The effects of DLH and DLI on the dienelactones **1** and **2** are illustrated in Fig. 1 and the K_m and k_{cat} values characterising these interactions are summarised in Table 1. Hydrolysis of each of the lactones **1** and **2** is catalysed efficiently by DLH and there is no evidence of isomerisation of the substrates in the presence of this enzyme. In complete contrast, DLI catalyses the interconversion of the lactones **1** and **2**, to the equilibrium mixture where they are present in the ratio 53 : 47, and little hydrolysis of either substrate **1** or **2** is discernible, even long after equilibration of the substrates **1** and **2** is complete. On this basis, the k_{cat} values for hydrolysis of the lactones **1** and **2** by DLI are at least 100-fold less than those for substrate isomerisation.

Table 1 Kinetic parameters for interaction of DLH and DLI with the lactones **1** and **2**[a]

Enzyme	Substrate	k_{cat}/s^{-1}	10^3 K_m/mol dm^{-3}
DLH	**1**	14 ± 1 (9.2)[b]	0.20 ± 0.015 (0.17 ± 0.007)[b]
DLH	**2**	19 ± 0.2 (30)[c]	0.011 ± 0.001 (0.016)[c]
DLI	**1**	0.63 ± 0.03	4.4 ± 0.10
DLI	**2**	0.18 ± 0.003	2.7 ± 0.13

[a] In 0.02 mol dm^{-3} HEPES buffer containing 0.001 mol dm^{-3} EDTA, at pH 7.0 and 298 K. [b] Data from ref. 4. [c] Data from refs. 1 and 13.

The contrasting behaviour of DLH and DLI is not due simply to substrate isomerisation and hydrolysis by DLH and substrate isomerisation without hydrolysis by DLI. Hydrolysis of the *Z*-lactone **2** by DLH is catalysed *ca.* 25 times more efficiently (k_{cat}/K_m) than that of the *E*-isomer **1** under the conditions of this study. Isomerisation accompanying hydrolysis of the *E*-lactone **1** by DLH would therefore be expected to result in a build-up in the concentration of the *Z*-isomer **2**, until its proportion of the residual lactones **1** and **2** approached at least 4%. Isomerisation

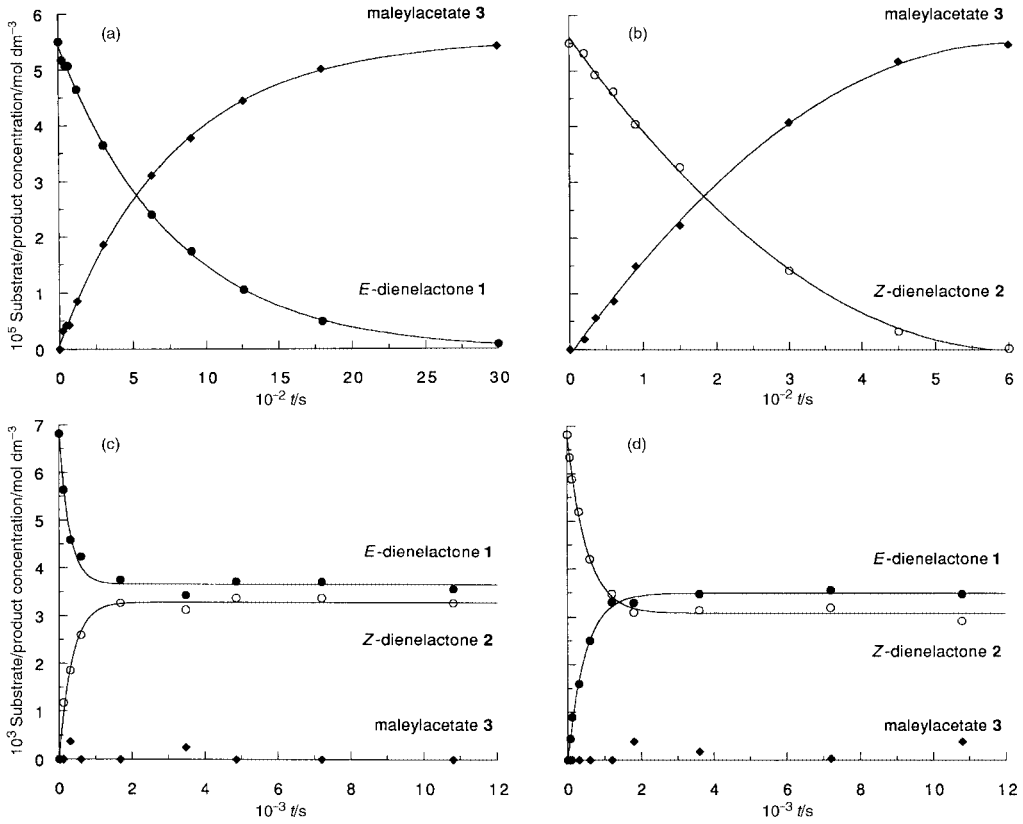

Fig. 1 Concentrations[a] of the *E*-dienelactone **1** (●), the *Z*-isomer **2** (○) and maleylacetate **3** (◆) in mixtures obtained by treatment[b] of (a) the lactone **1** with DLH (2×10^{-8} mol dm^{-3}), (b) the lactone **2** with DLH (1.2×10^{-8} mol dm^{-3}), (c) the lactone **1** with DLI (1.07×10^{-5} mol dm^{-3}), and (d) the lactone **2** with DLI (1.07×10^{-5} mol dm^{-3}). [a] Determined by HPLC. [b] In 0.02 mol dm^{-3} HEPES buffer containing 0.001 mol dm^{-3} EDTA, at pH 7.0 and 298 K.

of the *Z*-lactone **2** by DLH would be expected to lead to the accumulation of an even larger proportion of the *E*-isomer **1**, at least up to the equilibrium value of 53%. Such proportions (even the 4%) are well above the limits of detection, so there is no indication that DLH catalyses substrate isomerisation, only substrate hydrolysis. With DLI, substrate isomerisation occurs without hydrolysis.

The reactions of the lactones **1** and **2** with DLH involve formation of the thioester intermediate **4a** (Scheme 2).[10] In principle, DLI could react in a quite different manner, by reversible Michael addition of the enzyme's active site serine to the enolic carbon of the substrates **1** and **2**, with isomerisation. However, this mechanism seems implausible, since a similar process involving the thiolate of DLH would be more likely to lead to isomerisation if that was the case, and the distance between the serine oxygen of DLI and the enolic carbon of the substrates **1** and **2** is likely to be too great. The crystal structure of the lactam analogue of the lactone **2** bound in the active site of DLI indicates that this distance is 4.2 Å.[10] Thus it seems more reasonable that DLI reacts *via* the ester intermediate **4b** (Scheme 2). The lack of hydrolysis of this species may indicate that water is not available, at least in the necessary orientation, in the active site of the mutant protein. Alternatively, it could be due to non-productive collapse of the tetrahedral intermediate **5b**.[14] Whereas the intermediate **5a** will readily collapse with loss of the thiolate group, to give maleylacetate **3**, the analogous serine derivative **5b** should most readily lose hydroxide to revert to the ester **4b**, which could then recyclise. By analogy, with UDP-glucose dehydrogenase it has been found that the Ser mutant, obtained by displacing the active site Cys-260, reacts with the substrate to give an acyl enzyme, that is less labile towards hydrolysis than the corresponding putative thioester formed from the native protein.[15] However, the UDP-glucose dehydrogenase mutant is not active catalytically, unlike the situation with DLH and DLI, where both proteins are catalysts but of different processes. Irrespective of the mechanism, this difference between DLH and DLI is clear. The reaction of DLI with the lactone **1** affords ready access to the isomer **2**, and the general utility of this interconversion is currently being explored.

We are grateful to J. B. Kelly for assisting with the preparation of the *Z*-lactone **2**.

The first examples of enantiomerically pure metallomesogens containing the chiral centre directly bonded to the metal are reported; the chiral complexes show different phase behaviour to the racemic modifications.

There are many examples of chiral liquid crystals. Since the properties that chirality can confer to liquid crystals, such as ferroelectricity, are very attractive for technological applications, interest in chiral liquid crystals is more than purely academic. Whilst there has been an upsurge of interest in metal containing liquid crystals (metallomesogens) over the last two decades,[1–3] there have been relatively few examples of chiral metallomesogens. Most of these metallomesogens have relied on a chiral centre remote from the central core of the molecule to induce the asymmetry.[4–8] To date, no-one has fully investigated the effect of directly bonding a chiral centre to a metal within the metallomesogen. Early examples include a family of platinum stilbazole alkene complexes which proved to be unresolvable,[9,10] and a family of ruthenium bipyridyl compounds, where no attempt was made to separate enantiomers.[11]

Sulfoxides are widely used as ligands in platinum chemistry, normally bonding through the sulfur. Chiral sulfoxides with two different substituents are configurationally stable, and can be resolved into enantiomers.[12,13] Thus chiral sulfoxides, with two different alkyl chains, present themselves as ideal ligands for platinum based metallomesogens. By using a stilbazole ligand to complete the coordination sphere of the platinum, we can prepare direct analogues of the alkene complexes reported earlier.[9,10] It has been shown that such a highly unsymmetrical structure can be very beneficial, with reductions in the melting and clearing points of up to 100 K.

Enantiomerically pure methyl(*n*-alkyl)sulfoxides are available[14] and the methodology for the synthesis of appropriate platinum complexes is well understood. Crucially, the chirality at the sulfur has been shown to be configurationally stable on coordination to platinum with no racemisation observed even on ligand displacement.[15] Thus, using both racemic and enantiomerically pure sulfoxides we were able to isolate the required neutral complexes in a simple two step procedure, in effectively quantitative yield (Scheme 1).† Recrystallization of the products in diethyl ether–chloroform gave analytically pure samples which were analysed by NMR,‡ elemental analysis,§ polarimetry,¶ DSC and hot-stage polarised optical microscopy (Table 1).

All the new complexes reported here showed mesogenic behaviour at accessible temperatures. The phase behaviour of the new complexes is listed in Table 1 and summarised in Fig. 1. Thus it can be seen that all the complexes showed a melting transition into a mesophase at around 70 °C and cleared into the isotropic between 120 and 135 °C.

The most significant observation is the difference between the thermal behaviour of the racemic and chiral forms. The racemic compounds clearly exhibit two mesophases: a highly

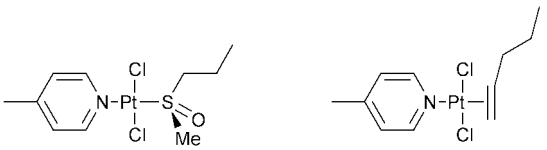

Fig. 2

ordered crystal smectic G followed by a smectic F‖ at higher temperatures, whereas the enantiomerically pure compounds only exhibit the smectic F phase. The melting points of the enantiomerically pure compounds are all about 10 K higher than the racemic compounds, though the clearing points are much more similar.

That the melting points of the chiral and racemic forms show a large difference is not totally unexpected: the packing arrangements within the crystal forms (assuming that the racemic form crystallises with both enantiomers present in the unit cell) must be substantially different—thus the melting points must be different. The presence of a short lived crystal smectic G for the racemic form at a temperature before the enantiomerically pure compound even melts can also be attributed to the differing crystal forms. At higher temperatures the molecules are much more mobile, therefore the intermolecular forces are more of an average, and thus less dependent on the precise structure of the molecule. Hence, the effect of enantiopurity on thermal behaviours is reduced and the final transition to the isotropic liquid is much the same for both racemic and enantiomerically pure compounds.

This type of effect has been seen on a number of occasions with organic compounds, with perhaps the most graphic demonstration being the existence of the so-called twist grain boundary phases,[16] though such a large effect has never been observed before with metallomesogens. This is almost certainly due to the presence of the chiral centre directly bonded to the mesogenic core, rather than remote on a chain. One group have reported the use of chiral carboxylates to bridge palladium centres within a dimeric metallomesogen, which gives rise to blue phases which would not have been present in the racemic mixtures.[8]

The alkene complexes reported earlier[9,10] typically melt into a smectic A phase at around 50 °C which persists until clearing at a temperature of around 90 °C. Thus the mesogenic range of the new sulfoxide complexes is greater than that of alkene complexes reported earlier, albeit at a slightly higher temperature. However, the major difference is the observation of the more ordered smectic F phases with the sulfoxide complexes, compared to the relatively disordered smectic A phase for the alkene complexes. This difference is highly significant, as it implies much stronger lateral interactions between the sulfoxide complexes than between the alkene complexes. Simplistically, one could ascribe this difference to one or both of two factors: the steric arrangement around the platinum, or the electronic effects of the different ligands. The geometry of a coordinated sulfoxide at platinum is known to approximate to a tetrahedral sulfur,[17] thus resulting in a compact arrangement and allowing the long chains to freely lie along the main axis of the molecule. In contrast, a coordinated alkene bonds *via* a face-like interaction, resulting in the alkyl chain being forced away from the main axis of the molecule (Fig. 2). Thus these steric factors would suggest the sulfoxide complexes would be able to achieve the greater lateral interactions necessary for the smectic F phase, whereas the alkene complexes could not. The major electronic difference between the two families relates to the sulfur–oxygen double bond. However since this bond is known to only be weakly polarised, any dipole that arises is almost certainly insignificant. Changing the sulfoxide for the alkene also has some effect on the melting point—the octadecene (effectively a 16 carbon chain) complex has a melting point of 64 °C compared with 75 °C for the racemic C-16 sulfoxide **1c** and 84 °C for the chiral analogue. The corresponding clearing points are 88 °C for the octadecene, and 119 and 122 °C for the racemic and chiral sulfoxides, respectively. Once again the most probable cause of the variation is the steric effect of the alkene which will destabilise both the crystal and the mesophase, resulting in lower transition temperatures.

We are now investigating the full range of platinum sulfoxide complexes over the full range of enantiopurity in order to see if the effects we observe are accentuated with longer or shorter chain lengths and to fully characterise the effect of enantiopurity on phase behaviour.

We would like to thank the British Council and MURST for a joint project grant.

Notes and references

† Methyl alkyl sulfoxide **1** (0.30 mmol) dissolved in DMF (4 ml) was added to a suspension of potassium tetrachloroplatinate (0.30 mmol) in DMF (1 ml). The mixture was stirred (40 °C, 16 h) giving a deep yellow solution. The solution was filtered to remove KCl and **2** precipitated as a yellow compound upon addition of diethyl ether (20 ml) followed by hexane (20 ml).

Alkoxy stilbazole (0.10 mmol) dissolved in acetone (5 ml) was added to a solution of **2** (0.10 mmol) in acetone (50 ml). The solution was stirred (1 h) by which time it had changed to a paler yellow colour. The solution was concentrated to one third of the original volume and **3** precipitated by addition of diethyl ether. The product was collected by filtration, washed with diethyl ether, then methanol and dried in air. Yield: 95% (0.095 mmol).

The chiral sulfoxides used were (*S*)-**1a**, (*R*)-**1b** and (*S*)-**1c**. Note that the priority at sulfur reverses on coordination to platinum, thus an (*R*)-sulfoxide becomes an (*S*)-platinum complex.

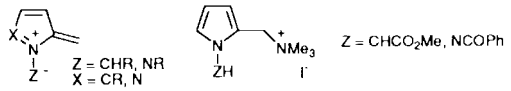
Received (in Cambridge, UK) 24th February 2000, Accepted 7th March 2000
Published on the Web 30th March 2000

The transient 8π 1,7-dipolar azafulvenium methides 5 and 8 undergo sigmatropic [1,8] H shifts and the acyl derivatives 12 electrocyclise to give novel pyrrolooxazines 13; the related diazafulvenium methide 15 can be intercepted in 8π + 2π cycloadditions with silylated acetylenes.

1,3-Dipolar cycloaddition is an allowed 4π + 2π pericyclic process and has been of considerable value in organic synthesis.[1] 1,4-Sigmatropic shifts[2] and electrocyclic reactions[3] in 1,3-dipoles are also well established. However, although 1,5[4] and 1,7[5]-dipolar cyclisation are well recognised reactions, other pericyclic reactions of extended dipoles (those with more than 4π electrons) are less familiar.[6] In designing an extended dipole suitable for cycloaddition, competing electrocyclisation has to be prevented and the termini of the dipole must be a convenient distance apart for bonding to an appropriate cycloaddend. These principles are illustrated in the oxidopyridinium betaines, studied by Katritzky *et al.*,[6,7] which function as 4π 1,3-dipoles with 2π systems but as 6π 1,5-dipoles with dienes. We report here, our preliminary studies with the novel aza- and diaza-fulvenium ylide systems **1** (X = CR, N) which, in principle, can act as 4π 1,3-dipoles or as 8π 1,7-dipoles.

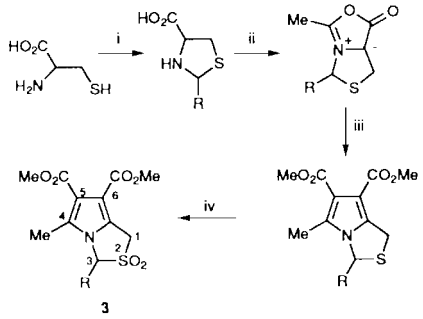
Initial, unsuccessful approaches towards the azafulvenium methides and imides **1** (X = CR) involved attempted base catalysed elimination from the pyrrole derivatives **2**. Earlier, an analogous elimination approach to systems of type **1** (X = CR)



1 **2**

by Padwa *et al.*[8] also failed. Padwa had also considered the thermal extrusion of SO_2 from the dihydrothienopyrrole *S,S*-dioxide **3** (R = H) but found it to be too thermally stable. Our own experience with extrusion of SO_2 from heterocyclic sulfones and with flash vacuum pyrolysis (FVP)[9] led us to reinvestigate this thermolysis. The sulfone **3** (R = H) did not extrude SO_2 when heated in solution at 300 °C. However, on FVP at 700 °C/10^{-3} mm SO_2 was eliminated although no identifiable products arising from the dipole were detected on the cold receiver. Intermolecular trapping was attempted by cocondensation of the pyrolysate at −180 °C with methyl vinyl ketone or by condensation in a matrix with dichloromethane, which was allowed to thaw and mix with a solution of *N*-phenylmaleimide or dimethyl acetylenedicarboxylate below −100 °C. No evidence was obtained for the formation of adducts.

Encouraged by the extrusion of SO_2 we designed derivatives for which the formation of the dipole might be revealed by intramolecular trapping in the FVP experiment. Introduction of aryl groups (phenyl, 4-anisyl and 2-thienyl) at the 3-position was accomplished using the appropriate aldehyde in the synthesis of the thienopyrrole (Scheme 1). However, on FVP, there was no evidence for electrocyclisation of the type seen with *ortho*-quinodimethanes.[9] On the other hand, introduction of methyl groups at both the 1- and the 3-positions led to vinylpyrroles **6** and **9**, respectively, on FVP. Their formation



3

can be explained by allowed, suprafacial [1,8] H shifts in the 8π, 1,7-dipolar systems **5** and **8**, respectively. Synthesis of the 3-methyl derivative **4** was achieved by use of acetaldehyde in the route to the thienopyrrole (Scheme 1) and the 1-methyl derivative **7** was obtained from sulfone **3** (R = H) by methylation using LHMDS and iodomethane. Subsequent methylation of the 1-methyl compound **7** gave the 1,1-dimethyl derivative **10**. As expected the 1-proton in **3** (R = H) is more acidic than the 3-proton since it is activated by the 6-ester group.

The reaction of the 3-methyl derivative **4** to give the *N*-vinylpyrrole **6** was clean but the 1-methyl compound **7** gave the 2-vinylpyrrole **9** contaminated with an unidentified product showing vinylic H in the NMR spectrum. For sigmatropic shifts to occur the methyl groups must adopt an inward configuration. In a delocalised dipolar system there will be a barrier to rotation around the partial double bonds but rotation at the high temperatures of the FVP is not unreasonable. The difference between the two derivatives **4** and **7** may reflect the differing ease with which the dipoles can attain the required configurations having inward methyl groups (only the inward configurations are illustrated in Scheme 2). Significantly, the reaction of

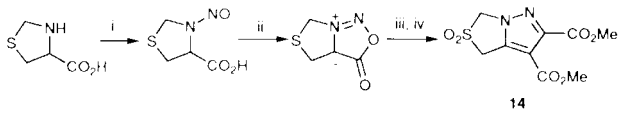
Scheme 3 *Reagents and conditions*: i, LHMDS; ii, RCOCl; iii, 200 °C/1,2,4-trichlorobenzene.

the 1,1-dimethyl derivative **10** where one of the methyl groups must necessarily be inward was cleanest.

A series of 1-acyl derivatives **11**† (Scheme 3) was also obtained by treatment of sulfone **3** (R = H) with LHMDS followed by an acyl chloride. Optimum conditions involved sequential treatment with base (1 equivalent), acyl chloride (1 equivalent) followed by further equivalents of base and acyl chloride. On FVP (600 °C/10^{-3} mm) the benzoyl derivative **11** (R = Ph) gave the pyrrolooxazine **13** (R = Ph), the first example of this new ring system and further strong evidence for generation of the desired dipolar system. Introduction of the acyl group lowers the temperature required for extrusion of SO_2 and the reaction, which can be carried out in solution at 200 °C, is general for all the acyl derivatives (Scheme 3).† The ability to generate the dipole in solution opened up the possibility of intermolecular trapping in a cycloaddition but extrusion of SO_2 in the presence of *N*-phenylmaleimide, dimethyl acetylenedicarboxylate or bis(trimethylsilyl)acetylene gave only the oxazine and no trace of cycloadduct. Prolonged heating of the oxazine in the presence of the dipolarophiles gave only recovered starting material and there was no evidence for reversibility in the electrocyclic ring closure.



Scheme 4 *Reagents and conditions*: i, $NaNO_2$/HCl; ii, TFAA/Et_2O; iii, DMAD; iv, MCPBA.

The pyrazole analogue **14** was obtained as shown (Scheme 4). Alkylation and acylation of **14** proved difficult but extrusion of SO_2 from this unsubstituted sulfone occurs more easily and can be achieved in solution. The extra pyrazole ring N thus appears to exert the same effect as an electron withdrawing acyl group at the 1-position of the pyrrole system. Extrusion of SO_2 in refuxing 1,2,4-trichlorobenzene in the presence of *N*-phenylmaleimide or dimethyl acetylenedicarboxylate gave no adducts but in the presence of bis(trimethylsilyl)acetylene (a reactive electron rich dienophile at high temperatures[10]) a cycloadduct **16** was obtained in 34% yield providing the first evidence for formation of these dipolar systems by intermolecular trapping (Scheme 5).† When the reaction was carried

out in a sealed tube with prolonged heating the aromatised adduct **17** was isolated (24%) (Scheme 5)†. Under similar conditions trimethylsilylacetylene gave a mixture of regioisomers. It may be significant that the dipolar systems undergo cycloaddition only with the electron rich dipolarophile and that addition occurs across the 1,7 and not the 1,3 positions. Molecular orbital calculations[11] for the pyrazole derivative (Fig. 1) indicate that dipole LUMO–dipolarophile HOMO interactions are dominant and that the MO coefficients are larger at the 1 and 7 positions than at the 3 position.

Vanadium species in tetrahedral and octahedral coordination in V-MCM-41 molecular sieve are characterized by UV resonance Raman bands at 1070 and 930 cm^{-1} respectively.

Vanadium-substituted molecular sieves have been found to be excellent catalysts for many selective oxidation reactions.[1–3] In particular, V-MCM-41 has drawn much interest owing to its large pore diameter which is suitable for selective oxidation of large organic compounds.[4–6]

The catalytic activity and selectivity of vanadium-substituted molecular sieves are directly related to the coordination structures of the vanadium species in the molecular sieves. In general, three forms of vanadium species, isolated tetrahedral, two-dimensional octahedral species and crystalline V_2O_5, are believed to be present.[4,5,7,8] The coordination structure of vanadium species in V-MCM-41 has been investigated by ^{51}V NMR, UV–VIS absorption spectroscopy and many other techniques,[4,5,8] but identification of vanadium species in tetrahedral or octahedral coordination environments is not straightforward. Raman spectroscopy is a potentially viable technique for the study of the structure of vanadium species in V-MCM-41, since it has been used to characterize supported vanadium oxides with both tetrahedral and octahedral coordination structures.[9,10]

However, there have been relatively few Raman studies on vanadium-substituted MCM-41,[8] mainly because of fluorescence interference and the low sensitivity of conventional Raman spectroscopy. The limited amount of substituted vanadium atoms also hinders the application of Raman spectroscopy in characterization of vanadium atoms in V-MCM-41.

UV Raman spectroscopy has been proved to be a powerful technique for the study of catalysts and other solids,[11,12] especially, for the identification of isolated transition metal atoms substituted in the framework of molecular sieves[13] or grafted on metal oxides.[14] An increase in the intensity of Raman signal and decrease in the intensity of fluorescence background help to increase the sensitivity of the Raman spectra. Moreover, the resonance Raman effect will selectively enhance the intensity of the Raman signal by several orders of magnitude when the excitation laser line is close to the electronic transition absorption of the samples.

In this work, for the first time, we study the different vanadium species in V-MCM-41 using UV resonance Raman spectroscopy. Based on the UV resonance Raman effect the vanadium species in tetrahedral and octahedral environments in V-MCM-41 can be successfully identified by UV resonance Raman spectroscopy.

MCM-41 and V-MCM-41 were synthesized according to the method reported in the literature.[4] V-MCM-41 samples which possess Si/V ratios of 250, 125 and 60 are denoted V-MCM-41 (250), V-MCM-41 (125) and V-MCM-41 (60), respectively. The as-synthesized samples show XRD patterns matching well with these reported in the literature.[4,5,15] UV Raman spectra were recorded on a homemade UV Raman spectrometer.[12] 244 and 488 nm lines from a Innova 300 FRED (Coherent) laser were chosen as the excitation sources. The laser power at the samples were kept below 2.0 mW for the 244.0 nm line and 100 mW for the 488 nm line. The spectral resolution is estimated to be 2.0 cm^{-1} for UV Raman spectra and 1.0 cm^{-1} for visible Raman spectra.

Fig. 1 shows Raman spectra of V-MCM-41 and MCM-41 samples excited by the 488 nm line. The signal to noise ratio of visible Raman spectra is very poor because of both fluorescence interference and the inherently low sensitivity of visible Raman spectroscopy. The MCM-41 sample excited by the 488 nm line showed weak Raman bands at 490, 610, 810 and 970 cm^{-1}. Bands at 490 and 610 cm^{-1} are attributed to the 3 and 4 Si siloxane rings, respectively,[10] while the bands at 810 and 970 cm^{-1} are assigned to the siloxane bridges (Si–O–Si) and surface silanol groups of MCM-41.[8,10] The visible Raman bands of V-MCM-41 are similar to that of MCM-41 in that no additional bands of V-MCM-41 due to vanadium species are observed. This means that the Raman bands associated with vanadium species in MCM-41 are too weak for detection by visible Raman spectroscopy.

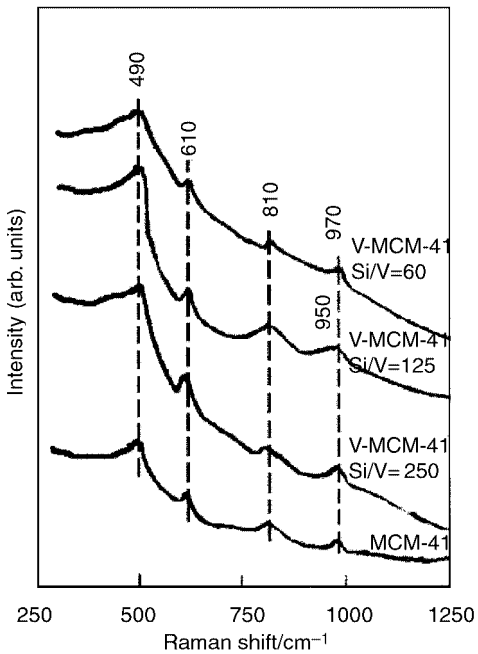

Fig. 1 Visible Raman spectra of V-MCM-41 and MCM-41 excited by 488 nm line radiation.

Compared with visible Raman spectra, UV Raman spectroscopy gives significantly different spectra, (Fig. 2). Besides the Raman bands at 490, 610 and 810 cm^{-1} which appear in the visible Raman spectra, Raman bands in the region 900–1200 cm^{-1} are present in the UV Raman spectra of MCM-41 and V-MCM-41 samples. The band at 970 cm^{-1} of MCM-41 is assigned to surface silanol stretching vibrations while weak bands in the region 1000–1200 cm^{-1} of MCM-41 are attributed to the asymmetric stretching modes of Si–O–Si bridges. These

DOI: 10.1039/b000557f

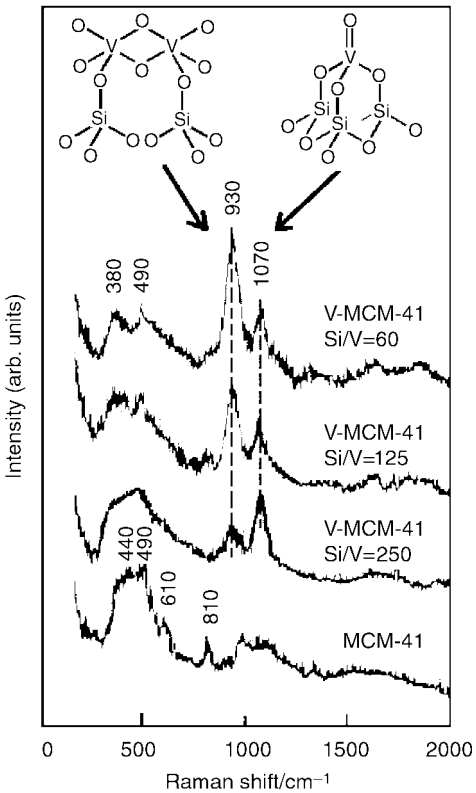

Fig. 2 UV Raman spectra of V-MCM-41 and MCM-41 excited by 244 nm line radiation.

bands become observable owing to reduced fluorescence interference when the excitation is changed from 488 to 244 nm. It is significant that two new bands at 930 and 1070 cm^{-1} are detected in UV Raman spectrum of V-MCM-41. Taking into account that the laser line at 244 nm is close to the charge transfer absorption of the vanadium species in V-MCM-41, the high intensity of the 930 and 1070 cm^{-1} bands must be a result of enhancement by the resonance Raman effect.

Two main absorptions bands are present at 275 and 340 nm in the UV–VIS diffuse reflectance spectrum of V-MCM-41.[15] These bands are assigned to low energy charge-transfer (CT) associated with framework vanadium species in tetrahedral coordination.[8,15] The band centered at 275 nm is very broad covering the range 230–300 nm. Thus the 244 nm laser line is within the electronic transition band of tetrahedral vanadium species. The UV–VIS absorption bands also appear in a similar region for polymerized vanadium oxides supported on SiO_2.[16] A band at 250 nm together with a shoulder at 320 nm is observed in the UV–VIS absorption spectrum of vanadium oxide. Therefore, the 244 nm laser line can excite both the band centered at 275 nm associated with the isolated vanadium species and the band centered at 250 nm of polymerized vanadium oxides. In other words, the 244 nm laser line can excite the electronic absorptions of vanadium species in tetrahedral and octahedral coordination simultaneously. Obviously the 488 nm laser line (visible Raman spectroscopy) lies outside of the UV–VIS absorption region for vanadium species in V-MCM-41.

The absence of a typical band at *ca.* 1000 cm^{-1} of V_2O_5 in Fig. 1 and 2 implies that no crystalline V_2O_5 is formed in V-MCM-41. This suggests that the vanadium species in V-MCM-41 are isolated or, at least, are highly dispersed on the surface. The Raman bands in the 900–1000 cm^{-1} region of supported vanadium oxides are usually attributed to hydrated polymerized vanadium oxides.[9,17] Thus the band at 930 cm^{-1} can be attributed to the V=O symmetric stretching mode of polymerized vanadium oxides.[9] The band at *ca.* 1030 cm^{-1} has been assigned to the V=O stretching vibration of monometric vanadyl species bound directly to the support. [8,9,10] The V=O stretching frequencies of VOF_3, $VOCl_3$ and $VOBr_3$ occur at 1053, 1035 and 1028 cm^{-1}, respectively.[18–20] Therefore the band at 1070 cm^{-1} is reasonably assigned to a tetrahedral V=O group bonded to the MCM-41 host. It should be noted that the band position (1070 cm^{-1}) of V-MCM-41 is higher than that of tetrahedral vanadate in the literature (*ca.* 1030 cm^{-1}).[10] An empirical relationship between V–O bond lengths and Raman stretching frequencies has been assumed based on vanadium oxides.[21] According to this assumption, a higher frequency position corresponds to shorter V–O bonds; the highest frequency position at 1070 cm^{-1} thus corresponds to the shortest V=O bond distance. This result provides evidence for the isolated mono–oxo vanadate species in V-MCM-41 molecular sieve being of tetrahedral structure with strong structural tension. This structure is metastable and aggregates into the octahedral vanadium species at high temperature as indicated by the disappearance of the band at 1070 cm^{-1} and the growth of the band at 930 cm^{-1} after calcination at high temperatures.

In summary, UV resonance Raman bands of V-MCM-41 at 1070 and 930 cm^{-1} are detected for the first time. These bands provide direct spectroscopic evidence for vanadium species in tetrahedral and octahedral environments, respectively. The vanadium species in tetrahedral coordination is an isolated species with strong structural tension, while that in the octahedral form corresponds to highly dispersed polymerized oxides. This study also demonstrates that UV resonance Raman spectroscopy is a powerful technique to selectively identify transition metal species in molecular sieves or on supports.

The silver mercurate Ag_2HgO_2 is accessible by oxygen high pressure synthesis; the compound crystallizes in a novel structure type with three interpenetrating Ag–O–Hg (10, 3) nets.

Following research into high-T_c superconductivity the Hg-based copper oxides have been found to represent a remarkable group among the cuprate HTSCs: the highest transition temperature so far has been found in the system $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ at *ca*. 133.5 K. Within a short period it has been possible to synthesize series of Hg-based homologues, which differ in the number of CuO_2 layers per unit cell.[1–4] Compared to the related group of superconducting Tl-based copper oxides[5,6] the differences in the oxidation states and coordination chemistry of Tl and Hg are significant. Whereas Tl^{3+} cations prefer a distorted octahedral oxygen environment, Hg^{2+} cations are usually coordinated by two oxygen ions in a linear 'dumb-bell' like arrangement. The higher T_c of $HgBa_2CuO_{4+\delta}$ relative to $TlBa_2CuO_{5-\delta}$ could be a result of this difference in the coordination chemistry, which influences the oxygen stoichiometry in the HgO_δ and $TlO_{1-\delta}$ layers. Oxygen depletion in the mercury compound is possible, whereas the coordination of Tl^{3+} in the thallium compound only allows a small amount of oxygen depletion.

As a consequence of the presence of toxic heavy metal cations in the above mentioned superconducting phases, many attempts have been made to replace them by non-toxic cations. A promising candidate for the substitution of mercury in these layered oxides is silver, owing to its preference to linear coordination in silver oxides. However, all attemps to synthesize superconducting layered oxides containing silver instead of mercury have so far failed. As a first step towards Ag-based superconductors we have investigated the synthesis of ternary silver mercurates that might allow a partial substitution of silver for mercury by proceeding *via* solid state reactions of oxide mixtures, *e.g.* Ag_xHgO_y/BaO/CuO. The novel material Ag_2HgO_2 represents such a precursor, containing Ag^+ and Hg^{2+} cations in the characteristic oxygen 'dumb-bell' coordination mode.

Black crystals of Ag_2HgO_2 were prepared by solid state reaction of Ag_2O (precipitated from an aqueous $AgNO_3$ solution by adding 3 M NaOH solution) and HgO (Aldrich, 99%) under oxygen pressure. The binary oxides were mixed in a molar ratio of 1:1 and then annealed for 3–5 days in gold crucibles placed in stainless steel autoclaves. The optimized reaction temperature and oxygen pressure were 310 °C and 150 MPa, respectively. As an accelerator 3 ml water or 1 ml 1 M KOH solution for single crystalline products were added.

According to the structure determination using single-crystal diffractometer data, Ag_2HgO_2 shows a novel structure type.† Both cations are in d^{10} configuration exhibiting characteristic linear oxygen coordination (Table 1). The O–Ag–O units (Ag–O distances: 211.7 and 212.1 pm; O–Ag–O angle: 178.5°) form zigzag chains along [100] and [010]. These chains are connected *via* O–Hg–O units (Hg–O distance: 202.6 pm; O–Hg–O angle: 165.6°) to a three-dimensional net, consisting of decagons with oxygen atoms forming the knots (Fig. 1). As a consequence of these connectivities oxygen attains a threefold coordination (2 × Ag, 1 × Hg). The (10, 3) net is topologically identical to the net formed by silicon in $ThSi_2$ or by boron in α-B_2O_3.[7] In this respect, Ag_2HgO_2 can be regarded as antitypic to boronoxide. The crystal structure consists of three such identical (10, 3) nets, interpenetrating each other.

The silver partial structure in Ag_2HgO_2 shows a structural feature which is very common to silver-rich oxides: in spite of their positive charges, the silver cations form cluster-like agglomerates[8,9] with Ag–Ag distances ranging in general from *ca*. 280 to 330 pm, some may even be shorter than the distance in silver metal (289 pm). In Ag_2HgO_2 the presence of two different cations in d^{10} configuration yields an unprecedented situation. The shortest Ag–Hg distances of *ca*. 333.4 pm are somewhat larger than the Ag–Ag contacts, which range between 297.4 and 308.7 pm, however, they are still less than the van der Waals distance. This suggests the presence of weak bonding interactions between all d^{10} configurated cations in Ag_2HgO_2. Considering all Ag–Ag contacts up to the van der Waals distance for silver of *ca*. 340 pm, the silver atoms form a three dimensional network of corner-sharing tetrahedra. Includ-

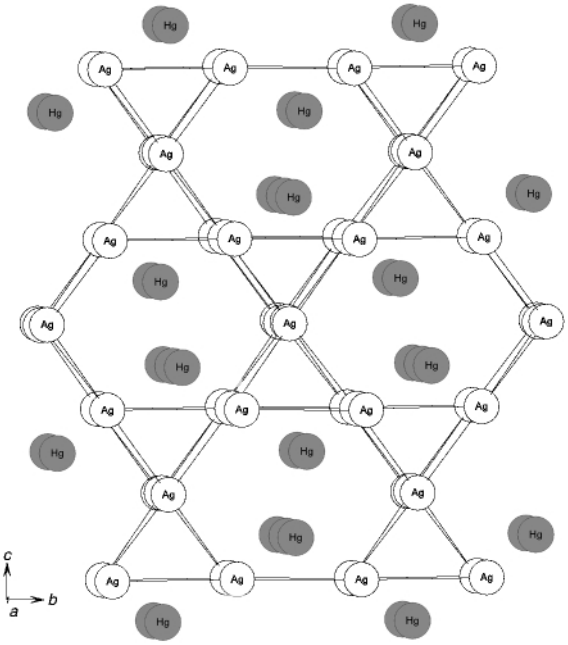

Fig. 2 The cation partial structure of Ag_2HgO_2.

ing mercury the resulting arrangement closely corresponds to Laves phase $MgCu_2$. In this description the silver cations occupy the Cu positions, whereas the mercury cations are located on the Mg positions in $MgCu_2$ (Fig. 2). Thus, the approach of describing crystal structures of extended non-metallic solids starting with the partial structures of the constituting metals applies well to Ag_2HgO_2.[10, 11]

The title compound decomposes at 340 °C in one step into its elements. According to EDX analyses (average of 20 spots), the Ag/Hg ratio is 1.95:1 and the samples are free of potassium. Measurements of the magnetic susceptibility show temperature independent diamagnetic behavior ($\chi_{obs} = -127 \times 10^6$ cm^3 mol^{-1}; $\chi_{cal} = -109 \times 10^6$ cm^3 mol^{-1}). In the temperature range investigated, 50–300 K, Ag_2HgO_2 is semiconducting ($\Delta E_{gap} = 0.24$ eV).

In our view the novel silver mercurate Ag_2HgO_2 might be of significant importance in the field of superconductivity either after doping or for use as a starting material for the synthesis of Ag/Hg/Ca/Ba/Cu/O phases.

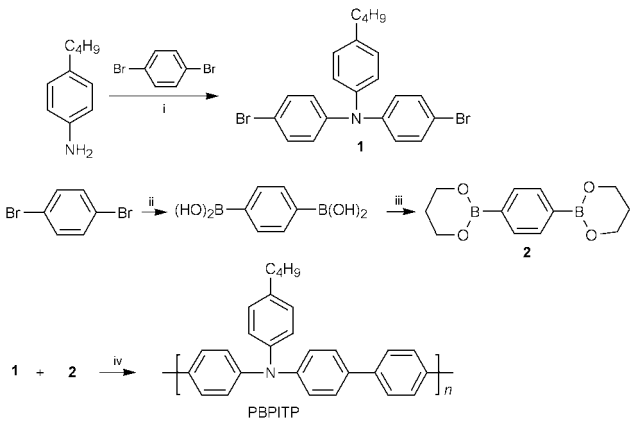
Published on the Web 30th March 2000

A new soluble triphenylamine-based conjugated polymer, poly[*N*-(4′-butylphenyl)imino(1,1′:4′,1″-terphenyl-4′4″-ylene)], (PBPITP), has been synthesized, which emits blue photoluminescence (PL) with high absolute PL quantum efficiency (45 ± 3%) but exhibits red electroluminescence (red shifted by as much as 157 nm from the PL spectrum).

In the last two decades, conjugated polymers have attracted considerable attention because of their promising applications in optoelectronic devices.[1] In particular, significant progress has been achieved in the development of light-emitting diodes (LEDs) based on conjugated polymers.[2] The important molecular structures for light-emitting applications have been reviewed recently.[3,4] In the past few years, some effort has also been devoted to introducing group 13 and 15 elements, such as boron and nitrogen, into backbones of conjugated polymers to explore new functional materials.[5–8] Although the conjugation is limited because of the introduction of B or N atoms, in which the B or N atoms are connected with C atoms with three σ covalent bonds, extension of π-conjugation along the backbones *via* the vacant p-orbitals of boron atoms or the lone-paired electrons of nitrogen atoms is observed. Some attractive properties, such as improved solubility, high PL efficiency and high stability toward air oxidation, have been demonstrated in such polymers.[5,6] Among the new developed polymers, triarylamine-based ones are particularly interesting because they have low ionization potentials (I_p) and exhibit good hole transporting properties in organic LEDs.[9,10] Here, we report the synthesis of a new triarylamine-based conjugated polymer, poly[*N*-(4-butylphenyl)imino(1,1′:4′,1″-terphenyl-4′,4″-ylene)](PBPITP), and its unusual light-emitting properties.

The chemical structure and the synthetic route to the new polymer PBPITP are depicted in Scheme 1. Monomer **1** was synthesized (30% yield) through a modified Hartwig–Buchwald coupling reaction between 4-butylaniline and a 5-fold excess of 1,4-dibromobenzene in toluene in the presence of tris(dibenzylideneacetone)dipalladium [$Pd_2(dba)_3$], 1,1′-bis(diphenylphosphino)ferrocene (dppf) and $NaOBu^t$.[11,12] Monomer **2** was synthesized (overall yield 60%) in two steps from 1,4-dibromobenzene. 1,4-Dibromobenzene was first converted to *p*-phenylenediboronic acid following the procedure in the literature.[13] *p*-Phenylenediboronic acid was then refluxed with propane-1,3-diol in toluene to afford monomer **2**. Polymerization was performed by a Suzuki coupling reaction using K_2CO_3 as base and toluene as solvent. The polymer was isolated by pouring the hot (*ca.* 60 °C) reaction mixture into stirred methanol and was washed with water, methanol and acetone successively. The polymer was further purified by re-dissolving in THF and then precipitated from methanol twice prior to drying *in vacuo* at room temperature. The polymer was finally obtained as a pale yellow powder (yield 36%). The structure of the polymer was confirmed by ^1H and ^{13}C NMR and elemental analysis.†



Scheme 1 Synthetic route to PBPITP. *Reagents and conditions*: i, $Pd_2(dba)_3$, dppf, toluene, $NaOBu^t$, 90 °C; ii, (1) Mg, THF, (2) $B(OMe)_3$, THF, −78 °C, (3) H^+, 0 °C; iii, $HO(CH_2)_3OH$, toluene, reflux; iv, $Pd(0)(PPh_3)_4$, K_2CO_3(aq), toluene, *ca.* 100 °C.

The polymer readily dissolves in highly polar solvents, such as THF, chlorobenzene and 1,3-dichlorobenzene, but shows low solubility in low polar solvents, such as toluene and xylene (dissolves upon heating). Uniform and pinhole-free thin films on substrates can be obtained by spin-coating chlorobenzene solutions of the polymer. Poor solubility in toluene and xylene allows the deposition of additional polymer on such films from these solvents. The molecular weight of the polymer was measured by gel permeation chromatography (GPC), using polystyrenes as standard and THF as eluent. The number-average molecular weight (M_n) and polydispersity (PD) were determined as 6400 and 1.75, respectively.

Polymer films on a variety of substrates (micro slides, ITO-coated glasses and quartz plates) emit intense blue light upon exposure to UV light. Fig. 1 shows the UV-VIS absorption and fluorescence (excited at 375 nm) spectra (curves 1 and 2) of the polymer measured from a film on a quartz plate at room temperature. The absorption spectrum peaks at 375 nm and onsets at 448 nm. The π–π* band gap, E_g, is estimated from the

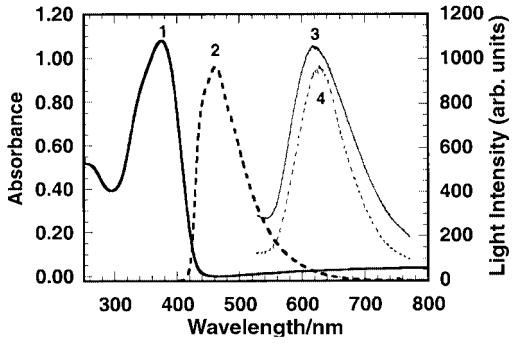


Fig. 1 UV–VIS absorption (1) and photoluminescence (excitation at 375 nm) (2) spectra of PBPITP, and EL spectra recorded from ITO/PBPITP/Ca (3) and ITO/PBPITP/PDHFDDOP/Ca (4).

DOI: 10.1039/a909857g

onset wavelength as 2.77 eV. The fluorescence spectrum exhibits a maximum at 461 nm with a shoulder around 440 nm. The absolute PL efficiency of the polymer as a neat film was measured in an integrating sphere as 45 ± 3%. These results indicate that PBPITP is an efficient blue emissive polymeric PL material.

The redox behavior of the polymer was investigated by cyclic voltammetry (CV) with a standard three-electrode electrochemical cell in a 0.10 M tetrabutylammonium perchlorate solution in acetonitrile at room temperature. The anodically scanned cyclic voltammogram is shown in Fig. 2. The oxidative process starts at *ca.* 0.6 V (*vs*. standard calomel electrode, SCE) and gives a sharp oxidative peak at 1.04 V. The oxidation is highly reversible, and the corresponding reduction peak appears at 0.77 V. The energy level of the highest occupied molecular orbital (HOMO) of the polymer, E_{HOMO}, can be estimated from the oxidative onset potential, to be −5.0 eV.[14] In the cathodic scan, no reduction peak (down to −2.5 V *vs*. SCE was observed). The energy level of the lowest unoccupied molecular orbital (LUMO), E_{LUMO}, can be estimated by subtracting the optical band gap energy, E_g, from E_{HOMO} as determined by the electrochemistry. This leads to an estimate of E_{LUMO} of −2.17 eV.

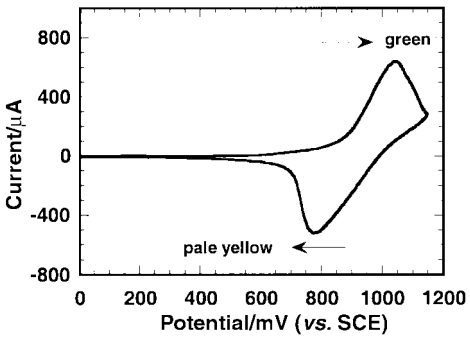

Fig. 2 Cyclic voltammogram of PBPITP. Working electrode: PBPITP film-coated platinum plate (square, *ca.* 1 cm^2); counter electrode: platinum wire; reference electrode: $Ag/AgNO_3$ (0.10 M). Scan rate: 20 $mV.s^{-1}$ room temperature. The arrows indicate the film color change during scan.

Single-layered electroluminescent (EL) cells, ITO|PBPITP(1000 –1500 Å)|Ca (1500 Å), were fabricated. The devices emitted bright red light above *ca.* 15 V under a forward bias (ITO wired positive). The EL spectrum is shown in Fig. 1 (curve 3) and exhibits a maximum at 618 nm. The EL spectrum is red-shifted by 157 nm (0.7 eV) in comparison with the PL spectrum. A layer (1000–1500 Å) of poly(9,9-dihexylfluorene-*alt*-*co*-2,5-didecyloxy-*para*-phenylene) (PDHFDDOP), an efficient blue EL polymer,[10] was further deposited on the PBPITP film to fabricate double polymer-layer ITO|PBPITP|PDHFDDOP|Ca devices, in which the PBPITP film was kept from direct contact with the calcium electrode by the PDHFDDOP layer. The double-layered devices also emitted red light. The EL spectrum (curve 4 in Fig. 1) is almost the same with that recorded from the single-layered devices. The results reveal that an interface effect is not the cause of the large red-shift of EL compared with PL. In addition, the threshold voltages for current flow and light emission were dramatically decreased to *ca.* 5 V upon addition of the PDHFDDOP layer. The external EL quantum efficiency was increased from *ca.* 0.01 to *ca.* 0.025% by the addition of the PDHFDDOP layer. It is evident that the role of the PDHFDDOP film is to serve as an electron-transporting rather than as an emissive layer. The improved EL performance can be attributed to the lower LUMO energy level of PDHFDDOP (− 2.6 eV)[15] compared with that of PBPITP, which results in a smaller energy barrier for electron injection. Also, the improved EL demonstrates the good hole transporting property of PBPITP.

It can be concluded from the results that PBPITP is a promising red EL polymeric material.

In conventional conjugated polymers, PL and EL normally originate from the same molecular excitation, *i.e.* singlet excitons. This results in the EL emission spectrum of a conjugated polymer closely resembling its PL spectrum. The large difference between the PL and EL spectra here implies that the recombination mechanisms of charge carriers for PL and EL in PBPITP are different. A similar phenomenon was reported most recently in a binaphthalene-containing conjugated polymer.[16] Excimer emission might be responsible for the unusual emissive phenomenon.[17] Further investigation is required in order to understand the origin of the unusual emissive phenomenon and what mechanisms are responsible for it, and are actively being pursued.

In summary, a new soluble triarylamine-containing conjugated polymer has been synthesized through a Suzuki coupling reaction. The polymer in the form of a film exhibits high absolute PL efficiency and good hole transporting properties. The PL emission of the polymer is blue whereas its EL emission is red. The wavelength difference between the PL and EL spectrum is as large as 157 nm. It is evident that the PL and EL spectrum correspond to different molecular excitations. Such a polymer provides a good opportunity to understand the PL and EL processes in conjugated polymers.

Part of the work was carried out in the University of California, Santa Barbara (UCSB). We would like to thank Dr Vojislav Srdanov (UCSB) for his kind help in the measurement of PL quantum efficiency.

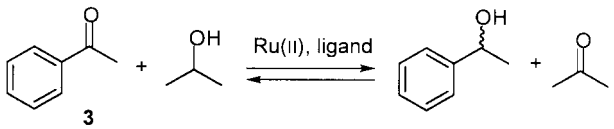
Received (in Basel, Switzerland) 17th January 2000, Accepted 10th March 2000
Published on the Web 30th March 2000

A new high-throughput screening-technique based on IR spectroscopy has been developed for ruthenium catalysed asymmetric transfer-hydrogenation by comparing the reaction rate of the reduction of ketones using (*R*)- *vs.* (*S*)-secondary alcohol as the hydrogen donor.

Combinatorial chemistry and rapid screening techniques are widely recognised as very promising tools in the development of novel catalysts.[1] Recent research has been focussed on two important aspects, *viz.* the parallel synthesis of new catalysts and the development of new rapid screening techniques. Most of the screening methods developed so far are based on UV–VIS, fluorescence spectroscopy and more recently also IR thermography[2] and involve screening of the activity of the catalyst only. The number of screening methods that have been reported involving enantioselective catalysis is rather small.[3–5] Here we report on a novel technique based on IR spectroscopy for the rapid screening of enantioselective transfer-hydrogenation catalysts.

Asymmetric transfer-hydrogenation is an efficient, mild and clean method for the synthesis of chiral alcohols.[6] Only a few examples are known of the enantioselective transfer-hydrogenation of functionalised ketones,[7] dialkyl ketones[8] and imines[9] that finally may lead to useful intermediates for the fine-chemical industries. Therefore, a combinatorial approach to develop efficient chiral transition metal catalysts for the transfer-hydrogenation of different substrates and a method to rapidly screen and optimise these catalysts is pivotal.

In order to test our proposed new rapid screening technique we used a known reaction: the reduction of acetophenone in propan-2-ol (Scheme 1) using (1*R*, 2*S*)-ephedrine **1** on (*R*)-phenylglycinol **2** in combination with ruthenium(II) as the catalyst.[10] The use of **1** gives rise to a high enantioselectivity (89%), whereas the use of **2** as the amino alcohol ligand results in a much lower enantioselectivity (24%) (Table 1).

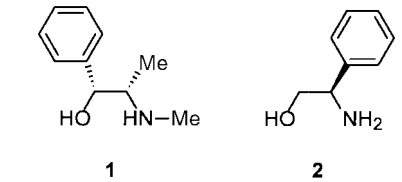


3

Scheme 1

The carbonyl of the aryl alkyl ketone absorbs at a different wavenumber in the IR than the dialkyl ketone (1682 and 1707 cm-1, respectively) which allows the reaction to be monitored by IR spectroscopy (Fig. 1). We performed a test reaction (reduction of acetophenone using propan-2-ol as the H-donor) that was followed both by IR and gas chromatography (GC) giving identical results. This indicates that IR is a reliable technique (Fig. A, ESI†).

A drawback of the transfer-hydrogenation reaction using an alcohol as the hydrogen source is its reversibility. At the same time, however, this property can be utilised for the kinetic resolution of secondary alcohols.[11] When the reduction of acetophenone occurs with an enantiofacial differentiation of $k_{Si}/k_{Re} \approx 100$, the dehydrogenation of (*R*)-1-phenylethanol is also *ca.* 100 times faster than that of (*S*)-phenylethanol. Here, we use the reversibility of the reaction to set up a rapid screening technique for enantioselective hydrogen transfer catalysts. Instead of monitoring the transfer-hydrogenation reaction we screen on the reverse reaction by determining the difference in dehydrogenation rate using (*R*)- and the (*S*)-1-phenylethanol. The difference in *dehydrogenation rate* between the (*R*)- and the (*S*)-alcohol is a measure of the enantioselectivity of the reaction and can be determined rapidly by IR spectroscopy. Table 1 shows the results of the ruthenium(II)-amino alcohol catalysts, containing ligands **1** and **2**, in the dehydrogenation of (*R*)- and (*S*)-1-phenylethanol (entries 3–6). These reactions were monitored with time by IR spectroscopy and Fig. 2 shows the results of experiments with **1** as ligand whereas Fig. B (ESI†) shows the results for ligand **2**.



1 **2**

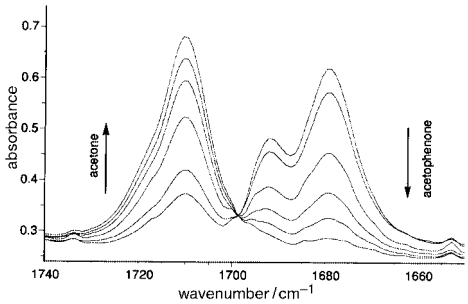


Fig. 1 The hydrogen transfer reaction followed by IR spectroscopy.

The reaction rate for the dehydrogenation of (*R*)-1-phenylethanol is much faster than the dehydrogenation of (*S*)-1-phenylethanol. The initial reaction rate calculated from the IR data is *ca.* 15 times higher for (*R*)-*cf.* (*S*)-1-phenylethanol (k_R/k_S = 15). This is in very good agreement with the k_{Si}/k_{Re} ratio of 17 calculated from the enantioselectivity in the hydrogenation reaction (entries 1 and 2). A smaller difference in dehydrogenation rate is observed for the Ru(II)–phenylglycinol catalyst (Table 1, Fig. B, ESI†). The much smaller k_R/k_S ratio of 2, calculated from the IR data, was again in very good agreement with the k_{Si}/k_{Re} ratio calculated from the enantioselectivity in the hydrogenation reaction.

To use this technique for rapid screening of novel chiral catalysts, a single measurement per reaction mixture should suffice to determine an approximate ee value. Therefore the

6	**2**	**4**	(*S*)-1-Phenylethanol	60	—		

[a] Reactions were carried out at room temperature using a 0.1 M ketone solution (33.3 mmol) in alcohol. Substrate : [$RuCl_2$(*p*-cymene)]2 : ligand : Bu^tOK = 400 : 1 : 5: 12.5. [b] Conversions were determined after 40 min by GLC analysis and/or IR spectroscopy. [c] Determined by capillary GLC analysis using a chiral cycloSil-B column. [d] The product configurations are (*R*). [e] k_{Si}/k_{Re} = (100 − *x*)/*x*; *x* = (100 − ee)/2. [f] Determined by IR spectroscopy after 5 min.

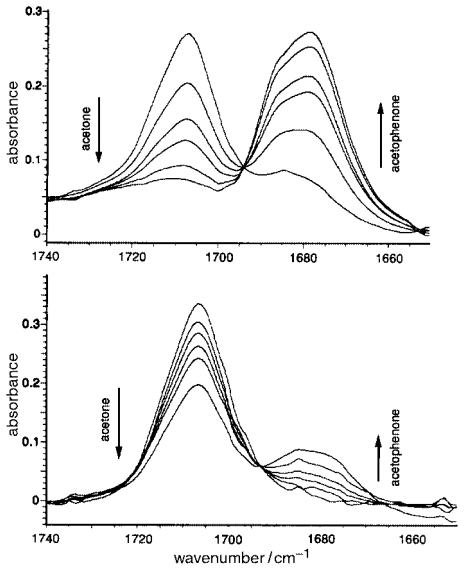

Fig. 2 Dehydrogenation of (*R*)- (top) and (*S*)-1-phenylethanol (bottom) using ligand **1**.

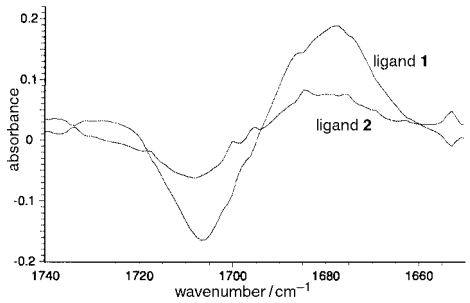

Fig. 3 IR-difference spectra of the dehydrogenation of (*R*)- and (*S*)-1-phenylethanol taken after 30 min reaction time, using **1** and **2** as the ligand.

difference in dehydrogenation rate between (*R*)- and (*S*)-1-phenylethanol was measured after 30 min and visualised as a difference spectrum (Fig. 3). Catalysts that give no chiral induction will give a flat line, whereas active and highly enantioselective catalysts will result in large peaks. Indeed the difference in reaction rate between the oxidation of (*R*)- and (*S*)-1-phenylethanol is much larger when Ru(II)–**1** is used than when Ru(II)–**2** is used as the catalyst. A good estimation of the enantioselectivity can be made simply from two IR measurements. Using an automated set up one could easily measure 100 IR spectra per hour,[12] which makes this rapid screening technique an order of magnitude faster than the known techniques as GC, HPLC and NMR.

Screening catalysts for reduction of dialkyl ketones using propan-2-ol as the donor using the above method is troublesome since the signals of acetone **4** and other dialkyl ketones overlap in the IR spectrum. Therefore acetophenone **3** and benzophenone **5** were used as substrates, using (*R*)- and (*S*)-hexan-2-ol as the H-donor, allowing the reaction to be followed by IR spectroscopy (Fig. C, ESI†). The k_{Si}/k_{Re} ratio calculated from the IR data was between 1 and 2 for both experiments, *i.e.* using ligands **1** and **2**. This is again in full agreement with the hydrogen transfer experiment, since only low ee values were obtained in the transfer-hydrogenation of hexanon using either ligand **1** or **2**.

In conclusion, IR spectroscopy proved to be a very useful technique to determine the performance of enantioselective transfer-hydrogenation catalysts. The reaction can be followed with time by performing it in the IR cell, or samples can be taken from a reaction mixture and subsequently analysed. The former method is especially interesting if non-linear effects are involved, whereas the single point measurements are more suited for rapid screening techniques. The difference in dehydrogenation rate between the (*R*)- and (*S*)-alcohol, *i.e.* the ratio k_R/k_S, serves as a reliable prefatory measure for the enantioselectivity of the transfer-hydrogenation of both aryl alkyl and dialkyl ketones.

When parahydrogen induced polarisation is used to examine hydrogenation reactions involving $[Rh(\mu\text{-}Cl)(PPh_3)_2]_2$ and $RhCl(CO)(PMe_3)_2$, binuclear dihydride complexes are detected, characterised, and shown to be capable of alkene hydrogenation.

The *in situ* study of H_2 oxidative addition reactions using NMR spectroscopy in conjunction with para-enriched hydrogen (p-H_2)[1] has led to the detection of many new dihydride complexes.[2,3] This phenomenon enables the generation of a non-Boltzmann spin population for the ensemble of nuclei originally in p-H_2 which in turn allows their detection *via* signal strengths that often exceed the norm by 1000 times.[2] Prior work in this area has shown that monitoring the oxidative addition of p-H_2 to $RhCl(CO)L_2$ and $RhClL_3$ (L = PPh_3, PMe_3) enables the detection of binuclear dihydride species.[4] Here, we demonstrate how p-H_2 can be used to monitor the hydrogenation process directly and facilitate the detailed characterisation of species such as $(H)_2Rh(PPh_3)_2(\mu\text{-}Cl)_2Rh(PPh_3)$(alkene). We also show that the addition of a sacrificial alkene can facilitate the characterisation of previously uncharacterised dihydrides.

Initially, a series of C_6D_6 solutions containing *ca.* 1 mg of $[Rh(\mu\text{-}Cl)(PPh_3)_2]_2$ and varying amounts of styrene were monitored by ^1H NMR spectroscopy at 295 K while under 3 atm of p-H_2. At early reaction times these solutions immediately yielded polarised hydride resonances at δ −18.72 and −19.51, arising from the previously reported complex $(H)_2Rh(PPh_3)_2(\mu\text{-}Cl)_2Rh(PPh_3)$(styrene) **2a**.[4] A 2D-^1H–^{31}P HMQC experiment [Fig. 1(a)] revealed that this product contains two mutually coupled phosphorus resonances separated by 1210 Hz, at δ 35.23 and 42.73.† The large J_{PP} coupling of 427 Hz confirms that the two detected phosphines are located in a *trans* arrangement in the product.[7] The analogous species formed with hex-1-ene, **2b**, also possesses inequivalent phosphines, although the separation between the ^{31}P signals is reduced to 590 Hz. However, the corresponding species with *cis*-stilbene, **2c**, yields a single ^{31}P resonance in the same experiment which requires the two phosphines to be equivalent.†

Hence for **2a** and **2b** the alkene substituents are unsymmetrically displaced about the plane containing the Rh centres and thereby render the PPh_3 ligands inequivalent. For the *cis*-stilbene complex **2c** the presence of a mirror plane makes the phosphines equivalent. These experimental results are consistent with calculations that show it is favourable for an alkene to bind to a ML_3 fragment with the C=C bond arranged perpendicular to the plane containing the framework atoms.[5] Surprisingly, when 1,2 diphenylethene is employed, the analogous product **2d** also contains equivalent phosphines. This suggests that steric interactions can force the alkene to bind with the C=C bond arranged in the plane of the two metal centres.

In these studies, the observed hydride signals for species of type **2** decay rapidly as the hydrogen present in solution is consumed by alkane formation. However, the absolute intensity of the hydride signals for **2** increased consistently when solutions were examined which contain lower alkene, and identical rhodium and p-H_2, concentrations. In order to learn more about this effect we adapted the 1D NOE sequence of Keeler for use with p-H_2.[6] Selective pulses were used in conjunction with a suitable mixing time (for chemical exchange and NOE build-up) to probe the behaviour of a single, pre-selected, hydride resonance. We note that there are several possibilities for dynamic behaviour involving the hydride

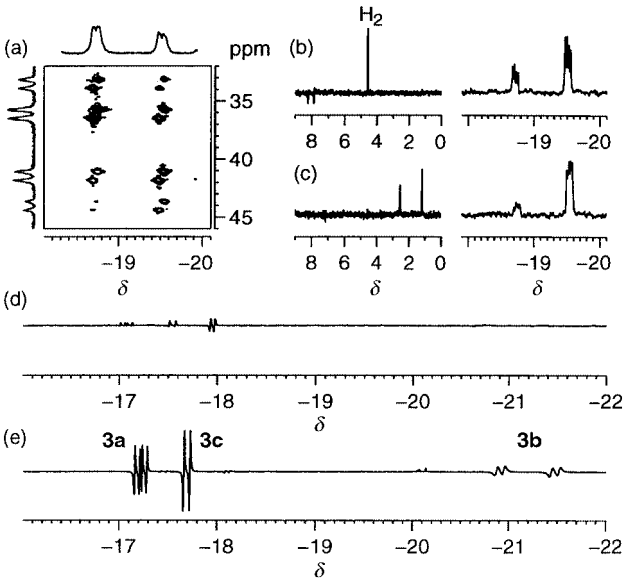

Fig. 1 (a) Selected cross peaks (absolute value display) and projections of the ^1H–^{31}P HMQC spectrum of **2a** showing hydride and phosphorus connectivity. (b) $^1H\{^{31}P\}$ 1D-NOE spectrum of p-H_2 enhanced **2a** at 295 K with resonance selection at δ −19.51 and a mixing time of 400 ms. Intramolecular hydride interchange is indicated. (c) $^1H\{^{31}P\}$ 1D-NOE spectrum of parahydrogen enhanced **2a** at 295 K with resonance selection at δ −19.51, mixing time of 200 ms, and *ca.* 20-fold reduction in [styrene]. Peaks indicate intramolecular hydride interchange, conversion to ethylbenzene and exchange with free H_2. (d) ^1H NMR spectrum showing the hydride region of a sample containing $RhCl(CO)(PMe_3)_2$ and p-H_2 in C_6D_6 at 295 K. DOI: 10.1039/b000607f

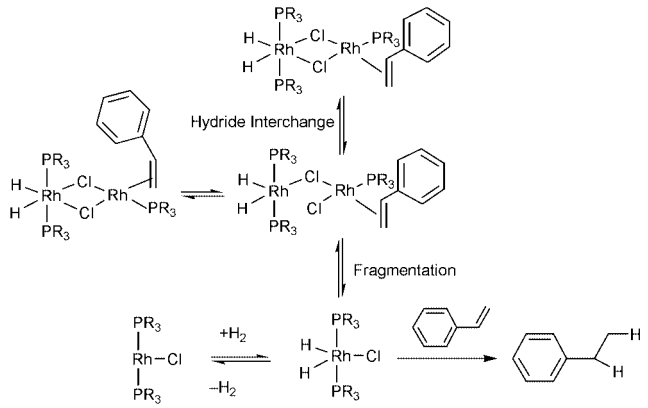
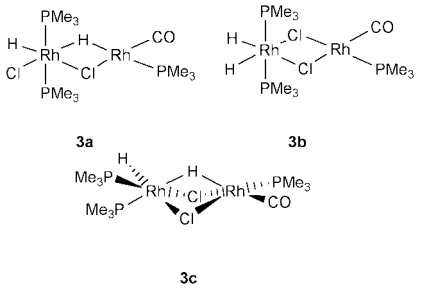
ligands of **2**: (i) intramolecular hydride interchange (ii) exchange with free hydrogen and (iii) transfer into the alkene (bound or free).

When the hydride resonances of **2a** at δ −18.72 or −19.51 were probed in separate experiments, NOE connections were visible, with both selections, to two *ortho* phenyl resonances at δ 8.20 and 7.85, supporting the conclusion that the two phosphines of the Rh(III) centre are inequivalent. The spectrum shown in Fig. 1(b) illustrates the result for the δ −19.51 hydride resonance of **2a**. The presence of the second peak, at δ −18.72, indicates that hydride interchange occurs during the mixing time. The magnitude of this exchange peak, for a given mixing time, proved to be independent of the concentration of styrene, and catalyst, which suggests that the hydride interchange process is intramolecular. Eyring analysis of the resulting rate data yielded activation parameters for hydride interchange, $\Delta H^{\ddagger}$ = 42 ± 4 kJ mol^{-1} and $\Delta S^{\ddagger}$ = −100 ± 12 J K^{-1} mol^{-1}. A process involving halide bridge rupture, followed by rotation about the remaining Rh–Cl bridge, and bridge re-establishment is consistent with this information (Scheme 1).[7]



Scheme 1 (R = Ph).

The overall situation is complicated by the fact that the hydride resonances of **2** also connect to the resonance of free H_2. Surprisingly, as the concentration of alkene in solution falls both the proportion (rate) of reductive elimination of H_2 from **2** and the relative signal intensities of the two hydride resonances increase. For example, when the alkene concentration was reduced by a factor of 16, the associated hydride signals of **2a** increased by over 100 times. Significantly, at even lower alkene concentrations magnetisation transfer from the hydrides of **2a** to the alkyl protons of the hydrogenation product ethylbenzene is observed [Fig. 1(c)]. This corresponds to direct evidence for the binuclear metal dihydride complexes themselves being linked to alkene hydrogenation. In order to account for this complex kinetic behaviour the hydrogenation process cannot simply involve bridge opening followed by alkene binding. A logical option would be for hydrogenation to proceed *via* binuclear complex fragmentation with trapping of the resultant $RhClH_2(PR_3)_2$ fragment by alkene, rather than halide of a mononuclear rhodium centre, being productive in this regard. We therefore examined the hydrogenation activity of $RhCl(CO)(PMe_3)_2$. As a control, a benzene solution of $RhCl(CO)(PMe_3)_2$ was first reacted with p-H_2 at 295 K. The corresponding 1024 scan ^{1}H spectrum, shown in Fig. 1(d), contained polarised signals due to $(H)(Cl)Rh(PMe_3)_2(\mu\text{-}H)(\mu\text{-}Cl)Rh(CO)(PMe_3)$ **3a**.[7] When an identical sample was prepared and monitored in the presence of a 1.5 fold excess of styrene relative to $RhCl(CO)(PMe_3)_2$, the spectrum shown in Fig. 1(e) was obtained. Now the new species $(H)_2Rh(PMe_3)_2(\mu\text{-}Cl)_2Rh(CO)(PMe_3)$ **3b** and $HRh(PMe_3)_2(\mu\text{-}H)(\mu\text{-}Cl)_2Rh(CO)(PMe_3)$ **3c** are clearly visible, and there is a dramatic 16 fold increase in size of the associated hydride signal intensities of **3a**; the spectral features of these species are



similar to those of their iodide derivatives.[7] These additional complexes are visible because p-H_2 cycling in **3** is enhanced by the hydrogenation pathway (in addition to simple reversible H_2 exchange).

In summary, these studies have demonstrated that there is a role for binuclear dihydride species as a 'hydrogen store' during hydrogenation catalysis. For **2**, this corresponds to direct evidence for H_2 transfer from the binuclear complex to the substrate *via* initial fragmentation to $RhH_2Cl(PPh_3)_2$. Significantly, we have shown that (metal–dihydride)–p-H_2 exchange reactions can be promoted by the addition of a sacrificial alkene with the result that previously unseen species become observable with this technique.

High-resolution solid-state MAS ^{73}Ge NMR spectra of organogermanium compounds have been observed for the first time; the chemical shifts and half-widths of tetraphenylgermane and tetrabenzylgermane were recorded with and without high-power decoupling.

Though the natural abundance is comparaable with the ^{29}Si isotope, recording of ^{73}Ge resonances is known to be very difficult because of the low value of γ, along with its nuclear spin of $-9/2$ and large quadrupolar moment. These cause distortion of the electric field gradient around the germanium nucleus leading to excessive broadening of the signals. In solution ^{73}Ge NMR spectroscopy, it was observed that when the symmetry of the structure around the germanium atom is high, a sharp signal can be observed (as found for ^{14}N NMR) while the signal tends to broaden as the symmetry is lost. For instance the half-width of tetramethylgermane, a compound with the highest symmetry, is only 1,4 Hz[1] while corresponding values of germacyclohexane, 1-methylgermacyclohexane and 1,1-dimethylgermacyclohexane are 15.4, 22.3 and 15.6 Hz, respectively.[2] It was also observed that when either halogen or oxygen atoms are unsymmetrically substituted, as found in 1-bromo-1-methylgermacyclohexane, an excessive broadening took place to such an extent that observation of signals was impossible.

Given these factors, it has generally been accepted that observation of ^{73}Ge signals in the solid state would be even more difficult, and to the best of our knowledge, there have been no reports on ^{73}Ge signals of organogermanium compounds in the solid state.

In a series of papers on solution ^{73}Ge NMR spectra over the last 15 years we have accumulated data for a variety of organogermanium compounds.[3] We noted that the rapid development of NMR hard- and soft-ware has made observation of ^{73}Ge signals more feasible. We thought that by an appropriate modification of hardware it might be possible to observe solid-state high-resolution ^{73}Ge NMR spectra of organogermanium compounds with the aid of high-field instruments. Thus, we initiated an investigation to observe ^{73}Ge NMR spectra of solid-state samples.

We chose tetraphenylgermane **1** and tetrabenzylgermane **2** for over first attempt because of their high symmetry.[4] To our surprise, **1** gave an unexpectedly sharp signal, even without high-power proton decoupling, after an accumulation of a few hundred FIDs. Under similar measurement conditions, the half-width of the signal of 2 is much broader, and required much more accumulation for signal recording. ^{73}Ge chemical shifts and the half-width of the signals for **1** and **2** are given in Table 1. There is a small shift, in comparison to values in solution, arising from a solid-state effect. When high-power proton decoupling was applied to **1**, the half-width became slightly smaller. Fig. 1 shows the^{73}Ge NMR spectra of **1** and **2**.

As is always the case for NMR signals for low-γnuclei, there is some possibility that the observed signal may be an artifact. We eliminated this possibility by several means: (i) the FID shows a clear ringing pattern; (ii) a systematic change of irradiation frequency yields a corresponding change of resonance frequency; (iii) removal of the sample tube caused the disappearance of the signal.

It is unusual that there is such a large difference in the half-width for the two compounds since X-ray crystallographic analysis indicated a very high symmetry around germanium atom for both **1** and **2**.[6] There is, however, a small difference in the structures (**2** exhibits four independent phenyl rings while **1** exhibits only one in the asymmetric unit), which may be the reason for the difference in half-width.

Given the above encouraging results it will be important and interesting to delineate the scope and limitation of high-resolution solid-state ^{73}Ge NMR spectroscopy for organogermanium compounds. We believe that most if not all

Table 1 Chemical shifts and half-width of ^{73}Ge signals for **1** and **2** in the solid state [a]

Compound	δ[b]	Half-width/Hz
1 (proton decoupled)	−31.0 (−3.6)[c]	40 (6)[c]
1 (proton coupled)	−31.0	49
2 (proton decoupled)	0.14 (0.04)	*ca.* 350 (24)

[a] Values in parentheses are solution data for the same compounds. [b] We measured the ^{17}Ge NMR spectrum for tetraethylgermane (liquid) filled in a cell without rotation and assumed that the chemical shift under this measurement condition was δ 17.3 (the same value as in solution). The chemical shifts of **1** and **2** in the solid state were referenced to this value. [c] Data taken from ref. 1.

DOI: 10.1039/b001011l

symmetrically substituted germanes will give signals. It will also be of interest whether asymmetrically substituted germanes can also rise to signals. A study along such lines is under progress in our laboratories.

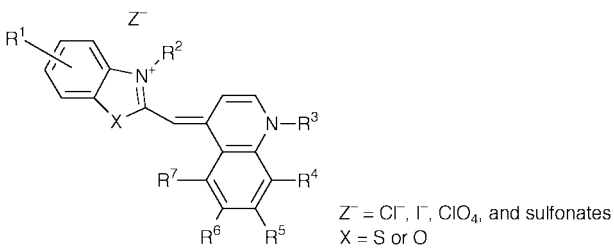
We report the fluorescence lifetimes of the DNA-stain dye PicoGreen and discuss the difference exhibited in the upon binding to single-stranded *vs.* double-stranded DNA; we here developed a direct method for determining single-to-double stranded DNA ratios in solution by measurement of the pre-exponential factors in the fluorescence decay traces of dye–DNA complexes.

The search for new non-radioactive analytical techniques to determine minute amounts of DNA in solution and gels brought about the development of a family of new fluorescent probes.[1,2] Many studies have been concerned with determining the properties of these dyes free in solution,[3] and when complexed to dsDNA.[2,4–6] These recently patented[7,8] fluorescent stains derived from unsymmetric cyanine dyes (Scheme 1) exhibit a high increase (*ca*. 1000 fold) in their fluorescence quantum yields upon binding to double-stranded DNA (dsDNA) as compared to free in solution, making them sensitive probes for DNA detection. These dyes are free to rotate about their central methine bridge while in solution, but this non-radiative deactivation pathway is closed when the dye intercalates between the DNA base-pairs. This explains their high sensitivity as dsDNA sensors.[4,6]

We have explored the possibility that in a complex with single-stranded DNA (ssDNA) a less rotationally restricted dye should be present, as compared to that with dsDNA and that this difference can be reflected in the fluorescence lifetimes. Thus, we have studied the complexes formed with PicoGreen (PG), a representative of the family of cyanine dyes of Scheme 1 which exhibits the greatest sensitivity for selective detection of dsDNA in solution.[7–10] Our results show not only that the dye–ssDNA complexes are more prone to deactivate non-radiatively, but also that the different lifetimes characteristic for each of the complexes (*i.e.* dye–dsDNA and dye–ssDNA) allow a simple approach to quantify their relative amount in solution by determining the pre-exponential factors for the fluorescence decay in a mixture containing both types of DNA. The choice of PG is not accidental, preliminary screening of a range of common dyes showed PG to be that with the best lifetime discrimination between ssDNA and dsDNA.

Our work was performed on calf thymus DNA (type I) (CT DNA) and salmon testes DNA (type III) (ST DNA) suspensions prepared on a TRIS (10 mM) buffer (pH 7.4) solution consisting of distilled and deionized water with Trizma Pre-set crystals, Na_2H_2EDTA (1 mM) and (NaCl) 100 mM. The ssDNA was obtained after boiling a dsDNA solution for 30 min followed by immersion in an ice bath. The fluorescence enhancement of PG upon binding to CT dsDNA, as compared to CT ssDNA was *ca*. 1.89, measured on a PTI 1.2 X luminescence spectrometer. This value is slightly higher than the reported one of 1.56.[9] We also noticed a broader fluorescence band for the dye–ssDNA complex (data not shown), with the maximum red shifted by 3 nm. The unbound dye fluorescence band is also broader than that of the dye–dsDNA complex, though it is hard to quantify this shift since the spectrum in the absence of DNA is very noisy. While the broadening had been previously reported, it was measured at high dye–DNA base pair ratios (*i.e.* 1:1); under this conditions, not only intercalation but groove binding can occur.[5,11] In our work we kept dye/DNA base-pair ratios always lower or around 1/7 to ensure that the predominant binding mode would be that of intercalation.[5] Specifically, the preferred concentrations were 11 mM for PG, and 70 and 150 mM for CT and ST DNA, respectively, both expressed as base pairs.



Scheme 1

Assuming that there is only one kind of complex for each ssDNA and dsDNA, and considering that, for other dyes of the same family, there exists a single lowest energy excited singlet state,[4] we would anticipate that the lifetimes for each of these complexes should be monoexponential. Thus, we measured the lifetimes following picosecond laser excitation using streak camera detection.[12] The results obtained following 355 nm irradiation of the sample with a $\leqslant$50 ps pulse show a virtually pure monoexponential decay with a lifetime of 4.5 ns for dye–dsDNA (for both CT or ST type DNA). The decay obtained for the complex formed with ssDNA was biexponential, with lifetimes of 1.16 ns (51%) and 3.09 ns (49%), where the weight of each exponential is given in parentheses (Fig. 1). The fact that the trace is biexponential may reflect two different phenomena. We are either dealing with two types of binding of the dye (*vide supra*), or there exists some DNA that renatured before data acquisition took place. The dye/DNA ratio employed was low enough as to have only intercalation in the case of dsDNA; however, ssDNA, that may have a lower binding constant,[10,13–15] might show other forms of dye interaction. In relation to the possibility that some DNA may have renatured, we tested our method of DNA denaturation by comparing the absorbance at 260 nm, immediately after the denaturation process, for a treated sample and an untreated one. We determined that within the experimental error, all of the sample had been denatured.[16] In principle, some DNA could renature before data acquisition, however this delay was kept to only 15 min. We cannot rule out either of the two possibilities described, and, conceivably, we may be dealing with a system presenting both some traces of renatured DNA, and some non-intercalated bound dye. This uncertainty does not influence our ability to discriminate between ssDNA and dsDNA.

The fluorescence broadening does not develop over time; rather it is evident immediately after excitation (data not shown). In any event, from the calculated fluorescence lifetime of the free dye in solution, *i.e.* shorter than *ca*. 5 ps, we assume that rotation takes place too fast for our acquisition setup to detect it.

DOI: 10.1039/b000473l

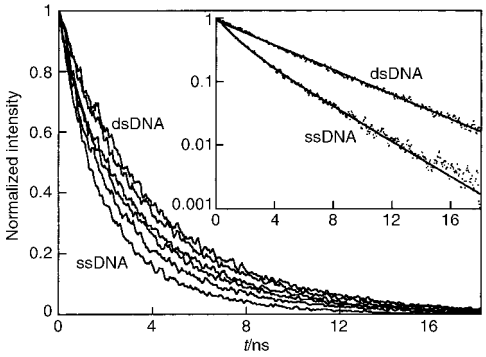


Fig. 1 Normalized fluorescence decay profiles measured on static 2 ml quartz cells in air equilibrated solutions of DNA in TRIS buffer (pH = 7.4) following 355 nm laser excitation; ST DNA base-pair concentration = 150 μM, PG = 11 μM, for 100, 80, 60, 40 and 20% dsDNA and of dsDNA alone. Insert: semi-log plot and fit for dsDNA (single exponential) and ssDNA (double exponential).

In view of the noticeable difference in fluorescence lifetimes between dye–ssDNA complex and dye–dsDNA complex, we attempted and succeeded in developing an analytical technique that would enable us to monitor in solution the ssDNA/dsDNA ratio with a simple method devoid of any operator subjectivity. To that effect, we determined the fluorescence lifetimes in different mixtures containing known amounts of ssDNA, dsDNA (we employed both CT DNA and ST DNA) and PG. From the previous analysis (*vide supra*), we expect a triexponential decay in this system [eqn. (1)]; *i.e.* dye–dsDNA decays with its characteristic rate constant, and ssDNA complexes exhibit their biexponential decay.

$$I = a_{ds}e^{-k_{ds}t} + a_2e^{-k_2t} + a_3e^{-k_3t} \quad (1)$$

where a_{ds} is the preexponential factor for dsDNA, and k_{ds} the reciprocal of its lifetime, while a_2, a_3, k_2 and k_3 are the corresponding parameters for ssDNA, and t is the time.

Though complicated in appearance, we know the three decay rate constants for this system (that of dsDNA, and each of the two for ssDNA); on the other hand, the addition of the preexponential factors for the decays has to be equal to unity for the normalized profile. At this point a six-variable function initially needed to fit this decay (three pre-exponential values, and three decay rate constants), is now reduced to one with two parameters, *i.e.* the two pre-exponential values. Further, since the relative values for the two pre-exponential values for the ssDNA decay are known, and coincidentally they are about equal, *i.e.*

$$a_{ds} + a_2 + a_3 = 1$$
$$a_2 \cong a_3$$

Combined these factors lead to a one-parameter fit according to eqn. (2):

$$I = a_{ds}e^{-0.22t} + [1 - a_{ds}) (e^{-0.86t} + e^{-0.32t})/2] \quad (2)$$

When we plot the recovered pre-exponential value (a_{ds}) corresponding to the dsDNA rate constant *vs.* the fraction of dsDNA in the sample (see inset in Fig. 2) for CT DNA and for ST DNA, a straight line is obtained with a slope of 0.80 and an intercept of 0.048. The theoretical line should go through the origin and have a slope of 1.0. The difference is not surprising; analysis according to eqn. (2) of computer simulated data shows that only perfect data (*i.e.* noise-free) leads to perfect recovery of the pre-exponential factors, particularly for the pure forms, dsDNA and ssDNA; addition of random noise always leads to apparent small weights for other DNA components. Effectively, the percentage of dsDNA present in a sample can be calculated according to eqn. (3), although we note that different instruments may lead to slightly different deviations from the ideal equation; in this sense a recalibration may be desirable.

$$\%(\text{dsDNA}) = 100(a_{ds}^{\text{recovered}} - 0.048)/0.80 \quad (3)$$

It is worthwhile noting that for the fittings, the rate constants used corresponding to ssDNA (0.32 and 0.86 × 10^9 s^{-1}) and dsDNA (0.22 × 10^9 s^{-1}) where those determined in the absence of the other form of DNA, and are the same for CT or ST DNA, and are not adjustable parameters. We believe this new method

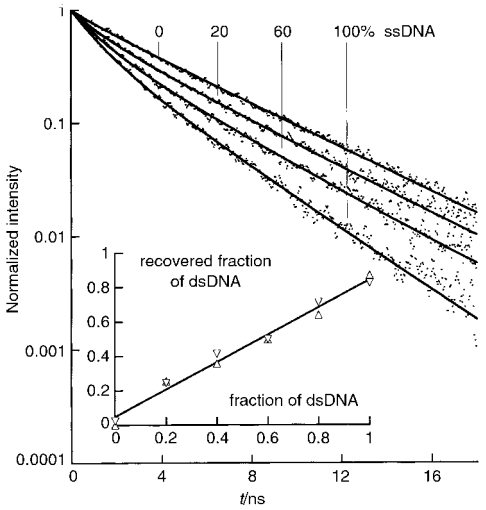

Fig. 2 Normalized fluorescence decay profiles measured on static 2 ml quartz cells in air equilibrated solutions of DNA in TRIS buffer (pH = 7.4) following 355 nm laser excitation; ST DNA base-pair concentration = 150 μM, PG = 11 μM, for various percentages of dsDNA, showing the fit of the data to the one-parameter function of eqn. (2); Insert: linear plot of the recovered dsDNA fraction as a function of the actual fraction in the sample for (△) CT DNA and for (▽) ST DNA.

may find application not only in solution, but also in gels where this information may prove useful for methods such as the comet assay.[17] Finally, we note that while our work involved a sophisticated picosecond fluorescence system, similar measurements could be developed around less expensive light sources, such a short pulse diodes.

The reaction between [NiCl$_2$(PPh$_3$)$_2$] and [Li{C(SiMe$_3$)$_2$(SiMe$_2$C$_5$H$_4$N-2)}] in tetrahydrofuran gave the monomeric Ni(I) compound [Ni{C(SiMe$_3$)$_2$(SiMe$_2$C$_5$H$_4$N-2)}(PPh$_3$)], which shows planar coordination at Ni with Ni–C 2.025(4) Å, together with the Ni(II) silanolato compound [Ni{C(SiMe$_3$)(SiMe$_2$C$_5$H$_4$N-2)(SiMe$_2$O)}]$_2$ as a minor product, however, the corresponding reaction with [PdCl$_2$(PPh$_3$)$_2$] gave [Pd(μ-Cl){C(SiMe$_3$)$_2$(SiMe$_2$C$_5$H$_4$N-2)}]$_2$, which has a chloride-bridged structure with an unusual fold angle of 60° at the Cl···Cl axis.

Organonickel compounds have been widely studied, particularly because of their applications as catalysts.[1] Some catalytic processes are thought to involve Ni(I) intermediates[2] but, although triorganophosphine and amine complexes have been obtained,[3] attempts to isolate organo–Ni(I) compounds commonly lead to precipitation of elemental nickel.

We have previously isolated organometallic compounds of the s-, p- and f-elements containing ligands C(SiMe$_3$)$_n$(SiMe$_2$X)$_{3-n}$ in which the groups X have lone pairs of electrons.[4] We reasoned that, if the substituents X had π-acceptor properties, it might be possible to obtain compounds of d-block elements without unwanted reduction. Reactions of the precursor Li{C(SiMe$_3$)$_2$(SiMe$_2$C$_5$H$_4$N-2)} **1** to give the novel derivatives **2**–**4**, show that this is indeed the case.

The Ni(I) compound **2** (the first structurally characterised compound to contain a Ni(I)–C σ-bond, and, apart from the electrochemically characterised dimeric species [Cu$_2$R$_2$]$^{2+}$ [R = C(SiMe$_3$)$_2$(C$_5$H$_4$N-2)],[5a] the first d^9 σ-bonded organometallic compound) was obtained from the reaction of NiCl$_2$(PPh$_3$)$_2$ with 2 equivalents of **1**,† and crystals suitable for an X-ray study‡ (Fig. 1) were isolated from hexane. Compound **2** appeared to be stable in the solid state under Ar, but solutions in hexane deposited metallic nickel. The EPR spectrum in toluene at 298 K (g = 2.239) was broad but similar to that of [NiCl(PPh$_3$)$_3$],[6] and the magnetic moment of 1.55 μ_B at room temperature was as expected for a d^9 complex with one unpaired electron. The coordination at Ni is planar (sum of angles 360°) with a bite angle of 98° for the bidentate ligand and a wide C–Ni–P angle, reflecting the repulsion between the SiMe$_3$ groups and the phosphine ligand. The dihedral angle between the pyridine ring and the NiCNP coordination plane is 22°, the Ni–P bond distance is normal, and the Ni–C and Ni–N distances, 2.025(4) and 2.007(3) Å, suggest that the covalent radius for Ni(I) is *ca.* 1.25 Å. Longer Ni–C and shorter Ni–N distances are found in [Ni{C(SiMe$_3$)$_2$(C$_5$H$_4$N-2)}Cp] and [Ni{C(SiMe$_3$)$_2$(C$_5$H$_4$N-2)}$_2$],[7] reflecting the greater strain in the four-membered metallacycles than in the five-membered ring of **2**.

We have found no evidence for the presence of an alkylnickel(II) chloride in the products from the reaction between [NiCl$_2$(PPh$_3$)$_2$] and **1**. Nevertheless such a species is probably formed at the surface of the sparingly soluble [NiCl$_2$(PPh$_3$)$_2$] and rapidly reduced to **2** by the excess of **1**. Compound **2** is probably prevented by the steric requirements of the ligand from giving aggregates with Ni–Ni bonds and ultimately metallic nickel, and remains in solution as a Ni(I) species stabilised by the soft PPh$_3$ and C$_5$H$_4$N ligands. Compound **2** was also the principal product from a 1:1 [NiCl$_2$(PPh$_3$)$_2$]:**1** mixture but in this case we isolated a few crystals of a second compound identified‡ as the silanolato compound **3** (Fig. 2). Our [NiCl$_2$(PPh$_3$)$_2$] probably contained a trace of hydroxide and intra- or inter-molecular elimination of CH$_4$ from [Ni(OH){C(SiMe$_3$)$_2$(SiMe$_2$C$_5$H$_4$N-2)}] could lead to compound **3**. Cleavage of C–Si bonds under mild conditions is highly unusual, but a few examples are known where an OH group is held in a favourable position with respect to an SiMe$_3$ group.[5b,8] Trialkylsilanolatonickel derivatives have not apparently been reported before.

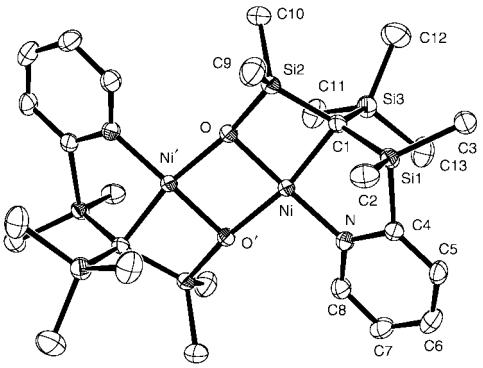

Fig. 2 The molecular structure of **3**. Selected bond lengths (Å) and angles (°): Ni–N 1.881(5), Ni–O 1.891(45), Ni–O′ 1.918(4), Ni–C(1) 1.980(6), mean Si–C(1) 1.852(6), Si–Me 1.875(7), Si–O 1.651(4); O–Ni–O 84.00(18), Si–O–Ni 93.2(2), Ni–O–Ni′ 96.00(18), Si–C(1)–Si 126.0(3), 115.0(3), 115.6(3), Ni–C–Si(2) 84.5(2), C(1)–Ni–O 84.2(2), Ni–O–Si(2) 93.2(2), Si(2)–C(1)–Ni 84.5(2).

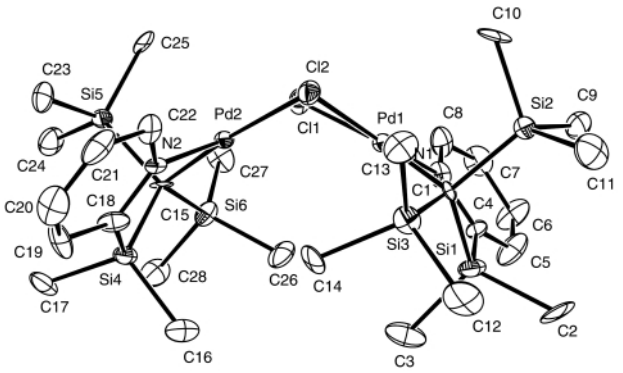

Fig. 3 The molecular structure of **4**. Selected mean bond lengths (Å) and angles (°): Pd··Pd 3.1433(15), Pd–N 2.026(10), Pd–C 2.123(12), Pd–Cl 2.325(3), 2.465(3), Si–C(1,15) 1.877(12), Si–Me 1.873(13), Si–C(py)1.864(15), N–C(Si) 1.362(16); N–C(C) 1.329(16), N–Pd–C 89.9(4), N–Pd–Cl 92.0(3), Cl–Pd–Cl, 82.62(11), C-Pd-Cl, 95.6(3); Pd–Cl–Pd 81.95, Pd–C–Si(py) 100.0(5), C–Si–C(py) 102.6(6), Si–C–N 113.6(8), C(py)–N–Pd 118.7(8), Si–C–Si 112.8(6), Me–Si–Me 106.4(6). Angles between pyridyl and Pd coordination planes 26.5, 30°.

The palladium compound **4** is obtained from equimolar quantities of **1** and $[PdCl_2(PPh_3)_2]$.§ It is stable in the solid state under Ar but Pd metal is deposited slowly from solutions in hexane at room temperature. The dimer‡ (Fig. 3) shows no crystallographic symmetry but there is an approximate C_2 axis perpendicular to and bisecting the Pd··Pd and Cl··Cl vectors. The coordination at Pd is square planar and the Pd–Cl bonds *trans* to C [2.465(3) Å] are longer than those *trans* to N [2.325(3) Å], as in similar compounds containing the NCPd(μ-Cl)$_2$PdCN core. The Pd–N bond lengths are normal and the Pd–C lengths are at the upper end of the usual range. The most intriguing feature of the structure is the large fold angle (60°) at the Cl··Cl axis since most Cl-bridged Pt(II) dimers with bidentate *C,N*-ligands are planar or nearly so. Two compounds with fold angles of 37–39°, and one with a fold angle of 58°, have been reported.[9,10] That the palladium compound **4** is much more easily isolated than the nickel analogue is in accord with the generalisation that the stabilities of M(II) organometallic compounds increase in the series from Ni to Pt.

We thank the EPSRC for financial support.

Carbon dioxide gas accelerates solventless synthesis†

Philip Jessop,* Dolores C. Wynne, Scott DeHaai and Denise Nakawatase

Department of Chemistry, University of California, Davis, CA, 95616 USA. E-mail: jessop@chem.ucdavis.edu

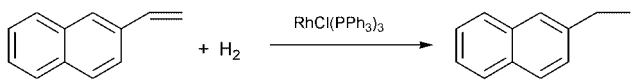
Received (in Covallis, OR, USA) 8th December 1999, Accepted 8th March 2000
Published on the Web 30th March 2000

Some solventless reactions involving solid reactants or products can be accelerated by the influence of subcritical gaseous CO_2.

Although the utility of supercritical carbon dioxide for solventless synthesis has been well publicized,[1] it is less well known that *subcritical gaseous* CO_2 can promote such reactions. At temperatures above 31 °C and pressures below 74 bar, carbon dioxide exists as a gas and not a supercritical fluid. It therefore does not dissolve organic solids or liquids to a significant extent. However, it is capable of dissolving *into* organics, and in so doing can affect the properties of the organic material such as its viscosity, diffusion coefficient,[2] dielectric constant, melting point,[3] glass transition temperature,[4] or ability to dissolve hydrogen.[5] In each of these ways, the presence of gaseous CO_2 could affect a reaction taking place in the organic phase. These possibilities have not been much explored. We now present examples of the effect of gaseous CO_2 on reactions involving organic solids.

Three reactions are offered as examples of the accelerating effect of CO_2. In each case, the reaction performance under gaseous CO_2 is compared to the performance in the absence of CO_2. In the first example, the starting material is a solid at the reaction temperature, while the product is a liquid. In the second example, the product is the solid. In the last example, both the starting material and the product are solids.

The first example is the hydrogenation of 2-vinylnaphthalene (lit.[6] mp 65–66 °C, mp of commercially available sample 62–65 °C) catalysed by $RhCl(PPh_3)_3$ (Scheme 1). In the absence of CO_2, this reaction can be performed at temperatures of 36 °C or higher (entry 4 in Table 1). The fact that it can proceed at temperatures somewhat below the melting point of 2-vinylnaphthalene is probably a result of a slow surface reaction



Scheme 1

Table 1 Hydrogenation of 2-vinylnaphthalene in the absence of added solvent[a]

Entry	*T*/°C	P_{CO_2}[b]/bar	*t*/h	Conv. (%)	TOF[c]/h^{-1}
1	33	0	0.5	0	0
2	33	56	0.5	52[d]	310
3	33	0[e]	0.5	16	96

6	36	56	1.5	100	200

[a] 7 mg (7.6 μmol) $RhCl(PPh_3)_3$, 350 mg (2.27 mmol) 2-vinylnaphthalene, 10 bar H_2, vessel size 160 mL. [b] Calculated as $P_{total} - P_{H_2}$. [c] Turnover frequency = mol product per mol catalyst per hour. [d] Average of two runs. [e] H_2 pressure 66 bar.

† Electronic supplementary information (ESI) available: experimental procedures for the hydrogenation of 2-vinylnaphthalene and oleic acid, and the hydroformylation of 2-vinylnaphthalene See http://www.rsc.org/suppdata/cc/a9/a909703a/

generating a small quantity of the product, 2-ethylnaphthalene (mp −7.4 °C),[7] which acts as a liquid solvent for further reaction. Thus one would expect the reaction to proceed very slowly until enough liquid product has formed, at which point the system would accelerate. However, at 33 °C no conversion is observed in 30 min (entry 1).

In the presence of subcritical gaseous CO_2, the reaction proceeds more rapidly.† At 36 °C, the enhancement of the rate over that observed in the absence of CO_2 is at least an order of magnitude (entries 4 and 5). Complete conversion is obtained within 90 min (entry 6). At 33 °C, the yield after 30 min is obviously superior to that in the absence of CO_2 (compare entries 1 and 2). Hydrogen gas seems to be less effective than CO_2 in enhancing the rate (entry 3). Note that in all of the experiments, the pressure of CO_2 (56 bar) is below the critical pressure of CO_2 (73.9 bar),[8] while the total pressure of the H_2/CO_2 mixture (P_{tot} = 66 bar) is below the mixture critical pressure.‡ Thus one can be certain that the gaseous phase is not supercritical. It is unlikely that the reaction takes place in the gaseous phase because: (a) at the pressure used, the density of the gaseous CO_2 is so low (*ca.* 0.14 g mL^{-1} at 36 °C and 56 bar of CO_2)[8] that it can dissolve neither the substrate nor catalyst to any significant extent, (b) the catalyst used here has not been modified to render it soluble in CO_2, and (c) all of the product mixture was found inside the glass liner at the end of the reaction. The most likely explanation of the rate enhancement is the effect of gaseous CO_2 on the melting point of 2-vinylnaphthalene.

This explanation involves the phenomenon of gas-induced melting (or gas-induced melting point lowering) of organic solids. Melting of a solid compound A can not normally be achieved below the temperature of its triple point. However, in the presence of a gas B, the melting temperature of A becomes a function of the pressure of B. The melting temperature of A can be significantly lowered from its triple point, especially at pressures approaching the critical pressure of gas B. The degree of melting point lowering depends on the solubility of B in molten A, and can be limited by the occurrence of a critical end point in the binary phase diagram.§ The end result of this phase behaviour is that solid organic compounds can be made to melt even at temperatures well below their normal melting points. This phenomenon is the basis of the recently-developed PGSS (Particles from Gas Saturated Solution) process for the micronization of solids.[9–11] Note, however, that this effect alone can not bring the melting point of 2-vinylnaphthalene to as low as 36 or 33 °C; a combination of the induced-melting effect and some initial surface reaction is required to explain the rapid rate at these temperatures.

The hydrogenation of oleic acid to stearic acid, catalysed by 5% Pt/C (Scheme 2), is also affected by the induced-melting effect. Oleic acid is a model compound for the unsaturated fatty acids in vegetable oils.[12] While oleic acid is a liquid (mp 13–16 °C),[13] the hydrogenation product stearic acid (mp 69–70 °C)[14] is a solid at room temperature. Therefore, one would expect that the solventless hydrogenation would proceed

Table 2 Hydrogenation of oleic acid in the absence of added solvent[a]

Entry	*T*/°C	*t*/h	Conv. (%) P_{CO_2} = 0 bar	Conv. (%) P_{CO_2} = 60 bar
1	35	1	90	97
2	35	4	90	97
3	35	25	90	—
4	50	1	94	98
5	50	4	95	99
6	50	25	95	—

[a] 100 mg (0.35 mmol) oleic acid, 3.5 μmol Pt (as 5% Pt/C), 10 bar H_2, vessel size 160 mL, vial diameter 12 mm. P_{CO_2} calculated as $P_{total} - P_{H_2}$.

readily at temperatures above 4 °C, but the reaction should stop short of completion because at high conversions the melting point of the reaction mixture would climb above the ambient temperature; the conversion at which the reaction 'stalls' should be a function of the reaction temperature. At 50 °C, for example, the conversion climbs no higher than 95% even after 25 h (Table 2). The reaction in the presence of subcritical gaseous CO_2 attains 99% conversion within 4 h.† At 35 °C, the reaction in the absence of CO_2 climbs no higher than 90% even after 25 h, while it reaches 97% after 1 h in the presence of CO_2. Thus gaseous CO_2 has a strong effect on this reaction at high conversions.

The third reaction to be described is the solventless hydroformylation of 2-vinylnaphthalene catalysed by $RhH(CO)(PPh_3)_3$ (Scheme 3). This reaction generates 2-(2-naphthyl)propanal (mp 53 °C),[15] plus traces of 3-(2-naphthyl)propanal (mp 42 °C).[16] In the absence of CO_2, the melting point of the reaction mixture starts at 65 °C (the melting point of 2-vinylnaphthalene), drops after partial conversion (because a mixture forms), and rises up towards the melting point of the product as the reaction approaches completion. Thus in the absence of CO_2 and at temperatures below 50 °C, one would predict that the reaction would start slowly, accelerate after some product is formed, and become slow again at high conversions. Indeed, the presence of subcritical gaseous CO_2 was found to make the reaction start more quickly (Table 3, entries 1, 2, and 4) and reach completion more readily (entries 6–8).†

There are many advantages to performing a reaction by induced-melting rather than in a SCF: (1) the pressure of the SCF/gas is lower, (2) the volume of vessel required is lower, (3) the concentration of reagent in the reaction phase is much higher, which could lead to greater rates, (4) homogeneous catalysts do not have to be designed to be CO_2-soluble, and (5) depending on the substrate, the polarity of the reaction phase may be much higher than the very low polarity of $scCO_2$. The disadvantage of the induced-melting option is that it is only effective for organic solids which have melting points within 30–40 °C of the reaction temperature. Even for those reactions, one could perform the reaction by melting the reagent in the usual manner of raising the temperature, but this may not always be an option, depending on the temperature dependence of the selectivity (particularly for enantioselective reactions).

In conclusion, we have demonstrated, with three examples, the acceleration of solventless synthesis by the application of subcritical (gaseous) CO_2. The hydrogenation and hydroformylation reactions of 2-vinylnaphthalene are accelerated by CO_2 pressure, while the conversions obtained from the hydrogenation of oleic acid and hydroformylation of 2-vinylnaphthalene are improved by CO_2 pressure. The use of gaseous CO_2 can thus extend the range of temperatures at which 'neat' reactions can be performed. Future work will include the testing of other gases and other reactions.

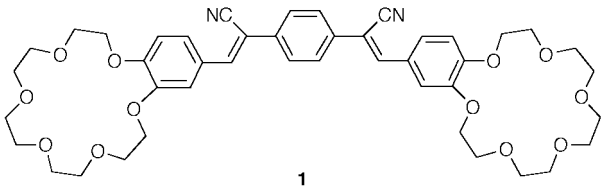
Received (in Corvallis, OR, USA) 9th February 2000, Accepted 8th March 2000
Published on the Web 30th March 2000

A novel caesium selective fluorescent chemosensor has been designed and synthesized; the chemosensor exhibited a selective fluorescent enhancement in the presence of other alkali metal ions.

The rapid and selective measurement of trace ions *in situ* has significant environmental and biological applications.[1] The selective sensing of trace amounts of caesium is important in detecting leaks from nuclear waste storage tanks (^{137}Cs in particular), which may cause serious problems to the environment.[2] Currently, there is no method available for *in situ* quantitative determination of Cs^+ in nuclear solutions. Very recently, Dabestani and coworkers developed a first-generation caesium selective fluorescent chemosensor based on a calix-[4]arene derivative.[3] Nevertheless, it is still necessary to develop more sophisticated and more selective caesium chemosensors that can be easily handled.

Recently, we reported a highly selective fluorescent chemosensor for potassium, a dicyano-substituted distyrylbenzene derivative containing two 15-crown-5 rings which has a low emission quantum yield in acetonitrile ($\phi = 0.001$).[4] Studies showed that the high potassium selectivity of the sensor upon the complexation of potassium ions results from formation of a sandwich complex between the 15-crown-5 and a potassium ion that leads to a large enhancement of the fluorescence of the disytrylbenzene derivative. We have denoted this type of fluorescence enhancement Self-Assembling Fluorescent Enhancement (SAFE) since the luminescence is believed to result from formation of a structure in which each crown of the fluorophore is part of a sandwich complex.[5] Herein, we report a novel caesium-selective fluorescent chemosensor **1** that consists of a dicyano-substituted distyrylbenzene derivative and two 18-crown-6 rings.[6]



1

In acetone solution, **1** shows a broad absorption at 380 nm. With the addition of Cs^+ ion [$Cs(CF_3CO_2)$ in acetonitrile], a slight decrease of the absorption is observed. However, a significant change is observed in fluorescence spectra of **1** when Cs^+ ions are added as shown in Fig. 1. The fluorescence intensity is enhanced significantly and the fluorescent peak red-shifts from 482 to 526 nm. The insert in Fig. 1 shows the titration curve of **1** with Cs^+. Stoichiometry studies indicate that **1** forms a 1:1 complex with caesium ion, indicating that each Cs^+ ion coordinates to two 18-crown-6 moieties. At saturation in acetone solution the maximum fluorescence intensity of **1** complexed with Cs^+ is about 20 times that of free **1**. Other alkali metal ions such as Li^+, Na^+ and K^+ were also examined. No significant fluorescent enhancement was observed with any of these, even though 18-crown-6 is known to bind K^+ strongly.[7] The results strongly suggest the formation of a sandwich complex consisting of two 18-crown-6 substituents and Cs^+. A similar fluorescence enhancement of *ca.* 12–15 times was also observed when CsF was used as a cation source. Stability constants, expressed as log *K*, determined assuming 1:1 complex formation are 4.3 in acetone and 5.7 M^{-1} in chloroform–acetonitrile (9:1, v/v).

The fluorescence behavior of **1** in the presence of Cs^+ is strongly dependent on solvent. In acetonitrile, sensor **1** shows a similar fluorescent enhancement when Cs^+ ions are added, but the enhancement is significantly lower than that in acetone. The saturation enhancement is only a factor of 4 in acetonitrile. The diminished enhancement could be due to a variety of factors such as differences in the emission quantum yield of the $Cs(\mathbf{1})_2$ sandwich complex in the two solvents or competitive formation of other Cs^+/**1** complexes involving acetonitrile displacement of a crown [*i.e.* formation of $Cs(\mathbf{1})(MeCN)_n$ complexes]. The use of mixed solvents containing chloroform and a small amount of acetonitrile (9:1, v/v) results in a much larger fluorescence enhancement than observed in pure acetonitrile. The titration curve, monitoring emission at 512 nm, is shown in Fig. 2. An enhancement of a factor of 20 is observed when two equivalents of Cs^+ ion are added to solutions containing 20 μM **1**. However, the luminescence intensity *decreases* with increasing Cs^+ concentration above Cs^+/**1** ratios of 2 (no new emission with a different maximum is observed). The decrease may result from break-up of the sandwich structure to form 1:1 (Cs^+:18-crown-6) complexes with the excess Cs^+ present. Results from ^1H NMR measurements support this hypothesis.[8] It should be noted that the fluorescence enhancement observed in acetone in greatly diminished upon addition of water as a cosolvent. For instance, acetone–water (9:1, v/v) little change in luminescence occurs with less than a ten-fold excess of Cs^+ and the maximum enhancement observed is only a factor of 3.5.

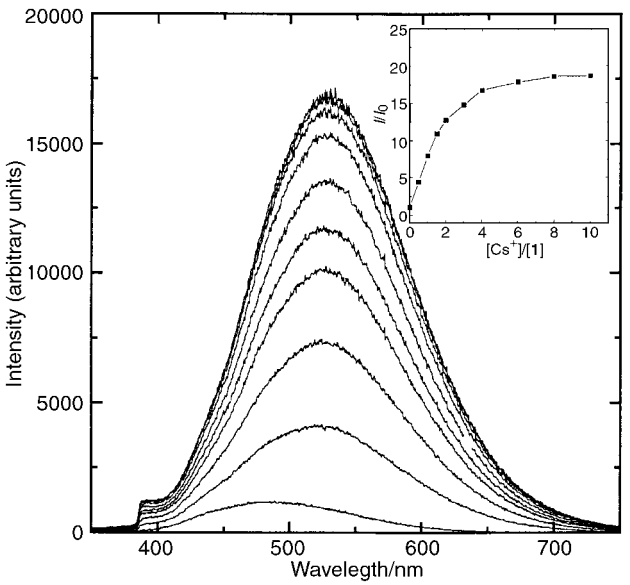


Fig. 1 Fuorescence spectral change upon the addition of caesium ions in acetone, [**1**] = 2×10^{-5} M. The insert shows the titration curve of Cs^+ in acetone (monitored at 526 nm, excited at 350 nm).

DOI: 10.1039/b001139h

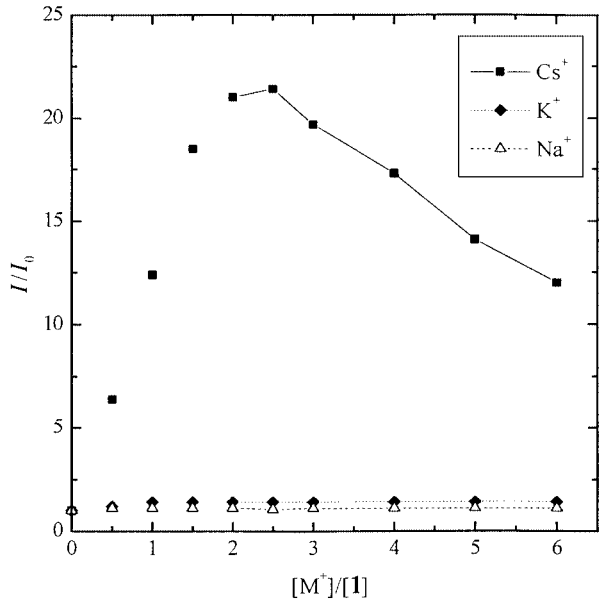

Fig. 2 Titration curve of **1** with metal ions ([**1**] = 2 × 10^{-5} M) monitored at 512 nm.

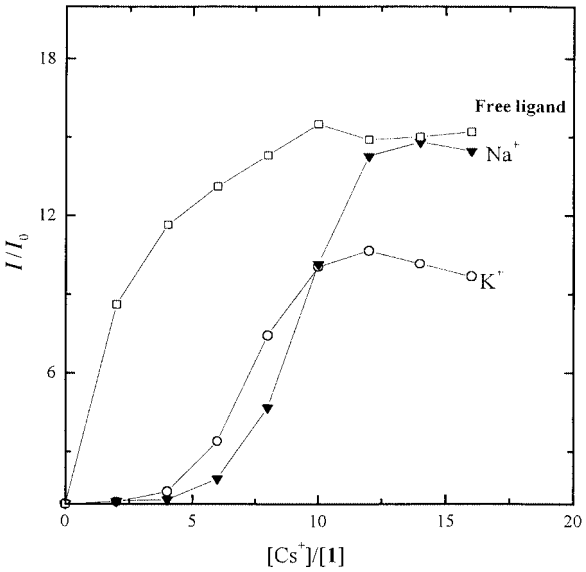

Fig. 3 The fluorescence intensity change upon the addition of Cs^+ ion in acetone in the presence of K^+ and Na^+ ([K^+] = 3.75 ×10^{-4} M, [Na^+] = 3.75 × 10^{-4} M). The intensity was monitored at 526 nm; [**1**] = 2 × 10^{-5} M.

The selectivity of this novel sensor for Cs^+ was also examined by competition experiments. Fig. 3 shows fluorescence intensity changes upon addition of Cs^+ when either K^+ or Na^+ is also present. Although K^+ and Na^+ each cause some interference to the fluorescence response at the beginning stage of the addition of Cs^+ ions, the fluorescence is turned on when [Cs^+]/[K^+] or [Cs^+]/[Na^+] reaches *ca.* 1:4. Further increases in the Cs^+ ion concentration lead to increases in the fluorescence intensity until a plateau in the emission is reached at [Cs^+]/[M^+] and [Cs^+]/[**1**] ratios of 1:3 and 5:1, respectively. Competition studies between the Cs^+ ion and K^+ or Na^+ ions are also consistent with the assumption that only the formation of a sandwich structure will result in the turn-on of the fluorescence.

We are grateful to the Tulane/Xavier Center for Bio/Environmental Research (DOD/ONR) for partial support of this research.

Synthesis and structural characterization of a silacycloheptadiene

Honglae Sohn,*[a] Hee-Gweon Woo*[b] and Douglas R. Powell[c]

[a] *Department of Chemistry and Biochemistry, University of California, San Diego, CA 92093, USA. E-mail: hsohn@ucsd.edu*
[b] *Department of Chemistry, Chonnam National University, Kwangju 500-757, Korea*
[c] *Department of Chemistry, University of Wisconsin, Madison, WI 53705, USA*

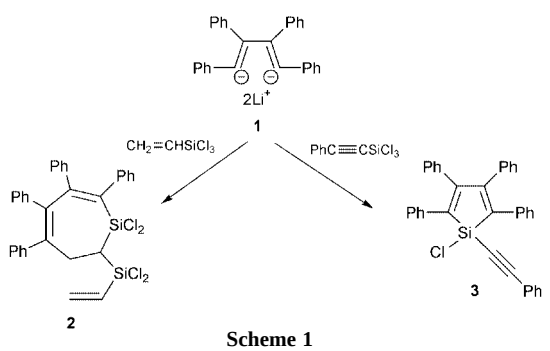
Received (in Corvallis, IR, USA) 18th January 2000, Accepted 8th March 2000

The dilithium salt of tetraphenylbutadiene (1) reacts normally with phenylethynyltrichlorosilane to give 1-chloro-1-phenylethynyl-2,3,4,5-tetraphenylsilole (3), but with vinyltrichlorosilane the unexpected product is the silacycloheptadiene 2, and X-ray crystal structures were obtained for 2 and 3; the seven-membered ring in 2 adopts a boat conformation, and a possible mechanism for the formation of 2 is suggested.

The reaction of vinylchlorosilanes with a bulky organolithium compound such as *tert*-butyllithium has been reported by Jones and Lim[1] and later extensively studied by Auner[2] for almost 20 years. However only one report, by Balasubramanian and George,[3] for the reaction of 1,2,3,4-tetraphenylbuta-1,3-diene dianion **1** with an alkenylchlorosilane, $Me(CH_2{=}CH)SiCl_2$, to give 1-methyl-1-vinyltetraphenylsilole has been published.[3]

Here, we report the reactions of **1** with phenylethynyltrichlorosilane and vinyltrichlorosilane. Although many synthetic routes for siloles have been reported,[4] siloles can often be synthesized in high yield by using our previously reported method[5] in which a solution of the dilithio compound **1** is frozen with liquid nitrogen, an excess of a chlorosilane is added *via* a syringe in one portion and the mixture is slowly warmed. However, the reaction of **1** with vinyltrichlorosilane using the method described above gave, surprisingly, a reaction involving two molecules of the chlorosilane yielding silacycloheptadiene **2** (Scheme 1).† No evidence for the formation of the expected silole $C_4Ph_4SiCl(CH{=}CH_2)$ was observed. Even preparative scale reactions of **1** with just 1 equiv, rather than an excess of vinyltrichlorosilane, gave only **2** in 50% yield, leaving 50% of **1** unreacted**.** The reaction produced two enantiomers which could result from the chiral carbon C(6).

The X-ray crystal structure of **2** was determined and is shown in Fig. 1.‡ The molecule has two localized double bonds, and the vinyldichlorosilyl substituent group is attached to carbon atom C(6), as shown. The conformation of the seven-membered ring is boat like. The silicon atom Si(1) and carbon atoms C(1), C(2), C(3) are nearly coplanar, as are carbon atoms C(2), C(3), C(4), C(5), but there is a twist (51.3°) between C(2) and C(3), and a strong bend at the C(4)–C(5) junction (−89.8°). The result is that the silyl substituent group is moved away from the hindering phenyl groups on the ring.



Scheme 1

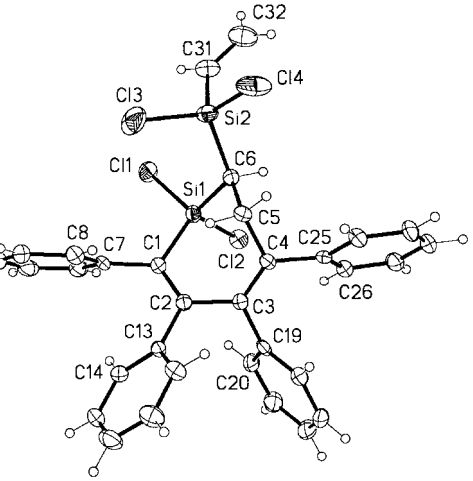


Fig. 1 Thermal ellipsoid diagram of structure of **2**. Selected bond lengths, (pm): Si1–C1 187.2(4), Si1–C6 186.8(4), Si1–Cl1 205.23(13), Si1–Cl2 207.01(13), Si2–C6 186.7(4), Si2–C31 183.5(4), C1–C2 136.1(5), C2–C3 150.7(5), C3–C4 135.3(5), C4–C5 152.0(5), C5–C6 156.2(5), C31–C32 131.5(6), Intramolecular angles, (°): C1–Si1–C6 111.8(2), Si1–C1–C2 118.8(3), Si1–C6–C5 105.9(2), C1–C2–C3 121.5(3), C2–C3–C4 122.7(3), C3–C4–C5 122.2(3), C4–C5–C6 110.4(3), Si1–C6–Si2 118.4(2), C6–Si2–C31 115.0(2), Si2–C31–C32 123.4(4), Cl1–Si1–Cl2 103.83(6), Cl3-Si2–Cl4 107.32(8). Selected torsion angles, (°): C1–C2–C3–C4 51.3(5), Si1–C1–C2–C3 −0.7(5), C2-C3–C4–C5 3.9(5), C3–C4–C5–C6 −89.8(4), C4–C5–C6–Si1 55.5(4), C4–C5–C6-Si2 −172.9(2), C7–C1–C2–C13 7.5(5), C13–C2–C3–C19 51.2(4), C19–C3–C4–C25 7.8(5).

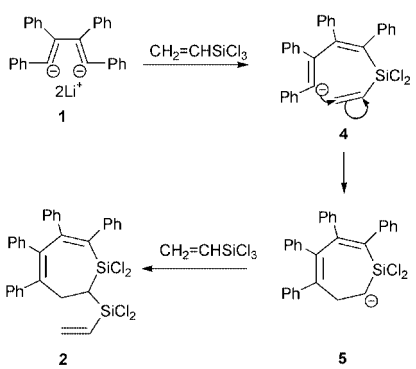
A possible mechanism for the formation of **2** is shown in Scheme 2. Nucleophilic reaction of the butadiene anion in **4** with the β-carbon atom of the vinyldichlorosilane moiety could give an intermediate which could close to give the dichlorosilacycloheptadienyl anion **5**. This anion could react with another molecule of vinyltrichlorosilane to give **2**. An alternative mechanism would involve loss of LiCl from the anion of **5** to give a Si=C bond. This would then be followed by Si–Cl addition across the Si–C double bond to give the product **2**. However, the reaction of **1** with 1 equiv. of vinyltrichlorosilane



Scheme 2

DOI: 10.1039/b000585l

in the presence of a trapping reagent such as a 2,3-dimethylbutadiene gave only **2** without any addition product of buta-1,3-diene across the Si=C bond. This result argues against the alternative mechanism.

In contrast to the reaction described above, the reaction of **1** with phenylethynyltrichlorosilane proceeded normally to give the silole **3**,§ with no indication of formation of a seven-membered ring, even when an excess of $PhC{\equiv}CSiCl_3$ was present. The crystal structure of **3**, shown in Fig. 2,‡ is very similar to that for previously known siloles.[6] The ring is nearly planar, with a torsion angle C(1)–C(2)–C(3)–C(4) for the butadiene moiety of 5.3°. The Si(1)–C(29) bond distance of 181.6 pm for **3** is shorter by *ca.* 3.6–4.6 pm than intra ring bond distances of Si(1)–C(1) and Si(1)–C(4). The angle Si(1)–C(29)–C(30) of 174.3° and the torsion angle Si(1)–C(29)–C(30)–C(31) of 25.0° show that the Si–C≡C–C moiety is non-linear; this distortion may result from crystal packing forces.

Tetraphenylsilole and its polymers have been reported to exhibit interesting photophysical properties.[7] Surprisingly, silacyclohepta-2,4-diene **2** is also photoluminescent. Compound **2** and **3** exhibit two broad bands at *ca.* 300 and 380 nm in their electronic absorption spectra, assignable to the butadiene moiety. As shown in Fig. 3, both **2** and **3** have a broad emission band at *ca.* 380 nm in the fluorescence spectra.

Although several silacyclohepta-2,4,6-trienes[8] and silacycloheptenes[9] are known, as are some dihydrobenzosilepins,[10] **2** appears to be the first example of a silacycloheptadiene. We plan to extend the method used for the synthesis of **2** to prepare other new silacycloheptadiene compounds and their polymers.

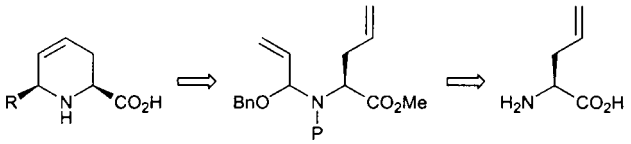
Received (in Cambridge, UK) 15th February 2000, Accepted 15th March 2000

A combination of palladium-catalysed *N,O*-acetal formation, ruthenium-catalysed ring-closing metathesis and *N*-sulfonyliminium ion-mediated C–C bond formation constitutes an efficient and versatile route to a set of enantiomerically pure 2,6-disubstituted unsaturated pipecolic acid derivatives.

