successful. It may be that MTO releases a free carbene to carry out this chemistry, an idea that finds credence in the sensitivity of these reactions to moisture, a feature not found in most MTO-catalyzed reactions.

In summary

The catalyst methyltrioxorhenium has proved its abilities and its versatility. It seems assured of a useful place in the repertoire of



Scheme 13

catalysts that activate hydrogen peroxide and also provide other pathways for oxygen atom transfer. The fact that MTO is soluble in different media, and retains its catalytic activity therein, enhances its usefulness. Other substances act as catalysts for peroxide reactions, among them molybdates, tungstates, and other Mo(VI) and W(VI) complexes.[27] But MTO, advantageously, does not engage in any oligomerization or pH-dependent equilibria, unlike molybdate and tungstate, greatly simplifying the characterization of its reaction mechanisms.

Acknowledgements

I am grateful to my coworkers in this area, whose names are given in the referenced publications. Support is acknowledged from the US Department of Energy, Office of Basic Energy Sciences, Division of Chemical Sciences under contract W-7405-Eng-82 for research concerning the MTO catalyst, particularly selective oxidation reactions, and the development and study of catalytic organic reactions; to the National Science Foundation (CHE–9007283) for support of research in the area of O-atom transfer, and to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for partial support of research concerning organic transformations.

Received (in Cambridge, UK) 28th October 1998, Accepted 5th February 1999

Novel water-soluble Ir and Rh complexes with tris(hydroxymethyl)phosphine catalyse the selective hydrogenation of the C=O bond of cinnamaldehyde and the hydroformylation of pent-1-ene both under biphasic conditions.

The use of aqueous/organic biphasic systems is attracting growing interest in catalytic reactions by transition metal complexes.[1] The biphasic systems have benefits in catalyst separation and recycling, and the reduction or elimination of organic solvents is also advantageous for the development of economical and environmentally friendly processes. The key for such biphasic catalysis is to use water-soluble phosphines as ligands. Since the launch of the commercial propylene hydroformylation process by Ruhrchemie/Rhône-Poulenc,[2] sulfonated derivatives of PPh_3 such as $PPh_2(C_6H_4$-*m*-$SO_3Na)$ (TPPMS) and $P(C_6H_4$-*m*-$SO_3Na)_3$ (TPPTS) have been widely used as ligands in hydroformylation, hydrogenation, and related reactions catalysed by transition metals.[1,3]

Tris(hydroxymethyl)phosphine, $P(CH_2OH)_3$ (THMP) is a highly water-soluble phosphine and has unique reactivity towards a number of reagents to give functionalised hydroxymethylphosphines.[4] Although many transition metal complexes of THMP are known,[5] there are limited examples of catalytic reactions using the THMP complexes. Chatt *et al.* reported the first examples of THMP complexes of Rh, Pd and Pt; however, these complexes showed low catalytic activities in hydrogenation and hydroformylation of olefins.[5a] Recently, Pringle and coworkers showed high efficiency of THMP complexes of Pt, Pd and Ni in catalytic hydrophosphination of formaldehyde,[6] and biphasic hydrogenation of sorbic acid was reported using THMP complexes of Ru.[7] In this study, we have prepared novel THMP complexes of Ir and Rh, and their catalytic performances have been tested for hydrogenation of cinnamaldehyde and hydroformylation of pent-1-ene.

Reaction of $[IrCl(cod)]_2$ (cod = cycloocta-1,5-diene) with THMP[5c] (P/Ir ratio = 3) in THF at room temperature under N_2 readily precipitated a white powder, which was purified by recrystallisation from EtOH–Et_2O to give $[Ir(cod)\{P(CH_2OH)_3\}_3]Cl$ **1** in 91% yield [eqn. (1)]. Complex **1** was characterised by analytical and spectroscopic methods.‡ Electrospray mass spectroscopy (ESMS) of **1** in MeOH at a cone voltage of 20 V gave a single peak at *m*/*z* 673 due to $[Ir(cod)(THMP)_3]^+$ with the same isotope pattern as calculated. In the $^{31}P\{^1H\}$ NMR of **1** in $(CD_3)_2SO$, only a singlet peak was observed at δ −17.5, which was shifted lower than free THMP at δ −25.7. A variable-temperature NMR study was performed

$$[IrCl(cod)]_2 + 6\ P(CH_2OH)_3 \xrightarrow[\text{room temp.}]{\text{THF}} \underset{\mathbf{1}}{2\ [Ir(cod)\{P(CH_2OH)_3\}_3]Cl} \quad (1)$$

using CD_3OD as a solvent. Similarly, only a singlet peak was observed at δ −17.6 with a half width of 5 Hz at 20 °C. On cooling to −80 °C, the singlet peak was gradually shifted lower to δ −15.7 and slightly broadened (half width 12 Hz), and the NMR spectral change was reversible on warming again to 20 °C. The broadening of the peak suggests that **1** is fluxional in this temperature range. When THMP was added to **1**, the peaks of **1** and THMP were independently seen at 20 °C in the $^{31}P\{^1H\}$ NMR, thus excluding the intermolecular exchange of the ligands. In accordance with the $^{31}P\{^1H\}$ NMR, the ^1H NMR of **1** gave a doublet (J_{HP} 4.5 Hz) due to CH_2 of THMP at δ 4.12 and a broad peak due to OH at δ 5.53, and these peaks were shifted to lower field than those of free THMP [CH_2 at δ 3.85 (t, *J* 5.1 Hz) and OH at δ 4.68 (q, *J* 5.1 Hz)]. The ^1H NMR data including integrals and elemental analysis also support the formation of five-coordinate complex **1**.

One might expect that $[IrCl(THMP)_2]_2$ or $[Ir(cod)(THMP)_2]Cl$ would also be formed in the reaction of $[IrCl(cod)]_2$ and THMP; however, in the presence of 3 equiv. of THMP complex **1** is exclusively formed. This type of $[Ir(cod)L_3]^+$ complex is known for compact phosphines,[8a] and $[Ir(cod)(PMe_3)_3]Cl$ was prepared from the reaction of $[IrCl(cod)]_2$ with 3 equiv. of PMe_3.[8b]

Similar reaction of $[RhCl(cod)]_2$ with THMP (P/Rh ratio = 3) in THF at room temperature under N_2 gave a complicated mixture, and isolation of products was unsuccessful. On the other hand, the reaction with 4 equiv. of THMP precipitated a yellow powder, and recrystallisation from EtOH–CH_2Cl_2 gave *cis*-$[RhH_2\{P(CH_2OH)_3\}_4]Cl$ **2** in 74% yield based on Rh.‡ The formation of the hydride complex was unexpected; however, the presence of Rh–H was confirmed by ^1H NMR and IR. In the ^1H NMR of **2** in $(CD_3)_2SO$, RhH was observed at δ −11.26 with couplings to Rh and P (J_{RhH} 120.8 Hz, J_{PH} 12.9 Hz), which is characteristic for *cis*-$[RhH_2(PR_3)_4]^+$.[9] In the IR spectrum, ν_{RhH} appeared at 2007 cm^{-1}. The $^{31}P\{^1H\}$ NMR gave two doublets of triplets with equal intensity at δ 21.2 (J_{RhP} 86, J_{PP} 22 Hz) and 34.9 (J_{RhP} 97, J_{PP} 22 Hz), showing the *cis* geometry of **2**. ESMS and elemental analysis also support the structure of **2**.

The hydride origin is not clear at this moment. THMP itself is a reactive agent, and the reactions of THMP such as deprotonation and elimination of formaldehyde were reported in the preparation of THMP complexes of Pt[6] and Ru.[5f] Other possible hydride sources are the cod ligand, the solvents (THF, EtOH, Et_2O and CH_2Cl_2), or a trace of water included in the reaction mixture.§ The possibility of cod is excluded, since a quantitative amount of free cod was observed in the reaction of $[RhCl(cod)]_2$ with THMP (P/Rh = 4) in $(CD_3)_2SO$. In the $^{31}P\{^1H\}$ NMR of this reaction, the resonances of **2** and THMP oxide (δ 44) were detected, thus suggesting that a trace of water can react with Ru intermediates to give **2** and THMP oxide. When D_2O was added to **2** in $(CD_3)_2SO$, the Rh–H and OH peaks in ^1H NMR were significantly decreased, and the peaks completely disappeared in pure D_2O. This result shows a facile

Table 1 Biphasic hydrogenation of cinnamaldehyde catalysed by [Ir(cod){$P(CH_2OH)_3$}$_3$]Cl **1**[a]

Run	THMP/**1**[b]	H_2[c]/atm	*T*/°C	Conv. of **3** (%)	Selectivity (%)[d]		
					4	**5**	**6**
1	0	30	100	90	76	2	22
2	0	100	100	99	88	2	9
3	5	90	100	20	97	3	0
4	5	90	125	97	97	2	0.3

[a] *Conditions*: **1** 0.015 mmol, cinnamaldehyde 7.5 mmol, water/benzene = 5 ml/5 ml, reaction time 24 h. [b] Molar ratio of added THMP to **1**. [c] Initial pressure at room temperature. [d] (Mol of product)/(mol of converted **3**) × 100.

H–D exchange of Rh–H with D_2O, indicating that Rh–H has protic character.

Hydrogenation of cinnamaldehyde **3** in the biphasic water/benzene media was performed as a test reaction of the catalysis using complex **1** (Scheme 1). Selective hydrogenation of the C=O bond would give cinnamyl alcohol **4**, which is more valuable than hydrocinnamaldehyde **5** from the C=C bond hydrogenation and hydrocinnamyl alcohol **6** from the complete hydrogenation of both the C=O and C=C bonds.[3c] Under the conditions of 100 °C and 30 atm, with complex **1**, the conversion of **3** was 90% and the proportion of **4**:**5**:**6** was 76:2:22 (Table 1, run 1). At the H_2 pressure of 100 atm, the proportion was 88:2:9, with 99% conversion (run 2). The addition of 5 equiv. of THMP to **1** at 90 atm decreased the conversion to 20%; however, the selectivity of **4** was increased to 97% (run 3). Interestingly, under the conditions of 125 °C and 90 atm in the presence of 5 equiv. of THMP, the conversion was 97% and the proportion of **4**:**5**:**6** was 97:2:0.3 (run 4). The role of added THMP in the catalytic mechanism is being studied.

Rh complex **2** catalysed the biphasic hydroformylation of pent-1-ene to give oxo aldehydes. Under the conditions of 100 °C, CO/H_2 20 atm/20 atm, water/benzene 4 ml/4 ml, and substrate/catalyst ratio 90, pent-1-ene was quantitatively converted to hexanal (43% yield) and 2-methylpentanal (57%) in 20 h.

In all the catalytic hydrogenation and hydroformylation reactions, the substrates and products were recovered from the benzene layer, and the catalysts were present in the water layer. In order to test the catalyst stability three catalytic runs were repeated, recycling the same water layer containing **1** or **2**. No decrease was observed in the reaction rates and product selectivities, showing the reliable stability of THMP complexes **1** and **2**.

We are grateful to the Asia 2000 Foundation of New Zealand for financial support.

Cyclopropanation in the reaction of $[M(CO)_3Tp]^-$ [M = Mo, W; Tp = hydridotris(pyrazolyl)borate] with $I(CH_2)_3I$ and the insertion of isocyanide into metal–acyl bonds

Harry Adams, Rachel J. Cubbon, Mark J. Sarsfield and Mark J. Winter*

Received (in Basel, Switzerland) 21st December 1998, Accepted 27th January 1999

Treatment of $I(CH_2)_3I$ with anions $[M(CO)_3Tp]^-$ (M = Mo, W) leads to an η^2-acyl cyclopropanation product $M(CO)_2\{\eta^2\text{-}C(O)(c\text{-}C_3H_5)\}Tp$ which decarbonylates to give π-allyl complexes and reacts with CNBu^t by formal insertion of isonitrile into the metal–acyl bond.

We have described earlier reactions between dihaloalkanes such as $I(CH_2)_3I$ and $[M(CO)_n(\eta^5\text{-}C_5H_5)]^-$ (n = 3, M = Mo, W; n = 2, M = Fe) which lead to the formation of the cyclic carbene complexes $MI(CO)_{n-1}\{=\overline{C(CH_2)_3O}\}(\eta^5\text{-}C_5H_5)$.[1,2] We are interested in these compounds in connection with their ability to act as precursors for compounds which undergo migrations to carbene. While examining related compounds but containing the hydridotris(pyrazolyl)borato (Tp) ligand, we discovered a remarkable cyclopropanation process and highly unusual insertions of isonitrile into metal acyl bonds.

The reaction between $[W(CO)_3Tp]^-$ **1** with $I(CH_2)_3I$ affords small quantities of the η^2-acyl cyclopropyl complexes $W\{\eta^2\text{-}C(O)(c\text{-}C_3H_5)\}(CO)_2Tp$ **2**. The η^2-ligand is suggested by the solution IR spectrum (ν_{CO}1958 and 1824 cm^{-1}) which is typical of previously reported η^2-acyl complexes.[3] Other spectroscopic and spectrometric methods suggest the presence of the cyclopropyl group in complex **2**, but given that the few known cyclopropyl acyl complexes are formed from preconstructed cyclopropyl rings,[4] it was felt necessary to confirm this unusual result by X-ray crystallography (Fig. 1). The cyclopropyl ring is orientated approximately perpendicular to the plane of the η^2-acyl group while the η^2-acyl group itself is best regarded as occupying a single coordination site of a slightly distorted octahedral tungsten. In the solid state, the acyl group does not lie on a mirror plane, and there is likely to be a low energy solution fluxional process as has been demonstrated *via* EHMO calculations on the complex $Mo\{\eta^2\text{-}C(O)Me\}(CO)_2Tp$ **3**. This process is described as a rapid net rocking motion of the acyl group about the plane of symmetry which bisects the angle between the carbonyls and the two pyraozole groups *cis* to the acyl group.[3]

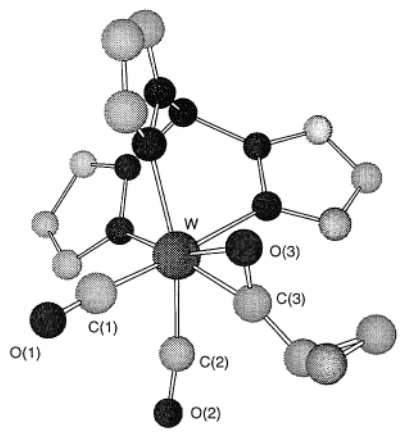

Fig. 1 Molecular structure of $W\{\eta^2\text{-}C(O)(c\text{-}C_3H_5)\}(CO)_2Tp$ **2**. Selected bond lengths (Å) and angles (°), W–C(3) 2.02(2), C(3)–O(3) 1.25(2), O(3)–W 2.217(10), C(1)–W–C(2) 80.6(6), C(3)–W–O(3) 34.0(4).

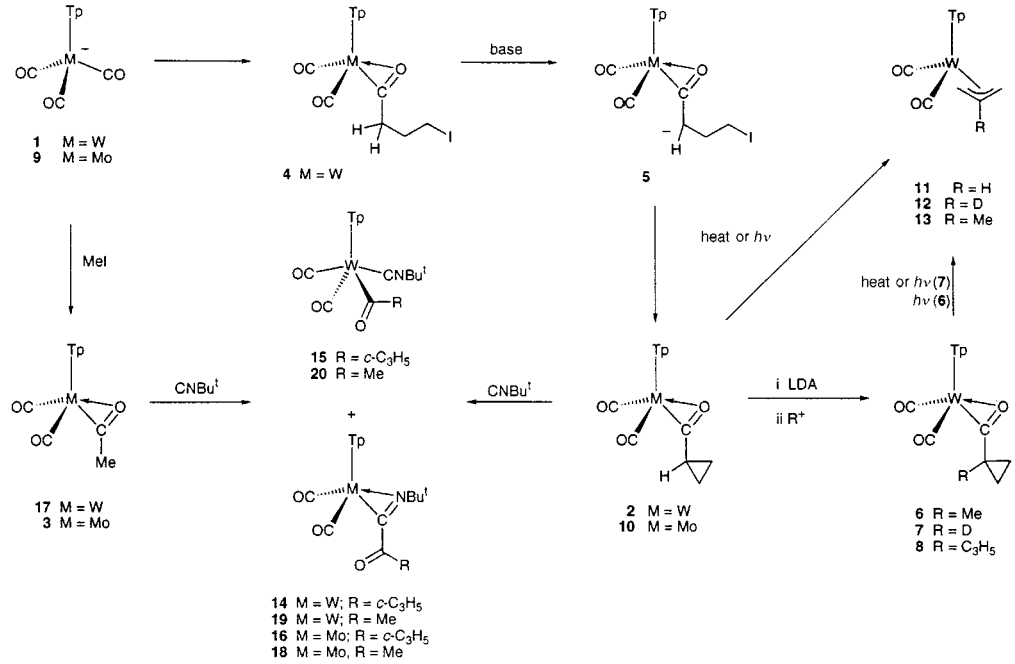
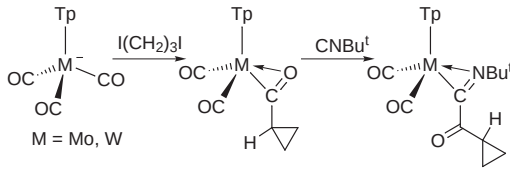
During the formation of **2**, monitoring by IR spectroscopy shows additional bands associated with the hydride $WH(CO)_3Tp$ (by comparison with an authentic sample made by the analogous route known to give $MoH(CO)_3Tp$).[5] Further, IR and NMR evidence indicates the presence of the η^2-acyl **4** in the reaction mixture. The inference that the anion $[W(CO)_3Tp]^-$ acts as a base and removes a proton from the η^2-acyl **4** (to give **5**) so inducing cyclization to give **2** is supported by the observation that addition of proton sponge [1,8-bis(dimethylamino)naphthalene] to the reaction mixture prevents the formation of $WH(CO)_3Tp$ and increases the isolated yield of **2** to 74%. Therefore, the mechanism for cyclopropyl formation is believed to proceed (Scheme 1) *via* a deprotonation α to the acyl carbon and ring closure process. That the position α to the η^2-acyl ligand in general is acidic is reinforced by earlier observations which show an α proton in complexes such as $Mo(\eta^2\text{-}COMe)(CO)_2Tp$ **3** is removed by base such as Bu^{n}Li or KH[6] and our finding that deprotonation of **2** with LDA followed by acidification or alkylation of the resulting anion affords the functionalized derivatives $W(CO)_2\{\eta^2\text{-}C(O)(c\text{-}C_3H_4R)\}Tp$ (**6**, R = Me; **7** M = D; **8**, R = allyl). The corresponding reaction of the molybdenum anion $[Mo(CO)_3Tp]^-$ **9** with $I(CH_2)_3I$ in the presence of proton sponge affords complex **10** (68%).

Complex **2** displays further interesting reactivity. Thermolysis or photolysis of **2** results in decarbonylation and ring opening of the cyclopropyl function to give the η^3-allyl complex **11**.[7] By way of partial comparison, an earlier report describes the ring opening of the cyclopropyl methyl complex $Mo(CO)_3(CH_2\text{-}c\text{-}C_3H_5)(\eta\text{-}C_5H_5)$ in refluxing hexane to give the η^3-allyl $Mo(CO)_2(\eta^3\text{-}C_3H_4Me)(\eta\text{-}C_5H_5)$.[8] Mechanistic insight into the formation of **11** in this way is given by the photolysis or thermolysis of the deuterated material $W(CO)_2\{\eta^2\text{-}C(O)(c\text{-}C_3H_4D)\}Tp$ **7** which affords $W(CO)_2(\eta^3\text{-}C_3H_4D)Tp$ **12** with > 95% deuterium labelling at the central carbon of the allyl group. Since no D-scrambling occurs, it is clear that the ring-opening process involves C–C bond cleavage between the two CH_2 groups and rearrangement to give **12**. The corresponding photolysis (but not thermolysis) of **6** affords the allyl derivative **13**.

Addition of CNBu^t to a solution of **2** in THF results in a remarkable reaction (48 h at ambient temperature for completion) leading to the α-keto-η^2-iminoacyl **14** together with the seven-coordinate Tp tungsten η^1-acyl complex **15**. There are examples of η^1-α-ketoacyl complexes in the literature (however their formation is concurrent with oxidation at the metal centre[9]) and at least one example of a α-keto-η^1-iminoacyl[10] (but made from a pre-assembled ketoimidoyl group). Because of this unusual reaction, the structure of **14** was confirmed by X-ray crystallography (Fig. 2).† The iminoacyl bond length [C(12)–N(7) 1.257(14)Å] of **14** is in the range of those reported for other η^2-iminoacyl complexes.[11] Stirring a solution of **15** in THF over three days results in only partial conversion of **14** with formation of unidentified decomposition products. Consequently, it may well be that in the reaction of **2** with CNBu^t to



Scheme 1



Scheme 2

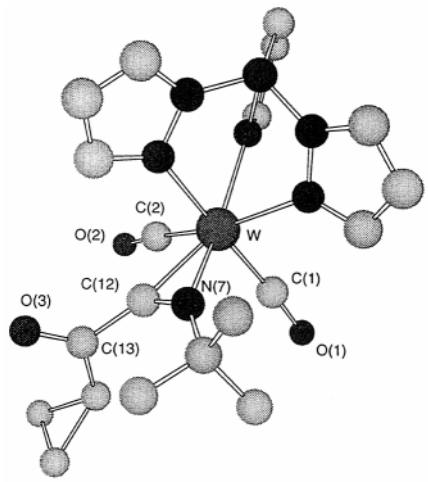


Fig. 2 Molecular structure of W{η^2-C(NBu^t)CO(*c*-C_3H_5)}$(CO)_2$Tp **14**. Selected bond lengths (Å) and angles (°), W–C(12) 2.101(11), C(12)–N(7) 1.257(14), N(7)–W 2.190(8), C(1)–W–C(2) 80.0(5), C(12)–W–N(7) 34.0(4).

form **14**, a route *via* **15** is not the major path leading to **14**. The insertion of isonitrile into metal acyl bonds of this type is reasonably general. Thus, CNBu^t reacts with the molybdenum species **10** to form **16** and we also find that the complexes M{η^2-C(O)Me}$(CO)_2$Tp (**3**, M = Mo;[3] **17** M = W) react with CNBu^t to give the insertion products $M(CO)_2$\{η^2-C(NBu^t)(COR)}Tp (**18** M = Mo; **19**, M = W). In the tungsten case, the η^1-acyl **20** is also isolable.

We are pleased to acknowledge assistance from the EPSRC for a postgraduate studentship award to M. J. S.

Received (in Bloomington, IN, USA) 4th December 1998, Accepted 9th February 1999

Laser ablation of electrochemically deposited $C_{60}M_n$ [M = Pt, $Ir(CO)_2$] films produces $[C_{59}M]^+$ whose electronic and geometric structures have been investigated by density functional theory.

A number of clusters based on a fullerene-like cage with heteroatoms incorporated into the cage framework have been observed in mass spectrometric studies. These clusters include examples where boron,[1] nitrogen,[2] silicon,[3] and niobium[4] are incorporated into the cages. The dimer, $\{C_{59}N\}_2$, has been prepared *via* a chemical route and isolated.[5] Recently, Branz *et al.* reported gas phase studies that generated $C_{60}M_x$ and $C_{70}M_x$ by evaporation of the metal into the fullerene vapor.[6] Subsequent photofragmentation of $C_{60}M_x$ and $C_{70}M_x$ produced clusters with the compositions, $C_{59-2n}M$ and $C_{69-2n}M$ with M = Fe, Co, Ni, Rh, Ir and n = 0, 1, 2. Here we report complementary studies that show that $C_{59-2n}M$ and $C_{69-n}M$ can be formed by laser ablation of electrochemically deposited films that are believed to contain polymeric, covalently bound chains: $\cdots C_{60}ML_nC_{60}ML_nC_{60}ML_n\cdots$, where ML_n = $Ir(CO)_2$ or Pt.[7]

Fig. 1 shows the results of laser ablation studies of the electrochemically deposited $C_{60}\{Ir(CO)_2\}_n$ film, which was obtained by electrochemical reduction of a toluene–acetonitrile (4 : 1 v/v) solution of C_{60} and $Ir(CO)_2Cl(NH_2C_6H_4Me\text{-}p)$ as described previously.[7] The lower trace shows the entire spectrum in the positive ion mode from laser desorption with a 340 nm N_2 laser from a film of $C_{60}\{Ir(CO)_2\}_n$. The spectrum reveals a strong $[C_{60}]^+$ peak at *m/z* 720 with the usual set of lower mass peaks due to loss of C_2 units from the fullerene. At higher mass the second most intense feature in the spectrum is a multiplet that is indicative of the presence of $[C_{59}Ir]^+$. Additionally a feature is seen at *m/z* 877 that corresponds to the presence of $[C_{57}Ir]^+$. Inset 1 shows an expansion of the spectroscopic multiplets for the $[C_{59}Ir]^+$ and $[C_{57}Ir]^+$ features and comparison with the calculated spectra based on the natural abundances of isotopes of C and Ir. No other iridium containing peaks are seen in the spectrum, the other peaks in the spectrum between those of $[C_{57}Ir]^+$ and $[C_{60}]^+$ correspond to the fullerene ions, $[C_{70-2n}]^+$. There is also no evidence in this spectrum for the presence of the $[C_{60}Ir_n]^+$ ions which were a prominent feature of the mass spectra that were obtained by Branz *et al.*[6] in their studies of the reactions of C_{60} and iridium vapors that led to the prior detection of $[C_{59}Ir]^+$.

Fig. 2(a) shows the corresponding spectral features for formation of $[C_{69}Ir]^+$ that was obtained by desorption from a film prepared by electrochemical reduction of a solution of C_{70} and $Ir(CO)_2Cl(NH_2C_6H_4Me\text{-}p)$. Fig. 2(b) shows the spectral features for the formation of $[C_{59}Pt]^+$ which was obtained by desorption from a film of $C_{60}Pt_n$ prepared by electrochemical reduction of a solution of C_{60} and $PtCl_2(pyridine)_2$. In the negative ion mode, the spectra from all three films show only the features due to $[C_{60}]^-$ and its fragmentation products; no evidence for the existence of $[C_{59}Ir]^-$, $[C_{69}Ir]^-$ or $[C_{59}Pt]^-$ was seen. We believe that the ions, $[C_{59}Ir]^+$, $[C_{69}Ir]^+$ and $[C_{59}Pt]^+$, are formed during the laser ablation process from $(\eta^2\text{-}C_{60})M$ units that are present in the electrochemically deposited films.

In order to understand the electronic and geometrical structures of these heterofullerenes, the optimal geometries have been computed by means of DFT calculations† under the

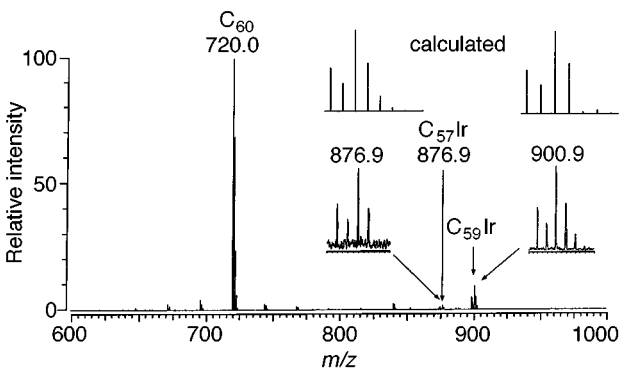

Fig. 1 Mass spectra (positive ion mode) obtained by laser ablation of electrochemically deposited films from C_{60} and $Ir(CO)_2Cl(NH_2C_6H_4Me\text{-}p)$. Inserts show expansions of the multiplets observed for $[C_{59}Ir]^+$ and $[C_{57}Ir]^+$ and comparisons with the calculated spectra.

Table 1 Computed energies (in eV) of C_{60} and metal–fullerene compounds

	C_{60}	$C_{59}Pt$	$C_{59}Ir$	$(\eta^2\text{-}C_{60})\text{-}Pt(PH_3)_2$	$(\eta^2\text{-}C_{60})\text{-}\{Pt(PH_3)_2\}_2$
IP	8.28	7.39	7.10	7.35	6.82
EA	3.49	3.56	3.71	3.08	2.73
E(LUMO)	−5.37	−5.34	−5.08	−4.86	−4.45
E(HOMO)	−7.03	−6.05	−5.64	−6.22	−5.97

restrictions of C_s symmetry. The computed geometries, which correspond to the substitution of one carbon atom by a metal atom, are similar for M = Pt and Ir. The optimization yields a geometry with a local distortion in the vicinity of the metal atom (Fig. 3). The computed M–C bond lengths are 1.954 and 1.905 Å for $C_{59}Ir$ and 1.992 and 1.934 Å for $C_{59}Pt$.

The electronic configuration of $C_{59}Pt$ is a closed-shell singlet in which the HOMO–LUMO gap was computed to be 0.7 eV. The triplet structure with one electron in the HOMO and another in the LUMO was also optimized but its relative energy with respect to the singlet structure was quite high (10.1 kcal mol^{-1}). Mulliken population analysis indicates that there is significant charge transfer from metal to the carbon fragment, since the net charge on platinum is +1.3 e. The electronic populations of the s, p and d platinum orbitals are 2.38, 6.03 and 8.24 e, respectively. Other models of space partitioning predict less charge transfer. Hirshfeld and Voronoi procedures assign a net charge of +0.5 e to the platinum atom.[8,9] The metal orbitals in $C_{59}Pt$ are spread through a range of molecular orbitals and each of the molecular orbitals in the metallofullerene has a low metal contribution. Specifically, the participation of the metal orbitals is 19% in the HOMO and 17% in the LUMO. The ground state for the analog iridium cluster is a doublet of symmetry A′ in which the spin density is quite delocalized with 0.22 e on the metal center, 0.27 e on C(2) and the rest of the spin density delocalized through the carbon cage in smaller increments. Hirshfeld and Voronoi population analyses suggest that the charge on the iridium atoms is *ca.* 0.35 e, and that the charge transfer from the metal to fullerene is somewhat lower than in the platinum analog.

In order to get more information about the physical properties of these clusters we have also computed the vertical ionization potentials (IP) and electron affinities (EA). These data and the energies of the HOMOs and LUMOs are presented in Table 1 for C_{60}, $C_{59}Pt$, $C_{59}Ir$, $(\eta^2\text{-}C_{60})Pt(PH_3)_2$ and $(\eta^2\text{-}C_{60})\{Pt(PH_3)_2\}_2$. Substitution of a carbon by a metal increases the energy of the HOMO in both $C_{59}Pt$ and $C_{59}Ir$ relative to C_{60}. As a consequence of this increase, the IP's of the substituted fullerenes are lower than those of C_{60} itself.

Smalley and coworkers[10] estimated from photoelectron spectra an EA of *ca.* 2.60–2.80 eV for C_{60}. Although present DFT calculations probably predict an excessively high value for C_{60}, the computed relative EAs for $(\eta^2\text{-}C_{60})\{Pt(PH_3)_2\}_n$ (n = 1 and 2) are in very good concordance with the electrochemical studies of Fagan and coworkers who proposed that coordination of one $Pt(PR_3)_2$ group to C_{60} lowers the EA of the carbon cluster by 0.34 eV while coordination of two groups to C_{60} decreases the EA by 0.70 eV.[11]

The energies of the LUMOs in $C_{59}Pt$ and C_{60} are very similar, −5.34 and −5.37 eV, respectively. Consequently, the difference between the EAs of C_{60} and $C_{59}Pt$ was computed to be very small (0.05 eV). The added electron in $C_{59}Ir$ goes to a half-filled orbital at an energy of −5.64 eV, which is 0.27 eV lower than the energy of the LUMO of C_{60}. Thus, the EA of $C_{59}Ir$ is 0.22 eV higher than the EA of C_{60}.

The ability of $C_{59}Pt$ to coordinate PH_3 or CO was also analyzed. For both molecules, the DFT calculations yielded an optimal geometry in which the metal has a tetrahedral coordination with three quasi identical Pt–C bond lengths. The new computed Pt–ligand bond distances are 2.409 Å for PH_3 and 1.983 Å for CO. The corresponding bonding energies were calculated to be 14.2 and 6.2 kcal mol^{-1}, respectively. In the case of $C_{59}PtCO$, the ground state is a triplet since the HOMO and LUMO are quasi degenerate orbitals.

We thank the National Science Foundation (Grant CHE 9610507) for financial support, Johnson Matthey for a loan of platinum and iridium salts, and L. Voss, Dr A. de Bettencourt-Dias and Dr C. Bo for assistance. DFT calculations have been carried out on workstations purchased with funds provided by the DGICYT of the Government of Spain and by the CIRIT of Generalitat of Catalunya (Grants no. PB95-0639-C02-02 and SGR97-17).

Notes and references

† *Computation*: gradient corrected DFT calculations were carried out with the ADF program.[12] We used the local density approximation with Vosko–Wilk–Nusair parametrization for correlation.[13] Becke's non-local corrections to the exchange energy and Perdew's non-local corrections to the correlation energy were added.[14] Slater basis sets of double-ζ + polarization quality were used to describe the valence electrons of C, O, P and H. For iridium and platinum, the 5sp electrons were described by double-ζ Slater functions, 5d and 6s by triple-ζ functions, and 6p by a single orbital.

Predictions for possible new, doubly and triply bridged oxides and peroxides of C, N, P, and S

Pekka Pyykkö

Department of Chemistry, University of Helsinki, P.O.B. 55 (A. I. Virtasen aukio 1), FIN--00014 Helsinki, Finland. E-mail: Pekka.Pyykko@helsinki.fi

Received (in Cambridge, UK) 2nd December 1998, Accepted 16th February 1999

By regarding the $X^{2-,3-}$ oxoanions of main group elements as pseudochalcogenides or pseudopnicogenides, and possibly cutting the peroxide bridges to oxide bridges, one arrives at a series of so far experimentally unknown oxides and peroxides, X_2, having high, but not exceedingly high energies.

Pseudohalides, such as CN^-, are known to form corresponding pseudohalogens, like NC–CN. Similarly, certain divalent and trivalent polyatomic anions, $X^{2-,3-}$, can be regarded as pseudochalcogenides and pseudopnicogenides. They can in principle form the corresponding neutral molecules X_2.[1] Now, consider an oxoanion, such as $X^{2-} = CO_3^{2-}$ from this point of view. The corresponding neutral X_2 dimer is $(CO_3)_2$, for which we consider the structure {O=C(–O–O–)$_2$C=O} **1**. If the peroxide bridges are shortened to oxide ones, the structure O=C(μ-O)$_2$C=O **2** is obtained. We here point out the possible existence of an entire class of such compounds. Further variations on the theme are obtained by replacing some or all of the oxygens by sulfurs, by adding or omitting terminal oxygens, by replacing them with halogen atoms, or by varying the total charge.

Related singly bridged peroxide systems are known. Peroxodisulfate, $S_2O_8^{2-}$, is one of the most powerful oxidizing agents.[2] Note that below we discuss the neutral S_2O_8. The peroxydicarbonate, $C_2O_6^{2-}$ is known. We here discuss the neutral C_2O_6. The diphosphate **9** is six electrons short of $2PO_4^{3-}$. These proposed oxidized oxoanion dimer molecules, if they can be made, are likely to be even stronger oxidants than the known peroxo compounds.

Triply bridged, 'confacial tetrahedral geometries' are rare.[3,4] We are not aware of experimentally known molecules with (–O–)$_3$ bridges.

The second-order Møller-Plesset or B3LYP density functional calculations were performed using GAUSSIAN 94. The obtained structures are reported in Table 1 and shown in Fig. 1. It was checked that all geometries correspond to local minima. The vibrational frequencies for species **1**–**5** are shown in Fig. 2. The pseudochalcogen corresponding to carbonate **1** is found to have a relatively low energy, Table 2. In the calculated structure the two coaxial carbonate planes are rotated through 37.8°. Double peroxide bridges are previously known in the cyclic peroxides of type R$_2$C(–OO–)$_2$CR$_2$.[5] We now replace the –CR$_2$ groups by –C=O groups.

Perhaps the most interesting result is that carbon dioxide would be able to form the metastable planar dimer **2** only about 200 kJ mol^{-1} above two monomers. Both this dimer and a $(CO_2)_3$ trimer have been recently discussed by Lewars.[6] He finds for the dimer **2** at the MP2/6-31G* level a barrier of 41 kJ mol^{-1}, which would make it a possible low-temperature species, that merits further studies. The structure of **2** does not offend chemical intuition, although the four-ring is strained. Furthermore the structures, vibrational frequencies and heats of formation are very similar at the four levels [(a)–(d)] of approximation. Four-rings with two opposite > C=O groups and two opposite > N–Ph groups are known.[7] If the ring oxygens are replaced with sulfur atoms, the resulting dimers **3** and **5** are only *ca.* 100 kJ mol^{-1} above two carbonyl sulfide or carbon disulfide monomers, respectively. The alternative $C_2O_2S_2$ structure **4** lies higher.

Of the present ten species, one is experimentally known. High-pressure experiments on CS_2 are thought to yield **5**, identified on the basis of an IR band at 1150 cm^{-1}.[8] The present calculations find a b_{1u} vibration with large intensity (814 km mol^{-1}) at 1125 cm^{-1} at the B3LYP/6-31G* level (c). The corresponding frequency for **2** and **3** is predicted to occur at

Table 1 Calculated geometries for the peroxide-bridged dimers X_2 corresponding to anions $X = EO_n^{q-}$. The geometries of the corresponding oxygen-bridged species are also given. E–O$_t$ is the terminal and E–O$_b$ the bridging distance, respectively. α is the dihedral E–O–O–E angle. Some sulfur analogues are included

				Distance/pm			Angle/°	
X	Species	No.	Symmetry	E–O$_t$	E–O$_b$	O–O	O$_t$–E–O$_b$	α

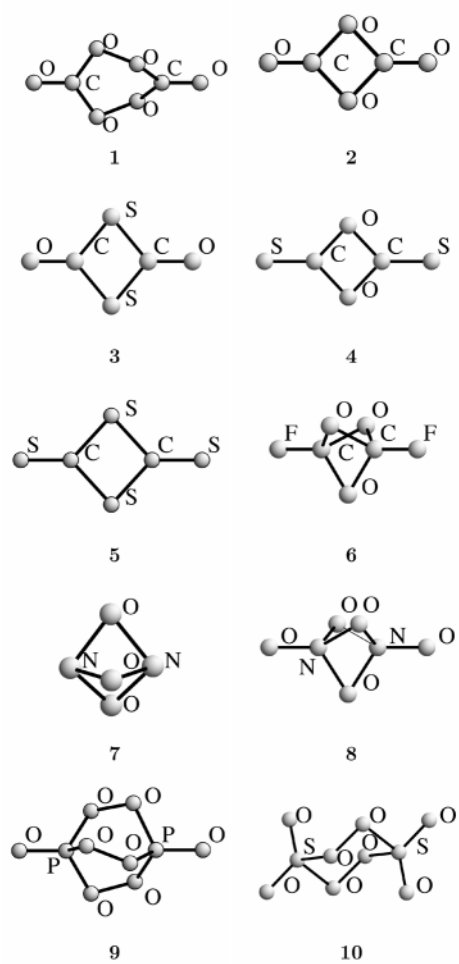

Fig. 1 The calculated structures of species **1**–**10**

Table 2 Calculated heats of formation, ΔH (kJ mol^{-1}), with respect to the reference compounds given, without zero-point energy corrections. For footnotes, see Table 1

Molecule	Reference	ΔH
1[a]	$2CO + H_2O_2 - 2H_2$	−9
2[a]	$2CO_2$	206
2[b]	$2CO_2$	196
2[c]	$2CO_2$	174
2[d]	$2CO_2$	202
3[c]	2OCS	111
4[c]	2OCS	225
5[c]	$2CS_2$	115
6[a]	$CO + CO_2 + F_2$	−19
7[a]	$N_2 + \frac{3}{2}O_2$	653
	$ON–NO_2$	552

1951 (a) or 1950 (d) and 1863 (c) cm^{-1}, respectively, Fig. 2. As the dimerisation energies for **3** and **5** are comparable, compression of OCS should result in **3**.

Compound **6** has a favourable heat of formation, as seen from Table 2. Its e′ and a_2'' frequencies at 1187 and 1419 cm^{-1} have intensities of 320 and 820 km mol^{-1}, respectively, at MP2/6-311G* level.

The trigonal bipyramidal, D_{3h}, structure **7** of N_2O_3 is calculated to lie at very high energy, 552 kJ mol^{-1} above the experimentally known $ON–NO_2$ structure. The vibrational frequencies of the high-energy form are, however, all positive and quite large (e″ 525, e′ 648 (42), 732(3), a_2'' 722(41), a_1' 848, 1120 cm^{-1}). It is a possible high-energy species. The IR

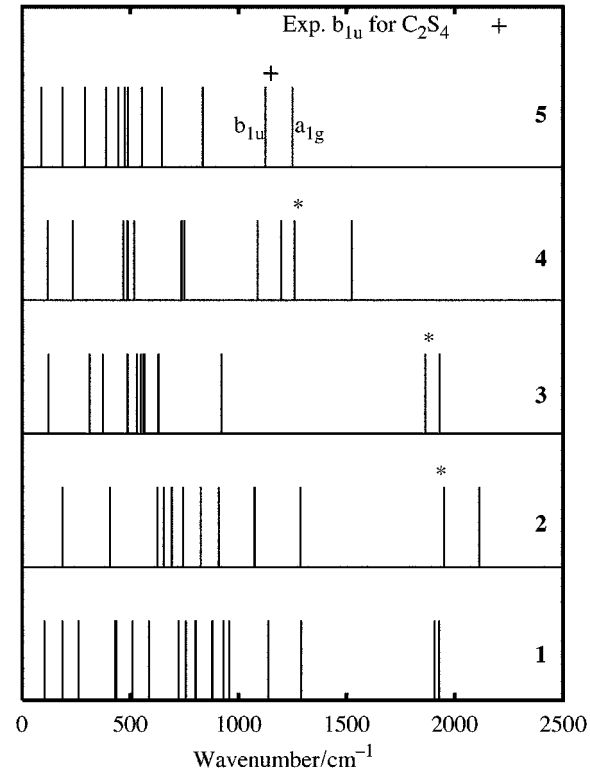

Fig. 2 The calculated vibrational frequencies of species **1**–**5**. The predicted, intensive b_{1u} vibration frequencies of **2**–**4** are marked with a star.

intensities (in parentheses) are quite low and the static dipole moment is zero. For the valence isoelectronic P_2S_3, the D_{3h} structure is calculated to lie only slightly above the lowest 'W' one.[9]

The structure of **8** is of the same type as that calculated for $[O=Si(–O–)_3Si=O]^{2-}$ by Cederbaum and coworkers.[10] The corresponding $C_2O_5^{2-}$ was here found to be unstable, having two negative frequencies.

Concluding, we suggest that the carbonyl sulfide dimer **3** is likely and the carbon dioxide dimer **2** conceivable as a synthetic goal. The latter has already been proposed by Lewars[6] as a possible low-temperature species.

The proposed molecules might have applications as strong oxidants or as high-energy species.

This study is supported by The Academy of Finland.

Aerobic oxidation of a disulfide to its sulfonate leading to supramolecular pyridine-2-sulfonato Cu(II) and Zn(II) complexes

Kentaro Kimura, Takahiro Kimura, Isamu Kinoshita,* Nobuaki Nakashima, Ken'ichi Kitano, Takanori Nishioka and Kiyoshi Isobe

Department of Molecular Materials Science, Graduate School of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558-8585, Japan. E-mail: isamu@sci.osaka-cu.ac.jp

Received (in Cambridge, UK) 7th December 1998, Accepted 1st February 1999

A one-dimensional copper(II) complex with pyridine-2-sulfonate donors, [{Cu(3-mpSO$_3$)$_2$}$_n$] (3-mpSO$_3$ = 3-methylpyridine-2-sulfonate), is formed *via* the air oxidation of 3-mpds (2,2′-bis(3-methylpyridyl)disulfide) in the presence of CuBr$_2$, and a mononuclear zinc complex, [Zn(3-mpSO$_3$)$_2$(H$_2$O)$_2$], which has two-dimensional H-bonded networks and luminescent properties in solid state, is prepared by the reaction of ZnBr$_2$ with 3-mpSO$_3$H.

A variety of complexes with pyridine derivatives have been extensively investigated as a motif in supramolecular architecture.[1] On the other hand, one of the pyridine derivatives, pyridine-2-sulfonate, has been used for studies on ligand effects on GoAgg^{II} oxidation and chromic acid oxidation,[2] which can be expected to serve as a simple chelating ligand. Luminescent complexes of pyridine-2-sulfonate with several lanthanoids have also been prepared.[3] However, except for a silver(I) complex preliminarily reported by Charbonnier *et al*.[4] and a cobalt(III) complex recently reported by Murata *et al*.,[5] there is no report on the crystal structures of pyridine-2-sulfonato complexes.

In the present work, a supramolecular entity with a pyridine-2-sulfonate donor has been unexpectedly found in the reaction of 2,2′-bis(3-methylpyridyl)disulfide (3-mpds) with CuBr$_2$ under aerobic conditions, where the air oxidation of 3-mpds to 3-methylpyridine-2-sulfonate (3-mpSO$_3$) took place to afford a one-dimensional copper(II) complex, [{Cu(3-mpSO$_3$)$_2$}$_n$] **1**. By using the sulfonato ligand we have also synthesized a photoluminescent complex, [Zn(3-mpSO$_3$)$_2$(H$_2$O)$_2$] **2**, which is assembled by intermolecular hydrogen bonds in the solid state.†

Addition of a methanolic suspension of 3-mpds[6,7] in air to a methanol solution of CuBr$_2$ immediately afforded brown and red crystals, which were removed by filtration after 2 days.‡ The filtrate was allowed to stand for a month, yielding green crystals of sulfonato complex [{Cu(3-mpSO$_3$)$_2$}$_n$] **1**.§

As shown in Fig. 1, the molecular structure of **1** consists of an infinite one-dimensional chain of octahedrally co-ordinated centrosymmetric copper atoms, bridged by 3-mpSO$_3$ ligands. Two 3-mpySO$_3$ ligands are co-ordinated to the Cu ion to form a basal plane with two five-membered chelate rings in a *trans* fashion. The apical sites are occupied by two oxygen atoms of the 3-mpSO$_3$ ligands bridging to the adjacent Cu centres; the axial Cu–O bond lengths are longer than the corresponding equatorial ones by 0.44 Å.

Oxidation of 2,2′-dipyridyl disulfide to pyridine-2-sulfinate in the presence of the Cu(II) ion and water under both aerobic and anaerobic conditions has already been reported by Seff *et al*.[8] In general, further oxidation of disulfides or sufinate compounds to the corresponding sulfonates requires a strong oxidizing agent such as hydrogen peroxide or halogen.[5,9] Surprisingly, in the present experiment, 3-mpds was oxidized to 3-mpSO$_3$ even under relatively mild oxidative conditions. Such an oxidation phenomenon is considered to be a preceding process of oxidative desulfurization and to be a mimic of the metabolism of sulfur *in vivo*.[10]

The sulfonato zinc complex, [Zn(3-mpSO$_3$)$_2$(H$_2$O)$_2$] **2**, was obtained from the reaction of ZnBr$_2$ with 3-mpSO$_3$H[6,11] in water, and the molecular structure is shown in Fig. 2.¶ The zinc ion is co-ordinated by two 3-mpSO$_3$ ligands through the aromatic nitrogens in *trans* positions and sulfonate oxygens in *cis* positions and by two water molecules *cis* to each other. This N$_2$O$_4$ donor set forms the octahedral co-ordination geometry around the Zn atom. As depicted in Fig. 3, all of the co-ordinated water molecules and the unco-ordinated sulfonate oxygens are used for intermolecular hydrogen bonds (O(2)···O(4) 2.818(2) Å, O(3)···O(4) 2.723(2) Å), forming two-dimensional H-bonded networks parallel to the *bc* plane. Interestingly, the zinc complex **2** in the solid state displays luminescence with maximum peaks at 345 and 490 nm at room temperature when excited at 311 nm (Fig. 4). The higher energy emission is presumably a fluorescence. On the other hand, the

Dual reaction behaviour of an *in situ* generated nitrilium phosphane ylide complex towards carbon–sulfur π-systems

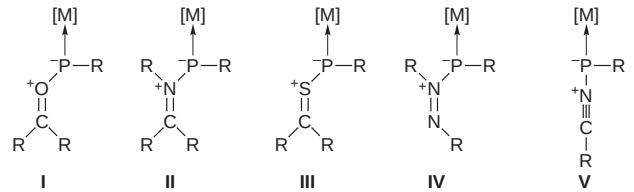
Rainer Streubel* and Christoph Neumann

Institut für Anorganische und Analytische Chemie der Technischen Universität Braunschweig, Postfach 3329, D-38106 Braunschweig, Germany. E-mail: r.streubel@tu-bs.de

Received (in Basel, Switzerland) 15th December 1998, Accepted 8th February 1999

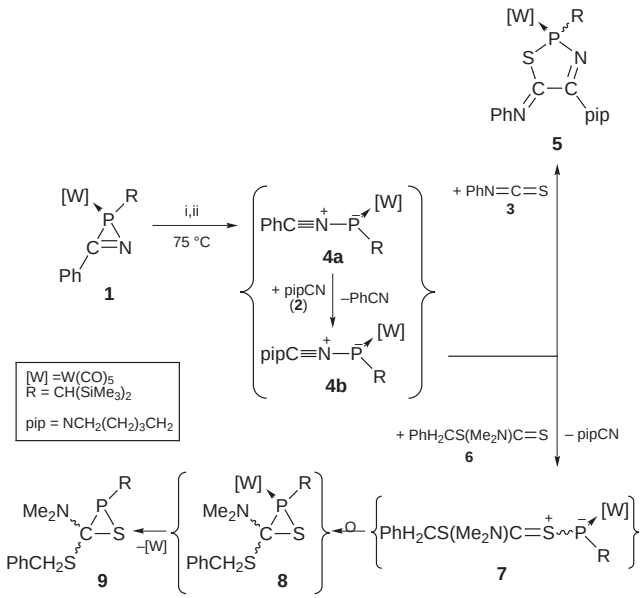
[3 + 2] Cycloaddition of *in situ* generated nitrilium phosphane ylide complex 4b with phenylisothiocyanate yielded *N*-piperidino-substituted Δ³-1,3,2-thiazaphospholene complex 5 regioselectively, whereas with benzyl *N*,*N*-dimethyl dithiocarbamate ester the thiaphosphirane 9 is obtained; these reactions, a 1,3-dipolar cycloaddition and a transylidation, shed first light on the reactivity of a nitrilium phosphane ylide complex towards different C,S π-systems.

Betaines **I**,[1] **II**,[1b,2] **III**, **IV**[3] and **V**[4] with a phosphorus atom in the central 1,3-dipole skeleton are of increasing interest in phosphorus and heterocyclic chemistry (Scheme 1).[5] Recently, we gained strong evidence for the transient formation of nitrilium phosphane ylide complexes (**V**) by employing dialkyl cyanamides and different trapping reagents such as dimethyl acetylene dicarboxylate[6] or nitriles.[7] Although we gained some evidence that transiently formed 2*H*-azaphosphirene complexes[7] and, under some circumstances, transition states of the 2 : 1 donor–acceptor adduct-type, with nitriles as donors and a terminal phosphanediyl complex as acceptor,[8] may be involved in transylidation processes, those reactions are not completely understood. To shed more light on this process and to exploit synthetically the transylidation methodology, we have now started to investigate the reaction behaviour of transiently formed nitrilium phosphane ylide complexes towards different C,S π-systems such as isothiocyanates and dithiocarbamates.



Scheme 1 1,3-Dipole complexes ([M] = metal complex fragment, R denotes ubiquitous organic substituents).

Thermal ring-opening of the 2*H*-azaphosphirene complex **1**[9] in toluene in the presence of 2 equiv. of 1-piperidinonitrile **2** and 2 equiv. of phenylisothiocyanate **3** furnished the Δ³-1,3,2-thiazaphospholene complex **5**, regioselectively; neither regioisomers nor isomers resulting from a cycloaddition reaction of intermediately formed **4b** with the C,N π-system of **3** have been observed. Employment of benzyl *N*,*N*-dimethyl dithiocarbamate ester **6** under the same reaction conditions gave the thiaphosphirane **9** exclusively; neither five-membered heterocycles, formed by reaction of **4b** with **6**, nor the corresponding thiaphosphirane complex **8** could be detected spectroscopically (Scheme 2). It is remarkable that this reaction did not change, even when benzonitrile was employed as solvent. Therefore, the formation of both heterocycles is explained by reactions of the *in situ* generated nitrilium phosphane ylide complex **4b**, which leads either to **5** *via* [3 + 2] cycloaddition or to **9** *via* an intersystem-transylidation-type reaction giving 1,3-dipole complex **7**, which undergoes ring-closure to **8** and subsequent decomplexation to give **9** as the final product. Because a transient formation of terminal phosphanediyl complex $[(OC)_5WPCH(SiMe_3)_2]$ can be achieved *via* thermally induced



Scheme 2 *Reagents and conditions*: i, 1 mmol of **1** was treated with 6 mmol of phenylisothiocyanate and 2 mmol 1-piperidinonitrile in 2 ml of toluene at 75 °C for 1.5 h. Work-up by column chromatography at low temperature and crystallization from pentane afforded **5** as a yellow solid (28%, mp. 98 °C); ii, 1 mmol of **1** was treated with 5 mmol of benzyl *N*,*N*-dimethyldithiocarbamate ester in 3 ml of toluene at 75 °C for 2 h.Work-up by column chromatography at low temperature afforded **9** as a pale yellow oil (13%).

ring-cleavage of **4a** in toluene,[4] we repeated the reaction of **1** and **6** in toluene in the absence of **2** and obtained, once more, thiaphosphirane **9** as the only phosphorus-containing product. This result also supports the assumption of complex **7** as a highly reactive intermediate in this reaction course.

The compositions of the Δ³-1,3,2-thiazaphospholene complex **5** and the thiaphosphirane **9** are confirmed by elemental analyses and mass spectrometry;† the structural formulation is based on their characteristic NMR spectral data† in solution. The connectivity of the heterocyclic ring atoms of complex **5** was also confirmed by X-ray structure analysis, although the refinement was unsatisfactory because of heavily disordered substituents at the five-membered ring system; therefore, the structure will not be further discussed here.

The phosphorus nucleus of **5** displays a resonance at δ 105.8, which is significantly high-field shifted compared to Δ³-1,3,2-oxazaphospholene complexes (δ 190–205[6]), with a markedly decreased phosphorus–tungsten coupling constant of 287.1 Hz (*cf.* 300–306 Hz[6]). The carbon atom resonances of the heterocycle appear at δ 157.7 and 160.9 with phosphorus–carbon coupling constants of 9.2 and 12.8 Hz, respectively. Similarly to Δ³-1,3,2-oxazaphospholene complexes, these carbon resonances display small carbon–phosphorus coupling constants; this seems to be a characteristic phenomenon for such heterocyclic ring systems. The phosphorus and the ring carbon atom of the thiaphosphirane **9** display resonances at low field

[δ(^{31}P) 36.4; δ(^{13}C) 106.5; *cf.* ref. 10], which indicates a deshielding influence of the two directly bonded electronegative N- and S-atoms of the *exo*-substituents on the atoms of the thiaphosphirane ring.

We are currently investigating the reactivity of *in situ* generated nitrilium phosphane ylide complexes towards other heterocumulene systems.

This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

Incompletely condensed silasesquioxanes as models for zeolite defect sites: an FTIR and density functional study

Received (in Cambridge, UK) 10th December 1998, Accepted 16th February 1999

FTIR hydroxyl vibration bands in highly dealuminated zeolites could be unambiguously assigned to well defined hydroxyl clusters present at defect sites by the use of density functional calculations on incompletely condensed silasesquioxane complexes which, in addition, provided useful spectroscopic references.

Because of their defined cage like structures, it is expected that silasesquioxane complexes are not only suitable for mimicking silica surfaces[1] but can be considered as parts of zeolites as well, resembling for instance the zeolite double-four-ring (D4R). In this respect, the studies on defect sites as a part of zeolite research, in which still much is unknown about the precise zeolitic structure,[2] could profit from useful reference data obtained from silsesquioxane chemistry. Especially the assignment of zeolite defect sites by means of FTIR analysis, despite the numerous reports on these defects,[3–7] is surrounded by controversy.

In this report, we elucidated the FTIR assignment of the different possible defect sites in zeolite structures with incompletely condensed silasesquioxane complexes as references and by using computational chemistry. This powerful combination is a new approach in this field and results in a molecular level understanding of the actual hydroxyl clusters, which form the different zeolite defect sites (Fig. 1). Furthermore, a reaction of these hydroxyl clusters with different probe molecules will enable us to distinguish between defect sites located inside or outside the zeolite microporous system.

In general, the major part of the various hydroxyl bands found upon aluminium extraction out of a zeolite framework can be categorised roughly into two regions. The first is a relatively broad band between 3500 and 3560 cm^{-1} and the second, which is in most cases somewhat sharper, is present between 3680 and 3730 cm^{-1}. These bands are referred to as the 3500 and 3700 cm^{-1} bands, respectively. It is important to note that both bands can be found in various dealuminated zeolites such as ZSM-5,[3] beta,[4] faujasite[5] and mordenite,[6,7] which indicates that the different defect sites are not unique for one particular zeolite but have a more general character. The assignment of the two different hydroxyl bands which arise upon dealumination is not straightforward. A dealumination study of Wu *et al.*[6] showed a similar behaviour of both bands upon Si/Al ratio. A study by Moreno and Poncelet, however, showed a significantly different response of the 3500 and 3700 cm^{-1} bands as a function of temperature, indicating a different origin of these bands.[7]

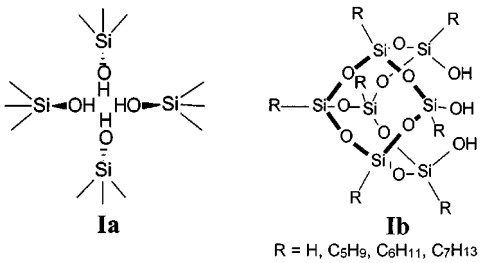

Fig. 1 A two-dimensional representation of a hydroxyl nest in a zeolite (**Ia**), in comparison with the incompletely condensed silasesquioxane complex (**Ib**).

The FTIR spectrum of dealuminated mordenite clearly shows the broad band at 3500 cm^{-1} and the band around 3700 cm^{-1}, as can be seen from Fig. 2A [dealumination with nitric acid resulted in a Si/Al ratio increase from 6.7 (spectrum a) to 39 (b), 47 (c) 79 (d) and 150 (e)]. Furthermore, the Brønsted acid band around 3610 cm^{-1} is only just apparent. This band decreases with decreasing aluminium content (increasing Si/Al) and is practically gone at Si/Al = 150, as can be seen from Fig. 2A (spectrum e). Since the 3500 cm^{-1} band is shifted about 240 cm^{-1} to lower frequency compared to the isolated silanols (present at 3745 cm^{-1}) we assume that these OH bonds are highly weakened due to their mutual hydrogen bonding. Moreover, the broad appearance of this band is indicative of a strong disturbance caused by the hydrogen bridges. The shift of the 3700 cm^{-1} band is only *ca.* 40 cm^{-1} (compared to the isolated silanol band) and is considerably less broad in comparison with the 3500 cm^{-1} band. This different appearance of the 3700 cm^{-1} band implies again that this band arises from a different, but still moderately disturbed, OH species.

Incompletely condensed silasesquioxanes contain OH groups and, as such, can be used for modelling OH clusters in zeolites. Some of these complexes, which can be considered as possible models for defect sites in zeolites, are shown in Table 1. Clearly, a zeolite-like T-atom vacancy can be recognised in complex **Ib** (see also Fig. 1), whereas complex **III** represents an isolated, non-hydrogen bridged OH group at the outer surface of the zeolite, and complex **II** can be considered as a hydrated Si–O–Si bridge. The geometry of these complexes was fully optimised.† Complex **III** as a model for isolated OH groups has the highest calculated frequency for its OH stretching vibration. This frequency of 3697 cm^{-1} is in good agreement with the measured FTIR frequency for the isolated OH stretching vibration of this complex at 3705 cm^{-1} (measured in pressed KBr pellets). A shift of *ca.* 300 cm^{-1} is obtained for the

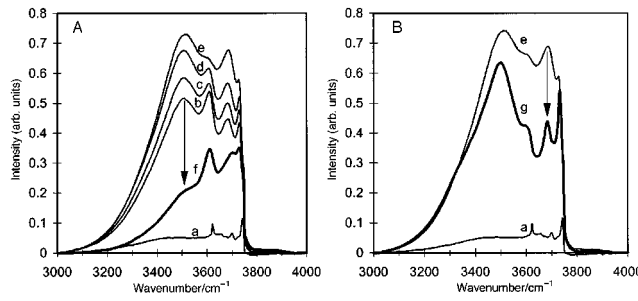

Fig. 2(A) FTIR spectra of parent Na-mordenite (a), which was dealuminated using 7 M (b), 9 M (c), 10 M (d) or 14 M (e) aqueous HNO_3 at reflux for 4 h (10 ml g^{-1}); sample 'b' subjected to a titanation using gaseous $TiCl_4$ at 400 °C (f). (B) FTIR spectra of parent Na-mordenite (a), which was dealuminated using 14 M (e) aqueous HNO_3 at reflux conditions for 4 h (10 ml g^{-1}); sample 'e' subjected to an aqueous phase titanation using a buffered 0.05 M $(NH_4)_2TiF_6$ solution (g).

calculated main bands of complex **I**, the silasesquioxane model for a zeolite T-atom vacancy, *i.e.* the actual hydroxyl nest (as plotted in Fig. 1). This shift is in good agreement with the 250 cm^{-1} shift found experimentally for the 3500 cm^{-1} band in the FTIR spectra of dealuminated zeolites (Fig. 2A). The comparable shift is a strong indication for the fact that the three membered hydroxyl nest is a reliable model for a four membered hydroxyl nest. It is important to mention the significant increase of the average OH bond distance upon hydrogen bridging, while the hydrogen bridge distance reduces to only 1.89 Å (see Table 1, complex **Ib** and **III**). Considering complex **II**, only a small shift is obtained for the OH stretching vibrations, indicative of weakly hydrogen bonded OH groups. This is confirmed by the scarcely changed OH distance and the large OH bridging distance for this complex. The small shift of the OH stretching band (22 cm^{-1} for the symmetric vibration) is in good correspondence with the measured shift of *ca.* 40 cm^{-1} for the 3700 cm^{-1} band in dealuminated zeolites. Moreover, the weaker hydrogen bridges for this type of defect site should result in a less broad signal, which is indeed obtained for the dealuminated mordenite (Fig. 2A).

Since it is concluded that the two FTIR hydroxyl bands at 3500 and 3700 cm^{-1} cannot be ascribed to the same defect site, it is interesting to know where these different defect sites are located in the zeolite microporous structure. To investigate this, the two different hydroxyl clusters are reacted with different probe molecules. Well known titanium precursors are used as probes, $TiCl_4$ and $(NH_4)_2TiF_6$, usually applied in post-synthesis procedures in the preparation of titanium zeolites.[8] The latter however, used in aqueous applications, is considered to be more bulky, especially in its hydrated form. Moreover, its siliceous analogue, $(NH_4)_2SiF_6$, is reported to be almost unable to enter the mordenite 12-ring.[9] It is assumed, therefore, that also the large $TiF_6(H_2O)_n^{2-}$ ion hardly enters the mordenite microporous structure.

Applying the different titanium precursors to the same kind of dealuminated mordenite, results in a totally different behaviour of the two above mentioned hydroxyl defect site bands. $TiCl_4$ reacts primarily with the hydroxyl nests shown by the significant decrease of the 3500 cm^{-1} band upon titanation [Fig. 2A(*f*)]. The 3700 cm^{-1} band seems hardly affected by this titanation treatment. This result is in agreement with the spectra reported earlier of dealuminated mordenite reacted with $TiCl_4$.[8c] Correspondingly, in a report concerning the titanation of dealuminated beta, the broad FTIR band present around 3500 cm^{-1} is significantly reduced upon reaction with $TiCl_4$.[10] Using aqueous $(NH_4)_2TiF_6$ as the titanium source, however, results in the opposite behaviour. The FTIR spectrum of a dealuminated mordenite titanated with this titanium source shows mainly a decrease of the 3700 cm^{-1} band [Fig. 2B(g)]. Since the 3500 cm^{-1} band was assigned to hydroxyl nests resulting from the extraction of framework aluminium, these nests are located in the zeolite micropores. The 3700 cm^{-1} band, on the other hand, was attributed to hydroxyl pairs. Since this band is affected predominantly by the titanation with the bulky $(NH_4)_2TiF_6$, we believe that these pairs are located mainly on the outer (or mesoporous) surface of the zeolite.

In conclusion, our new approach to the controversy of the assignment of the different hydroxyl bands in FTIR analysis, using silasesquioxane as models for defect sites in zeolites, is a powerful tool to clarify the different defect site structures. Based on its FTIR shift and the OH distances of the model compound **Ib**, the band at 3500 cm^{-1} must indisputably be assigned to hydroxyl nests (*i.e.* T-atom vacancies, as depicted in Fig. 1). Simultaneously, the band at 3700 cm^{-1} cannot be assigned to the same kind of hydroxyl cluster and evidence is found for the assignment of this band to a hydroxyl pair, featuring less hydrogen bonding. Regarding their location in the zeolite microporous structure, the use of titanium probe molecules shows that, in contrast to the hydroxyl nests present in the mordenite micropores, the hydroxyl pairs seem to be located primarily on the outer surface of the zeolite crystals.

Table 1 Incompletely condensed silasesquioxane complexes[a] and their calculated O–H stretching vibrations and O–H distances†

	Ib	**II**	**III**
			OH stretching vibrations (shift in **bold**)[b] /cm^{-1}	3403(asym)(**294**) 3396(asym)(**301**) 3331(sym) (**366**)	3698(asym)(**-1**) 3675(sym) (**22**)	3697 (**0**)
Average O—H bond distance/Å	0.996	0.980	0.978
Average O•••H bridge distance/Å	1.89	2.62	–

[a] Lines in figures represent Si–O–Si units which are terminated by hydrogen atoms at each corner. [b] The shift is defined as the difference of the calculated vibration with the 3697 cm^{-1} vibration for complex **III**.

Notes and references

† *Computational details*: calculations are based on the density functional theory (DFT)[11] as implemented in the Dgauss program (version 4.0) produced by Oxford Molecular Ltd.[12] A generalised gradient approximation to the exchange (Becke)[13] and correlation (Lee, Yang and Parr)[14] was used, and applied self-consistently. The Gaussian basis sets used are of double-zeta quality and include polarisation functions for all atoms (DZVP2).[15] A second set of basis functions, the fitting basis set, is used to expand the electron density in a set of single-particle Gaussian-type functions. All geometry optimisations were carried out fully relaxed, so as to avoid introducing unnatural strain in the molecules. The second derivatives are calculated analytically in the harmonic approximation, giving a good approximation to compute vibrational spectra.

Coupling of acid–base and redox functions in mixed sulfide monolayers on gold

Marcel W. J. Beulen, Frank C. J. M. van Veggel* and David N. Reinhoudt*

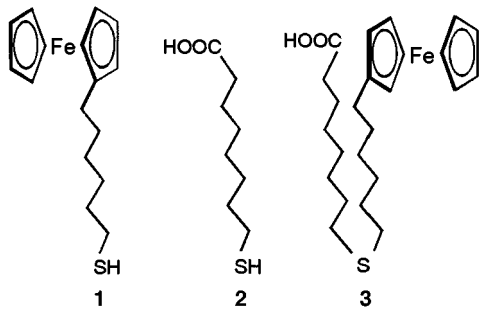
Laboratory of Supramolecular Chemistry and Technology, and MESA Research Institute, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands. E-mail: d.n.reinhoudt@ct.utwente.nl

Received (in Liverpool, UK) 15th December 1998, Accepted 2nd February 1999

A mixed acid-ferrocene self-assembled sulfide monolayer on gold shows a pH-dependent electrochemical response by through-space communication between the receptor and ferrocene readout unit.

Self-assembled monolayers on gold show great promise for a variety of applications.[1] Recently, we reported the electrochemical detection by electrochemical impedance spectroscopy of the selective complexation of alkali and alkaline-earth cations (Na^+_{aq}/K^+_{aq} > 100) by self-assembled monolayers of crown ethers.[2] The advantage of electrochemically-active (*e.g.* ferrocene) monolayers is that the redox signal can be used as an internal readout.[1b] Mixed ferrocene-thiol/alkanethiol monolayers form complexes with calix[6]arene, and β- and γ-cyclodextrin from aqueous solution.[3] Rojas and Kaifer reported that the interaction of catechol or indole with a mixed monolayer of thiolated paraquat and decanethiol gives a cathodic shift of the redox potential.[4] A more general electrochemical detection of electrochemically-*inactive* compounds would be possible by decoupling the redox center and the receptor.[5] Complexation by the receptor in close proximity of the redox center should change the redox properties. Here we describe such a system in which protonation and deprotonation of a carboxylate group is detected *via* a ferrocene readout unit.

This concept was first studied in a mixed monolayer of ferrocene-thiol **1** and acid-thiol **2**[6,7] because it is known that



ferrocene monolayers are pH-independent.[8] Mixed monolayers were prepared from a solution containing a 1 : 3 ratio of ferrocene-thiol **1** and acid-thiol **2**.[9] The adsorbed monolayer has about half of the surface covered by ferrocene-thiol and the other half by acid-thiol (pure Fc-**1** monolayer: Q = 19.5 μC;[10] mixed Fc-**1**/acid-**2** SAM: Q = 8.6 μC). Fig. 1 shows the redox signal for the system at pH 1 and 11.[11] At high pH deprotonation of the acid group introduces a negative charge in the monolayer which stabilizes the ferrocenium ion and this results in a cathodic shift of the redox signal. The pH can be switched backward and forward leading to a small (around 10%) loss in ferrocene signal over a large number of measurements at different pHs, indicating a fairly stable system. Reductive desorption of the monolayer occurs at more cathodic potentials.[12] The cyclic voltammogram at high pH shows two very broad peaks: part of the ferrocene centers is responsive to the pH, the other part is not. Apparently, not all ferrocenes experience the same influence of deprotonation of the acid function. This is an indication of an inhomogeneous monolayer.[13]

This problem of inhomogeneity was circumvented by covalently linking the two components, which is very simply achieved in a mixed *sulfide* like **3**.[14] With this molecule, domain formation is impossible and the covalent attachment forces a 1 : 1 ratio of the binding site and the redox center. This is one of the very few examples of a monolayer adsorbate with multiple functional units.[15] We prepared monolayers of sulfide **3** that were characterized by wettability studies, X-ray photoelectron spectroscopy (XPS), time-of-flight secondary ion mass spectrometry (TOF-SIMS) and electrochemistry. Contact angles with water indicated a surface with moderate polarity and the hysteresis between the advancing and receding angle shows a disordered monolayer ($\theta_{adv/rec}$ [H_2O]: 64–20). XPS measurements of the monolayer show all the elements of the adsorbate (Fe, C, O, and S) in fair correspondence with the expected relative ratios (C : S ratio/calc. : found = 32 : 1/31 : 1). In the positive scan of the TOF-SIMS measurements the peaks for M^+ (444) and $[M + Au + H]^+$ (642) give further evidence that sulfides adsorb without C–S bond breaking on gold.[16] Electrochemical characterization showed all the characteristics of electrochemically-active monolayers, *e.g.* a linear dependence of the redox current on the scan rate. Calculation of the ferrocene charge (4.5 μC) indicates a loosely-packed monolayer, by comparison with the charge related to the pure ferrocene-thiol **1**, and mixed ferrocene-thiol **1**/acid-thiol **2** monolayers described above. The relatively high hysteresis found in the wettability studies and the moderate ferrocene coverage obtained from cyclic voltammetry confirm our previous finding[11a] that sulfides that are connected by one attachment point to gold, forming loosely-packed monolayers.[17]

The electrochemical response of the sulfide **3** monolayer is strongly influenced by the pH of the electrolyte solution (Fig. 2). The redox signal shifts cathodically but hardly broadens. This latter phenomenon is consistent with a homogeneous monolayer. These cyclic voltammograms reveal the communication between the components of the mixed sulfide monolayer, *i.e.* the redox unit senses the protonation and

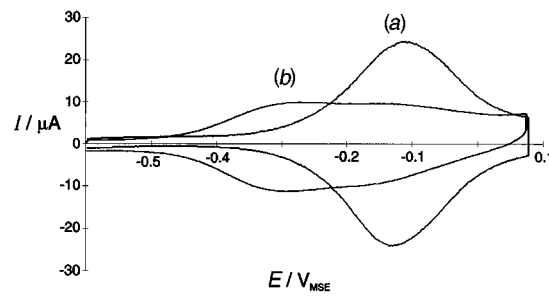


Fig. 1 Electrochemical response of a mixed ferrocene-thiol **1**/acid-thiol **2** monolayer. (*a*) pH 1, 0.1 M $HClO_4$; (*b*) pH 11, 0.1 M $NaClO_4$ + 1 mM NaOH [0 V_{MSE} = +0.61 V_{NHE}].

deprotonation of the carboxylate group. Titration with mixtures of different pH ($HClO_4$, $NaClO_4$, and NaOH) shows a strong dependence of the redox potential on the pH (Fig. 3).[18] With increasing pH values the carboxylates stabilize the ferrocenium state of the redox couple, and as a consequence the redox potential shifts cathodically. The ferrocene response curve shifts over a large pH window. It is known that the pK_a value for organic acids which in solution is about 3-4, increases for well-packed monolayers to 6–7.[19] The loose packing of monolayers of sulfides using one attachment point can result in a more exposed acid function, which will have a lower pK_a, more comparable to the solution value of 3–4. Furthermore, it is important to note that Fig. 3 is not the titration curve of the acid function in the monolayer, but the response of a complex multicomponent system to changes in the pH of the electrolyte solution. The electrochemical oxidation of ferrocene to ferrocenium might change the *apparent* pK_a of the acid function, rendering the communication mutual. A similar effect was recently described by Corn *et al.*, who showed by SPR measurements that the adsorption of the positively charged avidin on an acid-terminated monolayer shifted the apparent pK_a to lower values.[20]

A self-assembled monolayer consisting of receptor and readout units can be used to detect electrochemically-inactive compounds electrochemically. Here we have shown the pH-dependent response of mixed acid–ferrocene monolayers. At the moment we are investigating the effect on the redox signal of the ferrocene unit of the binding to the carboxylate groups of different cations. Preliminary results indicate that the binding properties of $Et_4N^+_{aq}$, and Na^+_{aq} or K^+_{aq} to the carboxylate groups (low and high binding, respectively) are reflected in the cyclic voltammograms.

Akzo Nobel Central Research is gratefully acknowledged for the XPS and SIMS measurements and CW-NWO and STW (project number 349-3332) for financial support.

Reactions of homoallylstannanes with carbon electrophiles: stereoselective cyclopropylmethylation based on the γ-effect of tin

Masanobu Sugawara and Jun-ichi Yoshida*

Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Kyoto 606-8501, Japan. E-mail: yoshida@sbchem.kyoto-u.ac.jp

Received (in Cambridge, UK) 7th January 1999, Accepted 29th January 1999

Homoallylstannanes reacted with carbon electrophiles such as acetals, acid chlorides and aldehydes in the presence of Lewis acids to give the cyclopropylmethylated products with high stereoselectivities.

Enormous advances have been made in the study of the β-effect of silicon, and a number of reactions have been developed based on this effect and utilized for a variety of synthetic applications.[1] The γ-effect of silicon, however, seems to be less effective and has not been embraced as a viable principle in organic synthesis.[2] On the other hand, studies on the γ-effect of tin revealed the effectiveness of this effect[3] and have uncovered a rich variety of synthetic applications in recent years.[4] Previously, we have reported that the γ-effect of tin is stronger than the β-effect of silicon in intramolecular competition and that cationic cyclopropanation of 'tin carbenoids' with alkenes can be achieved based on the γ-effect of tin.[5] We have also been interested in the intermolecular competition between the γ-effect of tin and the β-effect of silicon. During the course of this study we found a cyclopropylmethylation reaction using homoallylstanannes that would be useful in organic synthesis.[6] We report here the preliminary results of these studies.

The intermolecular competition between the γ-effect of tin and the β-effect of silicon was examined using an electrophilic reaction of a homoallylstannane and an allylsilane. Thus, a 1 : 1 mixture of homoallyltributylstannane **2a** and allyltrimethylsilane **3** in CH_2Cl_2 was treated with 1 equiv. of benzaldehyde dimethyl acetal **1a** in the presence of TMSOTf (Scheme 1). Most of **2a** was recovered unchanged and only allylated product **5** was obtained in 87% yield. The cyclopropylmethylated product **4a** was not detected.

This result indicates that **3** is much more reactive than **2a** toward the oxonium ion ($PhCH{=}OMe^+$) generated from **1a** and suggests that the β-effect of silicon is stronger than the γ-effect of tin in intermolecular competition. In other words, the β-silyl group activates the carbon–carbon double bond more effectively toward the electrophilic reaction than the γ-stannyl group. This difference can be explained in terms of molecular orbital considerations. In the case of allylsilane **3**, the energy level of the π orbital of the carbon–carbon double bond is increased by interaction with the neighboring carbon–silicon σ orbital (σ–π interaction).[7] Therefore, the reactivity toward electrophiles is increased. In the case of homoallylstannane **2a**, however, the energy level of the π orbital should to be similar to that for normal carbon–carbon double bonds, because the interaction between the π orbital of the carbon-carbon double bond and the carbon–tin σ orbital seems to be very weak, due to the flexibility of the conformation.[8]

The next question which naturally emerged in our mind is whether the reactivity of the carbon–carbon double bond of the homoallylstannane is the same as those of simple terminal alkenes. Thus, we examined the intermolecular competition between the homoallylstannane and normal terminal alkenes. A 1 : 1 mixture of homoallylstannane **2a** and dodec-1-ene **6** was allowed to react with **1a** in the presence of TMSOTf. Although it required a slightly higher temperature, the reaction of **1a** and **2a** took place to give the cyclopropylmethylated product **4a** in 60% yield. Most of **6** was recovered unchanged (Scheme 2).

This result indicates that the homoallylstannane is definitely more reactive toward electrophiles than terminal alkenes. Therefore, there seems to exist some interaction between the carbon–tin σ orbital and the π orbital of the carbon–carbon double (**B** in Fig. 1) even if it is not particularly strong. This led us to a new aspect of the γ-effect of tin.

The following mechanism seems to be plausible. The oxonium ion is generated by the reaction of acetal **1a** with TMSOTf and then adds to the carbon–carbon double bond of homoallylstannane **2a** to give the γ-carbocation to tin. The facile γ-elimination of tin to form a cyclopropane ring takes place to give the final product **4a**.

The successful reaction of homoallylstannane **2a** and acetal **1a** prompted us to develop new reactions of homoallylstanannes with carbon electrophiles. As shown in Table 1, acetals, acid

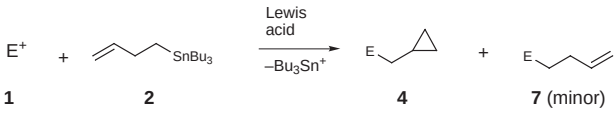
Table 1 Reactions of homoallylstannanes with carbon electrophiles in the presence of Lewis acids[a]



1 **2** **4** **7** (minor)

Electrophile	Homoallylstannane	4	Yield (%) 4 (*erythro* : *threo*)[c]	7
 **1a**[b]	 **2a** (1.3 equiv.)	 **4a**	87	<1[d]
 **1b**	**2a** (1.0 equiv.)	 **4b**	87	12
 **1c**	**2a** (1.2 equiv.)	 **4c**	76	7
1c	 **2b** (1.3 equiv.)	 **4d**	86	10
1c	 **2c** (*E*:*Z* = 88:12) (1.1 equiv.)	 **4e**	87 (97:3)	7
 **1d**	**2c** (1.1 equiv)	 **4f**	83 (>99:1)	3[d]
 **1e**	**2c** (1.1 equiv.)	 **4g**	87 (97:3)	5[d]
1e	 **2d** (*E*:*Z* = 1:>99) (1.2 equiv.)	**4g**	78 (68:32)	<1[d]

[a] Reaction conditions; 0.50 mmol of **1**, 1.0–1.3 equiv. of **2** and 1.1 equiv. of $TiCl_4$ in CH_2Cl_2 (1.8 ml) at −78 °C for 3 h. [b] TMSOTf (1.05 equiv.) was used instead of $TiCl_4$, at −40 °C, 3 h. [c] Determined by GLC. [d] The homoallylated product **7** was not fully characterized.

halides and aldehydes were found to be effective as carbon electrophiles. In the case of acid halides and aldehydes, $TiCl_4$ was more effective than TMSOTf. The corresponding cyclopropylmethylated products **4** were obtained in good yields together with small amounts of homoallylated by-products **7**.[2]

The diastereoselectivity of the present reaction is remarkable. For example, the *erythro* product was obtained selectively (97 : 3) starting from **1e** and (*E*)-pent-3-enyltributylstannane (*E* : *Z* = 88 : 12).[9] Presumably, the addition to the carbonyl group took place in an antiperiplanar fashion.[10] The reaction of **1e** and (*Z*)-pent-3-enyltributylstannane (*E* : *Z* = 1 : 99), however, resulted in a decrease of the selectivity (68 : 32). The low selectivity of the *cis* isomer might be explained in terms of the competition between the antiperiplanar transition state and the synclinal transition state.[11]

In summary, intermolecular competition revealed that a β-silyl group activates carbon–carbon double bonds toward electrophilic reactions more effectively than a γ-stannyl group. It was also found that the γ-stannyl group activates the carbon–carbon double bond slightly more effectively than alkyl groups. We also found that the reactions of homoallylstannanes with carbon electrophiles such as acetals, acid halides and aldehydes took place smoothly in the presence of Lewis acids. These reactions serve as a stereoselective method for cyclopropylmethylation of carbonyl compounds. Further mechanistic studies on the evaluation of the γ-effect of tin and its synthetic applications are under investigation.

Efficient synthesis of non-natural ganglioside (pseudo-GM3) and fluorescent labelled lysoGM3 on the basis of polymer-assisted enzymatic strategy

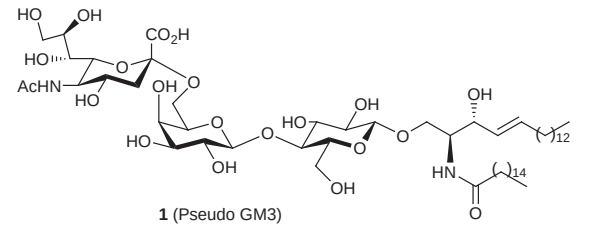
Kuriko Yamada, Susumu Matsumoto and Shin-Ichiro Nishimura*

Laboratory for Bio-Macromolecular Chemistry, Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan. E-mail: nishimura@polymer.sci.hokudai.ac.jp

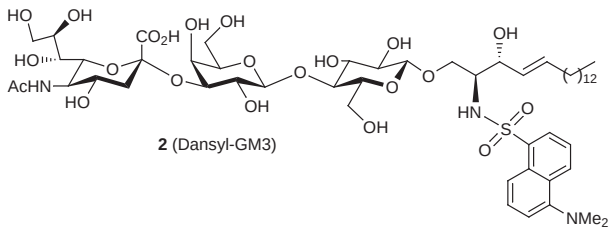
Received (in Cambridge, UK) 14th December 1998, Accepted 12th January 1999

The versatility of polymer-assisted enzymatic synthesis of non-natural and biologically significant glycolipid derivatives was demonstrated by constructing pseudo-ganglioside GM3 1 having the trisaccharide sequence Neu5Acα-(2→6)Galβ(1→4)Glc and a fluorescent labelled lysoGM3 2.

Cell surface glycoconjugates such as glycoproteins and glycolipids are an important class of biomolecules providing a great deal of significant information on cell–cell interactions.[1] The advent of efficient and practical methods for glycoconjugate synthesis is urgently required. Enzymatic synthesis of carbohydrates with glycosyltransferases[2] and glycosidases[3] has been recognised as a promising practical alternative to chemical synthesis. Recently, we found an efficient synthetic strategy for glycoconjugates based on novel water-soluble polymer supports with specific linkers.[4–7] It was suggested that polymer **8** bearing ceramide-mimetic linkers might yield a practical procedure for the construction of natural sphingoglycolipid GM3.[6] In addition to the synthesis of naturally occurring gangliosides, our attention is now directed toward the applicability of this strategy to the synthesis of non-natural and biologically significant glycolipid derivatives. Here we report efficient syntheses of pseudo-ganglioside GM3 **1** having the



1 (Pseudo GM3)

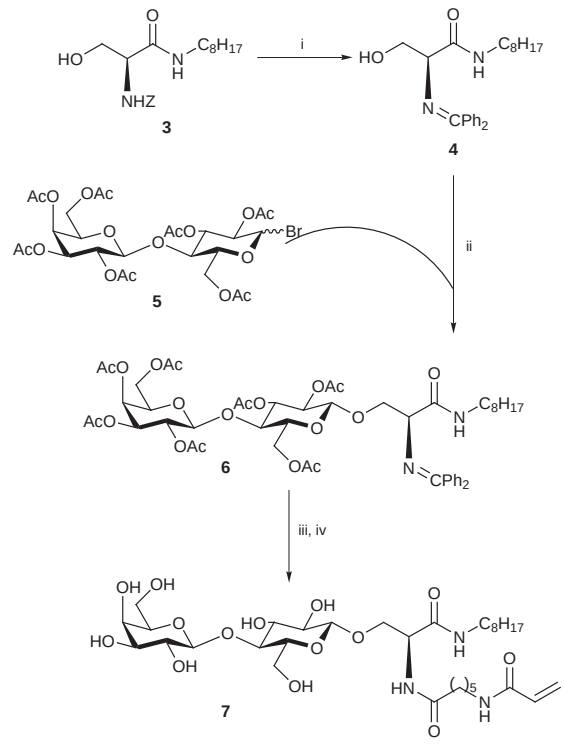


2 (Dansyl-GM3)

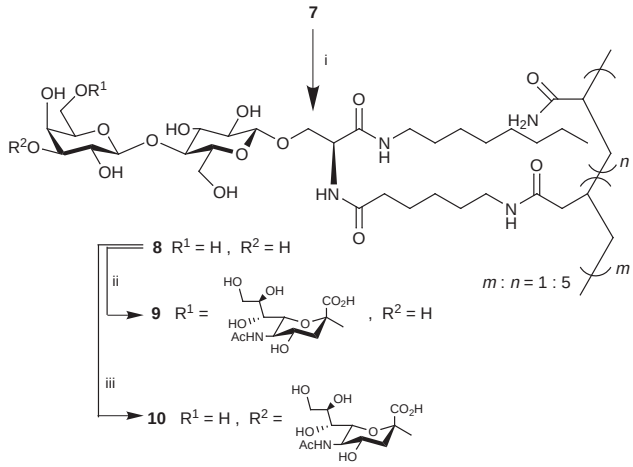
trisaccharide sequence Neu5Acα(2→6)Galβ(1→4)Glc and a fluorescent-labeled lysoGM3 **2** *via* enzymatic manipulations on the polymer support **8**.

Scheme 1 indicates an improved synthetic route to key glycomonomer **7**.[6] The nucleophilicity of the hydroxy group of glycosyl acceptor **4**,† *N′*-octyl-*N*²-diphenylmethylene-L-serinoamide, to the anomeric carbon of a glycosyl donor **5** was drastically enhanced by employing a Schiff base-type protective group[8] at the amino group, and the yield of the glycoside **6**†‡ was improved from 48 to 82%. Removal of the diphenylmethylene group by hydrogenation, subsequent coupling with 6-(*N*-acrylamido)hexanoic acid and *O*-deacetylation proceeded smoothly and afforded compound **7** in 78% yield from **6**. Water-soluble polymer **8** prepared from **7** by the usual radical copolymerisation with acrylamide was employed for further sugar elongation and subsequent transglycosylation reactions, as shown in Scheme 2.

In the previous report,[6] it was demonstrated that rat recombinant α(2→3)-(N)-sialyltransferase (Calbiochem®), known as an enzyme catalysing sialylation reactions of glycoprotein biosynthesis in nature, successfully transferred sialic acid residues to the glycolipid-mimetic polymer **8**. In order to evaluate the versatility of this procedure in other glycosyltransferases, we decided to synthesise non-natural ganglioside isomer **1** (pseudo GM3) utilising rat liver α(2→6)-(N)-sialyltransferase (Boehringer Mannheim). As anticipated, this enzyme also recognised polymer **8** as a 'glycoprotein-mimetic polymer' rather than as 'glycolipid-type clusters'. Novel glycopolymer **9** carrying trisaccharide Neu5Acα-(2→6)Galβ(1→4)Glc was obtained in quantitative yield and this non-natural trisaccharide moiety was subsequently transferred from polymer **9** to C16 ceramide using ceramide glycanase (CGase, Boehringer Mannheim) to afford the target glycolipid **1**† in 60% yield (11 mg) from **9** (Scheme 3). This result shows clearly that CGase exhibits broad substrate



Scheme 1 *Reagents and conditions* : i, Pd-C, H_2 gas, MeOH, 25 °C, 6 h, then $Ph_2C{=}NH$ (1.0 equiv.), CSA (0.1 equiv.), CH_2Cl_2, 25 °C, 24 h, 82.3% from **3**; ii, lactosyl bromide **5** (1.2 equiv.), 4 Å molecular sieves, AgOTf (1.2 equiv.), CH_2Cl_2, 0 °C, 15 h, 82.0% from **4**; iii, Pd-C, H_2 gas, MeOH, 25 °C, 2 h, then 6-(*N*-acrylamido)hexanoic acid (1.1 equiv.), 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (1.1 equiv.), benzene, EtOH, 25 °C, 24 h, 78.0% ; iv, NaOMe (0.4 equiv.), THF, MeOH, 25 °C, 1 h, 100 % from **6**.



Scheme 2 *Reagents and conditions*: i, acrylamide monomer (5.0 equiv.), TMEDA (2.4 equiv.), ammonium persulfate (APS) (0.96 equiv.), DMSO, H_2O, 50 °C, 24 h, 92.0% from **7**; ii, CMP-Neu5Ac (1.2 equiv. for lactose), bovine serum albumin (BSA), calf intestinal alkaline phosphatase (CIAP) (20 units), 50 mM sodium cacodylate buffer (pH 7.40), $MnCl_2$, NaN_3, α-2,6 sialyltransferase (0.1 units, 2.7 munits per 1.0 μmol acceptor), 37 °C, 48 h, 100%; iii, CMP-Neu5Ac (1.2 equiv. for lactose), BSA, CIAP (20 units), 50 mM sodium cacodylate buffer (pH 7.40), $MnCl_2$, Triton CF-54, α-2,3 sialyltransferase (0.3 units, 8.0 munits per 1.0 μmol acceptor), 37 °C, 72 h, 100%.

specificity of transglycosylation with regard to the carbohydrate structure of glycolipids.

Next, our interest focused on the substrate specificity of the transglycosylation reaction carried out by CGase against glycosyl acceptor substrates,[9] as it will significantly influence the versatility of the present technology in the combinatorial synthesis of 'libraries of glycolipids and their mimetics'. We selected D-sphingosine (*trans*-D-erythro-2-amino-4-octadecene-1,3-diol) as a potential candidate for the synthesis of functional sphingoglycolipid derivatives, since the amino group of D-sphingosine is convenient for further modification. We were pleased to find that CGase transferred the GM3 oligosaccharide [Neu5Acα(2→3)Galβ(1→4)Glc], to the primary hydroxy group of D-sphingosine from the polymer **10** and intermediate **11** was directly dansylated to afford a fluorescent-labelled lysoGM3 **2**† in 50% yield (12 mg) from compound **10**.

In conclusion, we have demonstrated the versatility of water-soluble polymer supports in the enzymatic synthesis of non-natural and biologically important glycolipid derivatives. It should be noted that this synthetic strategy should greatly accelerate efficient combinatorial synthesis of libraries of glycolipids varying both in the carbohydrate and in the lipid portions.

4 + 3 and fluorinative 4 + 3 cycloadditions of alkyne 1,4-diether dicobalt complexes

Manoj M. Patel and James R. Green*

Chemistry and Biochemistry, School of Physical Sciences, University of Windsor, Windsor, Ontario, Canada N9B 3P4. E-mail: jgreen@uwindsor.ca

Received (in Corvallis, OR, USA) 8th December 1998, Accepted 3rd February 1999

The $BF_3{\cdot}OEt_2$ mediated reactions between alkynyl diether hexacarbonyldicobalt complexes 1 and stannylsilanes 3 or 7 afford cycloheptenyne cobalt complexes 4 or fluorocycloheptyne complexes 8 depending upon the conditions of reaction.

The synthesis of seven-membered carbocyclic compounds is of much interest, due to their presence in a wide variety of natural products and due to the relative paucity of good ways to make the system.[1] The most conceptually attractive routes to the preparation of cycloheptanes are the 4 + 3 cycloaddition approaches, by virtue of the rapid assembly of the ring system and their superficial analogy to [4 + 2] cycloaddition reactions. A number of these cycloadditions have been reported,[2] most extensively those employing oxyallyl cations with dienes[3] and those condensing bis(trimethylsilyl) enol ethers with 1,4-diones.[4]

A potentially valuable variant of the 4 + 3 cycloaddition would be the reaction of sequentially formed cations from alkynyl diether complexes **1** with allyldimetal equivalents **2** or

3. The resultant cycloheptyne complexes **4** are known to have good thermal stability,[5,6] and possess an (alkyne)hexacarbonyldicobalt function capable of synthetically important substitution[7] and cycloaddition reactions.[8] This possibility was realized by Takano's group, but they were unable to induce a Lewis acid mediated condensation between disilane **2** and **1a** to form either a cycloheptyne complex, or even useful yields of acyclic products.[9] Recent work in our laboratory has demonstrated the unexpected reactivity pathway of **2** with propargylcobalt cations bearing remote carbonyl functions, and the superiority of stannylsilanes **3** in the formation of acyclic allylation products **5**.[5]† In view of this, we have decided to investigate the viability of 4 + 3 cycloadditions between **1** and **3**.

Addition of 5 equiv. of $BF_3{\cdot}OEt_2$ to a 0 °C CH_2Cl_2 solution of **3a** and **1a** (10^{-1} M) over a period of 0.5 h gave a small amount of cycloadduct **4a** (*ca.* 10%), along with several acyclic allylation and diallylation products. Significantly improved yields of the cyclization product could be realized with methyl ether **1b** and ethyl ether **1c**, and with the triethylsilyl-substituted allyltin **3b**. Under the strictly analogous conditions, these reagent combinations afforded cycloheptenyne complex **4a** in 62 and 72% yields, respectively.

Use of reagent **3b** was investigated under these conditions with substituted alkynyl diether complexes. Methyl substituted **1d** and phenyl substituted **1e** gave cycloheptenyne complexes **4b** and **4c** as regioisomeric double bond mixtures with **4b′** (**4b** : **4b′** = 2.2 : 1) and **4c′** (**4c** : **4c′** = 1.7 : 1), respectively. In both cases, the predominant regioisomer obtained implies the preferential initial formation of the *less* substituted cation **6a**

over **6b**. Although a kinetic effect cannot be ruled out at this time, these results are consistent with the reported greater stability of less substituted propargylcobalt cations, as demonstrated by the pK_{R^+} measurements of Nicholas.[10] Dimethyl-substituted substrate **1f** gave the corresponding cycloheptenyne complexes **4d** in a more modest yield, in a 4.0 : 1 mixture of *trans* : *cis* diastereomers.‡ Finally, the isobutene dianion equivalent **7a**[11] reacted with **1c** to give methylenecycloheptyne complex **4e** in 53% yield.

Attempts were made to improve on the regiochemical selectivity for **4b** and **4c** by incorporating a bulkier ether

function at the more substituted propargylic site. To this end, TBDMS ethers **1g** and **1h** and isopropyl ethers **1i** and **1j** were tested in their reactions with **3b**. Substantial improvements in regioselectivity were observed. Each of these cases resulted in the formation of the 6-substituted isomers (**4b** and **4c**) to the exclusion of the 3-substituted isomers (**4b′** and **4c′**); chemical yields were higher in both systems with the isopropyl ethers.

These cycloadditions were found to take a slightly different pathway under altered reaction conditions. Very slow addition of 5 equiv. of $BF_3{\cdot}OEt_2$ (over 12 h) to a highly dilute CH_2Cl_2 solution of **1c** and **3b** (10^{-3} M) at 0 °C resulted in the formation of fluorinated cycloheptyne complex **8a** (70% yield) to the exclusion of cycloheptenyne complex **4a**. Compound **8a** could also be obtained by rapid $BF_3{\cdot}OEt_2$ addition at 10^{-1} M concentrations, but the yield of this compound (57%) was inferior.

This fluorinative 4 + 3 cycloaddition was also found under the slow addition, high dilution conditions with the substituted diethers **1d**–**f**, giving **8b**–**d** as separable diastereomeric mixtures.[12] In monomethyl substituted **8b** and phenyl substituted **8c**, the *trans* isomers were found to predominate in a *ca.* 2.5 : 1 ratio. Stereoisomer assignments were based on the relatively upfield ^{1}H NMR chemical shift (in *cis*-**8b**) of the axial H atom geminal to fluorine (δ 4.55 in *cis*-**8b** *vs.* δ 5.11 in *trans*-**8b**), the larger vicinal coupling constants for that axial H atom ($J_{ax\text{-}ax}$ (average) = 10.9 Hz in *cis*-**8b** *vs.* $J_{eq\text{-}eq}$ (average) = 7.2 Hz in *trans*-**8b**), and a preferred chair conformation for the complexed cycloheptyne ring.[13]§¶ Dimethyl substituted **8d** was also formed as a mixture of three diastereomers, in a *trans, trans* : *cis, cis* : *trans, cis* ratio of (1.9 : 1 : 0.14). Notably, the ratio of the two diastereomers with *cis* methyl groups to the one with the *trans* orientation of methyl groups corresponds to 21 : 1. The reasons for the preferential formation of *cis*-dimethyl isomers of **8d** in the fluorocycloheptyne series, as opposed to the preferential formation of *trans*-dimethyl **4d** in the cycloheptenyne series, are not understood at this time. Finally, **1c** reacted with isobutene dianion equivalent **7b** under these conditions to afford tertiary fluoride **8e** in fair yield (48%).

In summary, rapid access into cycloheptynecobalt ring systems has been found to occur *via* both fluorinative- and non-fluorinative versions of a 4 + 3 cycloaddition reaction. Work on the preparation of more diversely substituted versions of these compound classes, and studies on the use of these compounds in the preparation of 5,7- and 6,7-ring systems, are in progress and will be reported in due course.

We are grateful to NSERC (Canada) for support of this research.

Notes and references

† These allylation products **5** may also be converted into cycloheptenyne complexes **4** (ref. 5).

‡ Diagnostic for the ^{1}H NMR based assignment of *trans*-**4d** as the major diastereomer is the existence of a 1.7% integrated NOE of the absorption for the pseudoaxial methylene proton (δ 2.00) upon irradiation of the allylic methine resonance (δ 3.75), and a 2.7% integrated NOE of the absorption for the allylic methine proton upon irradiation of the pseudoaxial methylene resonance.

§ MM2 Calculations (PC Model®) predict $J_{ax\text{-}ax}$ values of 11.8 and 11.8 Hz for the proton geminal to fluorine in *cis*-**8b**, and $J_{eq\text{-}eq}$ values of 7.0 and 7.1 Hz for the analogous proton in *trans*-**8b**.

¶ A 4.3% NOE integrated enhancement of the absorption for the propargylic methine H atom (δ 2.89) upon irradiation of the δ 4.55 resonance in *cis*-**8b** also supports the assignment of an axial orientation for these two protons.

Dis-assembling lithium amide ladder structures: new insight through the structure of [{[$PhCH_2N(H)Li]_2$·thf}$_\infty$], a polymer of $(NLi)_2$ planar rings connected by thf-bridged $(NLi)_2$ butterfly junctions

William Clegg,[a] Stephen T. Liddle,[a] Robert E. Mulvey*[b] and Alan Robertson[b]

[a] *Department of Chemistry, University of Newcastle, Newcastle upon Tyne, UK NE1 7RU*

Received (in Cambridge, UK) 14th January 1999, Accepted 10th February 1999

One can visualise how the novel hemi-solvated polymeric ladder structure of the title compound would dis-assemble at its long, weak cisoid-$(NLi)_2$ butterfly junctions on further solvation, to release transoid-$(NLi)_2$ planar dimeric rings, the expected product of full solvation.

While our understanding of the complicated bond-making and bond-breaking processes involved in lithium amide aggregational chemistry[1,2] has deepened considerably in recent years primarily through the 'ring-laddering' principle,[3] it remains far from comprehensive. Most conspicuously, at the time of writing, there is still no example of a crystallographically characterised polymeric ladder structure of a pure (*i.e.*, donor-free) lithium amide. Mono-lithiated ethylenediamine [{$H_2NCH_2CH_2N(H)Li$}$_\infty$][4] does exist as an infinite sinusoidal wave-shaped ladder, but its NH_2 amine arms function as internal donor ligands. There is also little tangible information hitherto on the coordination chemistry taking place when coordinating solvent molecules approach a long (high oligomeric/polymeric) ladder framework. However, light has been shed on subsequent processes, specifically on the possible sequence of steps involved when lower oligomeric ladders break down to tetrasolvated $(NLi)_2$ ring dimers on gradually increasing the number of solvent ligands in the system.[5] In contrast, here, we report an unique example of a ladder structure which stays polymeric in the presence of coordinating thf molecules, in the hemi-thf complex of lithium benzylamide [{[$PhCH_2N(H)Li]_2$·thf}$_\infty$] **1**. Attention is drawn to the pattern of solvent ligation in **1**, which is without precedent in any previously reported lithium structure, amide or otherwise; and to how this extends our knowledge of the dis-assembling process in lithium amide ladder chemistry. The new structure also provides a contrast with that of the polymeric phosphide [{CyP(H)Li·thf}$_\infty$][6] which has conventional, terminal thf solvation.

Regarding the synthesis of **1**, it is a trivial matter to abstract one NH proton from benzylamine by the action of *n*-butyllithium provided a routine inert-atmosphere protocol is followed. However, obtaining a pure crystalline thf complex of the lithium benzylamide so produced is more challenging. Only pink slurries could be prepared on subjecting a 1 : 1, Bu^n-Li : $PhCH_2NH_2$ mixture with various amounts of thf (1, 2 or 6 molar equivalents). Alternatively, when excess amine was employed (*e.g.* in a 1 : 2 : 1 mixture), the known amide–amine complex [{[$PhCH_2N(H)Li]_2$·H_2NCH_2Ph}$_\infty$][7] **2** preferentially crystallised from solution. Success eventually came from a 1 : 2 : 2 mixture in hexane–toluene solution, with **1** forming as colourless crystals,† though the product was still contaminated with crystals of **2**. This product is only partially soluble in arene solvents. ^{1}H NMR spectra in d_6-benzene solution always show both benzylamine and thf molecules (in variable and inconsistent amounts) as well as *smaller* amounts of amide anions. Thus it can be reasoned that the polymeric ladder framework easily loses donor ligands, which escape into solution leaving behind a solid residue of unsolvated lithium benzylamide. In turn, the excess donor molecules in solution can dissolve a portion of this solid to generate a soluble, but weak oligomeric solvate (possibly a tetrasolvated dimer, see later). This notion of a weak solution complex is consistent with the fact that while lithium benzylamide is completely soluble in concentrated benzylamine or thf solutions, only polymeric solids are deposited from such solutions.

Pure unsolvated lithium benzylamide almost certainly has an infinite ladder structure with an alternating cisoid–transoid pattern of laterally fused $(NLi)_2$ rings. This deduction is based on the evidence that the same basic ladder framework is found in both **1** and **2**. But, of particular interest here, is the unique manner in which the solvent ligands in **1** attach themselves to this ladder framework. Spanning a four-rung section of the ladder, the central Li–N–Li(a)–N(a) ring is solvent free, while those adjacent to it, Li–N–Li(b)–N(b) and Li(a)–N(a)–Li(c)–N(c) are capped on one side by μ-bonding thf ligands, which alternate above and below the ladder plane (Fig. 1).‡ The first mentioned ring is transoid and strictly planar by virtue of its centrosymmetry. In contrast, the other two are cisoid and butterfly shaped (deviations from planarity ± 0.326 Å), with N···N hinges (folding angle 119.4°) and Li wingtips, due to the pull exerted by thf ligands, which lie on twofold rotation axes passing through oxygen atoms. As a result of symmetry, there are only three unique N–Li bond lengths in **1**: ladder edges are short [2.046(3) Å] and long [2.098(3) Å] within the non-solvent-bridged and solvent-bridged $(NLi)_2$ rings respectively; the ladder rungs are all equivalent and have an intermediate length [2.087(3) Å]. The O–Li bond lengths are also equivalent [2.146(4) Å] reflecting the symmetrical fit of the thf ligand over the puckered $(NLi)_2$ ring face.

Consideration of the architecture and dimensions of **1** leads to a more complete picture of the multistepped, ladder dis-

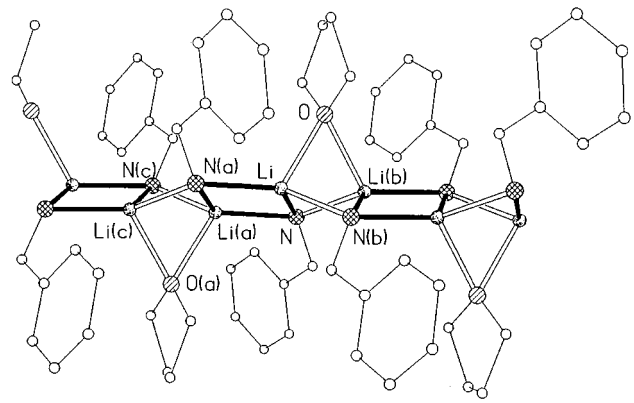

Fig. 1 Polymeric structure of **1** with atom-labelling. Hydrogen atoms are omitted for clarity. Key dimensions (Å and °): Li–N 2.087(3), Li–N(a) 2.046(3), Li–N(b) 2.098(3), Li–O 2.146(4), Li···Li(a) 2.440(6), Li···Li(b) 2.230(6), N–Li–N(a) 107.64(13), N–Li–N(b) 103.83(14), Li–N–Li(a) 72.36(13), Li–N–Li(b) 64.38(14), Li–O–Li(b) 62.60(17).

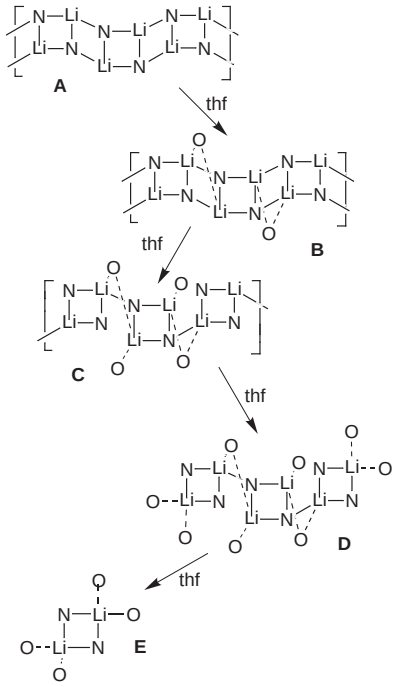

Scheme 1

assembling process than that previously outlined.[8] In particular, they provide valuable new insight into the possible early steps involved. These are included in the full sequence of steps, as we now perceive them, in Scheme 1. **A** represents the infinite ladder structure, the framework of which provides the foundation of both **1** and **2**. **B** represents the new structure **1**. This is a key structural finding as previously it was assumed that the attachment of donor ligands would automatically encourage ladder fragmentation (oligomerisation); but in **B** the polymeric arrangement is retained. Noting that lithium amide polymers are generally insoluble in arene solvents, the **A→B** transformation also has implications for the coordination chemistry developing at the solid–solution interface which eventually leads to the dissolution of the amide in an arene–thf mixture. The next transformation, **B→C**, takes place on the addition (or involvement) of more thf molecules. From the crystal structure of **1** the weakest points of the $(NLi)_\infty$ ladder framework are those bridged by the thf ligands. Logically, therefore, as the incoming thf molecules approach the metal centres in **C** (note that they all occupy identical steric environments), one of the longer, weaker N–Li edge bonds of the $(NLi)_2$ butterfly-shaped rings will cleave. This leaves the shorter, stronger bonds of the adjacent $(NLi)_2$ rings (*i.e.* those in **1** unbridged by the thf ligands) intact. The transformation **C→D** should not be regarded as a single step, polymer→oligomer one. It is more likely to be a fragmented process. To elaborate, as the solvation pattern in **C** develops along the polymer backbone, it will undoubtedly lead to increased steric repulsions caused by the presence of both bridging and terminal thf ligands. Hence, not the whole of **C**, but sections of it (possibly covering six N–Li rungs) will periodically break away from the remainder of the infinite ladder to form the oligomer **D**. Completing the sequence is the **D→E** transformation, the evidence for which is based on the structural characterisations of $[\{PhN(H)Li\}_6\cdot 8thf]$[8] and $[\{PhN(H)Li\cdot 2thf\}_2]$[9] respectively, as discussed previously. Note that the discrete $(NLi)_2$ rings in the final product **E** can be traced back to the 'unsolvated' $(NLi)_2$ rings in **1**, as both are planar and transoid.

In the specific case of lithium benzylamide, the tetra-thf solvated ring dimer possibly exists in solution. However, steric crowding probably destabilises it (note that the dibenzylamido analogue is only bis-solvated[10]) with respect to **1** which preferentially crystallises from solution. This crystallisation process is in effect the retro-counterpart of Scheme 1, and would be induced by collisions between dimers and concomitant cleavage of some thf ligands.

