The concept of channels has been with us more than a century. For half a century, biologists have studied the remarkable workings of protein and peptide channels that permit various cations and small molecules to pass through the phospholipid bilayer membrane. During the past decade, attempts have been made by chemists and biochemists to examine the action of channel compounds from the chemical point of view and to model their function using synthetic structures. What follows is a description of our own efforts to design, synthesize, and characterize a cation transporter that functions in a phospholipid bilayer.

Introduction

During the second half of the 20th century, there have been three important trends in organic chemistry. By the 1950s, the study of physical organic chemistry had moved to the forefront of the science. The study of steric and electronic effects and their influence on mechanism was at center stage. The refinement of physical organic principles provided the critical underlayment for the systematic development of synthetic methodology and strategy. Synthetic chemistry was built on the dual foundations of imagination and physical organic chemistry and reached ascendancy during the 1970s and 1980s. The importance of these two areas continues to be profound. Our understanding of mechanism and our ability to synthesize essentially whatever we can envision has spurred the organic chemist's imagination into supramolecular chemistry, particularly into the realms of bioorganic chemistry and materials development. Both of these areas face a similar challenge. In short, it is to design a compound that has a desired property or function without knowing precisely how such function is controlled. We have referred to the effort to design compounds having specific functions rather than specific structures as 'property-directed synthesis'.[1] This article is about our efforts to design compounds that perform as transmembrane channels[2] in phospholipid bilayers.

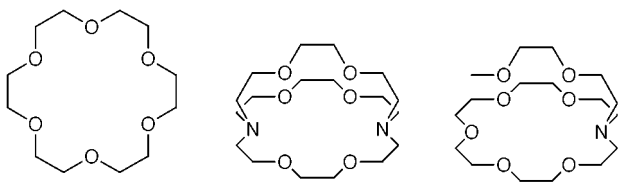
George Gokel was born in New York City but moved as a child to Florida where he grew up. He studied chemistry at Tulane University in New Orleans and earned a doctorate in chemistry at the University of Southern California in Los Angeles. After post-doctoral work with Donald Cram at UCLA and a short stint at the DuPont Chemical Co., Dr Gokel began his academic career. He has held positions in chemistry departments at the Pennsylvania State University, the University of Maryland, and the University of Miami. He is currently Professor in the Department of Molecular Biology and Pharmacology and Director of the Bioorganic Chemistry Program at the Washington University School of Medicine in St. Louis.

At the beginning of our effort to design functional synthetic channel compounds, we confronted a difficulty faced by everyone who attempts to mimic nature. The problem is to design a chemical compound that will function as the natural material does even though Nature's mechanism or mode of action may be imperfectly understood. This problem was compounded in the case of channel models because many in the biological community viewed proteins as the only authentic channels. Even peptides that exhibited channel-like function were regarded by some as intriguing but marginally useful.

Design strategy

The basic issue that must be considered in the design of a cation-conducting channel is how to get the cation from one side of a bilayer membrane to the other. Organic chemists have dealt with the issue of transporting cations across various membranes by designing, preparing, and using a variety of carrier molecules. These carriers function by complexing a cation at one surface of a membrane, carrying it 'ferry-boat style' across the non-polar or insulator regime of the membrane, and then releasing it at the opposite membrane surface. Crown ethers have proved to be particularly successful in transporting cations across bulk membranes. In this context, many combinations of macrocycles, salts, and solvents have been studied.[3]

Our early work with macrocycles led us to confront an interesting problem. The cation complexation constant is given by K_S (usually as the decadic logarithm, *i.e.* log K_S). The equilibrium constant is determined by the rates at which complexation and decomplexation occur, *i.e.* $K_S = k_1/k_{-1} = k_c/k_d = k_{complex}/k_{decomplex}$. Simple crown ethers[4] such as 18-crown-6 show fast binding and release kinetics as required



for successful carrier transport but cation binding selectivity is relatively poor. The cryptands are strong binders that show excellent cation selectivity but their binding and release kinetics are poor. We thus developed the family of compounds we named 'lariat ethers'[5] that could achieve the three-dimensional binding arrangement characteristic of cryptands and that also would exhibit good binding dynamics.[6]

The use of compounds that combine structural features thought to be important with flexibility (and therefore adaptability) was a cornerstone of our channel design philosophy. What

were the critical structural features? The first consideration was whether or not the channel would span the bilayer. This is a particularly intriguing question because in 1989, when the original design work was underway, the thickness of a bilayer was at least subject to interpretation if not unclear. Actually, there are three identifiable regions within the bilayer as shown in Fig. 1. These are the insulating regime or 'hydrocarbon slab', the polar headgroups, and the midpolar regime. The overall thickness of the membrane will depend upon the identities of the headgroups and the fatty acids.[7]

Chemists generally consider the 'membrane thickness' to be the entire width of the bilayer. This is known from X-ray structures of liposomes to be about 40 Å or more.[8] Biologists often regard the thickness of a membrane to be 30–35 Å since this is the value obtained from electrophysiological measurements that corresponds to the insulator regime.[9] The two values are different but both are correct in their context. The question of what, exactly, requires to be spanned by a channel model compound clearly remains. Should the channel's length be 30 or 50 Å?[10] Is the 'correct' length somewhere in between?

This issue illustrates a fundamental problem in modeling biological function. We may choose a span of either 30 or 40 Å to incorporate into our design. Assume we choose 40 Å, complete the design and synthesis, and then assess transport activity. If no cation transport is observed, does that mean that the length is wrong or that some other design feature is inappropriate? The length may be changed to 35 Å. If no cation transport occurs, should lengths of 30, 45 Å, *etc.* be tried? No variation in length will make the molecule function if some critical feature different from span is ill-designed. Combinatorial approaches could lead to optimization of this length but only after a functional design is in hand.

Several variables can immediately be recognized as bearing on channel function. These include the presence of donor groups, the 'relays', headgroups, and the conceptual models for the channel. Each of these variables has aspects that must be considered in the design of a synthetic channel. The consideration must, in the channel case, be done without having an adequate picture of how the wonderful and complex proteins actually work.

Donor groups

It seems reasonable that donor groups such as O, N or S must be present in a channel compound or how would the channel interact with a cation? In the design of the channel, one must consider which donor groups to incorporate. Do we wish only a few donors to be present or should they be numerous? Perhaps the decision about numbers will be influenced by whether the donors are strong or weak. The strength or weakness of a donor group depends on the cation with which it interacts. For example, sulfur (thioether) is a good donor for Zn^{2+} but less effective for K^+.

Ether oxygens, like water, are good donor groups for alkali metals. In that case, what sort of scaffolding should be used to organize the donor groups? Should the donor groups be incorporated into a macrocycle? 18-Crown-6 is selective for K^+ but will a channel incorporating 18-crown-6 also be selective for this cation? Indeed, can we think about cation selectivity in channels in the same way we conceive of complexation?[11] Let us consider 18-crown-6 and its ability to complex Na^+ and K^+. In aqueous solution, where binding constants are low, 18-crown-6 is selective for K^+ over Na^+. The respective binding constants are: K_S (Na^+) = 6.5; K_S (K^+) = 118.[12] This translates to an 18-fold selectivity for K^+ over Na^+. As noted above, $K_S = k_{complex}/k_{release} = k_1/k_{-1}$. The binding rates are known for these two cases and they differ by 2-fold: k_1 (Na^+) = 2.2×10^8 M^{-1}; k_1 (K^+) = 4.4×10^8 M^{-1}. The selectivity therefore lies principally in the ~10-fold difference in cation release rates: k_{-1} (Na^+) = 3.4×10^7 s^{-1}; k_{-1} (K^+) = 3.7×10^6 s^{-1}.

The reaction rates are important because a channel is a dynamic structure. The selectivity of a crown ether or cryptand is determined by what cation is bound relative to another. Which cations are transported rather than retained must define the selectivity of a channel. Thus, the *binding selectivity* of 18-crown-6 for K^+ over Na^+ may mean that a channel incorporating this macrocycle would pass Na^+ and thus show *transport selectivity* for it rather than for K^+. When we observed above that 'sulfur (thioether) is a good donor for Zn^{2+} but less effective for K^+', the context was binding rather than 'permitting' the cation to pass by. Thioether might be a 'good' channel donor group for an alkali metal or alkaline earth metal ion in the sense that it permits K^+ or Ca^{2+} but restricts Zn^{2+}.

Headgroups

An amphiphile is a compound having two different affinities or 'philicities'. The amphiphile sodium dodecyl sulfate has a polar sulfonic acid that constitutes the 'head' and a 12-carbon span that comprises the 'tail'. It seems reasonable that a channel would be an amphiphile since it must insert into a bilayer membrane that is constituted of phospholipid amphiphiles. If a single molecule spans the channel, it must be a twin-headed amphiphile.

In a channel molecule, the headgroup is required to play a second role: it must serve as, or lead to, a cation entry portal. One point of a membrane is, after all, to prevent salts from getting into or out of a cell. If the channel is to function, it must facilitate the entry and exit of cations (anions, small molecules

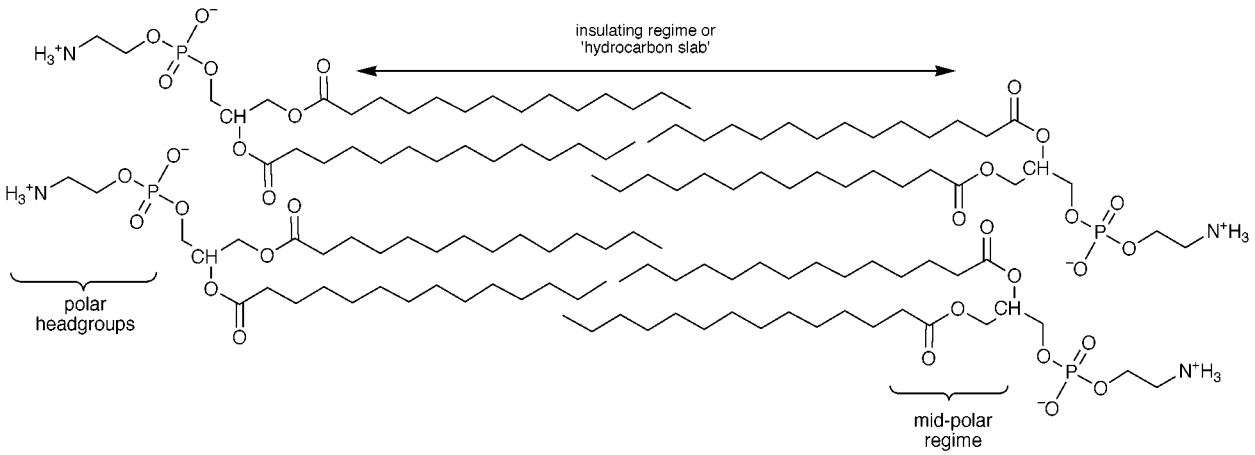


Fig. 1

etc.) without disrupting the membrane structure. It must create a controlled orifice in both the intra- and extra-vesicular surfaces of the bilayer.

There are two obvious challenges in the design of headgroups for a synthetic channel. First, where should the headgroup be placed relative to membrane elements? One possibility is at the membrane surface but an alternative is in the midpolar regime, which is the gateway to the hydrocarbon slab. Second, how polar should the headgroup be? If it is fully charged, should the field be positive or negative? It seems reasonable that a negatively charged headgroup would attract a cation and a cationic headgroup would favor an anion but this is more intuition than knowledge. Information about headgroup preferences might be gleaned from the specifics of protein channel structures. Although the amino acid sequences of many protein channels are known, the three dimensional structures of few have been established.

For most proteins, transmembrane segments are identified by subjecting the amino acid sequence to hydropathy analysis.[13] Typically, a computer program examines the entire length of the protein searching for sequences of amino acids that are hydrophobic. A transmembrane segment is about 20 amino acids if it is α-helical and it is about 10 amino acids if it is a β-sheet. Assuming an α-helical transmembrane segment (the common situation), the program looks for a sequence that is expected to partition into a low polarity medium. It is interesting to note that in an α-helix, each amino acid spans about 1.5 Å. Thus, a 20 amino acid sequence translates to a 30 Å span—the estimated thickness of the insulating regime. From this discussion, the problem is apparent. If one doesn't know the exact structure of the protein, it is hard to guess whether the polar residues, if any, are on the membrane surface or in the midpolar regime. In a synthetic channel, should there possibly be 'headgroups' in both positions? If one is unsure of the headgroup position(s), then guessing whether the environment is positively or negatively charged is obviously a challenge.

Water[14] is a ubiquitous element in biology and certainly present in bilayer membranes as well as in many proteins. What role will water play in transport? It seems reasonable to think that cations will be only partly desolvated as they pass through the membrane. Complete desolvation is a high-energy process and it is hard to see why all of the water would be stripped from a cation on the periplasmic side of the membrane when it must be rehydrated on the cytoplasmic surface. If water is attached to a cation, how does this affect transport? Must we consider the larger size of the fully hydrated cation rather than its crystallographic diameter? Will discrete molecules of water remain attached to individual ions or will there be exchange with the environment? How does the presence of water affect the choice of donor groups? Amidst all of these variables, one thing that seems clear is that it will be difficult for any positively charged species to traverse a 30 Å, nonpolar span without some interim stabilization.

Our original design for a cation-conducting channel is shown in Fig. 2. The questions posed above were dealt with as follows. Diaza-18-crown-6 polyethers were selected to serve as both headgroups and entry portals. It was known[15] that the crowns could bind both Na^+ ($\log K_S = 2.99$)[16] and K^+ ($\log K_S = 3.80$). It was also known from the early work of Kuwamura[17] and of Okahara[18] that alkyl-substituted crown ethers formed micellar aggregates when sonicated in aqueous suspension. We demonstrated that twin-tailed diazacrowns could form stable liposomes, suggesting that the crown would be effective as a head group.[19]

The two distal macrocycles were expected to serve both as headgroups and as entry portals. A K^+ cation (ionic diameter ~2.7 Å) can pass through the center of the macrocycle as can Na^+ (~2 Å). The central macrocycle was also expected to serve as a portal. Its role was predicted to be as a 'relay station' for the transient cation. The polar interaction of the crown with the transient cation at the least polar locale within the bilayer (the midplane) was expected to provide transient stabilization so the transmembrane journey could be completed. It was unknown at the time of the design how this might be accomplished within a protein channel.[20]

Dodecyl groups were chosen to be the hydrocarbon spacer chains and sidearms. The notion was that the two covalently attached chains would define the channel's overall length while the flexible sidearms organized along the lipid axis to provide the other 'wall' of the channel. A C–C bond is about 1 Å in the linear sense. The dodecyl chain is therefore just under 14 Å. This provides a span of ~28 Å plus the thickness of the macrocycle. Such a span was expected to cover the insulator regime of the bilayer. The arbitrary decision was made to locate the channel's headgroup in the bilayer's midpolar regime rather than on the membrane surface.

Diaza-18-crown-6 groups were chosen as the macrocycles because invertable nitrogen imparts flexibility to the system and obviates the problem of stereoisomerism. The protonation state of the nitrogen atoms within the bilayer is unknown at the time of this writing. It is worth noting that the schematic of the channel and four phospholipid monomers shows the latter with headgroups proportional to the lipid chain lengths.

Alternative designs

The development of synthetic channel models has been considered in a number of groups.[21] In some cases, compounds were designed *de novo* and in others the structures of the products of certain reactions suggested that they might possess channel activity. On occasion, the transport of Na^+, K^+ or Ca^{2+} was not studied but the assessment of transport efficacy was

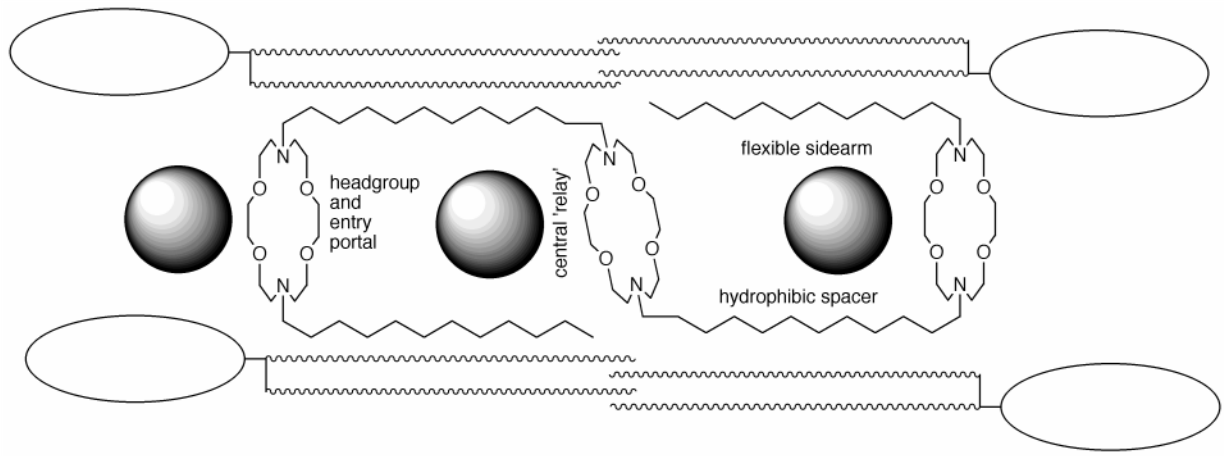

Fig. 2

limited to H^+ or Co^{2+}. Thus, the references cited represent a great range of approaches, designs, structural types and success.

Synthesis of channel 1

The first channel in the tris(macrocycle) family, designated C_{12}<N18N>C_{12}<N18N>C_{12}<N18N>C_{12} in a shorthand we developed some years ago,[22] presented the interesting problem of being nearly, but not quite, symmetrical. Of course, there is two-fold symmetry through the central macrocycle. The distal crowns, however, are attached to dodecyl chains on either side but are not symmetrical. Our best current synthetic approach[23] is accomplished as follows.

In the first step, diaza-18-crown-6 is monoalkylated by 1-bromododecane to give C_{12}<N18N> (Scheme 1). This, in turn, is treated with 1,12-dibromododecane to give C_{12}<N18N>C_{12}Br. Use of the latter to dialkylate diaza-18-crown-6 affords channel 1 (**1**). This approach was the model for the more than 30 members of this novel structural family now in hand.

Assessment of ionophoretic activity

Three methods were used to assess the efficacy of the synthetic cation transporters: fluorescence, ^{23}Na NMR and planar bilayer conductance. The fluorescence technique[24] was used for determining proton flux in a few compounds and only at an early stage of the study. Planar bilayer methods are discussed below. The bulk of the quantitative measurements were accomplished by using a dynamic NMR method. In short, phospholipid liposomes (vesicles) are created in the presence of NaCl. ^{23}Na NMR shows a single line for Na^+(inside) and Na^+ (outside). When Dy^{3+}, a shift reagent, is added to the external solution, the chemical shift of the external Na^+ changes. When an ionophore is added to the bilayer, internal and external Na^+ may equilibrate and the exchange rate constant may be determined from the concentration dependence of the linewidth change: $K = 1/\tau = \pi(\Delta\nu_1 - \Delta\nu_0)$.[25]

Multiple experiments at concentration ranges from 0–20 μM are required to determine the rate constant for a single transporter. The experiments were therefore done in tandem with a standard of known activity. In the early work, this standard was the naturally occurring, channel-forming peptide gramicidin.[26] Gramicidin is an excellent pore-former that sometimes functions even when experimental conditions are not properly maintained. Thus, the failure of a synthetic channel-former to transport Na^+ might occur due to poor experimental conditions rather than lack of efficacy and gramicidin might function despite the experimental problems. We have thus adopted Dn<N18N>C_{12}<N18N>C_{12}<N18N>Dn (Dn = dimethylaminonaphthylsulfonyl or dansyl) as our experimental standard. The 'dansyl channel' transports cations very reproducibly but fails when experimental conditions are not properly maintained. We have also modified the [Na^+] from 100 to 250 mM which gives better entrapment and more reproducible experimental results.

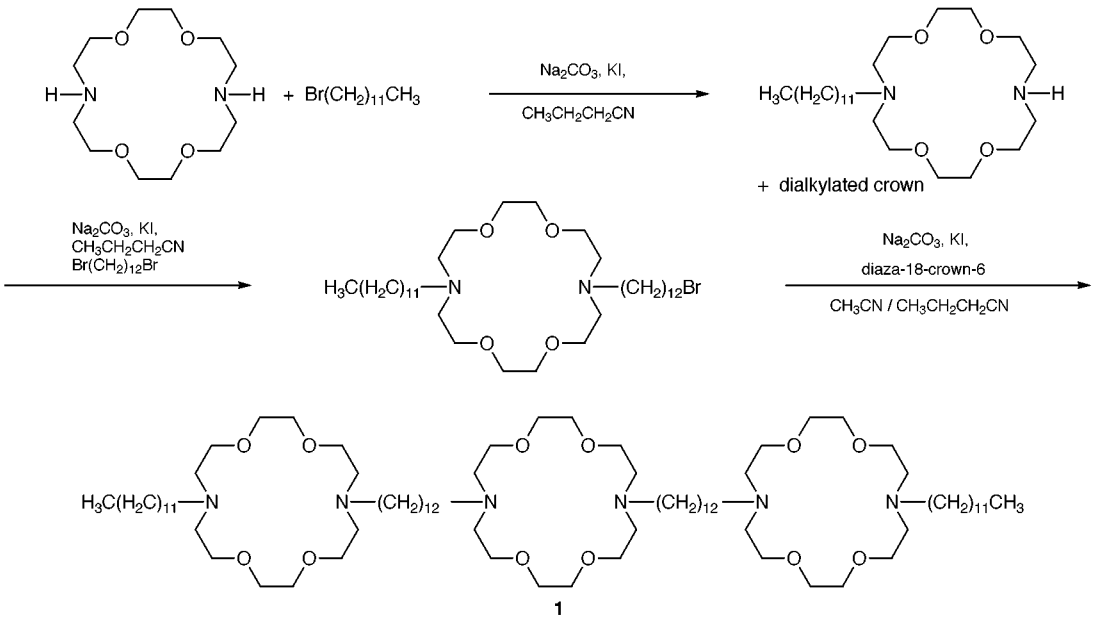
Using the ^{23}Na NMR method, we found channel **1** transported Na^+ across a phospholipid bilayer at a rate about 27% of that observed for gramicidin. The exchange rate observed for gramicidin is ~175 s^{-1} so channel **1** is transporting cations on the millisecond time scale. We were also able to correlate the transport rate with a number of structural variations although the details are beyond the scope of this review. It was interesting to note, however, that when terminal macrocycles were altered from C_{12}<N18N>~ to <18N>~ (aza-18-crown-6), Na^+ transport activity was lost. Replacement of the sidearm by benzyl, substituted benzyl, naphthyl, dansyl and others led to differences in transport rates but most sidearm changes afforded functional channels.

Naming the family of compounds

Many of the early channels were tris(macrocycle)s and we referred to these compounds as such. As structural variations led to the removal of one or more macrocycles, the name was no longer appropriate. We considered the name 'hydraphile' as a possibility because of its association with the two-headed monster slain by Hercules. The dictionary[27] provided additional inspiration in two other definitions. A hydra is 'any of several small freshwater polyps of the genus *Hydra* and related genera, having a naked cylindrical body and an oral opening surrounded by tentacles'. Clearly the shape and tentacles were highly suggestive. An additional definition added to the appropriateness of the name: 'A persistent or multifaceted problem that cannot be eradicated by a single effort'.

Control experiments

The fact that sodium flux was observed in the presence of **1** was very encouraging but not conclusive. It could mean that all of



1

Scheme 1

the design concepts were as originally conceived. It is always nice to have one's ideas proven successful. Still, the fact of sodium transport was permissive rather than conclusive. It was possible, for example, that the tris(macrocycle) functioned simply by detergent action. To assess this possibility, the tris(macrocycle) ionophore was replaced by either Triton X-100, a neutral detergent, or sodium dodecyl sulfate, an anionic detergent. The concentration range in the ^{23}Na NMR experiment was expanded from the typical 0–20 μM by ten-fold to 0–200 μM but no cation flux (line broadening) could be detected in either case.[21]

It was possible that the tris(macrocycle)s were unusually active carrier molecules rather than pore-formers. A conventional concentric tube apparatus was used to assess carrier transport through a bulk $CHCl_3$ membrane in a group of 10 compounds.[28] In this experiment, a beaker is charged with $CHCl_3$ and water. A glass tube is then suspended in the beaker through the upper water layer and into the $CHCl_3$. The outer, upper aqueous ring is thus separated from the inner core of water. A NaX salt can be carried through the $CHCl_3$ bulk membrane from inner core to outer ring. On the atomic scale, a distance of $\sim 10^7$ Å must be traversed so the channel mechanism is precluded. The transport rates observed in this experiment (relative to valinomycin) were compared to those obtained for the same compounds in the ^{23}Na NMR/bilayer experiment (relative to gramicidin). In short, the data showed no discernible correlation. This does not prove the channel mechanism but clearly discounts carrier transport within the bilayer.[29] These findings comport with the observation that fragments of the channel such as $C_{12} < N18N > C_{12} < N18N > C_{12}$ or $< 18N > C_{12} < N18N > C_{12} < N18 >$ and known carriers such as $PhCH_2 < N18N > CH_2Ph$ were not sufficiently active to show transport when assessed by the NMR method.

It is interesting to note that addition of the tris(macrocycle)s to the $CHCl_3$ concentric tube system led to a dramatic increase in hydration of that solvent.[27] No further work was undertaken to resolve this issue because it was tangential to the main thrust of the effort.

It was possible that the rate differences observed for structurally related channels might be due only to variations in the extent of membrane penetration. Octanol–water partition coefficients[30] were determined for several substituted crown ethers and the experimentally determined values were compared to data calculated by the Hint module of Sybyl.[27] Agreement between experiment and calculation was good. The data showed that the tris(macrocycle)s favored octanol (*i.e.* the membrane) by $> 10^{10}$ up to as much as 10^{30}. Although the rate differential was not due to differences in partitioning, a minor kinetic effect was observed. When the ionophore was added to the preformed suspension of liposomes and then analyzed immediately, the plots of $1/\tau$ *vs.* [ionophore] showed curvature. If NMR analysis was delayed for an hour, the lines were essentially straight. Likewise, if the vesicles were formed in the presence of the ionophore (direct incorporation) linear data were obtained. Care was thus taken to permit equilibration of the sample system.

The channel's conformation

Changing the size of the central macrocycle diminished the transport rate but did not preclude it. Substituting the central macrocycle by an $O(CH_2CH_2O)_3$ chain again impeded but did not prohibit sodium transport. We concluded that the central macrocycle in $R < N18N > C_{12} < N18N > C_{12} < N18N > R$ was parallel to the lipid axis rather than parallel to the other two macrorings. Thus, we inferred that the cation passed by but not through the central macrocycle. This conformation is illustrated in Fig. 3.

Assessment of optimal distances

The tris(macrocyclic) channels were designed to function in a phospholipid bilayer but membrane dimensions and the placement of a channel within it are elusive. An attempt was therefore made to experimentally determine the optimal length of the channel. This was done by varying the length of the covalent, hydrophobic spacers in $PhCH_2 < N18N > C_{12} < N18N > C_{12} < N18N > CH_2Ph$. It was assumed that the overall conformation would remain similar as the chain length was varied by 2 methylenes on either side of the central macrocycle. The starting point for this exercise is indicated on the graph (Fig. 4) by an arrow. It was anticipated that incremental lengthening of a flexible assembly would lead to some reduction in efficacy as less favorable conformations were adopted. As chain length diminished, it was expected that a point would be reached at which the structure was simply too small to span the bilayer. Note that each change of 2 methylene units in the spacer is an overall change of 4 methylenes or ~ 4 Å in span. Shortening the chain by 4 Å or lengthening by 8 Å drops the transport rate to about half. Shortening by 8 Å leads to an inactive ionophore. Note that by 'inactive' we mean that no transport activity can be detected by the ^{23}Na NMR method.

Assessment of the conformation and location of the channel within the bilayer

The synthetic tris(macrocycle) channel compounds can readily be modified to incorporate various structural probes. In

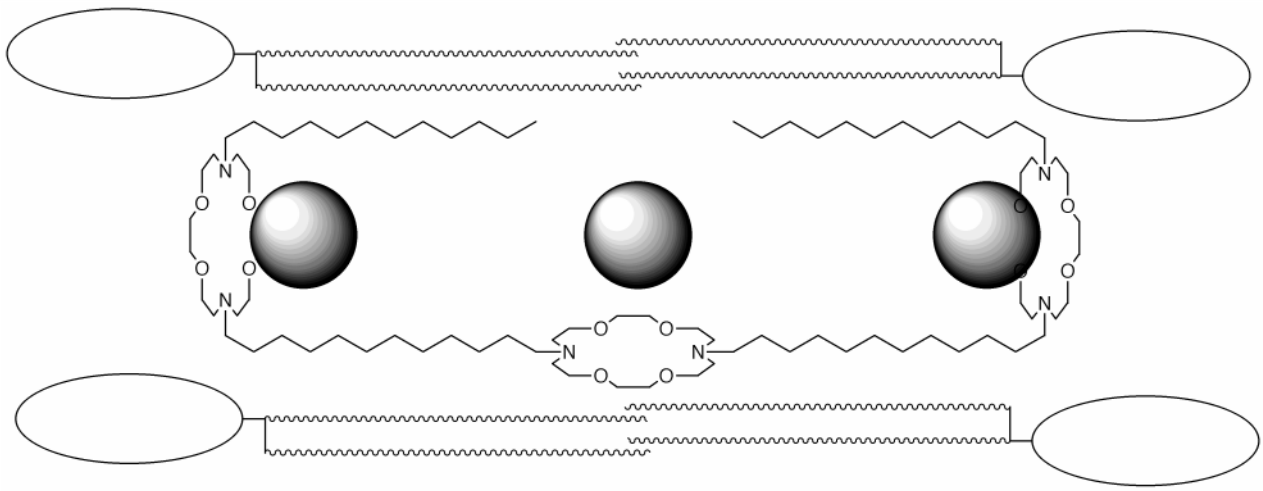


Fig. 3

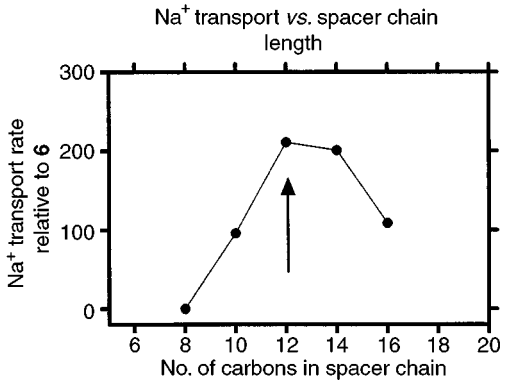

Fig. 4

particular, fluorescent headgroups can be included as an integral part of the structure. In biochemical studies, for example, the indolyl residue of tryptophan is often used as a fluorescent probe. Fluorescent dansyl residues were incorporated into the channel as headgroups: Dn < N18N > C_{12} < N18N > C_{12} < N18N > Dn, **2**. The fluorescence spectrum was determined in a variety of solvents from nonpolar to polar as well as in a phospholipid bilayer. Note that lipids were carefully screened to be sure that any fluorescent impurities were absent. The fluorescence maxima (λ_{max}) are shown in Fig. 5, plotted as a function of solvent polarity (the

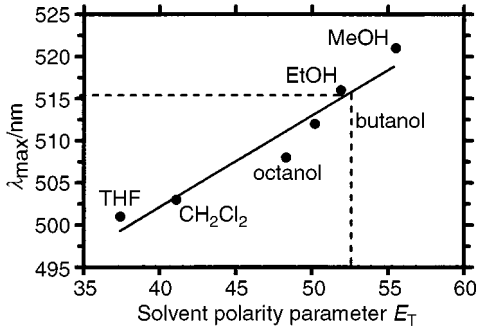

Fig. 5

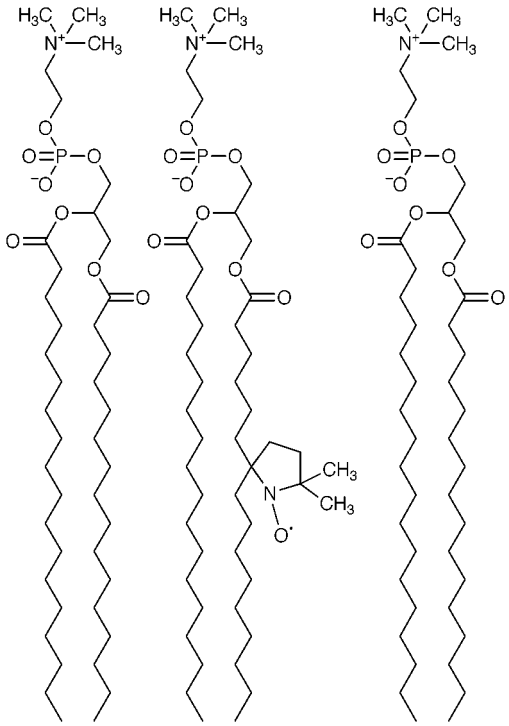
Reichardt parameter, E_T).[31] A dashed line indicates the fluorescence maximum determined for the dansyl channel. The polarity experienced by the dansyl group is between that of ethanol and methanol—about what would be expected for the glyceryl ester regime of a phospholipid. In any event, the dansyl environment of the channel is significantly more polar than would be expected were it embedded in the membrane's 'hydrocarbon slab.

Fluorescence depth quenching

The heterocyclic 'doxyl' group quenches fluorescence by virtue of its unpaired electron spin. By using doxyl-substituted phospholipids, it is possible to estimate how far from the bilayer's midplane is the dansyl 'headgroup'. 7-Doxyl- and 12-doxyl-palmitoyl-substituted phosphatidylcholines were

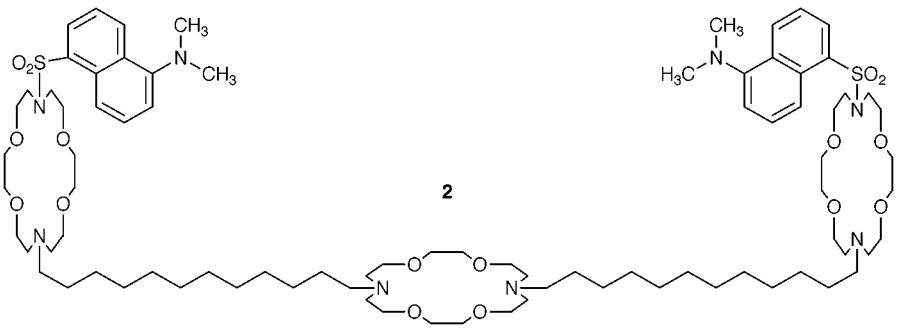


used along with the dansyl channel to estimate headgroup separation.[32] Application of the appropriate equations[33] gives a value for the headgroup separation of 28 Å (*i.e.* the distance of the headgroup from the bilayer's midplane is 14 Å). If the hydrocarbon slab is approximately 30 Å thick and the dansyl groups are ~6 Å, whether measured laterally or transversely, one concludes that the channel's termini are in or near the midpolar region created by the glyceryl ester residues. This comports with the position estimated from dansyl fluorescence.

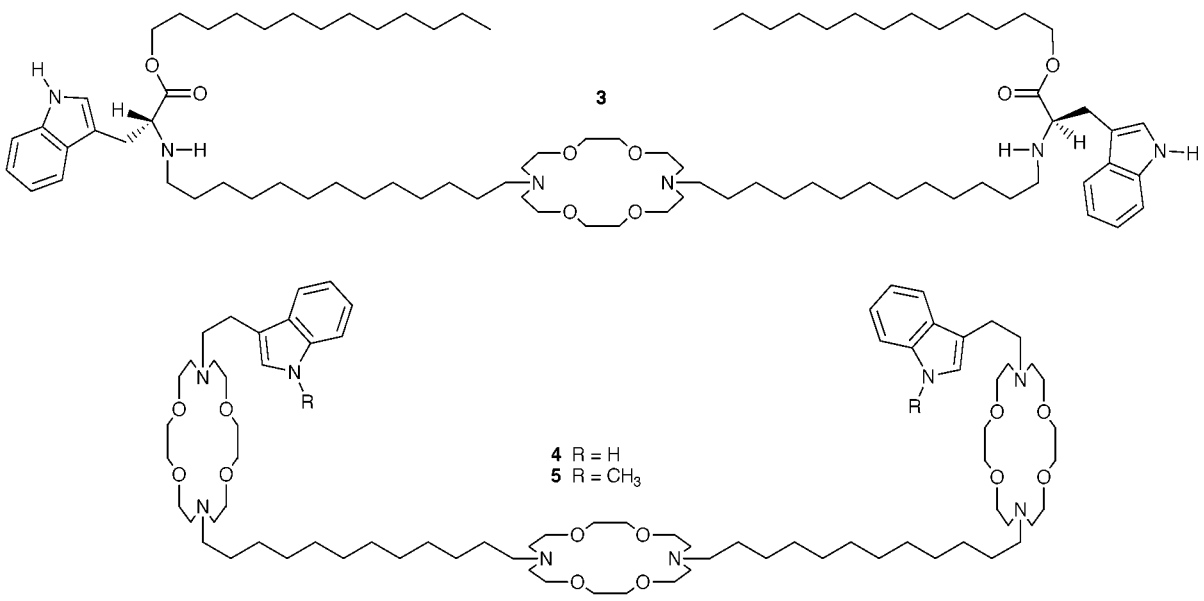
Experiments designed to address headgroup issues

It was assumed that the conformation illustrated in Fig. 1 required the distal macrocycles to function both as headgroups and entry portals. An effort was made to confirm experimentally the ability of diaza-macrocycles to serve as amphiphile headgroups. It was found that a range of 2-armed diaza-18-crown-6 derivatives could form stable liposomes when sonicated in aqueous suspension.[34] In a molecule such as C_{18} < N18N > C_{18}, the octadecyl chains can function only as hydrophobic tails so the macrocycles must comprise the headgroups. Successful formation of stable liposomes from R < N18N > R clearly implies the efficacy of the crown as a headgroup. Evidence on the interaction of the headgroup with cations is discussed below.

The frequent observation of the rare amino acid tryptophan at the boundary margins of putative transmembrane segments of proteins suggested that it might play some important role in channel formation. In separate work, we demonstrated that indole, the sidechain of tryptophan, could function as a



2



headgroup for the formation of stable liposomes.[35] Clearly, tryptophan cannot function as an entry portal for cations in the same sense that crowns do. We prepared **3**, which incorporated the essential channel elements shown in Fig. 1, but lacked the cation entry portal. Compound **3** showed no cation transport ability as judged by any of the analytical methods attempted.

H-bond-induced blockage of the headgroup

Because of our[35] and others'[33,36] speculation that tryptophan and/or its indole residue could play an anchoring role in phospholipid bilayer membranes, we prepared a tris(macrocycle) terminated in the indolylmethyl residue, *i.e.* $InCH_2CH_2 < N18N > C_{12} < N18N > C_{12} < N18N > CH_2CH_2In$**4**. Although structurally similar to the highly active benzyl channel ($PhCH_2 < N18N > C_{12} < N18N > C_{12} < N18N > CH_2Ph$), the indolyl channel showed no ability to transport Na^+.[37] Both CPK models and Monte Carlo simulations showed that a hydrogen bond between the indole NH and a macroring oxygen atom could form. An infrared band, attributable to H-bond formation, did not alter its position during 100-fold dilution. This suggests that the H-bond is intramolecular.

This result, although inferential, is clearly important. It implies that weak H-bond interactions can block the channel. This, in turn, implies that the conformation in Fig. 2 is correct or why would occlusion of the entry portal block the channel? Replacement of the indolyl residue by a methylindolyl, *i.e.* replacement of the NH group by NCH_3, gave a compound, **5**, that was fully active as a channel.

Application of the Hammett equation

If a cation enters the channel by going through or passing by the distal macrocycle(s), it should experience the stereoelectronics of that group. We prepared three channel compounds of the type $PhCH_2 < N18N > C_{12} < N18N > C_{12} < N18N > CH_2Ph$ in which the aromatic ring of the benzyl group was *para*-substituted. The substituents were H (shown), 4-methoxy and 4-nitro. A straight-line relationship was observed.[38] Admittedly, the graph (Fig. 6) involves only three points but the difficulty of synthesis and analysis will be apparent.

The critical results are as follows. First, r^2 for the three-point line is 0.95—a respectable value. Second, the slope of the line is negative as expected for the interaction of a cation with a neutral host. The slope is shallower than observed for complexation of cations by dibenzyldiaza-18-crown-6 derivatives.[39] This is expected for a transient interaction. A third point, not apparent from the graph, is that when relative transport rates obtained in the concentric tube experiment (see above) were plotted *vs.* Hammett σ^0, the straight-line 'correlation' had a zero slope and $r^2 = 0.4$.

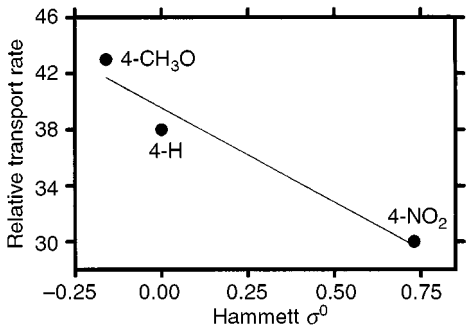


Fig. 6

Changes in headgroup size

Only limited work has thus far been completed to assess the influence of headgroup size. Two channels were prepared for this study. In both cases, the terminal residue ('flexible sidearm' in Fig. 1) was fluorobenzyl. The distal macrocycles were either 15- or 18-membered. When cation transport was assessed by using the NMR method, transport of Na^+ by the 15-membered ring channel was found to be about 60% of that determined for the compound having 18-membered distal macrocycles.[40]

The aggregation state of the channel

The availability of both the dansyl (**2**) and *N*-methylindolyl (**5**) channels provided an opportunity to assess the aggregation state of the channel. We found that the *N*-methylindolyl-sidearmed channel absorbed light at 283 nm and fluoresced at 343 nm—the wavelength at which the dansyl-terminated channel absorbs. An experiment was undertaken in which the amount of channel was held constant and the mole fractions of **2** and **5** were varied from 0→1 and 1→0, respectively. A logarithmic plot of the fluorescence ratio as a function of mole fraction gave a line with a slope of 1.12. The slope of this line has been interpreted to be the aggregation state. Thus, at least for these two compounds,

the channel operates, within experimental error, as a monomer.[41]

^{23}Na NMR transport results

The ^{23}Na NMR experiment as it is used to assess transport in a bilayer membrane was described above. A number of structural variations have been incorporated into channel **1** and the relative transport abilities of these compounds have been measured. Selected results are shown in Table 1 using the shorthand described above in which <N18N> represents 4,13-diaza-18-crown-6.

Table 1 Sodium ion transport by hydraphiles

Sidearm	Headgroup	Spacer	Center	k_{rel}
Dodecyl ($C_{12}H_{25}$)	<N18N>	$C_{12}H_{24}$	<N18N>	27
Benzyl ($CH_2C_6H_5$)	<N18N>	$C_{12}H_{24}$	O–2,6–$C_{10}H_6$–O	<2
Benzyl	<N18N>	$C_{12}H_{24}$	<N18N>	39
Dansyl	<N18N>	$C_{12}H_{24}$	<N18N>	24
Dansyl	<N18N>	$C_{12}H_{24}$	<N15N>	19
4-Fluorobenzyl	<N18N>	$C_{12}H_{24}$	<N18N>	26
2-(3-Indolyl)ethyl	<N18N>	$C_{12}H_{24}$	<N18N>	<2
2-(*N*-Methyl-3-indolyl)-ethyl	<N18N>	$C_{12}H_{24}$	<N18N>	23
None	<18N>	$C_{12}H_{24}$	<N18N>	<2

Patch clamping results

The ability of various synthetic and peptidic compounds to function as cation-conducting channels may be demonstrated by a technique called 'planar bilayer conductance', or PBC. In this technique, a phospholipid bilayer is formed in a pinhole separating two salt phases. When the membrane is formed over the pinhole, it turns dark and the system is sometimes referred to as a black lipid membrane. Using electrodes and a patch clamp amplifier, the electrical response of a bilayer membrane imbued with a transporter may be observed. A membrane is normally insulating so increases in the electrical response are interpreted as the passage of ions through it.

We conducted a number of experiments that confirmed ion transport. Our most recent PBC results are for a calixarene-based channel.[42] The patch clamp or PBC technique is wonderfully sensitive but it is a difficult method to master and to reproduce. In some cases, supposedly identical samples show high and no channel activity. In other cases, the membrane itself collapses and terminates the study before sufficient data have been acquired. We have thus preferred the NMR method; it is cumbersome but, so far at least, it has proved to be reliable.

Conclusions

Clearly many channel models are possible. Our basic design is effective and its modular design is proving useful to assess individual structural issues. In work that is yet to be published, we have explored covalent attachment of the sidearms and variations in the central relay unit. Cation/anion selectivity, ion selectivity in general, and rectification all remain important challenges in this emerging area.

Acknowledgment

I warmly thank the many co-workers whose names are on the cited references who have been intimately involved in this project. I appreciate their hard work, their clever ideas, and their keen insight and criticism. Support of this work by grants from NIH (GM 36262), NATO and NSF (CHE-9805840) is gratefully acknowledged.

5 The name lariat ether was suggested by the CPK models that resembled a looped rope. Moreover, the mode of complexation was envisioned as a 'rope and tie' combination of macroring and sidearm. When the first manuscript was submitted to this august Journal, it was accepted but an editor deleted the name lariat because he or she felt that the name was not officially sanctioned nomenclature. We felt the name was an important element in conceptualizing these compounds. We therefore withdrew the paper with the intention of submitting it elsewhere. The editor relented and the report appeared in due course: G. W. Gokel, D. M. Dishong and C. J. Diamond, *J. Chem. Soc., Chem. Commun.*, 1980, 1053.

A rigid 1,3,5-phenylene-based metallodendrimer containing a ruthenium(II) bis(terpyridyl) complex

Mutsumi Kimura,* Tetsuo Shiba, Tsuyoshi Muto, Kenji Hanabusa and Hirofusa Shirai

Department of Functional Polymer Science, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386-8567, Japan. E-mail: mkimura@giptc.shinshu-u.ac.jp

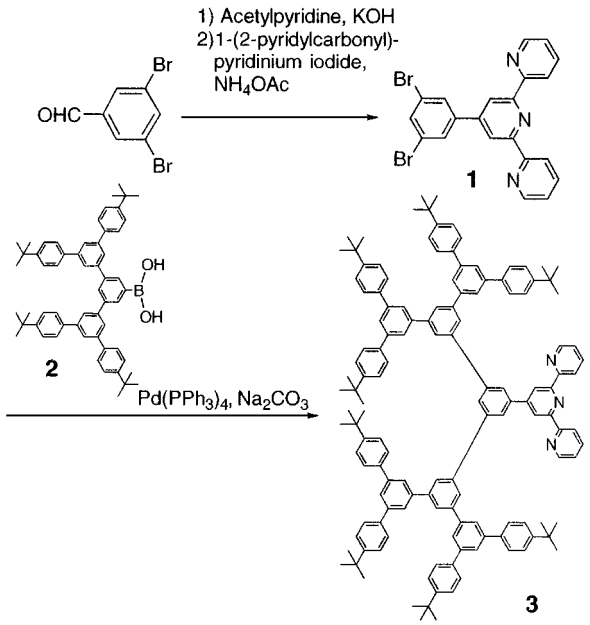
Received (in Cambridge, UK) 26th October 1999, Accepted Accepted 18th November 1999

A new 1,3,5-phenylene-based metallodendrimer containing a ruthenium bis(terpyridyl) complex was prepared and characterized; the rigid dendritic branches are found to affect the electrochemical properties of the redox-active core.

Dendrimers are well defined, highly branched macromolecules constructed from an interior core with a regular array of branch units.[1] To investigate the influence of dendritic structures on electrochemical, photochemical and catalytic properties, dendrimers containing functional units have been designed and synthesized.[2] The dendritic structures influence the microenvironment around the cores and modify their properties.[3] Polypyridyl ruthenium(II) complexes ($[Ru(bpy)_3]^{2+}$ and $[Ru(tpy)_2]^{2+}$) are widely used for the construction of dendrimers because of their unique electrochemical and photochemical properties.[4] However, these dendrimers have been prepared by attaching flexible dendron units around metal complexes. Rigid dendrimers have been prepared using phenylene, phenylacetylene and phenylenevinylene units as repeating units in the dendritic structures.[5] The construction of a well defined rigid dendritic structure around a redox-active metal complex unit may result in interesting electrochemical and optical changes.

Herein, we report the first rigid metallodendrimer containing $[Ru(tpy)_2]^{2+}$ in the interior core. The synthesis of the new 1,3,5-phenylene-based dendritic ligand **3** was performed using the methodology developed by Miller *et al.* (Scheme 1).[6] The terpyridyl core **1** was obtained from 3,5-dibromobenzaldehyde and 1-(2-pyridylcarbonylmethyl)pyridinium iodide according to the literature.[7] The dendron **2** was prepared in a stepwise manner through a Suzuki coupling reaction between an arylboronic acid and 3,5-dibromo-1-(trimethylsilyl)benzene.[8] Finally, the coupling of **2** to **1** using $Pd(PPh_3)_4$ as a catalyst proceeded smoothly to give the dendritic ligand **3** in 70% yield. This new dendritic ligand was characterized by ^{1}H NMR and matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometric techniques. MALDI-TOF mass spectra of **3** gave the correct molecular peak ($[M + H^+]$ *m/z* = 1823). Fig. 1 shows the ^{1}H NMR spectrum of **3** in $CDCl_3$ which provides structural information. The ^{1}H NMR spectrum in the aromatic region of **3** is very simple and readily assignable and indicates the successive generation of a highly symmetric layered structure.

Treatment of **3** with $RuCl_3 \cdot 3H_2O$ generated the desired metallodendrimer $[Ru(\mathbf{3})_2]^{2+}$ (Scheme 2) which was purified by column chromatography after anion exchange with hexafluorophosphate ion. The presence of *tert*-butyl groups at the exterior positions of the dendrimer completely encapsulates the $Ru(tpy)_2$ core and enhances the hydrophobicity with metallodendrimer $[Ru(\mathbf{3})_2]^{2+}$ being highly soluble in a variety of organic solvents such as alkanes, but not in polar solvents such as acetonitrile and alcohols. By contrast, the low molecular weight complex bis(4′-(*p*-tolyl)-2,2′:6′,2″-terpyridyl)ruthenium(II) complex ($[Ru(tpy\text{-}phMe)_2]^{2+}$) only showed solubility in polar solvents. The Homogeneity of $[Ru(\mathbf{3})_2]^{2+}$ was demonstrated by GPC analyses and MALDI-TOF mass spectrometry. Examination by GPC analysis showed that $[Ru(\mathbf{3})_2]^{2+}$ has a sharp and symmetrical elution peak with a polydispersity (M_w/M_n) of < 1.01. The MALDI-TOF mass spectrum of $[Ru(\mathbf{3})_2]^{2+}$ gave the correct mass at *m/z* 3891 for the $[M - PF_6]$ peak. Fig. 2 shows the absorption spectra of **3** and $[Ru(\mathbf{3})_2]^{2+}$, with absorption maxima (λ_{max}) and molar absorption coefficients (ε) collected in Table 1. The spectrum of $[Ru(\mathbf{3})_2]^{2+}$ in the visible region showed a characteristic MLCT transition at 490 nm, indicating the formation of a $[Ru(tpy)_2]^{2+}$ core.[10] The molecular coefficient for the MLCT band of $[Ru(\mathbf{3})_2]^{2+}$ was almost the same as that of $[Ru(tpy\text{-}phMe)_2]^{2+}$. Moreover, the absorbance at 260 nm of $[Ru(\mathbf{3})_2]^{2+}$ was approximately double that of the dendritic ligand **3**. As revealed by a computer generated ball-and-stick model, the dendritic ligand **3** is a hemispherical structure with a radius of *ca.* 1.5 nm (Scheme 2). The metallodendrimer $[Ru(\mathbf{3})_2]^{2+}$ is thus formed by metal-mediated



Scheme 1

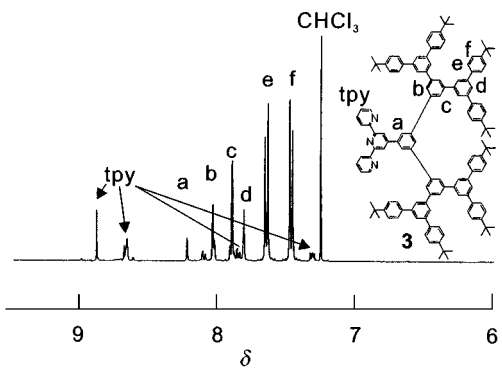


Fig. 1 ^{1}H NMR spectrum of **3** in $CDCl_3$.

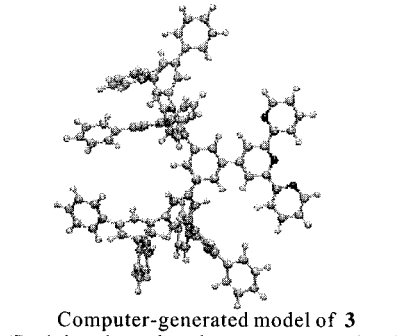
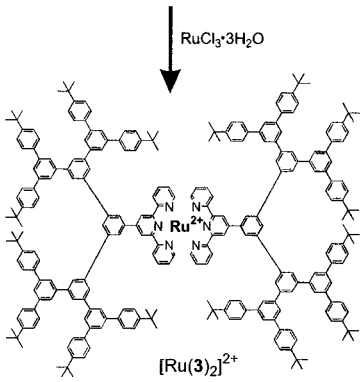


Computer-generated model of **3**
(Peripheral *tert*-butyl groups were omitted)



Scheme 2

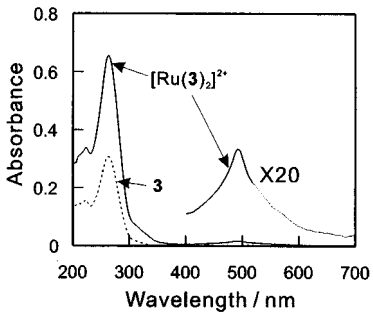


Fig. 2 UV–VIS absorption spectra of **3** and $[Ru(\mathbf{3})_2]^{2+}$ in CH_2Cl_2. ([**3**], $[Ru(\mathbf{3})_2]^{2+}$ = 1.0 μM).

assembly through the formation of a metal complex between two ligands possessing well defined hemispherical dendritic structures and one Ru^{2+} ion.

The influence of the rigid dendritic branches on the redox properties of the redox-active $[Ru(tpy)_2]^{2+}$ core was studied by cyclic voltammetry in CH_2Cl_2 using Bu_4NPF_6 (0.1 M) as supporting electrolyte (Table 1). The metallodendrimer $[Ru(\mathbf{3})_2]^{2+}$ exhibited one oxidation ($E_{1/2}$ = +1.25 V *vs.* SCE) and two reduction processes ($E_{1/2}$ = −1.28 and −1.43 V *vs.* SCE). The average peak potentials ($E_{1/2}$) for these processes were almost the same as those of the non-dendiritic $[Ru(tpy\text{-}phMe)_2]^{2+}$ complex.[4a,9] However, $[Ru(\mathbf{3})_2]^{2+}$ showed a large voltage difference between the current maxima of the reduction and return oxidation wave (ΔE), indicative of slower electron transfer than for the non-dendritic complex. This observation was similar to the electrochemical results of a flexible metallodendrimer containing redox-active core subunits.[3,4] The rigid dendritic branches around the $[Ru(tpy)_2]^{2+}$ core lead to a distance of 1.5 nm between the core and the electrode surface. The remoteness of the redox-active core from the electrode surface was found to hinder the electron transfer processes.

Table 1 Structural, spectroscopic and electrochemical data for $[Ru(\mathbf{3})_2]^{2+}$

	m/z[a]	Absorption[b] λ_{max}/nm (ε/M^{-1} cm^{-1})	$E_{1/2}$[c]/V *vs.* SCE	ΔE[c]/ mV
$[Ru(\mathbf{3})_2]^{2+}$	3891	490 (25000)	+1.25	180
	[M − PF_6^-]	260 (653000)	−1.28	120
			−1.43	125
$[Ru(tpy\text{-}phMe)_2]^{2+}$		490 (28900)	+1.20	76
			−1.24	71
			−1.46	83

[a] *m/z* Value determined by MALDI-TOF experiments. [b] CH_2Cl_2 solution. [c] From cyclic voltammetry in CH_2Cl_2 solution, 100 mV s^{-1} scan rate, Bu_4NPF_6 supporting electrolyte, Pt electrode, Ag/AgCl reference. $E_{1/2}$ is defined as the average of the two voltages at the current maximum/minimum of the redox waves. ΔE is defined as the difference of the peak voltages for the reduction and return oxidation waves.

In summary, we have reported the construction of a new rigid metallodendrimer, in which the metal complex is encapsulated in a precise position within the rigid dendritic macromolecule. Further photochemical investigations of the rigid metallodendrimer are currently in progress.

This research was supported in part by a Grant-in-Aid for COE Research 'Advanced Fiber/Textile Science and Technology' (#10CE2003) and Scientific Research (#11450366) from the Ministry of Education, Science, Sports and Culture of Japan.

The first ester complexes of bismuth(III) using thiolate anchored bifunctional ligands

Glen G. Briand, Neil Burford* and T. Stanley Cameron*

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia B3H 4J3, Canada. E-mail: burford@is.da.ca

Received (in Bloomington, IN, USA) 1st September 1999, Accepted 11th November 1999

The isolation and characterization of bismuth complexes involving ester functionalities on bifunctional ligands demonstrates the use of thiolates as anchors for weaker donors and in the context of the medicinal relevance of bismuth compounds, offers the opportunity to study the interaction of all biorelevant functional groups with bismuth.

The developing coordination chemistry of bismuth is hindered by the facile hydrolysis of most bismuth–element bonds to give the bismuthyl unit (BiO^+), which involves essentially quantitative precipitation.[1] Consequently, complexes of weakly donating functionalities can only be isolated in the absence of moisture and many conventional types of ligand have not yet been observed on bismuth. The high thermal and hydrolytic stability of the sulfur–bismuth bond[2] has enabled synthetic control using bifunctional ligands involving a thiolate anchor,[3] which offer the additional advantage of satisfying the high coordinative capacity of the bismuth center and thereby inhibit intermolecular interactions and coordination polymerisation. As a result, the complexes exhibit relatively high solubility allowing for crystallization and structural and spectroscopic characterization. We have exploited these realizations to prepare the first examples of ester complexes of bismuth, despite the relatively low basicity of the ester (carbonyl) (pK_b 21.5; *cf.* OH pK_b 16.5, NR_2 pK_b 9.2, CO_2^- pK_b 9.2) functionality. The significance of these new complexes lies in their relationship to the extensive and medicinally relevant carboxylate chemistry of bismuth. In this context, one of the new ester complexes adopts a pendant donor intermolecular arrangement that is reminiscent of the ubiquitous dimer structure **1** observed for the most extensively studied colloidal bismuth subcitrate (CBS).[1,4–7]

Reactions of potassium (methylester)methanethiolate with bismuth(III) chloride in 95% ethanol at the appropriate stoichiometry give bis[(methylester)methanethiolato]bismuth(III) chloride **2** (2:1) and tris[(methylester)methanethiolato]bismuth(III) **3** (3:1), respectively.†‡ Reaction of (methylester)methanethiol with bismuth(III) chloride also give **2**, which was identified by its distinctive Raman spectrum as the dominant product, independent of reaction stoichiometry (4:1, 3:1, 2:1).

Compound **2** adopts a one-dimensional polymeric array in the solid state (Fig. 1), with hepta-coordination for bismuth imposed by four equatorially disposed sulfur centers, two oxygen centers (carbonyl) and one chlorine center. The long and essentially equivalent Bi–S distances result from the strong

trans influence[8] induced by intermolecular Bi–S contacts [S(1)-Bi–S(2a) 154.5(2) and S(2)–Bi–S(1a) 170.3(1)°]. Although a molecular unit represented by drawing **2** is indistinguishable in the polymeric solid state structure, the analogy with the more molecular hydroxy/thio **4a**[9] and amino/thio **4b**[3,9,10] derivatives is important. We attribute the more polymeric structure of **2** to the restrictions imposed by the backbone sp^2 hybridized carbonyl carbon center and the consequential chelate ring strain.

The structure of the tris(esterthiolato)bismuth complex (Fig. 2) may, at first glance, be viewed as two tris-chelated bismuth centers **3**, as observed for the keto/thiolate **5a**[11] and aminothiolate complexes **5b**.[3] However, closer inspection of the Bi–S bond distances [*i.e.* Bi···S(2a), 3.331(2) is substantially longer than Bi–S(2), 2.608(2), Table 1] reveals that one of the ligands clearly functions as an internuclear (Bi···Bi) bridge, rather than a chelating ligand, imposing a distinct dimer structure $(\mathbf{3})_2$. In comparison with the polymeric structure of **2**, substitution of the chloride for a third thiolate is manifested in the dislocation of the $\cdots S_2BiS_2Bi\cdots$ chain with consequential enhancement (shortening) of the three facial thiolate interactions (Table 1).

The dimeric structure $(\mathbf{3})_2$ imposed by the pendant ester is analogous to that observed for CBS **1**.[12] In contrast, the methyl groups preclude the interdimer interactions observed in the carboxylate complexes, resulting in a relatively simple molecular structure and highlighting the ester functionality as an important stepping stone to understanding the carboxylate chemistry of bismuth.

The identification and isolation of the first ester complexes of bismuth is demonstrative of the synthetic value of the thiolate as an anchor for weaker donors at the other terminus of bifunctional ligands. In the compelling quest to understand the bioactivity of bismuth compounds,[13–15] we now have the opportunity to study the interaction of all biorelevant functional groups with bismuth. For example, we are currently developing synthetic procedures towards bifunctional thiolate/amide [$C(O)NR_2$] ligand complexes, which represent an alternative derivatization of the carboxylate functionality and for which we anticipate an intermediate number of intermolecular interactions between those of the carboxylate and ester complexes.

First triphenylene based non-symmetric donor–acceptor triple mesogen possessing disc-like and rod-like characteristics

Swen Mahlstedt,[a] Dietmar Janietz,*[a] Andreas Stracke[b] and Joachim H. Wendorff[b]

[a] *Universität Potsdam, Fachbereich Chemie und Institut für Dünnschichttechnologie, Kantstr. 55, D-14513 Teltow, Germany. E-mail: janietz@rz.uni-potsdam.de*

[b] *Universität Marburg, Institut für Physikalische Chemie und Wissenschaftliches Zentrum für Materialwissenschaften, Hans-Meerweinstr., D-35032, Marburg, Germany*

Received (in Cambridge) 27th September 1999, Accepted 16th November 1999

The synthesis and thermal properties of a novel donor–acceptor mesogen which is composed of a disc-like triphenyl ene donor group linked to a flat trinitrofluorenone acceptor *via* a rod-shaped azobenzene moiety are presented.

Thermotropic liquid crystals may be composed of molecules possessing rod-shaped as well as disc-like anisometric geometry. The molecular shape is known to determine the type of mesophase that is formed. Rod-like mesogens predominantly form smectic phases whereas molecules possessing on average a flat rigid core surrounded by a certain number of long flexible side chains preferably organize into columnar mesophases. A disadvantage for certain applications is that disc-like and rod-like mesogens are not miscible and that phase separation occurs on a macroscopic scale. Even the chemical linkage of molecular sub-units with different anisometric shapes *via* flexible spacers[1–3] does not necessarily lead to mesomorphic properties.

On the other hand, self-organization with formation of liquid crystalline structures can arise from attractive intermolecular interactions such as hydrogen bonding or charge-transfer complex formation between complementary molecules. For example, CT interactions between flat aromatic electron donors such as triphenylene ethers or radial multialkynylbenzene compounds with acceptor molecules may cause the stabilization as well as the induction of columnar mesophases.[4–6]

The combination of the two principles, molecular geometry and CT interactions, has led to the design of charge-transfer twin molecules with a flat electron donor group separated from an intramolecular acceptor function by a flexible alkyl spacer.[7–9] It could be shown that the chemical linkage of the donor with an acceptor molecular sub-unit gives rise to liquid crystalline structures that cannot be achieved by simple mixing of the components.

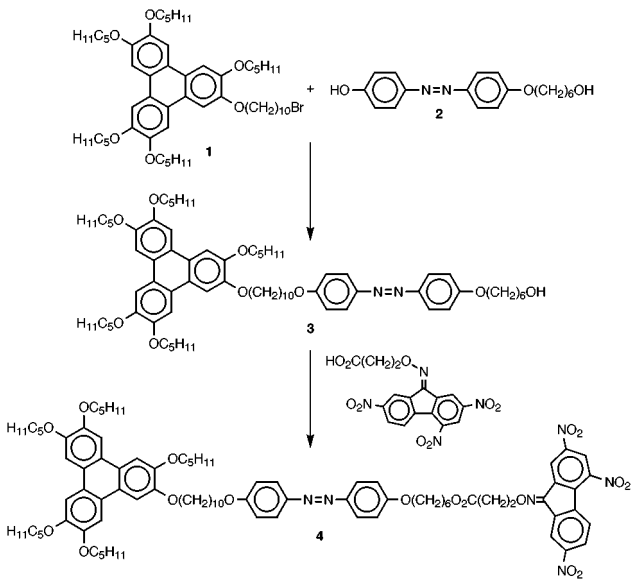
The concept is that the covalent linking of a disc-like donor to a calamitic moiety, with structure formation tendencies promoted by an additional intramolecular acceptor function, will avoid destruction of mesomorphic order. New aspects for the control of supramolecular structures may arise from this combination of three structural elements, differing in shape and functionality, within one molecule. Recently we reported the first compounds aimed to realize this concept. These are charge-transfer molecules with a calamitic group placed between an enlarged pentaalkynylbenzene donor and a flat acceptor moiety. The novel compounds were found to display a nematic-columnar like phase with the individual columns separated by rod-like groups.[10]

We present here the non-symmetric trimer **4** which is the first disc-rod triple mesogen composed of a disc-like alkoxy-substituted triphenylene donor group and a nitrofluorenone based acceptor unit, the two complementary parts being linked chemically *via* alkyl spacers to the termini of a rigid rod-shaped azobenzene moiety.

As shown in Scheme 1, the reaction sequence leading towards the donor–acceptor triple molecule **4** starts out from the alkoxytriphenylene **1** carrying one terminal bromine substituent. Compound **1** was converted into the non-symmetric dimer **3**, which combines a disc-like triphenylene donor and a rod-like sub-unit *via* an ether bridge, by reaction with the azobenzene derivative **2**.† Subsequent esterification of the remaining free aliphatic hydroxy group in the intermediate **3** with 3-(2,4,7-trinitrofluoren-9-ylideneaminooxy)propionic acid[7] in the presence of *N,N′*-dicyclohexylcarbodiimide and catalytic amounts of 4-dimethylaminopyridine yielded the triphenylene based trimer **4**.‡

Differential scanning calorimetry (DSC) gives evidence that the triphenylene donor–acceptor molecule **4** exhibits a glass transition at 19.4 °C followed by a phase transition into the isotropic phase at 56.3 °C (ΔH_i = 1.5 kJ mol^{-1}). Enantiotropic mesomorphic behaviour is confirmed by polarizing microscopy. The optical textures, however, are small-sized and non-specific. Considering the fact that there is no indication of liquid crystalline phase formation for the disc-rod dimer **3** it follows that, as found for charge-transfer triple mesogens based on a flat pentaalkynylbenzene donor moiety,[10] the mesophase of the triphenylene CT-triple **4** predominantly originates from donor–acceptor interactions due to the additional chemical linkage of the acceptor sub-unit. Further work is in progress to characterize charge-transfer complex formation of compound **4** spectroscopically.

The wide angle X-ray diffractogram of the triphenylene trimer **4** is presented in Fig. 1. It displays a distinct reflection in the small angle region corresponding to a distance of 1.56 nm. The value agrees approximately with the diameter of the triphenylene donor group. The amorphous halo which appears at larger scattering angles points to the liquid-like ordering of the flexible alkoxy chains. The halo is superimposed on an



Scheme 1

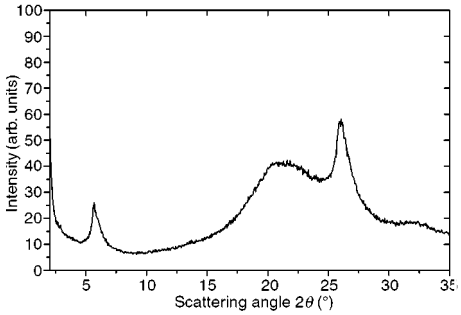


Fig. 1 Wide angle X-ray diffractogram of the triphenylene disc-rod triple mesogen **4**.

intense reflection which is characteristic for a periodical packing of flat anisometric cores in a column. The intracolumnar distances amount to 0.34 nm. This value is typical for columnar mesophases of hexaalkoxytriphenylenes doped with electron acceptors such as 2,4,7-trinitrofluoren-9-one (TNF).[4]

Certainly, the individual columns are formed through an intercalated stacking of the flat donor and acceptor groups of different molecules **4**. Furthermore, it is reasonable to suggest that the alkyl spacers connecting the three rigid molecular subunits preferably adopt more or less stretched conformations. This gives an arrangement of the calamitic moieties with their long axis predominantly oriented orthogonal rather than parallel to the column axis. The distance of 1.56 nm, corresponding to the small angle reflection, would be quite reasonable for the mean distance between adjacent columns perpendicular to the main axis of the molecules. We further have to take into account the unusually high viscosity that is observed by polarizing microscopy within the mesophase range of the triphenylene triple molecule **4**, which is typical for liquid crystalline polymers rather than for low molar mass mesogens. Therefore, we assume that as a result of the covalent linkage a one-dimensional quasi-chain incorporating the rod-shaped azobenzene units is realized which connects the alternating stacks of the donor and acceptor fragments of the molecules. A two-dimensional structure model arising from these considerations is presented schematically in Fig. 2.

The absence of mixed reflections in the small angle region indicates that the columns are not arranged on a two-dimensional lattice, rather that a layer structure exists along one direction. Further investigations are in progress to clarify this point.

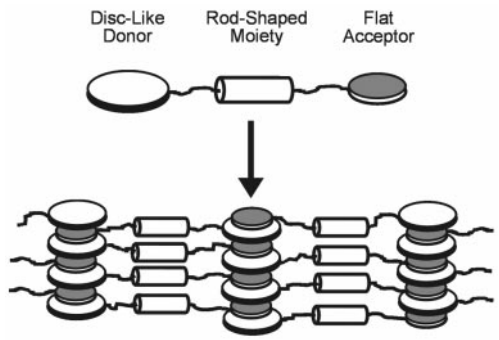

Fig. 2 Two-dimensional structure model for the novel mesophase of the donor–acceptor molecule **4** combining features of calamitic liquid crystalline phases with those of columnar mesomorphic structures. For sake of clarity the peripheral alkoxy substituents of the triphenylene donor are not shown. The appearance of only one small angle reflection along with the relatively small clearing transitional enthalpy seem to indicate a strongly distorted structure. Therefore, the model has to be considered as an 'ideal' structure at a local molecular level.

In summary, the CT-triple compound **4** is the first representative of a novel family of non-conventional thermotropic liquid crystals arising from the chemical linkage of a disc-like triphenylene donor, a rod-shaped moiety and an acceptor subunit. The concept of combining the three different structural elements in a defined manner within one molecule along with charge-transfer interactions introduced by the intramolecular acceptor function provides a powerful tool towards novel thermotropic mesophases, bridging the gap between smectic layer structures and columnar liquid crystalline phases.[12] Interesting properties such as optical biaxiality may be expected for such intermediate phases. Further work is currently in progress to modify molecular parameters such as the number of methylene groups in the spacer segments separating the three rigid moieties of the triphenylene based donor-acceptor triple mesogens.

The financial support of the Deutsche Forschungsgemeinschaft and of the Land Brandenburg is gratefully acknowledged.

Notes and references

† The 2-(6-bromodecyloxy)-3,6,7,10,11-pentapentyloxytriphenylene **1** used as the starting material was available *via* ferric chloride mediated regioselective coupling of 3,3′,4,4′-tetrapentyloxybiphenyl with 2-(6-bromodecyloxy)-1-pentyloxybenzene (ref. 11). The azobenzene compound **2** was prepared by alkylation of 4-acetylaminophenol with 6-chlorohexan-1-ol followed by acidic *N*-acetate cleavage, diazotisation of the resulting aniline and coupling with phenol.

‡ All new compounds **1**–**4** had spectroscopic data (IR, ^{1}H NMR, ^{13}C NMR) consistent with the assigned structure. *Selected data* for **4**: δ_H(300 MHz, $CDCl_3$) 8.90 (s, 1H, TNF), 8.56 (m, 2H, TNF), 8.25 (d, 1H, TNF, *J* 8.75) 8.03 (d, 1H, TNF, *J* 8.76), 7.70 (d, 4H, phenyl, *J* 8.71), 7.62 (s, 6H, phenyl), 6.89 (m, 4H, phenyl), 4.80 (t, 2H, CH_2-O-N, *J* 6.16), 4.15–4.24 (m, 12H, CH_2-O-phenyl and 2H, CH_2-O-CO), 3.95–4.02 (m, 4H, CH_2-O-phenyl), 2.95 (t, 2H, CH_2-COO, *J* 6.15), 1.25–2.05 (m, 54H, CH_2), 0.99 (t, 15H, CH_3, *J* 7.05); δ_C(300 MHz, $CDCl_3$): 170.50 (1C, COO), 161.10 (2C, phenyl C-O), 160.89 (1C, TNF C=N), 148.65 (6C, phenyl C-O), 148.42 (1C, TNF C-NO_2), 146.64 (1C, TNF C-NO_2), 146.56 (2C, phenyl C-N), 143.65 (1C, TNF C-NO_2), 138.85 (1C, TNF), 133.67 (1C, TNF), 131.25 (1C, TNF), 128.34 (1C, TNF CH), 128.78 (1C, TNF CH), 125.79 (1C, TNF), 124.13 (4C, phenyl CH), 122.72 (6C, phenyl and 1C, TNF CH), 120.52 (1C, TNF CH), 119.48 (1C, TNF CH), 114.48 (2C, phenyl CH), 114.43 (2C, phenyl CH), 106.26 (6C, phenyl CH), 72.75 (1C, CH_2-O–N), 69.29 (6C, CH_2-O-phenyl), 68.20 (1C, CH_2-O-phenyl), 67.88 (1C, CH_2-O-phenyl), 64.94 (1C, CH_2-O-CO), 34.26 (1C, CH_2-CO-O), 29.52–22.57 (27C, CH_2), 14.10 (5C, CH_3); ν(KBr)/cm^{-1} 1760 (COO), 1530 (NO_2), 1340 (NO_2).

$Hf_{27}Si_6P_{10}$, a novel metal-rich compound with P_2 groups

Chang-Cang Huang, Jörg Neuhausen and Wolfgang Tremel*

Institut für Anorganische Chemie und Analytische Chemie, Universität Mainz, Duesbergweg 10-14, D-55099 Mainz, Germany. E-mail: tremel@indigotrem1.chemie.uni-mainz.de

Received (in Cambridge, UK) 24th August 1999, Accepted 9th September 1999

The new ternary metal rich compound $Hf_{27}Si_6P_{10}$ has been synthesized by reduction of HfP with Hf and Si; $Hf_{27}Si_6P_{10}$ crystallizes in a new structure type, a characteristic and unexpected feature of which is the presence of P_2 groups; the structural results are interpreted with the aid of high-level band structure calculations.

The large family of metal-rich binary compounds that are formed between a transition metal (M) and a variety of main-group non-metals, metalloids and adjacent metals (Q) exhibit a remarkable range of compositions, structures and properties. It is surprising that these compounds challenge our basic assumptions about the chemistry of the transition elements and our chemical understanding in general. The existence and structure of none of these compounds can be predicted *a priori* and a rationalization of their structures *a posteriori* does not give chemically conclusive hints why seemingly simply binary compounds of the early transition metals (*e.g.* with composition M_2Q) display as many differences as they do.[1–5] Furthermore, the possibility of metal segregation in mixed-metal systems allows the formation of pseudo-binaries (M–M′)–Q which have no counterparts in the binary systems.[6]

Nonetheless, this group of compounds also shows some common characteristics regarding their structures as well as their electronic and bonding features. (i) In all known representatives the non-metal atoms are situated in capped trigonal-prismatic voids of the metal sublattice, and there are no filled voids adjacent to each other, *i.e.* from a topological point of view, there is no possibility for Q–Q bonding. (ii) Owing to appreciable differences in the electronegativities and valence energies of the component atoms, pnictides may be viewed as polar intermetallics; the more electronegative main-group element in these compounds contributes mostly to the low-lying valence band, especially for compounds of the early transition metals, whereas the conduction band has large contributions from the metal atoms. The stability is mostly based on strong heteroatom M–Q bonding; in addition, metal-rich phases also exhibit strong M–M but no Q–Q bonding.[7]

In the quest for new metal-rich quasi-binary early transition metal pnictides we have investigated reactions in the system M–Q–Q′ (M = Zr, Hf; Q = P, As, S, Se; Q′ = Si), the rationale behind this synthetic approach being to mimic the electron count in known binary compounds by the use of three components. $Hf_{27}Si_6P_{10}$ was prepared in a two step synthesis. To avoid a loss of P during the arc melting, HfP[8] was synthesised in a silica tube at 800 °C from the elements in a 1 : 1 ratio. In the second step, stoichiometric mixtures of HfP, Hf and Si were pressed into pellets with a hydraulic press. The pellets were melted under argon on a water-cooled copper hearth. Reactions with the approximate starting compositions 'Hf_6SiP_2' led to homogeneous products. EDX investigations on selected crystals indicated a phase width of ±10% within the limits of accuracy. According to the results of the X-ray structure determination[9] $Hf_{27}Si_6P_{10}$ crystallizes in a new structure type which contains fragments of a *bcc* packing. The crystal structure is depicted in a projection along the short *a* axis in Fig. 1. All atoms are located at $x = 0$ or 0.5 along the crystallographic *a* axis, *i.e.* each layer in Fig. 1 is fused to identical layers above and below the projection plane. The unit cell contains 54 metal atoms (nine crystallographically independent metal atoms per asymmetric unit) and 32 Si and P atoms (which cannot be distinguished by X-ray diffraction). The P and Si atoms are located in mono-, bi- and tri-capped trigonal Hf prisms with Hf–P/Si bond lengths ranging between 2.572(6) and 3.083(7) Å, where the larger Si atoms are assumed to be located in the nine-coordinate sites (Si and P mixing on the non-metal positions, however, cannot be ruled out). Based on this assumption the composition $Hf_{27}Si_6P_{10}$, in agreement with the analytical results, has been assigned. In an alternative description the $Hf_{27}Q_{16}$ structure may be viewed as being built up from M_6Q_8 clusters and cluster fragments.[10] The $Hf_{27}Q_{16}$ structure contains two variants of fused M_6Q_8 clusters that are condensed *via* common corners along [100]: Hf_5 fragments of the Hf_6Q_8 cluster where a Hf atom from the equatorial plane of the complete Hf_6X_8 unit is missing, and two types of Hf_6Q_8 clusters which are linked *via* common corners with Hf_5 and Hf_6 units. The first type of Hf_6Q_8 cluster (dark grey in Fig. 1) is linked to four Hf_5 units (medium grey) in the projection plane to give an entity with a 'bow-tie' shape. The second type of Hf_6Q_8 cluster (shown in light grey) is connected to two Hf_5 and two Hf_6 units in such a way that four type-2 Hf_6Q_8 clusters form a tetrameric entity. The entity in turn is linked by sharing common corners with four Hf_5 units. These condensed cluster units form a ribbon-like pattern along [001] which is highlighted in Fig. 1. Each of these ribbons is fused with two adjacent ribbons by Hf–Hf bonds and by sharing common P/Si atoms. Thus, all Hf atoms belong either to Hf_5 or Hf_6 units.

The shortest Hf–Hf bonds occur between the apical and basal atoms of the cluster units [distances ranging from 3.035(1) to 3.215(1) Å], whereas the equatorial Hf–Hf distances are significantly longer [3.544(2)–3.825(2) Å]. As is apparent from the length of the *b* axis, the octahedra are tetragonally compressed; as a result, the distances between the apical Hf atoms are 3.573(1) Å.

The most important and unexpected feature of the $Hf_{27}Q_{16}$ structure are two short P–P separations of 2.58(2) and 2.69(13) Å which are clearly in the bonding range. In addition, the Hf–Hf contacts across the P–P units are, at 3.270(2) and 3.225(1) Å,

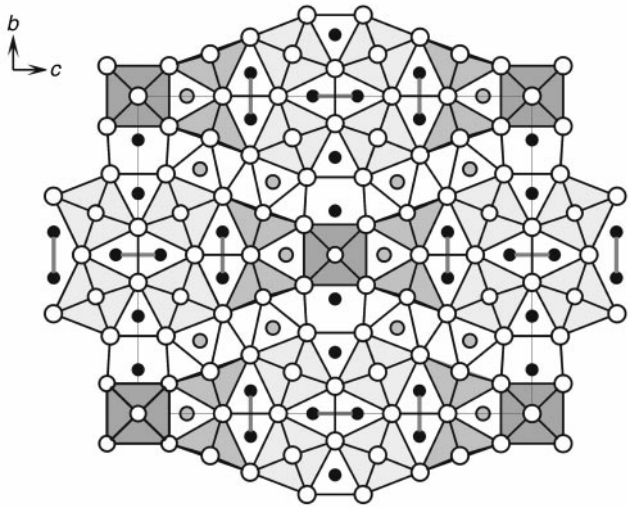

Fig. 1 View of the $Hf_{27}Si_6P_{10}$ structure along *a*. White circles, Hf atoms; grey circles, Si atoms; black circles, P atoms.

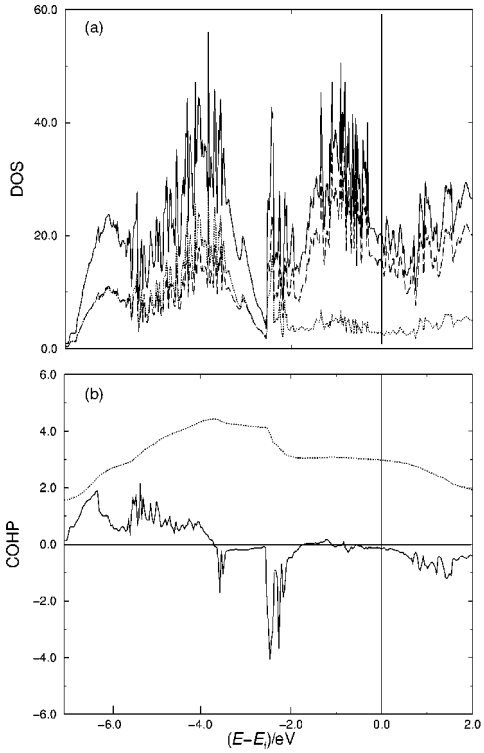

Fig. 2 (a) LMTO density of states for '$Hf_{27}P_{16}$'; solid line: total DOS; dashed line: Hf contribution; dotted line: Si/P contribution. The Fermi level is indicated by the vertical bar. (b) Crystal orbital Hamiltonian populations (COHP) for the P–P interactions. Upper part of the diagram is bonding, the lower part antibonding. The dotted line represents the integrated P–P overlap population.

very short. Based on Pauling's formula[11] $d_n = d_1 - 0.6 \log n$, the bond orders for the P–P contacts are 0.23 and 0.15 *i.e.* P–P bonding is present to a significant extent. These empirical results are also supported by the results of first-principles *ab initio* band structure calculations (*vide infra*) that have been performed on hypothetical $Hf_{27}P_{16}$ (the binary electron-rich end member of the ternary system $Hf_{27}Si_xP_{16-x}$ where the weakest P–P interactions might be expected). The presence of non-metal–non-metal bonding interactions in metal-rich compounds of an early transition metal is remarkable for at least two reasons: (i) since the non-metal atoms are the more electronegative partners in these compounds, the non-metal states should be occupied whereas the high-lying metal states are about to be filled. As a result, bonding interactions between non-metal atoms are unlikely. (ii) The non-metal atoms are situated in the voids of the metal sublattice and the probability of having filled voids adjacent to each other decreases with increasing M:Q ratio.

The $Hf_{27}Q_{16}$ structure contains two adjacent bicapped trigonal-prismatic sites. One of them is embranced by four Hf_6 clusters of the tetrameric unit, while the second is located at the intersection of the tetrameric unit and the 'bow-tie' shaped fragment. In order to clarify if this topological arrangement is only accidental, or if P–P interactions are significant for the structure stability, we have analysed the electronic structure of the title compound.

Considering the short P–P contacts as P–P bonds the electronic structure of $Hf_{27}Q_{16}$ may be formally described as $(Hf^{1.78+})_{27}(Si^{4-})_6(P_2{}^{4-})_3(P^{3-})_4$, *i.e.* approximately two electrons are available for each Hf atom for metal–metal bonding. According to the results of TB–LMTO–ASA calculations[12] the 3p block of the Si and P atoms is located well below the Fermi level. Fig. 2 shows the computed total density of states for hypothetical '$Hf_{27}P_{16}$' with the metal and non-metal contribution [Fig. 2(a)] as well as the results of the P–P bonding analysis in form of the COHP plot [Fig. 2(b)]. The P–P bonding states are separated by a small gap from the antibonding states that appear to be very localised just below −2 eV. The strong localisation indicates that a fraction of the P 3p orbitals is preferentially engaged in P–P bonding. A significant density of states is found at the Fermi level. Considering the M–M bonds along all directions in the structure of $Hf_{27}Q_{16}$, metallic properties can be safely assumed. The different site preferences for Si and P can be understood based on the differences in M–Q bonding. The bonding analysis of '$Hf_{27}P_{16}$' shows that higher bond orders are associated with the higher coordinated sites, and this situation should be increased for Si because of the greater expansion of the 3p orbitals and the lower electronegativity of Si relative to P.

In summary, $Hf_{27}Q_{16}$ is a metal-rich compound of an early transition metal whose structure is stabilized to a significant extent by bonding between the non-metal atoms. This is associated with a partial electron transfer from the anionic to the cationic components, which has also been observed for metal tellurides;[13,14] a comparable feature has been reported for two compounds of the heavy group homologues, Hf_6TiSb_4[15] and $(Zr, V)_{13}Sb_{10}$,[16] but is unprecedented for the lighter congeners.

This work was supported by the Fonds der Chemischen Industrie. We are indebted to Heraeus Quarzschmelze Hanau (Dr Höfer) for a generous gift of silica tubes.

Bucky-bowls. A general approach to benzocorannulenes: synthesis of mono-, di- and tri-benzocorannulenes

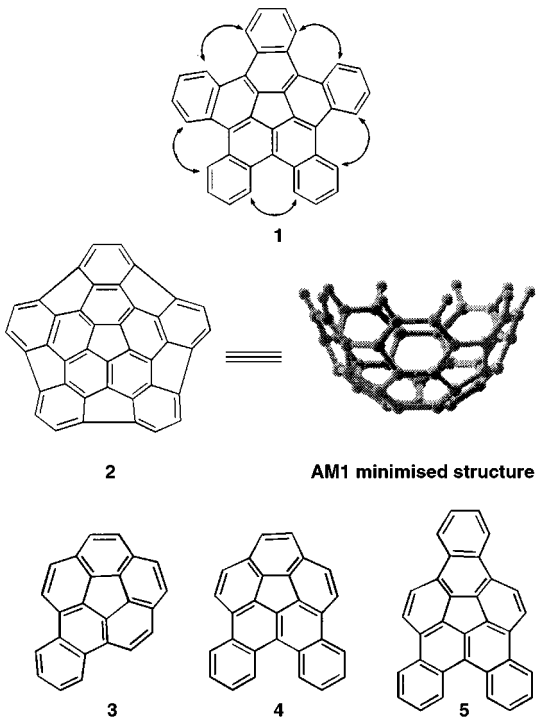
Goverdhan Mehta* and P. V. V. Srirama Sarma

Department of Organic Chemistry, Indian Institute of Science, Bangalore, 560 012 India.
E-mail: diroff@admin.iisc.ernet.in

Received (in Cambridge, UK) 8th November 1999, Accepted 16th November 1999

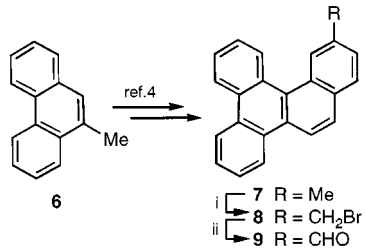
We outline a conceptually simple and general route to bowl-shaped benzocorannulenes based on readily assembled PAHs which on flash vacuum pyrolysis result in the sequential formation of a five- and six-membered ring; following this approach, syntheses of mono-, di- and tri-benzocorannulenes have been achieved.

As a part of our continuing interest in the synthesis of C_{60} fullerene (bucky-ball) and its fragments (bucky-bowls),[1,2] we became interested in developing a synthetic approach to pentabenzocorannulene **1** *en route* (see transannular bridging indicated in **1**) to the 'deep-bowl' **2**, $C_{40}H_{10}$.[3] Bowl-shaped **1** and **2** represent 2/3 of the carbon content of C_{60} with eleven and sixteen rings, respectively, constituting a dominant cross-section on the fullerene surface. Both **1** and **2** evoke considerable synthetic interest and are formidable objectives. As a prelude to efforts towards **1** and **2**, we have developed a new and



general synthetic route to benzoannulated corannulenes in which an appropriately constructed aromatic array upon flash vacuum pyrolysis (FVP) undergoes two-fold C–C bond formation involving cyclodehydrogenation to generate a five-membered ring, followed by insertion of vinylidene carbene or equivalent species to form a six-membered ring. Herein, we report the synthesis of mono-, di- and tri-benzocorannulenes **3**–**5**.

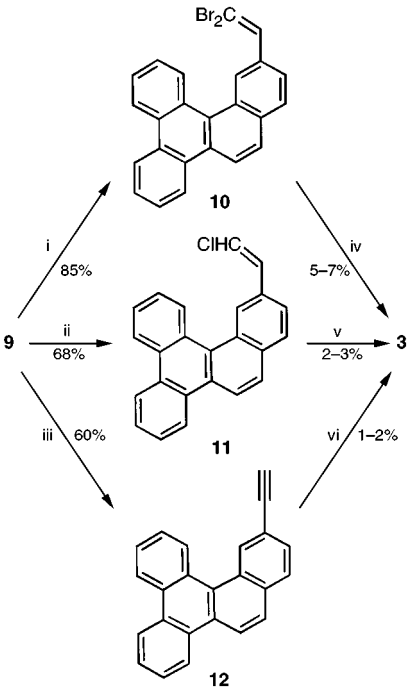
Our approach to benzocorannulene **3** emanated from 13-methylbenzo[*g*]chrysene **7**, readily available from 9-methylphenanthrene **6** through a tactical modification of the reported



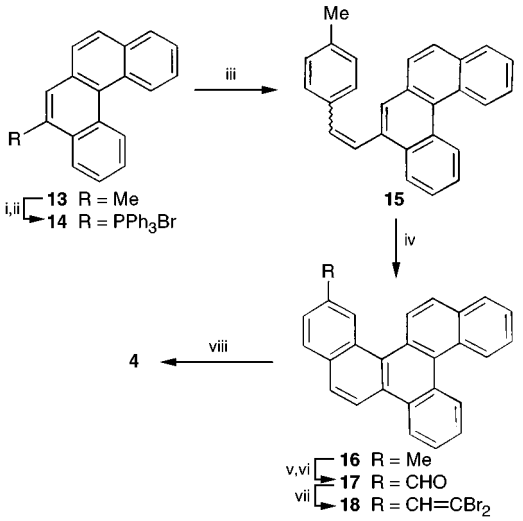
Scheme 1 *Reagents and conditions*: i, NBS, AIBN, CCl_4, 73%; ii, $(Bu_4N)_2Cr_2O_7$, $CHCl_3$, 76%.

procedure.[4] The methyl group in **7** was oxidised to the required aldehyde **9** in two steps *via* the intermediate bromide **8** (Scheme 1). The aldehyde functionality in **9** was then elaborated to **10**–**12** having active functionalities, which on thermal activation under FVP conditions were expected to result in the projected two-fold cyclization. Indeed, FVP of **10**–**12** furnished **3**, albeit in low yields characteristic of such reactions (Scheme 2).[2] Benzocorannulene **3** was readily identified through its spectral characteristics (UV, 2D NMR, mass).[5,6]

Our approach to dibenzocorannulene **4** originated from 5-methylbenzo[*c*]phenanthrene **13**, in turn readily accessible from commercial 2-methylnaphthalene.[7] Naphthoannulation on **13** through the intermediacy of the Wittig salt **14** and photocyclization of the resulting stilbene derivative **15** led to 13-methyldibenzo[*c*,*p*]chrysene **16** (Scheme 3). The methyl



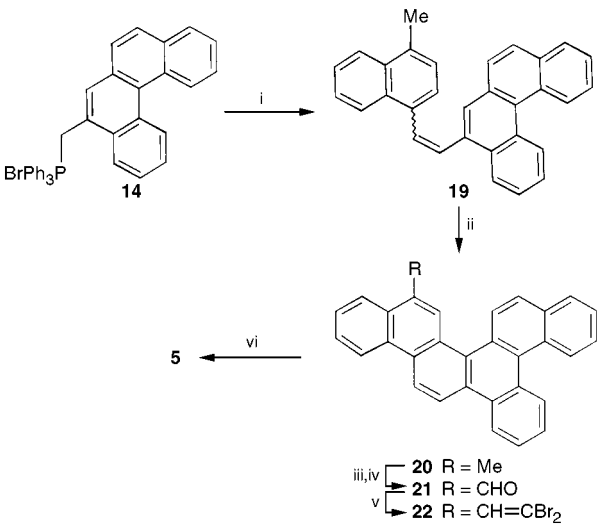
Scheme 2 *Reagents and conditions*: i, CBr_4, PPh_3, Zn, CH_2Cl_2, 85%; ii, $ClCH_2PPh_3Cl$, Bu^tOK, 0.5 h, 68%; iii, $ClCH_2PPh_3Cl$, Bu^tOK, 2 h, 60%; iv, FVP, 1150 °C, 5–7%; v, FVP, 1150 °C, 2–3%; vi, FVP, 1150 °C, 1–2%.



Scheme 3 *Reagents and conditions*: i, NBS 99%; ii, PPh_3, C_6H_6, 79%; iii, *p*-MeC_6H_4CHO, Cs_2CO_3, Pr^iOH, 80%; iv, *hv*, I_2, C_6H_6, propylene oxide, 65%; v, NBS, CCl_4, 44%; vi, $(Bu_4N)_2Cr_2O_7$, $CHCl_3$, 77%; vii, CBr_4, PPh_3, Zn, CH_2Cl_2, 85%; viii, FVP, 1150 °C, 5–7%.

group in **16** was oxidised to the aldehyde **17** and in the light of the relatively more efficient conversion **10**→**3** was further transformed to the hexacyclic *gem*-dibromoalkene **18**, the desired FVP precursor. On thermal activation **18** underwent the expected double cyclization to furnish the new dibenzocorannulene **4** and was fully characterised on the basis of incisive spectral analyses[5] (Scheme 3).

Interestingly, 5-methylbenzo[*c*]phenanthrene **13** and the Wittig salt **14** derived from it also served as the precursor for the synthesis of tribenzocorannulene **5**. Wittig coupling between **14** and 4-methylnaphthaldehyde gave **19** which on photocyclization led to the naphtho[1,2-*f*]picene derivative **20** (Scheme 4). The methyl group in **20** was again elaborated to the aldehyde **21** and further to the FVP precursor **22**. As planned, FVP on **22**



Scheme 4 *Reagents and conditions*: i, 4-methylnaphthaldehyde, Cs_2CO_3, Pr^iOH; ii, *hv*, I_2, C_6H_6, propylene oxide, 50% (2 steps); iii, NBS, CCl_4, 45%; iv, $(Bu_4N)_2Cr_2O_7$, $CHCl_3$, 70%; v, CBr_4, PPh_3, Zn, CH_2Cl_2, 55%; vi, FVP, 1150 °C, 1–2%.

furnished the desired tribenzocorannulene **5**, which was spectroscopically characterised (Scheme 4).[5,6]

In short, we have accomplished the syntheses of bowl-shaped benzocorannulenes **3**–**5** from appropriate polycyclic aromatics employing FVP as the key step, in which a five- and a six-membered rings are sequentially formed. The precursor polycyclic platforms were assembled from simple aromatic starting materials through an iterative sequence involving Wittig olefination and photocyclization steps. Notwithstanding the low yields in the final FVP step, which is not uncommon for such cyclizations,[1,2] this work demonstrates the generality of our approach and sets the stage for the synthesis of **1** and **2**.

We thank JNCASR for financial support and the SIF facility at I.I.Sc for high field NMR data. One of us (P. V. V. S. S.) thanks CSIR for a research fellowship. We thank Professor L. T. Scott for generously providing copies of spectra for comparison purposes.

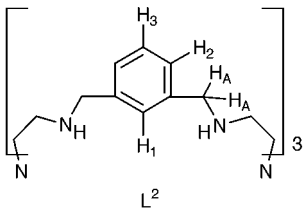
Received (in Basel, Switzerland) 21st October 1999, Accepted 12th November 1999

An aminocryptand host enforces approach of encapsulated Tl(I) ions to just within 4.4 Å; despite this relatively large separation, strong Tl(I)···Tl(I) interaction is observed and the aromatic proton of the bridging link exhibits a large through-space coupling to the pair of equivalent Tl nuclei.

In recent years we have become interested in the consequences of enforced proximity between cations encapsulated within azacryptand hosts.[1] In the transition series, this steric enforcement generates a previously uncharacterised bonding situation: a one-electron bond between copper ions in an average-valence +1.5 redox state.[2–6] Steric enforcement of close approach for transition ions implies use of relatively small hosts such as (imBT)† and amBT(= imBT + 12H), while larger hosts such as $(N[(CH_2)_2N{=}CH(C_6H_4\text{-}m)CH{=}N(CH_2)_2]_3N$ (L^1) and its amino form L^2 (= L^1 + 12H) have suitable cavity size to accommodate



L^2

pairs of larger main group cations such as Tl^+. Our earlier studies with cryptates of L^2[7,8] and the analogous iminocryptand ligand, L^1, demonstrate[9,10] that these hosts offer internuclear distances of between 3 and 6 Å according to the preference of the guest cation, as the cryptands can make use of a triple helical twist mechanism[11,12] which allows them to adapt to the preferred coordination site separation of the cationic guests.

There is interest[13] among bonding theorists in interactions between the formally closed shell low-valent p-block cations. In a number of dimeric and oligomeric structures[13,14] with Tl···Tl distances (some supported by bridging donors) ranging from 3.5 to 4.0 Å, there is evidence for varying degrees of $s^2\cdots s^2$ interaction. Another point of interest is the possible existence of weakly attractive arene···heavy metal interactions,[15], which could assist the close approach of Tl(I) ions.

The dithallium(I) cryptates of L^2 are synthesised‡ by direct reaction of preformed ligand with the appropriate thallium(I) salt. ^1H NMR studies on the triflate salt, $Tl_2L^2(CF_3SO_3)_2$ **1,** in the solid state and in solution, suggest a simple and symmetric structure where each Tl(I) cation occupies the site defined by the N4 cap. There is evidence of a low-activation dynamic process in solution in that both methylene-cap signals of **1** present as broad temperature-independent singlet resonances with no discernible fine structure due to geminal or vicinal [^1H,^1H] methylene coupling. Sharp signals for the H_2 and H_3 resonances show well defined ortho coupling; however the expected singlet H_1 resonance (Ar_1), which in analogous L^1 disilver(I) and dicopper(I) iminocryptates[16] is strongly affected by guest encapsulation both in respect of breadth and position, appears here as a severely broadened triplet (apparent ^1J ($^{205,203}Tl$,^1H) ≈ 17 Hz) at δ *ca.* 6.8. The triplet structure is just discernible at 400 MHz; broadening is a function of the magnetic field, approximating to 16:9:6 for 400, 300 and 250 MHz spectra, in proportion to the square of the magnetic field used [Fig 1(a)]. The signal from the methylene H_A hydrogens adjacent to the aromatic ring is a similarly broadened triplet [Fig 1(b)] and decoupling experiments fail to relate the coupling of the broad triplets to any proton resonance. Also the resonances are not narrowed significantly at high temperature, thus ruling out broadening *via* an exchange process. These observations implicate through-space coupling to thallium, the latter relaxing by a chemical shift anisotropy mechanism.[17] The splitting of the α-methylene signal confirms that the two $^{205,203}Tl$ nuclei couple to each other with J(Tl,Tl) > > 17 Hz, an example of the strong coupling case.[17b] The size of the coupling to the lone Ar_1 hydrogen is unexpected because no formal bond to thallium exists. Nor can it be explained on a through-bond basis as, despite an identical bond pathway, the H_3 resonance shows no thallium coupling. It appears that this coupling has to be explained on the basis of interaction between the lone aromatic hydrogen Ar_1 and the pair of Tl(I) ions which, although unbonded, are constrained by geometry to lie in close proximity.

The low solubility of **1** in CD_3CN allows only a weak ^{13}C solution spectrum where the noise level hinders the unambiguous attribution of $^{205,203}Tl$, ^{13}C couplings. There are indications of such coupling in the unique Ar_1 carbon resonance which appears at δ *ca.*129.9 as a broadened ≈ 80 Hz triplet. The methylene carbons give rise to two sharp resonances at δ 57.5 and 49.3 with a broader, possibly Tl-coupled, feature at δ 54.1 representing the methylene carbon adjacent to the aromatic ring. In the CP MAS ^{13}C spectrum signal breadth is generally sufficient to conceal any $^{205,203}Tl$,^{13}C coupling although splitting of a weak resonance in the region δ 120–130 may derive from such a cause. The weak ^{15}N CP MAS spectrum obtained for **1** likewise fails to show any coupling to thallium; just one relatively broad signal (half-width 150 Hz) centered at

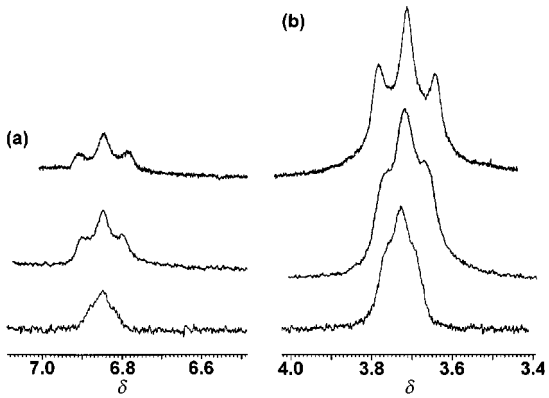


Fig. 1 The Tl-coupled Ar_1 (a) and CH_2(A) (b) resonances in different magnetic fields: bottom trace, 400; middle trace, 300; top trace, 250 MHz. (Spectra run in CD_3CN, 295 K, chemical shift in ppm from $SiMe_4$).

δ −307 (*vs.* NH_4NO_3 standard) appears, representing overlapped cryptand N(H) and N_{br} resonances.

In order to confirm the hypothesis of close approach of Tl nuclei, crystallographic evidence was sought,§ using the synchrotron source at Station 9.8 at CLRC Daresbury. The structure is illustrated in Fig. 2. The $[Tl_2L^2]^{2+}$ cation has $\bar{6}$ point symmetry and the anion lies on a threefold axis, so the asymmetric unit contains one sixth of the cation and one third of the anion. The Tl atom is coordinated to the bridgehead nitrogen (N1) and to three secondary amine groups (N11, N11A and N11B); it is displaced from the plane of the secondary amines by 1.087(3) Å towards the centre of the cavity and the Tl···TlA distance is 4.3755(4) Å. The Tl(I) cations are thus farther from the N_{br} apices than in other dinuclear cryptates we have studied.[1] The Tl–N distances are around 2.7–2.8 Å, at the long end of the range for Tl(I)–N distances,[14,18,19] suggesting a predominantly ionic character for bonding in this complex. The ligand host is fully extended to accommodate the pair of large spherical cations, and there is no helicity of cryptand strands. The structure is thus of unusually high symmetry for a cryptate. The distance between Tl(I) cations and the Ar_1 hydrogen is 3.816 Å. The shortest arene carbon···metal contact is 4.207 Å , almost 0.5 Å longer than the van der Waals sum. Edge to face intermolecular H···π contacts of *ca.* 2.49 Å involve all the arene rings.

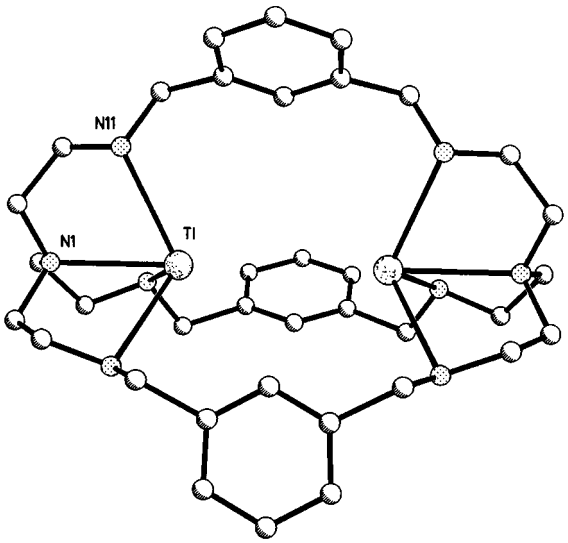

Fig. 2 Structure of $Tl_2L^2(CF_3SO_3)_2$. Selected distances (Å): Tl–N(I) 2.728(5), Tl–N(11) 2.796(3), Tl···Tl 4.3755(4), Tl··H(9) 3.816.

The structural data make it clear that the sizeable coupling between the Ar_1 proton and ^{205,203}Tl is formally through space, although the average separation of these nuclei in the dynamic solution environment may not be identical with that in the crystal where intermolecular H···π packing effects operate. The thallium–thallium coupling of >> 17 Hz must also be classified as a through space effect given the relatively large separation of Tl(I) cations, almost 1 Å greater than the internuclear distance (3.4 Å) in the element. We believe that this represents the largest recorded through-space coupling.

In most dimeric or quasi-dimeric structures,[13,14,19] Tl···Tl distances, in the range 3.6–3.9 Å are significantly shorter than noted here and the closest Tl···arene carbon distance of 3.816 Å in this structure exceeds that typical of weakly interacting arene–heavy metal systems.[19] Nonetheless, we have clear evidence of coupling between both the pair of Tl(I) cations and between this $Tl(I)_2$ pair and the unique aromatic proton Ar_1, despite the ionic character which explains the absence of ^{203,205}Tl, ^{1}H couplings elsewhere in the cryptate spectrum. It is intriguing that the only ^{203,205}Tl, ^{1}H couplings observed in this cryptate are mediated *via* a non-bonded pathway, *e.g.* that involving steric compression of the $Tl^+\cdots[H]\cdots Tl^+$ moiety. The implication is that coupling information can be efficiently transmitted in large soft cations like Tl(I) by non-directional overlap of electron density.

We thank EPSRC for access to the Solid State NMR service at Durham and to SRS station 9.8 at Daresbury. We are indebted to Dr M. Arthurs of Coventry University for the 250 MHz 1 H NMR spectrum.

Electrostatic interactions between positively charged porphyrins and nucleotides or amides: buffer-dependent dramatic changes of binding affinities and modes†

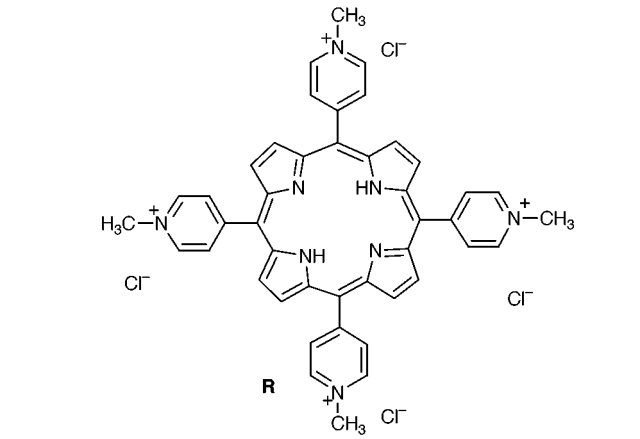
Mallena Sirish and Hans-Jörg Schneider*

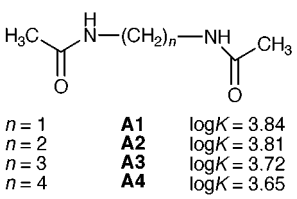
FR 11.2 Organische Chemie der Universität des Saarlandes, D-66041 Saarbrücken, Germany. E-mail: ch12hs@rz.uni-sb.de

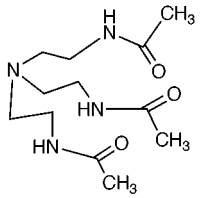
Received (in Cambridge, UK) 20th September 1999, Accepted 5th November 1999

The association strength of positively charged porphyrins with anionic species can be orders of magnitude higher than reported in the literature, depending on the chosen buffer; the buffer also determines the dominating interaction mechanism, leading to stronger stacking contributions at higher salt concentrations; even electroneutral amides show a hitherto not recognized interaction between the negatively charged carbonyl oxygen and the positively charged π-surface of the porphyrin system.

Porphyrins with pyridinium substituents (**R**) have been used for some time as partners in supramolecular complexes, in particular with nucleotides,[1] as well as ligands for DNA.[2] As major binding contributions, electrostatic and stacking interactions have been identified.[1,3] In the context of recent studies with a new porphyrin-based peptide receptor[4] we have measured associations with the underlying tetrapyridinium framework **R** under different conditions and have found large affinity changes to anionic species such as nucleotides. The results indicate at the same time strong changes in the binding modes, supported by the observed complexation-induced NMR shifts.







The binding constants were determined as reported earlier;[4] the titrations showed isosbestic points, in line with the fitting to a 1:1 equilibrium. It was secured that there was no pH change during titration; the very small change of the anyway very low ionic strength has a negligible influence on the association equilibria.[5] Measurements with amides like **A1**–**A5** showed changes of ΔA in the Soret band absorption similar to those observed earlier with a related receptor and peptides.[4] Association constants around 5000 M^{-1} with diamides **A1**–**A4** and over 10000 M^{-1} with the triamide **A5** reveal that even eletroneutral molecules can strongly interact with the positive charges in the extended aromatic receptor moiety. Experiments with corresponding diesters **E** (n = 1–3) and also α,ω-alkane diols with **R** showed in contrast to the other ligands no appreciable ΔA in the UV spectra, indicating that hydrophobic or lipophilic interactions cannot be a major binding force. These observations are only in line with additive interactions between the cationic porphyrin skeleton and the carbonyl oxygen atoms, which are known to bear a substantial negative charge in amides, in contrast to *e.g.* in esters where we cannot detect binding.

If such interactions with amide oxygens already lead to such high affinities, larger numbers should be expected with fully charged anions. In consequence, the association constants are expected to be substantially lowered by anions present in concentrations below the molarity of the amide type ligands. We therefore decided to re-eaxamine the affinity of the often used tetrapyridinium porphyrin **R** towards different anions, with and without the commonly used buffers.[1] Indeed we find that the binding constants are larger by one to two orders of magnitude than those reported in the literature (Table 1), if one measures them not in the presence of added buffer anions; this is illustrated with the selected isotherms in Fig. 1. Even with simple halides we find rather large log K values (Table 1).

Association of nucleotides with tetrapyridinium porphyrin is thus much stronger than known before; it increases as expected with the charges in the range AMP < ADP < ATP, and falls off steeply with higher buffer concentrations (Table 1). Noticeably, the distinct base selectivity observed, in the older work between purine and pyrimidine bases with **R**,[1] is almost absent at low salt concentrations, and appears again with higher buffer concentrations. Obviously, in the absence of competing buffer anions the electrostatic interactions between the nucleotide phosphate and the cationic receptor dominate so strongly that stacking interactions play a minor role. On the other hand, with decreased ion pairing at higher buffer concentrations the lipophilic interactions gain in energetic importance, as the salt

[a] Measured by UV–visible titration of **R** with nucleotides in water in the absence and in the presence of 0.1 and 0.3 M phosphate buffer (pH 7.9 ± 0.2) at 25 °C. Titrations were carried out by adding concentrated stock solutions of nucleotides ([nucleotide] = 10 mM) containing *ca.* 2 μM of porphyrin to an equally concentrated solutions of porphyrin in a 10 mm cuvet. Error limits: log*K* ± 5%. [b] *K* value can not be determined accurately as the ΔA value is negligible.

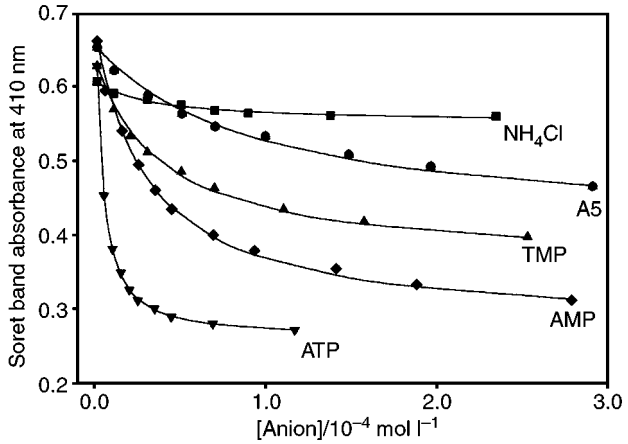

Fig. 1 Non-linear least square fit of UV–visible titration curves for receptor **R** with selected anions. Conditions: AMP, ATP and TMP without buffer (see Table 1); **A5** in water at pH 6.9 ± 0.2; NH_4Cl in water without buffer at pH 7.9 ± 0.2.

bridges do not 'draw away' as strongly the nucleobase from contacts to the porphyrin surface. That the nucleotide indeed stacks to the porphyrin moiety is established, by the significant shielding observed both at the nucleobase *and* the ribose protons.

In conclusion, the results show that the buffers used in host–guest complexation studies can significantly alter the dominating non-covalent interaction mechanisms, and thereby both the affinity and the selectivity seen in such systems. Moreover, permanent charges in a large receptor surface such as the tetrapyridinium porphyrin can even in water also lead to significant binding with the partial negative charges of electroneutral species such as amides.

Our work is supported by the Deutsche Forschungsgemeinschaft, Bonn, and the Fonds der Chemischen Industrie, Frankfurt. M. S. thanks the A. v. Humboldt foundation for a stipend.

Received (in Cambridge, UK) 5th October 1999, Accepted 22nd November 1999

High activity and *para*-selectivity in the nitration of aromatic compounds is achieved by a high density of acidic sites and ready formation of the *para*-isomer in the pores of zeolite beta with low Si/Al ratio as revealed by molecular modeling studies.

Nitration of aromatic compounds is a ubiquitous reaction to realise organic intermediates required in large tonnages for the fine chemical industry. The conventional nitration process,[1] employing a nitrating mixture of nitric and sulfuric acid, for the last 150 years has remained unchallenged in the commercial arena owing to uneconomical alternative options. Selective synthesis of the desired isomer in the nitration of substituted aromatic compounds is of topical interest to reduce pollution caused by unwanted isomers and specifically to respond to market demand. Earlier we reported selective nitrations by employing a solid acid, Fe^{3+} montmorillonite in the presence of acetic anhydride–nitric acid.[2] Later, various novel options, meeting international environmental laws, and also avoiding the recovery of the spent acid in the conventional mixed acid process have been explored that include Laszlo's[3] claycop (copper nitrate impregnated on K10 montmorillonite) acetic anhydride and recently claycop–nitric acid–acetic anhydride, Smith's[4a] mordenite–benzoyl nitrate, Kwok's[5] ZSM-5-propyl nitrate and Olah's[6] Nafion-H–*n*-butyl nitrate. However these options fall short of expectations to commercial realisation in view of low space time yields, high dilution, and use of expensive mixtures in the form of acetic anhydride–nitric acid or expensive acyl or alkyl nitrate whereas Sato's[7] and Prins's[8] vapour phase nitrations of benzene conducted employing clays and mordenite zeolite provided low space time yields. The zeolite beta-acetic anhydride-nitric acid system developed later by Smith *et al.*,[4b,c] afforded good space time yields but required great care in large scale operations. Barrett and coworkers[4d] employed La(III) triflates as recyclable catalysts for aromatic nitrations but such systems required longer reaction times to obtain good yields without any explicit selectivity towards *o*-/*p*-isomer.

Herein, we present a unique methodology for the nitration of aromatic compounds that offers high space time yields, near zero emission of effluents, especially high *p*-selectivity for monosubstituted products, essential for commercial processes, employing nitric acid at a concentration of 60–90%, with reuse of the solid acid catalysts being possible by azeotropic removal of water formed in the reaction and present in nitric acid.†

We executed a two-fold approach employing modified clays and zeolites to realise a high space time yield as well as high selectivity of the desired *p*-isomer as indicated in Table 1. In an earlier investigation,[9] a series of different metal-exchanged and pillared clay catalysts were prepared[10] and employed in the nitration reactions of aromatic compounds under identical conditions. Fe^{3+} montmorillonite catalyst was found to be the most active owing to its high metal content and highly acidic sites. This catalyst (entry 1) is far superior in terms of space time yield, when compared even with gas phase reactions conducted with various metal-exchanged montmorillonites[7] and mordenite.[8] In the nitration of benzene, mononitrobenzene is obtained selectively without formation of any di- or poly-nitrobenzenes and the *p*-selectivities in the nitration of monosubstituted benzenes are improved.

Our main emphasis is to achieve higher *p*-selectivity to meet market demand. Accordingly, various zeolites which have well

[a] Product yield based on total amount of HNO_3 used. [b] Space time yield: kg product/kg catalyst/h. [c] By GC. [d] Results from ref. 7. [e] Yields based on benzene. [f] Yields calculated based on HNO_3 actually consumed, *i.e.* subtracting the amount of nitric acid azeotropically distilled out from the reaction vessel and collected in the Dean–Stark trap from the total amount of nitric acid used. The nitric acid collected is reused after adjusting to the desired concentration. [g] Zeolite beta-I, II: SiO_2/Al_2O_3 molar ratio = 22, 27. [h] Yields based on aromatics with aromatic compound and HNO_3 in 1:2 ratio. [i] Dichloroethane used as solvent.

defined pore structures and channels that are derived from the networking of SiO_2 and Al_2O_3 making them attractive candidates for shape selective catalysis[11] were employed[12] to achieve higher shape selectivity in the nitration of substituted aromatics. Zeolite beta-I[13] (entry 6) is found to the best catalyst for the nitration of aromatic hydrocarbons to nitroaromatics with high *p*-selectivity. When compared with the selectivities obtained using classical mixed acid, zeolite beta-I catalyst displayed a major shift towards *p*-selectivity as is evident, for example; for toluene: from 38 to 67%, for cumene: 58 to 81%, for chlorobenzene: 64 to 90%, for anisole: 40 to 75% (Table 1). The production of the *p*-isomer in higher ratio for toluene and cumene meets the timely demand of the market and at the same time avoids the burning of undesired *o*-isomers occasionally resorted to by the manufacturers which causes environmental pollution. Increased formation of the *p*-isomer in the nitration of chlorobenzene eases the isomeric separation to a considerable extent and helps to save energy. Whereas the change from methyl (toluene) to the larger isopropyl (cumene) substituent increases the *para* selectivity, the reverse applies for halogens, for which the best *para* selectivity is obtained with the smaller substituent, namely chlorine owing to electronic factors.

We carried out nitration of toluene with various zeolite catalysts and zeolite beta of different Si/Al ratios (Table 1). Zeolite beta proved to be the best catalyst among the zeolites used in terms of space time yield and *p*-selectivity. On decreasing the Si/Al ratio in zeolite beta, an increase in *p*-selectivity as well as overall activity is observed (entry 6 and 7). An increased number of Bronsted acid sites reduces the available space in the pore and this result substantiates our inference that the formation of *o*-isomer, which requires more space, is unfavourable. These observations are in accord with the results observed by Bellussi *et al*. in alkylation reactions.[14] It is also found that with an increase of catalyst concentration the *p*-selectivity of toluene nitration increased further to 73%. Zeolite beta catalyst showed consistent activity and selectivity even after five cycles (entry 6). Careful analysis of the regenerated catalyst after recycling it five times showed no change in the Si/Al composition indicating that no dealumination of catalyst has taken place.

Sorption studies of the reactant and isomers of the product and their intermediates (transition states) undertaken using the sorption module of Cerius[2] which implements rapid Monte Carlo statistical mechanical calculations[15] clearly predicted high *p*-selectivity possible with ease of formation of the intermediate of the *p*-isomer in the pores. The result of shape selectivity observed employing zeolite beta derives further support from the results obtained with metal exchanged clays, wherein mesopores of montmorillonite formed due to acid treatment also induced some shift in *p*-selectivity (entries 4 and 5). The higher shape selectivity for the zeolite is ascribed to the induction of larger steric effects by the 3D structure of zeolite beta in comparison to the 2D structure of clay catalysts.

Nitration involves electrophilic attack on the aromatic ring by the nitronium ion, NO_2^+. Bronsted acidic sites are responsible for the generation of NO_2^+ ion from nitric acid. Reaction conducted with fuming nitric acid without azeotropic removal of water is totally inhibited after some time owing to a poisoning effect of water formed in the reaction. It is necessary to scavenge the water out of the reaction zone formed during the reaction to facilitate regeneration of active acid sites on the catalyst. The rate of addition of nitric acid to the reactor containing powder catalyst and substrate is matched with the rate of removal of water present in nitric acid and the reaction zone through extractive distillation with a Dean–Stark apparatus using the substrate as the solvent or chlorohydrocarbon solvent for high boiling aromatic compounds to afford optimum selectivity, activity and protection of the catalyst from degradation. This protocol envisages the instant reaction of added nitric acid and establishes that the solid acid catalysts used here act as bifunctional catalysts generating the electrophile, nitronium ion, as well as acting as an instant adsorbent for water formed during the reaction.

On the other hand ZSM-5 under such conditions affords low space time yield and selectivity (entry 8) in the nitration of toluene when compared to the high *p*-selectivity obtained by Kwok *et al*.[5] employing acyl nitrate as nitrating agent. This is attributed to low diffusion of aqueous HNO_3 in the hydrophobic pores of ZSM-5 and the resulting density of acidic sites is too low to promote the generation of nitronium ions from nitric acid. Therefore the reaction on ZSM-5 mainly takes place on the surface of the zeolite.

In conclusion, a simple methodology for nitration employing solid acids dispensing with the use of acetic anhydride or acyl nitrate described here leading to high space time yields and high *p*-selectivities, appears to be a promising alternative to the conventional acid mixture of nitric and sulfuric acid. Enhanced *p*-isomer formation to meet market demands, dispensing the use of sulfuric acid, achieving near zero emission of effluents, non-corrosivity and low water requirement are other attractions.

Notes and references

† *General procedure for the nitration of monosubstituted aromatics*: A mixture of toluene (161 ml; 1.5 mol) and zeolite beta-I catalyst (10 g) were added to in a 1 litre-reactor flask equipped with stirring rod and Dean–Stark apparatus. 60% nitric acid (120 ml, 1.5 mol) was added in a controlled manner with an infusion pump over a period of 80 min to the above mixture, which was preheated to the refluxing temperature. The liberated water collected into the Dean–Stark apparatus was continuously removed. After completion of the reaction, the catalyst was filtered off and the reaction mixture was concentrated to obtain the mixture of nitrotoluenes. Nitration of other aromatic hydrocarbons was similarly carried out on a 76 mmol scale.

Reusable photographic films based on iron-containing clay minerals

Yea Wenn Liou and Chong Mou Wang*

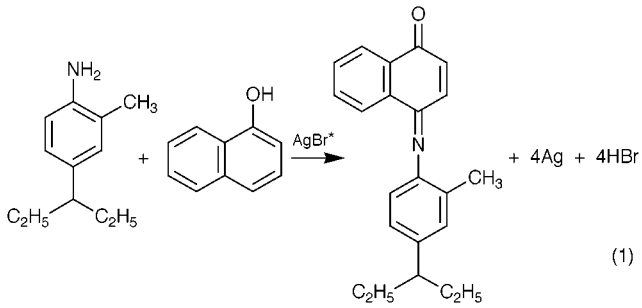
Department of Chemistry, National Taiwan Normal University, Taipei 11718, Taiwan, Republic of China.
E-mail: checmw@scc.ntnu.edu.tw

Received (in Cambridge, UK) 25th October 1999, Accepted 15th November 1999

A non-silver-based photographic film has been developed from 9-methylacridinium-intercalated clay particles (denoted clay|AcH$^+$) and this inexpensive clay film showed potential reusability.

Substantial efforts have recently been directed towards the development of artificial photosynthetic systems,[1–5] which, in turn, unite the understanding of the structure of natural photosynthetic systems, the advances in instrumentation, and the development of novel materials for optical and chemical detection.[6–8] For the latter aspects, we recently carried out a series of investigations on clay modified electrodes, and found that iron-containing clay minerals proved useful in many applications, such as biosensing and optical recognition.[9–12] The iron containing species are likely to be key in mediating the electron reactions on the clay surface.[13,14] Besides, we also found that this inexpensive solid, if properly tailored, may be useful for lithography or image-recording.

Photography can be dated back to 1727 as Johann Heinrich Schulze reported that solid AgCl darkens when exposed to light. Thereafter, most color and black-and-white photography was developed on the basis of the photochemistry of AgBr. A representative example [eqn. (1)] is the following coupling reaction between α-naphthanol and *N*,*N*-diethyl-2-methyl-1,4-phenylenediamine (DEPD) sensitized by AgBr:[15,16]



(1)

Meanwhile, many other dyes have showed excellent sensitivity to colored objects or to images only visible under IR or UV light. However, for most cases, silver bromide is sacrificed and the film is not recoverable. Here we describe that a potentially reusable photographic film can be developed from inexpensive iron-containing clay minerals.

When the clay|AcH$^+$ modified electrode is simultaneously biased at +0.4 V *vs*. SCE and illuminated with light of $\lambda > 350$ nm (100 W Hg lamp, 1 min), Fig. 1 shows that indophenol blue ($\lambda_{abs} \approx 625$ nm) is immediately formed on the surface of the clay film from a solution containing DEPD ($\lambda_{abs,max} = 257$ nm, pH 10) and α-naphthanol ($\lambda_{abs} = 250$, 337 nm, pH 10). Here, the clay|AcH$^+$ particles were prepared by reacting clay (Aldrich, montmorillonite K10, 0.5 g) with $AcHPF_6$ (10 mM, 50 mL in CH_3CN)[13] for two days followed by extensive washing with CH_3CN; the loading of AcH$^+$ in clay was estimated to be *ca*. 10^{-5} mol g^{-1}. The clay-modified electrode was fabricated on conductive ITO glass (indium-doped, 0.7 mm thick, 20 Ω cm^{-2}; Delta Technol.). Typically, a portion of the clay|AcH$^+$ slurry (30 μL cm^{-2}, 100 mg/100 mL water) was spin-coated onto glass sheets and dried at room temperature. Then, the clay

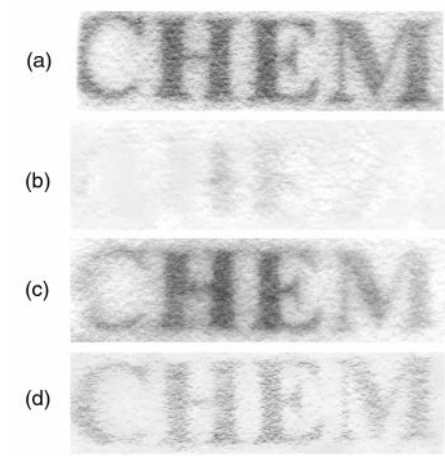


Fig. 1 (a) Photoimage formed on the clay|AcH$^+$ modified electrode in a solution containing 2 mM of DEPD and 3 mM of α-naphthanol (pH 4) under illumination ($\lambda > 350$ nm) and at $E = 0.4$ V *vs*. SCE for 1 min; (b) image erasing, after the image obtained in (a) was dipped in a dilute sulfuric acid for 1 s; (c) image recovering, the electrode in (b) was re-exposed to light in solution (a); (d) the image obtained after 20 consecutive exposure and erase cycles.

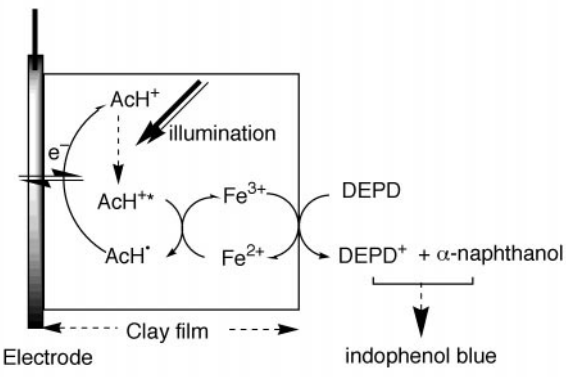
film was reinforced with polystyrene [PS, M_w 13000, Aldrich, 30 μL cm^{-2}, 10 mg mL^{-1} in ethyl acetate–toluene (1 : 1, v/v)]. The mechanism of formation of indophenol blue on the clay surface is proposed in Scheme 1 and control experiments support the proposed mechanism. As is evident in Fig. 2, insignificant photocurrent is detected for electrodes made from the bare clay particles in a pH 4 solution containing 1 mM of DEPD, whereas a greater photocurrent is obtained when the electrode is incorporated with AcH$^+$ ($\lambda_{abs,max} = 357$ nm; $\lambda_{em} = 500$ nm). Laser flash photolysis experiments (Fig. 3) show that the lifetime of $AcH^{+*}_{(aq)}$ (dotted lines) is 36 ns whereas the decay for $AcH^{+*}_{(clay)}$ (solid lines) occurs in the same time scale as the instrumental response ($\ll$10 ns), indicating that the excited acridinium, $AcH^{+*}_{(clay)}$, can be quickly quenched by iron species, presumably Fe^{2+}, in the clay particle, at Fe^{II} sites.[13] The fast decay of AcH^{+*} suggests a reductive quenching mechanism [eqn. (2)].



Scheme 1 Proposed mechanisms for the formation of indophenol blue on the illuminated clay|AcH$^+$ modified electrode.

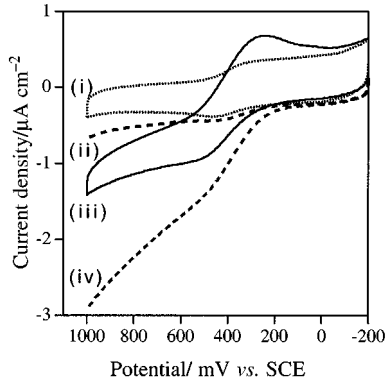


Fig. 2 *J*–*V* curves for DEPD (1 mM, pH 4): (i) with the electrode prepared with the bare clay particles, in the dark; (ii) with the clay|AcH$^+$ electrode, in the dark; (iii) with the electrode as in (a), under illumination; (iv) with the clay|AcH$^+$ electrode as in (b), under illumination. Scan rate: 50 mV s^{-1}.

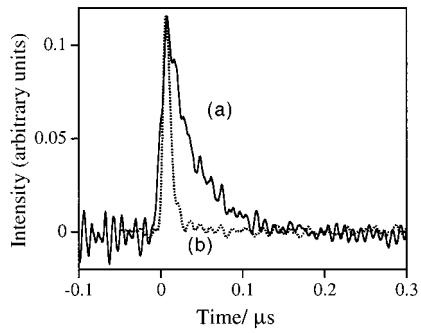

Fig. 3 Time-resolved laser spectroscopy (pH 4, acetic acid–acetate buffer, $I \approx 0.1$ M, $\lambda_{em} = 500$ nm) for free AcH$^+$ (a) and clay|AcH$^+$ (b).

$$AcH^{+*}{}_{(clay)} + Fe^{2+}{}_{(clay)} \longrightarrow AcH^{\cdot}{}_{(clay)} + Fe^{3+}{}_{(clay)} \quad (2)$$

The lack of an electron transfer product from AcH^{+*} in the clay is believed to be a consequence of the fast reaction of AcH$^{\cdot}$ with Fe^{3+} species in the Fe^{III} sites in the clay. To prevent the back reaction of eqn. (2) from occurring, an anodic regeneration for AcH$^+$ (at $E° \approx -0.4$ V *vs.* SCE, pH 4)[13] from AcH$^{\cdot}$ appears to be necessary.

The photoquality in terms of the contrast between the blue regions and the background is a function of the electrode potential, pH and the concentration ratio of the reactants. For instance, a high pH environment greatly favored the formation of indophenol blue. However, for a solution pH of >6, the formation of indophenol blue became too rapid to be controlled. As a consequence, a lower pH environment (pH 4), although less favorable for the formation of indophenol blue on the clay electrode, was, in turn, less interfering. The electrode potential is another key factor determining the image quality. Control experiments showed that the formation of indophenol blue tended to a limiting rate as the electrode potential approached 0.4 V *vs.* SCE (*i.e.* the formal potential of $Fe^{III/II}{}_{(clay)}$)[10] according to the absorbance monitored at 625 nm (the peak absorption of indophenol blue). This effect is attributed to the regeneration of $Fe^{III}{}_{(clay)}$ from $Fe^{II}{}_{(clay)}$ [eqn. (3)]

$$Fe^{II}{}_{(clay)} \longrightarrow Fe^{III}{}_{(clay)} + e^- \quad (3)$$

after the photooxidation of DEPD by $Fe^{III}{}_{(clay)}$ [eqn. (4)]

$$Fe^{III}{}_{(clay)} + DEPD \longrightarrow Fe^{II}{}_{(clay)} + DEPD^+ \quad (4)$$

The concentration ratio of DEPD to α-naphthanol is also an important factor for the performance of the clay film. Experiments showed that as [DEPD]/[α-naphthanol] approaches 3 : 2, a better contrast between the illuminated regions and the background could be obtained.

This filmed electrode appeared to be reusable since the image could be erased after dipping in dilute (1 mM) sulfuric acid [Fig. 1(b)] and once the electrode was reexposed a clear image could be restored [Fig. 1 (c)]. Long-term tests [Fig. 1 (d)], in addition, showed that although the clay|AcH$^+$ electrode gradually loses its sensitivity (tentatively ascribed to leaching of AcH$^+$), it could be reused more than twenty times. In summary, such very cheap iron-containing clay minerals after proper tailoring, may be useful materials for image-recording.

We thank the National Science Council, Republic of China and Chinese Petroleum Company for financial support (grant number: NSC 88-2113-M-003-016; NSC 88-CPC-M-003-002).

Porous gold structures with nearly regular 15 μm channels have been prepared by a novel route in which the calcium carbonate skeletal plates of echinoids (sea urchins) are used as templates.

Biological materials are characterised by unique structures and morphologies that cannot typically be replicated through laboratory synthesis. Nature uses materials not traditionally recognised for their engineering properties, such as calcium carbonate, to produce structures with superior mechanical properties. This is possible owing to control over morphology, composition and spatial organisation. Profiting from existing materials with unusual forms, we describe experiments using a structured calcium carbonate biomineral to template the production of porous inorganic solids (gold in this case) with pore diameters in the order of 15 μm. Few synthetic methods exist to produce materials that are spatially patterned on this length scale.

There is much interest in the preparation of materials with well defined pore sizes. Microporous solids, characterised by pore sizes of the order of 10 Å, include the zeolites. Mesoporous solids exhibit pore sizes in the range 10–1000 Å and represent a relatively new class of materials. A number of methods have been used to synthesise mesoporous materials based on surfactant templating.[1–5] These have been applied to a wide range of inorganic materials, including metals, silicates and metal oxides.[1–5] Reports on the synthesis of porous solids with pores in the micrometer size range are considerably more limited. Lamellar aluminophosphates with surface patterns on the sub-micrometer to millimeter size range have been produced using vesicle templates.[6] Bicontinuous microemulsions have been used to prepare porous shells of crystalline calcium carbonate with pore sizes ranging from 35 to 225 nm,[7] and calcium phosphate materials with microstructures comprising pore diameters of up to several micrometers.[8] The method of emulsion templating[9] is perhaps most general and has been used to produce macroporous titania, silica and zirconia with pore sizes from 50 nm to several microns.

Here we describe the use of the skeletal plates of echinoids (sea urchins) to template porous structures with pore sizes of the order of 15 μm.† The example material chosen here is gold, but the method is quite general. A continuous coating of gold is deposited over the entire surface area of the skeletal plates. Subsequent dissolution of the plate leaves the gold coating in the form of the original structure. Sea urchin plates were selected owing to their unique morphology. The skeletal plates and the spines of echinoids[10] are a low/high magnesium calcite (depending on genetic and geographical control) and each behave as single crystals when examined by diffraction or polarised light. The microstructure, however, is quite remarkable and complex, exhibiting a unique fenestrated structure of interconnected trabeculae and pores that are approximately 15 μm in diameter [Fig. 1(a)]. The porous network and inorganic fractions of the shell occupy approximately equal volumes, and display non-crystallographic curved surfaces. Indeed, the pore diameters and pore size distributions are highly controlled, and some species of urchin are characterised by highly uniform distributions of pores in very regular structures.[11]

A typical SEM image in cross section through a skeletal plate is presented in Fig. 1(a), showing the bicontinuous, sponge-like structure of the mineral with a length scale in the order of 15 μm. The mineral surface is very smooth even when viewed at higher magnification (not shown). Fig. 1(b) shows a similar skeletal plate after gold coating and annealing. The coating of gold particles on the surface of the mineral is clearly seen as a very marked roughening. Dissolution of the calcium carbonate component of a gold-coated echinoid plate produced the gold structures shown in Fig. 2(a) and (b). These images demonstrate that the echinoid plate acts as a template to produce porous gold with a structure mirroring that of the original plate. The gold particles produce a coating on the calcite, rather than filling the

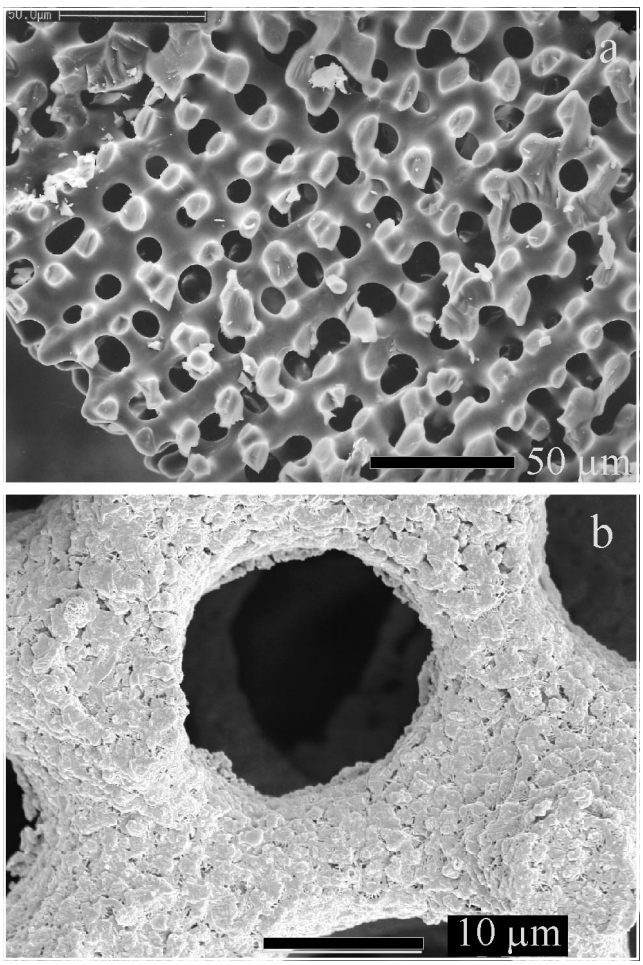

Fig. 1 Scanning electron micrographs of (a) a cleaned echinoid skeletal shell and (b) shell coated with gold and annealed. The bars correspond to (a) 50 μm and (b) 10 μm.

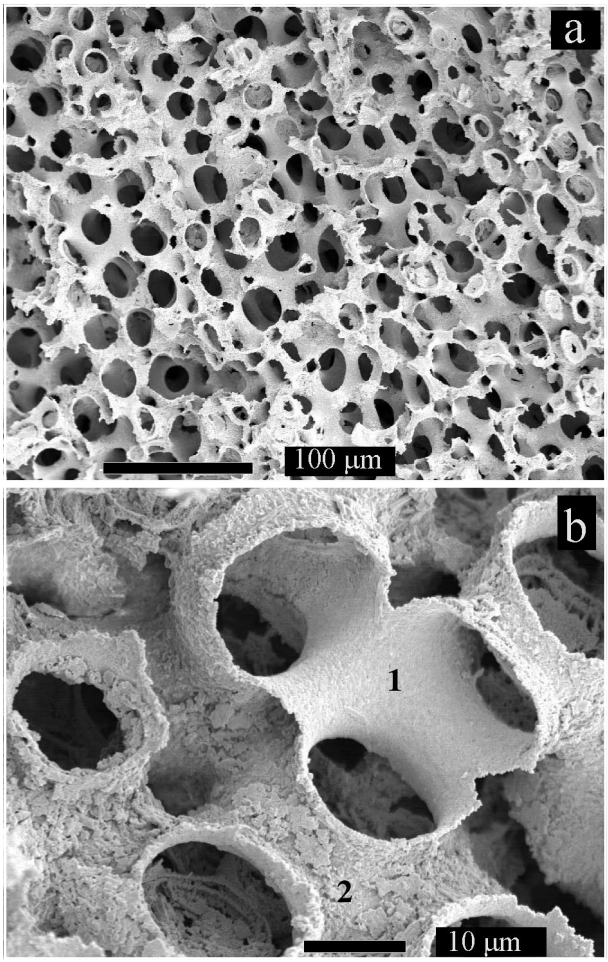

Fig. 2 SE micrographs of gold-coated echinoid skeletal shell after *in situ* dissolution of the calcium carbonate shell. 1 and 2 in (b) mark the smooth inner and rough outer surfaces of the templated gold structure. The bars correspond to (a) 100 μm and (b) 10 μm.

entire pore structure, so a double-sided surface is produced. This is clearly shown in Fig. 2(b), where the gold surface originally in contact with the calcite is smooth (area 1) while the surface directed into the original pore is rough (area 2).

Dissolution of the gold-coated plates in acid solution produced a solid of the same dimensions as the original plate. The solid produced was rather fragile and thus difficult to transfer to sample stubs without some damage to the structure. The best images of the porous gold were thus obtained from samples dissolved *in situ* on the sample stub. Further work will be directed to producing thicker metal coatings and even filling the entire pore structure to produce a replica of the original bicontinuous structure. This should produce a stronger material.

It is demonstrated that the skeletal plates of echinoids can be used to template the synthesis of porous materials (gold being chosen as an example) with unique structures. The technique is very general and it is envisaged that it can be applied to a wide range of inorganic solids. Indeed, preliminary experiments to produce macroporous TiO_2 structures *via* a sol–gel method suggest that the method is feasible, depending upon refinement of the kinetics of the reaction and control of shrinkage during annealing. Further experiments to deposit a wider range of solids and to control the thickness of the templated material are underway.

The class of new materials presented here may find application as light-weight structural ceramics. Ordered macroporous materials with pore dimensions comparable to optical wavelengths could display unique optical properties. Applications as catalyst supports are also possible, particularly in situations where the traditional materials with smaller pore sizes result in unacceptable pressure drops in the catalysis process.

Notes and references

† Specimens of the echinoid *Ircinia oros* were collected at Depot Beach, NSW, Australia, and were cleaned of organic material with hypochlorite solution using standard procedures.[12] Experiments were carried out with clean skeletal plates that had been abraded to a thickness of *ca.* 1 mm, sonicated in water to remove attached particles and subsequently dried. One end of a dry plate was then placed in gold paint (Johnson Matthey, Brilliant Gold, PM 002), and the paint was absorbed into the plate *via* capillary action, as evidenced from a colour change in the plate from white to dark brown–purple. The plate was then removed from the paint and was heated using a hot air gun to burn off the protective organic matter in the paint. The plate was allowed to cool slightly before repetition of the dipping/heating cycle. The cycle was repeated ten times and was then annealed in a furnace at 400 °C for 36 h.

The samples were examined using a JEOL 6300F scanning electron microscope (SEM), fitted with a field emission source and operating at 5 kV. Samples were prepared for (SEM) by mounting on aluminium stubs using adhesive carbon tape, either with the original outer surface of the plate exposed or in cross-section after fracture, and all were sputter-coated with a thin layer of gold prior to viewing to enhance conductivity. Pieces of echinoid plates were examined after cleaning [Fig. 1(a)] and subsequent to annealing of the absorbed gold [Fig. 1(b)]. Samples were also studied after dissolution of the calcium carbonate with acid. The annealed gold plates were immersed in solutions of 2% acetic acid or 2 M HCl until all of the original calcite plate has been dissolved, and the remaining gold material was mounted on SEM stubs. Plates were also mounted on SEM stubs and were dissolved *in stiu* with 2 M HCl [Fig. 2(a) and (b)].

Received (in Cambridge, UK) 11th November 1999, Accepted 18th November 1999

New heterogeneous catalyst systems have been developed employing a proline-derived ligand immobilized on mesoporous silicas; asymmetric diethylzinc addition to benzaldehyde was carried out using the catalyst systems; the reaction enantioselectivity was found to be largely dependent upon the pore size of the mesoporous silicas, capping of free silanol moieties with trimethylsilyl group and employment of Bu^{n}Li.

Optically active secondary alcohols are important intermediates for the construction of optically active natural products and biologically active compounds. Among various methods for the construction of optically active secondary alcohols, addition of diorganozinc reagents to aldehydes in the presence of a catalytic amount of a chiral β-aminoalcohol has been extensively studied.[1] Extremely high enantioselectivity has been reported in the reactions employing a variety of aminoalcohol ligands. However, in order for these reactions to be successfully exploited in large-scale applications, the chiral ligand has to be readily available or easily recycled. Toward this goal, immobilization of chiral ligands onto heterogeneous supports has been investigated and a number of support materials such as inorganic solids and polymers have been developed.[2] Recently, various mesoporous silicas with pore sizes ranging from 2 to 10 nm have been synthesized using self-assemblies of surfactants and block copolymers as templates.[3] These mesoporous silicas have been successfully employed as supports for various chiral catalysts.[4] Herein, we report on new heterogeneous catalyst systems that utilize proline derivatives anchored on the mesoporous silicas such as MCM-41 and SBA-15.

Although the reactions of diethylzinc with benzaldehyde using ephedrine immobilized onto amorphous silica gel[5] and mesoporous silica[6] have been investigated, the degree of enantioselection under these heterogeneous catalytic conditions has been less than satisfactory. In connection with the low enantioselectivty, several issues need to be addressed: (1) employment of a more selective ligand, (2) suppressing undesired catalytic activity on the silica surface, (3) changing silica pore sizes, and (4) addition of extra metal reagent. In terms of a more selective ligand system, a prolinol-based ligand developed by Soai *et al.*[7] was selected in our study. Since the free SiOH moieties of the silica surface could catalyze the reaction,[6] thus lowering the reaction enantioselectivity, mesoporous silicas containing the chiral ligand having its surface capped with trimethylsilyl groups[8] have been prepared. To investigate the effect of the pore size on the enantioselectivity, we have used two different mesoporous silicas, MCM-41 and SBA-15, which have similar hexagonal pore arrays but with different pore dimensions. We have also investigated reaction enantioselectivity when the catalyst system was treated with Bu^{n}Li before addition of the aldehyde.

The synthetic procedure including preparation of the ligand, immobilization onto silicas and capping with trimethylsilyl moieties is shown in Scheme 1. The new chiral aminoalcohol **3** was synthesized as follows. The amine group of 4-hydroxyproline (Aldrich Chemicals™) was protected using ethyl chloroformate and the acid was converted to a methyl ester to give the carbamate ester **2**. Treatment of compound **2** using phenylmagnesium chloride furnished a tertiary alcohol, and the carbamate group was converted to the corresponding methylamine through treatment with lithium aluminium hydride (LAH) yielding compound **3** in an overall yield of 72% from **1**. MCM-41 and SBA-15 were synthesized according to the previously reported procedures.[3] Chloropropyl linkers were grafted on the walls of mesoporous silicas by treating with $(CH_3CH_2O)_3Si–CH_2CH_2CH_2Cl$ in refluxing toluene. Reaction of the resulting chloropropyl-derivatized mesoporous silicas (**5b** and **5c**) with the chiral pyrrolidinemethanol **3** yielded silicas **6b** and **6c**, respectively. In order to cap remaining free SiOH groups on the walls of mesoporous silicas, **5b** and **5c** were treated in refluxing hexamethyldisiloxane (HMDS) for 12 h. To the best of our knowledge, this is the first anchoring of SBA-15 silica with a chiral ligand and the X-ray diffraction (XRD) patterns of SBA-15 derivatized samples have been taken during various stages of the preparation. The XRD results clearly demonstrated that the mesoporous structure of SBA-15 was preserved during the preparation of the catalyst. Table 1 lists the surface areas, the mean pore dimensions, and the amounts of grafted organic groups for the mesoporous silica based catalysts. The surface area decreased substantially during the chloropropyl-grafting step, especially for SBA-15. Nonetheless, the pore dimensions of the SBA-15 based systems did not change significantly during these synthetic steps. For comparison, the chiral ligand **3** was attached to amorphous silica to provide both non-TMS capped catalyst (**6a**) and TMS-capped catalyst (**8a**) using the same reaction conditions applied to the mesoporous silicas.

[a] N_2 adsorption and desorption isotherms were collected at STP on a Micrometrics ASAP2010 gas adsorption analyzer after the materials were degassed at 250 °C at 30 μTorr for 5 h. The surface areas were calculated by the BET method and the pore size distributions were calculated from the adsorption branch of the nitrogen isotherm by the BJH method.

We have investigated asymmetric addition of diethylzinc to benzaldehyde using these silica-based catalysts and the results are outlined in Table 2. For each silica catalyst, two different sets of reactions were run with 6 mol% of catalyst and either 3 equiv. of diethylzinc to benzaldehyde (method A) or 7.2 mol% of Bu^{n}Li followed by 3 equiv. of diethylzinc (method B). To evaluate our catalyst systems against the parent homogeneous catalyst, compound **4** was prepared from **3** through etherification of C(4)–OH with benzyl bromide. Reactions employing the homogeneous catalyst **4** provided products with 90 and 93% ee, respectively, *via* methods A and B (entries 1 and 2, Table 2). However, when the chiral catalysts anchored on amorphous silica were tested using method A, **6a** and **8a** gave only 16 and 37% ee, respectively (Table 2 entries 4 and 5). When the reactions were carried out using method B, slight improvements in the enantioselectivities were observed (entries 6 and 7). A noticeably higher enantioselectivity was observed in the reactions employing MCM-41-based catalyst (entries 8–11) and the best results were obtained with the catalysts based upon SBA-15 (entries 12–15). It is of particular note that catalysts based upon SBA-15 consistently gave higher enantioselectivity than that of MCM-41. In both MCM-41 and SBA-15 systems, TMS-capping as well as the employment of Bu^{n}Li improved the enantioselectivity significantly. Product of the highest ee (75%) was obtained for TMS-capped SBA-15 based catalyst utilized after treatment with Bu^{n}Li (entry 15). To test the catalytic activity of the silica without a chiral ligand, TMS-capped SBA-15 (**7c**) was used under otherwise the same reaction conditions, and a 15% yield of the product was observed. It appears that, even with TMS-capping, there remains some residual activity of the silica, resulting in a reduction of the enantioselectivity.

Table 2 Asymmetric diethylzinc addition to benzaldehyde using various catalysts

In summary, new mesoporous silica-based catalysts incorporating a chiral pyrrolidinemethanol derivative have been prepared and the asymmetric diethylzinc addition to benzaldehyde examined. Among various catalytic systems, the best result (75% ee) was obtained with the TMS-capped SBA-15 based catalyst treated with Bu^{n}Li.

Received (in Cambridge, UK) 17th November 1999, Accepted 26th November 1999

Two organic liquid biphase systems containg poly(ethylene oxide), heptane and either CH_2Cl_2 or methanol have been tested in the catalytic hydrogenation of hex-1-ene using, respectively, Wilkinson's catalyst and a cationic rhodium complex, both leading to high yields and selectivity, with the latter showing a better performance and enabling easy and efficient product separation and catalyst recycling.

Liquid biphase systems have been the focus of great attention in catalysis recently as media for alternative less polluting and more efficient catalytic processes, providing an easier separation between products and catalyst. Among the strategies studied so far, examples include the use of aqueous/organic biphase systems with water soluble catalysts,[1] fluorous biphase systems, where the use of fluorinated ligands leads to catalyst solubility in the perfluorinated phase,[2] functionalised thermosensitive polymers as supports for traditional organometallic homogeneous catalysts [3] and the application of molten salts as ionic liquids.[4] All these procedures present some advantages and disadvantages. Among the latter, is the need for specially prepared catalysts, occurrence of catalyst leaching, or the somewhat difficult handling of the biphase system.

We have recently described[5] an organic biphase system containing poly(ethylene oxide) (PEO), CH_2Cl_2 and heptane which shows a strong segregation between the polar polymer and the hydrocarbon solvent, the polymer being concentrated in the bottom phase. Further studies[6] revealed that this phenomenon is also observed in mixtures containing other polar solvents such as methanol, chloroform and acetonitrile. Because of its characteristics, this ternary mixture may be interchanged between homogeneous and biphasic regions by either composition or temperature changes. These features suggest a variety of applications in different separation processes where the absence of water is desirable including catalysis.

This communication describes studies on the application of these biphase systems in the hydrogenation of hex-1-ene catalysed by Wilkinson's complex, $RhCl(PPh_3)_3$, and by the cationic complex $[Rh(cod)(dppe)]PF_6$, cod = cycloocta-1,5-diene, dppe = 1,2-bis(diphenylphosphine)ethane].† Hydrogenation was chosen as a test reaction because of its technological importance and hex-1-ene was used as substrate owing to its easy product characterisation. The rhodium complexes used were selected considering their well established hydrogenation catalytic behaviour and poor solubility in apolar solvents. Therefore, ideally, this reaction may be conducted in a homogenous system and, after induced phase separation, the catalyst may be selectively separated from the products, allowing for their removal and recycling. In a similar procedure Bianchini *et al.*[7] performed two catalytic reactions in a mixture of methanol and hydrocarbons that was homogeneous at high temperatures and formed a biphase system at room temperature, using a rhodium complex with a chosen ligand that ensured the complex solubility only in the alcohol-rich phase.

The phase diagram for the ternary system PEO 3350–CH_2Cl_2–heptane has been previously reported[5] and that for the ternary system PEO 3350–MeOH–heptane (not shown) is similar, though with a larger biphase area. Additional experiments have shown that in both systems there are only small changes when the polymer molecular weight is varied from 200 to 10 000, provided the polymer content is expressed on a monomer basis. There are, however, some important changes of the phase boundaries with temperature, with the biphase region increasing as the temperature decreases.[6]

Of relevance to this investigation, there are some compositions at which the system may be moved from a biphasic to a homogeneous region by temperature increase, for instance, with 19.5% of PEO 3350, 51.6% of CH_2Cl_2 and 28.9% heptane [compositions expressed on the basis of mol% (for PEO this refers to mol of monomer units)], this transition occurs at 9 °C. However, a significant rhodium loss was spectrophotometrically detected to the upper phase (*ca.* 15%) for this and other compositions which presented temperature-driven phase separation, causing poor recycling properties.

For this reason, we developed another procedure to improve the selectivity of catalyst partitioning. As temperature decreases, these polymer solutions show phase separation of UCST (upper critical solution temperature) type. For PEO solutions in CH_2Cl_2, these phase separation temperatures range from −80 to −40 °C, for PEO 3350 concentrations between 1 and 60% (w/w). As the polymer phase separates, we have verified that most of the catalyst is also removed from the solution phase. Therefore, by cooling the reaction system with liquid N_2, it is possible to selectively separate the catalyst and the reaction products. The striking feature is that, probably owing to large density differences, this biphase system is kinetically stable for a long time (even hours) even at temperatures close to room temperature, allowing easy separation of the liquid phases. Although this system is not in thermodynamic equilibrium, this procedure has provided an easy way of catalyst recycling.

This procedure was employed using Wilkinson's catalyst in the hydrogenation of hex-1-ene,‡ allowing product recovery with no apparent catalyst leaching to the apolar phase (verified spectrophotometrically) and efficient and selective substrate conversion. However, a marked decrease in the catalytic activity was observed after the third recycle. This could be related to the recycling process, which may induce a continuous loss of the triphenylphosphine free ligand in equilibrium with the rhodium complex, as revealed by ^{31}P NMR spectra, generating inactive species.

In order to overcome this problem, a cationic rhodium complex containing a chelating phosphine, $[Rh(cod)(dppe)]PF_6$, was tested as a catalytic precursor. This complex showed poor catalytic activity using the ternary mixture containing CH_2Cl_2. On the other hand, as suggested by other catalytic hydrogenation studies,[8] its performance using methanol as the polar component of the ternary mixture was clearly enhanced. With this second ternary system, the procedure of inducing phase separation by cooling was not effective since the volume of the upper phase was too small thus impeding the

product separation. This reaction was then conducted in a homogenous system containing 14 mL of MeOH, 3.6 g of PEO, 0.0335 mmol of Rh complex and 8.01 mmol of hex-1-ene, at room temperature and under H_2 flow. This system requires an activation period of *ca.* 2.5 h to reach its maximum activity. The reaction products were analysed by GC§ 30 min after this period and during eight cycles, producing a 54 ± 5% conversion associated with 90 ± 10% selectivity to hydrogenation. Under these conditions, the estimated turnover frequency was 4 min^{-1}. Maintaining the reaction for 1 h, the substrate was completely and selectively converted to *n*-hexane, suggesting that the isomerisation reaction is faster than hydrogenation and that the isomers produced are reactive towards the catalyst being slowly, but continuously, converted to *n*-hexane. The product was then extracted by heptane addition, with three extractions with 4 mL heptane aliquots yielding 75% of product recovery. In the biphase system then formed, the extent of rhodium leaching was determined by ICP-atomic emission analyses of the upper phase,¶ revealing losses of only 0.083% of metal. Such a low rhodium loss qualifies this procedure as an efficient catalyst recycling.

This reaction is efficient even when performed under biphase conditions as, for instance, using a system composed of MeOH (14 mL), PEO (3.6 g) and *n*-heptane (14 mL), the same rhodium and olefin content as above, with 10 bar of H_2. Under these conditions five runs were made with complete conversion of the substrate to the hydrogenation product and no loss of catalytic activity or selectivity was noted. A kinetic study of this system allowed the determination of an activation time of 50 min. After this time, GC analysis revealed a complete conversion of hex-1-ene to *n*-hexane in 15 min, allowing determination of a turnover frequency of *ca.* 16 min^{-1}. This system can be recycled, at least eight times, with no changes in activity or selectivity.

In conclusion, this set of results, comprising experiments performed with two catalysts under different conditions, have proved the great potential for use of these organic biphase systems as reaction media that enable an easy product separation and efficient catalyst recycling. Furthermore, this procedure allows the use of common catalysts in homogeneous catalysis, requiring, therefore, no special reagents. These biphase systems also display advantages over binary solvent mixtures in that, owing to the presence of the polar polymer, the phase compositions are more different, increasing the partitioning selectivity, without the need of special ligands for the catalyst. The only requirement for their application is the selective partitioning of catalyst and of the desired product, however, this procedure is flexible enough to allow modifications (changing solvents, composition or temperature) that may suit a wide range of catalytic reactions and products.

The authors are grateful to R. F. de Souza and the Laboratório de Reatividade e Catálise - UFRGS for access to their facilities, and to M. Spitzer for providing phase equilibria data for some of the systems used.

Notes and references

† Wilkinson's catalyst was prepared according to the procedure described: J. A. Osborn and G. Wilkinson, *Inorg. Synth.*, 1967, **10**, 68 while $[Rh(cod)(dppe)]PF_6$ was prepared and characterised following R. R. Schrock and J. A. Osborn, *J. Am. Chem. Soc.*, 1971, **93**, 2397.

‡ In all the catalytic tests, the reactor, a 100 mL stainless steel autoclave, was previously purged by vacuum–argon cycles, then pressurised with hydrogen (99.999%). CH_2Cl_2, methanol and *n*-heptane were distilled prior to use, under argon from P_2O_5, activated molecular sieves (3 Å) and Na/benzophenone respectively. Hex-1-ene (Alpha, 99.9%) was stored over activated molecular sieves (3 Å) under argon. PEO 3350 (Sigma), was dried over P_2O_5. All reactions were conducted at room temperature under magnetic stirring.

§ The chromatographic analyses were performed using a Varian Star 3400 CX Chromatograph, equipped with a 30 m × 0.25 mm LM-1 capillary column, at 50 °C and 1 mL min^{-1} (10 psi) of H_2 as carrier gas.

¶ Rhodium analyses were performed by ICP-atomic emission spectrometry with a segmented-array charge coupled device detector (Optima 3000, Perkin Elmer, Newark, CT). Operating conditions: auxiliary argon flow 0.5 L min^{-1}, plasma argon flow 15 L min^{-1}, nebulizer argon flow 0.8 L min^{-1}, variable incident power (0.75–1.5 kW), cross-flow nebulizer and axial observation. Duplicate aliquots of the upper phase were digested with *aqua regia* for 12 h and then adjusted to produce concentrations close to 0.1 ppm. The final rhodium loss was determined as (0.083 ± 0.001)%.

Received (in Oxford, UK) 27th August 1999, Accepted 22nd November 1999

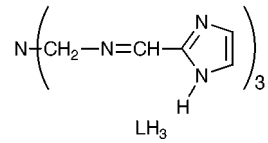
The use of a C_3 complex bearing three imidazolate groups as a 'building block' allowed us to synthesize an infinite corrugated two-dimensional (2D) low-spin Fe(III)–high-spin Mn(II) polymer exhibiting weak ferromagnetic intralayer interaction through imidazolate bridge.

Imidazolate is a highly studied bridge in dimetallic compounds,[1a] as models of (Cu–Zn)SOD[1b,c] and cytochrome c oxidase.[1d] Imidazolate has been previously used in building two- or three-dimensional homo or poly-metallic polymers[2a,b] and is known to induce moderate magnetic coupling.[3]

In order to construct bidimensional structures, we used a pseudo-octahedral iron complex from a N-tripodal ligand (LH_3 = tris{[2-(2-imidazol-2-yl)methyl]iminoethyl}amine) bearing an imidazolate group at the end of each chain as a building block. A dimer based on an analogous iron complex with imidazole substituted in the 4-position has been previously prepared.[2c] We chose a 2-substituted imidazole group to design a more planar M1–imidazolate-M0–imidazolate–M1 geometry.† The iron monomer used is a stable neutral triimidazolate Fe(III) low-spin complex.[4]

Here, we report the X-ray structure of $[Mn(hfac)_2]_3[Fe(L)]_2$ (hfac = 1,1,1,5,5,5-hexafluoroacetylacetonate), an infinite 2D polymer and a preliminary magnetic study of this compound.

Small dark-blue crystals suitable for X-ray diffraction‡ were obtained readily by slow evaporation of a mixture of methanolic solutions of the iron and manganese complexes [Fe(L)] and $[Mn(hfac)_2]$.§ X-Ray crystallography shows an infinite honeycomb-like layered structure in the product. Each Fe(III)(L) entity is linked by imidazolate bridges with three Mn(II), whereas each $Mn(hfac)_2$ is bound in *cis* position to two Fe(III) complexes. The



iron atoms are alternately capped above and below by the tripodal ligand L [Fig. 1(a)]. Within each layer the iron complexes display the same helicity, however, the crystal is non-chiral as revealed by the space group. The iron atoms of a given layer are located at the vertices of a chair-like structure (see Fig. 2) leading to a corrugated 2D-network similar to the Cr–Ni cyanide-bridged compound described by Ferlay *et al.*[5a] A remarkable feature is the *cis* substitution of imidazolate bridges around the manganese. This probably favours overall compactness and therefore the formation of a very stable hexagonal structure.[5a,b] Also, the small imidazolate–Mn–imidazolate angles) compensate for the large Mn–imidazolate–Fe–imidazolate–Mn distance.

The magnetic properties of $[Mn(hfac)_2]_3[Fe(L)]_2$ (Fig. 3) were recorded using a SQUID magnetometer with an applied field H = 1 kOe in the temperature range 50–300 K and with an

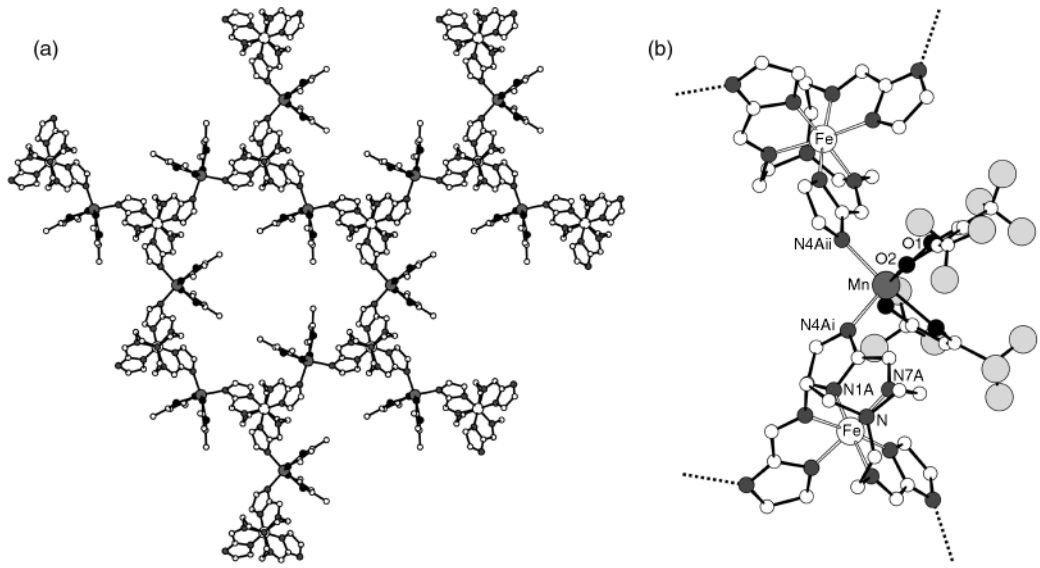


Fig. 1 (a) View of a sheet down the *c* axis. H atoms and F atoms have been omitted for clarity. Shortest Fe···Mn, Fe···Fe and Mn···Mn separations are 5.889(3), 11.26(1) and 9.62(1) Å, respectively. The Mn–Fe–Mn angle is 109.5°; (b) Molecular structure of two iron units bonded to one manganese unit. H atoms have been omitted for clarity. Each F atom has two partially occupied positions with those shown being in the major sites. Selected bond lengths (Å): Fe–N 3.130(10), Fe–N(1A) 1.924(5), Fe–N(7A) 1.983(5), Mn–N(4A) 2.176(5), Mn–O(1) 2.209(6), Mn–O(2) 2.164(5). Symmetry operations: i = x, y, z; ii = $x - y + 1/3, -y + 2/3, -z + 1/6$).

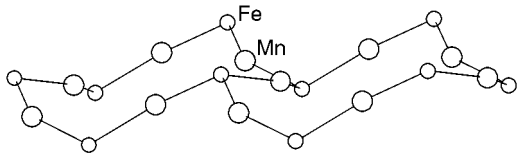

Fig. 2 View of the iron–manganese network showing the corrugated structure of a layer. Only two adjacent chair-like arrangements are represented.

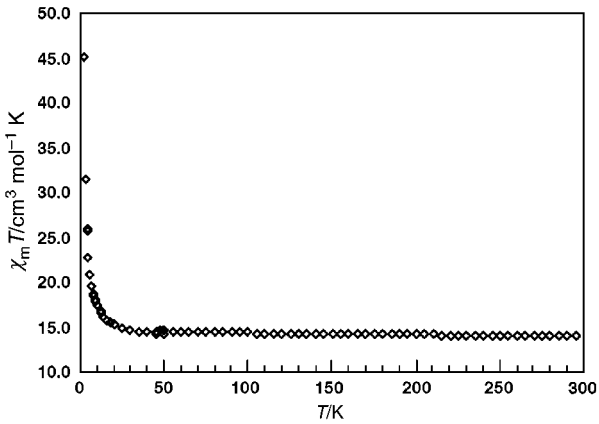

Fig. 3 Experimental temperature dependence of $\chi_M T$ (χ_M susceptibility). From 300 to 50 K, the magnetization was recorded with an applied field of 10 kOe, and from 50 to 2 K with an applied field of 100 Oe. The diamagnetic contribution of the ligands has been subtracted as usual.

applied field H = 100 Oe in the temperature range 2–50 K to avoid saturation.¶ At 300 K $\chi_M T$ = 14.1 cm^3 K mol^{-1}, in good agreement with the expected value for two non-coupled low-spin iron(III) (g = 2.28) and three high-spin manganese(II) (g = 2) ions.‖ Upon cooling, $\chi_M T$ increases and reaches a value of 45 cm^3 K mol^{-1} at 2 K. This behavior indicates the occurrence of a short range ferromagnetic exchange coupling between low-spin Fe(III) and high-spin Mn(II) through the imidazolato bridge. The variation of magnetization as a function of field has also been measured at 2 K. At saturation, expected values would be 17 μ_B (S = 17/2) and 13 μ_B (S = 13/2) for ferromagnetic and antiferromagnetic coupling, respectively (assuming an average g-value of 2). The observed magnetization reaches a value of 16.27 μ_B per Fe_2Mn_3 unit at 5.5 kOe which clearly indicates a ferromagnetic coupling. The overall shape of the M = f(H) curve and the low value (45 cm^3 K mol^{-1}) observed at 2 K for $\chi_M T$ shows only weak magnetic correlation within a layer,** restricted approximately to one Fe_2Mn_3 unit. Moreover, no interaction between the layers is observed down to 2 K. The compound can be considered at most as two dimensional from the magnetic point of view.

This compound is a good example of the ability for C_3 complexes, derived from a tripodal ligand bearing three bridging groups, to be a building block for 2D polymers. As far as we know, it is the first example of a 2D-bimetallic compound containing imidazolate bridges.[6]

We thank Dr E. Rivière for his contribution to magnetic measurements and Professor T. Mallah for useful discussions.

Notes and references

† The Mn–Fe–Mn angle for the present compound is 109°. For a 4-imidazolate iron complex this angle is estimated to be 80°.

‡ *Crystal data*: $[C_{66}N_{20}O_{12}H_{48}F_{36}Mn_3Fe_2]_n$, M = 2273.76, trigonal, space group $R\bar{3}c$, a = b = 18.328(9), c = 48.80(2) Å, γ = 120°, V = 14196(11) Å^3, Z = 6, D_c = 1.596 g cm^{-3}. The asymmetric unit is 1/6 of the molecular entity as defined above with Fe, the tripodal N atom and Mn, located in special positions (symmetry 3, 3 and 2). A blue dark prism single crystal (0.2 × 0.3 × 0.5 mm) was mounted on an Enraf-Nonius CAD4 diffractometer with graphite monochromated Mo-Kα radiation (λ = 0.7107 Å). The unit cell dimensions were refined from setting angles of 25 reflections ($6 < \theta < 9°$). The data collection was *via* the θ–2θ scan technique mode (range 2–25.8°). Three standard reflections were measured every hour and showed no significant decay. A total of 7674 reflections was collected ($-22 \leqslant h \leqslant 19$, $0 \leqslant k \leqslant 22$, $0 \leqslant l \leqslant 54$). From 2294 independent reflections, 1279 were considered with [$I > 2\sigma(I)$]. Lorentz-polarisation and absorption corrections were applied. The structure was solved by direct methods (program SHELXS86) and refined on F^2 for all reflections by the least-squares method using SHELXL-93. Hydrogen atoms were included in the refinement at their ideal positions with an isotropic thermal parameter 1.2 times that of the bonded atoms. The crystal structure is affected by disorder. Two different sites of each CF_3 group were found from difference Fourier syntheses. Best convergence was obtained with occupancy factors of 60 and 40%. Refinement was performed with constraints. The final conventional residuals are $R1$ = 0.054 and $wR2$ = 0.14 for [$I > 2\sigma(I)$] and $R1$ = 0.11 and $wR2$ = 0.19 (all data). CCDC 182/1490. See http://www.rsc.org/suppdata/cc/a9/a907068k/ for crystallographic files in .cif format.

§ Sample elemental analysis is in agreement with the proposed formula while the IR spectrum of the polymer is the superimposition of the spectra of iron and manganese building blocks. This is consistent with the geometric similarity of the Fe unit in the monomer and in the polymer (X-ray structure).

¶ Magnetic properties have been recorded for ground crystals from the same batch used for X-ray diffraction and elemental analysis.

‖ At 300 K, $\chi_M T$ = {[0.125$g_{Fe}^2 S(S+1)$] × 2} + {[0.125$g_{Mn}^2 S(S+1)$] × 3}. A g_{Fe}-value of 2.28 is consistent with the g_{Fe} value obtained for the iron monomer (2.35).[4]

** This is entirely consistent with imidazolate bridges which are known to induce only very weak magnetic interactions.[1]

High-resolution ^{1}H MAS NMR spectra of 2:1 phyllosilicates

María D. Alba,* Ana I. Becerro, Miguel A. Castro and Ana C. Perdigón

Departamento de Química Inorgánica, Instituto de Ciencia de Materiales, Universidad de Sevilla, Consejo Superior de Investigaciones Científicas, Avda. Américo Vespucio s/n. 41092-Sevilla, Spain. E-mail: alba@cica.es

Received (in Oxford, UK) 9th August 1999, Accepted 22nd November 1999

Solid-state ^{1}H MAS NMR at high magnetic fields and high spinning speeds provides a powerful means of identifying the different proton sites in smectites and affects information on the octahedral nature, the octahedral layer charge deficit and the charges on the cations residing in the interlayer space of the silicate.

Solid-state magic angle spinning nuclear magnetic resonance, MAS NMR, spectroscopy has long been recognised as a powerful tool for the study of the structural and physicochemical properties of inorganic silicates, aluminosilicates and zeolites, as well as for the study of the structure of adsorbed molecules and the sorbate–sorbent interactions between molecules and such solids. In consequence, MAS NMR is an experimental technique widely used in solid state chemistry research, both from basic and applied points of view.[1]

In particular, solid-state proton NMR offers an extremely useful tool in the characterization of both the proton-containing parts of the solids, *i.e.* structural hydroxyls and water, and the adsorbed molecules in these materials.[2] Moreover, it provides several advantages over other experimental techniques, such as X-ray diffraction and IR spectroscopy: (i) it is an intrinsically quantitative measurement, the area of the spectrum being directly proportional to the amount of hydrogen present;[3] (ii) the chemical shifts are characteristic of the hydrogen environment, different bands being associated with different structural sites;[4] (iii) both the inter-hydrogen distances, $d_{H–H}$,[5] and the hydrogen bonding distances[6] can be determined; and (iv) the strength and concentration of Brönsted acid sites can be quantitatively studied.[7]

However, conventional proton MAS NMR spectra in the solid state are usually very broad due to homo- and heteronuclear dipolar interactions and, to a lesser extent, chemical shift anisotropy. The main problem generally encountered in ^{1}H MAS NMR is the strength of the homogeneous dipolar interactions among protons, which produce significant linebroadening. Experimental techniques that make use of combined rotation and multiple-pulse spectroscopy, such as CRAMPS and WAHUHA, improve the quality of these spectra but imply the acquisition of more complicated experimental systems.[8] Partial deuteration of the samples reduces the spectral broadening but, again, a more complicated manipulation of the samples and a much more expensive preparation is involved.[9]

In contrast with these disadvantages, the advent of higher field magnets and the technical possibility of achieving very high spinning speeds has allowed the acquisition of high-resolution proton spectra through conventional single-pulse MAS NMR experiments on solids samples, provided that either the hydrogen density in the sample is less than about 15 atoms nm^{-3} or the motions of the molecules containing protons are fast enough, which is in accordance with classical works on the subject.[10] This technique has been successfully used to characterise many hydrous species in minerals, including pyrophyllite and talc, the two end-members of the smectite family.[11] However, the application of the solid-state ^{1}H MAS NMR technique to the study of clay minerals and their reactions has been largely unexplored, even when the information which could be obtained might be extremely useful for those numerous researchers who employ these samples in various areas of the chemistry.

This report details the study of proton spectra of samples representative of the smectite group and analyses the relationship between the spectra and the mineralogical composition of the samples. Likewise, useful applications for such measurements are proposed.

Samples of representative species among smectites with mineralogical compositions close to ideal were selected and homoionised in sodium. The set of samples was supplied by the Source Clay Minerals Repository of Missouri University (Columbia), and includes members of the dioctahedral and trioctahedral series as well as others with different tetrahedral Si/Al ratios. Additionally, the samples were also homoionised with different interlayer cations. The structural formulae of the samples studied in this report are included in Table 1 and characterised in more detail elsewhere.[12]

High-resolution ^{1}H MAS NMR spectra were recorded at room temperature for the smectites equilibrated in air (hydrated samples) and after heating at 150 °C, to ensure the complete removal of interlayer water (dehydrated samples), in order to separate both contributions. A more detailed description of the experimental procedure is given elsewhere.[12] Spectra were acquired in a magnetic field of 9.39 T and rotors were spun at 12 kHz. Pulse spaces of 5 s were used and the radiofrequency field for protons was 60 kHz.

^{1}H MAS NMR spectra of the different sodium-saturated smectites described in Table 1, after dehydration at 150 °C, are given in Fig. 1 (dotted lines in the right-hand column). The spectra of talc and pyrophyllite have also been included. All of the spectra show a single component, assigned to structural hydroxyl groups, which have been fitted with a Lorentzian curve (solid lines in the right-hand column of Fig. 1). The chemical shift (δ) and the full-width at half-height (fwhh) values are displayed in the upper-right-hand graph of Fig. 1.

Table 1 Structural formulae of the selected smectites

Short name	$^{[4]}Si^{4+}$	$^{[4]}Al^{3+}$	$^{[6]}Al^{3+}$	$^{[6]}Fe^{3+}$	$^{[6]}Mg^{3+}$	$^{[6]}Li^{+}$	$^{[6]}Ti^{4+}$	M^{+}
Talc	8.00	—	—	—	6.00	—	—	—
SHCa-1[a]	7.96	0.04	0.04	—	5.30	0.66	—	0.66

Pyrophyllite	8.00	—	4.00	—	—	—	—	—
Trancos[c]	7.64	0.36	3.09	0.28	0.69	—	—	0.87
SAz-1[c]	7.97	0.03	2.71	0.14	1.13	—	0.02	1.14

[a] Hectorite. [b] Saponite. [c] Montmorillonite.

The hydroxyl NMR bands show a value of *ca*. 0.5 ppm for the trioctahedral samples and of *ca*. 2.0 ppm for the dioctahedral ones. The difference in chemical shift between these samples is a consequence of differences in the composition of the octahedral sheet and is in agreement with the ^{29}Si MAS NMR data reported for these materials.[13] In trioctahedral minerals, OH bond axes are perpendicular to the layers and point toward the hexagonal cavities, while they are almost parallel to the layers in dioctahedral minerals.[14] In consequence, the proton position in the dioctahedral smectites allows an interaction between these OH groups and the apical oxygen atoms of the tetrahedral sheets, a hydrogen bond, which causes a deshielding of the protons and, hence, a displacement of their resonances to lower fields.

Within each series, the chemical shift value is related to the octahedral layer charge: the higher the octahedral layer charge, the higher the field. This fact is explained on the basis of the localisation of charge deficits created by isomorphous substitutions in the smectites.[15] If the deficit originates in the octahedral sheet, the excess negative charge tends to be delocalised around the whole sheet and the proton shielding of the structural hydroxyls increases as the octahedral charge is elevated. However, if the deficit occurs in the tetrahedral sheet, the excess negative charge tends to be localised on single oxygen atoms and the effect on the hydroxyl proton shielding is negligible.

As regards the band widths, these are influenced by both structural and compositional parameters. Firstly, trioctahedral structures provide a more symmetrical environment for the hydroxyl protons than dioctahedral minerals. In the latter structures, the hydroxyls are tilted and pointing toward one of the tetrahedra of the hexagonal array, a librational motion being allowed. In consequence, the trioctahedral minerals show a unique hydroxyl chemical environment and narrower ^{1}H NMR signals, whilst dioctahedral minerals show an average of different hydroxyl orientations and wider bands.

Secondly, the mineralogical composition affects the band width in a two-fold manner: those samples without isomorphic substitutions show the narrowest bands in each series and the incorporation of paramagnetic impurities and NMR-active nuclei causes a broadening of the signals.

In order to evaluate the influence of the interlayer cation, ^{1}H MAS NMR spectra of saponite exchanged with different cations are included in the left-hand column of Fig. 1, similar results being obtained for the other smectites. Dehydrated and exchanged saponites display similar ^{1}H NMR hydroxyl signals regardless of the identity of the interlayer cations, indicating that these species have no influence on the OH protons.

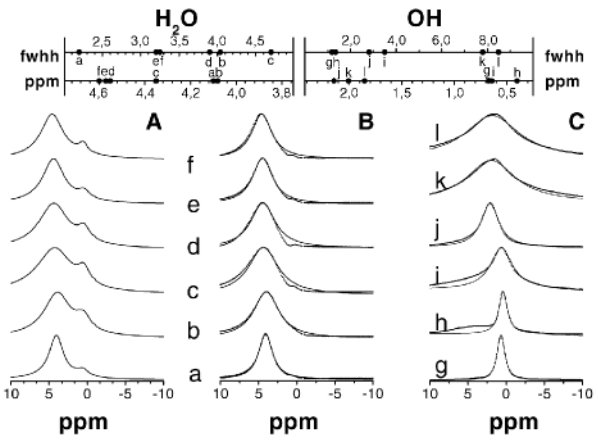

Fig. 1 A: ^{1}H MAS NMR spectra of saponite saturated with Na^{+} (a), Li^{+} (b), Mg^{2+} (c), Al^{3+} (d), La^{3+} (e), and Lu^{3+} (f) ions. **B**: Subtraction from ^{1}H MAS NMR spectra shown in the left column of the ^{1}H MAS NMR spectra obtained from the samples after dehydrating at 150 °C (dotted lines) and Lorentzian fitting curves (solid lines). Chemical shifts and full-widths at half-height are shown in the upper-left diagram for each fitting curve. **C**: ^{1}H MAS NMR spectra of (g) talc, (h) Na-hectorite, (i) Na-saponite, (j) pyrophyllite, (k) Na-Trancos montmorillonite, and (l) Na-SAz-1 montmorillonite after dehydrating at 150 °C (dotted lines). Lorentzian fitting curves have been included for each experimental curve (solid lines). Chemical shfts and full-widths at half-height are shown in the upper-right diagram for each fitting curve.

As regards the ^{1}H NMR water signal, the centre column of Fig. 1 exhibits, as dotted lines, the experimental spectra shown in the left-hand column, after subtraction of the corresponding spectra of the dehydrated samples. These spectra are composed of a single component, associated with the interlayer water of these materials. A clear relationship between the chemical shift value and the interlayer cation charge is observed. As the charge of the cation increases, the proton acidity increases and the band is shifted to lower fields: chemical shifts for the water protons of samples exchanged with trivalent cations are found to lie within the narrow range 4.60–4.55 ppm; those of samples exchanged with divalent cations lie close to 4.36 ppm; and those of samples exchanged with monovalent cations lie around 4.10 ppm. Identical chemical shifts were found for the other smectites exchanged with the same cations. Therefore, the position of the water band is uniquely affected by the charge of the interlayer cation.[16,17]

However, the fwhh is less influenced by both the charge and the size of the cation, the response being much more complicated. The variations in the linewidths of proton spectra in similar systems are affected by the mobility of water and, in consequence, complicated diffusion processes are involved, more sophisticated models being necessary for a discussion of these effects.

In summary, this report shows that the combined use of high magnetic fields and spinning speeds affords single-pulse ^{1}H MAS NMR spectra of smectites of similar quality to those currently obtained by using multiple-pulse sequences. Moreover, these spectra require only very short acquisition times and a simple instrumental set up. The spectra directly provide information on the octahedral nature, the octahedral layer charge, and the charge of the interlayer cation of the mineral, structural aspects of elevated importance in the study of these materials. In particular, they can be used as initial characterization measurements and can be valuable for monitoring structural changes in the course of many treatments in which smectites can change their layer charge, suffer leaching processes, or modify their interlayer compositions. Finally, such spectra afford the opportunity to develop two-dimensional cross-polarisation experiments with other nuclei, such as ^{27}Si, ^{29}Al and ^{7}Li, which would improve the information currently obtained from MAS NMR spectroscopy.

We thank DGICYT for financial support (Project No. PB97-0176).

Received (in Cambridge, UK) 12th October 1999, Accepted 23rd November 1999

A novel compound of the formula Ag_2·CA (CA = cyanuric acid) possessing Ag sheets and hydrogen-bonded CA chains, exhibits anisotropic conductivity and acts as an infinite parallel plate capacitor with a high dielectric constant.

Design of infinite two- and three-dimensional arrays of metal–ligand networks has attracted considerable attention in the last few years not only because of the structural and topological novelty of such engineered solids but also due to the potentially interesting electrical, magnetic and other properties.[1,2] Recently, interesting structures containing polymeric Ag(I) species and heterocyclic as well as aromatic compounds have been described.[2–4] For instance, Ag(I)–benzenesulfonate has a layered structure containing a planar hexagonal array of Ag(I) ions incorporating the anion.[4] A coordination network of dicyanodiphenylacetylene comprising Ag(I) sheets with an Ag···Ag separation of 3.39 Å has also been reported.[5] Equally interesting are the supramolecular Ag(I) complexes constructed with several aromatic compounds involving novel stacking of the aromatics such as the herringbone packing pattern.[6,7] Many of these compounds have Ag···Ag separation significantly shorter than the van der Waals contact distance, with Ag(I) having linear, trigonal, tetrahedral or hexagonal coordination,[8] however, the materials are generally either insulators or semiconductors with no unusual properties.

During the course of our investigations of supramolecular assemblies of cyanuric acid, $C_3H_3N_3O_3$ (CA), involving both hydrogen bonding and metal-ion coordination, we have isolated a novel silver compound possessing two-dimensional Ag sheets with the CA molecules in the interlayer space, forming linear hydrogen-bonded chains. This compound of composition Ag_2·CA, is a unique organic–inorganic hybrid with novel electrical properties, and is entirely different from the supramolecular assemblies described above, and from other Ag complexes and salts with short Ag···Ag distances.[9] Here, we describe the fascinating structure and properties of this Ag(I) compound.

Reaction of $AgNO_3$ with CA under hydrothermal conditions† gave single crystals of composition Ag_2·CA suitable for X-ray diffraction studies. The structure was determined‡ using the SHELXTL package,[10] with the intensity data collected on a Siemens smart diffractometer equipped with CCD area detector. The asymmetric unit of the compound is shown in Fig. 1. The structure viewed down the *b*-axis (Fig. 2) reveals the presence of two-dimensional sheets of Ag atoms separated by CA molecules, the inter-sheet separation being *ca*. 6 Å. The average Ag···Ag distance in the sheets is 2.95 Å, slightly longer than the Ag–Ag distance in metallic silver (2.89 Å). The dative Ag–O and Ag–N bond distances are in the range 2.22–2.76 and 2.09–2.12 Å, respectively, and the CA molecules are linked by relatively short N–H···O hydrogen bonds (H···O 1.90 Å, N···O, 2.75 Å), giving rise to a linear chain (Fig. 2). The arrangement of the CA molecules in the layers perpendicular to the Ag sheets is illustrated in Fig. 3. Another noteable feature of Ag_2·CA is that the organic spacer itself is the anion. Ag_2·CA can also be compared with Ag_3O with an *anti*-BiI_3 structure with the O atoms occupying 2/3 of the octahedral holes.[11] The Ag···Ag and Ag–O distances in Ag_2·CA are slightly longer than in Ag_3O, except for one Ag–O bond of 2.22 Å.

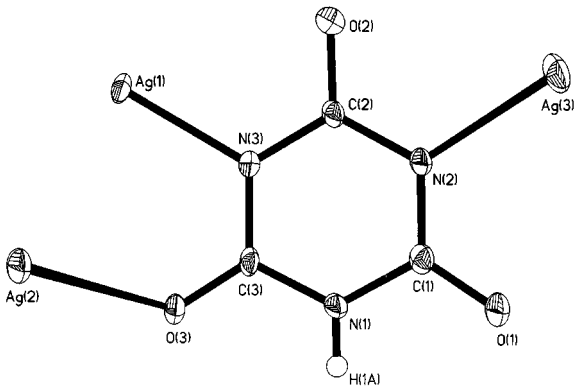

Fig. 1 ORTEP drawing showing the asymmetric unit of Ag_2·CA.

The presence of multipoint recognition patterns between CA and Ag in Ag_2·CA is of interest. For instance, the hydrogen bonding motif (a) in Scheme 1, found in the structure of CA,[12] is replaced by the motif (b) in Ag_2·CA by the substitution of Ag for H. Motif (b) is similar to that present in Ag carboxylates, except that two of the O atoms are replaced by N atoms. In addition, there are three-point recognition patterns (c) and (d) in Ag_2·CA, comparable to the hydrogen bonding pattern (e) found in the adduct of CA with melamine.[13]

Ag_2·CA crystals are mica-like and are readily cleaved because of the layer structure and the presence of weakly bound Ag sheets. The presence of two-dimensional Ag sheets is expected to give rise to anisotropic conductivity. Accordingly, the values of the dc conductivity parallel and perpendicular to the Ag sheets (*bc* plane) are *ca*. 5×10^{-3} and *ca*. 2×10^{-5} S cm^{-1}, respectively, at 300 K. The conductivity along the sheets is temperature-independent down to 15 K. Ag_2·CA, in which the conducting Ag sheets are separated by the organic spacer molecules, can be considered as an infinite parallel plate capacitor. In accord with this, the crystals possess a high static dielectric constant of *ca*. 22 000 at 300 K, a phenomenally high value which promises potential applications. This value of the

dielectric constant is comparable with that of barium titanate (*ca*. 12000 at 300 K).

Notes and references

† A solution (10 mL) consisting of a mixture of $AgNO_3$ (0.170 g) and CA (0.129 g) in water in a Teflon flask was placed in a steel bomb. The bomb was placed in an oven maintained at 180 °C for 24 h and then cooled to room temperature (25 °C) over a period of 3 h. Good quality off-white plate-like single crystals, were obtained and the composition of the product was established as Ag_2·CA, consistent with that derived from X-ray crystallography. There were no other products in the reaction.

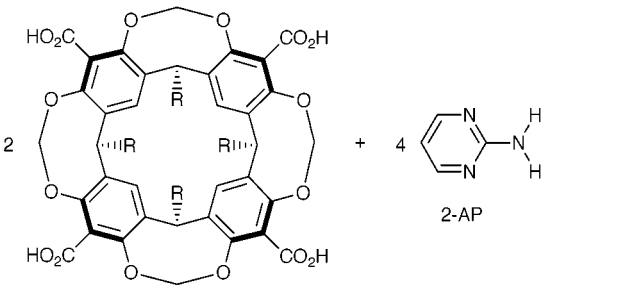
Received (in Cambridge, UK) 18th October 1999, Accepted 17th November 1999

Two molecules of cavitand tetracarboxylic acid and four molecules of 2-aminopyrimidine assemble into a capsule *via* 16 hydrogen bonds, as shown by ^{1}H NMR titration and X-ray crystallographic analysis; in the solid state, two molecules of nitrobenzene are encapsulated in the capsule.

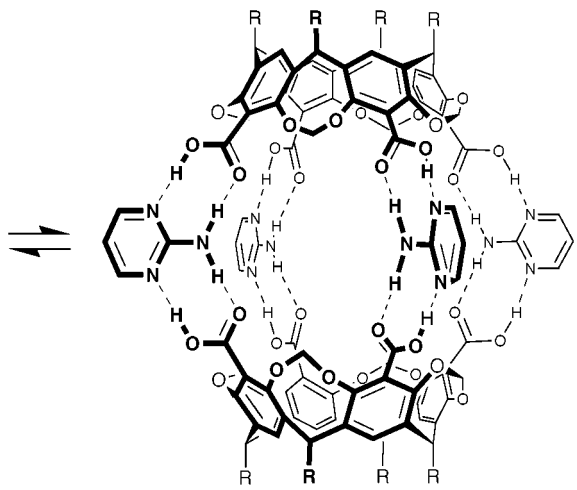
Error correction through thermodynamic equilibration, minimization of synthetic effort by use of modular subunits and control of assembly processes through subunit design are characteristic of supramolecular approaches to self-assembly.[1,2] Carcerands, in which two calix[4]resorcinarene cavitands are held together by four covalent linkages, have been synthesized and well-characterized by Cram and others, and have attracted considerable attention from the viewpoint of stabilization of reactive intermediates and microvesicles for drug delivery by confinement of guest molecules inside the capsules away from bulk phases.[3] Recently, the field of molecular capsules has advanced to a stage where self-assembly through noncovalent interactions such as hydrogen bonds and metal coordination has proved to be a reliable tool.[4,5] Based on hydrogen bonds, homodimers of functionalized cavitands in solution[6,7] and multicomponent assemblies of calix[4]resorcinarenes with solvent water or alcohol molecules as linkers in the solid state[8,9] have been reported. Metal-bridged assemblies of functionalized cavitands have also proved to be a viable alternative.[10] We have chosen the cavitand tetracarboxylic acid **1** as a concave subunit[11] and 2-aminopyrimidine (2-AP) as a hydrogen-bonded linker subunit. Our strategy for capsule formation is based on the combination of carboxylic acids with 2-AP to form a 2:1 hydrogen-bonded complex in the solid state.[12] Herein we report the construction of capsule **2** from six components *via* 16 hydrogen bonds: two molecules of **1** are indirectly held together in a rim-to-rim fashion by hydrogen bonding bridges involving four molecules of 2-AP (Scheme 1).

The cavitand **1** alone has a low solubility in $CHCl_3$ at room temperature { < 5 mM for **1a** [R = $(CH_2)_6CH_3$] and < 1 mM for **1b** [R = $(CH_2)_2Ph$]}. On the other hand, in the presence of 2 equiv. of 2-AP, **1** becomes very soluble in $CHCl_3$ (> 100 mM). The titration of a suspension of **1a** in $CDCl_3$ at 25 °C with aliquots of 2-AP was monitored by ^{1}H NMR spectroscopy. Fig. 1 shows the chemical shift changes for the NH_2 protons of 2-AP and the inward and outward methylene protons at the rim of **1a** as a function of 2-AP/**1a**.† Below the 2:1 ratio of 2-AP/**1a**, the NH_2 protons of 2-AP apparently give a saturated downfield shift ($\Delta\delta_{obs}$ = 2.95 ppm), independent of 2-AP/**1a**, while the methylene protons of **1a** are increasingly shifted downfield upon addition of 2-AP. At the 2:1 stoichiometry of 2-AP/**1a**, the mixture becomes completely homogeneous.† Beyond the 2:1 ratio, the former chemical shift changes decrease due to the average of signals between the free and complex 2-AP, whereas the latter ones remain unchanged. The fact that both titration curves have an inflection point at the 2:1 stoichiometry of 2-AP/**1a** indicates that an *n*:2*n* complex of **1a** with 2-AP is formed *via* hydrogen bonds and that this formation may be a cooperative process. The cavitand **1a** and 2-AP possess four and two hydrogen bonding sites, respectively. In principle, 1:2 and/or 1:4 complexes of **1a** with 2-AP may be conceivable. In such complexes, however, half of the hydrogen bonding sites still remain intact. The titration data obtained here suggests the formation of a capsule **2a** in solution from two molecules of **1a** and four molecules of 2-AP (Scheme 1).‡ The capsule **2a** in $CDCl_3$ was disrupted upon addition of DMSO-d_6 as a cosolvent.

The stability of **2a** was evaluated by the dilution method in $CDCl_3$ at 25 °C using ^{1}H NMR, where the ratio of 2-AP/**1a** is maintained at 2:1. The chemical shift changes for the NH_2 protons of 2-AP decreased at less than 10 mM of 2-AP. The association constant for the formation of **2a** calculated from a nonlinear curve fitting was estimated to be $K_a = 3.7 \times 10^{19}$ M^{-5} in $CDCl_3$ at 25 °C with $\Delta\delta_{sat}$ = 2.96 ppm and a correlation



1a R = $(CH_2)_6CH_3$
1b R = $(CH_2)_2Ph$



2a R = $(CH_2)_6CH_3$
2b R = $(CH_2)_2Ph$

Scheme 1

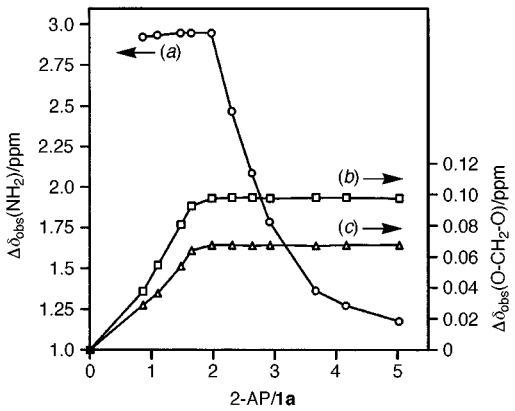


Fig. 1 Chemical shift changes for (*a*) the NH_2 protons of 2-AP and (*b*) the inward and (*c*) outward methylene protons at the rim of **1a** as a function of 2-AP/**1a** in $CDCl_3$ at 25 °C.

coefficient r = 0.99.§ This corresponds to an average $\Delta G°$ = −1.6 kcal mol^{-1} per hydrogen bond.[13]

Recrystallization of a mixture of **1** and 2-AP from various solvents such as *p*-xylene, anisole–$CHCl_3$ and nitrobenzene–$CHCl_3$ gave co-crystals composed of **1**:2-AP = 1:2 without exception. The IR spectra showed a shift (10 cm^{-1}) to lower wavenumbers of the $\nu_{C=O}$ for **1** upon adduct formation. The O–H stretching bands appeared at 2500 and 1900 cm^{-1}, which are characteristic of a carboxylic acid hydrogen bonded to an aromatic ring nitrogen.[12] When pyridine was used in place of 2-AP, co-crystals of **1**:pyridine = 1:4 were obtained. These results support the formation of **2** from **1** and 2-AP in the solid state.

Single crystals suitable for X-ray diffraction analysis were grown by allowing a hot solution of **1b** and 2-AP in nitrobenzene to slowly cool to room temperature.¶ As shown in Fig. 2, the molecular structure after symmetry operations unambiguously reveals the capsule **2b** in which two molecules of the hemispherical cavitand **1b** associate indirectly in a rim-to-rim fashion by hydrogen bonding bridges involving four molecules of 2-AP located on an equatorial position. The NH_2 protons and aromatic ring nitrogens of 2-AP form hydrogen bonds with the acid carbonyl oxygens and OH protons of **1b**, respectively. The hydrogen bonding distances of N(H)···O are 2.866(7), 2.841(7), 2.897(7) and 2.872(7) Å, and those of N···(H)O are 2.770(7), 2.604(7), 2.711(6) and 2.718(6) Å. Thus, the capsule **2b** is constructed *via* 16 hydrogen bonds between two molecules of **1b** and four molecules of 2-AP. The

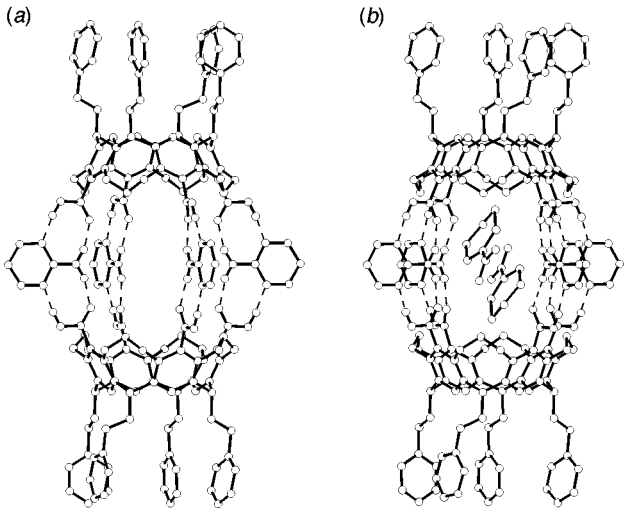

Fig. 2 Molecular structure of capsule **2b** (*a*) without and (*b*) with encapsulated nitrobenzenes. Nitrobenzenes which are not located inside the cavity and hydrogen atoms except for NH_2 protons of 2-AP and acid protons of **1b** are omitted for clarity. Dashed lines represent intermolecular hydrogen bonds.

dihedral angles between the carboxylic acid groups and the resorcinol rings of **1b** are almost perpendicular (83.5, 85.7, 105.9 and 80.2°), probably due to the electronic repulsion between the oxygen atoms of their moieties. This orientation plays an important role in the formation of the capsule. The capsule **2b** features dimensions of *ca.* 9 × 15 Å. Two molecules of nitrobenzene are encapsulated in the cavity of **2b** in an antiparallel fashion with an inter-ring distance of *ca.* 3.3 Å. They are oriented with the nitro groups towards the equatorial windows of **2b**.

In summary, we have demonstrated the capsule **2**, composed of two molecules of the cavitand tetracarboxylic acid **1** and four molecules of 2-aminopyrimidine, as a hydrogen-bonded linker. Exploration of linkers such as bipyridine derivatives and transition metals in order to control the cavity size of the capsules is currently underway in our laboratory.

Notes and references

† The concentration of **1a** is 20 mM if completely soluble in $CDCl_3$. The equilibrium is reached immediately. At the 2:1 stoichiometry of 2-AP/**1a**, the signal of the acid protons of **1a** was observed at δ 16.00 at −30 °C. Irradiation of the C(4,6) hydrogens of 2-AP showed a 3% NOE at the acid protons of **1a** at −30 °C.

‡ No evidence for the encapsulation of guests into **2a** in $CDCl_3$ is available, probably due to favorable accommodation of $CDCl_3$ as a bulk phase in **2a**.

§ A constant ratio [2-AP]:[**1a**] = 2:1, and the assumption that free **1a**, free 2-AP and capsule **2a** are the only components present, give eqn. (1),

$$[\text{2-AP}] = \{(\Delta\delta_{obs}/\Delta\delta_{sat})/[K_a(1 - (\Delta\delta_{obs}/\Delta\delta_{sat}))^6]\}^{0.2} \quad (1)$$

where $\Delta\delta_{obs} = \delta_{obs} - \delta_{free}$ and $\Delta\delta_{sat} = \delta_{sat} - \delta_{free}$ are the observed and saturated chemical shift changes of the NH_2 protons of 2-AP, respectively.

¶ *Crystal data* for **1b**·2(2-AP)·6($PhNO_2$): $C_{112}H_{96}N_{12}O_{28}$, M = 2058.05, crystal size 0.52 × 0.45 × 0.40 mm, triclinic, space group $P\bar{1}$, a = 17.79(2), b = 19.78(1), c = 15.047(5) Å, α = 107.32(4), β = 96.18(3), γ = 79.05(5)°, U = 4955(6) Å^3, Z = 2, D_c = 1.379 g cm^{-3}, μ(Mo-Kα) = 1.00 cm^{-1}, $2\theta_{max}$ = 50.2°. Intensity data (11593) were measured on a Rigaku RAXIS-II diffractometer at 120 K. The final least-squares refinement based on F for 8815 unique reflections [with $I > 3.0\sigma(I)$] and 1396 parameters converged with R = 0.110 and R_w = 0.124. CCDC 182/1489. Kinetic resolution of amines by acylation using 3-diacylaminoquinazolin-4(3*H*)-ones

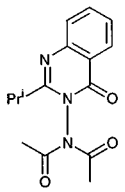
Abdullah G. Al-Sehemi, Robert S. Atkinson, John Fawcett and David R. Russell

Department of Chemistry, Leicester University, Leicester, UK LE1 7RH. E-mail: vow@le.ac.uk

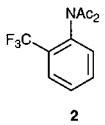
Received (in Cambridge) 4th October 1999, Accepted 16th November 1999

Four diastereoisomeric 3-diacylaminoquinazolinones 8a–d have been separated and identified by X-ray structure determinations on three of them: their stoichiometric reactions with α-phenylethylamine and with 2-methylpiperidine (2 equiv. of amine) gave the corresponding *N*-(2-acetoxypropanoyl)amine and unreacted amine in high diastereomeric/enantiomeric excess.

3-Diacylaminoquinazolinones (DAQs), *e.g.* **1**, are highly selective acylating agents for primary amines in the presence of secondary amines and for the less hindered of two secondary amines.[1] Recently the *N*,*N*-diacetamide **2** has been claimed to be even more chemoselective than DAQ **1** as an acetylating agent: a 1:1 mixture of pyrrolidine and piperidine (ΔpK_a = 0.01) reacts with **2** to give a 15:1 ratio of the corresponding *N*-acetylated amines.[2]



1

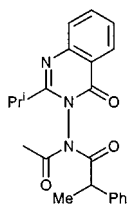


2

The DAQs **3**, **4** and **5** were available to us by acetylation of the corresponding 3-aminoquinazolinones[3] and, when reacted with a mixture of pyrrolidine and piperidine (1 equiv. each) at 0 °C in CH_2Cl_2 gave the ratios of the corresponding amides shown in Scheme 1. Unexpectedly, the chemoselectivity increases as the substituent R on the chiral centre decreases in size from Bu^t → Me with a 20:1 ratio for methyl.†

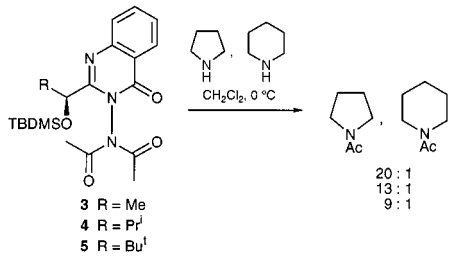
Since DAQs **3**, **4** and **5** are enantiopure we were particularly interested in a greater potential advantage which their use offered over that of *e.g.* **2**, namely as enantioselective acetylating agents.[4] However, reaction of DAQ **3** (1 equiv.) with racemic 2-methylpiperidine (2 equiv.) gave a sample of recovered amine having zero optical rotation and hence there is no kinetic resolution in this acetylation.

For 3-aminoquinazolinones *N*,*N*-disubstituted with different acyl groups, we have previously shown that the *N*–*N* bond is a chiral axis: in DAQ **6** the presence of two chiral elements gives rise to diastereoisomers with a barrier $\Delta G^{\#}$ = 121 kJ mol^{-1} for their interconversion by rotation around the *N*–*N* bond.[4]



6

Successive acylation of enantiopure 3-aminoquinazolinone **7**[3] with (*S*)-2-acetoxypropanoyl chloride and isobutanoyl chloride (Scheme 2) gave four DAQ diastereoisomers **8a**–**d** in order of their elution on chromatography (see below). The major diastereoisomer **8b** was separated by crystallisation (35%) after flash chromatography to remove unreacted mono-acylquinazolinone (MAQ) and pure samples of the other three, **8a** (5%), **8c** (7%) and **8d** (26%), were obtained by separation using a chromatotron.



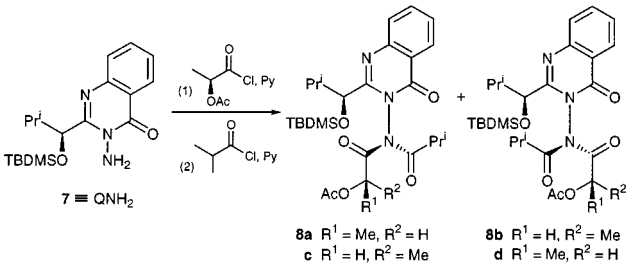
Scheme 1

X-Ray crystal structure determinations of DAQs **8b** and **8c** (Fig. 1) showed them to have the expected (*S*)-configuration at their α-acetoxypropanoyl chiral centres but different configurations at their *N*–*N* chiral axes.‡ Heating ($CDCl_3$, 60 °C, 42 h) interconverted **8b** and **8c** and gave a 5:4 ratio respectively at equilibrium, presumably as a result of rotation around the *N*–*N* bond: no interconversion with **8a** or **8d** occurred.