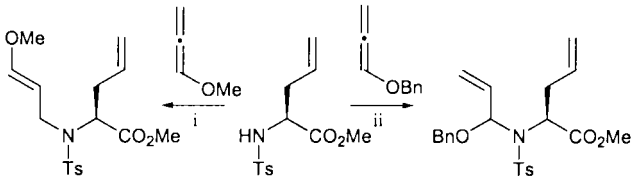
The pipecolic acid derivatives **1**, heterocycles containing a variety of functional groups, constitute an interesting compound class. They are rigid amino acids and may therefore be used to introduce conformational restriction in peptides.[1] Furthermore, this class of cyclic amino acid derivatives is a versatile starting point for the construction of (libraries of) biologically active compounds and for the synthesis of naturally occurring alkaloids.[2] Although a few approaches towards the synthesis of such systems are known,[3] general access to a wide range of these types of amino acids is still rather limited. Here we present an efficient and flexible route to the unsaturated 2,6-disubstituted pipecolic acid derivatives **1** consisting of (i) a novel amidopalladation reaction of an alkoxy-substituted allene to form the allylic *N,O*-acetals **2a** and **2b**, (ii) Ru-mediated ring-closing metathesis of these intermediates and (iii) selective functionalisation at the 6-position *via* allylic *N*-sulfonyliminium ion chemistry (Scheme 1).[4] The starting material is enantiomerically pure allylglycine (**3**), which is commercially available but alternatively can be efficiently prepared in both enantiomeric forms.[5]



1 **2a**: P = Ts; **2b**: P = Ns **3**

Scheme 1 Retrosynthesis.

This route was inspired by previous work in our group on the synthesis of oxygen heterocycles, where one of the key steps consisted of a highly efficient acetal formation *via* oxypalladation of methyl propadienyl ether.[6] We envisioned that formation of the corresponding *N,O*-acetals should be possible in a similar fashion.[7] However, treatment of Ts-protected allylglycine methyl ester (**4**) with methyl propadienyl ether in the presence of $Pd(OAc)_2$ at 80 °C surprisingly led to the undesired enol ether **5**, formed by reaction of the tosylamide at the least hindered γ-position of the allene (Scheme 2). Interestingly, a similar reaction with benzyl propadienyl ether[8] did not require these refluxing conditions to proceed, but instead



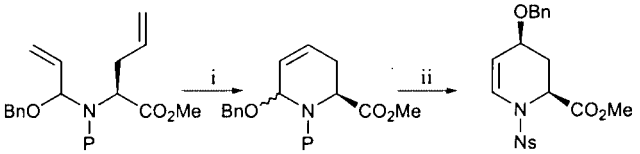
5 **4** **2a**

Scheme 2 *Reagents and conditions*: i, methyl propadienyl ether, $Pd(OAc)_2$, dppp, Et_3N, MeCN, sealed tube, reflux, 50%; ii, benzyl propadienyl ether, $Pd(OAc)_2$, dppp, Et_3N, MeCN, room temperature, 85%.

went to completion in one hour at room temperature to selectively give the desired *N,O*-acetal **2a** in 85% yield.[9] Most probably, at higher temperatures the thermodynamic product is formed, whereas at room temperature the kinetic product is produced.

The *N,O*-acetal formation proceeded well for both the Ts- and Ns (4-nitrobenzenesulfonyl)-protected allylglycine derivatives (yield of **2b**: 84%; both **2a** and **2b** were obtained as *ca.* 1:1 mixtures of diastereomers), but did not work satisfactorily for the corresponding carbamates. It should be stressed that this amidopalladation of benzyl propadienyl ether represents a novel method of generating *N,O*-acetals. More general application of this smooth reaction to convert sulfonylamides into the corresponding *N,O*-acetals[10] in principle paves the way to a large variety of *N*-sulfonyliminium ion precursors.[4]

Having these stable diolefins in hand, the compounds were subjected to standard ring-closing metathesis conditions using the well-established Grubbs Ru–benzylidene catalyst[11] to give the desired cyclic *N,O*-acetals **6a** and **6b** in excellent yields as *ca.* 1:1 mixtures of *cis/trans*-isomers (Scheme 3)



2a: P = Ts; **2b**: P = Ns **6a**: 95%; **6b**: 90% **7**

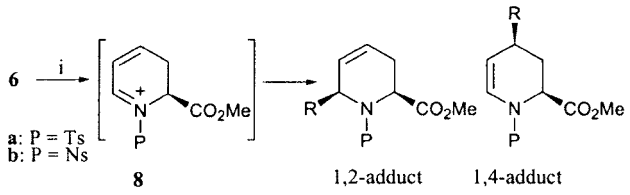
Scheme 3 *Reagents and conditions*: i, $Cl_2(Cy_3P)_2Ru{=}CHPh$, CH_2Cl_2, room temperature; ii, $BF_3{\cdot}OEt_2$, CH_2Cl_2, −78 °C, 90%.

Treatment of this mixture with $BF_3{\cdot}OEt_2$ at −78 °C led to isomerisation of **6b** to the thermodynamically more stable vinylogous *N,O*-acetal **7**,† which consisted of an 8:1 mixture of *cis/trans* isomers. After comparison with literature data[3c] and based on the observed NOE signals in the ^1H NMR spectrum, the major isomer was identified as the *cis*-product. This isomerisation was a useful indication of the feasibility of cationic reactions *via* such types of *N*-sulfonyliminium ions.

To establish CC-bond formation, precursors **6a** and **6b** where treated with a variety of nucleophiles in the presence of different Lewis acids. In Table 1, the results with $BF_3{\cdot}OEt_2$ are shown,

† Electronic supplementary information (ESI) available: characterisation data for compounds **7**, **9** and **16**. See http://www.rsc.org/suppdata/cc/b0/b001253j/

Table 1 *Reagents and conditions*: i, nucleophile, $BF_3{\cdot}OEt_2$, CH_2Cl_2, −78 °C → room temperature; yields were determined after flash column chromatography. The enantiopurity of the products was checked by chiral HPLC (Chiracel OD, heptane–isopropyl alcohol = 80:20)



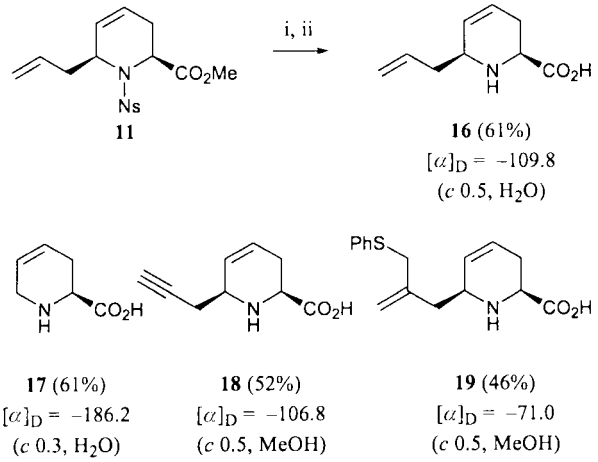
8

Entry	Substrate	Nucleophile	Product	Ratio (1,2:1,4)	Yield (%)
1	**6b**	Et_3SiH	**9** (R = H)	100:0	88
2	**6a**		**10** (R = Allyl)	90:10	62
3	**6b**		**11** (R = Allyl)	75:25	79
4	**6b**		**11** (R = Allyl)	98:2	94
5	**6a**	$Me_3Si{-}C{\equiv}N$	**12** (R = CN)	100:0	70
6	**6b**	$Me_3Si{-}C{\equiv}N$	**13** (R = CN)	100:0	89
7	**6b**		**14** (R = Propargyl)	100:0	75
8	**6b**		**15** (R = )	80:20	67

since this Lewis acid appeared superior in terms of selectivity and yield. The most simple nucleophile (Et_3SiH, entry 1) provided selectively the unsaturated pipecolic acid **9** in 88% yield. The enantiopurity of the product was checked by analysis of the enantiopure and the racemic product with chiral HPLC (as in all other entries) to confirm that racemisation during the *N*-sulfonyliminium ion reaction does not take place. With allyltrimethylsilane as the nucleophile (entries 2 and 3), mixtures of 1,2- and 1,4-addition products were obtained, both as single diastereoisomers. The stereochemistry of the 1,2-adduct was assigned on the basis of ^1H NMR NOE studies after deprotection to the free amino acid (10% enhancement of H6 upon irradiation of H2 and *vice versa*) and was in accordance with previously published observations.[3a] The *cis*-configuration of the 1,4-adduct was concluded *via* comparison with ^1H NMR data of **7**. The regioselectivity of this reaction could not be influenced by using different Lewis acids, but instead by applying the more reactive nucleophile allyltributyltin a highly selective reaction took place at the six-position. In addition, both trimethylsilylcyanide and 1,2-propadienyltributyltin[12] (entries 5–7) reacted solely and with complete diastereoselectivity at the six-position to give the corresponding cyanide- and propargyl-substituted product, respectively. Inversely, the chloromethyl-substituted allylsilane (entry 8) provided again a mixture of regioisomers.

Eventually, most of the Ns-protected products were converted into the corresponding free pipecolic acid derivatives (Scheme 4). A straightforward sequence involving (i) cleavage of the sulfonamide with K_2CO_3 and PhSH, (ii) LiOH-mediated hydrolysis of the ester and (iii) purification by ion exchange chromatography yielded the cyclic amino acids in good to moderate yields over these two steps without detectable epimerisation of the stereocentres. Thus, a number of differently substituted amino acid building blocks were obtained, including the natural product baikiain (**17**: $[\alpha]_D$ = −182.6 (*c* 0.3, H_2O); lit.,[13] −201.6 (*c* 1, H_2O)) and the allylic sulfide **19**, which arose from nucleophilic substitution of the chloride during the deprotection.

In summary, we developed a practical and concise transition metal-catalyzed route to a variety of substituted pipecolic acid



Scheme 4 *Reagents and conditions*: i, PhSH, K_2CO_3 DMF, room temperature; ii, LiOH, MeOH–H_2O (1:1), room temperature.

derivatives including the natural product baikiain. At present, we are further extending the scope of the cyclic *N,O*-acetals as synthetic intermediates in different (metal-catalysed) types of C–C bond forming reactions and are also exploring the possibilities to apply these building blocks in natural product synthesis.

Competition between photosensitization and charge transfer in soluble oligo(naphthylenevinylene)–fullerene dyads

Received (in Liverpool, UK) 5th January 2000, Accepted 14th February 2000

In a novel series of soluble C_{60}–oligo(naphthylenevinylene) dyads both singlet–singlet energy transfer and intramolecular electron transfer were found to take place and to compete with each other.

Conjugated, polymeric semiconductors are effective and stable electron-donor materials. Upon illumination of the polymer, a valence band electron is excited across the band-gap into the conduction band and generates a highly reactive donor state. Charge separation evolving from the latter process is facilitated by a possible charge delocalization within the polymer or by structural relaxation. On the other hand, fullerenes also display strong electron-acceptor properties in their ground and excited states. In mixed composites of these two donor acceptor materials ultrafast photoinduced electron transfer can occur with high quantum efficiency.[1] This feature attracted interdisciplinary effort to utilize conjugated polymer/C_{60} blends as novel materials for photovoltaic cells (*i.e.* the conversion of photon energy into electricity).[2]

The tendency of C_{60} to phase-separate and crystallize limits its solubility in conjugated polymers. However, uniformity and high quality of conjugated polymer/C_{60} thin films are essential requirements for opto-electronic device applications. Thus, soluble functionalized C_{60} derivatives have been synthesized in an attempt to suppress the phase separation once these derivatives are blended with the conjugated polymers.[3]

A viable alternative for fabricating stable bicontinuous networks is the synthesis of molecular dyads[4] and triads[5] bearing conjugated oligomer moieties covalently linked to an electron acceptor, such as a fullerene.[6] Well structured oligomers allow the possibility for mimicking the basic structural and electronic properties of the related polymers and, therefore, have emerged as interesting materials for opto-electronic applications.[7,8]

Here, we report the preparation of a covalently linked [60]fullerene–oligo-2,6-naphthylenevinylene (ONV) derivative **4** as well as that of the [60]fullerene–monomer analogue **6**. Furthermore, a detailed investigation of intramolecular energy and electron transfer reactions in both dyads is presented.

Among the suitable procedures for the functionalization of fullerenes, the 1,3-dipolar cycloaddition of azomethine ylides to C_{60} emerged as an important methodology for the production of stable fullerene derivatives.[9] We have adapted this synthetic approach for the preparation of dyad **4** which was obtained in 63% yield (*i.e.* based on recovered C_{60}) by reacting sarcosine, C_{60} and the formylsubstituted trimeric material **3** in refluxing toluene for 24 h. Oligomer **3** was obtained from the dibromoderivative **1**[10] by using a two step reaction pathway. Treatment of **1** with copper cyanide in dimethylformamide[11] under stoichiometric control led to a mixture of the monocyanoderivative **2** (49%) and dicyano derivative (21%) which were subsequently separated by column chromatography. Reduction with DIBAL-H at −78 °C of oligomer **2** yielded the aldehyde **3** in a 40% yield (Scheme 1).

Reaction of 2-bromo-6-formyl-1,5-dihexyloxynaphthalene[10] with [60]fullerene and sarcosine in refluxing toluene for 24 h yielded dyad **6** (Scheme 1). The good solubility afforded by the alkoxy chains allowed full spectroscopic and electrochemical characterization of both dyads (**4** and **6**).

The redox properties of the fullerene-linked oligomers were studied by cyclic voltammetry in toluene–acetonitrile (5 : 1 v/v) at room temperature. Dyads **4** and **6** both exhibit an amphoteric redox-active behaviour. In particular, they show an oxidation wave at $E_{1/2}$ *ca.* 1.4 V, (1.48 V for **3** *vs.* SCE) due to the oxidation of the oligomer, and three quasireversible waves at $E_{1/2}$ = −0.59, −1.04 and −1.66 V corresponding to the fullerene reduction.

The absorption spectra of dyads **4** and **6** in dichloromethane solution disclose superimposed features of the C_{60} and the trimeric or monomeric unit, respectively. Taking the electrochemical data and the absorption features into consideration, we reached the conclusion that no significant interactions arise between the two redox-active moieties in the ground state of the combined units.

Relative to the strong emission of the oligomer references [*i.e. ca.* 400 nm (**5**) and 430 nm (**3**)], the trimer and monomer emission in dyads **4** and **6** is nearly quantitatively quenched.[5] Instead, a familiar fullerene fluorescence spectrum was found with a strong 0→0 emission at 715 nm, despite exclusive excitation of the oligomer moiety (Table 1).[12] To unravel the mechanism of producing the emission, an excitation spectrum was measured. The excitation spectra of dyads **4** and **6** were exact matches of the ground state absorption of the oligomer (**3**) and monomer (**5**) moieties with maxima at 412 and 360 nm respectively. This implies that there is a rapid transfer of singlet excited state energy from the photoexcited oligomer to the covalently linked fullerene.

[a] In toluene. [b] In THF. [c] Measured at 550 nm. [d] Measured at 880 nm.

In ps-resolved transient absorption measurements, oligomer **3** and monomer **5** gave rise to a broadly absorbing transient with a maximum at *ca.* 550 nm. On the ps timescale (*i.e.* up to 6000 ps), no significant decay of the excited state absorption was observed. C_{60}-oligomers **4** and **6**, on the other hand, displayed a drastically different behavior. The spectral features recorded immediately after the laser pulse (*i.e.* maximum at *ca.* 550 nm) clearly confirmed the excitation of the oligomer moieties. In contrast to reference compounds **3** and **5**, the excited state absorption was short-lived. In particular, lifetimes of 66 and 53 ps for dyads **4** and **6** (Table 1), respectively, corroborated the efficient emission quenching.

Once the rapid disappearance of the excited oligomer absorption comes to an end (*i.e. ca.* 200 ps after the laser pulse), only characteristics of the fullerene singlet excited state absorption remain. The noted maximum (880 nm) is reminiscent of that found for a reference fulleropyrrolidine.[13] In line with an energy transfer mechanism the singlet–singlet absorption revealed a two step grow-in dynamics. The faster process stems from the direct excitation of the fullerene core, while the slower component is ascribed to the actual transfer of excited state energy. The latter assignment is based on the nearly identical dynamics [49 ps (**4**) and 45 ps (**6**)] observed for the second components relative to those of the decays at 500 nm.

Another process follows the conclusion of the energy transfer reaction, the outcome of which on the timescale of a few thousand ps is the formation of a distinct, new maximum at 700 nm. This absorption is in excellent agreement with the triplet excited state absorption of a fulleropyrrolidine reference, which infers that the underlying reaction is an intersystem crossing (ISC) from the fullerene singlet to the energetically lower-lying triplet excited state.

In order to quantify the energy transfer, and to probe a possible contribution from an electron transfer channel, triplet quantum yields were measured in different solvents. The quantum yields deviate substantially from unity (Table 1) and are in the range of 57–63% for **4** and 72–83% for **6**. It is noteworthy that the values are particularly low in polar solvents.

Taking the redox potential of the electron accepting fullerene and those of the two oligomers into account (see above), the possibility of electron transfer is thermodynamically feasible, especially considering the high energies of the photoexcited trimer (**3**; E_{singlet} = 2.88 eV) and monomer (**5**; E_{singlet} = 3.09 eV). None of the photoexcited fullerene states (*i.e.* E_{singlet} = 1.76 eV; E_{triplet} = 1.50 eV) should, however, be powerful enough to initiate the intramolecular electron transfer and to yield the charge-separated radical pair ($E_{\text{charge-separated}}$ *ca.* 2 eV).

In the context of confirming the electron transfer mechanism, the strong triplet–triplet absorptions ($\varepsilon_{700\text{ nm}}$ = 16 100 $\text{M}^{-1}\text{cm}^{-1}$) should be noted, which dominate in large the ps and ns spectra. Consequently, to obtain direct evidence in support of the weaker absorbing radical pair ($\varepsilon_{1000\text{ nm}}$ *ca.* 8000 $\text{M}^{-1}\text{ cm}^{-1}$) subtraction of the triplet absorption features from, for example, the ns spectrum became necessary. The resulting differential absorption changes reveal a near IR-maximum at 1000 nm and a visible-doublet at 660 and 800 nm, characteristics of the reduced fullerene moiety and the oxidized oligomer,[14] respectively. Another argument for an intramolecular electron transfer is the solvent dependence on the triplet quantum yields mentioned above. Lower Φ-values in polar solvents correlate with larger free energy changes ($-\Delta G°$) for the associated electron transfer and, in turn, indicate a stronger competition to the energy transfer.

In summary, with a novel series of fullerene oligomer composites, we have demonstrated that an intramolecular electron transfer competes with the dominant singlet–singlet energy transfer. This observation is in good agreement with the thermodynamics of the investigated systems that predict a highly exergonic energy transfer ($-\Delta G°$ *ca.* 1.25 eV) and a less exergonic electron transfer reaction ($-\Delta G°$ *ca.* 1.0 eV). More important, lowering the energy of the charge-separated radical, by means of increasing the solvent polarity, enhances the efficiency of the electron transfer channel.

Clean catalytic combustion of nitrogen-bearing gasified biomass

Robert Burch and Barry W. L. Southward*

Catalysis Research Group, Department of Chemistry, The Queen's University of Belfast, Belfast BT9 5AG, Northern Ireland. E-mail: b.w.l.southward@qub.ac.uk

Received (in Cambridge, UK) 24th January 2000, Accepted 15th March 2000

Zero NO_x emissions are obtained in the catalytic combustion of simulated biomass mixtures containing substantial amounts of ammonia by optimisation of NH_3 oxidation and NO_x reduction using a 2%Rh–Al_2O_3 catalyst.

Renewable energy sources will be of increasing importance for power generation in the future. Attempts have been made to harness biomass-derived fuels for combined heat and power generation.[1–3] However, gasified biomass contains significant quantities of NH_3 (600–4000 ppm) in addition to substantial amounts of CO (9.8–17.2%), H_2 (9.8–13.2%) as well as CH_4, CO_2, H_2O and N_2.[3] The NH_3 represents a particular challenge since its combustion in the gas phase results in the formation of an equivalent amount of NO_x.

The environmental benefits of cleaner power generation has prompted much interest in catalytically stabilised combustion to reduce harmful emissions of nitrogen oxides (NO_x) and unburnt fuels.[1,2,4] A key question is whether catalytic combustion of biomass-derived gases can be controlled so as to avoid the conversion of ammonia into NO_x. The novel solution to this problem which we have discovered,[5] and which is reported here, is to first oxidise all the ammonia to NO_x and then utilise the large excess of CO and H_2 in the gas stream to reduce the NO_x to N_2 through the NO/CO and NO/H_2 reactions.

The catalyst used was 2%Rh–Al_2O_3 prepared by incipient wetness impregnation of CK300 Al_2O_3 (ex Akzo, surface area 200 $m^2\ g^{-1}$). The dried Al_2O_3 (120 °C, 24 h) was impregnated with Rh III nitrate (ex Johnson Matthey) and dried at room temperature for 24 h, then at 120 °C for a further 24 h prior to calcination at 700 °C in flowing O_2/He for 12 h. A second catalyst comprising 2%Rh–10%CeO_2–Al_2O_3 was prepared by sequential impregnation/calcination of $Ce(NO_3)_3{\cdot}6H_2O$ followed by $Rh(NO_3)_3$. Catalyst testing (60 mg, prereduced for 4 h at 700 °C in CO/H_2/He) was performed in a standard quartz flow microreactor at a GHSV of 240000 h^{-1}. Product analysis was by mass spectrometry (Hiden DSMS) with NO_x emissions and residual NH_3 levels being corroborated using an external NH_3 oxidation reactor (with independent oxygen supply) coupled with a NO_x chemiluminescence detector (Signal series 4000).

A conventional direct oxidation of NH_3 over 2%Rh–Al_2O_3 at typical gasifier output temperatures (Fig. 1) shows a low conversion initially but with a high selectivity to N_2. However, whilst both conversion and N_2 yields increase with temperature, N_2O and NO are also formed. N_2O and N_2 concentrations peak at *ca.* 375 °C (*ca.* 85–90% N_2) before decreasing, consistent with previous results,[2,6] whilst NO formation is seen to increase steadily with temperature to become the major product at $T >$ 500 °C. Fig. 1 therefore illustrates the difficulty of selectively oxidising NH_3 by conventional methods.

However, such problems may be overcome by making use of the other components of the biomass gas, namely CO and H_2 and by controlling the process conditions. Thus, catalytic reduction of NO by CO is very facile,[7] and the reduction of NO_x by H_2 has also been demonstrated.[8] Therefore, if NH_3 is first oxidised to NO_x, the other components of the biomass gas (CO and H_2) could be used for the catalytic reduction of NO_x to N_2. Hence by coupling NH_3 oxidation with NO_x reduction in an oxygen-limited environment it should be possible to convert NH_3 completely to N_2 in a pseudo-two-stage process. Thus, the strategy we propose is to first catalyse the complete oxidation of the NH_3 to NO_x in a limited amount of O_2, followed by catalytic reduction of NO_x by the CO or H_2 present in the biomass gas.

The main challenge is to selectively oxidise NH_3 in the presence of a large excess of CO and H_2. Our success in achieving this with a Rh catalyst is illustrated in Fig. 2. This shows that conversion of NH_3, rather than reaction selectivity, is the limiting factor for the selective oxidation. Thus, at low temperatures NH_3 does not react but H_2 and CO are very reactive. In contrast, at higher temperatures, the NH_3 begins to react and by around 600 °C the conversion of ammonia is effectively 100% whereas the combustion of H_2 has dropped to close to zero. Of course, the overall levels of oxidation are limited, deliberately, by controlling the O_2 concentration. Clearly, with this catalyst the selective oxidation of NH_3 to NO_x in the presence of a large excess of CO and H_2 has been achieved. The second stage, namely, the reduction of the NO_x

Table 1 Lifetime performance of (1) 2%Rh–Al_2O_3 and (2) 2%Rh–10%CeO_2–Al_2O_3

Entry	$\%O_2:CO/H_2:H_2O$	$\%N_2$ at 1 h	$\%N_2$ at 2 h	$\%N_2$ at 3 h	$\%N_2$ at 4 h	$\%N_2$ at 5 h
1	0.275:1.7:0	98.3	97.5	96.7	96.6	96.6
2	0.275:8.9:2.5	100	100	100	99.9	99.8

by residual CO and/or H_2 occurs sequentially within the same bed of catalyst because the only nitrogen-containing product detected is N_2. This methodology has also been examined for its efficacy under more severe conditions for extended periods with minimal loss of activity (Table 1) underlining its potential for commercial application. Moreover it should be stressed that in case of the 2%Rh–10%CeO_2–Al_2O_3 catalyst, a significantly higher CO/H_2 concentration was employed, which in theory should mitigate *against* the activation of the NH_3 due to significantly enhanced competition for active sites, when in fact this sample exhibited almost no deactivation over the duration of the experiment.

In conclusion, we have developed a strategy for the complete removal of NH_3 from biomass-derived gases by coupling the total oxidation of NH_3 with the reduction of NO_x by CO and/or H_2. Experiments have demonstrated that the concept is viable and provides a novel way to overcome the environmenal problems associated with the direct combustion of biomass-derived gas. The strategy is equally applicable to any comparable gasification gas (from coal, or from other renewable sources). Future work will examine the potential poisoning effects of sulfur, alkali metals and chloride ions on activity, although given the net reducing conditions employed in this new process the impact of the former is expected to be limited given previous experience of the negligible effect of sulfur on 3-way catalysts.[9]

We are pleased to acknowledge the financial support of ABB-Alstom power, the DTI and the EPSRC through the FORESIGHT Challenge initiative. Ab initio simulation of the interaction of hydrogen with the {111} surfaces of platinum, palladium and nickel. A possible explanation for their difference in hydrogenation activity

Graeme W. Watson,*† Richard P. K. Wells, David J. Willock and Graham J. Hutchings

Department of Chemistry, Cardiff University, PO Box 912, Cardiff, UK CF10 3TB

Received (in Oxford, UK) 25th January 2000, Accepted 14th March 2000

Density functional theory calculations have been performed on Pt, Pd and Ni {111} surfaces showing a considerable difference in adsorption energies for different sites on Pd and Ni while Pt shows an almost uniform adsorption energy which may be linked to the difference in activity of the these metals for hydrogenation.

Platinum, palladium and nickel, despite their close structural relationship and their proximity in the periodic table, show several significant differences in their chemistry. For example, for a given olefin the ease of hydrogenation over metal catalysts decreases in the order Pd > Rh > Pt > Ni >> Ru.[1] Under low hydrogen pressure conditions olefin isomerisation can also occur. Pt shows little isomerisation activity while Pd (together with Ni) promotes double bond migration *via* the formation of π-allyl intermediates. The degree of isomerisation over metal catalysts tends to decrease in the following order: Pd > Ni > Rh > Ru > Os ≅ Pt .[2,3] From this data it is clear that there are significant differences in the interaction of olefins and/or hydrogen with the metal surfaces. In this study we focus on one aspect of these differences, the interaction of hydrogen.

Molecular hydrogen adsorbs dissociatively on most transition metal surfaces with heats of chemisorption of between 30 and 60 kJ mol^{-1} (per H atom). Owing to its small size it can enter a metal surface fairly deeply leading to strong perturbations of the electronic structure. In most cases, including Pt and Ni, this only results in a relaxation of the first few atomic layers. However, some metals, including Pd, undergo a surface reconstruction which can lead to bulk absorption and the formation of PdH. The presence of sub-surface hydrogen in Pd has been illustrated by both temperature programmed desorption (TPD)[4] and H–D exchange reactions.[5]

Here, we consider the energetic differences between hydrogen atoms adsorbed at alternative sites of the clean {111} surfaces of Ni, Pd and Pt. We have employed the periodic plane wave pseudopotential density functional theory (DFT) method as implemented in the code VASP (Vienna *Ab initio* Simulation Program).[6] The Kohn–Sham equations are solved self consistently within the generalised gradient approximation, using the parameterisation derived by Perdew *et al.*[7] *k*-Point sampling, obtained using the Monkhorst–Pack scheme,[8] was used to treat the extended electronic states of the metal band structure with convergence accelerated using second order Methfessel–Paxton smearing[9] with a width of 0.1 eV. In this study a *k*-point grid of 5 × 5 × 1 was used which has been shown to provide accurate results.[10]

The {111} surfaces were constructed using the calculated equilibrium lattice constants of 3.990 Å (Pt), 3.950 Å (Pd) and 3.526 Å (Ni). These compare well with the experimental values of 3.924 Å (Pt), 3.891 Å (Pd) and 3.524 Å (Ni). A p(2 × 2) surface unit cell with three atomic layers, containing 12 metal atoms, was constructed. A vacuum gap equivalent to three layers was introduced to create the surfaces (one each side of the slab) with one hydrogen atom placed on one side of the slab corresponding to a surface coverage of 0.25 of a monolayer. The position of the hydrogen atom at each adsorption site was optimised with the metal surface held rigid. The adsorption energy is defined as the energy released on adsorption and is given by

$$E_{ads} = -[E(M + H) - E(M) - \tfrac{1}{2} E(H_2)]$$

Where E(M + H) is the energy of the hydrogen adsorbed on the metal, E(M) is the energy of the bare metal slab and $E(H_2)$ is the energy of a gas phase H_2 molecule. A positive value of E_{ads} implies that chemisorption from gas phase H_2 is thermodynamically favourable.

Fig. 1 shows a plan view of the {111} surface illustrating the four adsorption sites examined, the atop, bridge, fcc hollow and hcp hollow. Table 1 lists the adsorption energies and structures of hydrogen adsorbed onto each on these sites on the {111} surfaces of Ni, Pd and Pt. The differences in the influence of the H coordination on the adsorption energy for different metals is striking.

The adsorption onto the {111} surface of Ni increase with the coordination number of the hydrogen atom. The most stable site is the three-fold hcp hollow site (63.8 kJ mol^{-1}) closely followed by the three-fold fcc site (63.6 kJ mol^{-1}). The least stable is the atop site (10.1 kJ mol^{-1}) with the two-fold bridge site having an intermediate value (51.4 kJ mol^{-1}). The Ni–H bond lengths also follows the coordination number with the singularly coordinated atop site having the shortest bond and the three-fold hollow sites the longest bonds. Table 1 also lists the height Z(h) of the H atom above the first surface layer, clearly demonstrating that the atop hydrogen is significantly above the surface.

The results for Ni are in good agreement with experiment. Christmann *et al.*[11] found an adsorption energy of 49 kJ mol^{-1} while the stability of the hcp and fcc sites is consistent with the observed c(2 × 2)-2H structure.[12] Previous *ab initio* calculations[13] at a coverage of $\theta = 1$, gave rise to the same trend in the adsorption energy with the higher coordinated sites having the largest adsorption energies.

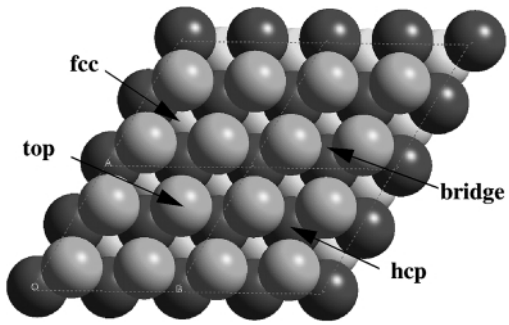

Fig. 1 Schematic illustration of the four adsorption modes for hydrogen investigated on the {111} surfaces of nickel, palladium and platinum. The one-fold atop site, the two-fold bridge site and the three-fold hollow sites (hcp and fcc) with the metal atoms not shown to scale so that the top, second (dark) and third (light) metals layers are clearly visible.

Table 1 Comparison of the adsorption energies, bond lengths and height of the hydrogen atom above the surface for hydrogen adsorption on the {111} surfaces of nickel, palladium and platinum. The numbers in parentheses indicate the coordination number of the hydrogen atoms in each case

	Nickel			
	Atop	Bridge	hcp hollow	fcc hollow
E_{ads}/kJ mol^{-1}	10.1	51.4	63.8	63.6
Ni–H distance/Å	1.469 (×1)	1.626 (×2)	1.708 (×3)	1.708 (×3)
Z(H)/Å	1.47	1.04	0.92	0.92
	Palladium			
E_{ads}/kJ mol^{-1}	3.1	36.4	45.2	49.1
Pd–H distance/Å	1.552 (×1)	1.725 (×2)	1.818 (×3)	1.818 (×3)
Z(H)/Å	1.552	1.012	0.840	0.838
	Platinum			
E_{ads}/kJ mol^{-1}	44.8	42.4	43.2	43.9
Pt–H distance/Å	1.565 (×1)	1.772 (×2)	1.876 (×3)	1.875 (×3)
Z(H)/Å	1.565	1.071	0.927	0.922

Adsorption on the Pd {111} surface follows closely the results obtained for Ni {111} but with slightly lower adsorption energies. In this case the fcc hollow site (49.1 kJ mol^{-1}) is slightly more stable than the hcp hollow site (45.2 kJ mol^{-1}). The bridge site is again slightly less stable (36.4 kJ mol^{-1}) and the atop site the least stable (3.1 kJ mol^{-1}). These results are consistent with thermal desorption spectroscopy,[14] which gave an adsorption energy of 43.4 kJ mol^{-1}, and low energy electron diffraction[15] (LEED) which suggests that the hydrogen occupies the fcc hollow site with a Pd–H distance of 1.78–1.80 Å. Previous calculations[13,16,17] also identified the hcp hollow site as the most stable with the stability reducing as a function of the coordination of the hydrogen. In the previous computational studies, the effect of surface relaxation was also investigated and found to be very small thus justifying our use of rigid surfaces.

For the Pt {111} surface the results are significantly different. All four adsorption sites have very similar energies, around 44 kJ mol^{-1} which is also in good agreement with microcalorimetric experiments on hydrogen adsorption to Pt powders[18] (45 kJ mol^{-1}). Although there is no relationship between the adsorption energy and the coordination number, surprisingly, the Pt–H distance follows the same trend as for the Ni and Pd with the atop site the shortest and the hollow sites the longest. For Pt {111} there are no previous *ab initio* calculations with which to compare.

From this it is clear that the interaction of hydrogen with the surface of Pt is significantly different to Pd and Ni. This is likely to have significant implications for reactions involving hydrogen on the surfaces of these metals. The atop will be more accessible for reacting with other adsorbed species and for Pd and Ni it is clear that hydrogen will not occupy this site. For Pt the atop site is in fact the most stable (although only marginally) implying that both the atop site and the hollow sites will be significantly populated and thus hydrogen will be more accessible for reaction.

More significantly the similar adsorption energies for all sites on Pt imply that the diffusion of hydrogen across the surface will be more rapid than for the other two metals. Recent experimental evidence to this effect has been obtained from quasi-elastic helium scattering.[19] If a hydrogen atom is located on a fcc hollow site on the {111} surface it will have to pass through either an atop or bridge site to diffuse across the surface. For Pt {111}, the energy of these sites is almost identical, and thus the energy barriers to diffusion are likely to be small. For Pd and Ni, the lowest energy pathway is through the bridge site, which is less stable than the fcc hollow site by 12 kJ mol^{-1} for Ni and 13 kJ mol^{-1} for Pd, compared to a difference of only 1.5 kJ mol^{-1} on Pt {111}. Diffusion over the Pd and Ni {111} surfaces will thus be hindered since H adsorbates have to pass through the bridge site creating a significant energy barrier compared to that on Pt. Evidence for this effect can be found in the isomerisation data presented earlier. At low partial pressure of hydrogen Pd and Ni allow olefin isomerisation while Pt does not. This can be explained by the rate of the hydrogenation reaction on Pd and Ni being limited by the transport of hydrogen to the reaction site. On Pt, owing to the faster diffusion, hydrogen transport will not be a significant factor.

The results presented indicate that there are fundamental differences in the interaction of hydrogen on the surfaces of platinum, paladium and nickel, and that these differences may contribute to the differences in the hydrogenation activity. While we have not considered sub-surface hydrogen in our calculations on Pd, the similarity of our results for Pd and Ni, where sub-surface hydrogen is known to be less important, suggest that our conclusions regarding the surface hydrogen species are valid.

We would like to thank the EPSRC IMI, Synetix, Johnson Matthey, BP-Amoco, Cambridge Reactor Design, Molecular Simulations Inc and OCF for financial support.

Controllable pH modulation of lanthanide luminescence by intramolecular switching of the hydration state†

Mark P. Lowe and David Parker*

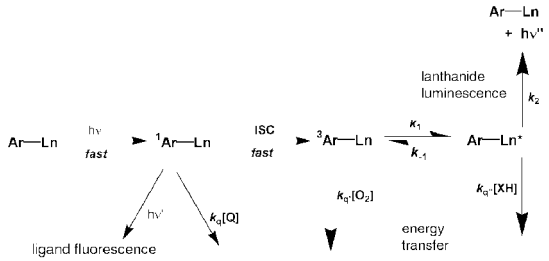
Received (in Cambridge, UK) 28th February 2000, Accepted 16th March 2000

The pH dependent ligation of a pendant arylsulfonamide group allows switching between the $q = 0$ and $q = 2$ states to be reported by changes in lanthanide luminescence emission over the pH range 5.5–7.5 and in the presence of serum albumin.

The behaviour of responsive luminescent lanthanide complexes is being studied actively at present, in which changes in the lanthanide emission intensity, lifetime or polarisation are used to signal selectively concentration variations of a target analyte.[1,2] Particular attention has focused on well-defined, kinetically stable Eu and Tb complexes, and examples of pH,[3] pO_2[4] and pX[5] dependent luminescence have been reported in high salt aqueous media. These cases rely upon a perturbation either of the singlet or triplet excited states of the sensitising chromophore or the longer-lived $^5D_0$ and $^5D_4$ states of Eu and Tb respectively (Scheme 1). In the latter case, the lifetime and emission intensity are primarily determined by the nature and proximity of energy-matched XH oscillators, which quench the lanthanide excited state by vibrational energy transfer.[6] Thus reversible binding of HCO_3^- to di-aqua Eu or Tb complexes of chiral heptadentate ligands, causes displacement of the bound water molecules and an enhancement in emission intensity and lifetime as well as marked changes in emission polarisation.[5b] We now report a new example of controllable modulation of lanthanide luminescence, whereby variations in pH allow a switching between $q = 0$ and $q = 2$ states associated with the on/off ligation of an arylsulfonamide group (Fig. 1). Furthermore, by varying the structure of the macrocyclic ligand, competitive binding by endogenous anions and proteins may be suppressed, thereby paving the way for the development of complexes which operate directly in 'biological' samples (*e.g.* serum).



Scheme 1

For the preparation of the initial target complexes (Fig. 1), advantage was taken of the ring opening reaction of *N*-*p*-methoxyphenylsulfonylaziridines with secondary amines.[7] For example, reaction of *N*-*p*-trifluoromethylphenylsulfonyl-aziridine with 1,4,7-tris(*tert*-butoxycarbonylmethyl)-1,4,7,10-tetraazacyclododecane in MeCN followed by TFA deprotection and metal complexation ($LnCl_3$, H_2O, pH 6) yielded the desired complexes.[8] The rate constants for decay of the Eu (and Tb) complexes were measured at pH 10 and 4 (λ_{exc} = 270 or 397 (Eu)/355 (Tb); 295 K) and gave values (Table 1) that are consistent with hydration states *q*, of 0.2 at pH 10 and 1.6 at pH 4. Profound changes in the form and intensity of the Eu emission spectra, especially the hypersensitive $\Delta J = 2$ and $\Delta J = 4$ transitions also characterised this pH change. In addition the Eu and Tb spectra, following sensitised excitation, were much more intense in the $q = 0$ régime, as not only the quenching bound OH oscillators have been displaced but also the aryl chromophore is much closer to the Ln centre, enhancing the efficiency of the intramolecular energy transfer step (Scheme 1). In accord with the hypothesis, quantum yields following excitation at 270 nm of 0.39% (pH 10) and 0.11% (pH 4) were recorded for [Eu·**1**] (R = OMe; 295 K, H_2O), and the corresponding values for [Tb·**2**] were 3.5% (pH 10) and 0.17% (pH 4).

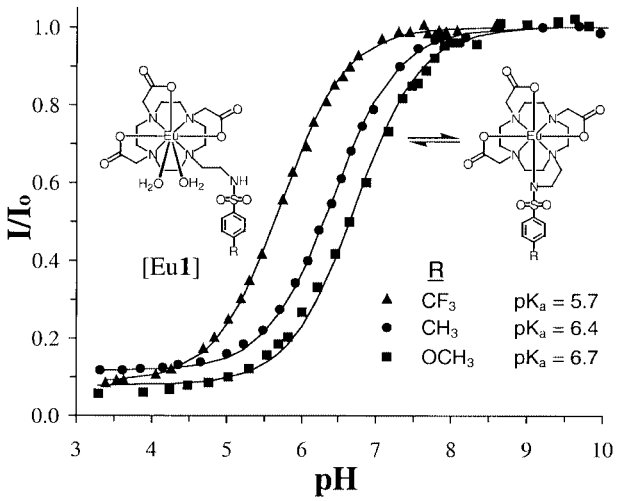


Fig. 1 pH Dependence of the europium luminescence (I/I_0) of [Eu·**1**] at 295 K (1 mM complex, 295 K, 0.1 M NaCl; λ_{exc} = 270 nm; λ_{em} = 612 nm ($\Delta J = 2$); solid lines show the fit to the experimental data).

Table 1 Rate constants *k* (ms^{-1}) and hydration states *q*, for decay of the lanthanide luminescence at limiting pH values (295 K, *I* = 0.1 M NaCl)

	pH/D 4			pH/D 10		
Complex	k_{H_2O}	k_{D_2O}[a]	q[a]	k_{H_2O}	k_{D_2O}	q
[Eu·**1**](*p*CF$_3$)	2.35	0.76	1.6	1.09	0.74	0.1
[Eu·**1**](*p*Me)	2.27	0.70	1.6	1.20	0.80	0.2
[Eu·**1**](*p*OMe)	2.32	0.66	1.7	1.43	0.93	0.3
[Eu·**2**]	2.21	0.65	1.6	1.11	0.72	0.2
[Tb·**2**]	0.90	0.56	1.4	0.45	0.40	0

[a] *q* Values were estimated using the equations $q^{Eu} = 1.2 (k_{H_2O} - k_{D_2O} - 0.25)$, $q^{Tb} = 5 (k_{H_2O} - k_{D_2O} - 0.06)$, which allow for contribution of unbound water molecules.[6a] Non-integral values may reflect the presence of a coordination equilibrium between the $q = 1$ and 2 states[6b] or the presence of a relatively 'long' Ln-OH_2 bond.[6a]

† Electronic supplementary information (ESI) available: examples of representative spectra of Eu and Tb complexes and their pH dependence. See http://www.rsc.org/suppdata/cc/b0/b001629m/

DOI: 10.1039/b001629m

Variation of the *p*-substituent in the arenesulfonyl group determines the basicity of the sulfonyl nitrogen and hence the pH at which protonation of the complex occurs. The pH dependence of the luminescence emission intensity was measured (295 K, I = 0.1 M, NaCl) for the series of terbium and europium complexes, (Fig. 1), showing behaviour in accord with the change in basicity at N. Thus the *p*-CF_3 europium complex gave a pK_a of 5.7 (±0.05) and the *p*-Me/*p*-OMe analogues yielded values of 6.4 and 6.7 respectively. The large pH-dependent changes in the form and intensity of the Eu emission allows the precise definition of pH (amenable in principle to multivariate calibration) with an estimated tolerance of ±0.1 pH units.

A limitation to the application of such complexes in a mixed salt or 'biological' background is the competititve binding of oxyanions (*e.g.* HCO_3^-, HPO_4^{2-} and lactate/citrate) or proteins (*e.g.* human serum albumin) to the q = 2 complex.[9] In order to obviate this problem, polyanionic analogues of the macrocyclic ligand were prepared by introduction of a carboxyethyl substituent α to three of the ring nitrogens.[8,10] The resultant complexes are tri- or tetra-anionic, inhibiting intermolecular anion binding to the q = 2 state. The pH-dependence of the terbium emission intensity (Fig. 2) was the same in 0.1 M NaCl and in a simulated 'clinical-anion' background—with an apparent pK_a of 6.7 (295 K). Moreover in the presence of an excess of human serum albumin (0.2 mM complex; 2 mM HSA) there was no change in the form and relative intensity of the Eu complex emission spectrum at pH 7.4, 6.9 and 5.5; the emission decay curves were also identical for each of these pH values.

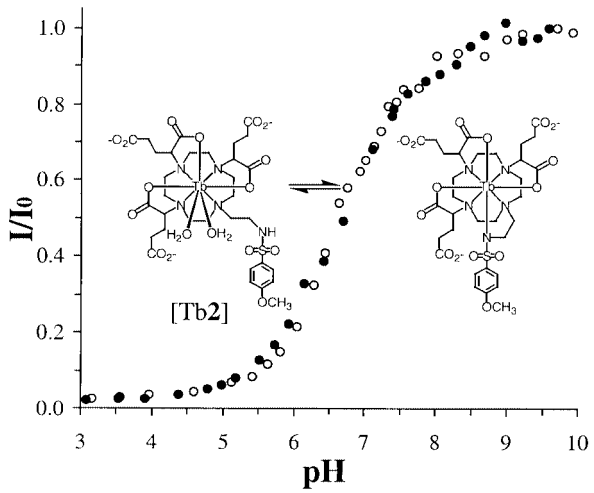

Fig. 2 pH Dependence of the terbium luminescence (I/I_0) of [Tb·**2**] at 295 K [1 mM complex; filled circles: 0.1 M NaCl, 30 mM $NaHCO_3$, 2.3 mM Na lactate, 0.13 mM citrate, 0.9 mM NaH_2PO_4; λ_{exc} = 272 nm, λ_{em} = 541 nm (ΔJ = 1); open circles: 0.1 M NaCl only; pK_a = 6.7 (±0.06)].

Such behaviour augurs well for the application of such complexes in the pH determination of serum samples, for which longer wavelength excitation (*e.g.* λ_{exc} = 355 nm) may be achieved by using a 6-phenanthridinesulfonyl group as an antenna chromophore. Moreover, the characteristics of the Eu/Tb complexes strongly suggest that the corresponding Gd complexes may be used as contrast agents to report pH changes *in vivo*. This aspect will be reported in a subsequent communication.

We thank the EPSRC, BBSRC and the COST-D18 action for support and Professor Silvio Aime for discussions on parallel work on Gd complexes of alkylated DO3A ligands.

Nematic mesomorphism in laterally substituted palladium complexes of alkoxystilbazoles

Received (in Cambridge, UK) 15th February 2000, Accepted 17th March 2000

Attachment of lateral carboxylate chains to polycatenar stilbazole complexes of palladium(II) unexpectedly leads to a series of materials with only nematic phases.

In the study of liquid crystals in general, a major objective is to be able to control the liquid-crystalline properties of a material *via* control of the molecular structure. As the subject advances and new types of molecules showing liquid-crystal properties appear, so there is a need to establish whether new structure–property relationships apply or whether existing principles are sufficient to understand the observed behaviour. Two of the more exciting areas of development in recent years have been the emergence of liquid crystals based on metal complexes[1] and the synthesis of polycatenar mesogens.[2]

In the former case, the field has developed rather rapidly in the last 10 years and mesogens based on metals with coordination numbers from 2 to 9 are known showing all the major phase types and exhibiting phase types and properties known for organic systems, such as ferroelectricity.[3] In addition, it is interesting to note that because of the presence of the metal centre in the molecule, the substitutional possibilities are enhanced over those offered by purely organic systems leading to materials with interesting geometric arrangements. Polycatenar liquid crystals can be defined as those with a rod-like core which possess three or more terminal chains. Much of the interest arises as these systems can show the nematic and lamellar mesomorphism characteristic of calamitic mesogens as well as the columnar mesomorphism characteristic of disk-like systems. This is best shown in systems where there are four terminal chains (tetracatenar mesogens) with each end of the molecule carrying two of these in the 3- and 4-positions of the terminal phenyl rings. In such a case, an individual mesogen can show either nematic or smectic C mesophases at short chain lengths and columnar phases at long chain lengths, with cubic phases sometimes being seen at intermediate chain lengths. A good example of this progression across a phase diagram is provided by some 5,5′-disubstituted-2,2′-bipyridines which we reported in 1998.[4]

We have for some time been interested in metal complexes of alkoxystilbazoles and have reported mesomorphic systems based on Ag(I),[5] Ir(I) and Rh(I),[6] Pd(II) and Pt(II).[7,8] In particular, we draw attention to a comparison which can be made between some complexes of Ag(I) and related systems based on Pd(II) (Fig. 1). Thus, we have reported[9] that Ag(I) complexes of 3,4-dialkoxystilbazoles bearing dodecylsulfate counter-anions (Fig. 1, **1**) show either a cubic or columnar phase depending on the chain length of the stilbazole. We have interpreted this behaviour in terms of the mesomorphism of polycatenar mesogens, but we notice that in the phase diagram, there is no sign of a smectic C phase which would be expected at shorter chain lengths. This may well be due to the presence of the dodecylsulfate anion acting as a lateral chain. Analogous complexes of 3,4-dialkoxystilbazoles have also been synthesised on palladium(II)[8] (Fig. 1, **2**) and this time we found a smectic C phase at shorter chain lengths and a columnar phase at longer chain lengths, but with no complexes showing both phases and no cubic phase at intermediate chain lengths.

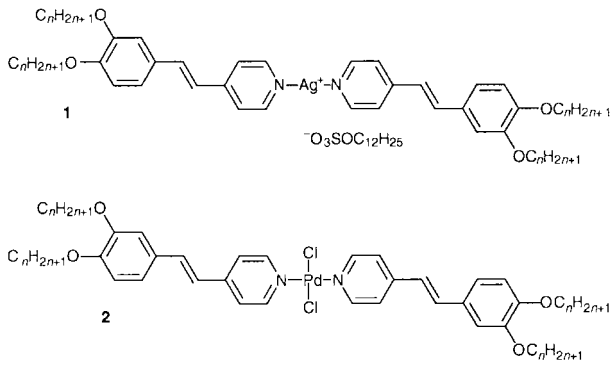

Fig. 1 Structure of dialkoxystilbazole complexes of Ag(I) and Pd(II).

We were interested, therefore, to see whether we could understand these differences in purely structural terms and so we set out to synthesise some stilbazole complexes of palladium(II) bearing lateral chains. In order to do this, we adopted an approach which we had used previously, namely to react the stilbazole with palladium carboxylates, $[Pd(O_2C–C_mH_{2m+1})_2]$, obtained from $[Pd(OAc)_2]_3$ and the carboxylic acid.[10] A number of palladium carboxylates can be obtained in this way and so reaction with 2 equiv. of dialkoxystilbazole will lead to the complexes shown in Fig. 2.

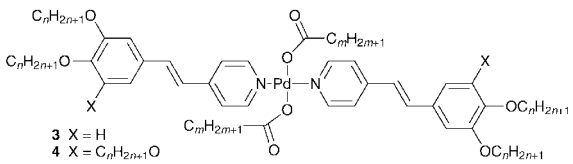

Fig. 2 Structure of the palladium complexes with lateral chains.

The reasons we adopted this approach were to do with ideas about the factors controlling the formation of lamellar, cubic and columnar phases in polycatenar mesogens. Thus, arguments are presented in which the curvature at the interface between the rigid core and the alkyl chains (Fig. 3) determine the mesophase formed in a manner analogous to that described for lyotropic systems.[11] Thus, at short chain lengths, there is no imbalance between the volumes of the core and the chains, no interfacial curvature and hence no barrier to the formation of a lamellar phase. However, at longer chain lengths, the volume required by the chains becomes much greater than that required by the core and so an interfacial curvature is established. When this curvature is large, the smectic layers are disrupted and columnar phases can form, with the columnar repeat unit being an aggregate of typically three or four molecules as shown in Fig. 4. At intermediate curvatures, cubic phases may form. Thus, it

† Present address: IPCMS, Groupe des Materiaux Organiques, 23 rue du Loess, BP 20CR, 67037 Strasbourg cedex, France.

DOI: 10.1039/b001268h

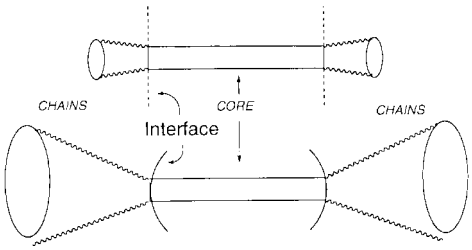

Fig. 3 Schematic to show the origin of the interfacial curvature in polycatenar mesogens.

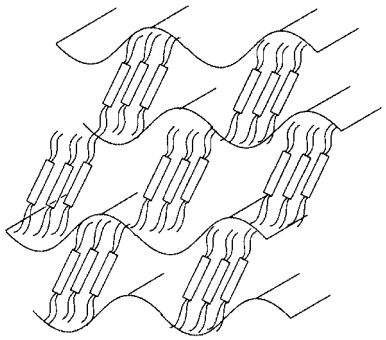

Fig. 4 Schematic to show the break-up of a lamellar structure into columnar units.

is possible to view phase formation as being dependent on the balance between the volume of the mesogen core and its chains.

We therefore speculated that in the case of the palladium mesogens, the rate of change of the volume of the chains (four methylene groups per homologue – *i.e.* about 108 Å^3) was quite rapid for the size of the core and so the transition from lamellar to columnar behaviour would be rather rapid as a function of the chain length accounting for the fact that this transition happens at a given chain length. Therefore, we reasoned that we could influence the volume of the core by introducing lateral substituents, and so modulate the effect of the increase in the chain volume. To this end, we synthesised a number of complexes **3** (Fig. 2) in which we varied the stilbazole chain length and the carboylate chain length.

The results are summarised in Table 1 and show somewhat unexpected phase behaviour. Thus, for all dialkoxystilbazoles examined with all carboxylates from butanoate upwards (shorter carboxylates did not give mesomorphic materials), only a nematic phase was seen. Previously, Maitlis and coworkers[7a] had shown that palladium complexes of *mono*alkoxystilbazoles with lateral carboxylates gave nematic phases, consistent with the known behaviour of organic systems where the introduction of lateral chains suppresses smectic phase formation.[12] Other examples of lateral substitution in metallomesogens may be found as compounds **24**–**39** in ref. 1*a*. However, here we are dealing with a polycatenar mesogen and so we might expect the lateral chains to behave differently, particularly when the chain length on the stilbazole was long. Thus, we might have expected to see a smectic C or columnar phase depending on whether the chains added to the core or radiated out, respectively. Curious then to pursue this further, we extended the approach by accessing the complexes **4** in whch we used a 3,4,5-trialkoxystilbazole ligand. All of the palladium dichloride complexes of these ligands which were mesomorphic showed a columnar mesophase[8] and so we reasoned here that by increasing the volume of the core with the lateral chains, it would be possible to find smectic C or even cubic phases. Alternatively and perhaps most likely, the complex would simply behave as a classical discotic mesogen with eight peripheral chains and continue to show a columnar phase. Table 1 shows that even these thoughts were misplaced and once more we found

complexes which showed only the nematic phase. Thus, for compounds of this type with six or eight peripheral chains to show only nematic phases is, we believe, unprecedented.

The questions now arise as to the nature of the nematic phases of these complexes and why they arise. Are the nematic phases of complexes **4** 'discotic nematic' or are they composed of more rod-like systems, *i.e.* how are the chains arranged? What is the behaviour of the lateral chains in these systems which causes the formation of only nematic phases irrespective of the nature of the ligands and unrelated to the phases formed by the parent dichloride systems? These are clearly quite unique materials which require further detailed study both to ascertain why nematic phases are formed exclusively and how their mesomorphism contributes to the understanding of the mesomorphism of polycatenar liquid crysals. It is also important to note that a study of this type is greatly facilitated by the substitutional possibilities offered by the metal centre.

We thank the University of Exeter and the DAAD for support and Johnson Matthey for generous loans of precious metal salts.

Received (in Liverpool, UK) 19th January 2000, Accepted 15th March 2000

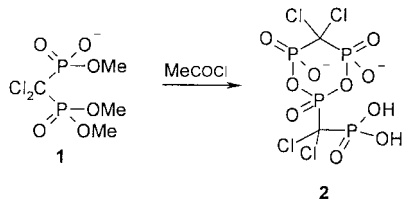
$Cl_2C[P(O)(OMe)_2P(O)(OMe)(O^-Z^+)]$ selectively reacts with acetyl chloride to provide a new enzymatically stable heterocyclic bis(bisphosphonate); the structure is confirmed by X-ray crystallography.

Methylenebisphosphonates (MBP), such as clodronate (Cl_2MBP), are an important class of drugs which have proven to be effective in the treatment of various diseases of bone and calcium metabolism including Paget's disease, non tumor-induced hypercalcaemia, and osteoporosis.[1] Recently, we reported[2] the synthesis and *in vitro* evaluation of clodronic acid dianhydrides as bioreversible prodrugs of clodronate. Exploration[3] of new strategies to prepare clodronate anhydrides lead us to a discovery of the selective synthesis of a new cyclic bis(bisphosphonate) anion **2**. The prepared dimer is the first approach to the self-prodrug of clodronate in which the number of promoities are minimised. We report here the selective synthesis and the X-ray structure of a stable cyclic dimer of clodronate, and its stability in aqueous buffer and human plasma.

Triester **1** (0.206 mmol), prepared by known method,[4] reacted selectively with acetyl chloride (2.196 mmol) in dry acetonitrile (4.0 ml) under reflux for 2 h to give a cyclic bis(bisphosphonate). The mixture was concentrated *in vacuo*, dissolved in CH_2Cl_2 and extracted once with cold water to give $[NMeBu_3]_2$**2**† as a colourless oil in 92% yield after evaporation of the aqueous phase (Scheme 1). The backbone structure was assigned by ^{31}P NMR spectroscopy, where peaks with intensities of 1:2:1 appeared as two doublets at δ 1.78 ($^2J_{PP}$ 16.9 Hz) and −2.17 ($^2J_{PP}$ 42.6 Hz), and a triplet of doublets at δ −17.58 (ring phosphorus). This structure was confirmed by X-ray crystallography‡ (Fig. 1).

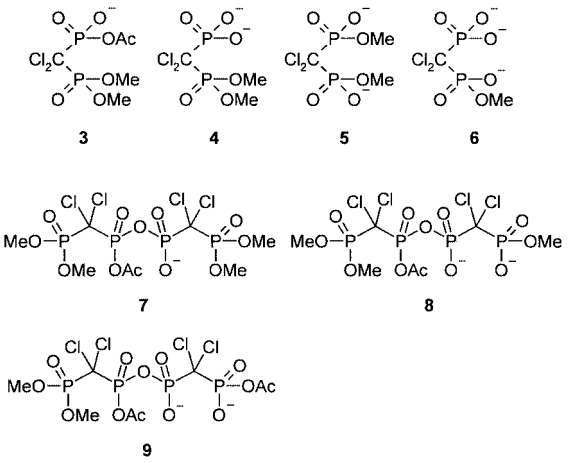
This type of selective and quantitative cyclisation reaction is rather unusual.[5–8] According to NMR studies, the reaction starts with the removal of the methyl group (first step) as MeCl from the anionic phosphorus **1** to form monoacetyl compound **3**. The formation of anionic bisphosphonates **4**–**9** was also detected during the reaction by 2D ^{31}P NMR P,P-COSY. However, all these species led to selective formation of **2**.

X-Ray diffraction study of $[NMeBu_3]_2$**2** showed a strained six-membered ring as a consequence of the O13–P1–C1 and O23–P2–C1 angles of 98.8°, 6° smaller than for acyclic derivatives.[9] The bond angle distortion of P1–O13–P3 is *ca.* 15° wider than in non-cyclic derivatives.[9] The stability of the cyclic structure is likely due to the short hydrogen bonds between



1 **2**

Scheme 1 Preparation of **2**.



3 **4** **5** **6** **7** **8** **9**

O12–O43 and O21–O42. Moreover, the two oxygens bonds, O11(O22) and O12(O21) at P1(P2), are short (1.466 and 1.490 Å) indicating a strong double bond character for both bonds. Other bond lengths are within normal ranges.

The usefulness of the cyclic structure as a prodrug was investigated in aqueous buffer and human plasma. Ring **2** was cleaved to an acyclic dimer **10** (Scheme 2) in 50 mM aqueous

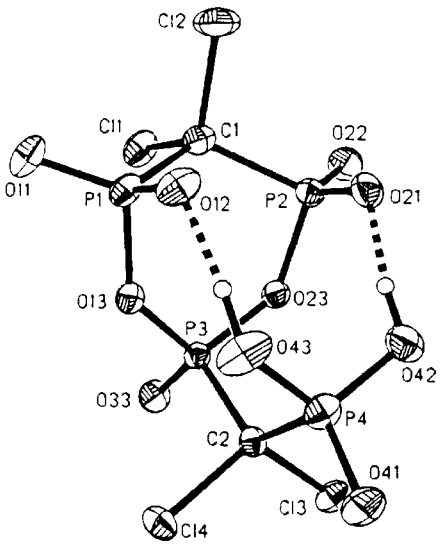


Fig. 1 Crystal structure of the anion **2**.

phosphate buffer solution at 37 °C. The half-lives for chemical degradation of **2** were 60 min (pH 5.0) and 63 min (pH 7.4). Further hydrolysis of dimer **10** to clodronate was not observed during 9 h at pH 7.4. Compounds **2** and **10** are resistant to enzymatic hydrolysis, probably because the bridging carbon prevents[10] stepwise hydrolysis, which is generally observed for terminal phosphates.

Received (in Cambridge, UK) 7th February 2000, Accepted 20th March 2000

A new cyano-bridged Ni(II)–Cr(I) complex, $[NiL']_3[Cr(CN)_5(NO)]_2\cdot 10H_2O$ (L′ = 3,10-dimethyl-1,3,5,8,10,12-hexaazacyclotetradecane) with a honeycomb molecular structure, displays a long-range magnetic ordering at T_c = 4.5 K.

In the area of molecule-based magnets, many chemists have been interested in the topologies leading to ferromagnetic interactions between paramagnetic metal ions. The approach of the strict orthogonality of magnetic orbitals has been most frequently utilized. On this basis, cyanide-bridged bimetallic assemblies derived from low-spin $[M(CN)_6]^{3-}$ (M = Cr^{III}, Mn^{III}, Fe^{III}) and high-spin $[ML]^{2+}$ (M = Cu^{II}, Ni^{II}, L = neutral ligand) are anticipated to be ferromagnetic, which has been verified by many experimental results.[1] Some of them exhibit spontaneous magnetization owing to the efficient propagation of magnetic coupling through the cyanide bridges and the hydrogen bonds.

Very recently, square-planar macrocyclic Ni(II) complexes have been employed to construct cyano-bridged 2D Ni_3M_2 (M = Cr^{III}, Fe^{III}) assemblies that exhibit ferromagnetic behaviour.[1j–m] In order to construct new molecule-based magnetic materials it is desirable to explore alternative building blocks containing cyanide groups. Most recently, Holmes and Girolami have presented some Prussian blue analogues containing $[Cr^{I}(CN)_5(NO)]^{3-}$, and found that the complex $K_{0.5}Mn[Cr(CN)_5(NO)]_{0.83}\cdot 4H_2O\cdot 1.5MeOH$ possesses a cubic structure based on powder XRD analysis, and that the NO^+ group in $[Cr(CN)_5(NO)]^{3-}$ is involved in bridging on the basis of the IR spectrum in which the N=O stretching frequency is *ca.* 60 cm^{-1} higher than that in $K_3[Cr(CN)_5(NO)]$ (1630 cm^{-1}).[2] In order to gain further evidence on the binding modes of $[Cr(CN)_5(NO)]^{3-}$ with transition metal complexes, we have studied the reaction of $[NiL']^{2+}$ (L′ = 3,10-dimethyl-1,3,6,8,10,12-hexaazacyclooctadecane) with $[Cr(CN)_5(NO)]^{3-}$, and obtained a new two-dimensional honeycomb assembly, $[NiL']_3[Cr(CN)_5(NO)]_2\cdot 10H_2O$ **1**. The adoption of $[Cr(CN)_5(NO)]^{3-}$ is due to the electronic configuration [$3d^5$, $(3d_{xz})^2(3d_{yz})^2(3d_{xy})^1$] of low-spin Cr(I) ion together with the approximate C_{4v} symmetry of $[Cr(CN)_5(NO)]^{3-}$ that is quite different from the O_h symmetry of $[Fe(CN)_6]^{3-}$.[3] The magnetic coupling between the magnetic orbitals of the neighbouring nickel(II) and chromium(I) ions is expected to be ferromagnetic. Here, we present the synthesis, single crystal structure analysis and magnetic properties of the new complex.

To an aqueous solution (15 mL) of $[NiL'](ClO_4)_2$[4] (0.3 mmol) was added dropwise, with stirring, a solution of $K_3[Cr(CN)_5(NO)]\cdot H_2O$[5] (0.2 mmol) in 10 mL of water. This led to the immediate precipitation of yellow microcrystals that were collected by suction filtration, washed with water and dried in air.† The complex is insoluble in most organic and inorganic solvents and stable in air.

The IR spectrum of the complex shows two sharp bands in the range 2000–2200 cm^{-1} which are attributed to C≡N stretching modes. The shift of ν(C≡N) to higher wavenumber (2140 cm^{-1}) compared with that of $K_3[Cr(CN)_5(NO)]$ (2120 cm^{-1})[6] suggests the formation of CN^- bridges, as observed for other cyano-bridged systems.[1] Further, the blue shift of ν(N=O) with respect to that of $K_3[Cr(CN)_5(NO)]$ (1630 cm^{-1})[6] also suggests the distortion of $[Cr(CN)_5(NO)]^{3-}$ from C_{4v} symmetry as a result of the formation of Cr–C≡N–Ni linkages and that the cyanide ligand *trans* to the NO ligand has been involved in bridging.

The structure of **1** was determined by single crystal X-ray crystallography (Fig. 1).‡ It consists of a neutral stair-shaped layer network with the stoichiometry $[NiL']_3[Cr(CN)_5(NO)]_2$. Each $[Cr(CN)_5(NO)]^{3-}$ unit uses three *cis*-C≡N groups to connect with three $[NiL']^{2+}$ groups, whereas the two remaining CN^- and the NO^+ groups are monodentate. The adjacent Cr···Ni distances are 5.293(2) Å for Cr···Ni(1), 5.300(1) Å for Cr···Ni(2) and 5.270(1) Å for Cr···Ni(2a), respectively (a denotes the symmetry operation $-x + 0.5$, $y - 0.5$, $-z + 0.5$). Each NiL′ unit is linked to two $[Cr(CN)_5(NO)]^{3-}$ ions in *trans* positions. Four secondary amine nitrogen atoms of the macrocycle coordinate to the nickel center with an average Ni–N distance of 2.097(4) Å for Ni(1), 2.074(4) Å for Ni(2). Two nitrogen atoms of the bridging C≡N ligands axially coordinate to the Ni(II) ions with Ni–N_{ax} contacts of 2.153(3) Å for Ni(1)–N(3) and 2.105(4) Å (average) for Ni(2)–N, respectively, which are slightly larger than those of the corresponding Ni–N_{eq} bonds. The bridging cyanide ligands coordinate to the nickel(II) ions in a bent fashion with the Ni–N≡C bond angles ranging from 164.3(3) to 172.8(4)°. The coordination symmetry about the Cr atom is C_{4v} or distorted octahedron, and the Cr–N–O and Cr–C–N groups are nearly linear. The Cr–C distances range from 1.926(5) to

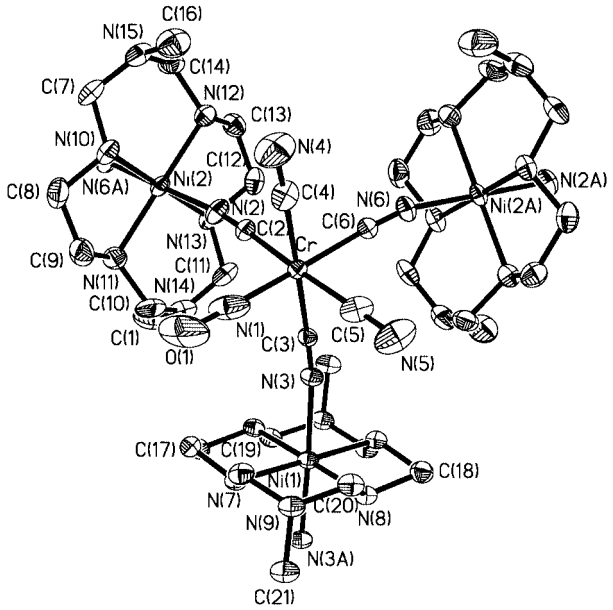

Fig. 1 ORTEP plot of **1** (hydrogen atoms are omitted for clarity).

DOI: 10.1039/b001005g

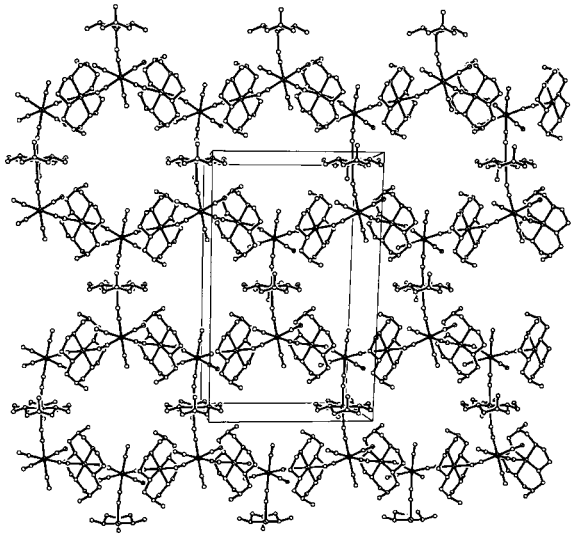

Fig. 2 Projection showing the 2D honeycomb-like layer containing Cr_6Ni_6 hexagons.

2.083(5) Å, whereas the Cr–N distance of 1.866(5) Å is comparatively long. These compare with the structural results for the double salt $[Co(en)_3][Cr(CN)_5(NO)]\cdot 2H_2O$.[7] The particular local molecular disposition leads to a honeycomb-like layered structure (Fig. 2). The shortest interlayer metal–metal distance is 6.910 Å for Cr··Ni(2m) (m: x, $1 - y$, $-0.5 + z$).

The magnetic susceptibilities of **1** have been measured on a Model Maglab System2000 magnetometer in the temperature range 2.0–280 K. A plot of $\chi_m T$ *vs.* T for **1** (H = 1 T) is shown in Fig. 3, where χ_m is the magnetic susceptibility per Ni_3Cr_2 unit. The $\chi_m T$ value at 280 K is *ca.* 4.8 emu K mol^{-1} (6.2 μ_B), higher than expected (3.75 emu K mol^{-1}) for three high spin nickel(II) ions (S = 1, g = 2.0) and two low-spin chromium(I) ions (S = 1/2,[5] g = 2.0) in a dilute system, and equal to that calculated assuming the g_{Ni} value of 2.32. With a decrease of the temperature, $\chi_m T$ increases smoothly down to *ca.* 50 K and then sharply reaches a maximum value of 14.2 emu K mol^{-1} (10.66 μ_B) at 6.4 K, which is much larger than the spin-only value of 10.0 emu K mol^{-1} (8.9 μ_B) for S_T = 4 resulting from the ferromagnetic coupling of three nickel(II) ions (S = 1, g = 2.0) and two low-spin chromium(I) ions (S = 1/2, g = 2.0), suggestive of the occurrence of magnetic ordering. Below 6.4 K, $\chi_m T$ decreases rapidly, which indicates the presence of interlayer antiferromagnetic interaction and/or the zero-field splitting effect of the nickel(II) ions. The magnetic susceptibility above 6 K obeys the Curie–Weiss law with a positive Weiss constant θ = + 10.0 K, which also proves the presence of ferromagnetic coupling within the Ni_3Cr_2 sheet of **1**. The abrupt increase in M at *ca.* 11 K suggests a phase transition in the complex (Fig. 3).

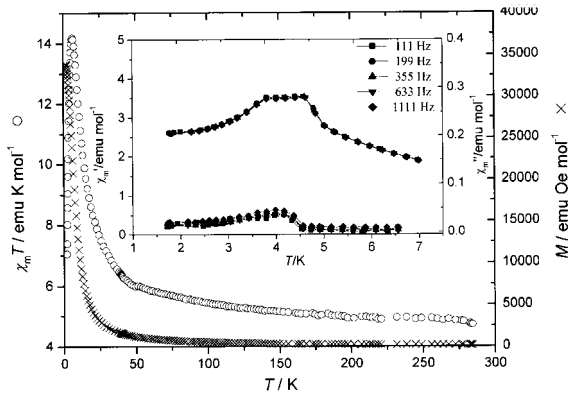

Fig. 3 Temperature dependences of $\chi_m T$ and M for **1**. Inset: real, χ' (top), and imaginary χ'' (bottom) ac magnetic susceptibilities as a function of temperature taken at 111, 199, 355, 633 and 1111 Hz for **1**.

The onset of a long-range magnetic phase transition is further confirmed by the temperature dependence of ac molar magnetic susceptibilities displayed in the inset of Fig. 3. The real part of the zero field ac magnetic susceptibility, $\chi'(T)$, has a maximum at *ca.* 4.5 K for frequencies of 111, 199, 355, 633 and 1111 Hz, suggesting that T_c of complex **1** is about 4.5 K. The frequency independence of χ_{ac}' and χ_{ac}'' suggests a non-glassy ground state. The field dependence of the magnetization at 1.75 K reveals a hysteresis loop with a coercive field of 170 Oe and a remnant magnetization of *ca.* 0.19 $N\mu_B$.

The ferromagnetic interaction between the chromium(I) and nickel(II) ions is due to the strict orthogonality of the magnetic orbitals of the low-spin Cr(I) [d^5, $(3d_{xy})^1$] and high-spin Ni(II) [d^8, $(d_{x^2-y^2})^1(d_{z^2})^1$] ions. According to ligand field theory, the high-spin nickel(II) ion in octahedral surroundings has two unpaired electrons in $d_{x^2-y^2}$ and d_{z^2} orbitals that interact with the MOs of the cyano bridge with the same symmetry producing a magnetic orbital with σ-character. The low-spin chromium(I) ion in distorted octahedral surroundings has an unpaired electron in the d_{xy} orbital[3] that interacts with the MOs of the cyano bridge with the right symmetry generating a magnetic orbital with π-character. Consequently, strict orthogonality is obeyed and the interaction between Ni(II) and Cr(I) ions through the cyano bridge should be ferromagnetic.

Received (in Cambridge, UK) 14th December 1999, Accepted 21st March 2000

Millimeter-sized tubular crystals of Ag_2Se are successfully grown for the first time *via* a hydrothermal reaction route from AgCl, Se and NaOH at 155 °C.

The synthesis of large three-dimensional (3D) mesoscale (millimeter- to centimeter-scale) objects has recently been the focus of much attention.[1–3] Existing technologies for making 3D microstructures are the limited stereolithography,[4] free-form laser sintering (slow)[5] and traditional casting, machining and assembly which are difficult with a complex or porous structure. Whitesides and coworkers reported the fabrication of open regular 3D mesostructures by self-assembly.[1–3] The newly discovered fullerene-like nest polyhedra (NP) and nanotubules have been observed for metal dichalcogenides[6–8] and micrometer-sized hexagonal, hollow needles of CdSe have been prepared by electrodeposition from molten salts.[9] However, a mesoscale crystal with open structure is, to the best of our knowledge, hitherto unknown for Ag_2Se. Here we report for the first time the growth of millimeter-sized tubular Ag_2Se crystals by a known hydrothermal reaction route.

The synthesis was carried out in an autoclave and was based on the disproportionation reaction of Se:

$$4AgCl + 3Se + 6NaOH \rightarrow 2Ag_2Se + Na_2SeO_3 + 4NaCl + 3H_2O \quad (1)$$

An appropriate amount of AgCl (0.383 g), Se (0.160 g) and NaOH (0.20 g) was put into a Teflon-lined autoclave (50 mL capacity). The autoclave was then filled with distilled water to 80% of the total volume, maintained at 155 °C for 10 h and then allowed to cool to room temperature. The products were filtered off and washed sequentially with distilled water and absolute ethanol to remove the residual impurities. After drying in a vacuum at 70 °C for 2 h, metallic-gray crystals were obtained.

Fig. 1 shows the X-ray diffraction (XRD)† pattern of several Ag_2Se crystals that were crushed. All the reflections could be indexed to the orthorhombic Ag_2Se phase with lattice constants a = 4.333, b = 7.062, c = 7.764 Å, in agreement with the reported data for Ag_2Se (JCPDS Card File, 24-1041). No characteristic peaks of other impurities such as Ag_2O, Se or AgCl were observed.

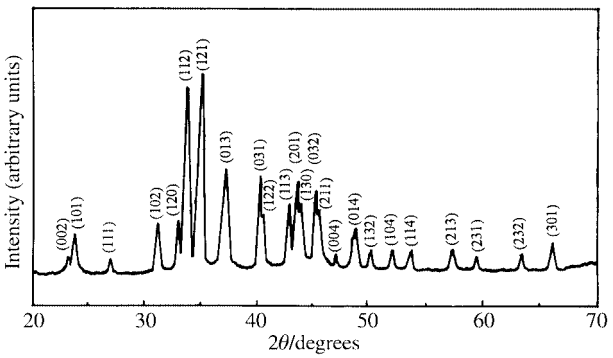

Fig. 1 X-Ray powder diffraction pattern of several Ag_2Se crystals that were crushed.

Fig. 2 shows the scanning electron microscopy (SEM)‡ images of as-grown Ag_2Se crystals. It can be seen that Ag_2Se crystals show tubular hexagonal prism structure. Typically, this structure is 10–15 mm in length, 80–120 μm in diameter and 20–25 μm in thickness. It is of considerable interest that some tubes appear to have one closed-round end [Fig. 2(*b*)], and others show hollow cavities which run through the whole length [Fig. 2(*c*) and 2(*d*) are two undersides of one prism crystal]. From these SEM images, we can see that the as-grown tubular Ag_2Se crystals may show near single crystal nature.

To confirm that single crystals of Ag_2Se were obtained, we recorded the transmission X-ray Laue§ photographs of the tubular crystals. Fig. 3 shows one of these Laue photographs of the Ag_2Se samples. It revealed that the crystal obtained was nearly a single crystal. From the eight-fold symmetrical patterns of the X-ray Laue photographs, we can deduce it is due to the (121) patterns of the characteristic X-ray (Cu-Kα and Cu-Kβ) diffraction. This result was in good agreement with the strong (121) reflection in the XRD pattern.

To provide further evidence for the formation of Ag_2Se crystals, the samples were also characterized by X-ray photoelectron spectra (XPS).¶ The two strong peaks in the spectra (spectra not shown) at 368.00 and 53.65 eV corresponding to Ag 3d and Se 3d binding energy, respectively, are consistent with the formation of Ag_2Se.[10] Quantification of the XPS peak intensities gave elements with a stoichiometry of $Ag_2Se_{1.03}$. No

obvious peaks for silver or selenium oxides were detected, which indicated a high purity of the Ag_2Se crystals produced.

Although the growth mechanism for the tubular crystals is unclear, the reaction temperature and the change of pH were critical factors in the formation of this morphology. Structural studies indicate that Ag_2Se exists as a low-temperature phase β-Ag_2Se (orthorhombic structure) and a high-temperature phase α-Ag_2Se (cubic structure) and the transition from β to α takes place at *ca.* 136 °C.[11] In our hydrothermal route, the essential temperature range for the tubular form was at 150–160 °C. However, the tubular Ag_2Se crystals existed as the low-temperature phase. It may be concluded that the temperature condition falls into the growth thermodynamic stability range of the tubular morphology. According to Korczynski *et al.*,[12] we first prepared the Na_2Se solution (pH 8–9) through the reaction: $3Se + 6NaOH \rightarrow 2Na_2Se + Na_2SeO_3 + 3H_2O$, and then obtained Ag_2Se by the reaction of AgCl with Na_2Se in aqueous media at 150–160 °C. However, the Ag_2Se obtained deviated from its theoretical composition and did not show the tubular morphology. For the growth of tubular crystals of Ag_2Se, we selected a one step hydrothermal reaction from AgCl, Se and NaOH. An initial feedstock pH (NaOH solution) above 13 was needed. In the hydrothermal process, the pH value of the reaction system decreased. So, it is believed that the change of pH value was matched with the nucleation and growth of crystalline Ag_2Se. This matching effect may be beneficial to the formation of the tubular morphology.

In summary, tubular β-Ag_2Se crystals were synthesized successfully for the first time through a hydrothermal reaction at 155 °C. Group 11 chalcogenides have wide applications in semiconductors, pigments,[13] luminescence devices,[14] solar cells, IR detectors and optical fiber communication.[15] It is believed that hollow tubular crystals should be expected to have novel properties, and may offer exciting opportunities for both fundamental research and technological applications. Deeper understanding of the growth mechanism of tubular Ag_2Se crystals and controlling the reaction kinetics are clearly needed.

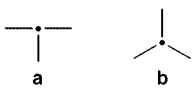
Received (in Cambridge, UK) 14th January 2000, Accepted 7th March 2000

The crystal structure of {[NaCr(2,2'-bipy)(ox)$_2$]$_2$[bis(1-pyrazolyl)methane]•2H$_2$O}$_n$ reveals the first 2-D stair-shaped architecture which constructs a 3-D network *via* interlayer π–π interactions with guest water molecules present in the cavities.

The synthesis and characterization of 2- or 3-D coordination polymers with well defined pores have been an area of rapid growth and will continue to grow, especially with development of materials of new compositions, predetermined structures and useful properties, *e.g.* catalysis, magnetism, electronics and chemical separation.[1] In recent years the preparation of porous materials whose host frameworks can facilitate the removal/addition of guest molecules has been explored largely owing to their potential applications.[2] In particular, the incorporation of transition metals into coordination polymers is significant in the crystal engineering of novel heterogeneous catalytic systems,[3] as well as non-linear optical, conducting and ferromagnetic materials.[4] Supramolecular synthons are bridged mainly by two types of modules **a** and **b**. Developments in crystal engineering



have also shown that hydrogen-bonding and π–π stacking interactions have enormous potential for assembling multi-component inorganic–organic molecules into well organized architectures.[5] It is clear that the strategy of utilizing transition metals with rigid or flexible bifunctional ligands affords an array of new network architectures through self-assembly.[6] However, little attention has been paid to alkaline ions acting as both counter ions and structural elements toward the synthesis of new multidimensional structure.[7] In this contribution, we report the first 2-D stair-shaped network containing hetero-bimetallic Cr^{III}–Na^{I} centers, [NaCr(bipy)(ox)$_2$]$_2$(bpm)·2H$_2$O **1** [bipy = 2,2'-bipyridine, ox = oxalate dianion, bpm = bis(1-pyrazolyl)methane], which forms a 3-D structure containing cavities which can incorporate small molecules.

The reaction of [NaCr(bipy)(ox)$_2$(H$_2$O)]·2H$_2$O and bpm in methanol leads to formation of red plates of [NaCr(bipy)(ox)$_2$]$_2$(bpm)·2H$_2$O, suitable for single X-ray diffraction.† The fundamental tetranuclear unit is shown in Fig. 1. The coordination geometry around the Cr(III) ion is a six-coordinate distorted octahedron, and is similar to those in related complexes.[8] The sodium atoms are also six-coordinate distorted octahedral with larger differences in bond lengths (shown in Fig. 1). Although only the coordinated water molecule has been replaced by the pyrazole nitrogen atom of bpm, the structure has changed significantly. Fig. 2(a) shows that the compound exists as an open railroad framework polymer with channels of 15.0 × 7.3 Å, and shows that the complex molecule is located on a crystallographic two-fold screw axis along the ox bridge ligands. The structure can be represented schematically as a stair-shaped supramolecular architecture as illustrated in Fig. 2(b). This particular supramolecular structure is unprecedented among molecular frameworks.[1b,6c,9]

Within a layer, hydrophilic nitrogen atoms (head or tail) interact with two 1-D inorganic precursors to form two natural hydrophilic–hydrophobic domains. It is interesting that the ligand, bpm, acts as a bidentate bridging ligand rather than as a chelating ligand.[10] In particular, between the layers, the stair-shaped frameworks stack the 2-D structure together *via* interlayer π–π interactions of pyridine rings to form a quasi-3-D structure containing small-pore channels. The narrowest interplanar distance of the aromatic moieties (bipy) is *ca.* 3.560 Å. The π–π interactions enhance the stability of the complex and result in a higher dimensional structure with the channels parallel to the *b* axis. The effective void size of the channels is 18.6 × 9.3 Å. The cavities are filled with guest water molecules which are hydrogen bonded to oxalato oxygen atoms (2.911 Å) (Fig. 3).

Mixed solvents (V_{MeOH}/V_{H_2O} = 1:1, V_{EtOH}/V_{H_2O} = 1:1, V_{EtOH}/V_{H_2O} = 9:1) were also employed instead of water in the synthesis, but no alcohol molecules were found in the solids obtained.

In conclusion, the design of metal-containing coordination polymers by self-assembly is of great promise. The sizes of the channels offer appreciable potential for guest molecule uptake, and the formation of this type of porous metal–organic

compound demonstrates that this aspect of crystal engineering has many potential implications for materials science as new candidates for catalysis or separation processes. We expect that many new functional solid coordination polymers will be synthesized and applied based on these results.

Received (in Cambridge, UK) 5th January 2000, Accepted 15th March 2000

Novel dendritic macromolecules consisting of uracil units (L*n*U-OBn) with the numbers of the nucleobase layers (*n*) of 2–4 were synthesized; L3U-OBn and L4U-OBn both formed 1:1 complexes with La^{3+}, where the L4U-OBn–La^{3+} complex, in particular, was highly robust towards methanolysis.

Dendrimers are hyperbranched, three-dimensional macromolecules with a pseudo network structure,[1] and have a potential for trapping of guest molecules.[2] In particular, dendritic molecules bearing binding sites for metal ions have attracted great attention.[3–5] Herein, we report the synthesis of the first dendritic polynucleobase, and highlight its very high activity for multidentate ligation with lanthanum ion.[6]

For the synthesis of the dendritic architecture, we chose uracil as a building block. Synthesis of the dendritic polyuracils (L*n*U-OBn; *n* = number of the nucleobase layers) was carried out by the convergent approach (Scheme 1) starting from (i) bromination of 1,3-dibenzyl-5-benzyloxymethyluracil (L1U-OBn) with HBr–AcOH,[7] followed by (ii) an alkaline-mediated coupling reaction of the resulting 5-bromomethyl derivative (L1U-Br) with 5-benzyloxymethyluracil **1**, to give L2U-OBn. Repetition of these two steps allowed formation of higher-generation L*n*U-OBn (*n* = 3, 4).[8] The absence of structural defects in L*n*U-OBn (*n* = 2–4) was confirmed by ^{1}H NMR, MALDI-TOF-MS and SEC analyses. For example, L*n*U-OBn (*n* = 2–4) all showed a single MALDI-TOF-MS peak due to $[M + Na]^+$ [Fig. 1(a) (I)–(III)] and a unimodal SEC chromatogram [Fig. 1(b)]. L*n*U-OBn (*n* = 2–4) were highly soluble in common organic solvents such as CH_2Cl_2, $CHCl_3$, benzene, acetone, MeCN and DMF, but scarcely soluble in protic solvents such as MeOH and water. In the electronic absorption spectra in MeCN, L*n*U-OBn (*n* = 2–4) showed an absorption band due to the uracil units at 274.8–275.6 nm, which is red-shifted from that of non-dendritic L1U-OBn (270.0 nm), indicating some intramolecular electronic interactions among the dendritic uracil units.

Dendritic polyuracils bear many heteroatoms and are expected to show potential for trapping of multi-coordinate metal ions. La^{3+} was chosen as a substrate, which is characterized by the largest ionic radius among rare-earth metal ions, and its preference to adopt a high coordination number (up to 12).[9] Typically, upon titration of an MeCN solution of L3U-OBn (10 μM) with $La(OTf)_3$ at 25 °C, the absorption band of the uracil units red-shifted from 275.2 to 281.4 nm with clear isosbestic points at 248.4 and 275.0 nm (Fig. 2, inset). Plots of the absorbance at 296.6 nm *vs.* $[La(OTf)_3]_0$ showed a clear inflection point at a mole ratio $[L3U\text{-}OBn]_0/[La(OTf)_3]_0$ of unity (Fig. 2). Job plots of ΔA at 296.6 nm also exhibited a maximum at a mole ratio $[L3U\text{-}OBn]_0/[La(OTf)_3]_0$ of unity. Furthermore, MALDI-TOF-MS spectrometry of a mixture of L3U-OBn and $La(OTf)_3$ (1:2) showed a peak at 2133 due to $[L3U\text{-}OBn\text{–}La(OTf)_2]^+$ (calc. *m/z* 2134) in addition to that of a Na^+ adduct [Fig. 1(a) (ii)]. These observations indicate a strong one-to-one complexation between L3U-OBn and La^{3+} with an association constant $> 10^7$ M^{-1}.[10] Likewise, titration of one-generation larger L4U-OBn with $La(OTf)_3$ (Fig. 2) showed a similar red shift (275.6 to 281.0 nm) with two isosbestic points (246.8, 271.8 nm), and a Job plot again indicated a 1:1 complexation of L4U-OBn with La^{3+}. Furthermore, a MALDI-TOF-MS peak due to the one-to-one adduct $[L4U\text{-}OBn\text{–}La(OTf)_2]^+$ (calc. *m/z* 3847) was observed [Fig. 1(a) (iii)].

An MeCN solution of L3U-OBn (2.5 mM) at 25 °C showed two C=O stretching vibrational bands at 1708 [C(2)=O] and 1665 cm^{-1} [C(4)=O] [Fig. 3(a)].[11] On the other hand, when $La(OTf)_3$ (5.0 mM) was added to the solution, a new IR band at 1609 cm^{-1}, assignable to the coordinated C=O functionality,

DOI: 10.1039/b000318m

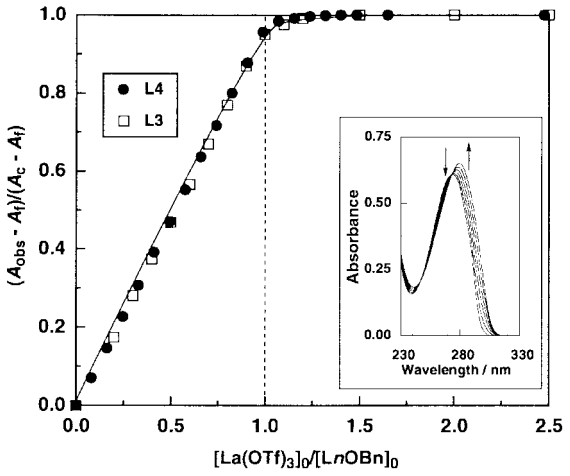

Fig. 2 Spectroscopic titration of MeCN solutions of L*n*U-OBn (10 μM) (*n* = 3 [□], 4 [●]) with $La(OTf)_3$ at 25 °C monitored at 296.6 nm. Plots of $(A_{obs} - A_f)/(A_c - A_f)$ *vs.* $[La(OTf)_3]_0/[LnU\text{-}OBn]_0$. A_{obs} represents the observed absorbance, while A_f and A_c denote the absorbances of free and complexed uracil units, respectively. Inset: absorption spectral change.

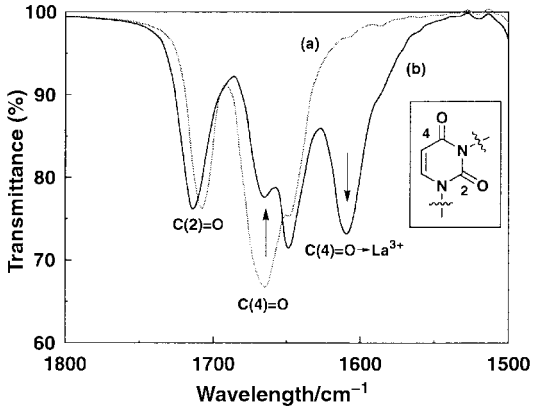

Fig. 3 IR spectra of (a) L3U-OBn (2.5 mM) and (b) a 1 : 2 mixture of L3U-OBn and $La(OTf)_3$ (2.5, 5.0 mM) in MeCN at 20 °C.

appeared at the expense of the non-coordinated C(4=O band [Fig. 3(b)]. Considering also a small shift due to the C(2)=O frequency (1708 to 1714 cm^{-1}), the C(4)=O functionality is likely involved predominantly in the complexation with La^{3+}.[12] As estimated from the decrease in integral area of the free C(4)=O band at 1665 cm^{-1},[13] an La^{3+} ion accommodates four out of seven C(4)=O groups in L3U-OBn for complexation. On the other hand, in the complexation with higher-generation L4U-OBn having fifteen C(4)=O groups, seven C(4)=O groups were estimated to coordinate to a La^{3+} ion.

From the above results, it is expected that La^{3+} ion is trapped by L4U-OBn more strongly than lower-generation L3U-OBn. In fact, the L4U-OBn–La^{3+} complex was highly robust towards methanolysis: when an MeCN solution of a mixture of L3U-OBn (10 μM) and $La(OTf)_3$ (20 μM) was titrated with MeOH (Fig. 4), the absorption spectral change at 296.6 nm showed a complete dissociation of La^{3+} from L3U-OBn at a MeOH content of 40%. On the other hand, the L4U-OBn–La^{3+} complex showed a spectral profile of only 30% dissociation under the same conditions (Fig. 4).

The high activity of L*n*U-OBn for the complexation with La^{3+} is considered to take great advantage of the multidentate coordination characteristics of the dendritic polyuracil architecture, since non-dendritic L1U-OBn did not show any substantial spectral changes upon mixing with $La(OTf)_3$. Spectral changes were also small when L*n*U-OBn (*n* = 3, 4) were mixed (1 : 1 mol ratio; in MeCN) with metal ions such as

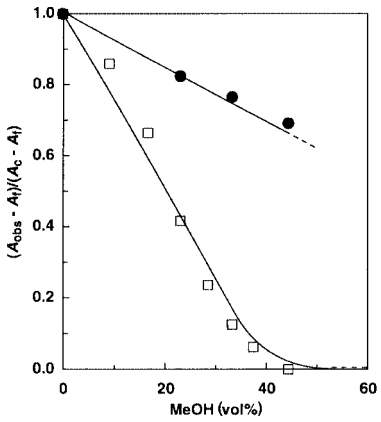

Fig. 4 Spectroscopic titration of an MeCN solution of a 1 : 2 mixture of L*n*U-OBn (10 μM) (*n* = 3 [□], 4 [●]) and $La(OTf)_3$ (20 μM) with MeOH at 25 °C monitored at 296.6 nm. Plots of $(A_{obs} - A_f)/(A_c - A_f)$ *vs.* vol.% of MeOH.

Na^+, K^+, Zn^{2+}, Cu^+, Cu^{2+} or Ag^+ (triflate salts) having a preference for lower coordination numbers.

Dendrimer complexes of lanthanide ions have attracted attention as luminescent materials[4] and have also been applied as MRI contrast agents.[5] On the other hand, a nucleobase complex of a transition metal such as platinum has been studied for biomedical applications.[14] The new metal-ligating nucleobase dendrimer consisting of uracil units may therefore have good potential for a variety of applications in materials science and medicinal chemistry.

Homologations of boronate esters: the first observation of sequential insertions

Li Ren and Cathleen M. Crudden*

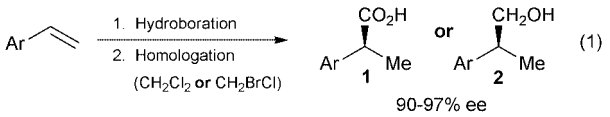
Received (in Corvallis, OR, USA) 10th January 2000, Accepted 2nd March 2000

By employing dibromo or diiodomethane as halomethyllithium precursors, the *in situ* double and triple homologation of boronate esters has been obtained for the first time.

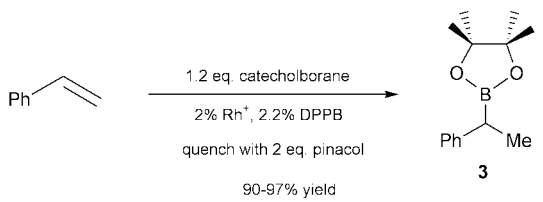
Homologation reactions of boronate esters and other borane species have been well explored, most notably by Brown *et al.*[1] and Matteson *et al.*[2] We have recently reported a variant in which the chirality is introduced *catalytically via* a Rh–binap-mediated hydroboration with catechol borane.[3,4] Homologation of the intermediate boronate ester with CH_2Cl_2 or CH_2BrCl in the presence of Bu^nLi yields either 2-arylpropionic acids **1** or 2-arylpropanols **2** respectively [eqn. (1)]. This asymmetric hydroboration–homologation (AHH) reaction was used in the synthesis of enantiomerically enriched 2-arylpropionic acids, such as Ibuprofen™ [eqn. (1)].



(1)

During our study of the latter reaction, we were intrigued by the observed chemoselectivity. In both cases, the products of the homologation reaction, prior to oxidation, are also boronate esters and might be expected to undergo homologation themselves. The boronate ester resulting from homologation with $LiCHCl_2$ is sufficiently distinct from the starting boronate ester **3** [eqn. (2)] by virtue of the chlorine substituent. However, the boronate ester from homologation with $LiCH_2Cl$ **7** [eqn. (5)] should be susceptible to further homologation. Despite this fact, no such sequential homologation with halomethane reagents has been reported to the best of our knowledge. Brown *et al.* have reported a ring-expansive sequential homologation reaction using halomethane reagents, in which the halomethane reagent was added in successive portions after isolation of the previously generated boracycle.[5] Shea *et al.*[6] have reported that sulfur ylides can homologate triorganoboranes sequentially in the same pot to yield long chain aliphatic alcohols after oxidation but such a reaction has not been observed with boronate esters. We wish to report that by adjusting the leaving group ability of the halomethane reagent, double and triple homologations can be achieved.

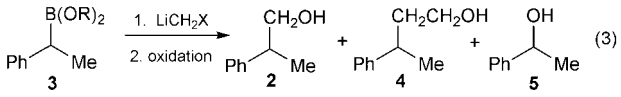
Using our standard protocol, boronate ester **3** is generated by hydroboration of styrene with catechol borane in the presence of $[Rh(cod)_2]^+BF_4^-$ and dppb,† followed by transesterification with pinacol which permits isolation of the boronate ester by chromatography [eqn. (2)].[4]



(2)

Treatment of **3** with $LiCH_2Cl$ provided, after oxidation, the expected product **2** (Table 1).‡§ The nature of the halogen which is transmetallated to generate $LiCH_2Cl$ has little effect on the outcome of the homologation. Thus ICH_2Cl gave 79% homologation while $BrCH_2Cl$ gave 88%. However, the nature of the leaving group was significant. Using $BrCH_2Br$ as the precursor to the homologation reagent, a new product **4** was observed which resulted from the incorporation of two CH_2 units. Diiodomethane also gave the product of double homologation, but with lower overall conversion (entry 4). This is presumably due to the decreased stability of $LiCH_2I$.[7] (Note that any unreacted boronate ester **3** is converted into **5** after oxidation with $NaOH/H_2O_2$.) Although the amount of the doubly homologated alcohol could be increased by increasing the amount of $LiCH_2Br$ (see below), no double homologation was observed with $LiCH_2Cl$ even when it was used in excess (entry 5).

Table 1 Observation of single and double homologation



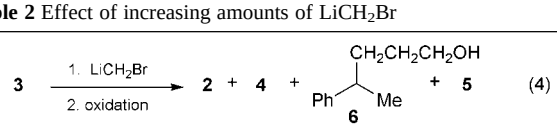
(3)

Entry	Reagent precursor	Homologation reagent	Equiv.	Single insertion **2**[a]	Double insertion **4**	Unreacted **5**
1	$BrCH_2Cl$	$LiCH_2Cl$	1.1	88%	0%	12%
2	ICH_2Cl	$LiCH_2Cl$	1.1	79%	0%	21%
3	$BrCH_2Br$	$LiCH_2Br$	1.1	74%	15%	11%
4	ICH_2I	$LiCH_2I$	1.1	43%	17%	40%
5	$BrCH_2Cl$	$LiCH_2Cl$	2.0	83%	0%	17%

[a] Relative ratios determined by integration of appropriate resonances in NMR; NMR yield calculated by use of internal standard is within several percent of quoted ratios.

Using dibromomethane as the candidate for further study, the effect of increasing the amount of the homologating reagent was examined. As shown in Table 2, the percentage of doubly homologated alcohol **4** which was formed in the reaction increased when the amount of $LiCH_2Br$ was increased above 1 equivalent. A significant increase was not, however, observed as the amount of $LiCH_2Br$ was increased further. It should be noted that a 5–10% variance was generally observed in the relative ratios reported in Table 2, which may be attributable to

Table 2 Effect of increasing amounts of $LiCH_2Br$



(4)

Entry	Equiv. of $LiCH_2Br$	Single insertion **2**[a]	Double insertion **4**	Triple insertion **6**	Unreacted **5**

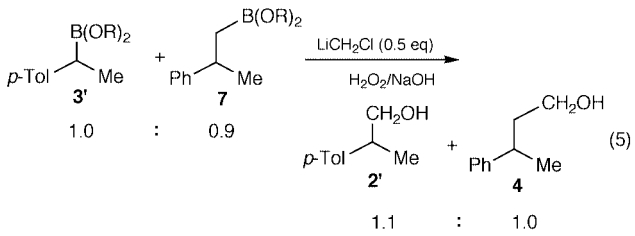
DOI: 10.1039/b000243g

differences in rates of addition of Bu^nLi, especially as we attempted to generate increasing amounts of $LiCH_2Br$. At these higher loadings, we also observed alcohol **6**, resulting from incorporation of *three* CH_2 units. One interesting trend which can be gleaned from Table 2 is that as the amount of $LiCH_2Br$ used is increased, there is a concomitant increase in the amount of alcohol **5** resulting from unreacted starting material (compare entry 1 with 4 and 5).

This observation led us to postulate that homologated boronate esters such as **7** were more reactive than the seondary boronate esters **3**. This reactivity difference could be rationalized by the different steric requirements of **3** *cf.* primary homologated derivatives such as **7**. To test this hypothesis, we prepared and isolated **7** and also prepared boronate ester **3′** by hydroboration of *p*-methylstyrene. A *ca.* 1 : 1 mixture of **7** and **3′** was then treated with $LiCH_2Cl$ [eqn. (5)]. This homologating reagent was chosen for two reasons. Firstly, its use would obviate complications due to double homologations observed with $LiCH_2Br$; and secondly, as $LiCH_2Cl$ is the least reactive of the homologating reagents, it would presumably be the best probe of reactivity differences.



Much to our surprise, in the presence of a limiting quantity of $LiCH_2Cl$ (50%), boronate esters **7** and **3′** gave equal amounts of homologated products **4** and **2′** (19 and 21% respectively) indicating no difference in the reactivity of the secondary and primary boronate esters under these conditions. It should be noted that the introduction of the *para* methyl substituent will skew the results somewhat as it alters the electronic nature of the migrating group. An isotopically labeled analog of **3** is currently being prepared and the results of this study will be reported in due course. Experiments are also underway to elucidate the reason for the remarkable differences in the reactivity of $LiCH_2Cl$ and $LiCH_2Br$.

In conclusion, we have shown that the homologation of boronate esters derived from the hydroboration of styrene and its derivatives can be carried out in a sequential, one-pot manner depending on the nature of the homologating reagent used. Homologation with $LiCH_2Cl$ yields only the product of single homologation regardless of the number of equivalents used, and $LiCH_2Br$ yields the doubly homologated product even at 1 equivalent loading. Increasing the amount of this reagent leads to the incorporation of three CH_2 units in a single reaction.

† cod = Cycloocta-1,5-diene, dppb = 1,4-bis(diphenylphosphino)butane. Note that the asymmetric version of this reaction employs binap [2,2'-bis(diphenylphosphino)-1,1'-binapthyl]. See ref. 4 for appropriate experimental procedures.

‡ The following procedure is representative. *Double homologation with* $LiCH_2X$: in a 10 mL flame dried round bottomed flask, (1-phenethyl)pinacolboronate **3** (229.8 mg, 1.0 mmol) and $BrCH_2Br$ (0.077 mL, 1.1 mmol) were dissolved in 2.0 mL of THF. After cooling to −78 °C using a N_2/isopropyl alcohol bath (bath temperature monitored by a low temp. thermometer), Bu^nLi (2.17 M in hexane, 0.50 mL, 1.1 mmol) was added dropwise over 15 min to the center of the flask with vigorous stirring. The reaction mixture was then allowed to warm gradually to room temperature overnight under N_2. The solvent was removed *in vacuo*, and the resulting residue diluted with 10 mL of saturated aqueous NH_4Cl. The aqueous layer was extracted with light petroleum (bp 30–60 °C, 20 mL × 4), and the combined organic layers dried over $MgSO_4$. After filtration and removal of solvent *in vacuo*, crude (1-phenylpropyl)pinacolboronate (231 mg) **7** was obtained.

Boronate ester **7**, (231 mg), was dissolved in 10 mL of diethyl ether, 2.0 mL of methanol and 4.0 mL of 1 M NaOH (8.0 mmol). The flask was flushed with nitrogen and 0.285 mL of H_2O_2 (30% w/v in H_2O, 2.27 mmol) was added slowly at room temperature. The reaction mixture was left at room temperature under N_2 overnight. The ether layer was separated and the aqueous layer washed with diethyl ether (20 mL × 3). The combined organic layers were dried over $MgSO_4$. After filtration and removal of solvent *in vacuo*, a mixture of 1-phenethanol **5** (11%), 2-phenylpropanol **2** (74%) and 3-phenylbutanol **4** (15%) was obtained. The ratio was determined by 400 MHz ^1H NMR. The NMR yields (11, 74 and 15%, respectively) of the aforementioned products were determined by integration of the peaks of interest *vs*. added internal standard (*p*-nitrotoluene).

Polynuclear compounds of magnetic transition metal ions are attracting large interest after the discovery that their magnetisation may relax very slowly at low temperature. Since their behaviour is similar to that of bulk magnets they may be called single molecule magnets. Here we review the magnetic properties of iron(III) clusters showing such features which may be interesting for future applications, as well as strategies for designing new molecules with increased performances.

Introduction

The magnetic properties of large polynuclear compounds containing transition metal and/or rare earth ions have become the focus of much attention in the last few years,[1–4] after the discovery that the magnetisation of a cluster comprising twelve manganese ions, $[Mn_{12}O_{12}(MeCO_2)_{16}(H_2O)_4]\cdot 2MeCO_2H\cdot 4H_2O$.[5] Mn12Ac, relaxes so slowly at low temperature that the individual molecules behave in manner reminiscent of bulk magnets.[6] In fact if a molecule is magnetised at 2 K by applying a magnetic field, after 2 months the magnetisation is still *ca*. 40% of the saturation value, if the sample is kept at that temperature. In order to achieve the same result at 1.5 K it will be necessary to wait for *ca*. 40 years! Clusters, which behave like Mn12Ac, have been called single-molecule magnets.[1] In a sense this is a misnomer, because the term magnet must rigorously apply only to systems in which the spin correlation length diverges, *i.e.* goes to infinite, and this is clearly not possible in a cluster with a finite size. However the term is evocative, and in our opinion it can be used, provided its true meaning is understood.

One of the features of Mn12Ac which has attracted much interest is that the slow relaxation of the magnetisation gives rise to hysteresis effects, similar to those observed in bulk magnets, but of molecular origin: therefore it becomes in principle possible to store information in one single molecule.[6] The second appealing feature of Mn12Ac is that the relaxation of its magnetisation shows clear quantum effects, and the single molecule magnets can be used to investigate the macroscopic range in which quantum and classical behaviour coexist.[7,8] In principle these features can be exploited for developing new classes of computers in which quantum coherence is used to store and elaborate information. Currently the most promising results seem to be achieved using NMR techniques in solution,[9] but also Josephson junctions and magnetic nanoparticles can be taken into consideration.

In order to be considered for real applications, single molecule magnets must have the highest possible blocking temperature. The blocking temperature is that below which the relaxation of the magnetisation becomes slow compared to the time scale of a particular investigation technique. For instance for NMR the time scale is 10^{-8}–10^{-9} s, while for ac susceptibility measurements it is 10^{-2}–10^{1} s. Therefore the magnetisation of a molecule may appear as blocked in NMR but still dynamic in ac susceptibility measurements. Further it is also important that the molecules show clearly observable quantum effects.

After Mn12Ac, many attempts have been made in order to increase the blocking temperature of the single molecule magnets. In order to reach this goal it is necessary to build molecules which have the largest possible value of the total spin S in the ground state. Mn12Ac itself has $S = 10$ in the ground state, with the magnetisation corresponding to that of an atom with twenty unpaired electrons,[10] but molecules with up to 33 unpaired electrons have been reported.[11] We must emphasize that in general these molecules have many spin states which are thermally populated, therefore the properties associated to the ground state will only show up at low temperatures, when the excited states are depopulated. Clearly in order to increase the blocking temperature it is required that the ground state is the only populated one at relatively large temperatures.

The second requisite for observing single molecule magnet behaviour is that the ground state must have a high magnetic anisotropy of the easy-axis (Ising) type. This means that the magnetisation at low temperature may be stable either parallel or antiparallel to a given axis, and that an energy barrier must be overcome during the reversal of the magnetisation, passing for instance from the orientation 'up' to the orientation 'down'. In

Dante Gatteschi, born in Florence, Italy, in 1945 studied Chemistry at the University of Florence, and he is now Professor of General and Inorganic Chemistry at the same University. His research interests range from the use of spectroscopic techniques, particularly EPR and recently high frequency EPR, for the investigation of metal ion compounds to molecular magnetism. In the latter area his main achievements have been in the field of system comprising metal ions interacting with stable organic radicals and recently in the development of single molecule magnets.

Roberta Sessoli graduated in 1987 and obtained her PhD in Chemistry in 1992 studying the magnetism of molecular materials based on organic stable radicals and transition metal or rare earth ions. Since 1997 she has been an associate researcher at the University of Florence. Her main interests are presently in the magnetism of mesoscopic systems like clusters of magnetic metal ions or nanostructured materials.

Andrea Cornia, born in Modena, Italy, studied Chemistry and graduated in 1992. He obtained his PhD in Chemistry in 1996 under the supervision of D. Gatteschi and A. C. Fabretti. His research interests range from the supramolecular synthesis and structural investigation of nanomagnetic materials to the application of physical techniques in molecular magnetism and solid-state inorganic chemistry.

† Dedicated to the memory of Professor Olivier Kahn.

a system with spin S this occurs when the components with $M = \pm S$ lie lowest ($-S \leq M \leq S$). For axially distorted systems the energies of the M components are given by $E(M) = M^2D$, where D is the axial zero-field splitting (zfs) parameter. Therefore an Ising type anisotropy will be observed when D is negative. For Mn12Ac this condition is met and the barrier for the re-orientation of the magnetisation has been observed to be *ca.* 44 cm^{-1} or 64 K.

Beyond the obvious chemical variants of Mn12Ac,[12–14] other manganese complexes[13,15–17] have been found to behave as single molecule magnets. A few iron,[18–20] chromium[21–23] and vanadium[24] clusters also exhibit similar properties. Certainly the goal of a large ground spin state can be most easily achieved by assembling individual ions with a large ground spin state. Two ions with $S = 5/2$ ferromagnetically coupled have a ground state with $S = 5$, while it is necessary to assemble a cluster of ten $S = 1/2$ ions in order to achieve the same result. This is the reason why ions with large spin, like high spin iron(III) ($S = 5/2$), manganese(III) and iron(II) ($S = 2$), have been largely used.

Iron is certainly a very interesting ion in order to prepare single molecule magnets, not only because of the large spin state, but also because ferritin, the iron-storage protein in most living organisms, can be considered itself as a nanosize magnetic particle. In fact ferritin has been investigated for quantum tunnelling effects of the magnetisation.[25] Many large iron clusters have been reported, ranging from binuclear up to thirty nuclear species. We want to show here how several clusters containing iron behave as single molecule magnets, and discuss which conditions may favour this behaviour. All the clusters of this type so far reported are characterised by antiferromagnetic coupling between the iron(III) ions so that large spin in the ground state can only arise if the number of 'up' spins is different from that of 'down' spins. Therefore the clusters behave as single-molecule ferrimagnets. An example of a bulk ferrimagnet with a similar type of non-compensation of magnetic moments is maghemite, γ-Fe_2O_3. Ferrimagnetic iron–oxo clusters can indeed be considered as models of this prototype mineral.

Properties of iron(III) ions and exchange interactions in pairs

In order to understand which are the best strategies for obtaining single molecule magnets using iron(III) it is necessary to understand which are the conditions favouring both a strong magnetic coupling between the iron ions and a large magnetic anisotropy. The exchange interactions in oxo-bridged iron(III) pairs have been much investigated both theoretically and experimentally, also due to the relevance of these systems to non–heme metallo-proteins containing binuclear iron units in their active site.[26,27] The simplest approach considers two parameters, the average metal–oxygen distance, P, and the metal–oxygen–metal angle, α. Magnetic data recorded on a large series of iron complexes suggest that the P-dependence of the exchange coupling constant, J, is well represented by eqn. (1):[27]

$$J = 1.753 \times 10^{12} \exp(-12.663P) \quad (1)$$

where J is expressed in cm^{-1}, P in Å, and the exchange Hamiltonian is in the form $H = JS_1 \cdot S_2$. The coupling constant is largely insensitive to the Fe–O–Fe angle for $\alpha > 120°$. For smaller angles an effect is clearly observed, J becoming smaller as the angle α is reduced. A systematic study has been performed in a series of binuclear complexes with two alkoxo bridges[28] and similar Fe–O distances. The values of α range from 102 to 106°, while J varies between *ca.* 15 and 21 cm^{-1}. The simplest correlation was found to be of the type given by eqn. (2):

$$J = 1.48\,\alpha - 135 \quad (2)$$

with J in cm^{-1} and α in degrees. An extrapolation of eqn. (2) suggests that for $\alpha \approx 90°$ the coupling should become ferromagnetic. A justification for these experimental results was found on the basis of extended Hückel calculations, which however indicate that for small angles ($\alpha \approx 90°$) the coupling should become antiferromagnetic again, due to the importance of direct overlap between the iron(III) magnetic orbitals. In fact if the Fe–O bond distances are kept constant while the α angle is progressively reduced, the shortening of the Fe–Fe distance favours direct exchange. More experimental data are certainly needed to check this prediction. It should be remarked that the decrease in the antiferromagnetic coupling constant for a < 120° has been predicted also by a complete exchange model recently suggested by Güdel and Weihe.[29]

The anisotropy of the pairs depends on the anisotropy of the individual ions, and on an additional term that is brought about by the interaction between the two iron ions.[30] The former contribution is referred to as single-ion anisotropy, while the latter is known as spin–spin anisotropy. High spin iron(III) has a d^5 configuration, which yields an orbital singlet ^6S ground term for the free ion. The ground state of the complexed ion is also orbitally non-degenerate, therefore the Zeeman anisotropy is very low, with $g_x \approx g_y \approx g_z \approx 2.0023$. However some admixture with excited states of lower spin multiplicity is allowed by spin–orbit coupling and the ground $S = 5/2$ state does show zero field splitting, which may easily be of the order of 1 cm^{-1}. This splitting determines the single ion anisotropy.

Single ion contributions to the anisotropy cannot be rigorously calculated, and so far even the experimental data are lacking in the sense that no significant correlation between structural features and values of D has been established. Recently Neese and Solomon have suggested[31] that it is possible to calculate the zfs parameters by using a MO approach, while traditional ligand field models have been implemented in the Angular Overlap Model, AOM, formalism.[32] For instance it has been found that a trigonal distortion from octahedral geometry yields a negative zfs parameter D for elongation, and positive for compression. In order to have direct information on the zfs in model compounds the HF-EPR spectra of a tris ß-diketonate complex, $Fe(dpm)_3$, where dpm = 2,2,6,6-tetramethylheptane-3,5-dionate, were recorded.[20] The spectra yielded $D = -0.18\ cm^{-1}$ and $E/D = 0.25$. These values were reproduced in a reasonable way by using the AOM. However, more experimental and theoretical work is needed in order to establish useful correlations between structure and zfs of iron(III) ions. Given their relevance also for biological systems this seems to be indeed an important task.

The anisotropy associated with the spin–spin interaction can be described to a good approximation by the interaction between the magnetic point dipoles centred on the two iron ions. For a pair of antiferromagnetically coupled ions the dipolar interaction orients the two spins orthogonal to the vector $\boldsymbol{r}$ connecting the two centres. In fact the poles of the same sign would be in contact for an orientation parallel to $\boldsymbol{r}$. Therefore the plane perpendicular to $\boldsymbol{r}$ [Fig. 1(a)] is a hard plane for the magnetisation of the antiferromagnetic dimer, which is more easily magnetised when the field is applied parallel to the axis connecting the two spins. Dipolar interactions thus provide an Ising-type contribution to the magnetic anisotropy.

These considerations can be extended to polynuclear systems as well. In particular, when antiferromagnetically coupled metal ions are arranged in a planar structure with axial symmetry, like in some of the iron(III) clusters described in the forthcoming sections, nearest-neighbour dipolar interactions determine a *XY*-anisotropy with an easy plane of magnetisation when the ground state has $S = 0$ [Fig. 1(b)]. In fact, in the lowest-energy configuration, the individual spins are antiparallel to their nearest neighbours (owing to exchange interactions) *and* perpendicular to the average plane through the metal array

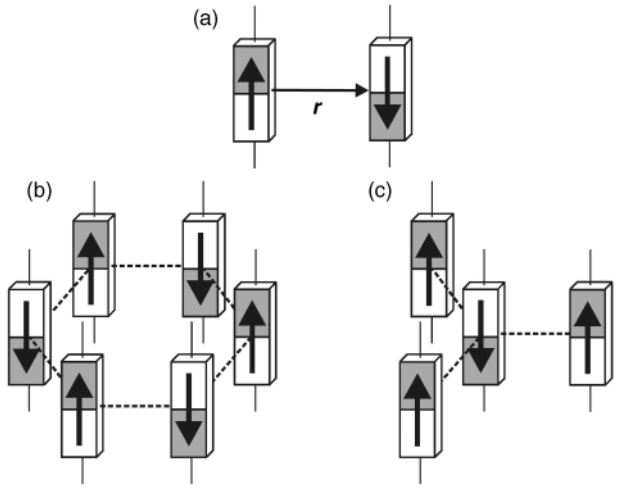

Fig. 1 Schematic view of the preferred spin orientation due to the dipolar interaction in an antiferromagnetic dimer (a), in a cyclic antiferromagnetic cluster (b), and in a ferrimagnetic tetrameric cluster (c).

(owing to dipolar interactions). By contrast, when the ground state has *S* different from zero, *i.e.* in ferrimagnetic clusters, the system exhibits an Ising-type anisotropy [Fig. 1(c)]. It is noteworthy that dipolar interactions alone lead to an Ising-type anisotropy in planar ferrimagnetic clusters, thus giving the possibility to observe single molecule magnet behaviour. The topology of the metal ions can thus strongly influence magnetic anisotropy *via* dipole–dipole interactions, establishing a direct connection between the shape of the cluster and its magnetic properties.

Iron rings: quantum size effects and anisotropy

Using alkoxides or carboxylates as bridging ligands it has been possible to synthesise six-,[33,34] eight, ten-[35] and twelve-[36] membered iron(III) rings. In all the cases the iron–iron interaction is antiferromagnetic, yielding a ground $S = 0$ state. The energies of the lowest lying *S* states can be expressed by eqn. (3):

$$E(S) = J_{\text{eff}}S(S + 1) \qquad (3)$$

where $J_{\text{eff}} = 4J/N$, with *N* the number of iron ions in the ring. Below 1 K the rings are in the non-magnetic ground state, and consequently under low field conditions the magnetisation is zero. However, on increasing the field, the excited magnetic states are stabilised, until eventually they become the ground state. This gives rise to a typical stepped magnetisation, with a first jump at the field where the lowest lying $S = 1$ state becomes the ground state, then where the $S = 2$ crosses over to become the ground state, and so on.[35,37] These observations are clear evidence for quantum effects, corresponding to the fact that the lowest $S = 0$ level is separated by a gap from the first excited level. The larger the ring the smaller the gap, until eventually the levels must merge in a continuum. In fact the magnetisation of one-dimensional magnetic materials, that can be considered as the extrapolation of rings to infinite, does not show steps.[38] Therefore it would be extremely important to make available larger and larger rings in order to follow the passage from microscopic to bulk. In fact the thermodynamic properties calculated for finite rings have long been used to extrapolate the properties of the infinite chains. Another interesting goal is that of synthesising odd membered rings of half integer spins, which should show spin frustration effects.[39]

All the measurements referred to above are static measurements, which do not provide any information on the dynamics of the magnetisation and on possible tunnelling phenomena. Dynamic measurements can in principle be made with a variety of techniques, ranging from ac susceptometry to magnetic resonance. In this respect NMR is particularly appealing, because it can monitor the variations in the relaxation rate of the nuclear moments under the influence of the electron magnetisation. In fact, it can be expected that when two levels cross, the electron relaxation at low temperature is drastically influenced. Therefore the field dependence of the nuclear relaxation rate should show anomalies corresponding to the crossover fields. This has been recently observed[40] in a decanuclear ring, the so-called ferric wheel, whose structure is shown in Fig. 2. All the methods exploiting NMR have potential interest for quantum computing applications, given the recent implementation of NMR techniques in solution.[9]

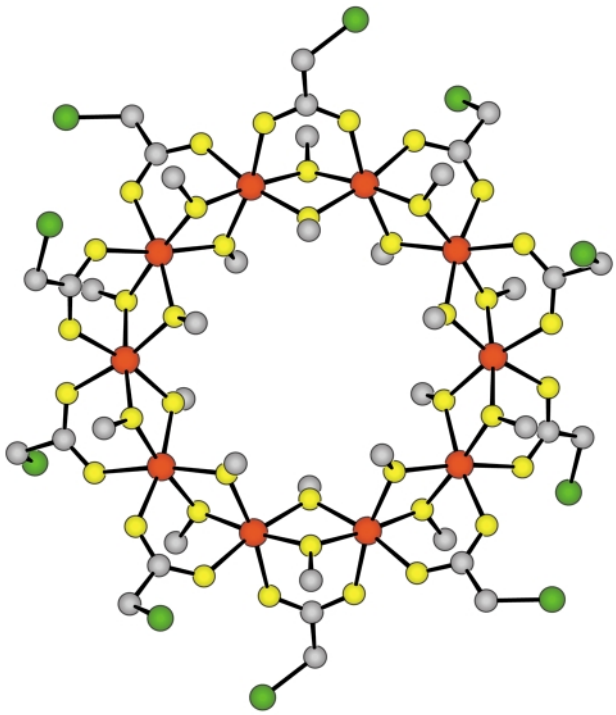

Fig. 2 View of the structure of the cluster $[Fe(OMe)_2(O_2CCH_2Cl)]_{10}$, the so-called 'ferric wheel'. The iron atoms are in red, oxygen in yellow, carbon in grey and chlorine in green. The ten iron atoms lie in a plane within ±0.009 Å and the diameter of the cluster, defined as the longest Fe···Fe distance, is 9.80 Å.

Stepped magnetisation has been observed also in smaller iron(III) rings, like LiFe6 and NaFe6, whose structure is depicted in Fig. 3 The alkali-metal ion, Li^+ or Na^+, is hosted in the. centre of the ring, which behaves like an inorganic crown ether.[34] Solution studies have shown that the affinity of the Fe6 ring is higher for sodium than for lithium ions. Further, LiFe6 and NaFe6 can be neatly obtained by adding lithium or sodium ions to a solution of a twelve-membered iron(III) ring which does not host any alkali-metal ion.[36]

The magnetisation of small single crystals of LiFe6 and NaFe6 was investigated through new torque magnetometers using a sensitive cantilever which directly provided the magnetic anisotropy of the excited *S* states.[41] The central alkali-metal ion strongly influences not only the isotropic exchange interaction, which passes from 14 to 20 cm^{-1} by replacing Li^+ with Na^+, but also the magnetic anisotropy. In fact the zero-field splitting of the first excited $S = 1$ state is $D = 1.16$ cm^{-1} for the lithium derivative and $D = 4.32$ cm^{-1} for the sodium derivative. The former value corresponds almost exactly to the calculated dipolar contribution. By contrast, the magnetic anisotropy of the sodium derivative points to the presence of large single ion contributions. Minor differences in the environment of the individual iron(III) centers, such as those induced by the different size of the guest ion, may thus induce

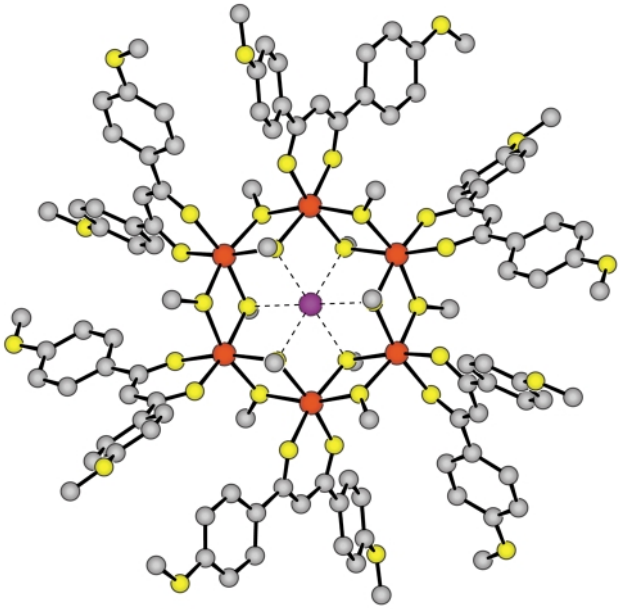

Fig. 3 View of the structure of the hexanuclear iron cluster $[NaFe_6(OMe)_{12}(pmdbm)_6]^+$, where pmdbm = 1,3-di(4-methoxyphenylpropane)-1,3-dionate (colour code as in Fig. 2). Li^+ can replace the Na^+ cation in the centre with significant changes in the intracluster magnetic exchange interaction and in the magnetic anisotropy.

large zfs variations. This clearly indicates that the control of the magnetic anisotropy of the clusters is a difficult task.