Finally, note that this ladder dis-assembling pathway should not be considered as all-embracing, as it is likely to be dependent on the particular donor solvent employed.

We thank the EPSRC for supporting this research.

Received (in Basel, Switzerland) 18th January 1999, Accepted 8th February 1999

Polymorphs of the charge transfer salt (bedt-ttf)$_4$[(H_3O)-$Cr^{III}(C_2O_4)_3$]·PhCN [bedt-ttf = bis(ethylenedithio)tetrathiafulvalene] which are either superconducting or semiconducting differ in the spatial distribution of Δ and Λ enantiomers of $[Cr(C_2O_4)_3]^{3-}$ within the unit cell.

Solids built from molecules give chemists the ability to create materials with structural complexities not found in traditional continuous lattice materials. Subtle changes in structure may lead to large differences in collective physical properties such as electrical transport or magnetism. For example, molecular charge transfer salts of the donor bedt-ttf, bis(ethylenedithio)-tetrathiafulvalene, exhibit room temperature electronic ground states as diverse as metallic, wide band gap semiconducting and insulating. Some even display superconductivity.[1] Their transport properties vary with the acceptor anion and different structural modifications of bedt-ttf are possible with the same anion.[2–4] The collective electronic properties of such materials depend crucially on the charge distribution, distances and relative orientations of neighbouring donor molecules in the crystal, *i.e.* on the packing motif. Motifs can be controlled by organisation of the anions, *via* 'docking' of the terminal methylene H atoms of the bedt-ttf into cavities provided by the anions organisation.[5] Anion–cation atomic contacts provide further means of self assembly within the unit cell.

The series of compounds with general formula (bedt-ttf)$_4$[$AM^{III}(C_2O_4)_3$]·PhCN (M = Fe, Cr; A = H_3O^+, K^+, NH_4^+) has been structurally characterised by room temperature and low temperature X-ray crystallography.[6–8] Their conducting and magnetic properties have been determined by single crystal resistivity measurements, SQUID magnetometry and variable temperature electron paramagnetic resonance. One polymorph of the compound with M = Cr and A = H_3O^+ (**I**)[8] has a metal to superconducting transition at T_c = 6.0(5) K. At high temperatures the bulk magnetic susceptibility is dominated by unpaired d electrons associated with the Cr(III) ion (S = 3/2). The Curie–Weiss law is obeyed from room temperature to just above T_c together with a small Pauli contribution as is usual for metallic salts. Below T_c the Meissner effect is observed and this is suppessed by an external field of 40 mT. The point symmetry about Cr is D_3 and so $[Cr(C_2O_4)_3]^{3-}$ exhibits optical isomerism although **I** is prepared from a racemic mixture of the tris(oxalato) starting material and crystallises in an achiral space group, *C*2/*c*. In contrast using enantiomerically pure $[Cr(C_2O_4)_3]^{3-}$ as a starting material we obtain another achiral phase (**II**) with identical stoichiometry to phase **I**† but with strikingly different physical properties. Transport measurements on **II** indicate semiconducting behaviour while no Meissner effect is seen and the magnetic susceptibility can be fitted to a Curie–Weiss law from ambient to low temperatures. The difference in physical properties between **I** and **II** arises from an unprecedented difference between their crystal structures namely a different spatial arrangement of the chiral enantiomers in the unit cell.

In both polymorphs‡ layers of cationic bedt-ttf molecules are interleaved by layers containing $[Cr(C_2O_4)_3]^{3-}$, H_3O^+ and PhCN. Each anionic layer forms a so-called 'honeycomb' lattice with alternate intralayer O (of H_3O^+) and Cr forming an approximately hexagonal network with benzonitrile molecules occupying the hexagonal cavities. The Cr atoms are octahedrally coordinated to three bidentate oxalate dianions, which confers the D_3 site symmetry about each transition metal. The uncoordinated O (oxalate) atoms surround a cavity occupied by H_3O^+. The area of the hexagonal cavities are almost identical and they are filled by a benzontrile molecule with little void space into which the terminal CH_2 groups of the bedt-ttf can 'dock'[5].

Despite identical stoichiometry, the organisation of the bedt-ttf layers is quite different in the two polymorphs: **I** has the so-called β″ packing motif (*C*2/*c* space group) whereas **II** presents a motif which we refer to as pseudo-κ (*Pbcn* space group). Analysis of the pseudo-κ C=C and C–S bond lengths[9] within the central ttf (tetrathiafulvalene) unit indicates that there are two different bedt-ttf molecules with charges close to 0 and +1. The +1 cations occur as face to face dimers and are surrounded by six neutral molecules. Neighbouring dimers are approximately orthogonal as in normal κ phases.[1] In the β″ phase the molecules are arranged into stacks with short S···S distances between them and bond length analysis reveals that all bedt-ttf molecules have similar but not identical positive charges close to +0.5. (Note that the sum of the bedt-ttf charges implies that in both polymorphs the water is present as H_3O^+). In **II** the centroids (centre of the ttf C=C bond) of the neutral molecules describe approximately hexagonal networks where the positively charged dimers lie close to oxalate anions, leading to H-bonding (2.51–3.05 Å) between the terminal ethylene hydrogens and oxygens (oxalate). The neutral bedt-ttf molecules are either positioned over H_3O^+ or close to the solvent.

The difference between the packing motifs of the donor cations in **I** and **II** must arise from the pattern of short atomic contacts, specifically H-bonds, between the organic and anionic layers. Evidence for such interactions between terminal CH_2 groups of bedt-ttf and the anion layer comes from translation of the $[Cr(C_2O_4)_3]^{3-}$ units within the plane of an anion layer on passing from one layer to the next. The displacement of the $[Cr(C_2O_4)_3]^{3-}$ matches the tilt of the long axis of the intervening bedt-ttf molecules, so that the contacts between H (CH_2) atoms and O (oxalate) are identical at both ends of the bedt-ttf.

The basic topography of the inorganic layers is very similar in both phases, so why should the packing of the organic donor molecules be so different? The answer lies in the distributions of enantiomeric $[Cr(C_2O_4)_3]^{3-}$. In **I** each anionic layer contains exclusively one enantiomer and the next layer contains the other giving a Δ-Λ-Δ-Λ-Δ-Λ . . . pattern. However, each anionic layer in **II** contains both Δ and Λ enantiomers arranged in rows. In adjacent layers the chiral centres are organised in an identical fashion, barring layer translation, which gives a ΔΛ-ΔΛ-ΔΛ-ΔΛ . . . pattern. In neither polymorph does relative translation of the inorganic layer affect the bedt-ttf packing motif, but only the tilt angle of the long axis of these molecules. The arrangement of the enantiomers in a single anionic layer for **I**

and **II** are shown in Fig. 1(*a*) and (*b*), respectively indicating two ways in which equal proportions of each enantiomer are accommodated in the lattice to give an achiral crystal structure. The different spatial distributions of enantiomers form the basis of the observed polymorphism and are responsible for self assembly into either pseudo κ or β″ bedt-ttf packing motifs, which determine the strikingly different electrical properties of the two phases.

The spatial relationship between the bedt-ttf packing motifs and a nearest neighbour anionic layer is given in Fig. 2(*a*) and (*b*). The bedt-ttf layer is in the foreground and superimposed, as the background, are the positions of the metal atoms and the H_3O^+ molecules (O atom is marked A) of the anion layer. The chiral environment about the metal atoms is shown as Δ or Λ, and the hexagonal honeycomb lattice marked with full lines. H-bonding interactions occur between the neighbouring O (oxalate) atoms and the H (CH_2) atoms on the extremity of each bedt-ttf. Fig. 2 shows that the two packing arrangements of the bedt-ttf are very closely related, the β″ phase being a more regular form of the pseudo-κ phase. If all enantiomers in alternate rows of **I** are changed to the other isomer then the inorganic layer topography is transformed to that of **II**. A corresponding rotation of the donor cations, maintaining the same number and disposition of H-bonds, transforms the pseudo κ phase into a phase almost identical to β″. In effect this gives a β″ phase, generated from the pseudo κ phase, which therefore contains dimers and the original pseudo-κ charge distribution.

In conclusion we have shown that there are two polymorphs of the molecular charge transfer salt (bedt-ttf)$_4$[$(H_3O)Cr(C_2O_4)_3$]·PhCN, with distinctly different, though related, packing arrangements of the bedt-ttf donor cations. The salts have either β″ or a pseudo-κ motif and they have contrasting physical properties, being superconducting or semiconducting respectively. The two modes of bedt-ttf packing are promoted by two different spatial distributions of the chiral enantiomers Δ- or Λ-$[Cr(C_2O_4)_3]^{3-}$ to give overall racemic lattices. It has been previously found that exposure to either racemic or enantiomer excess of components or additives in a crystallisation process can lead to different polymorphs of a solid.[12,13] However, to the best of our knowledge this is the first time that this specific source of polymorphism has been identified in any crystalline material. We are continuing our efforts to make related chiral compounds and to explore the supramolecular organisation in this family of organic conductors.

We acknowledge financial support from the UK Engineering and Physical Sciences Research Council.

Notes and references

† The salts were prepared by *in situ* electro-oxidation of neutral bedt-ttf at constant currents of between 0.05 and 0.2 μA, in the presence of the anion and relevant solvent. For **I** the anion source was racemic $(NH_4)_3[Cr(C_2O_4)_3]\cdot 3H_2O$.[10] The starting material used for **II** was either the pure Δ- or Λ-ammonium salt of $[Cr(C_2O_4)_3]^{3-}$, prepared by literature methods,[11] both of which gave identical products. In both syntheses the solvent was distilled and degassed just prior to use and then several drops of water were added to the electrochemical cell. All starting materials were purified by repeated crystallisation. It was noted that the crystals began to grow within two days when using racemic starting materials but only after two weeks when using a single enantiomer. The time delay confirms that at least partial racemisation must occur in the latter case prior to crystal formation.

Preparation of a new poly(arylacetylene) with a tetrathiafulvalene (TTF) unit in the side chain

Takahisa Shimizu and Takakazu Yamamoto*

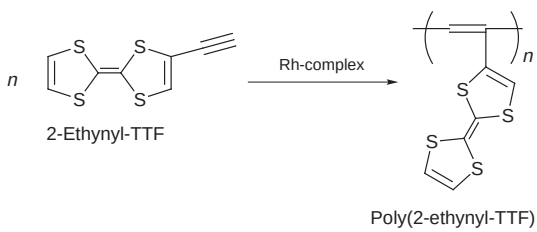
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Japan. E-mail: tyamamoto@res.titech.ac.jp

Received (in Cambridge, UK) 11th January 1999, Accepted 16th February 1999

A new poly(arylacetylene) having a strongly electron donating unit, a tetrathiafulvalene (TTF) unit, in the side chain has been prepared by Rh-catalyzed polymerization, and optical, electrochemical and electric properties of the polymer have been revealed.

Tetrathiafulvalene (TTF) and its analogues have long attracted the attention of chemists because of their ability to form highly electrically conducting charge transfer (CT) complexes with electron acceptors.[1] Many efforts have been made to prepare polymeric materials of TTF in order to obtain mechanically tough CT adducts with a larger π-conjugation system, and preparation of π-conjugated polymers containing the TTF unit has been reported.[2] However, preparation of a poly(arylacetylene) containing the TTF unit in its side chain has not been reported. Recent synthesis of an acetylenic derivative of TTF, 2-ethynyl-TTF, by Otsubo *et al.*[3] has prompted us to carry out the polymerization of 2-ethynyl-TTF, and here we report the results of the polymerization and redox properties of the obtained polymer.

Polymerization of 2-ethynyl-TTF was carried out by using $[Rh(\mu\text{-}Cl)(\eta^4\text{-nbd})]_2$ (nbd = norbornadiene), which is known as an active catalyst for polymerization of arylacetylenes, and NEt_3 as the cocatalyst [eqn. (1)].[4] Addition of PPh_3, for modification of the catalyst, was also carried out.



(1)

The polymerization of 2-ethynyl-TTF proceeds smoothly at room temperature and a dark-brown powder of poly(2-ethynyl-TTF) was obtained.† When the polymerization was carried out in neat NEt_3 without THF, insoluble polymer was obtained (Table 1, entry 1), although the IR spectrum of the polymer was essentially identical to those of polymers obtained in other runs. The insolubility of the polymer obtained in neat NEt_3 seems to arise from its very high molecular weight. It is reported that use of neat NEt_3, instead of other solvents, in the polymerization of phenylacetylene with the Rh catalyst leads to the formation of a polymer with a much higher molecular weight.[4c] On the other hand, carrying out the polymerization in THF (Table 1, entry 2) gave a soluble polymer having a number average molecular weight (M_n) of 11 700 in 47% yield at a high catalyst concentration of 41 mM. Lower concentration of the catalyst and shorter reaction time (entry 3) as well as addition of PPh_3 (entry 4) gave polymers with lower molecular weight. Since the Rh complex catalyst was inert over several days towards usual low molecular weight TTFs, occurrence of side reactions such as cleavage of the C–S bond of the monomer or the polymer by the catalyst was unlikely.

Table 1 Results of the polymerization of 2-ethynyl-TTF[a]

Entry	Solvent	Ligand added	Catalyst/ mM	*t*/h	Yield (%)	M_n[b]	M_w/M_n[b]
1	None	—	5	18	26	[c]	[c]
2	THF	—	41	2	47	11 700	1.23
3	THF	—	5	3	52	10 000	1.49
4	THF	PPh_3 (0.1 mM)	5	48	52	6 000	1.85

[a] Carried out in THF in the presence of NEt_3 (2.4 M) at room temperature except for entry 1 (in NEt_3). Concentration of 2-ethynyl-TTF = 0.21 M. Catalyst = $[Rh(\mu\text{-}Cl)(\eta^4\text{-nbd})]_2$. [b] Determined by GPC (polystyrene standards; eluent = DMF containing 0.006 M LiBr). [c] Insoluble.

The obtained polymers in entries 2–4 of Table 1 were soluble in some polar solvents including Me_2SO and DMF. Fig. 1 compares IR spectra of 2-ethynyl-TTF and poly(2-ethynyl-TTF). The IR spectrum of the polymer exhibits absorption bands characteristic of the TTF unit (*e.g.* 775, 793 and 1432 cm^{-1}). However, the ν(C≡C) peak (at *ca.* 2100 cm^{-1}) and the ν(C–H) peak of terminal acetylene (at *ca.* 3250 cm^{-1}) observed with 2-ethynyl-TTF completely disappear after polymerization. Poly(2-ethynyl-TTF) is stable under N_2, however, it is gradually degraded under air. Fig. 1(c) shows the IR spectrum of the polymer after exposure to air for one month. The IR spectrum exhibits new absorption peaks, which are considered to originate from OH, OOH, epoxide, and/or ether groups formed by air-oxidation. Similar air-sensitive properties and IR changes have been reported for polyacetylene[5a,b] and an analogous polymer.[5c] No apparent change in colour of the polymer, however, was observed after one month.

The ^1H NMR spectrum of poly(2-ethynyl-TTF) in $(CD_3)_2SO$ showed only broad peaks in the range δ 6.2–6.9, similar to those of reported poly(arylacetylene)s such as poly(phenylacetylene).[6] The TTF and vinyl protons are considered to overlap

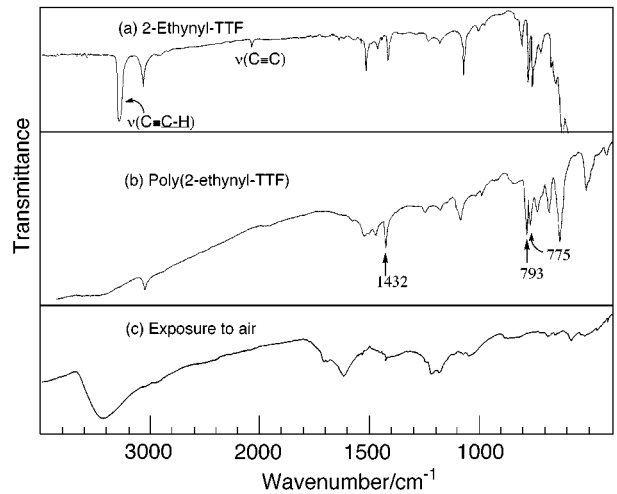


Fig. 1 IR spectra of (a) 2-ethynyl-TTF, (b) poly(2-ethynyl-TTF) (Table 1, entry 2) and (c) poly(2-ethynyl-TTF) after exposure to air for a month; (a) between NaCl crystal plates, (b) and (c) as KBr disks.

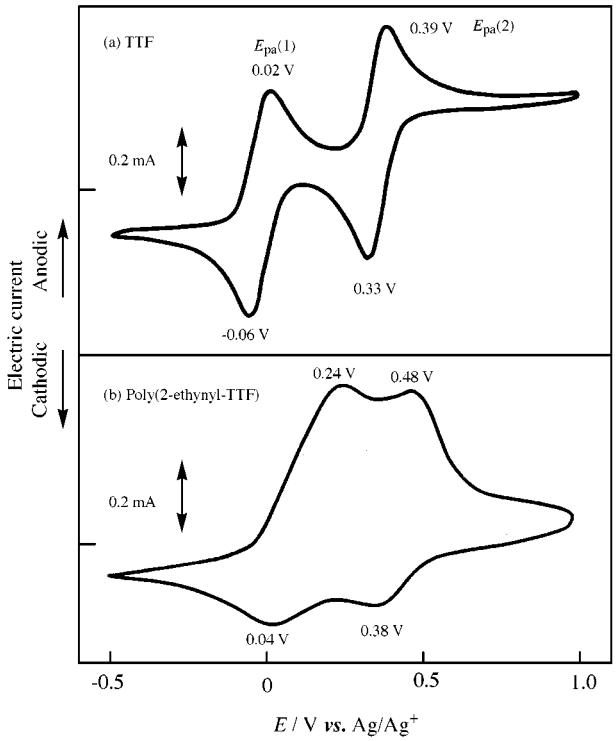

Fig. 2 Cyclic voltammograms of (a) TTF (0.10 M) and (b) poly(2-ethynyl-TTF) cast on a Pt plate (1× 1 cm) in an acetonitrile solution of $[NEt_4]BF_4$ (0.10 M). Scanning rate = 50 mV s^{-1}.

with each other to give the broad signal. The π–π* absorption band of the monomer at 395 nm disappeared after the polymerization, and poly(2-ethynyl-TTF) gives rise to a new broad absorption band at *ca*. 490 nm due to the expansion of the π-system.

Poly(2-ethynyl-TTF) is electrochemically active, and its redox behaviour has been followed by cyclic voltammetry with a film cast from a Me_2SO solution. As shown in Fig. 2(b), the cyclic voltammogram of the insoluble poly(2-ethynyl-TTF) film shows first and second E_{pa} values at 0.24 and 0.48 V *vs.* Ag/Ag$^+$ in MeCN solution containing 0.1 M $[NEt_4]BF_4$.

For TTF in solution, the two oxidation peaks, $E_{pa}(1)$ and $E_{pa}(2)$, are clearly separated with a potential difference, $E_{pa}(2) - E_{pa}(1)$, of 0.37 V [*cf*. Fig. 2(a)]. However, for the film of poly(2-ethynyl-TTF), the separation is not clear and the two peaks overlap with a smaller $E_{pa}(2) - E_{pa}(1)$ of 0.24 V. Similar differences between monomeric and π-conjugated polymeric compounds in their electrochemical redox processes have been reported for a two-step reduction of anthraquinone in a solution and π-conjugated poly(anthraquinone) in a film.[7] In Me_2SO containing 0.1 M $[NEt_4]BF_4$, both solutions of TTF and poly(2-ethynyl-TTF) give rise to $E_{pa}(1)$ and $E_{pa}(2)$ peaks at almost the same positions (0.11, 0.32 V and 0.14, 0.35 V, respectively, *vs.* Ag/Ag$^+$) although the anodic peaks of the polymer are also considerably broadened.

Poly(2-ethynyl-TTF) shows a low electrical conductivity of $< 1 \times 10^{-9}$ S cm^{-1}. The polymer reacts to give CT adducts with electron acceptors such as 7,7,8,8-tetracyanoquinodimethane (TCNQ), tetrafluorotetracyanoquinodimethane ($TCNQF_4$), dichlorodicyanoquinone (DDQ), and iodine. The ν(C≡N) band of the electron acceptors is shifted to a lower frequency by 10–50 cm^{-1} upon adduct formation, similar shifts having been reported for the CT complexes of TTF with electron acceptors.[8] Among these adducts, the CT complex with TCNQ [poly(2-ethynyl-TTF) : TCNQ = 5 : 1 molar ratio] shows the highest electrical conductivity of 2.1×10^{-3} S cm^{-1} as measured on a compressed pellet of the adduct.

Received (in Cambridge, UK) 27th November 1998, Accepted 19th February 1999

Mo–V–M–O (M = Al, Fe, Cr and Ti) complex metal oxide catalysts have been prepared by hydrothermal synthesis for the first time and showed activity for the partial oxidation of ethane to ethene and acetic acid.

In the last decade much progress has been made in the selective partial oxidation of light alkanes with molecular oxygen in gas phase.[1] Many types of metal oxides have been used to create catalytically active solid phases for various oxidation processes for promoting both the conversion of alkanes and the selectivity to partial oxidation products.[2] The most well known catalyst is crystalline V–P–O complex oxide for the selective oxidation of *n*-butane to maleic anhydride.[3] Crystalline forms or fine composites of complex metal oxides seem to be necessary for achieving high conversion and selectivity in alkane oxidation. It has already been shown that the Mo–V–O catalyst system, characterized by an X-ray diffraction peak near 4.0 Å (2θ = 22°, CuKα), is active for the oxidative dehydrogenation of ethane.[4,5] We have thus started studies to prepare monophasic materials or uniform fine composites of Mo–V–M–O catalysts by a hydrothermal synthetic method and recently succeeded in synthesizing solid materials which gave the same X-ray diffraction peaks and were catalytically active for the partial oxidation of ethane to ethene and acetic acid. We report here the synthetic method and the catalytic performance.

Since hydrothermal treatments at 175 °C did not give solid materials either from a mixed aqueous solution of $(NH_4)_6Mo_7O_{24}$ and NH_4VO_3 or from a solution of $(NH_4)_6Mo_7O_{24}$ and $VOSO_4$, we tried to add other metal cations for organization of Mo and V. For this purpose, Anderson-type heteropolymolybdates were chosen and metal cations such as Al, Fe, Cr, Bi, Co as heteroatoms in the Anderson structure were found to be effective organization elements. The Anderson-type heteropolymolybdates were prepared according to the reported procedure using $(NH_4)_6Mo_7O_{24}$ and metal sulfate (or alum).[6,7] The phase purity of the crystallized heteropolymolybdate samples was ascertained by XRD analysis. Hydrothermal reaction of the various Anderson-type heteropolymolybdates and $VOSO_4$ in water was carried out at 175 °C for 48 h in a PTFE lined autoclave (50 ml) without mixing. Typically, a sample, such as MoVAlO(621), where the numbers in parentheses show the atomic ratios of each element in the preparation, respectively, was synthesized in the following manner. To an aqueous solution (25 ml) of the prepared crystalline Anderson-type heteropolymolybdates, $(NH_4)_3H_6AlMo_6O_{24}\cdot 7H_2O$ (2.4 mmol) and an aqueous solution (15 ml) of $VOSO_4$ (4.8 mmol) was added dropwise with stirring at 50 °C, giving a brown–black liquid which was then allowed to undergo hydrothermal reaction in the autoclave. All reagents used were of commercially available research grade. After *ca.* 4 h reaction a small amount of black solid became observable on the wall of the autoclave and the mixed solution was black–blue. After 48 h the reaction was almost complete, yielding a substantial amount of solid in the bottom of the autoclave as well as on the wall. The obtained dark purple solid material was separated from the solution which was light green–yellow probably due to remaining V^{5+} in solution. The separated mass was washed with distilled water and dried at 40 °C overnight in air. The yield was 60 wt%. It was ascertained by XPS that the oxidation states of molybdenum and vanadium in the hydrothermally synthesized sample were 6+ and 4+, respectively, and an ICP analysis revealed that the sample contained each metal cation with a composition of $Mo_6V_{2.1}Al_{0.9}O_x$. Samples containing other metal cations (Fe, Cr, Bi or Co) were also synthesized by the same manner.

XRD patterns of the samples are shown in Fig. 1. The patterns are quite characteristic; only two sharp diffraction peaks were observed at 2θ *ca.* 22 and 45° ascribed to (00*l*) reflections and other very broad diffraction peaks appeared at 8, 11 and 27°. Mo–V–O based complex oxides giving these characteristic diffractions at 22 and 45° has already been reported in papers and patents as a key catalyst phase for acrolein oxidation to acrylic acid, ethane oxidation to ethene, and propane ammoxidation to acrylonitrile.[4–10] In these cases, however, the materials were synthesized through complicated reduction–oxidation processes in the preparation liquid and also by high-temperature heating processes, so that the materials thus prepared are multiphasic and of poor crystallinity. In the hydrothermal synthesis presented here for the first time, the preparation is very simple and highly reproducible, and sharp XRD diffraction peaks were observed, implying that the hydrothermally synthesized materials have higher crystallinity. In fact we observed rod-shape uniform crystals (0.1 μm × 0.3 μm × 10 μm on average) by SEM.

As can be seen in Fig. 1, the XRD characteristics are almost independent of the added metal cations but the relative intensities between the sharp and broad peaks are obviously different. It is, therefore, obvious that all the samples are at least

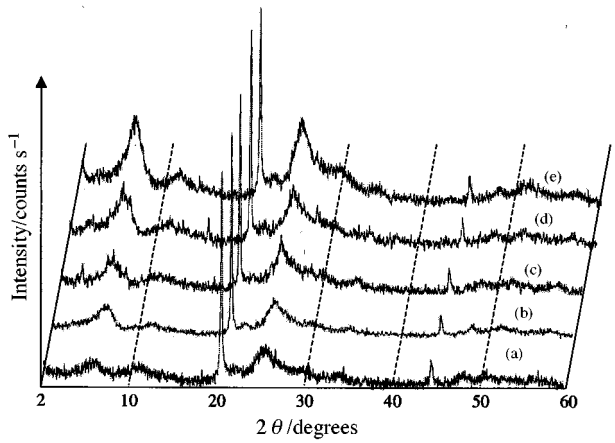

Fig. 1 XRD patterns of the hydrothermally synthesized Mo–V–M–O catalysts. XRD data were collected using a X-ray diffractometer with Cu-Kα radiation: (a) MoVCrO(621), (b) MoVFeO(661), (c) MoVBiO(621), (d) MoVAlO(621), (e) MoVCoO(621).

biphasic; one gives a set of the narrow diffraction lines and the other a set of the broad lines. For the phase giving the set of the narrow diffraction lines, we speculate, on the basis of layer-type structures proposed for Mo–V–O based oxides giving a diffraction peak at $2\theta = 22°$,[9,11] that self-organization takes place between Anderson-type heteropolyanion units and vanadyl cations under the hydrothermal reaction conditions, forming slabs with these being stacked to form a solid with a layer structure in which one crystal direction is ordered giving clear XRD peaks. Obviously we need more experimental results to clarify the structure and such work is being undertaken now.

The hydrothermally synthesized solid materials showed high catalytic activities for C_1–C_4 alkane oxidation, particularly for the production of ethene and acetic acid from direct ethane oxidation as shown in Table 1. Prior to the catalytic ethane oxidation, the catalysts were heat-treated at 410 °C for 2 h in a nitrogen stream. By this treatment the catalysts became active for the reaction but the XRD patterns did not change. When the reaction was conducted using the catalyst containing Al, Fe or Cr at 340 °C under the conditions indicated, ethane was oxidized into ethene and acetic acid quite selectively and the other products were carbon oxides. The Cr-containing catalyst tends to promote more complete oxidation. All the catalysts were highly stable under the reaction conditions, giving constant activity and selectivity. We also tried to incorporate titanium into the Mo–V–Al–O catalyst in order to improve the catalytic performance since the benificial effect of titanium has already been reported in the V–Ti–O system.[12] The catalysts MoVAlTiO were prepared by adding known amounts of $(NH_4)_2Ti(C_2O_4)_2$ into the preparative solution for hydrothermal reaction. As shown in Table 1 we observed a significant increase of the oxidation activity without significant alteration in the product selectivities. Since no additional XRD peaks were observed in the MoVAlTiO catalysts but the peaks of (00l) reflections widened, the activity increase seems to result from the increase of active area of the catalysts. As a consequence, the present result provides a new preparation route to Mo–V–O based complex oxide catalysts.

Table 1 Partial oxidation of ethane over Mo–V–M–O catalysts[a]

	Conversion (%)		Selectivity (%)			
Catalyst	C_2H_6	O_2	C_2H_4	$MeCO_2H$	CO_2	CO
MoVAlO(621)	3.9	13.2	70.4	8.1	7.6	13.9
MoVCrO(621)	4.2	18.4	55.8	10.7	12.4	21.0
MoVFeO(621)	2.6	8.4	71.0	11.2	6.8	11.0

Synthesis of 16-desmethylepothilone B: improved methodology for the rapid, highly selective and convergent construction of epothilone B and analogues

K. C. Nicolaou,* David Hepworth, M. Ray V. Finlay, N. Paul King, Barbara Werschkun and Antony Bigot

E-mail: kcn@scripps.edu

Received (in Corvallis, OR, USA) 21st December 1998, Accepted 4th February 1999

During a synthesis of 16-desmethylepothilone B new methods for the convergent and highly stereoselective synthesis of epothilone B and analogues were developed.

Due to their great potential as anticancer drugs with a paclitaxel-like mechanism of action, the epothilones have recently been at the focus of widespread scientific investigations.[1] In particular, significant attention has concerned chemical synthesis of the epothilone natural products, which we and others have successfully achieved.[1–3] In connection with on-going studies in the epothilone area we were interested in preparing analogues of epothilone B containing less conformationally restrained heteroaromatic side-chains, in particular the 16-desmethyl analogue **1** (Fig 1). Since this endeavour required a complete resynthesis of the epothilone macrocycle we took this opportunity to develop new methods for the swift assembly of epothilone B analogues with improved selectivities and yields.

Our aims were to combine the benefits of our highly modular and convergent approach to epothilone A and analogues *via* olefin metathesis,[1] which allowed for extremely rapid macrocycle construction, with the improved stereoselectivities inherent in our macrolactonisation strategy to epothilone B.[1] We envisioned that our approach to epothilone B analogues could be made more convergent by employing a fully functionalised C7–C12 fragment in a highly selective olefination reaction to construct the C12–C13 bond. This approach would also allow access to C26 modified analogues as previously described.[1,3*a*] Furthermore, we wished to retain a hydroxy group at the C26 position until a late stage in the synthesis and thus profit from a chemo-, regio- and stereo-selective Sharpless epoxidation.[1,3*a*] In adopting this route we were aware that a method for subsequent deoxygenation at the C26 position (adjacent to the epoxide) would have to be developed. Finally, we hoped to improve the pivotal aldol coupling step which provides the stereocentres at C6 and C7 of the macrocycle. Previously we have found this reaction to be somewhat capricious.

The thiazole aldehyde fragment **6a**† was prepared in an analogous fashion to the related epothilone B fragment with minor changes in experimental conditions (Scheme 1). An asymmetric allylboration was the key step used to introduce the stereogenic centre at C15.‡ The regioselectivity of the dihydroxylation was lower than in the epothilone B series which slightly impaired the overall yield for this fragment. The fully functionalised phosphorane **14** was prepared in short order from commercially available **7** without the need for chiral auxiliaries.

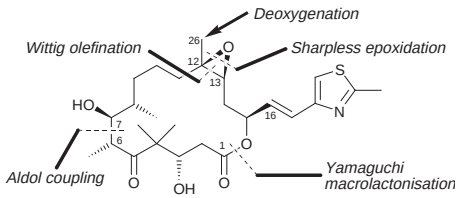

Fig. 1 Numbering and bond disconnections for **1**.

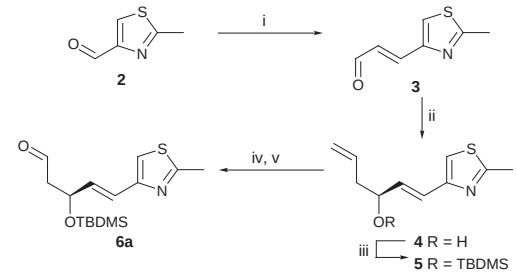
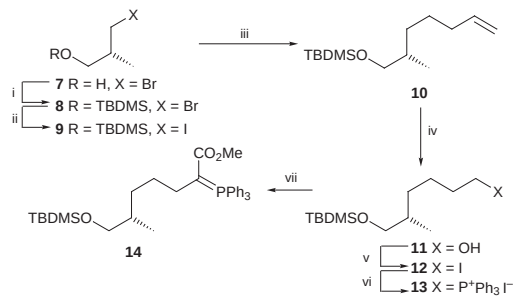


Scheme 1 *Reagents and conditions*: Ph_3P=CHCHO, CH_2Cl_2, reflux, 12 h, 82%; ii, (+)-Ipc_2B(allyl), CH_2Cl_2, Et_2O, pentane, −100 °C, 2 h, 100%; iii, TBDMSCl, imidazole, DMF, 0 → 25 °C, 2 h, 99%; iv, OsO_4 (cat.), NMO, THF, Bu^tOH, H_2O, 25 °C, 12 h, 68%; v, $NaIO_4$, MeOH, H_2O, 0 → 25 °C, 1 h, 89% (Ipc = isopinocampheyl).

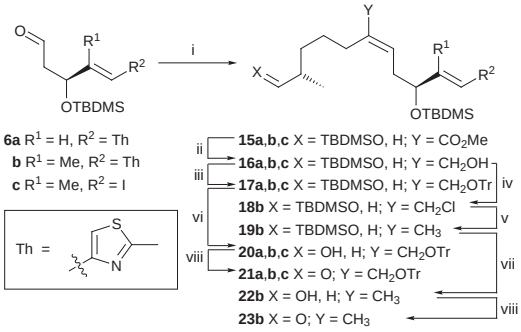
The reaction sequence includes an efficient cuprate coupling,[4] and a chloroformate quench of an unstabilised ylide[5] as the key steps (Scheme 2). Control of temperature during the latter reaction is critical to obtain phosphorane of good quality.§

The all-important Wittig coupling of **14** and **6a** proceeded smoothly with excellent yield and selectivity ($E:Z > 30:1$ in all cases) to provide the coupled product **15a**, which was processed to **21a** (Scheme 3). We have since extended this approach to the natural epothilone B series **23b**, the 26-hydroxyepothilone B series **21b** and the highly flexible vinyl iodide series **21c**, which we have shown to be invaluable for producing heterocycle-modified epothilones.[1,3*b*,*c*] This route also enabled us to approach the highly epimerisation-prone aldehydes **21a**-**c** and **23b** through stereochemically 'safe' alcohol oxidation procedures.¶

We reasoned that the moderate and variable stereoselectivities obtained in the coupling of **24** with chiral aldehydes such as **21a**–**c** and **23b** may be due, at least in part, to the reversible nature of aldol reactions using ketone-derived lithium enolates.[7] In an attempt to alleviate such problems we have performed the reaction with an excess of enolate,‖ very short reaction time and a rapid low temperature quench (AcOH). Gratifyingly, the



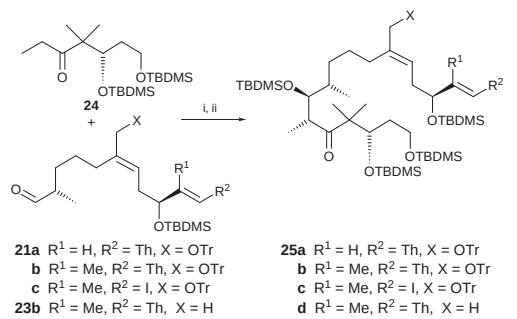
Scheme 2 *Reagents and conditions*: TBDMSCl, imidazole, DMF, 0 → 25 °C, 1 h; ii, NaI, acetone, reflux, 12 h, 99% (2 steps); iii, CH_2=$CHCH_2CH_2MgBr$, Li_2CuCl_4 (cat.), THF, 0 °C, 1 h, 96%; iv, (a) O_3, CH_2Cl_2, −78 °C, then PPh_3; (b) $NaBH_4$, EtOH, 0 °C, 30 min., 91% (2 steps); v, I_2, PPh_3, CH_3CN, Et_2O, 0 → 25 °C, 1 h, 100%; vi, PPh_3, neat, 100 °C, 2 h; vii, KHMDS, THF, 0 °C, 30 min, then MeOCOCl, −78 °C, 3 h (*ca.* 100%, 2 steps, unpurified).



Scheme 3 *Reagents and conditions*: i, **14** (1.3 equiv. based on **12**), C_6H_6, reflux, 18 h, 84–93%; ii, DIBAL-H, THF, −78 °C, 3 h, 71–95%; iii, TrCl, DMAP, DMF, 70 °C, 18 h, 82–95%; iv, CCl_4, PPh_3, reflux, 18 h, 80%; v, $LiEt_3BH$, THF, −78 °C, 1 h, 92%; vi, HF•Py.Py, THF, 25 °C, 4 h, 66–73%; vii, CSA, MeOH, 25 °C, 1 h, 95%; viii, SO_3•Py, DMSO, Et_3N, THF, 0 °C, 1 h.

application of these conditions to aldehydes **21a–c** and **23b** lead to significant amelioration of stereoselectivity which was naturally accompanied by an improved yield of the desired aldol stereoisomer in each case (Scheme 4, Table 1). Intermediates **25a–d** were obtained in good overall yields after subsequent TBDMS-protection. Under these closely defined conditions the aldol reaction is highly reproducible and applicable to multigram quantities. These results, in terms of diastereoselectivities and yields, are at least as good as those obtained by Schinzer and co-workers in their epothilone B syntheses.[2b] Since our approach features a rather convenient protecting group strategy, we believe this development renders our modified route the most effective solution to date for epothilone B.

The TBDMS-protected aldol product **25a** was processed through to 26-hydroxy-16-desmethylepothilone B **30** in the same fashion as our published route to 26-hydroxyepothilone B (Scheme 5).[3a] As projected, the Sharpless epoxidation proceeded with complete stereo- and regio-control at the C12–C13 position. It should be noted that for this analogue series, competitive side-chain epoxidation would likely have been problematic upon use of conventional oxidants. In order to complete the synthesis, removal of the C26 hydroxy group was required. This was achieved by initial conversion to iodide **31** followed by reductive deiodination with $NaBH_3CN$[7] to provide

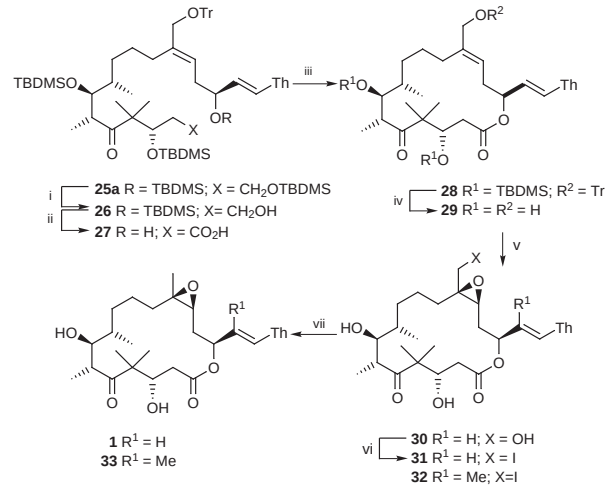


Scheme 4 *Reagents and conditions*: i, LDA (2.4 equiv.), **24** (2.3 equiv.), THF, −78 → −40 °C, 1 h, then add **21** or **23**, THF −78 °C, 2 min, then AcOH, −78 → 0 °C; ii, TBDMSOTf, 2,6-lutidine, THF, −78 → 0 °C, 1 h.

Table 1 Yields and stereoselectivities for aldol reactions

Aldehyde	Selectivity[a]	Aldol product (%)[b]	**25** (%) (2 steps)[c]
21a	⩾10 : 1	76	72
21b	⩾15 : 1	77	73
21c	⩾10 : 1	79	75
23b	⩾10 : 1	71	67

[a] Conservative estimates based upon mass recovery of the major isomer relative to all other polar impurities. [b] Often contaminated with small amounts (= 5%) of starting aldehyde. Yields are compensated. [c] Single stereoisomer free from traces of aldehyde and other impurities.



Scheme 5 *Reagents and conditions*: i, HF•Py.Py, THF, 25 °C, 3 h, 87% (after 1 recycle); ii, (a) $(COCl)_2$, DMSO, CH_2Cl_2, −78 °C, 30 min, then Et_3N, −78 → 0 °C, 30 min; (b) $NaClO_2$, Me_2C=CHMe, NaH_2PO_4, Bu^tOH–H_2O, 25 °C, 2 h; (c) TBAF, THF, 25 °C, 12 h, *ca.* 100% (3 steps); iii, 2,4,6-$Cl_3C_6H_2COCl$, Et_3N, THF, 0 °C, 1 h, then add to DMAP in toluene, 75 °C, 1 h, 73%; iv, HF•Py, THF, 0 → 25 °C, 24 h, 78%; v, (+)-diethyl L-tartrate, $Ti(Pr^iO)_4$, Bu^tOOH, CH_2Cl_2, 4 Å MS, −30 °C, 2 h, 80%; vi, (a) TsCl, Et_3N, DMAP, CH_2Cl_2, 0 → 25 °C, 1 h; (b) NaI, acetone, 25 °C, 15 h, 91% (2 steps); vii, $NaBH_3CN$, HMPA, 45 °C, 40 h, 67–70%.

our desired analogue **1** in good overall yield. Furthermore, this deoxygenation sequence has also been demonstrated for the production of epothilone B (**33**) itself from our previously reported iodide **32**. Thus, all of the synthetic methodology described herein is applicable to epothilone B, which renders our approach now *highly selective at every step*, and significantly increases the speed of access to this and related structures. Work is currently underway to assess the biological activity of **1** and related analogues of epothilone B.

We thank D.-H. Huang and Gary Siuzdak for NMR and MS studies, respectively. This research was financially supported by the National Institutes of Health USA and The Skaggs Institute for Chemical Biology, from the George Hewitt Foundation (to N. P. K.), the Deutsche Forschungsgemeinschaft (to B. W.), and grants from CaPCURE and Novartis.

Notes and references

† All new compounds exhibited satisfactory spectral and exact mass data.
‡ The ee was shown to be ⩾97% by chiral HPLC (Chiralcel OD-H column) by comparison with the racemate.
§ Due to high polarity and complex NMR spectra **14** was not purified as characterized. We observed full mass return for **12** → **14** and used the material crude using quantities assuming purity.
¶ The aldehydes were freshly prepared and not purified prior to use.
‖The unreacted ketone **24** is easily recovered by chromatography.

V–Zr–P oxide catalysts for highly selective oxidation of propane to acrylic acid

Yi-Fan Han, Huai-Ming Wang, Hua Cheng and Jing-Fa Deng*

Department of Chemistry, Fudan University, Shanghai 200433, People's Republic of China.
E-mail: jfdeng@srcap.stc.sh.cn

Received (in Cambridge, UK) 6th January 1999, Accepted 19th February 1999

V–Zr–P oxide catalysts have been prepared and exhibited high selectivity in the oxidation of propane to acrylic acid.

The selective oxidation of lower alkanes to other chemicals is attracting attention for economic reasons and their availability. The best-known oxidation of lower alkanes is the selective oxidation of *n*-butane to maleic anhydride over vanadium phosphorus oxide catalysts (VPO).[1] Moreover, oxidation of propane to propylene,[2–4] acrolein[5] and acrylonitrile[6] has been widely developed. It was found first by Ai[7,8] that a VPO based catalytic system could directly oxidize propane to acrylic acid effectively. The V_2O_5–P_2O_5–X_nO_m (X_nO_m = SO_3, TeO_2, Nb_2O_3, Sb_2O_3, SiO_2 and B_2O_3) type catalysts have been tested and the catalytic performance in this process is clearly improved. However, the reaction carried out on VPO catalysts at relatively high temperature (400 °C) not only results in a low selectivity to acrylic acid, but also leads to serious formation of coke on the catalyst surface and shortage of lifetime. To solve these problems, we have reported the use of a titania–silica xerogel supported VPO catalyst in this reaction[9] which showed highly selective oxidation of propane to acrylic and acetic acid at low temperature (300 °C). So far, the yield and selectivity to acrylic acid for all developed catalysts are too low to be applied at commercial level. For this reason, we sought to develop a new catalyst that possesses good performance at low temperature in order to give high yield and selectivity to acrylic acid without coking.

In our study, it was demonstrated that V–Zr–P (Zr : V = 0.5) oxide catalyst showed significant high selectivity and yield to acrylic acid at 340 °C, and had the potential for practical use.

V–Zr–P oxide catalysts were prepared by the following procedure: a mixture of V_2O_5 and $ZrOCl_2{\cdot}H_2O$ in stoichiometrical atomic ratio (Zr : V) was reduced by refluxing in a solution of isobutanol (20 ml)–benzyl alcohol (10 ml) for 12 h; a black blue or gray suspended precipitate formed. Then, an appropriate amount of 85% H_3PO_4 [atomic ratio P : (Zr + V) = 1.0] was added to the solution, which was refluxed for 6 h to give a light blue–green suspended precipitate and a black–blue solution. The precipitate was filtered off and the obtained paste was dried in an oven at 120 °C overnight. The resulting precursor was ground and sieved to obtain a 40–60 mesh size portion. VPO (V : P = 1.0) and ZrPO (Zr : P = 1.0) catalysts were also prepared by the same procedure to enable comparison. The activation of precursor and oxidation of propane were carried out in a continuous tubular flow fixed-bed microreactor. The precursor of the V–Zr–P oxide catalyst (1.0 ml) was packed into a stainless steel reactor (id: 6.0 mm, length: 20 cm) and the temperature was raised to 773 K at a rate of 20 K min^{-1} in a mixture of air–propane–water vapor (75.6 : 1.2 : 23.2) at a rate of 20 ml min^{-1} for 12 h. The sample was then cooled to the reaction temperature within 6 h.

The X-ray diffraction patterns for all the catalysts are in Fig. 1. Lines at 2θ = 23.1, 28.4 and 29.9° are attributed to $(VO)_2P_2O_7$, and those at 2θ = 22.0, 26.0 and 28.9° are attributed to $VOPO_4$, respectively.[10] It can be seen that the bare VPO catalyst is mainly constituted of $(VO)_2P_2O_7$ with some $VOPO_4$. The X-ray line due to $(VO)_2P_2O_7$ broadened and diminished with increase of the atomic ratio of Zr : V in the V–Zr–P oxides. Only small broad diffraction peaks were detected

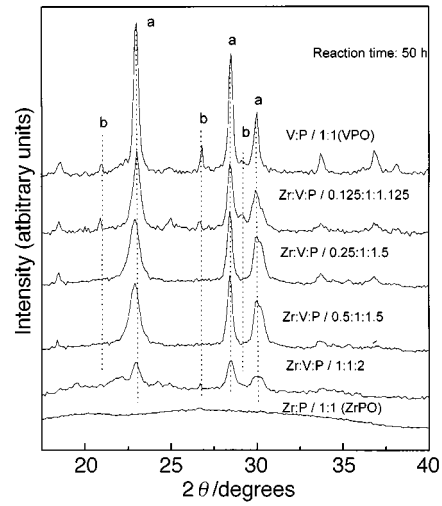

Fig. 1 XRD patterns of V–Zr–P oxide catalysts; (a) $(VO)_2P_2O_7$, (b) $VOPO_4$.

when Zr : V was raised to 1.0, indicating that $(VO)_2P_2O_7$ starts to become disordered. No distinct XRD line can be found for ZrPO, suggesting that ZrPO is an amorphous material. In addition, no zirconium phosphate was evidenced for any V–Zr–P oxides, implying that ZrPO can only disperse into the structure of VPO or form a solid solution with $(VO)_2P_2O_7$. It is also interesting to observe that the $VOPO_4$ phase disappears as Zr : V is increased to 0.25, which suggests that its formation has been suppressed.

All catalysts employed in this study were tested for the selective oxidation of propane to acrylic acid. The optimal results summarized in Table 1 show that ZrPO is inert to this reaction. For VPO catalyst, the yield and selectivity to acrylic acid are 11.2 and 48.1%, respectively. With the addition of Zr, the yield and selectivity increase sisgnificantly in comparison with the VPO catalyst. As Zr : V is changed from 0.125 to 0.5, the selectivity increases from 70.0 to 81.0% and the yield increases from 13.5 to 14.8%. With continuous increasing ratio of Zr : V to 1.0, the activity and selectivity start to decrease.

It can be seen in Fig. 2, that the temperature for achieving maximum selectivity shifts from 400 (VPO) to 340 °C (V–Zr–P

Table 1 The performance of V–Zr–P oxide catalysts[a]

V : Zr atomic ratio	*T*/°C	Conv. (mol%)	Yield (mol%)	Sel. (mol%)
1 : 1	340	16.1	12.7	70.3
1 : 0.5	340	17.5	14.8	81.0
1 : 0.25	360	18.4	14.2	71.0
1 : 0.125	380	18.5	13.5	70.0
VPO	400	23.0	11.2	48.1
ZrPO	400	—	—	—

[a] *Reaction conditions*: GHSV = 1000 h^{-1}, feed gas = air–propane–water = 73.4 : 3.2 : 23.4, time = 50 h, cat. 1.0 g; analysis: on-line gas chromatograph.

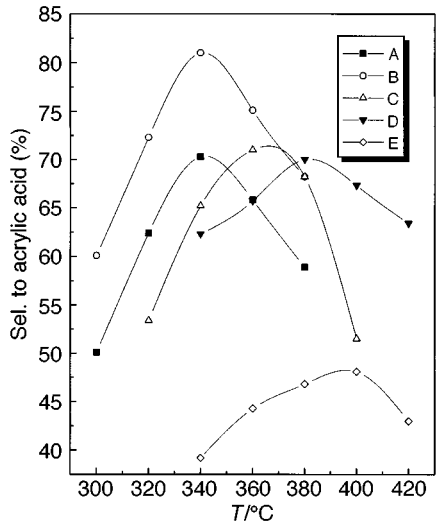

Fig. 2 Dependence of selectivity of acrylic acid on reaction temperature; (A) Zr : V : P = 1 : 1 : 2, (B) Zr : V : P = 0.5 : 1 : 2, (C) Zr : V : P = 0.25 : 1 : 2, (D) Zr : V : P = 0.125 : 1 : 2, (E) VPO. Reaction conditions: GHSV = 1000 h^{-1}, feed gas = air–propane–water vapor (73.6 : 3.2 : 23.2), time = 50 h.

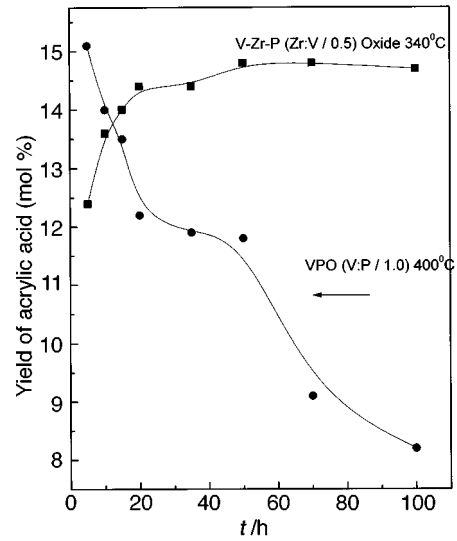

Fig. 3 Dependence of reaction time on the yield of acrylic acid. Reaction conditions: GHSV = 1000 h^{-1}, feed gas = air–propane–water vapor (73.6 : 3.2 : 23.2).

oxide, Zr : V = 0.5). It is well known that lowering temperature is favorable for reducing coke formation and beneficial in increasing the lifetime of the catalyst. Fig. 3 shows that V–Zr–P (Zr : V = 0.5) oxide catalyst shows significantly higher catalytic stability than that of VPO after 100 h of operation.

Comparison of XRD patterns with the catalytic properties of V–Zr–P oxides, as shown in Fig. 1 and Table 1, suggests a correlation of XRD line strength for $(VO)_2P_2O_7/VPOP_4$ with the catalytic performance of the catalyst. $(VO)_2P_2O_7$ most likely acts as the active phase in oxidation of propane as found in the VPO based catalytic system in oxidation of butane.[10] Further, the addition of amorphous materials in the structure of V–Zr–P oxide may effectively disperse VO_x or $(VO)_2P_2O_7$, and make an important contribution in enhancing the selectivity of catalyst.

In summary, V–Zr–P oxide catalysts exhibit satisfactory performance for selective oxidation of propane to acrylic acid. The best result, 14.8% yield and 81.0% selectivity, is shown by the catalyst with V : Zr : P = 1 : 0.5 : 1.5, at an optimum reaction temperature of 340 °C. It is clear that V–Zr–P oxide catalysts are promising for use in the selective oxidation of propane to acrylic acid.

Self-assembly of a linear multicomponent porphyrin array through axial coordination

Kelly Chichak and Neil R. Branda*

Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2G2. E-mail: neil.branda@ualberta.ca

Received (in Columbia, MO, USA) 14th October 1998, Revised manuscript received 21st January 1999, Accepted 9th February 1999

The bis[4′-(4‴-pyridyl)-2,2′:6′,2″-terpyridine]ruthenium and osmium complexes 1a and 1b react with 2 equiv. of [Ru(TTP)(CO)(EtOH)] 4 to generate linear multicomponent arrays 3a and 3b; intramolecular phosphorescence quenching is observed for both arrays in contrast to their molecular building blocks which phosphoresce.

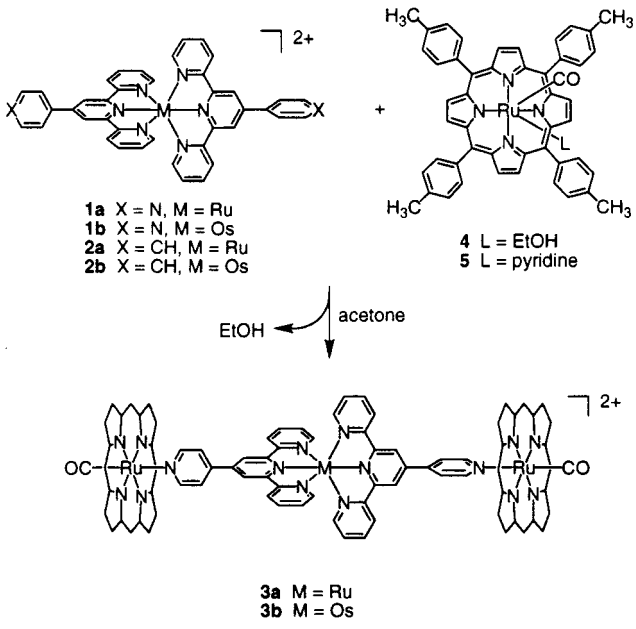
The rich photo- and redox chemistry of porphyrins has led to the design of sophisticated multicomponent molecular arrays held together by covalent or noncovalent interactions.[1] Efforts in this area have been spawned primarily by attempts to model solar energy capture and transfer in naturally occurring photosystems as well as to generate photoactive molecular devices.[2] One of the major concerns when designing such models is the ultimate control over the spatial organization of the chromophoric units within the arrays, where the photoinduced energy- and/or electron-transfer reactions of the resulting complexes will be governed by the supramolecular topology.

Our interests in this area are in the design and construction of molecular assemblies with well defined rigid architectures based on hybrid arrays of transition metal complexes axially coordinated to octahedral metalloporphyrins. We report here two linear multicomponent arrays **3a** and **3b** formed through the self-assembly of a central bis(terpyridine)transition metal complex linking two ruthenium(II) porphyrins *via* axial coordination.[3] The core units of triads **3a** and **3b** $[M(pytpy)_2]^{2+}$, pytpy = 4′-(4‴-pyridyl)-2,2′:6′,2″-terpyridine; M = Ru **1a**, Os **1b**] were prepared as their air-stable hexafluorophosphate salts as previously described.[4] The final triads **3a** and **3b** were prepared by adding 2 mol equiv. of [Ru(TTP)(CO)(EtOH)] **4**[5]† to 1 equiv. of $[M(pytpy)_2]^{2+}$ in acetone and gently heating (Scheme 1). Alternatively, the triads can be prepared at room temperature by adding an excess of the metalloporphyrin. In either case, the fully assembled triad complexes were isolated as red (Ru) and red–brown (Os) solids and characterized by UV–VIS spectroscopy, ^{1}H NMR spectroscopy and mass spectrometry.

The ^{1}H NMR spectra of both complexes **3a** and **3b** show significant upfield shifts for all hydrogen atoms of the $M(pytpy)_2^{2+}$ core unit as anticipated for protons lying within the shielding cone of the porphyrin (Fig. 1).[6] The anisotropic effect never completely disappears and extends over the entire distance spanned by the core unit (*ca.* 11 Å). We attribute this to an additive effect of both porphyrins forming the complex's walls. As expected, the protons immediately adjacent to the pyridine nitrogen of the core unit are the most affected and are seen to move as much as 7.5 ppm upfield upon complexation (protons H_a in Fig. 1). The smallest, but still significant, shielding effect acts upon the hydrogen atoms closest to the central metal which are shifted 0.5 ppm to higher field (protons H_c in Fig. 1).

The ^{1}H NMR studies reveal that, even in a competitive solvent such as acetone, coordination to the metalloporphyrin is strong and ligand-exchange is slow on the NMR timescale, and sharp, unchanging peaks for the statistical mixture of mono- and di-addition products were clearly visible when only 1 mol equiv. of [Ru(TTP)(CO)(EtOH)] **4** was added (Fig. 1, inset). This observation is useful when preparing complexes *in situ* and is utilitarian when constructing larger porphyrin arrays.‡

Initial photophysical studies show that the absorption spectra in the UV–VIS region of complexes **3a** and **3b** are essentially the sum of the absorption spectra of the triads' constituents. The steady-state emission properties of the triad complexes, however, differ greatly from those of their building blocks. In order



Scheme 1

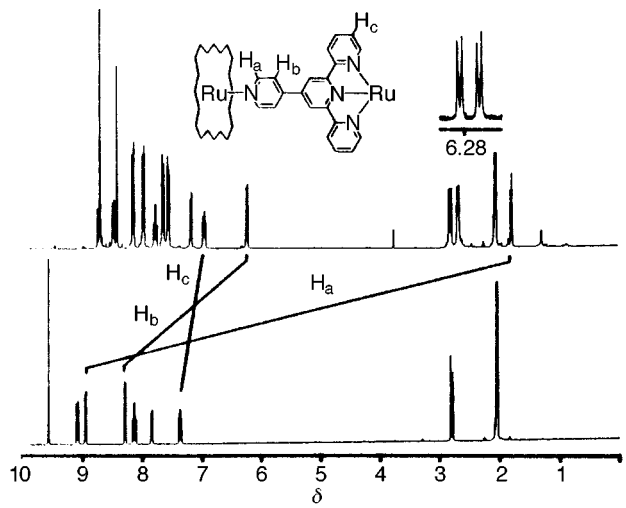


Fig. 1 ^{1}H NMR (300 MHz, acetone-d_6) spectra of $[Ru(pytpy)_2](PF_6)_2$ **1a** (bottom trace) and triad **3a** (top trace). The inset spectrum corresponds to protons H_b when only 1 mol equiv. of [Ru(TTP)(CO)(EtOH)] was added showing both mono- (peaks on the left) and bis-coordination (peaks on the right) arrays.

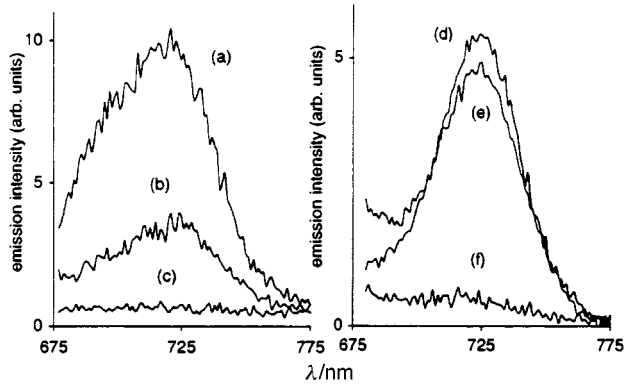

Fig. 2 Emission spectra (uncorrected) of CH_2Cl_2 solutions of (a) **2b** (λ_{ex} = 670 nm), (b) **1b** (λ_{ex} = 670 nm), (c) **3b** (λ_{ex} = 670 nm), (d) **5** (λ_{ex} = 530 nm), (e) 2 : 1 mixture of **5** and **2a** (λ_{ex} = 530 nm), (f) **3a** (λ_{ex} = 530 nm). All spectra were run in dry deoxygenated solvent.

to evaluate the photoemission properties of each of the triads' building blocks without complications from the other luminescent species, the triads composed of the two different core units **1a** and **1b** were investigated independently. The osmium core unit **1b** phosphoresces from its triplet excited state[2] at room temperature in CH_2Cl_2, but the phosphorescence of the triad **3b** is significantly quenched (Fig. 2). Here, the substantial reduction in phosphorescence intensity of the core unit on going from bis(terpyridine)osmium **1b** to triad **3b** can most likely be ascribed to ligation-induced quenching, where the porphyrin is acting as a Lewis acid for the monodentate pyridine of **1b**. This claim is supported by the complete luminescence quenching of **1b** upon *in situ* protonation with 2 equiv. of trifluoroacetic acid, although, at this stage, intramolecular triplet energy transfer from the core complex to the porphyrin cannot be completely ruled out.[9]

The lack of room temperature photoemission of the bis(terpyridine)ruthenium core unit **1a** enabled us to study the porphyrin unit, which shows substantially weaker phosphorescence intensity at room temperature in comparison with osmium core unit **1b**.[7] Again, significant phosphorescence quenching was observed for triad **3a** in comparison with the free pyridine-coordinated porphyrin species [Ru(TTP)(CO)(py)] **5** (Fig. 2). In order to rule out the existence of intermolecular phosphorescence quenching between non-coordinated chromophores, the phenyl analog of **1a**, $[Ru(phtpy)_2]^{2+}$ (phtpy = 4′-phenyl-2,2′ : 6′,2″-terpyridine) **2a**, which cannot axially coordinate to the metalloporphyrin, was prepared.[8] There was no observable intermolecular quenching of the excited state of porphyrin chromophore **5** when treated with 2 mol equiv. of **2a**, clearly indicating that the luminescence quenching occurs only when the metalloterpyridine complex is intimately coordinated to the porphyrin. We can conclude from these observations that there is effective electronic communication between chromophores within the assembled triad. A possible explanation for the luminescence quenching is that photoinduced electron-transfer occurs, followed by non-radiative decay of a charge-separated species.§ Identification of this charge-separated species and characterization of the phosphorescence quenching process within the arrays are currently under investigation.

This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. We are grateful to the reviewers for their helpful comments and suggestions.

† The abbreviation TTP refers to 5,10,15,20-tetratolylporphyrinato dianion.

‡ Manuscript in preparation.

§ Excited states of metalloporphyrins are known to exhibit photoredox behaviour involving both oxidative and reductive quenching. Literature precedent suggests an electron-transfer process (see ref. 9 and references cited therein), although examples of the less frequent energy-transfer process have also been documented for covalently bound porphyrin-terpyridine hybrids (see Flamigni *et. al*. in ref. 1, for example).

Baeyer–Villiger oxidations with a difference: molecular sieve redox catalysts for the low-temperature conversion of ketones to lactones

Robert Raja, John Meurig Thomas and Gopinathan Sankar

Davy Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albemarle Street, London, UK W1X 4BS. E-mail: dawn@ri.ac.uk

Received (in Liverpool, UK) 4th January 1999, Accepted 5th February 1999

Redox molecular sieve catalysts MAlPO-36 (M = Mn or Co) convert cyclopentanone, cyclohexanone, 2-methylcyclohexanone and adamantan-2-one to their corresponding lactones with high efficiency (selectivities in excess of 90%, conversions in the range 50 to 85%), in the presence of O_2 and PhCHO as sacrificial oxidant.

In 1991 Mukaiyama and co-workers reported[1] that various aldehydes could be smoothly oxidised to their corresponding carboxylic acids by molecular oxygen in the presence of $Ni^{II}(dmp)_2$ catalysts [Hdmp = 1,3-bis(*p*-methoxyphenyl)propane-1,3-dione]. They also reported[2] an efficient method for epoxidising olefins using the same catalyst, O_2 and sacrificial aldehydes (Scheme 1).

These conditions are of considerable interest in that they offer attractive alternatives to the use of environmentally less acceptable oxidants (many of which function stoichiometrically rather than catalytically) such as CrO_3, $KMnO_4$, $Pb(OAc)_4$, RuO_4 Ag_2O and $Co(acac)_3$.[3] H_2O_2 in the presence of an appropriate catalyst (*e.g.* by methyltrioxorhenium[4]) is also a good oxidant for the conversion of olefins to epoxides and cyclic ketones to lactones[5] (Scheme 2).

In pursuit of our goal to design and synthesise microporous solid catalysts for the selective aerobic oxidation of hydrocarbons, we have found that transition metal ion (framework) substituted aluminophosphates (MAlPO, where M = transition metal ions) can effectively convert alkanes[6–8] and aldehydes to their corresponding carboxylic acids. This prompted us to investigate the potential of these microporous solids for oxidation of ketones, in the presence of a sacrificial aldehyde, using air as an oxidant. Sacrificial aldehydes for the conversion of ketones to lactones (an example of Baeyer–Villiger oxidation) have been shown to be effective using various homogeneous catalysts.

Several heterogeneous catalytic systems based on hydrotalcites[9] or heteropolyoxometalates[10] have been used to effect Baeyer–Villiger oxidations. However, to the best of our knowledge, there are no reports of the use of microporous redox molecular sieves for the shape-selective conversion of ketones to lactones. Taking account of the redox properties[11] and pore dimensions of a range of metal ion substituted AlPOs, we have identified three different structures of potential catalysts that contain small amounts (up to 4 atom%) of either manganese or cobalt redox cations. The catalysts we have used are CoALPO-36, MnALPO-36, CoAlPO-5, MnAlPO-5, CoALPO-18 and MnALPO-18. The structure[12] of aluminium phosphate No. 36 (IZA structure code ATS) has well-defined, oval-shaped channels (6.5 × 7.5 Å) (Fig. 1), which, by appropriate preparative means,[7,12] may be lined with a substantial number of either cobalt or manganese ions framework-substituted in place of Al^{III} ions. Similarly, two other types of materials, AlPO-5 (AFI) and AlPO-18 (AEI) with pore dimensions of 7.3 and 3.8 Å, respectively, were synthesised with specific metal ions having identical concentrations.[11] By calcining the as-prepared MAlPOs (M = Co or Mn) samples in oxygen at 550 °C, the substituted ions may be converted[12] to their +3 oxidation states, to a degree that is dependent on the structure; the trend in the concentration of the +3 state in the three structures is AlPO-18 > AlPO-36 > AlPO-5.[11] The results of Bayer–Villiger oxidation of a number of ketones to lactones, performed with these catalysts, are given in Table 1, and a typical kinetics plot for the MnAlPO-36 catalyst is shown in Fig. 2.†

Although the mechanistic details of the aerobic oxidation of ketones to lactones reported here still requires elucidation, preliminary studies (*cf.* ref. 6) point to the fact that the active centres in the redox catalysts are the Co^{III} (or Mn^{III}) ions that line the micropores. We know that the higher conversions are effected by the framework-substituted higher valence ions in the molecular sieve catalysts for several reasons. Firstly, divalent ion substituted AlPO-36 analogues such as Mg^{2+} (or Zn^{2+}) that are not raised to higher oxidation states upon calcination in O_2 yield conversions not significantly different from those of the Mukaiyama sacrificial oxidations with benzaldehyde alone (see Table 1, entries 5 and 7). Secondly, in a parallel experiment (Table 1, entry 6) using the smaller pore CoALPO-18 (or MnALPO-18), where all the transition-metal ions are in the +3 oxidation state,[7,11] and the diameter of micropores is 3.8 Å, no catalytic conversion of cyclohexanone to ε-caprolactone occurs when benzaldehyde is used as a sacrificial oxidant because the

[a] Reaction conditions: substrate = *ca*. 20 g; catalyst = *ca*. 0.15 g; substrate:benzaldehyde = 1:3 (mol/mol); O_2 (air) = 30 bar. [b] TOF = turnover frequency = moles of ketone converted per hour per mole of metal (Co, Mn) in the catalyst. [c] ε-Caprolactone. [d] After the reaction the catalyst was filtered off, washed thoroughly with MeOH and calcined at 550 °C for 12 h. It was then re-used twice without significant loss in catalytic activity. The reaction mixture (after 6 h) was also analysed by ICP (and atomic absorption spectroscopy) and only trace amounts (< 2 ppb) of metal were detected. In a separate experiment, the solid catalyst (entry 3) was filtered off from the reaction mixture (at 323 K) after 2 h (conversion = 29%) and the reaction was continued for a further 4 h (conversion after 6 h = 33%) with the resulting filtrate [which also had trace amounts (< 2 ppb) of metal]. No substantial increase in conversion was observed, clearly showing that the reactions are heterogeneously catalysed. [e] The TOF have not been calculated in these cases, as the conversions obtained here are non-catalytic. [f] Hexanal was used instead of benzaldehyde. [g] δ-Valerolactone.

latter is too large to gain access to the active site. (In addition, this clearly rules out the possibility of autoxidation by surface or transition metal impurities.) Further, to substantiate that the autoxidation of the aldehyde is shape-selective, we used the straight-chain hexanal, which is small enough to enter the 3.8 Å cages of the CoALPO-18 catalyst, as a sacrificial oxidant. The Baeyer–Villiger conversion of cyclohexanone to ε-caprolactone (Table 1, entry 8) freely ensues, because the hexanal gains ready access to the framework active sites and forms the peroxy acid. Thus, large-pore CoALPO-36 (or MnALPO-36) and CoAlPO-5 (or MnAlPO-5) catalysts offer easy access to bulky sacrificial oxidants (such as bezaldehyde), and oxidise a number of ketones, including adamantan-2-one, to their corresponding lactones with very high selectivity.

The implications are clear: the aldehyde is first converted by O_2 at the active sites to the corresponding peroxy acid inside the micropores, and this peroxy acid, in the manner first outlined by Criegee[5,13]—involving its initial nucleophilic attack at the carbonyl carbon—leads to the production of the lactone. In addition, as in our study of the selective oxidation of cyclohexane,[7] there appears to be a clear trend in the dependence of catalytic activity on the combination of the pore-dimension of the molecular sieve and the framework-substituted ion: the ATS structure shows higher conversion and selectivity compared to AFI, and Mn^{II} containing catalysts are slightly more active than their Co^{III} analogues. This agrees well with our estimation of the fraction of the metal ions that undergoes redox reaction.[11]

In summary, a heterogeneous redox molecular sieve catalyst first of all converts the sacrificial aldehyde involved in the Mukaiyama reaction shape-selectively (inside the micropores of the catalyst) into the active peroxy acid. This peroxy acid then converts the cyclic ketone to the lactone (outside the catalyst).

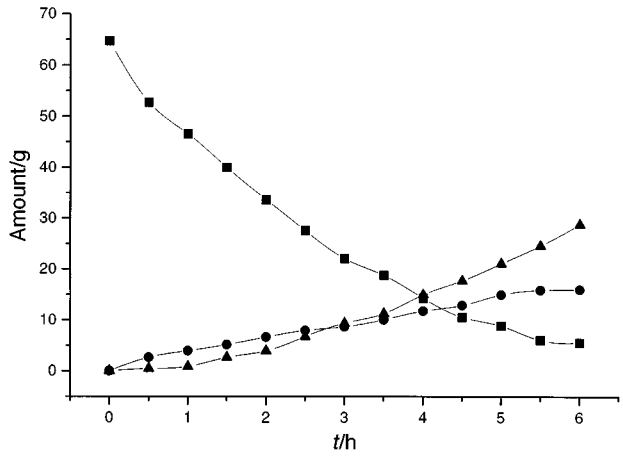

Fig. 2 Typical kinetics plot for the oxidation of cyclohexanone using MnAlPO-36, in the presence of air and benzaldehyde: (■) benzaldehyde, (●) caprolactone and (▲) benzoic acid. When the amount of aldehyde is decreased (cyclohexanone : benzaldehyde = 1 : 1), the rate of formation of the lactone decreases. We believe that the ketones compete with the aldehyde for access to the interiors of the micropores, thereby inhibiting the oxidation of the aldehyde to the peroxy acid.

Received (in Liverpool, UK) 14th January 1999, Accepted 12th February 1999

The use of routine refocused-decoupled INEPT ^{29}Si NMR spectroscopy, in the presence of the chiral lanthanide shift reagent Eu(tfc)$_3$, allows convenient enantiomeric excess determination of chiral α-*C*-silylated amines and alcohols for the first time.

The constant interest in α-*C*-silylated amines, from a synthetic[1] and biological[2] point of view, has led a large number of authors to propose different syntheses for these compounds. Recently we proposed several methods giving access to 1-(trimethylsilyl)alkylamines.[3] One of these consisted of the reduction of acylsilane imines obtained *via* reductive silylation of cyanohydrins.[4]

Because of the potential biological interest of these amines and their derivatives, their synthesis in enantiomeric form is of importance. Although the literature provided us with some examples,[5] no synthesis of such chiral primary amines were described before our recent publication.[6] This led us to search for an accurate, reliable and convenient method for measuring the enantiomeric purity of the synthesized amines.

Many new NMR spectroscopic techniques for the determination of ee now exist.[7] We made our first different attempt using ^{1}H and ^{13}C NMR spectroscopy and the chiral auxiliary Eu(tfc)$_3$. We obtained poor separation and the spectra were complicated by the many protons and carbon atoms present in the compound and the lanthanide shift reagent (LSR). We turned next to ^{29}Si NMR spectroscopy, although methods exploiting the chemical shift sensitivity of this nucleus in organosilicon compounds have not so far been reported. Our experiments required the use of a routine polarization transfer technique, the ^{29}Si NMR refocused-decoupled INEPT experiment, based on the INEPT sequence,[8] which allowed us to circumvent the long relaxation time of the silicon atom. The sensitivity of this technique, which depends on the number of coupled protons, was enhanced in the case of trimethysilylated compounds. The refocusing delay time parameter (Δ = 0.02 s) was graphically chosen with the computer program SIMEPT,[9] on the basis of analytical expressions for the theoritical enhancement of decoupled INEPT spectra,[10] in order to obtain optimum enhancement, which depends on delay times. The chiral auxiliary Eu(tfc)$_3$, which converts the mixture of enantiomers into a diastereoisomeric mixture, was directly added into the NMR sample.

We studied racemic amines first. After a few minutes, the decoupled ^{29}Si NMR spectrum showed two signals of approximately the same intensity due to rapid exchange at equilibrium between the diastereoisomeric adducts and the parent racemic mixture of stereoisomers. The shift of these signals from the signal of the starting racemic mixture increased with the quantity of the europium salt added, as was the broadening of the signals. Best results were obtained with an LSR : substrate molar ratio in the 3–10% range. The results shown in the Table 1 (compounds **1**–**3**) proved the validity of the method.

In order to show that this method could be valuable for other α-*C*-silylated compounds, we also tested racemic α-*C*-silylated alcohols (Table 1, compounds **4**–**6**), synthesized by reduction of the parent acylsilanes obtained by standard methods.[11]

Table 1 Enantiomeric ratios measured for racemic α-*C*-silylated amines and alcohols

Compound		Z	R	LSR/ mol%	$\Delta\delta$ (ppm)[a]	Diastereoisomeric ratio[b]
	**1**	NH_2	Pr	6.2	0.021	50.7 : 49.3
	2	NH_2	C_6H_{11}	8.0	0.069	50.2 : 49.8
	3	NH_2	Bu^t	5.5	0.032	50.5 : 49.5
	4	OH	Me	6.2	0.031	50.3 : 49.7
	5	OH	Pr^i	3.2	0.138	50.1 : 49.9
	6	OH	Ph	10.0	0.031	50.3 : 49.7

[a] In $CDCl_3$ at 25 °C. ^{29}Si NMR chemical shift and separation have been shown to be solvent, substrate, LSR concentration and temperature dependent. See ref. 12. [b] Based on the integration of the ^{29}Si NMR resonances (±1%).

The ratios obtained from ^{29}Si NMR integrations confirmed that the parent mixtures were racemic and showed that this method was valuable also in these cases. However, failure was observed with α-*C*-silylated chloroalkanes, probably because the lower basicity of the chlorine atom stops the molecule complexing with Eu(tfc)$_3$.

An example of the results obtained using this technique is shown in Fig. 1.

Non-racemic mixtures of 1-(trimethylsilyl)butylamine **1** were obtained *via* asymmetric reduction of butyryltrimethylsilane imine under various conditions.[6] The NMR technique was applied to the determination of the ee of these mixtures (see example in Fig. 2) and the results were in good agreement with the mesured specific rotations (Table 2).

In summary, the $\Delta\delta_{Si}$ values of α-*C*-silylated amines and alcohols, obtained from routine refocused-decoupled INEPT experiments in the presence of Eu(tfc)$_3$, indicate that the chemical shift sensitivity of the silicon nucleus allows the determination of ee. This technique is possible because the observed silicon nucleus is close to the chiral and the complexation centers. From a practical point of view, this new and simple method (a single signal in the spectrum is converted into a double one) will be useful in the frame of the asymmetric synthesis of α-*C*-silylated amines and alcohols because it allows a rapid, convenient and accurate determination of the ee.

12 A representative procedure is as follows: 20 mg of the substrate was placed in a 5 mm NMR tube, and 4 cm^3 of dry $CDCl_3$ and Eu(tfc)$_3$ were added. The tube was sealed under nitrogen with cling-film and shaken briskly by hand to ensure complete dissolution. After 30 min, the ^{29}Si NMR spectrum (39.76 MHz) was collected (256 scans) at 300 K on a Bruker Avance DPX 200 MHz spectrometer over a spectral width of 7961 Hz with a repetition delay of 1 s between scans to allow for complete relaxation. INEPT delay time parameters choosen were τ = 0.0357 s and Δ = 0.02 s. Slight line Gaussian multiplication (−0.1 Hz) was applied to aid resolution. The FIDs were Fourier transformed and phased automatically, the same phase corrections being applied for each sample. Integration gave the relative proportions of the diastereoisomeric complexes as listed in Table 1.

New polymerization catalyzed by palladium complexes: synthesis of poly(*p*-phenylenevinylene) derivatives

Dekun Wang and Zhe Wu*

Department of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110, USA.
E-mail: zwu@cstp.umkc.edu

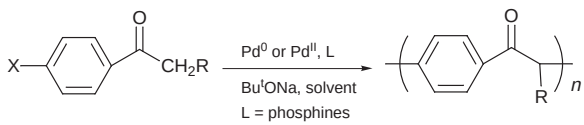
Received (in Corvallis, OR, USA) 4th January 1999, Accepted 9th February 1999

Palladium complexes are found to catalyze the condensation polymerization of halophenyl alkyl ketones to form polyketones, which can be readily converted to poly(phenylenevinylene) and its derivatives.

Recently, palladium-catalyzed cross-coupling reactions have received a great deal of attention. A number of important carbon–carbon bond formation processes have been realized.[1] Palladium-catalyzed coupling reactions are also of growing importance in the synthesis of macromolecules. Several important coupling reactions catalyzed by palladium complexes, such as the Stille coupling reaction,[2] the Suzuki coupling reaction,[3] and the Heck reaction,[4] as well as the reaction of a diyne or bisallene with an aryl dihalide,[5] have been successfully applied in the synthesis of macromolecules. In our ongoing program, we are interested in developing other palladium-catalyzed polymerization reactions and utilizing these reactions to synthesize important materials.

Poly(*p*-phenylenevinylene) (PPV) and its derivatives have attractive properties, such as electrical conductivity,[6] large third-order nonlinear optical response[7] and photo- and electroluminescence in the visible region.[8] However, the extended planar topology of the PPV backbone, which renders it infusible and insoluble in non-reactive media, limits its capacity for subsequent synthesis and fabrication. The problem can be overcome by synthesis of an intermediate soluble polymer, which is typically synthesized from the precursor route first developed by Wessling and Zimmerman,[9] in which the soluble precursor polymer is synthesized through a Wittig or nucleophilic displacement reaction. Thermal induced elimination to PPV can then be accomplished under mild conditions. Other routes to PPV based on this strategy were also reported.[10] We describe here our efforts in developing new polymerization methodology using aryl and ketone coupling reactions, and the application of these reactions to the synthesis of soluble poly(phenylenenevinylene) derivatives.

It was reported recently by Buchwald *et al.* that Pd^0 complexes catalyzed the coupling reaction of a ketone and an aryl halide to form an alkyl aryl ketone.[11] We envision that this reaction might be useful for polymer synthesis, providing new approaches to novel materials. We found that halophenyl alkyl ketones readily underwent condensation polymerization in the presence of a catalytic amount of Pd^0 or Pd^{II} complex, base and phosphine ligand [eqn. (1)].



(1)

R = H, alkyl

X = Br, I

1a R = H
b R = Me
c R = Pr

We find that both mono- and bis-phosphines are effective ligands for the polymerization reactions. The influence of α-alkyl substitutent R on the polymerization (Table 1) was also examined. The α-alkyl substitutents can dramatically enhance the solubility and yield of the polymers. For example, when the α-substitutent is H (entries 1 and 2) the polymers are insoluble and are obtained in low yields. When monomers with longer alkyl substitutents were used, polymers with higher molecular weights (M_n = 11000) were obtained after fractional precipitation.

Table 1 Polymerization of 4-halophenyl alkyl ketones[a]

Entry	X	R	Yield (%)	M_n	M_w
1	Br	H	60	1800[b]	2500
2[c]	I	H	76		
3	Br	Me	70	1700	2100
4	Br	Bu	90	3200	4100
5	I	Pr	65	10100	13200

[a] $Pd(dba)_3$/BINAP was used as catalyst. [b] The polymer is slightly soluble in THF and molecular weights are determined from the soluble portion. [c] The polymer is insoluble in THF.

The polymerization was also studied in the presence of phosphines with different steric and electronic properties. As shown in Table 2, polymers were obtained in high yield and with high molecular weights in the presence of both bulky and electron-donating phosphines, such as PBu^t_3, which indicates that steric bulk and electron-donating phosphines favor the polymerizations. The results further imply that steric and electronic factors need to balance in order to achieve the optimized polymerization conditions. This observation can be understood from the fact that bulky and electron-donating ligands facilitate both oxidative addition and reductive elimination processes, which are believed to be involved in the rate-limiting steps of the catalytic cycle. We also observed that 4-iodophenyl propyl ketone, as compared to bromovalerophenone, polymerized faster and yielded higher molecular weight polymers. This observation suggests that oxidative addition of Pd^0 species to the aryl halide is also a crucial step involved in determing the rate of the polymerization.

The polymerization was also investigated in the presence of different solvents. Polar solvents seem to enhance the polymerization. For example, polymers prepared using a catalytic amount of $Pd(OAc)_2$–ligand exhibited higher molecular weights in THF than in other solvents. Better yields of polymers were also obtained in solvents such as *o*-$C_6H_4Cl_2$ and Ph_2O. No

Table 2 The effect of phosphine ligands on the polymerization[a]

Entry	Ligand	Yield (%)	Cone angle/°	*M*n	*M*w
1	PBu^t_3	63	182	11500	15200

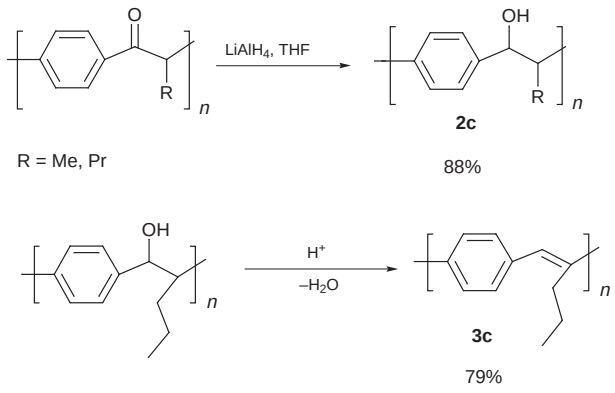

Scheme 1

polymerization was observed when DMA was used as a solvent, which may be attributed to deactivation of the catalysts.

The polymers were isolated by precipitation and the structures of the polymers were determined by spectroscopic techniques. For example, polymer **1c**† shows a peak at δ 4.67 in its ^{1}H NMR spectrum corresponding to the CH resonance. The carbonyl resonance was observed at δ 199.2 and was further confirmed by IR spectroscopy (ν = 1696 cm^{-1}). The single resonance at δ 53.2 in the ^{13}C NMR spectrum corresponds to the methine carbon in polymer **1b**, indicating that the polymerization is selective. The molecular weight was determined by gel permeation chromatography (GPC) using polystyrene as standards. The molecular weights (M_n) of the polymers obtained range from 2000 to 16 000 depending on the catalyst, ligand and solvent used.

The carbonyl groups in the polymers can be quantitatively converted to hydroxy groups using $LiAlH_4$ (Scheme 1). The ^{13}C NMR and IR spectra indicated the complete reduction of the carbonyl groups. Polymer **2c**‡ was obtained as a white solid and was insoluble in hexane. To obtain the PPV derivative, polymer **2c** was further treated with a catalytic amount of H_3PO_4 in toluene. Rapid elimination of H_2O was observed to yield polymer **3c**§ (Scheme 1). The polymer is soluble in common organic solvents, such as THF and CH_2Cl_2. The IR and ^{1}H NMR spectra indicated complete elimination. Both ^{1}H and ^{13}C NMR analysis indicated that the double bonds formed in the polymer backbone are predominantly *trans*. The polymer has a UV absorption (λ_{max} = 290 nm) and exhibits a strong blue emission at 420 nm (Fig. 1) when excitation at 290 nm is applied, which indicates that the polymer is a photoluminescence material.

We have demonstrated that palladium-catalyzed coupling of aryl halides and ketones can be used for polymer synthesis. This has led us to develop a new polymerization reaction and a novel approach to the synthesis of poly(phenylenenevinylene) derivatives. Our studies suggest that the steric and electronic properties of the ligands as well as the nature of the solvent have significant effects on the outcome of the polymerization. The polymers synthesized are soluble and exhibit photoluminescence properties. Synthesis of other electro- and/or photoluminescent polymers using this methodology are currently underway.

We thank the University of Missouri Research Board for support and Dr Zhi Xu for measurement of the fluorescence spectrum.

Sterically protected 1,2,3-dithiazolyl radicals: preparation and structural characterization of 4-chloro-5-pentafluorophenyl-1,2,3-dithiazolyl

Tosha M. Barclay,[a] Leanne Beer,[b] A. Wallace Cordes,[a] Richard T. Oakley,*[b] Kathryn E. Preuss,[b] Nicholas J. Taylor[b] and Robert W. Reed[b]

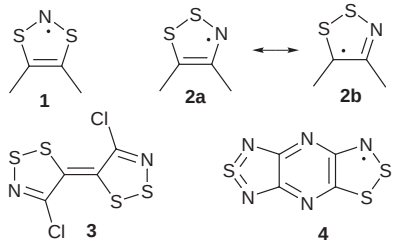
Received (in Cambridge, UK) 22nd December 1998, Accepted 9th February 1999

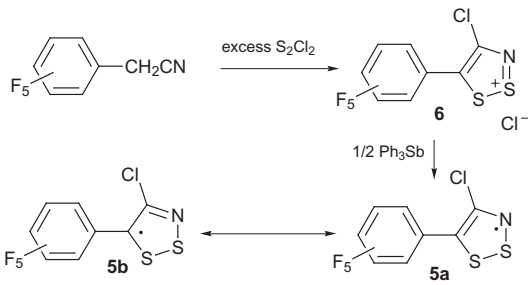
Steric protection afforded by a pentafluorophenyl group at the 5-position facilitates the first isolation and structural characterization of a monocyclic 1,2,3-dithiazolyl as its S–S bonded dimer.

The solid state structures of many 1,3,2-dithiazolyl radicals **1** have been established by X-ray crystallography. Dimerization



through long S–S bonds is normally observed,[1,2] but unassociated radicals are also known.[3,4] By contrast, the solid state properties of 1,2,3-dithiazolyls **2** have remained elusive, as have the structural and chemical implications of the two possible resonance formulations **2a** and **2b**. Recently, however, we demonstrated that the reduction of the 4,5-dichloro-1,2,3-dithiazolylium chloride (Appel's salt[5]) leads to C–C coupling at the 5-position, with the eventual formation of the tetrathiadiazafulvalene **3**.[6] This tendency to associate through carbon (resonance structure **2b**), and hence rearrange, illustrates one of the fundamental difficulties associated with the use of 1,2,3-dithiazolyls as building blocks for molecular conductors.[7] In our efforts to overcome this problem we have shown that delocalization of spin density away from the 5-position, as in the fused ring derivative **4**, suppresses C–C association.[8] We are now investigating the effect of sterically bulky substituents on radical association, and have found that the attachment of a pentafluorophenyl group at the 5-position provides an effective block to C–C bond formation. This has allowed us to isolate and characterize structurally, for the first time, a simple monocyclic 1,2,3-dithiazolyl radical as its S··S bonded dimer.

The synthesis of the title compound **5** involved the preparation of the corresponding dithiazolylium cation (Scheme 1) by the reaction of pentafluorophenylacetonitrile (2.6 g, 0.125 mmol) with excess (5 ml) S_2Cl_2 in 10 ml CH_2Cl_2 containing Bu^n_4NCl (0.20 g). After 10 days a canary yellow solid (2.7 g, 0.079 mmol, 63%) was filtered off and recrystallized from hot MeCN to afford orange needles of **6**, mp 211–213 °C. The reduction of **6** (0.68 g, 2.0 mmol) to **5** was very sensitive to the reaction temperature and the nature of the reducing agent. The best results were obtained using Ph_3Sb (0.38 g, 1.06 mmol) as reductant, and the reaction was performed in liquid SO_2 (5 ml) at −70 °C. After 5 min the solvent was evaporated from the still cold mixture to leave a black matrix, from which **5** (0.17 g, 0.54 mmol, 27 %) could be sublimed, at 45 °C/10^{-2} Torr, as lustrous green–black blocks, mp > 52 °C (decomp.).†



Scheme 1

Compound **5** dissolves in CH_2Cl_2 at room temperature to afford bright yellow solutions which exhibit a strong and persistent EPR signal (g = 2.0089) characteristic of a simple 1,2,3-dithiazolyl radical.[9,10] In addition to the expected triplet structure arising from hyperfine coupling to nitrogen, the spectrum (Fig. 1) also displays rich secondary structure arising from coupling to the 4-chlorine and to all five fluorines on the 5-C_6F_5 group. The a_N value (0.61 mT) is consistent with that expected for a simple 1,2,3-dithiazolyl. Cyclic voltammetry on solutions of **5** in MeCN (Pt electrodes, $Bu^n_4NPF_6$ supporting electrolyte) reveals a reversible oxidation wave with $E_{\frac{1}{2}}$(ox) = 0.38 V (*vs.* SCE) and an irreversible reduction wave with a E_{pc} (red) of −1.1 V (*vs.* SCE). The $E_{\frac{1}{2}}$(ox) potential is more anodic than that for benzodithiazolyls,[8] as expected from the more localized electron distribution in the monocyclic derivative. Indeed the potential is similar to those observed in 1,2,3,5-dithiadiazolyl radicals,[11] where spin density is formally restricted to the five-atom CN_2S_2 ring.

The crystal and molecular structures‡ of both **5** and **6** have been established by X-ray crystallography. The structure of the salt **6** (Fig. 2) consists of ion pairs in which the S–S bond of the cation is bridged by a chloride anion, with S··Cl contacts of 2.8947(16) and 2.9617(18) Å. This arrangement is reminiscent of that observed in the halide salts of 1,2,3,5-dithiadiazolylium cations.[12] The mean plane of the heterocyclic ring makes a dihedral angle of 68.6° with the plane of the C_6F_5 group. The internal structural parameters are typical of a 1,2,3-dithiazoly-

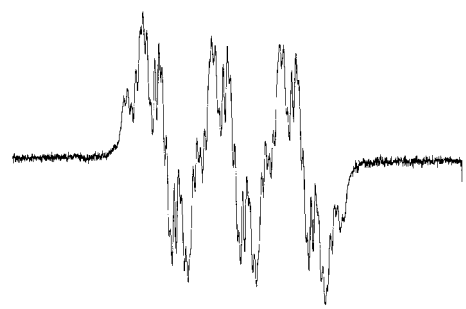


Fig. 1 EPR spectrum (293 K, CH_2Cl_2, SW = 4 mT, g = 2.0089) of radical **5**. Hyperfine coupling constants (derived by simulation with Bruker Simfonia) are a_N = 0.610, a_F = 0.175 (2 F), 0.038 (1 F), 0.031 (2 F), a_{Cl} = 0.1050 (^{37}Cl), 0.0875 (^{35}Cl) mT.

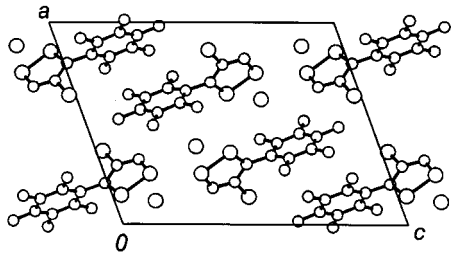

Fig. 2 PLUTO drawing of the cation/anion packing in the chloride salt of **6**. Bond distances within the heterocyclic ring are: *d*(S–S) 2.0284(4), *d*(S–N) 1.605(4), *d*(S–C) 1.673(4), *d*(N–C) 1.309(5), *d*(C–C) 1.393(2) Å.

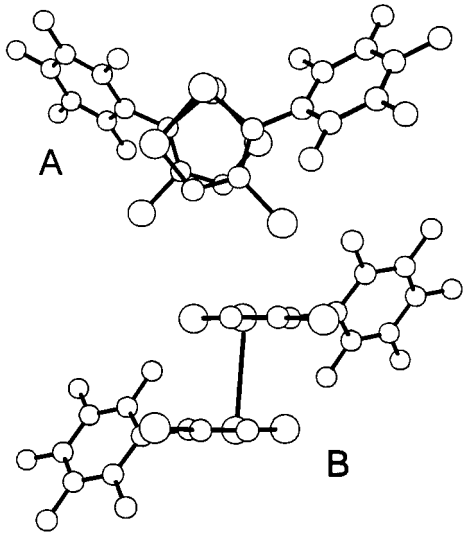

Fig. 3 PLUTO drawings of the radical dimer of **5**, showing the orientation of the overlap of the heterocyclic rings (A) and the interannular S··S contact (B). Bond distances within the heterocyclic ring are: *d*(S–S) 2.0717(8), *d*(S–N) 1.639(2), *d*(S–C) 1.724(2), *d*(N–C) 1.317(3), *d*(C–C) 1.390(3) Å.

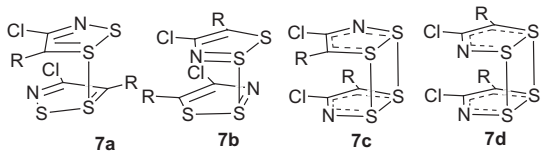
lium salt.[13,14] In the structure of **5** the plane of the C_6F_5 group is again twisted (by 58.3°) away from the plane of the C_2S_2N ring, thereby providing the desired sterically protected 'pocket' for the 5-carbon. The radicals are nonetheless dimerized (Fig. 3). The two halves of the dimer are related by a two-fold axis, and are linked by a single interannular S··S contact of 3.2987(13) Å. This interaction is longer than the corresponding S··S interactions found in *any* known dimer of **1**, and stretches even further the conventional limit of a covalent S–S bond.[15] Taken collectively, the changes observed in the internal bond lengths (Fig. 2 and 3) upon reduction of the 6π-cation to the 7π-radical dimer are consistent with the bonding properties of the singly occupied molecular orbital of the radical.[15]

The mode of association of **5** provides an interesting lesson regarding the interplay of steric and electronic requirements. Dimerization cannot occur at the 5-carbons, for steric reasons, and so occurs through the 1-sulfurs, *i.e.* **7a**, as a result of which these atoms become hypervalent (with a S=C double bond). This arrangement is electronically *less* favored than dimerization at the 2-position, *i.e.* **7b**, which generates a hypervalent sulfur with a S=N double bond, or the more delocalized four-centre modes **7c** and **7d**, which are reminiscent of the cofacial



dimers commonly observed for 1,2,3,5-dithiadiazolyls.[16] Structure **7a** is, however, the *only* cofacial dimerization mode that precludes Cl/R or Cl/Cl and R/R steric interactions. The steric protection afforded by the C_6F_5 groups also affects the packing of dimers. Thus, instead of forming π-stacks, the dimers are clustered about a $\bar{4}$ site, with the dimers linked by S··S′ contacts of 3.7286(9) Å.

We thank the NSERC and the State of Arkansas for financial support. We also acknowledge the NSERC for a post-graduate scholarship to K. E. P.

Notes and references

† Satisfactory chemical analysis were obtained for compounds **5** and **6**.

‡ *Crystal data* for **5** and **6**: Data were collected at 293 K on Siemens P4 (**5**) and Enraf-Nonius (**6**) automated diffractometers with graphite-monochromated Mo-Kα radiation (λ = 0.71073 Å) using omega (**5**) and θ–2θ (**6**) scans. The structures were solved by direct methods and refined by full-matrix least-squares analysis which minimized $\Sigma w(\Delta F)^2$. Compound **5**: $ClS_2F_5NC_8$, M = 304.66, tetragonal, space group $I\bar{4}2d$, with a = 13.8634(8), c = 21.0268(4) Å, V = 4041.2(4) Å^3, Z = 16, D_c = 2.00 g cm^{-3}, μ = 0.82 mm^{-1}. 155 Parameters were refined using 1622 unique observed reflections [$I > 0.0\ \sigma(I)$] to give R = 0.029 and R_w = 0.033. Compound **6**: $Cl_2S_2F_5NC_8$, M = 340.11, monoclinic, space group $P2_1/n$, with a = 12.334(2), b = 6.0917(17), c = 15.947(3) Å, β = 110.382(16)°, V = 1123.4(4) Å^3, Z = 4, D_c = 2.01 g cm^{-3}, μ = 0.98 mm^{-1}. 163 Parameters were refined using 1502 unique observed reflections [$I > 2.0\ \sigma(I)$] to give R = 0.044 and R_w = 0.050. Received (in Cambridge, UK) 4th January 1999, Accepted 15th February 1999

The distribution of the eleven protons present in a six-electron reduced form of metatungstate, $[(H)_2\{W^{IV}_3(OH_2)_3\}W^{VI}_9O_{34}(OH)_3]^{3-}$, in dry CD_3CN is mapped by ^{1}H and ^{183}W NMR, allowing assessment of structural changes which accompany reduction.

The four trinuclear capping units of Keggin polyoxo anions $[X^nW^{VI}_{12}O_{40}]^{n-8}$ (T_d point symmetry; see framework in Fig. 1) are linked to define a tetrahedral cavity encapsulating atom X.[1] Six-electron reduction leads, for X^n = $2H^I$, B^{III}, Si^{IV}, to the 'poly-browns'.[1,2] X-Ray crystallographic and aqueous solution NMR data suggest effective C_{3v} point symmetry for these species, consistent with localisation of the added electrons in a single trinuclear cap whose terminal oxo ligands are protonated to aqua ligands.[3–6]

$$(W^{VI}{=}O)_3 + 6\ e^- + 6\ H^+ \rightarrow (W^{IV} \leftarrow OH_2)_3$$

The salt $(NH_4)_4[(H)_2\{W^{IV}_3(OH_2)_3\}W^{VI}_9O_{35}(OH)_2]$ **I** was synthesised by controlled potential electrolysis in aqueous HCl and converted to $(NBu_4)_3[(H)_2\{W^{IV}_3(OH_2)_3\}W^{VI}_9O_{34}(OH)_3]$ **II** by phase transfer.[7] In D_2O, **I** exhibits a single ^{1}H NMR resonance (two equivalent internal hydrogen atoms) and three ^{183}W resonances (3 : 3 : 6) consistent with effective C_{3v} point symmetry.[2–4,8] However, in dry CD_3CN, **II** exhibits five ^{1}H resonances (a–e) integrating for eleven protons and seven ^{183}W resonances (A–G) integrating for three W^{IV} and nine W^{VI} centres (Fig. 2, Table 1).

The intensities of the ^{1}H (4 : 2 : 1 : 2 : 2) and ^{183}W (1 : 2 : 2 : 2 : 2 : 2 : 1) resonances imply the presence of a mirror plane consistent with effective C_s point symmetry. It is apparent that proton exchange rates are reduced significantly in dry CD_3CN, allowing detection of surface-bound protons and differentiation of inequivalent tungsten sites. What is the driving force responsible for the effective change from T_d to C_s symmetry that accompanies the six electron reduction process?

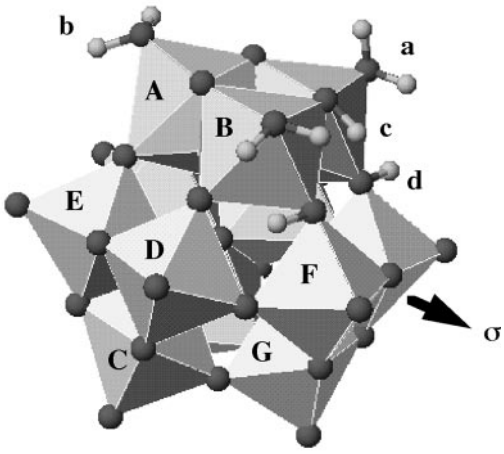

Fig. 1 Polyhedral representation of $[(H)_2\{W^{IV}_3(OH_2)_3\}W^{VI}_9O_{34}(OH)_3]^{3-}$. W atoms are centred in each 'octahedron' of O atoms.

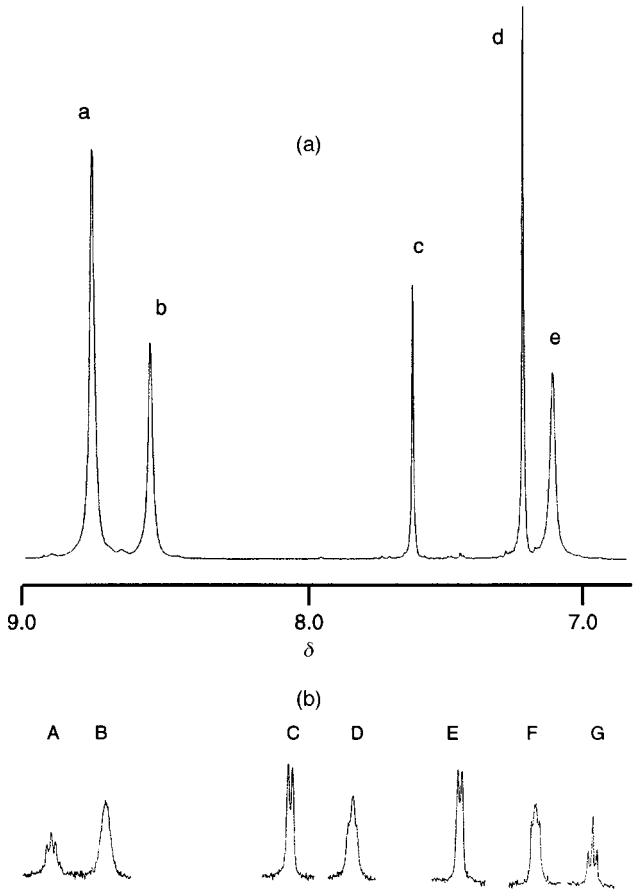

Fig. 2 NMR spectra of **II** (0.15 M) in CD_3CN (anion resonances only) (a) ^{1}H, (b) ^{183}W (99 atom% ^{183}W).

H_2O addition experiments assign resonance e to the slowly exchanging internal protons H_e and indicate that the protons H_a and H_b are in chemically similar sites.[10] Their relative intensities a : b = 4 : 2 allow assignment to the W^{IV}–aqua ligand protons. Tungsten resonances A and G of intensity 1 must be assigned to the unique W^{IV} and W^{VI} atoms lying on the mirror plane. The five resonances B–F of intensity 2 are due to five pairs of W atoms related by the mirror plane. B must be assigned to W^{IV} and so the fragments $W_AO(H_b)_2$ and $\{W_BO(H_a)_2\}_2$ are identified (Fig. 1).

A sample of II was enriched to 99 atom% ^{183}W. Its ^{183}W NMR spectrum featured resolved fine structure (13–18 Hz) assigned as $^{2}J_{WOW}$ coupling characteristic of corner-sharing WOW bridges [Fig. 2(b)].[11] Assigned resonances A and G are triplets consistent with corner-sharing to two equivalent W

Table 1 NMR data for $(NBu_4)_3[(H)_2\{W^{IV}{}_3(OH_2)_3\}W^{VI}{}_9O_{34}(OH)_3]$ **II** (0.15 M, CD_3CN)

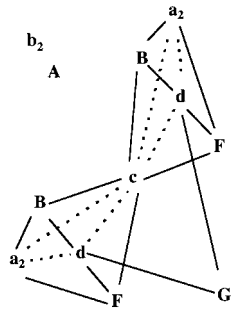

Fig. 3 Map of dipolar HH (----) and scalar WH (——) connectivities to protons H_a–H_d in **II**. Longer range interactions bd and Ad are are also observed but are omitted for clarity.

atoms (Fig. 1). On the other hand, C and E are doublets. A COSY experiment displayed a $W^{VI}W^{VI}$ cross-peak CG which allows assignment of C to the pair of tungsten atoms corner-sharing to unique atom W_G and E to the pair of tungsten atoms corner-sharing with unique atom W_A (Fig. 1). The only other $W^{VI}W^{VI}$ COSY crosspeak detected was DF and tungsten atoms W_D and W_F were assigned on the basis of multiple WOW corner-sharing interactions [Figs. 1, 2(b); *vide infra*: ref. 12].

Assignment and location of the three protons H_c and H_d were addressed initially by a HH ROESY experiment. Cross peaks ac, ad, bd and cd were detected. These dipolar interactions are mapped in Fig. 3. No interactions were observed between internal protons H_e and any of the external protons H_a–H_d.

Mapping of scalar interactions utilised WH HMQC experiments. ^{183}W–^1H coupling was not detected in the 1D spectra (*cf.* Fig. 2) implying that $^2J_{WOH} < W_{1/2} = 2$–9 Hz, allowing constraints to be set on mixing times. A spectrum is shown in Fig. 4 and the scalar connectivities are included in Fig. 3.[12]

The mapping indicates that resonances c and d may be assigned to three hydroxyl protons associated with the reduced $W^{IV}{}_3(AB_2)$ and unique $W^{VI}{}_3(GF_2)$ caps (Figs. 1, 3). Hydrogen oxide ligands $H_3O_2^-$ ligands which bridge pairs of metal atoms have been identified previously,[13] but similar stereochemistry does not appear possible here.

The C_s point symmetry of II is imposed by the positions of the three hydroxyl protons H_c and H_d (Fig. 1). The electronic feature which drives this localisation of protons is the localisation of the six added electrons in the reduced cap AB_2. In six-electron reduced $K_5[B^{III}\{W^{IV}{}_3(OH_2)_3\}W^{VI}{}_9O_{37}]\cdot 13.5H_2O$, the W^{IV}–W^{IV} bond lengths [mean 2.543(3) Å] in the reduced cap are *ca.* 0.77 Å shorter than the $W^{VI}\cdots W^{VI}$ separations in the oxidised caps.[6] The resulting mismatch in dimensions causes the boron atom to move *ca.* 0.4 Å within the internal BO_4 unit and away from the reduced cap but C_{3v} symmetry is retained. The internal cavity in **II** features two hydrogen atoms only and this anion accommodates the mismatch in a different way: three WOW links are converted to longer W(OH)W links [Fig. 1]. Ongoing work will provide more details.

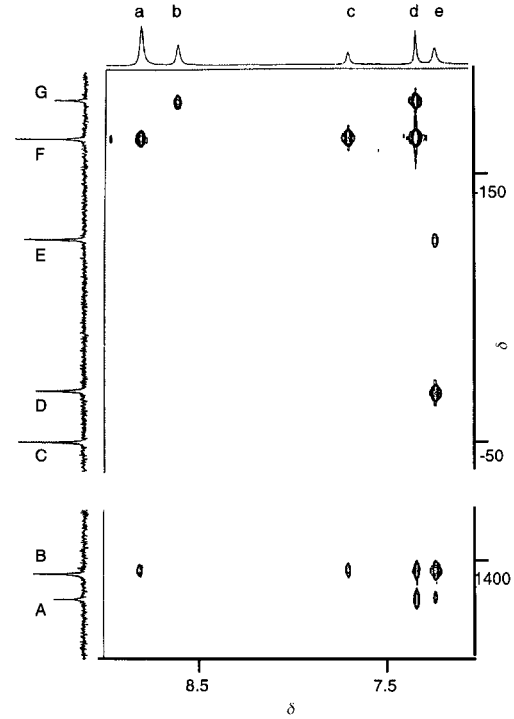

Fig. 4 ^{183}W–^1H HMQC spectrum of **II** (0.15 M, natural abundance) in CD_3CN (t_m = 60 ms; 128 × 4 K, 256 transients per increment; 25 °C).

Unprecedented efficient hydrogenation of arenes in biphasic liquid–liquid catalysis by re-usable aqueous colloidal suspensions of rhodium

Jürgen Schulz, Alain Roucoux* and Henri Patin

Laboratoire de Chimie Organique et des Substances Naturelles, CNRS ESA 6052 Ecole Nationale Superieure de Chimie de Rennes, Avenue du Gal Leclerc, 35700 Rennes, France. E-mail: Alain.Roucoux@ensc-rennes.fr

Received (in Cambridge, UK) 19th January 1999, Accepted 18th February 1999

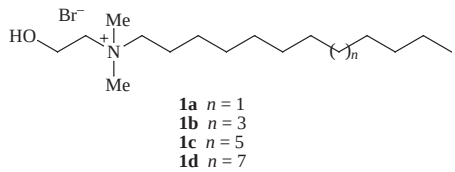
A reduced aqueous colloidal suspension of rhodium shows efficient activity for the catalytic hydrogenation of various benzene derivatives under biphasic conditions at room temperature and under atmospheric hydrogen pressure; the aqueous phase containing the Rh(0) particles can be re-used for further runs with a complete conservation of activity.