Diastereoisomers **8a** and **8d** arise from epimerisation at the α-acetoxypropanoyl centre as shown by the (*R*)-configuration in the X-ray crystal structure of **8d** (Fig. 1).‡ Interconversion of **8a** and **8d** by heating ($CDCl_3$, 60 °C, 13 h) gave a 6:1 ratio at equilibrium, respectively: no interconversion with **8b** and **8c** occurred in this equilibrium.

Although in their crystal structures DAQ **8b**–**d** all have the usual[4] *exo*/*endo* conformation for their imides, **8b** and **8c** have their α-acetoxypropanoyl groups *endo* and the isobutanoyl group *exo* whereas **8d** has the positions of these two groups reversed.

We find that these DAQs **8a**–**d** are enantioselective acylating agents for racemic amines. Thus DAQ **8c** (1 equiv.) reacts with α-phenylethylamine (2 equiv.) in CH_2Cl_2 at 5 °C to give (2*R*,2′*S*)-*N*-(-2-acetoxypropanoyl)-α-phenylethylamine [77% based on (*R*)-α-phenylethylamine, 88% de] by NMR comparison with authentic samples of both diastereoisomers: the recovered *S* enantiomer of the amine [90% based on (*S*)-α-phenylethylamine] was of 91% ee from its specific rotation (Scheme 3).



Scheme 2

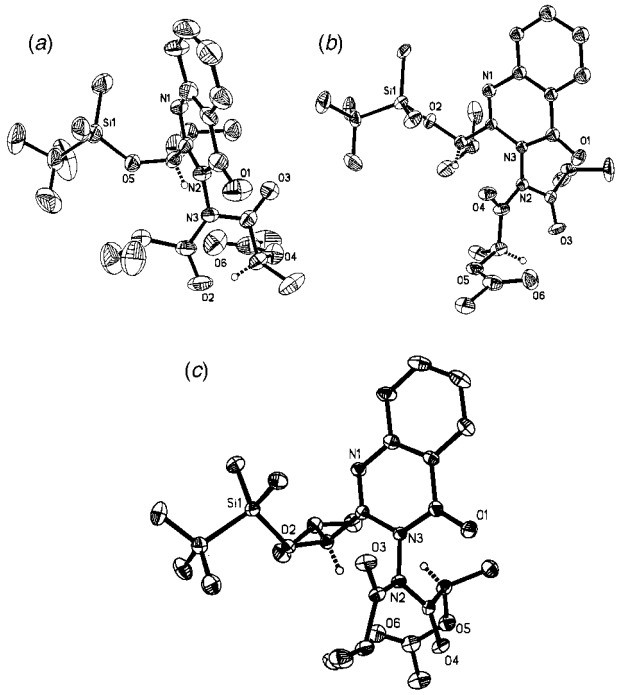


Fig. 1 Molecular structures of (*a*) **8b**, (*b*) **8c** and (*c*) **8d** showing atom labelling schemes and 30% probability displacement parameters. H atoms at chiral centres are shown with dashed bonds, all other H atoms are omitted for clarity.

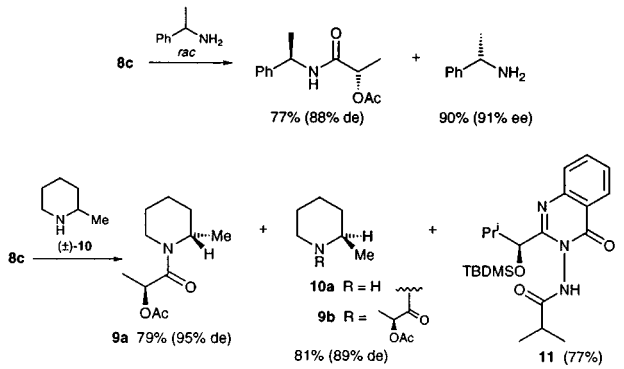

Scheme 3

Reaction of DAQ **8c** (1 equiv.) with racemic 2-methylpiperidine **10** (2 equiv.) in CH_2Cl_2 at 5 °C for 24 h gave, after chromatography, monoacylquinazolinone (MAQ) **11** (77%) and (2*S*,2′*S*)-1-(2′-acetoxypropanoyl)-2-methylpiperidine **9a** (79%) (Scheme 3) whose diastereopurity (de) as measured by NMR spectroscopy was 95%. The unreacted 2-methylpiperidine enantiomer was recovered from the crude reaction mixture by extraction with HCl (2 M) and derivatised by reaction with (*S*)-2-acetoxypropanoyl chloride to give **9b** (81%) of 89% de: at 400 MHz and 50 °C the OCOC*H*$_3$ signals of diastereoisomers **9a** and **9b** are well separated.§

Since DAQ **8b** was recovered unchanged when re-subjected to the conditions of the second acylation in Scheme 2, it appears that epimerisation at the 2-acetoxypropanoyl chiral centre occurs in the second acylation step.¶ An alternative, more stereoselective route to these DAQs was to carry out the second acylation using the lithium salt of the MAQ. Thus reaction of the lithium salt of MAQ **11** with (*S*)-2-acetoxypropanoyl chloride gave DAQ **8c** (71%) and **8a** (8%) (based on recovered starting material), *i.e.* with less epimerisation than previously.

Kinetic resolution is usually carried out in the presence of excess of the substrate to maximise enantiopurity in its derivatised enantiomer. Even under the most testing conditions of stoichiometry as in Scheme 3, DAQ **8c** delivers both derivatised and unreacted enantiomers of the substrate with high enantioselectivity.

We thank the Ministry of Education, Saudi Arabia for funding (to A. G. Al-S).

Notes and references

† This increase may be related to the preference for a defined conformation around the C–OSi bond in the (Q) 2-substituent in **3** but not in **4** or **5** (see R. S. Atkinson, M. P. Coogan and I. S. T. Lochrie, *Tetrahedron Lett.*, 1996, **37**, 5179.

‡ *Crystal data* for **8b**: $C_{27}H_{41}N_3O_6Si$, M = 531.72, orthorhombic, space group $P2_12_12_1$, a = 10.146(1), b = 13.296(2), c = 22.618(3) Å, V = 3051.4(7) Å^3, Z = 4, μ(Mo-Ka) = 0.118 mm^{-1}, 3845 reflections measured, 3639 unique (R_{int} = 0.013) which were all used in calculations. Final R_1 = 0.052 and wR_2 = 0.114 (all data). For **8c**: $C_{27}H_{41}N_3O_6Si$, M = 531.72, orthorhombic, space group $P2_12_12_1$, a = 9.391(2), b = 13.554(6), c = 23.908(13) Å, V = 3043(2) Å^3, Z = 4, μ(Mo-Ka) = 0.118 mm^{-1}, 3756 reflections measured, 3592 unique (R_{int} = 0.035) which were all used in calculations. Final R_1 = 0.102 and wR_2 = 0.309 (all data). For **8d**: $C_{27}H_{41}N_3O_6Si$, M = 531.72, orthorhombic, space group $P2_12_12_1$, a = 12.152(9), b = 13.170(7), c = 18.293(9) Å, V = 2928(3) Å^3, Z = 4, μ(Mo-Ka) = 0.118 mm^{-1}, 3666 reflections measured, 3455 unique (R_{int} = 0.155) which were all used in calculations. Final R_1 = 0.044 and wR_2 = 0.099 (all data). Data were measured on a Siemens P4 diffractometer at 190 K using graphite monochromated Mo-Ka radiation (λ = 0.7107 Å) using an ω-scan technique. Three standard reflections monitored every 100 scans showed no significant variation in intensity, the reflections were corrected for Lorentz and polarisation effects. The structures were solved by direct methods and refined by full-matrix least-squares on F^2. The absolute configurations of the compounds were established by the known configuration at the silyloxy substituted carbon atom. All examined crystals of **8c** diffracted weakly; to preserve an observed data to variable ratio of 6:1 the 13 most closely isotropic atoms were constrained to be isotropic. All hydrogen atoms were included in calculated positions (C–H = 0.96 Å) using a riding model. CCDC 182/1486. See http://www.rsc.org/suppdata/cc/a9/a907970j/ for crystallographic data in .cif format.

§ A mixture of amide diastereoisomers **9a** and **9b** was prepared by reaction of (*S*)-2-acetoxypropanoyl chloride with racemic 2-methylpiperidine. An authentic sample of amide **9b** was prepared from (*R*)-2-methylpiperidine, $[\alpha]_D$ (HCl salt) 8.9 (*c* 2, EtOH), itself prepared from the racemic amine by resolution using (*R*)-mandelic acid.

¶ Significantly, the MAQ recovered from the reaction in Scheme 2 was also found to be a mixture of two diastereoisomers, epimeric at the 2-acetoxypropanoyl chiral centre.

Received (in Columbia, MO, USA) 14th September 1999, Accepted 8th November 1999

Nucleobase molecular recognition on a self-assembled monolayer was studied in supercritical carbon dioxide and obtained kinetics were compared with those in air and liquid phases.

Molecular recognition is an essential phenomenon in living systems, as observed in complementary hydrogen bond formation in DNA. In recent years, a number of artificial receptors containing base pairing models of DNA have been reported.[1] They confirm selective binding of small guest molecules *via* complementary hydrogen bonds in hydrophobic organic solvents and at the air-water interface, although it hardly occurs in bulk water.[2] Molecular recognition in the gas phase has also been investigated, as it would form a most simple system avoiding any solvation effects on both host and guest molecules.[3] Supercritical fluid is attractive as a third medium, in addition to the liquid and gas phases, because its physical properties (*e.g.* solvation, density, diffusiveness and viscosity) are intermediate between those of a gas and a liquid, and can be manipulated by small changes in pressure or temperature.[4] Several spectral studies of hydrogen bonding interactions[5a–c] and inclusion phenomena[5a,e] have been carried out in supercritical fluid. It is useful to study and compare molecular recognition in these three different states of matter. A quartz-crystal microbalance (QCM) is a useful instrument for detecting directly guest molecular binding processes by measuring mass changes at a host monolayer, as it is independent of media and can be used in an air phase,[3a–c] in aqueous solution,[6] and even in supercritical fluid.

Here we report the binding behavior and kinetics of small guest molecules in supercritical carbon dioxide ($scCO_2$) at a self-assembled monolayer of decanethiol having thymine at the terminus on a highly sensitive 27 MHz QCM (see Fig. 1); these data are then compared with those obtained in the gas phase[3a–c] and in aqueous solution.[6]

A 27 MHz, AT-cut QCM was connected to a handmade oscillator.[6,7] Frequency changes were followed by a universal counter (Hewlett Packard Co., Ltd., model 53131A) attached to a microcomputer system. Calibration of the 27 MHz QCM showed that 0.62 ng cm^{-2} of substrate binding corresponds to 1 Hz of frequency decrease, which was consistent with the Sauerbrey equation[8] and our previous papers.[6,7] The thymine monolayer was immobilized on Au electrodes on both sides (4.9 $mm^2 \times 2$) of the QCM according to the previous papers.[3a–c] The frequency decreased by 500–600 Hz (mass increase, Δm = 310–370 ng cm^{-2}) due to the monolayer immobilization. The theoretical mass of the monolayer on the two gold electrodes was calculated to be 350 ng cm^{-2}, if the surface roughness was assumed to be about 2. These values indicate that the Au electrode was covered with a monolayer of the thymine derivative.

Liquid CO_2 was pumped into a reservoir vessel containing guest molecules at 10–15 MPa using a LC pump (Jasco PU-980 HPLC pump) connected to a CO_2 cylinder. The vessel was warmed up to 40 °C to create the supercritical state. A mixture of guest saturated $scCO_2$ and pure $scCO_2$ was passed at a rate of 3–5 ml min^{-1} into a reaction vessel at 40 °C and 10 MPa, in which the monolayer immobilized QCM was set with a magnetic stirrer. Guest concentrations were controlled by changing the mixture ratio of the two fluids.

Fig. 2 shows typical time courses of frequency changes of the 27 MHz QCM immobilized with the thymine monolayer responding to exposure to the same concentration (1.0×10^{-4} M) of various guest molecules in $scCO_2$ at 40 °C and 10 MPa. Both 9-ethyladenine and 2-aminopyridine (an adenine analogue) were bound reasonably well onto the thymine monolayer, probably due to complementary two-point hydrogen bonding with the host thymine membrane. In spite of having a two-point hydrogen bonding ability with thymine, 1-cyclohexyluracyl and 2-pyrrolidone (a uracil analogue) were hardly adsorbed onto the thymine monolayer. Similar selective binding of adenine derivatives to the thymine monolayer was observed when the binding experiments were carried out in the air phase[3a–c] and on the thymine monolayer at the air-water interface.[6]

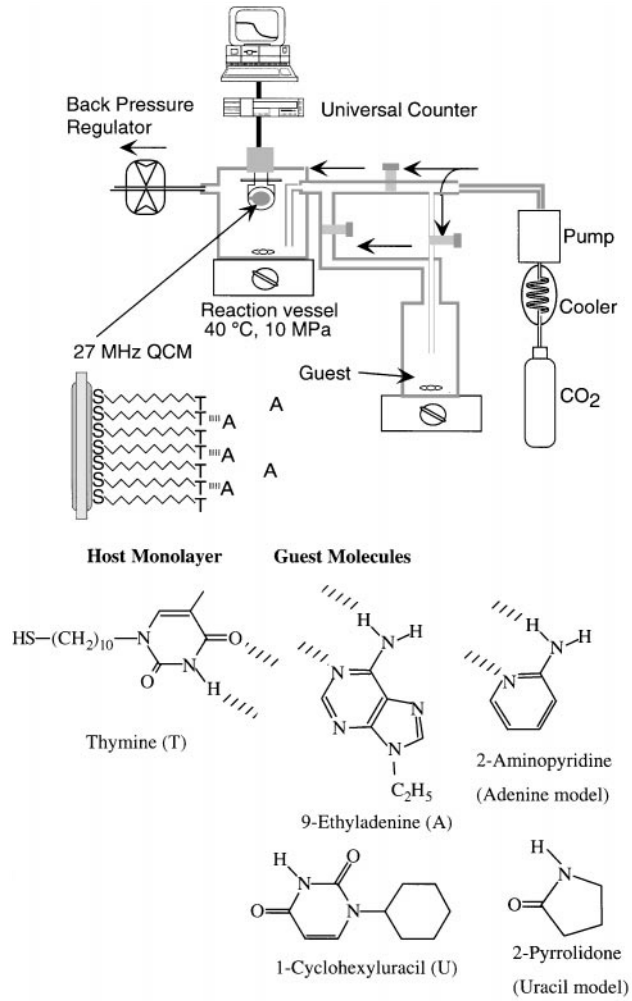

Fig. 1 Schematic illustration of nucleobase binding to a thymine monolayer on a 27 MHz QCM in a supercritical CO_2 flow system.

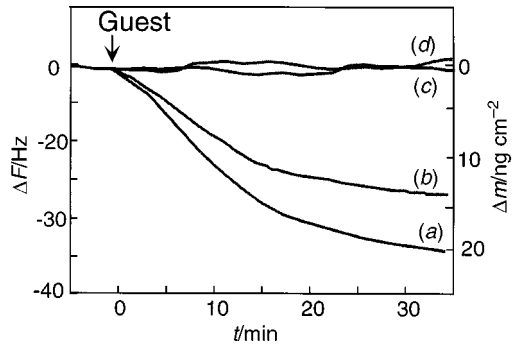

Fig. 2 Time courses of frequency decreases (mass increases) of the 27 MHz QCM immobilized with the thymine monolayer, responding to exposure of guest molecules (1.0×10^{-4} M) in supercritical CO_2 (40 °C and 10 MPa); (*a*) 9-ethyladenine, (*b*) 2-aminopyridine (an adenine model), (*c*) 1-cyclohexyluracil and (*d*) 2-pyrrolidone.

Table 1 Association constants (K_a) and initial binding rate constants (k_1) for guest bindings to the thymine monolayer in various media

Media	Guests	$K_a/10^3$ M^{-1}	k_1/M^{-1} s^{-1}
$scCO_2$[a]	9-ethyladenine	1.2	2.0
	2-aminopyridine (an adenine model)	2.6	8.0
	1-cyclohexyuracil	0.02	0.1
	2-pyrrolidone (a uracil model)	0.02	0.2
Air[b]	2-aminopyridine (an adenine model)	73 000	190 000
	2-pyrrolidone (a uracil model)	780	21 000
Water[c]	adenosine	0.23	0.5
	uridine	< 0.01	< 0.01

[a] 40 °C, 10 MPa. [b] 25 °C, see refs. 3(*a*) and 9. [c] 25 °C, pH 7.5, 0.01 M phosphate buffer, see refs. 6 and 10.

When the concentration of guest molecules increased (2×10^{-5} to 5×10^{-4} M), the typical saturation binding curves were obtained. From the reciprocal plots, association constants (K_a) could be obtained from linear correlations. From the initial slopes of the frequency decreases (mass increases) of Fig. 2, the apparent binding rate constants (k_1) were calculated. These data are summarized in Table 1, as are those values obtained using the same QCM system in the air[3a,9] or on the monolayer at the air-water interface.[6,10]

Complementary binding between the thymine monolayer and 9-ethyladenine or 2-aminopyridine (an adenine model) showed $K_a = (1.2–2.6) \times 10^3$ M^{-1}, which is about 100 times larger than K_a = 10–20 M^{-1} for noncomplementary binding of 1-cyclohecyluracil or 2-pyrrolidone. Similar selectivity was observed between the thymine monolayer and 2-aminopyridine (an adenine model) or 2-pyrrolidone (a uracil model) in the air phase at 25 °C, and between the thymine monolayer and adenosine or uridine in the aqueous solution (25 °C, pH 7.5, 0.01 M phosphate buffer). In the air phase, 2-aminopyridine and 2-pyrrolidone were employed as adenine and thymine models, respectively, since nucleobases are difficult to vaporize under the usual conditions. In aqueous solution, adenosine and uridine were employed due to their high solubility to aqueous solution.

Complementary hydrogen bonding between nucleobases has been confirmed by FT-IR spectral measurements in $CDCl_3$ solution.[11] We measured FT-IR spectra in the bulk $scCO_2$ using a pressure-resistant stainless steel vessel with ZnSe windows.[12] The $\delta_{N–H}$ at 1604 cm^{-1} for 2-aminopyridine (an adenine model) was shifted to 1616 cm^{-1} in the presence of an equal amount of 2-pyrrolidone (a uracil model) in $scCO_2$ (40 °C, 10 MPa), indicating that both molecules interact through hydrogen bonding as efficiently as in $CDCl_3$ solution.[11]

The selectivity (about 100 times) of the thymine monolayer for complementary guest molecules was similar among the three phases (air, water and super critical fluid). However, association constants (K_a) and initial binding rate constants (k_1) largely depended on the medium. K_a and k_1 values obtained in the air phase were very large due to the lack of solvent effects in the gas state, and those values in supercritical fluid were closer to, but still 10 times larger than, those in the aqueous phase. In supercritical fluid, the medium itself is thought to form fluid clusters, by which substrates are weakly solvated like a monolayer.[4a] This means that the very thin, weak solvation of the host and/or guest molecules in the supercritical fluid significantly reduced the interaction compared with the bare interaction in gas phase, and became close to the fully solvated interaction in the solution. Although the reaction conditions and guest molecules are slightly different for the three media, the K_a and k_1 values reflect the physical properties such as solvation and diffusiveness in each medium.

In conclusion, we could observe selective interactions between nucleobases in a supercritical fluid, and the QCM system is useful to monitor this binding behavior even in supercritical fluid, as well as in the liquid and air phases. One of advantages of supercritical fluid as a medium is that its physical properties, such as density, diffusion rate and solvation, can be reversibly changed by varying the temperature or pressure of the $scCO_2$ state.[13] We are currently studying the effect of solvation on molecular recognition by changing the physical state of the supercritical fluid.

9 In the air phase, the thymine monolayer-immobilized QCM was set in the atmospheric flow of dry N_2 gas and guest molecules were added into the flow using a system similar to that shown in Fig. 1.

10 In the aqueous phase experiments, the monolayer of the amphiphile having thymine as a hydrophilic head group was spread on the water phase, the bare QCM plate was attached horizontally from the air phase on the amphiphile monolayer, and then guest molecules were injected into the water phase (ref. 6).

12 Although we attempted direct detection of the hydrogen bond formation on the monolayer using an RAS-IR at the interface, we could not obtain clear results due to a lack of the sensitivity.

13 For example, density and relative permittivity can be changed over the ranges 0.1–0.8 and 0.1–0.5, respectively, by changing the pressure from 7 to 20 MPa at 40 °C.

The insertion of sulfur dioxide into palladium–methyl bonds: the synthesis and X-ray crystal structure of an unusual $[(dppp)PdOS(Me)O]_2[BAr'_4]_2$ dimer

Derek P. Gates, Peter S. White and Maurice Brookhart*

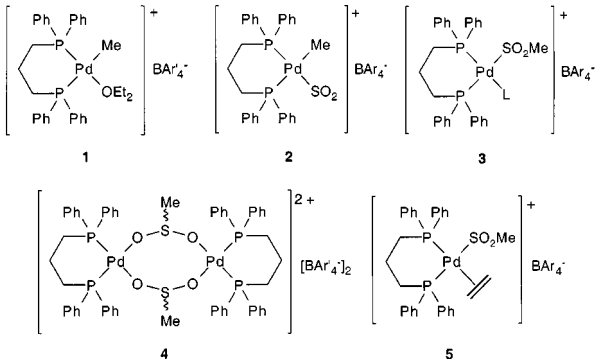
Department of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-3290, USA. E-mail: brook@net.chem.unc.edu

Received (in Bloomington, IN, USA) 26th July 1999, Accepted 22nd October 1999

The migratory insertion of sulfur dioxide into the palladium(II)–methyl bond of [(dppp)Pd(Me)(OEt_2)]BAr'_4 [Ar′ = $C_6H_3(CF_3)_2$-3,5] to yield a unique dimeric eight-membered palladacycle was followed by NMR spectroscopy, and the product characterised by X-ray crystallography.

Palladium(II) complexes possessing bidentate ligands are known to efficiently catalyse the copolymerisation of olefins with carbon monoxide to form polyketones.[1] Sulfur dioxide is an attractive monomer for catalytic copolymerisations with olefins since SO_2, like CO, is known to undergo facile insertion reactions into a variety of transition metal–alkyl bonds.[2,3] Indeed, Drent recently patented alternating copolymerisation of ethylene with SO_2 using various palladium(II) complexes.[4] In 1998, Sen and coworkers also reported that [(dppp)PdMe(NCMe)]BF_4 was an effective catalyst for the copolymerisation of SO_2 with ethylene, propylene and cyclopentene.[5] Here, we report our preliminary investigations of the insertion reactions of SO_2 into Pd(II)–methyl bonds and the attempted spectroscopic detection of the copolymerisation of ethylene and SO_2.

The cationic 1,3-bis(diphenylphosphino)propane (dppp) palladium(II) complex **1** can be prepared by the low temperature



1 **2** **3** **4** **5**

reaction of $(dppp)PdMe_2$ **6** with $H(OEt_2)_2[BAr'_4]$ [Ar′ = $C_6H_3(CF_3)_2$-3,5].[6] We have previously studied the reactions of carbon monoxide with **1** at −70 °C, and have found that insertion proceeds *via* initial displacement of diethyl ether with CO followed by migratory insertion into the Pd–Me bond.[7] Immediately after treating a solution of **1** in CD_2Cl_2 with an excess of SO_2 (*ca.* 25 equiv.) at 193 K, the ^{1}H NMR spectrum shows the presence of free diethyl ether. Analysis of the reaction mixture by ^{31}P NMR spectroscopy (193 K) shows the formation of a major product (*ca.* 80%) which exhibits a singlet at δ 15.7 indicating equivalence of the phosphorus nuclei. In addition, two minor products (*ca.* 20%) with singlet resonances at δ 15.4 and 14.5 are also observed. The expected products, **2** and **3**, both of which would possess inequivalent phosphorus atoms, are not observed under these conditions. In addition, the ^{1}H NMR spectrum exhibits three new singlets[5] at δ 0.52 (78%), 0.42 (8%) and 0.25 (14%) which are assigned to $-CH_3$ groups, no signals were observed downfield at *ca.* 2–3 where resonances for an $-S(O)_2CH_3$ group would be expected.[8] A preparative scale reaction† was carried out in an attempt to isolate single crystals. Indeed, pale yellow crystals suitable for X-ray diffraction were isolated after recrystallisation of the crude product from dichloromethane–hexanes at −30 °C.‡

The molecular structure of the isolated product **4** is shown in Fig. 1, and confirms that insertion of SO_2 into the Pd–Me bond had taken place, however dimerisation resulted in the formation of an eight-membered cyclic compound in which the phosphorus atoms are equivalent, consistent with the ^{31}P NMR observations. In particular, the eight-membered ring consists of a plane of palladium and oxygen atoms, with the sulfur atoms located above and below the plane. The six-membered rings formed by the dppp ligand are in the chair conformation.

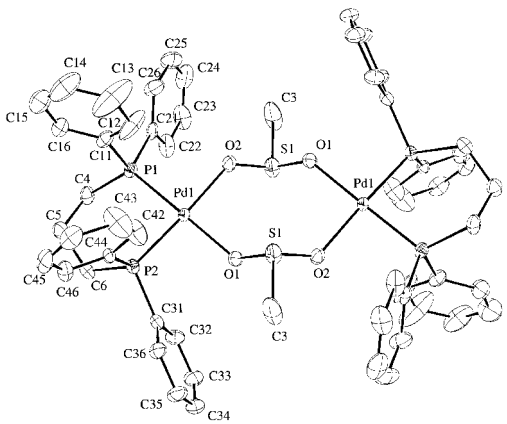


Fig. 1 Molecular structure of **4** (BAr'_4 anion omitted for clarity) with thermal ellipsoids shown at the 50% probability level. Selected bond lengths (Å) and angles (°): Pd(1)–P(1) 2.2354(20), Pd(1)–P(2) 2.2393(19), Pd(1)–O(1) 2.078(5), Pd(1)–O(2) 2.088(5), O(1)–S(1) 1.494(5), O(2)–S(1) 1.507(5), S(1)–C(3) 1.786(10); P(1)–Pd(1)–P(2) 90.12(7), P(1)–Pd(1)–O(2) 89.00(15), P(2)–Pd(1)–O(1) 90.47(15), O(1)–Pd(1)–O(2) 90.92(19), O(1)–S(1)–O(2) 109.5(3), O(1)–S(1)–C(3) 98.4(5), Pd(1)–O(1)–S(1) 128.0(3).

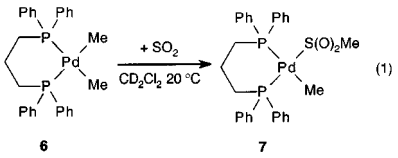
A variable temperature NMR experiment was carried out on **4** in CD_2Cl_2 solution. As the temperature is raised from 193 K the three singlet ^{31}P resonances (δ 15.7, 15.4, 14.5) begin to broaden at *ca.* 260 K and coalesce to a singlet above *ca.* 300 K. This process is reversible. Similarly, the three methyl signals also coalesce to a singlet but at a somewhat lower temperature (*ca.* 280 K) owing to the smaller spread in resonance frequencies. Since the inversion barrier at tetrahedral sulfur in **4** is expected to be high, the most likely source of the isomerism observed here[9] comes from ring inversion of the chair conformation of the dppp ligand.

We have also studied the behaviour of **1** towards mixtures of ethylene and SO_2 in an attempt to spectroscopically observe the insertion of SO_2 and ethylene in an alternating fashion. Thus, treatment of a solution of **1** in CD_2Cl_2 with a mixture of ethylene (10 equiv.) and SO_2 (10 equiv.) results in quantitative displacement of ether with ethylene at 193 K forming [(dppp)Pd(Me)(η^2-C_2H_4)]BAr'_4[10] which was characterised by ^{31}P [δ = 17.5 (d, *J* 56 Hz), −1.5 (d, *J* 56 Hz)] and ^{1}H NMR spectroscopy [δ 5.18 (bound C_2H_4), 0.34 (dd, Pd–CH_3, *J* 7, 4 Hz)]. Upon warming the reaction mixture to 223 K for *ca.* 30

min complex **4** was formed in nearly quantitative yield. No evidence for insertion of ethylene into the Pd–Me bond was detected, nor was any direct insertion of SO_2 into the Pd–Me bond of the methyl ethylene complex observed to form **5**. This suggests that formation of **4** from [(dppp)Pd(Me)(η^2-C_2H_4)]BAr′$_4$ (or **1**) involves displacement of ethylene (or diethyl ether for **1**) to yield **2** which then undergoes a rapid migratory insertion reaction to form **3** which then dimerises yielding **4**. This is in contrast to observations by Jones for analogous L_2PtMe_2 complexes which readily insert SO_2 *via* a five coordinate intermediate.[8] We have also carried out the analogous reaction of Pd complex **6** with SO_2 to form **7** presumably also *via* a five coordinate intermediate [eqn. (1)].†



6 **7** (1)

In an attempt to obtain conclusive evidence for a migratory insertion mechanism, a low-temperature NMR experiment was carried out using $CDCl_2F$ as solvent. Thus, SO_2 (10 equiv.) was added to a solution of ether complex **1** in $CDCl_2F$ at 153 K. Upon warming to 173 K several new products could be detected in addition to **1**. The ^{31}P NMR spectrum exhibited resonances assigned to **4**, and also two sets of doublets at δ 22.0 and −5.5 (J_{PP} 50 Hz) and δ 18.8 and 17.4 (J_{PP} 20 Hz). In the ^{1}H NMR spectrum, in addition to **4**, two new products were observed which exhibited a methyl singlet at δ 1.6 and a methyl doublet of doublets at δ 0.0 (J_{HP} 7, 4 Hz). The signal at δ 0.0 is clearly due to a Pd–CH_3 group of a (dppp)Pd$(CH_3)^+$ moiety and, since this species is not observed in the absence of SO_2, we assign this resonance to complex **2**, [(dppp)Pd$(CH_3)(SO_2)]^+$. The ^{31}P resonances at δ 22.1 (d, *J* 50 Hz) and δ −5.6 (d, *J* 50 Hz) can be assigned to **2**. The low field methyl resonance at δ 1.6 [^{31}P resonances δ 18.8 (d, *J* 20 Hz), δ 17.4 (d, *J* 20 Hz)] is assigned to monomer **3**, a precursor to dimer **4**, formed *via* a migratory insertion reaction of **2**. The ligand (L) occupying the fourth coordination site in **3** is likely to be either SO_2 or Et_2O. As the reaction mixture was warmed in 5 °C increments, the signals for **2**, **3** and **4** increased in intensity and those for **1** decreased. At 213 K, only isomers of **4** could be detected. We speculate that in **3** the SO_2Me is bound through oxygen, rather than sulfur, based on the molecular structure of the final product **4**.

A copolymerisation was attempted using hex-1-ene (10% v/v) in CH_2Cl_2 purged with SO_2 in the presence of a catalytic quantity of **1** (14 mg).[11]† After *ca.* 14 h, the reaction was quenched with methanol. Solvent removal *in vacuo*, yielded a small amount of a polymeric material (23 mg). The polymer was precipitated with methanol and was characterised by gel permeation chromatography (M_n = 61 000: PDI = 5.8), and the ^{1}H and ^{13}C NMR data are identical with those reported for the hex-1-ene/SO_2 alternating copolymer prepared using a free-radical initiator.[12] Comparing the amount of **1** used as initiator (9×10^{-6} mol), the amount of hex-1-ene consumed (1.6×10^{-4} mol) and the estimated M_n of the polymer produced (61000) suggests that if chain growth occurred at Pd only a very small fraction of the Pd centers were active (< 5%). Results from repeated polymerisations proved quite erratic with varying amounts of polymer produced both in the presence and absence of **1**. Reactions conducted in the presence of the radical scavenger galvinoxyl failed to produce polymer.[13] These results, coupled with the failure to spectroscopically observe ethylene insertion in these systems and the ready formation of the stable dimer **4**, suggest that the copolymerisation of hex-1-ene and SO_2 under conditions reported above does not occur by a coordination–insertion process initiated by **1**. A radical chain growth mechanism appears very likely, although we cannot rule out copolymerization in the presence of **1** which is initiated by traces of a palladium complex of unknown structure present in **1** and which can be deactivated by galvinoxyl. The copolymerizations reported by Sen and coworkers[5] were carried out at higher pressures (600 psi), so it is uncertain how these results relate to those experiments.

We thank NSF for support of this work. D. P. G gratefully acknowledges NSERC of Canada for a Postdoctoral Fellowship. Thanks to S. Svejda for providing a sample of $CDCl_2F$ and to S. Shultz for useful discussions.

Notes and references

† *Preparation* of **4**: under an atmosphere of argon, SO_2(g) (150 mL, 6 mmol) was slowly purged through a cloudy white stirred suspension of **1** (102 mg, 0.07 mmol) in CH_2Cl_2 (7 mL) at −78 °C. After stirring for 10 min a clear yellow solution was observed and the solvent was removed *in vacuo* yielding a yellow solid. The crude product was recrystallized by dissolution in 3 mL of CH_2Cl_2 at −78 °C and layering pentanes (1.5 mL) over the solution. Overnight at −30 °C light yellow crystals formed. Yield 28 mg (30%). ^{1}H NMR (CD_2Cl_2, 193 K); major isomer (78%): δ 7.72 (s, 8H, BAr′$_4$: *o*-H), 7.53 (s, 4H, BAr′$_4$: *p*-H), 7.5–7.2 (m, 20H, C_6H_5), 2.49 (br, 2H, PCH_2), 2.34 (br, 2H, PCH_2), 2.07 (m, 2H, CH_2), 0.52 (s, CH_3), minor isomers: δ 0.42 (s, CH_3) (8%), 0.25 (s, CH_3) (14%); ^{31}P (CD_2Cl_2, 193 K) δ 15.7 (major isomer, *ca.* 80%), 15.4, 14.5 (minor isomers, *ca.* 20%). Anal. Calc.: C, 49.32; H, 2.83. Found: C, 49.37; H, 2.81%.

(dppp)Pd(Me)S(O)$_2$Me **7**: ^{1}H NMR (CD_2Cl_2, 293 K) δ 7.6–7.2 (m, 20H, C_6H_5), 2.4 (m, 4H, PCH_2), 2.21 (s, 3H, SO_2CH_3), 2.1 (m, 2H, CH_2), 0.52 (pseudo t, J_{PH} 6 Hz, 3H, CH_3); ^{31}P NMR (CD_2Cl_2, 293 K); δ 18.9 (J_{PP} 48 Hz), 3.1 (J_{PP} 48 Hz).

Polymerisation studies: a 10% solution of freshly distilled hex-1-ene (5 mL) in CH_2Cl_2 (45 mL) was purged with SO_2 for 7 min at room temperature. A solution of **1** (14 mg, 9 μmol) was added at −78 °C, and the reaction was stirred at room temperature for 14 h. Methanol (*ca.* 10 mL) was added to quench the reaction, the solution concentrated *in vacuo*, and methanol added to precipitate the polymer. Yield 23 mg. ^{1}H NMR ($CDCl_3$) δ 4.1–3.6 [br, 2H, SO_2CH_2], 3.3 [br, 1H, C*H*(Bu)SO_2], 2.5–1.7 (br, α-CH_2), 1.7–1.3 (br, 4H, CH_2CH_2), 0.9 (t, 3H, CH_3); GPC (THF, *vs.* PS standards): M_n = 61000, PDI 5.8. Identical conditions were applied for the reactions in the absence of **1** or in the presence of galvinoxyl (10 mg).

Vanadium [dicyanoperfluorostilbene]$_2$·*y*THF: a molecule-based magnet with $T_c \approx 205$ K†

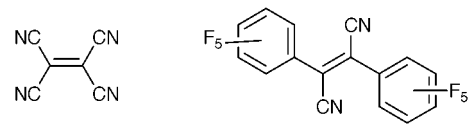
Received (in Bloomington, IN, USA) 16th September 1999, Accepted 17th November 1999

A new radical anionic bridging ligand, derived from the *in situ* reduction of α,α′-dicyanoperfluorostilbene, is reported to support ferrimagnetic ordering below 205 K in a three-dimensional vanadium-based coordination polymer.

In 1991, Miller and coworkers reported that the reaction of $V(C_6H_6)_2$ and tetracyanoethylene (TCNE), in dichloromethane yields an air-sensitive solid that is magnetically ordered at room temperature.[1] This compound, formulated as $V(TCNE)_2 \cdot 0.5CH_2Cl_2$ based on elemental analysis, represented the first example of ferrimagnetism above room temperature in a molecule-based system. The structure is presumed to be a three-dimensional coordination polymer consisting of solvent-ligated V^{2+} cations bridged by $TCNE \cdot^{1-}$ anions, though only limited structural information has been obtained.[2] One factor perhaps contributing to the amorphous nature of the solid is that, in principle, TCNE may bridge up to four metal centers, resulting in a degree of structural randomness.[3] Miller and coworkers have subsequently studied the effects of coordinating solvent[2] and improved on the synthesis, replacing $V(C_6H_6)_2$ with the more readily available precursor, $V(CO)_6$.[4] In recent work, they have shown that $MI_2 \cdot x$MeCN salts, (M = Mn, Fe, Co or Ni), are viable sources of building blocks for analogous $M(TCNE)_2$ magnets in which T_c ranges from 44 to 121 K.[5]

Despite this progress, no organic acceptor has been reported to substitute for TCNE in reactions with $V(CO)_6$ or $V(C_6H_6)_2$ to give a magnetically ordering compound.[2] Although many candidates possess the requisite electrochemical properties, those that have been examined, including 7,7,8,8-tetracyanoquinodimethane (TCNQ), 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) and tetrachloro-1,4-benzoquinone, react to yield paramagnetic solids, none of which show any signs of magnetic order.[2] These results have left it unclear what special properties of TCNE, such as molecular size, shape, redox properties or the ability to coordinate more than two metal centers, are critical to achieving a magnetically ordered solid. The *absence* of another efficacious acceptor has hampered efforts to elucidate the detailed mechanism of magnetic coupling in $V(TCNE)_2$ and to further develop this intriguing family of ferrimagnetic three-dimensional coordination polymers.

Here we report the discovery of a second magnetically ordering compound in the V(acceptor)$_2$·*y*(solvent) family. Pursuing a strategy involving the design and synthesis of ethylenic acceptors related to TCNE,[6] has led to the discovery that α,α′-dicyanoperfluorostilbene, (DCPFS), reacts with $V(CO)_6$ in THF to give an air-sensitive, charge-transfer coordination polymer, $V(DCPFS)_2 \cdot y$THF, a compound that orders, apparently ferrimagnetically, with $T_c \approx 205 \pm 5$ K. Because many of the characteristics of DCPFS are so unlike those of TCNE, its examination helps to delineate the properties that are unimportant in the design of potential new radical anionic bridging ligands. The construction of coordination polymer magnets with radical anionic bridging ligands is an attractive approach because the versatility of organic chemistry can be exploited and because the compounds produced are inherently three-dimensional, which favors higher T_c values.



TCNE DCPFS

DCPFS was prepared by the oxidative dimerization of pentafluorophenylacetonitrile utilizing a modification of the method described by Cook and Linstead.[7,8] Both *cis* and *trans* products are fully characterized, air-stable, crystalline, white solids. Using cyclic voltammetry, it was found that *trans*-DCPFS exhibits a quasi-reversible one-electron reduction at *ca.* −1.0 V *vs.* ferrocene.[8] This value is 0.7 V more negative than the first reduction of TCNE, revealing that DCPFS is only a modest electron acceptor. It does not, for instance, oxidize decamethylmanganocene in CH_2Cl_2.

In spite of its relatively negative reduction potential, DCPFS reacts readily with $V(CO)_6$. In a typical preparation, $V(CO)_6$ in THF is treated with 2.2 equiv. of *trans*-DCPFS at room temp. in an inert atmosphere glove box.[8] The color immediately changes from yellowish green to reddish purple, but in sharp contrast to reactions between $V(CO)_6$ and TCNE, this reaction appears to remain homogeneous for at least several minutes after mixing of the two reactants. Over the course of 1 h, however, a small amount of dark precipitate deposits on the sides of the flask. This initial precipitate exhibits magnetic order, but at a relatively low T_c, perhaps because the degree of polymerization is still low. To obtain the higher T_c material, the solvent is removed under vacuum and the residue is triturated in Et_2O for 15 min. The black solid is collected on a fritted glass filter and washed with Et_2O until the filtrates run clear. Once precipitated, the solid cannot be redissolved in the original solvent.

Unfortunately, despite the greater solubility of incipient $V(DCPFS)_2 \cdot y$THF in organic solvents, we have not yet been able to crystallize it. Powder X-ray diffraction shows that the isolated compound is amorphous. IR spectrometry reveals little about the coordination environment except that there is no CO present. Elemental analysis of the product is variable, as was previously observed for the TCNE analog.[4] However, the results on five independently prepared samples are roughly consistent with the formulation, $V(DCPFS)_2 \cdot y$THF, ($y \approx 2$). The analyses were usually high in vanadium, a fact not too surprising given the method of isolation.

To support this proposed formulation, additional experiments have been performed in which the reactant ratios were varied. As expected, preparing the compound beginning with a 1:1 ratio of acceptor to donor, resulted in a product with a much lower critical temperature, and in much lower yield. In contrast, the product obtained from the 4:1 reactant ratio was magnet-

† Electronic supplementary information (ESI) available: preparation and spectral data for α,α′-dicyanoperfluorostilbene. See http://www.rsc.org/suppdata/cc/a9/a907535f/

ically equivalent to that obtained from the 2:1 procedure and the quantity of isolated product was essentially the same.

A sample [henceforth abbreviated $V(DCPFS)_2$] for magnetic studies was sealed under vacuum in a glass holder as previously described.[9] The plot of gram magnetization, *M*, *vs.* temperature, *T*, measured in 2 G applied field is shown in Fig. 1. It clearly shows the onset of magnetic order below *ca.* 205 K. The continuous decrease in magnetization with increasing temperature is reminiscent of the behavior observed for the TCNE analog. The feature at *ca.* 120 K might be the result of a second magnetic phase transition or indicate the presence of a second magnetic phase. The plot of ac susceptibility for $V(DCPFS)_2$ is also quite similar to that observed for $V(TCNE)_2$.[10] The data appear as a broad, featureless, frequency-independent maximum in χ' with a small non-zero χ'' component.[8]

Like $V(TCNE)_2$, $V(DCPFS)_2$ is a soft ferromagnet. Fig. 2 shows the plot of gram-magnetization, *M*, *vs.* applied field, *H*, at 5 K. At this temperature, the amount of hysteresis is very small; the coercive field is < 20 G. Gram-magnetization was plotted because of the uncertainty in the formula unit. However, assuming the stoichiometry $V(DCPFS)_2 \cdot 2THF$, one calculates the saturation magnetization to be *ca.* 7000 emu-G mol^{-1}, roughly consistent with ferrimagnetic coupling of two spin 1/2 anions and one spin 3/2 cation per formula unit.

It is important to note that the observed magnetic properties are not due to an impurity phase: by cooling a sample to 77 K in a sealed round bottom flask, one can easily attract and move the entire sample with a Sm–Co permanent magnet. Further, while one might suspect the presence of a vanadium-based Prussian blue-type ferrimagnet *via* the reductive decomposition of DCPFS, that seems very unlikely given no such rationally designed phase has been reported that contains only vanadium and no other metal.[12–14] Also, if such a compound did exist, it would have to possess ordered CN ligands around ordered mixed-valent V cations (no low-spin electron configurations exist for octahedral V in oxidation states two or higher) and these would have to arise from our one-pot synthesis.

Several modifications of the above standard procedure for preparing $V(DCPFS)_2$ were found to result in samples with inferior magnetic properties. For instance, carrying out the reaction in CH_2Cl_2 instead of THF gives a material with $T_c \approx 100$ K. This result is in sharp contrast with the corresponding reaction of $V(CO)_6$ with TCNE for which CH_2Cl_2 is the solvent of choice and coordinating solvents such as THF give rise to products with lower T_c values.[14] In THF, using $V(C_6H_6)_2$ in place of $V(CO)_6$ as a source of V^0 results in an ordering phase,

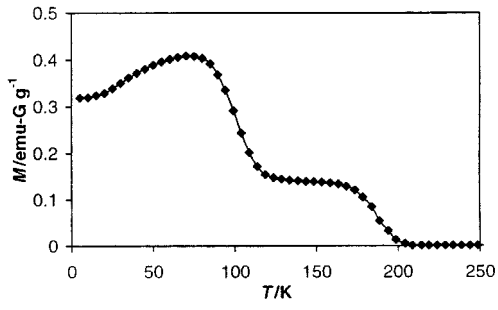


Fig. 1 Plot of magnetization, *M*, *vs.* temperature, *T*, measured at 2 G.

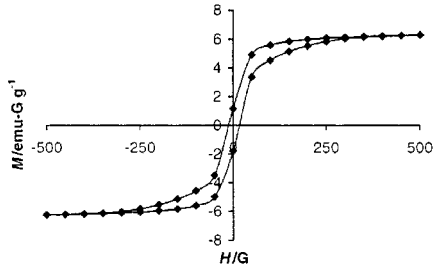

Fig. 2 Plot of magnetization, *M*, *vs.* applied field, *H*, measured at 5 K.

although the T_c is considerably lower (*ca.* 80 K). On the other hand, we have found that *cis*-DCPFS reacts with $V(CO)_6$ to give a magnetically identical product to that obtained from *trans*-DCPFS. This result, coupled with the observation that the Et_2O washes contain mixtures of *cis*- and *trans*-DCPFS, suggests that isomerization about the double bond occurs upon formation of the radical anion.

In conclusion, we have discovered $V(DCPFS)_2 \cdot y$THF to be a molecule-based magnet possessing a T_c of 205 K. Its magnetic behavior is quite reminiscent of the room temperature magnet, $V(TCNE)_2$. It is unclear what sets TCNE and DCPFS apart from other organic acceptors in reactions with $V(CO)_6$ and $V(C_6H_6)_2$. At this point, we can comment more meaningfully on the differences between DCPFS and TCNE and their impact on the choice of future synthetic targets:

1 Redox properties; TCNE is a relatively good acceptor, but DCPFS is a poor acceptor. This means that many more weak acceptor bridging ligands need to be investigated for their ability to mediate exchange.
2 Number of N donor sites; TCNE has four, but DCPFS has only two. Thus, despite the fact that each DCPFS ligand can act as a bridge between only two V cations, a ratio of two acceptors per donor is sufficient to form a three-dimensionally ordered magnetic solid.
3 Molecular size and shape; planar TCNE is the smallest acceptor and DCPFS is one of the largest and probably not flat. This result can be interpreted to mean that steric repulsion does not play a significant role, provided the fumaronitrile unit is left intact. Thus, larger, more complex ligands can be envisioned and should be investigated.

We thank the National Science Foundation for support of this work and the National Institute of Standards and Technology for use of the SQUID magnetometers. We also acknowledge Mr Christopher M. Holloway for synthetic help and Mr Roger Sommer for electrochemistry experiments.

Metal catalysed addition of B–H and N–H bonds to aminopropyl vinyl ethers

Christopher M. Vogels, Paul G. Hayes, Michael P. Shaver and Stephen A. Westcott*

Department of Chemistry, Mount Allison University, Sackville, NB E4L 1G8, Canada. E-mail: swestcott@mta.ca

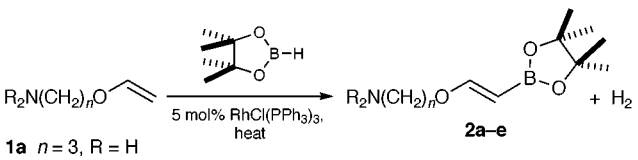
Received (in Bloomington, IN, USA) 12th October 1999, Accepted 18th November 1999

The rhodium catalysed addition of pinacolborane to aminopropyl vinyl ethers gave selective formation of the corresponding alkenylboronate esters while palladium or platinum complexes catalysed the hydroamination of aminopropyl vinyl ether to give tetrahydro-2-methyl-1,3-oxazine.

The catalytic addition of B–H bonds to unsaturated carbon–carbon bonds using 1,3,2-benzodioxaborole (catecholborane) is of significant importance in organic synthesis.[1] Indeed, the use of a metal catalyst can give organoboronate ester products with stereo-, chemo- and regio-selectivities complementary or opposite to those obtained from the corresponding uncatalysed variants. As part of our ongoing study of generating novel aminoboron compounds,[2] we have examined the catalysed addition of B–H bonds to aminopropyl vinyl ethers ($R_2NCH_2CH_2CH_2OCH{=}CH_2$) and report our initial findings herein.

We have found that addition of catecholborane to commercially available aminopropyl vinyl ether **1a** and dialkylated derivatives **1b**–**e**† using 5 mol% of $RhCl(PPh_3)_3$ gave a number of products derived from an initial dehydrogenative borylation pathway. Formation of products derived from such pathways are well precedented[2a,3–5] and presumably occur *via* initial oxidative addition of the catecholborane B–H bond to the rhodium centre. This step is followed by insertion of the alkene into the Rh–B bond with subsequent ß–H abstraction to give dihydrogen and alkenylboronate esters.[2a] Further reaction of alkenylboronate esters formed in this study with catecholborane or dihydrogen occurs rapidly, as evidenced by the disappearance of the alkenyl peaks in the ^{1}H NMR spectra, to give a number of borated products. Product distributions were further complicated by the formation of Lewis acid–base adducts between the amine moiety and either unreacted catecholborane or the borated products. Although a number of rhodium complexes‡ were investigated as possible catalysts for this reaction, all gave several boron-containing products.

Pinacolborane (HBpin, pin = 1,2-$O_2C_2Me_4$), a less reactive hydroborating agent than catecholborane, was used in an attempt to improve selectivities for this reaction. Interestingly, reactions using HBpin and 5 mol% of $RhCl(PPh_3)_3$[6] at 65 °C gave the corresponding alkenylboronate esters **2a**–**e** (Scheme 1) as the *only* new boron-containing species.§ Similar reactivities were observed using other rhodium catalysts.‡ Although metal catalysed alkenylboronate ester formation using catecholborane is well established,[3–5] analogous products derived from such a pathway using pinacolborane are much less common and only occur in low yields.[6]



1a $n = 3$, R = H
1b $n = 3$, R = Me
1c $n = 3$, R = Et
1d $n = 2$, R = Et
1e $n = 3$, R = $SiMe_3$

Scheme 1

Unlike hydroborations of aminoalkenes using 9-BBN (9-borabicyclo[3.3.1]nonane),[7] protection of the amine hydrogens is not necessary when R = H, as HBpin reacts rapidly with **1a** to form the intermediate $(pinB)NHCH_2CH_2CH_2OCH{=}CH_2$ with loss of dihydrogen. The weak Lewis-acidic nature of HBpin also precludes the formation of adducts, which are observed in reactions with catecholborane.

The formation of alkenylboronate esters in these reactions is intriguing as previous studies on the addition of B–H bonds to vinyl ethers using BH_3 have shown exclusive formation of *anti*-Markovnikov hydroboration products.[8] We have also found that addition of HBpin to ethyl vinyl ether under similar catalytic conditions gave the corresponding borated product $CH_3CH_2OCH{=}CHBpin$, suggesting that the amine group is not responsible for the formation of alkenylboronate products in reactions with aminopropyl vinyl ethers.[9] The directive effects exerted by heteroatoms on the hydroboration of substituted vinyl derivatives has been reported elsewhere.[8,10–12]

The methodology described above provides a rapid and efficient means of generating novel air-stable alkenylboronate esters, which have remarkable synthetic utility in Suzuki–Miyaura cross-coupling reactions.[13] Vinyl ether derivatives are also versatile synthetic intermediates in polymer chemistry.[14] Further work is currently being conducted on the role the catalyst and the effect the heteroatom α to the vinyl group plays on selectivities in these reactions.

Interestingly, while some palladium and platinum complexes are known to be efficient hydroboration catalysts,[1] we have found that 'hydroboration reactions' using **1a** and catalytic amounts of palladium and platinum compounds gave products derived from addition of the corresponding borane to tetrahydro-2-methyl-1,3-oxazine **3**. Formation of cyclic **3**[15] presumably proceeds *via* an intramolecular hydroamination of the starting aminopropyl vinyl ether (Scheme 2). In fact, in the absence of a hydroborating agent, a number of platinum and palladium complexes effectively catalyse (using 5 mol% of metal) this reaction with high turnover numbers (Table 1).¶ The

[a] All reactions were carried out in toluene (10 mL) at room temperature. [b] Turnover number. [c] dba = dibenzylideneacetone.

palladium catalysed intramolecular hydroamination reaction is generally believed to occur *via* initial coordination of the alkene to the metal centre, which acts to polarize the alkene moiety and thereby making it more susceptible to nucleophilic attack by the amine.[16] In this study, subsequent addition of the N–H bond to the alkene moiety results in selective formation of the six-membered ring product.

While palladium iodide (Table 1, entry 1) is an active catalyst precursor for this hydroamination reaction, reduced activities (entry 7) were observed in reactions utilizing the corresponding chloride salt. Higher turnover numbers were achieved, however, using the cyclooctene metal chloride dimers (entry 4), presumably owing to their increased solubility in common organic solvents.[2b] Reactions using preformed bis-amine complexes (for instance PdI_2L_2, where L = **3**, entry 2) also gave oxazoline formation in high turnover numbers suggesting that these complexes may be resting states in the catalytic cycle. Attempts to affect the intermolecular hydroamination of ethyl vinyl ether and propylamine using these catalysts proved unsuccessful. Likewise, no reaction was observed when 2-(1-cyclohex-enyl)ethylamine was treated with these metal complexes, suggesting that the ether group in aminopropyl vinyl ether may also facilitate in activating the alkene towards nucleophilic attack. Studies of an asymmetric variant of the hydroamination chemistry, as well as expanding the scope of this reaction, are currently under investigation.

Thanks are gratefully extended to Drs Terri Bright, Giuliano Muccin and Sabine Weiguny (BASF) for the generous gift of aminopropyl vinyl ether and diethylaminoethyl vinyl ether, Dr R. Tom Baker (LANL) for helpful discussions, the Natural Sciences and Engineering Research Council of Canada, Mount Allison University, and Johnson Matthey Ltd. for the palladium and platinum salts.

Notes and references

† Dialkylated aminopropyl vinyl ethers were prepared by addition of 2.2 equivalents of Bu^nLi to **1a** at −78 °C in THF under an atmosphere of dinitrogen. After 2 h, 2 equivalents of the corresponding alkyl halide were added dropwise at 0 °C. Removal of solvent and extraction with hexane, followed by distillation, gave the desired products. *Spectroscopic NMR data* ($CDCl_3$): **1b** (15% yield): ^{1}H δ 6.37 (q, *J* 5 Hz, 1H), 4.08 (d, *J* 16 Hz, 1H), 3.87 (d, *J* 5 Hz, 1H), 3.62 (t, *J* 5 Hz, 2H), 2.29 (t, *J* 5 Hz, 2H), 2.10 (s, 6H), 1.74 (m, 2H); ^{13}C{^{1}H} δ 151.8, 86.4, 66.3, 56.4, 45.5, 27.3. **1c** (10% yield): ^{1}H δ 6.41 (q, *J* 5 Hz, 1H), 4.11 (d, *J* 16 Hz, 1H), 3.89 (d, *J* 5 Hz, 1H), 3.65 (t, *J* 5 Hz, 2H), 2.47 (overlapping m, 6H), 1.76 (m, 2H), 0.95 (t, *J* 5 Hz, 6H); ^{13}C{^{1}H} δ 152.0, 86.3, 66.6, 49.5, 47.1, 26.9, 11.9. **1e** (27% yield): ^{1}H δ 6.50 (q, *J* 5 Hz, 1H), 4.18 (d, *J* 16 Hz, 1H), 3.99 (d, *J* 5 Hz, 1H), 3.65 (t, *J* 5 Hz, 2H), 2.92 (t, *J* 8 Hz, 2H), 1.76 (m, 2H), 0.07 (s, 18H); ^{13}C{^{1}H} δ 152.1, 86.2, 65.9, 42.6, 34.8, 2.24.

‡ Other complexes examined include $[RhCl(cod)]_2$ (cod = cycloocta-1,5-diene), $RhH(PPh_3)_4$, $RhH(CO)(PPh_3)_3$, $[RhCl(coe)_2]_2$ (coe = *cis*-cyclooctene) and $[RhCl(coe)_2]_2/2PPh_3$.

§ The following procedure was used for the dehydrogenative borylation of aminopropyl vinyl ethers. Pinacolborane (190 mg, 1.5 mmol) was added to a solution of aminopropyl vinyl ether (1 mmol) and catalyst (5 mol%) in 10 mL of THF. The mixture was heated to reflux for 3 h under an atmosphere of dinitrogen whereupon solvent was removed and the reaction mixture analyzed by multinuclear NMR spectroscopy. *Selected NMR data* ($CDCl_3$): **2a**: ^{1}H δ 7.07 (d, *J* 16 Hz, 1H), 4.43 (d, *J* 16 Hz, 1H), 3.80 (m, 2H), 3.47 (m, 2H), 1.81 (m, 2H), 1.22 (s, 12H); ^{11}B{^{1}H} δ 34.0; ^{13}C{^{1}H} δ 162.2, 88.0 (br, C–B), 82.2, 68.0, 40.5, 32.2, 23.9. **2b**: ^{1}H δ 6.99 (d, *J* 16 Hz, 1H), 4.41 (d, *J* 16 Hz, 1H), 3.81 (t, *J* 5 Hz, 2H), 2.99 (m, 2H), 2.64 (s, 6H), 2.08 (br m, 2H), 1.24 (s, 12H); ^{11}B{^{1}H} δ 31.0; ^{13}C{^{1}H} δ 162.5, 87.7 (br, C-B), 82.7, 67.9, 51.6, 46.3, 26.2, 24.7. **2c**: ^{1}H δ 7.04 (d, *J* 16 Hz, 1H), 4.43 (d, *J* 16 Hz, 1H), 3.81 (t, *J* 5 Hz, 2H), 3.42 (t, *J* 5 Hz, 2H), 2.51 (overlapping m, 6H), 1.24 (s, 12H), 1.03 (t, *J* 5 Hz, 6H); ^{11}B{^{1}H}, δ 31.4; ^{13}C{^{1}H} δ 163.0, 87.3 (br, C–B), 82.6, 67.0, 48.9, 46.5, 26.2, 24.5, 11.0. **2d**: ^{1}H δ 7.09 (d, *J*16 Hz, 1H), 4.46 (d, *J* 16H z, 1H), 3.87 (t, *J* 8 Hz, 2H), 2.76 (t, *J* 5 Hz, 2H), 2.61 (q, *J* 8 Hz, 4H), 1.25 (s, 12H), 1.05 (t, *J* 8 Hz, 6H); ^{11}B{^{1}H} δ 31.5; ^{13}C{^{1}H} δ 162.6, 87.3 (br, C–B), 82.9, 66.0, 51.0, 47.5, 24.8, 10.6. **2e**: ^{1}H δ 7.06 (d, *J* 16 Hz, 1H), 4.41 (d, *J* 16 Hz, 1H), 3.68 (t, *J* 8 Hz, 2H), 2.87 (m, 2H), 1.69 (m, 2H), 1.23 (s, 12H), 0.07 (s, 18H); ^{11}B{^{1}H} δ 32.0; ^{13}C{^{1}H} δ 163.4, 87.3 (br, C–B), 82.8, 66.6, 42.4, 34.7, 24.9, 2.2.

¶ In a typical reaction, a known amount of aminopropyl vinyl ether was added to a stirred solution or suspension of catalyst (5 mol%) in 10 mL of toluene. The reaction mixture was allowed to stir for an additional 6 h upon which solvent was removed and the reaction analyzed by ^{1}H NMR spectroscopy.[15]

Received (in Cambridge, UK) 26th October 1999, Accepted 18th November 1999

Two tetrahedral four-coordinate Au(I) complexes, $[Au(4\text{-}R\text{-}dppn)_2]PF_6$ (R = H or Me), have been synthesized and the crystal structure of $[Au(dppn)_2]Cl$ has been determined by X-ray crystallography; the complexes have been found to exhibit both photoluminescent and electroluminescent behaviour.

Unlike d^{10} Cu(I) and Ag(I) species in which complexes with coordination number greater than two are commonly observed, most Au(I) complexes adopt a two-coordinate linear geometry.[1] Studies on four-coordinate Au(I) systems[2,3] have mainly been confined to those of structural characterization, with a few examples on cytotoxic[4a] and antitumor activities.[4b] Despite the recent growing interest in the study of luminescent two-[5] and three-coordinate[6] Au(I) systems, there have been no reports on the luminescence behaviour of four-coordinate Au(I) complexes. Besides, with the growing interest in the design and construction of light-emitting diodes (LEDs)[7] and the employment of metal complexes[8] as the emissive layer in electroluminescence (EL) devices, the use of Au(I) complexes in such studies is rare[8f,g] despite the rich luminescence behaviour associated with a number of Au(I) systems.[5,6,9]

Here, we report the synthesis of two four-coordinate Au(I) complexes, $[Au(4\text{-}R\text{-}dppn)_2]X$ [dppn = 1,8-bis(diphenylphosphino)naphthalene; R = H, X = PF_6 **1a**, Cl **1b**; R = Me, X = PF_6 **2**], and the X-ray crystal structure of **1b**. The first report on the photoluminescent and electroluminescent properties of this tetrahedral four-coordinate Au(I) system is also described.

To the freshly reduced solution of Au(I), prepared *in situ* by treatment of $K[AuCl_4]$ (0.1 mmol) with an excess of 2,2′-thiodiethanol in methanol (20 ml), was added the diphosphine ligand, 4-R-dppn (0.2 mmol). The chloride salt of the product was isolated by slow evaporation of the solvent. Diffraction quality crystals of **1b** were obtained by recrystallization from acetonitrile. Orange solids of **1a** and **2** were collected after the metathesis reaction with NH_4PF_6 in methanol. Recrystallization from dichloromethane–diethyl ether afforded **1a** and **2** as orange crystals. The identities of both have been confirmed by ^{1}H NMR spectroscopy, IR, positive FAB-MS, and elemental analyses.† The X-ray crystal structure of **1b** has also been determined.‡

Fig. 1 depicts the perspective view of the complex cation of **1b**. The structure shows a Au(I) centre in a highly distorted tetrahedral coordination geometry, as required by the steric demand of the dppn ligand. The P–Au–P angle of 86.9(2)–133.3(2)° are comparable to other four-coordinate Au(I) diphosphine complexes such as $[Au(dppe)_2]^+$ [P–Au–P 85.4(1)–129.6(1)°][3c] and $[Au(pdma)_2]^+$ [pdma = *o*-phenylenebis(dimethylarsine), P–Au–P 86.7–121.8°].[3a] The Au–P bonds of 2.379(6)–2.388(6) Å are slightly shorter than those of $[Au(dppe)_2]^+$ [2.389(3)–2.416(3) Å],[3c] but are longer than those of two-coordinate Au(I) phosphine complexes.[5e,f,9]

The electronic absorption spectra of **1a** and **2** are very similar, and are dominated by an intense high energy absorption band at *ca.* 300 nm with a weak low energy band at *ca.* 400 nm with tails extending to *ca.* 500 nm. The photophysical data of **1a** and **2** are collected in Table 1. With reference to previous spectroscopic work,[9,10] the intense absorption at *ca.* 300 nm which closely resembles that found in the free ligand, is assigned as an intraligand $\pi\rightarrow\pi^*$(naphthalene) transition while the lowest energy absorption band is a $\sigma\rightarrow\pi^*$(naphthalene) transition. An assignment of these low-energy absorption bands as d→p transitions, similar to those suggested for three-coordinate d^{10} complexes of Au(I)[6b,c] and Pt(0)[5a,11] is unlikely, given the approximately tetrahedral AuP_4 structure in which the valence p orbitals are strongly σ antibonding. Such d→p transitions are expected to occur at fairly high energy, for example, at 240 nm for $[Au(dcpe)_2]^+$ [dcpe = 1,2-bis(dicyclohexylphosphino)ethane].[6b] Excitation of solid samples of **1a** and **2** gave intense orange emission both at room temperature and 77 K. Room temperature luminescence in degassed dichloromethane solution has also been observed. The observation of the emission lifetime in the microsecond range is suggestive of an emission origin associated with a spin-forbidden transition. No such emission was observed in the related $[Au(dcpe)_2]^+$ complex, which was reported to be non-emissive both in the solid state and in solution.[6b] However, similar emission bands were observed in a related two-coordinate $[Au_2(dppn)(C{\equiv}CR)_2]$,[9d] in which an assignment of the emission origin as derived from states of $\sigma\rightarrow\pi^*$(naphthalene) transition is suggested. It is likely that the photoluminescent properties of **1a** and **2** are characteristic of the dppn unit. The observation that the emission of **2** in

Table 1 Photophysical data for **1a** and **2**.

Complex	Medium (T/K)	λ_{abs}/nm (ε/dm^3 mol^{-1} cm^{-1})	λ_{em}/nm (τ_o/μs)
$[Au(dppn)_2]PF_6$ **1a**	Solid (298)		640 (3.2)
	Solid (77)		653
	CH_2Cl_2 (298)	294 (35 870), 398(sh) (5000)	693 (0.7)
$[Au(4\text{-Me-dppn})_2]PF_6$ **2**	Solid (298)		642 (1.3)
	Solid (77)		647
	CH_2Cl_2 (298)	300 (33 720), 400(sh) (5330)	666 (1.5)

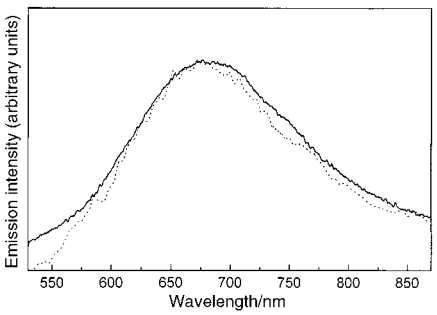

Fig. 2 EL (———) and PL (·····) spectra of **2** in thin films.

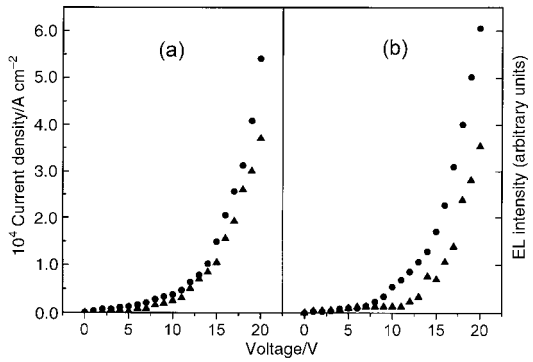

Fig. 3 Current density–voltage (●) and EL intensity–voltage (▲) curves for EL devices of ITO|**1a**–PC|Al (a) and ITO|**2**–PC|Al (b).

dichloromethane is at higher energy than **1a** is in agreement with an assignment of emissive states derived from the σ→π*(naphthalene) transition, since introduction of the methyl group would enhance the hyperconjugation effect, leading to an increase in the σ→π*(naphthalene) transition energy.

Besides exhibiting photoluminescence (PL) behaviour, both **1a** and **2** are also found to show electroluminescence (EL) when doped in polycarbonate (PC) as the emissive layer in a single-layered EL device (ITO|Au–PC|Al).† Upon being forward biased with the ITO electrode at positive polarity, the EL devices exhibit intense orange emission. The EL and PL spectra of **2** in thin films are shown in Fig. 2. The close resemblance of the EL and PL spectra suggests that the EL of these four-coordinate Au(I) complexes probably involves the same excited state as PL, *i.e.* triplet state of σ→π*(naphthalene) transition. The current density–voltage and EL intensity–voltage characteristics of the two single-layered EL devices, (ITO|**1a**–PC|Al) and (ITO|**2**–PC|Al), are shown in Fig. 3. The EL intensity exhibits an approximately linear relationship with current density and has a turn-on voltage of *ca.* 7 V. The EL intensities of the devices of **1a** and **2** at 13 V were 82 and 73 cd m^{-2} with an estimated external quantum efficiency of 0.02 and 0.01% respectively.

Received (in Oxford, UK) 5th October 1999, Accepted 18th November 1999

We report the application of ^{27}Al and ^{29}Si MAS NMR to provide a direct probe of alkali metal cluster formation and distribution in the α-cages of zeolite A (LTA).

The reaction of alkali metals with framework aluminosilicates produces a rich variety of inclusion compounds comprising metal clusters and filamentary structures, confined and ordered, within the intracrystalline channels and cavities.[1] With zeolite pore dimensions typically *ca.* 1 nm or less, these may be regarded as the ultimate nanostructured materials, and as such have justifiably attracted considerable experimental and theoretical attention on account of a range of remarkable electronic, magnetic, optical and catalytic properties.[2–6] Although the presence in such compounds of low-nuclearity (n = 6) paramagnetic clusters is well documented,[7–12] these are present as minority species in all but a few cases.[1,2] Pioneering ^{23}Na MAS studies by Nakayama *et al.*[13] have suggested the possible formation of Na_5^{3+} and Na^-, in zeolites X, Y and A, but in general there is a dearth of information about the diamagnetic species present, in particular higher nuclearity clusters (n > 10) presumed to occupy the larger zeolite cages. Here, we report the first application of ^{27}Al and ^{29}Si MAS NMR to provide a direct probe of cluster formation and distribution in the α-cages of zeolite A.

We prepared a number of deeply coloured compounds M'_x/M-A (where A denotes the LTA framework)[14] by exposing alkali metal (M) ion-exchanged and dehydrated zeolite samples to a measured amount of alkali metal (M′) vapour in sealed, evacuated quartz tubes.[15,16] The products, which were virtually black, were subsequently handled under dry Ar. Unusual MAS NMR[17] spectral shifts (Table 1) were observed for several compositions, and for the first time in zeolite A, a number of compounds exhibited two distinct signals (Figs. 1 and 2) for each T_d nucleus (T_d = ^{27}Al and ^{29}Si), even though the materials were crystallographically single phase.[18] When exposed to air the colour centres were gradually quenched, yielding white powders, whose MAS NMR spectra closely resembled those of the 'empty' dehydrated hosts, with only one T_d signal. Dehydrated zeolite K-A exhibited a single sharp resonance in both the ^{27}Al and ^{29}Si MAS NMR spectra, at the usual shifts for zeolite A (δ *ca.* 58 and −89, respectively). In metal-loaded 'black' K_5/K-A, however, sharp T_d resonances shifted to lower frequency, δ 52.5 and −100.2, respectively, were observed. The magnitudes of the shifts suggest a structural and/or electronic perturbation of the framework.

Topologically, LTA is a cubic array of sodalite cages mutually separated by double 4-ring (D4R) windows to form a large α-cage. Each T_d atom in the structure belongs to one sodalite cage, two α-cages and one double 4-ring. In dehydrated K-A, all the α-cages contain eight K^+ cations that are coordinated to oxygen atoms in the 6-rings and partly balance the negative charge of the framework. The structure has a pseudo unit cell size (assuming no Si, Al ordering) of *ca.* 12.3 Å in space group $Pm\bar{3}m$. In K_5/K-A, alternate α-cages contain either eight K^+ cations coordinated to 6-rings as in the dehydrated host, or a K_{12}^{4+} cluster whose partly reduced potassium cations occupy 4-ring sites. This results in a doubling of the unit cell to 24.6324 Å in space group $Fm\bar{3}m$.[16,19] Owing to the strict alternation of the cage contents, the structure retains a single unique crystallographic T_d site.[16] We suggest that the observed low frequency T_d shifts in K_5/K-A may be due to an increase in the average T_d–O–T_d bond angles[20] in the cluster-containing material relative to those in the empty host, which is consistent with an observed increase in lattice parameter.[16,19] It is interesting that there is no paramagnetic T_d shift or broadening of lines observed in this compound, suggesting that the T_d atoms do not interact appreciably with the paramagnetic clusters known to be present.[16,19]

Similar low frequency NMR shifts were observed for Cs_5/K-A, but in this case, the deeply coloured material exhibited two sharp resonances for both T_d nuclei (Fig. 1). The first one, labelled line 1, is only slightly shifted relative to the dehydrated host and is assigned to T_d atoms at the vertices of α-cages that contain only 6-ring cations. Line 2 resembles the T_d resonance in K_5/K-A, both in shift and signal breadth, and therefore is assigned to T_d atoms which are part of one α-cage that contains 6-ring cations and one that contains a 'reduced' cluster. As caesium cations are both less likely to occupy the 4-ring site in preference to potassium, and less likely to be found partly reduced, we speculate that K_{12}^{4+} clusters may again be present. Structural studies are under way to confirm this hypothesis.[18] The relative intensities of the two lines are consistent with the

Table 1 Summary of 156.4 MHz ^{27}Al and 71.5 MHz ^{29}Si MAS NMR shifts (ppm), linewidths [$\Delta\nu_{1/2}$ (Hz)] and intensity ratios of the framework T_d resonances

Material	^{27}Al (line 1)	^{27}Al (line 2)	^{29}Si (line 1)	^{29}Si (line 2)	Ratio 1:2
Cs_5/K-A	59.3	52.2 (2150, total)	−89.7 (540)	−101.9 (420)	3:2
Exposed Cs_5/K-A	59.9 (1160)	—	−89.5 (320)	—	—
K_5/K-A	—	52.5[a]	—	−100.2 (400)	—
K-A host (dehydrated)	57.7 (890)	—	−89.3 (490)	—	—
Rb_7/Rb-A	83.8	67.9 (4320, total)	−64.1 (910)	−86.1 (840)	3:1
Exposed Rb_7/Rb-A	61.0 (940)	—	−86.1 (570)	—	—
Rb-A host (dehydrated)	57.8 (700)	—	−89.1 (490)	—	—

[a] ^{27}Al shift measured at 93.8 MHz. For comparison, the 93.8 MHz ^{27}Al shifts of Cs_5/K-A are at δ 57.5 and 51.0

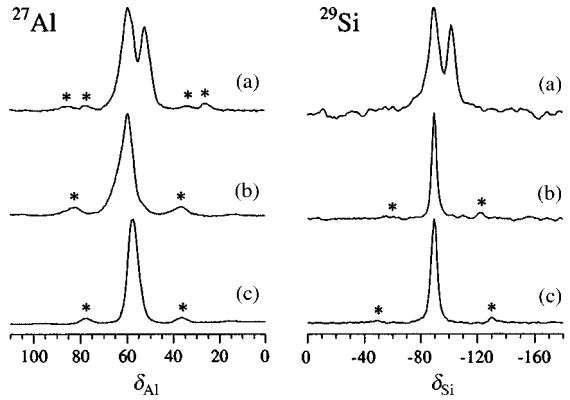

Fig. 1 ^{27}Al and ^{29}Si MAS NMR spectra of (a) 'black' Cs_5/K-A, and (b) air-exposed 'white' Cs_5/K-A and (c) dehydrated 'empty' K-A. Asterisks denote positions of spinning sidebands.

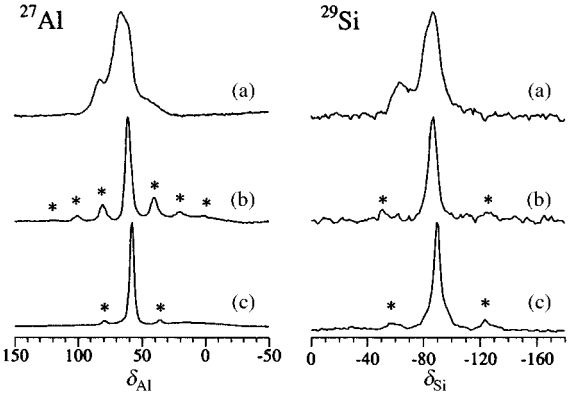

Fig. 2 ^{27}Al and ^{29}Si MAS NMR spectra of (a) 'black' Rb_7/Rb-A, (b) air-exposed 'white' Rb_7/Rb-A and (c) dehydrated 'empty' Rb-A. Asterisks denote spinning sidebands.

presence of a cluster in about one fifth of the α-cages. Exposure of 'black' Cs_5/K-A to air resulted in complete loss of colour and a single T_d resonance in both the ^{27}Al and ^{29}Si MAS NMR spectra (Fig. 1).

Two distinct T_d resonances were also observed in 'black' Rb_7/Rb-A and these collapsed to a single signal when the samples were exposed to air (Fig. 2). In this case the lines are significantly broader than in the dehydrated host, which may indicate some site distribution (static disorder) or broadening from nearby paramagnetic clusters. Additionally, both lines are shifted to higher frequency relative to the host. The framework in this fully loaded zeolite is also expanded relative to the empty host,[18] therefore there is no straightforward structural explanation for the observed shifts. One plausible explanation is that the framework in this case is directly affected by paramagnetic clusters of guest atoms, similar to the shift trends observed in 'black' sodalite.[12]

We thank the EPSRC for financial support. PAA is a Royal Society University Research Fellow.

Received (in Cambridge, UK) 4th October 1999, Accepted 23rd November 1999

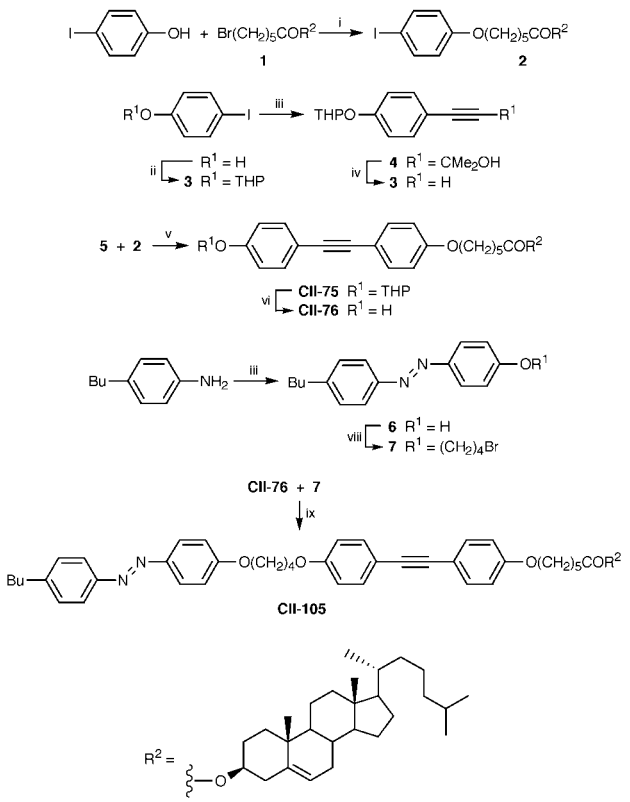
The synthesis and evaluation of the mesomorphic properties of the first trimesogen consisting of three non-identical calamitic mesogenic entities have been described.

Liquid crystalline dimers[1] (dimesogens) consisting of two identical (symmetrical) or non-identical (non-symmetrical) mesogenic units have gained attention as these are regarded as model compounds for main chain[2] and side chain liquid crystalline polymers.[3] The non-symmetrical dimers are markedly different from those of symmetrical ones as they exhibit interesting polymorphic sequence[4] and stabilize wide range chiral nematic (N*)[5a] and smectic A (SmA) mesophases.[5b] The addition of one more mesogenic moiety to a dimer *via* a flexible spacer results in the next higher oligomer, which has been called a trimesogen, trimer or triplet liquid crystal.[6] We shall adopt the term 'trimesogen' in this article. Based on the molecular structure of the individual calamitic entities there can be three possible combinations: (i) all of them are structurally identical, (ii) two of them are identical while the third entity is different, and (iii) all three are different. These trimesogens are of interest because of the recent demonstration that a flexible backbone based virtual trimer model successfully accounts for the transitional properties of side chain liquid crystalline polymers.[3b] Trimesogens of type (i) and (ii) were reported for the first time in 1986[7] and since then a few other examples of these types have been reported.[6] To the best of our knowledge trimesogens of type (iii) have not been reported to date. In continuation of our work on oligomeric liquid crystals, here we present the synthesis of the first type (iii) trimesogen composed of three different calamitic mesogenic entities, namely, cholesteryl ester, diphenylacetylene (tolan) and azobezene moieties.

In our recent investigations we had demonstrated that the combination of a cholesteryl ester unit and a tolan unit through an *n*-pentyl (odd) spacer stabilizes a wide-range N* phase.[5a] Owing to a change in the helical pitch the N* phase shows a temperature dependent wavelength of selective reflectivity (thermochromism). Another field of materials research that has been of considerable current interest is the phenomenon of photochromism, which holds lot of promise for applications such as optical information storage technology.[8] Therefore we aimed to synthesize a trimesogen which is multifunctional, satisfying two criteria: (i) it exhibits thermochromism over a wide range of temperature, and (ii) it is photochromic at the same time. A major advantage of single component multifunctional liquid crystal is that the problem of phase separation, which occurs in mixtures of mesogenic monomers and functional monomers, is avoided.[9] Here we report the synthesis of such a multifunctional liquid crystal and a preliminary investigation of the mesomorphic properties of this novel trimesogen.

The synthetic approach employed for the trimesogen, cholesteryl 6-{4-[4-[(4-butylphenylazophenoxy)butoxy]phenylethynyl]phenoxy}hexanoate (**CII-105**), is shown in Scheme 1. It was conceived that **CII-105** could be prepared by combining two key fragments, the non-symmetrical dimeric phenol **CII-76** and butylbromo azobenzene **7**. Accordingly, both the fragments were synthesized and coupled under mild basic conditions to give **CII-105** as a yellow crystalline compound.†

The liquid crystalline properties of **CII-105** were studied using an optical polarizing microscope (Leitz DMRXP) and a differential scanning calorimeter (Perkin Elmer DSC7). For polarizing microscopic observations, glass plates coated with a polyimide solution and unidirectionally rubbed were used. On cooling from the isotropic phase (I) at 247.7 °C the N* phase with a characteristic planar texture is seen in which the nematic director lies in the plane of the substrates. This ensures that the helical axis is perpendicular to the glass plates, *i.e.* along the viewing direction. At a second transition below 215 °C, the texture changes to a square grid pattern, which persists down to 119 °C, when it transforms into a third mesophase. If the sample is observed in a wedge type cell with similar surface treatment to the parallel cell, Grandjean Cano dislocation lines are observed in both the cholesteric and second mesophases demonstrating that there is a helical twist normal to the plates in both cases. Thus the low temperature phase shows the Cano lines superposed on the square grid pattern (see Fig. 1). If the plates are treated to give a homeotropic alignment, a filament texture is observed with an undulatory structure whose



Scheme 1 *Reagents and conditions*: i, anhydrous K_2CO_3, cat. Fig. 1 Optical microscopic texture observed (magnification 400×) for the $UTGB_{C*}$ phase at 212.3 °C while cooling from the N* phase. (*a*) The Grandjean Cano lines (the two striations running from the top to the bottom of the picture) indicate the presence of a helix whose axis is normal to the photograph.The square grid patterns [shown on an enlarged scale in (*b*)] arise from a two-dimensional modulation perpendicular to the helix. The simultaneous existence of both these features is supposed to be proof of the existence of the $UTGC_{C*}$ phase.

periodicity is approximately the same as that of the spacing in the square grid pattern mentioned above. Again, the filament texture remains unchanged down to 119 °C. The features described here for the low temperature mesophase are identical to the textural observations for the very recently reported[10] undulated twist grain boundary ($UTGB_{C*}$) phase in a binary system as well as in a single compound. While in the binary mixture the $UTGB_{C*}$ phase is reported to occur over a narrow range of temperature (~4 °C),[10a] the range is not mentioned in the case of the single compound.[10c] In view of these observations it is remarkable that the second mesophase in **CII-105**, which shows the essential features of the $UTGB_{C*}$ phase, *viz.* simultaneous existence of a square grid texture and a helical structure perpendicular to it, exists over a large temperature range of 90 °C. According to the proposed model,[10a] the $UTGB_{C*}$ phase is a highly frustrated phase characterized by modulations in all the three dimensions, with the two-dimensional undulation of the smectic C*-like blocks being orthogonal to the helix of the TGB structure. Hence, it is all the more interesting to see that a phase with such a highly-frustrated structure exists over a wide temperature range. The mesophase below 119 °C seems to be a highly ordered one, and its detailed characterisation is underway.

The transition temperatures obtained from the cooling mode DSC scan along with the enthalpies are given in Scheme 2 (the transition from the cholesteric to the second mesophase was too weak for any reliable calculation of the enthalpy). It is worth mentioning here that the trimesogen **CII-105** is thermally stable during repeated heating and cooling cycles through the mesophases–isotropic transition, as confirmed by a ^{1}H NMR scan of the same sample which had been subjected to the DSC experiments. The profile obtained was identical, within experimental error, to that for the pristine sample.

In conclusion we have achieved the synthesis of the first trimesogen containing three non-identical calamitic mesogenic

Scheme 2 The number in parenthesis indicates the transition enthalpy; X is a highly ordered mesophase and yet to be fully characterized; K = crystal.

entities connected by flexible spacers. The compound is multifunctional, containing themochromic and photochromic mesogenic units. Such substances have potential as materials for information storage technology and replace mixtures of mesogenic compound in different applications, thereby solving phase separation problems associated with such mixtures. These may perhaps also serve as model compounds (which are yet to be realized) for co-polymeric liquid crystals. Interestingly, this oligomer stabilizes a recently discovered $UTGC_{C*}$ phase—supposed to be a highly frustrated phase—over a wide temperature range of 90 °C and thus invites systematic investigations so as to understand this behavior.

We are grateful to Professor S. Chandrasekhar for many useful discussions and thankfully acknowledge Dr Geeta G.Nair for her help in the experiments.

Multi-functionalization of oligodeoxynucleotide: a facile post-synthetic modification technique for the preparation of oligodeoxynucleotides with two different functional molecules

Kazuo Shinozuka, SatoruKohgo, Hiroaki Ozaki and Hiroaki Sawai*

Department of Chemistry, Faculty of Engineering, Gunma University, 1-5-1 Tenjin-cho, Kiryu City 376-8515, Japan. E-mail: sinozuka@chem.gunma-u.ac.jp

Received (in Cambridge, UK) 30th September 1999, Accepted 23rd November 1999

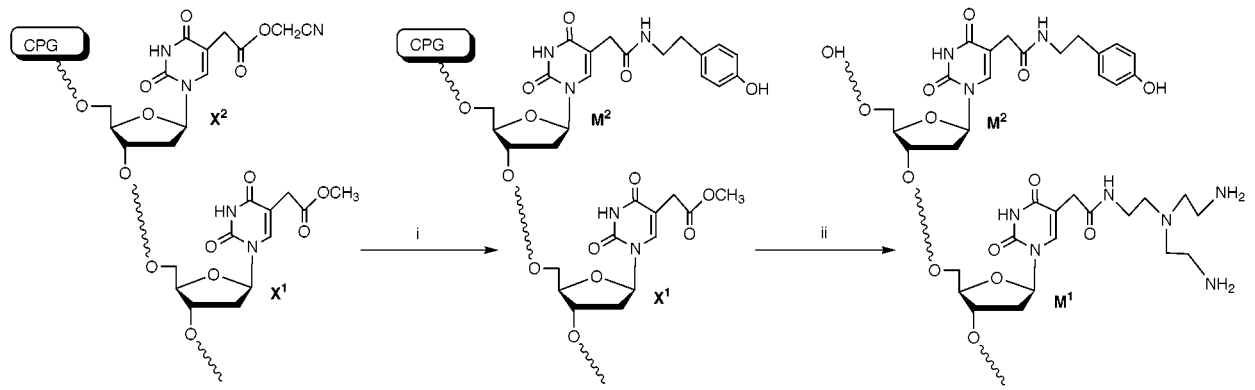
Treatment of the support-bound novel multi-functionalizable oligodeoxyribonucleotides bearing both 5-cyanomethoxycarbonylmethyl- and 5-methoxycarbonylmethyl-uridine with tyramine followed by tris(2-aminoethyl)amine facilitated multi-functionalization of oligodeoxyribonucleotides having different amine molecules.

Modification of oligodeoxyribonucleotides (ODNs) through incorporation of an appropriate molecule such as an intercalating agent, metal chelating agent, fluorescent dye, *etc*. has been widely studied to produce functionalized ODNs which can be used for biological and biophysical studies.[1] Recently, a new and convenient post-synthetic modification method for the functionalization of ODNs has been reported. In this method, ODNs containing a specially designed convertible unit is assembled first by an automated solid-phase synthesizer, then a functional molecule is introduced to the ODNs.[2] Previously, we have reported that the nucleoside analogs 5-methoxycarbonylmethyl- and 5-cyanomethoxycarbonylmethyl-uridine can be utilized as the convertible unit in the post-synthetic modification technique.[3] Thus, the treatment of ODNs substituting the normal thymidine residue with the convertible nucleoside unit with mono-, di- or poly-amine molecules resulted in the corresponding oligomers carrying the amine derivatives at the 5-position of the uridine derivatives *via* nucleophilic displacement reaction. The method is very attractive since one can site-specifically introduce the desired functional molecules into ODNs after the assembly of the oligomer and, therefore, avoid the tedious preparation of each nucleoside precursor and the corresponding phosphoramidite prior to the assembly of the oligomers.

Meanwhile, further investigation of the nucleoside analogs revealed that reactivity towards the amine-involved nucleophilic displacement reaction is significantly different between the analogs. So far, a report dealing with the site-specific modification of ODNs with several different functional molecules *via* a post-synthetic modification technique has not been known. This background prompted us to develop a versatile method which allows the site-specific introduction of several different functional molecules into ODNs by a facile one-pot reaction. Here, we report preliminary results of our study to produce multi-functionalized oligonucleotides *via* a post-synthetic modification technique.

Phosphoramidite derivatives of 5′-*O*-dimethoxytrityl-5-methoxycarbonylmethyl- and 5-cyanomethoxycarbonylmethyl-uridine were prepared according to the previously reported procedure.[3,4] Preparation of CPG-bound ODNs containing 5-methoxycarbonylmethyl- and 5-cyanomethoxycarbonylmethyl-uridine residues was performed by a DNA synthesizer (ABI 381-A) using the corresponding phosphoramidites on a 1 μmol scale. Two different ODNs, namely, ODN-1 (T**X²**TT**X¹**T) and ODN-2 (**X²**TCC**X¹**GCCA**X¹**AG), were prepared (Scheme 1). In the ODNs, **X¹** and **X²** denote the 5-methoxycarbonylmethyl- and 5-cyanomethoxycarbonylmethyl-uridine residues, respectively. An extended coupling period of 360 s for **X¹** and **X²** phosphoramidites was required to obtain reasonable coupling yields (*ca.* 95%) in the synthesis of the ODNs. *N*⁴-Acetyldeoxycytidine (dC^{ac})phosphoramidite[5] was utilized in the synthesis instead of the usual dC^{bz} phosphoramidite to avoid possible transamination[6] during the amine treatment of the oligomers. The normal synthetic protocol was followed otherwise. It should be noted that the sequence of ODN-2 is complementary to the *rev* region of HIV-1 mRNA.[7]

To check the feasibility of the current multi-functionalization concept, we first studied ODN-1. Thus, the CPG support attached to the oligomer (CPG-ODN-1) was removed from the column and placed into a vial with a Teflon-coated screw cap. The support was first treated with a saturated DMA solution of tyramine in the presence of 1,2,4-triazole for 3 days at room temperature.[3b] The support was then washed thoroughly with



CPG-ODN-1 $^{5'}$T**X²**T T**X¹**T $^{3'}$- CPG
CPG-ODN-2 $^{5'}$**X²**TC C**X¹**G CCA **X¹**AG $^{3'}$- CPG

M-ODN-1 $^{5'}$T**M²**T T**M¹**T $^{3'}$
M-ODN-2 $^{5'}$**M²**TC C**M¹**G CCA **M¹**AG $^{3'}$

Scheme 1 *Reagents and conditions*: i, tyramin, 1,2,4-triazole, DMA; ii, 50% tris(2-aminoethyl)amine in dry EtOH.

Table 1 The sequence, yields and nucleoside compositions of the multi-functionalized ODNs (M-ODNs)

Oligodeoxynucleotide sequence	Isolated yield (OD units)	Nucleoside composition A : G : C : T : M_1 : M_2
TM²TTM¹T	13.2	4.0 : 0.9 : 1.1
M²TCOM¹GCCAM¹AG	22.7	1.7 : 1.8 : 4.3 : 1.2 : 1.7 : 1.2

DMA, followed by MeCN.After drying by Savant Speed Vac concentrator, the support was treated with 50% tris(2-aminoethyl)amine in dry ethanol (1 ml) for 48 h.[3a] After collection and concentration with an N_2 evaporator to remove volatile material, the obtained solution was diluted with 1 M tetraethylammonium acetate buffer (pH 7.0) to adjust the volume to approximately 1 ml and applied to gel filtration using a Sephadex G-25 column. The appropriate fractions were collected and purified by reversed-phase (C-18) HPLC. The obtained oligomer was treated with 20% acetic acid to remove the 5′-*O*-DMTr group, followed by EtOH precipitation and gel filtration (Sephadex G-25). The isolated oligomer (M-ODN-1) was subjected to enzymatic digestion to confirm its structure using snake venom phosphodiesterase, alkaline phosphatase and nuclease P1. In reversed-phase HPLC (C-18) analysis, the digested M-ODN-1 gave three peaks corresponding to thymidine and the modified 2′-deoxyuridine residues (**M¹** and **M²**, Scheme 1). The structures of the modified nucleosides were identified by the co-injection of independently prepared authentic samples. As listed in Table 1, the nucleoside composition calculated from the HPLC analysis agrees well with the expected ratio of dT : **M¹** : **M²** (4 : 1 : 1, respectively) for M-ODN-1.

We further examined the applicability of the current method to the ODN consisting of four natural nucleoside units. Thus, CPG-ODN-2 was treated with tyramine and tris(2-aminoethyl)-amine as mentioned above except that the treatment of the CPG-bound oligomer with tris(2-aminoethyl)amine–EtOH mixture was extended to 3 days. After the work up as above, the obtained oligomer (M-ODN-2) was subjected to enzymatic digestion. As shown in Table 1, HPLC analysis of enzyme digested oligomer indicates that the multi-functionalized oligomer was generated *via* the sequential treatment of the amine derivatives (expected ratio of dA : dG : dC : dT : **M¹** : **M²** = 2 : 2 : 4 : 1 : 2 : 1 for M-ODN-2).† Although in Table 1, **M**² residue was slightly over represented in both oligomers, we could not detect any measurable amount of side products which would result from the reaction of the tyramine with the 5-methoxycarbonylmethyl residue. Thus, the introduction of two different functional molecules to DNA having all four natural nucleoside units was also successful. It should be noted that tyramine in M-ODNs can be used as the substrate for ^{125}I labeling *via* the chloramine-T method,[8] and tris(2-aminoethyl)-amine in M-ODNs is effective to enhance the stability of the duplex formed by the ODN and its complement.[9] The T_m study suggested, indeed, that the M-ODN-2 containing duplex has a slightly enhanced stability (higher T_m value) compared to the corresponding duplex having the unmodified oligomer (N-ODN-2).‡ The yields of the multi-functionalized oligomers obtained by the current method were short of excellent but still within the acceptable range (Table 1).

In conclusion, we were able to successfully demonstrate the feasibility of a facile one-pot modification method to produce multi-functionalized oligonucleotides in a post-synthetic manner. The current method would provide an easy access to ODNs which have a combination of a variety of functional molecules useful for chemical and biological studies.

Total spontaneous resolution of a cyanoguanidine showing only conformational chirality

Ian D. Cunningham,*[a] Simon J. Coles[b] and Michael B. Hursthouse[b]

[a] *Department of Chemistry, School of Physics and Chemistry, University of Surrey, Guildford, UK GU2 5XH. E-mail: i.cunningham@surrey.ac.uk*

[b] *Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ*

Received (in Cambridge, UK) 16th September 1999, Accepted 23rd November 1999

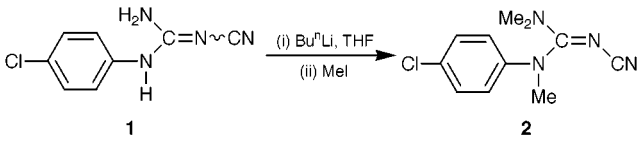
The total spontaneous resolution of *N*-(4-chlorophenyl)-*N′*-cyano-*N*,*N″*,*N″*-trimethylguanidine, a compound which shows only conformational chirality, is described; variable temperature NMR experiments show that rotation of the dimethylamino group is rapid in solution at room temperature as is conformer interconversion by rotation of the arylmethylamino group.

Total spontaneous resolution is a relatively rare phenomenon whereby a racemic mixture crystallises as a single enantiomer.[1] It may be seen where a potentially chiral molecule is configurationally labile in solution, but stable in the solid state. These criteria are most commonly met when chirality is due *solely* to a chiral conformation and to the maintenance of this conformation by topology in the solid state. Despite its relative rarity, examples of total spontaneous resolution are known and the phenomenon is best illustrated by *rac*-1,1′-binaphthyl which has been known to crystallise in up to 95% ee.[2]

What raises the phenomenon of total spontaneous resolution above a mere curiosity is its importance in crystal engineering,[3] its potential for asymmetric synthesis starting from achiral reagents,[4] and its relevance to the origin of enantiomeric homogeneity in nature.[5]

Of course many organic compounds, while lacking a 'traditional' asymmetric carbon, adopt a chiral conformation in the solid state. However, as with more configurationally stable chiral compounds, crystallisation as a racemic compound is most common, or in certain cases as a conglomerate.[6] Examples of the latter are not uncommon, and the synthetic use of homochiral crystals has been reviewed.[7] However, in many cases the so-called 'absolute asymmetric synthesis' is based on selection of a 'single crystal' from what may well be a conglomerate, *or* on use of homochiral crystals obtained by seeding.[8] What is of more fundamental interest is where such a chiral conformer can not only be isolated in the crystalline state, but can be shown to be an example of total spontaneous resolution. Total spontaneous resolution is usually described for examples such as 1,1′-binaphthyl where racemization following dissolution is slow enough to be detected (k_{rac} *ca.* 10^{-2} s^{-1}). However, such examples are very rare and if studies can be extended to include solid state conformational isomers where the racemization in solution is fast (k_{rac} *ca.* 10^{4} s^{-1}), the scope of these studies can be greatly increased. We herein report such a material.

The compound *N*-(4-chlorophenyl)-*N′*-cyanoguanidine **1**, prepared from 4-chloroaniline and dicyanamide,[9] is weakly acidic.[10] Treatment of **1** with BuLi and excess MeI yielded *N*-(4-chlorophenyl)-*N′*-cyano-*N*,*N″*,N″-trimethylguanidine **2** (Scheme 1) as a mass of small microcrystals (56 mg, 17% yield).[11] Preliminary X-ray crystallographic analysis of *one* of these crystals indicated a chiral space group $P2_12_12_1$. Since no chirality was present in the starting material or in any of the reagents used to prepare **2**, this suggested a chiral conformation in the solid state. At this stage it was not possible to distinguish whether this material existed as a conglomerate or was an example of total spontaneous resolution. Therefore, a sample



Scheme 1

comprising 18.2 mg was selected at random from the fine mass, dissolved in CH_2Cl_2 and allowed to recrystallise by slow evaporation of solvent to yield a single crystal of weight 16.2 mg (89% recovery).

X-Ray crystallographic analysis of a carefully cut piece of this single crystal again showed the $P2_12_12_1$ space group and the chiral conformation shown in Fig. 1 and schematically in Fig. 2;[12] the absolute configuration was a*S*.[13]

The chirality arises due to the twisting of the ArMeN portion relative to the rest of the molecule by *ca.* 47° (C4–N1–C8–N2). The twisting of the ArMeN group is all the more remarkable in that it results in loss of conjugation between the ArMeN lone pair and the C=N system. This is reflected in the increased length of 1.385(2) Å for the ArMeN–C bond compared to the Me_2N–C and C=N bonds at 1.340(2) and 1.325(2) Å, respectively.[14] The lack of planarity can be attributed to 'steric crowding', and the fact that the ArMeN nitrogen lone pair can delocalise 'towards' the Ar, as an alternative to the C=N–CN, probably explains why this group, rather than the Me_2N, is rotated.

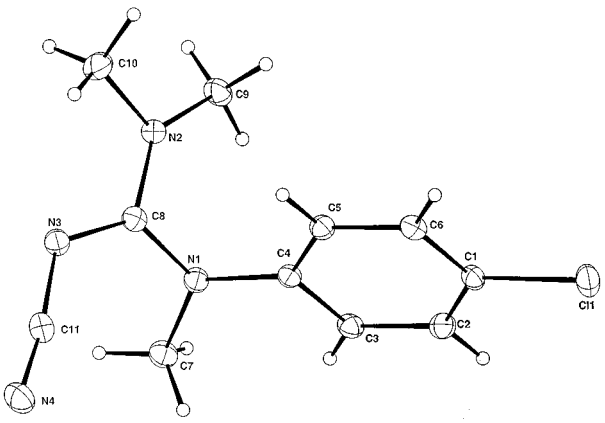


Fig. 1 ORTEP diagram of compound **2**; The numbering is arbitrary.

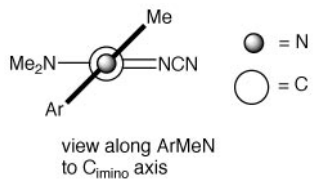

Fig. 2 Schematic representation of the conformation of **2**.

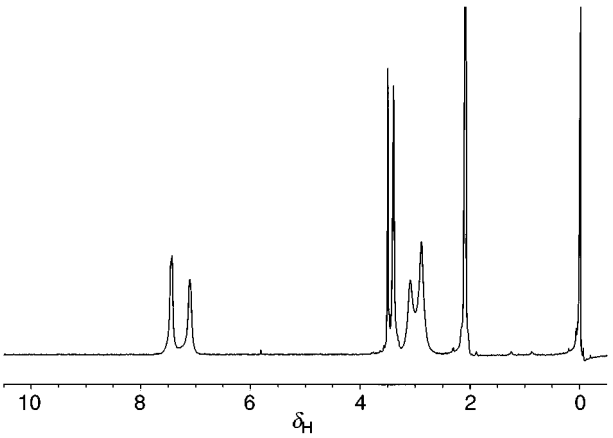

Fig. 3 Spectrum of **2** in acetone-d_6 at 223 K. Peaks at *ca.* δ 2.0, 3.4 and 3.5 are due to residual acetone, the Ar*Me*N and water, respectively.

The following facts prove that this is an example of total spontaneous resolution of a chiral conformer. Firstly, the X-ray crystallographic analysis shows that the *whole* crystal consists of only one chiral conformer [Flack *x* parameter = 0.02(6)[15]]. Secondly, this single crystal constitutes an almost quantitative yield of precipitate from homogeneous solution. Thirdly, the homogeneous solution was obtained using a relatively large randomly selected sample of the original material.[16]

Interestingly, in acetone-d_6 solution the formally non-equivalent dimethyl groups (of Me_2N) separated into two peaks at low temperature and variable temperature NMR experiments gave a coalescence temperature of 231 K. A value for $\Delta G^{\ddagger}_{rot}$ of 46 ± 1 kJ mol^{-1} is obtained from eqn. (1) where R, h and k_b are gas, Planck and Boltzman constants, respectively, and T_c is the coalescence temperature).[17]

$$\Delta G^{\ddagger}_{rot} = -RT_c\ln[\pi h(\Delta\nu)/1.4142k_bT_c] \quad (1)$$

As the Me_2N rotates 'out of plane' so the 'twisted' ArMeN would be expected to rotate 'into plane' and beyond.[18] Therefore, the $\Delta G^{\ddagger}_{rot}$ barrier of 46 ± 1 kJ mol^{-1} measured for the former sets an upper limit for rotation of the latter and also therefore for interconvertion of the chiral conformers in solution (see Fig. 2 where rotation of the ArMeN group yields the mirror image conformer). This translates to an interconversion, rate constant of $> 10^4$ s^{-1} in solution at 25 °C. Given this relatively high interconversion rate (compared to binaphthyl at *ca.* 10^{-2} s^{-1}) it is clear that the chirality is maintained (as opposed to effected) by the topology within the crystal.

Experimental support for possible 'coupled' rotation of the Me_2N and ArMeN groups comes from the NMR. On warming from *below* T_C, one of the methyl peaks (that at higher δ) becomes noticeably broader than the other one (see Fig. 3: NMR spectrum at 223 K, Me_2N signals at δ 3.10 and 2.85) before a broad but symmetrical peak is obtained on coalescence. We attribute this to restricted rotation of the methyl closer to the ArMeN group because of mutual steric interaction as the Me_2N fragment begins to rotate 'past' the ArMeN; some evidence of broadening of the aryl *ortho* hydrogens is also evident in the NMR spectrum at 223 K.

We are grateful to Dr D. C. Povey and Mr G. W. Smith of the University of Surrey for some preliminary X-ray crystallographic studies.

N-(2-Methoxycarbonyl-2-yloethyl)phenylaminyl: EPR observation of a triplet nonconjugated 1,3-diradical with two different kinds of radical centers

Hideyuki Tukada

Graduate School of Integrated Science, Yokohama City University, Kanazawa-ku, Yokohama 236-0027, Japan. E-mail: htht@yokohama-cu.ac.jp

Received (in Cambridge, UK) 6th October 1999, Accepted 24th November 1999

EPR observation of *N*-(2-methoxycarbonyl-2-yloethyl)phenylaminyl at cryogenic temperature shows that the diradical has a triplet ground state, and is thermally labile for ring-closure reaction with low and distributive activation energies centered around 3.2 kJ mol^{-1}.

Diradicals,[1] reactive intermediates frequently appearing in both thermal and photochemical reactions, are unique in that they show dichotomous reactivities depending on their spin states. Recently numerous conjugated diradicals have been explored in efforts to develop building blocks for organic magnetic substances.[2] On the other hand, localized diradicals linked with σ-bonds have not yet received sufficient attention as magnetic molecules. Among the localized diradicals, 1,3-diradicals, such as trimethylene,[3] are the simplest and representative.[1] Here we report *N*-(2-methoxycarbonyl-2-yloethyl)phenylaminyl **1**, a diradical with two different kinds of formal radical centers,[4] localized and conjugated, on N and C atoms. To the best of our knowledge this is the first example of EPR observation of an open-chain nonconjugated 1,3-diradical. It is of interest how the energy gap between the singlet and the triplet in **1** is affected by heteroatom substitution on one side of the radical site in trimethylene, and how the lone pair on the nitrogen atom affects the kinetic stability of **1**.

Photolysis (330 ± 20 nm) of methyl 1-phenyl-4,5-dihydro-1*H*-1,2,3-triazole-4-carboxylate **2**[5] in a 1:1 mixture of C_2D_5OD–CD_3OD (50 mmol dm^{-3}) was performed in an EPR cavity (X-band) with a 500 W super-high-pressure mercury lamp and glass filters at 5 K. The EPR spectrum after irradiation for 5 min persisted for at least 1 h at this temperature, and showed a set of signals characteristic of a triplet biradical (half-field signal; 0.1569 mT) with zero-field-splitting (ZFS) parameters of $|D| = 3|E|$[6] (Fig. 1).

The signals at 2516 and 3953 mT were assigned to overlapping signals due to transition of Z and Y with the ZFS parameters $|D/hc| = 0.06716$ cm^{-1} and $|E/hc| = 0.02239$ cm^{-1}. The *D* value is close to those of cyclobutane-1,3-diyls[7] ($|D/hc| = 0.050$–0.11 cm^{-1}) and cyclopentane-1,3-diyls[8] ($|D/hc| = 0.041$–0.084 cm^{-1}), and is fully consistent with a localized 1,3-diradical structure with an average distance of 0.34 nm between two unpaired electrons.[8]

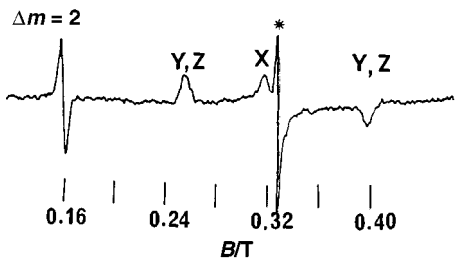

Fig. 1 X-Band EPR spectrum of **1** obtained after UV irradiation (330 ± 20 nm) to methyl 1-phenyl-4,5-dihydro-1*H*-1,2,3-triazo-4-carboxylate **2** in a 1:1 mixture of C_2D_5OD–CD_3OD matrix for 5 min at 5 K ($\nu = 9.0067$ GHz, power = 0.2 mW, modulation = 1 mT). Asterisk denotes doublet impurities.

EPR measurements were then performed on warming from 5 to 50 K in the dark. At each temperature (T_i) the signal intensity (I) stabilized within 3 min. Re-cooling from T_i to 5 K did not regenerate the initial intensity, which indicates that the biradical was irreversibly diminished by the reactions. However, no further decrease in signal intensity was observed between T_i and 5 K. The temperature dependence of the signal intensity for the annealed sample obeyed the Curie law (IT = constant) between 5 and T_i.

Consequently, the *IT vs. T* plot for the warming process did not become flat [line (i) in Fig. 2], whereas the plot for the post-annealed process showed a constant value [line (ii) in the Fig. 2]. The latter indicates that the triplet is the ground state of biradical **1**.

It seems reasonable that the initial decrease in signal intensity of the triplet can be attributed to decay through a ring-closure reaction to give methyl 1-phenylaziridine-2-carboxylate, which is the main photo-product at room temperature in solution (Scheme 1).[5] Decay by hydrogen abstraction from the matrix can probably be excluded because no new signals and no increase in the doublet species (indicated as * in Fig. 1) were observed up to 50 K. At 35 K, the triplet EPR signals originating from the biradical dissappeared immediately and simultaneously.

The same thermal behaviour of **1** was observed using 2-methyltetrahydrofuran as the matrix, indicating that the hardness of the surroundings of the diradical had little influence on ring-closure.

The former behavior [line (i)] can be interpreted as decay through transition states with distributive activation energies due to matrix site effects and conformers of **1**, rather than classical or tunneling processes having a single activation

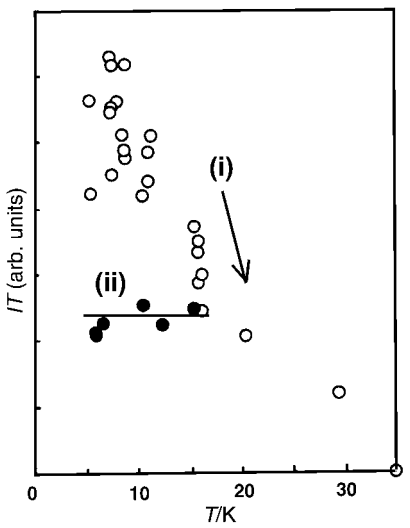

Fig. 2 *IT vs. T* plots, where I is the EPR signal intensity of the $|\Delta M_s| = 2$ transition of **1** in a 1:1 mixture of C_2D_5OD–CD_3OD, and T is the absolute temperature. (i) Open circles indicate a heating process from 5 to 35 K, and closed circles show the temperature dependence of the signal intensity between 5 and 18 K after annealing at 18 K.

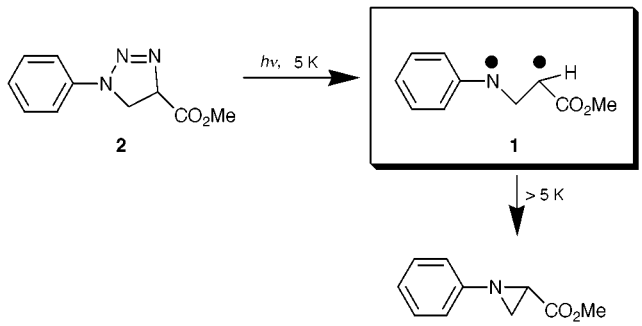

Scheme 1

energy. Such a mechanism with distributive activation energies was successively analyzed by a 'distribution slicing method' in the case of cyclobutane-1,3-diyls by Dougherty's group.[7] Applying this method to our case (50% of **1** decayed at 16 K) gave an average activation energy, E_a = 3.2 kJ mol^{-1}, under the assumption that $A = 10^8$ and t = 180 s, where A is a frequency factor in the Arrhenius equation and t is the slicing time. The activation energy, which possibly corresponds to that required for spin inversion (ISC), is slightly smaller than that in the case of cyclobutane-1,3-diyls (E_a = 4.0–9.7 kJ mol^{-1}) or cyclopentane-1,3-diyls (E_a = 8–> 20 kJ mol^{-1}).

The low activation energy in the case of **1** is attributable primarily to the flexible open chain structure and secondly to the interaction between a lone-pair on the aminyl radical and the p-orbital of the counterpart carbon radical.

According to density functional theory calculations (U-B3LYP/6-13G*)[9] for the biradical **1**, the triplet has a (0,0) conformation (following the notation for trimethylene)[3] and lies below the singlet by 1.3 kJ mol^{-1} (vertically; the singlet biradical has no minimum on the energy surface, and the optimization of the structure gives methyl 1-phenylaziridine-2-carboxylate). The computed energy gap $\Delta E_{S\text{-}T}$ is consistent with the result of the EPR experiment. Most of the spin populations of triplet **1** are distributed on both the formal radical centers (spin/charge = 0.63/−0.47 on the N atom, and 0.90/−0.16 on the C2′ atom), and agree with the average distance between unpaired electrons as estimated from the experimental D parameter.

In conclusion, we have been able to detect triplet diradical **1**, a heteroatom analogue of trimethylenemethane, and found that the diradical is thermally labile above 5 K with low and distributive activation energies.

A spirooxazine showing crystalline state photochromism

Sophie Bénard and Pei Yu*

Laboratoire de Chimie Inorganique, Bat. 420, UMR 8613, Université Paris Sud, F-91405, Orsay, France.

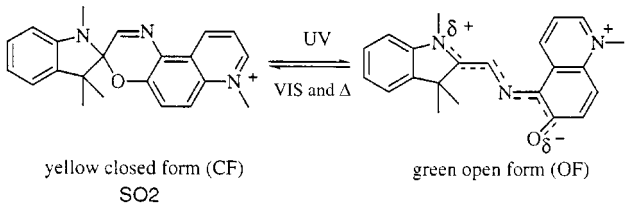
Received (in Oxford, UK) 18th September 1999, Accepted 24th November 1999

A cationic spiroquinoxazine (SO2) is found to be photochromic both in solution and in the crystalline state.

Among the large number of investigated so far photochromic molecules,[1,2] few have been found to be photochromic in the crystalline state.[3–8] Photochromic organic crystals are interesting not only for the design of new materials for optical data processing and storage,[4,6] but also because the photoinduced molecular transformations might be used to gain control over other physical properties in the solid state. For instance, the photoswitching of NLO properties has been recently achieved in a photochromic organic crystal.[9] Spirooxazines (SO) are known to offer remarkable stability towards photo-fatigue in solution and in various matrices,[10–14] but to the best of our knowledge none of them has been reported to be photochromic in the crystalline state. We report herein the first spirooxazine to exhibit photochromism both in solution and in the pure crystalline state.

N-Methylation of spiroquinoxazine[10,12c] (SO1) with MeI in THF yielded the yellow microcrystalline cationic SO[15a] (SO2, see Scheme 1).



Scheme 1

Photochromism of spirooxazines is based on photocleavage of the C(spiro)–O bond, giving rise to an equilibrium between a colorless or weakly colored closed form and a strongly colored open form. The usually less stable open form reverts back to the closed form both photochemically and thermally. In the present case such an equilibrium is shown in Scheme 1.

Electronic absorption spectral changes of SO2 upon UV irradiation (365 nm)[15b] in $CHCl_3$ are depicted in Fig. 1. The main characteristics of the closed and open forms as well as the thermal color fading rate (k) of the latter are reported in Table 1.

Table 1 Spectral and kinetic properties of SO2 in different solvents

Compound	Solvent	Form	λ/nm (ε/dm^3 mol^{-1} cm^{-1})	k/s^{-1}
SO1[a]	EtOH	Open	564,[b] 599	0.23
	Toluene	Open	561,[b] 590	0.34
SO2	EtOH	Closed	375 (5700)	9.3×10^{-5}
		Open	592, 563[b]	
	$CHCl_3$	Closed	387 (4700)	8.2×10^{-6}
		Open	611, 575,[b] 469	
	Toluene	Closed	370 (4400)	2.5×10^{-4}
		Open	615, 580[b]	

[a] Ref. 12(*a*). [b] Shoulder.

The photochromic properties of SO2 are markedly different from those of SO1. First, at room temperature the thermal color decay of the open form of SO2, which follows a single exponential equation in the same manner as SO1, is very slow. Depending on the solvent, the constant k of this decay is about 10^3 to 10^4 times smaller than that of SO1. In other words, the *N*-methylation of the quinoline on the oxazine moiety stabilizes in a dramatic way the open form. Second, in contrast to the parent SO1 and other SO molecules, which are known to show positive solvatochromism,[10,12a] the open form of SO2 is characterized by a negative solvatochromism (Table 1), indicating that its ground state is more polar than the exited one. These two observations suggest a predominantly zwitterionic structure for the open form of SO2 rather than the less polar quinoidal one.

Irradiation of a microcrystalline sample of SO2 was carried out using an ultra-thin pressed pellet. The UV–VIS absorption spectra after different irradiation times are shown in Fig. 2. Upon UV irradiation (365 nm) a broad absorption band appeared between 550 and 650 nm and continuously increased while the initial yellow pellet turned green. When the sample

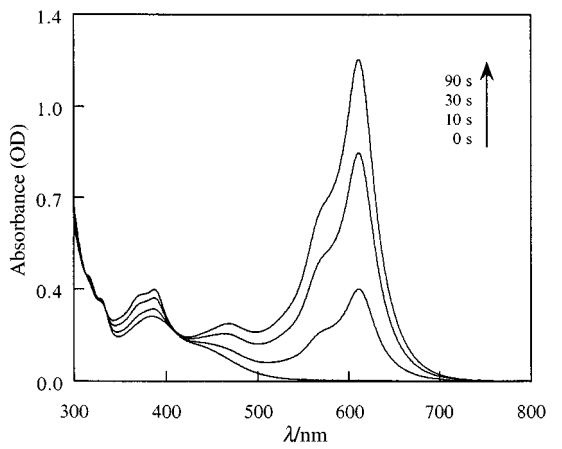


Fig. 1 UV–VIS spectral changes of SO2 in $CHCl_3$ solution (5×10^{-5}M, room temperature) upon UV irradiation.

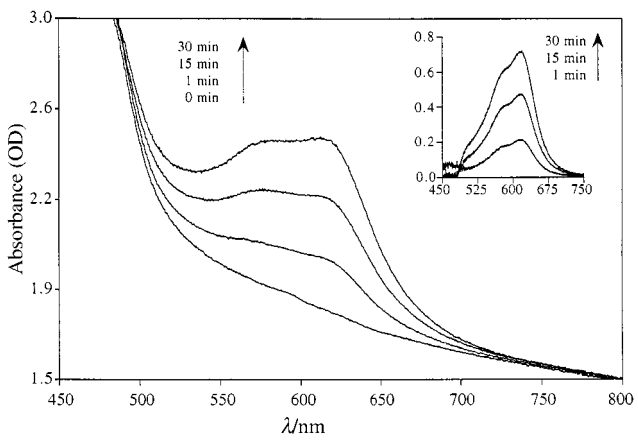

Fig. 2 Crystalline state UV–VIS spectral changes of SO2 upon UV irradiation. Insert shows the differential optical density between the spectra before and after UV irradiation.

was left in the dark at room temperature after irradiation, the green color faded slowly and the yellow colour returned very slowly. In contrast, visible light (550 nm) irradiation considerably accelerated the color decay. This behavior is similar to that observed in solution and indicates clearly that SO2 is photochromic in the crystalline state.

By monitoring the decay of the absorption band in the visible region at room temperature, the thermal decoloration rate of the thin pellet was found to deviate significantly from first order kinetics, but can be fairly well fitted to a biexponential equation with $k_1 = 1.6 \times 10^{-4}$ s^{-1} and $k_2 = 5.8 \times 10^{-6}$ s^{-1}. This behavior can be tentatively interpreted as the result of two different environments surrounding the open form of SO2 in the bulk sample. The open form molecules located near the surface of the solid are surrounded mostly by similar open form molecules. On the contrary an open form molecule lying deeper inside the bulk would have mainly closed form molecules as neighbors.

Finally, it is worth pointing out that the color change was not accompanied by any significant structure modifications, as the X-ray powder pattern of the irradiated sample did not show any detectable changes as compared to that of the initial one, while the large differences in geometry between the closed and open forms would lead one to expect rather large structure changes. A possible explanation would be that under current experimental conditions the photochemical process is mainly limited to the surface of the bulk sample, so the amount of the photoinduced open form is too small to give any significant changes in the X-ray powder pattern.

The reasons why SO2 shows crystalline state photochromism are not yet clearly understood. Nevertheless, the large stabilization of a predominantly zwitterionic open form brought about by the *N*-methylation of the quinoline ring seems to be an important factor in permitting solid state photochromism. On the other hand, the presence of iodide ions could result in more space or free volume in the crystal structure of SO2 as compared to the parent SO1. In other words, the anion, although not directly involved in the photochemical process, may have a kind of dilution or matrix-like effect on the cationic photoactive spirooxazine. These remarks are supported by the following observation: two derivatives of SO2, prepared by replacing the iodide anion in SO2 by nitrate or toluene-*p*-sulfonate, were also found to show similar behavior. This rather anion-independent behavior strongly suggests that crystalline state photochromism in this class of compounds depends mainly on the cationic nature of the photoactive species, and the role of the anion is probably minor. This particular feature would be of interest in the perspective of associating solid state photochromism with other properties that could be introduced through the anion.

We are grateful to Dr Keitaro Nakatani and Professor René Clément for many helpful discussions.

Received (in Basel, Switzerland) 28th September 1999, Accepted 1st December 1999

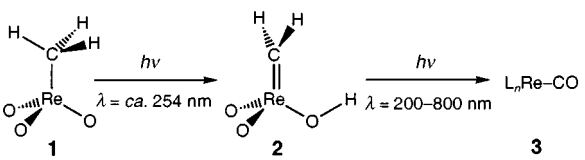
Matrix-isolated $[CH_3ReO_3]$ tautomerises to $[H_2C{=}Re(O)_2OH]$ under the influence of UV light; the carbene has been characterised in its normal and ^2H- and ^{13}C-enriched isotopic forms by its IR spectrum with results well replicated by quantum chemical calculations.

Since methyltrioxorhenium(VII), $[CH_3ReO_3]$ **1**, was first described, its rôle in promoting and catalysing numerous organic reactions has been explored in detail.[1,2] In fact, **1** is probably the most widely active organometallic catalyst reported to date. This activity encompasses two general areas: (i) oxidation reactions (including olefin epoxidation, Baeyer–Villiger and aromatic oxidation);[2–5] and (ii) olefin isomerisation and metathesis.[6] The peroxo derivatives of **1** active in many reactions of type (i) have been isolated and characterised both structurally and spectroscopically.[7] By contrast, the species responsible for catalytic activity of type (ii) have eluded direct detection, although a tautomer of the form $[H_2C{=}Re(O)_2OH]$ **2**, has long been presumed to be the active form of **1**.[2,8] There are numerous reports of rhenium–carbon multiple bonds in the literature generally, but not exclusively, involving rhenium in formal oxidation states $< +7$.[8,9]

Photolysis of **1** in solution appears to result in homolysis of the Re–C bond.[10] Our studies reveal, however, that the matrix-isolated molecule exhibits altogether different behaviour, initially tautomerising to the previously unknown carbene derivative **2** under the influence of UV light at wavelengths near 254 nm (Scheme 1). Tautomer **2** is also photolabile, broad-band UV–VIS irradiation (λ = 200–800 nm) causing it to decay to a product containing an Re–CO fragment, **3**, possibly $[H_2Re(O)(OH)CO]$.

Exposure of **1** isolated in an Ar matrix at 14 K to UV radiation with λ = *ca.* 254 nm for several minutes results in the decay of the IR absorptions due to **1** and the simultaneous appearance and growth of new absorptions apparently due to a single product **2** (Fig. 1). Irradiation of the matrix with broad-band UV–VIS light (λ = 200–800 nm) was observed to cause the evolution from **2** of at least one further product **3** which could not be conclusively identified by its IR spectrum. The IR bands identified on the evidence of their growth-decay patterns enable **2** to be characterised as $[H_2C{=}Re(O)_2OH]$, the conclusions being underpinned (i) by the observed effects of ^2H- and ^{13}C-enrichment of the products derived from the species $[CD_3ReO_3]$ **1**-d_3, and $[^{13}CH_3ReO_3]$ **1**-^{13}c, (ii) by parallels with the spectra of related carbene and Re=O derivatives, *e.g.* $CoCH_2$[11] and ReO_2F_3,[12] and (iii) by comparisons with the results of Density Functional Theory (DFT) calculations. (Calculations were carried out in Gaussian 98[13] with geometries optimised at the BPW91/LANL2DZ level of theory; standard 6-31G(d,p) basis sets were used for C, O and H, whilst the Re basis set was augmented with an additional f-type polarisation function.) Prominent among its IR absorptions were those at 3650.0, 992.2, 963.3 and 668.4 cm^{-1} which are identifiable by their frequencies, intensities and responses to ^2H- and ^{13}C-enrichment with the modes ν(O–H), ν_s(Re=O), ν_{as}(Re=O) and ν(Re–OH), respectively. The presence of the $Re{=}CH_2$ unit is signalled by bands at 3079.6, 2985.8, 1320.9, 778.8, 756.4 and 627.9 cm^{-1} which we associate with the modes detailed in Table 1; each assignment is attested by analogy with the corresponding mode of $CoCH_2$[11] and by the ^2H and ^{13}C isotopic shifts, although the description of the motion is sometimes less than exact. The spectrum is well simulated by a scaled force field computed for **2** on the basis of DFT calculations (Table 1), the 36 frequencies measured for **2**, **2**-d_3 and **2**-^{13}c being matched with an r.m.s. deviation of only 1.66%. It is also evident that mixing of the ν(Re=C), $\rho(CH_2)$ and δ(OH) motions complicates the interpretation of the spectrum in the region 600–800 cm^{-1}, preventing the identification of any one feature with the ν(Re=C) mode. The relative intensities of the bands due to the well defined modes ν_{as}(Re=O) and ν_s(Re=O) imply an O=Re=O angle in the order of 116°, in good agreement with the optimum geometry computed for **2**.

Similar experiments with $[CH_2DReO_3]$ **1**-d_1 give rise not only to $[H_2C{=}Re(O)_2OD]$, but also to the isotopomer



Scheme 1

[c]	233.2 (0.03)	[c]	233.2 (0.03)	[c]	208.5 (16)	$d(CReO_2)$

[a] Frequencies in cm^{-1}; all intensities normalised to that of the most intense band set equal to 100 (in parentheses). [b] Calculated frequency scaled by a factor of 0.9740. The r.m.s. deviation between observed and scaled calculated frequencies is 1.66%. [c] Indicates a feature too weak to be observed.

[H(D)C=Re(O)$_2$OH] **2**-d_1. Here the ν(C–H) fundamental is isolated from all other modes in the molecule and so gives access, in principle, to relatively precise estimates of the dimensions of the CH_2 unit.[14] The measured value of ν^{is}(C–H) (3035.4 cm^{-1}), taken together with ν(^{12}C–H), ν(^{13}C–H) and ν(^{12}C–D) data for the other isotopomers, affords values that tally with the results of the DFT optimisations given in parentheses: r_0 = 1.088 Å (r_e = 1.099 Å), ∠HCH = 119 ± 4° (∠$_e$HCH = 115.8°).

Although **2** was formed almost exclusively when matrix-isolated **1** was photolysed at wavelengths near 254 nm, exposure to broad-band UV–VIS light gave rise to a secondary change. The sole detectable product **3** formed from **2** under these conditions, but always in the presence of an abundance of **1** and **2**, could be identified by a single IR band at 2051.4 cm^{-1}. Assignment to the ν(C–O) mode of an Re–CO moiety is strongly urged by a minimal change of frequency when **3** is formed from **1**-d_3 or **1**-d_1 but by a shift to 2003.8 cm^{-1} when it is formed from **1**-^{13}c. The circumstances preclude positive identification, but a possible candidate for **3** is the novel rhenium(v) compound [H_2Re(CO)(O)OH] formed by photo-isomerisation of [H_2C=Re(O)$_2$OH] in a change that would parallel the conversion of [H_2COSi] to [H_2Si:CO].[15] DFT calculations provide some support for [H_2Re(CO)(O)OH], finding a potential energy minimum 126 kJ mol^{-1} above that of [H_2C=Re(O)$_2$OH] with a structure approximating to a square-based pyramid having the unique oxide ligand at the apex, and a calculated ν(C–O) frequency of 2040 cm^{-1} (^{12}C/^{13}C shift = 44.5 cm^{-1}).

[CH_3ReO_3] is active in olefin metathesis only when activated by a co-catalyst (S_4N_4/$AlCl_3$), or when supported on silica or alumina.[8] DFT calculations indicate that **2** lies *ca.* 89 kJ mol^{-1} higher in energy than **1**, and hence is inaccessible under normal thermal conditions. Model calculations on [CH_3ReO_2{(η^2-$OSiH_2$)$_2$O}] **4**, the product formed by condensation of [CH_3ReO_3] with disilanol ([H_2Si(OH)]$_2$O), show the tautomeric H-atom transfer to occur preferentially to an Re–O–Si bridging oxygen atom rather than to an Re=O unit. The resulting carbene species [H_2C=ReO_2{(η^2-$OSiH_2$)(O)(SiH_2OH)}] **5** is effectively stabilised by *ca.* 48 kJ mol^{-1} relative to complex **4**. This alternative H-atom transfer to the Re–O–Si bridge would seem to be a more realistic mechanism for carbene formation on supported [CH_3ReO_3].

Received (in Bloomington, IN, USA) 5th October 1999, Accepted 18th November 1999

Visible wavelength ligand-to-metal (LMCT) activated N_2 release from tris(3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one]iron(III) produces localized ligand radical intermediates capable of cleaving DNA and represents a new chemical approach to photonuclease design for biological applications.

The antibiotic 6-diazo-5-oxo-L-norleucine utilizes a terminal diazo unit to generate unimolecular diradical intermediates following thermal incubation and loss of N_2.[1] The kinamycin antibiotics also possess the reactive terminal diazo unit,[2] and UV photolysis of kinamycin analogs is thought to generate diradical intermediates that effect DNA cleavage.[3] Bioorganic chemists have incorporated this strategy into the design of synthetic photonucleases by preparing diazene and benzotriazole agents that produce diradical intermediates capable of cleaving DNA upon UV excitation.[4,5] Although effective, the ability to promote diradical formation using visible region excitation would have significant advantages for *in vivo* photodynamic therapy applications owing to the increased optical penetration depth by longer wavelengths.[6] To this end, we have recently initiated efforts toward developing novel transition metal diazo compounds that use the metal center to activate ligands for N_2 release upon optical excitation into metal–ligand charge transfer transitions typically occurring in the visible spectral region. Application of the resulting radical intermediates to DNA cleavage provides approach toward the development of self-contained unimolecular photonucleases for biological applications.

Photochemical activation of diazo compounds occurs *via* UV irradiation of the $^1(n–\pi^*)$ transition which leads to extrusion of N_2 and formation of radical intermediates.[7] However, diazo compounds are also unstable to chemical and electrochemical oxidation and rapidly release N_2 as a reaction product.[8–10] We have chosen to exploit this property by preparing Fe(III) complexes with ligands that posses the reactive –N=N– subunit. Fe(III) is a powerful excited state oxidant[11] and is thermodynamically potent to activate these ligands for N_2 release.

The compound 3-hydroxy-1,2,3-benzotriazine-4(3*H*)-one **1** (Aldrich) contains the target N_2 subunit, and in its deprotonated form, the 3-hydroxy-4-one functionalities strongly chelate Fe(III).[12] Reaction of **1** with 3 equiv. of $Fe(NO_3)_3{\cdot}9H_2O$ in THF–Et_3N yields the tris-(chelate **2** as a red powder in nearly quantitative yield.[13] The electronic absorption spectrum of **1** in acetonitrile exhibits pronounced $\pi–\pi^*$ transitions in the 300 nm region and a shoulder at 325 nm corresponding to the forbidden $n–\pi^*$ transition of the diazo unit.[7] Photolysis of **1** at $\lambda \geq 345$ nm yields a triplet radical EPR signal (5 K, EtOH) with the signature half-field transition at 1700 G, as well as copious N_2 evolution as detected by GC–MS, reflecting the propensity for diradical formation *via* N_2 loss from this organic framework. The absorption spectrum of **2** in the same solvent (Fig. 1) reveals three distinct bands corresponding to a ligand-centered transition (λ_{max} = 300 nm), and two moderately intense O→Fe ligand-to-metal charge transfer (LMCT) bands (λ_{max} = 340, 425 nm) similar to those of Fe(III) tris-catecholates.[14]

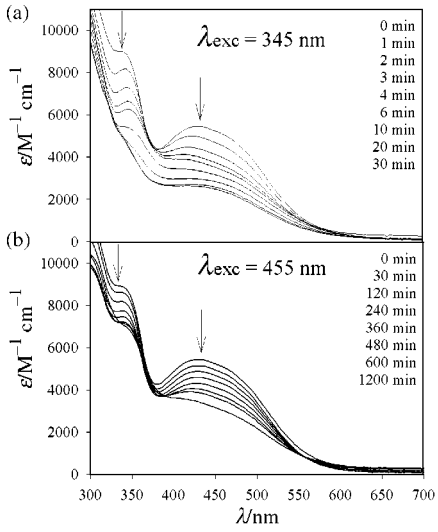

Fig. 1 Electronic absorption profiles for anaerobic photolyses of 0.1 mM acetonitrile solutions of **2** at (a) $\lambda \geq 345$ nm and (b) $\lambda \geq 455$ nm.

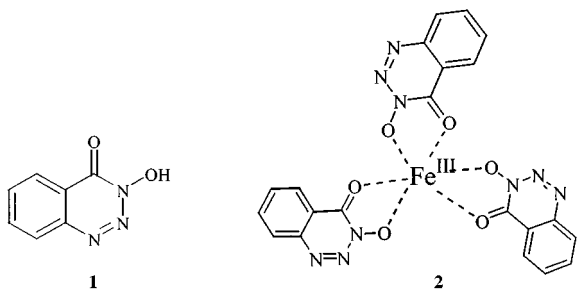
Anaerobic photolyses of **2** were performed in acetonitrile (0.1 mM) at $\lambda \geq 345$ and 455 nm and monitored with UV–VIS spectrophotometry (Fig. 1). In both cases, rapid photobleaching of the optical spectra are observed upon LMCT excitation of the complex, with partial recovery upon exposure to O_2, consistent with formation of Fe(II) in solution. This is confirmed by the disappearance of the rhombic Fe(III) EPR signal at g = 4.3 (Fig. 2) following variable time photolyses at 20 °C. Both reactions exhibit first-order kinetics at early photolysis times, with the reaction at $\lambda \geq 345$ nm ($k_{obs} = 9.3 \times 10^{-2}$ min^{-1}) proceeding considerably more efficiently than photolysis at $\lambda \geq 455$ nm ($k_{obs} = 4.0 \times 10^{-3}$ min^{-1}) under identical experimental conditions. In addition to excitation of both LMCT bands with $\lambda \geq 345$ nm, the disparate reactivity can be attributed to the greater quantum yield for decay of the starting compound upon excitation into the higher energy transition ($\phi_{365} = 2.1 \times 10^{-4}$ *cf.* $\phi_{436} = 3.6 \times 10^{-5}$). This results in simultaneous excitation of both the LMCT and ligand centered $n–\pi^*$ transitions of the Fe(III) compound. To verify LMCT activation of the triazine ligand, photolysis of **1** was conducted in acetonitrile with $\lambda \geq$ 455 nm and yielded no reactivity over a 12 h period indicating that photoactivation of **2** at lower energies derives solely from



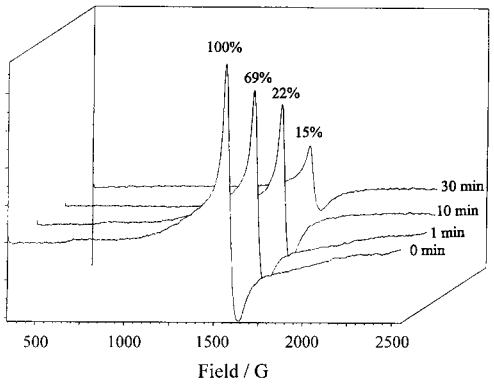


Fig. 2 Disappearance of the high spin Fe(III) EPR signal of **2** at $g = 4.3$ as a function of photolysis ($\lambda \geq 345$ nm) time. Relative spin quantitations are denoted above each trace.

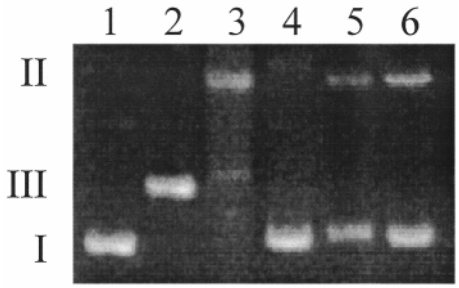

Fig. 3 Photoinduced DNA-cleavage of 30 μM/bp pUC 118 by 300 μM **2** following 400 nm photolysis for 12 h at 20 °C (2% agarose gel). Form I: supercoiled plasmid. Form II: nicked plasmid. Form III: linear plasmid. Lane 1: supercoiled DNA; lane 2: linear DNA from EcoRI digest; lane 3: DNA + **2** + *hν*; lane 4: DNA + **2**, no *hν*; lane 5: DNA + *hν*; lane 6: 900 μM **1** + DNA + *hν*.

LMCT excitation. Furthermore, reactivity of **2** has been demonstrated at wavelengths up to 500 nm, effectively ruling out the requirement for participation by higher energy excited states in the photoactivation of the triazine ligand.

To correlate the observed reactivity with N_2 extrusion, wavelength dependent photolyses ($\lambda \geq 345$ and 455 nm) were performed on 800 μL solutions of 15 mM **2** under argon in degassed benzonitrile. From headspace GC–MS analysis, N_2 production was gauged by comparison of the N_2/O_2 ratios above the photolyzed solutions relative to unphotolyzed controls. The average of four trials at each wavelength produced an increased N_2 content of 112% at $\lambda \geq 345$ nm and 9.7% at $\lambda \geq 455$ nm).[15] Together, these results demonstrate that the overall strategy to induce radical formation from charge transfer excited states is indeed operative.

Electronic structure studies of Fe(catecholate)$_3^{3-}$ have shown that the LMCT excited state is best described as a charge-separated Fe^{2+}–ligand radical. The energy required to photochemically produce a Fe^{2+}–$L^{\cdot+}$ state can be estimated by the sum of the redox potentials for the free ligand and the metal center, where $\Delta E = -E_{ox}(\mathbf{1}) + E_{red}(\mathbf{2})$. The cyclic voltammogram (CV) of **1** demonstrates an irreversible oxidation wave at a peak potential of +1.7 V *vs.* Ag/AgCl [E_{ox}(**1**)], derived from rapid denitrogenation.[8–10] The CV of **2** exhibits a reversible Fe(III)/(II) redox couple with a half potential of −0.3 V *vs.* Ag/AgCl [E_{red}(**2**)]. Therefore, the minimum energy required to produce the charge-separated excited state, ΔE, is *ca.* −2.48 eV, or 500 nm from the ground state. However, the energy of this state is exergonic with respect to LMCT excitation at $\lambda \geq 455$ nm and is therefore consistent with charge transfer induced activation and denitrogenation of the triazine ligand at these wavelengths.

The ligand radical intermediate produced upon LMCT excitation of **2** is an effective DNA photocleaving agent. Cleaving ability (%) was determined by quantitating the effectiveness in converting circular supercoiled plasmid DNA (form I) to nicked (form II) and linear DNA (form III) following subtraction of background cleavage due to photolysis of DNA alone (35%). Fig. 3 illustrates the agarose gel electrophoresis of photolysis products of 300 μM **2** in the presence of pUC 118 plasmid DNA (30 μM/bp where bp represents a base pair). Solutions were irradiated anaerobically for 12 h in 1:9 DMSO–Tris buffer (20 mM, pH 7.55) at $\lambda \geq 400$ nm.[16] Photolysis produced a mixture of linear (38%) and nicked (27%) forms (lane 3), while thermal incubation effected no DNA cleavage (lane 4). As Fig. 3 shows, the relative amount of cleavage by **2** is significant as photolysis of both plasmid alone (lane 5) and 900 μM free ligand (lane 6) yield identical amounts of nicked DNA (35%), indicating only background levels of DNA photodegradation. Our results demonstrate that although **2** did not generate exclusively linear DNA, it is the only species in Fig. 3 to produce the linear form and consume 100% of the supercoiled form. Additionally, the absence of O_2 from the reaction and the presence of the hydroxy radical scavenger DMSO in the buffer effectively rule out participation by O_2-derived radicals in the cleavage reaction and implicate a ligand-centered radical as the key intermediate.

In conclusion, the above studies describe the preparation and photoreactivity of a novel transition metal triazine compound. The overall strategy of metal complex activation *via* LMCT excitation in the visible spectral region is operative. Irradiation of the Fe(III) complex in the presence of plasmid DNA affords both single- and double-strand cleavage, with significantly greater efficiency than photolysis of free ligand in threefold higher concentration. From a mechanistic perspective, detection of Fe(II) as a reaction product raises important questions concerning the mode of activation of the kinamycins and 6-diazo-5-oxo-L-norleucine. Are these antibiotics redox activated, and if so, are diradicals or radical ions responsible for the DNA-cleaving reactivity of these agents? Further studies designed to probe the specific nature of the intermediates as well as modulate the reactivity of this system are ongoing.

Study of the accessibility of phosphorus centres incorporated within ordered mesoporous organic–inorganic hybrid materials

Robert J. P. Corriu,* Christian Hoarau, Ahmad Mehdi and Catherine Reyé

Laboratoire de Chimie Moleculaire et Organisation du Solide, UMR 5637 CNRS, Université de Montpellier II, Sciences et Techniques du Languedoc, Place E. Bataillon, F-34095 Montpellier Cedex 5, France.
E-mail: reye@crit.univ-montp2.fr

Received (in Oxford, UK) 22nd September 1999, Accepted 18th November 1999

Phosphorus centres incorporated within surfactant-directed mesoporous hybrid materials are shown to be more easily accessible than those incorporated within the corresponding materials prepared in the absence of surfactant.

The one step preparation of organically functionalised ordered mesoporous silica by using non-ionic[1,3] and ionic surfactants[4–9] as structure-directing agents constitutes a new and very promising route to hybrid materials with organised functionalities. Our contribution in this field was the preparation of surfactant-directed mesoporous hybrid materials incorporating phosphino groups.[3] We showed that such materials are easily accessible and undergo further chemical reactions at phosphorus (sulfuration and quaternization) without disrupting the ordered structure and without changing notably the textural characteristics, thus suggesting the location of the P centres within the mesopore channels.[5] The potential applications of these materials containing P centres for catalysis[10] and separation which are strongly connected with the chemical accessibility of the functionalities have led us to further studies. Here, we show that, in surfactant-directed mesoporous hybrid materials, phosphorus centres are more easily accessible than in the corresponding materials prepared in the absence of surfactants.

The hybrid materials $\mathbf{X}_n$ and $\mathbf{X'}_n$ were obtained by co-hydrolysis and polycondensation of mixtures $Ph_2P(CH_2)_3Si(OMe)_3/nSi(OEt)_4$ (n = 6, 9 and 19) in the presence of *n*-hexadecylamine as template for $\mathbf{X}_n$ and in the absence of template but in the presence of 1% TBAF as catalyst for $\mathbf{X'}_n$ (Scheme 1). The molar composition of each mixture was: $1 - x$ $Si(OEt)_4$:$xPh_2P(CH_2)_3Si(OMe)_3$: 0.27 *n*-hexadecylamine : 24.2 H_2O : 9.1 EtOH. The xerogels were prepared according to previously published procedures[3] and some relevant physical properties are given in Table 1. The BET surface areas were determined by N_2 adsorption–desorption isotherm measurements. $\mathbf{X}_n$ (n = 6, 9, 19) exhibit type IV isotherms,[11] characteristic for mesoporous materials. In contrast, the isotherms of $\mathbf{X'}_n$ are indicative of macroporosity.[11] XRD patterns for $\mathbf{X}_n$ exhibit a single diffraction peak corresponding to d_{100} spacing while no peak was observed for $\mathbf{X'}_n$. Organic incorporation was calculated by thermogravimetric analysis. It is worth noting that the calculated values are slightly closer to theoretical values for the mesoporous xerogels than for the others and this, in particular for high 'dilutions' of the organic moiety in silica. Another interesting observation in relation to the effect of dilution was made from the ^{31}P NMR data of the materials. As shown in Fig. 1, the ^{31}P NMR spectra for $\mathbf{X'}_n$ displayed signals which are always broader than those for $\mathbf{X}_n$. This is an indication of a greater mobility for the P centres in $\mathbf{X}_n$ than in $\mathbf{X'}_n$. Furthermore, on going from the 'dilution' n = 9 to the higher 'dilution' n = 19, the $Dn_{1/2}$ values remain stable for the ordered hybrid materials while for the others $\mathbf{X'}_n$, they regularly decrease as the 'dilution' increases. Thus it can be concluded that from n = 9 all the P centres within $\mathbf{X}_n$ have the same surroundings, the organic pendants being regularly dispersed at the surface of the mesopores while for the solids $\mathbf{X'}_n$ the distribution of the organic groups is random.

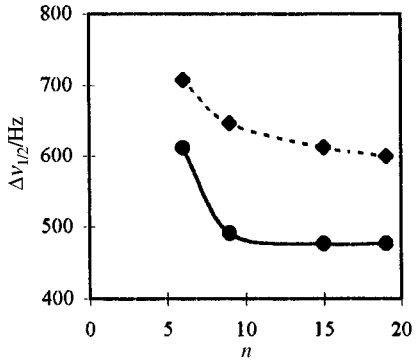

Fig. 1 Half linewidth ($\Delta\nu_{1/2}$) of the solid state ^{31}P NMR signals for $\mathbf{X}_n$ (———) and $\mathbf{X'}_n$ (-----) as a function of the 'dilution' n.

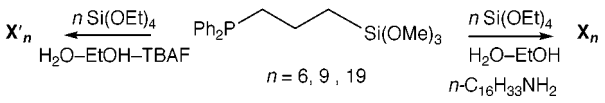
The accessibility of the P centres in these materials was investigated by using the reactions of quaternization and complexation of phosphorus centres. All the reactions at phosphorus were monitored by solid state ^{31}P NMR spectroscopy which is a reliable and sensitive probe for immobilized phosphorus groups.[12]

The solids $\mathbf{X}_n$ (n = 6, 9, 19) were treated with 1 equiv. of benzyl bromide **1** or 0.5 equiv. of α,α′-dibromoparaxylene **2** per P centre in CH_2Cl_2 at 20 °C. It is to be noted that after treatment, the ^{31}P NMR spectra of materials exhibited no signal corre-



Scheme 1

Table 2 Percentage of quaternization of P centres within $\mathbf{X}_n$ treated with **1** or (**2**) as reagent

Reaction time/h	$\mathbf{X_6}$	$\mathbf{X_9}$	$\mathbf{X_{19}}$
2	48 (35)	56 (58)	78 (74)
16	63 (68)	72 (82)	95 (90)
72	83 (83)	100 (93)	100 (100)

Table 3 Percentage of quaternization of P centres within $\mathbf{X}_n$ and $\mathbf{X'}_n$ after treatment for 24 h at 20 °C with **1** or (**2**) as reagent

n	6	9	19
$\mathbf{X}_n$	71 (73)	87 (92)	94 (95)
$\mathbf{X'}_n$	60 (72)	64 (82)	79 (70)

sponding to the oxidation of the P centres. The results given in Table 2 show that the percentage of quaternization of P centres increase with the dilution of the organic moieties in silica with both reagents. The reaction is quantitative with **1** after 72 h from $\mathbf{X_9}$ and $\mathbf{X_{19}}$. It is also quantitative with the bifunctional compound **2** from $\mathbf{X_{19}}$ after 72 h and almost quantitative from $\mathbf{X_9}$ which is noteworthy as in that case all the P centres are bridged. The same reactions were carried out on $\mathbf{X'}_n$ and the percentage of quaternization was calculated after 24 h of reaction. These results are compared to those obtained from $\mathbf{X}_n$ after the same reaction time in Table 3. It appears that the percentage of reaction with **1** is always lower from $\mathbf{X'}_n$ than from $\mathbf{X}_n$, whatever the dilution. Thus the P centres are more easily accessible within ordered mesoporous materials $\mathbf{X}_n$ than within the amorphous $\mathbf{X'}_n$. Interestingly, with the bifunctional reagent **2**, the gap between the percentage of quaternization of P centres obtained from $\mathbf{X}_n$ and $\mathbf{X'}_n$ increases with the dilution in favour of the ordered materials $\mathbf{X}_n$. This result is due to the regular distribution of organic moieties in $\mathbf{X}_n$. Indeed, while the substitution of the second bromide of **2** is promoted by the dilution within $\mathbf{X}_n$, it is rendered difficult within $\mathbf{X'}_n$ because of the random distribution of the organic groups in silica. The distribution of the organic moieties within the solids was further studied by treating the materials with 0.5 equiv. *cis*-$(PPh_3)_2PdCl_2$ per P centre. We observed that the solid state ^{31}P NMR spectra of the materials after 24 h of reaction at 20 °C in CH_2Cl_2 displayed a resonance at δ −16 corresponding to the remaining starting phosphine and a resonance at δ +16 which was assigned to the *trans* anchored phosphine Pd^{II} complex.[12] A further resonance at δ +36 was attributed to starting phosphine oxidation, which never exceeded 15%. Treatment of the materials with a large excess of the nucleophile PBu^n_3 allowed the complete elimination of the palladium liberating the starting phosphine (δ −16). The presence of the unchanged signal at δ +36 after this treatment confirmed the oxidation of the starting phosphine. The extent of the anchored phosphine Pd^{II} complex obtained from $\mathbf{X}_n$ and $\mathbf{X'}_n$ determined by ^{31}P NMR spectroscopy is shown in Fig. 2. The difference between the reactivity of materials $\mathbf{X}_n$ and $\mathbf{X'}_n$ (n = 9, 19) is important. Thus the diffusion of a bulky molecule like $(PPh_3)_2PdCl_2$ through

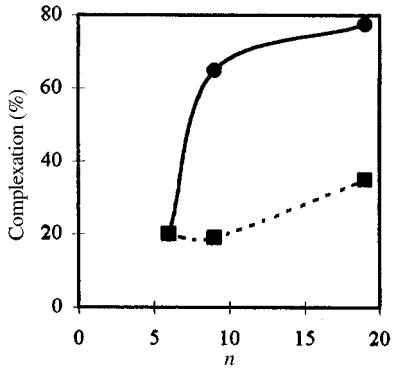

Fig. 2 Percentage of anchored phosphine Pd^{II} complex within $\mathbf{X}_n$ (———) and $\mathbf{X'}_n$ (-----).

materials $\mathbf{X'}_n$ is much more difficult than through the ordered mesoporous materials $\mathbf{X}_n$. The very low extent of reaction for $\mathbf{X_6}$ compared to $\mathbf{X_9}$ and $\mathbf{X_{19}}$ should be due to steric hindrance, which implies also that P centres are mostly located within the mesopores of $\mathbf{X}_n$.

In conclusion, we have shown that in surfactant-directed mesoporous hybrid materials, phosphorus centres are more easily accessible than in the corresponding materials prepared in the absence of surfactants. Furthermore the accessibility of phosphorus centres within ordered mesoporous hybrid materials depends on the 'dilution' of the organic part in silica. The higher the 'dilution', the greater the accessibility of the organic part in particular towards bulky reagents for which a minimum 'dilution' (n > 6) seems to be required. The study of hybrid materials with very low concentration of organo groups is in progress.

Cationic palladium(II) complex-catalyzed [2 + 2] cycloaddition and tandem cycloaddition–allylic rearrangement of ketene with aldehydes: an improved synthesis of sorbic acid

Tetsutaro Hattori,* Yutaka Suzuki, Osamu Uesugi, Shuichi Oi and Sotaro Miyano*

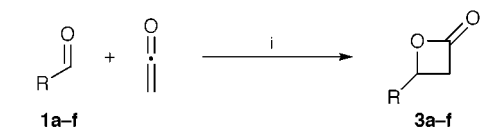
Received (in Cambridge, UK) 2nd November 1999, Accepted 24th November 1999

Cationic palladium(II) complexes $[PdL_2(PhCN)_2](BF_4)_2$ efficiently catalyze the [2 + 2] cycloaddition of ketene with aldehydes to give the corresponding oxetan-2-ones, among which 4-vinyl-substituted ones are further isomerized under the conditions to give 3,6-dihydro-2*H*-pyran-2-ones in good yields.

There has been much current interest in the preparation of oxetan-2-ones (β-lactones) because they are not only structural units in biologically active natural products but also versatile synthetic intermediates.[1] Among various synthetic routes to this class of compounds, the most efficient and concise is the Lewis acid-catalyzed [2 + 2] cycloaddition of ketenes with aldehydes.[1] Recently, we have reported the first asymmetric version of the cycloaddition mediated by a catalytic amount of Corey's aluminium-based bissulfonamides.[2] However, the reaction requires the use of at least 10 mol% of the catalyst to obtain the lactones in practical yields, as has been revealed in the related reactions catalyzed by typical metal-based Lewis acids. This may be ascribed to the highly oxophilic nature of the acid, which causes competitive ligation between the reactants and the product to the catalyst to reduce the catalytic efficiency. Deactivation of the catalyst by a trace amount of incidental water in the reaction system is another plausible problem.

On the other hand, it has been recognized in the last decade that certain transition metal complexes have considerable Lewis acid character and can displace conventional Lewis acids in a variety of the so-called Lewis acid-catalyzed reactions.[3] Furthermore, some of the transition metal-based Lewis acids are reported to be effective even in the presence of water.[4] These facts prompted us to examine whether this class of Lewis acids can effect the cycloaddition reaction. Herein, we report a highly efficient [2 + 2] cycloaddition of ketene with aldehydes **1** using cationic palladium(II) complexes $[PdL_2(PhCN)_2](BF_4)_2$ **2**[5] as the catalyst (Scheme 1).

The general procedure for the [2 + 2] cycloaddition is as follows (Method A): to a solution of complex **2** (50.0 μmol) in dry CH_2Cl_2 (20 cm^3) was added aldehyde **1** (1.00 mmol) under nitrogen at an appropriate temperature. Gaseous ketene (*ca.* 2.5 mmol) was bubbled into the mixture over a period of 5 min and the resulting mixture was stirred at this temperature for 1 h.



1,3a R = Cy
b R = Et
c R = hexyl
d R = Pr^i
e R = Bu^t
f R = Ph

$[PdL_2(PhCN)_2](BF_4)_2$
2a $L_2 = (PPh_3)_2$
b L_2 = dppe
c L_2 = dppp
d L_2 = dppb
e L_2 = dppf

Scheme 1 *Reagents and conditions*: i, **2**, CH_2Cl_2. dppp = 1,3-bis(diphenylphosphino)propane, dppf = 1,1′-bis(diphenylphosphino)ferrocene.

After usual work-up, the crude product was subjected to GC analysis to determine the yield of lactone **3**.

The results are listed in Table 1. The reaction of cyclohexanecarbaldehyde **1a** with ketene in the presence of 5 mol% of a palladium complex **2a**–**e** proceeded even at −78 °C to give the lactone **3a** (entries 1–5). The catalytic activity of the palladium complexes **2a**–**e** varied depending on the coordinating phosphine ligands, among which dppb (**2d**) was the most effective. Addition of powdered molecular sieves (3 Å) did not improve the yield of lactone **3a** (entry 6). An irregular temperature dependence of the product yield was found in the reaction conducted at −40 °C (entry 7, as compared with entries 4, 8 and 9). This may be ascribed to the balance between an increase in the rate constant with the rise in the reaction temperature and a significant decrease in the concentration of ketene around its boiling point (−41 °C). Lactone **3a** was obtained in quantitative yield at room temperature, even if the quantity of the catalyst was reduced to 1 mol% (entry 10). Judging from the high catalytic activity and the lack of apparent effect of the dehydrating agent (entry 6), the catalyst seems to be compatible with the trace amounts of water in the system. The reaction of several other aldehydes **1b**–**f** with ketene afforded the corresponding lactones **3b**–**f** in good to excellent yields (entries 11–15).

Next, our interest was directed toward the possibility of using the palladium complex **2d** as the catalyst for the cycloaddition of ketene with α,β-unsaturated aldehydes **1g**–**k** (Scheme 2). The reaction of ketene with crotonaldehyde **1g** under the standard conditions (Method A, *vide supra*) afforded not the β-lactone **3g** but a δ-lactone, 3,6-dihydro-6-methyl-2*H*-pyran-2-one (isoparasorbic acid) **4g**,[6] though only in poor yield, along with an unidentifiable polymer (*vide infra*) (Table 2, entry 1).[7] Low-

ering the reaction temperature and changing the molar ratios of ketene and catalyst **2d** to aldehyde **1g** did not improve the product yield, while dilution of the reaction solution was found to be highly effective (entry 2). Eventually, lactone **4g** could be obtained in good yields by adding aldehyde **1g** and ketene portionwise to a dilute solution of catalyst **2d** (Method B†) (entries 3 and 5). Under these conditions, 2.5 mol% of the catalyst **2d** was sufficient to complete the reaction (compare entry 6 with entry 3). Similar δ-lactones **4i–k** were also obtained in the reaction of α,β-unsaturated aldehydes **1i–k**, while acrolein **1h** afforded β-lactone **3h** under the same conditions (entries 7–10).

The formation of lactone **4** can be rationalized by the initial [2 + 2] cycloaddition of aldehyde **1** with ketene to give the allyl ester **3**, followed by its allylic rearrangement to form lactone **4**. It is known that this type of 1,3-rearrangement of allylic esters is promoted by Pd^0 and Pd^{II} complexes.[8] It should be noted, however, that the palladium(II)-catalyzed reaction is reportedly a [3,3]-sigmatropic rearrangement of allyl esters, which is impossible for the said lactones **3g–k** due to steric reasons. On the other hand, the palladium(0)-catalyzed rearrangement is believed to involve a π-allylpalladium(II) intermediate. It is also reported that palladium(II) salts promote the ring opening of 4-vinyl- (**3h**), and 4-isopropenyl-oxetan-2-one to afford the corresponding penta-2,4-dienoic acids.[9] A metallacyclic σ-allylpalladium intermediate generated by oxidative addition of the C(4)–O bond of the oxetan-2-ones to a palladium(0) species is proposed for the reaction. Thus, an allylpalladium species may be a possible intermediate for the present reaction. We found, however, that $BF_3{\cdot}OEt_2$ also catalyzed the rearrangement to give lactone **4g**, though only in 13% yield, when aldehyde **1g** was treated with ketene (method B) in Et_2O (200 cm^3) at room temperature in the presence of 1.5 equiv. of the acid.[10] This observation, along with the result that lactone **3h** did not isomerize to lactone **4h**, may suggest another possibility, that coordination of the carbonyl oxygen of 4-vinyl lactones **3g**, **i–k** to Lewis acid **2d** promoted the heterolytic cleavage of the C(4)–O bond of the lactones to form a zwitterion, recombination of which at the other allylic terminus afforded lactones **4**.

Further treatment of lactone **4g** with EtOH in the presence of HCl followed by saponification of the resulting ethyl sorbate, gave hexa-2,4-dienoic acid (sorbic acid) **5** in 90% yield (Scheme 2). Therefore, the present method provides an easy access to the acid **5**. It should be noted that sorbic acid **5** is important as a mould and yeast inhibitor, the first step of an industrial synthesis of which relies on the cycloaddition of ketene with crotonaldehyde **1g** catalyzed by a zinc carboxylate.[11] However, the product obtained from the reaction is not the β-lactone **3g** but its ring-opening polymer, poly(3-hydroxyhex-4-enoic acid), the viscosity of which causes a great deal of trouble during the subsequent destructive distillation of the polyester to the acid **5**. Further studies on the scope and limitations of the allylic rearrangement, as well as the [2 + 2] cycloaddition, are in progress.

This work was supported in part by grants from the Center of Interdisciplinary Research (Tohoku University), the Takasago International Corporation and the Chisso Corporation.

Oligoacetylenic sulfides

Albert W. M. Lee,* Anissa B. W. Yeung, Mabel S. M. Yuen, H. Zhang, X. Zhao and W. Y. Wong

Department of Chemistry, Hong Kong Baptist University, Kowloon Tong, Kowloon, Hong Kong. E-mail: alee@hkbu.edu.hk

Received (in Cambridge, UK) 13th October 1999, Accepted 26th November 1999

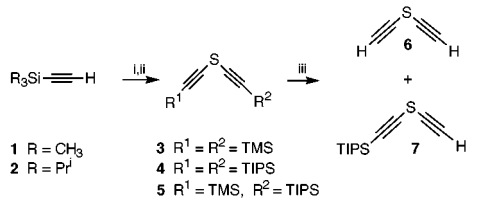
Linear acetylenic and diacetylenic sulfides consisting of up to eight triple-bond units with alternating sulfur atoms and acetylene units were synthesized.

The synthesis of conjugated or homoconjugated cyclic or linear oligoacetylene systems is a rapidly developing research frontier and has attracted considerable attention from both fundamental and applied viewpoints.[1] These all-carbon or carbon-rich acetylene-based scaffolds are expected to exhibit a variety of unusual structural, electronic, electrical and optical properties.[2–4] Linear rigid oligoacetylenic molecular rods of defined length in nanometer-sized structures could also serve as molecular wires in molecular electronic application.[5–7]

For the conjugated oligoacetylenic systems, a representative example is a compound with six conjugated diacetylene units synthesized by Diederich's group through end-capping polymerization.[8] Molecular wires end-capped with redox-active metal groups have also been reported.[9,10] The longest molecule of this group has up to ten conjugated acetylene units. Novel heterocycles comprising alternating phosphorus atoms and acetylene units reported by Scott's group are also known.[11] Dendrimers with acetylenic units[12] and alkynyl sulfides[13] have also been prepared. However, to the best of our knowledge, there is no report on linear oligoacetylenic compounds containing heteroatom bridging between all or some of the acetylene units. Based on our experience in the preparation and uses of acetylenic sulfoxides and related compounds in organic synthesis,[14] a systematic approach to the syntheses of oligomeric acetylenic sulfides with up to eight acetylene units is reported here.

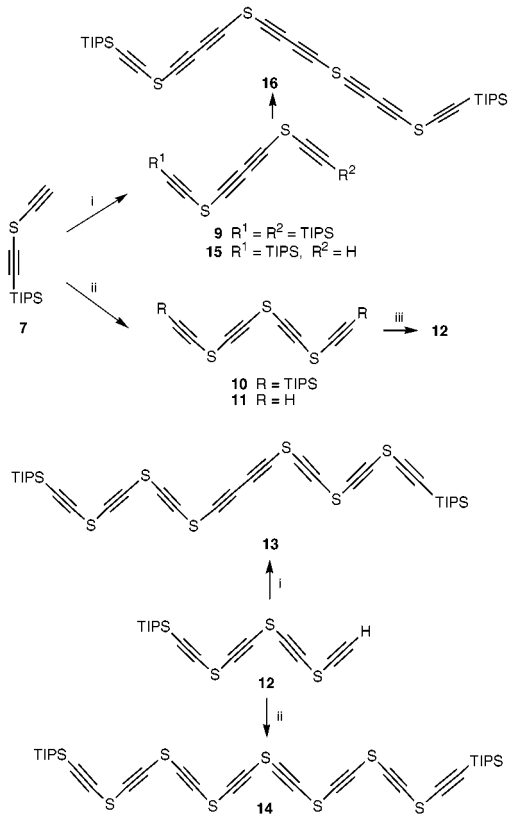
Two key reactions, namely sulfurization and oxidative coupling *via* Hay and Glaser-type related methods,[15] were used in building up the oligomeric acetylenic sulfides. Chain length is doubled in each cycle of the reaction.

The crucial starting material, a mono-protected bis-acetylene sulfide **7**, was first prepared. When an equal molar ratio of trimethylsilylacetylene **1** and triisopropylsilylacetylene **2** was treated with 1 equiv. of BuLi followed by 0.5 equiv. of SCl_2 at −78 °C, a mixture of silylated bis-acetylene sulfides (**3**–**5**) were formed (Scheme 1). The reaction mixture was placed under mild desilylation conditions (K_2CO_3/MeOH). The TMS group was hydrolyzed while the TIPS group remained intact. The volatile bis-acetylene sulfide **6** resulting from the hydrolysis of **3** was lost during work up and solvent evaporation. The remaining mono- and di-TIPS bis-acetylene sulfides **7** and **4** could be easily separated by column chromatography, with the mono-silylated compound **7** being the more polar component. The overall isolated yield of the desirable mono-protected compound **7** was 40%. The recovered di-TIPS acetylene sulfide **4** could also serve as the precursor of **7** through careful monodesilylation with KF in MeOH under close monitoring with TLC.



Scheme 1 *Reagents and conditions*: i, BuLi; ii, SCl_2, −78 °C; iii, K_2CO_3, MeOH.

Oxidative coupling and sulfurization reactions were then used in the chain elongation of the acetylenic sulfide. Several sets of oxidative coupling conditions for acetylene compounds were studied. Eventually, we found that the original Hay conditions[16] using CuCl and TMEDA afforded satisfactory results. For sulfurization, freshly distilled SCl_2 was used. Alternatively, a stable solid sulfurization agent, bis(benzenesulfonyl) sulfide **8**,[17] used extensively by Scott could also be used. As shown in Scheme 2, oxidative coupling of **7** afforded diacetylene compound **9** in 94% yield. Sulfurization of **7** with SCl_2 afforded sulfide **10** in 72% yield. Mono-deprotection of **10** to **12** was achieved by a carefully controlled desilylation procedure using KF in THF–H_2O in the presence of a catalytic amount of Bu_4NBr. The reaction was monitored closely *via* TLC and was stopped when **11** started to appear. Mono-deprotected **12** could be isolated in 35% yield after column chromatography with the recovery of about 16% of the starting material. If the desilylation reaction was allowed to run for a longer time at room temperature, the unprotected terminal acetylene compound **11** could also be isolated. The unprotected



Scheme 2 *Reagents and conditions*: i, CuCl, TMEDA, air, $CHCl_3$; ii, BuLi or LIHMDS, then SCl_2 or **8** ($PhSO_2SSO_2Ph$); iii, KF, THF–H_2O, Bu_4NBr (cat.).

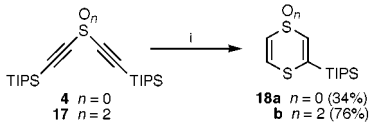

Scheme 3 *Reagents and conditions*: i, Na_2S, Al_2O_1, DMF–MeOH.

and mono-protected acetylenic sulfides **11** and **12** are very unstable, especially when concentrated.

Freshly prepared **12** was subjected to the coupling and sulfurization cycles to extend the chain to eight acetylene units. Coupling afforded diacetylene compound **13** in 55% yield. For the sulfurization process, we found that BuLi reacted with the triple bonds of **12** to give complicated products. Therefore, LIHMDS was used instead and **14** was prepared in 25% yield using **8** as the sulfurization agent. Monodesilylation of **9** to **15** could also be achieved under carefully controlled conditions. However, the coupling product **16**, which could be detected by FAB MS, was extremely unstable and could not be isolated in pure form.

All these new acetylenic sulfides were characterized by NMR, IR and MS. Some of the spectral data are summarized in Table 1. The typical IR frequency of the triple bond is around 2100 cm^{-1}, and the terminal acetylene C–H signal appears around 3300 cm^{-1}. UV spectra of oligoacetylene sulfides **4**, **10**, **13** and **14** were also recorded. There is no observable bathochromic shift (λ_{max} = 231–237 nm) for compounds **4**, **10** and **14** as the chain length increased. This indicated that the degree of conjugation between the acetylene units is weak. Compound **13**, being a diacetylene compound, showed a slight bathochromic shift (λ_{max} = 260 nm) relative to compounds **4**, **10**, **14** and had a large molar absorptivity.

We also explored the chemistry of double conjugate addition of nucleophiles to the terminal positions of the bis-acetylene sulfides and the corresponding sulfones.[18] Reactions with Na_2S impregnated on neutral alumina[19] took place readily in DMF–MeOH mixture at 0 °C and room temperature respectively for **4** and **17** (Scheme 3). However, to our surprise the mono-desilylated compounds **18a**,**b** were the only isolated products. The structure of cyclic sulfone **18b** was confirmed by X-ray analysis (Fig. 1).†

In summary, the first syntheses of a series of oligoacetylenic sulfides with alternating sulfur atoms and acetylene or diacetylene units were accomplished using the monoprotected bis-acetylene sulfide **7** as the starting material. Studies on the synthesis of some cyclic and metal end-capped analogs[20] are in progress.

Financial support from the Research Grants Council (RGC/97-98/48, HKBU 2048/97P) is gratefully acknowledged.

Synthesis and characterization of cross-conjugated polyenynes

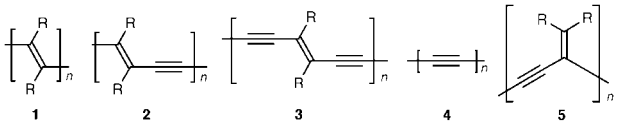
Yuming Zhao, Robert McDonald and Rik R. Tykwinski*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2. E-mail: rik.tykwinski@ualberta.ca

Received (in Corvallis, OR, USA) 24th August 1999, Accepted 9th November 1999

Extended, cross-conjugated polyenynes are reported as well as a description of their electronic (UV–VIS) characteristics and an X-ray crystallographic analysis of hexayne 9 that shows solid-state molecular alignment suitable for topochemical polymerization.

The sequential combination of sp and/or sp^2 hybridized carbons affords a series of wire-like π-conjugated carbon chains typified by the structures of polyacetylene (**1**),[1] polydiacetylene (PDA, **2**)[2,3] and polytriacetylene (PTA, **3**)[4] in a progression that ultimately concludes with the one-dimensional carbon allotrope, carbyne (**4**).[5–7]



1 **2** **3** **4** **5**

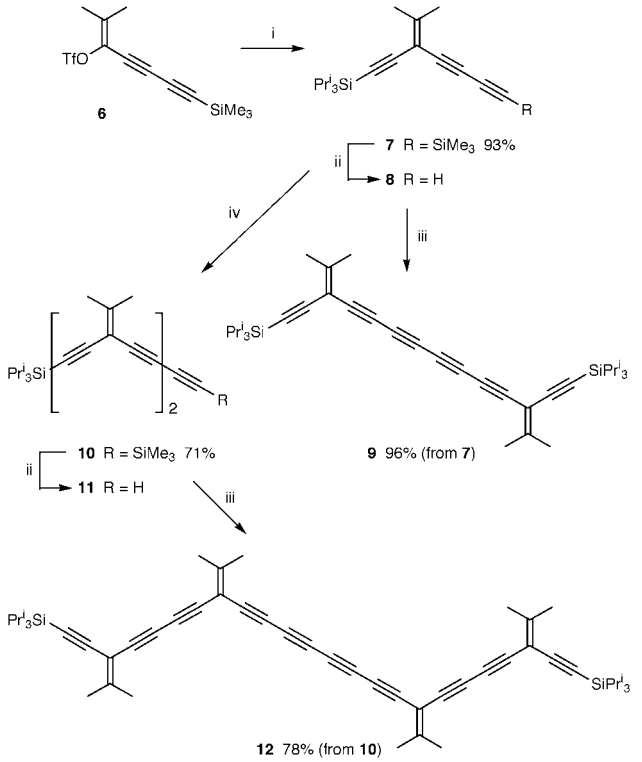
The most recent addition to this mélange of enyne oligomers is *iso*-polydiacetylene (*iso*-PDA, **5**),[8] the cross-conjugated isomer of **2**.[9] Studies of *iso*-PDAs have shown that π-electron communication is present along the cross-conjugated framework, albeit to a much lesser extent than for PDAs. To provide a better understanding of the physical and electronic characteristics of cross-conjugated enynes, we have extended the skeleton of **5** by inserting additional alkyne groups. Herein, we report the first synthesis of these cross-conjugated polyenynes and a preliminary description of their electronic, X-ray crystallographic and solid-state chemical characteristics.

The enyne oligomers were synthesized as outlined in Scheme 1. Vinyl triflate **6**[10] was coupled with triisopropylsilylacetylene in THF at ambient temperature. Work-up and flash column chromatography, gave the triyne **7** in 93% yield.† Protodesilylation of **7** gave terminal alkyne **8**, which was then oxidatively homocoupled[11] to hexayne **9** in 96% yield as a stable, light yellow solid.

Triyne **8** was also elaborated to pentayne **10** in 71% yield *via* reaction with vinyl triflate **6**, as described for the formation of **7**. Desilylation of **10** gave the terminal alkyne **11**, which afforded a good yield of decayne **12**. Notably, the ^{13}C NMR of **12** shows individual resonances for all 10 acetylenic carbons, as well as four unique signals for the alkylidene methyl carbons.‡

Yellow single crystals of hexayne **9** were grown by diffusion of MeOH into a CH_2Cl_2 solution at –20 °C, and the structure was determined by X-ray crystallographic analysis (Fig. 1).§ The π-framework of **9** is virtually planar, with a maximum deviation of 0.130(17) Å from the least-squares plane for the 16-carbon conjugated skeleton.¶ All six triple bonds are essentially the same length, suggesting little bond length alteration as a result of π-conjugation and contrasting results for PDA oligomers of similar size.[12] The eight tetrayne carbons are virtually linear, showing only a gradual curvature with bond angles deviating less than 3° from 180°.

Analysis of the crystal packing of **9** down the *b*-axis shows the molecules are aligned in a parallel fashion (Fig. 1). The intermolecular proximity of the tetraynes in the crystal suggests the potential for topochemical polymerization as is well established for suitably aligned butadiynes and hexatriynes.[2,13,14a] The solid-state polymerization of octatetraynes has also been previously described, albeit in much less detail.[14]



Scheme 1 *Reagents and conditions*: i, triisopropylsilylacetylene, $PdCl_2(PPh_3)_2$, CuI, Pr^i_2NH, THF, room temp; ii, K_2CO_3, wet MeOH–THF (1:1), room temp; iii, CuI, TMEDA, O_2, CH_2Cl_2 room temp; iv, **6**, $PdCl_2(PPh_3)_2$, CuI, Pr^i_2NH, THF, room temp.

The parameters describing the intermolecular relationship of molecules **9** are depicted in Fig.1(*c*).[2,13a,14a] Polymerization of **9** *via* 1,2- or 1,4-addition, as described for tetrayne systems,[14] is unlikely considering that $R_{1,2}$ (6.7 Å) and $R_{1,4}$ (4.7 Å) are both considerably more than the ideal distance of 4 Å between reacting carbon atoms. The angle ϕ between the tetrayne rod and the stacking axis at *ca*. 28° is significantly less than the optimum value of 45° determined for 1,4-addition in di-, tri- and tetraynes.[2,13a,14a] Thus, two alternative addition patterns might occur for **9**, namely 1,6-addition ($R_{1,6}$ = 3.6 Å) and 1,8-addition ($R_{1,8}$ = 4.2 Å). The stacking angle ϕ is nearly identical to the value of 27° that denotes highest 1,6-reactivity in triacetylenes, and the stacking distance between monomer units at 7.7 Å is quite near the desired value of 7.5 Å.[13a] In view of these values, 1,6-addition is the expected mode of reaction for **9**.

Differential scanning calorimetry showed that crystals of **9** have a well-defined melting point at 103–104 °C that is followed by decomposition at 145 °C. Attempts to thermally effect polymerization of single crystalline **9** were conducted at 90 °C. Over the course of 8 h, the crystals darken slightly to yield an opaque solid. A loss of crystal integrity for the resultant material was confirmed by the absence of any X-ray diffraction pattern. To date, the product(s) of this thermal reaction has not been identified.

Photochemical polymerization of a single crystal of **9** was attempted by monochromatic irradiation at 280 nm.[15,16] After

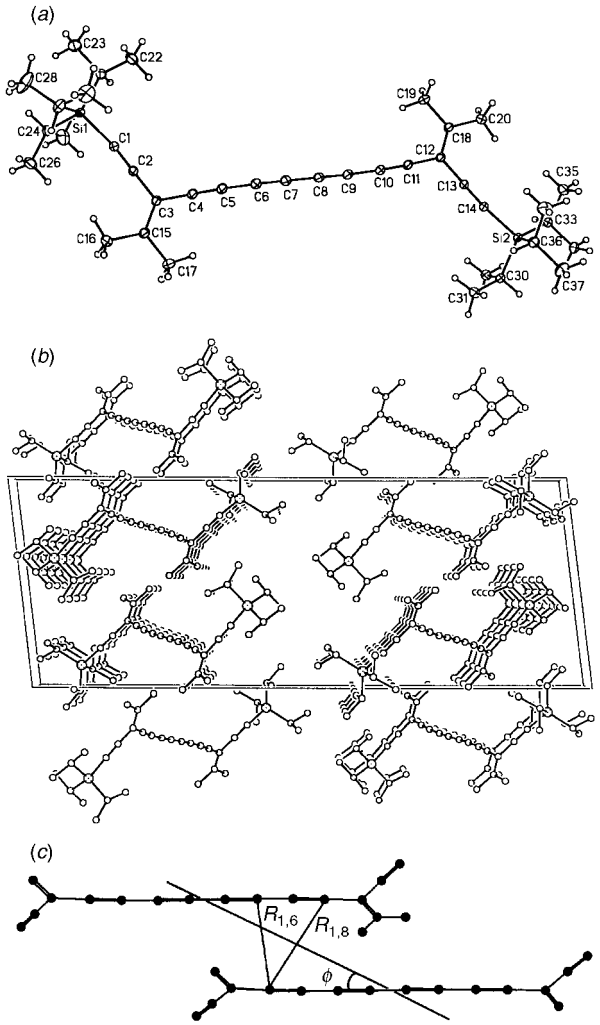


Fig. 1 (*a*) ORTEP drawing (20% probability level) of **9**, (*b*) crystal packing of **9** as viewed along the *b*-axis, and (*c*) crystal packing parameters for **9**.

approximately 2 h, a darkening of the crystal to yellow–orange was observed. Irradiation was continued for another 4 h with little additional darkening. X-Ray analysis of the crystal afforded a diffraction pattern and cell parameters identical to that of pure **9**, indicating little change in the solid beyond that which may have occurred at the outer surface of the crystal.

The electronic absorption spectra of **9**, **12** and 1,8-bis(4-*tert*-butylphenyl)-octa-1,3,5,7-tetrayne **13**, are shown in Fig. 2. The lower energy region is dominated by the absorption pattern of the tetrayne moiety and is remarkably similar to that of **13**.[17] Each compound displays three absorptions at *ca*. 405, 374 and 348 nm. Whereas the UV spectra of elongated *iso*-PDAs show evidence of π-electron communication *via* cross-conjugation,[8] this effect is absent in **9** and **12**, as the three lowest energy absorptions of **12** are each red-shifted by only 1 nm *versus* those of **9**.

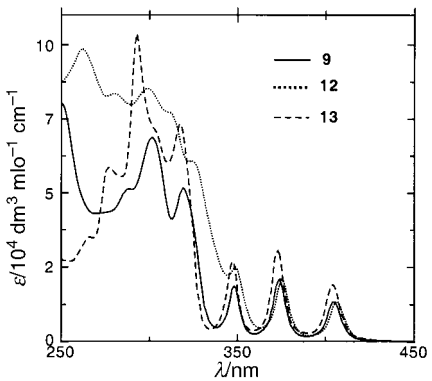

Fig. 2 UV–VIS spectra in $CHCl_3$ comparing polyynes **9**, **12** and **13**.

In conclusion, cross-conjugated polyenynes **7**–**12** can be synthesized in high yields as relatively stable solids. The UV–VIS spectra of **9** and **12** show a minimal contribution from cross conjugation. The solid state organization of **9** is suitable for topochemical polymerization, although initial attempts to effect thermal and photochemical polymerization have been unsuccessful. Further studies on **9** and **12** are currently underway.

This work was supported by a Gen-Science Endowment from the University of Alberta and by NSERC. We thank Professor M. M. Haley for providing a sample of **13**.

Thermotropic and lyotropic behavior of novel amphiphilic liquid crystals having hydrophilic poly(ethyleneimine) units

Seiji Ujiie* and Yumi Yano

Department of Material Science, Interdisciplinary Faculty of Science and Engineering, Shimane University, Matsue 690-8504, Japan

Received (in Cambridge, UK) 27th September 1999, Accepted 25th November 1999

Novel ionic amphotropic liquid crystals, in which a hydrophilic poly(ethyleneimine) chain with hydroxy side-groups was attached to an azobenzene mesogenic core through an alkylene chain, showed a thermotropic smectic A mesophase and lyotropic smectic A and C mesophases.

Amphiphilic compounds such as ionic and nonionic surfactants always consist of hydrophilic and lipophilic groups. They can form thermotropic liquid crystalline phases in themselves and lyotropic liquid crystalline phases upon the addition of a solvent such as water.[1] The thermotropic liquid crystalline systems of the amphiphiles build up layered structures with distinct arrangements of the molecules within their layers. In the lyotropic liquid crystalline systems, the hydrophilic group conveys water solubility, while the hydrophobic group drives the formation of self-assembled aggregates. Lyotropic liquid crystalline systems can form liquid crystalline phases such as lamellar mesophases, which resemble thermotropic smectic A phases, columnar and cubic mesophases. Surfactants with an aromatic mesogenic group can show liquid crystal formation due to the anisotropy formed by aggregation of the polar head groups and interactions between the aromatic mesogenic groups.[2–4] They can show both thermotropic and lyotropic liquid crystalline behavior. It is of high importance in the field of supramolecular chemistry that new thermotropic and lyotropic liquid crystal forming amphiphilic compounds are sought. This makes it possible to develop novel types of functional liquid crystalline materials. During our study of new ionic liquid crystals,[5–8] we synthesized novel types of ionic liquid crystalline amphiphiles in which a hydrophilic poly(ethyleneimine) unit with hydroxy side-groups is attached to an aromatic mesogenic core. They showed amphotropic behavior. Here we describe the phase transitions and orientational behavior in the thermotropic and lyotropic liquid crystalline systems containing these novel amphiphilic compounds.

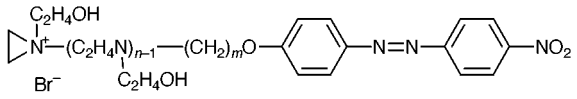
The ionic amphiphilic compounds prepared by us were obtained by ring-opening polymerization of aziridine-1-ethanol (AE) using 6-bromo-1-[4-(4-nitrophenylazo)phenoxy]hexane (Br6N) [or 12-bromo-1-[4-(4-nitrophenylazo)phenoxy)dodecane (Br12N)] as the polymerization initiator. AE (0.05 or 0.07 mol) and Br6N (0.01 mol) were dissolved in $CHCl_3$, and the mixture was stirred for 300 h at room temperature. After the reaction, the solution was concentrated and diluted in THF. The target material precipitated from the solution and was filtered off. The degree of polymerization (n) of the poly(ethyleneimine) unit was estimated by ^{1}H NMR. The ratio of the numbers of protons involved in methylene groups directly attached to the hydroxy group (3.7 ppm) and the phenyl ring (7.05 ppm) was examined. The existence of a terminal ionic group was shown by the peak at 3.5 ppm in the ^{1}H NMR spectra. The phase transitions of the samples were examined by DSC (Mettler DSC-20 and Shimadzu DSC-50Q) and polarizing microscopy (Nikon polarizing microscope equipped with a Mettler hot stage FP82). The X-ray diffraction measurements were performed using a Rigaku Rint 2100 X-ray diffractometer with Ni-filtered Cu-Kα radiation at various temperatures; the samples were inserted into a Linkam hot stage HFS91.

Table 1 Phase transitions of thermotropic liquid crystalline systems

Sample	Phase transition temperatures[a]/°C					
4E-6N	T_g = −2.78	K	31.1	SmA	109.6	Iso
6E-6N		G	−28.2	SmA	101.0	Iso
3E-12N		K	115.2	SmA	185.4	Iso

[a] T_g = glass transition point; K: solid phase; G: glass phase; SmA: smectic A phase; Iso: isotropic phase.

The phase transition temperatures of the thermotropic liquid crystalline systems are summarized in Table 1. The amphiphilic liquid crystals (6E-6N, 4E-6N) having a hexamethylene linkage



Sample	n	m
4E-6N	4	6
6E-6N	6	6
3E-12N	3	12

chain showed a thermotropic smectic A phase upon heating and cooling. Both 6E-6N and 4E-6N formed focal conics and a perpendicular alignment in the smectic A phase. The amphiphilic liquid crystal (3E-12N) with a dodecamethylene spacer unit also exhibited a thermotropic smectic A phase with focal conic fan and oily streak textures. The smectic A liquid crystal formation in 6E-6N, 4E-6N and 3E-12N is due to the aggregation of the hydrophilic poly(ethyleneimine) units and an overlapping arrangement of the aromatic mesogenic groups due to the strong interaction of the nitro terminal groups.

In this study, the lyotropic systems of 3E-12N were prepared, and their lyotropic liquid crystalline properties were estimated. 3E-12N was water-miscible and easily dissolved in water. The lyotropic systems (L1) consisting of 3E-12N and water formed a lyotropic smectic C phase, as well as the lyotropic smectic A phase (Fig. 1). In L1, focal conics and a perpendicular alignment were formed upon cooling from the isotropic phase to the

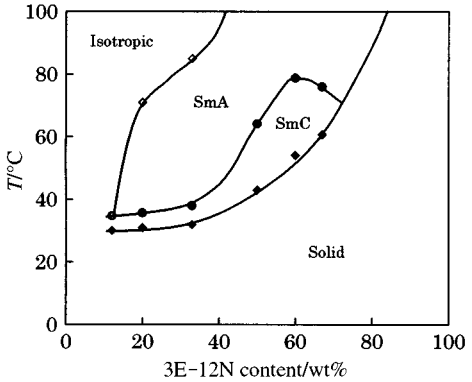


Fig. 1 Phase diagram of lyotropic system (L1) of 3E-12N.

lyotropic smectic A phase, and in the lyotropic smectic C phase, broken fan and schlielen textures clearly appeared (Fig. 2).

The lyotropic smectic C phase is induced by the addition of water to the amphiphilic 3E-12N because anhydrous 3E-12N cannot form the smectic C phase by itself. It is common that lyotropic liquid crystals form nematic, smectic A-like lamellar, columnar and cubic mesophases. However, a tilted smectic type of lyotropic mesophase, such as a smectic C phase, is seldom formed, and only a few reports have described the observation of the lyotropic smectic C phase for nonionic amphiphile/water mixtures.[9] The formation of the lyotropic smectic C phase in L1 is a rare case and is probably related to the balance of the hydrophilic and hydrophobic units in the 3E-12N molecule.

The X-ray diffraction pattern of thermotropic 3E-12N consists of sharp reflections at small angles and a broad reflection in the wide-angle region. The layer spacing of thermotropic 3E-12N was 44 Å. In the thermotropic smectic A

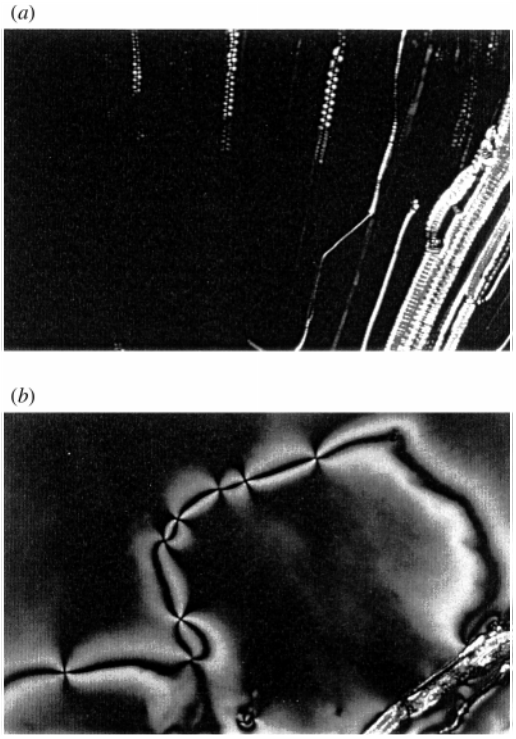

Fig. 2 Optical textures of L1 (50wt%): (*a*) lyotropic smectic A phase (70 °C); (*b*) lyotropic smectic C phase (50 °C).

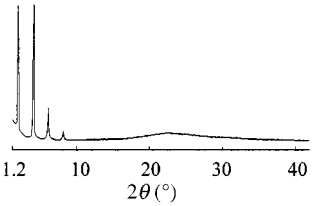

Fig. 3 X-Ray diffraction pattern for lyotropic smectic C phase of L1 (50 wt%) at 45 °C.

structure with hydrophobic and hydrophilic sublayers, the nitroazobenzene groups form the interdigitated structure, and poly(ethyleneimine) groups aggregate through hydrogen bondings and ionic interactions.

In the lyotropic mesophase, L1 showed X-ray diffraction patterns consisting of sharp reflections at small angles and a broad reflection in the wide-angle region (Fig. 3).

In L1 (50 wt%), the smectic A and C layer spacings were 50 (65 °C) and 45 Å (45 °C), respectively. In the lyotropic smectic phases, the nitroazobenzene mesogenic units overlap each other, and the poly(ethyleneimine) units and water aggregate through hydrogen bonding. It is expected that the layer structure of the lyotropic smectic A phase resembles that of the thermotropic smectic A phase. In the lyotropic smectic C phase, the hydrophobic sublayers, in which the mesogenic units were tilted with respect to the layer normal, are separated by the hydrophilic units and water.

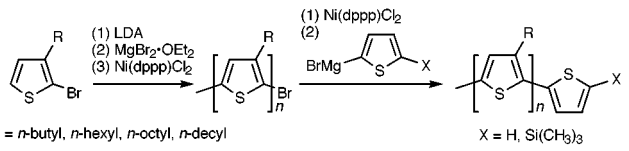
Received (in Cambridge, UK) 8th November 1999, Accepted 22nd November 1999

An efficient and simple procedure for end-group modification of poly(3-alkylthiophene)s is presented which can be incorporated into the last step of the polymerisation reaction or employed as a post-polymerisation modification.

Poly(3-alkylthiophene)s (P3ATs) constitute an important class of conjugated polymers.[1] Being chemically and thermally stable materials, soluble P3ATs are attractive for exploring their electronic and optical properties. The side chains not only ensure solubility, but are a key parameter for the mesoscopic structure in thin films and, hence, as a property determining element. Perfection of the primary structure of the polymer, including molecular weight and polydispersity, is a prerequisite to obtain well-defined materials in a reproducible manner. Recently, regioregular P3ATs have been incorporated as the active material in transistors in which a preferential supramolecular ordering of the polymer chains induces a high field-effect mobility of up to 0.1 $cm^2\ V^{-1}\ s^{-1}$,[2,3] approaching that of single crystal oligothiophenes.[4] End-group functionalisation of these polymers would open the possibility to graft P3ATs onto surfaces, prepare block copolymers, or attach specific electroactive end groups and thereby extend the range of applications of these materials. Here we describe a simple and convenient procedure to introduce new end groups on the P3ATs.

Various synthetic routes to obtain regioregular P3ATs have been advanced over the last decade.[5-8] The McCullough route is most frequently employed to prepare regioregular P3ATs (Scheme 1). Typically a 3-alkyl-2-bromothiophene is converted to the (4-alkyl-5-bromo-2-thienyl)magnesium bromide Grignard reagent, which is polymerised *in situ* using $Ni(dppp)Cl_2$ as catalyst.[5] The work-up procedure involves extensive Soxhlet extractions with MeOH, hexanes, CH_2Cl_2 and $CHCl_3$,[9] and provides fractionated polymers with a polydispersity (PD) = 1.3–1.5 and molecular weight (M_w) increasing from 4–5 kg mol^{-1} for the hexanes fraction to ~30 kg mol^{-1} for the $CHCl_3$ fraction as determined by SEC analysis in $CHCl_3$ against polystyrene standards. Although regioregularities exceeding 99% have been claimed previously for P3ATs synthesised in this way, it has become clear that these polymers are less perfect than presumed initially.[10,11] Elemental analysis has revealed that synthesised P3ATs (where the alkyl group is *n*-butyl, *n*-hexyl, *n*-octyl or *n*-decyl) may contain a considerable amount of bromine (typically 1–2 wt%).[10,11]†

By investigating the hexane Soxhlet fraction of poly(3-hexylthiophene) (P3HT) with HPLC and preparative SEC in combination with MALDI-TOF mass spectrometry, it became clear that polymer chains terminated with 0, 1 and 2 bromines are present (Fig. 1).[10,11]‡ HPLC analysis of the hexane fraction confirms the presence of at least two series of P3HTs with alternating signal intensities [Fig. 2(*a*)]. The main progression in the HPLC trace [Fig. 2(*a*)] is identified as regioregular P3HT



Scheme 1

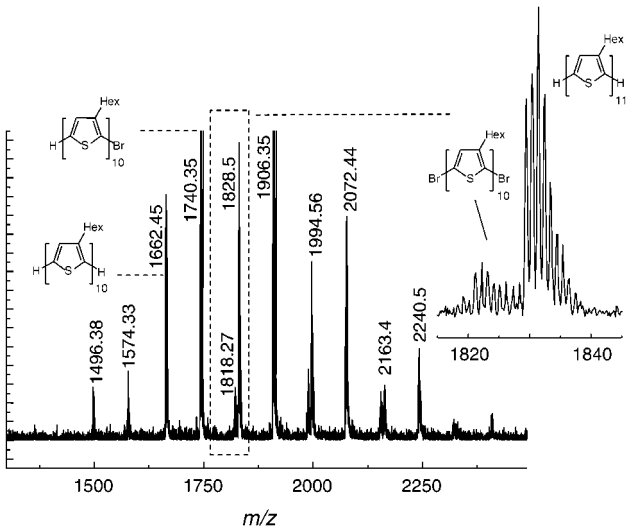


Fig. 1 MALDI-TOF of a narrow molecular weight fraction (M_w = 2.96 kg mol^{-1}, PD = 1.05) of P3HT obtained by preparative SEC showing the signals of chains with no, one and two bromine end groups. Note that SEC calibrated against polystyrene standards overestimates the molecular weight by a factor of 1.6.

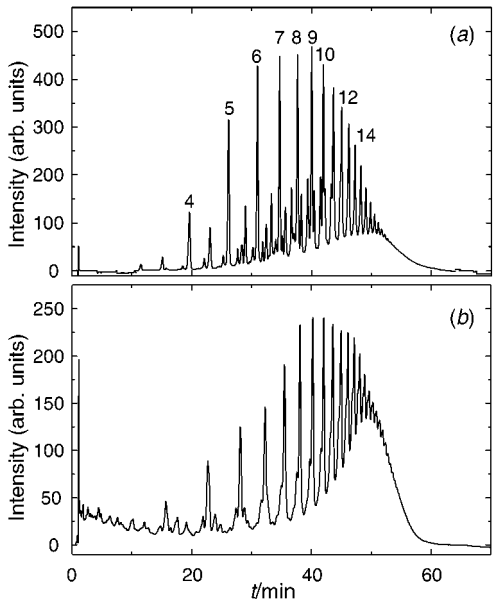

Fig. 2 HPLC of P3HT hexanes fraction before (*a*) and after (*b*) introduction of thiophene end groups. The numbers in the top graph indicate the number of thiophene rings of P3HT oligomers carrying one bromine end group.

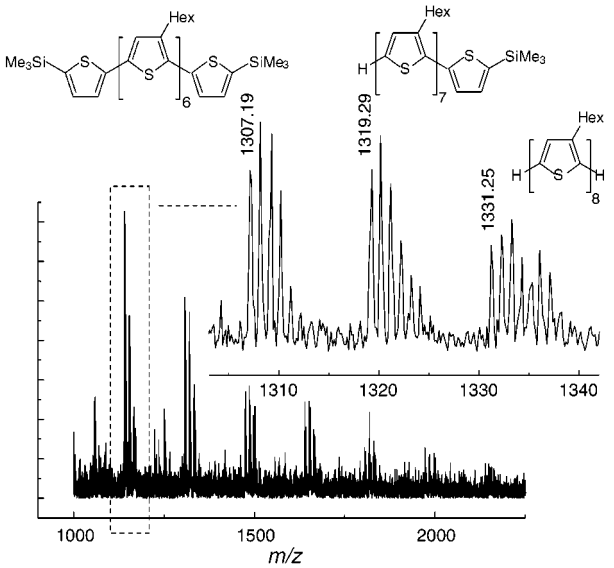

Fig. 3 MALDI-TOF of P3HT after end-capping with 5-trimethylsilyl-2-thienyl groups.

containing one bromine end group. This result is corroborated by the ^{1}H NMR spectrum of the $CHCl_3$ fraction of these polymers, which typically exhibits peaks for the benzylic resonances at δ 2.80 and 2.60 in a 20 : 1 ratio. While the δ 2.80 signal is due to benzylic protons in a regioregular head-to-tail dyad, the signal at δ 2.60 can be assigned to regioirregular head-to-head dyads and bromine terminated thiophene end groups.[9,12] The ratio of the benzylic ^{1}H NMR signals is a more sensitive gauge[6] to determine the regularity of the polymer than the aromatic protons and provides values on the order of 95% for the best materials.

Although the terminal bromines constitute a structural and chemical imperfection, they can be utilised to modify the polymers by introducing new end groups. We found that a post-polymerisation reaction of the polymer with a thiophene Grignard reagent under addition of fresh catalyst works rather well.§ Analysis with HPLC of a sample treated in this way showed essentially a single progression of P3HT chains [Fig. 2(*b*)]. To get a greater insight into the efficiency of the end-group modification reaction, a sample of P3HT was treated with 5-trimethylsilyl-2-thienylmagnesium bromide to introduce 5-trimethylsilyl-2-thienyl end groups under addition of fresh catalyst. MALDI-TOF analysis of short chains gives unambiguous evidence of the incorporation of the (5-trimethylsilyl-2-thienyl) end groups, with no signals for bromine-terminated chains (Fig. 3). The MALDI-TOF spectrum shows that both α and α,ω substitution occurs. The introduction of trimethylsilyl groups is also supported by the ^{1}H NMR spectrum, which shows a signal at δ 0.33.

In addition to adding a Grignard reagent at the end of the polymerisation reaction together with a fresh amount of catalyst to introduce specific end groups, the same reaction can also be performed on previously synthesised and isolated material.¶ This post-polymerisation reaction leaves the polymer intact, as inferred from a comparison of the molecular weights before and after performing the end-capping reaction.

In conclusion we have shown that *via* the Ni(dppp)Cl_2 mediated Grignard coupling it is possible to modify the bromine end groups that result from a McCullough type polymerization reaction of P3ATs, either as the last step in the polymerization or in a post-synthesis procedure on already isolated material. The procedure can be used to introduce end groups that are reactive to surfaces or to other functional groups. This opens the way to use P3ATs in adhesion, block-copolymerisation, electrooptical end groups and energy harvesting.

Financial support from the European Commission (Esprit 24793) is gratefully acknowledged.

Notes and references

† The bromine content was determined by Schöniger combustion.

‡ The molecular mass of the polymers was measured using a Perseptive DE PRO Voyager MALDI-TOF spectrometer utilising a α-cyano-4-hydroxy-cinnamic acid matrix. A solution of 1 mg ml^{-1} P3AT in THF was mixed with the matrix material at a molar ratio of *ca.* 1 : 10^{-3} (matrix : P3AT) and crystallised on the target immediately before measurement. HPLC column specifications: Waters, Nova-Pak C18, 60 Å, 4 μm, dimensions 3.9 × 150 mm. The HPLC runs (detected at 400 nm) were performed with an MeCN–THF gradient of 90 : 10 to 20 : 80, 1% min^{-1}, with Supra Gradient solvents from Biosolve.

§ In a typical procedure distilled Pr^i_2NH (2.8 ml, 20 mmol) was dissolved in 70 ml of dry THF. At room temperature BuLi (10.6 ml, 1.6 M in hexane, 17 mmol) was added. After stirring for 1.5 h, the solution was cooled to −60 °C and 2-bromo-3-hexylthiophene (4.0 g, 16 mmol) was added. The mixture was stirred for 1 h at –60 °C, and for 1 h at −40 °C. At −65 °C $MgBr_2{\cdot}OEt_2$ (4.4 g, 17 mmol) was added. The mixture was allowed to warm to 0 °C slowly. When all $MgBr_2{\cdot}OEt_2$ was dissolved, 0.09 g (0.18 mmol) Ni(dppp)Cl_2 was added and the mixture was stirred at room temperature for 20 hs. Then 20 mmol of freshly prepared 2-thienylmagnesium bromide (X = H) or 5-trimethylsilyl-2-thienylmagnesium bromide [X = $Si(CH_3)_3$] in Et_2O were added together with another portion of 0.18 mmol of Ni(dppp)Cl_2 and stirring was continued for 20 h. The reaction mixture was precipitated in MeOH, and further purified *via* Soxhlet extractions using MeOH, hexane and CH_2Cl_2. Isolation *via* Soxhlet extraction with $CHCl_3$ gave M_w = 25.6 kg mol^{-1} (PD = 1.42) for X = H and M_w = 14.6 kg mol^{-1} (PD = 1.48) for X = $Si(CH_3)_3$.

¶ To a mixture of P3HT (0.50 g, M_w = 11.0 kg mol^{-1}, PD = 1.4) in 15 ml THF and Ni(dppp)Cl_2 (0.4 g, 0.7 mmol) was added freshly prepared 2-thienyl magnesium bromide (5.9 g, 36 mmol 2-bromothiophene and 0.9 g, 37 mmol Mg) in 15 ml THF. The mixture was refluxed for 3 h. After removal of THF the P3HT was fractionated by Soxhlet extractions with MeOH, CH_2Cl_2 (0.32 g, M_w = 10.8 kg mol, PD = 1.51) and $CHCl_3$ (0.15 g, M_w = 19.4 kg mol^{-1}, PD = 1.23), respectively. The same work-up procedure on the original P3HT sample afforded M_w = 12.0 kg mol^{-1} (PD = 1.27) and M_w = 19.9 kg mol^{-1} (PD = 1.23).

Received (in Cambridge, UK) 2nd November 1999, Accepted 29th November 1999

A novel Dewar benzene approach to the construction of oligophenylene macrocycles has been developed by introducing Dewar benzene 1 as a building block and applied to the synthesis of a molecular rectangle 8, whose structure was characterized crystallographically.

During the course of our study on small cyclophanes generated from the corresponding Dewar derivatives,[1] we were interested in exploiting a Dewar benzene for the construction of macrocyclic structures, especially for the synthesis of *p*-phenylene-based rigid, and thus strained, macrocycles. Since the bent shape of Dewar benzene is expected to provide a unique template effect on the cyclization, novel macrocyclic systems which are difficult to access from planar benzene derivatives may well become available based on the Dewar benzene approach. Here we report the rational and efficient synthesis of a novel rectangular macrocycle **8** using acetal-bridged Dewar benzene **1** as a building block, together with its crystallographic characterization. Phenylene acetylene macrocycles have attracted considerable recent attention in supramolecular chemistry and materials science.[2]

Dewar benzene **1** was readily prepared in four steps and on a gram scale from DMAD and 1,2-dichloroethylene.[3] Palladium-catalyzed coupling of **1** with **2**† afforded diethynylation product **3** (55% yield), which was then deprotected to **4** in 80% yield (Scheme 1). Copper-mediated oxidative coupling of **4** with $CuCl/Cu(OAc)_2$[4] in pyridine under pseudo-high-dilution conditions produced cyclic dimer **5**‡ in 70% yield. Acid hydrolysis of **5** followed by the silylation of resulting tetraol **6** afforded **7**§ in 73% yield. Photochemical isomerization of **7** proceeded smoothly and cleanly by irradiation with a high-pressure mercury lamp through Pyrex at 12 °C to afford **8**§ in quantitative yield. The less symmetrical product resulting from the rearrangement of only one of the Dewar benzene units was not detected by ^{1}H NMR monitoring of the reaction.

It is interesting to note that, in the ^{1}H NMR spectra, the benzylic protons of **7** appear as a pair of AB doublets (δ 4.10 and 4.12, J = 11 Hz) while those of **8** appear as a singlet (δ 4.95), indicating that these protons are diastereotopic in **7** and operationally enantiotopic in **8**. These observations would be most reasonably explained by postulating fast interconversion between the rotamers **8a** and **8b**, namely, fast rotation of the *p*-phenylene unit(s) in **8** on the NMR timescale despite the strained nature of the macrocycle.[5]

Crystals of **8** suitable for X-ray structure determination (Fig. 1) were obtained by slow diffusion of EtOH into a solution of **8** in $CHCl_3$ at room temperature.¶ The molecule adopts a nearly planar conformation in the crystal and the dimension of framework is 7.32 × 11.54 Å, as defined by the four inner *m*-phenylene carbon atoms. Interestingly, the framework appears to be distorted to a parallelogram to accommodate two $SiMe_2OCH_2$ moieties inside the cavity. The twist angles of the benzene rings from the least-square plane formed by the acetylenic carbon atoms are 3.7 and 0.4° in the *m*-phenylene units and 3.4° in the *p*-phenylene units. The benzene rings are essentially planar (deviation < 0.01 Å) while the acetylene units show small deviation from linearity with the C≡C–C angles of 168.7(3)–179.9(3)°.

In conclusion, we have successfully synthesized and characterized a novel rectangular macrocycle **8** by introducing **1** as a building block. The high efficiency of the macrocyclization of **4** into **5** demonstrates the synthetic utility of a Dewar structure as a 'masked' *p*-phenylene unit. Further elaboration and application of the present Dewar benzene strategy are now in progress.

We thank Professor Tamotsu Inabe, Hokkaido University, for the use of X-ray analytical facilities. This work was supported in part by a Grant-in-Aid for Scientific Research (No. 09640620) from the Ministry of Education, Science, Sports and Culture of Japan.

Novel liquid-crystalline PPE-naphthalene copolymers displaying blue solid-state fluorescence

Neil G. Pschirer, Mary E. Vaughn, Y. B. Dong, Hans-Conrad zur Loye and Uwe H. F. Bunz*

Department of Chemistry and Biochemistry, The University of South Carolina, Columbia, South Carolina 29208, USA. E-mail: bunz@psc.sc.edu

Received (in Columbia, MO, USA) 14th September 1999, Accepted 5th October 1999

Synthesis of poly(*p*-phenyleneethynylene)s (PPEs) containing 1,5-diethynyl-3,7-di-*tert*-butylnaphthalene leads to novel phenylene-naphthylene-ethynylene copolymers which show strong blue luminescence in the solid state.