Iron-containing single molecule magnets

The smallest iron cluster showing slow relaxation effects in the magnetisation at low temperature is $[Fe_4(OMe)_6(dpm)_6]$, Fe4.[20] The structure of Fe4 is shown in Fig. 4. A central iron ion is

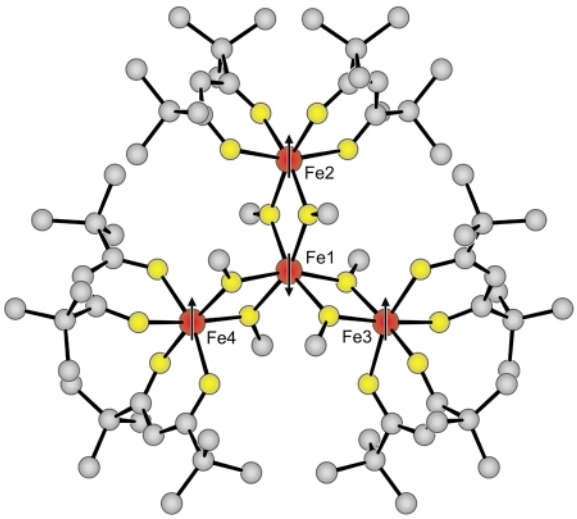

Fig. 4 Structure of the ferrimagnetic cluster $[Fe_4(OMe)_6(dpm)_6]$ where dpm = 2,2,6,6-tetramethylheptane-3,5-dionate (colour code as in Fig. 2). The arrows correspond to the spin structure in the ground $S = 5$ state.

connected to three terminal ions by three double μ-alkoxo bridges. Crystal symmetry requires a C_2 axis in the cluster passing through Fe1 and Fe2. The three external iron(III) ions define an almost equilateral triangle. In this case the spin topology, which for antiferromagnetic coupling orients the central spin 'down' and the external ones 'up' determines the non-compensation of the spins. The ground state has $S = 5$, and the ferrimagnetic nature of the cluster is clearly shown by the χT *vs.* T curve which goes through a broad minimum at *ca.* 150 K and then reaches 14.6 emu K mol^{-1} at low temperature, in reasonable agreement with an $S = 5$ state ($\chi T = 15$ emu K mol^{-1}, for $g = 2.00$). The temperature dependence of χT has been successfully reproduced calculating the energies of the total spin states using the spin Hamiltonian eqn. (4):

$$H = J\,(\boldsymbol{S_1}\bullet\boldsymbol{S_2} + \boldsymbol{S_1}\bullet\boldsymbol{S_3} + \boldsymbol{S_1}\bullet\boldsymbol{S_4}) + J'\,(\boldsymbol{S_2}\bullet\boldsymbol{S_3} + \boldsymbol{S_3}\bullet\boldsymbol{S_4} + \boldsymbol{S_2}\bullet\boldsymbol{S_4}) \quad (4)$$

The best-fit values are: $J = 21.1$ cm^{-1}, $J' = -2.1$ cm^{-1}, in reasonable agreement with the values expected using eqns. (1) and (2).

The anisotropy of the ground state has been determined using high field EPR spectroscopy, and it has been shown to be quasi axial, and of the Ising type, with $D = -0.20$ cm^{-1}. This means that the ground $S = 5$ state is split in such a way that the $M = \pm5$ levels lie lowest, with $M = \pm 4$ at 1.8 cm^{-1}, $M = \pm3$ at 3.2 cm^{-1}, $M = \pm2$ at 4.2 cm^{-1} and $M = 0$ at 5 cm^{-1}. If the system is magnetised at low temperature, the $M = -S$ state will be selectively populated. On switching the field off, the system will revert to thermal equilibrium, *i.e.* it will equalise the populations of the $M = -S$ and $M = +S$ states. At the simplest level of approximation this cannot occur directly, but the system must climb all the levels, one at a time, up to $M = 0$, and then descend.[42] Under this simplifying approximation the barrier for the re-orientation of the magnetisation is given by the difference in energy between the lowest $M = +S$ and the top $M = 0$ level [eqn. (5)]:

$$\Delta = |D|\,S^2 \quad (5)$$

and the relaxation of the magnetisation is expected to follow the Arrhenius law:

$$\tau = \tau_0 \exp(\Delta/kT) \quad (6)$$

where τ_0 is expected to be proportional to S^6/Δ^3. Eqn. (6) is the same as that appropriate to classical superparamagnets.[43]

Below 1 K Fe4 shows slow relaxation of the magnetisation in ac susceptibility measurements. The relaxation time follows the Arrhenius law with $\tau_0 = 1.1 \times 10^{-6}$ s and $\Delta/k = 3.5$ K. This means that at 0.2 K, the lowest measurement temperature, the relaxation time is of the order of one minute. This relaxation is much faster than that of Mn12Ac,[6] as it should be expected given the smaller S and the lower barrier.

The height of the barrier, calculated with eqn. (5), is larger than the experimental value. This has been found to be the case in all systems showing slow relaxation of the magnetisation investigated so far. It must be concluded that eqn. (5) is only a loose approximation. In particular, the simplified model does not take into account direct tunnelling within a formally degenerate $\pm M$ pair. This point will be addressed in detail in the following section on Fe8.

Given the small number of magnetic ions in Fe4, detailed calculations were performed of the energies of the spin levels. Attempts were made also to rationalise the anisotropy of the ground state. As outlined in a previous section, the dipolar contribution has the same sign as the observed anisotropy, although spin–spin interactions alone can not quantitatively account for it. Attempts were made to calculate the single ion contributions, using the AOM, but no really acceptable results were achieved.[20] More efforts are needed in this field.

Fe8, the quantum magnet

The structure of $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$, Fe8, where tacn = 1,4,7-triazacyclononane, which Wieghardt *et al.* originally reported as the bromide salt,[44] Fe8Br, is shown in Fig. 5. The analysis of the temperature dependence of the magnetic susceptibility,[45] provided evidence for a ground $S = 10$ state, which can occur if six spins are up and two down. Since there are several triangles in the exchange pathways connecting the iron(III) ions spin, frustration effects[39] can be anticipated. This means that the ground state is not correctly described by simply putting the spins up or down on different metal ions. However

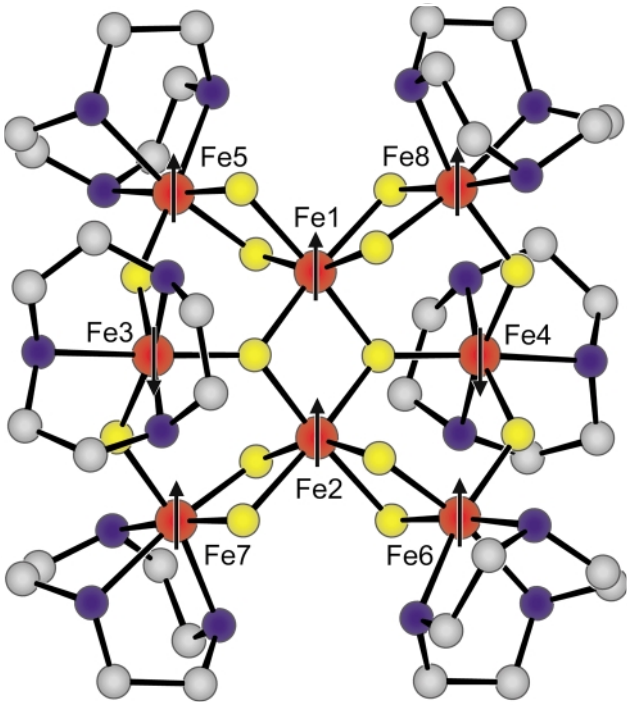

Fig. 5 View of the cluster $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$ where tacn = 1,4,7-triazacyclononane. The arrows correspond to the spin structure previously suggested by the analysis of the magnetic susceptibility and then determined from single crystal polarised neutron diffraction experiments (see ref. 46).

it was possible to obtain a direct picture of the spin density by using polarised neutron diffraction techniques.[46] These showed that the spin density on Fe3 and Fe4 is negative, and that on all the other iron ions is positive. These data are in qualitative agreement with the values obtained from the fit of the temperature dependence of the magnetic susceptibility. The spin density however does not correspond to five unpaired electrons on each iron ion, confirming that the 'up-down' description is an oversimplification.

The ground state is largely split in zero field, as evidenced by HF-EPR[19] and inelastic neutron scattering, INS,[47] experiments. When neutrons interact with the clusters they may induce transitions between the M levels of S multiplets, according to the selection rules $\Delta M = 0, \pm 1$. Therefore, by measuring the INS it is possible to obtain detailed information on the spectrum of the M energy levels. The INS of Fe8Br is particularly rich, and it has shown, for the first time, how the technique can be fruitfully used also on systems with many protons in the energy window up to 60 cm^{-1}. In fact, after the spectra of Fe8Bt, recently the spectra of Mn12Ac have been reported[48] showing a similar abundance of absorptions. The INS spectra of Fe8Br are shown in Fig. 6, together with the assignment of the peaks to the transitions within the lowest $S = 10$ multiplet.

The HF-EPR and the INS spectra have provided essentially the same sets of parameters to describe the splitting of the ground $S = 10$ state. In particular, they agree on the fact that the spin Hamiltonian for describing the zero field splitting requires the inclusion of both second order and fourth order terms. This means that the splitting of the ground state is determined by both quadrupolar terms, described by the parameters D and E, and hexadecupolar terms described by the B_4^0, B_4^2 and B_4^4 parameters. Single crystal EPR spectra have also provided the principal directions of the zero field splitting tensors, and consequently the principal directions of the magnetic anisotropy. The easy axis, *i.e.* that of prevailing orientation of the individual spins, makes a small angle, *ca.* 10°, with the perpendicular of the plane of the iron ions, while the hard axis

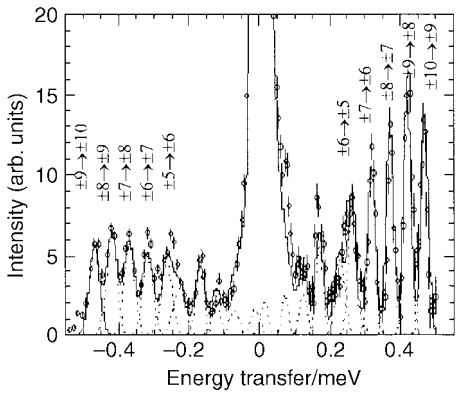

Fig. 6 Inelastic neutron scattering spectrum recorded at 10 K on Fe8Br cluster microcrystalline powder. The large peak at zero energy corresponds to the elastic contribution. On the left side the emission spectrum is reported while on the right side are the absorption lines. The transitions at the extremes of the spectrum can be easily assigned as shown in the picture using the basis of the eigenvalues of $\boldsymbol{S}_z$ (1 meV = 8.065 cm^{-1}).

passes through the Fe1 and Fe2 ions. The energies of the M levels of Fe8Br are shown in Fig. 7. The lowest lying levels

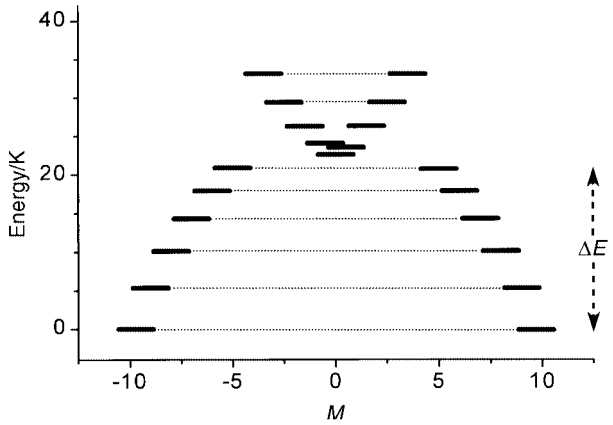

Fig. 7 Schematic view of the splitting in zero field of the $S = 10$ ground manifold of Fe8Br using the spin Hamiltonian parameters of ref. 47. The height of the classical energy barrier is shown. Underbarrier transitions dominate at low temperature. The levels above *ca.* 22 K cannot be labelled with M and their assignment on the graph is arbitrary.

correspond to $M = \pm S$, and on increasing temperature, the levels are progressively more admixed. This is essentially determined by the non-zero E parameter that admixes levels differing in M by ±2. In particular from Fig. 7 we learn that at the top of the manifold there is not a unique level corresponding to $M = 0$. Therefore the meaning of eqn. (5) for defining the barrier for the reorientation of the magnetisation is completely lost and the barrier is significantly reduced.[49] However, if it is used in a first approximation, Δ/k is calculated to be 29 K, and therefore slow relaxation effects are expected at low temperature.

In Mössbauer experiments, which have a time scale of 10^{-8}–10^{-9} s slow relaxation of the magnetisation of Fe8Br is observed[19] below 20 K, while the same effect can be detected by ac susceptibility measurements only below 3 K. The relaxation times however do not rigorously obey an Arrhenius type relation (6). The relaxation time of the magnetisation becomes so slow below 1 K that hysteresis loops of molecular origin can be observed.[50] The hysteresis, shown in Fig. 8, has a dynamic nature, as revealed by the strong dependence on the rate of the field sweep, and the same stepped appearance first reported for Mn12Ac.[7,8] The flat regions correspond to fields at which the relaxation is slow, while the steps correspond to fields at which a rapid increase of the relaxation rate is observed. This behaviour has been attributed to thermally assisted quantum tunnelling. In a magnetic quantum system the relaxation of the magnetisation may occur either with the mechanism described

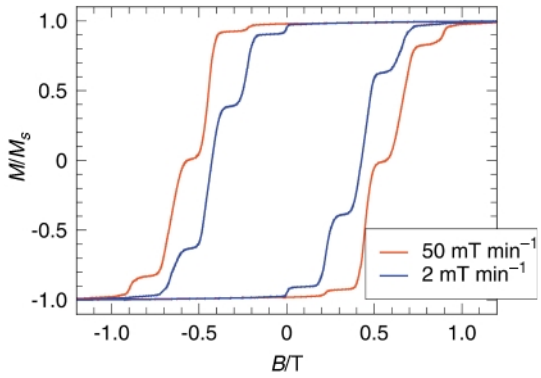

Fig. 8 Hysteresis loops recorded for Fe8Br at 0.30 K and two different field scan speeds. The dynamic nature of the hysteresis is revealed by the strong dependence on the sweep rate. The stepped shape is due to the tunnelling of the magnetisation, which occurs when two levels on the opposite sides of the barrier are brought in coincidence by sweeping the field, which accelerates the magnetic relaxation giving rise to the jumps in the magnetisation.

above, where the absorption or emission of a phonon allow the transition from the M to the $M \pm 1$ level, or by tunnelling between pairs of degenerate levels. In zero field the lowest lying pairs of M levels meet the tunnelling condition, and the relaxation is comparatively fast. In the presence of an external field the energy of the $+M$ level increases and that of the $-M$ level decreases, making quantum tunnelling impossible, as shown schematically in Fig. 9. However the condition for

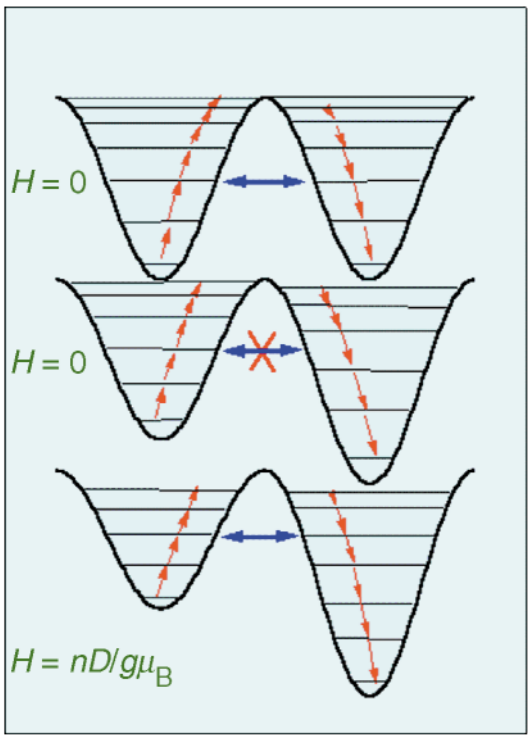

Fig. 9 Schematic drawing of the energy barrier for the reversal of the magnetisation generated by the magnetic anisotropy. The levels correspond to the M states of the ground spin multiplet and for the sake of clarity an axial zero field splitting has been considered. In zero applied field the $\pm M$ states are degenerate allowing a shortcut of the barrier through a tunnelling process. An external magnetic field removes the energy correspondence of the states on the opposite sides of the barrier, thus hampering the underbarrier mechanism of relaxation, except for critical values of the field for which the energy correspondence is re-established.

tunnelling are restored for fields at which the $+M$ level has the same energy as of the $-M + n$ level, where $n = 1,2,\ldots$*etc*. The fields where these conditions are met can be calculated using the spin Hamiltonian parameters obtained from HF-EPR and INS experiments. The calculated fields correspond to the fields where steps are observed in the hysteresis. These tunnelling processes occur not only between the lowest levels, but also between the higher thermally populated levels. Therefore the overall mechanism has been described as thermally assisted quantum tunnelling.

Direct measurements of the relaxation time of Fe8Br can be performed at low temperature by first saturating the magnetisation and then monitoring its time decay.[50] In this way it is observed that below 350 mK the relaxation becomes temperature independent, thus confirming the quantum tunnelling effects. Under these conditions only the lowest $M = 10$ levels are populated, and tunnelling occurs between them. This has been the first experimental evidence of pure quantum tunnelling in a magnetic nanoparticle. Attempts to observe this behaviour in particles obtained by techniques other than molecular chemistry had failed, essentially because it was impossible to have absolutely monodisperse particles.

The way the molecules undergo tunnelling is still a matter of debate, but evidence is accumulating in favour of the mechanism to be discussed below. The $M = \pm 10$ levels are degenerate in axial symmetry. If a transverse anisotropy is present, *i.e.* a matrix element different from zero, $\Delta/2$, connects the two states, then tunnelling is possible. The two levels are split by the transverse field, $H_t = \Delta/g\mu_B$, and the magnetisation can fluctuate with a frequency proportional to Δ, the tunnel splitting. This picture is correct if no additional fields are present. These however cannot be avoided because the molecule is embedded in a lattice with other magnetised molecules that generate a dipolar field, H_d. If this is larger than H_t the effect of the matrix element is quenched and no tunnelling is observed. In Fe8Br, H_d is of the order of 1–10 mT, while H_t is of the order of 10^{-9} T, therefore the condition for tunnelling is not met at this level of approximation. However the above picture neglects the role of the magnetic nuclei present in the cluster. The ^{1}H ($I = 1/2$), ^{14}N ($I = 1$), and ^{79,81}Br ($I = 3/2$) nuclei generate a fluctuating hyperfine field, H_{hy}, at the magnetic centres broadening the $M = \pm 10$ levels. The broadening is of the order of 1 mT and it may restore the tunnelling conditions for the molecules for which $H_d < H_{hy}$. However, since the distribution of dipolar fields is broader than that of hyperfine fields, the process should stop soon. In order to justify the observed continuous quantum relaxation to thermal equilibrium it must be considered that when a molecule tunnels it changes its magnetisation. Consequently, the dipolar field felt by the neighbouring molecules also changes, creating regions in the sample where the condition $H_d < H_{hy}$ is met.

Another way of imposing the condition that the tunnel splitting is larger than the local fields is to apply a field perpendicular to the easy axis. The applied field will increase the tunnel splitting which then can be more easily measured.

Using micro SQUID techniques it was also possible to measure the intrinsic width of the tunnel splitting.[51] This has been experimentally shown to be proportional to the hyperfine field in Fe8Br.[52] In fact when the naturally occurring non-magnetic Fe isotopes have been substituted with the magnetic ^{57}Fe ($I = 1/2$) the width of the splitting has been measured to increase from 0.8 to 1.2 mT as shown in the inset of Fig. 10. When the ^{1}H nuclei are partially substituted with the less magnetic ^{2}H nuclei the width decreased to 0.6 mT. The hyperfine field generated by the nuclei also strongly affects the relaxation rate of the macroscopic magnetisation, which is fastest in ^{57}Fe-enriched samples and slowest in the partially deuterated ones. This is shown in Fig. 10, where the time needed to relax 1% of the saturation magnetisation is plotted as a function of the temperature. These results showed the fundamental role of nuclei for the relaxation of the magnetisation of Fe8Br in the quantum regime and open the possibly of controlling the dynamics of the magnetisation by acting on the nuclei.

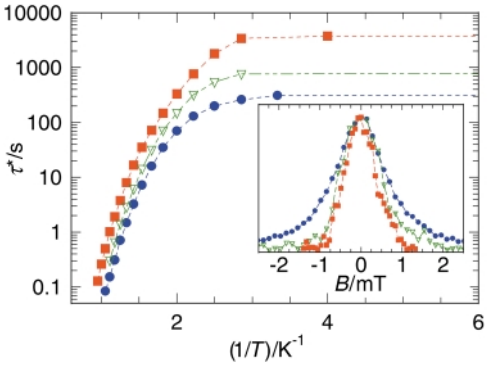

Fig. 10 Isotopic effect on the relaxation of the magnetisation and on the intrinsic line-width of the resonant tunnelling process (inset). τ^* corresponds to the time needed to relax 1% of the saturation magnetisation and its temperature dependence is studied for three isotopic samples of Fe8Br: natural sample (green),^{57}Fe enriched sample (blue), partially deuterated sample (red). In the inset the resonance line, estimated from the field dependence of the relaxation rate, is reported for the three isotopic samples. In order to study the intrinsic linewidth and to avoid the broadening due to dipolar interaction a hole-burning technique has been employed (see ref. 51).

Chemical modifications to Fe8Br have been also attempted. So far the most successful has been the partial substitution of bromide anions with perchlorate anions. $[Fe_8O_2(OH)_{12}(tacn)_6]Br_4(ClO_4)_4$, Fe8ClO4, has been shown to behave similarly to Fe8Br, with a ground $S = 10$ state. However the zfs of the ground state is slightly different in the two compounds. In particular the E/D ratio, which determines the rhombic splitting of the magnetic anisotropy, is larger than that of Fe8Br. Therefore the blocking temperature and the onset of quantum regime are different. It may be hoped that these small variations may provide additional handles to test the theories of quantum tunnelling.

Perspectives

The field of molecular nanomagnetism is just at the beginning. The advantage of molecular clusters, compared to all the other types of magnetic nanoparticles, is that they are all identical to each other and their structure is known. Further, intermolecular interactions in the crystal lattice are so weak that in most cases the response of the crystal is the same as that of an individual molecule. Therefore it is possible to measure a molecular response by using traditional macroscopic techniques. On the other hand, the fact that the molecules are bistable makes them interesting objects to be addressed individually. Therefore it can be foreseen that in the next few years techniques to address single molecules will be developed. Another important development to be expected is the synthesis of larger clusters, which will be investigated for a large number of different properties, such as those related with biocompatibility (for MRI contrast agents, or for magnetic drug delivery) and for the development of new physics. In fact the results already obtained have shown that these materials open exciting new perspectives in mesoscopic physics. For instance Fe8Br has for the first time provided an experimental confirmation of the so-called Berry phase in magnets,[53] a phenomenon long looked for. There are high expectations for the fundamental contributions that this highly interdisciplinary area can bring.

On-chip catalysis using a lithographically fabricated glass microreactor—the dehydration of alcohols using sulfated zirconia

Natalie G. Wilson and Tom McCreedy*

Department of Chemistry, University of Hull, Hull, UK HU6 7RX. E-mail: T.McCreedy@chem.hull.ac.uk

Received (in Cambridge, UK) 2nd March 2000, Accepted 22nd March 2000
Published on the Web 13th April 2000

A heated microreactor has been fabricated for heterogeneous catalysis, employing channels microfabricated in glass using photolithography and wet chemical etching; the demonstration reaction is the dehydration of alcohols.

There remains growing interest in miniaturised systems for chemical analysis and synthesis. These chemical analysis devices are commonly referred to as micro total analytical systems (μTAS), and have been reported for a diverse range of applications. Hadd *et al.*[1] employed laser induced fluorescence detection to determine a number of acetycholinesterase inhibitors after electrophoretic separation on a glass chip. A polymeric microchip was employed for the analysis of PCR products of the hepatitis C virus,[2] again laser induced fluorescence detection was employed. Fibre optically linked spectrophotometric detection of analytes on chip provides a convenient detection method for on-chip measurements, including the determination of nitrite *via* the formation of an azo dye,[3] and orthophosphate *via* the molybdenum blue reaction.[4] The integration of microfabricated devices with mass spectrometry offers a potentially powerful analytical tool, for example in the rapid analysis of proteolytic digests.[5] While electrophoretic processes prove vital for separations on chip, electroosmotic flow offers a very convenient pumping mechanism for fluidic manipulation, such as for moving solutions through micromachined filters.[6]

However, while great interest exists in μTAS, the application of similar devices to synthetic applications is deriving much interest. One only has to look through the proceedings of recent conferences (such as IMRET 3, Frankfurt, April 1999) to see the potential applications of such devices. These include highly exothermic reactions, *e.g.* the direct fluorination of aromatic compounds, the *in situ* generation of hazardous compounds, *e.g.* phosgene, and rapid energy transfer systems, *e.g.* fuel pumps. However, one area of interest to us is on chip heterogeneous catalysis. This represents an important area in organic synthesis, and there are many potential applications for miniaturised synthetic reactors able to utilise small amounts of catalysts in conjunction with very limited reaction volumes. This latter feature permits very rapid mass transfer and control of reaction conditions. In addition, the potential to employ electroosmotic pumping with such devices represents a very attractive feature, permitting reagents to be pumped by a device with no moving parts. Within the Hull group, much extensive work is on-going in the area of microreactors employing catalyst mediation, but the work reported here is the first in a heated system. Miniaturised catalytic devices can be used to conveniently gain kinetic and thermodynamic data for reactions. They are also convenient for screening new reactions and catalysts. The screening can either be with respect to the catalyst, *i.e.* to determine which catalysts show activity, or with respect to the reaction, *i.e.* which reaction shows promise on a certain catalyst.

Here, we report the dehydration of hexanol to hexene, and ethanol to ethene (with some degree of cracking). The catalyst used was sulfated zirconia (zirconia treated with sulfuric acid). This catalyst is known as a super acid catalyst with well documented reactions including the conversion of methanol to hydrocarbons,[7] isobutane/but-1-ene alkylation,[8] and the methoxymethylation of alcohols.[9] It has also been reported for the dehydration of alcohols to the associated alkene, with the added advantage that the reaction conditions are significantly milder than those required for other acid catalysts, such as silica-alumina. In a previous paper,[10] a 1 mm diameter reactor was reported to offer conversion efficiencies of only 3% for the conversion of hexanol to hexene, however in this paper, conversion efficiencies approaching 100% are reported (compared to the industrial process that only gives *ca.* 30% conversion).

Sulfated zirconia (ZrO_2/SO_4^{2-}) catalyst (MEL Chemicals, Swinton, Manchester, UK) was first activated by heating to 600 °C for 1 h in a microwave furnace (CEM). The microreactor used with syringe pumping was constructed from two plates. The base plate was produced by photolithography and wet chemical etching. The mask was produced in house and used to transfer the pattern onto glass coated with chrome and photo resist layers (Alignrite, Bridgend, South Wales). After etching in 1% $HF{\cdot}NH_3$(aq) for 1 h at 70 °C, the remaining photo-resist and chrome was removed. The channel dimensions were 200 μm wide by 80 μm deep and 30 mm long (in a 'Z' shaped configuration). The top plate was prepared from Sylgard 184 (ISL, West Midlands, UK), a polydimethylsiloxane (PDMS) resin and cast in a mould containing inserts to form the reservoirs. After baking for 1 h at 100 °C, the resin was released from the mould and the inserts removed. The mating face was then coated with a thin layer of PDMS and activated catalyst dusted over the surface; it was then baked at 100 °C for 1 h. The effect of this step was to give a high surface area for the catalyst reactor, but with the catalyst firmly immobilised. When these two surfaces were clamped together, the effect was to produce a reactor with one wall of the channel being catalytically active. The *in situ* heater was fabricated from Nichrome wire (Ni90/Cr10) 0.25 mm o.d. (Goodfellows, Cambridge, UK) immobilised in the PDMS top plate. The heating wire was inserted into the mould near to the mating face before the liquid PDMS was poured into the mould. The PDMS was stable to heating up to 175 °C (this temperature was not exceeded so no data exists beyond this point). Heating was achieved by a potentiostat (0–270 V) and monitored *via* a digital thermometer (Jencons model 2003) with the temperature probe (RS components) located close to the reaction channel. Where electroosmotic flow was used as a pumping method, a 2 cm long tube (0.5 mm i.d.) was inserted into the base plate, butting up to the start of the reaction channel. On-chip electroosmotic pumping is at present unreliable owing to vapourisation of the ethanol on the heated chip, however, this limitation is being overcome with the aid of a heat sink.

The hexan-1-ol was obtained from Avocado Research Chemicals (Heysham, UK), while other alcohols were obtained from supplies bottled in-house. Alcohols were purged with nitrogen for 10 min prior to use in order to minimise coking in the reactor; a frequent problem at high temperatures when trace oxygen is present. Pumping was achieved using a syringe pump (Baby Bee, BAS) or an electroosmotic pump fabricated as previously reported.[10]

The effect of temperature on the dehydration of hexan-1-ol to hexene has been studied in prior work, and an optimum conversion occurred at a temperature of 155–160 °C. This was

DOI: 10.1039/b001705l

used in this work. Currently, no optimisation of the ethanol temperature has been undertaken.

Hexan-1-ol was pumped through the reactor chip at a flow rate of 3 μL min^{-1} and a reaction temperature of 155 °C. The products were collected and analysed by gas chromatography using a Porapak Q column at 220 °C. From the gas chromatogram, a hexan-1-ol to hexene conversion on average between 85 and 95% could be determined. No additional products were detected, and the reaction was specific to hexene. The conversion efficiency is favourable compared to that observed with large-scale reactors, where 30% is common. The reactor was used constantly over three working days, and no degradation of the performance was observed.

Ethanol has been pumped by both electroosmotic flow and by means of a syringe pump. Initially, ethanol was pumped through the chip at a flow rate of 3 μL min^{-1} using a syringe pump and a reaction temperature of 155 °C. The products were collected and analysed by gas chromatography using a Porapak Q column at 50 °C. Only trace amounts of ethanol were detected, with most of the feedstock converted to ethene (68%), ethane (16%), and methane (15%). The electroosmotic pump produced repeatable flow rates of 0.9–1.1 μL min^{-1} at a field strength of 200 V cm^{-1}, giving a significantly greater residence time for ethanol in the reactor. The effect of this could clearly be seen in the GC results obtained where the only detectable product was methane. This indicates that the reaction has gone beyond dehydration to complete cracking of the feedstock. Trace amounts of methanol were also detected.

In conclusion, open channel on-chip microreactors have been demonstrated for the dehydration of alcohols to the associated alkene. While excellent results have been obtained with mechanical pumping, electroosmotic pumping appears to offer a significant advantage over other types of pumping, namely a very slow flow rate resulting in long residence times in the reactor. This can lead to a significant decrease in the required path length for reaction. Electroosmotic flow has a disadvantage since many liquids, *e.g.* hexanol exhibit no flow under applied potential, indeed the volume flow rate is inversely proportional to carbon chain length. The obvious outcome of this will be the further miniaturisation of reactors, and the potential for *in situ* production of chemicals.

We express thanks to Mel Chemicals (Manchester) for the donation of the sulfated zirconia. N. G. W. was funded by the Department of Chemistry, University of Hull.

Synthesis and structural characterization of a volatile, intramolecularly coordinated monomeric homoleptic magnesium alkylamide

William S. Rees Jr.,* Henry A. Luten and Oliver Just

School of Chemistry and Biochemistry and School of Materials Science and Engineering and Molecular Design Institute, Georgia Institute of Technology, Atlanta, GA 30332-0400, USA. E-mail: will.rees@chemistry.gatech.edu

Received (in Columbia, MO, USA) 2nd December 1999, Accepted 16th December 1999

The design, synthesis and X-ray crystal structure of the first intramolecularly coordinated homoleptic, monomeric and highly volatile magnesium alkylamide example, $Mg\{N[Si(CH_3)_3](CH_2)_3N(CH_3)_2\}_2$, are described.

The majority of structurally characterized magnesium–amide complexes, monomeric[1] or dimeric,[2] contain three- or four-coordinate metal centers, with a few compounds reported containing two-[3] or six-coordinate[4] magnesium. Numerous examples exist with intermolecular Lewis-base complexation, however, an intramolecular coordination motif for the central atom is uncommon for magnesium amides. Monomeric magnesium complexes possessing bidentate monoanionic ligands also are rather rare. In an ongoing effort to design and synthesize precursors for electronic materials, we have focused on developing highly volatile, thermally robust, ambient atmosphere stable, coordinatively saturated, oxygen-free magnesium alkylamide compounds as potential dopant sources for the CVD of GaN:Mg.[5] The synthesis and structural examination of the first intramolecularly coordinated monomeric magnesium alkylamide, which concomitantly possesses both substantial volatility and vapor phase integrity, are described herein.[6]

Magnesium bis[(γ-dimethylaminopropyl)trimethylsilylamide] **1**,† was prepared by reaction of the new secondary amine, γ-dimethylaminopropyl(trimethylsilyl)amine **2**‡ with dibutyl magnesium in hexane. This white solid has a high vapor pressure (intact sublimation at 80 °C and 10^{-2} Torr),[7] substantial vapor phase stability, and has been demonstrated, by TGA to have exceptionally clean transport characteristics (Fig. 1). The rather unusual combination of heightened vapor phase robustness and mild vaporization conditions are, to our knowledge, unique among magnesium compounds.

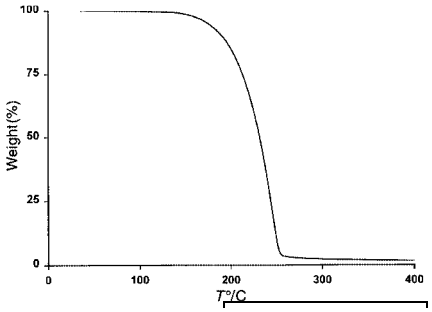

Fig. 1 Thermogravimetric analysis of $Mg\{N[Si(CH_3)_3](CH_2)_3N(CH_3)_2\}_2$, heating rate 10 °C min^{-1}, 1 atmosphere Ar.

A single crystal of suitable quality, obtained from a hexane solution at −80 °C, was mounted on a diffractometer under a cooled argon stream. The solid state structure of **1**, determined by X-ray diffraction,§ contains two crystallographically independent molecules in the asymmetric unit. Compound **1** is monomeric, has a four-coordinate distorted tetrahedral magnesium center, composed of four nitrogen atoms, two of which form covalent metal–amide interactions (ORTEP plot: Fig. 2). Nitrogen atoms bearing three fully saturated aliphatic groups and available lone pairs intramolecularly coordinate with the magnesium center, occupying the remaining two coordination sites.[8] The N1–Mg1–N3 (N5–Mg2–N7) interatomic angles of 137.57° (136.01°) are considerably wider than analogous angles present in di-solvated, four-coordinate, monomeric magnesium bis(amide) species $Mg\{N[Si(CH_3)_3]_2\}_2(THF)_2$[1a] (127.9°), $Mg\{N[Si(CH_3)_3]_2\}_2((2,3,5\text{-collidine})_2$[1c] (120.9) and $Mg\{N[Si(CH_3)_3]_2\}_2(4\text{-picoline})_2$[1c] (125.5). A similar trend is observed for the N2–Mg1–N4 and N6–Mg2–N8 angles (109.71 and 109.07°), which are substantially larger than the corresponding angles for the O(N)–Mg–O(N) donor interactions present in the compounds mentioned above: 89.9,[1a] 87.9[1c] and 86.8°.[1c] This may be explained by the diminished steric constraints imposed on the overall geometry of the complex by the newly designed, flexible, intramolecularly coordinated γ-dimethylaminopropyl(trimethylsilyl)amine ligand. A comparably disordered tetrahedral environment around the central metal atom (covalent N–Mg–N angles of 135.1 and 138.7°; dative N→Mg←N angles of 116.8 and 117.8°) also is encountered for the intramolecularly coordinated complex $Mg[N(8\text{-quinolyl})(SiMe_3)]_2$,[1d] which contains the rigid aromatic quinolyl ligand.

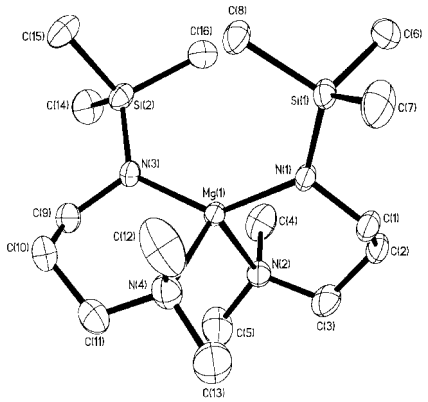

Fig. 2 ORTEP Representation of $Mg\{N[Si(CH_3)_3](CH_2)_3N(CH_3)_2\}_2$ with 30% probability thermal ellipsoids, and all hydrogen atoms omitted for clarity in viewing. Selected interatomic distances (Å) and angles (°) for compound **1**: Mg1–N1 1.988(2), Mg1–N2 2.190(2), Mg1–N3 1.982(2), Mg1–N4 2.185(2); N1–Mg1–N2 97.20(8), N1–Mg1–N3 137.57(9), N2–Mg1–N4 109.71(10), N3–Mg1–N4 98.19(9), Mg1–N1–Cl 116.64(15), Mg1–N2–C3 114.31(17), Mg1–N3–C9 117.52(16), Mg1–N4–C11 113.23(18).

The interatomic angles present within the rings formed as a consequence of N:→Mg intramolecular coordination for **1** (114.3–115.4°), well within standard data,[9] are evidence of lack of significant molecular strain, imposed as a consequence of ring formation. The N3–Mg–N4 plane forms an angle of 80.08(8)° with the Ni–Mg–N2 plane (80.71° for N5–Mg2–N6 and N7–Mg2–N8), thereby lending **1** a pseudo spiro geometry.

The magnesium–nitrogen interatomic distances found for **1** can be placed into two categories. Dative bond distances, resulting from interactions between tertiary nitrogen atoms and Lewis-acid sites on Mg^{2+}, Mg1–N2 and Mg1–N4 (Mg2–N6 and

DOI: 10.1039/a909746e

Mg2–N8) 2.190(2) and 2.185(2) Å [2.188(2) and 2.198(2) Å] agree well with previously reported values ranging between 2.096 and 2.259 Å.[1,2] The metal–amide distances Mg1–N1 and Mg1–N3 (Mg2–N5 and Mg2–N7) of 1.988(2) and 1.982(2) Å [1.977(2) and 1.983(2) Å] represent relatively short interactions, compared with corresponding data for other magnesium–amide compositions, which fall into the range of 1.959–2.188 Å.[1,2] In the present structure, no significant perturbation is evidenced in either type of Mg–N interaction for **1**, as compared with earlier work involving non-intramolecularly coordinating ligands, be they anionic or neutral in character. It is suggested that, to a great degree, the observed combination of high vapor pressure and high vapor phase molecular integrity for **1** has its origin in these structural details. The design of an appropriate (*i.e.* flexible arm on a saturated alkyl tether) pendant amine to intramolecularly coordinate the metal center fulfills its requirements as manifested by the 'normalcy' of the metrical and geometrical data measured for **2**. As clearly demonstrated in the TGA (Fig. 1), **2** is quite volatile, even at 1 atm. Unlike simple organic compounds, where vapor pressure, to a first order, inversely follows molecular weight, organometallic compounds show not only simple van der Waals interactions in the condensed state. The dominant intermolecular forces for organometallic compounds in the condensed state are dipole–dipole interactions. Thus, the unusually high vapor pressure exhibited by **2** would seem to indicate that it might have a relatively small dipole moment. In related work, we have shown recently that such trends serve some predictive role for zinc bis(amide) compounds.

One interesting feature of **1** emerges upon examination of the ^{1}H and ^{13}C solution state NMR data. The methyl groups represented by C4, C5, C12 and C13 are magnetically inequivalent in this environment. This is understood best by examination of the plane represented by N3–Mg–N4 (or N1–Mg–N2), and noting that C12 resides on the side of the plane containing N2, while C13 resides on the N1-containing side. This is evidenced by a ^{1}H NMR chemical shift difference of 0.44 ppm for the methyl groups, and a 2.0 ppm ^{13}C NMR chemical shift difference. As expected, the ambient temperature solution dynamic structure portrays a single environment for the TMS methyl groups; however, ^{1}H inequivalence also is exhibited at C3 and C11 (difference of 0.38 ppm) and C1 and C9 (difference of 0.29 ppm), while C2 and C10 experience equivalence under these conditions. Apparently, ring flip motion equilibrates the later, while the methylene positions α to each nitrogen, both amide and amine, bear the influence of asymmetry. This may be compared with an extremely recent example of a Mg bis(1-azaalkyl) compound, which has a rigid chair skeletal conformation in the solid state, yet has solution NMR data reported which indicate dynamic behavior at ambient spectrometer conditions on the observational time scale.[10]

In summary, the first example of intramolecular coordination for a monomeric magnesium alkylamide has been designed, prepared and structurally characterized.[12] The two nearly perpendicular rings, exhibiting negligible strain, as evidenced by typical interatomic angles, are formed by the simultaneous occurrence of both tertiary amine donation at the end of a flexible alkyl tether and ionic amide attachment to the metal center. Compound **1**, highly stable in the vapor phase and portraying substantial vapor pressure, differs from earlier intermolecular adducts,[2d] which can irreversibly dissociate free Lewis base, penultimately producing lower coordinate transients that subsequently oligomerize into low vapor pressure species.[12]

We gratefully acknowledge the ONR for financial support. W. S. R. was awarded an Alexander von Humboldt Fellowship with Prof. H. Schumann at the TU Berlin in 1998–1999.

6 The use of the nomenclature magnesium(alkylamide) is standard to differentiate the organic substituent present on the amide. For an example of a magnesium(arylamide) see ref. 1(*d*).

7 Compounds with intermolecular coordination have been reported recently; however, little data related to vapor phase stability was provided.

8 To our knowledge, the only other reported example of a structurally characterized intramolecular coordination in a magnesium amide involved the aromatic amine quinoline.

1-Iodohexa-1,3,5-triyne (I) and hexa-1,3,5-triyne (II) spontaneously polymerise in aprotic solution to form a solid carbonaceous product which contains polyyne-like structures and multi-walled carbon nanotubes with outer diameter *ca.* 10–20 nm and length 100–200 nm.

Carbon nanotubes are conventionally produced by high-temperature (T > 1000 °C) catalytic processes. Nanotubes and fullerenes can also be prepared, albeit in low yield, at room temperature by chemical defluorination of perfluorocyclopentene, perfluorodecalin and perfluoronaphthalene.[1] Kawase *et al*.[2] have shown that a totally defluorinated poly(tetrafluoroethylene) (PTFE) can be partly transformed into carbon nanotubes (10–50 nm diameter, 1 μm length) by irradiation with fast electrons (100 kV; 103 C cm^{-2}) at 800 °C. The process assumes the presence of reactive polyyne, which is formed by electrochemical reductive defluorination of PTFE,[2] Scheme 1.

$$(-CF_2CF_2-)_n \xrightarrow[-4n\ F^-]{4n\ e^-} (-C{\equiv}C-)_n \xrightarrow{800\ °C,\ e^-} \text{C-nanotubes}$$

Scheme 1

However, the polyyne, $(-C{\equiv}C-)_n$ hardly exists in the pure state.[3] The actual precursor of nanotubes in Scheme 1 is, probably, a disordered graphitic carbon containing some chemically bound oligoyne segments with conjugation lengths less than 16 C-atoms.[3,4] If the electron/heat treatment in Scheme 1 was omitted, no nanotubes grew.[2] Also, no defined carbonaceous nanoclusters were found in PTFE defluorinated by alkali metal amalgams.[1]

To avoid the poorly defined precursor in Scheme 1, we have explored whether carbonaceous nanoparticles can be synthesised as in Scheme 1, but from chemically defined low-molecular-weight oligoynes. The reactants of choice seem to be hexatriyne derivatives: butadiyne is almost inert against chemical carbonization,[5] but higher homologues are too reactive to be handled safely.

Hexa-1,3,5-triyne (**II**), was prepared from prop-2-ynylol.[6] 1-Iodohexa-1,3,5-triyne (**I**) was synthesised from hexa-1,3,5-triyne according to a procedure developed by ourselves[5] Briefly, **II** was monolithiated by a stoichiometric amount of MeLi in THF at −30 to −40 °C, and Li was subsequently substituted with iodine.[5,7] Both precursors **I** and **II** are ultimately stable only in solution at low temperatures.

'Poly(iodohexatriyne)' was prepared as follows: a freshly made 0.3–0.4 M solution of **I** in *n*-hexane–diethyl ether (*ca.* 1 : 1 *v/v*; water concentration < 50 ppm; stored under Ar) was vacuum evaporated at room temperature over several minutes, while an insoluble, explosive, brown solid remained. Its composition was not too far from that of the precursor. (Elemental analysis: C 39.65, H 1.23, I 57.20%. Calc. for C_6HI: C 36.04, H 0.50, I 63.46%). The solid was, presumably, produced as a result of radical polymerisation of **I**, which progressed according to a *brutto* scheme (Scheme 2) A more stable, non-explosive material was prepared by slow polymerisation of **I**. This occurred simply after storing the solution

$$n\ IC{\equiv}C-C{\equiv}C-C{\equiv}CH \longrightarrow {=}(IC-C{\equiv}C-C{\equiv}C-CH)_n{=} \Longleftrightarrow -(IC{=}C{=}C{=}C{=}C{=}CH)_n-$$

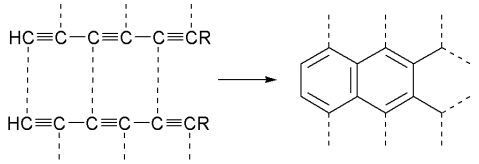
Scheme 2

under Ar for 1–2 d at room temperature. During this time, a dark brown powder precipitated, and a brown-yellow film deposited on the walls of the reaction vessel. When the reaction progressed, the film tended to peel off and roll into fine tubes. The addition of a small amount of *n*-undecane to the solution impeded the film formation and the product was mostly powder. On the contrary, the film formation was promoted by the addition of THF or ethyl acetate. The product was isolated by filtration, washed with hexane and diethyl ether, dried in vacuum at room temperature and stored under Ar. Elemental analysis evidenced some carbonisation, as the iodine content decreased: C 53.50, H 1.17, I 45.20%. [The difference from 100% mostly corresponds to adsorbed Ar (*vide infra*)]. The loss of iodine was further promoted by illumination with UV light (100 W high-pressure Hg lamp). The photo-assisted polymerisation–carbonisation of **I** gave a product containing: C 57.27, H 1.55, I 38.90%. Infrared spectra of 'poly(iodohexatriyne)' (both powder and film) exhibited comparable features with a characteristic intense band of conjugated sp-bonded carbon atoms (polyyne-like) between 2184–2194 cm^{-1}.

The polymerisation of hexatriyne **II** in *n*-undecane or *n*-hexane (water concentration < 50 ppm) was considerably faster compared to that of iodohexatriyne. It occurred within *ca.* 1 h at room temperature or within 1 d at 0 °C. The reaction accelerated with temperature (from 0–60 °C) and the concentration of **II** (up to 0.8 M). The addition of THF, diethyl ether or benzene promoted the formation of a yellow-brown film at the walls of the reaction vessel. Methanol, on the other hand, blocked any precipitation, and only soluble products were formed. Elemental analysis of a solid 'poly(hexatriyne)' gave: C 88.21, H 3.37%. The sample reversibly lost about 10% of its weight at 250 °C in vacuum, but this was almost completely re-captured if the outgased sample was exposed to Ar (weight increase 9.2%). This roughly accounts for the difference of analytical data from 100%, if we assume that Ar adsorbs from the sample's environment (calculated for C_6H_2: C 97.28, H 2.72%). The 'poly(hexatriyne)' exhibited two IR bands at 2110 and 2188 cm^{-1}, whose intensity was much smaller compared to those of 'poly(iodohexatriyne)'.

A pure 'one-dimensional' polymerisation (Scheme 2) seems to take place only after a fast rise of the concentration of **I**. Slow reactions in the solution are dominated be 'two-dimensional' polymerisation, which occurs *via* cross-linking of oligoyne sections in the precursor and/or in the primary chain-like polymer (*cf.* Scheme 2). The cross-linking of hexatriyne to yield graphene segments is shown in Scheme 3, where R = I, H. There are numerous theoretical[8] and experimental[3] arguments that the two-dimensional polymerisation (Scheme 3) is highly favoured, while it may produce extended graphite-like structures. The graphitisation (Scheme 3) seems to also provide a driving force for the partial splitting off of iodine and hydrogen

DOI: 10.1039/b000895h



Scheme 3

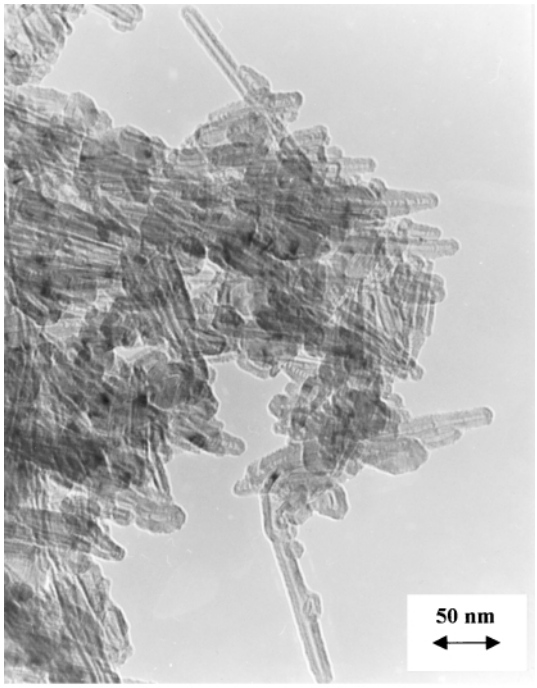
from the precursor. However, the mechanism of propagation of the extended graphene is unknown.

The presence of iodine in the precursor **I** retards the polymerisation–carbonisation and stabilises the chain-like structure (Scheme 2). Hence, hexatriyne **II** exhibits a larger tendency towards the two-dimensional polymerisation (Scheme 3). Analogously, iodobutadiyne and 1,4-diiodobutadiyne[5] are inert in *n*-hexane (they polymerise only after UV excitation).[5] Butadiyne in *n*-hexane exhibited a very slow spontaneous polymerisation at room temperature in the dark, yielding solely a thin film at the walls, but the film showed a strong IR band at 2246 cm^{-1}. These results match the general conclusion that the stability of sp-bonded all-carbon chains against cross-linking increases when the chains contain bulky substituents at defect sites.[3]

Transmission electron microscopy (TEM) of both 'poly(iodohexatriyne)' and 'poly(hexatriyne)' revealed a presence of multi-walled carbon nanotubes (Fig. 1). The nanotubes were found in all the studied samples except 'poly(hexatriyne)' generated at temperatures ⩾40 °C. (At higher temperatures, the hexatriyne conversion to planar graphene (graphite) seems to prevail). The highest content of nanotubes was found in 'poly(hexatriyne)' polymerised at 0 °C. The nanotubes were not spread statistically in the sample: they formed agglomerates (as in Fig. 1) embedded in a material with an amorphous shape. Hence, the yield of nanotubes cannot be precisely determined. By comparison with many TEM pictures, we estimate the yield of nanotubes to be roughly 1% in good samples. Some products showed also a casual occurrence of spherical onion-like nanoparticles (*cf.* Fig. 1). The nanotubes in 'poly(hexatriyne)' and 'poly(iodohexatriyne)' resemble those generated by reductive defluorination of perfluorocyclopentene.[1] Typically, the nanotubes, are straight, multi-walled, with diameter 10–20 nm and length 100–200 nm, and they are capped by onion-like hemispheres. The presence of curved moieties (onions, nanotube-caps) requires that some five-membered carbon rings are also formed *via* the interchain reaction (Scheme 3). However, the mechanism of pentagon-formation is again unclear. Our nanotubes (grown at low temperature both from hexatriyne and fluorocarbons[1]) are narrower and shorter than those grown from ex-PTFE 'polyyne' by electron bombardment at 800 °C.[2]

Raman spectra of the nanotube-rich 'poly(hexatriyne)' displayed only two broad bands at 1350 and 1600 cm^{-1}, which can be assigned to polycrystalline graphite and/or multi-walled carbon nanotubes. (These two structures are difficult to distinguish by Raman spectroscopy). If we assign the Raman bands at 1350 and 1600 cm^{-1} to the graphite D and G lines, respectively,[4] their intensity ratio (0.43) allows the size of graphite crystals to be estimated at about 10 nm. (Similar-size graphite nanocrystals result also from cross-linking of PTFE-borne 'polyyne'.[3,4]) In accord with TEM, no single-walled carbon nanotubes were detectable in the region of the radial breathing mode (*ca.* 200 cm^{-1}).

In conclusion, hexatriyne derivatives show a pronounced tendency towards conversion into disordered graphene-like nanostructures, *viz* multi-walled carbon nanotubes. The production of nanotubes from hexatriyne seems to be more facile and more efficient, compared to the processes based on defluorination of octafluorocyclopentene and similar precursors.[1] Further effort should concentrate on the understanding and optimisation of the chemical synthesis of nanotubes. This knowledge might also help us to understand the mechanism of production of carbon nanotubes in the common high-temperature catalytic processes.



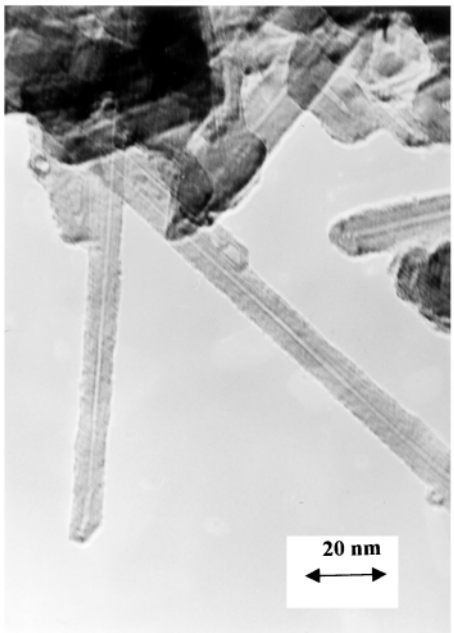


Fig. 1 Transmission electron microscopy of carbonaceous material prepared by spontaneous polymerization of hexatriyne at 0 °C.

Received (in Cambridge, UK) 19th January 2000, Accepted 28th March 2000
Published on the Web 13th April 2000

Mesoscopic string structures of single 5,5′-dichloro-3,3′-disulfopropyl thiacyanine J aggregates produced in an aqueous solution were observed directly by both fluorescence microscopy and microspectroscopy.

J aggregates are specific organic dye assemblies discovered by Jelley and Scheibe,[1,2] and characterized by a narrow and intense absorption band that shows a bathochromic shift compared to the relevant monomer band.[3] On the basis of such optical characteristics, the aggregates have been often used as spectral sensitizers in photography.[4] Recent interest has also focused on the ability of J aggregates to exhibit coherent excitation phenomena which provide large optical nonlinearities.[5,6] Since the aggregate structure reflects highly on its spectroscopic properties such as the spectral line shape and peak energy, detailed investigations of the structures and/or morphologies of *single* aggregates are of primary importance. Previous studies demonstrated that a pseudoisocyanine (PIC) dye produces J aggregates at a mica/solution interface, and the single aggregate has a three-dimensional disk-like island structure in the mesoscopic size range as elucidated by tapping mode AFM (atomic force microscopy) in solution.[7,8] On the other hand, although structural and/or morphological differences are expected between the J aggregates at a solid/liquid interface and those produced in bulk solution,[9] details have been poorly understood since a real structure of the aggregates in solution have not been observed *in situ*. In this study, we report a direct observation of single thiacyanine J aggregates in an aqueous solution by both fluorescence microscopy and microspectroscopy.

Sample solutions were prepared by dissolving a 5,5′-dichloro-3,3′-disulfopropyl thiacyanine sodium salt [abbreviated as TC; chemical structure shown in the inset of Fig. 1; Nippon Kankoh-Shikiso Kenkyusho (99%)] in an aqueous NaCl (5.0 mM) solution under moderate heating (< 60 °C). Fluorescence microscope images were obtained by using a CCD camera (Hitachi, Remote Eye) set on an optical microscope (Nikon, Optiphoto-2). Fluorescence spectroscopy under the microscope was conducted by using a polychromator–multichannel photodetector set (Hamamatsu Photonics, PMA-11) equipped on the microscope.[10] An Xe beam (Hamamatsu Photonics, L2273) passed through an interference filter (KL-45, Toshiba Glass) or an Ar^+ laser beam (Coherent, Innova 70) at 454.5 nm were used as the excitation sources for fluorescence imaging and spectroscopy, respectively. A sharp-cut filter (Y-47, Toshiba Glass) was mounted in front of the CCD camera–photodetector set to eliminate scattering light of the excitation beam. Measurements were performed at room temperature.

Fig. 1 shows the absorption and fluorescence spectra of TC in aqueous NaCl solutions at different concentrations ([TC] = 0.2, 0.1, 0.05 and 0.03 mM) with a set optical path length of 300 μm. When the concentration of TC is > 0.05 mM, the absorption spectrum [Fig. 1(a)] showed a sharp and intense J band at *ca.* 464 nm in addition to the monomer (430 nm) and dimer bands (408 nm). The peak position and line width of the J band was constant under these concentrations, indicating that the internal structure of the J aggregate was unchanged. The fluorescence spectrum [Fig. 1(b)] does not show a Stokes shift, which is characteristic of J aggregates.[11]

In concentrated solutions, distinctive opalescence was observed. Therefore, fluorescence microscopy was conducted to examine the microstructures of the TC J aggregates. Fig. 2 shows fluorescence microscope images at [TC] $\geqslant$ 0.05 mM, above which the J band appears and mesoscopic string structures were clearly observed. Since a characteristic fluorescence image was not detected below 0.05 mM, the strings distributed in solution were considered to be J aggregates of TC. To the best of our knowledge, this is the first observation of mesoscopic J aggregates in a solution phase. The length of the string was several tens of μm while the width was very narrow; sub- or a few μm. This string structure of the J aggregate is probably due to anisotropic interactions between TC molecules in solution (*i.e.* quasi-one-dimensional stacking interactions), different from that of PIC J aggregates observed at a solid/liquid interface.[7,8] A single string is likely to bend in an arc form, suggesting that the mesoscopic J aggregate is flexible and polycrystalline-like. The fluorescence images also show that morphologies of the aggregates were dependent on the TC concentration. With a decrease in the concentration, the density of the string decreased while the length of the aggregate was slightly increased. The results are probably due to lower supersaturation at a low concentration which leads to generation of fewer nuclei, and the string would grow to a larger size; *cf.* microcrystallite formation processes. It is worth noting, furthermore, tha single J aggregates could be optically trapped by

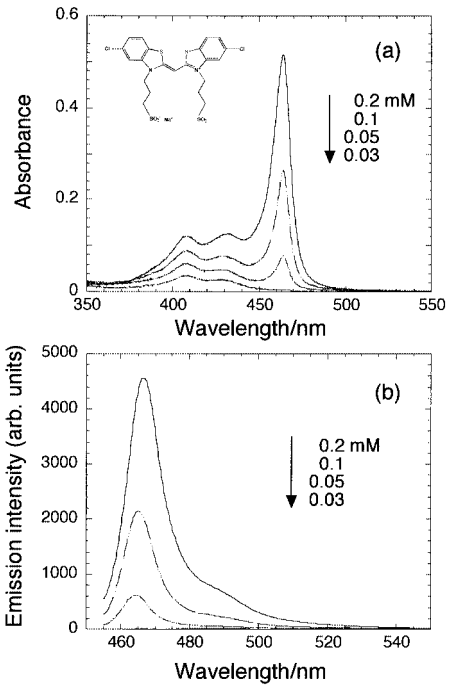

Fig. 1 Absorption (a) and fluorescence (b) spectra of TC in an aqueous NaCl solution ([NaCl] = 5 mM): optical path length = 300 μm.

DOI: 10.1039/b000548g

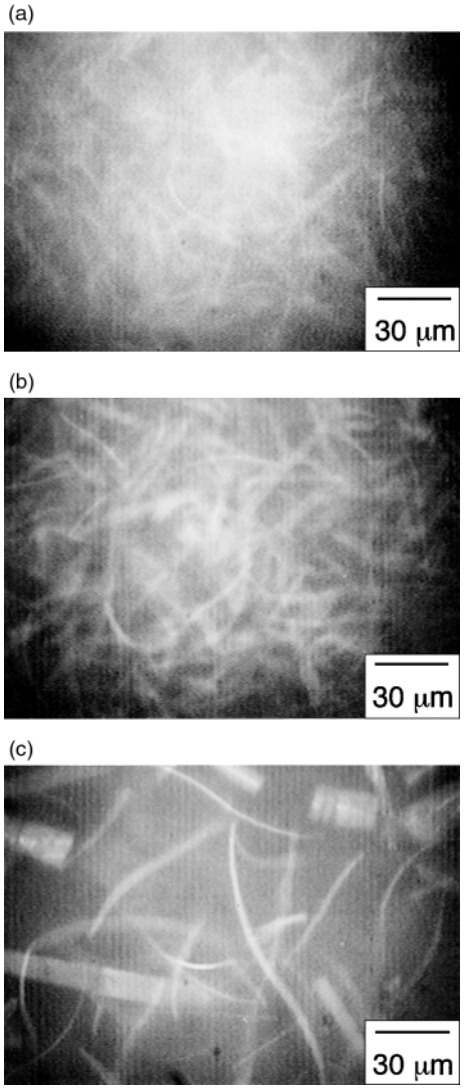

Fig. 2 Fluorescence microscope images of the TC J aggregates in aqueous NaCl solutions. (a), (b) and (c) show images at [TC] = 0.2, 0.1 and 0.05 mM, respectively. The mesoscopic strings correspond to the TC J aggregates.

a focused laser beam at 1064 nm (optical tweezers) and details will be described elsewhere.[12]

Fig. 3 shows fluorescence spectra observed for a single string and at the periphery of the string {[TC] = 0.05 mM, corresponding to Fig. 2(c)}. The excitation beam diameter was *ca.* 10 μm, and the measurements were conducted at various positions in the string. However, the spectral band shape did not change with the observation position in the string. Since the spectrum was quite similar to that in Fig. 1(b), the strings seen in Fig. 2 were concluded to be TC J aggregates.[13] It is noteworthy that fluorescence was scarcely observed at the outer periphery of the strings, indicating that TC in an aqueous solution produces exclusively mesoscopic-size J aggregates.

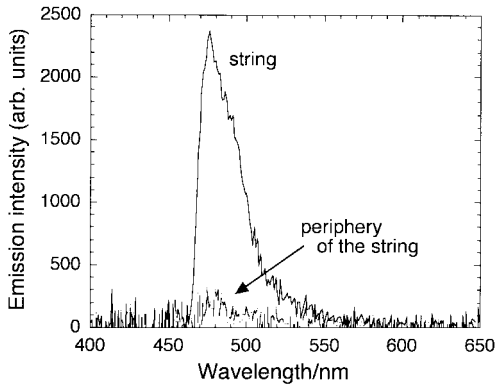

Fig. 3 Fluorescence spectra observed for a *single* string of TC J aggregates and at the periphery of the string: concentration of TC = 0.05 mM.

Recently, the structures of TC J aggregates with different counter cations in solution have been studied by synchrotron XRD and NMR spectroscopy by Tiddy *et al.*[14,15] The results suggested that the J aggregates involve thousands of molecules, which generate a liquid-crystalline lamellar phase composed of ordered dyes and water layers in an aqueous solution. If similar morphologies are also expected in our system, the observed single string could show a lamellar phase, and the water content could be more than *ca.* 95%, which would probably be the origin of the flexibility of the aggregates. Thus, detailed microstructures of the J aggregates are worth studying by various local sensing tools such as AFM and SNOM (scanning near-field optical microscopy), and work along such lines is now in progress.

Received (in Cambridge, UK) 31st January 2000, Accepted 27th March 2000
Published on the Web 13th April 2000

Surface plasmon resonance measurements have been conducted to construct a unique electrochemical enzyme sensor which detected the reversible change in the refractive index of a redox film containing an enzyme.

A number of electrochemical biosensors have been constructed based on the enzymatic consumption of substrates and the electrochemical regeneration of an active enzyme by electron mediators. These electrochemical biosensors convert the analyte concentration to faradic current and this current is proportional to the concentration gradient of the electrochemically active molecules on the electrode surface. Meanwhile, surface plasmon resonance (SPR) has been used to measure biological reactions in real time. For instance, DNA elongation by polymerase has been measured in real time using SPR.[1] We have shown that SPR measurements can be used to detect certain electrochemical reactions.[2,3] The combination of SPR and electrochemical measurements will make it possible to detect the refractive index of an electrochemically activated enzyme-mediator film. Here we describe our SPR-based analysis of immobilized enzyme films for electrochemical biosensor applications, and propose a novel transducer element.

Thin gold film electrodes were coated with a horseradish peroxidase (HRP)–osmium redox polymer solution and dried for immobilization.[4] It is expected that reduced and oxidized HRP–osmium films in an electrolyte will have different refractive indices, and that the refractive index will change with the electrode potential and can be used to indicate an enzymatic reaction. However, the refractive index may also depend on the redox reaction of HRP, osmium ions and their ionic environment, the substrate/product concentration, and the packing of the film. When the redox reaction chain is working, all these values change and this affects the minimum reflection angle in SPR measurements (θ_{SPR}). We investigated the effect of catalytic electrochemical reactions on θ_{SPR} values. First, we measured θ_{SPR} for the HRP–osmium redox polymer immobilized electrode simultaneously with cyclic voltammetry without the HRP substrate. The cyclic voltammogram (CV) showed a narrow peak separation and symmetric waves which are characteristics of reactions of an immobilized species.[5] In the absence of hydrogen peroxide (substrate of HRP), Os^{3+} ions are not regenerated by chemical reaction. Therefore, the θ_{SPR} change in the CV was the result of the redox reaction of the osmium film. The θ_{SPR} response showed a bimodal change with potential (similar to that in Fig. 1). We also observed similar θ_{SPR} changes in a solution containing 1 M $NaClO_4$. The value of θ_{SPR} increased at lower potentials, and the potential at which the θ_{SPR} value showed the steepest change was the same as the CV peak potential. This is because of the change in the concentration of ions in the film to compensate the charge neutrality which depends on the valence state of the osmium ions.[6]

In the presence of the HRP substrate the CV shown in Fig. 1 was obtained. In this CV, the hydrogen peroxide was reduced by HRP and a catalytic current was observed. The dependence of θ_{SPR} on the potential was flat in the potential region far from the formal potential, indicating that θ_{SPR} changes from other factors is small. In the potential range in which the catalytic current was observed, oxidized osmium ions (Os^{3+}) were regenerated by the enzymatic reaction. However, the curve of θ_{SPR} *vs.* potential showed a bimodal change, and the graph was almost the same as that obtained without hydrogen peroxide. Therefore, the effect of the redox state of the enzyme and hydrogen peroxide on the θ_{SPR} was far less than that of the mediator film. In the above experiments, the maximum concentration gradient in the film was at the electrode surface when a catalytic current was observed. When the electrode potential is not controlled, the mediator will be oxidized chemically by the enzyme until it is fully oxidized. The concentration ratio of the reduced and oxidized mediator at the electrode surface can be monitored in terms of the electrode potential by means of a potentiometric experiment.

Next, we carried out chronopotentiometry for the catalytic electrochemical reaction as shown in Fig. 2A. Before the chronopotentiometry was started (E = 0 mV), θ_{SPR} increased because of reduction of the film. At zero time, the working electrode was set in the potentiometer mode and θ_{SPR} remained unchanged in the absence of hydrogen peroxide (0 M). In the presence of hydrogen peroxide, θ_{SPR} began to decrease with this being more marked with an increase in hydrogen peroxide concentration. This indicates that the ratio of the reduced form of the film (Os^{2+}) near the electrode surface decreased through the enzymatic consumption of hydrogen peroxide by HRP. The rate of change of θ_{SPR} can thus be used to determine the substrate concentration. Moreover, this method does not require electrochemical instrumentation; we can simply employ the chemical reduction of a mediator using a flow system. Fig. 2B shows the potential change measured by chronopotentiometry. As with the SPR measurement, a potential change was observed in the presence of hydrogen peroxide owing to a decrease in the reduced form of the film. At low hydrogen peroxide concentra-

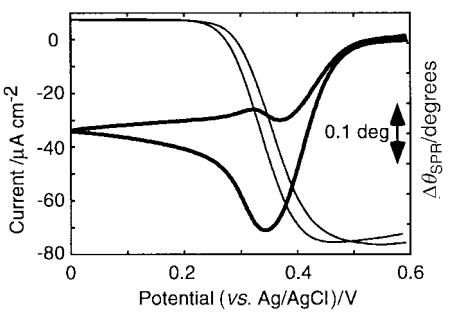

Fig. 1 θ_{SPR} (thin line) dependence of the electrode potential measured simultaneously with cyclic voltammetry (thick line) for an HRP–osmium redox polymer immobilized electrode in 0.1 M phosphate buffer (pH 7) with 10 mM hydrogen peroxide: scan rate 10 mV s^{-1}, geometric surface area = 0.16 cm^2.

DOI: 10.1039/b000866o

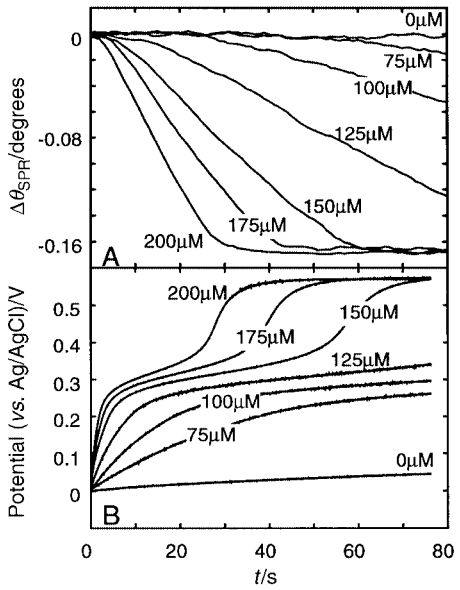

Fig. 2 Time course of θ_{SPR} (A) and equilibrium potential (B) in the chronopotentiometry of an HRP–osmium film with various substrate concentrations. The SPR measurement was initially held a potential at 0 mV for 1 min and then the working electrode was set in the potentiometer mode (t = 0) and simultaneous chronopotentiometry was started. The formal potential ($E^{0\prime}$) was evaluated from the peak potentials of the CV in the absence of the substrate, F is the Faraday constant, R is the gas constant and T is the measuring temperature.

tions, the potential change was also smaller than at higher hydrogen peroxide concentrations. As the concentration ratio of reduced Os ions (Os^{2+}) approached 0.5, the electrode potential change became slower, and a potential plateau (Fig. 2B) was observed.

Fig. 3 shows the relation between θ_{SPR} and the electrode potential of the experiment in Fig. 2. The fraction of reduced film was calculated from the measured potential (Fig. 2B) based on the Nernst equation, and θ_{SPR} was plotted. Despite the

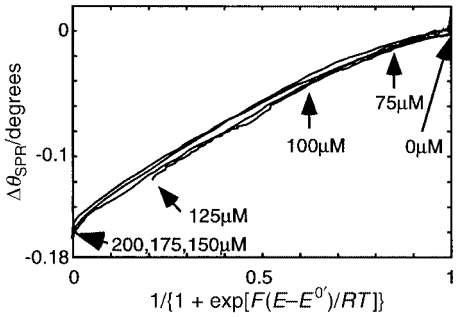

Fig. 3 Relation between θ_{SPR} and surface concentration ratio in the experiment shown in Fig. 2. The arrows indicate the position at 80 s for each substrate concentration.

different substrate concentrations, the trajectories traced the same curve. This implies that the film reacted uniformly and θ_{SPR} represented the redox state of the mediator film in real time. The SPR detection of an enzyme containing redox film can provide a new method of enzyme sensor detection. The physical sensing space can be greatly reduced because of the nature of SPR, and a small dead volume sensor can be constructed. The time response of this method can be improved using a higher sampling rate for the SPR signal. In addition, kinetic information on the multistage enzyme reaction can be obtained. We are currently constructing enzyme sensors using glucose oxidase.

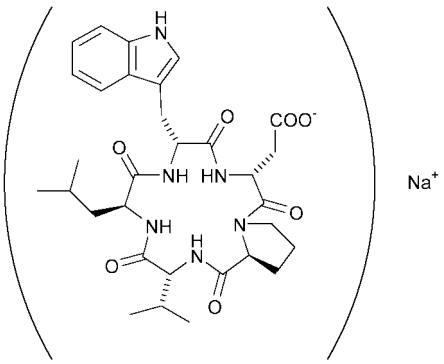
Received (in Cambridge, UK) 28th November 1999, Accepted 20th March 2000

The crystal structure of *cyclo*(D-Trp-D-Asp$^-$-Pro-D-Val-Leu-)·Na$^+$, a potent endothelin-1 antagonist, showed four conformational isomers and two Na$^+$-caged structures in pairs.

Endothelin (ET) is an endogenous vasoconstrictor peptide with 21 amino acid residues.[1] Two cyclic peptapeptides of BE18257A and B, isolated from *Streptomyces misakiensis*,[2,3] antagonize the ET induced vasoconstriction by binding to the ET-A receptor subtype.[4] The peptide BQ123, *cyclo*(-D-Trp-D-Asp-Pro-D-Val-Leu-), was designed from these leading peptides (Scheme 1).[5,6] Many NMR studies have been carried out on ET,[7–11] and it was recently suggested[11] that BQ123 partially resembles the structure of ET-1 determined by X-ray diffraction.[12,13] In spite of such intensive approaches, no structures of ET antagonists have been elucidated in the solid state. We reported here, the crystal structure of the sodium salt of BQ123.† This is the first X-ray structural analysis of an ET antagonist.



Scheme 1

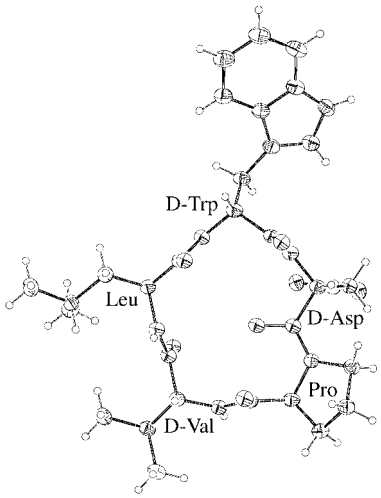


Fig. 1 Molecular conformation of BQ123. Since the conformations of four independent molecules are very similar to each other, only molecule 1 is drawn.

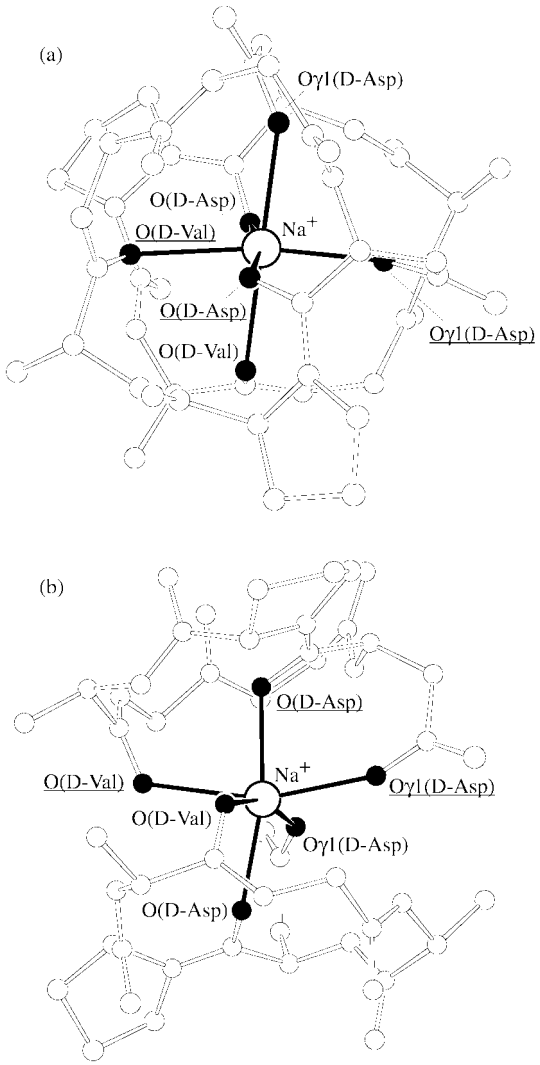

Fig. 2 A caged structure composed of two peptides and a Na$^+$ ion. (a) Top and (b) orthogonal side (rotated −90° for horizontal axis) views. Hydrogens and side chains of D-Val, Leu and D-Trp are omitted for clarity. Filled bonds and balls represent Na–O bonds and coordinated oxygen atoms, respectively. Oxygen atoms of independent molecules 1 and 2 are distinguished by underlined labels. This structure corresponds to one of two similar caged structures in the crystal.

DOI: 10.1039/a909413j

Four independent peptide molecules are located in an asymmetric unit. Conformational differences are observed in the side chain rotation of Trp and the puckering of Pro among the independent molecules, although their overall conformations are similar to each other; the rms deviations are 0.10–0.17 Å in the main chains. Fig. 1 shows the conformation of a single peptide molecule. The conformation of BQ123 is similar to the solution structure of the Na^+-free form in methanol and chloroform,[10] though some local differences are induced *via* the interactions with ions. The most prominent feature in the crystal is the Na^+-coordinated form sandwiched between two independent peptides in pairs, as shown in Fig. 2. The carbonyl oxygens (C=O) of D-Asp and D-Val and the carboxyl oxygens (COO^-) of D-Asp are coordinated to the Na^+ ion, forming an octahedral structure. In this form, the carboxyl and the carbonyl oxygens of the Asp residues are coordinated at the *cis* and *trans* positions, respectively, and these six Na–O bonds range in distance from 2.2 to 2.5 Å. Intermolecular hydrogen bonds are formed between the two BQ123 molecules wrapping the Na^+ ion (not shown in Fig. 2), and thus the peptide molecules form a unique caged structure specific for the Na^+ ion. Two similar caged structures are formed in the crystal, and are distinguished based on interaction modes with the solvents and the two remaining Na^+ ions forming either five- or six-coordinate bonds.

Although we surveyed the characteristics of the structures of ET-1 and the Na^+-ion and BQ123 complexes, no similarities were found, except for a number of amino acids (ET-1 is composed of 21 amino acids, and the total residue number of the four independent cyclic pentapeptides is 20). However, considering that both peptides selectively bind to the ET-A receptor, such differences and the unique structure of the sodium salt of BQ123 are important information for identifying the stereospecificity of the ET-A receptor.

Notes and references

† *Crystal data* for BQ123·Na: $4C_{31}H_{41}N_6O_7Na{\cdot}10H_2O{\cdot}8C_3H_7OH$, M = 3192.6, orthorhombic, space group $P2_12_12_1$, a = 25.3987(3), b = 34.7167(3), c = 25.7365(3) Å, V = 22693.4(24) Å^3, Z = 4, D_c = 0.934 g cm^{-3}, $F(000)$ = 6864, μ = 0.076 mm^{-1}, λ = 0.834 Å, T = 100 °K, 35804 independent reflections were used, θ_{max} = 31.42° (0.80 Å resolution). The molecular weight of BQ123·Na is > 3000 Da, and all attempts to solve the structure using the intensity data collected using commercial X-ray generators (Rigaku RU200/300) failed. The data were, therefore, measured using a Rigaku RAXIS-4 on a synchrotron, SPring-8/BL24XU-A (the figure-eight undulator and double-crystal monochromator system), with the approval of Hyogo prefecture and the Japan Synchrotron Radiation Research Institute (Approval No. C99A24XU-005N and 006N). The structure was finally solved by the electron density modification method using LODEM[14] and refined using SHELXL-97.[15] The solvent molecules were located by difference Fourier syntheses, and 8 isopropyl alcohol and 16 water molecules were found between the peptides. Some solvent sites were disordered: the calculated occupancies of two isopropyl alcohol molecules were 0.55 and 0.75, and those of 8 water molecules ranged from 0.16 to 0.36. Hydrogens of peptides were calculated in geometrically ideal positions by the 'ride on' method, and the hydrogens of solvent molecules were found from the Fourier map considering hydrogen-bonding networks. All hydrogens were included in the calculation of structure factors with isotropic temperature factors. A total of 2088 refinement parameters were divided into three blocks, and the positions and temperature factors were refined in a single refinement cycle. The $R1$ and wR values converged to 0.0845 and 0.2146, respectively, and goodness of fit = 1.044, $\Delta\rho_{max}$ = 0.572 e Å^3 and $\Delta\rho_{min}$ = −0.383 e Å^3.

Received (in Cambridge, UK) 17th February 2000, Accepted 21st March 2000

An Fe ion-exchanged BEA zeolite (Fe-BEA), which effectively performs selective catalytic reduction of N_2O with methane in the presence of excess oxygen, is much more active than Fe-MFI zeolite reported in the literature.

Nitrous oxide (N_2O) and methane (CH_4) are strong greenhouse-effect gases with a global warming potential (GWP) per molecule of *ca.* 300 and 30 times that of carbon dioxide (CO_2), respectively.[1] N_2O is also identified as a contributor to the destruction of ozone in the stratosphere.[2] From the point of view of the environment, therefore, it is of interest to study selective catalytic reduction (SCR) of N_2O by CH_4 which can lead to simultaneous abatement of N_2O and CH_4 in emission gases. Recently, the groups of Segawa[3,4] and Turek[5,6] reported that the SCR of N_2O by hydrocarbons such as C_3H_6 and C_3H_8 took place effectively over Fe-MFI catalysts even in the presence of coexistent gases such as excess O_2 and H_2O. However, little detailed work with respect to other catalysts and/or reductants in the SCR of N_2O has been performed. We have been studying the SCR of N_2O with hydrocarbons over different Fe ion-exchanged zeolite catalysts (*e.g.* Fe-MFI, Fe-MOR, Fe-NaY, *etc.*).[7] During the course of this study, an Fe ion-exchanged BEA (Fe-BEA) catalyst was found to be much more active for the SCR of N_2O than Fe-MFI zeolite reported in the literature. We report here that the Fe-BEA catalyst performs effectively for the SCR of N_2O with CH_4 even in the presence of an excess of oxygen.

Fe-BEA (SiO_2/Al_2O_3 = 27.3) catalyst was prepared by ion-exchange with a dilute solution of $Fe(SO_4)$ at 50 °C for 20 h under a nitrogen atmosphere, and calcined in air for 12 h at 500 °C.[3,4] For comparison, Fe-MFI (SiO_2/Al_2O_3 = 23.8) was also prepared by the same procedures as Fe-BEA. The zeolite supports (H-BEA, Na-MFI) were supplied by TOSOH Co. The loading weight of Fe on BEA and MFI supports was 0.77 wt% (25 % exchanged with Fe^{2+}) and 2.90 wt% (80% exchanged with Fe^{2+}), respectively. The reaction was carried out in a standard fixed-bed flow reactor by passing a gaseous mixture of N_2O (950 ppm), CH_4 (500 or 3000 ppm) and O_2 (10%) in an He flow at a total flow rate of 50 cm^3 min^{-1} over 50 mg of catalyst [total pressure: 1 atm; space velocity (SV): 60 000 h^{-1}]. The samples were pretreated at 500 °C with O_2 for 1 h in a flow reactor, followed by a He purge at the initial reaction temperature. Catalytic experiments on various reaction systems were performed as detailed in Table 1. The products were monitored by an on-line gas chromatograph (Shimadzu GC-8A) equipped with Molecular Sieve 5A (N_2, CH_4, CO) and Porapak Q (N_2O, CO_2, H_2O) columns. The catalytic activity for the reduction of N_2O with CH_4 was evaluated by the percentage conversion of N_2O and CH_4 to N_2 and CO_x (CO_2 and/or CO), respectively.

Figs. 1 and 2 show N_2O and CH_4 conversions in the different reaction systems (over Fe-BEA and Fe-MFI catalysts), respectively. As shown in Fig. 1, the catalytic activities of N_2O decomposition on both Fe-BEA and Fe-MFI catalysts were significantly promoted by adding CH_4, while N_2O decomposition was inhibited in the presence of O_2. Compared with the N_2O (950 ppm)/O_2 (10 %)/CH_4 (500 ppm) system, the N_2O conversion curve shifted to lower temperature in the absence of O_2 (O_2: 10 → 0%: **No. 3** and **4** in Fig. 1), while the N_2O conversion was scarcely affected by the composition of CH_4 in this range (CH_4: 500 → 3000 ppm: **No. 4** and **5** in Fig. 1). For both Fe-BEA and Fe-MFI, increases of CH_4 conversions correlated well with that of N_2O conversions. N_2, H_2O and CO_2 were observed as the main products in the $N_2O/CH_4/O_2$ system for both catalysts. Moreover, it was found that there was a plateau in CH_4 conversion after N_2O conversion reached 100% (*ca.* 350–450 °C, Fig. 2). This is due to the fact that N_2O in the mixture gas was completely consumed by reaction with CH_4 at such temperatures. It should be noted that oxidation of CH_4 by O_2 over the Fe-BEA catalyst began above 450 °C (**No. 6** in Fig. 2). These results indicate that the reduction of N_2O and the oxidation of CH_4 in this reaction system ($N_2O/CH_4/O_2$) concomitantly take place at much lower temperature than each of original reaction temperatures in the N_2O decomposition (N_2O alone: **No. 1** in Fig. 1) and the CH_4 oxidation (CH_4/O_2

Table 1 List of the reaction systems on the catalytic experiments

Reaction No.	Catalyst	Feed composition in mixture gases		
		N_2O (ppm)	O_2 (%)	CH_4 (ppm)
1	Fe-BEA	950	0	0
2	Fe-BEA	950	10	0
3	Fe-BEA	950	0	500
4	Fe-BEA	950	10	500
5	Fe-BEA	950	10	3000
6	Fe-BEA	0	10	500

mixture: **No. 6** in Fig. 2). Therefore, O atoms from N_2O molecules are much more efficient in activating CH_4 than O atoms from O_2 molecules at low temperature (< 400 °C).

As also shown in Fig. 1, catalytic activities (per g cat) for the decomposition of N_2O and the selective catalytic reduction (SCR) of N_2O by CH_4 over the Fe-BEA catalyst are much higher than those over the Fe-MFI catalyst. Table 2 shows TOF values based on the catalytic activities in N_2O (**No. 1** and **7**) and $N_2O/O_2/CH_4$ (**No. 4** and **9**) systems over Fe-BEA and Fe-MFI. The TOF values were estimated by assuming that all of loaded Fe (exchanged with Fe^{2+}) act as active sites. These TOF values, of both the decomposition of N_2O and the SCR of N_2O by CH_4 over Fe-BEA are more than one order of magnitude higher than those over Fe-MFI. From the above results, it is strongly suggested that Fe-BEA zeolite is much more active than Fe-MFI zeolite. The difference in the catalytic activities between Fe-BEA and Fe-MFI suggests that the decomposition of N_2O and the SCR of N_2O by CH_4 may be influenced by the structure of zeolite and/or states of the Fe ions.[7] On the other hand, the TOF values of N_2 formation on the SCR of N_2O by CH_4 were significantly higher than those for the decomposition of N_2O over both zeolites. This result indicates that the reaction mechanism for the SCR of N_2O by CH_4 is substantially different from that for the decomposition of N_2O.

Table 2 Comparison of TOF values for N_2O decomposition and SCR of N_2O

	10^{-4} TOF[a]/s^{-1}		
		SCR of N_2O by CH_4[c]	
Catalyst	Decomposition of N_2O[b] N_2 formation	N_2 formation	CO_2 formation
Fe-BEA	16.8	21.8	4.35
Fe-MFI	1.19	1.73	0.07

[a] Turnover frequency (TOF: s^{-1}): number of product molecules per number of Fe ions s^{-1}. [b] At 430 °C (reaction **No. 1** and **7**). [c] At 300 °C (reaction **No. 4** and **9**).

The present results have demonstrated that the SCR of N_2O by CH_4 in the presence of an excess of O_2 occurs effectively over the Fe-BEA catalyst. Interestingly, the reaction temperatures for the SCR of N_2O by CH_4 and the selective oxidation of CH_4 by N_2O over Fe-BEA are much lower than those for N_2O decomposition ($2N_2O \rightarrow 2N_2 + O_2$) or CH_4 combustion ($CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$) even in the presence of excess O_2. We are currently undertaking further investigations in our laboratory with respect to the detailed mechanism, the effect of coexistent gases (SO_2, NO, H_2O, *etc.*) and the characterization of active sites (Fe ion states *etc.*).

A bisporphyrin substituted bipyridine ligand and several metal derivatives are described.

There has been great interest in recent years in the photochemical and electrochemical properties of supramolecular assemblies composed of mononuclear metal polypyridyl complexes.[1] Such systems have applications in solar energy harvesting[2] and in molecular device technology.[3] These functions may be achieved by programming such assemblies, through molecular design, so they transduce energy in one particular direction. This is possible by using binuclear complexes with different metals or by having different terminal ligand substituents.[4]

We have a particular interest in the assembly of polychromophore systems, especially those involving porphyrins.[5] More recently we have been investigating the chemistry of porphyrins that have pendant groups such as pyridine capable of acting as ligands.[6] Here, we report the expansion of this work to include the bipyridyl ligand.

Treatment of 4,4′-diformyl-2,2′-bipyridine **1** with 1 equivalent of tetraxylylporphyrin phosphonium salt (TXP-CH_2PPh_3Cl) **2** proceeds to give the porphyrin functionalised bipyridine **3** in 91% yield (Scheme 1). The remaining aldehyde group can be treated with a further equivalent of **2** to give the bisporphyrin–bipyridine compound **4**. Alternatively, **3** can be treated with other Wittig reagents such as the tetraphenylporphyrin or variants[7] of **2** such as tetra(di-*tert*-butylphenyl)porphyrin[5] to give the hetero-bisporphyrin–bipyridines **5** and **6**. All of the compounds **3**–**6** are insoluble in hexane or alcohols but are very soluble in most other organic solvents.

The ^{1}H NMR spectrum of **4** is consistent with a symmetrical compound. In particular the symmetry is demonstrated by the presence of only three signals associated with the bipyridyl group. A doublet at δ 7.30 (^3J 5.2 Hz) identified as the two equivalent 5-position protons ($H_{5,5'\text{-bpy}}$), the two 3-position bipyridine protons ($H_{3,3'\text{-bpy}}$) appear as a singlet at δ 8.41 while protons of the 6-position ($H_{6,6'\text{-bpy}}$) give rise to a doublet (^3J 5.2 Hz) at δ 8.81. The lack of steric restrictions apparent from the spectrum of **4** is confirmed by its CPK model with no unfavorable steric interactions being apparent.

Treatment of **4** with suitable transition metal complexes results in the formation of stable coordination complexes where it acts as a bidentate ligand. Thus, heating $ReCl(CO)_5$ and **4** in benzene at reflux temperature gives the rhenium complex **7** in

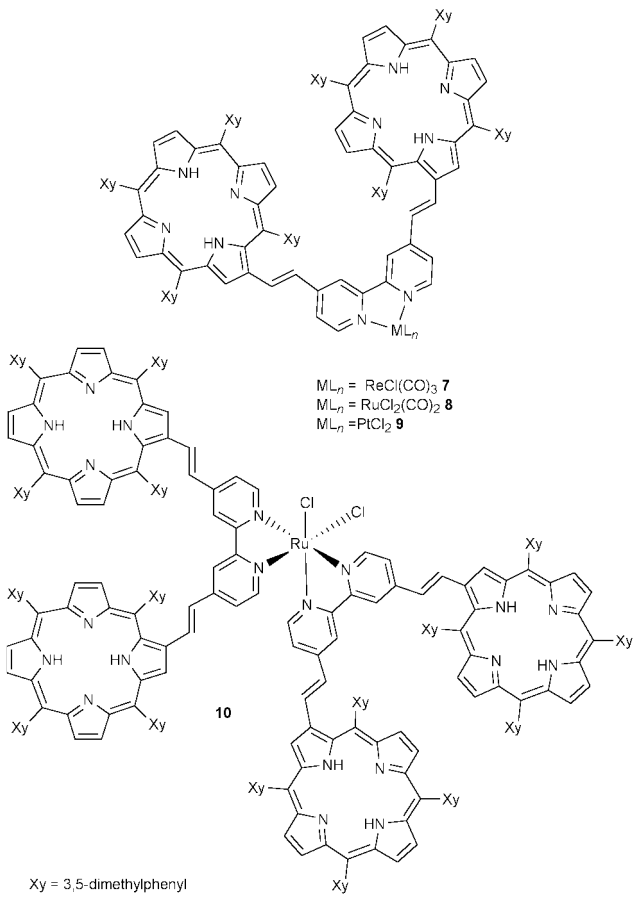

Fig. 1 Molecular structures of compounds.

DOI: 10.1039/b000364f

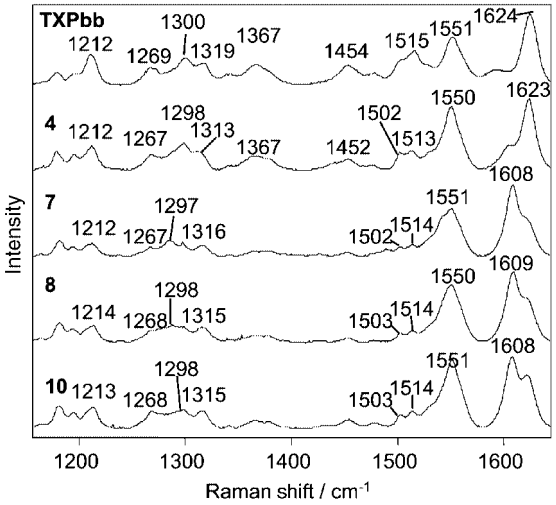

Fig. 2 Resonance Raman spectra of **4**, **7**, **8** and **10** in dichloromethane (1 mM). Excitation wavelength was 457.9 nm (20 mW).

74% yield. Similar complexes of ruthenium **8** and platinum **9** can be obtained by treating **4** with $[Ru(CO)_2Cl_2]_n$ and $PtCl_2(Me_2SO)_2$, respectively (Fig. 1). The ^{1}H NMR spectra for **7**–**9** are little changed from **3**, with only slight shifts observed in the positions of the resonances.

The reaction of **4** with $RuCl_2(Me_2SO)_4$ results in the formation of a complex **10** where 2 equivalents of **4** are coordinated. The yield is 28%, but all of the unreacted **4** can be recovered and reused. The ^{1}H NMR spectrum of **10** is particularly interesting as it enables the geometry of the metal complex to be established unequivocally. In contrast to **4** and the complexes **7**–**9** where the resonances of the protons attached to the bipyridyl rings give only three signals as expected for symmetrical coordination, six signals are observed for these protons in the ^{1}H NMR spectrum of **10**. This indicates that the chloride ligands must be *cis* to each other, imposing an asymmetry in the bipyridine ligand.

The electronic absorption spectra of the ligands **4**–**6** show porphyrin character with the $\pi \rightarrow \pi^*$ band of the bpy evident at 299 nm in **4**. The metal complexes **7**, **8** and **10** appear to possess only porphyrin character in their visible spectra but close examination of the spectra shows a broadening and asymmetry in the Soret band owing to the presence of the metal to ligand charge transfer under the Soret. The spectra are effectively the sum of the spectra of the porphyrin and $M(bpy)_3$ components.[8] Emission studies on these systems show similar results to other bpy–porphyrin complexes[8] with significantly reduced porphyrin emission, and no emission attributable to the M(bpy) portion of the system observed. The emission quenching observed in these systems is thought to be energy transfer similar to that observed in terpy based systems by Flamigni *et al.*[8b,c] The resonance Raman spectra of **4**, **7**, **8** and **10** are shown in Fig. 2. Also present is the spectrum of TXPbb, which is a vinyl-phenyl substituted tetraxylyl porphyrin, for comparative studies. The spectra for **4**, **7**, **8** and **10** are largely porphyrin in nature, with the only feature attributable to the MLCT transition the band at 1608 cm^{-1} in **7**, **8** and **10**. In **7** a band due to the carbonyl can be observed at 2020 cm^{-1}. An investigation of systems such as these in solar energy conversion is currently underway in our laboratory.

We are grateful to The Public Good Science Fund (MAU602 and MAU809), the Massey University Research Fund, the Research Institute of Innovative Technology for the Earth, and the Marsden Fund of New Zealand (MAU810) for support of this work.

The paramagnetic, heterometallic manganese cubanes [{$E_2(NCy)_4$}$(MnCp)_2$] (Cy = C_6H_{11}, Cp = C_5H_5, E = As, Sb)†

Received (in Cambridge, UK) 17th December 1999, Accepted 23rd March 2000
Published on the Web 13th April 2000

The heterometallic cubanes [{$E_2(NCy)_4$}$(MnCp)_2$] (E = Sb 1, As 2; Cy = C_6H_{11}, Cp = C_5H_5) are the first examples of complexes in which a paramagnetic metal ion has been incorporated into a p block ligand framework.

The coordination chemistry of ligand systems based on *p* block element imido frameworks has become increasingly studied in recent years.[1,2] Species such as the homologous group 15 dianions $[E_2(NR)_4]^{2-}$ (E = P–Bi)[1,3] offer readily accessible building blocks for the assembly of cage complexes containing a broad variety of mixed p block element/main group and transition element compositions.[1a] However, so far studies of the coordination chemistry of imido p block ligands have only involved main group and transition metal ions which possess closed-shell electronic configurations (for the transition metals d^0 or d^{10} only have been reported).[1,4,5] A current interest of ours involves utilising the differing geometric and bonding demands in homologous ligands of this type to control the degree of magnetic and/or bonding interactions between the ligand-supported metal frameworks present in these species.[4c] The heterometallic complexes [{$Sb_2(NCy)_4$}$(MnCp)_2$] **1** and [{$As_2(NCy)_4$}$(MnCp)_2$] **2**, presented here, provide the first opportunity to investigate ligand control of magnetic properties in these systems.

[{$Sb_2(NCy)_4$}$(MnCp)_2$] **1** and [{$As_2(NCy)_4$}$(MnCp)_2$] **2** were prepared by the nucleophilic substitution reactions of $MnCp_2$[6] with [{$E_2(NCy)_4$}$_2M_4$] (E = Sb, M = Na;[6] E = As, M = Li[3b]), with the elimination of CpM (Scheme 1.‡ ^{1}H NMR studies of both showed only broad ill defined resonances which are consistent with paramagnetic materials.

The low-temperature X-ray structures of **1** (Fig. 1) and **2** (Fig. 2)§ reveal that both complexes have similar pseudo-cubane structures in the solid state, which are composed of two (formally 17e) $CpMn^+$ fragments[7] complexed by $[Sb_2(NCy)_4]^{2-}$ and $[As_2(NCy)_4]^{2-}$ dianions. The similarity of the endo- and exo-cyclic Sb–N and As–N bonds of their $[Sb_2(NCy)_4]^{2-}$ and $[As_2(NCy)_4]^{2-}$ anions with those observed in the precursor Na complexes [{$Sb_2(NCy)_4$}$_2Na_4$][8] and [{$As_2(NCy)_4$}$_2Na_4$][4c] illustrates that, like these complexes, the anion units have the primary role in dictating the overall structures of **1** and **2**. The reduction in the endo-cyclic Sb–N and As–N bond lengths from **1** to **2** (of *ca.* 0.19 Å) has a major affect on the Mn_2N_2 rings in both complexes. In order to retain similar Mn–N bond lengths within these units (*ca.* 2.20 Å in both complexes[9]), this ring is far more puckered in **2** (the angle between the MnN_2 planes being 161.9° in **1** and 142.6° in **2**).

Mean angles (°): N(1A)–As(1,2)–N(1D) 83.0, N(1C)–As(1)–N(1A,1D) 91.9, N(1B)–As(2)–N(1A,1D) 91.3, Mn(1)–N(1B,1C)–Mn(2) 83.4, N(1C)–Mn(1,2)–N(1B) 90.8. Dihedral angles (°) between planes; MnN_2 142.6, AsN_2 176.2.

Scheme 1

† Electronic supplementary information (ESI) available: plots of the effective magnetic moments of **1** and **2** as a function of temperature. See http://www.rsc.org/suppdata/cc/a9/a910196i/

Although this distortion has only a small affect on the Mn–N–Mn and N–Mn–N angles within the Mn_2N_2 ring units, a consequence of the presence of the more compact $[As_2(NCy)_4]^{2-}$ ligand in **2** is a large reduction in Mn···Mn separation [from 3.041(2) Å in **1** to 2.934(2) Å in **2**]. The Mn···Mn separation in **2** is almost identical to that in $Mn_2(CO)_{10}$ (2.93 Å).[10]

Whilst Mn(II) ions are almost invariably high spin, the large ligand field associated with the π-donor Cp^- ligand makes the high- and low-spin electronic configurations energetically similar. Indeed, for manganocenes ($MnCp^R_2$; Cp^R = substituted Cp) examples of pure low-spin, pure high-spin and high-/low-spin equilibria have been observed (depending on the donor or acceptor character and steric demands of ring substituents).[11,12] For the half-sandwich ($MnCp^R$) derivatives, pure high-spin behaviour has been observed.[13] For **1** and **2**, the possibility of high-/low-spin equilibria is complicated by the potential for superexchange *via* the bridging imido ligands. Preliminary magnetic studies of **1** and **2** (5.5–380 K) show a marked temperature dependence of μ_{eff} (ESI†). Even at 380 K, the observed moments (6.0 and 6.6 μ_B for **1** and **2**, respectively) are significantly less than that expected for two high-spin Mn(II) ions per molecule (8.37 μ_B). The value of μ_{eff} decreases steadily on cooling, reaching 2.6 μ_B for **1** and 1.9 μ_B for **2** at 5.5 K. While the value for **1** is consistent with two non-interacting low-spin Mn(II) ions (2.5 μ_B), the significantly lower value for **2** may indicate intramolecular exchange between the Mn ions.

Attempts to model the data for **1** and **2** have so far proved inconclusive.¶ The suggestion that a high-/low-spin equilibrium may be occurring over a wide temperature range for both complexes is apparently inconsistent with the long Mn–C bond lengths in **1** and **2** [range 2.389(10)–2.615(8) Å], which are typical of high-spin manganocenes (*cf. ca.* 2.11–2.14 Å in low-spin species).[12] Although some shortening of the Mn–C bonds is anticipated for the high-/low-spin equilibrium at the temperatures at which the structures of the complexes were obtained (180 K for **1** and 223 K for **2**), a possible reason for the maintenance of long metal–ligand bonds in both complexes is the sterically congested nature of the $[E_2(NCy)_4]^{2-}$ ligand frameworks (making closer approach of the Cp ligands unfavourable[12*b*]). A detailed study of the magnetic behaviour (EPR and solid-state susceptibility) and variable-temperature X-ray diffraction studies of **1** and **2** will be the subject of a full paper.

We gratefully acknowledge the EPSRC (A. B., S. J. K., J. S. P., M. McP., P. R. R., D. S. W.) and The Leverhulme Trust (M. A. B.) for financial support. We also thank Dr J. E. Davies for collecting X-ray data on **1**. We are also particularly grateful to the referees for their helpful comments regarding the magnetic behaviour of **1** and **2**.

Notes and references

‡ *Syntheses*: **1**: solid $MnCp_2$ (0.273g, 1.48 mmol) and $[\{Sb_2(NCy)_4\}_2Na_4]$ (0.676 g, 0.74 mmol) were mixed together in a glove box under argon. The mixture was dissolved in toluene (20 ml) and brought to reflux, producing a fine gelatinous solid of CpNa which was separated by the addition of thf (10 ml) followed by filtration. The red filtrate was reduced to dryness under vacuum and the solid residue dissolved by the addition of hexane (10 ml) and toluene (10 ml) and gentle heating. Storage (25 °C, 12 h) gave red plates of **1**. Yield 0.520 g (81%). Decomp. *ca.* 200 °C. δ_H(+25 °C, thf-d_8, 250 MHz), 4.75 (Cp), 1.8–0.7 (Cy groups) (Found: C 46.2; H 6.0; N 5.3. Calc. for **1**: C, 46.8; H, 6.2; N, 6.4%).

2: $[\{As_2(NCy)_4\}_2Li_4]$ was prepared *in situ* by the reaction of $As(NMe_2)_3$ (5.0 ml, 2.43 mol dm^{-3} solution in toluene, 12.15 mmol) with a solution of $CyNH_2$ (1.39 ml, 12.15 mmol) in toluene (8 ml), followed by the addition of a suspension of CyNHLi (12.15 mmol) in toluene (8 ml). $MnCp_2$ (2.25 g, 12.15 mmol) in thf (10 ml) was added to this mixture and a white precipitate of CpLi was formed after bringing to reflux. Filtration gave a yellow solution which was stored (25 °C, 12 h) to give yellow plates of **2**. Yield 1.62 g (34%). Decomp. *ca.* 210 °C. δ_H(+25 °C, thf-d_8, 250 MHz), *ca.* 6.5 (Cp), 2.5–0.5 (Cy groups) (Found: C, 51.5; H, 6.6; N, 6.2. Calc. for **2**: C, 52.4; H, 6.9, N, 7.2%).

§ *Crystal data*: for **1**: $C_{34}H_{54}Mn_2N_4Sb_2$, M = 872.20, tetragonal, space group $P4_12_12$, Z = 4, a = 11.775(2), c = 26.095(5) Å, U = 3618.1(11) Å^3, D_c = 1.601 g cm^{-3}, $F(000)$ = 1752, μ(Mo–Kα) = 2.187 mm^{-1}, T = 180(2) K. Data in the θ range 1.90–25.06° were collected on a Nonius Kappa CCD diffractometer. The structure was solved by direct methods. Full-matrix least-squares refinement on F^2 with 190 parameters was based on 3156 independent data (total collected 5231, R_{int} = 0.044). Final R_1 = 0.028 [$I > 2\sigma(I)$], wR_2 = 0.126 (all data).[14] Largest peak and hole in the final difference map 0.808 and −1.750 e Å^{-3}. Absolute structure parameter −0.09(6).

For **2**: $C_{34}H_{54}As_2Mn_2N_4$, M = 778.53, monoclinic, space group $P2_1/c$, Z = 4, a = 10.336(2), b = 17.095(6), c = 20.506(5) Å, β = 103.99(2)°, U = 3516(2) Å^3, D_c = 1.471 g cm^{-3}, $F(000)$ = 1608, μ(Mo-Kα) = 2.615 mm^{-1}, T = 223(2) K. Data in the θ range 2.03–23.01° were collected on a Siemens P4 difractometer, and corrected for absorption effects using Ψ scans. The structure was solved by direct methods. Full-matrix least-squares refinement on F^2 with 379 parameters was based on 4893 independent data (total collected 6294, R_{int} = 0.0509). Final R_1 = 0.054 [$I > 2\sigma(I)$], wR_2 = 0.156 (all data).[14] Largest peak and hole in the final difference map 0.868 and −0.877 e Å^{-3}.

CCDC 182/1581. See http://www.rsc.org/suppdata/cc/a9/a910196i/ for crystallographic files in .cif format.

¶ *Magnetic behaviour* of **1** and **2**: solid samples were measured between 5.5 and 380 K using a SQUID magnetometer in fields of 100 (for **1**) and 1000 G (for **2**). They were corrected for diamagnetism using Pascals' constants. Attempts to model the magnetic behaviour as a low-spin ground state with a thermally accessible high-spin state were unsuccessful as was an attempt to fit the data to two interacting Heisenberg S = ⅝ ions. For **1**, a high-spin/low-spin thermal equilibrium fits the data throughout the temperature range 5.5-380 K, and also for the range 25–380 K for **2**.

Paramagnetic signals have been observed in the ^{1}H NMR spectra of copper-containing nitrite reductases ($M_r \approx 110$ kDa), which provide a detailed fingerprint of the type 1 centres in these proteins.

Copper-containing nitrite reductases (NiRs) function in the dissimilatory denitrification pathway of certain micro-organisms, reducing nitrite to nitric oxide.[1] Structural studies have shown that these proteins are trimeric[2–4] with each subunit ($M_r \approx 36$ kDa) possessing a type 1 copper site. In addition, the protein possesses three inter-subunit type 2 copper centres (sites of nitrite binding) in close proximity to the type 1 centres. The arrangement of the two copper centres in one of the monomers of nitrite reductase is shown in Fig. 1. The presence of type 1 centres in NiRs results in them having unique spectroscopic features, including intense LMCT bands in their visible spectra. NiRs can be either green or blue, with the distinction due to differences at the type 1 centre.[4–7] Herein, we investigate the differences at the type 1 centres of the green NiR from *Achromobacter cycloclastes* and the blue NiR from *Alcaligenes xylosoxidans* using paramagnetic ^{1}H NMR spectroscopy.

Recent studies have demonstrated that isotropically shifted ^{1}H NMR resonances can be observed and assigned for simple, low molecular weight ($M_r \approx 12$ kDa), type 1 copper proteins (cupredoxins).[8,9] In all cases, a number of broad resonances can be observed and assigned. The assigned spectra provide a detailed fingerprint of the active sites of the various cupredoxins. We now show that similar resonances can be observed for the type 1 centre in the more complex copper-containing nitrite reductases. This is possibly the largest copper protein that has been studied to date using paramagnetic NMR spectroscopy. Interpretation of the isotropic shifts experienced by these resonances provides details of the structure of the type 1 copper centres in these proteins and highlights differences between blue and green NiRs.

The paramagnetic ^{1}H NMR spectrum[10] of the type 2 depleted (T2D, *i.e.* with copper removed from the type 2 centres) green NiR from *A. cycloclastes*[12] is presented in Fig. 2A. Also shown (Fig. 2B) is the spectrum of the protein which possesses > 80% Cu(II) at its type 2 centre.[14] The spectrum of the T2D blue NiR from *A. xylosoxidans*[15] is shown in Fig. 2C. The chemical shifts of the observed resonances are listed in Table 1 along with spin–lattice (T_1) relaxation times.

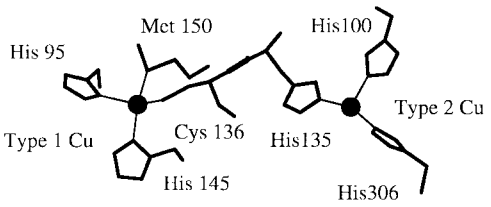

Fig. 1 Structure of the Cu(II) sites in one of the monomers of NiR (the His306 ligand of the type 2 copper centre originates from the adjacent monomer). Black spheres indicate the copper ions. This picture was produced using the coordinates of the crystal structure of the protein from *A. cycloclastes*.[3]

The spectra of the green NiR and the corresponding T2D enzyme show no significant differences in chemical shift values and relaxation times (see Table 1). This clearly demonstrates that all of the observed resonances are due to protons associated with the type 1 centre, and that the binding of Cu(II) to the type 2 centre has no effect on the structure, or electronic properties, of the type 1 site.[16,17] The temperature dependence of the chemical shifts of the resonances observed in Fig. 2A has been investigated in the range 292–328 K, and in all cases they exhibit Curie-type behaviour (data not shown).

In previous paramagnetic ^{1}H NMR studies on the oxidised forms of the cupredoxins amicyanin[8] and plastocyanin,[9] the assignment of paramagnetic resonances has relied upon the ability to correlate these peaks to their counterparts in the spectrum of the reduced (diamagnetic) protein, utilising the electron self-exchange reaction. This is clearly not possible in the case of NiRs. However, a comparison to the assigned cupredoxin spectra provides a very reliable initial analysis of the NiR spectra.

The exchangeable resonance d arises from one of the N$^{\varepsilon 2}$H of the two His ligands. Spectra were acquired of the proteins in H_2O–D_2O (9 : 1, v/v) at lower pH values, but there was no evidence for a second such resonance.[18] These observations

[a] *A. cycloclastes.* [b] *A. xylosoxidans.* [c] Estimated error ±0.1 for sharp resonances and ±0.3–0.5 for broader peaks. [d] Estimated error is ±5%; this is larger for the very fast relaxing signals. [e] The numbering of the residues is as found in NiR from *A. cycloclastes*. [f] n.d. = not determined.

point to peak d belonging to the N$^{\varepsilon 2}$H of the more buried His95 ligand in both proteins.[19] The corresponding resonance of the exposed His145 ligand is broadened beyond detection owing to fast exchange with the bulk solvent.

The two very broad resonances a and b have counterparts in the spectra of amicyanin[8] and plastocyanin,[9] and can be assigned to the two C$^{\delta 2}$ protons of the histidine ligands. Resonance e has an apparent T_1 value of 0.46 ms in the T2D green NiR and is most likely due to one or both of the C$^{\gamma}$H signals of the axial Met150 ligand. In the paramagnetic ^{1}H NMR spectra of other cupredoxins a very broad peak, comprised of the two C$^{\varepsilon 1}$H resonances of the two histidine ligands, has been found at δ *ca.* 30–35, which could also be present in the spectrum in Fig. 2A overlapping with one, or both, of the Met C$^{\gamma}$H signals. The histidines C$^{\varepsilon 1}$H peak is present in the spectrum of the blue NiR (peak c), whilst peak e (Met150 C$^{\gamma}$H) now overlaps with peak f (*vide infra*).

Resonance f is the least paramagnetic signal in the spectra of the two T2D NiRs (see Table 1). A corresponding resonance has been found in the region δ *ca.* 12–18 in all such studies on proteins possessing type 1 centres. In the published study on Cu(II) amicyanin[8] this resonance was assigned to the C$^{\alpha}$H of the coordinated Cys ligand. However, in the Cu(II) plastocyanin work[9] the corresponding resonance has been assigned to the C$^{\alpha}$H of Asn38, the backbone amide group of which makes a strong hydrogen bond to the thiolate sulfur of the coordinated Cys ligand (the Cys C$^{\alpha}$H is upfield shifted and has a T_1 value of < 1 ms in plastocyanin, *vide infra*). The long spin–lattice relaxation time and relatively small linewidth of peak f clearly point to it belonging to the C$^{\alpha}$H of Asn96 in the NiRs, whose backbone amide makes a hydrogen bond with the S$^{\tau}$ of the ligand Cys136.

Finally, resonance g is the only upfield shifted signal observed in the spectra of the NiRs. In studies on amicyanin and plastocyanin two upfield shifted resonances have been observed. For the former, these have been assigned as the two C$^{\beta}$ protons of one of the His ligands.[8] For plastocyanin, the most upfield shifted resonance has been assigned to the C$^{\alpha}$H of the Cys ligand with the other upfield shifted resonance due to a His C$^{\beta}$H.[9] Due to the assignment of peak f as the C$^{\alpha}$H of Asn96 we conclude that peak g must belong to the C$^{\alpha}$H of Cys136.

The hyperfine shifts of the ^{1}H NMR signals associated with type 1 copper centres are made up mainly of a Fermi-contact contribution, and therefore directly provide information about the spin density distribution of the unpaired electron. The shifts observed for the two NiRs are, on the whole, very similar and are also reminiscent to those observed in the published studies on type 1 copper centres.[8,9] This is especially so for the signals derived from the two histidines, the Cys C$^{\alpha}$H and the Asn C$^{\alpha}$H resonances, consistent with very similar type 1 architectures in the various proteins. The major difference between the spectra of the blue and green NiRs lies in the shifts experienced by the Met C$^{\gamma}$H resonances (peak e). This signal in the green NiR lies at δ = 25.1, *cf.* δ < 18 in the blue enzyme. This indicates *ca.* 1.5 times more spin density on this proton in the green protein, which cannot be due to differences in the Cu–S(Met) distances as structural studies have shown this bond length (precision *ca.* 0.1 Å) to be very similar in the green (2.56 Å)[3] and blue (2.64 Å)[4] NiRs. These variations are therefore probably due to differences in the Cu–S$^{\delta}$–C$^{\gamma}$–H$^{\gamma}$ dihedral angles in the two proteins.[20] Further paramagnetic NMR studies on Co(II)-substituted NiRs are currently underway to clarify this issue.

10 Samples (2–3 mM) for NMR were prepared in 20 mM phosphate buffer in both D_2O and H_2O–D_2O (9:1, v/v) usually at pH 7.5. ^{1}H NMR spectra were acquired on a Varian Unity 500 and a JEOL Lambda 500 spectrometer usually at 25 °C using the super-WEFT pulse sequence,[11] typically with a spectral width of 100 kHz. The data were processed using 20–50 Hz exponential line broadening as apodization.
11 T. Inubushi and E. D. Becker, *J. Magn. Reson.*, 1983, **51**, 128.
12 The green NiR from *A. cycloclastes* was isolated and purified as described previously.[13] The isolated enzyme possesses *ca.* 10% copper at its T2 centre and this sample was used for the T2D spectra.
13 S. Suzuki, S. Deligeer, K. Yamaguchi, K. Kataoka, K. Kobayashi, S. Tagawa, T. Kohzuma, S. Shidara and H. Iwasaki, *J. Biol. Inorg. Chem.*, 1997, **2**, 265.
14 The incorporation of copper at the T2 centre of *A. cycloclastes* NiR was achieved by dialysing (Spectra/Por CE DispoDialyzer, MWCO 10000) the protein in 50 mM Tris buffer at pH 7.0 against a similar buffer solution containing 1 mM $Cu(NO_3)_2$. Dialysis was carried out over 4–7 days immediately prior to the acquisition of NMR spectra. The excess copper was dialysed out of the protein solution against 50 mM Tris at pH 7.0.
15 The blue NiR from *A. xylosoxidans* was isolated and purified according to a literature method.[13] The isolated enzyme possesses *ca.* 70% copper at its T2 centre. The T2D protein was obtained as described in the literature[13] and contained < 10% copper at the type 2 centre.
16 Spectra of green NiR in the presence of nitrite were also obtained, and exhibited very little difference to those of either NiR or of the T2D enzyme. This shows that binding of the substrate at the type 2 centre has very little effect on the structure and electronic properties of the type 1 site.
17 Spectra were obtained of the blue NiR with and without Cu(II) at its type 2 centre. No significant differences were observed between these spectra. For example the δ_{obs} and T_1 values of peak d in blue NiR are 26.5 and 2.9 ms, respectively.
18 In the spectrum of the T2D blue NiR in H_2O–D_2O (9:1, v/v) there is an indication of a second exchangeable resonance at δ *ca.* 46. However, this peak appears to be quite broad and overlaps with resonances a and b making any definite conclusions impossible.
19 The type 1 ligands are numbered as in *A. cycloclastes* NiR. The corresponding residues in *A. xylosoxidans* NiR are His89, Cys130, His139 and Met144.
20 Analysis of the crystal structures of the green and blue NiRs reveals that one of the Cu–S$^{\delta}$–C$^{\gamma}$–H$^{\gamma}$ dihedral angles is in the region 50°–60°. If the contact shift of the Met C$^{\gamma}$H$_2$ protons follow a $\cos^2\theta$ Karplus law, where θ is the Cu–S$^{\delta}$–C$^{\gamma}$–H$^{\gamma}$ dihedral angle, then small changes in this angle could result in quite large differences in the observed shift. It should be noted that in the crystal structures of *A. cycloclastes* NiR small differences (greater than the estimated precision of 3°) are observed in these dihedral angles for the type 1 sites in the different monomers, and also in the proteins crystallised under different conditions (see ref. 3).

Negative solvatochromism of azo dyes derived from (dialkylamino)thiazole dimers

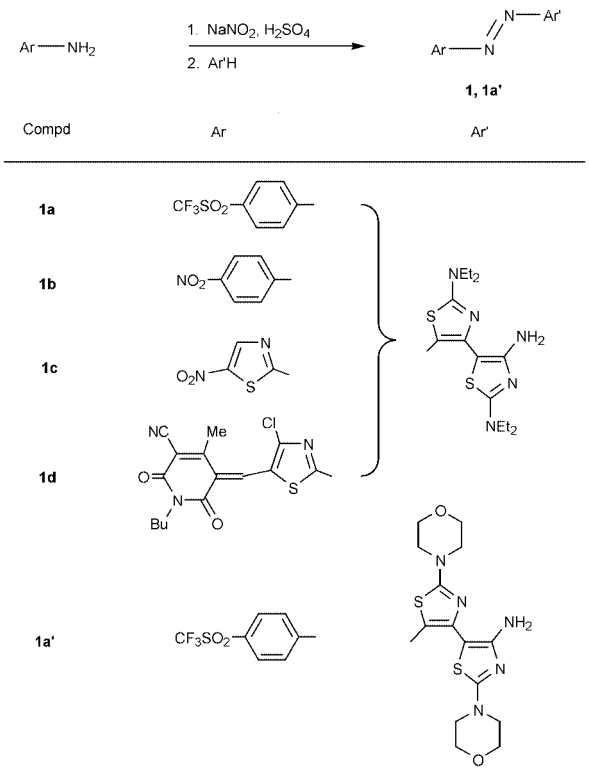
Received (in Cambridge, UK) 1st March 2000, Accepted 23rd March 2000
Published on the Web 13th April 2000

The first examples of negative solvatochromism in neutral azo dyes containing both strongly electron-donating bis-(dialkylamino)thiazolyl and electron-withdrawing 4-(trifluoromethylsulfonyl)phenyl or 2-thiazolyl moieties are reported.

The absorption bands of azo dyes depend on the combination of electron-donating and -withdrawing moieties in the molecules.[1] Recently, (dialkylamino)thiazole dimers, assumed to be very electron-rich substrates, have been synthesized.[2] It was of interest to examine the solvatochromic behavior of azo dyes having both strong electron-donating and -withdrawing moieties in a molecule. We report here, the solvatochromism of azo dyes derived from (dialkylamino)thiazole dimers.

The azo dyes **1a**–**d** and **1a′** derived from (dialkylamino)thiazole dimers were synthesized in low to good yields by the diazotisation-coupling reaction shown in Scheme 1.[3,4] The absorption spectrum of **1a** is shown in Fig. 1. The azo dye **1a** showed absorption bands at 637 nm (ε = 82 000 dm^3 mol^{-1} cm^{-1}) and 449 (25 000) in dichloromethane, while the absorption spectra of the other azo dyes are summarized in



Scheme 1

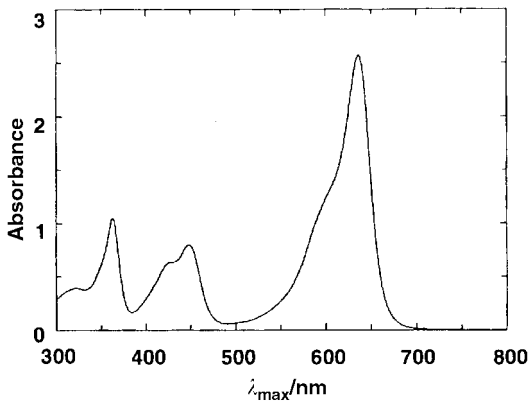


Fig. 1 Absorption spectrum of **1a** in dichloromethane.

Table 1. The lower energy absorption band of **1d**, containing a very strong electron-withdrawing moiety, was most bathochromic among the azo dyes **1**.