Among catalytic processes, hydrogenation of arenes is of great interest, in particular with the increasing industrial demand for low-aromatic diesel fuels[1] and the conversion of benzene to cyclohexane which still represents the most important industrial hydrogenation reaction.[2] Generally, the catalytic transformation is carried out with heterogeneous catalysts.[3] Recently some pure homogeneous[4] or microheterogeneous[5] systems under drastic conditions (pressure and/or high temperature) have been reported for hydrogenation of arenes.

Biphasic systems consisting of a water-phase containing catalytic species and a non-miscible organic phase continue to attract interest for economic and ecological reasons. In most cases, water-soluble homogeneous catalysts containing hydrophilic phosphines are widely used.[6] An original approach is to use colloidal metallic particles[7] finely dispersed in water. The colloidal suspension must be stabilized by highly water soluble protective agents such as polymers,[8] surfactants[9] or ionic species[10] to prevent aggregation and to facilitate recycling. Recently, our laboratory described hydrogenation of alkenes by colloidal suspension of rhodium(0) stabilized by trisulfonated molecules.[11]

Here we describe the complete hydrogenation of various benzene derivatives under biphasic liquid–liquid (water/hydrocarbon) systems by protected rhodium(0) colloids. This metal is known to reduce arenes[12] but to our knowledge, this is the first example allowing an efficient conversion with recycling at room temperature and under atmospheric hydrogen pressure.

In this system, the catalytically active aqueous suspension is made of metallic rhodium(0) particles prepared by reducing rhodium trichloride with sodium borohydride in dilute aqueous solutions of hydroxyalkylammonium salts **1a**–**d** (Scheme 1). These compounds, easily synthesized[13] by quaternization of *N*,*N*-dimethylethanolamine with the appropriate bromoalkanes, are highly water soluble. Surface tension measurements† of compounds **1a**–**1d** show that they are surfactants and self aggregate into micelles at critical micellar concentrations (cmc) of 1×10^{-2}, 2.5×10^{-3}, 1×10^{-3} and 2.5×10^{-4} mol l^{-1}. The interfacial tensions of aqueous solutions decreased from 72 to *ca*. 37 mN m^{-1}. Nevertheless, only **1c** and **1d** (alkyl chain containing 16 and 18 carbons) are efficient protective colloid agents for rhodium nanoparticles with an effective electrosteric stabilization. Transmission electron cryomicroscopic observations‡ show that the average particle size of system Rh–**1c** was 3.6 nm. The size distribution histogram was obtained on the basis of measurement of about 300 particles (Fig. 1). No evolution of distribution was observed after catalysis, consequently, these monodispersed aqueous suspensions are highly stable and can be re-used for further runs.



1a $n = 1$
1b $n = 3$
1c $n = 5$
1d $n = 7$

Scheme 1

The hydrogenation of benzene derivatives using the catalytic system (Rh/**1c**–**d**/water) under biphasic conditions is very selective and gives the corresponding cyclohexanes. Stable suspensions prepared in the presence of surfactant **1c** or **1d** with an optimized molar ratio **1c**,**d**/Rh = 2 give a better activity and prevent aggregation. This sytem is sufficient to maintain colloidal particles within the aqueous phase during the catalytic process and thus allows its recycling. In contrast with **1c**, CTAB (cetyltrimethylammonium bromide) gives poor results during recycling (Table 1, entry 9). This justifies the use of the hydroxyalkylammonium salt **1**. No hydrogenated intermediates are observed during the catalysis. The reaction is monitored by the volume of hydrogen consumed and gas chromatographic analysis. The conversion is usually complete after 7 h (Table 1). No induction period is observed but steric and electronic effects of substituents affect the reaction time and arenes substituted by electron-withdrawing groups react slowly (Table 1, entry 12) or not (Table 1, entry 13) whereas the reaction is favoured with electron-donating substituents. In the latter case the substrate should be preferentially adsorbed on the colloid (Table 1, entries 1–11). Analogous effects have been observed by Lemaire and coworkers.[5] The chemoselectivity of the reaction is good, with ester and ether functions remaining unaffected (Table 1, entries 6 and 12). In addition to the hydrogenation of

[a] *Conditions*: catalyst (3.8×10^{-5} mol), surfactant (7.6×10^{-5} mol), water (10 ml), substrate (3.8×10^{-3} mol), hydrogen pressure (1 atm), temperature (20 °C), stirred at 1500 min^{-1}. [b] Determined by GC analysis. [c] Turnover frequency defined as mol of H_2 per mol of rhodium per h. [d] Similarly PhI, PhCl and PhF are not reduced.

the aromatic ring, *exo*-C–C double bonds are hydrogenated (Table 1, entry 15). A complete hydrogenation is also observed with disubstituted benzene derivatives (Table 1, entries 16–18). The *cis*-compounds are largely the major products as usually observed in heterogeneous catalytic systems.[14] Finally, we have observed the formation of cyclohexylamine by reduction of aniline (Table 1, entry 14) but in this case, the colloidal suspension is insufficiently stable and aggregates. Accordingly the catalytic activity during the second run dramatically decreases to become negligible. We suggest a reaction between the product and the surfactant.

The durability of the catalytic system was tested by using it for four successive hydrogenations of anisole. In the first cycle, the turnover frequency (TOF) was 60 h^{-1}. Then, the aqueous phase containing the catalyst was separated from the hydrogenated product by simple decantation and re-used in a second hydrogenation cycle. In the same manner the catalyst was recycled for a third and fourth run. The aqueous suspension shows a comparable turnover activity during the four runs of catalysis. As the activity during recycling depends on the amount of colloidal particles which remain in water after decantation, an efficient biphasic catalytic system with good remaining activity at the fourth run is a demonstration of the stability of the catalytically active suspensions with compound **1c**.

In conclusion, these results show that rhodium nanoparticles, protected by hydroxyalkylammonium salts containing at least 16 carbons leading to electrosteric stabilization, can be readily used for quantitative reduction of arenes. The interfacial tension parameter can be modulated to favour the contact between the catalyst and the substrate localised in two phases. Finally, we describe an efficient recycling process for hydrogenation of benzene derivatives without loss of activity and usable under standard conditions (20 °C, 1 atm H_2).

We thank CNRS and the Region Bretagne for financial support. We would also like to thank Dr Rolland (University of Rennes 1) for helpful comments and TEM micrographs.

Notes and references

† Surface tension measurements were performed at 20 °C using the ring method with a Du Nouy tensiometer (Krüss K10T).

‡ TE Cryo-Microscopic studies were conducted using a PHILIPS CM 12 transmission electron microscope at 100 keV. Samples were prepared by a dropwise addition of the stabilized colloid in water onto a copper sample mesh covered with carbon. The colloidal dispersion was removed after 1 min using cellulose, then the samples were quickly frozen in liquid ethane before transfer to the frozen microscope.

Synthesis of functional 1,4-diphosphaindenes and their related anions

Patrick Rosa, Louis Ricard, François Mathey* and Pascal Le Floch*

Laboratoire 'Héteroéléments et Coordination', UMR CNRS 7653, Ecole Polytechnique, 91128 Palaiseau Cedex, France. E mail: lefloch@mars.polytechnique.fr

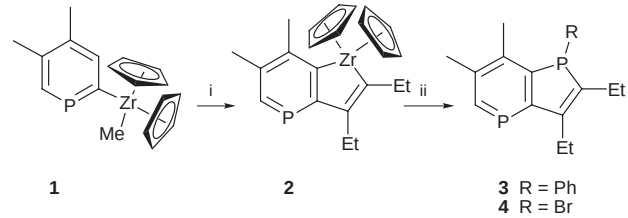
Received (in Liverpool, UK) 4th January 1999, Accepted 16th February 1999

Treatment of a 1-zircona-4-phosphaindene complex with PBr_3 affords a 1-bromo-1,4-diphosphaindene, which can be used as a convenient precursor for the preparation of the related 1,4-diphosphaindenyl mono- and tri-anions and (1*R*)-functional derivatives.

The search for new sophisticated ligands including sp^2-hybridised phosphorus atoms as bonding sites is a current and topical field of investigation.[1] Among these ligands, phosphinines play a significant role and continuous efforts have been made to improve the synthesis of their functional derivatives.[2] Whereas several routes towards polyfunctional mono-, bis- and tris-phosphinine based ligands[3] and macrocycles[4] have been developed, fused aromatic and non-aromatic ring systems have received much less attention. Although some polyaromatic systems are known,[5] only two examples of heterocyclic-fused ring systems incorporating the phosphinine nucleus have been described so far.[6] In view of the importance of phospholes and their related phospholide anions in coordination chemistry,[7] we decided to investigate the synthesis of 1,4-diphosphaindene species, a new type of ligand which could combine the chemistries of phosphinines and phospholes. Herein we report on these investigations.

Among the different synthetic approaches conventionally used for the synthesis of phospholes, metallacycle transfer reactions from zirconacyclopentadiene complexes appear very attractive.[8] Indeed, this simple process was used for the preparation of 1-phosphaindene ligands from η^2-benzyne zirconocene complexes, alkynes and PCl_3.[9] The recent discovery of η^2-phosphabenzyne zirconocene complexes[10] prompted us to investigate the corresponding transformation. All the experiments were conducted with the 1-zircona-4-phosphaindene complex **2** whose synthesis was previously reported from the reaction of the PMe_3 adduct of the η^2-phosphabenzyne complex with hex-3-yne. As a prelude to this work we found that the use of the Zr–Me complex **1** as precursor provided a more straighforward access to **2**. This complex turns out to be less reactive than that of its corresponding carbon counterpart. It seems likely that the decrease of electron density at the β positions of the phosphinine is responsible for this situation.[11] Preliminary experiments with PCl_3 only led to the recovery of starting material after several hours of reaction in CH_2Cl_2. Better results were obtained using $PhPCl_2$ as transfer reagent since the 1-phenyl-1,4-diphosphaindene **3** could be prepared after 5 to 10 days reaction, depending on the concentration used, in 15% yield. Finally, we found that the use of PBr_3 dramatically increased the rate of the reaction as well as the yield. After 1 h, the 1-bromo-1,4-diphosphaindene **4** was isolated in 80% yield as a slightly moisture- and oxygen-sensitive yellow oil after extraction with hexanes (Scheme 1).

The reaction of **4** with lithium is of particular interest. With a stoichiometric amount of lithium in THF at 25 °C, the monoanion **5a** is formed quantitatively according to ^{31}P NMR analysis. All available data (^{31}P, ^{1}H, ^{13}C NMR) support the structure proposed for **5a**. Whereas the ^{31}P NMR chemical shift of **5a** is comparable to those recorded for other phosphaindenyl anions, that of the phosphinine subunit experiences a dramatic upfield shift (δ 146.6 in **5a** *vs*. 176 in **4**). This observation shows



Scheme 1 *Reagents and conditions*: i, hex-3-yne, 80 °C, 3 h; ii, $PhPCl_2$, CH_2Cl_2, 5–10 d, then PBr_3, CH_2Cl_2, 1 h.

that a substantial delocalization of the negative charge occurs in **5a**. As expected, anion **5a** can be used as a convenient source of functional derivatives *via* reaction of electrophiles at the nucleophilic P atom of the phospholide unit (Scheme 2). Reactions of **5a** with $Br(CH_2)_2CN$ and MeI afford compounds **6** and **7** which were isolated in modest yields (40 and 50% respectively).† The corresponding $PSiMe_3$ derivative **8** was too sensitive towards hydrolysis to be isolated. An X-ray crystal structure analysis (Fig. 1) was carried out on the sulfide **9**‡ which was obtained by treating **7** with elemental sulfur in toluene. The structure of **9** deserves no special comment. Apparently, the phosphinine unit is not perturbed by the presence of the fused phosphole moiety as shown by the equivalency of the two C=P sp^2 bonds and by the value of the internal C–P–C angle, which is close to that recorded for other phosphinines.

Another interesting observation concerns the reduction of anion **5a**. We found that care must be taken to avoid over-reduction. Indeed, a prolonged contact with excess lithium or sodium cleanly affords a new species whose structure was ascribed to trianions **10a**,**b** on the basis of NMR data.[12] Evidence supporting the formulation proposed for **10** was given by oxidation with one equivalent of iodine, which leads back to the monoanions **5a**,**b** (Scheme 3). Further experiments aimed at developing the use in coordination chemistry of ligands such as monoanions **5**, whose synthesis was the real aim of this work, are currently under progress in our laboratories.

We are grateful to the CNRS and the Ecole Polytechnique for the financial support of this work.

For **10a**: δ_P(C_4D_8O) 34.7 (d, $^3J_{P,P}$ 13.8, P_1), 24 (P_4); δ_H(C_4D_8O) 7.20 (d, 1H, $^2J_{H,P}$ 40.1, H_5); δ_C(C_4D_8O) 150.6 (dd, $^2J_{P,C}$ 17.6, $^3J_{P,C}$ 3.9, C_6), 150 (dd, $^1J_{P,C}$ 37.1, $^2J_{P,C}$ 6.8, C_2), 146 (dd, $^1J_{P,C}$ 43.3, $^3J_{P,C}$ 4.2, C_9), 144.9 (d, $^1J_{P,C}$ 41.6, C_5), 139 (dd, $^1J_{P,C}$ 40, $^2J_{P,C}$ 10.4, C_8), 114.7 (dd, $^2J_{P,C}$ 12, $^2J_{P,C}$ 7.5, C_3), 61.1 (dd, $^3J_{P,C}$ 24.2, $^2J_{P,C}$ 8.4, C_7). For **10b**: δ_P(C_4D_8O) 39.3 (d, $^3J_{P,P}$ 12.2, P_1), 20.4 (P_4).

‡ *Crystal data* for **9**: Crystals of **9** ($C_{14}H_{20}P_2S$) were grown from MeOH. Data were collected at 123 ± 0.5 K on an Enraf-Nonius CAD4 diffractometer using Mo-Kα radiation (λ = 0.71073 Å) and a graphite monochromator. The crystal structure was solved and refined using the Enraf-Nonius MOLEN package. The compound crystallises in space group $P2_1/n$ (14), a = 9.861(1), b = 15.219(2), c = 10.715(1) Å, β = 110.95(1)°, V = 1501.89(59) Å^3, Z = 4, D_c = 1.249 g cm^{-3}, μ = 4.0 cm^{-1}, F(000) = 600. A total of 4725 unique reflexions were recorded in the range $2 \leqslant 2\theta \leqslant 60.0$ of which 1153 were considered as unobserved [$F^2 < 2.0\sigma(F^2)$], leaving 3572 for solution and refinement. Direct methods yielded a solution for all atoms. The hydrogen atoms were refined with isotropic temperature factors in the final stages of least-squares while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a p factor equal to 0.08. The final agreement factors were R = 0.033, R_w = 0.053, GOF = 1.10. CCDC 182/1177. Received (in Cambridge, UK) 27th January 1999, Accepted 12th February 1999

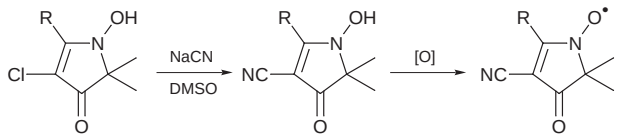
A method for the synthesis of persistent vinylnitroxides (vinylaminoxyls) has been developed and, for one of the radicals synthesized, an extremely high energy of intermolecular exchange interaction (−101 K) has been found.

Vinylnitroxides are traditionally considered transient radicals, since even EPR methods are often not powerful enough to detect them without using spin traps.[1] We succeeded in synthesizing persistent vinylnitroxides **1** and **2** and isolating them as individual solids (Scheme 1).†



3a R = Ph
b R = *m*-pyridyl

4a R = Ph
b R = *m*-pyridyl

1 R = Ph
2 R = *m*-pyridyl

Scheme 1

The vinylnitroxides isolated are similar to nitronyl nitroxides, whose synthesis was developed by Ullman *et al.*,[2] in that they have effective delocalization of spin density. The EPR data of solutions of **1** and **2** indicate that the spin density in **1** and **2** is significantly delocalized from the N–O• group to the nitrile group [$a_{N(N–O•)}$ = 6.0 G, $a_{N(CN)}$ = 1.0 G for **1** and $a_{N(N–O•)}$ = 6.0 G, $a_{N(CN)}$ = 1.2 G for **2**).

The magnetic properties‡ of solid **1** and **2** deserve special attention. Treatment of the experimental dependence $\chi(T)$ for **1** (Fig. 1) and **2** showed that the experimental curves perfectly fit the exchange chain model[3] with parameters g = 2.04, J/k = −101 K and x = 0.02 for **1** and g = 2.01, J/k = −55 K and x = 0.03 for **2**. Due to these strong exchange interactions in solid **1** and **2**, even at room temperature the μ_{eff} values of the compounds (1.49 μ_B for **1** and 1.58 μ_B for **2**) are considerably smaller than the theoretical value of 1.73 μ_B corresponding to the presence of one unpaired electron per molecule. The effective magnetic moments of **1** and **2** continuously decrease to 0.2 and 0.4 μ_B at 2 K, respectively. In $CHCl_3$ solutions of **1** and **2**, the magnetic moments equal the theoretical value within

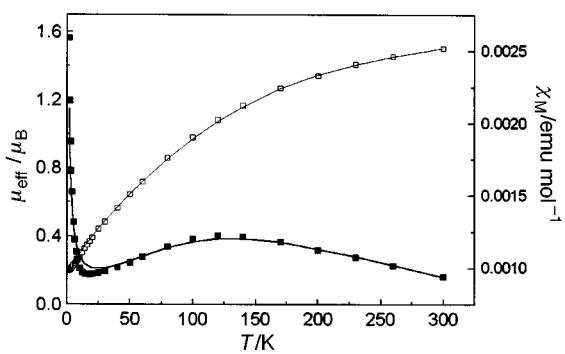


Fig. 1 Plots of effective magnetic moment (μ_{eff}) (□) and magnetic susceptibility (χ_M) (■) for **1**.

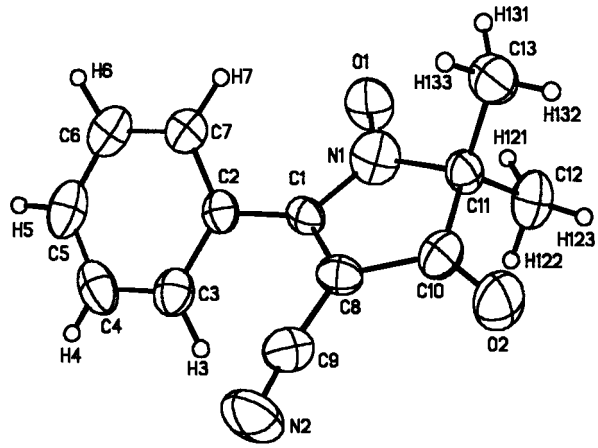

Fig. 2 ORTEP plot of the structure of **1**.

experimental error (1.70 μ_B for **1** and 1.73 μ_B for **2**) and do not change when the temperature decreases. Thus the experiment with vinylnitroxide solutions confirmed that strong spin–spin interactions are inherent in the solids. This prompted us to study the crystal structure of the vinylnitroxides. For **1** we succeeded in growing a single crystal of good quality (Fig. 2).§ In solid **1**, the shortest intermolecular contacts are at least 3 Å. Therefore, the structure of **1** should be considered molecular. However, the magnetic structure of **1**, as noted above, involves magnetic chains. The shortest intermolecular contacts in solid **1** are shown in Fig. 3. These are the nearly equal distances from the nitroxyl oxygen atom of one **1** molecule to both vinyl carbon atoms of the neighboring **1** molecule ($d_{O(N–O•)\cdots\beta\text{-}C(C=C)}$ = 3.183 Å and $d_{O(N–O•)\cdots\alpha\text{-}C(C=C)}$ = 3.296 Å). It is reasonable to assume that the 'magnetic chains' are formed by these contacts in solid **1** and are responsible for the strong exchange interactions (−101 K) in **1**.

To understand the magnetic behavior of **1** we carried out *ab initio* calculations on the electronic structure and intermolecular exchange interaction parameters in a two-radical model system [Fig. 4(*a*)]. It was found that the traditional HF (ROHF, UHF) and post-HF (direct CI, CASSCF) methods failed to give the

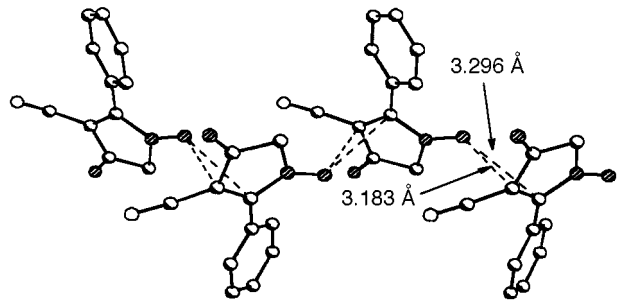

Fig. 3 Structure of the exchange chain in solid **1** (H atoms and CH_3 groups are omitted for clarity).

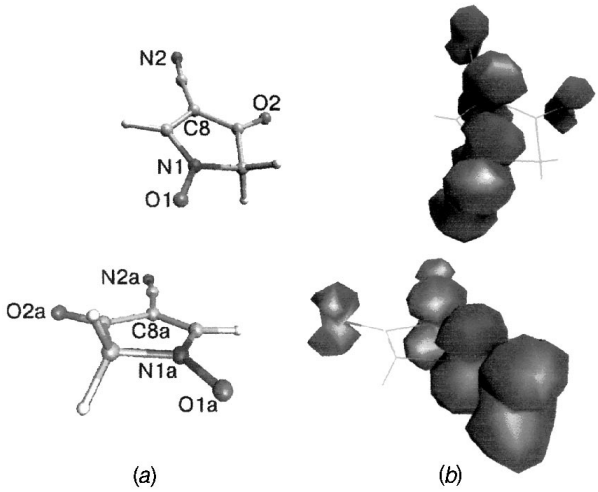

Fig. 4 Truncated (two-radical) model system (*a*) and general view of the spin density distribution for the model system (*b*).

Table 2 Main calculated atomic spin densities (VWN approach)

	Basis set	
Atom	DZVP	BG
O1	0.420	0.547
N1	0.214	0.124
O2	0.101	0.107
C8	0.237	0.212
N2	0.093	0.074
O1a	0.437	0.548
N1a	0.201	0.119
O2a	0.098	0.106
C8a	0.235	0.211
N2a	0.088	0.074

sign of the exchange interaction parameter, whereas DFT/Broken Symmetry methods gave the same sign and order of the *J* parameter as in the experiment (Table 1). Analyzing the spin density distribution [Table 2 and Fig. 2(*b*)] calculated by the VWN method, one can assume that the most preferable intermolecular exchange channel passes through the vinyl β-carbon atom (C8a). The part (0.21–0.24) of the unpaired electron spin density localized on the C8a atom in one molecule contacts the spin density localized on the nitroxyl group of the neighboring molecule, causing an effective intermolecular exchange interaction between the neighboring radicals.

Thus, we succeeded in synthesizing persistent vinylnitroxides and revealed their surprising ability to form magnetic chains with strong interchain exchange interactions at long intermolecular distances (> 3 Å) in formally molecular solids. The quantum-chemical calculations adequately explain these strong exchange interactions in solid vinylnitroxides. It appeared that these strong interactions are favored by localization of the spin density of the N–O$^{\bullet}$ group of one nitroxide near the β-carbon of the vinyl group bonded to the nitroxyl group of the neighboring nitroxide.

Notes and references

† The starting 2-phenylpyrroline **3a** was obtained according to V. A. Reznikov, L. A. Vishnivetskaya and L. B. Volodarsky, *Izv. Akad. Nauk., Ser. Khim.*, **1990**, 390. The pyridine derivative was synthesized in a similar manner.

Synthesis of **4a**: 0.5 g (2 mmol) of chloropyrroline **3a** was added over 15 min to a solution of 0.2 g of NaCN (4 mmol) in 5 ml of anhydrous DMSO with stirring and cooling. The mixture was stirred further for 30 min at 20 °C and then diluted with 15 ml of water with cooling. The solution was acidified with 5% HCl to pH 3. The product precipitate was filtered off, washed with water and a 1 : 1 EtOAc–hexane mixture, and dried (80%); mp 213–216 °C (from EtOAc–MeOH); ν_{max}(KBr)/cm^{-1} 2200 (C≡N), 1675 (C=O); λ_{max}(EtOH)/nm (log ε) 245 (4.27), 346 (3.88); δ_H([$^2H_6$]DMSO) 1.35 [s, 6H, 5-(CH$_3$)$_2$], 7.64 (m, 3H), 7.84 (m, 2H, Ph); δ_C([$^2H_6$]DMSO) 20.75 [5-(CH$_3$)$_2$], 71.08 (C-5), 77.96 (C-3), 115.41 (C≡N), 125.82, 128.45, 128.84, 132.64 (Ph), 170.92 (C-2), 194.96 (C-4). The pyridine derivative **4b** was obtained in a similar manner.

Synthesis of **1**: A suspension of 0.2 g of the hydroxy compound **4b** and 2 g of MnO_2 in 10 ml of $CHCl_3$ was stirred for 30 min at 20 °C. The excess of the oxidant was filtered off, the solution was evaporated, and the residue was chromatographed on silica gel, with $CHCl_3$ as eluent (60%), mp 143–145 °C (from hexane); ν_{max}(KBr)/cm^{-1} 2200 (C≡N), 1700 (C=O), 1540, 1600 (C=C); λ_{max}(hexane)/nm (log ε) 250 (4.17), 270 (4.11), 313 (3.73), 334 (3.93), 397 (3.68), 578 (3.26) [Found (calc.): C, 68.5 (68.7); H, 4.8 (4.8); N, 12.1% (12.1%)]. An analogous procedure with the pyridine derivative **4b** afforded the corresponding radical **2** in 40% yield, mp 113–115 °C (from hexane); ν_{max}(KBr)/cm^{-1} 1705 (C=O), 1590 (C=C), 2200 (C≡N); λ_{max}(hexane)/nm (log ε) 246 (4.14), 308 (3.48), 333 (3.67), 395 (3.48), 564 (3.05) [Found (calc.): C, 55.7 (55.6); H, 4.2 (4.5); N, 15.3% (15.6%)].

‡ Magnetic susceptibility was measured with an MPMS-5S SQUID magnetometer over 2–300 K.

A novel acylative ring cleavage of benzothieno[3,2-*b*]pyran-4-ols: application to the synthesis of dibenzothiophenes and fused-ring derivatives

Christopher D. Gabbutt,* John D. Hepworth, B. Mark Heron and Jean-Luc Thomas

Department of Chemistry, University of Hull, Hull, UK HU6 7RX. E-mail: c.d.gabbutt@chem.hull.ac.uk

Received (in Liverpool, UK) 26th January 1999, Accepted 11th February 1999

The benzothienopyranols 3, readily available from the ketone 1, are transformed to the carbamates 5 on treatment with *N,N*-dimethylcarbamoyl chloride, subsequent thermal electrocyclisation provides access to dibenzothiophene derivatives 6 and 11–13.

Dibenzothiophene and its congeners are not only of intrinsic interest but find applications as intermediates for the synthesis of dyes, pharmaceuticals, organic conductors and novel heterohelicenes[1,2] and hydrocarbons.[3] Dibenzothiophene and, especially, its benzologues are also of environmental concern because of their presence in fossil fuels and their combustion products.[4a,b]

The most frequently employed ring syntheses of dibenzothiophenes employ Friedel–Crafts related chemistry.[5] Routes involving the benzologation of benzo[*b*]thiophene by alternative means are less common. Thus, cycloadditions to benzo[*b*]thiophene-2,3-quinodimethanes[6] and Diels–Alder reactions of benzothienopyran-2- and 3- ones[7] have been investigated. The photodehydrocyclisation of 1-aryl-2-(thienyl)ethylenes has proved to be of value for construction of polycyclic condensed thiophenes.[4a,5,8] In contrast, benzannulation of thiophenes, in particular, benzo[*b*]thiophene, by thermal electrocyclisations has been much less studied.[5] 3-Substituted dibenzothiophene-1-carbonitriles are accessible from a tandem thermal cyclisation–elimination reaction of 2-(3-benzothienyl)-5-(dimethylamino)penta-2,4-dienonitriles.[9] More recently, 1-acetoxydibenzothiophenes have been obtained by thermolysis of 4-(2-benzothienyl)-2,3-disubstituted cyclobut-2-enones.[10]

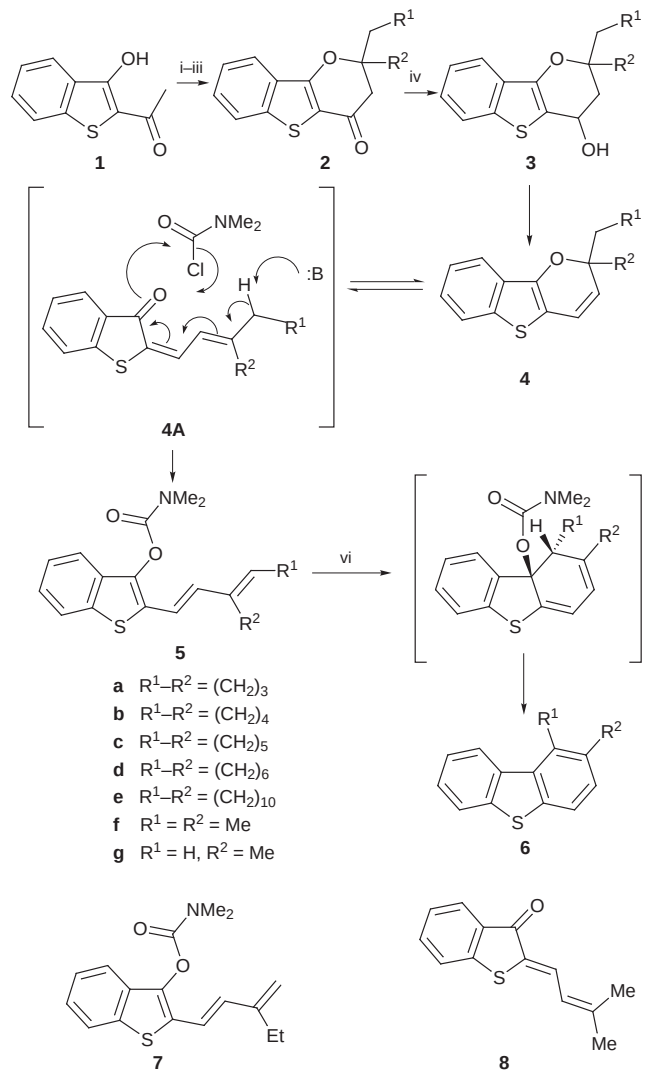
We now report a novel thermal electrocyclisation–elimination protocol for the synthesis of dibenzothiophenes in which the key step involves formation of the carbamates **5** by an unprecedented acylative ring cleavage of benzothieno[3,2-*b*]pyran-4-ols **3** with Me_2NCOCl. The pyranols are readily prepared as shown in Scheme 1.†

2-Acetyl-3-hydroxybenzo[*b*]thiophene **1**, accessible in a single step from thiosalicylic acid,[11] was treated with 2 equiv. of LDA in THF at −40 °C to give a deep red solution of the dianion. Addition of the appropriate ketone (1 equiv.) followed by aqueous work-up provided the corresponding β-hydroxy ketone that was cyclised with methanolic-HCl to the benzothienopyranones **2a**–**g** (62–70%). Subsequent reduction gave **3a**–**g** in high yield.

Attempts to dehydrate **3a** to **4a** which, we envisaged, would function as a Diels–Alder diene, with TsOH in toluene, or with TsCl or MsCl in pyridine, failed to give a tractable product. The Chugaev-type elimination *via in situ* formation of the thiocarbonate from PhOCSCl was also unsuccessful. A mechanistically related, though little used, route to alkenes from alcohols involves the formation of carbamates, (from R_2NCOCl–pyridine), the elimination step being accomplished separately by flow pyrolysis at *ca*. 300–500 °C.[12] When **3a** was heated with Me_2NCOCl in pyridine (*ca.* 5 h) the anticipated *O*-acyl derivative was not obtained, the only isolable product was, remarkably, **5a** (mp 134–135 °C). Yields were optimised (74%) when 2 equiv. of Me_2NCOCl were used. Under the same conditions **3b**–**f** gave **5b**–**f** in excellent yields (70–90%). The ^1H NMR spectra of these compounds indicated *trans* stereochemistry of the alkene moiety.‡

We suggest that the benzothiophenes **5** are formed *via* initial *O*-acylation of **3** followed by elimination to give the pyran **4**§ which undergoes electrocyclic ring opening to the dienone **4A**. Subsequent deprotonation followed by *O*-acylation generates **5**. In accord with this proposal, it has recently been demonstrated that in solution ($CDCl_3$) 5,5-dimethyl-5*H*-thieno[3,2-*b*]pyran is in equilibrium with its dienone valence tautomer.[13]

Interestingly this elimination–acylation reaction not only affords carbamates **5** stereospecifically, but regiospecifically also. Thus **3f** gave **5f** (mp 116–118 °C, 85%) exclusively. None of the terminal alkene **7**, arising by deprotonation of the methyl



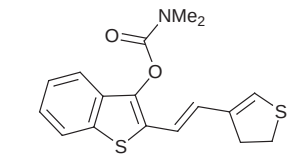
Scheme 1 *Reagents and conditions*: i, LDA, THF, −40 °C; ii, $R^1CH_2COR^2$, dil. HCl; iii, MeOH–HCl; iv, $NaBH_4$, EtOH; v, Me_2NCOCl (2 equiv.), pyridine, reflux; vi, triethylene glycol, reflux.

group in **4Af**, was observed.¶ The *E*,*E* stereochemistry of **5f** was established from its ^{1}H NMR spectrum and a NOESY experiment which confirmed the *cis* disposition of the methyl groups.

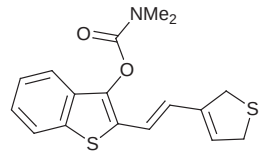
Support for the intermediacy of **4A** was provided by the behaviour of **3g**, which gave the yellow (*Z*)-dienone **8** (mp 118–120 °C, 50%),‖ *via* isomerisation of **4Ag**, as the only identifiable product. Attempts to convert **8** into **5g** by further reaction with Me_2NCOCl–pyridine were unsuccessful. Formation of the least substituted alkene is, apparently, disfavoured.

The carbamates **5** possess a contiguous triene system and have the potential to cyclise with extrusion of Me_2NCO_2H to give dibenzothiophenes. After much experimentation, it was found that when **5a**–**f** were heated in triethylene glycol (bp 285 °C) for 6 h formation of a new, non-polar compound was complete (TLC). Aqueous work-up followed by flash chromatography gave the novel fused systems **6a**–**e** (30–42%). The preparation of **6f** (28%) represents an improved route to this compound.[14] Thermal isomerisation of the *trans* alkene moiety in **5** precedes disrotatory ring closure and a concomitant E_i reaction generates **6**.

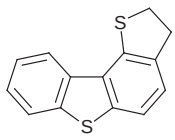
The dianion of **1** and 3-oxotetrahydrothiophene gave, ultimately, **9** and **10** (38 and 25% from the pyranol), which were



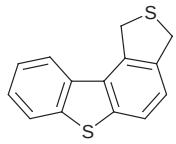
9



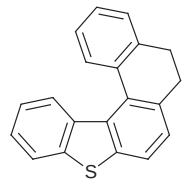
10



11



12



13

readily separated by flash chromatography. Thermal cyclisation provided the tetracycles **11** (mp 84–85.5 °C, 44%) and **12** (mp 79–80.5 °C, 35%) respectively. In like manner the pentacycle **13** (mp 108–109 °C, 28%) was obtained *via* 2-tetralone.

Although the yields are modest this method offers a facile entry to polycyclic thiophenes which is complementary to the current protocols. Existing procedures would not permit ready access to tetracycles **6a**–**e** nor to the isobenzothiophene **12**. Applications to the synthesis of more complex polycycles will be forthcoming.

We thank the EPSRC for provision of the mass spectrometry service at the University of Wales, Swansea, and James Robinson Ltd. for financial support to J.-L. T.

Notes and references

† All new compounds were characterised by ^{1}H and ^{13}C NMR, HRMS and elemental analysis.

‡ The *vicinal* alkene protons appeared as doublets at *ca.* δ 6.5 and 6.7, *J* 16 Hz, ($CDCl_3$) for **5a**,**b**,**e** and **f**. However, in **5c**,**d** the signals were coincidental (δ 6.59, 2H, s for both) and *trans* stereochemistry was assumed for these compounds by analogy with the other examples.

§ We are unaware of any examples in which carbamoylation with Me_2NCOCl is accompanied by *in situ* elimination. The nature of the elimination step (**3** to **4**) is a matter of conjecture but a pericyclic (*syn*) process cannot be excluded. Examples of such non-pyrolytic carbamate eliminations are rare, but the thermolysis of 1,1,3,4-tetramethyl-3-(phenylcarbamoyloxy)-2,3-dihydrosilole (CCl_4, Δ, 10 h) to 1,1,3,4-tetramethylsilole, is illustrative; A Laporterie, H. Iloughmane and J. Dubac, *Tetrahedron Lett*., 1983, 3521.

¶ Existing models that account for the stereoselectivity of ketone and enone deprotonations are not easily extrapolated to explain the outcome from **4Af**. For a review see; J.O. Williams and M. J. A reinvestigation of the $Rh_2(OAc)_4$-catalysed decomposition of 1-diazo-4-(2-methoxyphenyl)alkan-2-ones: evidence for ionic 'ring-walk' rearrangement in norcaradiene derivatives

Paolo Manitto,* Diego Monti, Simona Zanzola and Giovanna Speranza

Dipartimento di Chimica Organica e Industriale, Università di Milano e Centro di Studio sulle Sostanze Organiche Naturali, via Venezian 21, I-20133 Milano, Italy. E-mail: manitto@icil64.cilea.it

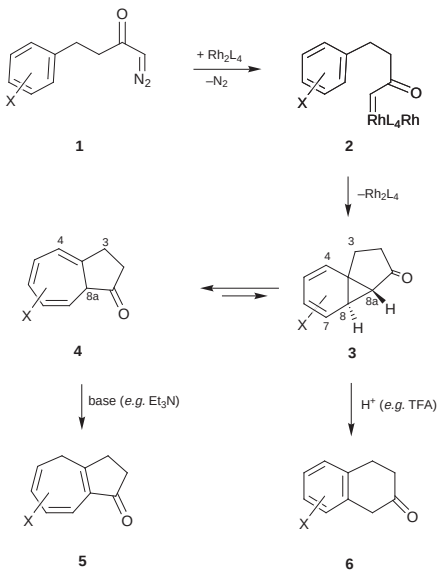
Received (in Corvallis, OR, USA) 8th January 1999, Accepted 10th February 1999

On $Rh_2(OAc)_4$-catalysed decomposition of 1-diazo-4-(2-methoxyphenyl)butan-2-one (9) and its methyl-substituted analogue (18), norcaradienones 10 and 19, respectively, were observed as the only regioisomers resulting from intramolecular cyclopropanation, indicative of attack by the metal carbene away from the methoxy group; to explain the transformation of 10 and 19 into dihydroazulenones 15 and 23, interconversion of 10 and 19 into their isomers 14 and 22 must be invoked, and an ionic 'ring-walk' rearrangement is suggested for such an isomerization.

The intramolecular Buchner reaction, (Scheme 1)† has emerged as a prominent synthetic method[1] after the discovery by Teyssié and co-workers[2] that rhodium(II) carboxylates strongly facilitate nitrogen loss from diazo compounds **1**, probably forming carbenoid species such as **2**. Thus, either 3,4-dihydroazulen-1(*2H*)-ones **5** or 2-tetralones **6** can be obtained in good yields from the equilibrium mixtures of norcaradienones (NCD) **3** and cycloheptatrienones (CHT) **4** by addition of a base or a protic acid, respectively.

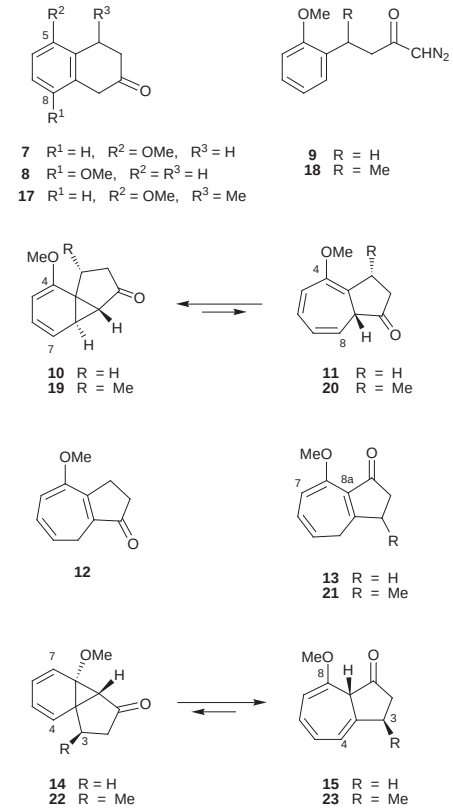
The fact that 5-methoxy-2-tetralone **7** results from 1-diazo-4-(2-methoxyphenyl)butan-2-one **9**,[3] instead of 8-methoxy-2-tetralone **8**,[1b] was explained by Cordi *et al.*[3] with the assumption that the tricyclic ketone **10** is formed through direct cyclopropanation of the benzene bond away from the methoxy group.

On the other hand, the trienone **13** could be envisaged as arising from the base-induced stabilisation of a reaction mixture consisting of the NCD/CHT couple **14**/**15**, *i.e.* of compounds formed by the attack of the carbenoid center on the 1,2-bond of the benzene ring. This direction of the intramolecular Buchner cyclisation had previously been suggested by McKervey and co-workers[1b] on the basis of the observation that the signal at *ca.* δ 5.0, which is characteristic of H-8 in 3,8a-dihydroazulen-1(*2H*)-one derivatives such as **4**,[4] was missing from the NMR spectrum of the crude product obtained by decomposition of **9**. Thus, structures **15** (instead of **11**) and **13** (instead of **12**) were assigned to the dihydroazulenone occurring in the reaction mixture and to its Et_3N-stabilised product, respectively.[1b]



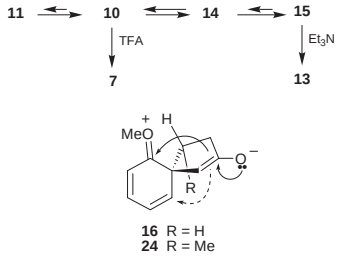
1 **2** **4** **3** **5** **6**

Scheme 1



We report here spectroscopic evidence proving structure **10** for the early reaction product in the decomposition of **9** under $Rh_2(OAc)_4$ catalysis and propose a reasonable explanation for its spontaneous conversion into **15** (giving rise to **13** by Et_3N treatment) and for the formation of **7** as the final product of the TFA-ended procedure.

The decomposition of **9**[1b] was performed in CH_2Cl_2 containing catalytic amounts of $Rh_2(OAc)_4$ at 0 °C for 1 h.[1a] After the usual work-up of the reaction mixture at 0 °C, the HPLC analysis‡ of the crude product revealed the presence of two main compounds showing different electronic absorptions: λ_{max} at 280 nm for the faster moving substance and at 260, 295sh, 315sh nm for the other. Such electronic absorptions appeared to be in agreement with those expected for a norcaradiene[5,6] and for a cycloheptatriene derivative,[6] respectively. The intensity ratio of the HPLC peaks was 2 : 1 in favour of that having the shorter retention time. However, after keeping the CH_2Cl_2 solution of the crude reaction product at



Scheme 2

room temperature overnight the peak of the faster moving substance disappeared completely. HPLC separation of the time-stabilised CH_2Cl_2 solution gave a pure compound (t_R = 11.2 min, yellowish oil, 75% yield)‡ to which the structure of 8-methoxy-3,8a-dihydroazulen-1(2*H*)-one (**15**)§ was assigned on the basis of its spectroscopic data.[1b,4] This structure was confirmed by NOE correlations (2.7 and 1.1% intensity enhancement of H-4 and H-3 by irradiation of H-3 and H-4).

Treatment of **15** with Et_3N in CH_2Cl_2 at room temperature furnished a compound (oil, 63% yield) whose spectroscopic data were consistent with the structure of a cross-conjugated dihydroazulenone,[1b,4] *i.e.* **13**.§ Thus, the occurrence of **14** as a precursor of **15** (and **13**) could be inferred. However, addition of a few drops of TFA to a CH_2Cl_2 solution of **15** or of the crude reaction product resulted in the rapid, quantitative formation of the tetralone **7**.[3]

All attempts to isolate the substance (t_R 8.7 min) accompanying **15** in the reaction mixture failed. Nevertheless, the ^{1}H NMR signals of that unstable component could be acquired by subtracting the spectra of **15** from those of the crude reaction mixture. The resulting congruent set of signals indicated a norcaradiene structure such as **10**§ having *three* olefinic hydrogens only. It must be pointed out that compound **10** does not correlate with the dihydroazulenone **15** through a direct electrocyclic reversion, but corresponds to an attack of the metal carbene on the benzene ring away from the methoxy group.

The above results can be interpreted in terms of a multiple equilibrium (Scheme 2) based on the following assumptions. The rhodium(II)-catalysed decomposition of **9** gives rise to the norcaradienone **10** (and possibly to **14,** to a lesser extent) through an intramolecular aromatic cycloaddition. Then compound **10** slowly converts into its isomer **14** (*vide infra*) which rapidly collapses to the much more stable dihydroazulenone **15**. By contrast, the NCD/CHT equilibrium[7] **10**/**11** must be assumed to be largely shifted toward the tricyclic form, *i.e* **10**. This seems plausible since it is known that hydroxy and trimethylsilyloxy groups at the 2- and/or 5-position of a cycloheptatriene ring have a strong stabilising effect on the tautomeric norcaradiene system.[8] The presence of **15** as the only final product in the reaction mixture is also consistent with the finding that among the four methoxycyclohepta-1,3,5-trienes the 1-methoxy isomer is the most stable.[9]

With regard to the possible mechanisms for the interconversion between **10** and **14** the intermediacy of a spiro derivative such as **16** (or its protonated form) seems the most likely explanation.

When 1-diazo-4-(2-methoxyphenyl)pentan-2-one **18** was decomposed by $Rh_2(OAc)_4$ in CH_2Cl_2 at 0 °C and the reaction mixture worked up in the usual manner, HPLC and ^{1}H NMR analysis revealed the presence of one reaction product. After purification by preparative HPLC this product (60% isolated yield) was shown to be the norcaradienone **19**,¶ which quickly furnished 5-methoxy-4-methyl-2-tetralone (**17**) by TFA treatment in almost quantitative yield. Compound **19** was found to be stable in CH_2Cl_2 at −20 °C for weeks; on the other hand, addition of catalytic amounts of Ph_3CBF_4 to a solution of **19** in CH_2Cl_2 caused rapid formation of the 8-methoxy-3-methyl-3,8a-dihydroazulen-1(2*H*)-one **23**,¶ which in turn gave rise to the cross-conjugated ketone **21**¶ when treated with Et_3N.

These results reinforce the above assumption concerning the occurrence of two NCD/CHT equilibria connected by ionic (cation-catalysed) interconversion of 4- and 8-methoxynorcaradienones. The fact that **19** appears to be more stable than **10** in respect to isomerization may be due to steric repulsion between the methyl group at the 3-position and the hydrogen atom at the 4-position in the spiranic intermediate **24** as well as in the tricyclic ketone **22**. In fact the methyl group in **19** was shown by NOE data¶ data to be oriented out of the plane of the six-membered ring thus minimizing its interaction with the methoxy group.

DMAP-promoted racemization-free deacylation of carboxthioimide† adducts: carboxthioimide as a versatile carboxy protecting group

Dah-Wei Su, Ying-Chuan Wang and Tu-Hsin Yan*

Department of Chemistry, National Chung-Hsing University, Taichung, Taiwan 400, Republic of China.
E-mail: thyan@mail.nchu.edu.tw

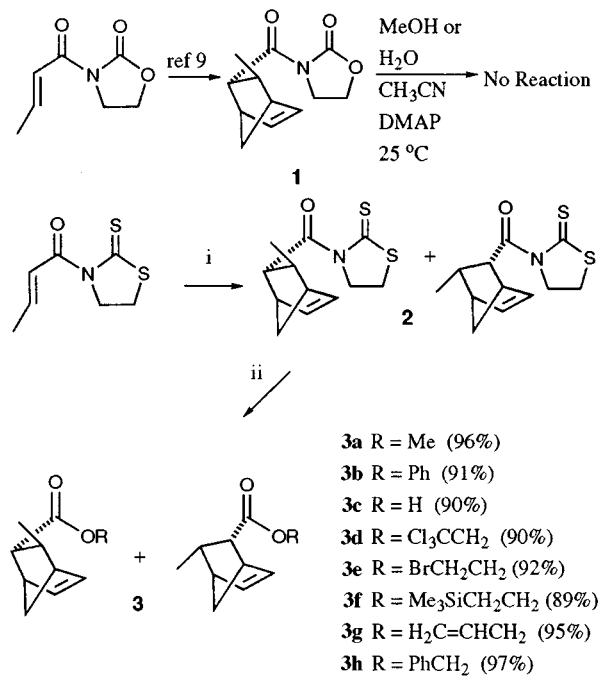
Received (in Cambridge, UK) 21st January 1999, Accepted 9th February 1999

The DMAP-promoted deacylation of carboxthioimide adducts can be directed to form either acid or various ester protecting groups with no detectable levels of epimerization.

The development of protecting groups of carboxy functionality which are stable under the usual reaction conditions and which can be activated by a specific reagent for nucleophilic deacylation under very mild conditions has been a challenging undertaking. Oxazolidinone-derived carboximides[1–4] as well as oxazolidinethione- and thiazolidinethione-based carboxthioimides[5,6] have proven to be valuable carboxy-protecting groups for the construction of enantiomerically pure substances. While, traditionally, the use of basic reagents ($LiOCH_2Ph$, BrMgOMe, LiOH, LiOOH, K_2CO_3/MeOH)[6,7] for the nucleophilic cleavage of imide the thioimide adducts has been the method of choice for removing the auxiliary from substances, progress in nucleophilic catalyst-promoted imide and thioimide deacylation with oxygen nucleophiles like H_2O, alcohols and phenol remains far less developed. Effecting such nucleophilic acyl substitution may have the advantage of (i) controlling the nucleophilic cleavage without causing racemization of the newly created stereocenters, (ii) promoting further useful transformations of the initial adducts without influencing the pendent functional groups, and (iii) enhancing synthetic efficiency by direct conversion of the initial adducts to various ester protecting groups. The tremendous impact of DMAP[8] in catalyzing the acylation of alcohols suggested the feasibility of DMAP as a catalyst to effect transesterification or hydrolysis of imides and thioimides. Here we report protocols whereby the thioimide transesterification promoted by DMAP can be directed to form either acid or various ester protecting groups with no detectable levels of epimerization.

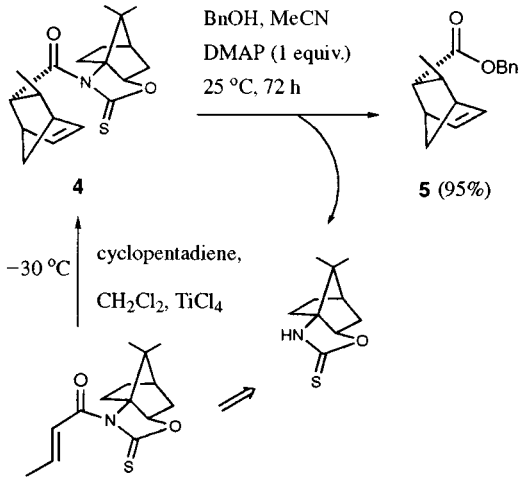
The reactions of crotonyloxazolidinone-derived Diels–Alder adduct **1** with MeOH and H_2O were chosen to test the feasibility of the DMAP-promoted oxazolidinone deacylation (Scheme 1). In view of the well-documented excellent shelf lives of *N*-acyloxazolidinones,[9] we were not surprised to observe no detectable methanolysis and hydrolysis at the exocyclic carbonyl center. Believing a more polarizable auxiliary might facilitate nucleophilic attack, we turned to the deacylation of carboxthioimide derived adducts. Initial work centered on the deacylation of the Diels–Alder adduct **2** derived from the unsaturated *N*-acylthiazolidine-2-thione (*cf.* Scheme 1) which has been shown to exhibit enhanced dienophilic reactivity in a copper(II)-catalyzed asymmetric cycloaddition.[10] The requisite thioimide adduct **2** was available by treating crotonylthiazolidienethione with excess cyclopentadiene (5–10 equiv.) and 1.2 equiv. of $ZnCl_2$ in CH_2Cl_2 at 0 °C. Treatment of thioimide **2** with 1.5 equiv. of MeOH in MeCN with 20 mol% DMAP at room temperature gave the methyl ester **3a** in 96% yield along with a 93% recovery of the auxiliary (Scheme 1). The DMAP-promoted thiazolidinethione deacylation exhibited good generality. Thus, switching the nucleophile from MeOH to PhOH had little effect. The same conditions effected transesterification of **2** to afford phenyl ester **3b** in 91% yield. Similarly, DMAP (1.1 equiv.) promoted hydrolysis of **2** with H_2O as the nucleophile afforded the acid **3c**. The broad scope of the transesterification is illustrated by the tolerance of β-substituents on ethanol. Thus deacylation of **2** with 2,2,2-trichloroethanol under the same conditions gave the corresponding β-substituted ethyl ester protecting group. A labile alcohol, 2-bromoethanol, also proved to be a satisfactory nucleophile under our standard conditions in the presence of the DMAP catalyst. Trimethylsilylethanol gave similar results, albeit in a somewhat slower reaction. After 24 h, an 89% yield of 2-(trimethylsilyl)ethyl ester **3f** was obtained.‡ The utility of allyl and benzyl esters as useful carboxy-protecting groups led to our examination of allyl and benzyl alcohols, which participated equally well, giving the corresponding esters **3g** and **3h** in excellent yield (≥95%).[11] Steric hindrance plays a role; in contrast to the above, *tert*-butyl alcohol failed to react with thioimide adduct **2** under the above conditions.

The suitability of these mild conditions for oxazolidinethione deacylation is illustrated by the additional examples provided below. Camphor-based *N*-acyloxazolidinethiones such as Diels–Alder cycloadduct **4** and aldol adduct **6**[5] were utilized to test the feasibility of DMAP-promoted nucleophilic cleavage. The DMAP-promoted transesterification of cycloadduct **4**, which was prepared from the $TiCl_4$-mediated Diels–Alder reaction of camphor-based crotonyloxazolidinethione with cyclopentadiene, with benzyl alcohol proceeded more slowly



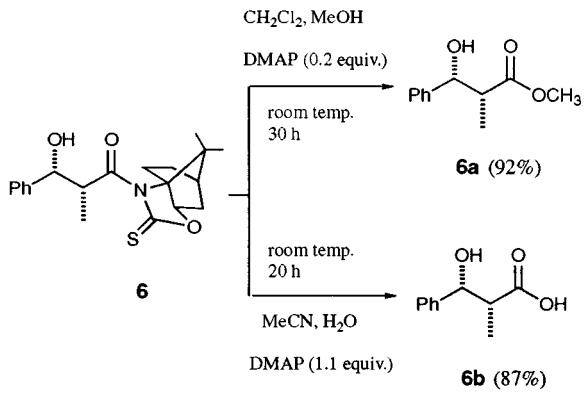
Scheme 1 *Reagents and conditions*: i, $ZnCl_2$, cyclopentadiene, CH_2Cl_2 0 °C; ii, ROH or H_2O, DMAP (0.2–1.1 equiv.), MeCN, room temp., 4–24 h.

† General IUPAC name: 3-acyl-1,3-thiazolidine-2-thione.



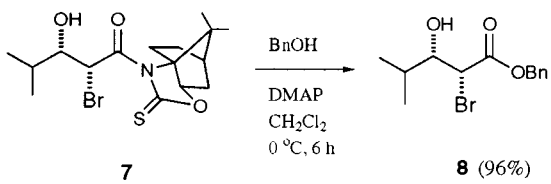
Scheme 2

but still in excellent yield (Scheme 2). After 72 h, the transesterification product **5**, $[\alpha]_D^{25}$ +129.3 (*c* 0.9, CH_2Cl_2),[9] was obtained in 95% with no detectable levels of epimerization. Using the above standard conditions, both hydrolysis and methanolysis of aldol adduct **6** were easily effected without racemization of either center (Scheme 3). The acid **6a**, $[\alpha]_D^{25}$ +13.6 (*c* 1.1, CH_2Cl_2), and ester **6b**, $[\alpha]_D^{25}$ +22.5 (*c* 1.4, CH_2Cl_2),[2] were obtained in 87 and 92% yield, respectively.



Scheme 3

In conjunction with a program directed toward the asymmetric synthesis of β-hydroxy-α-amino acids, a key intermediate toward biologically active peptides and β- and γ-lactam antibiotics,[12] we were particularly interested in bromohydrin substrates.[13] To demonstrate the utility of this protocol, we examined the transesterification of bromohydrin aldol **7**,[14] which by virtue of the ease of bromide displacement demands very mild methods. In the DMAP (0.2 equiv.) catalyzed transesterification ($PhCH_2OH$) of bromohydrin **7** at 0 °C, epoxide formation was completely suppressed and benzyl β-hydroxy-α-amino ester **8** was isolated in 96% yield with no apparent loss of stereochemistry (Scheme 4).‡ This result is in directed contrast to the BnOLi deacylation conditions for



Scheme 4

oxazolidinone bromohydrins, in which benzyl α,β-epoxy esters are formed.[3]

In conclusion, we have demonstrated that carboxthioimides are very versatile and useful carboxy-protecting groups. Significantly, the thioimide transesterification *via* DMAP catalysis provides the acids or various ester protecting groups without danger of racemization. The successful control of oxazolidinethione deacylation *vs.* cyclization of nucleophiles with bromohydrin aldol adducts illustrates the power of our newly developed DMAP-promoted nucleophilic cleavage. Further details in this area will be forthcoming.

We thank the National Science Council of the Republic of China for support of this work (NSC 88-2213-M-005-006).

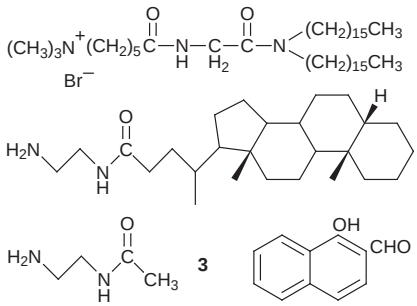
Received (in Cambridge, UK) 4th January 1999, Accepted 22nd February 1999

A bile acid derivative, *N*-(2-aminoethyl)-5β-cholan-24-amide, acts as an artificial cell-surface receptor capable of activating lactate dehydrogenase by performing double signal recognition and phase reorganization in a synthetic bilayer membrane.

Recently, bile acids have been employed as a key building block for design of artificial hosts capable of performing molecular recognition in various physical phases such as the solid state,[1] and aqueous[2] and organic media.[3] The molecular rigidity provided by the steroidal moiety is of great advantage for the functionalization of such host molecules. Meanwhile, there are few reports on bile acid derivatives, such as steroidal porphyrins[4] and cyclophanes,[5] each being a supramolecular element in bilayer membranes. We report here on the signal recognition and response of an artificial steroidal receptor, *N*-(2-aminoethyl)-5β-cholan-24-amide **2**, embedded in the bilayer membrane formed with a synthetic peptide lipid, *N*,*N*-dihexadecyl-*N*$^{\alpha}$-[6-(trimethylammonio)hexanoyl]glycinamide bromide **1**.†



1 **2** **3** **4**

In aqueous media **1** formed a morphologically stable bilayer membrane with a gel-to-liquid crystalline phase transition at 26.0 °C (ΔH = 31.0 kJ mol^{-1}) in a manner similar to those reported for the analogous peptide lipids having a different amino acid residue.[6] Bilayer vesicles were prepared by sonication of an aqueous dispersion containing **1** and water-insoluble **2** in a 40 : 1 molar ratio with a bath-type sonicator at 80 W for 60 min in 2-[4-(2-hydroxyethyl)piperazin-1-yl]-ethanesulfonate (HEPES) buffer (100 mmol dm^{-3}, pH 7.0). The formation of single-walled bilayer vesicles was confirmed by negative-staining electron microscopy, and the vesicular size as evaluated by means of dynamic light scattering measurements was 120 nm.

Next we examined the molecular recognition behavior of the receptor **2**. 1-Hydroxy-2-naphthaldehyde **4** was effectively bound to **2** homogeneously dispersed in the bilayer vesicle by forming an imine bond between the formyl group and the amino group, as confirmed by electronic absorption spectroscopy. The binding process was reversible and in equilibrium under the present conditions. The dissociation constant for the Schiff's base was evaluated from the aldehyde-dependent absorbance changes at 440 nm to be 1.5 μmol dm^{-3} at 30.0 °C. The binding of **4** with **2** was much enhanced upon addition of copper(II) ions due to the formation of the corresponding metal chelate having an absorption maximum at 388 nm. The continuous variation method[7] applied to the present bilayer system clearly indicates that the Schiff's base and copper(II) ions form a 2 : 1 chelate accompanying the phase reorganization of the steroidal moieties in the liquid crystalline state of the membrane. Such metal-ion-induced phase reorganization behavior was reflected by an increase in the phase transition temperature and sharpening of the peak for the hybrid membrane in the dispersion states, as evaluated by differential scanning calorimetry. Thus **2** acts as an artificial host being capable of recognizing both **4** and copper(II) ions in the bilayer membrane.

We have also clarified that pig heart lactate dehydrogenase (LDH; Boehringer Manheim, Germany) was bound to the membrane surface of the cationic peptide lipid mainly through electrostatic interactions, and that the LDH activity was specifically inhibited by copper(II) ions.[8] On these grounds, we constituted an artificial signaling system with **1**, **2** and LDH as schematically shown in Fig. 1 and evaluated the signal transduction ability of the steroidal host as an artificial cell-surface receptor. We chose **4** and copper(II) ions as an external signal of the receptor **2** and the second messenger signals between **2** and LDH, respectively. Under the conditions used the metal binding affinity of the components increases in the

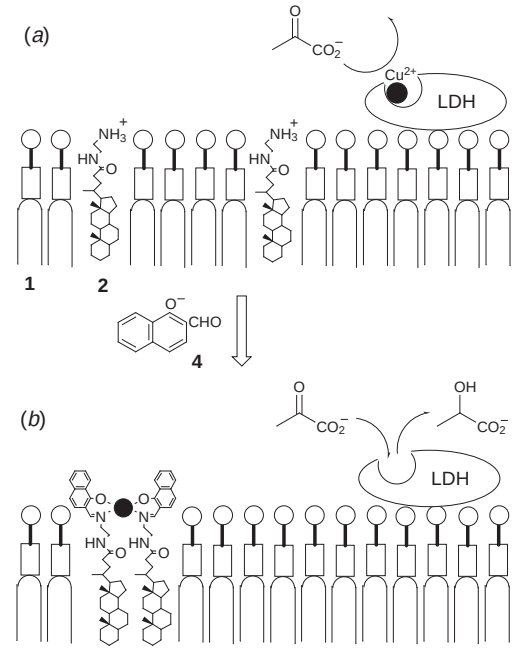


Fig. 1 Schematic illustration of switching of LDH activity mediated by an artificial cell-surface receptor **2**. (*a*) and (*b*) represent the off- and on-states of LDH in the absence and presence of an external signal **4**, respectively.

Table 1 LDH activities in an aqueous HEPES buffer (100 mmol dm^{-3}, pH 7.0) at 30.0 °C[a]

Entry	Species/μmol dm^{-3}				v_0[b]/μmol dm^{-3} s^{-1}	Activity[c] (%)
	1	**2**	**4**	Cu^{2+}		
1	0	0	0	2	0.45 (1.20)	37
2	0	0	30	2	0.37 (1.14)	32
3	1200	0	0	2	0.25 (1.17)	21
4	1200	0	30	2	0.15 (1.18)	13
5	1200	30	0	2	0.17 (1.16)	15
6	1200	30	30	2	1.00 (1.22)	82

[a] Concentrations: pyruvate, (150 μmol dm^{-3}); NADH (250 μmol dm^{-3}); LDH (170 μg dm^{-3}). [b] Initial velocity for LDH catalyzed reaction. The value in the absence of copper(II) ions is in parentheses. Values are accurate within ±3%. [c] Magnitude of v_0 in the presence of $Cu(ClO_4)_2$ relative to that of the corresponding metal-free system.

following order: **2** < LDH < the **2**–**4** complex, giving the signal transduction behaviour shown in Fig. 1. In the absence of an external signal ligand, the catalytic performance of LDH is blocked by coordination of copper(II) ions [Fig 1(*a*)], since the steroidal receptor behaves as a weak unidentate ligand for metal ions. Upon binding of the signal ligand **4** with the receptor **2**, the resulting receptor–ligand complex acts as a strong bidentate ligand to snatch the metal ion from LDH, resulting also in phase reorganization of **2** in the bilayer membrane [Fig. 1(*b*)]. Thus the LDH activity can be indirectly controlled by an external signal in the present artificial receptor system.

The catalytic activity of LDH in the reduction of pyruvate to L-lactate was evaluated spectrophotometrically by following a consumption rate (v_0) of NADH in the presence and absence of the supramolecular elements and the signaling species (Table 1). In the absence of copper(II) ions, the LDH activity was not significantly influenced by the presence of **1**, **2** and **4**. However, inactivation of LDH by copper(II) ions was highly specific, since the catalytic activity was not influenced by the presence of zinc(II) or nickel(II) ions at similar concentrations. The inhibition of LDH by copper(II) ions was reversible and competitive as analyzed by the Lineweaver–Burk plots; the inhibition constant, defined as the dissociation constant of the LDH–copper(II) complex, was 0.22 and 2.2 μmol dm^{-3} in the presence and absence of the bilayer membrane, respectively. Thus the extent of inactivation of LDH by copper(II) ions in the vesicular system was larger than that in aqueous solution (Table 1, entries 1 and 3). Inhibition of the enzymic activity by copper(II) ions was somewhat enhanced upon addition of **4** (Table 1, entry 2), and such behavior was also observed in the presence of the bilayer membrane (Table 1, entry 4). As expected, the LDH activity of the hybrid system depicted in Fig. 1(*a*) was low (Table 1, entry 5), reflecting the larger metal-binding ability of LDH than the steroidal receptor. Upon addition of the signal ligand **4** to this system, however, the LDH activity, defined as the magnitude of the initial velocity in the presence of copper(II) ions relative to that of the corresponding metal-free system, was drastically increased to 82% from 15% (Table 1, entry 6) as a consequence of the change in the metal binding mode, as shown in Fig. 1(*b*). When the receptor **2** was replaced by water-soluble **3** lacking the steroidal moiety in the supramolecular system shown in Fig. 1, the LDH activity increased only a little to 41% from 32% under similar concentration conditions. Accordingly, it is clear that the signal transduction occurrs with extremely high efficiency on the membrane surface of the hybrid molecular assembly formed from the peptide lipid **1**, the steroidal receptor **2** and LDH. The present hydrid system shows marked signal selectivity. For example, only 38% LDH activity was observed by replacement of **4** with 2-naphthaldehyde under the conditions of entry 6 in Table 1.

In conclusion, we have demonstrated here the first example of a supramolecular assembly in which an artificial cell-surface receptor is able to switch on enzymic activity *via* accompanying double signal recognition and phase reorganization. Although the reversibility in the system remains a problem, the present results may provide a useful guide for the design of supramolecular devices that mimic the signal transduction behaviour observed in biological systems such as G-protein mediated cell signaling. Catalytic aerogel-like materials dried at ambient pressure for liquid-phase epoxidation

J. L. Sotelo,* R. Van Grieken and C. Martos

Chemical Engineering Department, Faculty of Chemistry, Complutense University of Madrid, 28040 Madrid, Spain. E-mail: rada@eucmax.sim.ucm.es

Received (in Cambridge, UK) 18th November 1998, Accepted 19th February 1999

Titanium-containing hydrophobic silica with a pore volume and pore sizes in the range of aerogels was prepared by silylation before drying of well-dispersed mixed oxides obtained *via* a sol-gel method; it showed remarkable properties as a catalyst in the epoxidation of styrene with Bu^{t}OOH.

Environmental concern surrounding chemical processes for the production of commodity and fine chemicals has led to the development of environmentally-friendly processes based on heterogeneous catalysts. Among them, the epoxidation of olefins is a major target since the epoxide functional group is one of the most useful intermediates in organic synthesis.[1] Heterogeneous catalysts such as silica-supported titania are used on an industrial scale for propylene epoxidation using alkyl hydroperoxides as oxidant.[2]

The discovery that the Ti-substituted silicalite molecular sieve TS-1 (an isomorphous ZSM-5 zeolite) is a catalyst for selective oxidation reactions with H_2O_2[3] has promoted investigation of its use in several oxidation reactions.[4] To overcome the restriction imposed by the relatively small average diameter (*ca.* 0.55 nm) of the channel system, Ti has been incorporated into materials with larger pore sizes such as zeolite beta,[5] or hexagonal mesoporous silica (HMS).[6] Other attempts to obtain suitable epoxidation catalysts have been based on grafting of Ti compounds onto the silica surface[7] and the use of the sol-gel technique.[8] The latter has been used to obtain epoxidation catalysts ranging from amorphous microporous[9] to mesoporous titania–silica mixed oxides,[8] and even solid precursors with the appropriate properties for Ti-containing zeolite synthesis.[10]

The many potential advantages inherent to the use of sol-gel techniques in preparing epoxidation catalysts are strongly dependent on the drying method. Supercritical drying prevents the network collapse induced by capillary forces arising from the liquid–vapour interface, leading to materials with high porosity called aerogels with suitable properties to be used as catalysts,[11] although supercritical processing has numerous drawbacks due to the extreme conditions used. Recently a simpler method at ambient pressure for the preparation of aerogel-like films has been reported[12] based on the use of a silylating agent which is reacted with the hydroxy groups on the surface of an inorganic gel, preventing the irreversible shrinkage of the porous structure during drying.

We report here a simple route, based on the above mentioned silylation procedure, for the preparation of titania–silica mixed oxides with adequate textural properties and highly dispersed Ti atoms, both features leading to active catalysts in epoxidation reactions with *tert*-butyl hydroperoxide (TBHP).

The catalysts were prepared following a two-step sol-gel method. In the first step, a solution of tetraethoxysilane (TEOS) was prehydrolyzed with aqueous HCl (0.05 M) for 45 min at room temperature (samples **1**–**3**). Other catalysts were prepared by diluting TEOS in EtOH (samples **4**–**6**); the solution was prehydrolized with aqueous HCl for 90 min, since less water is added to these samples. Then, the Ti precursor [titanium(IV) butoxide, TNBT] diluted in Pr^{i}OH was added to give gel molar ratios (TEOS : H_2O : HCl : EtOH : Pr^{i}OH : TNBT) of $1:4:3.6\times10^{-3}:0:1:0.023$ for samples **1**–**3** and $1:1.25:9\times10^{-4}:2:1:0.023$ for samples **4**–**6**, with additional hydrolysis times of 20 and 75 min, respectively. The second step of the synthesis procedure increased the condensation rates by changing the pH to higher values with aqueous NH_3 (1 M) for samples **1**–**3** and dilute NH_4OH (1 M) in EtOH (1 NH_3 : 5.6 H_2O : 0.7 EtOH) for samples **4**–**6**. Once the gel point of the sol had been reached, the solid gels were aged for 48 h and samples of **1** and **4** were dried at 110 °C overnight, whereas the other catalysts were washed with *n*-hexane and treated with a TMSCl solution in *n*-hexane before drying. For comparison, a silica obtained by an analogous sol-gel procedure was impregnated with a solution of $TiCl_4$ in EtOH (Si/Ti = 54) and calcined at 550 °C for 5 h. Also, a Ti-containing HMS was provided by Dr Tuel from CNRS[13] with a Si/Ti molar ratio of 87.3. All the catalyst samples were tested in the oxidation of styrene with TBHP at 60 °C in N_2 atmosphere. Conversions and selectivities were determined by GC, ^{1}H NMR analysis and iodometric titration.

All samples were characterised by diffuse reflectance UV–VIS spectra (DR UV–VIS) in the range 190 to 500 nm. They presented a maximum absorption band centered at 220 nm, and no absorption around 330 nm was detected. Nitrogen adsorption–desorption isotherms of the samples obtained on an ASAP 2010 from Micromeritics showed a hysteresis loop corresponding to a type IV isotherm, typically assigned to mesopores present in the materials. Samples **1** and **4** present similar textural properties independent of the presence of EtOH as a diluting agent (Table 1), with BET surface areas above 600 $m^2\ g^{-1}$ pore volumes around 1 $cm^3\ g^{-1}$ and average pore sizes in the range of 50 Å as the result of the BJH analysis on the adsorption branch of the isotherm. The silylation procedure leads to a decrease in the final Ti content of the catalysts as a consequence of the reaction of TMSCl with the OH groups at the surface of

2	NO	YES	NO	73	871	1.8	71
3	NO	YES	YES	69	849	1.3	68
4	YES	NO	YES	43	604	1.0	57
5	YES	YES	NO	73	723	3.0	132
6	YES	YES	YES	69	688	2.3	125

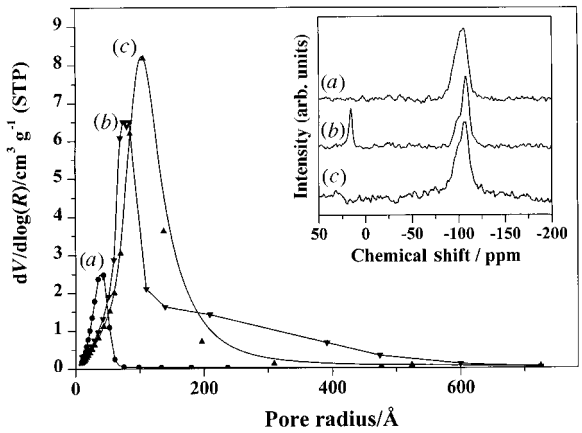

Fig. 1 Pore volume distribution (BJH analysis of the adsorption branch of the isotherm) of (*a*) **4** (xerogel), (*b*) **5** (silylated) and (*c*) **6** (silylated and calcined). Inset: ^{29}Si MAS NMR spectra of these samples are shown.

the gel, which prevents irreversible shrinkage during drying. There is a remarkable increase in the BET surface area, pore volume and mean pore size in the samples prepared with EtOH. It is interesting to note how the silylation procedure is capable of preserving at least partially the different gel structures derived from the use of increasing amounts of EtOH as solvent, something that is not shown in the textural properties of the xerogels when conventional drying is used (samples **1** and **4**). Similarly, after calcination, the differences are clearly shown not only in comparison to the xerogels but also between the materials prepared with different dilution levels, *i.e.* EtOH content. The calcination of the silylated samples leads to a decrease mainly in the pore volume of the samples compared with the uncalcined ones, showing some evidence of pore collapse. In any case, the pore volumes are clearly higher than those corresponding to xerogels and are in accordance with the textural properties of the starting non-calcined silylated samples. The used samples, after reaction, showed similar textural properties to the fresh ones.

Fig. 1 shows the pore size distribution coming from BJH analysis of the N_2 isotherms of samples **4**–**6**. There is a shift in the pore size distribution towards higher values when the silylation procedure is used, with a decrease in the size of the largest pores after calcination. The ^{29}Si MAS NMR spectra of **4**–**6** are shown in Fig. 1 (inset), recorded in a Varian 300 MHz with a spinning rate of 4 kHz. It is clearly shown how the silylation procedure decreases the large Q^3 contribution at −100 ppm in the non-silylated sample, showing up as a peak 15 ppm upfield corresponding to trimethylsilyl groups (TMS) formed in the reaction of TMSCl with the silanol groups of the gel surface.[14] The calcination procedure removes the TMS groups, with partial recovery of the surface OHs shown by the increase of the shoulder at −100 ppm. This behaviour is also seen in the IR spectra of the samples, since in the silylated catalysts there is a large decrease in the band corresponding to Si–OH vibrations (3000–3750 cm^{-1}), which is partly recovered after calcination.

Table 2 Activity of the different titanium-containing materials in the epoxidation of styrene[a]

6	41.6	17.6	66	1.2	87.8	11.0

[a] Reaction conditions: T = 60 °C, t = 3 h, autogenous pressure, no solvent, stirring speed = 300 rpm, inert atmosphere, catalyst loading = 400 mg, styrene = 100 mmol, TBHP = 40 mmol; ST = styrene; TBHP = *tert*-butyl hydroperoxide; SO = styrene oxide; BADH = benzaldehyde; 22ET = 2-phenyl-2-*tert*-butoxyethanol. [b] In moles of styrene per mole of titanium per hour.

The catalytic activities of these samples and the materials used as reference were tested in the epoxidation of styrene with TBHP. Besides the conversion of styrene and TBHP, Table 2 shows the turnover numbers (TON), relative to the total amount of Ti in the catalyst, and the selectivity of styrene towards the different products for the different catalysts, including a blank test. Different products were obtained besides the primary product, styrene oxide (SO): benzaldehyde (BADH) formed from oxidative cleavage of styrene by TBHP and 2-phenyl-2-*tert*-butoxyethanol (22ET) formed from nucleophilic attack of Bu^{t}OH on oxirane ring of the primary product.

The Ti-containing silica xerogels prepared without the use of the silylation procedure (samples **1** and **4**) show similar TON to that of the TiO_2 impregnated silica xerogel, although the selectivity towards SO is higher for the latter. Silylated samples show very high selectivity towards the epoxide with negligible formation of the product coming from the opening of the oxirane ring. The reuse of the silylated sample **5** shows a slight decrease in styrene conversion (X_{ST} = 14.2%) without any change in selectivity (S_{SO} = 98.5%). Once the silylated samples are calcined a decrease in SO selectivity is observed due to the regeneration of HO groups on the sample surface, which promotes the catalytic reaction of the epoxide with Bu^{t}OH formed from TBHP. The pore volume of the Ti-containing silica is an important factor in the preparation of these catalysts, since for comparable BET surface areas (samples **2** and **5**, for example), the higher the pore volume the thinner the pore walls; therefore there is a higher probability of the Ti atoms being located at the surface. Although at first sight the silylation procedure could lead to the complete blocking of Ti atoms at the catalyst surface, hindering their oxidation activity, not all this surface is covered by the silylating agent, as was proved by the catalytic activity of the silylated samples.

The method reported in this work is an easy and reproducible way to obtain a highly hydrophobic Ti-containing material with aerogel properties, oxidation activity comparable to Ti-HMS and higher selectivity towards epoxide formation, without the use of templates or surfactants as in the case of zeolites or micelle structured zeolitic materials.

We are grateful to Dr Tuel (CNRS) for supplying Ti-HMS, CEPSA for the X-ray fluorescence measurements. This work was supported by the EU through the Brite-Euram Project (No. Br.-1169).

Received (in Columbia, MO, USA) 10th November 1998, Accepted 11th January 1999

Though *p*-amino-*p*′-nitrobiphenyl (PANB) is essentially planar in its crystalline form, it takes on a twisted conformation in its 2 : 2 crystalline inclusion complex with β-cyclodextrin (β-CD); the angles between the two phenyl rings are 40.6(2) and 42.0(1)° for the two molecules respectively, compared with 44.1(1)° for biphenyl in the gas phase, thus indicating the absence of constraints in the β-CD dimer cage.

Cyclodextrins are among the most widely used molecular hosts in the field of supramolecular chemistry.[1] They are used extensively in industry and are also chiral host molecules which can be used as models for studying weak interactions involved in molecular recognition. Room temperature diffraction studies typically show disorder, attributed to the absence of strong host–guest interactions in the inclusion complexes. Such disorder should be reduced at very low temperatures, thus allowing a more precise determination of the molecular parameters of the included species, and analysis of the influence of the geometry on the molecular conformation and electron density.

We report the synthesis and 20 K crystal structure of a *p*-amino-*p*′-nitrobiphenyl (PANB)–β-cyclodextrin (β-CD) complex. To the best of our knowledge this study represents the lowest temperature β-cyclodextrin crystallographic investigation to date. PANB has a long-lived excited triplet state, in which charge is transferred from the amine donor to the nitro acceptor group of the molecule.[2] Accordingly, a large increase in dipole moment of PANB upon excitation occurs.[3] As the diffraction analysis of molecular excited states is now becoming feasible,[4] such effects provide additional motivation for the current study.

Crystals of (β-CD–PANB)$_2$ pentaicosahydrate were prepared by adding 8 mg of PANB[5] to 20 ml of saturated aqueous β-CD. This solution was heated and stirred in a sealed flask at 85 °C for 2 h, hot filtered to remove any undissolved PANB, and allowed to cool to room temperature over 3–4 days. Small, yellow, wedge-shaped crystals of the complex were obtained.

The crystalline β-CD–PANB inclusion complex (Fig. 1) consists of face-to-face β-CD dimers including two guest PANB molecules in the extended torus.[6] The two PANB molecules pack in the β-CD dimers with overlapping phenyl rings parallel to each other. A difference map ($F_o - F_c$) calculated near the end of refinement revealed an alternate position with much lower occupancy for each of the PANB molecules. The minor component PANB molecules were included in the final cycles with a conformation restrained to be similar to that of the major PANB molecules. The refinement led to a 17% occupancy of the minor sites. Standard deviations in the molecular bond lengths and angles are satisfactory (typically 0.004 Å and 0.4° for non-hydrogen bond distances and angles, respectively). The bond lengths and angles in the two independent molecules are identical within the experimental uncertainty. They are also similar to those found in neat PANB crystals[7] (Fig. 2). In *p*-nitroaniline,[8] the nitro N–C bond is much shorter than observed in nitrobenzene,[9] the amine N–C bond is much shorter than in aniline,[10] and the aromatic ring displays alternating long and short bonds, features indicative of a quinonoid resonance form reflecting migration of charge from donor to acceptor. In β-CD–PANB, nitro N–C and amine N–C bond lengths are somewhat shorter than the corresponding bonds in nitrobenzene and aniline. But the difference is not as marked as in *p*-nitroaniline, and no significant distortions of the aromatic rings are found, thus indicating a smaller degree of charge-transfer in PANB.

Even though the bond lengths and angles are very similar in the neat crystals and in the inclusion complex, there are marked differences in overall conformation. Thus, there is a different balance between the requirements of π-conjugation of the phenyl rings and packing forces, and the steric repulsion between the *ortho* hydrogens which is reduced in the non-planar conformer. The PANB molecules in neat crystals are essentially planar [inter-ring twist angle (IRTA) of 2.3(5)° whereas in the β-CD dimer they display a twisted conformation [IRTA =

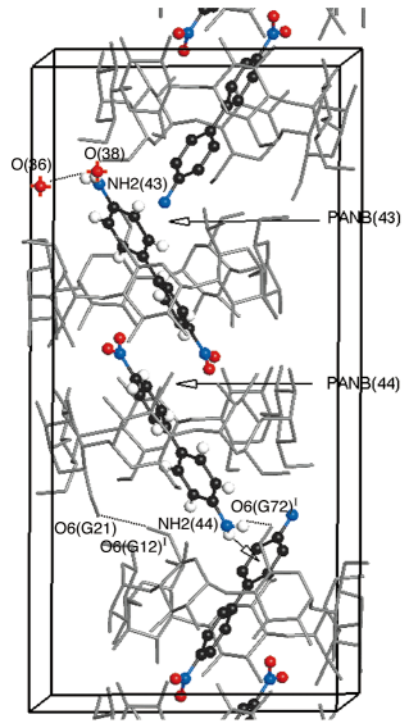

Fig. 1 Structure of the (β-CD–PANB)$_2$ complex. CDs are in grey while the atoms of the guest PANB molecules are colored as follows: carbon = black; oxygen = red; nitrogen = blue; hydrogen = white. For clarity, only the hydrogens of the PANB molecules in the assymetric unit are shown. Only water oxygen atoms involved in important guest–water interactions are shown. See text for details.

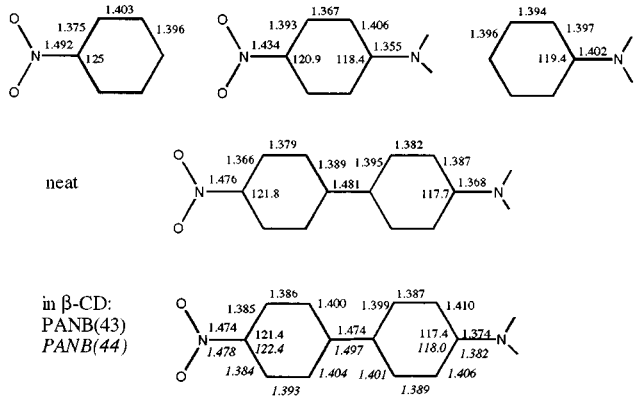

Fig. 2 Comparison of bond lengths and angles in nitrobenzene,[9] *p*-nitroaniline,[8] aniline,[10] neat PANB,[7] and the PANB molecules included in β-CD. Values reported are the average of one or two bond lengths.

40.6(2)° and 42.0(1)° for PANB(43) and PANB(44), respectively]. The difference between the two phases is similar to that observed for biphenyl, which is essentially planar in the solid state,[11] but takes on a twisted conformation in both the gas phase[12] (IRTA = 40–45°) and in its crystalline β-CD inclusion complexes [IRTA = 44.1(1)° as determined by solid state NMR[13]]. Similarly, biphenyl has been observed to take on twisted conformations in other co-crystals[14] (33,[14a] 40.5[14b] and 36.6° [14c]). *Ab initio* geometry optimization of biphenyl and PANB gives twisted conformations for the ground state of both molecules, with twist angles of 45.5 and 41.9°, respectively.[15] Evidently, the β-CD dimer interior provides a 'gas-phase-like' environment, in which the crystal packing forces that produce planar conformations in the neat crystals are no longer operative.

The host dimer entities pack in a 'screw channel' motif.[16] Host–guest interactions include both hydrogen bonding and hydrophobic interactions. The two PANB molecules reside within the β-CD dimer in the same manner, with the nitro ends of the molecules centered in the torus of the dimer. The amine ends of the PANB molecules, which may donate two hydrogen bonds and accept one, protrude from the primary ends of the dimer. One of the PANB molecules, PANB(44), serves as a hydrogen bond donor to a primary hydroxy of an adjacent β-CD dimer [NH2(44)···O6(G72)^{I} = 3.011(4) Å, ∠C6(44)–NH2(44)···O6(G72)^{I} = 111.2(3)° (I = $-x$, y − 1/2, $-z$)]. As a result, this primary hydroxy group (G72) is a +*gauche* conformer[17] with the C6–O6 bond directed towards the host cavity. The other amine hydrogen of PANB(44) is involved in a unique N–H···π face electrostatic interaction with the aniline half of a PANB molecule protruding from the primary face of the adjacent β-CD dimer. The N-to-phenyl ring plane distance is 3.277(6) Å. The two amine hydrogens of PANB(43) are involved in guest–water hydrogen bond interactions [NH2(43)···O(36) = 3.153(7) Å, ∠C6(43)–NH2(43)···O(36) = 110.8(3)°; NH2(43)···O(38)‡ = 3.275(11) Å, ∠C6(43)–NH2(43)···O(38) = 112.8(4)°]. The packing of the PANB molecules within the β-CD dimers leads to quite different intermolecular PANB interactions than exist in neat PANB crystals. The PANB molecules in the latter form an infinite chain of molecules connected by inter-molecular $NH_2\cdots NO_2$ hydrogen bonds, while such interactions are absent in the host–guest complex. Nevertheless, the donor–acceptor charge transfer, judged by the C–N bond lengths, is similar in the two crystals.

The structure determination at 20 K reveals a complex in which the guest PANB molecules are sufficiently ordered to allow an accurate and detailed structure determination. Comparison with the theoretically obtained geometry shows the guest molecules to have a conformation close to that calculated for the gas phase. The use of very low temperatures in structural analysis of host–guest complexes has significant advantages, provided, of course, that no first order phase transformations occur on cooling.

This study was supported in part by funds from CMRA UNL. Financial assistance for travel to Brookhaven National Laboratory (BNL) was provided to T. J. B. by the Warren F. and Edith R. Day Student-Aid-Fund of UNL. T. J. B. and J. J. S. (CHE-9812146), and PC (CHE-9615586) gratefully acknowledge support by the NSF. The SUNY X3 beamline at the National Synchrotron Light Source (NSLS) is supported by the Division of Basic Energy Sciences of the US Department of Energy (DE-FG02-86ER45231). Research carried out in part at the NSLS, which is supported by the US DOE, Division of Materials Sciences and Division of Chemical Sciences. Samples of β-CD were provided by Cerestar USA, Inc. (Hammond, IN).

5 PANB was prepared by nitration of 4-nitrobiphenyl with nitric acid (H. C. Gull and E. E. Turner, *J. Chem. Soc.*, 1929, 491). The product was isolated and reduced with sodium hydrogen sulfide to give PANB (J. P. Idoux, *J. Chem. Soc., Sect. C*, 1970, 435).
6 *Crystal data*: for $(C_{42}H_{70}O_{35})_2\cdot(C_{12}H_{10}N_2O_2)_2\cdot 25.5H_2O$, M_r = 3157.81, monoclinic, $P2_1$ (no. 4), a = 15.454, b = 31.693, c = 15.255 Å, β = 102.92°, Z = 2, D_c = 1.440 g cm^{-3}, crystal size 0.094 × 0.063 × 0.063 mm. T = 20.0(1) K. Data were collected by the oscillation method at the X3A1 beamline station at the NSLS at BNL at a wavelength of 0.643 Å. A single 20 × 40 cm Fuji BAS-III imaging plate was used for data collection. The HKL suite (Z. Otwinowski, *Data Collection and Processing*, ed. L. Sawyer, N. Isaacs and S. Bailey, SERC Daresbury Laboratory, Warrington, UK, 1993, p. 56) was used for data processing (R_{merge} = 0.058). In all, 20607 unique reflections were recorded to a resolution of 0.68 Å. The structure was solved by isostructural replacement of the β-CD coordinates from an isomorphous structure. Least-squares refinement on F^2 of 1951 parameters was carried out using SHELXL97 (G. M. Sheldrick, *SHELXL97. Program for the Refinement of Crystal Structures*, University of Göttingen, Germany, 1997) and converged to a final R_1 = 0.0584, wR_2 = 0.1539, and GOF = 1.047 for 18109 reflections with $F_o > 4\sigma(F_o)$. All non-hydrogen atoms were treated anisotropically except those of the lower occupancy PANB sites which were refined as a rigid body with a single group isotropic displacement parameter. A final difference electron density map showed no distinct features with ρ_{max} = 1.352 and ρ_{min} = −0.828 e Å^{-3}. CCDC 182/1140.

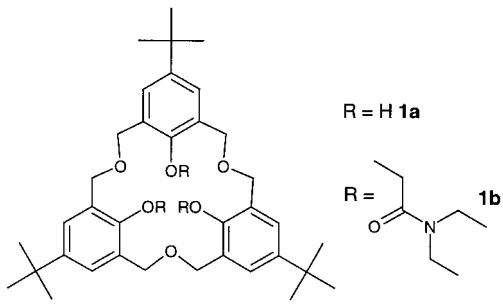
Received (in Columbia, MO, USA) 29th October 1998, Accepted 2nd February 1999

The X-ray crystal structure of the 2 : 1 Na^+ complex of the hexahomooxacalix[3]arene diethylamide derivative 1b shows capsular and nesting inclusion of the two Na^+ cations suggesting a mechanism by which Na^+ and K^+ ions are desolvated and pass through biological ion channels.

The transport of the sodium and potassium cations across biological phospholipid membranes *via* Na^+ and K^+ channel proteins is crucial to many biological processes, notably electrical signalling in the nervous system.[1–3] Key features of the transport of both Na^+ and K^+ are the high degree of selectivity of the discrimination between the two ions (factors of *ca.* 10^4) and the very rapid rate of their diffusion through the channel pore (*ca.* 10^8 ions s^{-1}).[4] Current understanding of this process has advanced markedly this year with the publication of the first X-ray crystal structure of an alkali metal channel protein.[4] This work has demonstrated that alkali metal cations diffuse in solvated form throughout most of the length of the channel before entering a cone-shaped selectivity filter. The selectivity filter discriminates on a size basis, with the cation passing through the neck of the cone with little remaining solvation shell. The high rate of throughput is explained by a 'billiard ball' effect in which incoming cations exert an electrostatic repulsion upon the metal within the selectivity filter, expelling it on to the other size of the membrane.[4] We now report the first model compound to give insight into the mechanism of this 'billiard ball' effect. This work suggests that the incoming cation is robbed of its solvation shell as it enters the cone-like selectivity filter in conjunction with a single solvent molecule in a concerted fashion, as if being squeezed through a tube of toothpaste.

Extensive work over the past fifteen years has centred around the use of the calixarenes as biological models.[5–7] However, the small size of the cone-shaped calix[4]arene does not present a significant aperture for the passage of metal cations through the annulus, although this has been suggested for K^+ recently.[8] The larger, 18-membered ring hexahomooxacalix[3]arenes of type **1**



represent a more appropriate channel mimic. In biological membrane channels the inner surface of the selectivity filter is covered by successive rings of carbonyl oxygen atoms from the main chain amino acid residues.[1,4] This is simulated in the model compound **1b** discussed herein by the phenolic oxygen atoms of the oxacalix[3]arene and the carbonyl groups of the pendant amide functionalities, resulting in a three dimensional cavity comprising a double ring of six oxygen donors. The *p-tert*-butyl aryl moieties provide a hydrophobic, conical entrance to the donor site.

Reaction of pore mimic **1b** with $NaPF_6$ in water–methanol solution results in isolation of a crystalline complex of formula $[Na_2L](PF_6)_2\cdot H_2O\cdot 2MeOH$ **2** (L = **1b**). Ligand **1b** has been shown to exhibit a 1:1 binding constant for $Na^+ > 10^7$ $dm^3\ mol^{-1}$ and the transannular nucleophilic channel is an excellent size match for this cation, while being less readily able to expand sufficiently to encapsulate a K^+ ion.[9] The X-ray crystal structure of **2**† (Fig. 1) shows that the complex has a symmetrical basket, or lobster-pot shape, with one cation, Na(1) firmly encapsulated within the pocket formed by the phenolic and amide oxygen atoms, resulting in a chiral core possessing a pseudo-threefold rotation axis. In addition to the calixarene donor atoms the seven-coordinate Na(1) is also bound to a water molecule situated at the boundary between the hydrophobic cavity formed by the aryl moieties and the binding pocket. While the Na(1)–OH_2 distance is relatively long, 2.437(5) Å, the water molecule is stabilized by hydrogen bonds to the calixarene etheric bridges. Fascinatingly this water molecule also ligates a second Na^+ cation, Na(2), which is apparently in the process of entering the cavity, Na(2)–OH_2 2.277(5) Å. Cation Na(2) exhibits a highly distorted octahedral coordination geometry. In addition to a strong interaction with the intra-cavity water molecule, it is also ligated by two other solvent molecules (methanol) and forms a salt bridge to an extra-cavity PF_6^- anion. In addition to these interactions, Na(2) is strongly bound to one of the oxygen atoms of the calixarene $-CH_2OCH_2-$ bridges. The sixth and final coordination site is filled by an intriguing cation–π interaction with one of the calixarene aryl rings, Na(2)–C 3.026(6) Å. The coordination environment of Na(2) is an excellent illustration of the desolvation process which must occur in biological systems as alkali metal cations enter the conical selectivity filter as they traverse trans-membrane channel pores. The cation interacts with the macrocyclic ligand *via* a mixture of coordination and cation–π interactions, which have been strongly implicated in biochemical systems,[10,11] however, it still retains a partial solvation shell in which all three coordinated solvent molecules are involved in strong hydrogen bonding interactions either to the calixarene itself or to extra-cavity anions. In natural systems these anions are present in the form of anionic carboxylato residues of the channel protein. These second sphere coordination interactions compensate for the enthalpically unfavourable desolvation of the cation as it approaches the narrowing pore aperture. In effect the cation is squeezed into the binding pocket as a consequence of the trans-membrane concentration gradient, with solvent molecules being side-tracked by peripheral stabilising interactions. The feature of the bridging water molecule insulating one cation from another as they progress through the selectivity filter is an experimentally determined property of the K^+ channel of *Streptomyces lividans*, a protein considered to be highly representative of both K^+ and Na^+ channels.[4] Water is a small enough ligand to pass entirely through the pore in an axial coordination site and may well act as a molecular 'staple', dragging the second cation along after it as it follows the first on its passage through the channel,

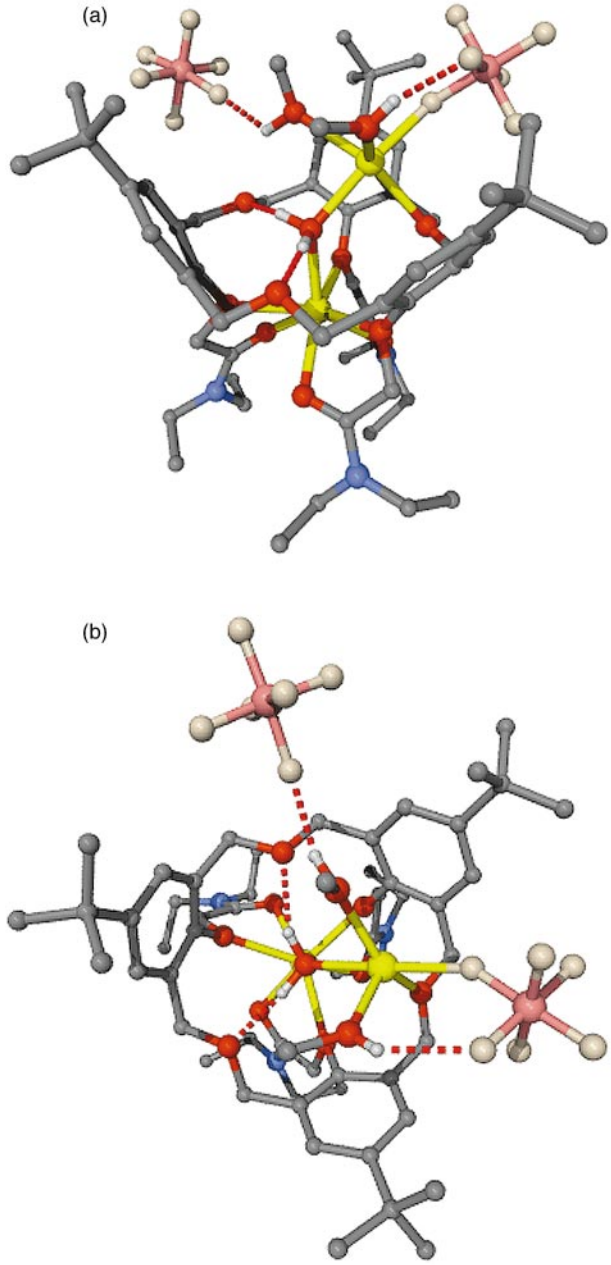


Fig. 1 (a) Side and (b) top views of the conical Na^+ channel mimic **2** showing the encapsulation of one Na^+ ion within the sodium selective cavity, while the second metal ion is beginning the process of desolvation as it enters the conical pore and forms a salt bridge to an extra-cavity hexafluorophosphate anion. The two metal ions are linked by a water molecule situated in the centre of the cavity and able to interact with the etheric oxygen atoms. Colour key: Na, yellow; O, red; N, blue; C, grey; H, small white; P, pink; F, white atoms attached to P. Hydrogen bonding interactions involving the three solvent molecules are represented by red dotted lines. Hydrogen atoms which do not take part in specific hydrogen bonding interactions are omitted for clarity. Selected distances: Na(1)–O(1A) 2.299(4), Na(1)–O(1B) 2.333(5), Na(1)–O(3B) 2.35(2), Na(1)–O(3C) 2.403(12), Na(1)–O(1C) 2.404(5), Na(1)–O(3A) 2.42(2), Na(1)–O(1) 2.437(5), Na(2)–F(1) 2.199(5), Na(2)–O(1) 2.277(5), Na(2)–O(2) 2.292(5), Na(2)–O(3) 2.348(5), Na(2)–O(2A) 2.378(5), Na(2)–C(6A) 3.027(6).

stabilized by hydrogen bonding interactions at every point. This type of mechanism is key to the understanding of the apparently contradictory features of the biological systems; their high selectivity and hence binding ability and their fast kinetics, suggesting only partial desolvation.

The model structure reported herein demonstrates conclusively, in a well-characterised system, the ability of conical channels to stack multiple cations by means of a wide variety of stabilizing interactions. Clearly identifiable features, namely inter-cation insulation by a single solvent molecule, strong cation binding and stabilising interactions conducive to desolvation, mimic closely those implicated in natural systems. Preliminary electrophysiological results‡ indicate an inward current at a potential consistent with sodium crossing the cell membrane, together with attenuation of the trans-membrane potassium current, when ligand **1b** is allowed to superfuse the cells. These initial data suggest that ligand **1b** inhibits transport of potassium and allows an influx of sodium thus performing the function of a selectivity filter on the surface of a cell. As a whole, the structure of complex **2** provides a well resolved 'snap-shot' of the cation transport process.

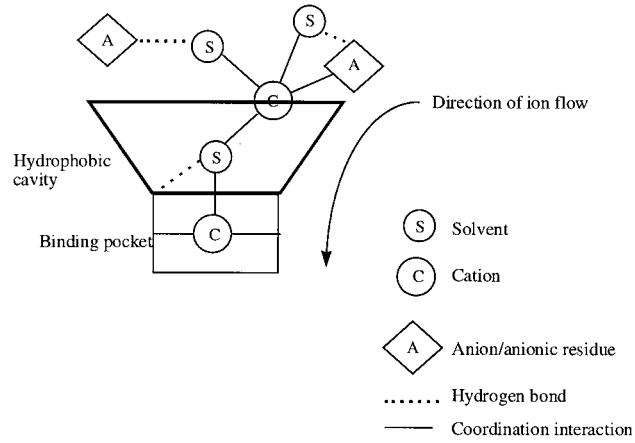

Fig. 2 Diagrammatic representation of the key structural features of **2**.

Unsaturated α-aminopimelic acids as potent inhibitors of *meso*-diaminopimelic acid (DAP) D-dehydrogenase

Andrew Sutherland, Jennifer F. Caplan and John C. Vederas*

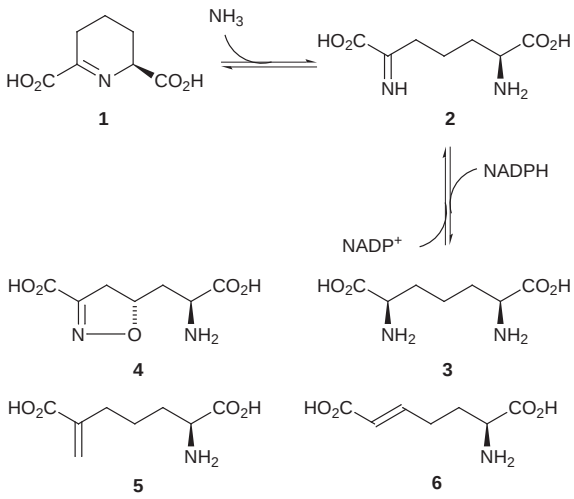
Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2. E-mail: john.vederas@ualberta.ca

Received (in Corvallis, OR, USA) 8th January 1999, Accepted 4th February 1999

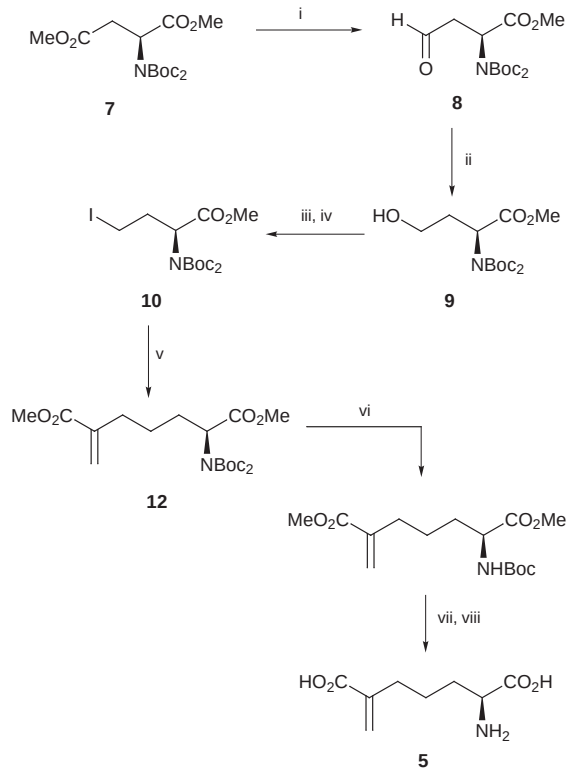
Two nonproteinogenic amino acids 5 and 6 have been efficiently prepared using an S_H2' allylstannane coupling reaction and a Wittig reaction, respectively, to effect the key steps; kinetic studies show these compounds to be reversible inhibitors of DAP dehydrogenase with K_i values of 5.3 (competitive) and 44 μM (noncompetitive), respectively.

Due to the increasing problems associated with antibiotic resistance, alternative strategies to disrupt microbial cell wall synthesis have become highly desirable.[1] The key crosslinking amino acid in the peptidoglycan cell wall layer of Gram negative bacteria is *meso*-diaminopimelic acid (DAP), the biosynthetic precursor of L-lysine, which is used as the crosslinker by many Gram positive organisms.[2] The biochemical pathway to this molecule is not present in animals, which require L-lysine in their diet, and therefore specific inhibitors of the DAP enzymes are likely to be antimicrobial agents with low mammalian toxicity. One of the enzymes used by certain bacteria[2] is *meso*-DAP D-dehydrogenase (EC 1.4.1.16), which converts L-tetrahydrodipicolinate (THDP) **1** to *meso*-DAP **3**, presumably *via* an imine **2** which is reduced stereospecifically by NADPH to generate the D-amino acid center (Scheme 1).[3] We previously demonstrated that a conformationally restricted isoxazoline analogue **4** having the DAP skeleton and a planar α-carbon attached to a basic nitrogen is a potent reversible inhibitor of DAP dehydrogenase and has antimicrobial activity.[4] However, recent X-ray crystallographic studies show that it binds in an unexpected fashion in the active site which places the L-amino acid center rather than the imine bond near the NADP moiety.[5] We now report the syntheses of two new inhibitors **5** and **6** of DAP dehydrogenase which contain a planar α-carbon but lack the characteristic basic nitrogen at the presumed reactive end of the molecule.

The synthesis of unsaturated amino acid **5** is outlined in Scheme 2. The aspartic acid derivative **7** was selectively reduced to the γ-aldehyde **8** in good yield using DIBAL-H.[6]



Scheme 1

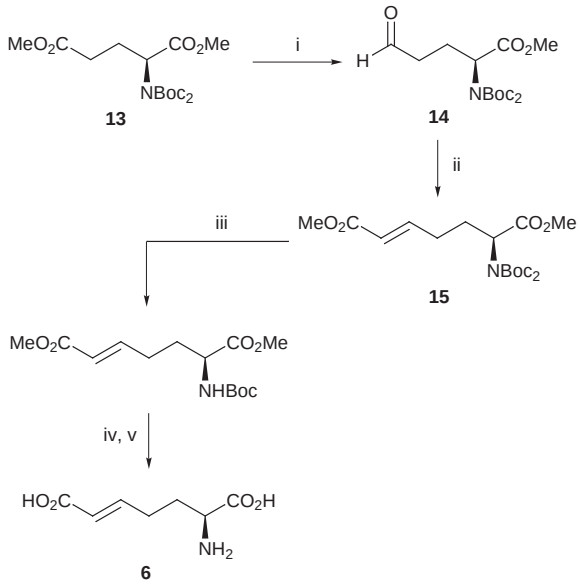


Scheme 2 *Reagents and conditions*: i, DIBAL-H (1.2 equiv.), Et_2O, −78 °C, 87%; ii, $NaBH_4$, THF, 82%; iii, MsCl, NEt_3, DMAP, CH_2Cl_2, 85%; iv, NaI, acetone, Δ 89%; v, AIBN, $MeO_2CC(=CH_2)CH_2SnPh_3$ **11**, C_6H_6, Δ, 60%; vi, TFA (1.2 equiv.), CH_2Cl_2, 76%; vii, LiOH, MeOH, H_2O, 84%; viii, TFA, CH_2Cl_2, 95%.

Further reduction gave the primary alcohol **9** which was converted to the iodide **10** using standard procedures.[7] Radical coupling of iodide **10** with stannane **11**[8] was initiated thermally using AIBN to give the protected α-aminopimelic acid analogue **12** in 60% yield. Selective removal of one of the Boc groups, followed by ester hydrolysis and finally cleavage of the second Boc group gave the parent amino acid **5** in excellent yield (20% overall for eight steps from **7**).

Reduction of the protected glutamate **13** with DIBAL-H similarly gave aldehyde **14** in good yield (Scheme 3). Wittig coupling with the stabilized ylide, methyl (triphenylphosphoranylidene)acetate, gave solely the *trans*-alkene **15**[9] which was deprotected to **6** in a similar manner as above.