Conjugated polymers are organic semiconductors and find *inter alia* applications in electroluminescent devices[1,2] and 'plastic lasers'.[3] We have recently reported an efficient synthesis of high molecular weight poly(*p*-phenyleneethynylene)s (PPEs) by alkyne metathesis utilizing simple 'instant catalysts'.[4] PPEs are promising materials, because they show quantum yields of 1.0 and blue emission in dilute solution. However, in the solid state, the emission spectra of PPEs are much weaker and considerably red-shifted as a consequence of aggregation and concomitant excimer formation in the solid state.[5,6] Likewise poly(3,7-di-*tert*-butylnaphthyleneethynylene), which we recently synthesized, is effectively non-fluorescent as film or powder.[7]

Herein we repot the synthesis and characterization of the unsaturated copolymers **3** which are efficient blue emitters in the solid state (Fig. 1). The polymers **3** are obtained by adding defined amounts of 3,7-di-*tert*-butyl-1,5-dipropynylnaphthalene **2**[7] to 1,4-dipropynyl-2,5-dialkylbenzenes **1** (Scheme 1) in our alkyne metathesis protocol utilizing an instant catalyst formed of $Mo(CO)_6$ and 4-chlorophenol.[8]† The catalyst and a varying ratio of monomers **1** and **2** were stirred in 1,2-dichlorobenzene at 140 °C for 11–25 h under a flow of N_2. This protocol results in a series of high molecular weight copolymers **3**. Longer polymerization times give rise to higher degrees of polymerization, as examined in the PPE system in detail.[8]

The UV–VIS spectra of **3a**–**d** in dilute solution show a λ_{max} of 388–395 nm, very similar to that of dialkyl-PPEs (388 nm). To our surprise, thin film absorption spectra of **3a**–**d** are identical to those in solution, which is in stark contrast to the PPE case where a dramatic red-shift is observed. The unusual optical behavior prompted us to investigate fluorescence of **3a**–**d**. In solution an intense blue emission is observed (**3a**, 425 nm; **3d**, 419 nm), again similar to dialkyl-PPEs (425 nm). In the solid state, however, the situation is different, and in thin films

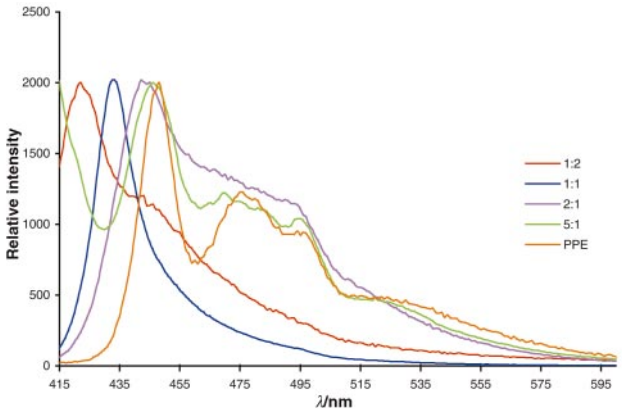

Fig. 2 Solid-state emission spectra of thin films of **3a**–**d** and PPE.

of **3a**–**d** we find emission maxima ranging from 446 (5 : 1, **3a**) to 422 nm (1 : 2, **3d**), (Fig. 2), thus allowing the manipulation of solid-state emission maximum from yellow–green to blue *via* the amount of added monomer **2**. The less PPE character the copolymer **3** has, the further its emission is blue-shifted towards that observed in dilute solution. We conclude that in the copolymers **3** aggregation and supramolecular ordering are efficiently suppressed by the presence of the bulky *tert*-butylnaphthyl groups.[9] This scenario must lead to a disordered solid state in **3**. To test this hypothesis we performed powder diffraction on polymers **3** (Fig. 3). The polymers **3a**–**c** display a broad diffraction peak of large intensity according to d = 4.2 Å. This diffraction peak can be attributed to the interchain distance of the polymers. A second, weak diffraction peak is observed at d = 8.8–11.7 Å, but is very weak in **3a**–**c**. In the naphthalene-rich polymer **3d** the small-angle diffraction at 11.7 Å is most prevalent. Molecular modeling indicates that this represents the distance between the two 3,7-*tert*-butyl groups on individual naphthalene units.[10]

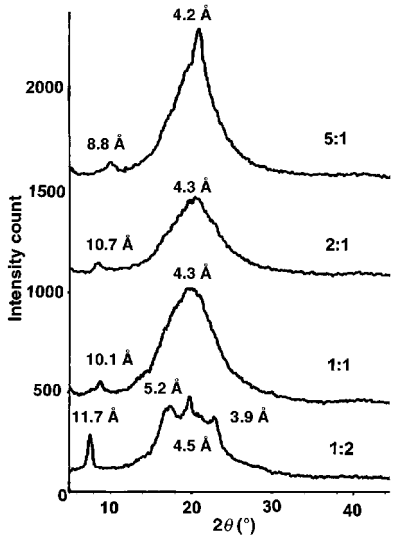

Fig. 3 Diffraction data of polymers **3a**–**d**.

For device purposes, liquid crystalline behavior offers the entry to polarized emission. DSC and polarizing microscopy performed upon **3a**–**c** shows that **3a**,**b** are thermotropic nematic (**3a**: isotropic → nematic 160 °C DSC; nematic → isotropic 170 °C → nematic 149 °C, evidenced by polarizing microscopy, cooling. **3b**: 194 °C polarizing microscopy, cooling isotropic → nematic), both displaying Schlieren textures. Copolymer **3c** displays a broad halo at 4.3 Å, and a weak small angle feature, suggesting either small domain sizes or a disordered structure. No identifiable textures develop upon thermal treatment. Only in the case of **3a** is the isotropic → nematic transition observed in the DSC and it is exothermic, with 0.27 kcal mol^{-1} per repeating unit, a small but not unexpected value.[11] Polymer **3d** is crystalline and does not show any phase transition up to 300 °C.

In conclusion we have presented the synthesis and characterization of a new series of liquid-crystalline PPE copolymers **3** which exhibit blue solid state fluorescence. The blue shift increases with the amount of naphthalene. Particularly attractive is the intensity of luminescence of **3** in the solid state. The increased solid-state fluorescence is attributed to the absence of aggregates and excimers, which normally reduce PPE's quantum efficiencies of emission in the solid state. Application of **3** in LEDs and sensory materials[12] is currently being explored.

We acknowledge Professor C. J. Murphy and L. Gearhart for help with the fluorescence spectra. This work was generously supported by the NSF (CHE 9814118, PI Bunz) and the Research Corporation.

Ring-closing alkyne metathesis with simple catalyst systems: an access to molecular triangles and rhomboids

Neil G. Pschirer, Wei Fu, Richard D. Adams* and Uwe H. F. Bunz*

Department of Chemistry and Biochemistry, The University of South Carolina, Columbia, South Carolina 29208 USA. E-mail: bunz@psc.sc.edu

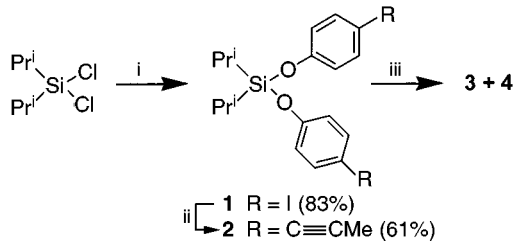
Received (in Columbia, MO, USA) 26th October 1999, Accepted 30th November 1999

Treatment of the siloxane monomer 2 with a mixture of molybdenum hexacarbonyl and 4-chlorophenol at 140 °C furnished the corresponding cyclotrimer 3 and the cyclotetramer 4.

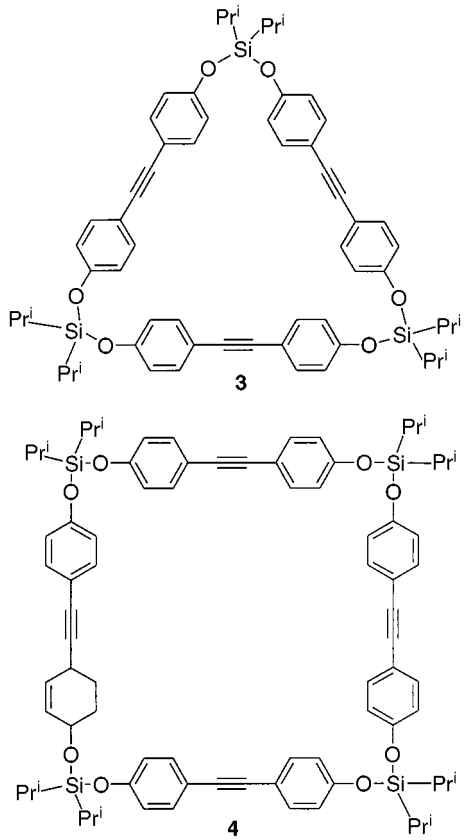
Ring-closing alkene metathesis utilizing well-defined organometallic catalysts[1–4] has developed into a powerful synthetic tool. A variety of rings have been prepared by this method. Cyclic polyynes are also of great interest,[5] but their synthesis *via* ring-closing alkyne metathesis is much less explored.[6] Fürstner[7] has reported the preparation of large-ring alkynes by ring-closure of suitable dipropynylated precursors utilizing Schrock's tungsten carbyne.[8]

We have recently developed an efficient and simple protocol for alkyne metathesis[9,10] and we now report the first examples of ring-closing metathesis using our 'instant' catalyst. This powerful catalyst is formed *in situ* from $Mo(CO)_6$ and 4-chlorophenol using off-the-shelf quality solvents.

The synthesis of shape-persistent macrocycles, potentially useful as molecular boxes, presents a new and interesting challenge.[11,12] We have chosen diyne **2** to be a convenient precursor to the novel molecular siloxane triangles/boxes **3** and **4**. Compound **2** was prepared in two steps from **1**, which was, itself, obtained from 4-iodophenol by treatment with $Pr^i_2SiCl_2$ in Et_3N (Scheme 1). A palladium-catalyzed coupling of **1** with propyne affords the monomer **2** in 61% yield.[13] Alkyne metathesis of **2** with $Mo(CO)_6$ and 4-chlorophenol at 140 °C in 1,2-dichlorobenzene under a steady stream of N_2 (Scheme 1) furnished the novel cycles **3** and **4**.† Sufficient dilution is an important factor for obtaining cyclic rather than polymeric products, although minor changes in concentration did not result in decreased yields of the macrocycles. Separation was difficult due to the similar retention times of **3** and **4**, and their corresponding open congeners. However, we were able to isolate **3** (14% yield) and **4** (18% yield). GC-MS confirmed that the isolated fractions of **3** and **4** were uncontaminated by other cycloisomers. The molecular structures of **3** and **4** were established by single crystal X-ray diffraction analyses.‡



Scheme 1 *Reagents and conditions*: i, 4-IC_6H_4OH, Et_3N, THF; ii, propyne, $Pd(PPh_3)_2Cl_2$, CuI, piperidine; iii, $Mo(CO)_6$, 4-ClC_6H_4OH.



The crystal of **3** contains three symmetry-independent molecules. All three display similar conformations and the molecular structure of one of these is shown in Fig. 1. The cyclotetramer **4** is crystallographically centrosymmetric. It exhibits a rhomboidal structure with a large interior cavity that contains two molecules of hexane as solvate, from which it was crystallized (Fig. 2). This feature indicates the potential of these box-shaped molecules to engage in important host–guest chemistry.

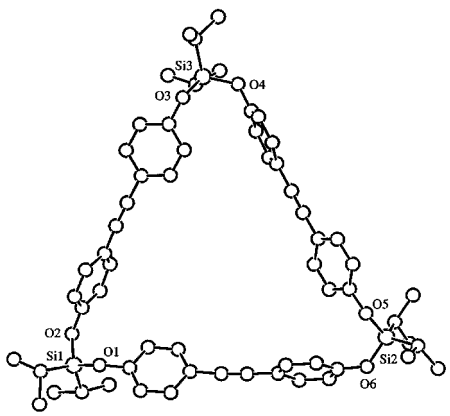


Fig. 1 A structural diagram of the cyclic triyne **3**. Selected bond distances (Å) and angles (°) are C≡C = 1.22(2), 1.20(2) and 1.16(2), Si(1)–O(1) = 1.616(9), Si(1)–O(2) = 1.624(9), Si(2)–O(5) = 1.67(1), Si(2)–O(6) = 1.63(1), Si(3)–O(3) = 1.63(1), Si(3)–O(4) = 1.66(1); O(1)–Si(1)–O(2) = 109.8(5), O(5)–Si(2)–O(6) = 106.9(5), O(3)–Si(3)–O(4) = 108.1(6).

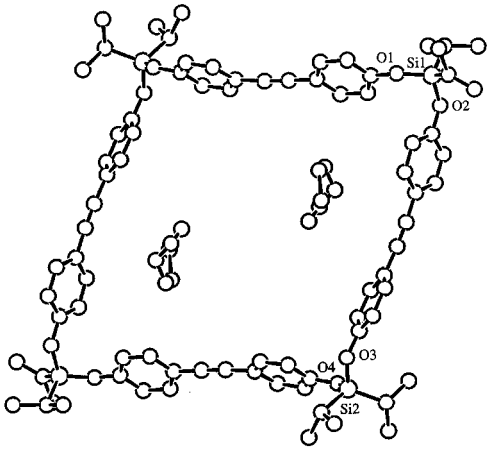

Fig. 2 A structural diagram of the cyclic tetrayne **4** showing two molecules of occluded hexane in the interior of the ring. Selected bond distances (Å) and angles (°) are C≡C = 1.179(9) and 1.213(9), Si(1)–O(1) = 1.635(4), Si(1)–O(2) = 1.646(4), Si(2)–O(3) = 1.654(4), Si(2)–O(4) = 1.652(4); O(1)–Si(1)–O(2) = 110.6(2), O(3)–Si(2)–O(4) = 109.9(2).

We have now demonstrated that ring-closing alkyne metathesis with our 'instant' catalyst system provides a convenient route to novel alkyne-containing macrocycles. Functionalized rings should also be accessible *via* this methodology as we have already shown that the mixtures of $Mo(CO)_6$ and 4-chlorophenol are metathesis-active in the presence of a variety of different functional groups.[8,9]

Formation of a benzenetrienoid resonance structure in a cyclophane containing a trinitrotriaminobenzene unit

J. Jens Wolff,* Uwe Seibold and Thomas Oeser

Organisch-Chemisches Institut der Ruprecht-Karls-Universität Heidelberg, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany. E-mail: wolff@donar.oci.uni-heidelberg.de

Received (in Liverpool, UK) 8th October 1999, Accepted 26th November 1999

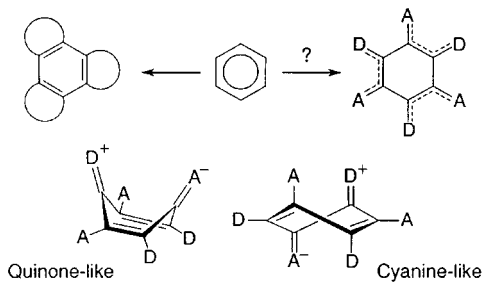
The [6_3](1,5,9)triphenyleno(1,3,5)cyclophane 1 shows a trienoid Kekulé-type structure for the planar donor–acceptor substituted benzene part.

The deviation of small aromatic molecules like benzene and naphthalene from the usual equal bond lengths to bond length alternations has been the object of synthetic and theoretical investigations.[1,2] The known X-ray structures with considerable bond length alternations reminiscent of the extremum of a Kekulé structure require a threefold incorporation into strained rings which shorten the incorporated bonds. This leads to almost single-bond character for the bonds not incorporated. At first glance, steric strain may not be the only way to ease the formation of such structures with a Kekulé bond length alternation: the complete symmetrical substitution with three electron donating and three accepting groups might also lead to it. In an extreme situation, the interaction between donors and acceptors could equally result in Kekulé-type structures with three groups of separated double bonds that bear one donor and one acceptor, each interacting only with each other. Thus, this type of bond length alternation might also occur within such a ring without great strain.

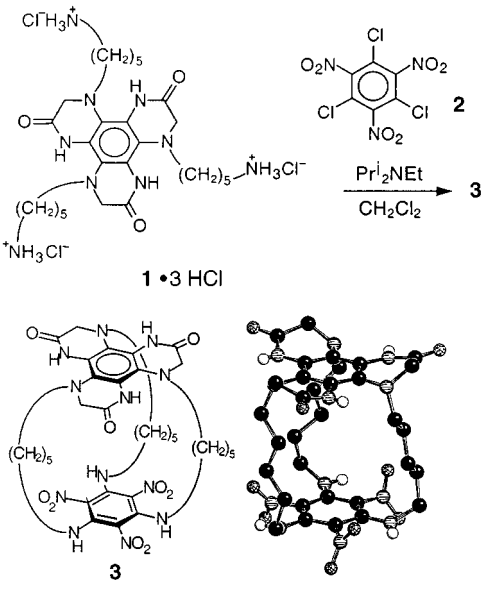
A closer look, however, shows disappointing results. For example, while all 1,3,5-trinitro-2,4,6-triamino-substituted benzene derivatives known[3–5] do show bond length alternations, they are far from the threefold symmetry required for a Kekulé structure: the six-membered ring has a clear maximum of C_{2v} or C_2 symmetry. Almost all of the central rings of the molecules analyzed by X-ray adopt either a strongly nonplanar boat or a twist form. The same holds true for substitution with other donors like the hydroxy group or its anion. For these highly nonplanar molecules, the shown quinoid and bis-trimethine cyanoid resonance forms are the only geometric structures observed (Scheme 1). Planar ones correspond to usual benzene derivatives with some substituent-dependent bond length alternation.

We were therefore surprised when an X-ray structure† (Scheme 2) was obtained of an intermediate **3** in the construction of bis-hexaaminobenzene derivatives[6] used by us for the study of intramolecular electron transfer.[7] Both aromatic rings are close to planar.[8] While this would not be very surprising for most benzene derivatives, it has never been observed before for trinitrotriaminobenzenes, which are only close to planar in the hydrogen-bonded solid state structure of trinitrotriaminobenzene itself; even with only two amino groups and one alkylamino group, some folding of the ring is observed.[4] In addition, the donor–acceptor substituted ring shows C_3 symmetry and the bond lengths within the ring are 1.399(4) and 1.416(4) Å. Thus, the clear formation of a benzene ring with a Kekulé structure can be observed which lacks significant steric strain but has symmetrical donor–acceptor substitution. The higher C–C bond length occurs between the nitro and the amino groups that are linked by a weak intramolecular hydrogen bond (2.29 Å). Some interaction is also visible to the other direction, between the other oxygen of the nitro group and a proton of the methylene group next to the nitrogen (2.27 Å).[9] The oxygen of the nitro group which is engaged in intramolecular hydrogen bonding with the amino group also shows intermolecular contact to the NH of the hexaazatriphenylene (2.34 Å). Both possible enantiomeric forms are present in the crystal, related to each other by inversion symmetry.

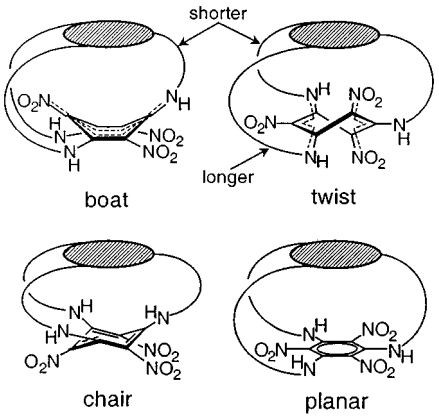
A closer inspection provides a reason for the unexpected planarity. Since the bridges between the two rings need to keep approximately the same distance between them, they have to adopt comparable conformations. The hexaaminobenzene derivative part of **3** is expected to exist with a stable planar conformation for its central benzene ring.[7,10,11] Then, the second, donor–acceptor substituted ring can adopt neither boat nor twist forms, because the distance of the chains to the first ring would become quite different (Scheme 3). These conformations are thus unlikely to be observed. While equality of the distances would be possible in a chair conformation, it is not truly compatible with the electronic requirements of the push–pull interaction between the substituents and is thus rarely found even for non-polar benzene derivatives with strong steric interactions.[12] The only possible conformation for the usually



Scheme 1



Scheme 2



Scheme 3

highly distorted six-membered ring is therefore a planar one. While in this conformation the donor–acceptor interactions are quite reduced in comparison with known structures, they are nevertheless still present. Therefore a moderate, but definitely existent Kekulé distortion can be detected.

Support by the German Research Council ('DFG', Wo495/3-1 and Heisenberg fellowship for J. J. W.) is acknowledged. We would like to thank Mrs U. Wiesinger for assistance in the structural determination and also one of the reviewers for valuable comments.

6 *Synthesis* of **3**: The synthesis of starting material will be described elsewhere. To a suspension of **1**·3 HCl (235 mg, 0.360 mmol) in dry CH_2Cl_2, a mixture of Hünig's base (282 mg, 2.18 mmol) and 1,3,5-trichloro-2,4,6-trinitrobenzene **2** (ref. 13) (114 mg, 0.360 mmol) in CH_2Cl_2 (100 ml) was added within 3 h. The mixture was stirred overnight and then, after addition of four drops of AcOH, filtered over silica gel (CH_2Cl_2–MeOH = 25/1). The solvents were removed and the chromatography was repeated. The cyclophane **3** was obtained as a yellow powder (18 mg, 0.024 mmol, 7%), decomp. > 230 °C. Crystals for X-ray analysis were obtained from diffusion of pentane into a solution in CH_2Cl_2. δ_H(300 MHz, DMSO-d_6) 1.08 (m, 6H), 1.26 (m, 6 H), 1.42 (m, 6H), 2.76 (m, 6H), 3.12 (m, 3H), 3.19 (m, 3H), 3.41 (d, J 17.1, 3H), 3.50 (d, J 16.9, 3H), 9.09 and 9.12 (br s, together 6H); δ_C(75.5 MHz, DMSO-d_6) 23.30, 24.82, 27.38, 45.67, 53.53, 56.21, 114.82, 115.07, 126.57, 147.40, 168.97 [FAB-MS: calc. for $C_{33}H_{42}N_{12}O_9$: 750.32, found 750.48 (15, M^+); $C_{33}H_{42}N_{12}O_9 + Na^+$: 773.31, found: 773.48 (3, $M + Na^+$)].

8 The sum of absolute torsional angles within the donor-substituted six-membered ring is 19°, and 15° in the donor–acceptor substituted one.

9 C–H···O interaction (see, *e.g.*: G. R. Desiraju, *Acc. Chem. Res.*, 1996, **29**, 441) could influence which type of bond is lengthened, and which one shortened. While the distance between NO and the second methylene group is fairly large (2.55 Å for C–H···O, 3.45 for C···O), it is smaller for the contact between the non-hydrogen-bonded oxygen and the first methylene group (2.27 and 2.99 Å). Since the nitrogen of the amino group will draw electron density from this carbon atom, it will also give a slightly more electron-deficient hydrogen more engaged in the dipolar interaction. AM1 or PM3 calculations indeed give a bond length alternation (0.026 *vs.* 0.017 Å) for a tris(diethylamino)trinitrobenzene with torsional angles derived from the structure of **3**, which decreases for the corresponding trimethyl derivative (0.014 Å), and vanishes for the corresponding triamino derivative.

Delamination of layered double hydroxides by use of surfactants

Mariko Adachi-Pagano, Claude Forano* and Jean-Pierre Besse

Laboratoire des Matériaux Inorganiques, CNRS ESA 6002, Université Blaise Pascal, 63177 Aubière Cedex, France. E-mail: forano@chimtp.univ-bpclermont.fr

Received (in Oxford, UK) 29th November 1999, Accepted 29th November 1999

Delamination of the layered double hydroxide structure $[Zn_2Al(OH)_6][C_{12}H_{25}SO_4{\cdot}nH_2O]$ was realized by dispersion in butanol; translucent colloidal solutions are stable for at least 8 months with oriented LDH materials with extended crystallite size being obtained; the results presented here suggest that total delamination occurs in the colloidal solution.

Delamination of low dimensional solids is of tremendous practical importance in applications ranging from polymer reenforcement,[1] self assembling monolayers (SAM) and Langmuir–Blodgett film preparation[2] or emulsion stabilizations.[3] Dispersions of clay minerals have been studied more extensively owing to their extended swelling properties and a great ability to undergo surface modification with organophilic cations.[4] Exfoliation of other layered structures such as MoS_2, layered phosphates and metal oxides have also been achieved by manipulation of the interlayer interactions.[5]

Layered double hydroxides (LDHs) are layered materials constituted by a stacking of positive hydroxylated layers $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2]^{x+}$ separated by interlayered anionic species and water molecules $[X^{q-}_{x/q}{\cdot}nH_2O]$. They are known for their unique anion exchange properties and their rich chemistry which make them good catalysts or catalyst precursors.[6] However, the high charge density of the LDHs layers and the high content of anionic species and water molecules result in strong interlayer electrostatic interactions between the sheets and significantly hydrophilic properties. Such dense interlamellar hydrogen bonding networks lead to a tight stacking of the lamellae. The rigid spheroidal 'sand rose' morphology of intergrown platelets prevents both accessibility to the major part of the surface or exfoliation of the sheets in water or in any other non-aqueous solvents. However, exchange of inorganic anions by organophilic anions, such as fatty acid salts or anionic surfactants proceeds readily.[10] This leads to a substantial modification of the surface properties, from hydrophobic to hydrophilic. Moreover, the van der Waals interlayer interactions introduced by the introduction of such species weakens the stacking of the layers and favours interactions with non-aqueous solvents.

The purpose of this study was to develop a method of delamination of LDHs which will lead to a novel generation of LDH based materials in which the total surface of the layered compound will be rendered accessible for chemical reactivity or for the preparation of new porous or oriented materials. The delaminated structure of the $Zn_2Al(OH)_6Cl{\cdot}2H_2O$ LDH phase ([Zn–Al]) would reach a theoretical specific surface aera of 800 $m^2\ g^{-1}$, while the experimental BET measured surface areas reach only 10–50 $m^2\ g^{-1}$.

We have already reported the influence of organic solvents (ethanol, methanol, acetone, ethylene glycol, glycerol) on the modification of the surface and porosity properties of LDHs.[7] However, complete delamination of LDHs has, as yet not been reported. Now successful LDH delamination has been achieved using various anionic surfactants and we report, for the first time, stable colloidal solutions of LDHs. In this study, we demonstrate total delamination of the [Zn–Al] LDH using dodecyl sulfate (DS) as an anionic surfactant and butanol as the dispersant.

The $Zn_2Al(OH)_6Cl{\cdot}2H_2O$ LDH precursor ([Zn_2Al–Cl]) was prepared by the coprecipitation method previously described by Bonnet *et al*.[9] The preparation of the surfactant modified LDH ([Zn_2Al–DS]) was realized by the anion exchange reaction in deionised water of 1.00 g of [Zn_2Al–Cl] with a 1.54 molar excess (1.34 g) of sodium dodecyl sulfate (Across). Intercalation of the surfactant was monitored by X-ray diffraction (Siemens D501 X-ray powder diffractometer, Cu-Kα radiation) and FTIR spectroscopy (Perkin-Elmer-FTIR16PC). The chemical formulae of the various compounds were calculated from elemental analysis. In all cases, the Zn/Al ratio was 2.2 and for the DS exchanged LDH, S/Al was equal to 0.98 in accord with total exchange of the Cl anions.

Intercalation of dodecyl sulfate in $Zn_2Al(OH)_6Cl{\cdot}2H_2O$ leads to the expanded phase $Zn_2Al(OH)_6(C_{12}H_{25}SO_4){\cdot}nH_2O$ ([Zn_2Al-DS]) with an increase of the basal spacing from 0.77 to 2.52 nm (Fig. 1) as reported in the literature.[12] The particle widths for both precursor and modified LDHs were measured by SEM (Cambridge Stereoscan 360, 20 kV, at Techinauv S.A). The measured thickness of [Zn_2Al–Cl] platelets was 0.05 μm, corresponding to a stacking of *ca.* 60 layers, while expansion of the basal spacing for [Zn_2Al-DS] leads to lamellae thickness of 0.15 μm. The number of stacked layers is retained after anion exchange confirming that the anion exchange proceeds by a topotactic mechanism.

Dispersion of [Zn_2Al–DS] in water, methanol, ethanol, propanol or hexane under reflux conditions leads to unstable suspensions which settle after a few hours and only a minor part of the material was dispersed. Dispersion in methanol appears to be kinetically controlled by the slow replacement of water molecules by methanol. After one week stirring, *ca.* 50% of the LDH can be exfoliated. By contrast, reflux in butanol at 120 °C for 16 h leads to a translucent colloidal solution, which remains stable for at least 8 months. Up to 1.5 g of [Zn_2Al–DS] per liter of butanol can be dispersed. Similar results have been obtained with higher alcohols such as pentanol and hexanol.

The size of the LDH colloids was measured by dynamic light scattering (Zetasizer–Malvern instrument). The mean equiva-

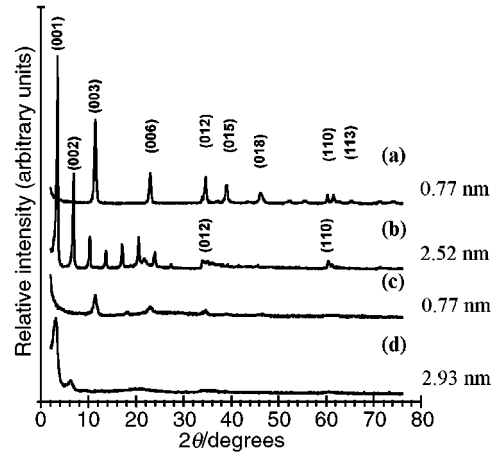

Fig. 1 Diffraction patterns of (a) [Zn_2Al–Cl], (b) [Zn_2Al–DS], (c) [Zn_2Al–Cl]$_{recov}$, (d) [Zn_2Al–DS]$_{recov}$.

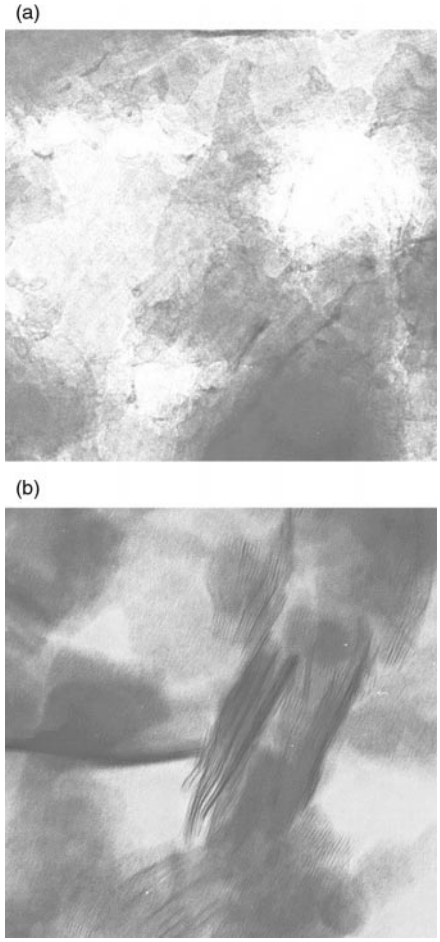

Fig. 2 TEM micrographs of [Zn_2Al–DS] dispersed in (a) butanol and (b) ethanol.

lent spherical diameter (d_s) is *ca.* 140 nm, smaller than the width of the hexagonal sheets measured by SEM (200 nm). Transmission electron micrographs of [ZnAl–DS] particles recovered from the colloidal solution [Fig. 2(a)] show assemblies of dispersed platelets all oriented parallel to the grid surface and confirm that delamination has occurred at the layer level while aggregates of stacked sheets are observed for the same materials dispersed in ethanol [Fig. 2(b)]. This argues in favour of a total delamination in butanol.

We note that the hydration state of the modified LDH is a critical parameter. Delamination was only observed when the organo-LDH compounds were previously dried under vacuum at room temperature for 1 day but not when a freshly wet prepared LDH was used or if the [Zn_2Al–DS] was thoroughly dried under vacuum at 80 °C for 4 h. Such intense drying leads to a new DS containing LDH phase with a smaller basal spacing of 1.68 nm corresponding to a tilted intertwined DS single layer. This LDH displays a densely packed structure which is resistent to exfoliation. It appears that the use of butanol with a boiling point higher than that of water and reflux conditions allows for a rapid replacement of all the intercalated water molecules by the solvent molecules. This seems to be the key process to completely exfoliate of the solid material.

When butanol is removed from the colloidal solution by evaporation (120 °C) or by lyophilization, a new LDH phase ([Zn_2Al–DS]$_{recov}$) is obtained with larger size and well oriented platelets as shown by an SEM micrograph [Fig. 3(a)]. This extended bidimensional orientated material displays a basal spacing of 2.93 nm in accord with incorporation of butanol in the interlamellar spaces. The typical 'sand rose' morphology of the LDH precursor is then lost and a thin film of LDH is obtained.

Comparison between FTIR spectra of the oriented LDH and [Zn_2Al–DS], particularly in the 400–1800 cm^{-1} wavenumber

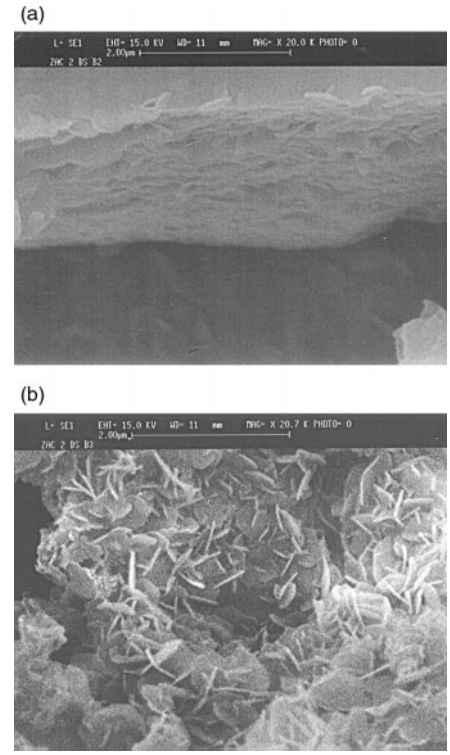

Fig. 3 SEM micrographs of (a) [Zn_2Al–DS]$_{recov}$ and (b) [Zn_2Al–CO_3]$_{recov}$.

range in with unchanged lattice vibrations are superimposed on surfactant vibrations, confirms that the LDH structure is retained after delamination. When NaCl or Na_2CO_3 are added to the colloidal solution, flocculation of particles occurs and reversible back anion exchanges to give [Zn_2Al–Cl]$_{recov}$ and [Zn_2Al–CO_3]$_{recov}$ results (Figs. 1, 3(b)). The recovering of LDH structures under solvent extraction or precipitation confirms the presence of delaminated LDH in the colloidal solution.

The preparation of colloidal solutions of LDHs appears to be of substantial importance for the development of novel chemistry of the LDHs. It is now possible to develop the chemistry of LDHs in non-aqueous media, *e.g.* for electrochemistry applications. Ultrathin films based on LDHs can now easily be prepared by a soft chemistry route. Preparations of novel based-LDH materials with improved chemical or porosity properties are now envisaged through interstratified LDH/LDH, LDH/clay, LDH/polymer or nanoporous LDH/SiO_2 materials.

Luminescent molecular logic gates: the two-input inhibit (INH) function

Thorfinnur Gunnlaugsson,*[a] Dónall A. Mac Dónail[a] and David Parker[b]

[a] *Department of Chemistry, University of Dublin, Trinity College Dublin, Dublin 2, Ireland. E-mail: gunnlaut@tcd.ie*

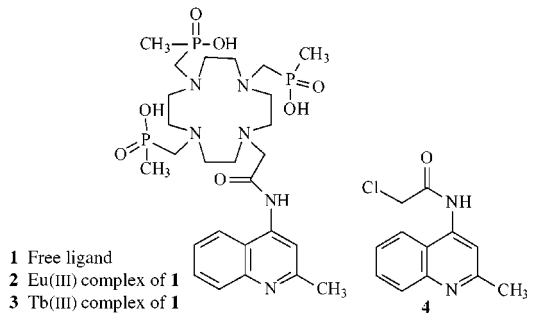
Received (in Cambridge, UK) 10th November 1999, Accepted 3rd December 1999

The Tb(III) complex 3, is the first example of a molecular logic gate corresponding to a two-input INHIBIT function, A ∧ B′ where the 'output', a sharp, line-like, terbium emission, is only observed with two chemical inputs (i) the presence of protons and (ii) the absence of molecular oxygen.

Developments in supramolecular chemistry and nanotechnology have stimulated interest in the construction of simple electronic or photonic driven systems and networks that function as molecular-level devices.[1] Examples include simple host–guest complexes as well as more advanced switches,[2] wires,[3] grids,[4] shuttles[5] and molecular machines.[6] Mimicking the functions of semiconductor logic gates used in modern computing is of particular interest,[7] where the relationship between input and the output may be described by truth tables, where 1 represents an active input/output and 0 an inactive one.[8] For a two input system there are 16 different logic gate functions.[8b]† Some of these functions have recently been demonstrated where ions and molecules are used as inputs,[7] including the ID (or YES), AND, OR and NOT logic functions designed by de Silva *et. al.*[9] and the XOR function designed by Balzani *et al.*[10] Among the remaining logic gates is the inhibit (INH) function which can be interpreted as a particular integration of an AND and a NOT logic functions, where the output signal is inhibited by one of the active inputs.‡ Recently the more complex three-input integrated INH logic gate was demonstrated.[11] However, the fundamental two-input INH gate has not been reported.



Here, we demonstrate that in water the Tb(III) based quinolyl derived macrocyclic 1,4,7,10-tetraazacyclododecane (cyclen) conjugate, **3**, yields such an INH logic gate. The two inputs are H^+ (the nitrogen moiety of the quinoline acting as a proton acceptor) and O_2 (or rather the absence of O_2, since this input is not asserted when O_2 is present). The output signal is a delayed line like Tb luminescence (owing to the deactivation of the Tb $^5D_4$ excited state to the ^7F_J, J = 6, 5, 4 and 3), occurring at long wavelengths. These are important features since sharp, long wavelength emissions give minimal signal interference, critical for high performance signalling systems. Tb was chosen because, unlike Eu(III), pyridine based Tb and related complexes are known to be spectroscopically sensitive to O_2,[12] opening the possibility of a gate with O_2 as a second input. Moreover, lanthanide based cyclen derivatives have been shown to be kinetically stable in water.[13]

The syntheses of the α-chloroamide **4**, the free ligand in **1** and the Eu complex **2**, have previously been described; **2** was designed as a delayed Eu luminescence pH sensor.[14] **3**, the Tb complex of **1**, was synthesised in a similar manner to **2**, and obtained in 55% yield after treating **1** with $Tb(CF_3SO_3)_3$ in refluxing acetonitrile, followed by a purification on alumina. Complexation was established by electrospray (ES^+) mass spectrometry and ^{31}P NMR.§

The absorption spectrum of **3** showed a similar pH dependence to **2** and **4**, with λ_{max} at 314 nm (log ε = 4.18) and a band at 261 nm under acid conditions with λ_{max} shifting to 295 nm (log ε = 4.0) in the presence of base (isosbestic points at 299 and 271 nm). The Eu luminescence (occurring from $^5D_0$, E = 17200 cm^{-1})[15] of **2** (1×10^{-5} mol dm^{-3}) in H_2O under ambient conditions ([O_2] *ca.* 0.23 mmol dm^{-3}) was highly pH dependent when excited at 330 nm, with a 250 fold luminescence enhancement (LE) observed upon addition of acid ([CF_3CO_2H] = 3 mmol dm^{-3}/pH = 2.5). This pH dependence signals the protonation of the remote quinoline nitrogen moiety (pK_a = 5.8) and the 'tuning' of the so-called antenna effect, the energy transfer mechanism from the singlet excited state (S_1) of the chromophore (*via* the triplet, T_1) to the lanthanide excited state.[12,13]¶

The Tb luminescence of **3** (appearing at 491.5, 547.5, 588.0 and 623.0 nm, J = 6, 5, 4 and 3 respectively) was somewhat different. The excited state emission from $^5D_4$ (E = 20500 cm^{-1}) was only weakly observed in alkaline solution under ambient conditions, with only a 1.7 fold enhancement upon acidification as seen in Fig. 1(a) ([CF_3CO_2H] = 1.26 mmol dm^{-3}/pH = 2.9) when excited at 330 nm. The corresponding fluorescence changes were more apparent; both a hypsochromic shift from 373 to 357 nm (isoemissive point at 387 nm) and intensity changes were observed upon acidification (two shoulders at 371 and 345 nm).

The measurements were repeated in degassed solution ('freeze–pump–thaw', [O_2] < 10^{-6} mol dm^{-3}). In alkaline solution the Tb emission spectrum and lifetime (τ_{Tb} = 0.39 ms) were unaffected (owing to the inefficient population of the lanthanide excited state¶). However, in acid solution degassing yielded a *ca.*50 fold increase in the Tb luminescence intensity at 547.5 nm [Fig. 1(b)], and an almost threefold increase in the lifetime (τ_{Tb} = 0.98 ms); these conditions 'switch on' the Tb emission [note the different scales in Fig. 1(a) and 1(b)]. The fluorescence spectra were however only marginally affected by the removal of O_2.

The small Tb emission in aerated acidic solution arises from the fact that the T_1 state of the quinoline (T_1 E = 21978 cm^{-1}, as measured for the protonated form of **4**) is partly quenched by an ambient level of O_2. The Tb $^5D_4$ state can also participate in a back-energy transfer mechanism to the T_1 state (the energy difference being 1478 cm^{-1}); these combined processes lead to efficient quenching of the $^5D_4$ state (*i.e.* the Tb emission is switched off). Upon removal of O_2 this quenching process is largely suppressed leading to more efficient population of the Tb $^5D_4$ state (the antenna effect is more efficient) and switching on of the Tb emission.[12]

From the perspective of logic functions, the Eu emission (**2**) is determined only by the presence of single ionic input (H^+), back energy transfer from $^5D_0$ is inefficient and the complex is

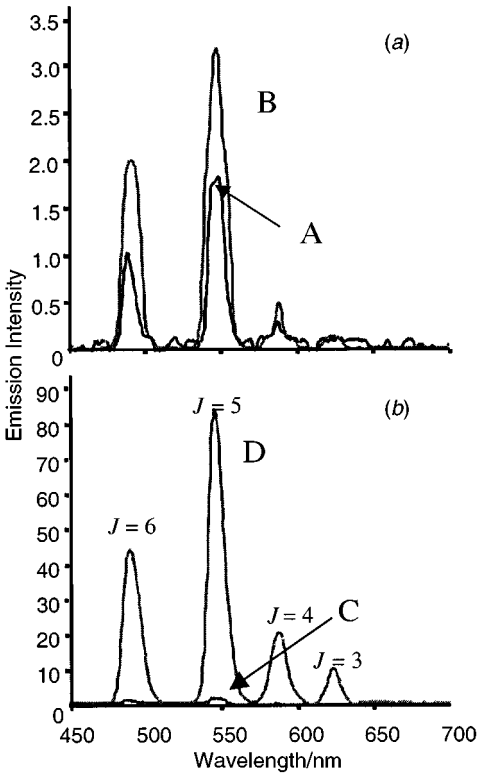


Fig. 1 Tb(III) emission of **3** (1×10^{-5} mol dm^{-3}) in water at 293 K, 10.0 mmol dm^{-3} NMe_4ClO_4 (to maintain constant ionic strength): (a) in *aerated* solution at: (A) pH = 11, (B) pH = 2.9; (*b*) in *degassed* solution at: (C) pH = 11, (D) pH = 2.9. Note the difference in the intensity scales.

thus insensitive to O_2,[7] and can as such be regarded as a pass logic function (YES[9] or ID[8b] logic gate). The emission of the Tb complex (**3**) is more interesting and is switched on *only* in the presence of H^+ and absence of O_2. Under other circumstances, the absence of H^+, the presence of O_2, or both, no significant Tb emission is observed (based on discrimination in LE factors; *ca.* 50 when O_2 *absent cf.* 1.7 with O_2 *present*, at 547.5 nm, Fig. 1). This behaviour may be conveniently described using logic notation,[7,9] written A ∧ B′, where A and B represent the H^+ and O_2 inputs respectively. The corresponding truth table is shown in Fig. 2(a), where an active output (X = 1, corresponding to emission) is obtained only when A = 1 and B = 0.[8] This logic gate is the inhibit (INH) function, Fig. 2(b).

(a)

A	B	X
0	0	0
0	1	0
1	0	1
1	1	0

(b)

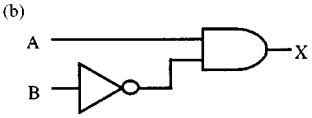

Fig. 2 (a) A truth table for the INH logic gate; inputs A and B correspond to the H^+ and O_2 respectively; X [Tb(III) emission], is the output signal. (b) The INH gate represented using a conventional gate notation; an active output signal (Tb emission) is obtained when A = 1 and B = 0.

Even though more advanced practical integration of such molecular level logic gates into circuits is somewhat beyond the horizon, progress depends of the generation of all fundamental logic operations. Our goal was to generate a two-input INH logic gate, and the Tb emission based gate reported herein is the first example of such a two-input molecular gate. Importantly, unlike many previous molecular logic gates where the output is a broad emission,[7,9,11] the output signal for **3**, is a set of line-like Tb emission bands occurring at long wavelengths (Stokes shifts of 160–300 nm for *J* = 6–3, respectively) with narrow bandwidth (*ca.* 10 nm) giving rise to a high signal quality. Complex **3**, is thus an important contribution to the development of molecular logic devices, not least since the current silicon based computer chips are expected to reach their physical limits in the near future.[16]

We are grateful to the BBSRC and Kinerton Ltd. for financial support, Professor John M. Kelly, Dr J. C. Penedo Esteiro and Dr Hazel M. Moncrieff for valuable discussions.

Notes and references

† The ONE and ZERO functions are trivial, the output being a 1 or 0 respectively, regardless of the input. Four functions depend on a single input, namely both ID and both INV (or NOT) functions. The remaining ten are functions of two inputs, and of these AND, OR, XOR, NAND, NOR and EQU (or XNOR) satisfy commutation. The last four functions corresponding to INH and IMP gates do not satisfy commutation.

‡ The INH function, A ∧ B′, should not be confused with the NAND function, (A ∧ B)′.

§ ES^+: *m/z* 802.94 (15, $M^+ + 1$), 826.30 (13, M + Na^+). ^{31}P NMR (101 MHz, CH_3CN): δ 441.71 (br s) and 427.76 (br s) *cf.* δ 42.95 and 33.54 for **1**.

¶ Population of the quinoline S_1 (λ_{ex} = 330 nm) and subsequent population of the lanthanide excited state (the antenna effect) is inefficient in alkaline solution since the chromophore is only weakly absorbing at this wavelength. On acidification the S_1 population is greatly enhanced since absorption is shifted to longer wavelengths.

Liquid phase methanol carbonylation catalysed over rhodium supported on hydrotalcite

M. P. Kapoor and Yasuyuki Matsumura*†

Osaka National Research Institute, 1-8-31 Midorigaoka, Ikeda, Osaka 563-8577, Japan

Received (in Cambridge, UK) 19th October 1999, Accepted 29th November 1999

A solid catalyst, Mg–Al hydrotalcite containing nanometer size rhodium particles, is active for liquid phase methanol carbonylation to methyl acetate at 473 K in the presence of methyl iodide.

Acetic acid and methyl acetate are industrially synthesised by carbonylation of methanol with a homogeneous rhodium catalyst promoted by methyl iodide.[1,2] Attempts have been made to use heterogeneous catalysts for methanol carbonylation,[3,4] because such a system would be advantageous in separation and recovery of the products and recycling of the catalyst, providing greater economic advantages and minimizing the environmental impact of the process. A number of supported rhodium systems such as zeolites,[5,6] polymers,[7] activated carbon[8] and inorganic oxides[9] are reported to be active under vapour phase conditions. In the liquid phase, polymer supported Rh(I) catalysts have been reported,[10] however, this system is unstable due to loss of rhodium.

Hydrotalcite, $[Mg_{1-x}Al_x(OH)_2(CO_3)_{x/2}{\cdot}yH_2O]$, consists of positively charged brucite-like layers with charge–balancing anions and water molecules.[11] The material shows strong basicity and is often employed as a precursor for catalysts or catalyst supports owing to its structure.[12] In the present work, we have demonstrated that nanometer size rhodium particles can be stabilized on hydrotalcite and the solid effectively catalyses the liquid phase carbonylation of methanol in the presence of methyl iodide. This may provide a realistic solution to problems such as separation, recovery, *etc.* associated with homogeneous catalytic systems.

An Mg–Al hydrotalcite (Mg/Al = 2/1) was synthesised using the procedure reported by Reichle.[13] Rhodium was loaded on the Mg–Al hydrotalcite by a deposition–precipitation method. In a typical procedure, Mg–Al hydrotalcite was placed in an aqueous solution of $Rh(NO_3)_3$ (Kanto Chemical) at 343 K and an aqueous solution of Na_2CO_3 (1 M) was added dropwise. The pH of the solution was kept at 10 for 1 h. The resulting solid was filtered off and washed thoroughly with distilled water, dried and then calcined in air at 673 K for 4 h. A rhodium catalyst was also prepared by the impregnation technique. After evaporation of a mixture of the solution of $Rh(NO_3)_3$ and hydrotalcite, the wet solid was dried and calcined in air at 673 K for 4 h. The Rh contents in the samples was analysed by ICP emission spectrometry.

Adsorption experiments were performed with a vacuum system equipped with Baratron vacuum gauges after the samples were reduced with hydrogen at 673 K for 2 h. The BET surface areas of the samples were determined from nitrogen physisorption isotherms.

Powder X-ray diffraction (XRD) patterns of the samples were recorded with a Rigaku Rotaflex 20 diffractometer using nickel-filtered Cu-Kα (40 kV, 150 mA) radiation.

Catalytic tests were performed in an autoclave (0.2 dm^3). Prior to the reaction, the catalyst (0.20 g) was activated under evacuation followed by reduction with hydrogen at 673 K for 2 h and sealed in a glass capsule. The capsule was placed in the reactor along with a mixture of methanol (780 mmol) and methyl iodide (35 mmol), and CO was introduced at 0.5 MPa (42 mmol) after displacing air inside the reactor with argon. The capsule was broken during pressurization and the reactor was heated to 473 K. The products were analysed with an Ohkura-802 gas chromatograph (TCD) with PEG 1500 (2 m) and Porapak T (2 m) columns.

The powder XRD pattern of the parent hydrotalcite confirmed that the sample was well crystallised, but broadening of the peaks was observed for the hydrotalcite containing rhodium (Fig. 1). A change in the BET surface area after modification with rhodium was also observed. The surface area decreased with an increase in the rhodium content for the hydrotalcite with an original surface area of 232 $m^2\ g^{-1}$ (Table 1). The surface area of the sample prepared by the impregnation method was very small in comparison with the samples prepared by deposition–precipitation.

Carbon monoxide was adsorbed on the samples containing rhodium reduced at 673 K. The amount of carbon monoxide adsorbed was saturated at *ca.* 1 kPa. On the basis of the amounts saturated, the surface areas of rhodium in the samples were tentatively calculated, assuming atomic adsorption of CO on a

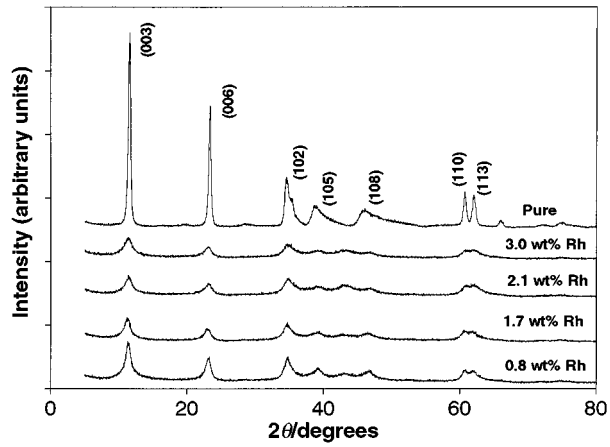

Fig. 1 XRD patterns of hydrotalcite modified with rhodium by deposition-precipitation.

Table 1 Some surface properties of Rh/Mg–Al hydrotalcite catalysts prepared by the deposition–precipitation method

1.5[b]	7.7	0.2	9	21

[a] Reaction time = 1 h. [b] Prepared by impregnation.

rhodium site and a site density of 0.058 nm^2 (Table 1). The mean particle sizes of rhodium were calculated from the data in Table 1 assuming that all the rhodium particles are spherical and on the surface, and gave values of 5, 6 and 11 nm, respectively, for deposition–precipitation samples containing 1.7, 2.1 and 3.0 wt% of rhodium. The Rh particle size for the sample prepared by the impregnation method (1.5 wt% of Rh) was calculated as 12 nm. Particles of > 10 nm are expected to be large enough to enable detection by XRD. However, no peaks attributed to rhodium metal were evident in the patterns of any of the samples after reduction, with the XRD patterns being similar to those of Fig. 1. Since the stoichiometry of the adsorption varies with the chemisorption mode of CO (for bridge-type adsorption a CO molecule occupies two rhodium sites), the rhodium surface areas in Table 1 may be underestimates and would result in larger particle sizes. Hence, the actual particle sizes of rhodium may well be smaller than the values estimated by adsorption of carbon monoxide. The reduction of the BET surface area after modification of rhodium suggests that some of the rhodium particles are incorporated in the bulk phase of the hydrotalcite and so will be another reason for the apparent contradiction of the adsorption and XRD results.

Mg–Al hydrotalcites containing rhodium were found to be active for methanol carbonylation at 473 K. The main products were methyl acetate (MeOAc) and dimethyl ether (DME) with a small amount of acetaldehyde (Table 2). Neither acetic acid, nor other decomposition products such as hydrogen were detected. Loss of methyl iodide was not observed and no trace of rhodium was detected in the liquid phase after the reaction. The XRD patterns of the catalyst recovered after the reaction were very similar to those prior to the reactions, showing that the catalysts retain the hydrotalcite structure during reaction. No reaction products were obtained with rhodium-free Mg–Al hydrotalcite. An increase in rhodium content to 2.1 wt% enhanced formation of MeOAc while a further increase of rhodium to 3.0 wt% resulted in a lower yield of MeOAc. The catalyst prepared by the impregnation method with a rhodium content of 1.5 wt% was the least active. The activity towards MeOAc mainly depends on the estimated surface area of rhodium (*cf.* Tables 1 and 2).

No methanol carbonylation occurred in the absence of methyl iodide for the catalyst containing 1.7 wt% of rhodium except for formation of a small amount of DME. Hence, methanol cannot be directly carbonylated over the catalyst, and the presence of methyl iodide is essential in the carbonylation. This suggests that carbonylation of methyl iodide to acetyl iodide is a key step of the carbonylation as also found for homogeneous carbonylation with rhodium complexes.[14] Formation of MeOAc was low after reaction for 1 h with the catalyst containing 1.7 wt% of Rh while DME formation was considerable (Table 2). This result indicates an induction period for the formation of MeOAc. Formation of homogeneous rhodium species during the induction period might be possible. However, no acetic acid, which is one of the major products in homogeneous carbonylation,[2] was detected in the reaction with the heterogeneous catalyst. In the mechanism for homogeneous carbonylation, methyl acetate is formed as a product of a subsequent esterification of acetic acid and methanol.[2] The product distribution with the heterogeneous catalys is similar to that found for the vapour phase carbonylation of methanol in the presence of methyl iodide over rhodium supported on activated carbon[8] while methyl acetate appears to be directly produced in the reactions. The similarity suggests that the carbonylation with rhodium containing hydrotalcite takes place on the surface of rhodium particles. Carbonylation of DME to MeOAc has been proposed in the vapour phase reaction, and can account the selective formation of MeOAc and the induction period.[15]

In summary, nanometer sized rhodium particles can be stabilised on hydrotalcite, and methyl acetate is directly formed in the liquid-phase methanol carbonylation with supported rhodium catalysts. A detailed kinetic study is in progress, which should provide stimulating results for practical modifications of the methanol carbonylation process.

Induction and reversal of chirality of heterohelicene by charge transfer interaction in aqueous SDS micelles

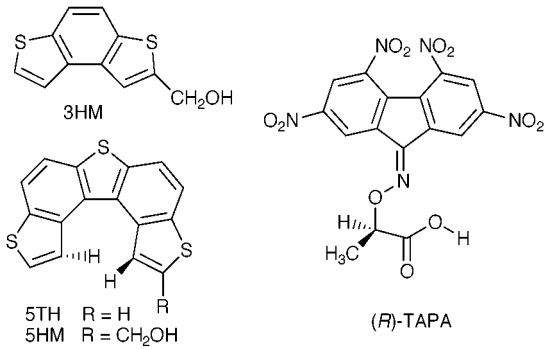
Received (in Cambridge, UK) 1st November 1999, Accepted 30th November 1999

2-Hydroxymethylthieno[3,2-*e*:4,5-*e*′]di[1]benzothiophene and 2-(2,4,5,7-tetranitrofluoren-9-ylideneaminooxy)propionic acid in SDS micelles initially formed a 1:2 complex with a negative Cotton effect around 360 nm, which with time or sonication gradually changed to a 1:1 complex giving a reversed Cotton effect.

Chiral recognition occurs in artificial chiral environments such as membranes[1] and micelles[2] despite their intrinsically high fluidity. This is of interest because it mimics chiral recognition in biological receptors. Differences in diastereomeric interactions between each enantiomer of an incorporated racemic guest and the chiral host molecules have effected such recognition and have been sustained, so far, mainly by hydrogen bonding. Since charge-transfer (CT) interaction is one of the fundamental forces in molecular recognition by biological macromolecules,[3] we investigated whether CT bonding exerts effective chiral discrimination between enantiomers in aqueous sodium dodecyl sulfate (SDS) micelles. We used 2-hydroxymethylthieno[3,2-*e*:4,5-*e*′]di[1]benzothiophene (5HM) as a



donor and 2-(2,4,5,7-tetranitrofluoren-9-ylideneaminooxy)propionic acid (TAPA) as a chiral acceptor. Although the helical shape of 5HM arises from steric repulsion between the terminal hydrogen atoms in the molecule,[4] inversion of the helix readily occurs in solution, causing a rapid racemization at room temperature.[5] However, the racemic 5HM is totally converted into the (*P*) enantiomer[6] on uptake by the serum albumin of several species,[7] and exhibits a slight (*M*) enantiomeric excess on incorporation into alkyl β-D-pyranoside micelles.[8] Furthermore, X-ray crystallographic analysis determined that racemic 5TH was entirely converted into the (*P*) enantiomer upon crystallization to give the deep-red 1:1 CT complex with (*S*)-TAPA.[9]

Both 5HM and TAPA are practically insoluble in water. A dioxane solution of (*R*)-TAPA (120 μl, 1.0×10^{-2} mol dm^{-3}) was added to an aqueous SDS solution (2 ml, 2×10^{-2} mol dm^{-3}), which resulted in a pale yellow transparent solution. Then, a dioxane solution of 5HM (27 μl, 1.0×10^{-2} mol dm^{-3}) was dissolved in this, and a pale red colour developed due to the CT interaction between the two components. The total volume of the solution was adjusted to 3 ml by adding SDS solution, which yielded concentrations of (*R*)-TAPA (4.0×10^{-4} mol dm^{-3}) and 5HM (9.0×10^{-5} mol dm^{-3}) in the SDS micellar solution (2×10^{-2} mol dm^{-3}) containing *ca.* 5% dioxane. CD measurements of this micellar solution at 20 °C gave intense absorptions in the range of 250–400 nm [Fig. 1(*b*), state (*b*)]. The wavelengths of these CD absorptions almost corresponded to those of the UV absorptions[8] of 5HM in $CHCl_3$ and in SDS micelles. A $CHCl_3$ solution of a mixture of (*R*)-TAPA and 5HM with the same concentrations as above, despite the development of a reddish colour, demonstrated small CD absorptions which were quite similar to those of (*R*)-TAPA alone in the micelles [Fig. 1(*a*)]. Moreover, a lower planar homologue of 5HM, 2-hydroxymethylbenzo[1,2-*b*:4,3-*b*′]dithiophene (3HM), showed no special CD absorptions in the presence of (*R*)-TAPA in the micelles, though the colour did change to yellow. These facts lead to the following reasoning: (1) the appearance of the CD absorptions [Fig.1(*b*)] is attributable to chiral 5HM being fixed to one enantiomer by the CT bonding of 5HM with chiral TAPA, and (2) the configuration of that enantiomer is determined as (*M*) by comparing the negative Cotton effect around 360 nm with the Cotton effects of 5HM incorporated in several albumins[7] or in chiral micelles,[8] and the CD spectrum of the 5TH-(*S*)–TAPA complex crystals in a KBr disk.[9]

On standing the micellar solution of 5HM and (*R*)–TAPA, the CD absorptions changed slowly with time. The intensity of Fig. 1(*b*) decreased to one fifth after 15 h at 20 °C. The decrease became faster with a rise in temperature. After *ca.* 10 h at 30 °C, the absorptions almost disappeared; instead, new absorptions began to appear in the opposite direction. Subsequently, the intensity increased very slowly over time, and finally the micellar solution became turbid after *ca.* 3 days, presumably because of the slow formation of the precipitate of the CT complex. This spontaneous alteration in the CD absorptions was accelerated by ultrasonic irradiation [Fig. 1(*b*)–(*f*)].[10] Only 1 min of sonication converted the sign of the Cotton effect around 360 nm to the opposite sign [Fig. 1(*c*)]. By subsequent sonication, the absorption intensities were gradually enhanced so as to reach the maximum in *ca.* 15 min [Fig. 1(*f*), state (*f*)]. These changes with time imply the reversal of handedness of 5HM in the micelles, that is, an (*M*) enantiomer to a (*P*). It is noteworthy that the shape of curve (*f*) is not strictly symmetrical

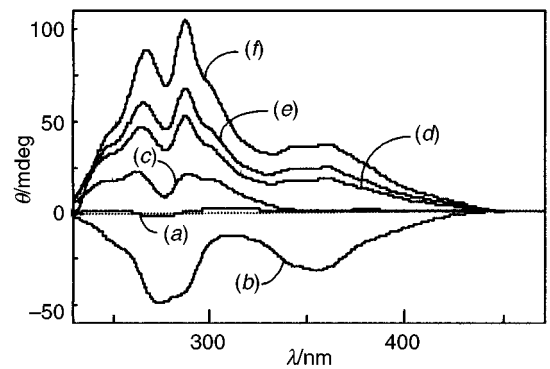


Fig. 1 Alterations in CD absorptions of 5HM–(*R*)-TAPA complex in SDS micelles: (*a*) (*R*)-TAPA alone, (*b*) immediately after the sample preparation, (*c*) sonication for 1, (*d*) 2, (*e*) 5 and (*f*) 15 min. [5HM] = 9.0×10^{-5} mol dm^{-3}, [(*R*)-TAPA] = 4.0×10^{-4} mol dm^{-3}, [SDS] = 2.0×10^{-2} mol dm^{-3}.

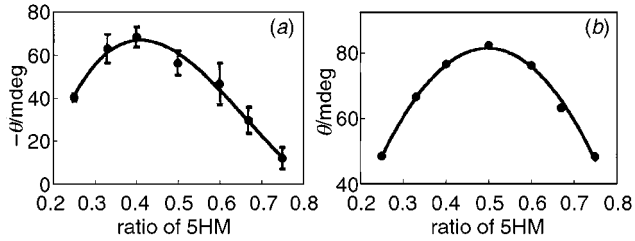

Fig. 2 Continuous variations experiments on the CD intensities at 359.2 nm: (*a*) for state (*b*) in Fig.1, (*b*) for state (*f*) in Fig.1, (the standard deviations are within the circles). [5HM] + [(*R*)-TAPA] = 5.0×10^{-4} mol dm^{-3}, [SDS] = 2.0×10^{-2} mol dm^{-3}.

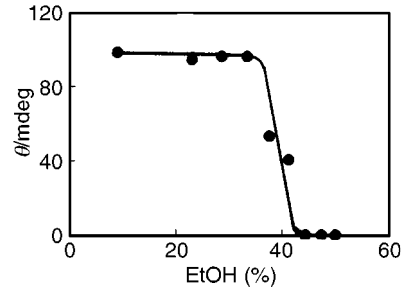

Fig. 3 Effect of an increase of EtOH content on the CD intensities at 287.0 nm for state (*f*) in Fig.1.

with that of the initial curve (*b*), though they are similar to each other.

In order to account for this phenomenon, binding stoichiometries between 5HM and TAPA were determined for both states (*b*) and (*f*) by the methods of continuous variations[11] and HPLC. Fig. 2 illustrates how the CD intensities at the trough [state (*b*)] or the peak [state (*f*)] around 360 nm vary with the mole ratio of 5HM to TAPA. For state (*b*), the plots reveal a maximum in the vicinity of the ratio = 0.35, indicating the presence of a 1:2 complex. On the other hand, a 1:1 complex can be estimated for state (*f*) because the maximum is observed in the vicinity of the ratio = 0.5. These stoichiometries were substantiated by HPLC experiments. On preparing a micellar solution containing (*R*)-TAPA (9×10^{-4} mol dm^{-3}) and 5HM (9×10^{-5} mol dm^{-3}), the precipitation occurred immediately. The precipitate collected was extracted with $CHCl_3$, the $CHCl_3$ solution being washed with water. The content of 5HM and TAPA in the $CHCl_3$ solution was determined by HPLC (silica gel column, $CHCl_3$–hexane–EtOH = 15:4:1), revealing a ratio of 5HM/TAPA = 0.47. Furthermore, the micellar solution containing (*R*)-TAPA (6×10^{-4} mol dm^{-3}) and 5HM (9×10^{-5} mol dm^{-3}) was sonicated for *ca.* 15 min, giving CD absorptions similar to Fig. 1(*f*). After the solution was left for 3 days, the resulting precipitate was collected and treated in the same way as above. The 5HM/TAPA ratio was estimated by HPLC to be 1.02. The results provided by the HPLC experiments were in excellent agreement with those of the continuous variations method.

TAPA is a carboxylic acid that has a tendency to dimer formation. Therefore, TAPA incorporated by way of a dimeric form in the micelles can be expected to encounter 5HM and produce the 1:2 CT complex. The 1:2 complex thus formed would be gradually converted into a more stable 1:1 complex as observed in the 1:1 complex crystals of (*S*)-TAPA and 5TH. Accompanying such change in the composition of the complex, configurational alteration is evoked in the 5HM molecules, causing the reversal of chirality of 5HM. These phenomena can be said to result from micellar effects. With an increase of ethanol content in the solution of state (*f*), the CD absorptions were rapidly decreased and completely missing (Fig. 3) owing to destruction of the micellar structure. When the same experiments concerning the alternative combination, 5HM and (*S*)-TAPA, were carried out, the same results were obtained except for the difference in the handedness of the 5HM molecules. In summary, the CT interactions have been proved to achieve effective recognition of chirality of heterohelicene in the SDS micelles. In particular, it is of interest that the initially fixed handedness of heterohelicene came to be spontaneously reversed with the composition change of the complex, although the structure of the 1:2 complex remains uncertain.

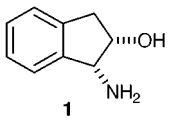
Received (in Liverpool, UK) 7th October 1999, Accepted 26th November 1999

The use of electrospray ionisation mass spectrometry for the detection of the intermediate species involved in the ruthenium(II)/amino alcohol reduction of ketones to alcohols is described.

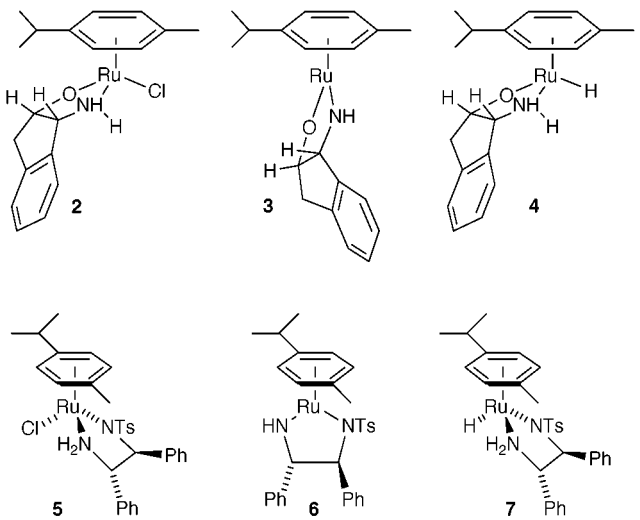
The use of transfer hydrogenation for the asymmetric reduction of ketones to enantiomerically enriched secondary alcohols has recently been the subject of intense international research work.[1] Of the many methods reported for this process, complexes of η6-arene/ruthenium(II) species with β-amino alcohols[2] or monotosylated 1,2-diamines[3] give some of the very best results in terms of activity and enantioselectivity. In the case of monotosylated diamines the resulting complexes may be employed in conjunction with either Pr^{i}OH–KOH or formic acid–Et_3N as hydrogen source.[3] In contrast we have found that the corresponding amino alcohol complexes appear to be compatible only with the Pr^{i}OH system. In order to gain an insight into the mechanism of the reduction using ruthenium(II)



1

complexes of aminoindanol **1**, on which we have recently published, we wished to identify the key intermediates likely to be involved in the process.

Our initial speculation, taking as a starting point the results obtained by Noyori on the analogous monotosylated diamine system, was that the 'pre-catalyst' formed by the combination of **1** with ruthenium(II) dimer $[RuCl(\eta6\text{-cymene})]_2$ was likely to be the 18-electron species **2**. Treatment of **2** with base would, we predicted, lead to elimination of HCl to give the 16-electron intermediate **3** which would subsequently be reduced to the 18-electron ruthenium hydride complex **4** by hydrogen transfer from the solvent. In the case of monotosylated diamines Noyori was able to isolate, and characterise through the use of X-ray crystallography, all three intermediates **5**–**7** analogous to **2**–**4**.[4] Despite a number of efforts on our part, we have as yet been unable to obtain crystalline derivatives of any of our speculated intermediates, possibly due to lack of stability relative to the monotosylated diamine variants.



2 **3** **4** **5** **6** **7**

An alternative approach to this problem was, we considered, through the use of electrospray ionisation mass spectrometry (ESI-MS). This technique has been employed recently for the determination of intermediates in a number of catalytic processes, including the oxidative coupling of arylboronic acids[5] and a study of the aggregation states of organocopper complexes in solution.[6] In the event, this proved to be a highly valuable approach, as described below.

In our first experiment, we prepared a 0.1 M solution of our speculated 'pre-catalyst' **2** by combining a slight excess of *cis*-aminoindanol **1** with ruthenium(II) dimer $[RuCl(\eta6\text{-cymene})]_2$ in Pr^{i}OH solution.[7] ESI-MS [8] of the resulting solution diluted to 25 mM concentration gave a clean spectrum showing an isotope cluster centred around m/z = 420 (Fig. 1). The masses observed for this cluster and the intensity ratio of the different isotope peaks are in excellent agreement with the calculated pattern for the protonated expected molecule $C_{19}H_{25}NORuCl$.

In the next step of our investigation we added *ca*. 2 equiv. of an Pr^{i}OH solution of KOH to the initial solution of **2**. After a short period of time (5–10 min) at room temperature, this solution was again examined by ESI-MS by direct injection into the instrument. The resulting spectrum (Fig. 2) showed clearly, in addition to the isotope cluster of compound **2**, a new isotope cluster with the isotope at m/z 386 as the highest signal, but starting at m/z 378. The shape of this isotope cluster revealed that both expected molecules **3** and **4** were present. Fig. 3 shows a comparison between the experimentally observed intensities in this cluster and the calculated intensities when it is assumed that the protonated forms of the products **3** and **4** were present at a ratio of 1 to 3. This indicates that the reduction of compound **3** to **4** is likely to be faster than the production of **3** from **2**. The

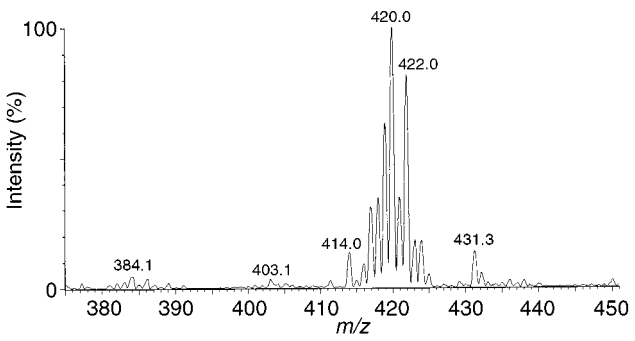


Fig. 1 ESI-MS of complex **2** in Pr^{i}OH.

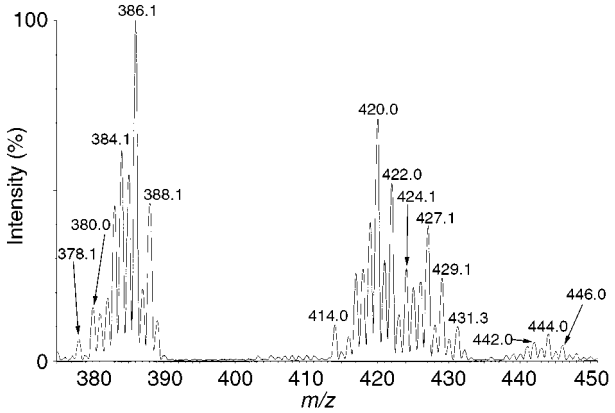

Fig. 2 ESI-MS of complex **2** in Pr^{i}OH, following addition of KOH.

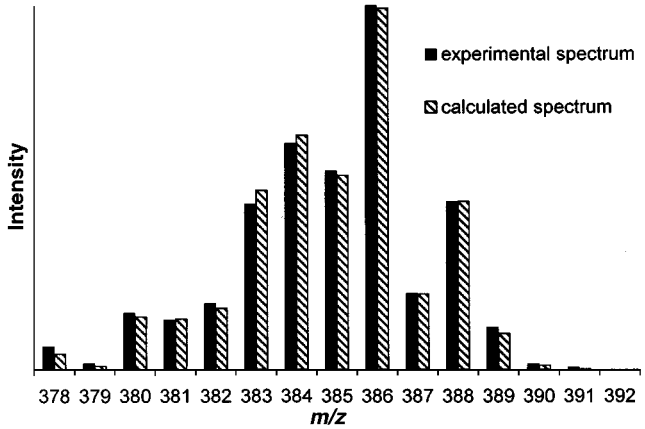

Fig. 3 Comparison of calculated *vs.* experimental ESI-MS spectra for a mixture of **3** and **4**.

less abundent isotope clusters observed around *m/z* 427 and 444 may be explained by assuming that Pr^{i}OH can also react with compound **3** (*m/z* 444) followed by loss of ammonia (*m/z* 427).

In an attempt to obtain evidence for the reduction of **3** by Pr^{i}OH we repeated the above reaction but with the use of CH_2Cl_2 as solvent. An ESI-MS spectrum was recorded shortly after the addition of base (Fig. 4) in which a strong set of peaks centred at *m/z* 384 was observed. The masses and the measured isotope signal intensities correspond to the mass predicted for the compound **3**. In the CH_2Cl_2 solution no suitable hydride source exists for reduction of **3**, therefore its lifetime is longer in this solvent.

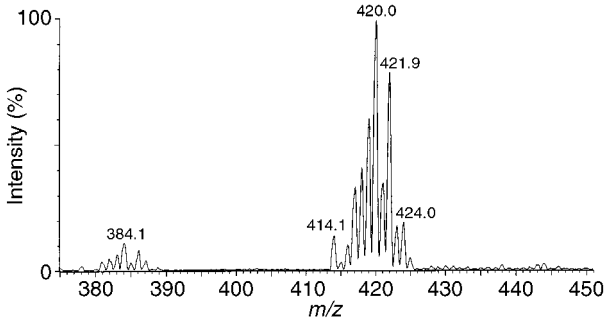

Fig. 4 ESI-MS of complex **2** in CH_2Cl_2 following addition of KOH.

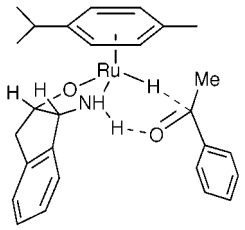

Fig. 5 Mechanism of hydrogen transfer.

In a final revealing set of studies, samples were taken of a solution of **4** in Pr^{i}OH (formed by addition of base) over a period of 90 min following addition of a quantity of acetophenone, which was reduced during this time. Remarkably, species **3** was observed to persist in solution, together with a quantity of unreacted **2**, but **4** was not observed. This observation is somewhat at odds with the result illustrated in Figs. 2 and 3, which suggested that **3** was shorter lived than **4**. Clearly the presence of ketone (and alcohol reduction product) has an effect of the equilibrium of the reaction.

In view of the results described above, and the lack of evidence for any complex of reduction product (1-phenethanol) with ruthenium, we believe that the hydrogen transfer mechanism probably proceeds *via* a 6-centre transition state proposed by Noyori for the corresponding reactions of monotosylated diamine complexes of ruthenium(II) (Fig. 5).[5] Whilst caution should be exercised in the interpretation of any transition state through inferences from observed intermediates, particularly since the method provides no information on the relative configurations of chiral centres in the complexes, we would consider that our evidence thus presented represents a solid foundation on which to build further studies of the synthetically important process of asymmetric transfer hydrogenation.

We thank the EPSRC and SmithKline Beecham Pharmaceuticals for support of a CASE studentship (to J. A. K.) and the British Council for a UK–Dutch Joint Scientific Research Programme Travel Grant.

Received (in Cambridge, UK) 18th October 1999, Accepted 6th December 1999

The water soluble Fe(II) macrocyclic phosphine complex $[Fe(H_2O)_2\{RP(CH_2N(CH_2PR_2)CH_2)_2PR\}]SO_4\cdot 4H_2O$ (R = CH_2OH) has been characterised by single crystal X-ray diffraction and is formed by a remarkable self-assembly reaction between iron(II) ammonium sulfate and tetrakis(hydroxymethyl)phosphonium sulfate (THPS).

There is increasing interest in catalytic transformations carried out in aqueous media employing water soluble phosphine metal complexes.[1–4] In the latter context, phosphine ligands such as $P(CH_2OH)_3$ have been shown to be useful precursors for the synthesis of water soluble transition metal complexes.[4] Albright and Wilson have an interest in the related phosphonium salt $[P(CH_2OH)_4]_2SO_4$[5] because of its effectiveness as a biocide in oil wells. Recently, it was noted that $[P(CH_2OH)_4]_2SO_4$ also aids the dissolution of iron sulfide deposits and particulates. Iron sulfide arises both from anaerobic microbial activity in oil wells and as a result of indigenous H_2S; deposits cause flow restrictions in vessels and pipework and particulates can upset oil/water separation and lead to damage. In oil well situations, the dissolution of FeS by $[P(CH_2OH)_4]_2SO_4$ is accompanied by a red coloration of produced water from the well. The aim of this study was to explain how $[P(CH_2OH)_4]_2SO_4$ aids the dissolution of FeS and to identify the origin of the resulting red coloration which it was believed might be due to a water soluble iron complex.

The reactions of $[P(CH_2OH)_4]_2SO_4$ and the related phosphine $P(CH_2OH)_3$ with various Fe(II) and Fe(III) salts, *e.g.* FeS, $[Fe(NH_4)_2(SO_4)_2]$, $FeCl_3$, $FeCl_2$ and $FeSO_4$, were investigated to find an iron containing laboratory reagent that would model the red complex formed in the oil wells. Only $[Fe(NH_4)_2(SO_4)_2]$ produced a red colour with $[P(CH_2OH)_4]_2SO_4$ or $P(CH_2OH)_3$ and it was shown that other alkyl phosphonium salts do not give red complexes. Thus it appears that the formation of red water soluble complexes requires an Fe(II) salt, $[P(CH_2OH)_4]_2SO_4$ or $P(CH_2OH)_3$ and, crucially, the presence of ammonium ions. Following optimisation of the reaction conditions it was found that addition of 2 equiv. of $[P(CH_2OH)_4]_2SO_4$ to iron(II) ammonium sulfate in water at room temperature, followed by the slow addition of base (NaOH), so that the pH was maintained between 4.5 and 5.0, immediately produced a deep red solution which gave deep red crystals of $[Fe(H_2O)_2\{RP(CH_2N(CH_2PR_2)CH_2)_2PR\}]SO_4\cdot 4H_2O$ (R = CH_2OH) **1** on standing at 5 °C for two weeks.

The X-ray crystal structure† of **1** (Fig. 1) reveals a cationic octahedral Fe(II) complex with a remarkable tetradentate phosphine ligand in which alternating phosphorus and nitrogen atoms are linked by CH_2 spacers to form an eight-membered macrocyclic ring which functions as a *cis* bidentate phosphine donor to iron. The two nitrogen atoms carry pendant CH_2PR_2 groups which occupy *trans* diaxial sites in the metal coordination sphere. Two molecules of H_2O occupy the remaining *cis* coordination sites at iron. The complex is highly symmetric and has crystallographically imposed twofold symmetry leading to chemically equivalent pairs of axial and equatorial phosphorus sites. The $^{31}P\{^1H\}$ and ^1H NMR spectra‡ of the low spin d^6 complex **1** are consistent with the solid state structure being maintained in solution. Thus the $^{31}P\{^1H\}$ NMR spectrum shows two triplets at δ 20.1 [t, ^2J(PP) 53 Hz] and −1.5 [t, ^2J(PP) 53 Hz] as expected for the two pairs of chemically inequivalent phosphine sites in the complex.

The precise mechanism by which complex **1** is formed is uncertain but it seems likely that the reaction involves a Mannich-like condensation of $[P(CH_2OH)_4]_2SO_4$ with two ammonium ions, with the iron(II) ion acting as a template which controls the formation of the macrocycle and its pendant phosphine arms. When the reaction of $[P(CH_2OH)_4]_2SO_4$ and iron(II) ammonium sulfate with more prolonged base addition was monitored by $31P\{^1H\}$ it was observed that the triplets associated with **1** gradually diminished with concomitant

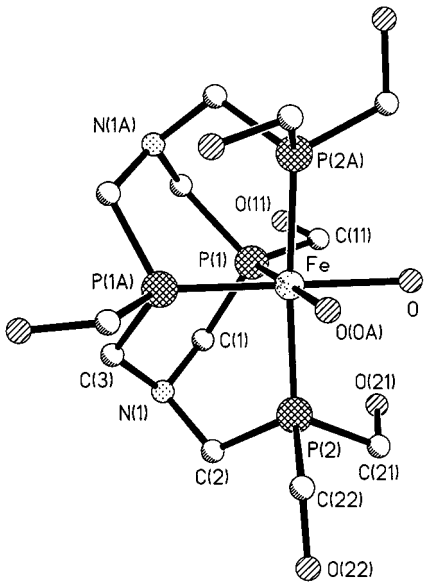

Fig. 1 Molecular structure of the cation of **1** with hydrogen atoms omitted for clarity. Scheme 1 Proposed mechanism for formation of **1** and **2**.

formation of a new complex **2** characterised by two new triplet resonances at δ −12.0 [t, ^2J(PP) = 76 Hz] and −22.8 [t, ^2J(PP) 76 Hz]. The latter pattern is very similar to that observed for the complex **1** suggesting a related structure, and although complex **2** has not yet been isolated and fully characterised, we tentatively suggest that it might be a neutral hydroxy **2a** or oxy-bridged complex **2b** of the type shown (Scheme 1) arising from base induced deprotonation of the coordinated H_2O molecules in **1**.

This investigation was stimulated by the need to explain how $[P(CH_2OH)_4]_2SO_4$ aids the dissolution of FeS in oil fields leading to a red coloration of the treated water. The speciation of the Fe/S system in natural environments such as oil wells is necessarily complex but our model reactions allow us to tentatively propose that $[P(CH_2OH)_4]_2SO_4$ and NH_4^+ ions self-assemble iron complexes similar to **1** from FeS that has formed in oil wells owing to sulfate reducing bacteria or indigenous H_2S. The key ammonium ions required for the condensation reaction are usually naturally present in oil field waters where $[P(CH_2OH)_4]_2SO_4$ is used. Also, ammonium bisulfite is often added as an oxygen scavenger to oil field injection water used to pressurise oil-bearing formations, thus providing an additional source. The observation that $[P(CH_2OH)_4]_2SO_4$ and FeS do not appear to react in the absence of NH_4^+ ions, but immediately give red solutions on addition of NH_4^+, adds further support for the proposed mechanism.

Whilst it was not the original intention of this study to prepare new water soluble catalysts, the novel tetradentate macrocyclic phosphine ligand which has been prepared has obvious potential in this context because it imposes facial octahedral coordination whilst leaving two *cis* sites free for potential catalytic transformations. Moreover, the ability of self assembled phosphine ligands of this type to strongly bind transition metals suggests that such systems might have a role to play in waste clean-up procedures. The chemistry involved in the self-assembly of the new Fe complex **1** is novel and a patent has been raised to protect its potential applications.[1]

The authors would like to thank Gary Woodward (Albright & Wilson UK Ltd) and Martin Murray (School of Chemistry, University of Bristol) for their help in spectral interpretation.

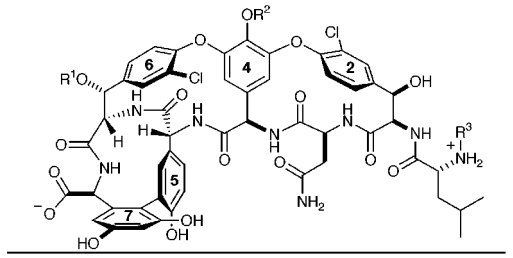
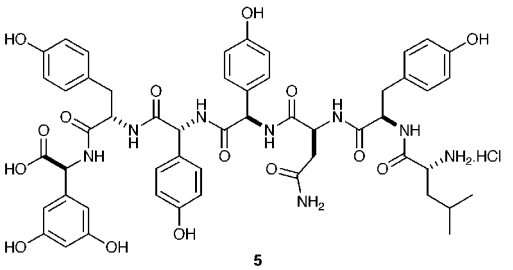
Received (in Cambridge, UK) 4th October 1999, Accepted 15th November 1999

An *N*-methyltransferase responsible for methylating the *N*-terminal leucine of a vancomycin group antibiotic has been expressed, and its activity assayed against a series of putative vancomycin precursors.

Vancomycin (**1**) and teicoplanin are the drugs of choice against methicillin-resistant *Staphylococcus aureus* (MRSA).[1] The



Compound	R^1	R^2	R^3
1	H		CH_3
2			CH_3
3	H		H
4	H	H	H



5

emergence of vancomycin-resistant enterococci (VRE) has highlighted the need for the development of new antibiotics.[2–4] We have sequenced the DNA containing a gene cluster assumed to encode enzymes for the biosynthesis of chloroeremomycin (**2**).[5,6] This assumption is strongly supported by the expression of a glycosyl transferase within the cluster, which was able to add glucose to an aglycone form of chloroeremomycin.[7] Recently, gene disruption in another glycopeptide producing strain has indicated the oxidative genes involved in cross-linking the aromatic groups along the peptide backbone, and led to the isolation of a linear heptapeptide precursor of a vancomycin group antibiotic.[8]

We now report the successful expression and assay of an *N*-methyltransferase from this cluster (MtfA, previously referred to as ORF 16) responsible for *N*-methylating the *N*-terminal leucine of chloroeremomycin. MtfA has significant sequence homology to the *N*-methyltransferase EryCVI which is involved in the synthesis of the desosamine moiety of erythromycin D.[9] The MtfA gene was amplified from cosmid pCZA361 using primers which introduced suitable restriction sites for cloning into the expression vector pET28a(+) (Novagen). The protein was then expressed in *E. coli* BL21 (DE3) under the control of the T7*lac* promoter as a His_6-tagged fusion protein which allowed one-step purification using Novagen His-Bind Quick 900 Cartridges. The relative molecular mass of the purified protein (which gave rise to a single band following SDS-PAGE) was found to be 32.52 kDa (using ESI-MS) which was in excellent agreement with that calculated (32.519 kDa) from the protein sequence.

We assayed MtfA against four different substrates. Each substrate represents a putative precursor corresponding to a different stage of the pathway. The first substrate was *N*-demethylvancomycin (**3**) which is identical in structure to *N*-demethylchloroeremomycin with the exception that the latter has an additional residue 6 amino-sugar (4-*epi*-vancosamine) and the residue 4 sugar is *epi*-vancosamine rather than vancosamine. The second substrate was the aglycone of **3** (**4**). These substrates allow assays for putative late stage methylation in the biosynthetic pathway. The third substrate was the linear heptapeptide D-Leu-D-Tyr-L-Asn-D-Phpg-D-Phpg-L-Tyr-L-Dhpg-OH (**5**).[10] This has the same linear peptide sequence as vancomycin but has no cross-linking between the aromatic side chains, no chlorine atoms or benzylic hydroxy groups and lacks the residue 4 sugars. This substrate allows an assay for a methylation step near to the middle of the biosynthetic pathway. The final substrates were the *R*- and *S*-enantiomers of leucine. These substrates allow assays for methylation at the start of the biosynthetic pathway. Although the *N*-terminal leucine of chloroeremomycin is the *R*-isomer, the possibility of post-methylation epimerisation cannot be ruled out.

Assays were performed in 50 mM Tris–HCl buffer, pH 7.5 at 25 °C. The concentrations of substrate (100 μM), (*S*)-adenosyl-L-methionine (200 μM) and enzyme (1 mg) were identical in each assay, as was the incubation time (24 h). Reaction mixtures were then subjected to analytical reverse phase HPLC and fractions analysed by FT-ICR mass spectrometry. The extent of methylation was determined by comparing the ratios of the intensities of the peaks corresponding to the singly charged parent ions of the substrates and their methylated products (Table 1). Appropriate controls were carried out.[11,12] Where

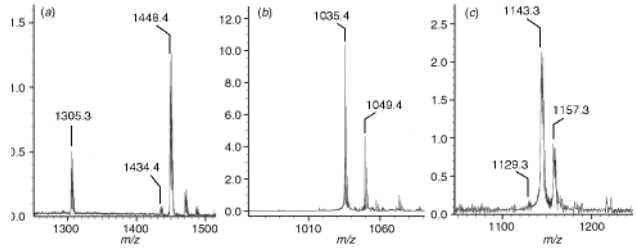


Fig. 1 FT-ICR spectra showing the MH^+ peaks due to substrate and methylated product(s) following MtfA assays for (*a*) **3**, (*b*) **5** and (*c*) **4**.

Table 1 Extent of methylation of various substrates by MtfA determined by FT-ICR spectrometry and HPLC analysis (parentheses). Each assay was performed under identical conditions of 100 μM substrate, 200 μM (*S*)-adenosylmethionine and 1 mg of enzyme for 24 h

Substrate	Substrate monomethylation (%)	Substrate dimethylation (%)
3	95 (> 95)	0 (0)
4	68	30
5	30	0
(*R*)-Leucine	0	0
(*S*)-Leucine	0	0

HPLC retention times of products and substrates did not overlap significantly, peak integration was also used to determine the extent of methylation (Table 1). Leucine and *N*-methylleucine have very weak UV absorption properties and mass spectrometry was used for their detection.[13]

Approximately 95% of **3** was monomethylated by MtfA to vancomycin [Table 1 and Fig. 1(*a*), *cf.* peaks at *m/z* 1434 and 1448]. In Fig. 1(*a*) the fragmentation peak at *m/z* 1305 corresponds to the loss of the residue 4 vancosamine from the methylated product, indicating that *N*-methylation occurs at the *N*-terminal leucine and not the amino group of vancosamine. Species **4** also proved a good substrate for MtfA with over 95% methylation. Interestingly, 30% underwent a second methylation to form a dimethylated product [Table 1 and Fig. 1(*c*), *cf.* peaks at *m/z* 1129, 1143 and 1157]. In contrast, only 30% of **5** was monomethylated [Fig. 1(*b*), *cf.* peaks at *m/z* 1049 and 1035] and no methylation of (*R*)- or (*S*)-leucine was detected. Each substrate was additionally assayed in the absence of MtfA and no methylation was observed.

We also carried out competition experiments in which an equimolar concentration of two substrates (100 μM each) was incubated with enzyme (2 mg) and (*S*)-adenosyl-L-methionine (200 μM) (Table 2).[14] In the competition experiment between substrates **3** and **5**, approximately 95% of **3** was monomethylated whereas no methylation of **5** was detected, confirming that **3** is a much better substrate than **5**. In the competition experiment between substrates **3** and **4,** 90% of **4** was monomethylated whereas only 30–35% of **3** was monomethylated. No dimethylated products were detected. The lack of a second methylation of **4** in this competition experiment implies that the *N*-methylated aglycone is a poorer substrate for the enzyme than is **3**. Most importantly, this result also implies that **4** is a better substrate than **3** and hence the best substrate of those tested.

Table 2 Extent of methylation of substrates after competition experiments in which mixtures of two substrates (100 μM each) and MtfA (1 mg) are subjected to a limiting concentration of *S*-adenosyl-L-methionine (200 μM). % values determined by FT-ICR spectrometry and HPLC analysis (parentheses)

	Substrate methylation[a] (%)		
Substrates	**3**	**4**	**5**
3,4	35 (30)	90	—
3,5	95 (> 95)	—	0

[a] All values refer to monomethylation only, since no dimethylation was observed in either experiment.

These results indicate that the order of specificity of the substrates tested for MtfA is **4** > **3** > **5** > (*R*)- and (*S*)-leucine. This order suggests that *N*-methylation is a late step in the biosynthetic pathway of chloroeremomycin, taking place after the oxidative crosslinking of the heptapeptide backbone but before the addition of the ring 4 disaccharide. However, the importance of the chlorine atoms on substrate specificity is yet to be determined.

We thank Dr Yan Husheng of Nankai University, People's Republic of China, for providing *N*-demethylvancomycin, Dr Jochen Görlitzer for synthesising the aglycone of demethylvancomycin, and the Royal Society (University Research Fellowship to J. B. S), Eli Lilly (S. O'B.), the EPSRC (T. S, D. O'B. and P. N. K), the BBSRC and Unilever for funding.

10 This peptide was synthesised using a combination of solution phase and solid phase methodology. Phpg and Dhpg refer to 4-hydroxyphenylglycine and 3,5-dihydroxyphenylglycine, respectively.
11 Equimolar mixtures of (*R*)-*N*-methylleucine and (*R*) leucine, vancomycin and *N*-demethylvancomycin and vancomycin aglycone and *N*-demethyvancomycin aglycone were subjected to FT-ICR mass spectrometry. For a given solution, the intensities of the singly and doubly charged parent ion peaks of each component were the same to within 10%.
12 Fragmentation peaks corresponding to *N*-demethylvancomycin, *N*-demethylvancomycin aglycone and (*R*)-leucine were not observed in the FT-ICR spectra of vancomycin, vancomycin aglycone and (*R*)-*N*-methylleucine, respectively.
13 Solutions of leucine and *N*-methylleucine were subjected to reverse phase HPLC and fractions were collected at intervals of 30 s. Each fraction was then subjected to FT-ICR mass spectrometry to test for the presence of the corresponding compound. By progressively narrowing the time interval between collections the retention time of the compounds was determined to within five seconds. For each reaction assay, samples corresponding to these retention times were collected and subjected to FT-ICR mass spectrometry.
14 60% of 100 μM substrate **3** is methylated in the presence of 100 μM (*S*)-adenosyl-L-methionine and MtfA, whereas 95% is methylated under the same conditions with 200 μM (*S*)-adenosyl-L-methionine. Hence, a 1:1 mixture of (*S*)-adenosyl-L-methionine and substrate provides a cofactor concentration which limits the extent of conversion.

Conducting polymers, such as poly(aniline) or poly(3-methylthiophene), change their conductivity by many orders of magnitude upon oxidation or reduction. This modulation of the conductivity of the polymer by redox reactions can be utilised to fabricate microelectrochemical transistors—electrochemical devices that behave in many ways as analogues of solid state junction field effect transistors. When combined with suitable redox enzymes these devices can be developed as miniature biosensors which offer a number of interesting advantages, particularly for use with small sample volumes or at low analyte concentrations.

Introduction

Electrochemical biosensors have been extremely successful as disposable devices for the measurement of blood glucose for use by diabetics world-wide. This success is based on ease of manufacture at low cost but with high control of quality and reproducibility combined with ease of use. The clinical range for glucose in blood lies between 1 and 20 mM. In this concentration range direct amperometric measurement at millimetre sized electrodes yields readily measured currents in the microamp range. Future applications will require much smaller devices so that more assays can be carried out in a single drop of blood and assays for analytes such as hormones, drugs or enzymes present at much lower concentrations (typically nano- and micro-molar). Taken individually and together these requirements will be difficult to meet with present types of amperometric biosensor because as the size of the electrode and/or the concentration of the analyte decreases the current measured also decreases. It is therefore appropriate to look for other types of electrochemical biosensor which, while retaining the simplicity of use and low cost of the amperometric devices, also provide the potential for greater sensitivity and small size.

The majority of electrochemical biosensors are based on either potentiometric or amperometric detection (Fig. 1). In the case of a potentiometric enzyme electrode the electrode senses the steady state concentration of some species, usually a product of the enzyme catalysed reaction (such as H^+, NH_4^+ *etc.*), at the electrode surface. This steady state concentration is determined by the kinetics of the enzyme catalysed reaction and by the mass transport of reactants to, and products away from, the electrode. Under suitable circumstances this steady state concentration is directly related to the concentration of the analyte in the solution. The operation of potentiometric enzyme electrodes suffers from a number of problems which limit their sensitivity for many applications.[1] In addition an accurate and stable reference electrode is essential and this is not easy to fabricate as a disposable structure. Consequently amperometric approaches have generally been favoured, although this is not always possible (for example in measurement of urea or penicillin). In an amperometric enzyme electrode the current is a direct measure of the rate of the enzyme catalysed reaction and therefore, under suitable circumstances, is directly related to the concentration of analyte. The great majority of redox enzymes or coenzymes such as NADH and NADPH do not undergo rapid, direct electrochemical reaction at electrode surfaces and

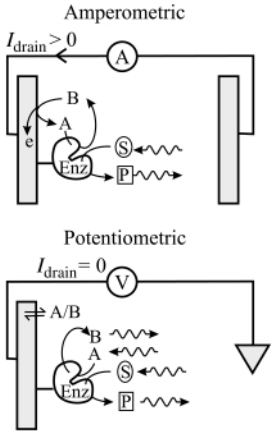

Fig. 1 Schematic representations of an amperometric enzyme electrode and a potentiometric enzyme electrode. In the amperometric enzyme electrode the conversion of substrate, S, to product, P, by the enzyme is linked to the electrode through the mediator couple A/B. The current for the conversion of B to A is then related to the rate of the enzyme catalysed reaction and thus to the substrate concentration. In the potentiometric enzyme electrode the electrode senses the concentrations of A and B at the electrode surface. These concentrations depend on the rate of the enzyme catalysed reactions and the rates of mass transport of the A/B couple and the substrate in solution.

Philip Bartlett did his first degree in Oxford and his PhD at Imperial College, London, under the supervision of Professor John Albery FRS. In 1984 he was appointed as a lecturer in Physical Chemistry at the University of Warwick, in 1991 he became Professor of Physical Chemistry at the University of Bath and in 1993 Professor of Electrochemistry at the University of Southampton. His research interests focus on the design, modification and characterisation of electrode surfaces and the application of electrochemically deposited thin films as chemical sensors. He has worked extensively in the areas of redox enzyme and coenzyme electrochemistry studying the mechanism and kinetics of modified electrodes and immobilised enzymes. He is currently chair of the organising committee for Faraday Discussion 116 on Bioelectrochemistry to be held in Southampton in July 2000.

Yann Astier was born in Rennes, France, in 1973. He received his degree in molecular chemistry from Rennes 1 University in 1997 and is now doing his PhD in electrochemistry at the University of Southampton with Professor P. N. Bartlett on electrochemical immunoassays.

consequently it is necessary to provide some means to couple the enzyme catalysed reaction to oxidation or reduction at the electrode surface. In the first amperometric enzyme electrodes, such as the Clark glucose electrode,[2] this was done by oxidising or reducing one of the co-reactants or products of the enzyme catalysed reaction at a metal electrode. The enzyme glucose oxidase (E.C. 1.1.3.4) catalyses the reaction of β-D-glucose with oxygen to give D-glucono-δ-lactone and hydrogen peroxide. This reaction occurs in two stages. In the first step [eqn. (1)] the oxidised flavin prosthetic group, FAD, bound in the enzyme active site is reduced by reaction with glucose to give the bound reduced flavin, $FADH_2$, and the product gluconolactone, which undergoes hydrolysis to give gluconic acid [eqn. (2)]. In a subsequent step the reduced flavin is reoxidised by reaction with molecular oxygen [eqn. (3)].

$$GOx(FAD) + \beta\text{-D-glucose} \rightarrow GOx(FADH_2) + \text{D-glucono-}\delta\text{-lactone} \quad (1)$$

$$\text{D-glucono-}\delta\text{-lactone} + H_2O \rightarrow \text{D-gluconate} + H_3O^+ \quad (2)$$

$$GOx(FADH_2) + O_2 \rightarrow GOx(FAD) + H_2O_2 \quad (3)$$

These reactions can be followed electrochemically by either measuring the rate of consumption of molecular oxygen or by measuring the rate of production of hydrogen peroxide. Although both approaches have been adopted they suffer from a number of problems. At high glucose concentrations, or in situations where the supply of oxygen is restricted, the response can be limited by the oxygen supply rather than by the concentration of glucose. In addition both oxygen and hydrogen peroxide are difficult species to measure electrochemically because of their poor electrode kinetics. Consequently measurements in whole blood, serum or other biological media are often difficult because of interference from other, readily oxidised compounds such as uric acid or ascorbate present in the sample. For these reasons it is preferable to avoid the use of oxygen and replace the second reaction by one in which a redox mediator is used to reoxidise the enzyme [eqn. (4)].

$$GOx(FADH_2) + 2M^+ + 2H_2O \rightarrow GOx(FAD) + 2M + 2H_3O^+ \quad (4)$$

Using this approach the mediator can be chosen so that it has both a fast reaction with the reduced enzyme, good stability and fast electrode kinetics at a potential where the interferences from other species present in the sample are minimal. The most successful example of this approach has been the use of ferrocene derivatives to mediate oxidation of glucose oxidase first suggested by Cass *et al.*[3] and subsequently the basis of a very successful commercial disposable glucose sensor.

For glucose oxidase, direct electrochemical oxidation of the enzyme is slow because the active site is buried deep within the enzyme core.[4] Homogeneous solution mediators, such as the ferrocene derivatives, are presumably able to diffuse into and out of the enzyme's active site and thus to act as a shuttle carrying electrons from the active site to the electrode. Although the use of homogeneous, freely diffusing mediators has proved a very successful and flexible approach to the problem it is not ideal for all applications because the mediator can diffuse away from the electrode surface and be lost. For this reason other approaches have been investigated including the co-immobilisation of the enzyme and mediator in carbon paste electrodes and sol-gel electrode structures, the covalent modification of the enzyme by attachment of the redox mediator to amino acid residues of the protein,[5,6] and the immobilisation of the enzyme in redox polymer films containing the covalently attached mediator. This last approach, pioneered by Heller,[7] has been very successful in linking the re-oxidation of several flavoproteins, including glucose oxidase, to electrodes for use in amperometric biosensors.

Despite these successes in designing amperometric enzyme electrodes there are important limitations to their performance if we wish to go towards either smaller sensors or analytes at lower concentrations. In an amperometric enzyme electrode the current is directly related to the rate of turnover of the enzyme. For example for glucose oxidase the maximum rate of turnover of the enzyme is 800 s^{-1}. For a monolayer coverage of the enzyme (1.6×10^{-12} mol cm^{-2})[8,9] on a 1 cm^2 electrode this corresponds to a maximum current of 240 μA. As the size of the electrode is decreased the current will also decrease because the number of enzyme molecules decreases. For a 70 micron diameter electrode (the diameter of a human hair, 3.85×10^{-5} cm^2) the maximum current for a monolayer coverage of glucose oxidase will be 9.2 nA; for a 1 micron diameter electrode (7.85×10^{-9} cm^2, a realistic size using present fabrication techniques) the current will be reduced to 1.9 pA. Clearly, in principle, this current can be increased if the enzyme coverage is increased from a monolayer to multilayer. However the increase in current will be less than linear with increasing enzyme coverage because of the restriction on diffusion of the substrate through the enzyme layer at the electrode surface. Thus, realistically we can probably only expect an increase of one or two orders of magnitude in the current if we use multilayer enzyme coverage on the electrode.

These currents are for high concentrations of the analyte (> 20 mM) and for an enzyme with fast kinetics. At lower concentrations, or for many other enzymes, the currents would be less. This also becomes a problem when we try to develop amperometric biosensors for analytes such as hormones or drugs which are biologically active at much lower concentrations.

To address these problems it is appropriate that we investigate other electrochemical sensing strategies which maintain the advantages of electrochemical biosensors in terms of low cost and ease of use and manufacture, but which offer other mechanisms to allow enhanced sensitivity at low analyte concentrations for devices of small size. One such approach is provided by the microelectrochemical transistor or switch devices first described by Wrighton and colleagues.[10] These devices make use of the ability to switch the conductivity of thin conducting polymer films by five or more orders of magnitude on oxidation or reduction. This large change in conductivity of the polymer leads to amplification of the signal and can be used as the basis of a chemical sensor or biosensor which acts as a electrochemical transistor analogous to a junction field effect transistor in its operation and characteristics. In addition these devices can be made very small so that they may be suitable for use in small sample volumes.

Conducting polymers

The microelectrochemical transistors and diodes described by Wrighton make use of the very large changes in the conductivity of electronically conducting polymers which accompany oxidation or reduction of the polymer backbone. Conducting polymers, such as poly(pyrrole) or poly(3-methylthiophene) are formed by oxidative coupling of the respective monomers. This coupling can be carried out chemically or electrochemically. The latter approach has the advantage that the polymerisation process is localised at the electrode surface and that the amount of polymer deposited can be controlled through the total amount of charge passed. On cycling the potential of the conducting polymer film in a solution of background electrolyte the polymer can be repeatedly oxidised and reduced (Fig. 2). The amount of charge passed in this process depends on the amount of polymer present. For polymers such as poly(pyrrole) and poly(3-methylthiophene) the oxidised form is conducting and the reduced form is insulating. Conduction in the oxidised form of the polymer is through the mobile bipolarons[11] (Fig. 2).

The oxidation and reduction of the conducting polymer is also accompanied by the ingress and egress of anions, cations and solvent and by polymer chain relaxation processes. Thus the dynamics of the redox transformation of these films is a complex process and one which we are only now beginning to

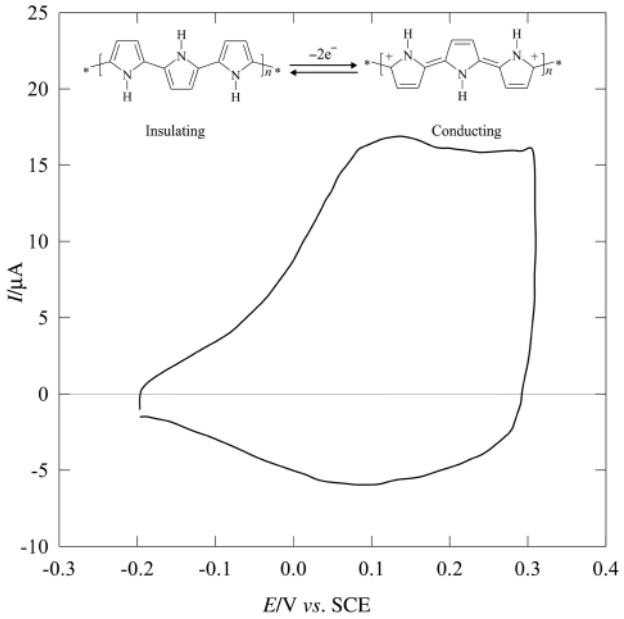

Fig. 2 A cyclic voltammogram of a poly(pyrrole) film recorded at 200 mV s^{-1} in 2 mol dm^{-3} H_2SO_4. The film was grown on a 0.5 mm diameter platinum electrode at 0.65 V *vs.* SCE from a solution of 0.5 mol dm^{-3} pyrrole in 1 mol dm^{-3} KCl. The inset shows the schematic structures for the insulating and conducting forms of the polymer. Note that in the fully oxidised polymer there is typically one charge for every four monomer units.

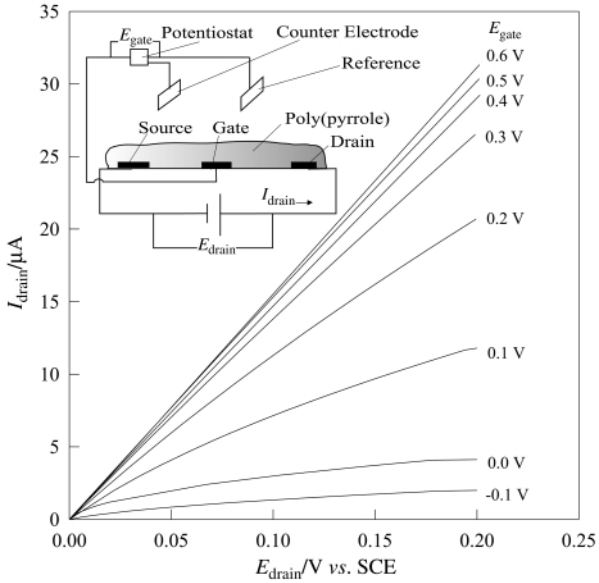

Fig. 3 Plots of the drain current, I_{drain}, as a function of the drain voltage, E_{drain}, for a poly(pyrrole) based microelectrochemical transistor operated in MeCN containing 0.1 mol dm^{-3} Bu_4NClO_4. Each curve corresponds to a different value of the gate voltage, E_{gate}. As the gate voltage increases from –0.1 V *vs.* SCE to 0.6 V the resistance of the poly(pyrrole) film decreases. The inset shows the arrangement used to make the measurements. (Adapted with permission from White *et al.*[10] Copyright 1984 American Chemical Society.)

fully comprehend through the use of a variety of *in situ* techniques.[12,13] This movement of ions is essential to maintain the electroneutrality of the polymer film. This requirement for the motion of ions to accompany the oxidation and reduction of the polymer constrains the maximum rate at which these films can switch between conducting and insulating states.

Microelectrochemical transistors and diodes

The first microelectrochemical transistor, described by Wrighton and colleagues in 1984,[10,14] comprised a poly(pyrrole) film deposited across the gaps between three independent gold microband electrodes 1.4 μm apart on a oxidised silicon substrate (Fig. 3). By analogy with a junction field effect transistor the three gold electrodes are referred to as the source, gate and drain. By using the central gate electrode Wrighton and colleagues were able to alter the redox state of the poly(pyrrole) film. With the gate at potentials, E_{gate}, negative of −0.2 V *vs.* SCE the polymer is insulating and no current flows through the polymer film between the outer source and drain electrodes when a voltage, E_{drain}, is applied between them—the device is in the 'off' state. When the gate potential, E_{gate}, is changed to more positive values the poly(pyrrole) film becomes oxidised and changes to its conducting state. Now when a voltage is applied between source and drain a significant drain current, I_{drain}, flows between the source and drain electrodes through the poly(pyrrole) film—the device is in the 'on' state. Fig. 3 shows the current–voltage characteristics of the device at different gate voltages. In this device a small signal applied to the gate electrode leads to a large change in the drain current flowing through the polymer; thus the device amplifies the signal in the same way that a solid state transistor can be use to amplify a signal.

A significant difference between the type of microelectrochemical transistor described here and conventional solid-state devices lies in their response times. In a solid-state semiconductor device the switching is achieved by movement of electrons or holes within the semiconductor. In the microelectrochemical enzyme transistor the switching is accompanied by the movement of ions and solvent within the film (see above). Consequently the process is much slower; switching for Wrighton's first poly(pyrrole) device took on the order of 10 s.[10] In subsequent studies Wrighton and colleagues demonstrated that other conducting polymer such as poly(3-methylthiophene) and poly(aniline) could be used to make microelectrochemical transistors[15,16] and that these devices could be made to operate faster by careful choice of the polymer film and by reducing the size of the inter-electrode gap. In this way they were able to demonstrate power amplification up to frequencies of 10 kHz.[17] Nevertheless this is still considerably slower than for solid-state devices.

However although switching in microelectrochemical transistors is slow they have other properties which solid state devices do not possess, notably that the devices can be switched by chemical reactions and therefore can, in principle, be used as chemical sensors. Thus, instead of using a potentiostat and external circuit the redox state of the polymer film can be changed by oxidation or reduction by a species in solution and this change can again be sensed by a change in the drain current flowing through the device—the chemical reaction switches the device between 'on' and 'off' states. The first examples of this used simple outer sphere redox couples such as $[Fe(CN)_6]^{3-/4-}$ or $[Ru(NH_3)_6]^{3+/2+}$ to turn devices based on poly(aniline) films 'on' and 'off' respectively.[16] The amount of redox reagent which can be detected with this type of device is very small. For example for a poly(3-methylthiophene) based transistor Wrighton *et al.* were able to detect the injection of 1×10^{-9} mol of $[IrCl_6]^{2-}$ corresponding to the reaction of 8×10^{-16} mol of the reagent at the polymer surface.[18] Subsequently responses to molecular hydrogen and oxygen were demonstrated for microelectrochemical transistors based on poly(3-methylthiophene) films modified with platinum particles to catalyse the reactions of hydrogen and oxygen[19] (Fig. 4). Despite the use of the platinum particles to catalyse the reduction of oxygen the response of the devices was still rather slow, taking around 2 min to respond to 1 atm of dissolved molecular oxygen. In these devices the microelectrochemical transistor acts as a sensor for the redox potential of the solution without any particular chemical selectivity for the species present.

Whilst these initial studies by Wrighton and colleagues demonstrated the concept of using a microelectrochemical

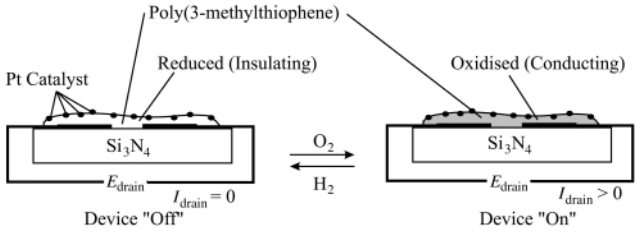

Fig. 4 A two terminal poly(3-methylthiophene) based microelectrochemical enzyme transistor. The device can be turned 'off' by reduction with hydrogen or 'on' by oxidation with oxygen. The platinum particles are necessary to catalyse the reactions of the gases at the surface of the polymer. (Adapted with permission from Thackeray *et al.*[19] Copyright 1986 American Chemical Society.)

transistor as a chemical sensor they did not go on to demonstrate selective devices or to look at the possible use of other types of catalyst to provide selectivity in the device response.

Microelectrochemical enzyme transistors

An obvious way to impart chemical selectivity to a microelectrochemical transistor is to use an immobilised enzyme as the catalyst.[20] However this has proved to be difficult because of the problems of coupling the enzyme electrochemistry to the conducting polymer film and finding the right conducting polymer with the correct properties for the application. The obvious starting point is to use poly(pyrrole) or one of its derivatives since these polymers can be deposited from neutral aqueous solutions and can be used to entrap enzymes such as glucose oxidase during deposition of the polymer.[21–23] This was the approach adopted by Matsue to make the first microelectrochemical enzyme transistor, an NADH responsive device based on diaphorase.[24] They used an interdigitated platinum electrode structure fabricated on glass with 10 μm wide bands separated by 10 μm wide gaps. These were coated with a thin electropolymerised film of co-polymerised pyrrole and *N*-methylpyrrole containing diaphorase (E.C. 1.6.99.- purified from *Bacillus stearothermophilus*). In order to couple the enzyme catalysed reaction to the reduction of the polymer 1 mM anthraquinone-2-sulfonate was added to the solution as a mediator. On addition of NADH the oxidation of NADH, catalysed by the diaphorase, led to reduction of the pyrrole–*N*-methylpyrrole copolymer film causing the device to switch from 'on' to 'off'. This change in the conductivity of the polymer was observed by recording the change in the drain current, I_{drain}, flowing through the device as a function of time after exposure to NADH (Fig. 5). After exposure to NADH the device is in its 'off' state and must be reset by reoxidising the polymer before it can be used to make another measurement of NADH. This was achieved by electrochemical oxidation of the polymer film.

Despite proving to be a useful way of immobilising enzymes at electrode surfaces for amperometric enzyme electrodes,[21–23] poly(pyrrole) and its derivatives are not the most suitable polymers for the fabrication of microelectrochemical enzyme transistors because the stability of the polymer in solution at neutral pH is not good, it is hard to reproducibly deposit the films from neutral aqueous solutions, and the electrical conductivity of the polymer is irreversibly destroyed by reaction with hydrogen peroxide.[25,26] This is a particularly serious problem if one wants to use flavoproteins, such as glucose oxidase, which inevitably generate some peroxide even when a redox mediator is incorporated into the film with the enzyme.[27]

These problems can be overcome by using poly(aniline) which is stable, does not react with hydrogen peroxide and which can be deposited very reproducibly by electrochemical methods. The electrochemistry of poly(aniline) is more complex that that of poly(pyrrole) because there are three accessible oxidation states: the leucoemeraldine, emeraldine, and pernigraniline forms[28,29] (Fig. 6). Of these three forms only the protonated emeraldine form is electronically conducting. The emeraldine base (Fig. 6) is an insulator. Thus poly(aniline) generally only exists in its conducting form in acidic solution and the polymer is normally electrochemically deposited from

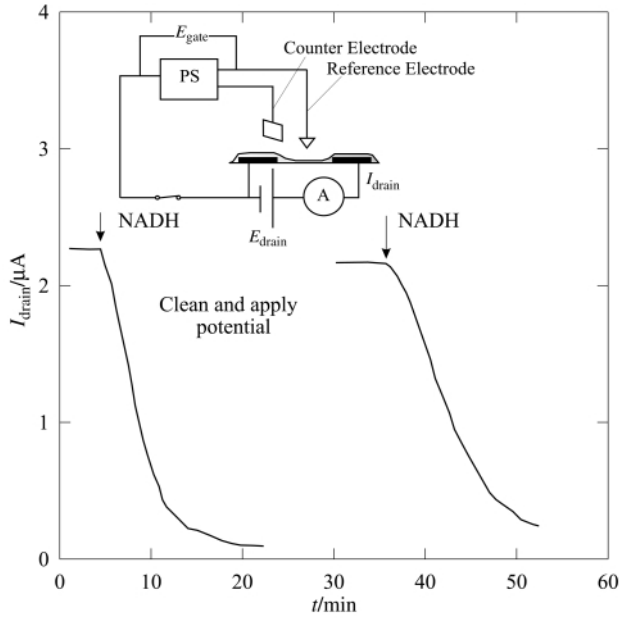

Fig. 5 Response of the drain current, I_{drain}, to the addition of 1 mmol dm^{-3} NADH for a microelectrochemical enzyme transistor based on a copolymer of pyrrole and *N*-methylpyrrole and incorporating diaphorase and anthraquinone-2-sulfonate. The device was operated at a drain voltage of 20 mV in 0.1 mol dm^{-3} KNO_3 in 20 mmol dm^{-3} phosphate buffer at pH 6.8. The inset shows the experimental arrangement for the measurement. (Adapted from Matsue *et al.*[24])

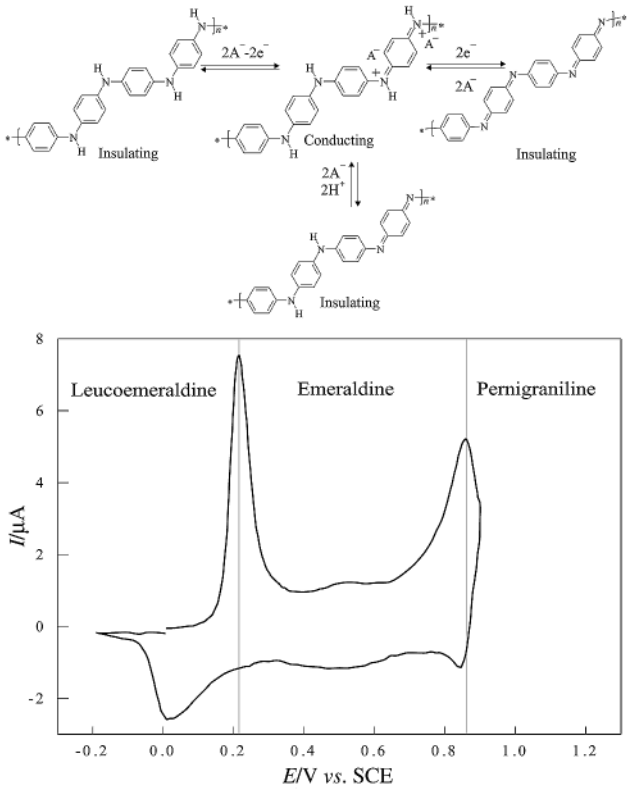

Fig. 6 Cyclic voltammogram for a poly(aniline) film recorded at 20 mV s^{-1} in 2 mol dm^{-3} H_2SO_4. The film was grown on a 0.5 mm diameter platinum electrode at 0.9 V *vs.* SCE from a solution of 0.4 mol dm^{-3} aniline in 2 mol dm^{-3} H_2SO_4. The three different forms of the material are indicated. Of the three only the protonated emeraldine form is electronically conducting. The diagram also shows schematic representations of the structures of the different forms.

acidic solutions (such as 1 M H_2SO_4). Poly(aniline) films can be cycled between the three redox states electrochemically in acidic solutions (Fig. 6) but at low pH the pernigraniline form is unstable and undergoes hydrolysis leading to degradation of the film.

In order to use poly(aniline) films with flavoproteins it is essential to work in neutral, or at best weakly acidic, solutions to avoid the destruction of the enzyme. The workable pH range for poly(aniline) films grown from sulfuric acid solution is determined by the pK_a of the emeraldine form of the polymer. This is around 5.5, so that these films can be operated in buffered solutions at pH 5. Microelectrochemical enzyme transistors responsive to glucose were fabricated by electrochemically depositing a thin film of poly(aniline) from sulfuric acid solution across a 20–25 μm gap between two screen printed carbon microbands.[30,31] Glucose oxidase was then immobilised on to the surface of the poly(aniline) in a second step carried out in buffered solution at pH 5. The glucose oxidase was immobilised on the poly(aniline) surface in an electropolymerised film of 1,2-diaminobenzene. 1,2-Diaminobenzene forms a thin insulating film under these conditions which is permselective and can be used to give selectivity against interferents in solution.[32] Thus the film serves the dual purpose of immobilising the enzyme onto the surface of the poly(aniline) and providing some selectivity against interference from solution species. The fact that the film is deposited electrochemically also means that it coats the surface of the device evenly. The construction of the device is shown in Fig. 7. To

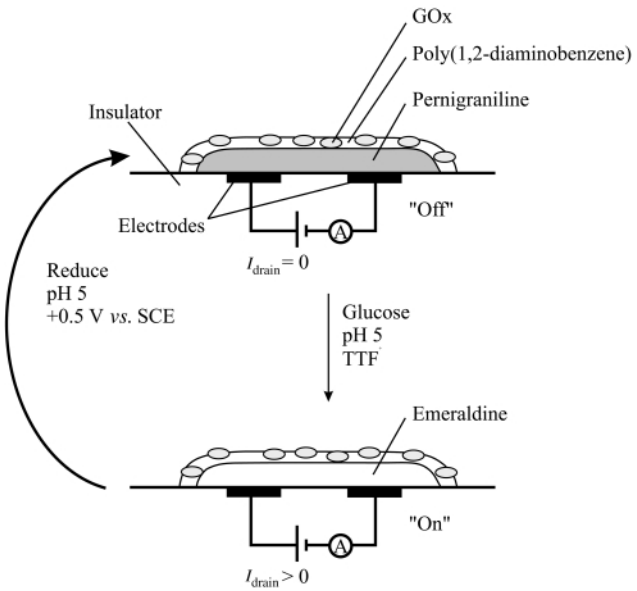

Fig. 7 The construction and operation of a microelectrochemical enzyme transistor responsive to glucose. The device is based on a poly(aniline) film deposited across the gap between two electrodes. On top of the film the enzyme glucose oxidase (GOx) is immobilised in a electropolymerised film of poly(1,2-diaminobenzene). The device is switched from 'off' to 'on' on exposure to glucose. The device can be reset by electrochemical oxidation of the poly(aniline) film at +0.5 V *vs.* SCE at pH 5.0 to the insulating pernigraniline state.

couple the enzyme catalysed oxidation of glucose to the reduction of the poly(aniline) film tetrathiafulvalene (TTF) was used as a mediator. The overall reaction scheme is then given by eqns. (5)–(8),

$$\text{GOx(FAD)} + \beta\text{-D-glucose} \rightarrow \text{GOx(FADH}_2\text{)} + \text{D-glucono-}\delta\text{-lactone} \quad (5)$$

$$\text{D-glucono-}\delta\text{-lactone} + H_2O \rightarrow \text{D-gluconate} + H_3O^+ \quad (6)$$

$$\text{GOx(FADH}_2\text{)} + 2\text{TTF}^+ + 2H_2O \rightarrow \text{GOx(FAD}^+\text{)} + 2\text{TTF} + 2H_3O^+ \quad (7)$$

$$\text{TTF} + \text{PANI(ox)} \rightarrow \text{TTF}^+ + \text{PANI(red)} \quad (8)$$

where PANI(ox) represents the fully oxidised, insulating, pernigraniline form of poly(aniline) and PANI(red) the partially oxidised, conducting, emeraldine form. Thus the enzyme catalysed reaction turns the device from 'off' to 'on' (Fig. 7). Following exposure to glucose the device can be reset by electrochemical oxidation of the poly(aniline) to the pernigraniline form at 0.5 V *vs.* SCE.

For a device of this type the rate at which the drain current increases upon exposure to the analyte and the time taken for it to switch between states depend on the concentration of analyte. Fig. 8 shows a set of response curves for a single device exposed

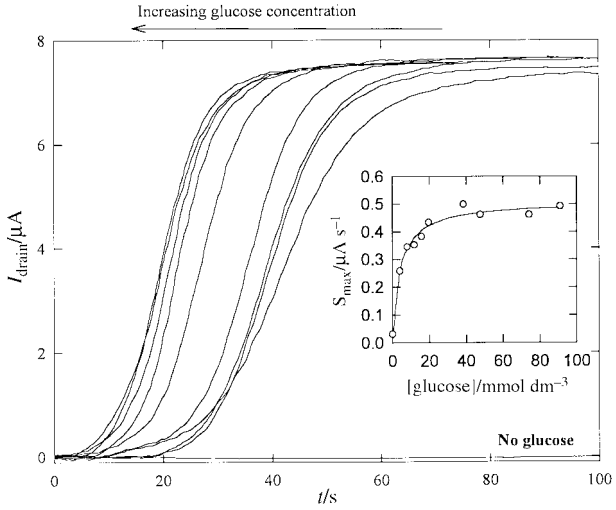

Fig. 8 A set of response curves for a glucose oxidase based microelectrochemical enzyme transistor. The structure of the transistor is shown in Fig. 7. Between each measurement the device was reset electrochemically to its insulating state at 0.5 V vs. SCE. Measurements were made with a drain voltage, E_{drain}, of 20 mV in pH 5 phosphate/citrate buffer containing 0.5 mol dm^{-2} Na_2SO_4 and 0.5 vol % Triton X100 saturated with tetrathiafulvalene. In each case aliquots of sample solution were added at time zero. In the absence of glucose the drain current, I_{drain}, flowing through the device does not change. When an aliquot of glucose is added the drain current increases with time following the addition until it eventually reaches a plateau when the device is in the 'on' state. The time taken for the device to switch on and the maximum switching rate, S_{max} (defined as the maximum slope of the plot of drain current against time), depends on the concentration of glucose. The inset shows the calibration curve for this device. (Reprinted from Bartlett and Birkin.[30] Copyright 1993 American Chemical Society.)

to different concentrations of glucose. First it is clear that the device can be reused at least nine times with no apparent loss in function, in fact many more than nine consecutive operations are possible for this device under these conditions. It is also clear that the response of the device depends on the concentration of glucose added to the solution. Without added glucose there is no change in the drain current over the course of the experiment. When glucose is added there is initially no change in the drain current flowing through the poly(aniline) film but then, as the enzyme catalysed reaction begins to reduce the polymer it is converted to its conducting, emeraldine state and the drain current increases, eventually reaching a plateau when the polymer is highly conducting and the drain current is limited by the base resistance of the carbon microband structure (in this case about 3 kΩ). Note that on switching from 'off' to 'on' the resistance of this device changes by around 3 orders of magnitude. We can show that the device does indeed operate through changes in the oxidation state of the poly(aniline) film by following the potential of the film during switching [Fig. 9(*a*)]. Before addition of glucose the potential of the polymer is around +0.28 V vs. SCE, where the poly(aniline) film is insulating. On addition of glucose the potential immediately begins to shift cathodic as the poly(aniline) is reduced and then the drain current increases as the polymer becomes more conducting. Fig. 9(*b*) shows the variation of the polymer resistance with potential.

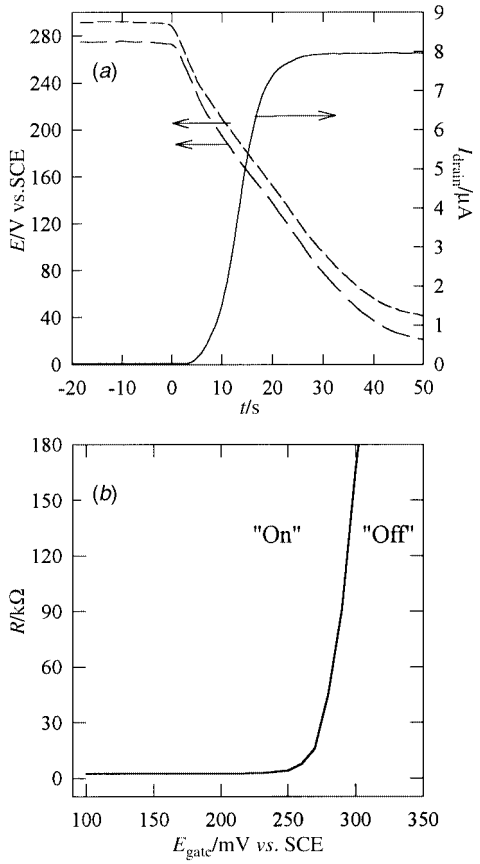

Fig. 9 (*a*) Simultaneous measurement of the drain current, I_{drain}, and the potentials of the two microband electrodes as a function of time after addition of glucose. (*b*) resistance of a poly(aniline) film as a function of the redox potential at pH 5. (Reprinted from Bartlett and Birkin.[31] Copyright 1994 American Chemical Society.)

Studies of the effect of varying the amount of polymer deposited onto the device and the enzyme loading allow us to optimise the speed of response of these devices to glucose and support our model of the operation of these devices.[31] By optimising the amount of poly(aniline) deposited across the 20 μm gap a switching time of less than 10 s can be achieved. This is significantly faster than the best switching times reported by Matsue *et al.* for their NADH responsive device.[24] The selectivity of this type of device for glucose over other sugars is largely determined by the selectivity of the enzyme itself, with D-(+)-glucose giving much faster switching rates than D-(+)-mannose or D-(+)-galactose (Table 1).

Table 1 Comparison of the relative homogeneous rates, amperometric response, and switching rate recorded for a single device in the presence of 0.15 mol dm^{-3} substrate and 1.4 mmol dm^{-3} TTF^+ (from ref. 31)

Substrate	Relative homogeneous rate[a]	Amperometric response/μA	Switching rate/s^{-1}
D-(+)-Glucose	100	63	0.209
2-Deoxy-D-glucose	25	42.5	0.218
D-(+)-Mannose	0.98	8.8	0.081
D-(+)-Galactose	0.14	3.3	0.034

Advantages of microelectrochemical enzyme transistors

Microelectrochemical enzyme transistors have a number of potential advantages as biosensor devices which could be beneficial in some applications. First, the devices do not require a potentiostat or a reference electrode to operate. Measurement of the drain current can be achieved with very simple instrumentation and, at least for devices operating in the 'off' to 'on' direction (see below), the instrumentation required to re-set the device after each measurement can be very simple. Second, the devices can be made very small without loss of sensitivity. As the gap between the electrodes is decreased and the polymer film is made thinner the speed of response will increase and the magnitude of the drain current will increase. Third, these devices can be thought of as counting the number of molecules which have reacted with the enzyme. Thus it will take a certain number of glucose molecules to switch the device from its 'off' state to its 'on' state. This number of molecules depends on the amount of poly(aniline) in the device—for a device 50 μm by 50 μm we estimate that 60 fmol of glucose is required to reach the halfway point where I_{drain} is one half its maximum value. As the size of the device decreases the number of moles of glucose will also decrease. Fourth, the device integrates the analytical signal. Thus if the device is removed from the solution containing glucose the drain current does not fall back to zero but stays at the value reached. If the device is returned to the glucose solution the drain current increases once more. This is because the enzyme catalysed reaction causes the reduction of the polymer so that each molecule of glucose which reacts injects one charge carrier into the polymer and these charge carriers accumulate there leading to the increase in conductivity. This is in direct contrast of the operation of superficially similar devices also based on conducting polymer films and enzymes which operate by sensing a local change in pH caused by the enzyme catalysed reaction.[33–35] In these devices the response returns to the baseline value when the analyte is removed and in their operation they resemble potentiometric enzyme electrodes and suffer from the same problems as these devices in terms of sensitivity and effect of solution buffer concentration.[1]

We have made use of this ability of the microelectrochemical enzyme transistor to integrate the analyte signal in the measurement of low glucose concentrations using a device of the type described above.[36] In this work we were able to show that by the choice of suitable deposition and fabrication conditions we can make microelectrochemical enzyme transistors responsive to glucose with good reproducibility and that they can be used with good repeatability to make measurements of glucose concentration down to 2 μM in air-saturated buffer at pH 5. This was 40 times better than the performance of the corresponding amperometric device.

Despite the success in fabricating working devices responsive to glucose some problems and disadvantages remain. First it is important to realise that devices of this type will suffer from similar problems of interference, enzyme kinetics and selectivity as amperometric enzyme electrodes. Indeed if a device works as a microelectrochemical enzyme transistor then it will generally also function as an amperometric sensor simply by holding it at the appropriate potential and measuring the current. The advantages of the microelectrochemical enzyme transistor over the amperometric enzyme electrode lie in its sensitivity and simplicity of measurement. Second, for the devices described above freely diffusing mediator species have been necessary to couple the enzyme reaction to the reduction or oxidation of the polymer. Third, the use of poly(aniline) with bisulfate counterion is restricted to pH 5 and below and this is not compatible with all enzymes or enzyme assays. In the next section we address some of these challenges.

Further developments

Not all enzymes require the use of redox mediators to achieve oxidation or reduction at electrode surfaces. For glucose oxidase the flavin redox active site is buried deep within the core of the protein, making direct oxidation at an electrode very difficult, but this is not the case for all enzymes. For horseradish

peroxidase (E.C. 1.11.1.7) the haem redox site is located at the periphery of the enzyme and is solvent accessible. In this case direct reduction of the haem at electrode surfaces is possible.[37–39] Horseradish peroxidase can also be directly reduced at poly(aniline) coated electrodes[40] and so it is possible to make microelectrochemical enzyme transistors responsive to hydrogen peroxide using horseradish peroxidase as the catalyst.[41] In this case the reactions are those in eqns. (9) and (10).

$$H_2O_2 + HRP(red) \rightarrow HRP(compound\ I) + H_2O \quad (9)$$

$$HRP\ (compound\ I) + PANi(red) \rightarrow HRP(red) + PANi(ox) \quad (10)$$

In this case the poly(aniline) is converted from its reduced, conducting, emeraldine form to its oxidised, insulating, pernigraniline form so that the device operates in the 'on' to 'off' direction [see Fig. 9(*b*)], rather that the other way around, as was the case for the glucose responsive device. This has an important consequence. Because the device starts in the conducting state the time taken to switch the device in any given concentration of analyte is much more sensitive to the choice of setting potential for the poly(aniline) film (the initial value of E_{gate}). This is because the more cathodic the initial gate potential the greater the amount of charge that must be removed from the polymer before its conductivity will change significantly, switching the device 'off'. In contrast, for the glucose responsive device the poly(aniline) starts in the insulating state where the capacitance of the polymer is orders of magnitude lower. As a result small differences in the initial gate voltage make no difference in the switching time for the device and for the same reason the switching times are significantly faster.[41] The clear conclusion from this comparison is that, if possible, it is better to configure devices so that they operate in the 'off' to 'on' direction than *vice versa*.

The work described above for both glucose and hydrogen peroxide responsive devices was all carried out using poly(aniline) at pH 5. It is obviously desirable to remove this constraint and to be able to work at neutral pH. For poly(aniline) the problem is that the emeraldine form of the polymer deprotonates above about pH 5 (see Fig. 6 above) and that the deprotonated form is not an electronic conductor. For a poly(aniline) film the deprotonation of the emeraldine form is associated with the egress from the film of both the protons and the associated counter anions, [Fig. 10(*a*)]. This is only possible if the counter anions are small and mobile, for example chloride or bisulfate anions. If these mobile counter anions are replaced by long chain polymeric counter anions these become trapped within the poly(aniline) film and the overall process changes [Fig. 10(*b*)]. Now if the protons leave the film they must be replaced by cations from the solution in order to maintain electroneutrality. As a consequence of this change the conductivity of the poly(aniline) can be maintained to much higher pH[42] [in effect there is a Donnan type potential established across the poly(aniline) solution interface which alters the electrochemical potential of the protons within the film]. We have made use of this effect to deposit films of poly(aniline) with polymer counterions such as poly(vinylsulfonate) or poly(styrenesulfonate) which remain electrochemically active and conducting at neutral pH. These composite films can be used to make microelectrochemical enzyme transistors responsive to glucose[43] and to make devices responsive to NADH operating at pH 7.[44] In the latter case no enzyme is required because poly(aniline) is an excellent catalytic surface for the oxidation of NADH to NAD^+.[45]

Thus for glucose we have shown that we can make microelectrochemical enzyme transistors which respond rapidly and reproducibly,[25,30,31] that such devices show sensitivity to low glucose concentrations,[36] and that we can make them operate at pH 7.[43] However in all cases it has been necessary to use a freely diffusing redox mediator to couple the oxidation of the reduced flavin to the reduction of the poly(aniline). There

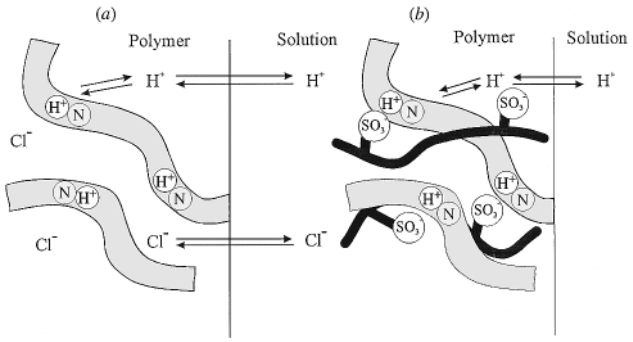

Fig. 10 Protonation equilibria for poly(aniline) films. For poly(aniline) grown with a mobile anion (*a*), such as chloride, the emeraldine state of the polymer can deprotonate on contact with neutral solutions by simultaneous expulsion of protons and chloride ions to leave the insulating emeraldine base. In contrast, for poly(aniline) films grown with long chain polymeric anions (*b*), such as poly(styrenesulfonate), the polymer can only deprotonate if it exchanges protons for cations from the solution. As a result the emeraldine form of the polymer remains protonated even when placed in contact with neural solution.

are two potential strategies to overcome this problem. The first, following the work of Heller on redox hydrogels,[7] is to use a redox polymer deposited on top of the poly(aniline) to establish electrochemical communication between the enzyme and the conducting polymer. Another alternative is to covalently attach the redox mediator to the enzyme.[5,6,46] Both approaches have been demonstrated in amperometric measurements and should work with microelectrochemical enzyme transistors if the redox potentials and rate constants for mediation are suitable.

Conclusions

Microelectrochemical enzyme transistors are good examples of integrated chemical systems as described by Wrighton[47] and Bard.[48] They are constructed by combining together, in a spatially organised manner, a number of distinct chemical components. These components (conducting polymer, insulating polymer, redox enzyme, redox mediator *etc*.) are each individually selected to perform a particular role in the final device and each possess different specific properties. By combining these discrete components in the proper way we are able to make functioning molecular devices. An important aspect of this approach is in the methods used to construct the final devices. These methods need to allow spatial control over the localisation of the different components. In constructing our microelectrochemical enzyme transistors we have used electrochemical polymerisation and adsorption to localise and immobilise the different components onto structures made using screen printing or photolithographic methods.

We believe that the prospects for the exploitation of microelectrochemical enzyme transistors and related devices are good. Their construction and operation is compatible with the current developments of disposable microsensor structures, sensor arrays[49–51] and conducting polymer based electronic circuits.[52] Microelectrochemical enzyme transistors offer significant advantages for the detection of analytes at low concentrations as a result of the inherent integration of the analyte signal and amplification that they provide. These features could be of significant benefit in developing small, disposable devices for immunoassay and DNA assay applications. Finally we note that the output of a microelectrochemical enzyme transistor can be treated digitally, that is it is possible to use such devices to make digital, as opposed to the conventional analogue, chemical sensors. In such devices the concentration of the analyte is encoded as a frequency of switching rather than as an analogue voltage or current. This is an as yet unexplored area. In addition, by combining arrays of microelectrochemical

enzyme transistors responsive to different analytes it is, in principle, possible to make devices which perform simple logical operations, again opening up a new and potentially useful field of study.

Stabilisation of charge-separated states *via* gain of aromaticity and planarity of the donor moiety in C_{60}-based dyads

Nazario Martín,*[a] Luis Sánchez[a] and Dirk M. Guldi*[b]

Received (in Liverpool, UK) 2nd November 1999, Accepted 26th November 1999

The gain of aromaticity and planarity, associated with the oxidation of a π-extended TTF electron donor, is the key feature for obtaining strong stabilisation of photolytically generated radical pairs in novel C_{60}-based dyads.

The remarkable electron-acceptor properties of fullerenes[1] evoked the implementation of fullerenes as an electron acceptor unit in the design of novel artificial light harvesting superstructures.[2] One viable approach to photosynthesis modelling has been the covalent linkage of various redox active chromophores. In this context, light-induced intramolecular charge-separation (CS) has been reported for several C_{60}-based donor–acceptor systems endowed with various electron donors. CS evolves, in most of these systems, from the singlet excited state of the fullerene unit through a series of small distance intramolecular electron transfer events yielding a charge-separated state.[3,4]

The ultimate goal is to design a system that converts sunlight into a usable form of energy with a near unit quantum efficiency. The key to accomplish this is to optimise the stability of the charge-separated state. This requirement led researchers to pursue two important concepts: (i) the increase of the donor–acceptor separation, and (ii) the use of multicomponent systems (donor–acceptor triads, tetrads, *etc.*) either in conjunction or separately.[5]

We reported recently a strategy probing organic donor molecules [*e.g.* tetrathiafulvalenes (TTFs)], linked to the fullerene core, that gain rather than lose aromaticity on CS. In particular, the one-electron oxidised form of TTF forms the 1,3-dithiolium cation, which, in contrast to the ground state, displays an extended aromatic character.[6] In fact, the lifetime of the charge-separated state was increased by a factor of *ca.* 4 relative to comparable systems that do not contain TTF.[6]

Here we present the synthesis of novel fulleroids and methanofullerenes endowed with highly conjugated TTFs having a *p*-quinodimethane structure. Cyclic voltammetry is combined with optical absorption and emission spectroscopy to study the electronic properties and excited-state interactions in dyads **3a**,**b** and **4a**,**b**.

The motivation for the current work stems from the possibility of obtaining a higher degree of stabilisation of the oxidised donor *via* adding aromatic arenes to the heteroaromatic rings of TTF. Addition of the latter is expected to enhance the aromatic stabilisation energy. In the oxidised form, the π-conjugation is extended over the entire anthracene backbone and as a net result, the dicationic species is completely aromatic.[7]

The syntheses of dyads **3a**,**b** and **4a**,**b** were carried out by a cycloaddition reaction of diazo compounds with C_{60}.[8] In the present case, diazo compounds are generated *in situ* from the extended TTF containing *p*-tosylhydrazones (**2a**,**b**) by treatment with base. Compounds **2a**,**b** are in turn prepared in good yields from the respective aldehydes (**1a**,**b**)[9] and toluene-*p*-sulfonohydrazide (Scheme 1).

The reaction of *p*-tosylhydrazones (**2a**,**b**) with C_{60} under basic conditions in toluene at 70 °C afforded the kinetic product **3a**,**b** in 27–31% yield as a mixture of the two possible [5,6] isomers.[10] [6,6]Methanofullerenes (**4a**,**b**) were prepared either under basic conditions from *p*-tosylhydrazones (**2a**,**b**) with C_{60} in refluxing toluene or from the respective [5,6]fulleroid (**3a**,**b**) by refluxing for 30 h in toluene in quantitative yield.

The ^{1}H NMR spectra of fulleroids **3a**,**b** confirm the presence of both [5,6] isomers, showing the combination of two singlets at δ 6.9 ppm (*i.e.* the isomer with the methylene hydrogen atom above a five-membered ring) and 4.1 (*i.e.* the isomer with the methylene hydrogen atom above a six-membered ring).[11] In contrast, [6,6]methanofullerenes (**4a**,**b**) give rise to a typical ^{1}H NMR singlet at δ ~5.2 corresponding to the cyclopropane proton.†

All compounds studied show the presence of four one-electron reduction steps of the fullerene core, similar to those found for the parent C_{60}, though the underlying reduction potentials are shifted to more negative values. This shift evolves from the partial loss of conjugation of the C_{60} sphere, which raises the LUMO energy of the resulting modified fullerenes.[12] Although the [5,6]fulleroids do not undergo the loss of conjugation and retain the 60π electron configuration of C_{60}, essentially no difference in the reduction potentials were found between the two isomers (*i.e.* [5-6] *vs.* [6-6], see Table 1).[13] In the anodic region, a single two-electron oxidation wave, to form the dication of the TTF moiety, was noticed for all dyads (**3a**,**b** and **4a**,**b**).[7]

Pico- and nano-second-resolved transient absorption measurements with C_{60}–(π-extended)TTF donor–acceptor dyads (**3a**,**b** and **4a**,**b**) in toluene, CH_2Cl_2 and PhCN reveal the instantaneous formation of the fullerene singlet excited state.

[a] In V *vs.* SCE; GCE; $Bu_4N^+ClO_4^-$ (0.1 M); PhMe–MeCN (4:1); 200 mV s^{-1}; **5**: 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene; in CH_2Cl_2.

Due to the presence of the electron donor [*i.e.* (π-extended)TTF] the singlet excited state absorption (λ_{max} ~ 880 nm) transforms rapidly into a broadly absorbing product. It should be noted that the decay kinetics of the singlet excited state absorption correlates with the grow-in kinetics of the new species.

Spectroscopic evidence suggests that this newly formed transient can be ascribed to the charge-separated radical pair, namely, $C_{60}^{\bullet-}$–(π-extended)$TTF^{\bullet+}$. In particular, maxima at 660 and 680 nm are in excellent agreement with the pulse radiolytically generated (π-extended)TTF π-radical cations at 660 (R = H) and 675 nm (R = SMe), respectively.[14] On the other hand, the two isomeric fullerenes give rise to different π-radical anion absorptions at 1040 ([6-6]-closed)[15] and 1070 nm ([6-5]-open).[16]

Generally, the intramolecular ET rates (see Table 1) depend on (i) the donor strength of the π-extended tetrathiafulvalene derivative (*e.g.* R = H *vs.* R = SMe), (ii) the excited state energy of the fullerene derivative (*e.g.* [6-6]-closed *vs.* [6-5]-open isomer) and (iii) the solvent polarity (*e.g.* toluene *vs.* PhCN).

Independent confirmation for the rapid and, more importantly, solvent-dependent deactivation of the fullerene singlet excited state in dyads **3a**,**b** and **4a**,**b** evolves from complementary fluorescence measurements. The fluorescence quantum yields (Θ) and also the fluorescence lifetimes (τ) showed, beside a marked solvent dependence, a correlation with the donor strength of the TTF moiety. Specifically, Θ and τ values in photoexcited **3a** and **4a** are lower relative to **3b** and **4b**, respectively.

The lifetimes of the charge-separated states in all these C_{60}–(π-extended)TTF dyads (**3a**,**b** and **4a**,**b**) are remarkable. For example, they are in the range of several hundred nanoseconds in deoxygenated PhCN and slightly lower in the less polar CH_2Cl_2. In contrast, the parent TTF dyads (*e.g.* a donor moiety that undergoes simply a gain of aromaticity upon oxidation) or zinc tetraphenylpoprhyrin dyads (*e.g.* an electron donor which lacks both the gain in planarity and in aromaticity upon oxidation) yielded radical pairs with lifetimes of about 2[6] and 0.5 ns,[4] respectively. Therefore, we rationalise the increased stability of the $C_{60}^{\bullet-}$-(π-extended)$TTF^{\bullet+}$ pair with the stabilisation of the donor. The gain of aromaticity and planarity, associated with this oxidation, yields a state of lower energy. Consequently, reduction of the oxidised (π-extended)TTF donor, in a sense of charge recombination, requires a higher activation energy to proceed than the corresponding processes in C_{60}–TTF and C_{60}–ZnTPP dyads.

We are indebted to DGICYT (Project PB98-0818) for financial support. Part of this work was supported by the Office of Basic Energy Sciences of the U.S. Department of Energy (contribution No. NDRL-4188 from the Notre Dame Radiation Laboratory).

16 Since this is the first report on the π-radical anion absorption band of a [6-5]-open fulleroid, we conducted complementary pulse radiolytic experiments to reduce the fullerene under experimental conditions described in ref. 15. The recorded spectrum with λ_{max} at 1070 nm is identical to the photolytically generated spectrum and, thus, serves as additional confirmation for the spectral assignment.

Conjugate addition of diethylzinc to α,β-unsaturated lactones catalyzed by copper–phosphite complexes

Ming Yan, Zhong-Yuan Zhou and Albert S. C. Chan*

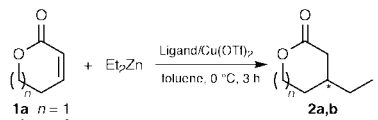
Open Laboratory of Chirotechnology and Department of Applied Biology and Chemical Technology, The Hong Kong Polytechnic University, Hong Kong, China. E-mail: bcachan@polyu.edu.hk

Received (in Cambridge, UK) 25th October 1999, Accepted 23rd November 1999

Highly enantioselective conjugate addition of diethylzinc to α,β-unsaturated lactones was achieved by using chiral diphosphite–copper catalysts; the structure of a chiral diphosphite–copper(I) catalyst was determined by single crystal X-ray diffraction.

The enantioselective conjugate addition of organometallic reagents to α,β-unsaturated ketones and esters provides an efficient method for asymmetric carbon–carbon bond formation in organic synthesis.[1] In recent years copper complexes of various chiral phosphorus ligands have been used as efficient catalysts for the conjugate addition of organozinc reagents to enones,[2] but there are no reports concerning the asymmetric conjugate addition of organozinc reagents to α,β-unsaturated lactones. Tomioka reported the enantioselective conjugate addition of Grignard reagents to 5,6-dihydro-2*H*-pyran-2-one catalyzed by a chiral phosphine–copper iodide catalyst with good enantioselectivity. However, a high loading of chiral ligand (32 mol%) was necessary to achieve high enantioselectivity.[3] Recently we found chiral aryl diphosphites to be efficient ligands for the copper-catalyzed conjugate addition of diethylzinc to cyclic enones.[4,5] Here we report the enantioselective conjugate addition of diethylzinc to α,β-unsaturated lactones with chiral diphosphite–copper catalysts. A cationic chiral diphosphite–copper(I) catalyst was isolated and its structure was determined by single crystal X-ray diffraction.

Table 1 Conjugate addition of diethylzinc to α,β-unsaturated lactones catalyzed by copper–phosphorus complexes[a]



1a $n = 1$
b $n = 0$

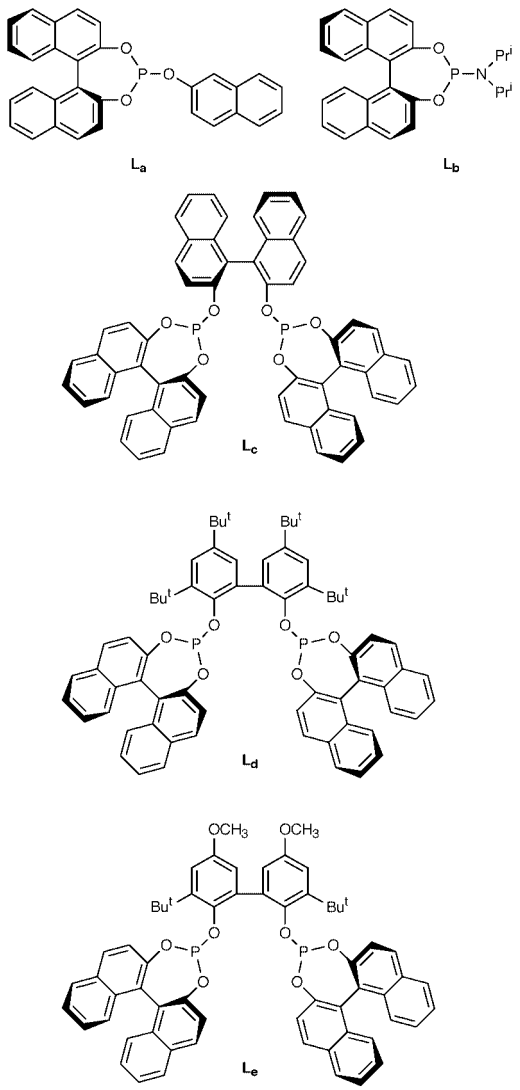
2a,b

Entry	Ligand	Substrate	Conversion (%)[b]	Ee (%)[b]
1	—	**1a**	—	—
2	PPh_3	**1a**	14.3	—
3	$P(OPh)_3$	**1a**	10	—
4	$P(OEt)_3$	**1a**	17	—
5	$\mathbf{L_a}$	**1a**	68.4	10
6	$\mathbf{L_b}$	**1a**	66.9	16.8
7	$\mathbf{L_c}$	**1a**	100	73
8	$\mathbf{L_c}$	**1b**	85.2	38.5
9	$\mathbf{L_d}$	**1a**	100	92
10[c]	$\mathbf{L_d}$	**1a**	100	91.1
11[d]	$\mathbf{L_d}$	**1a**	100	86.7
12[e]	$\mathbf{L_d}$	**1a**	93	88.3
13	$\mathbf{L_d}$	**1b**	77	56.0
14	$\mathbf{L_e}$	**1a**	94.6	89.5
15	$\mathbf{L_e}$	**1b**	100	38.6

[a] The reactions were carried out in toluene at 0 °C for 3 h (copper : ligand : substrate : Et_2Zn = 0.01 : 0.02 : 1 : 1.5). [b] The data on conversion and the ee values of **2a** and **2b** were determined by GC with a Chiraldex A-TA column (30 m × 0.25 mm). [c] $[Cu(OTf)]_2$·benzene was used as the source of copper ($\mathbf{L_d}$/Cu = 2). [d] $[Cu(OTf)]_2$·benzene was used as the source of copper ($\mathbf{L_d}$/Cu = 1). [e] Isolated $[Cu\mathbf{L_d}(MeCN)_2]^+$ $CF_3SO_3^-$ was used as the catalyst.

The conjugate addition of diethylzinc to 5,6-dihydro-2*H*-pyran-2-one **1a** was selected as a model reaction. Typically the reaction was carried out in toluene at 0 °C for 3 h, using 1 mol% $Cu(OTf)_2$ and phosphorus ligands (4 mol% monodentate phosphorus ligands or 2 mol% bidentate phosphorus ligands) as the catalysts, and the results are summarized in Table 1.

$Cu(OTf)_2$ did not show catalytic activity activity in the absence of phosphorus ligands (entry 1). The $Cu(OTf)_2$ complexes of PPh_3, $P(OPh)_3$ and $P(OEt)_3$ showed low catalytic activity (entries 2–4).[6] Chiral phosphite $\mathbf{L_a}$ and phosphorus amidite $\mathbf{L_b}$ provided higher acceleration effects, but the enantioselectivities were rather poor (entries 5 and 6).[7,8] When aryl diphosphite $\mathbf{L_c}$ and $\mathbf{L_d}$ were examined in the reaction, high catalytic activity was achieved (entries 7 and 9). In addition excellent enantioselectivity was obtained when $Cu(OTf)_2$–$\mathbf{L_d}$



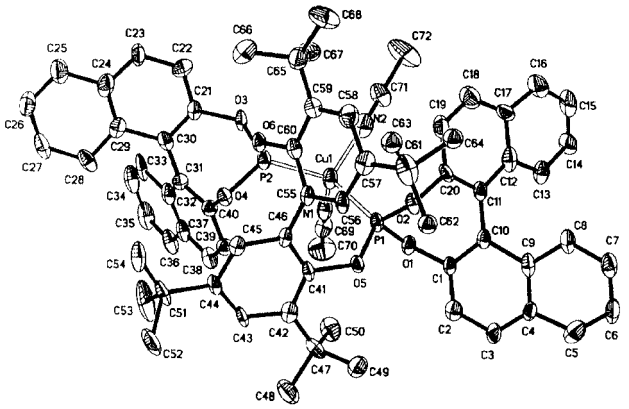


Fig. 1 ORTEP drawing of the molecular structure of [Cu$\mathbf{L_d}$(MeCN)$_2$]$^+$OTf$^-$. The triflate and hydrogen atoms have been omitted for clarity. The *tert*-butyl group (C47–C50) is disordered and only one of the disordered sets of atoms is shown. The P1–Cu–P2 angle is 119.1°. The bond lengths of P1–Cu and P2–Cu are 2.242 and 2.214 Å, respectively. The dihedral angles of the two binaphthyl units are 57.4 and 55.7°. The bridging 3,3′,5,5′-tetra-*tert*-butylbiphenol unit has a dihedral angle 61.5°.

complex was used as the catalyst (entry 9). To the best of our knowledge, this is the first example of the highly enantioselective conjugate addition of an organozinc reagent to an α,β-unsaturated lactone. The reaction was found to be highly regioselective and no 1,2-addition product was observed by GC analysis. When [Cu(OTf)]$_2$·benzene–$\mathbf{L_d}$ was tested as the catalyst in the conjugate addition of diethylzinc to **1a**, similar enantioselectivity was observed as that from using Cu(OTf)$_2$–$\mathbf{L_d}$ complex (entry 10 *vs.* entry 9). The $\mathbf{L_c}$–Cu(OTf)$_2$ and $\mathbf{L_d}$–Cu(OTf)$_2$ complexes were also tested in the addition of diethylzinc to 5*H*-furan-2-one **1b** and 38.5 and 56.0% ee were obtained respectively (entries 8 and 13).

A catalytic cycle for copper-catalyzed conjugate addition of diethylzinc to cyclic enones had been proposed by Fergina.[2a] A copper(I) species was proposed to be the catalyst in the reaction and direct evidence to support this hypothesis is desirable. To this end we carefully chose crystallization conditions and obtained colorless crystals from an MeCN solution of $\mathbf{L_d}$ and [Cu(OTf)]$_2$·benzene. A single crystal X-ray diffraction study of this species revealed a Cu$^{\text{I}}$ complex with the molecular formula [Cu$\mathbf{L_d}$(MeCN)$_2$]$^+$ OTf$^-$ which took a twist tetrahedron geometry (Fig. 1).† The *tert*-butyl group (C47–C50) is disordered.

As expected the isolated [Cu$\mathbf{L_d}$(MeCN)$_2$]$^+$OTf$^-$ crystals were also found to be an efficient catalyst in the conjugate addition of diethylzinc to **1a** (entry 12) and the enantioselectivity was similar to that obtained using the [Cu(OTf)]$_2$·benzene–$\mathbf{L_d}$ catalyst prepared *in situ* ($\mathbf{L_d}$/Cu = 1. entry 11). The X-ray crystallography of the [Cu$\mathbf{L_d}$(MeCN)$_2$]$^+$OTf$^-$ complex showed that the two terminal binaphthyl units form a good chiral pocket around the copper atom. In addition the four *tert*-butyl groups in the bridging biphenyl unit effectively fix the conformation of the complex and shield the space above the copper atom. In order to assess the importance of the *tert*-butyl groups at the 5,5′-positions of the bridging biphenyl unit, ligand $\mathbf{L_e}$ was prepared and tested for the reaction. The Cu(OTf)$_2$–$\mathbf{L_e}$ complex also gave good enantioselectivity in the conjugate addition of diethylzinc to **1a** (entry 14).

We thank The Hong Kong Polytechnic University and The Hong Kong Research Grant Council (Project number PolyU34/96P) for financial support of this study.

Pd^0-catalyzed cyclization reaction of aryl or alk-1-enyl halides with 1,2-dienyl ketones: a general and efficient synthesis of polysubstituted furans

Shengming Ma* and Junliang Zhang

Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Lu, Shanghai 200032, P. R. China. E-mail: masm@pub.sioc.ac.cn

Received (in Cambridge, UK) 29th October 1999, Accepted 30th November 1999

Under catalysis by Pd^0 and Ag_2CO_3, the reaction of 1,2-allenyl ketones and organic halides in PhMe using Et_3N as the base provides a new general access to polysubstituted furans with good to excellent yields.

Furans, one of the most prominent classes of heterocyclic compounds, can be found in many naturally occurring products,[1] commercially important pharmaceuticals, and flavor and fragrance compounds.[2] They are also considered as important synthetic intermediates for the preparation of numerous cyclic and acyclic compounds.[3] Usually, 3-, 2,3-, 2,4-, 3,4-, 2,3,4- and 2,3,5-substituted furans[4] can be synthesized *via* acyclic precursors or derivatization of simple furans.[5] Owing to its potential and diversity, much attention has been paid to the synthesis of furans from acyclic precursors. Some of the most important and interesting methodologies are as follows: (i) cyclization of alk-4-yn-1-ols;[6] (ii) cyclization of alk-3-yn-1-ols;[7] (iii) $AlCl_3$-catalyzed cyclization of acyl chlorides with 1,2-allenyl silanes;[8] (iv) epoxidation and subsequent HgO-catalyzed cyclization of alk-1-enyl alk-1′-ynyl methanols;[9] and (v) Pd-catalyzed cyclization of (*Z*)-2-iodoalk-2-enyl ketones.[10]

Recently, Marshall *et al.*[11] reported the Rh^+- or Ag^+-catalyzed direct one-component cyclization of 1,2-dienyl ketones to afford substituted furans with obvious limitations (mainly R^3 = H, Scheme 1). Since the introduction of substituents at the 3- and/or 4-position of the corresponding unsubstituted furans is difficult, efficient and general methodologies for furans with substituents at some or all of the four positions are still of current interest. During the course of our study of functionalized allenes,[12,13] we envisioned that a Pd^0-catalyzed cyclization of an organic halide with a 1,2-dienyl ketone would provide an efficient and general route to polysubstituted furans with the unique assembly of substituents at the different positions, depending on the substitution of both reactants (Scheme 1).[14]

1,2-Dienyl ketones with different substitution patterns are easily available.[12c,14b,15] As a starting point, we studied the Pd^0-

[a] Generally, the reaction was carried out using 1,2-allenyl ketone (1.5 equiv.), R^3X (1.0 equiv.), and 5 mol% of $Pd(PPh_3)_4$ in PhMe, unless otherwise stated. [b] The numbers in the parenthesis are the equiv. of R^3X used. [c] Isolated yield. [d] The configuration of the C=C bond in R^3 is *trans*.

catalyzed cyclization reaction of heptadeca-3,4-dien-2-one **2a** with PhI under various reaction conditions. After some screening, we found that the $Pd(PPh_3)_4$-catalyzed cyclization reaction of PhI with **2a** afforded the expected product **3a** in 88% yield together with the formation of **4a** in only 9% yield by using 5 mol% ($Pd(PPh_3)_4$ as the catalyst, toluene as the solvent, and Et_3N (2.0 equiv.)–Ag_2CO_3 (10 mol%) as the base. Similar to the cyclization reaction of 1,2-allenic carboxylic acids, we observed that a catalytic amount of Ag_2CO_3 is crucial to this reaction (Scheme 2).

Using these standard conditions, we studied this new and efficient synthetic methodology for the synthesis of polysubstituted furans with differently substituted 1,2-dienyl ketones as well as different kinds of organic halides (Scheme 3). The results are summarized in Table 1.

The results in Table 1 show that (i) the yields for this reaction range from moderate to excellent, with the highest being 97% (entry 11, Table 1); (ii) both electron-rich and electron-deficient aryl halides afforded the corresponding furans; (iii) substituents at different positions of furans could be introduced, depending on the structure of allenyl ketones and organic halides; and (iv) the reaction of methyl (*Z*)-3-iodopropenoate[16] yielded the product **3h**, providing an opportunity for further elaboration of the substitutions at the 4-position (entry 8, Table 1).

In conclusion, we have developed an efficient method for the synthesis of substituted furans with different substitution patterns. The study of new methodologies for differently substituted 1,2-allenyl ketones and the scope of this cyclization reaction, as well as its application in the synthesis of target molecules with potential activities, are currently being carried out in our laboratory.

We are grateful to the National Natural Science Foundation of China, the Chinese Academy of Sciences and the Shanghai Municipal Committee of Science and Technology for financial support. S.M. thanks the Hong Kong Qiu Shi Foundation of Science and Technology for the 1999 Qiu Shi Award for Young Scientific Workers (1999–2003).

A new benchmark for the non-enzymatic enantioselective acylation of amines: use of a planar-chiral derivative of 4-pyrrolidinopyridine as the acylating agent

Yutaka Ie and Gregory C. Fu*

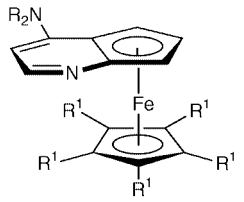
Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139 USA. E-mail: gcf@mit.edu

Received (in Corvallis, OR, USA) 27th October 1999, Accepted 23rd November 1999

_N_-Acetylated Ph-PPY*, a new planar-chiral derivative of PPY, serves as an effective reagent for the enantioselective acylation of racemic amines, providing amides with very good stereoselectivity.

In recent years substantial progress has been made in the development of non-enzymatic catalysts for the enantioselective acylation of alcohols.[1,2] In contrast, to the best of our knowledge there have been no reports of effective non-enzymatic catalysts for the enantioselective acylation of amines.[3,4] Indeed, there has been only limited success even with stoichiometric chiral acylating reagents.[5]

We have recently described applications of planar-chiral



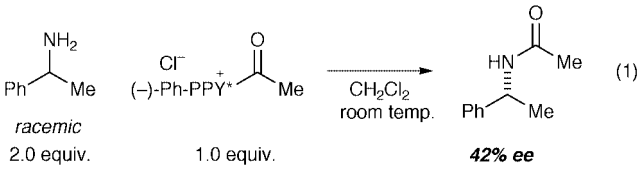
R^1 = Me, NR_2 = dimethylamino (–)-**1** (DMAP*)
R^1 = Me, NR_2 = pyrrolidino (–)-**2** (PPY*)
R^1 = Ph, NR_2 = dimethylamino (–)-**3** (Ph-DMAP*)
R^1 = Ph, NR_2 = pyrrolidino (–)-**4** (Ph-PPY*)

heterocycles (*e.g.* **1**–**3**) as nucleophilic catalysts for a variety of processes, including the enantioselective acylation of secondary alcohols.[6,7] Unfortunately, our attempts to extend this catalytic process to amines were frustrated by the facility with which amines react directly with acylating agents such as acetic anhydride, thereby providing a competitive, non-enantioselective pathway.

We therefore defined our immediate objective to be the development of a highly enantioselective stoichiometric reagent for the acylation of amines. Since progress toward this goal has been quite modest,[5] we felt that this in itself would be a worthwhile achievement.[8] Building on our recent discovery that planar-chiral Ph-DMAP* (**3**) undergoes *N*-acylation when treated with 1 equiv. of acetyl chloride,[2d] we examined the use of the acylated derivatives of iron complexes **1**–**4** as chiral reagents for the stereoselective acylation of (±)-1-phenylethylamine.

Our initial studies revealed that 4-pyrrolidino complexes provide higher ee than do 4-dimethylamino complexes and that complexes that bear the more bulky C_5Ph_5 group furnish better enantioselectivity than do those that bear the C_5Me_5 group. These cumulative substituent effects lead to the acylated form of a new planar-chiral PPY derivative (**4**; Ph-PPY*) being the most enantioselective acylating agent among complexes **1**–**4** [eqn. (1)].[9–11]

An optimization study established that the enantioselectivity with which acylated Ph-PPY* reacts with (±)-1-phenylethylamine varies with solvent. Although at room temperature several solvents furnish greater enantiomeric excess than does CH_2Cl_2 (Table 1), the stereoselection in CH_2Cl_2 is significantly



racemic 2.0 equiv. 1.0 equiv. 42% ee (1)

temperature-dependent, and acylation in CH_2Cl_2 at −78 °C affords the highest ee of the conditions that we have examined (78% ee; entry 3). Interestingly, the relationship between ee and solvent that we observe for the acylation of (±)-1-phenylethylamine differs from what we have observed for the catalytic asymmetric acylation of (±)-1-phenylethanol.[2b]

For enantioselective acylations of this sort, the ee of the amide product should increase when the ratio of amine to acylating agent is increased.[12] Consistent with this expectation, under otherwise identical conditions we obtain amide with 87% ee when we employ 8.0 equiv. of amine (Table 2, entry 1), compared with 78% ee when we use 2.0 equiv. of amine (Table 1, entry 3).

Under these reaction conditions, we can achieve the stereoselective acylation of a family of racemic amines with very good enantioselection (Table 2).[13] With respect to substituent effects, we observe somewhat lower ee as the steric demand of the alkyl substituent increases (entry 1 *vs.* entry 2). The stereoselectivity appears to be modestly dependent on the electronic nature of the aryl substituent, with acylations of (±)-1-phenylethylamine proceeding with higher enantioselection than either more electron-rich or more electron-poor derivatives (entry 1 *vs.* entries 3 and 4, respectively). As illustrated in Table 2, *N*-acylated Ph-PPY* efficiently differentiates the enantiomers of amines that bear a range of aromatic substituents (*e.g.* see entries 5 and 6).

[a] Average of two runs.

In summary, we have established that *N*-acylated Ph-PPY*, a new planar-chiral derivative of PPY, can serve as an effective reagent for the enantioselective acylation of racemic amines. Compared with other reagents that have been reported for this process, the level of stereoselectivity furnished by *N*-acyl Ph-PPY* represents a significant advance in the state of the art. This work thus marks an important first step toward the development of an efficient non-enzymatic catalyst for the asymmetric acylation of amines. Ongoing investigations are focused on the discovery of acylating agents that will permit this challenging goal to be achieved.

Support has been provided by Bristol-Myers Squibb, Merck, the National Institutes of Health (National Institute of General Medical Sciences, R01-GM57034), Pfizer, Pharmacia & Upjohn, and Procter & Gamble. We thank J. Craig Ruble and Beata Tao for preliminary studies.

Chem. Soc.*, 1998, **120**, 11 532; B. L. Hodous, J. C. Ruble and G. C. Fu, *J. Am. Chem. Soc.*, 1999, **121**, 2637.

8 For example, with respect to the development of non-enzymatic methods for the kinetic resolution of alcohols, the discovery of effective stoichiometric reagents (D. A. Evans, J. C. Anderson and M. K. Taylor, *Tetrahedron Lett.*, 1993, **34**, 5563; E. Vedejs and X. Chen, *J. Am. Chem. Soc.*, 1996, **118**, 1809) preceded the discovery of effective catalysts (refs. 1 and 2).

9 The stereochemical preference of the complex appears to be the 'same', regardless of whether the substrate is an amine or an alcohol: acylated (−)-Ph-PPY* preferentially acylates (*R*)-1-phenylethylamine, and (−)-Ph-PPY*/Ac_2O preferentially acylates (*R*)-1-phenylethanol.

10 A preliminary study indicated that other *N*-acyl groups (*e.g.* pivaloyl) furnish lower enantioselectivity.

11 In contrast to our earlier papers on kinetic resolutions, in which we assessed stereoselection by focusing on the selectivity factor, in this work we have chosen to focus instead on the enantiomeric excess of the product. This is due to the fact that, because amine hydrochloride is the other product of these acylation reactions, calculation of a selectivity factor is not completely straightforward (the amine substrate is being 'consumed' both by acylation and by protonation).

12 H. B. Kagan and J. C. Fiaud, *Top. Stereochem.*, 1988, **18**, 249.

13 We have established that at the end of a reaction we can recover Ph-PPY* in 95% yield.

Received (in Basel, Switzerland) 21st October 1999, Accepted 6th December 1999

Previously unobserved pentadentate coordination of a tris(pyrazolyl)borate ligand has been ascertained in the compound Ir[κ^5(*N*,*N*′,*N*″,*C*^{Ph},*C*$^{Ph'}$)-Tp^{Ph}](η^2-C$_2$H$_4$) (Tp^{Ph} = hydridotris(3-phenylpyrazolyl)borate] that forms by thermal activation of a mixture of [IrCl(coe)$_2$]$_2$ (coe = cyclooctene) with TlTp^{Ph} and ethene, through the intermediacy of Ir[κ^4(*N*,*N*′,*N*″,*C*^{Ph})-Tp^{Ph}](Et)(η^2-C$_2$H$_4$).

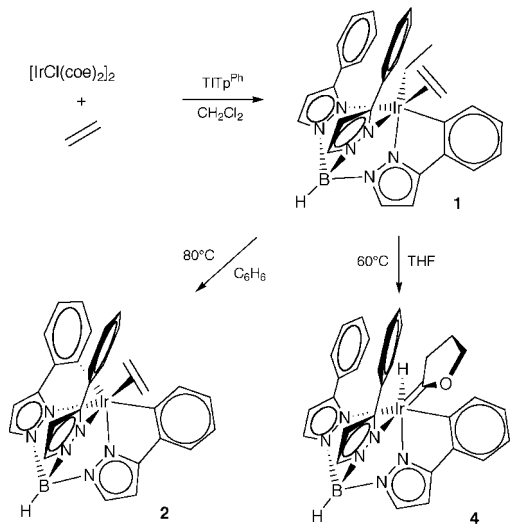
Denticity beyond κ^4 has never been encountered for Tp^R where R contains no heteroatoms. We are reporting herewith the synthesis of the first examples of a Tp^{Ph} ligand acting in an unprecedented pentadentate, as well as tetradentate, fashion in Ir(III) complexes, and the structural characterization of representative compounds.

Homoscorpionate ligands, Tp^R, where R is a 3-substituent on the pyrazolyl ring, have overwhelmingly exhibited a κ^3 coordination mode, usually κ^3-*N*, *N*′,*N*″,[1] and sometimes also κ^3-*N*, *N*′,*H*,[2,3] although lower denticity, such as κ^2-*N*,*N*′, κ^2-*N*,*H*, κ^1-*N*, and even κ^0 (where the Tp^R ligand serves only as an uncoordinated counter ion) has also been encountered.[4] By contrast, expansion of Tp^R denticity beyond κ^3 is rare. On the one hand this can occur by way of the 3-R substituent containing donor atoms, as in the demonstrably hexadentate Tp^{py},[5] or in the potentially hexadentate ligands Tp^{oAn},[6] or Tp$^{2,4(OMe)2Ph}$.[7] On the other hand, tetradenticity has been reported in Tp^R ligands where R contained no donor atoms, either by way of agostic bonding,[8] or through cyclometalation taking place at one of the aliphatic R groups per ligand,[9] or when an oxidative functionalization of one R group per ligand took place, leading to a C–O–M bond.[10,11] An example of reversible oxidative addition of the *ortho*-C–H of the phenyl group in the RhTp^{Ph}(CO)$_2$ complex, thus making the Tp^{Ph} ligand κ^4, has been reported in a dissertation.[12]

The reaction of [IrCl(coe)$_2$]$_2$ (coe = cyclooctene) with ethene and TlTp^{Ph} in CH$_2$Cl$_2$ produced the cyclometalated compound Ir[κ^4(*N*,*N*′,*N*″,*C*^{Ph})-Tp^{Ph}](Et)(η^2-C$_2$H$_4$) **1** (Scheme 1).† This was in sharp contrast to the related reactions of [IrCl(coe)$_2$]$_2$ with ethene and KTp or KTp^{Me2}, which under identical conditions produced the Ir(I) complexes IrTp^{Me2}(η^2-C$_2$H$_4$)$_2$. The propensity of the Ir(I)Tp^R fragments to induce C–H bond activation, enhanced in the present case by the increased steric bulk of the Tp^{Ph} ligand, and coupled with the close proximity of the phenyl rings to the metal, can be used to rationalize the facile activation of one of the phenyl rings, and one of the ethene ligands. The X-ray structure of **1** (see ESI) showed Ir in a distorted octahedral environment,‡ as indicated by the bite angles of the Tp^{Ph} ligand: N(3)–Ir–N(5) 83.3(1)°, N(1)–Ir–N(3) 92.8(2)°, N(1)–Ir–N(5) 76.1(1)°. The difference between the latter two (16.7°) is substantially larger than usual values (< 10°). The metalated phenylpyrazolyl unit showed a strong distortion by which the boron atom and the phenyl ring are considerably displaced from the plane of the pz ring: B by 0.73 Å, Ir by 0.37 Å and C(4) by 0.28 Å. At this stage, it appears appropriate to draw attention on the similarity of the cyclometalation of the phenylpyrazolyl unit of the Tp^{Ph} ligand that leeds to complex **1**, with related transformations that involve donors such as 2-phenylpyridine, 1-phenylpyrazole or bipyridine.[13,14] The metalation of the benzene ring of these compounds attached to the functional group that possesses the donor atom, requires, in general, more forcing conditions[14] than those needed for the generation of **1** but yields related organometallic complexes that incorporate the heterocyclic donor atom.[14]

Refluxing complex **1** in benzene for 17 h produced the bismetalated species Ir[κ^5(*N*,*N*′,*N*″,*C*^{Ph},*C*$^{Ph'}$)-Tp^{Ph}](η^2-C$_2$H$_4$) **2**, as the only product (NMR monitoring).§ The proposed κ^5 coordination mode was suggested by the presence of four carbon signals in the range δ 123.2–122.5 (this is also the case in compound **3**, *vide infra*). Refluxing **1** in toluene, converted it completely to **2** in 4.5 h. It can be concluded, therefore, that **2** is thermodynamically favored over the *a priori* expected compound Ir[κ^3(*N*,*N*′,*N*″)-Tp^{Ph}](Ph)$_2$(L), where L could be either ethene or dinitrogen, as was in the case with IrTp*(η^2-C$_2$H$_4$)$_2$.[15]

A related compound, which also contained a κ^5-Tp^{Ph} ligand, Ir[κ^5(*N*,*N*′,*N*″,*C*^{Ph},*C*$^{Ph'}$)-Tp^{Ph}](κ^1(*N*^{1})-3-phenylpyrazole) **3**, was formed upon treatment of [IrCl(coe)$_2$]$_2$ with 2,3-dimethylbutadiene and TlTp^{Ph}, the 3-phenylpyrazole resulting from partial ligand degradation. Surprisingly, a direct reaction of **2** with the free pyrazole, Hpz^{Ph}, proceeded only slowly, and yielded other products, in addition to **3**. Spectroscopic data for **3** were in agreement with the proposed structure. While ^{11}B NMR and ν(B–H) data for **3** (as for **1** and **2**) did not indicate the coordination mode of the Tp^{Ph} ligand,[16] the ^{13}C NMR spectrum showed characteristic signals for carbon atoms of the metalated rings at δ 122.9, 122.5, 122.4, and 121.5. By comparison, **1** had only two signals in this region, at δ 122.2 and 121.9. It is



Scheme 1

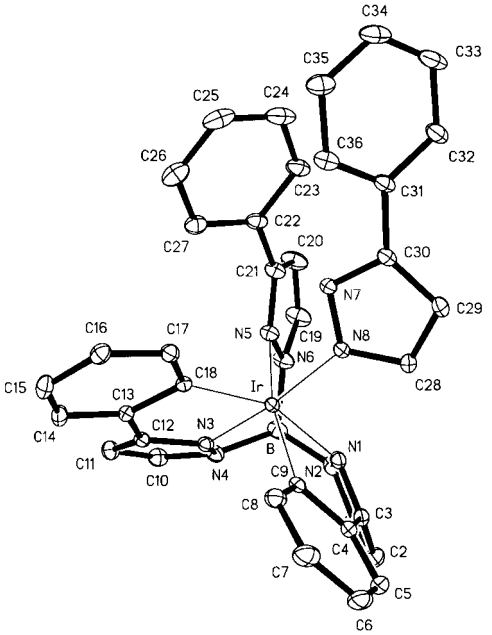

Fig. 1 ORTEP plot of **3** (hydrogen atoms omitted for clarity; thermal ellipsoids are at the 20% probability level). Selected bond lengths (Å) and angles (°): Ir–N(1) 2.114(2), Ir–N(3) 1.989(2), Ir–N(5) 2.219(2), Ir–C(9) 2.053(2), Ir–C(18) 2.051(2), Ir–N(8) 2.059(2), N(3)–Ir–N(1) 84.1(1), N(3)–Ir–N(5) 79.2(1), N(1)–Ir–N(5) 88.7(1), N(3)–Ir–N(8) 172.7(1), N(3)–Ir–C(9) 103.6(1), N(3)–Ir–C(18) 79.3(1), C(9)–Ir–N(1) 77.7(1), C(18)–Ir–C(9) 91.4(1).

noteworthy, that both **2** and **3** contained inequivalent pyrazolyl and phenyl rings. Thus, the diastereoselective cyclometalation of the 3-phenyl group of the pz^{Ph} ring *trans* to the monodentate ligand (in the case of **3**, 3-phenylpyrazole), gave rise to asymmetry of the molecule.

The ORTEP diagram of **3**, along with important bond lengths and angles is shown in Fig. 1.‡ The two Ir–C bond lengths are identical within experimental error [2.053(2) Å] and are also identical to the two Ir–C_6H_5 bonds of the somewhat related compound $[IrTp^*(Ph)_2]_2(\mu\text{-}N_2)$ [2.06(2) Å],[15] while Ir–C(9) of **1** is slightly shorter [2.030(4) Å]. Considerable distortion of the pentadentate Tp^{Ph} ligand is evident from Fig. 1. Whereas the d^6 Ir(III), and the bonding implicit in the coordination to the three N atoms of a Tp^R ligand strongly favour octahedral coordination,[17] an unstrained metalation of the two phenyl rings would lead to trigonal prismatic geometry. Reconciling these two desiderata, the dimetalated Tp^{Ph} ligand becomes highly distorted. The degree of distortion of the two Ir–C^{Ph} bonded entities is manifested by the values of the bond angles around iridium [77.7–103.6(1)°, *cisoid*; 157.4–172.7(1)°, *transoid*], and also by the out-of-plane bending of B, Ir and the C atoms C(4) and C(13) of the phenyl substituents with respect to the pz planes. These deviations are 0.763(4), 0.889(4) and 1.101(4) Å for B, Ir and C(4), respectively, referred to the N(1)N(2)C(1)C(2)C(3) ring, and 0.619(4), 0.860(3) and 0.294(3) for B, Ir and C(13), respectively, with respect to the ring containing N(3) and N(4).

In conclusion, we have demonstrated the first instance of κ^5 coordination of a Tp^R ligand. This work also shows that the tendency of Tp^R ligands to strongly favor octahedral geometry at the coordinated metal centers is so pronounced that even severe ligand distortions can be accommodated. The thermodynamic stability of the metalated compounds in refluxing benzene is surprising, in view of the results observed in related systems, and may be due to the chelate effect. The presently reported compounds and related Ir(I) complexes seem to be suitable for various C–H activation reactions. As represented in Scheme 1, compound **1** reacts in THF at 60 °C to yield the Fischer carbene complex **4** as the sole product. Moreover, the phenyl groups could be used as internal probes for C–H activation, as was demonstrated by the incorporation of 1.6 deuterium atoms into only one of the phenyl rings during the reaction of **1** with THF-d_8, producing the appropriate analog of **4**. These, and related, C–H activation reactions are currently being studied.

See http://www.rsc.org.suppdata/cc/a9/a908478i/ for crystallographic files in .cif format.

§ Following an NMR-tube reaction (benzene-d_6, 60 °C) an intermediate could be observed, which was not characterized, but was thought to be Ir[κ^4(*N*,*N*′,*N*″,*C*^{Ph})-Tp^{Ph}](Ph)(η^2-C_2H_4). Cyclohexane and hexafluorobenzene as the solvents gave **2**, but a related intermediate was not observed. Using C_6D_6 as the solvent results in perdeuteration of **2** but not of the ethene-ligand.

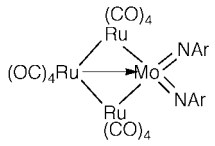
Received (in Basel, Switzerland) 8th November 1999, Accepted 7th December 1999

Room temperature reaction of $K_2[Ru_3(CO)_{11}]$ with the molybdenum(VI) bis(imido) complexes $Mo(NAr)_2Cl_2(dme)$ (Ar = $C_6H_3X_2$-2,6; X = Me, Pr^i, Cl; dme = 1,2-dimethoxyethane) affords new high-low valent clusters $Ru_3(CO)_{12}\{Mo(NAr)_2\}$ which adopt a butterfly arrangement of metal centres with $[Ru_3(CO)_{12}]^{2-}$ acting as a ligand at a molybdenum(VI) centre.

Molecular transition metal complexes can broadly be divided into those containing the metal centre in either a high and or low oxidation state. While in most respects the chemistry displayed in these two areas is quite different, metal–metal bonding is prevalent in both. Moreover, there is an increasing number of examples in which metal–metal bonds are formed between high- and low-valent metal centres. These include the classic W(V)–W(I) complex $Cp^*W(CO)_3$–WO_2Cp^* prepared by Alt *et al.*,[1] while Sundermeyer has recently reported a range of related bi- and tri-nuclear imido-containing complexes.[2] In these, metal–metal bonds are found between the high- and low-valent centres but, even when more than one of the former is present, there are no metal–metal bonds between the low-valent centres. That is, clusters of this type are of the linear variety. Chi and coworkers[3,4] have synthesised a number of group 6/8 mixed-metal clusters containing imido ligands, however, here it is noted that the π-donor ligands are rarely bound in a monodentate fashion,[4] but rather bridge two or more metal centres.[3] As such, all metal centres in such clusters can be considered to be of similar valency. In contrast, Puddephatt and coworkers[5] have prepared the tetrahedral cluster cation $[Pt_3(ReO_3)(\mu\text{-dppm})_3]^+$ where the formal metal oxidation states may be considered as Re(VII) and Pt(0), yet it is characterised by three strong Pt–Re interactions.

Over the past thirty years, low-valent carbonyl clusters have been the focus of intensive research and a wide range of cluster geometries have been found.[6] Cluster frameworks are generally soft and deformable, with the geometries adopted dependent upon the number of electrons. Further, many are easily oxidised and/or reduced and as such have the ability to act as efficient electron sinks. Both of these properties, if controllable, would make the cluster useful as a ligand. Herein we describe the use of the low-valent cluster $[Ru_3(CO)_{12}]^{2-}$ as a ligand to a high-valent, bis(imido) stabilised molybdenum centre.

Room temperature addition of thf solutions of $K_2[Ru_3(CO)_{11}]$[7] and $Mo(NAr)_2Cl_2(dme)$[8] resulted in the formation of very dark solutions which were left to stir overnight. Work-up in an aerobic atmosphere resulted after chromatography in the isolation of $Ru_3(CO)_{12}$ and the new clusters $Ru_3(CO)_{12}\{Mo(NAr)_2\}$ **1a**–**c** in yields of 20–30% Clusters **1a**–**c** show good solubility in hexane and are air-stable in this solvent. Characterisation was made on the basis of IR, NMR and mass spectra.† Crystals of **1a** suitable for X-ray analysis were easily grown upon cooling a saturated hexane solution to −20 °C, the results of which are summarised in Fig. 1.‡



1

Ar = $C_6H_3R_2$-2,6: **a** R = Me, **b** R = Pr^i, **c** R = Cl

The molecule consists of a butterfly arrangement of one molybdenum and three ruthenium atoms, with a fold angle of 25.4° about the hinge vector, Mo(1)–Ru(1). The molybdenum centre retains its two imido ligands while each ruthenium centre is ligated by four CO ligands. Of the three ruthenium–molybdenum interactions, two are extremely short [Mo(1)–Ru(2) 2.7165(5), Mo(1)–Ru(3) 2.7025(4) Å] while the third, the hinge vector, is much longer [Mo(1)–Ru(1) 3.1094(8) Å]. Indeed, as far as we are aware, these bonds within **1a** span the range of all known molybdenum–ruthenium bonds in mixed-metal clusters.[9] The very short Mo–Ru interactions are probably a result of the smaller radii of high- *vs.* low-valent metal centres and high polarity of the heterometallic interaction $M^{\delta+}$–$M^{\delta-}$ as noted previously by Sundermeyer *et al.*[2] The longer hinge vector is dative in origin, the electron-rich ruthenium tetracarbonyl unit acting as a donor to the high-valent molybdenum centre. One way of looking at **1a** is as a molybdenum(VI) bis(imido) centre bound to a chelating $[Ru_3(CO)_{12}]^{2-}$ ligand. In the free state this dianion would lose CO to afford

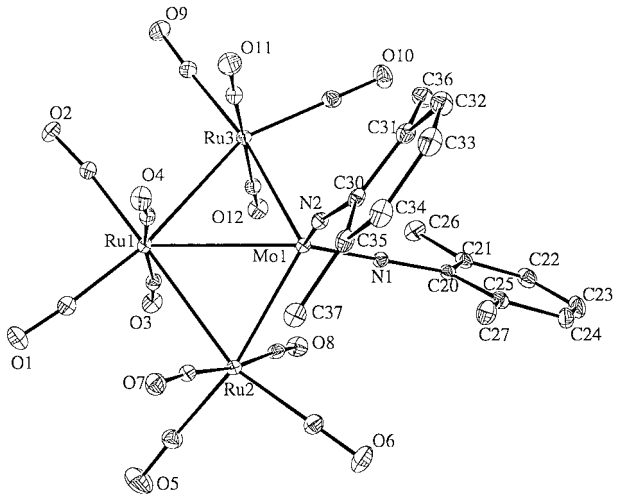


Fig. 1 Molecular structure of **1a** with selected bond lengths (Å) and angles (°): Mo(1)–Ru(1) 3.1094(8), Mo(1)–Ru(2) 2.7165(5), Mo(1)–Ru(3) 2.7025(4), Ru(1)–Ru(2) 2.9315(5), Ru(1)–Ru(3) 2.9556(5), Mo(1)–N(1) 1.766(2), Mo(1)–N(2) 1.761(2), Ru(2)–Mo(1)–Ru(3) 115.88(2), Mo(1)–Ru(3)–Ru(1) 66.50(2), Ru(3)–Ru(1)–Ru(2) 102.54(2), Ru(1)–Ru(2)–Mo(1) 66.68(2), N(1)–Mo(1)–N(2) 112.39(7), Mo(1)–N(1)–C(20) 163.60(13), Mo(1)–N(2)–C(30) 162.26(13).

$[Ru_3(CO)_{11}]^{2-}$, however, on the basis of a localised bonding model it would be expected to contain one long and two short ruthenium–ruthenium vectors. Ruthenium–ruthenium distances [Ru(1)–Ru(2) 2.9315(5), Ru(1)–Ru(3) 2.9556(5) Å] are *ca.* 0.1 Å longer than the average of 2.854 Å found in $Ru_3(CO)_{12}$,[10] however, this is expected as the outer ruthenium atoms carry a negative charge, while the Ru(2)–Ru(3) distance of 4.593 Å is clearly non-bonding. Thus, the triruthenium unit has the attributes expected of $[Ru_3(CO)_{12}]^{2-}$. Ignoring the dative Ru–Mo interaction, the molybdenum centre is approximately tetrahedral and related tetrahedral bis(imido) units are common for Mo(VI)[11] and known for Mo(IV).[12] Metal–nitrogen bond lengths in imido complexes are known to vary only slightly over a wide-range of complexe,[13] with no clear distinction between Mo(VI) and Mo(IV). Molybdenum–nitrogen distances in **1a** [Mo(1)–N(1) 1.766(2), Mo(1)–N(2) 1.761(2) Å] and the N(1)–Mo(1)–N(2) angle of 112.39(7)° are within the ranges found for both Mo(VI) and Mo(IV) complexes.[11–13]

Butterfly clusters are usually associated with an effective atomic number (EAN) of 62 electrons. As the imido ligands are linear [Mo(1)–N(1)–C(20) 163.60(13), Mo(1)–N(2)–C(30) 162.26(13)°] then both might be expected to be able to act as four-electron donors and such a scenario would give the expected 62-electron count. However, there are only three d orbitals of π-symmetry on any one metal centre, and thus the total donor capacity of the two imido ligands is six.[13] This suggests that cluster **1** has only 60 electrons and is formally electron deficient at molybdenum.

The mode of formation of **1** is not yet fully understood. Clearly CO scavenging must occur and this would be a reasonable explanation for the moderate yields obtained. The major byproduct of all reactions is $Ru_3(CO)_{12}$. This probably results from electron-transfer being competitive with nucleophilic substitution. We have also, however, noted that while **1a**–**c** are all indefinitely stable in hexane, thf solutions decompose over a period of hours under anaerobic conditions giving $Ru_3(CO)_{12}$ and an as yet unidentified molybdenum product. The differing stabilities of **1** in coordinating and non-coordinating solvents may reflect the strong polarisation of the Mo–Ru bonds and the electron deficiency at molybdenum.

Attempts to extend this type of cluster to aryl imido ligands without *ortho* substituents has so far been fruitless. For example, addition of $K_2[Ru_3(CO)_{11}]$ to $Mo(NPh)_2Cl_2(dme)$ yielded $Ru_3(CO)_{12}$ and $H_2Ru_4(CO)_{13}$ as the only tractable products. The reason for this is unclear but given the instability of **1a**–**c** in thf (the reaction solvent), it may be that $Ru_3(CO)_{12}$-$\{Mo(NPh)_2\}$ decomposes as rapidly as it is generated. We are currently exploring different solvents for these reactions, and plan to extend the metathesis methodology to other group 8 cluster anions and high-valent metal complexes, and explore the reactivity of this new class of high-low valent cluster complexes.

We are grateful to the National Research Council of Canada and the Natural Sciences and Engineering Research Council for financial support of this work. S. A. thanks University College London for financial support and the award of a Thomas Witherton Batt scholarship (1997–8).

ChemComm

A new route to the metastable FCC molybdenum carbide α-MoC_{1-x}

Christophe Bouchy, Sharifah Bee Derouane-Abd Hamid* and Eric G. Derouane

Leverhulme Centre for Innovative Catalysis, Department of Chemistry, The University of Liverpool, Liverpool, UK L69 3BX. E-mail: sharifhd@liverpool.ac.uk

Received (in Cambridge, UK) 16th September 1999, Accepted 6th December 1999

The carburisation of a prereduced MoO_3 provides a new method for the synthesis of the metastable α-MoC_{1-x}.

Because of their potential as catalysts substituting noble metals, transition metal interstitial compounds,[1] especially carbides and nitrides of group VI (Mo, V, W),[2–5] have received considerable interest. Several routes have been proposed for their preparation and their catalytic properties have been evaluated for a variety of reactions.

The direct temperature programmed reduction (TPR) and carburisation of MoO_3 using methane allows the preparation of the thermodynamically stable β-phase of molybdenum carbide, β-Mo_2C, whose structure is hexagonal close packed (HCP), with specific surface areas in the range 50–100 $m^2\ g^{-1}$.[6] The metastable α-phase of molybdenum carbide, α-MoC_{1-x}, whose structure is face-centred cubic (FCC), possesses catalytic properties which differ from those of the β-phase as observed, for example, in the hydrogenolysis of ethane.[7] Two procedures have been proposed for its synthesis. The first one involves the initial reduction and nitridation of MoO_3 by ammonia followed by the carburisation of the γ-Mo_2N nitride.[8] The second consists in the direct reduction and carburisation of MoO_3 containing a small amount of platinum.[9] The first method is rather tedious whereas the second leads to α-MoC_{1-x} contaminated by platinum, which may affect its catalytic behaviour. We now report a new and direct route for the synthesis of α-MoC_{1-x} using pure MoO_3 as precursor.

The MoO_3 used was analytical grade and obtained from Aldrich. The structural transformations occuring during its reduction and carburisation were followed *in situ* using powder X-ray diffraction (XRD). A Paar XRD *in situ* cell, capable of operation up to *ca*. 900 °C and 10 bar, was mounted in a Siemens D5001 powder X-ray diffractometer (θ–2θ mode) equipped with a position sensitive detector enabling the fast (< 6 min) acquisition of detailed X-ray diffraction patterns.

The new synthesis route to α-MoC_{1-x} can be described as follows. MoO_3 is first reduced at 350 °C under pure dihydrogen flow for 24 h. *In situ* XRD characterisation showed (Fig. 1) that MoO_3 is converted by this reduction treatment into a mixture of the sub-oxide MoO_2 and of another phase previously identified as the oxyhydride MoO_xH_y.[10] The oxyhydride has an FCC structure with a_{cub} = 0.410 nm and is formed by reduction and hydrogen insertion in the MoO_3 lattice, the overall process being topotactic.[11]

Dihydrogen was then replaced by methane and the sample (mixture of MoO_2 and MoO_xH_y) heated progressively to 710 °C (3 °C min^{-1}). *In situ* fast scan XRD analyses were performed at regular 30 °C temperature intervals to follow the carburisation of the sample. As shown in Fig. 2, carburisation started at 620 °C and yielded eventually (680–710 °C) the nearly pure metastable carbide α-MoC_{1-x} with only traces of the stable carbide β-Mo_2C. The unit cell parameter (a_{cub}) of the FCC structure was found to be 0.428 nm, confirming that a pure carbide, and not an oxycarbide (lower a_{cub} values),[11,12] was synthesised. The particle size (coherent domain size) of α-MoC_{1-x}, calculated from the broadening of the XRD pattern, is *ca*. 3.4 nm, corresponding to an estimated surface area of 187 $m^2\ g^{-1}$. However, the specific surface area of the sample measured by the BET method was found to be much smaller (S_{BET} = 90 $m^2\ g^{-1}$), possibly because of the plugging of mesoporosity owing to carbon deposition on the sample during synthesis. The presence of carbon deposits was confirmed using the method of Lee *et al*.[6] and a $C/Mo_{surface}$ atomic ratio of 7 was found. The C_{bulk}/Mo_{bulk} atomic ratio of the sample was then estimated by *in situ* TPO of sample whose surface was coke-free, as a result of the former treatment. This ratio was found to be equal to 0.7 ± 0.1. The value of this ratio and of a_{cub} support the deduction that the carbide synthesised is similar to the FCC carbide previously reported in the literature.[13] An FCC carbide without coke contamination, *i.e.* directly usable for catalytic application, was synthesised by replacing the pure CH_4 gaseous flow by a H_2–CH_4 (9:1) mixture. In this case, S_{BET} was 179 $m^2\ g^{-1}$, with a pore size distribution centred around 3 nm. The formation of β-Mo_2C, in very small amount, is attributed to the

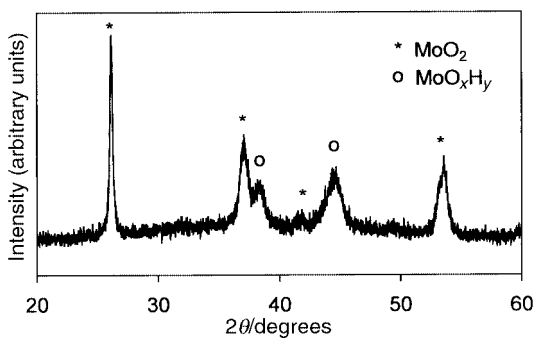

Fig. 1 *In situ* XRD pattern of the material obtained following reduction of MoO_3 by dihydrogen at 350 °C for 24 h.

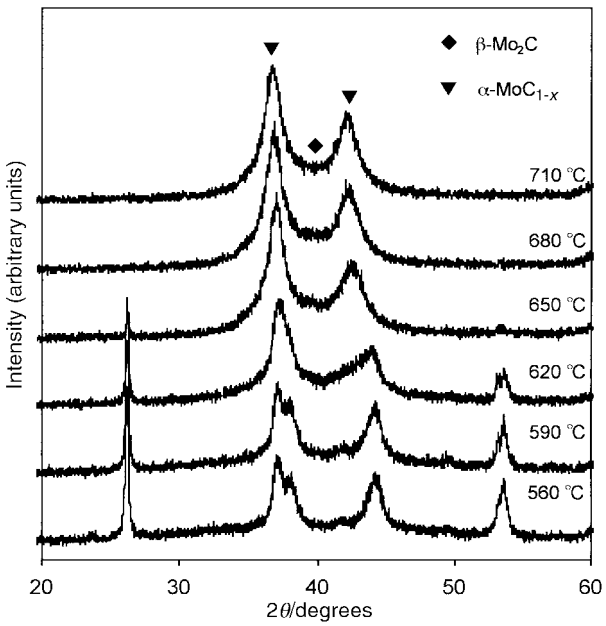

Fig. 2 *In situ* XRD characterisation of the MoO_2–MoO_xH_y mixture during methane carburisation.

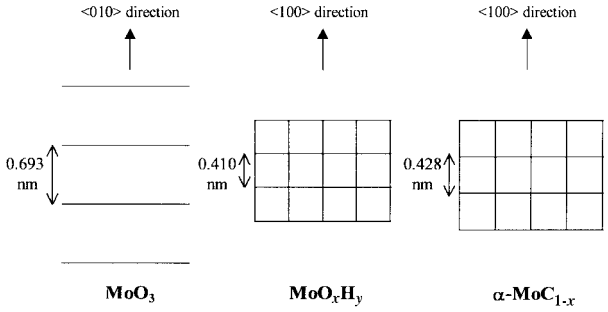

Fig. 3 Topotactic synthesis of FCC MoC_{1-x}: the < 010 > direction of the starting material is conserved during the synthesis.

carburisation of the MoO_2 sub-oxide as reported in the literature[14] whereas the carburisation of the oxyhydride MoO_xH_y yields α-MoC_{1-x}, both compounds having a FCC structure.

The synthesis of the FCC α-MoC_{1-x} carbide is enabled by the topotactic formation at low temperature of the FCC MoO_xH_y oxyhydride whose subsequent carburisation, occurring *via* a topotactic process,[11] leads to the FCC carbide. It appears that, as in the case of the topotactic synthesis of γ-Mo_2N from MoO_3,[15] the < 100 > direction of the FCC carbide is parallel to the < 010 > direction of the starting oxide (Fig. 3). The first step, *i.e.* the oxyhydride synthesis, is a further illustration of Figlarz's concepts about the usefulness of "soft chemistry"[16] when applied to the synthesis of new compounds in the MoO_3-WoO_3 system.

When compared to the two methods previously reported for the synthesis of α-MoC_{1-x}, the new route described above has two advantages. The first is its simplicity as no initial nitridation of MoO_3 with ammonia is required. The second is that the FCC carbide is obtained directly from pure MoO_3 and is thus not contaminated by traces of platinum.

These facts are certainly relevant if the α-MoC_{1-x} carbide is to be used as a catalyst, in order to avoid secondary reactions resulting from contamination by either γ-Mo_2N nitride (and its further reaction products) or platinum.

For example, it is known that bifunctional Mo-containing H-MFI zeolites, using $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ or MoO_3 as molybdenum sources, are efficient catalysts for the direct aromatisation of methane and that the active Mo-species in such systems is molybdenum carbide.[17,18] The new procedure proposed here for the preparation of α-MoC_{1-x} has enabled the quantitative evaluation and comparison of the performance of acidic zeolites modified by both the α- and β-phases of molybdenum carbide[19] without secondary effects owing to the presence of platinum impurities or to possible structural modifications of the zeolite or microporous solid following its prolonged exposure to ammonia at high temperature.[20]

In addition, as the carburisation of MoO_2 and MoO_xH_y leads to two different Mo-carbides, the treatment described above may be used to evidence the formation of the MoO_xH_y oxyhydride phase after a low temperature reductive treatment of MoO_3.[21,22]

In conclusion, a new simple and direct route has been found for the synthesis of the pure α-MoC_{1-x} carbide. This should enable a better quantification of its surface properties and reactivity and may impact on its use as catalyst for a variety of reactions.

R. Anderson, I. Schmidt and Dr A. Green are gratefully acknowledged for having performed some of the experiments.

Facile synthesis and crystal structure of a $Ga_{22}R_8$ cluster†

Gerald Linti* and Alexander Rodig

Institut für Anorganische Chemie der Universität, Engesserstr. Geb. 30.45, 76128 Karlsruhe, Germany. E-mail: linti@achpc9.chemie.uni-karlsruhe.de

Received (in Basel, Switzerland) 31st August 1999, Accepted 30th November 1999

A new metalloid cluster $Ga_{22}R_8$ with a central gallium atom exhibiting an unusual coordination number of 13 and the gallatetrahedrane Ga_4R_4 are obtained by reaction of 'GaI' with the lithium tris(trimethylsilyl)germanide $Li(thf)_3R$.

In the past decade, the chemistry of low valent gallium compounds has garnered widespread interest.[1] An appropriate and easily accessible starting material for gallium cluster compounds is 'GaI', prepared by treating gallium and iodine in toluene with ultrasound.[2] 'GaI', the structure of which is still unknown, has been used to synthesize a gallium(I) pyrazolyborate derivative[3] and the trigallane Ga_3I_5•$3PEt_3$.[4] The reaction of 'GaI' with lithium tris(trimethylsilyl)silanide as its thf solvate $Li(thf)_3R'$ (Scheme 1) afforded the gallatetrahedrane **1**, the electron-precise tetragallane **2** and the nonagallane **3** together with the disproportionation products **4** and **5**[5] as well as a silagallane cluster.[6] The structure of **3**, a cluster anion of composition $[Ga_9R'_6]^-$, is, in conformity with Wade–Williams cluster rules, a Ga_7 *closo* cluster with four R′ and two GaR′ ligands. Obviously, three Ga atoms are attached to other Ga atoms only. Such ligand free cluster atoms are rare in main group chemistry but are also found in $\{Al_{77}[N(SiMe_3)_2]_{20}\}^{2-}$ [7] and $In_{12}(SiBu^t_3)_8$.[8] In **1** and **3** the ligands shield the gallium core entirely. Thus, the question arises whether other ligands allow the preparation of cluster compounds with different gallium cores. Here, we report on the use of the tris(trimethylsilyl)germanyl group (R) in gallium cluster chemistry and the easy, high yield synthesis of a Ga_{22}-cluster.

When sonochemically prepared 'GaI' is reacted with $Li(thf)_3R$ in toluene (Scheme 2), a dark red–violet solution is obtained from which colourless gallium(III) products of the type R_2GaI_2•$Li(thf)_n$ **6** precipitate.‡ Obviously, a disproportionation reaction has occurred, but the formation of elemental gallium was not observed, implying that gallium species with oxidation states of $\leqslant 1$ had formed. Consequently, the gallatetrahedrane **7** was isolated in considerable yields while the main product of the reaction was $Ga_{22}[Ge(SiMe_3)_3]_8$ **8**. The tris(trimethylsilyl)silyl analogue of **8**, $Ga_{22}[Si(SiMe_3)_3]_8$,[9] was not accessible *via* 'GaI' but was synthesised *via* metastable GaBr solutions, the preparation of which is very complicated.

Compound **7** (Fig. 1)§ exhibits a nearly ideal tetrahedral Ga_4 core with average Ga-Ga distances of 258.7 pm. Thus, **7** is very similar to **1** ($d_{Ga–Ga}$ = 258.8 pm)[10] and $Ga_4(SiBu^t_3)_4$ ($d_{Ga–Ga}$ = 257.9 pm),[11] but has shorter Ga–Ga contacts than $Ga_4[C(SiMe_3)_3]_4$ ($d_{Ga–Ga}$ = 268.8 pm).[12]

X-Ray structure analysis of **8** (Fig. 2)§ shows a cluster consisting of 22 Ga atoms with eight R substituents and can be viewed as a Ga_{14} core with eight attached GaR units. The Ga_{14} core can be regarded as metalloid, yet this framework has no equivalent in any known modification of elemental gallium. The Ga_{14} core consists of a central gallium atom Ga(1), which is surrounded by 13 other gallium atoms with long Ga–Ga distances ranging from 285.5 to 312.4 pm (av. 295.1). The coordination sphere around the central gallium atom is an unusual Ga_{13} polyhedron of the type M_3–M_6–M_4 with eight four-membered and four three-membered ring facets. This is similar to the M_{12} cuboctahedron (M_3–M_6–M_3) in closest packing spheres of metals. The Ga–Ga distances within the Ga_{13} shell average 282.9 pm, longer than the Ga–Ga distances in elemental gallium (240–280 pm)[13] or in the Ga_{12} icosahedra in $Na_xMg_{5-x}Ga_9$ ($d_{Ga–Ga}$ = 269–273 pm).[14] All four-membered ring facets of this Ga_{13} shell are capped by GaR units in μ_4 and μ_3-modes [$d_{Ga–Ga}$ = 256.6 pm (av.)]. The gallium atoms

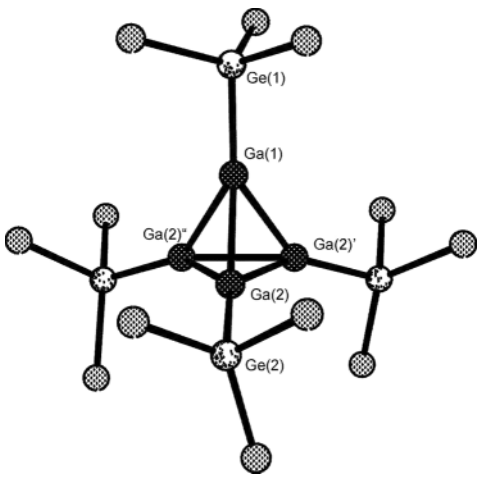

Fig. 1 View of a molecule of **7**. Methyl groups are omitted for clarity. Selected bond lengths (pm): Ga(1)–Ga(2) 258.2(5), Ga(2)–Ga(2)′ 259.1 (5), Ga(1)–Ge(1) 246.8(6), Ga(2)–Ge(2) 245.5(4), Ge–Si 235(2)–238(2).