Neutral azo dyes have been reported to show a positive solvatochromism[5–12] while two types of ionic azo dyes, 4-[2-(triphenylphosphonio)phenylazo]phenolates and 2-(1-methylpyridiniumazo)- and 2-(1-methylqunoliniumazo)-tetracyanocyclopentadienides, have been reported to reveal negative solvatochromic behavior.[13,14]

Interestingly, the azo dyes **1** showed either positive and negative solvatochromism depending on the diazo components. Typical solvatochromism is shown in Fig. 2 where the λ_{max} values of the first (lower energy) absorption band are plotted against the molar electronic transition energy (E_T) of the solvent.[15] Azo dyes **1a**, **1c** and **1d** showed negative solvatochromism, especially, so for **1d**. While azo dye **1b** showed a positive solvatochromic behavior, azo dye **1a′** also showed negative solvatochromic behavior.[16] Thus the azo dyes containing very strong electron-withdrawing moieties such as 4-(trifluoromethylsulfonyl)phenyl and 2-thiazolyls showed negative solvatochromism. This result is in contrast to a positive

Table 1 Absorption spectra of **1a**–**d** and **1a′** in dichloromethane

Compound	λ_{max}/nm	ε/dm^3 mol^{-1} cm^{-1}
1a	449	25 000

DOI: 10.1039/b001697g

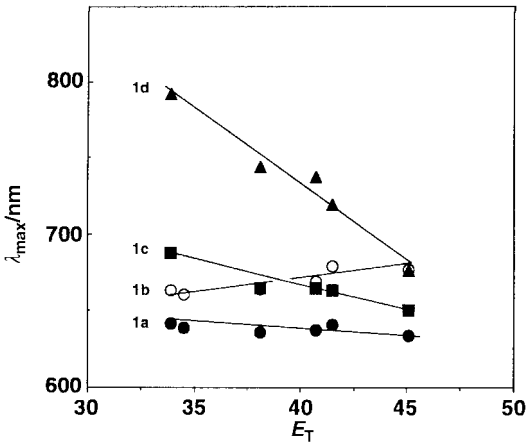

Fig. 2 Solvatochromism of azo dyes **1**. The absorption spectra were measured in toluene (E_T: 33.9 kcal mol^{-1}), diethyl ether (34.5), ethyl acetate (38.1), dichloromethane (40.7), benzonitrile (41.5), dimethyl sulfoxide (45.1). Azo dyes **1c** and **1d** were insoluble in diethyl ether.

solvatochromism of the near-IR absorbing push–pull 5-acetylamino-4-[2-(4-chloro-5-substituted thiazolylazo)]-2-methoxy-*N*-(2-hexyl)aniline derivative.[17] The structures of the azo dyes were optimized by a MOPAC AM-1 program and the dipole moment (μ) of the azo dyes in the excited and ground states were calculated by a CNDO/S program. The μ values of **1b** in the ground and excited states were calculated to be 14.58 and 18.98 D, respectively. This calculation is consistent with the positive solvatochromic behavior of **1b**. Interestingly, the electron-withdrawing nature of the nitro group [$\sigma_p(NO_2)$ = 0.78] was not strong enough to cause a negative solvatochromism in the azo dyes **1**. The ground state of the 4-(trifluoromethylsulfonyl) derivative **1a** [$\sigma_p(CF_3SO_2)$ = 0.93][18] was calculated to be slightly more polar (μ = 15.96 D) than the excited state (15.85 D). The ground state of **1d** was also calculated to be more polar (24.67 D) than the excited state (23.26 D). These results support the negative solvatochromism of **1a** and **1d**.[19]

The possible structures of **1a** in the ground and excited states are depicted in Fig. 3.

More polar charge-separated diazamerocyanine structures **A**, **A′** and **A″** could be predominant in the ground state and with a less polar neutral azo form **B** in the excited state. The other azo

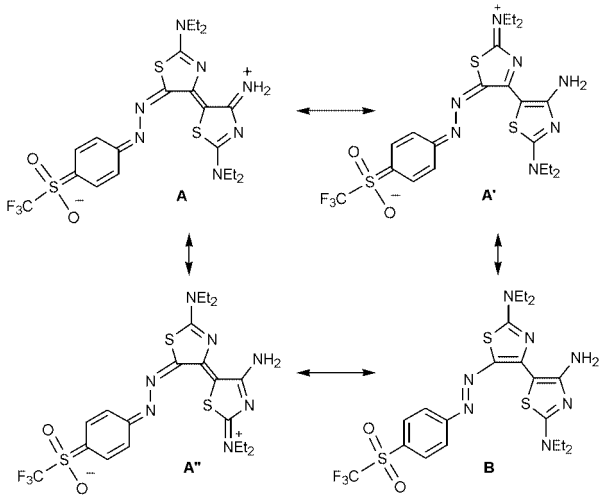

Fig. 3 Possible structures in **1a**.

dyes **1c**, **1d** and **1a′** which showed negative solvatochromism can also have charge-separated diazamerocyanine structures. This is different from the reported negatively solvatochromic azo compounds, which can have charge-separated azo and neutral diazamerocyanine structures in the ground and excited states, respectively.[13,14]

In conclusion, we have synthesized azo dyes derived from strong electron-donating coupling components, (dialkylamino)thiazole dimers. The azo dyes derived from diazo components with strong electron-withdrawing substituents such as 4-(trifluoromethylsulfonyl)aniline and 2-aminothiazoles showed a negative solvatochromism, owing to the ground state having a predominantly charge-separated polar diazamerocyanine structure.

A cationic vesicle interface exhibited a filter function for less hydrophobic anions, and highly selective anion recognition *via* hydrogen bonding was achieved by thiourea-based chromoionophores (C_n-TU) located deep inside the vesicle.

Selective recognition and *in situ* sensing of biologically important anions are of current interest in host-guest chemistry.[1,2] Several synthetic neutral receptors possessing amide,[3] urea[4] and thiourea moieties[5] as a binding site for anion recognition have been reported, in which the binding takes place exclusively *via* hydrogen bonding interaction. Recently we have shown that thiourea-based chromoionophore (C_1-TU) interacts strongly with anions *via* formation of hydrogen bonds in non-aqueous media (Fig. 1) and produces a readily observable color change with a selectivity of $MeCO_2^-$ > $H_2PO_4^-$ > Cl^- >> ClO_4^-, reflecting anion basicity.[6] For anion sensing in aqueous media, however, the hydrogen bonding interaction of the binding site encounters significant interference from anion hydration. In biological systems, hydrophobic microenvironments produced by the supramolecular structure of receptors are cleverly utilized for ion recognition.[7] Thus, a simple strategy to achieve anion recognition in water is to incorporate the chromoionophore into hydrophobic regions, such as vesicle media, to shield their binding site from water.[8–10]

To develop an anion sensing system in water using a chromoionophore/vesicle complex as a mimic of a biological system, two factors are important: (i) the positioning of the thiourea binding site inside the vesicle, and (ii) the role of the cationic vesicle interface in anion recognition. To elucidate these factors, we have designed novel thiourea-based chromoionophores having various length of alkyl chains (C_n-TU)[11] and examined their anion recognition function in cationic vesicle solutions. We report here, the first positioning-dependent anion recognition by C_n-TU chromoionophore/vesicle complexes in water.

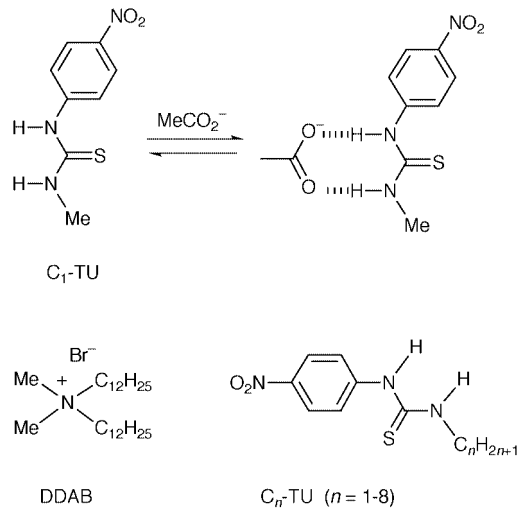

Fig. 1 Anion recognition by thiourea-based chromoionophores.

As a well known cationic amphiphile which forms single lamellae vesicles in water, didodecyldimethylammonium bromide (DDAB) was selected.[12] Films of C_n-TU/DDAB (1:10 mol%) were prepared by evaporation of a chloroform solution containing 1.0×10^{-5} mol C_n-TU and 1.0×10^{-4} mol DDAB on the inside of 100 mL-round bottomed flask. The films were left under vacuum for 1 day, followed by hydration with 10 mL of pure water at 40 °C by vortex mixing. The solution temperature was maintained at 40 °C while being probe-sonicated for 3 min using a power of 30–40 W. The resultant clear solution of C_n-TU/DDAB was diluted 20× with 0.01 M 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid buffer (HEPES, pH 7.50) containing guest anions as sodium salts.

In acetonitrile, all C_n-TU show the same UV-VIS spectra with λ_{max} at 340 nm ($\varepsilon = 1.4 \times 10^4$ M^{-1} cm^{-1}), which can be assigned as an intramolecular charge transfer (CT) absorption band, despite the difference in their alkyl chain lengths (n = 1–8). However in DDAB solution, the λ_{max} of C_n-TU shifts monotonously to higher wavelengths with an increase in alkyl chain lengths from 338 nm (ε = 1.1 x10^4 $M^{-1}cm^{-1}$) for C_1-TU to 361 nm (ε = 1.5 x10^4 M^{-1} cm^{-1}) for C_8-TU (Fig. 2). The CT absorption bands generally show a bathochromic shift when the solvent polarity is increased.[13] Thus the results in Fig. 2 clearly reveal that the positioning of chromophore binding sites is controlled by the alkyl chain length of C_n-TU; the binding site of C_n-TU bearing a long alkyl chain is located on the surface of the cationic vesicle (hydrophilic microenvironment), whereas that of C_n-TU bearing a short alkyl chain is positioned deep within the vesicle (hydrophobic microenvironment).

The thiourea proton associated with the *p*-nitrophenyl unit dissociates under basic conditions and a new peak in the UV–VIS spectrum appears at 450 nm. Thus the apparent pK_a of C_n-TU in DDAB solution can be assessed by pH titration analysis.[14] Observed pK_a values are 9.9 ± 0.1 for C_1-TU and 9.5 ± 0.1 for C_8-TU. The larger pK_a value observed for C_1-TU supports the finding that the binding site of C_1-TU is located in the hydrophobic microenvironment. In DMSO-d_6, the ^{1}H NMR spectra of the vicinal phenyl protons in all C_n-TU show the same chemical shifts at δ 7.80/8.16. However in DDAB–D_2O solution, the chemical shifts of these phenyl protons are δ 8.00/8.21 for C_1-TU and δ 8.22/8.39 for C_8-TU. The chemical shifts of C_1-TU observed at higher magnetic fields are ascribed

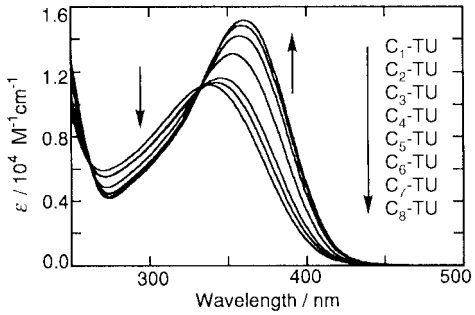

Fig. 2 UV-VIS spectra of C_n-TU in DDAB; [C_n-TU] = 5.0×10^{-5} M in 5.0×10^{-4} M DDAB solution, pH = 5.5–6.0 at 25 °C.

DOI: 10.1039/a909758i

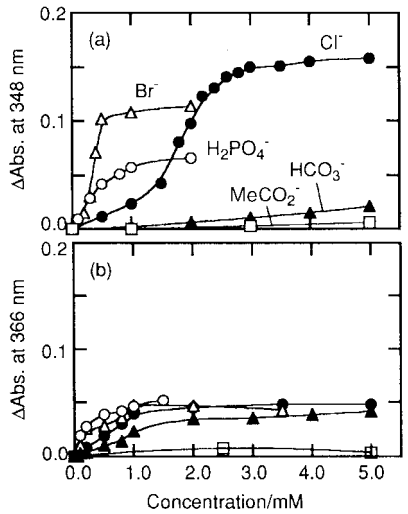

Fig. 3 Effect of anion concentration upon the spectral response of (a) C_1-TU and (b) C_8-TU in DDAB. (○) $H_2PO_4^-$, (△) Br^-, (●) Cl^-, (▲) HCO_3^-, (□) $MeCO_2^-$. [C_n-TU] = 5.0×10^{-5} M in 5.0×10^{-4} M DDAB solution. pH = 7.5 (adjusted by HEPES buffer at 25 °C).

to the hydrophobic effect,[15] which is additional evidence that C_1-TU is present deep within the vesicle.

The spectral responses of C_n-TU/DDAB complexes in water upon addition of anions were examined at pH 7.5 (Fig. 3). Increasing the anion concentration produced a bathochromic shift in λ_{max} with an enhanced molar absorptivity. These spectral changes are ascribed to (i) complex formation of anions with the thiourea moiety *via* hydrogen bonding as reported in acetonitrile,[6] and/or (ii) changes in the location of the chromophore within the vesicle due to the hydrophilic nature of the anion complexes. It is interesting that C_n-TU/DDAB complexes in water exhibit no response for $MeCO_2^-$, which differs from the response selectivity recorded in acetonitrile.[6] Since $MeCO_2^-$ is strongly hydrated in water,[16] the low binding affinity of $MeCO_2^-$ on the surface of DDAB vesicle may cause this poor response. This is a unique filter function of the cationic vesicle interface. The observed selectivity for C_1-TU/DDAB complex is Br^- > $H_2PO_4^-$ > Cl^- >> HCO_3^-, $MeCO_2^-$, reflecting a Hofmeister series [Fig. 3(a)].[16] On the other hand, no distinct selectivity is recorded for the C_8-TU/DDAB complex [Fig. 3(b)]. The spectral change (ΔAbs) upon addition of HCO_3^- is even larger for C_8-TU than for C_1-TU. This indicates that the binding of fewer hydrophobic anions takes place mainly on the vesicle surface. For C_n-TU with alkyl chain lengths from n = 2 to 7, an intermediate response between those of C_1-TU and C_8-TU is clearly observed.†

Thus it is apparent that the response selectivity is strongly affected by the positioning of C_n-TU in DDAB vesicles (Fig. 4).

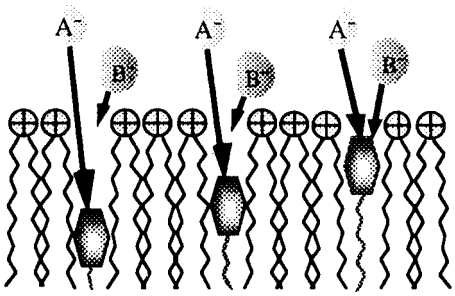

Fig. 4 Positioning-dependent anion recognition by C_n-TU in DDAB.

This is the first report that positioning dependent anion recognition can be carried out in aqueous vesicle solution.

In summary, the shifts in λ_{max}, pK_a, and ^{1}H NMR resonances revealed that the positioning of chromophore binding sites in DDAB was successfully controlled by the alkyl chain length of C_n-TU. This first report of positioning-dependent anion recognition *via* hydrogen bonding has been achieved by use of C_n-TU/DDAB complexes in water. Based on the filter function of the vesicle interface as well as the depth dependent distribution of the chromoionophores, this molecular assembled system should provide a new methodology for specific ion and molecule recognition in aqueous solutions.

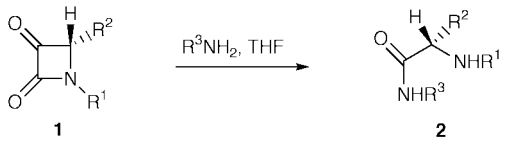
Received (in Cambridge, UK) 9th December 1999, Accepted 27th March 2000
Published on the Web 13th April 2000

An unprecedented one-step synthesis of unnatural α-amino acid and peptide derivatives, in both the racemic and optically pure forms, using azetidine-2,3-diones as building blocks has been developed by treatment with primary amines.

As the defining subunit of peptides and proteins, α-amino acids play a central role in chemistry and biology, and the development of new stereoselective strategies for the synthesis of α-amino acids has evolved in a very active field in recent years.[1] In addition to the need for large-scale preparation of the 20 common proteinogenic α-amino acids, there is an ever increasing demand for the much rarer nonproteinogenic α-amino acids. Peptides containing α-amino acids that are not naturally occurring can also be used in biological studies, either to provide information on the active conformation of related peptides,[2] or as enzyme inhibitors.[3] On the other hand, while the chemistry of 6-oxopenicillanates and 7-oxocephalosporanates has been the focus of intense effort,[4] little was known about the synthesis and application of monocyclic azetidine-2,3-diones[5] and even less on their optically active derivatives,[6] until Palomo *et al.* elegantly merged into this field.[7] In our ongoing project directed toward the asymmetric synthesis and synthetic applications of functionalised 2-azetidinones,[8] we have recently described both the allylation and the stereoselective Baylis–Hillman reaction of enantiopure azetidine-2,3-diones.[9] In connection with this work, we report here, the unexpected manner in which azetidine-2,3-diones **1** and a variety of primary amines undergo reaction to give novel α-amino acid and peptide derivatives **2** (Scheme 1). The concise and convergent approach described herein presents a practical opportunity to connect the rapidly expanding fields of β-lactam chemistry and α-amino acid and peptides.[10]

Starting substrates, azetidine-2,3-diones **1**, were prepared both in racemic and in optically pure forms following our previously reported methods. Racemic compound **1a** was obtained from 3-methylidene-4-phenyl-2-azetidinone by dihydroxylation followed by oxidative cleavage with $NaIO_4$.[11] Enantiopure azetidine-2,3-diones (+)-**1b** and (−)-**1c** were available in high yield by Swern oxidation of the corresponding 3-hydroxy-β-lactam.[9] We sought to explore the reactivity of azetidine-2,3-diones **1** with various primary amines. To our surprise, under the usual conditions utilized for imine formation,† α-amino acid derivatives **2** can be smoothly prepared in both the racemic and enantiopure forms, instead of the expected imino-β-lactams (Table 1).‡ This result is in sharp contrast with the smooth reaction of related indoline-2,3-diones with primary amines to afford imino-γ-lactams.[12] Of particular interest was the reaction of azetidine-2,3-diones **1** with α-amino esters such as methyl glycinate or methyl alaninate, showing the utility of this approach in the rapid synthesis of optically pure peptides (Table 1, entries 4, 8 and 9).§ Treatment of azetidine-2,3-dione (+)-**1b** with (*S*)-alanine methyl ester forms in 55% yield the peptide **(–)-2i**, bearing three chiral centers.¶ Compound (−)-**2i** showed a single set of signals in ^{1}H NMR spectrum, thus proving that this transformation proceeded without detectable racemization.



1 **2**

Scheme 1

Palomo *et al.* have reported the synthesis of some α-amino acid derivatives from *N*-carboxy anhydrides (NCA), with NCAs being obtained through Baeyer–Villiger oxidation of azetidine-2,3-diones.[7] However, our one-step flask synthesis of α-amino acid derivatives starting from azetidine-2,3-diones is significant and should have application in organic synthesis.

This process could be rationalized through an initial nucleophilic addition of the amine to the ketone moiety of the azetidine-2,3-dione **1**, forming an intermediate carbinolamine **3**. This intermediate **3** may react through two different pathways to give the expected 3-imino-β-lactam **4** or the intermediate **5**, but presumably evolves to the fused aziridine-β-lactam **5**. We believe that the N1–C2 bond of intermediate **5** should be very labile, evolving to aziridinone **6**. Compound **6** under the reaction conditions furnish *N*-formylamide **7**. Intermediate **7** appears as the final, not isolable product, in the reaction. It is well known that *N*-formylamides, related to **7** smoothly lose CO under basic conditions to give the corresponding NH-amides.[13] Furthermore, heating in a sealed tube at 90 °C may well favour

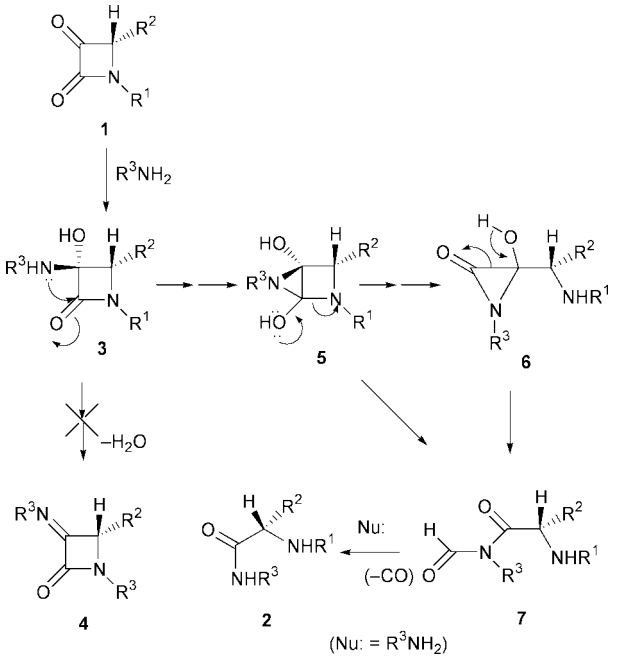

Scheme 2

the suggested CO extrusion and hence the shorter time needed for the thermal process in comparison with the reaction at room temperature (Scheme 2).

The suggestion that the reactive species involved in the reaction is the aziridine **5**, is presently made to explain the formation of α-amino acid derivatives rather that of the expected 3-imino-β-lactams. The different behaviour of azetidine-2,3-diones and pyrroline-2,3-diones may be due to differences in the carbinolamine presumably involved in the reaction, perhaps in the easier opening tendecy of the more strained four-membered ring.

In conclusion, a rapid one-step synthesis of unnatural α-amino acid and peptide derivatives both in racemic and in optically pure forms, starting from azetidine-2,3-diones has been developed. Furthermore, as far as we know, this unusual reaction of azetidine-2,3-diones with primary amines to afford α-amino acid derivatives is unprecedented, allowing structure variability and facile incorporation of functional groups. Studies concerning the scope and generality of this methodology are underway in our laboratory, and further details will be reported in due course.

Notes and references

† Preliminary experiments were carried out under the usual anhydrous conditions utilized for the formation of imines, using $MgSO_4$, but we then realised that this was not necessary. Also, initial experiments with the most volatile amines were carried out in large excess (10 equiv.), however we later performed the reaction using equimolecular amounts of amine/substrate obtaining the same results as previously. Besides, we have carried out the experiments either with or without argon and with or without rigurously dry and degassed THF, obtaining similar results in all cases.

‡ No loss of optical purity was evident by ^{1}H NMR spectroscopy in presence of a chiral shift reagent of europium(III).

§ *Representative experimental procedures* for the synthesis of α-amino acid and dipeptide derivatives **2**: *method A* [Compounds **2a**–**c**, (−)-**2f**–**g**]: A solution of the appropriate amine (0.5 mmol) in tetrahydrofuran (1 mL) was added to a solution of the azetidine-2,3-dione **1** (0.5 mmol) in tetrahydrofuran (5 mL) and the solution was heated in a sealed tube at 90 °C for 2–6 h. The reaction mixture was allowed to cool to room temperature, the solvent removed under reduced pressure and after flash chromatography eluting with hexanes–ethyl acetate or dichloromethane–ethyl acetate, compounds **2** were obtained in analytically pure form.

Method B [Compounds **2a**, (−)-**2d**–**e**, (−)-**2h**–**j**]: a solution of the appropriate amine (0.5 mmol) in tetrahydrofuran (0.1 mL) was added to a solution of the azetidine-2,3-dione **1** (0.5 mmol) in tetrahydrofuran (5 mL) and the solution stirred at room temperature for 2–24 h. Compound (−)-**2j** required more prolonged reaction time (4 days). The solvent was removed under reduced pressure and after flash chromatography eluting with hexanes–ethyl acetate or dichloromethane–ethyl acetate, compounds **2** were obtained in analytically pure form.

¶ All new compounds were fully characterised by spectroscopic data and microanalysis and/or HRMS.

Received (in Cambridge, UK) 7th February 2000, Accepted 29th March 2000

The reaction of $SeCl_2$ with *tert*-butylamine in THF yields the acyclic imidoselenium(II) dichlorides $ClSeN(Bu^t)NSeCl$ and $ClSeN(Bu^t)SeN(Bu^t)SeCl$, in addition to the six-membered ring $Se_3(NBu^t)_3$.

Numerous selenium–nitrogen (Se–N) compounds have been discovered in the past decade.[1–3] These include a number of nitride halides of Se(III) and Se(IV), *e.g.* the cyclic system $Se_3N_2Cl^+$,[4] the acyclic cations $N(SeCl)_2^+$ and $N(SeCl_2)_2^+$,[5,6] and the anion $N(SeCl_3)_2^-$.[7] Transient selenonitroso derivatives ArN=Se (Ar = 4-XC_6H_4, X = Br, Me; Ar = 2-XC_6H_4, X = SMe, SeMe) have been trapped as Diels–Alder adducts with dimethylbutadiene,[8] but oligomers of this unit [cyclic Se(II) imides] have not been described. The only known cyclic Se(II) imides, $Se_6(NBu^t)_2$ and $Se_9(NBu^t)_6$, contain Se–Se linkages.[9] We report here, the preparation and X-ray structures of $ClSe[N(Bu^t)Se]_nCl$ (**1**, n = 1; **2**, n = 2), the first two members of a homologous series of imidoselenium(II) dihalides, which represent a new class of SeN compounds, and $Se_3(NBu^t)_3$ **3**, the first cyclic oligomer of an SeNR unit. There are no sulfur or tellurium analogues of **1** and **2**.

The reaction of $SeCl_2$[10] with Bu^tNH_2 in a 2:3 molar ratio in THF at −80 °C yields a mixture of **1** and **2**,† in addition to the cyclic Se(II) imide **3**. The lower solubility of the imidoselenium(II) dihalides allows them to be isolated as red crystals by fractional crystallization. Both **1** and **2** are extremely moisture-sensitive and the crystals of **1** melt below room temperature. Compound **2** can be isolated in 34% yield when the reaction of $SeCl_2$ with Bu^tNH_2 is conducted in a 1:2 molar ratio. The identities of **1** and **2** were established by X-ray crystallography.

The X-ray analysis of **1**‡ revealed an acyclic ClSeNSeCl arrangement with planar geometry at the nitrogen atom [Σ < N(1) = 359.7°] (Fig. 1). The two Cl substituents are in similar orientations above the SeNSe plane as indicated by the ClSeNSe torsion angles of 84.8(4) and −92.9(4)°. By contrast, the related Se(III) system $[ClSeNSeCl]^+$ is planar and both *cis*,*cis* and *cis*,*trans* isomers have been observed in the solid state.[5] Presumably the rotation of the Se–Cl bonds away from planarity in **1** minimises lone pair–lone pair repulsions between Se and N. The mean Se–N bond distance of 1.810 Å in **1** is slightly shorter than the value of 1.869 Å found for $Se[N(SiMe_3)_2]$[11] and the predicted Se(II)–N single bond value of 1.86 Å.[12] The mean Se–Cl bond length of 2.219 Å is, as expected, somewhat longer than the corresponding value of *ca.* 2.15 Å found for the cation $[ClSeNSeCl]^+$.[5]

An X-ray structural determination‡ showed that **2** consists of a U-shaped SeNSeNSe unit terminated by Cl atoms, which adopt very different orientations (Fig. 2). The torsion angles Cl(1)–Se(1)–N(1)–Se(3) and Cl(2)–Se(2)–N(2)–Se(3) are 83.0(2) and −116.5(1)°, respectively. The SeNSeNSe unit is distinctly non-planar with torsion angles of 40.8(2) and -69.4(2)° for Se(1)–N(1)–Se(3)–N(2) and N(1)–Se(3)–N(2)–Se(2), respectively. The marked difference in torsion angles is apparently reflected in a variation in the Se–N bond lengths. Those involving N(2) are almost equal, 1.803(3) and 1.822(3) Å, while the values for the two Se–N(1) bonds differ by 0.19 Å. The geometry at the nitrogen atoms is approximately planar [Σ < N(1) = 355.2°, Σ < N(2) = 357.0°]. The Se–Cl bond distances are 2.269(1) and 2.312(1) Å in **2** *cf.* 2.219 Å for **1**. Negative hyperconjugation [lp(N) → σ*(Se–Cl)] may contribute to a lengthening of the Se–Cl bonds.[5b]

The NMR data for **1** and **2** are consistent with their solid-state structures.† Single NBu^t environments are observed in both the ^1H and ^{13}C NMR spectra. The ^{77}Se NMR spectrum of **1** in toluene exhibits a singlet at δ 1854 and that of **2** shows two resonances at δ 1620 and 1613, which are assigned to NSeCl and NSeN, respectively, on the basis of their relative intensities.

The formation of **1** and **2** can be envisaged to occur *via* the intermediate $[Bu^tN(H)SeCl]$ **4** (Scheme 1). When the molar ratio $SeCl_2$:Bu^tNH_2 is increased to 1:3 a complex mixture of selenium(II) imides is produced, including the known cyclic systems $Se_6(NBu^t)_2$ and $Se_9(NBu^t)_6$[9] and a new SeN heterocycle $Se_3(NBu^t)_3$, **3**, which was isolated in *ca.* 10% yield as yellow crystals by fractional crystallization from *n*-hexane. An X-ray structural determination showed that **3** is a six-membered ring [|*d*(Se–N)| = 1.833 Å] in a chair conformation analogous

to that of the tellurium analogue.[13] Details of this structure and our ^{77}Se NMR investigations of these systems will be given in a full account of this work.

In summary, we have isolated and structurally characterized the first two members of a novel class of Se(II)–N compound, the imidoselenium(II) dihalides, **1** and **2**, as well as the first example of a cyclic oligomer of a selenonitroso compound, **3**. The acyclic systems are potentially versatile reagents for the synthesis of Se(II)–N macrocycles, while **3** can be viewed as a tridentate Se(II) ligand.

Notes and references

† A solution of SeCl$_2$ (15 mmol)[10] in THF (10 mL) was added to a solution of Bu^{t}NH$_2$ (2.2 mL, 22.5 mmol) in THF (40 mL) at −80 °C. The reaction mixture was stirred for 1 h at −80 °C and then for a further 1 h at 23 °C. The precipitate of [Bu^{t}NH$_3$]Cl was removed by filtration and solvent was evaporated under vacuum to give a dark red oil. A hexane solution of this oil at −22 °C deposited X-ray quality dark red crystals of **1** and red crystals of **2**, which were separated manually. The total yield of **1** and **2** was estimated to be *ca.* 50% from the ^{77}Se NMR spectrum of the reaction mixture.

NMR characterization data: **1** δ (^{1}H) (C$_7$D$_8$, 25 °C) 1.10 [*s*, C(CH$_3$)$_3$]; δ (^{13}C) (C$_7$H$_8$, 25 °C) 74.1 [*C*(CH$_3$)$_3$], 31.4 [C(*C*H$_3$)$_3$]; δ (^{77}Se) (C$_7$D$_8$, 25 °C) 1857 (NSeCl) (referenced to an external saturated solution of SeO$_2$ at 25 °C); chemical shifts are reported relative to Me$_2$Se(l) at 25 °C [δ(Me$_2$Se) = δ(SeO$_2$) + 1302.6].

2 δ (^{1}H) (C$_7$D$_8$, 25 °C) 1.16 [*s*, C(CH$_3$)$_3$]; δ (^{13}C) (C$_7$H$_8$, 25 °C) 26.8 [C(*C*H$_3$)$_3$], not observed [*C*(CH$_3$)$_3$]; δ (^{77}Se) (C$_7$H$_8$, −30 °C) 1620 (NSeCl), 1613 (NSeN).

3 δ (^{1}H) (C$_7$D$_8$, 25 °C) 1.23 [*s*, C(CH$_3$)$_3$]; δ (^{13}C) [C$_7$H$_8$–C$_7$D$_8$ (4:1), 25 °C] 64.8 [*C*(CH$_3$)$_3$], 30.7 [C(*C*H$_3$)$_3$]; δ (^{77}Se) [C$_7$H$_8$–C$_7$D$_8$ (4:1), 25 °C] 1396 (NSeN).

Synthesis and catalytic activity of Ti-ITQ-7: a new oxidation catalyst with a three-dimensional system of large pore channels

María-José Díaz-Cabañas, Luis A. Villaescusa† and Miguel A. Camblor*

Instituto de Tecnología Química (CSIC-UPV), Avda. Los Naranjos s/n, 46022 Valencia, Spain. E-mail: macamblo@itq.upv.es

Received (in Oxford, UK) 18th January 2000, Accepted 28th March 2000

Isomorphous substitution of Si by Ti in the framework of ITQ-7, the crystalline silica polymorph of lowest density, has been achieved by direct synthesis, affording its three dimensional system of large pore channels to be used in selective oxidation reactions.

After the discovery of the medium pore zeolite TS-1[1] and of its outstanding properties as a catalyst for the selective oxidation of organic compounds with aqueous hydrogen peroxide,[2] the isomorphous substitution of Si by Ti in zeolites has received much attention.[3] Aside from a fundamental interest in understanding the remarkable catalytic properties of TS-1, there has been a considerable effort in making new Ti-zeolites that could enlarge the field of application of these materials in industrially important oxidation reactions. Within this aim, the search for catalysts with larger pores allowing processing of larger molecules and/or the use of oxidising agents larger than H_2O_2 has been particularly relevant. New materials with larger pores such as zeolite Ti-beta[4] and the non-zeolite mesoporous Ti-MCM-41[5] have been developed and their catalytic properties tested. Although those materials, particularly Ti-beta, have clear advantages from the point of view of pore size, they are also intrinsically less active than TS-1. Very interestingly, Ti-beta presents peculiar differences in catalytic properties when compared to TS-1 (with regard to catalytic behaviour in different solvents and selectivity in the epoxidation of olefins and in the hydroxylation of phenol) which appear to be due to the different crystalline structure of both materials[6] rather than to differences in their hydrophobicity, Al content or degree of isolation of Ti in tetrahedral positions as initially assumed. Unfortunately, a detailed structural investigation of those differences is hindered by the very complex, severely intergrown nature of the structure of zeolite beta.[7] Here, we present Ti-ITQ-7 (structure code ISV), a new three dimensional large pore zeolite which presents a more ordered structure than zeolite beta.[8] In addition to the opportunities that Ti-ITQ-7 may offer in the investigation of the structure/activity/selectivity relationships in Ti-zeolites, its distinct pore architecture could give rise to differences in its catalytic performance when compared to Ti-beta.

Ti-ITQ-7 can be prepared in conditions similar to those described for the pure silica polymorph,[8] by first cohydrolyzing tetraethylorthotitanate (TEOTi) and tetraethylorthosilicate (TEOS) in an aqueous solution of the hydroxide form of the structure directing agent (SDA) 1,3,3-trimethyl-6-azonium-tricyclo[3.2.1.4[6,6]]dodecane. Crystallites of ITQ-7 may be added as seeds to promote the crystallisation. In a typical synthesis, 0.76 g TEOTi and 13.87 g TEOS were hydrolysed in 27.77 g of a solution of the hydroxide form of the SDA (1.0 mol kg^{-1}). Then, 0.65 g H_2O_2 (aq. 35 wt.%) were added and the mixture was stirred at room temperature allowing evaporation of all the ethanol and of the water needed to obtain the final composition given below. Then, 1.38 g HF (aq. 48 wt.%) were added before the final addition of a suspension of SiO_2 ITQ-7 crystallites in water (0.20 g zeolite, 2.50 g water). The final composition of the gel was SiO_2 : 0.05 TiO_2 : 0.10 H_2O_2 : 0.5 SDAOH : 0.50 HF : 3 H_2O. The mixture was poured into Teflon-lined stainless steel autoclaves and crystallised under rotation at 150 °C for 12 days (yield: 27.48 g Ti-ITQ-7 per 100 g synthesis mixture; Si/Ti ratio of Ti-ITQ-7 : 120). The solid presents an XRD pattern characteristic of zeolite ITQ-7 and, in order to remove its guest species, it can be calcined to 580 °C without structural damage (Fig. 1).

In the absence of seeds, the crystallisation of Ti-ITQ-7 in the presence of relatively high Ti contents (Si/Ti $\leq$ 30) does not proceed to completion: while the zeolite nucleates and starts growing, the crystallisation stops at certain point and the partially crystallised solid remains essentially unchanged by powder XRD even if heating is extended for an additional month. At present we do not have a clear explanation for this observation, which appears difficult to rationalise given that Ti-ITQ-7 may be crystallised from gels with even higher Ti contents if seeds are used (see example above). For Si/Ti ratios of 50 or above in the starting gel, no seeds are required.

The isomorphous substitution of Si by Ti in the framework of ITQ-7 (the crystalline silica polymorph of lowest density known to date)[8] has been confirmed by the usual techniques. The diffuse reflectance UV spectra of calcined Ti-ITQ-7 sample (Fig. 2) show a band at 205–220 nm, typically assigned to a electronic transition with ligand to metal charge transfer character involving isolated Ti in the framework of zeolites.[9] Only for TiO_2 contents of 1.1% or above, does the band have a tail at high wavelength which suggests the presence of a small amount of TiO_2 anatase. The IR spectra of the calcined materials in the region of framework vibrations show a band at 960 cm^{-1}, characteristic of Ti-zeolites and assigned to the Si–O stretching in Si–O–Ti groups.[10]

The activity and selectivity of Ti-ITQ-7 in the selective epoxidation of hex-1-ene with H_2O_2 was tested and compared to the performance of aluminium-free Ti-beta synthesised in fluoride media[6] (Table 1). Three main conclusions may be derived from the results in Table 1. First, the activity and selectivity of Ti-ITQ-7 for the oxidation of this alkene is equivalent to that of Ti-beta with similar Ti content. Second, the

Ti-beta	1.40	MeOH	20.0	50	98
Ti-beta	1.40	MeCN	39.2	100	100

[a] Batch reactor, 50 °C, 17 mmol hex-1-ene, 11.8 g solvent, 0.4 g H_2O_2 (35 wt%), 100 mg catalyst, 7 h. The Ti-beta catalysts were prepared according to ref. 6. [b] H_2O_2 selectivity is defined in terms of mol of oxidized products (epoxide and glycols) per 100 mol of H_2O_2 consumed in the reaction.

activity of Ti-ITQ-7 is much higher in acetonitrile than in methanol, in contrast to the known behaviour of TS-1, for which protic solvents work better,[11] and much alike that of Ti-beta. The better defined XRD pattern of ITQ-7 (Fig. 1) compared to Ti-beta might allow a more detailed structural study of the striking observation that Ti-zeolites with different structures perform much differently when used as catalysts in different solvents. Finally, the catalytic results support the conclusion, primarily derived from the characterisation results described above, that Ti has been successfully substituted for Si in the zeolite ITQ-7 framework.

Ti-ITQ-7 is the first high-silica zeolite catalyst with a three dimensional system of large pore channels circumscribed by windows of 12 tetrahedra since the discovery 30 years ago of the aluminosilicate zeolite beta,[12] and follows the very recent publication of the non-catalyst all-SiO_2 zeolite ITQ-7.[8] Despite the very similar catalytic performance of Ti-ITQ-7 and Ti-beta in the epoxidation of a small alkene such as hex-1-ene, the different pore architecture of both materials, especially in the crystallographic *c* direction (Fig. 3), might give rise to differences in shape selectivity if a different, larger substrate of particular shape is used.

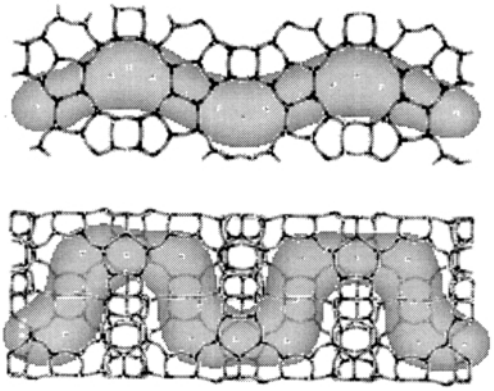

Fig. 3 Comparison of the non-linear large pore channels running along the [001] direction of ITQ-7 (ISV, bottom) and one of the polymorphs of zeolite beta (*BEA, top). The frameworks, depicted in a stick model, are viewed in projection down the [110] (ISV) or [100] direction (BEA) to show the largest deviation from linearity of the [001] channels, which are drawn as gray tubes. Both structures show linear large pore channels (not emphasized in the figure) running along the [100] and [010] crystallographic directions.

We gratefully acknowledge financial support by the Spanish CICYT (project MAT97-0723).

Received (in Liverpool, UK) 17th February 2000, Accepted 28th March 2000

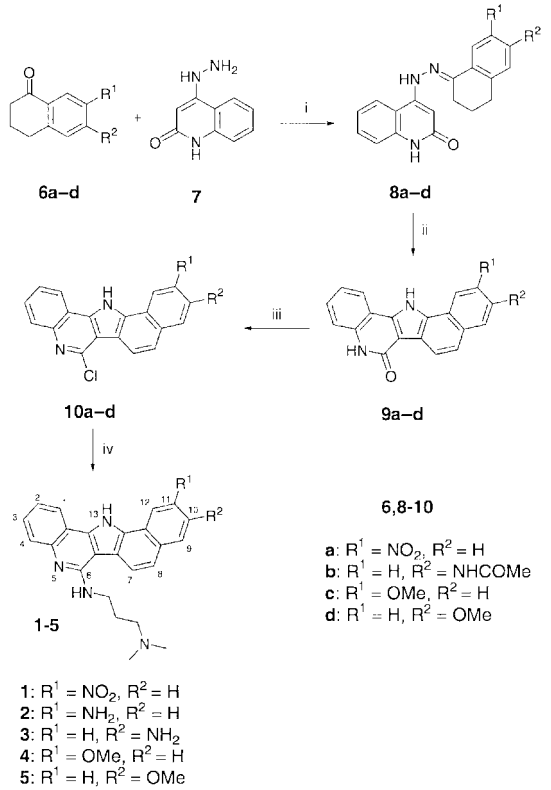
The triple helix stabilization property of 13*H*-benzo[6-7]indolo[3,2-*c*]quinoline was significantly improved by changing the electron-donor acceptor properties of the substituent at position 10 or 11.

Sequence-specific recognition of double-stranded DNA (dsDNA) by triplex-forming oligonucleotides (TFOs) offers a promising strategy to control the expression of genetic information and to develop new molecular tools.[1–3] TFOs bind to the major groove of dsDNA through formation of Hoogsteen or reverse Hoogsteen hydrogen bonds with the purines already engaged in Watson–Crick base pairs.[2] For this reason, triplex helix formation is mainly restricted to oligopyrimidine–oligopurine tracts of dsDNA. As a triple helix is generally thermodynamically less stable than a double helix, considerable efforts have been made to stabilize triple helices, and thus to extend the scope of dsDNA targeting by TFOs to shorter and therefore more numerous oligopyrimidine–oligopurine sequences. A number of triplex-specific ligands have thus been developed to promote the formation of triple helices, which would be otherwise unstable under physiological conditions.[4]

Recently, we have designed and synthesized a series of 13*H*-benzo[6-7]indolo[3,2-*c*]quinolines (B[6,7]IQ) which are pentacyclic crescent-shaped aromatic molecules.[5] Characteristic of the B[6,7]IQ compounds is their great efficacy for triplex stabilization, and weak binding towards duplexes. Possessing an extended aromatic surface, B[6,7]IQ derivatives are able to intercalate into triplexes, and to provide large π orbital overlap with the neighboring triplets at the intercalation site. In an effort to further optimize the design of an efficient triplex stabilizer, we report herein, the synthesis and DNA binding behavior of B[6,7]IQ derivatives **1**–**4**, bearing either an electron-donating or an electron-withdrawing functionality at the C–10 or C–11 center.

B[6,7]IQs **1**–**4** were obtained according to adaptations of the procedure reported for compound **5**[5] (Scheme 1). The tetralones **6a**–**d**, either commercially available, or obtainable through reported syntheses,[6] were reacted with 4-hydrazinoquinolin-2-(1*H*)-one **7** in acetic acid to form the corresponding hydrazones **8a**–**d**. Compounds **8b**–**d** were subsequently converted directly to the benzoindoloquinolones **9b**–**d** in a 'one pot' process involving thermal Fisher indolization, followed by addition of palladium/carbon (large excess) to effect aromatization of the dihydro intermediate formed. For **8a**, the treatment with Pd/C was accompanied by a further palladium-promoted reaction of the nitro group by the molecular hydrogen generated *in situ*. To circumvent this problem, compound **9a** was obtained by reaction of the isolated Fisher indolization product with a stoichiometric amount of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in DMF. Conversion of benzoindoloquinolin-6-ones **9a**–**d** to the corresponding 6-chloro derivatives **10a**–**d** was then achieved through reaction with benzyltriethylammonium chloride, *N*,*N*-diethylamine and phosphorus oxychloride.[7] These intermediates were then reacted with *N*,*N*-dimethyl-1,3-propanediamine under reflux. This latter reaction proceeded smoothly for the methoxy-substituted substrates **10c**,**d** yielding products **4** and **5** in 64 and 93% yields, respectively.[5] In a similar way the acetamido derivative **10b** was converted directly to compound **3** in 75% yield. However, for the nitro-containing substrate **10a** a mixture of both nitro (**1**) and amino-containing (**2**) substitution products (15 and 9%, respectively) was obtained. Even though the yield of this reaction was poor, it produced enough material to permit study of both compounds **1** and **2** for their ability to stabilize triple helices.

Triple helix stabilization by ligands **1**–**4** and **5**[5] was investigated by thermal denaturation experiments while monitoring the absorbance of double- or triple-helical DNA complexes at 260 nm (Fig. 1). The extent of duplex and triplex stabilization was estimated by measuring the melting temperature of the corresponding nucleic acid structures in the presence and absence of ligands **1**–**5**.



Scheme 1 Synthetic pathway and conditions of B[6,7]IQ derivatives (see text and ESI† for details): i, HOAc, room temp. 18–36 h, 79–99%; ii, for **9a**: (1) Ph_2O, reflux 4.5 h, (2) DDQ, DMF, reflux 2 h, 69%; for **9b**–**d**: Ph_2O, reflux 2–3.5 h, then 10% Pd/C, reflux 1–2 h, 44–76%; iii, $C_6H_5NEt_2$, $PhCH_2NEt_3Cl$, MeCN, $POCl_3$, reflux 24–48 h, 42–95%; iv, $NH_2(CH_2)NMe_2$, reflux 3 h, 9–93%.

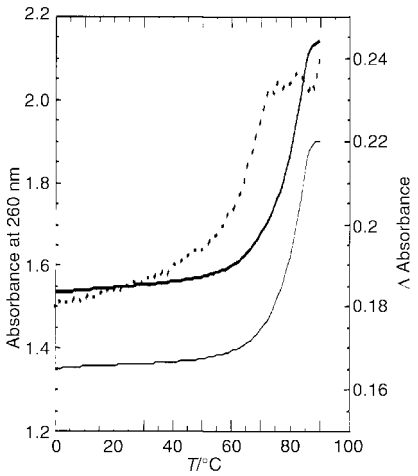

Fig. 1 Melting curves of 1.5 μM double- and triple-helices 14C3 (thin and thick lines, respectively) in the presence of 15 μM compound **5**. The triplex–duplex transition is better shown by subtracting the duplex melting curve from the triplex one (dashed thick line, scaled to the right) than by usual first derivative plot, owing to closely overlapped transitions. All thermal denaturation experiments were carried out in 10 mM sodium cacodylate buffer (pH 6.2) containing 100 mM sodium chloride.

In agreement with previously reported studies, it was determined that all five ligands, which share a common extended aromatic ring system, are able to stabilize the triplex more strongly than the duplex. Regardless of the ligand and the sequence, the differences in melting temperatures for the transition from duplex to single strands exhibited only modest variations (+13 to +19 °C). In contrast, the changes in the triplex-to-duplex melting temperatures were much higher (between +38 and +65 °C for the 14C3 triplex, or between +29 and +45 °C for the 14C5 triplex) and showed marked susceptibility to the nature of the R^1 and R^2 functional groups (Scheme 1). Thus, whereas the amino-bearing ligands **2** and **3** showed significant stabilization, with a $\Delta T_m^{3\rightarrow2}$ of +38 and +43 °C, respectively, in the presence of the 14C3 triplex sequence, and +29 and +35 °C in the presence of the 14C5 sequence, the methoxy-bearing ligands **4** and **5** induced significantly better triplex stabilization (+51 and +50 °C for the 14C3 sequence, and +39 and +41 °C for the 14C5 sequence).

The nitro-containing ligand **1** shows unprecedented triplex-promoting properties with a $\Delta T_m^{3\rightarrow2}$ of +65 and +45 °C in the presence of the 14C3 and 14C5 sequences, respectively. Furthermore, this ligand shows only modest affinity for double-helical structures (the $\Delta T_m^{2\rightarrow1}$ for the 14C3 and 14C5 sequences are +15 and +16 °C, respectively: Table 1). Thus, compound **1** presents a significantly greater specificity for triplexes as compared to duplexes.

To rationalize the trends that we observed, at least two parameters need to be taken into account: (i) the electron withdrawing capacity of the substituent group at position 11: triplex stabilization increases in the order NH_2 < OMe < NO_2, and (ii) the position of the substituent : substitution at position 10 appears to be more stabilizing than at position 11 (at least for the 14C5 sequence).

According to molecular models,[5] substitution at position 10 or 11 occurs in a region which is supposed to interact with Hoogsteen bases in base triplets. As a consequence, these substitutions should have a smaller effect on duplex than on triplex stabilization. The complete set of data is reported in Table 1.

The observations reported herein show that a significant part of the binding energy for intercalation of B[6,7]IQ derivatives into a triplex can be ascribed to the electron-donor acceptor (EDA) properties of the substituent at position 10 or 11. This leads us to the conclusion that further improvements in the design of triplex-stabilizers could take advantage of the fact that electron-withdrawing groups provide triplex-specific intercalators with both improved efficiency and selectivity. Polynitrated or polycyanated structures which not only expand the hyper-conjugated surface, but also increase the electron-withdrawing capabilities of intercalator might represent interesting candidates to explore for their triplex stabilizing properties. Synthetic studies toward such molecules are currently in progress.

Table 1 Sequences of the triple helices studied in this work (14C3 and 14C5) and the increased melting temperatures of triple- and double-helices ($\Delta T_m^{3\rightarrow2}$ and $\Delta T_m^{2\rightarrow1}$, respectively) in the presence of the B[6,7]IQ derivatives (see the legend of Fig. 1 for experimental conditions). The oligopyrimidine–oligopurine sequence for triplex formation in the double-stranded DNA fragment is in bold letters. In the absence of ligands, the $T_m^{3\rightarrow2}$ of the triplexes 14C3 and 14C5 are 16 and 17 °C, respectively, whereas the $T_m^{2\rightarrow1}$ of the corresponding duplexes are 62 and 63 °C, respectively. The accuracy of T_m values is *ca.* ±1 °C

Received (in Liverpool, UK) 25th February 2000, Accepted 27th March 2000

Replacing phosphodiester linkages in DNA with neutral 3′-*N*-sulfamate groups has little effect on the binding affinity for complementary DNA or RNA, whereas incorporation of sulfamide groups into DNA results in considerable destabilisation of isosequential duplexes.

Modified oligonucleotides with neutral linkages replacing the native phosphodiester groups are of interest in the development of improved antisense and antigene agents.[1] Methylphosphonates, one of the earliest examples of this class, can only be efficiently prepared at present as a mixture of diastereoisomers at the phosphorus atom and have low affinity for complementary nucleic acids.[2] More recently neutral methylene(methylimino) (MMI),[3] amide[1] and 3′-thioformacetal[4] modified oligonucleotides have been developed which exhibit improved affinity for complementary nucleic acids. Furthermore, neutral formacetal[5] and dimethylenesulfone[6] linkages have been used effectively in the development of modified DNA aptamers[5] and dsDNA transition state analogues[6] that can bind to specific protein targets.

Earlier we reported the synthesis of dinucleotide analogues in which the phosphodiester linkage is exchanged for a neutral sulfamide group.[7] Here, the effects of the sulfamide **1** and 3′-*N*-sulfamate **2** (Scheme 1) internucleoside linkages on nucleic acid conformation and duplex stability are described. It was envisaged that the block synthesis approach could be used to synthesise chimeric oligodeoxynucleotides in which one or more of the phosphodiester groups are replaced by the neutral linkages. With the sulfamide phosphoramidite **10** in hand[7] a route to the 3′-*N*-sulfamate dinucleosides was required. Although isomeric 5′-*N*-sulfamate dinucleosides have been prepared before, the synthesis uses explosive sulfuryl chloride azide ($ClSO_2N_3$) and the overall yields are low.[8] Therefore, the development of an alternative method was necessary. Initially the coupling of 2–hydroxyphenyl sulfamate **5**[7] with the 5′-alcohol **8** was investigated. However, compound **5** proved insufficiently reactive and failed to give any of the sulfamate dinucleoside **11** despite the earlier observation that **5** reacts smoothly, albeit at high temperature, with the 5′-amine **7** to give the sulfamide dinucleoside **9**. In light of this, the more reactive 4–nitrophenyl sulfamate **6** was prepared by treating the 3′-amine **3** with 4–nitrophenyl chlorosulfate **4**.[9] Coupling of **6** with 5′-alcohol **8** was successful resulting in the sulfamate dinucleoside **11** in excellent yield at room temperature. Similarly the sulfamide dinucleoside **9** could also be prepared more effectively at room temperature from **6** and the 5′-amine **7**. Desilylation of dinucleoside **11** and 3′-phosphitylation gave the required phosphoramidite **12**.

The sulfamate dinucleoside d(TnsoT) **2** was also prepared and its conformation compared with d(TnsnT) **1**, and the native dinucleoside phosphate d(TpT) using NMR spectroscopy. As expected the sum of the $J_{1'2'}$ and $J_{1'2''}$ vicinal coupling constants ($\Sigma 1'$) for the 5′-terminal ribose ring of d(TnsoT) revealed a higher proportion of the C3′-*endo*, or northern (N), sugar conformation (69% N at 30 °C) than the native d(TpT) which exists predominantly in the C2′-*endo*, southern, conformation (36% N).[7] This can be attributed to the lower electronegativity of the 3′–amino substituent of d(TnsoT) and a reduced *gauche* effect between this substituent and the deoxyribose O4′ atom. Furthermore, the shift in the % of N-conformer with change in temperature for both deoxyribose rings of d(TnsoT) was virtually the same as that observed for d(TnsnT),[7] with the largest change occurring in the 5′-terminal ring (63% N at 70 °C increasing to 78% at 10 °C). The native d(TpT) shows little or no variation in sugar pucker with change in temperature. To investigate if this effect is due, in part, to an increase in base stacking of the modified dimers circular dichroism (CD) spectra of d(TnsoT) d(TnsnT) and d(TpT) were recorded at various temperatures. All spectra revealed the same basic characteristics

[a] T_m values are accurate to within ± 0.5 °C. [b] The changes in T_m per modification (ΔT_m/mod.) are shown in parentheses.[c] T_m was not determined.

of strong and weak positive bands at 280 and 225 nm, respectively, as well as a negative band at 255 nm, suggesting that the native and the modified dimers are adopting similar overall conformations. Upon increasing temperature all showed a significant decrease in the intensity of the bands at 280 and 255 nm. Notably the change in band intensity for d(TnsoT) was twice the magnitude of that observed for d(TnsnT) and d(TpT) which were virtually identical. This suggests that d(TnsoT) has an higher propensity to adopt a base stacked helical conformation than d(TnsnT) and d(TpT), which base stack to a lesser extent.[10]

Solid phase synthesis of 16-mer chimeric oligodeoxynucleotides, incorporating 3′–*N*-sulfamate or sulfamide linkages, was carried out under standard conditions using the modified dimer phosphoramidites **10** and **12**. The oligonucleotides prepared, **13**–**18**, were characterised by electrospray mass spectrometry and all have the same sequence GCGT$_{10}$GCG[11] (Table 1). The duplex melting temperatures (T_m) of modified oligonucleotides with complementary DNA were then determined by variable temperature UV spectroscopy and compared with the T_m for the native duplex. Modified oligonucleotides with one and three central sulfamide linkages, **14** and **15**, both show a similar change in T_m per modification (ΔT_m/mod.), compared with the native duplex, of −3.2 °C at 0.02 and 0.1 M salt concentration [Na^+]. At 1.0 M salt concentration the modification was even more destabilising. In contrast incorporation of one, three and five sulfamate groups, **16**, **17** and **18**, has little effect on duplex stability with complementary DNA and is even moderately stabilising at low salt concentration with an observed increase in T_m of 0.3 °C per modification. Upon increasing salt concentration the T_m dropped by 0.4 °C for one sulfamate modification. It is likely that the neutral linkages reduce the electrostatic repulsion between strands which is more evident at low salt concentration when fewer cations are present to mask the negatively charged phosphodiester groups. With complementary RNA at 0.1 M salt concentration, the sulfamide group had a similar effect on duplex stability with a drop in T_m of *ca.* 3.0 °C per modification. However the 3′-*N*-sulfamate modified oligonucleotides formed slightly less stable duplexes with RNA than DNA with a drop in T_m of 1.2 °C for one modification and a more moderate drop in ΔT_m/mod of 0.3 and 0.6 °C for three and five modifications respectively. It is probable that oligonucleotides with more 3′-*N*-sulfamate linkages have an higher proportion of C3′-*endo* sugar rings and are therefore more likely to adopt an A–type conformation which is preferred for binding to RNA.

From these results it is clear that 3′-*N*-sulfamate modified oligonucleotides hybridise with complementary nucleic acids with similar binding affinity as native DNA, whereas the sulfamide congeners have significantly lower affinity. It is possible in light of the CD spectra that the sulfamate modified oligonucleotides are more preorganised into a base stacked helical conformation, in the single stranded state, which would reduce the loss of entropy on binding to complementary RNA and DNA and account for the greater stability of the resulting duplexes. Furthermore, the 3′-*N*-sulfamate modified oligonucleotides appear to form more stable duplexes than DNA incorporating the isomeric 5′-*N*-sulfamate modification, which is reported to result in a drop in T_m of 1.5 °C per modification.[8] The destabilisation of duplexes by sulfamide and 5′-*N*-sulfamate modifications may be accounted for by the 5′-amino substituent common to both. In the case of isosteric and isoelectronic N5′→P3′ phosphoramidate DNA, the presence of a 5′-NH group completely abolishes base pairing with complementary nucleic acids.[12] This is attributed to poor hydration and steric clashes between the 5′-amino hydrogen atom and either the H2′ atom of an adjacent deoxyribose ring in an A–type conformation, or the pyrimidine H6 and deoxyribose O4′ atoms in a B-type conformation.[12]

The data reported here suggest that the 3′-*N*-sulfamate modification may be of use in the development of improved antisense or antigene agents. Moreover, given that the 3′-*N*-sulfamate group causes minimal disruption of nucleic acid duplexes, is sterically and electronically more similar to the phosphodiester group than other neutral linkages so far developed, it might also be useful as a general phosphodiester replacement for other applications. For example, one can envisage probing nucleic acid–protein interactions using this modification to determine which phosphodiester groups are involved in electrostatic contacts with protein residues. Alternatively 3′-*N*-sulfamate groups might be used to stabilise aptamers, or hammerhead ribozymes for use *in vivo*.

We thank the EPSRC for studentships to K. J. F. and D. T. H., Polkit Sangvanich for assistance with electrospray mass spectrometry and the EPSRC National Chiroptical Spectroscopy Service.

Received (in Bloomington, IN, USA) 11th November 1999, Accepted 13th March 2000

A zinc(II)–neocuproine based ribozyme mimic has been constructed for the sequence-selective transesterification of RNA using a begin metal catalyst.

We report the *de novo* synthesis of a Zn-based ribozyme mimic that can cleave HIV mRNA in a sequence-specific manner, with excellent activity. The design of artificial ribonucleases that are both biocompatible and sequence-specific has attracted much attention for their potential use as catalytic, gene-specific therapeutics.[1–8] Many of the artificial ribonucleases prepared thus far are constructs that contain chelates of copper or chelates of heavy metals. Two of our goals in the construction of artificial ribonucleases are: (i) the use of bioavailable, innocuous metals such as zinc, and (ii) the optimization of activity. The most specific artificial ribonucleases are referred to as 'ribozyme mimics' owing to the fact they mimic the Watson–Crick derived sequence-specific activity of some ribozymes. With ribozyme mimics, the large catalytic domain of a natural ribozyme is replaced by a small-molecule catalyst.

The RNA cleavage ability of free mononuclear and dinuclear zinc complexes and conjugates has been demonstrated in previous work from our lab and from other groups, but the cleavage activity of Zn reagents has generally been low. In 1995, sequence-specific cleavage of RNA was demonstrated by Lönnberg and coworkers[9] when they used a 5′-imidazole DNA conjugate in concert with free zinc ions to form an active artificial ribonuclease that cleaved 2–5% of the target RNA in 19 h at room temperature. It was followed by a 1998 communication by Matsuda *et al.* where a novel dinuclear Zn(II)–DNA conjugate was used to effect sequence-specific cleavage of RNA.[10] The dinuclear construct cleaved 5% of the RNA after 3 h at 37 °C ([RNA] = 0.2 μM; [cleavage agent] = 5 μM). Here we report the *de novo* construction of an active, sequence-specific artificial ribonuclease containing an internal serinol-neocuproine residue embedded in a DNA 17-mer (Fig. 1).

We have previously reported the synthesis and activity of a ribozyme mimic derived from serinol and copper(II)–terpyridine (Cu–terpy) (Probe 1, Fig. 1).[1,11] The serinol residue introduced an abasic site into the ribozyme mimic–RNA duplex, and was shown to be three times more efficient at RNA cleavage than a fully duplexed Cu(II)–terpy derived ribozyme mimic. The phosphoramidite **1**, a serinol-neocuproine conjugate, was synthesized according to Scheme 1 and incorporated into a DNA 17-mer (Probe 2) using standard automated DNA synthesis.§ This 17-mer is complimentary to a region of the mRNA from the HIV *gag*-gene. Probe 3 (Fig. 1), which contains a three-carbon spacer produced from a commercially available (Glen Research) phosphoramidite, was used to test for cleavage associated with the presence of an abasic site in the RNA/DNA duplex.

The modified DNA conjugates that were synthesized are shown here where X indicates the modified position. RNA cleavage reactions were conducted with two RNA substrates: a 159-mer from a relatively well conserved sequence from the *gag* mRNA of HIV (775-933), and a 28-mer that contains the same 17-mer recognition sequence (Fig. 2). The 28-mer substrate allowed identification of cleavage products and the 159-mer allowed assessment of the sequence-specificity of the ribozyme mimic in the presence of numerous binding sites. Reactions were conducted at both 37 and 45 °C, at pH 7.4 (HEPES Buffer).

High-resolution polyacrylamide gel-electrophoresis was used to analyse the RNA cleavage, and a typical image of the 28-mer reaction mixture is shown in Fig. 1. No sequence-specific cleavage was observed with probe 2 in the absence of added metal. In the presence of EDTA, probe 1 gave no

sequence-specific RNA cleavage. In accordance with previous reports, EDTA treatment is necessary to suppress cleavage in the case of probe 1 because of the high binding constant of terpy for copper. This extremely high affinity allows ribozyme mimics that contain pendant terpy ligands to scavenge trace amounts of Cu(II) from commercial buffer salts.[11] In the presence of copper, both probe 1 and 2 form active ribozyme mimics, and in the presence of zinc, probe 2 forms an active ribozyme mimic. The products of all of the cleavage reactions co-migrate with alkaline hydrolysis and Ribonuclease T_1 (G specific) digestion products, which lends strong evidence that, in the presence of either metal, these ribozyme mimics react *via* a biomimetic pathway of transesterification and hydrolysis.

The extent of cleavage is shown in Table 1. The major site of RNA scission by probes 1 and 2 varies by one base. Probe 1 induces nucleophilic cleavage of the RNA at the 3′ side of A^{16} while probe 2 cleaves on the 5′ side of this nucleotide. No sequence-specific cleavage is observed in the presence of Cu(II) or Zn(II) alone (with no DNA probe). Probe 3, the control oligonucleotide containing the abasic site and no pendant ligand, is completely inactive for RNA cleavage in the presence of Cu(II) and Zn(II) (data not shown for Zn). This control tested for any site-specific cleavage derived solely from the presence of metal ions and an abasic site.

The Zn(II) conjugate of probe 2 is only the third example of a zinc based artificial ribonuclease derived from Zn(II), and the second mononuclear example. Direct comparisons of sequence-specific RNA cleavage efficiencies are very difficult because of differences in reaction time and temperature, but the zinc–neocuproine-mediated cleavage reported here is higher than the sequence-specific cleavage previously reported. We have demonstrated that high cleavage efficiencies that can be attained using benign inorganic chemistry. The extent of cleavage by ribozyme mimics observed in these studies is as follows:

Cu(II)–neocuproine > Zn(II)–neocuproine > Cu(II)–terpy.

The observed trends result predominately from two phenomena: (i) The speciation between metal-bound water and metal bound hydroxide (the most probable active species) *i.e.* the trends in the pK_a of the coordinated waters and (ii) the suppression of bis(μ-hydroxide) dimers by the methyl groups of neocuproine.[12]

The *in vivo* concentration of zinc in human serum is 17.2 μM,[13] three times greater than the concentration of zinc used in these *in vitro* experiments. There remains controversy over the amount of free zinc in the cell. Note also that the free copper concentration *in vivo* has recently been determined to be approximately zero.[14] The large cleavage efficiency of the zinc

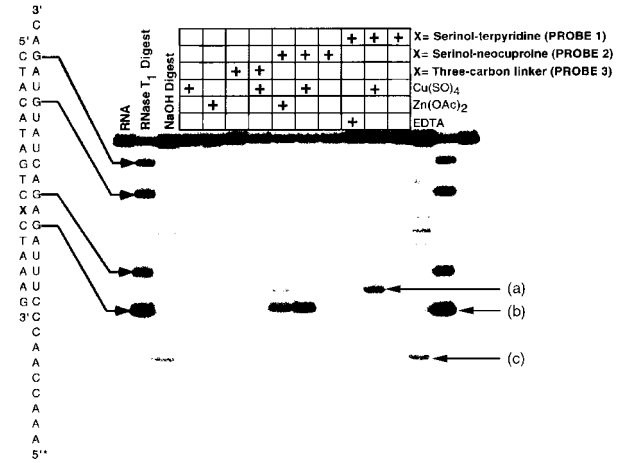

Fig. 3 Audioradiogram of the sequence-specific cleavage of the 5′-end labeled 28-mer RNA substrate 5′-CTA CAT AGT CXC TAA AG-3′ by ribozyme mimics; (a) sequence-specific cleavage by probe 1 (minor site probe 2), (b) sequence-specific cleavage by probes 2, (c) hot spot for RNA cleavage.

based ribozyme mimic bodes well for the production of biocompatible sequence-specific artificial ribonucleases.

§ The compounds synthesized in Scheme 1 were fully characterized by ^{1}H, ^{13}C and ^{31}P(phosphoramidite **1**) high-resolution NMR spectroscopy and high-resolution fast-atom-bombardment (HR-FAB) mass spectrometry (MS). All probes were characterized by matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry and electrospray mass spectrometry.(Mass spectrometry was provided by the Washington University Mass Spectrometry Resource, an NIH Research Resource (Grant No. P41RR0954)).

The 159-mer RNA was synthesized by runoff transcription and 5′ end labeled with ^{32}P (We thank Dr Lee Ratner for the plasmid containing the HIV *gag*-gene fragment). The 28-mer RNA was purchased (Oligo's *etc.*) and ^{32}P 5-end labeled in a similar fashion. RNA cleavage reactions were carried out in 10 mM *N*-(2-Hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) buffer pH 7.4, with 0.1 M $NaClO_4$, [0.1 μM RNA (28-mer) and 0.01 μM RNA (159-mer), 5 μM probe, and 5 μM metal (total reaction volume = 10 μL. The reactions were heated to the desired temperature and time. The reactions were quenched by the addition of 5 μL loading buffer, and loaded on a denaturing polyacrylamide gel (20% 28-mer and 6% 159-mer). The gel image was quantified using a Molecular Dynamics PhosphorImager™ and the ImageQuant™ software package.

Low-density hydrogen-bonded networks in crystals and at the air/water interface

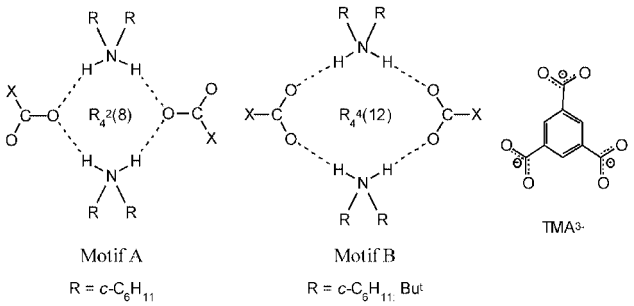
David J. Plaut, Kristian M. Lund and Michael D. Ward*

Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN, USA. E-mail: wardx004@tc.umn.edu

Received (in Columbia, MO, USA) 13th December 1999, Accepted 9th March 2000

Trimesic acid and various alkylamines assemble into ordered two-dimensional hexagonal hydrogen-bonded networks in both bulk crystals and at the air/water interface.

Interest in low-density open organic frameworks, assembled by non-covalent interactions, has increased significantly owing to their potential application as designer solids for separations, catalysis, and electronic materials.[1] Controlling the structure of porous networks can be complicated by interpenetration of equivalent frameworks[2] and the influence of guest or solvent molecules on structural isomerism of the framework.[1d,3] A recent study of a single crystal of a 3:1 complex consisting of dicyclohexylamine and trimesic acid (H_3TMA), crystallized from a 1:1 mixture of butan-1-ol and methanol,[4] revealed a low-density hydrogen-bonded network with the 'chicken-wire' motif A, rather than the more symmetrical structural isomer based on motif B. We report herein, three new compounds that



contain the cyclic $R_4^4(12)$ motif B,[5] in which both carboxylate oxygen atoms form hydrogen bonds with the dialkylammonium protons. The formation of these compounds illustrates the sensitivity of structural isomerism to different guest molecules. We also demonstrate that these hydrogen-bonded motifs can be generated at the air/water interface from long chain aliphatic amines and H_3TMA.

Vapor diffusion of acetone into methanol or isopropyl alcohol solutions containing H_3TMA and dicyclohexylamine afforded single crystals of $[NH_2(c\text{-}C_6H_{11})_2^+]_3[TMA^{3-}]\cdot Me_2CO\cdot 0.5MeOH$ **1** and $[NH_2(c\text{-}C_6H_{11})_2^+]_3[TMA^{3-}]\cdot 2.5\ Me_2CHOH$ **2**, respectively. Similarly, vapor diffusion of acetone and di-*tert*-butylamine into an isopropyl alcohol solution of H_3TMA afforded single crystals of $[NH_2(Bu^t)_2^+]_3[TMA^{3-}]\cdot Me_2CO$ **3**. Single crystal X-ray diffraction reveals 2D hydrogen-bonded 'honeycomb' networks in each of these materials.† These networks can be viewed as expanded versions of the 'chicken-wire' motif reported for H_3TMA alone.[2] Pairs of ammonium cations acts as 'spacer' molecules between pairs of carboxylate substituents on the TMA^{3-} anions as depicted in motif B. The 2D sheets pucker to different extents in these structures, reflecting an intrinsic flexibility that enables this network architecture to persist despite the differently sized alkyl groups and solvent molecules included within the networks. Nevertheless, the formation of motif B apparently is quite sensitive to the crystallization solvent, given that motif A was observed in methanol solvated crystals grown from butan-1-ol–methanol solutions.

Compound **1** crystallizes in the space group $P\bar{1}$ and exhibits two crystallographically independent flat 2D hydrogen-bonded layers (Fig. 1). The cyclohexyl substituents of one of these layers project into the hexagonal pores, with six cyclohexyl groups lying in the midplane of the pore, three projecting above the plane, and the remaining three projecting below the plane. The second layer (not shown) also has the identical honeycomb motif but the cyclohexyl substituents are twisted out of the layer plane to a greater extent. These layer structures reflect the flexibility of the hydrogen bonds and the ability of the carboxylate groups to rotate around the C–C bond. The two independent layers alternate along the *a* axis with the pores overlapping, creating a continuous channel along this direction. This contrasts with the previously reported methanol solvate, which crystallized in the hexagonal space group $P6_3$ and exhibited 2D hydrogen-bonded sheets that were organized along the six-fold screw axis such that pores were not continuous. Disordered acetone and methanol molecules occupy the pores in **1**, filling the void space not occupied by the cyclohexyl groups. The guest stoichiometry was determined by thermal gravimetric analysis and ^1H NMR spectroscopy.

Compound **2** crystallizes in space group $P\bar{1}$ and exhibits hydrogen-bonding motif B. However, two carboxylate groups of each TMA^{3-} anion each have one oxygen that is hydrogen bonded to the dialkylammonium protons as well as an isopropyl alcohol molecule that resides below the plane of the 2D hydrogen-bonded sheet. Each puckered 2D sheet can be described as interconnected hexagons with chair-like conformations. If the hexagon is defined by the centroids of the TMA^{3-}

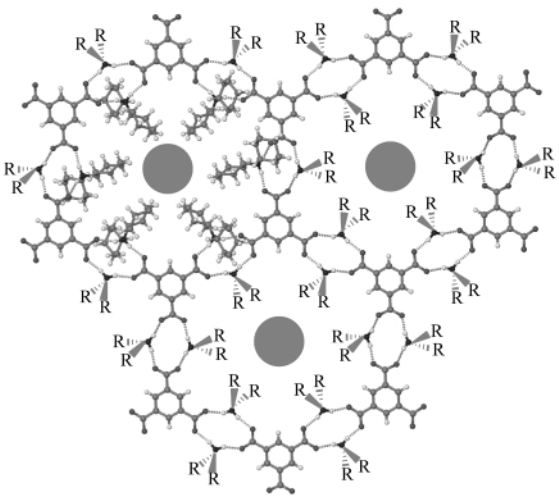


Fig. 1 A portion of one of the two unique 2D hydrogen-bonded networks in **1**. Of the twelve cyclohexyl substituents on the interior of each pore, six project along the midplane of the pore while the remaining six project above or below the plane. The pore at the upper left is depicted with all its cyclohexyl substituents; in the remaining two pores these have been denoted as R for simplicity. The disordered guest molecules are depicted by the circles in the center of the pores.

DOI: 10.1039/a910252n

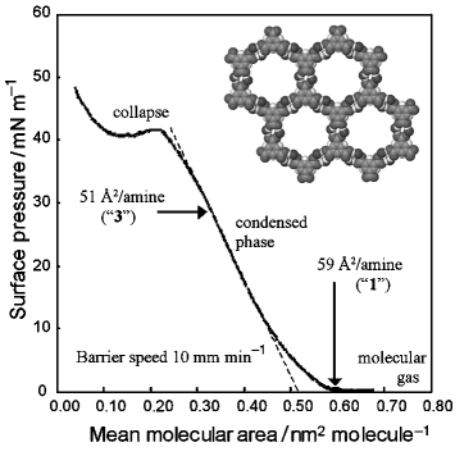

Fig. 2 Pressure–area isotherm of ODA over an aqueous H_3TMA subphase, indicating a molecular area of *ca.* 59 Å^2/amine at lift-off, and 51 Å^2/amine before collapse. The insert depicts the *bc* plane of compound **1** (cyclohexyl groups and guest molecules omitted for clarity), which has a calculated area matching that obtained from the Langmuir isotherm.

anions, the torsion angles associated with the chair-like conformations are 19.1, 16.2 and 18.4°. The hexagonal pores in adjacent sheets are slightly offset but still create a continuous channel, along the *a* axis, that is filled with disordered isopropyl alcohol guests.

Compound **3** crystallizes in the space group $P2_1/n$, and exhibits motif B with hydrogen-bonded sheets consisting of chair-like hexagons that are more severely puckered than in **2**, with torsion angles measuring 22.9, 23.9 and 25.5°. Two acetone molecules occupy the void space not occupied by the *tert*-butyl groups of the amines within each pore.

The bulk structure of organic crystals can often be described as 2D molecular layers that stack in the remaining third dimension. Consequently, these layer motifs can be used as models for the design of monolayers on solid substrates and at the air/water interface. The latter requires amphiphiles with polar head groups capable of organizing at the air/water interface into motifs that mimic the structure of the 2D layers in the bulk crystals.[3a,6]

The pressure–area isotherm measured for the long chain amphiphile octadecylamine (ODA), spread over an aqueous subphase of H_3TMA, exhibits lift-off at a molecular area of 59 Å^2/amine. Extrapolation of the linear compression regime afforded a molecular area of 51 Å^2/amine (Fig. 2). In contrast, a molecular area of *ca.* 20 Å^2/amine was measured when ODA was spread over a basic subphase without H_3TMA.[7] Similar isotherms were collected for methyloctadecylamine (MODA) and dioctadecylamine (DODA), both exhibiting linear compression regimes that were consistent with an area of 54 Å^2/amine.‡ The molecular areas measured from the isotherms collected over H_3TMA lie within the range of the molecular areas occupied by the 2D hydrogen-bonded networks in **1**–**3** (58.6, 56.6 and 51.5 Å^2/amine, respectively). This strongly supports the formation of a 2D porous hydrogen-bonded monolayer at the air/water interface having motif B. Notably, the molecular area for the methanol solvate of **1** and **2** (motif A), based on the reported crystal structure, is only 45 Å^2/amine. Furthermore, the range of lift-off and extrapolated values reflected by the different isotherms, suggests that the monolayers possess the flexibility evident from the bulk crystalline networks.

We anticipate that porous Langmuir monolayers can serve as structural mimics of isostructural porous 2D networks in crystalline solids. These monolayers, for which interpenetration is not possible, may promote the nucleation and growth[6,8] of crystalline phases containing such networks. Porous monolayers, transferred to permeable solid substrates by the Langmuir–Blodgett method, may also be useful as size exclusion membranes in which the pore sizes can be adjusted by molecular design.

We gratefully acknowledge Maren Pink and Victor J. Young of the X-ray Crystallographic Laboratory at the University of Minnesota for the acquisition of crystallographic data. Financial support was provided by the National Science Foundation and the University of Minnesota Industrial Partnership in Interfacial and Materials Engineering (IPRIME).

Notes and references

† *Crystal data*: for **1**: $C_{45}H_{75}N_3O_6\cdot(CH_3)_2CO\cdot0.5CH_3OH$, triclinic, $P\bar{1}$, a = 16.9805(3), b = 19.5242(4), c = 20.0428(4) Å, α = 116.268(1), β = 111.491(1), γ = 95.189(1)°, U = 5284.2(2) Å^3, T = 173 K, Z = 4, μ(Mo-Kα) = 0.062 mm^{-1}, 35303 reflections measured, 17825 unique (R_{int} = 0.0289) which were used in all calculations. There is disordered solvent present in this structure. Attempts were made to model this, but were unsuccessful since there were no obvious major sire occupations for the solvent molecules. PLATON/SQUEEZE[9] was used to correct the data for the presence of the disordered solvent. A potential solvent volume of 1091.1 Å^3 was found. 300 electrons per unit cell worth of scattering were located in the void. The stoichiometry of solvent was calculated independently by NMR and TGA to be one molecule of MeOH and two molecules of acetone per unit cell, which results in 228 electrons per unit cell. The modified dataset improved the *R*1 value by *ca.* 10%; final *R*1 = 0.0563, *wR*2 = 0.1379.

For **2**: $C_{45}H_{75}N_3O_6\cdot2.5(CH_3)_2CHOH$, triclinic, $P\bar{1}$, a = 10.5401(6), b = 15.815(1), c = 18.711(1) Å, α = 107.648(1), β = 105.627(1), γ = 97.211(1)°, U = 2788.3(3) Å^3, T = 173 K, Z = 2, μ(Mo-Kα) = 0.074 mm^{-1}, 22227 reflections measured, 9779 unique (R_{int} = 0.0385) which were used in all calculations. Two isopropyl alcohol molecules were found and refined in the structure. The structure contains disordered solvent in a channel along (*x*,1/2,1/2). Attempts to model this were unsuccessful. PLATON/SQUEEZE was used to correct the data for the presence of the disordered solvent. A potential solvent volume of 246.9 Å^3 located in the above mentioned channel was found. 38 electrons per unit cell worth of scattering were located in the void. The electron count suggests the presence of *ca.* one isopropyl alcohol molecule per unit cell. The modified dataset improved the *R*1 value by *ca.* 6%; final *R*1 = 0.0642, *wR*2 = 0.1895.

For **3**: $C_{45}H_{75}N_3O_6\cdot(CH_3)_2CO$, monoclinic, $P2_1/n$, a = 9.745(1), b = 18.486(2), c = 23.157(2) Å, β = 101.644(3)°, U = 4090.0(5) Å^3, T = 173 K, Z = 4, μ(Mo-Kα) = 0.073 mm^{-1}, 30377 reflections measured, 7227 unique (R_{int} = 0.0828) which were used in all calculations; final *R*1 = 0.0600, *wR*2 = 0.1752. The dataset was checked for twinning and disordered solvent, however, no evidence for either was found.

CCDC 182/1580. See http://www.rsc.org/suppdata/cc/a9/a910252n/ for crystallographic files in .cif format.

‡ Interestingly, the isotherm of DODA initially reveals a linear compression feature corresponding to 94 Å^2/amine, but collapses at 23 mN m^{-1} to the linear region associated with the 54 Å^2/amine value. We surmise that this value corresponds to a condensed phase in which one of the alkyl chains lies at the air/water interface until increased compression drives both alkyl chains away from the air/water interface to form a 2D structure similar to the monoalkylamine layers.

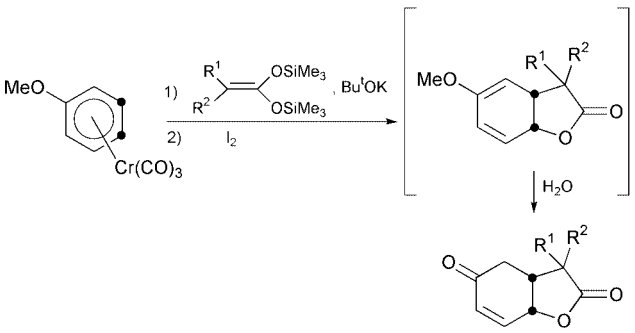
Received (in Liverpool, UK) 11th February 2000, Accepted 21st March 2000

Bis(trimethylsilyl) ketene acetals react successively with allylic acetates, in the presence of Pd(0) then with H_2O_2, in the presence of methyltrioxorhenium, to give δ-hydroxy-γ-lactones *via* γ-unsaturated carboxylic acids.

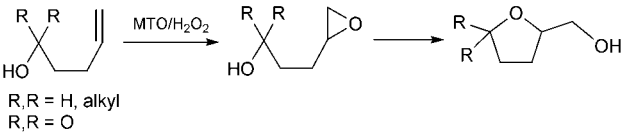
η³-allyl palladium complexes, formed upon oxidative addition of allylic compounds to Pd(0), have found wide applications, as intermediates, in their reaction with nucleophiles.[1] Much effort has been devoted to the modification of the structure of the allylic moiety, the ligands around the metal, and also of the nucleophiles. It is this last point on which will focus our attention. Indeed, we have shown recently that bis(trimethylsilyl) acetals of ketenes could be used either as nucleophiles or versatile precursors of nucleophiles, when suitably activated, in reactions with a large variety of electrophiles such as carbonyl compounds, organic and organometallic peroxo derivatives,[2] and arene tricarbonyl chromium complexes.[3] These acetals lead *directly*, in contrast to other precursors, to functionalized carboxylic acids in high yield. Moreover, for chromium complexes, a direct double nucleophilic addition of potassium enolates originating from these acetals on a carbon–carbon double bond of anisole (and its derivatives) has been brought to the fore. This one pot reaction leads to functionalized lactones (Scheme 1).

Alkoxy monotrimethylsilyl ketene acetals have already been used in palladium(0) catalyzed alkylations in conjunction with allylic acetates for the preparation of unsaturated esters.[4–6] Under the same conditions, bis(trimethylsilyl) ketene acetals might thus lead to unsaturated carboxylic acids. Moreover, we have shown[7] that γ-unsaturated hydroxyalkenes underwent a high yield catalytic oxidative cyclization to lactols promoted by the system H_2O_2/MTO (methyltrioxorhenium),[8] a reaction which has recently been applied to the transformation of γ-unsaturated carboxylic acids into hydroxylactone (Scheme 2).[9]

Taken together, the interaction of bis(trimethylsilyl) ketene acetals first with allylic acetates to give unsaturated carboxylic acids, then with MTO/H_2O_2 to give hydroxylactones (Scheme 3) would constitute a means for the catalytic addition of two nucleophiles on a carbon–carbon double bond,[10] and would thus



Scheme 1



Scheme 2

parallel, on a formal point of view, the transformation of anisole depicted in Scheme 1. And this indeed turned out to be the case.

Depending on the nature of the starting ketene acetals, cyclopropane carboxylic acids could be isolated as secondary products, and epoxycarboxylic acids detected by NMR as intermediates in the lactonization reactions.

Thus, a mixture of allyl acetate (10 mmol) and bis-(trimethylsilyl)ketene acetal **1a**† (11 mmol) was heated in THF (70 mL) for 24 h in the presence of $Pd(PPh_3)_4$ (0.2 mmol, 2%). Evaporation of the volatiles, under vacuum, left a residue which was diluted in dichloromethane and filtered through a pad of silica gel. Extraction with aqueous sodium hydroxide followed by acidification and extraction with dichloromethane gave a mixture of acids. After cooling the solution to 0 °C, MTO (5% with respect to the unsaturated acids) was added followed by a 30% solution of hydrogen peroxide (1.1 equiv. with respect to the acids). The biphasic mixture was then stirred for three days at room temperature, the excess oxidant destroyed with aqueous sodium bisulfite, and the organic products extracted with dichloromethane. Treatment of the organic layer with dilute sodium hydroxide left an organic phase containing the hydroxy-lactone (5 mmol). Acidification of the aqueous layer followed by extraction with diethyl ether gave, after evaporation of the solvents, the cyclopropyl acid (1.5 mmol).

The same reactions were carried out on a series of bis(trimethylsilyl) ketene acetals and two allylic acetates.† They led to hydroxylactones and, for the more substituted ketene acetals, to mixtures of lactones and cyclopropyl acids (Table 1).‡

For cinnamyl acetate **2a** (R^3 = Ph) and the ketene acetal **1a** (R^1 = R^2 = Me), the two acids **3a** and **4a** resulting, respectively, from S_N2 and S_N2' reactions, were separated by crystallization and by silica gel chromatography. Their oxidation led, respectively, to the lactones **6a** and **7a** (Scheme 4). Whereas the transformation of **3a** into **6a**, obtained as a single isomer was complete within 6 h, the conversion of **4a** into **7a** took three days. This result is in agreement with the difference of epoxidation rate observed for substituted and terminal olefins with the system H_2O_2/MTO.[8]

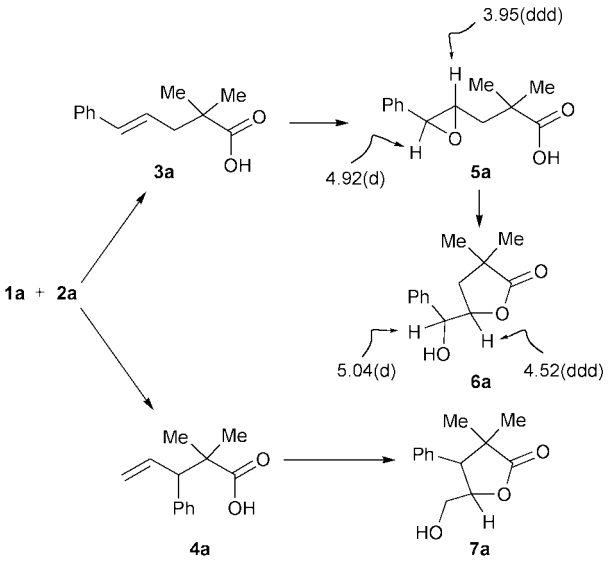

Scheme 4

That indeed epoxides were formed as intermediates in these oxidation reactions as for γ-hydroxyalkenes[7] was demonstrated as follows: when the acid **3a** was subjected to the oxidation reaction, a labile precursor could be detected by ^{1}H NMR spectroscopy after 2 h giving a doublet and a multiplet at δ 4.92 and 3.95, respectively attributable to the two hydrogens of the epoxide **5a** (Scheme 4). These signals disappeared progressively in favour of those due to the hydroxylactone **6a** at δ 5.04 (doublet), and δ 4.52 (multiplet). Attempts to isolate the epoxide **5a** by silica gel chromatography failed however, a result which is reminiscent of previous observations.[7]

The results described herein allow the following comments to be made.

As for mono(trialkylsilyl) ketene acetals, no base was required for the interaction with the allylic acetates: the ketene acetals are thus nucleophilic enough to interact as such with the π-allyl complexes of palladium.[6,10]

In addition, these transformations are interesting from a double point of view. First, highly substituted, unsaturated carboxylic acids can be obtained *directly* in the first step of the process. Second, for the disubstituted ketene acetals, cyclopropyl acids are formed, yet, up to now, in rather low yield. Their purification, without the need of chromatography, can easily be achieved by the use of the second step of the process; indeed, the separation of the lactones from the cyclopropyl acids, whenever formed, is possible by a simple extraction process.

The interaction of mono(trialkylsily) ketene acetals with allylic acetates in the presence of complexes of palladium had already been shown to give, besides unsaturated esters, cyclopropyl esters in variable amounts.[5] The reasons behind this dual reactivity of the intermediate π-allyl complexes with the nucleophiles (central *vs.* terminal addition) have not been clearly established since contrasting results have been found in the literature.[12–15] Up to now, no attempts have been made in order to optimize the yields of the reactions described above by modifying the nature of the catalyst and the experimental conditions, or to drive them in one or the other direction. It seems nevertheless likely that steric factors are important both as far as the ligands around the metal and the substituents on the ketene acetals are concerned.

Received (in Oxford, UK) 4th January 2000, Accepted 28th March 2000

Growth of a mesostructured silica thin film at the air/water interface was observed *in situ* using Brewster angle microscopy and surface pressure measurements allowing real time observation of nucleation of the film and its rapid growth to full surface coverage at the end of the induction period.

Mesoporous inorganic materials, such as the hexagonally ordered silica MCM-41, can be synthesized by template-directed reactions using surfactant or block copolymer self-assembled templates. Although much work has been carried out on the preparation of these materials in bulk, powdered forms, many applications particularly in the fields of filtration, separation and catalysis, require thin film geometries. Several groups have reported films formed by dip[1,2] or spin coating,[3] or by growth at the air/water,[4,5] mica/water,[6] and graphite/water interfaces.[7] Although films have been studied by X-ray and neutron reflectivity,[8–10] TEM and SEM,[11] AFM and optical microscopy,[12,13] none of these techniques have allowed detailed examination of the *in situ* growth of the silicate film. Here, we report the use of Brewster angle microscopy (BAM) and surface pressure measurements to trace the real-time evolution of growing films of mesostructured silica at the air/water interface. The data provide new insights into the formation mechanism and growth kinetics of such films as the measurements can be made on a much finer timescale than was previously possible. From these measurements it seems that the film is nucleated at many points across the surface and grows together from nuclei that are only a few microns across.

The growth of mesostructured silica thin films at the air/water interface of a synthesis solution† in a Langmuir trough showed three distinct stages observable by BAM: an induction period; a period of rapid film growth to cover the interface; and a period of coarsening of the surface film. The induction period (*ca.* 330 min from mixing), was characterized by a relatively constant value in the surface pressure measurements‡ (Fig. 1). The length of this period decreased with higher concentrations of CTAB and TMOS but was reproducible to within 10 min for a given set of conditions. A reproducible fluctuation in the surface pressure was observed during the induction period that consisted of a pressure increase followed by a decrease of *ca.* 1 mN m^{-1} between 125 and 285 min after mixing (Fig. 1).

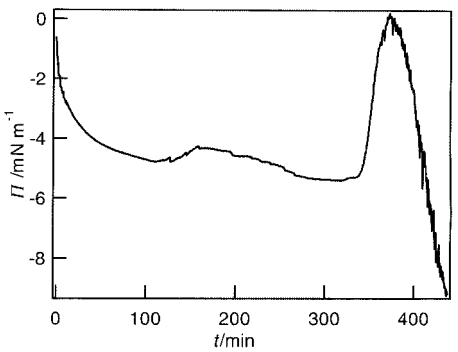

Fig. 1 Surface pressure changes with time during growth of a surfactant–silica mesostructured film at the air/water interface.

Corresponding BAM images§ taken during the induction period showed a uniform background with randomly distributed high-contrast point features, 5–10 μm in size [Fig. 2(a)]. These features increased slightly in number with time and moved across the interface owing to convection currents in the sub-phase. On the surface of a similar solution, CTAB in 0.2 M HCl with no TMOS present, such features are visible but are much less numerous and do not increase in number with time. Degassing the acid solution prior to adding CTAB and TMOS did not affect the appearance of the point features, indicating that they were not gas bubbles.

Taken together, the surface pressure measurements and BAM images indicate significant changes in the surface behaviour of the synthesis solutions prior to film formation. The results suggest that surfactant molecules are partitioned at the air/water boundary as a surface excess in the form of a continuous monolayer. Polysilicate binding to the cationic headgroups of the surfactant then gives rise to domains with modified thickness or molecular orientation. This is consistent with a model in which silicate binding in discrete regions under the monolayer is responsible for preferential nucleation of the silica–surfactant mesophase at the air/water interface, rather than bulk deposition in solution, although some precipitation from the bulk also occurs. An interaction between silica and surfactant at the surface of a CTAB/tetraethoxysilane solution has been proposed on the basis of X-ray and neutron reflectometry measurements.[4,9] These showed a slight decrease in the thickness of the surfactant monolayer from 3 to 2.7 nm and an increased scattering length density prior to film growth, indicating silica gathering at the interface. Reflectometry measurements, however cannot distinguish a low density, uniform silica/surfactant film from local regions of higher

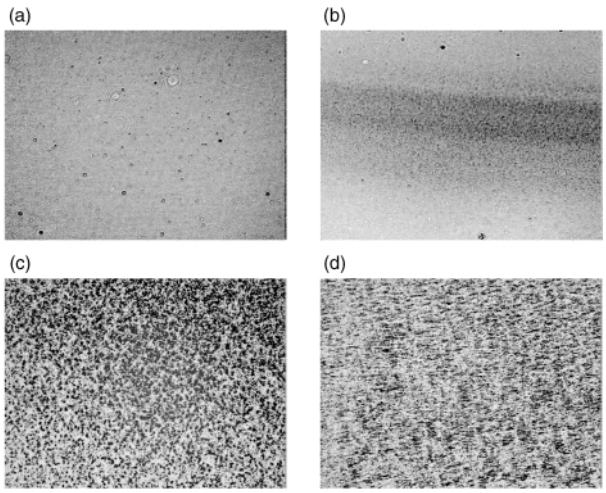

Fig. 2 Brewster angle microscope images following the evolution of a silica–surfactant composite film at the air/water interface (a) during the induction period, (b) just after the onset of film growth, 331 min after mixing of the reagents, (c) 350 min after mixing and (d) 407 min after mixing, showing growth and coarsening of the film at the interface. The horizontal edge of each image corresponds to 430 microns.

DOI: 10.1039/b000375l

density silica at nucleation sites scattered over the surfactant monolayer as is observed in the BAM.

The end of the induction period (330 min after mixing) was marked by a rapid increase in surface pressure over a period of 50 min (Fig. 1) owing to the formation of a densely packed surface film of mesostructured silica. Further growth resulted in an apparent decrease in pressure owing to the attachment of the film to and consequent increase in weight of the Wilhelmy plate. Corresponding BAM images showed an increase in the homogeneity of the surface film just prior to the rapid increase in surface pressure. Many of the point features in the BAM images became less distinct and merged with the background to give a lower contrast continuous texture that was still mobile on the liquid surface. Some point features were still visible, but their movement became associated with that of the continuous phase. The onset of film formation was associated with an increased density of the low contrast texture and a cessation of individual motion of the points over the whole region [Fig. 2(b)]. The texture then coarsened and became more distinct with growing visual contrast between dark and light regions, producing a dense coverage of 5–10 μm dots over the surface which began to merge [see Fig. 2(c)]. The lighter coloured horizontal bands across the image [Fig. 2(b)] were seen in most film forming preparations, appearing just prior to visible film formation in the BAM. They move across the surface in the same manner as the point features, so are connected with the surface, rather than the sub-phase. They do not appear in CTAB-only solutions and may be related to formation of oriented domains of the porous mesostructure in the growing surface film. Further evolution of the film, over 75 min from its first appearance, produced a network of strands with none of the original dots or the horizontal bands visible [Fig. 2(d)]. Similar fibrous structures in the final film have been reported using laser scanning confocal microscopy.[5]

The existence of point features with distinct contrast from the surrounding surface early in the induction period suggests that the film development process occurs *via* nucleation at many discrete points on the surface, rather than as a gradual building up of more or less uniform structures over the whole surface. During the induction period gradual condensation of the hydrolysed TMOS molecules proceeds, resulting in silica polyanions which interact with the surfactant monolayer at the interface causing nucleation of domains 5–10 μm across. These point features observed from the beginning the induction period are however, large compared to the coherence length expected from peak width studies of bulk hexagonal phase surfactant templated materials (several hundred nanometers[14]). Encouraging the growth of such domains may be a route to increasing long range homogeneity in these films. Once favourable conditions are achieved, possibly through concentration of the reacting species after evaporation of methanol, or by optimisation of headgroup spacing for the surfactant template by charge interaction with the polysilicates, the film forming process accelerates and full surface coverage is reached in a few minutes. Further condensation of the silica in the local environment and continuing addition of material from the sub-phase have been suggested to cause such films[5] to warp and buckle and are probably the cause of the development of ridges and the fibrous texture ultimately observed here.

Overnight, the film developed to a thickness of *ca*. 0.1 mm and showed macroscopic wrinkling, presumably induced by the confined area of the trough and from microscopic stresses such as local shrinkage of the system during polymerisation. *In situ* X-ray reflectometry on the final film showed two well developed broad Bragg peaks at Q = 0.132 and 0.257 Å^{-1} indicating formation of an ordered silica–surfactant mesophase. Reflectometry measurements however were too slow to follow the growth of the film during the induction period. Further work on the structural characterization of this material is in progress.

We thank Arach Goldar for assistance with the X-ray reflectometry. The financial support of the EPSRC Materials Committee (Grant no. GR/M15989) is gratefully acknowledged.

Notes and references

† Thin films of mesostructured silica were prepared using a molar ratio of CTAB : water : HCl : TMOS of 1.53×10^{-3} : 1 : 3.63 $\times 10^{-3}$: 0.011. The surfactant template, cetyltrimethylammonium bromide (CTAB, Sigma 99%) was dissolved in 0.2 M HCl and tetramethoxysilane (TMOS, Merck 98%) was added dropwise. This clear solution was transferred to a Teflon Langmuir trough 3.5 mm deep, surface area *ca.* 40 cm^2, so that the liquid formed a raised meniscus. Other experiments on this system have shown that at these reactant concentrations, films will grow in sealed containers where no evaporation can occur, however during these experiments, evaporation did occur and this undoubtedly affects film growth. Film formation was nevertheless highly reproducible with respect to induction time, morphology and surface pressure behaviour.

‡ Surface pressure measurements were made at 30 s intervals by a Wilhelmy plate method using a Nima surface pressure sensor. The measurements began 7 min after mixing, during which time the solution was poured into the trough and initial wetting of the Wilhelmy plate occurred. Evaporation of methanol generated by TMOS hydrolysis led to a change in plate buoyancy and an initial decrease in surface pressure; however this leveled off *ca.* 100 min after mixing. A similar although less rapid decrease in surface pressure of 0.7 mN m^{-1} owing to evaporation of water from the sub-phase was noted for a solution of CTAB in 0.2 M HCl with the same surface area in the absence of TMOS, over a 90 min period.

§ The Langmuir trough was mounted under a Brewster angle microscope (BAM2, Nanofilm Technologie GmbH) so that the surface structure and surface pressure of the synthesis solution could be monitored simultaneously. Light from a diode pumped frequency doubled Nd : YAG laser at 532 nm was used. At the Brewster angle, the reflectivity of polarised light at the interface is zero, so any small changes in interfacial refractive index, such as the presence of a surface film, are clearly visible. BAM images were taken every 30 s during the rapid growth phase of the film and every 5–10 min during the induction period. Evolution of the film structure was monitored in real time with the aid of a video camera attached to the BAM.

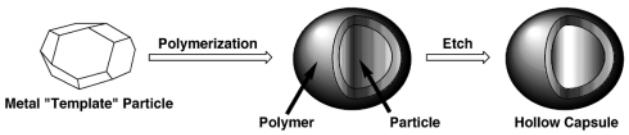
Received (in Columbia, MO, USA) 17th January 2000, Accepted 13th March 2000

A tripodal alkythiolate ligand has been assembled on gold nanoparticles, which upon metathesis polymerization and particle etching, yields crosslinked spherical hollow polymer capsules.

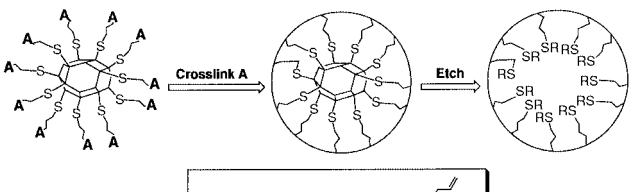
In previous reports, we have shown that gold particles are useful templates for the synthesis of hollow nanoscopic poly(pyrrole) and poly(*N*-methylpyrrole) capsules.[1] In that work, polymerization was initiated in an aqueous suspension of gold particles. Owing to the insolubility of pyrrole-based polymers in water, a polymer shell formed around the particle, which upon gold etching could be converted to a hollow capsule (Scheme 1). The hollow core volume and shell thickness were easily tuned *via* template diameter and polymerization time, respectively; guest entrapment within the host polymer capsule was demonstrated by attaching the guest to the gold particle prior to polymer formation and particle etching.



Scheme 1

Here, we demonstrate an alternative strategy for the formation of hollow polymer capsules. The strategy is similar to that reported by Mirkin and coworkers recently in which a surface-bound ω-substituted alkanethiol was polymerized to form polymer/gold composite particles.[2] In our work, the alkene-terminated tripodal ligand **A** was designed and synthesized in order to maximize polymer crosslinking. Crosslinking is important in forming structurally rigid hollow capsules following removal of the gold particle. Moreover, as demonstrated below, polymerization of **A** leaves alkene functionalities that may be further modified to manipulate the chemical properties of the resulting polymer capsule (Scheme 2).

The tripodal ligand was prepared in seven steps from 1-decen-1-ol and 11-bromo-1-undecanol.[3] Selective hydrolysis of the ester/thioacetate intermediate using methanolic potassium hydroxide in the presence of air gave high yields of the triene functionalized disulfide. Formation of triene functionalized thiol derivatized gold nanoparticles was then accomplished directly from the disulfide using procedures reported previously.[4] The thiol derivatized nanoparticle was purified by precipitation from toluene with ethanol–methanol followed by filtration. TEM images revealed spherical nanoparticles, *ca.* 5 nm in diameter. IR spectral analysis of the thiol-derivatized nanoparticle clearly indicated the presence of the ester at 1725 cm^{-1} (compared to 1731 cm^{-1} in the free ligand) and, as shown in Fig. 1(a), the terminal alkene CH bending modes at 908 cm^{-1} (compared to 908 cm^{-1} in the free ligand) and C=C stretching modes (1632 cm^{-1}) are observed. The free disulfide ligand exhibited a triplet in its ^{1}H NMR spectrum at δ 2.67 for the methylene protons adjacent to sulfur. However, upon complexation to the gold nanoparticle, the signal at δ 2.67 was no longer observed, as expected.[4b] As shown in Fig. 2(a), the terminal alkene protons were observed in the ^{1}H NMR spectrum of the thiol derivatized nanoparticle as very broad multiplets



Scheme 2

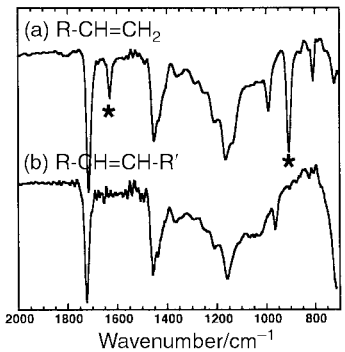


Fig. 1 (a) IR spectrum (neat film) of alkene-terminated thiol-derivatized gold nanoparticles. * Indicates terminal C=C stretching and alkene CH bending modes. (b) IR spectrum (neat film) of thiol-derivatized nanoparticles after reaction with Grubbs catalyst. Note lack of terminal C=C stretching and alkene CH bending modes, while other spectral features remain intact.

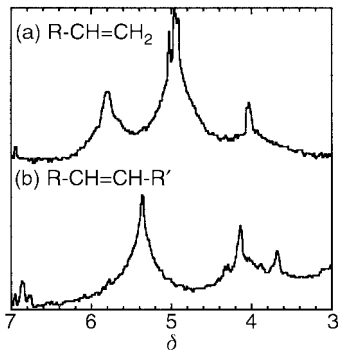

Fig. 2 (a) ^{1}H NMR spectrum (alkene region) of alkene-terminated thiol-derivatized gold nanoparticles. Alkene resonances appear as broad signals at δ *ca.* 4.9 and 5.9. (b) ^{1}H NMR spectrum (alkene region) of thiol-derivatized nanoparticles after reaction with Grubbs catalyst. Note new alkene resonances at δ *ca.* 5.3.

DOI: 10.1039/b001019g

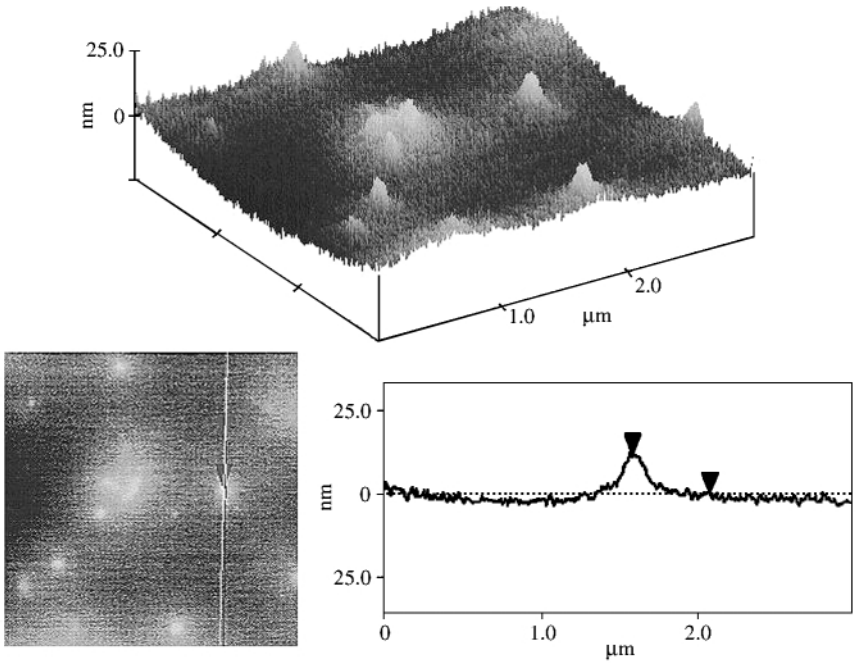

Fig. 3 Atomic force images of hollow polymer capsules. See text for details.

centered at δ *ca.* 5.9 and 4.9 which corresponded very well with the chemical shifts observed in the free triene ligand.

Metathesis of the thiol derivatized nanoparticles was then carried out using *ca.* 7 mol% of Grubbs catalyst[5] per alkene in benzene at room temp. Precipitation of the product from benzene by the addition of ethanol provided a purple waxy solid. The assumption that intramolecular polymerization to form a highly crosslinked polymeric surface occurred is strongly supported by the spectral data of the polymerized nanoparticles. As shown in Fig. 1(b), the IR spectrum shows a lack of *both* the C=C terminal alkene stretches at 1632 cm^{-1} and the alkene CH bending modes at 908 cm^{-1} for the polymerized particles. The changes in the IR spectrum are paralleled by the changes in the ^{1}H NMR spectrum: the signals for the terminal alkene protons collapsed to a single broad peak at δ *ca.* 5.3, as shown in Fig. 2(b). The signals for the terminal alkene protons collapsed to a single broad peak at δ 5.4.

Removal of the gold from the thiol derivatized particles under the same conditions used for the polypyrrole capsules [0.1 M KCN, 0.002 M $K_3Fe_2(CN)_3$] was not possible. However, sonication of a THF–water solution of KCN, $K_3Fe_2(CN)_3$ and the particles produced a change from purple to brown, indicative of particle etching. Treatment of the brown particles with hydrogen peroxide was necessary to effect complete removal of the gold. ^{1}H NMR spectra of the hollow polymerized tripodal ligand also indicated the absence of gold by virtue of the now sharp and well defined spectrum.[4b] Treatment of the nanoparticles with hydrogen peroxide efficiently oxidized the polyalkene particle to a polyol particle as evidenced by signals in the range δ 3.6–4.2 in the ^{1}H NMR spectra.

The fate of the sulfur atoms in the linker is unclear from the data in hand although it is very likely that the sulfur has been oxidized along with the alkenes. In addition, the internal ester linkage may have been partially cleaved. IR data shows hydroxy groups at 3350 cm^{-1}, and a significantly diminished CO stretch at 1723 cm^{-1}.

Atomic force microscopy confirmed that the structural integrity of the polymer capsules was maintained following gold dissolution (Fig. 3).[6] Qualitatively, AFM revealed the presence of spherical capsules, which were relatively impressible compared to gold particles or hollow polypyrrole capsules. Quantitatively, the dimensions of the capsules were 10.47 ± 2.54 nm based on the relative height of 25 capsules. This value agrees well with the diameter expected based on the size of the template gold particle (*ca.* 5 nm) and the length of alkythiol spacer.

In summary, a method has been described for converting alkylthiolate monolayers on gold particles into hollow polymer capsules. The synthetic design of the tripodal ligand provides the potential to ultimately control the functionality present on the surface of the particle as well as that present internally.

This work was supported in part by grants from the North Carolina Biotechnology Center and the NSF (DMR-9900073).

We thank Professor Christopher Gorman for helpful discussions.

Received (in Cambridge, UK) 20th December 1999, Accepted 28th March 2000

Decreasing the flexibility of the $Ph_2PCH_2CH_2PPh_2$ (dppe) backbone by making the central carbon atoms part of a cyclobutane ring leads to the formation of Pd(II) catalysts for CO/ethene copolymerization that are more efficient than those of dppe by a factor of ten.

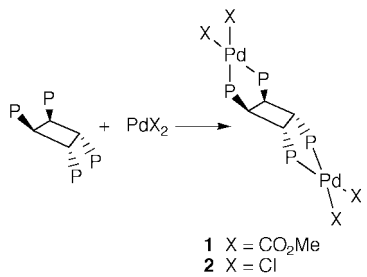
Polyketones obtained by alternating copolymerization of carbon monoxide and olefins are important innovative materials prepared on industrial scale by homogeneous palladium catalysis [eqn. (1)].[1]

$$n C_2H_4 + n CO + MeOH \xrightarrow{cat} Et\text{-}(CCH_2CH_2)_{n-1}\text{-}C(=O)\text{-}OMe \quad (1)$$

The diphosphine 1,3-bis(diphenylphosphino)propane (dppp) is the ligand of choice for the copolymerization of CO and ethene;[2,3] indeed, dppp forms Pd(II) catalysts that are more efficient than those with the lower homologue 1,2-bis(diphenylphosphino)ethane (dppe) by almost one order of magnitude.[1–3] The ability of the chelate ring size (as determined by the number of carbon atoms separating the PPh_2 groups) to modulate the flexibility of the Pd(P–P) moiety is the factor that, most commonly, is invoked to account for the dramatically different activity of the dppp and dppe catalysts.[3–5] In particular, several studies have tried to correlate the greater catalytic activity of the dppp complexes to the higher flexibility of the dppp backbone as compared to that of dppe.[3–5]

In this work, we prove experimentally that efficient Pd catalysts are formed also with diphosphine ligands containing two carbon atoms between the PPh_2 donors on the condition, however, that ligand *flexibility* is substantially *reduced*.

Reaction of the tetraphosphine *cis*,*trans*,*cis*-1,2,3,4-tetrakis(diphenylphosphino)cyclobutane[6] (*cyclo*-tetraphos) with 2 equiv. of either $Pd(CO_2Me)_2$ or $PdCl_2$ in CH_2Cl_2 yielded the bimetallic complexes Pd_2(*cyclo*-tetraphos)$(OCOMe)_4$ **1** and



1 X = CO_2Me
2 X = Cl

Pd_2(*cyclo*-tetraphos)Cl_4 **2**, respectively.‡ The latter complex was quantitatively transformed into the acetonitrile derivatives $[Pd_2$(*cyclo*-tetraphos)$(MeCN)_4]Y_4$, **3** Y_4 (Y = PF_6 or BF_4) by treatment with AgY in acetonitrile solution.

† Electronic supplementary information (ESI) available: experimental section. See http://www.rsc.org/suppdata/cc/b0/b000376j/ for crystallographic data in .cif format.

Under standard copolymerization conditions (Table 1),[2,3] **1** and **3** $(PF_6)_4$ give rise to the same catalyst system with a productivitiy of 10 kg of polyketone (g of Pd)$^{-1}$ (entry 2). This productivity value is higher than that obtained with Pd(dppe)$(OCOMe)_2$ **4** by a factor of *ten* (entry 1) and is comparable with that of the industrial catalyst Pd(dppp)$(OCOMe)_2$.[2,3] The increase in productivity using either **1** or **3**$(PF_6)_4$ in the place of **4** is not accompanied by a change in the average molecular weights of the copolymers (*ca.* 6 kg mol^{-1}).[3,7]

A single-crystal X-ray analysis has been carried out on **3**$(BF_4)_4 \cdot 2MeCN \cdot 3.4CH_2Cl_2$.§ As is shown in Fig. 1, a perfectly planar cyclobutane ring connects two equivalent $(-PPh_2)_2Pd(NCMe)_2$ moieties in each of which the Pd(II) centres adopts a slightly distorted square-planar coordination. The bond angles and distances in the cyclobutane ring are close to those of an ideal square. The P–Pd–P chelate angle and the Pd–P distances are in the usual range for dppe Pd(II) complexes with nitrogen ligands.[8] The two symmetry-related metalla-rings in **3** adopt an envelope conformation. As a consequence, each phosphorous centre of the asymmetric unit exhibits one equatorial and one axial phenyl group with the two axial phenyl rings being related by a mirror plane. The conformation of the metalla-ring and the mutual disposition of the phenyl substituents represent the most striking difference between **3** and square-planar dppe complexes in which the ligand generally assumes a twisted conformation and the phenyl groups can be all equatorial.[8,9] Therefore, in terms of steric hindrance (quadrant effect),[10] each palladium centre in **3** has a larger space for coordination and reactivity than in dppe complexes.

Since the envelope conformation of each metalla-ring is maintaned in solution, at least on the NMR time scale, the remarkable increase in catalytic activity of the *cyclo*-tetraphos

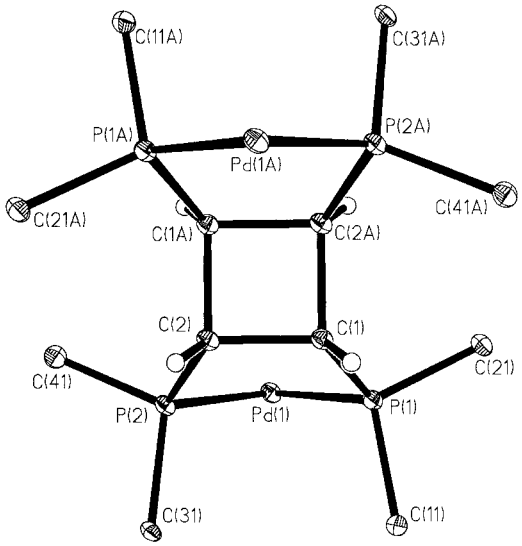

Fig. 1 ORTEP drawing of $\mathbf{3}(BF_4)_4{\cdot}2MeCN{\cdot}3.4CH_2Cl_2$ (coordinated MeCN ligands are omitted for clarity). Selected bond lengths (Å) and angles (°): Pd–P(1) 2.2484(8), Pd–N(1) 2.070(3), Pd–P(2) 2.2505(8), Pd–N(2) 2.077(3), P(1)–Pd–P(2) 82.81(3), N(1)–Pd–N(2) 89.35(12), N(1)–Pd–P(1) 93.94(9), N(2)–Pd–P(1) 174.63(9), N(1)–Pd–P(2) 176.72(9), N(2)–Pd–P(2) 93.85(9).

complex as compared to the dppe derivative may reasonably be associated to the substantial rigidity of the former that ultimately controls the steric hindrance at the metal centre. In an attempt to verify this hypothesis, the structurally rigid complexes Pd(*o*-dppbe)$(OCOMe)_2$ **5** and Pd(*cis*-dppen)$(OCOMe)_2$ **6** have been prepared and employed as catalyst precursors for CO/C_2H_4 copolymerization under the same experimental conditions [*o*-dppbe = *o*-bis(diphenylphosphino)benzene, *cis*-dppen = *cis*-bis(diphenylphosphino)ethylene].‡ Neither **5** and **6** are as efficient as **1** or **3** in the copolymerization reaction (likely due to the different electronic nature of the phosphine donors), but still the productivities are *ca*. six times higher than that of the dppe precursor **4**, yielding copolymers with comparable chain lengths.[3,7]

In conclusion, we have shown here that high rigidity of the control ligand is a structural feature that improves CO/olefin copolymerization Pd(II) catalysts. Recent studies with dppp-based catalysts are consistent with the present results as it has been found that the introduction of methyl substituents into the dppp backbone has beneficial effects on the copolymerization rate.[11] Conformational rigidity has also been invoked to account for the higher activity of the C_4-bridged bis(tetramethylphosphole) complex $[(Me_4C_4P)_2X]Pd(CO_2Me)_2$ [X = $CH_2(C_6H_4)CH_2$] as compared to C_2- [X = $(CH_2)_2$] and C_3-bridged [X = $(CH_2)_3$] analogs. The copolymerization activity of the *o*-xylene-bridged bis(phosphole)-based complex is, however, quite low [300 g of polymer (g Pd)$^{-1}$ h^{-1}].[12]

Nickelocene in benzene reacts with the Brønsted acid H_2O–$B(C_6F_5)_3$ to give the salt $[(\eta\text{-}C_5H_5)Ni(\eta\text{-}C_6H_6)Ni(\eta\text{-}C_5H_5)][B_3(\mu\text{-}O)_3(C_6F_5)_5]$ which is the first example of a triple-decker nickel sandwich with a bridging η-benzene ligand; the borate anion is also unprecedented; treatment of $Ni(\eta\text{-}C_5H_5)_2$ with Brookhart's acid $[H(OEt_2)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]$ in benzene gives the paramagnetic bis(η-benzene)nickel derivative $\{[Ni(\eta\text{-}C_6H_6)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]_2{\cdot}Ni(\eta\text{-}C_5H_5)_2\}$ in which nickelocene is present as a molecule of crystallisation.

Large and very weakly coordinating anions $[BR_4]^-$ [R = 3,5-$(CF_3)_2C_6H_3$, C_6F_5] have recently attracted interest owing to their ability to stabilise highly electrophilic metal cations.[1] The strong Lewis acid $B(C_6F_5)_3$, is currently of interest as a methyl abstracting agent and activator of early transition metal Ziegler–Natta polymerisation systems.[2] Recently the mono-aquo adduct H_2O–$B(C_6F_5)_3$ was reported, and the solution behaviour as a Brønsted acid was described.[3,4]

Here, we report reaction between nickelocene and the Brønsted acids H_2O–$B(C_6F_5)_3$ or $[H(OEt_2)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]$ (Brookhart's acid) which give unexpected new chemistry.

Treatment of nickelocene with Brookhart's acid $[H(OEt_2)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]$ in toluene gives green–blue crystals of the Ni(III) compound $[Ni(\eta\text{-}C_5H_5)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]$ **1**†. The nickelocenium cation has been isolated previously as the BF_4^- salt,[5] but no crystal structure was reported. The cation $[Ni(\eta\text{-}C_5Me_5)_2]^+$ has been structurally characterised as C_{60}^- and $[HTCNQF_4]^-$ salts.[6] The crystal structure of **1** has been determined and the ORTEP of $[Ni(\eta\text{-}C_5H_5)_2]^+$ (Fig. 1) shows eclipsed cyclopentadienyl rings as observed in $[Ni(\eta\text{-}C_5H_5)_2]$.[7] The average Ni–C distance of 2.075 Å is slightly shorter than in $[Ni(\eta\text{-}C_5H_5)_2]$ (2.178 Å). The magnetic moment of **1** at room temperature is 1.69 μ_B and corresponds to one unpaired electron, consistent[8] with the ground state configuration $\delta^4\sigma^2\pi^1$.

Treatment of nickelocene with H_2O–$B(C_6F_5)_3$ in CH_2Cl_2–benzene, gave brown crystals of the triple-decker sandwich compound $[(\eta\text{-}C_5H_5)Ni(\eta\text{-}C_6H_6)Ni(\eta\text{-}C_5H_5)][B_3(\mu\text{-}O)_3(C_6F_5)_5]$ **2**. In contrast, the reaction between nickelocene and the Brønsted acid $HBF_4{\cdot}Et_2O$ gave the cation $[Cp_3Ni_2]^+$.[9] We envisage the cation $[(\eta\text{-}C_5H_5)Ni(\eta\text{-}C_6H_6)Ni(\eta\text{-}C_5H_5)]^{2+}$ is formed by the addition of two intermediate $[Ni(\eta\text{-}C_5H_5)]^+$ fragments to a benzene molecule. Each nickel centre is formally equivalent to the 18-electron centres in $[Ni(\eta\text{-}C_5H_5)(\eta^3\text{-allyl})]$.[10] The crystal structure of **2** (Fig. 2) shows the rings are eclipsed with an average Ni–C_{Cp} distance of 2.121 Å, and the C–C–C angles lie between 106.6(5) and 109.2(4)°; the corresponding Ni–$C_{benzene}$ distance is 2.168 Å, with the C–C–C angles between 118.5(6) and 121.8(5)°. This compound is the first η-benzene–nickel(II) sandwich compound to be structurally characterised. The only other η-benzene–nickel compound is the Ni(0) phosphine compound, $[Ni(\eta\text{-}C_6H_6)(Bu^t_2PCH_2PBu^t_2)]$.[11] Nickel(II) compounds with one η-toluene or η-mesitylene ligand have been structurally characterised.[12]

The counter ion in **2** is a new dianion. The six-membered B_3O_3 ring is surrounded by five C_6F_5 groups, giving one neutral, three-coordinate boron, B(1), and two anionic tetrahedral boron centres, B(2) and B(3). There are only two non-solvent moieties present in the crystal structure, and to maintain electrostatic balance we assign a charge of −2 to the anion. The average B–O bond distance is 1.448 Å and the average B–O–B angle is 120.9°. The anion likely results from acidic decomposition and aryl group loss in H_2O–$B(C_6F_5)_3$.

Treatment of nickelocene with Brookhart's acid in benzene gives red–brown crystals of **3** and the crystal structure of **3** shows the presence of $Ni(\eta\text{-}C_5H_5)_2$, $Ni(\eta\text{-}C_6H_6)_2$ and two

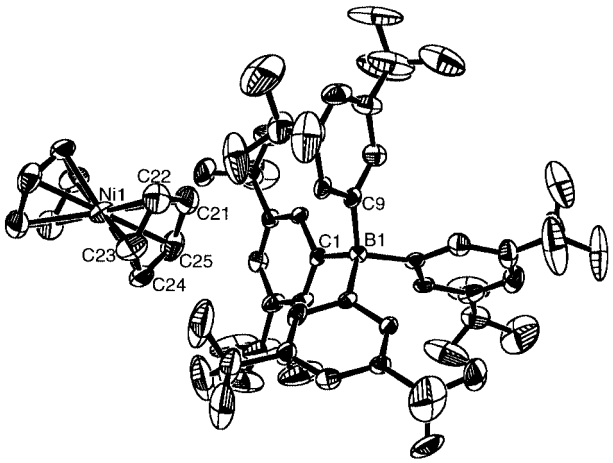

Fig. 1 Crystal structure of **1**. Selected bond lengths (Å) and angles (°): Cp_{cent}–Ni(1) 1.70, B(1)–C(1) 1.631(8), B(1)–C(9) 1.636(8); C(23)–C(22)–C(21) 109.3(8), C(22)–C(21)–C(25) 105.3(7), C(23)–C(24)–C(25) 106.6(7), C(22)–C(23)–C(24) 108.4(7), C(24)–C(25)–C(21) 109.1(7).

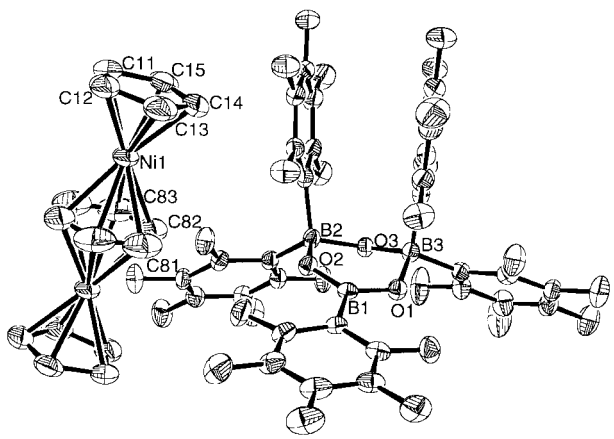

Fig. 2 Crystal structure of **2**. Selected bond lengths (Å) and angles (°): Cp_{cent}–Ni(1) 1.744, $benzene_{cent}$–Ni(1) 1.795, B(1)–O(1) 1.349(4), B(2)–O(2) 1.438(4), B(3)–O(3) 1.549(4); O(1)–B(1)–O(2) 123.8(3), O(2)–B(2)–O(3) 108.0(2), O(1)–B(3)–O(3) 107.6(2).