With compounds **5** and **6** available, DAP D-dehydrogenase was isolated and purified from *Bacillus sphaericus* IFO 3525 as previously reported.[3a,4] Inhibition studies with this enzyme were done at pH 7.8 using the reverse reaction (oxidative deamination by $NADP^+$ of the D-amino acid center of **3** to give **1**). This produces NADPH and thereby allows continous spectrophotometric assay at 340 nm. The unsaturated amino acids **5** and **6** were first individually tested as possible substrates for DAP D-dehydrogenase in the absence of *meso*-DAP **3**, and



Scheme 3 *Reagents and conditions*: i, DIBAL-H, Et_2O, −78 °C, 86%; ii, $Ph_3P{=}CHCO_2Me$, THF, 85%; iii, TFA (1.2 equiv.), CH_2Cl_2, 82%; iv, LiOH, MeOH, H_2O, 98%; v, TFA, CH_2Cl_2, 87%.

as expected, showed no conversion. Subsequent inhibition studies showed both compounds to be very good but rapidly reversible inhibitors (not time-dependent) of DAP D-dehydrogenase. More detailed kinetic analyses demonstrated that **5** is a competitive inhibitor with an inhibition constant (K_i) of 5.3 μM. In contrast, a Michaelis–Menten plot for **6**, which has the double bond in the backbone, showed noncompetitive inhibition with a K_i value of 44 μM, indicating different binding modes for the two unsaturated analogues.

DAP D-dehydrogenase from *Corynebacterium glutamicum* exists as a homodimer with each monomer unit (*M ca*. 35200) possessing a similar fold but somewhat different overall conformation based on crystallographic studies.[5,10] Although there may be structural differences between the *B. sphaericus* and *C. glutamicum* enzymes,[11] their overall mechanism and inhibition by **4** are similar. Since isoxazoline **4** is a competitive inhibitor with respect to L-tetrahydrodipicolinate **1** (K_i = 4.2 μM) but a noncompetitive inhibitor with respect to *meso*-DAP (K_i = 23 μM),[4] it seems likely that the nearly equipotent noncompetitive inhibitor **6** may bind in a similar fashion. This indicates that interactions of the isoxazoline nitrogen and oxygen with active site water molecules seen in crystallographic studies may play a minor role in binding.[5] However, **5** is directly competitive with *meso*-DAP **3** and is one of the most potent substrate analogue inhibitors for this enzyme found thus far. This suggests that **5** may be a true mimic of the imine intermediate **2**, and that normal catalysis by DAP D-dehydrogenase can be blocked by conformational changes induced in the protein by binding of **4** or **6** in the adjacent subunit at a site normally occupied by THDP **1** (Fig. 1). Additional crystallographic studies with the unsaturated α-aminopimelic acid derivatives **5** and **6** may help to clarify the subunit interactions and the detailed mechanism of this enzyme. Further studies on the synthesis of DAP analogues[12] and their interactions with other DAP enzymes are in progress.

The authors thank Dr Jonathan Parrish for assistance with molecular modeling. Financial support from the Alberta Heritage Foundation for Medical Research (Fellowship to A. S.) and the Natural Sciences and Engineering Research Council of Canada (Scholarship to J. F. C. and Operating Grant) is gratefully acknowledged.

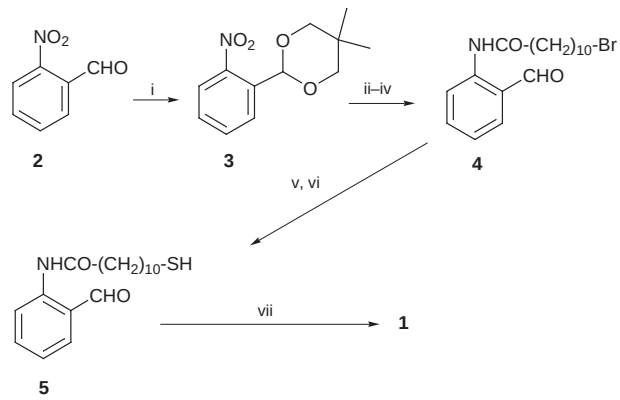
Received (in Cambridge, UK) 21st December 1998, Accepted 22nd February 1999

A stable anodic photocurrent was observed in the presence of an electron sacrificer when a gold electrode modified with a self-assembled monolayer of C_{60} was illuminated with monochromic light, indicating the generation of a vectorial electron flow from the electron donor to the gold electrode *via* the excited states of C_{60}.

The unique three-dimensional structure of C_{60} has prompted many researchers to apply it to materials science.[1] In this context, fullerene thin films formed using a variety of methods, including Langmuir–Blodgett (LB) techniques and evaporation, have displayed interesting physical and chemical properties.[2] Self-assembled monolayers (SAMs) are useful for constructing highly ordered, two- and three-dimensional structures on substrates.[3] Several groups have already reported the preparation, electrochemistry and surface properties of C_{60} SAMs.[4–9] However, to the best of our knowledge, there have been no reports of the photoelectrochemical properties of SAMs of fullerenes. Here we report the preparation and photoelectrochemistry of a SAM of C_{60}-tethered alkanethiol **1** on a gold electrode (Fig. 1).

The synthetic route to C_{60}-linked polyalkanethiol **1** is shown in Scheme 1. It is well established that alkanethiols with a polymethylene chain form densely packed monolayers on gold surfaces. It is reported that the presence of an amido group in a chain enhances the stability of monolayers due to intermolecular hydrogen bonding.[10] Thus, it is expected that the attachment of a long alkyl chain to C_{60} with an amide linkage would allow us to produce a well-ordered C_{60} SAM on a gold electrode. Aldehyde **5** was prepared *via* six steps from 2-nitrobenzaldehyde **2**. Compound **1** was synthesized by the condensation of *N*-methylglycine, C_{60} and **5**.[11] The structures of **1** and related compounds were confirmed by spectroscopic methods including ^{1}H NMR and mass spectra.† Cyclic voltammetry of **1** in CH_2Cl_2 containing 0.1 M Bu_4NPF_6 as electrolyte exhibited reversible waves due to the first and the second reductions of C_{60} (−0.59, −1.00 V *vs.* Ag/AgCl), as shown in Fig. 2.

A monolayer of **1** was formed by the spontaneous bonding of **1** onto Au(111)/Cr/Si(100) substrates (hereafter, **1**/Au, where / represents an interface). The bonding was carried out from a 20 μM $CHCl_3$ solution for 20 h to complete the formation. After soaking, the electrode was washed well with $CHCl_3$ and dried with a stream of argon. Cyclic voltammetry of **1**/Au in CH_2Cl_2 containing 0.1 M Bu_4NPF_6 with a sweep rate of 100 mV s^{-1} showed a wave at $E_{1/2}$ = −0.63 V (*vs.* Ag/AgCl) and a second smaller wave at $E_{1/2}$ = −1.07 V, which correspond to the first and second reduction/oxidation peaks of C_{60}, respectively (Fig. 2). The values of the peak splittings (ΔE_{peak} = 210 mV) are large, compared with the ideal value in solution, indicating the slow kinetics between the C_{60} and the gold electrode due to structural constraints. Integration of the area under the curve observed for the first reduction due to the C_{60} corresponds to a surface coverage of Γ = 1.4 × 10^{-10} mol cm^{-2} (120 Å^2 molecule^{-1}),‡ which agrees well with the value (1.4 × 10^{-10} mol cm^{-2}) in similar C_{60} SAM systems.[8,9] The value is somewhat larger than the values of the hexagonal (78 Å^2



Scheme 1 *Reagents and conditions*: i, neopentyl glycol, TsOH, 91%; ii, H_2, Pd/C, 72%; iii, 11-bromoundecanoic acid, *N*-methylmorpholine, 2-chloro-4,6-dimethoxy-1,3,5-triazine, 99%; iv, H_2SO_4, TFA, 99%; v, potassium thioacetate, 80%; vi, KOH, 96%; vii, *N*-methylglycine, C_{60}, 13%.

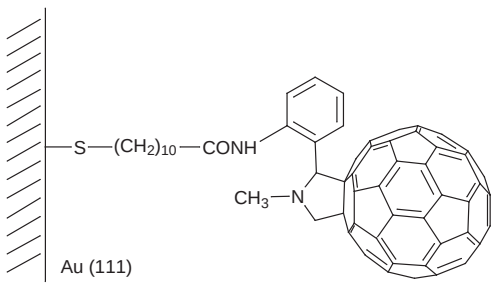


Fig. 1 A self-assembled monolayer of **1**/Au (111).

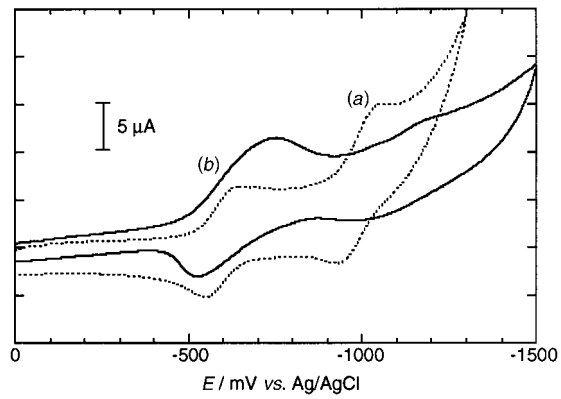

Fig. 2 Cyclic voltammograms of (*a*) **1** in CH_2Cl_2 (dotted line) and (*b*) **1**/Au in CH_2Cl_2: sweep rate 100 mV s^{-1}, electrode area 0.48 cm^2, initial potential 0 V.

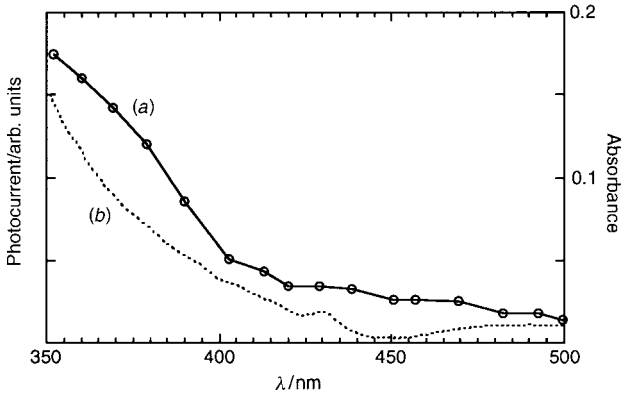

Fig. 3 Action spectrum of (*a*) C_{60} SAM cell and (*b*) absorption spectrum of **1** in $CHCl_3$ (8.88 μM).

molecule^{-1}) or the simple square (98 Å^2 molecule^{-1}) packing in similar C_{60} LB films.[12] This may be related to steric hindrance around the phenyl group on the pyrrolidine ring attached to C_{60}.

Photoelectrochemical measurements were carried out for **1**/Au in an argon-saturated 0.1 M Na_2SO_4 solution containing 50 mM ascorbic acid (AsA) as an electron sacrificer using a modified gold electrode as the working electrode, a platinum counter electrode, and a Ag/AgCl reference electrode (hereafter, Au/**1**/AsA/Pt, where / represents an interface). A stable anodic photocurrent flowed immediately after the gold electrode was irradiated and fell instantly when the illumination was terminated. The photoelectrochemical response was repeated for tens of times without any signs of attenuation when the light was switched on and off. An increment of the anodic photocurrent with an increase of positive bias to the gold electrode (−400 mV to +200 mV) in the system demonstrated that the direction of the photocurrent takes place from the cathode to the anode through the electrolyte. The intensity of the photocurrent for the Au/**1**/AsA/Pt cell is an order of magnitude larger than those of the Au/**1**/Pt cell or the bare Au/AsA/Pt cell, indicating the involvement of AsA and C_{60} for the generation of the photocurrent. The agreement of the action spectrum with the absorption of **1** in $CHCl_3$ from 350–500 nm (Fig. 3) shows that C_{60} is the photoactive species. Under excitation with $\lambda = 403 \pm 6.9$ nm light of 6.6 mW cm^{-2} and 0.1 V bias voltage, we obtained a photocurrent density of 290 nA cm^{-2}. Assuming that the absorption coefficient of **1** on the gold surface is the same as that in $CHCl_3$, absorbance of **1**/Au at 403 nm is calculated to be 7.81×10^{-4}. Given the absorbance for **1**/Au, we can estimate that the quantum yield of the Au/**1**/AsA /Pt cell is 7.5%.§ The value is at least one order of magnitude larger than those in similar photoelectrochemical cells of porphyrin SAMs[13] and comparable to those (1.2–8.2%) in similar C_{60} LB cells.[14] These results indicate that C_{60} is an excellent electron mediator as well as a good electron acceptor.[15] Based on these data together with previous results, we can propose the photocurrent generation mechanism. It is plausible that the excited singlet state (1.11 V *vs*. Ag/AgCl) and/or the triplet state (0.82 V) of the C_{60} are quenched by AsA (−0.19 V).[15] The resulting C_{60} anion radical would give an electron to the gold electrode, resulting in the recovery of the initial state. Overall, electron flow occurs from AsA to the gold electrode *via* C_{60}.

In conclusion, a photoelectrochemical cell with a gold electrode modified with a SAM of C_{60} has been constructed for the first time. The high quantum yield implies that a combination of C_{60} and SAMs is promising for applications in materials science. Our results will provide the basic information for the development of photovoltaic devices and sensors.

Total synthesis of deoxypyridinoline, a biochemical marker of collagen turnover

Pietro Allevi,* Alessandra Longo and Mario Anastasia

Dipartimento di Chimica e Biochimica Medica, Via Saldini 50, 20133 Milano, Italy. E-mail: allevi@unimi.it

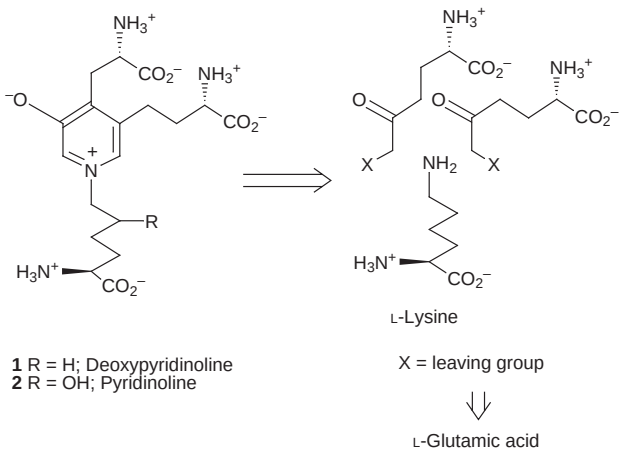
Received (in Cambridge, UK) 11th January 1999, Accepted 9th February 1999

A convergent synthesis of deoxypyridinoline is described which involves the assembly of a suitably polysubstituted 3-hydroxypyridinium ring starting with fully protected L-lysine and L-glutamic acid.

The paper describes the synthesis[1] and complete characterization of the optically pure deoxypyridinoline **1**. This compound and pyridinoline **2** represent two crosslinks of the mature form of collagen and, at present, are the most effective biochemical markers of collagen turnover correlated with diseases such as osteoporosis, bone cancer and arthropathies.[2]

Compounds **1** and **2** were isolated from bones after several purification steps, but despite the various efforts devoted to improve their extraction, the yields are currently very poor.[3] Although in only small amounts, deoxypyridinoline **1** and pyridinoline **2** have recently been obtained in high purity from bones,[4] and their individual UV molar extinction coefficient values have been established. These values are necessary for the correct standardization of the analytical techniques normally used in clinical determinations in human urine. On the other hand it is still impossible to have a definitive validation of these parameters determined from synthetic compounds using the only multistep synthesis of the deoxypyridinoline **1** (of unspecified diastereomeric purity) and of the pyridinoline **2** (as mixture of epimers at the hydroxylated alkyl carbon) so far reported.[5] This synthesis is accomplished starting with a single fully-protected synthetic L-amino acid, prepared according to the Schoelkopf's approach. However, the enantiomeric purity of this starting building block as well as the physico-chemical parameters (UV molar extinction coefficients, optical rotations, elemental analyses) of the final compounds **1** and **2** were unreported.

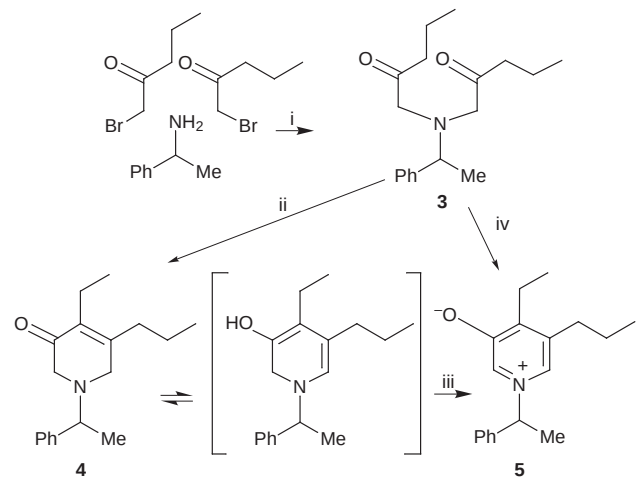
In our work we decided to start from enantiomerically pure and easily available natural L-α-amino acids, in order to avoid the formation of complex diastereomeric mixtures in a possible convergent synthesis of **1**. In particular, a strategic disconnection of the pyridinium compound **1** suggested its assembly from an L-lysine residue and from two identical fragments derivable from L-glutamic acid (Scheme 1).



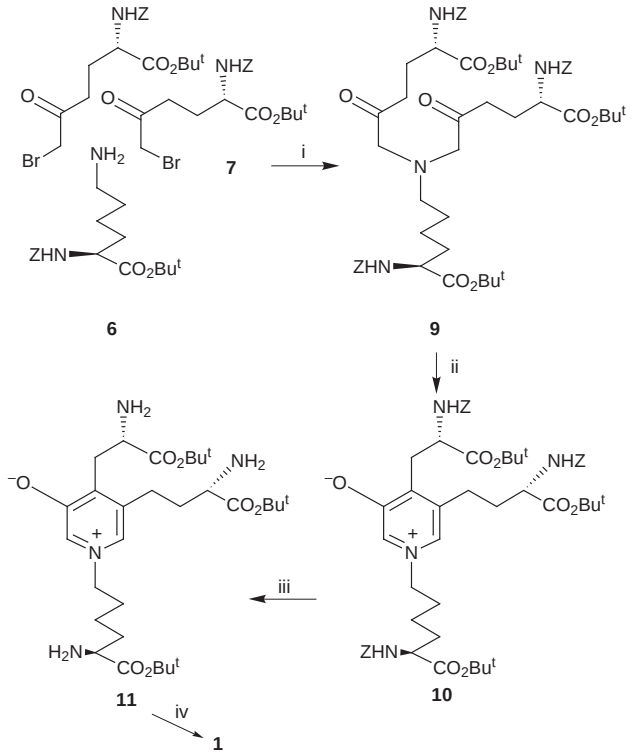
Scheme 1

With this in mind, the possibility of constructing the pyridine ring of **1** was first studied using a simpler model lacking the stereocenters and the amino acidic functionalities (Scheme 2). Easily available[6] 1-bromopentan-2-one was reacted with (*R*)-1-phenylethylamine to afford, using the best conditions (K_2CO_3, MeCN, 12 h, 25 °C), the diketoamine **3** in very high yield (80%).† Initially, various unsuccessful attempts were made to promote in the same reaction both the formation of the ketoamine **3** and its condensation to give the ketone **4**, by modulating the reaction conditions (reaction times, temperatures and/or addition of appropriate crown ethers). Subsequently, the internal condensation was attempted with the isolated and purified compound **3**. Surprisingly, treatment of amine **3** with K_2CO_3 in MeOH afforded (70% yield) a single fluorescent product, to which the structure **5**‡ could be assigned. Formation of compound **5** shows that, contrary to our expectations, the aldolic condensation occurred, followed by the oxidation of the possible intermediate cyclic ketone **4**.

The ketone **4** could be isolated and completely characterized when the reaction was performed under complete exclusion of oxygen. This compound was transformed into the pyridinium salt **5** when it was dissolved in MeOH and stirred in the presence of air and K_2CO_3. Compound **5** was also obtained, in a one-pot reaction, by mixing 1-bromopentan-2-one and (*R*)-1-phenylethylamine in an open vessel containing MeCN and K_2CO_3. When the complete formation of the ketoamine **3** was monitored, the addition of MeOH leads to the formation of the desired pyridinium salt **5**. Similar spontaneous oxidations were also recently observed[7] in other syntheses of pyridinium derivatives, but it was always impossible to map the mechanism of their formation. In our case, the isolation of compound **4** under anaerobic conditions and the observation that no tetrahydro derivative was detectable in the final reaction mixture made it possible to establish that oxygen, and not a disproportionation reaction, is responsible for the formation of pyridinium salt **5**.



Scheme 2 *Reagents and conditions*: i, K_2CO_3, MeCN, room temp., 80%; ii, K_2CO_3, MeOH, room temp., 85%; iii, K_2CO_3, air, MeOH, room temp., 81%; iv, K_2CO_3, air, MeOH, room temp., 70%.



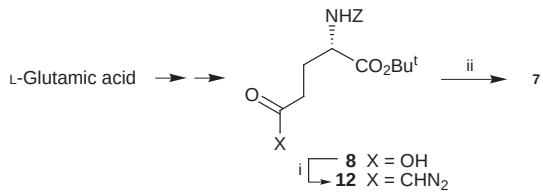
Scheme 3 *Reagents and conditions*: i, K_2CO_3, MeCN, room temp., 78%; ii, K_2CO_3, air, MeOH, room temp., 73%; iii, H_2, Pd/C, MeOH, room temp., 94%; iv, TFA, room temp., 72%.

The possibility of extending the method used for the synthesis of the simple model compound **5** to the more complex deoxypyridinoline **1** was then demonstrated by reacting under similar conditions (Scheme 3) the known[8] protected L-lysine **6** with the bromo ketone **7**§ obtained in two steps from *N*-(benzyloxycarbonyl)-L-glutamic acid 1-*tert*-butyl ester[9] **8** (Scheme 4).

Thus, the reaction in MeCN afforded the amine **9** in good yield [78% yield; an oil, $[\alpha]_D^{20}$ −0.8, $[\alpha]_{365}^{20}$ +3.1, ($CHCl_3$, 1% solution]. This amine is rather unstable in solution (decomposes in a few days) but it was transformed into the protected deoxypyridinoline **10**¶ when it was dissolved in MeOH containing K_2CO_3 and stirred in the presence of air.

Regeneration of the three protected amino groups of **10** by hydrogenolysis afforded the ester **11**‖ which, by treatment with TFA, easily gave deoxypyridinoline **1** as monotrifluoracetate salt in an epimerization-free process.[10] This salt of deoxypyridinoline **1** crystallized from aq. EtOH as a white monohydrate which was completely characterized.** Its UV molar extinction coefficients proved higher (10–20%) than those reported for the corresponding tetrachloride dihydrate salt.[4] The same difference was observed for the corresponding tetrachloride salt of **1**, which in our hands crystallized as monohydrate.

The preparation of the bromo derivative **7**, which required the activation of the ω-carboxylic group of the protected glutamic acid **8** and its substitution for an α-bromo ketone *via* an intermediate α-diazo ketone, merits comment. These transformations, well-established in the case of the shorter aspartic derivative,[11] were in our case complicated by the easy concurrent cyclisation to the known[12] (*S*)-5-(1,1-dimethylethoxy)carbonyl-1-benzyloxycarbonyl-2-pyrrolidone, cyclisation of which was not allowed in the case of the aspartic acid derivative. This cyclisation occurs during the activation of the ω-carboxylic group as an acid chloride (using $SOCl_2$ it is the only compound formed) or as mixed anhydride (using $ClCO_2Et$[13] it forms in 40% yield). Only when performing the activation with $ClCO_2Bn$ does the diazo ketone **12** [oil; $[\alpha]_D^{25}$ +16.6 ($CHCl_3$, 2% solution)] form in quantitative yield, avoiding the formation of cyclic pyroglutamate.



Scheme 4 Reagents and conditions: i, $ClCO_2Bn$, *N*-methylmorpholine, THF, −20 °C, then CH_2N_2, −20 °C → 0 °C, 88%; ii, HBr, AcOH, 0 °C, 64%.

Further work is currently underway to accomplish the synthesis of pyridinoline **2** by a similar convergent assembly of the pyridine nucleus starting from three L-glutamic units.

This work was supported financially by MURST COFIN progetto di ricerca 'Nuove metodologie e strategie di Sintesi di Composti di Interesse Biologico'. Dedicated to the memory of Professor Giacomino Randazzo.

Sulfate and acetate complexes comprising two-dimensional grids with square cavities and three-dimensional networks with hexagonal channels, respectively, have been prepared and characterised by X-ray single-crystal structural analysis.

Considerable research effort has recently been focused on the crystal engineering of supramolecular architectures organised by co-ordinate covalent or hydrogen bonding.[1,2] Although supramolecular co-ordination polymers have currently been constructed largely with the use of symmetrically-bridging ligands (such as 2-connectors, trigonal 3-connectors, and tetrahedral or square planar 4-connectors), the use of different synthons[1a,3,4] is one of several strategies that could be employed in the synthesis of frameworks having larger cavities or channels for possible application in separation processes and catalysis. Silver(I) is a good candidate as a simple spacer in L–M–L metallic synthons for the preparation of desired networks, and hexamethylenetetramine (hmt) as a potential tetradendate ligand seems quite suitable for self-assembly of supertetrahedral networks with metallic synthons although no supertetrahedral $[Ag_2(hmt)]$ hypothetical frame has, as yet, been isolated.[5–9] We report here the preparation and crystal structures of two novel two- and three-dimensional non-interpenetrating open-networks organised by μ_4-hmt ligand with simple spacers: $[Ag_2(\mu_4\text{-hmt})(SO_4)(H_2O)]\cdot 4H_2O$ **1** and $[Ag_2(\mu_4\text{-hmt})(\mu\text{-}O_2CMe)]MeCO_2\cdot 4.5H_2O$ **2**.

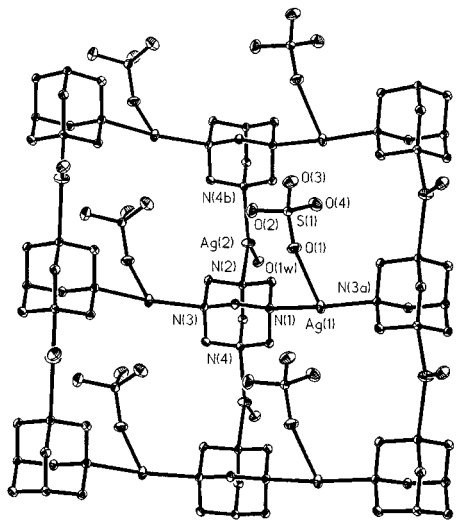

Fig. 1 ORTEP view showing the layer in **1** viewed along the *b* direction. Small open balls represent centres of mass of the hmt ligands. Relevant bonding parameters: Ag(1)–N(1) 2.292(4), Ag(1)–N(3a) 2.279(4), Ag(1)–O(1) 2.571(5), Ag(2)–N(2) 2.347(4), Ag(2)–N(4b) 2.311(4), Ag(2)–O(1w) 2.303(4) Å; N(1)–Ag(1)–N(3a) 172.81(15), N(1)–Ag(1)–O(1) 88.44(16), N(3a)–Ag(1)–O(1) 92.44(15), N(2)–Ag(2)–N(4b) 115.10(14), N(2)–Ag(2)–O(1w) 117.09(15), N(4b)–Ag(2)–O(1w) 127.80(15)°.

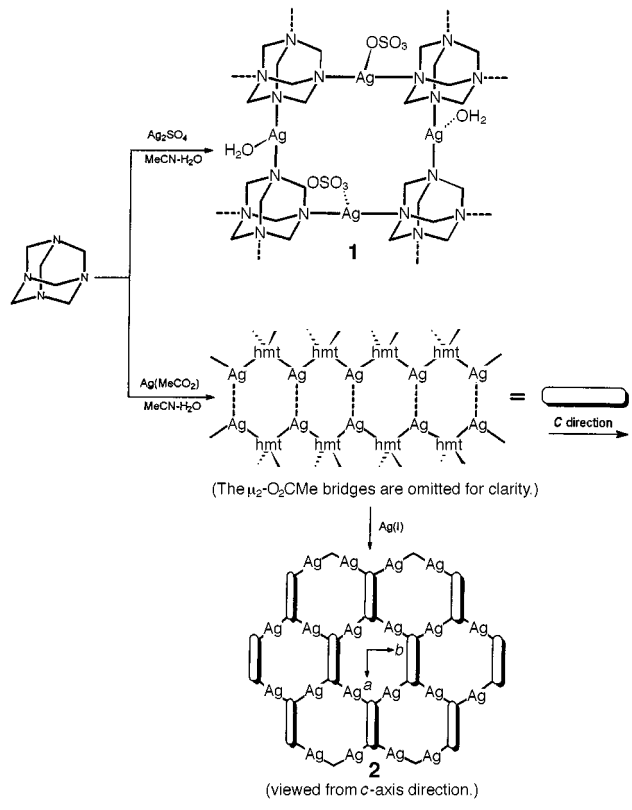
Both complexes were synthesised by self-assembly of the silver(I) salts with hmt, as shown in Scheme 1. An aqueous solution (5 cm^3) of hmt (0.140 g, 1.0 mmol) was added dropwise to a stirred MeCN solution (5 cm^3) of Ag_2SO_4 (0.156 g, 0.5 mmol) or $Ag(MeCO_2)$ (0.167 g, 1.0 mmol) at 50 °C for 15 min. The resulting colorless solution was allowed to stand in air at room temperature for two weeks, yielding colorless crystals [*ca.* 75% yield based on silver(I)]. Elemental analysis confirmed the formulae of **1** and **2**.† On performing the above reactions with an Ag(I) : hmt ratio of 2 : 1, crystals of **1** or **2** were correspondingly isolated in high yield, suggesting that the Ag(I) ion plays the role of a simple spacer in the self-assembly of **1** and **2**.

X-Ray crystallography‡ has established that **1** is made up of two-dimensional infinite wavy neutral layers of square units and lattice water molecules. As illustrated in Fig. 1, each square unit is organised by four Ag(I) ions in two types of geometries and four hmt molecules each at the midpoint of side and corner, respectively, in which the Ag(2) ion is in a trigonal geometry coordinated by two nitrogen atoms from different hmt ligands and one aqua ligand, while the Ag(1) atom is in a T-shaped geometry ligated by two nitrogen atoms from two hmt ligands and one monodentate SO_4^{2-} anion. Adjacent layers are connected by interlayer hydrogen bonds between the aqua



Scheme 1

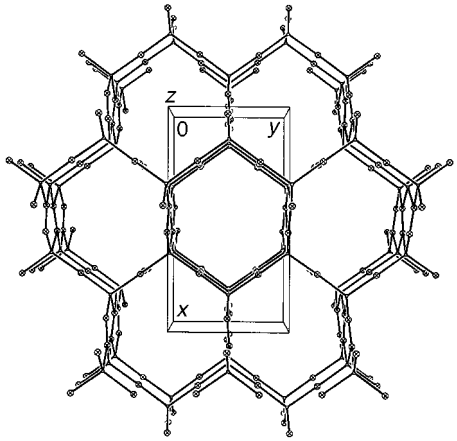


Fig. 2 View of 3-D networks in **2** along the *c*-axis direction. The μ_2-O_2CMe bridges are omitted for clarity. Small open balls represent centres of mass of the hmt ligands.

ligand and SO_4^{2-} anion with an O(1w)···O(SO_4) distance of 2.681–2.691 Å, resulting in a three-dimensional network having irregular pentagonal channels. The lattice water molecules are clathrated in these channels.

The structure of **2** consists of an open three-dimensional cationic network with hexagonal channels, acetate counterions and lattice water molecules. As shown in Scheme 1, the dimeric $Ag_2(MeCO_2)_2$ fragments are bridged by hmt ligands each using two nitrogen atoms into an infinite planar sheet with hexagonal cavities along the *c* direction. These sheets are further joined by the simple Ag(I) spacers through the two remaining nitrogen atoms of hmt ligand into a three-dimensional non-interpenetrating open-network having hexagonal channels along the *c*- and *b*-axis directions (Scheme 1 and Fig. 2). The uncoordinated acetate ions and lattice water molecules are clathrated in the channels.

In the $Ag_2(\mu$-$O_2CMe)_2$ fragments, the Ag(I) atoms are joined by two unusual non-coplanar skew–skew carboxylate bridges[10] with an Ag···Ag distance of 2.9144(8) Å, indicating a relatively strong Ag···Ag interaction;[11] each Ag(I) atom is further ligated by two nitrogen atoms from two different hmt ligands, completing a tetrahedral coordination geometry (Fig. 3).

It is noteworthy that **1** is the first two-dimensional open-network constructed by μ_4-hmt. Of the reported metal–hmt networks, hmt acts rarely in tetradendate coordination mode,[5,6,8,12–14] and only two compounds with μ_4-hmt ligand have been documented.[7,9] Moreover, the topology in **2** is, to the best of our knowledge, unprecedented. In **2**, each hexagon unit viewed from the *c*-axis direction is equivalent, and involves four Ag(I) atoms, two $Ag_2(O_2CMe)_2$ fragments and six hmt ligands, while the hexagonal units viewed from *b*-axis direction is non-equivalent and can be classified into two categories, one involves two $Ag_2(O_2CMe)_2$ fragments and two hmt ligands, another involves four Ag(I) atoms and four hmt ligands. These features are in contrast to those of the reported three-dimensional networks, a 3-D, 3-C enantiomorphic interpenetrating network in $[Ag(hmt)]PF_6 \cdot H_2O$,[6] a (3,4)-connected net in $[Ag_3(hmt)_2](ClO_4)_3 \cdot 2H_2O$,[7] and a triconnected 3D net in $[Ag_4(hmt)_3(H_2O)](PF_6)_4 \cdot 3EtOH$.[8]

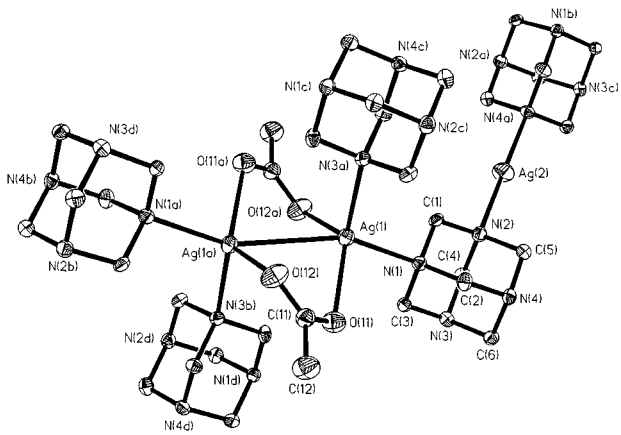

Fig. 3 Coordination environments (at 35% probability level) of the metal atoms in **2**. Relevant bonding parameters: Ag(1)–Ag(la) 2.9144(8), Ag(1)–N(1) 2.405(4), Ag(1)–N(3a) 2.403(4), Ag(2)–N(2) 2.240(4), Ag(2)–N(4a) 2.254(4), Ag(1)–O(11) 2.366(4), Ag(1)–O(12a) 2.391(4) Å; O(11)–Ag(1)–O(12a) 125.84(17), O(12a)–Ag(1)–N(3b) 108.63(14), O(12a)–Ag(1)–N(1), 91.41(15), N(1)–Ag(1)–N(3a) 115.61(14), N(1)–Ag(1)–O(11) 96.64(15), N(3a)–Ag(1)–O(12a) 108.63(14) and N(1)–Ag(2)–N(4a) 178.08(15)°.

As the self-assembly of supramolecular frameworks is highly influenced by factors such as the solvent system,[1a] template[15] and steric requirement of the counter ion,[16] our present work demonstrates that participation of counter ions plays an important role in self-assembly of these frameworks. The isolation of the title complexes and others[11,12] also suggests effective routes to constructing desired frameworks with organic molecules and metallic spacers.

Sequential multistep energy transfer: enhancement of efficiency of long-range fluorescence resonance energy transfer

Shun-ichi Kawahara, Tadafumi Uchimaru* and Shigeo Murata

Department of Physical Chemistry, National Institute of Materials and Chemical Research, Agency of Industrial Science and Technology, MITI, Tsukuba Science City 305-8565, Japan. E-mail: t_uchimaru@home.nimc.go.jp

Received (in Cambridge, UK) 14th December 1999, Accepted 15th February 1999

The efficiency of long-range (*ca.* 80 Å) fluorescence energy transfer was enhanced about 1.5 times by a third chromophore located midway between two chromophores, which suggests sequential multistep energy transfer across the three chromophores.

Fluorescence resonance energy transfer (FRET)[1] is widely used to estimate chromophore separation and structure on a nanometre scale.[2] FRET in a system consisting of a fluorescent energy donor and acceptor has been extensively studied.[1b] The FRET technique has been frequently applied to probe biological and other complex systems.[3]

Recently, covalently linked porphyrin arrays have attracted much attention as biomimetic models.[4] This is because multiporphyrin assemblies are involved in the reaction centre of photosynthesis[5] and light-harvesting antenna complexes.[4] Much effort has been directed towards the development of such model systems. Covalently linked chromophore arrays will offer new opportunities for exploring long-range energy transfer and also electron transfer systems. A few reports of non-covalently linked chromophore arrays have also been described.[6]

Here we report a non-covalently linked chromophore array indicating sequential FRET across three different chromophores. We have introduced different chromophores in a duplex of oligodeoxyribonucleic acid (oligo-DNA) in a sequential manner. We have revealed that the efficiency of FRET across the two chromophores at both ends of the oligo-DNA duplex is enhanced by a third chromophore located midway between them.

6-Carboxyfluorescein (**1**), 4,7,2′,4′,5′,7′-hexachloro-6-carboxyfluorescein (**2**) and 6-carboxy-X-rhodamine (**3**) shown in Fig. 1(*a*), were used as chromophores. These chromophores were introduced at the 5′-terminal position of oligo-DNA 25-, 15-, and 10mers through an aminohexyl phosphate linker: the carboxy groups located at the 3-position of the chromophores were connected *via* amide linkages with the terminal amino group of the linker. The sequence of the oligo-DNA 15- and 10mers are complementary to that of the 25mer. Thus, these oligomers form typical B type duplexes. As shown in Fig. 2, we

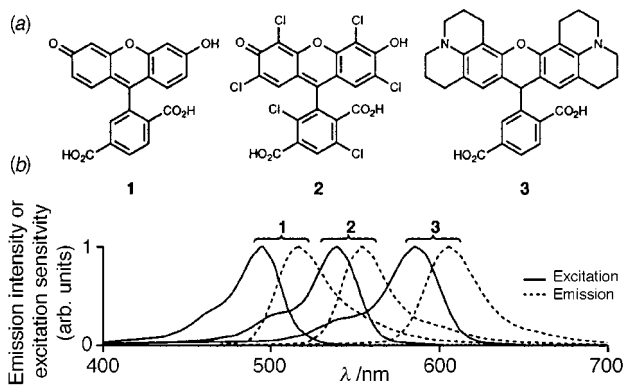

Fig. 1 (*a*) Structures of chromophores. (*b*) Excitation and emission spectra of each choromophore normalized at maximum.

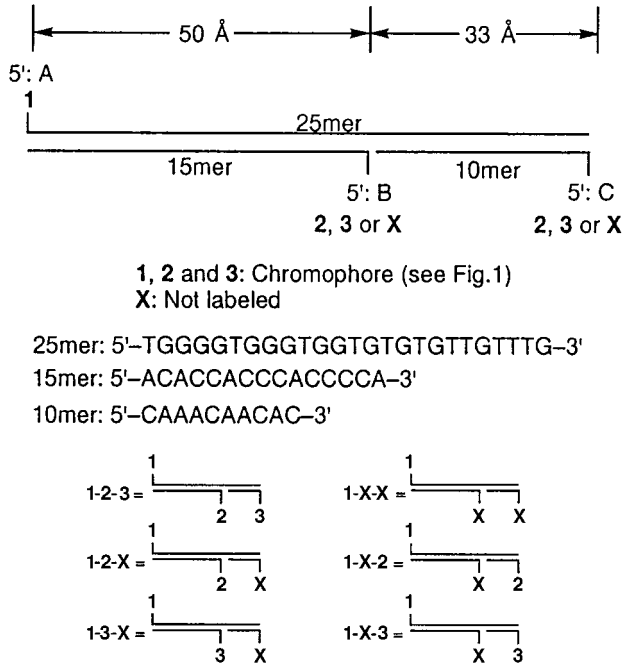

Fig. 2 DNA sequences and chromophore introduced positions.

call the 5′-terminal positions of the 25-, 15- and 10mers positions A, B, and C, respectively. Chromophore **1** was introduced at position A, while chromophores **2** and **3** were introduced at position B or C. Owing to characteristic structural features of the B type duplex, the chromophores introduced at position A, B, and C are located on the same side of the duplex chain. The distances between positions A and B and B and C are about 50 and 33 Å, respectively. Thus, position C is located *ca.* 80 Å from position A (see Fig. 2).

Fig. 1(*b*) shows the normalized emission and excitation spectra of the chromophores. The emission spectra of six duplexes (**1**-**2**-**3** through **1**-**X**-**X**,† see Fig. 2) excited at 450 nm are shown in Fig. 3(*a*) and (*b*).‡ The 450 nm light is absorbed by chromophore **1**, while the absorptions of chromophores **2** and **3** are quite weak or completely negligible at this wavelength [see Fig. 1(*b*)]. FRET from chromophore **1** to **2** or **3** was evidenced by fluorescence emission from chromophore **2** or **3**. The intensity of fluorescence from chromophore **1** was reduced as a

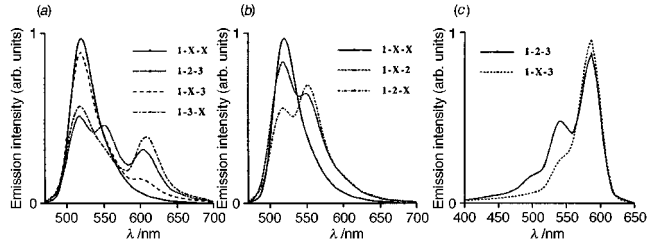

Fig. 3 (*a*) and (*b*) Emission spectra of each duplex. (*c*) Excitation spectra of **1**-**2**-**3** and **1**-**X**-**3**.

consequence of FRET across the chromophores. Correspondingly, fluorescence emission from chromophores **2** and **3** was observed. Table 1 shows the fluorescence quantum yields of each chromophore in the duplex relative to those of the same chromophore measured under the conditions without FRET.§

The results in Table 1 show that the efficiency of energy transfer from **1** to **2** or **3** decreases with the increase in the separation between the chromophores: the efficiency of energy transfer between position A and C with larger separation was lower than that between position A and B. Φ_f^{rel}(**2**) was reduced from 54% in duplex **1-2-X** to 32% in **1-X-2**. Conversely, for chromophore **1**, Φ_f^{rel}(**1**) was smaller in duplex **1-2-X** (57%) than in duplex **1-X-2** (85%). The same trend was seen for energy transfer from chromophore **1** to **3**. However, the efficiency of energy transfer from chromophore **1** to **3** was found to be lower than that from **1** to **2**. This is due to the fact that the fluorescence–absorption overlap between chromophores **1** and **3** is smaller than that between chromophores **1** and **2** [see Fig. 1(*b*)]. Φ_f^{rel}(**3**) in duplex **1-3-X** and **1-X-3** was 36 and 10%, respectively. Φ_f^{rel}(**1**) was 58 and 90%, respectively. These results indicate that our non-covalently linked chromophore arrays show normal behavior regarding energy transfer across the two chromophores.

Meanwhile, Φ_f^{rel}(**3**) was increased from 10% in **1-X-3** to 16% in **1-2-3** (see Table 1). Chromophore **2** inserted at the midway position B enhances the efficiency of the energy transfer from chromophore **1** to **3** located at positions A and C, respectively. Fluorescence excitation spectra of duplexes **1-2-3** and **1-X-3** observed at 605 nm (fluorescence maximum of chromophore **3**) are shown in Fig. 3(*c*). The excitation spectra suggested that the absolute fluorescence quantum yield of chromophore **3** was almost the same in these duplexes. Thus, we can safely conclude that the efficiency of FRET from chromophore **1** to **3** between position A and C was increased about 1.5 times due to chromophore **2** being inserted at midway position B.

Enhancement of the efficiency of energy transfer from chromophore **1** to **3** in duplex **1-2-3** can be interpreted as a consequence of sequential two-step energy transfer: energy transfer from chromophore **1** to **2** and subsequent energy transfer from chromophore **2** to **3**. Namely, chromophore **2** should work as a relay station for energy transfer, which suggests that use of an additional chromophore as a relay station should lengthen the range of energy transfer. Furthermore, sequential energy transfer *via* more than two relay stations may be possible. Such energy transfer might be called sequential multistep energy transfer. Sequential multistep energy transfer will provide us with information about the distance between chromophores with a separation larger than 100 Å, which is difficult using a simple energy transfer system consisting of just a fluorescent donor and acceptor. Thus, sequential energy transfer would be useful for research in various fields, not only in the fields of biochemistry[3] but also in the fields of supramolecular chemistry.[7]

In summary, we introduced three different chromophores in a duplex of oligo-DNA in a sequential manner. The efficiency of FRET across two chromophores was shown to be increased by a third chromophore located at the midway position between them. The third chromophore works as a relay station in energy transfer.

We thank Professor K. Tokumaru of the University of the Air for helpful discussions, and Science and Technology Agency for financial support.

Table 1 Values of Φ_f^{rel}(***n***)

Sequence	**1**	**2**	**3**
1-2-3	0.51	0.29	0.16
1-2-X	0.57	0.54	—
1-X-2	0.85	0.32	—
1-3-X	0.58	—	0.36
1-X-3	0.90	—	0.10

Notes and references

† **1-2-3** represents the oligo-DNA duplex possessing chromophores **1**, **2** and **3** at positions A, B and C, respectively. **X** means that no fluorescent chromophore is introduced at the position(s).

‡ All the fluorescence spectra were measured under the following conditions: 1 mM phosphate buffer (pH 7.0) with 0.1 M NaCl and 0.1 mM EDTA to remove the effect of contaminating metals. T = 20 °C. Concentration of oligomers = 1.0 μM. Under these conditions, three oligomers form duplexes (T_m^1 = 36–38 °C for dissociation of 10mer, T_m^2 = 60–63 °C for 15mer).

§ We derived the relative fluorescence yield, Φ_f^{apr}(***n***) in each duplex on the basis of observed fluorescence intensities of the chromophores. We employed eqn. (1), where ***n*** = **1**, **2** or **3**, Em(***n***)^{obs} = observed fluorescence

$$\Phi_f^{apr}(\boldsymbol{n}) = \left(\frac{\mathrm{Em}(\boldsymbol{n})^{obs}}{\mathrm{Em}(\boldsymbol{n})^{max}}\right)\left(\frac{\mathrm{EC}(\boldsymbol{n})}{\mathrm{EC}_{450}(\mathbf{1})}\right) \quad (1)$$

intensity of ***n*** in the FRET system excited at 450 nm, Em(***n***)^{max} = observed fluorescence intensity of ***n*** excited at the absorption maximum, EC(***n***) = extinction coefficient of **1** (48000/495 nm), **2** (79700/540 nm) and **3** (91200 /585 nm) under the present experimental conditions, and EC_{450}(**1**) = extinction coefficient of **1** at 450 nm (10800), calculated from excitation intensity and extinction coefficient at 495 nm.

However, the absorption of chromophore **2** at 450 nm cannot be completely neglected. Fluorescence emission from chromophore **2** results from not only energy transfer from **1** but also partially by direct excitation of **2** by irradiation at 450 nm. In duplex **1-2-3**, energy transfer will occur from directly excited **2** to **3**, which partially contributes to Φ_f^{apr}(**3**). We deducted these contributions of direct excitation of **2** from Φ_f^{apr}(**2**) and Φ_f^{apr}(**3**) and then derived the relative fluorescence yields of these two chromophores. Hereafter, we refer to these quantities as the relative fluorescence yields Φ_f^{rel}(***n***). The values of Φ_f^{rel}(***n***) are the fluorescence yields of emission from each chromophore solely due to the contribution of the energy transfer from chromophore **1**. For chromophore **1**, Φ_f^{apr}(**1**) = Φ_f^{rel}(**1**). In addition, for duplexes **1-3-X** and **1-X-3**, which do not possess chromophore **2**, Φ_f^{apr}(**3**) = Φ_f^{rel}(**3**). Thus, the relative fluorescence yields Φ_f^{rel}(***n***) in Table 1 do not include the contribution of fluorescence emission due to direct excitation of chromophore **2**.

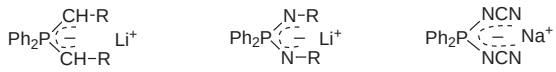
Received (in Liverpool, UK) 3rd November 1998, Accepted 4th February 1999

The first example of a stabilized diaminophonium diazaylide, sodium diphenylbis(cyanamido)phosphonium diylide, has been synthesized by a new variation of the Staudinger reaction; the corresponding copper complex can be described as a discrete dimeric unit with $[Ph_2P(NCN)_2]^-$ in both uni- and bi-dentate modes (X-ray structure).

Lithium phosphonium diylides **1** were first discovered by Wittig in 1949.[1] As part of the study of the reactivity of these reagents,



1 R = H, alkyl, C(O)R' *etc.* **2** R = alkyl **3** R = aryl **4** R = electron withdrawing group

4a

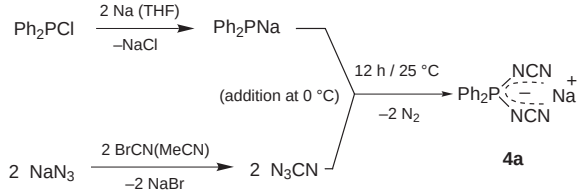
we have developed a general synthetic route to their direct precursors, the dialkyldiphenylphosphonium salts.[2] Our method thus allowed a convenient access to all types of diylides, regardless of their having non-stabilized, semi-stabilized or stabilized characters.

Thanks to their strong nucleophilic character, the phosphonium diylides **1**, until recently mainly used in coordination chemistry,[3] are excellent and versatile tools in organic synthesis.[2] Therefore, we have also developed a synthesis of their nitrogen analogs, the lithium diaminophosphonium diazaylides, in order to test their potential in synthesis.[4]

Until now our method, involving the direct dilithiation of the corresponding diaminophosphonium salts, was limited, in spite of many attempts, to the formation of non- and semi-stabilized diaminophosphonium diylides **2** and **3**.[4] We report here the synthesis of the first example of a stabilized diaminophosphonium diazaylide of type **4**, the sodium diphenylbis(cyanamido)-phosphonium diylide $Na[Ph_2P(NCN)_2]$ **4a**.

The diazaylide **4a**, which has a stronger nucleophilic character than the corresponding monoazaylide (Ph_3PNCN), has been obtained through a new variation of the Staudinger reaction, namely the reaction of Ph_2PNa with N_3CN (Scheme 1).

Under nitrogen, a solution of Ph_2PNa (30 mmol) in dry THF (80 ml) was added dropwise at 0 °C to a solution of N_3CN (65 mmol) in MeCN (80 ml). After the end of the addition, the reaction, performed under mild conditions, affords the sodium diphenylbis(cyanamido)phosphonium diylide $Na[Ph_2P(NCN)_2]$ **4a** in 80%.†



Scheme 1

The Staudinger reaction is usually described as a two-step reaction corresponding to a nucleophilic addition of a tricoordinated phosphorus center (R_3P) on an azide followed by N_2 elimination.[5] To the best of our knowledge, our reaction constitutes the first example of a Staudinger reaction involving a phosphide.

The diazaylide **4a**, whose reactivity we are currently testing in organic synthesis, may also attract interest in the field of coordination chemistry. Indeed, the corresponding non-stabilized diaminophosphonium diazaylides of type **2** are well-known bidentate ligands. The majority of the known complexes exhibit four membered MN_2P rings involving diazaylides substituted on the nitrogens by trimethylsilyl groups.[6] They are mainly represented by two categories with pentavalent phosphorus, the 1,3,2λ^5,4-diazaphosphametalletidines and the 1,3,5,7,2λ^5,6λ^5,4-tetraazadiphosphametallaspiro[3.3]bicycloheptanes.

The stabilized diazaylide $Na[Ph_2P(NCN)_2]$ **4a**, in aqueous solution with or without pyridine, forms quantitatively with metal ions (Ag^+, Ni^{2+}, Cu^{2+}) the complexes **4b**–**d** (Scheme 2).

The molecular structure of the copper complex **4d**,§ illustrated in Fig. 1, shows different structural features in comparison to corresponding complexes with non-stabilized diazaylides. Indeed, **4d** contains $[Ph_2P(NCN)_2]^-$ in two coordination modes. It can be described as a discrete dimeric unit with $[Ph_2P(NCN)_2]^-$ in both uni- and bi-dentate modes. The two copper atoms are doubly bridged by $[Ph_2P(NCN)_2]^-$ ligands, forming a 16-membered puckered cycle, which exhibits crystallographic $\bar{1}$ symmetry. The maximum deviation from the least-squares plane defined by all ring atoms amounts to −0.409(2) and +0.432(2) Å for P2 and P2′. The coordination of the copper atoms is trigonal bipyramidal. The phosphorus atoms are nearly tetrahedrally coordinated. Bonding distances and angles agree well with standard values and previous experience.[7] Lastly, it is noteworthy that, in comparison to diaminophosphonium diazaylides **2**, the $[Ph_2P(NCN)_2]^-$ anion shows different coordination properties, the preferential donor atoms being the terminal nitrogens.

The ligand properties of the $[Ph_2P(NCN)_2]^-$ anion are under investigation, as well as the synthetic potential of the corre-

Temperature and solvent effects in facial diastereoselectivity of nucleophilic addition: entropic and enthalpic contribution

Gianfranco Cainelli,* Daria Giacomini and Paola Galletti

Dipartimento di Chimica 'G. Ciamician', Università degli Studi di Bologna, Italy. E-mail: cainelli@ciam.unibo.it

Received (in Cambridge, UK) 27th October 1998, Accepted 23rd December 1998

Solvent and temperature effects on facial diastereoselectivity of nucleophilic addition have been long observed but often neglected. Temperature dependent measurements according to the modified Eyring equation allow the evaluation of stereoselectivity in terms of differential enthalpy and entropy of activation, and demonstrate the paramount importance of entropic contribution in directing the facial diastereoselectivity. Even the reaction solvent proved to be important in determining the isomer ratio. In many cases Eyring plots show a non-linear behavior consisting of two linear regions intersecting at a point called the inversion temperature (T_{inv}) which, for the same reaction, depends on the nature of the solvent and correlates with their melting points. We propose that T_{inv} is the temperature value for the interconversion between two different solvation clusters which should behave like two different molecules.

Introduction

Selectivity is the keyword for organic synthesis in recent years. Among the various categories, stereoselectivity represents the main goal for researchers involved either in total synthesis or in new methodologies. Moreover, the synthetic process for a new drug or for a biologically active compound cannot avoid a correct and accurate control on the final target stereochemistry.

Nowadays, many methods are available for stereocontrolled synthesis.[1] However, in spite of excellent experimental results obtained in asymmetric induction and asymmetric catalysis, comprehension of mechanisms and identification of the molecular species involved in transferring the chiral information is still at the beginning.

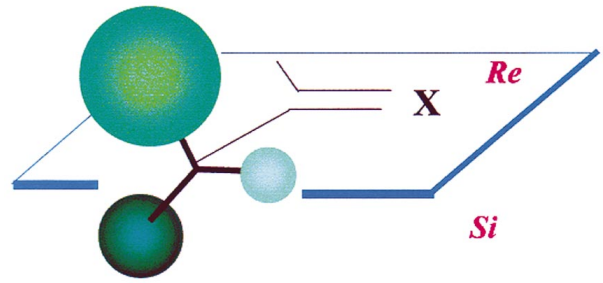

Fig. 1

The stereochemical aspect of addition reactions to carbonyls is discussed in terms of face-selectivity (Fig. 1).[2] The process will be stereotopically divergent[3] whenever, between the two competing attacks to either the *re* or *si* face, one is preferred. Such stereoselection is commonly observed in asymmetric induction on α-chiral π-compounds. In this case an addition reaction can afford two diastereoisomers (*anti* and *syn*[4]), whose kinetics are the same as those of parallel independent reactions with two different products. In a kinetically controlled process, the selectivity (*S*) is expressed as in eqn. (1), where *k* and *k*′ are

$$S = \ln (k/k') \quad (1)$$

the overall rate constants leading to the two isomers.

A lot of experimental and theoretical work deals with steric and stereoelectronic effects over face-selectivity,[4] while temperature and solvent effects have been less investigated.

Temperature-controlled diastereoselectivity

The temperature effect on diastereoselection has long been observed but often neglected. Its influence on diastereoselection is not uniform. Depending on the circumstances, upon increasing the reaction temperature the diastereoselection may decrease, but it may also be constant or even increase. In the latter case we could observe the best diastereomeric excess (de) at high temperature, a behavior that is generally not expected.

The temperature dependence in diastereofacial selectivity can be analyzed according to the Arrhenius equation for the two reaction paths [eqn. (2)], which in the framework of the Eyring

$$\ln (k/k') = -(E_a - E'_a)/RT + \ln A - \ln A' \quad (2)$$

transition state theory becomes eqn. (5) *via* eqn. (3) and (4),

$$\ln k/k' = -(\Delta G^{\ddagger} - \Delta G'^{\ddagger})/RT = -\Delta\Delta G^{\ddagger}/RT \quad (3)$$

$$\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\,\Delta S^{\ddagger} \quad (4)$$

$$\ln k/k' = -(\Delta\Delta H^{\ddagger}/RT) + (\Delta\Delta S^{\ddagger}/R) \quad (5)$$

Professor Gianfranco Cainelli was born in Trento (Italy). He received the Dipl. Ing. and Doctor der Technischen Wissenschaften from the ETH Zürich. After two years as a postdoctoral fellow with Professor O. Jeger in Zürich, he moved to the Politecnico of Milan as Assistant to Professor A. Quilico and in 1968 joined the faculty of the University of Bari as full Professor. He has been Professor of Organic Chemistry at the University of Bologna since 1971.

Dr Daria Giacomini was born in San Marino (Republic of San Marino), and is a Research Associate in the Department of Chemistry 'G. Ciamician' at the University of Bologna. A graduate in Chemistry (1982), she obtained her PhD fom the University of Bologna in 1987 and held a Researcher Scientist position at the National Council of Research ICoCEA for two years before she returned to the Faculty of Science at Bologna to take up her current position (1990).

Dr Paola Galletti was born in Bologna (Italy), where she graduated in Chemistry (1994). She is now finishing her PhD in Chemistry at the University of Bologna.

where k and k' are the observed overall rate constants, and $\Delta\Delta G^{\ddagger}$ is the difference in free activation energies for *re* and *si* face attack. In diastereoselective reactions, k/k' can be expressed as the final concentration ratio of the two isomers *anti* and *syn*. Temperature dependent measurements on the basis of eqn. (5) allow the evaluation of stereoselectivity in terms of differential enthalpy and entropy of activation. It is important to underline that in diastereoselective processes, where little differential enthalpic contribution exists, temperature values in the experimentally accessible range often render the differential entropy of activation a determining contribution, especially at high temperature.[5] Under these conditions, any prediction of stereoselectivity based on classical models, such as Cram's chelated model or the Felkin-Ahn model based only on enthalpic differences, are not effective because of entropy underestimation.

Entropy and enthalpy can play in favor of opposite isomers, leading to an inversion of selectivity by temperature.[6] In this case, we get a predominance of one diastereoisomer at low temperature and the other one at high temperature. In the linear Eyring plot of ln k/k' *versus* $1/T$ (Fig. 2), reversal of de by

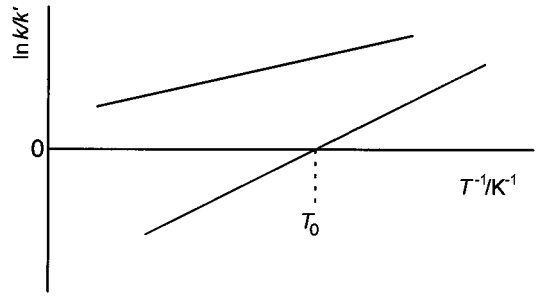

Fig. 2

reaction temperature[7] gives rise to an x-axis crossing (ln k/k' = 0, de = 0%) thus identifying an equiselective temperature T_o = $\Delta\Delta H^{\ddagger}/\Delta\Delta S^{\ddagger}$. Because of the positive value of absolute temperature, reversal of de occurs when the differential enthalpic and entropic terms have the same sign.

In this case, there exists a temperature range where $T\Delta\Delta S^{\ddagger} < \Delta\Delta H^{\ddagger}$ and another where $T\Delta\Delta S^{\ddagger} > \Delta\Delta H^{\ddagger}$. For example, in the formation of *anti* and *syn* isomers, whenever the former prevails, a negative value of the differential activation entalphy ($\Delta H^{\ddagger}_{anti} - \Delta H^{\ddagger}_{syn} = \Delta\Delta H^{\ddagger} < 0$) results. Assuming that an addition reaction is accompanied by a loss of activation entropy, $\Delta S^{\ddagger}_{anti}$ and $\Delta S^{\ddagger}_{syn}$ are both negative and the condition for the de inversion, $\Delta\Delta S^{\ddagger} < 0$, requires $|\Delta S^{\ddagger}_{anti}| > |\Delta S^{\ddagger}_{syn}|$: this means that the entropic loss in the formation of *anti* is larger than those of *syn*. As a consequence, the *anti* isomer is enthalpically driven whereas the *syn* is entropically driven: at low temperature the former prevails, while at high temperature the latter. It is important to emphasize that if both enthalpy and entropy cooperatively work in favor of the same isomer [this condition results when $\Delta\Delta S^{\ddagger}$ and $\Delta\Delta H^{\ddagger}$ have opposite signs in eqn. (5)], an inversion in the diastereomeric excess can never be obtained by solely controlling the temperature.

Eqn. (5) shows a linear correlation between $1/T$ and selectivity. However, there are experimental data that show a non-linear behavior (Fig. 3). In these cases, the corresponding Eyring plots generally consist of two linear regions intersecting at a point defining a temperature called the inversion temperature (T_{inv}).[8] This break point leads to two sets of activation parameters; one for $T < T_{inv}$ and the other for $T > T_{inv}$.

This phenomenon has been nicely reviewed by Scharf,[9] who considers the conditions for the existence of a T_{inv} in an Eyring plot showing the occurrence of two levels of selectivity in a two step reaction mechanism. He describes the T_{inv} as the temperature where a change occurs in the dominance of enthalpy and entropy in the partially selective step.

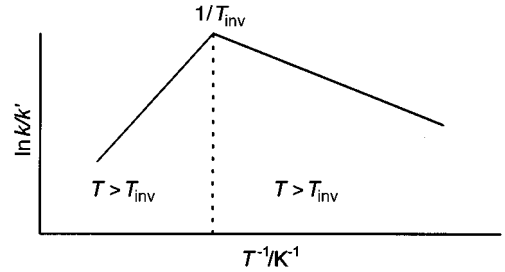

Fig. 3

More recently, Ridd[10] has interpreted non-linear Eyring plots as evidence of two potential rate determining steps in the reaction process, with only one of the two linear regions providing valid evidence on the enthalpic and entropic discrimination involved, the other coming from the transitional region in which no single stage of the reaction can be considered as rate determining.

Anyway, the debate on the very nature of inversion temperature is still open and we want to show experimental results that suggest a different interpretation.

Solvent-controlled diastereoselectivity

The solvent in which chemical processes take place is really a non-inert medium and it plays a prominent role in solution chemistry.[11] The complex interaction between solvent and solute molecules results in a gross modification of their free energies, and consequently, reactivities and stereoselectivities.

There are many examples of solvent effects on face-selectivity. In many cases a variation in the diastereomeric excess is observed[12] and other examples are known where a complete reversal of diastereoselectivity occurs because of a change in the reaction solvent. For example, some years ago, we reported a de reversal in MeMgBr addition to an *O*-triisopropylsilyloxy lactal.[13] The reaction leads to an *anti/syn* ratio of 64 : 36 in THF and 16 : 84 in Bu^{t}OMe. Very recently, Luh reported a reversal in diastereoselectivity of MeLi and Bu^{n}Li addition to hydrazones of 1,4-di-*O*-*tert*-alkoxy-L-threitols on going from THF to Et_2O.[14] These results show how the solvent plays a role in determining the prevailing isomer.

The solvent effect on face-selectivity reflects its different influence on the two diastereomeric reaction paths through a differential contribution to k and k' [eqn. (1)]. A change in the reaction medium corresponds to a change in the microscopic solute–solvent interactions. These interactions could differ in number or strength in different solvents, and they contribute to free activation energies $\Delta G^{\ddagger}$ and $\Delta G'^{\ddagger}$ in such a way that they can cause a face-selectivity reversal.

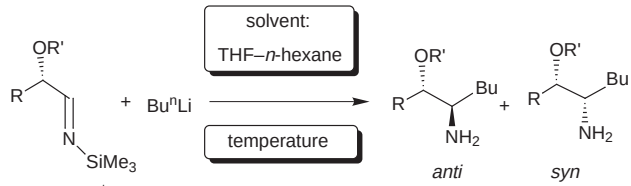
In the case of reaction in solution, it is hard to describe the system formed by reagents with their solvation shell or the solvated transition state, but some hypothesis can be considered. Two cases can be analyzed: (i) the solvent enthalpically favors and entropically disfavors an isomer whenever the solute–solvent interactions are high in strength or in number, thus stabilizing conformers with the lowest intramolecular steric interactions; (ii) the solvent entropically favors and enthalpically disfavors an isomer whenever the solute–solvent interactions are mild or low in number which results in the solvation being less ordered, thus making the system conformationally less rigid.[15]

By this brief discussion it appears to be clear that any theoretical model[4] for the analysis of stereochemical problems completely looses its predictive value by ignoring solvent effects. A detailed modelling of solvation[16] and information about its effects on the dynamics of stereoselective processes are necessary to get a deeper insight into the diastereofacial selectivity, but at the moment, research in this field is still at the beginning.

Diastereofacial selectivity in Bu^{n}Li addition to lactal imines[17]

During our studies on the stereocontrolled synthesis of 1,2-amino ethers by means of nucleophilic addition to *N*-trimethylsilyl imines of (2*S*)-lactal, we observed an impressive influence of solvent and temperature over the diastereofacial selectivity.

Bu^{n}Li cleanly reacted with *O*-protected *N*-trimethylsilyl imines of (2*S*)-lactal either in an ether (THF) or hydrocarbon (*n*-hexane) affording optically active *anti* and *syn* 1,2-amino ethers (Scheme 1). The stereochemical results are strongly dependent



1 R' = SiBu^{t}Me$_2$, R = Me
2 R' = SiPr$^i_3$, R = Me

Scheme 1

on solvent and temperature. We observed a complete reversal in the diastereomeric excess due to the solvent. For example, in the case of (2*S*)-*N*-trimethylsilyl-*O*-*tert*-butyldimethylsilyloxy lactal imine **1** at −90 °C in THF, we obtained an *anti/syn* ratio of 2 : 98, while in *n*-hexane the *anti/syn* ratio = 72 : 28. Moreover, a screening over a range of 150 °C showed a reversal of diastereoselection due to the reaction temperature (*e.g.* in *n*-hexane at T = −90 °C, *anti/syn* = 72 : 28, at T = 54 °C *anti/syn* = 22 : 78). In Fig. 4 the Eyring plots for all the imines **1**–**4** in THF and *n*-hexane are reported. The diastereomeric excess is defined as the difference % *anti* − % *syn*. Each imine–solvent pair showed a non-linear temperature dependence, and a characteristic inversion temperature (T_{inv}) was observed in all cases.

Diastereomeric excesses for imines **2** and **3** in THF cross the *x*-axis (de = 0%) at the equiselective temperatures T_o = −71.2 and −8.6 °C, respectively, so that a neat inversion in stereoselectivity occurred. In *n*-hexane, the imines **1**, **2** and **4** showed equiselective temperatures at T_o = −54.9, 15.4, and −36.5 °C.

In THF for $T > T_{inv}$, all the imines show a flattened trend of the de, meaning that in this range there is no temperature control of the stereoselectivity. According to eqn. (5), this result requires that the face-selection that still exists is entirely determined by $\Delta\Delta S^{\ddagger}$.

In this entropy driven region, the differentiating parameter between the four substrates is the protecting group. The *O*-TIPS and the *O*-TBDMS-*N*-TMS imines show opposite diastereofacial selectivity; for **2** the differential entropy $\Delta\Delta S^{\ddagger}$ is positive, for **1** it is negative. As a matter of fact, in one case the *anti* isomer is favored, in the other the *syn* is preferred. It is remarkable to note that for imine **1** the negative value of $\Delta\Delta S^{\ddagger}$ implies that the transition state leading to the *anti* isomer is more ordered than that which leads to the *syn* one. This result excludes the hypothesis that the prevailing *syn* isomer derives from a chelated transition state. At low temperature, all substrates give *syn* isomers. However, slopes are not markedly different and all four plots can be reproduced by translation of each other. Once again, in the face of small differential enthalpic contributions, an entropic factor determines the face-selectivity.

In *n*-hexane, imines **1**, **2** and **4** have a positive slope and exhibit a reversal of de on going from a predominance of *syn* isomers at high temperature to a predominance of *anti* isomers at lower *T*. Even the *O*-*tert*-butyl-*N*-TMS imine has a positive

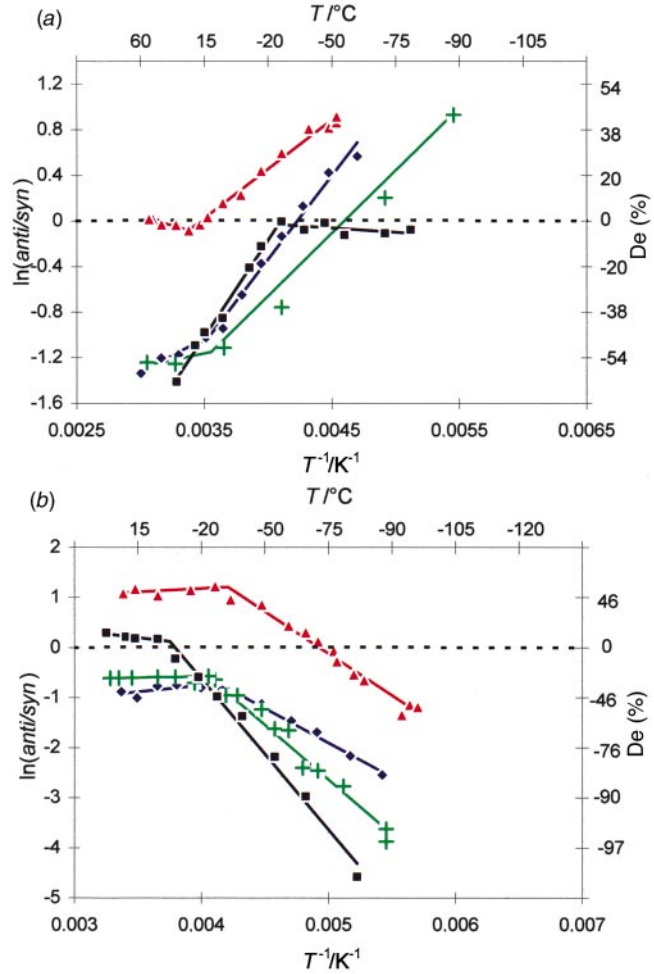

Fig. 4 Eyring plots for imines **1**–**4** in (*a*) *n*-hexane and (*b*) THF: (+) **1**, (▲) **2**, (■) **3** and (◆) **4**.

slope, and should behave in the same way as the others, but, in this case, the T_{inv} exerts a breakdown and starts up a new linear trend with a different intercept and slope, so that the de inversion is prevented.

Temperature and solvent effects on de might be attributed to different organometallic species involved. In fact, it is known that the aggregation state of Bu^{n}Li changes with these parameters.[18] However, the dynamic process that involves the aggregation state of Bu^{n}Li acts before the reacting event, so that their rate costants are identical for both diastereomers and vanish in eqn. (5). Thus a mere ground state effect would be irrelevant, but the Bu^{n}Li tendency to aggregate may to some extent influence the structure of the transition states. However, the de reversal with temperature and the existence of T_{inv} are observed in several different reactions[9,12] where no organometallic species are involved.[19]

All the activation parameters for $T > T_{inv}$ and for $T < T_{inv}$ are listed in Table 1.

It is significant to note that in all cases differential entropies and enthalpies have equal sign leading to an inversion of diastereoselectivity due to temperature, as discussed in the previous section. However, for imines **1**, **2** and **4**, but not **3**, the activation parameters for $T < T_{inv}$ showed a further switch in sign from THF to *n*-hexane, thus showing the overwhelming role of the solvent in determining the thermodynamic parameters.

Diastereofacial selectivity in Bu^{n}Li addition to 2-phenylpropanal[20]

The solvent effect obtained in the stereoselective addition of Bu^{n}Li to 2-phenylpropanal is quite peculiar (Scheme 2). We

established inversion temperatures in aliphatic hydrocarbons and Eyring plots for a series of linear and cyclic hydrocarbons are shown in Fig. 5.

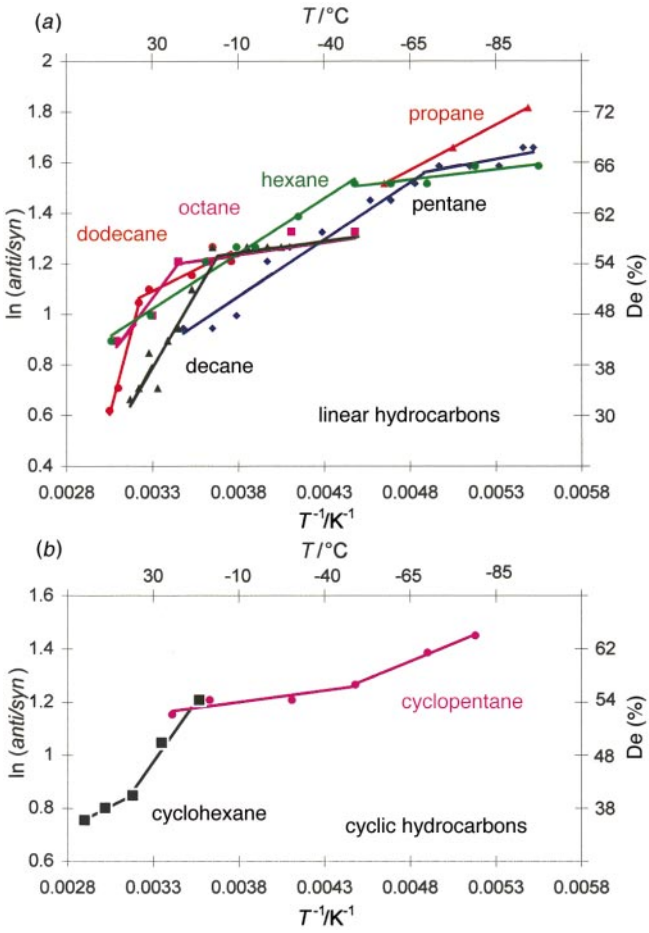

Fig. 5 Eyring plots for (*a*) linear and (*b*) cyclic hydrocarbons.

Interestingly, for cyclic and linear solvents the plot concavities are opposite. For linear hydrocarbons the pattern is consistent with the chain length of the solvent: the longer the chain, the lower the de; for example, the diastereofacial selectivity obtained with propane is doubled with respect to that of *n*-dodecane (*n*-propane de = 70%, *n*-dodecane de = 30%).

This result reveals the deep influence of solvation forces, although weak and non-specific, on the face-diastereoselectivity. The slopes of regression lines, which reflect the enthalpic contribution, flatten at low temperatures. Once more, differential entropy modulates the selectivity because only differences in the intercepts still remain when differential enthalpies vanish, and therefore the effect of solvent chain length on face-selectivity might be ascribed to entropic control. On the other hand, at high temperature, lengthening the solvent chain increases the slope, thus increasing the enthalpic contribution to de. The inversion temperatures for all linear and cyclic hydrocarbon solvents examined ranged between 205 and 317 K, increasing upon going from *n*-pentane to *n*-dodecane.

Assuming that the inversion temperature is unique to each substrate–solvent pair, all efforts to correlate inversion temperatures with classical solvent parameters, such as relative permittivity and viscosity, have failed. Interestingly, analyzing T_{inv} and the melting points of linear and cyclic hydrocarbons results in a straight line with a correlation coefficient r = 0.96 (Fig. 6).

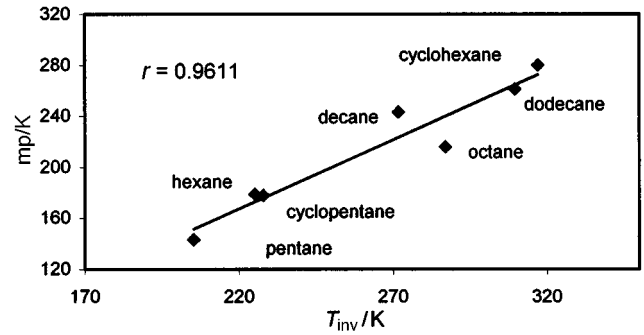

Fig. 6

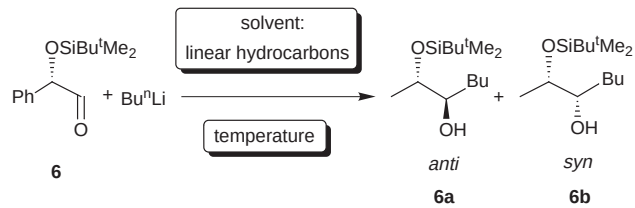
Diastereofacial selectivity in the Bu^{n}Li addition to mandelic aldehyde[21]

The dependence of facial selectivity upon hydrocarbon solvents becomes more strict in the case of Bu^{n}Li addition to *O*-*tert*-butyldimethylsilyloxymandelic aldehyde **6** (Scheme 3). On this



Scheme 3

substrate the reaction with Bu^{n}Li was performed in a series of linear hydrocarbons with odd and even numbers of carbon atoms.

Although this aldehyde produced diastereomeric excesses in a low range (from 20 to −10% de), in all plots an inversion

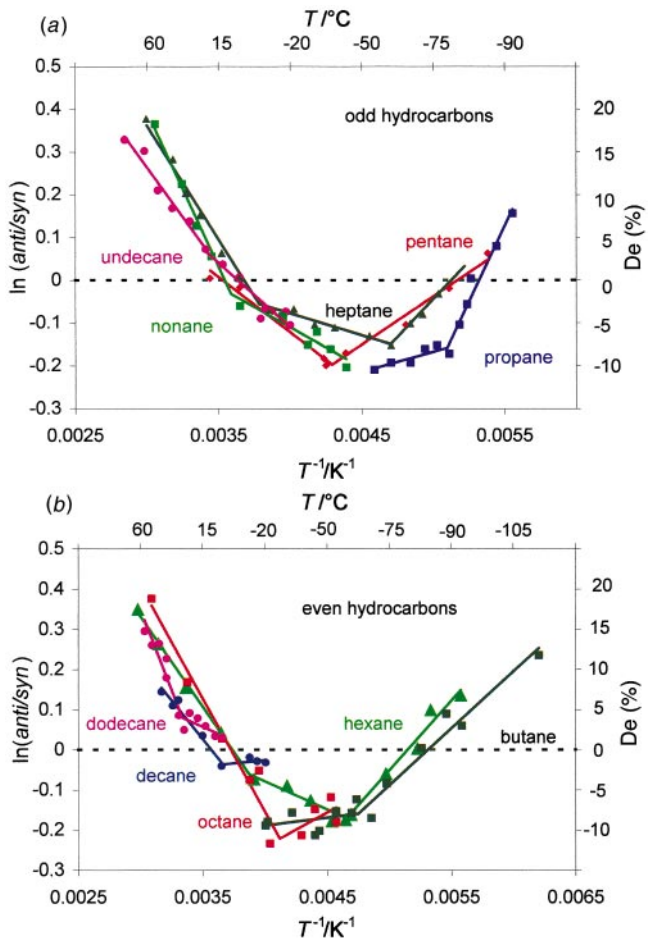


Fig. 7 Eyring plots for (*a*) odd and (*b*) even numbered hydrocarbons.

temperature was recognized (Fig. 7). Notably, this substrate exhibited the best diastereoselectivity at high temperature (T = 60.5 °C, de = 19%).

The majority of these plots cross the *x*-axis because of an opposition between the enthalpic and entropic contribution to the two isomers, as discussed above. Some plots cross the x-axis twice, once in the high and the other in the low temperature region. It is interesting to note that in the cases of *n*-hexane and *n*-heptane two inversion temperatures were obtained. It is hard to explain this experimental result as a consequence of a double change in the reaction mechanism in the light of the above mentioned interpretation of the T_{inv}.[22] As in the case of phenylpropanal **5**, the T_{inv} increases with the longer solvent alkyl chain. For mandelic aldehyde **6** each series shows a concavity opposite to that of **5**.

A plot of the inversion temperatures *versus* the number of solvent carbon atoms exhibits the same swinging feature as that for the melting points (Fig. 8). Even in this case the correlation of T_{inv} and the melting points exists, and it correlates better if we consider the odd and even series of hydrocarbons separately.

It is really surprising how the simplicity of a linear relationship between its two parameters overcomes the complexity of the physical events involved.

It is known that even and odd linear hydrocarbons differ in the crystalline form,[23] and this fact causes the melting point alternation. The same behavior has been observed for the inversion temperatures and this, along with the strict linear correlations found for both aldehydes **5** and **6**, suggests a relationship with the phase modification that occurs upon melting. An attractive possible explanation can be formulated: the inversion temperature could constitute a sort of transition between two 'phases' which, in the case of solutions, could be represented by two different solute–solvent clusters with a different order.[24] This 'phase transition' could be interpreted as the interconversion of two solute–solvent clusters having a

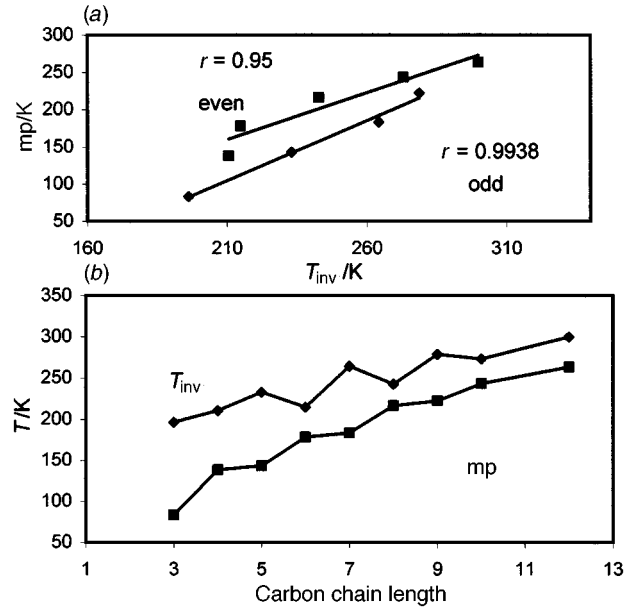

Fig. 8 (*a*) Plot of T_{inv} *vs.* mp of solvent. (*b*) Plots of T_{inv} and solvent mp *vs.* carbon chain length of solvent.

more defined tridimensional structure than generally supposed. These supramolecular structures behave like different molecules, producing a measurable change in their thermodynamic properties and therefore in the diastereoselectivity. In this hypothesis, the T_{inv} represents the interconversion temperature between two supramolecules and it does not imply any change either in the rate determining step or in the reaction mechanism.

Because of the complexity of the solvation process, it is difficult to formulate a detailed microscopic model of these supramolecules. However their interconversion could involve a solvent reorganization phenomenon due to transfer of solvent molecules between the bulk and the supramolecules or an internal rearrangement of the solvation cluster.

Conclusion

Our results confirm that not only do enthalpic contributions act in determining diastereocontrol, but even entropic factors can acquire importance with increasing reaction temperature. Indeed, whenever enthalpy and entropy favor different isomers, a de reversal can be obtained.

Solvent effects are determinant on face selectivity because solute–solvent interactions modulate the free activation energies acting on both enthalpic and entropic terms. In this way different solvents can lead to an opposite diastereoselectivity.

The correlation with melting points suggests an alternative interpretation of the very nature of inversion temperatures. We propose that T_{inv} is the temperature value for the interconversion between two different solvation clusters represented by two different supramolecules.

All these arguments support the hypothesis that the main factor in diastereofacial control is a stereospecific solvation of the π-system.[25]

Our interpretation simply constitutes an attractive proposal and an intriguing challenge for forthcoming research on stereoselectivity.

No deactivated production of hydrogen by pyrolysis of ethane over graphite-based catalysts using membrane-type reactors

National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305-8565, Japan.
E-mail: kmurata@nimc.go.jp

Received (in Cambridge, UK) 4th January 1999, Accepted 18th February 1999

A system consisting of a graphite catalyst and an Ag-Pd membrane reactor was found to be effective for ethane decomposition to hydrogen and carbon, where the H_2/C ratio was approximately 1.5, in accordance with the stoichiometric ratio; catalyst deactivation was not observed during reaction, since the graphite-like carbons produced by the reaction, probably also catalyze the reaction in the temperature range of 800–1000 K.

Hydrogen is expected to be used as an energy source for fuel cells such as the proton-exchange membrane (PEM) type. At present, hydrogen is typically produced *via* steam reforming and/or partial oxidation of hydrocarbon fuel.[1] Alcohols are used as precursors to hydrogen.[2] In these cases, however, carbon monoxide is a co-product. Therefore, the current PEM fuel cells require complete elimination of CO (< 1 ppm) from the hydrogen stream in order to prevent poisoning of the Pt catalyst of the cells. An alternative route is to directly decompose the hydrocarbons into hydrogen and carbon. In this case, no CO_2 is formed and the need for subsequent reactions, such as water–gas shift and CO oxidation, is eliminated. Metal oxide catalysts such as Ni/SiO_2 and Fe/Al_2O_3 are usually used for the decomposition reaction. However, over these catalysts, decomposition activity is reduced as the reaction proceeds, due to accumulation of carbon products at temperatures of 600–800 K. The undesirable formation of organic products (CH_4, C_2H_4, *etc*.) is also a significant problem.[3]

In the course of our research work on carbon-based catalysts,[4] we attempted decomposition of ethane to form hydrogen over metal-free carbon catalysts. We found that formation of hydrogen without deactivation was observed over a graphite catalyst over the temperature range 800–1000 K. The reaction was also found to be accelerated by elimination of *in situ* formed hydrogen through a Ag-Pd alloy tube. Now we report some of our results.

Commercially available carbon materials, such as activated carbon (Aldrich), C_{60} soots (MER Corp.) and graphite (Alfa) were dried at 493 K *in vacuo* for 3 h prior to use. The particle sizes of these materials were between 50–300 μ. Catalyst thus pretreated (1 g) was diluted with quartz sand (5 g)† and, for the fixed-bed reactor (FBR), placed in a quartz tube (12 mm inner diameter). An electric furnace was used for heating. The catalyst was pretreated in N_2 at 873 K for 3 h and then a premixed gas of nitrogen–ethane (2–20 vol% C_2H_6, 20 ml min^{-1}) was introduced at atmospheric pressure (W/F = 125 g h mol^{-1}).‡ For the Ag-Pd membrane reactor (PMR), a double-tubular type arrangement was used: the inner and outer tubes were Pd-Ag alloy (90Pd10Ag) (250 μ thick and 10 mm outer diameter) and quartz (1.5 mm thick and 19.5 mm inner diameter), respectively. The carbon catalysts were placed between the inner and outer tubes. The catalyst pretreatment was the same as that described above. The premixed gas was passed into the catalyst bed at atmospheric pressure (W/F = 125 g h mol^{-1}) and Ar gas (1500 ml min^{-1}) was fed through the inside of the Ag-Pd alloy tube at atmospheric pressure to remove permeated hydrogen. The organic and hydrogen products were analyzed by gas chromatography (GC) on Porapack Q and 5 Å molecular sieve columns, after 30 min on-stream at each temperature, and the yield of carbon was estimated by the mass balance of carbon [eqn. (1)].

$$C_2H_6 \rightarrow 3H_2 + 2C \quad (1)$$

As shown in Fig. 1, pyrolysis of C_2H_6 occurred at 850–1050 K in the presence of activated carbon catalyst (AC Darco G-60, **1**), and hydrogen, carbon and a small amount of organic material (methane, ethylene, benzene *etc*.) were formed. Over all these runs, the carbon yield estimated from the mass balance was in good accordance with that calculated by weighing after the reaction. The C_2H_6 conversion was as low as 47% at 948 K in the case of the fixed bed reactor (FBR) (Fig. 1). In contrast, the C_2H_6 conversion was found to be enhanced by removal of hydrogen through the Ag-Pd membrane tube and, as a result, was over 90% at 948 K. In this case, over 90% of hydrogen formed was eliminated from the reactant gas *via* permeation into the argon. For comparison, the conversion in a quartz sand/PMR system was less than that for the catalyst **1**/FBR system. Also, the conversion in a PMR system without the argon flow

was between that of the PMR with argon and that of the FBR system.These findings indicate that the combined use of the carbon catalyst and the PMR system was very effective for C_2H_6 pyrolysis.

Fig. 2 shows the effects of some carbon catalyst/PMR systems on the product yields at 973 K. The efficiency of pyrolysis (carbon yield) was in the order: **2**/graphite > **6**/AC Darco G-60 > **3**/AC Darco KB-B > **1**/AC Darco G-60/FBR > **5**/C60 soots > **4**/quartz sand. In the graphite catalyst, in particular, organic by-products were formed only in *ca.* 4% yield. In the activated carbons (**3** and **6**), the yield of organic products was *ca*. 15%, although their carbon yields were close to that on graphite. The use of a fixed-bed reactor (FBR) resulted in the formation of a larger amount of organic products (> 35% yield) than that in a Pd-membrane reactor (PMR) (compare **1** and **6**). In the cases of C_{60} soots (**5**) and quartz sand (**4**), the dehydrogenation of ethane to form ethylene predominates over decomposition.

In order to shed more light on the characteristics of carbon catalyst/PMR systems, the effects of the reaction parameters on the ethane decomposition were briefly examined. The effect of the flow rate of the argon on the activity was found not to be significant under the conditions employed, provided the flow rate is above 100 ml min^{-1}. This suggested that the rate of hydrogen permeation was, in general, greater than that of ethane decomposition over the carbon catalyst under the conditions employed. The ethane conversion at 923 K increased with an increase in contact time (W/F = 25–125 g h mol^{-1}). As expected thermodynamically, lower ethane concentrations (2–20%) gave higher ethane conversions, over the temperature range from 773 to 973 K.

The mechanism of decomposition over the carbon catalysts is not clear. However, the reaction is promoted by the removal of the hydrogen formed (Fig. 1) and it seems likely that a material with a graphite-like nature is formed during decomposition, as shown by X-ray powder diffraction and H_2 temperature programmed desorption of the carbon formed, carried out by analyzing methane formed by hydrogenation of the carbon product. It is well-known that catalyst deactivation occurs as a result of the formation of graphite-like carbon[5] when metal-oxide catalysts are used in the temperature range 600–800 K. In fact, even with the activated carbon catalyst (**3**)/FBR system without metal, the ethane conversion at 923 K decreased as the reaction proceeded [Fig. 3(*a*)]; as a result, the H_2/C ratio increased due to the reduction of carbon formation and predominant formation of organic compounds [Fig 3(*a*), inset]. On the other hand, we found that the deactivation did not occur when graphite catalyst (**2**) was used, and the ethane conversion increased [Fig. 3(*b*)] as carbon was formed. In the initial stages, the H_2t/C ratio (the molar ratio of total amount of H_2 to carbon) was greater than 1.5 [the value given by stoichiometric ethane decomposition, see eqn. (1)] because of the formation of organic products (> 20%). After 5 h, however, the ratio approached 1.5, and subsequently remained constant; this indicated that the decomposition reaction occurred predominantly. This is the first example of a catalyst not being deactivated even at high ethane conversion. It is possible that the graphite-like carbon produced by the reaction also efficiently catalyzes the reaction in the membrane reactor§ over the temperature range 800–1000 K. Further investigations are currently underway to elucidate the decomposition mechanism operative in the graphite/Ag-Pd membrane reactor system.

In summary, we have found that graphite is a very good catalyst for converting ethane to hydrogen in a Ag-Pd membrane system with high activity and no deactivation. We believe this to be an excellent procedure for hydrogen production for PEM fuel cells.

Notes and references

† In order to ensure a smooth gas flow, a weight ratio of graphite : quartz of 1 : 5 was used; the results were not affected by the amount of quartz.
‡ W/F = weight of catalyst (g) over flow rate (mol h^{-1}).
§ In these cases, both graphite and PMR are important. In fact, the minimum amount of organic products was formed in the graphite catalyst/PMR system, as can be seen from Fig. 2. In the graphite/PMR system, graphite-like carbon formed over the graphite surface would not undergo successive reaction such as methane formation from hydrogen and the carbon, because almost all of the hydrogen was eliminated from the graphite surface. Thus, it seems likely that the stable graphite-like carbon product could also catalyze the reaction. On the contrary, in the AC/FBR system, the carbon product could undergo many successive reactions, since hydrogen was still present over the surface. Thus, in this case, it seems unlikely that the carbon product could catalyze the reaction.

Physisorption of oxygen in narrow mesopores

Peter J. Branton,*† Katsumi Kaneko and Kenneth S. W. Sing

Department of Chemistry, Faculty of Science, Chiba University, 1-33 Yayoi, Inage, Chiba 263, Japan

Received (in Cambridge, UK) 29th January 1999, Accepted 16th February 1999

Pore filling by oxygen takes place reversibly at 77 K in pores of effective width of *ca.* 2.6 nm, whereas hysteresis is involved in the filling (by capillary condensation) of wider pores; it appears that the oxygen meniscus becomes unstable at cylindrical pore widths < *ca.* 2.9 nm.

The development of MCM-41 and other highly ordered mesoporous materials over the past decade has attracted much attention. Nitrogen adsorption measurements[1–3] at 77 K on a number of these materials have shown that the pore filling of narrow cylindrical mesopores (of effective pore width *ca.* 2–4 nm) can occur reversibly. Nitrogen isotherms given by typical 4 nm samples of MCM-41 exhibit steep and reversible pore filling risers at P/P_0 *ca.* 0.40–0.44, whereas the reversible filling of 2.5 nm pores occurs less sharply (at P/P_0 *ca.* 0.2–0.34). Samples containing wider pores always appear to give type H1 or H2 hysteresis loops.[4] These observations are consistent with the fact[5] that the lower closure points of many nitrogen hysteresis loops are located at P/P_0 *ca.* 0.42 and indicate that the mechanism of mesopore filling is dependent on the pore size.

Although nitrogen continues to be the preferred adsorptive for the characterization of porous solids, it is of interest to investigate the low-temperature adsorptive behaviour of other gases. We have studied oxygen adsorption at 77 K on a number of ordered materials comprising narrow distributions of uniform mesopores with mean pore diameters ranging from *ca.* 2 to 7 nm. Recently determined oxygen isotherms on two of these adsorbents (a narrow-pore version of MCM-41[6] and FSM-12, a modified kanemite[3]) are shown in Fig. 1 and 2, together with the corresponding α_s plots (with non-porous hydroxylated silica taken as the reference adsorbent). It can be seen that the isotherm on FSM-12 in Fig. 1 is completely reversible whereas that on the MCM-41 in Fig. 2 has a narrow type H1 hysteresis loop.

The surface areas of FSM-12 and the MCM-41 (930 and 1170 $m^2\ g^{-1}$, respectively) have been obtained by the BET-nitrogen method and analysis of the nitrogen α_s plots. By assuming these areas to be confined to the walls of non-intersecting cylindrical pores and taking the mesopore volumes as the equivalent volumes of liquid nitrogen adsorbed at $P/P_0 = 0.95$, we arrive at values of the mean pore diameter of 2.6 nm for FSM-12 and 2.9 nm for the MCM-41. If we now make the usual assumption that the same areas are available for oxygen adsorption, we obtain the apparent molecular area, $\sigma(O_2)$, values of 0.142 and 0.149 nm^2 for FSM-12 and the narrow-pore MCM-41.

With the exception of the 2.9 nm sample of MCM-41, all the ordered mesoporous adsorbents studied so far have given $\sigma(O_2) = 0.143 \pm 0.002$ nm^2 (in agreement with the value originally adopted by Brunauer and coworkers[7]). It must be kept in mind that the narrow-pore MCM-41 has a very large specific surface and an appreciable pore volume (0.87 $cm^3\ g^{-1}$) and therefore the pore walls must be extremely thin. It appears likely that this has resulted in some distortion of the surface structure, which could account for the slightly higher value of $\sigma(O_2)$.

The absence of narrow micropores is evident from the form of the α_s plots in Fig. 1 and 2. The upward deviations from linearity begin at similar relative pressures (*i.e.* P/P_0 *ca.* 0.1), but the upswing is clearly more pronounced in Fig. 2. Thus, pore filling by the 2.9 nm MCM-41 has occurred mainly over the range P/P_0 *ca.* 0.13–0.28, which would correspond to a corrected Kelvin diameter range of 2.2–3.5 nm. The apparent consistency of this range with the estimated value of 2.9 nm for the mean pore width may be misleading since the reliability of the Kelvin equation is questionable when applied to such narrow pores.[4]

The position of the lower closure point of the narrow hysteresis loop in Fig. 2 cannot be specified precisely, but it appears to be in the region of P/P_0 *ca.* 0.2. It is too early to claim that a mean pore diameter of 2.9 nm is close to the limit of stability of the oxygen meniscus at 77 K. However, it is already clear that the smaller pores in FSM-12 are not filled by the classical mechanism of capillary condensation. Furthermore, all

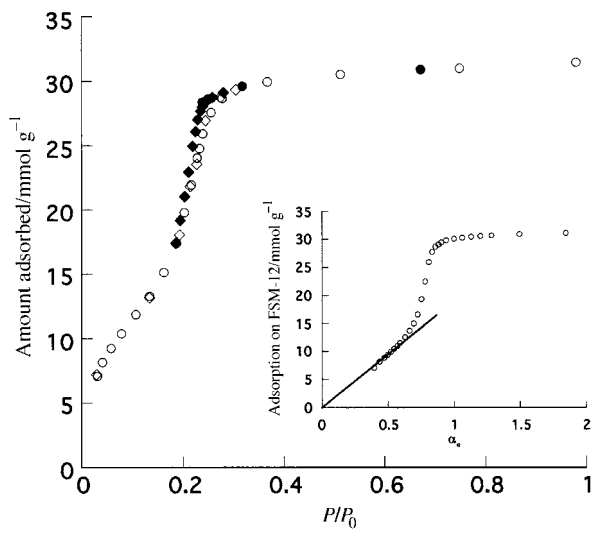

Fig. 2 Adsorption of oxygen at 77 K on MCM-41. Different symbols denote different runs. Open symbols denote adsorption, closed symbols denote desorption.

the ordered materials of wider pore-width studied so far have given hysteresis loops at relative pressures higher than 0.2. The results reported here indicate the distinctive nature of oxygen adsorption at 77 K, but more work will be required to establish its usefulness for the characterization of porous materials.

We should like to thank U. Ciesla and S. Schacht for providing the 2.9 nm sample of MCM-41.

Received (in Basel, Switzerland) 4th January 1999, Accepted 1st February 1999

Extremely rapid oxygen transfer from sulfoxides to a carbonyl ligand to give the corresponding thioether and coordinated CO_2 is observed in the reactions of unsupported Zr–Ru heterodimetallic complexes with sulfoxides; this is interpreted to arise from the cooperative reactivity of the two complementary metal complex fragments bound to each other through a highly polar metal–metal bond.

The exploitation of the cooperative reactivity of different metal complex fragments is the underlying aim of the study of di- or tri-nuclear complexes containing highly polar metal–metal bonds between early and late transition metals.[1,2] The heteropolar addition of a metal nucleophile and electrophile to an organic substrate is the simplest manifestation of such reactivity,[3] the insertion (and subsequent cleavage) of carbonyl derivatives, which we reported recently, providing an example for this basic pattern.[4] Here we report the extremely rapid oxygen transfer from sulfoxides to coordinated CO to give CO_2 in the coordination sphere of Zr–Ru heterodi- and tri-nuclear complexes.

Metal ion mediated oxygen transfer reactions involving sulfoxides have been known for some time,[5] the most thoroughly studied systems effecting this transformation being Pt(II) complexes in acidic solution[6] and low valent Group VI complexes which are transformed to the corresponding oxo-species.[7] Deoxygenation of sulfoxides may also be achieved by some metal carbonyl derivatives under forcing conditions generating CO_2 derived from metal bound CO.[8] An important step in the labilization of the strong S–O bond is the addition of an electrophile to the oxygen atom. In reactions with early–late heterobimetallic complexes containing CO-ligands coordinated to the late transition metal *both* the electrophilic activation of the substrate and the transfer to an oxygen acceptor ligand (CO) were thought to be possible within the coordination sphere of *one* molecule.

Upon reaction of one molar equivalent of Me_2SO and Ph(Me)SO with the Zr–Ru heterodinuclear complex [MeSi(Si-Me_2NTol)$_3$ZrRuCp(CO)$_2$] (**1**)[2b] at −40 °C in toluene an immediate transformation occurred yielding products which could be isolated as yellow solids by evaporation of the solvent *in vacuo*. On the basis of their analytical and ^{1}H, ^{13}C NMR as well as IR spectroscopic properties these were formulated as [MeSi(SiMe_2NTol)$_3$Zr(μ-O_2C)RuCp(CO){S(R)R′}] (R = R′ = Me: **2a**, R = Me, R′ = Ph: **2b**) (Scheme 1). Products of higher crystallinity were obtained upon addition of a second equivalent of sulfoxide giving μ-CO_2-linked dinuclear compounds containing an O-bonded sulfoxide ligand at the zirconium centre but being otherwise of analogous composition and spectroscopic properties: [MeSi(SiMe_2NTol)$_3$Zr{OS(R)R′-κO}(μ-O_2C)RuCp(CO){S(R)R′}] (R = R′ = Me: **3a**, R = Me, R′ = Ph: **3b**).

In order to establish the structure of the reaction products unambiguously a single crystal X-ray structure analysis of **3a** was carried out.† The centre piece of the molecular structure

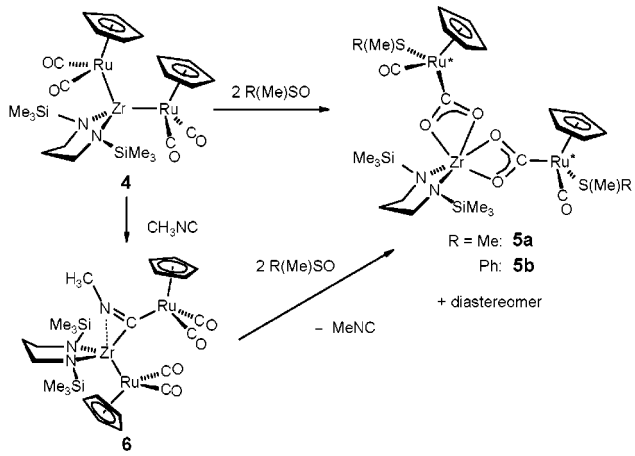
heterodinuclear complex, $[Cp_2Zr(Cl)(\mu\text{-}O_2C)Ru(Cp^*)(CO)]$, reported by Gibson *et al.*[9] The metallacarboxylato unit in **3a** is almost symmetrically coordinated to the zirconium centre [*d*{Zr–O(61)} 2.255(7), *d*{Zr–O(71)} 2.221(6) Å] and together with the Me_2SO ligand [*d*{Zr–O(51)} 2.261(7)] generates the hexacoordinate zirconium complex fragment the coordination geometry of which may be viewed as being highly distorted octahedral. The dimethyl sulfide molecule formed as a consequence of the sulfoxide deoxygenation is coordinated to the Ru atom making this a chiral centre (Fig. 1).

The complexes **2a**,**b** and **3a**,**b** have several very characteristic spectroscopic properties which aid the structural assignment. As a consequence of the generation of a chiral centre at the late transition metal fragment the ^{1}H and ^{13}C NMR resonances of the $Si(CH_3)_2$ groups in the tripod ligand are diastereotopically split. The coordination of the soft donor ligand RR′S at the Ru-centres is the reason for the observation of the single ν(CO) infrared band at faily low frequency (1924–1947 cm^{-1}). The chemical shifts of the ^{13}C NMR signals assigned to the μ-CO_2 units depend quite sensitively upon the presence or absence of the additional RR′SO-donor at the Zr-centre. For **2a**,**b** they are observed at, respectively, δ 235.4 and 232.0, while the electronic readjustment within the molecule following the sulfoxide coordination at Zr leads to a significant shift of this signal to higher field [δ(^{13}C) **3a**: 225.1, **3b**: 225]. A study of this reaction employing compound **1** which was ^{13}C-labeled at the CO ligands provided support for the assumption of the role of these ligands as O-acceptors and their transformation to the bridging CO_2-unit.

The remarkable reactivity of **1** towards sulfoxides and the selectivity of the reaction raised the question of the generality of this reactive pattern of metal–metal bonded early–late heterodinuclear {$CpRu(CO)_2$} derivatives. Reaction of the heterotrinuclear complex $[CH_2(CH_2NSiMe_3)_2Zr\{RuCp(CO)_2\}_2]$ **4**[10] which contains two structurally equivalent {$CpRu(CO)_2$} units bonded to a Zr amido complex fragment with two molar equivalents of Me_2SO and Ph(Me)SO led to the immediate conversion to reaction products which were formulated on the basis of their analytical and spectroscopic properties as $[CH_2(CH_2NSiMe_3)_2Zr\{(\mu\text{-}O_2C)RuCp(CO)(SMeR)\}_2]$ (R = Me: **5a**, Ph: **5b**) in which the Zr atom is coordinated by *two* metallacarboxy units and the thioethers derived from the sulfoxides are also bonded to the Ru centres (Scheme 2).

Remarkably, all attempts to isolate, or even unambiguously detect, intermediate species in which only one metal–metal bond is cleaved failed, an observation which implies that the conversion at one centre significantly enhances the reactivity of the other. This should be compared to the results from our previous studies of simple insertion reactions of unsaturated polar substrates into these metal–metal bonds in which the reaction involving the cleavage of only one Zr–Ru bond was observed exclusively.[10] We would like to point out in this context, that in contrast to the rapid deoxygenation reactions involving the Zr–Ir complex $[Cp_2Zr(\mu\text{-}N\text{Bu}^t)IrCp^*]$ studied in Bergman's group,[1c] the presence of carbonyl ligands in **1** and **4** leads to carboxy-linked species rather than oxo complexes. The formation of a C–O and two Zr–O bonds is the thermodynamic driving force in these conversions which is sufficiently strong even to effect the displacement of an inserted isonitrile molecule from the trinuclear complex $[CH_2(CH_2NSiMe_3)_2Zr\{\eta^2\text{-}C(=NMe)M(CO)_2Cp\}\{M(CO)_2Cp\}]$ **6** (Scheme 2).



Scheme 2 Oxygen transfer upon reaction of the $ZrRu_2$ heterotrinuclear complexes with sulfoxides yielding hexacoordinate zirconium complexes containing two ruthenacarboxylato 'ligands'.

In conclusion, the reactions reported represent the first examples of transformation involving amido ligand-stabilized unsupported early–late heterobimetallics (*i.e.* containing a M–M′ bond without a bridging ligand) in which not only both metal complex fragments interact with the substrate but involvement of a coordinated ligand in an atom transfer reaction occurs. This combined and complementary reactivity of the two metal centres enables the reduction of a sulfoxide by CO under extraordinarily mild conditions.

We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the European Commission (TMR network MECATSTN), the EPSRC and the DAAD and British Council for funding. We dedicate this paper to Professor Helmut Werner, Universität Würzburg, on the occasion of his 65th birthday.

Ferromagnetic interactions between triphenylmethyl radicals through an organometallic coupler

O. Elsner, D. Ruiz-Molina, J. Vidal-Gancedo, C. Rovira* and J. Veciana*

Institut de Ciència dels Materials de Barcelona (CSIC), Campus Universitari de Bellaterra, 08193, Cerdanyola, Spain. E-mail: vecianaj@icmab.es; cun@icmab.es

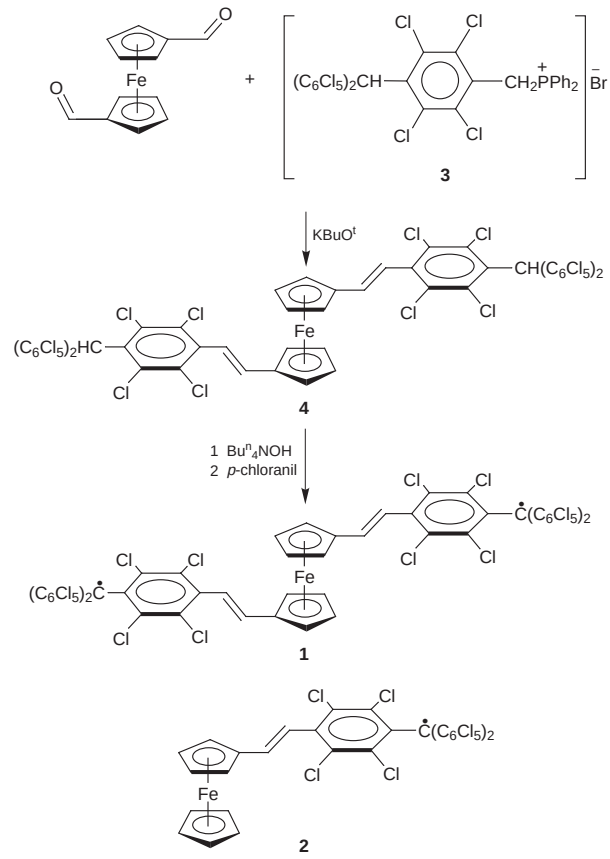
Received (in Cambridge, UK) 13th January 1999, Accepted 22nd February 1999

A diradical consisting of two polychlorinated triphenylmethyl radical units connected by a 1,1′-metallocenylendivinylene bridge has been synthesized and characterized; EPR frozen solution experiments down to liquid helium temperature showed that the organometallic unit acts as a ferromagnetic coupler.