† Dedicated to Prof. Nils Wiberg on the occasion of his 65th birthday.

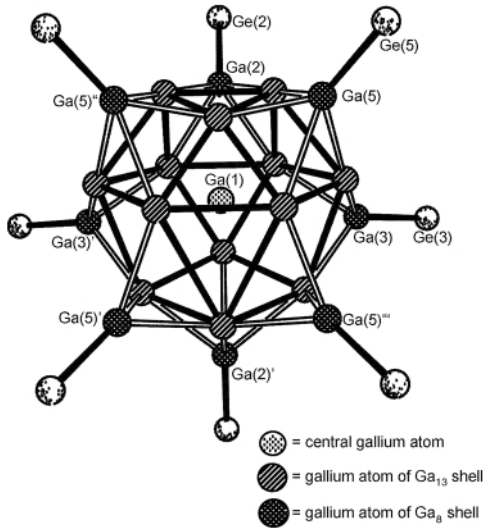

Fig. 2 View of a molecule of **8**. Trimethylsilyl groups are omitted for clarity. Selected bond lengths (pm): Ga(1)–Ga_{Ga13} 285.5(5)–312.4(5), Ga(2)–Ga_{Ga13} 244.7(5), 244.7(5), 245.8(4), 245.8(4), Ga(3)–Ga_{Ga13} 258.9(7), 246.0(5), 246.9(5), Ga(5)–Ga_{Ga13} 236.5(7), 240.3(7), 268.4(6), 269.3(5), Ga(2)′–Ga_{Ga13} 269.0(6), 274.6(8), 274.6(8), 300.5(8), Ga(2)–Ge(2) 243.0(2), Ga(3)–Ge(3) 242.8(2), Ga(5)–Ge(5) 242.9(3), Ge–Si 236.1(4)–238.4(5).

[Ga(2), Ga(3), Ga(5) and symmetry equivalents] of these eight GaR units form a quadratic antiprism ($d_{Ga–Ga}$ = 481–505 pm). Again, the bulky tris(trimethylsilyl)germyl ligands completely shield the gallium core.

Compound **8** is certainly not a typical Wade type cluster and should be viewed as a metalloidal cluster, in accordance with the jellium model.[9] However, when taking into consideration the long Ga–Ga distances involving Ga(1) and within the Ga_{13}-shell, as well as the short distances between the RGa units and the atoms of the Ga_{13} shell, the RGa groups may be viewed as electron pair donating ligands, attached to the Ga_{13} shell by two-electron multicenter bonds. Assuming a central Ga^+ ion, 15 cluster binding electron pairs are counted; thus the Ga_{13} shell may be regarded as a *nido* polyhedron. This 13-atom polyhedron resembles the M_3–M_6–M_4 arrangement recently reported for $(AlMe)_8C(CH_2Ph)_5H$.[15]

The results presented show the great synthetic potential of 'GaI' for the preparation of gallium cluster compounds. Examples include compounds **3** and **8**, which are intermediates in the disproportionation of low valent gallium species into metal and higher oxidized gallium compounds. Our current efforts are directed towards the synthesis of other silyl and germyl ligands with modified steric and electronic properties in order to influence the size of the gallium cluster.

‡ *Experimental*: $Li(thf)_3Ge(SiMe_3)_3$[16] (1.9 g, 3.7 mmol) dissolved in 25 mL of toluene at −78 °C was slowly added to a suspension of 'GaI' (0.7 g, 3.7 mmol) (prepared by the procedure given in ref. 2) in toluene (30 ml) at the same temperature. The mixture was stirred for 5 h at –78 °C and then allowed to warm to room temp. All volatiles were removed *in vacuo*, and the residue was extracted with methylcyclohexane (30 ml). The resulting dark red solution was filtered. Crystals of **6**, **7** and **8**, suitable for X-ray crystallography, were obtained from the concentrated filtrate at 0 and –30 °C, respectively.

Spectral data: for **7**•$0.5Ge_2Si_8C_{24}H_{72}O$•$0.5C_7H_8$ (*M* = 1867.1): yield: 259 mg (15%); ^{1}H NMR (C_6D_6): δ 0.46 [s, $OGe_2(SiMe_3)_6$], 0.39 [s, $GaGe(SiMe_3)_3$]; ^{13}C NMR (C_6D_6): δ 4.83 [$GaGe(SiMe_3)_3$], 4.65 [$OGe_2(SiMe_3)_6$]; MS (70 eV, EI): *m/z* (%) 1438 (2.7) $[M]^{\cdot+}$, 1365 (0.3) $[M - SiMe_3)]^+$, 1145 (5.0) $[M - Ge(SiMe_3)_3]^+$, 854 (1.3) $[M - 2\,Ge(SiMe_3)_3]^{\cdot+}$, 594 (2.6) $[OGe_2(SiMe_3)_6]^{\cdot+}$, 358 (34.5) $[GaGe(SiMe_3)_3]^{\cdot+}$, 293 (100.0) $[Ge(SiMe_3)_3]^+$.

For **8**•$0.25GeSi_4C_{12}H_{36}$ (*M* = 3962.9): yield: 127 mg (19%); MS (70 eV, EI): *m/z* (%) 362 (6.4) $[Ge(SiMe_3)_4]^{\cdot+}$, 293 (100.0) $[Ge(SiMe_3)_3]^+$.

§ *Crystal data*: STOE IPDS, Mo-Kα radiation, direct methods, full-matrix least squares against F^2, hydrogen atoms as riding model with Bruker AXS SHELXTL 5.1 (PC).

$Ga_4Ge_4Si_{12}C_{36}H_{108}$•$0.5Ge_2Si_8C_{24}H_{72}O$•$0.5C_7H_8$ **7**: crystal size: 0.20 × 0.20 × 0.10 mm, cubic, space group $Pa\bar{3}$ (no. 205), a = 2697.5(3) pm, V = 19.628(4) nm^3, Z = 8, D_c = 1.214 g cm^3, μ = 2.796 mm^{-1}, F(000) = 7424, 14038 measured reflections for 2θ = 2.5 − 42°, 3337 [1193 with $F > 4\sigma(F)$] independent reflections, 228 parameters. R_1 = 0.108, wR_2 = 0.289, max. residual electron density 1.56 e Å^{-3}. Several crystals tested were all very weakly diffracting, so this structure should be regarded as a preliminary one. Only Ga, Ge and Si atoms were refined anisotropically, C and O atoms isotropically. The nearly spherical molecules of **7** (residing on a threefold axis) pack in a primitive cubic lattice, providing large holes in the structure, which are occupied by disordered toluene and $[(Me_3Si)_3Ge]_2O$ molecules. The high residual electron density is due to partial oxidation resulting in a RGa_4O_4-heterocubane. Only *ca.* 10% of the oxygen positions are occupied, the R-values being unaffected, whether these are included in the refinement or not.

$Ga_{22}Ge_8Si_{24}C_{72}H_{216}$•$0.25GeSi_4C_{12}H_{36}$ **8**: crystal size: 0.20 × 0.10 × 0.02 mm, orthorhombic, space group *Pmmn* (no. 59), a = 2401.2(3), b = 2461.5(2), c = 1605.9(1) pm, V = 9.492(1) nm^3, Z = 2, D_c = 1.361 g cm^{-3}, μ = 4.520 mm^{-1}, F(000) = 3860, 16797 measured reflections for 2θ = 4 − 42°, 4661 [2160 with $F > 4\sigma(F)$] independent reflections, 366 parameters. R_1 = 0.088, wR_2 = 0.244 (all data), max. residual electron density 1.23 e Å^{-3}. The $GaGa_{14}$ core is disordered, so that two orientations of the Ga_{13} core overlie each other, interchanging the M_3 and M_4 facets. Thus the disordered molecule has crystallographic *mm* symmetry, while **8** has only mirror symmetry. Although the data were inspected thoroughly, no hint of a larger cell or superstructure was found. The almost spherical clusters are packed in a primitive cubic lattice, the cubic holes of which are occupied in part (*ca.* 25%) by disordered $Ge(SiMe_3)_4$ and pentane. Only the central Ge atoms were included in the refinement. Owing to the intensive disorder and the thinness of the crystal plates virtually no peaks with 2θ > 42° could be observed. Therefore, only gallium, germanium and silicon atoms were refined anisotropically.

Cycloruthenated tertiary amines and ethylene: further insight to the Ru-mediated olefin–aryl coupling reaction

Vincent Ritleng, Jean Pascal Sutter,† Michel Pfeffer* and Claude Sirlin

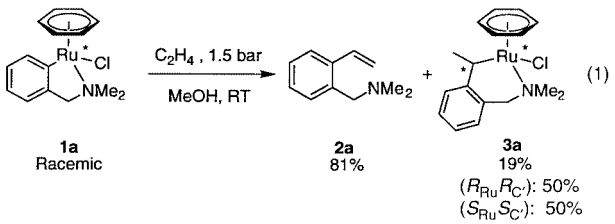
Laboratoire de Synthèses Métallo-Induites, UMR CNRS 7513 Université Louis Pasteur, 4 rue Blaise Pascal, 67070 Strasbourg, France. E-mail: pfeffer@chimie.u-strasbg.fr

Received (in Basel, Switzerland) 29th October 1999, Accepted 6th December 1999

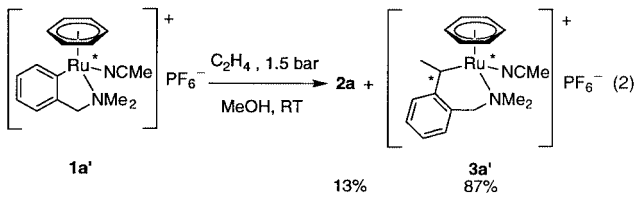
The reaction between cycloruthenated *N*,*N*-dimethylbenzylamine and ethylene under very mild conditions afforded 2-vinyl-*N*,*N*-dimethylbenzylamine and an organometallic Ru derivative resulting from the overall insertion of one carbon atom in the Ru–C bond of the starting material.

The insertion of an olefin in a transition metal–carbon σ-bond is a classical reaction in organometallic chemistry. With palladium, this process is followed by β-hydrogen elimination and is widely known as the Heck reaction.[1] Recently, functionalisation reactions of aryl C–H bonds with terminal olefins catalysed by ruthenium hydride complexes were reported.[2,3] In these reactions the products are alkyl substituted compounds resulting from the 'formal' insertion of the olefinic double bond into a C–H bond. We now report that air stable cycloruthenated *N*,*N*-dimethylbenzylamine derivatives react at low pressure (1.5 atm) and room temperature (RT) with ethylene to afford vinylbenzylamines, as in the Heck reaction, and an organometallic compound resulting from the insertion of ethylene into the Ru–C bond.

In a typical experiment, an orange suspension of (η^6-C_6H_6)Ru($C_6H_4CH_2NMe_2$)Cl **1a** in methanol was stirred at room temperature under 1.5 bar of ethylene over 1.5 h [eqn. (1)]. 2-Vinyl-*N*,*N*-dimethylbenzylamine **2a**‡ and the new organoruthenium compound **3a**‡ were isolated. The ^{1}H and ^{13}C NMR spectra and combustion analyses of **3a** are consistent with the structure depicted in eqn. (1).

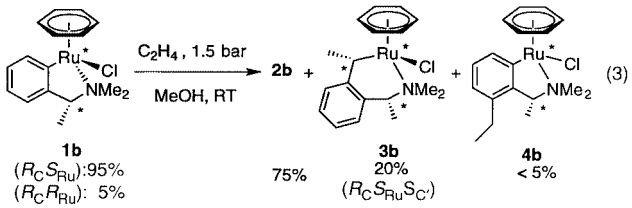


We found that it was possible to influence the ratio of **2a** to **3a** by removing the chloride ligand of the starting material. Thus, the yellow cationic derivative **1a′**[4c] led to a much higher yield of the red organometallic species **3a′** when it was treated with ethylene [eqn. (2)].



These reactions led to the formation of a chiral C atom σ-bonded to Ru, the Ru atom being itself a stereogenic center.[4] Interestingly, only one enantiomeric pair was observed by ^{1}H NMR in both cases, indicating that these reactions occur with a high level of diastereoselectivity. The stereochemistry of **3a** has been investigated by a ^{1}H NOE experiment. The η^6-benzene ring was found to interact strongly with one of the *N*-methyl and with the *C*-methyl which also interacts with the proton of the aryl ligand. The proton on the carbon α to Ru (C′) interacts neither with the latter nor with the η^6-benzene ring. Consequently, **3a** displays a boat conformation, with the C-methyl and the η^6-benzene ring in the equatorial and the axial positions respectively. The absolute configuration of the enantiomers are thus ($R_{Ru}R_{C'}$) and ($S_{Ru}S_{C'}$).

In order to confirm the chiral control of the reaction, the optically active complex (η^6-C_6H_6)Ru(C_6H_4-2-(*R*)-CH(Me)N-Me_2)Cl **1b** (de = 90%)[4] was treated with ethylene under the same conditions. Surprisingly in addition to **2b** and **3b**,‡ the respective analogues of **2a** and **3a**, a third product **4b**‡ was observed in trace amounts [eqn. (3)]. Its structure is that of a new cyclometallated benzylamine derivative displaying an ethyl substituent in position 3.



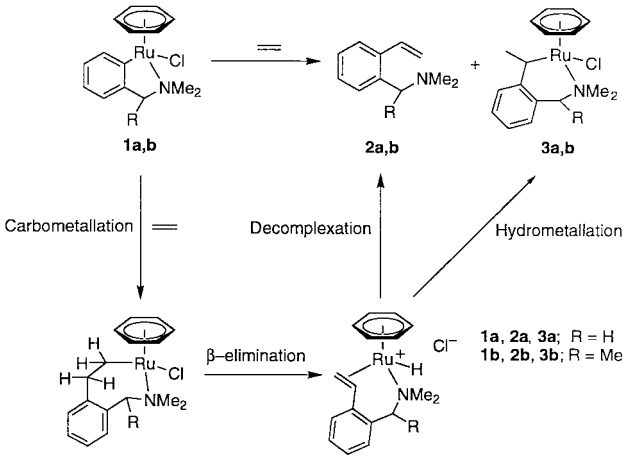
For complexes **3b** and **4b**, one diastereoisomer only was observed by ^{1}H NMR indicating that these compounds are the result of highly diastereoselective processes. Unfortunately owing to its instability, **3b** could not be isolated as a pure solid. Nevertheless its stereochemistry was investigated through a ^{1}H ROESY experiment of the crude reaction mixture. The methyl substituent of the carbon atom σ-bonded to Ru (C′) interacts with the proton of the aryl ligand and with the η^6-C_6H_6 ring whereas the corresponding proton interacts with none of these. These results indicate an equatorial position for the methyl group and axial position for the η^6-benzene ring as in **3a**. The methyl group α to N interacts equally with both *N*-methyls and with the proton of the aryl ligand but not with the η^6-benzene indicating an equatorial position as well. Moreover, the absence of any interaction between the η^6-benzene ring and the benzylic proton attached to N, together with the deshielding of the latter signal, indicate that this proton should be close to the chlorine atom as in the starting material **1b**. Consequently, **3b** should display a boat conformation with the protons α to Ru and N on bridgehead positions and its absolute configuration should therefore be ($R_CS_{Ru}S_{C'}$).

When **3b** was left in solution it isomerised slowly into **4b** together with decomposition but no conversion into **2b** was detected. Thus **2b** and **3b** are independent products which, however, are likely to come from the same intermediate (see below). The important instability of **3b** as compared to that of **3a** might be due to steric congestion around the Ru atom. The

† *Present address*: Institut de Chimie de la Matière Condensée de Bordeaux - UPR CNRS 9048-Avenue du Dr. Schweitzer 33608 Pessac, France.

rearrangement process **3b** → **4b** remains unclear yet. Running the reaction in CD_3OD did not result in deuterium incorporation in the new ethyl group. Moreover, when a sample of the crude reaction mixture was left in an aprotic solvent such as $CDCl_3$ this demetallation–remetallation process also occured. These observations tend to indicate that **4b** may be formed through an intramolecular rearrangement as demonstrated by Steenwinkel *et al.* for a related ruthenocyclic molecule.[5]

To the best of our knowledge the only precedent of a Ru-mediated functionalization of a C–H bond to afford a vinyl derivative such as **2a**,**b** was reported by Murai and coworkers[6] when reacting aromatic imines or imidates with mono-substituted olefins in the presence of catalytic amounts of $Ru_3(CO)_{12}$. It is generally assumed that this type of product is formed by β-H elimination from a carbometallation intermediate. Consequently the formation of **2a**,**b** and **3a**,**b** can be rationalised according to the reaction path depicted in Scheme 1. The first step involves the insertion of ethylene into the C–Ru bond followed by a β-H elimination leading to an olefin–hydride complex.[7] This leads on one hand to the metal free substituted olefin **2a**,**b** as in the Heck reaction and on the other hand to the one carbon-atom insertion complex **3a**,**b** by anti-Markovnikov hydrometallation of the olefinic unit (Scheme 1).



Scheme 1

Studies are currently under way to determine the conditions that would allow us to direct the reaction toward the exclusive formation of one of these products.

We thank INTAS (INTAS-97-166) for financial support of this work.

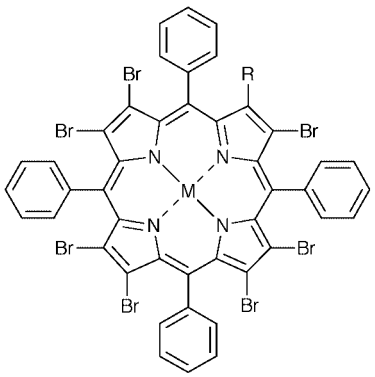
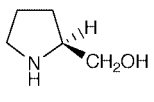
Received (in Corvallis, OR, USA) 14th October 1999, Accepted 29th November 1999

The chiral nonplanar porphyrin zinc(II) 3,7,8,12,13,17,18-heptabromo-2-(2-methoxyphenyl)-5,10,15,20-tetraphenylporphyrin has been synthesized and its properties investigated.

The porphyrin macrocycle provides a versatile platform upon which to build elaborate superstructures, and this feature coupled with a rich and well-developed synthetic chemistry has led to the synthesis of many models of heme protein active sites[1] and numerous porphyrin-based receptor molecules.[2] One characteristic which is not normally considered in the design of porphyrin-based receptors is nonplanarity of the porphyrin macrocycle,[3] although the nonplanar systems that have been investigated (*e.g.* a pyridine sensitive Venus Flytrap[4] and a chirality-memory molecule[5]) have displayed quite unusual properties. Herein, we describe the synthesis and characterization of a new porphyrin-based chiral receptor molecule (**1**)



1 R = 2-MeOC$_6$H$_4$, M = Zn
3 R = 2-MeOC$_6$H$_4$, M = 2H
4 R = Br, M = 2H



2

which exploits some structural features unique to nonplanar porphyrins.

Fig. 1 shows the four structures expected for porphyrin **1**. Structures **A** and **B** (or **C** and **D**) are enantiomers, structures **A** and **C** (or **B** and **D**) are related by rotation of the 2-methoxyphenyl group, and structures **A** and **D** (or **B** and **C**) are related by inversion of the nonplanar porphyrin macrocycle. Porphyrin **1** was calculated[6] to have a very high barrier for rotation of the 2-methoxyphenyl group (>146 kJ mol^{-1}), a low barrier for inversion of the porphyrin macrocycle[7] (*ca.* 40 kJ mol^{-1}), and a strong preference (ΔE = 8 kJ mol^{-1}) for structures **A** and **B** *vs.* structures **C** and **D**. Hence, it should be resolvable into two optically active components consisting primarily of structures **A** or **B**. Porphyrin **1** was designed with the aim of using a cavity formed by the nonplanar macrocycle to orient an axial ligand,[8] such that a hydrogen bond acceptor site (the methoxy group) could interact stereospecifically with hydrogen bond donor sites on the axial ligand. Fig. 2 shows the lowest energy structure calculated for a complex of **1** with (*S*)-2-pyrrolidinemethanol (**2**) which illustrates this ligand orientation effect and the formation of stereospecific hydrogen bonds with one enantiomer of the porphyrin (structure **B**). Note that the nonplanar deformation of the macrocycle serves a dual function as it also moves the methoxy substituent closer to the ligand than would be possible if the porphyrin were planar.

To prepare porphyrin **1**, porphyrin **3** was first synthesized using a Suzuki coupling reaction.[9] In this reaction, porphyrin **4** (1 equiv.), 2-methoxyphenylboronic acid (5 equiv.), Pd[(PPh$_3$)]$_4$ (0.15 equiv.) and K_2CO_3 (20 equiv.) in toluene under argon were heated at 90–100 °C for two days. MALDI mass spectrometry of the crude product revealed the presence of unreacted **4**, porphyrin **3**, and porphyrins with two or more 2-methoxyphenyl groups. Porphyrin **3** was isolated from this mixture using column chromatography (silica gel eluted with 3 : 2 $CHCl_3$–hexane) and obtained in 12% yield. The structure of **3** was confirmed by MALDI mass spectrometry and ^{1}H NMR spectroscopy. Zinc was then inserted using the metal acetate method to give **1**.

When porphyrin **1** was subjected to HPLC using a Chiralcel OD column eluted with 89 : 10 : 1 hexanes–$CHCl_3$–Pr^{i}OH, two fractions (elution times 12 and 28 min) were obtained. These fractions had identical optical spectra but their CD spectra were mirror images of each other. Leaving each fraction in the eluent and reinjecting it through the HPLC column 24 h after

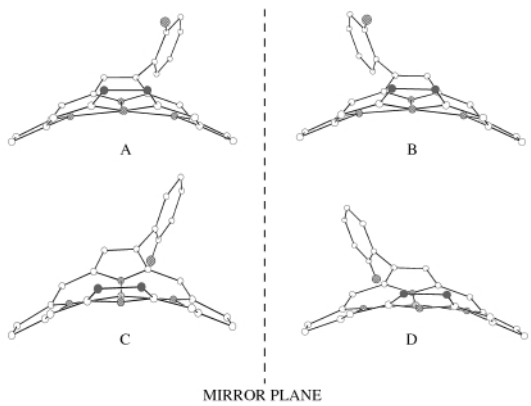


Fig. 1 Representations of the four structures expected for porphyrin **1**.

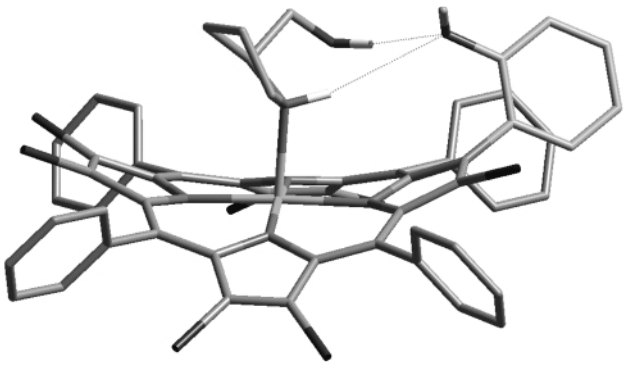

Fig. 2 Minimum energy structure calculated (ref. 6) for the complex of porphyrin **1** with ligand **2**. Porphyrin–ligand hydrogen bonds are indicated by broken lines.

separation revealed only a trace of racemization, in agreement with the high rotational barrier calculated for the 2-methoxyphenyl group. The isolation of only two HPLC fractions together with ^{1}H NMR studies of **1** confirmed that structures **A** and **D** (or **B** and **C**) were being interconverted by inversion of the porphyrin macrocycle.[7] The ^{1}H NMR spectrum of **1** showed a single broad methoxy signal at 295 K (δ 2.77) which split into two signals at 193 K (δ 2.30, integration 11.5 and δ 3.61, integration 1). As the methoxy signals at δ 2.30 and 3.61 could be assigned to **A** and **B** or **C** and **D** based on the expected ring current shifts of the methoxy protons in these structures, it was clear that the interconversion of **A** and **D** (or **B** and **C**) was rapid at room temperature and that **A** and **B** were significantly favored over **C** and **D**. Both the conformational energy difference (4 kJ mol^{-1} at 193 K) and the activation energy for macrocylic inversion (51 kJ mol^{-1} at the coalescence temperature of 273 K) were in reasonable agreement with the energies obtained from the modelling studies.

Despite repeated attempts we were unable to determine the X-ray structures of the porphyrins in the two HPLC fractions. However, modelling studies suggested that it should be possible to differentiate enantiomers **A** and **B** by their interactions with ligand **2**. In the case of structure **B**, ligand **2** should bind in essentially a single orientation because there is an energy difference of at least 5 kJ mol^{-1} between the minimum energy structure (Fig. 2) and other low energy structures (where the ligand is rotated approximately 180° in the cavity or is bound in either orientation in the cavity on the other face of the porphyrin). For structure **A**, the energy difference between these ligand binding geometries is calculated to be smaller, suggesting that the ligand should bind in multiple orientations. The hydrogen bonding seen in the lowest energy calculated structure of **B** (Fig. 2) is also expected to produce a downfield shift of the ligand NH and OH proton signals that should be absent or less pronounced for structure **A**. NMR spectra of the HPLC fractions dissolved in toluene-d_8 containing approximately 1 equiv. of **2** are shown in Fig. 3. The spectra were measured at 193 K where ligand exchange, ligand rotation, inversion of the porphyrin macrocycle, and rotation of the 2-methoxyphenyl group can all be demonstrated to be slow on the NMR timescale. The ligand proton region of the HPLC fraction with a retention time of 28 min shows only a single downfield-shifted pyrrolidine NH signal (definitively assigned by deuteration with D_2O) and agrees with the spectrum expected for structure **B**. In contrast, the HPLC fraction with a retention time of 12 min displays four NH signals (none of which are shifted downfield) consistent with the spectrum expected for structure **A**. Ligand signals were not seen for **C** and **D** in agreement with the higher energies calculated for these structures.

The results reported here provide further confirmation that nonplanar deformations of the porphyrin macrocycle can be exploited to produce unusual porphyrin-based receptor molecules. The present work also demonstrates the usefulness of molecular modelling techniques in the design and characterization of new porphyrin-based materials.

Synthesis of novel (bis)(diarylamino)thiophenes *via* palladium-catalysed reaction of (di)bromothiophenes with diarylamines

Makoto Watanabe,* Toshihide Yamamoto and Masakazu Nishiyama

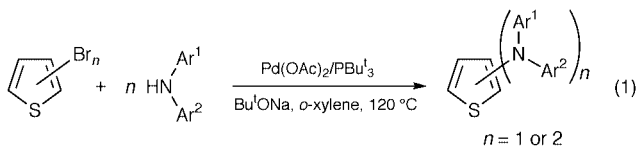
Received (in Cambridge, UK) 12th October 1999, Accepted 2nd December 1999

Synthesis of novel (bis)(diarylamino)thiophenes including 2,5-bis(diarylamino)thiophenes was attained by PBu^t_3-ligated palladium-catalysed coupling of (di)bromothiophenes with diarylamines.

Thiophene-containing compounds are widely known as an important class of materials which show intrinsic electronic properties such as luminescence,[1,2] redox activity,[3] nonlinear optical chromism[4] and electron-transport.[5] While triarylamines generally bear a role of hole-transport for organic electroluminescent (EL) display devices,[6] thienylphenylene-containing triarylamines showed different properties.[1,4] Thus, incorporation of a thiophene moiety into the triarylamine system is of current interest due to the product's potential applications. Nevertheless, synthesis of triarylamines bearing thienylamino group(s) is quite rare. 1,3,5-Tris(*N*-phenylthienylamino)benzenes have been synthesized by Ullmann coupling of tris(phenylamino)benzene and 2- and 3-iodothiophenes,[7] but there have been no reports of the synthesis of other (diarylamino)thiophenes.

Palladium-catalysed amination technology is widely known as a useful synthetic method for making arylamines from aryl halides with amines, and has been intensively examined for the synthesis of a wide range of arylamines since Buchwald and Hartwig reported the reaction.[8] However, halothiophenes have not been employed as substrates for the amination reaction. On the other hand, we recently reported that PBu^t_3 served as an excellent ligand for palladium-catalysed amination of aryl halides.[9] The catalytic system consisting of a palladium compound and PBu^t_3 also showed exceedingly high catalytic activity in the synthesis of triarylamines.[10] Herein we report the first palladium-catalysed synthesis of novel (diarylamino)thiophenes and 2,5-bis(diarylamino)thiophenes from (di)bromothiophenes and diarylamines [eqn. (1)].



(1)

The coupling of (di)bromothiophenes with diarylamines is most suitable for synthesizing (bis)(diarylamino)thiophenes because (di)bromothiophenes are commercially available and inexpensive. The coupling reaction was examined using Bu^tONa in *o*-xylene at 120 °C (Table 1).† Reaction of 3-bromothiophene with Ph_2NH smoothly proceeded in the presence of 0.25 mol% of $Pd(OAc)_2$ to afford 69% yield of 3-(diphenylamino)thiophene **1a** (entry 1). On the other hand, although 0.75 mol% palladium catalyst was required to give complete conversion of 2-bromothiophene (entry 2), the reaction with Ph_2NH gave the desired product using a small amount of the catalyst. 2-Bromo-3-methylthiophene was similarly coupled without any significant steric effect due to the methyl group (entry 3). Double amination of dibromothiophene with diarylamines gives larger molecules of bis(diarylamino)thiophenes with higher molecular weight, which can be expected to be morphologically more stable than mono(diarylamino)thiophenes for organic EL devices. The palladium catalyst was so active that 2,5-dibromothiophene in the reaction with Ph_2NH could be converted to 2,5-bis(diphenylamino)thiophene **1d** in 57% yield in the presence of 2 mol% of palladium catalyst per dibromothiophene (entry 4). When 2 mol% of $Pd(dba)_2$/BINAP was used as catalyst in the same reaction, the catalytic activity was low, and after 24 h at 120 °C, 2-bromo-5-(diphenylamino)thiophene and 2,5-bis(diphenylamino)thiophene were obtained in 34 and 6% GC yield, respectively. These results indicate that PBu^t_3, which is a bulky and electron-rich phosphine, facilitates the amination of highly electron-rich aryl halides. Reaction of 3,4-dibromothiophene with Ph_2NH was also attempted and gave only a 12% yield of 3-bromo-4-(diphenylamino)thiophene, which is the monoamination product (entry 5). Using the same catalyst, reaction of *o*-dibromobenzene with Ph_2NH gave no product.[10] Although amination of 3,4-dibromothiophene afforded a low yield of monoaminated product, the difference in the reactivity between 3,4-dibromothiophene and *o*-dibromobenzene may be ascribed to the difference of the angle of C–C–Pd bond of the resulting arylpalladium complex after oxidative addition, in which the intramolecular coordination of a vicinal bromine to the palladium complex obtained from *o*-dibromobenzene is more likely to prevent Ph_2NH from ligating to the Pd complex. The coupling of 2,5-dibromothiophene with other diarylamines such as 3-methyldiphenylamine and *N*-phenyl-1-naphthylamine was performed to give 2,5-bis(diarylamino)thiophenes (**1e** and **1f**) (entries 6 and 7). 2,5-Bis(*N*-phenyl-2-fluorenylamino)thiophene **1g** could be prepared by Pd-catalysed reaction of 2-bromofluorene with aniline followed by addition of 2,5-dibromothiophene to the resulting reaction mixture (entry 8). Therefore, this synthetic method can be applied to the synthesis of a variety of elaborate diarylaminothiophenes with aromatic fused ring systems *via* secondary arylamines.

We have demonstrated that the catalytic system consisting of a palladium compound and PBu^t_3 catalysed coupling of bromothiophenes and diarylamines to afford novel (bis)(diarylamino)thiophenes in good yields. Although 2(,5)-(di)bromothiophenes were presumed not to undergo the amination reaction due to their strong coordination to the palladium catalyst, this catalytic system allows the amination with diarylamines to occur in the presence of a small amount of catalyst. The employment of PBu^t_3, which is a bulky and electron-rich ligand, realised the Pd-catalysed formation of (bis)(diarylamino)thiophenes.

Notes and references

† *General procedure*: $Pd(OAc)_2$ (44.9 mg, 0.2 mmol), PBu^t_3 (2.4 ml, 50 mg ml^{-1} in *o*-xylene, 121.4 mg, 0.6 mmol), 2,5-dibromothiophene (2.42 g, 10 mmol), diarylamine (20 mmol), sodium *tert*-butoxide (2.11 g, 22 mmol) and *o*-xylene (40 ml) were mixed at room temperature and heated at 120 °C for 3 h under N_2. After addition of water and extractive work-up with Et_2O, *o*-xylene was stripped off *in vacuo*. The residue was purified by reprecipitation by adding MeOH (30 ml) for **1a** (1.73 g, 6.9 mmol), **1b** (0.90 g, 3.6 mmol), **1d** (2.39 g, 5.7 mmol), **1f** (2.90 g, 5.6 mmol) or column chromatography on Al_2O_3 (eluent; hexane–EtOAc = 100 : 0–1 : 1) for **1c**

Table 1 Palladium-catalysed synthesis of (bis)(diarylamino)thiophenes[a]

Entry	Substrate	Diarylamine	Product

Received (in Cambridge, UK) 18th October 1999, Accepted 5th December 1999

The synthesis and characterization of a novel mixed-valence MnGaPO phase is described; the 3D open-framework consists of discrete bioctahedra of $Ga_2O_{10}(H_2O)$ and GaO_5 trigonal bipyramids, connected *via* $Mn^{II}O_4$, $Mn^{II}O_4$ and PO_4 tetrahedra to generate intersecting tunnels within which piperazinium cations reside.

Substitution of first-row transition metal (TM) ions for Al^{3+} in the frameworks of aluminium phosphates is of particular interest for the enhancement of catalytic activity and the design of novel catalysts,[1,2] exemplified by MnAlPO-31 for the isomerization of but-1-ene,[3] and MnAlPO-5 which demonstrates reversible oxidation and reduction cycles.[4] The location and environment of the TM ion site is of considerable importance for understanding the catalytic and adsorptive properties of molecular sieves. As few single-crystal data are available for MAlPO-*n* samples,[5] evidence for incorporation of TM ions into the tetrahedral frameworks is difficult to establish.[1] Owing to the similarity in framework topology and the presence of even wider pores, in *e.g.* cloverite,[6] the search for gallium phosphates adopting microporous structures has attracted much attention. In contrast to MAlPOs, only a limited number of MGaPO compounds (M = V^{3+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+})[7–12] have been synthesized. Up to now, only three Mn-substituted gallium phosphates have been reported.[10–12] None of these MAlPOs and MGaPOs contain the same TM ions in mixed oxidation states, which would offer more possibility in understanding and designing redox-catalytic or magnetic molecular sieves.[13] By employing hydrothermal crystallization, we have synthesized the first mixed-valence manganese gallium phosphate phase, $(pipz)_2Mn_2Ga_5(H_2O)(PO_4)_8$ (pipz = $C_4H_{12}N_2^{2+}$), denoted MnGaPO-4. A reaction mixture of piperazine (0.258 g, 3 mmol), $Ga(NO_3)_3{\cdot}xH_2O$ (0.307 g, 1.2 mmol), $MnCl_2{\cdot}2H_2O$ (0.065 g, 0.4 mmol), H_3PO_4(aq) (85%, 6 mmol), ethylene glycol (5.8 mL) and H_2O (5.8 mL), was placed in a Teflon-lined digestion bomb (internal volume = 23 mL) and heated at 180 °C under autogenous pressure for 72 h. The final product contained a lot of light-brown tabular crystals mixed with a small amount of uncharacterized powder. A single-crystal structure analysis‡ indicated the tabular crystals to be $(pipz)_2Mn_2Ga_5(H_2O)(PO_4)_8$. The Mn:Ga:P ratios determined from single-crystal data (2:5:8) were corroborated by EMPA data (2.09:5.18:8.00). Elemental analysis also confirmed the organic content (Observed: C, 6.71; N, 4.19; H, 2.42%. Calc: C, 6.80; N, 3.97; H, 1.84%). Thermogravimetric analysis (N_2 atmosphere, heating rate 10 °C min^{-1}) on selected crystats showed a two-stage weight loss from *ca*. 200 to 1100 °C, with a total loss of 19.7%, corresponding to the removal of three water, two piperazine molecules and 1/5 P_4O_{10}.[9] It is also noted that another new Mn^{II}GaPO phase[14] results when piperazine is replaced by the bulkier 4,4′-trimethylenedipiperidine in the reaction mixture.

The three-dimensional anionic framework of MnGaPO-4 consists of GaO_6 octahedra and GaO_5 trigonal bipyramids, connected *via* MnO_4 and PO_4 tetrahedra (Fig. 1) to form intersecting tunnels along all three axial directions (Fig. 2). The pipz cations are located at the tunnel intersections, and four unique types of cages with different Mn content are found (Fig. 3). The open-framework nature of the structure is emphasized by a PLATON analysis[15] of the accessible solvent volume not occupied by the framework Ga, Mn, P and O atoms. The result showed that 457.5 Å^3 (*ca*. 28% of a unit cell volume) is 'solvent accessible'.

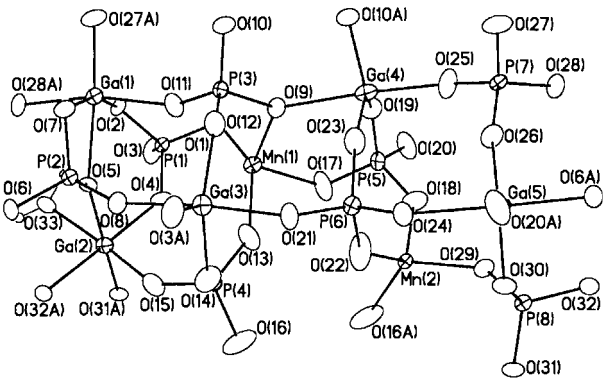

Fig. 1 ORTEP drawing of the building unit in MnGaPO-4. Average bond lengths (Å): Mn(1)–O 2.044(6), Mn(2)–O 1.888(6), Ga(1)–O 1.988(5), Ga(2)–O 1.974(5), Ga(3)–O 1.911(5), Ga(4)–O 1.909(5), Ga(5)–O 1.895(5), P–O 1.526(5) Å.

One remarkable feature of the structure is that the two distinct sites of the Mn ions adopt different charges, *i.e.* 2+ for Mn(1) and 3+ for Mn(2) based on bond-valence sum calculations.[16] The mixed-valence character is also evidenced by the color of the crystals of MnGaPO-4. According to a literature search, only three mixed-valence manganese phosphates have been previously structurally characterized *i.e.* $Cs_3Mn_4(P_6O_{18})_2$,

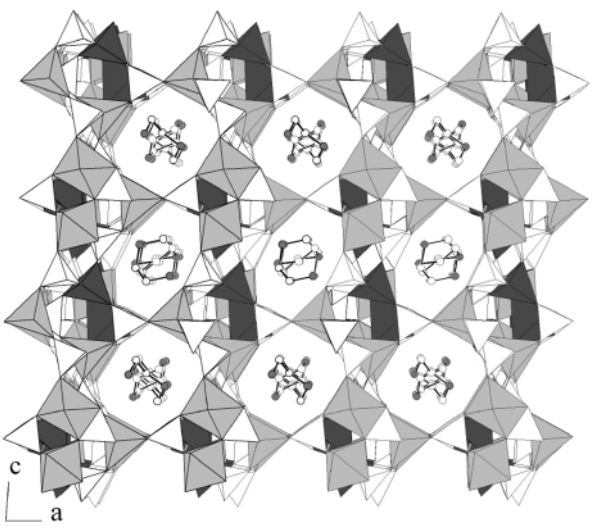

Fig. 2 View of the frameowork along [010], showing tunnels enclosed by eight-membered rings of diameter *ca*. 8 Å. The darker polyhedra are MnO_4, the lighter ones are GaO_5 and GaO_6, and the open tetrahedra are PO_4.

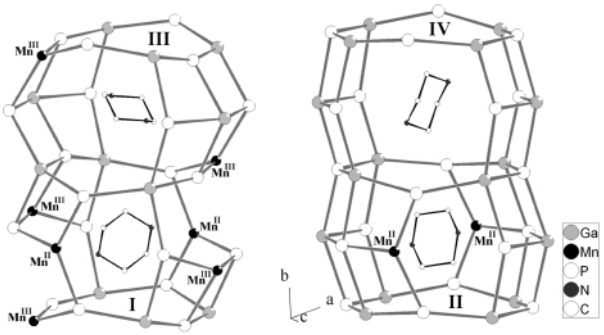

Fig. 3 Cages located at the interactions of three-dimensional tunnels. The pipz cations are located on inversion centers. Cages I show 8-ring windows and II, III and IV 4-ring windows when viewed along the *a*-axis direction.

$CsMn_2(P_6O_{18})$[17] and $Mn(H_2O)_4[Mn_2(OH)_2(PO_4)_2]$.[18] Unlike these, both Mn^{2+} and Mn^{3+} ions are tetrahedrally coordinated in our compound, having a distance to the fifth contact O atom at 2.61 and 3.06 Å, respectively. The four-coordinate Mn^{3+} ion in MnGaPO-4 is unprecedented for manganese phosphates where all of the Mn^{3+} ions are six-coordinate, typical of d^4 high-spin transition-metal ions. Furthermore, the charge distribution of the Mn centers varies in the enclosing structure of the cages; cage I has both Mn^{2+} and Mn^{3+} centers whilst cage II has Mn^{2+}, and cage III Mn^{3+} centers only (Fig. 3). This feature offers considerable possibilities in selective redox-catalytic applications. From the structural point of view, it may be anticipated that the Mn atoms have substituted for Ga rather than P atoms since the parent structure is an orthophosphate instead of a polyphosphate framework. The magnetic susceptibility data in the temperature range 50–300 K can be fitted to a Curie–Weiss law with $\theta = -17.2$ K and $C = 4.8$ emu, which corresponds to an effective magnetic moment per manganese ion of 6.2 μ_B, as expected, lower than that observed for pure Mn^{2+} ions in MnGaPO-2.[11]

Another interesting feature of the compound is in that an isolated $Ga_2O_{10}(H_2O)$ unit, built of corner-shared $Ga(1)O_6$ and $Ga(2)O_5(H_2O)$ octahedra, exists in the framework. Relative to gallium oxides, discrete gallium–oxygen cluster-containing phosphates are rare. The only example, $GaPO_4$-21,[19] was found to contain a dimer of corner-shared GaO_5 trigonal bipyramids. In the dimeric $Ga_2O_{10}(H_2O)$ cluster, a significant repulsion between the two Ga centers may arise since the distance between atoms Ga(1) and Ga(2) at 3.699 Å, is longer than that for two corresponding octahedral centers, 3.473 Å. As compared with $Ga(2)O_5(H_2O)$, the octahedron $Ga(1)O_6$ is much more distorted since it also shares a common edge with the $P(2)O_4$ tetrahedron. Atom O(5) bridges the Ga(1), Ga(2) and P(2) centers with the Ga(1)–O(5)–P(2) angle of 92.8°, deviating significantly from 120°, characteristic of trigonal planar geometry typical of a μ_3-O atom. In addition, the bridging Mn–O–P angles between corner-shared MnO_4 and PO_4 tetrahedra, ranging from 123.1 to 147.6°, span a rather wider range than those found in MnGaPOs and MnAlPOs.

Ti-ferrierite and TiITQ-6: synthesis and catalytic activity for the epoxidation of olefins with H_2O_2

A. Corma,* U. Diaz, M. E. Domine and V. Fornés

Instituto de Tecnología Química, UPV-CSIC, Universidad Politécnica de Valencia, Avda. de los Naranjos, s/n, Valencia, 46022 Spain. E-mail: acorma@itq.upv.es

Received (in Cambridge, UK) 3rd November 1999, Accepted 8th December 1999

A new zeolitic material TiITQ-6 has been obtained by the direct synthesis of a layered titanosilicate precursor, followed by delamination; titanium is tetrahedrally coordinated in framework positions and, while the zeolite derived from the precursor has little activity owing to geometrical constraints, the delaminated TiITQ-6 material is active and selective for the epoxidation of hex-1-ene with H_2O_2.

A new generation of oxidation catalysts started when TS-1[1] was synthesized and showed excellent catalytic activity in aqueous media using H_2O_2 as oxidant. Since then other Ti containing molecular sieves have been synthesized but only a few of them, of which TS-2[2] and Ti-beta[3] are outstanding, have shown to be active and selective for the epoxidation of linear olefins with H_2O_2. Recently[4] it has been proposed that the presence of Ti^{4+} ions tends to impede or to decrease the nucleation rates in the organothermal Ti-ferrierite (TiFER) system but by seeding with Si-ferrierite it was possible to prepare a Ti containing ferrierite. Unfortunately no catalytic activity for the sample was detected.[4] It was also demonstrated that it was possible to synthesize a laminar aluminosilicate precursor of ferrierite (PREFER)[5] that upon calcination could produce the ferrierite structure. In our case, we have succeeded in synthesizing directly, without seeding, the titanium containing laminar analogue TiPREFER. This was prepared in the following manner: 10 g silica (Aerosil 200, Degussa), 0.759 g of titanium(IV) ethoxide (Alfa 98%), 28.186 g H_2O (MiliQ), 26.008 g of 4-amino-2,2,6,6-tetramethylpiperidine (Fluka 98%), 9.246 g NH_4F (Aldrich 98%) and 3.462 g HF (Aldrich, 48.1 wt%) were mixed in an autoclave at 408 K for 10 days. The resulting product TiPREFER was filtered off, washed three times, and dried at 333 K. The X-ray diffraction (XRD) pattern of the product is shown in Fig. 1(a). The UV spectrum of the sample shows a single absorption band at *ca.* 210 nm corresponding to isolated framework Ti in tetrahedral coordination [Fig. 2(a)] and this band was maintained after calcination at 923 K for 12 h [Fig. 2(b)] to produce

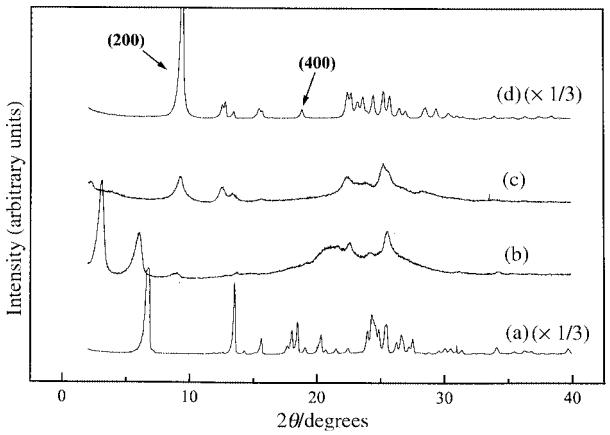

Fig. 1 X-Ray diffraction patterns of (a) TiPREFER, the laminar precursor of Ti-ferrierite, (b) TiPREITQ-6, the expanded material, (c) TiITQ-6, the delaminated zeolite and (d) TiFER, a Ti-ferrierite zeolite obtained after calcination of TiPREFER.

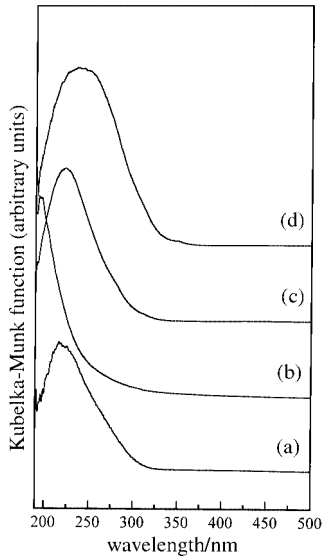

Fig. 2 Diffuse UV–VIS reflectance spectra of TiITQ-6: (a) as synthesised (TiPREFER), (b) Ti-Ferrierite, (c) TiITQ-6 and (d) TiITQ-6 after two reaction–calcination cycles.

the well crystallised Ti containing ferrierite TiFER [Fig. 1(d)]. The catalytic activity of this material for the epoxidation of hex-1-ene with H_2O_2 was tested in a batch reactor in the following way: 16.5 mmol olefin, 11.8 acetonitrile and 300 mg TiFER (1.3 wt% TiO_2) were introduced in a three necked glass flask which was heated to 323 K in a temperature controlled silicon bath. 4.5 mmol H_2O_2 (30% vol) was then added dropwise and the catalytic results obtained are given in Table 1. Very little conversion of hex-1-ene was observed for TiFER owing to diffusion limitation in the pores of this structure, in a similar manner found to that for another unidirectional 10-member ring pore zeolite Ti-ZSM-48.[6]

Table 1 Catalytic activity of Ti zeolites for hex-1-ene epoxidation[a]

Sample	$X_{\text{hex-1-ene}}$ (% of maximum)	Selectivity to epoxide (%)	Selectivity to H_2O_2 (%)	TON
TiFER	3.2	85.2	23	6
Ti-beta	18.0	97.2	77	20
TiITQ-6	19.7	95.5	73	23
TiITQ-6[b]	17.7	93.2	56	21

[a] *Reaction conditions*: 16.5 mmol olefin; 11.8 g acetonitrile; 4.5 mmol H_2O_2; 300 mg catalyst; 323 K, 5 h. [b] After two regeneration cycles.

Recently,[7] a new approach has been undertaken for expanding the use of zeolites to catalyze reactions when the accessibility of the reactants to the active sites is hindered. This involves the preparation of lamellar precursors of zeolites whose structure is subsequently delaminated making potentially catalytically active sites accessible through the external surface. Up to now the only delaminated material reported has been ITQ-2 which shows outstanding adsorption and catalytic

properties as an acid catalyst for large reactant molecules.[8] Unfortunately, the titanosilicate counterpart of ITQ-2 was not synthesized, and oxidation catalysts based on this material could only be prepared *via* secondary synthesis by anchoring Ti on external silanol groups.[9] The resultant materials were active and selective for epoxidation of olefins with organic peroxides, but they were not active when using the more desirable H_2O_2 as oxidating agent.

Here, we have succeeded in delaminating the Ti laminar precursor of TiFER in the following way: TiPREFER was suspended in a aqueous solution of cetyltrimethylammonium bromide ($CTMA^+Br^-$,29 wt%) and tetrapropylammonium hydroxide (TPA^+OH, 40 wt%) and refluxed for 16 h at 368 K. The XRD pattern of the expanded material is shown in Fig. 1(b). Delamination was performed by placing the slurry in an ultrasound bath (50 W, 40 kHz) at 323 K for 1 h, and maintaining the pH at 12.5. Finally the solid phase was washed thoroughly with water, dried at 333 K and calcined at 853 K for 7 h yielding TiITQ-6 with the XRD pattern shown in Fig. 1(c). The Ti in TiITQ-6 remained in tetrahedral coordination as shown by its UV spectrum [Fig. 2(c)]. Some removal of Ti has occurred during the delamination process (*ca.* 25%), nevertheless, when a sample of TiITQ-6 with a similar amount of Ti (1 wt% TiO_2) as in TiFER was prepared it showed a much higher activity and better selectivity for epoxidation of hex-1-ene than TiFER itself (Table 1). The increase in activity of TiITQ-6 is due to the higher accessibility of Ti-sites as a consequence of delamination of the TiPREFER structure. The external surface area of TiITQ-6 is 610 $m^2\ g^{-1}$ while that of the TiFER is only 60 $m^2\ g^{-1}$. In addition, the micropore volume of TiFER is 0.1304 cm g^{-1}, *cf.* 0.0016 cm g^{-1} for TiITQ-6. From these results it is clear that practically full delamination of the TiPREFER structure has occurred.

In order to have a reference for the catalytic activity of TiITQ-6, we carried out the same under the same conditions using Ti-beta with a similar Ti content (1.3 wt% Ti). The results in Table 1 show that the activity of TiITQ-6 is similar to that of Ti-beta. Moreover, the stability of TiITQ-6 under the reaction conditions is high since its activity remains close to that of the fresh catalyst after being subject to two reaction-regeneration cycles (calcination at 853 K for 7 h) (Table 1).

In conclusion, TiFER and a new zeolitic titanosilicate material (TiITQ-6) have been synthesized and, while the former presents a low catalytic activity for epoxidation of hex-1-ene with H_2O_2 owing to diffusional limitations of the reactants and products through the unidirectional 10MR channel of the zeolite, TiITQ-6 shows activities and selectivities similar to those of Ti-beta, owing to the good accesibility of the reactants to the active sites achieved by delamination of the TiPREFER laminar precursor.

A highly *dl*-stereoselective pinacolization of aromatic aldehydes mediated by $TiCl_4$–Zn

Tingyou Li, Wei Cui, Jigang Liu, Jianzhang Zhao and Zongmu Wang*

College of Life Science, Jilin University, Changchun, 130023, P.R. China. E-mail: liwei@mail.jlu.edu.cn

Received (in Cambridge, UK) 15th November 1999, Accepted 2nd December 1999

Reduction of $TiCl_4(THF)_4$ with Zn in CH_2Cl_2 gave a green solution, which was found to promote the reductive coupling of aromatic aldehydes to yield 1,2-diols with high *threo* selectivity.

The pinacol coupling reaction, which allows the generation of 1,2-diols in one step, is a powerful synthetic reaction, and therefore has been recognized as one of the most significant C–C bond forming processes in synthetic organic chemistry.[1,2] In addition, *threo*-1,2-diols have, after resolution, frequently been utilized as auxiliaries in asymmetric synthesis.[3] Although a number of methods have been developed for the reductive coupling of carbonyl compounds,[4–6] selective pinacolization to *threo*-diols has only been found with stannylene precursors,[7] 'active titanium(III) reagents' prepared from $TiCl_4$/BuLi in Et_2O at −78 °C,[8] $TiCl_4$/$Bu^i{}_2Te$ in DME,[9] $TiCl_3$/CH_2Cl_2 solution[10] or $(Cp_2TiCl)_2$.[11,12] $(Cp_2TiCl)_2$, a binuclear complex, can be easily prepared from Cp_2TiCl_2 and used in stiochiometric or catalytic amounts in the pinacol coupling reaction. Many of these reagents are expensive and/or air sensitive.

Here we report the $TiCl_4$–Zn promoted reductive coupling of aromatic aldehydes in anhydrous solvent at room temperature. By the choice of an appropriate mole ratio of $TiCl_4$ and Zn and an appropriate coordinating additive such as TMEDA, TiCl-Zn and $TiCl_4$–Zn–TMEDA reduce benzaldehyde and other actived aromatic aldehydes to the corresponding pinacols in good yields and, what is more important, the coupling is highly *dl* selective.

It is noteworthy that the reagents used are readily available, inexpensive and stable to air oxidation, and the method is easier and more convenient compared with those so far reported. Thus, we produced 'actived titanium' and reduced aldehydes in one pot in only a short time.

In 1973, Mukaiyama[13] reported that $TiCl_4$–Zn reduced aromatic aldehydes or ketones to produce the corresponding 1,2-diols in high yield, but the stereoselectivity was not reported. At the outset of the study, we used THF as solvent, with an aldehyde to $TiCl_4$ to Zn ratio of 1 : 1.5 : 3, and obtained the hydrobenzoin with a *dl* : *meso* ratio of 3 : 1. When CH_2Cl_2 was selected as the solvent, with THF as a ligand and a mole ratio of $TiCl_4$ to Zn of 2 : 1, better results were obtained.

A typical procedure is as follows: THF (11.7 mmol) was added dropwise to a solution of $TiCl_4$ (3.65 mmol) in 10 ml of CH_2Cl_2 under an atmosphere of argon at room temperature. To this solution Zn (1.82 mmol) was added in one portion. The color of the solution changed to green immediately. After stirring for 3 min benzaldehyde (3.65 mmol) in 3 ml of CH_2Cl_2 was added in one portion. After 30 min of stirring, the reaction was quenched with 15 ml of 10% K_2CO_3 and extracted with EtOAc followed by chromatography to give 0.22 g of hydrobenzoin (57%, 94 : 1 *dl* : *meso*).

When the reduction time was less than 20 min, acceptable yields and high *dl* selectivities were obtained. However, when the reduction time was greater than 1 h, the color of solution changes from green to black, and no product was obtained. According to the reports of Piotr Sobota[14] and Kirrsten Foling,[15] we assume that the $TiCl_4(THF)_2$ was first reduced to $[Ti_2(\mu\text{-}Cl)_2Cl_4(THF)_4]$ by Zn in CH_2Cl_2; $ZnCl_2$ can then abstract chlorine from $[Ti_2(\mu\text{-}Cl)_2Cl_4(THF)_4]$ and form ionized $[TiCl_2(THF)_4{}^+ \cdot ZnCl_3(THF)^-]$. We think the binuclear complex $[Ti_2(\mu\text{-}Cl)_2Cl_4(THF)_4]$ is the active compound which reduces the benzaldehyde to pinacol with high *dl*-selectivity, exactly as $(Cp_2TiCl)_2$ has high *dl*-selectivity. The ionized $[TiCl_2(THF)_4{}^+ \cdot ZnCl_3(THF)^-]$ has no activity to benzaldehyde. In order to lower the Lewis activity of the $ZnCl_2$ and suppress ionization of the $[Ti_2(\mu\text{-}Cl)_2Cl_4(THF)_4]$, a coordinating additive, especially Lewis bases such as Py and TMEDA, is added. When the reduction was carried out in the presence of 1.5 equiv. of TMEDA as an additive the yield improved to 76% and only the *dl*-isomer was obtained.

Under the optimised conditions, a variety of symmetrical 1,2-diols were synthesized in good yields and excellent selectivity, and could be obtained diastereomerically pure after

Table 1 Coupling of benzaldehyde mediated by $TiCl_4$–Zn

a single recrystallization. Functional groups, such as halide and cyano groups, are tolerated. Aromatic aldehydes bearing an electron-donating group showed lower reactivity, for example, *p*-anisaldehyde afforded no significant conversion *via* TLC observation.

Mechanistically it seems reasonable to assume that the active species is a binuclear titanium complex binding both ketyl radicals, in which the Ar groups are arranged *anti* to each other to minimized steric interaction. When the binuclear titanium complex is coordinated with TMEDA, the sterically crowded environment drastically improved the pinacol diastereoselectivities (Fig. 1).

Self-assembled monolayers of bis-thioctic ester derivatives of oligoethyleneglycols: remarkable selectivity for K^+/Na^+ recognition†

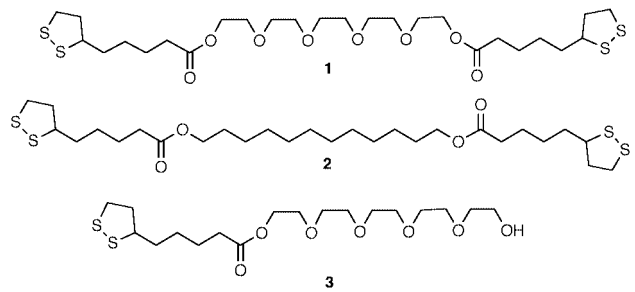
Received (in Columbia, MO, USA) 15th July 1999, Accepted 23rd November 1999

Bis-thioctic ester terminated derivatives of oligoethylene glycols form extremely stable self-assembled monlayers (SAMs) on gold electrodes and these can recognize K^+ selectively over Na^+, as measured by cyclic voltammetry and impedance spectroscopy.

The incorporation of crown-ether groups into self-assembled monolayers (SAMs) and their potential as metal ion sensors was reported very recently and almost simultaneously by Moore *et al.*[1] and by Flink *et al.*[2] In one case they prepared simple 12-crown-4 and 15-crown-5 derivatives with appended single chains terminated in thiol groups, and impedance spectroscopy was used to monitor ion binding events on the surface.[2] The other reported crown-annelated TTF derivatives which also contained single alkyl chains terminated in thiol groups.[1] The latter work exploited the direct response of the electroactive surface-confined crown-TTF groups to measure the effect of ion complexation, similar to previously reported work in homogeneous solution by Hansen *et al.*[3] These SAMs were apparently not very stable under several sets of conditions and the electrochemical responses observed were very weak and poorly resolved.[1] We have recently prepared and studied bis-thioctic ester derivatives of crown ether annelated TTFs, and these form remarkably stable SAMs, some of which are able to detect alkali metal ion binding electrochemically.[4] Here we report the easy synthesis, remarkable stability, and electrochemical (cyclic voltammetric and impedance) responses of SAMs of bis-thioctic ester derivatives of oligoethylene glycols (podands). The general idea was to use the glycols to form ion binding domains on the surface (similar to crown ethers) *via* self-assembly. The SAMs prepared showed amazing stabilities and selectivities for K^+ over Na^+ binding, making them potentially useful monolayer sensors.

Compounds **1**–**3** were easily synthesized in high yield by reacting the corresponding bis-alcohols [$HO(CH_2CH_2O)_4CH_2CH_2OH$ or $HO(CH_2)_{12}OH$] with thioctic acid in CH_2Cl_2 in the presence of DCC and 4-pyrrolidinopyridine or DMAP.[5] Compounds **1** and **3** were obtained from the same reaction as two separate products.



Glass-sealed, ultra-clean spherical gold bead electrodes prepared from ϕ 250 μm gold wire (99.9999%) were dipped into 5 mM EtOH solutions of the corresponding bis- or mono-thioctic ester compounds **1**–**3** for 24 h to form the corresponding SAMs.[6] After washing these with absolute EtOH and drying them in an Ar flow, these SAM modified electrodes were placed into 0.1 M aqueous Et_4NCl and the cyclic voltammograms (CVs) for 1 mM $Ru(NH_3)_6^{3+/2+}$ were recorded, using a platinum coil as counter and a Ag/AgCl as reference electrodes. The impedance response was also measured at the $E_{1/2}^0$ (−0.25 V) for the $Ru(NH_3)_6^{3+/2+}$ redox couple, between 1 kHz and 0.1 Hz.[7]

The CV response for the $Ru(NH_3)_6^{3+/2+}$ couple at a modified gold electrode of **1** is shown in Fig. 1(*a*) (dotted line).[8] It is clear that the insulating effect of the monolayer is poor, since the redox couple relatively easily undergoes electron transfer at the interface. This probably reflects poor surface coverage or good electron permeability through the monolayer. Interestingly, addition of 30 mM KCl to the solution results in a drastically reduced cathodic current and in the disappearance of the

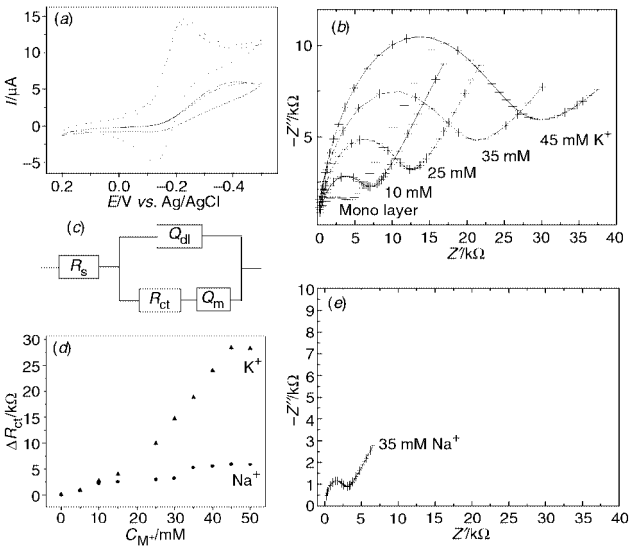


Fig. 1 (*a*) Cyclic voltammogram of $Ru(NH_3)_6^{3+/2+}$ in 0.1 M Et_4NCl using a monolayer-modified gold electrode (area = 0.02 cm^2) prepared from **1** before (dotted line) and after (solid line) addition of 30 mM of K^+ to the solution at a scan rate of 100 mV s^{-1}. (*b*) Impedance response of the same modified gold electrode in the absence and in the presence of varying amounts of [K^+]. The solid lines represent the fits of the experimental points to the equivalent circuit shown in (*c*). (*c*) Equivalent circuit used to fit the experimental data: R_S represents the solution resistance. The monolayer is described by a constant phase element Q_{dl} (used here as a generalized capacitance) in parallel with a resistance R_{CT} (the charge transfer resistance) and another constant phase element (Q_m) (related to diffusion controlled processes) in series. In admittance representation, a constant phase element is defined as $Y(\omega) = Y_0(j\omega)^n$ where Y_0 and n are adjustable parameters, n = 0, 1 and 0.5 correspond to an ideal resistor, a capacitor and a Warburg element, respectively, and ω is the angular frequency. The R_{CT} values can also directly be obtained from the diameter of the high frequency 'semicircle'. (*d*) Plot of the relative change of R_{CT} with [K^+] and with [Na^+]. (*e*) Impedance response of the same modified gold electrode in the presence of 35 mM NaCl. The response is essentially identical to that of the initial monolayer, see Fig. 1(*b*).

† Dedicated to Professor Jean-Marie Lehn on the occasion of his 60th birthday.

corresponding anodic process, indicating that electron transfer at the interface is dramatically inhibited, see Fig. 1(*a*) (solid line). On the other hand, addition of Na^+ has essentially no effect on the voltammetric response of this redox couple. These observations are consistent with complexation of K^+ (but not Na^+) with the monolayer, resulting in partial repulsion of the positively charged $Ru(NH_3)_6^{3+/2+}$ redox pair when K^+ is present. Note that the blocking effect due to K^+ addition is not perfect and some current is still observed.

Since none of the structural components of the SAM are electroactive, impedance spectroscopy was used to further probe ion recognition at the interface.[2] The impedance response for the same monolayer for which the CV is shown in Fig. 1(*a*) was measured in the absence and in the presence of increasing [K^+], and the data are presented in Fig. 1(*b*), as a Nyquist plot. Note that a very small R_{CT} (charge transfer resistance, determined as the diameter of the high frequency semicircle) is observed for the monolayer alone in the absence of K^+, 4.8 kΩ, and a significant diffusion component is observed as the linear portion at lower frequencies, indicating inefficient blocking to charge transfer. The fractional surface coverage (θ) was calculated to be 0.96 following well-established procedures.[9] These observations are consistent with the CV data already described, which showed that the SAM is either loosely packed or allows close approach of the redox probe to the modified electrode surface. Addition of K^+ to the solution resulted in dramatic and *reversible* increases in the R_{CT} values, from 7 kΩ at 5 mM to a limiting value of 31 kΩ at 45 mM, indicative of K^+ complexation at the interface and repulsion of the positively charged redox probe, in perfect agreement with the CV observations.[2] These values were obtained by a non-linear least-square fit of the experimental data to the equivalent circuit shown in Fig. 1(*c*), using the program EQUIVALENT CIRCUIT.[2] A plot of ΔR_{CT} *vs.* [K^+] shows two linear regions at different concentration ranges, and these intersect around 17 mM [K^+]. This complex ion response is in agreement with the non-linear fits, which yield different slopes for the CPE [Fig. 1(*b*)] and thus different '*n*' parameter values. At 45 mM KCl the surface binding sites must be saturated and no R_{CT} changes are observed with further salt additions. These SAMs are very stable and the results can be reproduced repeatedly over the course of days. With a useful range of 17–45 mM [K^+], this is not a practical sensor, but the novel principles established here should lead to improved designs in the future.

The same SAM electrode used to probe [K^+] was placed in solutions with increasing NaCl concentrations. The impedance results are presented in Fig. 1(*e*). In agreement with the results obtained by cyclic voltammetry, Na^+ showed almost no effect on the R_{CT} value of the monolayer [Fig. 1(*d*)], indicating that it is not binding significantly with the surface and thus not increasing its blocking effect. Simply based on the observations presented in Fig. 1(*b*) and (*e*) it is fair to say that a monolayer of **1** can act as a reversible and highly selective sensor for K^+ over Na^+. The selectivity for K^+ over Na^+ suggests the formation of a surface-confined *pseudo*-18-crown-6 structure, but further characterization is needed. Sensitivity, on the other hand, is not high, partly due to the inherent limitations of impedance response under the present conditions.

Control experiments with compounds **2** and **3** confirm the stated hypothesis. Compound **2** forms an initial monolayer which is a better insulator than **1** for charge transfer, as indicated by a high R_{CT}, 25 kΩ, but it exhibits no R_{CT} changes upon exposure to either K^+ or Na^+. That the initial monolayer is a good insulator is not surprising in view of its high hydrocarbon content. The mono-ester compound **3** has almost no charge transfer blocking ability in the absence or presence of alkali metal ions, and behaves essentially as a bare gold electrode.

In summary, we have prepared remarkably stable monolayers containing oligoethylene glycols on gold beads, and these exhibit impedance changes in the presence of K^+ but not with Na^+. While far from being useful sensors, the present SAMs are conceptually novel structures with unique cation binding properties exhibiting high selectivity.

7 Impedance measurements were performed using a three electrode cell configuration with a monolayer-coated gold bead, a coiled platinum wire and Ag/AgCl as working, counter and reference electrode, respectively. The potential was held at the formal potential of the redox couple, and readings were taken at ten discrete frequencies per decade with an ac amplitude of 5 mV. The formal redox potential [$E_{\frac{1}{2}} = (E_p^c + E_p^a)/2$], where [$Ru(NH_3)_6^{3+}$] = [$Ru(NH_3)_6^{2+}$] was determined from cyclic voltammetry. Impedance analysis was carried out using the commercially available program EQUIVALENT CIRCUIT written by B. A. Boukamp (University of Twente), which determines the parameters of the assumed equivalent circuit by a non-linear least-square fit.

8 All electrochemical experiments were performed using a BAS-100W system. Electrolyte solutions were prepared from recrystallized materials using spectroscopic grade solvents and purged with argon prior to use. A three-electrode configuration was used with a Ag/AgCl reference electrode and a platinum wire as the counter electrode.

Synthesis and single crystal X-ray structure of the first cationic Pd(II) complex of a tellurium-containing polyaza macrocycle: contrasting reactions of Pd(II) and Pt(II) with a 22-membered macrocyclic Schiff base

Saija C. Menon,[a] Arunashree Panda,[a] Harkesh B. Singh*[a] and Ray J. Butcher[b]

[a] *Department of Chemistry, Indian Institute of Technology, Powai, Bombay 4000 076 India. E-mail: chhbsia@chem.iitb.ernet.in*

[b] *Department of Chemistry, Howard University, Washington, DC 20059, USA*

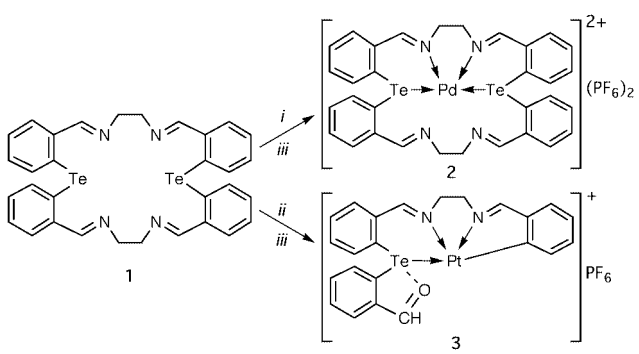
Received (in Cambridge, UK) 1st November 1999, Accepted 7th December 1999

The reaction of the tellurium containing macrocyclic Schiff base 1 with $Pd(PhCN)_2Cl_2$ and NH_4PF_6 gives the expected cationic complex $[Pd^{II}\mathbf{1}][PF_6]_2$; by contrast the reaction of 1 with $Pt(cod)Cl_2$ proceeds *via* novel transmetallation to yield an organoplatinum complex.

The chemistry of macrocycles bearing nitrogen or sulfur atoms has been very well developed.[1] The considerable effort which has been directed towards studying the coordination chemistry of polythio crowns in recent years has established that these macrocyclic ligands exhibit very different coordinating properties from their acyclic counterparts. This is principally due to the greater σ-donor effects caused by their cyclic nature which has facilitated stabilization of a wide range of metal ions in relatively unusual oxidation states. Polyselenoether macrocycles have an equally good potential to serve as ligands, however, the number of known polyselenoether macrocycles is very small.[2]

Recent studies by Levason *et al.* and others have established that the acyclic telluroether ligands are significantly better σ-donors compared to the lighter group 16 congeners.[3] Despite this, extension of this type of chemistry to the corresponding tellurium macrocycles is virtually unknown. A few notable examples include, 21-telluraporphyrins[4a] and 1,1,5,5,9,9-hexachloro-1,5,9-tritelluracyclododecane.[4b] Recently we have reported an easy, high yield template free synthesis, structure and preliminary coordination behaviour of the novel tellurium azamacrocycle **1**.[4c] The high yield and template free synthesis of **1** arises from intramolecular Te···N interactions in the macrocyclic ring.[4c] In continuation of this work, we report here, the synthesis and structure of the first cationic Pd(II) complex of the tellurium containing macrocyclic Schiff base **1**[4c] and the contrasting reaction of $Pt(cod)Cl_2$ with **1**. Both complexes **2** and **3** have been characterized by ^1H, ^{13}C, ^{125}Te NMR, mass and X-ray crystallography.

The reaction of **1** with 1 equivalent of $Pd(PhCN)_2Cl_2$ in $CHCl_3$ afforded a reddish yellow powder which was dissolved in methanol and treated with an excess of NH_4PF_6 to give the yellow complex **2** (Scheme 1). Slow diffusion of diethyl ether into an acetonitrile solution of this complex afforded yellow needles of **2**. This complex is fairly soluble in MeCN, $MeNO_2$, acetone, DMF and DMSO but insoluble in common chlorinated solvents. The IR spectrum of the complex confirmed the presence of PF_6^- [ν(P–F) 836, δ(F–P–F) 556 cm^{-1}] and showed a peak at 1639.8 cm^{-1} corresponding to the azomethine stretching frequency. The ^1H NMR spectrum of complex **2** exhibited two peaks in equal intensity at 8.99 and 8.82 ppm for the azomethine protons. The ^{13}C NMR spectrum showed two signals for the azomethine carbons at 170.81 and 163.76 ppm and for the methylene carbons at 58.11 and 63.75 ppm, suggesting coordination through only two imine nitrogens. However, the ^{125}Te NMR spectrum showed a single deshielded signal at 739.96 ppm *cf.* 607.1 ppm for the free ligand **1**[4c] thus indicating the coordination of Te to Pd and the presence of an identical environment around both the tellurium atoms. Elemental analysis data for complex **2** suggested the formation of a 1:1 product. The FAB mass spectrum of **2** showed a highest mass peak at *m/z* 977 corresponding to $\mathbf{2}^+ - PF_6^-$. Hence a formulation of $[Pd^{II}\mathbf{1}][PF_6]_2$ for the complex is suggested. The structure was further confirmed by single crystal X-ray diffraction studies‡.



Scheme 1 *Reagents and conditions*: i, $Pd(PhCN)_2Cl_2$, $CHCl_3$, 2 h; ii, $Pt(cod)Cl_2$, CH_2Cl_2, 16 h; iii, MeOH, NH_4PF_6, room temp.

Interestingly, a similar reaction of **1** with $Pt(cod)Cl_2$ in dichloromethane yielded a reddish brown precipitate of the complex **3**† (Scheme 1) which could be recrystallized by slow evaporation from acetonitrile. The IR spectrum of **3** showed peaks consistent with the presence of ν(C=O) and ν(C=N) stretching frequencies at 1697 and 1647 cm^{-1}, respectively. The peak at 10.24 ppm in the ^1H NMR spectrum of **3** was assigned to an aldehydic proton. In addition, two peaks at 9.17 and 8.73 ppm were observed for the azomethine protons. The ^{125}Te NMR spectrum showed a high intensity peak at 708.39 ppm and a low intensity peak at 684.12 ppm. Similar behaviour has been observed for $[Pt([16]aneSe_4)][PF_6]_2$ by Reid and coworkers who observed two resonances for ^{77}Se at 187 and 147 ppm in MeCN at 300 K.[5] These authors suggested the presence of at least two invertomers in solution. The FAB mass spectrum showed a highest peak at *m/z* 665 corresponding to $\mathbf{3}^+ - PF_6^-$. Elemental analysis also suggested the formation of complex **3** the structure of which was confirmed from X-ray crystallographic studies.‡ The novel organoplatinum complex **3** results from facile C–Te bond cleavage and transmetallation. McWhinnie *et al.*, we and others have observed a similar transfer of organic groups from tellurium to another metal in the reactions of $HgCl_2$,[4c,6] copper salts,[7] Pd(II)[8,9] and Pt(II)[3d,9] with telluroethers. The facile cleavage of the C–Te bond is due to strong N → Te intramolecular interactions which activate the *trans* C–Te bond.

A view of the cation of the Pd(II) complex **2** is shown in Fig. 1. The cation adopts a four coordinate geometry, with coordination by two nitrogen and two tellurium atoms. The N–Pd–N, Te–Pd–Te and N–Pd–Te angles are close to 90 and 180°. The Pd–Te(1A) and Pd–Te(1B) bond distances of 2.5443(7) and 2.5483(7) Å are comparable to the Pd(1)–Te(1) and Pd(2)–Te(3) distances of 2.540(2) and 2.549(20 Å,

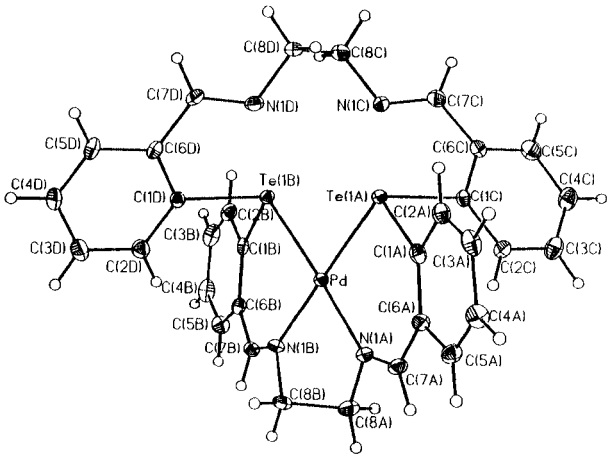


Fig. 1 An ORTEP diagram of Pd complex **2**. Selected bond lengths (Å) and angles (°): Te(1A)–Pd 2.5443(7), Te(1B)–Pd 2.5483(7), Pd–N(1A) 2.097(6), Pd–N(1B) 2.099(6), Te(1A)–N(1C) 2.739, Te(1B)–N(1D) 2.737, Te(1A)···Te(1B) 3.591, N(1B)–Pd–Te(1A) 176.9(2), N(1A)–Pd–Te(1B) 175.9(2), Te(1A)–Pd–Te(1B) 89.68(2), N(1A)–Pd–Te(1A) 94.4(2), N(1B)–Pd–Te(1B) 93.1(2).N(1A)–Pd–N(1B) 82.8(2).

respectively, in [{Pd(C_6H_4(TeMe)Te-*o*)I}$_4$].[8] The Te···N distances of 2.739 and 2.737 Å are well within the van der Waals distance (3.7 Å following Pauling[10]) and the Te–C–C–C–N moieties are planar. The tellurium is acting simultaneously as a Lewis acid and Lewis base. The Te···Te transannular bond distance of 3.591 Å is significantly shorter than the sum of the van der Waals radii (4.4 Å). This distance is also shorter than the transannular Te···Te bond distance (4.979 Å)[4c] in free ligand **1**.

The cation of complex **3** is shown in Fig. 2. The structure shows square planar geometry around the Pt(II) ion with coordination of carbon, tellurium and two nitrogen atoms. The angles around the Pt(II) ion lie in the range 80–100° and 162–177°, indicating the distorted square planar geometry. The Pt–Te bond distance of 2.5180(6) Å is comparable with the Pt–Te distance of 2.512(1) Å in [Pt{(NC_5H_4-2-$(CH_2)_2$-Te-C_6H_4-4-OMe}Cl_2].[11] The intramolecular Te···O distance of 3.004 Å implies a weak coordination of oxygen to tellurium as it is significantly shorter than the sum of the van der Waals radii (3.6 Å) of Te and O. However, this bond distance is longer than the mean tellurium–oxygen distance of 2.76 Å observed in bis(*o*-formylphenyl)ditelluride.[12] In addition, the cations are linked into weak dimers by weak intermolecular Te···Pt contacts (3.483 Å). Complex **3** is the first example of a structurally characterized organoplatinum complex having both intramolecular Te→Pt and intermolecular Pt···Te interactions.

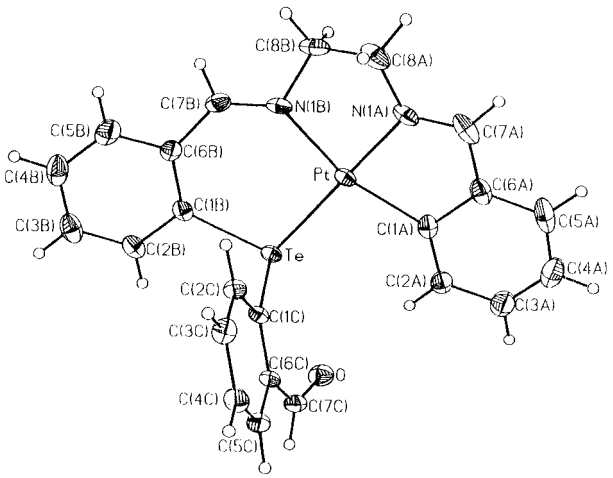

Fig. 2 An ORTEP diagram of Pt complex **3**. Received (in Basel, Switzerland) 26th November 1999, Accepted 10th December 1999

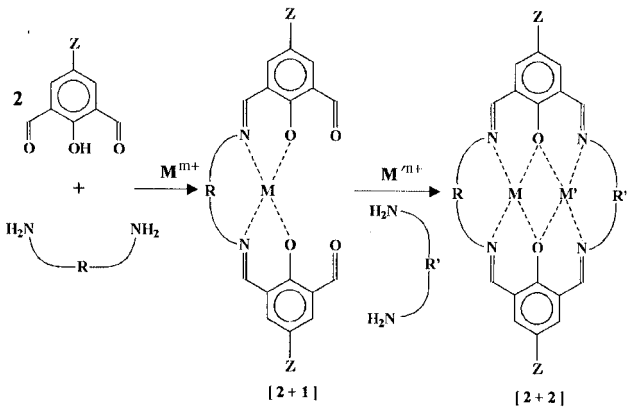
A heterodinuclear macrocyclic complex containing both Yb^{3+} and Na^+ ions has been synthesized and characterized by X-ray crystallography and ^1H and ^{23}Na solution NMR; at room temperature the coordinated Na^+ ion is in slow chemical exchange with free Na^+ ions and its NMR resonance is strongly shifted.

In recent years asymmetric compartmental ligands have been under intense scrutiny because it is expected that well defined bimetallic systems may find interesting applications in several areas of chemical research.[1–4] The synthesis of compartmental macrocycles is commonly pursued by a step-by-step condensation of 2,6-diformyl-4-substituted phenols with polyamines which may also contain other donor atoms. Heterodinuclear (M,M′) complexes may be conveniently prepared by reacting the intermediate [2 + 1] acyclic complex, obtained by template synthesis in the presence of M^{m+} ions, with a suitable polyamine in the presence of M'^{n+} ions.[5]

A marked difference in the set of donor atoms of the two adjacent chambers favours the formation of heterodinuclear complexes (with respect to homodinuclear complexes) thus limitating the possibility of positional heterodinuclear isomers.[6,7]

Here, we investigate the synthesis and characterisation of a Yb–Na dinuclear complex which represents the first example of macrocyclic compartmental complex containing a lanthanide and an alkali metal ions.

On the basis of the above considerations, it was thought that a suitable ligand should contain a Schiff base chamber for the lanthanide coordination and a crown-ether moiety for the coordination of the alkali metal ion. As diformyl precursor we used 3,3′-(3-oxapentane-1,5-diyldioxy)-bis(2-hydroxybenzaldehyde) which, upon reaction with 1,5-diamino-3-aza-methylpentane (Scheme 1) yields the asymmetric compartmental macrocycle shown in Fig. 1.[8,9]



Scheme 1

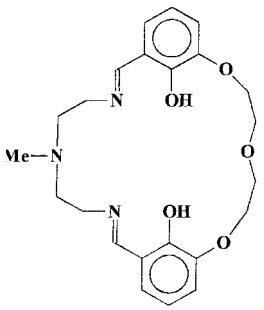


Fig. 1 Schematic representation of the compartmental macrocycle (L) designed for coordinating a lanthanide(III) ion into the Schiff base (N_3O_2) chamber and an alkali metal ion into the crown-ether moiety.

Rather surprisingly it was found that this macrocyclic ligand coordinates lanthanide(III) ions into the crown-ether chamber rather than into the N_3O_2 Schiff base.[9,10] On the other hand the same crown-ether chamber is involved in the coordination of alkali ions in the case of homonuclear alkaline metal containing species.[11] Thus, although both ions prefer coordination at the O_2O_3 chamber, we surmise that the use of the Na^+ containing complex may force the coordination of the lanthanide(III) ion into the Schiff-base chamber.

This synthetic strategy was successful as shown by the spectroscopic properties and X-ray structure of the obtained $YbNa(L)Cl_2$ derivative (Fig. 2).†

The ytterbium ion is coordinated by two chlorine atoms in *trans* positions and by three nitrogen and two negatively charged phenyl oxygen atoms of the ligand, reaching hepta-coordination with a pentagonal bipyramidal geometry. The sodium ion is coordinated by the three etheric oxygen atoms and the same two phenyl oxygens that act as a bridge. A methanol molecule is also coordinated in the apical position of the resulting pentagonal pyramidal polyhedron. The oxygen atom of the methanol is disordered and two positions have been found. The Yb···Na contact distance is 3.555(2) Å.

The high temperature ^1H NMR spectrum (65 °C, CD_3OD) of $YbNa(L)Cl_2$ (Fig. 3) is consistent with the occurrence of a motion in the macrocyclic ring which reduces to half (twelve) the number of the observed resonances. Although the spectrum covers a range of *ca.* 70 ppm, the resonances associated with the two N_3O_2 and O_2O_3 chambers can be unambiguously assigned. In fact, the paramagnetic Yb(III) ion causes a large spread of the five protons (and of the methyl group) associated with the Schiff base compartment (−15 to −57 ppm) whereas the proton associated with the crown ether and aromatic moieties fall in the region +7 to −8 ppm *i.e.* they 'feel' only in part the paramagnetism of the lanthanide ion.

The ^{23}Na NMR spectrum at ambient temperature consists of the broad absorption of the bound ion (Na^b) at *ca.* 40 ppm

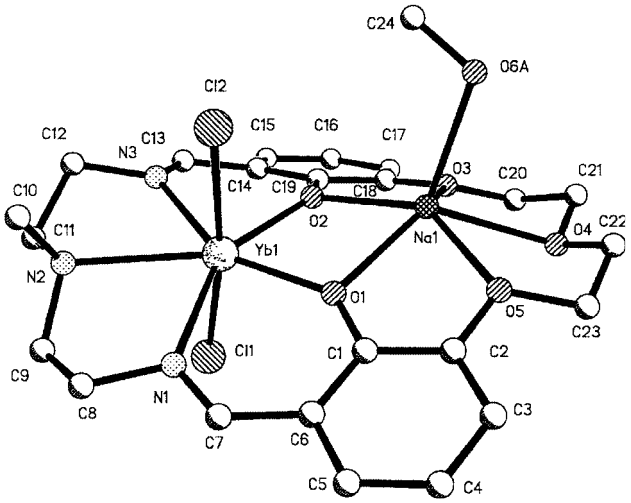

Fig. 2 ORTEP drawing of $[YbNa(L)Cl_2]\cdot MeOH$ with ellipsoids at the 50% probability level. Selected bond lengths (Å) and angles (°): Yb–O(1) 2.204(3), Yb–O(2) 2.226(3), Yb–N(1) 2.459(4), Yb–N(2) 2.593(4), Yb–N(3) 2.474(4), Yb–Cl(1) 2.582(1), Yb–Cl(2) 2.638(1), Na–O(1) 2.343(4), Na–O(2) 2.296(4), Na–O(3) 2.370(5), Na–O(4) 2.444(5), Na–O(5) 2.316(4), Na–O(6)(methanol) 2.35(mean); Cl(1)–Yb–Cl(2) 172.14(4), Yb–O(1)–Na 102.2(1), Yb–O(2)–Na 103.0(1).

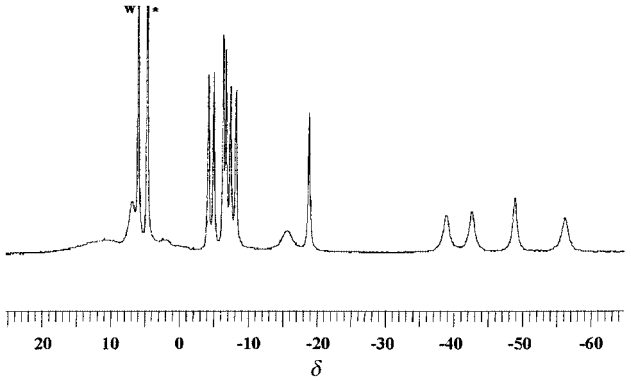

Fig. 3 400 MHz ^{1}H NMR spectrum of $YbNa(L)Cl_2$ at 65 °C in CD_3OD. The water and methanol resonances have been labelled with the symbols w and *, respectively.

upfield from that of the free ion (Na^f) [Fig. 4]. Upon increasing the temperature the exchange between Na^f and Na^b becomes fast on the NMR timescale [Fig. 4] and, at 65 °C, a relatively narrow absorption at *ca.* −16 ppm is observed. It seems reasonable to suggest that the release of Na^+ ion from the crown-ether chamber induces an overall flexibility of the macrocycle as the ^{1}H NMR spectrum recorded at ambient temperature is more complex than that obtained at 65 °C.

The high and negative paramagnetic ^{23}Na NMR shift observed for Na^b strongly suggests that the principal axis of the magnetic susceptibility tensor associated with the Yb(III) ion lies along the Yb–Na direction rather than along an axis perpendicular to the macrocyclic plane. This finding may be highly relevant to development of a novel class of ^{23}Na-shift

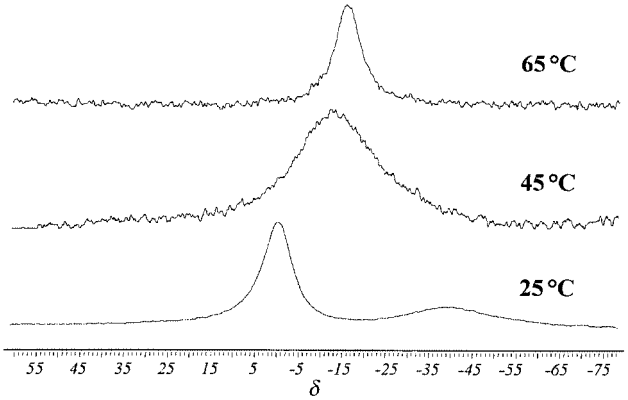

Fig. 4 Variable temperature ^{23}Na NMR spectra of $YbNa(L)Cl_2$ (25 mM) at 9.4 T in the presence of NaCl (30 mM) in CD_3OD.

reagents which could be very useful in separating the ^{23}Na NMR resonances for intra- and extra-cellular components.[12]

Solid-phase oligosaccharide synthesis with tris(alkoxy)benzyl amine (BAL) safety-catch anchoring

Jakob F. Tolborg and Knud J. Jensen*

Department of Organic Chemistry, Building 201, Kemitorvet, Technical University of Denmark, DK-2800 Lyngby, Denmark. E-mail: okkj@pop.dtu.dk

Received (in Liverpool, UK) 20th October 1999, Accepted 29th November 1999

A tris(alkoxy)benzylamine (BAL) handle strategy was developed for safety-catch anchoring of D-glucosamine derivatives in solid-phase synthesis of oligosaccharides; the linkage between the BAL handle and the amine proved stable to conc. TFA and Lewis acids, but after *N*-acylation the amide could be released by treatment with TFA–H_2O (19 : 1).

Cell-surface oligosaccharides are involved in many biological recognition processes.[1] Also, free oligosaccharides can have biological effects such as in rhizobial lipochitin oligosaccharides which function as nodulation factors.[2] Amino sugars are found in many biologically important poly- and oligo-saccharides, *e.g.* in glycans of *O*- and *N*-glycoproteins and -peptides, lipochitin nodulation factors, and amino glycoside antibiotics such as streptomycin.

Solid-phase synthesis of oligosaccharides, when performed combinatorially, offers the prospect of easy access to very large numbers of well-defined oligosaccharides as tools for glycobiology. Despite Frechet and Schuerch's early pioneering work[3] and recent significant progress,[4] considerable developments are required before solid-phase oligosaccharide synthesis can be put to general use. Crucial to any solid-phase synthesis plan is the efficient and reliable anchoring of the first building block, the stability of the anchoring linkage to the synthesis conditions, and upon completion of the synthesis the efficient release under conditions compatible with the structural integrity of the final product. The most common cleavage reagent in solid-phase peptide synthesis is conc. TFA. Previously reported handles for anchoring of carbohydrates to solid supports have included esters,[4a] silyl ethers,[4b] sulfonyl esters,[4c] acetals[4d] and thioalkyls[4e] and ethers.[4f,g]

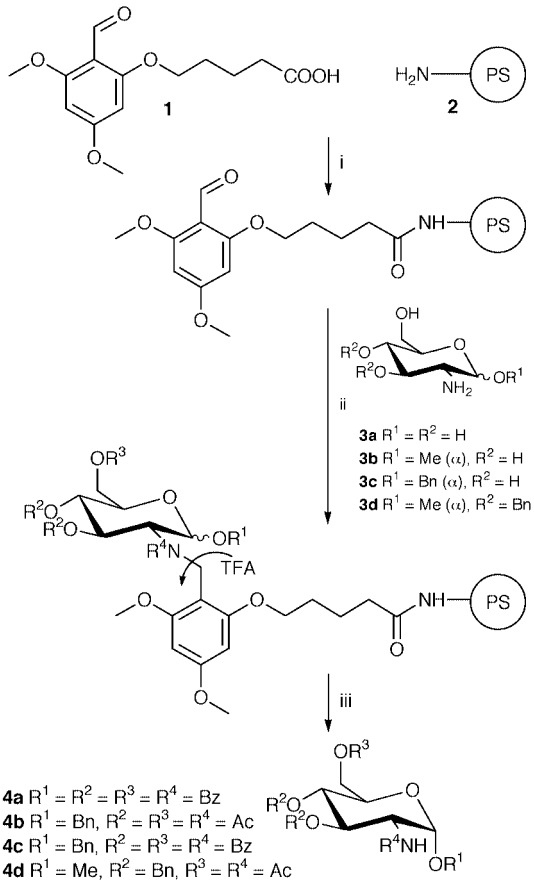
For the solid-phase synthesis of amino sugar containing oligosaccharides, we decided upon a strategy relying on release of final products by treatment with conc. TFA, with semi-permanent protecting groups to be removed in solution after purification and characterization.[5] The recently developed Backbone Amide Linker (BAL) handle strategy relies on anchoring of a peptide not through a carboxy group but through a backbone amide nitrogen leaving the *C*-terminus available for modifications.[6] Applied to anchoring of amino sugars, a BAL strategy would allow anchoring through an acetamido functionality leaving all hydroxy groups, including the anomeric, available for modification.

To investigate the anchoring concept, *o*-PALdehyde **1** was coupled to high-loading aminomethylated polystyrene **2** and unprotected D-glucosamine **3a** anchored through a BAL linkage by reductive amination in DMF–AcOH (99 : 1) in the presence of $NaBH_3CN$ (Scheme 1).† Perbenzoylation with BzCl followed by treatment with TFA–H_2O (19 : 1) yielded after column chromatography the α-pentabenzoate **4a** in 41% for a four step synthesis sequence. The presence of five benzoyl groups in the final product confirmed that anchoring had occurred through the amine rather than the putative *O*,*O*- or *O*,*N*-acetals.

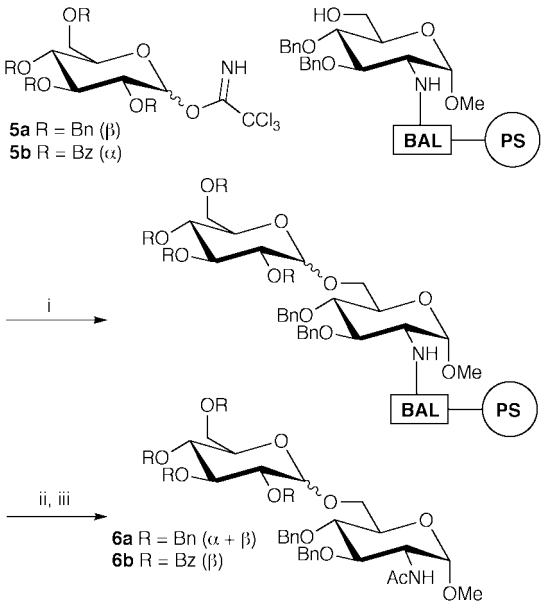
For fast and efficient quantification of resin-bound carbohydrates we used two techniques. In the first, UV-active amino sugar derivatives were released into solution with TFA–H_2O (19 : 1) followed by quantification with HPLC–UV from standard curves.

In the second technique, the resin-bound monosaccharide was treated with 4,4′-dimethoxytrityl chloride (DMTCl) to attach a DMT moiety at the primary 6-OH group. For quantification, the resin was exposed to TFA–MeCN (1 : 49) and released DMT estimated by UV. Quantification using DMT was performed on resin bound monosaccharides in order to determine the efficiency of the coupling of *o*-PALdehyde to the resin as well as the coupling of the amino sugar to the linker. The methyl and benzyl glycosides of D-glucosamine **3b** and **3c** were coupled with an efficiency of at least 95% (four steps from **2**, including DMT coupling and cleaving) independently of the resin loading. The solid-phase bound benzyl α-D-glucosaminide **3c** was then per-acylated with Ac_2O or BzCl. This yielded the fully acetylated and benzoylated products **4b** and **4c** in 91–96 and 82% yield, respectively, measured by HPLC standard curves.

Several solution-phase glycosylation methods have been adapted for solid-phase; they all require Lewis acids for activation.[4] While studying the use of trichloroacetimidates in



Scheme 1 *Reagents and conditions*: i, aminomethylated polystyrene **2**, **1** (2.0 equiv.), HBTU (1.9 equiv.), HOBt (2.0 equiv.), Pr^i_2NEt (3.9 equiv.), DMF, 10 h; ii, amino sugar (2.0 equiv.), $NaBH_3CN$ (10 equiv.), DMF–AcOH (99 : 1), 16 h, then protecting group chemistry including *N*-acylation; iii, TFA–H_2O (19 : 1), 30 min.



Scheme 2 *Reagents and conditions*: i, TMSOTf, CH_2Cl_2, 3 Å (Table 1); ii, Ac_2O–Py (2:1), 16 h; iii, TFA–H_2O (19:1), 30 min.

the presence of Lewis acid promoters for the glycosylation of BAL anchored D-glucosaminides, we realized that BAL anchoring could be operated in a safety-catch mode. The amine–BAL linkage proved stable to treatment with conc. TFA and more than stoichiometric amounts of Lewis acids such as $BF_3{\cdot}OEt_2$ and TMSOTf. After acylation to form the amide, the linkage became acid-labile and the carbohydrate could be released with conc. TFA.

For solid-phase glycosylations, we first synthesized the partially protected D-glucosamine derivative **3d**. Anchoring through a BAL handle to a polystyrene support was achieved as above, leaving the 6-OH free. In initial studies we used 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl trichloroacetimidate **5a**[7] in the presence of $BF_3{\cdot}OEt_2$ or TMSOTf as promoters (Scheme 2). Solid-phase reactions are most conveniently carried out at room temperature, but this gave only low yields of the disaccharide. However, when performing the glycosylation at −50 °C the disaccharide **6a** was obtained in 35% yield as an α/β mixture (five steps from **2**).

When using the *less reactive* benzoyl protected glycosyl donor 2,3,4,6-tetra-*O*-benzoyl-α-D-glucopyranosyl trichloroacetimidate **5b** in the presence of TMSOTf, yields of up to 82% of the disaccharide **6b**[8] were obtained (five steps from **2**), leaving as little as 2% of the unglycosylated monosaccharide (Table1). The disaccharide was obtained with an α:β ratio of < 1:10, the high β-selectivity being due to the neighboring group participation of the benzoyl group. Stoichiometric and sub-stoichiometric amounts of Lewis acids were used, relative to the donor. We found that TMSOTf was superior to $BF_3{\cdot}OEt_2$ as promoter, and MAS NMR revealed that the secondary amine did *not* carry a TMS group after exposure to TMSOTf in glycosylations. The high yield of 82% for the five step synthesis of **6b** also indicated that release of the final product with TFA–H_2O was near quantitative.

Table 1 Reaction conditions for synthesis of **6b**

T/°C	**5b**/equiv.	TMSOTf/ equiv.	Yield of **6b** (%) (β/α)
Room temp.	5.0	1.0	0
Room temp.	5.0	2.0	76 (14)
Room temp.	5.0	5.0	74 (20)
Room temp.	5.0	10.0	64 (17)
Room temp.	10.0	2.0	82 (11)
Room temp.	10.0	5.0	82 (16)
Room temp.	10.0	10.0	67 (17)

The initial resin loading of the aminomethylated polystyrene **2** was 0.40 mmol g^{-1}, which dropped to 0.36 mmol g^{-1} after coupling of *o*-PALdehyde **1** to the resin, and 0.32 mmol g^{-1} after attaching the partly protected monosaccharide **3d**. With high-loading resin (1.20 mmol g^{-1}) glycosylation became much less efficient..

In conclusion, we have developed a new and efficient strategy for anchoring amino sugars through a BAL handle to a solid support in which the amino sugar is attached by an efficient reductive amination. BAL anchoring was operated in a safety-catch mode as BAL linked amines were stable to Lewis acids and conc. TFA, whereas the corresponding amides were released from the support with conc. TFA. This allowed the use of Lewis acids in excess in solid-phase glycosylations. Using this strategy, we synthesized 1-6 linked disaccharides in high yields. The safety-catch protocol for BAL anchoring should also be useful for other applications.

We thank Flemming Jensen and Annette Lind Nordestgaard, Phytera, for MS, Drs Charlotte Godfredsen and Henrik Pedersen for MAS NMR, and the Lundbeck Foundation (K. J.) and the Danish Technical Research Council ('Talent Project' grant to K. J.) for financial support.

Notes and references

† All solid-phase reactions were carried out in plastic syringes at room temperature, except for glycosylations at −50 °C, which were carried out in glass flasks. Syringes were fitted with a polypropylene filter, a Teflon valve in the bottom, and closed in the top with the syringe plunger. For glycosylations, the syringe was instead closed with a septum, after the solid reactants were placed in the syringe. It was then dried in a desiccator *in vacuo* with the Teflon valve open. The desiccator was opened under argon, the Teflon valve closed, and the solvent and Lewis acid added through the septum. After 18 h the resins were washed and dried; final products were released from the support with TFA–H_2O (19:1). Glycosylations were typically performed on a 5 μmol scale. Quantifications were done by HPLC–UV integration of peak areas and use of standard curves established from benzyl and benzoyl containing compounds. Benzyl groups were monitored at λ = 215 nm, and benzoyl groups at λ = 265 nm. At the 5 μmol scale and without purification, the structure of **6b** was established by MS, ^{1}H NMR and gCOSY spectroscopy (ref. 8).

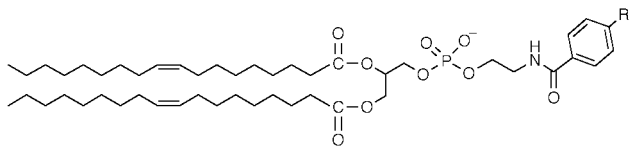
Received (in Columbia, MO, USA) 7th October 1999, Accepted 1st December 1999

Liposomes containing phospholipids bearing a sugar-binding boronic acid group exhibit enhanced binding to erythrocyte cells.

There is a need to develop liposomes that selectively self-assemble,[1] or interact with specific cell-types,[2] as this will likely lead to improved delivery systems and imaging agents.[3,4] The standard approach is to embed in the liposome membrane high molecular weight, biotic receptors (*e.g.* lectins) that have a selective affinity for cell-surface ligands, or conversely, to coat the liposome exterior with small ligands (*e.g.* folate) that bind selectively to receptor-containing cells.[5] If there is no natural binding partner for a desired cell-surface target then the only alternative is to construct an immunoliposome,[6] or perhaps a liposome coated with a rationally-designed synthetic receptor.†

Here we evaluate the cell-binding ability of a liposome system that contains phospholipids bearing a boronic acid. Over the last ten years a large number of boronic acid host compounds have been prepared and evaluated as synthetic saccharide-binding receptors.[13,14] In general, simple arylboronic acids have modest affinities ($K_a \sim 10$–10^4 M^{-1}) for saccharides containing a vicinal *cis*-diol. Since virtually all cell membranes include glycoproteins and/or glycolipids,[15,16] it is reasonable to expect that compounds containing boronic acid groups will bind to cell surfaces.[17] We find that liposomes containing the phospholipid–boronic acid conjugate DOPEBA have enhanced affinity for erythrocyte ghosts (red blood cells) as compared to related control liposomes that contain DOPEB, a structurally similar phospholipid that lacks a boronic acid residue.‡



DOPEBA (R = B(OH)$_2$)
DOPEB (R = H)

Erythrocytes are the simplest and best characterized human cells.[16] They are good models for binding and fusion studies since they cannot undergo endocytosis. Liposome-cell binding and membrane fusion were monitored using fluorescently labelled liposomes containing 0.3% of the phospholipid probe NBD-PE [*N*-(7-nitro-2,1,3-benzoxadiazol-4-yl)phosphatidylethanolamine] and its resonance energy transfer quencher Rh-PE [*N*-(lissamine rhodamine B sulfonyl)phosphatidylethanolamine].[19] Two measurements are listed in Table 1, the percentage of liposomes bound to the erythrocyte ghosts, and the percentage of the bound liposomes that appear to undergo lipid mixing with the erythrocyte membranes. These values were determined using a centrifugation method to separate the cell-bound liposomes from unbound liposomes.[20] NBD-PE/Rh-PE labeled liposomes (100 nmol) and erythrocyte ghosts (5×10^8 cells) were incubated for 40 min at 37 °C in 150 μl of EDTA containing MOPS buffered saline, pH 7.4, then the mixture was centrifuged at 6000 rpm. The pellet was suspended in buffer solution and liposome binding was determined from the Rh-PE fluorescence intensity in the presence of 0.2% $C_{12}E_8$ (octaethylene glycol monododecyl ether). The fluorescence of ghosts alone in the presence of 0.2% $C_{12}E_8$ was used as 0% binding while the fluorescence of a freshly prepared liposome–ghost mixture (no incubation and spin) in the presence of $C_{12}E_8$ was taken as 100% binding. The percent of cell-bound liposomes that subsequently underwent lipid mixing with the unlabelled erythrocyte ghosts was determined from the increase in NBD-PE fluorescence which was initially attributed to dilution of the NBD-PE/Rh-PE probes. The NBD-PE fluorescence for a freshly prepared liposome–ghost mixture (without incubation and spin) was measured in the presence and absence of 0.2% $C_{12}E_8$ to determine the 100 and 0% lipid mixing, respectively. The values listed in Table 1 were calculated using the formula described by Shangguan.[20]

The erythrocyte binding and subsequent lipid mixing of 4:1 DOPEBA/POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) liposomes was compared to 4:1 DOPEB/POPC liposomes, in the presence and absence of competing sodium D-glucarate or 4-carboxyphenylboronic acid.§ As described in Table 1, only 3% of the DOPEB/POPC (4:1) liposomes were bound to the erythrocytes at neutral pH, which is in agreement with another study on related liposome systems.[20] In the case of DOPEBA/POPC (4:1) liposomes, about 33% were erythrocyte-bound. Addition of 10 mM glucarate decreased this number by half, whereas addition of 10 mM 4-carboxyphenylboronic acid had no measurable effect. It appears that binding of dianionic glucarate to the surface of DOPEBA/POPC (4:1) liposomes makes them more negatively charged and decreases their affinity for the negatively charged surfaces of glycosylated erythrocyte cells. The inability of 4-carboxyphenylboronic acid to affect liposome-erythrocyte binding is likely an example of

Table 1 Binding and apparent lipid mixing of labelled liposomes with unlabelled erythrocytes

Liposomes	Additive	Liposomes bound to cells[a] (%)	Apparent lipid mixing[ab] (%)
DOPEBA/ POPC (4:1)	none	33	18
	sodium D-glucarate	17	19
	4-carboxyphenyl boronic acid	34	15
DOPEB/ POPC (4:1)	none	3	26
	sodium D-glucarate	3	25
	4-carboxyphenyl boronic acid	3	22

[a] Each value is the average of six runs, uncertainty ± 3%. [b] Percentage of cell-bound liposomes that appear to undergo lipid mixing.

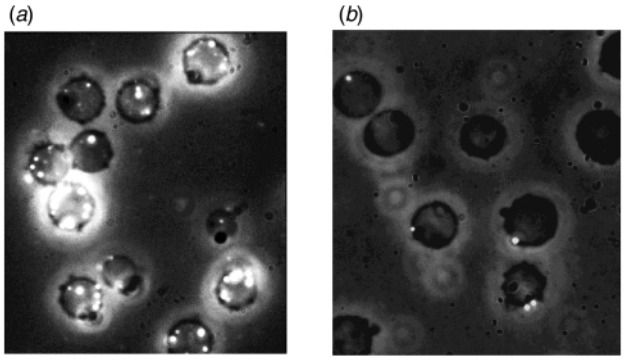


Fig. 1 Fluorescence and phase microscopy co-illumination images of Rh-PE containing liposomes bound to erythrocyte ghosts after a 10 min incubation followed by four wash cycles. The large dark circles are erythrocyte ghosts and the bright fluorescent dots are labelled liposomes. (*a*) DOPEBA/POPC (4:1) liposomes; (*b*) DOPEB/POPC (4:1) liposomes.

multivalency, where the binding constant for a monovalent boronic acid compound to the erythrocyte surface is quite weak, but the binding of a liposome that presents a partially organized array of boronic acid groups is much stronger. As expected, addition of glucarate or 4-carboxyphenylboronic acid had no effect on the binding of control DOPEB/POPC (4:1) liposomes (Table 1).

About 18% of the erythrocyte-bound DOPEBA/POPC (4:1) liposomes and 24% of the bound DOPEB/POPC (4:1) liposomes appeared to undergo lipid mixing (Table 1). Since the NBD-PE/Rh-PE lipid mixing assay is known to be susceptible to artefacts,[23,24] we decided to confirm binding and lipid mixing using a more direct method, namely, fluorescence microscopy.[20,25] In agreement with the binding data listed in Table 1, significantly more DOPEBA/POPC (4:1) liposomes were bound to the erythrocyte cells than control DOPEB/POPC (4:1) liposomes (Fig. 1). However, the fluorescence imaging showed no evidence for any lipid mixing (*i.e.* no evidence for the transfer of NBD-PE or Rh-PE probes from the liposomes to the erythrocytes),[20] which contrasts with the bulk solution data (Table 1). It appears that the increase in NBD-PE fluorescence seen in the bulk solution assay is not due to lipid mixing but is an artefact most likely due to liposome binding to the glycosylated structures on the cell surface. This result demonstrates the importance of using an alternative method to confirm the conclusions derived from lipid mixing assays.[23,24] Finally, we note that fluorescence imaging studies using liposomes filled with the water soluble dye, sulforhodamine B, produced no detectable evidence for enhanced delivery of liposomal contents.

Overall, the data is rationalized in terms of the following binding model. Unlike the DOPEB-containing liposomes, the DOPEBA-containing liposomes are able to bind strongly to the glycocalyx that projects from the erythrocyte cellular membrane. However, the DOPEBA-containing liposomes are still a significant distance from the erythrocyte membrane surface and there is no decrease in the energetic barrier to liposome–erythrocyte membrane adhesion and subsequent fusion.

The development of surface functionalized liposomes that bind to specific target cells appears to be feasible using current supramolecular technology.[2,7–12] A more difficult undertaking is the invention of structures that induce membrane fusion and thus facilitate drug delivery. Our initial efforts to address this problem will be published shortly.[26] This work was supported by the National Institutes of Health and the University of Notre Dame (Molecular Biosciences fellowship to Y. R. V.).

Notes and references

† There appears to be no previous report of enhanced cell-binding using a liposome coated with a rationally designed synthetic receptor. However, there are examples of artificial receptors enhancing small molecule recognition (ref. 7), liposome aggregation (ref. 8), and the binding and fusion of two different liposome populations (ref. 9). Also, the molecular recognition of monolayer surfaces using abiotic receptors and abiotic ligands is an active research area (refs. 10–12).

‡ The synthesis of DOPEBA has been reported before (ref. 18). DOPEB was prepared by treating dioleoylphosphatidylethanolamine with benzoyl cyanide. *Selected data* for DOPEB: δ ($CDCl_3$) 8.05 (s, 1H, N*H*), 7.86 (d, 2H, Ar*H*, *J* 7.2), 7.29–7.38 (m, 3H, Ar*H*), 5.27–5.39 (m, 4H, 2C*H*=C*H*), 5.13 (m, 1H, $POCH_2CH$), 4.27 (d, 1H, $POCH_2$), 3.83–4.04 (m, 5H, CH_2O-$POCH_2CHCH_2$), 3.60 (m, 2H, $NHCH_2$), 2.18 (t, 4H, $2COCH_2$, *J* 7.5), 2.00 (m, 8H, $2CH_2CH{=}CHCH_2$), 1.49 (m, 4H, $2COCH_2CH_2$), 1.26 [s br, 40H, $2COCH_2CH_2(CH_2)_4$ and $2(CH_2)_6CH_3$], 0.87 (t, 6H, $2CH_3$, *J* 6.6); HRMS (FAB) calc. for $C_{48}H_{81}O_9PNNa_2$ 892.5444, found 892.5475.

§ The liposomes were prepared by extrusion through polycarbonate filters as previously described (ref. 18). In each case, unilamellar vesicles (~100 nm diameter) were formed as determined by dynamic light scattering, encapsulation of aqueous contents, and lamellarity assays (ref. 21). Control experiments with liposomes containing NBD-PE/Rh-PE showed that the liposomes do not undergo significant morphology changes in the presence of sodium D-glucarate or 4-carboxyphenylboronic acid. This is in contrast to results obtained with non-liposomal aggregates of neutral and cationic amphiphiles with appended boronic acids (ref. 22).

Catalytic production of urethanes from amines and alkyl halides in supercritical carbon dioxide

Masaaki Yoshida,* Namiko Hara and Sanae Okuyama

Applied Chemistry, Faculty of Engineering, Utsunomiya University, Utsunomiya 321-8585, Japan.
E-mail: yoshidam@cc.utsunomiya-u.ac.jp

Received (in Cambridge, UK) 5th November 1999, Accepted 7th December 1999

Some common onium salts catalysed selective urethane production from amines and alkyl halides in supercritical carbon dioxide, which acted not only as an alternative to organic solvents but also as a phosgene replacement; the reaction efficiency was 50–100 times higher than that attained in heptane.

The most widely utilized method for the synthesis of urethanes uses highly toxic phosgene as a reagent in organic solvents, which are also toxic and flammable. Therefore the conventional method involves environmental and safety problems.

Owing to the above mentions, much effort has been directed toward alternative routes for preparation of urethanes using carbon dioxide as a phosgene replacement.[1–8] Carbon dioxide is well known to react rapidly with amines to form carbamic acid ammonium salts.[9] However, as the nucleophilicity of the carbamate anion is lower than that of the amine formed in the equilibrium of the salt formation reaction, the reaction of the carbamate salts with alkyl halides does not selectively afford urethanes.[2] So, the activation of the carbamate anion was attempted by addition of crown ethers[5] and strong bases.[4] Monsanto's chemists have achieved a highly selective urethane synthesis process using very strong bases (*e.g.* CyTMG: *N*-cyclohexyl-*N′*,*N′*,*N″*,*N″*-tetramethylguanidine).[7] However, because a stoichiometric amount of CyTMG was necessary in the reaction, the Monsanto process could not replace the conventional method.

We have successfully synthesized urethanes in high yields from amines, alkyl halides, potassium carbonate and a catalytic amount of an onium salt in supercritical carbon dioxide ($scCO_2$) [eqn. (1)]. Supercritical carbon dioxide is an attractive

$$R^1R^2NH + R^3X + K_2CO_3 \xrightarrow[scCO_2]{\text{onium salt}} R^1R^2NCOOR^3 \quad (1)$$

alternative to organic solvents as it is environmentally benign, essentially nontoxic, inexpensive, nonflammable and has relatively low critical conditions (P_c = 73 atm, T_c = 31 °C).†

The results of the one-pot urethane production are summarized in Table 1. Not only aliphatic primary and secondary amines but also aromatic amines reacted well. As these are catalytic reactions, the low yields should be improved by increasing the amount of catalyst or extending the reaction time.

The effect of catalyst on the conversion of a pyrrolidine, butyl chloride and potassium carbonate system in $scCO_2$ is given in Table 2. The reaction could be catalysed by amonium salts and a phosphonium salt. Among these, the catalysts that afforded the best results were tetrabutylammonium bromide and trioctylammonium chloride, which are commonly used in industry.

Sanchez and co-workers also reported a phosgene-replaced urethane synthesis in heptane using amines, alkyl halides, potassium carbonate and tetrabutylammonium hydrogensulfate, as a solid/liquid phase-transfer reagent, without any additional carbon dioxide.[3] In their system, the carbonyl source was potassium carbonate. In order to determine the carbonyl source in our system, we tried a reaction in $scCO_2$ with pyrrolidine, butyl chloride and potassium phosphate in place of potassium carbonate. From the resulting 98% yield of urethane, it was confirmed that $scCO_2$ acts not only as a solvent but also as a direct starting material for the urethane in our reaction system.[10]

Consequently, the mechanism of the reaction could be explained as follows (Scheme 1). First, the amine readily forms the carbamic acid ammonium salt upon the introduction of liquid carbon dioxide. The salt starts to dissolve in $scCO_2$ as the temperature increases. At the reaction temperature (100 °C), the ion exchange reaction takes place between the carbamate salt and tetrabutylammonium bromide. As a result, the carbamate anion is activated by the tetrabutylammonium ion and readily reacts with alkyl halide to form urethane and potassium halide in the presence of potassium carbonate. At the same time, tetrabutylammonium bromide is regenerated to complete the catalytic reaction cycle. If tetrabutylammonium bromide is absent, the amine formed by the reverse reaction of the equilibrium of the carbamate salt formation attacks alkyl halide

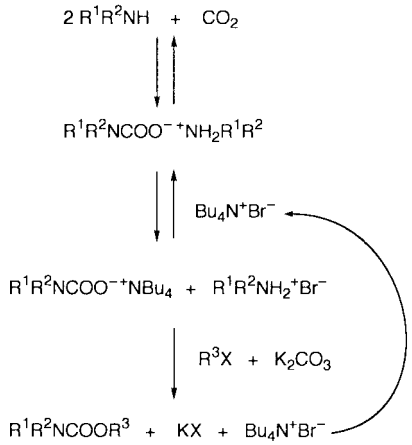
[a] Reaction was conducted at 100 °C, 80 atm in a 50 ml stainless steal autoclave containing pyrrolidine (5 mmol), butyl chloride (6 mmol), K_2CO_3 (10 mmol) and catalyst (0.5 mmol) without stirring for 2 h. [b] Estimated by ^{1}H NMR.



Scheme 1

to form highly alkylated amines, and as a result the selectivity of the urethane formation decreases.

Our reaction system is the first example of catalytic urethane production. Also we found that the efficiency of the reaction in $scCO_2$ is 50–100 times higher than that attained in heptane. Indeed, the urethane yield was less than 2% with pyrrolidine and butyl chloride, and less than 1% with butylamine and butyl bromide, in heptane.

In conclusion, we have achieved catalytic one-pot urethane synthesis from amines and alkyl halides in supercritical carbon dioxide and also achieved a phosgene replacement and organic solvent replacement by using common onium salts as catalysts. Our process is environmentally benign and also has benefits economically.

Notes and references

† *Typical experimental procedure*: For carrying out the reactions in $scCO_2$, a 50 ml stainless steel autoclave (Taiatsu Techno portable reactor TVS-N2) was used. Potassium carbonate (10 mmol), tetrabutylammonium bromide (0.25 mmol), pyrrolidine (5 mmol) and butyl chloride (8 mmol) were successively placed in the reaction vessel. The vessel was sealed and then liquid carbon dioxide (*ca.* 12.3 g) was introduced from a cylinder at room temperature. The reaction system was heated with a boiling water bath (*ca.* 100 °C). The pressure of the mixture reached *ca.* 80 atm and the mixture was stirred magnetically for 2 h. In completion, the reaction vessel was cooled with an ice bath and the pressure was released slowly to atmospheric pressure. The residual mixture was extracted with chloroform and the yields of urethane were estimated by ^{1}H NMR.

Received (in Cambridge, UK) 26th October 1999, Accepted 9th December 1999

Two new Keggin unit supported transition metal complexes, $[Ni(2,2'\text{-bipy})_3]_{1.5}[PW_{12}O_{40}Ni(2,2'\text{-bipy})_2(H_2O)]\cdot 0.5H_2O$ 1 and $[Co(1,10'\text{-phen})_3]_{1.5}[PMo_{12}O_{40}Co(1,10',\text{-phen})_2(H_2O)]\cdot 0.5H_2O$ 2, are synthesized by a hydrothermal method; complex 1 is characterized by X-ray crystallography, showing that the $[Ni(2,2'\text{-bipy})_2(H_2O)]^{2+}$ units are covalently bonded to the α-Keggin cluster $[PW^{V}_2W^{VI}_{10}O_{40}]^{5-}$.

There is considerable current interest in metal–oxo cluster compounds reflecting their diverse properties, with applications to sorption clathration, catalysis, electrical conductivity, magnetism and photochemistry.[1–11] Recently an important advance in transition metal oxide cluster chemistry has been study of polyanions substituted by transition-metal and polyoxoanion-supported inorganic or organometallic complexes.[12–20] Structures determined included $[\{Cu(4,4'\text{-bipy}\}_4(Mo_8O_{26})]$[16] and $[\{Cu(en\}_2(Mo_8O_{26})]$,[17] which possess infinite extended structures, $[La(Mo_8O_{26})_2]^{5-}$,[18] a molecular cluster and the organometallic compounds $[(CO)_3Mn(cis\text{-}Nb_2W_4O_{19})]$[19] and $[\{(C_5Me_5)Rh\}_2(Mo_{13}O_{40})]^{2+}$,[20] which have discrete cluster structures.

Here, we reported the hydrothermal synthesis and characterization of a α-Keggin heteropoly anion-supported nickel–bipyridyl and cobalt–phenanthroline complexes, $[Ni(2,2'\text{-phen})_3]_{1.5}[PW_{12}O_{40}Ni(2,2'\text{-bipy})_2(H_2O)]\cdot 0.5H_2O$ **1** and $[Co(1,10'\text{-phen})_3]_{1.5}[PMo_{12}O_{40}Co(1,10'\text{-phen})_2(H_2O)]\cdot 0.5H_2O$ **2**. No previous structural examples of transition metal complexes coordinated to Keggin anions have been reported. The structure determination of $[PW_{12}O_{40}Ni(2,2'\text{-bipy})_2(H_2O)]^{3-}$ in **1** indicates a novel α-Keggin heteropolyanion coordinated to a transition metal complex.

Compound **1** was synthesized as black blocks in 34% yield based on W (0.37 g) by a hydrothermal method. A mixture of $Ni(OAc)_2$ (0.4 g), Na_2WO_4 (1.0 g), 2,2′-bipyridine (0.4 g), and water (10 ml) was neutralized to pH = 4.0 with 50% H_3PO_3 and sealed in a 15 cm^{-1} Teflon-lined reactor, which was heated to 160 °C for seven days. After cooling to room temperature, black block crystals were isolated. The IR spectrum of **1** exhibited an intense band at 950 cm^{-1}, attributed to ν(W=O), and features at 1595, 1475, 1432 and 1309 cm^{-1} characteristic of 2,2′-bipyridine, bands at 1060 and 1090 cm^{-1}, can be attributed ν(P–O). Black prism crystals of **2** (0.30 g, yield 30% based on Mo) were obtained under the same reaction conditions using $CoCl_2$ (0.4 g), Na_2MoO_4 (0.8 g) and 1,10′-phenanthroline (0.4 g). Compound **2** was characterized by elemental analyses† and IR spectroscopy, while compound **1** was characterized by elemental analyses IR spectroscopy and single-crystal analyses.‡ Compounds **1** and **2** were soluble in DMF but not in water.

Crystals of **1** contain $[PW^{VI}_{10}W^{V}_2O_{40}Ni(2,2'\text{-bipy})_2(H_2O)]^{3-}$ heteropoly anions and $[Ni(2,2'\text{-biby})_3]^{2+}$ cations. As shown in Fig. 1, the novel anion $[PW_{12}O_{40}Ni(2,2'\text{-bipy})_2(H_2O)]^{3-}$ consists of a reduced Keggin heteropolyanion $[PW^{VI}_{10}W^{V}_2O_{40}]^{5-}$ and the cation $[Ni(2,2'\text{-bipy})_2(H_2O)]^{2+}$. As in other Keggin structures,[1] the reduced polyanion is formed from twelve WO_6 octohedra and one PO_4 tetrahedron. For PO_4, the P–O distances are 1.509(5)–1.565(5) Å while the O–P–O angles vary from 108.8(3) to 111.1(3)°. The W–O distances can be grouped into three sets: W–O_t 1.677(5)–1.727(5), W–O_b 1.780(4)–1.957(5), W–O_a, 2.378(5)–2.467(5), while bond angles at the W atoms range from 70.8(2) to 103.2(3)°. In comparison with other Keggin polyanions,[1] the unusual feature here is that the Keggin structural unit $[PW^{VI}_{10}W^{V}_2O_{40}]^{5-}$ acts as a ligand towards Ni^{2+}, to give a novel transition metal anion. A μ-oxygen, O(29) links the Keggin unit and Ni(3), the [W(12) –O(29) 1.780(4) Å, O(29)–Ni(3) 2.010(4) Å, Ni(3)–O(29)–W(12) 160.6(3], the W(12)–O(29) distance is longer than the other W–O_t bond lengths but shorter than W–O_b. In the polyanion, the Ni atom is coordinated by two 2,2′-bipy, one water molecule and one Keggin unit, with Ni–OW(1) 2.140(6) Å and Ni–N 2.072(7)–2.106(6) Å. The coordinated water

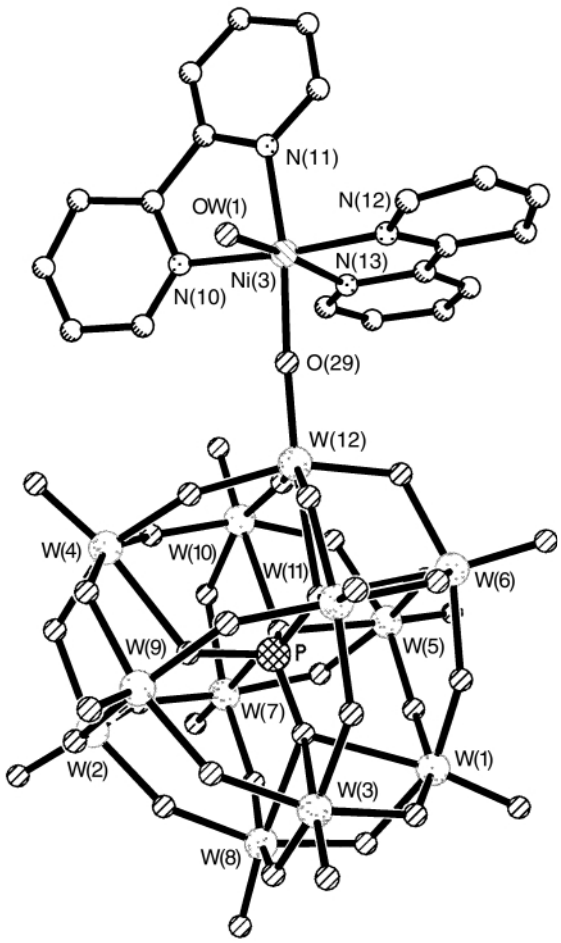

Fig. 1 The structure of the Keggin unit supported transition complex anion $[PW^{VI}_{10}W^{V}_2O_{40}Ni(2,2'\text{-bipy})_2(H_2O)]^{3-}$ in **1**.

molecule [OW(2) and its symmetry-related partner] link different polyanions by hydrogen bonding, to form a supramolecular assembly [Ow(2)··O(17a)(−*x*,1−*y*,1−*z*) 2.768(12) Å]. In each unit of **1**, the water molecules and heteropolyanion are involved in hydrogen bonding interactions, with OW(2)··OW(1) and OW(1)··O(29) 2.810(11) and 2.934(12) Å, respectively. In the cation $[Ni(2,2'\text{-bipy})_3]^{2+}$ of **1**, Ni is coordinated by three 2,2′-bipy molecules, with Ni–N 1.966(7)–2.102(6) Å. There are two W^V centres in the Keggin unit of **1**, and the assignment of the oxidation state for the W atoms is consistent with the electric charge and confirmed by bond valence sum calculations. Using an empirical bond valence calculation,[21] $S = \exp[-(R - 1.898)/0.315]$ (S = bond valence, R = bond length), leads to S values for W(1), W(2), W(3), W(4), W(5), W(6), W(7), W(8), W(9), W(10), W(11) and W(12) of 5.788, 5.950, 5.750, 6.081, 6.04, 5.786, 5.751, 6.060, 5.590, 5.946, 6.070 and 5.577, respectively. The average value for the calculated oxidation state of W is 5.866 (expected value 5.833 for $W^{VI}_{10}W^{V}_{2}$), consistent with the formula of **1**. Absorption of 600–2000 nm in the reflectance UV–VIS spectrum can be ascribed to d–d transitions and electron transitions between W^V and W^{VI} centres. Only a Ni^{2+} signal was observed (g = 2.013) in the room temperature EPR spectrum of **1**, the lack of signals for W^V indicate that the two unpaired electrons of the Keggin unit are delocalised.[1]

Received (in Liverpool, UK) 20th October 1999, Accepted 1st December 1999

(*S*,*S*)-2,3-Bis(diphenylphosphinoyl)butane, an immediate precursor of (*S*,*S*)-CHIRAPHOS, can be obtained with 70% de and 71% op *via* double asymmetric hydrogenation of 2,3-bis(diphenylphosphinoyl)buta-1,3-diene in the presence of Ru–(*S*)-BINAP catalysts.

Recently, we have described a new strategy for the synthesis of Chiraphos,[1]† a well-known bidentate chiral ligand for asymmetric catalysis. The key step of the synthesis is the diastereoselective hydrogenation of 2,3-bis(diphenylphosphinoyl)-buta-1,3-diene **1** which affords a pair of enantiomers (*R*,*R*)- and (*S*,*S*)-**2** and the *meso* species (*R*,*S*)-**2**. This latter isomer is useless, therefore its formation must be avoided in order to remove the need for a difficult purification step. In the previously reported synthesis,[1] a racemic mixture of (*R*,*R*)- and (*S*,*S*)-**2** was obtained in *ca*. 70% yield by reacting **1** with $NaBH_4$. Using this reducing agent, *ca*. 30% of *meso*-**2** was also produced, but was promptly separated and discarded since it forms an insoluble adduct with one molecule of NaOH and one molecule of $NaBH_4$.[1]

The recent improvements achieved in asymmetric hydrogenation[2] by means of homogeneous chiral transition metal catalysts prompted us to investigate the direct synthesis of enantiopure (*R*,*R*)-**2** or (*S*,*S*)-**2** by hydrogenation of **1** in the presence of an asymmetric catalyst (Scheme 1).

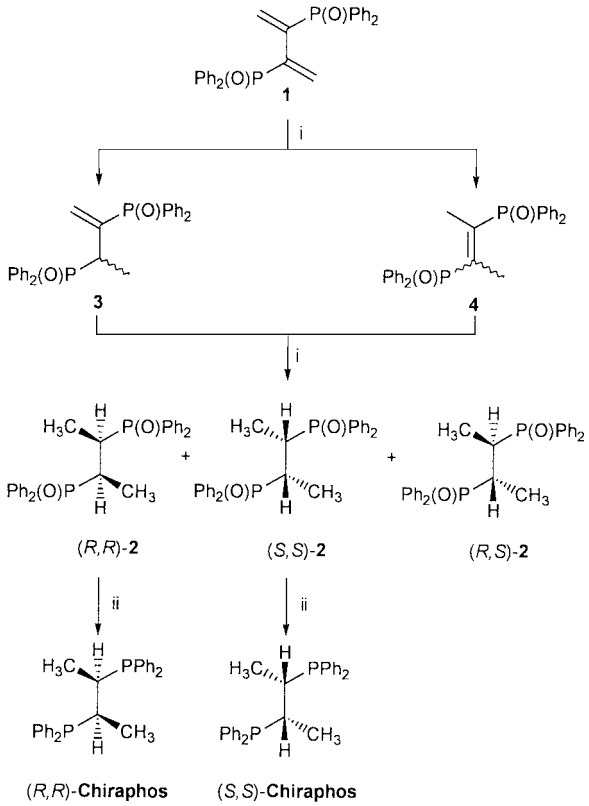
Interest in this subject goes beyond the synthetic application envisaged here since, although a large number of reports concerned with asymmetric reduction of monoenes have been published, only a few examples of asymmetric reduction of dienes have appeared so far.[3] Further interest is added by the peculiar nature of **1**.

Two different Ru-BINAP complexes, *i.e.* [RuCl(*p*-cymene){(*S*)-BINAP}]Cl[4] and $[Ru(OAc)_2\{(S)\text{-BINAP}\}]$,[5] were tested as catalysts. The relevant data, together with the reaction conditions, are reported in Table 1.

The reactions were carried out in a magnetically stirred stainless steel autoclave. The product's composition was determined by NMR spectroscopy, since in previous studies we found that all the species which may form during the reaction (see Scheme 1) give well-separate signals in the ^{31}P NMR spectrum.[1]

When only the stereoisomers of **2** were present into the crude reaction mixture, the enantioselectivity of the reaction was determined by polarimetry on samples recrystallized from benzene/n–hexane to remove the catalyst.[6] In the case of runs 1 and 4, owing to the presence of the chiral intermediate **3**, a catalyst-free sample of the crude reaction mixture was treated with (1*S*)-(+)-camphorsulfonic acid to form *inter alia* the corresponding (*S*,*S*)-**2**–(1*S*)-(+)-camphorsulfonic and (*R*,*R*)-**2**–(1*S*)-(+)-camphorsulfonic adducts. The enantioselectivity of the reaction was then calculated by integration of their relevant resonances in the ^{31}P NMR spectrum.[7]

Both catalysts require rather severe reaction conditions to carry out the hydrogenation. With [RuCl(*p*-cymene){(*S*)-BINAP}]Cl the hydrogenation of **1** proceeds with complete



Scheme 1 *Reagents and conditions*: i, H_2, catalyst; ii, $HSiCl_3$, NEt_3.

Table 1 Hydrogenation of 2,3-bis(diphenylphosphinoyl)buta-1,3-diene **1** with Ru–BINAP catalysts[a]

				Yield (%)			
Run	Catalyst	*T*/°C	*t*/h	**3**	(*R*,*S*)-**2**	(*S*,*S*)-**2** + (*R*,*R*)-**2**	Op **2** (%)[b]
1	[RuCl(*p*-cymene){(*S*)-BINAP}]Cl[c]	50	216	53	0	47	0
2	[RuCl(*p*-cymene){(*S*)-BINAP}]Cl[c]	100	120	0	0	100	8
3	$[Ru(OAc)_2\{(S)\text{-BINAP}\}]$[d]	100	67	45	10	45	ND[e]
4	$[Ru(OAc)_2\{(S)\text{-BINAP}\}]$[d]	100	163	18	13	69	68
5	$[Ru(OAc)_2\{(S)\text{-BINAP}\}]$[d]	100	310	—	15	85	71

[a] MeOH (15 ml), substrate (2.0 mmol), $P(H_2)$ = 100 atm. [b] In all cases the prevailing configuration is (*S*,*S*)-**2**. [c] Substrate/Ru = 120. [d] Substrate/Ru = 10. [e] Not determined.

diastereoselectivity since no *meso*-**2** is formed. Surprisingly, operating at 50 °C in the presence of this catalyst, a racemic mixture of **2** is obtained, while working at 100 °C a modest induction is observed (run 2). This rather unusual enhancement of the enantioselectivity on increasing the reaction temperature suggests that different catalytic species are actually at work; an example of such behaviour has been previously reported in the literature.[8]

With [Ru(OCOCH$_3$)$_2$\{(*S*)-BINAP\}] lower reaction rates are obtained. Thus, even at 100 °C and using a substrate/catalyst ratio of 10, long reaction times are necessary to achieve complete hydrogenation of diene **1** (run 5). Most significant is that the reaction proceeds with good diastereo- (de = 70%) and enantio-selectivity [the op of the prevailing (*S*,*S*)-**2** isomer is 71%]. Presumably the P=O bond is acting as a co-ordinating group in the reaction, rather as an amide does in the hydrogenation of acylamino acrylates.[9,10]

Concerning the reaction mechanism, there are two possible pathways for the hydrogenation of the diene **1** (Scheme 1): (i) two consecutive 1,2-hydrogen additions; (ii) an initial 1,4-hydrogen addition to give (*cis* or *trans*) **4** followed by hydrogenation of the remaining double bond.

At shorter reaction times (runs 3 and 4) only **2** and **3** are detected in the reaction mixture, suggesting that the reaction proceeds *via* two consecutive 1,2-hydrogen additions; moreover it appears that the first double bond hydrogenation is faster than the second one. On the other hand, an independent experiment showed that a pure sample of **4**[11] is not hydrogenated in the presence of [Ru(OCOCH$_3$)$_2$\{(*S*)-BINAP\}] under the conditions in Table 1.

In conclusion, even if the process is not yet ready for practical application owing to the incomplete stereoselectivity this work demonstrates the possibility of employing the asymmetric catalysis in the synthesis of a chiral diphosphine. According to this strategy a chiral ligand could be synthesised using another chiral phosphine ligand, thus giving a new example of chiral amplification.

6 Polarimetry measurements on different recrystallised samples of **2** have shown that there is no variation in the op due to recrystallisation from benzene–*n*-hexane.

7 The adducts between **2** and (1*S*)-(+)-camphorsulfonic acid were prepared as follows: an 80:20 mixture of **2**:**3** (~500 mg recovered by recrystallisation of a sample of run 4) was dissolved in 10 ml of $CHCl_3$ and the mixture was heated to reflux temperature (mixture A). Separately, 220 mg (0.88 mmol) of (1*S*)-(+)-camphorsulfonic acid were dissolved in 15 ml of EtOAc (mixture B). The hot mixture B was added to mixture A and the system was further heated for 2 min. The crude solid recovered after evaporation of the solvents was characterised by ^{31}P NMR ($CDCl_3$): δ 40.7 (s), 40.4 (s). Signals due to the adducts between **3** and (1*S*)-(+)-camphorsulfonic acid were also present: δ 38.23 (d, $J_{P,P}$ 20.0), 38.21 (d, $J_{P,P}$ 21.0), 35.06 (d, $J_{P,P}$ 21.0), 35.00 (d, $J_{P,P}$ = 20.0). Pure samples of (*S*,*S*)-(−)-**2**–(1*S*)-(+)-camphorsulfonict and (*R*,*R*)-(+)-**2**–(1*S*)-(+)-camphorsulfonic adducts were synthesised as described above starting from pure samples of (*S*,*S*)-(−)-**2** or (*R*,*R*)-(+)-**2** and (1*S*)-(+)-camphorsulfonic acid to identify the two species present in the ^{31}P NMR spectrum. *Selected data* for (*S*,*S*)-(−)-**2**–(1*S*)-(+)-camphorsulfonic adduct: δ_P($CDCl_3$, 85% H_3PO_4) 40.7 (s); δ_H($CDCl_3$) 0.83 (3H, s, C*H*$_3$C), 1.07 (3H, s, C*H*$_3$C), 1.25 (6H, m, C*H*$_3$) 1.50–2.70 (7H, m, C*H*$_2$C*H*$_2$C*H*C*H*$_2$), 3.00 (2H, m, C*H*$_3$CH), 3.00 (1H, d, C*H*$_2$SO$_3$H, $J_{H,H}$ 15.0), 3.50 (1H, d, C*H*$_2$SO$_3$H, $J_{H,H}$ 15.0), 7.30–-7.80 (20H, m, arom), 8.20 (1H, s, CH$_2$SO$_3$*H*); ν_{max}(KBr)/cm^{-1} 3400 (OH, br), 3000–2900 (aliphatic and aromatic C–H, w), 1700 (C=O, s); $[\alpha]_D^{23}$ −14.0 (*c* 2.0 in CH_2Cl_2). For (*R*,*R*)-(+)-**2**–(1*S*)-(+)-camphorsulfonic adduct: δ_P ($CDCl_3$, 85% H_3PO_4) 40.4 (s); δ_H($CDCl_3$) 0.91 (3H, s, C*H*$_3$C), 1.08 (3H, s, C*H*$_3$C), 1.30 (6H, m, C*H*$_3$) 1.54–2.60 (7H, m, C*H*$_2$C*H*$_2$C*H*C*H*$_2$), 2.95 (2H, m, C*H*$_3$CH), 3.05 (1H, d, C*H*$_2$SO$_3$H, $J_{H,H}$ 15.2), 3.54 (1H, d, C*H*$_2$SO$_3$H, $J_{H,H}$ 15.2), 7.30–7.80 (20H, m, arom), 8.20 (1H, s, CH$_2$SO$_3$*H*); ν_{max}(KBr)/cm^{-1} 3400 (OH, br), 3000–2900 (aliphatic and aromatic C–H, w), 1700 (C=O, s); $[\alpha]_D^{23}$+25.0 (*c* 2.0 in CH_2Cl_2). Slight differences in the ^{31}P NMR ($CDCl_3$) chemical shifts of the mixture containing the two diastereoisomers may be observed due to variations in sample concentration.

Symmetrical and unsymmetrical 2,6-dialkyl-1,1′-biaryls by combined catalysis of aromatic alkylation *via* palladacycles and Suzuki-type coupling

Marta Catellani,* Elena Motti and Monica Minari

Dipartimento di Chimica Organica e Industriale dell'Università Parco Area delle Scienze 17A, I-43100 Parma, Italy. E-mail: catell@unipr.it

Received (in Cambridge, UK) 17th November 1999, Accepted 6th December 1999

The title compounds are made readily accessible by a catalytic procedure, occurring under mild conditions, based on palladium-mediated *ortho* alkylation of aromatic iodides with alkyl bromides followed by reaction with arylboronic acids.

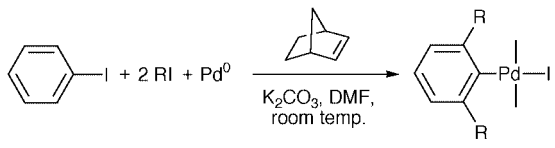
Biaryls are ubiquitous compounds, their unit being present in a variety of natural products and bioactive molecules as well as in many functional advanced materials, and there is wide interest in the development of new synthetic methodologies in spite of the many methods already available.[1] We recently described a new methodology for aromatic *ortho* alkylation based on the formation of palladium(II) and palladium(IV) metallacycles (Scheme 1).[2]

Combining this new alkylation procedure with the Heck reaction enabled us to achieve the catalytic synthesis of vinylarenes selectively substituted in both *ortho* positions with equal or different alkyl groups in a one-pot procedure.[3]

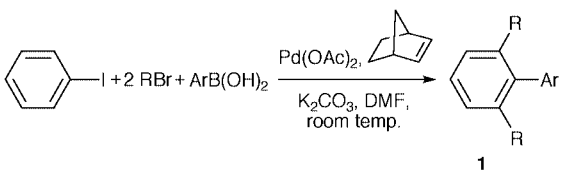
We have now found that a Suzuki-type coupling reaction[1k,l] can be caused to occur directly in the reaction mixture with selective formation of *ortho* substituted biaryls.

To this end we added an arylboronic acid to a reaction mixture containing an iodoarene, norbornene, an alkyl bromide (in two-fold excess), palladium acetate as catalyst and potassium carbonate in DMF. In spite of the possibility that the Suzuki coupling could occur with the initially formed arylpalladium iodide[1k,l] and with other intermediates involved in the aromatic alkylation, as described in the literature,[4] the desired 2,6-dialkylated 1,1′-biaryls were obtained in satisfactory to excellent yields at room temperature.

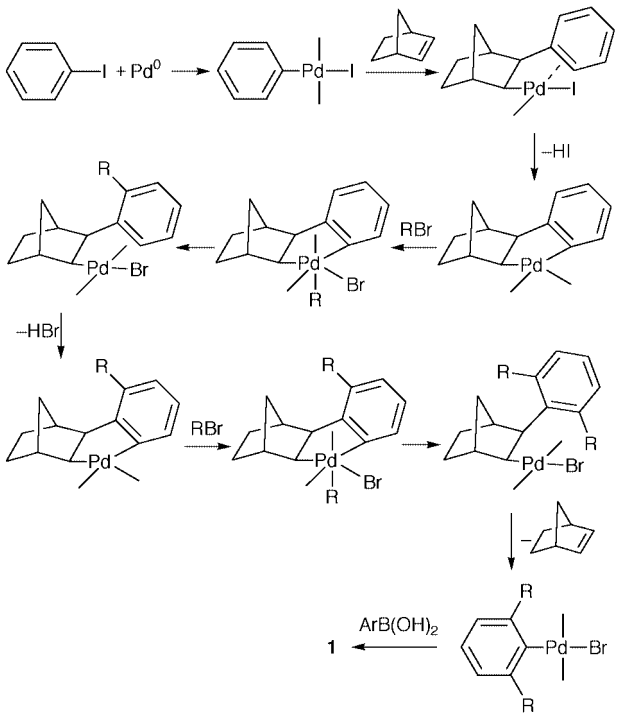
The overall reaction leading to the synthesis of symmetrically *ortho*-dialkylated biaryls is shown in Scheme 2 for iodobenzene. Thus the reaction of iodobenzene (82 mg, 0.4 mmol), 1-bromopropane (220 mg, 1.6 mmol), 2-norbornene (38 mg, 0.4 mmol) and phenylboronic acid (59 mg, 0.48 mmol) with $Pd(OAc)_2$ (9.0 mg, 0.04 mmol) as the catalyst and K_2CO_3 (332 mg, 2.4 mmol) as the base, in DMF (5 mL) at room temperature for 72 h afforded 2,6-di-*n*-propyl-1,1′-biphenyl in 95% yield.† Higher substrate-to-catalyst ratios can be used but so far no optimisation work has been carried out. The course of the reaction can be concisely represented as shown in Scheme 3.



Scheme 1



Scheme 2



Scheme 3

The reaction was also extended to *ortho*-substituted aromatic iodides. This offers the possibility of obtaining biaryls **2** with two different *ortho* alkyl groups, as shown in Scheme 4.

The scope of the reaction is currently being studied. As shown in Table 1, however, the procedure appears to be tolerant of substituents both in the iodoarene and in the phenylboronic acid, and it can be carried out with different alkyl bromides. Thus it offers a simple and direct tool to gain access to 2,6-dialkyl substituted 1,1′-biaryls. *ortho*-Substituted arylboronic acid gave very poor results both in terms of yield and selectivity, and are not reported.

The reaction is sensitive to the bulkiness of the reagents. Although the reaction becomes slow and longer reaction times are required, selectivity remains high (runs 9–11).

Small amounts (1–4%) of by-products are also obtained, corresponding to *o*,*o*′-disubstituted biaryls, formed as a consequence of aryl exchange between arylpalladium bromide and arylboronic acid,[5] or to *o*,*o*′-disubstituted norbornylbenzenes which result from hydrogenolysis of the palladium complex

Received (in Oxford, UK) 18th September 1999, Accepted 8th December 1999

Colossal magnetoresistance manganites have been synthesised by the microwave dielectric heating of metal nitrates, which act both as effective microwave susceptors, and a ready source of oxidizing NO_2 to induce mixed valency.

The perovskite mixed-valent manganites of generic formula $La_{1-x}A_xMnO_3$ (A = Ca, Sr, Ba; $0 \leqslant x \leqslant 1$), are currently the subject of intense enquiry in relation to the so-called 'colossal magnetoresistance' (CMR) effect.[1,2] The traditional ceramic (solid-state) synthesis of these CMR materials invariably requires conductive heating for extended periods at elevated temperatures; in some reported cases,[3] heating for 7 days at temperatures up to 1500 °C. Here, we illustrate the application of microwave dielectric heating to synthesise, in a period of minutes, a range of lanthanum alkaline-earth manganites exhibiting CMR. Importantly, we take advantage of the high intrinsic microwave susceptibility of component metal nitrate compounds [*e.g.* $Mn(NO_3)_2$] as compared to their moderately absorbing oxide counterparts (*e.g.* MnO_2, Mn_2O_3, *etc.*) in the synthesis of CMR materials. These findings are a clear illustration of the potential of microwave reaction selectivity—in this case *via* anion selectivity—in solid state chemical synthesis.

The microwave dielectric heating effect originates from the natural ability of certain substances to efficiently absorb, and then to transform electromagnetic (radiation) energy into heat. If sufficient heat can be generated at a local level, then chemical reactions may be initiated at a very rapid rate. More than a decade ago Mingos and co-workers carried out pioneering studies[4–6] of the use of microwave dielectric heating for the synthesis of advanced ceramic materials, most notably the high-temperature superconducting cuprates, $YBa_2Cu_3O_7$ and $La_{2-x}Sr_xCuO_4$. The strong microwave absorbing properties of one of the reactant (constituent) oxides, CuO, leads to a rapid and highly effective synthetic pathway. In fact, CuO reaches a temperature of *ca.* 700 °C after only 30 s of irradiation in a commercially available microwave oven. By contrast, the binary oxide constituents of the ternary CMR perovskites, *e.g.* La_2O_3, MnO_2, *etc.* attain temperatures of only 107 and 321 °C, respectively, after 1800 s (30 min) in a similarly configured microwave oven, while $SrCO_3$ does not absorb microwaves to any significant degree.[6]

The addition of fine-grained, graphitic carbon (known to be an efficient microwave absorber), homogeneously distributed through the starting materials, achieves the desired effect of significantly increasing the temperature of the reaction mixture and results in compound formation. However, the presence of this reactive carbon at elevated temperatures results in highly reducing synthetic conditions and this adversely affects the formation of mixed-valent manganese (Mn^{3+}/Mn^{4+}), known to be essential for the CMR phenomenon in the perovskite manganite materials.[1,2]

We have directly measured the room temperature microwave reflection of a variety of constituent starting materials over the frequency range 1–6 GHz using a HP8722A network analyser in conjunction with a specially designed open-ended coaxial probe; a selection of the data are shown in Fig. 1.

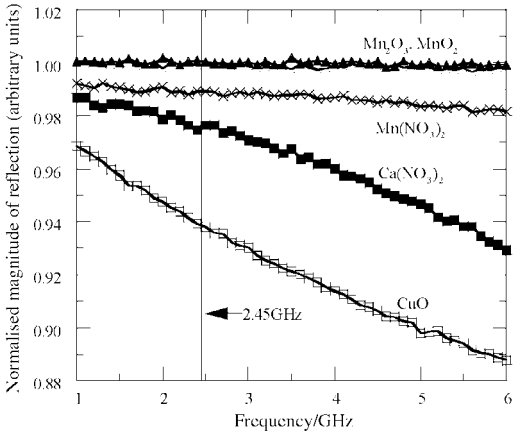

Fig. 1 Normalised magnitude of microwave reflection *vs.* frequency for various metal oxides and nitrates. The vertical line indicates the operating frequency of the microwave oven.

Whilst MnO_2 is frequently reported to be a good microwave susceptor,[5,7,8] we find that MnO_2 (and Mn_2O_3) are not as effective susceptors as compared with nitrate starting materials, *e.g.* $Ca(NO_3)_2$ and $Mn(NO_3)_3$. Moreover, there is another advantage in the use of nitrates; they decompose to yield highly oxidising NO_2 which facilitates the formation of the mixed Mn^{3+}/Mn^{4+} couple.

The manganites $La_{0.7}Sr_{0.3}MnO_{3+\delta}$, $La_{0.97}MnO_3$ and $La_{0.5}Ca_{0.5}MnO_{3+\delta}$ were formed by first dissolving stoichiometric amounts of the constituent metal nitrates in distilled water. The resulting solution was then transferred to an open quartz tube, supported in a firebrick. A small piece of aluminium foil was placed over the end of the tube to prevent the mixture boiling over, whilst allowing NO_2 to escape. This assembly was then placed in the centre of the turntable of a domestic 950 W microwave oven, operating at 2.45 GHz, and irradiated for 5 min at the full power setting. Following the loss of H_2O and NO_2, the sample glowed bright orange and continued to do so until the microwave power was switched off. The sample was then left to cool at a natural rate in the microwave oven. The resulting black, well sintered fine powder was ground using a pestle and mortar before being subjected to a further 5 min of microwave irradiation.

X-Ray powder diffraction patterns (Fig. 2) were collected using a Siemens D5000 system (Cu-Kα_1 radiation) and these clearly show the presence of the desired phases, but the diffraction peaks are consistently broader than those generally

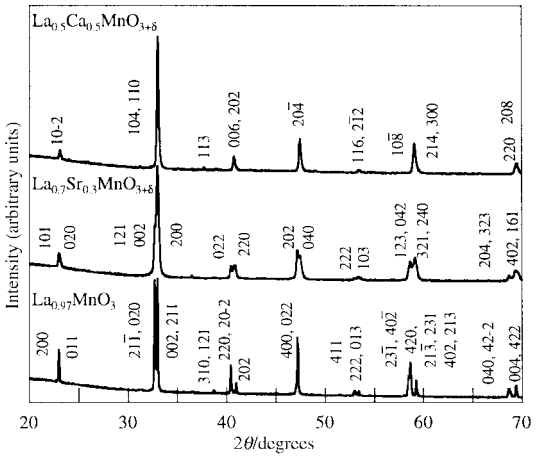

Fig. 2 X-Ray powder diffraction patterns for three manganites prepared using microwave dielectric heating.

produced by conventional solid state techniques.[9] This difference probably arises because microwave synthesis is somewhat akin to combustion synthesis in producing samples with small particle size.[10] The Rietveld method was applied to the refinement of crystal structures using the GSAS suite of programs.[11] The material $La_{0.7}Sr_{0.3}MnO_{3+\delta}$ is orthorhombic, a = 5.4640(4), b = 7.7277(6), c = 5.5285(4) Å, space group *Pnma*; $La_{0.97}MnO_3$ is monoclinic, a = 7.7970(4), b = 5.5271(3), c = 5.4842(3) Å, β = 90.8(2)°, space group *I2/a*; $La_{0.5}Ca_{0.5}MnO_{3+\delta}$ is rhombohedral, a = 5.4763(5), c = 13.379(1) Å, space group $R\bar{3}c$. These Rietveld refinements, combined with thermogravimetric analyses, indicated that these materials were fully oxygenated, with δ *ca*. zero.

The CMR properties of sintered pellets of the above materials were examined using a four-point resistivity probe in magnetic fields of 0 and 12 T. All three samples were found to exhibit CMR and the data are shown in Fig. 3. Whilst these samples show a very clear CMR effect, $La_{0.7}Sr_{0.3}MnO_{3+\delta}$ shows rather different CMR behaviour to materials produced by the conventional ceramic route.[12] This may be due to the orthorhombic symmetry of this sample resulting in reduced transfer of e_g electrons when compared with rhombohedral or pseudocubic phases.[13] The structural and CMR properties of the $La_{1-\delta}MnO_3$ system are extremely sensitive to synthesis conditions. For instance, the orthorhombic form shows no CMR properties at all.[14] Our sample of $La_{1-\delta}MnO_3$ adopts the less common monoclinic form and exhibits good CMR behaviour.[14] $La_{0.5}Ca_{0.5}MnO_{3+\delta}$ shows CMR comparable with previous literature reports.[12] Thermogravimetric analyses of these materials indicated no oxygen stoichiometry. Recently we have extended the microwave synthesis procedure to include the spinel manganates such as the battery material $LiMn_2O_4$ *etc*.

In summary, we have illustrated that dielectric heating represents a rapid and effective route to the synthesis of CMR manganites. Moreover, the direct measurement of microwave-reflecting properties (Fig. 1) greatly aids the choice of constituent starting materials.

We thank Merck Ltd. and the EPSRC for financial support, and Rod Riddle (Merck) for support and encouragement.

The first example of a substrate spanning the calix[4]arene bilayer: the solid state complex of *p*-sulfonatocalix[4]arene with L-lysine†

Received (in Columbia, MO, USA) 6th August 1999, Accepted 23rd November 1999

The complex of *p*-sulfonatocalix[4]arene with L-lysine shows a new type of intercalation behaviour with regard to the achiral hydrophobic bilayer assembly of the calixarenes, and represents the first structural example of a cationic organic substrate spanning such a bilayer.

It has recently been shown that the *p*-sulfonatocalix[*n*]arenes can act as heparin mimics,[1] and their interactions with the positively charged amino acids, lysine and arginine, has been investigated.[2] In the case of *p*-sulfonatocalix[4]arene, 1:1 complexes with lysine and arginine are observed, with binding constants derived from ^{1}H NMR spectroscopy at pH 5 of 600 and 1700. Undoubtedly such electrostatic interactions are also important in the activity of the sulfonatocalixarenes as chloride ion blockers.[3] In recent years, *p*-sulfonatocalix[4]arene salts have been extensively studied; these complexes crystallize with a large variety of cations in bilayer-type structures.[4] The basic molecular motif is achiral and formed by two calixarenes related by crystallographic symmetry. They are arranged in the up-down fashion with the sulfonate groups covering the surfaces of the bilayers which are separated by a hydrophilic layer containing the majority of the water molecules and cationic counterions. The structures of complexes of *p*-sulfonatocalix[4]arene with transition metal compounds[5] have demonstrated that an aromatic organic substrate can be intercalated into the bilayer. However, no example of substrates traversing the bilayer have been observed. We report here on a new type of intercalation within the calixarene bilayer system showing that a chiral cationic organic molecule possessing a flexible aliphatic side chain, in this case L-lysine, can span the bilayer. The crystalline title compound also exhibits a chiral hydrophilic layer, containing three other L-lysine molecules, which separates the bilayers.

The crystal structure belongs to the triclinic *P*1 space group,‡ and consists of two [calix[4]arenesulfonate]$^{4-}$ anions (**A** and **B**), four L-lysine counterions and 17.5 water molecules distributed over 20 sites. The calix[4]arene pattern is strongly pseudo-centrosymmetrical and similar to those already described in other complexes.[4,5] The four L-lysine molecules and the sulfonate groups interact largely with water molecules. No water sites have been detected within the calixarene cavities.

For all the L-lysine molecules, the α- and ε-amino groups show contacts indicative of N–H···O hydrogen bonds with oxygen atoms on the sulphonate groups of the calixarenes, but they display different types of interactions. One L-lysine molecule (**L1**) is seen to traverse the hydrophobic bilayer with the main chain directed towards the sulfonate groups of the 'up', (**A**), calixarenes. As its side chain is in the fully extended conformation [χ_1 = −68(1)°, χ_2, χ_3, χ_4 values close to 180°], the ε-amino group points towards the opposite edge of the bilayer, nearly at the level of the S atoms of the 'down' (**B**), calixarenes (Fig. 1). While the α-amino group is in short contact with one sulfonate group of an **A** calixarene [N···O separation of 2.75(1) Å], the ε-amino group is connected to three **B** calixarenes, related by crystallographic translations along the *a*- and *b*-axes [N···O separations ranging from 2.853(6) to 3.013(6) Å]. This L-lysine molecule is thus the first example of a ligand which truly spans the hydrophobic calixarene bilayer.

Of further interest in the structure is the chiral hydrophilic layer separating the bilayers which contains the other three L-lysine molecules. One L-lysine molecule (**L2**) is placed in the core of this layer§ and aligned parallel to the *a*-axis. As with **L1**, the side chain adopts the fully extended conformation [χ_1 = −66(1)°, χ_2, χ_3, χ_4 values close to 180°], which is that most usually observed.[6] The other two L-lysine molecules (**L3** and **L4**) lie just above the calixarene macrocycles (**A** and **B** for **L3** and **L4**, respectively). Their arrangement is illustrated in Fig. 2. For both, the α-amino and α-carboxylate groups are directed into the chiral layer and the side chain is nearly at the level of the S atoms of their respective calixarene, with the ε-amino group pointed towards the exterior of the cavity. A common structural characteristic of **L3** and **L4** is that their side chains exhibit a folded conformation (χ_1 = 65.7(6) and 54.2(7)°, χ_4 = −46.2(7) and −63.5(7)°, χ_2, χ_3 values close to 180°]. This unusual conformation[6] allows N–H···O contacts between one sulfonate group of the parent calixarene and the two amino groups of the same L-lysine molecule (Table 1). This conformation has been previously observed in the structure of the L-lysine

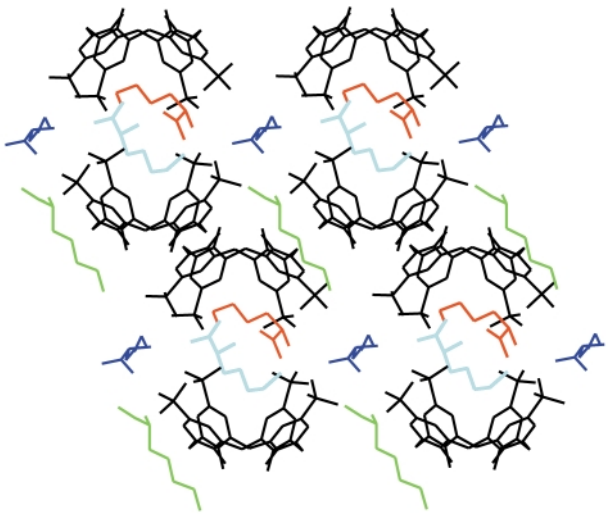

Fig. 1 Packing view along the *a*-axis of the structure demonstrating the spanning of one L-lysine molecule (**L1**, green) within the bilayer formed with the **A** (up) and **B** (down) *p*-sulfonatocalix[4]arenes. The other three L-lysine molecules are shown within the chiral layer which separates the bilayers (**L2**, dark blue; **L3**, light blue; **L4**, red).

† A figure showing the arrangement of the three L-lysine molecules within the chiral layer is available from the RSC web site, see http://www.rsc.org/suppdata/cc/a9/a906546f/

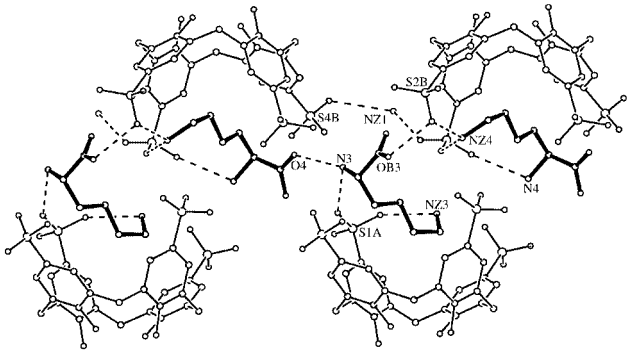

Fig. 2 A view of a section of the structure illustrating the arrangement of **L3** and **L4** within the chiral layer and representing the N(amino)··O(sulfonate) contacts (dashed lines) referred to in the text. The position of the ε-amino group of **L1** (NZ1) is also shown, the contacts between NZ1 and the sulfonate groups of two **B** calixarenes are indicated in dashed lines.

Table 1 Selected contacts (Å) between sulphonate oxygen atoms and the L-lysine molecules **L3** and **L4**

L3		**L4**	
N3···O41A	2.988(8)	N4···O43B	2.939(6)
NZ3···O21A	2.864(8)	NZ4···O33B	3.071(8)
OB3···O42B[a]	2.672(6)	NZ4···O42B	2.899(8)
N3···O31B	2.890(7)	OB4···O41A	2.635(7)
NZ3···O33B[a]	2.961(6)	NZ4···O23A[b]	2.806(10)

Symmetry codes: [a] $x + 1, y, z$. [b] $x - 1, y, z$. The minor components of the ε-amino groups are not considered.

sulfate,[7] with similar specific interactions between the L-lysine molecule and the sulfate anion. **L3** and **L4** are connected by an N–H··O contact between the α-amino group of **L3** and the carbonyl oxygen of **L4** [N··O separation 2.928(7) Å]. These dimers are only interconnected indirectly through one sulfonate oxygen atom (O42B) of the **B** calixarene, which is simultaneously in contact with the ε-amino group of **L4** and the hydroxy group of **L3**. The dimers are stacked along the *a*-axis. Thus, the L-lysine network within the chiral layer is composed of alternating rows of dimers and monomers. The bilayers are cross-linked through the chiral layer as **L3** and **L4** are also in contact with sulfonate groups of two calixarenes (**B** and **A**) lying in an adjacent bilayer (Table 1).

Thus, in contrast to the situation in solution, where a 1:1 complexation is observed, in the solid state a lysine–calixarene complex of 2:1 stoichiometry may be obtained. Actually, the system may be considered as two similar 1:1 complexes, each involving a folded L-lysine molecule (**L3** and **L4**), which would correspond to the situation observed in solution.[2] The other two L-lysine molecules, both with the side chain in the fully extended conformation, would be implicated in the solid state structure. Of the four independent L-lysine molecules, three are found within the hydrophobic layer separating the typical sulfonatocalix[4]arene bilayer, while the remaining molecule (**L1**) spans this bilayer in a manner resembling biomolecules traversing a lipid bilayer.¶ Further studies are underway to investigate the structural behaviour of the sulfonatocalix[*n*]arenes with peptides containing lysine and arginine.

‡ *Crystal data* for $2(C_{28}H_{20}O_{16}S_4)\cdot4(C_6H_{16}O_2N_2)\cdot17.5H_2O$: M_r = 2389.5; suitable crystals for X-ray diffraction were grown in sealed tubes from two to one lysine–calix[4]arene aqueous solution, at room temperature during six months; triclinic *P*1, a = 13.599(4), b = 14.369(2), c = 15.169(3) Å, α = 111.02(1), β = 100.02(2), γ = 99.02(2)°, V = 2646(1) Å^3, Z = 1, ρ_{calc} = 1.50 g cm^{-3}, $2\theta_{max}$ = 46°, μ(Mo-Kα) = 0.28 mm^{-1}, T = 293 K; 7673 independent reflections, 6530 with $I > 2\sigma(I)$; R_1 = 0.0863, wR_2 = 0.2553. The structure was solved by direct methods (SHELXS-86) and refined using the program SHELX-97. 17.5 water molecules were located, distributed over 20 sites. For three sulfonate groups, two O atoms are positionally disordered (two partially occupied sites for each). The ε-amino groups of **L3** and **L4** are disordered over two sites (0.75 and 0.25 occupancy factors). The parameters of the **A** and **B** calixarenes were refined in separate blocks. CCDC 182/1505. See http://www.rsc.org/suppdata/cc/a9/a906546f/ for crystallographic data in .cif format.

§ The **L2** molecule is situated in a large intermolecular space and all the atoms show high isotropic displacement parameters. Nevertheless, the amino groups of **L2** show contacts having relatively large separation distances with sulfonate oxygen atoms of two **B** calixarenes related by the *a*-translation [N··O separations of 3.02(1) and 3.07(1) Å]. A contact with a somewhat long N··O separation distance [3.09(1) Å] is also seen between the ε-amino group of **L3** and the carbonyl oxygen of **L2**.

¶ It is of interest to note that there was debate concerning whether the original sulfonatocalix[4]arene structures resembled those of bilipid membranes or clay minerals.

Epoxidation of alkenes using alkyl hydroperoxides generated *in situ* by catalytic autoxidation of hydrocarbons with dioxygen

Takahiro Iwahama, Gou Hatta, Satoshi Sakaguchi and Yasutaka Ishii*

Department of Applied Chemistry, Faculty of Engineering & High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan. E-mail: ishii@ipcku.kansai-u.ac.jp

Received (in Cambridge, UK) 2nd November 1999, Accepted 10th December 1999

Olefins were smoothly epoxidized under O_2 (1 atm) in the presence of a hydrocarbon such as ethylbenzene or tetralin, using *N*-hydroxyphthalimide (NHPI) and $Mo(CO)_6$ as catalyst; the present reaction involves autoxidation of the hydrocarbon assisted by NHPI and epoxidation of alkenes with the resulting hydroperoxide catalyzed by $Mo(CO)_6$; *cis*-alkene was epoxidized in a stereospecific manner to form the corresponding *cis*-epoxide in high yield.

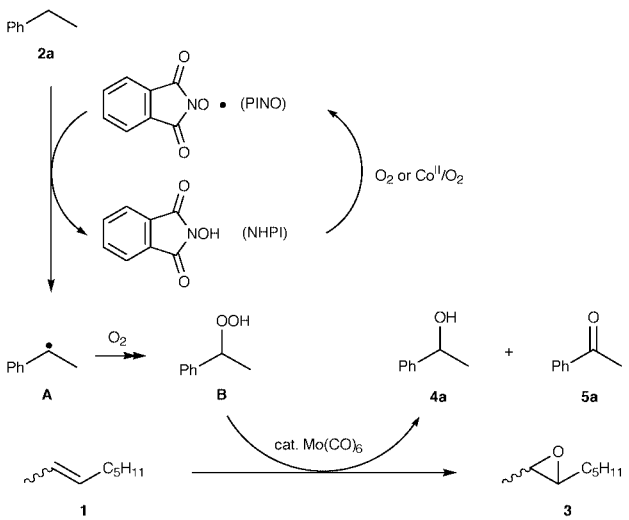
The epoxidation of alkenes using molecular oxygen *via* a catalytic process is a challenging subject in the field of oxidation chemistry.[1] Since the direct epoxidation of alkenes with molecular oxygen, which lies in triplet ground state, is inhibited, epoxidation using O_2 is carried out in the presence of a compound like an aldehyde which serves as an active oxygen carrier.[2] Although there have been many reports on the metal-catalyzed epoxidation of alkenes by O_2 in the presence of aldehydes, only a limited number of methods using O_2 as terminal oxidant have been developed.[3] There has been long-standing interest in the epoxidation of alkenes with alkyl hydroperoxides, as an active oxygen carrier, generated *in situ* from hydrocarbons and O_2. To the best of our knowledge, however, only one report has appeared on the epoxidation of alkenes by the use of cumene and O_2 with heteropolyoxometalates as catalyst.[4] A major difficulty in the epoxidation is attributed to the following: (i) autoxidation of aldehydes takes place very fast, at least two orders of magnitude faster than that of hydrocarbons; (ii) as a result, the epoxidation using hydrocarbons must be carried out under severe reaction conditions; and (iii) the epoxidizing ability of alkyl hydroperoxides is considerably lower than that of peracids or acylperoxy radicals derived from aldehydes and O_2.[5] Therefore, stepwise procedures are commonly utilized in epoxidations using alkyl hydroperoxides. For example, the Halcon process consists of the aerobic oxidation of ethylbenzene to α-hydroperoxyethylbenzene, and the Mo-catalyzed epoxidation of propylene with the α-hydroperoxyethylbenzene.[6] Consequently, development of an epoxidation system using a hydroperoxide generated *in situ* from ethylbenzene and molecular oxygen is very attractive from the synthetic and industrial points of view.

Recently, we have shown that hydrocarbons are efficiently oxidized with O_2 by *N*-hydroxyphthalimide (NHPI), which serves as a radical catalyst under mild conditions.[7] In this oxidation, hydrocarbons are converted into oxygen-containing compounds such as alcohols or ketones through *alkyl hydroperoxides (**B**)* as transient intermediates. If the alkyl hydroperoxides formed can be utilized as oxidants, it is possible to epoxidize alkenes using hydrocarbons and molecular oxygen. Here we report the Mo-catalyzed epoxidation of alkenes with hydroperoxides generated *in situ* by the NHPI-catalyzed aerobic oxidation of hydrocarbons such as ethylbenzene (Scheme 1).

Table 1 shows representative results for the epoxidation of oct-2-ene (**1**) with O_2 using hydrocarbons as a hydroperoxide source.† The epoxidation of **1** using ethylbenzene (**2a**) in the presence of NHPI (10 mol%), $Co(OAc)_2$ (0.1 mol%) and $Mo(CO)_6$ (5 mol%) at 60 °C under O_2 (1 atm) gave epoxide **3** in 61% selectivity at 67% conversion (run 1). An improvement of the present epoxidation by the addition of molecular sieves 4A (MS-4A) was observed, and thus the conversion of **1** and selectivity of epoxide **3** reached 81% and 70%, respectively (run 2). Using tetralin (**2b**) instead of **2a**, it was found that the selectivity of epoxide **3** was considerably improved (run 3). However, when toluene (**2c**) was employed as a hydrocarbon source, the selectivity of **3** was lowered to 44% (run 4). This is believed to be due to the occurrence of allylic hydrogen atom abstraction from **1** in competition with the benzylic hydrogen atom abstraction of **2c** by PINO.[8] Although AIBN was used as a radical source instead of NHPI, **1** was difficult to epoxidize to **3** (run 5). It is very interesting to note that the present epoxidation was induced even at room temperature to afford epoxide **3** in high selectivity (97%) at 31% conversion (run 7).[9] On the other hand, metal complexes such as $MoO_2(acac)_2$, $VO(acac)_2$ and $TiO(acac)_2$ were found to be inadequate for the present reaction (runs 8–10). Although molybdenum(VI) complexes have high catalytic activity for the epoxidation of alkenes with *tert*-butyl hydroperoxide,[10] $MoO_2(acac)_2$ was found to depress the formation of the hydroperoxide from **2b** under these conditions (run 8).

On the basis of these results, the epoxidation of various alkenes with O_2 using **2a** or **2b** was examined in the presence of catalytic amounts of NHPI, $Co(OAc)_2$ and $Mo(CO)_6$ under selected reaction conditions (Table 2).

trans-Oct-2-ene (*trans*-**1**) was epoxidized with excellent stereoselectivity to give *trans*-2,3-epoxyoctane (*trans*-**3**) (*trans* : *cis* = > 99 : 1) with 88% selectivity together with a small amount of octane-2,3-diol (4%) in 78% conversion. Similarly, the epoxidation of *cis*-**1** gave *cis*-2,3-epoxyoctane (*cis*-**3**) (*cis* : *trans* = 99 : 1) in good selectivity. It is noteworthy that the present epoxidation of *cis*-olefin proceeds with nearly complete stereoselectivity to give *cis*-epoxide, although the metal-catalyzed epoxidation of *cis*-olefins using an aldehyde and O_2 leads to a mixture of *cis*- and *trans*-epoxides.[11] This is because the resulting alkylperoxyl radical can abstract the hydrogen



Scheme 1

Table 1 Epoxidation of oct-2-ene (**1**) to 2,3-epoxyoctane (**3**) with O_2 in the presence of hydrocarbons using NHPI, $Co(OAc)_2$ and various transition metals as catalysts[a]

Run	Hydrocarbon	Transition metal	*T*/°C	Conversion (%)		Selectivity (%)		
				1	**2a**,**b**	**3**	**4a**,**b**	**5a**,**b**
1	Ethylbenzene **2a**	$Mo(CO)_6$	60	67	10	61	65	25
2[b]	**2a**	$Mo(CO)_6$	60	81	12	70	71	19
3	Tetralin **2b**	$Mo(CO)_6$	50	67	25	86	62	30
4[c]	Toluene **2c**	$Mo(CO)_6$	60	59	—	44	—	—
5[d,e]	**2b**	$Mo(CO)_6$	80	12	7	67	88	11
6[f]	**2b**	$Mo(CO)_6$	50	58	18	91	79	17

10	**2b**	$TiO(acac)_2$	50	15	21	80	47	40

[a] Oct-2-ene (**1**) (4 mmol) was allowed to react with O_2 (1 atm) in the presence of NHPI (10 mol%), $Co(OAc)_2$ (0.1 mol%), transition metal (5 mol%) and hydrocarbon (**2a**,**b**) in PhCN (2 mL) for 12 h. **2a** (40 mmol) and **2b** (20 mmol) were used, respectively. [b] MS-4A (200 mg) was added. [c] 6 h. [d] AIBN (5 mol%) was used instead of NHPI. [e] 8 h. [f] NHPI (5 mol%) was used.

Table 2 Epoxidation of various alkenes with molecular oxygen in the presence of tetralin (**2b**) or ethylbenzene (**2a**) catalyzed by NHPI, $Co(OAc)_2$ and $Mo(CO)_6$[a]

Run	Alkene	*T*/°C	Conversion (%)[b]	Selectivity (%)[b]
1	*trans*-Oct-2-ene	60 (60)	78 (71)	88 (79)[c]
2	*cis*-Oct-2-ene	50 (60)	83 (75)	87 (71)[d]
3	2,4,4-Trimethylpent-2-ene	70 (70)	90 (76)	84 (80)
4	Oct-1-ene	60 (70)	38 (37)	80 (81)
5[e]	Cyclohexene	60	80	74
6[e]	Cyclooctene	60	89	83
7	*trans*-Hex-2-ene-1-ol **6**	60	79	65
8[f,g]	**6**	60	97	92

[a] Alkenes (4 mmol) and **2a** (40 mmol) or **2b** (20 mmol) were allowed to react with O_2 (1 atm) in the presence of NHPI (10 mol%), $Co(OAc)_2$ (0.1 mol%), $Mo(CO)_6$ (5 mol%) and MS-4A (200 mg) in PhCN (2 ml) for 14 h. [b] The results using **2a** are in parentheses. [c] *trans*:*cis* = > 99:1. [d] *cis*:*trans* = 99:1 for **2b**, 94:6 for **2a**. [e] **2b** (40 mmol) was used. [f] $VO(acac)_2$ (0.5 mol%) was used instead of $Co(OAc)_2$ and $Mo(CO)_6$. [g] 6 h.

atom from NHPI or **2** to give hydroperoxide **B**, which serves as the oxidant of the molybdenum-catalyzed epoxidation of alkenes.‡ Therefore, the present epoxidation of *cis*-olefin proceeds in a stereospecific manner, in contrast to the epoxidation of *cis*-alkene using aldehyde and O_2, which leads to a mixture of *cis*- and *trans*-epoxides.

Trisubstituted olefins afforded the corresponding epoxides in good selectivity. A terminal olefin, oct-1-ene, was a reluctant substrate for epoxidation using the present catalytic system, forming 1,2-epoxyoctane in moderate conversion. Cyclohexene was also epoxidized to 1,2-epoxycyclohexene in satisfactory yield.

On the other hand, the epoxidation of allylic alcohol, *trans*-hex-2-en-1-ol, to epoxy alcohol was achieved in high yield when $VO(acac)_2$ was employed instead of $Mo(CO)_6$. The epoxidation of allylic alcohols with *tert*-butyl hydroperoxide is known to result in epoxides with higher rates and better yields using vanadium(V) complexes rather than molybdenum(VI) catalysts.[10] It is interesting to note that the present epoxidation of allylic alcohols was promoted smoothly even with a very small amount of $VO(acac)_2$ (0.5 mol%) in the absence of $Co(OAc)_2$. It is thought that $VO(acac)_2$ induces not only the generation of PINO from NHPI under O_2 but also acts as the epoxidation catalyst of alkenes.

In conclusion, we have developed a selective one-pot epoxidation of alkenes with molecular oxygen using hydrocarbons such as ethylbenzene and tetralin as the hydroperoxide source under mild conditions.

This work was partly supported by the Japan Society for the Promotion of Science under the Research for the Future program JSPS.

Notes and References

† *Typical procedure for the epoxidation of* **1**: A PhCN (2 ml) solution of **1** (4 mmol), NHPI (10 mol%), $Co(OAc)_2$ (0.1 mol%), $Mo(CO)_6$ (5 mol%) and **2a** (40 mmol) was placed in a two-necked flask equipped with a balloon filled with O_2. The mixture was stirred at 60 °C for 12 h, and then analyzed by GLC with an internal standard.

‡ In general, the reaction of acylperoxy radicals derived from an aldehyde with olefins has been reported to be *ca.* 10^5 times faster than that of alkylperoxyl radicals derived from hydrocarbons such as **2**: see Y. Sawaki and Y. Ogata, *J. Org. Chem.*, 1984, **49**, 3344.

Experimental test of the validity of the use of the *n*-alkanes as model compounds for polyethylene

Stewart F. Parker,*[a] John Tomkinson,[a] Dale A. Braden[b] and Bruce S. Hudson[c]

[b] *Department of Chemistry, University of Oregon, Eugene, OR 97403-1253, USA*
[c] *Department of Chemistry, Syracuse University, Syracuse, NY 13244-4100, USA*

Received (in Cambridge, UK) 15th October 1999, Accepted 10th December 1999

_n_-Alkanes are widely used as model compounds for the dynamics of the crystalline region of polyethylene; this use relies on the assumption of the transferability of the forcefield of the _n_-alkanes, a stringent test of this assumption is a comparison of the dispersion curves of the _n_-alkanes with those of polyethylene; the only direct measurements of the dispersion curves of polyethylene are for the ν_5 acoustic branch, the longitudinal acoustic mode (LAM), an in-plane skeletal mode of perdeuterated polyethylene; in the present work we have observed (by inelastic neutron scattering spectroscopy) and assigned (by the use of density functional theory calculations) the LAM modes of perdeuterated _n_-hexadecane in order to provide the first experimental test of the validity of the assumption.

Polyethylene is a major commodity polymer that is still the subject of active development.[1] Vibrational spectroscopy has played a key role in the characterisation of the material[2] and fundamental to the understanding of the dynamics of the polymer is a knowledge of the dispersion curves for the vibrational modes. The only direct method for the experimental determination of dispersion curves is by coherent inelastic neutron scattering (INS) spectroscopy. For hydrogenous polyethylene, this method fails because the background caused by the incoherent scattering from hydrogen completely swamps the coherent signal. This problem has been circumvented in two ways; the incoherent INS spectrum is related to the vibrational density-of-states which is in turn related to the dispersion curves. Comparison of the experimental spectrum[3] with dispersion curves and the density-of-states derived theoretically allows the quality of the calculations to be assessed. The second method is the use of the *n*-alkanes as model compounds for polyethylene.[4,5] This method relies on the assumption that the *n*-alkanes forcefield is directly transferable to polyethylene and that the end-effects caused by the finite length of the alkane chain can be neglected.

For perdeuterated polyethylene, the larger coherent and smaller incoherent cross-sections of deuterium[6] (H: incoherent 79.7 barns, coherent 1.758, deuterium: incoherent 2.0 barns, coherent 5.597 barns, 1 barn $= 1 \times 10^{-28}$ m^2) has allowed the ν_5 acoustic branch, the longitudinal acoustic mode (LAM), an in-plane skeletal mode, to be mapped by coherent INS.[7–10] These results are the only *direct* experimental measurement of any of the dispersion curves of polyethylene. Thus any test of the validity of the assumption that the *n*-alkanes are good models for polyethylene requires the determination of the LAM modes of a perdeuterated *n*-alkane. Unfortunately, while the LAM modes are formally IR and Raman active, their intensities are usually so small as to be unobservable for any but the first few modes (Raman) and the highest energy ones (IR).

We have recently shown that it is possible to both observe[11] and assign[12,13] the LAM modes of the *n*-alkanes (n = 5–25) by a combination of incoherent INS spectroscopy and *ab initio* calculations. In the present report we have extended the method to perdeutero-*n*-hexadecane in order to compare the experimental data for perdeuterated polyethylene with the measured LAM frequencies of $C_{16}D_{34}$.

It is only with the development of pulsed neutron sources with their high flux of epithermal neutrons that it has been possible to record incoherent INS spectra of perdeuterated compounds. With the increase in detected flux resulting from the recent installation of TOSCA[14] at ISIS (Rutherford Appleton Laboratory, Chilton, UK) it is now possible to routinely record spectra from such samples. Fig. 1 shows the incoherent INS spectrum of $C_{16}D_{34}$ in the region[15] below 500 cm^{-1}. All of the modes between 200 and 400 cm^{-1} are LAM modes, a further five modes occur below 200 cm^{-1} where the out-of-plane transverse acoustic modes and the external

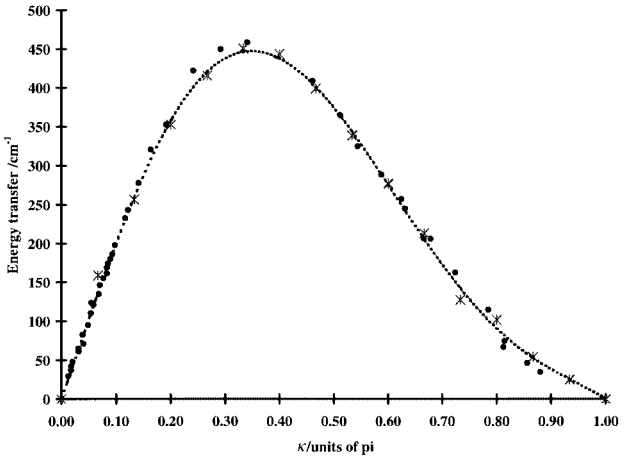

Fig. 2 Comparison of experimental data for the ν_5 mode of deuterated polyethylene (●) and the experimental LAM frequencies of $C_{16}D_{34}$ (*). The dashed line is a quintic least squares fit to the DFT data for perdeutero-*n*-hexadecane.

modes also occur. The density functional theory (DFT) calculations were performed using the GAUSSIAN-94[16] program in the B3LYP density functional approximation. The basis set used was 6-31-G**. The DFT results allow the modes to be assigned to a specific phase angle, κ. The results are shown in Table 1. The experimental frequencies below 200 cm^{-1} are given in parentheses since the DFT calculations show that out-of-plane modes lie close-by, thus there is some uncertainty (a few wavenumbers) in the exact value of the frequency.

Fig. 2 shows a comparison of experimental data for the ν_5 mode of perdeuterated polyethylene, the experimental frequencies and the frequencies calculated by DFT. The solid line is a quintic least squares fit to the DFT results for perdeuterated *n*-hexadecane as a guide to the eye. It can be seen that there is excellent agreement between all three sets of data. This provides the *first* experimental validation of the assumption that the forcefields derived from the *n*-alkanes are transferable to polyethylene.

This work is noteworthy for two other reasons: first that it is now possible to routinely obtain high quality incoherent inelastic neutron scattering spectra of perdeuterated samples and second the demonstration of the success of DFT calculations for the analysis of inelastic neutron scattering spectra provides a benchmark against which other methods can be tested.

This work was partially supported by the US National Science Foundation under grant CHE 9803058 and utilised the computer systems Exemplar and SGI PCarray at the National Centre for Supercomputing Applications, University of Illinois at Urbana-Champaign. The Rutherford Appleton Laboratory is thanked for access to neutron beam facilities.

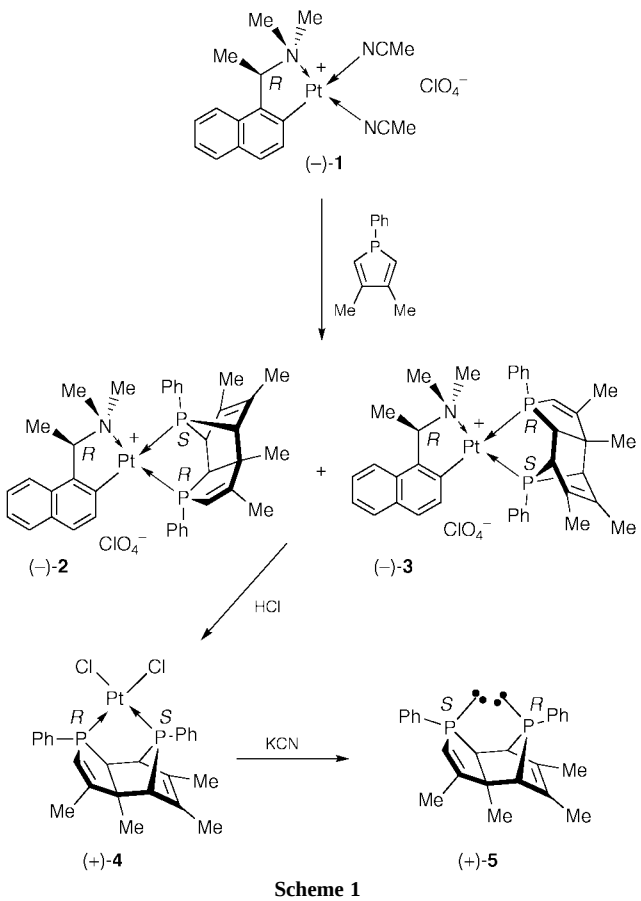
Received (in Cambridge, UK) 29th September 1999, Accepted 10th December 1999

An optically pure P-chiral diphosphine has been prepared efficiently from the asymmetric dimerization of 3,4-dimethyl-1-phenylphosphole in the presence of an organoplatinum(II) complex derived from (*R*)-*N*,*N*-dimethyl-1-(1-naphthyl)ethylamine.

Recently we have reported a series of asymmetric Diels–Alder reactions between the cyclic diene 3,4-dimethyl-1-phenylphosphole (DMPP) and various dienophiles in the presence of an organopalladium complex containing the enantiomerically pure forms of *N*,*N*-dimethyl-1-(1-naphthyl)ethylamine.[1] This organopalladium complex has been employed frequently because it is perhaps the most efficient reaction promoter and stereochemical controller for the activation of DMPP in these asymmetric syntheses. In cases where vinylphosphines were used as dienophiles, optically pure P-chiral diphosphines were obtained in high yields.[2] In theory, the [4 + 2] *exo*-cycloaddition reaction between two DMPP molecules will produce a rigid chiral diphosphine containing two phosphorus and four carbon stereogenic centres. Interestingly, this asymmetric dimerization process could not be achieved with the chiral organopalladium complex despite the fact that it has activated DMPP effectively as a cyclic diene in many cycloaddition reactions. Apparently, the organopalladium complex is not an efficent promoter for the activation of the dienophilicity of DMPP. Here we report the application of an analogous organoplatinum complex for the high yield synthesis of the desired optically active DMPP dimer.

As illustrated in Scheme 1, the reaction between the chiral platinum (−)-**1**[3] and 2 mol of DMPP in $CHCl_3$ at 30 °C for 60 d gave a 3:1 mixture of the regioisomers (−)-**2** and (−)-**3** in quantitative yield. The cationic complexes, which could not be separated by fractional crystallization, were separated efficiently by silica gel chromatography. The 202 MHz ^{31}P NMR spectrum of each regioisomer in $CDCl_3$ exhibited a pair of doublets. For the major isomer (−)-**2**, the doublet resonances occurred at δ 37.7 (J_{PtP} 3285 Hz, J_{PP} 7 Hz) and 133.7 (J_{PtP} 1548 Hz, J_{PP} 7 Hz). For the minor regioisomer (−)-**3**, the doublets were observed at δ 52.3 (J_{PtP} 1476 Hz, J_{PP} 7 Hz) and 104.8 (J_{PtP} 3216 Hz, J_{PP} 7 Hz). The low field doublets in these isomeric complexes are typical for bridgehead phosphorus adopting the *exo-syn* stereochemistry.[4] It is noteworthy that the Pt–P(bridgehead) coupling of (−)-**2** is significantly smaller than that of (−)-**3** as the former P(bridgehead) donor is located *trans* to a strong π-accepting aromatic carbon atom.[5] Treatment of both isomeric complex mixtures with conc. HCl removed the naphthylamine auxiliary chemoselectively to give the same dichloro complexes (+)-**4** as pale yellow prisms (70%), mp 200–202 °C (decomp.), $[\alpha]_D$ +58.4 (*c* 0.7, CH_2Cl_2). The ^{31}P NMR spectrum of (+)-**4** in $CDCl_3$ exhibited a pair of doublets at δ 39.6 (J_{PtP} 3193 Hz, J_{PP} 16.8 Hz) and 107.0 (J_{PtP} 3265 Hz, J_{PP} 16.8 Hz). The molecular structure and the absolute stereochemistry of (+)-**4** were determined by X-ray structural analyses (Fig. 1).† The studies reveal that the absolute configurations at P(1), P(2), C(1), C(4), C(5) and C(6) in the complex are *S*, *R*, *R*, *S*, *R*, and *R*, respectively. It should be noted that the dimerization process could be completed in 8 d by heating the reaction mixture at 100 °C in a sealed tube. Under these more vigorous conditions, however, product formation becomes less regioselective and a 1.5:1 mixture of (−)-**2** and (−)-**3** was obtained in somewhat lower yields.

Treatment of a CH_2Cl_2 solution of (+)-**4** with aqueous cyanide liberated the optically pure diphosphine (+)-**5** quantitatively as an air-sensitive oil with $[\alpha]_D$ +145 (*c* 0.5, CH_2Cl_2). The ^{31}P NMR spectrum of the free diphosphine in $CDCl_3$ exhibited a pair of doublets at δ 4.9 and 104.2 (J_{PP} 43.9 Hz). The low field ^{31}P resonance indicates that the *exo-syn* stereochemistry is retained. It is noteworthy that the apparent inversion of configuration that takes place at both phosphorus stereogenic centres during the liberation reaction is merely a consequence of the Cahn–Ingold–Prelog (CIP) rules.[6] The optical purity of (+)-**5** was confirmed by the quantitative repreparation of (−)-**2** and (−)-**3** from the liberated ligand and (−)-**1**; the 202 MHz ^{31}P NMR spectrum of the crude product exhibited signals due to the two regioisomers only. Unlike those obtained directly from the coupling reaction, the simple complexation process between (+)-**5** and (−)-**1** regenerated (−)-**2** and (−)-**3** as a 1:3 diastereomeric mixture. In a further test of optical purity, (+)-**5** was coordinated to the equally accessible (S_c)-(+)-**1**. The ^{31}P NMR spectrum of the crude product in $CDCl_3$ exhibited two new doublet resonances at δ 56.7 (J_{PtP} 1506 Hz, J_{PP} 10 Hz) and



Scheme 1

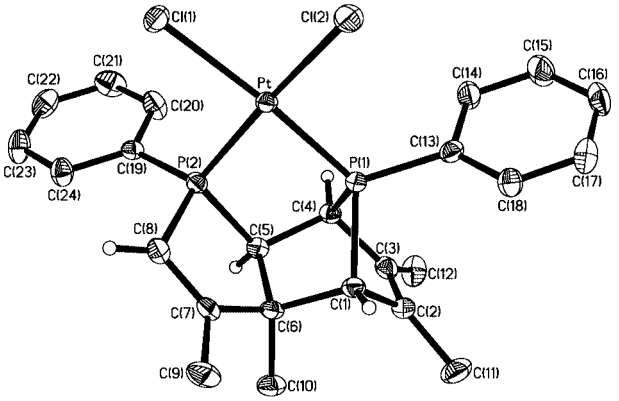


Fig. 1 Molecular structure and absolute stereochemistry of (+)-**4**. Selected bond lengths (Å) and angles (°): Pt–P(1) 2.214(1), Pt–P(2) 2.222(1), Pt–Cl(1) 2.381(1), Pt–Cl(2) 2.369(1), P(1)–C(1) 1.887(4), P(1)–C(4) 1.850(4), P(1)–C(13) 1.799(4), P(2)–C(5) 1.854(4), P(2)–C(8) 1.791(4), P(2)–C(19) 1.802(4), C(5)–C(6) 1.578(5), C(6)–C(7) 1.526(5), C(7)–C(8) 1.332(5), P(1)–Pt–P(2) 82.4(1), P(1)–Pt–Cl(1) 172.0(1), P(1)–Pt–Cl(2) 96.2(1), P(2)–Pt–Cl(1) 90.4(1), P(2)–Pd–Cl(2) 172.9(1), Cl(1)–Pt–Cl(2) 91.4(1), C(1)–P(1)–C(4) 80.2(2).

107.7 (J_{PtP} 3131 Hz, J_{PP} 10 Hz). According to the Pt–P coupling constants, these new signals are due to the S_c diastereomer of complex **3**. Interestingly, the S_c diastereomer of complex **2** was not formed *via* this coordination pathway, presumably due to steric reasons. More importantly, no resonance signals were detected at δ 37.7, 52.3, 104.8 and 133.7. It is noteworthy that the enantiomeric diphosphine (−)-**5** can be prepared similarly from the dimerization of DMPP using (+)-**1** as the chiral reaction promoter. However, diphosphine **5** was not obtained when the palladium analogue of **1** was used as the reaction promoter.

Finally, it is interesting to note that under different reaction conditions, complex **1** is able to activate DMPP both as a cyclic diene and as a dienophile toward the chemically reactive cyclopentadiene. Thus, when a $CHCl_3$ solution of (−)-**1**, DMPP, excess cyclopentadiene and a small quantity of NH_4Cl was heated at 60 °C for 24 h,[1] the ^{31}P NMR spectrum of the crude reaction mixture in $CDCl_3$ exhibited only two low field singlets of similar intensities at δ 98.3 and 98.1. The two singlets are of the same Pt–P coupling (3781 Hz). These low field NMR signals confirmed that two diasteromeric cycloadducts were formed and DMPP reacted as the cyclic diene under these conditions. On the other hand, when the reaction was carried out at room temperature for 24 h in the absence of the chloride anion,[1] only one isomer was produced. The ^{31}P NMR spectrum of the crude product exhibited a sole singlet at δ 14.5 (J_{PtP} 3703 Hz). This relatively high field ^{31}P NMR signal indicated that DMPP had reacted as the dienophile rather than the cyclic diene in this cycloaddition reaction. Investigations on the absolute stereochemistry of these cyclic adducts and the dienophilicity of DMPP toward other dienes are currently in progress.

We are grateful to the National University of Singapore for support of this research (Grant No. RP960675) and research scholarships to GSH.

Received (in Liverpool, UK) 12th November 1999, Accepted 6th December 1999

Carbon-13 and fluorine-19 NMR experiments in a chiral polypeptide liquid crystalline solvent (PBLG) are used to establish enantioselective propargylic monofluorination.

Fluorine strongly modifies the physical, chemical and biological properties of organic molecules, giving access to new drugs or pharmacological tools and useful agrochemicals.[1] Monofluorination remains a challenging problem in terms of regio- and stereo-control,[2] especially in positions vicinal to unsaturated systems, even if some transition metal complexes can control the dehydroxyfluorination.[3] An alternative is to prepare small, chiral, fluorinated building blocks which can be elaborated into the target molecules.[4] Since acetylenic derivatives have high potentialities for stereoselective synthesis,[5] propargylic fluorides should be versatile intermediates.[6] In this strategy, control of the absolute configuration at the stereogenic center is important, therefore the preparation of optically active propargylic fluorides becomes a central question.[7,8]

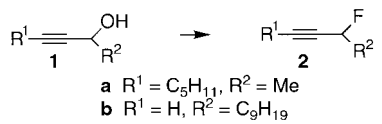
Here we report the first study of enantioselectivity in dehydroxyfluorination using alcohols **1a** and **1b** as models. Furthermore, we demonstrate NMR in chiral liquid crystals as a powerful method for the analysis of the enantiomeric purity of these propargylic fluorides.

The reaction of (±)-**1a** with diethylaminosulfur trifluoride (DAST) at −50 °C is regiocontrolled,[9] giving exclusively (55% yield) the propargylic fluoride (±)-**2a** (Scheme 1).[10] Such chiral propargylic fluorides appear rather difficult to discriminate, and until now, none of the usual tools in the field of enantiomeric analysis (chiral GC or HPLC, chiral shift reagents *etc.* have allowed the differentiation of the enantiomers of (±)-**2a** for instance. It was therefore of interest to explore other analytical approaches such as NMR in chiral liquid crystalline solvents.[11–13] Indeed, it has been demonstrated that ^{2}H, ^{13}C or ^{19}F NMR in organic solutions of poly(γ-benzyl L-glutamate) (PBLG) can provide a competitive alternative when normal methods fail. In proton-decoupled natural abundance ^{13}C NMR (^{13}C{^{1}H}), enantiomeric discrimination is observed through a difference in the ^{13}C chemical shift anisotropies (CSA), leading to two separated peaks for each discriminated carbon of the molecule. This allows the measurement of ees with an accuracy of about ±5%.[12] As the parameters governing the strength of the ^{13}C CSA mainly increases with the electronegativity of the substituents and the hybridization state of the carbons [$\Delta\sigma$ (sp) > $\Delta\sigma$ (sp^2) > $\Delta\sigma$ (sp^3)], we could expect to obtain a measurable chiral discrimination on the acetylenic carbons of the fluorinated propargylic compounds.[12]

Fig. 1(*a*) presents the 100.62 MHz ^{13}C{^{1}H} spectrum associated with the ethynyl carbons of (±)-**2a** recorded in the PBLG/$CHCl_3$ phase.†‡ Analysis of the spectrum shows two doublets centred at different chemical shifts for the C-1 and the C-2 carbons. The splittings, noted T_{CF}, arise from the ^{13}C–^{19}F scalar (J_{CF}) and dipolar (D_{CF}) couplings, the latter being also order sensitive ($T_{CF} = J_{CF} + 2D_{CF}$).[12] However, as indicated in Fig. 1(*a*), it appears that the two enantiomers are mainly discriminated through a difference of CSA. The chemical shift differences ($\delta_R - \delta_S$) for C-1 and C-2 are of 0.07 and 0.06 ppm, respectively. Note also that a small chiral discrimination was also observed on the sp^3 chiral carbon of (±)-**2a**.

With this tool in hand, it now becomes possible to study the enantioselectivity of the dehydroxyfluorination reaction on (+)-**1a** and (−)-**1a** at various temperatures. The synthesis of (+)-**1a** or (−)-**1a** (ee ⩾ 95%) is straightforward, starting from commercially available (*R*)- or (*S*)-but-3-yn-2-ol (Scheme 2). Fig. 1(*b*) presents the ^{13}C{^{1}H} NMR signals associated with the C-1 and C-2 carbons of (−)-**2a** prepared at −55 °C from (−)-**1a**. When comparing these data with that of (±)-**2a**, we clearly observe a difference in peak intensity for both sp carbons. The measurement of the ee for the spectrum in Fig. 1(*b*) is, therefore, possible using both the signal of C-1 and C-2, which enhances the confidence interval in the determination of the ee. Thus, at −55 °C, the ee calculated using either peak integration or deconvolution tools is 45 ± 5%, whereas the ee increases to 75 ± 5% when the reaction temperature is lowered to −95 °C. Note that the (*S*)-enantiomer exhibits the most shielded signal for both carbons and all these experimental values were confirmed when (−)-**1a** was replaced by (+)-**1a**.

Thus, the dehydroxyfluorination reaction of (+)-**1a** or (−)-**1a** has a good enantioselectivity (⩾75%) at low temperature. This



Scheme 1

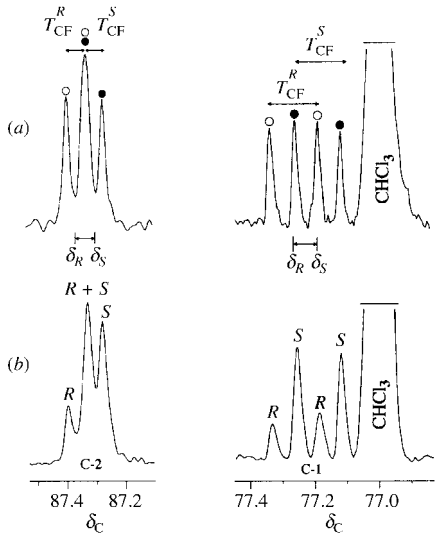


Fig. 1 ^{13}C{^{1}H} spectrum associated with the ethynyl carbons of (*a*) (±)-**2a** and (*b*) (−)-**2a** recorded at 298 K. Gaussian filtering was applied to enhance the spectral appearance. For (±)-**2a**, we measure T^R_{CF} = ± 14.9 Hz, T^S_{CF} = ± 14.4 Hz for the C-1 carbon, and T^R_{CF} = ± 6.9 Hz, for the C-2 carbon.

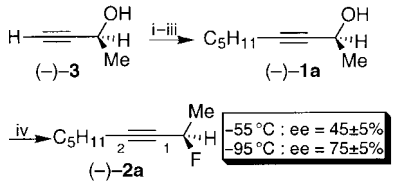
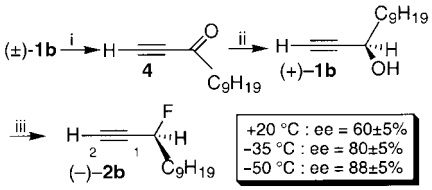


Scheme 2 *Reagents and conditions*: i, TBDMSCl, imidazole, DMAP, THF (84%); ii, BuLi, $C_5H_{11}Br$, THF–HMPA (3:1), −30 °C (85%); iii, Bu_4NF, THF (93%); iv, DAST, CH_2Cl_2 (55%).



Scheme 3 *Reagents and conditions*: i, PCC, AcONa, CH_2Cl_2 (56%); ii, *R*-Alpine-Borane (89%); iii, DAST, CH_2Cl_2 (51%).

reaction exhibits a strong temperature dependence since the ee is only 45% at *ca.* −55 °C. In agreement with the mechanism generally accepted for DAST fluorination,[14] inversion of configuration is assumed.

A similar sequence was followed by the case of **2b**. Starting from (±) = **1b**[6] the racemic derivative (±)-**2b** is obtained, together with a small amount of the corresponding enyne separated by chromatography. The optically active alcohol (+)-**1b** (ee = 90%) is obtained by asymmetric reduction of **4** (Scheme 3).[15] Once again, ^{13}C NMR in PBLG allowed the study of the enantioselectivity of the fluorination.

In this example, the results were also confirmed through 376.49 MHz $^{19}F\{^1H\}$ NMR. Fig. 2(*a*) presents the $^{19}F\{^1H\}$ spectrum and $^{13}C\{^1H\}$ NMR signal associated with the C-2 carbon of (±)-**2b**. As before, the analysis of the ^{13}C signal shows two doublets centred at two different chemical shifts ($\delta_S - \delta_R$ = 0.14 ppm). Note that the C-1 carbon was also significantly discriminated through a chemical shift difference ($\delta_S - \delta_R$ = 0.20 ppm). Unlike the compound (±)-**2a**, which showed no chiral discrimination *via* $^{19}F\{^1H\}$ NMR, the derivative (±)-**2b** exhibits specific ^{19}F CSAs for each enantiomer ($\delta_S - \delta_R$ = 0.03 ppm). This example is the first case of chiral discrimination through $^{19}F\{^1H\}$ NMR on a monofluorinated compound using a chiral liquid crystal.

Fig. 2(*b*) reports the $^{19}F\{^1H\}$ and $^{13}C\{^1H\}$ NMR signal of (−)-**2b** synthesised at −35 °C starting from (+)-**1b**. We can observe unambiguously the strong difference in intensity of the doublets of each enantiomer compared with (±)-**2b**, thus showing the high enantioselectivity of this reaction. For this example, the ee calculated through peak integration or deconvolution processes is 80 ± 5% at −35 °C. It is noteworthy that the synthesis of (+)-**2b** at −50 °C enable us to further enhance the ee to 88 ± 5%. Therefore, the dehydroxyfluorination of (+)-**1b** has a very high stereoselectivity (≥97%) at −50 °C. As for **1a**, the reaction shows a temperature dependence, since the ee is 80% at −35 °C and only 60% at room temperature. Note here that the (*R*)-enantiomer exhibits the most shielded signals for C-1 and C-2. These results were confirmed using (−)-**1b** as starting material.

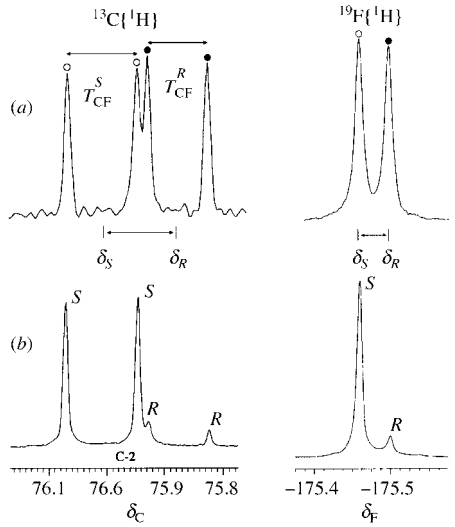


Fig. 2 $^{19}F\{^1H\}$ spectrum and $^{13}C\{^1H\}$ NMR signal associated to the C-2 carbon of (*a*) (±)-**2b** and (*b*) (−)-**2b** recorded at 294 K by adding 64 and 1500 scans, respectively. Gaussian filtering was applied to enhance the spectral appearance. For (±)-**2b**, we measure T_{CF}^S = ± 12.8 Hz, T_{CF}^R = ±11.1 Hz for the C-2 carbon.