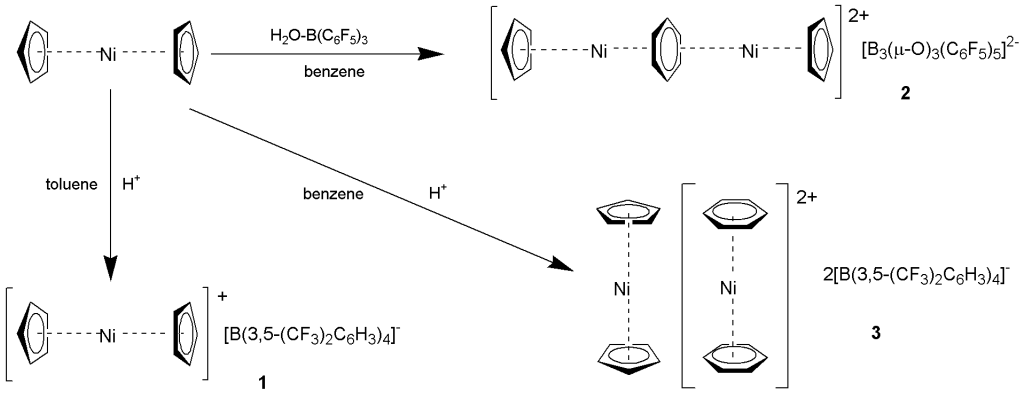
DOI: 10.1039/b001190h



Scheme 1

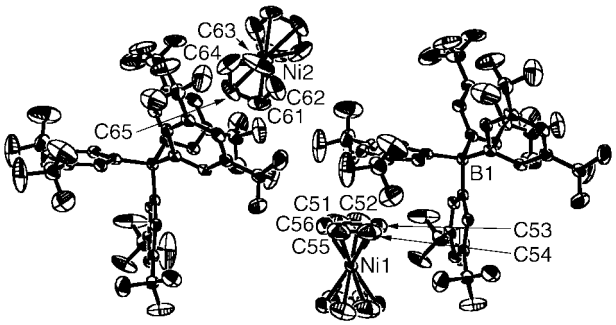


Fig. 3 Crystal structure of **3**. Selected bond lengths (Å) and angles (°): benzene$_{cent}$–Ni(1) 1.713, Cp$_{cent}$–Ni(2) 1.710, C(51)–C(52)–C(53) 124.2(15), C(56)–C(55)–C(54) 113.8(9), C(52)–C(51)–C(56) 126.2(16), C(63)–C(62)–C(61) 109.7(7), C(61)–C(65)–C(64) 107.0(7).

$[B(3,5\text{-}(CF_3)_2C_6H_3)_4]^-$ anions. The room temperature magnetic moment of **3** is 4.26 μ_B, corresponding to four unpaired electrons. These data are consistent with the presence in the crystal of neutral $Ni(\eta\text{-}C_5H_5)_2$ and dicationic $[Ni(\eta\text{-}C_6H_6)_2]^{2+}$; therefore we formulate this compound as $\{[Ni(\eta\text{-}C_6H_6)_2][B(3,5\text{-}(CF_3)_2C_6H_3)_4]_2\cdot Ni(\eta\text{-}C_5H_5)_2\}$, and the nickelocene is present as a molecule of crystallisation (Fig. 3). The average Ni–C distance in the dication $[Ni(\eta\text{-}C_6H_6)_2]^{2+}$ is 2.079 Å and the C–C–C angles are between 113.8(9) and 126.2(16)°. Bis(η-hexamethylbenzene)nickel(II) has been reported,[13] but not structurally characterised.

The new and often surprising reactions are summarised in Scheme 1.

Received (in Oxford, UK) 22nd February 2000, Accepted 27th March 2000

Ordered macroporous zeolite fibres are prepared from the infiltration of swollen bacterial supercellular threads with as-synthesized silicalite nanoparticles.

There is considerable interest in the production of inorganic materials containing frameworks with well defined pore networks. In general, strategies for synthesising these materials rely on the use of templates, the size and nature of which dictate the pore dimensions and architecture. Microporous (nanoporous) materials, such as zeolites, are prepared using molecular templates[1] whilst mesoporous solids, for example MCM-41 silicas, are structured by supramolecular aggregates.[2] We have previously demonstrated how supercellular templates can be used to extend the length scale of 3D inorganic patterning into the micrometre dimension.[3,4] For example, we were able to prepare MCM-41 silica-based fibres containing hierarchically organized pore structures at the meso- and micro-metre scale.[3] Subsequently, various other strategies, most notably the use of colloidal crystal templates,[5] have been employed to prepare ordered macroporous inorganic oxide structures by infiltration of the void spaces with alkoxide or inorganic precursors.[6] Both meso-[6] and micro-scopic[7] pores have been introduced into the macroporous architecture using a dual templating procedure.

Here, we report the synthesis and characterization of hierarchically structured zeolite fibres containing ordered pores at the nano- and micro-scopic length scale. In contrast to our previous work, in which we used *in situ* precipitation from a MCM-41 synthesis mixture,[3] here we use a stable aqueous dispersion of preformed zeolite nanoparticles as building blocks for the infiltration of a bacterial supercellular thread by reversible swelling. Silicalite nanoparticles are aggregated specifically within the organized micro-architecture, which consists of long multicellular filaments (0.5 μm in diameter) aligned parallel to the thread axis and arranged in a pseudo-hexagonally packed configuration.[8] Subsequent thermal decomposition of the bacterial template produces an intact zeolite fibre with ordered macroporous channels lined by 100-nm wide walls of coalesced silicalite nanoparticles. Because each nanoparticle consists of a periodic structure of intersecting nanoporous channels, the porous architecture is hierarchically ordered.

TPA-silicalite-1 nanoparticles were synthesized from clear solution by reflux of an aqueous solution containing tetraethylorthosilicate (TEOS) and tetrapropylammonium hydroxide (TPAOH) followed by repeated centrifugation and washing.† The resulting colloidal suspension was stable in deionized water at pH values between 10 and 11. Dynamic light scattering gave a mean hydrodynamic radius of 57 nm for the as-synthesized TPA-silicalite. This was in close agreement with transmission electron microscopy (TEM) which showed that the sample consisted of discrete nanoparticles with irregular surface texture and narrow particle size distribution (47 ± 10 nm) (Fig. 1). Significantly, the mean particle size was lower than that previously reported (95 nm),[9] possibly due to the reduced temperature (80 *cf.* 98 °C) and water content used in our synthesis mixture. High magnification TEM images suggested that the individual nanoparticles were constructed from aggregates of smaller primary clusters, and this was consistent with TEM analysis of the early stages of crystallization, which showed a predominance of 10 nm-size silicalite particles in samples extracted 24 h after the start of the reaction.

The crystallinity of the particles was confirmed by electron diffraction, XRD and FTIR spectroscopy. Powder X-ray diffraction (PXRD) patterns of the as-synthesized-TPA-silicalite-1 samples showed an orthorhombic lattice with broadened reflections and *d* spacings (d_{hkl} = 1.13 nm {011}, 1.00 nm {200}, 0.385 nm {501}, 0.373 nm {033}, 0.366 nm {133}) consistent with the PDF data base.[10] Corresponding FTIR spectra showed typical Si–O–Si framework bands, including the characteristic double ring vibration at *ca.* 550 cm^{-1}.[11] The sample also showed a shoulder at 960 cm^{-1} and bands at 2980 and 1380–1470 cm^{-1}, attributable to Q^3 Si–OH groups and TPA^+, respectively.[11,12] Thermogravimetric analysis gave a total weight loss of 20% that included the desorption of water and TPAOH (< 260 °C). The weight loss between 260 and 600 °C was 12% owing to decomposition of occluded TPA–OSi and loss of TPA^+ framework counter ions. This value was consistent with a theoretical value of 11.7 wt% for four TPA^+ cations per unit cell.

Bacterial threads‡ were swollen without loss of structural integrity in silicalite sols and air-dried to produce composite fibres consisting of a semi-ordered matrix of multicellular filaments embedded in a continuous framework of zeolite nanoparticles. The reversible swelling procedure gave good infiltration of the inter-filament spaces throughout the macroscopic fibre, and produced a highly compacted network of silicalite nanoparticles after air-drying. The composite fibres were calcined at 600 °C to remove the molecular (TPAOH) and supercellular (bacteria) templates. Thermogravimetric analysis gave a total weight loss of 75%, corresponding to removal of water, TPAOH and the bacteria template. The remaining inorganic phase was in the form of an intact white silicalite fibre with a macroporous internal structure (Fig. 2). Significantly, the replica consisted of an organized array of *ca.* 0.5 μm-wide channels that were oriented approximately parallel to the fibre axis [Fig. 2(c)]. The channel walls were *ca.* 100 nm thick as

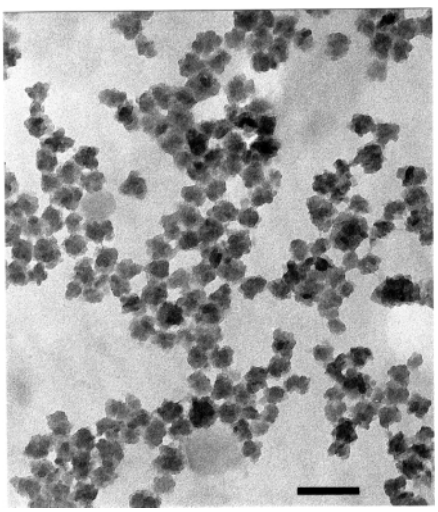

Fig. 1 TEM image of as-synthesized silicalite nanoparticles used as building blocks for the construction of porous zeolite fibres, scale bar = 100 nm.

DOI: 10.1039/b001528h

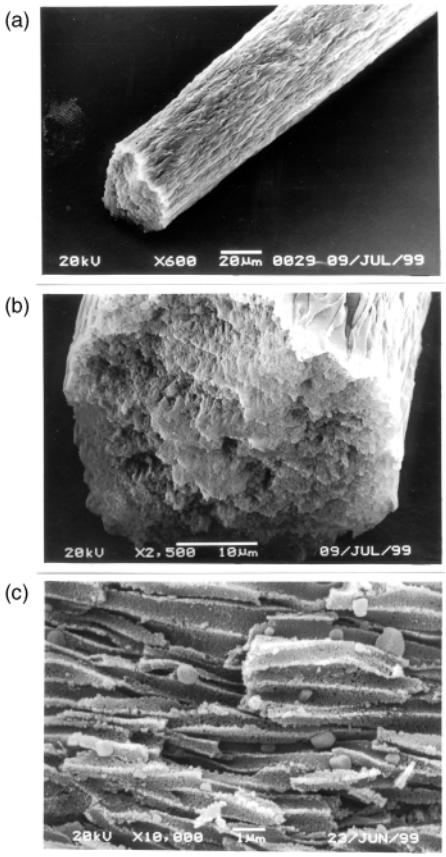

Fig. 2 SEM micrographs of silicalite-infiltrated bacterial thread after calcination at 600 °C: (a) intact zeolite replica, scale bar = 20 μm. (b) Fractured fibre tip showing the channel-like architecture, scale bar = 10 μm. (c) High magnification image of a thread fractured longitudinally, showing the continuous zeolite wall structure enclosing co-aligned channels, 0.5 μm in width, scale bar = 1 μm.

determined by SEM measurements. TEM images of lightly ground samples indicated that the wall structure consisted of closely packed aggregates of 50 nm sized silicalite nanoparticles. Corresponding electron diffraction data on the particles were consistent with crystalline silicalite. XRD patterns on the bulk calcined thread showed reflections with increased intensities, indicating an increase in the crystallinity of the nanoparticles compared with the as-synthesized zeolite. FTIR spectroscopy showed the characteristic double-ring vibration band at *ca.* 550 cm^{-1}, but no shoulder at 960 cm^{-1}, indicating almost complete condensation of the Si–OH groups in the calcined product.

Our results indicate that silicalite nanoparticles can be infiltrated into the ordered void spaces of a bacterial template where they can be used as building blocks for the construction of a macroporous inorganic framework. The mechanism responsible for high-fidelity inorganic replication of the bacterial superstructure has been described previously for macroporous fibres prepared from amorphous silica colloids.[3] The same considerations, such as surface-charge repulsion between the bacterial cell walls and the silicalite nanoparticles at high pH, and ionic strength-induced aggregation on deswelling, are likely to be responsible for the irreversible coalescence and compaction of the zeolite nanoparticles into the patterned architecture. Removal of both molecular (TPA^+) and micrometre-scale (multicellular filaments) templates by thermal degradation affords a zeolite fibre with hierarchical porosity that might have technological advantages owing to the high surface area and unidirectionality of the patterned architecture. Porous zeolite threads could also be aligned in thin films or flow tubes for separation processes or catalysis. By changing the template, it should also be possible to produce more complex macroporous zeolite monoliths by nanoparticle infiltration of patterned organic materials exhibiting reversible swelling. For example, recent studies indicate that sponge-like block copolymer gel templates can be used to prepare interconnected macroporous frameworks of coalesced magnetite or titania nanoparticles.[13]

We thank the EPSRC and the University of Bristol for financial support to S.A.D and B. Z, respectively.

Notes and references

† TPA-silicalite nanoparticles were synthesized from clear solutions following a modified version of the method described by Persson *et al*.[9] Tetraethylorthosilicate (16.0 g; Aldrich, > 98%) was added to 27.32 g of 1.0 M aqueous solution of tetrapropylammonium hydroxide (TPAOH; Aldrich) in a polypropylene bottle. The reactant mixture (molar composition: 9 TPAOH : 25 SiO_2 : 354 H_2O : 100 EtOH) was stirred for 24 h at room temp. to allow hydrolysis of the TEOS. The colourless solution obtained was heated under reflux in a preheated paraffin oil bath at 80 °C for 96 h without stirring. The colloidal particles produced were sedimented by centrifugation (12000 rpm) and washed by resuspending in deionized water. This process was repeated until the final pH of the suspension was 10–11. At this pH the particles have a net negative surface charge, and the dispersion is stable for several months. Dynamic light scattering and zeta potential measurements were performed on suitably diluted solutions, using a Brookhaven Instruments ZetaPlus particle sizer. Specimens for TEM were prepared by depositing a drop of the suspension onto carbon-coated, formvar-covered copper grids. Powder samples for XRD, FTIR and TGA were prepared by air drying the suspension.

‡ Macroscopic bacterial threads were produced from cell cultures of mutant FJ7 strain of *Bacillus subtilis* by methods described elsewhere.[8] Infiltration of the bacterial superstructure was achieved as follows. The tip of a 3–5 cm long prewashed bacterial thread was held by reverse tweezers and the fibre dipped into the washed silicalite colloidal solution (pH 10–11, 1–4% w/w) for at least 3 h at room temp. The swollen fibre was then very slowly withdrawn from the colloidal solution and allowed to dry in air. During the dipping process, the tweezers were held so that the tip of the thread was not immersed in the colloidal solution. This aided recovery of the intact mineralized fibre. Calcined materials were prepared by heating the composite fibres in a Carbolite furnace to a temperature of 600 °C at a rate of 2 °C min^{-1}. Samples were kept at 600 °C for at least 2 h before cooling to room temperature.

SEM and EDXA were carried out using a JEOL JSM5600LV instrument operated at 5 keV for uncoated samples or at 20 keV for gold-coated samples. The samples were mounted onto Al stubs, using carbon sticky pads. TGA was performed on a Netzsch TG209 instrument at a heating rate 5 °C min^{-1} from room temperature to 800 °C in a nitrogen atmosphere with flow rate 90 ml min^{-1}. The TGA residues were collected and used for PXRD and FTIR measurements. Powder X-ray diffraction studies were carried out on a Siemens D500 diffractometer with Cu-Kα_1 radiation, in the 2θ range 5–60°. FTIR spectra were recorded on a Bruker IFS 25 spectrophotometer using KBr pellets in the range 400–4000 cm^{-1}. For TEM and SAED analysis the calcined fibres were ground, dispersed in deionized water and then deposited on carbon-coated, formvar-covered copper grids.

Extension of a π-stacked N_2S ligand to form bi- and tri-nuclear silver(I) complexes†

Paula L. Caradoc-Davies, Lyall R. Hanton* and Kitty Lee

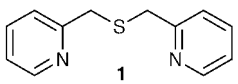
Department of Chemistry, University of Otago, PO Box 56, Dunedin, New Zealand.
E-mail: lhanton@alkali.otago.ac.nz

Received (in Cambridge, UK) 24th December 1999, Accepted 27th March 2000

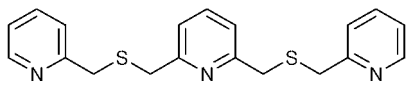
Reactions of tri- and penta-dentate thio-substituted oligopyridines with Ag(I) yielded two differently coded bi- and tri-nuclear structures containing strong intraligand π stacking of the heterocycles.

The design and construction of helicates from ligand threads and metal-ion induced self assembly has been much investigated.[1,2] However, alternatives to helicates exist, such as side-by-side arrangements which represent limiting non-helical structures formed by metal centres fixed between adjacent ligand threads.[1] These have been theoretically predicted and discussed in detail[2] but their observation is rare.[3] Such side-by-side structures offer the same opportunities for the development and understanding of the underlying construction principles of supramolecular chemistry. Both arrangements are driven by coding requirements, namely, the need to match ligand domains to the coordination preferences of the transition metal centres. Typically domains have been linked by non-coordinating species.[1] Incorporation of thioether donors into the linkers decreases the distance between the potential ligand domains thus bringing the metal centres closer together. Compressed conformations of this nature are more likely to favour side-by-side rather than helical arrangements about metal centres. With such an array of donors, ambiguity in coding may arise because of a mismatch of the number of donor atoms to metal-acceptor sites or a mis-allocation of the ligand domains to the metal centres. In such circumstances, the metal centres are required to compensate for this ambiguity. Hence, coordinatively flexible metal ions such as Ag(I) rather than Cu(I) are more likely to succeed in complex formation.

As part of our investigation of thio-substituted oligopyridines we found that the tridentate ligand **1** formed a side-by-side



1



2

dimeric silver complex $[Ag_2(\mathbf{1})_2]^{2+}$ with strong intraligand π stacking of the pyridine rings. The coordinatively flexible Ag(I) ions adopted a three-coordinate planar geometry to code as a [3 + 3] rather than a [4 + 2] complex. It was of interest to see if on extending the ligand from the tridentate **1** to the related pentadentate **2** the same important features of intraligand π stacking and coding information were retained on complex formation.

Equimolar reaction of **1**[4] with $AgNO_3$ in MeCN, followed by treatment with NH_4PF_6, led to isolation of a cream complex in 46% yield, which analysed with a 1:1 ligand:metal ratio and gave ^{1}H and ^{13}C NMR spectra consistent with a symmetrical but dynamic complex.‡ The ^{1}H NMR spectra measured in CD_3CN and d_6-acetone remained unchanged down to the temperature limit for each solvent. Reaction of a related ligand di-2-pyridyl sulfide with Ag(I) produces a binuclear dimer containing two ligands.[5] This work would suggest **1** may not be ideally suited to forming mononuclear Ag(I) complexes. Electrospray mass spectrometry under normal operating conditions showed parent ions with appropriate isotope patterns for $\{[Ag_2(\mathbf{1})_2]PF_6\}^+$ at *m/z* 790.8 and $[Ag_2(\mathbf{1})_2]^{2+}$ at *m/z* 323.5. In addition using the Onsager equation,[6] dilution conductivity measurements in MeCN confirmed the presence of a 2:1 electrolyte‡ indicating the dimer remains intact in solution.

X-Ray crystal structure analysis§ showed the dimer is constructed from two ligands related by a crystallographic two-fold axis at the mid-point between the two Ag atoms. Each ligand experiences strong π-stacking interactions (3.41 Å) leading to an *endo-syn* conformation where the pyridine rings are tilted by 16.4° with respect to each other. The Ag atoms adopt a distorted trigonal planar geometry (Fig. 1), which links the two symmetry-related ligands by N,S chelation from one ligand and N′ donation from the other, giving rise to a folded side-by-side arrangement. This is in contrast to the centrosymmetric dimer of di-2-pyridyl sulfide in which the four-coordinate Ag atoms are bound in a NNS′ fashion with an O from a NO_3^- ion completing the coordination sphere.[5] In $[Ag_2(\mathbf{1})_2]^{2+}$ the Ag ions are separated by a short Ag···Ag distance of 3.052 Å which lies in the middle of the range (2.86–3.22 Å) found for similar systems.[3,5,7] The Ag(I) ions diverge by 0.159 Å from the trigonal planes which are tilted at 61.0° with respect to each other. As a consequence of the packing, chains of alternating intra- and inter-molecular (3.56 Å) π-stacked rings run along the *c* axis.

Reaction of **2**[8] with $AgNO_3$ in a 1:1 molar ratio in MeCN gave an off-white powder which analysed as $[Ag_3(\mathbf{2})_2](NO_3)_3$. Subsequently, the same compound was obtained in 76% yield using a 2:3 molar ratio.‡ A ^{1}H NMR spectrum measured in CD_3CN was consistent with a symmetrical structure. Previously, **2** was found to act as a pentadentate ligand in the monomeric complex $[Co(\mathbf{2})Cl]^+$.[8] Such a coordination preference is seemingly inconsistent with the analytical data for the Ag(I) complex.

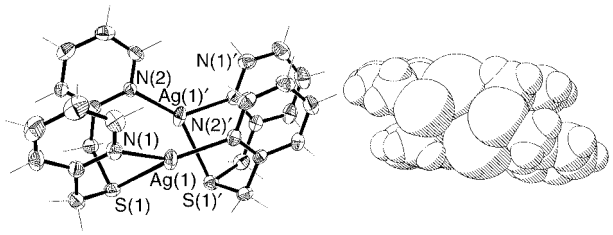


Fig. 1 Views of the binuclear $[Ag_2(\mathbf{1})_2]^{2+}$ cation, with the non-coordinating PF_6^- anions omitted: (left) Perspective view with thermal ellipsoids drawn at the 50% level. Selected distances (Å) and angles (°): Ag(1)–N(1) 2.263(3), Ag(1)–S(1) 2.5997(11), Ag(1)–N(2)′ 2.190(3); N(2)′–Ag(1)–N(1) 137.61(11), N(2)′–Ag(1)–S(1) 140.92(7), N(1)–Ag(1)–S(1) 79.77(8); (right) Space–filling view emphasising the π stacking of the ligands.

† Dedicated to Dr Charles R. Clark on the occasion of his 60th birthday.

DOI: 10.1039/a910342m

The trinuclear nature of the complex was confirmed by X-ray structural analysis (Fig. 2).§ The structure consists of three non-equivalent Ag(I) ions held in a linear chain (Ag···Ag···Ag 175.3°) by two folded ligands arranged in a side-by-side fashion 11.6 Å wide and 8.3 Å long. This linear silver core is particularly rare in both helicate[9] and side-by-side structures[10] where to date in helicate formation Cu(I) predominates.[11] The Ag(I) ions adopt [4 + 4 + 2] coordination rather than the anticipated [3 + 3 + 4], with Ag···Ag distances of 3.204 and 3.232 Å, respectively, lying at the long end of the range for similar systems.[3,5,7] The four-coordinate Ag(I) ions have distorted-tetrahedral geometries (NSN′S′) while the two-coordinate Ag(I) ion has a bent structure (NN′). In addition, two NO_3^- anions interact weakly with the two-coordinate Ag(I) centre [Ag(3)···O(23) 2.698 Å, Ag(3)···O(31) 2.712 Å]. The folding of the ligand is determined by strong intramolecular π stacking, as in $[Ag_2(\mathbf{1})_2]^{2+}$. The pyridine rings are separated from each other with values in the range 3.29–3.72 Å and are inclined with respect to each other with values in the range 13.4–26.0°.

Both pentadentate ligands have the same chirality, which causes the S donors attached to the four coordinate Ag(I) ions to be diametrically opposite each other. This contrasts with the structure of $[Ag_2(\mathbf{1})_2]^{2+}$ in which the S donors are adjacent. In the trinuclear complex, such an arrangement would require the two ligands to have opposite chirality. Chains of alternating enantiomers are arranged head-to-head and form intermolecular π-stacked chains (3.42 and 3.61 Å) along the diagonal axes [1 1 0] and [1 1 0].

The symmetrical nature of the ^{1}H NMR spectrum was at odds with the unsymmetrical [4 + 4 + 2] coding. Thus in solution either the complex is symmetrical or is undergoing rapid dynamic processes which may include equilibria between species of differing nuclearities. Electrospray mass spectrometry showed peaks which could be assigned to a number of species including a parent ion $\{[Ag_3(\mathbf{2})_2](NO_3)_2\}^+$ at *m/z* 1154.8, $\{[Ag_2(\mathbf{2})_2](NO_3)\}^+$ at *m/z* 983.9, $\{[Ag_2(\mathbf{2})](NO_3)\}^+$ at *m/z* 630.9 and $[Ag(\mathbf{2})]^+$ at *m/z* 459.9. However using the Onsager equation,[6] dilution conductivity measurements in $MeNO_2$ strongly indicated a 1:1 electrolyte‡ suggesting the trimer does not maintain its integrity in solution. Results from variable-temperature ^{1}H NMR spectra measured in d_6-acetone–10% CF_3CO_2D were inconclusive. They showed no changes other than significant broadening and collapse of peaks down to 188K.

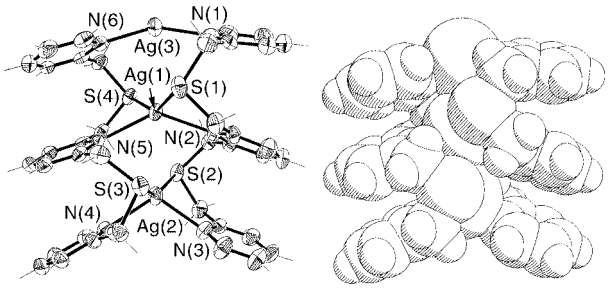

Fig. 2 Views of the trinuclear $[Ag_3(\mathbf{2})_2]^{3+}$ cation with NO_3^- anions, two weakly coordinating and one non–coordinating, omitted: (left) Perspective view with thermal ellipsoids drawn at the 50% level. Selected distances (Å) and angles (°): Ag(1)–N(2) 2.408(6), Ag(1)–N(5) 2.491(6), Ag(1)–S(4) 2.609(2), Ag(1)–S(1) 2.667(2), Ag(2)–N(4) 2.332(6), Ag(2)–N(3) 2.357(6), Ag(2)–S(2) 2.584(2), Ag(2)–S(3) 2.652(2), Ag(3)–N(1) 2.213(7), Ag(3)–N(6) 2.228(6); N(2)–Ag(1)–N(5) 133.8(2), N(2)–Ag(1)–S(4) 121.7(2), N(5)–Ag(1)–S(4) 75.9(2), N(2)–Ag(1)–S(1) 75.5(2), N(5)–Ag(1)–S(1) 114.7(2), S(4)–Ag(1)–S(1) 146.35(7), N(4)–Ag(2)–N(3) 112.7(2), N(4)–Ag(2)–S(2) 126.6(2), N(3)–Ag(2)–S(2) 79.0(2), N(4)–Ag(2)–S(3) 77.2(2), N(3)–Ag(2)–S(3) 111.5(2), S(2)–Ag(2)–S(3) 149.44(7), N(1)–Ag(3)–N(6) 150.6(2); (right) Space–filling view emphasising the extensive π stacking of the ligands.

We have shown that side-by-side structures can offer the diversity found in helicate structures. The intramolecular π stacking of the ligands was maintained in both complexes despite the ambiguity of coding being resolved in different ways to give different structural arrangements of side-by-side complexes.

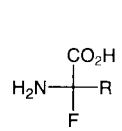
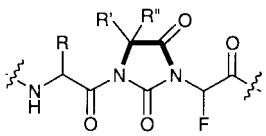
Gabriel reaction of hydantoins with bromofluoroacetate provides a general method for the synthesis of carbonyl-bridged peptides containing an α-fluoroglycine residue.

Introduction of fluorine atoms into amino acids is a powerful and reliable strategy for the design of potent biologically active amino acid and peptide derivatives.[1] Numerous fluorinated analogues encompassing essentially every class of amino acid have been synthesized and examined for biological activity. As part of an ongoing research program committed to preparation of multifunctional carbon compounds,[2] we have selected the α-fluoro α-amino acids **1** as synthetic targets. Fluorine substitution at the α-position of α-amino acids is of great interest because of the profound influence this has on the chemical properties of the carbonyl carbon and, in particular, the α-amino group, and the expected accompanying consequences on biological activity. However, there are few reports for the synthesis of α-fluoro α-amino acids. Bailey *et al.* developed pioneering work for this study in 1989.[3] They carried out an asymmetric synthesis of protected α-fluoroglycines utilizing the Gabriel reaction of chiral fluoroiodoacetamides with potassium phthalimide. We also independently reported the synthesis of a protected α-fluoroglycine in the following year[4] and recently applied our method to the preparation of protected α-fluoroglycine containing dipeptides.[5] Despite considerable effort, however, neither free α-fluoroglycine nor free fluorine-containing dipeptides have ever been isolated because of rapid dehydorofluorination under ambient conditions. Whereas we recognized the importance of a more recent report by Bailey *et al*. on the first isolation of a free α-fluoroglycine derivative, α-fluorobetaine,[6] it is obviously impossible to incorporate this structure into peptides. We herein disclose a general method for a synthesis of carbonyl-bridged peptides containing the α-fluoroglycine residue **2** using the Gabriel reaction of hydantoins **3** with bromofluoroacetate.



1



2

The design of the target carbonyl-bridged peptides **2** was based on the following strategies. First, the carbon–fluorine bond of **2** is stabilized to loss of fluoride by virtue of the electron attracting effect of the imide carbonyl groups. Second, peptides in a conformationally restricted environment are important structural features used in the field of peptidomimetics.[7] In addition, hydantoins are known to possess a broad range of biological activities, including antiviral, antibacterial, antifungal and herbicidal activity.[8] We first examined the synthesis of hydantoin-α-fluoroglycine-containing dipeptides **4** that are the key component parts of **2**. The Gabriel-type reaction of the commercially available diphenylhydantoin **3a** was performed by deprotonation, using NaH in DMF, followed by the addition of ethyl bromofluoroacetate (Table 1, entry 1). Although the desired **4a** was the predominant product, obtained in moderate yield, this procedure resulted in the formation of a mixture of **4a** and bis-alkylated product **5** along with recovered starting material **3a**. In an attempt to overcome this problem of selectivity in the alkylation reaction, optimization of the

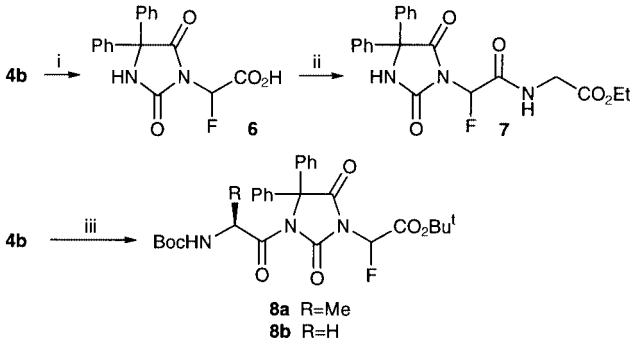
DOI: 10.1039/b001265n



Scheme 1 *Reagents and conditions*: i, TFA, CH_2Cl_2, room temp. (quant.); ii, H-Gly–OEt, DCC, HOBT, Et_3N, DMF, room temp. 12 h (76%); iii, isobutyl chloroformate, Et_3N, DMAP, DMF, THF, then Boc-Ala–OH or Boc-Gly–OH, −15 °C to room temp., 3 h (91% for **8a**, 79% for **8b**).

conditions was investigated by examining several bases and additives in several solvents at different temperatures. The best result was obtained in the reaction of **3a** with NaH, NBu_4Br and ethyl bromofluoroacetate in THF at room temperature to give **4a** in 91% yield (entry 3).[9] Other hydantoins **3b**,**c** having different substituents at the 5 position were treated with ethyl or *tert*-butyl bromofluoroacetate under the same conditions to give **4b**–**d** in moderate to good yields (entries 4–7). Lower yields (31–51%) of **4** were observed when unsubstitutued or 5-mono-substituted hydantoins **3d**–**g** derived from naturally occurring α-amino acids were used as starting materials (entries 8–11). However, the yields using these substrates were improved to 55–97% by the use of Boc protected hydantoins **3h**–**k** (entries 12–15) (Table 1).[10]

With the development of a general method for the synthesis of hydantoin-α-fluoroglycine-containing peptides **4**, we next demonstrated that **4** could be incorporated into the oligopeptide **2** by normal peptide coupling techniques. Deprotection at the *C*-terminus of **4b** was nicely achieved with TFA–CH_2Cl_2 to give free dipeptide **6** quantitatively. As expected, the free acid **6** is sufficiently stable for subsequent chemical manipulation under ambient conditions. Coupling of the carboxylic acid **6** obtained with glycine ethyl ester in the presence of DCC/HOBT furnished the tripeptide **7** in 76% yield. Furthermore, *N*-terminal chain elongation was achieved by coupling **4b** with Boc-Ala–OH or Boc-Gly–OH using the mixed anhydride method to give the tripeptides **8** in good yield (Scheme 1).

In summary, we have described the design and synthesis of fluoroglycine-containing peptides.[2] Neither free α-fluoroglycine nor free fluorine-containing dipeptides have been previously isolable.[3–6] The carbonyl-bridged strategy employed in the present work offers one solution to this problem.[11] Oligomerization of hydantoin-α-fluoroglycine-containing dipeptides **4** will be presented in the near future.

We thank the Ministry of Education, Science, Sports and Culture, Japan for a Grant-in Aid for Scientific Research and for Encouragement of Young Scientists. Y. T. thanks the Grant from Asahi Glass Foundation.

9 General procedure; to a stirred mixture of **3a** (100 mg, 0.40 mmol) and NBu_4Br (129 mg, 0.48 mmol) in THF (1.0 ml) was added NaH (60%, 19 mg, 0.48 mmol) at 0 °C. After 30 min stirring at room temperature, ethyl bromofluoroacetate (73.4 mg, 0.40 mmol) was added to the mixture which was stirred for 12 h. The reaction was stopped by addition of a saturated solution of NH_4Cl (1 ml) and the mixture was diluted with ethyl acetate (100 ml). The organic phase was washed with water (20 ml), brine (20 ml) and dried over $MgSO_4$. The solvent was removed under reduced pressure to give an oil that was purified by column chromatography on silica gel eluting with 60% ethyl acetate in hexane to give **4a** (128 mg, 91%) as a colorless oil.
10 Dipeptides **4d–l** were the 1 : 1 mixtures of diastereomers, which were not separated.

Received (in Cambridge, UK) 10th March 2000, Accepted 29th March 2000

The CFTA method using α-cyano-α-fluoro-*p*-tolylacetic acid (CFTA) can be reliable in assigning absolute configurations of chiral secondary alcohols based on both ^{1}H and ^{19}F NMR spectroscopy, and the most stable and most predominant conformer of the CFTA esters that can explain the ^{1}H and ^{19}F NMR data were supported by X-ray analysis and *ab initio* calculations.

Recent advances in enantioselective synthesis have produced an increasing demand for convenient and reliable techniques for assigning the absolute configuration of chiral molecules. A number of methods using chiral derivatizing agents (CDAs), such as α-methoxyarylacetic acids and α-methoxy-α-trifluoromethylphenylacetic acid (MTPA, Mosher's agent) by ^{1}H NMR spectroscopy have been developed for this purpose.[1] Among them, the well known modified Mosher method[2] using MTPA is one of the most reliable and widely applicable techniques to general secondary alcohols except sterically hindered ones. On the other hand, fluorine-containing CDAs are very useful with respect both to general applicability and convenience for the ee determination.[1c] In this case, the ^{19}F NMR spectroscopy is particularly useful because the shift differences are usually larger than those in the ^{1}H NMR spectra and there is seldom an overlap of signals. However, the ^{19}F-chemical shifts observed with MTPA[2] and fluorinated CDAs[3] can not be used for configuration determination because no general trend is observed. In the course of our continuing research to improve the utility of CDAs,[4] we have developed α-cyano-α-fluoro-*p*-tolylacetic acid (CFTA).[5] This agent far surpasses the capabilities of MTPA with respect to both reactivity and signal resolution ability. We report here, that the ^{19}F NMR-based CFTA method is promising for the determination of absolute configuration of chiral secondary alcohols. In addition, the CFTA method using ^{1}H NMR is not only of higher reliability but also of broader applicability compared to the modified Mosher method.

By a procedure similar to that used in the modified Mosher method,[2] we obtained the chemical shift difference, $\Delta\delta_H$ ($\delta_S - \delta_R$), for the corresponding protons in the diastereomeric (*S*)- and (*R*)-CFTA esters prepared from ten chiral secondary alcohols with known absolute configurations (Fig. 1). The results are as follows: (i) For all CFTA esters examined, the magnitude of $\Delta\delta_H$ was larger than that of the MTPA esters.[6] (ii) The signs of $\Delta\delta_H$ are distributed symmetrically with respect to the plane containing the carbinyl proton and the ester carbonyl (designated as the CFTA plane, Scheme 1). The $\Delta\delta_H$ values on the left side of the CFTA plane are positive and those on the right side negative. (iii) One of the most striking features of the CFTA method can be seen for the results for isomenthol. The signs of $\Delta\delta_H$ for the CFTA esters followed a regular plus order, while those for the MTPA esters did not. (iv) Another feature of the CFTA method can be seen for the application to 10-bromoisoborneol.[7] The CFTA esters were obtained, while the MTPA esters of this alcohol were not. These results validate the

usefulness of the CFTA method to elucidate the absolute configuration of the secondary alcohols. Owing to the larger and more predictable signs of the $\Delta\delta_H$ values, as well as the higher reactivity of CFTA chloride compared to MTPA chloride, the CFTA method based on ^{1}H NMR spectroscopy should be more widely applicable than the modified Mosher procedure using MTPA esters.

In addition to the satisfactory results in ^{1}H NMR, the ^{19}F NMR-based CFTA method is promising. By a procedure similar to that used in the MTPA method,[2] we obtained the chemical shift difference, $\Delta\delta_F$ ($\delta_{SR} - \delta_{RR}$ or $\delta_{RS} - \delta_{SS}$)[8] in the diastereomeric (*S*)- and (*R*)-CFTA esters (Table 1). The larger $\Delta\delta_F$ values of the CFTA esters compared with the MTPA esters showed correlations to the absolute configuration of the alcohols. In contrast, no consistent correlation was found with the MTPA esters.

The relationship between the sign of $\Delta\delta_H$ and absolute configuration observed for the CFTA esters can be explained by the correlation model[1d,e,2] depicted in Scheme 1. In the model, the C–F is *synperiplanar* (sp) to the C=O bond, to which the carbinyl C–H is *syn*. The sp conformer was seen by the X-ray structure of (*R*)-CFTA ester of (1*S*)-neomenthol.[9] The signals due to the substituents that confront the aromatic ring (R^2 and R^1 groups in the diastereomers A and B, respectively) are always shifted upfield by the aromatic ring. Accordingly, the $\Delta\delta_H$ values for each proton in the R^1 group should be plus and those in the R^2 group minus. This model was supported by *ab initio* calculations [GAUSSIAN 98, RHF/6-31+G(d)] on the ground state geometry and energy of the diastereomeric pair of (*R*)-α-cyano-α-fluorophenylacetic acid (CFPA)[4] esters of (1*S*)- and (1*R*)-menthol.[10] Two predominant rotamers regarding the C_α–CO bond were found: one is the sp described above and the other is *antiperiplanar* (ap) with the C–F and C=O bonds. Calculations predicted a preference of the sp rotamers that can explain the signs of $\Delta\delta_H$ over the ap ones by *ca.* 0.94 and 0.55 kcal mol^{-1} for (*R*,*S*)- and (*R*,*R*)-esters, respectively. The signs of $\Delta\delta_F$ can be explained on the basis of the calculated chemical shifts of ^{19}F nuclei in the two rotamers[11] and the conformational bias between these. Since the observed chemical shifts were averaged between the sp and the ap, and the conformational equilibrium is more biased to the sp in the (*R*,*S*) ester than in the (*R*,*R*) ester, the ^{19}F signal in the (*R*,*S*) ester is expected to appear at lower field than that in the (*R*,*R*) ester, as observed.

In order to ensure the reliability of our method and to extend the range of applications, further investigations are currently underway.

This work was supported by Grants-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture, Japan and partially by grants from Uehara Foundation and The Mitsubishi Foundation.

Received (in Cambridge, UK) 23rd February 2000, Accepted 29th March 2000

A series of dendritic BINAP ligands have been synthesised and their ruthenium complexes used as catalysts in asymmetric hydrogenation.

In recent years, the attachment of homogeneous catalysts to soluble polymer supports has been attracting considerable attention owing to its potential combination of the advantages, and minimization of the disadvantages, of homogeneous and heterogeneous catalysis.[1–3] Unlike traditional cross-linked polymer-supported catalysts in which the structure is usually not clear, soluble polymer-supported catalysts also offer opportunities for the study of polymer–catalyst interactions to fine-tune both catalytic activity and stereoselectivity through systematically adjusting the microstructure of the catalytic sites in the polymer supports. Recently, we have developed a soluble chiral polyester-supported Ru(BINAP) catalyst which offered a higher rate of reaction than the corresponding monomeric homogeneous catalyst while retaining high stereoselectivity.[4] Most recently, dendritic organometallic catalysts have become a very active field of research.[5–7] The dendrimer architecture might offer a means of better controlling the disposition of the catalytic species in soluble polymer-based catalysts. Such novel catalysts are well defined and highly branched three-dimensional macromolecules on the nano-scale size, which may aid the recycling of catalysts simply by supra-filtration or solvent precipitation methods.‡ For asymmetric catalysis, chiral dendrimers are required, however, so far, very few dendritic chiral catalysts have been described.[8–14] Two general strategies for the construction of chiral dendritic catalysts can be applied: multiple chiral metal complexes employed at the periphery of the dendrimer, or chiral metal complexes incorporated in the core of the dendrimer. For the second strategy the space-filling nature of the dendritic wedges near the metal center would alter the structure of the metal complex, and thus possibly influence the reactivity of the catalyst and/or the substrate selectivity of the catalytic reaction with increasing generations. This kind of dendritic catalyst has been thus termed 'dendrizyme'.[6] For chiral diphosphine-containing catalysts, such as Ru(BINAP), chiral information is transferred from the ligand to the catalytically active center *via* the arrangement of the four phenyl rings of the diphenylphosphino groups.[15] Therefore, upon incorporation of a chiral diphosphine-containing catalyst into the core of a dendrimer, the chiral information might be enhanced by the steric bulk of the dendritic wedges and forced towards the pocket of the catalyst, in which the enantioselective reaction takes place.

Here, we report the first use of chiral diphosphine ligands bearing dendritic wedges for asymmetric hydrogenation.[16] BINAP was chosen as a model ligand for this study, since it is probably the most versatile and effective ligand among all the chiral phosphine ligands which have been studied for asymmetric catalysis.[15] Both rhodium and ruthenium BINAP complexes have been extensively studied and several commercial processes based on these catalysts have been developed.[17] BINAP itself cannot be easily attached to a dendrimer so (*R*)-5,5′-diamino-BINAP (*R*-**1**) was synthesized according to the literature.[18] A polyether dendrimer was chosen owing to its inertness to catalytic reaction. Polyether dendritic wedges **2**–**4** with carboxyl groups located at the focal point were synthesised by the convergent-growth approach introduced by Hawker and Fréchet.[19] The chiral dendritic BINAP ligands **5**–**7** were synthesised in > 85% yield by condensation of the wedges **2**–**4** with *R*-**1** in the presence of triphenylphosphite, pyridine and calcium chloride in *N*-methyl-2-pyrrolidone (NMP) at 100 °C (Scheme 1). These ligands were purified by fast column chromatography and characterized by ^{1}H and ^{31}P NMR spectroscopy, MALDI-TOF mass spectrometry and elemental analysis. All results are in full agreement for the proposed structures.

Asymmetric hydrogenation of 2-[*p*-(2-methylpropyl)phenyl]acrylic acid **8** was used as the model reaction for the investigation of the catalytic activity and enantioselectivity of these dendritic Ru(BINAP) catalysts. *In situ* catalyst preparation was attained by mixing a dendritic BINAP ligand with $[Ru(cymene)Cl_2]_2$ in methanol–toluene (1 : 1, v/v) and stirring for *ca.* 40 min at 50 °C. Various generations (**5**–**7**) of these dendritic Ru(BINAP) catalysts were tested, and complete conversions of **8** were obtained with high enantioselectivities in 24 h with preliminary results summarised in Table 1. For

8	**7** (cycle 3)[f]	5	66.6	16.6	90.9	(*R*)

[a] Hydrogenations were carried out using a 0.06 M solution of **8** in methanol–toluene (1:1, v/v) as solvent under the following reaction conditions: *in situ* catalyst = $[Ru(cymene)Cl_2]_2$ + dendritic ligand or (*S*-BINAP); substrate/catalyst = 125 (mol/mol); NEt_3/substrate = 3:2 (mol/mol); H_2 = 80 atm, room temperature. [b] Based on GC analysis and ^1H NMR; all catalytic reactions reached 100% conversion in 24 h. [c] Average TOFs calculated over the quoted reaction time. [d] Ee values at 100% conversion of **8** were determined by GC with a Chrompack Chirasil-dex column (25 m × 0.25 mm). [e] Determined by comparison of optical rotations with literature values. [f] Recovered catalyst used.

example, with 0.8 mol% Ru(*R*-**6**) catalyst, hydrogenated product (ibuprofen) was obtained with 92.6% ee and 100% conversion in 20 h. Confirming the worth of designing Ru(BINAP) catalysts with dendritic wedges, all of the dendritic catalysts performed better compared to the parent BINAP complex. These catalysts showed higher ee values than Ru(BINAP), although the highest-generation catalyst Ru(*R*-**7**) gave slightly lower enantioselectivity (Table 1, entries 1–4).§ Most interestingly, the size of the dendritic wedges influenced the reactivity of these catalysts. Unlike common dendritic catalysts,[7a] the rate of the reaction increased using higher generation catalysts. This effect is most pronounced when going from generation 1 to 2 (Table 1, entries 2–4). The profound size effect is probably due to the steric bulk of the dendritic wedges which affects the dihedral angle of the two naphthalene rings in the Ru(BINAP) complex, and thus leads to a faster rate and/or better enantioselectivity of reaction. Similar acceleration effects have been observed in the asymmetric hydrogenation of unsaturated carboxylic acids catalyzed by Ru(II) catalysts containing polyester-supported BINAP,[4] H_8-BINAP[20] or a bis-steroidal phosphine,[21] which possess a larger steric bulk than BINAP itself.

The large molecular size and different solubilities of the dendritic Ru(BINAP) catalysts in various solvents provided a convenient and reliable method for the separation and reuse of the catalysts. For example, upon completion of the reaction, methanol was added to the reaction mixture and the catalyst Ru(*R*-**7**) was quantitatively precipitated and recovered *via* filtration. The recovered catalyst was reused for at least three cycles with the same activity and enantioselectivity (Table 1, entries 5–8).

In summary, we have demonstrated the importance of the dendritic wedges on the catalytic activity and enantioselectivity of dendritic Ru(BINAP) complexes. This study opens up a new frontier for the development of highly effective and easily separable chiral catalysts. Current work is aiming at a detailed insight of the nature of the dendritic effect and the exploration of these catalysts in other reactions.

We are grateful to the Foundation of the President of The Chinese Academy of Sciences and the Foundation of the Director of Institute of Chemistry, CAS, the National Natural Science Foundation for Youth of China (projects 29604009 and 29904009) and The Hong Kong Polytechnic University for financial support.

Notes and references

‡ Supra-filtration or solvent precipitation methods are suitable procedures for small scale high-value processes, but are not viable options for larger scale lower cost processes.

§ In three-times repeated experiments, the catalysts showed very similar ee values [experimental error (on a computer-controlled VISTA 6000 gas chromatograph) is ≤ ±0.5%]. Further demonstration of the 'dendrimer effect' on enantioselectivity is under way in our laboratory, by using higher generation dendritic BINAP ligands and exploring the catalysts in other reactions in which Ru(BINAP)-type catalysts are less effective.

Received (in Cambridge, UK) 2nd March 2000, Accepted 30th March 2000

A new assignment method based on the periodic *ab initio* calculation of ^{23}Na quadrupole coupling information using the CRYSTAL95 code is described and applied to the multi-site problem posed by $Na_5P_3O_{10}\cdot6H_2O$.

Modern solid-state NMR techniques for non-integer quadrupolar nuclei, particularly those based on MAS NMR techniques, are now commonly used in the characterisation of a wide range of materials including simple inorganic salts and complexes, zeolites, catalysts, minerals and ceramics.[1] In the particular case of the ^{23}Na nucleus (I = 3/2) an extensive body of experimental information for the quadrupole parameters, that is the quadrupole coupling constant ($C_Q = e^2qQ/h$) and the asymmetry parameter (η), has now been established. The assignment of ^{23}Na spectra, however, still remains problematic even in cases for which a crystal structure is available. One approach has been to use classical electrostatic modelling methods, although these are not always reliable.[2] Here we describe an *ab initio* approach which is specifically designed to be used in a routine manner for assignment purposes. It is based on the CRYSTAL95 code.[3] This package performs *ab initio* calculations of the properties of periodic systems taking into account the symmetry of the crystal lattice to form crystalline orbitals from a linear combination of atomic orbitals.

The ability to assign quadrupole parameters to individual sodium sites in a known crystal structure is important. This is because the magnitudes of these parameters are directly related to the nature of the electronic charge distribution surrounding a given sodium site. A more detailed understanding of this relationship can provide information on the electronic structure of a solid as a whole. At a more practical level, the knowledge gained is useful for more complex assignment problems such as those associated with glassy and amorphous materials.

We have selected as an example the hydrate of pentasodium triphosphate, $Na_5P_3O_{10}\cdot6H_2O$[4] since this material is recognised as presenting a particularly difficult assignment problem.[5] It crystallises in the triclinic space group $P\bar{1}$ with all atoms in general positions so that there are five different sodium sites with equal multiplicities.[6] The experimental ^{23}Na MAS NMR spectrum[7] is shown in Fig. 1 and, as expected, is complex with overlapping second-order quadrupolar lineshapes. Using our periodic *ab initio* approach we are able to provide a reasonable interpretation of this spectrum. In principle, MQMAS methods,[8] although experimentally demanding, could provide better spectral resolution and so comparison between the present work and any subsequent MQMAS investigation would be of direct interest.

We have used CRYSTAL95 to calculate the C_Q values for ^{23}Na for a wide range of sodium compounds with known crystal structures (19 in all involving 27 different sodium sites).[9] The Hartree–Fock calculations were based on the relatively small 3-21G molecular basis set of Pople and co-workers[10] and the basis sets for individual atoms were applied consistently across the whole range of compounds investigated. Only modest computer resources were required.[11] A key criterion was to obtain a good linear fit between calculated and experimental values of C_Q; exact agreement for each compound was not required. It can be noted that this approach is independent of the variability in the published values[12] of the nuclear quadrupole moment for ^{23}Na; in this work we use $Q = 0.1089 \times 10^{-28}$ m^2. For sodium, the 3-21G basis set was modified in the manner usually[3] adopted for alkali metal cations by replacing the valence orbitals by a single sp shell; we used an exponent of 0.18. Unmodified 3-21G basis sets were used for oxygen, sulfur and chlorine atoms, whereas some modifications to the values of the exponents for the outermost shells of hydrogen (0.183), nitrogen (0.273) and carbon (0.132) were required. In the case of aluminium, the outermost valence orbital of the 3-21G set is diffuse and this is known to cause convergence problems in periodic calculations.[3] Consequently, this orbital was removed giving a 3-2G set. The same modification of basis set was also found to be of benefit for silicon and phosphorus.

Fig. 2 shows a plot of experimental *versus* calculated C_Q values for ^{23}Na for all of the compounds that we have investigated.[13] The straight line in this figure represents the best linear fit to the data (R^2 = 0.977): the slope of the line is 0.979 ± 0.030 and the intercept is 0.084 ± 0.064 MHz. Since the sign of C_Q is usually not obtained in NMR experiments, it is assumed in Fig. 2 that the experimental value of C_Q takes the calculated sign. Overall we conclude that CRYSTAL95 calculations, based on the relatively simple 3-21G basis set, can calculate ^{23}Na C_Q values with sufficient accuracy to be useful for assignment purposes in multi-site problems.

In the case of $Na_5P_3O_{10}\cdot6H_2O$ the calculated values of the ^{23}Na C_Q for each of the five different sodium sites in the crystal structure are given in Table 1. These values provide a powerful starting point, along with the knowledge that the individual resonances must be of equal intensity, for the simulation of the experimental ^{23}Na MAS NMR spectrum shown in Fig. 1. The results of this simulation[15] are summarised in Table 1 and the simulated MAS NMR spectrum is compared with experiment in Fig. 1.

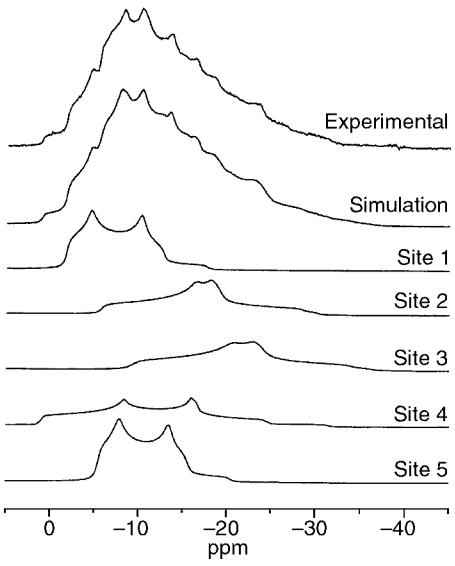

Fig. 1 Experimental (proton-decoupled) and simulated ^{23}Na MAS NMR spectrum of $Na_5P_3O_{10}\cdot6H_2O$. Individual contributions to the simulated spectrum are also shown.

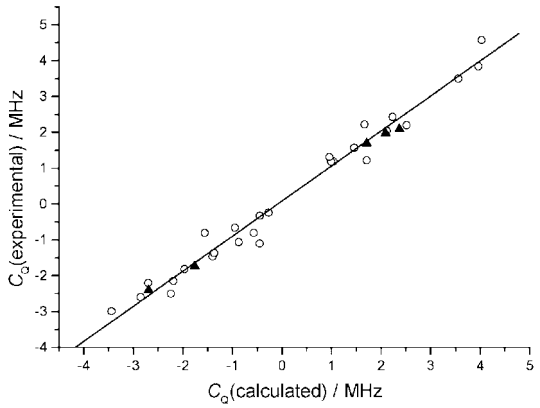

Fig. 2 A plot of experimental *versus* calculated ^{23}Na C_Q values for (i) sodium compounds involving oxyanions of silicon, sulfur, phosphorus, nitrogen, carbon, aluminium, chlorine and hydrogen (○) and (ii) the different sodium sites in $Na_5P_3O_{10}·6H_2O$ (▲): see Table 1.

Table 1 Information from both *ab initio* calculation and simulation of the experimental ^{23}Na MAS NMR spectrum for the different sodium sites in $Na_5P_3O_{10}·6H_2O$

	Calculation	Simulation			
Site[a]	^{23}Na C_Q/MHz	^{23}Na C_Q/MHz[b]	η	$\delta_{iso,cs}$(^{23}Na)[c]	Intensity[d]
1	−1.76	1.74	0.29	−0.55	0.21
2	2.09	1.97	0.85	−5.71	0.18
3	2.37	2.09	0.81	−9.09	0.19
4	−2.69	2.40	0.51	2.20	0.22
5	1.71	1.69	0.26	−4.20	0.21

[a] The labels correspond to those used in ref. 6. [b] The sign of these values cannot be determined from the ^{23}Na MAS NMR spectrum. [c] Isotropic chemical shift relative to external solid NaCl. [d] These values have been corrected using the method of Massiot *et al.*[14]

The assignment of the individual sodium sites (1–5) in Table 1 is based on the general linear relationship shown in Fig. 2; individual points corresponding to the assignment are plotted in this figure. The relatively small differences between the simulated ^{23}Na C_Q values does introduce some uncertainty into the assignment. Nonetheless, by using a consistent approach for all 5 sites we obtain, in the absence of any other information, a reasonable assignment. Potentially, the results also provide a very good starting point for a more detailed MQMAS investigation. It is worth noting that the sign of C_Q, if available experimentally, is an important assignment parameter; for example, in the present work it would resolve any ambiguity in the assignment of sodium sites 1 and 5.

In a wider context we have found the periodic *ab initio* approach described in this communication to be useful in a number of assignment problems in ^{23}Na solid-state NMR spectroscopy. In some cases it is sufficiently robust to indicate errors in published crystal structures.[16] In addition, we have found that it can be applied equally well to other widely-studied quadrupolar nuclei such as ^{17}O and ^{27}Al.

Infinite molecular tubes: structure and magnetism of $M(dca)_2(apym)$ [M = Co, Ni, apym = 2-aminopyrimidine, dca = dicyanamide, $N(CN)_2^-$]

Paul Jensen, Stuart R. Batten, Boujemaa Moubaraki and Keith S. Murray*

Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia. E-mail: Keith.S.Murray@sci.monash.edu.au

Received (in Cambridge, UK) 18th November 1999, Accepted 28th March 2000

The title compounds have a molecular tube-like structure topologically related to the α-$M(dca)_2$ rutile structure, and display unusual field-dependent magnetic moments at low temperature but without long-range order.

Since our initial report on the unusual molecule-based magnetism of α-$M(dca)_2$ [dca = dicyanamide, $N(CN)_2^-$],[1] a great deal of attention has focussed on the structural and magnetic properties of coordination polymers containing the dca ligand.[2–4] In the α-$M(dca)_2$ series of compounds, M = Co and Ni behave as ferromagnets while M = Cr, Mn and Fe behave as spin-canted antiferromagnets and M = Cu is a paramagnet. All these compounds are isostructural and possess a rutile-like topology, with the octahedral metal ions bridged by dca anions which coordinate through all three nitrogen atoms.

We report here the structural and magnetic properties of a series of polymeric complexes, $M(dca)_2(apym)$ (M = Co **1** or Ni **2**, apym = 2-aminopyrimidine), which form novel 'molecular tubes' that are structurally related to the rutile networks formed by the α-$M(dca)_2$ compounds, and which contain both two- and three-connecting dca ligands.

Reaction of apym, sodium dicyanamide and the corresponding metal nitrate in water resulted in formation of **1** or **2**.† These compounds are formed from the 1 : 2 adducts $M(dca)_2(apym)_2$, (M = Co, Ni). The $M(dca)_2(apym)_2$ compounds exhibit chain structures similar to those of $M(dca)_2L_2$, (L = MeOH, pyridine, DMF)[2,4b,c] full details of which will be published elsewhere.‡ Single crystals of **1** or **2** suitable for X-ray diffraction were grown by slow transformation of $M(dca)_2(apym)_2$ left in the reaction mixture for several months, and their structures were determined by X-ray crystallography.§ The IR spectra of **1** and **2** indicated the presence of both bidentate and tridentate dca ligands. X-Ray powder diffraction was used to prove that the bulk samples of **1** and **2** had the same structure as the single crystals, and were free from contamination.

Both structures are isomorphous (identical space groups), and the structure of **1** is shown in Fig. 1(a). It consists of infinite 1D 'molecular tubes' of square cross-section, with metal atoms occupying the edges and three-connecting dca ligands forming the sides of the tube. The octahedral coordination of the metal atoms is completed by chains of two-connecting dca ligands (with the amide nitrogens uncoordinated) which occupy the outside of each edge, and monodentate apym ligands. The sides of the tubes are 4.864 Å wide (4.821 Å in **2**).

The structure of the square tubes can be related back to the rutile-like structures of α-$M(dca)_2$. Fig. 1(b) shows the (distorted) rutile-like net of α-$Co(dca)_2$, with one of the channels of the structure highlighted. This highlighted channel has the same topology as the tubes. In effect, we have isolated a polymeric 1D section of the rutile-like network of α-$M(dca)_2$. Interestingly, while the channels in α-$M(dca)_2$ are buckled, the molecular tubes are not.

The tubes (all of which are crystallographically equivalent) pack in the crystal structure with extensive hydrogen bonding between the tubes *via* the apym ligands, as shown in Fig. 2. The apym groups form dimeric hydrogen bonded pairs with apym ligands in adjoining tubes, such that the amino group of one

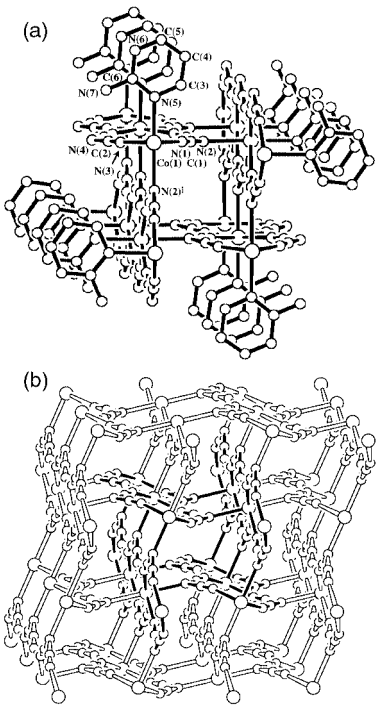

Fig. 1 (a) Structure of a single molecular tube in $Co(dca)_2(apym)$ **1**. Selected bond lengths (Å) for **1** (**2** in parentheses): Co(1)–N(1) 2.110(1) (2.074(3)), Co(1)–N(3) 2.089(1) (2.048(3)), Co(1)–N(5) 2.149(2) (2.126(4)), Co(1)–$N(2)^i$ 2.224(2) (2.201(4)). (b) The rutile-like network of α-$Co(dca)_2$ with a single channel with the same topology as the tubes highlighted.

ligand hydrogen bonds to the pyrimidine nitrogen of the adjoining ligand, and *vice versa*. These hydrogen bonding interactions (N(7)–H(1)···N(6) 178.6(3)° for**1** [177.4(5)° for **2**], H(1)···N(6) 2.200(3) Å [2.227(5) Å]) connect every alternate tube in the structure (black tube to black tube and white tube to white tube in Fig. 2), giving two separate sets of tubes. The two

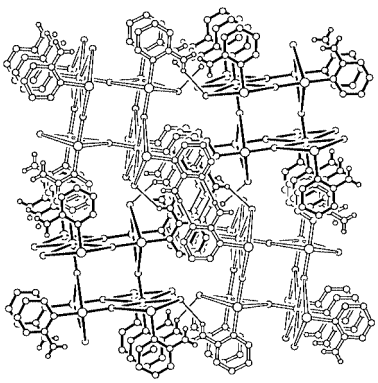

Fig. 2 Hydrogen bonding interactions between four tubes in the crystal lattice. For clarity, only the amino protons are shown. Hydrogen bonding interactions are shown by thin lines.

DOI: 10.1039/a909067c

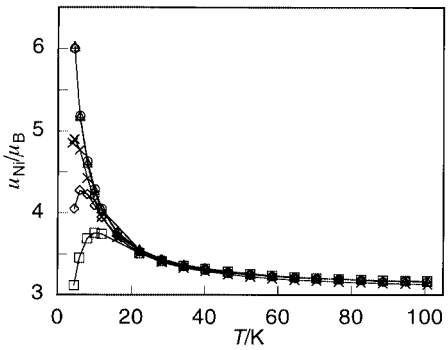

Fig. 3 Plots of the effective magnetic moment μ_{eff}, per Ni, *vs*. temperature for Ni(dca)$_2$(apym) **2**. Applied-field values are 20 Oe (Δ), 200 Oe (+), 10000 Oe (×), 20000 Oe (◇) and 40000 Oe (□). The μ_{eff} values are independent of field and essentially constant between 100 and 300 K.

sets of tubes are then connected by weaker hydrogen bonding interactions between the amino group of the apym ligands and the amide nitrogens of the two-connecting dca anions (N(7)–H(2)··N(4) 136.1(3)° for **1** [135.8(5)° for **2**], H(2)··N(4) 2.539(3) Å [2.517(5) Å]), white tubes to black tubes in Fig. 2.

Another feature of the packing is the interdigitation of the apym ligands of adjoining tubes into infinite π-stacked columns (Fig. 2). The mean planes of the ligands are separated by $c/2$ = 3.691 (for **1**) and 3.655 (for **2**) Å.

The magnetic data for **2** will be emphasised briefly here. The samples measured were shown to be free from any contaminant by checking the powder X-ray diffraction patterns. It can be seen in Fig. 3 that μ_{eff}, per Ni, remains constant at 3.1 μ_B between 300 and 100K in a field of 1 T as expected for octahedral Ni(II) centres. A gradual increase then occurs before reaching a maximum of 4.9 μ_B at 3.6K, behaviour indicative of ferromagnetic coupling. The corresponding χ^{-1}_{Ni} *vs*. temperature data are Curie–Weiss like, with θ = +3.1K. As the applied field is increased to 4 T, the μ_{max} region becomes broader in shape, with μ_{max} values lower and moving to higher temperatures. Magnetisation isotherms (*M vs. H*; 2–10 K) show rapid increases in *M* at low *H* and are indicative of ferromagnetic coupling, with a saturation value M_{sat} of 2.1 $N\beta$ noted at 2 K. Since μ_{eff} is a derived quantity (μ_{eff}^2 = 7.997 *M*T/*H*) the unusual shape of μ_{eff} at high fields and low temperatures to some extent will reflect this derivation since *M* is not linear with *H*. The shapes are also reminiscent of Zeeman level (M_S) depopulation effects noted in ferromagnetically coupled clusters.[6]

Measurements in low applied fields also lead to unusual behaviour. In Fig. 3 it can be seen that μ_{eff} increases sharply as *H* is decreased, then attenuates to a value of 6 μ_B for *H* = 200 or 20 Oe. The corresponding *M vs*. temperature plots are Curie–Weiss like with no sharp rise which would be indicative of a transition to long-range order. Other tests for long-range order such as measuring ac susceptibilities, χ' and χ'' (2–20 K), where χ'' was found to be zero at all temperatures between 4 and 20 K, or dc magnetisation in field-cooled or zero-field cooled modes, proved negative. In contrast to these puzzling features observed for **2**, the magnetic behaviour of the linear chain precursor, Ni(dca)$_2$(apym)$_2$, gives quite normal *S* = 1 behaviour with very weak antiferromagnetic coupling and/or zero-field splitting evident at low temperatures, and independent of *H*.

Further experimental and theoretical work is in progress on these novel tube-like materials to try and explain these magnetic anomalies, which are also present in the Co complex. Preliminary Heisenberg-type calculations made in collaboration with Kurmoo,[7] using a Ni_8 fraction of a tube, reproduce the 20 Oe data very well.

This work was supported by an Australian Research Council (Large) Grant (to K. S. M.) and an Australian Postdoctoral Research Fellowship (to S. R. B.). We thank Professor M. Kurmoo for stimulating discussions.

Notes and references

† *Preparative details*: **1**: an aqueous solution (7 ml) of Co(NO$_3$)$_2$·6H$_2$O (368 mg, 1.26 mmol) was added to an aqueous solution (3 ml) of Na(dca) (200 mg, 2.25 mmol) and apym (107 mg, 1.13 mmol) at room temperature yielding an instant pale pink precipitate [Co(dca)$_2$(apym)$_2$]. 10 ml H$_2$O was added and the reaction mixture boiled to dissolve the pink precipitate. Boiling was continued and the volume of the solution reduced to *ca.* 10 ml. A pink–purple microcrystalline powder formed and was filtered off (255 mg, 0.891 mmol, 79%). Found: C, 33.7; H, 1.5; N, 44.2. Calc. for $C_8H_5CoN_9$: C, 33.6; H, 1.8; N, 44.1%. Selected IR (dca) (cm^{-1}, Nujol): ν_{as}(C≡N) 2268m, 2260m; ν_s(C≡N) 2192s, 2182s(sh); ν_{as}(C–N) 1356, 1317. Crystals suitable for X-ray study were obtained by allowing the initial pink precipitate to transform in solution over several months.

2: a hot aqueous solution (10 ml) of Ni(NO$_3$)$_2$·6H$_2$O (375 mg, 1.29 mmol) was added to a hot aqueous solution (10 ml) of Na(dca) (200 mg, 2.25 mmol) and apym (110 mg, 1.16 mmol). The solution was boiled and the volume reduced to *ca.* 15 ml yielding a blue microcrystalline powder (245 mg, 0.857 mmol, 76%). Found: C, 33.6; H, 1.6; N, 43.9. Calc. for $C_8H_5NiN_9$: C, 33.6; H, 1.8; N, 44.1%. Selected IR (dca) (cm^{-1}, Nujol): ν_{as}(C≡N) 2274m, 2268m; ν_s(C≡N) 2198s; ν_{as}(C–N) 1354, 1314.

‡ Reedijk and coworkers[5] have just reported the crystal structure of Cu(dca)$_2$(apym)$_2$. It is the same as those of Ni and Co except for small symmetry differences owing to Jahn–Teller distortions.

Received (in Cambridge, UK) 18th February 2000, Accepted 23rd March 2000

An electrochemical synthesis yielded powdery $[Zn_2(L)(H_2O)]_n$ [H_4L = *N*,*N*′-bis(3-hydroxysalicylidene)-1,4-diaminobutane] and crystals of $[Zn_8(L)_4(H_2O)_3]\cdot H_2O\cdot 0.25MeCN$, whose X-ray crystal structure shows an unusual pseudo-tetrahedral Zn_8O_{13} core assembled by thirteen μ-phenoxo bridges, where Zn(II) ions are pentaco-ordinated.

A large number of S-bridged polynuclear zinc complexes are described in the literature,[1] but not so many examples of high nuclearity are found containing O- and N-donor ligands. An interesting approach to design these compounds is the assembly of simple units into polynuclear molecules.[2] The ability of compartmental or polynucleating ligands to hold closely metal ions is useful for this.[3,4] Therefore, the behaviour of the hexadentate Schiff base H_4L has been studied here. This ligand was prepared by condensation of 2,3-dihydroxybenzaldehyde and 1,4-diaminobutane in a 2 : 1 molar ratio.

The synthesis of the complexes was performed by using an electrochemical method,[4,5] with the cell summarised as: $Zn_{(+)}|MeCN + H_4L|Pt_{(-)}$. An acetonitrile solution of H_4L (0.10 g) was electrolysed (V = 14.5 V) for a calculated time (195 min) according to: $2Zn_{(s)} + H_4L \rightarrow Zn_2(L)(H_2O)_x + 2H_{2(g)}$. Anodic zinc was dissolved during the reaction (0.065 g), whilst hydrogen was evolved at the Pt cathode. An insoluble product $[Zn_2(L)(H_2O)]_n$,† was easily isolated from solution (yield: 90%). The brown solution obtained was slowly evaporated and small crystals were collected and later crystallographically identified as $Zn_8(L)_4(H_2O)_3\cdot H_2O\cdot 0.25MeCN$.‡

The study of the free ligand and both complexes by IR spectroscopy indicates that the Schiff base is behaving as hexadentate, through its potential oxygen and nitrogen donor atoms.[4–7] Positive ion ES mass spectrometry shows for $[Zn_2(L)(H_2O)]_n$ two peaks related to fragments of the type $Zn_2(L)^{2+}$ and $Zn_3(L)_2^{2-}$ at *m/z* (abundance) 453 (4×10^3) and 847 (2×10^3), respectively. This seems to be in accordance with a polymeric nature for the complex.

X-Ray diffraction studies of $Zn_8(L)_4(H_2O)_3\cdot H_2O\cdot 0.25MeCN$ revealed its molecular structure as a neutral octanuclear

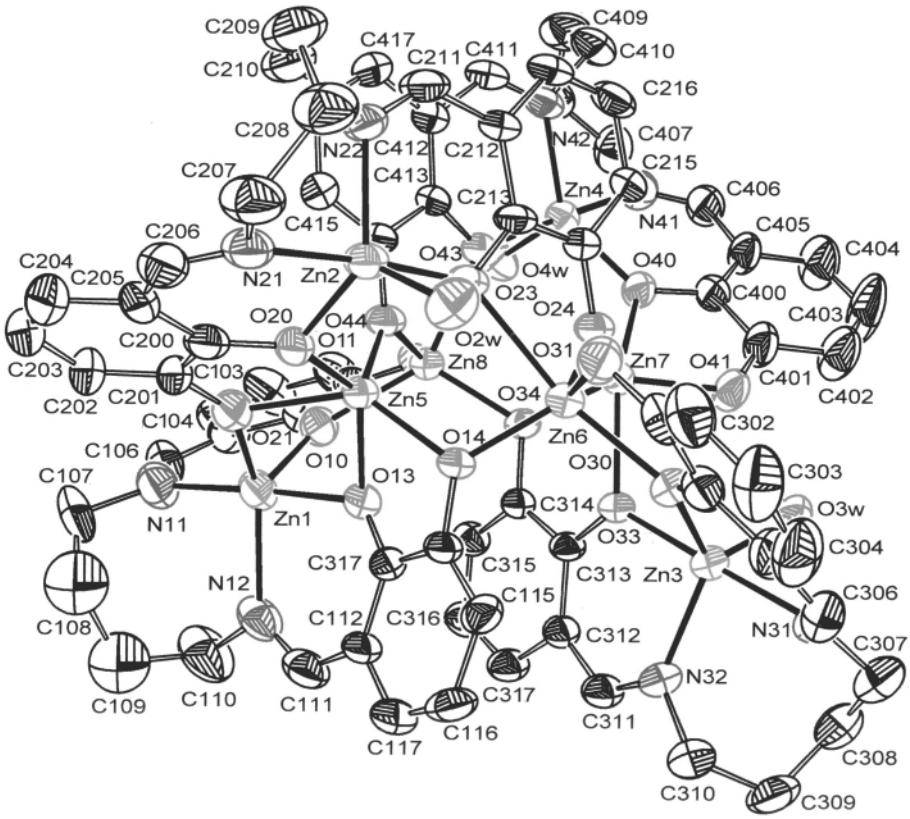

Fig. 1 ORTEP plot of $Zn_8(L)_4(H_2O)_3$. Atoms are represented by their 30% probability ellipsoids. Disordered atoms, H atoms, parentheses and some C atom labels are omitted for clarity. Angle ranges: Zn–O–Zn 126.8(3)–99.5(2)°; around Zn(1) 78.1(2)–176.8(3)°; around Zn(2) 87.5(2)–175.3(3)°; around Zn(3) 88.1(2)–178.3(3)°; around Zn(4) 88.0(2)–176.0(3)°; around Zn(5) 79.1(2)–137.3(2)°; around Zn(6) 76.5(2)–162.3(2)°; around Zn(7) 76.8(2)–155.5(2)°; around Zn(8) 77.5(2)–146.4(3)°.

complex (Fig. 1), where all the Zn ions are pentacoordinated. Four tetradeprotonated ligand units, L^{4-}, assemble the metal ions in a pseudo-tetrahedral arrangement by means of thirteen μ-phenoxo bridges. This is an interesting example of three-dimensional supramolecular architecture.

Atoms Zn(1), Zn(2), Zn(3) and Zn(4) lie on the pseudo-tetrahedron vertexes, having three water molecules bonded to three of them (Fig. 2). The other four inner Zn atoms [Zn(5)–Zn(8)] lie on four of the tetrahedron edges, and so they almost form a square. Additionally, the crystal contains encapsulated water (one molecule dispersed in five different positions with occupation factors of 20%) and acetonitrile (25% occupation factor) in the asymmetric unit.

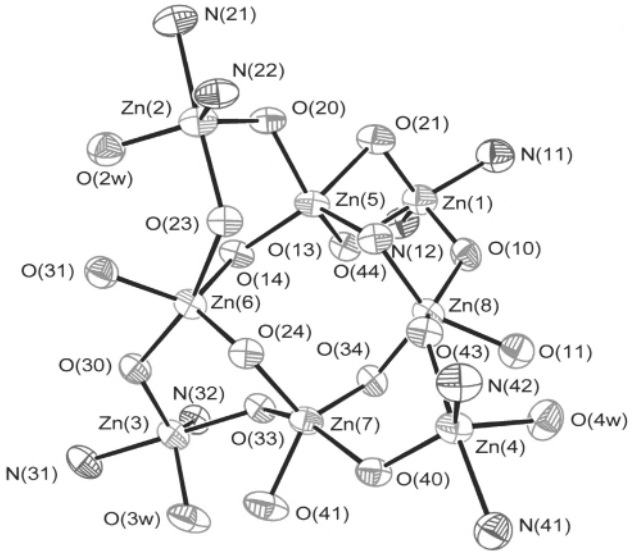

Fig. 2 A drawing of the coordination environments for $Zn_8(L)_4(H_2O)_3$. Dotted lines highlight the pseudo-tetrahedral shape.

Zn(*x*) (*x* = 1–4), are in N_2O_3 environments, which are formed by the inner N_2O_2 compartment of each L^{4-} unit and an additional O atom. This corresponds to a coordinated water molecule O(*x*w) for Zn(*x*) (*x* = 2–4), whilst for Zn(1) a μ-phenoxo bridge to Zn(5), through O(21), completes its coordination polyhedron. These environments can be described as slightly distorted trigonal-bipyramidal,[8] where Zn(1) is the most distorted. An imino N atom and its opposite inner phenolic O atom are occupying the axial positions in all cases.

Likewise, each one of these four outer metal centres is bound to two other inner Zn ions by two μ-$O_{phenolate}$ bridges through the inner oxygen atoms of their corresponding ligand units [O(*x*0) and O(*x*3)] for Zn(*x*) (*x* = 1–4). Additionally, Zn(1) is also bound through the outer O(21). Thus, Zn(1)···Zn(5) [3.182(2) Å] is the shortest Zn···Zn distance, the longest being 3.901(2) Å. These values are in the range found for other polynuclear zinc complexes containing imino or amino ligands with μ-oxo bridges.[2,9–11]

For the other four inner metal centres, Zn(5)–Zn(8), O_5 environments are formed exclusively by the sixteen phenolic donor atoms, with each metal ion simultaneously bound to three different ligand units. The polyhedron around Zn(6) can be also described as trigonal bipyramidal, with two inner O atoms in axial positions, and three outer phenolic O atoms in the equatorial plane. By contrast, the environments of Zn(5), Zn(7) and Zn(8) can be considered as distorted square pyramids.[8]

Zn–N and Zn–O distances [2.021(7)–2.156(9) and 1.910(6)–2.328(5), respectively], lie within the ranges found for other polynuclear complexes with N- and O-donor ligands.[9,12,13]

Some related Schiff bases had been previously designed as potentially compartmental and binucleating, being able to accommodate, two metal ions (d + f or less commonly d + d) in different modes.[6,7] Here, the intricate bridging behaviour of L^{4-} leads to much higher polynucleating ability. Thus, the ligand unit containing Zn(2) in its inner compartment is also coordinated to Zn(1), Zn(5), Zn(6) and Zn(7), whilst the other three ligand units are each bonded to four metal ions.

This structure is very unusual and one of the rare and recent examples of oxygen bridged octanuclear Zn(II) complexes.[9,14] No Schiff base ligands are present in these two cores, which are significantly different and contain additional bridging oxo or hydroxo groups.

Therefore, to our knowledge, this is the first example of an octanuclear μ-phenoxo bridged zinc complex containing Schiff base ligands. The long methylene chain of L^{4-} appears to provide enough flexibility to achieve such high nuclearity. This factor seems to be important. Thus, in the case of an amino octanuclear complex,[9] high nuclearity could not be observed when the more rigid imino ligand derivative was employed.

We would like to thank the Xunta de Galicia (Spain) for financial support (XUGA 20903B99).

Received (in Cambridge, UK) 12th January 2000, Accepted 14th March 2000

A new preparation of uniform hammer-like macromolecules of C_{60} with designed molecular weight and narrow molecular weight distributions in the range of 1.13–1.37 is developed by using C_{60}-monoadduct initiator (I) in a copper-mediated atom transfer radical polymerization (ATRP).

Recently, C_{60} (fullerene) has attracted much interest in the field of chemistry, physics and materials owing to its uniquely caged shape and intriguing properties. The structure, physical properties and photophysical behavior of C_{60} have been extensively studied.[1] Since the large-scale preparation of C_{60} was developed, there have been considerable reports on the macromolecular modification of C_{60} for practical purposes.[2–6,9–12] Since block polymers whose segments with different properties can be used as building units for aggregates,[7,8] it can be expected that an asymmetric hammer-like polymer containing C_{60} would self-assemble into a highly ordered supramolecular architecture with special electrical and optical properties. On the other hand, in order to establish the structure–property relationship of C_{60}-containing polymers, it is necessary to know the accurate content of C_{60} in the polymers. However, this has been proven to not be an easy task. The amount of C_{60} present estimated by thermogravimetry (TG), UV–VIS spectroscopy and gel permeation chromatography (GPC) do not agree well. In general, the actual amount of C_{60} incorporated in the polymer is usually much less than that in the feed.[5] Thus, there is an increasing need to synthesize well-defined C_{60}-containing polymers. This goal has been achieved partially by using different methods.[9–12] Recently, we tried an approach to synthesise well-defined C_{60}-containing polymers. In previous work,[12] well-defined bromo-terminated polymers obtained by ATRP[13] were treated with C_{60} under ATRP conditions to yield C_{60}-end-bonded PSt (PSt-C_{60}-Br) and PMMA (PMMA-C_{60}-Br). The final products were characterized to be mainly monoadducts and had controlled molecular weight with narrow molecular weight distributions, however, it was difficult to separate them from homopolymers. Here, we synthesized C_{60}-monoadduct **I** first, then it was used as an initiator for the ATRP of styrene to obtain uniform hammer-like macromolecules of C_{60} with designed molecular weight and narrow molecular weight distributions, Scheme 1.

Shown in Fig. 1 is the $\ln([M_0]/[M])$ *vs.* polymerization time plot. It can be seen that when the polymerization conversion was lower than 5%, it showed a linear relationship, meaning that the number of active species during the polymerization is constant under these conditions. This observation together with the linear evolution of molecular weight with conversion (as shown in Fig. 2) indicates that the initiation is fast so the contribution of chain breaking, transfer and termination is negligible; thus, when the conversion is lower than 5%, the process is controlled. When the conversion is higher than 5%, there is a deviation from the semilogarithmic kinetic plot, the consumption of styrene is faster than the initial stage, thus the termination on the C_{60} core can not be neglected, and the product obtained is no more well defined. The reason can be traced to the mechanism of ATRP. The initial stage of ATRP that generates radicals is a rate-determining step. In this step, a catalytic amount of the CuBr/bipy coordination complex reversibly abstracts the bromine atoms from the C_{60}-monoaduct initiator **I**, switching them from a dormant state to an active state, and generates a low concentration of C_{60}-based radicals. Since the concentration of

DOI: 10.1039/b000278j

Table 1 A summary of the conversion, molecular weight and molecular weight distribution of C_{60}-end-bonded polystyrene prepared *via* ATRP using C_{60}-monoadduct **I** as initiator

Run	Polymerization time/min	Conversion (%)	$M_{n,\,th}$ $(10^{-3})^a$	$M_{n,\,GPC}{}^b$ (10^{-3})	$M_w/M_n{}^b$
1	60	1.3	2.57	2.64	1.37
2	120	2.3	4.75	4.18	1.18
3	180	4.2	8.61	7.75	1.13
4	300	9.2	19.0	17.7	1.32

[a] Polymerization conditions for the bulk ATRP of St at 110 °C using C_{60}-monoadduct **I** as an initiator: $[St]_0$ = 9.26 M, $[CuBr]_0 = [bipy]_0/2 = [\mathbf{I}]_0 = 4.63 \times 10^{-2}$ M. [b] As determined by GPC in THF, low distribution polystyrenes were used as standards.

styrene is much higher than C_{60}-monoadduct initiator **I**, the addition of radicals to styrene double bonds occurs almost exclusively. As the polymer chains propagate, the relative concentration of styrene against C_{60}-monoadduct initiator **I** decrease, and the possibility of termination on the double bonds of C_{60} increase, thus making the molecular weight distribution broader. From the above observation, it is concluded that hammer-like macromolecules of C_{60} with designed molecular weight could be obtained by this method with low conversion.

The presence of C_{60} in polymers can be characterized by UV–VIS, DSC and NMR *etc*. Here we use 2-aminoacetonitrile (AAN) as an IR label of C_{60} in the polymers as we had reported previously.[15] Since the reaction between C_{60} and the aliphatic primary amino group of AAN proceeded smoothly under mild conditions *via* single electron transfer, the cyano group would display a characteristic peak at around 2250 cm^{-1}, while both PSt and PSt-C_{60} do not exhibit any absorption peak in the range 2000–2600 cm^{-1}. In the IR spectrum of NH_2CH_2CN-labeled PSt-C_{60}, an apparent new absorption peak appears at 2369 cm^{-1}. In a control experiment, the reaction product of pure PSt with NH_2CH_2CN does not absorb in this region. The result thus confirmed that C_{60} had been covalently bonded to PSt and this method can be extended to label other C_{60} derivatives.

Table 1 demonstrates that narrow molecular weight distribution C_{60}-bonded polystyrenes with high content of C_{60} can be obtained *via* this method. Since in ATRP, the molecular weight depends on the polymerization conversion, and the change of polymer chain length lead to the change of C_{60} content in the polymers, then by tailoring the polymer chain length, the content of C_{60} in the polymers can be well controlled.

Fig. 3(a) shows the GPC profiles of PSt-C_{60} with different molecular weight prepared by using C_{60}-monoadduct initiator **I** in THF. In all the GPC profiles the shapes are symmetrical, and there is no shoulder peak on the profiles of the PSt-C_{60} samples 2, 3 and 4 obtained by this method as compared to those obtained by preformed PSt which reacts with C_{60}.[15] This indicates that the sample possesses the designed hammer-like structure, not a mixture of PSt-C_{60} and PSt homopolymer.

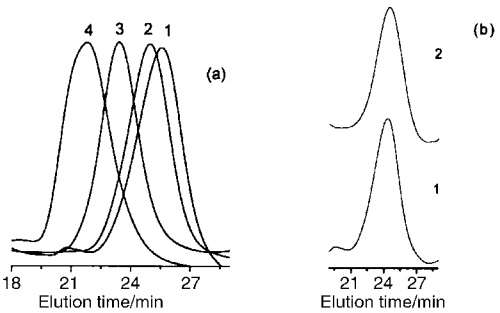

Fig. 3 (a) GPC profiles of C_{60}-end-bonded PSt prepared by using C_{60} monoadduct initiator (**I**) *via* ATRP (sample 1: $M_n = 2.64 \times 10^3$, sample 2: $M_n = 4.18 \times 10^3$, sample 3: $M_n = 7.75 \times 10^3$, sample 4: $M_n = 17.7 \times 10^3$) (b) GPC profiles of C_{60}-end-bonded polystyrene (sample 1, $M_n = 2.64 \times 10^3$) obtained by refractive index (1) and UV–VIS (2) dual detector, the working wavelength for the UV detector was set at 350 nm.

Fig. 3(b) shows the GPC profiles of C_{60}-end-bonded polystyrene (sample 1, $M_n = 2.64 \times 10^3$) obtained by UV and RI dual detector. The working wavelength of the UV detector was set at 350 nm where the PSt could not be detected and only derivatives of C_{60} can be recorded. Comparing the GPC profiles of C_{60}-end-bonded polystyrene, the profiles thus obtained are almost the same. The slight difference between the peaks at elution time is due to the different distance that the polymers passed from the pump to the detectors. This result indicates that C_{60} is bonded evenly in the polymers and the C_{60}-end bonded polystyrenes are monoadducts with well-defined structure.

Since the structure of C_{60}-end-bonded polystyrene obtained was defined with one C_{60} per polymer chain end, *i.e*. hammer shaped, by controlling the polymer chain length, the content of C_{60} in the polymers can be altered and the quantification of C_{60} in the polymers can be achieved thus aiding to establish the structure–property relationship of the C_{60}-containing polymers.

The preparation and the study of self-assembled aggregation behavior of these hammer-like macromolecules with well-defined flexible polymer chains including hydrophilic and amphiphilic chains are underway.

This work was financially supported by the National Natural Science Foundation of China (Nos. 59283032 and 29671030).

Notes and references

The C_{60}-monoadduct initiator **I** was synthesized according to the literature[14,15] as shown in Scheme 1. In a typical run, a mixture of *N*-methylglycine and 4-bromoacetoxybenzaldehyde was refluxed in toluene in the presence of C_{60}. The reaction proceeded readily over 8 h, affording the monoadduct **I** of the C_{60} *N*-methylpyrrolidine derivative in 35% yield after chromatography and recrystallization (70% based on C_{60} conversion). ^1H NMR of C_{60} monoadduct ($CDCl_3/CS_2$) δ 7.82 (br, 2H), 7.12 (d, 2H), 4.94 (s, 1H), 4.84 (d, 1H), 4.18 (d, 1H), 3.99 (s, 2H), 2.69 (s, 3H). UV–VIS (cyclohexane): 213.8, 257.2, 317.4, 430.5 nm.

The polymerizations of styrene were conducted in bulk in sealed glass tubes. The feed molar ratio was **I** : CuBr : bipy = 1 : 1 : 2. After the mixture was degassed three times, the tube was sealed under vacuum, and the polymerization was carried out in an oil bath of 110 °C for given times. The crude polymer was obtained by precipitation from methanol, dissolved in $CHCl_3$, and the solution then passed through a silica column to remove the catalysts. The polymer was recovered by precipitation from a large excess of methanol, and then dried under vacuum. A yellow to brown fine powdery polymer was obtained. UV–VIS (cyclohexane): 215.2, 259.3 nm.

Tribochromic compounds, exemplified by 3-dicyclopropylmethylene-5-dicyanomethylene-4-diphenylmethylenetetrahydrofuran-2-one

Abdullah M. A. Asiri, Harry G. Heller,* Michael B. Hursthouse and Alexander Karalulov

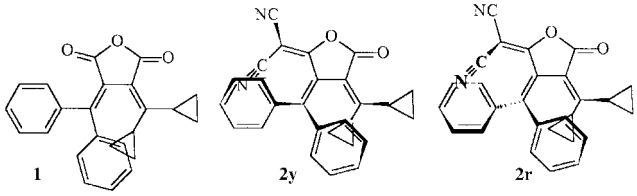
Chemistry Department, Cardiff University, PO Box 912, Cardiff, UK CF1 3TP. E-mail: heller@cardiff.ac.uk

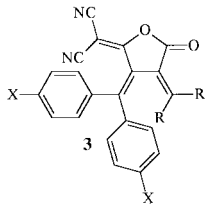
Received (in Cambridge, UK) 25th February 2000, Accepted 30th March 2000

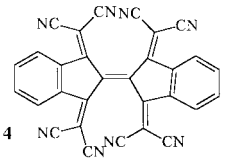
The title compound 2 is obtained as bright yellow metastable crystals, which on mechanical grinding change to the dark red stable form; unlike piezochromic compounds, the reverse colour change does not occur; X-ray crystallographic analyses shows that the yellow form has a folded structure while the red form has a twisted structure.

We introduce the term 'tribochromism' (Greek tribos rubbing, khroma colour) to describe the new phenomenon of metastable crystals that undergo a major and irreversible colour change on mechanical grinding. The coloured form is stable and does not undergo the reverse change when kept in the dark, on heating or when dissolved in an organic solvent. In contrast, piezochromism[1] defines stable crystals, which give highly coloured metastable forms on fracture, which undergo the reverse colour change under the conditions described above.

As part of our studies[2] on photochromic dicyanomethylene derivatives, the severely overcrowded 3-dicyclopropylmethylene-5-dicyanomethylene-4-diphenylmethylenetetrahydrofuran-2-one **2** was prepared by reaction of dicyclopropylmethylene(diphenylmethylene)succinic anhydride **1** with malononitrile in THF in the presence of diethylamine (2 equiv.) at room temperature. The resulting colourless salt was filtered off and treated with acetyl chloride in dichloromethane. Solvent and acetyl chloride were removed and the residue purified by chromatography on silica gel using ethyl acetate and light petroleum (bp 60–80 °C) as eluent. The deep red solution, on concentration, gave a first crop of bright yellow crystals **2y** (*ca*. 0.3 g) and a second crop of dark red crystals **2r** (*ca*. 0.1 g). Red crystals and yellow crystals gave red solutions that showed identical NMR and UV/visible spectra. Repeat experiments with recrystallisation from different solvents gave only red crystals. The deep red solutions gave only red crystals when seeded with yellow crystals. X-Ray crystallographic analysis (which presented difficulties with refinement) on the best of the crude yellow crystals **2y** showed that the diphenylmethylene group is folded (one phenyl lies above a cyclopropyl group and the other above a cyano group). [X-Ray crystallographic analyses on compound **3c(y)**, which was obtained only as tribochromic yellow crystals, showed a folded structure also.] X-Ray crystallographic analysis† of dark red crystals **2r** showed that the diphenylmethylene group is twisted (one phenyl lies above a cyclopropyl group and the other below a cyano group) (Fig. 1).







Gompper[3] has reported that di[1,1-bis(dicyanomethylene)-indan-2-ylidene] **4** exists in yellow and in red crystal modifications and that X-ray crystallographic analysis showed that in yellow crystals, molecules have a folded structure whereas in red crystals, molecules have a twisted structure.

The tribochromic properties were discovered accidentally. Since yellow crystals **2y** gave deep red solutions, it was not possible to observe whether compound **2y** was photochromic in solution. To produce a greater surface area to test for

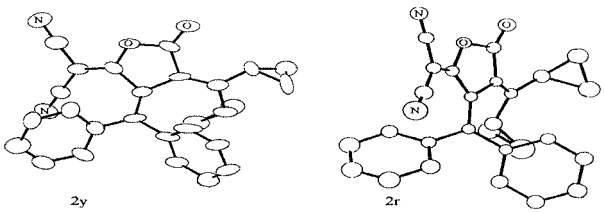


Fig. 1 X-Ray structures of yellow crystals **2y** and red crystals **2r**.

photochromism in the solid state by irradiation with ultraviolet light, yellow crystals were ground with a spatula. On grinding, they turned dark red.

A range of related compounds **3a**–**i** has been prepared in which the dicyclopropylmethylene group was replaced by 2-propylidene, adamantylidene and cyclopentylidene groups and in which 4-hydrogens on the phenyl groups were replaced by chloro and fluoro groups. Compounds were obtained either as yellow or dark red crystals (see Table 1) but never in both forms with the exception of **2y** and **2r**. All compounds obtained as yellow crystals were tribochromic.

We thank King Abdul Aziz University, Saudi Arabia for financial support (to A. M. A. A.) and the EPSRC for support for the X-ray crystallographic work.

Hydrogen bonds A–H···A′, where A and A′ are electronegative atoms have been widely discussed. Weak hydrogen bonds involving such different arrangements as X–H···A, where X can be C; X–H···π, with phenyl rings, C≡C bonds; X–H···M, where M is a transition metal; X–H···H–M and X–H···H–B, have also been described in recent years. While the first types are typical of organic and inorganic compounds, as well as biological molecules, those involving transition metal atoms are special to organometallic chemistry. Theoretical calculations of different kinds and at several levels have been performed for many systems, revealing that a similar geometrical arrangement can hide another type of interaction. This happens for N–H···M close contacts which can be agostic interactions or hydrogen bonds, not so easily distinguishable for 16-electron complexes. M–H···H–X interactions also exhibit a different behavior, depending on whether the complexes are neutral or ionic. The AIM approach, by analysing the topological properties of the charge density with the determination of critical points, provides another way of looking for bonds, as discussed in several examples.

Introduction

Hydrogen bonds have been known since the beginning of this century, but were brought into the common body of knowledge by Pauling in 1939, in his book *The Nature of the Chemical Bond*.[1] Strong and weak hydrogen bonds are discussed by Jeffrey and Saenger, in *Hydrogen Bonding in Biological Structures*.[2] They consider as strong hydrogen bonds only those of the types F–H···F$^-$, O–H···O$^-$, and O$^+$–H···O, which are always two-center bonds, involving short distances and strongly directional, with typical energies higher than 41 kJ mol^{-1}. On the other hand, the normal or weak hydrogen bonds would be X–H···A, where the acceptor A is an electronegative atom. Multicentered bonds start to appear, directionality is lost, and the bond energies drop to below 20 kJ mol^{-1}. The common feature to all of these bonds is the presence of an electronegative atom A as acceptor. More recently, other types of hydrogen bonds were identified. The acceptor can be a π system, usually a ring, and these are denoted X–H···π hydrogen bonds.[3] More interesting for the inorganic chemist are those involving a transition metal, either directly in X–H···M interactions,[4] or as a metal hydride, to form X–H···H–M groups.[5] A similar environment can be found when boron takes the place of the transition metal, giving rise to X–H···H–B interactions.[6] This latter type, where the hydrogen attached to X acts as a proton and the other as a hydride, has been denoted the dihydrogen bond, emphasizing the proximity of the two hydrogen atoms (Scheme 1).[6]

Scheme 1

As the hydrogen bonds become weaker, the difficulty of distinguishing between hydrogen bonds and van der Waals interaction becomes relevant and has been discussed.[7] The role of hydrogen bonds in supramolecular chemistry and solid design is extremely important, as well as in biochemical environments, namely in protein folding, and many publications deal with these themes.[8]

In this work, theoretical studies of the different types of weak interactions will be addressed, after a brief introduction to the computational methods that have been used for this purpose, with more or less success and limitations. Our interest lies mainly on the study of hydrogen bonds in systems containing transition metal organometallic complexes. They therefore constitute the main objective of this review, which is organized by type of bond, starting from weak X–H···A hydrogen bond, and moving on to X–H···π, X–H···M, and X–H···H–M(B). In some systems, the hydrogen bond takes place at the periphery of the molecules or ions, and the role of the metal is minimum. In such cases, results involving only main group elements are comparable. The X–H···H–B interaction also does not necessarily involve transition metals, but is very interesting to compare with X–H···H–M, in view of the differences between boron and a transition metal.

Computational methods

Many different approaches have been used to study weak hydrogen bonds, ranging from semiempirical calculations (extended Hückel,[4a,9] MNDO[10]) to *ab initio* studies (HF/MP2,[5c] B3LYP,[6,11] DFT[12]). These methods allow either a qualitative interpretation of the bond (extended Hückel), or geometry optimization, determination of binding energies, and calculation of charges and other relevant parameters. MP2 and B3LYP approaches are compared in a detailed study of formation of hydrogen bonded complexes of small molecules with water, where water can behave as donor or acceptor,

Maria José Calhorda is Professor of Inorganic Chemistry at the Department of Chemistry and Biochemistry of the Faculty of Sciences, University of Lisbon, since 1996, and has her research group at the Instituto de Tecnologia Química e Biológica, Oeiras, since 1990. She received her PhD from Instituto Superior Técnico, Lisbon (1980), and spent one year as a post-doc in Oxford (ICL) with D. M. P. Mingos. A sabbatical leave at Cornell University with R. Hoffmann and a later one at the MPI für Festkörperforschung, Stuttgart, with A. Simon contributed to a wide range of scientific interests, dealing essentially with the theoretical study of electronic structure and reactivity of inorganic systems, and a more recent one in the design of solids.

DOI: 10.1039/a900221i

depending on the type of molecule. B3LYP was found, by some authors,[11d] superior to MP2 in what concerns the quality of the results, and has the advantage of a much lower computational cost. In order to consider short-range, electrostratic, induction, and dispersion interactions, reliable quantitative calculations should include correlation effects, which are only taken into account by DFT and *n*th order Møller–Plesset methods, the lowest being MP2.[13a,b] Correlation determines dispersion interactions, and influences the others. There is much discussion about to what extent DFT methods can indeed be used when dispersion forces are significant, and the accepted view is that MP2 is better.[13] Another difficulty present in the determination of weak interaction energies is the basis set superposition error (BSSE). It can significantly reduce the magnitude of a weak interaction and eventually destroy it. Although its contribution should always be calculated, it has not been done, especially in less recent works and the results must be critically considered.[13a–c]

The theory of 'atoms in molecules' (AIM)[14] has been used to extract chemical bond information from wave functions (and therefore its 'value' depends on the theoretical calculations behind). An analysis of the topological properties of the charge density with the determination of critical points can help determine the presence of a bond and this reasoning has been applied to the study of hydrogen bonds.[15] Carroll and Bader studied, among others, the hydrogen bond formation between HF and a series of bases. They calculated critical points of the charge density, ρ, corresponding to open shell interactions (covalent bonds) and compared them with those resulting from closed shell interactions (Fig. 1).

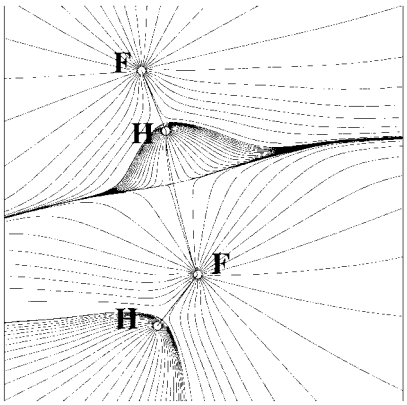

Fig. 1 Display of the gradient vector field of the charge density ρ for $(HF)_2$. Each line represents a trajectory of $\nabla\rho$. A nucleus acts as an attractor of the $\nabla\rho$ field, that is, all the trajectories in some open neighbourhood of a nucleus terminate at that nucleus. These trajectories are lines of steepest ascent through the charge density. An atom is the union of an attractor and its basin. Basins of neighbouring atoms are separated by trajectories that terminate at a bond critical point (denoted by a black dot). A pair of lines of steepest ascent (also shown as bold lines) originate at each critical point and terminate, one to each, at the neighbouring nuclei. They define the atomic interaction lines—lines along which ρ is a maximum with respect to any neighbouring line. If the system is at its equilibrium geometry, these lines are called bond paths.

In the first case, covalent bonds, the laplacian of the charge density, $\nabla^2\rho$, is negative at the critical point, while $\nabla^2\rho$ is positive for closed shell interactions, such as hydrogen bonds.[14b] The determination of critical points in the charge density and the signal of $\nabla^2\rho$ can therefore help in identifying bonds.

Weak hydrogen bonds of the type X–H···A

Weak hydrogen bonds, where X and A are not simultaneously very electronegative atoms, are important in organic and in organometallic chemistry, and a large group comprises C–H···A interactions, where A is an electronegative atom, such as oxygen. The use of the Cambridge Crystallographic Data Base (CSD)[16] has been of major importance in their detection. C–H···O short distances have been identified in organic[17] and organometallic compounds,[18] and also in nucleic acid molecules.[19]

The general properties of the C–H···O interactions were studied in detail, with an emphasis on the application of crystal correlation studies.[17] Calculated bond energies of organic C–H···O bonded dimers in vacuum led to values between *ca.* 2.1 and 15.8 kJ mol^{-1}, with an exceptionally high 38.9 kJ mol^{-1} for NH_3^+–CH_3···OH_2. Of course these values will be changed in solution, solvation being an important factor, but it is thought that the energies are essentially below 8.4 kJ mol^{-1}. The shortest contacts are *ca.* 3.0 Å (C···O) and *ca.* 2.0 Å (H···O).[17a]

C–H···O interactions are very much present in organometallic chemistry, namely in the crystal structures of carbonyl complexes simultaneously containing cyclopentadienyl, benzene, carbene, or any other group with a C–H group.[18] Electrostatic effects are determining in allowing the approach of C–H to an oxygen atom, and so the charges (positive in the hydrogen, negative in the oxygen) will play a major role. It is well known that the amount of back donation from metal centres to carbonyl ligands increases from terminal, to doubly bridging, to triply bridging carbonyls, leading to an increasing negative charge on the oxygen atom. Several families of compounds, obtained from a search in the CSD, were analysed in a molecular orbital study.[20] Triply bridging carbonyls should be the best at establishing strong hydrogen bonded networks in the solids. Would this effect overcome the natural preferences for carbonyl bonding in each complex? As a matter of fact, it does not, as covalent bonds are much stronger. Carbonyls bind in their preferred way to each metal, the trend being that the lighter the metal, the larger can be the number of bridging carbonyls. For instance, for the $(Cp^R)_3M_3(CO)_3$ clusters (M = Co, Rh, Ir), one finds, among other structures, $(Cp)_3Co_3(\mu_3\text{-}CO)_3(\mu\text{-}CO)_2$ and $(Cp)_3Ir_3(CO)_3$, bridges being observed for the lighter element clusters.[20b] Once the number and type of carbonyl is defined, the tendency to form stronger hydrogen bonds (defined here as having shorter distances and angles closer to 180°) lies with the triply bridging carbonyls.[20]

C–H···N hydrogen bonds with an estimated short H···N distance of 2.33 Å and an almost linear C-H···N arrangement are responsible for the packing in the crystals of bis(2,2′-dipyridylamido)cobalt(II).[7b] The authors question that many not so short C–H···X distances, along with not so linear C–H···X arrangements, are not indicative of hydrogen bonds, and sustain that most of them are indeed only classical van der Waals interactions. A reply has recently come out, giving more examples from the CSD.[7d]

A CSD search of hydrogen bonds to halides in organic and organometallic structures was recently reported, along with a statistical study, but no theoretical interpretations were attempted. One example of N–H···Cl interactions is found in 2,6-diphenylpyridinium tetrachloroaurate(III), where the Cl atom is coordinated to gold, and there is a bifurcated interaction between the N–H of the cation and two chlorides of the anionic complex.[21] The hydrogen bond between the chlorine atom in $OsHCl(CO)(PBu^t_2Me)_2$ and the hydrogen atom of alcohols was studied by NMR and computational methods (B3LYP and IMOMM, the integrated molecular orbital/molecular mechanics approach).[22] The bulk of the phosphines plays a significant role, preventing the formation of a Os←O bond, and only the IMOMM method, including a good basis set in the B3LYP part, provides a good reproduction of the experimental results. The role of fluorine in X–H···F hydrogen bonds has been discussed. Dunitz and Taylor demonstrated that, when covalently bound to carbon, fluorine does not participate in hydrogen bonds.[23] On

the other hand, fluorine in the PF_6^- anion, a very popular ion in organometallic chemistry, is observed in many X–H···F–P interactions, believed to be hydrogen bonds.[8]

Hydrogen bonds of the X–H···π type

Suzuki *et al.* investigated the benzene–water dimer using MP2 calculations with BSSE corrections and found that the water molecule stood over the benzene ring, with its centre of mass on the sixfold symmetry axis. The ring acted as a hydrogen-bond acceptor toward the two hydrogens. The dissociation energy was calculated as 7.4 kJ mol^{-1}.[24a] A similar study of the ammonia–benzene dimer was also carried out. The ammonia molecule also preferred a position such that its centre of mass coincided with the sixfold symmetry axis, but in the lowest energy arrangement only one hydrogen pointed toward the benzene ring.[24b] The energy difference to the next arrangement with two hydrogen atoms pointing toward the ring was very small.

The observation of X–H···π hydrogen bond has become frequent in recent years, as more examples of their presence in organic and organometallic crystals have been reported.[25] The first neutron diffraction study of an O–H···π hydrogen bond appeared in 1996.[25c]

A statistical study of these bonds, taking as donors O–H, N–H, $N–H^+$, sp^2 C–H, sp C–H, and S–H, and as acceptors phenyl or substituted phenyl rings, used the April 1996 version of the CSD and led to 1537 occurrences, in 530 of which the C_6H_5 ring participated.[10] The X–H approaches to the ring were classified in six groups. In group I, the hydrogen atom pointed at the centre and the X–H bond was perpendicular to the ring, while in group II X–H was no longer vertical. The other four groups included X–H bonds more or less near a carbon atom, rather than the centre, and more or less vertical. Types III and V were preferred by almost all donors, type I being significant for only $N–H^+···C_6H_5$. The authors performed semiempirical calculations (AM1, PM3) in a wide range of systems and *ab initio* calculations [HF with MP2, BSSE, ZPE (zero point energy) corrections] in a few. The interactions were always found to be attractive, with binding enthalpies decreasing in the order $N–H^+$ > O–H > N–H > sp^2 C–H > sp C–H. The interactions are described by shallow potentials allowing many binding arrangements (for instance, ammonia pointing with one, two, or three hydrogen atoms at the centre of the ring) and exhibit a long range nature.[10]

Theoretical calculations (GAUSSIAN92/DFT) were also performed on 5-ethynyl-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ol, a molecule which dimerizes in the solid (Fig. 2) and exhibits C–H···π and O–H···π interactions.

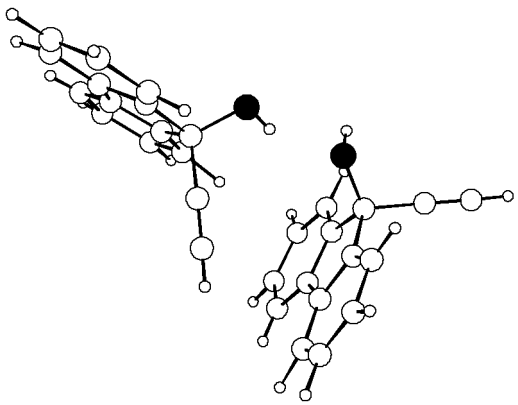

Fig. 2 The dimer of 5-ethynyl-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ol (the black circle represents the oxygen). Hydrogen bonds are intermolecular and not seen.

In C–H···π, the hydrogen is close to the centre of the ring and almost vertical, while the O–H in O–H···π is much closer to one of the carbon atoms. The interaction energies were calculated at *ca.* 1.3 kcal mol^{-1} for both types.[25a] The authors also point out the softness of the interaction, which allows many different geometric arrangements with similar energies, although the minimum energy is observed for the face-on bonds.

Other π bonds have been shown to participate in hydrogen bonding.[26] Philp and Robinson[26a] searched the occurrence of C≡C–H···π(C≡C) short contacts in the CSD (October 1997) and found 37 hits. They performed *ab initio* calculations (MP2) in order to determine cooperative effects when hydrogen bond networks were found. The energy determined for a C–H···π(C≡C) interaction was 1 kcal mol^{-1}, close to that of an O–H···π(C≡C) interaction (1.5 kcal mol^{-1}). Cooperative effects turned out not to be significant, while the 'independence' of the interaction energy from the interaction geometry was again noted, as well as the poor capabilities of the C≡C bond as a hydrogen bond acceptor. Mingos and coworkers[26b] also studied theoretically, using different approaches, the interactions between HC donors (HCN, $C_{4-n}H_n$) and C_2R_2 acceptors (R = H, Na, H_3PAu) in a T shaped geometry. They are very weak for ethyne (< 10 kJ mol^{-1}), but become much stronger (stronger than most hydrogen bonds) in the gold derivative (10 kJ mol^{-1}) and in C_2Na_2. Another conclusion of the study was that DFT methods, of the best quality, always underestimated weak interaction energies by failing to describe accurately the dispersion force,[26b] as pointed out above.[13]

X–H···π hydrogen bonds with X = Cl, F and the π bond a C=C or a C≡C bond, were studied using the formalism of AIM,[14] and HF/MP2 calculations.[27] Their energies ranged from 3.09 kcal mol^{-1} for Cl–H···π(HC≡CH), to 4.87 kcal mol^{-1} in other systems (HF with MP2 corrections) and the values of $\nabla^2\rho$ at the hydrogen bond critical point were all negative, reflecting an interaction between closed shells.[27]

The participation of a pyrazole ring as a hydrogen bond acceptor was reported for the first time recently and was observed in the $[Re_3(\mu\text{-}H)_3(\mu\text{-}\eta^2\text{-}pz)(CO)_9(Hpz)]^-$ complex. In the crystal structure, one N–H bond points perpendicularly toward the centre of the ring, and NMR data show that this interaction remains in solution.[25d]

Recently, we came across C–H···π intramolecular hydrogen bonds involving fluorenyl rings. One example is given by $[(C_{13}H_9)_2ZrCl_2]$, where Zr exhibits the pseudo tetrahedral coordination environment typical of bent metallocenes. The two rings are coordinated in a rather asymmetric fashion, one of them being a characteristically η^5 bound ring, while the second is slipped to an extent that made the authors call it a η^3-fluorenyl, as two Zr–C bonds are 2.8 Å long (the others range between *ca.* 2.39 and 2.64 Å).[28] There is considerable steric crowding around the metal. The slippage of the ring can be compensated by more π-donation from the chlorine atoms to the metal, and a small stabilization is in principle gained by the formation of the C–H···π hydrogen bond (Fig. 3).

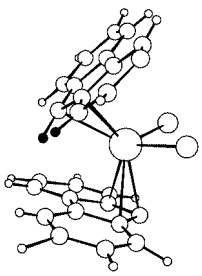

Fig. 3 The C–H···π hydrogen bonds in $[(C_{13}H_9)_2ZrCl_2]$.

A similar interaction is observed in $[(C_{13}H_9)(C_9H_7)_2Mo(CO)_2]$, a complex having one η^3-fluorenyl and one η^5-indenyl ring. Both in the experimentally determined structure and in the optimized geometry (DFT calculations, ADF program, with nonlocal and correlations corrections included in the calculation of gradients),[29] C–H groups from the indenyl are

involved in intramolecular hydrogen bonds with carbon atoms of the fluorenyl groups.[30]

X–H···M interactions

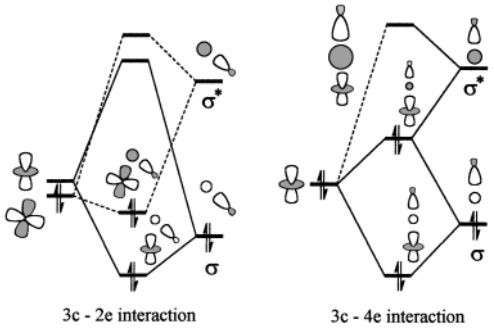
Short distances between a hydrogen atom attached to nitrogen or carbon and a metal have been known for a while, but were often interpreted as a manifestation of agostic hydrogens.[31] They were mainly observed in square planar Group VIII complexes, formally 16-electron species, where the X–H bond approached the metal from one of the axial positions.[32] Brammer *et al.* were among the first to assign X–H···M short contacts as intermolecular hydrogen bonds, in the study of $[NPr^n_4][PtCl_4][PtCl_2(NH_2Me)_2]$.[4a] The structure of this compound was determined at 4 K by neutron diffraction and showed a short N–H···Pt distance of 2.262(11) Å, with an N–H···Pt angle of 167.1(9)°. NMR evidence did not agree with the typical behavior of agostic hydrogens. As similar X–H···M distances had also been observed in d^{10} 18-electron complexes,[33] and agostic hydrogens were not expected, they were thought to be ideal systems worth further study. $[NHEt_3][Co(CO)_4]$ was chosen,[33a] and a neutron diffraction study at 15 K revealed a Co···H–N distance of 2.613 Å, C–H 1.054 Å, and an angle N–H···Co 180°.[4b] The authors performed EH calculations, but the results were not conclusive.[4b] Previous EH calculations on a related model $[NH_4][Ni(CO)(PPh_3)_3]^+$, had indicated a weak attractive interaction, made possible by mixing N–H σ* in the otherwise four-electron repulsive interaction between Ni d_{z^2} and N–H σ.[33b] The strength of the N–H···Co hydrogen bonds was further investigated by modifying ligands (to modify the basicity of the metal centre) or the cation. Indeed, replacing $[NHEt_3]^+$ by protonated DABCO (1,4-diazobicyclooctane), a less bulky cation, favouring the approach to the metal, the N···Co distance is reduced from 3.648 to 3.437 Å. Substitution of a carbonyl by a phosphine in the *trans* position relative to the N–H bond, leads to an N···Co distance of 3.294 in $(DABCO)H^+Co(CO)_3(PPh_3)$. The authors performed *ab initio* calculations (HF) on these systems, and found that transfer of hydride to cobalt was energetically preferred. The energy minimum for $(DABCO)[HCo(CO)_3(PPh_3)]$ was deeper than the minimum for $(DABCO)H^+Co(CO)_3(PPh_3)$, a result understandable by the fact that solvent effects were not considered.[34]

These weak X–H···M interactions are thus important in the context of metal protonation and reactivity, especially when square planar metal centres are involved.[35] The complex [*trans*-$Rh(CO)(8\text{-methylquinoline})(PPh_3)_2][BF_4]$, for instance, is a 16-electron complex containing a square planar d^8 species and exhibits a short C–H···Rh distance 2.21 Å. The authors were looking for agostic hydrogens, but the weak interaction detected between the axial methyl and the metal was not unambiguously an agostic hydrogen.[36]

In a typical agostic interaction, the metal centre is electron deficient and receives electrons from a C–H σ bond, back donation from the metal to the σ* C–H bond being possible. As a result, the C–H bond becomes weaker and relatively short metal···hydride (though much longer than metal–hydride) distances develop. Such bonds can be described as three-centre–two-electron bonds (C–H→M), as sketched in the left of Scheme 2.[37]

The agostic bond was theoretically studied using the AIM formalism,[38] and it was found that the criteria used to define hydrogen bonds did not apply in the systems studied ($CH_3TiCl_2^+$, $C_2H_5TiCl_2^+$, $C_3H_7TiCl_2^+$), emphasizing the difference between the two types of bonds. Indeed, in a hydrogen bond, the metal is not necessarily electron deficient, and the interaction is a three-centre–four-electron one (Scheme 2, right).[35]

NMR was used to distinguish between agostic and hydrogen bond interactions in 16-electron square planar complexes, as the proton resonance was shifted upfield for the first case, and

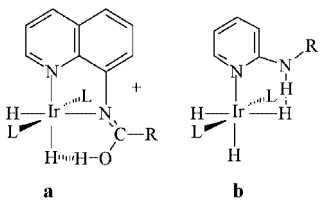


Scheme 2

downfield for the second, compared to the free ligand.[35] More recently, the CSD was searched for examples of complexes containing the X–H···M arrangement.[4c] The 50 hits included d^8 square planar complexes, d^6 square pyramidal complexes (the sixth position of the octahedron being taken by the H–X) and other systems. Only N–H and C–H bonds were found to interact with d^8 square planar centres. All the N–H groups were oriented perpendicularly to the plane of the complex, so that the orbitals of the metal which can overlap are d_{z^2} and p_z. As this last orbital has a very high energy, the interaction belongs to the three-centre–four-electron type (Scheme 2, right), namely a hydrogen bond, as in the 18-electron systems. The C–H···M arrangements were not so clearly cut, as many were not perpendicular and a final conclusion was not reached. The doubt remains as to whether a hydrogen or an agostic bond is present, but a weak hydrogen bond is favored.[4c]

The dihydrogen bond: X–H···H–M and X–H···H–B

The term dihydrogen bond was introduced by Crabtree and coworkers[6] to describe X–H···H–M bonds, where X is an electronegative atom and the metal–hydride σ bond behaves as an acceptor. The complex *cis*-$[IrH(OH)(PMe)_4][PF_6]$[39] was the compound where such an arrangement was seen for the first time in 1986.[39a] A low temperature neutron diffraction study was carried out later,[39b] showing a short O–H···H–Ir distance of 2.40(1) Å and a short Ir–O–H angle of 104.4(7)°. This weak interaction was assigned to a dipole–dipole interaction.[5e] Another O–H···H–Ir interaction was discovered by Crabtree and coworkers[5a] in the iridium complex **a** shown in Scheme 3, based on NMR evidence, as no hydrogen atoms could be detected in the X-ray crystal structure. The H···H distance was estimated as *ca.* 1.8 Å from the NMR data. Other related complexes were prepared and the first N–H···H–Ir (Scheme 3, **b**) interaction was observed.[5b]



Scheme 3

Calculations (HF, GAUSSIAN92) were performed on a model of complex **b**.[5c] The energy of the model $IrH_3(PH_3)_2(HNCHNH_2)$ was lower by 60.3 kJ mol^{-1} when the N–H group was in the same plane as IrH_3, as in **b**, showing a barrier to rotation due to breaking the N–H···H–Ir interaction. This value was corrected to 41.5 kJ mol^{-1} to account for the difference between formamidine (model) and 2-aminopyridine,

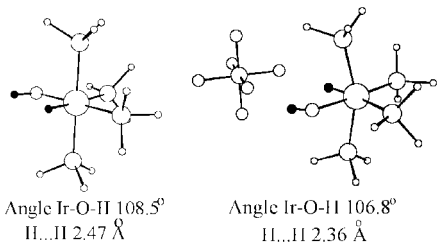
in good agreement with the experimental value of 45.1 kJ mol^{-1}. The strength of the hydrogen bond was estimated as 29.7 kJ mol^{-1}. The ligand *trans* to the hydride participating in the hydrogen bond may affect the bond; a poorer σ donor will cause a less negative charge on the hydride, decreasing the electrostatic interaction between the H^- and the H^+, and therefore leading to a weaker hydrogen bond.[5c]

Another interesting system, dealing also with N–H···H–Ir interactions, was reported in 1994. Morris and coworkers synthesized iridium hydride complexes containing aminothiolate ligands and exhibiting N–H···H(Ir)···H–N[5g] or two N–H···H–Ir interactions.[5h] The H···H interactions were detected by NMR experiments, as the position of the hydrogen atoms could not be located in the X-ray crystal structures. Liu and Hoffmann studied [Ir{H(η^1-SC_6H_4NH)(PH_3)}$_2$] (PH_3 instead of PCy_3, in the model) using EH calculations,[9] starting by locating the two hydrides. They found a positive, though small, overlap population for the H···H interaction and also noticed the increase in energy upon rotation of the aminothiolate and consequent disruption of the hydrogen bond. The bond was found to be weakly attractive and with a significant electrostatic contribution. Smaller related systems, where similar interactions could arise from intermolecular approaches, such as H–F···H–Li and H–F···$HMn(CO)_5$, were also studied (HF calculations). For H–F···$HMn(CO)_5$, an energy minimum (27.4 kJ mol^{-1}) at a distance of 1.683 Å was determined.

The search for H···H intermolecular dihydrogen bonds[40] had the first result in the cocrystallization of the complex $ReH_5(PPh_3)_3$ with indole. A neutron diffraction structure showed that two of the hydrides were interacting with the N–H bond of the indole (H···H distances 1.75 and 2.25 Å). B3LYP calculations led to a relatively good reproduction of the geometrical features (H···H distances 1.92 and 2.48 Å) and gave an interaction energy of 33.4 kJ mol^{-1}.[40a] Reaction of the Re precursor with imidazole afforded $ReH_5(PPh_3)_2$(imidazole), where two of the hydrides were involved in hydrogen bonding with the N–H of a free imidazole molecule (H···H distances 1.68 and 1.99 Å).[40b] The strength of the interaction was estimated from IR data to be 22.6 kJ mol^{-1}.

The related derivatives containing pyridine[40c] and *o*- or *p*-NHR substituted pyridine, were prepared and the hydride fluxionality studied by NMR[40d] and theoretically (B3LYP).[40e] The rate was accelerated with the introduction of the *o*-NHR substituent in pyridine, and ascribed to intramolecular dihydrogen bond formation. Comparisons were made with the *p*-NHR derivative as this substituent cannot form intramolecular hydrogen bonds but electronic substituent effects are similar. The turnstile mechanism, with simultaneous rotation of three hydrides, was found to be the preferred both from experimental and theoretical results, leading to comparable barriers. A detailed study of the reaction mechanism showed that, for the 2-aminopyridine complex, strong hydrogen bonding was found in an intermediate along the reaction pathway. There was a barrier before reaching the transition state, owing to repulsion between two hydrides, and this prevented more powerful consequences of hydrogen bond toward lowering the activation barrier for hydride rotation.

Reviews about these non-classical hydrogen bonds appeared[5d–f] and several searches in the CSD for crystals exhibiting short intra- and inter-molecular H···H contacts were made.[12,41,42] Many of the examples refer to intramolecular interactions involving X–H···H–M, where X is an electronegative atom (O, N, S), starting with the already mentioned *cis*-[IrH(OH)(PMe_3)$_4$][PF_6].[39] Other cationic mononuclear complexes belong to this group, such as [IrH_2(CO)(PPh_3)$_2$(pzH-*N*)][BF_4]·C_6H_5Me with H···H 1.998 Å,[43] [IrH(Cl)(L)][PF_6] (L = 7-methyl-3,7,11,17-tetraazabicyclo[11.3.1]heptadeca-1(17),13,15-triene) with H···H 2.335 Å,[44] as well as the neutral compounds IrH(Cl)(PEt_3)$_2$[NHPh(C_7H_{10})] with H···H 2.242 Å,[45] Ru(H)$_2$($CO)_2$($PHPh_2$)(PPr^i_3)$_2$, with H···H 2.63 Å, and the *cis*-dicarbonyl [OsH($CO)_2$($PHPh_2$)(PPr^i_3)$_2$][BF_4] with H···H 3.04 and 2.83 Å.[46] Spectroscopic evidence suggested the presence of M–H···H–N interactions in Ru complexes (NMR),[47] although no crystals of the product could be obtained. Polynuclear complexes and clusters also exhibit short H···H distances between a hydride and a X–H hydrogen. Examples are given by Cp_2Zr(NHAr)(μ-H)(μ-NBu^t)IrCp*, with an H···H distance of 1.717 Å,[48] the two related complexes [Rh_2H_2(μ-SH_2)$_2${$MeC(CH_2PPh_2)_3$}][BPh_4]·$HCONMe_2$[49] and [(μ-H)$_2$$Ir_2$-(μ-$NH_2$)$_2$($PEt_3$)$_4$($NH_3$)$_2$]·$Me_2CO$,[50] with H···H 1.891 Å and 2.260, 2.189 Å, respectively for the Rh and the Ir complex, (μ-H)Ru_3($CO)_9$(μ-C_6H_2-1-NH-2-NH_2-4,5-Me_2), with H···H 2.383 Å,[51] [Ru_6(μ-H)$_6$(μ^3-η^2-ampy)($CO)_{14}$] (ampy = 2-aminopyridine), with H···H 2.064 Å.[52] N–H···H–M interactions have also been detected in compounds without structural characterization, such as $OsH(NH_3)(CO)_9$,[53a] and [{η^5-$C_5H_4CH(CH_2)_4NMe$}Ir(PPh_3)H_2].[53b] The observation of these interactions in the polynuclear complexes containing bridging hydrides is particularly interesting, as these hydrides often behave like acids. A close observation of the structure, however, suggests that steric constraints are responsible for the observed short H···H contacts.[12a] The M–H bond can also participate in M–H···O hydrogen bonding,[18a] as seen from many structures, but most of the hydrides involved are doubly or triply bridging hydrides which are very likely to carry a positive charge, so that the situation is not so surprising from an electrostatic point of view. Theoretical studies (DFT) were performed on some of the complexes, the most interesting results relating to the two cationic species, *cis*-[IrH(OH)(PMe_3)$_4$][PF_6] and [IrH_2-($CO)($PPh_3$)$_2$(pzH-*N*)][$BF_4$].[12] The geometries of the cations were optimised (using PH_3 instead of PMe_3 or PPh_3) and the agreement with the experimental structures was not particularly good. Introduction of the counter ion (PF_6^- or BF_4^-) in the calculations led to a better geometry. The charge distribution in these complexes is compatible with an electrostatic interaction between the negatively charged hydride and the positive hydrogen attached to N or O. The relevant geometric features can be seen in Scheme 4 for *cis*-[IrH(OH)(PH_3)$_4$][PF_6].