In the last few years, the development and study of new coupling units that promote ferromagnetic interactions between pure organic radicals has been a subject of great interest.[1] Metallocenes are excellent candidates to be used as magnetic couplers not only because of their rich chemistry but also because they are electroactive species whose oxidation state can be controlled by means of a chemical or electrochemical stimulus; moreover their oxidized states are of open-shell character. However, although such complexes have been successfully used as building blocks of molecular solids promoting intermolecular magnetic exchange interactions,[2] their use as intramolecular magnetic couplers is new. Recently, we have reported a novel family of compounds consisting of two purely organic α-nitronyl aminoxyl radicals connected by different 1,1′-metallocenylene bridges where the metallocene units were shown to act as effective magnetic couplers that transmit the magnetic interactions through their skeletons.[3] However, the small spin density located on the metallocene units of these systems and the presence of intramolecular hydrogen bonds, which determines the existence of a direct intramolecular through-space magnetic interaction, lead to the appearance of an effective antiferromagnetic interaction between the two α-nitronyl aminoxyl radical units that is very sensitive to the molecular conformation.[4] For this reason, such complexes were not suitable candidates to study and rationalize the behaviour of 1,1′-metallocenylene bridges as magnetic couplers.

In order to overcome both these factors, diradical **1,** consisting of two polychlorinated triphenylmethyl radicals connected by a 1,1′-ferrocenylendivinylene bridge, was designed. The particular structure and topology of such a diradical leads to expectation of a non-negligible spin density on the ferrocene moiety making feasible the magnetic coupling between the two organic radical units.[5] In addition, the location of both radical units far away from each other avoids any possibility of having intramolecular contacts, and consequently, a significant direct through-space magnetic interaction. Here we report the synthesis and characterization of diradical **1.** The related monoradical **2** has also been synthesized and studied for comparison purposes.

As outlined in Scheme 1, the synthetic route for preparing these radical derivatives is based on two main steps. First, a Wittig reaction between the phosphonium bromide precursor **3** and the corresponding ferrocene carbaldehyde derivative; *i.e.* ferrocene 1,1′-biscarbaldehyde and ferrocene monocarbaldehyde for radicals **1** and **2**, respectively. Second, a subsequent deprotonation and oxidation to yield the desired radicals. In the first step of the synthesis of **1**, the substituted phosphonium bromide, α,α-bis(pentachlorophenyl)-2,3,5,6-tetrachloro-α′-(triphenylphosphonium)-*p*-xylene bromide **3**, was suspended in dry THF and treated with an equimolar amount of KOBu^t. The resulting yellow ylide suspension was stirred for *ca.* 1 h and after this time ferrocene 1,1′-biscarbaldehyde was added and stirred for a further 72 h. The reaction mixture was quenched with HCl and extracted with $CHCl_3$ to give 1,1′-bis{4-[bis(pentachlorophenyl)methyl]-2,3,5,6-tetrachlorostyryl}ferrocene **4** after chromatographic purification from *n*-hexane–$CHCl_3$ (1 : 1). Finally, a THF solution of **4** was treated with an excess of tetra(*n*-butyl)ammonium hydroxide. The solution, which immediately turned purple, was stirred at room temperature for 4 h. Subsequent oxidation of the resulting dianion with *p*-chloranil yielded the 4,4′-(1,1′-ferrocenylenedivinylene)di[α,α-bis(pentachlorophenyl)-2,3,5,6-tetrachlorobenzyl] diradical **1**, which was isolated as a clathrate (**1**·2C_6H_6) after chromatographic purification (*n*-hexane–CCl_4, 1 : 1) and recrystallization from C_6H_6. This diradical is completely stable in air both in the solid state and in dilute solutions. The related monoradical derivative, the 4-(ferrocenylvinylene)-α,α-bis-(pentachlorophenyl)-2,3,5,6-tetrachlorobenzyl radical **2** was prepared following the same procedure, from the phosphonium bromide derivative **3** and ferrocene carbaldehyde. Both radicals were obtained as dark green microcrystals and were characterized by elemental analysis, cyclic voltammetry, IR, UV–VIS and EPR spectroscopies.



Scheme 1

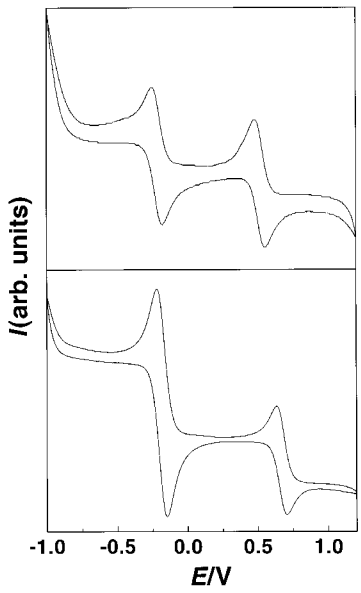


Fig. 1 Cyclic voltammograms recorded in a CH_2Cl_2 solution containing NBu_4PF_6 (0.1 M) of (a) monoradical **2** and (b) diradical **1**.

The cyclic voltammetric response of **2** shows one oxidation and one reduction process. The reversible process at +587 mV arises from the oxidation of the ferrocene unit while the reversible reduction process occurring at −177 mV is associated with the reduction of the triphenylmethyl radical unit. Cyclic voltammetry of diradical **1** (Fig. 1) shows one reversible oxidation process at +666 mV and one reversible reduction process at −181 mV that involves the simultaneous transfer of two electrons. The oxidation process was assigned, as in the monoradical species, to the oxidation of the ferrocene unit, while the reduction process was assigned to the reduction of both triphenylmethyl radical units. The fact that the oxidation process of the ferrocene unit of diradical **1** appears at a higher potential value than those observed for monoradical **2** and the unsubstituted ferrocene is the first direct evidence for the presence of an electronic interaction between the radical and the ferrocene units. Nevertheless, EPR spectroscopy provides more detailed and definitive information about the electronic structure as well as of the intramolecular electron–electron interactions in these compounds. X-Band EPR isotropic spectra of radicals **1** and **2** were obtained in toluene–CH_2Cl_2 (1 : 1). The spectra of both complexes at room temperature showed lines corresponding to the coupling of the unpaired electrons with the different nuclei with non-zero magnetic moments; *i.e.* with ^{1}H and naturally abundant ^{13}C isotope at the α and aromatic positions. Computer simulation gave the isotropic *g*-values (g_{iso}) and the isotropic hyperfine coupling constants (a_i) of the unpaired electrons with the different nuclei with non-zero magnetic moments. The g_{iso} values for diradical **1** and monoradical **2** were 2.0028 and 2.0033, respectively which are very close to that observed for other polychlorotriphenylmethyl radicals.[6] More interesting is the comparison of the isotropic hyperfine coupling constant values with the hydrogen atoms of the ethylene moieties and some of the carbon nuclei of the triphenylmethyl unit. The values of the coupling constant of diradical **1**, $a_1(^1H) \approx 0.80$ G (2H), $a_2(^1H) \leqslant 0.30$ G (2H) and $a(^{13}C) \approx 13.0$ G (1 C_α) are approximately half those found for monoradical **2**, $a_1(1^1H) \approx 1.77$ G (1H), $a_2(1^1H) \approx 0.57$ G (1H) and $a(^{13}C) \approx 29.0$ G (1 C_α) . It is then possible to conclude that the two electrons in diradical **1** are interacting with a magnetic exchange coupling constant, *J*, that fulfills $J >> a_i$. It is also worth noting that the coupling constants of diradical **1** are not exactly half of those observed for the monoradical **2** when measured under identical experimental conditions, suggesting that both molecules have small differences in the conformations of their bridges. The spectrum of diradical **1** in frozen toluene–CH_2Cl_2 (1 : 1) showed the characteristic fine structure of a triplet species and appeared to be symmetrical, indicating that this complex has a low (if any) anisotropy. The forbidden $\Delta m_s = \pm 2$ transition characteristic of a triplet species, was also observed at the half-field region of the spectrum and the intensity of the corresponding signal (I_{pp}), obtained by double integration, was measured in the range 4–100 K. The reproducibility of the results was confirmed by two independent experiments. Since the quantity $I_{pp}T$ is proportional to the population in the triplet state, the fact that $I_{pp}T$ (Fig. 2) increases with decreasing temperature indicates that the ground state of **1** is the triplet state and the singlet state should be regarded as a thermally accessible excited state.[7] A separation of +10 ±2 K (7 cm^{-1}) between both states was obtained from the fitting of the data in Fig. 2 to a Bleaney–Bowers equation.[8]

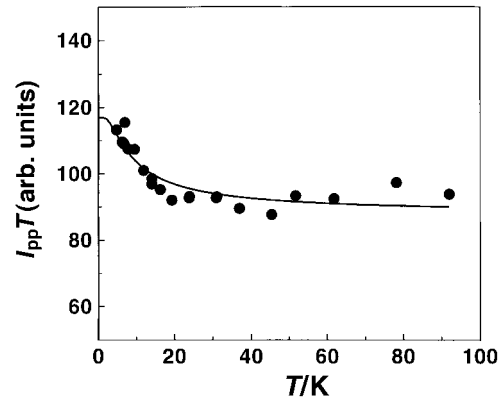

Fig. 2 Temperature dependence of $I_{pp}T$ of diradical **1**. The closed circles represent the experimental data and the continuous line the fit of experimental data to the Bleaney–Bowers equation.

In conclusion, we have shown that 1,1′-ferrocenylene bridges can act as ferromagnetic couplers when radical units with a suitable topology are connected to them. This concept can be extended to the synthesis of novel metallocene complexes bearing other organic and inorganic units providing a valuable access to this interesting class of materials.

4 The spin density on the metallocene units linked to the α-carbon atom of α-nitronyl aminoxyl radicals is very small because the SOMO orbital has a node on this carbon atom and therefore the spin density is transmitted only by a spin polarization mechanism.

5 By contrast, for diradical **1** both unpaired electrons can be delocalized by conjugation onto the ferrocene unit according to the particular topology of the diradical promoting a larger magnetic coupling.

Received (in Exeter, UK) 7th January 1999, Accepted 25th February 1999

Hyper Rayleigh scattering in solution is used for the determination of the first order hyperpolarizability $\beta_{colloid}$ of gold colloids in the size range 5–22 nm; these hyperpolarizabilities are found to range from 0.60×10^{-25} esu for 5 nm diameter colloids to up to 16.6×10^{-25} esu for 22 nm diameter colloids at the second harmonic wavelength of 532 nm; the strong size dependence of the hyperpolarisabilities reported here suggests that hyper Rayleigh scattering experiments can efficiently be used to calibrate the particle diameter of colloidal suspensions.

Gold colloids have been extensively investigated in the past owing to the potential applications of these particle suspensions. As a result, a wide range of techniques has been used for their characterisation, and in particular optical and microscopy techniques. For example, UV–VIS absorption spectroscopy and IR spectroscopy have been used to investigate the electronic properties of the particles. Also, transmission electron microscopy (TEM) measurements for deposited particles were performed to determine both the mean diameter and the size distribution of the preparations.[1,2] Recently, we have used the technique of optical surface second harmonic generation (SSHG) as a new technique for the study of noble-metal nanoparticles in diverse environmental conditions.[3,4] Indeed, it has been shown that this nonlinear optical technique is very sensitive to the surface plasmon excitation, the second harmonic signal being resonantly enhanced when the harmonic wavelength is tuned in the vicinity of the plasmon resonance. The hyper Rayleigh scattering (HRS) technique has already been used in the past for the determination of the absolute hyperpolarisability of compounds, in particular silver and gold colloids as well as SiO_2 particles.[5–7] Here, we report the use of the technique of HRS to investigate the size evolution of the first hyperpolarisability $\beta_{colloid}$ for colloids with sizes ranging from 5 to 22 nm. Within this size range, no significant surface plasmon peak shift occurs, a necessary requirement for single wavelength measurements. From the measurements and the simplicity of the experimental arrangement, we also propose this second order nonlinear technique as an efficient calibration technique for the determination of the size of nanoparticles in solution.

Colloidal gold nanoparticles with a mean particle diameter of 19 and 22 nm were prepared using the method of Turkevich *et al.*[8] Gold colloids of mean diameter 4.9 and 8.6 nm were purchased from Sigma.[9] TEM photographs of each colloidal preparation were taken and the average particle diameter along with the standard deviation were determined from at least 200 particles. The UV–VIS absorption spectrum of the gold colloid solutions presented a strong absorption band with a maximum at *ca.* 520 nm except for the 4.9 nm diameter one. Indeed, for this particle diameter, the plasmon resonance is damped owing to the size effects and therefore swamped by the sharp increase of the absorbance due to interband transitions, appearing as a mere shoulder blue shifted with respect to the true resonance location. Table 1 gives the size and the linear optical characteristics of the four gold colloidal solutions used.

The light source for the HRS experiments consisted of a Q-switched Nd : YAG laser providing pulses of 5 ns and < 4 mJ, at a repetition rate of 10 Hz at 1064 nm. The beam was focused into a 1 × 1 cm spectrophotometric cell and the experiments were performed well below the threshold for any undesirable adverse effects. A small fraction of the incident beam was directed onto a fast photodiode to monitor the intensity stability. The HRS light was collected at an angle of 90° from the incident direction by a lens and a mirror. Spectral discrimination of the second harmonic light from its linear counterpart was accomplished by two low-pass BG38 near IR filters and a 3 nm bandwidth interference filter peaked at 532 nm. The second harmonic light was then detected with a photomultiplier tube and the signal was integrated with a boxcar averager. The quadratic dependence of the HRS signal from the gold colloid solutions with the incident light intensity was always checked beforehand and the experimental conditions were first assessed on *p*-nitroaniline (pNA) in methanol. With the known value of $\beta_{MeOH} = 0.69 \times 10^{-30}$ esu, we extracted an absolute value of $\beta_{pNA} = (31 \pm 7) \times 10^{-30}$ esu in very good agreement with previous HRS measurements giving a value of $\beta_{pNA} = (34 \pm 4) \times 10^{-30}$ esu.[10]

The HRS signal $S_{2\omega}$ dependence on the incident light intensity I_0 is given according to

$$S_{2\omega} = GB^2 I_0 \, 10^{-A} \quad (1)$$

where G is a proportionality constant and A the absorbance at the harmonic wavelength. For the two component system at hand:

$$B^2 = < N_{colloid} \, \beta_{colloid}^2 + N_{H_2O} \, \beta_{H_2O}^2 > \quad (2)$$

where $N_{colloid}$ and $\beta_{colloid}$ are respectively the number density and the first hyperpolarisability of the aqueous colloids and N_{H_2O} and β_{H_2O} respectively the number density and the first hyperpolarisability of water. The factor 10^{-A} accounts for the losses due to linear absorption of the scattered light by the colloidal solution at 532 nm and was determined from the UV–VIS spectra.

HRS measurements at different number density of the 22 nm diameter colloids by dilution of the initial solution were first performed and the results are displayed in Fig. 1. A linear

Table 1 Size (mean diameter $< D >$ and dispersion), initial concentration, maximum of linear absorbance λ_{max} and first hyperpolarizability $\beta_{colloid}$ of gold colloids

Gold colloid	$< D >$/nm	Dispersion/nm	Initial concentration/ colloid dm^{-3}	λ_{max}/nm	$\beta/10^{-25}$ esu
a	4.9	0.7	4.4×10^{16}	508[a]	0.60 ± 0.09
b	8.6	1.0	6.9×10^{15}	518	2.0 ± 0.3
c	19.0	1.5	6.4×10^{14}	520	13.1 ± 2.0
d	22.0	1.7	4.6×10^{14}	520	16.6 ± 2.5

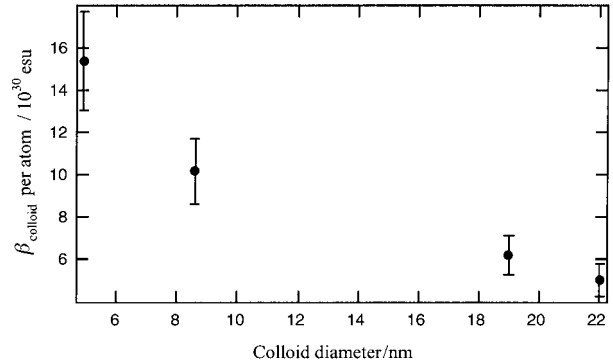

Fig. 2 Absolute value of the first hyperpolarizability $\beta_{colloid}$ calculated per gold atom in the colloid *versus* the mean diameter of the gold colloids.

behaviour is observed as expected after the correction for the absorption, and from the slope, the first hyperpolarisability of the 22 nm colloids $\beta_{colloid}$ is calculated to be $(16.6 \pm 2.5) \times 10^{-25}$ esu on the basis of $\beta_{H_2O} = 0.56 \times 10^{-30}$ esu.[7] Then, using this solution as an external reference, the first hyperpolarisability of the other colloids of size 4.9, 8.6 and 19 nm were obtained using the concentration of the initial solutions. The data are reported in the last column of Table 1. A 30-fold increase in the magnitude of the first hyperpolarisability is observed for a five-fold increase in diameter only. Such a large magnitude is however expected as it stems from the coupling between the SH field with the surface plasmon.[4] These values are rather different from the ones recently reported for 13 nm diameter gold colloids but are of the same order of magnitude as that obtained near resonance for silver colloids.[5,7] Fig. 2 shows the size dependence of the hyperpolarisability as calculated per atom, obtained dividing the value given in Table 1 by the number of gold atoms in the colloid. It is observed that the hyperpolarisabilities per atom decreases by a factor of 10 over the five-fold increase of the particle in diameter. The origin of such a behaviour may stem from the saturation of the collective effect contribution to the nonlinear optical activity when the colloid diameter gets too large.

These experiments emphasise the strong dependence of the first hyperpolarisability of the gold colloids on the particle diameter. As a result, the SH signal exhibits a 1000 fold increase in intensity for a five-fold increase in particle diameter only. For instance, for the 19 and 22 nm diameter colloids, the reported increase in the HRS signal is *ca.* 50% for a mere 16% increase in diameter. Therefore, in view of the simplicity of the experimental apparatus for these experiments, the HRS technique offers an efficient alternative to particle size determination with an external reference.

Hierarchical organization of mesoporous MCM-41 ropes

Hong-Ping Lin,[a] Shang-Bing Liu,[a] Chung-Yuan Mou*[b] and Chih-Yuan Tang[c]

Received (in Cambridge, UK) 15th December 1998, Accepted 1st March 1999

Millimeter long ropes of MCM-41 materials are made from micrometer-sized fibers by self-assembly and flow-induced orientation.

Self-assembly of surfactants and aluminosilicates provides a versatile means to create various nanostructures of aluminosilicates, such as MCM-41 and MCM-48,[1,2] with potential applications in biomaterials, microelectronics and catalysis. For many applications of the mesoporous materials, these materials should be tailored not only at the nanometer scale of the pore but also at the larger scale (micro- and milli-meter) of the morphology.[3–5] Biomimetic approaches based on hierarchical organization would be a good way of building larger structures. Recent discoveries in hierarchical organization of these nanomaterials have extended the structure order to micrometer level and include tubular, spherical and fibrous morphology.[6–8] The fiber organization of mesoporous materials is particularly interesting for possible use in embedding conducting materials, from semiconductors to superconductors. We report here a simple method of making bundles of MCM-41 fibers (micrometers in diameter) into millimeter size ropes in nitric acid under a shearing flow; thus extending the previously known primary hierarchy to a higher level of secondary hierarchical structure.[8]

Since our goal is to create millimeter-scaled rope bundles of MCM-41, two sub-goals have to be met: the creation of ultralong cylindrical micelles and their parallel alignment. Previously, long fiber forms have been created by adding polymers to the surfactant,[9] and elongation is due to the polymers, not the micelles themselves. In our method we use the nitrate ion as a counter ion to create long worm-like micelles of cationic quaternary ammonium halides. Secondly, the parallel alignments of the hexagonal phase can be realized in a shearing flow. Recent studies on surfactant systems indicate that shear flow induces the formation of long cylindrical micelles and the orientation of the hexagonal phase along the flow direction.[10] Pinnavaia and coworkers found that variation in morphology of mesoporous silica could be attributed to agitation effects during synthesis.[11] Recently, it has been shown that 3-D silicate structures[12a] and 2-D films[12b] can be induced through detailed control of shear flow conditions and reaction composition.

MCM-41 materials were synthesized from quaternary ammonium halide (C_nTMAX; X = Cl or Br)–tetraethylorthosilicate (TEOS)–nitric acid (HNO_3) systems under couette flow conditions. First, into a couette flow reactor (the diameter of the stator is 8.90 cm, and the rotor is 7.92 cm), a clear aqueous solution of C_nTMAX (n = 16 or 18) was mixed thoroughly with a suitable amount of the nitric acid to form a highly viscous solution. The silica source (TEOS) was added and then stirred for 12–24 h at the designed stirring rate and temperature. The composition of gel solution is 1 C_nTMAX : (6.0–12.0) TEOS : (9.0–36.0) HNO_3 : (1000–2000) H_2O. The resultant white silica ropes were recovered by filtration and washed.

Fig. 1A shows the SEM micrograph of the calcined silica products prepared from $C_{18}TMAB$–TEOS–HNO_3–H_2O at 40 °C under a stirring rate of 500 rpm. It is found that the silica ropes are almost at the millimeter scale. The length is not uniform, but the longer ones tend also to be the thicker ones. The yield is high at *ca.* 90%. It is seen by SEM that the length and morphology of the calcined ropes are the same as the as-synthesized materials. At higher magnification, we can clearly see that the silica products consist of micrometer-sized silica fibers entwined into ropes (Fig. 1B). The corresponding higher magnification SEM image of the cross-section of the fibers shows that the micron-sized silica fibers are nearly hexagonal (Fig. 1C). From an ultrathin section TEM micrograph of the cross section of the silica fiber (Fig. 1D), one can unambiguously see that the hexagonal-shaped fibers are constituted from hexagon-arrayed MCM-41 nanochannels. Thus we have made silica ropes in second-order hierarchical structure; nanometer MCM-41 channels, micrometer fibers and millimeter sized ropes. Linear structures at each higher level are built up from the corresponding structure at lower level.

The X-ray diffraction (XRD) patterns of the as-synthesized and calcined silica ropes are shown in Fig. 2. One can clearly recognize the order of the hexagonal array of the MCM-41 structure. Both materials exhibit four sharp XRD peaks, which reflects a typically well aligned MCM-41 structure. The XRD patterns are almost flat in the range 2θ 20–30°, indicating that no amorphous silica particles are formed. The shrinkage of the d_{100} value after calcination at 560 °C for 6 h is only *ca.* 0.1–0.2 nm. This shows the nanostructure of the silica rope possesses high thermal stability.

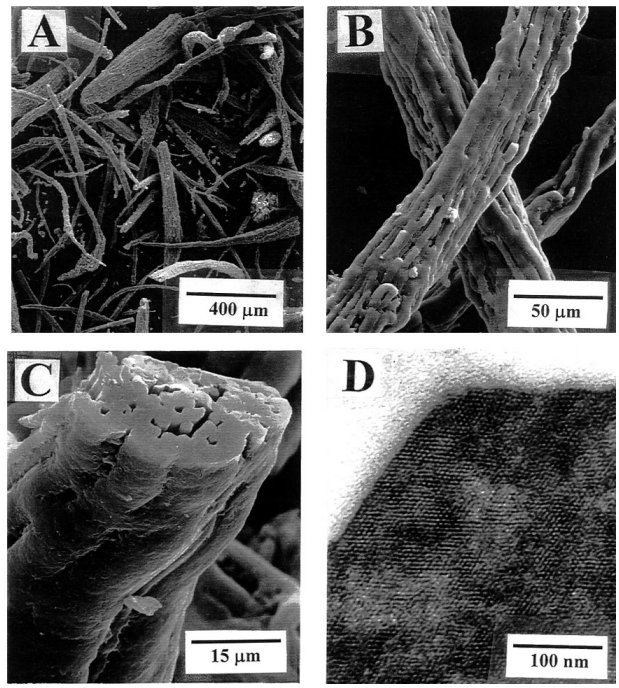

Fig. 1 SEMs of different magnifications and ultrathin TEM of millimeter-sized silica fibers obtained from the gel composition 1 $C_{18}TMACl$: 6.30 TEOS : 13.5 HNO_3 : 1002 H_2O. (A) × 50, (B) × 400, (C) × 1500, (D) ultrathin TEM of the cross section of the silica fiber.

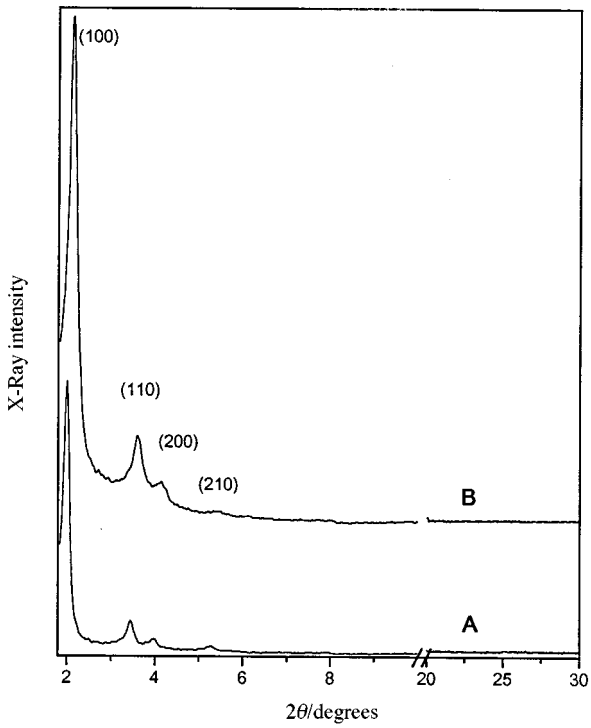

Fig. 2 XRD patterns of as-synthesized and calcined silica ropes prepared from the same gel composition of Fig. 1; (A) as-synthesized, (B) calcined.

In addition to using the surfactant C_{18}TMACl as the template, we can also fabricate millimeter-scaled silica ropes with similarly well defined XRD patterns from different C_nTMAX ($n \geqslant 16$) surfactants. The physical properties (d_{100} value, pore size, pore volume, BET surface area) of these materials after calcination are listed in Table 1. All of these mesoporous materials possess high thermal stability, large surface area and pore volume, uniformed-sized pores, the sizes of which can be varied (*i.e.* by changing the carbon chain length of surfactant) as those synthesized under basic conditions. The formation of long cylindrical micelles can be attributed to the NO_3^- anions of the nitric acid which has a stronger binding affinity to the cationic surfactant than do Br^- or Cl^- anions.[13,14] The ultra-long micelles of the $S^+NO_3^-$ acts as the template in combining with the cationic silica species (I^+), formed from the hydrolysis of TEOS, to form $S^+NO_3^-I^+$ intermediates. Then it transforms into the final mesoporous product with a constant pore size.

Table 1 Physical properties of the mesoporous silica ropes synthesized from C_nTMAX–TEOS–HNO_3–H_2O

C_nTMAX[a]	As-made d_{100} value/nm	Calcined d_{100} value/nm	BJH pore[b] size/nm	Pore volume[c]/ $cm^3\ g^{-1}$	BET surface/ $cm^2\ g^{-1}$
C_{18}TMACl	4.41	4.28	3.10	1.36	946
C_{18}TMAB	4.40	4.27	3.08	1.38	968
C_{16}TMACl	4.03	3.84	2.54	1.20	989
C_{16}TMAB	4.02	3.84	2.55	1.23	1002

[a] C_{18}TMAX systems were synthesized at 40 °C, C_{16}TMAX at 25 °C. [b] Values obtained from the adsorption portion of the N_2 adsorption–desorption isotherm. [c] Data taken at $p/p_0 = 0.9$.

The ability to control the mesoporous silica materials into a long rope form relies on the underlying physics and chemistry. From the chemical viewpoint, the NO_3^- anions of nitric acid have a strong binding strength with the cationic quaternary ammonium surfactant. Therefore the flexible and elongated rod micelles of $S^+NO_3^-$ would be formed as a supramolecalar template for the cationic silica species at a relative high concentration of nitric anions (*ca.* 0.4–0.9 M). When we use HBr or HCl as the source of acid, the morphology of the mesoporous materials is simply spherical.

From the physical viewpoint, the shearing flow also plays an important role for the formation of millimeter-scaled silica ropes. Under static condition, we obtain the mesoporous product in the facet and corrugated silica spheres as reported by Ozin's group.[6] By contrast, millimeter-sized silica ropes could only be synthesized under a steady continuous stirring.

In conclusion, mesoporous MCM-41 materials are produced in highly-ordered hierarchical form based on the combination of the elongation of the surfactant micelles using strongly binding nitrate counter ions, and the shear flow alignment which lead to formation of ropes of fibrous hexagonal nanochannels. This will provide a pathway to realize biomimetic hierarchical rope structures for other porous materials. In applications, fibrous MCM-41 materials of millimeter length could open up investigations in embedded and oriented metal and semiconductor nanorods.[15]

The condensation of *trans*-$[PdCl_2\{(C_4H_3O)SeMe\}_2]$ with acetone: formation and crystal structure of $[Pd_2Cl_2(\mu\text{-}SeMe)_2\{MeSe(C_4H_2O)\}_2CMe_2]$

Received (in Basel, Switzerland) 23rd November 1998, Accepted 18th February 1999

The condensation of the furan rings in two *trans*-$[PdCl_2\{(C_4H_3O)SeMe\}_2]$ complexes with acetone and the chlorine–selenium interactions in the coordination spheres of the two palladium atoms result in the formation of a dinuclear complex $[Pd_2Cl_2(\mu\text{-}SeMe)_2\{MeSe(C_4H_2O)\}_2CMe_2]$.

Mononuclear $[ML_2X_2]$ complexes (M = Pd, Pt; L = two organic monodentate ligands containing one selenium or tellurium donor atom each, or one didentate ligand containing two chalcogen donor atoms; X = halide) form a well explored series.[1] Most of the experimental work, however, has been carried out in solution[2] and the solid state information is sparse.[3] We have recently studied the structural and bonding trends in $[MCl_2\{(C_4H_3E)E'Me\}_2]$ (M = Pd, Pt; E = S, O; E′ = Se, Te) both in solution and in the solid state.[3*i*] Surprisingly, it turned out that the crystallization of $[PdCl_2\{(C_4H_3O)SeMe\}_2]$ **1** from acetone produced a dimer $[Pd_2Cl_2(\mu\text{-}SeMe)_2\{MeSe(C_4H_2O)\}_2CMe_2]$ **2**. In this work we report the crystal structure of the dimer and discuss the route of its formation from two monomeric complexes.

The preparation of $[PdCl_2\{(C_4H_3O)SeMe\}_2]$ **1**† yields orange microcrystalline material. The product was dissolved in $CDCl_3$ and $(CD_3)_2CO$ and the ^{77}Se and $^{13}C\{^1H\}$ NMR spectra of both solutions were recorded immediately upon preparation and again after a period of four weeks.‡ The spectra of both fresh and aged samples were identical.

A chloroform solution of **1** exhibits a single ^{77}Se resonance at δ 230 consistent with the chemical shift of δ 233 reported for both $[PdCl_2\{(C_4H_3S)SeMe\}_2]$ **3** and $[PtCl_2\{(C_4H_3S)SeMe\}_2]$ **4**.[3*i*] This implies the presence of only one isomer in solution. The crystal structure determinations of **3** and **4** have shown the existence of a *trans*-isomer in the solid state.[3*i*] The ^{77}Se resonance of **1** appears as a doublet of quartets implying that selenium is bound to the methyl group and to the furyl ring with the coupling resolvable to the nearest protons [Fig. 1(a)].§

Five signals are observed in the $^{13}C\{^1H\}$ spectrum of **1**. Four resonances at δ 146, 134, 119 and 112 are due to the furyl ring carbon atoms. These values bear a logical relationship to the $^{13}C\{^1H\}$ spectra of $[MCl_2\{(C_4H_3E)E'Me\}_2]$ (M = Pd, Pt; E = S, O; E′ = Se, Te) [for detailed assignment of the resonances to individual carbon atoms, see ref. 3(*i*)]. The fifth resonance at δ 15 is assigned to the methyl carbon. NMR spectroscopy clearly shows the sole presence of monomeric *trans*-$[PdCl_2\{(C_4H_3O)SeMe\}_2]$ in chloroform solution.

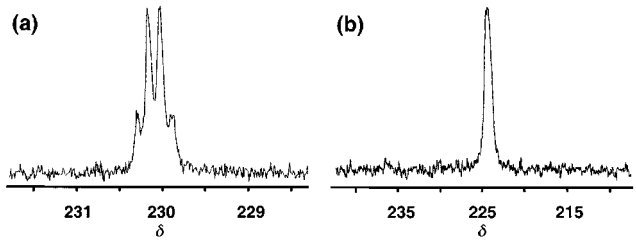

Fig. 1 The ^{77}Se NMR spectrum of $[PdCl_2\{(C_4H_3O)SeMe\}_2]$ **1** in (a) $CDCl_3$ and (b) $(CD_3)_2CO$. $^2J_{HSe}$ 11, $^3J_{HSe}$ 2 Hz.

The ^{77}Se and $^{13}C\{^1H\}$ spectra of **1** in acetone resemble those in chloroform. One ^{77}Se chemical shift is found at δ 224 and five ^{13}C resonances are observed at δ 148, 135, 118, 112 and 14. The most pronounced spectroscopic difference from the sample in chloroform is the loss of coupling information in the ^{77}Se resonance [Fig. 1(b)]. This may be due to fast exchange processes taking place in acetone solution.

Upon crystallization from acetone, a small amount of red crystals appeared together with the bulk of orange microcrystalline material of **1**.¶ The crystal structure determination of the red crystals established that **1** has condensed with acetone and dimerized, as shown in Fig. 2.‖ Both palladium atoms exhibit approximately square planar coordination sharing two bridging $MeSe^-$ ligands. The coordination planes around the two palladium atoms lie at an angle of 124.50(4)° from each other. Selected bond parameters are listed in Fig. 2. They are comparable to those observed for the related complexes and follow the trends established earlier.[3*a*,*c*,*i*]

The probable route of formation of **2** from **1** is shown in Fig. 3. The reaction can be conceived to be initiated by the

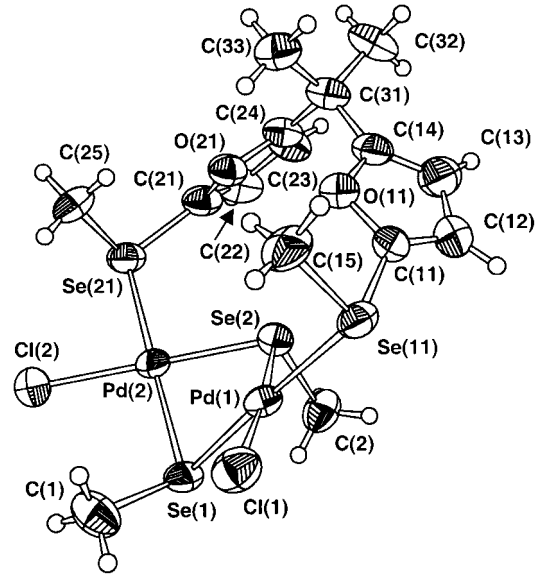

Fig. 2 The molecular structure of $[Pd_2Cl_2(\mu\text{-}SeMe)_2\{SeMe(C_4H_2O)\}_2CMe_2]$ indicating the numbering of the atoms. The thermal ellipsoids have been drawn at 50% probability level. Selected bond lengths (Å) and angles (°): Pd(1)–Se(1) 2.420(2), Pd(1)–Se(2) 2.397(1), Pd(2)–Se(1) 2.408(1), Pd(2)–Se(2) 2.396(2), Pd(1)–Se(11) 2.443(2), Pd(2)–Se(21) 2.437(1), Pd(1)–Cl(1) 2.351(2), Pd(2)–Cl(2) 2.336(3), Se(1)–C(1) 1.944(9), Se(2)–C(2) 1.962(8), Se(11)–C(11) 1.893(9), Se(11)–C(15) 1.946(8), Se(21)–C(21) 1.892(10), Se(21)–C(25) 1.960(9), C(14)–C(31) 1.49(1), C(24)–C(31) 1.52(1), C(31)–C(32) 1.52(1), C(31)–C(33) 1.56(1); Pd(1)–Se(1)–Pd(2) 85.46(4), Pd(1)–Se(2)–Pd(2) 86.23(4), Se(1)–Pd(1)–Se(2) 80.53(4), Se(1)–Pd(2)–Se(2) 80.79(4), Pd(1)–Se(11)–C(11) 109.4(3), Pd(2)–Se(21)–C(21) 110.7(3), C(14)–C(31)–C(24) 107.0(7), C(14)–C(31)–C(32) 111.0(8), C(14)–C(31)–C(33) 110.5(7), C(24)–C(31)–C(32) 108.9(7), C(24)–C(31)–C(33) 109.5(8), C(32)–C(31)–C(33) 109.8(8). The angle between the least-squares planes Pd(1)–Se(1)–Se(2)–Cl(1)–Se(11) and Pd(2)–Se(1)–Se(2)–Cl(2)–Se(21) is 124.50(4)°.

condensation of two furan rings from two separate *trans*-$[PdCl_2\{(C_4H_3O)SeMe\}_2]$ complexes by acetone. This type of condensation reaction between furan and ketones is well known.[6] Furan and acetone produce tetrametric $\{(C_4H_2O)CMe_2\}_4$ the crystal structure of which[7] shows a similar $-CMe_2-$ link between the two furan rings as **2**.

We have established[3i] that the packing in $[MCl_2\{(C_4H_3E)TeMe\}_2]$ and other related telluroether-containing palladium and platinum complexes[3d,g,h] involves close tellurium–halogen contacts. The strength of this interaction is directly proportional to the electron-withdrawing nature of the aromatic substituents bound to the tellurium atom. In the case of monomeric selenoether complexes no such halogen–chalcogen interaction is observed.[3a,c,i] The furan ring, however, may be sufficiently electrophilic to induce a chlorine–selenium interaction and form the intermediate **A**, as shown in Fig. 3. The formation of **A** is sterically very facile despite the constraint generated by the link between the two furan rings. In fact, the solid state packing of the dimer **2** involves two short intermolecular selenium–chlorine contacts of 3.505 Å and lends credibility to the intermediate **A**. Only slight rearrangement of the ligands around the two palladium atoms is needed to cleave two molecules of 2-furyl chloride and form **B**. The reaction is completed by the two $MeSe^-$ fragments that bridge the palladium atoms and thus regenerate the square-planar coordination around each.

Diorganoselenides generally act as neutral monodentate ligands without C–Se bond fission during the complexation.[1c,d] The presence of bridging $MeSe^-$ ligands in **2**, however, must be a consequence of the cleavage of the Se–C_{aryl} bond. This behaviour is consistent with the oxidative addition of organic tellurides to Pt(0) that results in the cleavage of the Te–C_{aryl} bond in preference to the Te–C_{alkyl} bond.[8]

It can be concluded that **2** is probably formed from **1** upon crystallization from acetone. Spectroscopic and compositional data indicate that the orange product obtained upon precipitation with hexane is pure monomer **1**. Upon crystallization from acetone, the solid monomer itself appears only as microcrystalline material, but small amounts of **2** build up as well formed red crystals. A systematic study on the factors affecting the formation of dimeric complex from $[MCl_2\{(C_4H_3E)SeMe\}_2]$ (M = Pd, Pt, E = O, S) and the optimization of the condensation reactions are currently in progress.

We thank Dr Maire Eloranta for inspiring discussions. Financial support from Neste Oy Foundation and Academy of Finland is gratefully acknowledged.

Notes and references

† The general procedure for the preparation of $(C_4H_3E)E'Me$ and $[MCl_2\{(C_4H_3E)E'Me\}_2]$ (M = Pd, Pt; E = S, O; E′ = Se, Te) has been described earlier.[3i] Methyl(2-furyl)selane (0.20 g, 1.3 mmol) in 5 ml acetone was added into 20 ml of acetone solution of $[PdCl_2(PhCN)_2]$ (0.17 g, 0.44 mmol) and stirred for 3 h. The solution was concentrated and hexane added. The precipitate was filtered off, washed with hexane, and dried. Yield 0.18 g, 82%. Anal. Calc. for $C_{10}H_{12}Cl_2PdO_2Se_2$: C, 24.05: H, 2.42. Found: C, 24.10: H, 2.50%. $\delta_H(CDCl_3)$ 2.62 (6H, s), 6.46 (2H, dd, $^2J_{HH}$ 1.7, 3.4 Hz), 6.95 (2H, d, $^2J_{HH}$ 3.4 Hz), 7.66 (2H, d, $^2J_{HH}$ 1.7 Hz); $[(CD_3)_2CO]$ 2.85 (6H, s), 6.60 (2H, dd, $^2J_{HH}$ 2.1, 3.4 Hz), 7.05 (2H, br), 7.86 (2H, br).

‡ The ^{77}Se and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker DPX 400 spectrometer operating at 76.31 and 100.61 MHz for ^{77}Se and ^{13}C, respectively. The solvent, $CDCl_3$ or $(CD_3)_2CO$, served as an internal ^2H lock. Saturated solution of SeO_2(aq) was used as an external standard for the ^{77}Se chemical shifts and $SiMe_4$ as an internal standard for the ^{13}C chemical shifts. The ^{77}Se chemical shifts are reported relative to neat Me_2Se, $[\delta(Me_2Se) = \delta(SeO_2) + 1302.6]$ and the ^{13}C shifts relative to TMS.

§ The coupling patterns of the ^{77}Se resonances in *trans*-$[PdCl_2\{(C_4H_3S)SeMe\}_2]$ **3** and *trans*-$[PtCl_2\{(C_4H_3S)SeMe\}_2]$ **4** are identical to that of **1** indicating that the structures of all three complexes **1**, **3** and **4** are similar.

¶ We were unable to obtain crystals from chloroform solution.

Rapid and highly base selective RNA cleavage by a dinuclear Cu(II) complex

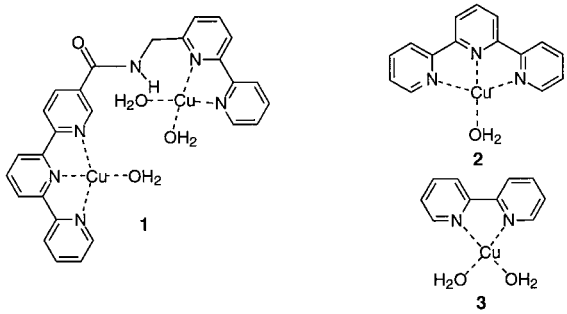
Shanghao Liu and Andrew D. Hamilton*

Department of Chemistry, Yale University, New Haven, CT, 06520, USA. E-mail: andrew.hamilton@yale.edu

Received (in Columbia, MO, USA) 21st October 1998, Accepted 9th February 1999

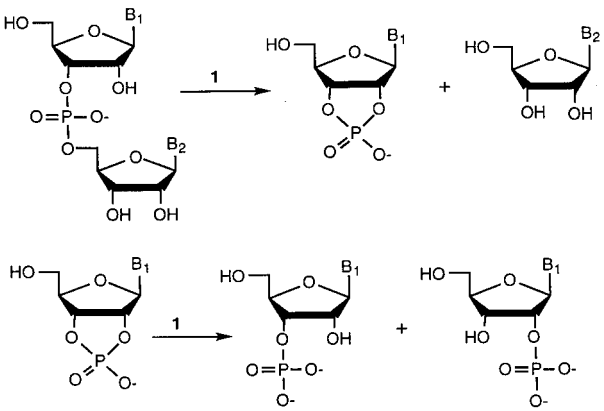
A bis-Cu(II) complex based on a covalently linked terpyridine and bipyridine ligand system is shown to rapidly cleave bis-ribonucleotides with remarkable selectivity for adenine bases.

Currently there is a great deal of interest in the design of catalysts for rapid and base selective RNA hydrolysis.[1,2] Such artificial ribonucleases may be useful as novel therapeutic agents for cancer and viral diseases[2f–i,3–5] or as chemical probes for RNA sequencing and structure mapping.[6] However, despite much effort none of the RNA cleaving agents developed so far has achieved the level of activity afforded by natural ribonucleases. Moreover, selective cleavage at specific base sites is a hallmark of the ribonucleases but is seen in few synthetic systems. We recently showed that dinuclear Cu(II) complex **1**



not only is more active than mononuclear complexes **2** and **3** but also exhibits remarkable base selectivity in promoting the hydrolytic cleavage of ribonucleoside 2′,3′-monophosphates, intermediates in RNA cleavage by natural ribonucleases.[7] We have now found that **1** is also highly active in promoting the hydrolysis of ribonucleotides and report here on this metal-based artificial ribonuclease that shows both potency and base selectivity.

Complex **1** was prepared as described previously.[8] The hydrolysis of RNA dimers in the presence of excess **1** was followed by HPLC.† The reaction proceeded by a transesterification–hydrolysis mechanism with ribonucleoside 2′,3′-monophosphates as intermediates (Scheme 1). All reactions followed first-order kinetics.The pH–rate profile in Fig. 1 shows



Scheme 1 Hydrolysis of RNA dimers in the presence of **1**–**3**. B_1 and B_2 are nucleobases.

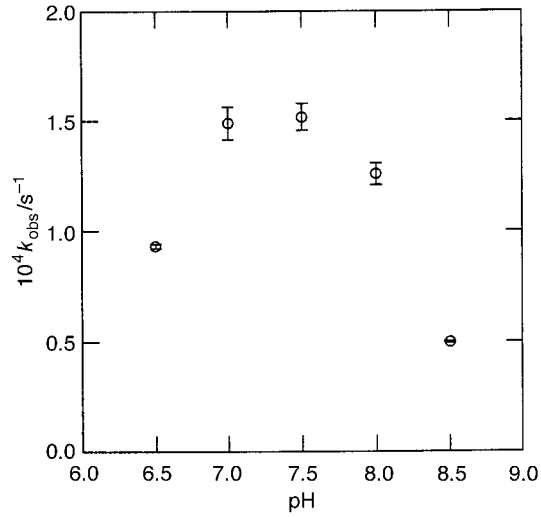


Fig. 1 pH–rate profile for the hydrolysis of ApA in the presence of **1** at 25 °C. [ApA] = 0.1 mM, [**1**] = 2.0 mM. The reaction media at pH 7.0, 7.5 and 8.0 are the HEPES buffers (0.05 M); that at pH 8.5 is the AMPSO buffer (0.05 M) and that at pH 6.5 is the MES buffer (0.05 M).

that **1** reaches its maximum activity at pH 7.5, consequently all other reactions were carried out at this pH. Table 1 summarizes the first-order rate constants and relative rates for the hydrolysis of six RNA dimers in the presence of dinuclear **1** and mononuclear **2**. All reactions with **2** as catalyst were carried out at pH 8.0 because previous work by Chin and coworkers found that related complexes reached their maximum activity near this pH in catalyzing the hydrolysis of ApA.[2c] The hydrolysis of RNA dimers in the presence of **3** was too slow to allow accurate determination of the first-order rate constants.

The remarkable base selectivity of dinuclear complex **1** is evident from the relative rates for different RNA dimers in Table 1. As in the hydrolysis of nucleoside 2′,3′-cyclic monophosphate, **1** is highly selective for adenine, hydrolyzing ApA 12, 17 and 87 times faster than CpC, UpU and GpG, respectively. The intrinsic differences in hydrolysis rate for the different dinucleotides (caused presumably by intra- or intermolecular interactions) are much smaller, with purine–purine

Table 1 First-order rate constants (k_{obs}) and relative rates (k_{rel}) for the hydrolysis of RNA in the presence of dinuclear Cu(II) complex **1** and mononuclear Cu(II) complex **2**

sequences (*e.g.* ApA) being among the slowest.[9] Replacement of either adenine group in ApA by a cytidine group diminished the rate of **1**-catalysed hydrolysis threefold. This level of base selectivity is unprecedented in a simple metal-based ribonuclease mimic that lacks any appended recognition elements (such as oligonucleotide strands). Dinuclear complex **1** is also highly active: at a concentration of 2.0 mM it provides over five orders of magnitude rate acceleration for the hydrolysis of its best substrate, ApA.[10] The data in Table 1 also show that mononuclear complex **2** has moderate selectivity for adenine. Apparently, attachment of a bipyridine–Cu(II) unit to **2** not only increases its activity but also amplifies its base selectivity.

We have suggested[7] that a strong π–π stacking interaction between adenine and the bipyridine–Cu(II) unit may be the principal reason for the high selectivity of **1** for adenine in **1**-catalyzed hydrolysis of nucleoside 2′,3′-cyclic monophosphates. This same interaction also appears to be responsible for the base selectivity shown by **1** in promoting the hydrolysis of RNA. First, the base selectivities for the dinucleotide and cyclic monophosphate substrates parallel each other, as can be seen in Table 2. Second, the high selectivity of **1** for adenine in the hydrolysis of RNA dimers is insensitive to the position of the adenine group relative to the phosphate bond to be cleaved since ApC and CpA have almost identical reactivity (Table 1). These observations are more consistent with association through a less specific π–π stacking rather than more directed interactions such as hydrogen bonding and metal coordination to the nucleobases as major sources of base selectivity. Face-to-face stacking provides an interaction that is adaptable to different nucleobase positions. If hydrogen bonding or metal coordination from **1** to the nucleobases were important in stabilizing the interaction, it is probable that different base selectivities between the RNA dimers and nucleoside 2′,3′-cyclic monophosphates would result due to the different orientations and flexibilities in the two sets of substrates. Likewise, ApC and CpA should also show quite different reactivities due to the different positions of adenine in the two substrates.

In conclusion, dinuclear Cu(II) complex **1** has been shown to function as a highly active artificial ribonuclease. In addition, a remarkable selectivity among the different nucleotide bases is seen with particularly effective cleavage of adenine-containing substrates. We are currently extending these dinuclear Cu(II) complex designs to enhance the level of activity and to alter the base selectivity.

† Hydrolysis of RNA dimers by **1** was followed by HPLC (Ranin). The following procedure is typical: 2.85 mL of **1** (2.1 mM) in a buffer solution was mixed with 0.15 mL of an RNA dimer (2.0 mM) in deionized H_2O. Aliquots (300 μL) of the reaction mixture were quenched with 50 mM EDTA (300 μL). After filtration, the quenched solution (15 μL) was injected onto a C-18 reversed-phase column and eluted for 10–15 min with 0–15% MeCN in H_2O containing 0.1% CF_3CO_2H (flow rate = 1.0 mL min^{-1}). The eluent was monitored at λ_{max} of the nucleobase (260 nm for adenine and uracil, 252 nm for guanine and 268 nm for cytidine) by a Ranin UV detector. The first-order rate constants (k_{obs}) were obtained as slopes of plots of $\ln(A_0/A_t)$ *vs.* *t*, where A_0 and A_t are the integrations of the areas of the HPLC peaks for the RNA dimer at $t = 0$ and *t*, respectively.

Synthesis and reactions of metallo-diethynylbenzenes: building blocks for redox-active poly(phenyleneethynylene)s†

Kevin D. John and Michael D. Hopkins*

Department of Chemistry, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA. E-mail: mdh1@vms.cis.pitt.edu

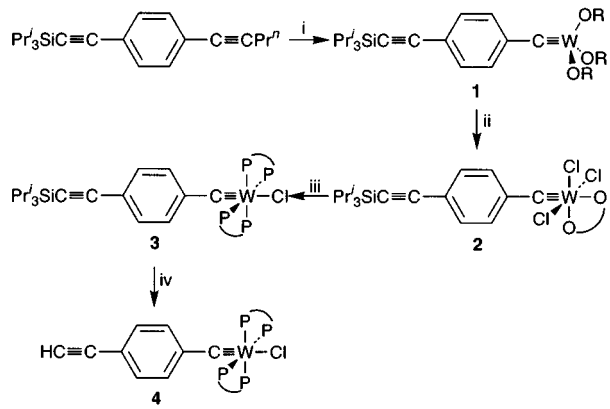
Received (in Bloomington, IN, USA) 25th November 1998, Accepted 8th February 1999

The metallo-diethynylbenzene complex W(≡CC_6H_4C≡CH-4)(dmpe)$_2$Cl, a precursor to metal-containing poly(phenyleneethynylene)s, has been prepared using alkyne-metathesis methodology and can be coupled into unsaturated organic frameworks at both the ethynyl moiety and the tungsten center and one-electron oxidized to the open-shell cation.

The unsaturation and limited conformational flexibility of phenylacetylenes (and, more generally, arylacetylenes) imparts to the polymeric materials derived from them extended π-electron systems and well defined lengths and shapes, respectively. These attributes have made poly(aryleneethynylene)s[1] the subjects of intensive research as regards their potential applications to molecular electronics,[2] photonics[3] and chemical sensing.[4] Control over the properties of poly(aryleneethynylene)s is achieved typically by changing the polymer terminating groups and the nature and connectivity of the aryl hubs. Here, we describe a different approach to functionalizing poly(aryleneethynylene)s: the replacement of triply bonded carbon atoms in the backbone with triply bonded metal centers of metal–alkylidyne complexes.[5]

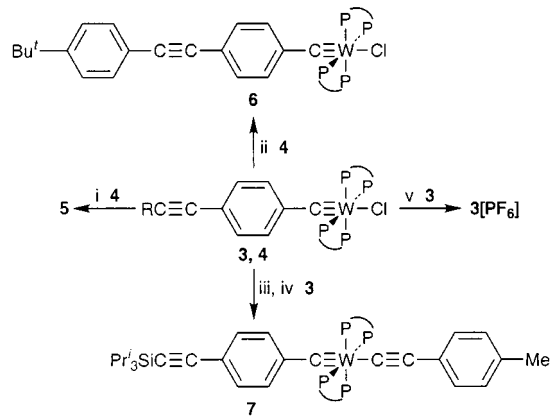
Covalent alkylidyne-containing polymers analogous to poly(aryleneethynylene)s have not yet been prepared, although metal–alkylidyne coordination polymers[6] and poly(aryleneethynylene)s to which metal centers are externally coordinated[7] have been reported. Recently, Mayr *et al.* reported an important advance toward this objective with their synthesis of Fischer-type alkylidyne compounds of the form W(≡CC_6H_4I-4)$(CO)_2$(LL)X (LL = tmeda, dppe; X = Cl, Br, I),[8] which undergo cross-coupling reactions with phenylacetylenes to give compounds with phenyleneethynylene alkylidyne ligands. Simultaneously, we have been seeking to develop routes to related compounds based on Schrock's alkyne-metathesis reaction[9] because of the ease with which this methodology allows the synthesis of complexes with unsaturated alkylidyne ligands and the fact that the W(≡CR)$(OR')_3$ metathesis products allow access[10] to carbonyl-free derivatives of the type W(≡CR)L_4X. This latter point is important because W(CR)$(CO)_nL_{4-n}$X compounds typically exhibit electrochemically irreversible oxidative processes,[11] which could limit their use as building blocks for redox-active polymers. Herein we report the synthesis, *via* an alkyne-metathesis route, of W(≡CC_6H_4C≡CH-4)$(dmpe)_2$Cl **4** (dmpe = $Me_2PCH_2CH_2PMe$), some reactions that lead to its incorporation into unsaturated organic frameworks, and its redox chemistry.

Our general strategy for synthesizing compounds of the type W(≡CArC≡CH)L_4X is to begin with readily prepared unsymmetrical diynylarenes (RC≡CArC≡CR′) into which the organic functionality of importance to the properties of the final compound is preincorporated, thus minimizing the number of reaction procedures necessary once the metal center is present. The terminal C≡CH unit of the target compound is masked in the starting diynylarene by a protecting R group that is sufficiently sterically demanding to prevent alkyne metathesis at the adjacent C≡C bond. The synthetic procedure for **4** using this approach is outlined in Scheme 1. For this compound the unsymmetrical diynylarene is *p*-$Pr^nC{\equiv}CC_6H_4C{\equiv}CSiPr^i_3$, which undergoes metathesis with $W_2(OBu^t)_6$[12] exclusively at the propynyl C≡C bond to give W(≡CC_6H_4C≡C$SiPr^i_3$-4)$(OBu^t)_3$ **1**.‡ Reaction of **1** with BCl_3 and dme,[10] provides W(≡CC_6H_4C≡C$SiPr^i_3$-4)Cl_3(dme) **2**,‡ which undergoes two-electron reduction by Na/Hg amalgam in the presence of dmpe to give W(≡CC_6H_4C≡C$SiPr^i_3$-4)$(dmpe)_2$Cl **3**.‡ The target terminal ethynyl derivative **4** is then obtained by protodesilylation of **3** with $[NBu^n_4]F{\bullet}xH_2O$.‡



Scheme 1 *Reagents:*‡ i, 0.5 $W_2(OBu^t)_6$; ii, 3 BCl_3, dme (excess); iii, 2 dmpe, 2 Na/Hg; iv, $[NBu^n_4]F{\bullet}xH_2O$ (excess).

Compound **4** can be incorporated into extended unsaturated organic frameworks by functionalization at both the metal center and the terminal ethynyl moiety. A survey of representative reactions at these loci is presented in Scheme 2. Crucially, the fingerprint spectroscopic parameters of the ethynyl moiety (^{1}H NMR δ 2.92, $\nu_{C\equiv C}$ 2099 cm^{-1}) indicate that it is not strongly electronically perturbed relative to phenylacetylene (δ 2.93,



Scheme 2 *Reagents and conditions*: i, $Li[N(SiMe_3)_2]$ (1 equiv.), THF, –78 °C (10 min), MeI (excess), 0 °C (2 h); ii, *p*-$IC_6H_4Bu^t$ (1 equiv.), $PdCl_2(PPh_3)_2$/CuI (cat.), NEt_2H, 25 °C (5 h); iii, $SiMe_3(OTf)$ (1 equiv.), toluene, 25 °C (1 h); iv, LiC≡CC_6H_4Me-4 (1 equiv.), DME, 0 °C (1 h), 25 °C (1 h); v, $[C_7H_7][PF_6]$ (1 equiv.), CH_2Cl_2–MeCN (1 : 1), 0 °C (1 h).

† Dedicated to Professor Warren R. Roper on the occasion of his 60th birthday.

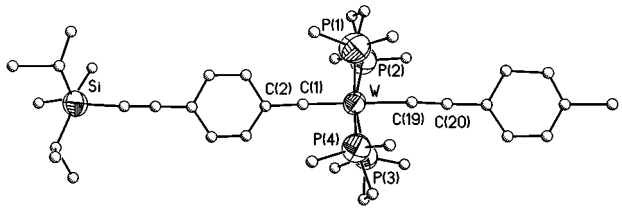


Fig. 1 Structure of W(≡CC_6H_4C≡CSiPr^i_3-4)$(dmpe)_2$(C≡CC_6H_4Me-4) **7**. Atoms are represented by spheres of arbitrary size (C) or thermal ellipsoids drawn at the 50% probability level (W, P, Si). Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): W–C(1) 1.93(3), W–C(19) 2.11(3), W–P_{av} 2.42[1]; C(1)–W–C(19) 179.3(12), C(20)–C(19)–W 174(3), C(1)–W–P_{av} 95.0(9), C(2)–C(1)–W 175(2).

2109 cm^{-1}) by the *p*-C≡W$(dmpe)_2$Cl group, and, thus, that its characteristic reactivity should be preserved. Consistent with this hypothesis, the ethynyl group of **4** can be deprotonated with Li[$N(SiMe_3)_2$] and subsequently methylated with MeI to give W(≡CC_6H_4C≡CMe-4)$(dmpe)_2$Cl **5**.‡ More importantly, the ethynyl group participates in Pd-catalyzed cross-coupling reactions with aryl halides: the reaction between **4** and *p*-$IC_6H_4Bu^t$ under standard conditions produces W[≡CC_6H_4(C≡$CC_6H_4Bu^t$-4)-4]$(dmpe)_2$Cl **6**‡ in nearly quantitative yield. At the tungsten center, substitution of the chloride ligand by unsaturated hydrocarbyl ligands can also be readily achieved. Treatment of **3** with $Me_3Si(OTf)$ to yield W(≡CC_6H_4C≡CSiPr^i_3-4)$(dmpe)_2$(OTf) followed by reaction with LiC≡CC_6H_4Me-4 provides W(≡CC_6H_4C≡CSiPr^i_3-4)$(dmpe)_2$(C≡CC_6H_4Me-4) **7**.‡ The structure of **7** (Fig. 1) is not of sufficient quality to provide quantitative insights but is interesting for the fact that it reveals that the phenyl rings are nearly coplanar, consistent with extended π conjugation in this compound.

In addition to the reaction chemistry of **3** and **4** that allows extension of their unsaturated frameworks, these compounds can be cleanly oxidized by one electron ($E_{1/2} \cong -0.8$ V *vs.* $FeCp_2^{0/+}$ in THF);[11b] accordingly, the reaction between **3** and [C_7H_7][PF_6] provides orange [W(≡CC_6H_4C≡CSiPr^i_3-4)$(dmpe)_2$Cl][PF_6] (**3**[PF_6], Scheme 2).‡ The molecular structure of **3** (unpublished results) is very similar to that of closely related [W(≡CPh)$(dmpe)_2$Br]$^+$[13] and we presume that it, too, possesses a $(d_{xy})^1$ electron configuration.

The electronic spectra of **3**–**7** indicate that their π-electron systems are extensively delocalized. These spectra exhibit characteristic bands attributable to the $(d_{xy})^2 \rightarrow (d_{xy})^1(d_{xz},d_{yz})^1$ [n→π*(W≡CR)] transition[13,14] as the lowest-energy features. This band strongly red shifts as unsaturated moieties are added to the alkylidyne ligand or to the axial site of the metal. Specifically, as the *para*-substituent on the alkylidyne ligand is changed from H [W(≡CPh)$(dmpe)_2$Cl] to C≡CSiPr^i_3 (**3**) to C≡$CC_6H_4Bu^t$-4 (**6**) the n→π* band shifts progressively to lower energy (19230, 16780 and 16500 cm^{-1}, respectively). Similarly, replacing the axial chloride ligand of **3** with C≡CC_6H_4Me-4 (**7**) results in a red shift of the n→π* band from 16780 to 15870 cm^{-1}. These red shifts must be attributed to a lowering of the energy of the π* LUMO as a result of extending the π-system, since the d_{xy} orbital is nonbonding (δ symmetry) with respect to the σ and π frameworks of the backbone.

The reactivity and physical properties of **4** suggest that this compound and its relatives should be important building blocks for new classes of poly(aryleneethynylene)s with expanded optical and redox functionality. There are no obvious reasons why the metathesis-based synthetic procedure reported here should not also yield building blocks with other aryl hubs (which are incorporated at the alkyne-metathesis step) or equatorial ligands [which are added in the course of the reduction of W(≡CArCCR)Cl_3(dme)], thus providing a high level of control over their physical properties. We are presently exploring the syntheses of such compounds.

We thank the National Science Foundation for supporting this research (Grant CHE-9700451). K. D. J. acknowledges support from Andrew W. Mellon and Lubrizol fellowships.

Novel glycosylidene-spiro-heterocycles from unprecedented solvent incorporation in Koenigs–Knorr-like reactions of *C*-(1-bromo-1-deoxy-β-D-glycopyranosyl)formamides

László Somsák,* László Kovács, Viktor Gyóllai and Erzsébet Ősz

Department of Organic Chemistry, Lajos Kossuth University, Debrecen, POB 20, H-4010 Hungary. E-mail: somsak@tigris.klte.hu

Received (in Liverpool, UK) 4th January 1999, Accepted 22nd February 1999

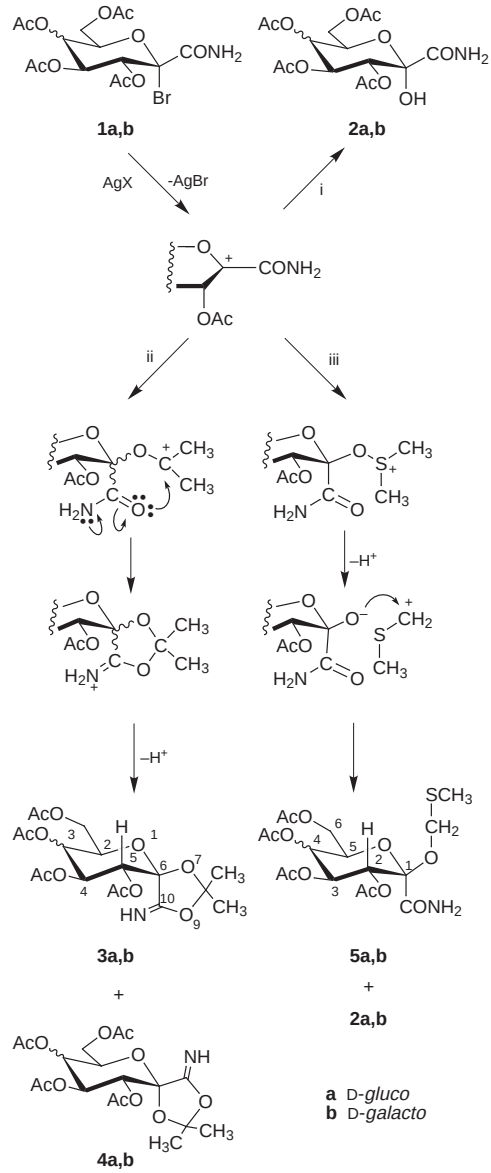
The title compounds give glycopyranosylidene-spiro-dioxolanes 3 and 4 in acetone and *C*-(1-methylsulfanylmethoxy-α-D-glycopyranosyl)formamides 5 in DMSO in the presence of Ag_2CO_3 and AgF, respectively.

As part of an ongoing program to synthesize new anomerically bifunctional monosaccharide derivatives[1–3] as glycomimetics and their precursors we have investigated the reactions of acetylated *C*-(1-bromo-1-deoxy-β-D-glycopyranosyl)formamides (**1a**[3] and **1b**[4]) with nucleophiles under Koenigs–Knorr conditions.[5] While reaction of **1a**,**b** with 1 equiv. of water in DMSO in the presence of Ag_2O (Scheme 1) gave the expected hydroxyformamide derivatives **2a**,**b** in a crystalline state[6] [**2a**: 85%, mp 177–179 °C, $[\alpha]_D$ +36 ($CHCl_3$, *c* 1.03); **2b**: 89%, mp 143–144 °C, $[\alpha]_D$ +53 ($CHCl_3$, *c* 1.0)], a similar transformation of **1b** in acetone[7] produced the spiro compound **3b** in addition to **2b** (ratio ~1:1 by ^1H NMR spectroscopy). Using dry acetone with Ag_2CO_3 gave **3a**,**b** [**3a**: 78%, mp 165–167 °C, $[\alpha]_D$ +21 ($CHCl_3$, *c* 1.0); **3b**: 71%, mp 155–157 °C, $[\alpha]_D$ +31 ($CHCl_3$, *c* 1.0)] and small amounts of **4a**,**b** [**4a**: 6%, syrup, $[\alpha]_D$ +39, ($CHCl_3$, *c* 2.06); **4b**: 4%, syrup, $[\alpha]_D$ +57, ($CHCl_3$, *c* 1.06)] and **2a**,**b** (~5% for each) after chromatographic separation. Carrying out the reaction in dry DMSO with AgF the methylsulfanylmethoxyformamides **5a**,**b** [**5a**: 11%, syrup, $[\alpha]_D$ +21 ($CHCl_3$, *c* 1.03); **5b**: 15%, mp 155–156 °C, $[\alpha]_D$ +29 ($CHCl_3$, *c* 1.07)] could be isolated as minor products over **2a**,**b**. Experiments with **2a** showed that this compound was unchanged after one day when dissolved in acetone or DMSO either in the absence or presence of Ag_2CO_3 or AgF, respectively.

Structure elucidation† of **3**–**5** was performed by NMR (Tables 1 and 2) and MS measurements. Incorporation of acetone in **3** and **4** was indicated by a molecular ion (*m/z* 431, M^+ for each) and by two methyl singlets. The presence of one exchangable proton belonging to an sp^2-hybridized nitrogen as shown by $^{15}N/^1H$ HSQC experiments, and carbon resonances indicative of an imino ether moiety (C-10) as well as for an acetal carbon (C-8) are in accordance with the cyclic stuctures. For each derivative the vicinal proton–proton couplings showed that the sugar rings existed in the $^4C_1$ conformation. The configuration of the spiro carbons was established by the three bond heteronuclear coupling between H-5 and C-10, indicating antiperiplanar arrangement for the nuclei involved in the given conformation (see Scheme 1). This was corroborated by the characteristic downfield shifts of the sugar protons *cis* to C-10 (H-2 and H-4 in **3a**,**b**, H-5 in **4a**,**b**) following a rule established recently for glycopyranosylidene-spiro-hydantoin derivatives.[2] This effect, which is a further indirect proof of the spirocyclic structure, is attributed to the shielding anisotropy contribution of the C=NH bond which occupies a fixed position with respect to the sugar ring.

Compounds **5** had a fragment ion (*m/z* 407, $[M - CONH_2]^+$ for each) and characteristic resonances for a $CONH_2$ group and a OCH_2SCH_3 moiety. The anomeric configurations followed from the $^3J_{H\text{-}2,CONH_2}$ couplings indicating the *trans*-diaxial relationship of the two nuclei in the $^4C_1$ conformation.

Based on the experimental data available at present we think that formation of these derivatives of novel structure can most probably be explained by participation of the solvents used. The first step probably common for each transformation may be the generation of a glycosylium ion destabilized by the electron-withdrawing $CONH_2$ substituent. This intermediate can com-



Scheme 1 *Reagents and conditions*: i, AgX = Ag_2O (1 equiv.), DMSO, H_2O (1 equiv.), 3 h, room temp.; ii, AgX = Ag_2CO_3 (1 equiv.), dry acetone, 18 h, room temp., N_2; iii, AgX = AgF (1.5 equiv.), dry DMSO, 0.5 h, room temp.

bine with a nucleophilic molecule present in the reaction mixture, *i.e.* water, acetone or DMSO. While deprotonation of the species obtained after combination of the glycosylium ion with a water molecule leads to the stable molecule **2**, the alkoxydimethylsulfonium intermediate (from combination with DMSO) may be deprotonated at one of the methyl groups to give **5** after a Pummerer-type rearrangement.[8] The intermediate (from combination with acetone) may be stabilized by an attack of the oxygen of the $CONH_2$ group at the positively charged carbon. The cyclic structure formed in this step can be deprotonated at the iminium moiety to result in the spirocyclic compounds **3** and **4**.

To the best of our knowledge similar solvent participation and incorporation is only known with some nitriles (mainly acetonitrile) in the sugar series.[9,10] These new, simple reactions provide ready access to novel glycopyranosylidene-spiro-heterocycles **3** and **4** that can be regarded as analogues of sugar spiro-hydantoin derivatives with important biological effects (see references in ref. 2) as well as to compounds of type **5** that can be useful orthogonally protected synthetic intermediates. The scope and limitations of the reported transformations are currently being investigated in our laboratory.

Instituto de Tecnología Química (UPV-CSIC), Avda. los Naranjos, s/n, 46022, Valencia, Spain. E-mail: itq@upvnet.upv.es

Received (in Cambridge, UK) 13th January 1999, Accepted 23rd February 1999

Quaternary organic tetraalkylammonium hydroxide grafted on MCM-41 is a strong Brønsted base catalyst, and represents a useful alternative to soluble bases in reactions such as Knoevenagel condensations, Michael additions and aldol condensations because of their high catalytic activity under mild conditions, and good stability.

The development of environmentally friendly solid catalysts for the production of fine chemicals is becoming an area of growing interest, and recyclable solid base catalysts are needed. Alkali ion-exchanged zeolites,[1,2] sepiolites,[3] alkaline oxides supported on microporous [4,5] and mesoporous aluminosilicates,[6] alkaline earth solids such as magnesium oxide,[7] aluminium–magnesium mixed oxides derived from hydrotalcites[8] and organic resins[9] can cover a wide range of basic strengths. The recently discovered family of mesoporous MCM-41 materials, with the possibility of being prepared with a wide range of pore dimensions, provides a unique inorganic support for introducing basic sites in a post-synthesis step and expanding the possibilities of the above described solid catalysts. Indeed, the reported anchored amines on MCM-41,[10] *e.g.* the immobilized 1,5,7-triazabicyclo[4.4.0]dec-5-ene on MCM-41,[11] have been shown to be efficient base catalysts. However, excluding anionic resins, the basicity of the solid inorganic catalysts developed up to now is associated with Lewis sites, and there is a need for stable catalysts containing Brønsted basic sites.

Here we report the preparation of a strong Brønsted basic catalyst obtained by preparing an inorganic–organic composite formed by an organic ammonium quaternary salt anchored on the surface of pure silica MCM-41. The truly catalytic behaviour of this material as well as the recycling characteristics is shown for Knoevenagel condensations, Michael additions and aldol condensations.

Pure silica MCM-41 with 3.7 nm pore diameter was synthesised following a well-known method from the literature.[12]

The functional tetraalkylammonium groups were anchored on the Si-MCM-41 surface by reacting 3-trimethoxysilylpropyl(trimethyl)ammonium chloride ($SiNR_4Cl$) with hydroxy groups located at the surface. This was achieved by contacting the dehydrated MCM-41 material with a solution of the appropriate amount of $SiNR_4Cl$ (provided by ABCR GMBH, 50 wt% in MeOH) in $CHCl_3$. This slurry was stirred for 1 h to allow the $SiNR_4Cl$ to diffuse inside of the pores. Then, Et_3N (molar ratio $Et_3N/SiNR_4Cl = 2$) in $CHCl_3$ was added to the above slurry. The final liquid/solid mass ratio was 20. The reaction was performed for 12 h and functionalized MCM-41 was obtained by filtration, exhaustive washing with $CHCl_3$ and CH_2Cl_2 and drying at 60 °C overnight. The MCM-41 structure was preserved.

The exchange of chloride by hydroxide anions was carried out by contacting the functionalized MCM-41 samples with a 0.21 M methanolic solution of NMe_4OH at room temperature for 10 min using a liquid/solid mass ratio of 50. The solid was recovered by filtration and extensively rinsed with MeOH, followed by vacuum drying, and the MCM-41 structure was preserved. The degree of exchange was calculated by titration of the NMe_4OH solution after exchange. The OH/N ratio found for all samples was close to 1. ^{29}Si MAS NMR spectroscopy and elemental analysis of the catalysts in the chloride and hydroxide forms show that no leaching of the anchored tetraalkylammonium occurs during the anionic exchange of chloride by hydroxide anions.

Table 1 Knoevenagel condensation between benzaldehyde **1** (10 mmol) and ethyl cyanoacetate **2a** (8 mmol) in the presence of MCM-41OH (80 mg) at 60 °C under N_2

Catalyst	Anchored NMe_4OH[a]	Intial rate[b]/ 10^{-4}	TON[c]/ 10^{-3}	Yield of **3a**
MCM-41OH1[d]	1.22	17.8	1.45	88[e]
MCM-41OH2[d]	0.88	11.0	1.25	77[e]
MCM-41OH1[f]	1.22	217	17.8	95[g]
MCM-41OH2[f]	0.88	163	18.6	90[g]
NMe_4OH[f]	0.064[h]	208[i]	32.5	100[g]

[a] In millimoles of NMe_4OH per gram MCM-41. [b] In moles of product per minute per gram of catalyst. [c] Turn over number in moles of product per minute per millimole of NMe_4OH. [d] $CHCl_3$ as solvent (5 ml). [e] 2 h reaction time. [f] Without solvent. [g] 0.5 h reaction time. [h] NMe_4OH added (in mmol). [i] In mol min^{-1}.

MCM-41OH1 was tested as a basic catalyst for the Knoevenagel condensation of benzaldehyde **1** with ethyl cyanoacetate **2a**. The reaction progress was monitored by withdrawing aliquots which were analyzed by GC, and the products were identified by GC–MS. The reaction was carried out in $CHCl_3$ at 60 °C under nitrogen atmosphere using the conditions shown in Table 1. After 2 h the conversion of ethyl cyanoacetate was 88% with 100% selectivity for the condensation product **3a** (Scheme 1).

When the condensation was carried out under the same reaction conditions described above, but in the presence of an MCM-41 sample containing a different amount of anchored tetraalkylammonium quaternary salt (MCM-41OH2), it was possible to see that the initial rate was proportional to the amount of anchored tetraalkylammonium hydroxide (Table 1), indicating that a highly homogeneous strength distribution of basic sites is obtained on these catalysts and there is total accessibility of reactants to the active centres.

The condensation was also carried out without solvent under the reaction conditions described above, and the yield, initial rate and TON obtained are given in Table 1. When the Knoevenagel condensation was carried out using other active methylene compounds, *i.e.* phenylsulfonylacetonitrile **2b**, in the presence of MCM-41OH1 at 70 °C, the reaction was completed within 1 h with 100% selectivity for phenylsulfonylcinnamonitrile **3b**.

Scheme 1

Table 2 MCM-41OH1 as a catalyst for Michael reactions[a]

Entry	Donor	Acceptor	*T*/°C	*t*/h	Yield (%)[b]
1	Ethyl 2-oxocyclo-pentanecarboxy-late	Methyl vinyl ketone	20	1	85
2	Ethyl cyanoacetate	Methyl vinyl ketone	20	2	72 (30)
3	Ethyl cyanoacetate	Methyl vinyl ketone	60	1	58 (37)
4	Ethyl cyanoacetate	Cyclopentanone	80	2	50 (10)
5	Ethyl cyanoacetate	Cyclohexanone	80	2	35
6	Diethyl malonate	Methyl vinyl ketone	60	2	10

[a] Reaction conditions: 8 mmol of donor, 8 mmol of acceptor, 60 mg of catalyst, 2 ml MeCN under N_2. [b] Molar yield of double-addition product in parentheses.

For comparison purposes, the reaction between ethyl cyanoacetate and benzaldehyde was also carried out using NMe_4OH as a homogeneous basic catalyst (Table 1), and the initial rate per mmol of OH^- is almost twice than with the heterogeneous catalyst. Taking into account the fact that the accessibility of the reactants to the active sites on MCM-41 must be almost unrestricted, the smaller intrinsic activity shown by the heterogeneous catalyst could be explained by considering that the hydroxide group might be interacting with the remaining silanol groups located on the inner part of the MCM-41 channels.

Michael additions using different donor and acceptor substrates and requiring stronger basicities than Knoevenagel condensations were also carried out (Table 2). In all cases, products coming from side reactions such as rearrangements, dimerizations or other condensations were not observed, and extremely high selectivities for the 1,4-adduct can be achieved. This excellent selectivity must be attributed to the well-defined strong basicity of the MCM-41OH.

These results show that MCM-41OH is an efficient catalyst for Michael additions with acceptable yields and selectivities when working under mild conditions with large substrates. This is in contrast with other modified MCM-41 materials reported previously, such as Cs-MCM-41 materials, which only catalyse Michael reactions under much more drastic conditions,[6] or the MCM-TBD catalyst,[11] where the bulky immobilized 1,5,7-triazabicyclo[4.4.0]dec-5-ene reduces the pore size of the catalyst inducing a transition state shape selectivity or even limiting the accessibility of bulky reactants to the active sites.

MCM-41OH1 was also tested as a basic catalyst for the aldol condensation between benzaldehyde and 2′-hydroxyacetophenone (10 mmol and 8 mmol, respectively; 15 wt% relative to the catalyst). The solid was able to catalyse the successive aldol condensation and intramolecular Michael addition to flavanone in a solvent-free system at 130 °C. After 8 h reaction time a conversion of 65% with a selectivity of 78% for flavanone was obtained.

The MCM-41OH1 catalyst used in the Knoevenagel reaction between ethyl cyanoacetate and benzaldehyde in EtOH was reused three times, after Soxhlet extraction with CH_2Cl_2, and no leaching and/or deactivation of the catalyst was observed.

Our results prove that it is feasible to introduce strong Brønsted basic sites into the MCM-41 structure by anchoring tetraalkylammonium hydroxide salts. This new solid base catalyst is a useful alternative to soluble bases in reactions such as Knoevenagel condensations, Michael additions and aldol condensations because of its high catalytic activity under mild liquid phase conditions. The mechanical stability of the inorganic support materials ensures easy separation of the solid catalyst together with waste minimisation and the possibility of recycling.

First donor–acceptor interaction promoted gelation of organic fluids

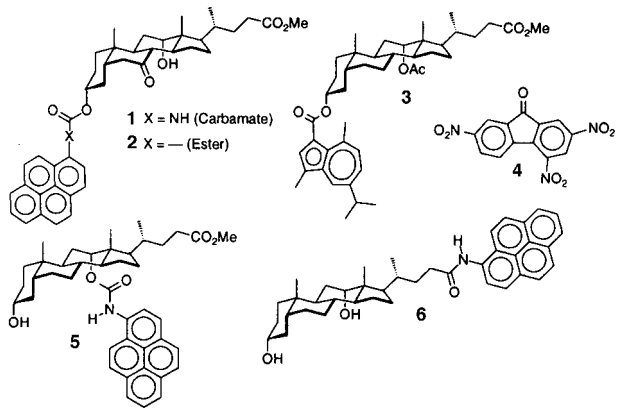
Received (in Cambridge, UK) 17th December 1998, Accepted 11th February 1999

Bile acid derivatives functionalized at the 3-position with an aromatic group formed gels in organic solvents in the presence of trinitrofluorenone.

In recent years there has been considerable interest in developing new types of gelators of organic solvents.[1] Despite the recent advances, *a priori* design of a gelator for gelling a given solvent has remained a challenging task. Various non-covalent interactions like hydrogen-bonding,[2] metal coordination[3] *etc.* have been used as the driving force for the gelation process. A special class of cholesterol-based gelators were reported by Weiss,[4] and by Shinkai.[5] Gels derived from these molecules have been used for chiral recognition/sensing,[6] for studying photo- and metal-responsive functions,[7] and as templates to make hollow fiber silica.[8] Other types of organogels have been used for designing polymerized [9] and reverse aerogels,[10] and in molecular imprinting.[11] Hanabusa's group has recently reported organogels with a bile acid derivative.[12] This has prompted us to disclose our results on a novel electron donor–acceptor (EDA) interaction mediated two-component[13] gelator system based on the bile acid[14] backbone.

During the course of our investigation on bile acid-based molecular tweezers[15] it was discovered that aromatic donor-substituted bile acid derivatives such as **1**–**3**† gelatinized certain organic solvents *in the presence of* trinitrofluorenone **4** as the acceptor.‡ Interestingly, the location of the pyrene unit on the bile acid appeared to be critical, as shown by compounds **5** and **6** which did not form gels in the presence of **4**. The results from the gelation studies are summarized in Table 1. Pyrene derivative **1** in general formed highly stable gels even with less than 1% of the gelator. Compound **4** in the presence of the methyl pyrene-1-carboxylate did *not* form a gel in BuOH and $CHCl_3$.



The stoichiometric requirement of the two components was easily established by measuring the T_{gel}[16] as a function of the ratio of **4**:**1** at a constant concentration of **1**. A steady increase of T_{gel} was observed with increasing amounts of **4** but after 1.25 equiv. were added there was no measurable increase, suggesting the requirement of a 1:1 stoichiometry for effective gelation. This experiment was also carried out in the reverse manner (constant concentration of **4** and variable concentration of **1**) with identical conclusion.

Table 1 Results from gelation studies[a]

Entry	Solvent	1/4	2/4	3/4
1	Bu^nOH	SG[b]	G	G
2	Bu^tOH	SG[b]	SG[b]	G
3	Bu^tOH–$CHCl_3$ (5:1 v/v)	G[c]	SG[c]	G
4	EtOH–$CHCl_3$ (3:1 v/v)	SG[b]	G[b]	G
5	Cyclohexanol	SG	SG	G
6	$CHCl_3$	G	S	S
7	*n*-Octanol	S	S	G
8	$(CH_2OH)_2$–$CHCl_3$ (3:1 v/v)	G	P	G
9	Trigol–$CHCl_3$ (3:1 v/v)	SG	P	G
10	Benzene	S	S	S
11	Cyclohexane	P	P	P
12	Cyclohexanone	S	S	S
13	$(CHCl_2)_2$	S	S	S

[a] SG = super gel (< 1 wt% gelator), G = gel (1–2 wt% of gelators), S = solution, P = precipitate. [b] These gels exhibited thixotrophy. [c] By changing the amount of $CHCl_3$ the T_{gel} could be increased or decreased.

The gels were dried in vacuum[5] and subjected to SEM analysis to examine the morphology.§ The SEM of a dried sample from **3**/**4** (Fig. 1) showed a complex three-dimensional fibrous structure with an average fiber diameter of *ca.* 2 μm. Such fibrous networks have been observed by many others, and appear to be characteristic of most gels. The SEM pictures from the xerogels derived from the other two systems did not show any obvious fibrous structure.

The gels formed from colorless **1** and **2** (and pale yellow **4**) are colored due to a charge-transfer band. The intensity of this band changes substantially during the gelation. The temperature dependence of this absorption band has been examined for **1** and **2** in $CHCl_3$ by UV-VIS spectroscopy (data for **1** are shown in Fig. 2). It is clear from this plot that the gelation process is associated with an increase in the donor–acceptor interaction because of the substantial increase in the charge transfer around

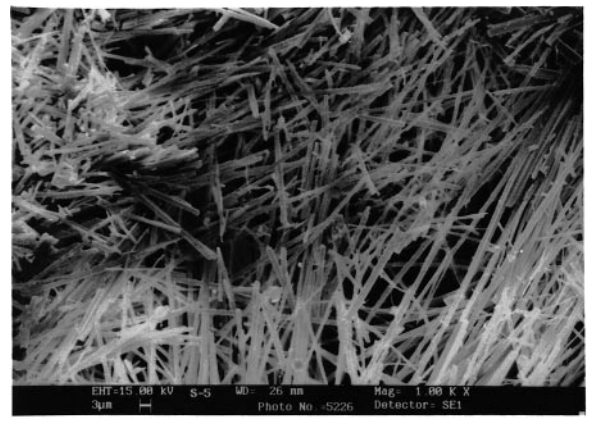


Fig. 1 Scanning electron micrograph of a dried gel derived from **3**/**4** in *n*-octanol (3% w/w) showing a fibrous network.

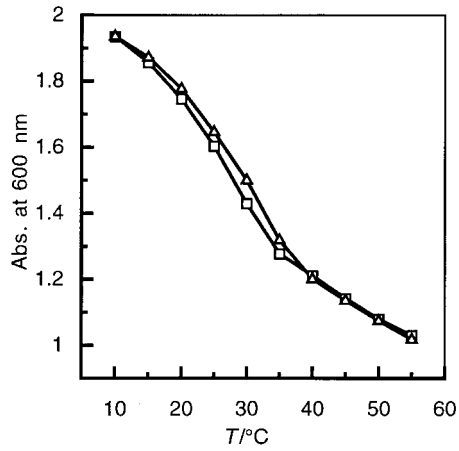

Fig. 2 Plot of A_{600} (1 mm cuvette) *vs.* temperature for gel obtained from **1** and **4** in $CHCl_3$ (62 mM each; this corresponds to 2.8% w/w of **1**): (□) cooling and (△) heating.

T_{gel}. With a true solution of **1** and **4** (in a 1 : 1 ratio) in $CHCl_3$ a monotonous increase in the absorbance was observed as the temperature was decreased in the same range. This, and the observation that no gelation occurs in the absence of **4**, suggest that the donor–acceptor interaction between the pyrene unit on the steroid and **4** is the primary driving force responsible for gelation.

Since **1** formed good gels in $CHCl_3$ (entry 6, Table 1), ^{1}H NMR spectroscopy was used to investigate the temperature dependence of the chemical shifts in $CDCl_3$. A 2.8 wt% sample was prepared in $CDCl_3$ and NMR spectra were recorded from 22 (gel) to 42 °C (fluid). Significant changes in chemical shifts were observed for the protons from **4** and the carbamate NH. A plot of the chemical shift against temperature for the C_3-H of **4** is shown in Fig. 3.[17] It is satisfying to observe that the T_{gel} determined from UV (35 °C) and NMR spectra (*ca.* 38 °C) of the same sample were comparable to that measured by the method of Takahashi *et al.*[16] (*ca.* 35 °C). The existence of hysteresis is also clear from this plot. It was also observed that the T_1 value (^{1}H) for the methoxycarbonyl group decreased from 1.48 s in the gel phase (3.8 wt %) to 1.08 s in the fluid phase (1.2 wt%) at 22 °C, suggesting reduced segmental motion of the sidechain in the gel in $CDCl_3$.

In conclusion, we have demonstrated for the first time a two-component organic gelator system which can gelatinize several organic fluids (primarily alcohols) through *donor–acceptor interaction*. The requirement of EDA for the gelation has been established from our studies, but the role of the bile acid backbone is yet to be uncovered. These systems are currently being extensively investigated to understand their structure–property relationships, three dimensional structures and material properties. We believe that these novel phases will expand our understanding of the gelation of organic fluids, and will also lead to the development of new materials for futuristic applications.[18]

A novel synthesis of chiral cyclopentyl- and cyclohexyl-amines

Pedro Pinho and Pher G. Andersson*

Department of Organic Chemistry, Uppsala University, Box 531, S-751 21 Uppsala, Sweden. E-mail: phera@kemi.uu.se

Received (in Liverpool, UK) 8th February 1999, Accepted 25th February 1999

A new route to multifunctionalised chiral cyclopentyl- and cyclohexyl-amines was developed by means of a new reaction involving the ring opening of a 2-azabicyclo-[2.2.1] or -[2.2.2] structure in high yields.

Functionalised chiral cyclopentylamines are of extreme importance in medicinal chemistry since this structural unit is present in a large number of antibiotics. The most interesting are amidomycin[1] and aristeromycin,[2] which have been shown to have antiviral properties, and carbovir[3] which is a promising antibiotic used for the treatment of AIDS[4] (Fig. 1).

We have previously reported our work on 2-azanorbornyl derivatives and their use in various reactions, *i.e.* copper-catalyzed allylic oxidation of olefins,[5a] ruthenium-catalyzed transfer hydrogenation of ketones,[5b] diethylzinc addition to both imines and aldehydes,[5c] borane reduction of ketones,[5d] rearrangement of *meso*-epoxides[5e] and preparation of cyclopentylglycine analogues.[5f] During research to modify the ligand structure, an interesting reaction was discovered that opens up a new, rapid route to substituted enantiomerically pure cyclopentylamines *via* a ring opening reaction of the bicyclic structure **A** [reaction (1)].

When attempting the preparation of the corresponding Grignard reagent of the bicyclic bromide **A**, an unexpected ring opening of the bicyclic structure occurred. Initially **C** was formed with the concurrent formation of another compound which was assigned to structure **B**. The 1 : 1 mixture of products (**B** : **C**) was inseparable by flash chromatography, but the compounds were assigned the structures displayed in reaction (1) by analysis of the spectral data of the mixture.

Despite the low selectivity, the novelty and usefulness of the ring opened product prompted us to optimize the conditions in order to favour its formation. Better results were obtained when the *N*-protecting PhEt group attached to the nitrogen in **A** was replaced by tosyl to give the corresponding tosylate **3** (Scheme 1). The electron-withdrawing properties of this group facilitate the ring opening reaction and the desired compound **4** was obtained in high yield as a single product.

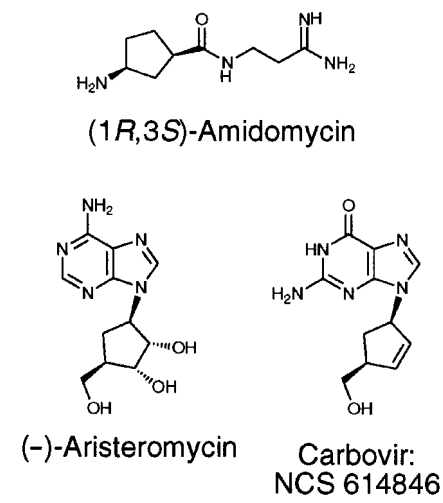

Fig. 1 Some examples of pharmaceutically active cyclopentylamines.

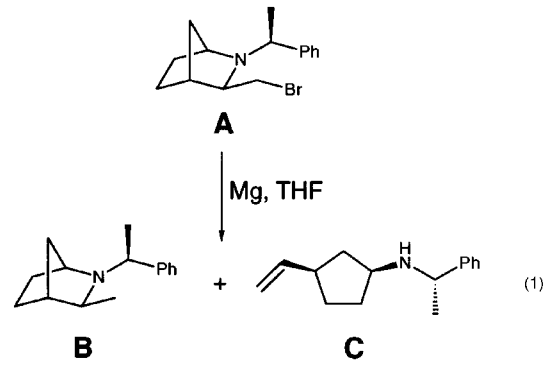
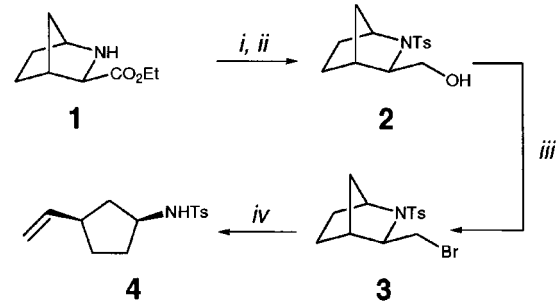


The synthetic route to the key intermediate **3** is outlined in Scheme 1. Compound **1** was obtained *via* a diasteroselective aza-Diels–Alder reaction between cyclopentadiene and the *in situ* generated imine ion of ethyl glyoxylate and (*S*)-1-phenylethylamine,[6,7] followed by simultaneous hydrogenation and hydrogenolysis to the corresponding free amino ester.[5c]

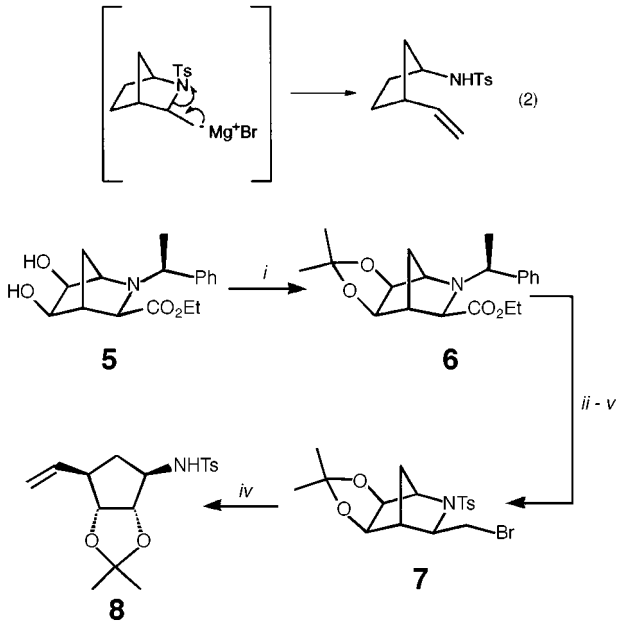
N-Tosylation and subsequent $LiAlH_4$ reduction of the ester functionality led to the alcohol **2**. The alcohol was then treated with CBr_4 and Ph_3P in CH_2Cl_2 to afford the key intermediate **3**. When treated with magnesium and tetrahydrofuran at reflux, the bicyclic bromide ring opened to give compound **4** *via* the mechanism outlined in reaction (2). Acid hydrolysis of the reaction mixture and purification of the crude residue by flash chromatography furnished the desired ring opened product in high yield.

This new methodology could also be extended to other derivatives of the 2-azanorbornyl structure. Catalytic dihydroxylation of the Diels–Alder adduct (used for the synthesis of **1**) with OsO_4 in the presence of NMO as a co-oxidant in *tert*-butyl alcohol at room temperature afforded diol **5** (Scheme 2).

Protection of diol **5** as the corresponding ketal was achieved by treatment with 2,2-dimethoxypropane and toluene-*p*-sulfonic acid in warm MeOH. Formation of product **6** required the use of slightly more than one equivalent of the acid probably due to protonation of the amine functionality, and under these conditions the reaction was completed in *ca.* 15 minutes. Solvent evaporation followed by addition of 20% aqueous NaOH and extractive work-up afforded the pure protected diol **6**. This product was treated with ammonium formate in EtOH at



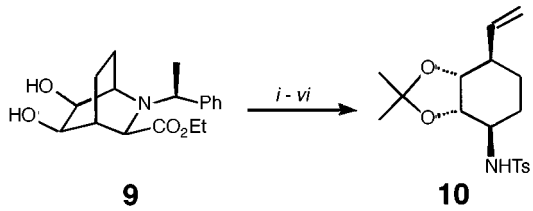
Scheme 1 *Reagents and conditions*: (i) TsCl, Et_3N, CH_2Cl_2 rt, overnight, 92%; (ii) $LiAlH_4$, THF, rt, 2 h, 95%; (iii) CBr_4, Ph_3P, CH_2Cl_2, rt, 24 h, 60%; (iv) Mg, $BrCH_2CH_2Br$, THF, reflux, 24 h, 90%.



Scheme 2 *Reagents and conditions*: (i) $(MeO)_2C(CH_3)_2$, TsOH, warm MeOH, 15 min, 87%; (ii) ammonium formate, Pd/C (10%), EtOH, reflux, 1 h, 99%; (iii) TsCl, Et_3N, CH_2Cl_2, rt, overnight, 90%; (iv) $LiAlH_4$, THF, rt, 2 h, 92%; (v) CBr_4, Ph_3P, CH_2Cl_2, rt, 24 h, 59%; (vi) Mg, $BrCH_2CH_2Br$, THF, reflux, 32 h, 89%.

reflux in the presence of Pd/C (10%) to afford the corresponding free amino ester, and then submitted to the same synthetic sequence as described for **1** to yield the corresponding bromide **7**. Compound **7** ring opened to give product **8** under the conditions described for **3**, albeit in a slightly slower reaction.

By simply using cyclohexa-1,3-diene in the aza-Diels–Alder reaction, a bicyclic [2.2.2] structure was obtained.[6] Dihydroxylation of the purified adduct under the conditions described earlier yielded compound **9** (Scheme 3) which, when submitted to the same synthetic sequence as **5**, yielded the ring opened product **10**.[8] The yields for the transformation of **9** into **10** were similar to those obtained in the transformation of **5** into **8**.[9]



Scheme 3 *Reagents and conditions*: (i) $(MeO)_2C(CH_3)_2$, TsOH, warm MeOH, 15 min, 87%; (ii) ammonium formate, Pd/C (10%), EtOH, reflux, 1 h, 99%; (iii) TsCl, Et_3N, CH_2Cl_2, rt, overnight, 91%; (iv) $LiAlH_4$, THF, rt, 2 h, 94%; (v) CBr_4, Ph_3P, CH_2Cl_2, rt, 24 h, 62%; (vi) Mg, $BrCH_2CH_2Br$, THF, reflux, 32 h, 85%.

This work opens up a new route to cyclopentyl- and cyclohexyl-amines *via* a novel ring opening reaction of [2.2.1] and [2.2.2] azabicyclic structures. The fact that the [2.2.2] structure ring opens without increased difficulty indicates that the reaction is not only a consequence of ring strain on the [2.2.1] system.

We thank the Swedish Natural Research Council (NFR), The Swedish Foundation for Strategic Research (SSF), The Swedish Research Council for Engineering Sciences (TFR) and Astra Arcus for generous financial support.

9 Representative spectroscopic and analytical data. (1*R*,3*S*)-1-Tosylamino-3-vinylcyclopentane (4). Magnesium metal (3.0 g, 123 mmol) was placed in a 50 mL two-neck round-bottom flask loaded with a magnetic bar. To one neck a condenser was adapted and to the other a septum. The system was evacuated and placed under argon, after which the magnesium was suspended in dry THF (3 mL). The stirring suspension was then set to reflux and a solution of compound **3** (6.0 g, 17 mmol) in dry THF (20 mL) was added in one portion *via* syringe. After stirring for 15 min a small amount of 1,2-dibromoethane was added to activate the magnesium and the mixture was heated at reflux for 24 h. The reaction was then cooled to 0 °C and quenched by addition of saturated NH_4Cl solution. After separation of the phases and extraction of the water phase with CH_2Cl_2, the combined organic layers were dried with magnesium sulfate. Solvent evaporation afforded a residue that was purified by flash chromatography to yield compound **4** (4.1 g, 15 mmol, 90%) as a white solid; mp 65–66 °C; R_f 0.11 (silica gel, pentane–ether: 80 : 20); $[\alpha]_D^{24} = -8.9$ (*c* = 1.0, CH_2Cl_2); $\nu(CH_2Cl_2)/cm^{-1}$ 3623, 3369, 2870, 1641, 1599, 1345, 1092, and 1047; $\delta_H(CDCl_3$, 400 MHz) 1.14–1.24 (1H, m), 1.38–1.45 (2H, m), 1.62–1.79 (1H, m), 1.80–1.90 (1H, m), 1.99–2.10 (1H, m), 2.34–2.42 (1H, m), 2.41 (3H, s), 3.57–3.63 (1H, m), 4.83–4.94 (2H, m), 5.65–5.75 (1H, m), 7.28 (2H, app. d, *J* 8.0), and 7.76 (2H, app. d, *J* 8.0); $\delta_C(CDCl_3$, 100 MHz) 21.5, 29.9, 32.6, 40.2, 41.8, 54.5, 113.1, 127.1, 129.6, 137.8, 141.9, and 143.2; *m/z* (EI) (rel. intensity) 264 (M^+, < 1%), 236 (25), 210 (13), 172 (14), 155 (62), 133 (44), 132 (36), 110 (41), 106 (17), 97 (12), 96 (43), 94 (13), 93 (25), 92 (35), 91 (100), 80 (21), 79 (17), and 65 (20) (Anal. First catalysis by corrole metal complexes: epoxidation, hydroxylation, and cyclopropanation

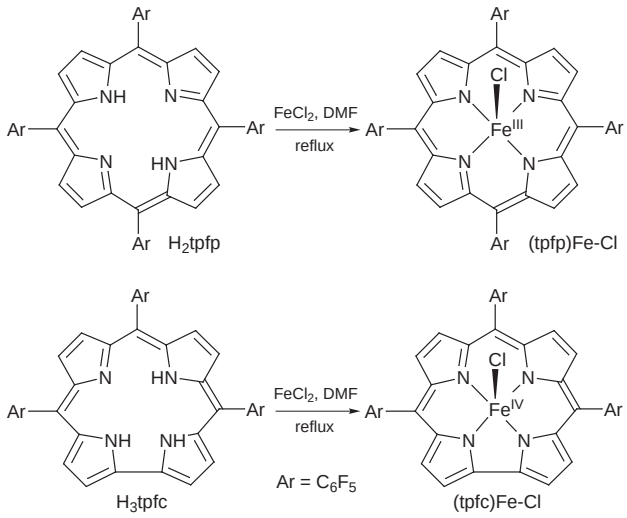
Zeev Gross,* Liliya Simkhovich and Nitsa Galili

Department of Chemistry, Technion - Israel Institute of Technology, Haifa 32000, Israel.
E-mail: chr10zg@tx.technion.ac.il

Received (in Cambridge, UK) 21st January 1999, Accepted 25th February 1999

The first ever application of corroles shows that their metal complexes are good catalysts, almost as potent as the corresponding metalloporphyrins in the oxygenation of hydrocarbons by iodosylbenzene and superior for the cyclopropanation of olefins by carbenoids.

Modified porphyrins have received increased attention in recent years, with emphasis on their syntheses, characterizations, and potential applications.[1] Some of these macrocycles form complexes with metal ions, which due to the alteration of the ligand's structure have quite different properties compared with the analogous metalloporphyrins.[2] The most interesting ligands in this respect are corroles, the one-carbon atom contracted porphyrin analogs, which may also be considered as the aromatic version of corrin—the cobalt's ligand in Vitamin B_{12}.[3] Similar to porphyrins, the corroles provide an equatorial tetradentate coordination plane, which is however trianionic and somewhat contracted (see Scheme 1). These last two properties have some remarkable effects on the coordination chemistry of corrole metal complexes (metallocorroles),[4] among which the stabilization of exceptionally high metal oxidation states is the most outstanding. The recent isolation of iron(IV) corroles[4a] and of an iron(IV) corrole radical[4b] could be relevant to catalysis by heme-enzymes and synthetic iron porphyrins, in which the analogous complexes are key intermediates.[5] But, there is still no information about corroles or their metal complexes in catalysis or in any other potential application. Presumably, it is only the lack of obvious procedures for the synthesis of corroles which prohibits such research. Thus, the first *meso*-substituted corrole—*meso*-aryl substitution is a prerequisite for a reasonable oxidation catalyst—was reported as late as 1993,[6] almost 30 years after the first reported corrole.[7] Also, in spite of the significant recent progress in corrole synthesis, even the most simple procedures reported to date require the preparation of non-commercially available starting materials.[8]

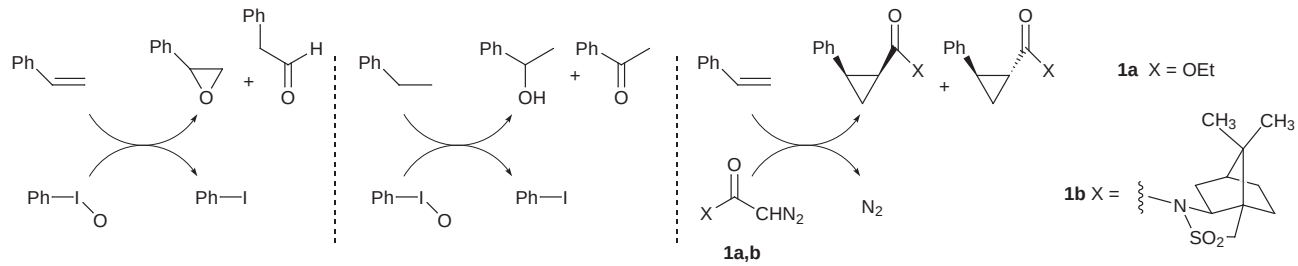


Scheme 1 Structures of *meso*-aryl substituted porphyrin and corrole, and of their iron complexes (note the different oxidation states of the metal).

We have very recently contributed to this field by disclosing the first synthesis of corroles by the direct reaction of pyrrole with aldehydes.[9] In particular, 5,10,15-tris(pentafluorophenyl)-corrole (H_3tpfc, Scheme 1) is now routinely prepared in our laboratory by this very simple and fast methodology. The structure of H_3tpfc is very similar to that of H_2tpfp, whose iron(III) complex is among the most active porphyrin-based catalysts.[10] Accordingly, we have now decided to compare the iron complexes of these two ligands as catalysts for the three main reactions catalyzed by metalloporphyrins.[11] These are the epoxidation of olefins and the hydroxylation of alkanes by iodosylbenzene, and the cyclopropanation of alkenes by carbenoids (Scheme 2).[12]

The results shown in Table 1 clearly demonstrate that (tpfc)Fe–Cl is a good catalyst in all three reactions. Still, it is not as effective as (tpfp)Fe–Cl for the epoxidation and hydroxylation of hydrocarbons. This is reflected in the higher yields of oxygenation products with (tpfp)Fe–Cl, as well as from the fact that at the end of the reactions the corrole complex, but not the analogous porphyrin complex, is completely bleached. However, for the cyclopropanation of styrene by **1a** (Scheme 2), (tpfc)Fe–Cl is superior. In addition, the catalyst is stable under the cyclopropanation conditions.

These results are reasonably accounted for by considering the proposed key intermediates in these processes, metal–oxo in oxygenation and metal–carbene in cyclopropanation.[5,12] It is well known that for iron(III) porphyrins, oxygen atom transfer from iodosyl benzene results in an oxoiron(IV) porphyrin radical intermediate, whose protection against self-destruction relies on the steric crowding of the four *meso*-aryl groups. By analogy, the oxygenation of (tpfc)Fe–Cl—an iron(IV) complex—will lead to an even more reactive intermediate. In addition, the



Scheme 2 Three catalytic transformations examined with (tpfc)Fe–Cl and (tpfp)Fe–Cl as catalysts.

Table 1 A comparison of (tpfc)Fe–Cl and (tpfp)Fe–Cl as catalysts for the processes shown in Scheme 1 with **1a**

(tpfc)Fe–Cl	71	1.8	41	0.9	25 (*1S,2S*)	66 (*1S,2R*)
(tpfc)Co–PPh_3	8	2.1	[d]			
(tpfc)Rh–PPh_3	87	2.0	56	1.0	60 (*1R,2R*)	10 (*1S,2R*)

[a] 0.25–0.28 mM catalyst, catalyst : **1** : styrene = 1 : 100 : 1000, in 2 mL CH_2Cl_2, at RT under Ar. [b] Combined yields of the *trans*- and *cis*-cyclopropyl esters after 1 h, except for (tpfc)Co–PPh_3 (24 h). With (tpfc)Fe–Cl and (tpfc)Rh–$P(Ph)_3$, the reactions are complete after 1 h (the rest of **1a** is transferred into its dimerization products), while with (tpfp)Fe–Cl the reaction continues (43% yield after 3 h). [c] Combined yields of the *trans*- and *cis*-isomers after 24 h, except for (tpfp)Fe–C1 (48 h). [d] Not determined.

absence of the fourth aryl ring in (tpfc)Fe–Cl leads to reduced steric protection. Accordingly, the lower efficiency and the greater bleaching of (tpfc)Fe–Cl during catalysis may be rationalized on both electronic and steric grounds, whose relative importance still needs to be resolved. On the other hand, both factors seem to be beneficial for the cyclopropanation process. It is known that the active oxidation state in catalysis by iron(III) porphyrins is iron(II), which for (tpfp)Fe–Cl is formed *via* reduction by **1a**.[13] Thus, the results suggest that the reduction of the iron(IV) corrole is easier and that the absence of the fourth aryl group is favorable for formation of the relatively large metal–carbene intermediate. The last effect is also reflected in the relatively small *trans* : *cis* ratio of the cyclopropyl esters, 2.3 with (tpfc)Fe–Cl *vs.* 5.7 with (tpfp)Fe–Cl.