These data appear to indicate a competition between S_N2 and S_N1 type processes. In the case of **1a**, the pentyl group can provide better stabilization for the carbocationic intermediate, leading to lower selectivities and a stronger temperature dependence compared to the hydrogen in **1b**. In addition, this study highlights the noteworthy potential of NMR in PBLG as an analytical method. Finally, these results, especially in the case of **2b**,[6] are of interest with regard to the preparation of fluorinated analogues of natural products.

We thank the region Bretagne for a fellowship to V. M.

Notes and references

† *Sample composition*: The liquid crystalline NMR samples were made from 100 mg of PBLG (DP = 534), 100 mg of a chiral material and 350 mg of $CHCl_3$. Sample preparation, see refs. 11–13.

‡ *NMR experiments*: NMR experiments were performed on Bruker DRX-400 (5 mm BBI probe) and ARX-400 (5 mm QNP probe) spectrometers. Broad-band proton decoupling was applied using the WALTZ-16 sequence. The interferograms were acquired using a pulse angle of ~60°, a recycle delay of ~1.5 s and 8 or 16 K of data points. Zero filling to 16 or 32 K was applied to increase the digital resolution.

A direct conversion of α,β-unsaturated ketones to vinylcyclopropanes: new zirconium-mediated reaction†

Philippe Bertus, Vincent Gandon and Jan Szymoniak*

Received (in Liverpool, UK) 5th November 1999, Accepted 6th December 1999

Various vinylcyclopropanes are synthesized from α,β-unsaturated ketones *via* a zirconium-mediated [1,2]-addition–deoxygenative cyclopropanation sequence; the latter step surprisingly proceeds under specific protic conditions.

Vinylcyclopropane derivatives are useful intermediates for a wide variety of transformations including rearrangements and stereoselective ring expansions, nucleophilic and electrophilic ring opening, and transition metal catalyzed reactions.[1] On the other hand, many natural or synthetic biologically active molecules contain a vinylcyclopropane moiety. The latter can be constructed using procedures that involve direct formation of the cyclopropane ring.[1,2] The limitation of these methods lies in the necessary use of the carbon–carbon double bond entity as a precursor. Thus, it appears worthwhile to search for new synthetic procedures aimed at relating the vinylcyclopropane moiety to other frequently encountered structural subunits.

Here we present a new approach to vinylcyclopropane derivatives.[3] The described procedure makes it possible to obtain them directly from α,β-enones, by zirconium-assisted deoxygenative addition of an ethylene dianion equivalent (in a formal sense). In practice, zirconocene (ethylene) complex, formed from Cp_2ZrEt_2, was used as a reagent.[4] In the first experiment, Cp_2ZrEt_2 was formed from Cp_2ZrCl_2 and EtMgBr (2 equiv.) in THF at −78 °C, and Cp_2Zr (ethylene) generated by allowing the reaction mixture to warm to 0 °C. Afterwards, benzylideneacetone (**1**) was added, and the reaction carried out at room temperature for 2 h.[5] The hydrolysis of the reaction mixture with 3 M HCl afforded alcohol **2** and an unexpected minor vinylcyclopropane derivative **3** (**3**:**2** = 22:78) (Scheme 1).[6]

Deuterolysis of the reaction mixture with DCl in D_2O (3 M) gave [^{2}H]-**2**, namely 5-deuterio-3-methyl-1-phenylpent-1-en-3-ol, with > 98% D incorporation. This result suggested that the reaction had involved an intermediate oxazirconacyclopentane (**A**), similar to those postulated for the reactions employing saturated ketones.[6]

Using 3 M H_2SO_4 instead of 3 M HCl for hydrolysis, the course of the final reaction changed. Thus, quenching of the reaction with 3 M H_2SO_4 resulted in predominant formation of vinylcyclopropane derivative **3** (**3**:**2** = 92:8) which was isolated in 45% yield (Scheme 1). We next ascertained that the cyclization process had not occurred before protonolysis, under the reaction conditions. In fact, no trace of **3** was detected in THF at 0 °C or at room temperature even after prolonged reaction time (36 h). This observation confirmed the crucial role of H_2SO_4 for cyclization. Thus, the title reaction markedly differs from the somewhat similar Kulinkovich hydroxy-cyclopropanation, which allows the preparation of cyclopropanols or cyclopropylamines from esters (carbonates) or amides and a Grignard reagent, in the presence of $Ti(OPr^i)_4$.[7] Whereas the latter involves the spontaneous rearrangement of the intermediate oxatitanacycle, specific protic conditions proved to be necessary for our cyclization to occur. Finally, we noticed that no cyclization reaction occurred with H_2SO_4 starting from the saturated ketones, and only the corresponding alcohols were isolated in all cases.

To further explore the scope of the title reaction other α,β-unsaturated ketones were tested. As shown in Table 1, the reaction can be applied to the synthesis of various vinylcyclopropane derivatives. Particularly, the spiro cyclopropane derivatives **11**–**15** (entries 3–7) could be prepared in moderate to excellent yields starting from the cyclic substrates. Thus, isophorone (**5**) and cholestenone (**6**) were transformed into the corresponding vinylcyclopropane derivatives **11** and **12**, respectively, in 75 and 91% yield (entries 3 and 4). The easily prepared **12** should be considered as a new potentially useful steroidal intermediate.[8] The carbonyl-conjugated C=C double bond may be in an exocyclic as well as endocyclic position, and even an additional isolated C=C double bond may be present in the substrate (entries 5 and 6). The reactions have also been accomplished starting from the relatively crowded tetramethylcyclopentenone (**9**) (entry 7). The absence of the corresponding alcohols using the cyclic substrates **5**–**9** is noteworthy. The less reactive acyclic enones **1** and **4** gave lower yields on average (entries 1 and 2). We thought that this might be due to the relative thermal instability of the Cp_2Zr(ethylene) complex,[4] performed *in situ* in the absence of the substrate. To overcome this limitation we tried to stabilize the complex by adding 1 equiv. of trimethylphosphine prior to increasing the temperature from −78 to 0 °C.[6] As a result, only slightly higher yields were observed (53 and 42% for **3** and **10**). Nevertheless, the phosphine-based procedure could also be applied to the preparation of substituted vinylcyclopropane derivatives, as exemplified by the synthesis of **16** (Scheme 2). This reaction did not proceed with a significant yield without PMe_3, possibly

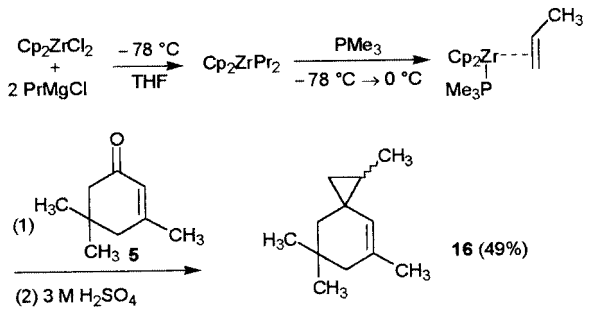
Table 1 Reaction of α,β-enones with Cp_2Zr/(ethylene), followed by hydrolysis with H_2SO_4

Entry	α,β-Enone	Product	Yield (%)[a,b]
1	 1	 3	45 (53)
2	 4	 10	31 (42)
3	 5	 11	75
4	6 (4-cholesten-3-one)	 12	91
5	 7	 13	47
6	 8	 14	40 (59)
7	 9	 15	55

[a] Yields of isolated products after column chromatography. [b] Yields for the reaction employing PMe_3 (1 equiv.) are given in parentheses.



Scheme 2

because of the generally more difficult incorporation of higher alkenes.[4]

Two aspects of the title reaction are remarkable: (i) the cyclopropanation (C–C bond formation) step occurs under protic conditions, and (ii) this selective reaction requires 3 M H_2SO_4, whereas the use of 3 M HCl leads to the predominant formation of the alcohol. Further studies are necessary to clarify the specific role of H_2SO_4 in the cyclization process. However, based on the dichotomous behavior of the two strong protic acids, 3 M HCl and 3 M H_2SO_4, a hypothetical rationale for the two different reaction modes can be proposed (Scheme 1). In the first step, oxazirconacyclopentane **A** must invariably be protonated under the strongly acidic conditions to give the oxonium intermediate **B**. Depending on whether HCl or H_2SO_4 is employed, strikingly different mechanistic pathways [(*a*) or (*b*)] can follow. The reasonably nucleophilic Cl^- apparently attacks at the Cp_2Zr residue with cleavage of the Zr–O bond, which is favourably accompanied by the formation of the relatively strong Zr–Cl bond. In contrast, the attack of the weakly nucleophilic HSO_4^- on Cp_2Zr is slower than the competing ring contraction, leading to a cyclopropane derivative. In this concerted process,[9] the partial positive charge developing on the allylic carbon atom is efficiently stabilized by the neighbouring double bond. Studies are underway to fully elucidate the cyclization step and to extend the synthetic scope of the reaction, and the results will be published in due course.

Taming early transition metals: the use of polydentate amido-donor ligands to create well defined reactive sites in reagents and catalysts

Lutz H. Gade

Laboratoire de Chimie Organométallique et de Catalyse, UMR 7513, Institut Le Bel, Université Louis Pasteur, 4, rue Blaise Pascal, 67000 Strasbourg, France. E-mail: gade@chimie.u-strasbg.fr

Received (in Cambridge, UK) 15th October 1999, Accepted 7th December 1999

Ligand design in early transition metal chemistry has focussed recently on amide chemistry. The availability of two substituent positions at the amido N-donor atom allows its integration into ligand systems of both podand and macrocyclic topology. Amido functions may be combined with other donor functionalities which possess a different formal charge and chemical hardness and, more generally, a different thermodynamic and kinetic stability of their interaction with the metal centre. Early transition metal complexes containing polydentate amido-donor ligands not only display unprecedented patterns of reactivity but are the focus of recent developments in olefin polymerization catalysis.

Introduction

Amido–transition metal chemistry, a field which developed with limited momentum after the pioneering work of the 1960s and early 1970s,[1,2] has grown dramatically during the past decade. These recent advances are not due to the received wisdom of the structural chemistry and reactive behaviour gained in the early studies having undergone dramatic changes. It is the realization that the amido donor function R_2N^- may be placed into a great variety of structural environments which has ultimately led to the dramatic expansion of the area. It may be readily incorporated into complex polydentate ligand structures and combined with other donor functionalities. Amido units are thus suitable tools in ligand design for early transition metal complexes.

The stabilization, *i.e.* protection, of part of the coordination sphere of a high valent, Lewis acidic early transition metal may be achieved by considering several important aspects. First, the ligands chosen for the non-reactive metal ligand interactions (frequently referred to as *spectator* or *ancillary* ligands) should adequately match the electronic demands of the metal centre.[3] In the case at hand this requires strong σ- and π-donor capabilities and, given the hard nature of the Lewis acid, matching chemically hard donor atoms. Secondly, the ancillary ligands must obviously have significantly different bonding and reactive properties in comparison to the *reactive* ligands, *i.e.* those which undergo transformations in the stoichiometric or catalytic processes of interest. Third, the distribution of donor functions over the protected sector of the coordination sphere should be well balanced. This latter situation is demonstrated particularly well by the early transition metal metallocenes and their derivatives which are at the centre of a vast area of modern organometallic chemistry.[4] During the past decade the dominating position of the cyclopentadienide complexes in the coordination chemistry of the d-electron poor metals has been challenged by the rapid development of amido complex chemistry.

The availability of two substituent positions at the amido N-donor atom allows its integration into ligand systems of both podand and macrocyclic topology (Fig. 1).[5] This not only leads to a well defined relative orientation of the ligating atoms but opens up manifold possibilities of steric control. Moreover, amido functions may be combined with other donor functionalities which possess a different formal charge and chemical hardness and, more generally, a different thermodynamic and kinetic stability of their interaction with the metal centre. In the latter case the strong metal–amide bonds form the anchoring elements of the polyfunctional ligands while the remaining donor functions may either influence the electronic properties of the central atom or mask potentially reactive coordination sites by virtue of their hemilabile nature. In catalytic applications of amido complexes, the availablity of additional weakly coordinating donor functions may crucially determine the lifetimes of certain intermediates in the catalytic cycle and thus the nature of the reaction products. It is the aim of this article to provide an overview of the present state of the area of amido complex chemistry in which the amido functions in the ligand are combined with other *neutral donors* and in which all these considerations have played a role.

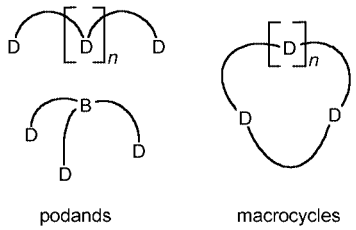

Fig. 1 Topologies of polydentate ligands (D = donor function, B = bridgehead function).

Combining anionic and neutral donor functions: amidoamine and amidopyridine ligands

The addition of a neutral tertiary amino function to a polydentate amido ligand may lead to a variety of conse-

Lutz H. Gade is Professor of Chemistry at the Université Louis Pasteur, Strasbourg. His research interests are in the fields of coordination chemistry, organometallic chemistry and catalysis. After completing his undergraduate studies at the University of Bonn and the Technical University of Munich, he went to Cambridge to work for his Ph.D. with Jack Lewis. Having returned to Germany after completing his thesis in 1991, he joined the Chemistry Department at the University of Würzburg where he finished his habilitation in 1996 and where he subsequently worked as a lecturer. In 1998 he moved to Strasbourg to take up his present position. His scientific work has found recognition through the award of the ADUC prize for 1994, the Heinz–Maier–Leibnitz Preis of the DFG and the Federal Ministry of Research and Education (1997), the Gerhard–Hess-Research Award of the DFG (1998) as well as the Award in Chemistry of the Academy of Sciences at Göttingen (1999).

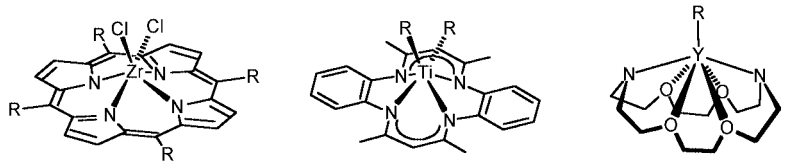

Fig. 2 N-donor macrocycles of different flexibility which have been employed in early transition metal chemistry.

quences. Incorporated within more or less rigid *macrocylic* structures they mostly remain coordinated to an early transition metal centre during transformations at the remaining coordination site(s) and thus serve the 'passive' purpose of maintaining a particular ligand environment with a given overall ligand charge thoughout the transformations. The extremes of macrocyclic rigidity and flexibility are represented by early transition metal porphyrins on the one hand[6] and metallated azacrown ethers on the other[7] as exemplified in Fig. 2. In both cases, the macrocycle–metal complex fragment does not seem to undergo significant changes in chemical reactions involving the reactive ligands. Other macrocyclic systems of intermediate flexibility include tetraazaanulenes the coordination chemistry of which has been recently reviewed.[8]

On the other hand, neutral amino groups (as well as ether or organosulfido groups, *vide infra*) are more readily displaced from early transition metal centres than anionic amido units and therefore may play a flexible role in organometallic transformations. The latter is of particular importance in the development of new early transition metal polymerization catalysts which will be discussed in detail below.

In contrast to the macrocyclic structures discussed so far, neutral donors in *bridgehead* positions of *podands* with amido 'arms' may remain essentially passive within the cage structure of the metal complexes containing these ligands. The paradigm for the use of such ligand systems are the triamidoamine ligands found in the azametallatranes **1** studied by Verkade, Schrock and others.[9,10] These are essentially tripodal ligands in which the apical bridgehead atom participates in the coordination to the metal centre generating a particularly stable cage structure. The arrangement of the triamidoamine creates a reactive site at the metal centre, occupied by the remaining ligand, which may be varied in size and geometry by choice of the appropriate peripheral substituents at the amido nitrogen donor atoms. A set of frontier orbitals comprising one σ and two π orbitals is in principle available for ligand binding at the remaining coordination site (Fig. 3).[10]

This situation is thought to provide the appropriate frontier orbital set at the metal for the extremely rich metal–ligand multiple bond chemistry found for these systems to date.[11] Whereas the tertiary amino function at the apex influences the orbital energies of the frontier orbitals, it apparently adopts a 'passive' role in most of the compounds studied to date. Only in rare cases has it been posssible to establish the involvement or association/dissociation of the amino function in reactions of

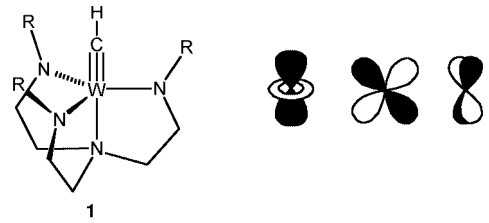

Fig. 3 Molecular structure of an azametallatrane, **1**, along with a depiction of the metal centred frontier orbitals which may be involved in ligand binding.

azametallatranes.[12] The chemistry of this class of complexes has developed rapidly during this decade and has been reviewed in detail.[9,10] It will therefore not be discussed in this overview of the field.

Greater flexibility in the coordination geometry and more open structures are found in a number of early transition metal complexes containing new types of diamidoamine ligands (Fig. 4). In these the amino donor function is less strongly bound and its *active* participation in chemical transformations, *i.e.* the coordination and dissociation, is possible. Whereas the tridentate diamidoamine ligand **A**, first reported by Cloke *et al.* adopts a facial coordination mode in **2**,[13] a meridional arrangement was observed in the crystal structure of the analogous complex **3** studied in Schrock's group.[14] Both compounds are precursors of cationic olefin polymerization catalysts the reactivity of which is strongly influenced by the availability of a neutral (dissociable) donor function (*vide infra*).

In contrast to these catalytically active dialkyldiamido zirconium complexes, complex **3a** bearing a tridentate ligand in which the aminofunction is not positioned between the anionic amido units has been found to be inactive in attempted polymerizations.[15]

The combination of a pyridyl unit with two amido functions leads to tridentate ligands which, depending upon their topology, may adopt meridional or facial coordination modes. Meridional coordination is achieved using ligands of type **D** (Fig. 5)[16] which have found application in the development of novel olefin polymerization catalysts of high activity (**4**, *vide infra*).[17] We first developed and studied the coordination chemistry of type **E** diamido pyridine ligands[18] which were found to adopt facial arrangents in early transition metal complexes such as **5**.[19]

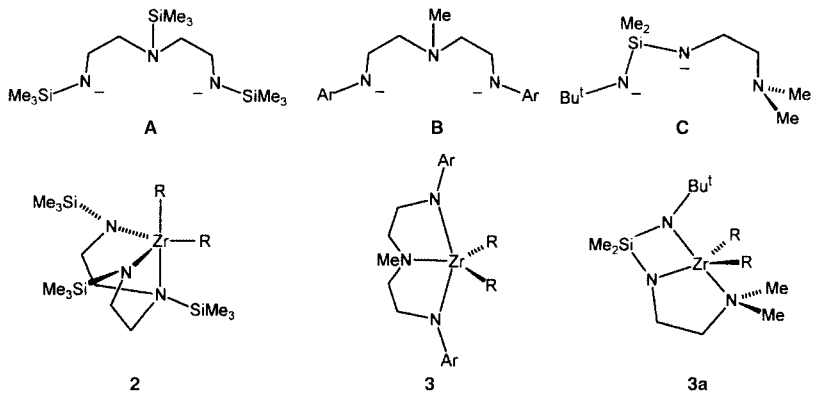

Fig. 4 Zirconium complexes containing the diamidoamine ligands **A**, **B** and **C**.

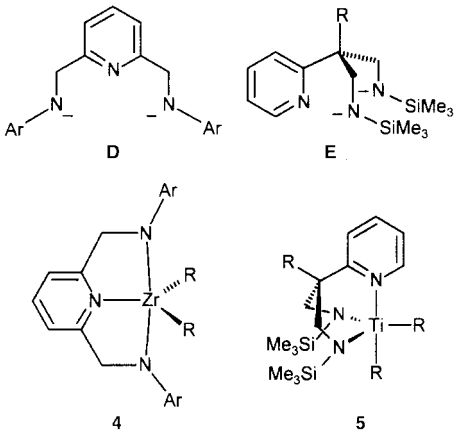

Fig. 5 The diamidopyridine ligands **D** and **E** adopting meridional and facial coordination modes, respectively.

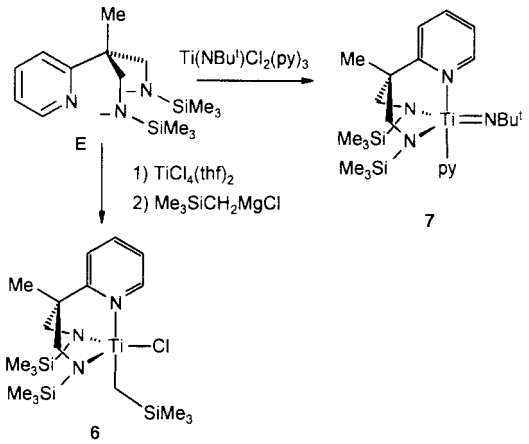
Formally, the dianionic tripods may be derived from the threefold symmetrical tripodal ligands through the replacement of one of the anionic amido 'claws' by the neutral pyridyl function. This class of ligands has been employed in the synthesis of tetravalent titanium and pentavalent vanadium group metal complexes. For the complexes of the Ti triad the ancillary ligand system has allowed the coordination of either two additional anionic (*e.g.* alkyl) ligands or,[19] alternatively, a formally dianionic unit as achieved in the synthesis of a series of stable imido complexes (Scheme 1).[20,21]



Scheme 1 Synthesis of pentacoordinate titanium complexes containing the diamidopyridine ligand **E**.

The coordination of the pyridyl unit to the metal centre and thus the formation of a pentacoordinate complex **7** (Fig. 6) of distorted trigonal bipyramidal coordination geometry depends upon the steric requirements of the additional ligands in axial and equatorial position. Decoordination of the pyridyl function has been observed in solution for a dialkyltitanium complex **8** bearing bulky neopentyl groups for which the fourfold coordination mode with a dangling py-unit has been established by NMR spectroscopy, or in the solid state, as demonstrated by the

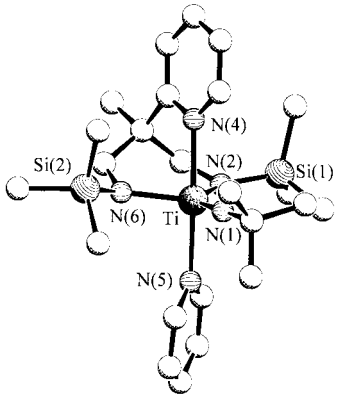


Fig. 6 Molecular structure of complex **7**.[20]

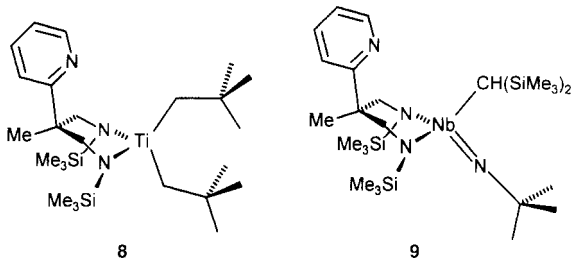

X-ray crystal structure analysis of [Nb{MeC(C$_5$H$_4$N-2)-(CH$_2$NSiMe$_3$)$_2$}(NBu^t){CH(SiMe$_3$)$_2$}] **9**.[19,21]

The imidotitanium complexes such as [Ti{MeC(C$_5$H$_4$N-2)-(CH$_2$NSiMe$_3$)$_2$}(NBu^t)(py)] **7** were found to have considerable thermal stability which allows their facile isolation and manipulation. However, they possess labile pyridine and pyridyl ligands that, under appropriate reaction conditions, may dissociate to yield unsaturated and highly reactive imido complexes of the type investigated by Wolczanski and coworkers *via* irreversible thermolysis of the respective precursor molecules (Fig. 7).[22] In fact, sublimation of **7** in high vacuum has yielded the four-coordinate complex **7a** which has been structurally characterized by X-ray crystallography.[21] In contrast, there has been no evidence, as yet, for the postulated highly unsaturated, three-coordinate species **7b**.

It is this flexibility of the tridentate ligand which is thought to be responsible for the remarkable reactivity of **7** towards a variety of organic substrates and represents an example of the 'taming' of a reactive structural element as implied in the title of this article. In reactions with methyl acetylenes we have found slow but selective cyclization yielding the metalla-azetidines **10**.[23]

This conversion is thought to occur *via* a C–H bond activation step of the methyl group to the Ti=N unit, as has been established for transiently generated imido compounds by Wolczanski and others,[22] and subsequent cyclization. The observation that the same products were obtained from the analogous substituted allenes may imply that an allenetitanium intermediate is involved in this conversion.

A cascade of C–-N and C–C coupling reactions is the result of exposing **7** to alkyl isocyanides to give metal bound

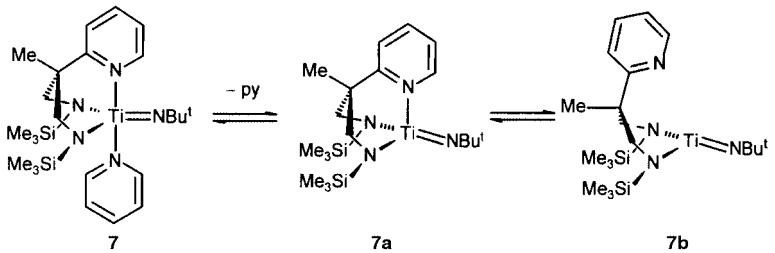

Fig. 7 Stabilization and "masking" of low-coordinate imidotitanium complexes.

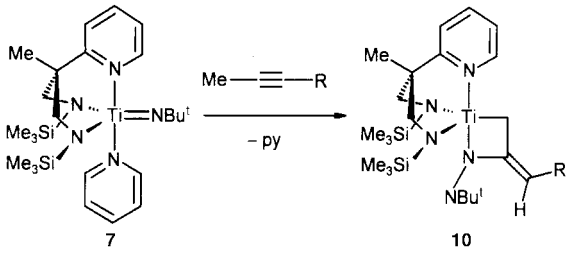
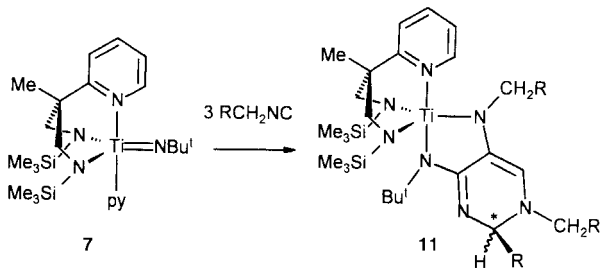


7 10

5,6-diamino-2,3-dihydropyrimidines **11**.[20] The reaction sequence is thought to occur along the pathway shown in Scheme 2.[24] Remarkably, no reaction intermediate could be detected for most of the isocyanide derivatives we studied. However, it has been possible to isolate and structurally characterize a derivative of **ii** which could be converted to **iii** upon addition of another molar equivalent of an isocyanide.



7 11

Several potentially tetra- and hexa-dentate amidopyridine ligands have been reported which contain deprotonated 2-aminopyridine units. Two of these have been connected *via* a bridging siloxane unit **F** and have been employed in the synthesis of heterodinuclear complexes in which they link neodymium and late transition metal fragments (for example **12**).[25] The combination of three aminopyridine fragments has been achieved in a trisilylmethane and trisilylsilane derived tripodal ligands for which titanium, zirconium and niobium complexes have been reported.[26,27] Although the pyridine donors in these systems are all coordinated to the respective metal centres in the crystal structures, their bonding situation in solution is not clear.

Stabilizing cationic early transition metal amido complexes: a new generation of non-metallocene polymerization catalysts

Few developments have fueled the interest in the organometallic chemistry of the early transition metals in the same way as the discovery of well defined olefin polymerization catalysts. To date, the majority of the systems, mainly based on titanium or zirconium, which have been investigated contain one or two cyclopentadienyl rings or their derivatives.[4] However, in recent years the focus has shifted to non-metallocene catalysts of which those containing chelating diamido ligands have received particular attention.[28] An ever increasing number of such complexes are currently being studied with regard to their activity as catalyst precursors for the polymerization of ethylene or longer chain α-olefins. The three complexes displayed in Fig. 8 were found to be procatalysts for highly active catalytic systems.[29]

In particular, the titanium complex **13** studied by McConville and coworkers,[29a,b] was found to behave as a living polymerization catalyst for hex-1-ene. The active species in these systems is thought to be a cationic monoalkyl complex which would be a solvated three coordinate species. In order to stabilize this

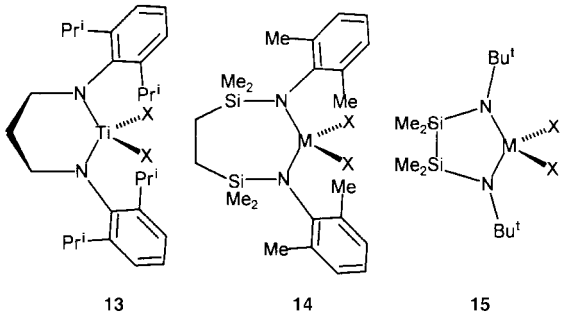

Fig. 8 Group 4 metal complexes containing chelating diamido ligands which are active catalysts for olefin polymerization.

cationic intermediate, ligand design has very recently been extended to include chelating diamido ligands which contain a third neutral donor function. As noted above, activity in olefin polymerization has mainly been observed for those systems in which the neutral donor is placed between the two anionic amido groups. In the five coordinate procatalysts shown in Fig. 9 the tridentate ligand may adopt either meridional or facial arrangements.[13,14,17,30–33]

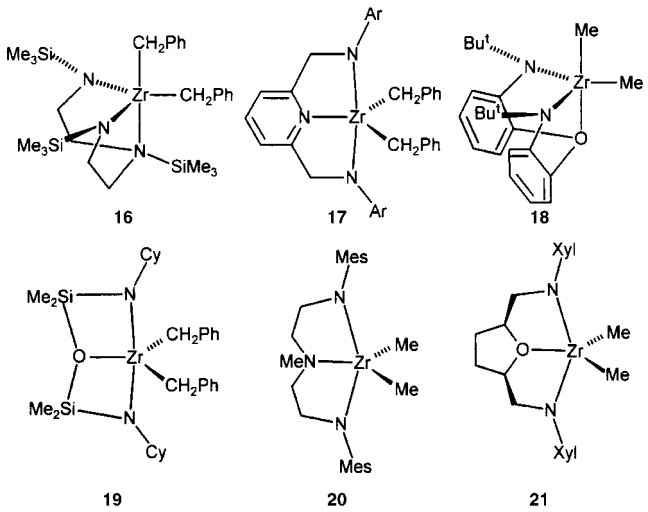

Fig. 9 Dialkylzirconium complexes, containing diamido-donor ligands, which are active olefin polymerization catalysts.

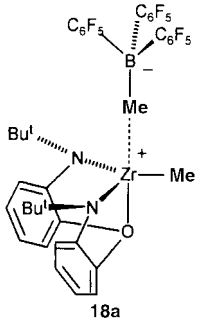
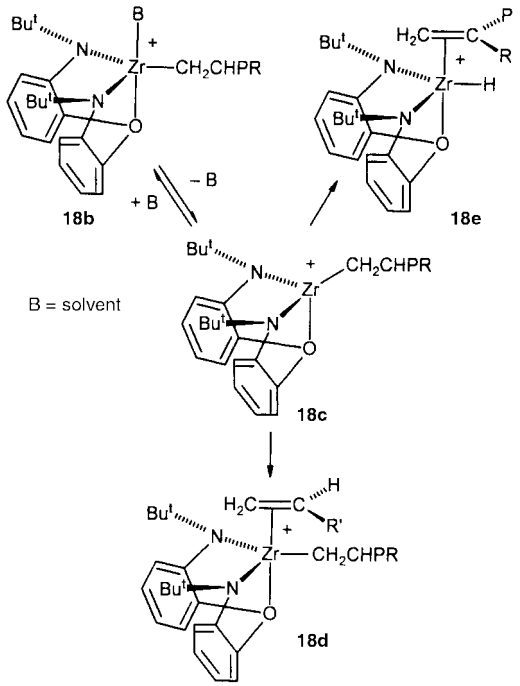
Compounds **16** and **17** have been studied by Cloke, Horton and McConville and represent the two possible arrangements of the donor functions.[13,17,30] While complex **16** was found to be moderately active in ethylene polymerization, the procatalyst **17** displays high activity. Very detailed studies into the mechanism of the polymerization and the role of the neutral donor functions have been carried out in Schrock's group. Compounds **18**, **20** and **21** are active catalysts for the polymerization of hexene.[14,31,33] An important feature in these complexes is the absence of N-bonded silyl groups which are not only easily hydrolyzed but may undergo cyclometallations. The chemically robust nature of **18**,[31] in particular, not only allows the living polymerization of hexene but has rendered the cationic intermediate suffiently stable to be characterized in solution.[34] The isolation and X-ray crystallographic characterization of the ionic adduct [{($Bu^tNC_6H_4$)$_2$O}ZrMe][MeB(C_6F_5)$_3$] **18a** upon reaction of **18** with the cocatalyst B(C_6F_5)$_3$, in which the boranate ion occupies the apical position, supports the notion that it is the apical alkyl group which is removed by the Lewis acid.[31]

Using $^{13}CH_3$-labeled **18**, it has been possible to detect the cationic solvent-stabilized catalyst by ^{13}C NMR spectroscopy in solution and to demonstrate that the 'insertion' of hex-1-ene into the Zr–CH_3 bond occurs in a 1,2 manner.[34]

Based on these studies, Schrock and Baumann have proposed the mechanism initiating the chain growth which is shown in



Scheme 3.[34] In the first step, the dissociation of the base in the apical position in **18b** generates the four-coordinate cationic complex **18c** to which the olefin monomer may coordinate generating a five coordinate cation **18d**. The monomer occupies the apical coordination site in this intermediate. In contrast to the mechanism proposed for the cationic metallocene catalysts, which adopt a pseudo-trigonal structure and in which the olefin may approach the metal–alkyl unit from two faces,[4] the pseudo-tetrahedral nature of **18c** restricts access to the metal centre to one face.



Scheme 3 Mechanism for the chain growth catalyzed by **18**.

That β-elimination which would terminate the living polymerization is a slow process is attributed to the steric congestion of the ligand sphere induced by the bulky N-bound *tert*-butyl groups. This renders the conversion of **18c** to **18c** kinetically unfavourable.

The studies discussed in this section impressively demonstrate the role played by the ancillary ligand in the control of the reactivity of a catalytic system. It is the combination of the electronic properties of the donor functions, the conformational degrees of freedom of the ligand backbone as well as the steric demand of both ligand backbone and peripheral substituents which influences their performance. This point is particularly apparent in the results of a comparative study of the catalytic properties of **21** and the simple dialkyl ether analogue [{O(CH_2CH_2NXyl)$_2$ZrMe$_2$] **22**.[33,35] Catalyst **21**, which contains a conformationally more rigid and sterically more demanding tetrahydrofuran-derived diamido-donor ligand, produced polyhexene of almost twice the molecular weight as compound **22**.

Amido ligands containing weakly coordinating donor functions: the *ortho*-fluorophenyl periphery

The neutral ligating units in the polyfunctional ligands discussed in the previous sections bind fairly strongly to the metal centres and are therefore thought to remain coordinated throughout most of the chemical conversions at the 'reactive' coordination site(s). However, the integration of very labile coordinating units into amido ligands enables the 'masking' of low coordination numbers and thus of potentially highly reactive species. The size of the reactive site in these systems is readily adjustable through coordination and decoordination of the hemilabile donors. We introduced such an *active ligand periphery* in several tripodal amido ligands in the form of *ortho*-fluorophenyl groups (Fig. 10).[36]

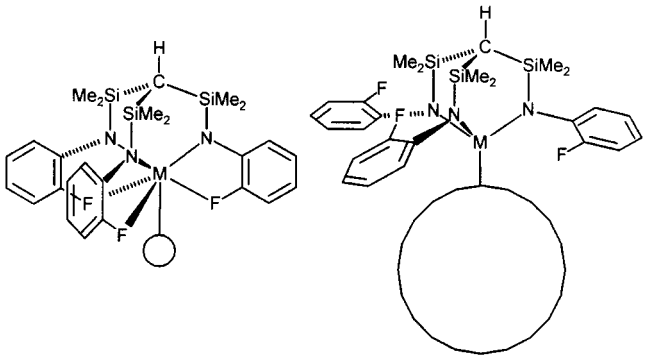


Fig. 10 Participation and non-participation of an active *ortho*-fluorophenyl ligand periphery in tripodal amido complexes.

The stabilization of Lewis acidic metal centres by weak C–F···M coordination has also been used in complexes containing appropriately functionalized monodentate amido ligands as well as in several metallocene derivatives.[37] The use of partially fluorinated aryl groups reduces the basicity at the amido N-atoms and thus increases their stability towards protolytic cleavage. Depending on the ionic radius of the metal centre and steric demand of the remaining anionic ligand(s), the coordination of one or more of the fluorine atoms both sterically shields and partially saturates the Lewis acidic metal centre. We have extended this approach to include N-bonded 2,3,4-trifluorophenyl groups which were found to stabilize complexes of the titanium triad even more efficiently.[36*b*]

The involvement of one, two or three *ortho*-F atoms in the coordination to the metal has been established by a systematic structural study. Coordination of all three C–F units has been observed for the yttrium complex **23** which together with an additional diethyl ether ligand leads to a sevenfold coordination geometry (Fig. 11).[36] This system was studied at the beginning of our work in view of its NMR-active metal nucleus ^{83}Y and indeed, ^{19}F NMR studies of the complex established the metal–fluorine interaction in solution by observation of ^{83}Y–^{19}F coupling.

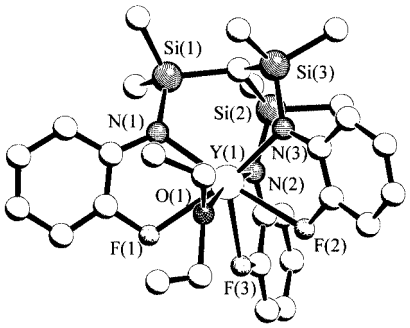

Fig. 11 Molecular structure of the yttrium complex [Y{HC[SiMe$_2$N(2-FC$_6$H$_4$)]$_3$}(OEt$_2$)] (**23**).

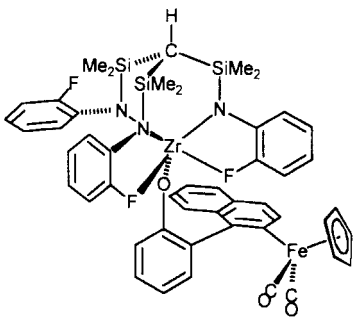
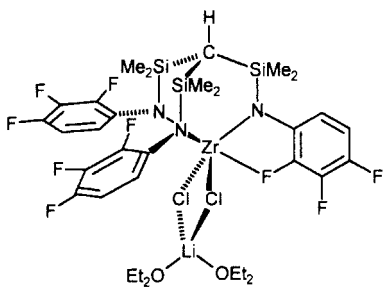
The structures of compounds **24**–**26** nicely demonstrate the relationship between the size of the anionic monodentate ligand(s) and the number of coordinated C–F groups.[37–39] While the coordination of the ligand periphery in **24** and **25** leads to sixfold coordination in the zirconium complexes, the large metal complex fragment {FeCp(CO)$_2$} which essentially acts as an anionic ligand in **26** enforces the dissociation of the hemilabile units (Fig. 12).

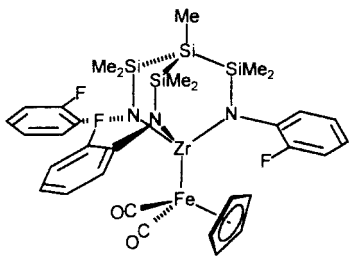
The role which the fluorine atoms adopt in the structures discussed above may be rationalized by assuming that the highly Lewis-acidic metal centre accepts as many additional donors as may be accommodated in their coordination sphere. The question of their importance in the chemical reactions of such species is more difficult to answer since intermediates are generally not detectable. However, we have carried out a comparative study of the kinetics of insertion reactions of unsaturated polar organic substrates into the polar metal–metal bonds in compounds such as **26**. These were related to the results obtained for complexes in which the fluorophenyl substituents were replaced by 'innocent' *para*-tolyl groups. In this study we found that the second order reaction rates of the fluorinated species are greater by a factor of *ca*. 10–50.[36*b*,39–41]



24



25



26

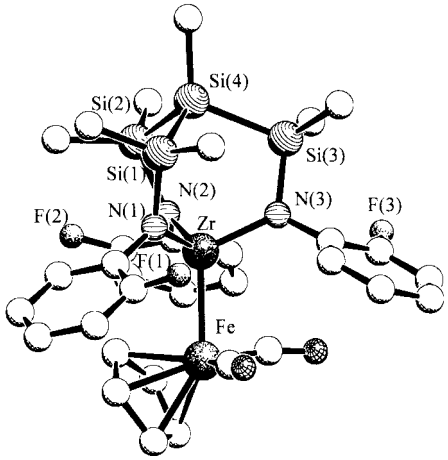


Fig. 12 Molecular structure of the Zr–Fe complex **26** showing the 'dangling' *ortho*-fluorophenyl groups.

The active periphery thus enhances the reactivity of the early–late heterobimetallics, an observation which may be understood in both possible mechanistic scenarios: an early or a late involvement of the F-donors in the process of metal–metal bond cleavage. Experimental evidence suggests that the attack of a Lewis-base at the early transition metal centre is the first step in the insertion reactions of polar substrates. The re-adjustment of electron density in the metal–metal bond destabilizes it and induces its subsequent scission. This process may be aided by the coordination of the CF groups before the cleavage of the Zr–M bond. On the other hand, the coordination of the fluorine atoms also stabilizes the fragments obtained after metal–metal bond breaking has occurred, a situation which will be reflected in the kinetics in the case of a late transition state. It has not been possible to differentiate between these two possibilities and it is quite likely that both play a role.

Labile coordination of *ortho*-fluorine atoms in N-bonded fluorinated aryl substituents has recently been observed in several other polydentate amides. X-Ray crystallographic studies carried out for [{$(C_6F_5NCH_2CH_2)_3$N}V] (V–F 2.65 Å)[42] and [{$(C_6F_5NCH_2CH_2)_2$N}$TaMe_2$] (Ta–F *ca.* 2.4 Å)[43] have also established metal–fluorine distances which are significantly longer than those found in binary fluorides or related compounds. This fact is to be seen in connection with the fluxionality of the orthofluorophenylamido complexes in solution which suggests that the strength of the interaction between the metal centres and the labile donor functions amounts to less than *ca.* 10 kcal mol^{-1}.

Combining hard and soft donor functions: chelating and macrocyclic amidophosphines

The stability of the metal–nitrogen bonds in amido complexes of the early transition metals enables their use as 'anchors' for polydentate ligands which also contain donor functions with less well matched electronic properties. This was part of the rationale behind the ligand design discussed in the previous sections. However, a particularly interesting variant of this concept has been developed and very successfully employed by Fryzuk *et al.* by combining the hard amido ligand with soft phosphine units in polydentate ligand systems.[3,44,45] The open chain PNP and NPN ligands **G** and **H** as well as the macrocyclic P_2N_2 ligand **I** displayed in Fig. 13 have been applied in the synthesis of organometallic complexes of the group 3–5 metals. Early work using **G**, which has been reviewed elsewhere, revealed that these systems may in fact be employed in the synthesis of stable late transition metal complexes with reversed roles of the two donor functions.[3,44] In d-electron rich complexes the soft phosphine ligands with their π-acceptor properties are to be viewed as the anchoring units which ensure the stabiliy of the molecules.

A series of early transition metal complexes containing the macrocyclic ligand **I** has been reported recently.[46,47] Particularly noteworthy is the coupling of two aryl rings in an yttrium(III) complex (Scheme 4).[47] This dinuclear species was

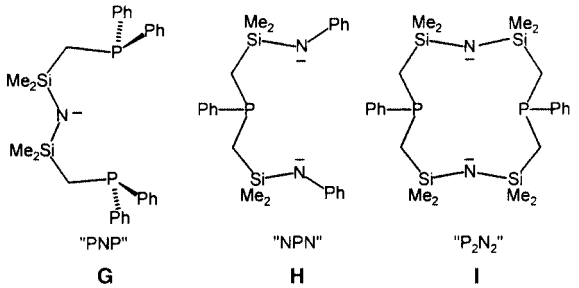

Fig. 13 Three polydentate amido-phosphine ligands introduced by Fryzuk and coworkers.

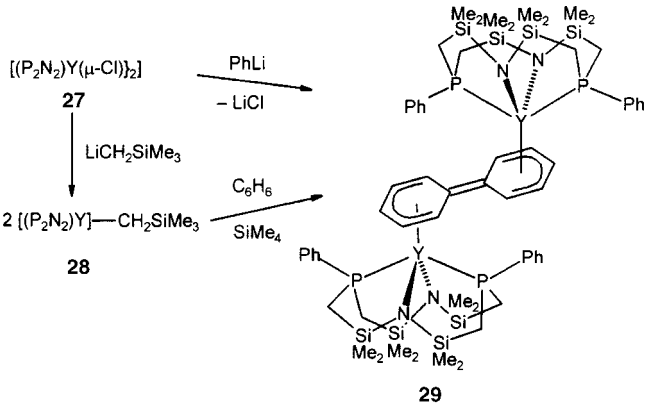
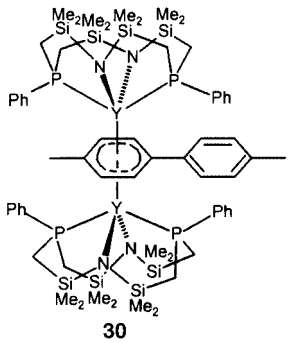


Scheme 4 Phenyl coupling induced by an yttrium complex stabilized by the macrocyclic P_2N_2 ligand **I**.

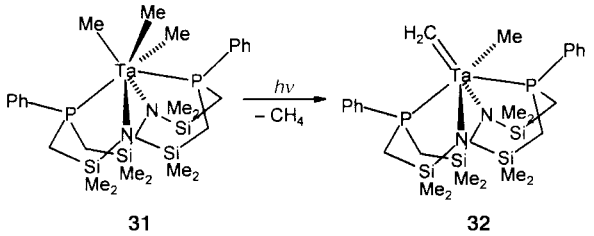
first discovered as the thermal decomposition product of the Me_3SiCH_2 complex **28** in benzene which yielded $SiMe_4$ and the dinuclear species **29** in which the bridging diphenyl ligand may be understood as being formally dianionic and thus leaving the oxidation state of the yttrium unchanged. The mechanism of this conversion which involved C–H bond activation is not yet fully understood. However, the same product was obtained upon reaction of the chloroyttrium(III) complex **27** with phenyllithium. This reaction of an aryllithium compound with a transition metal halide to give a product with a π-bonded arene unit is reminiscent of the chromium species which were first investigated in 1919 by Hein and coworkers but were only structurally understood after Fischer's synthesis of bis(benzene)chromium in 1955.[48]

It is remarkable that this coupling reaction may be extended to other aryl fragments as was shown in the generation of the ditolyl ligand on reaction of **27** with *para*-tolyllithium.[47] The structure of complex **30** which contains this bridging ditolyl



dianion shows that the arrangement of the two metal complex fragments coordinated to the organic unit appears to depend upon the substitution pattern of the latter. NMR studies carried out at variable temperature suggest a rapid migration of the complex fragments between the two ring positions in solution at room temperature.

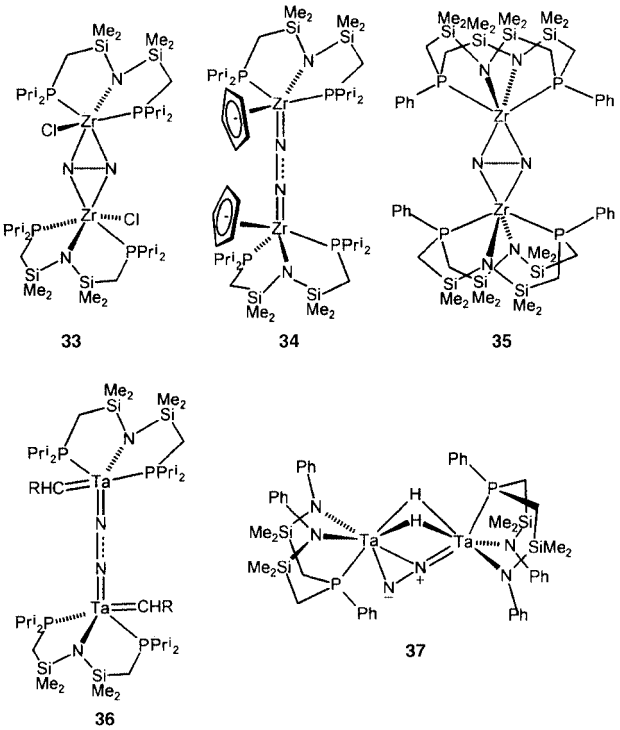
The macrocyclic diamidodiphosphine ligand **I** has been used in the synthesis of the trimethyltantalum complex **31** in which



31 **32**

all ligand donor atoms are bonded to the metal centre and which consequently adopts a sevenfold coordination geometry best described as capped trigonal prismatic.[49] This compound undergoes a photochemically induced methane abstraction to give the methylmethylidene complex **32**. The latter displays an interesting dynamic behaviour in solution which amounts to a libration and/or rotation of the Ta(=CH_2)Me unit relative to the macrocycle–Ta fragment.

The most spectacular application of the amidophosphine ligands **G** – **I** has been in the synthesis of the dinitrogen-zirconium and -tantalum complexes **33–37** (Fig. 14) which not



33 **34** **35**

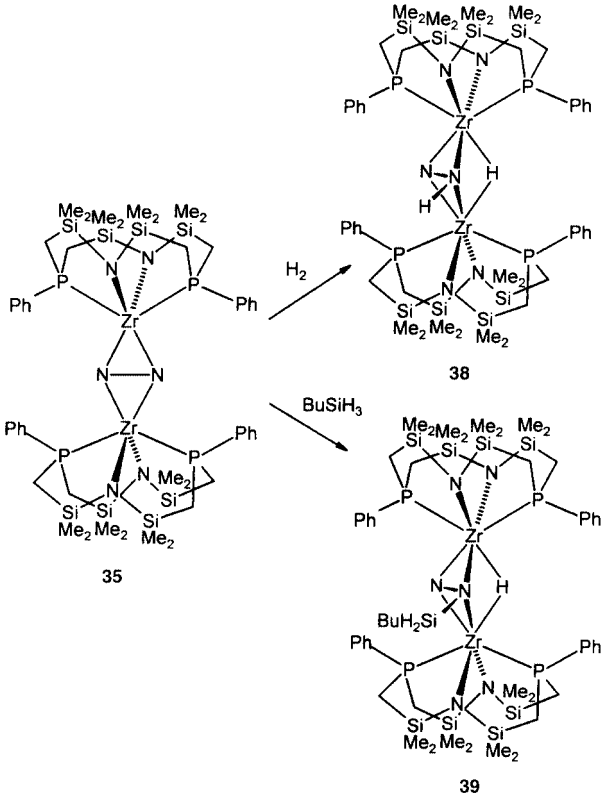
36 **37**

Fig. 14 Different structural types in dinuclear zirconium and tantalum complexes containing bridging N_2 ligands.

only display different N_2 bonding modes but remarkable chemical reactivity.[50–53] The different coordination modes in the zirconium complexes have been explained by the way the monodentate ancillary ligands, Cl^- or Cp^-, influence the set of frontier orbitals available for N_2 binding at the metal centre. In the chloro complex **33** the unavailability of one of the d-orbitals at the zirconium which would normally be involved in an end-on coordination mode favours the side-on coordination observed in the molecular structure of the compound.

The coordination mode of the dinitrogen ligand in the tantalum complex **37** is unprecedented in transition metal chemistry.[53] The compound was obtained by displacement of dihydrogen from the dinuclear tetrahydridotantalum complex [{(PhNSi$Me_2CH_2)_2$PPh}Ta(μ-H)$_2$]$_2$ which is the first time that N_2-binding is observed by substitution of hydrido ligands. This observation may be relevant to a potential catalytic cycle for the reduction of N_2 to NH_3. The second step would then entail N–H formation and addition of further H_2 to regenerate the hydride.

That N–H coupling is indeed feasible in such hydrido N_2-complexes has been shown for compound **35**.[52] Stirring of the dinitrogen complex in hexane under an H_2 atmosphere slowly produced the remarkable dinuclear μ-η^2-N_2H complex **38** (Scheme 5).



35 **38** **39**

Scheme 5 Hydrogenation of the (μ-N_2)Zr_2 complex **35** giving the (HN_2)Zr complex **38** and addition of Bu^nSiH_3 to **35** to give the {(BuH_2Si)N_2}Zr complex **39**.

The molecular structure of **38** was established by NMR spectroscopy in solution and by a single crystal neutron diffraction study for the solid state. An X-ray diffraction study of a closely related complex **39** has been carried out which was obtained by reaction of **35** with Bu_3SiH. This result confirms the previously noted close analogy between H–H and H–Si bonds in metal induced bond activation reactions.[54]

Conclusions and outlook

The amido function offers many possibilities of inclusion within a complex polydentate ligand system and the combination with other types of donor functionalities. This combination of hard, anionic amido functions with a range of neutral donor functions within the same ligand systems has led to the stabilization and isolation of new types of early transition metal complexes. Moreover, this concept has found its way into the systematic design of new olefin polymerization catalysts. Stabilization of the reactive site by additional ligating functions within a polydentate amide may play a role both in the isolated complexes themselves and in reactive intermediates in catalytic cycles.

The development of this area is still at an early stage, and the potential of creating novel types of reactive sites in the complexes of early transition metals is largely untapped. In particular, the combination of hard and soft donor functions appears to lead the way to novel patterns of structure and reactivity. The use of weakly coordination units, such as the CF fragments discussed above may offer an alternative strategy not only to stabilize otherwise highly reactive compounds but also to control the catalytic activity of molecular catalysts. More-

over, it is the combination of both the renewed academic interest in amide chemistry and the prospect of the commercial application of its results which provides the driving force for current and future progress.

Acknowledgements

I thank my coworkers who contributed to this area, in particular, Stefan Friedrich, Harald Memmler, Martin Schubart, Andreas Schneider and Dominique Trösch, for their enthusiasm and dedication. I also would like to acknowledge the fruitful collaborations with the research groups of Mary McPartlin (London), Philip Mountford (Oxford) and Joe Lauher (Stony Brook). Our own work has been supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

ChemComm

A simple one phase preparation of organically capped gold nanocrystals

Mark Green† and Paul O'Brien*‡

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: paul.obrien@man.ac.uk

Received (in Oxford, UK) 14th September 1999, Accepted 9th December 1999

A simple reproducible one-phase preparation of highly monodispersed organically passivated gold nanoparticles is described. The effect of the capping ligand on the particle size is discussed along with the manipulation of the nanoparticles into colloidal crystals and 2D arrays.

Recently, Brust *et al.* reported a simple two phase method for the preparation of high quality thiol passivated gold nanoparticles which were soluble in many organic solvents.[1,2] These nanoparticles have subsequently been used in the preparation of superlattices and electroactive materials.[3,4] Other applications of nanoparticles of gold include biomarkers in TEM experiments,[5] and more recently in single-electron transistors.[6]

One popular method for the preparation of (II/VI) or III/V) semiconductor quantum dots is the use of tri-*n*-octylphosphine oxide (TOPO) as both a reaction medium and passivating ligand.[7,8] Recent developments include the preparation of other compound semiconductors,[9] the use of single-molecular precursors such as dithio- or diseleno-carbamates, and the incorporation of nanoparticles into devices.[10–12] Sun and Murray have recently reported the preparation of cobalt nanoparticles using a similar methodology.[13]

We now report that the reduction of gold(IV) chloride by sodium borohydride in hot TOPO or a mixture of polar Lewis base solvents results in gold nanoparticles.§ The reduction of gold chloride (added as a solution in 4-*tert*-butylpyridine) in TOPO at *ca.* 190 °C resulted in relatively uncontrolled growth to particles with a wide range of shapes and sizes. Fig. 1(a) shows a typical TEM image in which square, triangular and spherical particles ranging in size from 10 to 100 nm in diameter can be seen. The isolated re-suspended nanoparticles were stable in toluene for only a matter of hours. In contrast, growth in a mixture of TOPO and octadecylamine (1 : 0.57 molar ratio) at 190 °C resulted in the controlled growth of spherical nanoparticulate gold particles (8.59 ± 1.09 nm), which have proved stable in toluene for months [Fig. 1(b)].

The morphology of the gold nanoparticle is controlled by various properties of the capping ligands. The Lewis basicity must be sufficient for significant interaction to occur and the bond formed has to be sufficiently labile to allow controlled growth. The length of the alkyl group on the capping ligand further affects the tuning of the size. Longer chain ligands tend to favour slower growth and hence the formation of, relatively, smaller nanoparticles. Hence, a balance must be achieved between the growth rate and ligand stability to facilitate growth of nanoparticle of a uniform size. A similar discussion of the role of organic capping agents in controlling particle size has been presented by Murray *et al.*, in describing processes in the growth of organically passivated cadmium chalcogenides[7] or cobalt nanoparticles.[13] The effect of capping group on particle size is being investigated further.

Evidence for the presence of the capping groups was obtained using IR spectroscopy, mass spectrometry and NMR. IR spectroscopy of the gold nanoparticles capped with octadecylamine and TOPO showed the bands associated with both ligands. There is a weak, broad feature not seen in the free amine spectrum at *ca.* 500 cm^{-1}, possibly a ν(Au–N) stretch.[14] TOPO also binds to the surface gold sites and a feature at *ca.* 1130 cm^{-1} is consistent with the shifted ν(P=O) bond deformation observed in other TOPO capped nanoparticles.[15] It is assumed that both TOPO and octadecylamine bind through the electron rich O or N atoms respectively.

The ^{1}H NMR spectrum of gold nanoparticles passivated with TOPO/octadecylamine displayed resonances associated with

organic ligands anchored to the nanoparticulate surface. Broad singlets at δ 0.9 and between δ 1.2 and 1.5 cannot be assigned as either TOPO or octadecylamine; broadening effects render resonances indistinguishable. The broadening of ^{1}H resonances of nanoparticle capping agents has previously been observed and attributed to either a reduction in rotational freedom at the surface site, or the inhomogeneous distribution of magnetic environments found on the nanocrystalline surface.[16,17] The ^{31}P NMR of capped gold nanoparticles show a single resonance at δ *ca.* 45; free TOPO displays a single resonance at δ 50. The upfield shift of 5 ppm is consistent with the surface metal shielding the phosphorus nuclei. This evidence again infers that the TOPO ligand bonds through the lone pair on the oxygen atom. FAB mass spectrometry of dots prepared in the mixed solvent system revealed the presence of not only TOPO (*m/z* 387) and octadecylamine (*m/z* 270), but also 4-*tert*-butylpyridine (*m/z* 136). It is assumed that only small amounts of 4-*tert*-butylpyridine are attached to the nanoparticle as no evidence for the ligand is found in either the ^{1}H NMR or the IR spectra. Powder X-ray diffraction data for the TOPO/octadecylamine capped dots showed broad peaks for the 111, 220, 200 and 311 planes of fcc gold (Fig. 2). Electronic spectroscopy of TOPO/octadecylamine gold dots showed the well documented plasmon resonance associated with colloidal gold at *ca.* 540 nm (2.29 eV).[18]

Murray *et al.* previously reported the controlled evaporation of solutions of TOPO capped CdSe and organically passivated Co, resulting in the preparation of superlattices and films.[13,19] Samples of as prepared octadecylamine/TOPO capped gold nanoparticles were washed with methanol removing all excess capping ligands and redispersed in the minimum amount of toluene. Aliquots of the toluene solutions were then placed either in a glass flask or on a glass slide and left to dry slowly (over *ca.* 3 days). Optical and electron microscopy revealed the presence of small cubic colloidal crystals with dimensions of the order of micrometers (Fig. 3, inset). XRD experiments on these colloidal crystals are currently in progress.

The as prepared octadecylamine/TOPO capped gold dots were found to spontaneously self assemble when deposited on a copper grid, forming ordered hexagonal close packed two-dimensional lattices (Fig. 3). Spontaneous self assembly has been observed before for highly monodispersed TOPO capped semiconductor nanoparticles.[20] We are at present developing this novel approach in the preparation of nanometric particles of different metals.

We acknowledge Keith Pell (QMW College) for electron microscopy and Jin-Ho Park (IC) for XRD. P. O. B. was Sumitomo/STS Professor of Material Chemistry during the duration of this work.

Notes and references

§ Nanoparticles were prepared using two different solvent systems. (1) In a typical synthesis, 0.07 g (23 mmol) $AuCl_4$ was dissolved in 7 ml 4-*tert*-butylpyridine. The solution was injected into a reaction flask containing 15 g TOPO and 0.0325 g $NaBH_4$ stabilised at 190 °C, left for 30 min, then removed from the heat source. The nanoparticles were isolated by solvent–non-solvent interactions at 60 °C, 30 ml of dry methanol was added leading to a precipitate which was isolated by centrifugation. The precipitate was stable in toluene for *ca.* 10 h.

(2) As above, injecting gold chloride dissolved in 4-*tert*-butylpyridine into a mixture of 10 g octadecylamine, 25 g TOPO and 0.0325 g $NaBH_4$ at 190 °C, with a growth time of 30 min. Upon injection, the reactants turned deep red. The nanoparticles were isolated using methanol as described above, and were found to be indefinitely stable in toluene. Once isolated as a powder, the nanoparticles were washed several times with methanol to remove excess capping agent before analysis.

Controlling oxygen states at a Cu(110) surface: the role of coadsorbed sulfur and temperature

Albert F. Carley, Philip R. Davies, Rhys V. Jones, K. R. Harikumar and M. Wyn Roberts

Department of Chemistry, Cardiff University, P.O. Box 912, Cardiff, UK CF10 3TB. E-mail: robertsmw@cf.ac.uk

Received 23rd August 1999, Accepted 9th December 1999

Chemisorbed oxygen induces a disorder–order phase change in adsorbed sulfur at Cu(110) to give a c(2 × 2) adlayer at 295 K with oxygen present as isolated (2 × 1)-O strings, while warming a disordered oxygen state present at 80 K to 295 K generates a biphasic oxygen adlayer exhibiting both c(6 × 2) and (2 × 1) structures.

It is well established that at 295 K the chemisorbed oxygen adlayer at a Cu(110) surface consists of copper–oxygen chains oriented perpendicular to the copper substrate rows.[1a]

With increasing surface coverage the chains increase in length and coalese to form well ordered close packed islands with a (2 × 1)-O structure. At low oxygen coverages the oxygen chains are short, isolated, mobile and highly reactive to ammonia to form well ordered imide species through an oxydehydrogenation reaction accompanied by desorption of water.[2] By comparison, the oxygen islands are less reactive, with only those oxygen adatoms present at the island peripheries showing comparable dehydrogenation activity.

Here, we establish that a coadsorbate, chemisorbed sulfur, can influence the structure of chemisorbed oxygen states at a Cu(110) surface and how these oxygen states can simultaneously activate a disorder–order transition in the sulfur adlayer. The coadsorbates therefore exhibit cooperative effects which promote within the mixed-adlayer specific structural arrangements of each separate component. We also show that disordered oxygen adatoms present at 80 K are thermally ordered on warming to 295 K to generate a two phase system composed of (2 × 1)-O strings and c(2 × 6)-O structure.

An ultra-high vacuum spectrometer combining facilities for both scanning tunnelling microscopy (STM) and X-ray photoelectron spectroscopy (XPS) was supplied by Omicron Vacuum Physik. The Cu(110) crystal was cleaned by argon ion sputtering (0.6 keV beam energy; *ca.* 10 μA ion current) followed by annealing at 750 K for 30 min. The surface was shown to be clean by XPS and the purity of gases checked mass spectrometrically.

A Cu(110) surface was exposed to hydrogen sulfide at 295 K and the intensity of the S 2p binding energy region monitored by XPS. The signal was centred at 162 eV, indicative of chemisorbed sulfur,[3] and corresponded to a concentration of 2.4 × 10^{14} S adatoms cm^{-2}. The STM image [Fig. 1(a)] showed no evidence for chemisorbed sulfur although the copper atoms of the Cu(110) surface are resolved. This is consistent with a high surface mobility for the sulfur adatoms, most likely occurring along the $\langle 1\bar{1}0 \rangle$ directed troughs where the activation energy for surface diffusion is least.

However, when the disordered sulfur adlayer corresponding to a surface coverage $\theta \cong 0.28$ (σ_s = 3.0 × 10^{14} cm^{-2}) was exposed to oxygen at 295 K, ordered structures were immediately observed in the STM images [Fig. 1(b) and (c)]. A disorder–order phase transition with increasing sulfur coverage

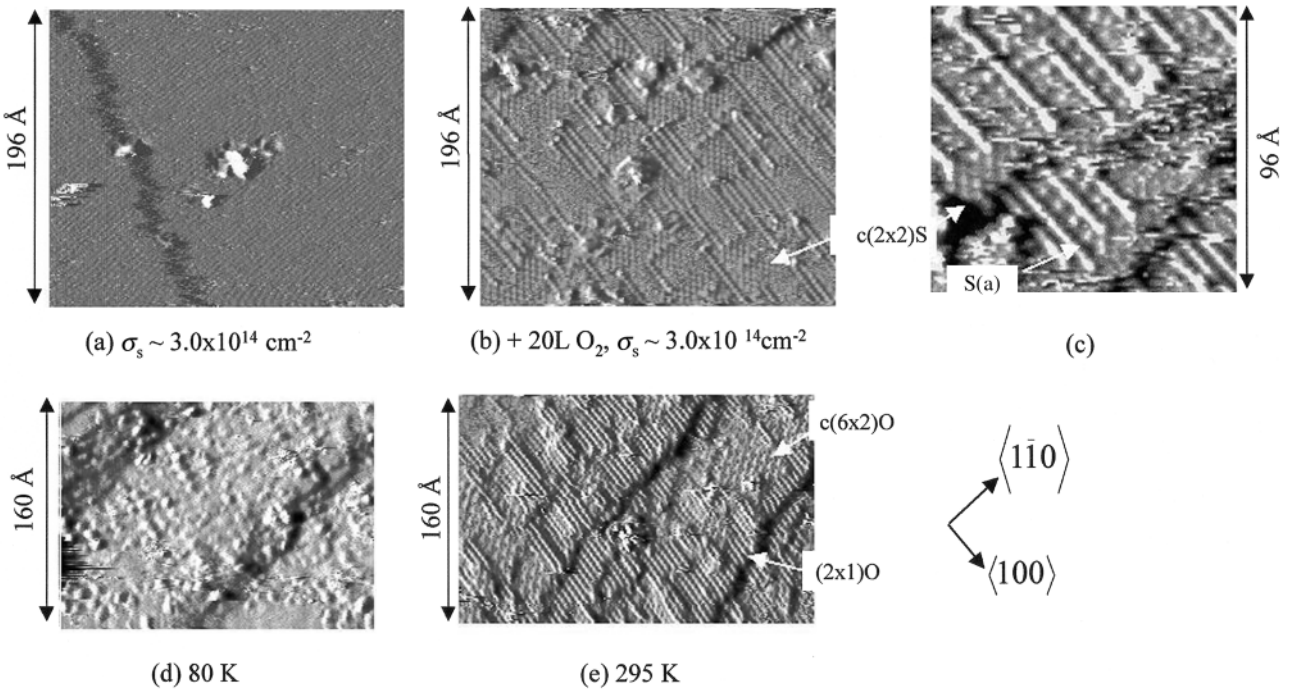

Fig. 1 STM images of (a) disordered chemisorbed mobile sulfur adatoms (σ_s = 3 × 10^{14} cm^{-2}; θ = 0.28) at a Cu(110) surface at 295 K, note the resolved copper atoms in the $\langle 1\bar{1}0 \rangle$ direction; (b) and (c) ordered structures of (2 × 1)-O and c(2 × 2)-S formed by an exposure of (a) to 20 L oxygen at 295 K [1 L (Langmuir) ≡ 10^{-6} Torr s]; chemisorbed sulfur adatoms separating (2 × 1)-O strings are visible in image (c); (d) disordered oxygen states present at a Cu(110) surface at 80 K; (e) ordered (2 × 1)-O and (6 × 2)-O states present after warming (d) to 295 K. The tunnelling conditions were typically [image (b)]: sample bias −0.38 V, feedback current 2.5 nA; loop gain 0.19%.

has been observed[1b] previously for Re(0001) but the role of a second adsorbate, in the present case oxygen, has not been reported. There are two distinct structures present at the Cu(110) surface, c(2 × 2) structures due to chemisorbed sulfur and (2 × 1) string or chain structures characteristic of chemisorbed oxygen. The presence of chemisorbed oxygen has clearly induced a disorder–order phase transition in the previously mobile disordered sulfur adlayer but with the simultaneous formation of oxygen strings well separated from each other (10 Å or more). The latter are distinctly different from the close packed oxygen island structures characteristic of the chemisorbed oxygen adlayer and more akin to the isolated oxygen chains present at Cu(110) at low oxygen coverage. In view of having established[2] that isolated oxygen chains were highly reactive in oxydehydrogenation reactions at Cu(110), we exposed this mixed sulfur–oxygen adlayer to ammonia at 295 K and confirmed the formation of imide species.

We, therefore, have an unusual phenomenon where during coadsorption two physiochemical processes occur: first chemisorbed oxygen inducing a phase change in the disordered S-adlayer to generate an ordered c(2 × 2)-S structure and second the presence of chemisorbed sulfur adatoms acting as a structural promoter of the isolated (2 × 1)-O strings. In some cases we have shown that the oxygen strings are separated from each other by just a single row of chemisorbed sulfur adatoms [Fig. 1(c)], in other cases the strings are well separated and present on terraces occupied predominantly by c(2 × 2) S-structures [Fig. 1(b)].

Although oxygen interaction at 295 K results in a well ordered (2 × 1)-O structure, if the Cu(110) is first exposed to oxygen at 80 K and the adlayer warmed to 295 K, the STM image indicates the presence of a biphasic oxygen adlayer [Fig. 1(d) and (e)]. In addition to the (2 × 1) structure there is also a (6 × 2)-O structure.

A c(6 × 2)-O structure has previously been reported by Wintterlin and Behm[1a] to exist at a Cu(110) surface when a (2 × 1)-O structure is exposed to 'much higher amounts of oxygen at $T \geqslant 300$ K'. Our STM results indicate that the same structure can develop through warming the chemisorbed adlayer at 80 K to room temperature, which offers a possible explanation for work function studies reported[4] some 30 years ago where the surface potential (change in work function) of chemisorbed oxygen on copper and nickel surfaces at 295 K differed by as much as 1 eV depending on whether or not the oxygen was chemisorbed first at 80 K. An earlier low energy electron diffraction study[5] also drew attention to the role of temperature in controlling the formation of the c(6 × 2) structure; Fig. 1(e) however provides atom-resolved evidence for the co-existence of the two phases at 295 K and the disorder–order transition that occurs between 80 and 295 K.

Since it is now well established that the chemical reactivity of oxygen at a Cu(110) surface is dependent on its structural state (isolated oxygen adatoms, isolated oxygen strings or close packed island structures), the ability to control the structural nature of the chemisorbed oxygen state through coadsorbed sulfur offers a novel approach to controlling selectivity in oxygenation catalysis. Sulfur, although more usually considered to be a surface 'poison', can also be a catalytic promoter with lateral interactions controlling surface structural states of oxygen.

We are grateful to the EPSRC for their support.

Novel dual-host approach in ion pair extraction: a simple tripodal nitrate host facilitates $CsNO_3$ transfer to 1,2-dichloroethane by a large crown ether

Konstantinos Kavallieratos,[a] Richard A. Sachleben,[a] Gary J. Van Berkel[b] and Bruce A. Moyer*[a]

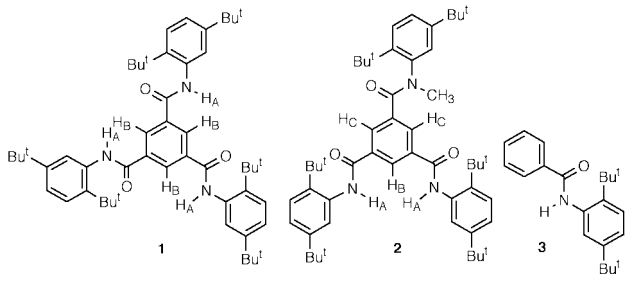
[b] *Organic and Biological Mass Spectrometry Group, Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, PO Box 2008, Oak Ridge, TN 37831-6365, USA*

Received (in Columbia, MO) 27th October 1999, Accepted 29th November 1999

The readily available benzene-1,3,5-tricarboxamide 1 enhances $CsNO_3$ extraction by tetrabenzo-24-crown-8 *via* hydrogen bonding to the nitrate anion, as demonstrated by NMR and electrospray ionization mass spectrometry.

Considerable effort has been expended toward developing host molecules for recognition of cations[1] and, more recently, anions.[2] Surprisingly little attention, though, has been given to recognition of targeted ion pairs,[3] despite potential applications.[4] Historically, ion-pair extraction of alkali and alkaline earth metal salts[5] has tended to be weak, owing to unfavorable dehydration–resolvation energetics for co-extraction of the common inorganic anions.[6,7] This effect simply reflects the normal electrostatic 'bias'[7b] disfavoring small, charge-dense anions (Hofmeister series).[8] Although various successful approaches have been developed to circumvent this 'anion problem',[5a,9] it was our thought that the combination of an anion host with a cation host would represent a singular advance by making anion transfer to the organic phase both more favorable and selective.[10] The idea was shown to work under some conditions in supported liquid membranes,[11] whereas we sought simpler and more synthetically accessible anion receptors as the key to widespread application. Nitrate represents an ion of particular significance in separation chemistry,[4] and certain of its salts, especially $CsNO_3$, are important components of nuclear waste.[4a] However, few designed nitrate receptors have been reported,[12] and neutral lipophilic nitrate hosts are rare.[12a,b] We now report that crown ether extraction of $CsNO_3$ is increased by a simple tripodal host that directly binds nitrate ion through amide N–H hydrogen bonds.

The anion host **1** and controls **2** and **3** were synthesized by standard methods from the corresponding anilines and acid



chlorides.[13] The chosen benzene-1,3,5-tricarboxamide skeleton combines the desired C_3 symmetry environment for recognition of the nitrate anion with synthetic ease and flexibility. Amides and ureas have been employed in anion host–guest chemistry.[2,14–17] Moreover, the potential for variation of the aniline moiety allows 'tuning' of the electronic and steric contributions to the binding, as well as solubility and hydrophobicity. Tetrabenzo-24-crown-8[18] was used as the cation host because it effectively complexes the caesium cation[19] in 1,2-dichloroethane, while keeping the encapsulated Cs^+ cation and the NO_3^- anion fully dissociated.[20]

The distribution results[21] (Fig. 1) show that amides **1** and **2** (but not monoamide **3**) enhance the extraction of $CsNO_3$ by tetrabenzo-24-crown-8. At 10 mM, tripodal amide **1** enhances the extraction by a factor of 1.9 ($D_{Cs} = 6.3 \times 10^{-3}$ for **1** *vs.* 3.3×10^{-3} for the crown-only experiment), whereas the same concentration of bipodal amide **2** enhances Cs extraction by a factor of 1.3 ($D_{Cs} = 4.2 \times 10^{-3}$). The enhancement is dependent on the amide concentration, as expected (Fig. 1). No extraction was detected with the amides alone ($D_{Cs} < 2 \times 10^{-5}$).

The nitrate binding affinities of **1** and **2** were determined by ^{1}H NMR titrations with $(Bu_4N)NO_3$ in 1,2-dichloroethane-d_4. Non-linear regression analysis[22] of the binding isotherms[23] obtained from the downfield chemical shift changes for the N–H amide (H_A) resonances ($\Delta\delta$ N–H), as well as for the *ortho* C–H aromatic (H_B) resonances ($\Delta\delta$ C–H), gave 1:1 association constants (K_a) of 250 M^{-1} for the formation of **1**·NO_3^- *vs.* 23 M^{-1} for **2**·NO_3^- (Table 1). For the diamide **2**, both H_A and H_B gave significant downfield shift changes, while the H_C chemical shift remained virtually constant. This is indicative of nitrate complexation by two hydrogen bonds.[16] In contrast, **1**·NO_3^- exhibited a single downfield-shifted resonance for H_B, suggest-

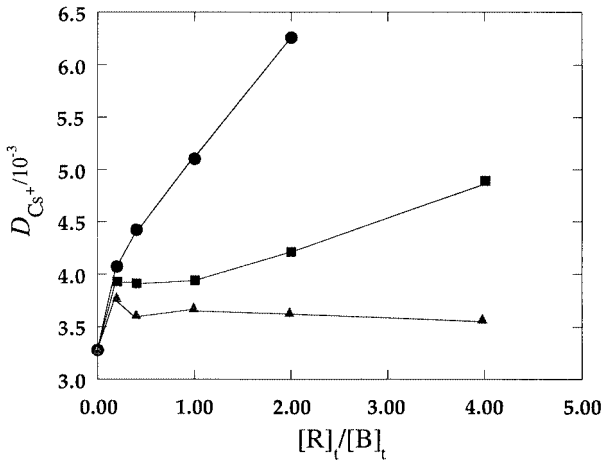


Fig. 1 Plot of D_{Cs} *vs.* $[R]_t/[B]_t$ at 25 °C, where $[R]_t$ is the total amide (R = **1**–**3**) concentration and $[B]_t$ is the total crown concentration (5 mM): (●) **1**, (■) **2** and (▲) **3**. Errors are estimated to be < 5%.

Table 1 Chemical shift changes, association constants, and ΔG^o values at 18.1 °C for **1**·NO_3^- and **2**·NO_3^- formation

Compound	δ_H(N–H)	δ_H(2-C–H)	K_a/M^{-1}	ΔG^o/kJ mol^{-1}
1	8.01	8.61		
1·[NO_3^-]	9.32	8.78	250[a]	−13.4
2	7.58	8.22		
2·[NO_3^-]	9.54	8.75	23[a]	−7.5

[a] Errors are estimated to be < 5%.

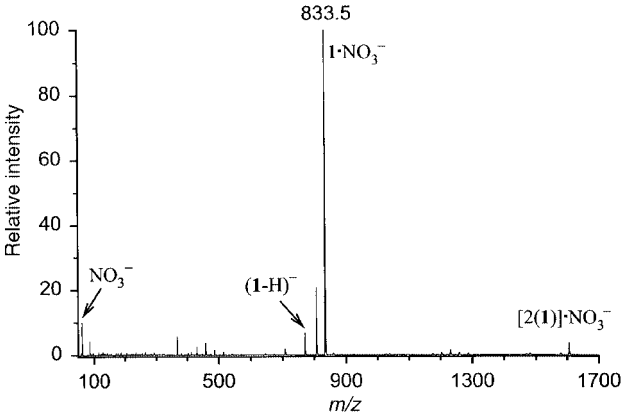

Fig. 2 Negative ion electrospray ionization mass spectrum for **1**·NO_3^- in extraction solvent. The peak at *m/z* 806.5 corresponds to **1**·Cl^- (ref. 25). The results were reproduced in solutions of **1** and $(Bu_4N)NO_3$.

ing participation of all three N–H groups, whether by pairs in fast equilibrium or in concert.

Negative ion mode electrospray ionization mass spectrometry[24] confirms the ^{1}H NMR conclusion of a 1:1 **1**·NO_3^- complexation stoichiometry (*m/z* = 833.5; Fig. 2). Receptor **2** also gave a peak corresponding to **2**·NO_3^-, but with a lower intensity. No evidence for **3**·NO_3^- was observed.

Based on these observations, and taking into consideration the ten-fold higher K_a for **1**·NO_3^- *vs.* **2**·NO_3^-, which cannot be attributed solely to the statistical factor (3), we suggest that a contribution of the third amide group in **1**·NO_3^- is primarily responsible for the higher extraction enhancement for **1** *vs.* **2**. The ^{1}H NMR association constants would ideally imply extraction enhancements of 3.5 and 1.2, respectively, which are consistent with the actual values of 1.9 and 1.3.[26]

In conclusion, the present results demonstrate the viability of employing two simple host molecules for transporting a selected salt *vs.* targeting only a single ion. The extraction enhancement obtained sets the ground for further research into using different hosts and target guest systems, as well as in elucidating aspects of speciation, selectivity, and structure of the supramolecular complexes involved.

We thank Peter V. Bonnesen, Tamara J. Haverlock, Jeffrey C. Bryan and Professor Robert H. Crabtree (Yale) for experimental assistance, information and useful suggestions. This research was sponsored by the Division of Chemical Sciences, Office of Basic Energy Sciences, U.S. Department of Energy, under contract number DE-AC05-96OR22464 with Oak Ridge National Laboratory, managed by Lockheed Martin Energy Research Corp. ES-MS instrumentation was provided through a cooperative research and development agreement with Perkin-Elmer Sciex Instruments (CRADA No. ORNL 96-0458). The participation of K. K. was made possible through an appointment to the ORNL Postgraduate Program, administered by ORAU.

Can α-sultone exist as a chemical species? First experimental implication for intermediacy of α-sultone

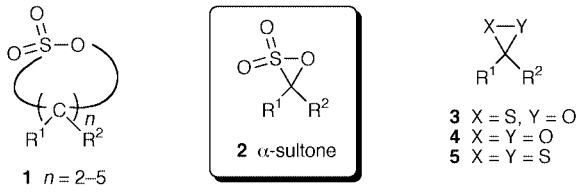
Yoshiki Morimoto,* Hajime Kurihara and Takamasa Kinoshita

Department of Chemistry, Graduate School of Science, Osaka City University, Sumiyoshiku, Osaka 558-8585, Japan. E-mail: morimoto@sci.osaka-cu.ac.jp

Received (in Cambridge, UK) 17th November 1999, Accepted 15th December 1999

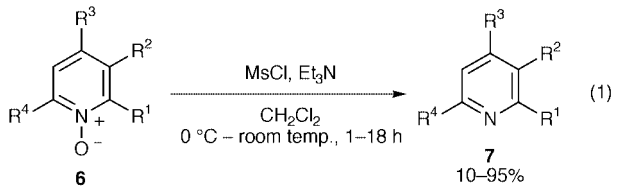
The treatment of 2,4,6-trimethylpyridine *N*-oxide 8 with $BnSO_2Cl$ and Et_3N in the presence of various olefins afforded unexpected γ-sultones 10 along with 2,4,6-trimethylpyridine 9, *via* the possible generation and/or intermediacy of an α-sultone 2 as a new reactive intermediate.

Sultones **1** are the internal esters of hydroxy sulfonic acids and



are the sulfur analogs of lactones. Since the term 'sultone' was first introduced into the literature by Erdmann in 1888,[1] there have been many new developments in sultone chemistry,[2] including industrial applications, biological properties and the current mechanistic research into the role of β-sultones in olefin sulfonation.[3,4] However, most of the sultones mentioned above have been restricted to four- to seven-membered rings. Can the α-sultone **2** exist as a chemical species? To the best of our knowledge, the description of an α-sultone has never been reported in the literature. On the other hand, S- and/or O-containing three-membered ring compounds such as **3–5** have attracted recent interest as labile reactive intermediates in organic chemistry.[5] From the viewpoints of labile reactive intermediates, the chemistry of small rings containing two heteroatoms and organosulfur chemistry as well as sultone chemistry, the question of whether α-sultone **2** can exist as a chemical species or not is a very stimulating and interesting subject in organic chemistry. Here we suggest the possibility of the generation and/or intermediacy of α-sultones as new reactive intermediates for the first time.

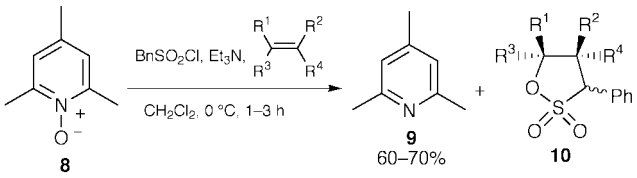
The reason why we suspected that the α-sultone might be generated as a reactive intermediate originated from an unexpected phenomenon. In the course of our recent synthetic studies on macrocyclic marine alkaloids, halicalmines A and B,[6] it was determined that an excess of MsCl resulted in the deoxygenation of pyridine *N*-oxides **6** under standard mesylation conditions (MsCl, Et_3N, CH_2Cl_2) without chlorination of the pyridine nucleus [eqn. (1)].[7] The problem is the reaction



mechanism of these unusual deoxygenations. After many unsuccessful experiments, products, which are very significant for deducing the reaction mechanism, have been trapped. The treatment of 2,4,6-trimethylpyridine *N*-oxide **8** with 7 equiv. of $BnSO_2Cl$ and 9 equiv. of Et_3N in the presence of 30 equiv. of 2,3-dimethylbut-2-ene afforded γ-sultone **10** ($R^1 = R^2 = R^3 = R^4 = Me$) in 21% yield as an isolable and identifiable product along with deoxygenated 2,4,6-trimethylpyridine **9** (entry 1 in Table 1).† How can the production of γ-sultone **10** be explained?

Possible reaction pathways leading to the γ-sultone **10** are depicted in Scheme 1. The generation of sulfenes by treating

Table 1 Production of γ-sultones **10** in the presence of several olefins



Entry	Olefin	Yield of **10**[a] (%)	α-Ph:β-Ph
1	$R^1 = R^2 = R^3 = R^4 = Me$	21	—
2	$R^1 = R^2 = R^3 = Me$, $R^4 = H$	26	60:40[b]
3	$R^1 = R^2 = Me$, $R^3 = R^4 = H$	36	35:65[b]
4	$R^1 = R^2 = (CH_2)_6$, $R^3 = R^4 = H$	40	45:55[c]

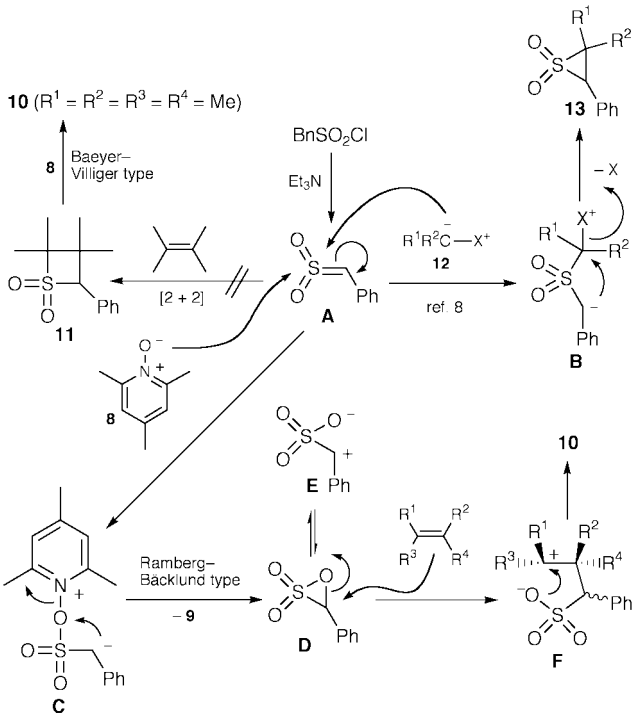
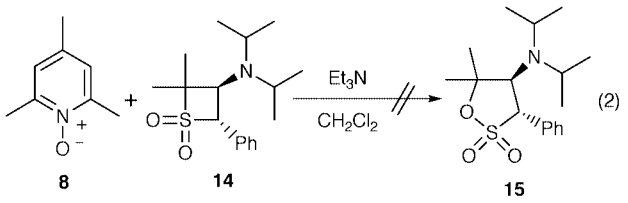


Scheme 1

alkanesulfonyl chloride derivatives possessing an α-hydrogen with triethylamine is a well-established process in sulfene chemistry.[8] The formation of thietane 1,1-dioxide **11**[9] by [2 + 2] cycloaddition between the sulfene intermediate **A** and 2,3-dimethylbut-2-ene and the subsequent Baeyer–Villiger type oxidation of **11** with *N*-oxide **8** may be considered as one possibility. This reaction pathway, however, appears to be ruled out, because the thietane 1,1-dioxide **11** could not be produced in the reaction of $BnSO_2Cl$ and Et_3N with 2,3-dimethylbut-2-ene in the absence of the *N*-oxide **8**. Furthermore, treatment of thietane 1,1-dioxide **14**‡ with *N*-oxide **8** in the presence of Et_3N in CH_2Cl_2 did not give γ-sultone **15**, but resulted in quantitative recoveries of **8** and **14** [eqn. (2)].



8 **14** **15** (2)

On the other hand, it is also well known that the reaction of sulfenes with diazoalkanes (X = N_2) and phosphonium (X = PPh_3), sulfonium (X = SR^3R^4) and sulfoxonium (X = SOR^3R^4) ylides **12** provides episulfones **13** *via* elimination of the neutral leaving group X from the intermediary adduct **B**.[8] Therefore, another possible reaction pathway closely related to this episulfone route may be more plausible to explain the production of γ-sultone **10**. The similar attack of the *N*-oxide **8** on the sulfur atom in the sulfene intermediate **A** may generate α-sultone **D** through the ring-closing reaction[10] such as the Ramberg–Bäcklund type[11] in the adduct **C** together with liberation of 2,4,6-trimethylpyridine **9**. The α-sultone **D** is postulated to be highly labile for the following reasons: (i) an intrinsic ring strain in the three-membered rings; (ii) a large polarization of the C–O bond which is characteristic of sulfonates and makes them good leaving groups; and (iii) the presence of carbon geminally disubstituted by two kinds of heteroatoms (oxygen and sulfur). Therefore, the alternative zwitterionic structure **E**, which is produced by spontaneous cleavage of the highly strained and polarized C–O bond, may then predominate over the α-sultone structure **D**. Finally, the interaction of α-sultone **D** or zwitterion **E** with 2,3-dimethylbut-2-ene could lead to the γ-sultone **10** ($R^1 = R^2 = R^3 = R^4$ = Me) by way of the cationic intermediate **F**.

The γ-sultones **10** were also obtained as stereoisomeric mixtures§ in the presence of olefins other than 2,3-dimethylbut-2-ene (entries 2–4). In the case of 2-methylbut-2-ene, the observation of only one regioisomeric γ-sultone **10** ($R^1 = R^2 = R^3$ = Me, R^4 = H) supports the intervention of the cationic intermediate **F** (tertiary *vs.* secondary). In entry 3, the fact that the stereochemistry of *cis*-but-2-ene was retained in the γ-sultone **10** ($R^1 = R^2$ = Me, $R^3 = R^4$ = H) may imply that in the carbocation **F** the ring-closure is much faster than the C–C single bond rotation. It is also of interest to note that yields of γ-sultones **10** reflect the reactivities (strain and steric hindrance) of the olefins examined.

In conclusion, we have proposed the possible generation and/or intermediacy of α-sultone **2** as a new chemical species for the first time in organic chemistry. Clarification of the detailed reaction mechanism for the production of γ-sultones **10** and determination of direct evidence for the α-sultone are in progress.

Resolution of racemic Sb-chiral stibindoles using an optically active *ortho*-palladated benzylamine derivative, *via* their diastereomeric complexes

Jyoji Kurita,*[a] Fujiko Usuda,[a] Shuji Yasuike,[a] Takashi Tsuchiya,[a] Yoshisuke Tsuda,[b] Fumiyuki Kiuchi[b] and Shinzo Hosoi[b]

[a] *Faculty of Pharmaceutical Sciences, Hokuriku University, Kanazawa 920-1181, Japan. E-mail: j-kurita@hokuriku-u.ac.jp*
[b] *Faculty of Pharmaceutical Sciences, Kanazawa University, Kanazawa 920-1155, Japan*

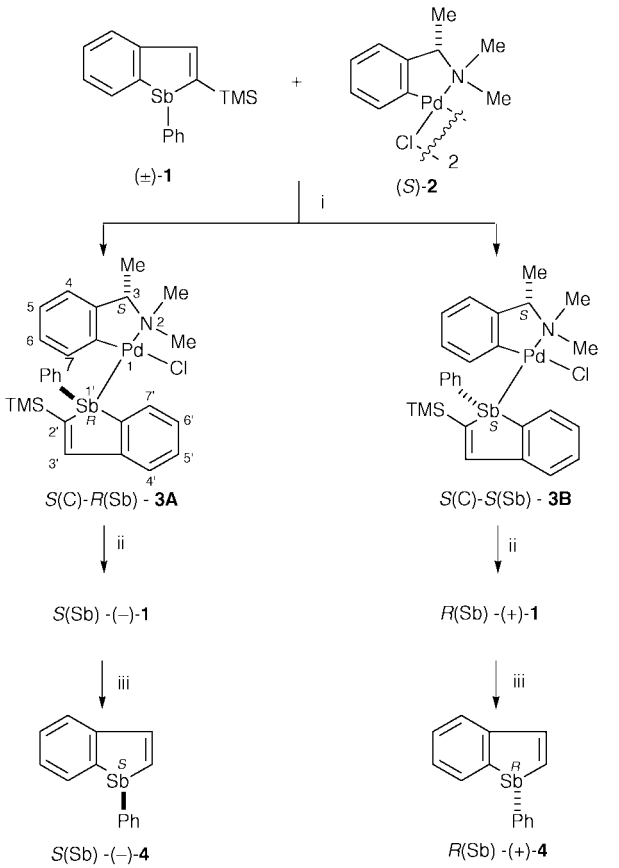
Received (in Cambridge, UK) 22nd November 1999, Accepted 17th December 1999

Resolution of racemic Sb-chiral (±)-1-phenyl-2-trimethylsilylstibindole 1 has been achieved by the separation of a mixture of the diastereomeric palladium(II) complexes 3A and 3B derived from the reaction of (±)-1 with di-μ-chlorobis{(*S*)-2-[1-(dimethylamino)ethyl]phenyl-*C*,*N*}dipalladium(II) 2, and optically pure 1-phenylstibindoles (-)-4 and (+)-4 have also been obtained from resolved (−)-1 and (+)-1, respectively.

The asymmetric synthesis and resolution of optically active trivalent phosphines and arsines have been extensively studied because of their use as chiral auxiliaries for a wide range of enantioselective transition-metal-catalyzed processes, such as hydrogenation of olefins, ketones and imines,[1,2] hydrosilylation of ketones, coupling reactions of olefins, and allylic alkylations.[2,3] For the preparation of optically active P-chiral phosphines and As-chiral arsines, a variety of chiral organometallic reagents, *e.g. ortho*-palladated α-arylalkylamines,[4–7] π-pinenyl nickel halides,[8] bisphosphine platinum complexes[9] and iron cationic complexes,[10] have been used as efficient resolving reagents. However, as far as optically active antimony(III) compounds are concerned, only a few limited examples of Sb-chiral stibafluorenes and triarylstibines bearing a hydroxycarbonyl or an amino group have been reported;[11] these functional groups are essential for resolution. Here, we report on an efficient and stereoselective resolution of the racemic Sb-chiral (±)-1-phenyl-2-trimethylsilylstibindole **1**,[12] *via* the separation of the diastereomeric stibindole–palladium complexes **3A** and **3B**, formed by the reaction of (±)-**1** with an optically active *ortho*-palladated benzylamine derivative **2**, and on the molecular structures of the complexes **3A** and **3B**. Optically pure Sb-chiral 1-phenylstibindole (−)-**4** and (+)-**4** are also obtained from resolved (−)-**1** and (+)-**1**, respectively. The present results are the first examples of resolution of neutral Sb-chiral compounds.

Treatment of racemic **1** with 0.5 equiv. of di-μ-chlorobis{(*S*)-2-[1-(dimethylamino)ethyl]phenyl-*C*,*N*}dipalladium(II) **2** (Scheme 1) resulted in coordination of the antimony atom to the palladium atom to give a 1 : 1 mixture of the diastereomeric Pd-complexes **3A** and **3B** quantitatively, which could be separated by silica gel column chromatography; **3A**: mp 158−159 °C, $[\alpha]_D^{23}$ −16.2 (*c* 0.6, acetone) and **3B**: mp 161–162 °C, $[\alpha]_D^{23}$ −79.7 (*c* 0.6, acetone).† Treatment of **3A** and **3B** with triphenylphosphine resulted in decomplexation to afford optically pure (−)-**1** and (+)-**1** {mp 73–75 °C; $[\alpha]_D^{23}$ ±415 (*c* 0.6 MeOH)}, respectively, in quantitative yields. The optically active (−)-**1** and (+)-**1** revert back to **3A** and **3B** on treatment with (*S*)-**2**. The trimethylsilyl group in (−)-**1** and (+)-**1** can be readily removed by treatment with TBAF in water-containing THF to give the corresponding optically pure 1-phenylstibindoles (−)-**4** and (+)-**4** {mp 49–50 °C; $[\alpha]_D^{23}$ ±726 (*c* 0.5 MeOH)}, without any loss of optical purity.‡ The racemic stibindole **4**[12] having no trimethylsilyl group also reacts with (*S*)-**2**, however, the resulting complexes are relatively unstable and attempts at separation were unsuccessful. Unlike stibafluorenes which have been reported to racemize in solution,[11a,b] the optically active stibindoles **1** and **4** possess high optical stability and did not undergo racemization even when heated at 80 °C for 8 h in benzene, although they gradually decomposed at that temperature. Furthermore, the rotations of optically active **1** and **4** were unchanged in either an acidic (10% AcOH–MeOH) or a basic (10% Et_3N–MeOH) solution over 48 h at room temperature.

When the dimeric palladium reagent (*S*)-**2** was treated with 8 equiv. of (±)-**1** and the resulting residue was recrystallized from benzene–hexane, the pure complex **3B** was obtained in 95% yield (calculated from (*S*)-**2**) without chromatographic separation. However, the reaction of (*S*)-**2** with 4 mol equiv. of (±)-**1** gave a 1 : 2.4 mixture of **3A** and **3B** in 94% yield. These results indicate preferential stereoselective formation of **3B** over **3A**. The use of a naphthalene-substituted palladium complex, di-μ-chlorobis{(*R*)-dimethyl-[1-(1-naphthyl)ethyl]-aminato-*C*^{2},*N*}dipalladium(II)[5,7] which has been reported to be a superior



Scheme 1 *Reagents and conditions*: i, dichloromethane, room temp., 5 min, quantitative; ii, PPh_3 (1.05 equiv.), dichloromethane, room temp., 30 min, quantitative; iii, TBAF/5% H_2O–THF, 60–65 °C, 3 h, 92–94%.

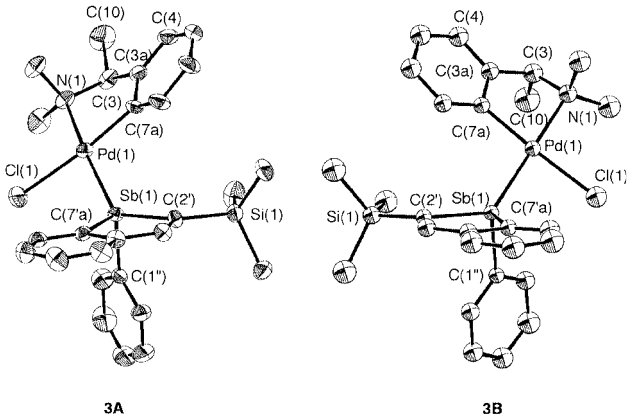


Fig. 1 Molecular structures of **3A** and **3B**. All hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°). For **3A**: Pd(1)–Sb(1) 2.4926(8), Pd(1)–C(7a) 1.984(8), Pd(1)–N(1) 2.144(7), Pd(1)–Cl(1) 2.407(3), Sb(1)–Pd(1)–N(1) 170.2(2), Cl(1)–Pd(1)–C(7a) 171.0(3), C(10)–C(3)–C(3a)–C(4) 17(1), plane N(1)–Pd(1)–C(7a)–plane Sb(1)–Pd(1)–Cl(1) 14.12. For **3B**: Pd(1)–Sb(1) 2.4942(6), Pd(1)–C(7a) 2.003(6), Pd(1)–N(1) 2.161(6), Pd(1)–Cl(1) 2.408(2), Sb(1)–Pd(1)–N(1) 178.1(2), Cl(1)–Pd(1)–C(7a) 176.2(2), C(10)–C(3)–C(3a)–C(4) 91(1), plane N(1)–Pd(1)–C(7a)–plane Sb(1)–Pd(1)–Cl(1) 4.099.

chiral reagent relative to **2** for the resolution of trivalent phosphines and arsines, was found to give inferior results for the resolution of (±)-**1**.

The solid-state molecular structures of **3A** and **3B**, including absolute configuration were determined by single crystal X-ray analyses (Fig. 1),§ which reveals that in **3A** and **3B**, the coordinated antimony ligand is situated *trans* to the dimethylamine moiety as in the related phosphine[4,5] and arsine[6] complexes. Also apparent is that the antimony atom in **3A** and **3B** has *S*- and *R*-configuration, respectively, and no noticeable difference in the Pd–Sb distance is seen between **3A** (2.493 Å) and **3B** (2.494 Å). One of the most conspicuous differences in molecular structure between **3A** and **3B** is the geometry of their benzylic methyl groups. The methyl groups are located in a pseudo-equatorial orientation for **3A** and are pseudo-axial for **3B**. It is known that both equatorial and axial conformations of the benzylic methyl group are accessible in phosphine–palladium complexes of phenyl ethylamino derivatives.[7b]

Despite a detailed inspection of the X-ray structures of **3A** and **3B**, no significant intracomplex H···H or H···C interactions between the stibindole and the palladacycle moiety were observed. It has recently been suggested that square planarity around the palladium atom is important when considering the conformational stability of bidentate phosphine–palladium complexes, since deviation from square planarity around palladium will occur to prevent hard atomic contacts between the ligands and palladacycles.[7b] In both diastereomers **3A** and **3B**, the four substituents around the palladium atom lead to a distorted square planar geometry and significant differences in the bond angles Sb(1)–Pd(1)–N(1) and Cl(1)–Pd(1)–C(7a) between **3A** (170–171°) and **3B** (176–178°) are observed. These differences give rise to a difference in the dihedral angles between the planes N(1)–Pd(1)–C(7a) and Sb(1)–Pd(1)–Cl(1), *i.e.* 14.1° for **3A** and 4.1° for **3B**. These results indicate that **3A** is more distorted than **3B**. Consequently, the more sterically stable **3B** forms preferentially to the less stable **3A** in the present reaction.

Notes and references

† For a typical procedure; a mixture of (±)-**1** and (*S*)-**2** in dichloromethane was stirred for 5 min at room temperature. After removal of the solvent *in vacuo*, the resulting residue was separated by chromatography on silica gel [dichloromethane–hexane–diethyl ether (10 : 10 : 1)], followed by recrystallization from benzene–hexane (1 : 8) to give **3A** and **3B**. *Selected* ^{1}*H NMR data* (400 MHz, $CDCl_3$, *J*/Hz): **3A**, δ 0.13 (9H, s, TMS), 1.66 (3H, d, *J* 6.6, CHCH_3), 2.75 and 2.99 (3H, s, NCH_3), 4.03 (1H, q, *J* 6.6, C*H*CH$_3$), 6.61 (1H, m, 5-H), 6.85 (1H, br d, *J* 7.3, 7-H), 6.9–7.0 (2H, m, 4- and 6-H), 7.25–7.7 (8H, 4′-, 5′-, 6′- and Ph-H), 7.82 (1H, br d, *J* 7.3, 7′-H), 8.00 (1H, s, 3′-H). **3B**, δ 0.08 (9H, s, TMS), 1.76 (3H, d, *J* 6.6, CHCH_3), 2.84 and 2.89 (3H, s, NCH_3), 3.81 (1H, q, *J* 6.6, C*H*CH$_3$), 6.63 (1H, m, 5-H), 6.86 (1H, br d, *J* 7.3, 7-H), 6.9–7.0 (2H, m, 4- and 6-H), 7.2–7.7 (8H, 4′-, 5′-, 6′- and Ph-H), 7.81 (1H, br d, *J* 7.3, 7′-H), 8.00 (1H, s, 3′-H).

‡ The optical purities of (−)-**4** and (+)-**4** could be determined by comparison of the ^{1}H NMR signals due to the 3′- and 7′-protons of their Pd complexes with those of (*S*)-**2**. *Selected* ^{1}*H NMR data* (400 MHz, $CDCl_3$, *J*/Hz): (−)-**4**+(*S*)-**2**, δ 1.67 (3H, d, *J* 6.6, CHCH_3), 2.79 and 2.98 (3H, s, NCH_3), 3.94 (1H, q, *J* 6.6, C*H*CH$_3$), 6.80 (1H, m, 5-H), 6.95–7.05 (2H, m, 4- and 6-H), 7.16 (1H, br d, *J* 7.7, 7-H), 7.25–7.75 (9H, 2′-, 4′-, 5′-, 6′- and Ph-H), 7.79 (1H, d, *J* 8.8, 3′-H), 8.01 (1H, br d, *J* 7.3, 7′-H). (+)-**4**+(*S*)-**2**, δ 1.72 (3H, d, *J* 6.6, CHCH_3), 2.82 and 3.93 (each 3H, each s, NCH_3), 3.90 (1H, q, *J* 6.6, C*H*CH$_3$), 6.81 (1H, m, 5-H), 6.95–7.05 (2H, m, 4- and 6-H), 7.18 (1H, br d, *J* 7.7, 7-H), 7.25–7.7 (9H, 2′-, 4′-, 5′-, 6′- and Ph-H), 7.82 (1H, d, *J* 8.8, 3′-H), 7.97 (1H, br d, *J* 7.3, 7′-H).

§ *Crystal data* for **3A**{**3B** where different}: $C_{27}H_{33}ClNPdSbSi$, *M* = 663.25, *a* = 11.679(2) {11.738(3)}, *b* = 20.597(3) {20.626(2)}, *c* = 11.631(1) {11.494(2)} Å, *V* = 2797.8(7) {2782.6(7)} Å^3, *T* = 296 {298} K, space group $P2_12_12_1$ (no. 19), *Z* = 4, μ(Mo-Kα) = 17.59 {17.70} cm^{-1}, 3641 {3608} reflections measured (Rigaku AFC5R diffractometer), 3365 {3151} reflections [$I > 3\sigma(I)$] were used in all calculations, *R* = 0.049 {0.028}, R_w = 0.060 {0.046}. The structures of **3A** and **3B** were solved by direct methods and all of the non-hydrogen atoms were refined anisotropically using full-matrix least squares based on F^2. The absolute configurations of the antimony atoms in **3A** and **3B** were determined by comparison with the known configuration (*S*) of the benzylic methine moiety of the palladium reagent (*S*)-**2**, used as a resolving agent. Selective oxygen capture to give a unique mixed-anion lithium aluminate: the synthesis and solid-state structure of {[PhC(O)N(Me)Al(Me)(Bu^t)OMe]Li·[PhC(O)N(Me)Al(Me)(OBu^t)OMe]Li}$_2$

Robert P. Davies, David J. Linton, Ronald Snaith† and Andrew E. H. Wheatley*

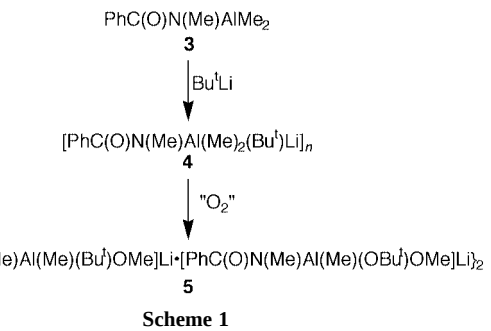
Received (in Cambridge, UK) 18th November 1999, Accepted 17th December 1999

While reaction of a solution of the amidoalane PhC(O)N(Me)AlMe$_2$ 3 with 1 equiv. of Bu^{t}Li affords the lithium aluminate PhC(O)N(Me)Al(Me)$_2$(Bu^t)Li 4, deliberate treatment of the reaction mixture with oxygen affords the unique mixed-anion species {[PhC(O)N(Me)Al(Me)(Bu^t)OMe]Li·[PhC(O)N(Me)Al(Me)(OBu^t)OMe]Li}$_2$ 5; in the solid state 5 has a (LiO)$_4$ ladder structure containing terminal mono-oxygenated aluminate ligands and tripodal bis-oxygenated aluminate ligands spanning end and central Li$^+$ cations.

There is much current interest in the syntheses, structures and reactivities of lithium-containing heterobimetallic species.[1–3] Recently, we have synthesised lithium aluminate monomers Me$_2$Al(μ$_2$-OAr)$_2$Li (Ar = aryl) by treating bis(aryloxy)methylalanes of type MeAl(OAr)$_2$ with RLi reagents (R = Me, Bu^t) and demonstrated the role of such species in 1,4-conjugate additions to α,β-unsaturated ketones.[1] We have also shown that BuLi reagents react with the (amido)methylalane Me$_2$AlN(2-C$_5$H$_4$N)Ph, **1**, to afford remarkable hydride-containing compounds,[2] *e.g.* Bu^{t}Li reacts with **1** to give [Li(Me$_2$AlBu$^t_2$)$_2$]$^-$·{Li$_8$(H)[N(2-C$_5$H$_4$N)Ph]$_6$}$^+$ **2**. With a view to investigating the effect that the choice of organic residue has on the formation of species such as **2** we have recently carried out reactions of Bu^{t}Li with a variety of molecules containing a Me$_2$AlN(C=X)C– unit (X = N, O *etc.*) akin to that found in **1**. We report here, on the reaction of the *N*-methylbenzamidoalane[4] **3** with Bu^{t}Li to afford the lithium aluminate, **4**, and on the isolation of the unique heterobimetallic mixed-anion ladder, **5**, which results when oxygen is subsequently and deliberately introduced to the reaction mixture (Scheme 1).

Reaction of a prepared solution of **3** with 1 equiv. of Bu^{t}Li affords a solution from which **4** can be obtained as the only isolable product.‡ ^{1}H NMR spectroscopy shows that, rather than being a hydride-containing compound, **4** is, in fact, a simple lithium aluminate. However, the controlled treatment of a solution of **4** with air followed by storage at −30 °C affords crystals of the unique mixed-metal/mixed-anion species [PhC(O)N(Me)Al(Me)(Bu^t)OMe]Li·[PhC(O)N(Me)Al(Me)(OBu^t)OMe]Li **5**.§ X-Ray crystallography¶ shows that in the solid state **5** is a dimer of this formulation (Fig. 1) with one molecule of toluene in the lattice. At the core of the solid-state structure is a (LiO)$_4$ ladder composed of three precisely planar edge-fused (LiO)$_2$ rings which incorporate the original carbonyl O-centres of **4**. Supplementary to this core, the two types of oxygenated aluminate anions, which have been afforded by treatment of **4** with air, operate in distinct ways. The two mono-oxygenated anions are terminal, using their generated OMe groups to complete the six-membered OCNAlO(Me)Li chelate rings [Li1–O4 1.900(6) Å] which stabilise the Li$^+$ centres at the ends of the ladder. In contrast, the two bis-oxygenated anions span ladder end- and central-Li$^+$ cations (Li1 and Li2A, respectively), coordinating to these metal centres through interactions involving their OBu^t [Li1–O3 1.935(6) Å] and OMe [Li2A–O5 1.896(5) Å] units, respectively. The observation that these Li–OR (R = Me, Bu^t) bonds differ significantly presumably derives from the shortness of the Li1–O4 bond in the mono-oxygenated monomer. Overall, these bis-oxygenated anions act as tripodal ligands forming, with the involved Li$^+$ centres of the ladder (Li1, Li2A), fused tricyclic arrangements. It is probably the contiguous nature of these three rings which accounts for the relatively long Li1–O2 and Li2A–O2 distances (mean 2.054 Å). While two of the ring systems incorporate one Li$^+$ centre each [OCNAlO(Bu^t)Li and OCNAlO(Me)Li stabilise Li1 and Li2 respectively], the third six-membered ring, involving two Li$^+$ centres, is based on a fairly symmetrical MO(M′O)$_2$ (M = Al, M′ = Li) heterocycle.

Aside from the method used for its synthesis, the solid-state stucture of **5** shows a series of particularly noteworthy features. While several structurally characterised lithium aluminates incorporate intramolecular Li–O interactions, these have generally been based either on simple heterobimetallic motifs [Al(μ$_2$-O)Li[5,6] or Al(μ$_2$-O)$_2$Li[1,5,7]] or on (AlO)$_n$ rings (*n* = 2,



Scheme 1

† Deceased.

3).[6] Here, however, **5** is constructed around a $(LiO)_4$ ladder. Only a very limited number of such homometallic ladders are known,[8] the vast majority of Li–O-containing metallo-organic species (*e.g.* alkoxides, enolates) being pseudo-cubane tetramers,[5] hexamers[5,9] or even higher[10] aggregates in the solid state. It is salient, therefore, that the adoption of an $(LiO)_4$ intercepted-ladder motif by **5** represents the first crystallographic evidence that ladder structures, known for a range of lithiated organic compounds (particularly lithium amides),[5,11] can also pertain for Li–Al heterobimetallic ones. Furthermore, whereas the $(LiO)_4$ core of **5** utilises the original carbonyl *O*-centres, it is clear that the coordinative requirements of the *different* types of Li^+ centre (Li1 and Li2) in the assembled ladder are satisfied by the *variability* of ligand oxygenation.

The final interesting aspects of **5** concern how and why it is formed in the first place. The complex can be obtained repeatedly, albeit so far in moderate yields, from exposure of a pre-formed solution of **4** to either normal (*i.e.* moist) or (P_2O_5) dry air. However, the use of normal air affords samples of **5** which ^{1}H NMR spectroscopy shows to be significantly contaminated with (expected) aluminoxane[12] hydrolysis products. These observations point to oxygen rather than moisture being responsible for the observed multiple oxo-insertion process. In this context, it is known that air-sensitive R_3Al species afford *tris*-oxygenated compounds, $(RO)_3Al$, upon exposure to oxygen.[13] The surprise in the synthesis of **5** is the *controlled* nature and dual s*pecificity* of oxo-insertion. Preliminary ^{1}H NMR spectroscopic evidence suggests that the treatment of **3** alone [having two Al–C(Me) bonds] with pre-dried air fails to afford any detectable reaction and it is only when **3**, Bu^{t}Li and O_2 are combined, *in that order*, that **5** results. Complete *tris*-oxygenation of the Al–C bonds has not occurred in **5**, but rather two of the aluminate anions have each undergone single oxo-insertion and two have each inserted oxygen atoms into two Al–C bonds. In this way, the two types of ligands produced are perfect for provision of additional coordination (terminal and spanning respectively) to the Li^+ centres of the $(LiO)_4$ core of **5**, raising each such centre to a coordination number of four. While the precise mechanism by which **5** is formed is not yet understood, the observations noted above suggest that oxo-insertion is either directly templated [*i.e.* that lithium aluminate **4** is, itself, a $(LiO)_4$ ladder] or else that the conversion of **4** to **5** requires that the processes of ladder formation *and* oxo-insertion occur concurrently.

Attempts to learn the *precise* structural nature of **4**, and to thus better understand the reasons for the dual specificity of oxo-insertion, are ongoing. Further work will also seek to investigate the effects of employing pure oxygen in place of dry air and will attempt to follow the reaction by low-temperature multinuclear NMR spectroscopy. More generally, it is planned to look at related systems of general type R_2AlL and R′Li (R, R′ = alkyl, aryl; L = *N*- or *O*-centred ligands) and to deliberately treat these with oxygen. In this way, it is hoped to judge how widespread and how useful the oxo-insertion process, and the concomitant ligand amendments, might be. It is clear already, from this and other work,[3] that deliberate aeration of selected main group organometallic species (usually handled under strictly inert-atmosphere conditions) can produce much interesting new chemistry.

We thank the UK EPSRC (D. J. L.) for a Studentship and St. Catharine's (R. P. D.) and Gonville & Caius (A. E. H. W) Colleges for Research Fellowships. This work is dedicated to the memory of Ron Snaith.

Notes and references

‡ Toluene (1 ml) was added to *N*-methylbenzamide (0.14 g, 1 mmol) at −78 °C under nitrogen and the resultant suspension treated with $AlMe_3$ (0.5 ml, 1 mmol, 2 M in hexane). The reaction mixture was warmed to room temperature and stirred for 30 min whereupon it was returned to −78 °C and Bu^{t}Li (0.59 ml, 1 mmol, 1.7 M in pentane) was added. The resultant solution was warmed to room temperature whereupon removal of the solvent afforded crude **4** as a white powder. Yield 65%, mp 86–88 °C. Satisfactory C,H,N. ^{1}H NMR spectroscopy (400 MHz, CD_3CN), δ 7.72–6.99 (m, 5H, Ph), 2.87–2.76 (m, 3H, NMe), 0.87–0.66 (m, 9H, Bu^t), −1.21, −1.36, −1.53 (m, 6H, AlMe).

§ As for **4** but upon returning to room temperature the resultant pale yellow solution was treated with dry air (P_2O_5) for 1 min and with hexane (0.5 ml) before being stored at −30 °C for 3 days whereupon colourless microcrystals of **5** were deposited. Yield 15% (based on Bu^{t}Li consumed), mp 128–130 °C. Satisfactory C,H,N. ^{1}H NMR spectroscopy (500 MHz, [$^2H_8$]THF), δ 8.05–7.20 (m, 10H, Ph), 7.19–6.98 (m, 2.5H, C_6H_5Me), 3.51–3.44 (m, 6H, OMe), 3.04–2.66 (m, 6H, NMe), 2.32 (s, 1.5H, C_6H_5*Me*), 1.20–1.15, 0.86 (m, 18H, Bu^t), −1.02, −1.07 (m, 6H, AlMe).

¶ *Crystal data* for **5**: $C_{31.5}H_{50}Al_2Li_2N_2O_5$; M = 604, triclinic, space group $P\bar{1}$, a = 12.333(3), b = 13.439(3), c = 14.021(4) Å, α = 109.87(1), β = 91.58(2), γ = 114.21(1)°, U = 1955.2(9) Å^3, Z = 2, D_c = 1.105 g cm^{-3}, Cu-Kα (λ = 1.54178 Å), μ = 0.972 mm^{-1}, T = 180(2) K. 8243 reflections (4837 unique, θ < 54.98°, R_{int} = 0.0301), data were collected on a Stoe Siemens four-circle diffractometer. Refinement on F^2 values of all data gave $wR2$ = 0.1766, conventional R = 0.0640 on F values of 4242 reflections with $F^2 > 2\sigma(F^2)$, 428 parameters. Residual electron density extrema are 0.69 and −0.24 Å^{-3}. CCDC 182/1509. See http://www.rsc.org/suppdata/cc/a9/a909135a/ for crystallographic files in .cif format.

Received (in Cambridge, UK) 20th October 1999, Accepted 17th December 1999

The reduction of $Cu(BF_4)_2{\cdot}xH_2O$ in 1 wt% poly(vinyl pyrrolidone)–methanol solution with trimethyl phosphite produced a solution containing cuprous complexes; the membrane prepared from this solution showed a maximum selectivity of 10 for propylene over propane at room temperature.

Separation of olefin/paraffin mixtures is one of the most important processes in the petrochemical industry.[1] Currently, the separation is often carried out by highly energy-intensive low temperature distillation. Among a number of alternative separation processes, separation by a facilitated transport membrane with Cu^+ or Ag^+ has attracted much interest because of its low energy consumption, compact unit and simple operation.[2] The basis for the separation is the reversible formation of a π-bonded complex between metal ions, like Cu^+ or Ag^+, and the olefin.[3,4] Many studies have been reported on the facilitated transport of olefins by using supported liquid membranes,[5] ion-exchange membranes[6] or dense polymer membranes[7] containing silver ions as carriers. Cuprous ions have also been applied as carriers for facilitated transportation in liquid membranes, but only for transportation of carbon monoxide and not for olefins.[8] Recently, Lin *et al*. reported the use of CuCl coated γ-alumina membranes in the separation of ethylene/ethane mixtures, but obtained a maximum selectivity of only 1.4 for ethylene over ethane.[9] To the best of our knowledge, reactive solid polymer membranes containing cuprous ions have never been reported, probably due to the low solubility and the instability of cuprous complexes in water or organic solvents.[10]

We report here, for the first time, the direct synthesis of reactive solid polymer membranes containing cuprous complexes and the application of such membranes to the separation of olefin/paraffin mixtures. The addition of trimethyl phosphite to a methanol solution of a cupric salt and an appropriate polymer produced a solution containing cuprous species, which was subsequently coated onto a porous asymmetric membrane. Trimethyl phosphite is known to reduce Cu(II) to Cu(I) as in eqn. (1).[11] The copper ions were found to exist only in the Cu(I) state, as identified by iodometry.[12]

$$Cu(BF_4)_2 + H_2O + P(OMe)_3 + PVP \rightarrow CuBF_4/PVP + 2HBF_4 + OP(OMe)_3$$

PVP: poly(vinyl pyrrolidone) (1)

The membranes were prepared as follows: $Cu(BF_4)_2{\cdot}xH_2O$ (3 mmol, 1 g) and $P(OMe)_3$ (6 mmol, 1.5 mL) were added to 1 wt% poly(vinyl pyrrolidone) (0.5 mmol, 0.05 g) solution in methanol. The resulting solution was applied to a 5 cm × 5 cm asymmetric porous polysulfone membrane. The membrane was dried for 12 h in air and then vacuum-dried for 12 h at room temperature. Membranes consisted of a thin nanoporous cuprous-poly(vinyl pyrrolidone) top layer and an asymmetric coarse-pore polysulfone support. The thickness of the active layer was 2–3 μm, determined by scanning electron microscopy (not shown).

Separation measurements were performed with the coated membrane placed in a stainless steel separation module with the olefin/paraffin (50/50) gas mixture as described elsewhere.[13] The flow rates of the mixed gas and the sweep gas (helium) were controlled using mass flow controllers. The total feed pressure of mixed gas was set at 20 psig by back pressure regulators. Average fluxes of ethylene/ethane and of propylene/propane through the membranes were 2×10^{-5} and 1×10^{-5} $cm^3\ cm^{-2}\ s^{-1}\ cmHg^{-1}$, respectively at room temperature. The permeated gas was analyzed by gas chromatography.[14]

Fig. 1 and 2 show the effects of molar ratios of $P(OMe)_3$/Cu(II) and Cu(II)/PVP on the separation of olefin/paraffin mixtures. The selectivity for olefin over paraffin increased with increasing molar ratio of $P(OMe)_3$/Cu(II) up to 2 and then

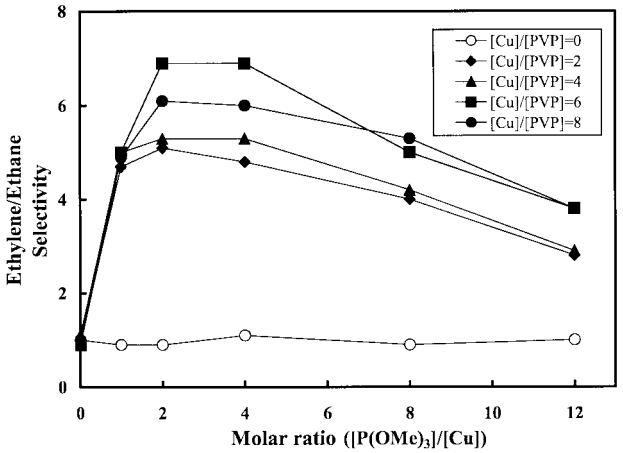

Fig. 1 Effects of molar ratios of $[P(OMe)_3]/[Cu]$ and [Cu]/[PVP] on the permeation selectivity of ethylene over ethane at 25 °C.

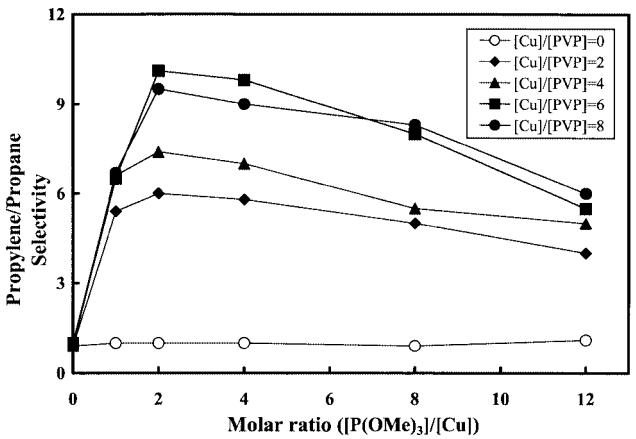

Fig. 2 Effects of molar ratios of $[P(OMe)_3]/[Cu]$ and [Cu]/[PVP] on the permeation selectivity of propylene over propane at 25 °C.

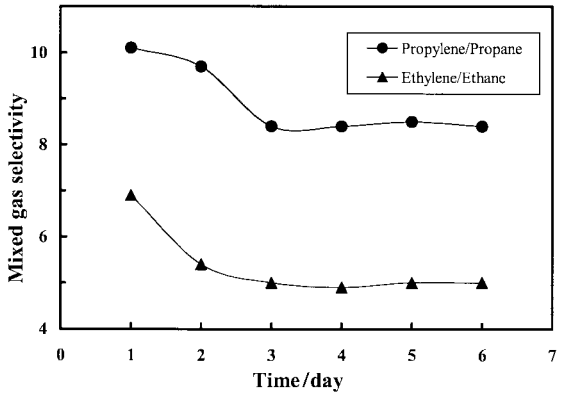

Fig. 3 Change of mixed gas selectivities with time.

gradually decreased with further increase in the molar ratio. It is likely that coordination of trimethyl phosphite is taking place to a certain extent, which could reduce the complexation ability of cuprous ion towards olefin. As expected, the membranes did not show any selectivity for olefin over paraffin at $P(OMe)_3/Cu(II) = 0$, confirming that only Cu(I) is responsible for the selectivity. The copper ions present in the membrane prepared in the absence of $P(OMe)_3$ exist only as Cu(II), for which complexation with olefin is impossible. The higher permeability ratio of propylene/propane in comparison with that of ethylene/ethane can be ascribed to the difference in diffusion rates of the mixed gases. The molar ratio of Cu(II)/PVP was also varied in the range from 0 to 8. As shown in Fig. 1 and 2, the selectivity increased with increasing molar ratio of Cu(II)/PVP up to 6. No appreciable selectivity at Cu(II)/PVP = 0 demonstrates that the PVP-only membrane is not effective for the olefin/paraffin separation and the separation is not taking place by simple diffusion and desorption across the PVP only membrane. Membranes with the molar composition of $P(OMe)_3$:Cu(II):PVP = 2:1:6 were subjected to a seven day permeation test as shown in Fig. 3. The selectivity decreased from 8 to 5 for ethylene/ethane and from 10 to 7 for propylene/propane during the first two days of the experiments and remained constant thereafter, demonstrating that the membranes were stable for at least a week. It is assumed that trimethyl phosphite present in the membranes may play a role in preventing Cu(I) from being oxidized to Cu(II) by trace amounts of oxygen or water in the feed gas.

Other cuprous membranes were also prepared using $Cu(ClO_4)_2$ and $Cu(SO_3CF_3)_2$, and tested for the separation of olefin/paraffin mixtures. The selectivities were lower by a factor of approximately 2 than the selectivities from the $Cu(BF_4)_2$ membranes. This can be attributed to the fact that ClO_4^- and $CF_3SO_3^-$ are more strongly binding anions than BF_4^- and consequently the reversible complexation of olefins is somewhat inhibited. In fact, the membranes containing CuCl showed much lower ethylene/ethane permeation selectivity, possibly due to the competitive complexation of ethylene and Cl^-.[9]

In a separate experiment, a polymer membrane containing $Cu(CO)PF_6$ was prepared according to eqn. (2).

$$1/2Cu_2O + HPF_6 + CO + PEOx \rightarrow Cu(CO)PF_6/PEOx + 1/2H_2O$$

PEOx: poly(2-ethyl-2-oxazoline) (2)

The membrane thus obtained was very unstable and showed no selectivity for the separation of propylene/propane mixtures. However, interestingly, when small amounts of trimethyl phosphite were added to the polymer solution of eqn. (2), the resulting membrane showed a maximum separation factor of 5 for the propylene/propane mixture. This result implies that trimethyl phosphite is functioning as a stabilizer for cuprous ion.

Investigations on the interactions between polymers and copper salts are in progress to improve the properties of cuprous ion-containing membranes.

Poly(zinc(II)-5,15-porphyrinylene) from silver(I)-promoted oxidation of zinc(II)-5,15-diarylporphyrins

Naoya Yoshida, Naoki Aratani and Atsuhiro Osuka*

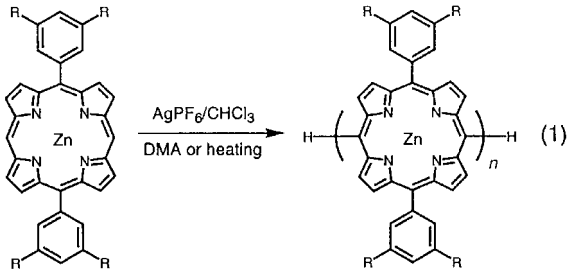
Received (in Cambridge, UK) 30th November 1999, Accepted 23rd December 1999

Zinc(II)-5,15-diarylporphyrins have been effectively polymerized to give poly(Zn(II)-porphyrinylene) in high yields in the reaction with 1.5 equiv. $AgPF_6$ in $CHCl_3$ either in the presence of 0.5% *N*,*N*-dimethylacetamide or upon heating.

Linearly π-conjugated polymers and oligomers have attracted considerable attention in light of their potential applications in the fields of electronics, optical devices, sensors and solar energy conversion.[1] Among these, poly(arene)s represented by poly(*para*-phenylene)s (PPP), poly(pyrrole)s, and poly(thiophene)s have attracted considerable attention owing to their increasing conductivities upon doping.[2] Porphyrins are an appealing building block for the modular construction of such linear π-conjugated systems, since they offer a variety of desirable features such as rigidity, high stability, intense electronic absorption, a small band gap, strong fluorescence emission, and the possibility to tailor optical and redox properties by appropriate metallation.[3] However, to the best of our knowledge, directly linked poly(porphyrinylene) has not been reported so far. Recently we found that a *meso–meso* coupling reaction of 5,15-diaryl zinc(II)-porphyrins can be effected by treatment with an Ag(I) salt[4a] or by anodic electrochemical oxidation.[4b] Interestingly the *meso–meso* coupling regioselectivity is quite high, allowing the formation of straight and directly linked porphyrin arrays up to the octamer by the latter method.

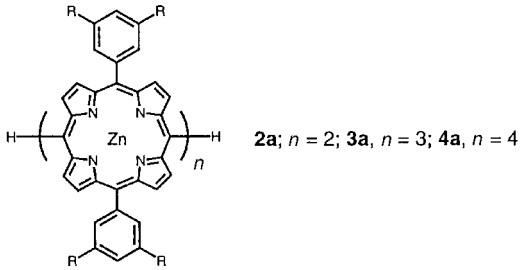
Now we report that the Ag(I)-promoted *meso–meso* coupling reaction can be extended to the preparation of long poly(porphyrinylene)s simply by the addition of *N*,*N*-dimethylacetamide (DMA) or slight heating [reaction (1)]. Formally, the



(1)

1a; R = Bu^t
1b; R = OC_8H_{17}

formation of one *meso–meso* bond is accompanied by the loss of two hydrogens and thus seems to need two equivalents of oxidant. This is nicely illustrated by the reaction of **1a** with 1.5 equiv. $AgPF_6$ in $CHCl_3$ at 20 °C for 4 h which gave, besides the recovery of unreacted **1a** (40–50%), **2a** (25–30%), **3a** (5–7%), and **4a** (1–2%) together with small amounts of higher oligomers (Fig. 1a).[4] In marked contrast, reaction under similar conditions but with the presence of a small amount of DMA (0.5% to $CHCl_3$) gave rise to enhanced oligomerization in only 0.5 h (Fig. 1b). The reaction mixture was examined by MALDI-TOF MS and a combined GPC–HPLC and UV-vis absorption method (Fig. 2). The former registered detectable peaks from 688 to 16500 Da (corresponding to 1- to 22-mers) with a repeat unit of *ca.* 750 Da, indicating the formation of diverse



2a; *n* = 2; **3a**, *n* = 3; **4a**, *n* = 4

oligomeric porphyrin arrays up to the 22-mer.[5] The spectra in Fig. 2b that were taken for the GPC–HPLC fractions as their free bases[6] display progressive red-shifts and broadening of the split Soret bands and Q-bands and are consistent with the highly regioselective *meso–meso* coupling even for larger porphyrin arrays. On the basis of the relationship of the molecular weights of discrete oligo(porphyrinylene)s *versus* the retention time of

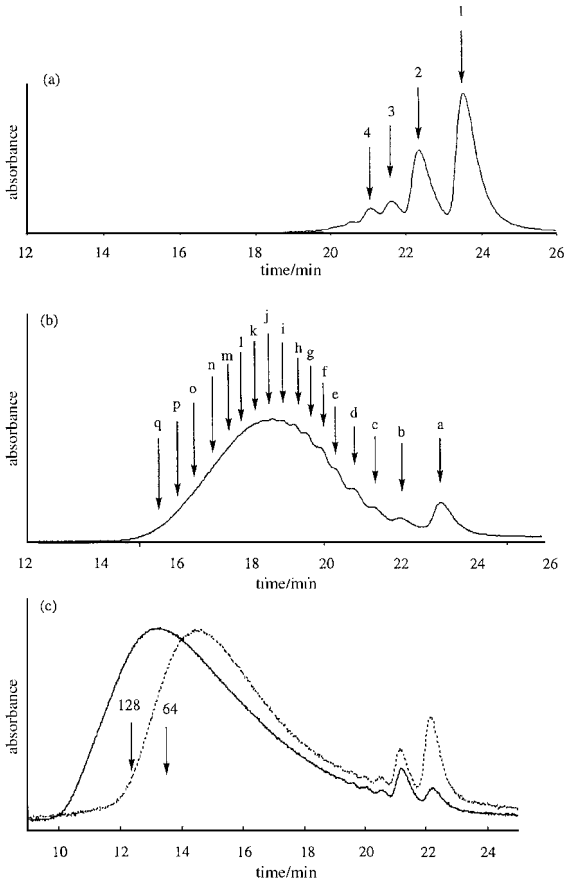


Fig. 1 GPC–HPLC charts of the reaction of **1a** and **1b** with 1.5 equiv. $AgPF_6$ in $CHCl_3$ detected at 413 nm: (a) **1a**, room temperature, 4 h, no DMA, arrows 1–4 indicate bands corresponding to **1a**, **2a**, **3a**, and **4a**, respectively; (b) **1a**, room temperature, 4 h, 0.5% DMA; (c) **1b**, 45 °C, 0.5% DMA, 11 h (dotted line); **1b**, 45°C, 0.5% DMA, 82 h (solid line), the retention times of the discrete 64-mer and 128-mer are indicated by arrows. The absorption spectra of fractions indicated by arrows a–q are shown in Fig. 2b.

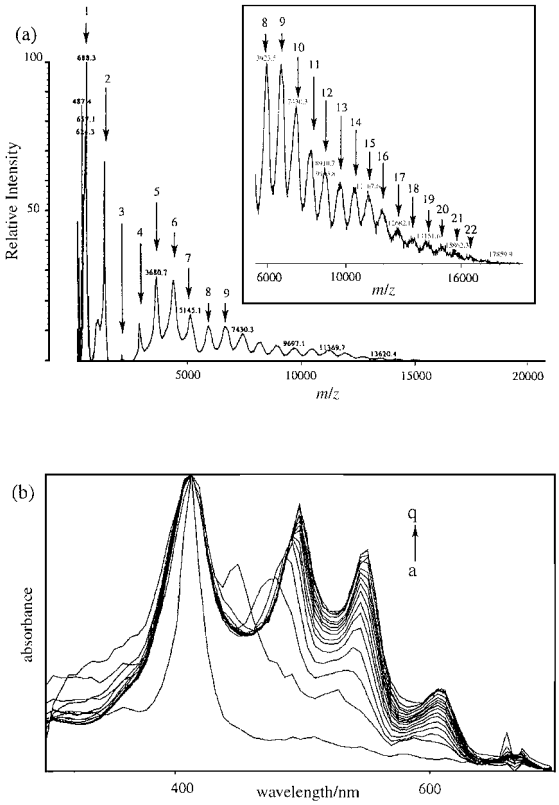

Fig. 2 Product mixture in the reaction of **1a** with 1.5 equiv. $AgPF_6$ in $CHCl_3$ containing 0.5% DMA: (a) MALDI-TOF MS spectrum; (b) absorption spectra of GPC–HPLC fractions after addition of TFA.

GPC–HPLC, we estimated M_w = 12 000 Da with a polydispersity of 1.46; the major oligomers eluting at *ca*. 19 min correspond to 8,9-mers and the detectable largest oligomers eluting at *ca*. 14.5 min correspond to *ca*. 50-mers. The polymerization depends on the amount of DMA, and is most effective upon addition of 0.5–3% DMA. The acceleration effect is only modest with less than 0.5% DMA and decreases with increasing amounts of DMA over 3%, and is completely suppressed upon addition of 20% DMA. Similar enhanced polymerization was also observed in the presence of DMF, HMPA, and DMSO with the enhancement order of DMA > DMF ≈ HMPA > DMSO. On the other hand, nitrogen bases such as pyridine, lutidine, triethylamine, and *N*,*N*-dimethylaniline were found to completely suppress the *meso–meso* coupling. It is also notable that even heating at 45 °C led to polymerization (M_w = 13 000 Da with a polydispersity of 1.37) after 24 h. In this thermally accelerated polymerization, however, the conversion of the monomer **1a** reached a maximum of *ca*. 70% after only 1–2 h but the increase of chain length proceeded rather slowly.

In the reaction of **1a**, there is a possibility that further polymerization may be interrupted owing to the poor solubility of the formed long porphyrin arrays. In order to circumvent this problem, we employed the much more soluble substrate **1b** as the starting monomer. **1b** turned out to be less reactive than **1a** probably due to its bulky dioctyloxy substituents; only 5% of **1b** was consumed even after 24 h in the reaction with 1.5 equiv. $AgPF_6$ in $CHCl_3$ at 20 °C [reaction (1)]. However, the addition of 0.5% DMA indeed accelerated the coupling to give poly(porphyrinylene) with M_w = 45 000 Da and a polydispersity of 1.7 after 24 h. As for **1a**, heating at 45 °C also led to the polymerization of **1b** (M_w = 21 500 Da with a polydispersity of 1.59), although a substantial induction period (10 h) was necessary to start the polymerization. When the reaction of **1b** with 1.5 equiv. $AgPF_6$ was conducted in the presence of 0.5% DMA at 45 °C, the polymerization proceeded extensively, giving poly(porphyrinylene)s with M_w = 75 000 Da and a polydispersity of 1.60 after 11 h, and M_w = 250 000 Da and a polydispersity of 2.78 after 82 h (Fig. 1c). Note that these large poly(porphyrinylene)s exhibit absorption and emission spectra similar to those of oligo(porphyrinylene) 64- and 128-mers of discrete size, which were separately prepared from **1b**.[7] Another merit of these polymers lies in their easy transformation to Ni(II) and Cu(II) complexes.[8]

The mechanism of this polymerization is not fully understood but can be considered to be initiated by one-electron oxidation of zinc(II)-porphyrin with silver(I) and the chain elongation process may be similar to those proposed for oxidative formation of PPP,[2a] involving a poly(5,15-dihydroporphyrinylene) intermediate which will be oxidized to poly(5,15-porphyrinylene)s. The superior acceleration effects of DMA over DMF suggest that it may play a reducing role to convert the cation radical intermediate to a biradical intermediate which may be more active for elongation of the chain.

In summary, sterically uncongested metalloporphyrins, **1a** and **1b**, can be polymerized in a regioselective manner to poly(zinc(II)-5,15-porphyrinylene)s in the reaction with silver(I) salt either in the presence of 0.5–3% of DMA or upon heating. Not fully optimized yet, it is evident that zinc(II)-5,15-diarylporphyrin can be polymerized under much milder conditions compared to the polymerization conditions of smaller aromatic and heteroaromatic molecules. Exploring synthetic conditions that allow the preparation of poly(porphyrinylene) with less polydispersity would be an interesting next target and is actively in progress in our laboratory.

5 MALDI-TOF MS was measured for the reaction mixture of **1a**. The peak at 688 corresponds to a parent peak of the demetallated free base form of **1a** and the envelopes in the higher molecular weight region contain many species with variable numbers of incorporated Zn(II) ions.

6 Owing to the poor solubilities of zinc(II)-porphyrin arrays formed from **1a**, GPC–HPLC analysis was performed on the reaction mixtures of free base porphyrin arrays by addition of a small amount of TFA. The observed absorption spectra were quite similar to those of discrete long free base porphyrin arrays. The reaction mixtures of **1b** were directly analyzed as Zn(II) complexes.

Rhodium-catalyzed silylative carbocyclization on C_{60}

Takako Muraoka, Hirotaka Asaji, Yoshihiko Yamamoto, Isamu Matsuda and Kenji Itoh*

Department of Applied Chemistry and Department of Molecular Design and Engineering, Graduate School of Engineering, Nagoya University, Chikusa, Nagoya 464-8603, Japan. E-mail: itohk@apchem.nagoya-u.ac.jp

Received (in Cambridge, UK) 16th November 1999, Accepted 17th December 1999

Rhodium-catalyzed three component coupling of hepta-1,6-diyne, hydrosilane and C_{60} proceeded smoothly to give a fullerene derivative in good yield.

Studies on the functionalization of C_{60} fullerene have attracted considerable attention,[1] because fullerene derivatives are expected to be effective precursors for advanced composite materials,[1c] photoconductive thin films,[2] electron transfer dyad,[3] efficient photosensitizers,[4] *etc*. Fullerene derivatives are also anticipated to form materials with stimulating biological properties,[1b,d] such as inhibition of HIV-1 protease,[5] promotion of DNA cleavage,[6] and enzymatic inhibition.[6e,7] In order to prepare a wide range of designed C_{60} derivatives, cycloadditions have proved the most useful method because well-defined mono-adducts can be easily obtained in most cases.[8] The obtained C_{60}-fused carbo- and heterocycles are interesting key molecular components for the construction of the aforementioned functionalized materials, which are often composed of organized molecular aggregates. In particular, the Diels–Alder reaction, employing C_{60} as a dienophile, is a reliable tool to obtain the cyclohexene-fused C_{60} derivatives.[8a] In addition, cycloaddition protocols include the reaction of C_{60} with appropriate addenda, such as carbenes, nitrenes, conjugated dienes, 1,3-dipoles, *etc*.[8b] No example of *a catalytic multicomponent coupling strategy* involving C_{60}, however, has been reported so far, although domino-type multi-component couplings catalyzed by a wide variety of transition metal complexes are now becoming a major focus in organic synthesis.[9] We herein report the first example of three-component coupling involving C_{60} catalyzed by a rhodium complex. Transition-metal promoted coupling reactions on fullerene are quite rare. This is ascribed to the finding that fullerenes preferentially form stable complexes with a wide range of transition metals. They are frequently too stable to show catalytic activity toward carbon–carbon bond formation with fullerene itself.[10] Only recently, the stoichiometric Ni-promoted cycloaddition of hepta-1,6-diynes and C_{60} was reported by Cheng *et al*.[11] Catalytic methods, however, are desirable as they are metal-economical and environmentally friendly processes. With these ideas in mind, we developed the Rh^{I}-catalyzed three-component domino coupling of C_{60}, hepta-1,6-diyne and hydrosilane *via* the silylative cyclization of the diyne followed by the Diels–Alder cycloaddition of the resultant diene and C_{60}.

We recently reported the rhodium-catalyzed silylative cyclization of hepta-1,6-diynes **1** with trialkylsilanes **2** leading to *cisoid* dienylsilane derivatives **3** (Scheme 1).[12] The obtained **3** has an exocyclic 1,3-diene moiety and can be utilized as a diene counterpart in the Diels–Alder cycloaddition toward fullerene. In fact, the thermal reaction between C_{60} and 1.5 equiv. of **3** [X = $C(CO_2Me)_2$, R_3Si = $PhMe_2Si$] in refluxing toluene for 1 h gave the desired cycloadduct **4a** in 58% isolated yield (88% yield based on consumed C_{60}). The structure of **4a** was determined on the basis of its ^{1}H and ^{13}C NMR, IR, and MS analyses.[13] First, its IR spectrum revealed that **4a** is the adduct of C_{60} and **3**, *i.e.* the typical absorption of the C_{60} core was observed at 527 cm^{-1} as well as the absorptions corresponding to the ester carbonyl groups and the silyl group at 1735 and 1249 cm^{-1}, respectively. In the ^{1}H NMR spectrum, cyclohexene ring protons [δ 3.13 (d, 1H, *J* 16.8 Hz), 3.38 (s, 1H), and 3.48 (m, 1H)] and cyclopentene ring protons [δ 3.64-3.77 (m, 2H) and 3.97–4.07 (m, 2H)] were observed along with the peaks assigned to the methyl and phenyl proton signals of the organic silyl group, and the methyl ester protons.[13] The molecular ion peak at *m/z* 1064 in the FAB-MS spectrum clearly indicated that **4a** is the expected 1:1 adduct. Furthermore, the ^{13}C NMR spectrum shows that the cycloaddition took place on the junction of two six-membered rings; among the ten peaks in the aliphatic region, the lowest-field signal at δ 66.62 is reasonably attributed to the fullerene sp^3 carbons of the 6,6-ring junction. The four sp^2 signal observed at δ 155.76, 156.39, 159.61 and 161.21 are also assigned to the C_{60} carbons next to the sp^3 carbon of the 6,6-junction.

The dienylsilane **3** is definitely an effective diene component in the Diels–Alder cycloaddition with C_{60}. Next, we investigated the three-component coupling from **1a**, **2** and C_{60}. Such three-component coupling is an attractive and more straightforward protocol for transition-metal-catalyzed carbocyclization on the fullerene framework in a single operation. The reaction of C_{60} (0.05 mmol) with **1a** (0.5 mmol) and **2** (0.5 mmol) under N_2 in refluxing toluene for 35 min in the presence of 3 mol% $RhCl(PPh_3)_3$ gave the expected **4a** in 36% isolated yield (55% yield based on consumed C_{60}; entry 1, Table 1). The spectral features of the product are identical to those from the Diels–Alder adduct of **3** with C_{60}. A decrease in the amounts of the diyne and the silane gave better results although longer reaction times are required (entries 2 and 3). The best yield (71%) was realized when 7 equiv. of **1a** and **2** were employed in refluxing toluene for 1 h (entry 2).

The significant feature of the present three-component domino coupling is that C_{60}, in spite of its strong tendency to form complexes with various transition metals,[10] never suppressed the catalytic silylative cyclization step. In sharp contrast, the three-component couplings of **1a**, **2** and *N*-phenylmaleimide (**5**) or maleic anhydride (**6**) failed although the Diels–Alder reaction of the isolated **3** gave the corresponding adducts with **5** or **6** in high yield.[14] These results suggest that

[a] The yield was based on comsumed C_{60} and isolated yield was shown in parenthesis.

these strong dienophiles inhibited the catalytic cycle *via* complex formation with a Rh^I species.

The other important feature is that dipropargyl ether **1b** and *N*,*N*-dipropargyl tosylamide **1c** were successfully adapted to the domino coupling, whereas they hardly gave silylative cyclization products in the absence of C_{60}.[14] As a result, interesting C_{60}-bound heterocycles **4a** and **4b** were successfully isolated in 41 and 32% conversion yields, respectively (entries 4 and 5). It seems reasonable to assume that unstable exocyclic diene intermediates **3b** and **3c** were immediately coupled with C_{60} before decomposition under the reaction conditions.

In conclusion, we have developed the Rh^I-catalyzed three-component domino coupling of C_{60}, hepta-1,6-diynes and a hydrosilane. Dienophile C_{60} did not interfere with the catalytic silylative cyclization and efficiently trapped the exocyclic 1,3-diene intermediates to furnish the corresponding C_{60}-linked carbo- and heterocycles in fair to good yields. The present method is the first example of transition-metal catalyzed domino coupling on the fullerene conducted in a single operation.

We gratefully acknowledge financial support (09305059, 10132222, and 11119223) from the Ministry of Education, Science, Sports, and Culture, Japanese Government. We also thank to Mr Kazumoto Kondo for mass measurements.

Received (in Bloomington, IN, USA) 7th October 1999, Accepted 23rd December 1999

A series of novel trinuclear metal complexes containing *fac*-(diimine)$Re^{I}(CO)_3$ chromophores and a stilbene-like bridging ligand have been synthesized and in CH_3CN exhibit photoswitchable luminescence arising from photoinduced intramolecular energy transfer from the *fac*-(diimine)-$Re(CO)_3$ chromophores to the bridging ligand.

Recently, molecular systems containing multiple electron or energy transfer donor–acceptors have been widely studied for potential applications as optical switches or gates in which the emission from these molecular systems can be switched on or off by external stimuli or environmental changes such as light or pH.[1] Polynuclear transition-metal complexes containing *fac*-(diimine)$Re^{I}(CO)_3$ chromophores have been used for extensive studies of photoinduced intramolecular energy transfer and electron transfer.[2] Earlier studies on ligand-bridged dimeric systems have illustrated that the bridging ligand π*-electron system has a profound effect on the spectroscopic, photochemical, and redox behavior of these complexes.[2,3]

The light-driven *cis–trans* isomerization processes of stilbenes and compounds containing stilbene units have undergone active investigation both through fundamental studies and practical applications.[4] The *cis*- or *trans*-stilbenes and their analogues are good triplet energy acceptors for exploring photosensitization and energy transfer processes.[5,6] We herein report the photophysics and photochemistry of trinuclear metal complexes containing *fac*-(diimine)$Re^{I}(CO)_3$ chromophores bridged by a stilbene-like tridentate ligand. The results show that following excitation into the Re (dπ) → diimine (π*) MLCT manifold, efficient triplet–triplet energy transfer from the ^{3}MLCT state to the bridging ligand occurs and this results in *trans–cis* isomerization of the bridging ligand. The structures of the bridging ligands and complexes studied here are shown in Scheme 1.

Complexes $[(NN)Re(CO)_3]_3(\mu\text{-TEEPB})(PF_6)_3$, where NN = bpy, 4,4′-$Me_2$bpy or 4-$NO_2$bpy, and TEEPB = 1,3,5-tris(2-ethenyl-4-pyridyl)benzene, were synthesized by refluxing a 3 : 1 molar ratio of $[(NN)Re(CO)_3(CH_3CN)]PF_6$ and TEEPB in THF solution and then standard workup procedures.[2c,7] All new complexes have been characterized by infrared spectra, ^{1}H, ^{13}C NMR and elemental analysis.‡

Photophysical parameters obtained from compounds **1**–**7** are summarized in Table 1. The absorption spectra of all these compounds feature a series of ligand localized π → π* and metal (dπ) to ligand (π*) charge transfer (MLCT) bands. Unlike most metal complexes containing the *fac*-(diimine)$Re^{I}(CO)_3$ unit, which are typically highly luminescent in solution,[2,3,6] compounds **1** and **3** show only weak luminescence (Φ_{em} < 0.0015) in room temperature CH_3CN solution. The quenching appears to occur *via* intramolecular sensitization of the π → π* transition localized on the olefin link of the bridging ligand accompanied by a *trans–cis* isomerization process.

$$[(NN)Re^{I}(CO)_3]_3(\mu\text{-}t\text{-TEEPB}) \xrightarrow{h\nu} [^3(NN^{\bullet-})Re^{II}(CO)_3]_3{}^*(\mu\text{-}t\text{-TEEPB}) \underset{k_{-ENT}}{\overset{k_{ENT}}{\rightleftharpoons}}$$

$$[(NN)Re^{I}(CO)_3]_3{}^3(\mu\text{-}t\text{-TEEPB})^* \xrightarrow[\text{isomerization}]{trans\text{–}cis} [(NN)Re^{I}(CO)_3]_3(\mu\text{-}c\text{-TEEPB})$$

This is supported by steady-state photolysis experiments. Fig. 1 shows the difference absorption spectrum of compound **1** in CH_3CN solution as a function of photolysis time. Photolysis into the MLCT band at 366 nm bleaches the ππ* absorption of the bridging ligand at *ca.* 280–370 nm and induces small increases at *ca.* 200–270 nm. A similar bleaching effect at *ca.* 280–330 nm was also observed for free TEEPB photolyzed at 313 nm. Furthermore, changes observed in the emission are very substantial and the emission quantum yield is 18 times greater for **1** (see inset in Fig. 1) and 21 times greater for **3** after 7 h of photolysis at 366 nm compared to the original spectra. The UV–VIS spectral changes and large increase in the luminescence intensity for **1** and **3** are consistent with the *trans–cis* isomerization of the bridging ligand, TEEPB,§[6a,b,8] and highly efficient energy transfer (*vide infra*). The energy transfer from the ^{3}MLCT state to the higher energy triplet excited state

[a] The excitation wavelengths are 380 nm. [b] The emission quantum yields were determined using [(bpy)Re(CO)$_3$(4-Etpy)](PF$_6$) ($\Phi_{em}^{CH_3CN}$ = 0.027) as reference.[2d] [c] Triplet–triplet energy transfer rate constant: see text for detail. [d] Quantum yield for generating ^{3}TEEPB excited state: see text for detail. [e] Generated by photolysis at 366 nm for 36 h. The k_r and k_{nr} values are calculated based on 100% *cis*-TEEPB presence in solution. [f] No emission detected.

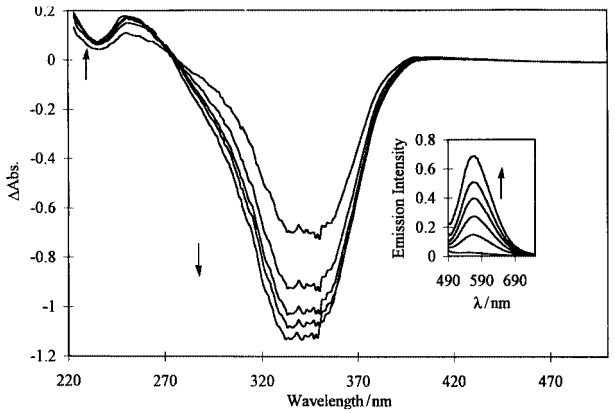

Fig. 1 UV–visible difference absorption spectra ($\Delta_{Abs} = A_t - A_{t=0}$) of [(bpy)Re(CO)$_3$]$_3$(μ-TEEPB)(PF$_6$)$_3$ in CH_3CN at 293 K as a function of photolysis time (λ = 366 nm; 0, 1, 2, 3, 4, 6 h). The inset shows the emission spectra before and after the photolysis.

localized on the *cis*-configuration bridging ligand is blocked or, at least, more unfavorable than direct deactivation from the ^{3}MLCT excited state to the ground state.

On the other hand, there is no emission detected from **5**, even after prolonged irradiation at 366 nm for 48 h. The lack of emission from **5** is attributed to the energy gap law, that is, the lower energy ^{3}MLCT excited state results in better vibrational overlap between the ground and excited states and the nonradiative decay increases as vibrational overlap increases.[9] The low energy ^{3}MLCT excited state in **5** also makes the energy transfer process energetically unfavorable.

Assuming that the MLCT intersystem crossing efficiency is unity, radiative (k_r) and nonradiative (k_{nr}) decay to the ground state and energy transfer (k_{ENT}) to TEEPB are the only deactivation processes for the ^{3}MLCT excited state, and that the decay from the ^{3}TEEPB excited state is much faster than energy transfer, then Φ_{em} and τ for [(NN)Re(CO)$_3$]$_3$(μ-TEEPB)(PF$_6$)$_3$ can be expressed as : $\Phi_{em} = k_r/(k_r + k_{nr} + k_{ENT})$ and $\tau = (k_r + k_{nr} + k_{ENT})^{-1}$. Calculated photophysical parameters are shown in Table 1. As expected, all the k_r values are very similar, *ca.* 1×10^5 s^{-1}, for the series of *fac*-(diimine)Re^{I}(CO)$_3$L complexes and in agreement with related Re(I) chromophores.[10] The energy transfer rate constant, k_{ENT}, and the efficiency for generating the ^{3}TEEPB excited state, Φ_{ENT}, at 293 K can be determined based on: $k_{ENT} = \tau^{-1} - \tau_{model}^{-1}$ and $\Phi_{ENT} = k_{ENT}/(k_r + k_{nr} + k_{ENT})$ with **6** and **7** as model compounds and their values are listed in Table 1.

It is not surprising that both the k_{ENT} and Φ_{ENT} values for **3** are larger than the corresponding values for **1**. The higher ^{3}MLCT excited energy in **3** results in a larger energy gap between the triplet donor and acceptor and, thus, a larger driving force that enhances the efficiency of energy transfer process.

We are grateful to the U.S. Department of Energy (Grant DE-FG02-89ER14039) for support of this research and CAPES for a scholarship to A. S. S.

Notes and references

‡ Two structurally similar compounds, [(NN)Re(CO)$_3$]$_3$(μ-TEPB)(PF$_6$)$_3$ [NN = bpy (**6**) or 4,4′-Me$_2$bpy (**7**) and TEPB = 1,3,5-tris(2-ethynyl-4-pyridyl)benzene] were prepared as model complexes (Scheme 1). Compounds **6** and **7** contain an sp-hybridized carbon link and, thus, avoid photoisomerization deactivation from the ^{3}MLCT excited state.

§ In a control experiment, the photolysis was performed in CD_3CN solution. The ^{1}H NMR spectra of both **1** and **3** showed the appearance of ethylene proton signals with coupling constants, J_{H-H} = 12 Hz (J_{H-H} = 16 Hz before photolysis), which unambiguously confirmed the formation of the *cis*-configuration bridging ligand. On the basis of the integrated areas in the ^{1}H NMR spectra, it was determined that all-*trans*-TEEPB in both **1** and **3** was less than 5% after 36 h of photolysis. The photolysis products are mixtures of *trans*-*trans*-*cis*-TEEPB, *trans*-*cis*-*cis*-TEEPB, and all-*cis*-TEEPB.

Received (in Cambridge, UK) 1st November 1999, Accepted 5th January 2000

The one-dimensional gallium fluorophosphate $Ga(HPO_4)_2F{\cdot}H_3N(CH_2)_3NH_3{\cdot}2H_2O$ 1 crystallises at room temperature from an aqueous mixture of Ga_2O_3, H_3PO_4, 1,3-diaminopropane, and HF; compound 1 converts to the three-dimensional microporous fluorophosphate ULM-3 on heating to 160 °C under hydrothermal conditions.

The determination of the crystallisation mechanisms of microporous solids is currently a great challenge in solid-state chemistry, because of the huge importance of these materials in many industrial applications (for example the use of aluminosilicate zeolites in catalysis, ion-exchange and gas absorption).[1] It is hoped that a detailed understanding of how microporous solids are formed will enable the rational design of new materials with properties required for a particular use.[2,3] We have studied the hydrothermal crystallisation of fluorophosphates of aluminium and gallium *in situ*, using both time-resolved energy-dispersive X-ray diffraction (EDXRD)[4–6] and NMR spectroscopy.[7] In our EDXRD study of open-framework gallium fluorophosphates of the ULM-*n* family[8] we have observed novel crystalline intermediate phases when the source of phosphorus was changed from H_3PO_4 to P_2O_5.[4–6] The compounds are only stable under hydrothermal conditions, and so structural characterisation has proved extremely difficult. In order to gain a greater understanding of these new transient phases we have investigated the crystallisation of metastable frameworks structures from reaction gels at low temperature.

We now report the crystallisation of a one-dimensional fluorophosphate, $Ga(HPO_4)_2F{\cdot}H_3N(CH_2)_3NH_3{\cdot}2H_2O$ **1**, at room temperature. Compound **1** was prepared by standing at room temperature the reaction mixture usually heated in a hydrothermal bomb to prepare ULM-3 $[Ga_3(PO_4)_3F_2{\cdot}H_3N(CH_2)_3NH_3{\cdot}H_2O]$.[9] 1 g of Ga_2O_3 was used, the mixture placed in a Teflon tube covered with film and stood for 1 week. A laboratory powder X-ray diffraction pattern of the solid product after recovering and washing with water showed that a novel crystalline phase had been produced, although contaminated with unreacted GaOOH and poorly crystalline β-Ga_2O_3, present in the Ga_2O_3 starting material. Examination of the solid product using a JEOL 2000FX transmission electron microscope, equipped with a Link 'Pentafet' EDX detector, revealed it to consist of well-formed thin sheets of maximum dimension ≈ 3 μm, mixed with a small quantity of shapeless material. X-Ray microanalysis using a $GaPO_4$ calibrant showed the plate-like crystallites to contain Ga and P in the ratio 1:2, and emissions characteristic of O, F, C and N were observed. The contaminant material contained only Ga and O, presumably the unreacted gallium oxides. A sample of the phosphorus-rich gallium fluorophosphate was subsequently prepared in a virtually pure form, by changing the reagent ratios; the Ga:P ratio in the initial gel was changed to be 1:2, the amount of HF doubled, and the pH adjusted to the same value as in the first reaction mixture (≈ 5.5) by addition of the appropriate amount of 1,3-diaminopropane. This sample exhibits only the strongest Bragg reflection of GaOOH, and the impurity is present in a very small amount (less than 0.5% on the basis of the diffraction results, *vide infra*). It has not been possible to prepare crystals of suitable size for single-crystal diffraction studies; for example if the reaction mixture is stood for longer periods (up to four months) no change in the sample nature is observed and seeding the mixture with pre-made sample afforded no larger crystals. If HF is omitted from the reaction mixture, then the only crystalline material produced is 1,3-propanediammonium phosphate hydrate.[10]

Powder X-ray diffraction data were collected from the new gallium fluorophosphate at room temperature on Station 2.3 of the Daresbury SRS in a 0.5 mm diameter glass capillary. An X-ray wavelength of 1.30041 Å was used, selected using a Si(110) double-crystal monochromator. The data were successfully indexed by the autoindexing program TREOR[11] on a triclinic unit cell (a = 7.0736 Å, b = 8.5062 Å, c = 11.6205 Å, α = 107.48°, β = 102.10°, γ = 90.28°) with good figures of merit [$M(25)$ = 24, $F(25)$ = 90.6]. An *ab initio* approach was taken to the structure solution† and the final Rietveld plot is shown in Fig. 1.

The X-ray structure determination reveals that **1** is constructed from only $\{GaO_4F_2\}$ octahedra and $\{PO_3OH\}$ tetrahedra. All bond distances [Ga–O_{av} = 1.99(2) Å, Ga–F_{av} = 1.869(2) Å, P–O_{av} = 1.54(1) Å, P=O_{av} = 1.51(2) Å] agree very well with those previously reported for gallium fluorophos-

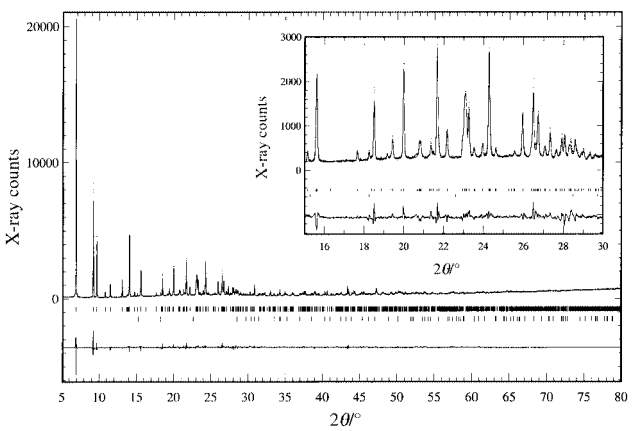

Fig. 1 Final Rietveld fit for $Ga(HPO_4)_2F{\cdot}H_3N(CH_2)_3NH_3{\cdot}2H_2O$. Inset is an expanded region of a small part of the data illustrating the small amount of the impurity GaOOH. Points are the experimental data, the line is the Rietveld fit, upper tick marks are for $Ga(HPO_4)_2F{\cdot}H_3N(CH_2)_3NH_3{\cdot}2H_2O$, and lower tick marks for GaOOH. The lower line is the difference curve.

phates.[8] The Ga polyhedra share the axial fluorines to produce an almost linear chain and all the (equatorial) oxygens are shared with the $\{PO_4\}$ tetrahedra. These phosphorus polyhedra bridge pairs of gallium octahedra along the chain on both sides (Fig. 2). Two of the phosphorus oxygens are terminal; these are assigned as one P–OH and one P=O per tetrahedron on the basis of charge-balancing considerations. Infra-red spectroscopy gave further evidence for the presence of this bonding; bands at 1380 cm^{-1} and 1005 cm^{-1} are assigned to the vibrations of phosphorus–oxygen bonds of P=O and P–OH respectively[12] and these are absent in ULM-3 in which all $\{PO_4\}$ oxygens are shared with Ga.[9] The chains of composition $Ga(HPO_4)_2F^{2-}$ are separated by charge-balancing $H_3N(CH_2)_3NH_3^{2+}$ cations and occluded water molecules. Thermogravimetric analysis is in agreement with the formulation of $Ga(HPO_4)_2F{\cdot}H_3N(CH_2)_3NH_3{\cdot}2H_2O$: a mass loss between 50 °C and 90 °C corresponds to the loss of the occluded water (observed 8.7%, expected 9.1%), and a mass loss between 300 °C and 700 °C corresponds to loss of the amine (observed 22.3%, expected 21.3%), presumably accompanied by collapse of the structure. The structure type has not previously been observed for an anionic gallium phosphate with organic counterions, although the arrangement of octahedra and tetrahedra is well known in the mineral chemistry of metal silicates, sulfates and phosphates,[13] Two one-dimensional anionic gallium phosphates, $Ga(PO_4)(HPO_4)^{2-}$, with charge-compensating alkylammonium cations are known and both of these were made using solvothermal methods.[14,15] In these compounds gallium is found only in tetrahedral sites. It is noteworthy that the previously reported one-dimensional gallophosphates have a Ga:P ratio of 1:2, and our new compound follows this pattern.

The use of ambient conditions to crystallise metal phosphates has previously received some attention, but the reagents used differ considerably from those usually used in solvothermal crystallisations.[16] It is interesting that the use of mild reaction conditions favours the formation of phosphates with low-dimensional structures, and thus it would appear that solvothermal conditions are necessary to synthesise three-dimensional (microporous) phosphates. The importance of the current work is that we have prepared a novel 1D phase at room temperature from *exactly* the same reaction mixture which yields a 3D phase if treated hydrothermally. The fact that the new chain phase contains only 6-coordinate gallium, whereas the hydrothermally-prepared ULM-3 contains both 5- and 6-coordinate gallium, is entirely consistent with recent *in situ* NMR spectroscopy results for related systems. For the aluminium fluorophosphate AlPO-CJ2 it was determined that there is a modification of Al coordination in solution from 6 to 5 on going from room temperature to hydrothermal conditions.[7]

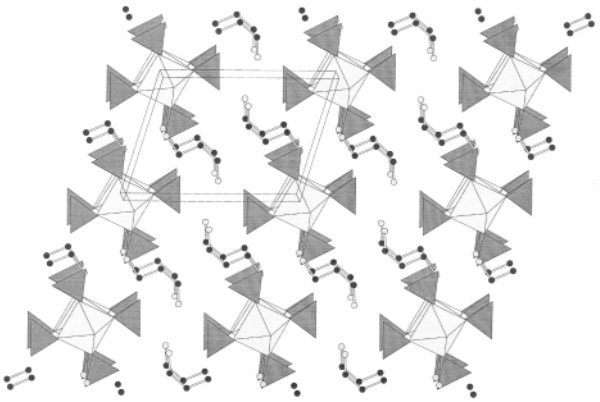

Fig. 2 A polyhedral view of the structure of $Ga(HPO_4)_2F{\cdot}H_3N(CH_2)_3NH_3{\cdot}2H_2O$ along *a*. Dark grey polyhedra are $\{PO_3OH\}$ tetrahedra and light grey polyhedra $\{GaO_4F_2\}$ octahedra. Black circles are carbon, and grey circles nitrogen. Occluded water molecules are not shown for clarity. The unit cell is shown by the faint line.

Such an observation will be of utmost importance in describing a reaction mechanism for the crystallisation and our structural data give some independent confirmation of this result. Heating **1** at 160 °C under hydrothermal conditions results in complete dissolution after ≈40 min followed by the almost immediate appearance of the 3D framework solid ULM-3.[17] Compound **1** may be thought of as a solid precursor to ULM-3 and we are investigating its possible transformation to other related gallium fluorophosphates, by the addition of other reagents. We have also recently shown that if H_3PO_4 is replaced by P_2O_5 in the room temperature reaction, a different gallium fluorophosphate is produced with a Ga:P ratio of 1:2. The structure of this second phase, which closely resembles material recovered by quenching from the hydrothermal synthesis of ULM-3 using P_2O_5,[6] we will report elsewhere.

We are grateful to the EPRSC, the Leverhulme Trust, the British Council (Alliance project) and the Novartis Trust Fund for financial support. We thank Dr C. C. Tang of Daresbury Laboratory for his assistance with measuring the powder diffraction data and Dr Lei Lixu for recording the infra-red spectra.

Notes and references

† The data were first analysed with a 'whole pattern fitting' algorithm to determine accurately the profile shape function, background and cell parameters. This preliminary study provided good estimates of R_{wp} and χ^2 that could be reached during structure refinement (16.9% and 2.0 respectively). The structure was solved in the space-group $P\bar{1}$. The gallium positions were located using the program EXPO.[18] The Reverse Monte Carlo program ESPOIR[19] was used to locate phosphorus and oxygen atoms of the inorganic framework, with gallium atoms fixed at the positions found by direct methods. The positions of the nitrogen and carbon atoms of the 1,3-diaminopropane and oxygen atoms of occluded water were found using Fourier difference maps with the previously found atoms constrained. In the final refinement cycle, atomic constraints on the inorganic macroanion (Ga–O, P–O and O–O distance constraints) were removed. A two-phase refinement was performed to account for the presence of the crystalline impurity GaOOH and the refinement converged with agreement factors R_p = 20.0%, R_{wp} = 18.4%, R_B = 9.6% χ^2 = 2.8.

Characterisation of a triply thiolate-bridged Ni–Fe amine–thiolate complex: insights into the electronic structure of the active site of [NiFe] hydrogenase†‡

Gunther Steinfeld and Berthold Kersting*

Institut für Anorganische und Analytische Chemie, Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany. E-mail: kerstber@sun2.ruf.uni-freiburg.de

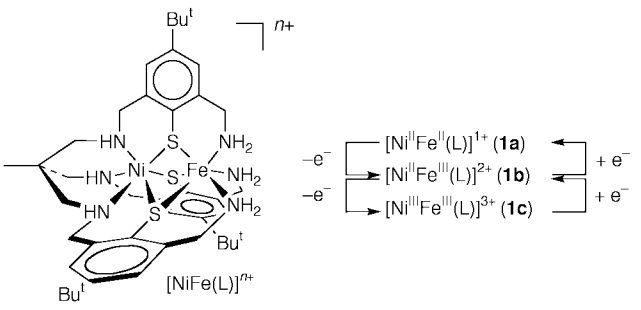
Received (in Basel, Switzerland) 7th October 1999, Accepted 5th January 2000

The synthesis and structural characterisation of a new Ni–Fe amine–thiolate complex are described; its chemical properties are related to the active site of [NiFe] hydrogenase.

The active site of the [NiFe] hydrogenase from *D. gigas* consists of a $(cys\text{-}S)_2Ni(\mu\text{-}cys\text{-}S)_2XFe(CO)(CN)_2$ bimetallic complex[1–3] that can exist in various redox states. Spectroscopic studies[4] and recent X-ray crystal structures of biological [NiFe] hydrogenases in their reduced, active forms[5] are indicative of changes in the electron density of both active site metal ions. The differences in the electron density could be due to the absence of a third bridging ligand X (which is a putative O^{2-} or OH^- ion in the oxidized, inactive form) or by the electron count of the Ni–Fe cluster. Despite the discovery of these active site features, the mechanism of biological hydrogen activation is still not well understood.[6] Model compounds are therefore being studied to understand the function of the more complex enzymes.[7] They also hold promise for cheap hydrogen catalysts, for example, in solar energy conversion.[3] Current studies focus on mono- and binuclear Fe thiolate complexes with Fe(CO) and Fe(CN) fragments[8] and Ni thiolate complexes.[9] However, only a few relevant NiFe complexes have been described.[10] We here describe the syntheses, X-ray structure and properties of a new heterobinuclear NiFe amine–thiolate complex which differs from previous examples by its reversible redox reactions.

The new complex $[Ni^{II}Fe^{II}(L)]^+$ (**1a**, Scheme 1) was obtained by reaction of $[Ni^{II}(L)]^-$ (prepared *in situ* from the nonadentate N_6S_3 ligand $H_3L{\cdot}6HCl$,[11] $NiCl_2{\cdot}6H_2O$, and NEt_3) with one equivalent of anhydrous $FeCl_2$ in methanol. It was isolated as the one-electron-oxidized form $[Ni^{II}Fe^{III}(L)]^{2+}$ in $\{[Ni^{II}Fe^{III}(L)]_2Cl\}[BPh_4]_3$ (**1b**) by exposing the reaction mixture to air and adding excess $NaBPh_4$.§

Crystallographic characterization of complex **1b**¶ confirmed the crystal structure to consist of a face-sharing bioctahedral NiFe complex, $[Ni^{II}Fe^{III}(L)]^{2+}$. The different metal–ligand bond lengths reflect the heterobinuclear nature of the C_3-symmetric complex (Fig. 1). It is assigned a $N'_3Ni^{II}(\mu\text{-}SR)_3Fe^{III}N_3$ core



Scheme 1

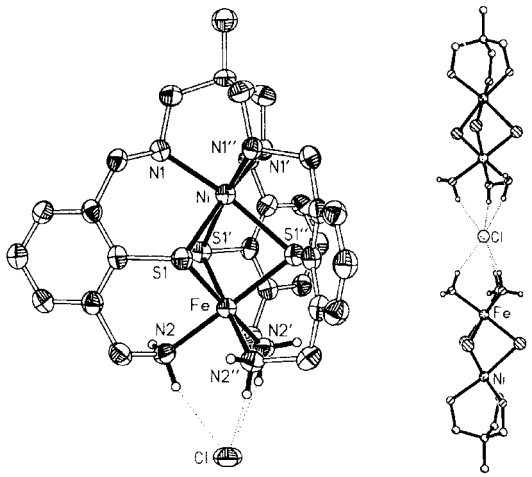

Fig. 1 Thermal ellipsoid plot of the $[Ni^{II}Fe^{III}(L)]^{2+}$ cation (left) and schematic representation of intermolecular hydrogen bonding interactions (right) in **1b**·12MeCN·H_2O. *tert*-Butyl groups and hydrogen atoms are omitted for clarity. Selected distances (Å) and angles (°): Ni–N(1) 2.083(4), Ni–S(1) 2.430(1), Fe–N(2) 2.047(4), Fe–S(1) 2.291(1); Fe–S(1)–Ni 79.79(5). Symmetry codes used to generate equivalent atoms: $1-x, x-y, z$ (′) and $1-x+y, 1-x, z$ (″).

structure‖ as the average M–N and M–S bond lengths of the N'_3NiS_3 site at 2.083(4) and 2.430(1) Å, respectively, match more closely with those of related $Ni^{II}N_3S_3$ complexes.[11] The short average M–N and M–S bond lengths of the other N_3MS_3 site at 2.047(4) and 2.291(1) Å confirm this assignment. These distances are too short for an octahedral $Ni^{II}N_3S_3$ complex, but are in excellent accord with those of low-spin Fe^{III} complexes in an octahedral N_3S_3 environment.[12–14] Preliminary results of ^{57}Fe Mössbauer spectroscopic investigations also support this oxidation state distribution (Fig. 2). At $T = 298$ K, **1b** gives rise to a single quadrupole doublet with $\delta = 0.26$ mm s^{-1} and $|\Delta E_Q| = 1.47$ mm s^{-1}, while at $T = 77$ K, $\delta = 0.32$ mm s^{-1} and $|\Delta E_Q| = 1.83$ mm s^{-1}. The temperature dependence of the quadrupole

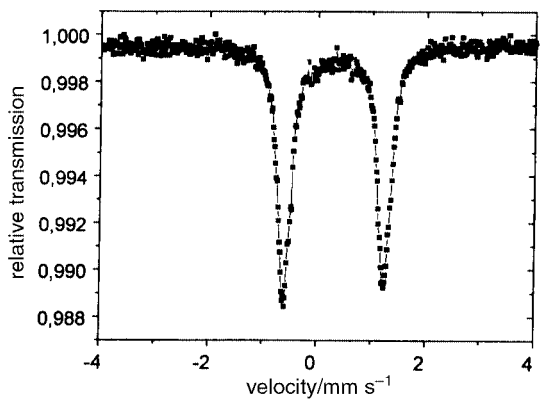

Fig. 2 ^{57}Fe Mössbauer spectrum of **1b**·12MeCN·H_2O at 77 K (relative to α-Fe).

splitting is consistent with the presence of a low-spin Fe^{III} ion.

It should be noted that the Ni···Fe distance at 3.030(1) Å is slightly longer than the Ni···Fe separation of 2.90 Å reported for the as isolated, inactive form of [NiFe] hydrogenase. The wide M–S–M angles [79.79(5)°], however, imply little, if any, attraction between the metal atoms.[14] The intermolecular hydrogen bonding interactions found for **1b** in the solid state are also worth mentioning: a chloride ion links two $[NiFe(L)]^{2+}$ dications *via* six equivalent N–H···Cl hydrogen bonding interactions (N···Cl 3.208 Å). In the resulting LNiFe···Cl···FeNiL subunit the intermolecular Fe···Fe and Ni···Ni distances are at 7.910(1) Å and 13.971(1) Å, respectively. It is unclear at present whether this assembly is retained in solution.

The 77K EPR powder spectrum of **1b** displayed a complex multiplet centered at $g \approx 2$ as the main component, a weaker resonance was observed at $g \approx 4$ (see ESI). Room temperature magnetic susceptibility measurements revealed the complex to be a paramagnetic species with $\mu_{eff} = 2.3\ \mu_B$. The results are indicative of an $S = \frac{1}{2}$ spin ground state which is most likely attained by an intramolecular antiferromagnetic exchange interaction between the Ni^{II} ($S_1 = 1$) and low-spin Fe^{III} ($S_2 = \frac{1}{2}$) ions. A cyclic voltammogram of **1b** in DMF solution displays two electrochemically reversible one-electron steps at $E^1_{1/2} = +0.45$ V [$\equiv E_{1/2}(Ni^{III}Fe^{III}/Ni^{II}Fe^{III})$] and at $E^2_{1/2} = -0.43$ V [$\equiv E_{1/2}(Ni^{II}Fe^{III}/Ni^{II}Fe^{II})$] *vs*. SCE. The CV is significantly different from those of homobinuclear complexes, $[Ni_2(L)]^{n+}$ and $[Fe_2(L)]^{n+}$,[11] and unambiguously confirms the heterobinuclear nature of **1b**.

There is a clearly discernible mutual influence of the constituent Fe^{III} and Ni^{II} ions on the respective $M^{III/II}$ potentials. Comparison with the electrochemical properties of homodinuclear complexes $[Ni_2(L)]^{n+}$ and $[Fe_2(L)]^{n+}$ reveals that the ferric ion raises the $Ni^{III/II}$ couple by *ca*. +400 mV to more anodic potentials, whereas the divalent Ni ion shifts the $Fe^{III/II}$ potential to more cathodic potentials. It is therefore plausible to assume that the reverse effects would occur in a complex in which $E_{1/2}(Fe^{III/II}) > E_{1/2}(Ni^{III/II})$, as for instance in the hydrogenase active site. Since the strong field ligands CO and CN^- keep the iron atom formally at the $+II$ oxidation level, a relatively low $Ni^{III/II}$ redox potential would result (at least for the oxidised, inactive form of the enzyme).

Compound **1b** is not a particularly close structural model of the active site of [NiFe] hydrogenase (lack of Fe-bound CO and CN^- ligands), however, it is an initial example for a thiolate-bridged NiFe complex which can exist in several different oxidation states. The effects of partial replacement of N or S donors of H_3L on the $M^{III/II}$ potentials of heterobinuclear NiFe complexes will be investigated in the future.

Financial support from the Deutsche Forschungsgemeinschaft is gratefully acknowledged. The authors thank Professor Dr C. Janiak for providing facilities for Mössbauer spectroscopic measurements.

§ An argon-purged solution of $H_3L{\cdot}6HCl$ (96 mg, 0.10 mmol) and $NiCl_2{\cdot}6H_2O$ (24 mg, 0.10 mmol) in methanol (10 mL) was treated with NEt_3 (90 mg, 0.90 mmol) to give a pale green solution. $FeCl_2$ (12.6 mg, 0.10 mmol) was then added. The mixture was stirred for 1 h under argon and then for 2 h with exposure to air. The resulting green-black solution was filtered. To the filtrate was added a solution of $NaBPh_4$ (0.17 g, 0.50 mmol) in methanol (1 mL). The green-black precipitate was isolated by filtration, washed with methanol and air-dried. Recrystallisation from acetonitrile afforded large single crystals of **1b**·12MeCN·H_2O (78 mg, 58%). Received (in Cambridge, UK) 29th November 1999, Accepted 17th December 1999

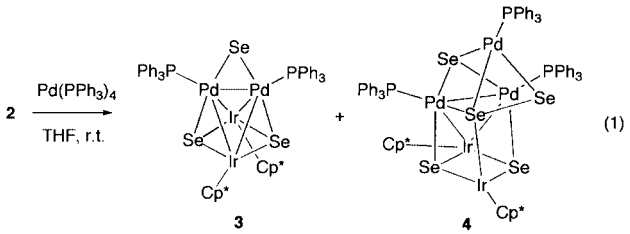
Treatment of $Cp^*IrCl(\mu\text{-}Cl)_2IrCp^*Cl$ ($Cp^* = \eta^5\text{-}C_5Me_5$) with Li_2Se_4 gave a tetraselenide-bridged diiridium complex $Cp^*Ir(\mu\text{-}Se_4)_2IrCp^*$, which reacted further with two equiv. of $Pd(PPh_3)_4$ to afford a mixture of bimetallic tetra- and penta-nuclear selenido clusters $(Cp^*Ir)_2\{Pd(PPh_3)\}_2(\mu_3\text{-}Se)_2(\mu_2\text{-}Se)$ and $(Cp^*Ir)_2\{Pd(PPh_3)\}_3(\mu_3\text{-}Se)_3(\mu_3\text{-}Se_2)$.

The chemistry of metal polysulfides has been progressing rapidly owing to their potential as synthetic reagents or catalysts as well as new materials. Stable polysulfide ligands are now known to be isolable with a variety of ring sizes and coordination modes,[1] which include a novel bridging nona-sulfide chain in $Cp^*Ir(\mu\text{-}SPr^i)_2(\mu\text{-}S_9)IrCp^*$ ($Cp^* = \eta^5\text{-}C_5Me_5$) prepared in this laboratory.[2] Recently, the coordination chemistry of inorganic selenium and tellurium ligands has also been attracting considerable attention.[1b,3] Hence, our studies on dinuclear noble metal–sulfur complexes consisting of half-sandwich Cp*M units[4] have been extended to related noble metal–selenium compounds.[5] Now we have found that reaction of $Cp^*IrCl(\mu\text{-}Cl)_2IrCp^*Cl$ **1** with Li_2Se_4 gives a complex containing a unique diiridium core bridged by two Se_4 ligands, $Cp^*Ir(\mu\text{-}Se_4)_2IrCp^*$ **2**.†



The structure of **2** has been determined in detail by X-ray analysis (Fig. 1).‡ In **2**, each of the Ir atoms has a chelating Se_4 ligand and is further bonded to either an α- or β-Se atom in the other Se_4 ligand. The distance between the two 18-electron Ir(III) centres is 4.179(3) Å. The Ir–Se bond lengths, varying from 2.42 to 2.50 Å, are comparable to those in $Cp^*Ir(PMe_3)(Se_4)$ [2.468(2) and 2.472(2) Å][6] and slightly shorter than that in $[Ir(Me_2PCH_2CH_2PMe_2)_2(Se_4)]Cl$ [2.542(3) Å],[7] while the Se–Se bond distances (2.28–2.41 Å) are unexceptional when compared with those in chelating tri- to penta-selenide ligands previously reported.[3b,c] The two $IrSe_4$ planes are folded and have envelope geometries. Thus, in the ring consisting of Ir(1) and Se(1)–Se(4), the Ir(1), Se(1), Se(3) and Se(4) atoms are almost coplanar within 0.003(4) Å while the distance of Se(2) from this least-square plane is 1.31 Å. For the other ring, the Se(6) atom is displaced 1.36 Å from the least-square plane defined by the Ir(2), Se(5), Se(7) and Se(8) atoms which show deviations of $< 0.10(2)$ Å. The $M(\mu\text{-}Se_4)_2M$ core observed in **2** is unprecedented, although the sulfur analogue has been demonstrated *via* the Rh complex $Cp^*Rh(\mu_2\text{-}S_4)_2RhCp^*$ obtained from the reaction of $Cp^*_2Rh_2(CO)_2$ with S_8.[8] More recently, the Ir complex $Cp^*Ir(\mu_2\text{-}S_4)_2IrCp^*$, produced from the reaction of $Cp^*Ir(2,5\text{-}Me_2C_4H_2S)$ with S_8 has been shown unequivocally to have a similar $M(\mu\text{-}S_4)_2M$ core,[9] while the complex generated by photolysis or thermolysis of $Cp^*Ir(S_4)(CO)$ was also formulated as $Cp^*Ir(\mu_2\text{-}S_4)_2IrCp^*$ based on spectroscopic data.[10]§

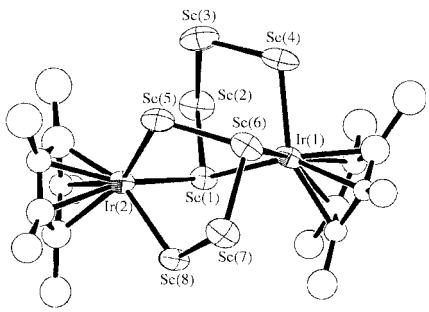


Fig. 1 Molecular structure of **2**. Hydrogen atoms are omitted for clarity. Selected bond distances (Å): Ir(1)–Se(1) 2.456(5), Ir(1)–Se(4) 2.468(5), Ir(1)–Se(6) 2.423(4), Ir(2)–Se(1) 2.454(5), Ir(2)–Se(5) 2.423(5), Ir(2)–Se(8) 2.496(5), Se(1)–Se(2) 2.405(7), Se(2)–Se(3) 2.285(7), Se(3)–Se(4) 2.309(8), Se(5)–Se(6) 2.312(7), Se(6)–Se(7) 2.391(7), Se(7)–Se(8) 2.325(7).

Although structures and reactivities of mixed-metal chalcogenido clusters are of particular interest, syntheses of mixed-metal selenido or tellurido clusters are still poorly explored in contrast to those of the corresponding sulfur compounds which have progressed rapidly. Employment of polychalcogenido complexes as precursors for synthesizing such clusters is essentially unexplored except for the reactions of certain dichalcogenido complexes with other low valent metal species giving chalcogenido clusters through E–E bond scission (E = S, Se or Te).[11] Transformation of **2** into mixed-metal clusters was therefore attempted, which led to the finding that when **2** was allowed to react with 2 equiv. of $Pd(PPh_3)_4$ in THF at room temperature, two readily characterizable Ir–Pd–Se clusters, $(Cp^*Ir)_2\{Pd(PPh_3)\}_2(\mu_3\text{-}Se)_2(\mu_2\text{-}Se)$ **3** and $(Cp^*Ir)_2\{Pd(PPh_3)\}_3(\mu_3\text{-}Se)_3(\mu_3\text{-}Se_2)$ **4**, were obtained in 11 and 12% yields, respectively.‡¶ In contrast, analogous treatment of **2** with $Pt(PPh_3)_4$ did not afford any tractable products.

Cluster **3** (Fig. 2) has a tetrahedral Ir_2Pd_2 framework having two capping selenido ligands on the Ir_2Pd faces and one bridging selenido ligand on the Pd–Pd bond. Among the six edges of the Ir_2Pd_2 tetrahedron, only the Ir–Ir separation of 3.4733(5) Å corresponds to a non-bonding interaction. The Ir–Se and Pd–Se bond lengths for the face-bridged Se(1) and Se(2) atoms, which are in the range 2.445(1)–2.455(1) Å, are slightly longer than the Pd(1)–Se and Pd(2)–Se distances for the edge-bridged Se(3) centre at 2.389(1) and 2.373(1) Å, respectively, and are not exceptional. In the ^1H and $^{31}P\{^1H\}$ NMR spectra, the protons of the two Cp* groups and the two P atoms appear

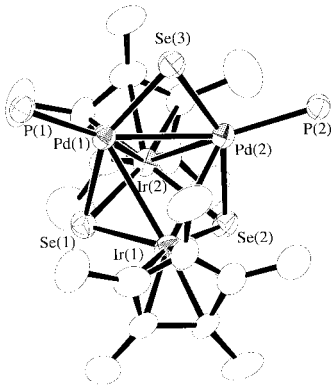

Fig. 2 Molecular structure of **3**. Hydrogen atoms are omitted for clarity. Selected interatomic distances (Å): Ir(1)–Pd(1) 2.9399(8), Ir(1)–Pd(2) 2.9530(8), Ir(2)–Pd(1) 2.9079(8), Ir(2)–Pd(2) 2.8584(8), Pd(1)–Pd(2) 2.773(1), Ir(1)–Ir(2) 3.4733(5).

as singlets, indicating a symmetrical structure with two mirror planes for **3** in solution.

Fig. 3 shows the structure of **4**,‡ whose core is composed of the $Ir_2Pd_2Se_3$ cluster framework of **3** as well as a triangular Pd(3)–Se(4)–Se(5) unit bound to it at the Pd(3) and Se(4) centres. The Se(4) atom is bound to Ir(2) and Pd(3) [2.472(1) and 2.526(1) Å], and weakly to Pd(2) [2.8510(9) Å], but not to Pd(1) [3.650(1) Å]. Owing to this unsymmetrical binding of the Se_2 ligand, no mirror plane exists for the cluster core and ^{1}H and ^{31}P NMR data are diagnostic of this structural feature. Metal–metal single-bonds are observed only for each of the three edges of the Ir(1)–Pd(1)–Pd(2) plane, although some bonding interaction may also be present between the Pd(1) and Pd(3) centres. Ignoring these metal–metal interactions, the geometries around Pd(1) and Pd(3) are distorted trigonal and square planar, respectively, while the Pd(2) atom has a trigonal pyramidal configuration with Se(4) at an apical position.

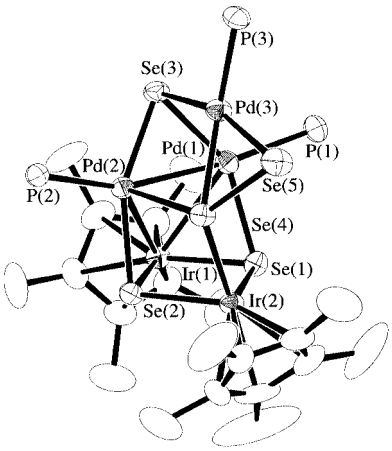

Fig. 3 Molecular structure of **4**. Hydrogen atoms are omitted for clarity. Selected interatomic distances (Å): Ir(1)–Pd(1) 2.8832(7), Ir(1)–Pd(2) 2.9175(8), Pd(1)–Pd(2) 2.7779(9), Ir(1)–Ir(2) 3.7640(4), Ir(2)–Pd(1) 3.9343(6), Ir(2)–Pd(2) 3.7644(7), Pd(1)–Pd(3) 3.079(9), Pd(2)–Pd(3) 3.2184(9).

In summary, a diiridium complex **2** containing two bridging Se_4 ligands has been prepared and characterized. A study on the reaction of **2** with $Pd(PPh_3)_4$ has verified that it serves as a versatile precursor for preparing mixed-metal Ir–Pd–Se clusters. It is of note that the sulfur analogue of **2**, $Cp^*Ir(\mu\text{-}S_4)_2IrCp^*$, did not give any characterizable products upon analogous treatment with $Pd(PPh_3)_4$. The reactivity of **2** towards other metal species as well as organic molecules is now under investigation.

Financial support by the Ministry of Education, Science, Sports, and Culture of Japan and The Iwatani Naoji Foundation's Research Grant (to Y. M.) is appreciated.

Notes and references

† Grey Se (1.74 g, 22.0 mmol) was suspended in THF (200 mL) and treated with 1.0 M $Li[BHEt_3]$ in THF (11 mL, 11 mmol) for 1 h at room temp. The resultant dark brown solution was warmed to 50 °C and **1** (1.99 g, 2.50 mmol) added. After stirring for 1 h at 50 °C, the mixture was dried *in vacuo* and the residue extracted with benzene. Addition of methanol to the concentrated extract afforded dark brown crystals of **2**·C_6H_6 (1.36 g, 40%). ^{1}H NMR ($CDCl_3$): δ 1.97, 1.71 (s, 15H, Cp*), 7.36 (s, 6H, C_6H_6). Anal. Peptide-encapsulated CdS nanoclusters from a combinatorial ligand library†

Glen Spreitzer, Jacqueline M. Whitling, Jeffry D. Madura and David W. Wright*

Department of Chemistry and Biochemistry, Duquesne University, Pittsburgh, PA 15282-1530, USA. E-mail: wrightd@duq.edu

Received (in Bloomington, IN, USA) 9th September 1999, Accepted 23rd December 1999

A spatially addressable combinatorial library of peptides, based on cysteine containing phytochelatins, has been shown to stabilize a variety of discrete CdS nanoclusters ranging in size from 19 to 26 Å in diameter.

Quantum confined structures have elicited a great deal of recent interest.[1] An important class of these compounds is the II–VI semiconductor nanoclusters exemplified by CdS. Although there are a variety of excellent techniques for the synthesis of these clusters, the use of thiolate ligands to cap the growing CdS cluster *in situ* yields nanoclusters more resistant to aggregation and more readily processable.[1e] Interestingly, a variety of yeast, plants and bacteria use a class of cysteine containing peptides known as phytochelatins to trap nearly monodisperse CdS nanoclusters, thereby efficiently sequestering a large number of cadmium ions per peptide.[2] The sequence of the phytochelatins is generally $(\gamma\text{-GluCys})_n\text{Gly}$, where *n* is the number of dipeptide repeats.[3] Comparisons between the $(\gamma\text{-GluCys})_2\text{Gly}$ peptide and the more common α-peptide linkage show that $(\alpha\text{-GluCys})_2\text{Gly}$ stabilizes smaller nanoclusters with higher band gap transitions than those with γ-linkages.[4] To investigate the influence of thiolate separation in multidentate capping peptides on the stabilization of various populations of CdS nanoclusters, a spatially addressable combinatorial library in which the spacer amino acids have been systematically varied for the n_3 phytochelatin, X-Cys-Y-Cys-Z-Cys-Gly, has been synthesized. We report, herein, the analysis of those peptides that lie along the library's diagonal in which X, Y, and Z are equivalent amino acids.

Based on the n_3 phytochelatin sequence X-Cys-Y-Cys-Z-Cys-Gly, the cysteine residues are kept constant, while the spacer residues are varied over all combinations of the spacer amino acids, resulting in an initial library of 125 peptide ligands. The five selected spacer residues include α-Glu, γ-Glu, γ-aminobutyric acid (GABA), SerGly and ε-aminohexanoic acid (ε-Ahx). The spacer residues include natural and non-natural amino acids having between 3 to 7 atoms in the backbone and spanning an idealized extended C_α–C_α distance between the cysteines ranging from 3.75 Å to 8.7 Å, respectively.[5] Additionally, the spacer residues provide a wide range of hydrophilicity. The library was synthesized using Chiron Technologies PepSets system.[6] Peptide synthesis yielded approximately 1 mmol of each target ligand. Control peptides were greater than 97% pure by HPLC and mass spectrometry (see Electronic Supplementary Information).

The peptides were reacted anaerobically with Cd^{2+} and S^{2-} in aqueous Tris buffer (100 mM, pH 8.6) in a 1.25 : 1 : 1 ratio, respectively, for 4 h.‡ Since all of the ligands in the library are likely to stabilize CdS cluster formation, it is important that multiple screens be applied to the reaction mixtures in order to develop meaningful selection criteria for a specific nanocluster characteristic. The resulting reaction mixtures were subjected to an array of screens to assess size, monodispersity, photooptical properties, photocatalytic potential and stability. The selected screens encompass many of the most commonly cited critical parameters for this class of compounds.[1] It should be emphasized that the employed screens are designed to maximize the information about any given peptide–cluster aggregation reaction, not to definitively characterize the reaction product. The results from the analysis of the library's diagonal are given in Table 1.

Table 1 Results of combinatorial library screens

	318	10.89	426		

[a] e, γ-Glu; E, α-Glu; g, GABA; h, ε-Ahx; S, Ser; G, Gly. [b] These results are consistent with those reported in refs. 2, 7 and 8. [c] After 24 h reaction time λ_{max} was 338 nm. R_{est} was 11.7 Å. All other reactions were unchanged after 24 h. [d] Ref 11.

The UV-visible absorption spectra of the resulting nanoclusters are shown in Fig. 1. The results indicate that each of the examined peptides is capable of stabilizing discrete populations of nanoclusters. The observed λ_{max} for the absorption spectra of the encapsulated $(\alpha\text{-GluCys})_3\text{Gly/CdS}$ (**1**) and $(\gamma\text{-GluCys})_3\text{Gly/CdS}$ (**2**) clusters at 306 and 320 nm, respectively, correspond well with previous reports for the *in vitro* synthesis of CdS nanoclusters using these peptides obtained from solid-phase peptide synthesis techniques or isolated from biological sources.[3] The absorption spectra for $(\text{GABACys})_3\text{Gly/CdS}$ (**3**) and $(\text{SerGlyCys})_3\text{Gly/CdS}$ (**4**) reveal similar distributions of clusters with λ_{max} near 313 nm. The absorption spectrum of the CdS clusters encapsulated by $(\varepsilon\text{-AhxCys})_3\text{Gly}$ (**5**) show two distinct populations of clusters centered with λ_{max} of 284 and 318 nm. Examination of **5** after 24 h shows a marked decrease in the cluster populations with λ_{max} centered near 282 and a new major population with λ_{max} centered at 338 nm. These results suggest that the cluster populations observed for the capping ligand $(\varepsilon\text{-AhxCys})_3\text{Gly}$ at 4 h represent intermediate metastable clusters which over time aggregate into the final cluster.

The photophysical properties of synthetic semiconductor nanoclusters are dictated by surface-mediated phenomena.[1a,b] Ultraviolet irradiation of the individual reaction mixtures at the respective absorption maxima resulted in luminescence in the visible spectral region with emission maxima ranging from 410 to 460 nm (Electronic Supplementary Information). The fluorescence behavior of clusters **1** and **2** is in good agreement with previously reported values.[3] Anaerobic excitation of all of the peptide encapsulated CdS nanoclusters in the presence of methyl viologen resulted in the reduction of the dye as monitored by characteristic absorbances near 380 and 600 nm. A significant back-reaction attributable to reoxidation of the dye by trapped holes (h+) on the particle's surface was also observed (Electronic Supplementary Information). In contrast to reports of glutathione (γ-GluCysGly) stabilized CdS nano-

clusters,[7,8] none of the examined nanoclusters were competent photocatalysts for the oxidative degradation of *p*-nitrophenol (PNP).

Each reaction mixture was examined for dispersity by size exclusion chromatography (Electronic Supplementary Information).[9] Chromatographic analysis of **1** and **2** revealed one major nanocluster containing fraction each, with an absorption maxima and full width at half maximum (FWHM) of the absorption peak essentially unchanged from that of the reaction mixture. Chromatograms of **3** and **4** had one major nanocluster fraction each, with a significant red shift in both the absorption maxima by 4 and 13 nm, respectively, and a 10–17% change in the absorption peak's FWHM. The resulting red shift is indicative of the separation of some fraction of smaller CdS clusters. The chromatogram of **5** resolved two major nanocluster fractions, the first containing only clusters with λ_{max} of 284 nm, while the second peak was a mixture of clusters with λ_{max} at 284 and 318 nm. The ratio of the two cluster populations is significantly altered from the crude reaction mixture demonstrating that two clusters are in fact being resolved. The chromatographic analysis clearly reveals that increasing the degree of rotational freedom within the spacer residue of the trapping ligand decreases the monodispersity of the resulting nanoclusters at the arbitrarily fixed end-point of the assay.

To verify the size of the resulting peptide-encapsulated CdS nanoclusters, a simplified compositional model of **1** and **2** was constructed using the methods of Dameron and Dance.[10] The model for the CdS core assumes an approximately equidimensional fragment of the cubic (sphalerite) lattice.§ The sizes of the CdS cores were estimated from the UV-vis spectra using Brus' effective mass model.[11] With a limiting cluster size, the number of peptides coating the particle was extrapolated from an analysis of S atom coordination. Based upon these models, the combined molecular weight of the peptide coat and CdS core was determined to be approximately 28 000 Da for nanoclusters **1** and **2**. The observed molecular weights from size-exclusion chromatographic analysis for **1** (30 137 + 5% Da) and **2** (28 438 + 5% Da) are in excellent agreement with this simplified compositional model. Similar modeling of clusters **3**–**5** is currently underway.

Through the use of a spatially addressable combinatorial library of peptide ligands inspired by the known phytochelatin sequence, peptide-coated CdS quantum-confined clusters have been synthesized. Analysis of the library's diagonal shows that the cluster size increases with the number of spacer bonds between the cysteine residues from 19.2 Å diameter for the peptide chelate $(\alpha\text{-GluCys})_3$Gly to 23.4 Å diameter for $(\varepsilon\text{-AhxCys})_3$Gly, resulting in a series of robust, photo-reductive clusters. The mechanism of size stabilizing selectivity is probably mediated by those peptides and/or peptide–$(Cd^{2+})_n$ complexes that trap growing nanoclusters when the surface of the aggregate presents sites which match the conformational spacing of the peptide or peptide complex. Such a mechanism, analogous to those proposed for the *in vivo* response of CdS sequestering organisms,[2] has important ramifications in the ability to control aggregation. From the perspective of the trapping moiety, it predicts that those peptides with greater degrees of rotational freedom in the peptide backbone may trap a variety of intermediate cluster sizes that are metastable due to steric crowding of the surface peptide coat and non-optimal surface coordination. From the perspective of the growing cluster, a trapping mechanism leads to stabilization of intermediate clusters with coordinatively unsaturated Cd^{2+} or S^{2-} ions that are shielded by the packing of the surface peptide coat. Such intermediate clusters eventually aggregate to more optimal sizes and surface coordination. This trapping termination of the growing aggregate is consistent with the intermediate clusters observed in the formation of **5**, as well as the increase in dispersity for those clusters encapsulated by peptides with greater degrees of rotational freedom. The complete analysis of the entire library is expected to produce important conceptual information about chelate features and lattice matching critical for the stabilization of CdS nanoclusters of specific size.

Notes and references

‡ The peptide (1 mmol) was disolved in 100 μL DMSO + 900 μL 0.1% TFA solution. In a 4 mL septum sealed vial, 250 μL peptide (1 mM) solution, 100 μL $CdCl_2$ (2 mM, 0.01 M HCl) solution and 1550 μL Tris (0.1 M, pH 8.5) were combined. With stirring, 100 μL aqueous Na_2S solution (2 mM) was added dropwise to the reaction mixture. After 4 h, the reaction solution was filtered through a 0.2 μm PVDF syringe filter for analysis.

§ The CdS lattice was constructed using the crystal builder feature of MOE (Chemical Computing Group, Inc., http://www.chemcomp.com). The lattice parameters used were space group $F\bar{4}3m$ with $a = b = c = 5.832$ Å and $\alpha = \beta = \gamma = 90°$. The unique Cd position was (0,0,0) and the unique S position was (0.25, 0.25, 0.25). The sphere was cut from a $6 \times 6 \times 6$ supercell using the proximity feature of MOE.

Received (in Basel, Switzerland) 21st October 1999, Accepted 2nd January 2000

Two new methods for the formation of $CpRe(CO)_3$ substituted steroids are presented; both imply a one-pot procedure involving a transmetallation process.

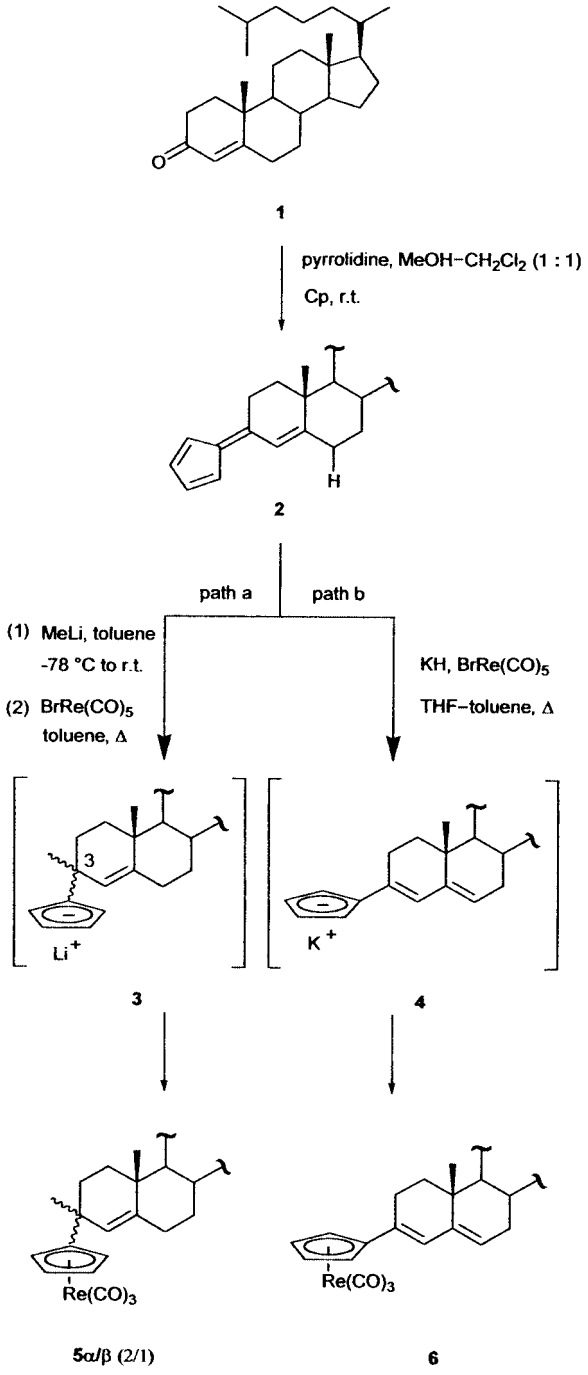
The emergence of bioorganometallic chemistry[1] has benefited from the enormous amount of synthetic work that has been done to prepare all kinds of organometallic compounds over the last half-century. However, access to compounds for use in bioorganometallic chemistry is not always achieved merely by adopting synthetic methods used in classical organometallic chemistry. This is particulary true in the challenging area of low valent organometallic radiopharmaceuticals of ^{186}Re, ^{188}Re and ^{99m}Tc[2] which requires the devising of new reactions in order to introduce the radioactive element onto the bioligand in the last step of the process. The fixation of a small, compact, robust and non polar substituted cyclopentadienyltricarbonylrhenium unit [$CpRe(CO)_3$] appears to be a strategic objective with this respect. In this field, we previously reported the synthesis of a large number of substituted steroids. Among them, a non-radioactive $CpRe(CO)_3$ oestradiol derivative has been shown to have an excellent binding affinity for the oestrogen receptor (ER) when fixed at the 17α position.[3] We present here another route to attach this organometallic unit based on the introduction of fulvenes in other selected positions of steroids, which allows the introduction of the $CpRe(CO)_3$ fragment in the last step of the synthesis.