Scheme 4

The energy increases by 20.8 kJ mol^{-1} when the torsion angle H–Ir–O–H changes from 0 to 180° in the cation. As the angle varies, the H···H interaction vanishes. The corresponding energy difference is 44.1 kJ mol^{-1} when the PF_6^- anion is present. The relevant conclusion is of a non-negligible role of the counter ion in helping to stabilize the short H···H arrangements. In order to understand more about these interactions, the AIM approach was used to detect the hydrogen bonds.[54] *cis*-[IrH(OH)(PH_3)$_4$][PF_6][39] and the neutral complex $IrH_3(PH_3)_2(HNCHNH_2)$, theoretically studied by Eisenstein and coworkers,[5c] were chosen, to allow a direct comparison between neutral and charged species. These two complexes have iridium as the metal, which is also an advantage, as all the calculations can be done under the same conditions. The gradient vector fields and the bond critical points (black circles) are shown in Fig. 4, in the plane containing the X–H···H–Ir bonds.

For the neutral $IrH_3(PH_3)_2(HNCHNH_2)$ there is a critical point between the hydride and the N–H hydrogen. The values

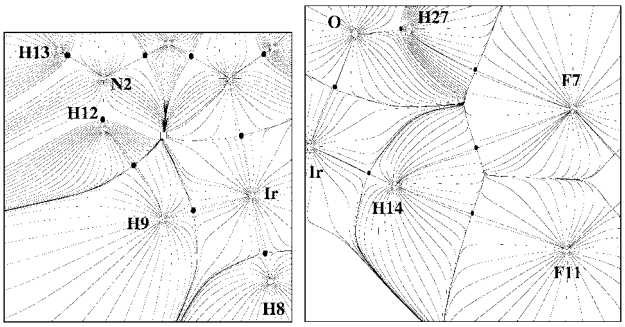


Fig. 4 The gradients of charge density and the critical points (black dots) along bonds in the Ir–H···H–N plane for $IrH_3(PH_3)_2(HNCHNH_2)$ (left) and *cis*-$[IrH(OH)(PMe_3)_4][PF_6]$ (right).

shown in Table 1 for the density ρ and the laplacian $\nabla^2\rho$ are typical for hydrogen bonds,[15] with positive $\nabla^2\rho$. For comparison, the critical points describing some relevant covalent bonds are also given. $\nabla^2\rho$ is now negative and the different values indicate, for instance, how the participation of H12 in the hydrogen bond with the hydride modifies the N2–H12 bond relative to N2–H13.

The cationic complex is different, because no critical point exists between the two hydrogen atoms. Instead, there are hydrogen bonds to the fluorine atoms in the PF_6^- anion. The H27(O) atom makes one hydrogen bond with F7, while the hydride is involved in hydrogen bond with the two fluorines, F7 and F11. The first hydrogen bond, H27–F7 is not surprising, as H27 carries a positive charge and F7 is negative. On the other hand, both the hydride H14 and the two fluorines F7 and F11 are negative. The values of $\nabla^2\rho$ and ρ for the bonds given in Table 1 are characteristic of covalent bonds (N–H, O–H) and hydrogen bonds (H···F). If this interpretation is indeed correct, the role of the counter ion is even greater than was thought.

The effect of charges in hydrogen bonds has also been assessed in the study of O–H$^-$···O$^-$ interactions in chains of oxalate anions (UHF). These are repulsive interactions. The reason why the atoms hold together is that they simultaneously participate in attractive interactions with the counter ion, K^+.[55] This is a situation where a short O–H$^-$···O$^-$ distance does not indicate a hydrogen bond.[18e] The point is controversial,[56] and brings forward the question whether distances by themselves provide an answer to the existence of a bond. As the previous example shows, short distances in O–H$^-$···O$^-$ chains can coexist with repulsive interactions, because a stronger cation–anion electrostatic attraction holds all ions in their place. A similar effect seems to take place in *cis*-$[IrH(OH)(PH_3)_4][PF_6]$.

Besides the previous examples, which include the oldest known systems, other intramolecular and intermolecular hydrogen bonds have been studied. Sometimes, they may be considered as the first step in the formation of a H–H bond, to give M–H_2 complexes, for instance. The $ReH_5(PPh_3)_3$·indole·C_6H_6 compound,[40] where two hydrides approach the N–H bond of indole, has already been mentioned. More recently, an equilibrium between the Ir–H_2 complex of $IrH(L)_2(bq\text{-}NH_2)$ (L = phosphine, bq-NH_2 = 2-amino-10-methylbenzo[*h*]quinoline) and the Ir–H···H_3N species was found to take place, its extent depending on the phosphine. Theoretical calculations (B3PW91) reproduce the trend: more basic phosphines lead to formation of the Ir–H_2 complex. An accurate modeling of the phosphine was critical and surprisingly PH_3 was not a good model for PPh_3.[5i]

A hydrogen bond between the H–O group in acidic alcohols and W hydrido complexes $WH(CO)_2(NO)L_2$ (L = phosphine) was detected by IR and NMR data and the H···H distance estimated as 1.77 Å, for L = PMe_3.[57] $Ru(dppm)_2H_2$ interacts with PhOH or 1,1,1,3,3,3-hexafluoroisopropyl alcohol, *via* Ru–H···H–O hydrogen bonds and forms the dihydride complex.[58] $ReH_2(CO)(NO)L_2$ (L = phosphine) also interacts with alcohols,[59] but both O–H···H–Re and O–H···O–N–Re hydrogen bonds may be formed, the latter becoming predominant when the phosphine is bulky (PPr^i_3). Theoretical calculations (DFT) were performed in the model compound $ReH_2(CO)(NO)(PH_3)_2\cdots OH_2$, allowing both types of approach to take place (to the M–H or to the O–N bond). The O–H···H–Re bond type is electronically favoured by 12.5–14.6 kJ mol^{-1}, but forces the OH carrying molecule to be very close to the metal, and this becomes difficult when two bulky axial phosphines are present. O–H···O–N–Re hydrogen bonds are then formed for steric reasons.[59]

Orlova and Scheiner performed calculations of different types (HF/3-21G, B3LYP, BLYP, B3PW91) to study the intermolecular bonding of molybdenum and tungsten hydrides with HR (R = F, OH, H_2O^+) complexes.[11a] The study of the interaction of HF with $Mo(CO)_2(NO)(PH_3)H$ led to the conclusion that the DFT/B3PW91 method was the best, even taking into account that all DFT methods tend to afford distances that were too long, and it was chosen for most studies. The Mo–H···H–F hydrogen bond energy was estimated as *ca.* 46 kJ mol^{-1}. Substitution of the *cis* ligand PH_3 by the better σ donor NH_3 increases the strength of the hydrogen bond, while changing the metal to W does not afford any major change. A greater acidity of the HR species also leads to a stronger hydrogen bond and formation of H_2-complexes, while, as expected, bulkier ligands have the opposite effect. The authors notice the inadequacy of Mulliken charges to adequately describe the system, but they rely on a Mulliken-type analysis (overlap populations) to interpret relative trends. The competition of formation of other bonds, such as F–H···O–N–Mo was investigated,[11a] as done previously for Re complexes.[59]

Orlova and Scheiner[11b] also addressed the interactions of CpReH(CO)(NO), $CpReH(NO)(PH_3)$ and $CpRuH(CO)(PH_3)$ with several proton donors (H_2O, $HOCF_3$, H_3O^+) with B3PW91 methods. The formation of H_2-complexes as a result of H···H hydrogen bonding and the alternative protonation at the metal to form dihydride complexes are discussed. $CpReH(NO)(PH_3)$ has a very strong nucleophilic centre at the metal and only the dihydride forms, while for $CpRuH(CO)(PH_3)$ only the H_2-complex forms with strongly acidic HR. When a weaker acid such as CF_3OH is considered, the R–H···H–Ru interaction also becomes a minimum on the potential energy surface. For the third complex, CpReH(CO)(NO), the three species (the dihydrogen complex, the dihydride complex and the hydrogen bonded complex with R–H··H–M) can be obtained from the calculations. The basicity of the metal is therefore an important factor in determining the formation of hydrogen bonds where the M–H bond behaves as acceptor.[11b]

The C–H bond can also engage in weak intra- and intermolecular hydrogen bonds of the type C–H···H–M. They were seen in some of the complexes referred to above, such as $[(\mu\text{-}H)_2Ir_2(\mu\text{-}NH_2)_2(PEt_3)_4(NH_3)_2]\cdot Me_2CO$,[50] with H···H 2.105 Å, and $ReH_5(PPh_3)_3$·indole,[40] with H···H 1.903, 1.929 Å. These and other complexes were hits in a CSD search for short C–H···H–M distances and the observation of the data suggested a new mechanism for cyclometallation.[60] Some other examples have been reported since then and structurally characterized.[61]

Table 1 The charge density and the laplacian of the charge density at some critical points between bonds in model complexes $IrH_3(PH_3)_2(HNCHNH_2)$ and *cis*-$[IrH(OH)(PH_3)_4][PF_6]$

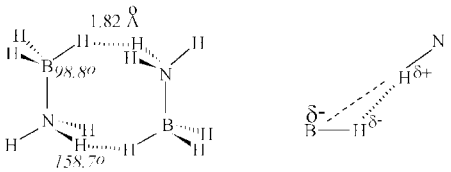
$IrH_3(PH_3)_2(HNCHNH_2)$			*cis*-$[IrH(OH)(PH_3)_4][PF_6]$		
Bond	ρ	$\nabla^2\rho$	Bond	ρ	$\nabla^2\rho$
N2–H12	0.352	−0.2129	H27···F7	0.193	0.714
N2–H13	0.366	−0.2175	H14···F11	0.252	0.782
H9···H12	0.168	0.4251	O1–H27	0.376	−0.234
			Ir2–H14	0.169	0.344

Intermolecular C–H···H–M hydrogen bonds are very weak and normally coexist with other types of not so weak hydrogen bonds involving N–H or O–H, especially if they are intramolecular. Intermolecular C–H···H–M hydrogen bonds are sometimes alone in holding together two molecules, as seen in many of the examples taken in CSD search (October 1996).[41]

$[N(PPh_3)_2]_2[W_2H_2(CO)_8]$ offers an interesting situation, where one C–H bond of a phenyl group approaches a bridging hydride on each side of the molecule.[62] EH calculations[41] indicate that the bridging hydride carries a negative charge, owing to the large electron richnness of the metal centres. Therefore, an electrostatic interaction between the negative hydride and the positively charged H–C is responsible for the short H···H distances. Only a very small positive overlap population of 0.01 is found between the hydrogen atoms. In *mer*-$[(Me_3P)IrH(Cl)(C_5H_4N)]$,[63] each hydride enters an interaction with a C–H bond of the pyridine ring of the adjacent molecule. These two Ir–H···H–C bonds hold together the dimer (data taken from CSD). Rotating the pyridine out of the plane disrupts the bond and increases the energy by *ca.* 58 kJ mol^{-1}.[41] In the other representative compounds of the group,[64] small positive overlap populations were found, and a charge distribution consistent with an electrostatic interaction.[41]

B–H bonds can replace M–H as hydrogen bond acceptors. This was recognized in 1995 and confirmed with a CSD search which gave 22 structures with H···H distance < 2.2 Å. The average H···H distance was 1.96 Å, in a range between 1.7 and 2.2 Å.[6]

The B–H···H–X bond was studied (PCI-80/B3LYP method) in the $[H_3BNH_3]_2$ dimer (Scheme 5, left) and although there is no available structure of this compound, the features seen in the optimized geometry are typical of other boron compounds.[6]



Scheme 5

A particularly interesting aspect of these bonds with boron is that a linear B–H···H–X arrangement is an exception. In $[H_3BNH_3]_2$, the calculated B–H–N angle is 98.8° and N–H–H is 158.7°. Although bent bonds were observed in other cases for weak bonds, here they seem to be rule. An explanation lies in the large negative charge carried by the boron atom, compared to the small negative charge carried by the hydrogen. In order to take advantage of the charge distribution, the H–N points toward the B–H bond rather than toward H (Scheme 5, right).[6]

Epstein *et al.*[65] studied these interactions theoretically (HF) and spectroscopically, using as models $BH_4^+\cdots OH_2$, $BH_4^+\cdots HOCH_3$, $H_3NBH_3\cdots HOCH_3$, $[H_3BNH_3]_2$. They determined minima for the approach of the B–H bond to the donor, for distances 1.836–2.209 Å, always smaller than the sum of van der Waals radii (2.4 Å), and small positive overlap populations between the hydrogen atoms. Contrary to the results of Siegbahn and coworkers,[6] a positive charge is assigned to boron.

Alkorta *et al.*[66] studied dihydrogen bonds for a variety of combinations of acid hydrogen atoms (NH_4^+, HCN, HC≡CH), basic hydrogen atoms (BH_4^-, LiH, BeH_2), and an amphoteric (CH_4), using several methods (HF, MP2) and correcting for BSSE. Frequency calculations were used to check the minima. The charge density at the critical points and the positive values of $\nabla^2\rho$, within the AIM approach, indicated strong hydrogen bonds. The geometries obtained were compared with structures taken from the CSD, which included B–H···H–N, B–H···H–O, B–H···H–C, Al–H···H–C, besides the ones described earlier in ref. 6.

The homonuclear dihydrogen bond?

The CSD searches for short H···H distances also afforded structures not belonging to any of the previous type, namely dimeric species, where both hydrogens must have the same charge and the electrostatic features of hydrogen bonds are not present.[41] The prototype is the dimer of $HMn(CO)_5$.[67] The structure has been determined both by X-ray and neutron diffaraction,[67a] and later by electron diffraction in the gas phase.[67b] There are two polymorphs in the solid, α and β, differing in the packing. In α, the hydride was not located. β-$HMn(CO)_5$ contains dimers with an H···H distance of 2.292 Å, approaching each other in a non linear way, as seen in Fig. 5.

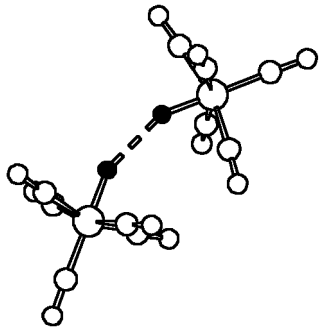


Fig. 5 The $HMn(CO)_5$ dimer, showing the short H···H distance.

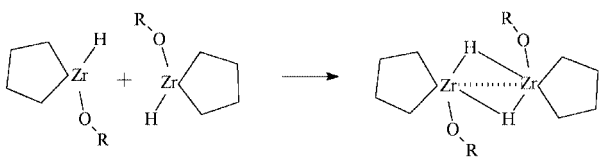
The monomer, which exhibits a distortion of the equatorial carbonyls toward the hydride, had been the object of an earlier theoretical study.[68] The approach geometry of the dimer was optimized using DFT calculations.[41] The H···H distance was found to be 2.008 Å, the Mn–H 1.559 Å and the angle between Mn–H bonds 147°. The experimental values are 2.292 Å, 1.601(16) Å, and 155.8°, respectively. The interaction energy was calculated as 0.4 kcal mol^{-1}. A qualitative EH analysis showed that there was some residual bonding character between the two hydrogens, as if an activated H_2 molecule was bridging the two manganese atoms. This same interaction has been suggested by other authors.[5d] A BSSE correction should be performed before giving a final answer to this problem.

The other example of M–H···H–M interaction is provided by the dimer $[(\eta^5\text{-}C_5H_5)_2Zr(\mu\text{-}H)(OSO_2CF_3)]_2\cdot 0.5THF$ with an H···H separation of 2.122 Å.[69] EH calculations indicated a repulsive interaction between the hydrogens. The monomer would be $[(\eta^5\text{-}C_5H_5)_2Zr(H)(OSO_2CF_3)]$, a 16-electron bent metallocene (Scheme 6).



Scheme 6

Two monomers interlock, allowing the hydride of each unit to engage in a bond with the other Zr atom. Although this is a longer bond, it is a covalent bond. The interaction can be termed agostic, as one Zr–H bond donates electrons into the empty orbital of the other Zr.[41]

C–H···H–C interactions in the methane dimer were studied at several levels of theory. MP2 provided the best method to study the approach of two methane molecules. All possible H···H contact arrangements were atractive, and the stabilization energy increases with the number of H···H contacts.[70]

Attractive interactions between identical hydrogen atoms can therefore exist in different contexts, either in organic molecules involving C–H bonds, or in organometallic complexes through M–H bonds.

Conclusions

Theoretical calculations of different types have been performed to study weak hydrogen bonds. Small attractive energies were determined in many cases, but owing to the size of the systems, BSSE corrections were not performed routinely, especially for organometallic systems. On the other hand, many studies rely on DFT (rather than MP2) calculations, which appear to lead to long distances and weak bonds, in spite of consideration of correlation effects. There is still much to be done to reproduce quantitatively these weak interactions: good models, high levels of theory and good basis sets are required. In ionic systems, the role of the counter ion is determining, therefore making calculations even larger and more difficult. The dihydrogen bond M–H···H–X in cationic complexes is one of such systems where the interaction appears to be dependent on the counter ion, as its introduction in the calculation leads to a better geometrical agreement with experimentally determined structures. The 'atom in molecules' approach appears to be very promising to study these weak bonds and to determine their origin, allowing one to distinguish between agostic and hydrogen bonds in some ambiguous situations. The quality of the results depends, however, on the level of theory used in calculating the electron density.

Acknowledgements

Dario Braga and Fabrizia Grepioni (Bologna, Italy) are thanked for having introduced me to the field of weak hydrogen bonds in organometallic compounds, as well as Emilio Tedesco who worked as a PhD student in Bologna and for some periods in Portugal. JNICT, FCT/CNR funding for this collaboration, extending over a couple of years, is acknowledged. I also want to thank, among other collaborators, Pedro E. M. Lopes who, as a PhD student, performed our first DFT calculations in some of the systems described, and whose enthusiasm and persistence led to the AIM pictures of M–H···H–X bonds, and Luis Veiros (IST, Portugal) for many discussions and unlimited help.

Changing cage structures through inter-ligand repulsions

Alasdair Graham, Stephanie Meier, Simon Parsons and Richard E. P. Winpenny*

Department of Chemistry, The University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ. E-mail: repw01@holyrood.ed.ac.uk

Received (in Cambridge, UK) 18th January 2000, Accepted 29th March 2000
Published on the Web 25th April 2000

The synthesis and crystal structure of decanuclear Co and nonanuclear Ni cages are reported: the cages feature carboxylate and pyridonate ligands and demonstrate that inter-ligand repulsions can lead to novel structures.

Considerable progress has been made in the rational design of supramolecular systems.[1] However, there is little element of design in the synthesis of large polynuclear cages. At present the best we can do is take note of similarities between structures, with the hope that the recognition of trends will lead to targeted synthesis in the future. A family of cages exists which are based on tricapped-trigonal prisms (ttps); such cages are known for the 3d metals chromium,[2] iron,[3] cobalt[4,5] and nickel.[5] As this polyhedron seems so favoured, it appeared the ideal candidate for examining whether the core could be disrupted by using ligands which are sterically demanding thus creating unusual cages. We have reported reactions with pivalate (trimethylacetate) which lead to nickel cages based on tetraicosahedral cores,[5] and here we report further studies which indicate that ligands which are either bigger, such as triphenylacetate, or where there are Coulombic inter-ligand repulsions, such as betaine ($O_2CCH_2NMe_3$), can cause further disruption. We feel this is a general method for synthesising novel cage structures.

Reaction of hydrated cobalt chloride (2.1 mmol) with $Na(O_2CCPh_3)$ (2.1 mmol) and Na(mhp) (4.2 mmol) (mhp = 6-methyl-2-pyridonate) in MeOH (50 ml) at room temperature for one day, followed by evaporation to dryness generates a purple paste. This was then extracted with ethyl acetate (10 ml), and the resulting purple solution allowed to stand at room temperature. Over four months the solution required repeated filtration before small red blocks of $[Co_{10}(OH)_6(mhp)_6(O_2CCPh_3)_6(Hmhp)_3(HCO_3)_3]$ **1** formed in *ca.* 4% yield.† X-Ray analysis‡ reveals a centred ttp which lies on a crystallographic C_3 axis (Fig. 1), however, the capping metal atoms are found on the edges of the prism rather than the faces, as in all previous ttp based structures.

At the centre of the cage is a Co(III) site [Co(2)], with all remaining cobalt atoms present in the +2 oxidation state. Both charge balance, and bond length considerations support this view. This site lies on crystallographic three- and two-fold axes, and the metal is surrounded by six μ_3-hydroxides which each bridge to one cobalt at a vertex of the prism, and one capping the edge. The cobalt sites capping the edges of the prism [Co(3) and symmetry equivalents (s.e.)] also lie on the crystallographic two-fold axes, while the cobalt sites [Co(1) and s.e.] at the vertices of the prism are in general positions. Triphenylacetate ligands bridge in a 1,3-fashion between vertex- and edge-capping cobalts, and the mhp ligands chelate to vertex-cobalt sites with the O atom forming a μ_2-bridge to a neighbouring vertex cobalt. Thus the upper- and lower-trigonal faces of the prism are covered by pyridonate ligands, while the sides of the prism have triphenylacetate groups attached.

This latter feature creates another oddity in the structure. The triphenylacetate groups do not pack sufficiently well to cover the surface of the cage, and two coordination sites on each face of the prism are left vacant. These are occupied by disordered Hmhp and HCO_3^- groups. While the assignment of a coordinated Hmhp fragment is uncontroversial, the assignment as coordinated hydrogencarbonate was only arrived at after careful consideration of the diffraction data. This indicates the presence of a trigonal fragment, and charge balance requires a monoanion in half these sites. Nitrate was not present in the reaction at any stage therefore it appears that atmospheric CO_2 has been incorporated into the structure. The requirement for formation of hydrogencarbonate may explain the long crystallisation times and low yield of this reaction. Preliminary results indicate formation of an equivalent cage with 6-chloro-2-pyridonate (chp). While refinement of this structure is incomplete owing to severe disorder problems involving lattice solvent, it is clear that the metal atoms form a tricapped trigonal prism with the same topology as **1**.

Reaction of CO_2 is also involved in the chemistry which leads to the cage $[Ni_9(CO_3)(OH)_6(chp)_3(Hchp)_3(O_2CCH_2NMe_3)_9Cl]^{6+}$ **2**. This is formed from the reaction of hydrated nickel chloride (1 mmol), Na(chp) (1 mmol) and $O_2CCH_2NMe_3$ (1 mmol) in MeOH (20 ml) followed by evaporation to dryness, and extraction of the green powder with EtOAc. Crystallisation takes a period of three months, whereupon green plates are found in 6% yield.† X-Ray analysis‡ shows the formation of the nonanuclear cage **2**, with a complicated set of anions including four $[Ni(chp)_3]^-$, a half-weight chloride and an anion consisting of chp hydrogen-bonded to Hchp.

The structure of **2** (Fig. 2), which lies on a crystallographic threefold axis, is dominated by two features. Firstly, the central carbonate ion which is μ_6-bridging, leading to a planar hexagon of Ni centres [Ni(1), Ni(2) and s.e.]. Secondly, the preference of the tertiary ammonium groups of the nine betaine ligands to lie as far apart as possible also supports a very open structure. Three of the betaines bridge alternate Ni···Ni vectors of the

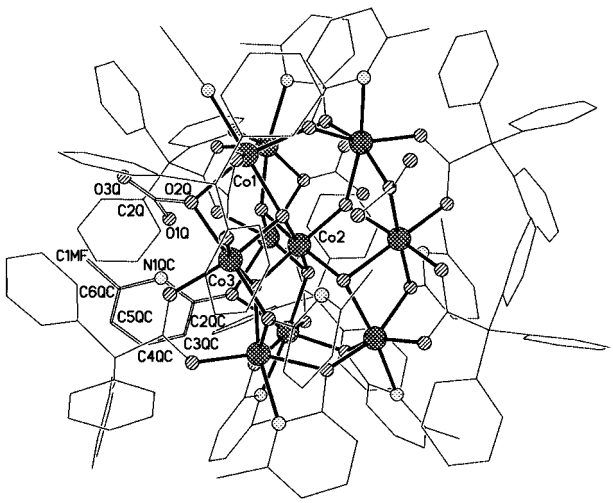

Fig. 1 The structure of **1** in the crystal, viewed perpendicular to the three-fold axis which passes through Co(2). One disordered hydrogencarbonate/Hmhp fragment is shown with open bonds. Fig. 3 The H-bonding between **2**, an $[Ni(chp)_3]^-$ unit and a chloride (shading as Fig. 2).

hexagon in a 1,3-fashion. Three further betaines attach three additional Ni atoms below the hexagon (Figs. 2 and 3), while the final three betaines bridge in a 1,1,3-manner, using one O-donor as a μ_2-bridge between Ni atoms within the hexagon, and the second O-donor to bind to one of the Ni atoms below the hexagon.

There are also six hydroxide anions in the cage. Three are μ_3-bridging [O(2) and s.e.], and are also involved in attachment of the three Ni atoms below the hexagonal plane. These three μ_3-OH groups are arranged so that the H atoms point towards the trigonal axis of the cage, and a chloride anion (Cl in Fig. 3) is attached at this point through three H-bonds (O···Cl 3.17 Å). The remaining three OH groups [O(1) and s.e.] are μ_2-bridging and lie above the hexagon, with the H atoms now involved in an interaction with a $[Ni(chp)_3]^-$ anion (Fig. 3). The three chp ligands chelate to the Ni atoms above the hexagon, while the three Hchp ligands act as μ_2-bridges through the O-donors, while forming H-bonds through the protonated N atom (O···N 2.63 Å). We have seen $[Ni(chp)_3]^-$ act as a 'tridentate' H bond acceptor in previous structures.[5]

As in **1**, one fragment, in this case carbonate, must have arisen from reaction of atmospheric CO_2 with the complicated metal–ligand 'soup' present during crystallisation. This, along with the low yields and long crystallisation times suggests that as syntheses these reactions are extremely poor. Conceptually something interesting is happening. By preventing formation of a strongly preferred structure—the ttp cage—we are inevitably going to lower yields and slow reaction times, but this process has also led to activation of small molecules, and, in the case of **2**, incorporation of a templating carbonate ligand which imposes structure on the metal array coordinated to it. This metal array in turn imposes a specific orientation on the zwitterionic betaine ligands, and probably brings them into a proximity they would rather avoid.

We thank the EPSRC for funding for a diffractometer and for a studentship (for A. G.), and the EU for an Erasmus Scholarship (for S. M.).

A combined intramolecular–intermolecular one-pot glycosylation approach for the synthesis of a branched trisaccharide

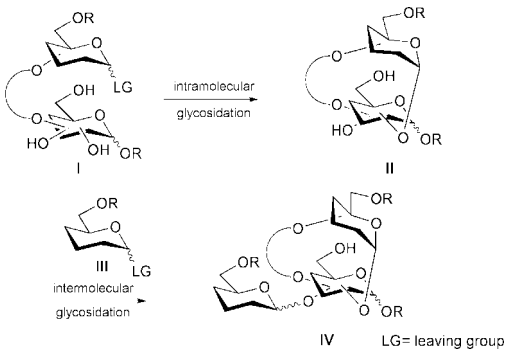
Received (in Cambridge, UK) 24th January 2000, Accepted 29th March 2000
Published on the Web 20th April 2000

Intramolecular and intermolecular glycosidic couplings have been combined in a one-pot protocol for the synthesis of a branched trimannan.

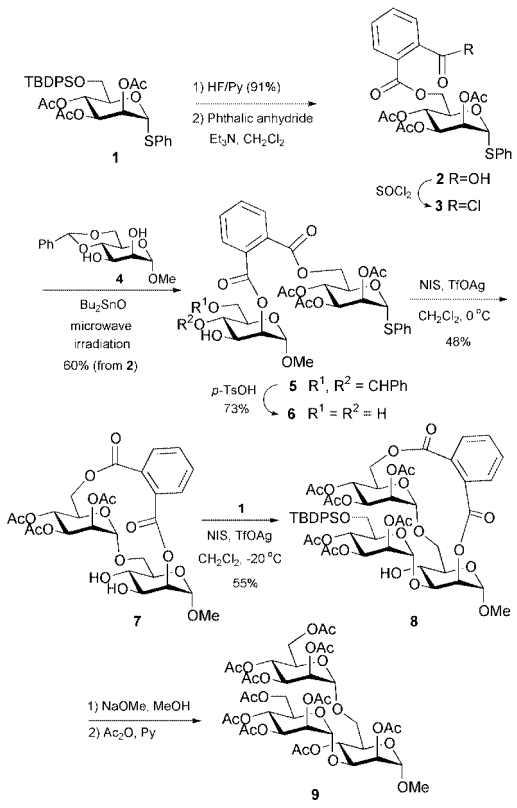
In the last few years strategies for stereocontrol in saccharide synthesis[1,2] based on intramolecular glycosidic couplings have been described,[3–15] and the rapid assembly of oligosaccharides has been addressed through a new chemoselective glycosylation strategy, the one-pot glycosylation,[16–20] which is based on reactivity differences between glycosyl donors.[21–23] Our group[8–10] has been interested in the development of an intramolecular approach for saccharide synthesis (*e.g.* **I→II**, Scheme 1), in which medium rings[8–15] rather than five-membered intermediates[3–7] are formed upon glycosidation. Here, we disclose some preliminary results of the extension of this approach for the synthesis of branched oligosaccharides by intermolecular glycosylation of an external glycosyl donor (*e.g.* **III**) onto the macrocyclic disaccharide (*e.g.* **II→IV**, Scheme 1). More interestingly, the sequence **I→IV** has also been carried out in one-pot operations, and applied to the preparation of the biologically important methyl 3,6-di-*O*-(α-D-mannopyranosyl)-α-D-mannopyranose **9**[24] (Scheme 2).

Phenyl thioglycoside, **1**, was readily transformed into the phthaloyl derivative **2**, and its carboxylic acid function activated on treatment with $SOCl_2$ to furnish **3**. Dialkylstannilen mediated coupling[25,26] of acid chloride **3** with diol **4** gave mixed diester **5** which upon removal of the benzylidene ring led to triol **6**. Glycosylation of **6** (CH_2Cl_2, NIS, TfOAg, 0 °C) led to disaccharide **7**.† Intermolecular glycosylation of glycosyl donor **1** with **7** (CH_2Cl_2, NIS, TfOAg, −20 °C) proceeded regioselectively at *O*-3‡ to give branched trimannose derivative **8**§ (55% yield),¶ which upon deprotection and re-acetylation afforded methyl 3,6-di-*O*-(α-D-mannopyranosyl)-α-D-mannopyranose derivative, **9**.§ A one-pot sequential glycosylation strategy was next examined in which cycloglycosylation of **6** (CH_2Cl_2, TfOAg 0.3 equiv., 0.018 M, −13 °C, 20 min) was followed by addition of **1** (1.1 equiv, −27 °C, 10 min) resulting in the formation of **8** (39% yield) [Scheme 3(a)]. Reaction of premixed **1** and **6** at lower temperature (CH_2Cl_2, TfOAg 0.3 equiv., 0.014 M, −40 °C, 40 min, then −30 °C, 40 min) resulted in the isolation of pseudotrisaccharide **10** (19%) along with unreacted **6** (30%) [(Scheme 3(b)], thus showing that intermolecular glycosylation had taken place prior to the intramolecular coupling.‖ On the hypothesis that the latter result could be a consequence of the difference in reactivities between donors **6** and **1**, owing to the influence of the electron withdrawing ester at *O*-6 in compound **6** when compared with the OTBDPS substituent at *O*-6 in **1**, as recently reported by Ley and coworkers in mannose systems,[22] we decided to examine the one-pot glycosylation of **6** and **11**. Accordingly, treatment of compounds **6** and **11** with TfOAg (CH_2Cl_2, 0.03 M, TfOAg, −8 °C, 10 min) resulted in the formation of a mixture of saccharides from which the branched saccharide **12** (30% yield) was the major observed isomer [Scheme 3(b)].** The structure for trisaccharide **12** was assigned by correlation with compound **13**§ which had been prepared from trimannan **8** [Scheme 3(c)].

In our opinion, several aspects of the synthetic scheme deserve further comment: (i) tethered cyclo-glycosylation of triol **6** takes place with complete regio- and stereo-control at *O*-6 to afford disaccharide **7**; (ii) intermolecular glycosylation of donor **1** and diol **7** occurs regioselectively at *O*-3 to yield trisaccharide **8**. The regio- and stereo-selectivies in the glycosyl couplings observed in this work (i, ii) are similar to those reported by Kaur and Hindsgaul in their relevant synthesis of a related trimannan by classical non-tethered methods with minimal hydroxy group protection.[24]

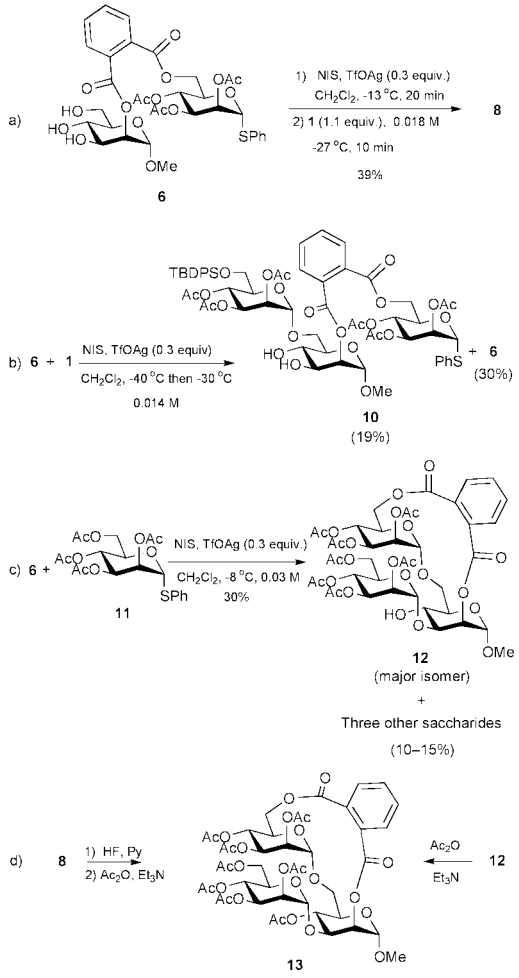


Scheme 1



Scheme 2

DOI: 10.1039/b000771o



Scheme 3

Another interesting aspect of our results, with implications in the success of the synthetic scheme, is the striking difference in behavior between glycosyl donors **1** and **11**, which is illustrated by the contrast between the results in Scheme 3(b) and 3(c). Thus, while one-pot glycosylation of **6** and **1** [Scheme 3(b)] resulted in the formation of pseudotrisaccharide **10** (with the intermolecular glycosylation taking place prior to the tethered cyclo-glycosylation), the one-pot glycosylation of **6** and **11** [Scheme 3(c)] yielded trisaccharide **12**, as the major isomer formed,** where the cyclo-glycosylation had preceded the intermolecular glycosyl coupling. The tuning of donor reactivity, by changes in the protecting group at *O*-6, in mannopyranosyl donors, **1** and **11**, is thus responsible for this behavior,[22] and, in our opinion, when coupled to further tuning between intra- and inter-molecular glycosidic coupling could open a new avenue for the preparation of branched saccharides and small saccharide libraries.

The procedures outlined here, although not yet optimized, serve to illustrate a novel concept for one-pot glycosylation which relies in the kinetic acceleration of an intramolecular *versus* an intermolecular glycosidic coupling rather than in large disparities between the reactivities of different glycosyl donors. The optimization of this protocol by changes in the concentration and/or nature of the glycosyl donors is currently under study.

Published on the Web 20th April 2000

A nickel and aluminium system including monodentate oxazoline ligands catalyzed the regioselective cyclotrimerization of enones and alkynes.

Since the pioneering work by Reppe,[1] the cyclotrimerization of unsaturated hydrocarbons using various transition-metal catalysts has represented a new method for preparing six-membered cyclic compounds.[2] In particular, intramolecular reactions have been used as an efficient synthetic approach.[3] In contrast, two- or three-component intermolecular cyclotrimerization has not yet been shown to be useful, since it is more difficult to control the chemo-, regio-, and stereo-selectivity. We recently reported a new cyclotrimerization of enones **1** and alkynes **2** by the synergistic effects of nickel and aluminium catalysts (L = PPh_3 in Scheme 1).[4] In this reaction, however, regioselection was dependent on the nature of **2** used (*vide infra*). We report here, a more efficient catalytic system for regioselective cyclotrimerization of **1** and **2**.

We investigated the effects of some ligands (L) on regioselection in the cyclotrimerization of 2-cyclopenten-1-one **1a** with (trimethylsilyl)acetylene **2a** by the $Ni(acac)_2$/L/Me_3Al/PhOH catalytic system (Table 1).‡ The cyclotrimerization

Scheme 1 *Reagents and conditions*: i, $Ni(acac)_2$ (10 mol%), L (20 mol%), Me_3Al (80 mol%), PnOH (200 mol%), THF, room temp.; ii, DBU, air, overnight.

† Electronic supplementary information (ESI) available: experimental and characterization data. See http://www.rsc.org/suppdata/cc/b0/b001151g/

adducts (regioisomeric mixture) obtained were treated with DBU in air to convert them to the corresponding aromatic compounds **3** and/or **4**, owing to the ease of regiochemical analysis by ^1H NMR spectroscopy. The reaction in the presence of PPh_3 or $P(C_6H_4Me\text{-}o)_3$ gave **4aa** as the sole product (runs 1 and 2), while the addition of other organophosphorus ligands or $AsPh_3$ failed (runs 3–6). In sharp contrast, the reaction using pyridine or **5** led to the selective synthesis of **3aa** (runs 7 and 8). Monodentate oxazoline ligands **6** strongly affected the regioselective cycloaddition (runs 9–14).[5,6] Most strikingly, when the reaction was carried out in the presence of **6d**–**f**, **3aa** was obtained in 95–96% selectivity (runs 12–14). Thus, ligands **6** in place of triarylphosphines caused *switching* of the regioselectivity in the cyclotrimerization. When a bidentate bis-oxazoline **7** (10 mol%) was used in the reaction,[7] the yield of **3aa** was low, even after 24 h (run 15).

The results of the catalytic cyclotrimerization of a variety of enones **1** and alkynes **2** are summarized in Table 2. In our initial efforts to achieve the regioselective cyclotrimerization of **1** and **2** using a $Ni(acac)_2$/PPh_3/Me_3Al/PhOH catalytic system, **2b** was reacted with **1a** to selectively give **4ab** (entry 1).[4] However, when the reaction was carried out in the presence of a Ni/Al catalytic system using **6e**, **3ab** was obtained predominantly (entry 2). A similar tendency was found in the reactions of **2a** with **1b** (entry 5 *vs*. 6). The product ratio of **8** and **9** derived from the reaction of **1c** with **2a** also depended on the nature of the employed ligands (L) (Scheme 2).[8] On the other hand, the reactions of alkyl-substituted alkynes such as **2c** and **2d** with **1** using **6e** gave a higher regioselection of **3** than those using PPh_3 (entries 3 *vs*. 4 and 7 *vs*. 8).

In summary, we have clarified the effects of monodentate oxazolines **6**, which have scarcely been used as ligands in catalytic reactions, in the Ni/Al-catalyzed cyclotrimerization of

‡ *Typical experimental procedure* (entry 2 in Table 2): to a solution of $Ni(acac)_2$ (27 mg, 0.1 mmol) and **6e** (0.1 mmol) in THF (4 mL) was added Me_3Al in 1.0 M hexane solution (0.8 mL) at 0 °C under N_2. After stirring for 5 min, PhOH (190 mg, 2.0 mmol) was added, and the mixture was stirred for 5 min. To the resulting dark red solution were added **1a** (1.0 mmol) and **2b** (2.0 mmol) at 0 °C. After the addition was completed, the whole mixture was stirred at room temperature for 2 h. DBU (350 mg, 2.3 mmol) was added to this reaction mixture in air, and this was again stirred at room temperature overnight. Aqueous HCl (0.2 M, 30 mL) was added, and stirring was continued for 10 min. The aqueous layer was extracted with diethyl ether. The combined organic layer was washed with $NaHCO_3$ and then with brine, dried over $MgSO_4$ for 30 min, filtered, and concentrated *in vacuo*. The residue was purified by column chromatography on silica gel (hexane–AcOEt, 14:1) to yield **3ab** (67%) as the sole product as a colorless oil; δ_H(400 MHz, $CDCl_3$, Me_4Si) 1.36 (s, 9 H, CH_3), 1.47 (s, 9 H, CH_3), 2.66 (t, *J* 6.1 Hz, 2 H, CH_2), 3.07 (t, *J* 6.1 Hz, 2 H, CH_2), 7.29 (s, 1 H, =CH), 7.40 (s, 1 H, =CH); δ_C(100 MHz, $CDCl_3$, Me_4Si) 25.85, 29.75, 31.12, 35.37, 35.95, 37.54 (CH_3, CH_2 and C), 121.20, 122.26, 132.30, 151.41, 157.81, 158.80 (Ar), 206.07 (CO); IR(neat) 1705 (ν_{CO}) cm^{-1}; GC–MS (EI, 70 eV) *m/z* (rel int, %) 244 (M^+, 55), 229 (100). A new phenol-based tetranucleating macrocycle, having two $N(amine)_2O_2$ and two $N(imine)_2O_2$ metal-binding sites in the macrocyclic framework, forms a $Cu^{II}_2Ni^{II}_2$ complex of a defective double-cubane structure.

Heteronuclear metal complexes are of current interest for their physicochemical properties and functions arising from an interplay of dissimilar metal ions in close proximity. In order to provide discrete heterodinuclear metal complexes, phenol-based dinucleating macrocyclic ligands containing two different metal-binding sites have been developed.[1] In contrast, less attention has been paid to multinucleating ligands that can provide mixed-metal complexes with higher nuclearities, though phenol-based macrocyclic ligands having four $N(amine)_2O_2$ or four $N(imine)_2O_2$ metal-binding sites have been reported.[2] We report here, a mixed-metal $Cu^{II}_2Ni^{II}_2$ complex derived from a phenol-based heteronucleating macrocycle R^{4-} that has two $N(amine)_2O_2$ and two $N(imine)_2O_2$ metal-binding sites (Fig. 1).

The macrocycle was obtained as a by-product in the cyclization of *N*,*N*′-dimethyl-*N*,*N*′-ethylenebis(2-aminomethyl-4-bromo-6-formylphenolato)copper(II)[3] ([Cu(L′)]) with ethylenediamine (Scheme 1). A solution of ethylenediamine (0.06 g, 1 mmol) in methanol (5 cm^3) was added dropwise to a hot solution of [Cu(L′)] (0.58 g, 1 mmol) in *N*,*N*-dimethylformamide (40 cm^3), and the mixture was stirred under reflux for 1 h to give a brown precipitate. This was shown to be a mixture of [Cu(L)] and $[Cu_2(R)]$ using FAB mass spectrometry; multiple signals centered at *m/z* 600 and 1200 are assigned to $\{Cu(L)\}^+$ and $\{Cu_2(R)\}^+$, respectively. The separation of the two products by fractional crystallization was difficult owing to the very low solubility of the two complexes in common solvents. The mixture of the complexes (0.20 g) was treated with $NiCl_2{\cdot}6H_2O$ (0.08 g) in methanol to form a $Cu^{II}Ni^{II}$ complex, $[CuNi(L)Cl_2]{\cdot}0.5H_2O$,[4] as dark green microcrystals (0.06 g). The solution remaining after removal of the CuNi complex was diffused with diethyl ether to obtain brown crystals, which were shown to be a mixed-metal tetranuclear $Cu^{II}_2Ni^{II}_2$ complex, $[Cu_2Ni_2(R)(Cl)_2]Cl_2{\cdot}H_2O$ (0.12 g).[5] FAB mass spectrometry showed signals centered at *m/z* 1422 and 1387 which are assigned to $\{Cu_2Ni_2(R)Cl_3\}^+$ and $\{Cu_2Ni_2(R)Cl_2\}^{2+}$, respectively.

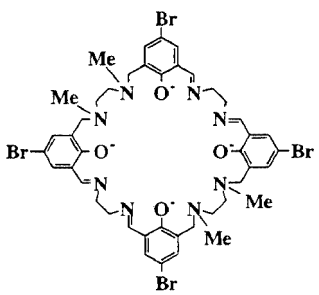

Fig. 1 Chemical structure of R^{4-}.

The structure of the $Cu^{II}_2Ni^{II}_2$ complex was determined by single-crystal X-ray crystallography[6] and an ORTEP view is shown in Fig. 2(a). The asymmetric unit consists of one half of the macrocycle $(R)^{4-}$, one Cu^{II} ion, one Ni^{II} ion and two chloride ions; the remaining two chloride ions and one water molecule are captured in the crystal lattice. Each Cu^{II} resides in an $N(imine)_2O_2$ site and each Ni^{II} resides in an $N(amine)_2O_2$ site. Thus, the Cu migrates from an aminic site to an iminic site in the cyclization process as previously observed in the conversion of [Cu(L′)] into [Cu(L)] and analogues.[7,8] The Cu adopts a square-pyramidal geometry with a chloride ion at the axial site. The Cu–Cl bond distance [2.563(4) Å] is elongated relative to the in-plane bond distances (1.93–1.98 Å) owing to the Jahn–Teller effect. The Ni in the $N(amine)_2O_2$ site has a near

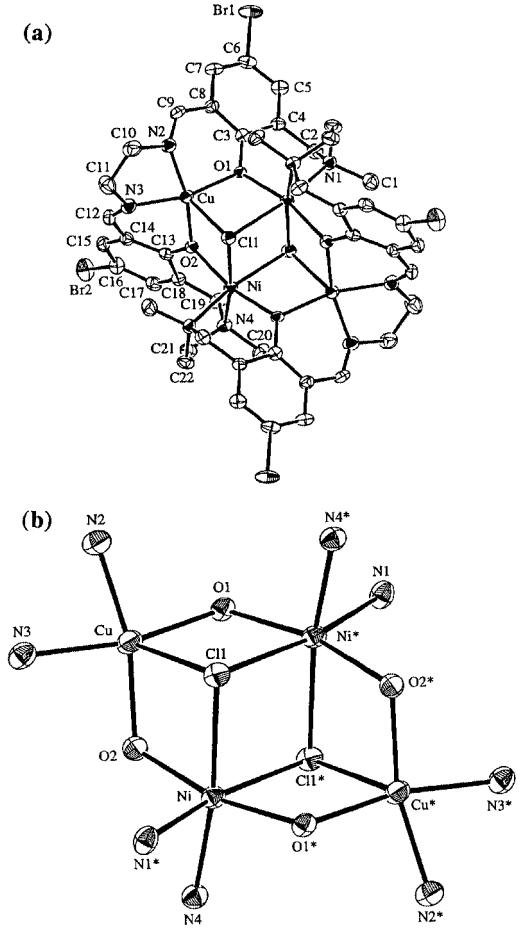

Fig. 2 (a) An ORTEP view of $[Cu_2Ni_2(R)Cl_2]Cl_2{\cdot}H_2O$ and (b) its core structure. Selected bond distances (Å) and angles (°): Cu–O(1) 1.972, Cu–O(2) 1.978(9), Cu–(2) 1.93(1), Cu–N(3) 1.93(1), Cu–Cl(1) 2.563(4), Ni(1)–O(1)* 2.068(9), Ni–O(2) 2.078(9), Ni–N(1)* 2.09(1), Ni–N(4) 2.08(1), Ni–Cl(1) 2.451(4), Ni–Cl(1)* 2.471(4), Cu··Ni 3.375(3), Cu··Ni* 3.366(3), Ni··Ni* 3.543(4); Cu–O(1)–Ni* 112.8(4), Cu–O(2)–Ni 112.6(5), Ni–Cl(1)–Ni* 92.0(1), Cl(1)–Cu–O(1) 81.1(3), Cl(1)–Cu–O(2) 80.6(3), Cl(1)–Ni–O(2) 81.5(3), Cl(1)–Ni–Cl(1)* 88.0(1), Cl(1)–Ni*–O(1) 81.6(3).

octahedral geometry together with two chloride ions [Cl(1) and Cl(1)*] in *cis* positions. The Cl(1) [Cl(1)*] is involved in a μ_3-bridge to Cu, Ni and Ni* (Cu*, Ni and Ni*), forming a defective double-cubane structure [Fig. 2(b)]. The Cu··Ni, Cu··Ni* and Ni··Ni* separations are 3.375(3), 3.366(3) and 3.543(3) Å, respectively. The asymmetric nitrogens N(1) and N(4) [N(1)* and N(4)*] have *R* and *S* configurations, respectively.

The electronic spectrum of the $Cu^{II}_2Ni^{II}_2$ complex in dmso shows an intense band at 354 nm (ε = 14000 M^{-1} cm^{-1} per molecule), a discernible shoulder near 440 nm and a weak band at 747 nm (ε = 380 M^{-1} cm^{-1}). The former intense band is assigned to the π–π* transition associated with the azomethine linkage[9] and the latter weak band to a d–d band due to Cu^{II}. A shoulder near 440 nm can be assigned to a charge-transfer band from Cl^- to Cu^{II}.[8] The d–d transition bands arising from Ni^{II} are not resolved.

The $Cu^{II}_2Ni^{II}_2$ complex has a magnetic moment of 4.94 μ_B (per Cu_2Ni_2) at room temperature, and the moment decreased with decreasing temperature to a plateau value of 3.3 μ_B around 30 K before sharply decreasing below 10 K. Evidently antiferromagnetic spin-exchange interaction operates within the tetanuclear core. Detailed magnetic analyses are under way.

A related macrocycle having four $N(amine)_2O_2$ metal-binding sites forms homotetranuclear Ni^{II} complexes of a rectangular or a non-symmetric core structure.[2] Mixed-metal trinuclear $Cu^{II}_2M^{II}$ (M = Zn or Mg) complexes have also been obtained which consist of a dinuclear $Cu^{II}M^{II}$ core and an isolated Cu^{II} center. The present macrocycle possessing alternating dissimilar $N(amine)_2O_2$ and $N(imine)_2O_2$ sites is a promising ligand for providing mixed-metal complexes of the $M^a_2M^b_2$ type; detailed studies for $Cu^{II}_2M^{II}_2$ complexes (M = Mn, Co, *etc*.) will be shortly reported.

Toward high nuclearity ruthenium complexes: creating new binding sites in metal complexes

K. Olof Johansson, John A. Lotoski, Christine C. Tong and Garry S. Hanan*

Department of Chemistry, University of Waterloo, ON, Canada N2L 3G1. E-mail: ghanan@uwaterloo.ca

Received (in Columbia, MO, USA) 20th December 1999, Accepted 31st March 2000
Published on the Web 20th April 2000

The nickel-catalyzed coupling of a ruthenium *ortho*-chloroimine complex creates a new vacant bidentate binding site suitable for generating higher nuclearity ruthenium complexes.

Current interest in ruthenium dendrimers stems from their light-harvesting properties.[1] Enhanced ruthenium content is vital to ascertain an increased probability of light absorption, however, there are inherent difficulties in synthesizing large metallodendrimers.[2] One synthetically powerfully approach (complexes-as-metals/complexes-as-ligands) calls for an iterative protection/deprotection sequence, which consumes both time and material.[3] Another drawback to most systems is the slow increase in metal ion content, which necessitates several more steps to obtain dendrimers with high (>20) metal ion content.[2a,b] In this work, we propose to create new binding sites in metal complexes in order to rapidly increase ion content in metallodendrimers. Previous work has demonstrated that ruthenium complexes containing anionic ligands may be homocoupled,[4] however, new chelating sites have never been created and utilized for further metal complexation.

In our synthetic approach, a ligand (Fig. 1, **a**) containing a bidentate binding site and an *ortho*-chloroimine site forms a ruthenium complex by selectively complexing a metal ion with octahedral coordination geometry in the free bidentate site of the ligand (Fig. 1, **b**). The *ortho*-chloroimine site in **b** is then coupled to create a new bidentate binding site (Fig. 1, **c**), which may in turn bind to another metal ion (Fig. 1, **d**), form a 'complex-metal' [Fig. 1, **e**; *cf.*, $Ru(bpy)_2Cl_2$], or give a closed dendrimer (Fig. 1, **f**). Repeating the steps that lead to **b** and **c** on the 'complex-metal' **e** will afford a new 'complex-ligand', capable of forming large metallodendrimers. The total metal ion content will grow more rapidly than with current approaches.[3] Although many stereoisomers may exist, the differences in their electrochemical and spectroscopic properties are not expected to be great.[5]

Our first goal was to outline the conditions for the nickel-catalyzed coupling reaction. Allowing 4-chloro-2,2′-bipyridine (Clbpy) to react with $Ru(bpy)_2Cl_2{\cdot}2H_2O$ gave monometallic complex **1a** in 92% yield.† Mixing 2 equivalents of **1a** in DMF with an *in situ* generated nickel catalyst[6] gave dimetallic complex **2a** in 57% yield,† in which the newly formed 2,2′:4′,4″:2″,2‴-quaterpyridine (qpy) ligand bridges two metal centres.[7]

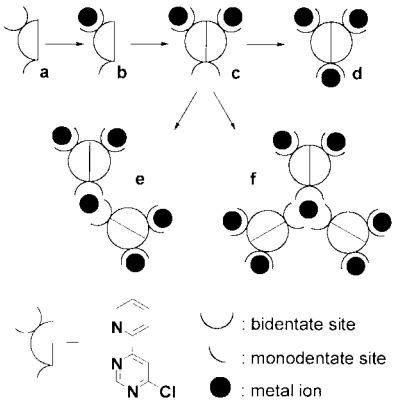

Fig. 1 Ligand **a** [*e.g.* 4-chloro-6-(2′-pyridyl)pyrimidine] contains a bidentate and a monodentate binding site, and reacts with a metal ion to give complex **b**. Homocoupling complex **b** creates a new bidentate binding site in **c**, which may then form a trinuclear complex **d**, a 'complex-metal' **e** (*cf.*, $Ru(bpy)_2Cl_2$), or a closed dendrimer **f**.

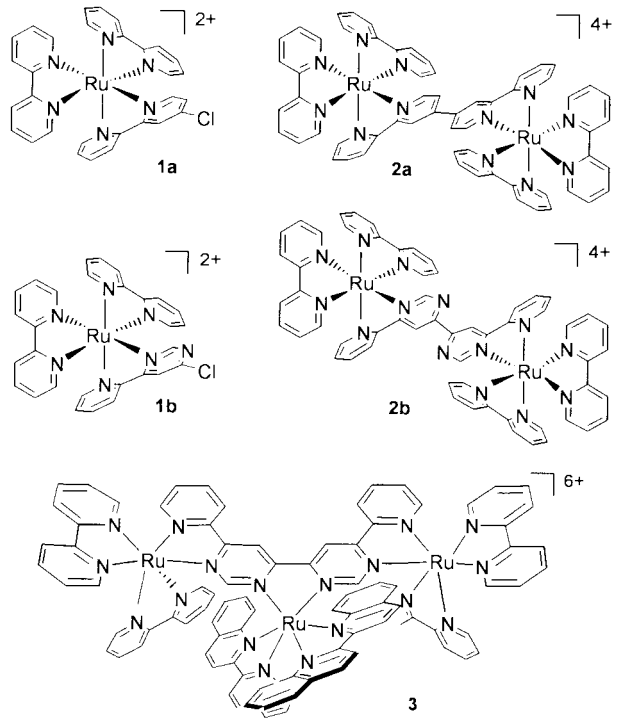

The absorption spectra (acetonitrile solution) of **1a** and **2a** are dominated by ligand-centred (LC) transitions in the UV region and metal-to-ligand charge-transfer (CT) transitions in the visible region.‡ A small red shift is noted in the metal-to-ligand CT band in **2a** (465 nm) compared to **1a** (448 nm) owing to the greater extent of electron delocalization in the qpy bridging (BL) compared to bpy. However, little electronic interaction between the metal centres is revealed by cyclic voltammetry (acetonitrile solution *vs.* SCE). Two chemically reversible coincidental one-electron oxidations are centred at +1.24 V. A reversible one-electron reduction at −1.12 V is followed by three further reductions at −1.42, −1.56 and −1.65 V.

With the proper reaction conditions now available, our next target ligand was 4-chloro-6-(2′-pyridyl)pyrimidine (ClPpy), as metal complexation is favoured at the bidentate pyridylpyrimidine site rather than the *ortho*-chloropyrimidine site. Thus, ClPpy was allowed to react with $Ru(bpy)_2Cl_2{\cdot}2H_2O$ in ethanol–water to afford red monometallic complex **1b** in 79% yield.† It is important to note that no protection/deprotection sequence was required; the bidentate pyridylpyrimidine moiety is a better binding site than the monodentate, sterically encumbered *ortho*-chloropyrimidine site.

DOI: 10.1039/a910257o

In complex **1b**, the Ru-to-BL CT band (480 nm) is lower in energy than the Ru-to-bpy CT band (433 nm), as expected based on earlier work with pyridylpyrimidines.[8] The higher energy UV region is dominated by LC π–π* transitions.[9] The first one-electron reduction is ascribed to the pyridylpyrimidine ligand (−0.92 V) and is followed by coincidental reductions of the two bpy units (−1.52 V).[8] The metal-based oxidation (+1.38 V) is at a slightly higher potential than that of $Ru(bpy)_3$ (+1.26 V), which is consistent with stabilized metal d_π orbitals owing to the presence of the electron deficient pyridylpyrimidine BL.

The addition of **1b** to the Ni-catalyst in DMF[6] gave the purple binuclear complex **2b** in 80% yield.†‡§ Thus, the sterically hindered *ortho*-chloropyrimidine site in **1b** has undergone C–C coupling to give a bidentate diimine site. The Ru-to-BL CT band undergoes a red shift to 554 nm as well as a slight blue shift to 431 nm for the Ru-to-bpy CT band. The latter is expected owing to the stabilization of the metal orbital due to better π-backbonding with the extended BL. The former usually occurs only on binucleation of the same heterocycle.[8] In this case, the electronic conjugation between the two heterocycles is enhanced owing to the *trans*-conformation of the pyridimine nitrogen lone pairs (N_{1p}), which minimize N_{1p}–N_{1p} and C–H···C–H repulsion, leading to a co-planar arrangement.[10]

The first two reductions (−0.57 and −0.99 V) are ascribed to the BL as the reduction of the bridging qpy in **2a** occurs at −1.12 V. Subsequent reductions at bpy (−1.49 and −1.78 V) are in accord with reductions of bpy in diruthenium complexes of diazine heterocycles.[11] The metal-centred oxidations occur at +1.42 V, with an anodic and cathodic separation of 120 mV, indicative of metal–metal interaction rather than irreversibility.[12]

The effectiveness of our approach was confirmed by the reaction of $Ru(biq)_2Cl_2$ (biq = 2,2′-biquinoline) with **2b**, which gave the green trinuclear complex **3** in 55% yield.† The effect of binding the $Ru(biq)_2$ unit into the central chelating site was threefold: it introduced biq LC bands at 271, 360 and 380 nm, a Ru-to-biq CT band at 567 nm and caused a red shift in the Ru-to-BL CT out to 616 nm. These effects are similar to those reported for the polynucleation of Ru(II)(2,3-dipyridylpyrazine)$_3$ with three $Ru(biq)_2$ units.[13] The oxidation potential is as expected for a linear trimetallic system; the external Ru centres oxidize first (+1.58 V), followed by the central Ru centre. However, the latter oxidation occurs outside of the solvent potential window (> +2.00 V) owing to the proximity of two Ru(III) ions and the stabilization of the metal d_π orbital by enhanced back-donation to biq.

The first reduction (+0.04 V) is ascribed to the bridging ligand and is induced by the electron-accepting $Ru(biq)_2$ unit. The next BL reduction (−0.38 V) occurs at a more positive value than the first reduction potential of **2b**. The next two one-electron reductions (−0.83 and −1.20 V) occur on the $Ru(biq)_2$ unit as biq has a lower reduction potential than bpy.[9] The next two waves are two simultaneous one-electron reductions of the external bpy units at −1.50 and −1.80 V. They are fully reversible and follow what one would expect in a heteroligand complex.[9]

Interestingly, the separation between the first and second reduction potential of the bridging ligand in both **2b** and **3** is approximately the same. This suggests that the delocalized BL orbital stays approximately the same 'size' in both **2b** and **3**. Electron delocalisation appears to be as complete with or without a metal ion, restricting rotation about the pyrimidine–pyrimidine C–C bond.

In conclusion, we have introduced a powerful new method for creating new binding sites for metal ions in polynuclear complexes. This methodology is extendable to other types of binding sites and metal ions. We are currently investigating the formation of dendrimeric complexes by using **2b** and analogues as 'complex-ligands' as well as the photophysical properties of these complexes.

We thank the Natural Sciences and Engineering Research Council (Canada), the Research Corporation (Tucson, Arizona), and the University of Waterloo for financial support.

Singlet oxygenation of 4-(4-*tert*-butyl-3,3-dimethyl-2,3-dihydrofuran-5-yl)-2-pyridone: non-stereospecific 1,4-addition of singlet oxygen to a 1,3-diene system and thermal rearrangement of the resulting 1,4-endoperoxides to stable 1,2-dioxetanes

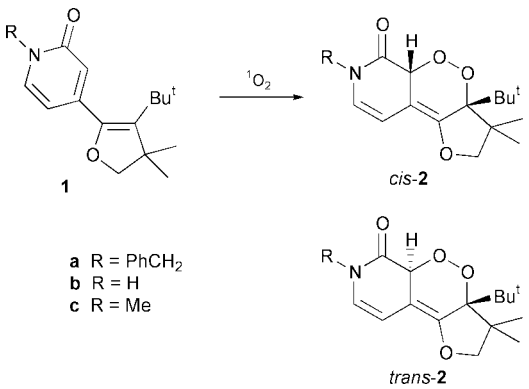
Singlet oxygen adds easily to a 1,3-diene 1, whose *E–Z* double bond isomerization can not take place, to give a mixture of stereoisomeric 1,4-endoperoxides 2 which rearranges into a thermally stable 1,2-dioxetane 5 selectively on heating in benzene.

Diels–Alder addition of singlet oxygen to certain 1,3-dienes has been reported to give 1,4-endoperoxides with lack of stereospecificity, for which two mechanisms have been proposed. The first is a mechanism where *E–Z* double bond isomerization of 1,3-diene proceeds under the reaction conditions and is followed by a concerted Diels–Alder addition of singlet oxygen.[1] The second is a stepwise addition of singlet oxygen, including participation of zwitterions, which causes isomerization of the initial 1,3-diene unit prior to the intramolecular cyclization.[2] Although these two are crucially different from each other (concerted or stepwise process), both mechanisms include, in common, isomerization of the initial double bond in the substrate followed by cyclization giving the endoperoxide. However, there formally remain other pathway(s) for Diels–Alder addition of singlet oxygen leading to a mixture of stereoisomeric endoperoxides without any isomerization of the initial double bond in a substrate; especially for the stepwise mechanism, if the intramolecular attack of a peroxidic intermediate such as peroxirane and zwitterion occurs onto both π-faces of the remaining double bond, the Diels–Alder addition would give a mixture of stereoisomeric endoperoxides (the third mechanism). We report here an example of non-stereospecific 1,4-addition of singlet oxygen for which the third mechanism would be the most advantageous. In addition, we report a unique rearrangement of the resulting 1,4-endoperoxides which occurs simply on heating without any catalyst to yield thermally stable 1,2-dioxetanes exclusively.

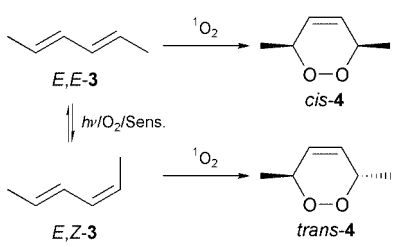
In the course of our investigation on the design of highly efficient chemiluminescent substrates, we attempted to examine the singlet oxygenation of *N*-benzyl-4-(4-*tert*-butyl-3,3-dimethyl-2,3-dihydrofuran-5-yl)-2-pyridone **1a**. When a pyridone **1a** (100 mg) was irradiated together with a catalytic amount of tetraphenylporphin (TPP) in dichloromethane (5 mL) with a 940 W Na-lamp at −78 °C, singlet oxygenation proceeded smoothly (1 h) to give a 65 : 35 mixture of stereoisomeric 1,4-endoperoxides **2a** exclusively (Scheme 1).† The mixture was separated into *cis*-**2a** (major isomer, colorless granules, mp 127.0–128.0 °C) and *trans*-**2a** (minor isomer, colorless oil) by silica gel chromatography. These two endoperoxides were characterized by ^{1}H and ^{13}C NMR, ^{1}H–^{1}H COSY, ^{13}C–^{1}H COSY, NOE, IR and mass spectral analysis.‡ It should be noted that little isomerization between *cis*- and *trans*-**2a** was observed under the reaction conditions and even at higher temperature. The parent pyridone **1b** and *N*-methyl analog **1c** were similarly oxygenated to give the corresponding mixture of isomeric endoperoxides **2b** and **2c**, respectively, though these mixtures could not be separated into pure isomers. These results provide the first example wherein singlet oxygenation of a 1,3-diene gives a mixture of stereoisomeric 1,4-endoperoxides though neither of the carbon–carbon double bonds of the diene system can undergo *E–Z* isomerization.

The rather simple 1,3-diene, (*E,E*)-hexa-2,4-diene (*E,E*-**3**) undergoes stereospecific 1,4-addition of singlet oxygen to give a *cis*-endoperoxide (*cis*-**4**), whereas singlet oxygenation of (*E,Z*)-hexa-2,4-diene (*E,Z*-**3**) affords a mixture of *cis*-**4** (main product) and its *trans*-isomer (*trans*-**4**).[1,2] Gollnick has suggested that the (*E,Z*)-diene isomerizes to the (*E,E*)-isomer prior to the concerted 1,4-addition of singlet oxygen as shown in Scheme 2,[1] and his suggestion has very recently been supported by Motoyoshiya *et al.* who have observed a similar phenomenon for the sensitized photooxygenation of 1-arylpenta-1,3-dienes.[3] On the other hand, O'Shea and Foote have suggested that the non-stereospecific endoperoxide formation from *E,Z*-**3** is most likely rationalized by the formation of a zwitterion which causes the isomerization leading to the *cis*-endoperoxide (*cis*-**4**) as shown in Scheme 3.[2] However, neither mechanism would apply to the present oxygenation of **1** giving **2** without any revision, since no *E-Z* double bond isomerization and only s-*cis*–s-*trans* isomerization can occur for the furanylpyridones **1**.

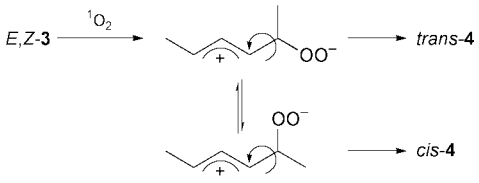
The concerted Diels–Alder reaction of singlet oxygen with **1** would give only *cis*-**2** so that this mechanism should be ruled out for the reaction giving *trans*-**2**, though *trans*-**2** could be formally produced by an antarafacial attack of singlet oxygen. Thus, a stepwise mechanism should be considered to rationalize



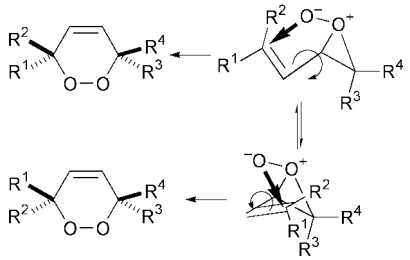
Scheme 1



Scheme 2



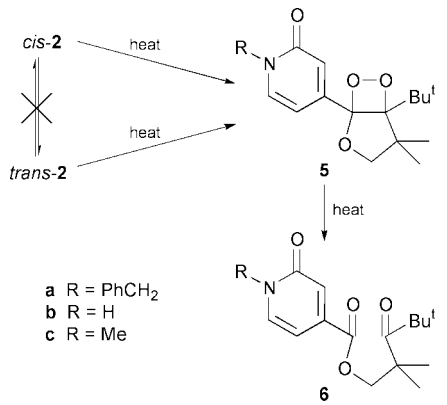
Scheme 3



Scheme 4

the present non-stereospecific 1,4-addition of singlet oxygen. Since no *E*–*Z* isomerization of the double bond in pyridone and dihydrofuran rings can occur for **1**, the isomerization of an intermediary zwitterion as in Scheme 3 can not proceed. The most likely explanation is that the initially formed peroxirane or zwitterion attacks the remaining double bond of the starting 1,3-diene from both π-faces. This process should be operable when two ethylene units of the 1,3-diene lie far from apart in the same plane as illustrated in Scheme 4 in which a peroxirane intermediate is adopted for convenience. Such structure of a 1,3-diene system is most likely feasible for **1** because of steric repulsion between the pyridone ring and a *tert*-butyl group in the dihydrofuran ring.§ Although singlet oxygen attacks possibly in the first step to a double bond of the pyridone and/or the double bond of dihydrofuran for **1**, the initial addition of singlet oxygen to the former may be more likely since the addition to the latter may lead more or less to a dioxetane as in the case of 4-*tert*-butyl-3,3-dimethyl-2,3-dihydrofurans bearing an aryl[4] or a styryl group[5] at the 5-position.

Although endoperoxides *cis* and *trans*-**2a** were not isomerized to each other, both endoperoxides changed gradually into a dioxetane **5a** even at room temperature. On heating in hot benzene, **2a** was transformed selectively into **5a** (colorless needles, mp 114.0–115.0 °C)¶ which was stable enough for handling at room temperature though it decomposed into a ketoester **6a** in hot toluene (Scheme 5). It should be noted that the thermolysis of **5a** (90 °C, toluene) gave light (λ_{max} = 411 nm) whose spectrum was in good agreement with the fluorescence spectrum of **6a**. Both reaction rates for isomerization of endoperoxide **2a** to 1,2-dioxetane **5a** and for decomposition of dioxetane **5a** to ketoester **6a** followed first-order kinetics. Thus, these reaction rates were measured in toluene-d_8 at various temperatures by ^{1}H NMR spectroscopy, and their activation



Scheme 5

Table 1 Thermal rearrangement of 1,4-endoperoxides **2a** to 1,2-dioxetanes **5a** and thermal decomposition of **5a** to ketoesters **6a**[ab]

Peroxide	$\Delta H^{\ddagger}$/kcal mol^{-1}	$\Delta S^{\ddagger}$/cal K^{-1} mol^{-1}	$\Delta G^{\ddagger}$/kcal mol^{-1}	$t_{1/2}$ (25 °C)/yr
cis-**2a**	29.8	13.9	25.7	0.07
trans-**2a**	29.1	11.9	25.5	0.05
5a	26.2	−9.5	29.1	19.6

[a] Rearrangement of **2a** to **5a** was carried out in toluene-d_8 at 40–60 °C, whereas decomposition of **5a** to **6a** was performed in toluene-d_8 at 90–110 °C. [b] For all the Arrhenius plots, $r > 0.999$.

parameters were estimated from Arrhenius plots as summarized in Table 1, which shows that dioxetanes **5a** are far more stable than endoperoxides **2a**. The other endoperoxides **2b** and **2c** rearranged thermally also into the corresponding dioxetanes **5b** and **5c**, whose thermolysis gave ketoesters **6b** and **6c**, respectively. Free energies of activation ($\Delta G^{\ddagger}$/kcal mol^{-1}) for these peroxides were also estimated as follows; **2b**: 24.3–24.4, **2c**: 24.4–24.7, **5b**: 27.1 and **5c**: 28.4.

Various 1,4-endoperoxides have been known to undergo acid-catalyzed decomposition to carbonyl fragments, presumably through 1,2-dioxetanes, whose spectroscopic identification and/or isolation has not been achieved in most cases. Schaap *et al*. have reported a successful spectroscopic identification of a dioxetane formed by the rearrangement of endoperoxide, and suggested that the relatively unstable dioxetane as a chemiluminescent substrate can be 'stored' as a precursor endoperoxide and generated when needed.[6] In contrast, the present dioxetanes **5** are far more stable than endoperoxides **2** so that they can be stored as such rather than be regarded as precursors.

Notes and references

† Similar singlet oxygenation of **1a** at 0 °C gave a 57 : 43 mixture of *cis* and *trans* isomers of **2a**.

A new approach for the synthesis of conjugated/non-conjugated poly(phenylene vinylene)–polyacrylamide copolymers

Ruifeng Zhang,* Guoqiang Zhang and Jiacong Shen

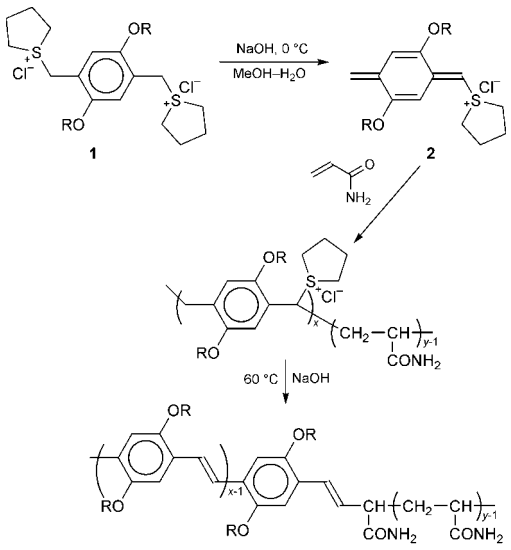
Key Lab of Supramolecular Structure and Spectroscopy, Department of Chemistry, Jilin University, Changchun 130023, P.R. China. E-mail: zhangrf@yahoo.com

Received (in Cambridge, UK) 2nd February 2000, Accepted 13th March 2000
Published on the Web 26th April 2000

A new type of poly(phenylene vinylene)–polyacrylamide copolymer has been synthesized by a modified sulfonium precursor route; the obtained copolymer is composed of hydrophobic PPV conjugated blocks and hydrophilic polyacrylamide segments; these two parts show strong phase separation and produce a multiphase structure in the solid state.

Some of the most promising candidates for the active layer in organic light-emitting diodes (LEDs) are polymers derived from poly(phenylene vinylene) (PPV).[1–5] Fully conjugated PPV derivatives often show low luminescent efficiencies owing to non-radiative decay resulting from the movement of excitons to quenching centers.[6,7] Exciton confinement can be achieved by preparing a polymer with low HOMO–LUMO gap energy blocks in between high ones. Therefore, attention has been paid to synthesizing conjugated/non-conjugated PPV derivatives. One way to realize this structure is to interrupt the conjugation of the polymer at short intervals with non-conjugated segments by sample modification during PPV synthesis.[8,9] Another way to obtain a polymer with well defined fluorescent units makes use of a Wittig condensation of an arylene bisphosphonium salt with a spacer containing bis(benzaldehyde).[10–12]

Recently, we found a new method for the synthesis of such copolymers. Our method originated from investigating the mechanism in the sulfonium precursor route (SPR) to PPV derivatives established by Wessling and Zimmerman.[13,14] We observed what happened when water-soluble monomer acrylamide (Am) was added in the polymerization of bis(sulfonium) compound **1** in an aqueous system, and found that copolymerization occurred in which the *p*-quinodimethane intermediate **2** might act as both monomer and free radical initiator. Scheme 1 outlines the process of the formation of PPV/polyacrylamide copolymers. Obviously, this copolymerization strongly supports a free radical mechanism for SPR. In fact, the copolymerization proceeds so well that the color of the product can be tuned by the feed ratio of two monomers. In other words, the conjugated length of the PPV blocks is shortened by the incorporation of polyacrylamide (PAm) segments in between. Furthermore, this kind of copolymerization also offers an opportunity to prepare amphiphilic polymers which may be very useful for self-assembly into ultrathin films and nanocomposites.



Scheme 1

The copolymers were synthesized through the following procedure: under vigorous stirring and nitrogen atmosphere, a solution of bis(sulfonium) salt **1** (1.04 g, 2 mmol) in MeOH (10 ml) was added dropwise to a solution of acrylamide and NaOH (0.08 g, 2 mmol) in 25 ml of water. The temperature was kept at 0 °C for 1 h. Then additional aqueous NaOH (0.5 M, 10 ml) was added, and the reaction mixture was heated to 60 °C for another hour. An orange precipitate was obtained and filtered off. After washing well with water and MeOH, the product was dried *in vacuo*. When the amount of acrylamide exceeded 20 g the produced copolymer was water-soluble. The polymer was purified by dialyzing against water for three days (3×1000 ml) to remove unreacted monomers and some acrylamide homopolymer (polymers with molecular weight of less than 12 000 were removed). The final solution was poured into a large amount of MeOH, and a pale yellow polymer was obtained and washed with refluxing MeOH and then dried *in vacuo*. Except for the water-soluble copolymer, the other polymers show poor solubility in solvents such as THF and DMF, probably owing to hydrogen bonding between amide groups. However, they are partially soluble in $CHCl_3$, which allows the photoluminescence (PL) spectra to be obtained. Such a low solubility, however, is not sufficient for GPC measurements. Therefore we focused our attention on the viscosity of the water-soluble copolymer at various concentrations and the GPC result obtained in aqueous solution. The composition of the copolymers were calculated according to the amount of nitrogen obtained by elemental analysis.

Table 1 summarizes the results of copolymerizations for different concentrations of acrylamide. With an increase in the amount of acrylamide in the reaction system, the weight percentage of PAm segments in the copolymers increase, while the product changes from red to pale yellow, and the PL peak shifts from 550 nm (yellow) to 509 nm (green). All these data showed that the conjugation length of the PPV block became shorter as more Am units were inserted into the polymer chain. However, even when a large excess of acrylamide was added to the reaction system, we failed to produce a copolymer with sufficiently short conjugated lengths of PPV blocks to produce blue luminescence. It seems that the present copolymerization is quite different from those in traditional free radical copolymerizations for vinyl monomers. The *p*-quinodimethane intermediate **2** shows a strong tendency to undergo homopolymerization even under very dilute concentrations and in the presence of a large excess of Am. The FTIR spectra of all the prepared copolymers support the structure of copolymer suggested. Peaks characteristic of PPV blocks such as at 1203 cm^{-1} (C–O stretching), 2961 cm^{-1} (C–H stretching of CH_3) and 970 cm^{-1} (C–H bending of *trans* vinylene) can be clearly

DOI: 10.1039/b000926l

Table 1 Results of copolymerizations using various amounts of acrylamide

Sample	Acrylamide/g	Weight of polymer obtained/g	Colour	PAm segemnt (wt%)	Solubility (in $CHCl_3$)	λ_{max} (PL) ($CHCl_3$)/nm
1	0	0.76	Red	0	Soluble	550 (λ_{ex} = 420 nm)
2	5	1.05	Red–orange	38	Slightly soluble	542 (λ_{ex} = 420 nm)
3	10	1.58	Orange	47	Slightly soluble	536 (λ_{ex} = 420 nm)
4	15	2.46	Yellow	64	Slightly soluble	524 (λ_{ex} = 420 nm)
5	20	3.85	Pale yellow	82	Water-soluble	509 (H_2O) (λ_{ex} = 400 nm)

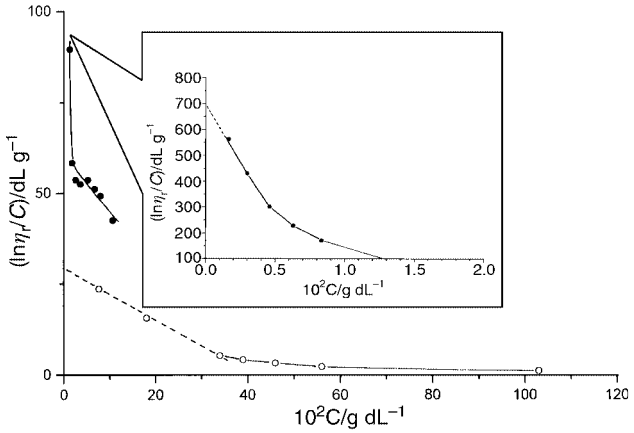


Fig. 1 The dependence of $\ln\eta_r/C$ on the concentration of polyacrylamide (○) or copolymer (●) in water at 30 °C.

observed. Signals from PAm segments including at 3400 cm^{-1} (wide band, N–H stretching of amide) and 1669 cm^{-1} (C=O stretching of amide) also appear in the spectra.

Fig. 1 shows the viscosity of the water-soluble copolymer and pure PAm measured at different concentrations in water at 30 °C; η_r is the relative viscosity using water as a reference. The insert is an enlarged plot for the copolymer at very low concentration. For both polymers, the value of $\ln\eta_r/C$ increases sharply as the concentration of polymer approaches zero. Obviously, the viscosity of the copolymer is higher than that of PAm at any concentration. By extrapolation of $\ln\eta_r/C$ to C = 0, it is seen that the intrinsic viscosity of the copolymer ($[\eta]$ = 700 dL g^{-1}) is 24 times as high as that of PAm ($[\eta]$ = 28 dL g^{-1}). According to the formula $[\eta] = KM_\eta^\alpha$ ($K = 6.31 \times 10^{-3}$, α = 0.80, T = 30 °C),[15] M_η of PAm is calculated as 3.46×10^4. Owing to the absence of a relationship between M_η and $[\eta]$, an exact value of M_η of the copolymer could not be obtained. We also studied M_w of the two polymers by GPC using sulfonated polystyrene as a standard in aqueous medium. The result showed that M_w of PAm and the copolymer were 4.12×10^4 and 9.67×10^4, respectively, with a PDI of 2.13 and 2.74, respectively. If we calculate the M_η of the copolymer using the relation KM_η^α, the result is 2×10^6, much higher than M_w of the copolymer measured by GPC. The above result confirmed that a high molecular weight copolymer was produced by copolymerization. The extraordinarily high viscosity of the copolymer may well be due to the presence of rod-like and alkyl chain-bearing PPV blocks which can aggregate with each other and form hydrophobic domains in aqueous medium. These domains are dispersed in solution and act as solid particles, or on the other hand, as physically cross-linking joints which link PAm segments to form a network and therefore considerably lower the mobility of the polymer solution. A multiphase structure in the solid state was revealed by TEM observation after hydrolysis of the copolymer in KOH solution and then treating with $BaCl_2$. Barium ions were introduced to increase the contrast of the two microphases in electron transmission. Fig. 2 is a TEM photograph of the Ba^{2+}-modified copolymer which can be denoted as poly[2,5-bis(heptyloxy)phenylene vinylene-*co*-Ba(acrylate)$_2$]. The light regions correspond to the hydrophobic domains occupied by PPV blocks, while the dark regions correspond to the hydrophilic phase mainly composed of poly[Ba(acrylate)$_2$] segments. The size of these domains is in the range of several nanometers. Since the conjugated and non-conjugated blocks are randomly arranged in the copolymer the formed multiphase structure is disordered. The above two results indicate that the copolymer has a rod/coil structure in which the two different units are not statistically distributed along the main chain.

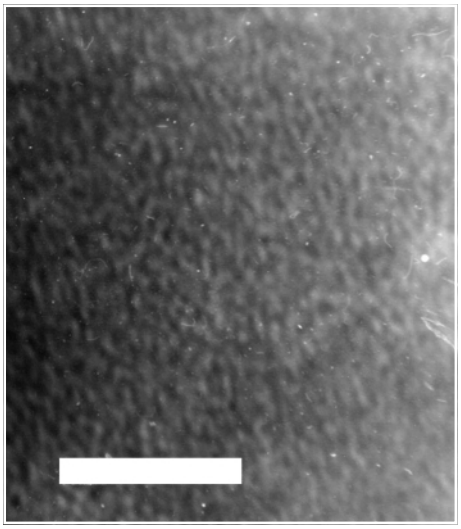

Fig. 2 TEM image of poly[2,5-bis(heptyloxy)phenylene vinylene-*co*-Ba(acrylate)$_2$]. The white bar corresponds to 20 nm.

1,1-Dimethylhydrazidogallane and a gallium hydrazide with two Ga_2N_2 rings bridged by two $NNMe_2$ ligands

Bing Luo and Wayne L. Gladfelter*

Volatile, thermally robust 1,1-dimethylhydrazidogallane, $[H_2GaN(H)NMe_2]_2$ 1 has been synthesized from the reaction of $H_3Ga(NMe_3)$ with H_2NNMe_2, whereas reaction of compound 1 with an excess of H_2NNMe_2 at elevated temperature afforded a gallium hydrazide derivative, $Ga_4[N(H)NMe_2]_8(NNMe_2)_2$ 2, which possessed a novel structure of two Ga_2N_2 rings bridged by $NNMe_2$ groups.

Gallium hydride derivatives with direct Ga–N bonds are attractive single-source precursors to gallium nitride. Two main advantages of these compounds over conventional precursors, such as trimethylgallium and triethylgallium, which are extensively used in MOCVD processes, are minimization of carbon contamination and reduction of deposition temperatures. We[1,2] and others[3,4] have reported that compounds with the above features, $(H_2GaNH_2)_3$ and $(H_2GaN_3)_n$, formed nanocrystalline GaN or GaN films at low temperatures. Related triazidogallium derivatives have also produced GaN nanoparticles.[5] Here, we report the syntheses and structures of a volatile, thermally robust dimeric 1,1-dimethylhydrazidogallane, $[H_2GaN(H)NMe_2]_2$ **1**, and a gallium hydrazide derivative with two Ga_2N_2 rings bridged by $NNMe_2$ groups, $Ga_4[N(H)NMe_2]_8(NNMe_2)_2$ **2**.

Hydrazine and 1,1-dimethylhydrazine have been used in conjunction with trialkyl-aluminum and -gallium compounds as alternative nitrogen sources replacing NH_3 for the preparation of AlN and GaN.[6–8] Several related group 13 hydrazide derivatives have been structurally characterized, including dimeric $[Me_2GaN(H)N(H)Ph]_2$,[9] $[Et_2GaN(H)NPh_2]_2$[10] and $[Me_2AlN(H)NMe_2]_2$,[11] a compound with a ladder-type structure, $Al_4[N(H)NMe_2]_6(NNMe_2)_4$,[12] and a compound with a Ga_4N_8 cage structure, $[MeGaN(H)NPh]_4$.[9]

Compound **1**[13] was obtained nearly quantitatively as a white crystalline solid after removal of the volatiles from the reaction of $H_3Ga(NMe_3)$ in excess H_2NNMe_2 at room temperature for 2 days (Scheme 1). Having an appreciable volatility (*ca.* 0.07 Torr) at room temperature, colorless crystals were obtained by sublimation at 55 °C under nitrogen (1 atm). Compound **1** melted at 62 °C and remained a stable liquid up to 90 °C. When heated at higher temperatures, compound **1** decomposed to gallium metal. These results suggested that compound **1** is potentially a clean precursor for deposition of gallium-containing films. The chemical ionization mass spectroscopic data of **1** were in good agreement with the formula of $[H_2GaN(H)NMe_2]_2$ ($[M + H]^+$, *m/z* 261.0, 100%). Two strong $\nu_{Ga–H}$ (KBr pellet) absorptions at 1897 and 1912 cm^{-1} and two $\nu_{N–H}$ absorptions at 3099 (broad) and 3145 (sharp) cm^{-1} were observed. Two singlets at δ 2.11 (sharp) and 2.35 (broad) in the ^1H NMR spectrum were assigned to N–H groups with the total integration of 2 H. The hydrides appeared as a broad resonance at δ 5.21. The presence of two N–H groups indicated the existence of a second isomer in solution. The ratio of the intensity of the δ 2.11 to the δ 2.35 resonances increased from 0.66 at 21 °C to 0.77 at 50 °C.

The molecular structure of **1**[14] (Fig. 1) was dimeric with a planar Ga_2N_2 core and a *trans* arrangement of the NMe_2 substituents. Along the *z* axis intermolecular hydrogen bonds were found between N(1) and N(2) of the neighboring molecule [N(1)···N(2) 3.238(7) Å, N(1)–H(1N)···N(2) 167(5)°]. The atoms N(3) and N(4) were not involved in hydrogen bonding. The hydrides were located on the difference Fourier map, and the only restraint applied in their refinement was to set similar the Ga–H bond lengths to the corresponding gallium atoms.

As also shown in Scheme 1, compound **2**[13] was obtained by refluxing the solution of compound **1** in H_2NNMe_2 for 4 days, followed by removal of volatiles and recrystallization from hexanes (63% yield based on gallium). The ^1H NMR spectrum of compound **2** was consistent with the solid state strtucture[14] (Fig. 2); the two unusual downfield shifts (δ 5.11 and 5.57) were assigned to two N–H bonds involved in hydrogen bonding (*vide infra*).

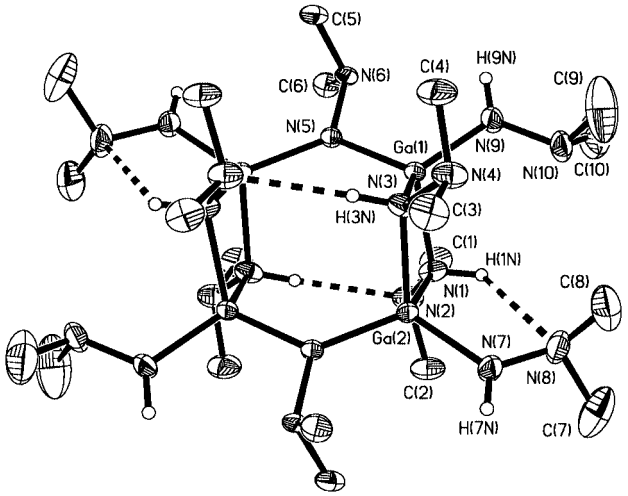

Fig. 2 Structure of **2** showing 30% thermal ellipsoids. Hydrogen atoms in the methyl groups are omitted for clarity. Selected bond distances (Å) and angles (°): Ga(1)–N(1) 1.989(3), Ga(1)–N(3) 2.029(3), Ga(1)–N(5) 1.847(3), Ga(1)–N(9) 1.833(3), Ga(2)–N(1) 1.990(3), Ga(2)–N(3) 2.034(3), Ga(2)–N(5A) 1.860(3), Ga(2)–N(7) 1.851(3), N(1)–N(2) 1.402(4), N(3)–N(4) 1.427(4), N(5)–N(6) 1.461(3), N(7)–N(8) 1.403(4), N(9)–N(10) 1.409(4); N(1)–Ga(1)–N(3) 84.30(11), N(1)–Ga(2)–N(3) 84.13(11), Ga(1)–N(1)–Ga(2) 96.53(12), Ga(1)–N(3)–Ga(2) 93.94(12), Ga(1)–N(5)–Ga(2A) 129.76(14), N(6)–N(5)–Ga(1) 108.5(2), N(6)–N(5)–Ga(2A) 121.7(2).

An inversion center correlated the two halves of the molecule **2**, which were connected by bridging $NNMe_2$ ligands and an intramolecular hydrogen bond between N(3) and N(2A). The distance N(3)···N(2A) was 3.214(5) Å and the angle N(3)–H(3N)···N(2A) was 174.8°. An additional intramolecular hydrogen bond was found between N(1) and N(8) [3.175(5) Å, 120.1°]. Each Ga_2N_2 ring adopted a sightly twisted shape with the gallium ends bending toward and the nitrogen ends away from the inversion center. The torsion angle N(3)–Ga(2)–N(1)–Ga(1) was 8.0(2)°. The four gallium atoms [Ga(1), Ga(2), Ga(1A) and Ga(2A)] and the two bridging nitrogen atoms [N(5) and N(5A)] were essentially on the same plane. The atom N(5) adopted a trigonal planar geometry with the sum of the angles being 360.0°. This suggested delocalization of the lone pair electrons of the nitrogen to the two adjacent gallium atoms, however, the bond lengths N(5)–Ga(1) [1.847(3) Å] and N(5)–Ga(2A) [1.860(3) Å] were not unusual for covalent Ga–N bonds.[15] With the exception of N(5)–N(6) [1.461(3) Å], the N–N bond lengths ranged from 1.402(4) to 1.427(4) Å, shorter than those in compound **1** [1.449(7) and 1.454(7) Å], $[Et_2GaN(H)NPh_2]_2$ [1.457(8) and 1.446(8) Å] and $[MeGaN(H)NPh]_4$ [1.489(3) Å].

A series of Mn porphyrins bearing one to eight β-nitro substituents were synthesized in high yield in three steps by using a new general method for selective nitration of a Zn(*meso*-tetraarylporphyrin); this Mn porphyrin series exhibits a remarkably wide span of Mn(III)/Mn(II) redox potentials from −290 to + 1150 mV (*vs.* SCE), and the Mn porphyrins bearing one to five β-nitro groups are particularly good catalysts for hydroxylation of aromatic compounds with H_2O_2, with yields up to 98, 83, 80 and 12%, respectively for anisole, naphthalene, acetanilide and ethylbenzene.

Cytochrome P450-dependent monooxygenases very efficiently catalyze the epoxidation of alkenes, the hydroxylation of alkanes and of aromatic rings, as well as N- or S-oxidations by O_2 or oxygen atom donors.[1] Three successive generations of Fe(III) and Mn(III) porphyrins have been developed during the last fifteen years as catalysts mimicking cytochrome P450 chemistry.[2] Several systems based on such Fe(III) or Mn(III) porphyrins were found to be very efficient for alkene epoxidation with quantitative yields and high turnover numbers, and for alkane hydroxylation with satisfactory yields.[2] Reproducing the P450-dependent selective hydroxylation of aromatic rings appears to be more difficult, presumably because of the very easy further oxidation of the expected phenol products in the medium. In fact, systems using strong oxidants such as PhIO that directly react by themselves with phenols generally led to low hydroxylation yields.[3] The best reported aromatic hydroxylation yields with these systems have been obtained with H_2O_2, a milder oxidizing agent.[3c,d,f] However, even these H_2O_2-dependent systems only led to hydroxylation yields of between 10 and 60% for the most reactive aromatic molecules. Some of the best reported yields were obtained with H_2O_2 in the presence of Mn(III) porphyrins bearing several electron-withdrawing substituents.[3d]

Based on these data, it appeared to us that it would be interesting to compare the abilities of Mn-porphyrins bearing one to eight β-nitro substituents as catalysts for aromatic hydroxylation with H_2O_2. We have recently reported[4] the synthesis of a Mn β-heptanitroporphyrin and showed that the redox potential of this Mn-porphyrin is more than 1 V higher than that of Mn(TDCPP).[5] Much more recently, we have succeeded in finding a new general method for selective nitration of Zn(TDCPP) which affords a full series of Zn porphyrins bearing one through to eight β-nitro groups in high yield. Here we report that some of the corresponding Mn complexes are particularly good catalysts for the hydroxylation of aromatic compounds with H_2O_2.

Scheme 1 shows the procedure used for preparing the eight Mn-porphyrins, Mn(TDCPN$_x$P) with ($1 \leqslant x \leqslant 8$), from Zn(TDCPP). Titration of Zn(TDCPP) with increasing amounts of HNO_3–CF_3SO_3H–$(CF_3SO_2)_2O$ selectively afforded the eight compounds of the Zn(TDCPN$_x$P) series with yields between 50 and 95%. All compounds of the Zn(TDCPN$_x$P) and TDCPN$_x$PH$_2$ series were fully characterized by elemental analysis and UV–VIS, ^{1}H NMR spectroscopy and mass spectrometry. Their detailed synthesis and characteristics will be published elsewhere.

Preparation of the corresponding Mn complexes was performed by reaction of $Mn(OAc)_2$ with the free bases TDCPN$_x$PH$_2$. Insertion of Mn(II) was increasingly easier as the number of NO_2 substituents increased. For instance, insertion of Mn(II) in TDCPPH$_2$ required several hours reaction at 153 °C in DMF, whereas insertion in TDCPN$_5$PH$_2$ was complete within a few minutes at 20 °C in $CHCl_3$–CH_3OH (80:20). After purification by column chromatography and treatment with gaseous HCl in aerobic CH_2Cl_2, the Mn-porphyrin complexes bearing between one and four β-nitro groups exhibited UV-VIS spectra characteristic of Mn(III)Cl porphyrins with a red-shifted Soret peak around 490 nm (482, 487, 493 and 498 nm for x = 1, 2, 3 and 4, respectively) and a smaller peak around 400 nm. Their mass spectra (MALDI) showed molecular peaks appearing as isotopic clusters identical to those simulated for Mn(TDCPN$_x$P)Cl, and major peaks corresponding to Mn(TDCPN$_x$P). Above x = 4, the Mn(TDCPN$_x$P) compounds mainly exist as Mn(II) complexes. For x = 5, even treatment with HCl in aerobic CH_2Cl_2 led to a mixture of Mn(II) (TDCPN$_5$P) and Mn(III) (TDCPN$_5$P)Cl. For x = 6, 7 and 8, it was only possible to isolate the Mn(II) (TDCPN$_x$P) complexes, which showed a single Soret peak at 466, 467 and 468 nm, respectively, and molecular peaks by mass spectrometry (MALDI) corresponding to Mn(TDCPN$_x$P). The existence of these electron-poor Mn porphyrins as Mn(II) complexes is not surprising; similar behavior was previously reported for β-polyhalogenated Mn-porphyrins[6] and for Mn(TDCPN$_7$P) itself.[4] This is also easily explained if one considers the high redox potentials (*vs.* SCE) found for the Mn(III)/Mn(II) couple which vary from +750 mV for x = 5 to + 1150 mV for x = 8. In fact, the Mn(TDCPN$_x$P) series with x = 1–8 exhibits a remarkably wide span of Mn(III)/Mn(II) redox potentials that range from −290 to +1150 mV (*vs.* SCE in 0.1 M NBu_4PF_6–CH_2Cl_2). The oxidation states of the Mn complexes were clearly established on the basis of their UV-VIS and EPR spectra and of their electrochemical properties.

The ability of these Mn-porphyrin complexes to act as catalysts for the hydroxylation of aromatic compounds with H_2O_2 was studied in the presence of a cocatalyst, ammonium

[a] *Conditions*: Mn-porphyrin : H_2O_2 : cocatalyst ratio = 1 : 50 : 20, [Mn-porphyrin] = 2 mM in CH_2Cl_2–CH_3CN (1 : 1), 2 h at 20 °C in the presence of substrate in excess; substrate/catalyst = 3000, 1600 and 500 for anisole, ethylbenzene and naphthalene, respectively. Yields (%) are based on H_2O_2; *p*-OH and *o*-OH represent *para*- and *ortho*-hydroxylated products; arom./benz. is the ratio (%) between aromatic hydroxylation and benzylic oxidation products derived from ethylbenzene.

acetate, that was previously described to give good results for the Mn porphyrin-catalyzed transfer of an oxygen atom of H_2O_2 to various hydrocarbon substrates.[7] Thus, Mn(TDCPP)Cl catalyzed the hydroxylation of anisole to *para*- and *ortho*-hydroxyanisole with 60 and 4% yields based on starting H_2O_2 when anisole was used in large excess relative to H_2O_2. From various ammonium carboxylates that have been tested as necessary cocatalysts for that reaction, ammonium mandelate gave the best hydroxylation yields. The latter cocatalyst was thus used in our comparison of the various Mn-porphyrins (Table 1). Interestingly, Mn(TDCPN_1P)Cl led to markedly higher yields of anisole hydroxylation with an almost quantitative use of H_2O_2 for formation of 90% and 7% *para*- and *ortho*-hydroxyanisole respectively. Mn(TDCPN_2P)Cl and Mn(TDCPN_3P)Cl also gave very high total yields based on H_2O_2 and were recovered unchanged at the end of the reaction (*ca.* 50 turnovers under the used conditions). With more β-nitro substituents, the hydroxylation yields greatly decreased from 79% with Mn(TDCPN_4P)Cl to < 2% with Mn(TDCPN_8P). Similar results were observed for hydroxylation of naphthalene, the best total yield of formation of α- and β-naphthols being maximum (83%) for Mn(TDCPN_2P)Cl (Table 1). Interestingly, the regioselectivity slightly changed upon increasing the number of β-nitro substituents [α : β ratio from 12 with Mn(TDCPP)Cl to *ca.* 6 for Mn(TDCPN_7P)]. The most spectacular results were observed in the case of ethylbenzene. Its Mn(TDCPP)Cl catalyzed oxidation with H_2O_2 exclusively led to products arising from hydroxylation of its very reactive benzylic position, 1-phenylethanol and acetophenone. Upon introduction of an increasing number of β-NO_2 substituents on the catalyst, *para*- and *ortho*-hydroxyethylbenzene were formed in significant amounts and the aromatic hydroxylation yield increased up to 12% for $x = 4$; then it markedly decreased for $x > 5$. Thus, the aromatic hydroxylation/benzylic hydroxylation ratio reaches maximum values *ca.* 30% for $x = 3$–5.

The above results illustrate the particular efficiency of Mn-porphyrins bearing between one and four β-nitro substituents for hydroxylation of aromatic molecules with H_2O_2 in the presence of an NH_4CO_2R cocatalyst. By a proper choice of the Mn catalyst it is possible to hydroxylate anisole and naphthalene, used in excess relative to H_2O_2, with yields (based on H_2O_2) up to 98 and 83%, respectively. Even ethylbenzene, that has a very reactive benzylic position, was hydroxylated at its aromatic ring with yields up to 12%. Another aromatic compound bearing an electron-donating substituent, acetanilide, was hydroxylated with the Mn(TDCPN_2P)Cl–H_2O_2–ammonium mandelate system, affording *p*-hydroxyacetanilide in 80% yield. Benzene itself or aromatic compounds bearing electron-withdrawing substituents were much poorer substrates, and lead to phenol yields < 5%.

The origin of the particular efficiency of Mn(TDCPN_xP)Cl catalysts, with $x = 1$–4, for hydroxylation of electron-rich aromatic compounds with H_2O_2, and of the changes observed in the regioselectivity of these hydroxylations as a function of x (Table 1) is currently under investigation. It is likely that the lower activities of Mn catalysts with $x = 5$–8 are due to their pronounced tendency to exist in the Mn(II) state.

The vapor phase Beckmann rearrangement of cyclohexanone oxime has been studied using a novel tantalum pillared-ilerite as catalyst: the cyclohexanone oxime conversion rate reaches 97.1% and the selectivity for ε-caprolactam is up to 89.1% at 350 °C.

Sulfuric acid as a catalyst plays an essential role in the industrial mass production of ε-caprolactam, a raw material for nylon-6. However, it poses significant environmental and operational problems such as generating undesirable salt and causing equipment corrosion. To overcome these problems, a number of heterogeneous catalysts for the vapor phase Beckmann rearrangement of cyclohexanone oxime have been proposed. Among typical heterogeneous catalysts for this reaction include solid acid catalysts such as boric acid, silica–alumina, zeolites like Y, ZSM-5, TS-1, B-ZSM-5 and tantalum oxide on silica.[1–4] Highly siliceous ZSM-5 and ZSM-5 modified with boron showed high activity and selectivity in the Beckmann rearrangement reaction.[5] However, the catalysts gradually deactivated with time. Solid acid catalysts of high activity with long catalytic lifetime are still under investigation.

Various types of hydroxy groups in amorphous silica or zeolites have been investigated as catalytically active sites for the Beckmann rearrangement reaction. A majority of researchers found that neutral or weakly acidic hydroxy groups present on the external surface of zeolites are effective for the Beckmann rearrangement reaction, whereas Brönsted acid sites of zeolites accelerate the formation of by-products.[6,7] This is suggestive that an efficient solid acid catalyst for the rearrangement reaction can be obtained if the catalyst is designed to include not only a controlled acidity but also a sufficient number of hydroxy groups.

In our study, an efficient solid acid catalyst for the vapor phase Beckmann rearrangement reaction is designed using layered silicates. A small amount of metal was intercalated between the silicate layers by the usual pillaring process to generate moderate acidity as a mixed oxide and to increase the thermal stability of the layered silicate for use in catalysis. Layered silicates, such as kanemite ($NaHSi_2O_5{\cdot}3H_2O$), magadiite ($Na_2Si_{14}O_{29}{\cdot}11H_2O$), kenyaite ($K_2Si_{20}O_4{\cdot}11H_2O$), makatite ($Na_2Si_4O_9{\cdot}5H_2O$) and ilerite ($Na_2Si_8O_{17}{\cdot}xH_2O$) are composed of tetrahedral silicate sheets only and the each silicate sheet is terminated by hydroxy groups.[8] Layered silicates, therefore, possess abundant hydroxy groups oriented in a crystallographically regular manner, and have a great potential to act as new catalysts for the vapor phase Beckmann rearrangement reaction.

Here, the synthesis, characterization and catalytic application to the Beckmann rearrangement reaction of layered silicate catalysts pillared with tantalum oxide is presented.

Na-ilerite ($Na_2Si_8O_{17}{\cdot}xH_2O$) was synthesized hydrothermally at 100 °C for two weeks from a suspension of Ludox-HS 40 and NaOH solution with a molar ratio of $SiO_2:NaOH:H_2O = 1:0.5:7$.[9] H-ilerite was prepared by acid titration of Na-ilerite. A suspension of Na-ilerite in water was titrated with 0.1 M HCl to a final pH of 2.0 and allowed to stand with stirring for an additional 24 h. The H-ilerite was recovered by filtering off, washing, and was dried at 40 °C. The sodium content of the sample was 0.11 wt% as determined by atomic absorption spectroscopy. Octylamine intercalation was performed to increase the interlayer spacing of ilerite by allowing H-ilerite to react with an excess of octylamine at room temperature.

The pillar precusor for tantalum oxide pillaring was prepared by the hydrolysis of tantalum pentaethoxide.[10] A small amount of octylamine was added to the solution to increase the degree of hydrolysis of tantalum pentaethoxide. The molar ratio of $Ta(OC_2H_5)_5:H_2O$:octylamine was adjusted to 1:12:0.3. The pillar precusor can be represented as $Ta_xO_y(OR)_z$. For comparison, silicon pillared-ilerite was prepared according to the procedure in the literature.[9] The pillar precusor for silicon oxide pillaring was prepared by mixing octylamine and TEOS in the molar ratio of 2:5. The pillar precusor solution was added dropwise to the octylamine-ilerite gel with continuous stirring. The final suspension was allowed to stand for three days with stirring at room temperature. The resultant product was washed with ethanol, filtered off and dried at 100 °C. Samples were calcined at 700 °C for 1 h to eliminate residual organic molecules. The tantalum content of tantalum pillared-ilerite samples, as determined by inductively coupled plasma (ICP) spectroscopy, ranged from 3.8 to 5 wt%.

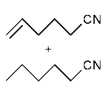
The as-synthesized metal pillared-ilerites have basal spacings of 27.2 Å (Ta) and 29.4 Å (Si) much larger than those of Na- and H-ilerites, (11.1 and 7.4 Å, respectively).[9] Although the basal spacings gradually decreased with increase in calcination temperature, the structures of the metal pillared-ilerites were preserved even after calcination at 700 °C (Fig. 1). Broad peaks in the XRD powder diffraction patterns indicate that poorly ordered structures are formed in metal pillared-ilerites. The N_2 adsorption–desorption isotherm of tantalum pillared-ilerite after complete elimination of organic molecules showed type IV behavior according to the BDDT classification. At high relative pressure ($P/P_o > 0.6$), hysteresis is observed owing to capillary condensation in mesopores, caused by pillaring of the layered silicates.

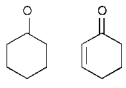
The BET surface areas of samples calcined at 700 °C are 395 $m^2\ g^{-1}$ for tantalum pillared-ilerite and 358 $m^2\ g^{-1}$ for silicon pillared-ilerite, much larger than those of the H- and Na-ilerites, (20 and 40 $m^2\ g^{-1}$, respectively).

The acidic properties of the tantalum pillared-ilerite was studied to identify the inherent acidity caused by incorporation of tantalum oxide between the layers of ilerite. In addition, the acidic properties of silicon pillared-ilerite was investigated to compare inherent acidities caused by incorporation of Ta or Si between the layers of ilerite. Acidities were determined by carrying out NH_3-TPD experiments. The TPD profile of the tantalum pillared-ilerite exhibits a broad desorption peak with a maximum at 220 °C. On the other hand, the silicon pillared-ilerite shows no desorption peak. This implies that tantalum pillared-ilerite contains a large number of acid sites of moderate acidity, whereas silicon pillared-ilerite shows no acidity.

The Beckmann rearrangement of cyclohexanone oxime was conducted using a continuous flow reactor under atmospheric

Table 1 Vapor phase Beckmann rearrangement of cyclohexanone oxime over various metal pillared-ilerites[a]

Catalyst	*t*/h	Conv. (%)	Selectivity (%)			
						




Ta-Ilerite	2	97.1	89.1	5.9	3.0	2.0
	8	96.9	85.7	9.3	3.1	1.8
Si-Ilerite	2	70.4	80.6	2.4	11.2	5.1
	8	30.5	54.2	7.8	26.3	11.7
Silicalite-1[b]	2	92.6	93.0	3.8	2.0	1.2
	8	89.1	89.8	5.1	3.7	1.4

[a] *Conditions*: T = 350 °C, P = 1 atm, WHSV = 0.5 h^{-1}, cyclohexanone oxime:EtOH:He = 1:9:10, Time on stream = 8 h. [b] Silicalite-1 was synthesized at 150 °C for 5 days using the mol ratio 0.1 TPABr:0.2 NaOH:1.0 SiO_2:35 H_2O.

pressure. Cyclohexanone oxime was dissolved in ethanol and injected with syringe pump at a WHSV of 0.5 h^{-1} under He flow with reaction carried out at 350 °C. The product was analyzed by GC using an SE-54 column.

The results of the rearrangement reaction over tantalum pillared-ilerite are shown in Table 1. The catalytic activity of tantalum pillared-ilerite was compared to Silicalite-1 (pure silica ZSM-5), which is known as the most selective catalyst for the vapor phase Beckmann rearrangement of oxime to lactam (Table 1). The tantalum pillared-ilerite showed a higher conversion of oxime than silicalite-1 while the selectivity for lactam over tantalum pillared-ilerite was slightly lower than that over silicalite-1. Also, the data was compared with that of silicon pillared-ilerite to investigate the effect of the metal as a pillar. For the tantalum pillared-ilerite catalyst, the cyclohexanone oxime conversion rate reaches 97.1% and the selectivity for ε-caprolactam is 89.1% at 350 °C. Tantalum pillared-ilerite catalyst is superior to the silicon pillared-ilerite in terms of both conversion and selectivity. Silicon pillared-ilerite shows quite high conversion and selectivity initially owing to inherent hydroxy groups from its layered features. However, it is rapidly deactivated within 8 h, which may be explained by the fact that it does not possess the moderate acidity required to catalyze the rearrangement reaction (ammonia TPD).

Although the exact role of the metal is not yet fully understood, it can be speculated that acidity of hydroxy groups in the metal pillared-ilerite is controlled by the metal used as pillar. The acid strength of the assumed species –Ta–O–Si–OH generated by the pillaring process is adequate enough to catalyze the rearrangement reaction.

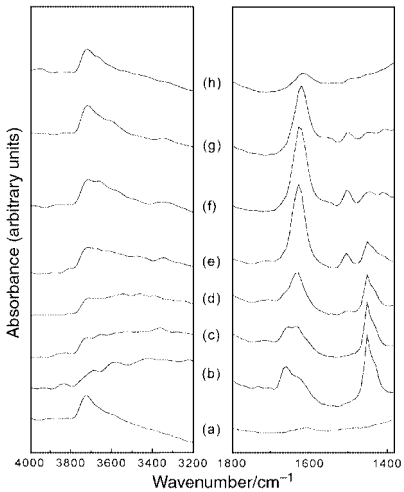


Fig. 1 FTIR spectra of tantalum pillared-ilerite measured at different temperatures (a) before and (b–h) after adsorption of cyclohexanone oxime [(a) 25, (b) 70, (c) 100, (d) 140, (e) 200, (f) 300, (g) 400 and (h) 550 °C]. These data were recorded on FTS-175 BIO-RAD FT-IR spectrometer.

FTIR spectra were measured for metal pillared-ilerite samples to elucidate the reaction pathway in detail. FTIR experiments were conducted using an *in situ* IR cell (Graseby, specac). Metal pillared-ilerite pellets were preheated at 550 °C under vacuum for 1 h. After the samples were cooled to room temperature, FTIR spectra were recorded [Fig. 1(a)]. One drop of a 1% ethanol solution of cyclohexanone oxime was added to the pellet held in the *in situ* cell under He gas flow. After the evacuation of physically adsorbed oxime at room temperature for 1 h, FTIR spectra were recorded at increments of 20 °C min^{-1} [(Fig. 1(b)–(h)].

The IR spectrum of tantalum pillared-ilerite [Fig. 1(a)] shows absorption bands of hydroxy groups[11] at *ca*. 3700 cm^{-1}. However, these bands disappeared upon adsorption of cyclohexanone oxime and new bands appeared at 1450 and 1663 cm^{-1} due to characteristic vibrations[12] of CH_2 and C=N groups of cyclohexanone oxime, respectively. This indicates strong interaction between the hydroxy groups of the catalyst and the reactant. For the temperatures above 100 °C, the characteristic vibration modes[12] of C=O and N–H of ε-caprolactam at 1635 and 1505 cm^{-1} were detected. However, with a stepwise rise of evacuation temperature, the C=O and N–H absorptions of ε-caprolactam were weakened around 400 °C and completely disappeared at 500 °C. The desorption temperature of the produced ε-caprolactam is shifted to a higher value than that observed in the catalytic reaction and might be due to the fast temperature increase rate in the FTIR experiment. IR spectra of silicon pillared-ilerite taken at different temperatures were similar to those of tantalum pillared-ilerite. However, the intensities of bands at 1635 and 1505 cm^{-1} due to the characteristic vibrations of C=O and N–H groups of ε-caprolactam were lower than those on tantalum pillared-ilerite, which implies that silicon pillared-ilerite has a low catalytic activity.

From the FTIR data, it is seen that the rearrangement to ε-caprolactam from cyclohexanone oxime over the tantalum pillared-ilerite takes place around 100 °C, while the desorption of the produced ε-caprolactam occurs at a higher temperature (> 350 °C). Also this data strongly suggests that the hydroxy groups are active sites as reported for other zeolite catalysts.[6,7]

In conclusion, we report the synthesis and characterization of a novel tantalum pillared-ilerite that is shown to be a new advantageous catalyst for the vapor phase Beckmann rearrangement of cyclohexanone oxime. The excellent catalytic performance of tantalum pillared-ilerite for the Beckmann rearrangement reaction is ascribed to a large number of well dispersed hydroxy groups over the interlayer surface of tantalum pillared-ilerite and their relatively weak acidity.

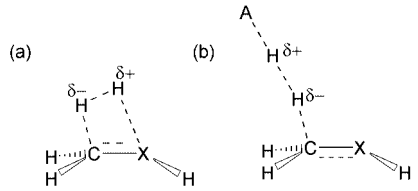
Published on the Web 28th April 2000

When a water molecule can act as a proton acceptor during the critical H–H bond heterolytic dissociation step of formaldehyde hydrogenation, the barrier drops—an observation which links dihydrogen activation chemistry to hydride transfer at a detailed molecular level.

The hardness of the H–H molecule is an obstacle to hydrogenation reactions, and consequently they usually require a catalyst, often in the form of a transition metal, in order to proceed. The reverse reaction type, H_2 eliminations, has been the subject of many gas phase studies. For example, detailed experimental and theoretical work has shown that loss of H_2 from protonated molecules of the type CH_3XH^+ (X = NH_2, OH, F, SH) take place *via* non-symmetrical 1,2-elimination mechanisms [Scheme 1(a)].[1–3] The resulting tight transition structures for these and similar H_2 eliminations give rise to substantial potential energy barriers. The dipolar nature of the emerging H_2 molecule during passage of the transition state has been noted.[4]

Very interestingly, it appears that intermolecular hydride transfer[5] is related to these hydrogenations/dehydrogenations. A special hydride transfer mechanism is found in superacid systems, particularly in the gas phase, where proton transfer may initiate H_2 elimination: $AH^+ + CH_3X \rightarrow CH_2X^+ + H_2 + A$. This reaction type has been reviewed in the context of chemical ionization mass spectrometry.[6] A reasonable transition structure for such a reaction is illustrated in Scheme 1(b). Although mechanisms of both unimolecular H_2 eliminations and hydride abstractions are reletively well known, the idea behind the present paper is to see how they are linked together at a detailed molecular level. We pursue this idea further by specifically asking if a third molecule, A, may change the reactivity in H_2 additions/eliminations.



Scheme 1

In order to do this we decided to perform quantum chemical calculations on a prototype system, hydrogenation of formaldehyde, using the methods MP2/6-31G(d,p)[7,8] and G2[9] with help of the program package GAUSSIAN 98.[10] Only the G2 values will be displayed in the following discussion.

According to our calculations hydrogenation of formaldehyde to give methanol [eqn. (1)]

$$CH_2O + H_2 \rightarrow CH_3OH \qquad (1)$$

is exoergic by $\Delta E = -78$ kJ mol^{-1} and has $\Delta G^o = -52$ kJ mol^{-1} which is in acceptable agreement with the experimentally known[11] exothermicity (at room temperature) of $\Delta H^o = -93$ kJ mol^{-1}. The reaction has a critical energy of $E_o = 301$ kJ mol^{-1} (Fig. 1, upper reaction path *via* the transition structure **TSa**).

Upon protonation [eqn. (2)],

$$CH_2OH^+ + H_2 \rightarrow CH_3OH_2^+ \qquad (2)$$

the critical energy is reduced to $E_0 = 122$ kJ mol^{-1} (Fig. 1, middle path *via* the transition structure **TSb**), which still is quite unfavourable for a direct gas phase reaction, but significantly below that of reaction (1). At the same time, as the result of the higher proton affinity of methanol, the overall reaction becomes somewhat more exoergic, with $\Delta E^o = -145$ kJ mol^{-1} and $\Delta G^o = -94$ kJ mol^{-1}. The corresponding experimental value[11] is $\Delta H^o = -142$ kJ mol^{-1}.

Upon providing the proton *inter*- rather than *intra*-molecularily a further, and substantial, drop in the critical energy is observed. The termolecular gas phase reaction [eqn. (3)]

$$CH_2O + H_2\ (+ H_3O^+) \rightarrow CH_3OH\ (+ H_3O^+) \qquad (3)$$

has barriers (corresponding to **TSc** and **TSd**) for which the potential energies are below that of the reactants (these values are $E_0 = -36$, -34 kJ mol^{-1}, respectively). Water is seen to promote reaction strongly through either of these closely parallel mechanisms. In the first step a proton is donated from the hydronium ion **3** to the oxygen of formaldehyde. Protonated formaldehyde may then form one of the two complexes **6a** (a C–H···O complex) or **6b** (a O–H···O complex) with the water

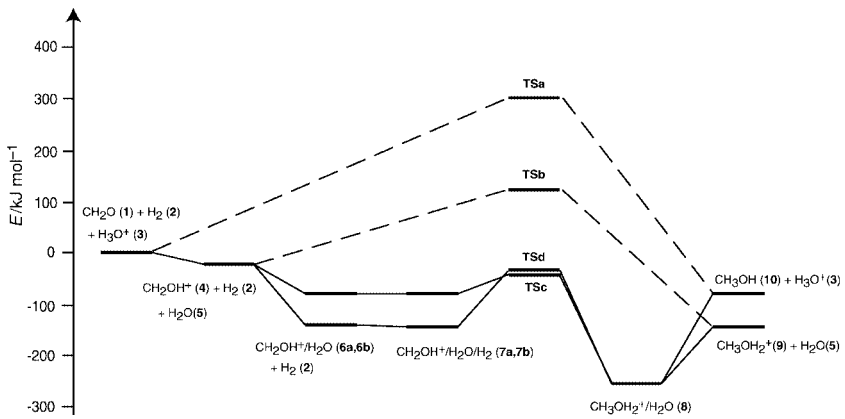


Fig. 1 Schematic potential energy diagram (G2) for the various routes for hydrogenation of formaldehyde. Potential energies are given in kJ mol^{-1}.

DOI: 10.1039/b001209m

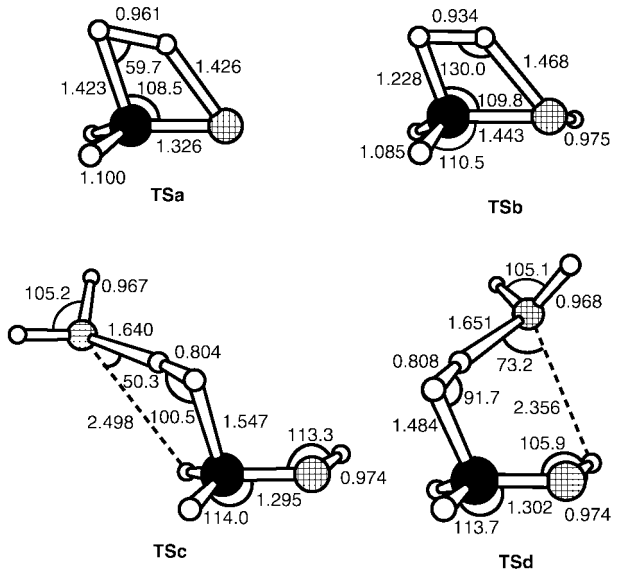

Fig. 2 Structures of the found transition structures (MP2/6-31G(d,p)) of the reactions studied. Black filled circles represent carbon, white open circles are hydrogen, while the patterned circles are oxygen. Bond lengths are given in Å and angles are in degrees. The connection between the transition structures and the minima indicated in Fig. 1 was verified through explicit calculation of minimum energy paths (intrinsic reaction coordinate).

molecule. In the next step of the parallel mechanisms, H_2 is associated with the corresponding complex (**6a** or **6b**). These new complexes are **7a** and **7b**, respectively. In the key step (*via* **TSc** or **TSd**) of the two parallel mechanisms, the H_2 molecule is split in a heterolytic process: the hydride ends up at the carbon and the proton ends up on water. All along the reaction the water is docked to the organic part through a hydrogen bond. The final products are obtained by breaking the hydrogen bonded complex **8**.

The transition structures **TSc** and **TSd**, are characterized by being cyclic. In contrast to **TSb** which has a tight four-membered ring, **TSc** and **TSd** form loose six-membered rings. While the H–H bond of **TSa** is 0.934 Å, it is only 0.804 Å in **TSc** and 0.808 Å in **TSd**, demonstrating that the latter transition structures are earlier along the reaction coordinate. These values should be compared to the MP2/6-31G(d,p) value of 0.734 Å for an intact H_2 molecule.

As indicated above, reaction (3), can be regarded from another perspective. When read from right to left (Fig. 1) **TSc** and **TSd** are the possible transition structures for the weakly endoergic hydride abstraction of methanol by H_3O^+.

We are not sure that the findings presented here may be of immediate practical use; a termolecular reaction through **TSc** or **TSd** is certainly difficult to achieve in the gas phase. This is illustrated by the fact that the free energies of these transition structures are +24 and +28 kJ mol^{-1}, respectively, compared to that of the reactants (**1** + **2** + **3**). In a strongly acidic water solution, in a suitable supercritical phase, or on an acidic surface (*e.g.* in a zeolite) the molecules are solvated, approximately corresponding to the situation in the complexes **7a** and **7b**. Despite this, the results presented here give an optimistic perspective on a non-transition metal hydrogenation catalysis chemistry.

We are aware of previous studies that illustrate the mediating effect of a water molecule in similar situations. As a good example we would mention that McKee *et al.*[12] showed that a water molecule slightly lowers the activation energy for the concerted dihydrogen exchange reaction (4).

$$CH_2O + CH_3OH \rightarrow CH_3OH + CH_2O \qquad (4)$$

In this reaction the two hydrogens are transferred through a one step cyclic relay type mechanism, which has several common features with reaction (3) above.