Because of the superiority of (tpfc)Fe–Cl in cyclopropanation catalysis, we turned our attention to other metal complexes of H_3tpfc, as well as to the unichiral carbenoid **1b**.[14,15] Table 2 summarizes the results of the reaction of styrene with **1a** and **1b**, catalyzed by (tpfp)Fe–Cl, (tpfc)Fe–Cl, (tpfc)Co–$P(Ph)_3$, and (tpfc)Rh–$P(Ph)_3$. Several aspects are clearly evident. First, the larger activity of the iron corrole relative to the analogous porphyrin in cyclopropanation by **1a** is further amplified in the reaction with the much bigger **1b**. Secondly, within the series of the corrole metal complexes the catalytic efficiency increases in the order of Co << Fe < Rh, similar to what is obtained with metalloporphyrins.[13] Finally, quite low *trans* : *cis* ratios are obtained for all metallocorroles, together with modest diastereomeric excesses (% de) in the reactions with **1b**. By analogy to our recent studies with the related metalloporphyrins,[14a] we anticipate that a significant increase in diastereoselectivity might be achieved by utilizing metal complexes of corroles with larger *o*-phenyl substituents. We have one such derivative,[9] but we still have to improve the synthetic methodology for its preparation.

In conclusion, this is the first report of catalysis by corrole metal complexes, and actually the first ever application of corroles. We have demonstrated that metallocorroles are good catalysts for the reactions which are traditionally investigated with metalloporphyrins. We trust that these promising preliminary results will encourage further exploration of the chemistry of corroles and their metal complexes.

Received (in Cambridge, UK) 6th January 1999, Accepted 26th February 1999

The well defined, conveniently accessible and coordinatively unsaturated allenylidene complexes [$RuCl_2$(=C=C=CPh_2)(PCy_3)$_2$] and [Ru_2Cl_4(=C=C=CPh_2)(PCy_3)(η-$MeC_6H_4Pr^i$-4)] are highly effective catalysts for the ambient temperature ring-closure metathesis of α,ω-dienes and dienynes, illustrated by the facile and high yielding formation of variously functionalised 5, 6, 7, 8, 15, 16 and 18 membered mono- and bi-cyclic ring systems.

The advent of Grubbs' catalysts [$RuCl_2$(=CHR)(PR'_3)$_2$] (R = Ph, CH=CPh_2; R′ = Ph, Cy)[1] has revolutionised alkene metathesis technology by offering a combination of functional group tolerance, high activity and catalyst durability. The rapid embrace of these catalysts as tools for organic fine chemicals synthesis has been truly remarkable.[2] The possibility that complexes of unsaturated 'C_1' ligands other than alkylidenes might also serve as pre-catalysts has however received considerably less attention. Recent key observations which however presage a significant role for such ligands include (i) the demonstration that vinylidene complexes may catalyse the ring-opening metathesis polymerisation (ROMP) of strained cyclic olefins,[3] and (ii) the report by one of us of a coordinatively saturated allenylidene complex [RuCl(=C=C=CPh_2)(PCy_3)(η-$MeC_6H_4Pr^i$)]$^+$ serving as a pre-catalyst for the ring-closure of α,ω dienes.[4] The actual nature of the true catalyst(s) in this latter system is open to conjecture, given that the catalysis only proceeds at elevated temperatures. It has been shown that the pre-catalyst may be activated by prior photolysis, possibly inducing arene dissociation, although subsequent heating is still required.[5] Some insight into the possible identity of the active species has been provided by our recent demonstration that the product mixture obtained from the reaction of [Ru_2Cl_4(η-$MeC_6H_4Pr^i$)$_2$] with HC≡$CCPh_2$OH and PCy_3 under the conditions of catalysis (toluene, 80 °C) includes the coordinatively unsaturated allenylidene complexes [$RuCl_2$(=C= C=CPh_2)(PCy_3)$_2$] **1** and [Ru_2Cl_4(=C=C=CPh_2)(PCy_3)(η-$MeC_6H_4Pr^i$-4)] **2**.[6] Although prior to our report there were no known examples of coordinatively unsaturated allenylidene complexes of group 8 metals,[7] complex **2** is related to the binuclear benzylidene complex [Ru_2Cl_4(=CHPh)(PCy_3)(η-$MeC_6H_4Pr^i$-4)] reported by Grubbs,[8] whilst complex **1** represents the allenylidene analogue of Grubbs' mononuclear catalyst. Complexes **1** and **2** are conveniently prepared in high yield *via* the synthetic sequence illustrated in Scheme 1.[6] With these complexes readily in hand, we wish to report herein, results of our ongoing study of their catalytic efficacy for alkene metathesis processes.

Table 1 summarises representative ring-closure processes mediated effectively by both the mononuclear complex **1** and the binuclear derivative **2**, according to a general procedure outlined below.† To summarise the salient features which emerge: (i) In contrast to previous results with the salt [RuCl(=C=C=CPh_2)(PCy_3)(η-$MeC_6H_4Pr^i$-4)]PF_6,[4] all cyclisations proceed at room temperature and in high to excellent yield, with no need for photolytic pre-activation. (ii) Both catalysts are highly tolerant of functional groups including sulfonamide, ester, bromide, ether, siloxane, amide and fluorenylmethoxycarbonyl substituents. (iii) Both catalysts are suitable for the preparation of buta-1,3-dienes *via* the ring-closure of dienynes. (iv) Five, six, seven, eight, fifteen, sixteen and eighteen membered mono and bicyclic ring systems have been successfully prepared. These include the precursors to Exaltolid®, a musk odored perfume ingredient[9] and epilachnene, an insect repellant alkaloid isolated from the pupae of a Mexican beetle.[10] (v) In general the binuclear catalyst **2**, whilst effective, is slightly less active than the mononuclear complex **1**, requiring somewhat longer reaction times (Table 2) and providing comparable or marginally lower yields. This observation is noteworthy for two reasons: Firstly, by far the most expensive step in the preparative sequence (Scheme 1) involves the synthesis of **2** from **1**. Secondly, Grubbs has shown that for the ROMP of cycloocta-1,5-diene, the binuclear complex [Ru_2Cl_4(=CHPh)(PCy_3)(η-$MeC_6H_4Pr^i$-4)] shows a substantially greater activity (by a factor of *ca*. 20) than the mononuclear complex [$RuCl_2$(=CHPh)(PCy_3)$_2$];[8] (vi) The activities and yields observed for complex **1** suggest that it is equipotent to Grubbs' mononuclear benzylidene complex. This is mechanistically reassuring, in that following the initial cycle of catalysis, the propagating species would be expected to be identical for the two catalysts, *viz* the methylene complex [$RuCl_2$(=CH_2)(PCy_3)$_n$] (*n* = 1 or 2).

These results taken together illustrate that well defined coordinatively unsaturated allenylidene complexes provide an alternative route into the catalytic cycles which operate from the less conveniently accessible benzylidene complex [$RuCl_2$(=CHPh)(PCy_3)$_2$]. The study of synthetic approaches to allenylidene complexes, in particular those of ruthenium,[7] has matured considerably in recent times. Although **1** and **2** are, to

Self-assembly of a bis-tridentate Py_2S_4 ligand and cadmium cation into 1- and 2-D coordination networks†

Marielle Loï,[a] Ernest Graf,[a] Mir Wais Hosseini,*[a] André De Cian[b] and Jean Fischer[b]

[a] Laboratoire de Chimie de Coordination Organique and [b] Laboratoire de Cristallochimie et Chimie Structurale, Université Louis Pasteur, F-67000 Strasbourg, UMR CNRS 7513, France. E-mail: hosseini@chimie.u-strasbg.fr

Received (in Basel, Switzerland) 18th January 1999, Accepted 16th February 1999

Using a Py_2S_4 bis-tridentate ligand and Cd(II), 1- and 2-D coordination networks were obtained and characterised in the solid state; whereas a 1-D network was obtained using the cadmium(II) dichloride salt, a 2-D network was obtained using a mixed chloride and tetrafluoroborate cadmium(II) salt; in the latter case, the inclusion of two $CHCl_3$ molecules within cavities formed by the organic and inorganic fragments was observed.

For some time now, intensive research on the design and preparation of coordination networks or polymers has been performed.[1] Although, nearly all cases reported deal with bis- or tris-monodentate systems,[2] examples of coordination polymers using bis-bidentate ligands have also been published.[3,4] On the other hand, only a few examples of characterised systems based on bis-tridentate ligands are known.[5,6]

The formation of coordination networks in the crystalline phase takes place under self-assembly conditions which require, on one hand, the reversible formation of the assembling core by complexation processes and its translation and, on the other hand, the conformity to the packing forces within the crystalline phase. Thus, for simple coordination networks, the choice of the two partners (metal, ligand) is the dominant feature. For porous coordination networks, in addition to the two partners mentioned before, one should also take into account the guest molecules initially occupying the pores. Owing to the fact that tridentate centres form rather stable and non-labile complexes with transition metals, the choice of the metal and the ligand is not obvious and therefore, not many characterised examples are available so far.

Here, we report the synthesis of a new bis-tridentate ligand and its self-assembly into 1- and 2-D coordination polymers using Cd(II) cation.

The design of the linear bis-tridentate ligand **7** (Scheme 1) is based on a combination of two pyridine moieties and four thioether groups. The two tridentate ligands are interconnected by a phenyl ring. Examples of other bis-tridentate ligands have been reported.[7]

Dealing with the metal cation, it has been shown previously that **1** forms a binuclear Cd(II) complex in which the two metal centres are bridged by two Cl^- anions.[8] This type of doubly bridged metal system has been reported for Co(II)[6b] and for Ni(II) complexes.[9]

Scheme 1

† Dedicated to Professor John A. Osborn on the occasion of his 60th birthday.

The synthesis of **7** was achieved starting from chelidamic acid **2**, which was first transformed into **3**.[10] The latter was reduced to **4**.[11] $Pd(PPh_3)_4$ catalysed coupling reaction of **4** with 1,4-phenyldiboronic acid[12] in dry THF gave **5** in 65% yield. Bromination of the latter using 33% HBr–AcOH afforded **6** in 61% yield. Finally, the treatment of **6** with NaSMe in dry THF afforded **7** in 71% yield. The latter, in addition to spectroscopic methods, was characterised by X-ray crystallography.

Upon slow diffusion at room temp. of a MeOH solution containing $CdCl_2{\cdot}xH_2O$ into a $CHCl_3$ solution of **7** (1 : 1 ratio of Cd : **7**), colourless crystals were deposited after 24 h. The X-ray study‡ showed the following features (Fig. 1): the crystal **I** (monoclinic) was composed of **7**, Cd(II), Cl^- anions, $CHCl_3$ and H_2O molecules. **7**, Cd(II) and Cl^- anions formed a neutral, infinite 1-D coordination network (Fig. 2).

Depending on the definition of the assembling core, the 1-D network $(\mathbf{7}Cd_2Cl_4)_n$ thus obtained may be described in two different ways. Considering the metallic core as a binuclear Cd_2Cl_4 unit (Fig. 2), the network may be regarded as resulting from the binding of two such units by the two PyS_2 fragments of **7** leading thus to the exo-tetranuclear Cd(II) complex and the repetition of the binding process leads to the 1-D coordination network. The same system may be also described as resulting from the bridging of consecutive exo-binuclear $\mathbf{7}{\cdot}Cd_2$ units by two Cl^- anions, and the remaining other two Cl^- anions behaving as ancillary ligands. For the ligand part, the pyridine rings were tilted by −37.6 and 38.3° with respect to the phenyl group. The CS and CN distances were roughly the same as those observed for free **7**. The coordination sphere around the Cd cations was composed of one N atom (d_{NCd} = 2.426 Å), two S atoms (d_{SCd} = 2.730, 2.747 Å) and three Cl^- anions. Among the three Cl^- present, two of them were shared between two Cd centres (d_{ClCd} = 2.591, 2.651 Å) whereas the third one was acting as an ancillary ligand (d_{ClCd} = 2.511 Å). The coordination geometry around the metal centre was distorted octahedral with S–Cd–S, Cl–Cd–Cl and N–Cd–Cl angles of 146.5, 172.0 and 175.2°, respectively. Within the $Cd_2{\cdots}Cl_4$ unit, the Cd···Cd distance was found to be 3.946 Å. The $CHCl_3$ and H_2O molecules were localised between the 1-D chains.

Interestingly, when instead of using $CdCl_2$, a mixed Cl^- and BF_4^- salt $[CdCl(BF_4)]$ was used, the same diffusion method afforded after two days another type of colourless crystal. The solid state analysis (Fig. 3)‡ showed that the crystal **II** was composed of **7**, Cd(II) cations, Cl^- and BF_4^- anions, $CHCl_3$ and MeOH molecules. **7**, Cd(II) and Cl^- anions formed a cationic infinite 2-D coordination network (Fig. 2). The latter may be described as the result of mutual interconnection of the 1-D coordination polymers described above through Cl^- anions acting now as bridging ligands. In a sense, the poor coordination ability of BF_4^- has created a Cl^- deficiency in the coordination sphere of Cd(II), made up for by an additional Cl^- bridging interaction.

Thus, the 2-D network may be regarded as the translation into two different space directions of an assembling core which may be defined $[\mathbf{7}_4Cd_4Cl_7]^+$ (Fig. 2). The charge neutrality being achieved by BF_4^- anions present in the lattice. Owing to the aromatic nature of the ligand used, the 2-D network was composed of cavities delimited in an alternating fashion by

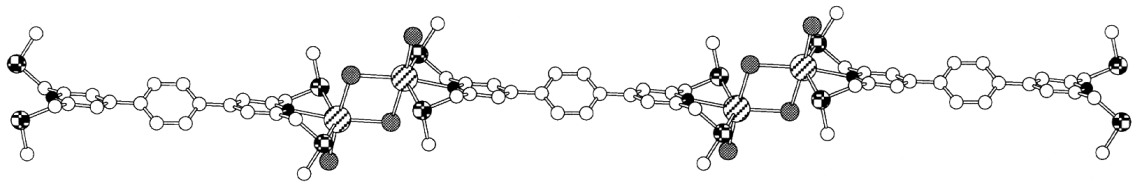

Fig. 1 A section of the X-ray structure of the 1-D coordination network **I** formed between **7** and $CdCl_2$. H atoms, anions and solvent molecules are not presented for clarity.

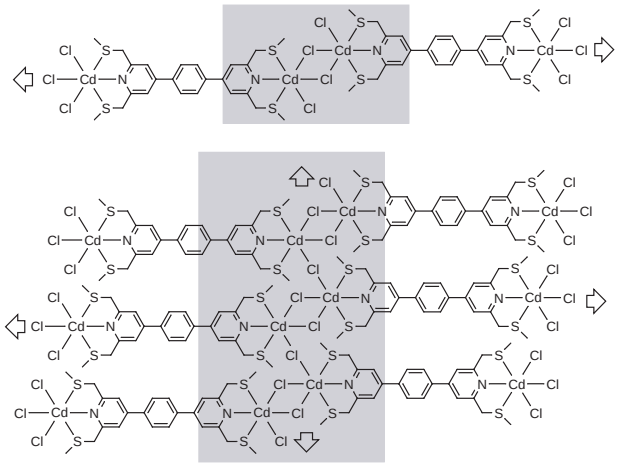

Fig. 2 Partial representation of the 1- and 2-D coordination polymers **I** and **II**.

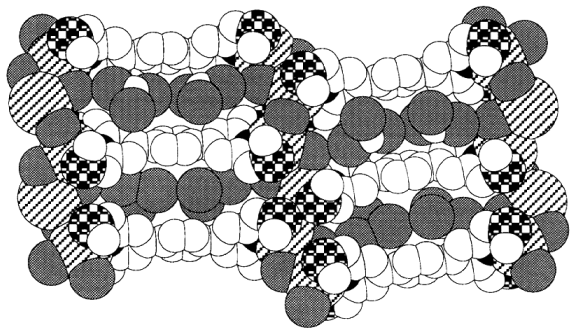

Fig. 3 A section of the X-ray structure of the 2-D coordination network **II** (see text). H atoms, anions and MeOH molecules are not presented for clarity.

organic and inorganic fragments. For **7**, the pyridine rings were tilted by −30.7 and 32.2° with respect to the phenyl group. The C–S and C–N distances were roughly the same as those observed for the free **7** and for the above-mentioned 1-D network. The coordination sphere around the Cd cations was again composed of one N atom (average d_{NCd} = 2.385 Å), two S atoms (average d_{SCd} = 2.697 Å) and three Cl^- anions. Although all three Cl^-, present in the coordination sphere of Cd cation, adopted a bridging role between the metallic centres, two of them were shared between two Cd centres (average d_{ClCd} = 2.608 Å) within the 1-D network, whereas the third one bridged two consecutive linear networks (d_{ClCd} = 2.559 Å) thus leading to a two-dimensional polymer. The coordination geometry around the metal centre was again distorted octahedral with S–Cd–S, Cl–Cd–Cl and N–Cd–Cl angles of 147.6, 169.0 and 163.6°, respectively. With the Cd_4Cl_7 unit, the Cd···Cd distances varied from 3.921 Å for the doubly bridged cations to 4.625 Å for the singly bridged centres. Interestingly, whereas MeOH and BF_4^- anions were localised between the 2-D sheets, the $CHCl_3$ molecules were included within the cyclophane type cavities composing the 2-D network.

In conclusion, using the N_2S_4 bis-tridentate ligand and Cd(II), 1- and 2-D coordination networks were obtained and characterised in the solid state. For the 2-D network the inclusion of two $CHCl_3$ molecules within cavities formed by the organic and inorganic fragments was observed. Based on the same strategy, the formation of magnetic networks using paramagnetic metal cations is currently under investigation.

Pseudopolymorphism: occurrences of hydrogen bonding organic solvents in molecular crystals

Ashwini Nangia and Gautam R. Desiraju

School of Chemistry, University of Hyderabad, Hyderabad 500 046, India. E-mail: grdch@uohyd.ernet.in

Received (in Cambridge, UK) 15th December 1998, Accepted 24th February 1999

Multi-point recognition with strong and weak hydrogen bonds between solvent and solute molecules facilitates the retention of organic solvents in crystals

Pseudopolymorphism is the phenomenon wherein a compound is obtained in crystalline forms that differ in the nature or stoichiometry of included solvent molecules.[1] This subject has not been treated systematically though it is perceived to be of general importance, for example in the pharmaceutical industry.[2] In a supramolecular sense, pseudopolymorphs of a compound are different chemical systems and should be treated as such. Here, we examine the likelihood of several hydrogen bonding organic solvents in crystal structures and attempt to provide some rationalisation for these occurrences. We have not considered hydration. The presence of water in organic crystals is so widespread and the reasons for its inclusion so varied[1–3] that it would not be realistic or practicable to include it with the other solvents considered here.

The method of analysis uses the Cambridge Structural Database (CSD, version 5.15, April 1998, 181 309 entries).[4] Organic structures† containing solvent of crystallisation were retrieved and 20 common solvents found to occur at least 50 times. A few hits contain two solvents and these are included under both in Table 1. The raw frequencies of occurrence N are listed in Table 1, which also contains the numbers of fully ordered crystal structures in each case, N_{ord}.‡ Given that some solvents are used for recrystallisation more frequently than others, these N (or even N_{ord}) values cannot be taken to correspond directly to the abilities of the respective solvents to give solvated crystals. To perform an appropriate, though still approximate, correction for differences in solvent usage, all organic structures (solvated or otherwise) in the 1986 and 1996 issues of *Acta Crystallographica Section C* were examined. The number of times each solvent was used for recrystallisation alone or in combination with other solvents is given as N_{Acta} in Table 1. The quantity (N/N_{Acta}) for a particular solvent was then taken as a measure of its ability to be included in the crystal. This quantity was scaled appropriately to give the usage corrected occurrence (O_{corr}). A value of 1.00 for O_{corr} indicates a solvent that forms solvates to an extent commensurate with its usage. Values of O_{corr} much larger or much smaller than unity indicate solvents that have a greatly enhanced or a greatly reduced tendency to be included in crystals.

Table 1 Occurrences of 20 common solvents in organic crystal structures in decreasing order of O_{corr}

Solvent	N	N_{ord}	N_{Acta}	O_{corr}[a]
DMF	122	63	5	5.69
DMSO	142	70	7	4.73
Dioxane	161	83	8	4.70
p-Xylene	49	22	3	3.81

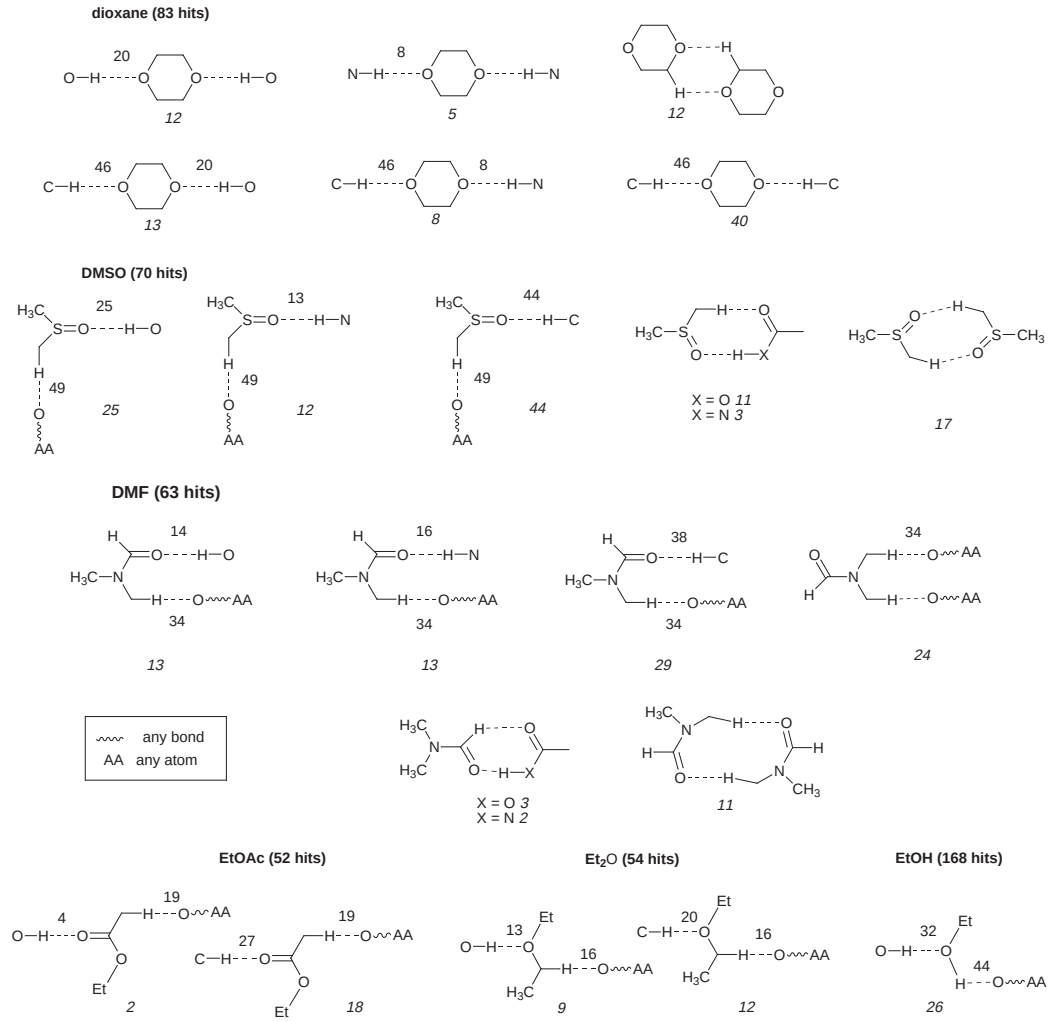
Pr^{i}OH	65	33	16	0.95
Cyclohexane	56	9	21	0.62
EtOAc	155	52	75	0.48
EtOH	406	168	206	0.46
Et_2O	144	54	96	0.35
Hexane	84	21	181	0.11
Total	4851	2131	1132	

[a] Calculated by the formula $(N/4851)/(N_{Acta}/1132) = 0.233\ (N/N_{Acta})$

The next step in the analysis focussed on the three solvents with the maximum values of O_{corr}. Let us consider the ordered dioxane solvates ($N_{ord} = 83$). Twenty hits contain an O–H···O hydrogen bond with specified metrics.§ In 12 of these cases, two O–H···O bonds approach a dioxane molecule as shown in the first synthon in Scheme 1. Similarly, 5 out of the 8 N–H···O hits correspond to two-point recognition with N–H groups.¶ This behaviour extends to hydrogen bonding by C–H groups. Forty six out of the 83 dioxane solvates contain a C–H···O bond to the solvent. When all the two-point cases are enumerated (13 with C–H, O–H; 8 with C–H, N–H; 40 with C–H, C–H), the total (61) is in excess of 46, indicating that in some of the cases, multiple donor groups approach the acceptor O-atom in the dioxane molecule. The overall situation is clear—when dioxane is included in an organic crystal, it is always hydrogen bonded and more importantly, to more than one donor. Generally, these donor groups (O–H, N–H, C–H) originate from different solute molecules though dioxane itself was noted to be the C–H donor in some cases (12 hits).

Multi-point recognition *via* strong and weak hydrogen bonding is also the favoured mode of association for DMSO (dimethyl sulfoxide) and DMF (dimethylformamide), both of which have a very high probability of being included in crystals. Whether the S=O group in DMSO is hydrogen bonded to an O–H, N–H or C–H group, the adjacent methyl group is invariably C–H···O bonded (25 out of 25 for O–H, 12 out of 13 for N–H, 44 out of 44 for C–H). It is interesting to note that all 44 hits that contain a C–H···O bond to DMSO as acceptor also contain a C–H···O bond from DMSO as donor. Like dioxane, DMSO shows a tendency to dimerise with itself (17 hits) or with acids (11 hits) and amides (3 hits). Many of these dimers are parts of extended hydrogen bonded networks and the various synthons shown in the scheme are not of an exclusive nature; any particular crystal structure usually contains more than one of the arrangements shown in Scheme 1. The situation with DMF is very similar. Multi-point recognition *via* C–H···O bonding from a methyl group of the solvent accounts for the majority of hits (13 out of 14 for O–H, 13 out of 16 for N–H and 29 out of 38 for C–H donors to DMF) while in 24 hits both methyl groups act as donors. As in DMSO, there is a tendency to form dimers and further these dimers extend into the general hydrogen bonding scheme. This tendency of dioxane, DMSO and DMF to self-associate as well as to form interactions with the solute improves the chances of solvent inclusion in crystals.

The final step of the analysis deals with solvates formed by EtOAc, EtOH and Et_2O. These three solvents are marked by an unusually reduced likelihood of being incorporated into solvate structures. The failure of these commonly-used solvents to be



Scheme 1 Multi-point supramolecular synthons formed by the frequently included solvents dioxane, DMSO and DMF. The numbers of strong and weak hydrogen bonds among the selected hits are given near the dotted lines. The italic numbers given below each synthon represent the incidence of two-point recognition. Notice the wide prevalence of C–H···O hydrogen bonding. The reduced incorporation of the solvents EtOH, Et_2O and EtOAc is reflected in the corresponding numbers for these solvents.

thus included is accounted for in terms of their inability to effectively participate in multi-point hydrogen bonded recognition schemes. Though EtOAc has a good acceptor group, the donors are largely unactivated. Et_2O has some acceptor ability but very poor donating capability. Unlike dioxane, neither of these solvents can act as multiple acceptors. To the extent, however, that the donors in EtOAc are more activated than in Et_2O, it is incorporated in crystals better. EtOH has a very good donor and a moderate acceptor group. However, it is generally included only in alcohol and acid structures and that too as part of a cooperative network, in which capacity it is also expendable. The numerical details in Scheme 1 bear out these qualitative generalisations. Of course, there must also be other reasons for the incorporation of organic solvents in crystals. Solvents like benzene, *p*-xylene and CCl_4 are included easily but generally in rigid framework structures where they are of the correct size to act as guests in a host lattice. Nonetheless, multipoint hydrogen bonding is clearly a dominant factor that governs the inclusion of the large number of solvents that are capable of exhibiting this phenomenon.

To conclude, why is multi-point recognition of the solvent so important in the formation of pseudopolymorphic structures? Crystallisation begins with solute–solvent aggregates that contain solute–solute, solute–solvent and solvent–solvent interactions. The entropic gain in eliminating solvent molecules from these aggregates into the bulk solution, and the simultaneous enthalpic gain in forming stable solute species that contain robust supramolecular synthons, provides an adequate driving force for nucleation and crystallisation with the result that most (85%) organic crystals are unsolvated. However, when solvent molecules are attached to solute molecules in a multi-point manner *via* either strong (O/N–H···O) or weak (C–H···O) hydrogen bonds, the extrusion of solvent from the aggregates into the bulk may become sufficiently disadvantageous from an enthalpic viewpoint with the result that the solvent remains an integral part of the nucleating crystal. The formation of a solvated crystal may therefore be likened to an interruption of the sequence of events that accompany the 'normal' crystallisation of an unsolvated form.

We thank the DST (SP/S1/G19/94) for financial assistance and Dr J. A. R. P. Sarma for discussions.

Modification of photochemical reactivity of *trans*-2-styrylpyridine: effect of cyclodextrin complexation

H. Shayira Banu,[a] A. Lalitha,[a] K. Pitchumani*[b] and C. Srinivasan*[a]

[a] *Department of Materials Science, Madurai Kamaraj University, Madurai -625 021, India. E-mail: matsci@pronet.xlweb.com*

[b] *School of Chemistry, Madurai Kamaraj University, Madurai -625 021, India*

Received (in Cambridge, UK) 1st December 1998, Accepted 2nd March 1999

In contrast to the solution irradiation of *trans*-2-styrylpyridine, photolysis of a γ-CD complex of the base in the solid state leads to the formation of the *syn*-head-to-tail dimer in fairly good yield.

While irradiation of the free base *trans*-2-styrylpyridine (*trans*-2-SP) under nitrogen in benzene solution leads only to its isomerization to *cis*-2-SP, photolysis of *trans*-2-SP in the solid state in the presence of oxygen yields the dimer in small amounts (2.6%) along with materials formed from photooxidation.[1,2] On the other hand, irradiation of the methiodide and hydrochloride of *trans*-2-SP in the solid state causes ready dimerization; the same process in benzene solution results both in isomerization to its *cis*-form and dimerization. The structure of the dimer has been suggested as one in which the quaternized rings dimerize in alternate positions so as to reduce steric as well as charge interference.[1,2] In another study unimolecular cyclization has been reported[3] during the photolysis of 2-SP in cyclohexane in the presence of oxygen to give benzo[*f*]quinoline in 35% yield, involving the intermediacy of dihydrobenzo[*f*]quinoline along with a minor product 1-phenyl-2-(2-pyridyl)ethanol (10%).

Microheterogeneous media such as micelles, monolayer assemblies, *etc*. are employed to control and achieve some selectivity in the dimerization of 4-styrylpyridinium cations.[4] When salts of 4-styrylpyridinium ions are irradiated in hexane–aerosol OT–water reverse micelles, efficient and selective formation of the *syn*-head-to-head (72%) dimer occurs. This is in contrast to the observation of photolysis in homogeneous solution wherein 13% of the *cis*-isomer and 60% of the *syn*-head-to-tail dimer are produced.[5] When intercalated between the interlayers of clay, 4-styrylpyridinium ions selectively yield the *syn*-head-to-tail cyclodimers.[6]

Cyclodextrins (CDs) are doughnut shaped cyclic oligosaccharides consisting of six, seven or eight glucose units (α-, β- and γ-CDs, respectively) with a hydrophobic inner cavity and a hydrophilic outside. Their cavities have internal diameters varying from 4.7 to 8.3 Å, permitting them to form inclusion complexes with a variety of guest molecules.[7] The depth of the binding cavity of all three CDs is almost the same (7.8 Å). Complexation between CDs and substrates in solution has been successfully exploited to induce selectivity in some unimolecular and bimolecular photochemical reactions.[8] Tamaki and co-workers[9] were the first to explore the utility of the CD cavity in effecting regio- and stereoselective dimerization of guest molecules like anthracene-2-sulfonate and anthracene-2-carboxylate. Photodimerization of acenaphthylene[10] and coumarin[11] upon complexation into the γ-CD cavity has been reported. [2 + 2] Photocycloaddition of a symmetrical stilbene derivative to yield a mixture of dimers in the presence of γ-CD has also been reported.[12] However, inclusion of stilbenes[13,14] in β-CD results in only *cis–trans* isomerization, suggesting that the cavity free volume in cyclodextrins plays a major role in controlling the reactivity of the included olefins.

This factor, coupled with the marked observed difference in behaviour during the photolysis of 2-SP and its salt in solution and the solid state, prompted us to study the effect of CD encapsulation on the photochemical behaviour of the free base 2-SP. As the widths of the cavities of α-, β- and γ-CDs increase in a regular manner and therefore the free space available for the guest increases, it is expected that the three CDs will have a varying influence on the photolysis of 2-SP encapsulated in CD. The results of irradiation of 2-SP in the three CDs are presented here.

Irradiation of an MeCN solution of *trans*-2-SP results only in isomerization with the absence of any bimolecular dimerization or unimolecular cyclization in the photostationary state (PSS). A change in the product distribution is noticed when CD complexes of *trans*-2-SP are subjected to irradiation (Table 1).

Upon irradiation of a α-CD–*trans*-2-SP complex in the solid state, a dramatic reduction in the percentage of the *cis*-isomer was observed in the PSS compared to the solution irradiation of 2-SP. Because of the smaller width of the α-CD, a restriction is imposed by the α-CD cavity on the photoisomerization of *trans*-2-SP. A small amount of the dimer† is possibly also formed from *trans*-2-SP which has not penetrated significantly into the cavity (Table 1).

The photochemical studies of the solid β-CD complex of *trans*-2-SP reveal not only a decrease in the percentage of *cis*-2-SP, but also a notable increase in the amount of unimolecular cyclized product, benzo[*f*]quinoline (Table 1), at the expense of the *cis*-isomer. The space available in β-CD is large enough to improve *trans–cis* interconversion and facilitate the cyclization of the *cis*-isomer. A deeper penetration of the base into β-CD compared to α-CD precludes any contact between two monomers and thus rules out the formation of a dimer. Also the conformation of the *cis*-form in β-CD (Scheme 1) is such that

Table 1 Product distribution on irradiation of *trans*-2-SP in different CDs

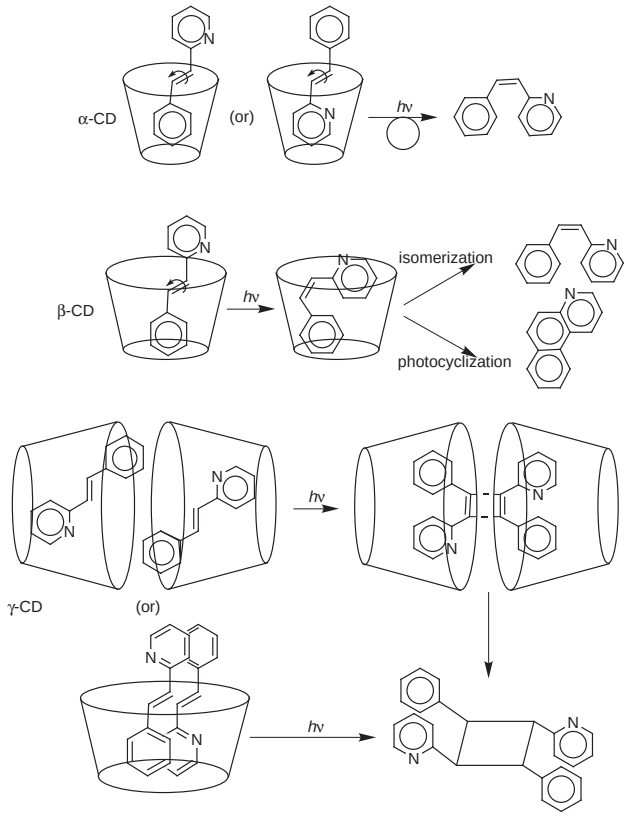
γ-CD–2-SP (solid)	1 : 2	33	7	50	10	—

[a] X = to be identified.



Scheme 1

the dimerization between two *cis*-molecules encapsulated in β-CD may not be easy.

In contrast to the above studies, during the photolysis of a 1 : 1 γ-CD–*trans*-2-SP solid complex a drastic decrease of *trans*-2-SP in the PSS with prominent formation of the dimer (Table 1) is observed. Since the width of the CD cavity is greatest in γ-CD among the three CDs, this free space is large enough to facilitate a marked increase in *trans–cis* photoisomerization. In the 1 : 1 complex with γ-CD the initially formed *cis*-2-SP can couple with another *cis*-2-SP molecule from the suitably oriented adjacent complex to produce the dimer (Scheme 1). The free space is so large in γ-CD that it can accommodate two molecules of the guest in the cavity of a single molecule of the host and in such a complex efficient photodimerization is expected.‡ Indeed we could prepare a 1 : 2 complex of γ-CD–*trans*-2-SP and during the photolysis of this solid complex, the yield of the dimer is slightly increased (Table 1). Since the dimer obtained in all the cases studied by us is *syn*-head-to-tail,† we presume that in the 1 : 2 complex the two *trans*-2-SP molecules are in an antiparallel alignment (Scheme 1).

Thus the observed results are significant as the dimerization is achieved with the free base while earlier reports require quaternization for effective cyclization. The present investigation suggests that it is possible to control the product of photolysis towards either unimolecular (photoisomerization and/or photocyclization) or bimolecular (photodimerization) reactions by choosing the proper CD.

2-SP was prepared and recrystallized as reported in the literature.[15] The dimer (*syn*-head-to-tail) was prepared[1] by the irradiation of 2-SP hydrochloride in benzene as a suspension for 15 h under nitrogen atmosphere using a 365 nm (8 × 8 W) annular photochemical reactor. Benzo[*f*]quinoline was prepared as reported in the literature.[3] α-CD (American Maize products, Indiana), β-CD (Aldrich) and γ-CD (American Maize Products, Indiana) were used as received. The CD complexes were prepared by a procedure reported elsewhere.[16] The CD complexes were irradiated using a 400 W (365 nm) water cooled, immersion type SAIC photoreactor. After irradiation was over, the products were extracted with $CHCl_3$ and the percentage of products were determined by PTLC. The products were characterized by ^1H NMR spectroscopy.

We wish to record our grateful thanks to the American Maize Products Company, Indiana, for the generous gift of α- and γ-CDs. Bioinformatics Centre, SBT, MKU is also acknowledged for the molecular modelling studies used in the present work. H. S. B. acknowledges financial assistance from CSIR, New Delhi.

Notes and references

† The dimer obtained in the present study is identified as the *syn*-head-to-tail dimer by its characteristic NMR pattern: $\delta_H(CDCl_3, 300\ MHz)$ 4.93 (2H, t), 5.10 (2H, t) (cyclobutyl protons), 7.11–7.59 (16H, m, ArH) and 8.66 (2H, d, Ar-H). It is also identified by its characteristic melting point, 189-190 °C (lit. 189–190 °C) (ref. 1,2).

‡ Molecular modelling studies [INSIGHT II (BIOSYM) using the DISCOVER module] were carried out to support the inclusion modes of *trans*-2-SP, *cis*-2-SP, 2 molecules of *trans*-2-SP and *cis*-2-SP inside α-, β- and γ-cyclodextrins. While 1 : 1 complexes are favoured in α-, β- and γ-CDs inclusion of two molecules of *trans*-/*cis*-2-SP is energetically allowed only in γ-CD. The results support our speculations of preferred modes of complexation. Details of the molecular modelling studies are available from the RSC website, see:http//www.rsc.org/suppdata/cc/1999/607/

Calix[4]arene-based Cs^+ selective optical sensor

Hai-Feng Ji, Gilbert M. Brown and Reza Dabestani*

Chemical and Analytical Sciences Division, Oak Ridge National Labotatory, PO Box 2008, MS-6100, Oak Ridge, TN 37831-6100, USA.E-mail: dabestanir@ornl.gov

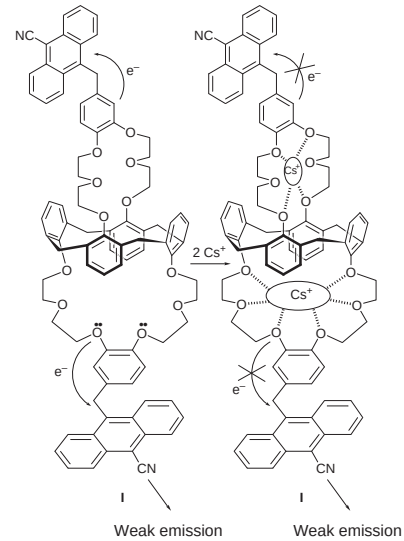
Received (in Columbia, MO, USA) 4th November 1998, Accepted 15th February 1999

1,3-Calix[4]bis(9-cyano-10-anthrylmethyl)-*o*-benzocrown-6 has been synthesized as a first generation caesium selective fluorescent probe, and its emission behavior in the presence of Li^+, Na^+, K^+ and Cs^+ ions has been examined.

The chemistry of calix[4]arenes, cyclic tetramers comprising phenolic and methylene moieties, has received considerable attention in recent years.[1,2] The available sites on these macrocyclic compounds that can be easily modified to tailor them for application as ionophores in catalysis,[3] and in heavy metal absorption,[4] alkali metal complexation[2] and chemical sensors[5,6] have been examined. Calix-crown compounds show high affinity for complexation of alkali and alkaline-earth metal ions.[2,7,8] Furthermore, it has been shown that derivatives of the 1,3-alternate calix[4]crown-6 ethers exhibit high selectivity towards Cs^+ ions in both acidic and alkaline media[9–12] with distribution coefficient ratios for Cs^+/Na^+ and Cs^+/K^+ exceeding 10^4 and 10^2 respectively, based on a solvent extraction technique.[12] Self-assembled ionophores with high cation selectivity for Cs^+ ions have also been reported.[13] We have taken advantage of the high selectivity of calix[4]crown ethers to synthesize a molecular recognition agent with high specificity for Cs^+ ion complexation in the presence of other alkali metal ions using the concept of fluorescence turn-on as a platform for its detection. Crown ethers have been proposed as potential extractants for the removal of Cs from nuclear waste solutions by solvent extraction.[14] ^{137}Cs produced during the nuclear era comprises a significant fraction of the radiological materials stored in the Department of Energy's (DOE) tank waste. A recent finding[15] suggests that leakage of nuclear material (^{137}Cs in particular) into the environment from the storage tanks at Hanford sites is far greater than previously estimated. Consequently, there is considerable interest within DOE to develop a caesium selective sensor that can be utilized to perform *in situ* determination of caesium in these tanks. However, to the best of our knowledge, current technologies do not provide a chemical method for *in situ* determination of Cs^+ ion concentration in nuclear waste solutions. We have undertaken this study as part of an effort to develop a technique for such determinations.

The fluorophore reporter molecule, 9-cyanoanthracene (9CA), was covalently attached to the parent molecule 1,3-alternate conformer of calix[4]bis-*o*-benzocrown-6 to prepare a molecular recognition agent that can serve as an optical sensor. The presence of caesium ions is signaled by an increase in the emission of the 9CA group upon complexation. In the absence of caesium ions, fluorescence is partially quenched by photo-induced electron transfer (PET) from the dialkoxybenzene moiety of the crown ring to the excited singlet state of 9CA.[16,17] Upon complexation, the oxygen lone pairs will no longer participlate in PET, causing the emission of 9CA to increase.

Compound **I** 1,3-calix[4]bis(9-cyano-10-anthrylmethyl)-*o*-benzocrown-6 (Scheme 1) was synthesized[18] as the first generation of caesium selective fluorescent probes. We have examined the emission behavior of **I** in the presence of the alkali metal ions Li^+, Na^+, K^+ and Cs^+ to evaluate its selectivity. The emission of **I** in CH_2CL_2–MEOH mixture (1 : 1) is only slightly affected by the presence of either Li^+ or Na^+ ions at concentrations as high as 0.1 M (Fig. 1), ruling out the possibility of strong complexation of these ions by **I**. In the



Scheme 1

presence of K^+ ions, the emission of **I** shows a slight enhancement up to a concentration of about 0.01 M, indicating some complexation of K^+ ions by **I** (Fig. 1). At higher concentrations of K^+ ions, the emission of **I** experiences a gradual decrease. The most dramatic change in the emission of **I** is observed in the presence of Cs^+ ions. As the concentration of Cs^+ ions increases, the emission of **I** increases, reaching its maximum value at a concentration of Cs^+ ions of *ca.* 10^{-3} M (Fig. 1). The observation of two plateau regions at 10^{-6} and 2×10^{-4} M Cs^+ (Fig. 1) implies that there are two sites for complexation. To the best of our knowledge, this is the first spectroscopic observation of a stepwise complexation process showing two plateau regions. The gradual quenching of the emission from **I** observed at high concentrations of K^+ and Cs^+ (Fig. 1) may be attributable to a medium effect caused by changes in the ionic strength of the solution. The magnitude of

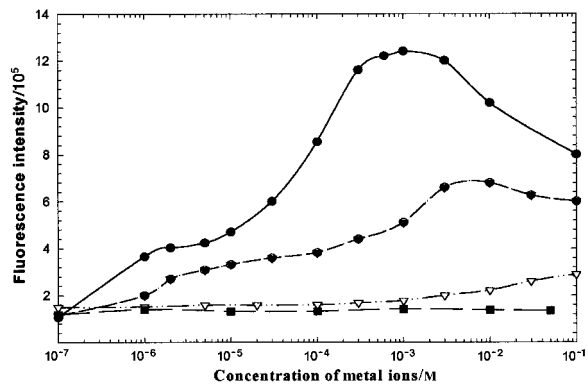


Fig. 1 Changes in the emission spectra (λ_{ex} = 320 nm) of **I** (10^{-6} M) in aerated CH_2Cl_2–MeOH (1 : 1) upon addition of alkali metal ions (acetate solution): (■) Li^+, (▽) Na^+, (▼) K^+ and (●) Cs^+.

this effect is less pronounced in the presence of Li^+ and Na^+ ions because the emission of **I** does not change significantly.

The stability constant for **I** can be estimated from the change in its fluorescence as the concentration of metal ion changes. Since **I** possesses two sites that can form a complex with Cs^+ ions (Scheme 1), eqn. (1) may be used to obtain the stability constant for complexation,[19,20] where α and χ are constants, K_{11} and K_{12} are association constants for the first and second metal ion complexation, I_o is the fluorescence intensity in the absence of metal ion, I_∞ is the intensity when no further change in fluorescence is observed upon addition of metal ion, and I is the intensity at different metal ion concentrations.

$$\frac{I - I_0}{I - I_\infty} = K_{11}[\mathrm{M}]\frac{\alpha + K_{12}\chi[\mathrm{M}]}{K_{11}[\mathrm{M}](\alpha - \chi) - \chi} \quad (1)$$

Computational fitting of the experimental fluorescence data to eqn. (1) for both K^+ and Cs^+ allows determination of parameters α, χ, K_{11} and K_{12}. Table 1 shows the values of these parameters obtained from such fits for both K^+ and Cs^+. The association constants K_{11} and K_{12} determined by us (Table 1) suggest 1 : 2 stoichiometry for calix[4]arene: K^+ (or Cs^+) and are in good agreement with the reported values for other systems that accommodate two metal ions at the complexing sites.[21] The fact that the ratio of $(K_{11}K_{12})_{Cs^+}/(K_{11}K_{12})_{K^+} = 277$ agrees reasonably well with the reported value of ~160 (for 1,2-dichloroethane) obtained *via* solvent extraction techniques[12] suggests that fluorescence spectroscopy can be used as a method to obtain the association constants for metal ion complexation. The reported quantum yields of fluorescence for **I** in the presence of different alkali metal ions shown in Table 1 are relative to 9,10-diphenylanthracene, which has $\Phi_f = 1$.[22]

Fig. 2 shows the change in fluorescence intensity profile for **I** as a function of the concentration of Cs^+ ions. The experiment was carried out *in situ* by combining equal volumes of an aqueous solution of $CsNO_3$ and a fixed concentration of **I** in CH_2Cl_2 in a quartz cell. After vigorous shaking, the two layers were allowed to separate and the fluorescence of the organic layers was obtained. The most dramatic increase in fluorescence intensity is observed over the range 10^{-3}–10^{-1} M $CsNO_3$ (Fig. 2). When the $CsNO_3$ solutions are doped with 1 M $NaNO_3$ and then added to **I** in CH_2Cl_2, the fluorescence intensity increases rapidly and then plateaus at $[Cs^+] > 1 \times 10^{-2}$ M. This rapid initial increase can be attributed to a common anion effect exerted by the presence of excess NO_3^- ions that enhances the complexation of caesium ions at low concentrations.

In conclusion, we have synthesized the first generation of caesium selective fluorescent turn-on probes based on calix[4]arene that can host two such ions upon complexation. Although the sensitivity of our probe is not as dramatic as we had hoped for practical application, we are currently exploring various ways to improve it by manipulating the parameters that have a pronounced effect on sensitivity. Along these lines, we are also examining other potential fluorophores that may induce a much stronger response upon complexation of Cs^+ ions.

This research was funded by the Environmental Management Science Program, Office of Environmental Management, U.S. Department of Energy. Oak Ridge National Laboratory is operated by Lockheed Martin Energy Research Corporation for the U.S. Department of Energy under contract number DE-AC05-96OR22464.

Table 1 Fluorescence quantum yields and association constants K_{11} and K_{12} values calculated for **I** in the presence of different alkali metal ions

Metal ion	Φ_{max}	K_{11}[a]/M^{-1}	K_{12}[a]/M^{-1}	α	χ
None	0.0082	—	—	—	—
Li^+	0.012	—	—	—	—
Na^+	0.016	—	—	—	—
K^+	0.049	6.0×10^5	5.0×10^2	1.0	2.9
Cs^+	0.096	8.3×10^6	1.0×10^4	1.0	4.5

[a] Metal ion concentration range was 10^{-7} to 2×10^{-3} M for K^+ and 10^{-7} to 1×10^{-3} M for Cs^+, respectively.

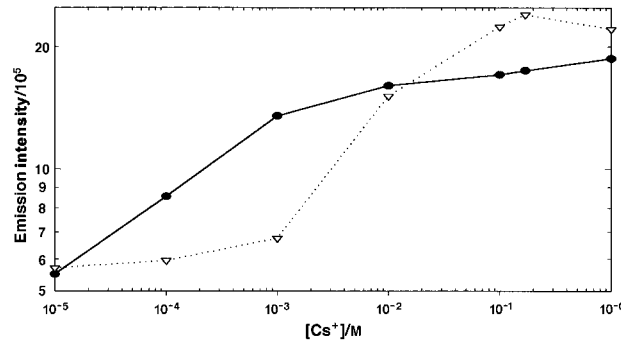

Fig. 2 Changes in the emission intensity of **I** in aerated CH_2Cl_2 as a function of Cs^+ ion concentration. Aqueous solutions of $CsNO_3$ were added to **I** in CH_2Cl_2 and after vigorous shaking the emission of the organic layer was obtained (λ_{ex} = 320 nm): (▽) without $NaNO_3$ and (●) with 1 M $NaNO_3$.

Catalytic asymmetric carbon–carbon bond forming reactions: preparation of optically enriched 2-aryl propionic acids by a catalytic asymmetric hydroboration–homologation sequence†

Austin C. Chen, Li Ren and Cathleen M. Crudden*

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick, PO Box 45222, Canada E3B 6E2

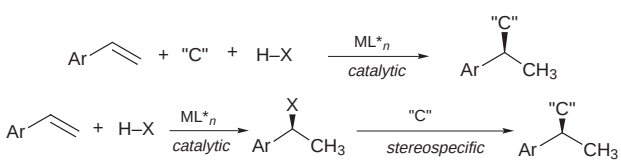
Received (in Corvallis, OR, USA) 2nd December 1998, Accepted 16th February 1999

A new catalytic asymmetric one-carbon homologation strategy has been developed which employs a rhodium catalyzed asymmetric hydroboration followed by homologation with $LiCHCl_2$ and oxidation to generate 2-arylpropionic acids of high enantiomeric purity.

Asymmetric carbon–carbon bond forming reactions are among the most important transformations in organic synthesis.[1] Catalytic methods are the most efficient means to affect these reactions, since the source of chirality is also used in catalytic quantities. The asymmetric synthesis of 2-aryl substituted carboxylic acids is of particular importance since non-steroidal anti-inflammatory agents such as Ibuprofen™ and Naproxen™ are among this class of compounds. Furthermore, the positive medicinal effects of these pharmaceuticals are ascribed to only one of the enantiomeric forms.[2] State-of-the-art catalytic asymmetric C–C bond forming methods for the synthesis of 2-aryl substituted propionic acids include hydrocarbonylation techniques employing carbon monoxide.[3] The key step in these methods is the enantioselective addition of a transition metal hydride across an olefin, which is followed by C–C bond formation (carbonylation). It occurred to us that an alternative strategy would be to employ a catalytic asymmetric reaction to install the required stereocentre followed by a second, stereospecific C–C bond forming reaction (Scheme 1). This basic principle has been realized in our labs leading to a highly enantioselective synthesis of 2-arylpropionic acids with the aid of catalytic asymmetric hydroboration.[4]

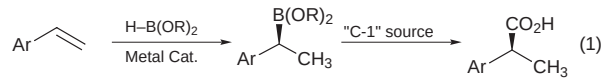
The catalytic asymmetric hydroboration reaction occurs with essentially complete regiochemical control and extremely high enantiocontrol in the hydroboration of vinylarenes to give the corresponding chiral 2-aryl boronate esters.[4] Despite the success of this transformation, it has thus far been relegated to a method for the preparation of enantiomerically enriched aryl methyl alcohols,[4] and more recently extended to include the preparation of amines.[5]

Although the application of chiral borane species prepared using *stoichiometric* amounts of chiral materials in C–C bond forming reactions has been reported in the elegant work of Matteson[6] and Brown,[7] no such use of the catalytically synthesized catecholate **1** has been described. We report herein a new asymmetric hydroboration–homologation method in which vinyl arenes are converted into 2-arylpropionic acids using only catalytic quantities of chiral material [eqn. (1)].

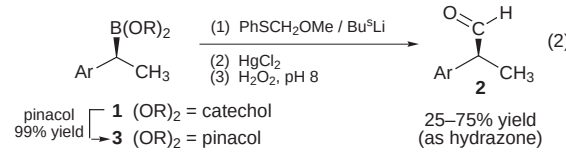


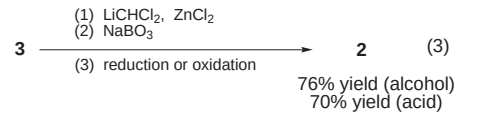
Scheme 1

† Presented in part: 80th Canadian Society for Chemistry conference, Whistler, B.C., June, 1998.

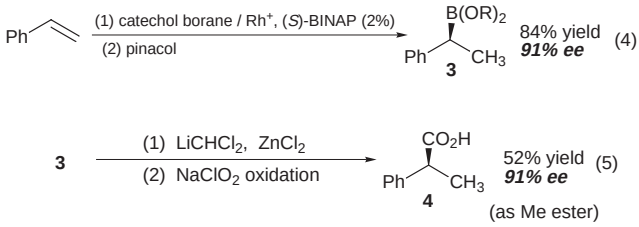


Several potential 'C-1' sources can be employed for the stereospecific C–C bond forming reaction. We first examined lithiated methylthiophenyl methyl ether,[7] but found the reaction to be low yielding with substrate **1** [eqn. (2)]. Transesterification of catechol boronate **1** to the corresponding pinacol boronate **3** prior to homologation gave **2** in higher yields, up to 75% isolated (as the hydrazone), but the highly capricious procedure requiring large quantities of $HgCl_2$ prompted us to consider alternative homologating reagents. Matteson has described the use of $LiCHCl_2$ in his homologation–Grignard addition strategy carried out on boronate esters prepared with stoichiometric amounts of chiral borane reagents.[6] Indeed $LiCHCl_2$ could be reliably prepared using Matteson's detailed procedure[6] and reacted with boronate ester **3** to yield, after oxidative workup, the homologation product **2** in good yield: 79% isolated as the alcohol after $BH_3{\cdot}SMe_2$ reduction, or 70% as the carboxylic acid after Lindgren oxidation [eqn. (3)].





Having established a reliable homologation method, we then carried out the sequence under asymmetric conditions. Reaction of styrene with catechol borane in the presence of catalytic amounts of $[Rh(COD)_2]^+BF_4^-$ and (*S*)-BINAP[4] generated the boronate ester **1** asymmetrically. Conversion of boronate ester **1** to pinacolate **3** allowed us to isolate and purify this species by column chromatography. The enantioselectivity of the process was high (91% ee).‡ The purified material was then homologated with $LiCHCl_2$. Oxidation of the intermediate chloroboronate using Kabalka's procedure[8] yielded aldehyde **2**, which was further oxidized to the carboxylic acid under Pinnick-modified Lindgren conditions.[9] Analysis of this material by optical rotation and chiral GC§ showed that the homologation–oxidation had proceeded with some loss of enantiomeric purity, yielding the desired product in only 77% ee. This decrease in ee was determined by independent experiments to be occurring *via* the aldehyde. Thus direct oxidation of the intermediate chloroboronate to the acid under Lindgren conditions[10] was affected and yielded the desired product in a slightly reduced yield, but with complete retention of enantioselectivity [eqns. (4) and (5)].¶



The slow addition of catechol borane as a solution in DME and maintenance of a low internal temperature were found to be crucial for achieving good enantioselectivities in our hands. (*R*)-BINAP gave slightly better enantioselectivities in the hydroboration, yielding **3** (*ent.*) in 95% ee (95% yield), which translated into 95% ee (45% yield) in the homologated carboxylic acid **4** (*ent.*).

The homologation method described herein is, to the best of our knowledge, the first use of chiral boronate esters prepared by *catalytic* hydroboration in a carbon–carbon bond forming reaction. With our method, the high regioselectivity observed in the catalytic asymmetric hydroboration is transferred to the subsequent C–C bond forming process, and the enantioselectivity is completely retained, offering a useful alternative to catalytic asymmetric hydrocarbonylation strategies. We are currently examining the application of this carbon monoxide-free hydrocarboxylation to more complex systems, and will report these results in due course.

The Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged for support of this research in terms of research grants to C. M. C. and a PGS-A scholarship to A. C. C. We thank Professors David Magee, Steven Westcott and Donald Matteson for helpful discussions.

Notes and references

‡ Determined by oxidizing a small portion of the boronate ester, and subjecting the resulting alcohol to chiral gas chromatography: Column = 2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl-β-cyclodextrin, (Suppelco, BETA DEX-225) 30 m, 0.25 mm diameter, 0.25 μm thickness, He carrier, 12.5 psi head pressure, 1.15 ml min^{-1} flow, FID detection. Retention time (t_R) = 44.6 (*R*) and 46.0 min (*S*) @ 70 °C for 5 min, then increase 1 °C per min to 150 °C for 30 min.

§ Column and conditions as above, **4**: (converted to Me ester by treatment with CH_2N_2) 154.1 (*S*) and 155.0 (*R*) min @ 50 °C for 100 min, then ramp at 1 °C per min to 160 °C.

¶ We thank a reviewer for pointing out this oxidation technique. The following procedure (styrene) is representative.

Hydroboration: In a flame dried round-bottomed flask, $[Rh(COD)_2]^+BF_4^-$ (32.4 mg, 0.078 mmol) and (*S*)-(−)-BINAP (54.8 mg, 0.088 mmol) were mixed. Dried, deoxygenated DME was added (4 ml) and the suspension stirred for 30 min. Styrene, previously distilled, was filtered through a plug of alumina and added to the mixture (0.46 ml, 4.0 mmol), which was then cooled to −66 °C. Catechol borane (0.5 ml, 4.7 mmol, distilled) was added as a solution in 2 ml DME dropwise over 45 min. During the addition, the internal temp did not exceed −66 °C. The solution was kept between −67 and −66 °C for 4 h. Pinacol (recrystallised and dried, 1.0121 g, 8.56 mmol) was added and the solution warmed slowly to room temperature overnight. Flash chromatography (silica gel, 24 : 1 hexane–EtOAc) yielded 761.4 mg (82%) of **3**. Enantioselectivity was determined to be 91% ee by oxidizing a small portion of this material under the conditions described in ref. 4, and analyzing the resulting material by chiral GC.

Homologation: this was carried out using $LiCHCl_2$ (1.25 mmol) generated by the slow addition of Bu^nLi (0.8 ml of a 1.57 M solution in hexane, 1.25 mmol) to a mixture of THF (6.5 ml) and CH_2Cl_2 (0.67 ml, 10 mmol) at −100 °C in a 95% EtOH–liq. N_2 bath. The clear colourless solution was stirred at −100 °C for 10 min before the rapid addition of boronate ester **3** (246 mg, 1.06 mmol) as a solution in 2 ml THF. $ZnCl_2$ (1.1 ml of a 1.0 M solution in Et_2O, 1.1 mmol) was then added. The reaction was left to warm to room temperature overnight. After this time, the volatiles were removed under a vigorous flow of N_2. The residue was quenched with 5 ml of sat. aq. NH_4Cl, extracted with light petroleum (4 × 20 ml), dried over $MgSO_4$, filtered and concentrated *in vacuo*. NMR analysis of the material thus obtained (283 mg, 95% crude yield) indicated no starting material remained, and only the chloroboronate product was present. This material was then oxidized to the acid directly following the procedure in ref. 9, (48 h reaction time were necessary). Purification of acid **4** was affected by an acid–base extraction, followed by methylation with CH_2N_2 and flash chromatography (7 : 1 hexane–EtOAc) giving the methyl ester of **4** in 52% yield (91% ee).

Defluorinative silylation toward a selective preparation of α-trimethylsilyl-α,α-difluoroacetates from trifluoroacetates

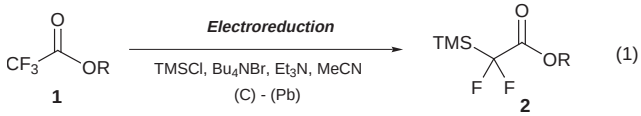
Kenji Uneyama* and Go Mizutani

Department of Applied Chemistry, Faculty of Engineering, Okayama University, Okayama 700-8530, Japan. E-mail: uneyamak@cc.okayama-u.ac.jp

Received (in Cambridge, UK) 18th January 1999, Accepted 2nd March 1999

Electrochemical reduction of *n*-hexyl trifluoroacetate 1a in MeCN, involving Bu_4NBr, TMSCl, and Et_3N using an H-type divided cell equipped with carbon plate as an anode and lead plate as a cathode at 50 °C, provided *n*-hexyl α-trimethylsilyl-α,α-difluoroacetate 2a in 62% yield, which is a promising precursor of an alkoxycarbonyldifluoromethyl carbanion equivalent and can be alkylated at the α-carbon by fluoride ion catalysis.

Difluoromethylene compounds have become one of the most important synthetic targets because of their unique biological activity.[1] Among the various difluorinated building blocks, difluoroketene silyl acetals **3** have often been employed for syntheses of difluorinated β-amino-β-hydroxy esters and β-ethoxycarbonyldifluoromethyl-β-lactams under mild conditions.[2] However, they are unstable in the presence of moisture[3] and zinc salts, so that they must be employed mostly *in situ* soon after their generation by Reformatsky reaction of halodifluoroacetates, and are utilized for alkylation in Lewis acid catalyzed carbon–carbon bond formation at the difluoromethylene carbon. Here we describe a first selective preparation of α-trimethylsilyl-α,α-difluoroacetates **2**,[4,5] a stable and isolable alternative of **3**, by electrochemical reductive defluorination[6] of trifluoroacetates, which are more readily available than halodifluoroacetates, and its fluoride ion catalyzed selective alkylation at the α-carbon [eqn. (1)].[7]



(1)

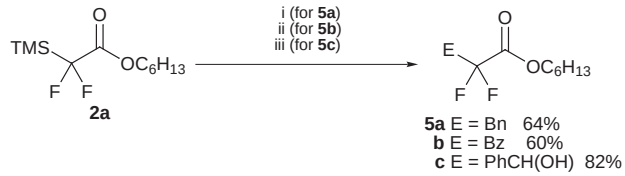
Electrochemical reduction of *n*-hexyl trifluoroacetate was conducted in MeCN involving Bu_4NBr, Et_3N and TMSCl using an H-type divided cell (with a sintered glass filter) equipped with carbon plate as an anode and lead plate as a cathode at 50 °C.† The product selectivity was found to be remarkably dependent on both reaction temperature and the concentration of TMSCl. At 50 °C the desired α-silylated acetate **2** was formed selectively in the presence of an excess of TMSCl (4 equiv.). On the other hand, a mixture of **2** and ketene silyl acetal **3** was formed at 0 °C in the presence of an excess of TMSCl (Table 1). Two-electron reduction followed by defluorination leads to the formation of the β,β-difluoro enolate which is trapped with TMSCl to give **3** as the kinetic product. *C*-Silylated product **2**[8,9] was the thermodynamic product since ketene silyl acetal **3** was found to be transformed to **2** under the electrolysis conditions at 50 °C. Meanwhile, formation of Claisen condensation product **4** was accompanied by **2** in the presence of only 1 equiv. of TMSCl. The selective formation of **2** was observed even in ethyl and *tert*-butyl esters [R = Et (47%), and Bu^t (58%)].

Table 1 Electrochemical preparation of **2**, **3** and **4**[a]

Entry	R	TMSCl/ equiv.[b]	*T*/°C	Yield(%)[c] **2**	**3**	**4**
1	n-C_6H_{13}	4	50	62 (68)	0	< 1
2	Bu^t	4	50	58 (68)	0	< 1
3	Et	4	50	47 (65)	0	< 1
4	n-C_6H_{13}	4	0	41	(18)	< 1
5	Et	1	0	< 5	0	(21)[d]

[a] *Reagents and conditions:* **1** (5 mmol), TMSCl (20 mmol), Et_3N (20 mmol), Bu_4NBr (12 mmol), in MeCN (70 ml), 80 mA cm^{-2}, 2 F mol^{-1}. [b] Relative to **1**, [c] Isolated yield (yield in parenthesis obtained by ^{19}F NMR). [d] **1** was recovered in 33%.

Fluoride ion catalyzed generation of the alkoxycarbonyldifluoromethyl carbanion and its alkylation were performed with benzyl bromide (64%), benzoyl chloride (60%) and benzaldehyde (82%), respectively (Scheme 1). This alkylation under basic conditions[9] is an alternative to Lewis acid catalyzed alkylation of ketene silyl acetals **3**.[2]



Scheme 1 *Reagents and conditions:* i, PhCHO (3.0 mmol), TBAF (1.0 mmol), THF, −78 °C, 1 h; ii, BnBr (1.0 mmol), KF (1.2 mmol), CuI (1.5 mmol), DMF, 80 °C, 5 h; iii, BzCl (3.0 mmol), KF (2.0 mmol), CuI (1.5 mmol), DMF, 80 °C, 10 h.

We are grateful to the Ministry of Education, Science, Sports and Culture of Japan for financial support (No. 09305058) and the SC-NMR Laboratory of Okayama University for ^{19}F NMR analysis.

Notes and references

† *Typical procedure* for **2a**: the electroreductive defluorination of *n*-hexyl trifluoroacetate **1a** (5 mmol) was carried out using a Pb cathode (2 × 5 cm^2) and a carbon anode in anhydrous MeCN (70 ml) containing Bu_4NBr (12 mmol), Et_3N (20 mmol) and TMSCl (20 mmol) in an H-type divided cell. A constant current of 80 mA was passed at 50 °C under an argon atmosphere until **1a** was consumed (2 F mol^{-1}). *Selected data* for **2a**: colorless oil, bp 80 °C (2 mmHg) (bath temperature) (62%); ν_{max}(neat)/cm^{-1} 1756 (C=O); δ_H($CDCl_3$, 200 MHz) 0.23 (s, 9 H), 0.89 (t, 3 H, *J* 6.6), 1.30–1.41 (m, 6 H), 1.62–1.72 (m, 2 H), 4.23 (t, 2 H, *J* 6.8); δ_F($CDCl_3$, 188 MHz, C_6F_6 as an internal standard) 38.7 (s, 2 F); δ_C($CDCl_3$, 50 MHz) 4.9, 13.9, 22.5, 25.4, 28.4, 31.3, 66.2, 121.0 (t, J_{CF} 269, CF_2), 166.3 (t, J_{CF} 26, C=O); *m/z* (GC/MS) 168 (M − C_6H_{12}), 152 (M − OC_6H_{12}), 73 (M − $CF_2CO_2C_6H_{13}$) (Found: C, 52.04; H, 8.99. Lithium templated synthesis of catenanes: efficient synthesis of doubly interlocked [2]-catenanes

Christiane Dietrich-Buchecker and Jean-Pierre Sauvage*

Received (in Basel, Switzerland) 21st December 1998, Accepted 8th February 1999

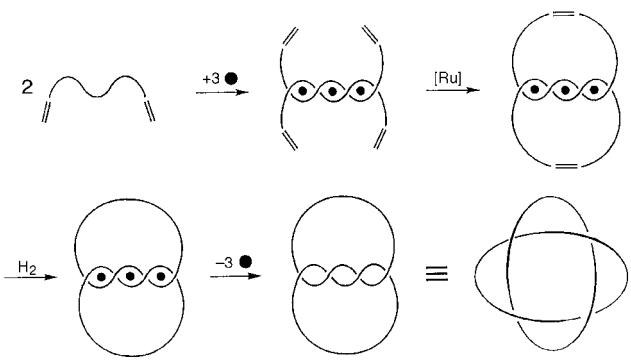
Li^+ (3 equiv.) is used as an assembling centre to generate a double-stranded helical complex from two linear coordinating fragments, each containing three 1,10-phenanthroline units and bearing terminal olefins at their ends; ruthenium-catalyzed ring-closing metathesis on the helical precursor leads to a 4-crossing [2]-catenane in 30% yield, making the procedure reasonably preparative.

The synthesis of interlocking rings[1,2] and molecular knots has undergone spectacular progress in the course of the last 15 years due to the development of templated strategies.[3–5] Copper(I) has been used extensively as an assembling and templating centre,[3] but a few examples based on other transition metals [Ru(II) or Co(II)] have also been reported.[6,7]

To the best of our knowledge, alkali or alkaline-earth cations have never been utilized. We now report that Li^+ is also well adapted to the formation of a double-stranded helical complex used as a precursor, and, in a subsequent reaction, to the synthesis of a doubly interlocked catenane.

Helical transition metal complexes ('helicates') constitute an important field of research in relation with so-called 'self-assembly' processes. Although known for more than two decades,[8] it is only recently that transition metal incorporating helices have been made deliberately and the properties of these multinuclear species studied.[9–11] A double stranded helical complex containing two Na^+ ions has been characterized by ^1H NMR spectroscopy.[12] Li^+ is known to display relatively strong affinity for ligands of the aromatic polyimines family.[13] In the present work, Li^+ turned out to be very well adapted to the formation of a trinuclear double helix, which surprisingly appeared sufficiently robust to resist the cyclization conditions.

The general strategy for preparing a 4-crossing [2]-catenane is shown in Scheme 1. It is based on two key reactions: (i) formation of a double-stranded helical precursor from 2 equivalents of a molecular string which incorporates three chelating units, and 3 equivalents of the templating metal; the string-like fragment bears olefinic functions attached at the ends of flexible fragments; (ii) the ring closing metathesis (RCM) reaction leading to the catenate.

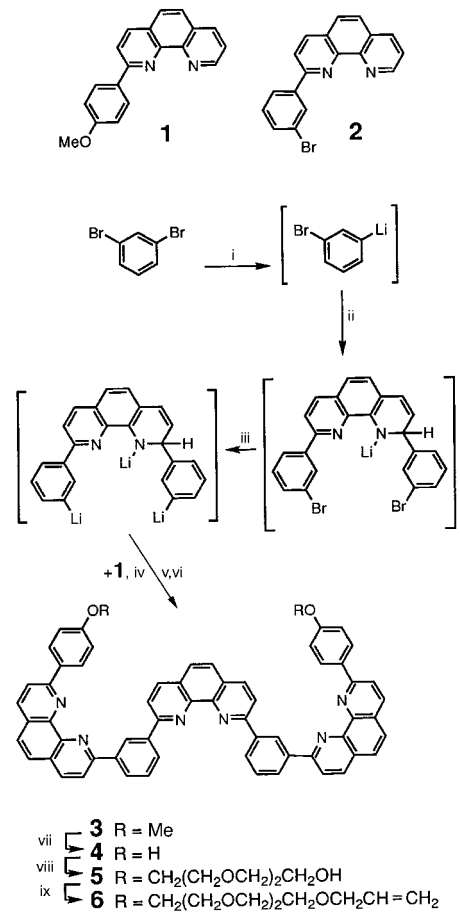


Scheme 1 General strategy for the preparation of 4-crossing [2]-catenanes.

In previous work, we could prepare small amounts of a 4-crossing [2]-catenane. Unfortunately, the yield was so poor (1.8%) that we could only characterize the compound by ^1H NMR and mass spectrometry (ES-MS and FAB-MS).[14] The modified strategy we describe now leads to dramatic improvement, affording the new doubly interlocked catenane in 30% yield. The main factors which are responsible for the much more preparative procedure of the present approach are (i) the quantitative formation of the three-lithium ion double-stranded helical precursor and (ii) the very mild and efficient RCM reaction,[15] as already used in previous work for making [2]-catenanes[16] or molecular trefoil knots.[17]

The various compounds prepared as well as the reactions leading to the target molecule are shown in Scheme 2.

The tris-chelating ligand **3** could be prepared in 11% yield from the monosubstituted phenanthrolines **1**[18] and **2**[19] in a multistep reaction shown in Scheme 2. Ligand **4** obtained



Scheme 2 *Reagents and conditions*: i, Bu^nLi, Et_2O, 2 °C; ii, **2** in THF, 0 °C; iii, Bu^tLi (4 equiv.), −78 °C; iv, **1** (2.5 equiv.) in THF, 10 °C; v, H_2O, 0 °C; vi MnO_2, excess; vii, HCl, pyridine, 210 °C; viii, Cs_2CO_3, DMF, 75 °C, $ClCH_2(CH_2OCH_2)_2CH_2OH$ (excess); ix, NaH, THF reflux, $BrCH_2CH{=}CH_2$ (excess).

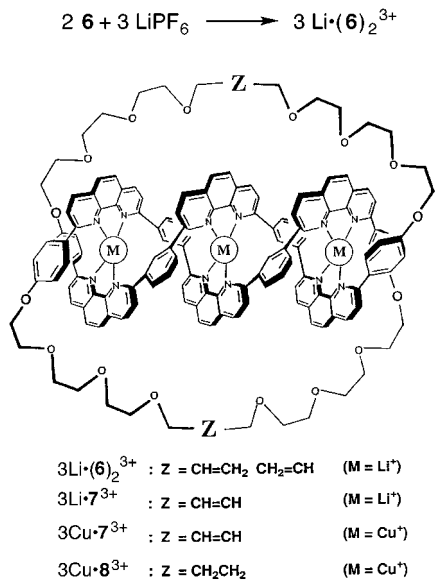


Fig. 1 Double stranded helix formation and cyclisation.

quantitatively after demethylation of **3** by HCl–pyridine,[20] was converted to diol **5** in 87% yield by reaction with 2-[2-(2-chloroethoxy)ethoxy]ethanol in DMF at 75 °C in the presence of Cs_2CO_3. **5** led to **6** in 88% yield after formation of the dialcoholate with NaH and subsequent reaction with an excess of allyl bromide in refluxing THF.

The tris-lithium helical precursor $3Li\cdot(\mathbf{6})_2^{3+}$ was formed quantitatively by addition of $LiPF_6$ in MeOH to a solution of **6** in CH_2Cl_2 at room temperature (Fig. 1). To avoid competitive protonation solid Li_2CO_3 was subsequently added to the solution until it was weakly basic. The double helix $3Li\cdot(\mathbf{6})_2^{3+}$, fully characterized by ^{1}H NMR and ESI-MS, was stable enough to survive the mild RCM conditions (0.05 mol equiv. of Grubbs catalyst $[RuCl_2\{P(C_6H_{11})_3\}_2(=CHPh)]$). The double cyclization could be monitored by ^{1}H NMR spectroscopy in the alkenic region. The unsuccessful attempt to separate the pure tris-lithium doubly interlocked [2]-catenate $3Li\cdot\mathbf{7}^{3+}$ from the oligomers arising from the intermolecular metathesis reaction led us to exchange Li^+ with Cu^+. This exchange was slow and required heating at 60 °C of a $3Li\cdot\mathbf{7}^{3+}$ acetonitrile solution in the presence of a large excess of $[Cu(MeCN)_4]PF_6$ for several days. Subsequent chromatography afforded the catenate $3Cu\cdot\mathbf{7}^{3+}$ in 30% yield. The cyclic alkenes remaining in $3Cu\cdot\mathbf{7}^{3+}$, originally present as a mixture of *cis* and *trans* isomers were later reduced by catalytic hydrogenation in EtOH–CH_2Cl_2 (1 : 1) with Pd/C affording $3Cu\cdot\mathbf{8}^{3+}$ quantitatively.

The unexpected stability of $3Li\cdot(\mathbf{6})_2^{3+}$ as well as the difficulty encountered to exchange the three lithium cations by copper(I) in $3Li\cdot\mathbf{7}^{3+}$, both reflect tight, highly entwined molecular structures.

Further evidence for the doubly interlocked topology of $3Cu\cdot\mathbf{8}^{3+}$ was obtained after its demetallation (excess KCN in refluxing MeCN) which led quantitatively to the free ligand **9** characterized by very broad and poorly resolved signals of its ^{1}H NMR spectrum : slow restricted molecular motions are clearly related to a topology which implies large mutual crowding between the rings. The FAB-MS of **9** confirms fully our assumption relative to a catenated structure characterized by peaks at *m/z* 2406, corresponding to the ion (**9** + Na^+) and *m/z* 1213.7, 1191.7 corresponding to the ions (**9**/2 + Na^+) and (**9**/2 + H^+), respectively. The two latter signals appear as monocharged species and thus can only originate from the cleavage of one ring followed by fast unthreading of the linear fragment produced.

In conclusion, RCM turned out to be again a surprisingly efficient reaction for preparing interlocking rings such as the present 4-crossing [2]-catenane, converting an exceedingly low yield synthesis, as reported a few years ago,[14] into a preparative procedure. The properties of the new ligand **9** and of its complexes are now under investigation.

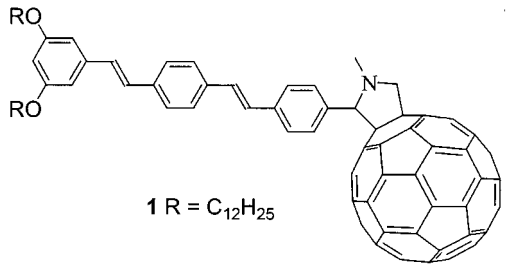
Received (in Cambridge, UK) 1st February 1999, Accepted 3rd March 1999

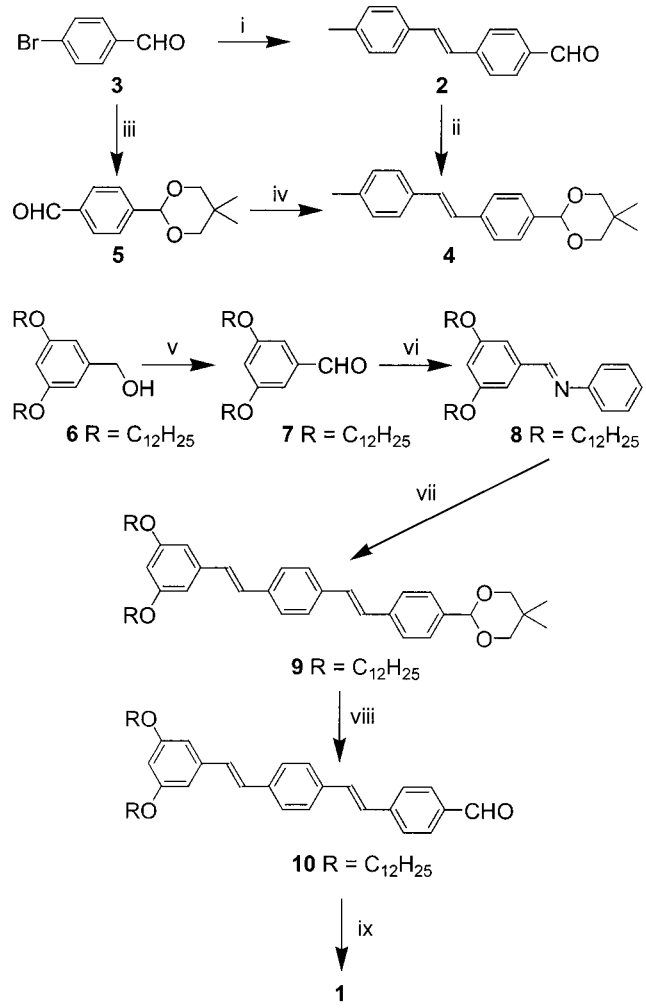
A fulleropyrrolidine derivative bearing an oligophenylenevinylene substituent has been prepared by 1,3-dipolar cycloaddition of an azomethine ylide to C_{60} and incorporated in a photovoltaic device.

In light of its unusual electrochemical and electronic properties, the fullerene C_{60} is an attractive functional group for supramolecular assemblies and new advanced materials.[1] For example, photovoltaic devices using thin films of interpenetrating bicontinuous networks of C_{60} derivative and a number of conjugated polymers such as polyphenylenevinylene or polythiophene have been demonstrated to show promise for large-area photodetectors and solar cells.[2] In this class of devices the network provides the spatially distributed interfaces necessary for efficient exciton dissociation into electrons and holes, and pathways for their subsequent collection at opposite electrodes. Therefore the film morphology is of crucial importance for the device performance. Usually the donor and acceptor molecules are incompatible and tend to strong and uncontrolled phase separation. An alternative approach to create the bicontinuous network is based on chemically connected donor–acceptor molecules. Recent developments in the functionalisation of fullerenes allows the preparation of covalent C_{60} derivatives bearing electro- and/or photo-active substituents.[3] Some of those systems provide entry into intramolecular processes such as photoinduced charge separation, therefore they appear as potential candidates for the preparation of photovoltaic cells. In this context, we now report the preparation of the fullerene–oligophenylenevinylene hybrid **1** and its utilisation for the construction of a solar energy conversion system.



The synthesis of compound **1** is depicted in Scheme 1. The *E*-stilbene **2** was prepared from 4-methylstyrene and 4-bromobenzaldehyde **3** under Heck conditions with $Pd(OAc)_2$ as catalyst in toluene–Et_3N in the presence of tri-*o*-tolylphosphine.

Treatment of **2** with 2,2-dimethylpropane-1,3-diol in refluxing benzene in the presence of a catalytic amount of *p*-toluenesulfonic acid (*p*-TsOH) gave **4** in 95% yield. Compound **4** could also be prepared from **3** as follows: protection[4] (2,2-dimethyl-1,3-propanediol, C_6H_6, *p*-TsOH cat.), subsequent treatment with Bu^{t}Li in THF followed by quenching with DMF and reaction of the resulting **5** with (4-methylbenzyl)triphenylphosphonium chloride under Wittig conditions. The parent stilbene was thus obtained in 70% yield as an *E* : *Z* isomer mixture in a 55 : 45 ratio. However, the *Z* isomer could be easily isomerized to the *E* form by treatment with iodine in refluxing toluene. Oxidation of alcohol **6**[5] with MnO_2 in CH_2Cl_2 followed by condensation of the resulting benzaldehyde **7** with aniline in



Scheme 1 *Reagents and conditions*: i, 4-methylstyrene, $Pd(OAc)_2$, tri-*o*-tolylphosphine, Et_3N, toluene, reflux, 48 h, 55%; ii, 2,2-dimethylpropane-1,3-diol, C_6H_6, *p*-TsOH cat., reflux, Dean–Stark trap, 24 h, 95%; iii, 2,2-dimethylpropane-1,3-diol, C_6H_6, *p*-TsOH cat., reflux, Dean–Stark trap, 48 h, then Bu^{t}Li, THF, −78 °C, 1 h, then DMF, −78 °C to room temp., 1 h, 85%; iv, (4-methylbenzyl)triphenylphosphonium chloride, Bu^{t}OK, EtOH, room temp., 2 h then I_2, toluene, reflux, 12 h, 70%; v, MnO_2, CH_2Cl_2, 1 h, 89%; vi, aniline, C_6H_6, reflux, Dean–Stark trap, 24 h, 90%; vii, **4**, Bu^{t}OK, DMF, 80 °C, 2 h, 74%; viii, TFA, CH_2Cl_2, H_2O, room temp., 4 h, 96%; ix, C_{60}, sarcosine, toluene, reflux, 16 h, 43%.

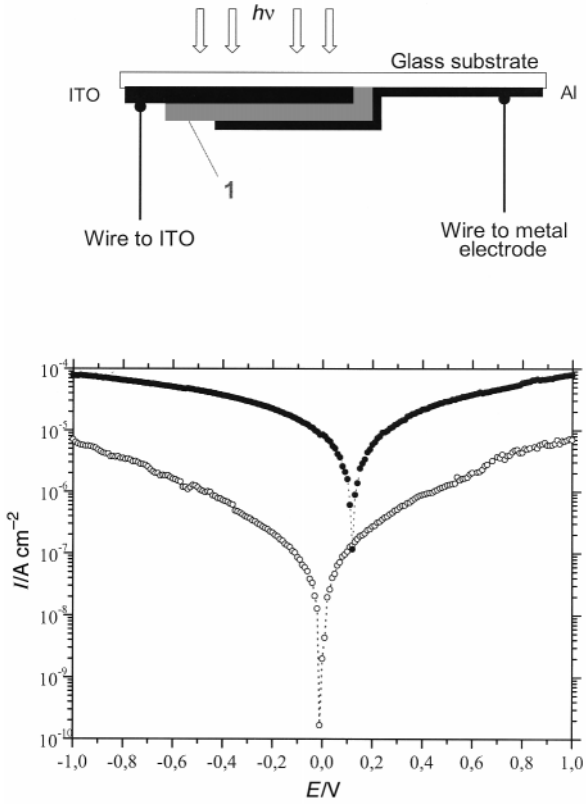


Fig. 1 Top: structure of the photovoltaic cell. Bottom: current–voltage characteristics of the ITO/C_{60}–oligophenylenevinylene/Al device in the dark (○) and under 5 mW cm^{-2} illumination (400 nm) (●).

refluxing benzene afforded **8** in an overall 80% yield. Benzaldimine **8** was subjected to the Siegrist reaction[6] with stilbene **4** to give protected trimer **9** in 74% yield. Treatment of **9** with CF_3CO_2H in CH_2Cl_2–H_2O (1 : 1) afforded aldehyde **10** in 96% yield. The functionalisation of C_{60} was based on the 1,3-dipolar cycloaddition[7] of the azomethine ylide generated *in situ* from **10**. The reaction of C_{60} with **10** in the presence of an excess of *N*-methylglycine (sarcosine) in refluxing toluene afforded fulleropyrrolidine **1** in 43% yield (or 62% based on the non-recovered C_{60}). All of the spectroscopic studies and elemental analysis results were consistent with the proposed molecular structures.† The UV–VIS spectrum of **1** corresponds to the sum of the spectra of its two components and shows the characteristic absorptions of a fulleropyrrolidine derivative at 254, 430 and 702 nm as well as the diagnostic oligophenylene-vinylene band at 363 nm indicating that there are no significant interactions between the two chromophores in the ground state. Preliminary luminescence measurements show a strong quenching of the oligophenylenevinylene fluorescence in **1**. Charge transfer is expected to occur and compound **1** appears as a potential candidate for the preparation of a photovoltaic cell. The device structure is schematically depicted in Fig. 1. The C_{60}-oligophenylenevinylene films were spin cast, on a glass substrate coated with indium–tin oxide (ITO), from a 4 wt% chloroform solution. The Al electrode was vacuum evaporated on the films to a thickness of 100 nm. Typical current–voltage curves (using ITO as positively and Al as negatively biased electrodes) measured under dark and under light (400 nm, 5 mW cm^{-2}) are presented in Fig. 1. Under the light the device shows clear photovoltaic behaviour with an open-circuit voltage of *ca.* 0.2 V and a short-circuit current density of 10 μA cm^{-2} corresponding to a collecting efficiency of 1%. Although we do not know the exact reason of the high dark current under reverse bias, we believe it leads to the relatively low collection efficiency and open-circuit voltage.

We have shown that photovoltaic cells can be prepared with a fullerene–oligophenylenevinylene conjugate. The device efficiency is not yet optimised and further improvements could be expected by utilisation of new fullerene derivatives with a stronger absorption in the visible range.

Received (in Liverpool, UK) 1st December 1998, Accepted 25th February 1999

New optically active copolymers containing binaphthyl units to control the conjugation length of the emitting chromophores show intense photoluminescence and high electron affinity.

The design of tailor-made π-conjugated polymers has been a subject of intensive research during the last decade due to their potential applications as novel materials for optoelectronics[1–5] given that they combine the optical and electronic properties of semiconductors with the processing advantages and mechanical properties of polymers.

The HOMO–LUMO gap in semiconducting polymers is roughly determined by the extent of π-delocalization along the backbone, the so-called effective conjugation length, which is responsible for the emitting properties of these materials. Introduction of non-conjugated segments into conjugated polymer backbones results in confinement of π-electrons in the conjugated fragment. Thus, the conjugation length of conjugated–non-conjugated multiblock copolymers can be effectively tailored by choice of the appropriate chromophores and spacers. Here we use functionalized chiral binaphthyl monomers as the non-conjugated spacer in conjugated–non-conjugated polymers **1**–**3** (Fig. 1).

Binaphthyl derivatives are optically active materials, their chirality being derived from the restricted rotation of the two naphthalene rings. The angle between the rings ranges from 60 and 120° and therefore, conjugation between the two naphthalene units is minimal.[6] Thus, the conjugated system in polymer containing binaphthyl units is confined to the region between two binaphthyl units [Fig. 1(*a*)].[7,8] The structure of these block-copolymers can be schematically represented as in Fig. 1(*b*) with consecutive conjugated systems linked to each other in a non-coplanar way.

In order to obtain processible polymeric materials, long alkoxy chains have been introduced as substituents on the monomeric units. Especially interesting is the presence of CN groups on the vinylene bridges of poly(arylenevinylenes), which is known to result in an increase in the electron affinity of polymeric materials for light emitting diodes (LEDs) with air stable electrodes.[9] The preparation of this prototype main chain chiral, cyano-containing binaphthyl-based copolymers was carried out using the Knoevenagel condensation[9] of appropriately functionalized binaphthyl (**4**, **5**) and naphthalene (**6**, **7**) monomers. Polymer **1** was obtained by reaction of the new bis(cyanomethyl)-substituted binaphthyl (**4**) with dialdehyde **5**. When **4** was reacted with 1,5-bis(hexyloxy)naphthalene-2,6-dicarbaldehyde (**7**)[10] under analogous conditions, polymer **2** was obtained. Reaction of binaphthyl dialdehyde (**5**) with 2,6-bis-(cyanomethyl)-1,5-bis(hexyloxy)naphthalene (**6**)[10] afforded polymer **3**.

Polymers **1**–**3** were obtained as orange solids in good yields (90, 80 and 75% respectively) with optical HOMO–LUMO onsets of 2.53 eV for **2**, 2.64 eV for **3** and 2.76 eV for **1**, measured *via* their UV-Vis absorption spectra (in CH_2Cl_2 solution). Gel permeation chromatography (GPC) against polystyrene revealed a weight average (M_w) of *ca.* 164 000 and a number average (M_n) of 22 000 (polydispersity (pd) = 7.62) for polymer **1**. Polymer **2** had the lowest mass (M_w = 15 300 and M_n = 9400, pd = 1.62). Polymer **3** presented M_w = 27 500 and M_n = 12 200 (pd = 2.27). Polymers were fully characterized using ^{1}H NMR, ^{13}C NMR, FTIR, and UV-Vis measurements. The infrared spectra displayed the characteristic CN stretching frequency at around 2212 cm^{-1} for the three polymers. ^{1}H NMR measurements exhibit the characteristic singlet of the vinylene proton at around δ 8.1 together with the expected signals of the naphthalene units and the alkoxy chains.†

Polymers were synthesized by using enantiomerically pure (*S*)-binaphthyl derivatives (**4**, **5**) and therefore main chain chiral polymers have been obtained. The observed optical rotations ($[\alpha]_D$) are 305 (*c* 0.2, $CHCl_3$) for (*S*)-**1**, 832 (*c* 1.3, $CHCl_3$) for (*S*)-**2** and 220 (*c* 0.7, $CHCl_3$) for (*S*)-**3**. Thus, these polymers rotate the plane of polarized light in the opposite direction to the binaphthyl dicyanomethyl-substituted species (*S*)-**4**, {$[\alpha]_D$ −34

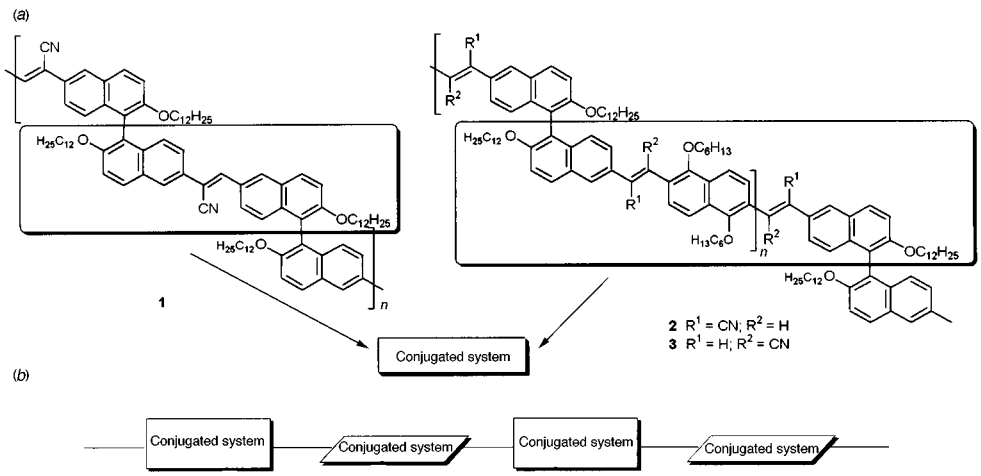

Fig. 1 (*a*) New block co-polymers showing the conjugated systems between binaphthyl units and (*b*) schematic representation of the polymers.

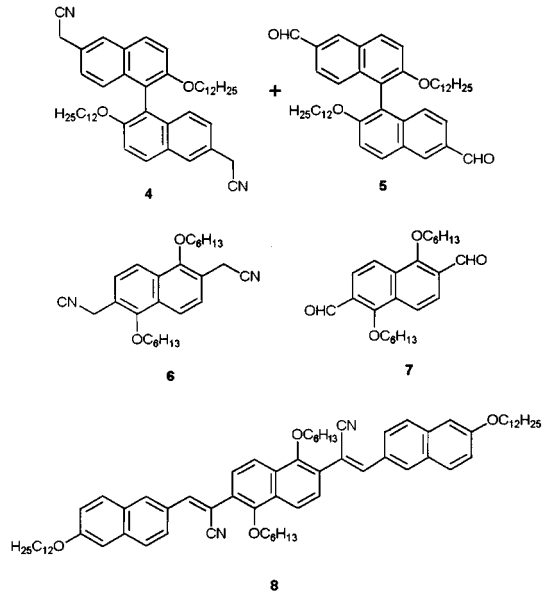

(*c* 0.6, $CHCl_3$)} and in the same direction as the binaphthyldicarbaldehyde (*S*)-**5** {$[\alpha]_D$ 56 (*c* 0.7, $CHCl_3$)}.

Cyclic voltammetry studies of polymers **1**–**3** were carried out in CH_2Cl_2 at room temperature using Bu_4NClO_4 as supporting electrolyte (0.3 mg ml^{-1}, SCE reference electrode and glassy carbon as the working electrode). It was found that all the polymers are oxidized at potentials above 1.2 V (*vs.* SCE) which is high compared with other conjugated polymers (0.6–1.0 V).[11] On the other hand, all the polymers were found to be reducible at potentials around −1.5 V (*vs.* SCE). The relatively good acceptor ability of these polymers can be ascribed to the presence of the cyanovinylene moieties on the conjugated system. As it was previously stated, high electron affinity materials are of special interest for the manufacture of LEDs providing that they can be used in combination with air stable electrodes, thus increasing device life time.[9]

The absorption maximum of these polymers increases from **3** (λ_{max} 378 nm) to **1** (λ_{max} 382 nm) to **2** (λ_{max} 422 nm). These polymers emit strong blue–green light under an UV lamp. The fluorescence spectrum of **1** shows emission maxima at λ_{emi} 475 nm when excited at 382 nm. The fluorescence spectrum of **2** displays λ_{emi} 496 nm when excited at 422 nm and **3** exhibits an emission maxima of λ_{emi} 485 nm when excited at 378 nm. Two factors may be considered in order to rationalize the observed absorption and emission data. First, there is the extension of the conjugated system, which for polymer **1** comprises two naphthalene units linked by a cyanovinylene group and for polymers **2** and **3** includes three naphthalene units linked by two cyanovinylene moieties. Second, there is the steric hindrance of the hexyloxy substituents with respect to the cyano groups in polymer **3** which may cause torsion of the chain, reducing the planarity of the backbone and therefore decreasing the degree of conjugation.[12] Thus, the more red-shifted absorption and fluorescence values, which may be correlated to a longer effective conjugation length, are observed for polymer **2** which has three naphthalene units conjugated through two cyanovinylene bridges and does not have alkoxy substituents in positions adjacent to the cyano groups. In polymer **3** the absorption and emission values are blue shifted in comparison with polymer **2**, probably as a consequence of the already mentioned steric hindrance. The blue shift of the absorption and emission in polymer **1** with respect to polymer **2** may be rationalized in terms of a shorter conjugated system.

In order to ascertain that the conjugated system in the new polymers is really confined to the region between the two binaphthyl moieties (Fig. 1), we have determined by semi-empirical calculations (PM3) the angle of rotation between the two naphthyl moieties of binaphthyl in a model compound constituted by the conjugated system of **3** end-capped by two naphthyl groups. The found values (85.7 and 92.1°) strongly suggest the lack of conjugation. Furthermore, we have synthesized compound **8**, which is the repetitive conjugated unit of polymer **3** (Fig. 1) in order to determine its UV-Vis spectrum. The data obtained (λ_{max} 380 nm) are in full agreement with that obtained for the related polymer **3** (λ_{max} 378 nm), showing the same onset value.

In summary, new optically active block copolymers containing binaphthyl units have been synthesized. They show an intense photoluminescence and a high electron affinity and therefore they are promising candidates for the fabrication of light emitting diodes. The main chain chiral character of these polymers may enable the observation of circularly polarized photo- and electroluminescence, which has not so far been reported.[13] Finally, a remarkable aspect of this contribution is that it might provide an effective approach to the synthesis of polymeric luminescent materials in which the emissive colors can be effectively tailored by reacting different appropriately functionalized fluorophores with binaphthyl monomers *via* Knoevenagel condensation polymerization.

This work has been supported by the Universidad Complutense de Madrid (Project PR49/98-7805) and DGICYT (Project PB95-0428-CO2). We are also indebted to Dr G. Orellana for the Photoluminescence measurements, Dr J. San Román and A. Gallardo for GPC measurements, and to Centro de Espectroscopía de la UCM.

Quantitative evaluation of steric effects for π-facial stereoselection: π-plane-divided accessible space

Shuji Tomoda* and Takatoshi Senju

Department of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo at Komaba, Meguro, Tokyo 153-8902, Japan. E-mail: tomoda@selen.c.u.-tokyo.ac.jp

Received (in Cambridge, UK) 28th January 1999, Accepted 26th February 1999

A simple method for quantitative evaluation of steric effects in π-facial stereoselection has been described.

Steric effects, defined as the exchange repulsion term between reactant molecules according to the Salem–Klopman equation,[1] often play a key role in stereochemical control of organic reactions. It is, however, commonly used only as a qualitative term. Nevertheless highly practical asymmetric syntheses have been designed through intuitive estimation of steric effects based on the size of substituents, such as *A* values[2] or van der Waals radii.[3] It is however often difficult to predict steric effects in π-facial selection[4] intuitively, in particular for substrates having complex substituents around the π-bond. A simple quantitative parameter of π-facial steric effects should provide a convenient means to gain clearer and more effective perception in designing organic syntheses. Herein we describe the first method that is useful for predicting π-facial steric effects for common organic unsaturated substrates.

The new method focuses on the three-dimensional space outside the van der Waals surface of a reactant molecule.[5] It is based on the simple assumption that the volume of the outer (exterior) space nearest to a reaction center should contain steric information of the reactant (substrate), since this volume precisely corresponds to the three-dimensional space available for a reagent to access the reaction center of the substrate. The exterior volume is calculated for the two faces of the π-plane separately. Fig. 1 illustrates the definition of the π-plane-divided accessible space (PDAS) as a reasonable quantitative measure of π-facial steric effects using formaldehyde as an example. The molecular surface is defined as an assembly of spherical atoms having the appropriate van der Waals radii.[3] Integration of exterior three-dimensional space for the PDAS of the carbonyl carbon is performed according to the following conditions. If a three-dimensional point P(*x*, *y*, *z*) outside the repulsive surface is the nearest to the surface of the carbonyl carbon (a reaction center on the *xz* plane) [*i.e.* if the distance between P and the van der Waals surface of the carbonyl carbon (d_C) is the shortest compared with the distances from P to the other atomic surfaces (two d_H and one d_O)] and if the point is located above the carbonyl plane ($y > 0$), the space at this point is assigned to the above-space of the carbonyl carbon. The integration (summation) of such points is defined as the PDAS of the carbonyl carbon for the above-plane. For the sake of convenience, spatial integration is limited to 5 au (2.65 Å) from the molecular surface, where extension of an electronic wave function is negligible beyond this limit. In general, the carbonyl plane is defined as the plane which includes the two sp^2 atoms of the π-bond and which is parallel with the vector connecting the two atoms at the α-positions. The basic concept of the PDAS definition is readily extended to other π-facial steric effects in compounds containing a general double bond other than a carbonyl. The calculation procedure usually begins with structure optimization at the HF/6-31G(d) level using GAUSSIAN 94.[6] PDAS calculation is then performed according to the three-dimensional lattice method with a unit lattice volume of 0.008 au^3 (1.18×10^{-3} Å^3). The method has been successfully applied to a variety of unsaturated substrates. A few examples, for which facial stereoselection has been previously explained without invoking steric effects, will be described.

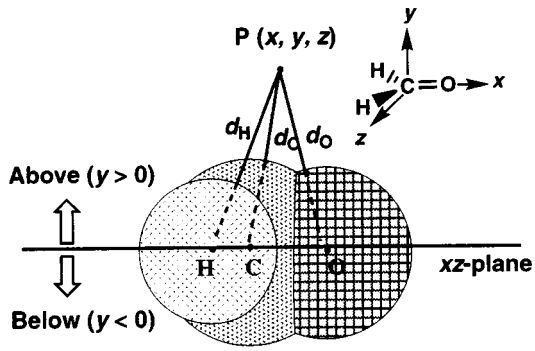

Fig. 1 Definition of π-plane-divided accessible space (PDAS) for the case of formaldehyde.

Table 1 collects the PDAS data of four cyclic ketones (**1**–**4**) along with two cyclohexanones for comparison. The *ax*-face of cyclohexanone (19.4 au^3) is indeed more hindered than the *eq*-face (47.2 au^3), as it is for *tert*-butylcyclohexanone.[7] The stereochemistries of these two and other alkyl-substituted cyclohexanones have been successfully rationalized with the EFOE model (exterior frontier orbital extension model)[8] and are apparently orbital-controlled. The stereochemical reversal observed for 4-*eq*-phenyl-1,3-dioxan-5-one (**1**)[9] and its sulfur analog (**2**)[10] has been the subject of intense investigation.[11,12] Not only the nearly constant stereoselectivity irrespective of the bulkiness of the Grignard reagent employed (RMgI; R = Me, Et, Pr^i),[9,10] but also the PDAS values for **1** and **2** clearly indicate that steric effects should be mainly responsible for the face selection of the heterocyclic ketones. Exclusive attack of $LiEt_3BH$ from the *ax*-face of 2-*ax*-methyl-3-*eq*-phenyl-5-*eq*-methoxypyran-4-one **3**[4,13] can also be explained by the substantially reduced PDAS value in the *eq*-face (13.8 au^3) compared to the *ax*-face (22.4 au^3). As seen in Table 1, exclusive equatorial hydride attack at 2-*eq*, 7-*eq*-dimethyl **4**[14] can be readily rationalized by severe steric hindrance in the *ax*-face where the PDAS value is only 5.5 au^3. In all these examples, the peculiar stereochemical behavior can be ex-

Table 1 π-Plane-divided accessible space (PDAS) for the carbonyl carbon of cyclic ketones and their observed π-facial stereoselectivity in nucleophilic additions[a]

Compound	PDAS/au^3 *ax*	PDAS/au^3 *eq*	Observed *ax*:*eq*

plained simply using ground-state conformations without resorting to transition state effects.[11,15]

Another intriguing example is the 3-substituted cyclohexanone system **5**. A plot of the PDAS values for the *ax*-face of **5** (*ax*-PDAS)[16] against facial stereoselectivity [ln(*ax*/*eq*)] for the reaction of **5** with MeLi reported previously by Cieplak[17,18] for eight substituents indicated an excellent linear correlation (r^2 = 0.95), strongly suggesting that the conformations of **5** are sensitive to the electronic properties of these substituents. Four major explanations have appeared to date to rationalize the enhancement of *ax*-attack in the cyclohexanone system carrying an electron-withdrawing substituent at C3 relative to 4-*tert*-butylcyclohexanone.[12*a*,17–20] Our PDAS calculations clearly indicate that subtle ground-state conformational changes in the cyclohexanone moiety caused by an equatorial substituent at C3 are most likely to be responsible for the observed trend of facial selection of this system.

5-Substituted adamantan-2-ones **6** (X = C or N; Y = substituent) have been regarded as sterically unnbiased systems, where both π-faces are assumed to be sterically equivalent.[21] The parent adamantan-2-one is less reactive with hydride than cyclohexanone,[22] despite the theoretical observation that the transition state antiperiplanar effects are much greater than those in cyclohexanone.[23] Table 2 collects the PDAS data of **6**.[6] The PDAS values of adamantan-2-one are both 11.1 au^3. This is much smaller than the PDAS value for the *ax*-face of cyclohexanone (19.4 au^3), suggesting that adamantan-2-one is *much more sterically demanding* than cyclohexanone. This in turn suggests that subtle changes in steric environment around the carbonyl of **6** may cause significant variation in π-facial stereoselection. The data in Table 2 exhibits a good correlation between the facial stereoselectivity (*anti* : *syn*) and the facial difference in the PDAS value [ω = PDAS(*syn*) − PDAS(*anti*)] (r^2 = 0.68). Among 16 substituents examined, those which pefer *anti*-selectivity are limited to two bulky substituents ($SiMe_3$ and $SnMe_3$; $\omega < 0$). This strongly indicates that in the adamantan-2-one system, where facial differences in frontier orbital extension are marginal, subtle steric effects may be especially important for facial stereoselection in agreement with the recent report by Gung.[24]

Received (in Liverpool, UK) 2nd February 1999, Accepted 25th February 1999

The monomer rotaxane 13, bearing two protected functional groups, is used to obtain a dimer, following a new approach of sequential deprotection–coupling steps which can lead to mechanically linked polyrotaxanes.

Rotaxanes and catenanes as well as their polymer derivatives appear increasingly in the literature. In the field of polymers, a number of fascinating polyrotaxane structures have been presented.[1] It has been shown that the properties of these compounds are in many cases very different compared to the 'naked' polymers.[2]

In the vast majority of the compounds synthesized so far, a covalently connected polymer backbone is surrounded by 'cyclic' molecules, or alternatively, rotaxane subunits are connected to the polymer backbone as side groups.[1,2] The very attractive concept of synthesizing oligomers and/or polymers where the repeating units are connected to each other in a non-covalent way was proposed some years ago,[3] but progress towards this aim has been achieved only very recently.[4–6] Such polymers and/or oligomers with non-covalent connections are expected to give materials with new rheological and mechanical properties. Until now, this research has mainly been focused on polycatenanes.[4] Reports on mechanically linked polyrotaxanes have only described small assemblies[5] and polypseudorotaxanes.[6]

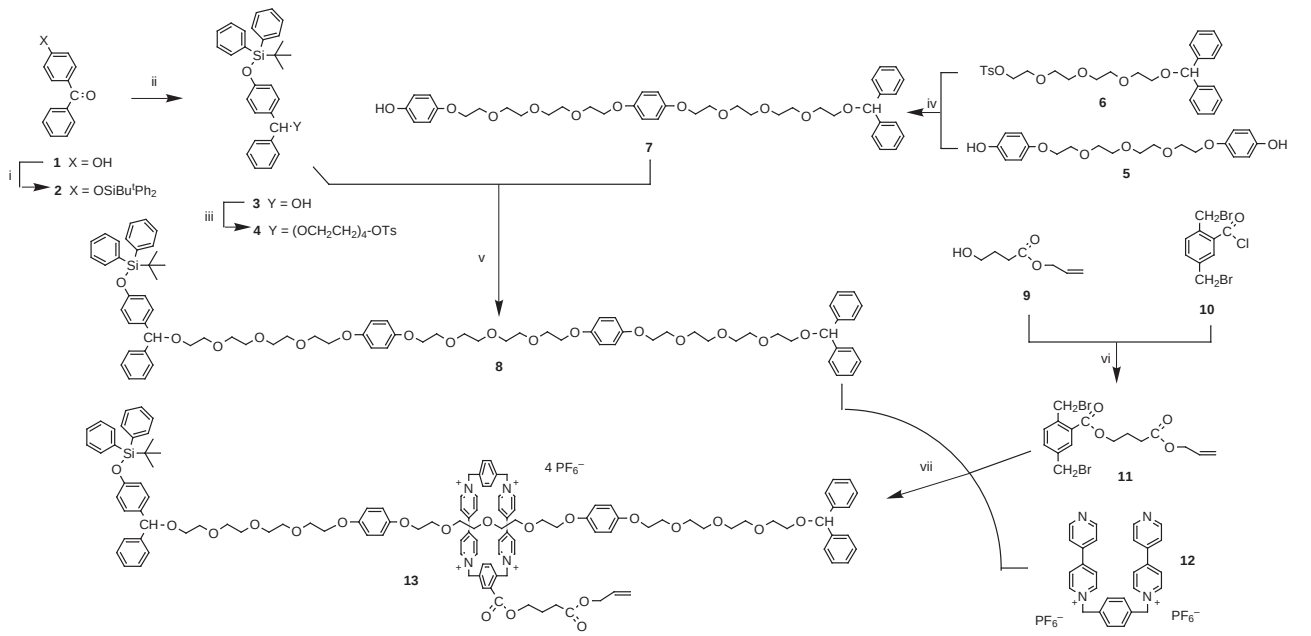
Here we present the synthesis of a new mechanically linked dimer rotaxane, where the repeating units are connected by non-covalent bonds. The synthesis is based on a new step-by-step approach consisting of sequential deprotection–coupling steps that can lead to well defined oligomers. A bisfunctionalized rotaxane is used as the starting monomer. The dimer synthesis and some preliminary studies are presented.