Fulvenes are easier to characterize and synthesize than the corresponding cyclopentadienes, which are often not stable and exist as mixtures of isomers.[4] As a source of rhenium we chose bromorhenium pentacarbonyl [$BrRe(CO)_5$] which can be used in a transmetallation process leading to substituted $CpRe(CO)_3$. Furthermore, we recently reported[5] a mild one pot access to this reagent starting from ammonium perrhenate, a Re^{VII} precursor which is easily accessible in radioactive forms.[6,7]

In a preliminary study, we began with cholest-4-en-3-one **1**. This compound was first submitted to the conditions reported by Little and Stone[8] for other substrates, to afford the corresponding fulvene **2** in less than 30% yield (Scheme 1). These results were attributed to the poor solubility of starting materials in MeOH. A thorough screening of solvents showed that the use of CH_2Cl_2 as cosolvent (MeOH–CH_2Cl_2 = 1:1) greatly enhanced yield (up to 70%) for the formation of **2**.

According to path (*a*) fulvene **2** was treated with MeLi in toluene at −78 °C and warmed to room temperature for 3 h. The resulting intermediate **3** was then submitted to transmetallation conditions[9]—$BrRe(CO)_5$ was added and the reaction mixture was heated to reflux for 15 h. Under these conditions, two diastereomers **5α/β** were produced in a 2:1 ratio in 39% yield which are distinguished by their relative configuration at the newly formed stereogenic center (steroid carbon center C-3). The major product was crystallized from CH_2Cl_2–hexane. An X-ray structural analysis shows that the newly introduced methyl substituent is attached to the α face of the steroid framework (Fig. 1).†

According to path (b), the fulvene **2**, KH and $BrRe(CO)_5$ were heated (110 °C) in a mixture of THF and toluene for only 1.6 h to give, after flash chromatography, the substituted $CpRe(CO)_3$ **6** in 67% yield.‡ No products resulting from the



Scheme 1

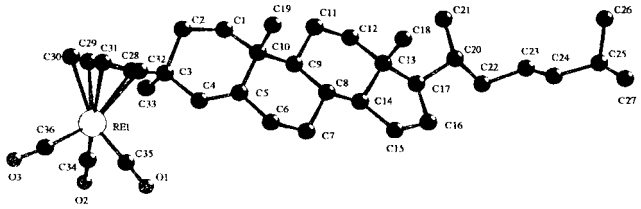


Fig. 1 X-Ray structure of **5α**.

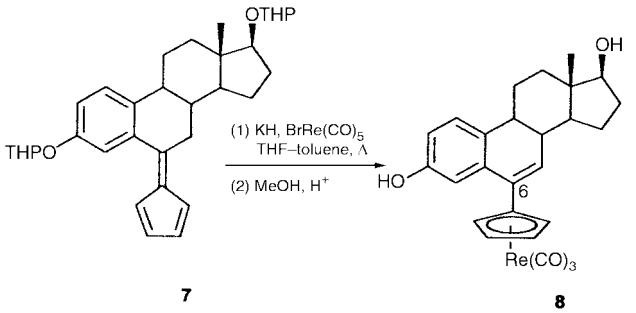

7 **8**

Scheme 2

deprotonation of the C-2 position were isolated using these conditions. In both cases, longer reaction times did not improve the yield, probably because of the degradation of the starting materials.

This second strategy was applied to the synthesis of an oestradiol derivative (Scheme 2). Thus, the fulvene **7**, obtained from the corresponding 6-oxoestradiol,[10] was submitted to the conditions of path (b). An acidic work up (MeOH, cat. TsOH) gives access to **8,** the first oestradiol derivative bearing an organometallic unit at the C-6 position. The relative binding affinity (RBA) of this complex for the ER was measured on lamb uterine cytosol according to a previously reported procedure.[11] Compound **8** is still recognized by the ER even if the RBA value is low (0.5%). This result confirms that a bulky substitution at C-6 induces a dramatic decrease in the affinity of the modified hormone for the ER.[12–14]

In conclusion, the results presented illustrate a new route to $CpRe(CO)_3$ substituted steroids. They show that (i) the introduction of the metal carbonyl unit on a steroid in the last step of the synthesis is possible [for this purpose, fulvenes are more interesting than the corresponding cyclopentadienes because of the great number of products accessible according to the conditions (basic versus nucleophilic) used] and (ii) $BrRe(CO)_5$ is a suitable precursor for the elaboration of $CpRe(CO)_3$ units in organic solvents.[15] We thus hope that this new strategy will greatly enhance progress in the area of organometallic radiopharmaceuticals.

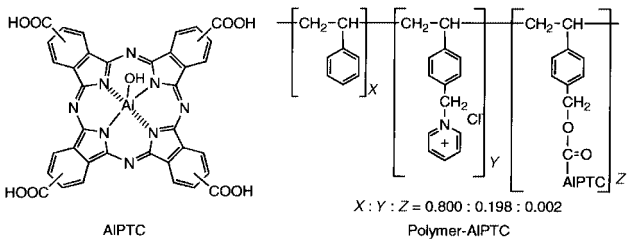
Received (in Cambridge, UK) 29th November 1999, Accepted 4th January 2000

A new water-insoluble polymer solid photosensitizer, prepared from an aluminium(III) tetracaboxyphthalocyanine and poly(styrene-*co*-chloromethylstyrene), has a photosensitizing ability for the photo-oxidation of phenol with singlet oxygen.

The photo-oxidation reactions of sulfides,[1,2] thiols,[3,4] phenols[5–7] and other organic compounds[8–11] have been reported using various low molecular weight photosensitizers such as Rose Bengal, Methylene Blue, porphyrins and phthalocyanines. Although these photosensitizers show high reaction activity, they are difficult to remove from the reaction cell because they are homogeneous. The use of polymer solid photosensitizers is expected to overcome this problem. Compared with low molecular weight photosensitizers, however, there are few reports on the application of polymer solid photosensitizers to photo-oxidation reactions.[12–14] Here, we describe the synthesis and characterization of a new water-insoluble polymer solid photosensitizer prepared from an aluminium(III) tetracaboxyphthalocyanine and poly[(styrene)-*co*-(4-chloromethylstyrene)] (polymer-AlPTC). Furthermore, the photo-oxidation of phenol is investigated in aqueous solution.

The poly[(styrene)-*co*-(4-chloromethylstyrene)] (St-*co*-CMSt) was prepared by free-radical copolymerization of styrene and 4-chloromethylstyrene with benzoyl peroxide as initiator in bulk. The degree of copolymerization was styrene:chloromethylstyrene = 0.8:0.2 (molar percentage), determined by elemental analysis and ^{1}H NMR. Gel permeation chromatography (GPC) measurements using polystyrene standards showed an average molecular weight of 8.0×10^4. The preparation of polymer-AlPTC was carried out as follows. St-*co*-CMSt (2.0 g) and aluminium(III) tetracarboxyphthalocyanine[3] (0.05 g) were heated at 90 °C for 24 h under a nitrogen atmosphere in a mixture of freshly distilled DMSO (20 ml) and acetone (10 ml). An excess of pyridine (20 ml) was added, and the heating was continued for 24 h. After the unreacted pyridine and acetone were completely removed by evaporation, the solution was slowly poured onto vigorous stirring Et_2O. The light green precipitate was filtered, washed with Et_2O, and then dried *in vacuo* for 12 h. The pure polymer-AlTPC, which is identified by elemental analysis, FTIR, and absorption spectrum measurements,[15] is shown below.



The absorption spectrum of the polymer-AlPTC in DMF showed an absorption maximum at 688 nm with a molecular absorption coefficient of *ca.* 40 000 in the visible region, which almost corresponded with that of AlPTC.[3] Although the copolymer of styrene and pyridiniomethylstyrene, corresponding to the parent copolymer of the polymer-AlPTC, is water-soluble, the polymer-AlPTC is water-insoluble. This is because the polymer-AlPTC has a structure which is partially bridged by AlPTC.

The photo-oxidation experiments were performed at 25 °C in an oxygen-saturated aqueous solution of pH 7, adjusted using a KH_2PO_4/Na_2HPO_4 buffer. A sample tube containing 2.0×10^{-6} mol dm^{-3} AlPTC or 0.84 mg polymer-AlPTC film (the same molarity as AlPTC) and 2.0×10^{-4} mol dm^{-3} phenol in aqueous solution (3 ml) was bubbled with oxygen for 10 min, and the capped sample solution was irradiated with a 300 W slide projector equipped with a UV cut-off filter ($\lambda > 440$ nm). The reaction was monitored by UV–VIS absorption spectrum measurements and also followed by GC and FTIR analyses.

Upon visible light irradiation of an oxygen-saturated aqueous solution of phenol and polymer photosensitizer, a new absorption band around 248 nm, characteristic for 1,4-benzoquinone (BQ),[14] increased. Fig. 1 shows the absorption spectral change in the heterogeneous reaction solution upon visible light irradiation at pH 7, and the initial formation rates of 1,4-benzoquinone are summarized in Table 1 In the presence of NaN_3 as

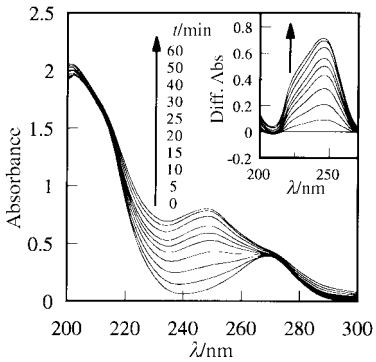


Fig. 1 Absorption spectral changes in an aqueous solution of polymer-AlPTC and phenol at pH 7 upon visible light irradiation. Inset: differential absorption spectral changes.

Table 1 Initial formation rates at pH 7 for polymer-AlPTC and AlPTC systems

	Initial rate[a]/mol dm^{-3} min^{-1}	[BQ][b]/mol dm^{-3}

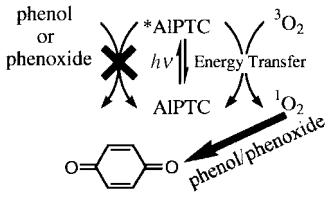

Scheme 1

a singlet oxygen quencher, the reaction rate and the amount of BQ formed are very small, and BQ does not form under Ar. Moreover, the absorption spectral change was not observed in the dark. These facts indicate that the present reaction is induced by excitation of the sensitizer itself and is the oxidation of phenol with singlet oxygen generated as shown in Scheme 1. Surprisingly, the photo-oxidation reaction using AlPTC photosensitizer, corresponding to the low molecular weight model complex, did not occur in a homogeneous aqueous solution at pH 7.[16] The polymer-AlPTC has hydrophobic segments (styrene residues) and positively charged segments (pyridinium residues) in the polymer backbone. These residues would concentrate phenol and/or phenoxide anion through hydrophobic and electrostatic attraction. Furthermore, the polymer-AlPTC can be readily separated by filtration from the reaction solution.

This work was supported by a Grant-in-Aid for COE Research (10CE2003) by the Ministry of Education, Science, Sports and Culture of Japan.

Tetrathiafulvalene–phenanthroline macrocycles as redox responsive sensors for metal ions

Kia Svane Bang, Mogens Brøndsted Nielsen, Roman Zubarev and Jan Becher*

Department of Chemistry, University of Southern Denmark (Odense University), Campusvej 55, DK-5230, Odense M, Denmark. E-mail: jbe@chem.sdu.dk

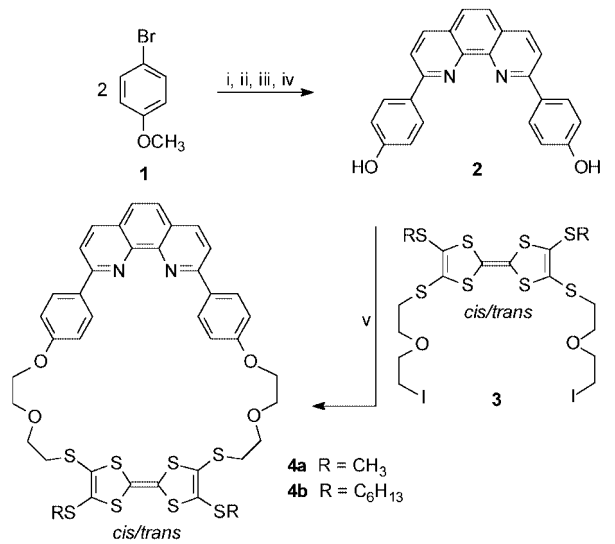
Received (in Cambridge, UK) 29th November 1999, Accepted 5th January 2000

Macrocycles containing a redox-active tetrathiafulvalene unit together with a phenanthroline ligand are able to recognise different metal ions (Cu^+, Ag^+ and Li^+) when part of a precatenate complex.

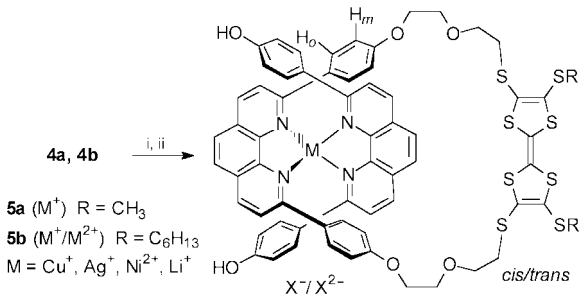
The redox responsive unit tetrathiafulvalene (TTF) has been incorporated into a number of oxygen, nitrogen and sulfur based crown ethers, resulting in sensors that are able to recognise alkali metal ions as well as silver and barium ions.[1] The strategy of using the templating abilities of Cu^+ to coordinate two phenanthroline ligands in a tetrahedral complex, originally developed by Sauvage and coworkers,[2] has been employed to prepare a TTF-containing Cu(I)-catenate.[3] Using this same strategy, we now report the use of TTF as a sensor unit for the metal ions Cu^+, Ag^+ and Li^+ in precatenate complexes (**5a**,**b**, **7**).

Synthesis of TTF–phenanthroline macrocycles **4a**,**b** were accomplished, using a modified procedure,[2] according to the route outlined in Scheme 1. First, *p*-anisyllithium was prepared by lithiation of *p*-bromoanisole using Bu^{t}Li and it was subsequently treated with 1,10-phenanthroline, affording a disubstituted tetrahydrophenanthroline derivative. Re-aromatisation upon treatment with MnO_2 afforded 2,9-di(*p*-methoxyphenol)-1,10-phenanthroline. Cleavage of the methylphenyl ether proceeded almost quantitatively in a reaction with anhydrous pyridinium hydrochloride, and after neutralisation with NaOH the diphenol **2** was isolated. *O*-alkylation of **2** with the TTF–diiodide **3**[4] under high-dilution conditions in the presence of Cs_2CO_3 gave the TTF–phenanthroline macrocycles **4a**,**b** in yields of 50–60%.

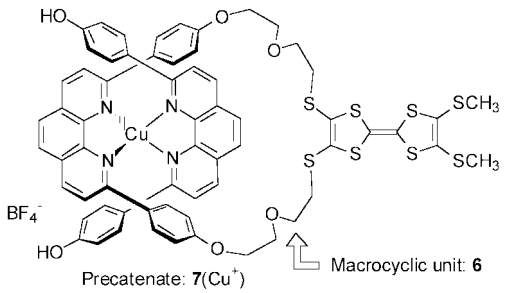
To a 1:1 mixture of the macrocycle and a metal salt, either $Cu(CH_3CN)_4BF_4$, $AgBF_4$, $NiSO_4{\cdot}7H_2O$ or $LiPF_6$, in CH_2Cl_2–CH_3CN (1:1) was added one equivalent of the molecular thread **2** dissolved in a very small amount of DMF (Scheme 2). In order to ensure the highest possible degree of complexation, the mixture was stirred overnight and then concentrated *in vacuo* to the solid complexes **5a**,**b**. The macrocycle **6** and its Cu^+ precatenate **7** were prepared in a similar manner.



Scheme 1 *Reagents and conditions:* i, Bu^{t}Li (2.5 equiv.), Et_2O, −30 °C; ii, 1,10-phenanthroline (0.27 equiv.), toluene, room temp.; iii, MnO_2, CH_2Cl_2, room temp.; iv, C_5H_5N, conc. HCl, 210 °C; 39% (4 steps); v, Cs_2CO_3 (3 equiv.), DMF, 60 °C, 50–60%.



Scheme 2 *Reagents and conditions:* i, MX (1 equiv.) [$Cu(CH_3CN)_4BF_4$, $AgBF_4$, $NiSO_4{\cdot}7H_2O$ or $LiPF_6$], CH_2Cl_2–CH_3CN (1:1), room temp.; ii, 2,9-(*p*-hydroxyphenyl)-1,10-phenanthroline (1 equiv.)/DMF, room temp.



The isolated complexes were first studied by ^{1}H NMR spectroscopy.† Significant chemical shift changes relative to the free macrocycle were observed for the aromatic protons of **5a**,**b** when M^+ = Cu^+, Ag^+ or Li^+ and for **7**(Cu^+) (Table 1). In particular, a *ca.* 1 ppm upfield shift of the eight *ortho* and *meta* phenolic protons on the macrocyclic unit confirmed that the complexations had occurred nearly quantitatively for these three metal ions, however, integration of signals were compli-

cated by rather broad signals for both the Ag^+ and Li^+ precatenates. A purity of *ca*. 95% is estimated for the isolated complex **7**(Cu^+) from its relatively simple ^1H NMR spectrum (devoid of *cis/trans* isomerism). No significant changes in the proton resonances of the macrocyclic unit were observed for the isolated product containing Ni^{2+}, indicating that the Ni^{2+}-precatenate had not been formed at all. This zero-yield is probably a result of the reluctance of a Ni^{2+} complex to adopt the tetrahedral geometry enforced by the precatenate structure.

Both MALDI and ESI mass spectrometry are useful techniques for characterising precatenates of this type. Studies on the Cu^+ based precatenates show that an applicable amount of the complex is transferred to the gas phase without dethreading. Thus, the mass spectra of **5a**(Cu^+) and **7**(Cu^+) reveal a peak at *m/z* 1291 ($z = 1$) which can be assigned to the singly charged Cu^+ containing precatenate (without the BF_4^- counter ion). However, fragmentation peaks corresponding to the dethreaded macrocycle with and without Cu^+ are also seen.

The redox behaviour of the complexes was studied by cyclic voltammetry and differential pulse voltammetry.[5] The voltammograms of the precatenate **5a**(Cu^+) (Fig. 1(a),(b)) show large anodic shifts relative to the free macrocycle of both the first and second TTF redox potentials as a result of the electrostatic influence exerted by the metal ion (Table 2). In between the two TTF oxidations, Cu^+ is oxidised to Cu^{2+}. The generated Cu^{2+} is not expelled but maintained in the complex since the second TTF oxidation is also affected by the presence of a positively charged metal center. It is noteworthy that the cyclic voltammogram of **5a**(Cu^+) shows the three redox processes to be reversible.

For **5b**(Ag^+) the two TTF oxidations are also shifted to higher potentials, which indicates that the Ag^+ ion is also complexed after the first TTF oxidation. However, even though the ^1H NMR spectrum in $CDCl_3$–CD_3CN (1 : 1) showed clear evidence for the formation of the **5b**(Li^+) precatenate, the TTF redox potentials were almost unaltered according to differential pulse

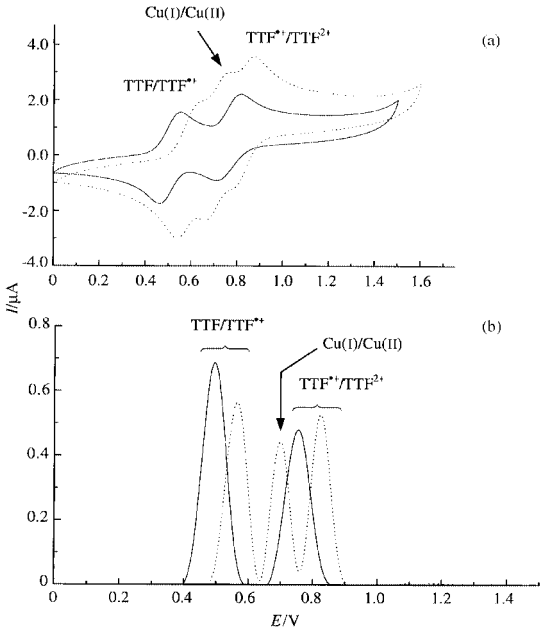

Fig. 1 (a) Cyclic voltammogram (scan rate 100 mV s^{-1}) and (b) differential pulse voltammogram of **4a** (—) and **5a**(Cu^+)BF_4^- (···) in CH_2Cl_2 containing 0.1 M NBu_4PF_6.

Compound	E_{ox}^1/V ($TTF^{\cdot+}/TTF^{+}$)	ΔE_{ox}^1/V	E_{ox}^2/V ($TTF^{\cdot+}/TTF^{2+}$)	ΔE_{ox}^2/V
4a	0.49	—	0.75	—
4b	0.53	—	0.78	—
5a(Cu^+)[a]	0.56	0.07	0.82	0.07
5b(Ag^+)	0.58	0.05	0.85	0.07
5b(Li^+)	0.54	0.01	0.79	0.01
6	0.44	—	0.80	—
7(Cu^+)[b]	0.54	0.10	0.83	0.03

[a] $E_{ox}(Cu^+/Cu^{2+}) = 0.70$ V. [b] $E_{ox}(Cu^+/Cu^{2+}) = 0.69$ V.

voltammetry. Thus, it seems that the precatenate is disrupted in the relatively polar solvent (0.1 M NBu_4PF_6 in CH_2Cl_2) used for the electrochemical studies. In agreement with this observation, Sauvage and coworkers found that the Li^+ complex was unstable in the polar solvent DMF.[6] For **7**(Cu^+) the first TTF oxidation is significantly shifted, whereas the second is less influenced.

In conclusion, we have investigated the ability of TTF–phenanthroline macrocycles to form precatenate complexes with different metal ions. The appearance of large shifts in the two TTF redox potentials for the Cu^+ and Ag^+ complexes demonstrates the advantage of employing such macrocycles as possible redox responsive sensors for transition metal ions.

Stereoselective catalytic hydrogenation of sorbic acid and sorbic alcohol with new Cp*Ru complexes†

Stephan Steines,[a] Ulli Englert[b] and Birgit Drießen-Hölscher*[a]

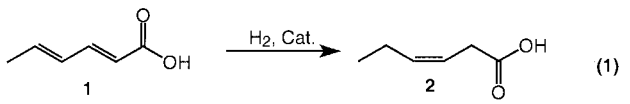
[a] *Institut f. Technische Chemie und Petrolchemie, RWTH Aachen, Templergraben 55, D-52056 Aachen, Germany. E-mail: drihoel@itc.rwth-aachen.de*

[b] *Institut f. Anorganische Chemie, RWTH Aachen, Templergraben 55, D-52056 Aachen, Germany*

Received (in Cambridge, UK) 26th November 1999, Accepted 6th January 2000

The new Cp*Ru complexes [Cp*Ru(η⁴-MeCH=CHCH=CHCO$_2$H)]$^+$X$^-$ (X$^-$ = $CF_3SO_3^-$ or [B{C$_6$H$_3$(CF$_3$)$_2$-3,5}$_4$]$^-$) are very effective catalysts for the hydrogenation of sorbic acid to *cis*-hex-3-enoic acid and of sorbic alcohol to *cis*-hex-3-en-1-ol (leaf alcohol) under mild conditions in liquid two-phase systems.

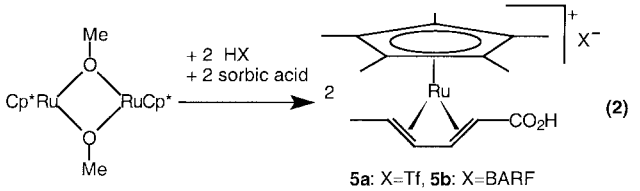
When sorbic acid **1**, a widely used preservative, or sorbic alcohol are hydrogenated, different products might occur. The mono-unsaturated products are of technical interest for the production of fragrances and vitamins.[1] This work focuses on the stereoselective preparation of *cis*-hex-3-enoic acid **2** [eqn. (1)] and of *cis*-hex-3-en-1-ol **3**, a fragrance commercialized as 'leaf alcohol'.



(1)

In early studies Frankel and coworkers showed that methylsorbate and sorbic alcohol can be catalytically hydrogenated by chromium(0) carbonyl compounds with high selectivities to methyl-*cis*-hex-3-enoate and to *cis*-hex-3-en-1-ol, respectively.[2a–d] Unfortunately the reaction only works with sorbic acid esters and sorbic alcohol but not with the cheaper sorbic acid **1**, and one must use toxic chromium catalysts and high catalyst/substrate ratios. Since the start of our studies on stereoselective hydrogenations of **1**[3,4] with complexes like [Cp*Ru(MeCN)$_3$]Tf **4**, we came to the conclusion that the [Cp*Ru]$^+$ fragment is essential for the stereoselectivity of the reaction. 'Naked' Cp*Ru complexes without inhibiting ligands should thus be more active and very selective.

We thus synthesized the model complexes [Cp*Ru(η⁴-MeCH=CHCH=CHCO$_2$H)]$^+$X$^-$ (X = Tf **5a**, X = tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (BARF) **5b**), in which the [Cp*Ru]$^+$ fragment is stabilized by a η⁴-bonded sorbic acid molecule. We assumed, that these complexes should have a similar structure as [Cp*Ru (η⁴-H$_2$C=CHCH=CH$_2$)I],[5] but should bear weakly coordinating ligands instead of an iodide ligand. The new complexes **5a**,**b** have been synthesized from [(Cp*Ru(μ-OMe))$_2$] [6] which was cleaved by 2 equivalents of trifluoromethanesulfonic acid or tetrakis[3,5-bis(trifluoromethyl)phenyl]boric acid (HBARF) in the presence of a slight excess of sorbic acid [eqn. (2)].



(2)

5a: X=Tf, **5b**: X=BARF

† Dedicated to Professor Wilhelm Keim on the occasion of his 65th birthday.

The complexes have been obtained as orange powders or crystals in 72% (**5a**) and 41% (**5b**) yield and have been characterized by ^{1}H NMR, ^{13}C NMR, secondary ion mass spectrometry and a crystal structure analysis.‡§ The η⁴-bonding mode of the sorbic acid in the complexes has been determined by a strong up-field shift of the olefinic proton signals in the ^{1}H NMR spectrum in comparison to free sorbic acid and by the crystal structure. In solution, the complexes may exist as monomers whereas Fig. 1 shows that complex **5b** is a dimer in the crystalline state which is bridged by the carbonyl oxygens of the acid. The hydroxy groups form hydrogen bridges to a THF molecule, the BARF anions do not interact with the cationic ruthenium complex. **5a**,**b** are the first sorbic acid–ruthenium complexes.

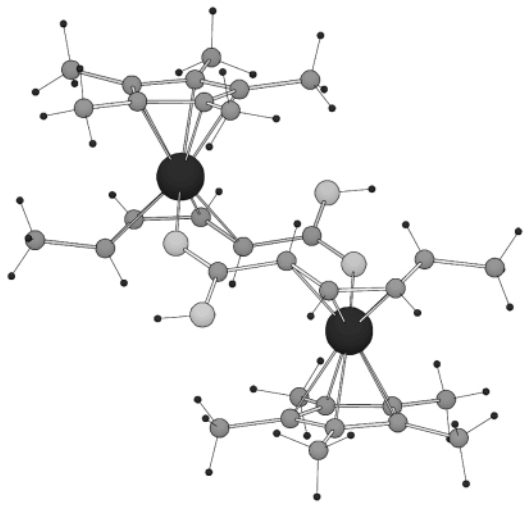


Fig. 1 Crystal structure of the cationic part of **5b**.

Complex **5a** is soluble in polar organic solvents such as alcohols, nitromethane or sulfolane, but it is insoluble in water and nonpolar organic solvents like ethers or alkanes. **5a** can thus be used as catalyst in liquid two-phase systems such as nitromethane–dibutyl ether, ethylene glycol–MTBE (methyl tertiary butyl ether) or sulfolane–MTBE, in which the complex remains in the polar phase. After the reaction the complex can be separated easily by decantation. Table 1 presents the results of the hydrogenation of sorbic acid in different solvents at 60 °C. At 60 °C the solvents in the systems nitromethane–dibutyl ether and sulfolane–MTBE become miscible, and at room temperature the two solvents form two phases.

The results obtained with the nitromethane systems (Table 1, entries 1 and 2) show that **5a** is about 30 times more active than [Cp*Ru(MeCN)$_3$]Tf **4**, which shows, that a naked [Cp*Ru]$^+$ fragment is more active. **5a**,**b** are active at room temperature whereas **4** is active only above 60 °C. Nitromethane is normally used as a weakly coordinating, aprotic solvent, therefore we expected good catalytic results. However, in this case the hydrogenation activities and the selectivities to *cis*-hex-3-enoic acid are lower in comparison to the stronger coordinating sulfolane and in comparison to the protic ethylene glycol.

Table 1 Stereoselective hydrogenation of **1** with **4** and **5a,b** as catalysts in various two-phase systems[a]

Entry	Solvent system	Catalyst	$p(H_2)$/bar	Conv. **1** (%)	Selectivity (S) *cis*-hex-3-enoic acid **2** (%)	Selectivity (S) *trans*-hex-3-enoic acid (%)	TOF/h^{-1}
1	$MeNO_2$–$Bu^n{}_2O$	**4**	60	45	93	6	3.1
2	$MeNO_2$–$Bu^n{}_2O$	**5a**	60	95	66	34	92

4[b]	Ethylene glycol–MTBE	**5a**	10	78	96	1	97
5	Sulfolane–MTBE	**5a**	60	68	71	29	580
6[c]	MTBE	**5b**	16	85	96	3	1057

[a] *Reagents and conditions*: 60 °C; 20 mmol sorbic acid; 0.06 mmol catalyst; catalyst phase: 30 ml solvent; nonpolar product phase: 44 ml solvent; Conv. = conversion; selectivity (S) = (*n*(product)/$\sum n$ (all products)) × 100; TOF = turnover frequency = ($\sum n$ (all products))/(*n*(catalyst) h).; [b] Some *trans*-hex-2-enoic acid is formed: (3) S = 7%, (4) 3%. [c] 40 mmol sorbic acid, 75 ml MTBE, 50 °C.

Table 2 Stereoselective hydrogenation of sorbic alcohol with **5a** as catalyst in ethylene glycol–MTBE[a]

Entry	*T*/°C	$p(H_2)$/bar	*n* (**5a**)/mmol	*t*/h	Conv. sorbic alcohol (%)	Selectivity to leaf alcohol **3** (%)	TOF/h^{-1}
1	21	20	0.0424	1.5	44	98.3	184
2	40	20	0.0426	0.42	70	98.9	1055
3	60	20	0.0219	0.40	88	98.6	2495
4	60	4	0.0428	0.77	86	97.8	714

[a] *Reagents and conditions*: 25–27 mmol sorbic alcohol; 25 ml ethylene glycol; 45 ml MTBE; in each experiment 1–2% *trans*-hex-3-en-1-ol is formed. Conv. = conversion; selectivity = (*n*(product) / $\sum n$ (all products)) × 100; TOF = turnover frequency = ($\sum n$ (all products))/(*n*(catalyst) h).

The highest selectivities (S) (S(*cis*-hex-3-enoic acid) = 96%) were obtained in ethylene glycol when the hydrogen pressure was reduced from 60 to 10 bar.

The highest activities with **5a** as catalyst (TOF = 580 h^{-1}) were obtained in sulfolane, but the selectivity was not as high as in ethylene glycol.

Since the BARF anion is much more lipophilic than the triflate anion, complex **5b** is more soluble in nonpolar solvents than **5a**. For this reason **5b** was used as catalyst in an MTBE solution instead of using it in a two-phase system. Experiments 5 and 6 in Table 1 can be compared because they both have been carried out in one-phase systems at the same reaction temperature. Evidently, **5b** is a more active catalyst than **5a** because the BARF anion has much weaker coordinating properties than the triflate anion.[7] Thus, the BARF anion does not compete with sorbic acid and hydrogen for free coordination sites at the ruthenium center in the catalytic steps of the reaction.

We also used hexa-2,4-diene-1-ol (sorbic alcohol) as substrate, which can be directly hydrogenated to *cis*-hex-3-ene-1-ol **3** (leaf alcohol). Preliminary results have shown that the catalytic hydrogenation is much faster with sorbic alcohol than with sorbic acid. It was thus possible to reduce the hydrogen pressure from 60 to 20 bar in the experiments shown in Table 2.

The best results were obtained with **5a**, which hydrogenates sorbic alcohol with a TOF of *ca*. 2500 h^{-1} at 60 °C in the two-phase system ethylene glycol–MTBE. Even at low hydrogen pressures of 4 bar, which allows working in glassware reactors, the reaction rate stays fairly high (TOF = 714 h^{-1}). The very high selectivity (98–99%) to leaf alcohol is virtually independent of the reaction temperature, while the hydrogenation activity raises as expected with increasing temperature. Other than in hydrogenations of sorbic acid the selecivity depends negligibly on the conversion. While the selectivity to *cis*-hex-3-enoic acid often decreases at conversion rates of > 90%, the selectivity to *cis*-hex-3-enoic alcohol remains constant even at 100% conversion.

We have thus shown that the concept of using 'naked' Cp*Ru complexes for stereoselective hydrogenations of functionalized dienes to *cis*-olefins is successful. In further work we will try to elucidate the mechanism and the kinetics of the reaction.

We thank the Bundesministerium für Bildung und Forschung and the Ministerium für Wissenschaft und Forschung des Landes NRW (Katalyseverbund NRW) for financial support.

Notes and references

‡ The complexes were synthesized in an argon atmosphere with dried solvents. Before the hydrogenation experiments the solutions of the complexes and the substrates were handled under argon.

General procedure for the synthesis of **5a**,**b**: 2.94 mmol [(Cp*Ru(μ-OMe))$_2$], which was prepared from 2.94 mmol [(Cp*$RuCl_2$)$_2$] according to the procedure described in the literature,[6b] were dissolved in 30 ml dichloromethane and 10 ml diethyl ether. A solution of 3.44 mmol sorbic acid and 3.15 mmol triflic acid (or HBARF) in 12 ml diethyl ether was added to the stirred solution of the complex at −78 °C. The reaction mixture changed immediately from deep red to brown. The reaction mixture was stirred for 10 min at −78 °C and was slowly brought to room temperature. After being stirred for a further 5 min at room temperature, the solvent was evaporated under reduced pressure. The residue was treated with 10 ml ethyl acetate to effect formation of an orange solid. For a better precipitation, 10 ml diethyl ether were added. The solid was filtered off washed twice with 10 ml diethyl ether and dried in high vacuum. 2.11 mmol **5a** were obtained (71.7% yield based on [(Cp*$RuCl_2$)$_2$]).

Convergent synthesis of adenophostin A analogues *via* a base replacement strategy

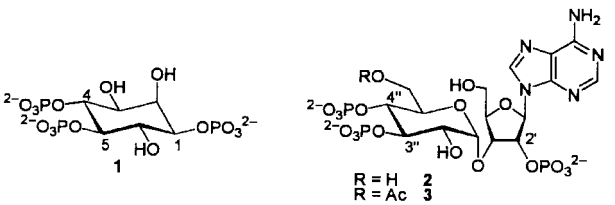
Rachel D. Marwood, Satoshi Shuto, David J. Jenkins and Barry V. L. Potter*

Wolfson Laboratory of Medicinal Chemistry, Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY. E-mail: b.v.l.potter@bath.ac.uk

Received (in Cambridge, UK) 26th November 1999, Accepted 5th January 2000

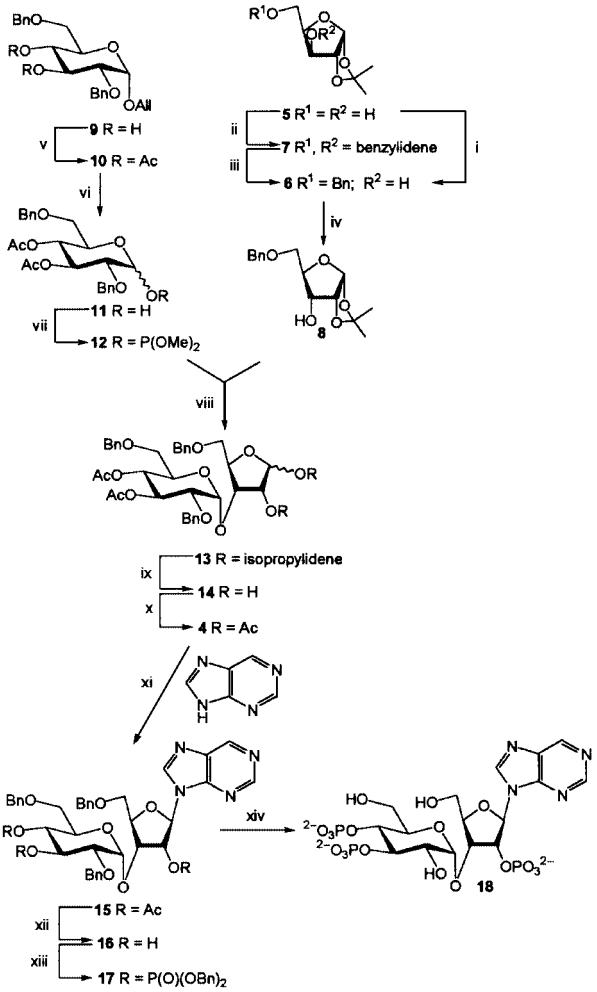
The first totally synthetic base-modified analogues of the natural product and potent D-*myo*-inositol 1,4,5-trisphosphate receptor agonist adenophostin A were efficiently synthesised from D-xylose and D-glucose using methodology employing base and surrogate base addition to a common disaccharide intermediate.

D-*myo*-Inositol 1,4,5-trisphosphate [Ins(1,4,5)P_3, **1**] is a second messenger which mediates the release of intracellular Ca^{2+} on binding to its own ligand-gated receptor.[1] The synthesis of Ins(1,4,5)P_3 analogues has provided insights into the structural requirements for binding and Ca^{2+} release at the Ins(1,4,5)P_3 receptor,[2] although inositol-based mimics with a potency exceeding that of Ins(1,4,5)P_3 have yet to be synthesised.



Adenophostins A and B (**2** and **3**)[3] were isolated from broths of *Penicillium brevicompactum*, and were found to be 10- to 100-fold more potent than Ins(1,4,5)P_3 in releasing Ca^{2+} and in receptor binding assays.[4,5] Design of chiral ligands based upon carbohydrates rather than cyclitols could provide novel synthetic signal transduction modulators. The biological activity of minimal structural analogues synthesised so far has not exceeded that of Ins(1,4,5)P_3[5–11] and it is likely that the adenine base is crucial for potency. Adenophostin A is finding widespread use as a tool to investigate cell signalling mechanisms[12] and there have been three syntheses of the molecule.[13–15] We required base-modified analogues of **2** and report here an efficient convergent route to five such compounds *via* a common disaccharide intermediate.

The disaccharide required for Vorbrüggen condensations, 1,2,3′,4′-tetra-*O*-acetyl-2′,5,6′-tri-*O*-benzyl-3-*O*-α-D-glucopyranosyl-D-ribofuranose (**4**), was prepared as follows. Species **5**[16] (Scheme 1) was selectively 5-*O*-benzylated by two different methods. Regioselective ring opening of a 3,5-*O*-dibutylstannylene derivative with BnBr yielded the 5-*O*-benzyl ether **6** (mp 45–47 °C; $[\alpha]_D$ +2.9) in one step. A 78% yield of benzylated products was isolated containing 90% of the desired regioisomer **6**. This method has since been reported by another group.[17] Alternatively, acid-catalysed treatment of **5** with benzaldehyde dimethyl acetal gave the crystalline benzylidene acetal **7** (mp 125 °C; $[\alpha]_D$ +3.8) as a single diastereoisomer in 89% yield; regiospecific cleavage of this acetal with $NaCNBH_3$–HCl also gave **6** in 68% yield. Inversion of the 3-hydroxy group to give the acceptor **8** (mp 83–85 °C; lit.[18] 81–83 °C) was achieved by oxidation with Ac_2O and DMSO and reduction of the corresponding 3-ulose with $NaBH_4$.[17] Acetylation of **9**, available in two steps from D-glucose,[6] gave diacetate **10** quantitatively and cleavage of the allyl glycoside was achieved using $PdCl_2$[19] to give **11** (mp 71–74 °C; $[\alpha]_D$ +83.0). Phosphitylation[15] gave the phosphite donor **12** as an oil in a 1:1 anomeric mixture as judged by ^1H and ^{31}P NMR spectroscopy.



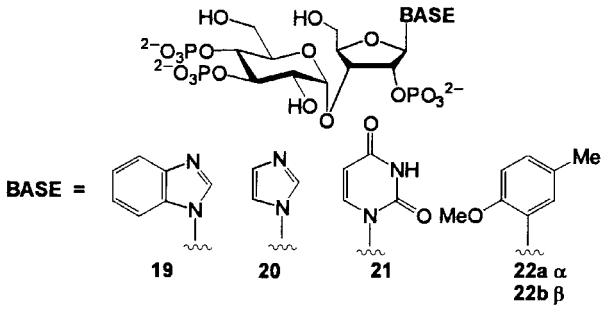
Scheme 1 *Reagents and conditions*: i, Bu_2SnO, BnBr, Bu_4NBr, MeCN, 4 Å sieves, Soxhlet, reflux, 24 h, 78%; ii, $PhCH(OMe)_2$, TsOH, DMF, 70 °C, –MeOH, 2 h, 89%; iii, $NaCNBH_3$–HCl, THF–Et_2O, 3 Å sieves, room temp., 5 min, 68%; iv, (*a*) Ac_2O–DMSO, 18 h, room temp., (*b*) $NaBH_4$, EtOH–H_2O (5:4), room temp., 1 h, 50% over two steps; v, Ac_2O, pyridine, room temp., 20 h, 100%; vi, $PdCl_2$, MeOH–CH_2Cl_2 (1:1), room temp., 3 h, 78%; vii, $(MeO)_2PNEt_2$, 1*H*-tetrazole, CH_2Cl_2, room temp., 30 min; viii, dioxane–toluene (3:1), 4 Å sieves, room temp., 2 h then $ZnCl_2$, $AgClO_4$, dark, room temp., 20 h, 81% (based on **8**); ix, AcOH–H_2O–$(CH_2OH)_2$ (14:6:3), reflux, 15 min, 75%; x, Ac_2O, pyridine, room temp., 20 h, 82%; xi, (*a*) purine, $(Me_3Si)_2NH$–Me_3SiCl (2:1), reflux, 20 h, (*b*) TMSOTf, $(CH_2Cl)_2$, reflux, 7 h, 61%; xii, conc. aq. NH_3–MeOH (1:5), sealed vessel, room temp., 20 h, 97%; xiii, $(BnO)_2PNPr^i_2$, 1*H*-tetrazole, CH_2Cl_2, room temp., 30 min, then MCPBA, −78 °C, 5 min, 80%; xiv, wet $Pd(OH)_2$/C, MeOH–cyclohexene–H_2O (11:5:1), reflux, 17 h, 56%.

Donor **12** and acceptor **8** were coupled together in a similar fashion to that described[11*b*] to give the desired disaccharide **13**

(mp 125–127 °C; $[\alpha]_D$ +101.6) in 81% yield; the reaction time had to be extended because of the deactivating effects[20] of the donor 3,4-di-*O*-acetate protecting groups. Note the high regiospecificity of this glycosylation, the α-coupled anomer being the sole isolated product in high yield. Cleavage of the isopropylidene acetal was accomplished by heating **13** at reflux in aqueous AcOH containing ethylene glycol[14] to give **14** (mp 126–128 °C; $[\alpha]_D$ +116.5) which was acetylated to give **4**.†

To exemplify our route the condensation of **4** with purine is described, using the method of Vorbrüggen *et al.*[21] with TMSOTf as catalyst. The major product was the 9-β-D-ribofuranosidopurine nucleoside (nebularine) derivative **15** ($[\alpha]_D$ +73.6) which exhibited a deshielded doublet at δ_H 6.44 (*J* 4.9 Hz) corresponding to H-1′ of a β-substituted product; purine signals in the ^{13}C NMR spectrum also corresponded closely to those of the known[22] 2′,3′,5′-tri-*O*-acetyl nebularine. Stirring **15** in a mixture of concentrated aqueous ammonia and methanol gave triol **16** ($[\alpha]_D$ +23.5) required for phosphorylation. Triol **16** was phosphitylated and the resulting trisphosphite was oxidised to trisphosphate **17** ($[\alpha]_D$ +17.9).[15] Deprotection of **17** to the purine analogue of **2** ('purinophostin', **18**) was achieved with catalytic transfer hydrogenation. The free acid was eluted from MP1 AG ion exchange resin with a gradient of aqueous TFA and converted into the sodium salt.

Other adenine-related base surrogates used were benzimidazole and imidazole, condensation being achieved similarly to above to give **19** and **20**. The imidazole analogue of adenophostin A ('imidophostin') **20**, in which the adenine six-membered



ring had been effectively deleted, was readily accessible by condensation of **4** with *N*-trimethylsilylimidazole.[23] A small amount of bis-glycosylated material was also formed. The desired product was deprotected, phosphorylated and deprotected as previously. We also synthesised an analogue ('uridophostin', **21**†) possessing the natural nucleic acid base, uracil. Condensation of **4** with 4-methylanisole gave both α- and β-substituted aryl C-glycosides in a *ca.* 1:1 ratio from ^1H NMR spectroscopy; these products were used to prepare the α- and β-4-methyl anisole analogues of adenophostin A, **22a** and **22b** respectively, by the coupling of 4-methylanisole and **4** in the presence of $AgCO_2CF_3$ and $SnCl_4$. This demonstrates the utility of our route also for the preparation of C-nucleoside analogues.

Convergent construction of **2** was described by van Straten *et al.*[14] This elegant approach was somewhat hampered, however, by a large number of protection/deprotection steps. Our present route allows efficient access to a central disaccharide **4**, whilst the choice of protecting groups requires minimal manipulation between Vorbrüggen condensation and target trisphosphates.

In summary, we report here an efficient route to the first synthetic base-modified analogues of adenophostin A.

We thank the Wellcome Trust for a Prize Studentship (R. D. M.) and Programme Grant Support (045491 to B. V. L. P.), the Ministry of Education, Science, Sports and Culture of Japan for support to S. S. and acknowledge discussions with Dr A. M. Riley and C. Mort for technical assistance.

High internal phase emulsions (HIPEs) containing divinylbenzene and 4-vinylbenzyl chloride and the morphology of the resulting PolyHIPE materials

Andrea Barbetta, Neil R. Cameron* and Sharon J. Cooper

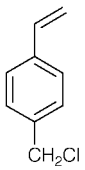
Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE. E-mail: n.r.cameron@durham.ac.uk

Received (in Oxford, UK) 15th November 1999, Accepted 5th January 2000

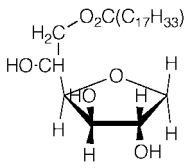
The cell size of DVB–VBC PolyHIPEs decreases with increasing VBC content, which appears to be due to the adsorption of VBC at the emulsion interface leading to a lower interfacial tension and a smaller droplet size.

High internal phase emulsions (HIPEs) are defined as emulsions in which the droplet phase occupies greater than 74.05% of the emulsion volume, this figure representing the maximum volume occupiable by uniform spheres. Such systems have been known for many years, and features such as their preparation, stabilisation, structure and rheology have been investigated in detail.[1] Our interest[2] in HIPEs, and that of several other groups,[3] lies in their ability to be used as templates for the production of highly porous polymers. Such materials, known as PolyHIPEs using Unilever's nomenclature,[4] are prepared by polymerising the thin monomer films that surround the droplets of inert solvent-in-monomer solution HIPEs. Subsequent removal of the droplets produces a highly porous material (Fig. 1).

During the course of our work on developing novel PolyHIPE materials we undertook the preparation of species containing 4-vinylbenzyl chloride (VBC, **1**). This monomer is



1



2

sufficiently hydrophobic to allow successful HIPE preparation, and results in materials possessing reactive chloromethyl functionalities that are amenable to functionalisation, potentially leading to a wide range of derivatised highly porous materials. VBC has been used previously to prepare HIPEs where it was present in either the droplet[5] or the continuous[6] phase, leading to the production of agglomerates of particles or foams, respectively. However, the influence of VBC on the emulsion and resulting polymer morphology was not described.

VBC-containing materials were easily prepared by addition of an aqueous solution of $CaCl_2.2H_2O$ and $K_2S_2O_8$ to a mixture of monomer(s) plus surfactant, using conditions optimised for the production of styrene–divinylbenzene (S–DVB) PolyHIPEs.[4,7] The ratio (wt%) of VBC to DVB[8] was varied, to give a range of foams, each with a pore volume of 90%. To our surprise, the resulting materials had smaller average cell sizes than those obtained from styrene and DVB (*e.g.* Fig. 1). SEM photographs (Fig. 2) clearly show that increasing the VBC content in the formulation causes a decrease in average cell size from 10 μm [Fig. 2(*a*)] to less than 5 μm [Fig. 2(*e*)]. Interestingly, the foam composed entirely of polyVBC [Fig. 2(*f*)] has no discernible cell structure. Previously, Williams[9] found that increasing the DVB concentration in styrene–DVB PolyHIPEs from 0 to 100% resulted in a decrease in average cell diameter by about 10 μm. He reasoned that DVB,

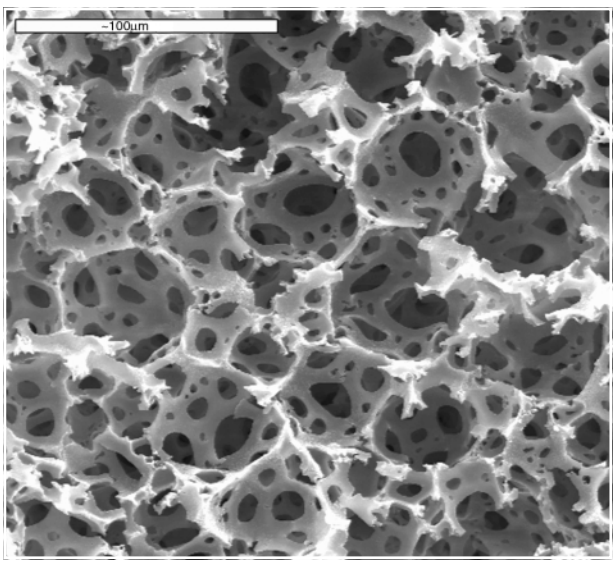


Fig. 1 SEM of a S–DVB PolyHIPE foam (pore volume *ca.* 90%, nominal crosslink density *ca.* 15%). Scale bar = 100 μm.

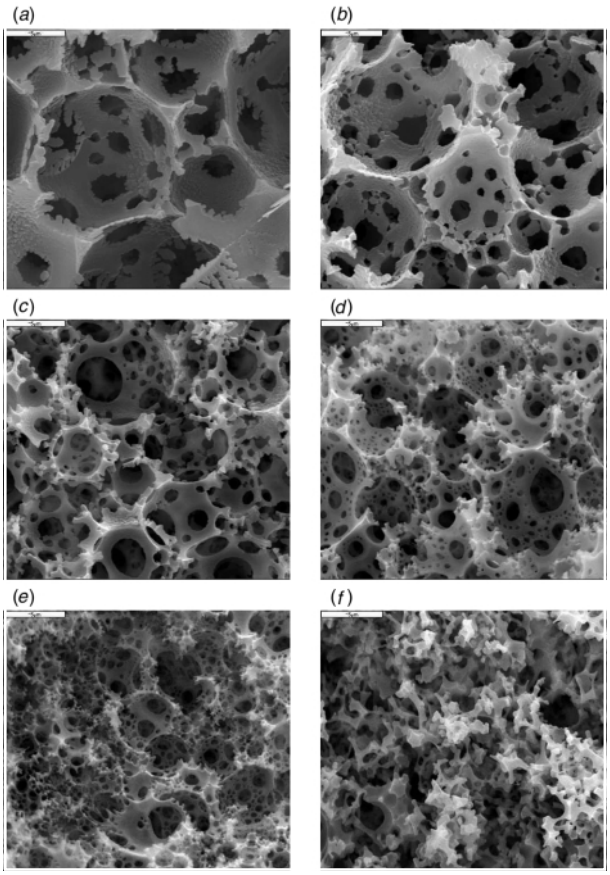

Fig. 2 SEMs of VBC–DVB PolyHIPE foams (ref. 16): (*a*) X80PV90; (*b*) V12.5X70PV90; (*c*) V37.5X50PV90; (*d*) V62.5X30PV90; (*e*) V87.5X10PV90; (*f*) V100X0PV90. Scale bar = 5 μm.

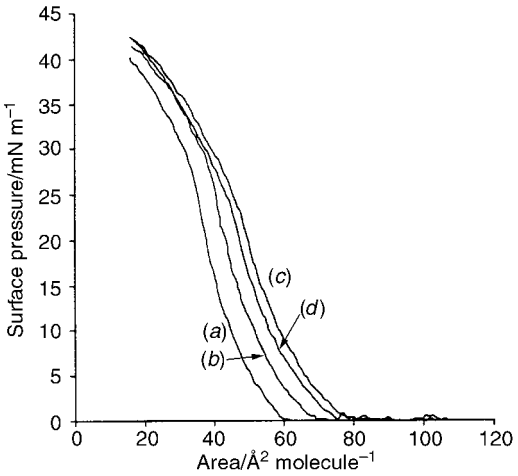

Fig. 3 π–*A* curves for films containing Span 80 alone (*a*) and Span 80 (17 mol% relative to total oil phase) plus DVB (*b*), VBC (*c*) and DVB–VBC (50 : 50 mol. mixture) (*d*).

being more hydrophobic, was leading to more stable emulsions. It is well known that droplet size decreases with increasing emulsion stability since the surface energy per unit area is lower. A decrease in emulsion droplet size leads to a decrease in PolyHIPE cell size since the foam is effectively a replica of the emulsion structure immediately prior to gel formation.

In our case, with VBC–DVB foams, increasing DVB concentration causes an increase in average cell size of the resulting foam. This implies that VBC leads to more stable emulsions than DVB. Emulsion stability is influenced by such factors as temperature, surfactant nature and concentration, phase composition and viscosity. Since the surfactant used was Span 80 (sorbitan monooleate, **2**) in each case, at constant concentration (20 wt% relative to monomer content), the polymerisation temperature was constant and emulsion preparation conditions were identical, the different behaviour must be due to differences in the physical chemistries of DVB and VBC. Both species being low molar mass entities, one would not anticipate tremendous differences in the viscosities of VBC and DVB.[10] We therefore concluded that the marked difference in their behaviour must be as a result of different interfacial properties. In particular, we wondered whether VBC could be concentrating at the interface and acting as a cosurfactant with Span 80.

It is well known that small molecules bearing polar and non-polar functionalities can adsorb at the interface of emulsions, the polar group locating in the aqueous phase and the non-polar group in the organic phase. Additionally, small molecule surface-active species can co-adsorb with surfactants possessing large head-groups, such as Span 80, leading to a better-packed interfacial film and consequently a more stable emulsion.[11] The presence of an aromatic moiety in the hydrophobic part of the cosurfactant may enhance its adsorption at the interface.[12]

Using a Langmuir trough, we measured the surface pressure against area (π–*A*) curves of films of Span 80 alone, and Span 80 with DVB, VBC and a 50 : 50 mixture of DVB and VBC.[13] The interfacial behaviour of the various components can be inferred from their π–*A* curves (Fig. 3). Span 80 [Fig. 3(*a*)] displays the behaviour of a typical surfactant; surface pressure is low and constant until critical film compression is reached, whereupon it increases drastically. The area corresponding to this compression represents the area of the condensed interfacial film where the surfactant molecules are densely packed. Adsorption of the other species (VBC, DVB) at the interface will cause greater crowding and lead to an increase in π at higher area (lower compression), which is indeed observed. From fig. 3 it can be inferred that DVB [Fig. 3(*b*)] is slightly adsorbed at the interface, but VBC [Fig. 3(*c*)] is adsorbed to a significantly greater extent. Therefore, VBC is co-adsorbed with Span 80 at the interface and leads to a more dense film. These results appear to confirm our hypothesis that VBC is acting as a cosurfactant. Williams[14] previously investigated the influence of 22 cosurfactants on the stability of S–DVB HIPEs and found that none enhanced stability.[15] However, all but three of those additives were alcohols and none possessed halide residues.

Further information on the interfacial behaviour of systems containing VBC can be deduced from closer inspection of Fig. 3. The curve of the film containing a 50 : 50 mixture of VBC and DVB [Fig. 3(*d*)] lies nearer to that of VBC [Fig. 3(*c*)] than to that of DVB [Fig. 3(*b*)], indicating that the greatest changes in interfacial properties occur on initial addition of VBC. This behaviour can also be inferred from the morphology of the PolyHIPE materials (Fig. 2); the decrease in cell size is more dramatic up to addition of 30% VBC [Fig. 2(*c*)], after which the cell size decreases only slightly. This implies that the interface is close to saturation at a VBC concentration in the HIPE of around 30%.

To conclude, we have prepared reactive PolyHIPE materials from VBC and DVB. These possess smaller average cell sizes than corresponding materials prepared from styrene and DVB. This phenomenon appears to be due to the adsorption of VBC at the interface, which lowers the interfacial tension, leads to a more stable emulsion with smaller droplets and therefore to the production of a foam with a smaller average cell diameter. The ability to control the morphology of these porous materials is crucial to their technological development.

Pentanuclear asymmetrical ladder structure of the 1,4-dimethylpiperazine solvate of lithium anilide and its implication for the unknown structure of amorphous lithium anilide

William Clegg,[a] Stephen T. Liddle,[a] Robert E. Mulvey*[b] and Alan Robertson[b]

Received (in Cambridge, UK) 13th December 1999, Accepted 7th January 2000

The weak solvating ligand 1,4-dimethylpiperazine appears to only partially disrupt the aggregation within lithium anilide, as evidenced by the structure of the title solvate: a three-dimensional polymer of solvent-linked irregularly shaped $(NLi)_5$ substructures, which can be interpreted as two interconnected ladders.

Long in the shadow of their better known secondary counterparts,[1] lithiated primary amines [{RN(H)Li}$_n$] are now emerging as valuable and versatile chemical intermediates themselves. Their ability to function as either amido [RN(H)$^-$][2] or imido (RN^{2-})[3] transfer agents, or sometimes as both simultaneously,[4] has proved particularly useful for the development of new heterometallic[5] and/or hetero-anionic[6] compositions. This paper focuses on one of the most important primary amides, lithium anilide. While its simple solvates with THF[7,8] or PMDETA[9] have been structurally elucidated, the pure solvent-free structure remains elusive. This situation is relatively common for lithium amides (whether primary or secondary) suspected of having polymeric constitutions (lithium anilide is thought to exist as a high oligomeric/polymeric ladder structure). Adding solvent ligands often produces smaller oligomers which can be crystallised and are therefore suitable for X-ray crystallographic study, unlike their solvent-free parent compounds which tend to be amorphous. Thus while lithium anilide is easy to prepare as a powder, so far it has not been possible to grow single crystals of it. However, keeping in mind that competition between aggregation and solvation can be delicately balanced, we have subjected it to the weak (weaker than THF or PMDETA) coordinating solvent 1,4-dimethylpiperazine (DMP) in the hope of crystallising a solvate with a structure more representative of the pure solvent-free compound, *i.e.* one in which the high (or infinite) aggregation has been only partially disrupted. As reported herein, the new solvate produced in this way, [{[{PhN(H)Li}$_5$·(DMP)$_2$]·(C$_6$H$_5$Me)$_2$·(DMP)$_{0.5}$}$_\infty$] **1**, possesses a remarkable structure. Besides fulfilling the aim of revealing a sizable ladder fragment (spanning five N–Li rungs), the structure also exhibits a new tetraanilido–lithium [{PhN(H)}$_4$Li] coordination mode, which facilitates the grafting of an additional N–Li bond onto a ladder edge. This unprecedented connectivity may provide an important clue as to the cause of the amorphous character of unsolvated lithium anilide.

The weak solvating power of DMP was reflected in the molar excess required (2.2 equivalents, 11 mmol) to dissolve a freshly prepared slurry of lithium anilide (5 mmol) in hexane–toluene solution. Cooling the resulting pale yellow solution to −30 °C for 2 days, afforded a crop of colourless crystalline **1**.† A standard inert-atmosphere protocol was used throughout this preparative and subsequent isolation procedure.

As determined by an X-ray crystallographic study,‡ the structure of **1** is made up of novel pentanuclear $(NLi)_5$ crossed ladder substructures (Fig. 1), linked together by bridging DMP ligands (Fig. 2) into a three-dimensional polymeric network. The crystal packing arrangement leaves spacious cavities in the

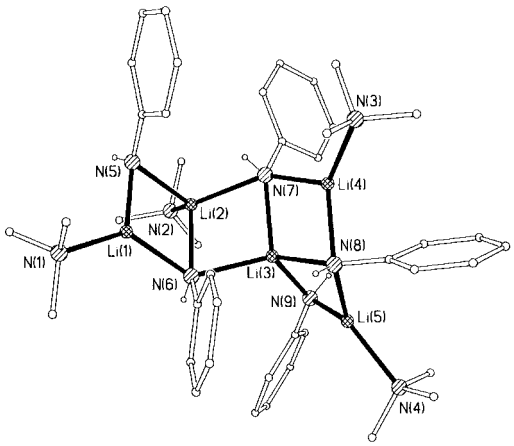

Fig. 1 Asymmetric unit of **1** showing atom labelling. Hydrogen atoms, except for N–H, are omitted for clarity, and solvent molecules are not shown.

structure which are filled by toluene solvent and free DMP molecules of crystallisation [2 and 0.5, respectively, per $(NLi)_5$ ladder]. Two essentially planar (anilidoN–Li)$_2$ rings, Li(1)N(6)Li(2)N(5) and Li(3)N(8)Li(4)N(7), joined together by Li(3)–N(6) and Li(2)–N(7) bonds, make up the main run of the ladder, the undulation of which is 'U-shaped' rather than 'stepped'. These rings can be classified as *cisoid*[10] (or *syn*), because their N–H substituents lie on the same side of the $(NLi)_2$ plane in each case. In contrast, at the junction of these two rings the conformation is *transoid* (*anti*) and the Li(2)N(7)Li(3)N(6) ring is butterfly shaped with an N···N hinge (folding angle, 138.4°) and Li wingtips. Located within the smaller cross-run of the ladder, the remaining Li(3)N(8)Li(5)N(9) ring is also *transoid* and butterfly shaped (folding angle, 151.7°). Those Li atoms positioned at ladder 'ends', Li(1), Li(4) and Li(5), have three-

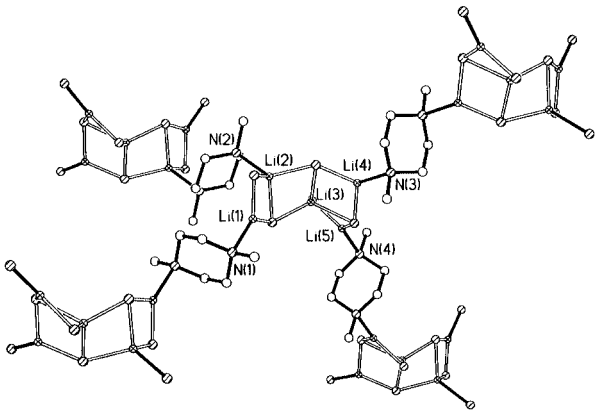

Fig. 2 View of **1** showing the bridging of four DMP ligands to neighbouring ladder substructures of which only Li and N atoms are shown.

coordinate, distorted trigonal planar geometries, though Li(4) is slightly pyramidalised (sum of bond angles, 353.2°). Occupying an inner rung, Li(2) displays a four-coordinate distorted tetrahedral geometry [bond angles, 99.8(3)–121.6(3)°]. Each of these Li atoms binds to one N atom from a chair-shaped DMP molecule which bridges through its second N atom to a Li atom of a neighbouring $(NLi)_5$ ladder. Connecting both runs of the ladder, Li(3) is unique as its distorted tetrahedral environment [bond angles, 96.7(3)–124.0(3)°] does not include a DMP molecule, but is made up exclusively of anilido N atoms. This coordination of Li by four monodentate anions is unprecedented for an anilide (and, to the best of our knowledge, for any amide). It is also rare generally in the wider context of organolithium chemistry, but not unknown, as a C_4Li coordination exists in the contact-ion pair structure of sodium tetraphenyllithate [{Na·(TMEDA)}$_3${$LiPh_4$}].[11] Three anilide anions in **1** [at N(6), N(7) and N(8)] engage in μ_3 bonding with Li atoms, while the other two situated in the end rungs [at N(5) and N(9)] are μ_2 bonded. These end rungs, N(5)–Li(1) and N(9)–Li(5), display the shortest lengths [1.934(8) and 1.954(7) Å, respectively] in the $(NLi)_5$ ladder framework reflecting the low coordination numbers (C.N.) involved (four for N; three for Li). Similarly, the longest such bond, N(8)–Li(3) [2.208(6) Å], reflects the high C.N. involved (five for N; four for Li). The remaining N–Li ladder lengths lie in the range 2.014(8)–2.178(7) Å. There is also a correlation between the dative (DMP)N–Li bond lengths and Li C.N. [where C.N. = 3, the mean length is 2.073 Å; where C.N. = 4, the length increases to 2.176(6) Å]. Turning to angular values, despite the ladder having an irregular shape and a variety of C.N., its endocyclic bond angles subtended at N cover a narrow range [73.1(3)–77.9(3)°]. The corresponding bond angles at Li cover a wider range [96.7(3)–107.8(3)°].

Pentanuclear aggregation is extremely rare in lithium structural chemistry. A previous example was reported for the anion of the lithium ketimidolithate complex [{Li·$(HMPA)_4$}$^+$-{$Li_5(N{=}CPh_2)_6$·(HMPA)}$^-$],[12] but in this case the (N_6Li_5) substructure is of a discrete cage anion, rather than a segment of a polymeric chain. The asymmetric unit of **1** represents the first pentanuclear Li_5 ladder conformation. Hitherto, homoaggregated lithium amide ladders generally have regular, symmetrical structures of laterally connected $(NLi)_2$ rings, the opposite facing N–Li bonds of which become either pairs of rungs or pairs of edges. Representative examples include the tetrameric 'concave' ladder of the piperidide [{$H_2C(CH_2)_4NLi{\cdot}HN(CH_2)_4CH_2$}$_4$],[13] the octameric cyclic ladder of [{$Bu^tN(H)Li$}$_8$],[14] and the polymeric sinusoidal wave-shaped ladder of [{$H_2NCH_2CH_2N(H)Li$}$_\infty$].[15] Aside from having an odd number of rungs, the ladder of **1** differs by virtue of the additional rung [N(9)–Li(5)] grafted onto the N(8)–Li(3) 'edge'. This is a new structural development§ since ladder edges usually stand alone, or in rare cases, are solvated at Li.[16] The presence of this special feature implies that removal of the DMP ligands from **1** would allow the laddering process to extend in several directions. Viewing the $(NLi)_5$ framework as two interconnected ladders, there are four end-rungs N(5)–Li(1), N(8)–Li(4), N(9)–Li(5) and N(7)–Li(4), from which further laddering might be possible, though the kinetics of growth at each site may be different. The amorphous nature of unsolvated lithium anilide may have its origin in the availability of such irregular branching. Hence this contrasts with the situation so far found in crystalline lithium amide polymeric ladders[15,16] where the laddering process is mono-directional.

We gratefully acknowledge the continued financial support of the EPSRC.

Probing the catalytic oxidation of alcohols *via* an anionic dimolybdate centre using multistage mass spectrometry

Tom Waters, Richard A. J. O'Hair* and Anthony G. Wedd

School of Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia.
E-mail: r.ohair@chemistry.unimelb.edu.au

Received (in Cambridge, UK) 26th November 1999, Accepted 6th January 2000

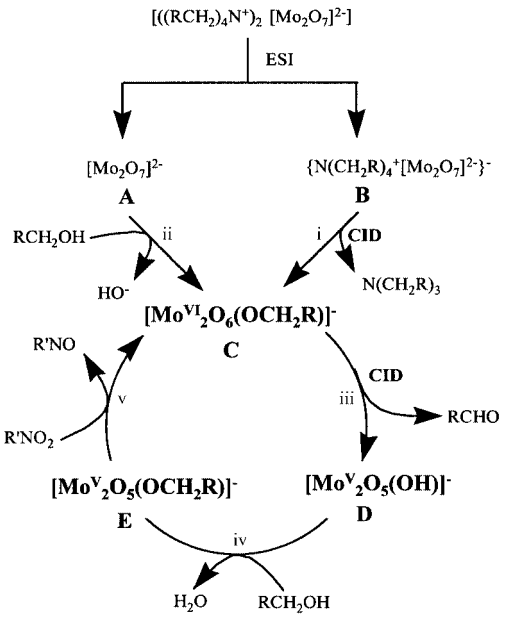
Multistage mass spectrometry experiments in a quadrupole ion trap combined with isotope labelling have revealed a novel gas phase catalytic cycle for the oxidation of alcohols *via* an anionic dimolybdate centre.

We report the catalytic oxidation of alcohols in the gas phase using a dimolybdate anion as the active species. The nature of each step in the catalytic cycle can be probed through (i) multistage mass spectrometry experiments using a modified quadrupole ion trap mass spectrometer[1] and (ii) isotope substitution experiments which involve labelling of neutral reagents and the dimolybdate centre.

Complex reactivity of alcohols in the gas phase has been observed for highly unsaturated transition metal ionic species,[2,3] including oxo–molybdenum cations.[2] In contrast, the present study demonstrates 'simple' modes of reactivity with an oxo–molybdenum anion which allow catalytic behaviour. The observation by multistage mass spectrometry of true gas phase oxidation catalysed by transition metal ions remains rare.[4] In addition, the present system may shed light on the industrial oxidation of methanol to formaldehyde as catalysed by amorphous solid state molybdate catalysts.[5] A detailed molecular understanding of the mechanisms of this process remains elusive.[6]

Quaternary ammonium salts of the dimolybdate anion in MeCN can be transferred to the gas phase *via* electrospray ionisation.[7] The main species observed are the dianion, $[Mo_2O_7]^{2-}$ **A** and the ion pair, $\{N(CH_2R)_4^+[Mo_2O_7]^{2-}\}^-$ **B**.[8] Both these species can act as precursors of $[Mo_2O_6(OCH_2R)]^-$ **C** which catalyses the oxygen atom transfer reaction (1) (Scheme 1; R = alkyl, R′ = aryl, alkyl):

$$RCH_2OH + R'NO_2 \rightarrow RCHO + H_2O + R'NO \qquad (1)$$



Scheme 1

Collision induced dissociation (CID) of **B** initiates an ion pair S_N2 reaction,[9] resulting in loss of trialkylamine and O-alkylation of **A** to form an alkylated dimolybdate species, **C** (Scheme 1(i)). Note that: (i) this is the first report of an ion pair S_N2 reaction involving an inorganic dianion and a tetraalkylammonium cation (*cf.* ref. 10) and (ii) thermolysis of trialkyloxonium salts of $[PMo_{12}O_{40}]^{3-}$ in the condensed phase also results in S_N2 O-alkylation.[11]

Gas phase ion–molecule reactions of **A**with various alcohols also yields **C**.[12] Labelling studies with $CH_3{}^{18}OH$ clearly reveal that this is not an S_N2 reaction (Fig. 1(a)). Rather, deprotonation of alcohol by a terminal oxo ligand[13] is followed by displacement of the resultant hydroxo ligand by the alkoxy anion (Scheme 1(ii), Table 1).

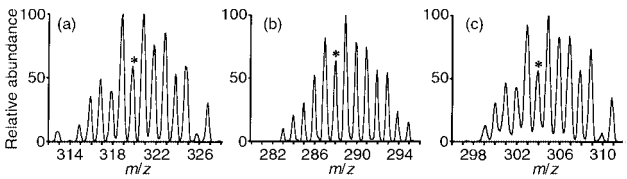


Fig. 1 Expansion of the isotope patterns for key product ions from gas phase reactions involving ^{18}O labelling experiments. The central peak of lower intensity in the isotope pattern is denoted by an asterisk, and is used to evaluate the outcome of the reaction. The numbering of the species and reactions is as according to Scheme 1. (a) shows that the product ion **C** from reaction (ii) is $[Mo_2O_6(^{18}OMe)]^-$; (b) shows that $[Mo_2O_6(^{18}OMe)]^-$ loses $CH_2{}^{18}O$ in reaction (iii), with concomitant formation of the product ion **D** $[Mo^V{}_2O_5(OH)]^-$; (c) shows that the product ion **E** from reaction (iv) is $[Mo^V{}_2O_5(^{18}OMe)]^-$.

CID of the alkylated dimolybdate species **C** results in reductive elimination of the alkoxo ligand as the aldehyde (Scheme 1(iii)). This corresponds to the formal redox half reaction: $RCH_2O^- \rightarrow RCHO + H^+ + 2e^-$. In the complementary half reaction, the dimolybdate(VI) centre is reduced by $2e^-$ and protonated to form $[Mo^V{}_2O_5(OH)]^-$ **D**. Labelling studies indicate that the oxygen from the alkoxo ligand is lost in this step (*i.e.* $CH_2{}^{18}O$ is lost; Fig. 1(b), Table 1).

The cycle is continued when **D** rapidly reacts with alcohol to form $[Mo^V{}_2O_5(OCH_2R)]^-$ **E** (Scheme 1(iv)). Once again the labelling studies reveal that this is not an S_N2 reaction (Fig. 1(c)), but rather a gas phase esterification reaction.

To complete the cycle, **E** is oxidised *via* an oxygen atom transfer to regenerate **C** (Scheme 1(v)). This reaction requires the presence of a second neutral reagent (along with alcohol) in the ion trap. To date we have used *m*-fluoronitrobenzene and nitromethane (*i.e.* $R'NO_2$ where R′ is Me or *m*-C_6H_4F) as oxygen atom donors.[14] Injection of $R'NO_2$ in the absence of alcohol indicates that oxygen atom transfer to **D** is also possible. This pathway does not compete with reaction (v) in Scheme 1 in the presence of alcohol owing to the fast rate of esterification.[15]

The present system raises questions about the mechanism(s) involved in the industrial oxidation of alcohols as catalysed by solid state molybdate catalysts.[5,6] In particular, can a related cycle (*cf.* reactions (iii)–(v) of Scheme 1) be applied to the layer compound $Mo_2O_5(OMe)_2$, proposed as a model heterogeneous

[a] *m/z* refers to the central peak of lower intensity in the isotope pattern. [b] Refer to Scheme 1 for labelling of ionic species. [c] A sample from Cambridge Isotope Laboratories (99% D). [d] A sample from Cambridge Isotope Laboratories (99.9% D). [e] A sample from Isotec (95%^{18}O).

catalyst?[6] Given its layer structure features alternating *trans*-$Mo^{VI}O(OMe)$ centres separated by bridging oxo ligands, a simple mechanism can be devised for the oxidation of MeOH to H_2CO involving two Mo^{VI} sites on adjacent layers. This accommodates the fact that O_2 transfers two O atoms (eqn. (2)), rather than the single O atom from $R'NO_2$ (eqn. (1))

$$2\ MeOH + O_2 \rightarrow 2\ CH_2O + H_2O \qquad (2)$$

Further gas phase work is underway to examine (i) whether larger polyoxoanions also catalyse the oxidation of alcohols; (ii) the behaviour of other oxygen atom transfer reagents (*e.g.* O_2); (iii) models of oxo–molybdenum and –tungsten enzymes which catalyse oxygen atom transfer reactions.[16]

12 A range of molybdenum alkoxides $[Mo_2O_6(OCH_2R)]^-$ **C** where R = H, Me, Et or Pr^n can be 'synthesised' using reactions (i) and (ii) of Scheme 1. We have also discovered an alternative gas phase synthesis, involving a gas phase ion–molecule 'transesterification' reaction whereby one alkoxo ligand is replaced by another. Unfortunately the related *tert*-butoxide $[Mo_2O_6(OBu^t]^-$ is unavailable presently owing to the poor volatility of Bu^tOH.

13 We have also synthesised a dimolybdate centre in which the six terminal oxo ligands are labelled with ^{18}O (for related O isotope labelling studies of polyoxoanions, see: G. D. Hinch, D. E. Wycoff and R. K. Murmann, *Polyhedron*, 1986, **5**, 487). Upon reaction of labelled **A** with $CH_3{}^{16}OH$ a mass increase of 13 Da was observed (*cf.* 15 Da with unlabelled **A**) indicating loss of a terminal oxo ligand with $^{18}OH^-$.

14 For a review on related oxygen atom transfer reactions, see: R. H.Holm and J. P. Donahue, *Polyhedron*, 1993, **12**, 571.

15 Neutral reagents were injected at a flow rate of 3 μL min^{-1} at a split of 1:5000 in the ratio RCH_2OH: $R'NO_2$ = 4:1. At these conditions, reaction of $[Mo^V{}_2O_5(OH)]^-$ with EtOH and *m*-$FC_6H_4NO_2$ results in the formation of $[Mo^V{}_2O_5(OEt)]^-$ (*m/z* 316, from esterification) at the almost complete exclusion of $[Mo^{VI}{}_2O_6(OH)]^-$ (*m/z* 304, from oxidation). This confirms oxygen atom addition to $[Mo^V{}_2O_5(OH)]^-$ does not compete with esterification. All MS^n experiments were carried out using a *Q* value of 0.25. Ion-molecule reactions times were typically: reaction (ii) = 5 s; reaction (iv) = 20 ms; reaction (v) = 200 ms. Typical CID reactions were carried out for 30 ms using the following activation amplitudes: reaction (i) = 0.75 V; reaction (iii) = 0.65 V.

Received (in Cambridge, UK) 29th November 1999, Accepted 6th January 2000

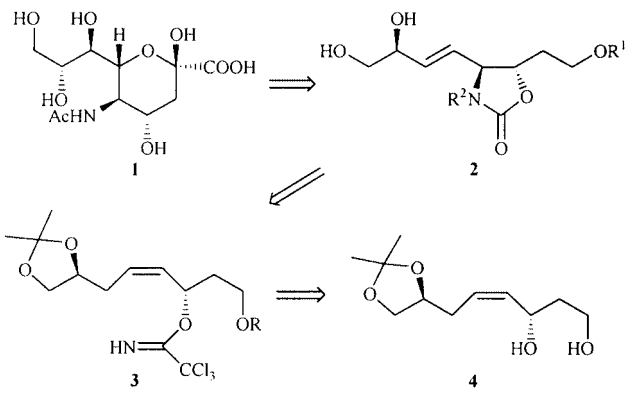
A highly diastereoselective synthesis of *N*-acetylneuraminic acid 1 has been completed by stereoselective functionalization of *cis*-olefin 6 and *trans*-olefin 10 *via* intramolecular phenylselenoamidation and osmylation, respectively.

Sialic or neuraminic acids are a family of amino sugars comprising nine or more skeletal carbon atoms, and usually occur at the nonreducing terminal positions of oligosaccharides, glycoproteins and glycolipids.[1] They are involved in the modulation of a variety of important biological phenomena[2] such as cellular aggregation,[3] recognition,[4] lifetime[5] and viscosity of biofluids.[6] The family provides a potential therapeutic lead in developing inhibitors of sialidase[7] and sialyltransferase.[8] The most common member is the nine-carbon derivative 5-(acetylamino)-3,5-dideoxy-D-*glycero*-D-*galacto*-2-nonulosonic acid **1** (*N*-acetylneuraminic acid, Neu5Ac),[9] which is an essential constituent of sialoglycosphingolipids (ganglioside) and other glycoconjugates which mediate cellular interactions, differentiations and growth.[10]

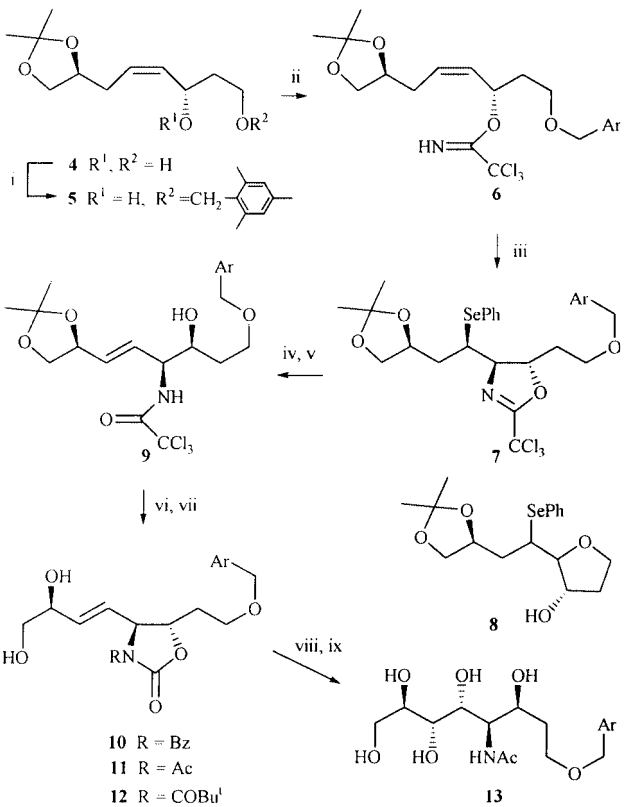
While most of the known syntheses of Neu5Ac have been attained from carbohydrate sources,[11] only two syntheses have been established from noncarbohydrate precursors *via* hetero-Diels–Alder cycloaddition[12] and azido hydroxylation of *cis*-1,2-dihydrocatechol,[13] respectively. Its intriguing molecular structure and biological significance also led us to the enantioselective synthesis of *N*-acetylneuraminic acid **1** from diol **4**, which had been readily prepared from (*S*)-butane-1,2,4-triol.[14] The key steps of our synthetic route to **1** include the intramolecular phenylselenoamidation of *cis*-olefinic allylic trichloroacetimidate **3** and the stereoselective dihydroxylation of *trans*-olefin **2**, followed by introduction of the indispensable α-keto carboxylic acid functional group (Scheme 1).

Diol **4** was regioselectively protected by reacting with dibutyltin oxide in toluene using a Dean–Stark trap and subsequently with 2,4,6-trimethylbenzyl chloride in the presence of TBAB[15] to give a 7:1 mixture of the desired ether **5**, $[\alpha]_D^{20}$ + 19.9 (*c* 1.2, $CHCl_3$), and the isomeric secondary alkyl benzyl ether in 96% combined yield (Scheme 2). For the disposition of the required amino group and (*E*)-olefinic double bond, the allylic alcohol **5** was sequentially subjected to Cl_3CCN in the presence of DBU in MeCN and benzeneselenyl bromide in the presence of methyl trichloroacetimidate in a 4:1 mixture of MeCN and propylene oxide to provide *trans*-oxazoline **7**, $[\alpha]_D^{21}$ −18.4 (*c* 1.1, $CHCl_3$), in 67% yield. While the stereoisomeric *cis*-oxazoline could not be identified in the phenylselenocyclization, 9% of the enantiomerically pure tetrahydrofuran **8** was isolated as the major side product after hydrolysis. It is noted that methyl trichloroacetimidate and propylene oxide were expected to function as dehydrating agent and acid scavenger. The oxazoline ring of **7** was partially hydrolyzed in the presence of PPTS in aqueous acetone and the residual phenylselenyl group was oxidatively eliminated to afford *trans*-olefin **9**, $[\alpha]_D^{24}$ + 19.0 (*c* 1.2, $CHCl_3$), in 75% overall yield along with 5–6% of the corresponding *cis*-isomer.

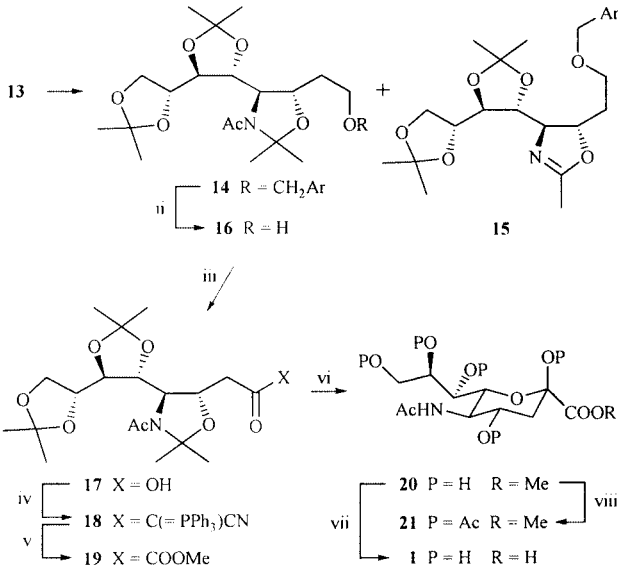
The pendent amino and hydroxy groups of **9** were variously functionalized in order to induce the best stereoselectivity in the subsequent dihydroxylation of the olefinic double bond. In consequence, **9** was converted into dihydroxy oxazolidinone **10**, mp 110.3–111.0 °C, $[\alpha]_D^{25}$ + 23.9 (*c* 1.05, $CHCl_3$), in 91%



Scheme 1



Scheme 2 *Reagents and conditions*: i, Bu_2SnO, PhMe, Dean–Stark trap, then 2,4,6-trimethylbenzyl chloride, Bu_4NBr, 80 °C; ii, Cl_3CCN, DBU, MeCN, −30 to −20 °C; iii, PhSeBr (3 equiv.), $MeOC(=NH)CCl_3$ (3 equiv.), propylene oxide–MeCN (1:4), −30 to 0 °C; iv, PPTS, H_2O–acetone (1:4), 20 °C; v, 30% H_2O_2, THF, 20 °C; vi, DBU, CH_2Cl_2, 20 °C, then BzCl, DMAP, Et_3N, 0 °C; vii, H_2O–AcOH (1:4), 20 °C; viii, OsO_4, NMO, H_2O–acetone (1:7), 0 °C; ix, $Ba(OH)_2$, H_2O–EtOH (1:2), 70 °C, then Ac_2O, 0 to 20 °C.



Scheme 3 *Reagents and conditions*: i, $C(OMe)_2Me_2$, PPTS, $CHCl_3$, 70 to 80 °C; ii, H_2, 20% $Pd(OH)_2/C$, $NaHCO_3$, EtOH, 20 °C; iii, $RuCl_3$ hydrate, $NaIO_4$, MeCN–CCl_4–H_2O (2:2:3), 20 °C; iv, $CH(=PPh_3)CN$, EDCl, DMAP, CH_2Cl_2, 20 °C; v, O_3, MeOH, −78 °C; vi, AcCl, MeOH, 20 °C; vii, K_2CO_3, H_2O, MeOH, 20 °C, then Dowex 50WX8-100 ion-exchange resin; viii, Ac_2O, DMAP, pyridine, 20 °C.

overall yield by a sequence of cyclization with DBU, *in situ* benzoylation with BzCl and deprotection in aqueous AcOH. The following dihydroxylation of **10** produced a mixture of several compounds, which seemed to be generated from migration of *N*-benzoyl group in the dihydroxylated products. The mixture was completely hydrolyzed with $Ba(OH)_2$ and the demasked amino group was acetylated in one pot to furnish an 18:1 mixture of the desired pentaol **13**, mp 190.4–191.0 °C, $[\alpha]_D^{22}$ −23.0 (*c* 0.3, MeOH) and the diastereomeric pentaol in 81% combined overall yield. Interestingly, dihydroxylation of acetyl carbamate **11** and pivaloyl carbamate **12** resulted in much lower stereoselectivities of 9:1 and 7:1, respectively.

Since **13** comprises all the requisite chiral functional groups of *N*-acetylneuraminic acid **1**, the remaining synthetic operation is to transform the benzyloxy group into an α-keto carboxylic acid functionality. Accordingly, **13** was protected as a triacetonide using 2,2-dimethoxypropane in the presence of PPTS in $CHCl_3$ to give the desired triacetonide **14** $[\alpha]_D^{22}$ −14.3 (*c* 1.2, $CHCl_3$), in 74% yield along with 12% of diacetonide oxazoline **15**, which was more significantly formed under a variety of other attempted reaction conditions (Scheme 3). After debenzylation of **14** in 94% yield by hydrogenolysis, Wasserman's protocol[16] was employed for the installation of α-keto carboxylate moiety to primary alcohol **16**, $[\alpha]_D^{24}$ −16.0 (*c* 0.9, $CHCl_3$). Alcohol **16** was oxidized with $NaIO_4$ in the presence of $RuCl_3$, followed by coupling with $CH(=PPh_3)CN$ in the presence of EDCI and DMAP. The resulting phosphorane **18** was exposed to O_3 in MeOH to provide α-keto ester **19**, $[\alpha]_D^{16}$ −11.9 (*c* 1.46, $CHCl_3$), in 71% overall yield from **16**. Triacetonide **19** was consecutively deprotected and cyclized with methanolic HCl, and then the generated methyl ester **20**[17,18] was hydrolyzed to *N*-acetylneuraminic acid **1**, $[\alpha]_D^{17}$ −32.0 (*c* 1.19, H_2O),[11b] in 84% overall yield. For further identification, **20** was peracetylated with Ac_2O to produce a 6:1 mixture of pentaacetate **21**, $[\alpha]_D^{18}$ −32.0 (*c* 0.54, $CHCl_3$),[11f,17c,18] and the corresponding anomeric acetate.[19]

Received (in Cambridge, UK) 22nd November 1999, Accepted 23rd December 1999

Boronic acid colour sensor 2 undergoes a large visible colour change, from purple to red in aqueous solution on the addition of monosaccharides.

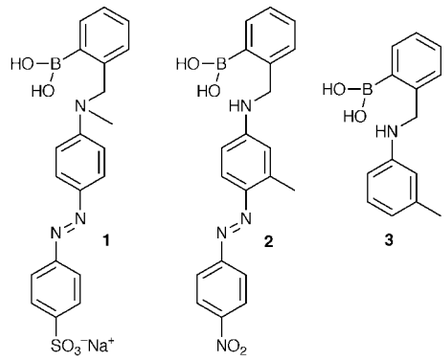
Much recent attention has been paid to the development of synthetic molecular receptors with the ability to recognise neutral organic species, including saccharides. A large majority of these systems have utilised hydrogen bonding interactions for the purposes of recognition and binding of guest species. However, there is still no designed, monomeric receptor which can compete effectively with bulk water for low concentrations of monosaccharide substrates.[1]

Boronic acids readily and reversibly form cyclic esters with diols in aqueous basic media. Saccharides contain a linked array of hydroxy groups ideal for binding to boronic acids. The most common interaction is with 1,2- and 1,3-diols of saccharides to form five- or six-membered rings respectively *via* two covalent bonds. Lorand and Edwards determined the selectivity and first stability trends of various polyols and saccharides towards phenylboronic acid.[2]

The complex stability increases from ethylene glycol to D-fructose, *i.e.* from the simple acyclic diols to the rigid, vicinal *cis*-diols of saccharides. This observed selectivity order is common to all monoboronic acids, not just to phenylboronic acid.[3] The suitability of the boronic acid functionality as a receptor for saccharides has been established in both circular dichroism and fluorescence detection studies. Indeed, a number of fluorescent sensors have been reported in the literature.[4–6]

A fairly recent development has been the study of the effect of saccharides on the colour of dyes containing boronic acid functionality. Russell[7] synthesised a boronic acid azo dye from *m*-aminophenylboronic acid which was found to be sensitive to saccharides. Nagasaki, Shinmori and Shinkai observed that chromophores containing boronic acid moieties and which aggregate in water, changed colour and deaggregated upon addition of saccharides.[8] This year Strongin[9] reported a system based on resorcinarenes for the visual sensing of saccharides. However, for a colour change to be observed the saccharide must be heated (90 °C) in DMSO.

In 1994 Sandanayake and Shinkai reported 'the first known synthetic molecular colour sensor for saccharides'.[10] This designed molecular internal charge transfer (ICT) sensor, dye molecule **1**, was based on the intramolecular interaction between the tertiary amine and the boronic acid group.[11,12] The electron-rich amine creates a basic environment around the electron-deficient boron centre, which has the effect of inducing the boronic acid–saccharide interaction and reducing the working pH of the sensor.[13] Electronic changes associated with this decrease in the pK_a of the boronic acid moiety on saccharide complexation were shown to be transmitted to the neighbouring amine. This creates a spectral change in the connected ICT chromophore, which can be detected spectrophotometrically. The pK_a value associated with the boron–nitrogen interaction shifted on saccharide addition.



The main drawback of this system is the relatively small shifts in the absorption bands of the chromophore upon saccharide binding. The aim with this research was to develop a molecular ICT sensor, which produces a large visible colour change on saccharide binding. If a system with a large colour change can be developed it could be incorporated into a diagnostic test paper for D-glucose, similar to universal indicator paper for pH. Such a system would make it possible to measure D-glucose concentrations without the need of specialist instrumentation. This would be of particular benefit to diabetics in developing countries.

Dye molecule **2** was prepared in three steps in high yield.‡ The imine formed between comercial 2-formylphenylboronic acid and *m*-toluidine was reduced using $NaBH_4$ to give amine **3** in 75% yield. The final step is to couple **3** with the diazonium salt of 4-nitroaniline to give the boronic acid azo dye molecule **2** in 74% yield. The *m*-methyl group of **3** ensures that only the *p*-isomer is obtained.[14]

Absorption–pH titrations, from pH 2 to 12, of **2** in 0.05 mol dm^{-3} NaCl in MeOH–H_2O (1:2, w/w), were followed using a UV-VIS spectrometer. The experiments were then repeated with 0.05 mol dm^{-3} D-fructose also present. The NaCl present acts as an ionic buffer because small amounts of NaCl are formed on adjustment of the pH with NaOH and HCl. Because the titrations are carried out in a MeOH–H_2O mixture rather than simply water, the concept of pH is not strictly applicable to this situation. However, De Ligny and Rehbach have shown that for solutions in 50% MeOH the pH is only changed by 0.1 of a pH unit compared to a 100% water solution.[15]

The pK_a of compound **2** calculated from the absorption–pH titrations[16] was 10.2 and in the presence of 0.05 M fructose the value drops to 6.95. This shift on saccharide binding is in agreement with previous work[2,3,5,6,10] and can be explained by the decrease in oxygen–boron–oxygen bond angle upon saccharide binding, which increases the acidity of the boron centre.[3]

During these titrations it was noted that the UV–VIS absorption maxima of **2** does not move to as long a wavelength at high pH with D-fructose present. To investigate this phenomenon D-fructose, D-glucose and ethylene glycol titrations were performed at pH 11.32. The absorption spectra of the D-glucose titrations are shown in Fig 1.

† Details of the colour changes upon addition of D-glucose to **2** are available as supplementary data, see http://www.rsc.org/suppdata/cc/a9/a909204h/

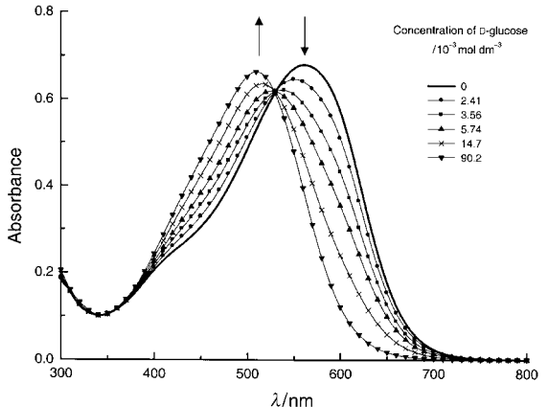


Fig. 1 Absorption spectral changes of dye molecule **2** (5.66×10^{-5} mol dm^{-3}) with increasing concentration of D-glucose at pH 11.32. pH 11.32 buffer: 0.01000 mol dm^{-3} KCl, 0.002771 mol dm^{-3} $NaHCO_3$, 0.002771 mol dm^{-3} Na_2CO_3 in 52.1% MeOH–47.9% H_2O (ref. 23).

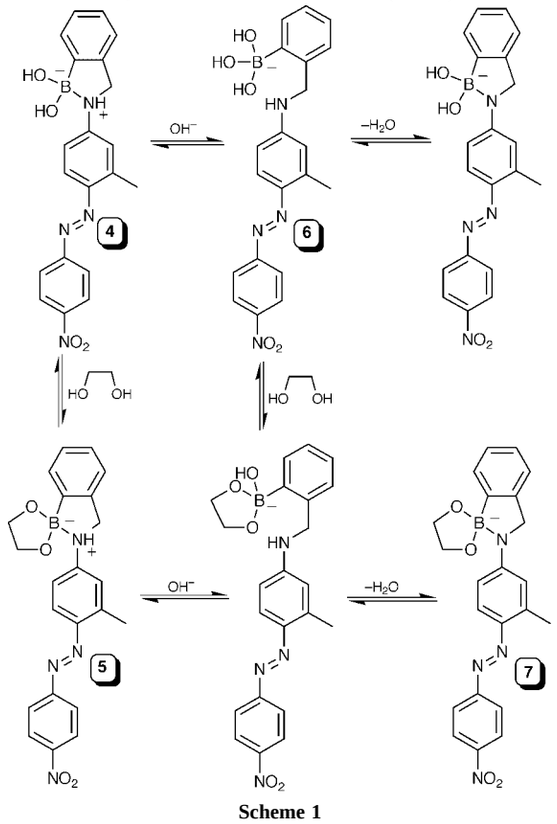

Scheme 1

The wavelength shifts by *ca.* 55 nm to shorter wavelength upon guest complexation. The concentration of the guest required to produce the change is different in each case, which is due to the different stability constants of the binding species, as mentioned earlier.[2] The wavelength shift obtained with **2** on addition of diols is the largest observed to date. The stability constants (log*K*) of the boronic acid dye–saccharide complexes were calculated from UV–VIS absorption–concentration profiles. The log*K* vales are D-fructose (3.75), D-glucose (1.85) and ethylene glycol (0.66) respectively.

Scheme 1 shows the species in equilibria responsible for the observed colour change, consistent with the experimental results. With dye molecule **1** Shinkai proposes that at intermediate pH a boron–nitrogen interaction is prevalent, whereas at high and low pH this bond is broken.[10] What makes the equilibria of dye molecule **2** more interesting is the presence of the *anilinic hydrogen*, which can give rise to different species at high pH. This apparently simple modification in the molecular structure is responsible for the enhanced response of these dyes relative to those previously reported.

In the absence of saccharide, at pH 11.32, the observed colour is purple and in the presence of saccharide the colour is red.† From previous work it is known that when saccharides form cyclic boronate esters with boronic acids, the Lewis acidity of the boronic acid is enhanced and therefore the Lewis acid–base interaction between the boronic acid and the amine is strengthened.[3,12] This stronger B–N interaction will favour the red species over the equivalent saccharide bound purple species. The reason for this can be understood by considering species **4** and **5** from Scheme 1. In the presence of saccharide the B–N interaction in species **5** is stronger than that in species **4**. The increased B–N interaction of species **5** will make the N–H proton of species **5** more acidic than the corresponding proton in species **4**. Therefore at higher pH, species **5** will deprotonate to form the red species **7**, whereas the weaker B–N bond in species **4** is broken by hydroxide ion to form the purple coloured species **6**.§

The colour change arises from the different electronic environment of the anilinic nitrogen. The anilinic nitrogen is conjugated to the azo chromophore. A change in the environment of this nitrogen leads to changes in the energy levels of the n and π^* orbitals of the azo chromophore and hence to a change in the absorption energy and wavelength. The proposal of these equilibrium species may also explain why dye molecule **1** did not give a visible spectral shift on saccharide binding. Because the anilinic nitrogen is tertiary in nature rather than secondary, there is no possibility of deprotonation, so the high pH boron–nitrogen bond cannot be formed. Hence there is no differentiation between the equilibrium species at high pH and consequently no spectral shift is observed.

Photodimerisation of a styrylpyrazine amphiphile suppresses the release of glucose entrapped in its mixed vesicle with DPPC

Jong-Mok Park, Shigeru Aoyama, Wanbin Zhang, Yohji Nakatsuji and Isao Ikeda*

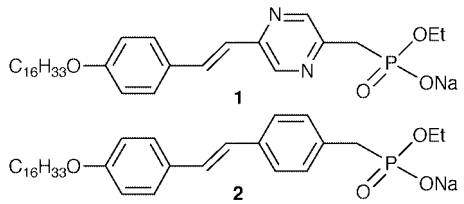
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565-0871, Japan. E-mail: ikeda@ap.chem.eng.osaka-u.ac.jp

Received (in Cambridge, UK) 1st October 1999, Accepted 5th January 2000

Photolysis of a styrylpyrazine amphiphile in the bilayer of a vesicle made from its mixture with DPPC, with irradiation above 300 nm, effectively suppressed the release of glucose entrapped in the vesicle, while the stilbene analogue induced a sudden perturbation to release the glucose under the same conditions.

Vesicles of lipid bilayers have been extensively studied as an excellent model for a drug-delivery system (DDS) over 20 years.[1] The study of DDSs using vesicles can be generally classified into two main areas: the transport of vesicles targeting a specified site in a living body, and the release control of drugs entrapped in the interior space of vesicles. Concerning the latter case, much effort has been devoted to introducing photochromic molecules such as azobenzene, spiropyran and stilbene into the bilayer of vesicles as a device for changing the permeability of the bilayer membrane in response to light irradiation.[2,3] Most of these studies, however, have been focused on application of intramolecular photochromism, such as *cis–trans* isomerism and a conformational isomerism in the case of spiropyran, to the release control system of substances entrapped in vesicles by light. Although this intramolecular photochromism has been successfully used to regulate the release rate with irradiation at two independent wavelengths, it was impossible to stabilize the bilayer and suppress the release using this strategy.

In our previous paper,[4] we reported that styrylpyrazine amphiphile **1** showed very fast and topochemically-controlled photodimerisation and intermolecular photochromism between



the monomer and its *syn* head-to-head cyclobutane dimer in aqueous dispersion. Our recent study has been directed toward application of this intermolecular photochromism to the photo-regulated release control of substances entrapped in vesicles. In the course of this study, we found that styrylpyrazine amphiphile **1** stabilizes the bilayer of the vesicle made from its mixture with L-α-dipalmitoyl phosphatidylcholine (DPPC) to suppress the release of glucose entrapped in the vesicle with irradiation above 300 nm, while the stilbene analogue **2** induces a sudden perturbation of the bilayer to release the glucose. Here we discuss these interesting observations from the point of view of the difference in molecular stacking modes of the two chromophores in the bilayer of the vesicles.

The mixed vesicles of **1** or **2** with DPPC were prepared by the conventional sonication method.† Permeability properties of the vesicles were studied by the measurement of glucose (%) released from vesicles in the course of storage time at 25 °C, as shown in Fig. 1. The release rate of glucose was decreased by incorporating **1** into the DPPC vesicle compared to that from the DPPC vesicle, whereas the release rate was greatly increased by incorporating **2** into the DPPC vesicle. Upon irradiation of the vesicle of **1** (**1**:DPPC = 1:4 molar ratio, hereafter referred to as vesicle **1**), which was stored for 13 h before irradiation, for 10 min under Ar atmosphere with a 500 W Xenon short-arc lamp through Pyrex glass, the release of glucose from the vesicle **1** was more suppressed than that from the untreated one. The mixtures of **1** with DPPC (**1**:DPPC = 1:3 and 1:2), however, were not able to form vesicles entrapping glucose under the same dispersion conditions. On the other hand, upon irradiation of the vesicle of **2** (**2**:DPPC = 1:6 molar ratio, hereafter referred to as vesicle **2**), which was stored for 17 h before irradiation, for 30 min under the same conditions, the release was initially accelerated and then suppressed. The vesicle of **2** (**2**:DPPC = 1:4 molar ratio) also indicated a similar acceleration effect of the release rate by the photolysis.

In order to explain these interesting results, we investigated the photochemical reactivities of **1** and **2** by irradiation above 300 nm in the bilayer matrix of DPPC vesicles by ^{1}H NMR spectroscopy. The aqueous dispersion of **1** (**1**:DPPC = 1:4) or **2** (**2**:DPPC = 1:6) obtained by the same procedure as referred to above was irradiated under Ar atmosphere with a 500 W Xenon short-arc lamp through Pyrex glass. ^{1}H NMR measurements were conducted in a mixed solvent (CD_3OD–$CDCl_3$ = 2:3) after removing the water *in vacuo*. It is obvious that the overall reaction process of **1** is very different from that of **2**, as shown in Fig. 2. In the case of **1**, the content (%) of the *trans*-monomer decreased rapidly with irradiation to give directly the corresponding *syn* head-to-head cyclobutane dimer, although a trace of the *cis*-isomer was detected. In the case of **2**, however, the content (%) of the *cis*-monomer increased rapidly to the

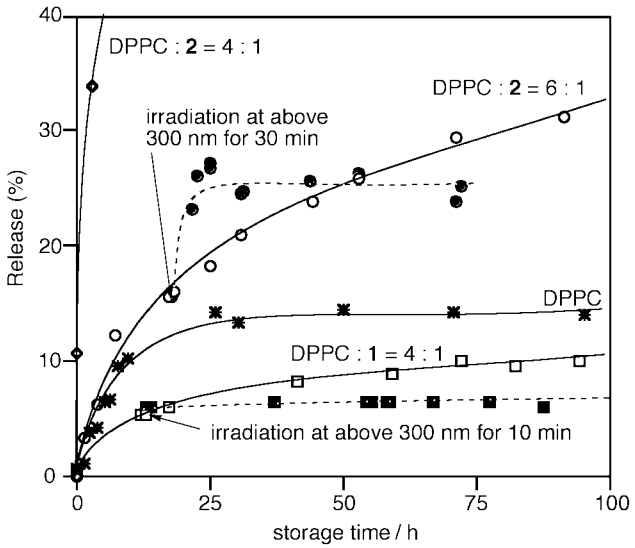


Fig. 1 Release (%) of glucose entrapped inside vesicles made from (※) DPPC, (□) a mixture of DPPC:**1** = 4:1, (■) DPPC:**1** = 4:1 after irradiation above 300 nm for 10 min at time = 13 h, (○) DPPC:**2** = 6:1, (●) DPPC:**2** = 6:1 after irradiation above 300 nm for 30 min at time = 17 h and (◇) DPPC:**2** = 4:1 as a function of storage time at 25 °C.

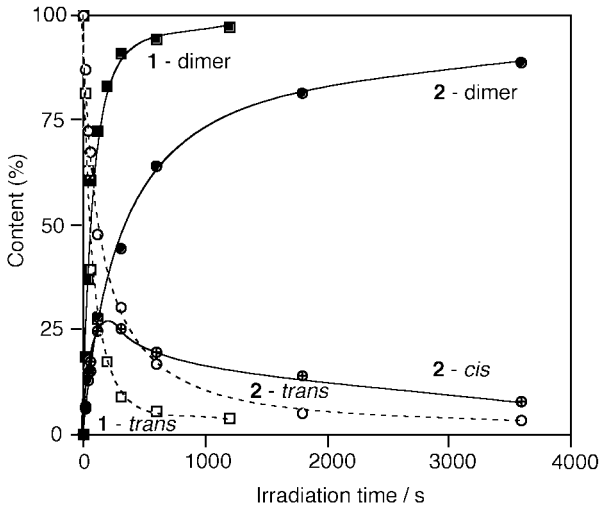

Fig. 2 Comparison of photoreactivities of **1** and **2** incorporated in the bilayer matrix of DPPC with irradiation at above 300 nm. Variation of content (%) of (□) **1**-*trans*, (■) **1**-*syn* head-to-head dimer, (○) **2**-*trans*, (⊕) **2**-*cis* and (●) **2**-*syn* head-to-head dimer as a function of the time of irradiation, where the suspension of **1** or **2** was prepared by dispersion of the mixture (**1**:DPPC = 4 μmol:16 μmol) or (**2**:DPPC = 2.8 μmol:17.2 μmol) in 2 ml of Milli-Q water, respectively.

level of 25% at the initial stage of irradiation with simultaneous formation of the corresponding *syn* head-to-head cyclobutane dimer, and then decreased progressively with the increase of the dimer formation. The reaction behavior of **1** in the bilayer matrix of DPPC was similar to that in the pure aqueous dispersion.[4] This observation suggests that **1** forms aggregates with a 'translation' structure having a strong face-to-face stacking through the multipole-multipole interaction even when **1** is diluted in the bilayer matrix of DPPC and, therefore, the photoisomerism is suppressed by the strong aggregation. On the other hand, the reaction behavior of **2** in the bilayer matrix of DPPC was considerably different from that in the aqueous dispersion.[4] The pure aqueous dispersion of **2** did not form the *cis*-monomer upon irradiation above 300 nm, while 5.5 mol% of 4-hexylstilbene-4′-butyric acid in a dihexadecyl phosphate vesicle gave a photostationary state containing 80% *cis*- and 20% *trans*-isomer upon irradiation at 315 nm.[3] These observations suggest that the intermolecular interaction of **2** is much weaker than that of **1** in the aggregate and, therefore, the fluidity of the bilayer membrane of the vesicle **2** is much higher than that of the vesicle **1**. This speculation is supported by the higher phase transition temperature (T_c) from the gel state to the liquid crystalline state of pure **1** (64 °C) than that of pure **2** (53 °C),[4] and the much lower permeability of the vesicle **1** (1:4) than that of the vesicle **2** (1:4). The weak intermolecular interaction of **2** may be due to the 'pinwheel' unit[5] aggregate having a face-to-edge stacking, as proposed by Whitten *et al.*

It is well known that the photoisomerisation of amphiphilic compounds containing *trans*-azobenzene and *trans*-stilbene to the *cis*-isomers in the bilayer membrane of vesicles increases the permeability of substances entrapped in their vesicles.[2] Therefore, the drastic acceleration of the release from the vesicle **2** at the initial stage of photolysis can be reasonably explained by considering the perturbation of the bilayer membrane induced by formation of the *cis*-isomer, and the suppression of the release from the vesicle **2** at the late stage and from the vesicle **1** may be ascribed to the formation of the corresponding *syn* head-to-head cyclobutane dimers. This was confirmed by investigating the release from the vesicle made from the pure *syn* head-to-head cyclobutane dimer of **1** and DPPC (1:8), the extent of which was smaller than that from the vesicle **1**.

Recently, a 'catastrophic' destruction of the vesicle made from a mixture of a styrylthiophene amphiphile with DPPC through the photodimerisation of the styrylthiophene,[6] inducing the release of substance entrapped within the vesicle, has been reported by Whitten *et al.* They proposed that the aggregation structure of the styrylthiophene amphiphile is a 'pinwheel' tetramer having face-to-edge stacking in the bilayer matrix of DPPC and, therefore, on the occasion of photodimerisation, some additional motion should be necessary to bring adjacent molecules close enough to dimerise. They pointed out the dimerisation, including a structural change, as the main reason for the vesicle disruption.

Considering the release property of the vesicle **2** and Whitten's result,[6] suppression of the release from the vesicle **1** without any perturbation during the dimerisation is unique. A simple topologically-controlled photodimerisation is expected to result in minimal disruption of the vesicle microstructure. Obviously, the vesicle **1** is just such a case. To the best of our knowledge, this is the first case for clean suppression of the release of substances from vesicles by [2 + 2] cycloaddition.

From the viewpoint of using the photochromism between a 1,2-diarylethylene monomer and the corresponding cyclobutane dimer as a new strategy for controlling the release of substances entrapped in vesicles, this clean suppression of the release is noteworthy. Naturally, since the reverse reaction, the cleavage of the cyclobutane dimer to the monomer,[4] is expected to increase the release rate, further study on the reversible release-control of vesicles by using **1** is now in progress in our laboratory.

Notes and references

† The thin layers of the mixtures **1** (**1**:DPPC = 4 μmole:16 μmole), or **2** (**2**:DPPC = 4 μmole:16 μmole, 2.8 μmole:17.2 μmole) with DPPC were prepared on the inside wall of a test tube by dissolving them in 2.5 ml of a MeOH–$CHCl_3$ (1:4, v/v) mixed solvent and evaporating the solvent *in vacuo*. After drying in a vacuum desiccator, 2 ml of an aqueous solution of glucose (300 mM) was added and sonicated for 5 min at 70 °C with a probe-type sonicator. Small unilamellar vesicles containing glucose were separated from the untrapped glucose by gel-filtration chromatography (Sephadex G-50, 1.5 × 18 cm, eluent: 150 mM NaCl aqueous solution). The formation of vesicles was confirmed by a well-established gel-filtration method (ref. 7). The determination of glucose was conducted by the measurement of absorbance at 505 nm of quinone dye produced by the Mutarotase GOD method described by Miwa *et al.* (ref. 8). The amount of glucose released (%) from the vesicles was calculated using eqn. (1),

$$\text{Glucose released (\%)} = A_t/A_{total} \times 100 \quad (1)$$

where A_t is the absorbance of the suspension after a definite period of storage, and A_{total} is the absorbance after addition of an aqueous solution of Triton X-100 (200 g l^{-1}) to the suspension.

Controlled/'living' radical polymerization of MMA *via in situ* ATRP process

Xiao-Ping Chen and Kun-Yuan Qiu*

Department of Polymer Science and Engineering, College of Chemistry and Molecular Engineering, Peking University, Beijing 100871, China. E-mail: kyqiu@chemms.chem.pku.edu.cn

Received (in Cambridge, UK) 19th November 1999, Accepted 23rd December 1999

Well-defined PMMA with very low polydispersity and α-Et_2NCS_2 and ω-Cl end groups was synthesized *via* a novel controlled/'living' radical polymerization (*in situ* ATRP process) using a tetraethylthiuram disulfide (TD)/$FeCl_3$/PPh_3 initiating system.

Recently, some effective controlled/'living' radical polymerization systems have been reported, such as stable free radical polymerization with 2,2,6,6-tetramethylpiperidinyl-1-oxyl (TEMPO),[1] atom transfer radical polymerization (ATRP) systems,[2,3] and reversible addition–fragmentation chain transfer (RAFT) systems.[4] Thus, the controlled/'living' radical polymerization has become a reality.

So far, there are two kinds of ATRP, *i.e.* conventional ATRP and reverse ATRP. In conventional ATRP, organic halides (RX) are used as initiators, transition-metal compounds in their lower oxidation state (M^n, where n is the oxidation state) are used as catalysts and electron-donating compounds are used as ligands (L). In this process, a dynamic equilibrium is established where the dormant polymer chains are reversibly activated *via* a halogen atom transfer reaction.

In reverse ATRP,[5–9] a radical initiator and a higher oxidation state transition-metal catalyst complex $M^{n+1}XL_m$ (where m is the number of ligands) are used. Reverse ATRP differs from conventional ATRP in the initiation step, where the initiating active species or the propagating active species can abstract a halogen atom from the oxidized transition-metal complex to form the dormant species and the reduced transition-metal species.

Here we report a novel ATRP (*in situ* ATRP), using TD/$FeCl_3$/PPh_3 as the initiating system. In the *in situ* ATRP process, the essential initiator [halide species (Et_2NCS_2Cl)], and the catalyst [transition-metal compound in its lower oxidation state ($FeCl_2$)] were both produced *in situ* from the reactions of TD and $FeCl_3$. The subsequent polymerization proceeded *via* a conventional ATRP process. The PMMAs synthesized using the TD/$FeCl_3$/PPh_3 system have very narrow polydispersities (1.04–1.07) and a very fast rate of polymerization.

The polymerization of MMA was carried out in bulk with the TD/$FeCl_3$/PPh_3 initiation system at 100 °C. Results for the system with the initial ratio of $[MMA]_0:[TD]_0:[FeCl_3]_0:[PPh_3]_0 \approx 200:1:10:30$ are shown in Fig. 1. It shows that the $M_{n\,(GPC)}$ (number-average molecular weight measured by GPC), increases linearly with conversion from 2200 to 7100, and the polydispersity index is very narrow (1.04–1.07) as the monomer conversion is increased from 21.5 to 85% in 8 min. The $M_{n\,(GPC)}$ is close to the $M_{n(th)}$, a theoretical number-average molecular weight computed from $M_{n(th)} = ([MMA]_0/2[TD]_0) \times MW_{MMA} \times$ conversion. The efficiencies of initiator f as calculated from $f = M_{n(th)}/M_{n(GPC)}$ are around 1.0. In a plot of $\ln([M]_0/[M])$ *vs.* time as shown in Fig. 2, a straight line is observed, indicating that the kinetics is first order in monomer. This means that the concentration of propagating radicals is constant during the polymerization.

When $[MMA]_0:[TD]_0:[FeCl_3]_0:[PPh_3]_0 \approx 200:1:10:30$, the results of solution polymerization of MMA in anisole are similar to those of bulk polymerization, while a lower rate of polymerization and slightly broader polydispersities (about 1.1) were obtained.

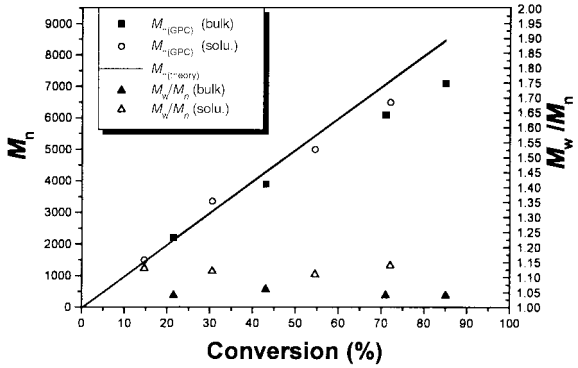

Fig. 1 Dependence of the PMMA molecular weight and polydispersity on the monomer conversion at 100 °C. Conditions: in bulk, $[MMA]_0 = 9.38$ mol l^{-1}, $[TD]_0 = 4.69 \times 10^{-2}$ mol l^{-1}, $[FeCl_3]_0 = 4.69 \times 10^{-1}$ mol l^{-1}, $[PPh_3]_0 = 1.41$ mol l^{-1}; in anisole, $[MMA]_0 = 4.69$ mol l^{-1}, $[TD]_0 = 2.35 \times 10^{-2}$ mol l^{-1}, $[FeCl_3]_0 = 2.35 \times 10^{-1}$ mol l^{-1}, $[PPh_3]_0 = 7.05 \times 10^{-1}$ mol l^{-1}. $M_{n(th)} = ([MMA]_0/2[TD]_0) \times MW_{MMA} \times$ conversion. Molecular weights and molecular weight distributions of polymer samples were measured using a Waters 515 GPC with polystyrene calibration standards.

From the results mentioned above, it can be observed that the MMA polymerization with the TD/$FeCl_3$/PPh_3 initiation system at 100 °C proceeds in a controlled/'living' manner.

From the FTIR, UV and NMR spectra, it can be seen that the Et_2NCS_2– group is one of the end groups of the polymer. The signals at 1267 and ~3450 cm^{-1} in the FTIR spectrum are characteristic absorption bands of the Et_2NCS_2– group. The UV spectrum of the PMMA powder identifies Et_2NCS_2– (~283 nm) is an end group. The number of Et_2NCS_2– groups was determined by UV spectroscopy in $CHCl_3$ to be *ca.* 1. In the ^1H NMR spectrum of the PMMA, the signal at δ_H 3.07 is that of the methylene of $Et_2NCS_2CH_2$–, and that at δ_H 3.70 is from the methylene of $(CH_3CH_2)_2NCS_2$–. The signal at δ_H 3.79 is that of the protons of the methoxy group, and that at δ_H 2.50 is from the methylene protons of the terminal MMA unit capped with an ω-chlorine, similar with that reported by Ando *et al.*[10] The $M_{n(NMR)}$ (6600) is close to $M_{n(GPC)}$ (6500), indicating that all the polymer chains have chlorine end groups. So, the polymers

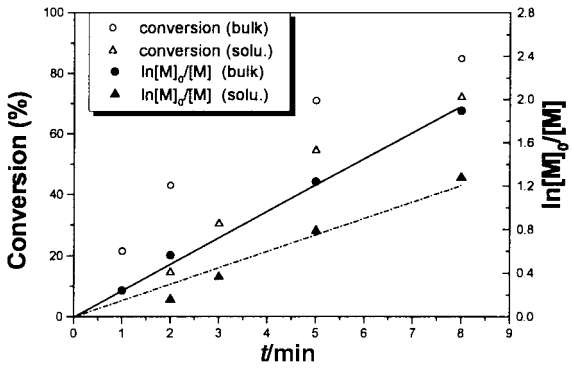

Fig. 2 Time dependence of $\ln[M]_0/[M]$ and conversion at 100 °C, where $[M]_0$ and $[M]$ are the MMA concentration at times 0 and t, respectively. Under the same conditions as in Fig. 1.

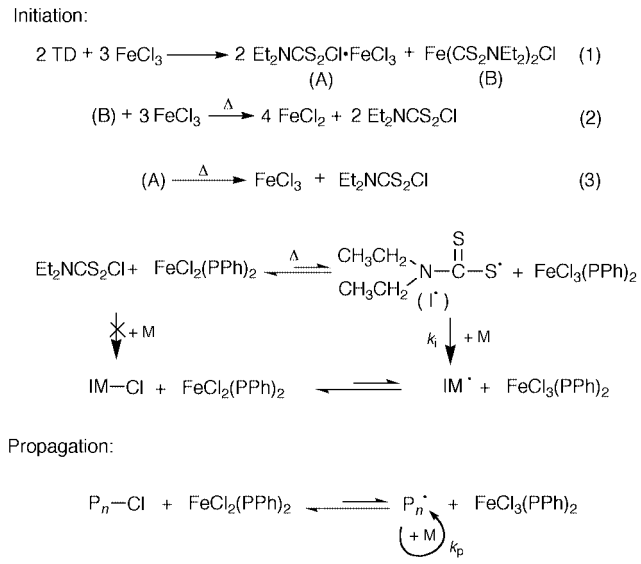

Scheme 1

produced using the initiation system are well-defined, not only with very narrow polydispersity but also with precise end groups, *i.e.* α-Et_2NCS_2– and ω-chlorine groups. The presence of an ω-chlorine end group in the obtained PMMA suggests the polymerization proceeds *via* an ATRP process.

In order to clarify the nature of the polymerization, we carried out some control experiments under fixed conditions: $[MMA]_0$ = 9.38 mol l^{-1}, $[TD]_0$ = 4.69 × 10^{-2} mol l^{-1}, $[FeCl_3]_0$ = 4.69 × 10^{-1} mol l^{-1}, $[PPh_3]_0$ = 1.41 mol l^{-1}, 100 °C. In this case, the conversion was 85% (8 min). However, the conversion decreased to 75% after 20 min in the presence of TEMPO ($[TEMPO]_0$ = 12.57 × 10^{-2} mol l^{-1}). This suggests that the activate species are possibly radicals. When H_2O was added ($[H_2O]_0$ = 281.4 × 10^{-2} mol l^{-1}), the polymerization still proceeded at a moderate rate with 49.3% conversion after 20 min. Generally speaking, MMA is an electron poor monomer and cannot be polymerized *via* a cationic process. It is impossible to perform an ionic polymerization in the presence of water ($[H_2O]_0/[TD]_0$ = ~60). Therefore, the polymerization with the TD/$FeCl_3$/PPh_3 system is a radical polymerization. When the polymerization was carried without the PPh_3 ligand, no polymer was obtained after 16 h but precipitated $FeCl_2$ was produced.

According to the results mentioned above, we propose a mechanism for the *in situ* ATRP as depicted in Scheme 1.

When TD was added to the mixture of $FeCl_3$, MMA and PPh_3 at room temperature, the color of the system instantly became dark green.[11] This indicated that TD rapidly reacted with $FeCl_3$ and two complex products of halide, $Et_2NCS_2Cl·FeCl_3$ (A) and $Fe(Et_2NCS_2)_2Cl$ (B) were produced,[12] as depicted in eqn. (1) in Scheme 1. At high temperature, such as 100 °C, (B) reacted with $FeCl_3$ to form Et_2NCS_2Cl and $FeCl_2$ [eqn. (2) in Scheme 1)]. (A) thermally decomposed into Et_2NCS_2Cl and $FeCl_3$ [eqn. (3) in Scheme 1]. Thus, the initiator (Et_2NCS_2Cl) and the transition-metal catalyst in its lower oxidation state ($FeCl_2$) for an ATRP system were *in situ* created. The primary radical $Et_2NCS_2^{\cdot}$, formed from the reaction of Et_2NCS_2Cl with $FeCl_2(PPh_3)_2$, can initiate MMA polymerization. The subsequent reactions proceeded following a conventional ATRP.

Due to the presence of an ω-chlorine end group on the polymer chain, chain extension polymerization of the PMMA can be carried out using a conventional ATRP initiation system. The results are as follows: in bulk at 100 °C, M_n of PMMA = 18 400, M_w/M_n = 1.11, $[PMMA]_0$ = 5.33 × 10^{-3} mol l^{-1}, $[MMA]_0$ = 8.23 mol l^{-1}, $[FeCl_2]_0$ = 5.33 × 10^{-3} mol l^{-1}, $[PPh_3]_0$ = 1.6 × 10^{-2} mol l^{-1}; a conversion of 70% was achieved after 36 h, M_n of the chain-extended PMMA = 157 700, M_w/M_n = 1.43.

A palladium metallacalix[4]arene capped with a gadolinium atom

Jorge A. R. Navarro* and Juan M. Salas

Departamento de Química Inorgánica, Universidad de Granada, E-18071 Granada, Spain. E-mail: jarn@ugr.es

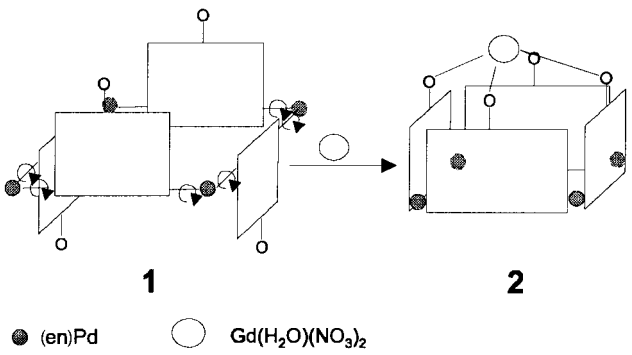
Received (in Basel, Switzerland) 15th November 1999, Accepted 7th January 2000

A molecular vase, analogous to a calix[4]arene, has been generated from (en)Pd^{II} and 4,6-dimethyl-2-hydroxypyrimidine, the X-ray crystallographic study showing that this compound is able to incorporate a gadolinium atom.

Calixarenes have been the subject of high interest owing to their wide range of applications.[1,2] Their cyclic frameworks associated with the presence of phenol oxygen atoms afford efficient complexing agents for metal ions,[3] while their hydrophobic cavities allow the inclusion of guest molecules. Formation of analogous inorganic macrocycles, metallacalixarenes, can be achieved by combining 120 and 90° bond angles provided respectively, by an appropriate ligand and a suitable metal entity.[4,5] Other angle combinations lead to molecular triangles,[6] squares,[7] and other structures of higher complexity.[8]

Reaction of $[(en)Pd(H_2O)_2]^{2+}$ with 4,6-dimethyl-2-hydroxypyrimidine (Hdmpymo) generates the cyclic species $[(en)Pd(dmpymo\text{-}N^1,N^3)]_4^{4+}$ **1**, (Scheme 1) by a self-assembly process. The presence of four exocyclic oxygen atoms of the pyrimidine moieties, suggested the possible coordination of additional metal atoms. Lanthanide metal ions were thought to be ideally suited in terms of both size and oxygen affinity. Addition of an excess of $Gd(NO_3)_3{\cdot}6H_2O$ to an aqueous solution of **1** affords $\{Gd(NO_3)_2(H_2O)[(en)Pd(dmpymo)]_4\}^{5+}$ **2** (Scheme 1),† which has been structurally characterised‡ and has been proved to be a metallacalix[4]arene of C_s symmetry (Fig. 1). The four Pd centres lie in a plane forming an almost perfect square with *ca.* 5.7 Å sides. The pyrimidine rings are not coplanar to the Pd_4 plane showing deviations of 35.2, 64.0 and 37.8°, respectively, for rings A, B and C, which results in the formation of a molecular vase. This is a consequence of Gd binding to the oxygen donor atoms of the dmpymo ligands which forces the four pyrimidine moieties to orient, from a high number of possibilities, in the same direction. The resulting conformation adopted by the metallacalixarene is that of a pinched cone. In classic organic calix[4]arenes stabilisation of the cone conformation, after binding of a single transition metal atom simultaneously to four phenol oxygens, is usual.[3] In metallacalix[4]arenes, however, the larger size of the oxo-surface, with O··O separations of *ca.* 4.4 Å, does not fit to transition metals, for which simultaneous binding to only two adjacent oxygen atoms has been observed.[9] The larger size of Gd^{3+} ideally suits the geometric requirements of the oxo-surface of **1** forming strong bonds to the four exocyclic dmpymo oxygens. The coordination sphere about Gd is completed by two bidentate nitrate anions placed over the calix lower rim and a water molecule completely encapsulated in the calix cavity. Calixarenes are well known for their ability to include guest molecules in their hydrophobic cavity.[1] Likewise, metallacalixarenes also possess a hydrophobic cavity which is also able to encapsulate organic residues.[9] In the present case, the opening of the cavity measured as the separation between C(5A)··C(5C) of 7.82(2) Å and C(5B)··C(5B#1) of 10.64(2) Å is big enough to permit inclusion of guest molecules. Additionally there is a water molecule coordinated to the Gd center which is completely included in the metallacalixarene cavity. This alters, the hydrophobic nature of the cavity[9] permitting the inclusion of an additional water molecule and a nitrate anion inside the cavity, which gives rise to strong H bonding interactions, namely O(1W)··O(5W) and O(1W)··O(91), with separations of 2.77(2) and 2.88(3) Å, respectively. This change in the hydrophobic nature of the cavity explains why it was not possible to find any host–guest chemistry of organic molecules for the $La[(en)Pt(uracilate)]_4(NO_3)_3$ species for which no X-ray structure was available.[9]

^{1}H NMR spectra of **1** are diagnostic of the N1, N3 bridging coordination mode of dmpymo, with retention of the original equivalence of its two methyl substituents. Replacement of the acidic protons at N1 and N3 in $H_2dmpymo^+$ by two metal entities is responsible for a significant downfield shift of the resonance of the aromatic proton H5 (−0.51 ppm) and upfield shift of the resonance of the methyl groups (δ +0.44 ppm) of dmpymo. The presence of only one set of dmpymo resonances in **1** is in agreement with its probable conformational flexibility.[5] We were also able to measure the ^{1}H NMR spectrum of **2** even thought it is paramagnetic. The spectrum is more complex than that of **1** with now two sets of signals for the



Scheme 1 Metallacalix[4]arene **1** presents conformational flexibility as a consequence of free rotation about the Pd–dmpymo bonds. In **2** Gd coordination to the oxo-surface of the metallacalix[4]arene is responsible for its fixed cone conformation.

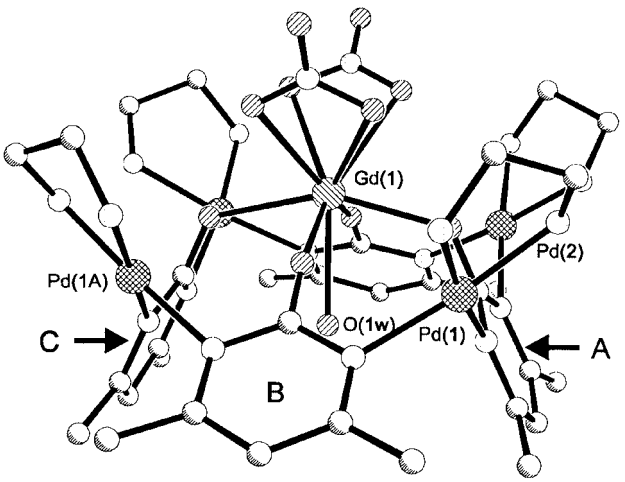


Fig. 1 Perspective view of the cation $\{Gd(NO_3)_2(H_2O)[(en)Pd(dmpymo)]_4\}^{5+}$ in the crystal structure of **2**. Pyrimidine rings A, B and C are labelled. Selected band lengths (Å): Gd(1)–O(2A) 2.309(8), Gd(1)–O(2C) 2.306(8), Gd(1)–O(2B) 2.323(6), Gd(1)–O(1W) 2.49(1), Gd(1)–O(41) 2.504(6), Gd(1)–O(31) 2.535(6), Pd(1)–N(1C) 2.071(7), Pd(1)–N(3B) 2.087(7), Pd(2)–N(3A) 2.072(7), Pd(2)–N(1B) 2.082(7).

dmpymo resonances of H5 (δ 6.31, 6.58) and methyl protons (δ 2.86, 3.04). We believe this can be attributed to the increased rigidity introduced to the metallacalixarene after Gd^{3+} coordination to **1**. Addition of La^{3+} has, however, no effect on the resonances of **1**. It is thought that the more polarising nature of Gd^{3+} with respect to La^{3+} leads to stronger bonds to the oxygen donor atoms of **1**.

Notes and references

† $[(en)Pd(dmpymo)]_4(NO_3)_4$ **1** was obtained as follows: $(en)PdCl_2$ (3 mmol) was suspended in water (30 mL), $AgNO_3$ (6 mmol) added and the mixture stirred for 2 h at 60 °C. The mixture was cooled and AgCl removed by filtration. Hdmpymo (3 mmol) was added to the filtrate, at this point the pH was adjusted to 5.0 by means of 1 M NaOH, and the resulting pale yellow solution heated to 60 °C for 5 h. Subsequent concentration of the solution to 15 mL by rotary evaporation gives **1** in 32% yield, after 7 days at room temperature. Radical cyclization of *O*-trityl oximino esters: a ring closure that preserves the oxime function

Derrick L. J. Clive* and Rajendra Subedi

Chemistry Department, University of Alberta, Edmonton, Alberta, Canada T6G 2G2.
E-mail: derrick.clive@ualberta.ca

Received (in Corvallis, OR, USA) 4th November 1999, Accepted 16th December 1999

_O_-Trityl oximino esters 1 undergo stannane-induced radical cyclization to regenerate an oxime function, affording oximino lactones 4; these can be converted into enamides (*e.g.* 11b), and such a transformation was used to make the natural product 14c.

We report radical ring closures of the type summarized in Scheme 1 (X = homolyzable group).[1,2] The special feature of such reactions is that the sp^2 status of the acceptor carbon is preserved—a result that is different from the one seen in the classical cyclization of hexenyl radicals or the radical cyclization of *O*-alkyl oxime ethers.[3–5] Regeneration of the oxime function after the radical closure must involve[6] tautomerization of an intermediate nitroso compound, as shown in Scheme 1, **3** → **4**.†

The starting oximino esters (*cf.* **1**) are prepared using the crystalline reagent **5** (mp 165–166 °C), which is easily made (76%) by stirring equimolar amounts of *O*-trityl hydroxylamine and glyoxylic acid monohydrate in THF for 4 h. Evaporation of

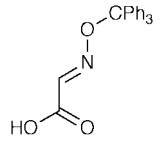
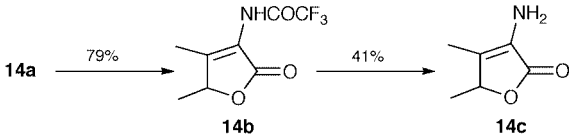
[a] Oxime geometries shown are arbitrary, except for **11** and **14a**. [b] A single product, which isomerizes on storage in MeOH. [c] Combined yield. Isomers **9a** and **9b** were obtained in a ratio of *ca.* 1:2. [d] Two isomers were isolated in yields of 61 and 25%. [e] A mixture (*ca.* 55:45) of two isomers was obtained.



5

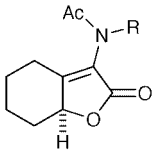


Scheme 2

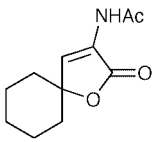
the solvent and column chromatography over silica gel (3:7 hexane–EtOAc) gives pure **5**, whose geometry in the solid state was established by X-ray analysis. The reagent (1 mmol) reacts smoothly with alcohols (1.1 mmol) in CH_2Cl_2 in the presence of DCC (1.1 mmol) and DMAP (1.1 mmol) to give the corresponding esters, after 1–26 h. Yields in these esterifications are generally high (see Table 1, entries 1–6 and 8–9). The parent alcohol for **11** is a known compound,[8,9] but one tentative structural assignment given[8] in the literature [(1-bromocyclohexyl)methanol] is incorrect; our X-ray analysis of **11** establishes the actual structure. In one case (Table 1, entry 7) we prepared the required starting ester by reaction of **5** (1.1 mmol) with a THF solution of the alkene (1.0 mmol) in the presence of NBS (1.1 mmol), and again the yield was high.

The radical cyclizations were done by slow addition (*ca*. 10 h, syringe pump) of separate toluene solutions of Bu_3SnH (0.17 M, 1.5–2.5 mmol per mmol ester) and AIBN (0.012 M, 0.1–0.2 mmol per mmol ester) to a refluxing toluene solution of the ester (1.0–1.8 mmol, 0.016 M). Refluxing was continued for an arbitrary period of 2 h after the end of the addition. The products were isolated in the yields indicated in Table 1, by evaporation of the solvent and flash chromatography. While the oxime geometry for **5**, **11** and **14a** was determined by X-ray analysis, the geometries shown for the other oximes are arbitrary assignments. All the cyclization products were single isomers, except for **14a**. In that example, the material was obtained crystalline, and X-ray analysis showed the crystals to be composed of the *trans,E* and *cis,E* isomers in a ratio of *ca*. 55:45; the same composition was evident from the ^{1}H NMR spectrum. During cyclization of **9** a 1,2-acyloxy rearrangement[10] occurs, driven by formation of a benzylic radical.

We have examined briefly the partial reduction of several of our α-oximino lactones. For example, treatment of **7a** with iron



7b R = H, 54%
7c R = Ac, 30%



11b, 80%

powder in Ac_2O[11] (room temperature, 14 h) gave a mixture of enamide **7b** (54%) and the doubly acetylated analog **7c** (30%). Under the same conditions, **11a** gave **11b** (80%), and no bis-acetylated product was isolated.

Treatment of **14a** with iron powder in TFAA gave enamide **14b** (Scheme 2), the fluorinated anhydride being used because we expected this choice to facilitate subsequent amide hydrolysis. In the event, treatment of **14b** with aqueous K_2CO_3 afforded enamine **14c**, which is a naturally-occurring substance[12,13] that is present in the flowers of the tree *Quararibea funebris* (Llave). Extracts of the flowers have been used[14] by the Zapotec Indians of Oaxaca, Mexico, to treat a number of disorders, including some of a psychological nature, but it is not known whether **14c** itself is biologically active. It has been suggested that the compound may be the biosynthetic precursor of several pyrrole alkaloids present in the flower extract.[14]

All new compounds were characterized spectroscopically, including high resolution mass measurements, except for **9b**, which was isolated as a mixture with **9a**.

Received (in Basel, Switzerland) 15th November 1999, Accepted 7th January 2000

Reaction of a tetracyano[1,1,1,1]metacyclophane blocked in the 1,3-alternate conformation and silver cations under self-assembly conditions leads to a tubular coordination network formed by double bridging of consecutive rings by linearly coordinated metal centres.

Tubular structures are interesting architectures, in particular with respect to their ability to transport ions and molecules. In principle, such structures may be obtained either using non reversible covalent bond formation processes or under self-assembly conditions using reversible interactions. It has been shown that tubular systems may be formed by 1-D chains adopting a helical structure, as observed for polypeptides in natural systems.[1,2] On the abiotic side, helical coordination polymers composed of synthetic organic ligands and metal centres,[3,4] which may be considered as tubular systems, have also been reported. Using self-assembly of silver ions and polydentate ligands, tubular systems formed by the interconnection of metallamacrocycles have been reported.[5,6] Other strategies based on the organisation of cyclic units into tubular arrangements using liquid crystalline phases[7] or polymeric backbones[8] have been shown to be successful as well. Finally, the formation of carbon nanotubes by rolling 2-D graphite sheets has also been demonstrated.[9]

Following the above-mentioned strategy based on the use of H-bonds between cyclic peptides, we reasoned that, by making the appropriate choice of ligands and metal centres, tubular coordination networks may be formed using the self-assembly strategy based on the formation of reversible coordination bonds. The formation of such a structure requires a complementary pair of ligand and metal cation that affords their reversible and mutual interconnection (Fig. 1).

Here, we report the synthesis of the exo-ligand **1** as well as the structural analysis of its tubular coordination network obtained in the presence of silver cations.

We believed that the exo-ligand **1** (Scheme 1) would be promising for the formation of infinite metallatubulanes. Ligand **1** is based on a [1,1,1,1]metacyclophane backbone that is blocked in the 1,3-alternate conformation and bears four nitrile groups as coordination sites, which are located below and above the main plane of the macrocycle in an alternate fashion and thus occupy the apexes of a pseudo-tetrahedron. The choice of **1** was based on the structural study of its hydroxy analogue **3**, which was demonstrated to be in the 1,3-alternate conformation,[10] the mercapto analogue **4**,[11] and on our previous observation dealing with the formation of 1-D coordination networks using ligand **6**.[12] Indeed, it was found that when using the calix **6**, owing to its inherent flexibility, two nitrile groups located on the same face of the ligand could act as a chelate for Ag^+ cations (Fig. 1). Thus, for the linear coordination network formed by bridging consecutive calix units by Ag^+ cations, the coordination geometry adopted by the latter was tetrahedral. In terms of topology, the above mentioned network is in principle of the tubular type; however, the presence of metal centres

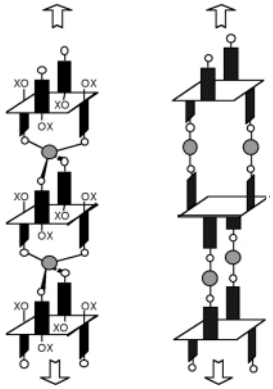

Fig. 1 Schematic representation of two types of tubular coordination networks which can be formed by the self-assembly of ligand **6** with Ag^+ cations adopting a tetrahedral coordination geometry (left) or ligand **1** and Ag^+ cations adopting a linear coordination geometry (right).

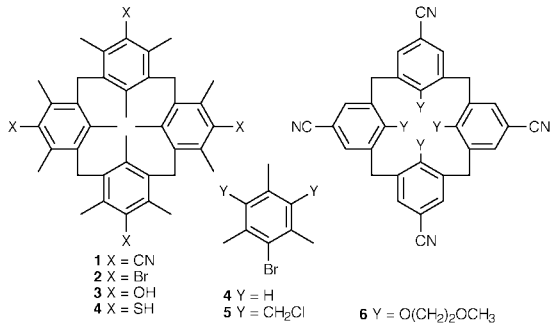
aligned along the tube axis obstructs the channel. In order to circumvent this, the ligand **1** was designed, which incorporates methyl groups that induce considerable rigidity and thus prevent the chelation process.

The synthesis of **1** (Scheme 1) was based on the strategy used for the preparation of **3**.[10] Starting with **4**, compound **5** was obtained in 84% yield upon treatment with $ClCH_2OMe$ in CH_2Cl_2 in the presence of $SnCl_4$ at −15 °C. Upon heating an equimolar mixture of **4** and **5** in $EtNO_2$ and in the presence of $SnCl_4$ for 6 h at 60 °C , the cyclic cyclophane **2** was obtained in 74% yield. The desired **1** was obtained in 54% yield upon treatment of **2** with CuCN in refluxing DMF for 15 h.[13] The 1,3-alternate conformation was established in the solid state by X-ray diffraction for both **1** and **2** (structures not reported here).

The metal cation used for the self-assembly of **1** into a tubular network was Ag(I), which forms kinetically labile complexes and can adopt a linear coordination geometry.[14] Furthermore, Ag^+ has been extensively used for the formation of coordination networks,[15] in particular using nitrile containing ligands.[16]



Scheme 1

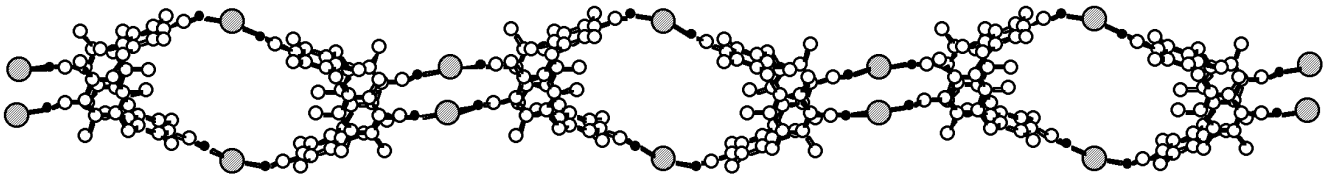


Fig. 2 A portion of the X-ray structure showing the formation of a cationic tubular coordination networks obtained by mutual bridging of Ag+ cations and ligands **1** (view perpendicular to the tube axis). For clarity, H atoms, solvent molecules and anions are not shown.

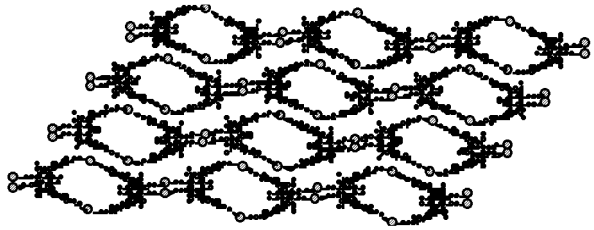

Fig. 3 A portion of the structure showing the packing of the cationic tubular coordination networks (projection normal to the tube axis). For clarity, H atoms and solvent molecules (CH_2Cl_2 and MeOH) are not shown.

Upon slow diffusion of a CH_2Cl_2 (0.75 ml) solution of the ligand **1** (2 mg, 3.18×10^{-6} mol) into a MeOH (1 ml) solution of $AgPF_6$ (8 mg, 3.18×10^{-5} mol) in large excess, colourless crystalline material was obtained. The analysis of single-crystals by X-ray crystallography† revealed the presence of disordered CH_2Cl_2 and MeOH solvent molecules in the lattice in addition to **1**, Ag^+ and PF_6^- anions. As predicted (Fig. 1), in addition to the anions and solvent molecules, the crystal was composed of cationic tubular coordination networks formed by the bridging of consecutive cyclic units by Ag^+ cations (Fig. 2). The ligand **1** adopts the imposed 1,3-alternate conformation. The nitrile groups are almost linear with an average C–C–N angle of *ca*. 177.5° and an average C–N distance of 1.142 Å. In the unit cell, two different Ag^+ cations are present. The coordination sphere around both crystallographically non-equivalent Ag^+ cations is composed of two nitrogen atoms (N–Ag–N 153.8 and 162.3°, C–N–Ag 171.5 and 150.3, 178.3°, N–Ag 2.155 and 2.126, 2.138 Å) and PF_6^- anions with Ag–F distances varying from 2.811 to 2.983 Å. Two Ag^+ cations located on the same face of the molecule are separated by 9.891 and 9.593 Å. The packing of the cationic component (Fig. 3) shows parallel disposition of tubular networks. Interestingly, the 1-D tubular networks are interconnected in a dihapto mode by strong metal–π interactions between Ag^+ cations and the aromatic moiety belonging to the next tubular strand (Ag^+–centroid distance of 3.087 Å). The same observation has been made with metallamacrocyles formed by connecting two cyclic *para*-dimethylaminopyridine derivatives with two Ag^+ cations.[14] Thus, taking into account the above interactions, the arrangement obtained may be described as a 2-D network with translations into two directions of space of two distinct assembling cores based on N–Ag^+–N and Ag^+–π interactions. Thus, the overall structure may be described as stacks of 2-D networks separated by PF_6^- anions. The tubular arrangement is not empty and occupied by solvent molecules. However, none of the solvent molecules (disordered CH_2Cl_2 and MeOH) present are included within the cavity of the cyclophanes but are rather located within cavities formed by interconnection of the cyclic units by silver cations.

In conclusion, employing the self-assembly strategy, the formation of a silver tubular coordination network using a [1,1,1,1]metacyclophane backbone that is blocked in the 1,3-alternate conformation and bears four nitrile groups was achieved and structurally characterised in the solid state by single-crystal X-ray analysis. The exchange of included solvent molecules, as well the enhancement of the size of the tubulane are currently under investigation.

† *Crystal data* for $C_{22}H_{22}N_2AgPF_6$•MeOH•0.75CH_2Cl_2: M = 663.01, monoclinic, space group $C2/m$, a = 24.2853(5), b = 19.1082(7), c = 11.9631(4) Å, β = 108.051(2)°, V = 5278.2(5) Å^3, Z = 8, D_c = 1.67 g cm^{-3}, μ(Mo-Kα) = 1.039 mm^{-1}. Data were collected on a Nonius KappaCCD diffractometer using Mo-Kα graphite monochromated radiation (λ = 0.71073 Å) at 173 K. A colourless crystal of dimensions 0.20 × 0.16 × 0.14 mm was used and a total of 28 326 reflections were collected, $2.5 < \theta < 27.5°$. 3937 unique reflections having $I > 3\sigma(I)$ were used for structure determination and refinement. Absorption corrections were partially integrated in the data reduction procedure. The structure was solved using direct methods and refined against $|F|$. Hydrogen atoms were introduced as fixed contributors when a residual electronic was observed near their expected positions. The MeOH and one of the CH_2Cl_2 molecules are disordered over two positions lying near symmetry elements of the space group. Site C28 was refined as containing a mixture of 50% of Cl and 50% of C and site C29 was refined as containing a mixture of 50% of C and 50% of O. Three solvent atoms were kept with isotropic temperature factors, all other atoms were refined with anisotropic temperature factors. Final results: $R(F)$ = 0.063, $Rw(F)$ = 0.083, GOF = 1.521, maximum residual electronic density = 0.98 e Å^{-3}. For all computations the Nonius OpenMoleN package17 was used. CCDC 182/1514. Received (in Cambridge, UK) 20th October 1999, Accepted 11th January 2000

Functionalization of the pentamethylcyclopentadienyl ligands by an electrophilic substitution of hydrogen atoms by $[B(C_6F_5)_3]$ is observed at the Cp* ligands of the alkyne complexes $[Cp^*_2M(\eta^2\text{-}PhC_2SiMe_3]$, connnected with (M = Ti, formation of 1) or without (M = Zr, formation of 2) loss of the alkyne and molecular hydrogen.

Recently we have published the reaction of the bis(trimethylsilyl)acetylene complex of titanocene $[Cp_2Ti(\eta^2\text{-}Me_3SiC_2\text{-}SiMe_3)]$[1] with $[HNMe_3][BPh_4]$ giving cationic complexes of the type $[Cp_2TiL_2][BPh_4]$ with L = THF and pyridine.[2] More recently we have found that in the interaction of $[Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)]$ with $[B(C_6F_5)_3]$ an electrophilic substitution of a hydrogen atom in one of the $\eta^5\text{-}C_5H_5$ rings takes place, and the paramagnetic zwitterionic titanium complex $[(\eta^5\text{-}C_5H_5)Ti\{\eta^5\text{-}C_5H_4B(C_6F_5)_3\}]$ is formed together with liberation of dihydrogen.[3] In this complex the *ortho*-fluorine atoms of two perfluorphenyl groups coordinate at the titanium centre.

Such an interaction but with only one perfluorphenyl group was described previously in the reaction product of the zirconacyclopentadiene $[Cp_2Zr(C_4Me_4)]$ with $[B(C_6F_5)_3]$ giving $[(\eta^5\text{-}C_5H_5)Zr\{\sigma\text{-}C(Me)=C(Me)\text{–}C(Me)=CHMe\}\{\eta^5\text{-}C_5H_4B(C_6F_5)_3\}]$.[4] Starting from the alkyne complex $[Cp_2Zr(PMe_3)(\eta^2\text{-}EtC_2Et)]$ and $[HB(C_6F_5)_2]$ the alkenyl complex $[(\eta^5\text{-}C_5H_5)Zr\{\sigma\text{-}C(Et)=CHEt\}\{\eta^5\text{-}C_5H_4BH(C_6F_5)_2\}]$ was obtained in which the hydrogen of the B–H groups coordinate at the Zr centre.[5]

Also, the so-called 'tuck in' permethylmetallocene complexes[5] were obtained with $[B(C_6F_5)_3]$ and $[HB(C_6F_5)_2]$. Some aspects of these compounds were reviewed by Piers in 1998.[5]

Here, we report the different reactions of the permethylmetallocene alkyne complexes $[Cp^*_2M(\eta^2\text{-}PhC_2SiMe_3)]$ (M = Ti[6] and Zr[7]) with $[B(C_6F_5)_3]$, leading to functionalization of the pentamethylcyclopentadienyl ligand.

The compound $[(\eta^5\text{-}C_5Me_5)Ti\{\eta^5\text{-}C_5Me_4CH_2B(C_6F_5)_3\}]$ **1** is formed by dissociation of the alkyne and an electrophilic substitution of a hydrogen atom in one methyl group of the Cp^* ligand together with liberation of dihydrogen (Scheme 1).†

The composition of the Ti(III) complex **1** was verified by elemental analysis‡ and crystallography.

The X-ray crystal structure analysis of **1**§ (Fig. 1) revealed a bent permethyltitanocene which consists of one unsubstituted and one substituted pentamethylcyclopentadienyl ligand. In this complex the *ortho*-fluorine atom of only one of the perfluorphenyl groups coordinates at the titanium centre [Ti–F152.406(3) Å]. This is longer than found in $[(\eta^5\text{-}C_5H_5)Ti\{\eta^5\text{-}C_5H_4B(C_6F_5)_3\}]$[3] (2.248, 2.223 Å).

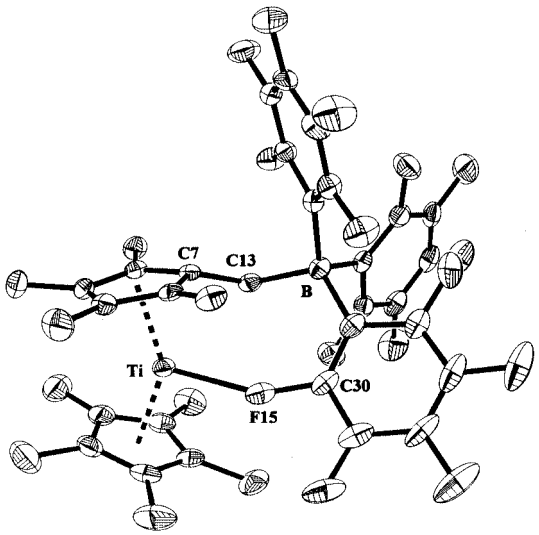

Fig. 1 Crystal structure of **1** at the 30% probability level for thermal ellipsoids. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Ti–F15 2.406(3), C30–F15 1.391(5), C7–C13 1.514(5), C13–B 1.649(6); B–C13–C7 124.8(3).

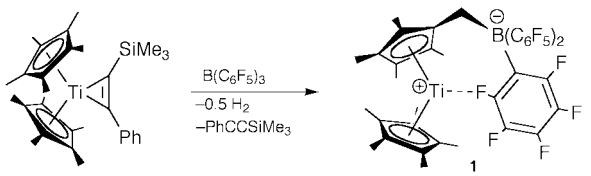
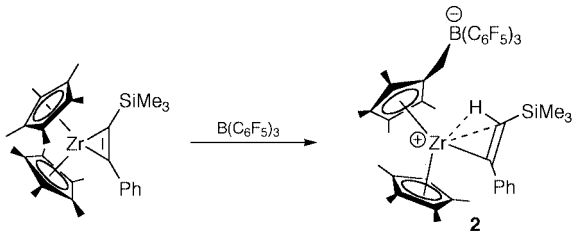
The alkenyl compound $[(\eta^5\text{-}C_5Me_5)Zr\{C(Ph)=CH(SiMe_3)\}\{\eta^5\text{-}C_5Me_4CH_2B(C_6F_5)_3\}]$ **2** is formed also by an electrophilic substitution of a hydrogen atom in one methyl group of the Cp^* ligand but without dissociation of the alkyne and liberation of dihydrogen (Scheme 2).¶

The composition of the diamagnetic complex **2** was verified by elemental analysis and crystallography. For solubility reasons, NMR investigations had to be carried out in THF-d_8, but some undefined changes prevented a full analysis of the spectra.‖ However, the borane attack at one methyl group is evident from a strong line broadening of both the ^1H and ^{13}C methylene signals (diastereotopic protons at 2.65 and 2.81 ppm). The chemical shifts for the vinyl group, a strong deshielding for the α carbon atom (228.9 ppm) and an upfield



Scheme 1



Scheme 2

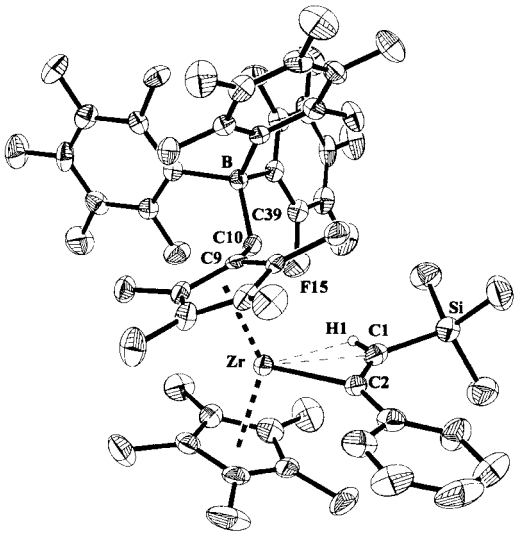


Fig. 2 Crystal structure of **2** at the 30% probability level for thermal ellipsoids. Hydrogen atoms except H1 are omitted for clarity. Selected bond lengths (Å) and angles (°): Zr–C1 2.518(6), Zr–C2 2.238(5), C9–C10 1.487(6), C10–B 1.694(6), Zr–H1 2.250, Zr–F15 4.744, C39–F15 1.369(5); C1–C2–Zr 86.5(4), B–C10–C9 121.6(4).

shift with a small coupling constant $^1J_{CH}$ (104.9 ppm, 111 Hz) for the β position, are characteristic for a 'β-CH agostic' structure[8] although the deshielding of the proton is not as pronounced for complex **2** as was found for other zirconium cyclopentadienyl compounds with this structural feature.[8,10*b*,12]

The X-ray crystal structure analysis of **2**§ (Fig. 2) revealed, similarly as found also for complex **1**, a bent permethylmetallocene which consists also of one unsubstituted and one substituted pentamethylcyclopentadienyl ligand, but no fluorine atom coordinates at the zirconium centre [shortest distance Zr–F15 4.744 Å]. Additionally an alkenyl group is σ-bonded with an agostic interaction[8] to the zirconium atom presenting the typical small angle Zr–C2–C1 of 86.5° for such a type of bonding. In complexes **1** and **2** an identically functionalized Cp* ligand [η^5-$C_5Me_4CH_2B(C_6F_5)_3$] is shown. Owing to the additional interaction in **1** the angle B–C13–C7 of 124.8(3)° is larger compared to the corresponding angle B–C10–C9 of 121.6(4)° in **2**.

The reactions of the corresponding complexes of bis-(trimethylsilyl) acetylene [$Cp^*_2M(\eta^2$-$Me_3SiC_2SiMe_3)$] (M = Ti[6] and Zr[9]) gave with [$B(C_6F_5)_3$] only oils or such solids which could not be purified by crystallisation.

The novelty of the reactions in this work is, in contrast to former observed *inter*molecular reactions for titanium[7*b*,10] and zirconium[7*b*,11] an *intra*molecular course *via* C–H activation for the formation of **1** and **2**. In the *inter*- and the *intra*molecular reactions the higher stability of the Ti(III) oxidation state as well as the larger zirconium atom can give an explanation for the different types of reaction: elimination or addition of the reacting substrate or group.

The work was supported by the Max-Planck-Gesellschaft, the Fonds der Chemischen Industrie and the Russian Foundation for Basic Research (Project code 99-03-33008).

Received (in Bloomington, IN, USA) 3rd September 1999, Accepted 23rd December 1999

Ionic liquids have been used as effective solvents to synthesize aerogels; a long aging time can be used to produce stable aerogel structures without the need for supercritical drying processes.

Aerogels are a novel class of porous materials with wide-ranging applications. The unique properties include low density, high surface area, low thermal conductivity and low dielectric permittivity.[1–3] So far, the synthesis of silica-based aerogels has been accomplished mainly through the controlled condensation of small colloidal particles produced by sol–gel processing in alcoholic aqueous solutions, followed by a supercritical drying process. A highly desirable goal in aerogel synthesis is the elimination of the supercritical drying process, the most expensive and risky aspect of the process. For example, Guo and Guadalupe have succeeded in synthesizing a silica-based aerogel from a metastable lamellar composite through cooperative interaction between silica and surfactant species.[4] The surfactant molecules used to generate pores can be removed from the silica network through conventional solvent extraction. The porous structure is stable during this procedure, and no supercritical extraction is used. Here, we report a new aerogel synthesis methodology based on the use of ionic liquids as solvents. The structural features of the synthesized silica aerogel are characterized.

Ionic liquids are a unique class of solvents that have virtually no vapor pressure and possess versatile solvent properties.[5–7] Recently, they have been effectively demonstrated as a superior solvent for conducting many organic reactions. For example, Chauvin *et al.* have shown that oligomers of alkenes can be efficiently synthesized using ionic liquid solvents.[8,9] More recently, many new organic reactions in various ionic liquids have been carried out by Seddon's group.[10,11] Our interest is in exploring the ionic liquids as solvents to conduct inorganic polymeric reactions for synthesizing novel inorganic materials. Conventional sol–gel synthesis of aerogels involves hydrolysis and condensation of tetraalkylorthosilicates to form gels in alcoholic aqueous solutions. During the aging process, the solvents evaporate, causing gel shrinkage before formation of a stable sol–gel network. If the aging period is too long, the pore volume tends to be reduced to that of the corresponding xerogel. However, too short an aging time may cause instability of the gel network, which can result in its collapse after extraction of the solvent. Therefore, control of the aging time is critical to the success of the aerogel synthesis. Ionic liquids offer an attractive method for achieving longer aging times without shrinkage of the gel network. When used as the solvent for sol–gel processes, their negligible vapor pressure prevents solvent evaporation, and their high ionic strength increases the rate of aggregation. These and other effects allow hydrolysis and condensation to proceed to completion, accordingly producing a stable gel network before solvent extraction.[12] All the preceding assertions concerning the advantages of using ionic liquids as solvents for the aerogel synthesis, of course, rely on the solvation capability of ionic liquids to form homogeneous solutions with aerogel precursors.

Tetramethylorthosilicate (TMOS) is used as the sol–gel precursor. The room-temperature ionic liquid used in this work is 1-ethyl-3-methylimidazolium bis[(trifluoromethyl)sulfonyl] amide ($EtMeIm^+Tf_2N^-$). This melt was synthesized as described in the literature.[13–15] Acid-catalyzed sol–gel processing was conducted: in a typical run,[16] 1 mL of TMOS, 2 ml of formic acid (Aldrich Chemical Co., 99%) and 1 mL of $EtMeIm^+Tf_2N^-$ were mixed. The sol–gel reaction can be described by eqn. (1).[17] The final mixture gelled overnight

$$2\ HC(O)OH + (CH_3O)_4Si \rightarrow SiO_2 + 2\ CH_3OH + 2\ HC(O)OCH_3 \quad (1)$$

and was cured at ambient temperature for three weeks. A transparent monolith glass was obtained. The entrapped ionic liquid was extracted by refluxing the above monolith in acetonitrile (Baker Chemical Co., HPLC grade) overnight. The extraction procedure did not result in any visible shrinkage of the gel. This may be attributed to the long curing time used to stabilize the aerogel network before the extraction. The C–H stretching vibrational IR features of the ionic liquid around 2900 cm^{-1} disappeared after extraction and vacuum drying. This indicates that all ionic liquid molecules were removed through extraction. Immersion of the aerogel in solvents with a high dielectric constant (*e.g.* water) can result in cracking of the aerogel monolith. However, the aerogel monolith is very stable in air.

The N_2 adsorption isotherm (Fig. 1) of the monolith glass after removal of the ionic liquid is identical to those of aerogels prepared using different solvent and supercritical extraction.[2,3] The surface area and pore volume calculated from Fig. 1 are 720 $m^2\ g^{-1}$ and 1.4 $cm^3\ g^{-1}$, respectively.[18] Further supports for the aerogel structure come from investigation by small-angle X-ray scattering (SAXS). Fig. 2 shows a typical SAXS curve of the aerogel prepared using the ionic liquid. The analysis of the SAXS data indicates that the aerogel is mass fractal with a fractal dimension of 1.4. This small fractal dimension indicates a highly porous sol–gel network and is consistent with the mass fractal dimension for the aerogel materials.[12] The constituent particles have a size distribution and the value of R_g (radius of gyration) ranges from 80 to 14 Å, based on Guinier analysis.

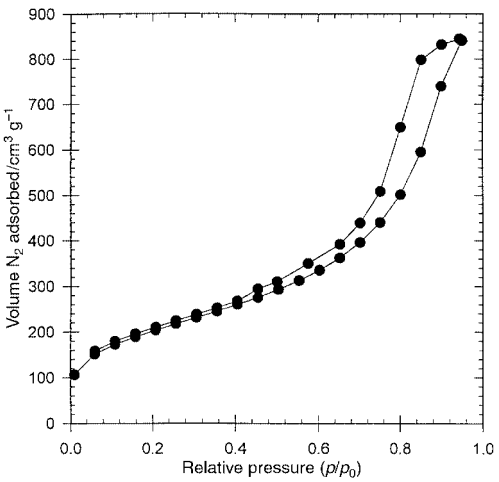

Fig. 1 Nitrogen adsorption–desorption isotherm.

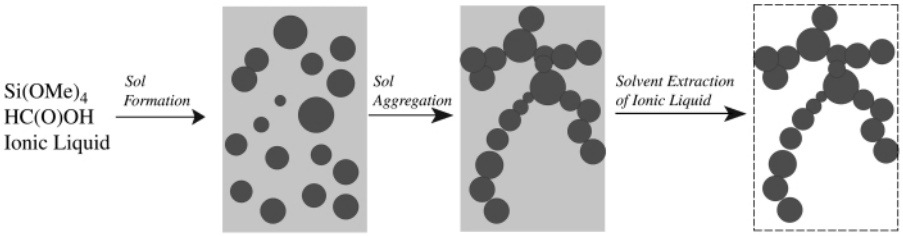

Scheme 1

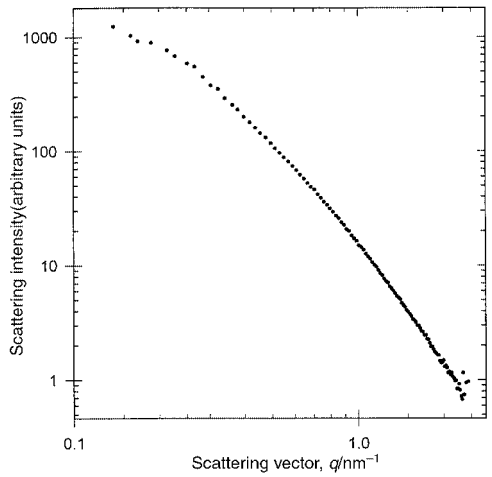

Fig. 2 Small-angle X-ray scattering curve for the aerogel.

Both the nitrogen adsorption and the SAXS data for our aerogel agree well with those obtained for the aerogels synthesized by conventional protocols.[1,3,13]

A possible mechanism for the aerogel formation in the ionic liquid is shown in Scheme 1. Formic acid initiates the formation of the sol particles, which effectively aggregate in the ionic liquid into a sol–gel network. Concurrently, the ionic liquid becomes entrapped in the growing covalent silica network, rather than being chemically bound to the inorganic matrix. A long aging time implemented before extraction of the non-volatile ionic liquid further enhances the stability of the aerogel network. No macroscopic phase separation between the gel and the ionic liquid solvent has been observed. The homogeneity is retained throughout the entire aging process. This indicates that the interaction between the sol particles and the ionic liquids is favored thermodynamically. The ionic liquid forms a homogeneous solution with sol–gel precursors. If other solvents (*e.g.* DMSO, water) are used in the sol–gel preparation, no appreciable pore volumes (< 0.1 cm^3 g^{-1}) are found. In fact, similar results have been reported in the literature concerning the doping of silica with organic liquids through sol–gel processes.[19]

In conclusion, the silica aerogel has been synthesized using an ionic liquid as a reaction solvent. This technique allows aerogel synthesis under mild chemical conditions and eliminates the risky supercritical drying process. We expect that this new methodology can find applications in synthesizing new aerogels and aerogel films for separation, catalysis, and insulation.

Received (in Cambridge, UK) 18th November 1999, Accepted 6th January 2000

A convenient method of preparing optically active (*S*)-*N*-tritylaziridine-2-carboxylate esters *via* intramolecular cyclization of (*S*)-*N*-trityl-β-haloamino acid esters is described.

The development of novel methods of synthesizing optically pure unnatural amino acids is an area of current interest.[1] (*S*)-*N*-Tritylaziridine-2-carboxylate [*N*-Tr-(*S*)-AZC] esters represent an interesting class of compounds since they can be considered a versatile synthetic equivalent of the 'β-alanyl cation' synthon suitable for elaboration into β-substituted (*S*)-amino acids,[2] enzyme substrates,[3] and irreversible inhibitors of proteases.[4] Despite their importance for synthetic use, only a few studies on the syntheses of *N*-Tr-(*S*)-AZC esters have been reported [5–9] and these methods involve multi-step procedures, require expensive starting materials, and produce a low yield or partial racemization of the intermediate in the synthetic scheme.

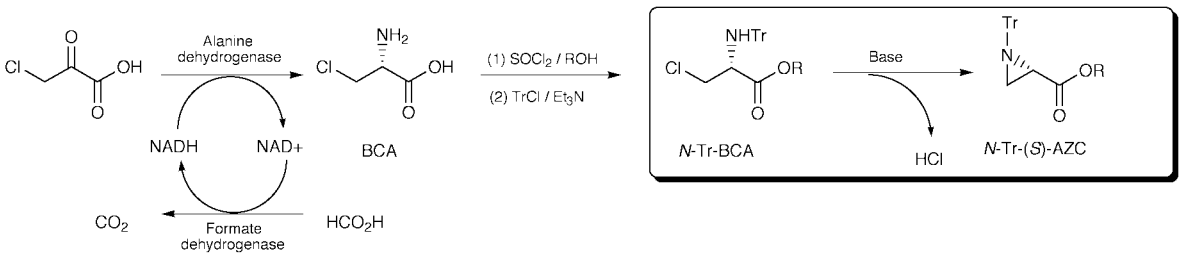
During the course of our studies on the application of enzymes in organic syntheses, we have discovered an efficient method for the production of halogen-containing α-amino acids *via* chemo-enzymatic reaction.[10] Using this process, optically pure (*S*)-β-haloamino acids, especially, (*S*)-β-chloroalanine (BCA) and *threo*-(2*R*,3*S*)-3-chloroaspartic acid, can be obtained in large quantities. We report herein a convenient method of synthesizing *N*-Tr-(*S*)-AZC esters *via* intramolecular cyclization of (*S*)-*N*-trityl-β-chloroalanine (*N*-Tr-BCA) esters,† which were derived from the enzymatically prepared BCA (Scheme 1).

In our first attempt at a base-catalyzed intramolecular cyclization reaction of *N*-Tr-BCA benzyl ester **1** to benzyl *N*-Tr-(*S*)-AZC **2** with 2 equiv. of strong base, such as NaH, Bu^{t}OK, DBU, DBN and Bu^{t}Li, in THF at room temperature, however, only the 1,2-elimination of hydrogen and chloride atoms occurred and *N*-trityldehydroalanine benzyl ester **3**‡ was obtained as the sole product (Table 1, entry 1). Reaction in another solvent, such as hexane, Et_2O, CH_2Cl_2, MeCN, DMF and DMSO, also gave **3**. It turned out that the expected aziridine **2**§ was formed when a weak inorganic base, KF, was used as the base in refluxing MeCN (entry 2) with some formation of **3**. Encouraged by this result, we further investigated the inorganic bases by changing their basicity and counter ions. Weaker bases and neutral salts such as LiF, NaF, LiCl, NaCl, KCl, NaBr, KBr, CsBr, RbBr, MgF_2 and SrF_2 were ineffective and afforded BCA benzyl ester **4** which was formed by deprotection of the trityl group of **1** (entry 4). However, the use of bisulfite salt, $KHSO_3$, could suppress both the 1,2-elimination and deprotection reaction to give the aziridine **2** as the sole product, although the reaction rate was decreased to one-third of that with KF (entry 5). Elongation of the reaction time could solve this problem and afforded **2** in almost quantitative yield (entry 6). The choice of the reaction solvent was quite important; alkyl nitriles *i.e.* MeCN, EtCN, PrCN, Pr^{i}CN, BuCN and Bu^{i}CN, were the only suitable solvents to form aziridine **2**. Other organic solvents such as THF, DMSO, DMF, 1,4-dioxane, CH_2Cl_2 and Et_2O were not useful; only the recovery of the starting material **1** was observed. The other weak acid salts of the potassium ion, $KHSO_3$, K_2SO_3, K_2HPO_4, K_2WO_4 and $K_2S_2O_5$, and weak organic amines, Et_3N and Pr^i_2NEt, were effective bases for the cyclization reaction and gave the cyclized aziridine **2** as the sole product. Interestingly, only a deprotected compound **4** was obtained using sulfate and persulfate salts, $KHSO_4$, K_2SO_4 and $K_2S_2O_7$. However, the use of stronger inorganic bases such as RbF and CsF deserves comment and produced only **3** (*e.g.* entry 7).

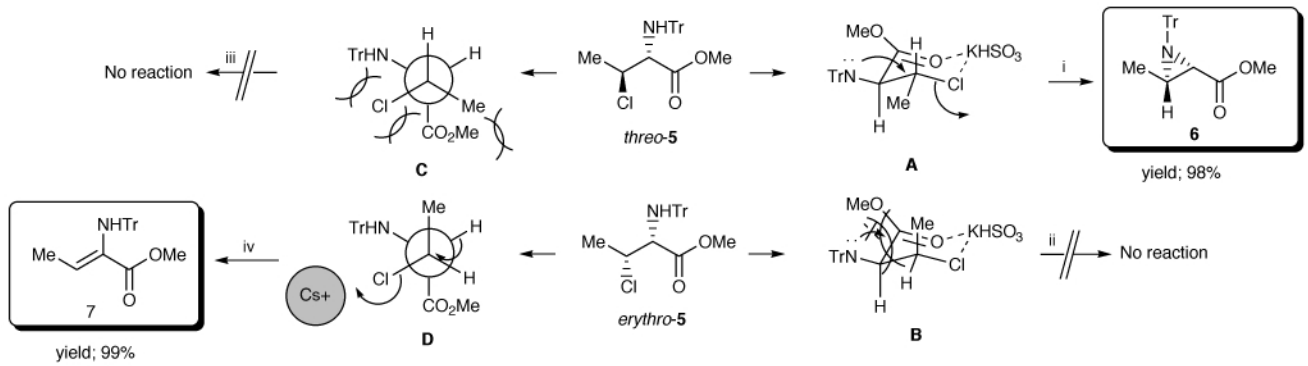
Under such suitable conditions,¶ the cyclization reactions of various esters of *N*-Tr-BCA were examined. Methyl, ethyl, *n*-propyl, *n*-butyl, *n*-pentyl, isopropyl and isobutyl esters of BCA were converted to the corresponding aziridines in yields of 90, 95, 94, 98, 92, 97 and 96%, respectively. These results suggest

Table 1 Base-catalyzed transformation of (*S*)-*N*-Tri-β-chloroalanine benzyl ester

				Products (%)			
Entry	Base	Solvent	Conditions	**1**	**2**	**3**	**4**
1	NaH	THF	rt 4 h	0	0	95	0
2	KF	MeCN	reflux, 24 h	0	64	36	0
3	KF	DMF	90 °C, 4 h	0	0	98	0
4	NaF	MeCN	reflux, 24 h	0	5	2	90
5	$KHSO_3$	MeCN	reflux, 24 h	66	34	0	0
6	$KHSO_3$	MeCN	reflux, 48 h	0	98	0	0
7	CsF	MeCN	reflux, 4 h	0	0	97	0



Scheme 1 Chemoenzymatic synthesis of (*S*)-*N*-tritylaziridine-2-carboxylate esters.



Scheme 2 *Reagents and conditions*: i, $KHSO_3$, MeCN, reflux, 63 h; ii, $KHSO_3$, MeCN, reflux, 120 h; iii, CsF, DMF, 100 °C, 60 h; iv, CsF, MeCN, reflux, 4 h.

that changing the ester moiety does not affect the yield or reaction rate of the formation of aziridine.

Based on these observations, we propose the following reaction mechanisms for the cyclization or 1,2-elimination reactions: (i) when the reagent is neutral or has Lewis acidity, only deprotection of the trityl group is seen; (ii) if the reagent exhibits basicity and dissociates into ions, the metal ions act as a base and catalyzed the 1,2-elimination reaction; (iii) if the reagent cannot dissociate into ions, it chelates both the chloride atom and carbonyl oxygen, allowing the cyclization reaction. This is supported by the fact that the KF-catalyzed cyclization reaction proceeds only in MeCN; the 1,2-elimination reaction preferentially occurred in polar solvents, such as DMF, DMSO, THF and 1,4-dioxane, in which the reagents dissociate more easily into the ion pairs (*e.g.* Table 1, entry 3).

We next examined the cyclization or 1,2-elimination reaction for each diastereomer of methyl (*S*)-*N*-trityl-3-chloro-2-amino-butyrate (*N*-Tr-BCAB), prepared from (*S*)-threonine or *allo*-(*S*)-threonine. As shown in Scheme 2, only the *threo* isomer of *N*-Tr-BCAB (*threo*-**5**) was cyclized to form (2*S*,3*R*)-3-methylaziridine-2-carboxylate **6**,‖ but *erythro*-**5** was not. If we assume a chair-like transition state, we can conceive a reaction mechanism. In the transition state, $KHSO_3$, which does not dissociate into K^+ and HSO_3^-, is chelated by both the chloride atom and the carbonyl oxygen; it allows an attack by a lone pair from nitrogen, giving cyclization and eliminating the chloride ion *via* an S_N2-like reaction (transition state A), resulting in the formation of aziridine **6**. In the case of *erythro*-**5**, steric repulsion by the axial methyl group stopped the attack of nitrogen (transition state B). In contrast, the 1,2-elimination reaction occurred only for *erythro*-**5** to give (*E*)-dehydroamino acid **7**‖ as the sole product. The results are explainable by Newman projections. The dissociated caesium ion acts as a base allowing the elimination of the chloride ion and *anti*periplanar proton, afforded 1,2-eliminated product **7** from *erythro*-**5** (transition state D), while *threo*-**5** cannot adopt a conformation able to 1,2-eliminate due to steric repulsion between the methyl, *N*-trityl and methoxycarbonyl groups, blocking reaction (transition state C).

In summary, we have shown here that (*S*)-*N*-tritylaziridine-2-carboxylate esters are quantitatively synthesized *via* the weak base-catalyzed cyclization of (*S*)-*N*-trityl-β-haloamino acid esters under mild conditions. By changing slightly the reaction conditions, 1,2-elimination takes place and affords *N*-trityl-dehydroalanine esters in good yield. Syntheses of (*S*)-amino acid derivatives by ring opening of the aziridine esters without racemization are currently underway.

This work was performed at the Life Science Research Center, Nippon Steel Corporation. We are grateful to Professor Katsuyuki Ogura, Chiba University, for helpful discussions.

Notes and references

† BCA was enzymatically synthesized in high chemical (> 90%) and optical (> 99.9% ee) yields from 3-chloropyruvate using alanine dehydrogenase from *Bacillus stearothermophilus* (Unitika, Kyoto, Japan) with regeneration of NADH by formate dehydrogenase (Boehringer Mannheim GmbH, Germany) as described previously (ref. 10). The BCA was converted to *N*-Tr-BCA esters by an esterification with $SOCl_2$ in an appropriate alcohol followed by *N*-tritylation with Tr-Cl–Et_3N in CH_2Cl_2.

Received (in Cambridge, UK) 2nd December 1999, Accepted 6th January 2000

Polychlorinated aromatic compounds are persistent environmental contaminants; we describe here the redesign and engineering of the haem monooxygenase cytochrome $P450_{cam}$ to oxidise these compounds efficiently to the chlorinated phenols which are readily degraded by many micro-organisms, thus providing a basis for novel systems for biological clean-up of these inert compounds.

Polychlorinated aromatic compounds are among the most problematic environmental pollutants because of their chemical inertness, lipid solubility and toxicity.[1] Naturally occurring micro-organisms have evolved to degrade and mineralise many, but by no means all, of these compounds. For example, the dioxins and heavily chlorinated biphenyls are degraded very slowly or not at all. Similarly, numerous micro-organisms have been isolated which together degrade most of the chlorinated benzenes,[2] but the most heavily chlorinated compounds pentachlorobenzene (PeCB) and hexachlorobenzene (HCB), as well as 1,2-dichlorobenzene (1,2-DCB) and 1,3,5-trichlorobenzene (1,3,5-TCB) are particularly inert to biodegradation.[3] We noted that chlorinated phenols are readily degraded by micro-organisms.[4] We reasoned that if a monooxygenase can be prepared that can efficiently oxidise polychlorinated benzenes to the phenol derivatives, then the monooxygenase system could be introduced into chlorophenol-degrading micro-organisms such as *Pseudomonas* bacteria to enable them to degrade polychlorinated benzenes. We report here the genetic engineering of the haem monooxygenase cytochrome $P450_{cam}$ from *Pseudomonas putida* to oxidise 1,2-DCB, 1,3,5-TCB and PeCB, creating a basis for novel bioremediation systems.

The criteria for successful redesign of the $P450_{cam}$ active site for the oxidation of polychlorinated benzenes are reasonable rates of substrate turnover and tight coupling of NADH consumed to substrate oxidation. Uncoupling wastes NADH and can produce harmful hydrogen peroxide,[5] both of which will put metabolic stress on the host organisms and thus reduce their viability. We have shown that the Y96A and Y96F mutations greatly improved the activity of $P450_{cam}$ for the oxidation of a wide range of organic compounds, including simple alkanes,[6] styrene[7] and naphthalene.[8] We proposed that these mutations at Y96 (Fig. 1) improve the turnover of such hydrophobic compounds by increasing the hydrophobicity of the enzyme active site. We also noted that the oxidation by the Y96F mutant of naphthalene, which is larger than the chlorinated benzenes considered here, had a coupling of 55% compared to 17% for the Y96A mutant. Since the Y96A mutant should have a larger active site, the Y96F mutation should be our starting point. The coupling could then be increased by improving the enzyme–substrate fit and by forcing the chlorinated benzenes to bind closer to the haem. Hence the active site volume was reduced by further substitutions with amino acids with bulkier side-chains at three other active site residues. Phenylalanines 87 and 98 are at approximately the same height as Y96 above the haem and near the top of the active site (Fig. 1), and valine-247 is just below these residues and closer to the haem.[9] The new mutants F87W–Y96F, F87W–Y96F–F98W and F87W–Y96F–V247L were prepared and their activities compared to the WT enzyme.

1,2-DCB was oxidised by all the $P450_{cam}$ enzymes to 2,3-dichlorophenol (2,3-DCP) and 3,4-dichlorophenol (3,4-DCP) in 9:1 ratio (Fig 2), and 2,4,6-trichlorophenol (2,4,6-TCP) was the only product from 1,3,5-TCB. The predominant product from PeCB oxidation was pentachloro-

[a] Given as nanomoles of NADH consumed per nanomole of $P450_{cam}$ per minute and the average of at least 3 experiments with all the data within 10% of the means. Incubation mixtures (1.70 ml) contained 50 mM Tris.HCl, pH 7.4, 1 μM $P450_{cam}$, 10 μM putidaredoxin, 2 μM putidaredoxin reductase and 200 mM KCl. Both 1,2-DCB and 1,3,5-TCB (200 μM) were added as a 0.1 M stock in ethanol. The mixture was incubated at 30 °C for 2 min after the addition of NADH (100 μM) and the reaction initiated by the addition of substrate. NADH absorbance at 340 nm was monitored over the course of the reaction. [b] The total amount (in nanomoles) of chlorinated phenol products formed per nanomole of $P450_{cam}$ per minute. After the addition of 100 μl of an internal standard to a turnover incubation, organics were extracted by solid phase methods using Varian Bond-Elut columns and products were analysed by reverse phase HPLC. To obtain quantitative results, mixtures containing known concentrations of a product and all of the incubation components except NADH were extracted and analyzed as described above. Linear calibration plots that passed through the origin were obtained for all of the products. [c] The coupling efficiency is the ratio of the total amount of products formed to the amount of NADH consumed and is expressed as a percentage.

phenol (PCP), but two small peaks (*ca.* 2% each) were ascribed by co-elution experiments to 2,3,5,6- and 2,3,4,5-tetrachlorophenols formed by oxidative dehalogenation.

As shown in Table 1, the wild-type (WT) had low rates (< 0.5 min^{-1}) and couplings (1–2%) for the oxidation of the chlorinated benzenes compared to the totally coupled (100%) camphor oxidation rate of 1050 min^{-1} under identical conditions. The mutants all had 2–3 orders of magnitude faster chlorinated benzene oxidation rates than the WT. The NADH turnover rates were up to 400 min^{-1}, and the coupling efficiencies were also much higher. The 50% coupling for 1,2-DCB oxidation by the F87W–Y96F–F98W mutant is a dramatic improvement, and the near total coupling for 1,3,5-TCB oxidation is truly remarkable because the structure of this molecule is completely different from that of camphor. Very importantly, the results also showed that the low solubility of PeCB in water was not a problem, in that a very reasonable NADH turnover rate of 229 min^{-1} could be attained although the coupling was low. The data show that the rationale for active site redesign, whilst empirical and qualitative in nature, was very successful indeed.

The strength of binding and catalytic efficiency of the $P450_{cam}$ enzymes for 1,2-DCB and 1,3,5-TCB oxidation were investigated. The dissociation constants (K_D) in Table 1 show that, as expected, the binding of these compounds was strengthened by the mutations, but by no more than a factor of three. On the other hand, the substrate oxidation rates (k_2) showed 2–3 orders of magnitude increases. There was no direct correlation between the values of K_D and the NADH turnover rates or, notably, the coupling efficiency, which is a stringent measure of the enzyme–substrate fit. Nevertheless, it is instructive to compare the relative specificity (k_{cat}/K_M) of the mutants. It has been suggested that the k_2/K_D ratio is a fair approximation for the k_{cat}/K_M ratio for $P450_{cam}$.[10] The k_2/K_D ratios in Table 1 again highlight the very dramatic accelerating effects achieved by the mutations although they are well short of the near-optimal ratio for camphor oxidation by the WT enzyme ($K_D = 0.27$ μM, $k_2 = 1050$ min^{-1}, $k_2/K_D = 6.5 \times 10^7$ M^{-1} s^{-1}). However, we conclude that the F87W–Y96F–F98W mutant represents an excellent compromise between reasonable rate and tight coupling, especially for the *in vivo* oxidation of polychlorinated benzenes, where very fast turnover could lead to the build up of polychlorinated phenols to toxic levels.

All the chlorophenol products in Fig. 2 are known to be degraded by various micro-organisms,[4] and therefore the mutants can be the basis of novel bioremediation systems for polychlorinated benzenes by genetically introducing the genes encoding the three proteins of the $P450_{cam}$ system into chlorophenol-degrading micro-organisms such as *Pseudomonas* bacteria. The F87W–Y96F–F98W mutant can be used for the particularly inert 1,2-DCB and 1,3,5-TCB. The coupling for PeCB and HCB can be improved by further active site mutations, and then even these highly inert compounds can be efficiently degraded.

We thank HEFCE and BBSRC for support of this work. J. P. J. thanks the EPSRC for a Studentship.

Received (in Cambridge, UK) 5th July 1999, Accepted 23rd August 1999

Photochirogensis, or photochemical induction of molecular chirality, is an attractive alternative to thermal or enzymatic asymmetric synthesis. Using the inherent advantage that the photochemical reaction is driven by light absorption, the effect of temperature on optical yield was investigated over a wide range. Unexpectedly, the stereochemistry of photoproduct was frequently inverted at a critical temperature (T_0), above which the optical yield increased with increasing temperature. The Eyring treatment of the relative rate constant for the production of each enantiomer revealed that the unusual temperature dependency originates from the non-zero differential entropy of activation for the enantiodifferentiating process. In this case, the enthalpy term dominates at lower temperatures, while the entropy term becomes more important above T_0, switching the product chirality. The absolute configuration of photoproduct obtained at temperatures lower than T_0 was correlated to that of the chiral sensitizer, except for those containing very bulky chiral auxiliaries, and the stereochemical outcomes are discussed on the basis of the molecular model examinations. Interestingly, similar switching behaviour was induced by varying the pressure from 0.1 to 400 MPa. The pressure effect was investigated at different temperatures to construct three-dimensional diagrams that correlate the optical yield with temperature and pressure as mutually independent factors. The combined use of temperature and pressure provides us with a convenient, powerful tool for controlling the product chirality and optical yield in asymmetric photochemistry.

† Dedicated to the memory of Professors Emeritus Yoshinobu Odaira and Setsuo Takamuka, who introduced me to photochemical research and who died on 21 March and 29 October 1999, respectively.

Introduction

Asymmetric synthesis is an area of vital importance in current chemistry, to which a considerable amount of effort has been devoted in recent years.[1–9] Thus, enantio- and diastereoselectivity are the principal objectives or prerequisites when developing a new asymmetric catalyst or synthetic methodology,[1–3] as well as in synthesizing chiral compounds such as naturally occurring compounds and pharmaceuticals.[4–9] The stereochemical outcome of these asymmetric reactions has been discussed in terms of empirical rules using the models of Cram,[10] Felkin-Anh[11,12] and others.[4,13] These models are based primarily on the relative steric bulk of the aligned substituents near the reaction centre, which are orientated by steric hindrance, dipole interactions or metal chelation. Obviously, the chiral discrimination mechanism based on these empirical rules can assess only the enthalpic contributions attributable to the steric/stereoelectronic

Yoshihisa Inoue was born in Nara (Japan). He received his PhD from Osaka University in 1977 (Professor H. Sakurai) before joining the Department of Applied Chemistry, Himeji Institute of Technology (Professor T. Hakushi). While on leave, he spent one year (1978–1979) at Columbia University (Professor N. J. Turro). In 1985, he moved to the Basic Research Laboratory as Associate Professor, and then to the Department of Material Science, Himeji Institute of Technology in 1990 (Professor A. Tai), where he was a PRESTO fellow of the JRDC from 1992 to 1994 (Professor K. Honda). In 1994, he returned to Osaka University to take a full professorship, and has also been engaged in the Inoue Photochirogenesis Project since 1996. His research interests include molecular recognition in the ground and excited states.

Takehiko Wada was born in Osaka (Japan) and received his PhD from Osaka University in 1989 (Professor K. Takemoto). He then joined the faculty of the Applied Fine Chemistry, Osaka University, where he worked with Professor K. Takemoto. In 1995, he moved to his current position as an Associate Professor, working with Professor Y. Inoue at the Department of Molecular Chemistry. His current research interests focus on asymmetric photochemistry and nucleic acids chemistry.

Sadayuki Asaoka was born in Osaka (Japan). He graduated from Kyoto University in 1992 and obtained his master's degree in 1994. After a short engagement (1994–1996) as a research chemist at Matsushita Battery Industrial Co., he resumed the study of photochemistry at the Department of Molecular Chemistry, Osaka University and is now finishing a PhD.

Hirofumi Sato was born in Osaka (Japan). He graduated from Osaka University in 1999 and is now a PhD student at the Department of Molecular Chemistry, Osaka University.

Jean-Pierre Pete is Professor of Chemistry in the Department of Chemistry of the University of Reims. After graduating as a Chemical Engineer from the University of Strasbourg (1961), he obtained his PhD in 1966 (Professor J. Levisalles). From 1961 to 1968 he was a research fellow at CNRS. He was a post-doctoral fellow (Professor P. de Mayo) at the University of Western Ontario (1966–1967), before joining the Faculty of Science at Reims in 1969. His research interests concern mainly organic photochemistry, photoinduced electron transfer processes asymmetric photoreactions and their applications to organic synthesis. He received the Grammaticakis–Neuman award from the Académie des Sciences in 1987 and is the co-author of more than 150 research publications.

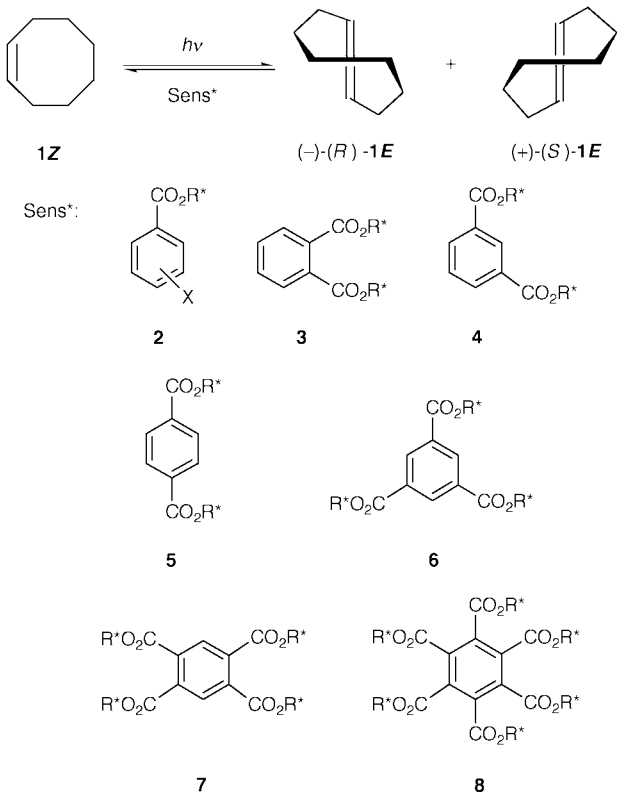
interaction between the substituent and attacking reagent, while the entropic contribution arising from the conformational changes and re-positioning of the solvent molecules during the transition state has not been discussed explicitly for thermal and enzymatic asymmetric syntheses. Nevertheless, these empirical rules, which only take the enthalpy term into account, are generally successful and are frequently employed in interpreting and/or predicting the dominant stereoisomer formed, and also the trend in optical yield obtained in a variety of asymmetric induction and asymmetric catalysis processes. Consequently, the entropic contribution has not been discussed globally, or experimentally examined as a factor in the mechanism of most thermal asymmetric reactions until recently,[14] in spite of some early observations of small to moderate temperature effects on enantio- or diastereoselectivity, *e.g.* in the addition of alcohols or amines to ketenes in the presence of acetylquinine,[15] in the $LiAlH_4$ reduction of acetophenone in the presence of quinine,[16] and in the oxidation of sulfides with optically active peracids.[17] That entropy plays an important role does not seem unreasonable, since the temperature range available is rarely wide enough to thoroughly survey the effect of this variable, and the possible incorporation of different reaction mechanisms or a switch in intermediates resulting from a change in temperature is not rigorously ruled out in many thermal asymmetric reactions.

In contrast, photochemical reactions are driven by the absorption of high-energy photons and proceed through the excited state, which renders them inherently free from temperature restrictions, and they are, therefore, advantageous for investigating the effect of the entropy factor upon stereoselectivity over a wide temperature range without undergoing any essential changes in reaction mechanism or intermediates formed. However, the temperature effect has been rarely and only recently explored in the rather short history of asymmetric photochemistry.[18,19] Thus, in the diastereodifferentiating Paternò–Büchi photocycloaddition of optically active phenylglyoxylic esters with several alkenes,[20] Scharf *et al.* showed that the diastereoselectivity of the oxetane produced not only depends on the irradiation temperature, but also gives a bent Eyring plot as a consequence of the alteration of the rate limiting step that determines the diastereoselectivity. In the enantiodifferentiating *Z–E* photoisomerization of cyclooctene sensitized by optically active sensitizers,[21] we demonstrated that the antipodal (*E*)-cyclooctenes, *i.e.* (*S*)-(−)- and (*R*)-(+)-enantiomers, can be obtained simply by changing the irradiation temperature from −88 to +50 °C, and that the enantiomeric excess (ee) of the product increases with increasing temperature, an observation that conflicts with the belief that lowering the temperature will generally enhance the ee. This unprecedented temperature dependence and the switching of the major enantiomer produced was revealed to be exclusively entropic in origin through an analysis of the Eyring plot of the enantioselectivity of the reaction. A similar 'unusual' temperature dependence of stereoselectivity, which leads to the switching of product chirality and/or higher selectivity at higher temperature, has been observed in many enantio-[22–25] and diastereodifferentiating photoreactions[26–30] over the last decade. More recently, we have revealed that the product chirality can be controlled, and in some cases actually switched, by changing the pressure from atmospheric to 400 MPa in the photosensitized enantiodifferentiating isomerization of cyclooctene.[31]

Here we present a global view of recent advances in 'photochirogenesis', particularly in enantiodifferentiating photosensitization reactions. We will also demonstrate how the entropic and enthalpic factors share the role of manipulating the stereochemical outcome of these enantiodifferentiating photoreactions. Finally, we will show that the combined use of entropy-related factors, such as temperature, pressure and solvent, provides us with a new method for the control of asymmetric photochemistry. Indeed, the basic concepts revealed here by asymmetric photochemistry should also be applicable to thermal and biological asymmetric reactions.

Temperature effect

In the 'Photochirogenesis' project, which aims to devise methods for highly efficient photochemical generation, transfer and multiplication of molecular chirality, we have chosen the enantiodifferentiating geometrical photoisomerization of (*Z*)-cyclooctene (**1Z**) sensitized by optically active aromatic esters as one of the most promising processes for development (Scheme 1), simply because this photosensitization was known

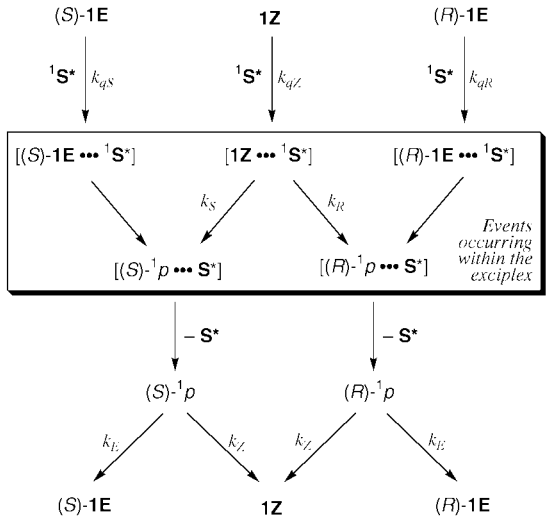


Scheme 1 Enantiodifferentiating *Z–E* photoisomerization of cyclooctene sensitized by chiral benzene(poly)carboxylates (Sens*).

to give chiral (*E*)-cyclooctene (**1E**) in high chemical and quantum yields and was also found to involve a singlet exciplex between the substrate and sensitizer.[32] The involvement of a structurally well-defined exciplex intermediate, which enables efficient transfer of chiral information in the excited state, is an essential condition for obtaining high optical yield in an enantiodifferentiating photosensitization.

Taking into account the simultaneous formation of the two enantiomers of **1E**, the original sensitization mechanism[32] was modified to include chirality, as shown in Scheme 2.[22a] The photosensitization is initiated by the formation of an encounter complex [**1Z**/**E**···^{1}**S***] between the excited sensitizer (^{1}**S***) and **1Z** or one of enantiomers of **1E**. Energy transfer within the exciplex intermediate and the subsequent rotation around the C=C bond of **1Z**/**1E** to a dihedral angle of *ca.* 90° afford a relaxed exciplex [^{1}***p***···**S***], which in turn releases the perpendicular singlet (^{1}***p***), regenerating the ground-state sensitizer (**S***). It should be noted that chirality is induced in ^{1}***p*** during the rotational relaxation step. The subsequent decay of ^{1}***p*** to **1Z** or **1E** concludes the photoisomerization cycle.

There are two steps in this mechanism that are potentially enantiodifferentiating: (i) the quenching of ^{1}**S*** by enantiomeric **1E**, and (ii) rotational relaxation within the exciplex [**1Z**···^{1}**S***]. Thus, the rate constants for quenching (k_{qS}, k_{qR}) and/or rotation (k_S, k_R) may be different from one another. Experimentally, no



Scheme 2 Enantiodifferentiating mechanism for photosensitized isomerization of cyclooctene (**1**) *via* exciplex, where **S*** and ^{1}**S*** are the chiral sensitizer in the ground and excited singlet states, and ^{1}***p*** is the twisted, excited singlet of **1**.

appreciable optical rotation was detected in **1E** recovered during the initial stages of the enantiodifferentiating photosensitization of racemic **1E**, and the *ee* of product **1E** did not show any conversion dependency in the enantiodifferentiating photosensitization of **1Z**,[22b] both of which rule out the possibility of enantiodifferentiation in the quenching process, and thus $k_{qS} = k_{qR}$. Hence, the rotational relaxation of **1Z** to ^{1}***p*** within the exciplex intermediate can be the only enantiodifferentiating step in this asymmetric photosensitization, and the *ee* of **1E** is determined exclusively by the relative rate k_S/k_R. This seems quite reasonable, since intimate interaction, which leads to efficient chiral recognition, is more likely to occur in the long-lived exciplex intermediate that possesses a more defined structure than during the collisional quenching stage.

In order to discuss quantitatively the temperature dependence of the ees observed for this asymmetric photosensitization, the rate constants k_S and k_R were analyzed according to the Arrhenius, or Eyring equation. The relative rate constant, k_S/k_R, can then be expressed by eqns. (1a) and (1b), where $\Delta E_{S\text{-}R}$

$$\ln(k_S/k_R) = -\Delta E_{S\text{-}R}/RT + \ln(A_S/A_R) \quad (1a)$$

$$= -\Delta\Delta H^{\ddagger}_{S\text{-}R}/RT + \Delta\Delta S^{\ddagger}_{S\text{-}R}/R \quad (1b)$$

represents the differential energy of activation, A_S/A_R is the relative frequency factor, and $\Delta\Delta H^{\ddagger}_{S\text{-}R}$ and $\Delta\Delta S^{\ddagger}_{S\text{-}R}$ denote the differential enthalpy and entropy of activation, respectively.

The enantiodifferentiating photosensitizations of **1Z** were performed in several solvents at temperatures ranging from +50 to −90 °C, using a variety of optically pure (poly)alkyl benzene(poly)carboxylates as chiral sensitizers.[22] Interestingly, the product chirality switched at a specific, or equipodal, temperature T_0, upon sensitization with most *ortho*-substituted benzenepolycarboxylates, whereas no chirality inversion was observed for non-*ortho* sensitizers; typical examples are shown in Fig. 1. This is the first observation of an enantiodifferentiating reaction where the ee of the product is not only inverted by temperature, but also increased with increasing temperature above T_0. It is also important that both enantiomers can be prepared simply by changing the temperature without using the antipodal sensitizer.

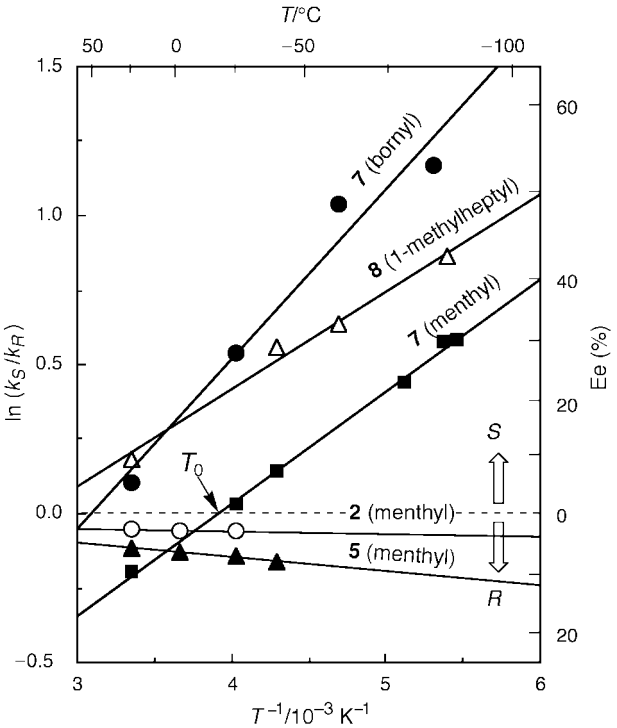


Fig. 1 Temperature dependence of the ee of the product in enantiodifferentiating photoisomerization of cyclooctene (**1Z**) sensitized by (−)-menthyl benzoate **2** (○) and terephthalate **5** (▲), (−)-menthyl and (−)-bornyl 1,2,4,5-benzenetetracarboxylate **7** (■ and △), and (−)-1-methylheptyl benzenehexacarboxylate **8** (●) in pentane. The chirality of product **1E** is switched at the equipodal temperature, T_0.

From eqns. (1a) and (1b) and the experimental plots exemplified in Fig. 1, the activation parameters were determined for these enantiodifferentiating photoisomerizations using various chiral benzenecarboxylate sensitizers; the relevant activation parameters and equipodal temperatures obtained for several sensitizers are listed in Table 1.

By examining eqn. (1), it is apparent that this temperature switching behavior of product chirality is attributable to the

Table 1 Activation parameters at 25 °C, determined from the temperature and pressure dependence of the *ee* of **1E** obtained in enantiodifferentiating photoisomerization of cyclooctene (**1Z**), sensitized by chiral benzenepolycarboxylates **2**–**5**, **7** and **8** in pentane

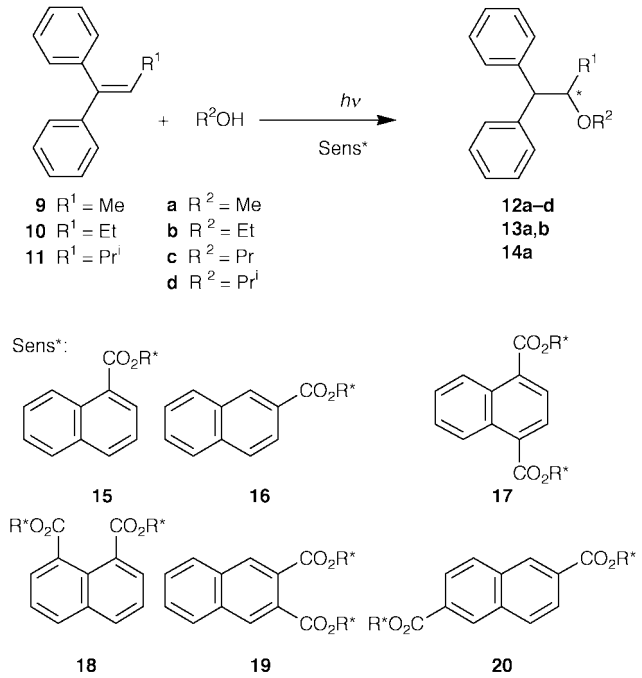
non-zero differential entropy of activation ($\Delta\Delta S^{\ddagger}_{S\text{-}R} \neq 0$) or the unequal frequency factor ($A_S \neq A_R$). Thus, the entropy factor is shown to play a decisive role in the enantiodifferentiation process. It should be emphasized that the *ortho*-substituted benzenepolycarboxylates, such as phthalate, benzenetetracarboxylate and benzenehexacarboxylate, afford very large deviations from unity for the ratio A_S/A_R, while benzoate and terephthalate show almost equal frequency factors for the (*R*)- and (*S*)-isomers, as can be seen in Table 1. This tendency is not incidental, but implies that the rotational motion of the double bond of **1** in the exciplex causes simultaneous global conformational changes of the closely situated *ortho*-alkoxycarbonyl groups of the sensitizer. Such dynamic changes during rotational relaxation in the exciplex inevitably produce large differences in the activation entropy of enantiodifferentiation.

Although we have hitherto concentrated on the enantiodifferentiating photoisomerization of **1**, similar chirality inversion phenomena have been observed in the enantiodifferentiating photosensitizations of 1-methylcyclooctene[22f] and cycloocta-1,3-diene,[24] as well as in the enantiodifferentiating anti-Markovnikov photoaddition of methanol to 1,1-diphenylpropene (**9**).[25b] Of these, the diphenylpropene case is particularly interesting, since this is the first bimolecular enantiodifferentiating photoreaction that affords the anti-Markovnikov adduct (**12**) upon sensitization with chiral 1,4-naphthalenedicarboxylates (**17**), with moderate ees of up to 33% observed (see Scheme 3 and Fig. 2). In this photosensitized polar addition, the



Scheme 3 Enantiodifferentiating photoaddition of alcohols to 1,1-diphenylalk-1-enes (**9**–**11**) sensitized by chiral naphthalene(di)carboxylates (**15**–**20**).

use of *ortho* aromatic esters is no longer required to cause the inversion of product chirality by altering the temperature, probably because the termolecular interaction of the attacking methanol with the initially formed sensitizer-substrate exciplex exaggerates the influence of the conformational differences on the enantiodifferentiating process.