In summary we have shown (a) that protonation of formaldehyde lowers the energy barrier for hydrogenation, and (b) the barrier is further lowered upon inclusion of a water molecule.

These calculations were made possible thanks to support through the NFR (The Norwegian Research Council) Programme for Supercomputing.

A new highly selective calix[4]crown-6 fluorescent caesium probe

Hai-Feng Ji, Reza Dabestani,* Gilbert M. Brown and Richard A. Sachleben

Chemical and Analytical Sciences Division, Oak Ridge National Laboratory, PO Box 2008, MS-6100, Oak Ridge, TN 37831-6100, USA. E-mail: dabestanir@ornl.gov

Received (in Columbia, MO, USA) 1st November 1999, Accepted 30th March 2000

We have synthesized 1,3-alternate di-deoxygenated calix[4](9-cyano-10-anthrylmethyl)benzocrown-6, 1 and 1,3-alternate calix[4](9-cyano-10-anthrylmethyl)benzocrown-6, 2 as the second generation of caesium selective fluorescent probes; probe 1 shows 54-fold fluorescence enhancement upon caesium complexation while 2 exhibits only 8-fold enhancement; the selectivity ratios for 1 to complex caesium ion over potassium and rubidium (K_{Cs}/K_K and K_{Cs}/K_{Rb}) are *ca.* 10 fold higher than those of 2 for the same ions; the observed selectivity ratios are consistent with data reported for other 1,3-alternate calix[4]crown-6 derivatives.

Calix[4]crown-6 ethers in the 1,3-alternate conformation bind caesium with remarkable strength and selectivity.[1] Consequently, significant effort has been directed towards their use in the sensing, monitoring and remediation of ^{137}Cs, a fission product present in the wastes generated during the reprocessing of irradiated nuclear fuels.[2] The need for sensitive caesium sensors has led to the study of calix[4]crown-6 ethers as fluorescent caesium probes, and we have shown that 1,3-alternate calix[4]-bis-*o*-benzocrown-6[3a] ethers bearing cyanoanthracene fluorophores exhibit 8–12 fold fluorescence enhancement in the presence of caesium ion. The K_{Cs}/K_K and K_{Cs}/K_{Rb} ratios of 13[3b] and 1.3,[3b] respectively, indicate that the observed selectivities are consistent with data reported for other 1,3-alternate calix[4]crown-6 derivatives using UV absorption and potentiometric measurements.[4]

Recently, it was reported[5] that 1,3-alternate di-deoxygenated calix[4]crown-6 ethers exhibit enhanced selectivity for caesium over potassium and rubidium compared with their 1,3-alternate dialkoxy calix[4]crown-6 derivatives. Here, we have taken advantage of this higher caesium to potassium selectivity to synthesize a new caesium selective probe **1**. Our results suggest that **1** exhibits not only enhanced selectivity towards caesium, but also shows a fluorescence turn-on response significantly higher than any previously reported caesium sensor.

The 1,3-alternate di-deoxygenated calix[4](9-cyano-10-anthrylmethyl)-benzocrown-6, **1** was synthesized from di-dehydroxylated calix[4]arene and 1,2-bis(5-iodo-3-oxa-1-pentyloxy)-4-(10-cyano-9-anthrylmethyl)benzene[3b] by a standard procedure reported earlier.[6] The fluorescence of the 9-cyanoanthracene is quenched by the benzo moiety owing to a photoinduced electron transfer (PET) process.[7] It has been shown that binding the oxygen lone pair electrons (on the benzo moiety) by metal ion complexation partially suppresses the PET process, causing the fluorescence of the cyanoanthracene to increase.[3a,7]

The emission behavior of **1** (1×10^{-6} M) in CH_2Cl_2–MeOH (1 : 1) in the presence of five different alkali metal cations is shown in Fig. 1. The data indicates that probe **1** exhibits a significant emission enhancement upon caesium complexation (*ca.* 20-fold increase compared to uncomplexed probe) at a concentration as low as 2×10^{-7} M where no other alkali metal ion shows any response (except for Rb^+ that shows *ca.* 2-fold emission enhancement at the same concentration, Fig. 1). The fluorescence quantum yields of **1** for various alkali metal cations shown in Table 1 were determined relative to 9,10-diphenylanthracene in MeOH, Φ_f = 0.94.[8] The fluorescence quantum yield of **1** is enhanced 54 times (relative to free ligand, Table 1) when fully complexed with caesium at *ca.* 2×10^{-5} M concentration of caesium ion. This is the most dramatic emission response upon caesium ion complexation of any caesium optical sensors reported to date. In comparison, the fluorescence of **2**, 1,3-alternate calix[4](9-cyano-10-anthrylme-

DOI: 10.1039/a908720f

Table 1 Maximum fluorescence quantum yields and the complexation constants for both **1** and **2** in the presence of different alkali metal ions[a]

	Free	Li^+	Na^+	K^+	Rb^+	Cs^+
Φ_{em-max} of **1**	0.012	0.014	0.068	0.405	0.491	0.625
Φ_{em-max} of **2**	0.010	0.010	0.036	0.044	0.061	0.082
log (*K*) of **1**	—	—	—	4.06	5.48	6.60
log (*K*) of **2**	—	—	2.60	5.50	6.96	7.08

[a] [**1**], [**2**] = 1×10^{-6} M in CH_2Cl_2–MeOH (1:1, v/v). Metal ion concentrations: $[Cs^+] = 2 \times 10^{-5}$ M, $[Rb^+] = 4 \times 10^{-5}$ M, $[K^+] = 1 \times 10^{-3}$ M, $[Na^+] = 1 \times 10^{-2}$ M, $[Li^+] = 0.1$ M.

thyl)benzocrown-6, with the same fluorophore but based on a slightly different calix[4]arene platform, showed only 8.2-fold enhancement when fully complexed with caesium (Table 1). The dramatic fluorescence increase of **1** compared to **2** could be attributed to changes in the binding cavity of **1** (*vida supra*). Although Rb^+ and K^+ complexation cause the fluorescence of **1** to increase (42.6- and 35.2-fold, respectively), their maximum responses occur at higher concentrations (6×10^{-5} M and 2×10^{-3} M, respectively), indicating that their association constants with **1** are much weaker than that of caesium. Na^+ and Li^+ ions show little effect on the fluorescence of **1**, suggesting a weak interaction (complexation) between these ions and **1**.

The 1:1 complexation constant can be calculated from the emission intensity and concentration of metal ion, [M], profile shown in Fig. 1 according to eqn. (1)[7]

$$\frac{I - I_0}{I_\infty - I_0} = K([\mathrm{M}]_t - [\mathrm{L}]_t(\frac{I - I_0}{I_\infty - I_0})) \quad (1)$$

where I is the emission response of the probe at certain metal ion concentration, I_0 is the emission response of the probe in the absence of metal ions, I_∞ is the emission response when no further changes occur upon addition of the metal ion, $[L]_t$ is the total concentration of probe molecule (**1** or **2**) and $[M]_t$ represents the total metal ion concentration. The complexation constants K reported in Table 1 were calculated using a non-linear curve-fitting method[9] to fit the observed experimental emission data.

The complexation constant of **1** with caesium (4.0×10^6 M^{-1}) is about one-third of the value obtained for **2** (1.2×10^7 M^{-1}). On the other hand, the emission enhancement for **1** is about 7 times higher than that of **2**. The more sensitive response of **1** to caesium complexation suggests a stronger interaction between the caesium cation and the ether oxygens of the benzo group in **1**. This in turn results in a greater charge dispersion onto the oxygen of the crowns and subsequently stronger interaction between caesium and the benzo moiety. Experimental support substantiating the above argument has been provided by X-ray crystallography data.[10] Crystallographic results for a closely related series of compounds show that the average Cs–O (benzo oxygen) distance of an analog to **1** is 0.15 Å shorter than the average bond length in an analog to **2**.[10]

The complexation constants of **1** with Rb^+ (3.0×10^5 M^{-1}) and K^+ (1.2×10^4 M^{-1}) are significantly lower than those of **2** (Rb^+: 9.1×10^6 M^{-1}, K^+: 3.2×10^5 M^{-1}), resulting in the selectivity ratios of $K_{Cs}/K_{Rb} = 13.2$ and $K_{Cs}/K_K = 347$. These selectivities are *ca.* 10-fold higher than those calculated for **2** ($K_{Cs}/K_{Rb} = 1.3$ and $K_{Cs}/K_K = 38$) and other 1,3-alternate calix[4]benzocrown-6 derivatives reported previously.[3,4] Such observation clearly highlights the remarkable sensitivity of **1** as a caesium selective sensor for low Cs^+ concentrations.

We also measured the change in emission behavior of **1** with caesium in MeOH and observed only a 6.5-fold enhancement. In addition, the complexation constants of **1** with caesium and potassium were much smaller in MeOH than in CH_2Cl_2–MeOH (1:1) (8.6×10^5 M^{-1} and 3.0×10^3 M^{-1}, respectively). This could indicate that PET quenching is more efficient in the more polar MeOH environment because polarity can affect the energetics of the receptor (crown moiety) relative to that of fluorophore (to enhance PET effect) and/or MeOH can complex with the receptor competing with caesium for binding.[11] The effect of solvent polarity on the emission behavior of **1** and previously reported probes will be published later.[3b]

In conclusion, the new di-deoxygenated calix[4]arene derived fluorescence sensor **1** shows a significantly greater emission response (fluorescence turn on) to caesium compared to **2** and the other previously reported probes and holds promise for the development of a highly selective caesium detection and monitoring system.

Non-ionic surfactant assembly of wormhole silica molecular sieves from water soluble silicates

Seong-Su Kim, Thomas R. Pauly and Thomas J. Pinnavaia*

Department of Chemistry, Michigan State University, East Lansing, Michigan 48824, USA

Received (in Columbia, MO, USA) 18th January 2000, Accepted 23rd March 2000
Published on the Web 28th April 2000

Thermally stable mesoporous silica molecular sieves with wormhole framework structures, previously obtainable only from silicon alkoxides, have been prepared from low cost soluble silicate precursors in the presence of non-ionic surfactants as structure directors.

Mesoporous molecular sieve silicas with wormhole framework structures (*e.g.* MSU-X,[1,2] and HMS[3]) are generally more active heterogeneous catalysts in comparison to their ordered hexagonal analogs (*e.g.* MCM-41,[4] SBA-3[5] and SBA-15[6]). The enhanced reactivity has been attributed, in part, to a pore network that is connected in three dimensions, allowing the guest molecules to more readily access reactive centers that have been designed into the framework surfaces.[7–10] All of the wormhole framework structures reported to date have been prepared through supramolecular S^oI^o[3] and N^oI^o[1,2] assembly pathways wherein I^o is an electrically neutral silica precursor (typically, tetraethylorthosilicate, TEOS), S^o is a neutral amine surfactant, and N^o is a neutral di- or tri-block surfactant containing polar polyethylene oxide (PEO) segments. One disadvantage of these pathways, as with other assembly pathways based on TEOS, is the high cost of the hydrolyzable silicon alkoxide precursor. Greater use of wormhole framework structures as heterogeneous catalysts may be anticipated if a more efficient approach to either S^oI^o or N^oI^o assemblies could be devised based on the use of low cost soluble silicate precursors, without sacrificing the intrinsically desirable processing advantages of these pathways (*e.g.* facile removal and recycling of the surfactant).

Recently, Guth and coworkers reported the preparation of disordered silica mesostructures by precipitation from sodium silicate solutions over a broad range of pH in the presence of Triton-X 100, an N^o surfactant.[11] The retention of a mesostructure was observed up to a calcination temperature of 480 °C, but the complete removal of the surfactant at 600 °C led either to the extensive restructuring of the silica framework, as indicated by the loss of mesoporosity or the formation of a completely amorphous material. In contrast, MSU-X mesostructures are structurally stable to calcination temperatures in excess of 800 °C. The present work demonstrates that mesoporous molecular sieve silicas equivalent in structure and thermal stability to MSU-X silicas (denoted MSU-X′) can in fact be prepared from soluble silicate precursors under the appropriate assembly conditions.

Our approach, like that of Guth and coworkers, uses a sodium silicate as the silica source and an N^o surfactant as the structure director, but our methodology results in thermally stable wormhole structures. In a typical synthesis the surfactant and an amount of acid equivalent to the hydroxide content of the sodium silicate solution (*e.g.* 27% SiO_2, 14% NaOH, Aldrich) are first mixed at ambient temperature and then added to the sodium silicate solution to form reactive silica in the presence of the surfactant. This allows the assembly of the framework structure at near-neutral pH and avoids the need for readjusting the pH once the reactive silica has been formed. The assembly process is carried out at a molar ratio SiO_2/surfactant in the range 13–7.0 and at a temperature in the range 25–60 °C for a period of 10–20 h. The surfactant is then removed from the washed and air-dried products either by solvent extraction with hot ethanol or by calcination in air at 600 °C.

Fig. 1 illustrates the powder X-ray diffraction patterns of as-synthesized and calcined MSU-X′ silicas prepared at three different temperatures using Brij 56 [$C_{16}H_{33}(EO)_{10}H$] as the structure-directing surfactant. Each product exhibits an intense reflection at low 2θ corresponding to a pore–pore correlation distance of *ca.* 63 Å with a broad shoulder in the 2θ range 2–3. These patterns are typical of disordered wormhole-like pore structures and are similar to those of MSU-X silicas assembled from the same surfactant, but with TEOS as the silica precursor. After calcination at 600 °C, the intensities of the pore–pore correlation peaks are substantially greater than the as-synthesized samples due to the removal of the contrast-matching surfactant. This result is consistent with the retention of the framework pore structure upon complete removal of the surfactant from the framework.

Further evidence for the wormhole framework pore structure of MSU-X′ silicas is provided by the typical transmission electron micrograph (TEM) image shown in Fig. 2. This micrograph clearly exhibits disordered wormhole-like pores similar to MSU-X materials. Fig. 3 illustrates the N_2 adsorption–desorption isotherms and Horvath–Kawazoe pore size distributions (inset) for the calcined MSU-X′ products assembled at 25, 45 and 60 °C. The sample assembled at 25 °C exhibits the smallest pore size (32 Å) in the series, and the largest HK pore diameter (50 Å) is observed for the 60 °C sample. The increase in framework pore size with increasing assembly temperature is a characteristic feature of an N^oI^o assembly pathway.[2] The desorption hysteresis observed for the product prepared at 60 °C is indicative of the necking of the interconnected wormhole pore structure. In addition, the pore

wall thickness, as obtained from the difference between the pore–pore correlation distance and the HK pore size, decreases with increasing assembly temperature (Table 1). This latter behavior, which is related to the increase in the hydrophobic character of the PEO block as the surfactant approaches the cloud point, also is a characteristic feature of N^oI^o assembly.[2] Because Na^+ ions are present in the assembly process, there may also be an electrostatic contribution to framework formation through complexation of Na^+ by the N^o surfactant. However, electrostatically controlled $[N^oM^+]I^o$ assembly processes tend to form ordered hexagonal or cubic framework structures, not wormhole frameworks.[12]

Wormhole silica molecular sieves can also be assembled from water-soluble silicate precursors using N^o surfactants other than Brij 56. Table 1 summarizes the textural properties of wormhole silica assembled from sodium silicate and other Brij surfactants, a Tergitol $[C_{11–15}H_{23–31}(EO)_{15}H]$ surfactant, and several alkyl-PEO/furan Tween X surfactants (X = 20, 40, 60 and 80). Table 1 shows that each of these surfactants form mesostructures with 33–51 Å pore sizes, and surface areas and pore volumes comparable to MSU-X silicas prepared from TEOS. TEM analysis of each product conformed the wormhole pore structure.

The successful assembly of thermally stable mesoporous silica molecular sieve silicas with wormhole frameworks from soluble silicate precursors suggests that it may be possible to substitute soluble silicate precursors for the assembly of many other silica mesostructures that heretofore have been assembled exclusively from silicon alkoxide precursors. Future studies will focus on the assembly of other members of the MSU family of mesostructures, as well as SBA mesostructures obtained through an electrostatic $N^o(H^+X^-)I^+$ assembly pathway.[6]

Practical method to recycle a chiral (salen)Mn epoxidation catalyst by using an ionic liquid

Choong Eui Song* and Eun Joo Roh

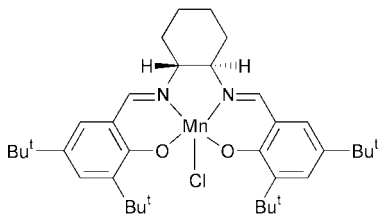
Life Sciences Division, Korea Institute of Science and Technology, PO Box 131, Cheongryang, Seoul, 130-650, Korea. E-mail: s1673@kistmail.kist.re.kr

Received (in Cambridge, UK) 18th February 2000, Accepted 11th April 2000
Published on the Web 28th April 2000

A practical recycling procedure for Jacobsen's chiral (salen)Mn^{III} epoxidation catalyst involving the use of the air- and moisture-stable ionic liquid [bmim][PF_6] has been developed.

Development of practical immobilisation methods[1] for chiral homogeneous catalysts is highly desirable, since immobilised chiral catalysts offer several practical advantages over soluble catalysts such as facilitation of catalyst separation from reagents and products, simplification of methods for catalyst recycling, and the possible adaptation of the immobilised catalyst for continuous flow processes. To this end, some homogeneous chiral catalysts have been immobilised either by anchoring the catalyst on a solid support[1a] or by use of a two-phase system.[1b] All of these approaches are interesting but usually require additional modifications of the catalyst. Moreover, such approaches frequently lead to partial loss of activity and/or enantioselectivity.

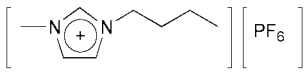
For Jacobsen's chiral (salen)Mn^{III} epoxidation catalyst,[2] [*N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexanediamine]manganese(III)] chloride **1**, several attempts to immobilise this catalyst have been made.[3–6] However, no successful immobilisation procedure has, as yet, been reported. Attempts to immobilise Jacobsen's catalyst up to now consisted of covalent attachment of the complex to insoluble solid supports,[3] steric occlusion in nano-sized cages of zeolites,[4] physical entrapment in a polydimethylsiloxane membrane,[5] and use of a fluorous biphasic system (FBS).[6]



(*R*,*R*)-**1**

Recently, a new approach has been adopted for catalyst separation and recycling in a few types of catalytic reaction involving the use of ionic liquids,[7] *i.e.* a salt mixture with a melting point below ambient. Air and moisture-stable room temperature ionic liquids consisting of 1,3-dialkylimidazolium cations and their counter anions, in particular, have attracted growing interest in the last few years.[8] In these solvents, catalysts having polar or ionic character can be immobilised and thus the ionic solutions containing the catalyst can be easily separated from reagents and products. Recent applications include Friedel–Crafts reactions,[8a] Diels–Alder reactions,[8b] alkylations,[8c] olefin dimerisation and oligomerisation,[8d] hydrogenation,[8e] Heck reaction,[8f] hydroformylation[8g] and palladium catalysed allylation reactions.[8h]

Herein, we report a practical recycling procedure of Jacobsen's catalyst (*R*,*R*)-**1** involving the use of the air- and moisture-stable ionic liquid, [bmim][PF_6] **2** ([bmim]$^+$ = 1-butyl-3-methylimidazolium cation). The ionic liquid **2** is conveniently prepared,[9] and an excellent solvent for many organic compounds, but is immiscible with saturated hydrocarbon solvents, dialkyl ethers and water. Taking into account the conditions of asymmetric epoxidation (involving the use of aqueous NaOCl) and the unique solvating properties of **2**, it was selected as a solvent for our experiments among many other ionic liquids (*cf.* the BF_4^- or triflate salts which are soluble in water).



[bmim][PF_6] **2**

Asymmetric epoxidations† were carried out in the presence of 4 mol% of (*R*,*R*)-**1** with 2,2-dimethylchromene, 6-cyano-2,2-dimethylchromene, indene, *cis*-β-methylstyrene, and 1-phenylcyclohexene as substrates in [bmim][PF_6]–CH_2Cl_2 (1 : 4, v/v) using NaOCl as the oxidant at 0 °C. Since the ionic liquid **2** solidifies at the reaction temperature (0 °C), the co-solvent system was used. Both the catalyst (*R*,*R*)-**1** and the ionic liquid **2** are soluble in CH_2Cl_2. The results obtained are shown in Table 1.

As shown in Table 1, conversion of alkenes to epoxides and enantioselectivity were satisfactory and comparable to those[10] obtained without an ionic liquid. In particular, the epoxidation of 2,2-dimethylchromene and 6-cyano-2,2-dimethylchromene in [bmim][PF_6]-CH_2Cl_2 afforded the corresponding chromene oxides in very high ee (96 and 94%, entries 1 and 2). Moreover, the reaction in the presence of the ionic liquid **2** proceeded faster than without an ionic liquid. For example, the epoxidation of 2,2-dimethylchromene in the presence of **2** was complete in 2 h (entry 1) whereas in a control experiment, the same reaction without **2** required 6 h to achieve a comparable degree of conversion. Furthermore, both the catalyst (*R*,*R*)-**1** and the ionic liquid could be easily recovered after reaction. The recovery procedure was as follows: the organic phase of the reaction

Table 1 Asymmetric epoxidation of alkenes in ionic liquid **2**[a]

Entry	Substrate	*t*/h	Yield[b] (%)	% ee[c]	Confign.[c]
1		2	86	96	(3*R*,4*R*)

mixture was washed with water and concentrated. After extraction of the product with hexane, the brown oily ionic liquid which contains the catalyst, was recovered, which could be reused for further catalytic reactions. The above procedure was repeated five times and results obtained are shown in Table 2. However, the enantioselectivity and the activity of the recovered catalyst decreased slightly upon successive use possibly due to minor degradation of the salen catalyst (*R*,*R*)-**1** under the oxidation conditions.

In summary, we have developed a practical recycling procedure for Jacobsen's chiral (salen)Mn^{III} catalyst **1** by use of ionic liquid **2**. Our results showed that the catalyst (*R*,*R*)-**1** in a reaction medium containing ionic liquid **2** exhibited comparable enantioselectivity (96% ee for 2,2-dimethylchromene) in asymmetric epoxidation of alkenes as those obtained without ionic liquid and, moreover, showed an increase in activity. At the end of reaction the immobilised catalyst in ionic liquid **2** could be easily recycled. In conclusion, the immobilisation method of **1** by using an ionic liquid provides not only simple recycling of catalyst, but also the additional advantage of use of the catalyst without any modification of its structure. A detailed study concerning the optimisation of this process and extension of this methodology to recycle other homogeneous chiral catalysts are currently in progress.

This research was supported by a grant from Korea Institute of Science and Technology.

† *Representative procedure* for asymmetric epoxidation using an ionic liquid: the pH of a solution of commercial household bleach (Clorox®) was buffered to pH = 11.3 with 0.05 M Na_2HPO_4 and 1 M NaOH (a few drops) and then cooled to 0 °C. To 110 mL of this solution was added a precooled solution (0 °C) of 2,2-dimethylchromene (5.0 g, 31.3 mmol) and the catalyst (*R*,*R*)-**1** (0.79 g, 1.25 mmol) in CH_2Cl_2 (30 mL) and [bmim][PF_6] (7.5 mL). The two-phase system was stirred at 0 °C and the progress of reaction was monitored by TLC. After 2 h, the organic phase was separated and washed twice with water. The volatiles were concentrated *in vacuo* and the residue was stirred with hexane. After concentration of the upper hexane phase *in vacuo*, the residue was purified by column chromatography on silica gel (deactivated with 1% NEt_3 solution in ethyl acetate–hexane) with ethyl acetate–hexane (1 : 10) as eluent, to afford 4.74 g (86% yield) of the epoxide with 96% ee. The brown oily ionic liquid phase (the lower phase) containing the catalyst was reused.

Ee values of products were determined by chiral HPLC or chiral GC: for 3,4-epoxy-2,2-dimethylchroman: Daicel Chiralpak AD, propan-2-ol–hexane (5/95), 0.8 mL min^{-1}; 9.30 min (3*R*,4*R*), 10.63 min (3*S*,4*S*). For 3,4-epoxy-6-cyano-2,2-dimethylchroman: Daicel Chiralcel OJ, propan-2-ol–hexane (30/70), 1 mL min^{-1}; 13.95 min (3*R*,4*R*), 26.88 min (3*S*,4*S*). For other epoxides: see ref. 11.

Fluorous soluble polymer ligands have been prepared and shown to be active and selective catalysts when combined with rhodium for the fluorous biphase hydroformylation of various olefins.

One of the most interesting recent developments in homogeneous catalysis is the concept and application of fluorous biphase catalysis (FBC).[1] The principle of FBC is based on the limited miscibility of common organic solvents with perfluorinated compounds. A very attractive aspect of FBC is that it provides, by means of phase separation, an elegant solution to the catalyst/product separation problem associated with homogeneous catalysis. Undoubtedly, successful application of FBC depends on rational design of catalysts that show high affinities to the fluorous phase. Until now, all the fluorous soluble metal catalysts have been based on molecular metal complexes containing conventional ligands modified with fluorinated groups.[2,3] The best known such catalysts are perhaps rhodium trialkylphosphine complexes appended with fluorous ponytails such as $[RhH(CO)\{P(CH_2CH_2C_6F_{13})_3\}_3]$. The applicability of these complexes has been convincingly demonstrated by Horváth and Gladysz in the fluorous biphase hydroformylation,[4] hydrogenation[5] and hydroboration[6] of olefins. As with their nonfluorinated counterparts, however, the rhodium fluoroalkylphosphine catalysts exhibit lower activity in the reactions studied in comparison with complexes containing arylphosphine ligands. Fluorinated, low molecular weight arylphosphines are less useful in FBC, on the other hand, owing to their solubility in common organic solvents such as toluene and hexane.[2,7] Herein we describe fluorous soluble fluoropolymer-supported arylphosphine ligands as an alternative to fluorous soluble low molecular weight ligands for FBC and the application of the new ligands in fluorous biphase hydroformylation of higher and functionalised olefins. We anticipated that by incorporating an arylphosphine into a fluoropolymer the solubility of the former in normal solvents would be minimised. A fluorous soluble copolymer has recently been reported by Bergbreiter and Franchina.[8]

Hydroformylation of higher olefins has been addressed in a number of publications.[9] The focal point is to search for more active and selective rhodium catalysts in conjunction with easy catalyst separation and reuse. The difficulty in catalyst separation encountered in the hydroformylation of higher olefins lies in the thermolability of conventional rhodium phosphine catalysts, high boiling points of the aldehyde product, and limited solubility of higher olefins in water, which could otherwise be employed to immobilise aqueous soluble catalysts. Polymer-supported rhodium catalysts including those that are water soluble have been investigated for the hydroformylation of olefins.[10–13] These catalysts, while potentially having the advantages of both homogeneous and heterogeneous catalysts, often display low catalytic activities.

The poly(fluoroacrylate-*co*-styryldiphenylphosphine) ligands **1** and **2** were prepared by free radical copolymerisation of 1*H*,1*H*,2*H*,2*H*-perfluorodecylacrylate with styryldiphenylphosphine at 65 °C in the presence of AIBN in α,α,α-trifluorotoluene (Scheme 1).[14] For the fluoropolymer **1**, an acrylate to styryldiphenylphosphine molar ratio of 5:1 was used. For **2**, the ratio was 9:1. After removing the solvent, the resultant solid was washed with hot toluene, affording the polymers as white powders in >90% yields. As expected, the polymers are not soluble in normal organic solvents such as toluene, acetone or alcohols but highly soluble in fluorinated solvents such as α,α,α-trifluorotoluene and perfluoromethylcyclohexane. The IR spectrum of both polymers showed the disappearance of the absorption due to C=C stretching, in line with the lack of resonances from olefinic protons in ^{1}H NMR spectra. The C=O absorption appeared at 1738 cm^{-1} for **1** and 1740 cm^{-1} for **2** in the IR spectra. The ^{31}P NMR spectrum of each polymer in α,α,α-trifluorotoluene ($CDCl_3$ external lock) displayed a relatively sharp singlet at δ *ca.* −6.2. The phosphorus content of the polymers was estimated to be 1.2% for **1** and 0.8% for **2** by ^{31}P NMR spectroscopy using bis(diphenylphosphino)methane as an internal standard. These values are close to the values of 1.1 and 0.6% calculated on the basis of the monomer ratios, and are consistent with the high yields of polymer synthesis.

To demonstrate the feasibility of phase separation when using the two polymers as ligands in catalysis, $[Rh(CO)_2(acac)]$ was added to a mixture of hexane (2 mL), toluene (1 mL) and perfluoromethylcyclohexane (2 mL) containing 100 mg of **1** (P/Rh = 6). The fluorous phase attained a yellow colour immediately, while the organic phase remained colourless and phase-separated from the perfluoro solvent at ambient temperature. Upon heating the solvent mixture to *ca.* 50 °C, a single homogeneous yellow phase formed and on cooling, the coloured fluorous phase separated quickly from the colourless organic phase. However, in the absence of hexane, the phase boundary remained even at reflux.

The catalytic performance of the fluoropolymer ligands **1** and **2** was tested in the fluorous biphase hydroformylation of alk-1-enes, styrene and *n*-butyl acrylate. The reaction was conducted in a batch reactor in a hexane–toluene–perfluoromethylcyclohexane (40:20:40, v/v) solvent mixture (10 mL). The catalyst was formed *in situ* by adding $[Rh(CO)_2(acac)]$ (5 μmol, P/Rh = 6) to the polymer-containing solvent mixture followed by introduction of syngas (30 bar, CO–H_2 = 1:1). Table 1 summarises the results obtained. The salient features of the results are (i) the activity of the fluorous soluble polymer catalysts are significantly higher than those reported for solid polymer- and aqueous soluble polymer-supported rhodium catalysts.[10–13] For example, the average turnover frequency

Table 1 Fluorous biphase hydroformylation of olefins by soluble polymer catalysts[a]

Olefin	Polymer	Olefin/Rh	Conversion (%)	Selectivity[b] (%)	L/B[c]
Dec-1-ene	**1**	2120	97	99	4.8/1
	2	2120	90	99	5.9/1
Hexadec-1-ene	**1**	2100	78	98	4.8/1
	2	2100	59	99	5.0/1
Styrene	**1**	3500	85	> 99	1/6.2
	2	3500	80	> 99	1/5.4
n-Butyl acrylate	**1**	2800	100	> 99	B[d]
	2	2800	100	> 99	B[d]

[a] *Reaction conditions*: 5 μmol $[Rh(CO)_2(acac)]$ (P/Rh = 6), 30 bar $CO–H_2$ (1 : 1), 100 °C for dec-1-ene and hexadec-1-ene, 80 °C for styrene and *n*-butyl acrylate, hexane–toluene–perfluoromethylcyclohexane = 4 : 2 : 4 (mL), 15 h reaction time. The products were analysed by ^1H NMR and the conversion and selectivity confirmed by GC. [b] To aldehyde, olefin isomerisation accounts for the product balance. [c] Linear to branched aldehyde ratio, determined by ^1H NMR. [d] The branched product was a 1 : 1 mixture of enol and aldehyde, the linear aldehyde was < 1%.

(TOF) for the fluorous biphase hydroformylation of dec-1-ene is 136 mol aldehyde h^{-1} per mol of rhodium catalyst with an aldehyde selectivity of 99%. In comparison, a rhodium catalyst supported on the water soluble polymer poly(enolate-*co*-vinyl alcohol-*co*-vinyl acetate) gave a TOF of 56 (100 °C, 41 bar) with an aldehyde selectivity < 70% in the aqueous hydroformylation of oct-1-ene.[13] As might be expected, ligand **1**, which has a higher phosphine loading, gave higher turnovers. (ii) As with solid polymer-supported catalysts,[10] the linear/branched (L/B) ratio is markedly higher than achievable with similar P/Rh ratios when using homogeneous rhodium phosphine catalysts, *e.g.* $[RhH(CO)(PPh_3)_3]$, which yielded a L/B ratio of 2.9 only in the presence of an excess of PPh_3 (P/Rh = 19) in the hydroformylation of pent-1-ene in benzene (100 °C, 27 bar).[15] (iii) Smaller olefins appear to give higher turnovers, probably owing to better miscibility of the olefins with the fluorous phase. In fact, when hex-1-ene was hydroformylated under conditions identical to those for dec-1-ene, a conversion of 70% with an aldehyde selectivity of 98% and a L/B ratio of 4.4 was obtained in 1 h reaction time, corresponding to a remarkable TOF of 1454. Again, a low olefin isomerisation selectivity of 1.7% was observed.

The activity and stability of the soluble fluoropolymer catalysts may also be judged by the hydroformylation of hex-1-ene when the olefin/Rh ratio was increased to 200 000. At 100 °C and 50 bar syngas with polymer **1** as the supporting ligand, the catalyst afforded a turnover number (TON, mole of aldehyde per mol of rhodium) of *ca.* 140 000 with a 98% selectivity to aldehyde (L/B = 4.4; 2% isomerisation) for 58 h reaction time. We also examined the recyclability of the fluoropolymer catalysts taking the reaction of hex-1-ene as a model example. The other substrates and related products should be easier to separate under the fluorous biphase conditions as they are less miscible with the perfluoro solvent. At 100 °C and 50 bar with olefin/Rh = 48 000, three consecutive hydroformylation reactions were run, giving a combined TON of 70 000 and an average aldehyde selectivity of 99%. A 1 ppm loss of rhodium accompanied with a 6% decrease in conversion in each recycle experiment was measured. This loss in rhodium and in catalyst activity appears to be largely due to the finite miscibility of the substrate/product with the perfluorinated solvent. At the end of the third run, all the perfluoromethylcyclohexane had leached to the product phase, thus making the polymer catalyst partially soluble in the product. By optimising the operating conditions, *e.g.* by varying the organic solvent, the problem of rhodium leaching can be minimised.

In conclusion, we have introduced a fluorous soluble polymer ligand for FBC and shown the arylphosphine-containing ligand, when combined with rhodium, to be highly active and selective in the fluorous biphase hydroformylation of various olefins. Given the easy availability of various vinyl monomers that can be used for fluoropolymer synthesis and the variability in FBC conditions, better performing soluble polymer catalysts coupled with efficient phase separation could be envisioned not only for FBC but also for fluorous combinatorial chemistry.

We are indebted to the EPSRC and the University of Liverpool Graduates Association (Hong Kong) for postdoctoral research fellowships (W. C. and L. X.).

Configurationally stable metal-centered chirality: stereospecific and regioselective rhodaacylation of alkynes controlled by the third generation of the [Cp′-P]H ligand

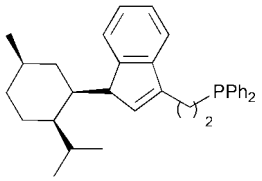
Yasutaka Kataoka,* Yoko Iwato, Atsushi Shibahara, Tsuneaki Yamagata and Kazuhide Tani*

Department of Chemistry, Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka 560-8531, Japan. E-mail: tani@chem.es.osaka-u.ac.jp

Received (in Cambridge, UK) 3rd March 2000, Accepted 7th April 2000

The rhodium cationic complex [[η⁵:η¹-{3-(NIM)Ind-P}$_{n=2}$]Rh(CO)Me]BF_4 (1) reacts with 1-phenylpropyne regioselectively and stereospecifically to afford the alkenyl complex [[η⁵:η¹-{3-(NIM)Ind-P}$_{n=2}$]Rh{η²-O=C(CH_3)-C(CH_3)=CPh}]BF_4 (2).

The design and synthesis of novel chiral transition-metal complexes having a stereogenic metal center provide an elegant and powerful method for stoichiometric or catalytic asymmetric transformations.[1–5] Nonetheless, chemistry using metal-centered chirality is much less developed than that using chiral auxiliaries or ligands.[6] In order to accomplish asymmetric reactions using metal-centered chirality, easy and convenient methods for the preparation of optically active complexes which are configurationally stable at the metal center should be supplied. Recently we have found that the third generation of



[{3-(NIM)Ind-P}$_{n=2}$] H

the [Cp′-P]H ligand, [{3-(NIM)Ind-P}$_{n=2}$]H was effective for controlling the central metal chirality in the oxidative addition of alkyl halide to the Rh carbonyl complex, compared to the first and the second generation of the [Cp′-P]H ligand.[7,8] Thus, oxidative addition using metal complexes with the third generation of the Cp′-P ligand could become a new preparation of an optically active complex having a metal-centered chirality. In order to use the chiral complex as an asymmetric catalyst, racemization or epimerization at the metal center must be prevented. Herein we show that the metal-centered chirality controlled by the {3-(NIM)Ind-P}$_{n=2}$ ligand[9] is configurationally stable, which causes the stereospecific and regioselective addition of alkynes to its cationic Rh complex.

The cationic rhodium complex, [[η⁵:η¹-{3-(NIM)Ind-P}$_{n=2}$]Rh(CO)Me]BF_4 (**1**), which was readily prepared from [η⁵:η¹-{3-(NIM)Ind-P}$_{n=2}$]RhI(COMe) and $AgBF_4$,[8] is a mixture of two diastereomers (major : minor = 96 : 4, 92% de).† Reaction of complex **1** with 1-phenylpropyne in CH_2Cl_2 at room temperature for 48 h afforded the alkenyl complex **2** in 79% isolated yield (Scheme 1).‡ From the ^1H or ^{31}P NMR of the reaction mixture, **2** was found to contain only two isomers (major : minor = 96 : 4). The structure of **2**-major was confirmed by the usual spectroscopic methods as well as X-ray crystallography (Fig. 1).§ The stereochemistry around the Rh is *S*, and the planar chirality is *R*. Complex **2** was produced through migratory insertion of CO into the Rh–Me bond in **1**[10] and the subsequent rhodaacylation of the alkyne,[11] followed by intramolecular coordination of the acyl oxygen to the Rh. Since four isomers from each diastereomer of **1**, based on the difference in the metal-centered chirality and the regiochemistry of the olefin, are possible, this transformation totally has the potential for the formation of the eight isomers. The results, however, indicated that only one isomer was produced from each diastereomer of **1**; the isomer ratio of **2** was the same as that of the starting complex **1**.† Thus, the metal-centered chirality did

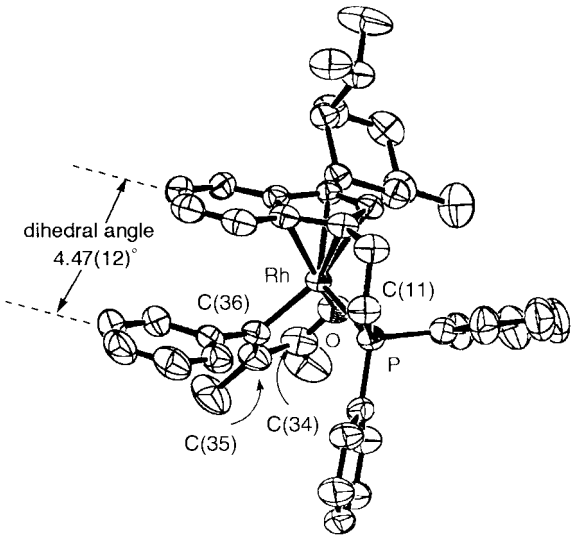

Fig. 1 ORTEP drawing of the X-ray crystal structure of the cationic part of **2**-major. Selected bond lengths (Å) and angles (°): Rh–O 2.0719(15), Rh–P 2.2690(6), Rh–C(36) 2.023(2), C(36)–C(35) 1.362(3), C(34)–C(35) 1.428(4), O–C(34) 1,258(3); Rh–O–C(34) 114.79(17), Rh–C(36)–C(35) 115.13(19), Rh–P–C(11) 105.86(12), O–C(34)–C(35) 118.5(2), C(36)–Rh–O 77.98(8), C(34)–C(35)–C(36) 113.5(2). The shortest interatomic distance between the indenyl group and the phenyl ring is 3.278(4) Å.

DOI: 10.1039/b001735n

not racemize or epimerize throughout these transformations and the regiochemistry of the olefinic part was completely controlled.

The mixed ligand complex containing both an indenyl and a tertiary phosphine ligand which are not connected by a spacer, $[Rh(\eta^5\text{-}C_9H_7)(PPh_3)(CO)Me]BF_4$, did not react with 1-phenylpropyne at room temperature. Although the cationic complex having the second generation Cp′-P ligand, $[[\eta^5:\eta^1\text{-}(Ind\text{-}P)_{n=2}]Rh(CO)Me]BF_4$, with 46% de (major : minor = 73 : 27) also reacted with 1-phenylpropyne under the same conditions, the corresponding alkenyl complexes comprised four diastereomers (69 : 24 : 5 : 1).† The third generation of the [Cp′-P]H ligand was much more effective for controlling the stereochemistry in this rhodaacylation.

Reaction of **1** (92% de) with phenyl acetylene in CH_2Cl_2 at room temperature for 12 h gave the corresponding alkenyl complex **3** with 92% de (Scheme 1).† The diastereomer excess of **3** was also almost the same as that of **1**. This reaction also proceeded stereospecifically. ^{1}H NMR of **3** showed a doublet with a small coupling constant (J = 1.4 Hz) at δ 6.21 for the olefinic proton and the HMQC spectrum showed that the proton was correlated to the β-olefinic carbon from Rh. Reaction of complex **1** (92% de) with trimethylsilylacetylene under the same conditions afforded the alkenyl complex **4** with 91% de (Scheme 1).†¶ This reaction also proceeded stereospecifically, but the opposite regioisomer to the product of the reaction with phenylacetylene was obtained. The structure of **4**-major was confirmed by the usual spectroscopic methods as well as X-ray crystallography. ^{1}H NMR revealed a doublet of doublets at δ 9.06 (J = 11.8 and 1.6 Hz) for the olefinic proton originating from the terminal acetylenic hydrogen. When trimethylsilylacetylene was used, the bulkier indenyl Rh moiety would attack the less hindered acetylenic terminal carbon selectively in the rhodaacylation process. In contrast, in the rhodaacylation of 1-phenylpropyne or phenylacetylene, the Rh–carbon bond was formed at the more hindered site.[12]

We are currently investigating application of the reaction to the stereoselective synthesis of general substituted olefins using a catalytic amount of a rhodium complex containing the Cp′-P ligand. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture of Japan, and General Sekiyu Research & Development Encouragement & Assistance Foundation.

Notes and references

† The isomer ratio was determined by ^{31}P NMR of the crude product obtained after removal of the solvents from the reaction mixture.

‡ *Preparation* of **2**: to a solution of **1** (20 mg, 0.028 mmol, 92% de) in CH_2Cl_2 (5 mL) was added 1-phenylpropyne (4 μL, 0.032 mmol) at room temperature. The reaction mixture was stirred for 48 h and then the solvent was removed *in vacuo* to give orange powders, which contained a diastereomeric mixture of **2**. The ratio was determined by ^{31}P NMR (major : minor = 94 : 6, 92% de). After washing with Et_2O (10 mL) and hexane (2 × 10 mL), recrystallization of the crude product from CH_2Cl_2 and Et_2O afforded **2** (18 mg, 0.022 mmol, 79%, major : minor = 94 : 6, 92% de) as analytically pure orange powders, mp 118–122 °C (dec.). δ_H ($CDCl_3$, major) 0.37 (d, J = 6.3 Hz, 3 H), 0.86 (d, J = 6.6 Hz, 3 H), 1.15 (d, J = 6.0 Hz, 3 H), 1.42 (d, J = 1.6 Hz, 3 H), 1.48–1.89 (m, 6 H), 1.92–2.10 (m, 2 H), 2.38 (d, J = 2.2 Hz, 3 H), 2.30–2.53 (m, 2 H), 2.69–2.98 (m, 2 H), 3.82–3.99 (m, 1 H), 4.05–4.23 (m, 1 H), 5.39 (s, 1 H), 6.15 (dd, J = 8.2, 1.1 Hz, 2 H), 6.29–6.38 (m, 1 H), 6.40–6.48 (m, 1 H), 6.83–6.93 (m, 1 H), 6.99–7.09 (m, 1 H), 7.16–7.41 (m, 8 H), 7.46–7.61 (m, 3 H) and 7.87–7.99 (m, 2 H). ^{31}P{^{1}H} NMR ($CDCl_3$) δ 55.1 (d, $J_{P–Rh}$ = 179 Hz, major) and 62.0 (d, $J_{P–Rh}$ = 181 Hz, minor). ^{13}C{^{1}H} NMR ($CDCl_3$) δ 232.2 (dd, J = 26, 12 Hz, *C*=C(Ph), major). 12 Although DeShong *et al.* reported that regiochemistry in the insertion of an unsymmetrical alkyne into the Mn–carbon bond was controlled by the electronic character of the substituents of the alkyne,[13] we think that one of the reasons for the regioselectivity in the reaction of arylacetylenes could be the π–π stacking between the phenyl ring and the indenyl benzene ring. The presence of the π–π stacking could be also supported by the X-ray crystallographic analysis of **2**-major (Fig. 1).

Effect of substitution on the curvature and bowl-to-bowl inversion barrier of bucky-bowls. Study of mono-substituted corannulenes ($C_{19}XH_{10}$, X = B^-, N^+, P^+ and Si)

***Ab initio* MO and DFT calculations predict that replacement of a single carbon by an isoelectronic species on the corannulene skeleton can effectively arrest the bowl shape or flatten it and the bowl rigidity, curvature and relative stabilties of the positional isomers are solely controlled by the size of the substituent and site of substitution.**

Corannulene, $C_{20}H_{10}$, which forms the 'polar cap' of the buckminister-fullerene is the simplest bucky-bowl, where the warping of sp^2-carbon surface enforces the molecule to adopt a bowl-like geometry. The curvature in bucky-bowls results in two distinct surfaces, convex and concave, and alters the properties such as dipole moment, ionization potential, metal binding *etc*.[1] Despite the substantial curvature present in corannulene, it is highly fluxional and the bowl-to-bowl inversion is rapid,[2,3] the resulting non-rigidity of its bowl structure is in contrast to that of fullerenes. Our interest lies in finding out simpler modifications that are required to effectively 'lock' the bowl geometry of corannulene. Previous studies indicate that locking the bowl structure requires the addition of one more fused five-membered ring.[4] Construction of a cyclophane bridge seems to be another strategy to lock the bowl structure.[5] Substitution on corannulene is not expected to have any significant effect on the rigidity or inversion barrier.[1b] It occurred to us that the simplest of the strategies might be to look at the replacement of skeletal carbon atoms on the corannulene by an electronically equivalent heteroatom substituent, such as X = B^-, N^+, P^+ or Si. Accordingly, as a first step mono-substitutions have been placed at three unique positions of corannulene namely at hub (**1**), rim-quat (**2**) and rim (**3**).

The geometries of all the structures of substituted corannulenes depicted in Scheme 1 are optimized at *ab initio* Hartree–Fock level using 3-21G basis set using the GAUSSIAN 94 program package.[6] Frequency calculations confirm that all the bowl structures are minima and planar structures are transition states corresponding to bowl-to-bowl inversion.† The effects of inclusion of electron correlation and improving the basis set quality on energetics are estimated by performing single point calculations using the B3LYP procedure with the 6-31G* basis set.

Scheme 1

The relative energies of the positional isomers in their minimum energy conformation as well as the TS for bowl-to-bowl inversions are given in Table 1. The reference structure is taken as the hub (**1**) substituted minimum energy isomer, which in general has a non-planar bowl-like geometry. A strong preference is shown to occupy the rim position (**3**) followed by rim-quat (**2**) and hub (**1**) positions for substituents, where X = B^-, P^+, or Si. In contrast, a complete reversal of the relative stabilities of positional isomers is seen for X = N^+, which results in the following increasing order of stability, **3b** < **2b** < **1b**. The thermodynamics of the positional isomers seems to be solely controlled by the size of the substituent. In this context, the C–X bond length is taken to gauge the size of X, as C–B, C–P and C–Si bonds are longer and C–N is shorter than the C–C bond, B^-, P^+ and Si are classified as larger substituents and N^+ as a smaller substituent. Accordingly, larger heteroatom substituents when compared to C prefer to occupy the rim position and smaller ones prefer the hub position, and this preference seem to be independent of the charge present on the system, as well as the electronegativity of the substituent. The relative stabilities of these positional isomers may be directly traced to the angular strain caused by the substituent, *i.e.* a larger atom at hub position will bring in more strain in the corannulene skeleton where as it relieves the strain at the terminal position. Accordingly, larger atoms prefer to be substituted at the rim (**3**) position, while the smaller at the hub (**1**) position. The curvature of the minimum energy bowl structures and the alteration of C–X bond lengths when going from the bowl structure to the transition state, which are key geometric changes, are depicted

[a] The angle ϕ which is a measure of pyramidalization is defined as $\phi = 360 - (\theta_1 + \theta_2 + \theta_3)$ where θ_1, θ_2 and θ_3 are the bond angles around the unique hub atom, which is X in **1** and C closest to X in **2** and **3**. [b] $\phi = 6.4$ for corannulene. [c] Unsubstituted corannulene shows: $r_1 = 1.415 \rightarrow 1.393$, $r_2 = 1.359 \rightarrow 1343$, $r_3 = 1.449 \rightarrow 1.467$, $r_4 = 1.368 \rightarrow 1.383$.

in Table 2. The curvature especially of hub substituted isomers, depends on the pyramidalization tendency of the substituent. Thus, second row substituents (P^+ and Si) gives deeper and more rigid bowls compared to their first row analogs (B^- and N^+). This reflects the fact that the structures with higher barriers show greater changes in C–X bond lengths and *vice versa*. The values of ϕ ranging from 1.5 to 78.1° indicate a broad spectrum of variations in the curvatures of the bowl isomers considered in the present study.

The most interesting finding is the effect of substitution on bowl-to-bowl inversion barriers. A clear qualitative difference between the substituents with larger atomic size than carbon and those with smaller atomic size is noted. Thus, when X = B^-, P^+ or Si, the inversion barrier is very high for **1** and decreases while going to rim-quat (**2**) and rim (**3**) substituted ones. In sharp contrast N^+ substituted at hub (**1**) position, **1b**, substantially reduces the bowl-to-bowl inversion barrier while the rim (**3**) substituted isomer, **3b**, doubles the inversion barrier compared to that of the pristine corannulene molecule. Thus, mono-substitution with larger substituents at hub (**1**) positions rigidifies the bowl, while at rim (**3**) position makes it more fluxional and flatter compared to the parent corannulene. The substitution by smaller substituents has exactly the opposite effect with regards to bowl-to-bowl inversion. The inversion barrier for all the rim-quat substituted (**2**) positional isomers, seems to be less sensitive to the nature of substituent and in all cases the barrier is of similar magnitude to that of corannulene.

Interestingly, the isomer with largest inversion barrier is found to be the least stable and possesses the highest ϕ indicating the maximum curvature. This highlights the interconnectivity of the curvature, stability and inversion barriers in this series of isomers. Therefore, effectively the size and site of substitution decides the curvature, stability and bowl-to-bowl inversion barriers. Thus, Si, the largest substituent considered, when substituted at hub (**1**) position gives the most rigid bowl and leads to an increase in the inversion barrier by almost seven-fold compared to that of unsubstituted corannulene! In contrast, **3d**, the rim (**3**) substituted Si isomer yields the least curved surface with an insignificant inversion barrier. The magnitude of the imaginary frequency seems to give a good measure of the inversion barrier, thus the highest value of 188.9i cm^{-1} and lowest of 53.2i cm^{-1} correspond to the structures with highest (**1d**) and lowest (**3d**) bowl-to-bowl inversion barriers, respectively.

The stabilities of the mono-substituted corannulenes are estimated using the isodesmic equation eqn. (1), in which the most stable isomer is considered in each case (**2a**, **1b**, **3c** and **3d**). C_5XH_6 and C_6H_6 represent the mono- and un-substituted benzene ring respectively in eqn. (1). The results indicate that, except for **1c** (P^+) and **1d** (Si), in all other isomers the replacement of a C by the isoelectronic X is more feasible (thermodynamically) in corannulene than in benzene.‡

$$C_{20}H_{10} + C_5XH_6 \longrightarrow C_{19}XH_{10} + C_6H_6 \quad (1)$$

X	a(2)	b(1)	c(3)	d(3)
ΔE/kcal mol^{-1}	−31.6	−19.8	−30.1	−21.6

The present study indicates that in mono-substituted corannulenes, the relative stabilities of positional isomers, curvature and bowl-to-bowl inversion barriers are interconnected and all of which seem to be mainly controlled by the size of the substituent. Rational synthetic design of fullerenes in a stepwise manner is severely hampered owing to the enormous strain energy build-up in the skeleton which is chiefly attributed to high incremental jumps in the strain as the curvature increases.[7] A rigid bowl with a substantial built-in strain might be a better precursor for further building-up of the cage structure, compared to a flat or flexible bowl. In this regard, P^+ or Si substituted corannulenes at **1** position promise to be good rigid frameworks for further fusing of five/six-membered rings *en route* to hetero-fullerene cages.

We thank UGC, New Delhi and AICTE for financial assistance.

Notes and references

† The planar isomer **3c** gives two imaginary frequencies in the force calculation. That with higher magnitude corresponds to bowl-to-bowl inversion, while the other much lower frequencies (69.1i cm^{-1}) can be ignored and the planar structure can be considered as a TS for all practical purposes.

‡ The energetics given are at HF/3-21G level.

[3]Rotaxanes employing multiple 1,2-bis(pyridinium) ethane binding sites and dibenzo-24-crown-8 ethers†

Stephen J. Loeb* and James A. Wisner

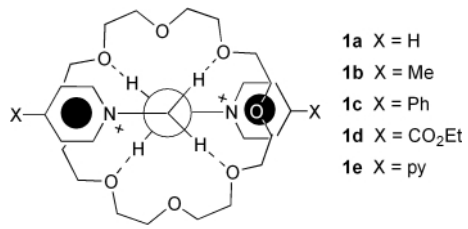
Received (in Columbia, MO, USA) 17th January 2000, Accepted 31st March 2000
Published on the Web 28th April 2000

Two binding sites of the 1,2-bis(pyridinium)ethane type are built into an extended axle on to which two molecules of dibenzo-24-crown ether (DB24C8) can thread to produce the first examples of [3]rotaxanes employing this templating motif.

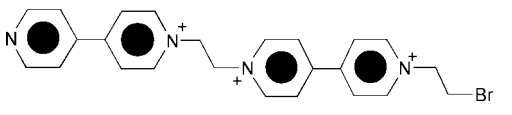
[2]Pseudorotaxanes are commonly used as precursors for the formation of permanently interlocked [2]rotaxanes by addition of 'stopper' components which are bulky enough to prevent unthreading.[1,2] We have recently demonstrated that various 1,2-bis(pyridinium)ethane dications will thread through the 24-membered crown ethers 24C8, B24C8 and DB24C8 to produce a new series of [2]pseudorotaxanes **1a**–**e**.[3]



For a 1,2-bis(4,4′-bipyridinium)ethane **1e**, (X = py) axle and a DB24C8 wheel, we have shown that the [2]pseudorotaxane is easily converted to a permanently interlocked [2]rotaxane.[4] This was achieved either by alkylation at the terminal pyridine nitrogen atoms with bulky *tert*-butylbenzyl groups, **2**, or stoppering with appropriately large organopalladium fragments, **3**.

Herein, we describe the synthesis of both symmetrical and unsymmetrical [3]rotaxanes by employing extended axles containing two binding sites for a dibenzo-24-crown-8 ether molecule. Although the rotaxanes presented here are saturated and therefore display no translational isomerism, such higher order [*n*]rotaxanes ($n > 2$) are not nearly as prevalent as simpler [2]rotaxanes.[5] The study of these multiple-sited systems is important for the future development of molecular devices such as those based on Stoddart's notion of a molecular shuttle.[6,7]

The key synthetic intermediate in this work is **4b**, which can be used to alkylate a pyridine derivative to create a second



4a X = Br
4b X = BF_4

bis(pyridinium)ethane binding site.[8] We reacted **4b** with 4-*tert*-butylpyridine, to produce **5** (Scheme 1), since the Bu^t group can act directly as a stopper and with 4,4-bipyridine, to yield **6** (Scheme 2), as this provides a terminal pyridine moiety. Subsequent monoalkylation of **5** and dialkylation of **6** with *tert*-butylbenzyl bromide yields the dumbbell shaped axles **7** and **8**.

† Dedicated to Professor Christopher J. Willis on the occasions of his retirement and 66th birthday.

The [3]rotaxanes **9** and **10** were prepared by mixing **5** and **6**, respectively, with four equivalents of DB24C8 in MeCN solution followed by a two-fold excess of the required equivalents of *tert*-butylbenzyl bromide.‡

Non-covalent interactions between axle and wheel are evident from significant chemical shift differences in the solution (CD_3CN) ^{1}H NMR spectra of **9** and **10** when compared to **7**, **8** and free DB24C8. A network of *sixteen* C–H···O hydrogen bonds from axle protons to crown ether O-atoms is evident in both **9** and **10** from the significant *downfield* shifts for all α^+-pyridinium (0.30–0.36 ppm) and $^+NCH_2$ protons (0.21–0.42 ppm). In addition, π-stacking between the electron-rich catechol and electron-poor pyridinium rings is indicated for both rotaxanes by *upfield* shifts observed for the β-pyridinium protons (0.25–0.56 ppm) and crown aromatic protons (0.17–0.42 ppm). Also, since the *tert*-butylpyridinium stopper for the asymmetric [3]rotaxane **9**, is one aromatic ring closer to the center of the molecule, we also observe a C–H···π interaction between the *tert*-butylpyridinium methyl protons and the crown aromatic group ($\Delta\delta = -0.24$ ppm). Unfortunately, the different environments of the DB24C8 catechol rings could not be distinguished by low temperature ^{1}H NMR spectroscopy owing to the facile nature of the interconversion process.

An X-ray crystal structure determination§ of **10** verified the nature of the interactions observed in solution (Fig. 1). The two DB24C8 rings are threaded on to the centrosymmetric tris(bi-

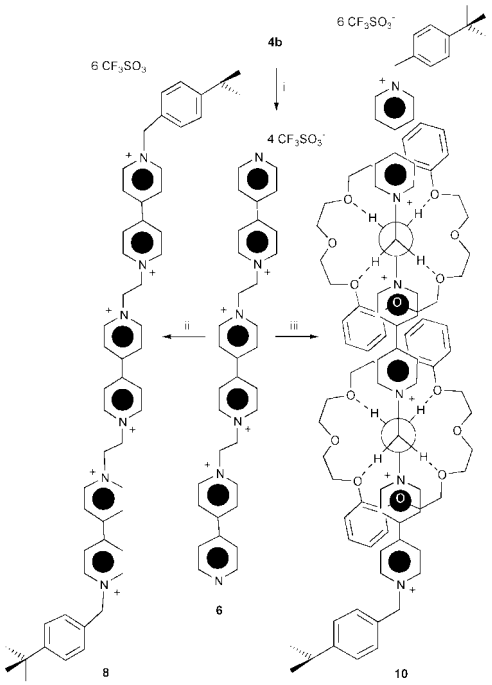
DOI: 10.1039/b001018i



Scheme 2 *Reagents and conditions*: i, 4,4′-bipyridine, $MeNO_2$, 60 °C, 3 days, $NaCF_3SO_3$(aq), 18%; ii, 4-*tert*-butylbenzyl bromide, $MeNO_2$, 60 °C, 24 h, $NaCF_3SO_3$(aq), 22%; iii, 4-*tert*-butylbenzyl bromide, DB24C8, MeCN, room temp., 2 days, SiO_2 [MeOH–$MeNO_2$–2.0 M NH_4Cl(aq), 3 : 1 : 1], R_f = 0.44, $NaCF_3SO_3$(aq), 15%.

pyridinium) axle such that the S-shaped crown ether rings stack stepwise over the three sets of bipyridinium rings. A unique feature of this particular [3]rotaxane design is that the central bipyridinium ring is sandwiched between two aromatic rings from separate crown ether wheels. This has the potential to allow direct communication between the two binding sites through the wheel–axle–wheel overlap. The centrosymmetric [3]rotaxane **10** shows $N^+\cdots O$ interactions ranging from 3.51 to 3.65 Å and *sixteen* C–H···O hydrogen bonds with CH···O distances in the range 2.26–2.77 Å. The orange–red colour of the solid material and the UV absorption data in MeCN solution are consistent with charge transfer interactions between the electron-rich rings of the crown ether and the electron-poor rings of the bipyridinium fragments.

It is clear that the 1,2-bis(pyridinium)ethane/24-crown-8 ether templating motif can be extended to multiply interlocked molecules as demonstrated herein by the synthesis of symmetrical and unsymmetrical [3]rotaxanes.

Axially coordinated porphyrins as new rotaxane stoppers

Kelly Chichak, M. Catherine Walsh and Neil R. Branda*

Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2G2. E-mail: neil.branda@ualberta.ca

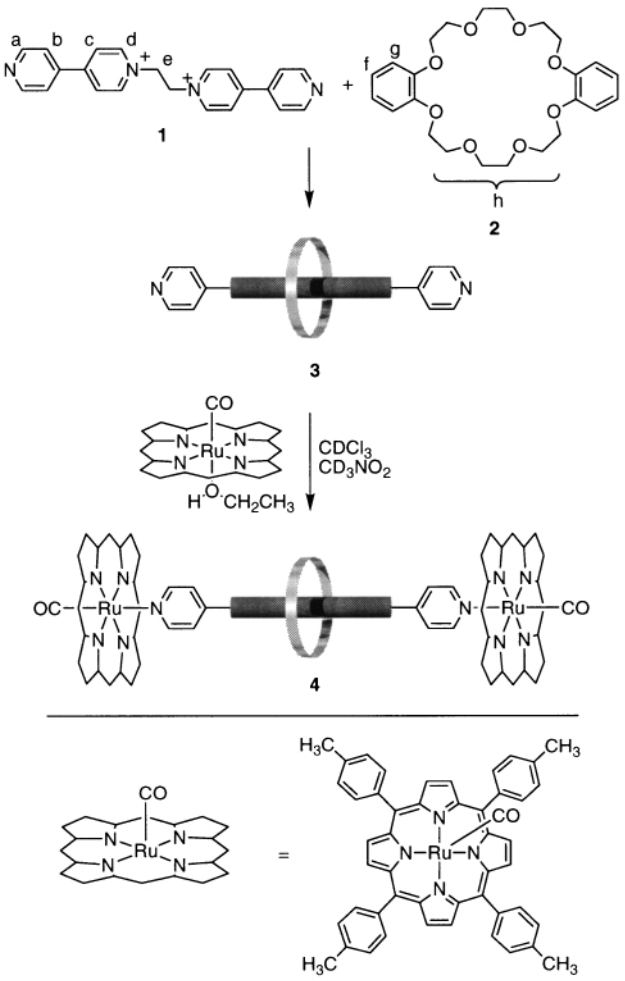
Received (in Columbia, MO, USA) 14th February 2000, Accepted 24th March 2000

Coordination to the axial position of the metalloporphyrin Ru(TTP)(CO) is an effective means to end-cap the 1,2-bis(4,4′-dipyridinium)ethane dication·dibenzo[24]-crown-8 [2]pseudo-rotaxane and generate the stable porphyrinic [2]rotaxane 4.

In order for rotaxanes to be used effectively as architectures when building nanoscale machines and new materials, the macrocyclic wheel, once threaded onto the molecular axle, must be held there to prevent the components from disassembling.[1] This task is typically carried out by covalently fastening bulky stoppers onto the two ends of the axle. Using this strategy, pseudo-rotaxanes are transformed into permanently interlocked rotaxanes.[2] An alternative approach (slippage), which is a thermodynamically driven self-assembly process, involves the threading of a presynthesized axle through the macrocyclic wheel under the influence of appropriate heating.[3] However, the harsh reaction conditions that tend to accompany the first strategy may not be conducive for synthesizing rotaxanes containing highly sensitive molecular components. The slippage strategy is also limiting in that rotaxanes can only be prepared from axles small enough to allow for the wheel to pass over them. A recently reported solution to these problems utilizes the dynamic nature of the imine bond to end-cap pseudo-rotaxanes under thermodynamic control.[4] An alternative to using reversible carbon–heteroatom bond formation is to exploit metal-directed self-assembly synthesis, which again has the advantage of being thermodynamically driven but is accomplished more rapidly and under milder conditions. Despite its being introduced almost two decades ago, there are few examples that utilize this approach to generate interlocking structures.[5]

The growing interest in rotaxanes containing chromophores as stoppers[6] prompted us to develop mild porphyrin-based end-capping methods. Porphyrins are particularly attractive stoppers not only because of their bulkiness, but also because of their rich electro- and photo-physical properties, which have played important roles in synthetic electron and energy transfer systems.[6] In this study, we continue to use axial coordination to the central metal of Ru(TTP)(CO)† as a means to self-assemble porphyrin arrays in light of our recent success in rapidly generating thermodynamically controlled multicomponent arrays.[7] What we sought was a pseudo-rotaxane displaying divergent Lewis-basic sites appropriately distanced from the threaded wheel so as not to interfere with the self-assembly process. The 1,2-bis(4,4′-dipyridinium)ethane dication·dibenzo[24]crown-8 [2]pseudo-rotaxane **3** recently spot-lighted by Loeb and Wisner[5] provided the suitable model rotaxane for our purpose (Scheme 1).

Dissolving equimolar amounts of **1** and **2** in a 1 : 1 mixture of $CDCl_3$ and CD_3NO_2‡ immediately generated [2]pseudo-rotaxane **3** as apparent by ^{1}H NMR spectroscopy. A comparison of the integrals of the signals for free and bound **1** and **2**, both of which were clearly separated in the ^{1}H NMR spectrum, allows for facile determination of the association constant (K_a) in the slow-exchange threading process. This value was measured to be in the range of 3000–10000 M^{-1} in the mixed-solvent system (1–3 mM solutions). We prefer to report K_a as being within a range because we found that the extent of threading was sensitive to the concentration of **1** and **2** in the sample, with the magnitude of the association constant increasing as the concentration of both components are raised.§ We attribute this unexpected concentration dependency to the trace amount of residual water in the solvents. Because the solvent shells surrounding all species (**1**–**3**) certainly can include water, it is reasonable to assume that the concentration of free and bound water would change throughout the complexation reaction at the low water concentrations found in these solutions. The result is that water cannot be eliminated from the thermodynamic equilibrium equation and will thus have a great effect on the ability to form the [2]pseudo-rotaxane **3**. In this way, the slightly hydrous nature of the solvents used affects the precision of our measurements. Our support for this suggestion comes in the observed lowering of K_a for solutions at any concentration when additional water was added to the sample. The association constants leveled out to 800–1000 M^{-1} when enough water (200–300 equivalents) was added so that its concentration remains unchanged during the threading process. Despite this, the strength of the interactions holding the interlocked components together compensates for the presence of such a competitive solvent like water.



Scheme 1 PF_6^- counter ion.

DOI: 10.1039/b001259i

^{1}H NMR analysis of **3** also revealed the C–H···O hydrogen bonds and π–π stacking interactions responsible for driving the threading process.[5] When 2 mol equivalents of Ru(TTP)(CO)(EtOH) are added directly to the NMR sample, signals for the hydrogen atoms of both **1** and **2** shift significantly upfield, as would be expected for protons that reside within the additive shielding cones of the porphyrin stoppers.¶ The hydrogen atoms immediately adjacent to the coordinating nitrogen are closest to the end-caps (2.7 Å average nitrogen-to-porphyrin distance) and are the most affected by the anisotropic effect (Table 1). The shielding is minimally felt by the methylene (CH_2) protons of the dication axle which are as far as 10.2 Å from the stoppers, although it is still significant ($\Delta\delta$ = 0.72 ppm). All protons on the crown ether are also shielded, the most effected being those on the phenyl ring which are 3.0 and 5.1 Å from the mean centre of the porphyrin planes.

Table 1 Selected ^{1}H NMR data (500 MHz) of **4** in $CDCl_3$–CD_3NO_2 (1:1)

Axle fragment					Wheel fragment			
	H(a)[a]	H(b)	H(c)	H(d)	H(e)	H(f)	H(g)	H(h)
δ	1.65	5.36	6.91	8.60	5.01	5.33	5.94	3.67–3.59
$\Delta\delta$[b]/ppm	−7.18	−2.14	−1.17	−0.72	−0.72	−1.37	−0.76	−0.48

[a] Atom numbering scheme refers to Scheme 1. [b] Refers to upfield shifts of the protons relative to those in the spectrum of [2]pseudo-rotaxane **3**.

Addition of an excess of a competitive Lewis basic solvent such as pyridine to solutions of **4** resulted in the quantitative displacement of the stoppers as Ru(TTP)(CO)(py) and the regeneration of the dynamic mixture of pseudo-rotaxane **3** and the non-threaded wheel and axle. This study reveals the dynamic nature of the end-capping process.

Crystals of [2]rotaxane **4** suitable for structure determination were obtained by treating acetone solutions of **1** with excess **2**, end-capping the quantitatively formed [2]pseudo-rotaxane **3** with 2 mol equivalents of Ru(TTP)(CO)(EtOH), followed by slow evaporation. The crystal structure‖ (Fig. 1) is consistent with the binding interactions observed in the ^{1}H NMR spectrum. All methylene protons of **1** are within hydrogen bond distances to the oxygen atoms of the crown ether (average C···O distance = 3.54 Å). Also, the phenyl rings of the crown ether wheel are lying parallel to the heterocycles of the axle within π–π stacking range (mean Ar–Ar distance = 3.4 Å). The crystal structure shows that the distance between the porphyrin walls [Ru(1)···Ru(2) 21.692(3) Å] is just enough to accommodate the entire crown ether fragment without sacrificing any of the favourable π–π stacking interactions between the wheel and the axle.

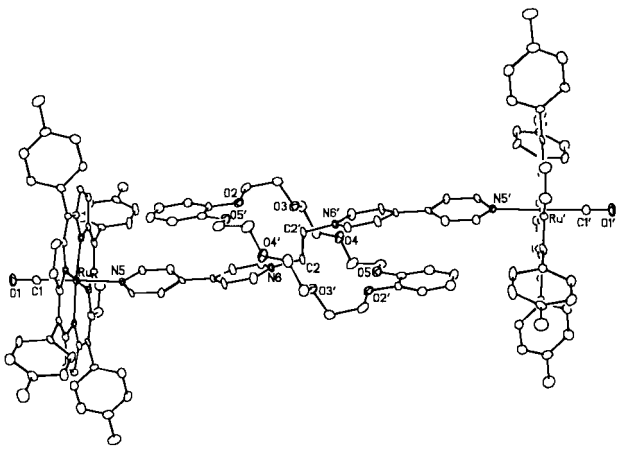


Fig. 1 Molecular structure of [2]rotaxane **4** in the crystal. The thermal ellipsoids are drawn at the 20% probability level.

We have shown that axial coordination is an effective self-assembly method to convert dynamic [2]pseudo-rotaxanes into stable interlocked [2]rotaxanes. The stoppers can be removed under mild conditions by treating **4** with the appropriate solvent. This end-capping strategy will be useful when removable stoppers are desired. Photochemical studies are underway in order to evaluate the influence the porphyrins have on the charge transfer process that has already been observed in the [2]pseudo-rotaxane.[5]

Notes and references

† TTP = 5,10,15,20-tetratolylporphyrinato dianion.

‡ Although the [2]pseudo-rotaxane is soluble in single-solvent systems such as nitromethane and acetonitrile, the poor solubility of Ru(TTP)(CO)(EtOH) in nitromethane alone eliminated the possibility of using this solvent. Acetonitrile was avoided as its nitrogen atom effectively competes as a Lewis base with those on **1** for coordinating to the transition metal. Once formed, however, the [2]rotaxane **4** is freely soluble in organic solvents alone such as $CHCl_3$ and CH_2Cl_2.

§ Representative K_a values were measured to be 4161 M^{-1} (1.2 mM solution), 4647 M^{-1} (2.2 mM solution) and 9356 M^{-1} (3.3 mM solution).

¶ Rotaxane **4** was also characterized by IR and ES-MS.

Received (in Columbia, MO, USA) 20th December 1999, Accepted 24th March 2000

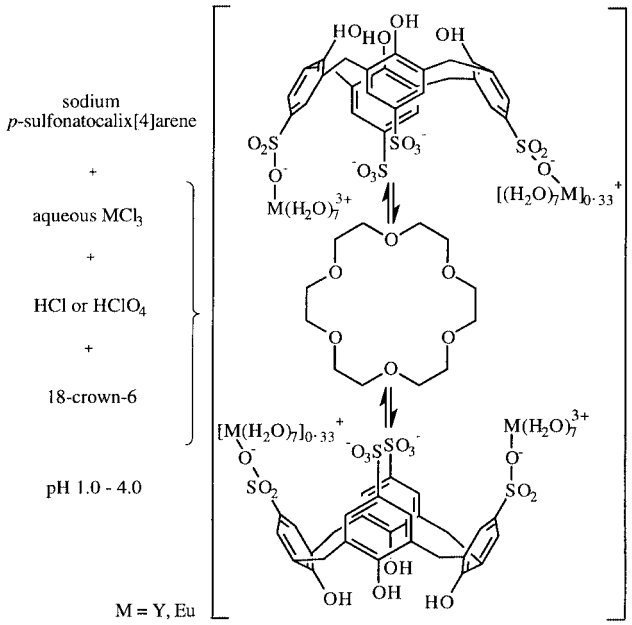
A combination of hydrogen bonding and metal coordination leads to the formation of the new solid state molecular capsule [{18-crown-6}⊂{($Y(H_2O)_7^{3+}$)$_{1.33}$(*p*-sulfonatocalix[4]arene^{4-})}$_2$] at pH between 1.0 and 4.0.

Certain rigid, non-planar molecules with curved or bowl shaped micro-environments have the extraordinary ability to assemble into capsules or cage molecules or ions.[1–12] These species may form nano-structures of relevance to materials and biological science, and their encapsulation of guest molecules has implications for drug delivery and catalysis.[13] The hydrophobic, bowl shaped motif of calixarenes and related resorcinarenes make them inherently versatile building blocks for the construction of ionic or molecular capsules. They afford capsules based on the assembly of two[4] or six[3] sub-units or supramolecular tectons in which the assembly is primarily driven by the interplay of hydrogen bonding between the subunits. This may involve additional hydrogen bonding associations with solvent molecules. Capsules derived from aqueous media usually rely on metal ion complexation to drive the assembly process.[10,11] An exception is the ionic capsule [{Na^+⊂(18-crown-6)$(OH_2)_2$}⊂{*p*-sulfonatocalix[4]arene^{4-})$_2$} + nH^+]$^{(7+n)-}$, which incorporates both hydrogen bonding and metal complexation.[12]

Herein, we report the use of a combinatorial approach for the synthesis of a complex based on molecular capsules, [{18-crown-6}⊂{($Y(H_2O)_7^{3+}$)$_{1.33}$(*p*-sulfonatocalix[4]arene^{4-})}$_2$] **1**.† Combinatorial chemistry has thus far been of limited application in supramolecular chemistry.[14] The supramolecular combinatorial library used contains all the interacting synthons including the degree of protonation of the calixarene (achieved by varying pH) and the relative ratios of the synthons, with crystallisation indicative of capsule formation. Its noteworthy that Atwood *et al.* have established a rich supramolecular chemistry of *p*-sulfonatocalix[4]arene and the lanthanides in the absence of crown ethers.[15,16]

Complex **1** crystallises from an aqueous solution of sodium *p*-sulfonatocalix[4]arene, 18-crown-6, yttrium(III) chloride, and hydrochloric acid as the tetrahydrate at a pH between 1.0 and 4.0 (Scheme 1). The highest optimised yield of 68% was for a pH close to 2.0 with the pH varied by 0.25 pH units. Above pH 4.0 and below pH 1.0 no complex precipitated from solution. Interestingly using perchloric acid resulted in oxidation of the calixarene and formation of crystalline $Y_2(SO_4)_3(H_2O)_8$ at pH < 2.0,‡ isostructural with other known $Ln_2(SO_4)_3(H_2O)_8$ complexes.[17] Complex **1** was characterised by electron microprobe analysis, which indicated a Y:S ratio of *ca.* 1:3, as well as microanalysis, IR spectroscopy and single crystal X-ray crystallography.§ The IR spectrum displayed a shift in the sulfonate absorptions from 1186 and 1048 cm^{-1} (for the sodium salt) to 1166 and 1041 cm^{-1}, which is indicative of metal coordination through oxygen centres.[18] Similar reactions were tried using other lanthanoid salts, and an isostructural Eu^{3+} complex has also been obtained at an optimal pH 2.5.¶

Complex **1** crystallises in the space group $P2_1/n$ with the capsule residing over a centre of inversion. The unit cell also contains eight solvent water molecules disordered over several



Scheme 1

positions. Results are shown in Fig. 1. Yttrium cations coordinate to the 1,3-sulfonate groups of the calixarene with two calixarene sub-units encapsulating an 18-crown-6 molecule, and indeed the crown ether may be the primary building component around which the capsule is formed. Surprisingly the 18-crown-6 is devoid of Na^+, and also Y^{3+}, but this ion is not well suited to interact with this crown ether.[19] The absence of Na^+ is in direct contrast to the ionic capsule [{Na^+⊂(18-crown-6)$(OH_2)_2$}⊂{(*p*-sulfonatocalix[4]arene^{4-})$_2$} + nH^+]$^{(7+n)-}$ and the related perched 'Ferris wheel' structure [{La^{3+}⊂(18-crown-6)$(OH_2)_3$}∩{(*p*-sulfonatocalix[4]arene^{4-} + 2H^+)}]$^+$.[20]

There are two types of Y metal, one of which is partially occupied and disordered, and both coordinate to seven water molecules [Y(1)–O 2.324(4)–2.405(4) Å, Y(2)–O 2.31(2)–2.38(2) Å], and one sulfonato group of the calixarene [Y(1)–O 2.308(4) Å, Y(2)–O 2.30(2) Å]. This is unexceptional for Y^{3+}.[21] Both are involved in RSO–Y–HOH···OSR hydrogen bonding leading to the dimerisation of calixarene sub-units in two distinct modes, shown schematically in Fig. 1(a). The first mode, of the ordered Y(1), involves a head-to-head dimerisation of the calixarenes [Fig. 1(a)(i)] to form the capsule, with YO···OS separations of 2.71–2.80 Å. This is undoubtedly facilitated by the encapsulation of the crown ether macrocycle (as discussed later). The second mode forms an S-type motif and involves the partially occupied Y(2)$(H_2O)_7$, [Fig. 1(a)(ii)]. This moiety is disordered over two adjacent sites by symmetry and each site has an occupancy of 1/3, determined by microprobe analysis, analysis of anisotropic displacement parameters and charge balance considerations. The YO···OS separations are 2.70 and 2.76 Å. The combination of the two modes of RSO–Y–HOH···OSR hydrogen bonding leads to a linear chain of

DOI: 10.1039/a910256f

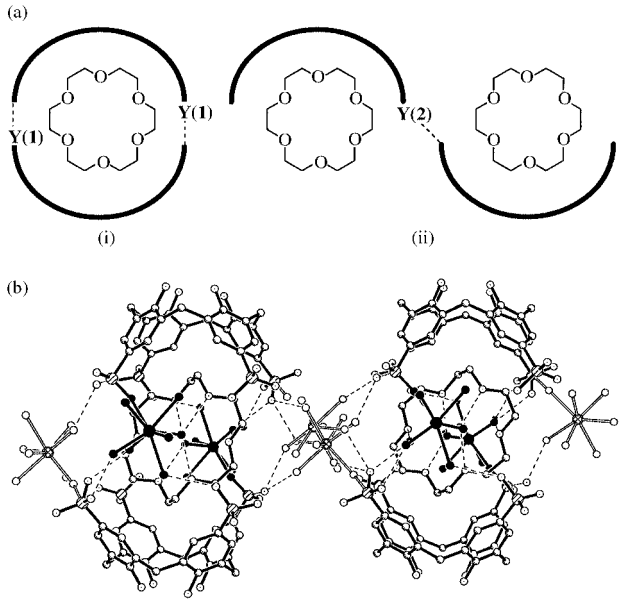


Fig. 1 (a) Schematic diagram of RSO–Y–HOH···OSR hydrogen bonding modes in $[(18\text{-crown-}6)_{0.5}(Y(H_2O)_7)_{1.33}(p\text{-sulfonatocalix[4]arene})]\cdot 4H_2O$ **1**, (i) head-to-head dimerisation of calixarenes around an 18-crown-6 molecule, (ii) S-type motif; (b) section of the crystal structure of **1** showing the linear chian of capsules,¶ $Y(1)(H_2O)_7$ is shown in black, while $Y(2)(H_2O)_7$ which is disordered with 1/3 occupancy is white. Hydrogen atoms have been removed for clarity and implied hydrogen-bonding interactions are represented by dashed lines. An isostructural complex can be formed with Eu.

capsules, a section of which is shown in Fig. 1(b). It is noteworthy that the sulfonatophenol group involved in Y(2) coordination has the largest tilt angle from the calixarene phenolic O_4 plane of 126.3° *cf.* 119.3, 115.6 and 124.5° for the other phenols.

The crown ether is at the core of the capsule. Hydrogen bonding occurs through each oxygen centre to water molecules coordinated to Y(1) at O···O separations of 2.77, 2.76 and 2.80 Å [Fig. 1(b)]. Driven primarily by this hydrogen bonding, but also by the complementarity of curvature of the calixarene cavity with the curvature of the crown ether (which optimises van der Waals interactions) the crown ether is held in the hydrophobic interior of the capsule. It is significantly distorted from its usual 'crown' shape due to exo-crown ether cavity hydrogen bonding, and hydrophobic interplay with the calixarenes.

In conclusion, using a combinatorial approach we have gained access to a novel multi-component capsule containing either Y^{3+} or Eu^{3+}. The same conditions for the formation of the capsule for solutions containing La^{3+} affords a perched structure involving one calixarene, one crown ether and a metal centre.[20] Other structural types are likely to be obtained from subtle changes in metal ion size and pH. We note that in the absence of crown ether, Ln^{3+} (Ln = Yb, Eu) can form complexes with *p*-sulfonatocalix[4]arene with the metal centre also bound to one sulfonato group, but ionic capsules do not form.[16] Clearly the presence of the crown ether is important for the formation of the capsule. However, other molecules with complementary size and curvature, which are also capable of hydrogen bonding, may also result in the formation of capsules.

We are grateful to the Australian Research Council for support of this work.

Received (in Oxford, UK) 10th March 2000, Accepted 4th April 2000

The reaction of suitable organic groups in combination with well defined inorganic silsequioxane cores leads to covalently bound organic–inorganic hybrid materials, which exhibit nematic and smectic C phase behaiour close to room temperature.

Much attention has been paid to the investigation of nanoscopic organic–inorganic hybrids which are amorphous, crystalline or which exhibit bicontinuos, columnar or lamellar morphologies.[1–4] This makes the investigation of systems where a covalently attached inorganic core is dispersed homogeneously in a nematic matrix a fascinating proposition.

Our approach is based on molecular designed LC materials where it has been established that the linkage of polyphilic groups to nematogenic molecules leads to layered structures.[5,6] This requires a systematic approach to arrive at the targeted nematic materials based on crystalline silsesquioxane cores **A**, shown in Fig. 1 as a model system for a monodisperse inorganic crystal of defined stereochemistry. The linkage of the liquid-crystalline rod-shaped mesogenic moieties to the inorganic cores is effected by spacers consisting of organic methylene groups bonded *via* 1,1,3,3-tetramethyldisiloxane groups to the core. Eight mesogenic groups are appended from the cuboid core leading to a molecular structure, where in the LC phase the nematic director field is responsible for the deformation of the spatially isotropic molecules to assemble into the nematic phase structure.

In order to assure the formation of liquid-crystalline phases above ambient temperature aromatic core structures of the mesogenic units were selected containing three and four aromatic rings, linked by C–C single bonds or ester groups shown in Scheme 1. In order to assure a suitable stability range of the liquid-crystalline phase terminal alkyl chains of eight or eleven methylene groups were selected. The lateral attachment of the mesogens to the central core was chosen to favour side-on interactions of the mesogens following an established concept.[7] A spacer of five methylene groups and a siloxane unit was used to obtain a suitable degree of decoupling of the rigid aromatic mesogens and the silsesquioxane crystalline core.

The synthesis of the functionalised monomer **5** is shown in Scheme 1. Alkylation of 2,4-dihydroxymethylbenzoate **1** with 1-bromooctane in the *p*-position of the aromatic ring and subsequently with 5-bromopent-1-ene in the *o*-position followed by removal of the protective methyl group leads to the intermediate **2**. Compound **4** containing four aromatic rings was obtained by esterification of **2** with **3**, the product of the esterification of octyloxybenzoic acid with one of the phenol groups of 4,4′-biphenol. The attachment of a 1,1,3,3-tetramethyldisiloxane group **B** to **4** in a hydrosilylation reaction using Karstedt's catalyst leads to the functionalised monomer **5**.

The structurally related mesogen **6** containing only three aromatic rings was synthesised as published earlier and hydrosilylated as described for **4** leading to the material **7**.[2]

In order to assess whether the phase behaviour is determined by microphase separation or by the size of the relatively bulky methyl groups of the siloxane units, **4** was reacted with 1,1,3,3,3-pentamethyldisiloxane **C** leading to material **8**, an anologue to compound **5**. The reaction of **6** with **C** in a similar manner yields compound **9**, structurally similar to material **6**.

11	[**6-B**]$_8$-**A**	T_g −19.3 SmX 37.6 N 50.5 Iso

The organic–inorganic hybrid materials containing a central silsesquioxane core were obtained by reacting octavinylsilsesquioxane **A** with **5** in a hydrosilylation reaction leading to material **10**. The bond formation could be monitored by the occurrence of the signals for the ethylene bridge in the ^{1}H NMR spectrum and unambiguously in this context by the appearance of peaks at δ 4.1 and 9.8 in the ^{13}C NMR spectra. The fusion of the inorganic core **C** in a similar manner with the functionalised mesogenic side-chain **7** containing three aromatic rings resulted in compound **11**. The materials were purified by column chromatography, indicating that the incorporation of siloxane groups in the spacer alters the solubility of these materials, when compared to related structures.[8,9] The eluent for material **11** was dichloromethane–hexane with the mixture gradient changed from 1 : 1 to 4 : 1 during the elution.

The transition temperatures of the liquid-crystalline materials **4**–**11** are listed in Table 1. All of these materials exhibit a nematic phase as the highest stable liquid-crystalline phase, characterised by a typical *schlieren* texture when observed using optical polarising microscopy.

For the four-ring system **4** the side-on attachment of the microphase seperating tetramethylsiloxane group leads to a marked decrease of the isotropisation temperature from 173.2 °C for **4** to 123.8 °C for compound **5**, a fall of 49.4 °C.

For the three-ring system **6** with an isotropisation temperature of 72.7 °C fusion to be tetramethylsiloxane group, leading to compound **7**, results in a decrease of the clearing temperature to 39.1 °C, a fall of 33.6 °C.

This modification of the mesogenic moieties by siloxane groups is additionally accompanied by a strong fall in the melting temperatures to 67.1 °C for **5** (99.4 °C for **4**) and to 18.0 °C for **7** (53.8 °C for **6**) when compared to the starting materials. An interesting feature is the occurrence of a low temperature smectic C phase characterised by broken focal conics and a *schlieren* texture for material **5**, a feature very unusual in rod shaped materials with a lateral side-chain.[10–12]

The structurally related materials containing a pentamethyldisiloxane endgroup, **8** and **9**, have similar isotropisation temperatures as observed for **5** and **7** containing tetramethyldisolaxane groups, indicating that the liquid-crystal phase behaviour is governed mainly by microphase separation of the organic and siloxane groups. The increase in the melting points for **8** (76.6 °C *cf.* 67.1 °C for **5**) and **9** (24.8 °C *cf.* 18 °C for **7**) can be attributed to the more bulky siloxane groups, leading to more stable crystalline phases.

The material **10** containing an inorganic core has an isotropisation temperature of 145.8 °C, a rise by 22 °C compared to the monomer **5**, indicating that the incorporation of a suitably functionalised inorganic core can promote the stability of the mesomorpic state. The increase of the stability range of the smectic C phase by 60 °C to 111.3 °C observable for material **10** is remarkable. This is accompanied by a fall of the crystallisation temperature to 59.5 °C of this structure. Additionally a monotropic highly ordered LC phase of undetermined structure was observed below 33.1 °C.

A special feature of the cuboid material **11**, where the inorganic core is decorated with eight mesogens containing three aromatic is the absence of a crystalline state, only a low glass transition temperature of −19.3 °C could be observed. The material clears from the nematic phase to the isotropic state at 50.5 °C and shows an underlying smectic phase (smectic X) at 37.6 °C, confirming thus the versatility of the selected systematic approach, geared towards low temperature organic–inorganic anisotropic fluids incorporating nanocrystalline cores.

We acknowledge the EC for funding in the framework of the TMR network 'Molecular Design of Functional Liquid Crystals' and thank the members of the network for the many helpful discussions.

Received (in Cambridge, UK) 15th March 2000, Accepted 7th April 2000

In a fourth generation poly(propylene amine) dendrimer decorated with 32 dansyl units at the periphery and containing 30 aliphatic amine units in the interior, the strong fluorescence of all the dansyl units is quenched when a Co^{2+} ion is incorporated into the dendrimer.

In the last few years there has been a great development in the field of fluorescent chemosensors.[1] These compounds are usually made of a fluorescent unit connected with a receptor. Recognition of a substrate by the receptor affects the fluorescent properties of the fluorophore. For example [Fig. 1(a)], coordination of a metal ion to the receptor can cause quenching of the excited state of the fluorophore by energy or electron transfer, thereby switching off the fluorescent signal. In order to achieve sensory signal amplification, we have designed and synthesized compounds in which one transition metal ion is able to quench the excited state of a great number of fluorophores [Fig. 1(b)].

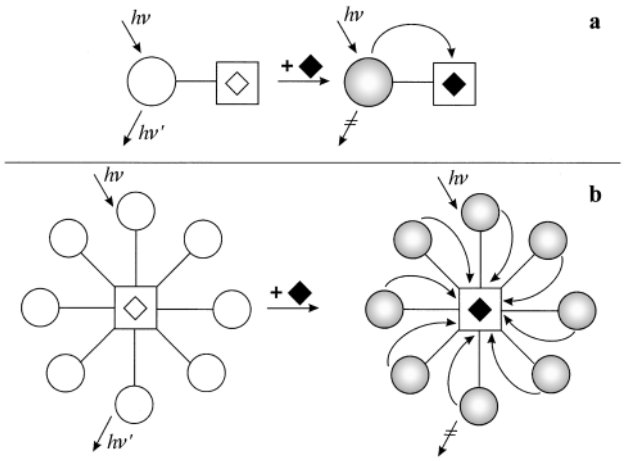

Fig. 1 Schematic representation of (a) a conventional fluorescent sensor and (b) a fluorescent sensor with signal amplification. The curved arrows indicate a quenching process. For more details, see text.

The described system belongs to the family of dendrimers, which are well defined macromolecules exhibiting tree-like structures.[2] By suitable design and synthetic strategies, it is possible to incorporate in a dendritic structure components exhibiting specific properties whose integration can lead to useful functions.[3] Continuing our investigations in the field of photoactive dendrimers,[4] we have prepared compounds that incorporate both receptor and fluorophore units, and we have shown that they can give rise to a strong signal amplification compared to fluorescence sensors carrying only one fluorescent unit (Fig. 1).

Because of its strong fluorescence, the dansyl group is often used as a fluorophore for sensory purposes.[5] When the dansyl unit is linked to a polyamine receptor,[6] coordination of a suitable metal ion by the receptor causes the quenching of the dansyl fluorescence. We have appended fluorescent dansyl units at the periphery of poly(propylene amine) dendrimers[7] which are able to coordinate metal ions by the aliphatic amine units contained in the interior of the structure. The formula of the fourth generation dendrimer **4D**, which contains 32 dansyl units at the periphery and 30 aliphatic amine units in the interior, is shown in Fig. 2.

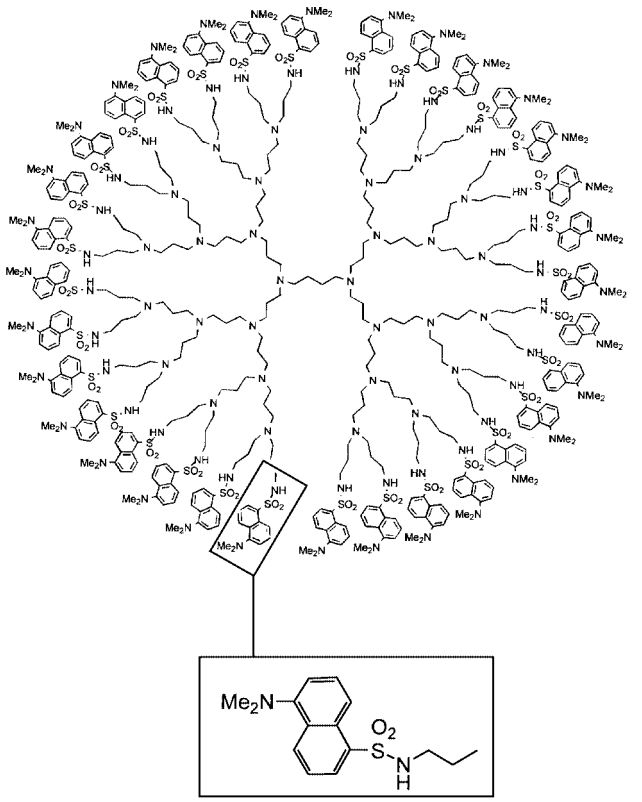

Fig. 2 Structure formula of the **4D** fourth-generation poly(propylene amine) dendrimer decorated with 32 dansyl units.

In acetonitrile–dichloromethane (5:1 v/v) solution, dendrimer **4D** exhibits intense absorption bands in the near UV spectral region (λ_{max} = 253 and 339 nm, ε_{max} = 357 000 and 113 000 M^{-1} cm^{-1}, respectively) and a strong fluorescence band in the visible region (λ_{max} = 514 nm, Φ = 0.25, τ = 13 ns).† Addition of Co^{2+} (up to 1.0×10^{-4} M, as $Co(NO_3)_2 \cdot 6H_2O$) to a 4.6×10^{-6} M solution of **4D** caused a strong quenching on the fluorescence intensity of the dansyl units appended at the periphery of the dendrimer, without affecting the absorption spectrum.

The observed quenching cannot be attributed to a dynamic process,‡ but it must originate from coordination of metal ions by the aliphatic amine groups which are present in the interior part of the dendrimer.[8] The **4D** dendrimer, in fact, can be considered as a polydentate ligand. In view of its size and of the 30 amine units, it can be expected that each dendrimer

DOI: 10.1039/b002116o

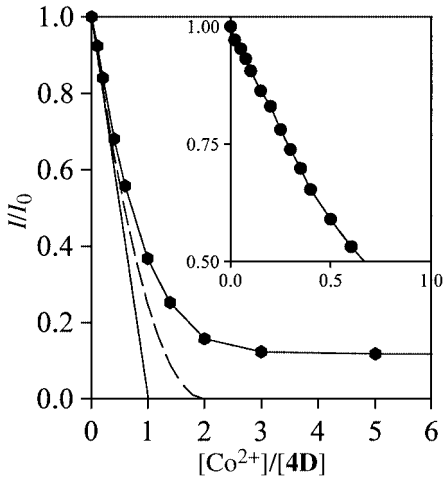

Fig. 3 Effect of addition of Co^{2+} ions on the fluorescence intensity of the **4D** dendrimer. The concentration of **4D** is 4.6×10^{-6} M. Inset shows the results of a detailed investigation at low Co^{2+} concentration.

coordinates several metal ions, giving rise to a complex titration curve (Fig. 3). The inset of Fig. 3 shows that for low Co^{2+} concentrations ($[Co^{2+}]/[\mathbf{4D}] \leqslant 0.3$) the fluorescence intensity decreases linearly with increasing $[Co^{2+}]$. More specifically, in this concentration range each Co^{2+} equivalent quenches 32 dansyl units, a number that corresponds to the dansyl units contained in each dendrimer. This means that at *low* metal ion concentration, 1 : 1 metal ion–dendrimer species are formed in which the dansyl fluorescence is completely quenched.§ Apparently, upon coordination of a metal ion the dendrimer shrinks around the metal, thereby allowing all the 32 dansyl units to be quenched when they are excited.

The titration curve (Fig. 3) is no longer linear on increasing Co^{2+} concentration further, which shows that species containing more than one metal ion per dendrimer are formed. The dashed curve in Fig. 3 corresponds to the behaviour expected if two metal ions can independently enter the dendrimer; the lack of fitting to this titration curve suggests that species containing more than two metal ions are also formed. Finally, it can be noted that the luminescence intensity does not fall to zero. Perhaps, since the metal ion is added as $Co(NO_3)_2 \cdot 6H_2O$, at very high Co^{2+} concentrations water molecules and/or counter ions may occupy part of the coordination sphere or even prevent complete dendrimer–Co^{2+} association. We have also found that, at high Co^{2+} concentrations, the titration curve is somewhat different when the metal ion is added as a chloride salt.

A most important property of a fluorescent sensor is, of course, sensitivity. By using dendrimer **4D** it is possible to amplify the sensitivity of a monodansyl compound by 32 times. The detection limit of Co^{2+} depends on the concentration used. Our results indicate that with a **4D** concentration of 4.6×10^{-6} M, a Co^{2+} concentration of 4.6×10^{-7} M causes a decrease in the fluorescence intensity of 5%. A signal amplification effect has already been obtained with polymeric chains of sensors.[9] Because of their well defined and fully programmable structures, dendrimers are more promising species for this kind of application.[10] Of course, several other requirements (*e.g.*, selectivity) are needed for useful sensory application.

This work has been supported by MURST (Supramolecular Devices Project), University of Bologna (Funds for Selected Topics), and CNR (Sensori Fluorescenti Supramolecolari).

Notes and references

† The equipment used has been described elsewhere.[4]

‡ Since the lifetime of the fluorescent excited state of the dansyl unit is 13 ns, the metal ion concentration is too low to cause sizeable effects even in the case of a diffusion controlled quenching process.

§ The straight line shown in the inset of Fig. 3 extrapolates to $I/I_0 = 0$ at $[Co^{2+}]/[\mathbf{4D}] = 1$, which confirms that at *low* metal ion concentration 1 : 1 metal ion/dendrimer species are formed in which the dansyl fluorescence is completely quenched.

Received (in Cambridge, UK) 2nd February 2000, Accepted 5th April 2000

The use of amorphous silica-supported titanium catalysts in which the titanium ions display a chemical environment similar to that of Ti-substituted zeolites, afforded excellent activity in the epoxidation of terminal linear and bulky alkenes with dilute solutions of hydrogen peroxide.

Despite numerous reports in the literature, the epoxidation of terminal alkenes remains a challenge in petrochemistry. Many different methods have been developed for the preparation of epoxides. However, in recent years maximum interest has focused on titanium-substituted zeolites in the framework, including TS-1,[1] Ti-β[2] and Ti-incorporated mesoporous silica,[3] which are claimed to be good catalysts for epoxidation with hydrogen peroxide. Although in the presence of methanol as a solvent all these catalysts display high activity and selectivity levels towards epoxide, they have poor mechanical strength and low thermal stability. Non-zeolitic TiO_2–SiO_2-supported catalysts are effective in the epoxidation of alkenes with organic hydroperoxides,[4,5] but it is generally believed that they are not effective in the epoxidation of alkenes with hydrogen peroxide. Nevertheless, titanium silica-supported catalysts have been reported to be active to the epoxidation of alkenes with hydrogen peroxide, but with low selectivity towards epoxide.[6]

Here we report a very simple route for the preparation of TiO_2/SiO_2 catalysts with highly dispersed titanium atoms. These catalysts are relatively inexpensive, easy to synthesise and regenerate, and at the same time show high conversion rates without the requirement of methanol as a solvent. Hitherto, these materials have not been used as catalysts in the epoxidation of alkenes (oct-1-ene, cyclohexene and norbornene) with hydrogen peroxide solutions.

The catalysts were prepared in the following manner:[7] 0.75 g of titanium isopropoxide was dispersed in the solvent (either *n*-decane, toluene or cyclohexanol to produce catalysts C3, C2 and C1, respectively) (150 ml). The solution was heated to 423 K (the boiling point of toluene solution) under stirring and then 5 g of silica (Grace Davison G-952, surface area: 310 $m^2\ g^{-1}$, pore volume: 1.5 ml g^{-1}) was added to the solution, which was stirred at 423 K for 2 h. The solid obtained was filtered off and washed twice with 150 ml of hot solvent and subsequently dried at 383 K and calcined at 773 K for 5 h. As reference catalysts, a titanium-supported silica (TiF/SiO_2), as described by Jorda *et al.*,[6] and a titanium silicalite (TS-1), as reported by Taramaso *et al.*,[1] were prepared.

The total amount of titanium introduced into the synthesis solution was incorporated to catalysts TiF/SiO_2, C2 and C3 (Table 1). However, when cyclohexanol was employed as the solvent (C1), only part of the titanium was incorporated into the catalyst. For TS-1, the degree of titanium incorporation was similar to that reported in the literature. The structural FTIR spectra of the catalysts diluted in KBr were inconclusive because the silica support displayed a broad peak at 960 cm^{-1}, which overshadowed the Ti–O–Si vibration mode (960 cm^{-1}).[8]

The DRS UV–VIS spectra (Fig. 1) of catalysts C1, C2, C3 and TiF/SiO_2 were clearly different from that of the TS-1 sample. The spectrum of the latter showed a single peak at 210 nm, which can be taken as a clear indication of isolated Ti(IV) in tetrahedrally coordinated sites. The slight shift in band position and the increase in bandwidth point to a distorted tetrahedral environment of the titanium. The broad adsorption band of the silica-supported samples shifted to high wavelength values; this can be explained in terms of: (i), the presence of titanium atoms in octahedral coordination (values between 290 and 333 nm),[9] as observed in catalysts C2 and C3, and as a small component in TiF/SiO_2; (ii) the hydrophilic nature of the silica surface, which favours the presence of hydrated titanium in tetrahedral coordination (232 nm),[9] as already seen for catalyst C1 and the major proportion of TiF/SiO_2. However, the absence of a band at 370–410 nm rules out the presence of free TiO_2 in all the catalysts.[9]

Table 1 Characteristics of the catalysts

Catalyst	Synthesis	Titanium content (%) (XPS)	XPS ratio (460 eV/ 458.5 eV)
C1	Cyclohexanol	0.8	2.1
C2	Toluene	2.6	0.5
C3	*n*-Decane	2.6	0.1
TS-1[1]		1.7	2.5
TiF/SiO_2[6]		1.1	—[a]

[a] Not determined owing to the presence of fluorinated species.

High resolution photoelectron spectra of Ti 2p core-levels of the *in situ* outgassed samples (Fig. 2) displayed the characteristics Ti $2p_{1/2}$/Ti $2p_{3/2}$ doublet. Although chemical information can be derived from each component, discussion should be based on the most intense Ti $2p_{3/2}$ component. Curve fitting of

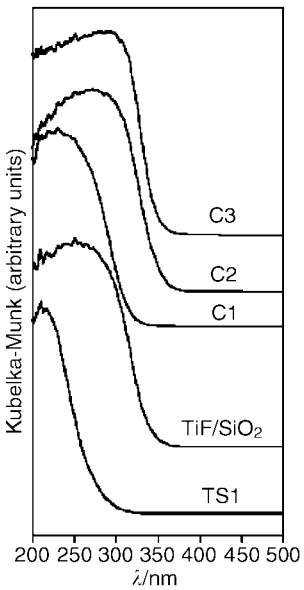

Fig. 1 DRS UV–VIS spectra of solids in ambient conditions recorded with a Shimadzu UV-2100 spectrometer.

DOI: 10.1039/b000929f

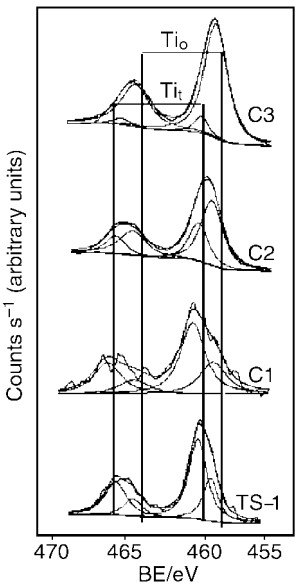

Fig. 2 Ti 2p core-level spectra of outgassed samples *in situ* at 473 K acquired with a VG Escalab 200R spectrometer.

the Ti $2p_{3/2}$ core level to two components shows the highest binding energy component (460.0 eV) can be attributed to titanium in tetrahedral coordination,[10] while the lowest binding energy component (458.5 eV) is usually assigned to titanium in octahedral coordination[10] or in interaction with surface hydroxy groups. Catalyst C3 shows a large part of the titanium in octahedral coordination (Table 1). For catalyst C2, the proportion of titanium in tetrahedral sites is higher than in C3, but most of the titanium still remains in octahedral coordination (Table 1). Catalysts C1 and TS-1 exhibit a titanium peak in tetrahedral coordination that is clearly more intense than the lowest binding energy component. This indicates that titanium ions are in a very similar environment in catalysts C1 and TS-1, although the synthesis route of silica-supported titanium catalyst (C1) is considerably easier than that for the Ti-silicalite sample. Both DRS UV–VIS and XPS spectroscopic techniques pointed to the necessity of carefully controlling the incorporation of titanium into silica (preparation of C1 in cyclohexanol) to obtain titanium in tetrahedral coordination. This is due to the fact that cyclohexanol interacts strongly with the titanium precursor which favours the formation of isolated titanium species, and also that only a fraction of the titanium added is incorporated as a consequence of the equilibrium of adsorption.

These catalysts were tested in the epoxidation of alkenes with dilute aqueous hydrogen peroxide solutions. Epoxidation was performed under ambient pressure in a round-bottomed flask equipped with a condenser and magnetic stirrer. The reaction procedure was as follows: 0.2 mol of alkene, 11 g of *tert*-butyl alcohol and 1 g of catalyst were stirred and heated to the reaction temperature (353 K). Then, 4 g of a dilute solution of hydrogen peroxide (6 wt% in 1-phenylethanol) was added dropwise under stirring over 2 h. Aliquots were taken at regular intervals. H_2O_2 consumption was evaluated by iodometric titration, and organic compounds were analysed by GC to determine their selectivity. The results are summarised in Table 2. The reference catalyst TS-1 showed low selectivity values towards epoxide, which is consistent with the requirement of the presence of methanol to obtain high selectivity values.[11] The method for preparing silica-supported titanium had a strong effect on performance for the epoxidation of oct-1-ene. The TiF/SiO_2 catalyst showed similar conversion and selectivity values to those reported in previous work,[6] but lower than those of TS-1. Catalysts C3 and C2 showed very low selectivity towards epoxide, in agreement with the high proportion of octahedrally coordinated titanium, as revealed by DRS UV–VIS and XPS spectroscopic techniques. Nevertheless, catalyst C1 had very high (95%) selectivity values towards epoxide, related to the high proportion of titanium in tetrahedral coordination as revealed by the DRS UV–VIS technique, and specifically by XPS spectroscopy. Finally, catalyst C1 also displayed very good performance in the epoxidation of bulky alkenes with hydrogen peroxide. In cyclohexene and norbornene, 91 and 98% selectivity towards epoxide, respectively, were reached. Used catalyst C1 was analysed and the Ti content found to be the same as in the fresh sample, thus excluding leaching.

Table 2 Data for alkene epoxidation with hydrogen peroxide after 1 h of reaction (T = 353 K)

Catalyst	Alkene	Conversion of H_2O_2 (%)	Selectivity to epoxide[a] (%)
TS-1	Oct-1-ene	96	70
TiF/SiO_2	Oct-1-ene	75	65
C3	Oct-1-ene	96	32
C2	Oct-1-ene	97	56
C1	Oct-1-ene	97	95
C1	Cyclohexene	98	91
C1	Norbornene	98	98

[a] Selectivity to epoxide = mol of epoxide formed/mol of H_2O_2 consumed.

In short, using a very simple route, we have prepared titanium-supported amorphous silica catalysts in which the chemical environment of titanium atoms is very similar to Ti-substituted zeolites. The use of cyclohexanol is pivotal to the production of very active and selective catalysts in the reaction of alkene epoxidation with hydrogen peroxide. These catalysts also display excellent performance with linear as well as larger or bulky alkenes.

Structural studies of supramolecular β-cyclodextrin complexes with butyrophenone and valerophenone: an explanation for photochemical reaction modification†‡

Tom J. Brett and John J. Stezowski*

Received (in Columbia, MO, USA) 31st March 2000, Accepted 5th April 2000

X-Ray crystallographic studies of β-cyclodextrin (β-CD) inclusion complexes with butyrophenone and valerophenone characterize these complexes as 2:2 β-CD/guest systems with the alkyl chains of the included guest molecules conformationally restricted; the structures explain the reported observation of the modification of the Norrish type II photoreaction for the included aryl alkyl ketones in crystalline β-CD complexes.

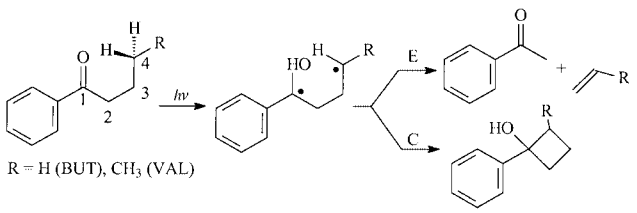
The use of controlling media to modify the outcome of photochemical reactions has been an active area of research since the late 1970s.[1] Understanding how the controlling media changes the outcome of a reaction is important for designing future experiments in which a specific outcome is desired. X-Ray crystallography represents a powerful tool for observing these influences at a molecular level.

β-Cyclodextin (β-CD), a cyclic oligomer composed of seven D-glucose units, is an example of one such host system in which the outcome of photochemical reactions, *e.g.* the photoreaction of aryl alkyl ketones, can be modified.[2] This Norrish Type II photochemical process involves photoexcitation of the carbonyl group and has been rigorously examined for aryl alkyl ketones.[3–5] They undergo γ-hydrogen abstraction exclusively from the $(n\pi^*)^3$ state yielding a triplet 1,4-diradical as the primary intermediate (Scheme 1). Once the 1,4-diradical is formed, intersystem crossing produces the singlet diradical which then reacts *via* one of two pathways. Overlap of radical orbitals leads to cyclization (C), producing cyclobutanols. The elimination pathway (E) involves cleavage of the central 2,3 σ bond producing acetophenone and alkenes.

The use of β-CD as a controlling media for modifying the outcome of the Norrish Type II photoreaction of aryl alkyl ketones in the solid state has been reported.[6] In these studies, crystalline powder samples of β-CD complexes with various aryl alkyl ketones were prepared and their photochemical reactions analyzed. The general observation was that inclusion in β-CD lead to an increase in cyclization products (as compared to solution phase studies), and this trend became more pronounced as the alkyl chain became longer. In an effort to determine how the β-CD environment influences the outcome of the photoreaction of the included aryl alkyl ketones,[7] crystallographic studies were pursued. This report presents the structures of the β-CD/butyrophenone inclusion complex and the β-CD/valerophenone inclusion complex.

The two crystal structures are very similar.[8] Both are composed of face-to-face β-CD dimers containing two included aryl alkyl ketone molecules with the β-CD dimers packing in a channel[9] (Fig. 1). The guest molecules are packed with their phenyl rings face-to-face located in the center of the β-CD dimer. This leaves the alkyl chains of the ketones extending to the primary hydroxy ends of the β-CD dimer.

Examination of the structures reveals the influence the β-CD dimer environment has on the observed reaction outcomes. Although defined conformations for the included guest molecules could not be unequivocally obtained because of disorder,



Scheme 1 Reaction scheme of the Norrish Type II reaction for butyrophenone (BUT) and valerophenone (VAL). Atom numbering shown pertains to text discussion.

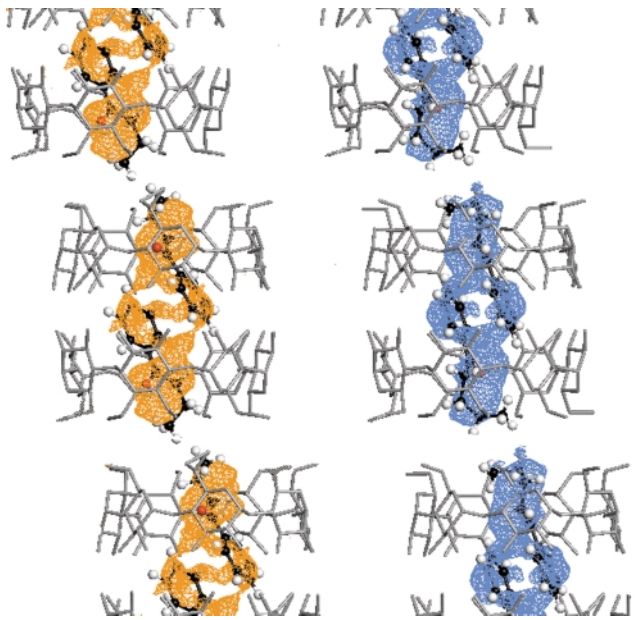


Fig. 1 Structures of the β-CD/butyrophenone (left) and β-CD/valerophenone (right) inclusion complexes. β-CD is shown as gray sticks while the guest molecules are shown in ball and stick with coloring as follows: red = oxygen; white = hydrogen; black = carbon. The difference electron density ($F_o - F_c$) the disordered guest molecules were fit to is shown in orange (β-CD/butyrophenone) and blue (β-CD/valerophenone).

‡ Chemical Insight from Crystallographic Disorder–Structural Studies of Supramolecular Photochemical Systems, Part 4; Part 3, T. J. Brett, J. M. Alexander and J. J. Stezowski, *J. Chem. Soc., Perkin Trans. 2*, 2000, in press.

DOI: 10.1039/b002828m

the interpretation of this disorder does reveal some relevant conformational restrictions. With the molecules included in the β-CD dimer with the phenyl rings packing face-to-face in the center, the alkyl chains must take on a cisoid conformation about the 2,3-bond. This helps bring a γ-hydrogen into close proximity with the carbonyl oxygen, as would be required for its abstraction.[10]

Once a γ-hydrogen is abstracted, the resultant 1,4-diradical is most surely conformationaly restricted by the β-CD dimer environment. It is well established that efficient cleavage requires a 1,4-diradical conformation in which the radical p orbitals can overlap significantly with the central σ bond being cleaved. If this does not happen, cyclization occurs from a conformation involving minimal orbital overlap.[11,12] Given these requirements, cyclization can only occur from a cisoid conformation of the 1,4-diradical while elimination can occur from either cisoid or transoid forms. With the phenyl rings of the molecules packed tightly in the center of the β-CD dimer, any such rotation must occur at the alkyl chain end of the molecule. Given the boundaries imposed by the β-CD dimer, the alkyl chains are not be able to undergo free rotations to transoid geometries.

The fashion in which the β-CD dimers pack also plays a role in the reaction modification. The observed channel type packing brings the alkyl chains of included molecules in adjacent β-CD dimer cavities within close proximity. Extension of the alkyl chain by one methyl group, *i.e.* going from butyrophenone to valerophenone, effectively stuffs the channel more tightly, limiting the allowed motion of the alkyl chain even more. This hindered motion accounts for the observed increase in cyclization products with increasing alkyl chain length.

The β-CD complexes with butyrophenone and valerophenone can be considered as 'reaction nanotubes' much akin to the β-CD/coumarin complex.[13] The mode of inclusion of the guest molecules produces conformational restrictions for the alkyl chains imposed by the surrounding β-CD dimer walls and intratube packing. Said restrictions produce cisoid conformations about the central 2,3-bond which will allow for the γ-hydrogen abstraction. The 1,4-diradical produced is also conformationally hindered in this manner and additionally restricted because of interactions between molecules in adjacent dimer cavities in the channel. This effect becomes more pronounced as the alkyl chain length is increased and is a contributing factor in the observed increase in cyclization products with increasing alkyl chain length. Further studies of inclusion complexes with aryl alkyl ketones possessing longer alkyl chains (*e.g.* hexanophenone, heptanophenone and ocatanophenone) will shed more light on this affect and are in progress.

Partial funding for this work was provided by the NSF (CHE-9812146). We thank Cerestar USA, Inc. (Hammond, IN) for samples of β-CD.

7 Since the study in ref. 6 was conducted on powder crystalline samples, it was necessary to verify that the elimination and cyclization processes occurred in our crystals. This was done as follows: photolyzed inclusion complex crystals were dissolved in water and the included compounds (unreacted ketones and photoproducts) were extracted with CH_2Cl_2. Analysis of the extraction mixtures by GC–MS and TLC revealed three components: the unreacted ketones, a cyclobutanol (C product) and acetophenone (E product). Full details are available as ESI.†
8 For both complexes, the methods of X-ray diffraction data collection and structure determination and refinement were similar and will be summarized here. Full details are available in the .cif file. Data were collected at room temperature on crystals sealed in glass capillaries using an automated Siemens P4 diffractometer with a sealed tube Mo target source. For the β-CD/butyrophenone complex, 6708 unique reflections (R_{int} = 0.0306) were collected to $2\theta_{max}$ = 50°. For the β-CD/valerophenone complex, 11163 unique reflections (R_{int} = 0.0241) were collected to $2\theta_{max}$ = 60°. For both structures, the phase problem was solved by molecular replacement of the β-CD coordinates from the isomorphous β-CD/coumarin complex (ref. 13). Difference electron density maps revealed the guest molecules were very disordered in both cases. The disorder was interpreted as phenyl ring face-to-face packing of the guest molecules with identically packing pairs distributed over multiple sites. Least-squares refinement on F^2 was carried out using SHELXL97 (G. M. Sheldrick, SHELXL97. Program for the Refinement of Crystal Structures. University of Göttingen, Germany, 1997). *Crystal data*: for $C_{42}H_{70}O_{35}{\cdot}C_{10}H_{12}O{\cdot}11.5H_2O$, M_r = 1490.36, monoclinic, space group *C*2 (no. 5), a = 19.352(2), b = 24.599(2), c = 15.916(2) Å, β = 109.378(7)°, Z = 4, D_c = 1.385 g cm^{-3}, crystal size 0.7 × 0.5 × 0.4 mm. Final refinement details: 923 parameters, R_1 = 0.0668, wR_2 = 0.1748 and GOF = 1.052 for 5202 reflections with $F_o > 4\sigma(F_o)$. For $C_{42}H_{70}O_{35}{\cdot}C_{11}H_{14}O{\cdot}11H_2O$, M_r = 1495.38, monoclinic, space group *C*2 (no. 5), a = 19.339(2), b = 25.581(1), c = 16.010(2) Å, β = 109.080(7)°, Z = 4, D_c = 1.327 g cm^{-3}, crystal size 0.6 × 0.4 × 0.4 mm. Final refinement details: 907 parameters, R_1 = 0.0915, wR_2 = 0.2504 and GOF = 1.020 for 6425 reflections with $F_o > 4\sigma(F_o)$. CCDC 182/1595. Characterization of a well resolved supramolecular ice-like $(H_2O)_{10}$ cluster in the solid state†

Leonard J. Barbour, G. William Orr and Jerry L. Atwood*

Department of Chemistry, University of Missouri-Columbia, Columbia, Missouri 65211, USA.

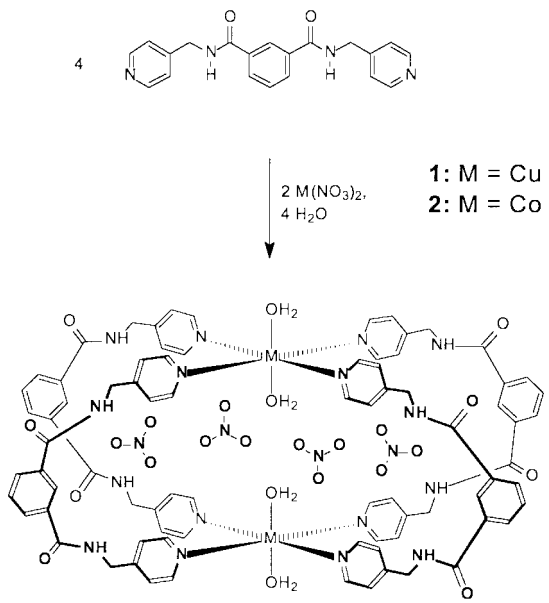
Received (in Cambridge, UK) 7th March 2000, Accepted 30th March 2000

The conformation of a previously observed ice-like water cluster in the solid state proves to be robust to geometric changes in its surroundings and the hydrogen bonded arrangement is finally revealed in detail.

Water clusters can play an important role in the stabilization of supramolecular systems both in solution and in the solid state and there is clearly a need for a better understanding of how such aggregates influence the overall structure of their surroundings.[1–5] In this context, we recently characterized a solid-state structure of a $[Cu_2(H_2O)_4L_4]\cdot nH_2O$ complex **1** (Scheme 1) featuring an $(H_2O)_{10}$ cluster with an ice I_c-like arrangement of the water molecules.[6] At the time, owing to inherently poor crystal quality and the lack of low temperature X-ray data collection capability, the structure was only modestly resolved and several important points remained to be addressed. First, although the positions of the water molecules constituting the decameric cluster were determined unequivocally, the water hydrogen atoms were never located. While an ordered arrangement of these hydrogen atoms was inferred from the discontinuous nature of the cluster (in contrast to the disordered hydrogen arrangement in the continuous ice lattice[7]), we were not able to verify this conjecture experimentally. Second, disorder of the contents of the macrocyclic cage, coupled with poor resolution, precluded us from determining the composition of the interior of the cage with sufficient certainty. Third, it was not known to what extent the geometry of the water cluster would be affected by relatively small changes in the overall geometry of the system (*e.g.* substitution of Cu by Ni or Co). We now present a new, well resolved low-temperature crystal structure that addresses all of the above issues satisfactorily.



Scheme 1

Since the metal ion of the Cu^{2+} complex exhibits Jahn–Teller distortion along the M···M vector that also passes through the center of the water cluster, we decided to introduce a slight geometric change to the system by substituting cobalt for copper. Crystals of **2** were grown as previously described[6] and the sngle crystal X-ray structure‡ is discussed below. While the cage complex in **2** is remarkably similar to that of **1**, the extended structures of the two systems are slightly different as evidenced by the unit cell information given in Table 1.

Both structures consist of linear arrays of the dinuclear cage complex (aligned parallel to the M···M axis) with the water cluster effectively acting as an exo-bidentate bridging ligand. Each of these arrays is surrounded by four identical arrays that are offset by half a structural unit along the M···M vector. This staggered arrangement of the globular cage molecules results in the formation of relatively large voids which are occupied by the decameric water clusters.

Fig. 1 shows selected portions of the two structures overlaid in order to illustrate the major differences between them. In the structure of **1**, successive cages are related to one another by $\bar{4}$ site symmetry and, accordingly, the orientation of the ligand amide groups alternates from one cage to the next within each strand. However, successive cages in **2** are related to one another by a simple unit cell translation and all the ligand arms therefore have the same orientation within a linear strand. Note that the cage complexes of **1** and **2** shown at bottom are almost identical in geometry with their M···M distances differing by only 0.441 Å [Cu···Cu 9.582(7) Å, Co···Co 9.141(4) Å].

Fig. 2 shows the arrangement of the water cluster in **2**. The distance across the decamer from O(1W) to O(4W) is 6.287(4) Å (*cf.* 6.35 Å in ice I_c)[7] while the corresponding distance in **1** is 5.65 Å [average of two unique distances: 5.779(7) and 5.512(7) Å]. This difference of about 0.6 Å in the length of the water cluster along the M···M vector is attributed to the longer M–O coordination bond in the Cu complex (average Cu–O 2.33 Å, average Co–O 2.10 Å). This clearly demonstrates that the flexibility of its internal hydrogen bonds allows the cluster to adjust its geometry in response to small changes in its environment and that the overall ice-like conformation is quite robust to such changes. All of the water hydrogen atoms were

located in difference electron density maps and the hydrogen bonded arrangement is indeed as inferred in our report of the structure of complex **1** (see .cif file for distances and angles relating to hydrogen bonds). The water cluster is situated on a two-fold rotation axis passing through O(1W) and O(4W) and only half of the remaining water molecules are crystallographically unique. O(1W) donates hydrogen bonds to O(9W) which in turn donates to O(8W) and O(10W). Similarly, O(4W) donates to O(7W) which also donates to O(8W) and O(10W). O(8W) and O(10W) each donates a hydrogen bond to a nitrate oxygen atom as well as to an amide oxygen atom from a cage complex of a neighboring strand. With the exception of O(7W) and O(9W), all water hydrogen atoms participate in the formation of four relatively strong hydrogen bonds. The closest non-covalent approach of any atoms to O(7W) and O(9W) are by the amide nitrogen atoms N(8B) and N(8A) of neighboring strands at distances of 3.549(4) and 3.357(4) Å, respectively. These distances are too long to be considered appreciably strong hydrogen bonds and are due to steric effects that inhibit a closer approach.