The rotaxane structure used as monomer (compound **13** on Scheme 1) is based on dialkoxybenzene units with a cyclophane containing two 4,4′-bipyridinium groups. Similar types of systems have been studied extensively by the group of Stoddart.[7]

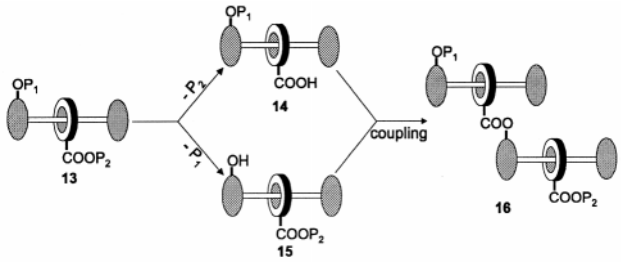
The synthesis of polyrotaxanes and polycatenanes has proven to be quite challenging. In the step-by-step approach, presented in Scheme 2, the initial monomer rotaxane **13** was designed to fulfil a number of requirements: (a) introduction of functional units so that polymerization is possible, (b) protection of these functional units for a step-by-step synthesis and (c) minimization of electronic and/or steric problems.

The positions of the two functional groups in the rotaxane were chosen in such a way that a dimerization and/or polymerization reaction could lead to oligomers with the repeating units connected non-covalently (Schemes 1 and 2). These groups are a phenol and a carboxylic acid. In general, between these two groups, a high-yield coupling reaction (esterification) can take place in only one synthetic step. This is important in order to minimize the number of reaction steps that involve the rotaxane molecule.

Although a number of protective groups are available for sequential removal, in our case the choice decreased significantly since selective deprotection of both groups is needed. In addition, the various sensitive groups in the rotaxane structure **13** should be inert to the deprotection conditions. This compound contains an ester bond and a bis(4,4′-bipyridinium) cyclophane derivative, which both show very limited stability in



Scheme 1 Synthesis of the bisprotected monomer **13**. *Reagents and conditions*: i, TBDPSCl, Et_3N, DMAP, Py, THF (71%); ii, $NaBH_4$, THF (79%); iii, NaH, $Ts(OCH_2CH_2)_4OTs$, THF (65%); iv, K_2CO_3, DMF (58%); v, NaH, THF (38%); vi, Pr^i_2EtN, CH_2Cl_2 (49%); vii, CH_3CN, $AgPF_6$ (4.8%).



Scheme 2 Schematic representation of the synthesis of the bisprotected dimer **16**.

alkaline pH. Furthermore, the two blocking groups are of the diphenylmethyl ether type and are unstable in acidic conditions. The hindered TBDPS protective group appears to be a good protective group for the phenol unit. It is stable under a variety of basic and acidic conditions[8] (necessary in steps ii, iii and v in the rotaxane synthesis), while it can be removed specifically with fluoride anions under very mild conditions. In the carboxylic acid case, our initial attempts were focused on the tetrahydropyranyl (THP) group. Unfortunately, despite encouraging results obtained with model compounds, it was found that this group was too labile, and was removed during simple work-up operations of the rotaxane **13**. In contrast, the allyl group was found to be suitable. The allyl ester bond is stable during steps vi and vii (Scheme 1) as well as during the reactions used in the synthesis of oligomers. At the same time, it can be selectively removed in the presence of other ester bonds by Pd catalysts under mild conditions.

The last point in the design of rotaxane **13** concerns the reactivity of the carboxylic acid group. It has been reported[9] that a carboxylic group directly connected to the bis(4,4′-bipyridinium) cyclophane is not active towards esterification. In preliminary experiments we found similar behaviour. Therefore, in molecule **13** the protected carboxylic group was moved to a position that is not in close proximity to the tetracationic cyclophane.

The synthesis of the rotaxane **13** was accomplished by reacting **8**, **11** and **12** in the presence of excess of $AgPF_6$ in 4.8% yield.† The low yield may be attributed[5] to the steric hindrance of the carboxylic ester group of **11**. Despite this low yield, at the end of the reaction most of the unreacted compound **8** can be recovered and used again in step vii. Compounds **5**, **6**, **10** and **12** were obtained according to literature procedures while molecule **9** was accessed by ring opening of γ-butyrolactone with allyl alcohol under acidic conditions. The procedures followed for the synthesis of molecule **8** are delineated in Scheme 1.

Selective deprotection of the two functional groups in two different batches was the first step towards the synthesis of the dimer. Thus, rotaxane **14** contained a free carboxylic acid group obtained by deprotection of **13** with $Pd(PPh_3)_4$, while rotaxane **15** contained a free phenol group, obtained by deprotection of **13** with Bu_4NF. In the last step, esterification (DCC/Py) between the acid **14** and the alcohol **15** gave the dimer **16** in a 30–40% yield. This compound also contains a protected phenol and a protected carboxylic acid, like the monomer **13**. Therefore, longer derivatives (tetramer, octamer *etc.*) can be obtained by sequential deprotection–esterification steps.

Both the monomer **13** and the dimer **16** were characterized by MALDI-TOF mass spectrometry and ^{1}H NMR and UV-VIS absorption spectroscopy. The ^{1}H NMR spectra of **13** and **16** in CD_3COCD_3 are consistent with the assigned structures.

The hexafluorophosphate salts of the rotaxanes **13** and **16** are red solids, insoluble in H_2O but soluble in acetone, CH_3CN and CH_2Cl_2. Also, they are insoluble in solvents of lower polarity such as Et_2O, $CHCl_3$ and hexane. The UV-VIS spectra of both **13** and **16** in CH_3CN and in CH_2Cl_2 show two absorption maxima; an intense peak at 265 nm and a very weak peak at 480 nm. The last one corresponds to the charge transfer interaction known in rotaxanes of similar structure.[10]

The MALDI-TOF mass spectrum of **16** with 2,5-dihydroxybenzoic acid as matrix [Fig. 1(*b*)] shows four peaks at 4303, 4159, 4015 and 3869 mass units (mu), corresponding to the ions $[M - 4PF_6]^+$, $[M - 5PF_6]^+$, $[M - 6PF_6]^+$ and $[M - 7PF_6]^+$, respectively. The peaks at lower masses can be easily identified as fragments of the molecular ion. By using 5-methoxysalicylic acid instead of 2,5-dihydroxybenzoic acid as matrix, a different series of ions can be identified $[M - 2PF_6]^+$, $[M - 3PF_6]^+$, $[M - 4PF_6]^+$ and $[M - 5PF_6]^+$. Similar results were found for the monomer **13**. The three peaks at 2299, 2154 and 2009 mass units (mu) correspond to the ions $[M - 2PF_6]^+$, $[M - 3PF_6]^+$ and $[M - 4PF_6]^+$, respectively [Fig. 1(*a*)].

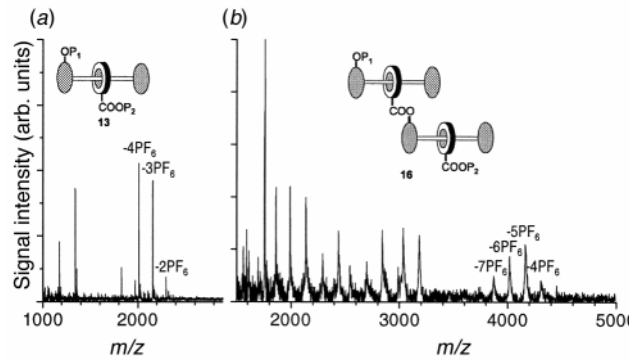


Fig. 1 MALDI-TOF spectra in 2,5-dihydroxybenzoic acid matrix: (*a*) monomer **13**, (*b*) dimer **16**.

In conclusion, we were able to synthesize the monomer rotaxane **13**, which bears two protected functional groups and can give oligomers in a controlled way for the first time, by sequential deprotection–coupling steps. Coupling between derivatives of **13** gives a dimer **16** which can be used for the synthesis of longer rotaxanes by applying the same approach. The connection of the repeating units in the dimer **16** provides a new way to obtain polyrotaxanes based on non-covalent bonds. Synthesis and study of the rheological properties of longer oligorotaxanes based on monomer **13** are in progress.

We are grateful to B. Kwant for help in the synthetic work and to Dr A. Kievit for his advice concerning MALDI-TOF spectrometry. This work was financially supported by the Netherlands Foundation for Chemical Research (NWO-CW).

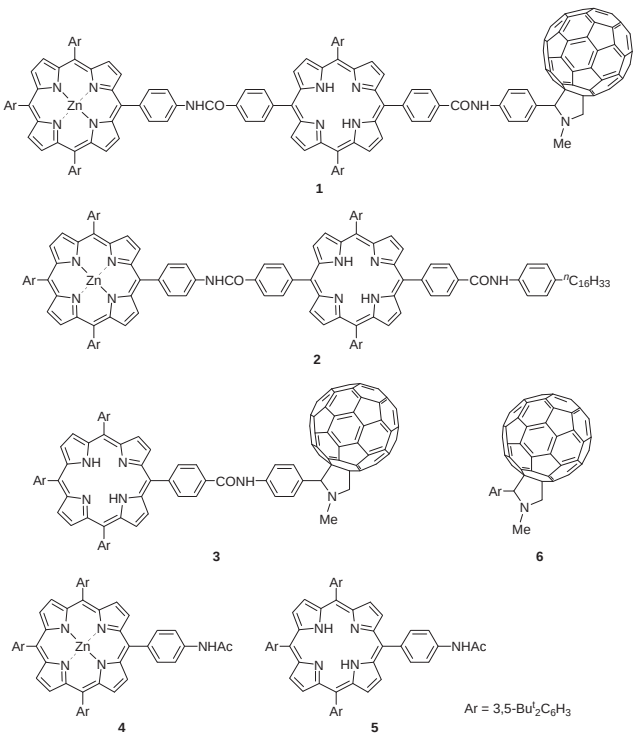
Received (in Cambridge, UK) 6th January 1999, Accepted 2nd March 1999

A novel covalently-linked diporphyrin–C_{60} triad has been prepared by 1,3-cycloaddition of C_{60} with a diporphyrin.

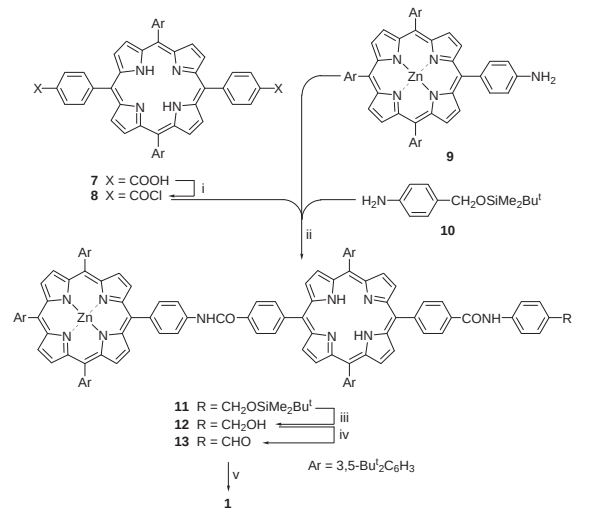
Fullerenes have fascinated many researchers during the last decade because of the large size and spherical shape of their delocalized π-electron system with high symmetry.[1] In particular, the unique three-dimensional structures of fullerenes make them a good candidate as an electron acceptor (A). As such, a number of donor (D)–fullerene dyads have been prepared.[2,3] We and other groups have found that C_{60} accelerates photoinduced charge separation (CS) and retards charge recombination (CR) in donor-linked C_{60} dyads. The peculiar effect of C_{60} in electron transfer (ET) is quite similar to the situation in photosynthetic multistep ET, and therefore we were encouraged to design fullerene-containing multicomponent systems as artificial photosynthetic models. There are several reports of triads and a pentad, such as D–S (sensitizer)–C_{60},[4] S–A–C_{60},[5] and S–$(C_{60})_n$ (n = 2,4)[6–11] systems. However, to the best of our knowledge, no reports concerning S–S′–C_{60} systems have appeared so far. Here we report the synthesis and photophysical properties of diporphyrin–C_{60} triad **1**.



The synthesis of **1** is shown in Scheme 1. The key features involve selective insertion of a zinc atom into the diporphyrin and its protection from the demetallation. Therefore, after the insertion all the procedures were carried out under neutral or basic conditions. Free base porphyrin carboxylic diacid **7** was converted to the corresponding bis(acid chloride) **8** by treatment with $SOCl_2$. Cross-condensation of **8** with zinc amino porphyrin **9** and 4-*tert*-butyldimethylsiloxymethylaniline **10** in benzene in the presence of pyridine afforded a mixture of porphyrins. The desired diporphyrin **11** was isolated in 34% yield by tedious chromatographic separation. Removal of the TBDMS group in **11** with Bu_4NF gave **12**, which was oxidized using activated MnO_2 to yield **13**. The triad **1** was obtained by 1,3-dipolar cycloaddition using **13**, *N*-methylglycine and C_{60} in toluene in 79% yield.[12] Diporphyrin **2** was synthesized from **8**, **9** and 4-hexadecylaniline by a similar method. The reference compounds **3**–**6** were also prepared. Their structures were verified by spectroscopic analyses including ^{1}H NMR and MALDI-TOF mass spectra.†

The absorption spectrum of **1** in THF was almost a linear combination of the spectra of **4**, **5** and **6**, indicating no significant interactions among the three chromophores in the ground state. Absorption due to the two porphyrin chromophores is much stronger than that of C_{60}. The redox potentials of **1**–**6** were measured by differential pulse voltammetry in CH_2Cl_2 using 0.1 M Bu_4NPF_6 as supporting electrolyte. The potentials of **1** (−1.52, −1.14, +0.29, +0.54 V *vs*. Fc/Fc$^+$) can be roughly explained by the sum of **4**, **5** and **6** (**4**: +0.25 V; **5**: +0.43 V; **6**: −1.54, −1.15 V *vs*. Fc/Fc$^+$), implying weak electronic coupling among the three moieties.

Fig. 1 shows steady-state fluorescence spectra of **1**, **2**, **4** and **5** in THF with excitation at 426 nm. The zinc porphyrin **4** exhibits emission maxima at 604 and 657 nm, while the free base porphyrin **5** displays maxima at 652 and 719 nm. The emission of **2** is almost the same as that of **5**, with no appreciable emission from the zinc porphyrin, which is in good agreement with the results in a similar diporphyrin system.[13] Considering that both the porphyrins in **2** absorb at 426 nm, it is suggested that efficient singlet–singlet energy transfer (EN) occurs from the first excited singlet state of a zinc porphyrin (^{1}ZnP*) to a free



Scheme 1 *Reagents and conditions*: i, $SOCl_2$, pyridine, benzene, reflux; ii, pyridine, benzene, 34% (2 steps); iii, TBAF, THF, 81%; iv, activated MnO_2, $CHCl_3$, 78%; v, C_{60}, $MeNHCH_2CO_2H$, toluene, reflux, 79%.

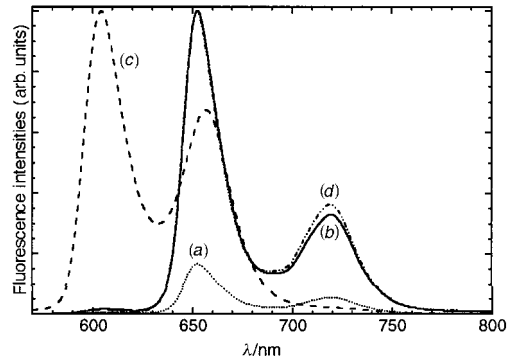


Fig. 1 Fluorescence spectra of (*a*) **1** and (*b*) **2** (2.0×10^{-6} M) in THF with excitation at 426 nm. The normalized spectra of (*c*) **4** and (*d*) **5** are shown as a comparison.

base porphyrin (H_2P). The emission of **1** was quenched strongly as compared with that of **2** when excited at 426 nm under the same concentration (relative intensity: 0.17). No apparent C_{60} emission (λ_{max} = 720 nm) could be detected.‡ Similar quenching behavior was seen for **3** *vs.* **5** (relative intensity: 0.19). These results show the rapid quenching of the excited singlet state of the porphyrin by the C_{60} in **1**.

Preliminary photophysical experiments of **1** and **2** in THF were carried out using a picosecond single photon counting technique with excitation at 422 nm, where both the porphyrins absorb, and monitoring at 655 and 720 nm, where the emission is due to both the porphyrins, and the free base porphyrin and the C_{60}, respectively. Fluorescence decay of **2** at 655 nm was analyzed by two exponential decays with time constants of 44 ps (A = 0.19) and 9.9 ns (A = 0.81). In contrast, the emission at 720 nm was fitted by a rise with a time constant of 44 ps and a decay with a time constant of 9.9 ns (A = 1.00) which agrees well with the fluorescence lifetime (9.8 ns) of **5** in THF. The matching of the time constants between the decay and the rise in **2** strongly supports the efficient EN from ^{1}ZnP* to H_2P in THF. Based on the results together with the fluorescence lifetime of **4** (2.0 ns) in THF, we can calculate the rate constant of EN to be 2.2×10^{10} s^{-1}. The component with the longer lifetime (9.9 ns) monitored at 655 and 720 nm can be assigned reasonably to the emission from the free base porphyrin. Similar results were obtained in **1**, except that a component corresponding to the longer lifetime showed a decreased time constant of 1.7 ns, which is consistent with the fluorescence lifetime of **3** (1.4 ns) in THF. The shorter time constant (τ = 1.7 ns, A = 1.00) of **1** due to the free base porphyrin, compared with that (9.9 ns) of **2**, indicates the photoinduced ET[4] or partial charge-transfer (CT) from ^1H_2P* to C_{60}[14] as shown in Fig. 2.§ These results suggest that initial photoinduced EN from ^{1}ZnP* to H_2P and subsequent CS or CT from $^1H_2P^*$ to C_{60} may take place in **1**.¶

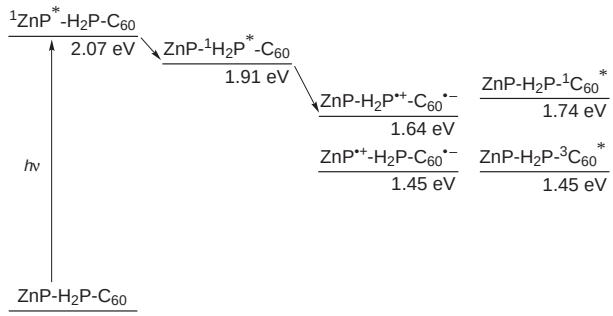

Fig. 2 Plausible reaction scheme and energy diagram for **1** in THF.

In conclusion, a diporphyrin–C_{60} triad has been prepared for the first time. Although our interpretation of the quenching mechanism is consistent with the results obtained by the fluorescence lifetime measurements, further details must wait transient absorption experiments, which are in progress.

† *Selected data* for **1**: δ_H(270 MHz; $CDCl_3$) −2.84 (s, 2H), 1.53 (s, 90H), 2.67 (br s, 3H), 3.67 (br s, 1H), 4.31 (br s, 1H), 4.50 (br s, 1H), 7.61 (br s, 2H), 7.79 (s, 3H), 7.81 (s, 2H), 7.96 (d, *J* 8, 2H), 8.04 (s, 4H), 8.09 (s, 6H), 8.20–8.31 (m, 8H), 8.42 (d, *J* 8, 2H), 8.48 (d, *J* 8, 2H), 8.70 (br s, 2H), 8.77 (d, *J* 4, 2H), 8.88–8.90 (m, 6H) and 9.01–9.03 (m, 8H); *m*/*z* (MALDI-TOF; positive mode) 2794 ($M+H^+$); (MALDI-TOF; negative mode) 721 (C_{60}^-); λ_{max} (THF)/nm 350 (sh), 361 (sh), 404 (sh), 420 (sh), 427, 485, 516, 555, 597, 649 and 704.

‡ In the steady-state fluorescence experiments it was quite difficult to discriminate the emissions from the free base porphyrin and the C_{60} because of overlapping at 700–750 nm as well as the weak fluorescence from the mono-functionalized C_{60}.

§ We cannot rule out the possibility that there are other competitive pathways, where EN from ^1H_2P* takes place to populate $^1C_{60}$*, followed by ET from the porphyrin to $^1C_{60}$* to produce $H_2P^{\cdot+}$–$C_{60}^{\cdot-}$, or equilibration with ^1H_2P* energetically and/or by intersystem crossing from $^1C_{60}$* to $^3C_{60}$*.

¶ Based on the energy level diagram in THF, a charge-shift might occur from ZnP to $H_2P^{\cdot+}$ in the ZnP–$H_2P^{\cdot+}$–$C_{60}^{\cdot-}$ state, leading to the production of ZnP$^{\cdot+}$–H_2P–$C_{60}^{\cdot-}$.

Reaction of (*Z*)-1-bromoalk-1-enyldialkylboranes with DMSO: regio- and stereo-selective formation of internal (*E*)-alkenyl bromides

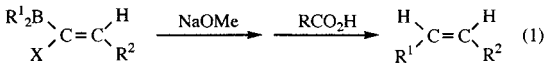
Masayuki Hoshi,* Hideyuki Tanaka, Kazuya Shirakawa and Akira Arase

Department of Applied and Environmental Chemistry, Kitami Institute of Technology, 165 Koen-cho, Kitami 090-8507, Japan. E-mail: HOSHI-Masayuki/chem@king.cc.kitami-it.ac.jp

Received (in Cambridge, UK) 25th January 1999, Accepted 2nd March 1999

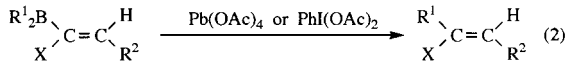
Treatment of (*Z*)-1-bromoalk-1-enyldialkylboranes 1 with DMSO results in 1,2-migration of an alkyl group from the boron to the α-carbon without elimination of bromine to give internal (*E*)-alkenyl bromides 2 with excellent stereoselectivity (> 99%).

(*Z*)-1-Haloalk-1-enylboranes, which can be prepared by hydroboration of 1-haloalk-1-ynes with borane derivatives, are versatile and potential precursors of alkenes.[1] For example, the reaction of (*Z*)-1-haloalk-1-enyldialkylboranes with MeONa followed by protonolysis with carboxylic acids offers regio- and stereo-selective syntheses of internal (*E*)-alkenes where one of the alkyl groups on the boron atom is introduced into the α-alkenyl carbon atom with elimination of a halogen atom [eqn. (1)].[2] This strategy could be applied to the synthesis of



(1)

prostaglandin analogues.[3] On the other hand, we reported that a similar alkyl group migration was performed without elimination of the halogen atom by treatment of (*Z*)-1-haloalk-1-enyldialkylboranes, whose alkyl groups were derived from a relatively hindered alkene, with lead(IV) acetate or (diacetoxyiodo)benzene giving internal (*Z*)-alkenyl halides in a highly stereoselective manner (95–98% for *Z*) [eqn. (2)].[4] Ster-

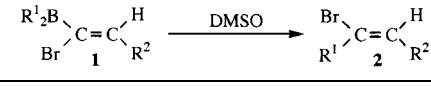


(2)

eodefined alkenyl halides are important substrates, especially as coupling partners of transition metal mediated cross-coupling reactions to give alkenyl units stereoselectively.[5] For example, (11*Z*)-retinal[6] and rapamycin[7] were synthesized using the above coupling reaction. In these reactions the purity of the haloalkene is important. This prompted us to investigate the alkyl group transfer reaction in the hope of obtaining highly pure internal alkenyl halides. We report here a new type of synthesis of internal (*E*)-alkenyl bromides **2** from (*Z*)-1-bromoalk-1-enyldialkylboranes **1** with excellent stereoselectivity (> 99%), on which DMSO has a decisive influence.

The reactions of **1** with DMSO were carried out under reaction conditions optimised using (*Z*)-1-bromohex-1-enyldicyclohexylborane **1a** as a typical substrate. Thus, **1a** was treated with 2 equiv. of DMSO in $ClCH_2CH_2Cl$ at 0 °C to room temperature for 18 h (Scheme 1). After work-up† (*E*)-1-bromo-1-cyclohexylhex-1-ene **2a**‡ was obtained in 73% yield and in > 99% isomeric purity (entry 1, in Table 1). The stereochemistry of **2a** was assigned the *E* configuration by comparing GC and ^1H and ^{13}C NMR analyses of **3a** (Scheme 2)

Table 1 Reaction of (*Z*)-1-bromoalk-1-enyldialkylboranes **1** with DMSO[a]



Entry	R^1	R^2	Product	Yield (%)
1	Cyclohexyl	Bu	**2a**	73
2	Hexyl[b]	Bu	**2b**	69
3	Pr(Me)$CHCH_2$[b]	Bu	**2c**	70

5	Cyclopentyl[b]	Bu	**2e**	68
6	Cyclohexyl	Ph	**2f**	59
7	Hexyl[b]	Ph	**2g**	45
8	Hexyl[b]	Bu^t	**2h**	28
9	Cyclohexyl	$(CH_2)_2CH_2Cl$	**2i**	60

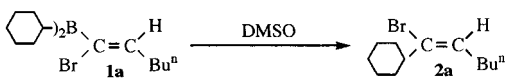
[a] Reactions were carried out in $ClCH_2CH_2Cl$ using 2 equiv. of DMSO unless otherwise noted. [b] Reactions were carried out in CCl_4.

with those of an authentic sample prepared according to the literature.[8]

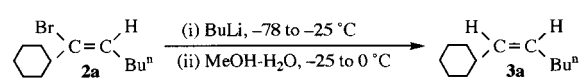
The above example demonstrates that the relatively hindered alkyl group on the boron atom is introduced to the alkenyl moiety of **2** as one of the alkyl substituents in a regio-and stereoselective manner. We next explored the reaction of **1**, which was prepared using a variety of dialkylboranes derived from less hindered alkenes through hydroboration with $BH_2Br{\cdot}SMe_2$,[9] followed by hydridation with $LiAlH_4$.[10] For example, (*Z*)-1-bromohex-1-enyldihexylborane **1b** reacted with DMSO under similar conditions§ to afford isomerically pure (*E*)-6-bromododec-5-ene **2b**¶ in 69% yield (entry 2).

In all cases listed in Table 1, internal (*E*)-alkenyl bromides **2** were obtained in > 99% isomeric purity. Accordingly, the present reaction can be applied not only to the cases of relatively hindered dialkylboranes (entries 1, 6 and 9) but also to the cases of less hindered dialkylboranes (entries 2–5, 7 and 8), demonstrating that a wide variety of compounds **2** can be formed using this strategy.

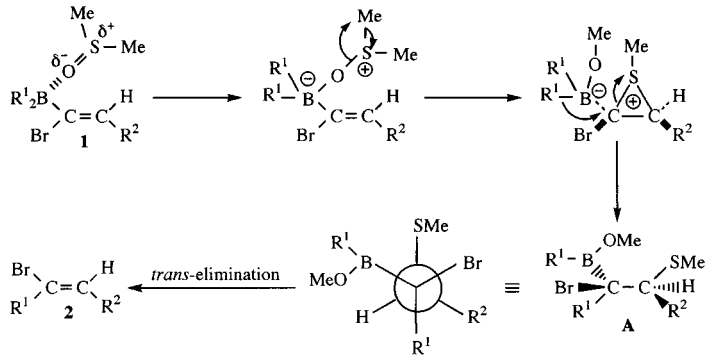
A plausible mechanism for the formation of internal (*E*)-alkenyl bromides **2** is shown in Scheme 3. It was observed that the yields of **2** depended considerably on the solvent employed. In addition, the addition of an equimolar amount of pyridine, a more polar compound than THF, to **1** inhibited completely the present reaction. These results suggest that the reaction is initiated by nucleophilic attack of DMSO. It appears that a concerted reaction, which involves the transfer of a methyl group from sulfur to oxygen and the concomitant formation of methylthio cation, occurs through two-electron oxidation. Then electrophilic addition of the methylthio cation to the carbon–carbon double bond followed by 1,2-migration of an alkyl group from boron to the α-carbon would take place to form intermediate **A**. Finally, intermediate **A** would undergo *trans*-



Scheme 1



Scheme 2



Scheme 3

elimination of an alkylmethoxyboryl group and a methylthio group‖ to yield **2**. In the case of entry 8, the large steric hindrance between R^1 and R^2 could be responsible for the low yield of (*E*)-4-bromo-2,2-dimethyldec-3-ene **2h**.

In summary, we have demonstrated that a variety of compounds **1** react with DMSO to provide the corresponding species **2** in > 99% isomeric purity, and thus both substituents (R^1 and R^2) in **2** can be selected from a wide range of possible groups. It should be noted that the present reaction is carried out under mild and essentially neutral conditions. Further studies on the application of this strategy to different types of species **1** with varying functionality and a similar nucleophilic attack on **1** are now in progress.

The biomimetic oxidation of dieldrin using polyhalogenated metalloporphyrins

Fumio Hino and David Dolphin*

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1. E-mail: ddolphin@qlt-pdt.com

Received (in Corvallis, OR, USA) 19th November 1998, Accepted 4th January 1999

Biomimetic oxidation of dieldrin produces the same metabolites as generated *in vivo*, which suggest a 'radical oxygen-rebound' mechanism.

Dieldrin **1**, like other insecticides, accumulates in the food chain and its use, as with other organochlorinated materials such as DDT, has been banned in many countries. Dieldrin accumulates principally in adipose tissue and is only slowly metabolized. Even though it has not been used in North America for more than two decades[1] it is, to this day, still found in the food chain. In the laboratory it was found that one year after injection of dieldrin only ~50% of the material had been metabolized and excreted, while half the dose was still retained by rabbits.[2] Some of the less interesting dieldrin metabolites arose from opening of the epoxide ring, but one particular metabolite, the intramolecularly bridged pentachloro ketone **6**, allowed for some very interesting speculation as to its mechanism of formation. McKinney *et al.* suggested[3] that the other principle mammalian metabolite, *syn*-9-hydroxydieldrin **3**, might be an intermediate in the formation of **6**, but they eventually considered this unlikely since feeding of **3** to a rat produced no pentachloro ketone in its liver, where it is known to accumulate. It was suggested, in 1975,[4] that a common intermediate, the species containing a radical at C-9 (**2**, Scheme 1), could account for the formation of both **3** and **6**; this suggestion is consistent with Groves' oxygen-rebound mechanism for the hydroxylation of alkanes by cytochrome P-450 which was formulated in 1976.[5,6]

We have been unsuccessful in oxidizing dieldrin using isolated liver microsomes, due principally to its solubility properties and the destruction of microsomes under forcing conditions. We also failed in oxidizing dieldrin using metalloporphyrins derived from tetrakis(2,6-dichlorophenyl)porphyrin as biomimetic catalysts since dieldrin is quite recalcitrant towards oxidation and the porphyrin catalysts were destroyed before sufficient substrate oxidation could occur.

Recently, however, new highly halogenated porphyrins containing eight halogen atoms on the porphyrin periphery have been reported and these third generation catalysts (**10**, **11**) are showing exciting potential as biomimetic and industrial catalysts.[7] The oxidizing power of these catalysts and the turnover numbers that they exhibit are extraordinary, and both the iron and manganese complexes **10** and **11** effectively oxidize dieldrin to give the same products (**3**, **6**) as those previously identified from mammalian metabolism studies.

We have examined a number of cooxidants in addition to those shown in Table 1 and found that Oxone ($KHSO_5$) and H_2O_2 caused considerable destruction of catalyst and, at best, gave only a trace of oxidized dieldrin. On the other hand, surprisingly good yields of **3** and **6** were observed using hypochlorite, iodosylbenzene (PhIO) and alkyl hydroperoxides in mixed aqueous/organic solvents; small amounts of the ketone **7** were also seen when the reaction was carried out in only organic solvents. Ketone **7** arises from the over-oxidation of **3**; when **3** was treated with **10a** and PhIO, **7** was isolated from the reaction in 24% yield. Similar overoxidation of an initially formed alcohol regularly occurs with these P-450 mimics, but the extent of overoxidation can be often controlled by choice of catalyst, cooxidant and reaction conditions.[11]

The general concensus is that the majority of P-450 mediated hydroxylations proceed *via* radical rearrangements. Radical rearrangements have been well-documented in P-450 biochemistry[6] and 'radical clocks' have been used to measure the rate of the rebound process.[12] Thus bicyclo[2.1.0]pentane gave a 7:1 mixture of *endo*-2-hydroxybicyclo[2.1.0]pentane and cyclopent-3-en-1-ol when oxidized by rat liver microsomes.[13] The bicyclo[2.1.0]pentan-2-yl radical rearranges to the cyclopent-3-en-1-yl radical with a rate constant of 2.4×10^9 s^{-1}.[14]

In addition, Groves *et al.*[15] have shown that when a chiral iron porphyrin hydroxylated ethylbenzene, the differences observed between the *pro-R* and *pro-S* hydrogen atoms were best explained *via* radical intermediates. Nevertheless, Newcomb, Hollenberg and their colleagues[16] have recently concluded, from their studies on a hypersensitive cyclopropyl radical probe, that ring opening of a cyclopropylmethyl radical is unreasonable in their system and that a cationic species is

[a] A: H_2O–CH_2Cl_2–MeOH = 2 : 10 : 30. B: pH 2 buffer–CH_2Cl_2–MeOH = 2 : 10 : 30. C: CH_2Cl_2. D: CH_2Cl_2–MeOH = 1 : 1. [b] Ref. 9. [c] Ref. 10.

intermediate in the rearrangements. In order to best accommodate their observations they suggest that the active oxidant in P-450 hydroxylations might be an iron–H_2O_2 complex and that the first species formed in the hydroxylation reaction is a protonated alcohol formed by 'OH^+' insertion into a C–H bond and that any subsequent rearrangements occur *via* solvolysis.

The question then arises as to how the principal oxidation product **6** is generated. Metabolic studies suggest that **6** does not derive from **3** and we have found no acid catalyzed reactions of **3** which generated **6**. Moreover, carbonium ion intermediates on the highly chlorinated 'perchlorocyclopentadiene ring' seem unlikely. Radical intermediates, however, would be consistent with the oxygen-rebound mechanism proposed by Groves and a radical at C-2 would be stabilized by the chlorine atom. Indeed, the P-450 mediated oxidation of dieldrin and the parallel biomimetic studies described here add further support to the oxygen-rebound mechanism and the intermediacy of substrate radicals where, as shown in Scheme 1, an initial hydrogen atom abstraction from C-9 by 'Compound I' (the common intermediate in these oxidations, $O{=}Fe^{IV+\cdot}$ **8**) would generate the substrate radical **2** and a heme intermediate **9** which can be formulated as an hydroxyl radical coordinated to (and stabilized by) the ferric iron. Intermediate **2** can then react at C-9 to give the alcohol **3** (and the ferric porphyrin ready for another catalytic cycle) or rearrange to the more stable tertiary radical at C-2 (**4**) where transfer of an hydroxyl radical from iron followed by loss of HCl would generate **6**.

The fact that we have been unable to bring about the acid catalyzed conversion of **3** → **6** does not preclude cationic intermediates in the P-450 metalated hydroxylation of dieldrin. Nevertheless, we conclude that the present study favors radical intermediates in the biomimetic oxidation of dieldrin and by analogy in the enzymatic reaction as well. Perhaps we should not be too surprised in either this case or that of Newcomb and Hollenberg *et al*. that electronically stacking a particular substrate may impose different reaction pathways for P-450-mediated hydroxylations.

As shown previously[7] these highly chlorinated metalloporphyrins can accurately mimic the cytochromes P-450. Not only can the production of natural metabolites be mimicked (and presumably predicted) but milligram (and even larger if required) amounts of such metabolites can be produced at the bench.

We thank the Canadian Natural Sciences and Engineering Research Council of Canada and Meiji Pharmaceutical University, Tokyo, Japan.

8 The cooxidant (0.66 mmol) was added with stirring, at room temperature, in ten equal portions every 30 min to a solution of the porphyrin catalyst (0.032 mmol) in 10 ml of solvent (A, B, or C). An hour after the last addition of cooxidant the mixture was poured onto water (50 ml) and CH_2Cl_2 (50 ml). After separation the aqueous phase was extracted with CH_2Cl_2 (2 × 20 ml). The combined organic phases were dried over $MgSO_4$, filtered and concentrated to 1 ml which was applied to a thick layer silica TLC plate and developed with light petroleum–EtOAc (5 : 1).
9 The isolated products had identical NMR and IR spectra to authentic samples.
10 A solution of dieldrin (0.26 mmol) and $Fe(ClO_4)_2$ (0.1 mmol) in MeCN (5 ml) was flushed with argon, H_2O_2 (0.1 mmol) in MeCN (0.5 ml) was slowly added over 15 min and the solution was then allowed to stand at room temperature for 1 h. The mixture was then extracted with CH_2Cl_2 (2 × 20 ml) and the products separated by TLC.

Self-assembly of novel trimers using dipyrromethene ligands

Alison Thompson, Steven J. Rettig† and David Dolphin*

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

Received (in Corvallis, OR, USA) 23rd November 1998, Accepted 25th January 1999

Ligands comprising two dipyrromethene units linked at the β-position have been used to prepare trimeric complexes with Zn^{II} and Co^{II}; the structure of the Zn^{II} complex is confirmed by X-ray analysis.

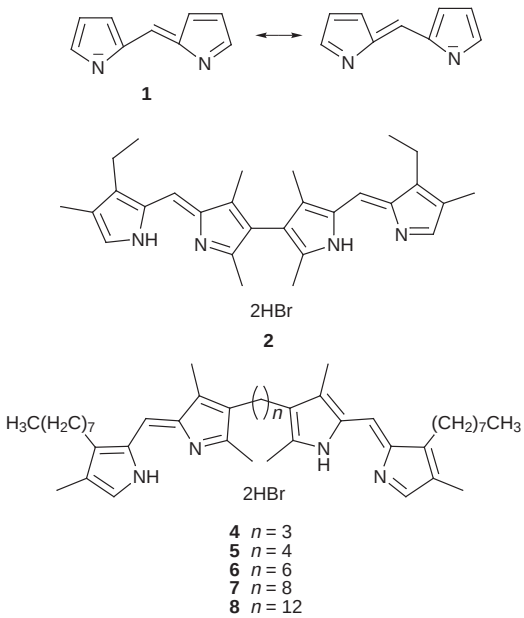
The self-assembly of supramolecular structures by complexation chemistry utilizing metal ions and suitable ligands is one approach to new structures with unusual and interesting properties.[1] Three-dimensional inorganic arrays have been forthcoming, giving helicates,[2] grids,[3] cages,[4] ladders[5] and rings,[6] through the coordination chemistry of polybipyridine ligands and transition metal ions. Multi-porphyrin structures have also been reported.[7] Dipyrromethenes, the building blocks of porphyrins, are themselves interesting ligands for supramolecular coordination chemistry and we have been able to rationally design new architectures through self-assembly of these ligands and transition metal ions.

Metal complexes generated from polybipyridine ligands[2–7] are rendered neutral by the use of counter-ions. This may give rise to problematic isolation procedures, or induce disorder in the solid state. Our efforts in this field are aimed towards the preparation of uncharged supramolecular architectures, in which counter-ions are not required. The dipyrromethene unit **1** is a useful ligand in metal chelation,[8] as it is a monoanionic ligand and the pyrrolic moieties are coplanar. Indeed, preliminary investigations in our group have shown that dipyrromethene units linked at the α-position can be used to generate helical complexes.[9] We sought to design ligands comprising linked dipyrromethene binding units, with which to construct neutral three-dimensional structures, including grids and ladders.

When a solution of $Zn(OAc)_2$ and NaOAc in MeOH was added to a solution of **2**[10]‡ in $CHCl_3$ a single complex **3** was formed in high yield.§ EI mass spectroscopy showed the molecular mass of the product to be 1468, which corresponds to the trimeric complex with a ligand : metal ratio of 3 : 3. The X-ray structure¶ of the trinuclear complex (Fig. 1) shows that it crystallizes in a triangular fashion, with the ligands linking the three metal centers overlapping, in a progressive manner: in each ligand, one dipyrromethene binding unit lies above the averaged plane of the molecule, whilst the other dipyrromethene unit lies below the averaged plane. The distances between the three metal centers are 9.27, 9.34 and 9.36 Å. Each metal center has distorted tetrahedral geometry in order to permit the triangular arrangement. Selected N–Zn–N angles are shown in Fig. 1. The six planar dipyrromethene sub-units lie at 63.6, 85.6 and 68.7° to their partner dipyrromethene unit within the same ligand.

Similarly, **2** was reacted with $Co(OAc)_2$ to give the corresponding cobalt trimer, with molecular mass of 1449, again in high yield. Several reaction conditions were applied to these preparations including temperature variations (−10 °C to reflux in MeOH) and different lengths of addition period (metal salts added in one portion, to over 24 h). In each and every case, the same trimers were formed in high yield, suggesting them to be both the kinetic and thermodynamic products.

Continuing with the theme of pyrroles linked at the β-position, we subjected several hydrobromide salts **4**–**8** with varying hydrocarbon spacer lengths (n = 3, 4, 6, 8, 12) between the β-positions[10] to standard complexation reactions with $Zn(OAc)_2$. Complexation was almost quantitative for each ligand. Table 1 shows that as the length of the hydrocarbon chain between the pyrrole moiety increases, so formation of the



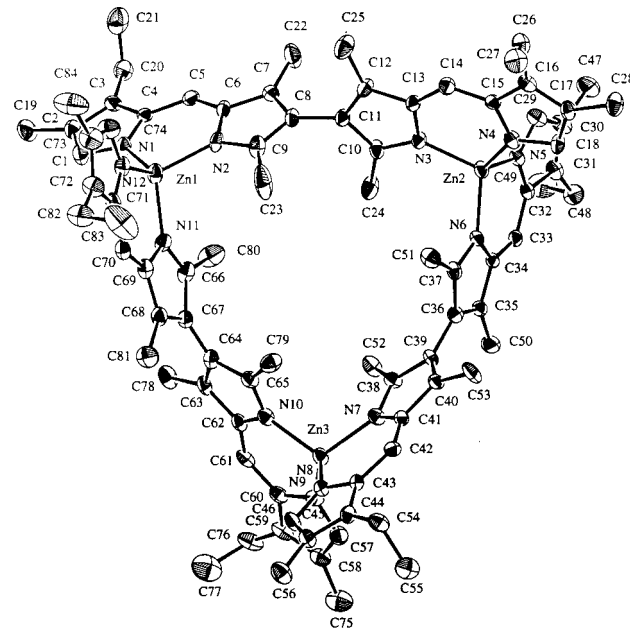


Fig. 1 X-Ray structure of **3** (hydrogen atoms and 2 $CHCl_3$ molecules of crystallization are omitted for clarity). Selected bond angles (°): N(1)–Zn(1)–N(2) 95.5(2), N(1)–Zn(1)–N(12) 116.4(2), N(1)–Zn(1)–N(11) 119.7(2), N(2)–Zn(1)–N(11) 111.3(2), N(2)–Zn(1)–N(12) 119.7(2), N(11)–Zn(1)–N(12) 96.0(2).

† Deceased October 27, 1998.

Table 1 Oligomeric ratios of metal complexes

Salt	*n*	Monomer : dimer : trimer[a]
2	0	0 : 0 : 1
4	3	0 : 1 : trace
5	4	0 : 1 : trace
6	6	1 : 1 : trace
7	8	1 : trace : trace
8	12	1 : 0 : 0

[a] Traces of higher oligomers were also observed for ligands **4**, **5** and **6**.

monomer dominates, as determined by MALDI spectroscopy. Molecular modeling[11] rationalizes this, as the longer spacer length allows the dipyrromethene units to fold back against each other, thus fulfilling the tetrahedral geometry requirements for binding to the metal ion. In the case of the ligand derived from salt **2** (n = 0) this folding is clearly not allowed and the trimer is formed. For **4** and **5** (n = 3 and 4, respectively) the spacer chain length permits sufficient folding for the corresponding dimers to be formed, but when n = 6 or greater, folding is sufficient to allow the monomer to form. However, MALDI spectroscopy showed small amounts of higher order complexes (trimers–hexamers) to be present in each case. Variation of reaction conditions did not alter the oligomeric ratio of products.

In summary, we have demonstrated the usefulness of linked dipyrromethene ligands in the self-assembled preparation of uncharged novel architectures. The properties of the trimeric complexes will be reported at a later date. Current work is focussed towards the construction of novel grids, ladders and supramolecular helicates using dipyrromethene ligands.

Highly electrophilic lanthanide complexes containing fluorinated amido ligands: multiple Ln···F interactions, agostic interactions and η⁶-arene coordination

Damon R. Click, Brian L. Scott and John G. Watkin*

Chemical Science and Technology Division, Mail Stop J514, Los Alamos National Laboratory, Los Alamos, New Mexico, 87545. E-mail: jwatkin@lanl.gov

Received (in Bloomington, IN, USA) 26th November 1998, Accepted 15th January 1999

Highly fluorinated amido ligands have been employed as supporting ligands for homoleptic lanthanide complexes; X-ray diffraction studies reveal multiple Ln···F interactions and a rare example of an η⁶-bound toluene solvent molecule.

The chemistry of the transition metals coordinated by mono-, di- and tri-amido ligands has recently generated a considerable amount of interest, due to many interesting observations of catalytic activity,[1] small molecule activation[2] and unusual coordination modes of neutral ligands.[3] A number of these studies have involved amido ligands which have electron-withdrawing fluorinated phenyl groups directly attached to nitrogen.[4] Lanthanide amido complexes[5] are also experiencing renewed attention, due in part to the emergence of this class of compounds as effective catalysts[6] and their use as source molecules for rare-earth doping of semiconducting materials.[7] We are currently interested in the chemistry of highly electrophilic metal amido complexes as potential catalysts for olefin polymerization. We report here the results of a structural study of lanthanide metals (Ln = Nd, Sm) coordinated by a series of highly electron-withdrawing amido ligands: $-NH(C_6F_5)$,$-N(SiMe_3)(C_6F_5)$ and $-N(C_6F_5)_2$.

Reaction of $Sm[N(SiMe_3)_2]_3$ **1**[8] with 3 equiv. of pentafluoroaniline in toluene leads to the formation of a pale yellow solution. Removal of solvent, followed by dissolution of the solid in THF and low-temperature crystallization, allows isolation of the thf adduct $[Sm(NHC_6F_5)_3(thf)_3]$ **2** in 58% yield.† An X-ray diffraction study‡ revealed a highly distorted nine-coordinate geometry about the metal center (Fig. 1), which may best be described as a distorted capped square antiprism in which F(18) caps the face defined by N(1), N(3), O(2) and O(3). Sm–N distances to the amido ligands are 2.352(5), 2.360(5) and 2.371(5) Å while Sm–O distances to the thf ligands lie in the range 2.444(4)–2.502(4) Å. The Sm–N distances are found to be very similar to those observed for the terminal arylamido ligands in the anionic samarium complex $[Sm(\mu\text{-}NHC_6H_3Me_2\text{-}2,6)(NHC_6H_3Me_2\text{-}2,6)_3]_2^{2-}$, which average 2.354(9) Å.[5b] Three relatively weak Sm···F interactions[9] of 2.847(4), 2.870(3) and 2.876(3) Å are made by an *ortho*-fluorine substituent of each $-NH(C_6F_5)$ ligand. A hydrogen-bonding network with F···H distances of 2.688 Å and N–H–F angles of 163.8° is observed within the extended three-dimensional structure of **2**, which may explain the low solubility of the complex in non-polar solvents. In addition, intermolecular π-stacking of the arene rings[10] with interplanar contacts of 3.227 Å is observed.

Reaction of **1** with 3 equiv. of *N*-trimethylsilylpentafluoroaniline in toluene allowed the isolation of the base-free homoleptic complex $Sm[N(SiMe_3)(C_6F_5)]_3$ **3**. Single crystal X-ray diffraction‡ revealed an unusual trigonal planar SmN_3 skeleton (planar to within 0.01 Å), with *six* additional secondary contacts with ligand substituents (Fig. 2). Three short Sm···F interactions of 2.561(6), 2.566(5) and 2.587(6) Å with *ortho*-fluorine substituents from each $-N(SiMe_3)(C_6F_5)$ ligand, and three agostic interactions [Sm–C 3.058(11), 3.148(10) and 3.142(10) Å] with trimethylsilyl groups complete the overall nine-coordinate, tricapped trigonal prismatic geometry about the metal center. Sm–N–C_{ipso} and Sm–N–Si angles are almost equal for each amido ligand [*e.g.* Sm(1)–N(3)–C(19) 119.9(6), Sm(1)–N(3)–Si(3) 113.3(4)°], unlike the situation encountered in the related neodymium complex $Nd[N(C_6H_5)(SiMe_3)]_3(THF)$,[11] in which significant Nd–C_{ipso} and Nd–C_{ortho} interactions cause the Nd–N–C_{ipso} angles (110.2° av.) to be much more acute than Nd–N–Si angles (134.1° av.). In common with many similar interactions between $-SiMe_3$ groups and an f-element metal center, no solid-state IR or solution NMR evidence (*e.g.* lowered C–H stretching frequency) was found for

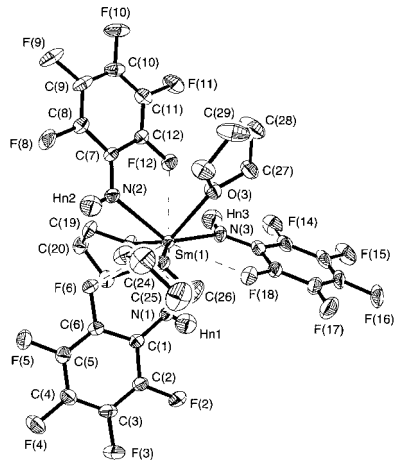

Fig. 1 ORTEP view (30% probability ellipsoids) of the molecular structure of $[Sm(NHC_6F_5)_3(thf)_3].thf$ **2**. Selected bond distances (Å): Sm(1)–N(1) 2.360(5), Sm(1)–N(2) 2.371(5), Sm(1)–N(3) 2.352(5), Sm(1)–O(1) 2.444(4), Sm(1)–O(2) 2.500(4), Sm(1)–O(3) 2.502(4), Sm(1)–F(6) 2.876(3), Sm(1)–F(12) 2.870(3), Sm(1)–F(18) 2.847(4).

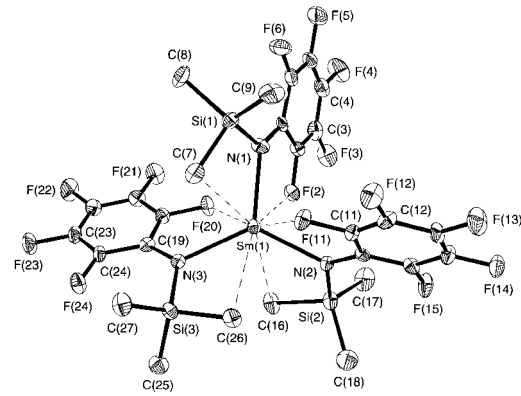

Fig. 2 ORTEP view (30% probability ellipsoids) of the molecular structure of $Sm[N(SiMe_3)(C_6F_5)]_3$ **3**. Selected bond distances (Å): Sm(1)–N(1) 2.329(8), Sm(1)–N(2) 2.330(7), Sm(1)–N(3) 2.362(8),Sm(1)–F(2) 2.566(5),Sm(1)-F(11) 2.587(6), Sm(1)–F(20) 2.561(6), Sm(1)–C(7) 3.058(11), Sm(1)–C(16) 3.148(10), Sm(1)–C(26) 3.142(10).

these 'agostic' interactions. ^{19}F NMR spectra of **3** (room temperature, toluene-d_8) reveal a 2 : 2 : 1 pattern for the *ortho*-, *meta*- and *para*-fluorine substituents. The resonances for the *para*- and *meta*-fluorines are sharp, whereas the *ortho* resonance is broadened almost into the baseline due to interaction with the paramagnetic samarium metal center. The observation of equivalent *ortho*- and *meta*-F resonances indicates rapid rotation about the N–C_{ipso} bond on the NMR timescale (indicative of a weak C–F···Sm interaction). No significant changes in the ^{19}F spectrum were observed upon cooling the sample. Reaction of **3** with stoichiometric quantities of Lewis bases such as thf results in the formation of adducts with reduced numbers of Sm···F–C and Sm···Me–Si interactions (*e.g.* structurally characterized Sm[N(C_6F_5)($SiMe_3$)]$_3$(thf)[12] displays two Sm···F–C and one Sm···Me–Si interaction).

Reaction of Nd[N($SiMe_3$)$_2$]$_3$ **4**[8] with 3 equiv. of decafluorodiphenylamine, [(C_6F_5)$_2$NH],[13] in toluene followed by crystallization from the same solvent leads to isolation of (η-C_6H_5Me)Nd[N(C_6F_5)$_2$]$_3$ **5** in good yield. An X-ray diffraction study‡ revealed a distorted three-legged piano-stool geometry about the metal center (Fig. 3). Nd–N distances to the amido ligands are 2.362(6), 2.392(7) and 2.397(7) Å, which is somewhat longer than those previously observed in neodymium amido complexes (*e.g.* 2.309 Å (av.) in Nd[N(C_6H_5)($SiMe_3$)]$_3$(thf),[11] 2.309(8) Å in Nd($NHC_6H_3Pr^i_2$-2,6)$_3$(thf)$_3$,[5b] and 2.270(2) Å in NdCl[N($SiMe_3$)($C_6H_3Pr^i_2$-2,6)]$_2$(thf)[11]]. Three significant Nd···F interactions of 2.572(5), 2.616(5) and 2.696(5) and one weak Nd···F interaction of 2.940(5) Å are also observed within the structure. The toluene ligand is bound in a rather asymmetric manner, with Nd–C distances lying in the range 2.98(2)– 3.324(13) Å. Although a number of lanthanide complexes exhibiting η^6-arene interactions have been described in the literature,[14] the majority of these interactions occur *via* intra- or inter-molecular ligand chelation. The only lanthanide complexes which have previously been shown to bind aromatic solvent molecules are of the class (η-arene)Ln(η^2-AlX_4)$_3$ (Ln = La, Nd, Sm, Er; X = Cl, Br).[15] We do note, however, that the Nd–C bond distances in **5** are somewhat longer than those found in the neodymium complex (η-C_6H_6)Ln(η^2-$AlCl_4$)$_3$ (2.93 Å (av.)],[15c] presumably indicative of a somewhat weaker Ln–arene interaction in the present case. Complexes such as **5** may also be considered as models for cationic Group 4 metallocene and related bis-amido olefin polymerization systems which have been found to bind toluene and other aromatic solvent, often to the detriment of catalytic activity.[16]

In conclusion, we have shown that fluorinated amido ligands may be used to support highly electrophilic lanthanide metal centers, which enter into multiple secondary interactions with C–F, C–H and C–C bonds of both ligands and solvent.

This work was performed under the auspices of the Laboratory Directed Research and Development Program. We acknowledge Dr. David L. Clark for providing funding to D. R. C. and Dr. Wayde V. Konze for experimental assistance. Los Alamos National Laboratory is operated by the University of California for the U.S. Department of Energy under Contract W-7405-ENG-36.

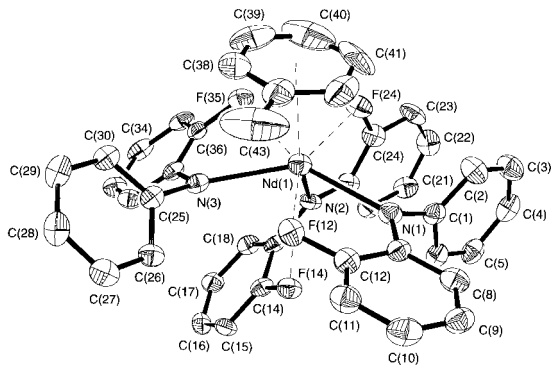

Fig. 3 ORTEP view (30% probability ellipsoids) of the molecular structure of (ηC_6H_5Me)Nd[N(C_6F_5)$_2$]$_3$ **5**. For clarity, only the fluorine atoms making Nd···F contacts are shown. Selected bond distances (Å): Nd(1)–N(1) 2.397(7), Nd(1)–N(2) 2.392(7), Nd(1)–N(3) 2.362(6), Nd(1)–F(12) 2.572(5), Nd(1)–F(24) 2.616(5), Nd(1)–F(35) 2.696(5), Nd(1)–F(14) 2.940(5), Nd(1)–C(41) 2.982(13), Nd(1)–C(40) 2.98(2), Nd(1)–C(42) 3.103(10), Nd(1)–C(39) 3.167(13), Nd(1)–C(37) 3.313(10), Nd(1)–C(38) 3.324(13).

† Experimental details for the preparation and characterization of **2**, **3**, and **5** are provided as electronic supplementary information (http//www.rsc.org/suppdata/cc/1999/633).

‡ *Crystallography*: in all X-ray diffraction studies, data were collected on a Siemens P4/PC diffractometer with Mo-Kα radiation (λ = 0.71069 Å). Patterson techniques were used to locate the lanthanide metal and the majority of all other atoms in the molecule. Subsequent Fourier synthesis gave the remaining light atom positions. Hydrogen atoms were refined using the riding model in the HFIX facility in SHELXL 93. CCDC 182/1182. See http://www.rsc.org/suppdata//cc/1999/633/ for crystallographic files in .cif format.

Crystal data: **2**·0.5thf: $C_{32}H_{35}F_{15}N_3O_{3.5}Sm$, M = 952.98, triclinic, space group $P\bar{1}$, a = 10.745(1), b = 10.773(1), c = 18.216(2) Å, α = 98.42(1), β = 95.81(1), γ = 114.02(1), V = 1874.8 Å^3, Z = 2, T = 203 K, μ = 16.79 cm^{-1}. The N–H hydrogens were located from the difference map and refined with free coordinates and fixed isotropic temperature factors (0.08 Å^2). The atoms of the solvent thf were refined isotropically at 1/2 occupancy. The final refinement (7673 reflections collected, 6535 independent) included anisotropic thermal parameters on all non-hydrogen atoms (except for atoms of the solvent thf) and converged to $R1$ = 0.0404 and $wR2$ = 0.1165.

3: $C_{27}H_{27}F_{15}N_3Si_3Sm$, M = 913.14, triclinic, space group $P\bar{1}$, a = 10.196(4), b = 10.868(4), c = 16.461(7) Å, α = 94.96(1), β = 107.33(1), γ = 95.26(1), V = 1721.4(12) Å^3, Z = 2, T = 198 K, μ = 19.16 cm^{-1}. The final refinement (5381 reflections collected, 4479 independent) included anisotropic temperature factors on all non-hydrogen atoms and converged to $R1$ = 0.0556 and $WR2$ = 0.1341.

5·C_6H_5Me: $C_{50}H_{16}F_{30}N_3Nd$, M = 1372.90, monoclinic, space group $P2_1/c$, a = 22.964(4), b = 8.712(2), c = 24.927(4) Å, β = 107.47(1), V = 4757 Å^3, Z = 4, T = 198 K, μ = 12.52 cm^{-1}. The final refinement (7834 reflections collected, 6217 independent) included anisotropic thermal parameters on all non-hydrogen atoms and converged to $R1$ = 0.0577 and wR_2 = 0.1015.

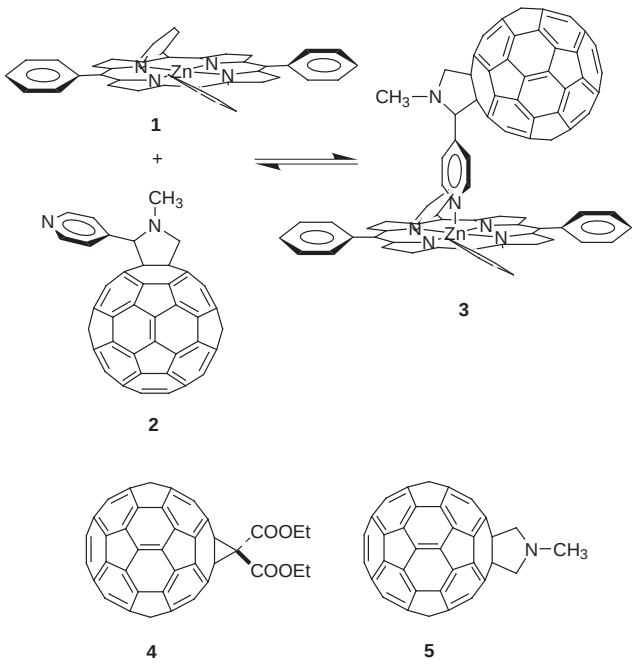
Received (in Cambridge, UK) 25th January 1999, Accepted 3rd March 1999

Photoexcitation of a Zn–tetraphenyl porphyrin–fullerene complex leads to electron-transfer with very long lifetimes of the charge-separated pairs.

Photoactive supramolecular systems, in which a donor and an acceptor moieties are non-covalently linked, are particularly appealing either as models for natural photosynthesis and for the conversion of light into electric current.[1–3] In essence, a rapid photoinduced electron-transfer (ET) should be followed by a diffusional splitting of the charge-separated radical pair, thus mimicking a key step in photosynthesis. Here, we describe the assembly of a rigidly connected dyad, in which a zinc tetraphenyl porphyrin [Zn(TPP)] is non-covalently linked to a C_{60} fullerene derivative *via* axial pyridine coordination to the metal.[4–6] Information associated with the photoprocesses has been achieved by optical spectroscopy, in full agreement with time-resolved EPR spectroscopy.

Ligand **2** (Scheme 1) was prepared by azomethine ylide cycloaddition to C_{60},[7,8] using sarcosine and 4-pyridine aldehyde as the starting materials.[9] Semiempirical (PM3) minimization gives 4.5 Å for edge-to-edge distance between the chromophores or 9.5 Å for center-to-center distance.

The absorption spectrum of Zn(TPP) (**1**) was measured at increasing concentrations of fullerene ligand **2** in different solvents. In non-coordinating solvents, such as toluene and dichloromethane, the spectra reveal a noticeable red-shift of the two Q-bands (in CH_2Cl_2: 548 → 559 nm; 588 → 598 nm), as well as a minor broadening of the Soret band. This effect is commonly attributed to the formation of pyridine-Zn(TPP) complexes.[10] In contrast, a similar addition of methanofullerene **4** or pyrrolidine **5** does not affect the porphyrin ground state absorption and, accordingly, the spectra of **1** and the respective fullerene derivative become virtually superimposable. In the more polar and coordinating solvents THF and benzonitrile, no dependence was observed of the spectral features of **1** from fullerene **2** concentrations, indicating a competition in the coordination of Zn between the fullerenic pyridine and the solvent. The ^{1}H NMR spectrum of a 1 : 1 mixture (3×10^{-3} M) of **1** and **2** in $CDCl_3$ shows that the pyridine 2-protons are shifted to δ 3.6 (from δ 8.7 in pure **2**), confirming that coordination of the Zn metal occurs through the pyridine nitrogen and not the pyrrolidine nitrogen, leading to **3** (Scheme 1).



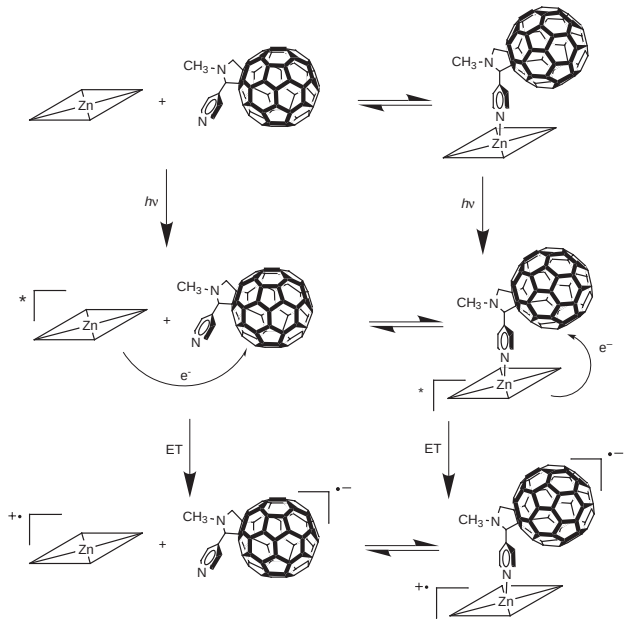
Scheme 1

Zn(TPP) displays a high lying (2.06 eV) and strongly emitting (Φ = 0.04) singlet excited state, $^1(\pi$–$\pi^*)$ Zn(TPP).[11] However, substantially lower emission yields were noticed upon excitation of (**1** + **2** ⇌ **3**) in solution relative to the Zn(TPP) reference. The emission quantum yields of the $^1(\pi$–$\pi^*)$ ZnTPP (**1**) (1.0×10^{-5} M) strongly decreased with progressing fullerene ligand **2** concentrations. Toluene and dichloromethane solutions of **1**, in the presence of 1.3×10^{-5} M **2**, gave rise to quantum yields (Φ) of 0.0156 and 0.0152, respectively. These values refer to kinetics much faster than diffusion, thus pointing toward intramolecular processes.

Time-resolved photolysis was carried out to complement the steady-state experiments and to characterize the resulting photoproducts. Irradiation into the porphyrin Q-bands yielded the characteristic $^1(\pi$–$\pi^*)$ Zn(TPP) absorptions, which decayed (τ = 2.5 ns), in the absence of any fullerene ligand **2**, into the energetically lower lying $^3(\pi$–$\pi^*)$ Zn(TPP) state (1.53 eV). A systematic addition of fullerene ligand **2** led to a substantial reduction of the singlet state lifetime. More importantly, the $^1(\pi$–$\pi^*)$ Zn(TPP) transforms into a new product with broad absorption features between 600 and 800 nm, which is a known characteristic for a one-electron oxidized porphyrin, [Zn(TPP)$^{\cdot+}$]. In addition, the charge-separated radical pair was unequivocally identified *via* the NIR-fingerprint absorption of ($C_{60}^{\cdot-}$) at 1010 nm.

While the insufficient polarity of toluene prevents an appreciable stabilization of the radical pair, in moderately polar dichloromethane a lifetime of 8.6 μs was measured. In contrast, parallel experiments using **4** or **5** instead of **2** did not result in any measurable ($C_{60}^{\cdot-}$)/[Zn(TPP)$^{\cdot+}$] absorptions.

In benzonitrile and THF, differential absorption changes in the NIR reveal the participation of two components in the formation of the ($C_{60}^{\cdot-}$). The faster process clearly evolves from an intramolecular ET process, while the slower one involves intermolecular quenching of the lower lying $^3(\pi$–$\pi^*)$ Zn(TPP) state. For the bimolecular quenching reaction a rate constant of 1.7×10^{10} dm^3 mol^{-1} s^{-1} was resolved. Kinetic



Scheme 2

analysis of the 1010 nm transient absorption ($C_{60}^{\bullet-}$) gives rise to a remarkable lifetime of the separated radical pair in deoxygenated benzonitrile of several hundred microseconds.

According to the above results, two different pathways can be envisioned for the ET processes (Scheme 2). The excitation of the porphyrin chromophore is followed by fast intramolecular ET inside the complex (right-hand pathway in Scheme 2). Alternatively, the free porphyrin is excited, undergoing intermolecular ET when the acceptor molecules approach closely enough during the molecular diffusion (left hand side pathway in Scheme 2). The former process is likely to occur in all solvents. However, in coordinating media, the solvent can displace **2** from the Zn metal, thus making intermolecular ET more effective. This latter ET process is slow enough to allow the excited porphyrin to convert from the singlet to triplet state by ISC.

Experiments performed by time resolved EPR (TREPR) fully support the mechanisms proposed in Scheme 2. The TREPR spectrum of (**1** + **2** ⇌ **3**) dissolved in THF (1×10^{-4} M) and detected at 180 K with 1 μs delay from the laser pulse is shown in Fig. 1. The spectrum consists of a broad signal superimposed to a narrow derivative-like EPR signal, displaying A/E spin polarization pattern (A and E mean absorption and emission), that is assigned to the singlet-born spin correlated radical pair (SCRP),[12,13] arising here from the CS state ($C_{60}^{\bullet-}$)/[Zn(TPP)$^{\bullet+}$] inside the complex and generated by intramolecular electron transfer. The spin system responsible for the narrow signal is described as two unpaired electrons weakly coupled by small spin exchange and electron–electron dipolar interactions, characterized by *J* and *D* constants, respectively. The spectrum is given by two doublets of lines with antiphase spin polarization pattern.[12] In our case, the low-field doublet is centered at the *g* value of ZnTPP$^{\bullet+}$ radical cation (2.0026)[14] and the high-field doublet at the *g* value of $C_{60}^{\bullet-}$ radical anion (1.9986).[15] The effect of the unresolved hyperfine interaction is taken into account by a linewidth contribution to the spectrum lines. Estimated linewidths are 1 and 0.1 mT for $C_{60}^{\bullet-}$ and Zn(TPP)$^{\bullet+}$, respectively.[14,15] Since Zn(TPP)$^{\bullet+}$ radical cation has a large inhomogeneous linewidth, while that of the fullerene (with little hyperfine interaction due to protons) is much smaller, the doublet due to the porphyrin radical cation is practically undetectable in the spectrum. Experimental and calculated spectra due to ($C_{60}^{\bullet-}$)/[Zn(TPP)$^{\bullet+}$] singlet-born SCRP are shown in Fig. 1.

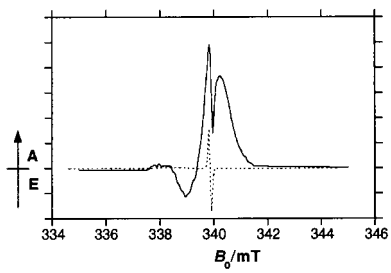


Fig. 1 TREPR spectrum (solid line) observed 1 μs after the laser pulse excitation of (**1** + **2** ⇌ **3**) dissolved in THF at 180 K. A Lambda Physik LPX 100 XeCl excimer laser (λ = 308 nm, 10 mJ pulse^{-1}) fed a Rhodamin G6 dye laser with emitting light at 581 nm (pulse duration 20 ns). The signal was taken directly from the microwave preamplifier immediately after the detection diode and fed into a EG&G Boxcar Averager mod. 162 equipped with a mod. 164 plug-in. It was operative with an integration window of 50 ns. Positive and negative signals indicate absorptive (A) and emissive (E) polarizations, respectively. Microwave frequency: $\omega/2\pi$ = 9.5256 GHz. Microwave field: B_1 = 0.023 mT.

The broad spectrum of Fig. 1 is attributed to the triplet-born radical ion pair[16] that is generated by intermolecular electron transfer between unlinked Zn(TPP)$^{\bullet+}$ cation and $C_{60}^{\bullet-}$ anion mediated by solvent molecules and stabilized by Coulomb attraction. Details on the spectrum simulation will be reported elsewhere. The separation between the outermost lines amounts to 2|*D*|, where *D* represents the dipolar coupling constants. If the classical expression of the point dipole model is used for *D*, from the measured value of $D = -1.72$ mT the estimated center-to-center distance of 11.7 Å between cation and anion is obtained.

The narrow transient signal detected at 339.9 mT was fitted by a single exponential function with decay time constant of 12 μs, this value being in good agreement with that measured by optical methods (11 μs, 1×10^{-5} M in THF).

Received (in Cambridge, UK) 26th January 1999, Accepted 4th March 1999

The condensation of a dipyrromethane with ferrocene aldehyde leads to a single atropisomer of α,α-5,15-bis(ferrocenyl)-2,8,12,18-tetrabutyl-3,7,13,17-tetramethylporphyrin 1; electrochemistry of 1 and Ni-1 reveals two consecutive ferrocene-based one-electron oxidation waves, which are separated by 0.19 and 0.41 V, respectively.

Discrete systems in which remote sites are electronically coupled have exciting possibilities for applications in molecular electronic devices.[1] However, despite much effort, particularly with compounds containing two connected ferrocene moieties,[2] useful devices have not yet been forthcoming. This is primarily because communication between the electronic (especially the redox) states at the two sites decreases rapidly with distance. Recent studies have identified a combination of factors that influence communication between connected ferrocene moieties, including the type of connection,[2] the length of the connector[3] and the orientation of the two ferrocenes.[4] Here, we report the synthesis, structure and properties of a bis(ferrocenyl)porphyrin **1** in which these factors are synergistically combined to give unprecedented strong coupling between the ferrocene moieties.

Porphyrin **1**‡ is formed in a classical condensation reaction between ferrocene aldehyde and a tetraalkyl dipyrromethane. The insertion of nickel gives Ni-**1**.§ To our surprise, compound **1** is formed as a single isomer in high yield (58%), with both ferrocenyl groups in a *syn* (or α,α-atropisomer) configuration with respect to the porphyrin macrocycle. The *anti* product, the α,β-atropisomer, is not observed. CPK-model studies indicate that the porphyrinogen conformation which leads to the α,α-isomer is the least sterically congested and thereby the most accessible to chemical oxidation to form **1**. This preference has not been observed previously and is a direct result of the unique steric requirements of the ferrocenyl moiety. Upon oxidation of the porphyrinogen, the methyl groups in the β-pyrrolic positions offer sufficient steric hindrance to prevent any isomerisation.

The geometry was confirmed by single-crystal structure determinations of **1**¶ [Fig. 1(a)] and its nickel(II)-substituted derivative Ni-**1**¶ [Fig. 1(b)]. The large steric bulk of the ferrocenyl moiety at opposite *meso* positions, clashing with the β-methyl substituents, not only prevents rotation of the ferrocenyl moiety but leads to a strongly ruffled porphyrin core. However, comparison of **1** and Ni-**1** reveals that the ferrocenyl moieties are not rigidly locked in a single conformation. Indeed the conformational disorder shown by Ni-**1** in the *solid state* provided further indication of the restricted conformational flexibility of the ferrocene groups, relevant to solution-state conformational flexibility and to the distinctive electrochemistry shown by these compounds.

The electrochemistry of **1** and Ni-**1** [Fig. 2(d)] shows two consecutive ferrocene-based one-electron oxidation waves

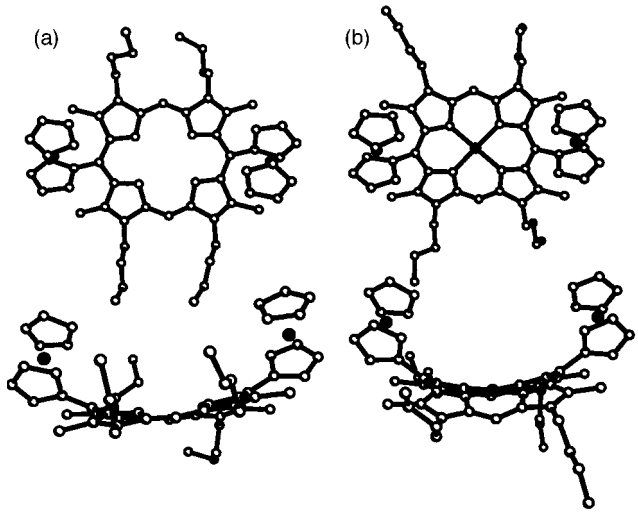

Fig. 1 Molecular structures of **1** (a) and the major conformation of Ni-**1** (b). The top view looking down on the porphyrin plane, showing the twist of the ferrocenyl moieties; the bottom view is side-on to the porphyrin plane, showing the distortions of the porphyrin ring.

† The authors would like to dedicate this paper to Professor Warren R. Roper on the occasion of his 60th birthday.

separated by 190 and 410 mV, respectively. Spectroelectrochemical UV–VIS studies of **1** and Ni-**1** reveal that both show the growth of an absorption at 1080 and 946 nm, respectively [Fig. 2(a) and (b)], with single electron oxidation. These are assigned as intravalence charge-transfer (IVCT) bands. Further oxidation leads to depletion of these features. The behaviour of **1** and Ni-**1** may be contrasted to that of the sterically less congested reference compound **3**.‖ This compound shows a single two-electron ferrocene oxidation[7] and no near-IR absorption when oxidised [Fig. 2(c)]. From the separation of oxidation waves in **1** and Ni-**1** a conproportionation constant (K_c) of 1.6×10^3 for **1** and 8.5×10^6 for Ni-**1** is calculated,[6] indicating strong coupling of the ferrocene moieties. The small bandwidth of the IVCT band for the Ni-**1**$^+$ complex ($\Delta\nu_{\frac{1}{2}} = 1400$ cm^{-1}) suggests that it is a class III (highly localised) mixed-valence species,[7] consistent with the large value of K_c. For **1**, $\Delta\nu_{\frac{1}{2}} = 2600$ cm^{-1}, suggesting a class II/III behaviour.[6]

For **1** and Ni-**1** the coupling between ferrocene units, at a separation of > 10 Å, is remarkably high. Biferrocene shows an oxidation-wave peak splitting of only 330 mV where the ferrocenyl irons are < 5.4 Å distant,[8] and **3**, where a ferrocene–ferrocene distance of at least 10 Å can be estimated, has no observable coupling. Such strong coupling between the two ferrocenes was largely unexpected, as the related 5,10,15,20-tetraferrocenylporphyrin **2** and 5,15-diferrocenyl-10,20-di-*p*-tolylporphyrin **3**[9] display no such coupling. These porphyrins, however, lack substituents at the β-pyrrolic positions, and the ferrocenyl moieties are free to rotate, as evidenced by ^{1}H NMR spectroscopy.

A density functional calculation,** seeking to establish a basis for the origin of differences between **2**, **3** and **1** (and Ni-**1**), was carried out on the monocation **1**$^+$. The singly occupied HOMO in this system is delocalised over both ferrocene moieties and is composed of ferrocene (xy, $x^2 - y^2$, e_{2g}) Fe d orbitals and the porphyrin a_{2u} π molecular orbital. The separation between the positive and negative combination of these orbitals has been proposed to be related to the strength of coupling between ferrocene centres in mixed-valence systems.[3,10] In this case the difference in energy for the alpha spin orbitals is *ca.* 0.1 eV. This strong coupling appears to be the result of extensive mixing of both ferrocenyl molecular orbital systems with that of the porphyrin connector π system, as is apparent in the diminished intensity of the Soret band at 410 nm for **1** and Ni-**1** but not **3** upon oxidation.

The low symmetry of **1** and Ni-**1** (at best C_{2v}), the possibility of extensive vibronic coupling as a result of the restricted rotational flexibility of the ferrocenyl groups propagating into distortions of the porphyrin core, and the molecular dipole created by the α,α-atropisomer are all possible factors that may underpin the strong coupling. A thorough study of this system will be made in order to determine (i) the factors that lead to the very strong coupling and (ii) the extent to which this communication between two ferrocenyl moieties can be modified and exploited. For now, these results show for the first time in diferrocenylporphyrin systems that strong coupling can be created between remote centres using the porphyrin core as a connector.

We are grateful to The Public Good Science Fund (MAU602 and MAU809), the University of Auckland Research Committee and the Marsden Fund of New Zealand (UOA613) for support of this work and to Dr Cliff Rickard and The University of Auckland for X-ray data collection.

Controlled synthesis of heterotetranuclear complexes

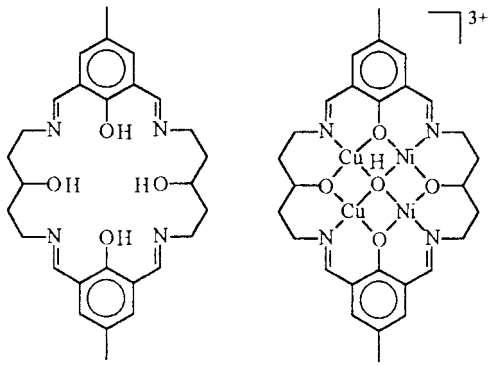
Paul E. Kruger, Frederic Launay and Vickie McKee*

Chemistry Department, Queen's University, Belfast, UK BT9 5AG. E-mail: v.mckee@qub.ac.uk

Received (in Basel, Switzerland) 18th January 1999, Accepted 1st March 1999

Template synthesis of a macrocyclic complex containing two copper(II) ions and two vacant coordination sites permits controlled access to a heterotetranuclear $Cu^{II}_2Ni^{II}_2$ complex without scrambling of the metal ions.

Heteronuclear complexes of the dinucleating 'Robson-type' macrocycles[1] have been known for many years.[2] Most commonly, these complexes are synthesised using ligands with dissimilar binding sites in either the final macrocyclic product or in a key non-cyclic intermediate in a stepwise synthesis. Here, we report a route for the controlled synthesis of heterotetranuclear complexes of a macrocycle with four identical binding sites.



H_4L^1 $[Cu_2Ni_2(L^1)OH]^{3+}$

Previous work using the ligand H_4L^1 has established the template formation of planar tetracopper(II)[3,4] and tetranickel(II)[5] complexes. The metal ions are separated by *ca.* 3 Å and interact through phenoxo and alkoxo bridges as well as through a central μ_4-OH ion. In tetracopper(II) complexes, the central μ_4-hydroxo moiety can be replaced by two 1,1-azido ligands to yield $[Cu_4(\mu\text{-}N_3)_2(L^2)(N_3)_2]\cdot 2MeOH$.[4] The geometry of the tetracopper(II) array is only slightly modified to allow the azide bridges to lie one on either side of the macrocyclic plane. Incorporation of a larger bridge might be expected to force the copper ions apart, disrupting the planarity of the complex.

Schiff-base condensation of 2,6-diformyl-4-methylphenol (dfmp) and 1,5-diamino-3-hydroxypentane (dahp) in the presence of $Cu(BF_4)_2\cdot 6H_2O$ and pyrazole (Hpyr) (mole ratios dfmp : dahp : Cu^{2+} : Hpyr = 1 : 1 : 2 : 1) in 1 : 1 methanol–ethanol, yielded a green powder. On recrystallisation by diethyl ether diffusion from acetonitrile containing excess pyrazole, two crystalline macrocyclic products were obtained. The major component (*ca.* 80%) consists of red–green dichroic crystals of formula $[Cu_2(\mu\text{-pyr})(H_3L^1)](BF_4)_2\cdot MeCN$ (**1**·MeCN), a minor amount (*ca.* 5%) of a dark green complex, $[Cu_4(\mu\text{-pyr})_2(L^1)](BF_4)_2$ **2** was also isolated. Both complexes have been characterised by single crystal structure analysis.†

The cation of complex **1**, $[Cu_2(\mu\text{-pyr})(H_3L^1)]^{2+}$, is a dicopper complex in which the copper ions are bridged by an alkoxo oxygen (O2) and a pyrazolate ion (Fig. 1). It can be viewed as resulting from the previously characterised $[Cu_4(L^n)(OH)]^{3+}$ core by loss of two copper ions and replacement of the central hydroxide by pyrazolate. The macrocyclic ligand is only monodeprotonated but, as observed in related systems,[6–8] the phenolic protons have transferred to the non-coordinated imine groups; these protons were located in the structure refinement. The cation thus has two vacant (if protonated) coordination sites, somewhat blocked by the presence of the pyrazolate ligand. The geometry at each copper ion shows a tetrahedral distortion from square planar which is necessary to accommodate the two-atom bridge. The Cu···Cu distance of 3.246(1) Å is somewhat shorter than the values found in other dicopper systems linked by the same two bridges (3.34–3.30 Å).[9,10] A marked twist in the saturated section of the macrocycle is similar to that observed in a non-cyclic structure with the same donor set[10] and is therefore likely to be imposed by the bridges rather than the cyclic nature of the ligand. Intermolecular π–π stacking involving both the macrocyclic π-systems is evident (interplanar distances 3.4–3.6 Å), as an intramolecular H–π interaction where the alcohol proton lies directly over the centre of the pyrazolate ring (H–ring centroid 2.18 Å). There are no significant interactions involving the acetonitrile solvate or BF_4^- anions.

The tetranuclear cation of **2** (Fig. 2) sits on a centre of inversion; bridging pyrazolate groups lie above and below the plane of the macrocycle, each linking a pair of copper ions which are also bridged by an alkoxo group. The mean planes of the pyrazolate ions are parallel, one on either side of the macrocycle, and are inclined at 46.4(2)° to the plane of the eight macrocyclic donors. The Cu(1)···Cu(2) and Cu(1)···Cu(1A) distances are 3.254(2) and 3.133(1) Å respectively, compared to 2.953(1) and 3.000(1) Å in the $[Cu_4(L^1)(OH)](NO_3)_3\cdot 3H_2O$ complex.[3] The copper ions are essentially four-coordinate, although Cu(2) interacts weakly [2.515(6) Å] with a fluorine atom of BF_4^-. Each pair of copper ions is displaced from the plane of the macrocyclic donors towards the coordinated

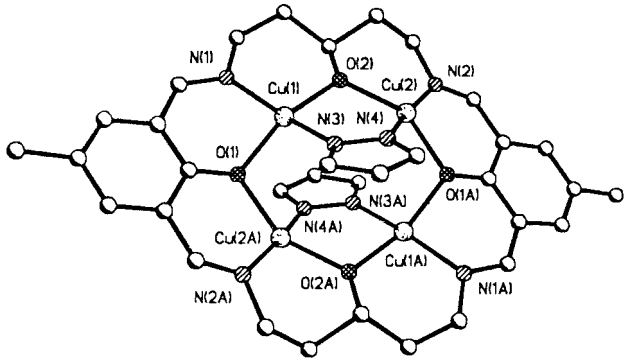

Fig. 2 Perspective view of the $[Cu_4(\mu\text{-pyr})_2(L^1)]^{3+}$ cation. Selected distances (Å) and angles (°): Cu(1)···Cu(2) 3.255(1), Cu(1)–Cu(2A) 3.133(1), Cu(1)–O(1) 1.949(5), Cu(1)–N(1) 1.945(7), Cu(1)–O(2) 1.918(6), Cu(1)–N(3) 1.954(6), Cu(2)–O(1A) 1.973(5), Cu(2)–N(2) 1.942(7), Cu(2)–O(2) 1.950(5), Cu(2)–N(4) 1.945(7); Cu(1)–O(1)–Cu(2A) 106.1(3), Cu(1)–O(2)–Cu(2) 114.6(2), Cu(1)–N(3)–N(4) 119.9(5), Cu(2)–N(4)–N(3) 118.4(5).

pyrazolate ligand and this arrangement causes the coordination geometry at copper to be substantially distorted towards tetrahedral. The resulting steric stress probably responsible for the formation of **1**, where the coordination geometry is more relaxed, as the major product.

Attempts to prepare a pure sample of the dinuclear complex **1**, using a ligand : Cu ratio of 1 : 2 rather than 1 : 4, have not proved successful to date. FAB and IR data are consistent with the suggestion that the initial green product contains the same complex as the crystals of **1** but recrystallised samples always contain a small amount of the tetranuclear complex **2**, suggesting an equilibration between **1** and **2** in solution. Clean samples of the tetranuclear complex can be obtained by treatment of $[Cu_4(L^1)(OH)](BF_4)_3$ with an excess of pyrazole in acetonitrile. In the solid state the two complexes can be distinguished from their IR spectra; **1** shows the expected split imine stretch (1637 and 1657 cm^{-1}) whereas **2** shows a single band at 1631 cm^{-1}. FAB mass spectra of the two complexes are also distinctly different; that of the initial green product shows peaks consistent with a dicopper complex **1**, while complex **2** clearly shows peaks due to tetracopper species.‡

In an attempt to fill the two vacant coordination sites of complex **1**, the crude dicopper complex was treated with an excess of nickel(II) acetate in 1 : 1 methanol–acetonitrile and refluxed overnight. The resulting green complex **3** was characterised from its FAB spectrum (Fig. 3). The spectrum is remarkably simple, showing only two significant clusters centered at *m/z* 807 and 748 which are assigned to $\{[Cu_2Ni_2(L^1)(OH)(MeCO_2)]^{2+}-H^+\}$ and $\{[Cu_2Ni_2(L^1)(OH)]^{+}-2H^+\}$ respectively; the isotope patterns in the

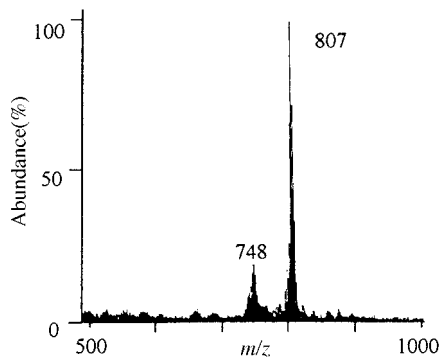

Fig. 3 FAB (SIMS) spectrum of the heterotetranuclear complex $[Cu_2Ni_2(L^1)(OH)(MeCO_2)](BF_4)_2$.

clusters match those predicted.[11] Notably, there are no peaks attributable to scrambled tetranuclear complexes (*e.g.* containing Cu_4, $CuNi_3$, Cu_3Ni or Ni_4 cores) or to unreacted complex **1**. The absence of metal ion scrambling in the FAB, together with the marked preference of tetranickel(II) complexes for bridging acetate groups,[5,12] suggests the structure shown in the scheme, with the addition of an acetate bridge linking the nickel ions is likely to be correct, *i.e.* $[Cu_2Ni_2(L^1)(OH)(MeCO_2)](BF_4)_2$.

This work was supported by EPSRC grant GR/J73773, we are also grateful to the EPSRC Mass Spectrometry Service for FAB (LSIMS) spectra and to QUB for the award of a postgraduate studentship (to F. L.).

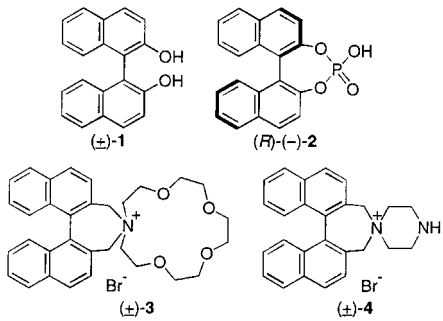
Received (in Liverpool, UK) 12th January 1999, Accepted 25th February 1999

The redox behaviour of the binaphthyl unit in quaternary ammonium salts with an appended crown ether (3) is dramatically affected by the presence of metal cations and this effect can be used as an analytical tool to detect micromolar concentrations of alkali metal ions.

Axially chiral 2,2′-disubstituted 1,1′-binaphthyls, such as BINOL **1**,[1] have been utilised as a scaffold to construct a fascinating array of molecules, ranging from chiral ligands applied in asymmetric, metal-catalysed reactions[2,3] to complex supramolecular structures employed in molecular recognition studies.[4–6] The binaphthyl skeleton itself is normally viewed as an inert, robust block, whose activity is confined to occasional racemization; very little is known of its actual chemistry.



Shoute has recently studied the pulse radiolysis of BINOL hydrogen phosphate **2** in aqueous solutions (at pH 9.5, where **2** is dissociated).[7] Using time-resolved absorption spectroscopy, he has been able to show that the initially generated radical anion ($\mathbf{2}^- + e^- \rightarrow {}^{-\bullet}\mathbf{2}^-$) either undergoes an acid-catalysed protonation (${}^{-\bullet}\mathbf{2}^- + H^+ \rightarrow {}^{\bullet}\mathbf{H2}^-$) or transfers an electron to organic molecules present in the solution.[7] Since the protonation of radical anions is generally known to be slowed down by electron-withdrawing groups,[8] we became interested in the electrochemical generation of radical species from tetraalkylammonium binaphthyl salts, as a continuation of our efforts to develop new chiral ligands and electrochemical sensors.[9–11] Herein, we disclose preliminary results of the elucidation of the redox properties of novel quaternary aza-crown ether salt **3** and show how this molecule can be used in an electrochemical sensor for alkali metal cations in solution.

The quaternary ammonium aza-crown ether (±)-**3** was prepared from (±)-2,2′-bis(bromomethyl)-1,1′-binaphthyl[12] and the commercially available 1-aza-15-crown-5 (20 °C, overnight; 55%) in analogy to the published procedure.† Fig. 1 shows a cyclic voltammogram of a 2×10^{-3} mol dm^{-3} solution of **3** in MeCN containing 0.1 mol dm^{-3} $TBABF_4$ on a pyrolytic graphite (PG) electrode which gave a quasi-reversible response with ΔE_p = 129 mV. The electron transfer process was also found to be reversible on a Hg/Au amalgam electrode but was significantly less reversible on Pt, Au, Fe and Ag electrodes.

A quasi-reversible process on the PG electrode was also observed when the crown ether unit was replaced with a piperazine ring, as in (±)-**4**.[13] By contrast, reduction of (±)-**1**, carried out under the same conditions, showed an irreversible process, suggesting that the relative stability of **3** and **4** originates in the presence of the N^+ group. The addition of 20 μmol dm^{-3} of HCl (aq) to a solution of **3** in MeCN caused the current for the re-oxidation of the radical species to decrease dramatically.

The radical species generated from **3** (and from its congener **4**) must be stable in the order of minutes to allow quasi reversible responses to be observed with slow scan rate voltammograms (ν = 10 mV s^{-1}). To demonstrate the increased stability of the $ArCH_2N^+$ system, the visible spectrum of **3** was measured during a bulk electrolysis experiment. Fig. 2 shows the spectrum of **3** in the electrolyte solution described above as a function of time following the application of a constant current density of 50 μA cm^{-2} to a PG rod electrode. The growth of a peak at 410 nm is consistent with the formation of a binaphthyl radical species analogous to that observed by Shoute[7] for **2** (*vide supra*). This peak disappeared following the addition of 20 μmol dm^{-3} of HCl (aq), suggesting a chemical reaction which must clearly be an irreversible process that would account for the loss of the reverse peak in Fig. 1 following the acidification of the solution.

The mechanism of stabilisation of the binaphthyl system in **3** by the N^+ group is intriguing. Whereas in conjugated systems the effect of an electron-withdrawing group[8] can easily be understood, in **3** the electron-withdrawing N^+ is insulated from the aromatic ring by the benzylic CH_2 group, so that direct conjugation is precluded. However, molecular modelling shows that the twisted-chair conformation of the dihydroazepine ring in **3** renders the CH_2–N^+ σ-bond almost perpendicular to the aromatic system (Fig. 3). Hence, this conformation is ideally predestined to allow a donation from the aromatic π-system to the low-lying σ* orbital of the C–N^+ bond, so that a stabilisation (similar to that observed with the 'normally' conjugated systems) can be anticipated.

The effect of the quaternary ammonium group of **3** can, *a priori*, be modified by complexation of the crown ether moiety with a metal cation. Note that the positive charge on nitrogen in **3** can be assumed to be partly stabilised either by interaction with a lone pair of one of the oxygen atoms or, more likely, *via*

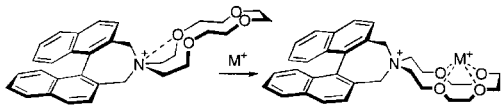

Scheme 1

the Cieplak effect.[14] Complexation of **3** with the metal cation (**3** → **5**; Scheme 1) should engage the latter, Lewis basic oxygen, leaving N$^+$ with a higher effective charge. To address this issue, the electrochemical experiments were repeated in the presence of $LiClO_4$ and $NaClO_4$, respectively. Fig. 4 shows that the peak current for the cathodic process decreases linearly as the concentration of Li$^+$ increases. Since the redox potentials of both processes are unaffected by the addition of Li$^+$, it can be concluded that the irreversible transformation of **3** is precluded by Li$^+$ binding. The decrease in current must result from the effective decrease in the concentration of unbound **3**. These results appear to be in agreement with the original hypothesis of increasing stabilisation of the binaphthyl system by enhancement of the neighbouring charge.

Fig. 4 also shows the effect of Na$^+$ on the cathodic current for the reduction of **3**. It can be seen that the current decreases more rapidly upon addition of Na$^+$ to the solution. This effect presumably results from the greater binding constant for Na$^+$ over Li$^+$ with the 1-aza-15-crown-5 unit.[15] However, because the reduction current has fallen to effectively zero with the addition of 0.5 equiv. of Na$^+$, it is likely that the Na$^+$ ion complexes with two crown ether molecules. Complementary

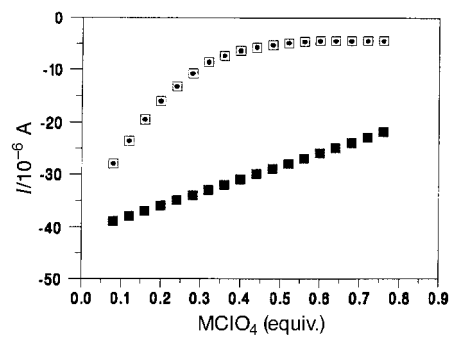

Fig. 4 Peak current for the reduction of (±)-**3** (5 × 10^{-3} mol dm^{-3}) in MeCN following the addition of $NaClO_4$ and $LiClO_4$ to the solution: (■) M = Li and ⊡ M = Na.

results were obtained with 1-aza-12-crown-4, a lower homologue of **3** which exhibited higher affinity to Li$^+$.

The observed response to the presence of Li$^+$ or Na$^+$ suggests that these systems can be potentially utilised as sensors for detecting alkali metal cations and, perhaps, of other cationic species. While there are numerous electrochemical, alkali metal sensors based on crown ethers,[16–18] most of them are potentiometric, relying on a change in energy of the electroactive moiety which tends to limit their sensitivity. As Fig. 4 clearly shows, a solution of **3** can detect the concentrations of Na$^+$ below 10 μmol dm^{-3}. Presumably, further tailoring the aza-crown ether cavity could generate molecules specific for other cations.

In conclusion, we have demonstrated for the first time that the radical species, generated electrochemically from a quaternary ammonium binaphthyl salt such as **3**, is relatively stable in non-acidic media. Since binding a cation to the appended crown ether moiety dramatically affects the redox behaviour of the binaphthyl unit, this novel class of binaphthyl crown ethers may be developed into very sensitive electrochemical sensors specific to alkali metal cations at micromolar concentrations which are beyond reach of the crown ether-based devices currently available.

Received (in Basel, Switzerland) 4th January 1999, Accepted 25th February 1999

Neutron diffraction, magnetic susceptibility and EPR spectroscopic studies of a dodecanuclear chromium cage are reported which show the molecule has an $S = 6$ spin ground state; this is the highest spin ground state known for a cage of this metal.

Research on high nuclearity paramagnetic cages has recently led to the discovery of single molecule magnets,[1–4] *i.e.* complexes which show hysteresis in magnetisation *versus* external field response which is of a molecular origin. The initial discovery was in a dodecanuclear mixed-valent manganese(III)/(IV) cage stabilised by carboxylate ligands.[1] Our interest in the area led us to examine a report of a mixed valent chromium cage,[5] of formula $[Cr_{12}O_{12}(O_2CBu^t)_{15}]$, where many of the features of the Mn_{12} single molecule magnets are present, at least in principle.

The synthesis is unusual, but straightforward. Reaction of $Cr(NO_3)_3{\cdot}9H_2O$ (0.050 mol) with $K(O_2CBu^t)$ (0.178 mol) in H_2O (500 cm^3) at *ca.* 80 °C gives a blue precipitate (90% yield) which is soluble in several organic solvents. Heating this precipitate at 400 °C under a stream of N_2 for 1 h eliminates HO_2CBu^t, yielding a dark green solid which analyses well for $[Cr_{12}O_{12-x}(OH)_x(O_2CBu^t)_{15}]$; electrospray mass spectrometry† of a CH_2Cl_2–MeOH solution of this solid indicates that the only significant species present in solution is $[Cr_{12}O_{12-x}(OH)_x(O_2CBu^t)_{15}]$. The yield of this compound is 77%. Very large green crystals could be grown by slow evaporation of an *n*-propanol solution of this material.

Initially we performed an X-ray structure determination of these crystals,‡ which revealed a dodecanuclear chromium cage, based on a centred-pentacapped-trigonal prism (Fig. 1). The complex has crystallographic D_3 symmetry, with the central Cr [Cr(1)] at the junction of the C_3 and C_2 axes, the Cr atoms [Cr(2) and symmetry equivalents (s.e.)] capping the triangular faces on the C_3 axis, and the Cr centres [Cr(3) and s.e.] capping the rectangular faces on the C_2 axes of the cage. Only the Cr atoms [Cr(4) and s.e.] at the vertices of the trigonal prism are in general positions. The cage is held together by μ_4-oxides [O(1) and s.e.], which bridge between the central Cr site, and one each of the vertex, triangular face-capping and rectangular face-capping sites; six μ_3-oxygens [O(2) and s.e.], which each bridge between two vertex sites and a cap on a rectangular face, and fifteen O_2CBu^t groups, which each bridge a Cr···Cr vector in a 1,3-bridging mode. Examination of the structure revealed that all Cr sites had similar bond lengths and angles; there was no sign of mixed valency which would lead to a charge imbalance if the apparent formula of $[Cr_{12}O_{12}(O_2CBu^t)_{15}]$ is correct. We therefore examined the alternative explanation, that some of the bridging oxide units were protonated, by performing a single crystal neutron diffraction study.‡

The presence of O_2CBu^t as the carboxylate ligand is not ideal for a neutron study, especially as all the methyl groups are disordered. However, the study unambiguously shows the presence of a half-weight hydrogen atom attached to the μ_3-O-atoms [O(2) and s.e.]. The formula should therefore be corrected to $[Cr_{12}(O)_9(OH)_3(O_2CBu^t)_{15}]$ **1**, and all Cr sites are Cr(III).

The magnetic properties of the cage remain interesting. Susceptibility studies§ reveal a double maxima in the $\chi_M T$ *vs.* T plot (where χ_M is the molar susceptibility) (Fig. 2). The low temperature maximum, at *ca.* 10 K, has a value of 21.6 cm^3 K mol^{-1}, consistent with an $S = 6$ ground state (χ_M calculated for $g = 1.99$ is 20.8 cm^3 K mol^{-1}), and the presence of the higher temperature maximum suggests a complicated ordering of the higher energy spin states. The complexity of the structure makes modelling this behaviour difficult, however further characterisation of the spin ground state comes from multifrequency EPR studies. At low temperature, and all frequencies studied (24, 34, 90, 180 GHz), a complex multiplet is observed (Fig. 3). The 90 GHz spectrum in Fig. 3(b) can be simulated¶ with the spin-Hamiltonian parameters: $S = 6$, $g_{zz} = 1.965$, $g_{xx} = g_{yy} = 1.960$, $D = +0.088$ cm^{-1}, $E = 0$ (where D and E are the axial and rhombic zero-field splitting parameters respectively) [Fig. 3(c)]. Simulations with other values for S result in significantly poorer fits with the experimental spectra. It is unusual to

observe such detail in spectra of high spin state cages.[9] The sign of D was determined by examining depopulation effects in spectra recorded at 180 GHz, between 20 and 2.8 K.

The cage is therefore the highest spin Cr cage known. Unfortunately the sign of D indicates that it will not be a single molecule magnet. Further studies of the cage will include a polarised neutron study which we hope will give the spin structure of the ground state of the cage directly.

We thank the EPSRC(UK) for funding for a diffractometer, SQUID susceptometer, an electrospray mass spectrometer, EPR spectrometers, access to ISIS and for Fellowships (to E. J. L. M and M. M.), and for an Advanced Research Fellowship (to G. M. S.).

Notes and references

† Electrospray mass spectra were obtained on a Finnegan LCQ spectrometer with the sample dissolved in CH_2Cl_2 which was added to MeOH prior to injection into the spectrometer.

‡ *Crystal data* for $C_{75}H_{138}Cr_{12}O_{42}\cdot 4.5H_2O\cdot C_3H_8O$ **1**: rhombohedral, space group $R32$, a = 18.3867(11), c = 36.034(6) Å, V = 10550(2) Å^3, M = 2477.0, Z = 3 (the molecule lies on a 32 site), T = 150.0(2) K, $R1$ = 0.0649. Data collection, structure solution and refinement were performed using programs DIRDIF[6] and SHELXL-97.[7] Neutron data were collected at 150 ± 1 K on the SXD instrument at the ISIS spallation neutron source using the time-of-flight Laue diffraction method.[8] The intensities of 5093 observed reflections were extracted and reduced to structure factors using standard SXD procedures,[8] which gave a merged data set comprising 1048 unique reflections. CCDC 182/1183.

§ Variable-temperature magnetic measurements on **1** in the region 1.8–325 K were made using a SQUID magnetometer (Quantum Design) with samples sealed in gelatine capsules. A diamagnetic correction for the sample holder was applied to the data.

¶ The simulation requires the line-width of the 2S allowed transitions to vary with the M_s states according to a power series $\Delta B = A + BM_s + CM_s^2$. The spectra were fitted with A = 400 G for z and 270 G for xy lines, B = 0 and C = 50 G.

Improvement of the enantioselectivity in the enantioselective hydrogenation of ethyl pyruvate by addition of achiral tertiary amines

József L. Margitfalvi, Emilia Tálas and Mihály Hegedûs

Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, 1025 Budapest Pusztaszeri út 59-67, Hungary. E-mail: joemarg@cric.chemres.hu

Received (in Liverpool, UK) 25th January 1999, Accepted 24th February 1999

In the asymmetric hydrogenation of ethyl pyruvate over the catalyst system cinchonidine–Pt/Al_2O_3 the enantioselectivity was significantly improved by addition of different achiral tertiary amines to the reaction mixture, however the effect appeared to be strongly solvent and concentration dependent.

The hydrogenation of α-keto esters and related compounds over cinchonidine–Pt/Al_2O_3 catalyst is of great scientific interest.[1] In these heterogeneous catalytic asymmetric hydrogenation reactions the enantioselectivity (ee) (ee = ([*R*] − [*S*])/([*R*] + [*S*])) appeared to be strongly solvent dependent.[2] In different solvents the ee increased in the following order: alcohols (ee = 0.70–0.75) < hydrocarbons (ee = 0.80–0.85) < acetic acid (ee = 0.92–0.95%).[2] In all solvents the ee depended strongly on the concentration of the modifier.[1,2] This effect was studied in detail in ref. 2, however neither the chemistry nor the surface phenomena responsible for the observed strong solvent effect could be explained. One of the most interesting observations is that in acetic acid (AcOH) ten times less cinchonidine is needed to obtain the maximum ee value than in toluene.[2]

We have also shown that the addition of small amounts of AcOH is sufficient to increase the ee value.[3] For instance, in EtOH at [AcOH] = 5 M the ee increased to 0.91 compared to 0.73 in its absence. In toluene, under similar conditions, the ee increased to 0.93 compared to 0.81 in its absence. Consequently, the above ee values were very close to those obtained in pure AcOH. However, it should be mentioned that the use of AcOH requires corrosion resistant stainless steel autoclaves and accessories, this fact strongly hinders its general use in academic research. Therefore, any new approach resulting in an increase in enantioselectivity in the absence of AcOH will be of great scientific and practical interest.

In this contribution we report that the addition of achiral tertiary amines (ACTAs) to the reaction mixture containing cinchonidine, substrate, solvent (*e.g.* toluene) and catalyst significantly increases both the rate and the enantioselectivity of the given asymmetric hydrogenation reaction. It is known that when the hydrogenation of ethyl pyruvate is carried out in the presence of ACTAs, *e.g.* triethylamine (TEA), quinuclidine (QN), pronounced rate acceleration is observed without asymmetric induction.[4–6] However, the rate acceleration was much less than in the presence of cinchona alkaloids.

In this study the modifier, either cinchonidine alone or its mixture with achiral tertiary amines, was injected by high pressure hydrogen at $t = 0$ into the reactor containing the catalyst, the substrate and toluene as solvent. Pseudo first order rate constants describing the kinetics for the first 6–10 min (k_1) and 10–40 min (k_2) were used to evaluate the effect of ACTAs. Details of the experimental method and the kinetic approach can be found elsewhere.[3,7,8]

Reaction kinetic data and enantioselectivities obtained in a series of experiments carried out at 20 °C either in the presence or absence of ACTAs are summarized in Table 1, while Fig. 1 shows the corresponding enantioselectivity *vs.* conversion dependencies. In these experiments the ACTAs : cinchonidine (CD) ratio was five and almost full conversion ($x < 0.99$) was achieved within 90 min. Thus, the addition of ACTAs did not result in any decrease in the rate of hydrogenation, moreover, as emerges from the data given in Table 1, the addition of ACTAs led to a considerable increase in both rate constants k_1 and k_2. The rate acceleration increased in the following order: TEA < DABCO < QN.