The roles of entropy and enthalpy

The contributions of the enthalpy and entropy factors to the enantiodifferentiating process can be discussed in terms of eqn. (1b), or using the Gibbs–Helmholtz equation for the differential

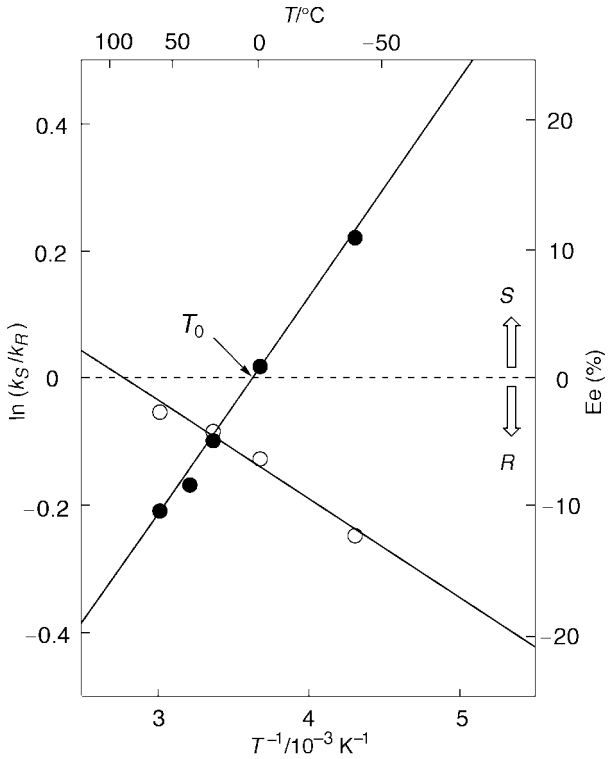


Fig. 2 Temperature dependence of the ee of the product in the enantiodifferentiating addition of methanol to **10**, sensitized by **17** with R* = (−)-menthyl (○) and 1,2:4,5-di-*O*-isopropylidene-β-D-fructopyranose (●) in methylcyclohexane.

activation free energy [eqn. (2)]. As can be seen from eqn. (2),

$$\Delta\Delta G^{\ddagger}_{S\text{-}R} = \Delta\Delta H^{\ddagger}_{S\text{-}R} - T\Delta\Delta S^{\ddagger}_{S\text{-}R} \qquad (2)$$

T_0 is the critical point at which the enthalpic and entropic contributions balance with each other ($\Delta\Delta H^{\ddagger}_{S\text{-}R} = T_0\Delta\Delta S^{\ddagger}_{S\text{-}R}$), affording no enantiodifferentiation. Below T_0, the enthalpy difference $\Delta\Delta H^{\ddagger}_{S\text{-}R}$ controls the enantiodifferentiating process, while the entropic term $T\Delta\Delta S^{\ddagger}_{S\text{-}R}$ is dominant at temperatures higher than T_0. If both $\Delta\Delta H^{\ddagger}_{S\text{-}R}$ and $\Delta\Delta S^{\ddagger}_{S\text{-}R}$ possess the same sign, switching of the dominant term in the enantiodifferentiation process leads to the inversion of product chirality, as exemplified above. In the enthalpy-controlled temperature region below T_0, the difference in the conformational freedom of the enantiodifferentiating transition states does not seriously affect the stereochemical consequence of the photoreaction, which is determined by the steric and stacking interactions in the exciplex intermediate. Since the π–π stacking interaction in the exciplex does not vary a great deal by changing the chiral auxiliary attached to the sensitizer, the majority of the enthalpy difference ($\Delta\Delta H^{\ddagger}_{S\text{-}R}$) may be attributed to different levels of steric interaction. In this context, it is reasonable to assume that the absolute configuration of the chiral sensitizer can be related directly and exclusively to that of the photoproduct. In the following section, we first examine the appropriateness of this simple theory and then explore its scope and limitations, using the enantiodifferentiating photoisomerization of cyclooctene as a representative system which can provide extensive information concerning the effects of temperature and chiral auxiliary on the ee of the product.

Stereochemical correlation

The chiral photosensitizers employed in the enantiodifferentiating photoisomerization of cyclooctene can be classified into two categories,[22] according to the temperature dependency of the ee of **1E** obtained. As shown in Fig. 1, non-*ortho* benzene(poly)carboxylate sensitizers give only small ee values and low gradient slopes in the Eyring plots, where the T_0 does not exist

at all, or appears only at an extreme temperature. In contrast, *ortho*-benzenepolycarboxylates, such as **3**, **7** and **8**, give much higher ees and steep slopes, and the product chirality is often switched at a readily accessible temperature. Since this contrasting behavior originates from the entropy term alone, it is probable that different enantiodifferentiation mechanism operates for the *ortho* and non-*ortho* sensitizers, from the conformational point of view.

In order to elucidate whether or not the absolute configuration of product **1E** can be correlated directly and globally to that of the stereogenic centre of the relevant chiral sensitizer, the data reported for the enantiodifferentiating photoisomerization of **1Z** sensitized by chiral benzene(poly)carboxylates in different solvents at ambient and low temperatures are summarized in Table 2.[22b,c] The sensitizers that carry phenyl group(s) in the chiral auxiliary are not included in Table 2, nor in the following

[a] Absolute configuration of the stereogenic center connected directly to the ester oxygen. [b] Enantiomeric excess of **1E**. Positive and negative signs for ee correspond to the formation of (*S*)-(+)- and (*R*)-(–)-isomers, respectively. [c] Absolute configuration of **1E**. [d] Dibenzoate. [e] Mixed ester.

discussion, since they are known to form an intramolecular exciplex, to which the substrate **1Z** approaches from the phenyl side.[22c]

Firstly, we will consider the stereochemical consequence observed upon sensitization with the non-*ortho* sensitizers (**2**, **4**, **5** and **7**). As demonstrated by several representative examples, these sensitizers do not exhibit chirality inversion behaviour caused by a change in temperature. It is reasonable, therefore, to discuss the relationship between the absolute configuration of **1E** obtained at any temperature with that of the stereogenic centre of the sensitizer. In examining this correlation, we will take into account only the stereogenic centre directly connected to the ester oxygen of the relevant sensitizer when the chiral auxiliary has many such centres. This approach may be justified, since the configuration around the stereogenic centre nearest to the benzenecarboxylate chromophore is expected, in general, to dominate the steric interactions in the exciplex intermediate. After examining the data for 23 different non-*ortho* sensitizers in a variety of solvents, we found a perfect stereochemical correlation between the stereogenic centres of the relevant sensitizer and product, in spite of the low ees obtained. Thus, non-*ortho* sensitizers with *R*-configuration at the nearest stereogenic centre afford (*R*)-(−)-**1E** without exception, and the opposite is true of *S*-configuration sensitizers.

Encouraged by the above result, we made further attempts to understand the seemingly complex stereochemical outcome observed for *ortho* sensitizers (*i.e.* **3**, **7** and **8**). *Ortho* sensitizers are known to cause the chirality inversion of product through a change in the reaction temperature as a consequence of the significant contribution of the entropy term. However, the entropic contribution is minimized or made negligible at temperatures below T_0. Under these conditions, the absolute configuration of the chiral sensitizer correlates to that of **1E**. Examining the results for the *ortho* sensitizers presented in Table 1, a highly consistent stereochemical correlation was observed again. Apart from those sensitizers that possess highly congested secondary and tertiary chiral auxiliaries, *e.g.* the *endo,endo*- and *exo,exo*-3-cyclohexylmethyl-2-bornyl, cedryl, 2-dicyclohexylmethyl-5-methylcyclohexyl and isopinocampheyl auxiliaries, the other 21 *ortho* sensitizers completely obey a rule which is opposite to that observed for the non-*ortho* sensitizers, *i.e. ortho* sensitizers with *R*-configuration afford (*S*)-(−)-**1E**.

These two mutually opposing stereochemical correlations, which are separately applicable to non-*ortho* and *ortho* sensitizers, urged us to derive plausible models which are compatible with them. A similar attempt to derive an exciplex model for a non-*ortho* sensitizer has already been carried out for (–)-menthyl benzoate, where an interaction of the ester carbonyl of excited benzoate with the C=C bond of **1Z** was proposed.[22b] This model is based on the fact that the ee values obtained upon sensitization with (−)-menthyl methyl terephthalate are exactly half of the values obtained with the (−)-dimenthyl analogue at

all temperatures examined, and that a semiempirical MNDO calculation for methyl benzoate indicates a good match between the MO lobes of the ester carbonyl and the C=C bond of **1Z**.[22b] In the present study, we carried out the MO recalculations on methyl benzoate and phthalate in the excited singlet state, using the PM3 program (MOPAC). The results are mostly consistent with the previous ones,[22b] except for the highly developed antibonding lobes on the carbonyl and the different pattern of the aromatic lobes in HSOMO. However, steric interactions in (−)-menthyl benzoate and phthalate are better evaluated by MM2 calculations to give the optimized conformations shown in Fig. 3. As can be seen from the front view [Fig. 3, bottom], the lower side of menthyl benzoate is covered by the menthyl isopropyl group preventing the approach of cyclooctene molecule to the ester carbonyl. If the top view is considered, it appears that the interaction of **1Z** with the C=O bond from the front side and the subsequent rotation of the C=C bond to the open side in the exciplex affords (*R*)-**1E**, in accord with the experimentally observed configuration. In the dimenthyl phthalate case (Fig. 3), the optimized conformation is substantially different from that of the benzoate due to steric hindrance between the adjacent menthoxycarbonyl groups. Thus, the two ester groups are non-equivalent, with one carbonyl orientated inside and the other outside. It is assumed that the less hindered C=O group, which is directed outwards, can interact with cyclooctene molecule from the open face, forming the exciplex (Fig. 3). The subsequent rotation in the exciplex towards the open side of the menthyl group results in the formation of (*S*)-**1E**, as observed experimentally at temperatures lower than T_0. In view of the low ees obtained, especially for non-*ortho* sensitizers, other rationales cannot be ruled out absolutely. However, we could not find any other model which was compatible with all of the experimental and MO calculation data.

Pressure effect

In the preceding sections, we have demonstrated that weak interactions in the exciplex intermediate can be controlled by temperature as a result of the contribution of the entropy term. In this context, it is interesting to study the way in which pressure can be used as an alternative tool for controlling the weak interactions that determine the stereochemical outcome in the excited state. Although pressure effects upon thermochemical and photochemical reactions have been studied in considerable detail,[33] very little effort has been extended to enantiodifferentiating photochemical reactions until recently, probably as a result of the low ees reported for such processes. However, we have recently discovered that the enantiodifferentiating photoisomerization of **1Z** (shown in Scheme 1) is significantly affected by pressure, resulting in inversion of product chirality.[31]

The pressure effect on the relative rate constant, k_S/k_R (Scheme 2), can be expressed as a linear function of pressure (P)

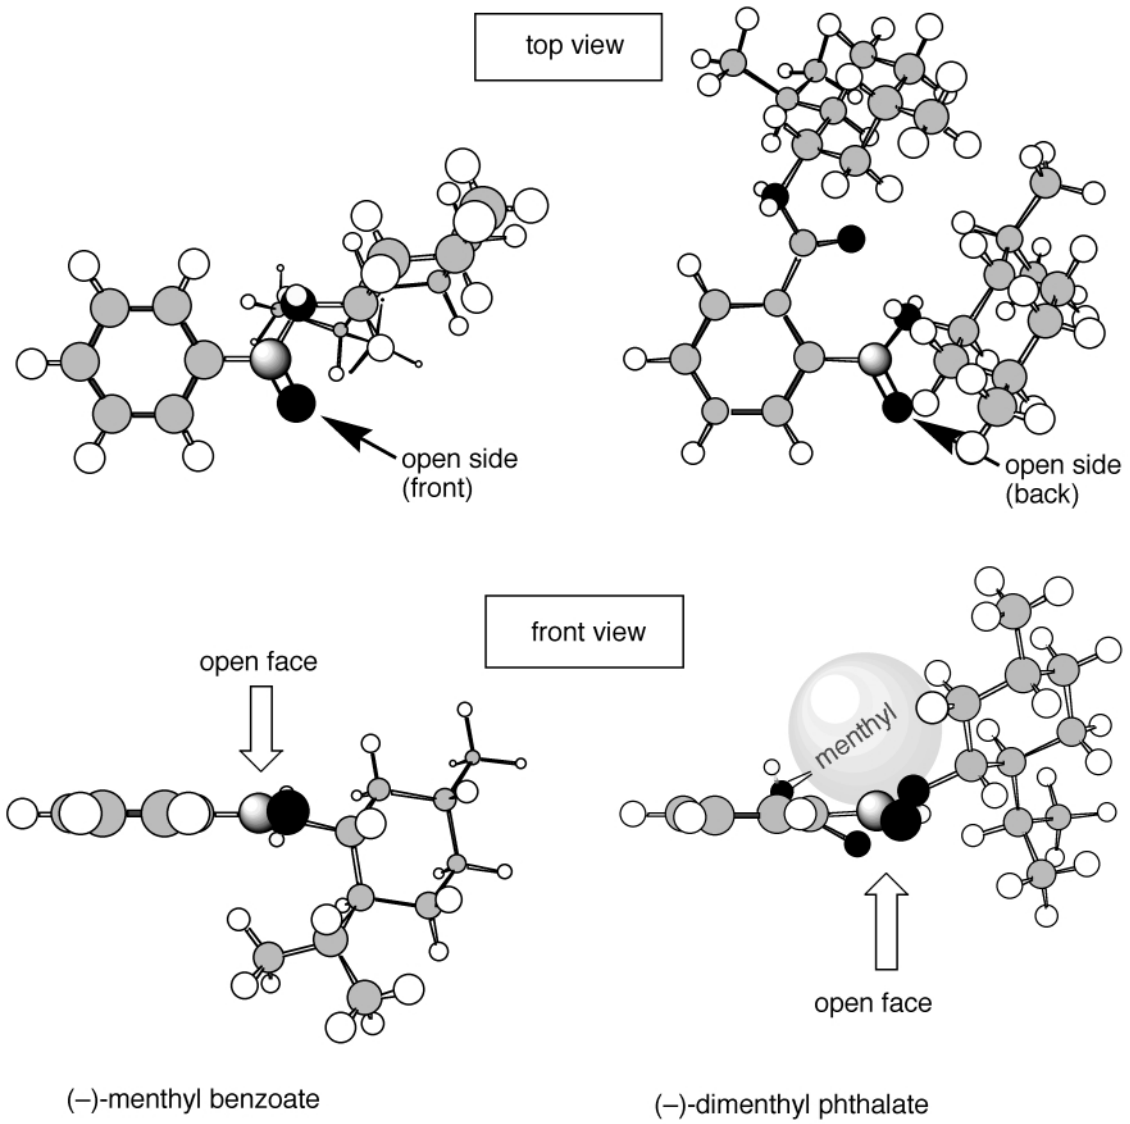

Fig. 3 Top and front views of MM2-optimized structures of (−)-menthyl benzoate **2** and phthalate **7**. In the latter structure, the shaded sphere represents the menthyl group located in the backside.

at a constant temperature [eqn. (3)][31] where $\Delta\Delta V^{\ddagger}_{S\text{-}R}$ represents

$$\ln (k_S/k_R) = -(\Delta\Delta V^{\ddagger}_{S\text{-}R}/RT)P + C \quad (3)$$

the difference in activation volume and C is equal to $\ln (k_S/k_R)$ at $P = 0$. The effect of hydrostatic pressures of up to 400 MPa was investigated in the enantiodifferentiating photoisomerization of **1Z** sensitized by chiral benzene(poly)carboxylates.[31] According to eqn. (3), the $\ln (k_S/k_R)$ values obtained were plotted against pressure.

As can be seen from Fig. 4, variations in the reaction pressure significantly affect the ee of **1E**, and often the product chirality is switched at the equipodal pressure (P_0) upon sensitization with *ortho* benzenepolycarboxylates (**3**, **7**, **8**). However, ees obtained for non-*ortho* sensitizers (**2**, **4**, **5**) were generally small and insensitive to pressure changes. This contrasting behaviour of the *ortho* and non-*ortho* sensitizers is similar to that observed for the temperature dependency of ee, again indicating a significant contribution of the entropy factor in the enantiodifferentiating process. However, the differential activation parameters obtained from the temperature- and pressure-dependence experiments,[22b,31] which are listed in Table 1, behave quite differently. Indeed, inconsistencies become evident particularly in the parameters obtained for *ortho* esters, as sensitizers that give large $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values do not always show a strong pressure dependency, and no consistent relationship is found for the signs of $\Delta\Delta H^{\ddagger}$ or $\Delta\Delta S^{\ddagger}$ and $\Delta\Delta V^{\ddagger}$.

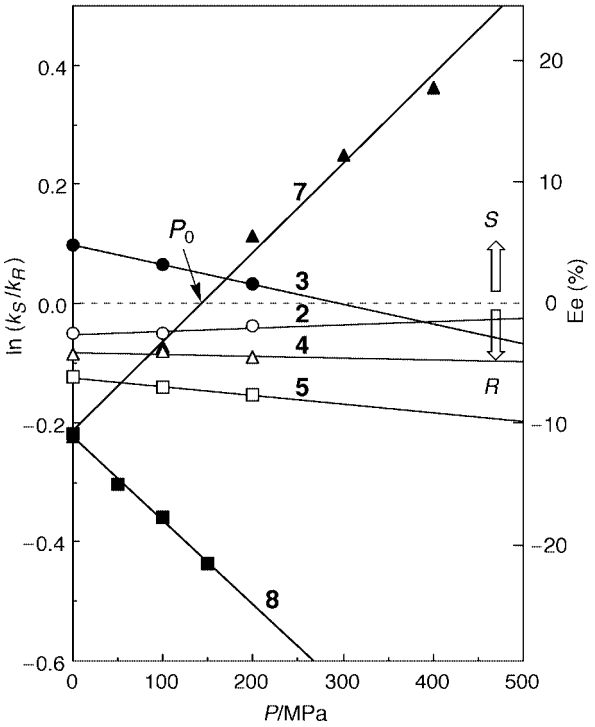

Fig. 4 Pressure dependence of the ee of the product in enantiodifferentiating photoisomerization of cyclooctene (**1Z**) sensitized by (−)-menthyl benzoate **2** (○), phthalate **3** (●), isophthalate **4** (△), terephthalate **5** (□), benzene-1,2,4,5-tetracarboxylate **7** (▲), and benzenehexacarboxylate **8** (■) in pentane at 25 °C; the chirality of product **1E** was switched at the equipodal pressure (P_0).

Multidimensional control of product chirality

The above discrepancy observed for temperature and pressure is not surprising, since both can be regarded as inherently independent variables. In order to verify this experimentally, and also to reveal the relationship between the ee of the product and these variables, we further investigated the effect of pressure on the enantiodifferentiating photoisomerization at several different temperatures, and found that the $\Delta\Delta V^{\ddagger}$ value depends critically on the reaction temperature.[31] From the data obtained, novel three-dimensional diagrams that correlate the ee with temperature and pressure were constructed for all possible cases. Two representative cases, which show inversion of the product chirality by temperature and/or pressure, are illustrated schematically in Fig. 5. In both cases, the enantiodifferentiating event occurs exclusively on one of the two intersecting planes that correspond to the antipodal sensitizers, and these two enantiodifferentiation planes are symmetrical to each other with respect to the T^{-1}–P plane. The temperature and pressure drive the product's ee in opposite directions in Fig. 5(*a*), where they act as independent factors, or in the same direction in Fig. 5(*b*). In spite of the limited number of sensitizers examined, a (−)-menthyl benzenetetracarboxylate sensitizer provides us with a fortuitous example, in which the ee of **1E** increases with decreasing temperature and increasing pressure, ultimately

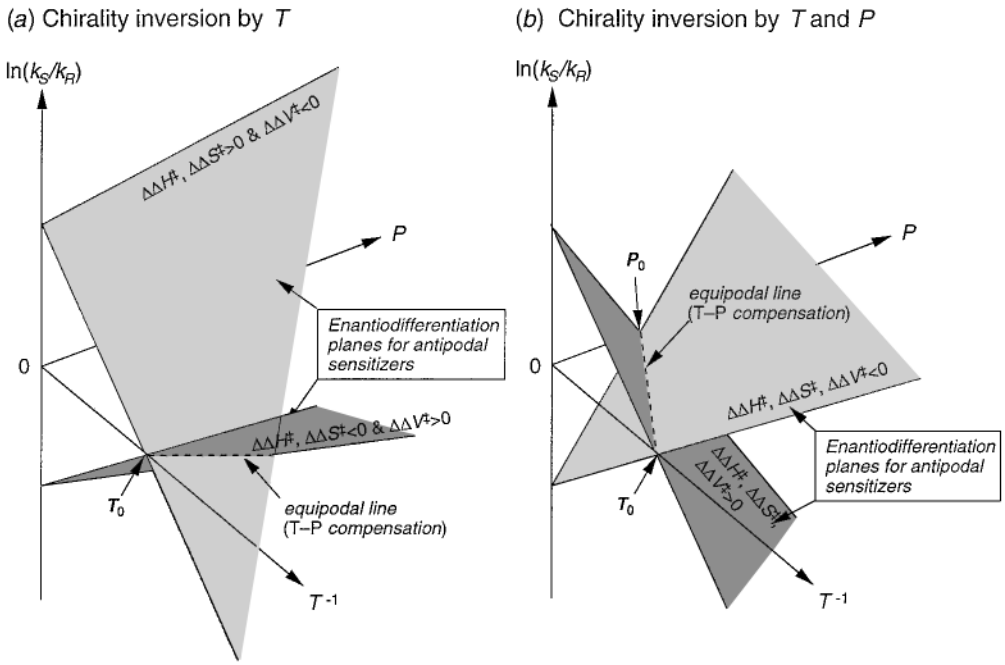

Fig. 5 Representative T^{-1}–P–$\ln(k_S/k_R)$ diagrams, correlating the ee of **1E** with temperature and pressure in the enantiodifferentiating photoisomerization of **1Z** sensitized by antipodal sensitizers; (*a*) the product chirality is inverted only by temperature as the signs of $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ are opposite to that of $\Delta\Delta V^{\ddagger}$; (*b*) the chirality is inverted by both temperature and pressure as the signs of $\Delta\Delta H^{\ddagger}$, $\Delta\Delta S^{\ddagger}$ and $\Delta\Delta V^{\ddagger}$ are all the same.

affording an extrapolated ee as high as 98.3% under conditions which are practically accessible, *i.e.* −9 °C and 1500 MPa.[31]

Conclusions

From the extensive experiments and comprehensive analyses of a variety of enantio- and diastereodifferentiating photochemical reactions,[20–31] it has been revealed that the entropy term plays an unexpectedly vital role in the stereodifferentiating processes where weak interactions determine rates and equilibria. However, it is important to emphasize that at temperatures below T_0, the stereoselectivity is dominated by the enthalpy difference arising mostly from steric and electrostatic interactions, while the dynamic behaviour of stereoselectivity over the whole temperature range, including the chirality switching phenomenon, is exclusively attributable to the entropy difference.

Experimental verification that temperature and pressure can function indeed as independent, yet cooperative, factors governing the product chirality in the enantiodifferentiating photosensitization gives us the new and versatile methodology of 'multidimensional control of asymmetric photochemistry'.[31] This strategy employs several entropy-related factors, such as temperature,[34] pressure, solvent,[35] concentration[36] and substituent flexibility, as tools for controlling the stereochemistry and stereoselectivity of photoproducts more conveniently and effectively through the manipulation of the steric and electronic weak interactions involved in the exciplex intermediates. Further, the concept of multidimensional control is not necessarily restricted to the asymmetric photochemical reactions described here, but may be applied in general to any thermal and biochemical reaction or equilibria where weak interactions are the principal driving force or determining factor, and therefore, where the entropy factor plays a major role.[37]

$[Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]$: a novel decameric molecular ring showing supramolecular properties

Emmanuel Cadot,* Bernadette Salignac, Jérôme Marrot, Anne Dolbecq and Francis Sécheresse

Institut Lavoisier. IREM, UMR 8637. Université de Versailles Saint Quentin, 45 Avenue des Etats-Unis, 78035 Versailles, France. E-mail: cadot@chimie.uvsq.fr

Received (in Basel, Switzerland) 15th November 1999, Accepted 10th January 2000

The new decameric $[Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]$ oxo–thio ring was prepared by self-condensation of $[Mo_2S_2O_2]^{2+}$ upon addition of hydroxide ion; crystals were obtained in dimethylformamide in the presence of tetrabutylammonium iodide; X-Ray diffraction analysis reveals a 10-membered ring-shaped cluster; the cyclic architecture exhibits a supramolecular assembly resulting from hydrogen bonding between two iodide anions and inner water molecules of the open cavity of the Mo_{10}-ring.

The synthesis of large and discrete species resulting from transition metal and sulfur combinations is an exciting challenge for the inorganic chemist. Indeed, transition metal sulfides represent a prominent class of compounds involved in many areas of chemistry.[1] Especially, such systems are studied extensively for their implications in both biological and industrial catalytic processes. The nuclearity of the thiometalates is generally low with topologies often limited to a restricted number of archetypal architectures.[2] These features contrast with polyoxometalates which have now reached the nanometric scale with spectacular examples such as the 'big wheel' for molybdenum blues[3] and the 'giant butterfly' for heteropolytungstates.[4] We reported in a previous work the characterization of the first oxo–thio molecular ring with high nuclearity[5] and we have now indications that other derived compounds might be synthesized through the original and convenient route of synthesis we are developing. The $[Mo_2S_2O_2(H_2O)_6]^{2+}$ precursor (aqua ion) reacts rapidly with hydroxo ions to give cyclic polymeric oxo–thio molecules, the first compound (solid **1**) isolated at pH < 3 from concentrated potassium iodide solution, leading after crystallization in water to $[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]$ (denoted Mo_{12}) a cyclic iodide-free dodecameric neutral cluster **2**.[5]† The Mo_{12} ring-shaped molecule results from the cyclic linking of six $\{Mo_2S_2O_2\}$ fragments by face-shared connections. We have demonstrated that the six water molecules lining the inner ring are labile enough to be exchanged by small anions such as phosphate or arsenate ions.[6] These exchange properties arising from the cationic character of the central open cavity hold much promise for the elaboration of a new generation of 'multicomponent systems' based on host–guest chemistry. In the presence of anionic structuring agents, such as oxalate[7] or even metalates such as molybdate,[8] the self-condensation of $[Mo_2S_2O_2]^{2+}$ produces an octameric $\{Mo_8S_8O_8(OH)_8\}$ ring encapsulating the structuring anion. With more concentrated phosphate or arsenate solutions, the condensation leads exclusively to the hexameric $[(HXO_4)_4Mo_6S_6O_6(OH)_3]^{5-}$ anion (X = As, P)[9] in which three building units $\{Mo_2O_2S_2\}$ condense around a central phosphate group through hydroxo and peripheral phosphato bridges.

The structural characterization of the new $[Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]$ ring-shaped cluster **3** (denoted Mo_{10}), obtained from **1** in a DMF solution containing tetrabutylammonium iodide represents a nice illustration of the self-condensation process. The synthesis is straightforward and consists of the dissolution of the reactants in dimethylformamide, leading to the crystallization of **3**‡ which has been fully characterized by X-ray diffraction, IR spectroscopy and elemental analysis.§

The results of the X-ray crystallographic investigation are shown in Figs. 1 and 2. The asymmetric unit contains one molecular Mo_{10}-ring, associated with two iodide anions and two tetrabutylammonium cations. The $[Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]$ molecular ring consists of five $\{Mo_2S_2O_2\}$ units connected to each other by hydroxo double bridges to form a cyclic neutral decamer. Two types of Mo–Mo distances are observed: short Mo–Mo distances [2.835(2)–2.847(2) Å] within the $\{Mo_2S_2O_2\}$ building block and long Mo–Mo interblock distances (3.314–3.324 Å). A terminal oxygen atom and two bridging sulfur atoms, both belonging to the preformed building block, complete the coordination of the Mo^V centers. Five oxygen atoms located in the open cavity of the $\{Mo_{10}S_{10}O_{10}(OH)_{10}\}$ ring bridge two neighboring Mo atoms through long Mo–O distances (2.572–2.630 Å). This arrangement confers an overall zero charge to the cluster. The presence of two iodide anions symmetrically located on both sides of the mean plane defined by the ten Mo atoms is a remarkable feature of the molecular structure (Fig. 2). The distances between iodides and the five inner water molecules are short enough (3.570–3.622 Å) to suggest that the stability of the bis-halide complex is directly related to hydrogen bonds. The hydrogen atoms of the five inner water molecules are symmetrically distributed on each side of the ring cluster, in two planes parallel to those defined by the ten molybdenum atoms. The five

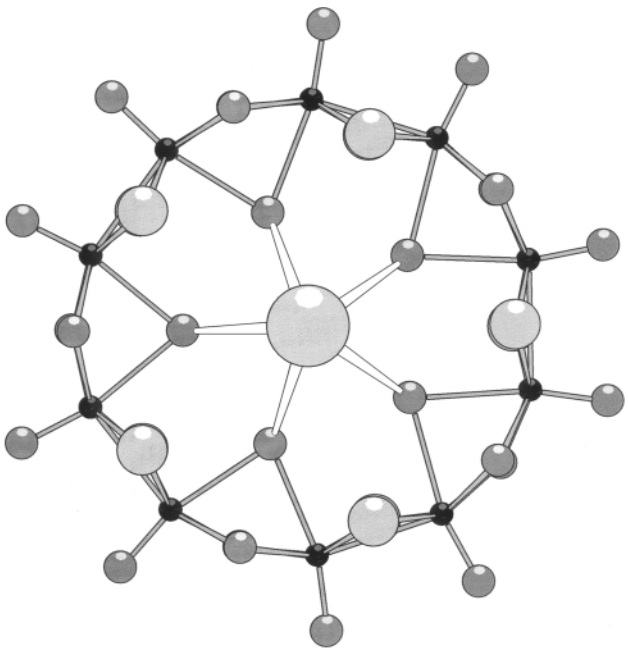

Fig. 1 Molecular structure of $[I_2Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]^{2-}$: ball and stick model showing the 10 membered ring with the central iodide anions (black spheres: Mo, light grey spheres: S, dark grey spheres: O, light grey central sphere: I).

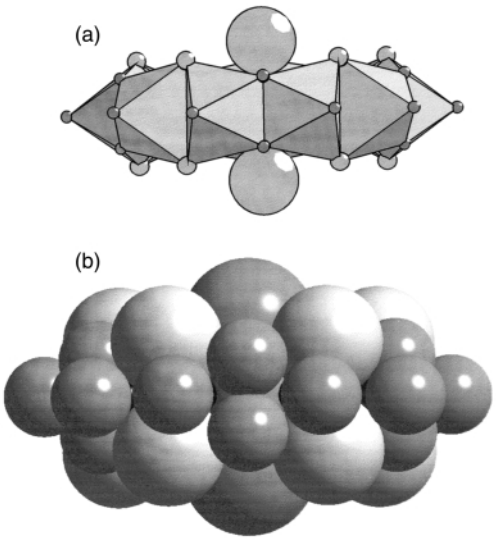

Fig. 2 Side view of $[I_2Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]^{2-}$ showing the two symmetric iodide anions floating over the cavity of the Mo_{10} ring-shaped cluster through hydrogen interactions: (a) polyhedral representation; (b) space-filling sketch with ionic radii of the elements (O^{2-} = 1.32 Å, S^{2-} = 1.84 Å, I^- = 2.20 Å).

[I⁻···H–O–H···I⁻] interactions provoke a pronounced shortening of the I···I distances (4.783 Å), rather close to the sum of the ionic radii (4.40 Å). The electrostatic balance in the crystal is ensured by two tetrabutylammonium cations.

In conclusion, this work illustrates the flexibility and the versatility of the cyclic oxo–thio architecture: in water, **1** leads to the dodecamer $[Mo_{12}S_{12}O_{12}(OH)_{12}(H_2O)_6]$ **2** while in iodide containing DMF solution, **1** gives the cyclic decamer $[Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]$ **3**. The solid state structure of **3** reveals a remarkable bis-halide complex resulting from the electrostatic interactions of two iodide ions with the inner cavity of the Mo_{10}-cluster. Such promising results demonstrate that supramolecular chemistry of anions can be considered in those inorganic systems.

Notes and references

† The crude product **1**, obtained by the synthetic procedure described in ref. 5 is a mixed K^+–NMe_4^+ salt of a neutral oxo–thio-cluster which incorporates iodide in the solid state. The elemental and thermogravimetric analysis for **1** led to the empirical molecular composition $\{K_{0.40}(NMe_4)_{0.1}I_{0.5}[Mo_2S_2O_2(OH)_2(H_2O)]\cdot 6.3H_2O\}_n$ with no direct evidence for the determination of the nuclearity *n*.

‡ *Synthesis of* $[NBu_4]_2I_2[Mo_{10}S_{10}O_{10}(OH)_{10}(H_2O)_5]\cdot H_2O\cdot 13DMF$ **3**. 1 g of **1** and tetrabutylammonium iodide (2.8 g, 7.6 mmol) were dissolved in 15 mL of DMF. After filtration, the solution was allowed to stand at room temperature for crystallization. After a week, well shaped orange crystals, suitable for X-ray diffraction were collected [yield: 41% (based on Mo)]. IR spectra (KBr pellet, ν/cm^{-1}) gave absorptions at *ca*. 1488w, 1434w, 1411w, 1388m, 1257m, 1150w, 1101m, 1063w, 968s, 876w, 666m, 533s, 413m, 378m. Crystals are strongly hygroscopic and not stable in air. Such a behavior explains the difference between the number of water molecules found in the solvate by X-ray diffraction (1.0 H_2O) and those determined by elemental analysis after hydration of the solid (18 H_2O). Received (in Cambridge, UK) 11th November 1999, Accepted 6th January 2000

A late transition metal catalyst has been used to polymerise hex-1-ene and ethene in supercritical carbon dioxide, yielding high molecular weight polymers; a comparison with polymerisations in CH_2Cl_2 reveal that polymers with identical molecular weight and polydispersity are formed.

Supercritical carbon dioxide ($scCO_2$) has recently emerged as an interesting substitute for organic solvents. CO_2 is environmental friendly compared to organic solvents and has a low critical temperature (31.1 °C) and pressure (73.8 bar). The physical properties of $scCO_2$ range from liquid-like to gas-like and can be manipulated by changing the pressure and the temperature. Physical properties like gas-like viscosities and diffusion rates, coupled with the liquid-like densities, can result in significant advantages in combined reaction, separation and purification processes. A drawback of $scCO_2$ is that only volatile or relatively non-polar compounds are soluble, as CO_2 is non-polar and has a low polarisability and relative permittivity.[1]

Polymerisation reactions using radical initiators and step growth mechanisms have been carried out in $scCO_2$.[2] More recently homogeneous catalysts have successfully been applied in $scCO_2$ for the preparation of small molecules[3] and polymers.[4–6] An interesting extension in the application of CO_2 is the use of CO_2 both as a reactant and as a solvent in a copolymerisation with cyclohexene oxide.[7] The goal of our research is to copolymerise α-olefins in $scCO_2$. Traditional catalysts for poly(olefin) production are based on early-transition-state metals, which are highly oxophilic and therefore not suitable for polymerisations in CO_2. As late-transition-state metal complexes are less oxophilic, they are more likely to be effective polymerisation catalysts in $scCO_2$. Here we describe the polymerisation of ethene and hex-1-ene catalysed by a homogeneous diimine palladium complex as catalyst,[8,9] also known as the Brookhart system, see Fig. 1.

In our polymerisation experiments we were primarily interested to see if high molecular weight polymers could be produced and whether the active catalyst would exhibit complexation behaviour with CO_2. The results of the polymerisations in CO_2 and in CH_2Cl_2 are listed in Table 1. The values of the turnover frequencies (TOFs) show that the activity of the catalyst is similar in both solvents, despite the large difference in phase behaviour of the reaction mixtures. Both the catalyst and the polymers are soluble in CH_2Cl_2. As expected, the polymer does not dissolve in $scCO_2$. Consequently, the polymerisations performed in CO_2 were all precipitation polymerisations as has been observed in the experiments. Although the differences in phase behaviour are rather large, the polymers produced are very similar, both in molecular weight and in molecular weight distribution. This behaviour indicates that there is no diffusion limitation, despite the precipitation in CO_2, suggesting strong swelling of the polymer, either by CO_2 or by the monomers used. More importantly, a similar molecular weight indicates that the active catalyst does not exhibit complexation behaviour with CO_2, since this would have resulted in a lower molecular weight.

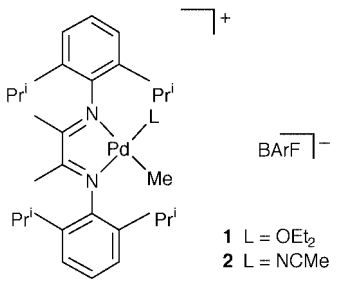

Fig. 1 Catalyst precursors used for polymerizations, BArF ≡ tetrakis[3,5-bis(trifluoromethyl)phenyl]borate.

Table 1 Polymerisation of ethene and hex-1-ene in CO_2 and CH_2Cl_2 for 2 h†

Experiment	Catalyst precursor	Catalyst/ 10^{-5} mol l^{-1}	Solvent	Pressure/bar	Monomer[a]/ mol l^{-1}	TOF[b]/h^{-1}	M_n[c]/kg mol^{-1}	M_w/M_n
1	**1**	42	CO_2	239	1.7	450	135	2.1
2	**2**	30	CH_2Cl_2	—	2.7	1010	93	1.5

4	**2**	13	CH_2Cl_2	—	2.3	810	101	1.7
5	**2**	13	CO_2	193	2.1	990	103	2.0
6	**2**	2.6	CO_2	156	0.27	2250	88	2.0

† High pressure polymerisations were conducted in a 75 ml stainless steel high pressure reactor equipped with sapphire windows, a heating jacket and a magnetic stirring bar. The solid catalyst precursor **1** (air and temperature sensitive) was put in the reactor in a glass ampulla, which broke under pressure; catalyst precursor **2** (stable at room temperature in air) was placed directly in the reactor. The air was carefully flushed with CO_2 at low pressure and the reactor was heated. In the case of hex-1-ene as the monomer, the reactor was first filled with CO_2 and then the monomer was added. In the case of ethene, the reactor was flushed and filled with ethene after which CO_2 was added. [a] Experiments 1–5: hex-1-ene, reaction temperature 35 °C; experiment 6: ethene starting pressure 6.9 bar, reaction temperature 40 °C. [b] Turn Over Frequency: mol monomer converted per mol catalyst per hour. [c] GPC (against polystyrene standards).

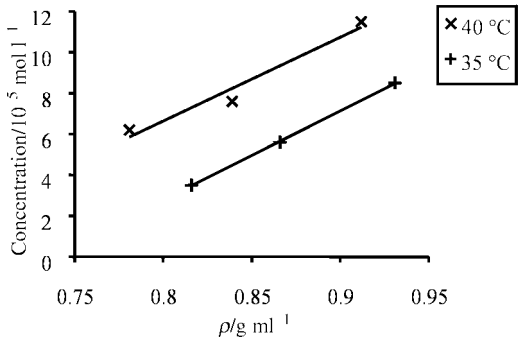

Fig. 2 Solubility of catalyst precursor **2** as a function of $scCO_2$ density.

To study the effect of catalyst concentration on the polymer yield two sets of experiments were conducted, one set with a relatively high catalyst concentration in CH_2Cl_2 and CO_2 (experiments 2 and 3, respectively) and one set with a low catalyst concentration (experiments 4 and 5, respectively). When the experiments were carried out with the high catalyst concentration, the TOF in CO_2 was lower than in the corresponding experiment in CH_2Cl_2. The experiments in the two solvents using the low catalyst concentration showed identical values for TOF, M_n and M_w/M_n, taking into account experimental error. In order to explain the effect of catalyst concentration to the TOF, the solubility of the catalyst precursor was measured in $scCO_2$ with a UV spectrophotometer‡ using a high-pressure view cell with sapphire windows. Although $scCO_2$ is a poor solvent for ionic compounds, the solubility at 35 and 40 °C was found to be in the order of 1×10^{-4} mol l^{-1}, see Fig. 2. However, the rate of solubilisation was low as it typically took 1 h to reach equilibrium. The relatively high solubility can be ascribed to the bulky anion (BArF). Generally, the solubility of an anion in hydrocarbon solvents is known to increase with increasing distribution of charge, *e.g.* the solubility increases in the order BF_4, PF_6, SbF_6, BArF and this is likely to apply for the apolar $scCO_2$ as well. All polymerisations of hex-1-ene in CO_2 were performed above the maximum solubility of the catalyst. Even in experiment 5 with the lowest catalyst concentration, only half of the added amount of catalyst is dissolved in the initial stage of the polymerisation, which follows from Fig. 2 and the density of the reaction mixture. During polymerisation, however, the solubility of the catalyst will be different from pure CO_2, since the catalyst is attached to a growing polymer chain. When the experiments with the low catalyst concentration are compared for the two solvents, no difference in TOF was observed. Obviously, the catalyst solubilisation was not limiting in experiment 5 using CO_2 as the activity was similar to experiment 4 using CH_2Cl_2. Comparing experiment 2 and 3 with the higher catalyst concentration, a difference in TOF was observed, which can be explained by the slow solubilisation and low solubility of the catalyst in CO_2. In experiment 6, ethene was polymerised in $scCO_2$ to high molecular weight polymer. It follows from this experiment that the catalyst is also active in $scCO_2$. In principle, this opens the possibility to copolymerise in $scCO_2$ with monomers such as ethene and propene.

From the foregoing it can be concluded that polymerisation of ethene and α-olefins can effectively be carried out in $scCO_2$. In the case of hex-1-ene, a comparison was made with polymerisation behaviour in an organic solvent, which yielded similar molecular weights and molecular weight distributions. In order to improve the solubility of the catalysts, we are currently modifying ligands to enhance the solubility in $scCO_2$.[10,11] Furthermore, a larger test set-up has been constructed to perform (co)polymerisations of propene, including the use of functional monomers as comonomers. Another extension to our work is the evaluation of other late-transition-state olefin polymerisation catalysts known from the literature.[12,13]

Notes and references

‡ Solubility experiments were conducted in a 1.4 ml high-pressure view cell equipped with sapphire windows and a heating jacket. The cell was filled with about 3 mg (2 μmol) solid catalyst. The air was carefully flushed with CO_2 at low pressure. The cell was then heated, filled with CO_2 at high pressure and placed in a UV spectrophotometer.

A novel magnetically coupled nonamanganese(II) 3 × 3 portcullis-like grid involving just oxygen bridges, generated by strict self assembly of the metal cation and a single heptadentate ligand

Liang Zhao,[a] Craig J. Matthews,[a] Laurence K. Thompson*[a] and Sarah L. Heath[b]†

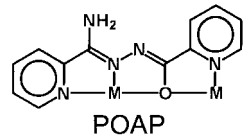
Received (in Cambridge) 19th November 1999, Accepted 11th January 2000

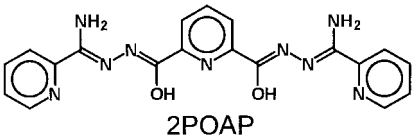
The heptadentate ligand 2POAP combines two bridging alkoxide oxygen donors with diazine and pyridine terminal nitrogen donors in a linear array with the binding sites positioned critically to accommodate three metal centres, but on reaction with $Mn(ClO_4)_2·6H_2O$ a strict self assembly process occurs, producing a unique homoleptic nonamanganese 'square' grid complex, involving six ligands.

Self assembly strategies for the formation of clusters with predetermined topological architectures are limited, and succeed only when carefully programmed subunits are incorporated in the ligand(s). The use of a single ligand with a repeating array of coordination pockets arranged in a 'linear' fashion has the potential to create a grid-like arrangement of metal centers, and some success has been achieved with linear polytopic ligands of this sort based on pyridazine and pyrimidine as a bridging subunit. Essentially flat 2 × 2 homotetranuclear grids have been achieved with Cu(I)[1] and Co(II)[2] with pyridazine and pyrimidine based ligands respectively, and a flat 3 × 3 nonanuclear grid with Ag(I)[3] involving a pyridazine based ligand. The Co(II) centers were shown to be antiferromagnetically coupled within the cluster, despite long distances of separation between the metals (6.5 Å).[4] The *n*-topic nature of the ligand creates a grid-like cluster of n^2 metal centres.[3] The ordering of paramagnetic metal ions in these grid-like arrays presents the possibility of extended spin communication within a lattice of closely spaced metal ion centers, if appropriate bridge groups can be incorporated into the ligand backbone.

Previous studies on tetradentate ligands (*e.g.* POAP) built on a flexible diazine (N–N) backbone, with a strategically positioned alkoxide fragment, have been shown to organize



POAP



2POAP

Mn(II), Co(II), Ni(II) and Cu(II) centers into square homotetranuclear clusters with just alkoxide bridges between the metal centers.[5,6] These systems display dominant antiferromagnetic exchange, except in the copper case where ferromagnetic coupling prevails.[6] In addition a unique, spin coupled, homoleptic trigonal-bipyramidal alkoxo-bridged cluster has been produced with Mn(II).[7]

† Present address, Department of Chemistry, University of York, Heslington, York, UK YO10 5DD.

This report describes the synthesis‡ and study of a heptadentate ligand that is a systematic extension of POAP, in which repeating N_2O coordination pockets are built on a 2,6-disubstituted pyridine central fragment (2POAP). Reaction of 2POAP with $Mn(ClO_4)_2·6H_2O$ in MeCN–H_2O produced red crystals (72% yield)‡ suitable for structural analysis.§ The structure of $[Mn_9(2POAP–2H)_6](ClO_4)_6·3.57MeCN·11H_2O$ **1** is unique (Fig. 1) with a 3 × 3 grid of nine pseudo-octahedral, alkoxo-bridged Mn(II) centres coordinated by two groups of three roughly parallel dianionic ligands arranged above and below the metal pseudo-plane. The Mn centres comprise three different types; *trans*-MnN_2O_4 (central), *cis*-MnN_4O_2 (corners) and *mer*-MnN_3O_3 (sides). The Mn_9O_{12} core (Fig. 2) shows that within each Mn_4O_4 subunit a puckered boat-like bridging arrangement exists involving an alternation of oxygens above and below the Mn_4 pseudo-plane. This then translates symmetrically throughout the fused arrangement that comprises the whole grid.

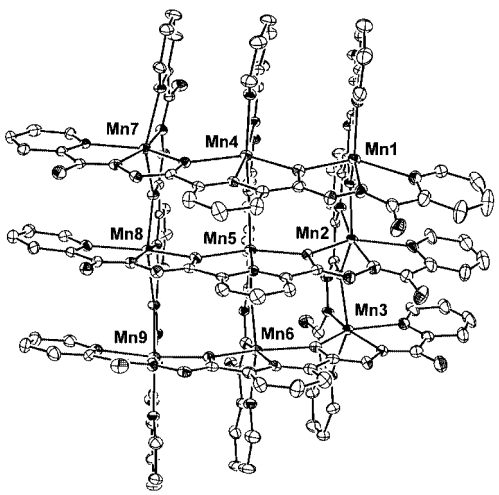


Fig. 1 Structural representation of the cation $[Mn_9(2POAP - 2H)_6]^{6+}$ (**1**) (40% probability thermal ellipsoids). Selected bond lengths (Å) and angles (°) Mn(1)–Mn(2) 3.953(3), Mn(1)–Mn(4) 3.956(4), Mn(2)–Mn(5) 3.918(4), Mn(4)–Mn(5) 3.928(3), Mn(2)–Mn(3) 3.909(3), Mn(3)–Mn(6) 3.956(4); Mn–O–Mn 126.6–130.0.

Variable temperature magnetic susceptibility measurements were carried out on a powdered sample of **1** in the temperature range 2–300 K.¶ Magnetic moments (per mol) drop smoothly from 16.9 μ_B at 300 K to 6.9 μ_B at 5 K, and then there is a very slight rise below this temperature. The room temperature value is consistent with the presence of nine high spin Mn(II) centers, and the drop to 6.9 μ_B at 5 K is associated with the presence of intramolecular antiferromagnetic exchange with the equivalent of one residual Mn(II) center in the spin coupled (S = 5/2) ground state. This situation is an exact parallel to that occurring in the pentamanganese(II) cluster of POAP.[7] The slight rise in μ_B at temperatures <5 K may be due to a very weak

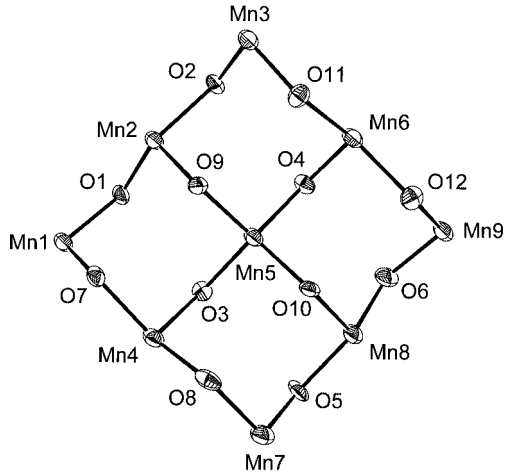

Fig. 2 Structural representation of the nonanuclear core in $[Mn_9(2POAP - 2H)_6]^{6+}$.

ferromagnetic component. An evaluation of the complex exchange coupling situation will be attempted and described elsewhere.

Electrochemical studies in acetonitrile revealed five sequential redox waves (cyclic voltammetry; $E^{1/2}$/(V)(ΔE_pmV) 0.61(220), 0.92(100), 1.13(140), 1.33(130), 1.53(110) at 100 mV s^{-1} (Fig. 3)). The $Zn(ClO_4)_2$ complex of 2POAP exhibits no significant waves in the range 0–1.6 V in acetonitrile. Coulometry (acetonitrile at 0.8 V) indicates that the first wave corresponds to a four-electron oxidation process, while the following four waves correspond to a further four-electron oxidation process in total (potential set at 1.65 V). Appropriate reduction sequences showed that eight electrons were required for complete reduction. The first wave reasonably corresponds to the oxidation of four equivalent Mn(II) centers to Mn(III), and is tentatively assigned to Mn(1), Mn(3), Mn(7) and Mn(9), which are equivalent and well separated. The sequence of four following waves is assigned to four other Mn(II) centers, which appear to be in communication, such that the oxidation potentials to Mn(III) become progressively more positive. These are assigned to Mn(2), Mn(6), Mn(4) and Mn(8), which are linked though Mn(5), and clearly all antiferromagnetically coupled to it. The visible spectrum of an oxidized acetonitrile solution of **1** shows the appearance of an intense band at 985 nm during the first four-electron oxidation process, followed by a further intensity increase after the full eight electron oxidation is complete. This band is reasonably assigned to an intervalence process.

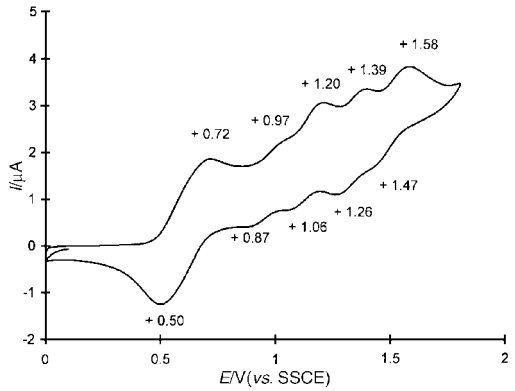

Fig. 3 Cyclic voltammetry for $[Mn_9(2POAP - 2H)_6](ClO_4)_6 \cdot 18H_2O$ **1** in acetonitrile (0.5 mM, 0.1 M NEt_4ClO_4; Pt working electrode, Pt counter electrode, SSCE reference electrode; BAS CV27 voltammograph; 100 mV s^{-1}).

The aggregation of nine octahedral manganese(II) centers (fifty four coordination positions) into an alkoxo-bridged, portcullis-like 3 × 3 grid by six heptadentate 2POAP ligands (fifty four donor positions) is a unique example of a self assembly process in which the coordination algorithm of the nine metal assembly is exactly matched by the aligned arrangement of the two sets of 'parallel' ligands arranged above and below the metal grid pseudo-plane. This strategy has general application, and $Cu(II)_9$ analogues have been prepared.[5] A simple extension of this type of ligand with additional five-membered chelate ring compartments can be envisaged to produce 4 × 4 and 5 × 5 grids, and even higher homologues. Efforts are currently underway to achieve this goal.

Notes and references

‡ 2POAP was synthesized in 85% yield by the reaction of 2,6-pyridinedihydrazide with the methyl ester of iminopicolinic acid. 2POAP (0.403 g, 1.00 mmol) was added to a hot solution of $[Mn(H_2O)_6](ClO_4)_2$ (1.45 g, 4.00 mmol) in water (5 mL). MeCN (15 mL) was then added and the mixture left at room temperature. Red crystals (72% yield) formed after several days. Found (vacuum dried sample): C, 35.77; H, 2.63; N, 19.61. Calc. for $Mn_9(C_{19}H_{15}N_9O_2)_6\ (ClO_4)_6 \cdot 18H_2O$ **1**: C, 35.81; H, 3.29; N, 19.78%. IR (Nujol mull, cm^{-1}): νNH/H_2O 3450, 3339, 3247 ; νCO/CN 1689, 1654; νClO_4 1095. UV–VIS. (Nujol mull): 546 nm (sh); (MeCN) 1027 nm (ε 19.6 $dm^3\ mol^{-1}\ cm^{-1}$). μ_{RT} = 16.9 μ_B (mol^{-1}).

§ *Crystal data* for $[Mn_9(2POAP - 2H)_6](ClO_4)_6 \cdot 3.57MeCN \cdot 11H_2O$: $C_{121.14}H_{122.71}N_{57.57}O_{47}Cl_6Mn_9$ **1**; M = 3844.3, monoclinic, space group $C2/c$, a = 26.0641(16), b = 26.0910(16), c = 53.291(3) Å, β = 102.473(1)°, U = 35385(4) $Å^3$, Z = 8, D_c = 1.443 g cm^{-3}, T = 150(2) K, μ(Mo-Kα) = 0.800 mm^{-1}. 2075 parameters were refined with 17267 unique reflections ($I > 2.0\sigma(I)$) to give $R1$ = 0.1419, $wR2$ = 0.3936 (30409 independent reflections, R_{int} = 0.0668) (Bruker Smart three-circle diffractometer with a CCD area detector set at 6 cm, graphite-monochromatized Mo-Kα X-radiation). Only the non-hydrogen atoms of the cation and the chlorine atoms of the anions were refined anisotropically. Hydrogen atoms were fixed at idealized positions (U 1.2 × U (riding atom)), except for the amino groups, and the eleven identified waters of crystallization, where they were not included. The structure also contains three fully occupied acetonitrile molecules of crystallization and one partially occupied molecule refined to an occupancy of 0.57. The perchlorate anions are very disordered and the oxygen atoms were modeled isotropically, each with its own free variable, giving a total of 6.9 perchlorates in the final cycle of least-squares. Attempts to use a SUMP command to constrain the total perchlorate occupancy to six resulted in unstable refinements. The cation is however clearly defined, despite difficulties with the structural refinement and identification of all lattice fragments. A preliminary structure on $[Mn_9(2POAPZ - 2H)_6](NO_3)_6 \cdot xH_2O$ shows that it has the same structure (2POAPZ is the terminal pyrazine equivalent of 2POAP).[5]

Received (in Cambridge, UK) 5th November 1999, Accepted 6th January 2000

The molecular recognition between phytyl phosphate giant vesicles and a polysaccharide (pullulan) bearing phytyl or cholesteryl groups and a fluorescent tag was investigated; the pullulan bearing phytyl chains did coat the surface of the vesicles, in contrast with the pullulan bearing cholesteryl groups.

We have postulated that polyprenyl phosphates possibly formed the most primitive vesicles.[1] We have also suggested plausible processes for 'primitive' vesicles becoming more complex 'proto-cells'.[2,3] We have now studied whether giant vesicles (5 μm or more)[4] made from single-chain polyprenyl phosphates[5] could be coated by a polysaccharide (pullulan, MW ~55000 Da) bearing hydrophobic polyprenyl chains (Fig. 1). This would lead to an assembly somewhat reminiscent of the cell wall of microorganisms. To the polysaccharide was also covalently attached a fluorescent tag, to make it possible to clearly observe coated vesicles with optical fluorescence microscopy. We have recently reported that POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) vesicles can indeed be coated with pullulan, to which had been linked cholesteryl groups (FITC-CHP, 1.17

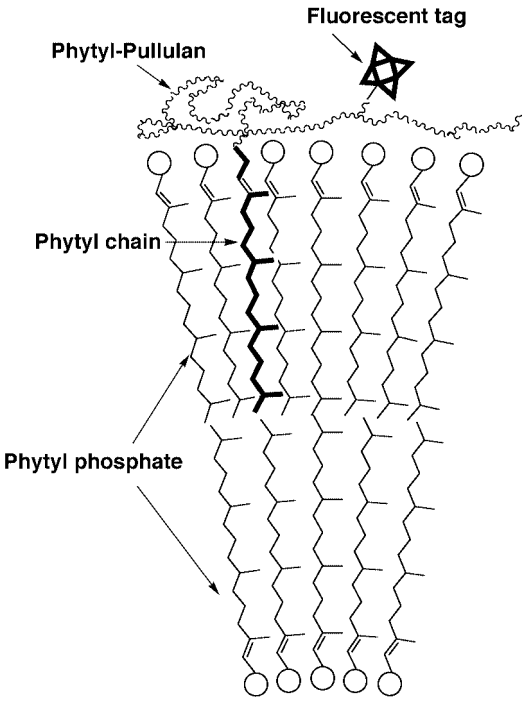

Fig. 1 Schematic representation of the coating of phytyl phosphate giant vesicles by phytyl-pullulan carrying fluorescent tags.

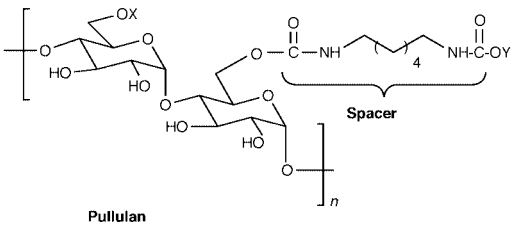
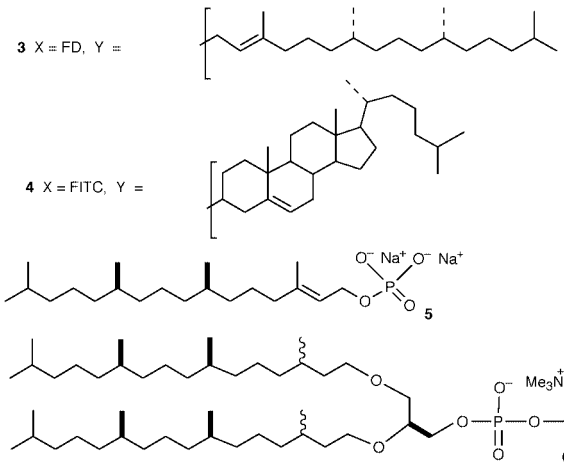
† Synthetic and spectroscopic data are available as supplementary data from the RSC web site, see http://www.rsc.org/suppdata/cc/a9/a908827j/



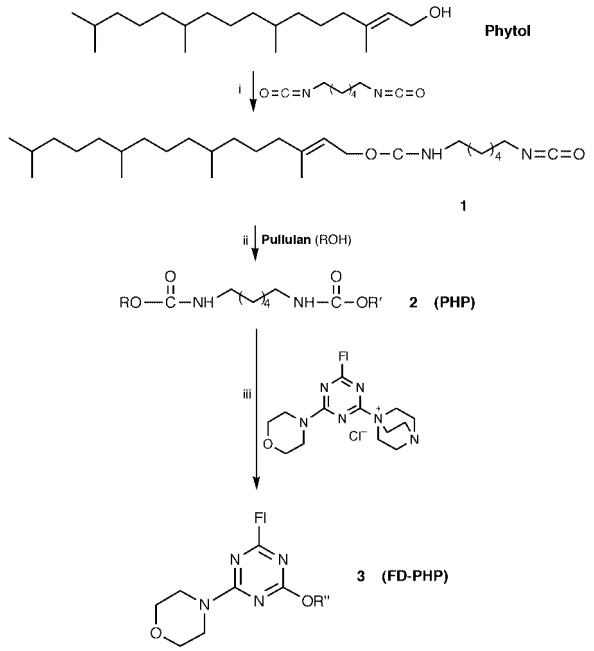
Pullulan



cholesteryl groups per 100 monosaccharide units) **4** (Scheme 1).[6] The cholesteryl groups of this 'cholesteryl-pullulan' insert themselves spontaneously into the membrane, in agreement with the fact that cholesterol itself is a widespread reinforcer of eucaryotic membranes, thereby spreading and anchoring the polysaccharide on the outer surface of the vesicles.

We first attempt to coat giant vesicles of phytyl phosphate **5** or of 2,3-diphytanyl-*sn*-glycero-1-phosphocholine (DPhPC) **6**, an archæal membrane constituent,[7] with 'cholesteryl-pullulan' **4**. This was unsuccessful, and cholesterol did *not* insert into either the monopolyprenyl phosphate or the dipolyprenyl phosphatidylcholine membranes. This was somewhat surprising, as cholesterol and phytol have similar amphiphilicity and overall shape. The non-incorporation of cholesteryl moiety does not depend on the nature of the head-group and must depend on the texture of the lipid part of the membrane. Indeed, Yamauchi *et al.*[8,9] have shown, by leakage studies, that diphytanyl phosphatidylcholine **6** membranes are relatively more rigid than those made of *n*-acyl lipids, which they explained by the lateral interdigitation of the phytanyl chains, which could also exclude the cholesteryl groups.

We then synthesized a novel pullulan derivative, replacing the cholesteryl moiety of (FITC-CHP) **4** by a phytyl chain (FD-



Scheme 1 *Reagents and conditions*: i, toluene–pyridine, 60 °C, 4 days, 100%; ii, DMSO–pyridine, 75 °C, 3 days, 55%; iii, rt, 24 h, 45%. ROH = pullulan, R′ = phytyl, R″ = hydrophobized pullulan (PHP), Fl = fluorescamine unit.

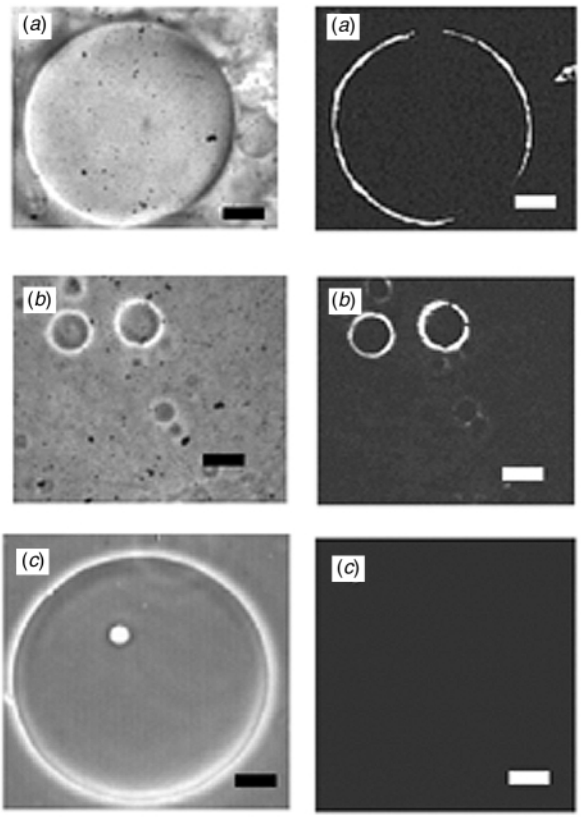


Fig. 2 Phase contrast image (left) and the corresponding fluorescent microscopic image (right) of coating (or not) of the surface of the preformed giant vesicles: (*a*) coating of phytyl phosphate vesicles by phytyl-pullulan (FD-PHP) **3**; (*b*) coating of diphytanyl phosphatidylcholine vesicles by phytyl-pullulan (FD-PHP) **3**; (*c*) absence of coating of phytyl phosphate vesicles by cholesteryl-pullulan (FITC-CHP) **4**. Bar: 10 μm.

PHP) **3**; this should of course be compatible with bilayers of phytyl phosphate **5** and permit the coating process. The synthetic route to obtain the fluorescent 'phytyl-pullulan' (FD-PHP) **3** is shown in Scheme 1. The phytyl moiety was linked to pullulan through an α,ω-dicarbamoylhexyl spacer, affording quantitatively a half-carbamate **1**, which was condensed with pullulan to produce the 'phytyl-pullulan' (PHP) **2** (55%). Finally, PHP was coupled to a morpholinyltriazine labelled with fluorescamine, followed by purification on a Sepharose gel, to yield a pure 'phytyl-pullulan' labelled with fluorescamine **3** FD-PHP (45%); content of phytyl groups: 2.9 per 100 glucose units; fluorescamine: 0.8 per 1 PHP molecule).‡

In contrast to the experiments with 'cholesteryl-pullulan', the entire outer surface of giant vesicles composed of phytyl phosphate **5** or DPhPC **6** could easily be coated with 'phytyl-pullulan' **3** (Fig. 2). Control experiments carried out with 'FITC-pullulan' (pullulan bearing the fluorescent tag but no hydrophobic moiety) confirmed that the coating of vesicles required the hydrophobic chains. Confocal microscopy showed that FD-PHP **3** spreads only on the surface of vesicles (not shown).

These results indicate that the criteria for efficient insertion of a lipophilic anchor into a bilayer are more stringent than we had initially expected; a near identical structure of the bilayer phospholipids and of the anchoring chains is required, or else the fit must be as closely adapted as is the case for cholesterol and *n*-acyl lipids.[10]

The recognition of a 'phytyl-pullulan' by a membrane of phytyl phosphate **5** or of diphytanyl phosphatidylcholine **6** is an interesting example of solubility guided by close structural similarity.

This work was supported in part by JST-ULP 'Supramolecules' Joint Research Project and by COST. We are grateful for support granted by the Ministry of National Education, France for a fellowship to S. J. Lee, CNRS to S. Ghosh. We express our gratitude to Dr S. Chasserot-Golaz, Strasbourg, for her help in obtaining the confocal microscopy images.

Notes and references

‡ Optical, fluorescence and confocal microscopies were carried out according to the procedures described in refs. 11–14. To coat the surface, it is sufficient to use oligosaccharide carrying 3% only of the stoichiometric amount of lipophilic chains.

ChemComm

Synthesis of new hybrid macromolecules with cyclo-dendritic architecture

Ivan Gitsov*[ab] and Pavlina T. Ivanova[a]

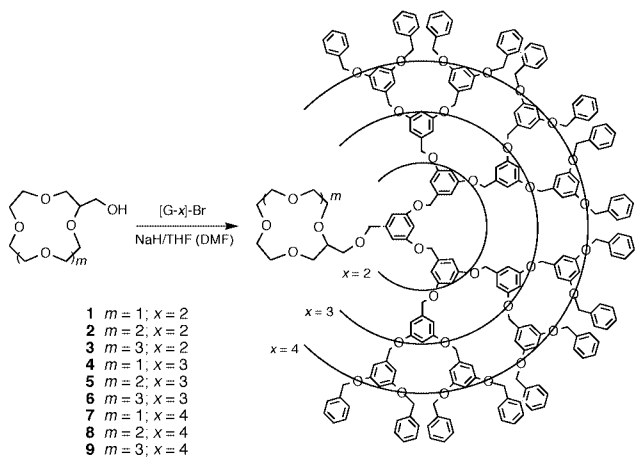
Received (in Corvallis, OR, USA) 28th September 1999, Accepted 22nd November 1999

Novel cyclo-dendritic hybrid macromolecules were synthesized using preformed blocks: hydroxymethyl crown ethers and poly(benzyl ether) monodendrons.

The highly symmetrical three-dimensional shape of dendrimers and their fractal construction make them excellent and unique biological models.[1] It is already known that the dendritic shell can provide specific and selective microenvironments greatly affecting host–guest interactions.[2,3] The combination of dendrimers and other macromolecular topologies as building blocks is an attractive and promising approach in the development of suitable biological replicas for the study of molecular recognition and other cell processes.[4,5]

Compounds containing both crown ethers and dendritic wedges might have interesting ligating properties.[6] The first example of this type was published by Percec and co-workers in 1993.[7] DCC-mediated transesterification was used to produce molecules containing a crown ether moiety and taper-shaped fragments that could also be regarded as first-generation monodendrons. In subsequent papers the same authors reported the intriguing self-assembling properties of these compounds that were able to form unique cylindrical supramolecular structures upon interaction with metal salts.[8] However, the investigation was limited only to a single type of crown ether (15-crown-5) and first-generation monodendrons with flat geometry. The influence of the size and shape of the reactive fragments and the reaction conditions on the formation of the cyclo-dendritic hybrids has not been explored.

Here we report the synthesis of a new series of hybrid compounds **1**–**9** (Scheme 1) containing crown ethers of different sizes and three generations of poly(benzyl ether) dendrimers with different geometry. These compounds can bind alkali and alkaline-earth metal ions *via* their crown ether cavities and complex other guest molecules through the voids and the peripheral shell in the dendritic part of the molecule. In distinction to previous reports, the Williamson reaction was used to create an ether bond between the dendrons and 2-hydroxymethyl crown ethers.



Scheme 1

The synthetic strategy for the formation of the dendritic crowns involves a reaction between two preformed fragments. Previously we have shown that this approach is a versatile tool for the generation of different types of dendrimer-containing hybrid macromolecules.[9] Because of the proven accessibility of the functional group at the 'focal' point of the dendrimer[10] it could be applied also in the present study. Earlier we found that linear aliphatic polyethers used as one of the building blocks in the formation of dendritic hybrids have a noticeable auto-acceleration effect on the Williamson reaction employed for their formation.[10] Therefore one of the additional goals in the present investigation is to trace the eventual influence of the size of the cyclic polyether on the speed and the efficiency of the synthetic procedure. The dendritic bromides were synthesized by a known method[11] and the 2-hydroxymethyl crown ethers (from Aldrich) were used without further purification.

Initially we explored the synthetic pathway based on typical phase-transfer reaction conditions that was successfully applied in the synthesis of the poly(benzyl ether) dendrimers.[10] The reaction, performed in refluxing acetone with K_2CO_3 and 18-crown-6 as catalyst, afforded a complex mixture, which did not contain the desired product. Stronger bases like dry THF/NaH or DMF/NaH systems proved to be more efficient. In a typical reaction procedure NaH (4 mmol) was added as a powder to a solution of 0.1 mmol of 2-hydroxymethyl-crown ether and 0.105 mmol of dendritic bromide in 10 ml dry THF. The reaction mixture was stirred under nitrogen at room temperature for 140 h. The progress of the reaction was monitored by TLC (CH_2Cl_2–Et_2O = 9:1). After no further change was observed the reaction was stopped and THF was evaporated under reduced pressure. The crude reaction product was purified by flash chromatography using gradient elution with a mixture of CH_2Cl_2–Et_2O for products containing the 12-crown-4 fragment (from 98:2 to 75:25 v/v) or CH_2Cl_2–acetone for larger cycles. When DMF was employed as the solvent at the end of the reaction the solution was precipitated into cold water and the crude filtered product was subsequently chromatographed.

The compounds composed of a second-generation dendritic bromide and all three 2-hydroxymethyl crown ethers are heavy oils; those of the higher generations are white foamy glassy solids. All reaction products were purified by flash chromatography and their purity was determined by TLC (single spot) on silica gel plates with fluorescent indicator and SEC at 40 °C in THF (single peak with double UV and RI detection). Their structure was confirmed by ^{1}H NMR spectroscopy.† All compounds yielded satisfactory elemental analyses and all exhibited very good correlation with the calculated molecular masses as evidenced by their MALDI-TOF spectra.

A summary of the reagents, reaction conditions and yields of the products is presented in Table 1. It can be seen that the Williamson synthesis performed in THF with NaH produced the desired products after long period of time in moderate yields. DMF (due to its higher polarity) facilitates the reaction and

Table 1 Influence of the reaction conditions and reagents' size on the yields of the cyclo-dendritic macromolecule[a]

Compound	Dendritic bromide	Crown ether	Yield (%) (purified)	*t*/h
1	[G-2]-Br	2-OH-12-crown-4	34.1	140
2	[G-2]-Br	2-OH-15-crown-5	29.2 (38.3)[b]	120 (24)[b]
3	[G-2]-Br	2-OH-18-crown-6	30.7 (37.1)[b]	96 (36)[b]
4	[G-3]-Br	2-OH-12-crown-4	20.2	140
5	[G-3]-Br	2-OH-15-crown-5	28.5 (45.4)[b]	120 (10)[b]
6	[G-3]-Br	2-OH-18-crown-6	24.1 (47.0)[b]	140 (24)[b]
7	[G-4]-Br	2-OH-12-crown-4	16.2 (17.0)[b]	140 (24)[b]
8	[G-4]-Br	2-OH-15-crown-5	21.5 (22.0)[b]	140 (24)[b]
9	[G-4]-Br	2-OH-18-crown-6	40.5 (39.8)[b]	140 (24)[b]

[a] Reaction conditions: dry THF, NaH, 5% excess of dendritic bromide. [b] Reactions performed in DMF at 70 °C.

improves the yields over reduced reaction times. An increase in reaction temperature to 70 °C and higher did not influence the reaction rate and the yields. To our surprise the ring size of the crown ethers did not effect substantially their nucleophilicity and all three of them have similar reactivity in the reaction with dendritic bromides. One would have expected 2-hydroxy-15-crown-5 to react faster and more effectively because of its additional complex binding towards Na^+, and this is partially true for the lower generations, but not with the fourth-generation dendritic bromide. The results from this study are not very conclusive in terms of dendritic activity. The change from a flat, two-dimensional geometry (second generation) to a globular shape (fourth generation) effects slightly the reactivity of the dendritic wedges. Despite the shielding effect of the large dendritic fragments, the focal point functionalities are still readily accessible for nucleophilic attack even in the fourth generation and this reconfirms our previous findings for the reactivity of dendrimers in Williamson reactions[10] and as macroinitiators for anionic ring-opening polymerization.[12]

The physical properties, self-assembling and binding capabilities of the new cyclo-dendritic hybrids are currently under investigation.

The authors would like to thank Rohm & Haas Co. and the Loctite Corporation for financial support. The analyses were performed in the Polymer Characterization Facility of the Cornell Center for Materials Research supported by the NSF (Award DMR-9632275).

Polymer immobilised TEMPO (PIPO): an efficient catalyst for the chlorinated hydrocarbon solvent-free and bromide-free oxidation of alcohols with hypochlorite

Arné Dijksman, Isabel W. C. E. Arends and Roger A. Sheldon*

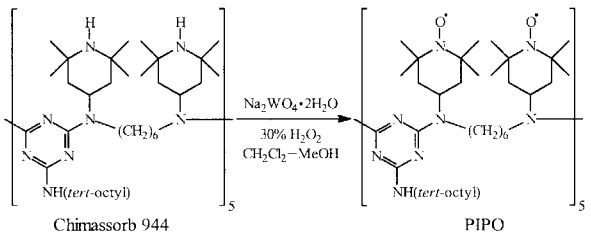
Laboratory for Organic Chemistry and Catalysis, Department of Biotechnology, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands. E-mail: secretariat-ock@stm.tudelft.nl

Received (in Cambridge, UK) 9th December 1999, Accepted 7th January 2000

PIPO, a readily prepared polymer immobilised TEMPO, can be employed as an efficient recyclable heterogeneous catalyst for the chlorinated hydrocarbon solvent-free and bromide-free bleach oxidation of a variety of alcohols and polyols.

The use of stable nitroxyl radicals, such as TEMPO, as catalysts for the oxidation of alcohols to aldehydes, ketones and carboxylic acids is well documented.[1] Typically, these transformations employ 1 mol% of the nitroxyl radical and a stoichiometric amount of a terminal oxidant, *e.g.* sodium hypochlorite,[2] MCPBA (*m*-chloroperbenzoicacid),[3] sodium bromite,[4] trichloroisocyanuric acid[5] and oxygen in combination with CuCl[6] or $RuCl_2(PPh_3)_3$.[7] In particular, the TEMPO-bleach protocol using bromide as co-catalyst introduced by Anelli *et al.*[2] is finding wide application in organic synthesis. Although only a small amount of catalyst is used, recyclability is an issue and several heterogeneous TEMPO systems have been reported.[8] For example, MCM-41[8g] and silica-supported TEMPO[8h,i] have been applied in oxidation reactions using hypochlorite as the oxidant. The preparation of these catalysts involves initial functionalisation of the support followed by covalent attachment of a 4-substituted TEMPO.

Here, we report the use of a readily prepared polymer immobilised TEMPO as a catalyst for alcohol oxidations. It was derived from a commercially available oligomeric, sterically hindered amine, poly[[6-[(1,1,3,3-tetramethylbutyl)amino]-1,3,5-triazine-2,4-diyl][2,2,6,6-tetramethyl-4-piperidinyl)-imino]-1,6-hexanediyl[(2,2,6,6-tetramethyl-4-piperidinyl-imino]], better known as Chimassorb 944 (MW ≈ 3000; see Scheme 1 for structure). This compound is used as an antioxidant and a light stabiliser for plastics. It contributes significantly to the long term heat stability of polyolefins and has broad approval for use in polyolefin food packaging.[9]



Scheme 1 Synthesis of PIPO.

Nitroxyl radicals are normally prepared by treating the analogous secondary amine with $Na_2WO_4 \cdot 2H_2O$ and hydrogen peroxide.[10] In the case of Chimassorb 944, the same procedure was applied resulting in the formation of an oligomeric TEMPO (Scheme 1). Probe-MS data revealed that the mass of each segment increased by 30 owing to transformation of two secondary amine moieties into the corresponding nitroxyl radicals. This new polymer immobilised TEMPO, further referred to as PIPO (polyamine immobilised piperidinyl oxyl), proved to be an effective catalyst for oxidations of alcohols with hypochlorite using the Anelli protocol.[2]†

Primary and secondary aliphatic and benzylic alcohols were smoothly converted to the corresponding aldehydes and ketones in CH_2Cl_2 (Table 1). Under these conditions the system was homogeneous as PIPO is soluble in dichloromethane. In contrast, in the absence of solvent (entry 3) PIPO was an active heterogeneous catalyst. The heterogeneous nature of the catalyst was confirmed in a filtration experiment, in which the reaction mixture was filtered after 10 min. The filtrate showed no activity at all during 1 h after filtration. The residue, however, could be reused at least twice as a catalyst. The minor loss of activity (< 5%) observed is probably due to mechanical losses occurring during filtration of the small amount of catalyst.

Table 1 PIPO-catalysed oxidation of alcohols with bromide/hypochlorite[a]

Entry	Substrate	Product	*t*/min	Conv.(%)[b]	Sel.(%)[b]
1	Octan-1-ol	Octanal	20	> 99	> 99
2	Octan-2-ol	Octan-2-one	20	> 99	> 99
3[c]			45	95	> 99
4	Benzyl alcohol	Benzaldehyde	20	> 99	> 99
5	1-Phenylethanol	Acetophenone	20	> 99	> 99

[a] 0.8 mmol substrate, 2.5 mg PIPO (1 mol% nitroxyl), 2 ml CH_2Cl_2, 0.16 ml 0.5 M KBr solution (10 mol%), 0.14 g $KHCO_3$, 2.86 ml 0.35 M hypochlorite solution (1.25 equiv.), 0 °C. [b] Conversion and selectivity determined by GC using *n*-hexadecane as internal standard. [c] No CH_2Cl_2 (solvent-free).

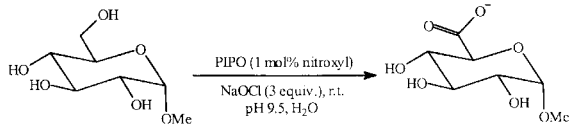
Further investigation revealed that the use of bromide was not necessary. Thus, in contrast to the conventional TEMPO-bleach oxidations, which use dichloromethane as solvent and bromide as a co-catalyst,[2] PIPO catalyses the oxidation of a variety of alcohols in the absence of organic solvent and using only a hypochlorite solution (0.35 M, pH 9.1) as the oxidant (Table 2). However, under these conditions primary aliphatic alcohols such as octan-1-ol, gave low selectivities to aldehydes owing to over-oxidation of octanal to octanoic acid (entry 1). This problem was circumvented by using MTBE as the organic solvent, in which PIPO is not soluble, affording an increase in selectivity to 94% (entry 2). Here again, filtration experiments confirmed that this system was heterogeneous, analogous to the solvent-free conditions.

In addition to primary and secondary aliphatic alcohols (entries 2–7), benzylic alcohols were also efficiently oxidised (entries 9 and 10), complete conversion being observed within 30 min. In competition experiments, the catalyst showed a marked preference for primary alcohols (entries 8 and 11). This is analogous to the already reported homogeneous[2] and heterogeneous[8h] TEMPO systems. Chirality on the α-position is not affected during oxidation as shown by the selective oxidation of (*S*)-2-methylbutan-1-ol to (*S*)-2-methylbutanal (entry 12).[11]

Table 2 PIPO-catalysed oxidation of alcohols with hypochlorite[a]

Entry	Substrate	Product	*t*/min	Conv. (%)[b]	Sel. (%)[b]
1	Octan-1-ol	Octanal	45	90	50[d]
2[c]	Octan-1-ol	Octanal	45	80	94
3[c]	Hexan-1-ol	Hexanal	45	89	95
4	Octan-2-ol	Octan-2-one	45	99	> 99
5	Hexan-2-ol	Hexan-2-one	45	99	> 99
6	Octan-3-ol	Octan-3-one	45	70	> 99
7	Cyclooctanol	Cyclooctanone	45	100	> 99
8[c]	Octan-1-ol/ octan-2-ol	Octanal/ octan-2-one	45	86/ < 1	96
9	Benzyl alcohol	Benzaldehyde	30	100	> 99
10	1-Phenylethanol	Acetophenone	30	100	> 99
11	Benzyl alcohol/ 1-Phenylethanol	Benzaldehyde/ acetophenone	30	95/4	> 99
12	(*S*)-2-Methyl-butan-1-ol	(*S*)-2-Methyl-butanal	45	90	> 99

[a] 0.8 mmol substrate, 2.5 mg PIPO (1 mol% nitroxyl), 0.14 g $KHCO_3$, 2.86 ml 0.35 M hypochlorite solution (1.25 equiv.), 0 °C. [b] Conversion and selectivity determined by GC using *n*-hexadecane as internal standard. [c] 2 ml MTBE as solvent. [d] Octanoic acid and octyl octanoate as side products.



Scheme 2 Oxidation of methyl α-D-glucopyranoside using PIPO/NaOCl.

Carbohydrates are also oxidised by the PIPO/NaOCl system analogous to TEMPO/NaOCl.[12] For example, methyl α-D-glucopyranoside afforded methyl α-D-glucopyranosiduronate in 70% yield (Scheme 2).‡ As in the case of the oxidation of simple alcohols, filtration experiments confirmed that the catalyst is truly heterogeneous. Further investigation in the field of carbohydrate oxidations using PIPO/NaOCl is in progress and will be reported on in due course.

Besides hypochlorite, oxygen can also be used as oxidant.[6,7] Unfortunately, in contrast to homogeneous TEMPO the combination of PIPO and $RuCl_2(PPh_3)_3$ in chlorobenzene[7] is not able to catalyse the aerobic oxidation of octan-2-ol, probably owing to coordination of ruthenium to the polyamine. On the other hand, in combination with $CuCl/O_2$ in DMF,[6] it is capable of completely oxidising benzyl alcohol to benzaldehyde within 2 h. This system, however, is limited to benzylic and allylic alcohols as for homogeneous TEMPO.

In summary we have developed a recyclable heterogeneous catalyst for the bleach oxidation of alcohols and polyols. In contrast to previously reported systems, neither a chlorinated hydrocarbon solvent nor a bromide is necessary to achieve good activity. A further advantage of our system is that the catalyst is readily prepared from inexpensive and commercially available raw materials. We believe that it will find wide application in organic synthesis.

We gratefully acknowledge IOP (Innovation-Oriented Research Program) for financial support.

Notes and references

† *General procedure* for the oxidation of alcohols with PIPO as catalyst: in a glass reaction vessel was placed 2.5 mg of PIPO (8 μmol based on complete functionalisation; degree of functionalisation = 3.2 mmol g^{-1}). Then a CH_2Cl_2 solution (2 ml) of the alcohol (0.4 M) and *n*-hexadecane (0.12 M; as internal standard) was added followed by an aqueous solution (0.16 ml) of KBr (0.5 M). After the cooling of the reaction mixture to 0 °C, 2.86 ml of aqueous NaOCl (0.35 M and buffered by the addition of 0.14 g $KHCO_3$ to pH 9.1) was added. Then, the reaction mixture was vigorously shaken for 45 min. After destroying the excess of hypochlorite with Na_2SO_3, the reaction mixture was extracted with diethyl ether, dried over Na_2SO_4 and analysed on GC (Chrompack CP-WAX 52 CB column; 50 m × 0.53 mm).

‡ *Procedure* for the oxidation of methyl α-D-glucopyranoside with PIPO as catalyst: in a glass reaction vessel was placed 15.7 mg of PIPO (50 μmol based on complete functionalisation; degree of functionalisation = 3.2 mmol g^{-1}) and 200 mg methyl α-D-glucopyranoside (1.03 mmol). Then, 8 ml of aqueous NaOCl (0.56 M and brought to pH 9.5 with an aqueous 1 M hydrochloride solution) was added. During the reaction the pH was kept constant at 9.5 by automatic titration with a 0.1 M KOH solution. When the hydroxide consumption stopped (1.3 equiv. of hydroxide were consumed), Na_2SO_3 was added to destroy the excess of hypochlorite. The crude mixture was analysed using HPLC.

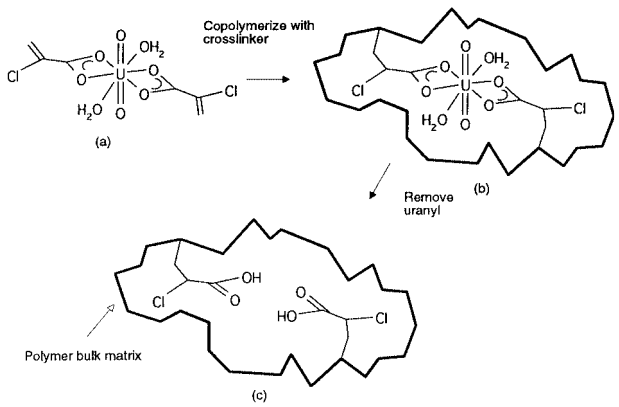
Received (in Cambridge, UK) 24th September 1999, Accepted 7th January 2000

Using a modified method in the preparation of an imprinted polymer, we report here the synthesis of a uranyl-imprinted copolymer of chloroacrylic acid and ethylene glycol dimethacrylate, which—after removal of the template—selectively extracts uranium from dilute aqueous solution over a range of +2, +3 and +4 competitor metal ions.

The technique of polymer imprinting has shown considerable promise as a method for preparing materials which are capable of molecular recognition.[1] Of late, the technique has seen some impressive successes in the selective absorption of both organic molecules and metal ions.[2] One important goal is the preparation of absorbents specific for uranium, because of uranium's large environmental impact and importance as an energy resource. Recent progress has been made by Murray *et al*. who showed that a uranyl-imprinted polydivinylbenzene/styrene-based polymer absorbs uranium over a range of +1 and +2 metal ions and also La^{3+} (at pH > 3).[3] We report here the preparation and characterisation of a new selective uranium-binding polymer. Importantly the polymer shows excellent selectivity against a range of 'strong' competitor metal ions, including Th^{4+} and Fe^{3+} (at pH < 3).

In our studies we have used the uranyl complex of chloroacrylic acid (caaH) as a template [Scheme 1(a)]. ^{13}C NMR in CD_2Cl_2 studies of $UO_2(caa)_2(OH_2)_2$ suggest that this complex contains a uranyl ion coordinated by two bidentate chloroacrylate ligands and two water molecules.‡ We have been unable to crystallise this complex, but we have studied the analogous $UO_2(caa)_2(O{=}PPh_3)_2$ complex by single crystal X-ray diffraction (Fig. 1).§ The structure of this complex shows both bidentate and monodentate chloroacrylate ligands along with two triphenylphosphine oxide ligands coordinating to the uranyl ion.

Co-polymers of 2-chloroacrylic acid (caaH) and the cross-linking agent ethylene glycol dimethacrylate (egdma) can be prepared by free-radical solution polymerisation, thermally initiated with azoisobutyronitrile (aibn) in refluxing dichloromethane. Imprinting with uranyl is achieved by replacing caaH with the soluble template complex $UO_2(caa)_2(OH_2)_2$ [prepared *in situ* by reaction of caaH with NEt_3 and $UO_2(NO_3)_2{\cdot}6H_2O$ prior to polymerisation]. In the solution polymerisation reaction the ratio of reactants was 91/9 mol/mol% egdma/$UO_2(caa)_2(OH_2)_2$—typically a total of 3.5 g reactants in 100 cm^3 of CH_2Cl_2. The imprinted polymer was obtained as a pale yellow precipitate after 5 h [Scheme 1(a) and (b)]. The material was washed with CH_2Cl_2 and then dried *in vacuo* prior to grinding to a fine powder (particle diameter *ca.* 50 μm). As a comparison, a 'random polymer' was prepared in an analogous manner without the addition of NEt_3 and $UO_2(NO_3)_2{\cdot}6H_2O$. We denote this as a 'random polymer' since the orientations and relative positions of the α-chloropropionic acid (cpaH) groups in the polymer are presumed to be random.



Scheme 1 Schematic reaction scheme for the preparation of uranyl-imprinted polymer.

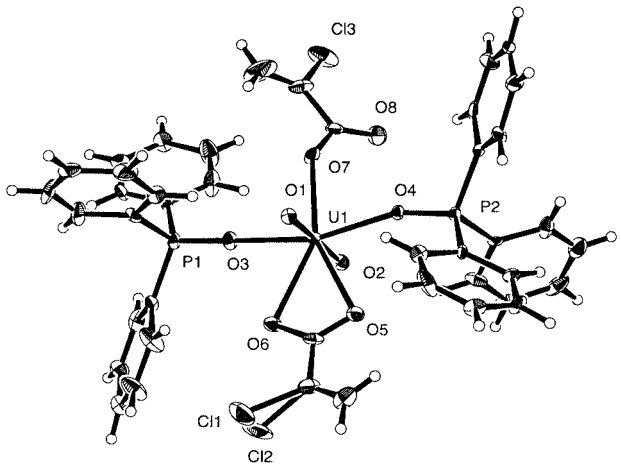


Fig. 1 ORTEP representation of the $[UO_2(caa)_2(O{=}PPh_3)_2]$ structure. Cl1 and Cl2 represent a single Cl atom disordered over two positions. Selected distances (Å): U1–O1 1.772(8), U1–O2 1.776(9), U1–O5 2.496(8), U1–O6 2.499(8), U1–O7 2.309(8), U1–O3 2.361(8), U1–O4 2.320(7).

Extraction of the uranyl from the imprinted polymer was achieved by treatment of the polymer with conc. HNO_3 under ultrasonication (30 kHz) for 15 min [Scheme 1(c)]. Following extraction, thorough washing of the polymer with deionised water and then drying *in vacuo* gave the imprinted polymer as a white powder. Elemental analysis of the polymer for uranium confirmed >95% extraction of the uranium from the polymer. Treatment of the random polymer with conc. HNO_3 in a 30 kHz sonic bath for 15 min did not change the percentage content of cpaH (determined by elemental analysis for chlorine), showing that the cpaH is tightly bound—probably *via* a covalent bond—to the polymer.

To investigate the effectiveness of the imprinting technique, rebinding of uranyl by the imprinted polymer was determined in the pH range 1–3. Approximately 2.60 g of polymer was stirred with a dilute aqueous solution of $UO_2(NO_3)_2{\cdot}6H_2O$ (50 cm^3, 0.5 mmol dm^{-3}) such that there was a fifty-fold mole excess of polymer-bound cpaH compared to uranyl. The pH was recorded after 4 min, after which the uranyl binding had equilibrated,¶ and the concentration of the uranyl ion in a small sample of the supernatant was determined by visible spectrophotometry using

† S. N. Port, M. J. Joyce, P. H. Walton and G. D. Saunders, *UK Pat. Appl.*, 979946.7, 1997; *Int. Pat.*, WO 99/15707, 1998.

the Arsenazo I method.[4] The pH was changed by the addition of small quantities of dilute HNO_3 or NaOH solutions and the extraction analysis procedure repeated.

The uranyl-binding behaviour of the imprinted and random polymers shows a reversible (*i.e.* the polymer can be reused) and smooth transition between low (*ca.* 10%) and high (> 98%) uranyl binding between pH 1.0 and 3.0. A plot of $\log_{10}[D_{ex}]$ *vs.* pH for the two polymers is shown in Fig. 2.‖ The near linearity of the data in the plots shows that the 'pH swing' binding model[5] is an accurate representation of this system. The gradient of the plots can be equated to *n*, the average stoichiometry of the $[UO_2(cpa)_n]$ complexes formed within the polymer, which, in turn, can be related to the fraction of imprinted binding sites (those containing two cpaH ligands) compared to non-imprinted binding sites (those with a single cpaH). In the random polymer *n* is approximately 1.1, showing that *ca.* 10% of the binding sites contain two cpaH ligands able to interact with a single uranyl ion. In contrast, for the imprinted polymer *n* increases to nearly 1.8 showing that *ca.* 80% of the uranyl binding sites contain two cpaH ligands. This increase can be attributed to the imprinting effect of the uranyl in the polymerisation process. The pH dependence of Th^{4+} binding to the polymer was also investigated, giving $n = 0.5$; a strong indication that most binding of Th^{4+} is associated with non-imprinted sites.

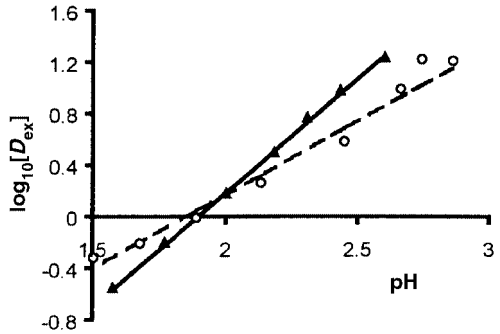

Fig. 2 $\text{Log}_{10}[D_{ex}]$ plots for the binding of uranyl by polymers as a function of pH. Black triangles, full line: imprinted polymer [gradient *n* - 1.77(3), R^2 = 1.00]. Circles, dashed line: random polymer [gradient $n = 1.14(7)$, R^2 = 0.97].

The selectivity of the imprinted polymer for uranyl was investigated by rebinding uranyl in the presence of various competitor metal ions. In a typical experiment 25 mg of polymer was mixed with a dilute aqueous solution of $UO_2(NO_3)_2$ (0.42 mmol dm^{-3}, 10 cm^3, 2.5 mmol dm^{-3} NO_3^- made up with KNO_3, constant pH 2.5) containing an equal concentration of one other competitor metal salt: hydrated salts of $Cu(NO_3)_2$, $VO(SO_4)$, $Al(NO_3)_3$, $Fe(NO_3)_3$ or $Th(NO_3)_4$. These competitor ions were chosen as the potentially strongest competitor ions for the uranyl binding sites. The resulting suspensions were shaken periodically over a period of 12 h before filtration. UO_2^{2+} and competitor metal concentrations in the supernatant were then determined by ICP-AES.

Table 1 lists the selectivity ratios ($S_{U/M}$) of uranyl *vs.* competitor metal binding to both random and imprinted polymers. It is clear that the random polymer exhibits no selectivity for the binding of the uranyl ion ($S < 1$), binding less uranyl than competitor ion in every case except Cu^{2+}. In contrast, the imprinted polymer displays a remarkable increase and even *reversal* of selectivity over the random polymer, increasing the relative polymer selectivity for uranium by over ten times in one case. The imprinted polymer exhibits a consistently higher binding of uranyl compared to each of the competitor ions, even against competitor ions such as Fe^{3+} and Th^{4+}, which would be expected to compete very strongly with UO_2^{2+} for the carboxylate binding sites. The results of the binding experiments show that the difference in metal binding between the random and imprinted polymers is due to the imprinting effect.

Table 1 Selectivity ratios for uranyl binding *vs.* competitor ion binding for random and imprinted polymers (23 °C, pH 2.5). U = uranyl, M = competitor ion. $S_{U/M} = S_U/S_M$. $S_M = V(C_i - C_f)/(C_f m)$ where C_i = concentration of solution before extraction, C_f = concentration of solution after extraction, $S' = (S_{U/M}$ imprinted$)/(S_{U/M}$ random), V = volume of solution, m = mass of polymer

	Selectivity ratios for U binding *vs.* competitor binding		
Competitor metal	Random polymer $S_{U/M}$ (random)	Imprinted polymer $S_{U/M}$ (imprinted)	Selectivity ratio increase S'
Cu^{2+}	6.5	8.1	1.2
V^{4+} (as VO^{2+})	0.32	3.8	11
Al^{3+}	0.29	2.5	8.6
Fe^{3+}	0.17	1.4	8.1
Th^{4+}	0.76	2.0	2.7

¶ In separate experiments the maximum capacity of the polymer for uranyl was determined by measuring the extent of uranyl uptake by the imprinted polymer as a function of [uranyl]. (Contact time between polymer and solution was *ca.* 12 h.) The data were then fitted to a Langmuir isotherm, with excellent agreement. Further experiments showed that uranyl binding by the imprinted polymer was > 95% of maximum binding after 4 min, with no subsequent significant increase.

‖ D_{ex}, the distribution coefficient of extraction, defined for a given volume of solution, given nitrate concentration and given mass of polymer as: (mol of uranyl ion bound to the polymer)/(mol of uranyl ion left in solution) for eqn. (1).

$$m NO_3^- + UO_2^{2+} + \text{polymer}\cdot n H^+ = \text{polymer}\cdot UO_2^{2+}\cdot m NO_3^- + n H^+ \quad (1)$$

Separate experiments showed that 100% egdma polymers do not bind uranium to any significant extent; demonstrating that the amount of uranyl binding to non-carboxylic acid sites (*i.e.* $n = 0$) is low. It is also assumed that the number of sites where three carboxylic acids can interact with a single uranyl is statistically very low. Hence the average value of *n* obtained from our experiments is approximately the number weighted average of the $n = 1$ and $n = 2$ binding sites within the polymer. For non-integral values of *n* a slight curve is expected in the $\log[D_{ex}]$ *vs.* pH plots. However, this curve is very shallow over the pH range studied and the relationship can be considered as linear. For a treatment of D_{ex} and the calculation of complex stoichiometries and applications to solid phase absorbents, see ref. 5.

Hydrogen bonding networks and anion coordination in (η^6-arene)$Cr(CO)_3$ complexes: metal carbonyls as hydrogen bond acceptors

Salvatore Camiolo, Simon J. Coles, Philip A. Gale,* Michael B. Hursthouse, Thomas A. Mayer and Michael A. Paver*

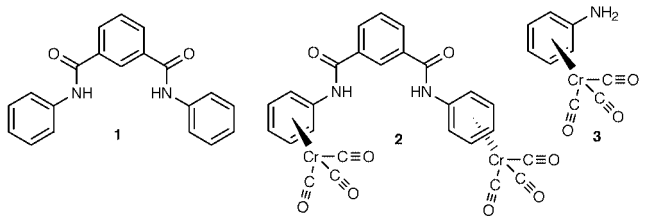
Received (in Cambridge, UK) 15th December 1999, Accepted 12th January 2000

A chloride selective amide cleft molecule 2 containing two $Cr(CO)_3$ moieties has been synthesised by condensation of (η^6-aniline)$Cr(CO)_3$ 3 with isophthaloyl dichloride; the X-ray crystal structure of 2 contains a network of Cr–CO···HN hydrogen bonds giving rise to an extended three-dimensional coordination array; the X-ray crystal structure of (η^6-aniline)$Cr(CO)_3$ 3 has been re-determined and found to contain bifurcated amine NH···OC–Cr hydrogen bonds.

The coordination chemistry of anionic[1–3] and neutral guest species[4] by hydrogen bond donating receptors is an area of supramolecular chemistry that continues to attract the attention of coordination chemists. One strategy that has been used to modulate the affinity or selectivity of a receptor for a particular guest is to alter the electronic environment of the guest-binding site. This may be achieved by synthesising a new receptor containing electron withdrawing or donating functional groups[5] or, alternatively, by coordinating transition metal fragments to a pre-existing receptor. This latter approach has been elegantly employed by Atwood *et al.* to transform calixarenes into anion-binding receptors.[6]

Receptors that contain hydrogen bond donating amide[7,8] or pyrrole[9] moieties have been shown to be effective and selective anion binding agents. Recently, Crabtree and coworkers have shown that simple amide cleft receptors based on compound **1**[10] are capable of binding halide anions.[11,12] As part of our programme of research in anion coordination,[13,14] we decided to synthesise an amide cleft receptor containing two electron withdrawing $Cr(CO)_3$ units that would serve to increase the acidity of the NH protons. However, we found that in addition to binding anions, hydrogen bonds were formed in the solid state between amide NH and chromium carbonyl moieties, leading to the formation of a three-dimensional coordination array.[15,16]

Compound **2** was synthesised by condensation of (η^6-aniline)$Cr(CO)_3$[17] **3** with isophthaloyl dichloride in dichloromethane in the presence of triethylamine and DMAP. The reaction mixture was purified by column chromatography on silica gel and crystallised from CH_2Cl_2–MeOH as yellow needles in 74% yield.



Crystals of **2** suitable for X-ray analysis† were obtained from CD_3CN solution. The crystal structure and atomic numbering scheme is shown in Fig. 1(a). The centrosymmetric nature of the space group causes the two (η^6-aniline)$Cr(CO)_3$ moieties to adopt orientations at 180° to each other on opposite sides of the molecule, fully enabling these groups to interact with other molecules. The presence of carbonyl and amide groups provide additional hydrogen bond donors and acceptors, facilitating the formation of a supramolecular assembly.[18] Each molecule of **2** donates six hydrogen bonds. These include an intramolecular interaction between H(5) and O(4) (2.22(3) Å), two intermolecular interactions between H(3) and O(4) and H(3′) and O(4′) (2.54(4) Å), and three intermolecular hydrogen bonds to metal carbonyl groups (H(1)··O(2) 2.47(2)Å and H(12) to two O(2) atoms in different adjacent molecules (2.50(3) Å)). This network of hydrogen bonds defines a continuous three-dimensional coordination array, a portion of which is shown in Fig. 1(b).

In light of the formation of this assembly, we decided to re-examine the solid state structure of (η^6-aniline)$Cr(CO)_3$ **3**. The

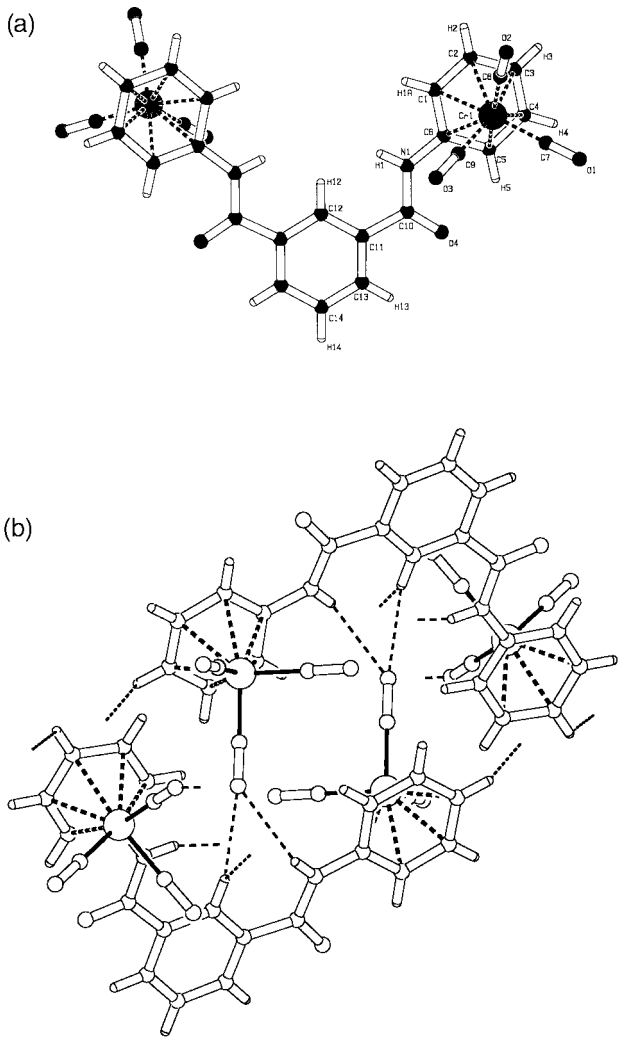


Fig. 1 (a) Crystal structure and atomic numbering scheme for **2** and (b) hydrogen bonding network.

structure of compound **3** was first solved in 1992 by Hunter, Zaworotko and co-workers.[19] In this case, compound **3** crystallised in a monoclinic lattice and contained no hydrogen bonding interactions. We found that if crystallisation occurs under different conditions (*i.e.* at room temperature from dichloromethane) from those used by Hunter *et al.*, a triclinic polymorph, with the same molecular geometry, reproducibly forms a hydrogen bonded network. These hydrogen bonds link molecules together into two-dimensional sheets (shown in Fig. 2). Two bifurcated hydrogen bonds are formed by one NH group to two OC–Cr moieties (H··O 2.55(6) and 2.32(7) Å) and a further hydrogen bond is formed from the other NH hydrogen to a OC–Cr moiety (H··O 2.50(6) Å) (Fig. 2). Each molecule therefore donates and accepts three hydrogen bonds.

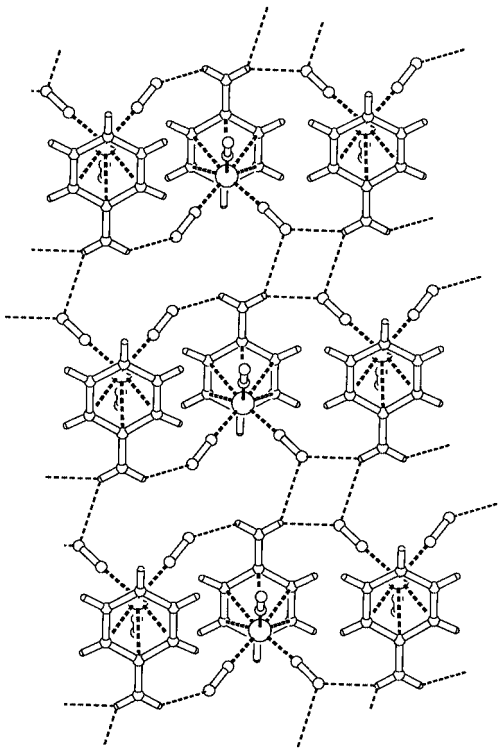

Fig. 2 Crystal structure of **3** emphasizing the hydrogen bonding network.

The anion coordination properties of **2** were studied using ^{1}H NMR titration techniques in CD_3CN by following the NH proton resonance. Stability constants were then calculated using the EQNMR computer program[20] and are presented in Table 1. Receptor **2** shows selectivity for chloride over the other putative anionic guests studied, with a stability constant that is higher than can be reliably measured by this technique (log K > 4). Interestingly the selectivity of **2** for chloride over dihydrogen phosphate is high. This may be due to the steric bulk of the $Cr(CO)_3$ moieties hindering the approach of the bulky dihydrogenphosphate anion to the amide cleft. A negative electrospray competititon experiment was run on an acetonitrile solution of **2** containing one equivalent of each of the anions shown in Table 1. Only peaks corresponding to the chloride complex were observed, confirming the chloride selectivity of **2**.

Table 1 Stability constants of compound **2** with a variety of anionic guests in CD_3CN at 298 K. Errors are estimated to be < 16%. All data fitted satisfactorily to a 1 : 1 receptor : anion binding model

Anion	Stability constant/ dm^3 mol^{-1}
F^{-a}	107
Cl^-	> 10^4
Br^-	2910
I^-	102
$H_2PO_4^{-a}$	119

[a] ArH proton used (broadening of the NH proton occurs during the titration).

The coordination of metal carbonyls by activated hydrogen bond donating ligands may lead to new strategies for the modification of the activity of carbonyl containing catalysts.[21] The presence of the hydrogen bonding networks in **2** and **3** leads us to suggest that the $Cr(CO)_3$ fragment in particular, may find future applications in the design of coordination polymers and extended networks in crystals as well as in the activation of NH groups for more effective or selective anion coordination.

P. A. G. thanks the Royal Society for a University Fellowship and the EPSRC for a project studentship (to S. C.).

Hydrogen bonds C–H···Cl as a structure-determining factor in the gold(I) complex bis(3-bromopyridine)gold(I) dichloroaurate(I)†

Matthias Freytag and Peter G. Jones*

Institut für Anorganische und Analytische Chemie der Technischen Universität, Postfach 3329, D-38023 Braunschweig, Germany. E-mail: p.jones@tu-bs.de

Received (in Basel, Switzerland) 13th September 1999, Accepted 13th January 2000

The crystal structure of the title compound involves three types of secondary interaction; hydrogen bonds of the form C–H···Cl account for the mutually perpendicular arrangement of the cations and anions.

We are interested in gold(I) complexes with amine ligands and have recently reported the synthesis and structure of such complexes with aliphatic amines[1] and with pyridines.[2] Our other current studies involve the investigation of intermolecular contacts such as hydrogen bonds (including non-classical cases such as C–H···X), aurophilic interactions,[3] and halogen–halogen contacts.[4] These fields naturally overlap, and we have established the importance of classical hydrogen bonds in gold(I) amine complexes,[1] and of C–H···Cl contacts in some gold(I) dppm complexes.[5]

Here, we present the structure of bis(3-bromopyridine)gold(I) dichloroaurate(I) **1**.‡ The compound was obtained from 3-bromopyridine and tetrahydrothiophene(chloro)gold(I).§ As will be seen below, the primary structure is unexceptional but the secondary interactions extensive and varied.

The structure analysis shows that compound **1** crystallizes in the ionic form $(L_2Au)^+(AuCl_2)^-$ (L = pyridine ligand); in principle, such complexes can also display the alternative molecular form LAuCl. The balance between the two forms is very sensitive, as can be seen from the fact that the 2-picoline derivative is molecular but the 3-picoline derivative ionic.[2] The non-substituted bis(pyridine)gold(I) dichloroaurate(I) also displays the ionic form.[6]

The asymmetric unit of **1** consists of one cation and one anion, each without imposed crystallographic symmetry. In both ions the geometry at the gold centre is, as expected, linear, with normal dimensions Au1–N 2.009(10), 2.035(10) Å, N–Au1–N 173.8(4)°, Au2–Cl 2.259(3), 2.267(3) Å, Cl–Au(2)–Cl 177.61(12)°. The bromo substituents, like the methyl substituents of the 3-picoline analogue (which displays strict inversion symmetry)[2] are *trans* to each other.

The extended structure of **1** involves three distinct kinds of secondary interaction: *aurophilic interactions*,[3] C–H···Cl *hydrogen bonds* and Br···Cl *interhalogen contacts*. It is well known that gold(I) centres have a marked tendency to aggregation. In **1**, short aurophilic contacts are observed both within the asymmetric unit [Au1···Au2 3.2681(7) Å], and *via* the inversion operator $1 - x, 1 - y, 1 - z$ [Au1···Au1# 3.3113(10) Å]. The ions are thereby connected to form 'isolated' (see below!) dimeric units containing a zigzag chain of four gold atoms (Fig. 2), similar to the complex bis(pyridine)gold(I) dichloroaurate(I).[6] In the 3-picoline complex, Au···Au contacts lead to infinite zigzag chains with alternating cations and anions.[2] In all three structures, the L–Au–L axes of cation and anion are approximately perpendicular to each other; a typical torsion angle in **1** is N1′–Au1–Au2–Cl2 −90.1(3°).

A more detailed inspection shows that the extended structure of **1** is not solely characterised by aurophilic contacts. Within the dimeric unit (Fig. 1) there are eight (four independent) C–H···Cl contacts (Table 1, first four entries), formed *via* the H atoms *ortho* to nitrogen. These may reasonably be considered as C–H···Cl hydrogen bonds,[7] since they are essentially linear, with H···Cl distances appreciably less than the sum of the van der Waals radii (2.95 Å); they are *charge-assisted*[8] by the opposite charges of anion and cation.. The corresponding H···Cl–Au angles lie in the range 72–85°. Although steric factors must also play a role, the formation of such hydrogen bonds provides a good explanation for the mutually perpendicular orientation of anions and cations. As far as we are aware, this is the first time that C–H···Cl interactions have been explicitly cited as conformation-determining factors in metal complexes.[9] The presence of a 2-methyl group in the 2-picoline derivative blocks one of the potential hydrogen bonding sites, which may be one reason why a non-ionic structure is preferred.[2] Inspection of the bis(pyridine)gold(I) dichloroaurate(I) structure[6] shows an exactly analogous framework to that of **1**. The 3-picoline derivative[2] exhibits two C–H···Cl contacts within

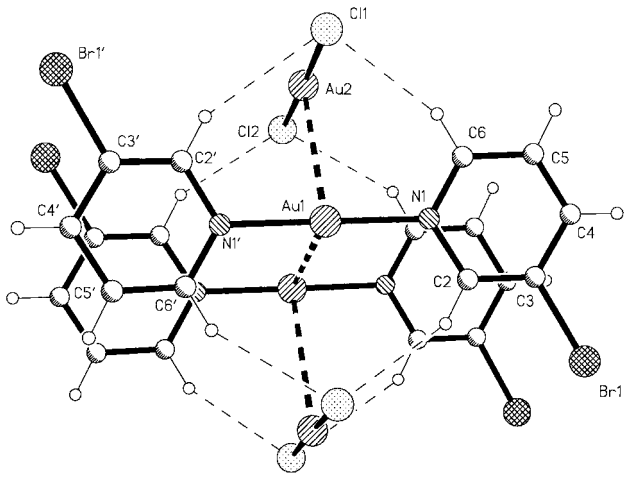

Fig. 1 Dimeric unit of **1** in the crystal. Radii are arbitrary. Only the asymmetric unit is numbered. Gold···gold contacts are represented by thick dashed lines, C–H···Cl contacts as thin dashed lines.

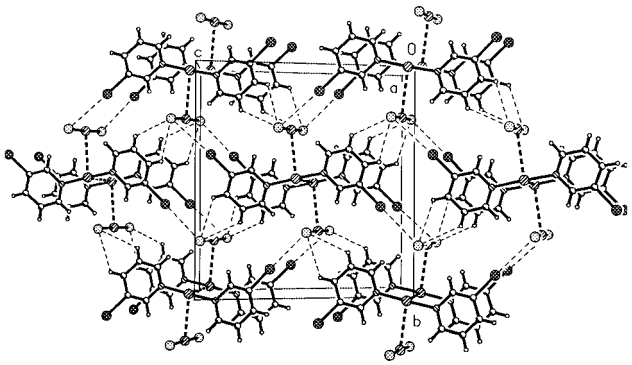

Fig. 2 Packing diagram of **1** parallel to the *x* axis. Gold···gold contacts are represented by thick dashed lines, C–H···Cl and Br···Cl contacts as thin dashed lines. C–H···Cl contacts within the dimeric units are omitted.

† Gold complexes with amine ligands, Part 5.[1]

Table 1 Geometrical data (Å, °) for the hydrogen bonds and interhalogen contacts in **1**[a]

System	*d*(H···Cl)[10]	∠(CH···Cl)	∠(H···Cl–Au2)
C2′–H2′···Cl1	2.69	151	72
C2–H2···Cl2#1	2.69	144	85
C6′–H6′···Cl2#1	2.62	144	80
C6–H6···Cl1	2.55	155	75
C4′–H4′···Cl2#2	2.92	120	92
C4–H4···Cl1#3	2.91	118	80
C5′–H5′···Cl2#2	2.87	123	75
C5–H5···Cl1#3	2.71	127	93
System	***d*(Br···Cl)**	**∠(CBr···Cl)**	
C3–Br1···Cl2#2	3.384(3)	169.6(4)	
C3′–Br1′···Cl1#4	3.441(4)	173.1(4)	

[a] Symmetry transformations: #1 1 − *x*,1 − *y*,1 − *z*; #2 1.5 − *x*,0.5 + *y*,1.5 − *z*; #3 −0.5 + *x*,0.5 − *y*, − 0.5 + *z*; #4 0.5 + *x*,0.5 − *y*,0.5 + *z*.

the chain and one between chains, with H···Cl 2.59, 2.84, 2.72 Å respectively;[10] regrettably, this did not attract our attention at the time.

An analysis of the packing of the dimeric units reveals further secondary interactions between the dimeric units. The packing diagram parallel to the *x* axis shows a layer structure (Fig. 2) with additional, slightly longer and less linear C–H···Cl contacts, leading to five-membered rings C4–H4···Cl···H5–C5 (Table 1, entries 5–8). Finally, there are Br···Cl contacts of 3.441(4) (Br1′···Cl1) and 3.384(3) Å (Br1···Cl2). These lie well below the sum of the van der Waals radii (3.6 Å), and the angles C3′–Br1′···Cl1 and C3-Br1···Cl2 [173.1(4) and 169.6(4)°] are essentially linear; thus these contacts may be classed as charge-assisted electrostatic interactions of the form $Br^{\delta+}\cdots Cl^{\delta-}$ (*cf.* analogous Cl···O [11] or Cl···Cl [4] contacts).

We conclude that non-conventional hydrogen bonds may play an important role in determining the structure of metal complexes. Furthermore, in view of the increasing interest in secondary interactions, great caution is needed in describing crystal packing in terms of *isolated* molecules or ions!

We thank the Fonds der Chemischen Industrie for financial support.

Microwave effects on the selective reduction of NO by CH_4 over an In–Fe_2O_3/HZSM-5 catalyst

Xiaodong Wang, Tao Zhang,* Changhai Xu, Xiaoying Sun, Dongbai Liang and Liwu Lin

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian 116023, China. E-mail: taozhang@ms.dicp.ac.cn

Received (in Cambridge, UK) 30th November 1999, Accepted 7th January 2000

Microwave effects have been shown to promote the activation of NO_x molecules in the process of selective reduction of NO by CH_4 over an In–Fe_2O_3/HZSM-5 catalyst and to enhance the water tolerance of this catalyst for NO reduction.

Microwave radiation technology has been applied in heterogeneous catalysis research in the last ten years.[1] The use of microwave radiation to stimulate catalytic reactions has provided some remarkable results.[2,3] However, the effects of microwave radiation on heterogeneous catalysis have not been clearly elucidated yet. Recently the selective catalytic reduction (SCR) of nitrogen oxides by hydrocarbons has received much attention as this process has the advantage of using a gas mixture very similar to that found in automobile exhausts. Since methane exists in nearly all combustion exhausts, the CH_4-SCR has attracted increasing interest, and various types of catalysts have been reported for this reaction.[4] We studied the selective catalytic reduction of NO with CH_4 in a microwave field.[5] An In–Fe_2O_3/HZSM-5 catalyst has been found to show high activity at low reaction temperatures. Here, we report on the microwave effects on this process.

The In–Fe_2O_3/HZSM-5 catalyst was prepared by impregnating a mechanical mixture of commercial pure Fe_2O_3 and HZSM-5 powders (SiO_2/Al_2O_3 = 25, supplied by Nankai University, China) with a required amount of an aqueous solution of $In(NO_3)_3$ (Tianjin No. 3 Reagent Plant, China). The samples were dried at 120 °C for 6 h and subsequently calcined in air at 700 °C for 6 h. The catalysts were denoted by the weight ratios of indium, iron oxide and HZSM-5 zeolite, for example, In–Fe_2O_3/HZSM-5(1:8:20) indicates In:Fe_2O_3:HZSM-5 = 1:8:20 (weight ratio).

The SCR of NO by CH_4 was carried out in a quartz microcatalytic single-pass flow reactor. The feed gas contained 2500 ppm NO, 2000 ppm CH_4 and 4.0% O_2 (balance He); 3.3% H_2O was added to this feed gas when the water tolerance effect was investigated. Under standard reaction conditions, 60 ml min^{-1} of this mixture were fed over a catalyst loading of 500 mg, which results in a space velocity of 3600 h^{-1}. Product analyses were performed with a gas chromatograph and a NO_x analyzer. The catalytic activity was evaluated in terms of the conversion of NO_x to N_2.

The microwave reaction system consisted of a microwave generator, a rectangular waveguide, a circulator, a resonant cavity and a plunger. The microwave energy was supplied by a 200 W, 2.45 GHz microwave generator and the effective power for this experiment ranged from 10 to 50 W. The reactor was placed at the center of the single mode resonant cavity, which was parallel to the direction of the electric field. An IR thermometer and a thermocouple were employed to measure the reaction temperature of the catalyst bed in the microwave field, both of which have been proven to be relatively accurate methods.[3,6]

Fig. 1 shows the conversion of NO to N_2 as a function of temperature over In–Fe_2O_3/HZSM-5(1:8:20) and In/HZSM-5(1:20) catalysts in microwave and conventional reaction mode. Although In/HZSM-5 exhibited high activity for NO conversion, it was inactive when operated in the microwave mode (not shown in Fig. 1). Probably, this is associated with the fact that the In/HZSM-5 has poor microwave absorption ability. On the other hand, NO conversion was very high and even reached 100% over the In–Fe_2O_3/HZSM-5(1:8:20) catalyst. Obviously the Fe_2O_3 component in this catalyst was responsible for the good activity. This can be attributed to the fact that Fe_2O_3 is a good microwave medium, so that microwave energy can be effectively converted into the activation energy of the reacting molecules adsorbed on the catalyst.

It is worthwhile to note that although the In–Fe_2O_3/HZSM-5(1:8:20) catalyst also showed high NO reduction activity in the conventional reaction mode, the reaction temperature needed was much higher than that in the microwave reaction mode. The mechanism of microwave catalysis is, as yet, not clear. However, it can be rationalized that a direct interaction of microwaves with the catalyst bed would cause a strong coupling between the microwave and the absorbing materials in the catalyst. Since the molecules in the gas phase are transparent to microwaves, no interaction will take place between the microwaves and the gaseous molecules. Our TPD experiments on Fe_2O_3 also agree well with the report of Otto and Shelef[7] that Fe_2O_3 is a good material for NO_x adsorption. Thus, it is speculated that a coupling may also occur between microwaves and the adsorbed polar NO_x molecules *via* Fe_2O_3, which is not only a good NO_x adsorber but also a microwave absorber. It has been reported that NO_2 plays an important role in the SCR of NO by hydrocarbon,[8,9] so coupling between microwaves and NO_2 molecules may weaken the NO–O bond and promote their activation and, in turn, greatly facilitate the activation of CH_4 by NO_2. As a result, it is reasonable to speculate that the activation energy of NO reduction by CH_4 on the In–Fe_2O_3/HZSM-5(1:8:20) will be reduced, so that the microwave-radiated reactor can operate at a lower temperature than the conventional reactor. It should be noted that although the In–Fe_2O_3/HZSM-5 was inactive for the NO + CH_4 reaction in the conventional reaction mode (not shown in Fig. 1), the reaction took place over this catalyst in the microwave reaction mode and the highest NO

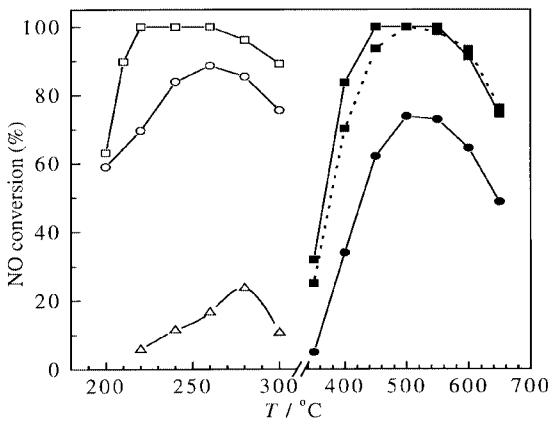

Fig. 1 NO conversions over In–Fe_2O_3/HZSM-5(1:8:20)(—) and In/HZSM-5(1:20)(----) in the microwave (open symbols) and conventional (filled symbols) reaction modes in the reaction systems NO + CH_4 + O_2 (squares), NO + CH_4 (triangles) and NO + CH_4 + O_2 + H_2O (circles).

conversion reached 23.6% (Fig. 1). This illustrates again that microwaves exhibit an effect on the activation of NO as the catalyst only chemisorbs NO_x.

The impact of H_2O on the NO conversion over the In–Fe_2O_3/HZSM-5(1:8:20) catalyst in both the conventional and the microwave reaction modes is also shown in Fig. 1. It is evident that the NO conversion suffered a more severe decrease in the conventional mode than in the microwave mode. As H_2O competes for the same adsorption sites as NO_x and inhibits the adsorption of the NO_x molecules, the catalyst will be deactivated in the presence of water vapor. However, H_2O is a strongly polar molecule and has a good microwave-absorbing ability, so that when H_2O molecules are adsorbed on the catalyst, they interact with the catalyst in the microwave field, leading to a strong coupling and resulting in the desorption of H_2O molecules from the adsorption sites, or in the weakening the adsorption of H_2O molecules on the catalytic surface. Therefore the microwave reaction mode provides the NO_x molecules with more adsorption sites than the conventional reaction mode when the feed contains water vapor. This suggests that microwave catalysis may lead to a new approach for the SCR of NO by hydrocarbons when dealing with feeds with high water content.

In conclusion, the In–Fe_2O_3/HZSM-5 catalyst shows some remarkable catalytic performances in the SCR of NO by CH_4 in a microwave field, indicating that microwaves have a beneficial effect on the activation of reacting molecules.

Crystal engineering of 2-D hydrogen bonded molecular networks based on the self-assembly of anionic and cationic modules†

Olivier Félix, Mir Wais Hosseini,* André De Cian and Jean Fischer

Université Louis Pasteur, Institut Le Bel, F-67000 Strasbourg, France. E-mail: hosseini@chimie.u-strasbg.fr

Received (in Basel, Switzerland) 14th November 1999, Accepted 13th January 2000

Using a self-assembly strategy based on both H-bonding and ionic interactions, a molecular module composed of two cyclic amidinium units and that bears two additional OH groups, thus possessing a total of six H-bond donor sites, was used to engineer 2-D crystalline molecular networks in the presence of carboxylate anions.

Molecular networks, formed in the crystalline phase by the self-assembly[1] of structurally defined and energetically programmed molecular modules,[2] are molecular assemblies possessing translational symmetry of one or several assembling cores.[3] The latter may be regarded as a series of interaction patterns between complementary molecular building blocks comprising the solid. In principle, any type or combination of intermolecular interactions such as H-bond,[4] van der Waals interactions[1] or coordination-bonds[5] may be used to design the assembling core. In the present contribution, we focus on the formation of molecular networks based on H-bonds. The dimensionality of molecular networks (1-, 2- or 3-D) is defined by the number of translations (1, 2, or 3 respectively) of the assembling cores.[3] Although, one dimensional networks have become more commonplace,[4,6] the formation of 2-[7] and 3-D-networks[8] is still a matter of active research interest.

Here we report the formation of β-networks using the tecton **2**-2H$^+$ and mono- (**3**$^-$) and di-carboxylate (**4**$^{2-}$) anions.

Molecular networks may be generated through self-assembly processes using either a monocomponent system based on a single self complementary module or a polycomponent system composed of several complementary units. Although the former case is ideal in terms of atom economy, in practice, such a system often leads to amorphous powders and thus eludes structural investigations. On the other hand, using polycomponent systems, for which both thermodynamic and kinetic parameters may be monitored, the structure of the network may be investigated by X-ray crystallography in some cases.

Although the majority of reported molecular networks are mainly based on nonionic hydrogen bonding,[3] the simultaneous use of directional hydrogen bonds and strong but less directional ionic interactions has been also reported.[4e,6] It has been shown that bis-amidinium dications such as **1**-2H$^+$[6] (Scheme 1) are interesting building blocks for the crystal engineering of hydrogen bonded molecular networks. Indeed, the **1**-2H$^+$ dication, owing to the presence of four acidic NH protons oriented in a divergent fashion, acts as a tetra H-bond donor.[6] Furthermore, owing to the appropriate spacing of the two cyclic amidinium moieties by an ethylene spacer, compound **1**-2H$^+$ was shown to interact with two carboxylate units by a dihapto mode of recognition on each side of the module (Fig. 1). It has been shown that in the presence of the monoanion **3**$^-$ acting as stopper, **1**-2H$^+$ forms a discrete exobinuclear complex [Fig. 1(a)], and in the presence of dicarboxylates, such as iso- or terephthalate **4**$^{2-}$ acting as connectors, the same compound leads to 1-D networks [Fig. 1(b)].

The enhancement of the dimensionality of the above mentioned network from 1- to 2-D, requires interconnection of the 1-D networks. This may be achieved using different design strategies. The most obvious one would consist of increasing the number of components. This has indeed been achieved using a three-component system based on the dication **1**-2H$^+$, fumarate dianion and fumaric acid.[6d] On the other hand, while using a two-component system, another possibility would be to increase the number of interaction sites within the dianionic module. This may be achieved by using a sp^3 centre such as in pyrophosphate instead of sp^2 carboxylate units.[6c] Finally, one may introduce additional H-bond donor sites within the cationic partner [Fig 1(c)].

The design of the bisamidinium **2**-2H$^+$ is based on a combination of NH and OH groups as H-bond donors. The quadruple H-bond donor module **1**-2H$^+$ may be transformed into a sextuple H-bond donor **2**-2H$^+$ by introduction of two OH groups within its framework. Owing to the half-chair conformation adopted by both cyclic amidinium moieties, the OH group, by virtue of its axial positioning should be oriented below and above the main plane of the module and thus should allow the interconnection of consecutive 1-D networks through strong OH$\cdots$O$^-$ hydrogen bonds. The synthesis of **2** was achieved following the reported procedure for the bisamidine **1**.[9] 1,3-Diamino-2-hydroxypropane was first transformed into its

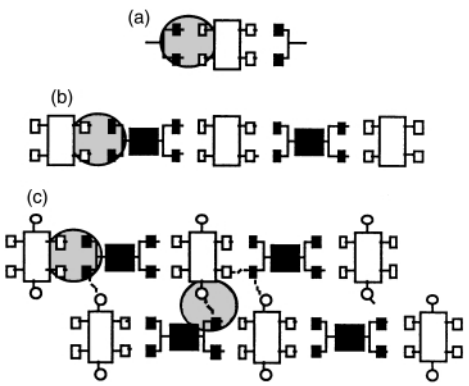

Fig. 1 Schematic representation of a discrete exo-binuclear complex (a), 1-D molecular network (b) based on the translation of a single assembling core (grey circle), and of a 2-D network based on the translation of two different assembling cores in two different spatial directions (c).

† Dedicated to the memory of Professor Olivier Kahn.

mono tosylate salt before it was treated with 0.5 equiv. of succinonitrile under argon for 1 h at 140 °C. Pure **2**-2TsOH was isolated as a white crystalline solid in 78% yield upon crystallisation from EtOH–H_2O.

Using the module **2**-2H$^+$, the formation of molecular networks in the crystalline phase was investigated using toluate **3**$^-$ (Fig. 2) as well as terephthalate dianions **4**$^{2-}$ (Fig. 3).

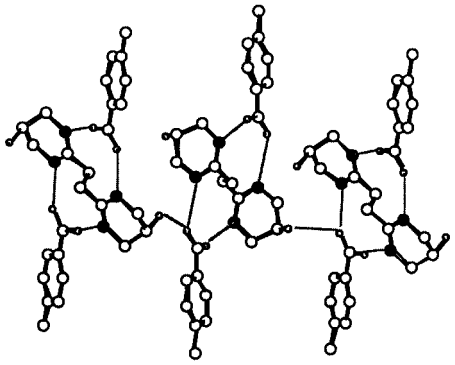

Fig. 2 A portion of the X-ray structure of (**2**-2H$^+$, 2**3**$^-$) co-crystals showing the formation of a 1-D network. In fact the co-crystal shows a 2-D network formed by H-bonds engaging the remaining OH groups.

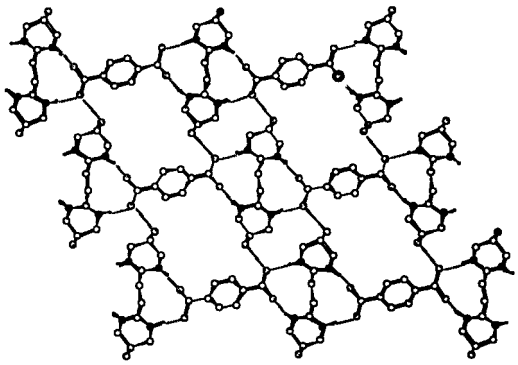

Fig. 3 A portion of the X-ray structure of (**2**-2H$^+$, **4**$^{2-}$) co-crystals showing the formation of a 2-D hydrogen bonded network that is formed by the interconnection of 1-D networks formed by the amidinium and carboxylate moieties, through strong OH··O$^-$ hydrogen bonds.

Upon mixing the free base **2** with 2 equiv. of toluic acid or 1 equiv. terephthalic acid in EtOH, colourless single crystals were obtained. The formation of molecular networks in the above mentioned co-crystals was investigated by X-ray crystallography which revealed the following common features for both structures (Fig. 2 and 3)‡: (i) for the centrosymmetric **2**-2H$^+$ unit, owing to the fully extended *trans* conformation of the ethylene chains, the two planes containing the amidinium groups are almost parallel but not coplanar; (ii) both six-member cycles adopt a half-chair conformation with the OH groups in axial positions, (iii) all four acidic protons are localised on **2** with an average N–H distance of *ca*. 1.01 Å; (iv) the N1··N3 and N2··N4 average distance is, as for **1**-2H$^+$,[6a], close to 5.0 Å, thus allowing the recognition of carboxylate groups through a dihapto mode of H-bonding (Fig. 2); (v) the recognition of two carboxylate moieties by the dication **2**-2H$^+$, as for **1**-2H$^+$,[6a] takes place in a symmetric mode on each side of the module through two strong H-bonds with an average N··O distance of *ca*. 2.72 Å an NH··O distance of *ca*. 1.72 Å and an average N–H–O angle value of *ca*. 172°.

Interestingly, whereas for (**1**-2H$^+$, 2**3**$^-$) co-crystals a 0-D solid composed of discrete units without any specific interactions between them was obtained[10] [Fig. 1(a)], for the (**2**-2H$^+$, 2**3**$^-$) salt, owing to the presence of the OH groups, the neutral complexes are interconnected into a β-network through strong H-bonds of the OH··O type (average d_{OHO} distance of *ca*. 2.64 Å) between the hydroxy moieties of **2** and carboxylate extremities of the anion **3**$^-$ (Fig. 3).

For the (**2**-2H$^+$, **4**$^{2-}$) co-crystals, as predicted and previously observed for the amidinum **1**-2H$^+$[6a] case, a 1-D network exclusively composed of **2**-2H$^+$ dication and **4**$^{2-}$ (Fig. 3) dianions interconnected through strong H-bonds was observed in the solid state. However, as for the (**2**-2H$^+$, 2**3**$^-$) salt, for (**2**-2H$^+$, **4**$^{2-}$) cocrystals, owing to the presence of the additional OH groups, the above mentioned 1-D networks were interconnected into a 2-D network through strong OH··O bonds with an average d_{OHO} distance of *ca*. 2.71 Å.

In conclusion, the dicationic molecular module **2**-2H$^+$ that bears both NH and OH groups and is capable of acting as a sextuple H-bond donor was designed and synthesised. The module **2**-2H$^+$, which is capable of specifically recognising two carboxylate units through strong H-bonds and ionic interactions, was assembled into 2-D networks using the additional hydrogen bond donor OH sites to interconnect 1-D networks formed between the amidinium dications and dicarboxylates in the crystalline phase. The extension of concepts discussed above for the design of 3-D networks is currently in progress.

High-loading resin beads for solid phase synthesis using triple branching symmetrical dendrimers

Christophe Fromont and Mark Bradley*

Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ

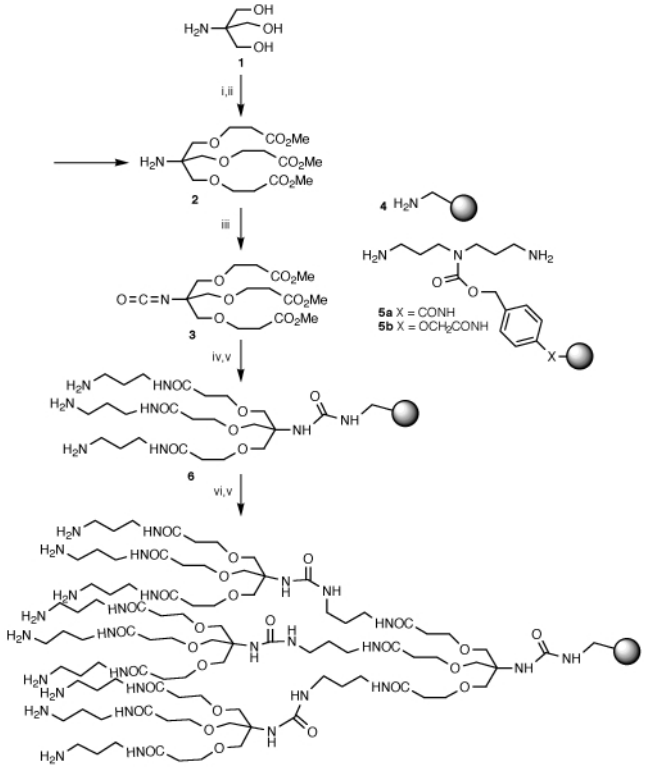
Received (in Liverpool, UK) 9th August 1999, Accepted 11th January 2000

Resin beads with a loading of 200 nmol per bead have been prepared using a Generation 2.0 tris-based dendrimer to amplify resin loading sites.

The process of split and mix by its very nature rapidly generates large libraries of compounds in such a manner that a single resin bead carries a single compound. It is one of the most efficient and cost effective chemical methods for the generation of large compound numbers,[1] with compound numbers increasing exponentially with only a linear increase in the number of synthetic steps. The single bead/single compound concept opens up the option of screening compounds released from single beads as a powerful tool for high throughput screening and thus several major pharmaceutical companies now use single bead screening in anger in the area of lead generation. The drawbacks to this process are the tiny amounts of compound found on single beads, usually in the order of a few hundred picomoles, and the identification of the compound on the bead. Compound quantity maybe sufficient for one or two biological assays but it is usually insufficient for IC_{50} determinations and chemical analysis/determination of the structure of the compound. These analysis issues have led to a number of elegant tagging solutions that encode the chemical sequence to which a bead has been exposed, although complicating the synthetic process.[2] However the need for encoding and resolution of the screening problems could be overcome if the loading of the solid support could be increased to a more practical level. We previously reported the synthesis of polyamine based Generation 3.0 PAMAM dendrimers on resins beads as a means of enhancing loading.[3]

Here we describe a practical approach to the synthesis of a tri-branching symmetrical dendrimer on the solid phase with an 18-fold amplification of resin loading per bead. Beads with a loading of 200 nmol per bead were prepared and used in a number of synthetic applications, with single beads containing more than sufficient compound for conventional analysis, including NMR!

The trifunctional dendrimer monomers[4] were prepared in bulk (> 50 g) by alkylation of tris **1** with acrylonitrile followed by nitrile hydrolysis in a saturated solution of HCl in dry MeOH to give the methyl ester **2**. Alternatively, the triacid could be obtained by direct hydrolysis. The hindered amine **2** was converted to the isocyanate **3** by treatment with Boc_2O and DMAP as described by Knölker[5] to give the stable symmetrical monomer **3**. Aminomethylpolystyrene resin (0.7 mmols g^{-1}, 250–300 μm, Polymer Laboratories) was directly derivatised with **3** as shown in Scheme 1. Displacement of the methyl ester by propane-1,3-diamine was followed by on-bead IR (ATR) and NMR analysis of cleaved material.† Repeating the process gave Generation 2.0 dendrimer beads with a loading of 85% of the theoretical maximum (36 nmol per bead). Swelling studies (Fig. 1) showed that the dendrimer beads swelled to a much greater degree in more polar solvents than the starting aminomethyl resin, as expected due to the nature of the dendrimer itself. It should however also be noted that swelling was measured in units of ml g^{-1}. Since the dendrimer beads have a density that is different to those of polystyrene (the mass of the generation 2.0 dendrimer is 2111 Da), trends rather than absolute swelling ratios in terms of bead sizes are being observed. The average diameters of the resin beads in DMF were: aminomethyl resin, 310 μm, PS-Gen 1.0, 400 μm and PS Gen. 2.0, 500 μm. These beads were extremely stable to solvation changes and extended manipulations and behaved in all respects as normal resin beads. They proved to be ideal for a broad range of chemistries. In addition, with *ca*. 27 000



Scheme 1 *Reagents and conditions*: i, acrylonitrile, 1,4-dioxane, 40% KOH, room temperature, 3 days; ii, HCl, MeOH, 4–6 h, reflux; iii, Boc_2O, DMAP (cat), CH_2Cl_2, room temp., 30 min; iv, **4** or **5a**,**b**, DMAP (cat), Pr^i_2NEt (2 equiv.), CH_2Cl_2 or DMF, 12 h; v, propane-1,3-diamine, MeOH, 3 days or propane-1,3-diamine, DMSO, 3 days; vi, **3**, DMAP (cat), Pr^i_2NEt (2 equiv.), DMF, 12 h.

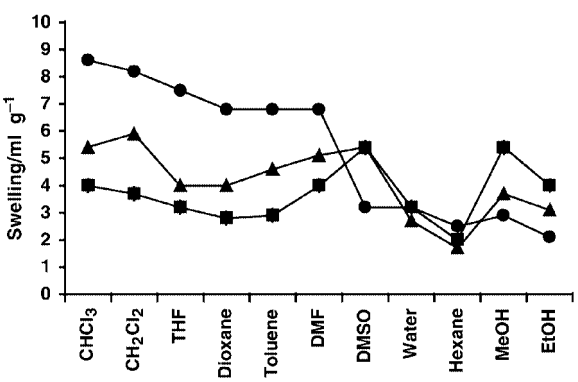


Fig. 1 Swelling studies: (●) aminomethyl resin; (▲) PS Gen 1.0; (■) PS Gen 2.0.

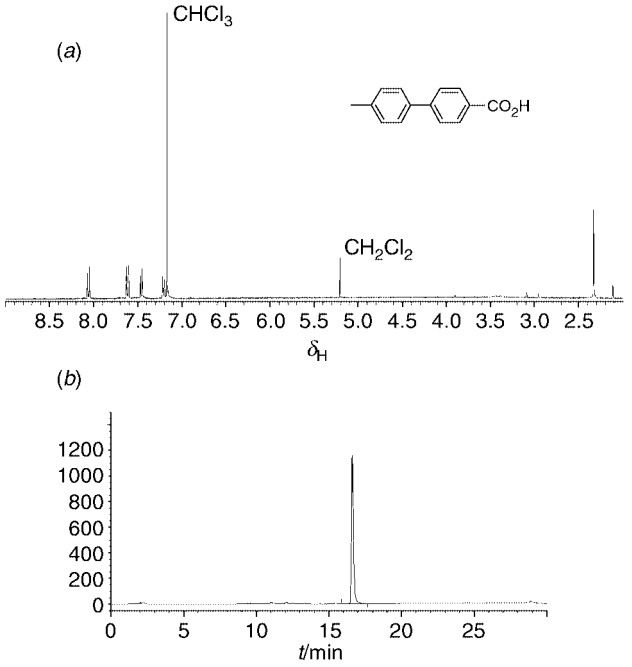

Fig. 2 (*a*) Crude ^{1}H NMR spectrum (5 mm NMR tube, 256 scans, 400 MHz) and (*b*) HPLC trace (10% of sample injected, 3.6 mm × 18 cm, C-18 column) for the Suzuki biaryl product cleaved from a single resin bead.

beads g^{-1} a split and mix synthesis on a gram of resin beads clearly provides the numbers of compounds and the amounts necessary for a serious single bead screening approach.

Dendrimer synthesis was also carried out on 400–500 μm aminomethyl polystyrene resin beads, loaded with the polyamine scaffolds **5a**,**b**,[3] as shown in Scheme 1. Generation 1.0 (8000 beads g^{-1}) had a loading of 116 nmol bead^{-1}, while Generation 2.0 (4300 beads g^{-1}) had a loading of 230 nmol bead^{-1}.‡ The dendrimer beads were used in a number of synthetic applications attaching a linker onto the free amino groups of the dendrimer to allow cleavage of the desired compound. This included peptide chemistry (synthesis of Fmoc-Val-Phe-Ala-OH) and a Suzuki coupling.[6] Thus 4-iodobenzoic acid was esterified onto the HMPB linker and 4-methylbenzene boronic acid coupled under standard conditions [K_2CO_3, $Pd(PPh_3)_4$, DMF, 110 °C, 16 h]. Cleavage of the biaryl compound from a single resin bead gave the HPLC and NMR data shown in Fig. 2. It should be noted that these very large beads were not as robust as the smaller beads used earlier, with solvent shock often causing the beads to shatter, necessitating a gradual change from one solvent to another and gentle handling, thereby limiting their utility.

We have thus devised a fast and efficient method of generating symmetrical tri-branched resin linked dendrimers in a very efficient manner. The smaller, robust Gen 2.0 beads with a loading of 36 nmol bead^{-1} (which has been extended to Gen 3.0, beads with a loading of 100 nmol bead^{-1}) are we believe ideally practical for single bead screening applications.

We acknowledge the Royal Society for a University Research Fellowship to M. B. and the BBSRC for generous support of this research (ROPA grant).

Notes and references

† Using cleavable linkers dendrimers were cleaved at the 0.5*n* and *n* generations and fully analysed, and clearly showed that dendrimer synthesis had proceeded cleanly and as anticipated.
‡ By Fmoc determination.

On the role of planar chirality: a tunable enantioselectivity in palladium-catalyzed allylic alkylation with planar chiral 1,1′-P,N-ferrocene ligands

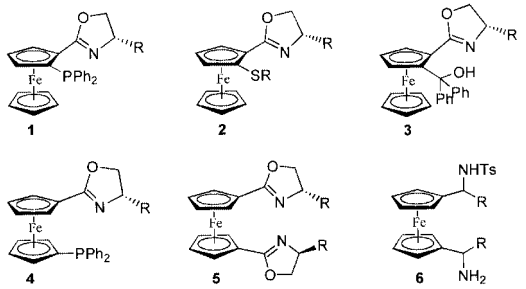
Wei-Ping Deng, Xue-Long Hou,* Li-Xin Dai, Yi-Hua Yu and Wei Xia

Laboratory of Organometallic Chemistry, Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, 354 Fenglin Lu, Shanghai 200032, China. E-mail: xlhou@pub.sioc.ac.cn

Received (in Cambridge, UK) 22nd November 1999, Accepted 7th January 2000

A series of planar chiral 1,1′-P,N-2′-substituted ferrocene ligands 9–12 and 16, prepared with diastereopurity > 99 : 1, have been used to examine the role of planar chirality, and significant effects on enantioselectivity as well as the control of absolute configuration in palladium-catalyzed allylic alkylation as a model reaction were observed.

Catalytic enantioselective reactions have attracted great interest among synthetic chemists in recent years, and many efforts in preparing efficient ligands have been made.[1,2] Most of the chiral ligands currently used consist of central chirality and/or axial chirality. Chiral ferrocene ligands with planar chirality began to be used in industrial processes only two or three years ago.[3] Ferrocene ligands have thus received more intensive attention.[4–7] Although these ferrocene ligands usually have planar chirality, the role of this chirality element is not clear. Some examples showed that the planar chirality had a significant effect on the enantioselectivity,[5] while in other examples the effect was not so apparent.[6] To date, there have been only a few attempts to ascertain the effect of planar chirality on stereochemical outcome in asymmetric synthesis.[5b,6a] Moreover, most works dealt with 1,2-disubstituted ferrocene ligands having two donor groups on the same Cp ring, such as compounds **1**,[7] **2**[5a] and **3**.[5b] Quite recently, Ikeda,[8a,b] Ahn[8c] and Knochel[9] reported new 1,1′-disubstituted ferrocenyl ligands



4–**6**, and good enantioselectivities have been obtained with these ligands. As a part of our program[5c,6] aimed at the design and application of chiral ligands to asymmetric synthesis, we studied the role of planar chirality in asymmetric induction. We envisage that, if planar chirality is introduced into this kind of 1,1′-disubstituted ferrocene ligand, it may provide a good model to investigate the role of planar chirality. Moreover, it is worthwhile to note that, after the planar chirality is introduced into such ligands, there are three elements of chirality—central, planar and axial chirality—upon their coordination with metal palladium. Herein we report the synthesis of planar chiral 1,1′-P,N-2′-disubstituted ferrocene ligands and the observation of significant effects on enantioselectivity as well as the control of absolute configuration in palladium-catalyzed allylic alkylation upon introducing a new element of chirality—planar chirality—into the 1,1′-P,N-ferrocene ligands.

As shown in Scheme 1, ferrocenyloxazoline derivative **7**, which was synthesized according to Bryce's method,[9] was treated with BuLi followed by trapping with Ph_2PCl to afford 1-diphenylphosphino-1′-oxazolinylferrocene **8** in 78% yield. Directed diastereoselective *ortho*-lithiation of **8** according to Richards' procedure[8e] and subsequent treatment with electrophiles gave 2′-substituted compounds **9**, **10** and **16**. Compound **9** was again lithiated followed by trapping with electrophiles to afford ferrocene derivatives **14** and **15**. Conversion of **14** and **15** to **11** and **13** respectively was accomplished by removing the TMS group with TBAF in THF at reflux. Then, a bromo–lithium exchange of **13** followed by quenching the resulting anion with TMSCl furnished **12**. The diastereopurities of all compounds containing planar chirality, determined by 300 MHz ^{1}H NMR, were > 99 : 1.

Chiral P,N-ligands have proved to be effective in several kinds of metal-catalyzed asymmetric reactions,[11] especially palladium-catalyzed allylic substitutions,[11a,b,12] and ligand **8** has also proved effective in palladium-catalyzed allylic substitutions with 91% ee.[8b–d] In our previous work, we studied the role of the planar chirality of 1,2-N,S-ferrocene ligands in palladium-catalyzed allylic alkylations.[6a] Therefore, in order to investigate the role of the planar chirality of this new kind of 1,1′-P,N-2′-disubstituted ferrocene ligand in metal-catalyzed asymmetric reaction, we also used allylic alkylation as the model reaction. The results are summarized in Table 1. Our attention was first focused on the role of planar chirality in this reaction. A dramatic change in the enantioselectivity of the reaction was observed with (S,S_p)-**9**; the enantioselectivity of the reaction product **22** changed from 91% with *S* configuration using ligand **8** to 69.7% with *R* configuration using ligand **9** (entries 1 and 3). In considering the change of absolute configuration, the effect of the newly introduced group is significant. This exciting result encouraged us to probe the effect of the newly introduced group with opposite planar

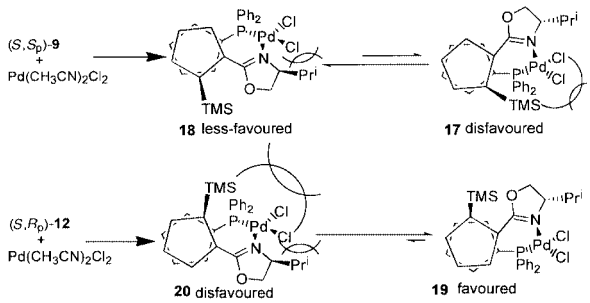
10	**12**	99	97.8	*S*
11	**16**	98	83.3	*R*
12	**16**	98	77.7[e]	*R*

[a] Molecular ratio: $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$: ligand : **21** : dimethyl malonate : BSA : KOAc = 2.5 : 5.2 : 100 : 300 : 300 : 5. [b] Isolated yield. [c] The ee value for **22** was determined by HPLC analysis using a Chiralcel OD column. [d] Configurations were assigned by comparison of the sign of optical rotation. [e] No KOAc was used. [f] 10 equiv. KOAc was used *vs.* ligand.

chirality, which may increase the ee value in comparison with that of ligand **8**. Therefore, (S,S_p)-**11** was synthesized and subjected to the same reaction. Just as expected, a remarkable improvement in the ee value (98.5%, *S* configuration) was revealed. This result indicates that the effect of planar chirality on the stereochemical outcome is significant in this model reaction. In order to study the steric effect of the 2′-substituted group, (S,R_p)-**10** and (S,R_p)-**12** were synthesized and also used for this reaction. A reasonable result was obtained, that is, the steric bulkiness of the group was found to directly correlate with the enantioselectivity; the larger the group, the higher the ee value (compare ligand **9** *vs.* **10** and **11** *vs.* **12**). From this result, we envisaged that further increasing the steric bulkiness of the 2′-substituent of ligand **9** should also increase the enantioselectivity of the reaction. As expected, a higher ee value (83.3% ee, entry 11) was obtained when ligand **16** was used for this reaction. It was reported in the literature[12] that the addition of KOAc may sometimes increase the ee value. However, non-uniform results were obtained in our case (Table 1).

In order to explain the significant role of the planar chirality of this kind of ligand in this model reaction, the complexation behavior of **8**, **9** and **12** with $Pd(CH_3CN)_2Cl_2$ in CD_3CN was examined by ^{31}P NMR. The results showed that the ^{31}P NMR of the complex of **8** with $Pd(CH_3CN)_2Cl_2$ gave two peaks in a ratio of 7 : 3, which was consistent with the literature.[8b] However, for **9** the ratio dropped to 2 : 3, which might be assigned as diastereomers **17** and **18**, and for **12** the ratio became 22 : 1, which might be assigned as diastereomers **19** and **20** (Scheme 2). The ^{31}P NMR data showed that the addition of a third group



Scheme 2

in a proper disposition may favor the formation of one rotamer over the other, consistent with the ee values of the products. On the other hand, from Scheme 2, if the TMS group of compound **17** is replaced by the larger Bu_3Sn group, the balance should move towards the left. As a result, the entioselectivity of the reaction should also be increased by using ligand **16** in comparison with ligand **9**. In fact, the experimental results did agree with the above reasoning (entries 3 *vs.* 11).

In summary, we have synthesized a new kind of 1,1′-P,N-2′-disubstituted ferrocene ligand in which planar chirality was introduced. Comparison of the results for ligands **8**, **9** and **12** showed that the planar chirality is decisive in exerting control over both absolute configuration and enantiomeric excess. In addition, this kind of ligand is unique due to its multi-chirality (central, planar and axial chirality) upon coordination with Pd, and provides a new approach to the design of novel ligands. Further studies on the detailed transition-state structures, and the mechanism, and the exploration of the scope of asymmetric reactions with these promising ligands are in progress.

Iron(II)-catalyzed intramolecular aminochlorination of alkenes

Thorsten Bach,* Björn Schlummer and Klaus Harms†

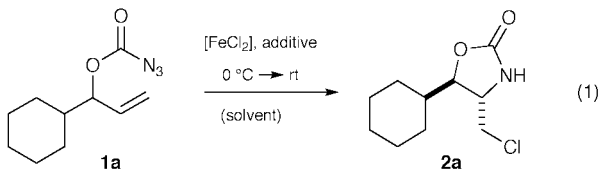
Fachbereich Chemie der Philipps-Universität Marburg, D-35032 Marburg, Germany.
E-mail: bach@chemie.uni-marburg.de

Received (in Liverpool, UK) 11th November 1999, Accepted 20th December 1999

2-Alkenyloxycarbonyl azides undergo an efficient intramolecular Fe^{II}-catalyzed aminochlorination with TMSCl in EtOH and furnish the corresponding 4-(chloromethyl)-oxazolidinones (60–84% yield), presumably *via* a stepwise single electron transfer pathway.

The catalytic aziridination of alkenes is a topic of current scientific interest.[1,2] In particular, transition metal catalysts which allow a nitrene transfer to alkenes and which can be modified by chiral ligands have attracted considerable attention.[3] Research in our group has been directed towards the transfer of *N*-alkoxycarbonyl substituted nitrene fragments to nucleophiles. We have shown that the reaction of *tert*-butoxycarbonyl azide ($BocN_3$) with sulfides and sulfoxides is catalyzed by $FeCl_2$ (10–25 mol%) and yields the corresponding sulfimides and sulfoximides in moderate to good yields.[4] We have now studied the Fe^{II}-catalyzed intramolecular nitrogen transfer to alkenes using the corresponding 2-alkenyloxycarbonyl azides.

Substrates of this type are known to undergo an intramolecular aziridination under thermal conditions.[5] The strained aziridines primarily formed are ring-opened readily by nucleophiles. Metal-catalyzed versions of this aziridination reaction have not been reported. Initial experiments in our laboratories were carried out with the azide **1a**[6] [eqn. (1)].



In all cases we studied, the *trans*-4-(chloromethyl)-oxazolidinone **2a** was obtained as the major nitrogen transfer product. An aziridine intermediate was not observed. In CH_2Cl_2 and THF the reaction proceeded sluggishly. MeCN proved to be a superior solvent for the desired transformation (Table 1, entry 1). Since a source of chloride ions was essential to guarantee an effective catalytic cycle we screened several candidates. TMSCl finally turned out to be the additive of choice (entry 2). It was, however, not possible to obtain acceptable yields using 0.1 equiv. of the catalyst in MeCN (entry 3). In search of another solvent which would allow a decreased catalyst loading we found EtOH to be ideally suited (entry 6). With 10 mol% of the catalyst a product yield of 72% was achieved (entry 7). In some instances, variation of the additive or the solvent led to complete inhibition of the reactions (entries 4, 5 and 8).

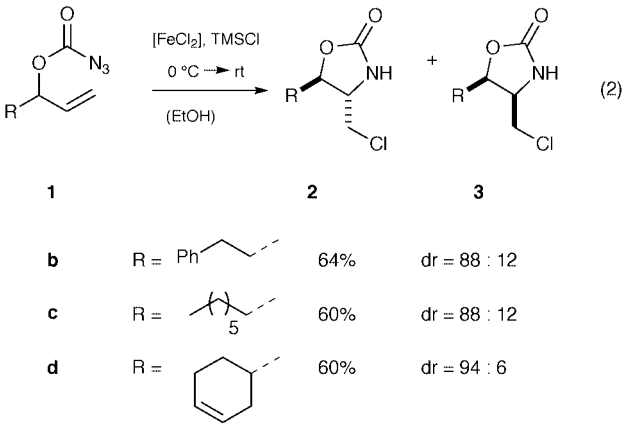
Table 1 Fe^{II}-catalyzed intramolecular aminochlorination of substrate **1a**

Entry	Solvent	$FeCl_2$/ equiv.	Additive	Yield (%)[a]	*trans*:*cis*[b]
1	MeCN	0.5	—	59	95:5
2	MeCN	0.5	TMSCl[c]	63	95:5
3	MeCN	0.1	TMSCl[c]	24	96:4
4	MeCN	0.5	$FeCl_3$[c]	< 5	—
5	MeCN	0.5	H_2O[d]	< 5	—
6	EtOH	0.5	TMSCl[c]	70	90:10
7	EtOH	0.1	TMSCl[c]	72	91:9
8	MeOH	0.5	TMSCl[c]	< 5	—

[a] Yield of isolated product after chromatographic purification. [b] Ratio of the two oxazolidinone diastereoisomers as determined by ^1H NMR spectroscopy. [c] 1.5 equiv. of the additive were employed.. [d] A 9:1 (v/v) solvent mixture of MeCN–H_2O was used.

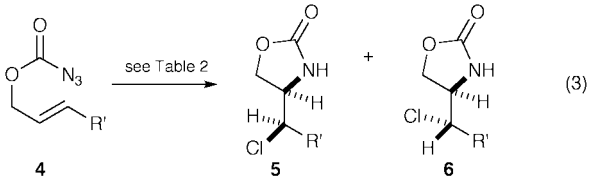
† To whom inquiries about the X-ray analysis should be addressed.

Under optimized conditions (0.1 equiv. $FeCl_2$, 1.5 equiv. TMSCl, EtOH)[7] other substrates **1** reacted equally well [eqn. (2)]. In the case of the azides **1b** and **1c**, which bear a smaller



primary alkyl group at the stereogenic center, the facial diastereoselectivity was slightly lower than with the secondary alkyl substituted substrates **1a** and **1d**. The product **2d** obtained from the diastereomeric mixure of the 3-cyclohexenyl-substituted substrate **1d** was as a mixture of two 4,5-*trans*-isomers due to the additional stereogenic center at the cyclohexene ring.

Mechanistically, we initially assumed an aziridination–ring opening sequence to be responsible for the formation of the 4-(chloromethyl)oxazolidinones **2** and **3**. We started to cast doubt on this idea when we studied the Fe^{II}-catalyzed reaction of the achiral (2*E*)-alkenyloxycarbonyl azides **4** [eqn. (3)]. One



would expect the aziridination to occur stereospecifically to yield a *trans*-aziridine, which would upon ring opening form the *erythro*-product **6**. Contrary to this expectation, the azide **4a** gave only a mixture of diastereoisomers (Table 2, entry 1). We conducted the same reaction in boiling 1,1,2,2-tetrachloroethane (TCE) in the absence of Fe^{II} and obtained exclusively a single product, albeit in much lower yield (entry 2). In this case an aziridine is known to be the intermediate[5b] and the ring opening occurs most likely by HCl, which is formed from TCE upon heating.[5a] Based on analogy with the reactions of azide **4b**

Table 2 Yields and diastereoselectivities determined in the intramolecular aminochlorination of 2-alkenyloxycarbonyl azides **4**

Entry	Substrate	R′	Meth1od	Yield (%)[a]	**5**:**6**
1	**4a**	Pr	$FeCl_2$ (EtOH)	84	49:51
2	**4a**	Pr	Δ*T* (TCE)	62	<1:99
3	**4b**	Ph	$FeCl_2$ (EtOH)	76	>99:1
4	**4b**	Ph	Δ*T* (TCE)	42	<1:99

[a] Yield of isolated product after chromatographic purification.

under the same two different conditions (*vide infra*), structure **6a** was assigned to this product. A thermodynamic equilibration was ruled out because the *erythro*-product **6a** did not interconvert to the *threo*-product **5a** upon treatment with $FeCl_2$.

The difference between the two reaction variants was even more dramatic when we used azide **4b** as the starting material. The Fe^{II}-catalyzed reaction delivered exclusively the *threo*-product **5b** (entry 3), whereas the thermal reaction furnished the *erythro*-product **6b** (entry 4). In this case the relative configuration of one diastereoisomer (**5b**) could be unambiguously proven by single X-ray crystallography[8] (Fig. 1).

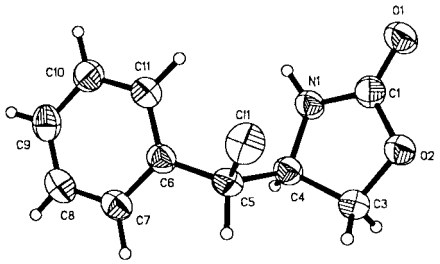


Fig. 1 A molecule of compound **5b** in the crystal.

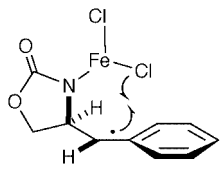
These observations are in line with an Fe^{II}-catalyzed nitrogen transfer *via* radicals as intermediates. Apparently, the intermediate formed from $FeCl_2$ and the azide does not transfer the fragment to the alkene in a concerted fashion, but in a stepwise fashion. The reaction of **4a** is not stereospecific, as a free rotation can occur after N–C bond formation. A possible explanation for the high preference in favor of *threo*-product **5b** in the aminochlorination of substrate **4b** is shown below. The intermediate **7** formed from **4b** adopts the preferred conformation shown owing to 1,3-allylic strain; within this conformation intramolecular chloride transfer can occur diastereoselectively.



7

If this picture is correct there is an obvious analogy between the reaction we study and intermolecular radical-type aminochlorination reactions of *N*-chloro-*N*-alkenyl amines and *N*-chloroalkenamides.[9] Mechanistic evidence might consequently be deduced from comparing the stereochemical outcome of these reactions with the results obtained by the Fe^{II}-catalyzed reaction of similar substrates. A direct comparison is not yet possible as reactions of *N*-chloro-*O*-alkenyl carbamates related to **1** have to the best of our knowledge not been reported.

In further work which is currently underway we plan to undermine our mechanistic hypothesis based on the above-mentioned analogy and based on suitable radical clocks.

6 The azides were prepared by successive treatment of the corresponding allylic alcohols with 1,1′-carbonyldiimidazole and NaN_3: P. Yuan, P. Plourde, M. R. Shoemaker, C. L. Moore and D. E. Hansen, *J. Org. Chem.*, 1995, **60**, 5360. **CAUTION**! Alkoxycarbonyl azides are potential explosives. Appropriate safety protection and utmost care are required while handling these compounds.

7 Representative procedure: A solution of **1a** (209 mg, 1.00 mmol) and TMSCl (163mg, 1.50 mmol) in dry ethanol (5 ml) was degassed with a stream of argon at 0 °C for 15 min. $FeCl_2$ (13 mg, 0.10 mmol) was added in one portion to the stirred solution. The formerly colorless reaction mixture turned yellow and nitrogen started to evolve. The solution was allowed to warm to room temperature and was stirred for another 20 h. It was then dissolved in EtOAc (20 ml) and washed with water (2 × 20 ml) and brine (20 ml). The organic layer was dried over $MgSO_4$ and the solvent was removed *in vacuo*. The brown residue was purified by chromatography on silica using pentane–*tert*-butyl methyl ether (2:8) as the eluent. A mixture of **2a** and **3a** was obtained as colorless crystals (156 mg, 72%, dr = 91:9). The analytical data were in agreement with the literature values (ref. 5).

8 *Crystal data* for **5b**: $C_{10}H_{10}ClNO_2$, *M* 211.64 g mol^{-1}, monoclinic, *a* = 789.0 (1), *b* = 583.8 (1), *c* = 2055.2 (1) pm, β = 94.175 (4)°; V = 944.1 (1) × 10^{-30} m^3, space group $P2_1/c$, *Z* = 4, λ = 3.358 mm^{-1}, reflections collected = 3750, independent reflections = 1922 [R_{int} = 0.0766], wR_2 = 0.1310, *R* = 0.0459 [$I > 2\sigma(I)$]. New fluoroionophores from aniline dimer derivatives: a variation of cation signalling mechanism with the number of amino groups

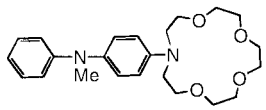
Pascale Crochet, Jean-Pierre Malval and René Lapouyade*

Laboratoire d'Analyse Chimique par Reconnaissance Moléculaire (LACReM), Ecole Nationale Supérieure de Chimie et de Physique de Bordeaux (ENSCPB), Talence, France. E-mail: lapouyad@enscpb.u-bordeaux.fr

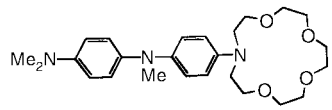
Received (in Liverpool, UK) 18th October 1999, Accepted 10th January 2000

New fluoroionophores, *N*-peralkylated dimers of aniline, are described.

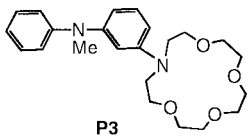
The direct connection of an ionophore to a luminophore provides an optical ion sensor if these two components are in electronic interaction in the ground state or in the excited state.[1] Sensing is based on the modification of the two components interaction when the ion is recognized by the ionophore. According to the nature of the ionophore–fluorophore interaction, the fluorescence signal is modified in intensity or/and in energy. Fluoroionophores which undergo spectral shift on cation binding allow the measurement of the cation concentration from the ratio of the fluorescence intensity at two different wavelengths. To obtain this wavelength dependence of the fluorescence intensity, fluoroionophores with two emitting states, monomer–excimer (exciplex)[2] or ICT–TICT states,[3] the populations of which are ion-dependent, have been designed.[4] In particular, when the ionophore has a heteroatom which is a ligand of the ion and which also takes part in the first electronic transition of the fluorophore, the recognition of an ion stabilizes the heteroatom electronic pair and the fluorophore has the electronic configuration of the unsubstituted compound. The fluorescence spectrum of the ion-probe complex will be that of the probe or of the unsubstituted fluorophore (or a mixture of the two) depending on the relative rate constants of radiative emission and of the decoordination of the cation from the probe.[5] We have prepared and characterized the optical properties of *N*-peralkylated *meta*- and *para*-dimers of aniline with the monoaza-15-crown-5 ionophore replacing the dialkylamino group at one end of the molecules (**P1** and **P3**) and the



P1



P2



P3

para-dimethylamino derivative of **P1** with the amino group in the *para* position (**P2**). The comparison of **P1** and **P3** should provide an additional example of the '*meta* effect'.[6] The addition of the Me_2N group in **P2** should, upon cation binding, restore the photoinduced charge transfer encountered for **P1**, as we have recently observed with similar electronically symmetrical stilbenes.[7] We report here that the calcium complexes of the azacrown derivative of the peralkylated aniline dimer and its *p*-dimethylamino derivative (**P1** and **P2**) do not decoordinate in the excited state and consequently lead to new emission bands, upon cation recognition, blue-shifted for **P1** because of cation-inhibition of the CT process, and red-shifted for **P2** as a result of a cation-induced electron acceptor group which leads to a charge transfer band.

The three compounds[8] were synthesized from an Ullmann coupling of the aniline derivatives with iodonitrobenzene, followed by methylation of the secondary amine,[9] reduction of the nitro group and transformation of the resulting primary amine into the aza-15-crown-5.[10]

The absorption spectra of **P1**–**P3** extend to 340 nm and do not show significant shift with increasing solvent polarity, whereas the fluorescence, always unstructured, is red-shifted in polar solvents (Table 1). This behaviour could be attributed to rapid relaxation of the initially formed Franck–Condon excited state to a charge-transfer (CT) state. Let us assume that there is only one emitting state, whatever the polarity of the solvent; by applying the Lippert–Mataga equation[11] we can estimate dipole moments of 20.6, 8.8 and 12.2 D for **P1**, **P2** and **P3** respectively (Table 1). The monoexponential decay of **P1** implies one emitting state or several in fast equilibrium. Nevertheless the charge transfer (CT) character of the fluorescing state is large for the *p*-aniline dimer (**P1**) where we can calculate, from the Rhem–Weller equation[12] ($\Delta G = E_{ox} - E_{red} - E_{ex}$), neglecting the Coulomb part of the stabilization energy, an exergonic stabilisation energy $\Delta G = -0.36$ eV for charge separation from the *p*-phenylenediamine group in the excited state ($E_{ox} - E_{ex} = -3.78$ eV for *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine) to the benzene substituent ($E_{red} = -3.42$ eV).[13] The excited state dipole moments of the *meta* isomer (**P3**) and of the symmetrical derivative (**P2**) are lower, relative to **P1**, because the electron donor group in **P3** has a higher oxidation potential and the potential electron acceptor substituent (dimethylaniline) in **P2** has a more negative reduction potential.

Addition of calcium perchlorate to solution of the probes in MeCN leads to the absorption spectra of the corresponding compounds without the azacrown substituent; for example, the absorption spectrum of the calcium–**P2** complex superposes with the absorption of **P1**. In fact the absorption spectra are not markedly shifted but the absorption intensity is altered enough to allow the measurement of the complexation constant K_s by a nonlinear least-squares analysis of the absorption intensity *versus* the concentration of the cation using the relation derived by Valeur[14] for probes with a sufficiently high K_s that the

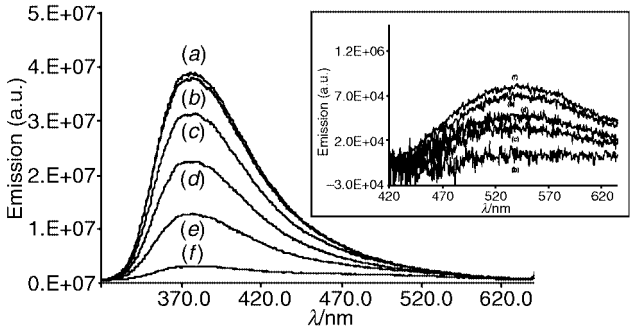

Fig. 2 Fluorescence spectra of **P2** (8.50×10^{-4} M) in acetonitrile with increasing amount of $Ca(ClO_4)_2$: $[Ca^{+2}] = 0$ M (*a*); 2.88×10^{-6} M (*b*); 8.64×10^{-6} M (*c*) 1.15×10^{-5} M (*d*); 1.73×10^{-5} M (*e*); 2.88×10^{-5} M (*f*).

concentration of the uncomplexed cation cannot be approximated to the concentration of the salt added. We obtained log K_s = 5.3 and 5.6 for **P1** and **P2**, respectively.[15] These values are higher than those found with fluoroionophores of the stilbene series built with the same ionophore but with the electron-accepting substituent in the *para* position (log $K_s \cong 4$) or even with a *p*-dimethylamino group (log $K_s \cong 4.9$).[7] The value of the complexation constants increases with the electron density on the nitrogen atom of the ionophore.

The effect of calcium on the fluorescence spectra of **P1** and **P2** is marked, while being peculiar for each compound (Fig. 1 and Fig. 2): the fluorescence of the probes is quenched, and a new emission appears of similar intensity and on the high energy side for **P1**, and with very low quantum yield ($< 10^{-4}$) and at longer wavelength for **P2**.

The complexation constants obtained from the fluorescence spectra have the same value as those from the absorption spectra. The fluorescence of the complex **P1**–Ca is in the same wavelength region as the fluorescence of Ph_2NMe and that of the complex **P2**–Ca corresponds to that of **P1**.

These characteristics indicate that there is no decoordination of the cation during the excited state lifetime of the probes. With **P1** the cation lowers the energy of the electron pair on the nitrogen atom of the azacrown, which accordingly is decoupled from the π aromatic system. In a first approximation we can estimate that the **P1**–Ca complex has the same electronic configuration as Ph_2NMe. With the same reasoning, we could consider that **P2**–Ca is identical to **P1**, but if the spectral position and the solvatochromism of the emission are comparable, the quantum yield of fluorescence of the **P2**–Ca complex is very low. The Ca–nitrogen atom interaction, which should be reinforced in the excited state, could open a new channel for non-radiative deactivation. In conclusion these *N*-peralkylated dimers of aniline provide interesting fluoroionophores with high complexation constants and distinct fluorescence shifts upon cation complexation. In conjugation with the phenyl-azacrown ionophore, the PhMeN substituent is an electron donor in the ground state of the probe, while the benzene group can be an electron acceptor with the probe in the excited state. As cation recognition by the azacrown should have the same electronic effect as protonation, the results reported here should be pertinent to the fluorescence modification of polyaniline when the protonic level of doping is increased. Longer and conformationaly constrained oligoanilines are under study to achieve oligomeric fluorescent cation probes[16*a*,*b*] and to better understand the electronic properties of polyaniline.

We thank Colette Belin and Jean-Pierre Desvergne for help with the fluorescence experiments and the Ecole Nationale Supérieure de Chimie et de Physique de Bordeaux for financial support.

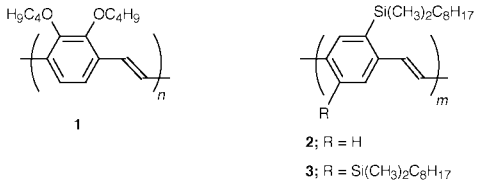
Received (in Cambridge, UK) 29th November 1999, Accepted 18th January 2000

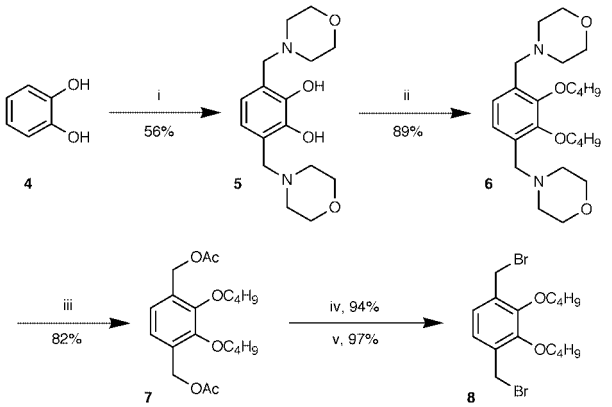
2,3-Dialkoxy-substituted poly(1,4-phenylene vinylene) (PPV) homo- and co-polymers have been prepared by the Gilch dehydrohalogenation polycondensation of the corresponding bishalomethyl-substituted benzene monomers, and double layer light emitting devices fabricated with these materials exhibited high electroluminescence efficiencies with low turn-on voltages.

Semiconducting organic polymers exhibiting electroluminescence (EL) have recently attracted considerable interest owing to their high potential for application as the active layer in polymer light-emitting devices (PLEDs).[1–5] The 2,3-disubstituted derivatives of PPV are of interest owing to the potential distortion of the intra- and inter-molecular chain interactions as a result of steric effects.[6] Poly(2,3-dibutoxy-1,4-phenylene vinylene)[7] **1** exhibits a blue–green solid state photoluminescence (PL) with 40% efficiency which is considerably higher than the prototypical 2,5-dialkoxy-substituted analogue, MEH-PPV.[8] We have also reported a new class of 2-silylated and 2,5-disilylated PPV derivatives which essentially behave as organic solvent processible analogues of PPV itself, but which are much more luminescent (PL efficiency 60%). However, single layer (100 nm) devices fabricated from poly(2-dimethyloctylsilyl-1,4-phenylene vinylene) (DMOS-PPV)[9,10] **2** and poly[2,5-bis(dimethyloctylsilyl)-1,4-phenylene vinylene] (BDMOS-PPV)[11] **3** suffered from rather high turn-on voltages of *ca*. 15 V. It has recently been reported that high efficiencies may be realised in ternary statistical copolymers of PPV derivatives,[12] and that the degree of defects is determined in part by non-regioregular coupling of the putative quinomethide precursor in the Gilch polycondensation.[13]

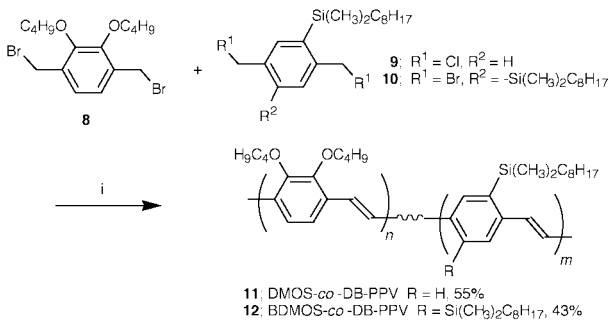


Here, we report an improved synthesis of 1,4-bis(bromomethyl)-2,3-dibutoxybenzene **8** and the exploitation of two important monomers to yield the statistical copolymers poly[(2-dimethyloctylsilyl-1,4-phenylene vinylene)-*co*-(2,3-dibutoxy-1,4-phenylene vinylene)] (DMOS-*co*-DB-PPV) **11** and poly-{bis[(2,5-dimethyloctylsilyl)-1,4-phenylene vinylene]-*co*-(2,3-dibutoxy-1,4-phenylene vinylene)} (BDMOS-*co*-DB-PPV) **12**, respectively, that combine the intrinsically high electroluminescence present in the three corresponding homopolymers **1**–**3** with the significantly reduced turn-on voltages of 2,3-dialkoxy-substituted PPVs.

The synthesis of the 2,3-dibutoxy monomer **8** is shown in Scheme 1. The key improvements were the use of the double Mannich reaction to introduce both carbon substituents and the conversion of the diol formed from saponification of the diacetate **7** with CBr_4 and PPh_3[14] into the crystalline 1,4-bis-bromomethyl compound **8**.‡ Statistical copolymersation under Gilch conditions of monomer **8** with **9**[9,10] and **10**,[11] using in both cases a feed ratio of 1:1, in the presence of excess KOBu^t in degassed THF at room temperature (Scheme 2) gave the copolymers **11** and **12**, respectively. The polymers were purified by precipitation from methanol and acetone or mixtures of methanol–water, respectively, and formed bright yellow fibres displaying high luminescence. ^{1}H NMR side-chain analysis of DMOS-*co*-DB-PPV **11** gave the ratio *n*:*m* of 3:4 and for BDMOS-*co*-DB-PPV **12** of 4:3.



Scheme 1 *Reagents and conditions*: i, CH_2O, morpholine, Pr^{i}OH, reflux, 1 h. ii, C_4H_9Br, K_2CO_3, EtOH, reflux, 20 h. iii, Ac_2O, NaOAc, HOAc, reflux, 72 h. iv, K_2CO_3, MeOH–THF–H_2O (50:9:3), 48 h. v, CBr_4, PPh_3, THF, 4 h.



Scheme 2 *Reagents and conditions:* i,KOBu^t, THF, 18 h.

Molecular weight determination of the purified polymers using size-exclusion chromatography (SEC) calibrated with polystyrene standards and multiple angle light scattering revealed high molecular weights and polydispersities, typical of dehydrohalogenation polycondensations (DMOS-*co*-DB-PPV: M_n = 290 000, M_w/M_n = 7.1; BDMOS-*co*-DB-PPV: M_n = 180 000, M_w/M_n = 5.5). DMOS-*co*-DB-PPV **11** and BDMOS-

† Electronic supplementary information (ESI) available: normal optical absorption, PL and EL spectra (Fig. S1) and cyclic voltammograms (Fig. S2) for BDMOS-DB-PPV. See http://www.rsc.org/suppdata/cc/a9/a909382f/

co-DB-PPV **12** readily dissolved in aprotic solvents such as THF, chloroform or xylene and formed good uniform transparent films on ITO-coated glass substrates. The thermal properties of the polymers were investigated by thermal gravimetry (TG) and differential scanning calorimetry (DSC) under nitrogen. Analysis of the TG trace (heating rate 10 °C min^{-1}) for DMOS-*co*-DB-PPV and BDMOS-*co*-DB-PPV revealed a 5% weight loss at *ca*. 370 and 320 °C, respectively. BDMOS-*co*-DB-PPV showed an exothermic phase transition at *ca*. 170 °C.

Optical absorption measurements in $CHCl_3$ solutions for DMOS-*co*-DB-PPV and BDMOS-*co*-DB-PPV showed λ_{max} of 440 and 442 nm, respectively. Interestingly, DMOS-*co*-DB-PPV showed for the λ_{max} in the solid-state a bathochromic shift to 448 nm, whereas BDMOS-*co*-DB-PPV revealed a slightly hypsochromically shifted value of 440 nm (Fig. S1 in ESI). The longest wavelength absorption maxima reflected the statistical composition of the respective monomeric building blocks; DB-PPV **1**: λ_{max} = 454 nm; DMOS-PPV **2**: λ_{max} = 414 nm; BDMOS-PPV **3**: λ_{max} = 436 nm. Both polymers are bright yellow materials exhibiting high solid-state PL efficiencies of 35 and 28%, with the longest wavelength emission peaks at λ_{em} = 548 nm (2.26 eV) and λ_{em} = 544 nm (2.28 eV, (Fig. S1 in ESI)), respectively.

Cyclic voltammetry (CV) was perfomed on thin polymer films of BDMOS-*co*-DB-PPV **12** spin-coated onto Pt disk electrodes in MeCN using a Pt wire as counter electrode and Ag/AgCl as a reference. In the anodic scan the onset of oxidation occurred at *ca*. 1.2 V followed by three subsequent non-reversible oxidations at 1.38, 1.63 and 1.80 V, respectively (Fig. S2 in ESI). The cathodic sweep showed onset of reduction at *ca*. −1.6 V and a quasi-reversible reduction step at −1.83 V (Fig. S2 in ESI). The electrochemically measured band gap was 2.8 V, which compares well with the HOMO–LUMO energy gap of 2.82 eV as measured from UV–VIS spectroscopy. The HOMO and LUMO energy levels of BDMOS-*co*-DB-PPV were estimated from the oxidation and reduction onset potentials to be HOMO = 5.6 eV and LUMO = 2.8 eV, respectively.[15]

Double layer devices with the configuration ITO/PEDOT:PSS/polymer/cathode were fabricated, [PEDOT:PSS is poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate)].§ Both polymers exhibited blue–green light emission. Interestingly, DMOS-*co*-DB-PPV LEDs only showed EL emission for Ca cathodes evaporated at pressures of *ca*. 10^{-3} mbar, but little or no EL for evaporation at pressures $\leqslant 3 \times 10^{-6}$ mbar. DMOS-*co*-DB-PPV **11** double layer LEDs with Al cathodes showed turn-on voltages of 2.0–2.4 V (threshold = 0.01 cd m^{-2}) with a power efficiency of 0.05 cd A^{-1} and a maximum luminance of 36 cd m^{-2} at 11 V. Substantially better performance (both efficiency and luminance) was noted for devices made with BDMOS-*co*-DB-PPV **12** and Ca cathodes compared with devices made with DMOS-*co*-DB-PPV **11**. The power efficiency was up to 0.72 cd A^{-1} with a maximum luminance of 1384 cd m^{-2} at 12 V and turn-on voltages of 4.0 V for a structure with an 80 nm active layer (Fig. 1). This compares well with a 6 V turn-on voltage for the BDMOS-PPV **3** based homopolymer device.[11] The EL emission peak was measured at λ_{em} = 533 nm (2.33 eV).

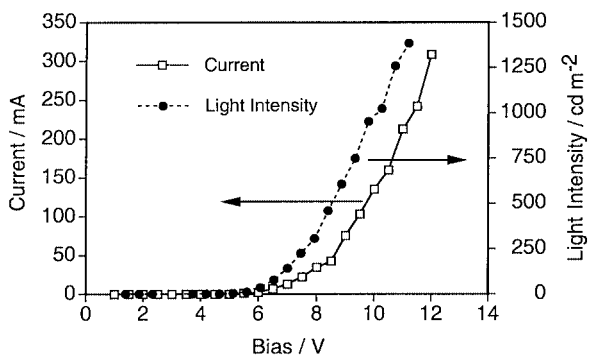


Fig. 1 Current–voltage–luminance (I–V–L) characteristics of an ITO/PEDOT (80 nm)/BDMOS-DB-PPV (80 nm)/Ca LED. The active area of the device is *ca*. 0.045 cm^2. EL emission turns on at 4.0 V and the maximum efficiency is 0.72 cd A^{-1}.

In summary, a new and versatile synthetic route for the preparation of 2,3-dialkoxy-1,4-bis(bromomethyl) monomers was developed. Improved EL performance of devices using statistical copolymers such as BDMOS-*co*-DB-PPV **12** as the active layer in comparison with the homopolymers was demonstrated, making this material a promising candidate for further optimisation.

M.), the Royal Society (University Research Fellowship to F. C.), the Commission of the European Union (Marie Curie Fellowship to F. G., TMR network 'SELOA' and Brite-Euram Contract BRPR-CT97-0469 'OSCA'), the Cambridge Commonwealth Trust and the CVCP (ORS studentship to B. S. C.) and Cambridge Display Technology (CDT) for generous support.

Notes and references

‡ All new monomers were characterised fully by their melting points, IR, ^1H and ^{13}C NMR spectroscopy, EI or CI MS spectrometry and elemental analysis.

§ Absorption and PL spectroscopy were carried out on thin films deposited onto spectrosil substrates by means of a Hewlett Packard B453 UV–VIS spectrophotometer (absorption) and of a CCD UV-enhanced spectrograph (PL). The PL efficiency was determined on films deposited on spectrosil substrates, using a nitrogen purged integrating sphere. Excitation was by means of the visible or multiline UV lines (*ca*. 351, 364 nm) of an Ar-ion laser. LEDs were prepared on commercial ITO substrates (Asahi), treated prior to use with a oxygen plasma for 10 min.[16] The PEDOT:PSS (Bayer) was coated from a water dispersion yielding a *ca*. 80 nm thick layer after drying (*ca*. 90 °C; 1 h).[17] Active layers were spin-coated from THF–*p*-xylene solutions on either the bare ITO or on ITO/PEDOT substrates to give film thickness of 80–100 nm. Cathodes (Al or Ca/Al) thermal evaporation (at *ca*. 5×10^{-6} mbar or less) completed the preparation of the diodes which were then tested in a 10^{-2} mbar vacuum.

Radical pair recombination stereoselectivity as a probe of magnetic isotope and magnetic field effects

George Lem and Nicholas J. Turro*

Chemistry Department, Columbia University, New York, New York 10027, USA. E-mail: turro@chem.columbia.edu

Received (in Corvallis, OR, USA) 22nd November 1999, Accepted 7th January 2000

Photolysis of *meso*- or *dl*-2,4-diphenylpentan-3-one within NaY zeolites, coadsorbed with a chiral inductor, lead to enantioselective radical pair recombinations which are sensitive to ^{13}C isotope effects, but insensitive towards external magnetic field effects.

We report here rationally designed systems, based on well-established radical pair chemistry, which investigate the stereoselectivity of recombination of prochiral radical pairs for which significant magnetic field effects and magnetic isotope effects have been observed in micelles.[1,2] The concept of the systems is the following. A prochiral triplet radical pair that can be produced reversibly is generated in a chiral, supramolecular[3] environment that (i) allows the separation of the pair to distances allowing for the exchange interaction between the partners of the pair to decrease to values of the order smaller than those available from external or internal magnetic fields,[1] and (ii) encourages reencounters of the pair. Each recombination of the pair can produce either the (+) or (−)-enantiomer, but in the presence of a chiral inductor within the supramolecular environment, a certain enantiomeric selectivity can result.[4] For any given system in which some ee is observed, the efficiency of ee resulting from radical pair recombination is expected to depend on the radical pair lifetime, which has consequences in terms of the effective interactions between the pair and the chiral inductor. In this scenario, magnetic field and magnetic isotope effects on the enantioselectivity may result if the lifetime of the pair is extended or diminished. From a survey of published results, we selected the supercage of NaY faujasite zeolites[5] as the host supramolecular environment,[6] the photolyses of *meso*- and *dl*-2,4-diphenylpentan-3-one (*meso*-**1** and *dl*-**1**, respectively) to generate triplet radical pairs and a co-adsorbed chiral inductor such as diethyl L-tartrate and (+)- or (−)-ephedrine as chiral inductors.

As depicted in Scheme 1, photolysis of *meso*-**1** results in the formation of *dl*-**1** and *vice versa* (for simplicity only the photoprocesses of *meso*-**1** are shown).[7] According to the conventional paradigm of ketone photochemistry,[8] α-cleavage of triplet excited **1** leads to the formation of *sec*-phenethyl and *sec*-phenethylacyl triplet geminate radical pairs (GRP). If the space available in the supercage allows rapid diffusional separation of the primary geminate pair, then decarbonylation of the *sec*-phenethylacyl radical and subsequent formation of diastereomeric 2,3-diphenylbutanes **2** occurs.[7] If diffusion is restricted, but rotation of the triplet radical pairs relative to one another is permitted, intersystem crossing (ISC) of the radical pairs occurs to yield *meso*-**1** or *dl*-**1**. Additionally, if the environment is chiral, *dl*-**1** with some degree of enantiomeric enrichment can be produced. Of these processes, only the rate of ISC is sensitive towards magnetic effects.[1a,b] Thus, the ratios between decarbonylation products and recombination products,[2c] as well as the ee of photoproduced *dl*-**1** can serve as probes for magnetic effects on the radical pair recombination stereochemistry. While we expect the ratio of recombination products/decarbonylation products to increase as the rate of ISC increases, predictions on the direction of change of the ee of photoproduced *dl*-**1** cannot be made *a priori*.

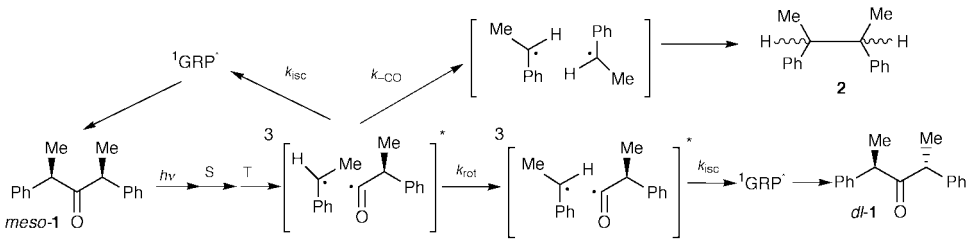
Table 1 summarizes the ee values of recovered *dl*-**1** upon photolysis of *dl*-**1** in NaY co-loaded with diethyl L-tartrate as a function of both external magnetic field strength and isotope. It can be seen that there are no differences, within experimental error, in the ee (measured by chiral GC) of the photolyzed *dl*-**1** when the photoreaction is carried out at either 0 or 2 kG. However, upon photolysis at 0 kG of *dl*-**1** enriched in ^{13}C (98% enriched) at the carbonyl carbon, a significant increase in the ee of the recovered *dl*-**1** is observed when the ^{13}C labeled isomer is photolyzed relative to the unlabeled isotopomer (3.0 *vs.* 1.6%, respectively). Additionally, a slight increase in the amount of recombination product *vs.* decarbonylation products was observed in the photolysis of *dl*-**1**-^{13}CO relative to *dl*-**1**-^{12}CO.[9] However, no such trend has seen in the photolysis of *dl*-**1**-^{12}CO performed at 0 *vs.* 2 kG.

In order to assess the influence of initial stereochemistry of **1** on the enantioselectivity of *dl*-**1** as a function of external magnetic field and isotope effects, photolyses of *meso*-**1** were performed in NaY using ephedrine as the chiral inductor.[10] From Table 2, it can be seen that photolyses of *meso*-**1** in NaY in the presence of ephedrine, significantly higher ees for *dl*-**1** are obtained compared to utilizing *dl*-**1** as the starting material and diethyl L-tartrate as the inductor. However, similar to the results obtained with diethyl L-tartrate, only a ^{13}C isotope effect is observed while external field effects are absent. Thus, an

Table 1 Photolysis of *dl*-**1** in NaY co-loaded with diethyl tartrate[a]

Magnetic field/kG[b]	Ketone	Chiral inductor	Ee of *dl*-**1** (%)[cd]
2	*dl*-**1**-^{12}CO	diethyl L-tartrate	+2.0 ± 0.2
0	*dl*-**1**-^{12}CO	diethyl L-tartrate	+1.6 ± 0.3
0	*dl*-**1**-^{13}CO	diethyl L-tartrate	+3.0 ± 0.1

[a] The average occupancy of *dl*-**1** in NaY is ~0.05 molecules per cage and that of diethyl tartrate ~1 molecules per cage; *dl*-**1** was photolyzed to 35–45% conversion. [b] Ref. 12. [c] Errors correspond to standard deviations derived from three or more independent experiments. [d] After photolysis, *dl*-**1** is separated from *meso*-**1** *via* preparative TLC and analyzed by chiral GC.



Scheme 1

Table 2 Photolysis of *meso*-**1** in NaY co-loaded with ephedrine[a]

Magnetic field/kG[b]	Ketone	Chiral inductor	Ee of *dl*-**1** (%)[cd]
2	*meso*-**1**-^{12}CO	(−)-ephedrine	+4.9 ± 1.9
0	*meso*-**1**-^{12}CO	(−)-ephedrine	+4.7 ± 1.9
0	*meso*-**1**-^{13}CO	(−)-ephedrine	+9.9 ± 1.3
2	*meso*-**1**-^{12}CO	(+)-ephedrine[e]	−4.3 ± 1.6
0	*meso*-**1**-^{12}CO	(+)-ephedrine[e]	−3.6 ± 0.6
0	*meso*-**1**-^{13}CO	(+)-ephedrine[e]	−7.1 ± 0.5

[a] The average occupancy of *meso*-**1** in NaY is ~0.05 molecules per cage and that of ephedrine ~1 molecules per cage; *meso*-**1** was photolyzed to 26–50% conversion. [b] Ref. 12. [c] Errors correspond to standard deviations derived from three independent experiments. [d] After the photolysis, *dl*-**1** is separated from *meso*-**1** *via* preparative TLC and analyzed by chiral GC. [e] The hemihydrate form was used.

approximate two-fold increase in the ee of *dl*-**1** is observed upon photolysis of *meso*-**1**-^{13}CO compared to that of *meso*-**1**-^{12}CO [+10% *vs.* +5%, with (−)-ephedrine] (Table 2). Additionally, more recombination product was observed for the photolysis of *meso*-**1**-^{13}CO compared to that of *meso*-**1**-^{12}CO.[11]

We can interpret the data in Tables 1 and 2 based on the mechanism of triplet–singlet ISC for triplet biradicals.[13,2c,f] It is recognized that if triplet radical pairs are separated by distances of several Å or more, the singlet–triplet energy gap is decreased and ISC is controlled by weak hyperfine couplings induced by nuclear-spin interactions which are magnetic field and isotope dependent. Thus, ^{13}C is expected to induce a faster ISC in the radical pair relative to ^{12}C, for which only protons provide a hyperfine mechanism for ISC. External magnetic fields can reduce the rate of ISC by increasing the S–T energy gap for two of the three triplet sublevels. Experimental results for such phenomena have been the subject of several reviews.[1,2]

In hydrocarbon solutions, *sec*-phenethylacyl radicals decarbonylate with a rate constant of $\sim 5 \times 10^7$ s^{-1}.[14] In polar solvents, the rate of CO loss can be reduced.[15] Since the internal cages of zeolite supercages are considered highly polar,[16] decarbonylation in the zeolite must be significantly slower than 5×10^7 s^{-1}. Recombination of structurally related benzoyl and cumyl radical pairs obtained from the photolysis of dimethyldeoxybenzoin, in SDS micellar solutions, has been measured to occur with a rate constant on the order of $\sim 1.2 \times 10^7$ s^{-1}.[17] This rate is expected to be increased by ^{13}C isotope effects, *via* changes in the rate of ISC. An increased rate of ISC can be manifested in the different ee values for recovered *dl*-**1** obtained upon irradiation of either *meso*- or *dl*-**1** containing different isotopic labels at the carbonyl carbon. Since there is a lack of information in the rotational dynamics between the prochiral GRPs and the chiral inductor, the trend of the ee of the photoreaction cannot be predicted *a priori*.

The experimental results show an increase in the ee of *dl*-**1**-^{13}CO relative to its ^{12}C isotopomer. Furthermore, photolysis of **1**-^{13}CO leads to a slight decrease in the amount of decarbonylated products relative to the ^{12}C labeled isotopomer.[9,11] Similar results have also been previously observed for the photolysis of dibenzylketone-^{13}CO in faujasites.[2c] Hence, an increase in the ee of the photoproduced *dl*-**1**-^{13}CO may be a function of its faster rate of ISC, leading to a greater number of recombinational processes from the primary GRP as compared to *dl*-**1**-^{12}CO which maintains a relatively lower rate of ISC from the triplet GRP and thus higher propensity to form decarbonylated products.[2a,b,4a,18]

According to the product ratios and the ee values expressed in Tables 1 and 2, there are no observable external field effects in the photolysis of either *meso*- or *dl*-**1**. At this time we lack a theoretical kinetic model to explain these experimental results. Although it has been widely demonstrated that magnetic field and magnetic isotope effects can influence the rate of ISC for triplet biradicals in opposite manners, there is a lack of information on the *magnitudes* of those rates. It can be argued that external field effects, as they pertain to **1** in faujasites, are very small and subtle as compared to magnetic isotope effects. Indeed, in similar product studies done with dibenzyl ketone (DBK) adsorbed in faujasites, external magnetic field effects were significantly smaller than those observed for ^{13}C isotope effects.[2c]

The results show that photochemical enantiomeric selectivity through geminate radical recombinations in zeolite cavities is feasible. The most important finding is that ee values are sensitive to magnetic isotope effects, and consequently can be used as a probe of radical pair dynamics in zeolites.

This work was supported in part by the NSF and the Department of Energy under Grant No. NSF CHE 9810367 to the Environmental Molecular Sciences Institute at Columbia University and National Science Foundation Grant No. CHE 98-12676. We are especially indebted to Dr Valery Tarasov of the Russian Academy of Sciences for helpful discussions and sharing unpublished data.

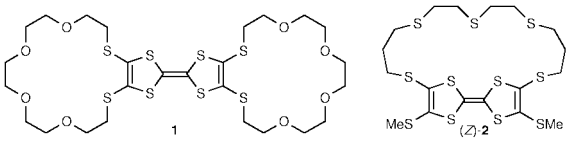
Received (in Liverpool, UK) 28th October 1999, Accepted 21st December 1999

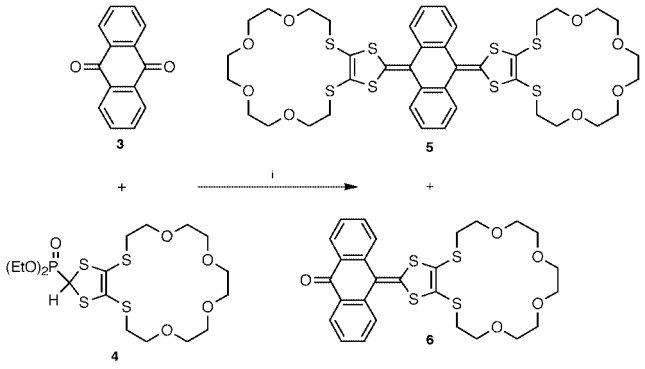
S_2O_4-Crown annelated derivatives of 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene function as efficient ligands in the voltammetric and spectroscopic recognition of Na^+ and Ag^+.

Redox-active ligand systems are important in the field of electrochemically-controlled uptake and release of guest metal cations.[1] For large shifts of the redox potential to be observed upon metal binding the antennae [*e.g.* crown ether unit(s)] should be situated close to the redox-responsive centre (*i.e.* the transducer), thereby enhancing the intramolecular electrostatic (through-space) effect which modulates the redox signal. Typical molecular[2] redox species for this purpose are ferrocene,[3] metal coordinated dithiolate[4] and diimine,[5] and tetrathiafulvalene (TTF) derivatives,[6] *e.g.* **1**[6a,b] and **2**.[6d] For these systems cation binding induces a positive shift of the one-electron oxidation potential E_1^{ox}.



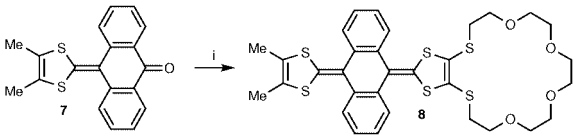
Derivatives of 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene are versatile building blocks in supramolecular and materials chemistry.[7] The special feature of this system is a *two-electron* oxidation wave [neutral → dication, E_1^{ox} *ca.* +0.35 V‡ (in MeCN, *vs.* Ag/AgCl) which is electrochemically quasi-reversible and chemically reversible].[8] Herein we report the first crown-annelated derivatives **5** and **8**.

Reaction of anthraquinone **3** with the new reagent **4**[9] under standard conditions[8,10] gave a mixture of the bis- and mono-crown annelated derivatives **5** and **6**, respectively (Scheme 1).§



Scheme 1 i, **4**, LDA, THF, −78 °C, 3 h, then addition of **3**, then −78 to 20 °C.

† Present address: Medicinal Chemistry Research, Novo Nordisk A/S, Novo Nordisk Park, 2760 Maløv, Denmark.



Scheme 2 i, **4**, LDA, THF, −78 °C, 3 h, then addition of **7**, then −78 to 20 °C.

The latter was characterised by X-ray diffraction.¶ Reaction of **4** with **7**[8a] gave the bis(1,3-dithiole) system **8** (Scheme 2).

An X-ray crystallographic study¶ of **8**·CH_2Cl_2 showed a motif of saddle-shaped molecules (Fig. 1) engulfing each other's dimethyldithiole ends. The anthracenediylidene moiety is folded along the C(9)···C(10) vector, the two benzene rings forming a dihedral angle of 39° (*cf.* 21° in **6**). The dithiole rings are folded along the S(1)···S(2) and S(3)···S(4) vectors by 15.5 and 8.7°, and the S(1)C(16)C(17)S(2) and S(3)C(19)C(20)S(4) planes form an acute dihedral angle of 81°.

The cation binding properties of **5** were assessed by ^{1}H NMR titration studies in $CDCl_3$ at 50 °C (at 20 °C a precipitate formed on addition of metal salts). In the presence of Na^+ and Ag^+ the resonances due to the $–SCH_2CH_2O–$ protons of the crown [(SCH_2) δ 3.05; (OCH_2) δ 3.66] shifted downfield by *ca.* 0.07 ppm in the presence of 10 equiv. of Na^+ and Ag^+, while the anthracenediylidene resonances were unaffected, confirming that cation binding occurs at the crown site. Li^+ and K^+ cations had essentially no effect on the ^{1}H NMR spectrum. UV–VIS absorption spectra for **5** in MeCN in the presence of both Na^+ and Ag^+ (as the perchlorate salts) resulted in a specific change in the spectra. No isosbestic points were observed, indicating that, most probably, both 1:1 and 1:2 complexes [*i.e.* **5**M^+ and **5**$(M^+)_2$] form simultaneously, and the absorption spectra of these species are different. Such behaviour is known for other bis(crown) chromoionophores.[11] Fig. 2 shows the changes in the spectrun of **5** upon complexation with Ag^+. The stability constants for the formation of **5**M^+ and **5**$(M^+)_2$ were estimated to be logK_1 *ca.* 3.4 and log K_2 *ca.* 5.5, respectively.

Cyclic voltammetry (CV) and square wave voltammetry (SQV) showed that **5** and **8** display a two-electron oxidation

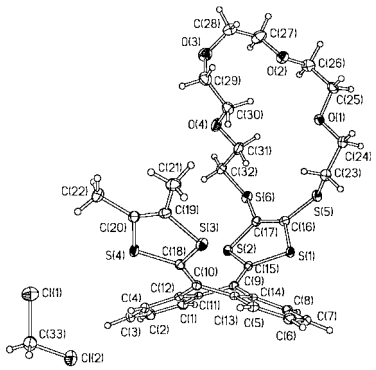


Fig. 1 Molecular structure of **8**·CH_2Cl_2 (50% displacement ellipsoids).

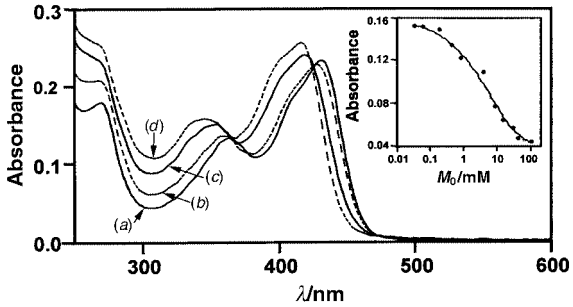

Fig. 2 Absorption spectra of **5** (2×10^{-5} M) in MeCN (1 cm cell) containing $AgClO_4$ at concentrations of (*a*) 0, (*b*) 0.5, (*c*) 8.0 and (*d*) 30 mM. Inset: absorption at 445 nm as a function of Ag salt concentration fitted with eqn. (1), where A_0, A_1 and A are the absorbances of the free ligand L and

$$A = A_0 + \frac{K_1M_0(A_1 - A_0)}{1 + K_1M_0 + K_2M_0^2} + \frac{K_2M_0^2(A_\infty - A_0)}{1 + K_1M_0 + K_2M_0^2} \quad (1)$$

complexes LM^+ and $L(M^+)_2$, respectively; K_1 and K_2 are equilibrium constants for complex formation.

wave: E_1^{ox} +0.405 V (**5**) and E_1^{ox} +0.345 V (**8**). A second reversible one-electron wave, ascribed to oxidation of the anthracene system[8b,c] (*i.e.* radical trication formation) was seen at E_2^{ox} 1.62 V for both compounds [CV data were recorded *vs.* Ag/AgCl, $Bu_4N^+ClO_4^-$ (0.1 M), MeCN, 20 °C, 100 mV s^{-1}]. The progressive addition of aliquots of metal triflate salts resulted in a positive shift of E_1^{ox} (and a similar positive shift of the coupled reductive peak on the cathodic scan), while E_2^{ox} remained unchanged, thereby acting as an internal reference. This is consistent with expulsion of the metal cation from the ionophore prior to the second oxidation wave. The maximum positive shifts (ΔE_1^{ox}) are as follows: Li^+ (15–20 mV), Na^+ (100 mV), K^+ (15–20 mV) and Ag^+ (115 mV). The values of ΔE_1^{ox} are essentially the same for the mono- and bis-crown systems **8** and **5**, respectively, whereas in the TTF series, *e.g.* **1**, a larger shift is observed for bis-crowns. This is likely to be a consequence of intramolecular steric interactions between the crown rings of **5**, and/or sandwich complexation between two crowns, favoured by the rigid saddle conformation. A comparison with related S_2O_4-crowned TTF systems[6] shows two important advantages of systems **5** and **8**: (i) the positive shifts for Na^+ and Ag^+ are significantly larger, and (ii) the system is significantly more sensitive, with saturation being achieved with < 10 equiv. of cation (Fig. 3) (*cf.* 200 equiv. for **1**[6a]).