The enantioselectivity *vs.* conversion dependencies show a monotonic increase type. This form of ee–conversion dependency has been observed by different authors.[2,3,7–10] In the absence of ACTAs the enantioselectivity *vs.* conversion dependency passes through a maximum and decreases slightly above 0.5 conversion giving a final ee value (ee_{end}) around 0.71. Similar behaviour had been observed in our earlier work when $[CD]_0 < 5 \times 10^{-5}$ M.[3,8,11] Analogous results were obtained when TEA was added, however in this case both the ee_{max} and ee_{end} values increased quite substantially (see Table 1). The addition of quinuclidine or DABCO altered the character of the enantioselectivity *vs.* conversion dependency as the monotonic increase in ee was maintained up to 0.99 conversion. This type

of enantioselectivity *vs.* conversion dependency was obtained[3,8,11] when $[CD]_0 > 5 \times 10^{-5}$ M. There was no measurable difference between quinuclidine or DABCO, however, the phenomena was well reproducible (see Table 1 and Fig. 1). In conclusion, results given in Table 1 and Fig. 1 precisely demonstrate that in the presence of ACTAs the final enantioselectivity (ee_{end}) increases from 0.71–0.72 to 0.91. This increase in enantioselectivity is considered to be a very pronounced selectivity improvement. Note that in toluene the highest ee value was 0.87 which was measured at $[CD]_0 = 6 \times 10^{-4}$ M. Similar ee values were reported in ref. 2. As emerges from data given in Fig. 1 the ability of ACTAs to increase the enantioselectivity increased in the following order TEA < DABCO = QN, *i.e.* the increase in ee is of a similar order as the rate acceleration effect. However, no measurable effect was induced by achiral tertiary amines when the concentration of CD increased to 10^{-4} M.

Analogous results were obtained in a series of experiments carried out at 10 °C. In these experiments quinuclidine was used as the ACTA and its concentration was varied. Related kinetic data and enantioselectivities are summarized in Table 2, which shows that the influence of ACTAs is strongly concentration dependent. These experiments indicate that the addition of quinuclidine (QN) in the given concentration range increases both the rate of the hydrogenation (rate constants k_1 and k_2) and the enantioselectivity. In these experiments, due to the decrease in the temperature, very high enantioselectivities were obtained. Table 2 shows the influence of ACTAs is already very pronounced at ACTA : CD = 0.5. The increase in the QN concentration resulted in a further increase in the k_1, k_2 and ee_{max} values. The increase in the rate constant k_1 and ee_{max} is gradual and levels off at ACTA : CD = 5–10, while the rate constant k_2 passes through a maximum. The enantioselectivities obtained in this series of experiments (ee_{max} = 0.93–0.94) are the highest values that have ever been obtained in this reaction in the absence of AcOH.

When EtOH was used as solvent no increase in ee was observed in the 10^{-5}–10^{-4} M concentration range of CD and at ACTA : CD = 1–5. No effect was observed in other alcohols, such as methanol or propanol. All of these results strongly indicate that the recognized effect induced by ACTAs depends on (i) the type of solvent used, (ii) the concentration of achiral tertiary amines, and (iii) the concentration of cinchonidine. Note that the observed effect appears at a very low concentration of cinchonidine (1.2×10^{-5} M), *i.e.* in the concentration range characteristic of enzyme catalytic reactions.

The observed increase of both the rate of hydrogenation and the enantioselectivity upon addition of ACTAs strongly resembles the influence of the initial concentration of cinchonidine on the kinetics and enantioselectivity.[2,3,8,11] Results obtained in this study indicated that addition of ACTAs would increase the amount of cinchonidine involved in the enantioselective hydrogenation. The above suggestion is strongly supported by results attained at difference concentrations of CD, but in the absence of ACTA. These results are summarized in Table 3. As emerges from the data in Tables 2 and 3, the increase in the concentration of both CD and ACTA resulted in similar changes in the reaction kinetics: (i) an increase of k_1, k_2 and ee_{max} values and (ii) alteration of the form of the enantioselectivity–conversion dependencies (see Fig. 1 in this paper and Fig. 2 in ref. 11).

The absence of any effect of ACTAs both at high concentrations of cinchonidine and in EtOH strongly resembles the solute–solute (alkaloid–alkaloid) interactions observed in the case of different dihydroquinines ((+)-DHQN and (−)-DHQN).[12] The (+)-alkaloid–(−)-alkaloid interaction was greatly reduced when an alcohol was used as solvent.[12] We propose that the alkaloid–alkaloid (cinchonidine–cinchonidine) interaction is not favourable for the given catalytic reaction as it reduces the amount of 'free alkaloid' required for asymmetric induction. It should be mentioned that in crystallographic form cinchonidine is stabilized by two hydrogen bonds between the OH group and the quinuclidine nitrogen,[13] consequently cinchonidine exists in the form of a cyclic 'dimer'. Based on the above literature analogy[12] we suggest that in the presence of ACTAs a new type of solute–solute interaction (*e.g.*, alkaloid–ACTA interaction) appears provided the concentration of the alkaloid is low and the solvent is not an alcohol. Due to the above interaction the amount of 'free alkaloid' required for asymmetric induction increases. Further studies are in progress in our laboratory to elucidate the character of interactions involved in the phenomena observed.

The partial financial support of OTKA (grants T023317, T025732) is greatly acknowledged.

Received (in Cambridge, UK) 19th January 1999, Accepted 3rd March 1999

The two-dimensional network compound $[MoS_4Cu_6I_4(py)_4]_n$ is the first example of a cluster polymer showing very large optical limiting effects; its nonlinear absorptive index α_2 and nonlinear refractive value n_2 are 1.5×10^{-9} m W^{-1} and -2.5×10^{-17} m^2 W^{-1}, respectively, in 6.5×10^{-5} mol dm^{-3} DMSO solution; the optical limiting threshold was determined to be 0.6 J cm^{-2}, which is about three times better than that of C_{60}.

Research into optical limiting (OL) materials has become increasingly intensive because of their potential applications in the protection of optical sensors from high-intensity laser beams. Thus the design and synthesis of new materials with large optical limiting capability represents an active field in modern chemistry, physics, and materials science.[1,2] Our research interest focuses on cluster compounds. Although many clusters show strong nonlinear optical (NLO) absorptive and NLO refractive properties, only the clusters $[NBu_4]_2[MoOS_3Cu_3BrCl_2]$, $[NBu_4]_2[MoOS_3(CuSCN)_3]$, $[NBu_4]_3[MS_4M'_3BrX_3]$ (M = Mo, W; M′ = Cu, Ag; X = Cl, Br, I), $[NBu_4]_3[MoOS_3Cu_3BrI_3]$, $[WS_4Cu_4(SCN)_2(py)_6]$, $[Mo_2Ag_4S_8(PPh_3)_4]$ and $[NEt_4]_4[Mo_2O_2S_6Cu_6Br_2I_4]$ exhibit large optical limiting effects.[3–10] The limiting thresholds of $[NBu_4]_3[MS_4M'_3BrX_3]$, $[WS_4Cu_4(SCN)_2(py)_6]$ and $[Mo_2Ag_4S_8(PPh_3)_4]$ were measured to be 0.6, 0.3 and 0.1 J cm^{-2}, respectively. These data are comparable to those of phthalocyanine derivations and better than that observed in C_{60}.[1,11]

The complex $[MoS_4Cu_6I_4(py)_4]_n$ is one of *ca.* 20 cluster polymers. While $[NBu_4N][MS_4Tl]$ (M = Mo, W) have strong NLO absorptive and NLO refractive properties,[12,13] they do not exhibit optical limiting effects. $[MoS_4Cu_6I_4(Py)_4]_n$ is the first cluster polymer to show strong optical limiting effects.

The polymer $[MoS_4Cu_6I_4(py)_4]_n$ was prepared by the reaction of $(NEt_4)_2MoS_4$, CuI and cyanopyridine with pyridine in MeCN solution. The crystal structure of $[MoS_4Cu_6I_4(py)_4]_n$, together with some bond parameters, is shown in Fig. 1.†

The basic structural unit of the polymer $[MoS_4Cu_6I_4(py)_4]_n$ may be regarded as an octahedron, in which MoS_4 is enveloped by six copper atoms. The same Mo–S bond lengths [2.268(3) Å] and similar S–Mo–S bond angles [108.6(1)–109.92(6)°] reveal that the structure of the central MoS_4 core is close to that of the $[MoS_4]^{2-}$ tetrahedron. Each S atom acts as a tetradentate ligand binding with three Cu atoms and one Mo atom. There are two types of copper atoms in the Cu_6 octahedron, two axial Cu(2) atoms and four equatorial Cu(1) atoms. The distance Cu(2)–Mo is not equal to Cu(1)–Mo, while several Cu–Mo–Cu bond angles are inequivalent. Thus, six Cu atoms form a distorted octahedron. Cu(2) atoms each coordinate with two S atoms and one terminal I(2) atom, and exhibit triangular planar geometry. Cu(1) atoms bind with two S atoms, one μ-I(1) atom and one N from py, and adopts a distorted tetrahedral geometry. Each $[MoS_4Cu_6I_4(py)_4]$ unit forms four Cu(1)–I(1)–Cu(1) bridges with four $[MoS_4Cu_6I_4(py)_4]$ units leading to the two-dimensional network structure.

Two shoulder peaks at 300 and 410 nm are observed in the electronic spectrum of $[MoS_4Cu_6I_4(py)_4]_n$. The polymer has a relatively low linear absorption in the visible and near IR region. Z-scan data indicate that the polymer exhibits both strong NLO absorption and NLO refraction (self-defocusing effects), which were measured as described in ref. 13.

It should be pointed out that both excited state population (and absorption) and two-photon absorption can be responsible for the measured NLO effect.[14] Fig. 2 shows typical Z-scan measurements of the polymer in DMSO solution without the aperture. The open circles are the experimental data, and the solid curves are the theoretical fit by using Z-scan theory described in ref. 13. It is obvious that the theoretical curves qualitatively reproduce well the general pattern of the observed experimental data. This fact suggests an effectively third-order characteristic for the experimentally detected NLO effects. The

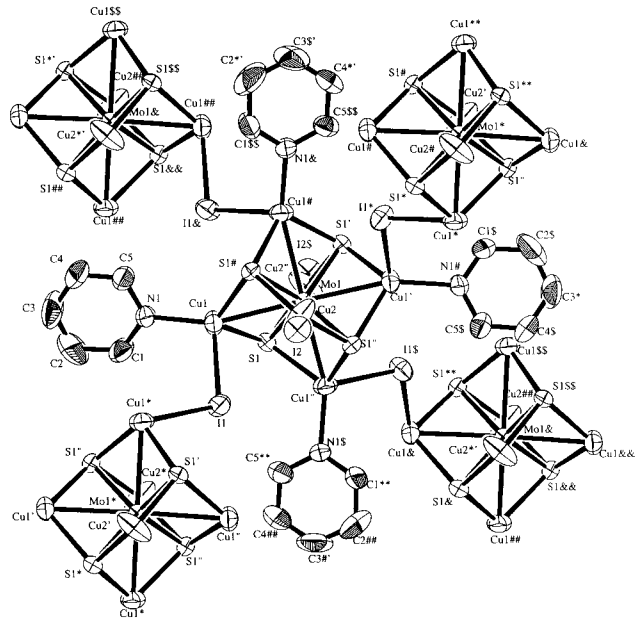

Fig. 1 The crystal structure of $[MoS_4Cu_6I_4(py)_4]_n$. Selected bond lengths (Å) and angles (°): Mo(1)–S(1) 2.268(3), Mo(1)–Cu(1) 2.684(2), Mo(1)–Cu(2) 2.653(2), I(1)–Cu(1) 2.784(2), I(2)–Cu(2) 2.455(2), Cu(1)–N(1) 1.995(10); S(1)–Mo(1)–S(1)′ 108.6(1), S(1)′–Mo(1)–S(1)″ 109.92(6), Cu(1)–Mo(1)–Cu(1)′ 168.80(7), Cu(1)–Mo(1)–Cu(2) 84.40(4), Cu(1)–Mo(1)–Cu(1)# 90.55(1), Cu(1)–Mo(1)–Cu(2)″ 95.60(4), Cu(1)–Mo(1)–S(1) 55.49(9), Cu(1)–Mo(1)–S(1)′ 117.19(9), Cu(2)–Mo(1)–S(1)′ 125.72(6), Cu(2)–Mo(1)–S(1)″ 54.28(6), I(1)–Cu(1)–S(1) 94.87(9), I(2)–Cu(2)–S(1)″ 125.82(7), I(2)–Cu(2)–Mo(1) 180.0, Mo(1)–S(1)–Cu(1) 71.33(9).

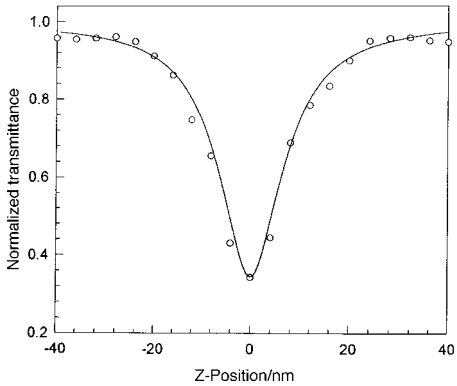

Fig. 2 Z-scan data showing NLO absorption of $[MoS_4Cu_6I_4(py)_4]_n$.

effective nonlinear absorptive index α_2 is 1.5×10^{-9} m W^{-1} in 6.5×10^{-5} mol dm^{-3} DMSO solution. The data is comparable to those of $[Mo_2Ag_4S_8(PPh_3)_4]$ and $[W_2Ag_4S_8(AsPh_3)_4]$ which have the largest α_2 values known, and superior to those of other inorganic clusters.

The Z-scan data measured with the aperture are depicted in Fig. 3. The data show that the polymer $[MoS_4Cu_6I_4(py)_4]_n$ has a negative sign for the refractive nonlinearity, which gives rise to self-defocusing behavior. A reasonably good fit between the experimental data and the theoretical curves described in ref. 13 was obtained. The effective third-order NLO absorptive index n_2 is -2.5×10^{-17} m^2 W^{-1}. The polymer is composed of octahedral structural units $[MoS_4Cu_6I_4(py)_4]$ and its NLO refractive behavior differs from that of cluster polymers $\{[NBu_4][MS_4Tl]\}_n$ (M = Mo, W), which consist of dinuclear structural units $[MS_4Tl]$ and exhibit strong self-focusing effects. However, twin nest-shaped clusters consisting of two nest-shaped structural units have the same NLO refractive properties as $[MoS_4Cu_6I_4(py)_4]_n$, with strong self-defocusing behavior.

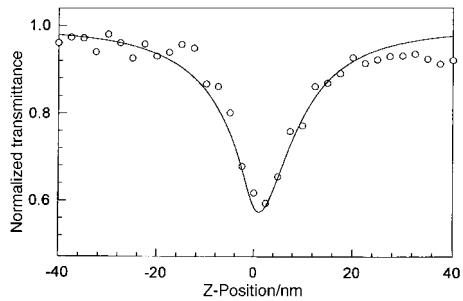

Fig. 3 Z-scan data showing NLO refraction of $[MoS_4Cu_6I_4(py)_4]_n$.

We also observed that the polymer possesses large optical limiting (OL) effects because of its very strong NLO absorption (α_2 value is the largest for any known inorganic cluster). The measurement of the transmitted pulse energy was conducted with a full collection of the transmitted pulse, and no aperture was used. The OL capability utilizing only the NLO absorption is demonstrated in Fig. 4 (open circles). The solid curves in Fig. 4 are from the theoretical model described in ref. 14. It is manifest that the observed OL effect arises as a direct consequence of the ionization recombination process. The light energy transmitted starts to deviate from Beer's law as the input light fluence reaches *ca.* 0.3 J cm^{-2}, and the solution become increasely less transparent as the incident fluence rises. The limiting threshold, which is defined as the incident fluence at which the actual transmittance falls to 50% of the corresponding linear transmittance, is 0.6 J cm^{-2} in DMSO solution. This value is three times better than that of C_{60}. These results clearly

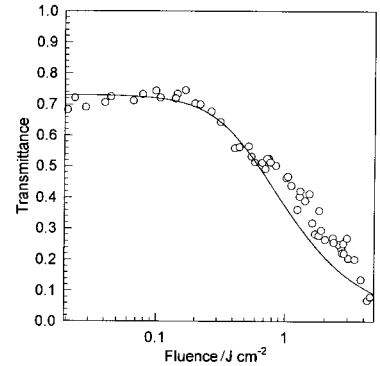

Fig. 4 Dependence of the transmitted energy at 532 nm of a DMSO solution of $[MoS_4Cu_6I_4(py)_4]_n$ on the incident light fluence. Beating rate: single shot (5 s interval).

indicate that the cluster polymer exhibits strong NLO properties and *also* a large OL capability. The properties should make the polymer a very promising candidate for broad-band OL application.

Received (in Cambridge, UK) 21st December 1998, Accepted 2nd March 1999

Polyaza[*n*]cyclophanes containing the 2,2′-biphenyl subunit are prepared in good yields by reaction of the corresponding pertosylated polyamine and 2,2′-bis(bromomethyl)biphenyl in basic media followed by detosylation with Na/Hg; the dynamic behaviour of those receptors is clearly affected by their interaction with different cationic and anionic guests.

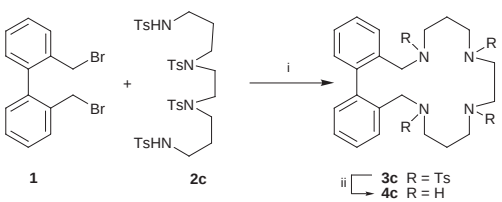
Macrocyclic receptors containing biphenyl subunits represent a very interesting class of hosts because of their dynamic properties provided by the presence of the biphenyl moiety. A clear example of the interest of this kind of compound is the work of Rebek in the development of simple allosteric systems.[1] Most work in this area has been directed towards the preparation of the all-oxygen macrocycles,[2] and only rarely has the synthesis of compounds in which some of the oxygen atoms have been substituted by nitrogen been reported.[3,4] However, our recent work on polyaza[*n*]cyclophanes[5] suggested to us that biphenyl polyaza macrocycles could represent a very interesting target as they combine the coordination trends of polyazacyclophanes with the dynamic properties of biphenyl crown ethers, giving rise to better regulated systems when supramolecular assemblies and catalytic properties are considered. Here we report on the first synthesis of such macrocyclic receptors and on preliminary results on their coordination properties that confirm their very interesting behaviour.

Synthesis of the expected macrocyclic receptors was carried out using a Richman–Atkins procedure optimized by us for the preparation of polyaza[*n*]cyclophanes (Scheme 1).[5a]

Cyclization of pertosylated polyamines **2** with **1** was performed very efficiently in 60–70% yield for **3c** and **3d** using MeCN as the solvent and K_2CO_3 as the base, without the need of high dilution conditions. Lower yields were obtained for the smaller macrocycles **3a** and **3b** due to the simultaneous formation of dimeric cyclic species **5** and **6**.[4] Detosylation was best carried out with Na/Hg,[5a] very good yields (*ca.* 70–80%) were obtained for the crude products. Chromatographic purification afforded the pure compounds in *ca.* 40% yield.

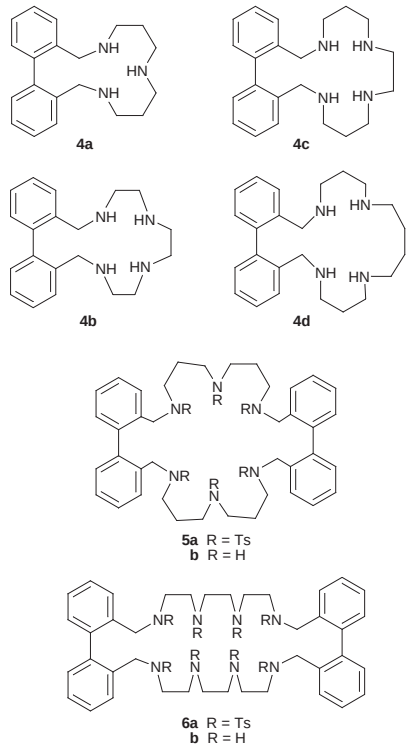
The dynamic properties of these systems are clearly seen in their ^{1}H NMR spectra, in particular when benzylic C–H signals are considered. In general, benzylic protons in compounds **4**, at 200 MHz in $CDCl_3$ at room temperature, appear as AB systems, in agreement with the presence of the slow equilibrium shown in Scheme 2.

Coalescence of the AB benzylic peaks occurs at not very high temperatures for the larger macrocycles, and variable temperature experiments allowed, for instance, us to determine for



1 2c

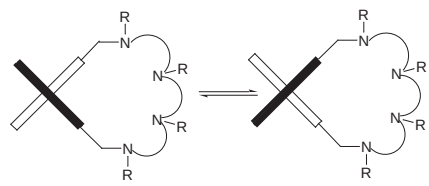
Scheme 1 *Reagents and conditions*: i, K_2CO_3, MeCN; ii, Na/Hg, THF–MeOH.



4c a coalescence temperature of 22 °C with $\Delta G = 14.5 \pm 0.3$ kcal mol^{-1}.

Blocking of the interconversion can be easily achieved by protonation of the nitrogen atoms, as indicated by the observation of the benzylic protons as two well-defined AB doublets. Protonation of compounds **4** could be followed by potentiometry and NMR techniques and showed similar trends to those found for related polyaza[*n*]cyclophanes.[5a] The observed separation of the two benzyl doublets is dependent on the pH. For **4c**, $\Delta\delta$ values at 300 MHz and room temperature vary from 41 Hz at pH 11 to 69 Hz at pH 2. Obviously interconversion of the two rotamers has to proceed through a coplanar disposition of the aromatic rings in which electrostatic repulsions are maximized, in particular when the protonated benzylic nitrogen atoms are considered.

These compounds seem to present a more versatile coordination chemistry than their simple polyaza[*n*]paracyclophane analogues, and this can be ascribed to the dynamic behaviour of



Scheme 2

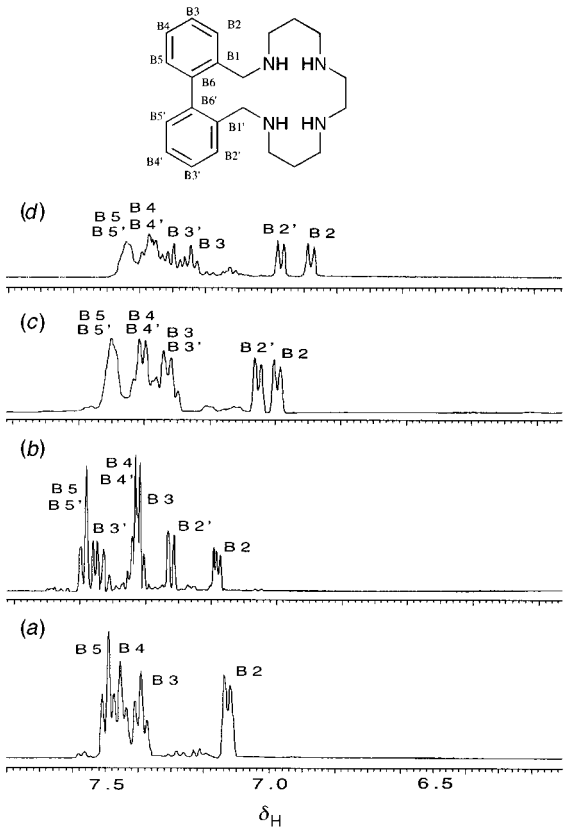


Fig. 1 ^{1}H NMR spectra (D_2O) (aromatic region): (*a*) **4c** at acidic pH, (*b*) **4c**·Pd^{2+} at basic pH, (*c*) **4c**·ATP at acidic pH, (*d*) **4c**·ATP at basic pH.

the biphenyl spacer. Thus, for instance, while coordination of **4c** to Cu^{2+} gives rise to a $[CuL]^{2+}$ complex with a stability constant of 18.7 logarithmic units, the related $[ZnL]^{2+}$ complex presents a constant of only 8.7 logarithmic units, strongly suggesting that the strength of the coordinative bonds formed tunes the conformation of the receptor. In the case of Cu^{2+} all the N donors would be participating in the recognition of the metal ion, while for Zn^{2+} just three out of the four N donors would be involved. These results are further supported by the presence in the Zn^{2+}·**4c** system of a hydroxylated species as well as by the large constant found for the protonation of the $[ZnL]^{2+}$ complex.† This behaviour is clearly dependent on the nature of the polynitrogenated bridge, which plays a very important role in determining the dynamic properties of the biphenyl moiety.‡

A particular situation is found when $PdCl_4^{2-}$ is used as the guest. The ^{1}H and ^{13}C NMR spectra at basic pH show that Pd^{2+} is coordinated to only three of the nitrogen atoms, introducing a high degree of rigidity in the macrocyclic framework. Thus, the ^{13}C NMR spectrum shows twelve signals for the aromatic carbons and ten for the aliphatic ones, denoting a complete loss of symmetry. On the other hand, while one of the benzylic signals appears with a chemical shift similar to that of the non-protonated free ligand, the other one is shifted downfield more than 6 ppm. Similar trends are observed in the ^{1}H NMR spectrum, all the hydrogen atoms being magnetically non-equivalent [see Fig. 1(*b*) for the aromatic region].

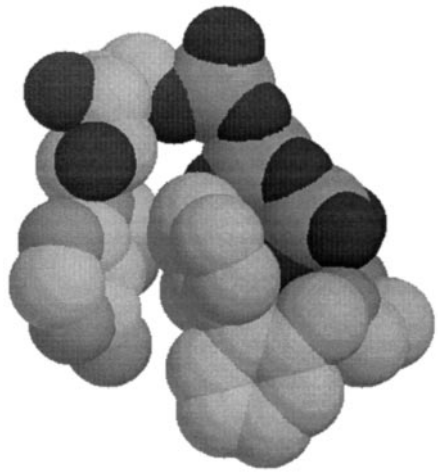

Fig. 2 CPK model of the calculated structure for the interaction of protonated **4c** and ATP (AMBER*, MACROMODEL® 5.0 package). GB/SA solvation model for water has been considered.

These receptors also strongly interact with anionic guests such as ATP.§ In this case a complete loss of symmetry is only observed for the aromatic region in the ^{1}H NMR spectrum [see Fig. 1(*c*) and 1(*d*)]. For **4c** four triplets and four doublets are observed in that region. These spectral features suggest a structure of the adduct in which the adenosine fragment of the ATP is located above the biphenyl moiety, freezing the rotation of and making non-equivalent both aromatic rings. These kinds of structures are also suggested by molecular mechanics calculations (see Fig. 2).

Additional work is being carried out in order to fully understand these interactions and to develop novel supramolecular systems based on these structures.

Financial support was provided by the CICYT (PB96-0792-C02) and Generalitat Valenciana (GV-D-CN-09-140-96). M. Querol and P. Díaz are indebted to Bancaja and CYCIT for predoctoral grants.

Notes and References

† Protonation constants of **4c** determined in 0.15 mol dm^{-3} $NaClO_4$ at 298.1 K are as follows: $\log K_{HL}$ = 9.91(2), $\log K_{H_2L}$ = 8.85(3), $\log K_{H_3L}$ = 6.55(3), $\log K_{H_4L}$ = 4.05(5). Stability constants for the formation of Cu^{2+} complexes with **4c**; $\log K_{CuI/Cu.L}$ = 18.66(3), $\log K_{CuHL/CuL.H}$ = 4.10(3). Stability constants for the formation of Zn^{2+} complexes with **4c**; $\log K_{ZnI/Zn.L}$ = 8.70(2) $\log K_{ZnHL/ZnL.H}$ = 6.91(3), $\log K_{ZnL(OH)/ZnL.H_2O}$ = −9.33(3). The degrees of protonation of receptor and substrate have been estimated taking into account their basicity constants.

‡ Stability constants for the formation of Cu^{2+} complexes with **4b** and **4d** are: $\log K_{CuI/Cu.L}$ = 23.19(7) and $\log K_{CuL/u.L}$ = 10.18(4).

§ Interaction of **4c** with ATP in 0.15 mol dm^{-3} $NaClO_4$ at 298.1 K gives rise to adduct species with AH_jL (j = 2 to 6) (A = ATP^{4-}, L = **4c**) with stability constants: $LH_4 + H_2A = H_6LA$, $\log K$ = 6.01(4). $LH_4 + HA = H_5LA$, $\log K$ = 6.30(4), $LH_3 + HA = H_4LA$, $\log K$ = 5.41(4), $LH_2 + HA = H_3LA$, $\log K$ = 5.55(4) and $LH_2 + A = H_2LA$, $\log K$ = 4.17(3).

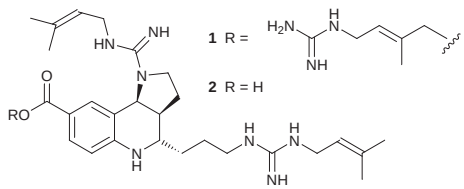
Received (in Corvallis, OR, USA) 7th December 1998, Accepted 10th February 1999

One pot reaction of anilines, benzaldehydes and 2-pyrrolines under lanthanide triflate catalysis affords substituted hexahydropyrrolo[3,2-*c*]quinolines in good to excellent yields.

Multi-component coupling reactions are of growing interest in synthetic organic chemistry, because of their applications in combinatorial chemistry.[1] Those reactions that provide access to novel heterocyclic structures are particularly useful, because of the importance of heterocycles as scaffolds in pharmaceutical development. However, there are relatively few examples of such reactions, and a need exists to expand the repertoire of multi-component coupling methods leading to heterocycles. Accordingly, we now report a versatile one-pot synthesis of substituted hexahydropyrrolo[3,2-*c*]quinolines utilizing a Lewis acid promoted three component coupling reaction.[2]

We have become interested in hexahydropyrrolo[3,2-*c*]quinolines because of the recent isolation of the alkaloids martinelline **1** and martinellic acid **2** from the roots of the



Amazonian plant *Martinella iquitosensis*.[3] These compounds are the first natural products containing a hexahydropyrrolo[3,2-*c*]quinoline core structure. Tetrahydroquinolines and 4-aminoquinolines, of which **1** is an example, are found in a number of pharmaceutically active compounds.[4] Indeed, martinelline has antibiotic activity, affinity for several G-protein coupled receptors, and was the first example of a naturally occurring non-peptidic bradykinin receptor antagonist.[3,5] The core structure is thus of pharmaceutical interest, with the potential for functionalization of the rigid heterocyclic scaffold and/or the two differentiated amine groups.

Although there are several reports of the synthesis of pyrrolo[3,2-*c*]quinolines, these usually require a number of steps, proceed in modest yields, and do not give compounds at the same oxidation state as **1**.[6] We envisaged a highly convergent route, involving a three-component coupling reaction of anilines **3**, benzaldehydes **4**, and the *N*-substituted 2-pyrroline **5**, for the synthesis of differentially substituted analogs **6** (Scheme 1). The *in situ* formed imine generated upon condensation of **3** and **4** can act as a diene, in a formal hetero-Diels–Alder reaction with the electron-rich dienophile **5**.[7] This approach is analogous to the formation of 4-alkoxytetrahydroquinolines, such as the $BF_3{\cdot}OEt_2$ and $EtAlCl_2$ promoted reaction of 2,3-dihydrofuran and the imine formed between aniline and benzaldehyde.[8] Recent findings by Kobayashi have shown that lanthanide triflates[9] will similarly catalyze the reaction of cyclopentadiene or dihydrofuran with *in situ* formed imines derived from anilines and aldehydes.[10]

Endocyclic enamine derivatives such as **5**[11] have not previously been employed in these reactions, and we were delighted to find that lanthanide triflates catalyze their addition (Table 1). Treatment of PhCHO (1.4 equiv.), $PhNH_2$ (1.4 equiv.) and **5** with $Dy(OTf)_3$ (0.07 equiv.) afforded **6a**‡ in 91% yield as an approximately 1 : 1 mixture of readily separable *endo* and *exo* diastereomers, where H3a and H4 have a *cis* and *trans* relationship respectively.[12] The reaction is remarkably facile, and because of the air and water stability of the catalyst, the reaction requires no special precautions. There is little effect on the choice of lanthanide triflate catalyst on the outcome of the reaction, although $Dy(OTf)_3$ gives marginally better yields. Deprotection of the BnO_2C group in the adducts is readily achieved by hydrogenolysis with Pearlman's catalyst. For example, deprotection of the *endo* and *exo* diastereomers of **6a** occurs in 87 and 98% yield, respectively.

The mechanism for the three component coupling reaction presumably involves complexation of the *in situ* formed imine by the lanthanide triflate catalyst, promoting stepwise nucleophilic addition of the electron-rich 2-pyrroline **5** (*i.e.* formation of the C3a–C4 bond), followed by electrophilic aromatic substitution of the aniline ring by the incipient *N*-acyl iminium ion intermediate (*i.e.* formation of the C9a–C9b bond). The initial addition step thus controls the diastereoselectivity of the reaction. The diastereoselectivity is strongly solvent dependent (Table 2). Although there is relatively little effect using dry solvents, a significant change in diastereoselectivity in favor of the *endo* product was observed using water as a co-solvent (entries 6–8, Table 2). The use of THF–water (4 : 1) as solvent results in an enhancement of the de to 92%, but occurs in lower yields (entry 8, Table 2). The origin of the enhanced diastereoselectivity is unclear, but the hydrophobic effect[13] would presumably favor the more compact transition state leading to the *endo* products.

Interestingly, we have found that in the absence of an aldehyde, anilines **3** will couple with *two equivalents* of endocyclic enamines such as **5**. For example, treatment of methyl 4-aminobenzoate with **5** gave **7** in excellent yield as mainly the *endo* diastereomer (Scheme 2).[14] Deprotection of **7** proceeded smoothly with Pearlman's catalyst to yield the free amine **8** in 88% yield as an 85 : 15 mixture of diastereomers in favour of the *endo* product (Scheme 2). The formation of **7** is the first example of a coupling of this type, and presumably occurs *via* the imine formed on condensation of the aniline with the *in situ* hydrolysis product of **5**. This imine may also form directly

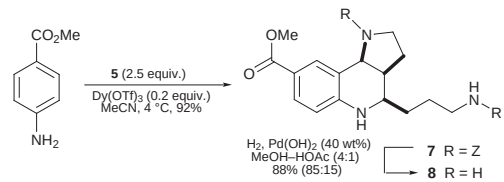

Scheme 2

via addition of aniline to protonated **5**, followed by ring-opening. The structural similarities of **7** with **1** may indicate an analogous process occurs in the biosynthesis of martinelline.

In summary, a convergent method for the synthesis of hexahydropyrrolo[3,2-*c*]quinolines has been established, using a lanthanide triflate catalysed three-component coupling reaction. Further studies towards control of the diastereoselectivity of this process for the synthesis of **1**, and other multi-component coupling reactions of endocyclic enamine derivatives, will be reported in due course.

Notes and references

‡ The synthesis of **6a** is representative. To a solution of $Dy(OTf)_3$ (32 mg, 0.05 mmol) in MeCN (2.0 ml) at 4 °C was added PhCHO (100 µl, 0.98 mmol) and $PhNH_2$ (89 µl, 0.98 mmol) in MeCN (1.0 ml) *via* cannula. After stirring for 5 min, a solution of **5** (108 mg, 0.705 mmol) in MeCN (1.0 ml) was added *via* cannula. The reaction was stirred under N_2 for 16 h at 4 °C. The reaction was quenched with H_2O and extracted with CH_2Cl_2 (3 × 30 ml). The combined organic extracts were washed with brine, dried, concentrated *in vacuo* and filtered through a plug of silica gel. The crude products were purified *via* flash chromatography (silica gel, EtOAc–hexanes, CH_2Cl_2 or CH_2Cl_2–MeOH) to yield the two separable diastereomers. Ratios of diastereomers were determied *via* ^{1}H NMR analysis of the crude mixtures.

New chemoenzymatic approach to glyco-lipopolymers: practical preparation of functionally active galactose–poly(ethylene glycol)–distearoylphosphatidic acid (Gal–PEG–DSPA) conjugate

Samuel Zalipsky,* Nasreen Mullah, Andrew Dibble and Terrence Flaherty

SEQUUS Pharmaceuticals, Inc., 960 Hamilton Court, Menlo Park, CA94025, USA. E-mail: samuelz@sequus.com

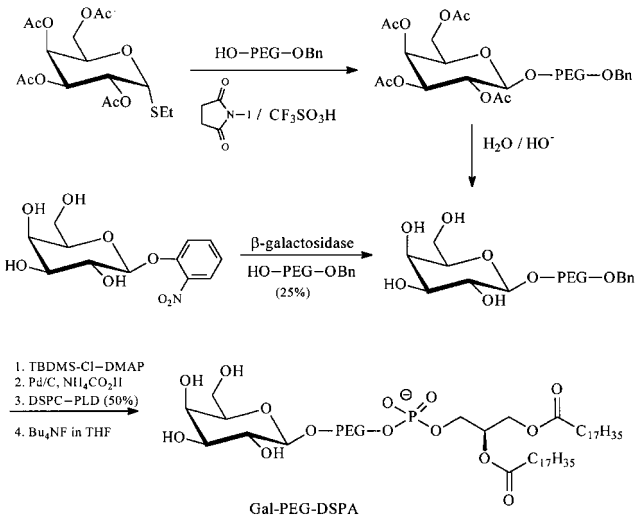
Received (in Corvallis, OR, USA) 11th January 1999, Accepted 24th January 1999

A practical approach to galactose–PEG–distearoylphosphatidic acid (DSPA) retaining full lectin binding, involves glycosylation of monobenzyl ether–PEG, suitable protection of the sugar hydroxy groups, debenzylation, followed by enzymatic transphosphatidylation with phosphatidylcholine and final deprotection.

The ability of poly(ethylene glycol) (PEG) conjugates of lipids, usually phosphatidylethanolamine (PE),[1] to increase systemic circulation and concomitantly decrease uptake of micelles or liposomes by the reticuloendothelial system is well recognized and routinely used. To combine this useful property with a ligand specific targeting, we and others introduced a series of ligand–PEG–lipid conjugates and their liposomes.[2] Among the ligands used in this capacity are antibodies, and fragments thereof, peptides, vitamins, and carbohydrates. The latter group of ligands is particularly promising. These are small and very polar molecules of low immunogenicity. There are a host of useful carbohydrate–receptor interactions suitable for utilization in PEG-grafted liposomes.[3] These ligands, even when individually of only weak binding affinity, maximize the targeting ability through a multivalent array presentation on the surface of a liposome. Saccharide–PEG–lipid conjugates are rather challenging synthetic targets. There are only a few examples of their preparation.[4–6] Here we describe a new chemoenzymatic approach to these constructs. The method is exemplified by the preparation of galactose–PEG–DSPA, which in its liposomal formulation exhibits substantial lectin-binding activity. This conjugate is potentially suitable for targeting liposomes to the asialoglycoprotein receptors expressed on liver hepatocytes.[7]

The synthetic pathways employed in this study are summarized in Scheme 1. Initially we explored preparation of PEG-yl–β-D-galactopyranoside (Gal–PEG). Enzymatic galactosylation of monobenzyl ether PEG (BnO–PEG–OH)[8] of molecular weight 2000 Da utilizing β-galactosidase proceeded well under modified conditions described by Matsushima *et al.*[9] resulting in formation of β-Gal*p*–O–PEG–OBn in 25% isolated yield. We also explored a two step chemical approach to the same product utilizing first iodonium ion promoted thioglycoside-mediated attachment of the peracetylated Gal*p* moiety,[10] followed by deacetylation. Although longer, this approach yielded galactosylated PEG derivatives in essentially quantitative yield. β-Glycosides were exclusively formed from both the enzymatic and chemical methods (Fig. 1a).

Recently we developed a new method for the preparation of phosphatidyl–PEG by an enzymatic process utilizing phospholipase D and distearoyl phosphatidylcholine.[11] To apply this reaction to Gal–O–PEG–OBn, the benzyl group had to be removed and the primary hydroxy group at C-6 of the galactose moiety had to be suitably protected.[12] Silylation with excess of TBDMS-Cl in presence of the DMAP provided the desired monoprotected saccharide along with several oversilylated products. Oversilylation had no bearing on the final outcome of the synthesis. Removal of the benzyl ether from the other terminal of the PEG chain proceeded quantitatively under catalytic transfer hydrogenation conditions with Pd/C and ammonium formate in MeOH.[13] Enzymatic elaboration of the distearoylphosphatidyl moiety proceeded smoothly in CCl_4–acetate buffer, pH 5.6, in 50% yield, and finally silyl groups



Scheme 1 Reaction pathways used in this study. Yields of the transformations shown were quantitative unless indicated in parentheses (PEG ≡ –(CH_2CH_2O)$_{44}$–CH_2CH_2–).

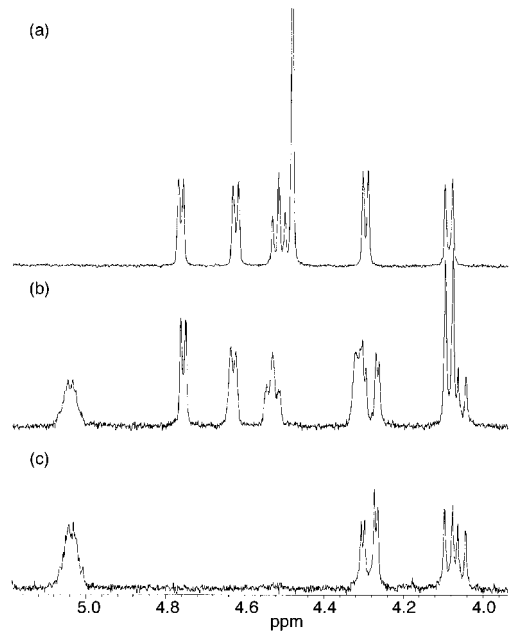


Fig. 1 ^{1}H-NMR (360 MHz, d_6-DMSO) spectra of (a) Gal–PEG–OBn, (b) Gal–PEG–DSPA, and (c) MeO–PEG–DSPA. Only the region 3.8–6 ppm containing the characteristic signals of the sugar and glycerophospho moieties is shown. Characteristic peaks of stearoyl (t 0.84, s 1.24, m 1.50, m 2.24 ppm in b and c only) and PEG (s 3.5 ppm) residues were present.

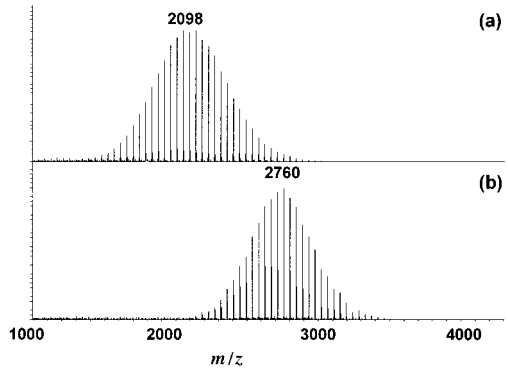

Fig. 2 MALDI-TOFMS of (a) Gal–PEG–OBn and (b) Gal–PEG–DSPA. Spectra were acquired on a PHI-EVANS MALDI triple electrostatic TOFMS analyzer using a 337 nm (600 ps pulse width) desorption laser, and gentisic acid as the matrix material.

were cleanly removed by fluoridolysis to provide Gal–PEG–DSPA. Fig. 1 illustrates the ^{1}H-NMR spectra of β-Gal*p*–O–PEG–OBn (a), β-Gal*p*–O-PEG–DSPA (b), and for comparison MeO–PEG–DSPA (c). The presence of a H-1 signal (d, 4.08 ppm, $J_{1,2}$ = 7.2 Hz) of the β-linked Gal residue as well as an additional primary and three secondary hydroxy groups is clearly seen. The final product also produced the characteristic signals of a glycerophospholipid moiety (dd at 4.1 and 4.3 ppm, as well as m at 5.1 ppm), the first two signals overlapping with the anomeric hydrogen and another secondary OH peak. Further corroboration of the structure of the glycosylated conjugates was obtained by matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) (Fig. 2). Single-modal distributions of signals equally spaced at 44 Da intervals of the ethylene oxide repeating unit of PEG are clearly visible. Average molecular weights of the galactosylated PEG derivatives were in accordance with the expected values.

To ascertain the functional activity of Gal–PEG–DSPA, the conjugate was incorporated at 0, 1, and 5 mol% into egg-phosphatidylcholine large unilamellar vesicles. Interaction of the liposomes with *Ricinus communis* lectin (RCA-I) was monitored turbidometrically as illustrated in Fig. 3. It was observed that the lectin caused agglutination of the liposomes, which was more intense with a higher content of Gal–PEG–DSPA. The agglutination process could be inhibited by Gal–PEG–OBn; however, a 10-fold excess over liposome-bound Gal was required to achieve 50% inhibition. Complete inhibition was observed at 25-fold excess of the competitor. Similar experiments with lactose acting as a competitor showed that it was approximately 5-fold more effective at inhibiting agglutination than Gal–PEG–OBn (data not shown). Thus the multivalent liposome was binding more avidly than either one of the two monovalent competitors. It is interesting that the presence of MeO–PEG_{2000}–DSPA conjugate in the same lipid vesicles greatly inhibited agglutination. We previously observed a similar inhibitory effect on the binding of folate–PEG–liposomes to folate receptor-bearing cells.[14] It is pertinent to note that our findings do not support observations of Shimada *et al.*[5] They prepared Gal–PEG–lipids containing acyl glycosidic linkages and PEG tethers of different lengths, and reported that only liposomal preparations of the conjugates with decaethylene oxide spacer, and no longer, were agglutinated with RCA lectin.

We developed a practical method for the preparation of glyco-lipopolymers of the type Gal–PEG–DSPA. Lectin binding activity of the galactopyranoside moiety was well preserved, although it was inhibited if substantial amounts of MeO-PEG-lipid was included in the same liposomes. Monovalent

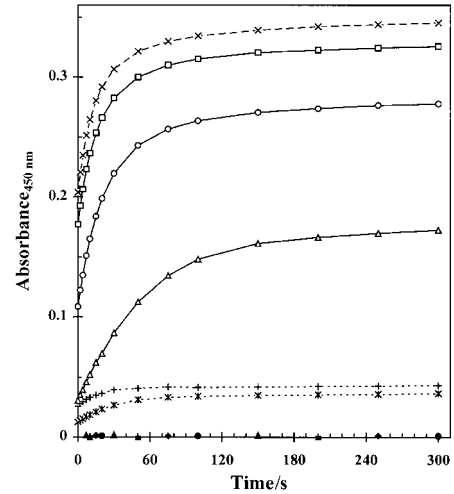

Fig. 3 Turbidometric measurements of RCA-I (50 μg ml^{-1}) mediated agglutination of Gal–PEG–DSPA containing liposomes (0.5 mM total lipid; 120–130 nm mean particle size). Liposomes containing 5 mol% Gal–PEG–DSPA (×), 5 mol% Gal–PEG–DSPA and 5 mol% MeO-PEG-DSPA (+), 1 mol% Gal–PEG–DSPA (✻), 1 mol% Gal–PEG–DSPA and 5 mol% MeO–PEG–DSPA (▲), without any PEG-lipids (●), 5 mol% MeO–PEG–DSPA (◆). Agglutination of liposomes containing 5 mol% Gal–PEG–DSPA in presence of Gal–PEG–OBn at 25 (□), 125 (○), 250 (△) and 625 μM (■).

Gal–PEG was more than one order of magnitude weaker at binding to the lectin than liposomal Gal–PEG–DSPA, suggesting that multivalent presentation of the carbohydrate moiety results in more effective binding.

Efficient thermochemical alkane dehydrogenation and isomerization catalyzed by an iridium pincer complex

Fuchen Liu and Alan S. Goldman*

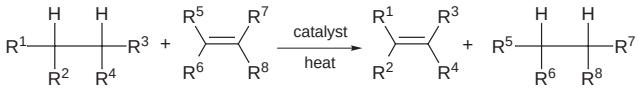
Received (in Bloomington, IN, USA) 22nd January 1999, Accepted 9th February 1999

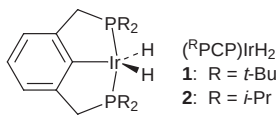
(i-^{Pr}PCP)IrH$_2$ is found to be a remarkably effective solution-phase catalyst for the 'acceptorless' thermochemical dehydrogenation of cycloalkanes (and isomerization in the case of cyclodecane), and the first such catalyst reported to effect the dehydrogenation of *n*-alkanes.

Alkanes are the world's most abundant organic resource, yet methods for their conversion to useful chemicals remain extremely limited. Alkenes, by contrast, are probably the single most useful and versatile class of feedstock for commodity-scale organic chemical syntheses. Methods for the dehydrogenation of alkanes to give alkenes are therefore of great interest.[1]

In general, the yields and selectivity afforded by heterogeneous alkane dehydrogenation catalysts are very low.[1] Soluble transition metal complexes, however, have held promise in this respect since the early 1980s when Crabtree and Felkin reported the development of catalysts for transfer-dehydrogenation.[2]

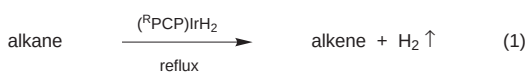


The initially reported catalysts suffered from ligand degradation which severely limited turnover numbers; systems were later developed that afforded much higher turnover numbers;[3] of these, the most important in the context of the present work was the 'pincer' complex, ($^{t\text{-Bu}}$PCP)IrH$_2$ [**1**; $^{t\text{-Bu}}$PCP = 2,5-C$_6$H$_3$(CH$_2$PBu$^t_2$]].[4]



(^{R}PCP)IrH$_2$
1: R = *t*-Bu
2: R = *i*-Pr

Recently [eqn. (1)] it was reported that refluxing alkane solutions of **1** resulted in dehydrogenation with evolution of dihydrogen; no sacrificial hydrogen acceptor was required.[5] Although this was by far the most efficient catalyst to date for such 'acceptorless' dehydrogenation,[6,7] the observed rates were still fairly low by the standards of practical catalytic systems.



To a significant extent, the pincer geometry 'holds back' the phosphinoalkyl groups such that they are further removed from the metal, and the molecule is sterically less congested, relative to a hypothetical analogous complex of monodentate ligands [*e.g.* Ir(PR$_2$Me)$_2$(Ph)H$_2$]. Nevertheless, Milstein and coworkers recently reported that H_2 adds to the carbonyl complex ($^{i\text{-Pr}}$PCP)Ir(CO)[8] whereas, in contrast, we find that the $^{t\text{-Bu}}$PCP analog undergoes no observable addition of H_2 (800 Torr). Thus in spite of the 'pincer effect' the *tert*-butyl groups are apparently still bulky enough to inhibit H_2 addition; this led us to suspect that alkyl hydrides and other presumed intermediates of a dehydrogenation cycle may be even more sterically disfavored by the *tert*-butyl groups. Accordingly we synthesized† and investigated the $^{i\text{-Pr}}$PCP analog of **1**, *i.e.* ($^{i\text{-Pr}}$PCP)IrH$_2$ (**2**).

Vigorously refluxing (151 °C) a cyclooctane solution of **2** (1.0 mM) leads to the formation of 47 mM cyclooctene (47 turnovers) after 30 min. The reaction rate subsequently levelled off; 105 mM cyclooctene was present after 15 h. This initial dehydrogenation rate (>94 turnover h^{-1}) may be compared with 11 turnover h^{-1} resulting from cyclooctane dehydrogenation catalyzed by **1** under similar conditions,[5] and 1.41 turnover h^{-1} reported for IrH$_2$(O$_2$CCF$_3$)(PCy$_3$)$_2$.[7]

Cyclodecane, with a reflux temperature of 201 °C, undergoes dehydrogenation at a much greater rate than cyclooctane: for example *460 turnovers cyclodecene* are obtained after 1 h of reflux, (*cis*:*trans* ratio of 4.6:1; see Table 1). This compares, for example, with 170 turnover after 4 h obtained from the use of catalyst **1**.[5] The isopropyl derivative **2** is thus an extremely efficient catalyst for acceptorless dehydrogenation of cycloalkanes, yielding turnover rates a full order of magnitude greater than the *tert*-butyl derivative.

The dehydrogenation enthalpy of cyclooctane, and probably that of cyclodecane as well, is anomalously low.[9–12]‡ Accordingly, with *n*-alkanes, the $^{t\text{-Bu}}$PCP catalyst **1** gave no observable yields of acceptorless dehydrogenation product.§ By contrast, **2** is able to catalyze the acceptorless dehydrogenation of *n*-alkanes, though the efficiency is less than that with cyclodecane. Refluxing an *n*-undecane solution of **2** (1.0 mM; 196 °C) yields 35.4 mM undecenes, as a mixture of internal isomers (not fully characterized), after 0.5 h. Unfortunately, the yield quickly levelled off and after 1 and 45 h the respective concentrations of undecenes were 42.3 and 44.1 mM. This represents the first report of a homogenous catalytic system for the dehydrogenation of *n*-alkanes.

To determine whether product concentrations level off due to catalyst decomposition or product inhibition, we allowed an *n*-decane solution of **2** to reflux (174 °C) until the decene concentration reached a constant value.§ Volatiles (decenes and decane) were then removed and fresh *n*-decane was added; upon refluxing, the kinetics of decene production were identical to those of the initial run indicating that the catalyst did not decompose. This result is similar to that obtained previously for **1**-catalyzed dehydrogenation of cyclooctane.[5] In the case of *n*-alkanes, however, the removal of product, if sufficiently rapid, could have an additional and very significant benefit. When *n*-alkane dehydrogenation is conducted (at 150 °C) using *a*

Table 1. Dehydrogenation and isomerization of cyclodecane catalyzed by **2**[a]

t/h	*cis*-Cyclodecene	*trans*-Cyclodecene	*cis*-DEC[b]	*trans*-DEC
1	378	82	16	10
4	619	145	38	59
8	692	163	42	79
20	700	163	43	81

[a] Refluxing cyclodecane; 1.0 mM **2**; values are turnover numbers (equal to concentration/mM). [b] DEC = diethylcyclohexane.

sacrificial acceptor, the major kinetic product is the terminal (α) olefin which then undergoes isomerization to the more stable internal olefins.[13] Presumably the same kinetic product is formed in the absence of an acceptor but isomerization is much more rapid relative to dehydrogenation; accordingly, added dec-1-ene is rapidly isomerized (> 99% in 2.5 min) in refluxing *n*–undecane. Thus, efficient dynamic removal of product from the mixture might lead not only to high turnover numbers, but also to high regioselectivity for α-olefins in the case of *n*-alkanes.

Returning to the **2**-catalyzed dehydrogenation of cyclodecane, two intriguing products other than *cis*- and *trans*-cyclodecene are observed to accumulate in significant concentration (by GC and GC–MS); GC–MS and ^{1}H NMR data indicate them to be diethylcyclohexanes (DEC). When *cis*- and *trans*-1,2-DEC were independently generated by the hydrogenation of 1,2-diethylbenzene; ^{1}H NMR, GC and GC–MS data were in complete agreement with those of the cyclodecane reaction products.

The unprecedented isomerization of cyclodecane to *cis*- and *trans*-1,2-DEC might seem to suggest the involvement of a cyclodecane C–C bond activation step. It is difficult, however, to envisage such a mechanism that would account for the selectivity of this ring-contraction. Furthermore, the formation of DEC's appeared to be a secondary reaction since the ratio of the DEC's to cyclodecenes significantly increased with time (Table 1). This leads us to propose, for the overall isomerization reaction, the mechanism of Scheme 1 which receives strong additional support from the following observations:

(i) A mixture of **2** (1.0 mM) and cyclodecene (200 mM) in *n*-undecane solvent was refluxed (196 °C). After 30 min, 4.2 mM diethylcyclohexane had appeared (*ca*. 2 : 1 *trans* : *cis*);¶ in addition, *ca*. 50% of the cyclodecene had been transfer-hydrogenated to cyclodecane (with commensurate formation of undecenes), while 98 mM cyclodecene remained. This rate of DEC formation (8.4 turnover h^{-1}; 149 mM time-averaged concentration of cyclodecene) is proportional to the time-averaged concentration of cyclodecene present in the reactions that began with cyclodecane only; *i.e.* this result is entirely consistent with the DEC being derived from cyclodecene (not directly from cyclodecane).

(ii) *trans*,*trans*-1,5-cyclodecadiene has been reported to undergo a thermal Cope rearrangement to give *trans*-1,2-divinylcyclohexane.[14]‖ Extrapolating the rate data to 201 °C gives a rate of 1.2 s^{-1},[14]** which is clearly consistent with Scheme 1 and the lack of build-up of observable quantities of the cyclodiene. Presumably, cyclodecadienes other than the 1,5-isomers are initially formed and these undergo isomerization to the 1,5-diene which then undergoes rearrangement.

(iii) Since divinylcyclohexane is not formed in an observable quantity, the mechanism of Scheme 1 requires that this intermediate is rapidly hydrogenated under the reaction conditions. Accordingly, when a cyclodecane solution of **2** (1.0 mM) and added vinylcyclohexane (100 mM) was refluxed, after only 10 min 100% conversion to ethylcyclohexane was observed.

In summary, we describe the first homogeneous catalyst system to dehydrogenate alkanes at rates that might be considered suitable for a practical and useful system. It would appear that efficient removal of the olefin product, by either physical or chemical means, might lead to dramatically increased yields and even regioselectivity. The formation of DEC represents a novel example of catalytic alkane functionalization proceeding *via* dehydrogenation and a secondary olefin reaction.

Support by the Division of Chemical Sciences, BES, OER, US Department of Energy is gratefully acknowledged. We thank Johnson-Matthey for a generous loan of iridium.

Notes and references

† The protonated $^{i\text{-Pr}}$PCP ligand was synthesized according to Milstein[8] and reacted with [Ir(cyclooctene)$_2$Cl] in refluxing toluene for 3 days. The resulting ($^{i\text{-Pr}}$PCP)IrHCl was isolated and converted to ($^{i\text{-Pr}}$PCP)IrH$_2$ using the procedure previously reported for ($^{t\text{-Bu}}$PCP)IrH$_2$.[4]

‡ The dehydrogenation enthalpy of cyclooctane is *ca.* 23.8(5) kcal mol^{-1} as determined by either direct measurement of hydrogenation or on the basis of enthalpies of formation.[9,10] The value for cyclodecane is less certain. Based on available data for enthalpies of formation it would appear to be rather high, at least 30 and 33 kcal mol^{-1} for formation of *cis*- and *trans*-cyclodecene respectively.[9–11] However, direct hydrogenation measurements yield values of −20.7(1) and −24.0(9) kcal mol^{-1}, respectively, in acetic acid solvent.[12] Enthalpies of other cycloalkene hydrogenations in acetic acid, determined by the same workers, are *ca*. 1.3 kcal mol^{-1} less negative than reliable values in hydrocarbon solvent.[9,12] Thus, 22 and 25 kcal mol^{-1} are probably the best estimates for the dehydrogenation of cyclodecane to give *cis*- and *trans*-cyclodecene respectively.

§ An attempt to dehydrogenate *n*-decane using catalyst **1** gave no detectable decene. It is difficult to set an upper limit on the amount of decene produced since as many as eight major isomers could be formed. Nevertheless, the reaction of *n*-decane catalyzed by **2**, unlike that of **1**, gave very easily detectable decene GC peaks indicating total concentrations of 14.4 and 16.1 mM after 0.5 and 5 h respectively.

¶ Both our dehydrogenations and our independent synthesis gave mixtures of the two DEC's; we are unable to assign their respective stereochemistry with high confidence. However, the ratio changes with time during the cyclodecane dehydrogenation and we tentatively assign the product that relatively increases in concentration as the more stable *trans*-DEC.

‖ The product of the uncatalyzed reaction of 1,5-*trans*,*trans*-cyclodecadiene is exclusively the *trans*-DEC isomer in contrast with our observation of a mixture of *trans* and *cis*. However, MOPAC calculations indicate that the 1,5-*cis*,*trans*-cyclodecadiene is the more stable diene; molecular modeling suggests that this isomer would yield *cis*-1,2-diethylcyclohexane. Furthermore, Cope rearrangements can be metal-catalyzed which might represent another pathway leading to the *cis* isomer.

** The measured rates (40–90 °C) give the following activation parameters: $\Delta H^{\ddagger}$ = 24.32 kcal mol^{-1}; $\Delta S^{\ddagger}$ = −7.81 cal mol^{-1} K^{-1}.[14]

Investigation of restricted backbone conformations as an explanation for the exceptional thermal stabilities of duplexes involving LNA (Locked Nucleic Acid):† synthesis and evaluation of abasic LNA

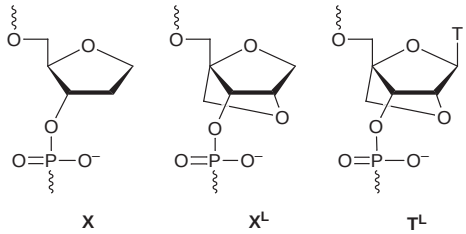
Lisbet Kværnø and Jesper Wengel*

Center for Synthetic Bioorganic Chemistry, Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark. E-mail: wengel@kiku.dk

Received (in Cambridge, UK) 18th January 1999, Accepted 25th January 1999

In order to investigate the structural basis of the unique hybridization properties of LNA (Locked Nucleic Acid), an abasic LNA monomer (a 1-deoxy-2-*O*,4-*C*-methylene-D-ribofuranose derivative) was synthesized and evaluated with respect to influence on duplex stability, showing that effects mediated *via* the nucleobase are pivotal for the properties of LNA.

In recent years much attention in the search for effective antisense oligonucleotides has been focused on the synthesis of conformationally restricted analogues, stimulated by the promise of entropically advantageous duplex formation.[1,2] So far,



X **X^{L}** **T^{L}**

LNA (Locked Nucleic Acid, thymine monomer **T^{L}**) is showing the most promising properties,[3–7,†] *e.g.* unprecedented thermal stabilities towards complementary DNA and RNA (ΔT_m/modification = +3 to +9 °C), stability towards 3′-exonucleolytic degradation, efficient automated oligomerization and good aqueous solubility. As an attempt to investigate the structural elements of LNA responsible for the remarkably enhanced duplex stabilities we have synthesized and evaluated the hydridization properties of oligonucleotides containing the novel abasic LNA monomer **X^{L}** in comparison with unmodified reference sequences, sequences containing the abasic DNA monomer **X**, and sequences containing thymine LNA monomer **T^{L}**.

The 4-*C*-hydroxymethylfuranose **1** was converted in two steps to the anomeric methyl furanosides **2** (Scheme 1).[8] As previously reported, treatment of **2** with NaH induced cyclization to give furanosides **3** which after hydrolysis afforded the monocyclic aldehyde.[8] Reduction of this aldehyde with $NaBH_4$ proceeded smoothly to give the novel diol **4** in 84% yield (from **2**). Selective tosylation of the primary hydroxy group followed by treatment with NaH afforded the bicyclic skeleton of abasic LNA whereafter hydrogenolysis to give diol **5**,‡ dimethoxytritylation and phosphitylation yielded the phosphoramidite building block **6** suitable for oligonucleotide synthesis. Except for prolonged coupling times (8 min compared with standard 1 min), normal coupling conditions were used for amidite **6** on an automated DNA synthesizer. The stepwise coupling yield was approximately 99% as was also obtained for both the unmodified DNA and RNA phosphoramidites as well as for the commercially available amidite leading to the abasic DNA monomer **X**.

In nucleic acids the conformation of the furanose ring is decisive for the type of duplex formed. The pentofuranose moieties in RNA normally exist in an N-type conformation leading to A-type duplexes, while an S-type conformation as generally seen in DNA leads to B-type duplexes. Also the dihedral phosphate backbone angle C4′–C3′–O3′–P (denoted ε^{t} and ε^{-} for *trans* and *gauche*, respectively[9]) and the furanose conformation have been shown to be interdependent for monomeric nucleotides or single stranded oligonucleotides.[9–12] Thus, for dinucleotides an N-type conformation strongly favours the ε^{t} dihedral angle while a mixture of ε^{t} and ε^{-} is seen for S-type conformations.[9] Studies of ethyl phosphate mononucleotides which mimic dinucleotides with total elimination of base–base stacking interactions likewise show an interdependency between the N/S and $\varepsilon^{t}/\varepsilon^{-}$ equilibria for ethyl ribonucleotides while these two equilibria seem to be independent for ethyl 2′-deoxyribonucleotides.[10–12] The rigid structure of an LNA monomer which restricts the furanose ring to the N-type conformation[3,4,13] is therefore expected to influence the local phosphate backbone fluctuations by quenching the $\varepsilon^{t}/\varepsilon^{-}$ equilibrium.

The question under investigation here is whether the abasic LNA monomer **X^{L}**, which is anticipated to display the same fixed furanose and restricted backbone conformations as the parent LNA monomers (*e.g.* monomer **T^{L}**) but with the exclusion of base–base stacking interactions, induces an increased duplex stability relative to the abasic DNA monomer **X** comparable to the one obtained for the parent LNA monomers relative to the DNA monomers. In this respect, the modified 9- and 13-mer oligodeoxyribonucleotides and oligo-

15		**X**^{L}	29

[a] T_m values measured as the maximum of the first derivative of the melting curve (A_{260} *vs.* temperature) recorded in medium salt buffer (10 mM $NaHPO_4$, 100 mM NaCl, 0.1 mM EDTA, pH 7.0) using 1.5 mM concentrations of the two complementary strands (assuming identical extinction coefficients for T and **T**^{L} and for the different monomeric nucleotides whether present in LNA, the unmodified references or the strands containing an abasic monomer). A = adenosine monomer, C = cytidine monomer, G = guanosine monomer, U = uridine monomer, T = thymidine monomer, **X** = abasic DNA monomer, **X**^{L} = abasic LNA monomer, **T**^{L} = LNA thymine monomer. Oligo-2′-deoxynucleotide sequences are depicted as d(sequence) and oligoribonucleotide sequences as r(sequence). [b] No T_m detected.

ribonucleotides depicted in Table 1 were synthesized§ and their hybridization to fully complementary oligodeoxyribonucleotide sequences [5′-d(GCATATCAC) and 5′-d(TCGCATATCACTG)] was studied. For each oligonucleotide sequence, the melting temperature (T_m value) for the unmodified reference was compared with the T_m values for the analogues containing either one LNA thymine monomer (**T**^{L}), one abasic DNA monomer (**X**) or one abasic LNA monomer (**X**^{L}). The effect of a single LNA monomer on the thermal stability, which hitherto has not been reported, is profound, with ΔT_m values of +8 and +5 °C for deoxy-LNA† (entries 2 and 9, **T**^{L} compared to a thymidine monomer) and +11 and +7 °C for ribo-LNA† (entries 6 and 13, **T**^{L} compared to a uridine monomer¶). In analogy with previously reported data,[14] we observed a detrimental effect of the abasic DNA monomer **X** on the thermal stability (entries 3, 10 and 14, ΔT_m values < -17 °C). The T_m values obtained for the abasic LNA monomer **X**^{L} (entries 4, 7, 11 and 15) were identical to those obtained for **X**. Thus, despite the very large stabilizing effect induced by incorporation of one LNA monomer **T**^{L} instead of a thymidine monomer, no effect resulted from the exchange of the abasic DNA monomer **X** with the abasic LNA monomer **X**^{L}.

NMR investigations[13] on single stranded LNA and LNA:DNA duplexes have shown that LNA monomers induce a shift towars an N-type conformation in neighboring unmodified monomers. Quenched backbone torsions and/or improved nucleobase stacking are possible explanations for this conformational effect. Since the structural difference for both pairs examined herein (**T**^{L} *vs.* T and **X**^{L} *vs.* **X**) is an oxymethylene bridge linking the 2(′)- and the 4(′)-carbon atoms the thermal denaturation studies have shown that conformational restrictions of the pentofuranose and backbone alone are not sufficient to induce an effect. We therefore conclude that the nucleobase is essential as a mediator of the conformational changes.

The Danish Natural Science Research Council, The Danish Technical Research Council and Exiqon A/S are thanked for financial support. Ms Britta M. Dahl is thanked for oligonucleotide synthesis and Dr Carl Erik Olsen is thanked for recording MALDI mass spectra.

Notes and references

† We have defined LNA as an oligonucleotide containing one or more 2′-*O*,4′-*C* methylene linked bicyclic ribonucleoside LNA monomers. Deoxy-LNA consists of 2′-deoxynucleotide and LNA monomers, while ribo-LNA consists of ribonucleotide and LNA monomers (see ref. 3–5).

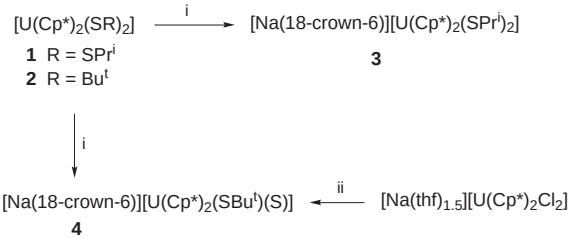
Received (in Cambridge, UK) 18th January 1999, Accepted 5th March 1999

The C–S bond cleavage of a thiolate ligand of [U(Cp*)$_2$(SBu^t)$_2$] was induced by treatment with Na(Hg) and the title compound was isolated after addition of 18-crown-6; the crystal structure exhibited the unsupported U–S–Na linkage of the molecular complex, with a U–S bond distance of 2.462(2) Å.

In the course of our studies of uranium complexes with sulfur ligands, we were interested in preparing a molecular compound with a U=S double bond. Such a sulfide of a f-element has not been described so far, whereas transition metal sulfides have received much attention in recent years because of their rich coordination chemistry and their relevance in bioinorganic systems and industrial catalytic processes.[1] A classical route to early transition metal sulfide groups is C–S bond cleavage of coordinated aliphatic thiolate ligands; this reaction is in fact a relatively common decomposition pathway for *tert*-butyl thiolate complexes.[2–5] However, the propensity of sulfides to bridge metal atoms is a serious obstacle in the synthesis of complexes containing M=S multiple bonds,[2,3] and the current formation of clusters has to be avoided by the presence of sterically demanding ligands, as recently demonstrated with pentamethylcyclopentadienyl derivatives of group IV and V metals.[4,5] From these considerations, we decided to examine thiolate C–S bond cleavage in the complexes [U(Cp*)$_2$(SR)$_2$] (R = Pr^i, **1** and Bu^t, **2**). Here we present the synthesis and X-ray crystal structure of [Na(18-crown-6)][U(Cp*)$_2$(SBu^t)(S)] **4**, isolated from the reduction of **2**; the results provide new information about the influence of the metal oxidation state on the cleavage of the thiolate C–S bond.

The uranium(IV) bisthiolate compounds **1** and **2** were simply synthesized by treating [U(Cp*)$_2$Cl$_2$] with a slight excess of NaSR in thf and were isolated as dark red microcrystals in 79 and 85% yield respectively.[6] Compounds **1** and **2** were quite stable in thf or benzene solution and in the solid state. Reduction of **1** (211 mg) with 2% Na(Hg) (369 mg) in the presence of 18-crown-6 (85.5 mg) in thf (100 ml) led to the formation of [Na(18-crown-6)][U(Cp*)$_2$(SPr^i)$_2$] **3** (Scheme 1); the reaction mixture was stirred for 24 h at 20 °C and after filtration and evaporation, the green microcrystals of **3** were washed with pentane and dried under vacuum (243 mg, 80%). The ^{1}H NMR signals of **3** are broader (30–50 Hz) than those of **1** (10–20 Hz) and are characteristic of a U(III) compound. After the triscyclopentadienyl derivative Na[U(Cp)$_3$(SR)],[7] **3** is a new example of a uranium(III) thiolate.



Scheme 1 *Reagents and conditions*: i, Na(Hg), 18-crown-6; ii, NaSBu^t,18-crown-6. All reactions in thf at 20 °C.

Treatment of **2** with sodium amalgam did not afford the corresponding U(III) anionic complex but readily gave a new product which contained, from the NMR spectrum, two Cp* ligands for only one SBu^t group; the narrow resonances indicated that this complex was in the +4 oxidation state. Concomitant formation of isobutylene and isobutane, detected by GLC, suggested that the likely intermediate [U(Cp*)$_2$(SBu^t)$_2$]$^-$ was oxidized into [U(Cp*)$_2$(SBu^t)(S)]$^-$ by facile homolytic C–S bond cleavage of a SBu^t ligand. The same complex was alternatively prepared by reaction of [Na(thf)$_{1.5}$][U(Cp*)$_2$Cl$_2$] (560 mg) and NaSBu^t (313 mg) in thf (50 ml); here again, isobutylene and isobutane evolved. After stirring for 18 h at 20 °C, the red solution was filtered and evaporated and the ochre powder extracted in pentane (482 mg, 95%). In the presence of 18-crown-6, red needles of **4** were obtained from thf-pentane (521 mg, 77%). Complexes **1**–**4** were characterized by elemental analyses (C, H, S) and ^{1}H NMR spectroscopy.†

The crystal structure of **4**, shown in Fig. 1 together with selected data,‡ first revealed the unsupported U–S–Na linkage of the molecular compound. Such heterobimetallics with a single sulfur bridge are very rare, being limited to Ta–M (M = Cr, Mo, W),[8] Re–Ru[9] and Zr–W[10] complexes. However, the most interesting feature of the structure is the U–S distances of the sulfide ligand [2.477(2) and 2.462(2) Å in the two independent molecules] which are shorter than those of the

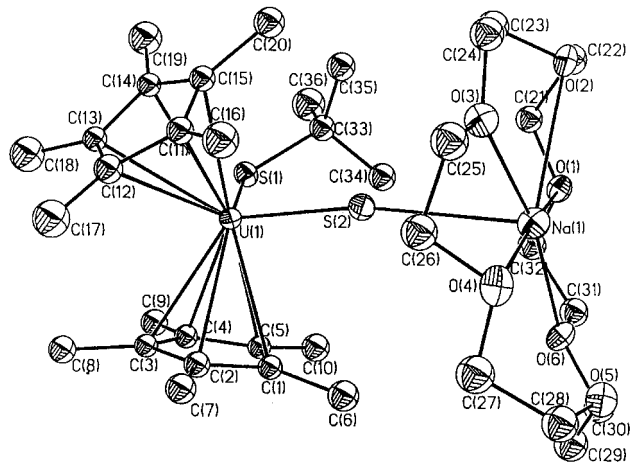


Fig. 1 X-Ray crystal structure of one of the two independent molecules of [Na(18-crown-6)][U(Cp*)$_2$(SBu^t)(S)] with thermal ellipsoids at the 20% probability level. Selected bond distances (Å) and angles (°) : U(1)–S(1) 2.744(2), U(1)–S(2) 2.477(2), Na(1)–S(2) 3.135(4), S(1)–U(1)–S(2) 101.71(7), U(1)–S(2)–Na(1) 168.7(1).

thiolate group [2.744(2) and 2.712(2) Å]. In fact, these are shorter than the shortest U–S distances previously reported, 2.57(2) Å in $[U_3(S)(SBu^t)_{10}]$[2] and 2.60(1) Å in $[\{U(Cp)_3\}_2(\mu\text{-}S)]$,[11] and is consistent with a formal U=S double bond. Thus, **4** ought to be viewed as the adduct of the terminal sulfide $[U(Cp^*)_2(SBu^t)(S)]^-$ to $[Na(18\text{-crown-}6)]^+$. Among the aforementioned compounds which contain an unsupported M–S–M′ linkage, such a dative coordination of a sulfur lone pair of the Ta=S double bond has been encountered in $[Ta(Cp^*)_2(H)(\mu\text{-}S)W(CO)_5]$[8] while the other complexes exhibit single metal–sulfur bonds. In the few adducts of transition metal terminal sulfides with alkali metal ions, such as $[Ti(Cp^*)(OR)(\mu\text{-}S)(\mu\text{-}Cl)Li(thf)_2]$[4] and $[Li_2(thf)_2(Cp^*)TaS_3]$,[5] the metal centres are linked by at least two bridging ligands. The Na–S bond distance and geometrical parameters of the $U(Cp^*)_2$ moiety are unexceptional; steric interactions between the two bulky bridged fragments would explain the large U–S–Na angle [168.7(1) and 174.3(1)°].

Finally, it is worth noting that **2** was stable towards thiolate C–S bond cleavage unless it was reduced by Na(Hg); this fact is in contradiction with previous indications that this reaction would be facilitated by a highly oxidized, electrophilic metal centre.[3] Our results thus give a new insight into the influence of the metal oxidation state on the activation and rupture of thiolate C–S bonds, which is of great importance in catalytic desulfurization processes.

‡ *Crystal data* for $[Na(18\text{-crown-}6)][U(Cp^*)_2(SBu^t)(S)]$: $C_{36}H_{63}NaO_6S_2U$, monoclinic, space group $P2_1/c$, a = 19.174(4), b = 18.548(4), c = 23.132(5) Å, β = 103.31(3)°, V = 8005(3) Å^3, Z = 8, D_c = 1.522 g cm^{-3}, Mo-Kα radiation (λ = 0.71073 Å), μ = 4.210 mm^{-1}, F(000) = 3696, total reflections = 31073, independent reflections = 8203, data/parameter ratio = 8142/808, R_1 = 0.0334 ,wR_2 = 0.0748, GOF = 1.071, residuals based on $I > 2\sigma(I)$. Diffraction collection was carried out on an Enraf-Nonius diffractometer equipped with a CCD detector at 123 K. Data were corrected for Lorentz-polarization effects but not for absorption. The structure was solved by the heavy-atom method and refined by full-matrix least squares on F^2 . There are two independent but similar molecules in the unit cell. A disorder was found on one half of the 18-crown-6 ether of the molecule containing U(2). This disorder is made of two distinct positions that were assigned a 0.5 occupancy factor; they share two carbon atoms which were given an occupancy factor of 1. All non-H atoms were considered anisotropic except those of the disordered half of the crown-ether. H atoms were introduced at calculated positions and constrained to ride on their parent C atoms with displacement parameters of 1.2(CH_2) or 1.5(CH_3) times that of the parent atom. All calculations were performed on an O2 Silicon Graphics Station with the SHELTX package.[13] CCDC 182/1188. See http://www.rsc.org/suppdata/cc/1999/659/ for crystallographic files in .cif format.

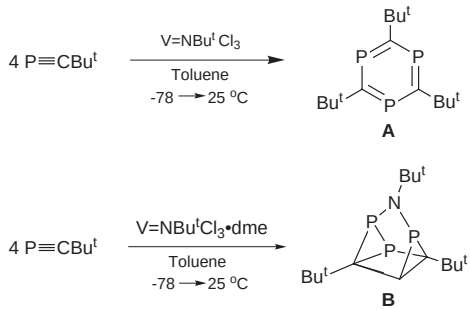
Received (in Cambridge, UK) 25th January 1999, Accepted 4th March 1999

The structures of novel complexes resulting from one- and two-step [2 + 2] cycloaddition reactions of four group 4 imides with the phosphaalkyne Bu^{t}CP are described.

Regitz and coworkers[1] have recently reported novel reactions of the phosphaalkyne Bu^{t}CP with vanadium(v) imido complexes to afford either 3-aza-1,2,4,6-tetraphosphaquadricyclanes **B** or 1,3,5-triphosphabenzenes **A**, the products critically depending on reaction conditions (Scheme 1). They proposed a mechanism for the formation of **A** and **B** which involves an initial [2 + 2] cycloaddition step of the vanadium imide with the phosphaalkyne, but no metal containing complexes have been characterised.

In order to better understand this interesting type of reaction, we now describe the first fully structurally characterised complexes of Zr(IV) and Ti(IV) resulting from one- and two-step [2 + 2] cycloaddition reactions of Bu^{t}CP with '[Zr(η^5-C_5H_5)$_2$(NC$_6$H$_3$Me$_2$-2,6)]' **1**[2] and [TiCl$_2$(NBu^t)(py)$_3$] **2**[3,4] respectively. In addition we report the NMR spectroscopically characterised [2 + 2] phosphaalkyne adducts of '[Zr(η^5-C_5H_5)$_2$(NBu^t)]' **3**[2], and [Ti{(SiMe$_3$)N[CH$_2$CH$_2$N(SiMe$_3$)$_2$]}(NBu^t)(py)][5] **4**.

Treatment of the transient imide complex **1** (prepared from the thermolysis of [Zr(η^5-C_5H_5)$_2$(NHC$_6$H$_3$Me$_2$-2,6)$_2$])[2] with an excess of Bu^{t}CP in toluene at 100 °C for 48 h yielded the orange crystalline complex [Zr(η^5-C_5H_5)$_2$(PCBu^{t}NC$_6$H$_3$Me$_2$-2,6)] **5** in 45% yield.† A single crystal X-ray diffraction study on **5**‡ established that its molecular structure (Fig. 1) contains the four membered planar metallacycle ($\Sigma_{\text{internal angles}}$ = 360 °C) resulting from the [2 + 2] phosphaalkyne–imide cycloaddition, in which the phosphorus is bonded to the nitrogen of the imide function, consistent with the bond polarity of the unsaturated reactive sites. This geometry is similar to that observed for the addition of internal alkynes to **1**.[2] The Zr–N–C(6) bond angle in **5** (147.8°) is typical of double bond character of the metal–nitrogen linkage. A similar adduct [Zr(C_5H_5)$_2$(PCBu^{t}NBu^t)] **6** can also be prepared from '[Zr(η^5-C_5H_5)$_2$(NBu^t)]' (generated *in situ* by thermolysis of [Zr(η^5-C_5H_5)$_2$(NHBu^t)$_2$])[2], as determined by NMR spectroscopy.§



Scheme 1

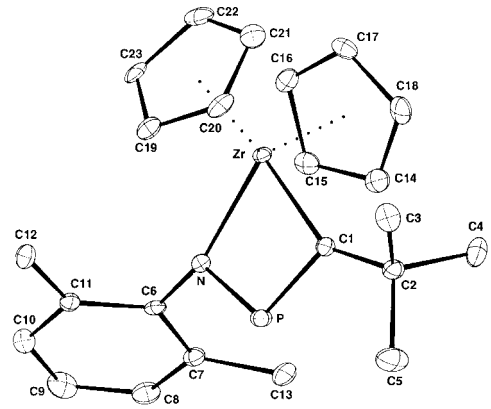


Fig. 1 Molecular structure of [(C_5H_5)$_2$Zr(PCBu^{t}NC$_6$H$_3$Me$_2$-2.6)] **5**. Selected distances (Å) and angles (°): Zr–N 2.101(4), P–N 1.729(4), P–C(1) 1.692(5), Zr–C(1) 2.188(5); Zr–N–P 91.0(2), C(1)–P–N 102.8(2), P–C(1)–Zr 89.1(2), N(1)–Zr–C(1) 77.1(2)°. Displacement elipsoids are shown at 50% probability level.

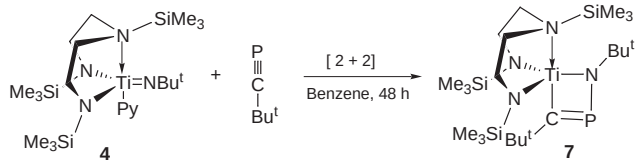
The investigation of this type of addition was subsequently extended to the sterically encumbered titanium imide **4**. Treatment of **4** with an excess of Bu^{t}CP at room temperature in toluene, yielded an orange oil after work up. NMR spectroscopic data were found to be very similar to that of **5** indicative of formation of the [2 + 2] cycloadduct [Ti{N(SiMe$_3$)[CH$_2$CH$_2$N(SiMe$_3$)]$_2$}(PCBu^{t}NBu^t)] **7**¶ (Scheme 2).

Since the reactivity presumably results from release of steric strain, complex **2** was reacted with an excess of Bu^{t}CP in toluene at 55 °C for 72 h to yield the dark-red crystalline complex [TiCl$_2$(P$_2$C$_2$Bu$^t_2$NBu^t)(py)] **8** (61% yield).‖** The corresponding pyridine free complex [TiCl$_2$(P$_2$C$_2$Bu$^t_2$NBu^t)] **8a** can be obtained (25%) by subliming **8** *in vacuo* at 110 °C. A single crystal X-ray diffraction study was carried out on **8**‡ and its molecular structure, (Fig. 2), reveals a TiC$_2$P$_2$N core in which the Ti(IV) centre is in an unsymmetrical environment resulting from being capped by a puckered 1,3-diphosphacyclobutadiene unit, whose P(1) atom is σ-bonded to the nitrogen of the imide function [interplanar angle between C(1)P(2)C(2) and C(1)P(1)P(2), 23.3°]. One representation of the bonding to the Ti centre involves an η^3-interaction with the 2-phosphaallyl fragment of the C$_2$P$_2$ ring which is augmented by interaction



Scheme 2

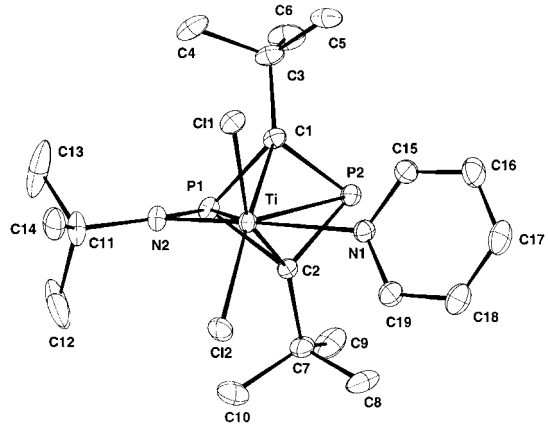


Fig. 2 Molecular structure of [Ti{NBu^{t}PCBu^{t}PCBu^t}Cl_2(py)]**8**. Selected distances (Å) and angles (°): P(1)–N(2) 1.727(2), Ti–N(2) 1.880(2), P1–C(1) 1.825(2), P(2)–C(1) 1.735(2), P(2)–C(2) 1.768(2), C(2)–P(1) 1.847(2), Ti–N(1) 2.394(2), Ti–P(2) 2.784(2), Ti–C(2) 2.221(2), Ti–P(1) 2.442(1), Ti–C(1) 2.439(2); Ti–N(2)–C(11) 148.31(14), Cl(2)–Ti–Cl(1) 109.57(2), C(2)–P(1)–C(1) 80.86(8), C(1)–P(2)–C(2) 85.65(8). Displacement ellipsoids are shown at 50% probability level.

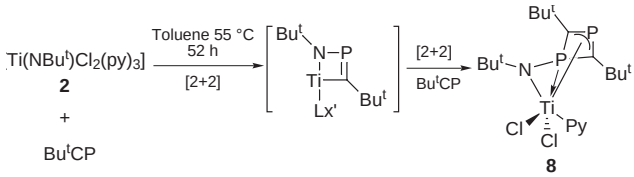
with the N, two Cl ions, P lone pair and the pyridine. As expected the Ti–N(2) bond length [1.880(2) Å] in **8** is considerably elongated when compared with the starting imide complex **2** [1.705(3) Å] and the Ti–N(pyridine) bond length [2.394(2) Å] is very long. The Ti–N–C(α) bond angle in **8** (148.3°) is typical for a metal–nitrogen double bond.

Although no reaction intermediates have been spectroscopically characterised, the formation of the TiC_2P_2N core in **8** is presumed to proceed by sequential [2 + 2] cycloaddition of Bu^{t}CP with (i) the titanium–nitrogen double bond and (ii) the resulting P=C double bond (Scheme 3).



Scheme 3

Interestingly, the course of the reactions involving complexes of type **2** is also affected by the nature of the imido N-substituent. Thus treatment of [Ti(NR)Cl_2(py)$_3$] (R = Ph, *p*-MeC_6H_4, *p*-$NO_2C_6H_4$ or Pr^i) with Bu^{t}CP gave the previously unknown 1,2,4-azadiphospholes $P_2C_2Bu^t_2NR$. The molecular structure of $P_2C_2Bu^t_2NPh$ has been determined and this new class of heteroaromatic ring systems will be the subject of a separate publication.[6] The range of products obtained with different metal and N-substituents indicates the possibility for a rich and diverse derivative chemistry.

Philip Mountford is the Royal Society of Chemistry Sir Edward Frankland Fellow for 1998–9.

Medicinal chemistry with fullerenes and fullerene derivatives

Tatiana Da Ros and Maurizio Prato*

Dipartimento di Scienze Farmaceutiche, Università di Trieste, Piazzale Europa 1, 34127 Trieste, Italy. E-mail: prato@univ.trieste.it

Received (in Cambridge, UK) 4th December 1998, Accepted 8th February 1999

The study of the biological applications of fullerenes has attracted increasing attention despite the low solubility of the carbon spheres in physiological media. The organic functionalisation of fullerenes has helped solubilisation by covalent attachment of hydrophilic appendages. Therefore, recently synthesised fullerene derivatives reach satisfactory concentrations in water. However, the tendency of the fullerenes to form clusters is enhanced in polar media, where better solubilisation can be achieved by means of multiple functionalisation or using micellar systems. Once homogeneously dissolved, the fullerenes and fullerene derivatives exhibit an interesting range of biological activities, especially promising in the field of photodynamic therapy, HIV, neuroprotection and apoptosis.

The fullerenes, a class of spheroidally shaped molecules made exclusively of carbon atoms, were observed for the first time in 1985[1] and isolated in bulk in 1990.[2] Since then, many research groups have been eagerly looking for practical applications of these novel materials.[3] Their interesting features are at the edge of different scientific disciplines, ranging from non-linear optical properties to superconductivity. Also in the biological field the fullerenes have had a strong impact, as it was discovered that functionalised fullerenes can be used in photodynamic therapy[4] or as inhibitors of the HIV-1 protease.[5,6] However, the general excitement was not followed by a comparable outburst of results. The main reason for the slow progress in this field is generally attributed to the total absence of solubility in aqueous media, a problem that has hampered systematic testing. On the other hand, it is clear that size, hydrophobicity, three-dimensionality and electronic effects make the fullerenes very appealing subjects in medicinal chemistry.[7] For instance, it can be easily conceived that the spheroidal shape of fullerenes is potentially accommodated inside hydrophobic regions of enzymes or cells, with biological applications in different fields.

Two excellent reviews cover the main achievements in the biological application of fullerenes up to 1996.[8,9] In this article, we will provide a general overview of the current state of the art of the medicinal chemistry of fullerenes, with particular emphasis on one hand on the most recent and promising general applicative aspects and on the other hand to our own achievements in this field.

Tatiana Da Ros was born in Palmanova, Italy, in 1969. She received her Laurea degree in Pharmaceutical Chemistry from the University of Trieste in 1995 working with Professor Marco De Amici (magna cum laude). *She then took her PhD in 1999, under the supervision of Professor Maurizio Prato, her dissertation dealing with the biological properties of water-soluble fullerene derivatives. She has a research contract with the University of Trieste and is currently working in the Department of Pharmaceutical Sciences.*

Maurizio Prato took his Laurea degree in Chemistry in Padova in 1978, under the supervision of Professor Gianfranco Scorrano. He then joined the Faculty of Science and the Organic Chemistry Department at the University of Padova. He moved to the University of Trieste in 1992, where he is currently Associate Professor of Organic Chemistry. He spent sabbatical terms at Yale University in 1986–1987 (with Professor Samuel J. Danishefsky) and at the University of California, Santa Barbara in 1991–1992 (with Professor Fred Wudl). He received the Federchimica Prize in 1995. His current research interests focus mainly on functionalised fullerenes for applications in materials science and medicinal chemistry.

Solubility

There have been several attempts to overcome the natural repulsion of fullerenes for water. The most widely used methodologies are: (a) encapsulation or microencapsulation in special carriers; (b) suspension with the help of co-solvents; (c) chemical functionalisation for the introduction of solubilising appendages.

Encapsulation

It has long been known that [60]fullerene can be solubilised in water in the form of complexes with cyclodextrins[10,11] or calixarenes.[12,13] More concentrated solutions (up to 4.1×10^{-5} M) can be achieved using polyvinylpyrrolidone (PVP)[14] or artificial membranes like Triton X-100, DODAB (dimethyldioctadecylammonium bromide), DHP (dihexadecyl hydrogen phosphate) or lecithin.[15,16] Colloidal systems are formed with ammonium halides such as cetyltrimethylammonium bromide or sodium dodecyl sulfate.[17] Also co-polymers such as polyphenyl quinoline/polystyrene form self-assemblying systems with well-organised structures.[18] Incorporation of [60]fullerene and photoactive [60]fullerene derivatives in liposomes suggests that a photoexcited fullerene is capable of initiating a redox cycle that has cytochrome *c* and ubiquinone as mediators.[19]

The combination of fullerenes and lipid membranes has led to very interesting results. Lipid bilayers are dynamically mobile structures, partially ordered and of biopharmaceutical interest for covering biocompatible surfaces or for the controlled release of drugs. Hexakis adducts of [60]fullerene with an octahedral pattern, functionalised with C_{12} or C_{18} chains, have allowed the formation of lipid systems with multilamellar vesicles of dipalmitoyl-*sn*-glycero-3-phosphatidylcholine.[20]

Suspensions

Suspensions of fullerenes can be prepared from saturated benzene solutions poured into THF. The resulting mixture is

added dropwise to acetone, and then water is slowly added. A yellow suspension is formed, and the solvents are evaporated to a final known volume of water.[21]

Soluble fullerene derivatives

So far, several fullerene derivatives relatively soluble in water or aqueous mixtures have been synthesised. Fullerenols or fullerols **1**,[22] for instance, are very soluble in water, and even though their structures are not well-defined, a lot of biological studies have been carried out (see below). Water soluble polymers, covalently attached to [60]fullerene, are also easily dissolved in water.[23] Well-defined compounds solubilised in water media include **2**–**5**. Among these, compound **4** reaches a maximum concentration of 1.5×10^{-5} M in H_2O–DMSO 9 : 1.[24] The record for water solubility among monofunctionalised fullerenes so far is to be attributed to dendrimer **5**, whose solubilty in water is 34 mg ml^{-1} at pH 7.4 and an outstanding 254 mg ml^{-1} at pH 10.[25]

In conclusion, when a hydrophilic appendage is covalently attached to [60]fullerene, solubilisation in aqueous solvents is ensured. However, addition of only one solubilizing chain appears insufficient to avoid clustering. The hydrophobic carbon spheres will stick together, leaving the hydrophilic chains on the outside of the aggregate.[26,27] More importantly, formation of clusters decreases the lifetime of the excited triplet state by 2–3 orders of magnitude,[28,29] thus affecting the potential of fullerenes in photodynamic therapy (see below). The degree of aggregation can be monitored by UV–VIS spectrophotometry, pulse radiolysis or light-scattering. Clustering seems to cause broadening of the absorption bands with decrease of absorption coefficients and loss of structural features.[16,26,30,31] To avoid aggregation of the fullerene spheres, either calixarenes or cyclodextrins can be used, or surfactants.[16,29] However, the presence of bulky functionalities, able to shield the fullerene spheroid from water, produces sufficiently homogeneous solutions. Dendrimer **5** shows an almost ideal behavior, with formation of very small aggregates whose size decreases with increasing pH.[25]

Multiple functionalisation can also be helpful. By means of controlled additions it is possible to place polar groups around the fullerene spheroid. It appears that bis-functionalisation is sufficient to avoid clustering in reasonably dilute solutions.[27] However, the radical quenching ability and the singlet oxygen production of the multiple adducts may depend on the number of addends. To test this, the reaction of OH• with a series of functionalised fullerenes was studied.[32] It was found that the reaction rates decrease with an increasing number of additions, fast reactions occurring with bisadducts and much slower reactions with fullerenols.[32] On the other hand, singlet oxygen production was found to be independent of the nature of the addends, but it did decrease with an increasing number of saturated double bonds on the spheroid.[33]

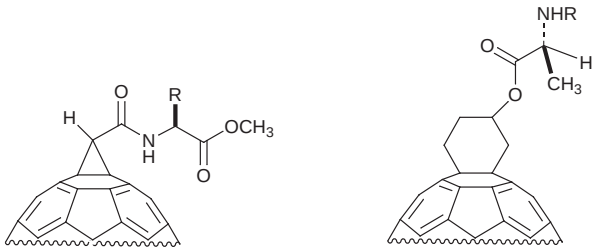
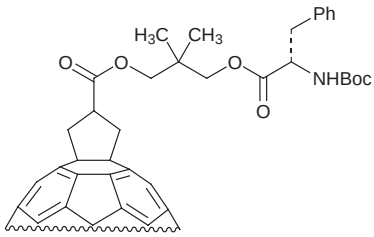
Fullerenic amino acids and peptides

Fullerene-based amino acids (*e.g.* **6**–**9**) have been synthesised by several groups.[34–42] The main objective of these studies is the potential incorporation of these non-natural amino acids in natural peptides and proteins.

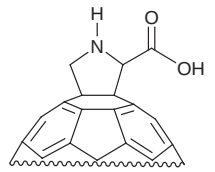


6

7



8

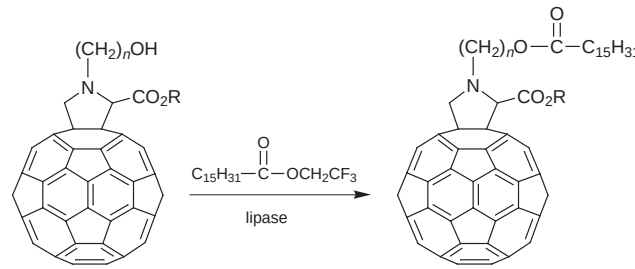


9

Fulleroproline **9** (abbreviated to Fpr using the three-letter code for amino acids), probably the biggest unnatural amino acid,[43] features a proline ring fused with the 6,6 ring junction of [60]fullerene.[37,44] Fpr forms peptides both at the amine and the carboxylic acid ends leading to di- and tri-peptides.[44–46] However, Fpr is usually prepared in racemic form, such that two diastereoisomers are formed when this amino acid is coupled with chiral amino acids. This problem can be overcome by using diastereoselective additions, starting with chiral components.[44,47] Alternatively, the diasteromeric mixtures can be separated by column chromatography or by preparative HPLC. In all cases, enantiopure fulleroprolines can be obtained.[44] Their absolute configuration can be easily established by means of circular dichroism. In all CD spectra of fulleroproline derivatives and peptides, a sharp maximum at about 428 nm was always observed. The sign of this Cotton effect is diagnostic for the determination of the absolute configuration of the chiral C^{α} atom in fulleroproline: a positive maximum is indicative of *R* configuration, whereas the *S* isomer gives rise to a negative maximum.[44]

Naturally encoded proline stands alone in the α-amino acid panorama, as it plays a central role in directing polypeptide folding and in providing conformational rigidifying effects to Pro-containing compounds.[48] Two conformational features contribute to the peculiarity of proline: (1) the propensity to induce a β-turn conformation and (2) the relatively slow rotation around the C–N tertiary amide bond, which results in *trans–cis* isomerism. Both aspects have been examined in fulleroproline peptides. A conformational study in solution has shown that the heterochiral -L-Fpr-D-Ala- sequence is mostly folded in a type-II β-turn conformation, in analogy with the known behavior of the -L-Pro-D-Ala- parent sequence.[45] On the other hand, it was found that the activation parameters for *trans–cis* isomerism in Ac-Fpr-OBu^t are very different from the model Ac-Pro-OBu^t. A difference of *ca*. 7 kcal mol^{-1} in the activation enthalpy makes the conformational interconversion much faster in the fullerene derivative.[46] This was attributed to a low level of availability of the nitrogen lone pair for carbonyl conjugation in fulleroproline.[46] In fact, the nitrogen in pyrrolidine and proline derivatives of [60]fullerene is much less basic than in the corresponding, non-fullerenic, amines.[49]

The ability of some representative hydrolytic enzymes to induce modifications in a series of fulleroprolines was tested with the aim of resolving racemic mixtures and also to obtain detailed structural information on the nature of the interaction.[50] Preliminary results show that, among the many enzymes tested, only lipase B from *Candida antarctica* (CALB) and lipoprotein lipase from *Pseudomonas specie* (LPL) were able to catalyse the acylation of fullerene derivatives, the former being more efficient (Scheme 1). However, even with these active enzymes, no reaction was observed when the functional group to be transformed is close to the fullerene spheroid (Scheme 1).



10

n = 2, 3

11

Scheme 1

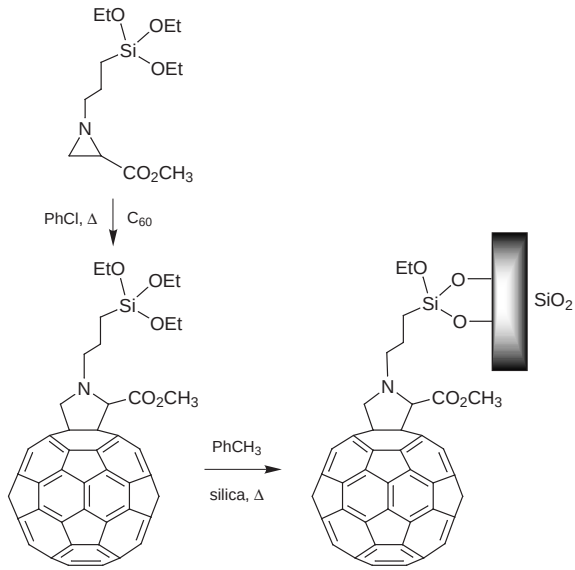
Relatively fast reactions and modest enantioselectivities (up to 45% ee) were observed for reaction centers spatially distant from the carbon sphere. These results seem to indicate that the [60]fullerene spheroid encumbers the productive fitting of the substrate either in the acyl- or alcohol-binding sites when the reaction center is close to the fullerene spheroid. This may also be due to the fact that [60]fullerene derivatives, owing to their size, cannot be easily accommodated inside the lipase active site. However, it looks as though the [60]fullerene spheroid is able to establish hydrophobic interactions with more superficial regions of the enzyme, while the proline moiety approaches the active site cavity of the lipase and the hydroxy group interacts with the catalytic triad.[50]

Other examples of fullerene–peptide conjugates have been reported. The first fulleropeptide reported contained a sequence of five hydrophobic amino acids.[51] On the basis of spectroscopic data, it was concluded that the conjugate possesses the properties of both [60]fullerene and peptide. The secondary structure adopted by the new peptide in solution was found to be the 3_{10}-helix[52] rather than the α-helix, owing to the high AIB content.[51] In a next step, the synthesis of a fullerene–peptide conjugate involving a series of highly hydrophilic amino acids was studied (**3**). The compound is reasonably soluble in water and exhibits interesting biological properties in terms of monocyte chemotaxis and anti-HIV activity (*vide infra*).[53]

More complex peptides such as alamethicin[54] and proteins such as azurin[55] have been covalently attached to [60]fullerene. IgG antibodies have been produced for the first time using [60]fullerene–bovine thyroglobulin conjugates, which could be used in very sensitive immunological procedures.[56]

Given the complexity of the biological systems, a quick way to establish potential interactions of fullerenes with enzymes and proteins would be of great help in preliminary screenings. To this aim, a stationary phase for HPLC was functionalised using a fulleroproline derivative, which, through a silicon alkoxide end group, ensures the chemical linking of the fullerene to the silica matrix (Scheme 2).[57]

The new phase is suitable for analysis in aqueous media, which represents a real practical advantage: tests of interactions of physiological solutions with fullerenes are possible without necessarily solubilizing the carbon cages in water. As a test of efficiency, a series of small peptides containing hydrophobic cavities, simulating a biological environment, was selectively recognised. Peptides characterised by electron-rich hydro-



Scheme 2

phobic clefts, thus giving rise to favourable interactions, were more strongly retained in the chromatographic runs.[57]

Toxicity studies

The absorption, distribution and excretion of fullerenes, together with their potential toxicity, are of fundamental importance in any biological evaluation and, accordingly, have been studied in detail using either unmodified [60]fullerene and water-soluble fullerene derivatives.

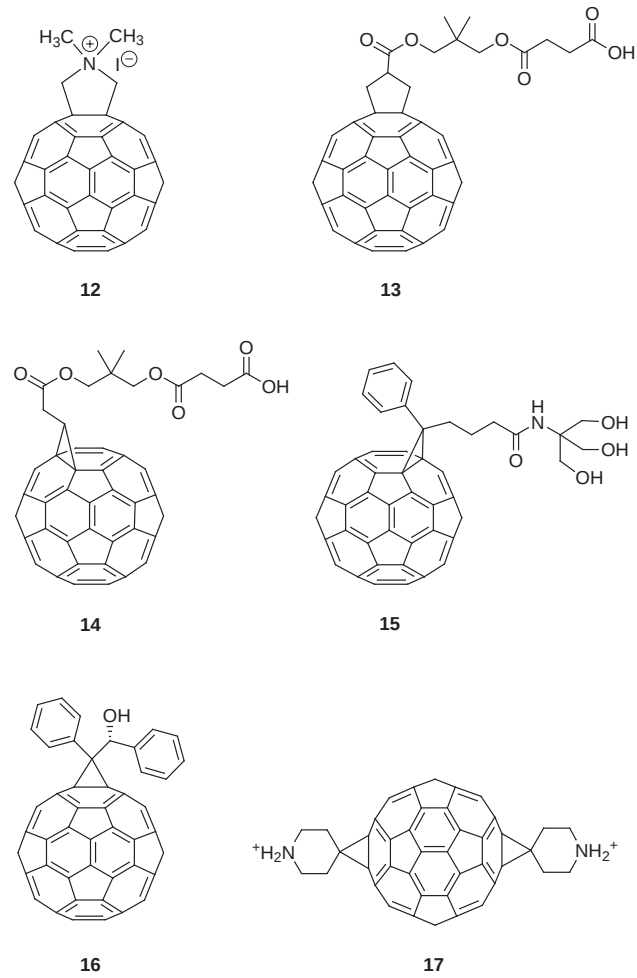
Unmodified [60]fullerene

A water suspension of ^{14}C-labelled [60]fullerene was added to a culture medium in which immortalised human keratinocytes were grown. [60]Fullerene was associated to the cells in a way dependent of time, such that after six hours about 50% of radioactivity was captured by keratinocytes.[21] No effects of [60]fullerene on the proliferation rate of keratinocytes and fibroblasts was observed, since no variations were detected on thymidine incorporation. *In vivo* tests, performed on Swiss mice and using a dispersion of micronised [60]fullerene in water containing surfactants, did not give any lethal effect, toxicity, or growth inhibition. The accumulation of [60]fullerene in fat-storing cells, in which the retinoid concentration is very high, led to an unusual metabolic path.[58] [60]Fullerene reacted *via* Diels–Alder addition, producing vitamin A derivatives. It was also found that [60]fullerene can be phagocytised by human leukocytes[59] and monocytes.[60] However, the associated usual increase of interleukin IL-1β release was not observed. This effect is not clear but it seems to be correlated with the lack of inflammatory response observed after [60]fullerene administration in Swiss mice.[61]

Hemolysis tests performed on sheep-red blood cells showed no effects of a [60]fullerene–PVP suspension.[14] The same suspension was used to study chondrogenesis in cells. Whereas PVP exhibits cytotoxicity, weakly increases chondrogenesis and decreases cell proliferation, the presence of [60]fullerene specifically increases the differentiation of LB cells (rat limb bud cells). The fullerene could then be incorporated in the endoplasmic reticulum and could promote the synthesis of proteoglycan with a mechanism similar to that known for other substances.[62] Damaging effects *in vitro* have been found in mouse MB cells (midbrain cells), since [60]fullerene decreases cell differentiation and proliferation. Embryos of pregnant mice treated *in vivo* with fullerene died with deformations: [60]fullerene was incorporated through maternal flux producing heavy disfunctions to the embryo morphogenesis.[63]

Fullerene derivatives

Pyrrolidinium salt **12** was synthesised using ^{14}C-labelled [60]fullerene.[64] It was possible to see that, after intravenous administration, the compound was rapidly adsorbed and accumulated by the liver. Only 9% of **12** was in the blood one



12 **13** **14** **15** **16** **17**

minute after application, a percentage reduced to 1.5% after 2 h. After five days, 95% of the compound was accumulated in the liver, whereas no traces were found in urine or feces.[64] Partially similar results were found for derivative **13**, differences from **12** probably arising from different hydrophobicities.[65] Oral administration of labelled **13** gave only a trace of radioactivity in the liver after 6 h, whereas 97% was excreted in 48 h, with traces in urine. Intravenous administration was followed by quick localisation in the liver with slow excretion (5.4% in the feces after 160 h). Compound **14** exhibited relative acute toxicity on ddY female mice, when administered intraperitoneally in concentrations of 200–500 mg kg^{-1}, with 5–10% weight loss, but full survival rate after a week.[65] Succinic derivative **2** (15 mg kg^{-1}) was injected intravenously in mice.[66] In this case, 99% was found to bind plasmatic proteins with fast distribution and slow excretion, with accumulation in the liver. Administration of higher doses (25 mg kg^{-1}) led to shortness of breath and death after five minutes.

Toxicity studies of fullerenols carried out intraperitoneally on male ICR mice and Sprague–Dawley rats showed that DL_{50} is 1.2 g kg^{-1} (confidence limits 0.5–2.4 g kg^{-1}). *In vivo* studies suggested that fullerenols can suppress the microsomial enzyme levels and decrease the activities of P450-dependent monooxygenase. These compounds can also inhibit mitochondrial

Mg^{2+}-ATPase activity, in a way that is dependent on fullerenol concentration, with an IC_{50} of 7.1 ± 0.3 μM. It was suggested that fullerenols can behave as artificial electron acceptors, thus decreasing the flux of reducing equivalents from NADPH to oxidase through NADPH-cytochrome P450 reductase.[67]

DNA cleavage and photodynamic therapy

The ground state absorption spectrum of [60]fullerene is characterised by intense absorptions in the UV region with weaker bands extending throughout the visible region up to 700 nm. Upon irradiation, [60]fullerene is excited to a short-lived singlet state (lifetime ≈ 1.3 ns), which converts almost quantitatively into a longer-lived triplet state (lifetime = 50–100 μs). The triplet state transfers energy very efficiently to molecular oxygen, generating singlet oxygen with almost unitary yield.[68] The triplet lifetime is fundamental for photoactivity in cells, whose viscosity is much higher than fluid solutions. In fact, it was suggested that only triplet states with lifetimes longer than 100 μs have enough cytotoxic potential.[69] Compound **14**, which has a triplet lifetime of 40 μs, was not active up to 50 μM concentrations, whereas at higher concentrations inhibited cell growth even in the absence of light.[69] The strongly oxidative properties typical of singlet oxygen are therefore considered to be responsible for a series of biological activities exhibited by fullerene solutions. In fact, the damaging effects are usually inhibited by the presence of singlet oxygen quenchers.

Supercoiled pBR322 DNA, incubated with compound **13** and irradiated by visible light, was cleaved with moderate efficiency.[4] Also membranes of cells grown on the surface of unmodified [60]fullerene were heavily damaged by photoirradiation.[70,71] Immobilised DNA on a monolayer containing [60]fullerene was cleaved.[72] DNA cleavage was improved when an acridine moiety was attached to [60]fullerene, most probably owing to the known affinity of acridine for DNA double helix.[73]