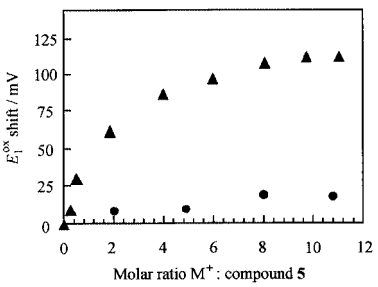

Fig. 3 Shift of E_1^{ox} in the CV of **5** with added equivalents of AgOTf (▲) and KOTf (●). Data were obtained in 0.2 M Bu_4NBF_4, MeCN, Pt disk electrode, 50 mV s^{-1}, Ag/AgCl reference electrode, referenced *vs.* decamethylferrocene.

We suggest that these results are a consequence of the unique combination of structural and redox properties of the 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene transducer unit: (i) the saddle-shape folding of the anthracenediylidene system places the crown ring(s) of **5** and **8** in close proximity to the redox-responsive moiety, and there is a marked conformational change upon oxidation,[7a] and (ii) the E_1^{ox} redox process which is monitored is a *two-electron* oxidation (*cf.* the one-electron wave of TTF, ferrocene *etc.*) thereby enhancing the electrostatic repulsion with the bound metal cation(s) leading to an increase in ΔE_1^{ox}.

In summary, using ligands **5** and **8** we have exploited for the first time the chromophoric and redox properties of the 9,10-bis(1,3-dithiol-2-ylidene)-9,10-dihydroanthracene system to provide efficient and controllable cation recognition within appended crown ether units. To enhance further these effects we suggest that redox species which undergo a *multi-electron* wave (*e.g.* certain dendrimers)[12] should be targets for future transducers in redox-controlled molecular recognition.

We acknowledge funding for this work from EPSRC, Office of Naval Research, Grant #: N00014-94-1-0592 (S. A. A.) and DOE Grant #: DE-FG07-98ER62708 (S. A. A.), and thank Dr A. J. Moore for helpful discussions.

Received (in Cambridge, UK) 29th November 1999, Accepted 19th January 2000

The encapsulation of pepsin by electrostatically controlled diffusion from solution into thermally evaporated fatty amine films is described and the catalytic activity of the immobilized enzyme on hemoglobin is investigated.

The entrapment of proteins in different inert matrices with the aim of protecting the proteins against microbial degradation, hydrolysis, autoproteolysis, deamidation, *etc*.; retention of the native protein structure and accessibility of the encapsulated proteins to cofactors, substrates and redox agents is a problem of current interest especially where application in biosensors/ biocatalysis is sought. Proteins have been immobilized in phospholipid bilayers,[1] on self-assembled monolayers (SAMs),[2] in silicate sol–gels,[3] in polymer matrices,[4] in Langmuir–Blodgett films,[5] within the galleries of α-zirconium phosphates[6] as well as polymer microspheres.[7] Developing on our earlier work on the spontaneous self-organization of fatty acid salts[8] and electrostatic assembly of colloidal nanoparticles,[9,10] we show here, that the proteolytic enzyme pepsin (which occurs in the gastric juice of all mammals), can be encapsulated *via* electrostatic interaction in thermally evaporated fatty lipid matrices (octadecylamine, ODA) by simple immersion of the lipid film in the protein solution under extremely mild preparation conditions (Schematic 1, inset of Fig. 1). The encapsulated enzyme showed good biocatalytic activity using hemoglobin as the substrate. The biocatalytic activity was determined by estimating the amount of acid-soluble tyrosine and tryptophan residues released by reaction of the encapsulated pepsin on hemoglobin.

Pepsin (molecular weight = 37400; pI ≈ 1 where pI represents the isoelectric point)[11] was obtained from Sigma Chemicals and used as received. A 10^{-6} M solution of pepsin was prepared in glycine–HCl buffer (0.05 M, pH 3), close to the pH value at which pepsin exhibits maximum catalytic activity. 250 and 1000 Å thick ODA (Aldrich) films were deposited by thermal evaporation on gold coated AT cut quartz crystals (for quartz crystal microgravimetry (QCM) measurements) and Si(111) substrates (for FTIR and activity measurements) in an Edwards E306A chamber. Fig. 1 shows a plot of the QCM mass uptake recorded *ex situ* from a 250 Å thick ODA film as a function of time of immersion in the pepsin solution. Details of the QCM measurement procedure may be obtained from our earlier reports.[9,10] It can be seen that the diffusion of pepsin into the lipid matrix is extremely rapid with maximum protein uptake being accomplished within 10 min of immersion. The small time scale for encapsulation of the enzyme in the lipid matrix is a particularly attractive feature of this approach and considerably improves upon the days to weeks timeframe required in other techniques for synthesis of such bio-composites.[3,6] At pH 3, the ODA matrix is positively charged (pK_B of ODA = 10.5) while the pepsin molecules are negatively charged (pI of pepsin ≈ 1.0) thereby leading to attractive electrostatic interactions and a rapid diffusion of the proteins into the lipid matrix (see inset of Fig. 1). The maximum mass loading in the film (Fig. 1) is measured to be *ca*. 3900 ng cm^{-2} of the film yielding a pepsin concentration of 6.3×10^{13} molecules per cm^2 of the ODA–pepsin composite film.

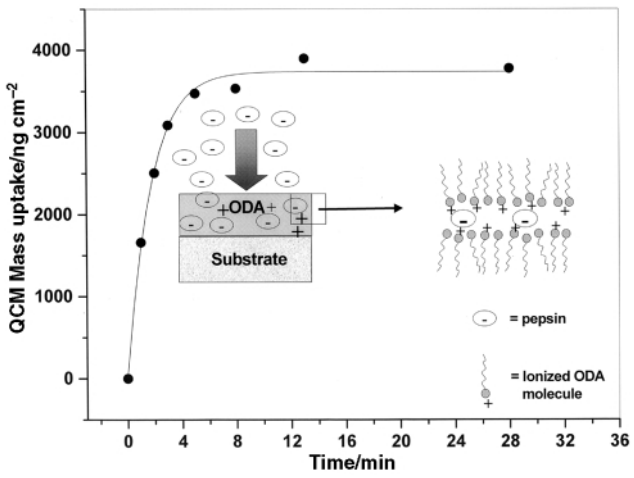

Fig. 1 QCM mass uptake curve measured *ex situ* as a function of time of immersion of 250 Å thick ODA films in 10^{-6} M pepsin solution at pH 3. The schematic in the figure illustrates the procedure adopted for synthesis of the pepsin–ODA composite and the probable microscopic structure of the film and enzyme encapsulation.

It is well known that proteins spontaneously concentrate at the phase boundaries[12] and simple surface adsorption of pepsin on the ODA film surface must be ruled out. Contact angle measurements of a sessile water drop (1 μl, Rame Hart 100 goniometer used) were carried out on a 250 Å thick ODA film on Si(111) substrates after immersion in 10^{-6} M pepsin solution at pH 3 for 60 min and careful washing of the film. The measurements carried out at different points on the film surface yielded a mean value of 90° which is very close to the contact angle of 100° recorded for the as-deposited ODA film. The contact angle recorded for the pepsin–ODA composite film is much higher than the values of 20 and 15° measured for the bare Si(111) substrate surface and a pepsin film formed on Si by evaporating a drop of the pepsin solution respectively, indicating clearly that the pepsin molecules are not adsorbed on the surface of ODA but within the lipid film.

Fig. 2 shows the FTIR spectra recorded from a 1000 Å thick as-deposited ODA film (curve 1), the ODA film after immersion in 10^{-6} M pepsin solution kept at pH 3 for 60 min (curve 2) and the pepsin–ODA nanocomposite film after testing the catalytic activity of the pepsin–ODA film by immersion in hemoglobin solution (curve 3, as discussed subsequently). A number of vibrational modes can be observed for the three films. The amide I band occurs at 1647 cm^{-1} for the pepsin–ODA nanocomposite film (feature A, curve 2, Fig. 2) and the film after reaction with hemoglobin (curve 3, Fig. 2). Whereas a small feature at this wavenumber does occur in the as-deposited ODA film, the intensity of this band increases in films 2 and 3 clearly showing that it originates in the pepsin molecules. The position of this band is close to that reported for native proteins in earlier reports[6,13] and indicates that the

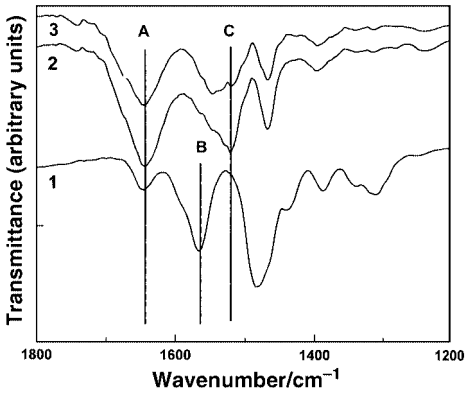

Fig. 2 FTIR spectrum recorded from a 1000 Å thick ODA film before (curve 1) and after immersion for 60 min in pepsin solution at pH 3 (curve 2). The spectrum measured from the pepsin–ODA film after assay with hemoglobin is also shown (curve 3). Features A–C are discussed in the text.

secondary structure of the enzyme in the ODA environment is unperturbed. The amide II band, which occurs at 1521 cm^{-1} (feature C, Fig. 2), can also clearly be seen for the pepsin–ODA composite film as well as the film after the activity test with hemoglobin (curves 2 and 3 respectively). This band also indicates that the secondary structure of the protein is maintained in the encapsulated form.[13] Small differences are observed in the amide II bands for the pepsin–ODA films before and after reaction with hemoglobin. This may be due to a contribution of hemoglobin molecules in the ODA matrix in the digested/undigested form and suggests a possible mechanism for the action of encapsulated pepsin on the heme-protein. However, further work is required before an unequivocal statement can be made on this observation. The origin of the band at 1564 cm^{-1} (feature B, Fig. 2) is as yet not fully understood but it clearly arises from the ODA matrix and its intensity is reduced on complexation of the ODA molecules with pepsin.

The biochemical activity of the enzyme encapsulated in the lipid matrix was determined by reaction with a solution of hemoglobin (5 mg ml^{-1}) prepared in glycine–HCl buffer (0.05 M, pH 3.0) and by incubating the reaction mixture at 37 °C for 30 min. Pepsin digests hemoglobin and yields acid soluble products which are readily detected by their strong UV signatures at 280 nm.[14] Quartz substrates of known dimensions coated with 250 Å thick ODA films were immersed in pepsin solution for 1 h until the pepsin density in the films reached equilibrium values (6.3×10^{13} pepsin molecules cm^{-2} of film, see QCM studies). These films were immersed in 1 ml of hemoglobin solution (5 mg ml^{-1}) and incubated at 37 °C for 60 min and then withdrawn. The reaction was quenched by addition of an equal volume of 1.7 M perchloric acid to the reaction mixture and the precipitate removed by centrifugation. The supernatant containing the acid soluble tyrosine and tryptophan residues was analysed using UV–VIS spectroscopy and the optical absorbance at 280 nm determined (Shimadzu-6201 PC spectrophotometer operated at a resolution of 1 nm). For comparison, the enzymatic activity of pepsin in solution was determined in a similar fashion. The values obtained from these activity measurements are given in Table 1. It is observed that the activity of pepsin in the ODA matrix is slightly less than that of the enzyme in solution. This may be a consequence of the orientation of the enzyme in the lipid matrix limiting the accessibility of the substrate hemoglobin to the active enzyme sites. Another possibility is that all the enzyme molecules do not participate in the biocatalysis in the first run. That this is so is indicated by the fact that one of the films showed enzymatic activity during three successive runs, albeit considerably reduced each time (Table 1).

Table 1 Comparison of enzymatic activity of pepsin in solution and ODA entrapped pepsin using hemoglobin as the substrate

System	Amount of pepsin/μg	Activity[a]/ units	Activity/ units μg^{-1}
Pepsin	2.0	7.5	3.75
Pepsin–ODA (film 1)	2.7	9	3.33
Pepsin–ODA (film 2, run 1)	3.6	10	2.77
Pepsin–ODA (film 2, run 2)	3.6	1.2	0.333
Pepsin–ODA (film 2, run 3)	3.6	0.5	0.136

[a] One unit of enzyme will produce a change in absorbance at 280 nm of 0.001 min^{-1} at pH 3.0 and 37 °C measured as PCA soluble products using hemoglobin as the substrate (ref. 14).

The different measurements on the pepsin–ODA composite films clearly establish the following. The electrostatically controlled diffusion of the enzyme molecules from the aqueous phase into the lipid matrix may be accomplished under conditions close to that where the enzyme shows maximum activity by suitable choice of the lipid (either cationic or anionic). The enzyme molecules are encapsulated within the ODA matrix without significant distortion to the native structure. The elasticity of the bilayers may be primarily responsible for this and enables the matrix to adopt the contours of the enzyme molecule (Schematic, inset of Fig. 1). The reasonably fast time-scales for the synthesis of the enzyme–lipid composites and the enzyme–friendly encapsulation conditions are a major improvement over other techniques currently being investigated.[1,3,4,6]

Synthesis of the chlorin macrocycle by the '3 + 1' approach

Dennis H. Burns,*[a] Dong Chuan Shi[a] and Timothy D. Lash[b]

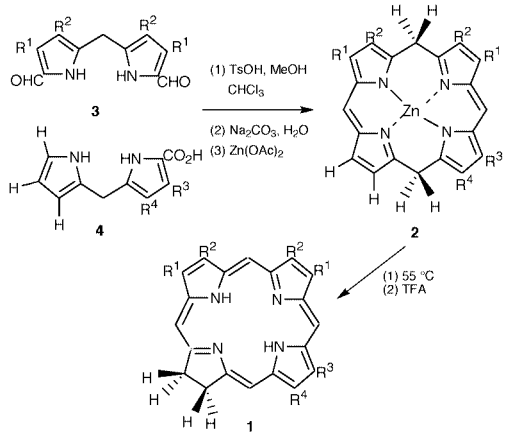
Received (in Corvallis, OR, USA) 1st November 1999, Accepted 29th December 1999

The one-step regioselective synthesis of a chlorin macrocycle from a tripyrrane and bisformylpyrrole is described for the first time; the chlorin is furnished in 46% yield and is constructed from readily prepared pyrroles.

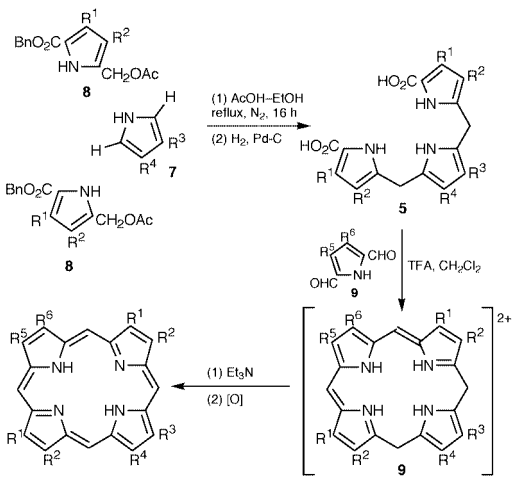
The magnesium chlorins (dihydroporphyrins) found in the photosynthetic proteins of green plants[1] are utilized in light harvesting arrays and electron transfer reaction centers. With similar photophysical characteristics to their chlorophyll counterparts, synthetic chlorins are potentially useful chromophores for use in molecular wires and antenna arrays, all of which make them interesting synthetic targets.[2] The preparation of chlorins regioselectively functionalized for supramolecular assembly is no small task, for in the preparation of an asymmetrically substituted macrocycle it is possible to produce a maximum of eight isomers: four pyrroline-ring regioisomers, each of which could exhibit *cis* or *trans* stereochemistry. We have recently reported the preparation of chlorins **1** from the rearrangement of metallated 5,15-porphodimethenes **2** (Scheme 1).[3] Advantages to this method are (i) the synthesis is highly regioselective, with only one out of four possible pyrroline ring isomers formed as shown, and (ii) the synthesis is short, as the porphodimethene is furnished directly from readily prepared open-chained pyrrolic intermediates *via* the '2 + 2' MacDonald condensation[4] of 1,9-diformyldipyrromethanes **3** and dipyrromethanes **4**. However, a general limitation to our approach is that one of the dipyrromethanes must be symmetrical or the '2 + 2' condensation will furnish two isomeric chlorin macrocycles.

The last few years have seen the active development of the '3 + 1' approach to the synthesis of porphyrins[5] and porphyrin analogs.[6] In this method the macrocyclic ring is furnished by the condensation of tripyrrane **5** with 2,5-diformylpyrrole **6** (Scheme 2). The tripyrrane is prepared in one step by the electrophilic substitution of pyrrole **7** with 2 equiv. of acetoxymethylpyrrole **8**. In theory, the method could allow the preparation of a porphyrin with four different pyrroles and the only symmetry constraint would be that the 2,5-diformylpyrrole must have identical β-substituents in order to form one isomeric porphyrin upon condensation with an asymmetrically substituted tripyrrane. The varied ring substituent pattern that this method allows makes the '3 + 1' approach to the construction of a chlorin macrocycle an attractive alternative to the more symmetry constrained '2 + 2' method. However, the intermediates of the condensation are not known. The 5,10-porphodimethene **9**, other dihydroporphyrins as well as porphyrinogens (5,10,15,20,22,24-hexahydroporphyrin) have all been postulated as intermediates.[5] The latter is not the correct oxidation state to rearrange to a chlorin, and it was not clear if all or just a portion of the dihydroporphyrin intermediates produced in the condensation could be easily metallated or then rearranged into a chlorin like the tautomer **2**. We now have determined the identity of the condensation intermediate and report the first synthesis of a chlorin that utilizes a '3 + 1' approach to prepare the macrocyclic ring.

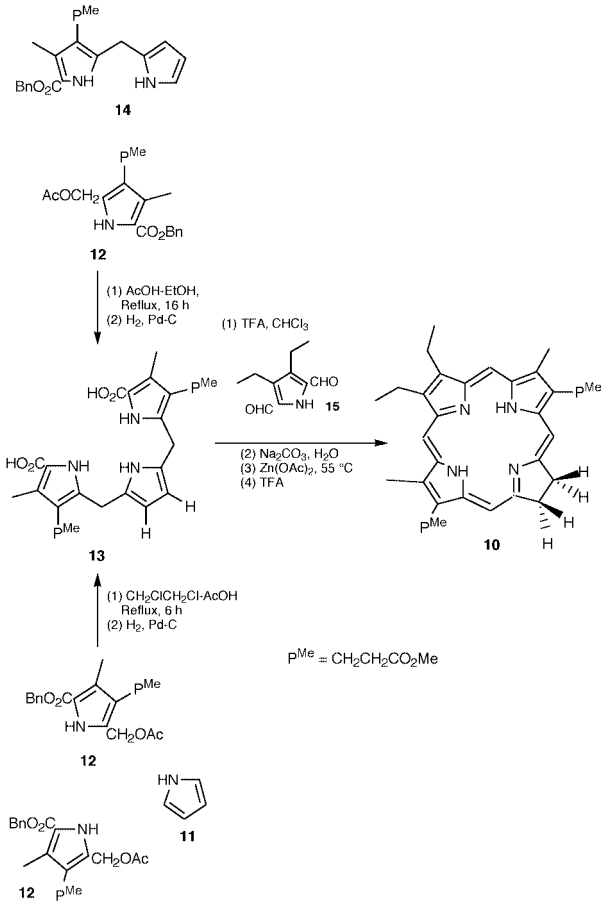
The '3 + 1' synthesis of chlorin **10** is shown in Scheme 3. To demonstrate the utility of the '3 + 1' approach, chlorin **10** was chosen as a target because its substituent pattern was not efficiently accessible *via* the '2 + 2' approach. Pyrrole (**11**) was used because the absence of β-substituents on this ring was expected to control the regiochemistry by analogy to the earlier '2 + 2' chlorin syntheses and furnish only the one ring-reduced isomer as shown.[3] Its use also precluded the formation of pyrroline ring stereoisomers. The propanoate ester pyrroles were used because it was felt that the ensuing substituent pattern on the chlorin macrocycle could lend itself to the fabrication of supramolecular chlorin assemblies of interest. Our initial attempts to make the precursor tripyrrane **13** in the usual manner[5,6] by refluxing pyrrole with 2 equiv. of acetoxymethylpyrrole **12** in an EtOH–AcOH solution overnight did not furnish **13** as expected. This literature procedure works well when the 2,5-unsubstituted pyrrole is substituted in its 3,4-position with electron-donating alkyl substituents. However, the electrophilic substitution reaction of pyrrole with **12** was slow, allowing the solvolysis of **12** and the resultant production of the unreactive ether by-product. We therefore prepared the known dipyrromethane **14**[3] first and refluxed it in an EtOH–AcOH



Scheme 1



Scheme 2



Scheme 3

solution overnight with the acetoxymethylpyrrole **12** to furnish tripyrrane **13** in 60% yield. This demonstrates for the first time that the mild reaction conditions which allow the formation of the acid-sensitive tripyrrane in one step from three pyrrole precursors also work well when using a dipyrromethane and acetoxymethylpyrrole. On the other hand, when pyrrole and 2 equiv. of acetoxymethylpyrrole **12** were refluxed in a 1,2-dichloroethane–AcOH solution for 6 h the tripyrrane **13** was furnished in 45% yield. Pyrrole **12** did not decompose to form an unreactive by-product in the modified reaction mixture.

The benzyl esters of tripyrrane **13** were hydrogenolysed over 10% palladium-on-charcoal and the resulting diacid tripyrrane condensed with 2,5-bisformylpyrrole **15**[5c] in the presence of 5% TFA in $CHCl_3$ under an inert atmosphere.[7] After 2 h the solution was neutralized with $NaHCO_3$, washed with water and dried over Na_2SO_4. The reaction mixture was filtered through an alumina plug, metallated with a saturated solution of $Zn(OAc)_2$ in MeOH, and heated to 55 °C for 2 h. The crude product was demetallated in TFA and chromatographed on alumina (Grade III, eluted with CH_2Cl_2–benzene 65 : 35) to furnish chlorin **10** in 46% yield along with 8% of the corresponding porphyrin.[8] UV–VIS spectroscopy of the reaction mixture after neutralization with $NaHCO_3$ and before metallation revealed that the main macrocyclic intermediate formed in the '3 + 1' condensation was a phlorin (432 nm, broad adsorption at 720 nm). This was a gratifying result, for we have previously shown that the reaction of $Zn(OAc)_2$ with a phlorin produced a metallated 5,15-porphodimethene that would rearrange to chlorin upon heating.[3a] If the 5,10-porphodimethene **9** was ever formed during the '3 + 1' condensation, it must have equilibrated rapidly to the thermodynamically more stable phlorin upon neutralization.

In conclusion, the '3 + 1' approach furnished chlorin in yields as high, if not higher, than with chlorins prepared *via* the '2 + 2' approach. The preparation of a tripyrrane from dipyrromethane and pyrrole precursors demonstrates the feasibility of synthesizing an asymmetrically substituted tripyrrane (*i.e.* one made from three different pyrroles), and corresponding asymmetrically substituted chlorin via the '3 + 1' approach. The relative brevity and simplicity of the synthetic route, utilizing readily prepared precursor pyrroles, makes this an attractive method for the regioselective synthesis of chlorins.

Coordination polymerization of ethylene in water by Pd(II) and Ni(II) catalysts

Anke Held, Florian M. Bauers and Stefan Mecking*

Institut für Makromolekulare Chemie und Freiburger Materialforschungszentrum der Albert-Ludwigs-Universität Freiburg, Stefan-Meier-Str. 31, D-79104 Freiburg, Germany. E-mail: mecking@ruf.uni-freiburg.de

Received (in Cambridge, UK) 29th October 1999, Accepted 5th January 2000

Ethylene is polymerized in water as a reaction medium by Pd(II) and Ni(II) complexes to afford branched or linear homopolymer.

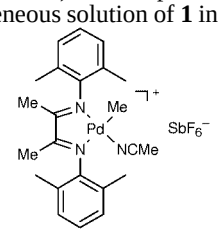
Water possesses unique properties as a reaction medium. It is highly polar and immiscible with most organic compounds, has a high heat capacity and also features a strong propensity for micelle formation. In addition, water is an ideal medium from an environmental and safety perspective. Thus, emulsion and suspension polymerization of olefinic monomers is employed on a vast scale, *e.g.* for the direct production of water-based lattices, used for coatings and paints. In contrast to these free radical polymerizations, transition metal catalyzed coordination polymerization reactions in water have received less attention, as the early transition metal catalysts[1] used predominately are extremely sensitive to moisture.

Late transition metal complexes are generally less sensitive to polar media due to their less oxophilic nature. Due to the propensity of late transition metal alkyl complexes for β-hydride elimination, dimers or oligomers are usually obtained in C–C linkage of ethylene.[2] Only a limited number of catalysts for polymerization to high molecular weight products are known. Most of them are based either on neutral Ni(II) complexes[3,14a] of formally monoanionic bidentate ligands or on cationic Fe, Co, Ni or Pd complexes[4] of neutral multidentate ligands with bulky substituted N donor atoms.[5] The aforementioned stability of late transition metal complexes is demonstrated by the tolerance of some of these polymerization catalysts towards polar functionalized comonomers[3d,4b,c] and polar organic solvents.[3c,d,4c,6]

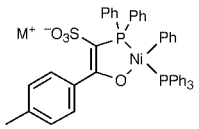
In the context of possible side reactions in transition metal catalysis in aqueous media[7] (such as hydrolysis of metal alkyl species, attack of water on coordinated substrates or coordination of water to the metal center as a ligand), regarding polymerization reactions a conceivable effect of water on chain transfer[8] is of specific interest as small (absolute) changes in the overall chain transfer rate will strongly influence product molecular weight.

A very slow (*ca.* 1 turnover per day) coordination polymerization of ethylene in water catalyzed by a Rh complex has previously been investigated.[9] We now report on the homopolymerization of ethylene in water by neutral Ni(II) and cationic Pd(II) complexes.

Exposure of an aqueous suspension of Pd complex **1**[4c] to ethylene at elevated pressure results in formation of high molecular weight, highly branched polyethylene (Table 1). The reaction is effective under mild conditions (7 bar, room temperature), an increase of the ethylene pressure to 40 bar resulting in a doubling of productivity (entry 1 *vs.* 3). Comparison of 3 and 16 h experiments reveals no significant deactivation of the cationic catalyst in the presence of water (entry 2 *vs.* 3). In comparison to polymerization employing a homogeneous solution of **1** in CH_2Cl_2 as a non-aqueous solvent



1



2a: $M^+ = Na^+$
2b: $M^+ = H_{33}C_{16}NMe_3^+$

(entry 3 *vs.* 4), activities are similar. However, branching is reduced in comparison to reaction in CH_2Cl_2 (69 to 83 branches per 1000 C atoms in runs 1 to 3 *vs.* 109 branches per 1000 C in run 4; determined by ^{1}H NMR). Also, GPC analysis reveals a much higher molecular weight of the polymers obtained in water (Table 1). These findings correspond to the physical appearance of the polymers: whereas the material obtained in CH_2Cl_2 is a highly viscous oil, the polymers obtained in the aqueous reaction medium are rubbery solids. In preliminary

Reaction temperature: room temp. (entries 1 to 4), 70 °C (entries 5 to 13). Total volume of water and/or organic solvent: 100 mL.

[a] Determined *vs.* polystyrene (entry 1 to 4) resp. linear polyethylene (entry 5 to 13) standards. [b] Phosphine scavenger [Rh(CH_2=CH_2)$_2$(acac)] (Ni : Rh 2 : 1). [c] Not determined. [d] Probably mass transfer limited.

experiments, the water ligand of the cationic complex [(ArN=C-(Me)C(Me)=NAr)PdMe(OH_2)]$^+SbF_6^-$ (Ar = 2,6-^{i}Pr$_2$C$_6$H$_3$)[10] was found to be displaced completely upon addition of ethylene in low temperature NMR experiments. This result implies that in catalysis in aqueous media with cationic complexes of this type no severe blocking of coordination sites by water should be expected, in accordance with the above polymerization experiments.

In ethylene polymerisation by a neutral Ni(II) complex with a P,O ligand, introduction of a sulfonate substituent has been reported to enhance formation of higher molecular weight products (toluene as reaction medium).[3c,d] At the same time, the sulfonate group affects water solubility. In order to produce higher molecular weight polymer the absence of strongly coordinating phosphine ligands is required.[3d,11] For this reason we have employed complex **2a**,[12,13] utilizing [Rh(H_2C=CH_2)$_2$(acac)] as a phosphine scavenger. For comparison to water-soluble **2a** with respect to aqueous polymerization in the presence of a water-immiscible solvent (*vide infra*) the novel complex **2b** was prepared by oxidative addition of 4-MeC_6H_4C(O)C($SO_3^-H_{33}C_{16}NMe_3^+$)=$PPh_3$ to [Ni(cod)$_2$] in the presence of PPh_3, or by addition to [Ni(PPh_3)$_4$].[13] Introduction of the large $H_{33}C_{16}NMe_3^+$ cation results in a strong increase in lipophilicity: whereas **2a** dissolves in the aqueous phase upon addition of water to a toluene solution of the complex, **2b** remains in the organic phase.

The stability of C–C linkage catalysts based on Ni complexes with anionic bidentate ligands towards protic media, including water, had been noted early on by the original inventors.[14] However, successful polymerization to afford higher molecular weight products in water has not been reported, to the best of our knowledge. The complex [{κ^2*P*,*O*-Ph_2PC(Ph)=C(OEt)O}NiPh-(PEt_3)] (removal of PEt_3 by phosphine scavengers) was reported to be completely inactive for ethylene polymerization in organic media in the presence of 1000 eq. water.[3d,15] For this reason, we were somewhat surprised to observe formation of linear polyethylenes employing catalysts **2a** and **2b** in an aqueous environment, utilizing only a small amount of water-miscible (acetone) or -immiscible (toluene) organic solvent to enable injection of the phosphine scavenger or the scavenger and **2b**, respectively (Table 1, entries 7 to 10). By comparison to polymerization in neat toluene or acetone[16] (entries 11 to 13), polymer molecular weight is significantly reduced and productivity is lowered in aqueous media. From the data presented, no dramatic effect of water on chain transfer reactions is evident, the lowering of polymer molecular weight also being attributable to a slower chain growth (as reflected by the lower productivity) caused by the lower solubility of ethylene in water. Considering catalyst stability, comparison of entries 5 *vs.* 6 and 9 *vs.* 10 shows that the catalysts are still active for polymerization after several hours in water. A preliminary comparison of the hydrophilic **2a** and the lipophilic **2b** in the multiphase system water/toluene/insoluble polymer (entries 8 and 9) reveals that phosphine abstraction from **2a** is not significantly hampered by the different solubilities of **2a** and [Rh(H_2C=CH_2)$_2$(acac)].

Interestingly, when performing the Ni(II)-catalyzed polymerization in the presence of ionic or non-ionic surfactants (SDS, Triton X-100), stable polyethylene emulsions are obtained. Typically, emulsions with particle sizes in the range of ϕ 80 to 300 nm are obtained at a catalyst productivity of, *e.g.* 1300 mol(ethylene) per mol(Ni) (conditions of run 7, surfactant added).

In conclusion, high molecular weight polymers can result from the coordination polymerizaton of ethylene in water at high catalyst activities. Branched or linear polymers are accessible in water as a reaction medium.

The authors thank R. Mülhaupt for his interest in our work. Financial support by BASF AG is gratefully acknowledged, and we thank B. Manders and M. O. Kristen for valuable discussions. A.H. thanks the Deutsche Forschungsgemeinschaft for a Graduiertenkolleg stipend. A generous loan of $PdCl_2$ was provided by Degussa-Huels AG. GPC analyses of linear polyethylenes were carried out by D. Lilge (BASF) and ^{31}P NMR analyses were provided by D. Hunkler (Freiburg).

Reaction of tetracyanoethylene with SCl_2: new molecular rearrangements

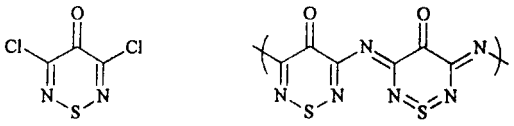
Panayiotis A. Koutentis, Charles W. Rees, Andrew J. P. White and David J. Williams

Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: c.rees@ic.ac.uk

Received (in Liverpool, UK) 23rd November 1999, Accepted 4th January 2000

The chloride ion catalysed addition of SCl_2 to TCNE gives the dicyanomethylene-1,2,6-thiadiazine 3 as major product together with two unexpected minor products, pyrimidine 4 and pyrroloimidazothiadiazine 5, whose X-ray crystal structures are described; the products are derived from interaction of SCl_2 with one cyano group with neighbouring group participation by two others.

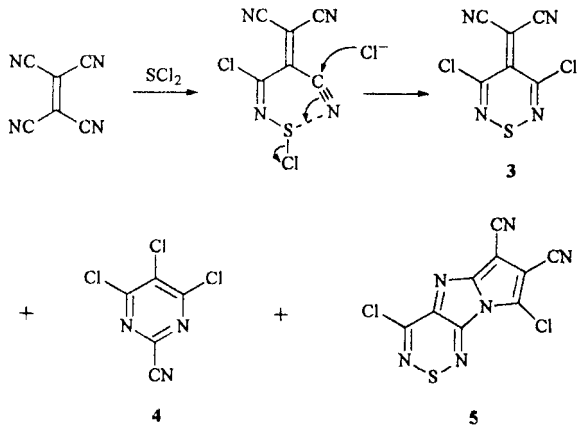
1,2,6-Thiadiazines which are not oxidised on sulfur are rare.[1] One notable exception is 3,5-dichloro-4*H*-1,2,6-thiadiazin-4-one **1** which is readily prepared from dichlorodicyanomethane and SCl_2, followed by hydrolysis with formic acid; the chlorines in **1** can be successively displaced by a range of



1 **2**

nucleophiles, the second requiring more vigorous conditions.[2] We needed a large scale synthesis of the 3,5-diamino derivative for incorporation into a conjugated polymer of type **2**. Since the displacement of the second chlorine of **1** by NH_3 required sealed tubes or pressure vessels, we decided to enhance the reactivity of the chlorines by replacing the 4-keto group in **1** by dicyanomethylene to give the monomer **3**.

The dicyanomethylene compound **3** was not formed by condensing the keto compound **1** with malononitrile, but it was formed slowly in up to 60% yield by the addition of SCl_2 to TCNE catalysed by $BnEt_3NCl$, in CH_2Cl_2 at room temperature (Scheme 1). However the formation of **3** was accompanied by the formation of two unexpected and puzzling minor products; 4,5,6-trichloropyrimidine-2-carbonitrile **4** (5%) and 4,8-dichloro-6,7-dicyanopyrrolo[1′,2′:1,2]imidazo[5,4-*c*][1,2,6]thiadiazine **5** (5%). The dicyanomethylene compound **3** was obtained as bright yellow flakes, mp 134–135 °C, the pyrimidine **4** as colourless, volatile needles, mp 64.5–65 °C, and the pyrroloimidazothiadiazine **5** as deep red needles or prisms, mp > 245 °C with sublimation.



3 **4** **5**

Scheme 1

For the thiadiazinone **1**, which is almost planar,[3] Bird calculated his aromaticity index I_A to be 54,[4] indicating a modestly aromatic compound, *cf.* I_A = 53 for furan and 100 for benzene. The dicyanomethylene analogue **3**, however, has a distinctly non-planar, shallow boat conformation (Fig. 1).† In all four independent molecules in the crystal the N(2)–S(1)–N(6) and C(3)–C(4)–C(5) planes are inclined by *ca.* 25°, thereby distancing the cyano groups from the bulky chloro substituents. Whereas the two C=N bonds in the thiadiazine ring have pronounced double bond character, the C(4)–C(7) linkage is delocalised. Compound **3** has a slightly higher aromaticity index (I_A = 60) than **1**, in spite of being less planar, presumably because the more strongly electron withdrawing group in **3** allows greater contribution from dipolar resonance forms.

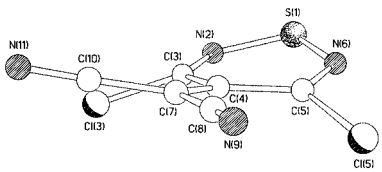


Fig. 1 The molecular structure of **3**. The average S–N, C=N and C(4)–C(7) distances over the four independent molecules are 1.616(7), 1.272(10) and 1.367(10) Å, respectively.

Compounds **4** (Fig. 2) and **5** (Fig. 3) are both planar and delocalised, the latter being the first example of this (14π aromatic) ring system. Crystals of **4** contain two independent molecules which are planar to within 0.031 and 0.071 Å, respectively. The molecules pack with the cyano group of one directed into the π system of the other (Fig. 2), the shortest N···ring centroid distance being 3.22 Å with a C≡N···π angle of 171°. Two polymorphs of **5** were identified; both are monoclinic but one crystallises in a centrosymmetric space group whereas the other is polar. The geometries of the two forms do not differ significantly, being planar to within 0.066 (form 1) and 0.117 Å (form 2), their tricyclic cores having maximum deviations from planarity of only 0.019 and 0.023 Å respectively (Fig. 3). There is distinct bond ordering in the thiadiazine ring and also to a lesser degree in the imidazole, whereas the terminal pyrrole exhibits delocalisation that

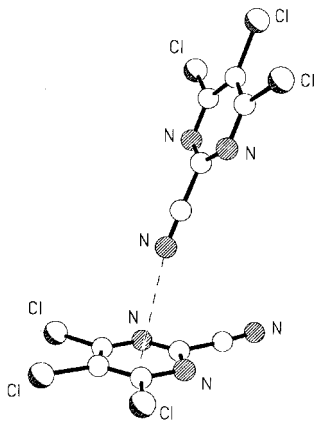

Fig. 2 The molecular structure of **4**.

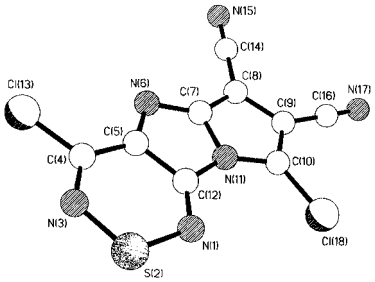

Fig. 3 The molecular structure of **5**.

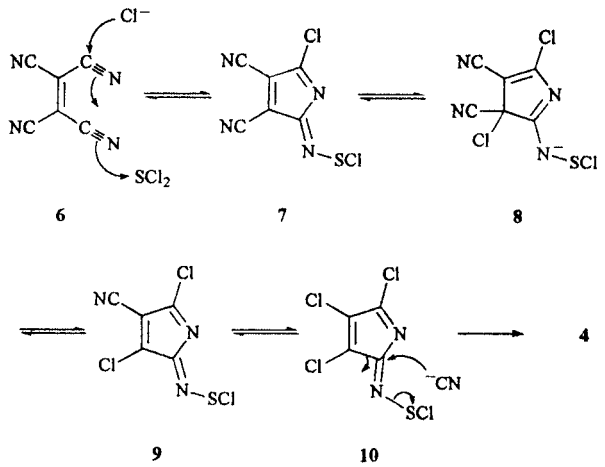
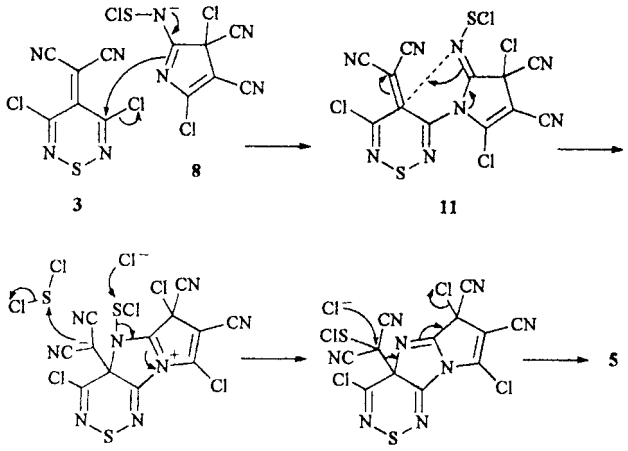
extends from C(8) to C(9) *via* N(11). Despite the differences in packing, both polymorphs contain loosely linked tapes of molecules formed by electrostatic N···Cl interactions.

The formation of **3**, **4** and **5** from TCNE and SCl_2 at room temperature required the presence of chloride ions for a significant rate of reaction; all are presumably initiated by coordination of the electrophilic SCl_2 to a cyanide nitrogen, which activates nucleophilic addition of chloride. This process can be repeated by addition of chloride to a geminal cyano group (Scheme 1), and cyclisation to form the aromatic thiadiazine **3**, which was always the major product. The mechanism of formation of the minor, rearranged, products is much less obvious. However it is possible that a *cis*-vicinal cyano group could also participate in the SCl_2 reaction, with its nitrogen now attacking carbon to form a five-membered ring as shown in **6** (Scheme 2). Various examples of such neighbouring group participation in the reactions of dicyanides with electrophilic reagents have been reported.[5] The intermediate **7**, thus formed, is highly electrophilic and would be subject to successive, reversible attack by chloride ions, ultimately displacing the cyano groups, *via* **8** and **9**, to give the fully chlorinated derivative **10**. This could then undergo a Beckmann-type rearrangement with the developing carbocation being captured by cyanide, in the anhydrous medium, to give the observed pyrimidine **4**. A related, classical, Beckmann rearrangement has been observed in the conversion of analogous azacyclopentadienone oximes into pyrimidones,[6] and Beckmann carbocation intermediates have been efficiently intercepted by cyanide ions.[7]

Formation of **5** could arise by condensation of the major product **3** and the intermediate **7**. One of the chlorine atoms in **3** is very readily displaced by nucleophiles,[8] and it would be expected to react rapidly with the adducts of **7** and chloride ions, such as **8**. The amidine-like nitrogen of **8** would displace a chlorine from **3** (Scheme 3) to give **11**, which could collapse to **12** and finally aromatise to give **5**. It is not known how the dicyanomethylene and other substituents are lost from **12**, but one possibility is shown in Scheme 3. Other bis-nucleophiles react with **3**, displacing a chlorine and the dicyanomethylene to give related polycyclic systems.[8]



Scheme 2



Scheme 3

Thus **3** has been prepared from TCNE and SCl_2, but this reaction is complicated by the involvement of geminal and vicinal cyano groups, after the initial interaction. These neighbouring group interactions lead to the formation of **3** (Scheme 1) or to new molecular rearrangements to give the minor products **4** and **5** (Scheme 2 and 3).

Polymer-supported cobalt carbonyl complexes as novel solid-phase catalysts of the Pauson–Khand reaction

Alex C. Comely,*[a] Susan E. Gibson (née Thomas)[a] and Neil J. Hales[b]

Received (in Liverpool, UK) 29th November 1999, Accepted 10th January 2000

Cobalt carbonyl complexes immobilised onto a 'polymer-bound triphenylphosphine' solid support are effective and practical catalysts of the Pauson–Khand reaction.

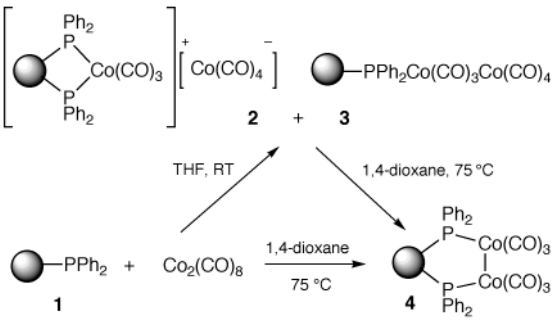
The synthesis of cyclopentenone derivatives *via* the cobalt carbonyl-mediated annulation of an alkyne, an alkene and carbon monoxide, the Pauson–Khand (P–K) reaction, was first described in 1971.[1] A synthetically very important process,[2] the P–K reaction is routinely applied using a stoichiometric amount of the transition metal complex. Although the catalytic process was reported as early as 1973,[1b] it was confined to the strained reactive alkenes norbornene and norbornadiene.

Ensuing years saw little development of the catalytic P–K reaction until a protocol developed by Rautenstrauch,[3] albeit one demanding extremely forcing conditions (310–360 bar ethene/CO, 150 °C) to realise only moderate yields, inspired several new approaches to catalysis. Promoters such as 1,2-dimethoxyethane or water have been investigated,[4] the addition of phosphites is shown to prevent inactive cluster formation[5] and the use of supercritical CO_2 as a reaction medium is described.[6] Alternative sources of zero valent cobalt [$Co(acac)_2/NaBH_4$[7] and (indenyl)Co(COD)[8]] and cobalt carbonyl clusters[9] have also been employed. Although yields and turnovers are excellent, these systems still suffer the requirement of high temperatures and pressures.

The current state-of-the-art can be attributed to Livinghouse who in 1996 reported a photochemically driven process requiring only mild temperatures (50–55 °C) and 1 atm CO.[10] A more recent report from the same group relates that careful control of temperature to within a narrow window (60–70 °C) dispenses with the need for photolytic promotion.[11] Rigorous purification of $Co_2(CO)_8$ in these systems can be obviated, reports Krafft, by prior base washing of the glassware.[12] Problems associated with the very labile $Co_2(CO)_8$, however, have also spurred the development of stable cobalt–alkyne catalyst precursors.[13]

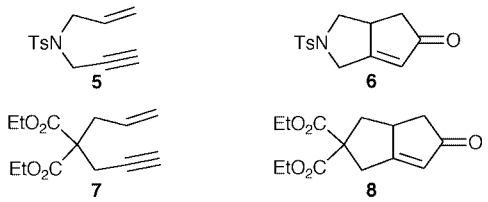
Given our current interest in polymer-supported cobalt complexes[14] and increasing awareness of the environmental and handling advantages conferred by such solid-phase methodologies,[15] we decided to determine the viability of the catalytic P–K reaction using immobilised cobalt carbonyls.† Our preliminary investigations, which reveal for the first time that polymer-supported cobalt complexes do indeed catalyse the P–K reaction, are reported herein.

The cobalt carbonyl resins to be tested as catalyst precursors were prepared as follows.[14] Reaction of 'polymer-bound triphenylphosphine' **1**‡ with $Co_2(CO)_8$ in THF at room temperature generated a resin-bound mixture of phosphine-substituted cobalt carbonyl complexes **2** and **3** (*ca.* 1:1) (Scheme 1). The purple resin, which is significantly more air-stable than $Co_2(CO)_8$, was characterised on the basis of its IR and ^{31}P NMR spectra.[14] Heating this resin at 75 °C in 1,4-dioxane cleanly converted it into a second form, assigned the structure of the neutral bisphosphine **4** on the basis of its IR and ^{31}P NMR spectra.[14] Resin **4**, however, can be more conveniently prepared directly from **1** and $Co_2(CO)_8$§ without prior isolation of **2** + **3**.



Scheme 1

In light of the mild and very attractive conditions reported by Livinghouse for the catalytic P–K reaction, and in particular the thermal window identified between 60 and 70 °C,[11] it was these conditions which were used as the basis for our initial experiments with the cobalt–carbonyl loaded resins.¶ At 65 °C we were very encouraged by the observation that 5 mol% of either precursor **2** + **3** or **4** effected a moderate conversion of enyne substrate **5**[17] to cyclopentenone **6**[10] after 24 h in THF



under a 50 mbar overpressure of CO (Table 1, entries 1 and 2). In preliminary steps to optimise the methodology, the first parameter investigated was temperature. An increase to 70 °C (Table 1, entries 3 and 4) resulted in a significant increase in conversion for both catalyst precursors, the bisphosphine-substituted complex **4** again proving to be the most effective

Table 1 Conversion of substrates **5** and **7** into **6** and **8** respectively *via* the catalytic Pauson–Khand reaction using cobalt resins **2** + **3** and **4**¶

Entry	Catalyst precursor (5 mol%)	*T*/°C	Substrate	Product	Yield (%)[a] (isolated)
1	**2** + **3**	65	**5**	**6**	22
2	**4**	65	**5**	**6**	48
3	**2** + **3**	70	**5**	**6**	37
4	**4**	70	**5**	**6**	66 (61)
5	**2** + **3**	75	**5**	**6**	21
6	**4**	75	**5**	**6**	28
7	**2** + **3**	70	**7**	**8**	28
8	**4**	70	**7**	**8**	57 (49)

[a] Describes percentage conversion measured by ^1H NMR spectroscopy. Isolated yields are those obtained after flash column chromatography. Products were characterised by comparison of their ^1H, ^{13}C and IR spectra with the literature values (ref. 10).

producing 66% conversion and 61% isolated yield of **6**. The consequence of a further 5 °C increase in temperature, however, was a precipitous drop in conversion for both forms of the catalyst alike (Table 1, entries 5 and 6).

A further substrate was subjected to our preliminarily optimised conditions. Hence, enyne **7**[10,18] was cyclised to cyclopentenone **6**[10] in a respectable 49% isolated yield, catalyst precursor **4** again resulting in the highest conversion (Table 1, entries 7 and 8).

In conclusion, we have shown for the first time that solid-phase cobalt carbonyl complexes have significant potential as catalysts of the P–K reaction. As with all supported catalysts, a very simple work-up procedure is required: filtration of the polymer-bound catalyst and concentration of the filtrate. A further advantage conferred by the increased air-stability of the immobilised cobalt complexes is ease of handling using readily available laboratory equipment. Our results, together with the environmental advantages of immobilising metal carbonyls on a solid support, suggest that this new approach to the P–K reaction is worthy of considerable further investigation.

The authors wish to thank AstraZeneca UK Ltd. for a studentship (A. C. C.).

Notes and references

† Polymer-bound P–K substrates have been cyclised in the presence of stoichiometric amounts of $Co_2(CO)_8$ (ref. 16).

‡ 'Polymer-bound triphenylphosphine' (commercially available from Fluka, ~1.6 mmol P g^{-1}) describes a diphenylphosphino polystyrene polymer crosslinked with 1% divinylbenzene.

§ The experimental procedure for the formation of **4** is as follows: commercial polymer-bound triphenylphosphine (1 g, ~1.6 mmol P) was suspended in oxygen-free anhydrous 1,4-dioxane (15 cm^3) and allowed to swell for 30 min under N_2 agitation. A solution of commercial $Co_2(CO)_8$ complex (383 mg, 1.12 mmol) in anhydrous, deoxygenated 1,4-dioxane (5 cm^3) was added under nitrogen agitation, the black mixture was left at room temperature for 30 min and subsequently heated to 75 °C for 16 h. After cooling, the resin beads were filtered, washed with alternate aliquots of THF and Et_2O until the filtrate became colourless, and dried *in vacuo* to afford deep purple beads of **4** {1.15 g, 50% P site complexation, 0.35 ± 0.05 mmol $[Co_2(CO)_6]$ g^{-1}}.

¶ A general experimental for the catalytic P–K reaction is as follows: resin **4** {63 mg, 0.025 mmol $[Co_2(CO)_6]$} and substrate **5** (125 mg, 0.5 mmol) were combined in a 10 cm^3 round-bottomed flask fitted with a condenser. The apparatus was thoroughly purged with CO and sealed under 1.05 bar CO. CO-saturated THF (5 cm^3) was added and the mixture was heated to 70 °C for 24 h. Filtration of the pale brown mixture, thorough washing of the polymer beads with alternate aliquots of THF and Et_2O, and concentration of the combined filtrates *in vacuo* afforded cyclopentenone **6** [66% conversion by ^1H NMR spectroscopy; 85 mg, 61% isolated by flash chromatography (SiO_2, EtOAc–light petroleum, 2:8 to 4:6 gradient elution), 0.31 mmol].

Synthesis of the macrocyclic core of apoptolidin

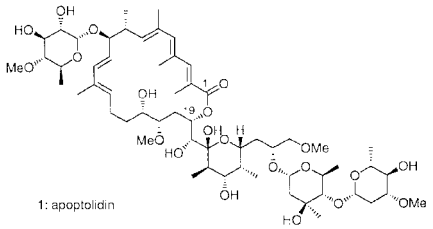
K. C. Nicolaou,* Yiwei Li, Bernd Weyershausen and Heng-xu Wei

Department of Chemistry and The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037, USA and Chemistry and Biochemistry, University of California San Diego, 9500 Gilman Drive, La Jolla, California 92093, USA. E-mail: kcn@scripps.edu

Received (in Cambridge, UK) 17th January 2000, Accepted 20th January 2000

The convergent synthesis of the apoptolidin macrocyclic core is described.

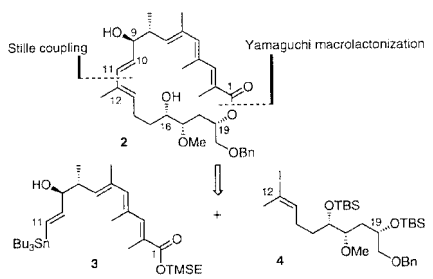
Apoptolidin (**1**) is a recently discovered natural product possessing impressive biological properties, including the



selective induction of apoptosis in rat glia cells transfected with adenovirus E1A oncogene[1] in the presence of normal cells.[2] Originally isolated from cultures of *Nocardiopsis* sp by Hayakawa and co-workers in 1997,[3] this compound possesses a novel molecular architecture whose central domain consists of a 20-membered macrocyclic lactone containing independent conjugated triene and diene systems. Because of its important biological activity and novel molecular features, apoptolidin (**1**) was deemed a prime target for total synthesis. Herein we report a convergent construction of the apoptolidin macrocyclic core (**2**) demonstrating a potential strategy for an eventual total synthesis of the natural product.

In developing a synthetic strategy to access **2** (Scheme 1), we envisaged union of key intermediates **3** and **4** *via* a Stille coupling reaction[4] followed by a Yamaguchi type macrolactonization[5] process as a means to construct the 20-membered macrocycle. Based on the expected conformational rigidity that would be conferred to the backbone of the seco, open-chain precursor of this macrocyclic system by the series of its double bonds, we hypothesize that C1–C19 lactonization would be highly preferred over C1–C16 or C1–C9 ring closures. To test this hypothesis, the synthetic strategy was tailored so that all three hydroxy groups (at C9, C16 and C19) would be free from protection prior to lactonization. The successful execution of this strategy is described below.

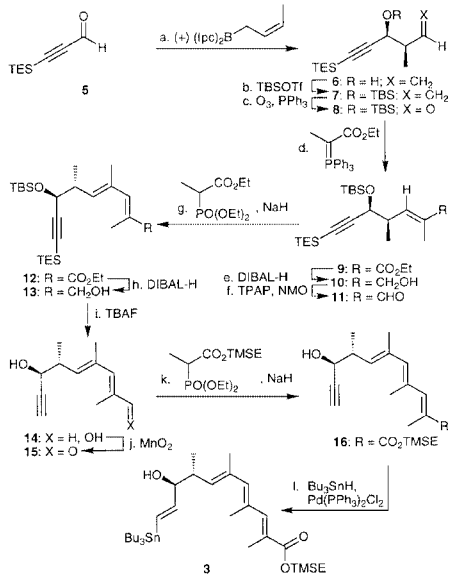
The construction of the C1–C11 fragment **3** began with **5** and proceeded as shown in Scheme 2. Thus, the known **5**[6] was treated with Brown's *cis*-crotylborane [(+)-Ipc$_2$B(*cis*-crotyl)][7] to furnish **6** (82% yield), which was readily protected as a TBS



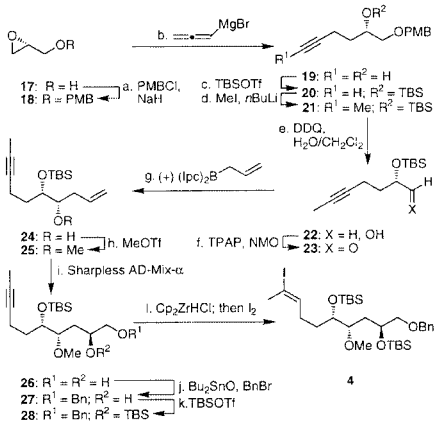
Scheme 1

ether (TBSOTf, 2,6-lutidine) to afford **7** (97% yield). Ozonolytic cleavage of the terminal olefin in **7** afforded **8**, which reacted with Ph$_3$P=C(CH$_3$)CO$_2$Et (toluene, 100 °C) to afford **9** in 90% yield after chromatography. Reduction of this intermediate using DIBAL-H (90% yield) followed by oxidation (NMO/TPAP) afforded **11** *via* **10**. Subsequent homologation employing a Horner–Wadsworth–Emmons reaction[8] [(EtO)$_2$P(=O)–CH(CH$_3$)CO$_2$Et, NaH] provided **12** in 90% overall yield from **10**. After reduction of the ester moiety in **12** (DIBAL-H, 89%) and TBAF-mediated removal of both silyl protecting groups (98% yield), it was found that upon exposure of the resulting diol **14** to MnO_2 in dilute CCl_4 solution, the primary hydroxy group was selectively oxidized to afford **15** in 97% yield. Use of a second Horner–Wadsworth–Emmons olefination [(EtO)$_2$P(=O)–CH(CH$_3$)CO$_2$TMSE, NaH, THF] provided the desired all-*trans* **16** in 65% yield. In the final transformation, Pd^0-catalyzed hydrostannation [Bu^{3}SnH, Pd(Ph$_3$P)$_2$Cl$_2$ cat., THF][9] provided a 4:1 mixture of β-(*E*) and α-regioisomers, which were separated chromatographically to afford the desired [β-(*E*)] vinylstannane **3** in 69% yield.

The synthesis of the C12–C19 fragment (**4**) commenced with PMB protection (PMBCl, NaH, 90%) of the commercially available (*S*)-glycidol (**17**) leading to **18** (Scheme 3). Addition



Scheme 2 *Reagents and conditions*: (a) (*Z*)-(+)-crotyldiisopinocampheylborane (2.5 equiv.), THF, −78 °C; then NaBO$_3$·4H$_2$O (15 equiv.), THF–H$_2$O (1:1), 25 °C, 12 h, 82%; (b) TBSOTf (1.5 equiv.), 2,6-lutidine (2.0 equiv.), CH_2Cl_2, 0 → 25 °C, 12 h, 97%; (c) O_3, Sudan red 7B (0.02 equiv.), CH_2Cl_2, −78 °C; then PPh_3 (1.5 equiv.), −78 → 25 °C, 12 h; (d) Ph$_3$P=C(CH$_3$)CO$_2$Et (10.0 equiv.), toluene, 100 °C, 12 h, 90% for 2 steps; (e) DIBAL-H (2.5 equiv.), −78 °C, 2 h, 90%; (f) TPAP (0.05 equiv.), NMO (6.0 equiv.), 4 Å MS, CH_2Cl_2, 25 °C, 30 min; (g) NaH (5.0 equiv.), (EtO)$_2$P(=O)CH(CH$_3$)CO$_2$Et (5.0 equiv.), THF, 0 → 25 °C, 1 h, 81% for 2 steps; (h) DIBAL-H (2.5 equiv.), −78 °C, 2 h, 89%; (i) TBAF (3.0 equiv.), THF, 0 → 25 °C, 1 h, 98%; (j) MnO_2 (20 equiv.), CCl_4, 25 °C, 3 h, 97%; (k) NaH (6.0 equiv.), (EtO)$_2$P(=O)CH(CH$_3$)CO$_2$TMSE (6.0 equiv.), THF, 0 → 25 °C, 5 h, 65%; (l) Bu$_3$SnH (4.0 equiv.). PdCl$_2$(PPh$_3$)$_2$ (0.05 equiv.), THF, 0 °C, 30 min, 69%. TPAP = Pr$_4$NRuO$_4$.

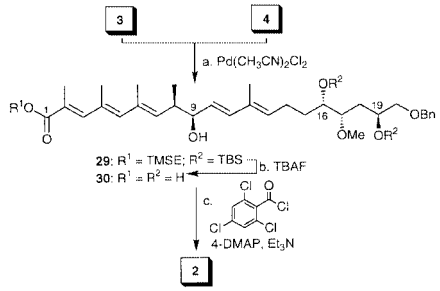


Scheme 3 *Reagents and conditions*: (a) PMBCl (2.0 equiv.), NaH (2.0 equiv.), $Bu_4N^+I^-$ (2.0 equiv.), DMF, 0 → 25 °C, 1 h, 90%; (b) Allenylmagnesium bromide (1.25 equiv.), Et_2O, −78 → 25 °C, 1 h, 90%; (c) TBSOTf (2.5 equiv.), 2,6-lutidine (4.0 equiv.), CH_2Cl_2, 0 → 25 °C, 97%; (d) BuLi (2.0 equiv.), MeI (5.0 equiv.), THF, −78 → 25 °C, 2 h, 95%; (e) DDQ (2.0 equiv.), CH_2Cl_2–H_2O (18:1), 0 → 25 °C, 97%; (f) TPAP (0.05 equiv.), NMO (6.0 equiv.), 4 Å MS, CH_2Cl_2, 0 → 25 °C, 2 h, 90%; (g) *B*-(+)-allyldiisopinocampheylborane (4.0 equiv.), Et_2O, −100 °C, 1 h; then $NaBO_3{\cdot}4H_2O$ (15 equiv.), THF–H_2O (1:1), 25 °C, 12 h, 85%, **24**: diastereoisomer *ca.* 10:1; h) MeOTf (3.0 equiv.), 2,6-di-*tert*-butyl-4-methylpyridine (5.0 equiv.), CH_2Cl_2, 40 °C, 24 h, 85%; (i) $K_3Fe(CN)_6$ (3.0 equiv.), K_2CO_3 (3.0 equiv.), $(DHQ)_2$-PYR (0.02 equiv.), OsO_4 (0.01 equiv. 2.5 wt% in Bu^tOH), Bu^tOH–H_2O (1:1), 0 °C, 12 h, 85%, **26**: diastereoisomer *ca.* 6:1; (j) Bu_2SnO (1.1 equiv.), toluene, 110 °C, 12 h; then BnBr (1.2 equiv.), $Bu_4N^+I^-$ (1.5 equiv.), toluene, 80 °C, 2 h, 85%; (k) TBSOTf (2.5 equiv.), 2,6-lutidine (4.0 equiv.), CH_2Cl_2, 0 → 25 °C, 97%; (l) Cp_2ZrHCl (2.0 equiv.), THF, 50 °C, 2 h; then I_2 (2.0 equiv.), THF, −15 → 25 °C, 0.5 h, 65%. $(DHQ)_2$-PYR = 2,5-diphenyl-4,6-bis(9-*O*-dihydroquinyl)pyrimidine.

of allenylmagnesium bromide[10] to **18** gave the desired hex-5-yne-1,2-diol (**19**) in 90% yield. Silylation of the free hydroxy group in **19** with TBSOTf–2,6-lutidine followed by methylation of the terminal alkyne (BuLi, McI) afforded **21** in 95% yield. Subsequent removal of the PMB group from **21** in the presence of DDQ in CH_2Cl_2–H_2O (18:1) (97% yield) followed by TPAP–NMO mediated oxidation of the resulting alcohol **22** readily provided **23** (90% yield). Exposure of **23** to β-(+)-allyldiisopinocampheylborane according to Brown *et al.*[11] furnished a mixture of diastereomeric alcohols (*ca.* 10:1 ratio, 85% combined yield) from which the major and desired isomer (**24**) was isolated chromatographically. Methylation of the hydroxy group (MeOTf, 2,6-di-*tert*-butyl-4-methylpyridine, 40 °C, 85% yield)[12] in **24** furnished **25** whose terminal olefin underwent stereoselective dihydroxylation in the presence of AD-mix-α[13] to provide **26** together with its (minor) diastereoisomer (*ca.* 6:1 ratio) in 85% combined yield. The two diastereoisomers could not be easily separated chromatographically at this stage, but after protection of the primary hydroxy group as a benzyl ether (Bu_2SnO, BnBr, toluene),[14] the desired diastereoisomer **27** was readily isolated by flash chromatography. Subsequent protection of the secondary hydroxy group of **27** as a TBS ether (TBSOTf, 2,6-lutidine, 97%) followed by hydrozirconation–iodonation (Cp_2ZHCl, THF, 50 °C; then I_2, −15 °C) generated the key intermediate **4** (65% overall yield) *via* **28**.

With both key intermediates **3** and **4** in hand, the stage was set for the crucial coupling and macrolactonization steps (see Scheme 4). Thus, upon treatment with catalytic amounts of $Pd(CH_3CN)_2Cl_2$ (0.05 equiv.) in DMF, **3** and **4** readily coupled to afford **29** in 60% yield. Subsequent exposure of **29** to TBAF resulted in concomitant removal of all three silyl protecting groups furnishing **30** in 80% yield. Finally, Yamaguchi macrolactonization of seco-acid **30** (2,4,6-trichlorobenzoyl chloride, DMAP, Et_3N) resulted in the ring-selective formation of macrocyclic core **2**† in 60% yield.

The described chemistry demonstrates the feasibility of the present strategy for the chemical synthesis of apoptolidin-like



Scheme 4 *Reagents and conditions*: (a) $Pd(CH_3CN)_2Cl_2$ (0.05 equiv.), DMF, 25 °C, 48 h, 60%; (b) TBAF (6.0 equiv.), THF, 25 °C, 12 h, 80%; (c) Et_3N (6.0 equiv.), 2,4,6-trichlorobenzoyl chloride (1.5 equiv.), THF, 1.5 h, 0 °C; then 4-DMAP (5.0 equiv.), benzene, 25 °C, 1 h, 60%.

compounds for biological screening purposes and paves the way for an eventual total synthesis of apoptolidin itself. Alternative strategies towards this macrocycle, including a palladium(0)-catalysed coupling to form the C11–C12 single bond and an olefin metathesis approach to form the C10–C11 double bond of the construct are in progress.

We thank Drs G. Siuzdak and D. H. Huang for mass spectrometric and NMR assistance, respectively. Facile β-trimethylstannyl promoted 1,5-hydride shifts in cyclooctyl and cyclodecyl systems

Matthew P. Glenn, Kerry G. Penman and William Kitching*

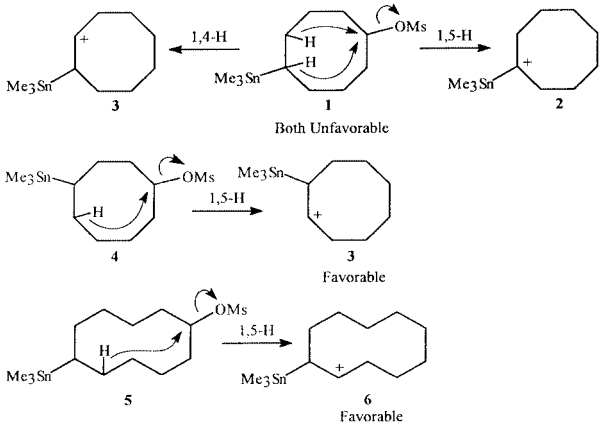
Received (in Cambridge, UK) 30th November 1999, Accepted 19th January 2000

Deuterium labelling and ^{2}H NMR mapping demonstrate that cyclooctyl and cyclodecyl mesylates in aqueous EtOH exhibit greatly enhanced or exclusive levels of 1,5-hydride shift, provided a Me_3Sn group is β to the migrating hydrogen, and after tin group loss from the formal β-stannyl cation, results in regiospecific, transannular alkene formation.

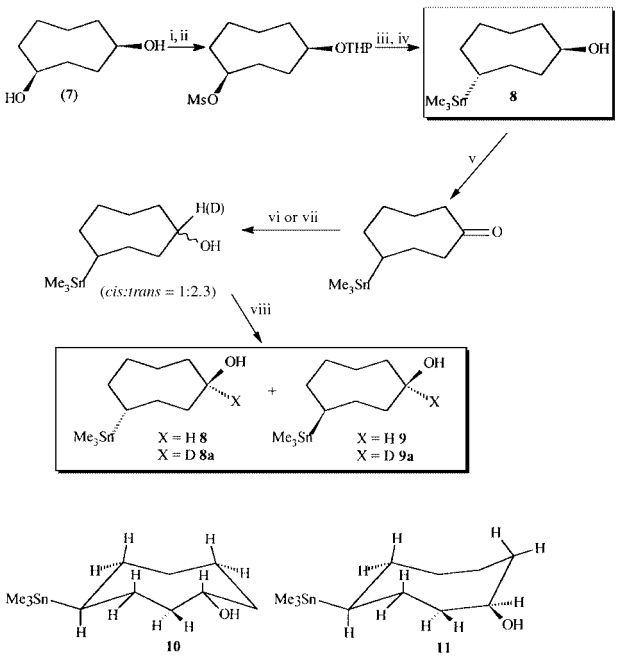
Recently we have described how suitably located Group 14 centred substituents (*e.g.* Me_3Si, Me_3Sn) may regulate transformations of medium-ring epoxides and mesylates.[1] Although 1,5-H shift occurs to the extent of *ca.* 50% in solvolysis of cyclooctyl mesylate,[1,2] this phenomenon is essentially completely suppressed in *cis*- and *trans*-5-mesyloxycyclooctyltrimethylstannanes **1** and is attributable to the relatively unfavourable nature of the α-stannyl cation **2**.[1] Nor do 1,4-hydride shifts compete in these systems, despite the generation of a formal β-stannyl cation intermediate **3**. Other pathways intervene.[1] However, there would be justifiable anticipation that in the 4-mesyloxycyclooctyl- and 6-mesyloxycyclodecyltrimethylstannanes **4** and **5** transannular hydride migration would be especially facile if the 'β-stannyl effect'[3] can operate to stabilise intermediates resembling **3** and **6**, as stable ion data[4] require that cyclooctyl and cyclodecyl cations possess the 1,5-μ-hydrido bridged stuctures (Scheme 1). This proposition is now verified. *cis*-Cyclooctane-1,4-diol **7**[5] was processed as shown below (Scheme 2) to provide *trans*- and *cis*-4-hydroxycyclooctyltrimethylstannanes **8** and **9**, respectively, and the corresponding 4-$^2H_1$-isotopomers **8a** and **9a**.[6]

All stereochemically validated cases of stannyl anion displacement of sulfonate ester groups proceed with inversion of configuration at carbon,[1,7] and on this basis, *cis*-diol **7** provides *trans*-stannyl alcohol **8**. The similar patterns of ^{13}C chemical shifts, through-bond ^{119}Sn–^{13}C coupling constants (especially $^3J_{Sn-C}$)[8] and certain ^{1}H chemical shifts for **8** and **9** indicate that the *chair–chair* (**10**) and *boat–chair* (**11**) conformations are important for the *trans* (**8**) and *cis* stannanes (**9**), respectively.

The behaviour of the mesylates from **8**, **8a**, **9** and **9a** in 75% EtOH–H_2O, buffered with 2,6-lutidine, was examined and the product profiles and ^{2}H location were determined by a combination of ^{1}H, ^{2}H and ^{13}C NMR spectroscopy of (total) product solutions, combined GC-MS analyses and comparisons with the spectra of authentic compounds. This data is summarised in Scheme 3.

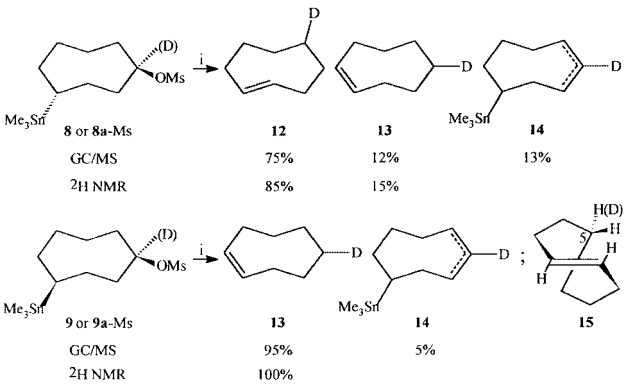


Scheme 1



Scheme 2 *Reagents and conditions*: i, dihydropyran, TsOH, CH_2Cl_2, 52%; ii, MsCl, Et_3N, CH_2Cl_2, 93%; iii, Me_3SnLi, THF, 84%; iv, TsOH, MeOH, 89%; v, tetrapropylammonium perruthenate, NMO, CH_2Cl_2, 77%; vi, $LiAlH_4$, Et_2O, 91%; vii, $LiAlD_4$, Et_2O, 93%; viii, HPLC.

trans-Mesylates from **8** or **8a** afforded very predominantly (*E*)-cyclooctene **12**, whereas *cis*-mesylates provided almost exclusively (*Z*)-cyclooctene **13** and very little Me_3Sn-containing products **14**. The ^{2}H NMR spectra of the cyclooctenes **12** and **13** from the labelled mesylates (from **8a** and **9a**) each

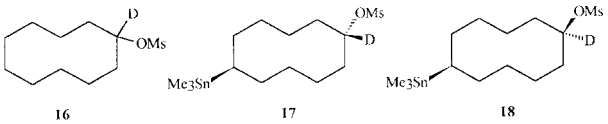


Scheme 3 *Reagents and conditions*: i, 75% EtOH–H_2O, 2,6-lutidine, 300 K.

consisted of a single, sharp high-field resonance at δ 1.42 for labelled (*Z*)-cyclooctene **13** and at δ 1.72 for (*E*)-cyclooctene **12**, confirming exclusive location of the label on a methylene carbon. Because we had already assigned the ^{13}C NMR spectra of a number of specifically ^{2}H-labelled (*Z*)- and (*E*)-cyclooctenes,[9] we were able to establish from the ^{13}C NMR spectra of the product that only 5-$^{2}H_1$-(*Z*)-cyclooctene **13** formed from **9a** and (as a minor product) from **8a** and only *one* diastereomer of **12** from labelled *trans*-mesylate **8a**.

Hence the H-shift was *complete* and *regiospecific* in a *1,5-sense*, and *diastereospecific* in the formation of **12**, which incorporates two stereogenic features. Furthermore, there is a substantial difference in the chemical shifts of the 'inside' and 'outside' protons on C-5 in the rigid (*E*)-cyclooctene systems[10] (see **15**) (δ 0.82 and 1.41;[11] δ 0.7 and 1.7[12]) that reflects the influence of the double bond. Deuterium is located only at an 'outside' position in **12** (δ 1.7) and this specificity appears to require that there is a nexus, perhaps weak, between ionisation and the 1,5-hydride shift. Consideration of the likely conformations **10** and **11** for the stannanes and likely distortions as ionisation proceeds, indicates a favourable pseudo-antiperiplanar disposition of the migrating C–H bond and β-Sn–C bond is accessible and meets the proximity and trajectory requirements of the migration.

β-Trimethylstannyl enhanced 1,5-H shifts have also been observed in similar reactions of the ^{2}H-labelled *trans*- and *cis*-6-mesyloxycyclodecyltrimethylstannanes **17** and **18**, which were acquired from *trans*-cyclodecane-1,6-diol[13,14] in the way summarised in Scheme 2 for the 1,4-cyclooctyl system.



16 **17** **18**

For 1-$^{2}H_1$-cyclodecylmesylate **16** the major products (~90%) were the (*E*) and (*Z*) cyclodecenes with about 67% of the ^{2}H label on the double bond (δ 5.3–5.4) representing unrearranged products, with *ca.* 20% corresponding to rearranged transannular product (δ 1.26).[15,16] However, the *trans*-stannane **17** also provided largely cyclodecenes (~80%) but now the majority of the label (~75%) is located transannularly (δ 1.26), confirming considerably enhanced 1,5-H migration. [Small amounts of both *cis* and *trans* decalins also form (δ 1.55 and 0.76, corresponding to bridgehead absorption)]. The labelled *cis*-mesylate **18** also provides cyclodecenes that are substantially rearranged (δ 1.33, 65–70%), in addition to *cis*-decalin (~20%, δ 1.54) which may result from 'back-lobe' bond formation, as proposed for the exclusive formation of *cis*-bicyclo[3.3.0]octane from *cis*-5-mesyloxycyclooctyltrimethylstannane.[1]

For a variety of alkyl and stannyl substituted cyclooctyl sulfonate esters, and for the stannyl substituted cyclodecylmesylates, relative to the parent system,[17] there is a narrow rate spread within each system, despite substantial variations in the levels of associated transannular hydride shift.[1,18] This fact, along with values for α-secondary ^{2}H-isotope effects,[19] implies that hydride shift lags behind primary ionisation. The present results confirm that 1,5- and not 1,6-H shifts are generally operative in cyclooctyl and cyclodecyl systems and are strongly promoted by a β-Me_3Sn group. These results and those from cyclononyl systems will be discussed in full at a later date, but demonstrate that Me_3Sn-driven transannular functionalization is facile and regiospecific.

The authors are grateful to the Australian Research Council for financial support.

Two different [1,3]-B shifts in phenalenyl(dipropyl)borane

Oleg L. Tok,* Ilya D. Gridnev,* Elena M. Korobach and Yuri N. Bubnov

A. N. Nesmeyanov Institute of Organoelement Compounds, Vavilova 28, 117813 Moscow, Russia.
E-mail: gridnev@scichem.c.chiba-u.ac.jp

Received (in Cambridge, UK) 6th December 1999, Accepted 24th January 2000

Both possible [1,3]-B sigmatropic shifts are observed in the title compound; benzylic rearrangement to position 9 is much faster than allylic migration to position 3.

Twenty years ago Butcher and Pagni argued that the phenalenyl ring system is an excellent choice for the exploration of fluxionality in its organometallic derivatives.[1] However, the trimethylsilyl and trimethylstannyl compounds prepared in their work were non-fluxional on the NMR time scale at temperatures up to 185 °C.[1] Due to orbital restrictions, both silicon[2] and tin[3–5] prefer to rearrange *via* [1,5]- or [1,9]-migration pathways (thermal [1,3]-Si shifts have very high activation barriers[6,7] and known [1,3]-Sn rearrangements are intermolecular).[3,4,8] However, there is only one possibility of intramolecular [1,5]-M migration in a molecule of monosubstituted phenalene, *i.e.* non-degenerate rearrangement to the central position. This is difficult to observe due to the obvious relative instability of the corresponding isomer.

On the other hand, introducing a [1,3]-migrating substituent into position 1 of phenalene provides the first example of a molecule where two different [1,3]-sigmatropic migrations may occur. Being interested in the regularities of the sigmatropic migrations of BR_2 groups,[9] which often migrate by the [1,3]-B shift mechanism,[10–14] we have synthesized a phenalenyl derivative of boron and studied its fluxional behaviour.

1-Phenalenyl(dipropyl)borane **1** was prepared by the reaction of phenalenyllithium **2**[1] with chloro(dipropyl)borane in pentane. Borane **1** is a light-yellow extremely air- and moisture-sensitive oil. It has only limited thermal stability that retards its purification. We failed to distil borane **1** and used samples of approximately 95% purity (main admixture is phenalene), obtained after evacuation of volatile products in vacuum, for the NMR studies.

Assignment of signals in the ^{1}H and ^{13}C NMR spectra of **1** was carried out by standard homo- and heteronuclear 2D chemical shift correlation techniques. The signal of H^9 in the ^{1}H NMR spectrum was distinguished from H^4 by its long-range coupling with H^1 [^4J(H^1–H^9) = 1.1 Hz, confirmed by double resonance].

The NMR spectra of **1** show reversible temperature dependence and are not affected by changes in concentration. Therefore, intramolecular rearrangements take place in **1**. The mechanism of these was elucidated by 2D ^{1}H–^{1}H EXSY (exchange spectroscopy) NMR experiments. Fig. 1 shows the chemical exchange NMR spectrum of **1** taken at 298 K. Four exchange cross-peaks observed in this spectrum unequivocally prove the mechanism of [1,3]-B sigmatropic migrations from position 1 to position 9 of the phenalene ring. The 2D EXSY experiments carried out at higher temperatures also show cross-peaks of lower intensity, corresponding to the second possible degenerate [1,3]-B migration from position 1 to position 3 (Fig. 2, Scheme 1). Thus, both [1,3]-B shifts are observed in **1**, but their rates differ significantly.

The kinetics of the [1,3][9]-sigmatropic migrations of the dipropylboryl group in **1** were measured from a series of 2D ^{1}H EXSY spectra recorded in the temperature interval 290–318 K. At this temperature, the second dynamic process does not manifest itself in the EXSY spectra at short mixing times (τ_m) and therefore, may be neglected. Rate constants were obtained from eqn. (1),[15] where I_{AA} and I_{BB} are the intensities of the diagonal peaks and I_{AB} and I_{BA} are the intensities of the cross-peaks. Rate constants and activation parameters so obtained, derived by Arrhenius and Eyring treatments of the kinetic data, are listed in Table 1.

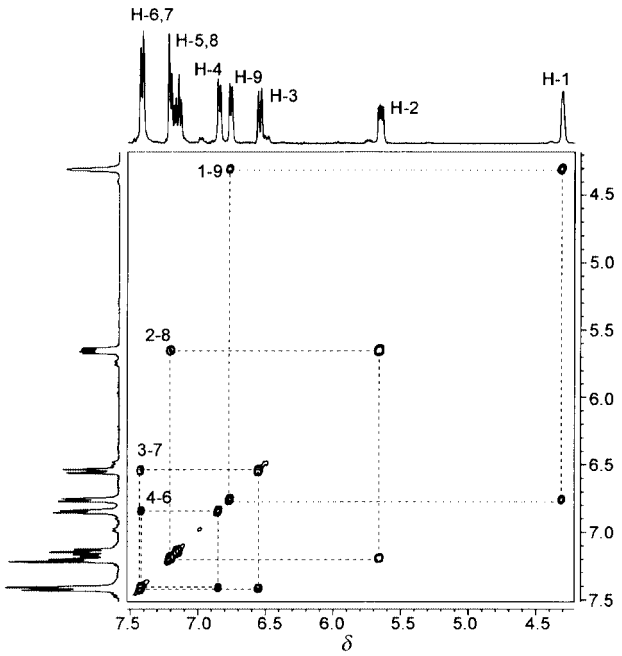

Fig. 1 2D ^{1}H–^{1}H EXSY spectrum (400 MHz, benzene-d_6) of dipropyl(phenalenyl)borane **1** at 298 K with a mixing time of 0.5 s.

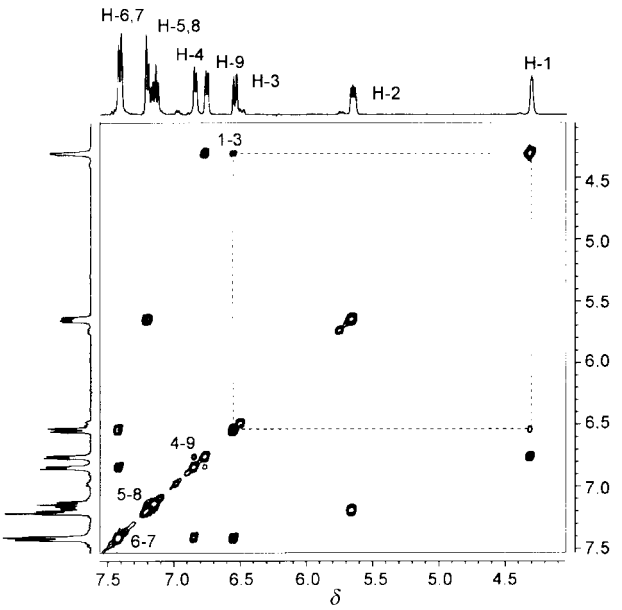

Fig. 2 2D ^{1}H–^{1}H EXSY spectrum (400 MHz, benzene-d_6) of dipropyl(phenalenyl)borane **1** at 313 K with a mixing time of 0.5 s.

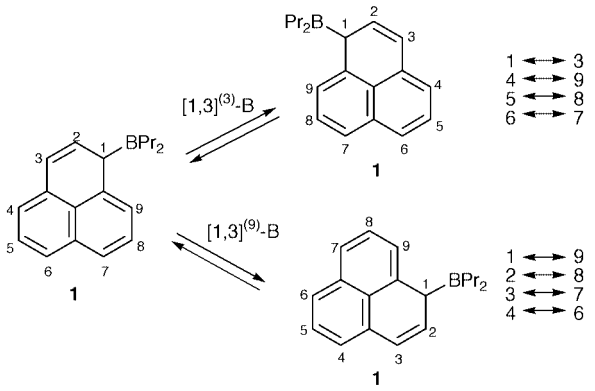
$$k = \frac{1}{\tau_m} \ln \frac{r+1}{r-1}, \quad r = \frac{I_{AA} + I_{BB}}{I_{AB} + I_{BA}} \qquad (1)$$

The kinetic analysis of simultaneous dynamic processes is possible *via* matrix analysis.[15] However, in the present case this approach is complicated by a considerable difference in the rates of the two borotropic migrations and the overlap of some diagonal and cross-peaks. Approximate evaluation of the available data shows that the [1,3]^3-borotropic migration in **1** at 323 K is about 10 times slower the [1,3]^9-B shift.

Either of two [1,3]-B shifts in isolation is spatially fixed to one allylic or benzylic fragment of **1**. However, the *combination of both* results in the possibility for the dipropylboryl group to wander around the whole molecule. This is experimentally illustrated by difference SST (spin saturation transfer) ^{1}H NMR spectra (Fig. 3). Irradiation of the H^1 signal leads to a decrease in the intensities of all signals due to α-protons in **1** (Fig. 3a). Similarly, irradiation of H^2 shows that it is in exchange with both remaining β-protons, H^5 and H^8 (Fig. 3b).



Scheme 1 Two possible borotropic migrations in **1**.

Table 1 Kinetic data and activation parameters for the [1,3]-B shift in borane **1**

T/K	k/s^{-1}	τ_m/s	
290	0.95	0.500	E_A = 19.1 ± 0.4 kcal mol^{-1}
295	1.41	0.300	ln A = 33.0 ± 0.7
298	1.97	0.200	$\Delta H^{\ddagger}_{298}$ = 16.6 ± 0.2 kcal mol^{-1}
303	3.33	0.050	$\Delta S^{\ddagger}_{298}$ = 5.0 ± 0.1 cal mol^{-1} K^{-1}
308	6.06	0.050	$\Delta G^{\ddagger}_{298}$ = 15.1 ± 0.2 kcal mol^{-1}
313	9.86	0.025	
318	14.80	0.010	

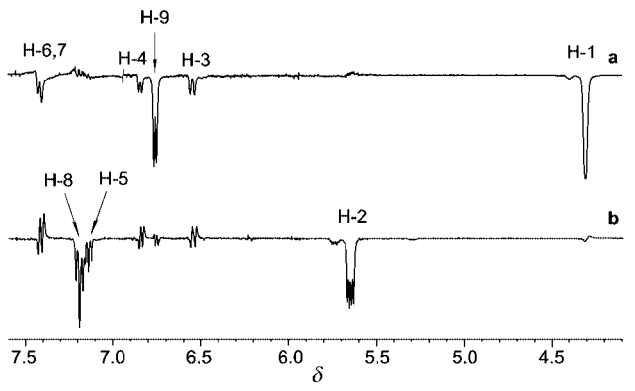


Fig. 3 Difference ^{1}H SST NMR spectra of borane **1** (400 MHz, benzene-d$_6$, 313 K): (a) irradiation of H^1; (b) irradiation of H^2.

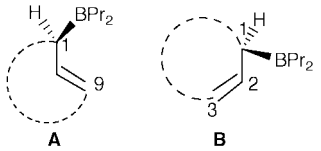

Scheme 2 Schematic representation of the geometries of allylic fragments for [1,3]^9-B (**A**) and [1,3]^3-B (**B**) shifts in **1**.

Since the configurations of the starting compounds and the product are equal for both observed rearrangements,[16] the difference in the activation barriers is exactly the difference in the energies of the corresponding transition states (TS). Therefore, one can conclude that the spatial arrangement of the allylic fragment **A** is much nearer in configuration to the TS than that of **B** (Scheme 2). This conclusion is in agreement with computational results for the [1,3]-B shift.[17]

Thus, we have observed for the first time two different [1,3]-B sigmatropic shifts in one molecule, *viz.* phenalenyl(dipropyl)borane. Further studies on the fluxional behaviour of organometallic derivatives of phenalene are underway in our laboratory.

Hyperbranched porphyrins—a rapid synthetic approach to multiporphyrin macromolecules

Stefan Hecht, Todd Emrick and Jean M. J. Fréchet*

Department of Chemistry, University of California, Berkeley, California 94720-1460, USA.

Received (in Corvallis, OR, USA) 22nd November 1999, Accepted 21st January 2000

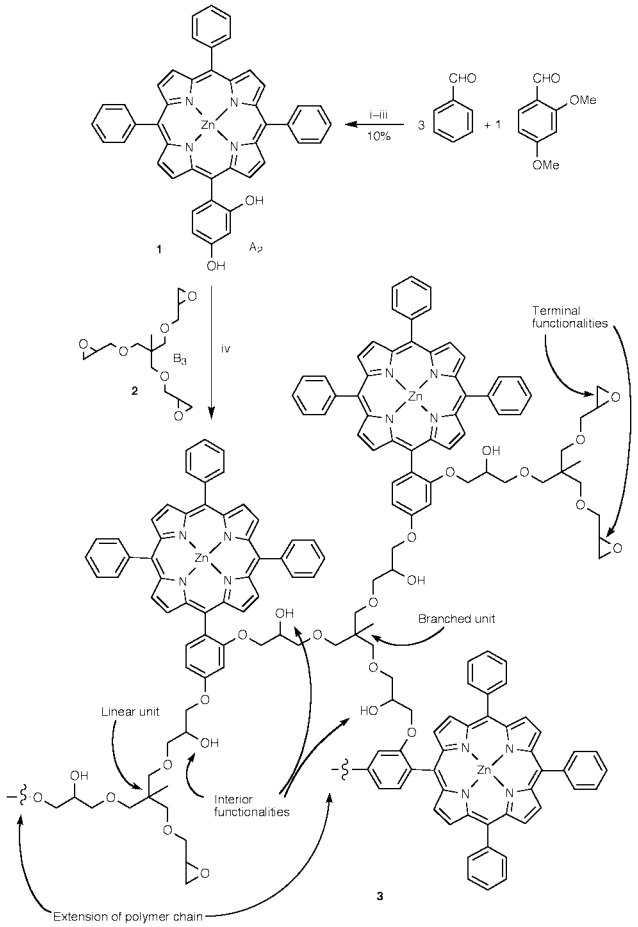
A new class of porphyrin containing hyperbranched polymers has been prepared *via* proton-transfer polymerisation utilising an $A_2 + B_3$ approach, thus providing an accelerated entry into the construction of branched multiporphyrin architectures.

In recent years, significant effort has been made to prepare and study covalently linked multiporphyrin arrays[1] due to their promising role in artificial photosynthesis.[2] The incorporation of porphyrin units into the framework of a dendrimer[3] is of special interest since the dendritic architecture allows for maximum interactions between the chromophores, a necessary condition for efficient energy and electron transfer processes. However, access to such multiporphyrin compounds represents a difficult synthetic challenge, thus only low generation dendritic porphyrins have been prepared to date.[1,4]

We report on an alternative approach to the construction of branched multiporphyrin architectures that takes advantage of the rapid one pot synthesis used for generating hyperbranched polymers.[5] This approach is based on our recent work in proton transfer polymerisation[6] that used an $A_2 + B_3$ route for the preparation of hyperbranched aliphatic polyethers.[7] The system described herein is designed following similar principles. In this case, bisphenolic porphyrin **1** serves as the A_2 monomer and the aliphatic trisepoxide **2**[8] serves as the B_3 monomer (Scheme 1).

Initiation of the polymerisation is expected to proceed *via* deprotonation of the phenol by the base catalyst. This should be followed by ring opening of an epoxide substituent by the nucleophilic phenoxide. Regeneration of phenoxide should then occur by an efficient proton transfer from a different phenol to the formed secondary alkoxide.[7] This process leads to a highly branched polyether architecture incorporating multiple porphyrin units.[9] It was envisaged that the formed polymer chain in the *ortho*-position of the *meso*-phenyl substituents would lead to good solubility by decreasing the porphyrin–porphyrin stacking interactions. The metalated derivative, *e.g.* zinc complex, was chosen to prevent participation of the pyrrole hydrogens in the proton transfer event.

The asymmetric zinc porphyrin A_2 monomer **1**† is accessible in gram quantities *via* a three step procedure in 10% overall yield. The polymerisations employed equimolar ratios of the monomers as a 0.2 M solution in THF at 60 °C using a catalytic amount of base (25 mol% per phenolic group). The successful incorporation of both monomers into the polymer backbone was monitored by matrix assisted laser desorption ionisation time of flight (MALDI-TOF) mass spectrometry (Fig. 1). Unfortunately, ionisation of higher molecular weight material becomes increasingly difficult by the MALDI technique. Therefore, gel permeation chromatography (GPC)‡ was used as an additional complementary method for MW analysis (Fig. 2). The kinetic growth profile appeared as expected for a polycondensation reaction (Fig. 2, inset).[6,7] Upon reaching MW ~10 000,§ the reaction was stopped by removing the heating source, and the resulting polymer **3**¶ was purified by precipitation into methanol (THF–MeOH 1 : 50) giving rise to a fairly narrow polydispersity (PD) of less than 2 (Fig. 2). Control over MW can be achieved easily by variation of reaction time (typically a few days). We reason that slow polymerisation is due to the high dilution conditions made necessary by the relatively low



Scheme 1 *Reagents and conditions*: i, pyrrole, $EtCO_2H$, $PhNO_2$, 120 °C; ii, BBr_3, CH_2Cl_2, 0 °C to room temp.; iii, $Zn(OAc)_2$, $CHCl_3$–MeOH, reflux; iv, $KOBu^t$, THF, heat.

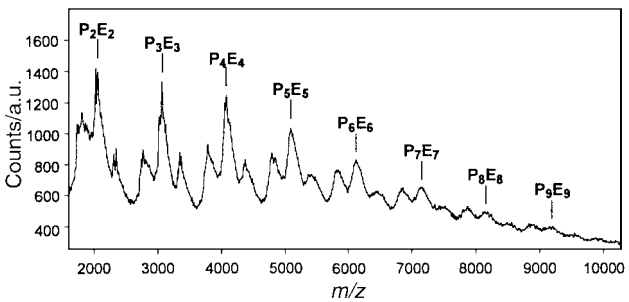


Fig. 1 MALDI-TOF mass spectrum of the polymerisation mixture showing the incorporation of the porphyrin (P) and epoxide (E) monomers. The peaks at lower (higher) mass of each major peak correspond to the loss (addition) of one epoxide unit.

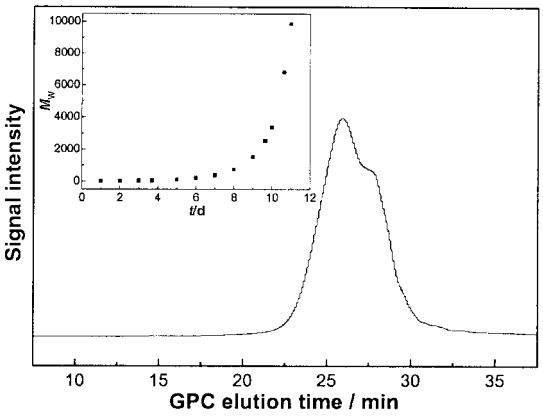

Fig. 2 GPC trace of polymer **3** after precipitation into MeOH (MW = 9900; PDI = 1.9). The inset shows polymer growth as a function of time for a polymerisation run at 60 °C.

solubility of **1**. Higher temperatures result in faster polymer growth, as well as increased PD of the polymers. The polymers were obtained as dark purple powders in 50–60% yields after precipitation, and showed good solubility in a variety of solvents such as $CHCl_3$, THF and DMSO.

Initial photophysical studies revealed only slight changes in the absorption behaviour of polymer **3** compared to monomer **1**, suggesting rather weak electronic coupling of the porphyrin units (Fig. 3).[10] However, a 30% decrease in fluorescence intensity of **3** compared to **1** was observed (Fig. 3, inset). This finding is attributed to an enhanced self-quenching of the chromophores within the macromolecule, presumably by cofacial interactions.

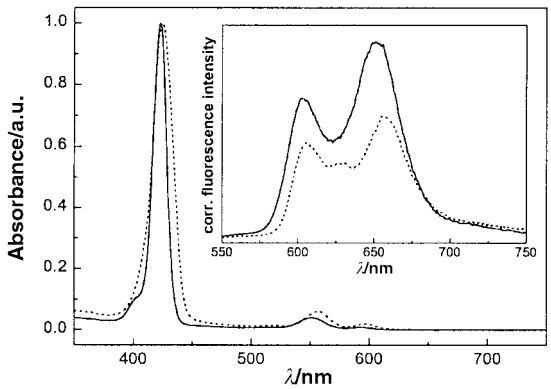

Fig. 3 UV–VIS absorption spectra of monomer **1** (—) and polymer **3** (···) in $CHCl_3$. The inset shows the corrected fluorescence spectra in $CHCl_3$ (λ_{exc} = 420 nm).

In summary, we have developed for the first time hyperbranched polymers incorporating porphyrin chromophores. The described methodology allows for the rapid synthesis of multiporphyrin architectures facilitated by the ease of purification, *e.g.* no chromatography, and it should be of general applicability. Such polymers could serve as interesting materials for a variety of photophysical and electrochemical studies as well as for the construction of optoelectronic devices.[11] Furthermore, structural modification of these polymers by transmetalation or derivatisation of residual functional groups should provide a diverse set of new materials.

Financial support from the AFOSR-MURI program and the National Science Foundation (NSF-DMR 9816166) is acknowledged with thanks.

Rhodium-catalyzed copolymerization of norbornadiene derivatives with carbon monoxide

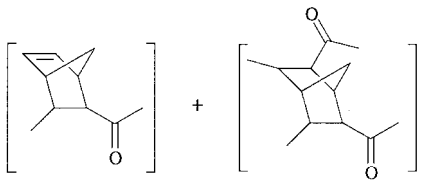
Shi-Wei Zhang and Shigetoshi Takahashi*

The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka, Ibaraki, Osaka 567-0047, Japan. E-mail: takahashi@sanken.osaka-u.ac.jp

Received (in Cambridge, UK) 24th November 1999, Accepted 19th January 2000

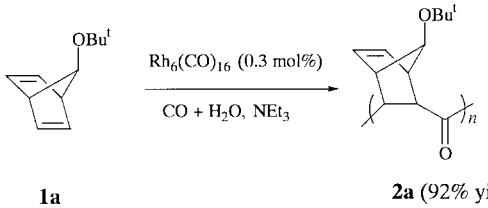
Alternate copolymerization of norbornadiene derivatives with carbon monoxide is catalyzed by a rhodium complex under water-gas shift reaction conditions selectively to give unsaturated polyketones in high yields.

Polyketones are of current interest in terms of functional materials exhibiting photo- and biodegradabilities as well as of starting materials for other classes of functionalized polymers.[1] As a useful method for the synthesis of polyketones, transition metal-catalyzed copolymerization between an olefin and carbon monoxide has been receiving much attention over the last few decades. Among transition metals, mono- and dicationic palladium complexes have predominantly been investigated and developed as excellent catalysts for the perfectly alternating copolymerization of olefins with carbon monoxide until recently.[2] The palladium catalytic system has also been extended to the copolymerization of several dienes with carbon monoxide, giving saturated poly(cyclic ketone)s.[3] Some reports described the copolymerization of norbornadiene with carbon monoxide in the presence of palladium complexes.[2a,4] but the resulting copolymers were characterized to be a mixture of structures A and B. Very recently, Novak and Safir have



A **B**

described a palladium-catalyzed copolymerization of 2,3-substituted norbornadiene derivatives with carbon monoxide to give alternating copolymers.[5] Other than palladium complexes, few effective catalysts are known for the copolymerization of olefins with carbon monoxide,† although the copolymerization of ethylene[7] and arylallene[8] with carbon monoxide catalyzed by rhodium complexes has been reported. In the course of our studies on the rhodium-catalyzed carbonylations of alkynes under water-gas shift reaction conditions,[9] we have now found that norbornadiene and its derivatives can smoothly be copolymerized with carbon monoxide. Here we report the first rhodium-catalyzed copolymerization of norbornadiene and its derivatives with carbon monoxide, producing perfectly alternating polyketones in which one of the two carbon–carbon double bonds of norbornadiene remains intact [eqn. (1)]. The structure



(1)

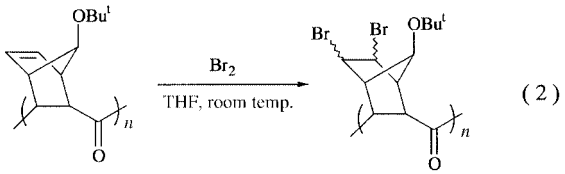
1a **2a** (92% yield)

has been characterized by chemical reactions as well as by spectral analyses.

Thus, a mixture of 7-*tert*-butoxynorborna-2,5-diene **1a** (5 mmol, 0.820 g), $Rh_6(CO)_{16}$ (0.015 mmol, 15 mg), triethylamine (2 ml) and water (1 ml) in benzene (15 ml) was stirred in an autoclave at 55 °C for 24 h under 100 atm of carbon monoxide. After venting the gases from the autoclave at room temperature, the reaction solution was poured into a large amount of methanol (*ca.* 200 ml). Precipitates formed were collected by filtration, washed several times with methanol, and dried *in vacuo* at 50 °C overnight to give product **2a** as a white powder (0.883 g, 92% yield). Product **2a** is soluble in a variety of organic solvents such as acetone, chloroform, benzene and THF, and the GPC analysis (polystyrene standards) indicated **2a** to be a polymer with a molecular weight of 24 500 and a narrow molecular weight distribution (M_w/M_n = 1.38). In its IR spectrum, polymer **2a** showed a characteristic absorption at 1715 cm^{-1} typical of the carbonyl groups of polyketones.[4b,5] The weak absorption band at 1630 cm^{-1} and the stronger band at 3059 cm^{-1} indicated the presence of a carbon–carbon double bond.[10] ^1H and ^{13}C NMR ($CDCl_3$) spectra of **2a** exhibited broad signals but a very simple pattern, suggesting that the copolymer may have a regular structure. The ^1H NMR spectrum showed broad signals in the range 2.55–3.95 ppm, indicating that **2a** contains a ring structure and may be a copolymer of **1a** with CO. Furthermore, the ^1H NMR spectrum revealed that the ratio of olefinic protons to the other protons present in the copolymer is consistent with that predicted on the basis of structure **2a**, suggesting that one of the two C=C bonds of norbornadiene remains intact. Indeed, the $^{13}C\{^1H\}$ NMR spectrum exhibited a signal at 132 ppm attributable to the C=C group and a carbonyl resonance at 208 ppm. When the $^{13}C\{^1H\}$ NMR experiment was performed using an NNE (Heterogated Decoupling without Nuclear Overhauser Effect) pulse sequence, the spectrum exhibited a ratio of sp^2 to sp^3 carbons for the norbornene units consistent with the proposed structure for **2a**, corresponding to an alternating 1:1 copolymer of **1a** with CO. Thermogravimetric analysis (TGA) revealed that **2a** appeared to degrade by a two-step process with a mass loss of 72% at the first degradation step. This mass loss rate corresponds to the theoretical value ($C_5H_5OBu^t/C_{12}H_{16}O_2$ = 0.719) calculated for the case where all of the *tert*-butoxycyclopentadiene moieties $(C_5H_5OBu^t)_n$ of **2a** are liberated by a retro-Diels–Alder reaction.

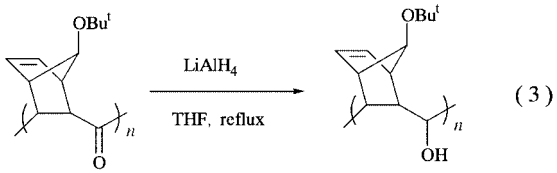
In order to characterize further and prove the structure of **2a**, we tried to convert it into functionalized polymers. Since **2a** has one C=O group and one C=C bond in the repeat unit, it may be easily modified chemically. Thus, as shown in eqn. (2), treatment of **2a** with an excess of bromine at room temperature gave dibromide **3a** in 84% yield. In the ^1H NMR spectrum of **3a**, the signal due to the olefinic protons of **2a** at 6.2 ppm disappeared completely and a new signal appeared at higher field around 4.5 ppm, while the IR spectrum showed that the absorption at 1715 cm^{-1} due to a carbonyl group remained, indicating that the polyketone structure was not affected.‡ In addition, the reaction of **2a** with $LiAlH_4$ in THF at 65 °C selectively gave polyol **4a** in 90% yield [eqn. (3)]. The IR spectrum of **4a** showed the disappearance of the C=O band at 1715 cm^{-1} of polyketone **2a** and the appearance of a new broad band at 3395 cm^{-1} attributable to a hydroxy group. The ^{13}C

NMR spectrum displayed the complete disappearance of the carbonyl carbon at 208 ppm, and the ^{1}H NMR spectrum is also consistent with the structure of **4a**.



(2)

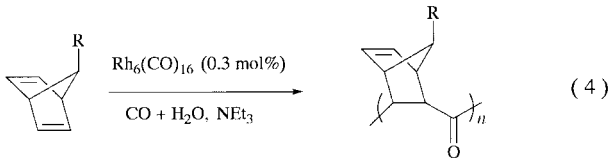
2a **3a** (84% yield)



(3)

2a **4a** (90% yield)

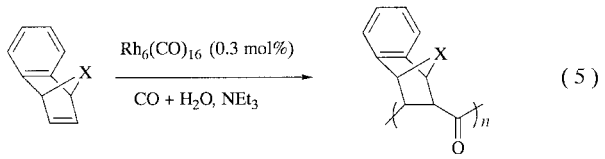
Besides 7-*tert*-butoxynorborna-2,5-diene **1a**, norbornadiene and its derivatives smoothly reacted with carbon monoxide in the presence of $Rh_6(CO)_{16}$ under the same reaction conditions to give the corresponding copolymers in good yields. As shown in eqn. (4), the reaction of norbornadiene **1b** (R = H) gave



(4)

1b R = H **2b** (95% yield)

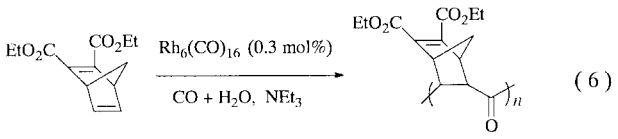
1c R = Ph **2c** (85% yield)



(5)

1d X = C=CMe$_2$ **2d** (90% yield)

1e X = O **2e** (81% yield)



(6)

1f **2f** (81% yield)

copolymer **2b** which is almost insoluble in organic solvents. The high-resolution solid-state ^{13}C NMR (CPMAS) spectrum of **2b** suggested that **2b** has the same structure as **2a**. 7-Phenylnorbornadiene **1c** (R = Ph), which was prepared by treatment[11] of 7-*tert*-butoxynorbornadiene with PhMgBr, also reacted with carbon monoxide to give copolymer **2c** in good yield with a molecular weight of M_w = 9000 (M_w/M_n = 1.38). Interestingly, 1,4-dihydro-9-isopropylidene-1,4-methanonaphthalene **1d** having a norbornadiene skeleton was copolymerized with carbon monoxide to give copolymer **2d** with a high molecular weight (M_w = 25 500) in a high yield [eqn. (5)]. In contrast to **1d**, the reaction of **1e** gave the corresponding copolymer in good yield but with lower molecular weight (M_w = 2570, M_w/M_n = 1.24). Similarly, 2,3-substituted norbornadiene **1f** gave copolymer **2f** in 81% yield, but also with low molecular weight (M_w = 2530, M_w/M_n = 1.20), as shown in eqn. (6). Different electron densities on the C=C bonds of monomers **1d**, **1e** and **1f** could be considered to be a factor affecting the chain growth of the copolymers. In the present reaction system, the steric effect of the substituents on the norbornadiene skeleton might be another factor.

It should be noted that the copolymerization did not occur in the absence of water and amine, suggesting that the copolymerization could be catalyzed by an active rhodium species formed from the reaction of rhodium carbonyl species with water and amine.[7d,9] Detailed investigations are now in progress.

We thank Dr Kenji Wada, Kyoto University, for the measurement of solid-state ^{13}C NMR spectra, and are grateful to the Material Analysis Center of ISIR, Osaka University, for elemental analyses.

Notes and references

† The first transition metal-catalyzed copolymerization of ethylene with carbon monoxide was performed using nickel cyanide complexes in aqueous medium with carbon monoxide pressures as high as 200 atm and at a temperature up to 250 °C to form 'high molecular weight polyketones' (ref. 6). The subsequent advances made using a variety of nickel complexes were outlined in a review [ref. 2(*c*)].

Synthesis of (±)-kainic acid by dearomatising cyclisation of a lithiated *N*-benzyl *p*-anisamide

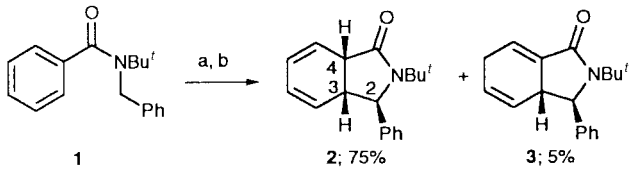
Jonathan Clayden* and Kirill Tchabanenko

Department of Chemistry, University of Manchester, Oxford Road, Manchester, UK M13 9PL. E-mail: j.p.clayden@man.ac.uk

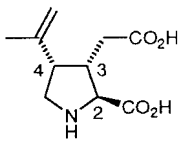
Received (in Liverpool, UK) 24th November 1999, Accepted 12th January 2000

_N_-Benzyl _p_-anisamide 6, on lithiation with Bu^{t}Li in the presence of HMPA, undergoes a stereoselective anionic cyclisation with loss of aromaticity to give a bicyclic enone which may be converted in nine steps to (±)-kainic acid.

We recently described[1] the dearomatising cyclisation reaction of lithiated *N*-benzyl benzamides **1** to give bicyclic cyclohexadienes **2** and **3** (Scheme 1).[2] The reaction is stereoselective, creating three new stereogenic centres, and it is noticeable that the pyrrolidine ring of the major product **2** has the relative stereochemistry of kainic acid **4**. (−)-Kainic acid[3] **4** was first isolated in 1953 from the Japanese marine alga *Digenea simplex*.[4] It has diverse biological activity: as an anthelmintic, *D. simplex* is a traditional remedy in which kainic acid is the active component.[5] Kainic acid is an extremely potent neuroexcitor, binding specifically at the kainate receptor and leading to specific neuronal death.[6,7] Both the anthelmintic and neuroexcitatory properties of kainic acid are dependent on the *cis* C-3–C-4 relative stereochemistry: allokainic acid, the C-4 epimer, is inactive as an anthelmintic[8] and has lower neuroexcitatory activity than kainic acid.[9]

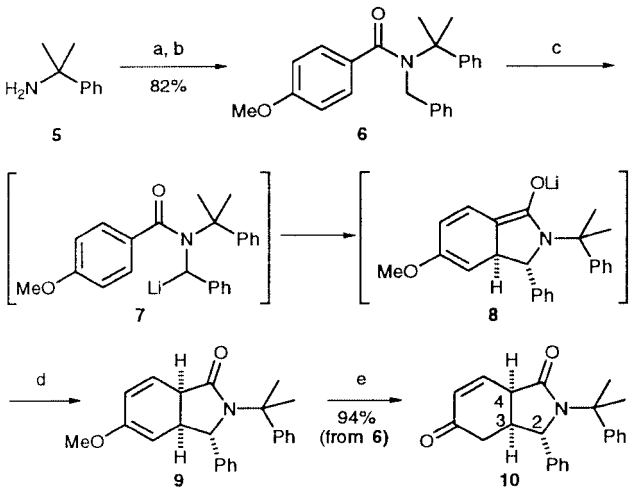


Scheme 1 *Reagents and conditions*: (a) Bu^{t}Li (1.3 equiv.), HMPA (6 equiv.), THF, −78 °C, 16 h; (b) NH_4Cl.

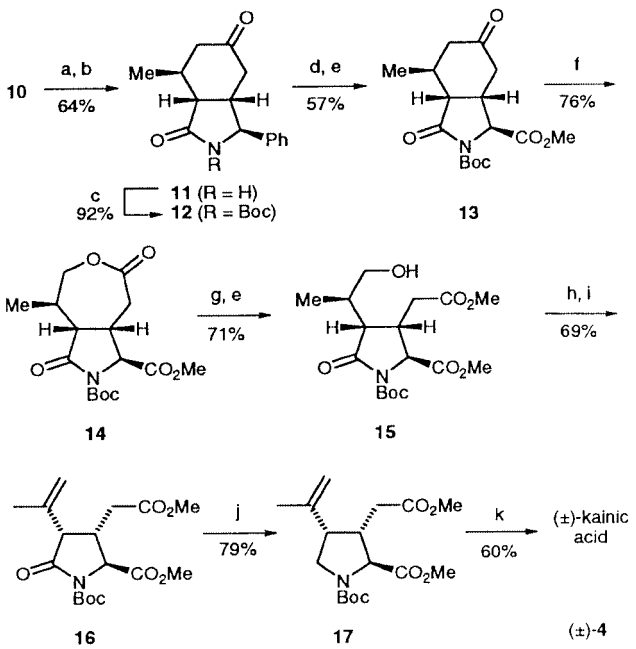


A number of syntheses of (−)-kainic acid[10] and (±)-kainic acid[11] have been reported, several of which[10g–k,p,s,11a] achieve control over the C-3–C-4 stereochemistry by forming these substituents from a cyclic precursor. Our approach to (±)-kainic acid, presented in Schemes 2 and 3, also uses this strategy, exploiting the relative stereochemistry of the dearomatising cyclisation reaction.

Acylation of cumylamine **5**[12] with *p*-anisoyl chloride, followed by alkylation of the secondary amide with benzyl bromide, gave the cyclisation substrate **6**. Tertiary *N*-substituents are necessary for good yields in the cyclisation step, and our early studies had all used *N*-Bu^t amides. However, we had considerable difficulty removing the *tert*-butyl group from the cyclised products: we turned to the cumyl group for ease of removal under acid conditions.[13] The *N*-cumyl-*N*-benzyl amide **6** was lithiated with Bu^{t}Li in the presence of HMPA, but the more bulky group slowed the reaction considerably and the cyclisation of **6** *via* **7** required 60 h at −40 °C to reach



Scheme 2 *Reagents and conditions*: (a) *p*-anisoyl chloride, Et_3N, CH_2Cl_2; (b) NaH, DMF, BnBr, 18 h; (c) Bu^{t}Li (2 equiv.), HMPA (12 equiv.), THF, −40 °C, 60 h; (d) NH_4Cl; (e) THF, 1 M HCl (aq).



Scheme 3 *Reagents and conditions*: (a) Me_2CuLi, Me_3SiCl, THF, −78 °C, 1 h; (b) CF_3CO_2H, reflux, 6 h; (c) Boc_2O, Et_3N, DMAP, CH_2Cl_2, (d) $NaIO_4$, cat. $RuCl_2$, 1:1 acetone–H_2O; (e) Me_3SiCHN_2, PhH, MeOH; (f) MCPBA, CH_2Cl_2; (g) NaOH (2.2 equiv.), MeOH, reflux, 2 h; (h) *o*-$NO_2C_6H_4SeCN$, Bu_3P, THF, rt; (i) H_2O_2, Py, THF, −40 °C; (j) $NaBH(OMe)_3$ (2 equiv.), THF, reflux; (k) 10:1 CF_3CO_2H–H_2O, reflux, 4 h.

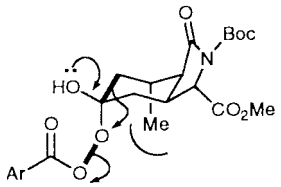
completion. The initial product of the cyclisation was the enolate **8**, which was protonated to give the dienyl ether **9** as a single regioisomer. This was hydrolysed *in situ* to the bicyclic

enone **10**, whose pyrrolidinone ring has the relative stereochemistry of kainic acid.

Lithium dimethyl cuprate, in the presence of trimethylsilyl chloride, attacked solely the *exo* face of the enone **10**: TFA catalysed both hydrolysis of the product silyl enol ether and removal of the cumyl group, and the lactam **11** was reprotected as its Boc derivative **12**.

The phenyl ring of **12** was oxidised with catalytic RuO_4, and we found that replacing the usual MeCN–CCl_4–H_2O system[14] with 1 : 1 acetone–water considerably improved the rate of the reaction. The carboxylic acid product was esterified with trimethylsilyldiazomethane[15] to give **13**.

We used Baeyer–Villiger oxidation to cleave the cyclohexanone ring of **13** into the two portions required in the target: remarkably, despite the fact that the ketone is almost identically substituted on both sides, the oxidation was fully regioselective and gave **14** with no trace of the other regioisomer. We tentatively propose that the regioselectivity is a consequence of the conformational preference of the intermediate peracid adduct in the Baeyer–Villiger reaction. Attack of the peracid on the *exo*-face of **13** gives **18**, whose pseudo-axial methyl group



18

may favour a conformation with the breaking O–O bond antiperiplanar to the C–C bond shown in bold, rather than the C–C bond to the other side of the former ketone.

Seven-membered lactone **14** was converted to diester **15** by hydrolysis with methanolic NaOH (slow addition of base avoided cleavage of the Boc protecting group) and esterification with trimethylsilyldiazomethane.[15] The elimination of water to give the isopropenyl group of **16** was achieved in one step by direct formation of a selenide[16] which was oxidised and eliminated under mild conditions.

Sodium trimethoxyborohydride selectively reduced the lactam carbonyl group of **16** in the presence of the two esters,[17] and wet trifluoroacetic acid both deprotected the amino group and hydrolysed the esters of the product **17**. The racemic product (±)-**4** was recrystallised from methanol and had spectroscopic properties (^{1}H and ^{13}C NMR) identical with those of natural kainic acid.

We are grateful to the Leverhulme Trust for a grant.

FEATURE ARTICLE

Fullerenes: three dimensional electron acceptor materials

Dirk M. Guldi

University of Notre Dame, Radiation Laboratory, Notre Dame, IN 46556, USA. E-mail: guldi.1@nd.edu

Received (in Cambridge) 28th September 1999, Accepted 3rd November 1999

This feature article highlights the advantages of employing [60]fullerene as a viable electron accepting building block in novel donor acceptor systems. Different strategies that aim towards improving charge separation in fullerene containing systems are presented. This is accomplished, for example, *via* utilisation of additional stabilisation forces of the radical pair or, alternatively, diffusional splitting of the last mentioned. Fine-tuning the topology of the electron donor moiety has been shown to be a powerful means of influencing the relative energies of the two states involved (*e.g.* the charge-separated state *vs.* the singlet ground state). Remarkable effects concerning the lifetime of the charge-separated radical pair were observed, in particular, in systems that upon charge separation led to a gain of aromaticity and planarity of the oxidised fragment.

Introduction

In the photosynthetic reaction centre (PRC), a variety of short-range electron transfer (ET) and energy transfer (ENT) events occur between well-arranged organic pigments and other cofactors. Thereby, charges are separated with remarkable efficiency to yield a spatially and electronically well-isolated radical pair and thus eliminate the energy-wasting back electron transfer (BET). The arrangement of the donor–acceptor couples in the PRC is accomplished *via* non-covalent incorporation into a well-defined protein matrix.[1]

Owing to the importance and complexity of natural photosynthesis, the study thereof necessitates suitable simpler models. The ultimate goal is to design and assemble synthetic systems which can efficiently convert solar energy into useful chemical energy. An important approach to PRC modelling has been the covalent linking of a photoexcitable chromophore with an electron acceptor or an electron donor. It is important to note that in these artificial systems the organising property is the covalent linkage between the redox active moieties.[2]

A number of factors have been systematically altered over the past decades to overcome the difficulties encountered in the early artificial, covalently linked donor-acceptor dyads:[2] the energies of the donor and acceptor molecules have been adjusted to increase the rates of the forward ET and to slow down the BET. Also, the electronic coupling between donor and acceptor moieties has been tuned to alter ET rate constants in favourable directions. The most important strategy, however, focuses on the incorporation of secondary electron donor or acceptor moieties into multicomponent arrays (triads, tetrads, pentads *etc*.).

In the following contribution some noteworthy features are summarised concerning [60]fullerene as a new, three-dimensional electron acceptor unit in artificial reaction centres. Additionally, different strategies are presented which aim towards improving charge separation in fullerene containing supermolecular (*e.g.* covalently linked) and supramolecular (*e.g.* non-covalently linked) systems. It should be pointed out that the highlighted systems are restricted to composites that bear a single electron acceptor and a single electron donor block. The key feature in these dyads relies on additional stabilisation of the radical pair such as (i) a gain in aromaticity and planarity of the electron donor, or (ii) a dissociation of the charge-separated state. These effects are expected to result in diminishing of the BET.

Small reorganisation energies of fullerenes

One of the most fascinating phenomena in the field of fullerene chemistry is the small reorganisation energy associated with almost all their reactions, especially in photoinduced electron transfer (PET).[3] This is an important requisite for the directional control and also the efficiency of ET reactions, as illustrated by the well-organised special pair (*e.g.* bacterial chlorophyll and ubiquinone) in the photosynthetic reaction centre. The total reorganisation energy (λ) is the sum of a solvent-independent term λ_i and the solvent reorganisation energy λ_s.[4] The λ_i contribution stems from the nuclear configurations, associated with the transformation of the molecule, for instance, in a photochemical reaction from an initial to a final state. It is notable that the rigid structure of the fullerene core leads to small Raman shifts under reductive conditions, and small Stokes shifts in excitation experiments.[5] A reasonable interpretation for these observations is the structural similarity between [60]fullerene in the ground, reduced and also excited states. It is also believed that the solvent-dependent term (λ_s) is small, thus requiring little energy for the adjustment of a generated state (*e.g.* excited or reduced states) to the new solvent environment.

These effects have fundamental consequences upon the classical Marcus treatment of ET theory.[4] The latter predicts an increase in rate with increasing thermodynamic driving force in

Dirk M. Guldi graduated from the University of Cologne (Germany) in 1988, from where he received his PhD in 1990 (under the supervision of Professor Fritz Wasgestian). In 1992, after a postdoctoral appointment at the National Institute of Standards and Technology (with Dr Pedatsur Neta), he took a research position at the Hahn-Meitner-Institute Berlin in the group of Professor Klaus-Dieter Asmus. After a brief stay as a Feodor-Lynen Stipend at Syracuse University (within the framework of the Alexander von Humboldt Foundation) he joined in 1995 the faculty of the Notre Dame Radiation Laboratory where he was promoted to Associate Scientist in 1996. In 1999 he completed his Habilitation at the University of Leipzig (Germany). His primary research interests are in the areas of charge separation in super- and supramolecular systems with three-dimensional electron acceptors and mechanistic aspects of radiation and photosensitization. He is particularly interested in molecular recognition as a means to control the dynamics in intra- and intermolecular electron transfer events and the efficiency of charge separation in donor–acceptor assemblies.

DOI: 10.1039/a907807j

the 'normal' region up to a maximum value, where $-\Delta G°$ equals the reorganisation energy λ. As the standard free energy becomes more negative ($-\Delta G° > \lambda$) the ET rate decreases in the 'inverted' region. Based on the small λ value for fullerenes, the maximum of the Marcus curve should be reached at smaller $-\Delta G°$, relative to two-dimensional electron acceptors, which in general have less rigid structures and higher reorganisation energies than three-dimensional fullerenes. This shifts the more exothermic BET clearly into the Marcus 'inverted' region, far from the thermodynamic maximum ($-\Delta G° = \lambda$) and inhibits the undesired BET event. At the same time, the 'normal' region is steeper, which leads to a notable acceleration of ET.

In conclusion, the ability of these three-dimensional carbon allotropes to inhibit BET and still combine it with a fast forward ET renders them as unique probes for *inter*- and *intra*molecular ET studies. In addition, the low reduction potential of [60]fullerene ($E_{1/2} = -0.44$ V *vs.* SCE) appears profitable for their utilisation as novel electron acceptors or relays in multicomponent donor acceptor systems.[6]

To illustrate the benefits of incorporating a fullerene rather than a quinone acceptor, which has a similar reduction potential but higher reorganisation energy, a fullerene-based porphyrin dyad with a rigid spacer guaranteeing a fixed separation between the two redoxactive moieties was compared with a quinone-based porphyrin dyad. Remarkably, the fullerene-based dyad gives rise to an accelerated ET (~6 times) and decelerated BET process (~25 times) relative to the kinetics of the corresponding quinone dyad.[3a]

Fullerene containing donor–bridge–acceptor dyads

The covalent linkage of fullerenes to a number of interesting electro- or photoactive species offers new opportunities in the preparation of materials that may produce long-lived charge-separated states in high quantum yields. Most importantly, the covalent linkage eliminates diffusion as the rate determining ET step and helps to enhance the transfer dynamics in donor acceptor dyads. Consequently, the PET event is converted to a truly *intra*molecular reaction controlled only by the activation energy of the reaction. A fixed and short distance between the two electroactive components prevents the undesired loss of excitation energy *via* alternative radiation and radiationless decay channels.

In this context various fullerene-based donor acceptor dyads, encompassing the linkage of the fullerene core to different donor moieties, ranging from ferrocene and aniline derivatives to phenothiazine, have been reported in recent years.[7] In these systems the fullerene moiety operates as the photosensitizer, absorbing the visible light to generate an excited species. The electron donor is not initially affected and remains in its singlet ground state (see Fig. 1). In a follow-up step the sacrificial electron donor is oxidised *via* quenching of the photoexcited sensitizer.

The singlet excited state energies of monofunctionalized fullerene building blocks, such as methanofullerenes[8a] (1.796 eV) or pyrrolidinofullerenes[8b] (1.762 eV) are sufficiently high to activate an *intra*molecular ET from the appended donor moiety.[5b] This principally yields the $C_{60}^{\bullet -}$–$D^{\bullet +}$ charge-separated state, in which $D^{\bullet +}$ denotes the oxidised donor moiety. A diagnostic probe for the identification of the π-radical anion of the fullerene moiety (*e.g.* $C_{60}^{\bullet -}$) is the sharp band in the NIR around 1000 nm.[9] The spectral signature allows a precise analysis of *inter*- and *intra*molecular ET and BET dynamics in [60]fullerene containing donor acceptor systems.

The Coulombic term, which results from the destabilisation when charges are separated, governs the fate of the $C_{60}^{\bullet -}$-$D^{\bullet +}$ pair. Accordingly, BET is, in general, very fast and produces the singlet ground state. Increasing the distance between the donor and acceptor, by means of increasing the size of the spacer units,

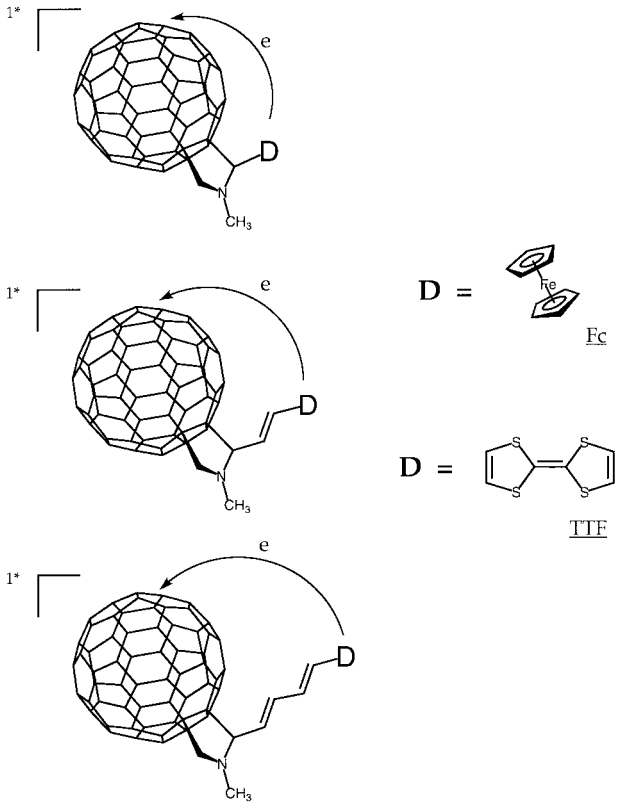

Fig. 1 Schematic illustration of photoinduced electron transfer processes from an electron donor [A = ferrocene (Fc) and tetrathiofulvalene (TTF)] to the singlet excited state of a fullerene moiety.

is one approach to reduce the Coulombic term and to slow down the BET kinetics. For example, substitution of a simple C–C linkage of the donor and acceptor moieties by various vinyl units or a norbornylogous bridge led to enhanced lifetimes of the charge-separated state.[10] At the same time, the spatial separation impacts the thermodynamic driving force ($-\Delta G°$) for an *intra*molecular ET event. Specifically, increasing the donor–acceptor separation lowers the free energy change. Thus, an ET that is exothermic in a closely spaced dyad may become endothermic or only weakly exothermic in a widely spaced dyad, and therefore cannot compete with other deactivation processes (*e.g.* radiation and radiationless decay channels).

One possible way to alter the free energy gap is to increase the chemical potential of the donor and/or acceptor moiety.[2,10] Alternatively, solvents with high relative permittivities may be used. Polar solvents impose two major effects on the ET dynamics: first, it assists in reactivating the ET even in widely separated dyads, and secondly, it helps stabilise the charge-separated radical pair by lowering the Coulombic term.

Employing the dielectric continuum model these solvents and separation effects can be quantified. This model handles the charge-separated radical pair as two spherical ions separated by a distance (R), submerged into a solvent of a static relative permittivity (ε).[11]

Gain of aromaticity

In addition to the Coulombic term, energetic considerations associated with the topology of the donor molecule also control the energies of the ground and oxidised states. Donor moieties, such as aniline and ferrocene, reveal aromatic structures in their ground states.[10,12] The delocalization that the aromatic core helps to stabilise the generated radical cation. For molecules whose ground state is aromatic, one-electron oxidation will result, however, in a partial loss of their aromatic resonance stabilisation (see case I in Fig. 2). This loss of aromaticity, consequently, yields a state of higher energy.

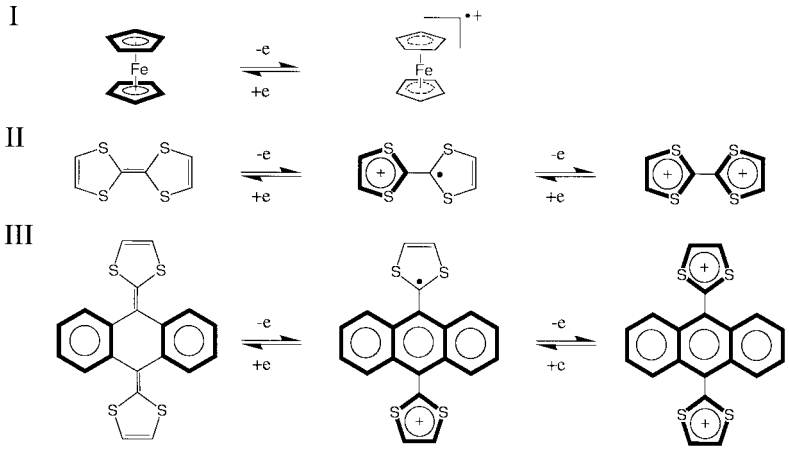

Fig. 2 Concept of gain of aromaticity and planarity. (I) Loss of aromaticity in one-electron oxidised ferrocene. (II) Gain of aromaticity in one- and two-electron oxidised TTF. (III) Gain of aromaticity and planarity in one- and two-electron oxidised (extended)TTF.

The gain in aromaticity associated with the reverse reaction (*e.g.* the BET reaction), on the other hand, provides a driving force for destabilisation of the oxidised species and acceleration of the BET in $C_{60}^{\bullet-}$-$D^{\bullet+}$ pairs. To circumvent this problem a strategy has been proposed for special donor–acceptor composites in which a series of novel organic donors were linked to the fullerene core that gain rather than lose aromaticity on charge separation (CS). This is an important difference to alternative approaches that imply stabilisation of the charge-separated state energy at the expense of subsequent, irreversible chemistry or decomposition of the oxidised donor. It is expected that the gain of aromaticity leads to noticeable effects by enhancing the lifetime of the charge-separated radical pair. This strategy was pursued using molecules, such as tetrathiafulvalenes (TTF), which contain donors whose electronic structure dictates that aromaticity is gained on CS. TTF molecules fulfil this important requisite by means of forming the 1,3-dithiolium cation, which, in contrast to the ground state, displays an aromatic character (see case II in Fig. 2).[13]

Steady-state and time-resolved photolysis studies reveal that the fullerene singlet excited states in C_{60}–TTF dyads[14] undergo rapid *intra*molecular ET events, yielding a charge-separated radical pair, namely, ($C_{60}^{\bullet-}$)-($TTF^{\bullet+}$). *Intra*molecular ET rate constants range between 1.2×10^{10} s^{-1} for closely spaced dyads (donor-acceptor separation of 4.8 Å) in benzonitrile and 1.5×10^{9} s^{-1} for widely spaced analogues (donor-acceptor separation of 10.5 Å) in toluene. The ET rate constants of these processes increase with increasing solvent polarity (*i.e.* larger $-\Delta G°$), which is consistent with the processes occurring in the 'normal' Marcus region. A radical pair lifetime of *ca.* 2 ns was observed for the closely spaced C_{60}–TTF dyads.[15] In comparison, lifetimes of 0.526, 0.05 and 0.294 ns are reported for similarly spaced carotene–C_{60}, ZnTPP–C_{60} and H_2TPP–C_{60} dyads, respectively.[16] This improvement is clearly an experimental demonstration of the 'gain of aromaticity' concept.

Gain of aromaticity and planarity

A further development with respect to increasing the degree of stabilisation is to add heteroaromatic rings to the aromatic arenes that posses larger aromatic stabilisation energies. This approach was successfully carried out by using conjugated TTF analogues with a *p*-quinodimethane structure (see case III in Fig. 2).[17] In addition to the aromatic 1,3-dithiolium cations, the π-conjugation in the oxidised form of the two isolated benzene rings is extended to the entire anthracene backbone. As a net result, the dicationic species is fully aromatic.

The geometrical features of *p*-quinodimethane analogues of tetrathiafulvalene further widens the scope of the stabilisation concept, from simply a gain of aromaticity to both a gain of aromaticity and of planarity.[18] In particular, the molecular geometries in π-extended tetrathiafulvalene derivatives with *p*-quinonoid structures reveal highly distorted orientations. They adopt a butterfly-shaped structure in the ground state to avoid the short contacts between the sulfur atoms and the hydrogen atoms. In contrast, optimisation of the two-electron oxidised state, *i.e.* the dication, with the aromatic anthracene as a basic constituent reveals a planar structure. The two aromatic 1,3-dithiolium cations align orthogonally with respect to the anthracene plane. It should be added that the oxidation process is fully reversible but necessitates, due to the loss of planarity and aromaticity, higher activation energies for the return process to occur.[18]

Pico- and nanosecond time-resolved transient absorption measurements with C_{60}–(extended)TTF dyads reveal that the initially formed singlet excited fullerene states transform rapidly into the charge-separated radical pairs. Generally, the *intra*molecular ET rates depend on (i) the spatial separation, (ii) the oxidation potential of the π-extended tetrathiafulvalene derivative, (iii) the reduction potential of the fullerene derivative, and (iv) the solvent polarity. They vary between 1.9×10^{10} s^{-1} (donor–acceptor separation of 4.4 Å) in benzonitrile and 1.3×10^{9} s^{-1} (donor–acceptor separation of 10.35 Å) in toluene. In all cases, the lifetimes of the charge-separated radical pair (*ca.* 100 ns) are promisingly increased relative to donor molecules which lack the gain in planarity or aromaticity upon oxidation (far less than 1 ns, see above).[19]

The above-summarised observations illustrate the key to controlling the structure *via* a combination of donor–acceptor potential and topology to fine-tune the relative energies of the two forms, namely, the singlet ground state and the charge-separated state.

Donor–acceptor complex association and dissociation

A major drawback, associated with *intra*molecular ET events, concerns the rapid BET, driven by the covalent linkage of the donor and acceptor moieties. The rate of BET determines the efficiency of a multicomponent system for practical applications.

In the following a supramolecular approach is summarised, which aims to retard the fast BET, commonly observed in supermolecular systems.[20] It entails the biomimetic assembly of two or more individual molecules, linked by weak *inter*molecular interactions such as van der Waals' forces, hydrogen bonding, salt bridges or ligand complexation. The reversible coordination of the acceptor moiety (ligand or substrate) to the donor (coordination centre or receptor) rather than their covalent linkage enables the diffusional splitting of the charge-separated radical pair after the initial ET takes place. Thus, complexation of the donor–acceptor couple appears a viable

alternative to supermolecular polyads (*e.g.* triads, tetrads, *etc*.) involving covalent links between the components. In the latter, a multistep electron relay along a vectorial redox gradient governs the lifetime of the radical pair: as the number of sequential steps involved in the electron relay increases, the lifetime lengthens. However, with each step the overall efficiency for transport of the charge from one end to the other decreases.

Ideally, light-induced intramolecular ET from the porphyrin chromophore to C_{60} proceeds very fast. Then, in a weakly coordinating solvent, complex dissociation should follow the ET event, which leads to diffusional separation of the charge-separated radical pair. As a consequence the BET is limited to a simple *inter*molecular process. In the case of the depicted fullerene complexes BET within the associated complex will compete with complex dissociation and, therefore, govern the quantum efficiencies of CS. Since the rate of complex dissociation depends on the strength of the coordination bond, optimisation of the CS is possible by using different coordination metals. For example, the strong π-back bonding in CO–RuTPP complexes *vs*. the weaker σ–bonding in ZnTPP composites leads to drastically different complexation strengths (see Fig. 3) with, for example, pyridine.[21] While the former complex is quite stable in solution, the latter exhibits a complexation equilibrium constant (K) of nearly 5900 $dm^3\ mol^{-1}$ (in toluene) and thus is only shifted towards the complexed form.

The assembly of a rigid but non-covalently connected dyad was obtained by coordinating a fullerene ligand to a zinc tetraphenylporphyrin (ZnTPP) *via* axial pyridine coordination to the metal. This ensemble gives rise to an edge-to-edge distance of 4.5 Å between the entities or a centre-to-centre distance of 9.5 Å. The complex association is conveniently followed by absorption spectroscopy (*e.g.* shift of the Q-band transitions) and also by steady state emission spectroscopy (*e.g.* fluorescence quenching). In particular, a concentration-dependent fluorescence quenching of the (^{1}*π–π)ZnTPP correlates with a very efficient CS upon irradiation.

It is pertinent to note that two different pathways for the ET processes exist (see Fig. 4). A fast *intra*molecular ET inside the associated fullerene-porphyrin complex follows the excitation of the porphyrin chromophore. Alternatively, the free porphyrin is excited and undergoes *inter*molecular ET as soon as the acceptor molecules approach closely enough during molecular diffusion. The former process, which occurs in all solvents, involves (^{1}*π–π)ZnTPP, while the *inter*molecular process is likely to dominate the quenching of the energetically lower lying (^{3}*π-π)ZnTPP. Complications arise from the fact that polar solvents, such as benzonitrile, interfere with the coordination of the zinc centre. It was shown that in coordinating media, the solvent displaces the fullerene ligand from the zinc, making the *inter*molecular route more effective.

Kinetic analysis of the fullerene π-radical anion transient absorption evolving from irradiation of the ZnTPP–C_{60} composite yields a remarkable lifetime of several hundred microseconds for the separated radical pair in deoxygenated benzonitrile. The quantum yield (Φ) for the truly separated radical pair, $C_{60}^{\bullet-}$ and $ZnTPP^{\bullet+}$ in deoxygenated dichloromethane is *ca.* 0.14.

The given example demonstrates the potential usefulness of these non-covalently linked systems in photovoltaic devices. But they also point to the fundamental challenge employment of a more polar environment, such as aqueous solutions, faces with respect to avoiding complexation of the zinc centre, while promoting the stabilisation of the radical pair. Future work will concentrate on water-soluble systems using additionally charged porphyrin macrocyclic ligands to slow down the BET step.

The coordination concept, namely, complexation of a fullerene–pyridine ligand by a macrocyclic π-system that bears

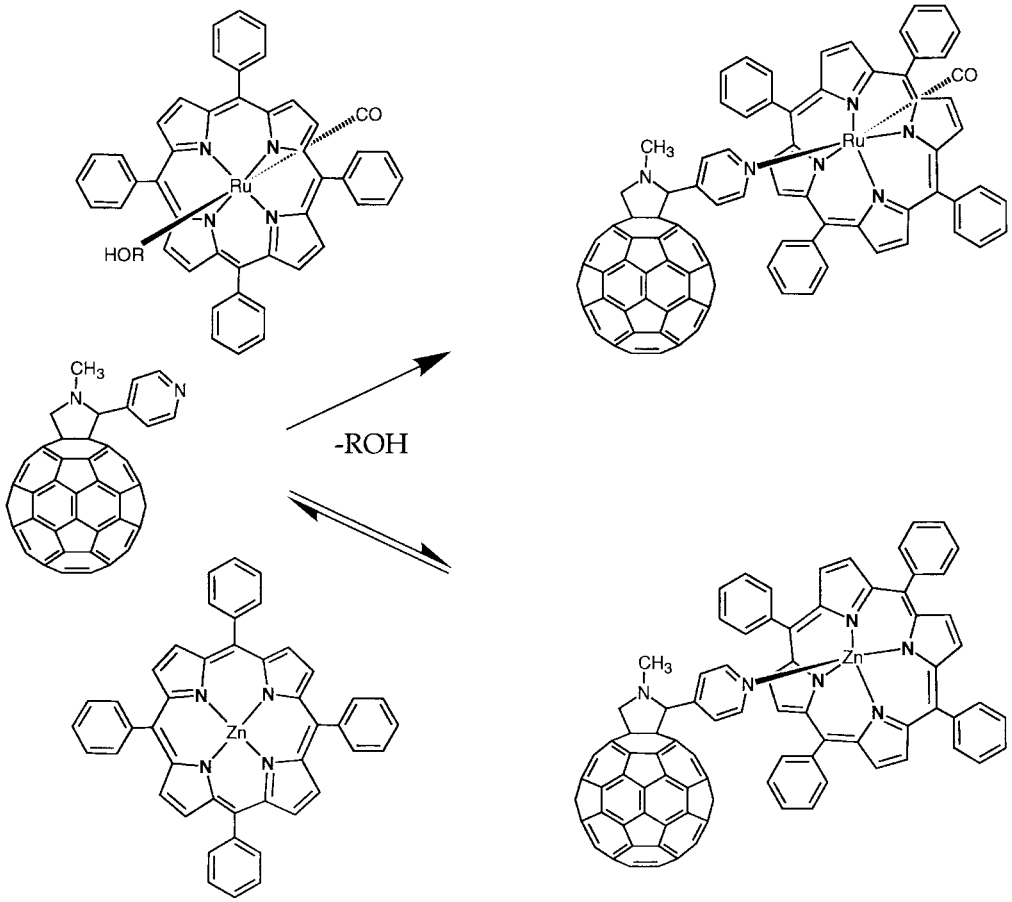

Fig. 3 Irreversible (upper case) and reversible complexation (lower case) of an electron acceptor (*e.g.* fullerene-pyridine derivative) to transition metal complexes (*e.g.* Zn^{II} and Ru^{II}) of tetraphenyl porphyrins.

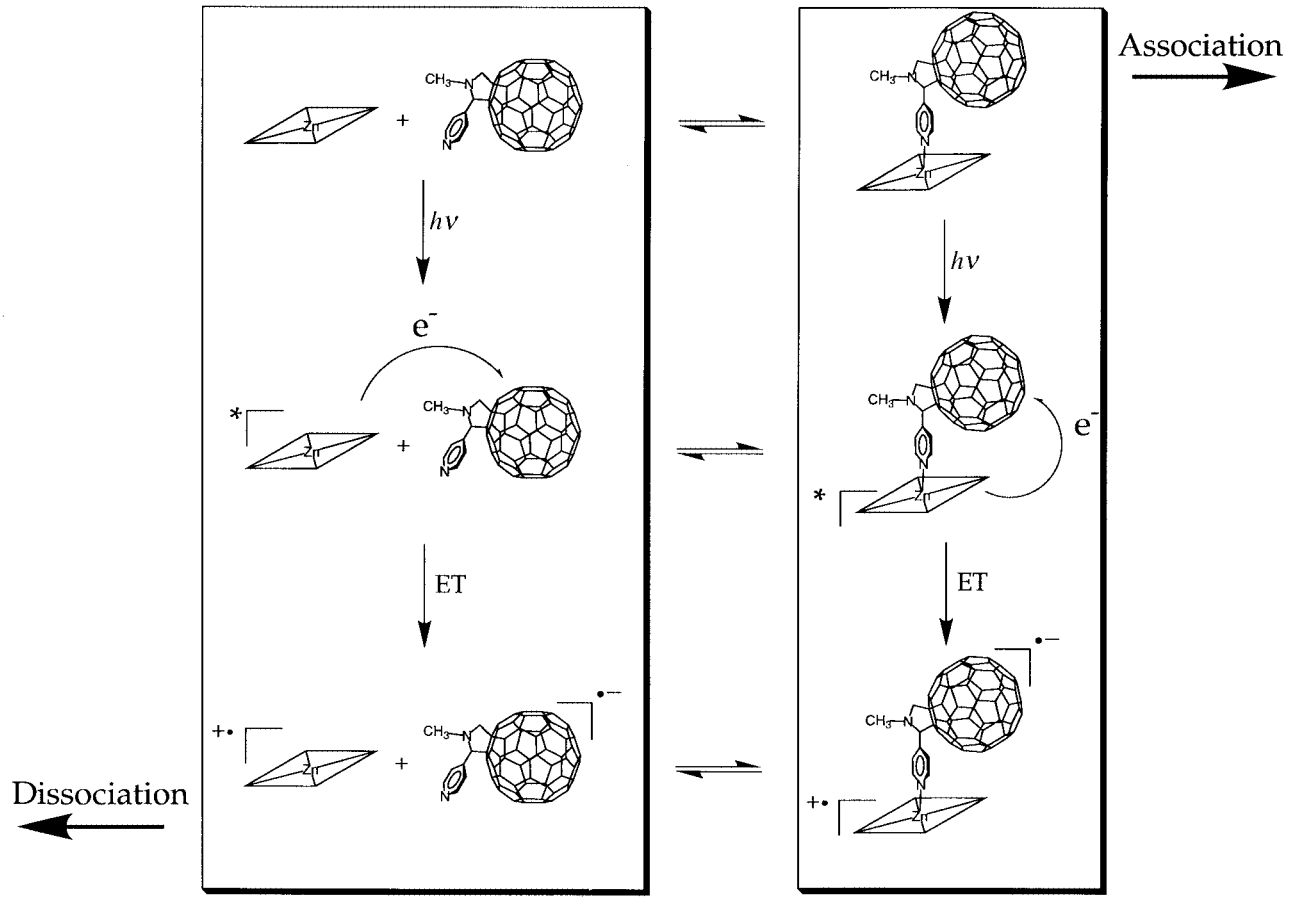

Fig. 4 Inter- and intramolecular electron transfer routes in an associated fullerene–porphyrin complex (right hand side) and in a free porphyrin fullerene mixture (left hand side), respectively.

a potential utilisation as a chromophore system, is very general and can be employed successfully for metallophthalocyanines and structural porphyrin isomers.[22]

Peptides as molecular rulers

Molecular systems that respond precisely to environmental changes occurring at a microscopic level and signal the response at a macroscopic level are of great interest in the field of chemical sensing and molecular electronics. Peptide-based interchromophore bridges are attractive probes since cooperative transitions between the secondary structure, *e.g.* between ordered and disordered states, can be conveniently monitored.[23] Hydrogen bonding is one means that was expected to influence donor–acceptor interactions in a peptide based donor–acceptor dyad. Also, the key role of hydrogen bonding should be noted, especially with respect to mediating ET processes in biological and artificial systems.[24]

Aib (α-aminoisobutyric acid) is a C^{α}-tetrasubstituted α-amino acid that strongly favours 3_{10}-helical structures more than any of the regular protein amino acids.[24] Tight helix–helix packing is a key feature of the α-helical bundle tertiary structures commonly found in biological proteins in which the photosynthetic reaction centre is embedded. In this context a hexapeptide (see Fig. 5) has been employed as a large molecular ruler to separate a pyrrolidinofullerene acceptor unit from a ruthenium(II) trisbipyridine (chromophore molecule) complex ($[Ru(bpy)_3]^{2+}$).[25]

The peptide-spaced ensemble, containing structurally constrained Aib, can be interrelated to rigid androstane- and flexible ethyleneglycol-spaced C_{60}–$[Ru(bpy)_3]^{2+}$ assemblies previously reported (see Fig. 5).[26] The role played by the spacer is not just structural since its chemical nature governs the electronic communication between the terminal units (*e.g.*

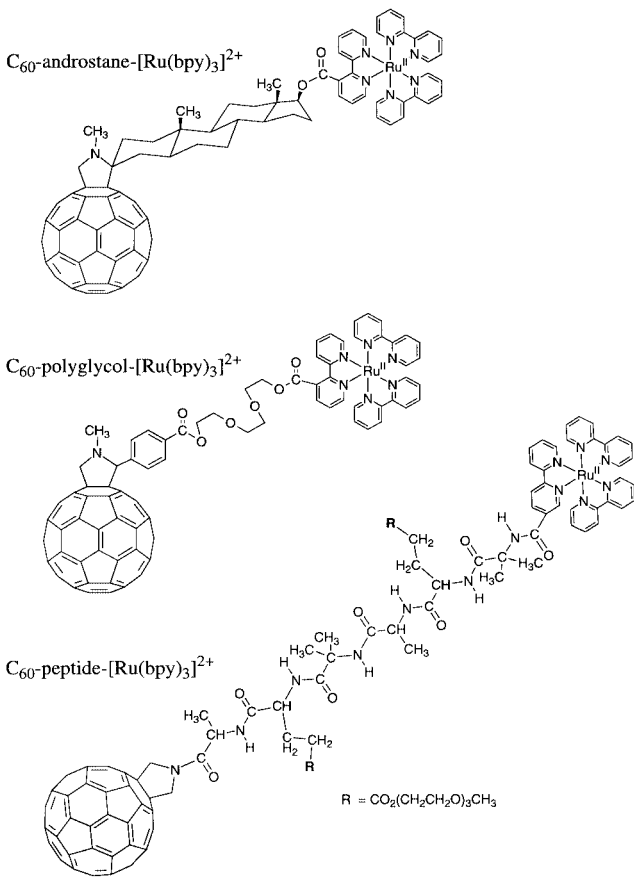

Fig. 5 Structures of C_{60}–androstane–$[Ru(bpy)_3]^{2+}$, C_{60}–polyglycol–$[Ru(bpy)_3]^{2+}$ and C_{60}–peptide–$[Ru(bpy)_3]^{2+}$ donor–bridge–acceptor dyads.

fullerene and $[Ru(bpy)_3]^{2+}$). Another important feature of the spacer is its modular composition, which allows alteration of the separation without affecting the electronic nature of the connection.

It may be pointed out that the geometry of the flexibly linked [*i.e.* $-(CH_2CH_2O)_n-$ chain] system is not well-defined, and the rapid deactivation of the ^{3}*(MLCT) $[Ru(bpy)_3]^{2+}$ state is ascribed to an '*intra*molecular exciplex' mechanism (case II in Fig. 6). Owing to the rigid structure of steroids, such as

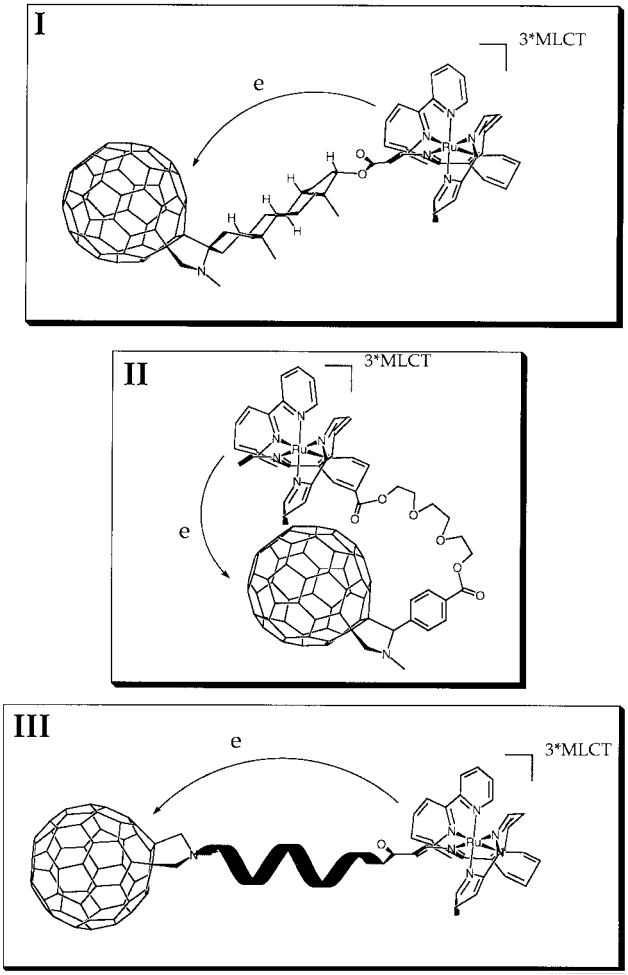

Fig. 6 Schematic illustration of photoinduced electron transfer processes from a ^{3}*(MLCT) state of a $[Ru(bpy)_3]^{2+}$ complex to an electron accepting fullerene moiety in (I) C_{60}–androstane–$[Ru(bpy)_3]^{2+}$, (II) C_{60}–polyglycol–$[Ru(bpy)_3]^{2+}$ and (III) C_{60}–peptide–$[Ru(bpy)_3]^{2+}$ dyads. Please note that the C_{60}–androstane–$[Ru(bpy)_3]^{2+}$ dyad is represented by one of the two possible diastereoisomers.

androstane, a 'through-bond' mediated ET(case I in Fig. 6) prevails in the C_{60}–androstane-$[Ru(bpy)_3]^{2+}$ dyad. The steroid acts as a wire allowing the electron to be passed from the donor to the acceptor through the intervening σ-bond framework. In both dyads (*e.g.* C_{60}–androstane–$[Ru(bpy)_3]^{2+}$ and C_{60}–polyglycol–$[Ru(bpy)_3]^{2+}$), quenching of the ^{3}*(MLCT) state of the $[Ru(bpy)_3]^{2+}$ complex by ET to the fullerene generates the $C_{60}^{\bullet-}$–$[Ru(bpy)_3]^{3+}$ radical pair. The different *intra*molecular ET mechanism in these dyads, leads, however, to quite different lifetimes for $C_{60}^{\bullet-}$–$[Ru(bpy)_3]^{3+}$. For example, in dichloromethane solutions the rigidly spaced C_{60}–androstane–$[Ru(bpy)_3]^{2+}$ dyad yields a lifetime of 304 ns, while no appreciable lifetime was noted for the flexibly spaced C_{60}–polyglycol–$[Ru(bpy)_3]^{2+}$ analogue.[26]

Structures, such as a 3_{10}-helix, are prone to conformational changes upon addition of protic solvents. In nonprotic solvents the helical secondary structure of the peptide spacer places the two redox active moieties into close proximity, which is favourable for their mutual electronic interaction. An edge-to-edge distance of *ca.* 12 Å provides the means for a rapid *intra*molecular ET from the ^{3}*(MLCT) $[Ru(bpy)_3]^{2+}$ state to the electron accepting fullerene (case III in Fig. 6). In fact, the initially formed ^{3}*(MLCT) $[Ru(bpy)_3]^{2+}$ state transforms readily (3.4×10^8 s^{-1}) into a long-lived charge-separated state (τ = 608 ns). Protic solvents, on the other hand, interfere with the *intra*molecular hydrogen bonding of the peptide backbone. Unfolding of the relatively compressed secondary structure of the ordered peptide results in a statistically unordered conformation. Consequently, the spatial separation between the two components, donor ($[Ru(bpy)_3]^{2+}$) and acceptor (C_{60}), located at the N- and C-termini of the peptide chain, respectively, tends to increase to a point that eventually disrupts their mutual electronic interactions. Despite the general flexibility of the peptide backbone, the experimental data fail to support either of the two possible ET mechanisms (*e.g.* a 'through bond' or an '*intra*molecular exciplex' route), instead the ^{3}*(MLCT)$[Ru(bpy)_3]^{2+}$ state decays with a lifetime of 535 ns (*e.g.* similar to a $[Ru(bpy)_3]^{2+}$ reference complex). This leads to the conclusion that the peptide backbone is relatively stiff in comparison to true flexibility found in a hydrocarbon chain.

An intriguing feature of the *intra*molecular hydrogen bonding within the peptide backbone is that the more randomised configuration can be reversibly transferred into the starting conformation (*e.g.* the 3_{10}-helical character). After careful removal of the protic component from a binary solvent mixture (protic and nonprotic; 1 : 1 *v/v*) the luminescence intensity of the $[Ru(bpy)_3]^{2+}$ chromophore becomes comparable again to that for the original non-protic solution prior to the addition of the protic solvent. The reversible activation–deactivation of the ET mechanism was successfully repeated many times (*e.g.* 10 times) and, thus, serves as a sensitive probe for the secondary structure of peptides.

The strong electrostatic fields (10^9 V m^{-1}) in helices have been used in rationalising the observation that only one of the two branches of the bacterial PRC is active.[27] An oriented dipole, which spans from the N- to the C-terminus of the helix, is responsible for this field. In the system presented a charge-separated radical pair is created which resembles the helices' own electrostatic field and, therefore, destabilises the charge-separated radical pair. The observed k_{ET}/k_{BET} ratio (209), as a meaningful measure of the usefulness of a PET system, is, nevertheless, promising. The k_{ET}/k_{BET} ratio may be further improved by exchanging the two building blocks. In such a system the ET will operate with the dipole moment of the helix and, thus, be accelerated, while simultaneously the BET is rendered more difficult.

Concluding remarks and outlook

The selected examples described in this article illustrate the continuing interest and potential of fullerenes as multifunctional electron storage moieties in well-ordered multicomponent composites. Noteworthy in this context is the recent introduction of elegant and versatile protocols concerning the chemical functionalization of the fullerene core.[8,28]

Remarkably, similar systems based on two-dimensional acceptors (*e.g.* quinone) failed to exhibit sufficient lifetimes of the charge-separated states formed because of the fast occurring BET. This is due, at least in part, to the slower ET and faster BET dynamics evolving from the larger reorganisation energies of two-dimensional electron acceptors. The unique delocalization, provided by the three-dimensional structure of the fullerene core, in combination with the small reorganisation energy, on the other hand, prevents a fast BET process in the contributed fullerene-containing systems.

The important idea presented by the current concepts (*e.g.* gain of aromaticity and planarity) is the stabilisation of the oxidised donor moiety and, in turn, of the resulting radical pair. In this line of thinking the diffusional splitting of the radical pair

in fullerene-metallocomplexes is the basis for the design of artificial photosynthetic systems with efficient and long-lived charge separation but fewer electron transfer steps and less energy loss.

In summary, the systematic investigation of fullerene chemistry has, already at a relatively early stage, played a significant role in the development of useful molecular composites. If the more technological problems can be solved, there is an almost unlimited field of application to be foreseen and eventually fullerenes may become important building blocks of future technologies, such as solar energy conversion, batteries and photovoltaics.

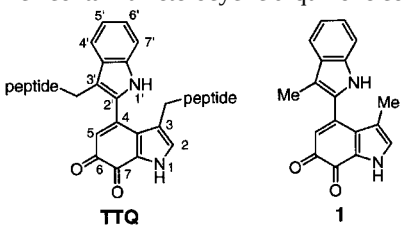
Received (in Cambridge, UK) 9th November 1999, Accepted 19th January 2000

Oxidation of benzylamine by a model compound of cofactor TTQ (tryptophan tryptophylquinone) of quinoprotein amine dehydrogenases is made possible by coordination of a monovalent cation such as Li^+ in anhydrous MeCN.

Bacterial methylamine dehydrogenase (MADH) and aromatic amine dehydrogenase (AADH) comprise a new class of enzymes which contain a heterocyclic *o*-quinone cofactor, TTQ



(tryptophan tryptophylquinone), at their active sites in the light subunits.[1–3]

Monovalent cations have recently been shown to influence not only the UV–VIS spectrum of the enzyme but also the redox reactivity of TTQ in the amine oxidation and the subsequent electron transfer to biological electron acceptor proteins such as amicyanin.[4–9] The enzymes have two different cation binding sites, one of which is located near the quinone carbonyl oxygen O(6) of the cofactor.[4] Thus, the cationic species incorporated into this binding pocket have been suggested to interact with the quinone moiety directly, affecting the electronic structure of the cofactor as well as the reactivity both in the amine oxidation reaction and the subsequent electron transfer process.[5–9] However, little is known about the binding model of the cationic species toward TTQ or how it affects the electronic structure as well as the reactivity of the TTQ cofactor. In this study, we have investigated the interaction of a TTQ model compound[10] with monovalent cations to demonstrate that an alkaline metal ion such as Li^+ binds to the quinone, leading to a significant enhancement of the amine oxidation reaction in anhydrous organic media.

Addition of a certain amount of $LiClO_4$ to an anhydrous MeCN solution containing TTQ model compound **1** (5.0×10^{-5} mol dm^{-3}) and benzylamine (1.0×10^{-2} mol dm^{-3}) caused a rapid spectral change in the UV–VIS region. Fig. 1 shows the spectral change of the titration of **1** with $LiClO_4$ (0–0.15 mol dm^{-3}) in the presence of benzylamine (1.0×10^{-2} mol dm^{-3}).[11] The characteristic absorption band at 408 nm due to the quinone itself decreases, accompanied by an increase in a new absorption band at 461 nm, with increasing the concentration of added $LiClO_4$. The binding constant K_{ML} for 1:1 complex formation between the quinone (Q) and the metal ion (M^+) can be expressed by eqn. (1), where A_0 and A_∞ are the initial and final absorptions of the titration, and $[M^+]_0$ and $[Q]_0$ denote the concentration of the added metal ion and the initial quinone concentration, respectively. The plot of $(A - A_0)/(A_\infty - A)$ *vs.* $([M^+]_0 - \alpha[Q]_0)$ [$\alpha = (A - A_0)/(A_\infty - A_0)$] gives a straight line passing through the origin, as shown in the inset in Fig. 1, from which a K_{ML} value of 15.6 dm^3 mol^{-1} was obtained from the slope. A similar spectral change was obtained in the titration of **1** with $NaClO_4$ although the binding constant was smaller (K_{ML} = 5.5 dm^3 mol^{-1}, λ_{max} = 454 nm).[12,13] It should be noted that the spectral change obtained in this system is fairly close to that observed in the titration of MADH with monovalent cations.[4,8] This result suggests that the monovalent cation binds to the quinone moiety of **1** at a similar position to that proposed in the enzymatic systems.[14]

$$\frac{A - A_0}{A_\infty - A} = K_{ML}([M^+]_0 - \frac{A - A_0}{A_\infty - A_0}[Q]_0) \quad (1)$$

Although *no* reaction takes place between benzylamine and quinone **1** in an aprotic solvent such as anhydrous MeCN, **1** was converted into the reduced form of TTQ in the presence of Li^+. Thus, the reaction of quinone **1** (5.0×10^{-5} mol dm^{-3}) and benzylamine (1.5×10^{-2} mol dm^{-3}) in the presence of $LiClO_4$ (0.15 mol dm^{-3}) in anhydrous MeCN at 25 °C under anaerobic conditions resulted in a drastic spectral change where the absorption band at 461 nm due to the Li^+ complex of the quinone decreases, accompanied by an increase in a new band at 323 nm due to the reduced TTQ in the aminophenol form (Fig. 2).[15] As reported in the previous model reactions between the TTQ model compound and benzylamine in MeOH,[16] the reaction consists of three distinct steps, where the first one [Fig. 2(*a*)] corresponds to addition of the amine to the quinone (k_1), the second one [Fig. 2(*b*)] is due to the spontaneous (k_2) and the amine-catalyzed (k_2') rearrangement from the substrate imine to the product imine intermediates, and the third one [Fig. 2(*c*)] is ascribed to the imine exchange reaction (k_3) to generate the aminophenol and *N*-benzylidenebenzylamine ($PhCH_2N{=}CHPh$), as summarized in Scheme 1.[15] Each process has its own isosbestic point, at 418, 383 and 372 nm, respectively, demonstrating the accuracy of the stepwise mechanism shown in Scheme 1. Since the difference in the rate

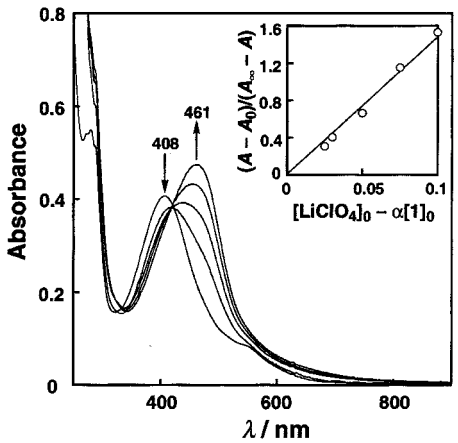


Fig. 1 Spectral change observed upon addition of $LiClO_4$ (0–0.15 mol dm^{-3}) to an MeCN solution of **1** (5.0×10^{-5} mol dm^{-3}) in the presence of benzylamine (1.0×10^{-2} mol dm^{-3}) at 25 °C. Inset: plot of $(A - A_0)/(A_\infty - A)$ *vs.* $[LiClO_4]_0 - \alpha[\mathbf{1}]_0$ $\{\alpha = (A - A_0)/(A_\infty - A_0)\}$.

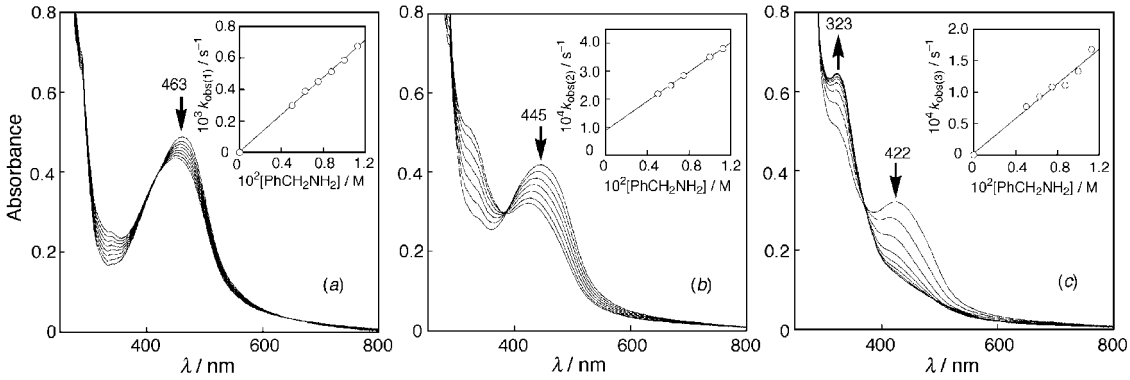

Fig. 2 Spectral change for the reaction of **1** (5.0×10^{-5} mol dm^{-3}) with benzylamine (1.5×10^{-2} mol dm^{-3}) in the presence of $LiClO_4$ (0.15 mol dm^{-3}) in anhydrous MeCN at 25 °C under anaerobic conditions. (*a*) The first stage (0–7200 s), 800 s interval. Inset: plot of $k_{obs(1)}$ *vs.* [$PhCH_2NH_2$]. (*b*) The second stage (9600–24000 s), 2400 s interval. Inset: plot of $k_{obs(2)}$ *vs.* [$PhCH_2NH_2$]. (*c*) The third stage (24000–49600 s), 3200 s interval. Inset: plot of $k_{obs(3)}$ *vs.* [$PhCH_2NH_2$].

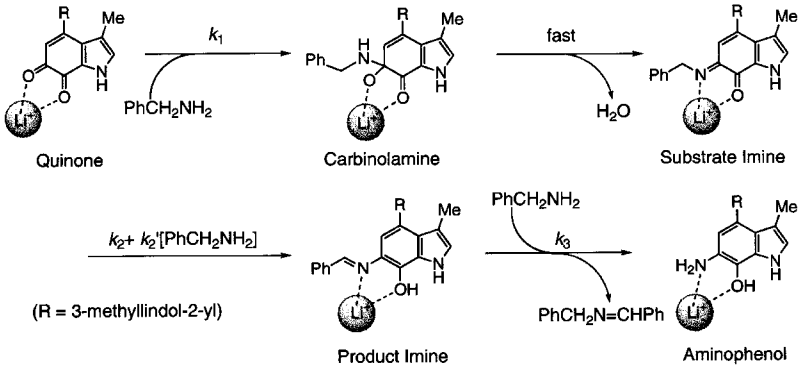

Scheme 1

of each step was not large enough to determine the rate independently, the pseudo-first order rate constants for the three steps ($k_{obs(1)}$, $k_{obs(2)}$ and $k_{obs(3)}$) were determined simultaneously by computer simulation of the time course of the absorption change using a non-linear curve-fitting program (Mac curve fit) as reported in the previous study.[16] From the dependence of k_{obs} in each step on the amine concentration the rate constants were determined as $k_1 = 5.9 \times 10^{-2}$ M^{-1} s^{-1}, $k_2 = 8.7 \times 10^{-5}$ s^{-1}, $k_2' = 2.6 \times 10^{-2}$ M^{-1} s^{-1}, and $k_3 = 1.4 \times 10^{-2}$ M^{-1} s^{-1}, as shown in the insets in Fig. 2. It should also be emphasized that the oxidation of benzylamine by the Li^+ complex of **1** proceeds catalytically, and molecular oxygen is used as an electron acceptor to regenerate the iminoquinone form from the reduced TTQ. Thus, benzylamine (0.10 mol dm^{-3}) was converted into *N*-benzylidenebenzylamine quantitatively when it was treated with a catalytic amount of **1** (1.0×10^{-3} mol dm^{-3}; 1 mol %) in the presence of $LiClO_4$ (1.0 mol dm^{-3}) under aerobic conditions for 24 h.

In summary, a monovalent cation such as Li^+ has been demonstrated for the first time to bind to TTQ at its quinone moiety and makes it possible for the catalytic amine oxidation to occur efficiently in anhydrous MeCN. The Li^+ binding may accelerate the addition step of the amine (k_1) and enhances the stability of the intermediates, leading to the efficient catalytic oxidation of benzylamine. These results gave us an important insight into the catalytic mechanism of the monovalent cations in MADH- and AADH-catalysed reactions.

The present study was financially supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Culture, and Sports of Japan.

10 S. Itoh, M. Ogino, S. Haranou, T. Terasaka, T. Ando, M. Komatsu, Y. Ohshiro, S. Fukuzumi, K. Kano, K. Takagi and T. Ikeda, *J. Am. Chem. Soc.*, 1995, **117**, 1485.
11 Each spectrum in Fig. 1 was taken just after the addition of $LiClO_4$, since the redox reaction between **1** and benzylamine gradually proceeded over a prolonged reaction time.
12 Because of the low solubility of NH_4ClO_4, $KClO_4$, $CsClO_4$ and CsOTf in anhydrous MeCN, interaction between the quinone and those monovalent cations could not be examined accurately.
13 In the absence of benzylamine, the spectral changes (bathochromic shifts) and the K_{ML} values are much smaller than those measured in the presence of the amine: for Li^+, λ_{max} = 430 nm; K_{ML} = 3.6 dm^3 mol^{-1}; for Na^+, λ_{max} = 425 nm; K_{ML} = 2.3 dm^3 mol^{-1}. Benzylamine may abstract the pyrrole proton of **1** to enhance the Li^+ binding.
14 In spite of our great efforts, a single crystal of the Li^+ complex of **1** suitable for X-ray analysis has yet to be obtained. The ^{1}H NMR spectrum of **1** (1×10^{-3} mol dm^{-3}) in CD_3CN in the presence of $LiClO_4$ (1 mol dm^{-3}) showed downfield shifts for 1-H, 2-H and 5-H ($\Delta\delta$ = 0.39, 0.16 and 0.05 ppm, respectively), suggesting the coordination of Li^+ at the quinone moiety of **1**.
15 Although the reaction intermediates (substrate imine and product imine) and the aminophenol product of TTQ have been successfully isolated in the previous reaction in MeOH (ref. 16), isolation and detailed characterization of those species in the present system were hampered by Li^+ existing in large excess. The spectral change of the present reaction is, however, fairly close to that of the reaction of **1** and benzylamine in MeOH, (ref. 16), strongly supporting the idea that the intermediates and reduced product are the same in both systems.

A novel hexakis(tetrathiafulvalene) derivative: synthesis, structure and electrochemical properties

Christian A. Christensen,[ab] Martin R. Bryce,*[a] Andrei S. Batsanov[a] and Jan Becher*[b]

[a] *Department of Chemistry, University of Durham, Durham, UK DH1 3LE. E-mail: m.r.bryce@durham.ac.uk*

Received (in Cambridge, UK) 16th December 1999, Accepted 19th January 2000

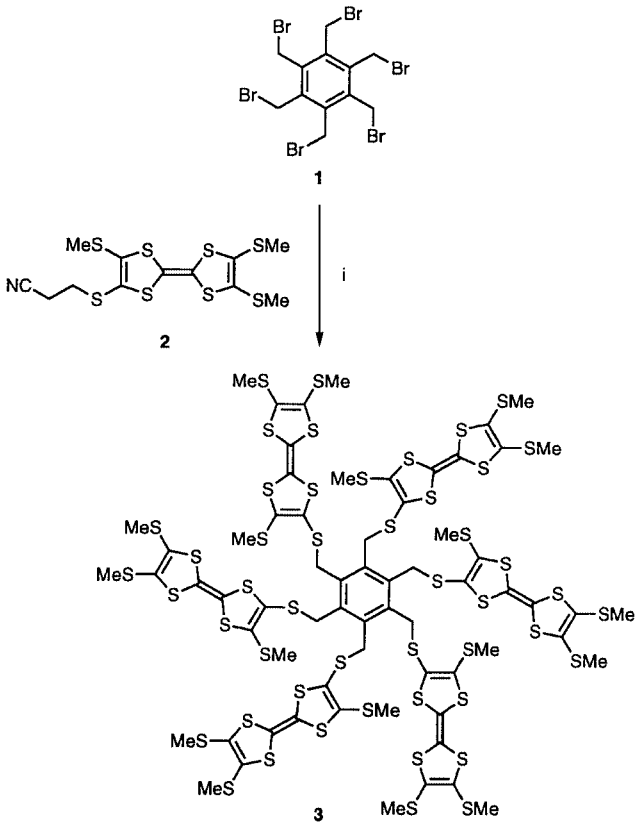
The hexakis(TTF) derivative 3 has been synthesised in 89% yield by six-fold reaction of the thiolate anion of reagent 2 with hexakis(bromomethyl)benzene: the solution electrochemistry of 3 shows sequential formation of the hexa-(radical cation) and the dodecacation species, and spectroelectrochemistry shows interacting radical cations; the X-ray crystal structure of 3 is reported.

Oligo(tetrathiafulvalene) (TTF) derivatives,[1] including dendrimers[2] and main-chain and side-chain polymers,[3] have received considerable attention recently. The two-step electrochemical oxidation of TTF,[4] to form sequentially the radical cation and dication, offers the prospect of controlled generation of oligo(radical cation) and oligo(dication) species, which may engage in intramolecular or intermolecular interactions, act as multi-electron redox switches,[2e] or modulate redox processes of organic guests incorporated within the oligo(TTF) host framework.[5] To date, all the pure TTF oligomers ($n > 3$) which have been characterised have required multi-step syntheses. We now report the remarkably efficient synthesis of the novel hexakis(TTF) molecule **3** along with its X-ray crystal structure and solution electrochemistry.

Six-fold reaction of hexakis(bromomethyl)benzene **1**[6] with the thiolate anion of 4-(2-cyanoethyl)-4′,5,5′-tris(methylsulfanyl)TTF **2**, which was generated using $CsOH·H_2O$ as described previously,[7] proceeded remarkably cleanly to afford the TTF hexamer **3** in 89% yield (Scheme 1).†

The X-ray crystal structure of **3**‡ is shown in Fig. 1. As far as we are aware, no compound containing more than three TTF moieties has been structurally studied previously, and the structures of very few tris(TTF) compounds have been reported.[8–11] Molecule **3** has crystallographic C_i symmetry. The central benzene ring is planar, with CH_2–S bonds directed alternately above and below its plane. All three independent TTF moieties adopt a boat-like conformation: the inner dithiole rings are folded by 25.5, 29.6 and 13.2°, the outer ones by 18.4, 10.2 and 11.4°, with a small twist around the central C=C bond, by 6.3, 5.5 and 2.9°, respectively. Such flexibility and easy rotation around (exocyclic) C–S bonds may explain the fact that **3** forms a relatively dense crystal packing (21.6 Å^3 per non-H atom, *cf.* 22.8 and 22.1 Å^3 in monoclinic[12] and triclinic[13] polymorphs of MeS_4TTF, respectively) with no significant cavities, while its poly-aryl analogues crystallise as clathrates, *e.g.* $C_6(CH_2SPh)_6·2CCl_4$,[14a] $C_6(CH_2SO_2CHMePh)_6·4AcOH$,[14b] $C_6(CH_2SC_6H_4Bu^t)_6·1/2C_{30}H_{50}$[14c] and $C_6(CH_2SCH_2Ph)_6$·dioxane.[14d] Three of the six outer methyl groups in **3** are disordered between two positions each, indicating some residual looseness of the structure. There is no intramolecular S···S contact shorter than twice the van der Waals radius (3.60 Å)[15] of sulfur (excluding the contacts within the same TTF moiety) although each molecule participates in four significantly shorter intermolecular contacts.

Cyclic voltammetry (CV) of compound **3** (Fig. 2) showed two oxidation waves at $E_1^{1/2}$ 0.55 V and $E_2^{1/2}$ 0.88 V (*vs.* Ag/AgCl) typical of a tetra(alkylsulfanylTTF) system.[4b] The first wave is reversible; the second wave is quasi-reversible. (The criterion applied for reversibility was a ratio of 1.0 ± 0.05 for the intensities of the anodic and cathodic currents I_a/I_c, and no shift of the half wave potentials with varying scan rates between 50 and 500 mV s^{-1}.) There is no apparent interaction between the different TTF units. Thin layer CV was performed with the one-electron reduction peak of 2,3-dichloronaphthoquinone providing the internal reference, using procedures detailed previously.[2d] The number of electrons exchanged per oxidation



Scheme 1 *Reagents and conditions*: i, $CsOH·H_2O$, MeOH, DMF, 20 °C.

DOI: 10.1039/a909882h

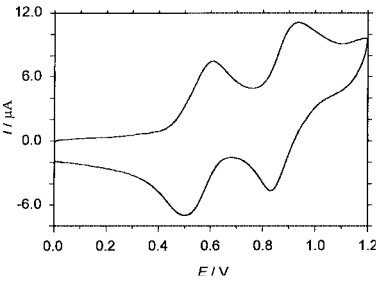

Fig. 2 Cyclic voltammogram of **3**.

wave was calculated to be 6.0 ± 0.5, which clearly suggests that complete oxidation occurs for all the TTF units. We note that in both CV and TLCV the reductive peak for the second redox couple (I_a/I_c = 0.8–0.9) is slightly smaller than for the first wave, as observed previously for some other multi(TTF) systems,[2d,16] indicating an associated chemical reaction, or a marked conformational change, at the highest oxidation level of the molecule.

The spectroelectrochemistry of compound **3** is shown in Fig. 3 [compound **3** (10^{-4} M), $BuNPF_6$ (10^{-1} M), $CHCl_3$]. The spectrum obtained at 0 V is consistent with neutral TTF units. On increasing the potential, as oxidation of the system proceeds, we see the concomitant emergence of the low energy absorption band of interacting TTF cation radicals (π–π dimers)[17] at λ_{max} 850 nm (Fig 3, spectrum at 0.65 V) along with a shoulder assigned to isolated (non-interacting) TTF cation radicals (λ_{max} 480 nm). On further increasing the potential to form the fully oxidised species precipitation of material was observed in the cell, so the spectra of the +12 species could not be obtained. It is apparent, therefore, that the dense packing of TTF moieties in **3** favours intramolecular interactions of their cation radicals. This contrasts with previous less densely packed TTF units for which isolated TTF cation radicals are clearly detected in the UV–VIS absorption spectra.[2c]

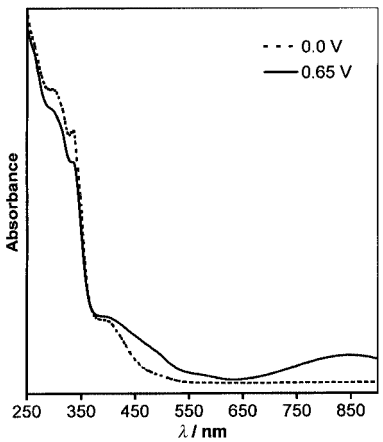

Fig. 3 Spectroelectrochemistry of **3**.

In summary, we report an extremely efficient one-pot synthesis of a hexakis(TTF) derivative **3**. This remarkably high-yielding six-fold reaction should make reagent **1** a suitable core unit for the convergent construction of higher TTF oligomers, including redox dendrimers, which are charged organic nanoparticles, relevant to miniaturisation in electronic materials.[18]

We thank the EPSRC and the Danish Research Academy for funding (C. A. C.), Dr L. M. Goldenberg for TLCV experiments and Dr P. Low for the design of the spectroelectrochemical cell.

Notes and references

† To a stirred solution of **2** (0.427 g, 1.00 mmol) in dry degassed DMF (60 cm^3) was added a solution of $CsOH·H_2O$ (0.185 g, 1.10 mmol) in dry MeOH (5 cm^3). The solution was stirred under nitrogen at 20 °C for 1 h. Compound **1** (0.095 g, 0.150 mmol) was added and the reaction mixture was stirred at 20 °C for 16 h to afford an orange suspension which was poured onto water (400 cm^3) and the orange pricipitate was filtered off, washed with MeOH (10 cm^3) and dried to afford analytically pure compound **3** (0.319 g, 89%), mp 214–215 °C. Recrystallisation from CS_2–hexane afforded red prisms. Elemental analysis: calc. for $C_{66}H_{66}S_{48}$: C, 33.05; H, 2.77. Novel arsine ligands for selective hydroformylation of alk-1-enes employing platinum/tin catalysts†

Lars A. van der Veen, Peter K. Keeven, Paul C. J. Kamer and Piet W. N. M. van Leeuwen*

Institute of Molecular Chemistry, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands. E-mail: pwnm@anorg.chem.uva.nl

Received (in Basel, Switzerland) 25th August 1999, Accepted 20th January 2000

The synthesis and application of new wide bite angle arsine based ligands in the platinum/tin-catalysed hydroformylation of oct-1-ene is reported; an unprecedented high activity and selectivity is obtained employing a mixed phosphine/arsine ligand.

Hydroformylation of alkenes is one of the world's largest homogeneously catalysed reactions in industry (Scheme 1), producing more than six million tons of aldehydes and alcohols annually.[1] The commercial hydroformylation processes are run exclusively on cobalt or rhodium complexes as catalysts. Platinum complexes also give active hydroformylation catalysts, but are mainly of academic interest. Both terminal and internal alkenes can be hydroformylated selectively employing platinum–diphosphine complexes activated by tin chloride as the co-catalyst.[2] Tin-free catalyst systems have been reported as well.[3] Despite the very high linear over branched (l:b) aldehyde ratios induced by the platinum/tin–diphosphine catalysts, these systems have mainly been applied to asymmetric hydroformylation so far.[1,4] The major drawbacks of these catalysts are extensive isomerisation and hydrogenation of the substrate alkenes.

Both in the rhodium- and in the platinum/tin-catalysed hydroformylation of alk-1-enes, widening of the natural bite angle of the diphosphine ligands has proven to be favourable for the catalytic performance.[2a,5] Recently, it was also demonstrated that in the selective hydroformylation of internal alkenes toward linear aldehydes wide bite angle diphosphine ligands can be very efficient.[6] Based on these results we wondered whether wide natural bite angles could also improve the catalytic performance of ligands having donor atoms other than phosphorus. Since the xanthene backbone is an excellent scaffold for the construction of ligands with wide natural bite angles, we set out to synthesise the (mixed) group 15 derivatives of the xantphos ligand **1** (Fig. 1). Here, we report the synthesis of the arsine analogues of xantphos **1** and their excellent performance in the platinum/tin-catalysed hydroformylation reaction. To our knowledge, xantarsine and xantphosarsine ligands **2** and **3** constitute the first efficient arsine modified platinum/tin catalysts for selective hydroformylation of terminal alkenes.

The xantarsine and xantphosarsine ligands **2** and **3** were synthesised *via* procedures similar to the synthesis of xantphos **1** (Scheme 2).[6a] Dilithiation of 4,5-dibromo-2,7-di-*tert*-butyl-9,9-dimethylxanthene **5** with *n*-butyllithium in THF at −65 °C, followed by reaction with chlorodiphenylarsine gave xantarsine

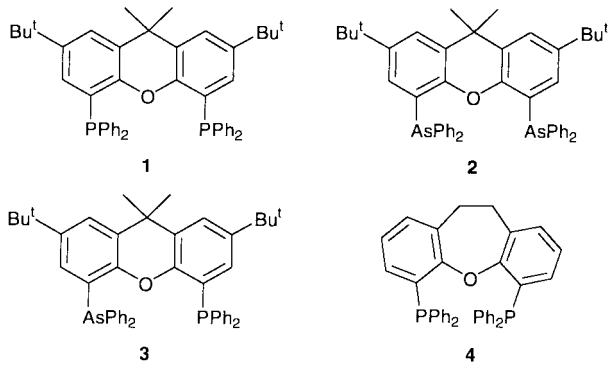

Fig. 1

2 in 83% yield. Xantphosarsine ligand **3** was obtained in 49% yield by monolithiation of bromoxantphos **6** and subsequent reaction with chlorodiphenylarsine. Bromoxantphos **6** was synthesised by monolithiation of compound **5**, followed by reaction with chorodiphenylphosphine. The calculated natural bite angles of ligands **1**, **2**, **3** and **4** are 110, 113, 111 and 102°, respectively.[7]

Ligands **1**–**4** were tested in the platinum/tin-catalysed hydroformylation of oct-1-ene (Table 1). In the hydro-

[a] Reactions were carried out in a 180 mL stainless steel autoclave in dichloromethane at 60 °C under 40 bar of $CO–H_2$ (1:1), catalyst precursor $[Pt(cod)Cl_2]$, [Pt] = 2.5 mM, $Pt:SnCl_2:P$:1-octene = 1:2:4:255. [b] Determined by GC with decane as the internal standard. [c] Averaged turnover frequencies (TOF) were calculated as (mol of aldehyde) (mol Pt)$^{-1}$ h^{-1} at 20–30% conversion.

DOI: 10.1039/a906903h

formylation of oct-1-ene the arsine based ligands **2** and **3** proved to give more efficient catalysts than the parent xantphos ligand **1**. The xantarsine ligand **2** is only slightly less selective than xantphos **1**, but more than 10 times as active. The xantphosarsine ligand **3** is even 20 times as active as xantphos **1**, while displaying the same excellent selectivity for linear aldehyde formation. This is remarkable, since up to now, without exception, arsine ligands have performed worse than phosphine ligands in platinum/tin-catalysed hydroformylation.[2c,3a,8] To our knowledge the high activity and selectivity displayed by the mixed xantphosarsine ligand **3** under these mild conditions is unprecedented.

Comparison of the activities of the xantphos ligands **1** and **4** reveals a dramatic effect of the natural bite angle. Narrowing of the natural bite angle from 110 to 102°, results in a 40 fold higher hydroformylation rate. This is accompanied, however, by a considerable increase in isomerization activity. As a result, the selectivity for linear aldehyde obtained for xantphos **4** is lower than that for xantphos **1**. It is striking that the selectivities of the xantphos ligands **1** and **4** observed in the platinum/tin-catalysed hydroformylation are virtually identical to those obtained before for rhodium.[5c,6a]

The high selectivities of ligands **1**, **2** and **3** compared to xantphos **4** can be ascribed to the wider natural bite angles of the former ligands.‡ Widening of the bite angle of the ligand will increase the steric congestion around the platinum centre resulting in more selective formation of the sterically less hindered linear aldehydes. An explanation for the higher activities of ligands **2**, **3** and **4** compared to xantphos **1** is still lacking, but we speculate that it is caused by the coordination behaviour of the ligands in the platinum/tin complexes. Increasing the natural bite angle of bidentate ligands favours the formation of *trans* complexes. Compared to xantphos **1**, xantphos **4** and the arsine ligands **2** and **3** probably give more or easier formation of the *cis*-platinum complexes, a prerequisite for efficient hydroformylation.[10]

In conclusion, wide bite angle arsine based ligands can give very efficient catalysts for selective hydroformylation of terminal alkenes. The catalytic performances of the arsine modified platinum/tin systems can compete with the best results obtained using rhodium catalysts.[1,5c,11] Especially in applications where very high l:b ratios are a necessity these systems could be interesting alternatives for rhodium–diphosphine catalysts.

Financial support from the Technology Foundation (STW) of the Netherlands Organization for Scientific research (NWO) is gratefully acknowledged.

Notes and references

‡ When comparing the activities and selectivities of ligands **1**, **2**, and **3**, it should be noted that in general the σ-donor ability and the steric effects of substituents on the donor atom decrease in the order of P > As.[9]

The chemical retro-Bingel reaction: selective removal of bis(alkoxycarbonyl)methano addends from C_{60} and C_{70} with amalgamated magnesium

Nicolle N. P. Moonen,[a] Carlo Thilgen,[a] Luis Echegoyen[b] and François Diederich*[a]

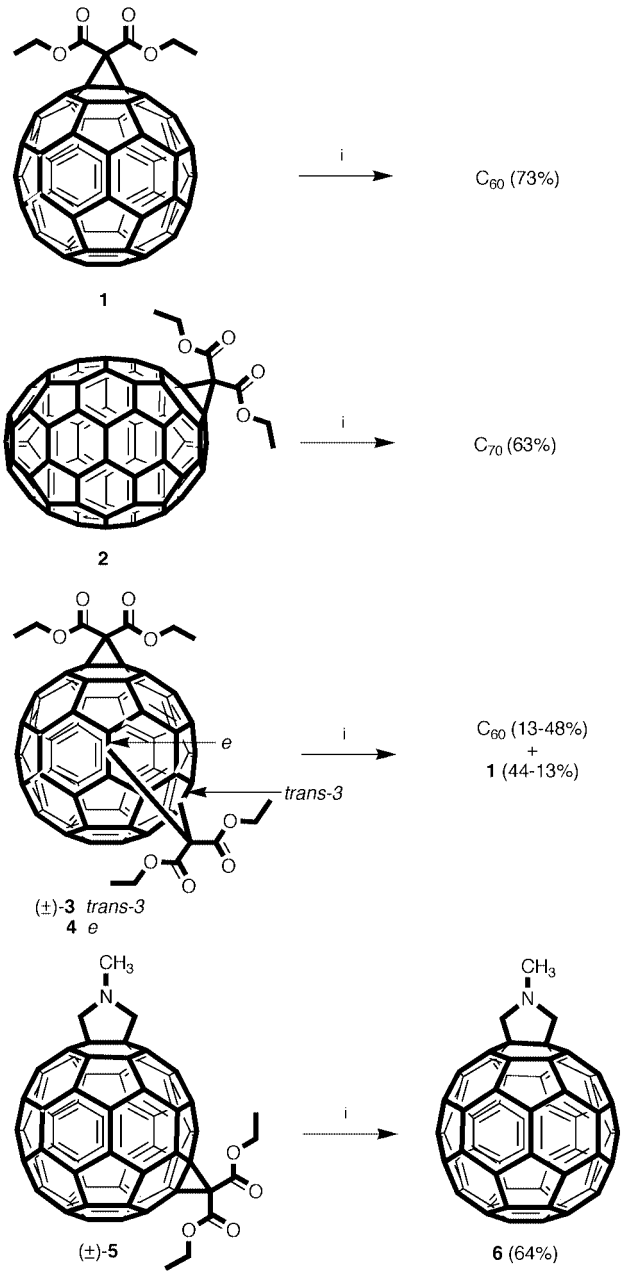
Received (in Cambridge, UK) 9th December 1999, Accepted 25th January 2000

Bis(alkoxycarbonyl)methano addends are removed from C_{60} and C_{70} derivatives by reaction with amalgamated magnesium in dry THF; this facile and selective retro-Bingel reaction, which leaves pyrrolidine rings fused to C_{60} intact, opens up the possibility of using bis(alkoxycarbonyl)methano addends as protecting and reversible directing groups in the regioselective multiple functionalization of fullerenes.

Regioselective multiple functionalization of fullerenes is a subject of great interest. A major strategy used to accomplish this task is tether-directed remote functionalization.[1] Another protocol, often used in combination with tether-directed remote functionalization,[2] is the temporary introduction of an addend which protects specific positions and, at the same time, directs new incoming addends regioselectively to other bonds on the carbon sphere. Examples for such addends, which are readily introduced and removed, are the [9,10]anthraceno bridge[3] as well as fullerene-fused cyclohexene[2,4] and isoxazoline[5] rings.

One of the most common fullerene functionalization methods is the nucleophilic cyclopropanation with 2-halomalonates, the so-called Bingel reaction.[6] Although the resulting bis(alkoxycarbonyl)methanofullerenes are generally quite stable, there were early hints that the Bingel-type addends may be removed under certain circumstances.[7] Closer investigations led to the discovery of the electrochemical retro-Bingel reaction, consisting of the preparative removal of bis(alkoxycarbonyl)methano addends from fullerene adducts by exhaustive electrochemical reduction.[8] The first successful applications of the Bingel–electrochemical retro-Bingel reaction sequence were reported in the chemistry of the higher fullerenes, with the preparation of enantiomerically pure D_2-C_{76}[8] and D_2-C_{84},[9a] pure D_{2d}-C_{84}[9a] and a new C_{84} isomer,[9a] and C_{2v}-symmetric C_{78}.[9b] The potential of bis(alkoxycarbonyl)methano addends as general protecting and reversible directing groups in fullerene chemistry prompted us to investigate the possibility of carrying out the retro-Bingel reaction under chemical conditions. Such a method would have the advantages of not requiring electrochemical equipment, avoiding the use of supporting electrolyte, and allowing conversions on a larger scale.

Initial attempts to remove the Bingel-type addend from **1** by electron transfer from Na metal or sodium naphthalenide in THF failed, leading only to materials that were insoluble in THF or toluene. Another convenient reducing agent which is easy to handle is metallic magnesium. Heating **1** with Mg powder (25 equiv.) in dry refluxing THF under Ar led to the formation of a brownish precipitate after *ca.* 1 d, and after 3 d, varying yields of up to 81% of C_{60} could be isolated from the mixture. In analogy to Grignard reactions, starting the retro-Bingel reaction with pure Mg sometimes proved to be quite difficult. This situation could only be partially improved through activation of the metal by treatment with I_2 prior to the addition of the fullerene derivative. Use of the highly active Rieke magnesium[10] only led to products that were insoluble in THF or toluene. Also, treatment of the commercial magnesium with $CuCl_2$ did not lead to better or more reproducible yields. The best and most consistent results were obtained by amalgamation of the Mg powder with 10% $HgBr_2$ in THF, followed by a replacement of the solvent with fresh THF, addition of the



Scheme 1 *Reagents and conditions:* i, Mg/Hg, THF, Ar, 80 °C, 3 d.

DOI: 10.1039/a909704j

methanofullerene and heating to reflux for 3 d.† Under these conditions, **1** afforded C_{60} in 73% yield while unchanged starting material was recovered in 23% yield (Scheme 1). Similarly, the C_{70} mono-adduct **2** provided 63% of the parent fullerene. These yields are comparable to those obtained by the electrochemical retro-Bingel reaction.[8] Traces of as yet unidentified by-products, which may provide useful information with regard to the reaction mechanism, were detected during chromatographic purification of the products.

Zn dust and the Zn/Cu couple[11] are both active reducing agents in the retro-Bingel reaction of **1**, but the yields (Zn: 47% C_{60}, Zn/Cu: 29% C_{60}) are lower and, particularly with pure Zn, the amount of unidentified by-products is higher.

In the case of Bingel-type bis-adducts of C_{60}, the yields were variable (Scheme 1). In different experiments, the reduction of the pure *trans*-3 and *e* regioisomers (±)-**3** and **4**, or of a mixture of the seven known regioisomers,[12] with Mg (100 equiv.) amalgamated with 10% $HgBr_2$ afforded between 48% C_{60} (and 13% mono-adduct **1**) and 13% C_{60} (and 44% **1**). These fluctuations contrast the clean conversion (up to 75% yield) of the bis-adducts to C_{60} by the electrochemical retro-Bingel protocol,[8] but the reasons for these differences are not yet understood. Interestingly, whereas the product mixture recovered from the non-exhaustive electrochemical reduction of constitutionally pure bis-adducts contained regioisomers of the starting material resulting from an intramolecular 'walk-on-the-sphere' rearrangement,[13] such isomerization was not detected in the reduction of pure (±)-**3** or **4** with amalgamated Mg.

Fused pyrrolidines introduced by 1,3-dipolar cycloaddition are among the most versatile addends in fullerene chemistry. We therefore explored whether a bis(dialkoxycarbonyl)methano addend could be removed from bis-adducts such as (±)-**5**[14] while leaving the methaniminomethano bridge intact. When (±)-**5**[15] was reacted for 3 d with amalgamated Mg (50 equiv.), fulleropyrrolidine **6**[16] was isolated in 64% yield, showing that the heterocycle is stable under the conditions of the chemical retro-Bingel reaction. This result opens up the possibility of using Bingel-type addends as protecting and reversible directing groups in future syntheses of fullerene multi-adducts that are not otherwise accessible. Investigations along these lines are now under way.

Support from the Swiss National Science Foundation is gratefully acknowledged.

Notes and references

† In a typical experiment, a mixture of Mg powder (50–150 mesh, purity ≥99.8%; 14 mg, 576 mmol) and $HgBr_2$ (20 mg, 57 mmol) (both reagents from Fluka) was sonicated in dry THF (8 ml) for 30 min under Ar, after which the solvent was replaced by fresh dry THF (8 ml) and C_{60} monoadduct **1** (20 mg, 23 mmol) was added. The mixture was sonicated for another 30 min and then heated to reflux for 3 d. Column chromatography (SiO_2; toluene–hexane 1:1) provided 12 mg (73%) of C_{60}.

Chemoselective oxidative debenzylation of tertiary *N*-benzyl amines

Steven D. Bull,[a] Stephen G. Davies,*[a] Garry Fenton,[b] Andrew W. Mulvaney,[a] R. Shyam Prasad[a] and Andrew D. Smith[a]

[a] *The Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QY. E-mail: steve.davies@chem.ox.ac.uk*

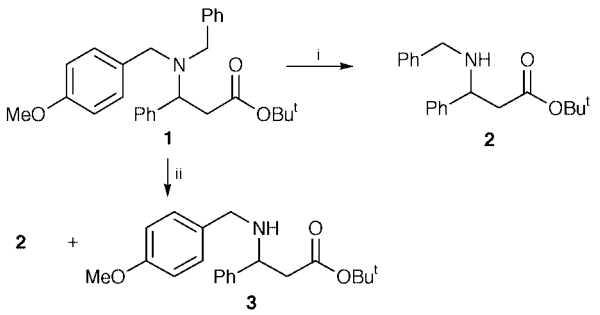
Received (in Liverpool, UK) 4th January 2000, Accepted 25th January 2000

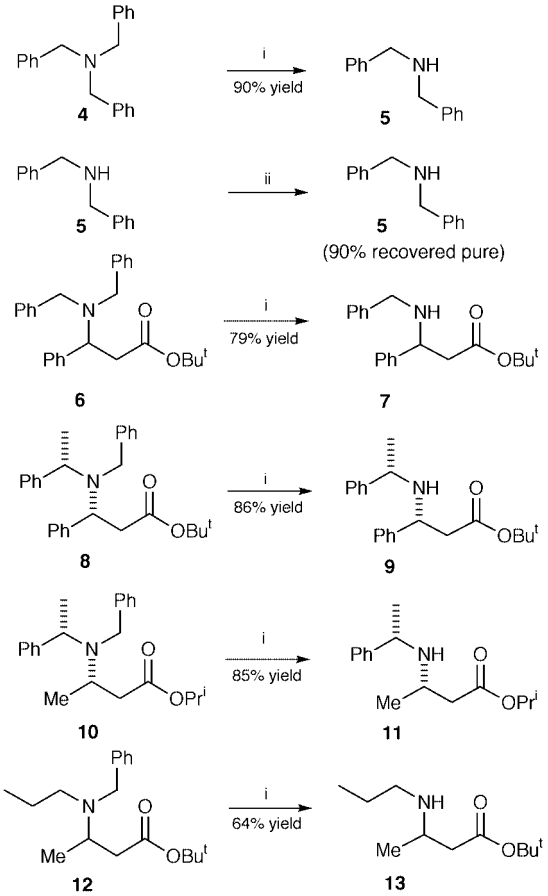
Treatment of tertiary amines containing one or more *N*-benzyl protecting groups with aqueous ceric ammonium nitrate results in clean *N*-debenzylation to afford the corresponding secondary amine.

Differentially protected homochiral lithium amide additions to α,β-unsaturated esters have proved to be an extremely versatile route for the asymmetric synthesis of homochiral β-amino acids and β-lactams.[1–3] In the course of studies directed towards extending the versatility of this lithium amide methodology, the synthetic applications of a novel debenzylation reaction observed when *tert*-butyl 3-[benzyl(4-methoxybenzyl)amino]-3-phenylpropionate **1** was treated with aqueous ceric ammonium nitrate (CAN) are reported herein. Thus, while treatment of **1** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) resulted as expected in smooth cleavage of the 4-methoxybenzyl protecting group to afford *tert*-butyl 3-benzylamino-3-phenylpropionate **2**, treatment of **1** with 2.1 equiv. of CAN in CH_3CN–H_2O afforded a 50:50 mixture of the monodeprotected products **2** and *tert*-butyl 3-(4-methoxybenzylamino)-3-phenylpropionate **3** (Scheme 1). It is noteworthy that in both cases the isolated products were those resulting from cleavage of the primary benzylic amine; the secondary benzylic centre (β-centre) remained unaffected under these conditions. This lack of selectivity for deprotection of tertiary amine **1** is in direct contrast to the well-established use of CAN for the orthogonal deprotection of 4-methoxybenzyl ethers in the presence of *O*-benzyl ethers.[4]

This unexpected reaction implies oxidation at the tertiary nitrogen atom rather than at the arene ring since the outcome of the reaction is unaffected by arene substitution and therefore should be equally applicable to debenzylation of simple tertiary benzylamines. Thus, treatment of tribenzylamine **4** with CAN gave dibenzylamine **5** in 90% yield after chromatographic purification to remove benzaldehyde.[5] The chemoselectivity of this oxidative debenzylation protocol for tertiary amines was confirmed by treating dibenzylamine **5** with excess CAN (10 equiv.), which resulted in essentially quantitative recovery of starting material. Treatment of tertiary amine **6**, which contains two *N*-benzylic and one α-substituted *N*-benzylic groups, resulted in chemoselective monodebenzylation to afford exclusively secondary amine **7** in 79% isolated yield. Similarly, *N*-debenzylation of homochiral tertiary amine **8**, which contains one *N*-benzylic and two α-substituted *N*-benzylic protecting groups, occurred without epimerisation, to afford homochiral secondary amine **9** {$[\alpha]_D$ −15.8 (*c* 1.0, $CHCl_3$); lit.[2] −16.3 (*c* 1.5, $CHCl_3$)} in 86% isolated yield. Extension of this methodology to the deprotection of tertiary amines containing either two or one benzylic groups was also demonstrated *via* treatment of tertiary amines **10** and **12** to afford secondary amines **11** {$[\alpha]_D$ −46.4 (*c* 1.0, $CHCl_3$)} and **13** in 85 and 64% isolated yield respectively (Scheme 2). The lower isolated yield for amine **13** was a result of its inherent volatility, however, no other product was detected in the ^1H NMR spectrum obtained from the crude reaction mixture.



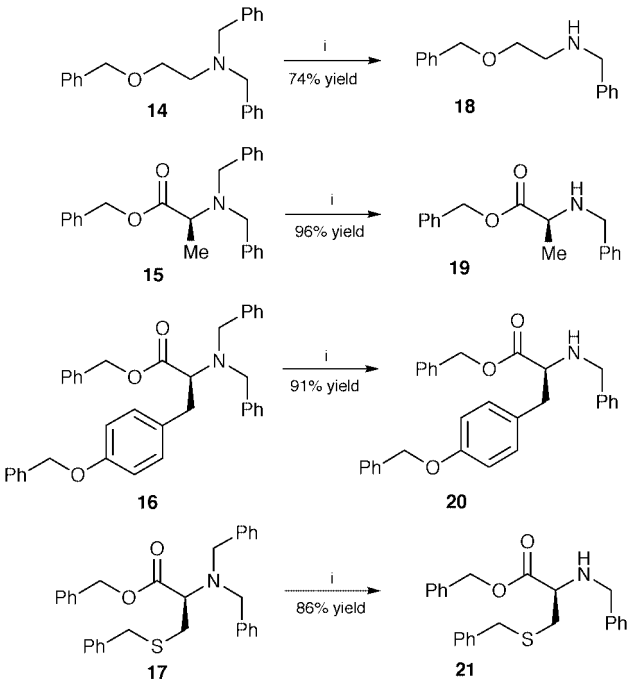
Scheme 1 *Reagents and conditions:* i, DDQ, CH_2Cl_2–H_2O (5:1); ii, CAN (2.1 equiv.), CH_3CN–H_2O (5:1).



Scheme 2 *Reagents and conditions:* i, CAN (2.1 equiv.), CH_3CN–H_2O (5:1); ii, CAN (10.0 equiv.), CH_3CN–H_2O (5:1).

Since benzyl groups are commonly employed as protecting groups for other heteroatom functionality the chemoselectivity of this transformation was examined by carrying out the CAN-mediated tertiary amine debenzylation protocol on a range of perbenzylated *N*,*N*-dibenzylamines which also contained ben-

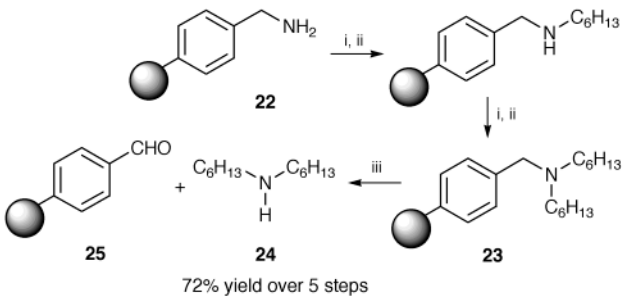
DOI: 10.1039/b000071j



Scheme 3 *Reagents and conditions:* i, CAN (2.1 equiv.), CH_3CN–H_2O (5:1).

zyl ethers, benzyl esters, benzyl phenolates and benzyl thiolates. Thus, treatment of **14**–**17** resulted in clean *N*-deprotection to afford the mono-*N*-debenzylated secondary amines **18**, **19** {$[\alpha]_D$ −38.6 (*c* 1.0); lit.[6] $[\alpha]_D$ for *ent*-**19** 40.4 (*c* 1.0)}, **20** {$[\alpha]_D$ −8.3 (*c* 1.2} and **21** {$[\alpha]_D$ −21.9 (*c* 1.1)} in good to excellent isolated yields (Scheme 3).

With this chemoselective debenzylation of tertiary amines in hand, the application of this novel cleavage protocol for solid phase synthesis was apparent. Thus, consecutive reductive alkylation[7] of aminomethyl polystyrene resin **22** with hexanal afforded polymer supported tertiary amine **23**, which was treated with CAN to afford dihexylamine **24** in 72% overall yield over the five steps (Scheme 4). This cleavage protocol constitutes a novel oxidative traceless linker synthesis of secondary amines on a solid support[8] and is of potential further utility in that cleavage of the secondary amine liberates formyl polystyrene resin **25** (ν_{max} 1700 cm^{-1}; lit.[9] 1700 cm^{-1}), thus affording the possibility of resin recycling.



Scheme 4 *Reagents and conditions:* i, $CH_3(CH_2)_4CHO$ (5.0 equiv.), trimethyl orthoformate; ii, $NaBH_4$ (10.0 equiv.), DMF–EtOH (3:1); iii, CAN (5.0 equiv.), CH_3CN–H_2O (5:1), room temp.