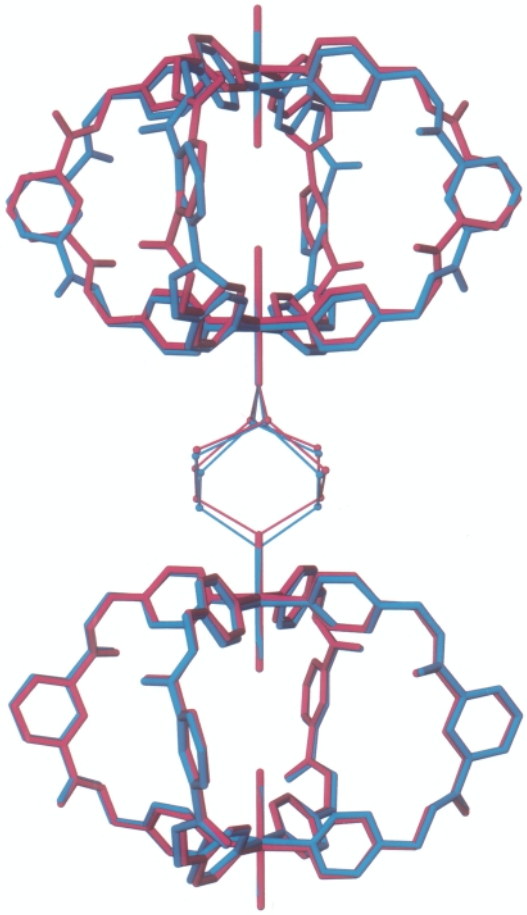

Fig. 1 Overlay of structures **1** (red) and **2** (blue) showing two cage complexes linked by an $(H_2O)_{10}$ water cluster.

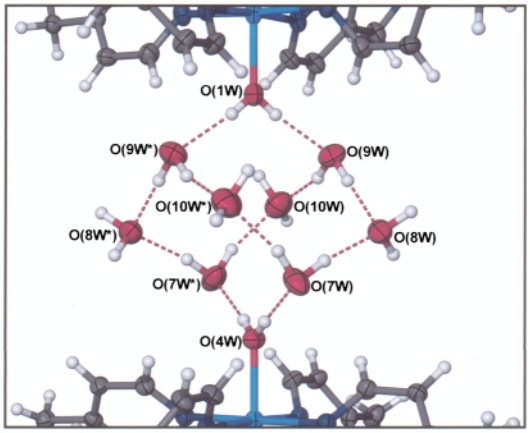

Fig. 2 Thermal ellipsoid (50% probability) plot of the water cluster in **2**. Asterisks within atom labels denote symmetry equivalent atoms.

The structure of **1** had not been determined with sufficiently high resolution to reveal with certainty the contents of the cage complex. Although **1** was modeled with six water molecules in the cage, it was thought that at least another two water molecules resided within the arms of the ligand. However, the low-temperature structural determination of **2** shows unequivocally that the interior of the cage complex does indeed consist of four nitrate anions and six water molecules. Two of the latter are coordinated to the metal cations and form hydrogen bonded contacts with the remaining four water molecules which, in turn, hydrogen bond to the nitrate oxygen atoms and this intricate hydrogen bonded arrangement imparts a high degree of rigidity to the cage interior.

We are grateful for funding from the National Science Foundation.

Formation of giant vesicles from diacylmannosylerythritols, and their binding to concanavalin A†

Dai Kitamoto,*[a] Sangita Ghosh,[b] Guy Ourisson[b] and Yoichi Nakatani*[b]

Received (in Liverpool, UK) 3rd February 2000, Accepted 11th April 2000

The structures of diacylmannosylerythritols, MEL-A, -B and -C, are determined; these microbial glycolipid biosurfactants efficiently self-assemble in water to form giant vesicles, which show excellent binding affinity towards the mannose-binding protein, concanavalin A.

The 'diacyl-mannosylerythritol' lipids (MELs) are very promising 'biosurfactants',[1] owing to their attractive properties (*e.g.* easy production conditions, low toxicity, biodegradability, biological activity) compared to most synthetic surfactants. MELs are abundantly produced by the yeast strain *Candida antarctica* T-34,[2a] and mainly consist of three components: MEL-A, -B and -C.[2b] These yeast glycolipids show not only excellent surface-activity[2c] but also remarkable cell differentiation and growth inhibition activities against human leukemia[2d] and mouse melanoma cells.[2e] On the other hand, glycolipids have received much attention as leading materials for drug-carrying microcapsules and artificial cells,[3] owing to their stabilizing effect on liposomes.[4] Finally, glycolipids also carry out vital functions in biomembranes, *e.g.* cell recognition, histocompatibility, antigenicity, and are of particular interest in studying surface recognition processes.[4c,5]

Here we report the complete structural characterization of the MEL glycolipids (MEL-A, -B and -C). We also describe, for the first time the spontaneous formation of giant vesicles from each of these glycolipids; finally, we show that these giant vesicles show an excellent binding affinity towards a mannose-binding protein, concanavalin A (Con A).

The three MELs consist of 4-*O*-[β-D-mannopyranosyl] *meso*-erythritol, esterified by two medium-chain fatty acids (C_8 to C_{12}) and one or two acetic acids; the individual esterified positions, however, remained to be determined precisely.[2b] Further structural characterization of the MELs was thus carried out. The mixture of MELs was obtained as reported previously,[2a] and purified by silica-gel column chromatography with modifications of the elution conditions.

The esterified positions of the individual acetyl and acyl groups on the mannosyl back-bone were determined by ^{1}H and ^{13}C 2D NMR ($CDCl_3$, 500 MHz) (Fig. 1). HMBC (heteronuclear multiple bond connectivity) long-range correlations ($^3J_{C-H}$) between the carbonyl carbons of the acyl groups and H-2′ and H-3′ of mannose were clearly observed on all the MELs,‡ indicating that the fatty acids are linked to the hydroxy groups at C-2′ and C-3′ of mannose. $^3J_{C-H}$ correlations between the acetyl carbons (δ_{CO} 169.6 and 170.9) and the mannose protons ($\delta_{H\text{-}4'}$ 5.24 and $\delta_{H\text{-}6'}$ 4.23), respectively, were observed exclusively on MEL-A, which was thus shown to be 4-*O*-[(4′,6′-di-*O*-acetyl-2′,3′-di-*O*-alkanoyl)-β-D-mannopyranosyl] *meso*-erythritol. On the other hand, a $^3J_{C-H}$ correlation between the acetyl carbon (δ_{CO} 171.8) and H-6′ (δ 4.44) was observed with MEL-B, while a correlation between the acetyl carbon (δ_{CO} 170.1) and H-4′ (δ 5.16) was observed only with MEL-C. From these results, MEL-B and -C were shown to be 4-*O*-[(6′-*O*-acetyl-2′,3′-di-*O*-alkanoyl)-β-D-mannopyranosyl] *meso*-erythritol and 4-*O*-[(4′-*O*-acetyl-2′,3′-di-*O*-alkanoyl)-β-D-mannopyranosyl] *meso*-erythritol, respectively. It was also confirmed that none of the three hydroxy groups in the erythritol moiety is esterified in any of the MELs.

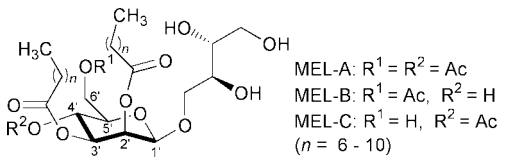

Fig. 1 Structure of diacylmannosylerythritols.

Membrane-forming properties of these MELs were then examined by phase contrast microscopy. All the MELs, when dispersed in water (pH 7.0) at 25 °C, spontaneously formed giant vesicles.§ Unilamellar vesicles of diameter larger than 10 μm were observed, beside multilamellar structures and tubules. Vesicle formation was confirmed by fluorescence microscopy, after addition of the lipophilic fluorescent probe Nile Red to the pre-formed vesicles (5 mol% to MEL) (Fig. 2). Some synthetic and natural glycolipids bearing a disaccharide or larger hydrophilic head group have been reported to form by themselves vesicular systems;[3] however, with the only exception of rhamnolipids,[3e] microbial glycolipids do not appear to have been reported to do the same.

Formation of giant vesicles should lead to surfaces covered by the multiantennary mannopyranoside residues, which could act as high affinity receptors for mannose-binding proteins. We therefore investigated the interaction between these giant vesicles and concavalin A. Succinyl Con A,[6] labeled with a fluorescence probe (FITC), was dissolved in a phosphate buffer

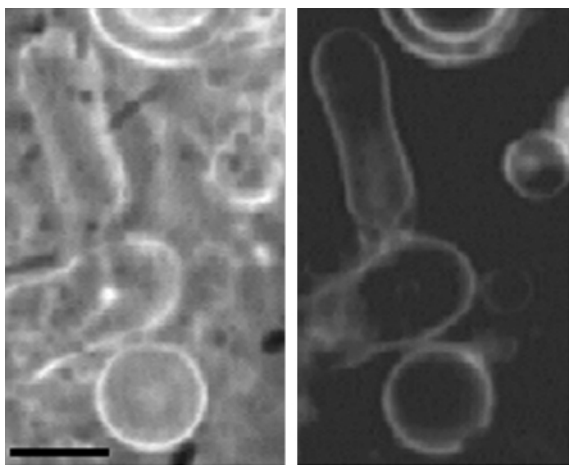

Fig. 2 Phase contrast (left) and fluorescence (right) microscope images of MEL-C giant vesicles stained with Nile Red. The bar represents 10 μm.

† Electronic supplementary information (ESI): preparation, optical microscopy details and NMR data for MELs. See http://www.rsc.org/suppdata/cc/b0/b000968g/

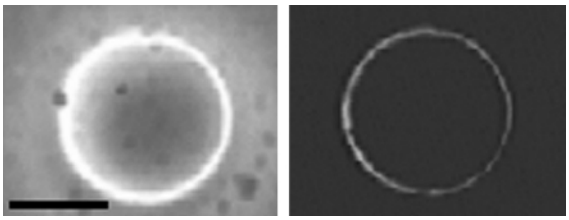

Fig. 3 Phase contrast (left) and fluorescence (right) microscope images of MEL-B giant vesicles coated with FITC-labeled concanavalin A. The bar represents 10 μm.

(pH 7.0) and added to the pre-formed vesicles, and were observed under fluorescence microscope. With MEL-B and -C vesicles, a clear fluorescent ring was observed around the outer edge of the vesicle. This clearly indicates the recognition by the fluorescence labeled Con A of the mannose residues of the glycolipid head-groups that are located on the vesicular surface (Fig. 3). The coating, as judged by the abundance of fluorescent vesicles, appeared to be efficient on the giant vesicles of MEL-B and -C; however, no clear coating was observed on those made of MEL-A.

Interactions of Con A with disk-like assemblies[4c] or small vesicles[5] of synthetic glycolipids have been previously reported. However, these small lipidic assemblies showed a tendency to aggregate and precipitate when treated with Con A, presumably due to interactions of one ConA molecule with several lipidic systems.[5,7] In the case of giant vesicles of MEL-B and -C, coating of the outer surface was not accompanied by aggregation and precipitation : the giant vesicles presumably provide a very large surface relative to the molecular size of Con A, which probably impedes the binding of the lectin to more than one vesicle at the same time, and thus aggregation does not occur.

In addition, most of the carbohydrate–receptor interactions observed are weak,[8] and in order to compensate for this low binding affinity, different strategies based on multivalent interactions have been designed, including carbohydrate clusters, glycopolymers and glycodendrimers.[5c,9] Our work describes yet another way of enhancing the interaction between a receptor (Con A) and a carbohydrate moiety (mannose), which is based on the spontaneous self-assembly of the glycolipids onto vesicles, thereby generating a multivalent surface. It should be noted that only the giant vesicles prepared from MEL-B and -C, both of which carry a free OH at C-4′ or C-6′, bind efficiently with Con A. There must therefore be a specific mode of binding, like multivalent interactions, on the vesicular surface, because Con A mainly recognizes and binds to the hydroxy groups at C-3′, C-4′ and C-6′ in D-mannose or D-glucose.[10]

We thank Dr R. Graf for NMR experiments, and Drs K. Haraya and H. Yanagishita, National Institute of Materials and Chemical Research, Japan, for helpful discussions.

Notes and references

‡ The following correlations ($^3J_{C-H}$) were observed between the carbonyl carbon of acyl groups and mannose protons: MEL-A, (δ_{CO} 173.8 and $\delta_{H\text{-}2'}$ 5.51) and (δ_{CO} 172.9 and $\delta_{H\text{-}3'}$ 5.06); MEL-B, (δ_{CO} 173.8 and $\delta_{H\text{-}2'}$ 5.49) and (δ_{CO} 173.7 and $\delta_{H\text{-}3'}$ 4.91); MEL-C, (δ_{CO} 173.6 and $\delta_{H\text{-}2'}$ 5.50) and (δ_{CO} 172.8 and $\delta_{H\text{-}3'}$ 5.09).

§ A typical procedure was as follows: MEL (10 mg) was dissolved in 1 mL of a 2:1 mixture of chloroform and methanol. An aliquot (5–10 μL) of the solution was dropped on a glass microscope slide with a well of 15 mm diameter. After 10 min drying (argon flow), 0.5 mL of water or a buffer (137 mM NaCl, 2.7 mM KCl, 4.3 mM Na_2HPO_4, 1.4 mM KH_2PO_4, pH 6.98) was added to the film, and the slide was incubated for 30 min at 25 °C to allow lipid hydration. Optical (phase contrast) and fluorescence microscopies were carried out according to the procedures described in ref. 11.

This showed unilamellar and multilamellar vesicles (diameter > 10 μm) as well as tubules. This was confirmed by the fluorescence observed after addition of Nile Red (5 mol%/MEL) to the pre-formed vesicle suspension.

The vesicles observed retained their structures at room temperature for at least 2 days.

Intramolecular 1,3-dipolar cycloadditions of 2-substituted norbornadiene-tethered nitrones

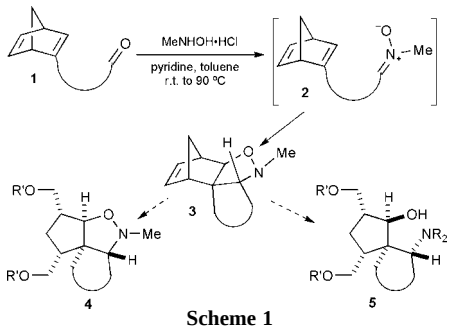
Geoffrey K. Tranmer, Peter Keech and William Tam*

Guelph-Waterloo Centre for Graduate Work in Chemistry and Biochemistry, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1. E-mail: tam@chembio.uoguelph.ca

Received (in Corvallis, OR, USA) 24th February 2000, Accepted 31st March 2000

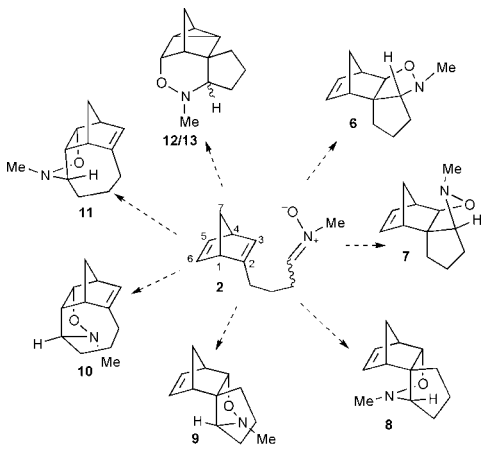
Efficient routes for the synthesis of norbornadiene-tethered nitrones have been developed and their intramolecular 1,3-dipolar cycloadditions were found to be highly regio- and stereo-selective.

Intramolecular cycloadditions with high regio- and stereo-control are important tools for the efficient assembly of complex molecular structures. We have recently initiated a program on the study of various types of intramolecular cycloadditions of substituted norbornadienes.[1] Our long-term goal is to develop an efficient route for the construction of angular fused tricyclic frameworks and spirocyclic frameworks with high regio- and stereo-control. 1,3-Dipolar cycloadditions offer a convenient one-step route for the construction of a variety of complex five-membered heterocycles.[2,3] Here we report our initial result on the intramolecular 1,3-dipolar cycloadditions of 2-substituted norbornadiene-tethered nitrones (Scheme 1).



Scheme 1

Three different types of regioisomers could be formed from the intramolecular 1,3-dipolar cycloaddition of the norbornadiene-tethered nitrone **2** (Scheme 2). Cycloaddition on the C_2–C_3 double bond would give cycloadducts **6**–**9**; cycloaddition on the C_5–C_6 double bond would give **10** or **11**, and a [3 + 2 + 2] cycloaddition with both of the double bonds would give cycloadducts **12** or **13**. Other than regiochemistry problems, different stereoisomers are also possible. Thus, a total of eight possible cycloadducts (**6**–**13**) could be formed in the cycloaddition of norbornadiene-tethered nitrone **2**.



Scheme 2 Possible cycloadducts

Efficient routes to the synthesis of norbornadiene-tethered aldehydes **19**, **20**, **27**–**29** and **32** were developed (Scheme 3) and these aldehydes served as precursors of the required nitrones for the cycloadditions. Deprotonation of norbornadiene **14** with Schlosser's base (Bu^tOK/Bu^nLi)[4] in THF at −78 °C, followed by addition of the resulting norbornadienyl anion to an excess of 1,4-dibromobutane or 1,5-dibromopentane provided the norbornadiene-tethered bromide **15** and **16**.[1] Conversion of these bromides to the corresponding alcohols followed by Swern oxidation provided the required aldehydes **19** and **20**. Norbornadiene-tethered aldehydes with an oxygen atom within the tether were prepared using a similar protocol. Trapping the norbornadienyl anion with paraformaldehyde, ethylene oxide and 3-bromopropan-1-ol provided norbornadiene-tethered alcohols **21**–**23**. A two-carbon homologation to the alcohols **24**–**26** was achieved by a two-step sequence[5] and Swern oxidation provided the required aldehydes **27**–**29**. An ester functionality

Table 1 1,3-Dipolar cycloaddition of norbornadiene-tethered nitrones

Entry	Starting aldehyde	Cycloadduct[a,b]	Yield[d](%)
1	 **19**	 **34**	51
2	 **20**	 **35**	19
3	 **27**	 **36**	71
4	 **28**	 **37**	60
5	 **33**	 **38**	47
6	 **29**	 **39**[c]	52
7	 **32**	 **40**	43

[a] *Reaction conditions*: MeNHOH·HCl (1.2–2 eq.), pyridine (3–5 eq.), 4 Å molecular sieves, toluene, r.t., 12–24 h then 60 to 90 °C 12–48 h. [b] Except in entry 6, the cycloadducts shown were the only regio- and stereo-isomers isolated in the cycloadditions. [c] An inseparable mixture of three isomers was obtained. [d] Isolated yields after column chromatography.

within the tether was prepared from alcohol **21**. Reaction of **21** with bromoacetyl bromide gave the a-bromo ester **30** which was converted to the nitrate ester **31** in two steps.[6,7] Treatment of the nitrate ester **31** with sodium acetate in DMSO provided the required aldehyde **32**.[6,7]

Addition of *N*-methylhydroxylamine to a solution containing aldehyde **19**, pyridine and 4 Å molecular sieves in toluene at room temperature lead to the formation of the corresponding norbornadiene-tethered nitrone which underwent spontaneous intramolecular 1,3-dipolar cycloaddition at 80 ºC to provide a single cycloadduct **34** in 51% isolated yield (Table 1, entry 1). Very little reaction was observed at a lower temperature and prolonged heating led to decomposition of the cycloadduct. Although as many as eight different cycloadducts could be formed in the reaction, only cycloadduct **34** was isolated. With one more carbon in the tether (entry 2), the only cycloadduct isolated was **35** but the yield was only 19%. For aldehydes with an oxygen atom within the tether (entries 3–5), the yields of the cycloadditions were generally much better than the all-carbon tethered substrates. Aldehyde **27** provided the 5-membered ring cycloadduct **36** in 71% yield while aldehydes **28** and **33** gave the corresponding 6-membered ring cycloadducts **37** and **38** in 60 and 47% yield. In all these reactions, cycloadducts **36**–**38** were the only cycloadducts isolated. Formation of a 7-membered ring cycloadduct **39** was also possible starting from aldehyde **29** (entry 6). In this case, 54% of an inseparable mixture of three isomers was obtained. Although some literature examples have shown that as the tether length increases, an alternative regioisomer (with oxygen attached to C_2 and carbon attached to C_3) could be formed as the major regioisomer,[8] we are certain that the two major isomers in this mixture have the same regiochemistry as in other cases (with oxygen attached to C_3 and carbon attached to C_2), since ^{1}H NMR showed that both of these two isomers have two vinylic protons and one proton next to an oxygen (regioisomers with oxygen attached to C_2 and carbon attached to C_3 will not have such a proton peak since the oxygen is attached to a quaternary carbon center). However, we are not certain about the regiochemistry of the third minor isomer in the mixture. Cycloaddition of the substrate with an ester functionality within the tether (entry 7) gave a single cycloadduct **40** in 43% yield. As we noticed that most of the cycloadducts were thermally unstable and they decomposed on prolonged heating, we attempted the reactions at a lower temperature with the use of Lewis acid catalysts. Unfortunately the isolated yields were even lower than the thermal reactions. The regio- and stereo-chemistry of the cycloadducts were confirmed by NMR experiments (HCOSY, HSQC and NOESY experiments). These assignments were also supported by X-ray crystallography.[9]

Several factors could control the regio- and stereo-selectivity of the cycloadditions. Those factors include: the *E/Z* ratio of the nitrones generated from the corresponding aldehydes, the distance and the flexibility of the tether to reach the double bonds, the *exo/endo* selectivity of the double bond (C_2–C_3) in the norbornadiene in the cycloadditions, and the strain and the stability of the cycloadducts formed. At this stage, we are not sure the reasons for the formation of single cycloadducts in the cycloadditions. Either the *E/Z* selectivity of the formation of nitrones was very high and the cycloadditions were highly regio- and stereo-selective, or other cycloadducts were formed but were too unstable and decomposed under the reaction conditions. The cycloadditions can also be reversible and thus giving rise to the most stable cycloadducts. Nevertheless, although up to eight possible cycloadducts could be formed in the cycloadditions, we were able to generate and to isolate single regio- and stereo-isomers in the cycloadditions.

In conclusion, we have demonstrated the first examples of the intramolecular 1,3-dipolar cycloadditions of norbornadiene-tethered nitrones. Single regio- and stereo-isomers were obtained in moderate to good yields. Further investigation on the effect of a substitutent at C_3 on the norbornadiene in the cycloaddition (*e.g.* electron-withdrawing groups on the norbornadiene may activate the alkene component in the cycloaddition and thus a lower reaction temperature may be possible), as well as subsequent cleavage reactions of the cycloadducts (Scheme 1) for the construction of angular-fused tricyclic and spirocyclic frameworks, are ongoing in our laboratory.

We thank the Natural Science and Engineering Research Council (NSERC) of Canada and the University of Guelph for the generous financial support of our program. G. K. T. thanks the Ontario government for a Ontario Graduate Scholarship (OGS). Dr Alan Lough (University of Toronto) is thanked for X-ray structure determination and Ms Valerie Robinson from our department is thanked for NMR experiments.

Synthesis and molecular structure of the unsymmetrically substituted magnesium alkyl Mg(Bu^n){CH[SPh][SiPh$_2$(CH$_2$NC$_5$H$_{10}$)]}

Carsten Strohmann,* Bors C. Abele, Daniel Schildbach and Katja Strohfeldt

Institut für Anorganische Chemie, Universität Würzburg, Am Hubland, 97074 Würzburg, Germany. E-mail: c.strohmann@mail.uni-wuerzburg.de

Received (in Basel, Switzerland) 12th January 2000, Accepted 10th April 2000

The unsymmetrically substituted magnesium alkyl Mg(Bu^n){CH[SPh][SiPh$_2$(CH$_2$NC$_5$H$_{10}$)]} (NC$_5$H$_{10}$ = 1-piperidyl) with a stereogenic metalated carbon atom is obtained by deprotonation of an (aminomethyl)[(phenylthio)methyl]silane with MgBu^{n}Bu^s and examined by single crystal X-ray diffraction analysis and theoretical methods.

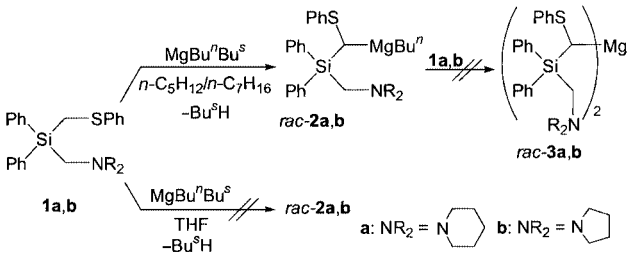
In selective transformations, enantiomerically enriched metal alkyls can work as chiral alkyl-transfer reagents. Moreover, they are valuable tools for studies on the stereochemical course of transmetalation and protonation reactions. Stereogenic metalated carbon centres are usually generated by deprotonation using alkyllithium reagents, giving the corresponding enantiomerically enriched lithium alkyls. These molecules have been investigated intensively.[1] Despite the huge synthetic potential of magnesium alkyls, only one example of an enantiomerically enriched magnesium alkyl is described in the literature.[2]

In a few reported cases, organomagnesium compounds have been used to abstract aryl protons (*e.g.* as part of crown ether systems[3]) and to deprotonate C–H-acidic molecules, such as cyclopentadiene or fluorene.[4,5,6] To turn the nucleophilic magnesium reagent into a deprotonating agent, the metal must be fixed next to the reactive centre by coordinating donor groups. (Aminomethyl)silanes, such as **1a** and **1b**, which are established in our workgroup,[7] intramolecularly provide a coordinating amino group. These (aminomethyl)silanes can be deprotonated easily by *tert*-butyllithium in non-polar solvents leading to (aminomethyl)(lithiomethyl)silanes that form definite aggregates in the solid state.[8]

Here we report the formation and molecular structure of the unsymmetrically substituted magnesium alkyls *rac*-**2a** and *rac*-**2b** with metalated stereogenic centres. *Rac*-**2a**,**b** were generated by deprotonation reaction with the purchasable MgBu^{n}Bu^s in *n*-pentane/*n*-heptane (6:1) in racemic form.

The synthesis of *rac*-**2a**,**b**† was carried out in *n*-pentane, kinetically controlled at low temperatures (−78 °C), by treating **1a**,**b** with 1 equiv. of MgBu^{n}Bu^s (solution in *n*-heptane). To our surprise, all attempts of building up the symmetrically substituted bis{[(aminomethyl)diphenylsilyl]methyl}magnesium compounds *rac*-**3a**,**b** by treating **1a**,**b** with only 0.5 equiv. of MgBu^{n}Bu^s failed. In all of these experiments, *rac*-**2a**,**b** was obtained in *ca.* 50% yield, while half the starting material remained unreacted. Even when the reaction mixture was heated to reflux temperature, only mono substitution occured. Furthermore, neither a *sec*-butyl-substituted product, nor a mixture of *sec*-butyl- and *n*-butyl-substituted products were observed. In all reactions, exclusively the MgBu^n fragment was transferred to the (aminomethyl)silanes **1a**,**b** (Scheme 1).

Earlier results in reactions of organolithium reagents indicated that there is a significant solvent effect on the reactivity of such polar metal–carbon bonds.[7] No detectable amounts of *rac*-**2a**,**b** were obtained, when the reaction of **1a**,**b** with MgBu^{n}Bu^s was carried out in THF. This can be explained by the fact that vacant coordination sites, which are essential for the precoordination of the metal by the aminomethyl ligand, are then occupied by solvent molecules. The importance of this



Scheme 1

intramolecular activation is revealed by the result that dimethylbis[(phenylthio)methyl]silane (**4**) is not metalated by MgBu^{n}Bu^s under the same conditions (Scheme 2).

To the best of our knowledge, the only magnesium alkyls containing a sulfur–carbon–magnesium unit, (PhSCH$_2$)$_2$Mg(thf)$_3$ (**5**) and (MeSCH$_2$)$_2$Mg(thf)$_3$ (**6**), were obtained by transmetalation and crystallographically examined by Steinborn and coworkers.[9] In the monomeric molecular structures of **5** and **6**, the magnesium atom is coordinated by three THF molecules. The crystal data of *rac*-**2a**,‡ together with that of **5** and **6**, is important for examining the role of the sulfur atom with respect to aggregation and reactivity.

Compound *rac*-**2a** crystallised from *n*-pentane/*n*-heptane in the triclinic crystal system, space group $P\bar{1}$. We detected two symmetry independent dimers of *rac*-**2a** in the asymmetric unit (molecule A and B) that are different in the conformation of the *n*-butyl groups and the phenyl substituents (Fig. 1). The central six-membered ring of two carbon, two magnesium and two sulfur atoms is built up by the intermolecular S–Mg coordination, that leads to an S(1)–Mg(1) distance of 275.5(1) pm. The Mg(1)–C(1) bond, which is 223.2(3) pm long, is part of another five-membered ring, due to the intramolecular coordination of the aminomethyl substituent [N(1)–Mg(1) 221.4(2) pm]. In the crystal, the metal is surrounded by four different substituents, which makes *rac*-**2a** a magnesium alkyl with a stereogenic magnesium centre. The S(1)–C(1) distances of **5** [177.7(6) pm] and *rac*-**2a** [178.1(3) pm] are nearly identical. This is not true for the S(1)–C(2) distance, which is 176.6(5) pm for **5** and 179.4(3) pm for *rac*-**2a**, as a result of the S → Mg coordination for *rac*-**2a**. The second dimer (molecule B) of *rac*-**2a** may be described in the same way and will, therefore, not be discussed. The crystal data of both molecules A and B can be found in Table 1.

Despite the intensive theoretical studies on organolithium compounds, the corresponding magnesium alkyls have not been investigated to this extent.[10] Sulfur substituents at metalated carbon atoms can increase the stability of the configuration at this centre.[11] For α-lithiated organosulfanes the rotation around

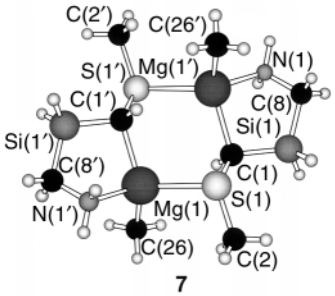

Fig. 2 B3LYP/6-31 + G(d)-optimized structure of a model system for *ab initio* studies on *rac*-**2a** (numbering scheme adopted from Fig. 1).

the C–S bond is the rate-determining step of the racemisation process. We tried to reproduce the molecular structure of *rac*-**2a** by applying density functional calculations [at the B3LYP/6-31+G(d) level] to the model system **7** (Fig. 2).[12]

Structural features, such as the shortened C–S_{alkyl} distance and the longer C–S_{aryl} bond, as well as the antiperiplanar conformation of the C–S–C–Mg unit, could be reproduced by our density functional calculations. Further studies on model systems of sulfur-substituted organomagnesium and organolithium compounds are currently in progress.

In order to build up enantiomerically enriched magnesium alkyls, which have a stereogenic carbon centre, systems of defined aggregation are necessary. The facile generation of unsymmetrically substituted dialkylmagnesium compounds like *rac*-**2a**,**b** opens up a new route to enantiomerically enriched (magnesiomethyl)silanes by using optically active aminomethyl substituents as chiral auxillaries. This has already been successfully demonstrated in the case of enantiomerically enriched (lithiomethyl)silanes.[7,13]

We gratefully acknowledge the Deutsche Forschungsgemeinschaft (DFG), the Sonderforschungsbereich (SFB) 347, and the Fonds der Chemischen Industrie (FCI) for financial support. B. C. A., D. S. and K. S. thank the FCI for the grant of three scholarships.

Optimization of enantiocontrol in *cis*-selective cyclopropanation reactions catalyzed by dirhodium(II) tetrakis[alkyl 2-oxaazetidine-4(*S*)-carboxylates]

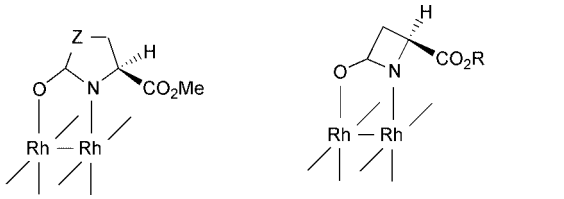
Michael P. Doyle,* Simon B. Davies and Wenhao Hu

Department of Chemistry, University of Arizona, Tucson, Arizona, 85721, USA. E-mail: mdoyle@u.arizona.edu

Received (in Corvallis, OR, USA) 18th February 2000, Accepted 7th April 2000

Both intermolecular and macrocyclic intramolecular cyclopropanation reactions occur with greater selectivity for the *cis*-(*Z*)-diastereoisomer than for the *trans*-(*E*)-diastereomer in reactions catalyzed by chiral dirhodium(II) azetidinonecarboxylates; the influence of the catalyst's ester alkyl group on enantiocontrol is substantial but appears to be delicately balanced by steric factors.

Chiral dirhodium(II) carboxamidate catalysts having the general structural framework of **1** have been widely employed to achieve high diastereoselectivity and enantiocontrol in a wide variety of catalytic metal carbene transformations.[1–3] The

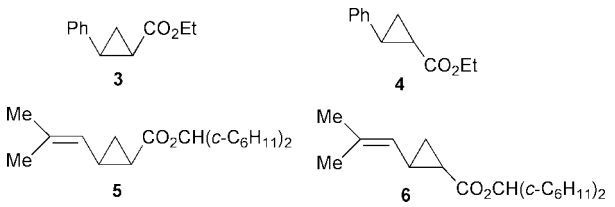


1a Z = CH_2: Rh_2(5*S*-MEPY)$_4$
1b Z = O: Rh_2(4*S*-MEOX)$_4$
1c Z = $NCOCH_2CH_2Ph$: Rh_2(5*S*-MPPIM)$_4$

2a R = Bu^i: Rh_2(4*S*-IBAZ)$_4$
2b R = Bn: Rh_2(4*S*-BNAZ)$_4$
2c R = Me: Rh_2(4*S*-MEAZ)$_4$
2d R = CH_2CMe_3: Rh_2(4*S*-NEPAZ)$_4$
2e R = *c*-C_6H_{11}: Rh_2(4*S*-CHAZ)$_4$

methyl ester has been commonly employed because early investigations showed no significant difference in enantiocontrol with ester variation from methyl to octadecyl and from isopropyl to neopentyl.[4–6] However, we recently reported the preparation of two chiral azetidinone-4-carboxylate-ligated dirhodium(II) catalysts, Rh_2(4*S*-IBAZ)$_4$ **2a** and Rh_2(4*S*-BNAZ)$_4$ **2b**, whose ester alkyl group seemed to have a significant influence on enantiocontrol in cyclopropanation[7] and insertion[8] transformations. We now report, from results obtained with a broad selection of these catalysts, that the size of the ester alkyl group has a modest influence on diastereoselectivity but has a substantial, but irregular, effect on enantiocontrol in addition reactions.

The catalytic reaction of ethyl diazoacetate (EDA) with styrene is the classic transformation with which stereoselectivity for cyclopropanation is measured and catalyst effectiveness is determined.[1,9] Products are *cis*- and *trans*-2-phenylcyclopropanecarboxylate esters **3** and **4**.



3 **4** **5** **6**

Chiral copper, ruthenium and cobalt catalysts show a marked preference for the *trans* isomer **4**, and this is also true for application of the dirhodium carboxamidate catalyst **1a**.[1,9] An exception is the Ru–salen catalyst recently reported by Katsuki and co-workers.[10] However, the use of chiral azetidinone catalysts **2** provides a distinct preference for the thermodynamically less stable **3** (Table 1), and enantiocontrol for the favored isomer is quite respectable. With 4-methylpenta-l,3-diene and dicyclohexylmethyl diazoacetate (DCDA)[11] these same catalysts show exclusive regioselection for addition to the less-substituted double bond (**5** + **6**), comparable diastereocontrol to that obtained with styrene/EDA, and exceptional enantiocontrol in the formation of **5**. The absolute configuration for the major isomer of **3** (and **5**) is (1*S*, 2*R*); that for **4** (and **6**) is (1*S*, 2*S*).

Table 1 Stereocontrol in intermolecular asymmetric cyclopropanation reactions catalyzed by **2**[a]

Catalyst	Isolated yield (%)[b]	**3**:**5**(**5**:**6**)	Ee(%) **3**(**5**)	Ee(%) **4**(**6**)
$PhCH{=}CH_2$ + EDA:[c]				
Rh_2(4*S*-IBAZ)$_4$ **2a**	62	69:31	76	52
Rh_2(4*S*-BNAZ)$_4$ **2b**	74	58:42	60	32
Rh_2(4*S*-MEAZ)$_4$ **2c**	65	55:45	58	32
Rh_2(4*S*-NEPAZ)$_4$ **2d**	69	66:34	67	34
Rh_2(4*S*-CHAZ)$_4$ **2e**	68	64:36	70	50
$Me_2C{=}CHCH{=}CH_2$ + DCDA:[d]				
Rh_2(4*S*-IBAZ)$_4$ **2a**[e]	81	54:46	>98	66
Rh_2(4*S*-BNAZ)$_4$ **2b**	89	42:58	>98	70
Rh_2(4*S*-MEAZ)$_4$ **2c**	86	43:57	91	63
Rh_2(4*S*-NEPAZ)$_4$ **2d**	91	49:51	>98	70
Rh_2(4*S*-CHAZ)$_4$ **2e**	80	53:47	83	60

[a] Reactions were performed in refluxing CH_2Cl_2 using 1.0 mol% catalyst. [b] Yield of **3** + **4** (or **5** + **6**) after chromatography. [c] [Styrene]/[EDA] = 10; % ee values obtained by GC on a 30 m Chiraldex B-DM column with *cis*-isomers eluting before *trans*-isomers. [d] [Diene]/[DCDA] = 4; % ee values obtained from the methyl esters following saponification and resterification with analysis on a 30 m Chiraldex G-TA column. [e] Data from ref. 7.

As can be seen from the data in Table 1, diastereoselectivity and enantioselectivity are responsive to the ester alkyl group of the catalyst ligand. Larger alkyl groups favor the *cis*-cyclopropanecarboxylate isomer more than do the smaller ones (**2b** and **2c**). In addition to suggesting the potential of **2** for predominant formation of highly enantioenriched *cis*-substituted cyclopropanecarboxylates, however, the data in Table 1 also allow us to correct data previously reported for Rh_2(4*S*-BNAZ)$_4$[7] which showed considerably lower enantioselectivities from those reported in Table 1.

Catalysts **1** have been shown to be particularly suitable for high enantiocontrol in intramolecular cyclopropanation reactions of allylic diazoacetates, providing the cyclized products in high yields and with ee values >94%.[1,3,12] With allyl diazoacetate **7**, for example, use of Rh_2(5*S*-MEPY)$_4$ **1a** gives the corresponding bicyclic lactone **8** in good yield and with 95% ee. In contrast, chiral azetidinones **2** do not have such high enantiocontrol in reactions with **7** (Table 2), but they do show a remarkable variation in % ee as a function of the ester alkyl group on the catalyst.

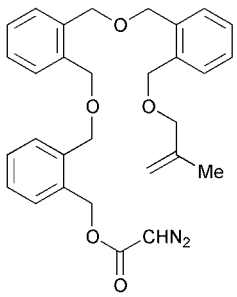
Table 2 Enantiocontrol in intramolecular asymmetric cyclopropanation reaction of allyl diazoacetate by **2**[a]

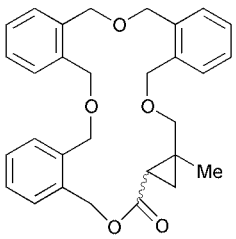
Catalyst	Isolated yield of **8** (%)[b]	Ee (%) of **8**[c]
Rh_2(4S-IBAZ)$_4$ **2a**	74	80
Rh_2(4S-BNAZ)$_4$ **2b**	70	56
Rh_2(4S-MEAZ)$_4$ **2c**	77	76
Rh_2(4S-NEPAZ)$_4$ **2d**	63	58
Rh_2(4S-CHAZ)$_4$ **2e**	90	68

[a] Reactions were performed in refluxing CH_2Cl_2 using 1.0 mol% catalyst. [b] Yield of **8** after chromatography. [c] Determined by GC on a 30 m Chiraldex G-PN column at 100 °C; the major isomer elutes first.

Macrocyclization in cyclopropanation reactions has recently been demonstrated to be a general transformation,[13] although less suitable for enantiocontrolled syntheses with catalysts **1** than with chiral copper(I) bis-oxazoline complexes.[14] In the limit, as the attachment of the carbon–carbon double bond to the diazoacetate becomes increasingly longer, enantioselectivity is expected to approach that obtained in the intermolecular transformation. To further evaluate the macrocyclization process, methallyl diazoacetate **9** was treated with each catalyst in the series of chiral dirhodium(II) azetidinones **2**. The (*Z*)- and (*E*)-cyclopropane products **10** were formed in high yield, and



9



10

% ee values for (*Z*)-**10** reached moderately high levels (Table 3). For comparison, intramolecular cyclopropanation of methallyl diazoacetate using Rh_2(4S-IBAZ)$_4$ formed the corresponding bicyclo[3.1.0]-derivative in 28% ee, which is consistent with our original hypothesis regarding enantiocontrol in macrocyclic cyclopropanation reactions.

Table 3 Stereocontrol in intramolecular asymmetric cyclopropanation reactions of **9** catalyzed by **2**[a]

Catalyst	Isolated yield of **10** (%)[b]	(*Z*)-**10**:(*E*)-**10**	Ee (%) of (*Z*)-**10**[c]
Rh_2(4S-IBAZ)$_4$ **2a**	64	78:22	69
Rh_2(4S-BNAZ)$_4$ **2b**	74	82:18	53
Rh_2(4S-MEAZ)$_4$ **2c**	78	78:22	56
Rh_2(4S-NEPAZ)$_4$ **2d**	64	82:18	62
Rh_2(4S-CHAZ)$_4$ **2e**	67	83:17	63

[a] Reactions were performed in refluxing CH_2Cl_2 using 1.0 mol% catalyst. [b] Yield of **10** following chromatography. [c] Determined following hydrogenolysis of **10** that converted (*Z*)-**10** to its bicyclo[3.1.0]-derivative with analysis performed by GC on a Chiraldex G-TA column.

The overall effectiveness of Rh_2(4S-IBAZ)$_4$ for the catalytic asymmetric cyclopropanation reactions reported here does not follow size considerations of the ligand's ester alkyl group. The isobutyl group is neither the largest nor the smallest alkyl group in the series. Yet in spite of differences exceeding 20% in enantiomeric excess, this catalyst consistently gives the highest level of enantiocontrol.

We are grateful to the National Science Foundation and to the National Institutes of Health (GM-46503) for their support of this research.

Preparation of a zeolite X-encapsulated copper(II) chloride complex and its catalysis for liquid-phase oxygenation of enamines in the presence of molecular oxygen

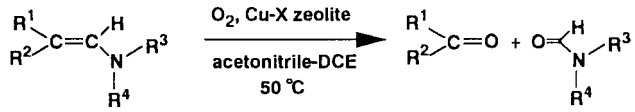
Kohki Ebitani, Kohji Nagashima, Tomoo Mizugaki and Kiyotomi Kaneda*

Department of Chemical Science and Engineering, Graduate School of Engineering Science, Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka 560-8531, Japan. E-mail: kaneda@cheng.es.osaka-u.ac.jp

Received (in Cambridge, UK) 24th February 2000, Accepted 11th April 2000

Copper(II) chloride complexes were readily prepared within pores of zeolite X with the modified zeolite found to act as a heterogeneous catalyst for the oxygenation of a variety of enamines in the presence of molecular oxygen without leaching of the active copper species.

Highly selective transformation of organic compounds catalysed by solid materials can contribute to the strong demand of environmental concerns in chemical processes because of the following advantages: (i) simple work-up procedures, (ii) reusable catalysts, and (iii) high thermal stabilities.[1–3] Use of metal catalysts in a liquid phase, however, sometimes leads to leaching of the active species from the solid surface into solution[4] which causes a serious loss of activity and contamination of the products. Here, we describe the synthesis of a Cu(II) chloride complex catalyst within the pores of zeolite X for the selective oxygenation of enamines in the presence of molecular oxygen (Scheme 1). This catalyst can be reused without leaching of the Cu species and retains its high catalytic activity and selectivity for the above oxygenation.



Scheme 1

Copper ion-exchanged X zeolite (Cu–X) was prepared by a treatment of Na–X zeolite, $Na_{86}(Al_{86}Si_{106}O_{384})\cdot 264H_2O$ (Si/Al = 1.23, Wako Co. Ltd.), with a 0.01 M aqueous solution of $Cu(NO_3)_2\cdot 3H_2O$. The powder was washed with deionized water, followed by drying and calcination at 300 °C to give a sky-blue Cu–X sample. The Cu content in this sample was 12.0 wt%, which corresponds to 83% ion exchange degree of Na^+. Retention of the crystal structure of the X zeolite was confirmed by XRD. *In situ* EPR, UV–VIS and Cu K-edge XANES spectra for the Cu–X sample indicated dispersed divalent Cu^{2+} with a centrosymmetric coordination environment, *i.e.* octahedral. Curve-fitting analysis of the Fourier-transformed copper EXAFS showed that the Cu^{2+} cations displayed Jahn–Teller distorted CuO_6 octahedra[5] with four short Cu–O distances (1.91 Å) and two long Cu–O distances (2.28 Å). The Cu–O distance of 1.91 Å is slightly shorter than the value of 1.97 Å found in Cu–Y zeolites.[6] A lack of a peak at *ca.* 3 Å in the Fourier transform of the Cu K-edge EXAFS indicated selective formation of monomeric Cu^{2+} species. A coordination sphere of the CuO_6 octahedra within the zeolite pores is proposed as shown in Fig. 1(a) where the Cu^{2+} ion is reasonably located in a vicinity of the exchangeable site II, just outside the sodalite cage in a large pore with 7.4 Å diameter.[7]

Cu–X (0.50 g) was further treated with 1,2-dichloroethane (DCE, 10 mL) at 50 °C for 1 h, followed by drying to afford an emerald greenish powder, Cu(Cl)–X. The presence of Cu–Cl bonds was confirmed by XPS measurements and elemental analysis; the atomic ratio of Cu to Cl was 1:1.8. EXAFS analysis of Cu(Cl)–X also revealed a Jahn–Teller distorted Cu^{2+}

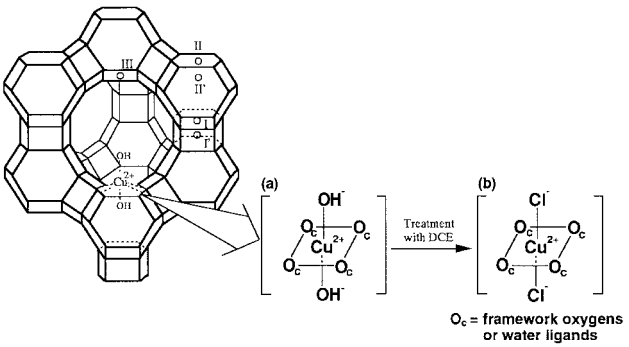


Fig. 1 Proposed schematic structure of Cu^{2+} octahedral species within the framework structure of zeolite X. (a) CuO_6 octahedral species, (b) CuO_4Cl_2 octahedral species. The octahedral CuO_4X_2 species is coordinated to oxygens of zeolite framework and H_2O ligands. The positions of exchangeable cations are indicated by Roman letters.

octahedron with four Cu–O bonds (1.92 Å) and two Cu–Cl bonds (2.29 Å). The Cu–Cl distance of 2.29 Å is consistent with a Cu–Cl bond length of 2.30 Å in $CuCl_2$ and a proposed structure of the monomeric Cu^{2+} chloride complex is shown in Fig. 1(b). To our knowledge, this is the *first* example of the synthesis of a copper(II) chloride species within a pore of zeolite X. It has been stated that Cu chloride complexes can not be formed within the pores of zeolite X by a simple exchange reaction of Na–X with $CuCl_2$ solution because of destruction of the faujasite structure of zeolite X.[8] In zeolite Y, adoption of burdensome methods such as chemical vapor deposition[6] or a solid-state ion-exchange[8] can afford monovalent copper chloride species. The chlorine in Cu(Cl)–X originates from a DCE molecule during the treatment of Cu–X with DCE. The fact is supported by the formation of dibenzyl ether upon treatment of Cu–X with benzyl chloride in place of DCE.[9]

We have already reported that copper chloride compounds are effective homogeneous catalysts for the oxidative cleavage of carbon double bonds of enamines in the presence of molecular oxygen.[10] To explore the potential catalytic abilities of the Cu(II) chloride complexes within the zeolite X,[11] oxygenation of enamines using Cu–X was performed.† Typical results for the oxygenation of enamines with Cu–X in acetonitrile–DCE are summarized in Table 1.‡ The carbon double bonds of many enamines were smoothly cleaved to give the corresponding amides and ketones (entries 1, 2 and 4–8). For a bulky enamine such as 1-(4-morpholino)-2,2-diphenylethene, the oxygenation rate with Cu–X was slower than that of a homogeneous $CuCl_2$ catalyst (entry 9 *vs.* 10). This different activity between the heterogeneous Cu–X and the homogeneous $CuCl_2$ catalyst might be ascribed to a shape-selective effect of Cu^{2+} species within the three-dimensional zeolite pores. The Cu–X catalyst was also active for the oxygenation of 2,3-dimethylindole (entry 11).§

The Cu–X catalyst could be easily separated from the reaction mixture and reused without an appreciable loss of its

activity for the oxygenation; the first, second and third runs of the reused catalyst for 1-(4-morpholino)-2-methylpropene gave *N*-formylmorpholine in >90% yield. The loss of Cu content in the spent Cu–X catalyst after several reuse experiments was <1%; the Cu content in the catalyst did not change even after the third reuse. ICP analysis of copper in the liquid phase after oxygenation showed that leached copper from the catalyst was <1% in the spent Cu–X catalyst.¶ The fact that the active copper complex does not leach from the zeolite X during the oxygenation and recycling procedures, indicates a reusable heterogeneous catalyst for the liquid-phase oxidation.

We presume that the oxygenation catalysed by the Cu(Cl)–X catalyst might involve one-electron transfer from the enamine to molecular oxygen in a ternary Cu^{2+} complex bonded to enamine and O_2, followed by the formation of Cu^{2+} and a dioxetane intermediate.[10] Strong binding of the Cu chloride complexes on the zeolite is due to the location of the divalent Cu ions within large supercages, bound to oxygens of the zeolite framework [Fig. 1(b)].[12] During the oxygenation, facile coordination of enamine and O_2 to the active Cu center can occur since some ligands such as H_2O on the Cu active species are labile.

In conclusion, monomeric copper(II) chloride species within the pore of zeolite X can be synthesized by a novel and convenient method, and are found to be effective catalysts for the cleavage of enamine double bonds in the presence of molecular oxygen. This zeolite X-encapsulated copper chloride complex is a unique instance of a heterogeneous and reusable catalyst which does not undergo leaching of the active species.

X-Ray absorption experiments were carried out under the approval of Japan Synchrotron Radiation Research Institute (JASRI) (proposal no. 1999A0083). We thank Professor Tsunehiro Tanaka at Kyoto University for providing his program for analysis of EXAFS. We are also grateful to Dept. Chem. Sci. Eng., Fac. Eng. Sci., Osaka Univ., for scientific support *via* 'Gas-Hydrate Analyzing System (GHAS)'.

Notes and references

† The order of the catalytic activity of various copper catalysts for the oxygenation of 1-(4-morpholino)-2-methylpropene is: Cu–X(93) > Cu–Y(82) > Cu-mordenite(76) > Cu/Al_2O_3(72) > Cu/SiO_2 (38), where values in parentheses are yields of *N*-formylmorpholine.

‡ We confirmed that the catalysis of Cu–X in the mixed solvent corresponded to that of Cu(Cl)–X. Cu(Cl)–X itself effectively oxygenated the enamine in acetonitrile alone (yield: 70%). Solvents having high dielectronic constants such as acetonitrile, DMF and ethanol were effective co-solvents for DCE, as similarly observed in the homogeneous catalyst system using $CuCl_2$.[10]

§ Interestingly, this heterogeneous catalyst showed higher activity than $CuCl_2$ for 2,3-dimethylindole,[13] however, the oxidation of 3-methylindole resulted in a low yield (34% after 24 h).

¶ When the filtrate at 50% enamine conversion was allowed to react further at 50 °C under an oxygen atmosphere, oxygenation did not occur.

Amidoalane, amidogallane and amidoindane, H_2MNH_2 (M = Al, Ga or In): a matrix study of three prototypal molecules with the potential for M–N multiple bonding

Hans-Jörg Himmel,* Anthony J. Downs and Tim M. Greene

Received (in Basel, Switzerland) 29th February 2000, Accepted 7th April 2000

Photolysis of Al, Ga or In atoms (M) isolated in NH_3-doped Ar matrices gives first the divalent amido derivative $HMNH_2$ (λ = 436 nm) and then the univalent and trivalent amido derivatives MNH_2 and H_2MNH_2 (λ = 200–800 nm); the measured and calculated properties of H_2MNH_2 are outlined.

Amido derivatives of group 13 metals are potentially relevant to the fabrication and properties of the III–V semiconductor materials AlN, GaN and InN.[1] Such compounds are normally oligomeric or polymeric, with a coordination number of four or greater at M; only with the introduction of bulky substituents at M and N can monomeric compounds with tri-coordinated M atoms be sustained under normal conditions.[2] The properties of these monomeric amido derivatives have attracted considerable theoretical attention, mainly in relation to the potential for M–N multiple bonding.[2,3]

Matrix isolation offers a highly instructive method of reconnaissance and characterisation for simple, previously unknown hydride derivatives of the main group metals.[4–6] Hence, for example, photoexcitation of metal atoms contained in solid Ar matrices doped with NH_3 has been shown previously to result in insertion of the metal into an N–H bond of NH_3 with the formation of the species $HMNH_2$ (M = Al[7]) and MNH_2 (M = Li[8] or Al[7]). Here we report specifically on the formation of the simple monomeric compounds H_2MNH_2 (M = Al, Ga or In) as products of the reactions set in train by photolysis of NH_3-doped Ar matrices containing the relevant M atoms.[9] The molecules have been identified by their IR spectra, with the conclusions being underpinned (i) by the observed effects of exchanging $^{14}NH_3$ for $^{14}ND_3$ or $^{15}NH_3$, and of the isotopes ^{69}Ga and ^{71}Ga present in natural Ga; (ii) by parallels with the spectra of related hydrido and amido derivatives, *e.g.* MH_3,[4] H_2MCl,[5,10] and $AlNH_2$[7] (M = Al, Ga or In); and (iii) by comparisons with the IR spectra forecast by density functional theory (DFT) calculations.[11] In the following account we will concentrate on the formation and characterisation of H_2GaNH_2; the aluminium and indium analogues follow a very similar pattern, with the results summarized in Table 1.

An Ar matrix containing *ca.* 0.2% Ga atoms and up to 2% NH_3 gave an IR spectrum including, in addition to the absorptions characteristic of NH_3 and $[NH_3]_n$,[12] a new absorption at 1104.2 cm^{-1} attributable to an adduct $Ga{\cdot}NH_3$ **1**. There was also associated with this product a visible absorption centered at 440 nm. Irradiation of the matrix with radiation having λ = 436 nm for 5 min resulted in the decay of the spectroscopic features due to **1** and the appearance of new IR bands at 1721.8, 1528.7, 746.2, 668.5/667.4 494.1 and 210.9 cm^{-1} attributable on the strength of their constant relative intensities to a second product **2**. All the criteria (i)–(iii) indicate that **2** is the gallium(II) amide $HGaNH_2$, showing clear spectroscopic analogies with GaH_2[4] and CH_3GaH.[6]

Photolysis for a further 30 min, but with broad-band UV–VIS light (200 < λ < 800 nm) led to the decay of the bands due to

Table 1 Structures (distances in Å, angles in degrees), rotational barriers ΔE (kJ mol^{-1}), wavenumbers [cm^{-1}, intensities (km mol^{-1}) are given in parentheses] and M–N force constants *f*(MN) (N m^{-1}) for H_2MNH_2 molecules (M = Al, Ga and In)

(b) Bottom: IR spectrum of H_2GaNH_2 in the region around 700 cm^{-1}; top: curve fit with two Lorentzian-type functions with an intensity ratio reflecting the proportions $^{69}Ga/^{71}Ga$ = 60.1 : 39.9 in naturally occurring Ga.

2 with the simultaneous appearance and growth of a new family of bands having a common origin in a third product **3**. Occurring at 3471.6, 1505.9, 589.3/587.9 and 314.5 cm^{-1}, these could be identified with the gallium(I) amide $GaNH_2$, a conclusion supported by the criteria (i)–(iii) and by analogy with the IR spectrum reported for $AlNH_2$.[7] Extending the period of photolysis resulted in the continued accumulation of **3** at the expense of **2**. Additionally, another group of bands, also with constant relative intensities and therefore associated with a fourth distinct product **4**, was observed to develop (see Fig. 1). The members of this group were located at 3510.7, 3413.4, 1970.8, 1530.4, 782.8, 779.6, 706.2/704.1, 567.7 and 304.9 cm^{-1}, those at 1970.8, 782.8, 706.2/704.1 and 304.9 cm^{-1} being the most prominent. Diagnostic aspects are (i) the strong absorption at 1970.8 cm^{-1} occurring in the region characteristic of ν(Ga–H) vibrations of terminal Ga(III)–H bonds (*cf.* GaH_3 1923.2 cm^{-1} [4] and H_2GaCl 1964.6–1978.1 cm^{-1} [9]); (ii) the absorptions at 3510.7, 3413.4 and 1530.4 cm^{-1} implying the presence of an NH_2 group; and (iii) the doublet pattern at 706.2/704.1 cm^{-1} attributable to $^{69}Ga/^{71}Ga$ splitting arising from the motion of a single Ga atom (see Fig. 1). The criteria (i)–(iii) leave little doubt that **4** is monomeric amidogallane, H_2GaNH_2, more familiar as a trimer which is stable at temperatures up to nearly 150 °C.[13] Out of the 11 IR-active modes ($5a_1 + 2b_1 + 4b_2$) expected for planar H_2GaNH_2 with C_{2v} symmetry, all but one have been satisfactorily located in the spectrum measured for **4**, the only absentee being ν_{12} (b_2) which is expected to lie near 420 cm^{-1} but is probably obscured by extraneous absorptions. In other respects the calculations anticipate remarkably closely the observed wavenumbers, relative intensities, and isotopic shifts to provide a convincing basis for the assignments entered in Table 1. For example, the observed $^{69}Ga/^{71}Ga$ splitting of 2.1 cm^{-1} displayed by the absorption near 705 cm^{-1} matches admirably the calculated value of 1.9 cm^{-1} for the ν(Ga–N) mode, ν_5 (a_1).

The amides H_2AlNH_2 and H_2InNH_2 have each been formed and characterised in analogous experiments involving Al and In atoms, respectively. With the indium compound, formed only in low concentrations, no more than four weak IR absorptions could be clearly associated, although the wavenumbers and isotopic shifts, allied to the circumstances, vouch for its identity. Nine of the IR-active fundamentals of H_2AlNH_2 were located with confidence. Two of the most prominent bands, at 1899.3 and 1891.0 cm^{-1}, tally with features reported in earlier matrix studies[7] of the reactions between laser-ablated Al atoms and NH_3 and assigned somewhat tentatively not to H_2AlNH_2 but to the quasi-linear, high-energy HAlNH molecule. Experiments with all three metals and involving different concentrations of NH_3 or mixtures of NH_3 and H_2 make it clear that H_2MNH_2 is formed from $HMNH_2$ or MNH_2 by the addition of H atoms generated by the photodecomposition of $HMNH_2$ (or MH_2 when H_2 is present[4]).

Calculated and observed properties of H_2AlNH_2, H_2GaNH_2 and H_2InNH_2 are listed in Table 1. In each case, the global minimum is calculated to correspond to a planar ethene-like geometry, although, as noted elsewhere,[2] a planar M–NH_2 geometry is not necessarily a sign of strong π bonding. The calculated M–N distances are indeed short, near or below the lower limits for the observed distances in tri-coordinated amido derivatives of these elements (1.78, 1.818 and 2.049 Å for M = Al, Ga and In, respectively);[2] with respect to related species the order is $M{\cdot}NH_3 > H_3M{\cdot}NH_3 > MNH_2 > MN > HMNH_2 \geqslant H_2MNH_2 > HMNH'$. The M–N stretching force constants, based where possible on the measured spectra, vary in the orders (i) $H_2MNH_2 \geqslant HMNH_2 \geqslant MNH_2 \gg H_3M{\cdot}NH_3 \gg M{\cdot}NH_3$, and (ii) M = B $\gg$ Al $\geqslant$ Ga > In for H_2MNH_2. Calculation of the energy of the transition state in which the H_2M and NH_2 planes are orthogonal gives an estimate of the barrier to rotation about the M–N bond, ΔE, in H_2MNH_2. The results included in Table 1 are consistent with those reported elsewhere,[2] with ΔE = 161.9, 50.6, 65.7 and 51.5 kJ mol^{-1} for M = B, Al, Ga and In, respectively. Gallium may then be seen once again to be out of line with its neighbours and to show a modest return to the behaviour of boron,[1] but the barriers support the general view that, with the exception of M = B, the primary influence on the M–N bonding is not the π interaction but the polarity of the unit.

We thank (i) the EPSRC for support of this research and the award of an Advanced Fellowship to T. M. G., and (ii) the Deutsche Forschungsgemeinschaft for the award of a post-doctoral grant to H.-J. H.

Palladium catalysed synthesis of pyrroles from enamines

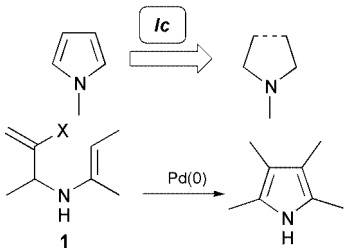
Ronald Grigg* and Vladimir Savic

Molecular Innovation, Diversity and Automated Synthesis (MIDAS) Centre, School of Chemistry, Leeds University, Leeds, UK LS2 9JT. E-mail: r.grigg@chem.leeds.ac.uk

Received (in Cambridge, UK) 20th March 2000, Accepted 14th April 2000

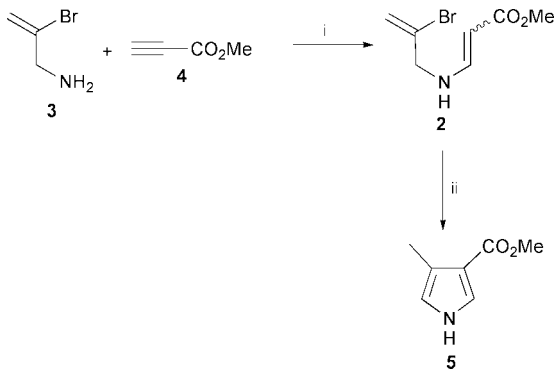
Substituted pyrroles are formed in moderate to good yields by the Pd-catalysed cyclisation of enamines containing β-vinyl bromide functionalities.

Pyrrole and its derivatives feature widely in natural products, drugs, polymers and dyes.[1,2] As a result many efficient synthetic procedures for their preparation have been developed.[3] The synthetic methodology for the preparation of pyrrole and its derivatives can be classified in terms of the number and location of the bonds formed in the reaction.[3a] We are particularly interested in the ***Ic*** approach (Scheme 1) since this approach although frequently used in the synthesis of indoles,[3a,b,4] is quite rare for pyrrole synthesis. It was expected that easily accessible enamines of type **1** would provide access to the desired synthetic procedure ***Ic*** (Scheme 1).



Scheme 1

The results of an initial experiment are shown in Scheme 2. The enamine **2** was prepared in 84% yield by reacting amine **3** and alkyne **4** in DMF at room temperature. The cyclisation step (DMF, 85 °C, oil bath temperature) in the presence of $Pd(OAc)_2$ (10 mol%)/PPh_3 (20 mol%) and K_2CO_3 (2 equiv.) as a base afforded the expected pyrrole **5** but in only 24% yield.

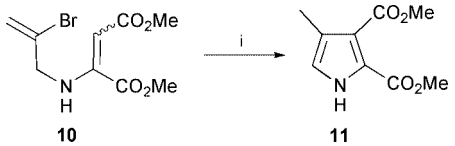


Scheme 2 *Reagents and conditions*: i, DMF, room temp., 84%; ii, $Pd(OAc)_2$, PPh_3, K_2CO_3, DMF, 85 °C, 24%.

Assuming that the low yield of **5** could be caused by instability of the pyrrole product, several other enamines (Table 1) were prepared using similar synthetic procedures in order to further investigate the cyclisation reaction. With bis-substituted alkynes (Table 1, entries c, d and h) the reactions were performed in DMF at 60–65 °C (oil-bath temperature) or in boiling ethanol[5] (Table 1, entry e) producing the required enamines in good yield. Monosubstituted alkynes (Table 1, entries a, f and g) afforded the enamines at room temperature. Enamine **8b** was prepared by addition of propenylamine to the allene in DMF at room temperature. Most of the enamines comprised mixtures of *Z*- and *E*-isomers and these mixtures were used for the cyclisation reactions without attempts to separate the stereoisomers.

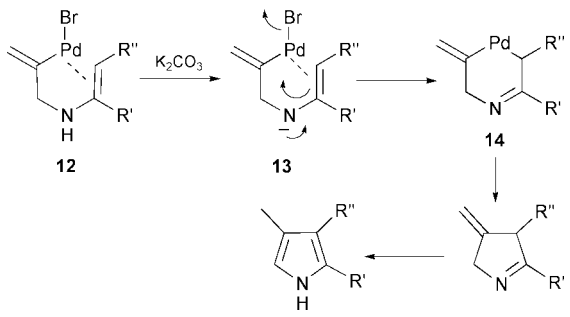
With **8a**–**h** in hand their conversion to the corresponding pyrroles was investigated. The reactions were performed in DMF at 85 °C in the presence of $Pd(OAc)_2/PPh_3$ and K_2CO_3 as already explained affording **9a**–**h** in moderate to good yields. The reaction tolerates a range of functional groups and reaction times are in most cases between 1 and 3 h.

Mechanistically the cyclisation step can be rationalised in several ways. It is possible that Pd(II) acts as a Lewis acid by coordinating either the enamine double bond or the electron withdrawing group (CO_2Me, $SO_2C_6H_4Me$-*p*) lowering the pK_a of the N–H group. This would facilitate the formation of the corresponding anion leading to cyclisation *via* nucleophilic attack on the vinyl bromide moiety. Interestingly we observed that for enamine **10**, where the pK_a of the N–H group is sufficiently low to allow deprotonation by K_2CO_3, the Pd-catalyst is not required (Scheme 3). The expected product **11** was formed by heating **10** in DMF (85 °C) in the presence of only K_2CO_3. The reaction with other enamines used in this study without the Pd-catalyst but in the presence of K_2CO_3 resulted in recovery of the starting materials. ^{1}H NMR spectroscopy of the crude reaction mixtures indicated the presence of a small amount of product only in the case of enamine **8e** after a significantly longer reaction time than for reaction performed in the presence of Pd-catalyst (6 *cf.* 1 h).



Scheme 3 *Reagents and conditions*: i, K_2CO_3, DMF, 85 °C, 53%.

Another mechanistic rationalisation of the reaction is shown in Scheme 4. This involves the oxidative addition of Pd(0) into the C–Br bond followed by coordination to the enamine double bond to form **12**. Formation of the anion **13** and nucleophilic substitution of bromide at the Pd[7] leads to palladacycles **14**



Scheme 4

DOI: 10.1039/b002211j

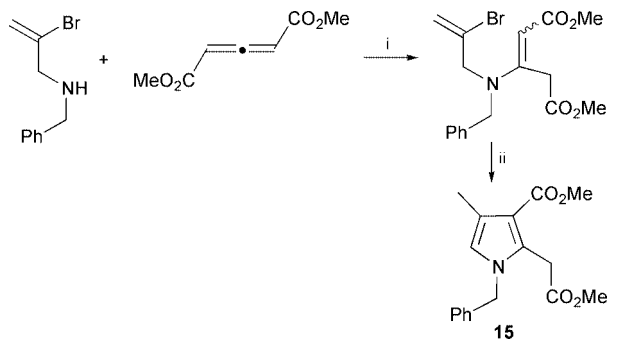
Table 1

Entry	Amine	Alkyne/allene **7**	Enamine **8** (yield)	Pyrrole **9** (yield)
a	**3**		 (94%)	 (39%)
b	**3**		 (82%)	 (41%)
c	**3**		 (41%)	 (68%)
d	**3**		 (90%)	 (65%)
e	**3**		 (78%)	 (69%)
f	 **6**[6]		 (84%)	 (35%)
g	**6**		 (90%)	 (68%)
h	**6**		 (84%)	 (73%)

which after reductive elimination and isomerisation produces the pyrroles.

Nucleophilic substitution at Pd(II) followed by reductive elimination is a process well known in the literature[7] and in the current reactions more likely than disfavoured 5-*endo* cyclisation. Some related synthesis of pyrrolidine[8] and pyrroline[9] derivatives that involve nucleophilic substitution at Pd(II) are known.

The same approach was applied for the synthesis of **15**, a potentially important pyrrole for the preparation of compounds with anti-inflammatory activity[10] (Scheme 5). Performing the cyclisation reaction in the presence of a Pd-catalyst afforded the desired pyrrole in 94% yield. In this case the anion is formed by deprotonation at the methylene group adjacent to the ester functionality.



Scheme 5 *Reagents and conditions*: i, DMF, room temp., 86%; ii, $Pd(OAc)_2$, PPh_3, K_2CO_3, DMF, 85 °C, 94%.

In conclusion, we report a novel synthetic route for the preparation of substituted pyrroles. The two step procedure involving enamine formation followed by Pd-catalysed cyclisation produces pyrroles in good yields.

We thank the EPSRC and Leeds University for support.

Completion of a catalytic cycle of zirconium-catalyzed alkylation of silanes by addition of organic halides

Yasuyuki Ura, Ryuichiro Hara and Tamotsu Takahashi*

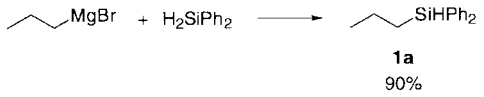
Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University; and CREST, Science and Technology Corporation (JST) Sapporo 060-0811, Japan. E-mail: tamotsu@cat.hokudai.ac.jp

Received (in Cambridge, UK) 28th March 2000, Accepted 11th April 2000

A catalytic cycle in zirconium-catalyzed alkylation of silanes with secondary Grignard reagents was completed by addition of organic halides which were not incorporated in the products.

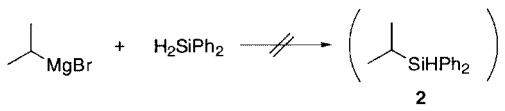
We have found and reported catalytic cycles containing a Zr(II) species and zirconacycles in carbon–carbon bond formation by the reaction of olefins and/or acetylenes with Grignard reagents.[1–5] One principle of the Zr(II)-mediated or -catalyzed reactions is the use of facile interchange of its oxidation states, II and IV. The zirconium(II) species is known to be of good π-electron accepting ability and oxidatively couples two unsaturated organic molecules. During the coupling reaction, the Zr(II) species is converted into Zr(IV). On these bases, zirconium(II)-catalyzed reactions have been developed involving olefins[1–4] and, in some cases, acetylenes.[5] We also reported not only unsaturated substrates but also dihydrogen[2] or silanes[3] as partners of unsaturated compounds such as olefins. During our investigations of zirconium-mediated alkylation reactions of silanes, we found that addition of organic halides led to a catalytic cycle in which the organic halides were not incorporated in the products. Herein, we report a novel type of catalytic cycle in alkylation of silanes with secondary Grignard reagents using zirconium.

It is well known that when H_2SiPh_2 is treated with Pr^nMgBr in THF at room temperature, a nearly quantitative yield of $Pr^nSi(H)Ph_2$ **1** is obtained [eqn. (1)].[6] It is interesting that



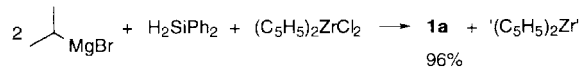
(1)

H_2SiPh_2 does not react at all with the more sterically hindered Pr^iMgBr under the same conditions [eqn. (2)].



(2)

However, we found that when a stoichiometric amount of $(C_5H_5)_2ZrCl_2$ was added in the presence of a two-fold amount of Pr^iMgBr, the reaction of H_2SiPh_2 with Pr^iMgBr proceeded to give **1a**, instead of the expected product $Pr^iSi(H)Ph_2$ **2** [eqn. (3)]. A stoichiometric amount of $(C_5H_5)_2ZrCl_2$ is required

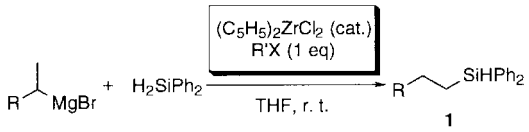


(3)

since the outcome of the reaction is explained by the total conversion to **1a**, '$(C_5H_5)_2Zr$,' *n*-C_3H_8 and 2 equiv. of MgX_2. Since the Pr^i group was changed to an Pr^n group in the product, it is reasonable to consider that the Pr^i group is converted into propene on zirconium and then reacts with silane to afford $Pr^nSi(H)Ph_2$ and the Zr(II) species.

In order to extend this stoichiometric reaction to a catalytic reaction, oxidation of the built-up Zr(II) species was investigated. We found that certain organic halides were suitable for oxidation of the '$(C_5H_5)_2Zr$' species *via* oxidative addition[7–9] and tolerate the reaction conditions.

Under catalytic conditions, typically 10 mol% of $(C_5H_5)_2ZrCl_2$ and 1 equiv. of an organic halide were employed [eqn. (4)]. The results of a comparison study using various



(4)

organic halides as additives are shown in Table 1 As a control experiment, when no organic halide was added, the reaction gave only 22% yield of Pr^nSiHPh_2 **1a**. When 1 equiv. of bromo- or iodo-propane was added, the desired product was obtained in 67 and 91% yield, respectively. This remarkable improvement clearly showed that a catalytic cycle was achieved. The best result of 99% yield was obtained when 1,3-dibromopropane was used as the additive. Though bromobenzene, bromopropane and iodopropane showed fairly good performances, iodobenzene showed a very poor effect on this reaction, which may be due to the readily occurring deiodination.[9] 1,3-Dibromopropane was the best choice by far as additive and the reaction proceeded with as little as 2 mol% of the catalyst. In the absence of $(C_5H_5)_2ZrCl_2$ **1a** was not formed.

Similarly, when H_2SiPh_2 was treated under the same conditions with 2 equiv. of Bu^sMgCl, Bu^nSiHPh_2 **1b** was obtained in 89% yield. In spite of our attempts, tertiary Grignard reagents such as Bu^tMgCl or secondary Grignard reagents such as cyclohexylmagnesium bromide did not successfully promote this reaction owing, probably, to the instability of the corresponding disubstituted-olefin zirconium complexes.

To understand the role and the superiority of 1,3-dibromopropane, 2-benzyl-1,3-dibromopropane **3** was used as an

Table 1 Reactions of Pr^iMgBr with H_2SiPh_2 in the presence of a catalytic amount of $(C_5H_5)_2ZrCl_2$ and various organic halides[a,b]

Entry	R′X	Cp_2ZrCl_2/ eq	Time/h	Yield (%)[c]
1	—	0.1	24	22
2	1-Bromopropane	0.1	6	67
3	1-Iodopropane	0.1	6	91

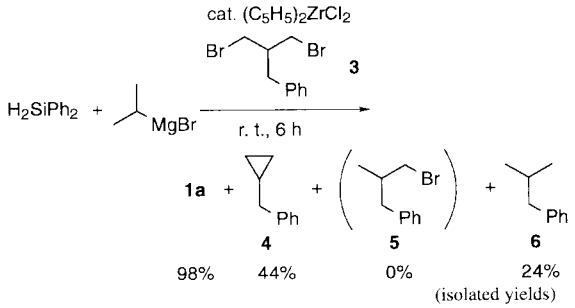
5	1,3-Dibromopropane	0.02	24	93
6	1,3-Dibromopropane	0.01	18	41
7	1,3-Diiodopropane	0.1	3	3
8	Bromobenzene	0.1	6	78
9	Iodobenzene	0.1	1	2[d]
10	2-Bromopropene	0.1	24	73

[a] R = Me, corresponding to eqn. (4). [b] Typical reaction conditions: H_2SiPh_2 (0.5 mmol), $(C_5H_5)_2ZrCl_2$ (as indicated), Pr^iMgBr (1.5 mmol), R′X (0.5 mmol); room temp. [c] Yields were determined by GC. [d] PhI was consumed in 1 h and further reaction did not proceed.

DOI: 10.1039/b002516j

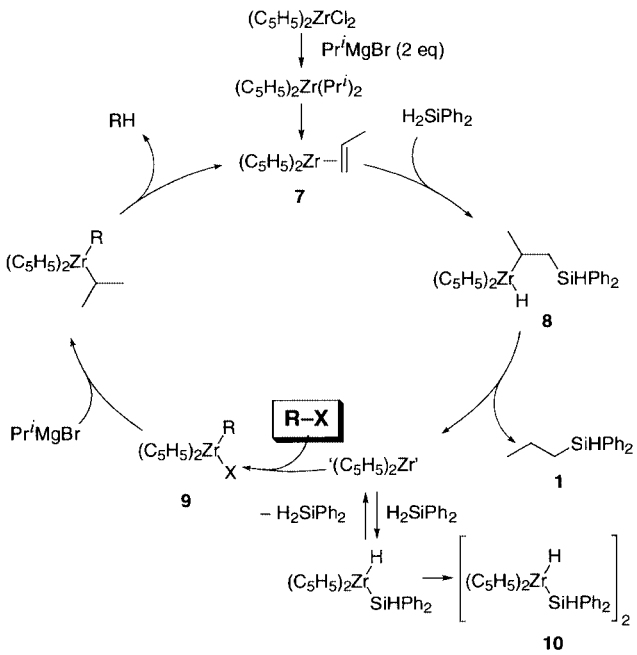
oxidation reagent and the catalytic reaction was carried out [eqn. (5)]. A mixture of three products, benzylcyclopropane **4**



(5)

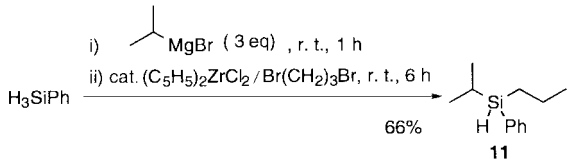
and reduction products **5** and **6** were obtained with **5** observed at an early stage. After completion of the reaction, two products, **4** and **6** were obtained in 44 and 24% yields, respectively. The formation of the major product **4** is explained by an oxidative addition of one carbon–bromine bond of **3** to the zirconium(II) species, followed by nucleophilic ring closure forming a cyclopropane ring and $(C_5H_5)_2ZrBr_2$.

On the basis of these observations, the mechanism of Scheme 1 is proposed. Zirconium–olefin complex **7** is formed and reacts with H_2SiPh_2 (**7** → **8**). Reductive elimination of the silylated compound gives Pr^nSiHPh_2 **1**. The so-formed '$(C_5H_5)_2Zr$' reacts with an alkyl bromide (RX) to give **9**,[7] followed by ligand exchange with Pr^iMgBr and β-hydride elimination to regenerate $(C_5H_5)_2Zr(C_3H_6)$ **7**. Alternatively, oxidation of '$(C_5H_5)_2Zr$' with alkyl bromides might afford $(C_5H_5)_2ZrX_2$ which is also converted into **7** by the reaction with Pr^iMgBr. An alkyl bromide plays an important role in reoxidizing the zirconium(II) species to zirconium(IV). In its absence, regeneration of the catalyst does not occur and '$(C_5H_5)_2Zr$' reacts with H_2SiPh_2 leading to the μ-hydride bridged dimer **10**.[3a]



Scheme 1

One-pot reaction of H_3SiPh with 3 Pr^iMgBr without a catalyst for 1 h followed by the addition of 10 mol% of $(C_5H_5)_2ZrCl_2$ and 1,3-dibromopropane selectively afforded $HSi(Pr^i)(Pr^n)Ph$ **11** in 66% yield [eqn. (6)]. An Pr^i group was



(6)

incorporated directly from the Grignard reagent in the absence of the catalyst, and an Pr^n group was incorporated after the addition of the zirconium catalyst with 1,3-dibromopropane.

We conclude that a zirconium(II) species is efficiently oxidized by organic halides, which assists regeneration of the active catalyst. We believe this is the first example of a zirconium(II)-catalyzed reaction in which an oxidant is explicitly added to complete the catalytic cycle. Further studies to clarify the mechanism are in progress.

Unusual solvatochromism in phosphonylated polythiophenes. Poly[3-(11-diethylphosphorylundecyl)thiophene]†‡§

Janusz Kowalik and Laren M. Tolbert

School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400, USA. E-mail: janusz.kowalik@chemistry.gatech.edu

Received (in Corvallis, OR, USA) 25th February 2000, Accepted 6th April 2000

Highly stereoregular poly[3-(11-diethylphosphorylundecyl)thiophene] 2 is soluble in both aprotic and protic solvents, yet displays a remarkable solvatochromism involving a hydrogen bond network with the phosphonate moiety.

Since their discovery and synthesis two decades ago, polythiophenes (pT) have progressed swiftly to applications.[1] A promising area for conducting polymers includes development of sensors by using macromolecules with specific receptor groups.[1b,2] The search for functional groups influencing the properties of pTs as well as allowing the design of multidimensional, supramolecular systems for truly molecular applications is well underway. Among the most important properties of polythiophenes are thermochromism and solvatochromism. The origin of both phenomena is the optical response to a conformon formation, twists in which the planarity of the backbone has been disrupted. Both features are believed to be single chain phenomena, that is, the coexistence of two separate phases in different ratios during the process is responsible for the chromic behavior.[3] Given the diverse conformational chemistry produced in nature by organophosphorus moieties, the use of a phosphonate group in the polythiophene structure provides an attractive approach to developing higher orders of organization (supramolecular systems). Here, we offer the first example of a polythiophene containing the dialkylphosphonate functionality.[4] The polymer belongs to a limited group of polythiophenes soluble in both protic and aprotic solvents, yet exhibits remarkably divergent behavior in the two solvents. Polymer **2** was synthesized in a stereocontrolled process involving nickel-mediated Negishi-type condensation of **1**[5a] obtained in a series of reactions illustrated in Scheme 1.

The resulting polymer was *ca.* 90% stereoregular, with a predominantly head-to-tail (HT–HT) connectivity.[5a,6] The

§ Electronic supplementary information (ESI) available: solutions of **2** in CH_2Cl_2 (left) and MeOH (right). See http: www.rsc.org/suppdata/cc/b0/b001621g/

polymer displayed a high degree of conjugation in the solid state, as indicated by the presence of a vibrational structure in the UV–VIS spectrum and a λ_{max} value at 558 nm with a shoulder at 606 nm.[5] In aprotic solvents (THF, $CHCl_3$) the absorption spectrum became featureless and the absorption maximum shifted to 440 nm ($\Delta\lambda_{max}$ = 118 nm). Remarkably, in protic solvents (ethanol, methanol) the shape of the absorption spectrum remained similar to that in the solid state with only a small higher-energy shift in the absorption maxima, Fig.1(*a*) and (*b*).

The solvatochromic properties of **2** were observed in a mixed CH_2Cl_2–MeOH system, with the results shown in Fig. 1. Increasing the concentration of the CH_2Cl_2 caused a reduction in the intensity of the absorption in the 550–650 nm region, with concomitant increase in the higher energy region with a maximum at *ca.* 440 nm. The presence of a pseudo-isosbestic point[7] suggested two separate species (conformons) existing in equilibrium at ratios which depended on the concentration of the protic and aprotic solvents. Interestingly, the vibrational structure of the absorption is maintained at 10% CH_2Cl_2 in MeOH, which suggests the extended conjugation within the polyaromatic backbone was rapidly lost beyond that point, owing to the enhanced freedom of rotation. There are at least three possible self-organization mechanisms to be considered: self-assembly *via* alkyl chain association, phosphoryl group dipole–dipole interaction and hydrogen bonding. Owing to exceptionally good vibrational characteristics and the sensitivity of the phosphonate moiety to its microenvironment, IR spectroscopy has long been an attractive technique in studying its hydrogen bond interactions. The highly polarized P=O bond in organophosphorus compounds is an excellent hydrogen bond acceptor, yielding complexes ranging from weak (<1 kcal mol^{-1})[8] to strong (>10 kcal mol^{-1})[9] as a function of the hydrogen bond donor. Fig. 2 illustrates the dependence of the wavenumber shift of the ν(P=O) vibration on the solvent used.

As expected by analogy with adsorption of phosphonates on transition metal surfaces,[10] the major interaction with the hydrogen donor involves bonding *via* the lone pair orbitals of

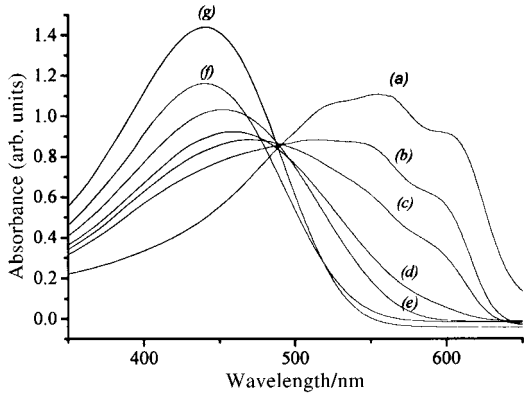

Fig. 1 Absorption spectra and solvatochromism of **2**: (*a*) solid film and (*b*)–(*g*) 10^{-4} M solutions in CH_2Cl_2–MeOH, v/v = *(b)* 0:10, (*c*) 1:9, (*d*) 2:8, (*e*) 3:7, (*f*) 8:2, (*g*) 10:0.

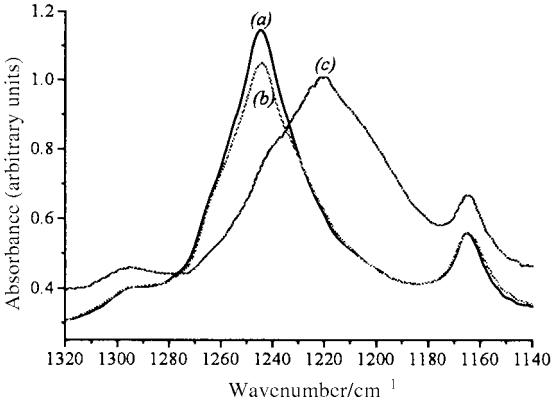

Fig. 2 IR spectra of **2** (P=O vibration): (*a*) solid film, (*b*) solid film saturated with CCl_4, (*c*) solid film saturated with MeOH.

the P=O oxygen atom. This leads to a weakening of the P=O bond and to a lowering of the corresponding mode frequency. In the gas phase, where the molecule is considered free, this peak has a maximum at 1276 cm^{-1}.[8] In our solid polymer film and the sample saturated with CCl_4 the P=O stretch appears at 1244 cm^{-1}. In the absence of a hydrogen donor it is likely that a dipole–dipole interaction between the phosphonate groups leads to aggregation[8,10a,11] and is responsible for the shift. Saturation of the polymer film with methanol leads to a shift of the P=O vibration to 1216 cm^{-1}. This absorption displays a shoulder at 1208 cm^{-1}. We suggest that the presence of two vibrational modes relates to the presence of two modes of interaction of the phosphoryl oxygen atom with the hydrogen bond donor, the 1208 cm^{-1} peak corresponding to interaction of the P=O group using both lone electron pairs.[8] The frequency shift of 28 cm^{-1} is considered indicative of a strong hydrogen-bonding interaction.[12] Hydrogen bond interactions were tested by NMR spectroscopy. ^{1}H NMR spectra for solutions of the polymer **2** in THF-d_8 and CD_3OD are shown in Fig. 3(*a*) and (*b*).

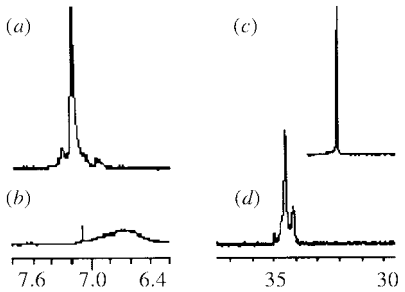

Fig. 3 ^{1}H NMR spectra of **2** (aromatic region) in: (*a*) THF-d_8, (*b*) CD_3OD (δ relative to TMS). ^{31}P NMR spectra of **2** in: (*c*) THF-d_8, (*d*) CD_3OD (δ relative to 85% H_3PO_4 (external)).

While the aromatic proton resonance of **2** in deuterated THF solution appeared as a sharp singlet at δ 7.08 (fast spin–spin relaxation), the corresponding resonance in CD_3OD solution showed line broadening characteristic of a spectrum of a highly associated species. The breadth of the aromatic proton signal in the range δ 6.3–7.1 could also arise from paramagnetic line broadening,[13] which is related to the observed extension of the effective conjugation in the polyheterocyclic chain. This is in agreement with the results of the UV–VIS spectroscopy. Fig. 3(*c*) and (*d*) illustrate ^{31}P NMR spectra of **2** in THF-d_8 and CD_3OD. The observed chemical shifts of δ *ca.* 32–34 (*vs.* 85% H_3PO_4, external) are consistent with the dialkyl phosphonate moiety.[14] A sharp, narrow signal at δ 32.11 due to an averaged species appeared in the THF-d_8 solution, whereas in CD_3OD solution broader, multiple resonances were observed in the range δ 34.97–34.12 ppm, with the most intense feature at δ 34.48. In contrast to the THF solution, for which delocalization of rapid spin diffusion resulted in a single averaged ^{31}P resonance, in CD_3OD solution the protonated segments of solvated phosphonate remained distinct on the NMR time scale giving rise to a multiplet of signals. The downfield shift of the resonance peak in methanol solution, $\Delta\delta$ = 2.4 ppm, is most likely a result of the deshielding effect due to hydrogen-bonding interactions. For interactions of diethyl 4-vinylphenylphosphonate with 1,1,1,3,3,3-hexafluoroisopropyl alcohol the $\Delta\delta$ value at 0.7 ppm corresponds to an enthalpy of hydrogen bond formation of $-\Delta H$ = 8.6 kcal mol^{-1}.[12b] Our considerably larger value of $\Delta\delta$ seems to indicate cooperative interaction of several factors, leading to a very efficient self-organization of **2** in a protic solvent.

In summary, we describe the first synthesis of a polythiophene containing a phosphonate function. The energy gap difference of *ca.* 0.4 eV between the polymer dissolved in a protic *vs.* aprotic solvent results in a remarkable solvatochromic effect. We suggest that a combination of London forces, dipole–dipole interactions and a hydrogen-bond network involving a protic solvent and the phosphonate moiety cooperate in stabilizing an extended conjugated form of the polymer.

Support of this research from the US Department of Energy is gratefully acknowledged. We thank Dr Tomasz Wąsowicz for the EPR spectra and Dr David M. Collard for valuable discussions.

Treatment of EI_4 (E = Si or Ge) with 2 equivalents of $K[P_3C_2Bu^t_2]$ affords the novel cage compounds $P_6C_4Bu^t_4SiI_2$ and $P_6C_4Bu^t_4GeI_2$ respectively, whose molecular structures, determined spectroscopically and by single crystal X-ray diffraction studies, are different both in solution and in the solid state.

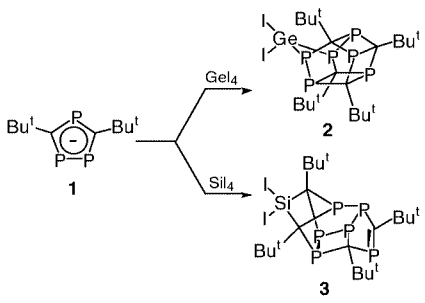
Phosphorus substituted analogues of the aromatic cyclopentadienyl anion, $C_nR_nP_{5-n}$ (n = 0–4), are of considerable current interest.[1] In particular, the 3,5-di-*tert*-butyl-1,2,4-triphospholyl anion, $P_3C_2Bu^t_2{}^-$ **1**, has been used in the preparation of a range of transition metal complexes[2–7] in which a variety of bonding modes have been observed such as in $[M(\eta^5\text{-}P_3C_2Bu^t_2)_2]$ (M = Fe or Ru), $[M(\eta^5\text{-}P_3C_2Bu^t_2)(\eta^5\text{-}C_5Me_5)\{W(CO)_5\}]$ (M = Fe or Ru) and *trans*-$[M(\eta^1\text{-}P_3C_2Bu^t_2)_2(PEt_3)_2]$ (M = Pt or Pd).

In contrast however, examples of main group element compounds derived from **1** are comparatively rare and to date are restricted to a handful of examples, namely $[In(\eta^5\text{-}P_3C_2Bu^t_2)]$, $P_3C_2Bu^t_2CH(SiMe_3)_2$, $[Tl(\eta^5\text{-}P_3C_2Bu^t_2)]$, $[M(\eta^5\text{-}P_3C_2Bu^t_2)_2]$ and $[M(\eta^5\text{-}P_3C_2Bu^t_2)(\eta^5\text{-}C_5Me_5)]$ (M = Sn or Pb).[8–11] We therefore decided to examine the reaction of **1** (in the form of its recently synthesised potassium salt),[9] with silicon and germanium tetraiodides.

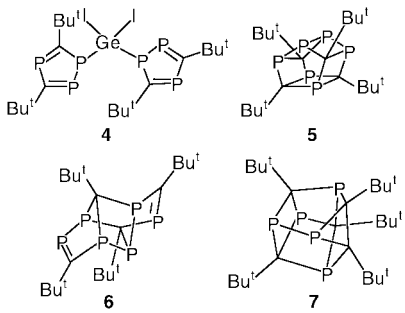
Surprisingly, although the resulting products both have the anticipated formulae $P_6C_4Bu^t_4EI_2$ (E = Ge **2**, E = Si **3**) in which two iodides may have been expected to have been replaced by $\eta^1\text{-}P_3C_2Bu^t_2$ ligands, they actually contain two different novel $P_6C_4Bu^t_4$ cages which arise from different *intra*-molecular coupling reactions of the adjacent 1,2,4-triphospholyl rings.

Thus, treatment of 2 equivalents of **1** with EI_4 (E = Si or Ge) led to the moisture sensitive compounds **2** (E = Ge) and **3** (E = Si), respectively (Scheme 1), which were recrystallised from diethyl ether (**3**, orange crystals, mp 190 °C; yield 55%) or hot heptane (**2**, red crystals, mp 275 °C; yield 52%). Both compounds exhibited the expected parent ions in their mass spectra (*m/z* 789 for **2**; 744 for **3**), however the solution $^{31}P\{^1H\}$ and ^1H NMR spectroscopic data are only consistent with the proposed cage structures, which were subsequently confirmed by single crystal X-ray diffraction studies (*vide infra*).

The ^1H NMR spectrum of **2** shows only two singlets for the two different types of Bu^t groups, while the $^{31}P\{1H\}$ NMR spectrum, which has been fully analysed and successfully simulated as an AA′MM′XX′ spin system,† confirms the symmetric structure and as expected contains no resonances involving unsaturated phosphorus atoms. The formation of the cage compound **2** clearly results from the anticipated bis-$(\eta^1\text{-}P_3C_2Bu^t_2)$–$GeI_2$ intermediate **4** which then rapidly undergoes two further intramolecular [2 + 2] cycloaddition reactions generating four new P–C bonds.



Scheme 1



The molecular structure of **2**‡ which is shown in Fig. 1, shows some similar features to the recently reported hexaphosphaprismane $P_6C_4Bu^t_4$ **5** synthesised by Regitz and coworkers[12] *via* an unusual light-induced valence isomerisation reaction of **6**, but is different from the $P_5C_5Bu^t_5$ cage structure **7** constructed by oxidative coupling of $P_3C_2Bu^t_2$ and $P_2C_3Bu^t_3$ ring anions.[13] Presumably the steric effect of the large iodide ligands attached to Ge in the presumed intermediate **4** facilitates the ring coupling reaction leading to **2**.

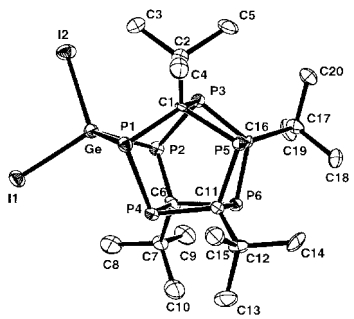


Fig. 1

The molecular structure of **3**, determined by a single crystal X-ray diffraction study,‡ which is shown in Fig. 2, unexpectedly shows that the Si is attached to two *carbon* atoms within the cage, resulting in a much more asymmetric structure than observed for **2** involving a P=C double bond between P(6) and C(4) and a five-atom phosphorus network P(1)–P(2)–P(3)–P(4)–P(5). In accord with the above structure, the 1H NMR spectrum exhibits four distinct resonances for the non-equivalent Bu^t groups, while $^{31}P\{1H\}$ NMR spectrum of **3** consists of

DOI: 10.1039/b001632m

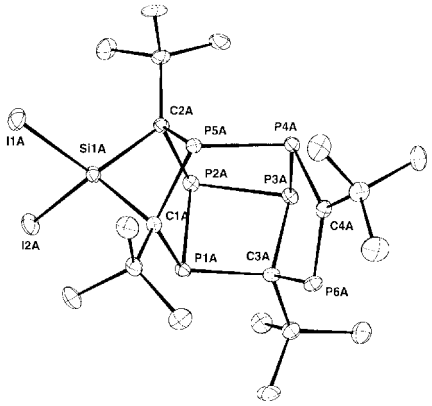

Fig. 2

six distinct resonances exhibiting several $^1J_{(PP)}$ couplings in the range 110–300 Hz. The lowest field signal (δ 357.0) which is in the region typical of P=C bonds and involves only small couplings clearly corresponds to P(6). The two highest field resonances (δ = −19.1 and −24.4) which exhibit a single large coupling, can readily be assigned to P(5) and P(1), respectively. The remaining resonances at δ 124.1, 78.4 and 24.6 can be attributed to P(2), P(3) and P(4), respectively.

The mechanism of formation of **3** is currently unknown but it seems likely that the first step involves Si–P bond formation. Attempts to form the novel silylene or germylene species $P_6C_4Bu^t{}_4E$: (E = Si, **8** , E = Ge, **9**) by treatment of **2** and **3** with sodium napthalenide in THF, led in each case to regeneration of the $P_3C_2Bu^t{}_2$ ring anion **1**.

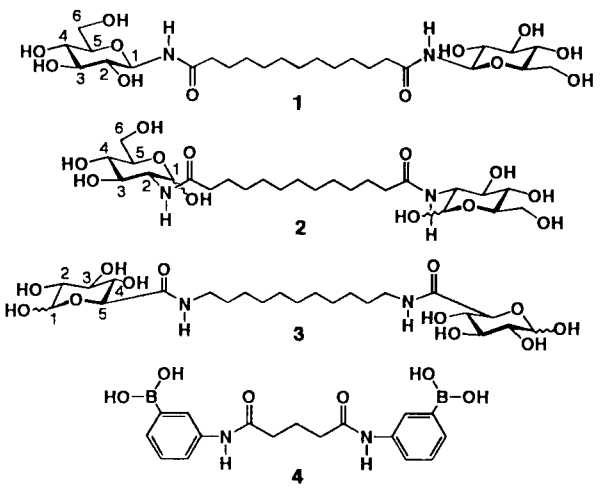
Received (in Columbia, MO, USA) 18th January 2000, Accepted 27th March 2000

Glucuronamide-based bolaamphiphiles are found to form a reversible, linear polymolecular array, *via* a boronate ester linkage attached to the 1,2-positions of the pyranose or furanose ring, upon complexation with an aromatic boronic acid-based homologue in aqueous solutions.

Aromatic boronic acids form complexes with *cis* diol-type hydroxy groups of carbohydrates *via* ester-linkage formation.[1–3] In particular, Shinkai *et al*. have intensively developed new aspects on aqueous sugar sensing by employing aromatic boronic acids.[4] Even though there have been some arguments about the boronate structure in aqueous solutions,[5–7] the complexes should contain a furanose form of the glucose moiety.[8] Norrild and Eggert have confirmed by ^{1}H and ^{13}C NMR spectroscopy that monoboronic acids bind preferentially to the 1,2-position and secondly to the 3,5,6-position of α-D-glucofuranose in aqueous solutions.[3] We have so far investigated the self-assembling properties of 1-glucosamide (**1**)[9] and 2-glucosamide bolaamphiphiles (**2**)[10] in water. Although the former derivative **1** possesses free C-3, C-4 and C-6 hydroxy groups, it cannot convert into the furanose form. On the contrary, the latter homologue **2** possessing the same free hydroxy groups can rearrange to the furanose resulting in free C-3, C-5 and C-6 hydroxy groups. In line with this molecular design, we have newly synthesized a glucuronamide-based bolaamphiphile (**3**)† possessing free 1,2-diols available for ester formation with a boronic acid. Comparison of the complex formation between these three sugar-based bolaamphiphiles (**1**, **2** or **3**) and an aromatic boronic acid-based homologue **4**,† should provide further insight into the complex structures. Mikami and Shinkai are the first to prepare main-chain sugar-containing polymers *via* self-condensation with diboronic acid under nonaqueous conditions.[11] Advantageously, we are also able to solve a problem concerning the sequential head-to-tail irregularity of the cyclic sugar-containing polymer. Here we describe the pH-dependent, reversible polymolecular boronate complexation between glucuronamide- **3** and boronic acid-based bolaamphiphiles **4** in aqueous solutions.



The glucuronamide bolaamphiphile **3** was efficiently synthesized in 4 steps from commercially available glucuronic acid, in a similar manner to that reported by Falkowski *et al.*[12] The related derivatives, 1-glucosamide (**1**) and 2-glucosamide bolaamphiphiles **2** were prepared according to a published procedure.[10,13] The boronic acid-appended bolaamphiphile **4** was also synthesized in the same manner as described by Kimura *et al.*[14]

^{1}H NMR spectroscopy of **3** in DMSO-d_6 containing a trace amount of D_2O clearly displayed two sets of well-defined signals for the H-1 (δ 4.32 and 4.93), H-5 (δ 3.51 and 3.93) and hydroxy OH-1 protons (δ 6.52 and 6.82). The presence of these two sets of signals with an average integral ratio of 56 : 44 implies that the bolaamphiphile **3** exists as a mixture of α-(56%) and β-anomers (44%) in the solution. ^{1}H NMR spectra of **4** were measured in the weak acidic (pD = 3) and alkaline aqueous solutions (pD = 10–12). The aromatic proton regions of the obtained spectra displayed entirely different spectral patterns under each condition, suggesting that the sp^2-hybridized boron atom can convert completely into the sp^3 mode at pH values above 10.

In order to confirm the linear complex formation between the cyclic sugar- and boronic acid-based bolaamphiphiles, we employed ^{11}B NMR spectroscopy‡ since it is very sensitive to the spin state of the boron atom. Therefore, we can easily differentiate the neutral sp^2, anion sp^3 and coordinated sp^3 states of the aromatic boronic acid moiety in the bolaamphiphile. Actually, ^{11}B NMR spectra of the boronic acid bolaamphiphile **4** (0.1 M) displayed distinct chemical shifts for the boron atom under weak acidic and alkaline conditions [δ 11 and −16, respectively, Figs. 1(*a*) and 1(*b*)]. The addition of equimolar 1-glucosamide bolaamphiphile **1** induced no spectral change in the ^{11}B NMR of **4** [Fig. 1(*c*)]. Thus, the potent C-4 and C-6 hydroxy groups of **1** in the pyranose form proved inactive for the ester linkage formation, resulting in no polymer formation. In contrast to this spectral feature, two separate ^{11}B NMR signals (δ −11 and −16), with an integral ratio of 1 : 2, appeared for **4** coexisting with equimolar 2-glucosamide bolaamphiphile **2** [Fig. 1(*d*)]. The minor signal in intensity (*ca.* 33%) is compatible with the presence of a covalently attached sp^3-type boronic moiety. Considering no possibility of the pyranose form existing, this finding implies that either of the C-3, C-5 and C-6 hydroxy groups of the glucofuranose can participate in binding. For a linear non-strained polymolecular complex with **4** the 3,5,6-binding mode could be the more probable compared to the binding of monoboronic acids [Fig. 2(*a*)].[3] On the other hand, the glucuronamide derivative **3** with the free C-1 and C-2 hydroxy groups was found to produce covalently attached sp^3 hybridization, giving a polymolecular complex (*ca.* 70%) equilibrated with a small amount of free anions [*ca.* 30%, Fig. 1(*e*)]. Whether the complex structure is a pyranose or a furanose form cannot be concluded at present from any other NMR

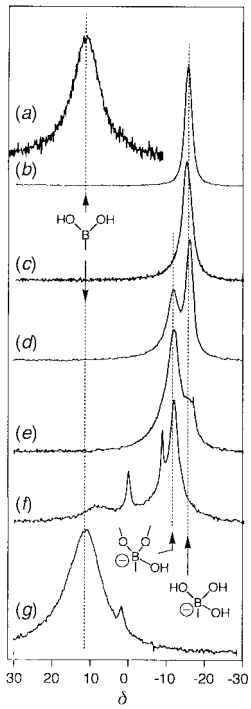


Fig. 1 ^{11}B NMR spectral change of the bolaamphiphiles **1**, **2** or **3** upon complexation with **4** (0.1 M, at 25 °C in D_2O/methanol-d_4 (6:4, *v/v*)). (*a*) **4** under weak acidic aqueous condition (pD = 3.0); (*b*) **4** under alkaline aqueous condition (pD = 12.7); a 1:1 mixture of (*c*) **1** and **4** (pD = 10.7); (*d*) **2** and **4** (pD = 10.3); (*e*) **3** and **4** (pD = 10.9); (*f*) **3** and **4** (pD = 6.4); (*g*) **3** and **4** (pD = 3.0).

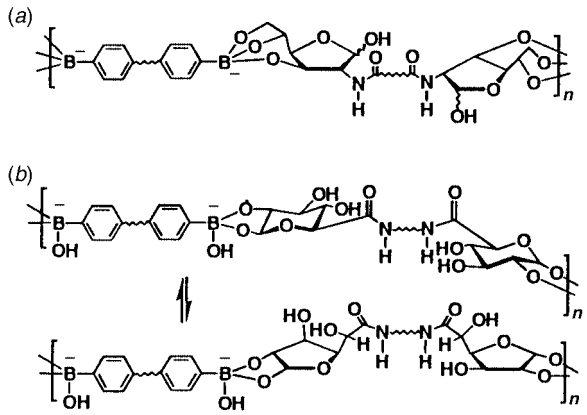

Fig. 2 Possible structures of the polymer main chains formed from (*a*) the mixture of **2** and **4**; (*b*) the mixture of **3** and **4**.

measurements including ^{13}C NMR [Fig. 2(*b*)]. Detailed structural analysis remains to be further investigated using single-head single-chain amphiphile models of **1**–**4**. It is well known that multiangle laser light scattering (MALLS)‡ detector measures, from the intensity of the scattering, the molar mass of biopolymers in solutions.[15] Especially, MALLS can provide a highly sensitive and useful method for the characterization of polysaccharides and protein oligomers. The weight-averaged molecular weight (M_w) for the present aqueous **3**·**4** polymer was evaulated by MALLS to be 2.04×10^6 g mol^{-1} at pD 10.8.

Dissociation of the boronate polymer complexes into each component **3** and **4** was investigated by neutralizing the solution with dilute hydrochloric acid. At neutral pH range (pD = 6.4), the ^{11}B NMR spectrum of the polymer indicated that a main signal (*ca.* 48%) attributable to the boronate complex still apears at δ −11 in addition to three minor signals at δ −8 (*ca.* 24%), 1 (*ca.* 13%) and 9 (*ca.* 15%), [Fig. 1(*f*)]. Complete dissociation of the polymer was achieved under weak acidic aqueous conditions (pD = 3). Namely, the decrease in the pH value of the aqueous solution from 11 to 3 resulted in a down-field shift of the main signal from δ −11 to 11 [Fig. 1(*g*)]. Thus, a reversible polymer formation and dissociation was realized depending on the pH conditions of the aqueous solutions. The monomers are connected to each other through identical cyclic sugar–boronate ester linkages, unike Mikami and Shinkai's cyclic sugar-containing polymer,[11] in a one-dimensional poly-molecular array. This kind of polymer system can be realized using both cyclic sugar- and boronic acid-based bola-form derivatives. In addition, the notably different features of **1** and **2** upon complexation with **4** gave unequivocal evidence for the participation of the furanose form of **2**.

Received (in Basel, Switzerland) 21st January 2000, Accepted 7th April 2000

According to a multinuclear NMR study, the cluster [{Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)}$_4$Mo$_4$O$_{16}$] exists as two isomers, the windmill-like form and the triple-cubane form, which are in equilibrium in solution, while the tungsten analogue, which has been obtained together with the double-cubane type cluster [{Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)}$_4$W$_2$O$_{10}$] by reaction of [{Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)Cl$_2$}$_2$] with (NBu$^n_4$)$_2$[WO$_4$] in acetonitrile, only displays the windmill-like structure.

Organometallic derivatives of polyoxometalates now form a full class of compounds.[1] We have recently reported a series of integrated organometallic oxo(alkoxo)molybdenum clusters containing *fac*-{M(CO)$_3$}$^+$ (M = Mn or Re) units.[2] The apparent structural relationships between these clusters and those of previously reported polyoxo(alkoxo)molybdates underscore the electronic connection between d^6-*fac*-{ML$_3$} (M = Mn or Re) and d^0-*fac*-{MoO$_3$} or d^0-*fac*-{MoO$_2$(OR)}$^+$ units. Then we turned towards the reactivity of [{(η⁶-arene)RuCl$_2$}$_2$] with oxometalates in order to extend the concept of topological equivalent units.

The cluster [{Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)}$_4$W$_4$O$_{16}$] **2**, whose molybdenum analogue [{Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)}$_4$Mo$_4$O$_{16}$] **1** was recently reported by Süss-Fink *et al.*,[3,4] has been obtained by reacting [{(η⁶-*p*-MeC$_6$H$_4$Pr^i)RuCl$_2$}$_2$] with (NBu$^n_4$)$_2$[WO$_4$] in acetonitrile.† In the solid state, **2** is isostructural with **1** and displays the so-called windmill-like structure,[3,4] *i.e.* it consists of a [W$_4$O$_{16}$]$^{8-}$ cubic core capped by four {Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)}$^{2+}$ groups each bound to a triply bridging and two terminal oxo ligands.‡ The only previous example of a polyoxoanion-supported organometallic complex based on [W$_4$O$_{16}$]$^{8-}$ is [{Ir(cod)}$_6$W$_4$O$_{16}$].[5] The ^{1}H, ^{183}W and ^{17}O NMR spectra indicate that **2** exists in a single form in chloroform. Moreover, the ^{17}O NMR spectrum of **2** is fully consistent with the windmill-like structure. Indeed, it displays four signals in approximate relative intensities 1:1:1:1 assigned to terminal (O$_t$), doubly bridging (there are two sets of four μ$_2$-O ligands) and quadruply bridging (μ$_4$-O) oxo ligands, in the order of increasing shielding (Fig. 1). On the other hand, a different pattern has been reported for the ^{17}O NMR spectrum of **1** in CD$_2$Cl$_2$,[4] and this prompted us to reinvestigate the behaviour of **1**.

During the course of this study, **1** and **1**·C$_6$H$_5$Me have been characterized by X-ray diffraction in addition to **1**·2C$_6$H$_5$Me that was described by Süss-Fink *et al.*[3,4] In the three compounds **1** displays the windmill-like geometry. The ^{1}H NMR spectra of the three compounds in solution are similar apart from the signals due to toluene. However the ^{1}H, ^{17}O and ^{95}Mo NMR spectra are dependent on the solvent and indicate the presence of two distinct species. Indeed two signals (^{95}Mo) or two sets of signals (^{1}H and ^{17}O) are observed with nearly equal intensities in chloroform but quite different intensities in dichloromethane. The change in solution was shown to be reversible. The major set of ^{17}O resonances in CH$_2$Cl$_2$ is consistent with the triple-cubane structure **1b** (Fig. 1). Indeed, it is composed of three signals in relative intensities 2:1:1, assigned to O$_t$, μ$_3$-O and μ$_4$-O, respectively, in the order of increasing shielding. This assignment, which is at variance with that of Süss-Fink *et al.*,[4] is further supported by the comparison with the ^{17}O NMR spectrum of the triple-cubane cluster [(Cp*Rh)$_4$Mo$_4$O$_{16}$].[6] The minor set of signals in CH$_2$Cl$_2$ is consistent with the windmill-like structure **1a**. It follows from this multinuclear NMR study that **1** predominantly exists in the triple-cubane form **1b** in dichloromethane. Considering the significant change in the equilibrium constant on going from dichloromethane to chloroform, the energy difference between the two forms of **1** should be low. This stereochemical change, which is slow on the NMR time scales, does not depend on the residual water content and could involve a concerted motion of two {Ru(η⁶-*p*-MeC$_6$H$_4$Pr^i)}$^{2+}$ groups (Fig. 1). There are only a few precedents for the mobility of organometallic cations on polyoxometalates.[7] In addition to the equilibrium between **1a** and **1b**, there is a faster dynamic process which exchanges the μ$_2$-O oxo ligands in **1a**.

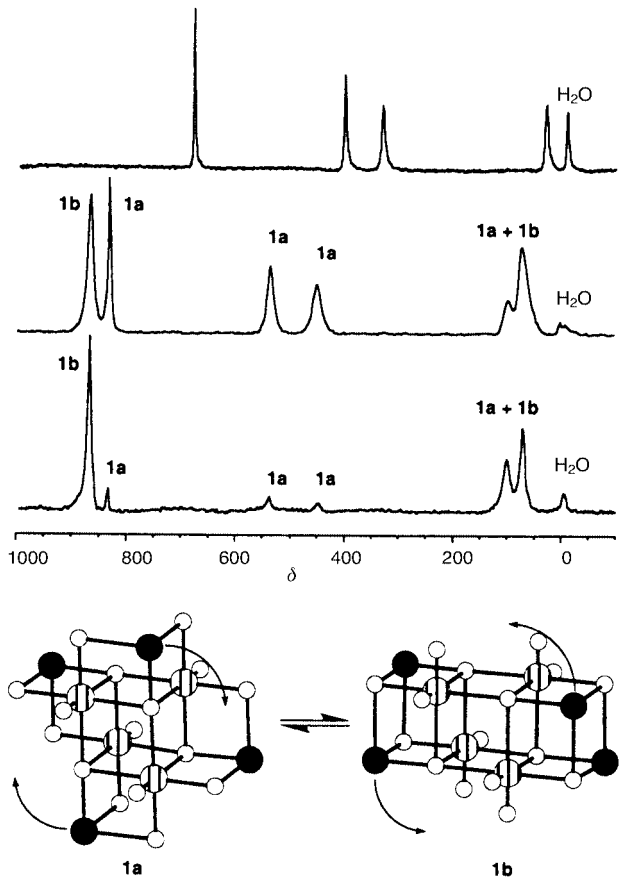

Fig. 1 Unlocked 40.7 MHz ^{17}O NMR spectra of enriched samples of **2** (top, CHCl$_3$, 333 K) and **1** (middle, CHCl$_3$, 297 K; bottom, CH$_2$Cl$_2$, 293 K) and postulated mechanism for the interconversion between the windmill-like form **1a** and the triple-cubane form **1b** (Mo atoms are shown as hatched spheres and Ru atoms as black spheres; *p*-cymene ligands have been omitted for clarity).

DOI: 10.1039/b000782j

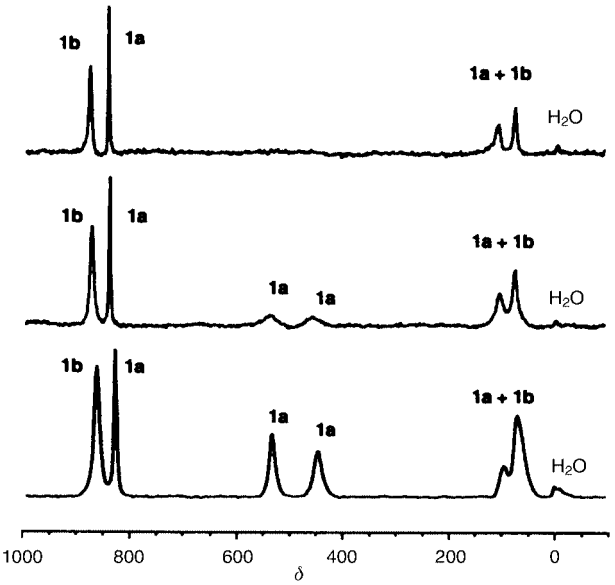

Fig. 2 Unlocked 40.7 MHz ^{17}O NMR spectra of enriched samples of **1** in $CHCl_3$ at 333 K (top), 313 K (middle) and 297 K (bottom).

Indeed the signals for the two types of μ_2-O ligands broaden as the temperature is raised and are hardly observed above 313 K (Fig. 2). The most likely mechanism to explain this phenomenon is a concerted motion of the four organometallic units along the diagonals of the faces of the central cubic core.

Another cluster, $[\{Ru(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)\}_4W_2O_{10}]\cdot 3H_2O$ (**3**·$3H_2O$), was obtained as a by-product in the preparation of **2**. An X-ray structure analysis‡ revealed that **3** displays a double-cubane framework consisting of two fused $[\{Ru(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)\}_2W_2O_8]$ cubes (Fig. 3). Discrete mono-cubane,[2,8] triple-cubane[6,9] and quadruple-cubane[9] clusters have been reported. To the best of our knowledge, **3** provides the first example of a discrete double-cubane cluster. The mono-cubane clusters $[\{Ru(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)\}_2W_2O_{10}]$ (M = Mo or W) are not expected to be stable because the environments of the two M atoms would violate the Lipscomb rule.[10] Thus such units, once formed, should undergo condensation processes.

We are currently investigating the influence of the arene on the equilibium between the two forms of **1** and we are exploring the potential of these and related species in catalytic reactions.

Published on the Web 10th April 2000

This article summarizes a series of recent and simple experiments to produce optically active substances from achiral precursors. These symmetry-breaking processes include either autocatalytic crystallization or asymmetric autocatalysis, and provide new insights into the origin of biomolecular homochirality. In addition, support from an extraterrestrial origin of chiral molecules has also come from recent findings.

Introduction

The question of the origin of life on Earth is invariably linked to the origin of enantiomerically pure compounds, even if there are no definitive arguments embracing both premises.[1] Ever since Pasteur's time, scientists have been fascinated with trying to understand the origin and amplification of chirality. A preliminary argument is that perhaps life needed no external influence beyond chance to choose its handedness. However, many scientists believe chirality of one or another form was inevitable because homochirality would have been a pre-condition for life. Racemic molecules would have been too inefficient for achieving biological processes such as self-replication, protein synthesis, regulation, and ultimately gene expression. Likewise, polymerization reactions affording long-chain stereoregular polymers (*e.g.* all-L-polypeptides or all-D-oligosaccharides) will not proceed in racemic solution since addition of a wrong monomer tends to stop the process.[2]

In principle, a biochemistry made up of D-amino acids or L-sugars should be just as efficient as L-amino acids or D-sugars found in our terrestrial life. An argument that reinforces this hypothesis is the fact that alternatives to ribose or deoxyribose can be synthesized and tried out as the sugar components of nucleic acids or new bases can be substituted for those nature uses. Evolution has selected the best available solution and not necessarily the best possible solution.[3] Nevertheless, even though the initial molecules are achiral, the handedness of the building blocks or the appropriate helicity of the oligomers had to be determined at an early stage. In fact only a small enantiomeric excess (ee) is required because such a value could be amplified by a series of mechanisms related to the concept of nonlinear stereochemistry.[4] Thus, a partially resolved chiral catalyst or auxiliary could give a stereoselection higher than its own ee. The phenomenon may be ascribed to diastereomeric interactions in solution, but there are also profound kinetic implications involved,[5] including the possibility that the diastereomeric catalysts have very different reaction rates.[6] Unfortunately, most nonlinear effects have been observed with organometallic reagents and in organic solvents. It is unlikely that these reaction conditions could be found in the prebiotic scene. Anyway, as we shall see later these unusual mechanisms involving cooperativity among the molecules do provide food for thought.

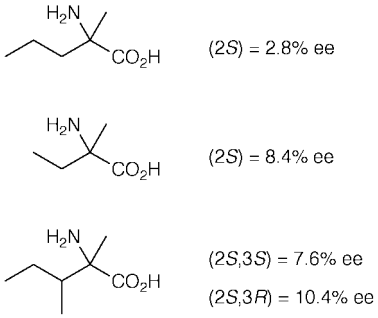
Martín Avalos, Reyes Babiano, Pedro Cintas, José L. Jiménez and Juan C. Palacios received their graduate degrees in chemistry and their PhD degrees from the University of Extremadura (UEX), where they are Professors of Organic Chemistry. Together with a group of talented and enthusiastic collaborators, they are investigating diverse areas of organic chemistry with a focus on stereochemistry. Their current research interests include the development of asymmetric reactions, conformational analysis, solvent-free reactions and the use of nonconventional techniques to accomplish organic transformations under milder conditions.

Cosmic chirality

Before we go any further, a few comments about the inherent handedness of matter are unavoidable. There are four forces in nature: electromagnetic, strong, gravitational and weak interactions, but only the latter is chiral. In other words, it can distinguish between right- and left-handedness in the spin polarization of elementary particles. Parity violation in the weak interactions was discovered in the late fifties as the radioactive decays of polarized ^{60}Co nuclei release more left-handed spinning electrons than right-handed spinning ones. Likewise, as far as we know there are no right-handed neutrinos: they are always left-handed.[7] The direct implication of these interactions is that there is a parity-violating energy difference between two enantiomers. Unfortunately, this energy shift is too small ($\sim 10^{-18}$ eV) to be measured with our current instruments, but theoretical calculations do confirm that the natural L-amino acids L-alanine, L-valine, L-serine and L-aspartate are more stable than their D-enantiomers by 10^{-17} kT, and D-glyceraldehyde was likewise found to be more stable than its unnatural counterpart by about 10^{-17} kT.[8] Although amplification mechanisms by factors of about 10^{17} could be suggested to explain the observed homochirality of molecules,[9] alternative hypotheses appear to be more plausible.

If the foundations of life are chiral cosmic forces operating at their origin, the finding of extraterrestrial chirality would provide a reasonable argument. In fact, we have learnt that circularly polarized light (CPL) or vortices may cause symmetry breaking, but even falsely chiral influences such as magnetic or gravitational fields, under kinetic conditions, might be sufficient.[10] The search for homochiral substances in the well-known Murchison meteorite reveals that L-enantiomers predominate slightly over D-enantiomers.[11] In particular, Cronin and Pizzarello have concentrated on branched α-amino acids,[11a] which are not present in terrestrial proteins, in order to exclude any sort of contamination from living systems. Although no appreciable ees were found for α-aminobutyric acid or norvaline, other ramified amino acids gave ees up to 10% (Scheme 1).

In an irony of fate, astronomers from the Anglo-Australian Laboratory reported that they had discovered high levels of CPL



Scheme 1 Enantiomeric excesses of α-ramified amino acids of extraterrestrial origin found in the Murchison meteorite.

(as much as 17%) in the constellation Orion.[12] Such radiation might have induced asymmetry in interstellar organic molecules, which could be delivered to the primitive Earth by comets or meteorites, a necessary surmise if one assumes that the distance from the solar system to the center of the nebula is estimated at about 1500 light-years!

One objection to this exciting work is that the authors observed only CPL in the infrared region, whereas UV light is required to deracemize chiral molecules. However, computations showed that circularly polarized ultraviolet light should also be present.[12,13]

Crystallization–induced resolution and autocatalysis

It would be interesting to devise a chemical system capable of producing a slight enantiomeric imbalance comparable with the levels of ees found in meteorites or achieved by CPL photolysis,[10a] which may be as low as 0.1%, but larger than those predicted by parity violation.

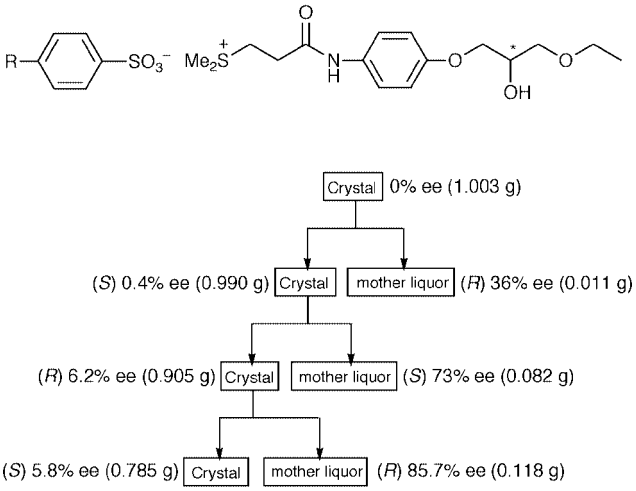
We must first overcome a common misconception taught at the freshman or even sophomore level: the assumption that racemates are made of *exactly equal* amounts of enantiomers. This belief goes against the logic of statistics, and in fact for n molecules in a racemate, the dominant component will have $(n/2) + n^{1/2}$ molecules.[14] As n becomes very large the ratio of the two enantiomers becomes very close to one. This does mean that the simple diffusional distance from 50:50 will result in a macroscopic observation (for instance through the examination of $[\alpha]_D$ values) of an optically inactive mixture.

Crystal growth is a good scenario that takes advantage of the statistical fluctuations in a system where crystallization of, let us say, a left-handed crystal acts as a seed and causes other crystals nearby to be left-handed also. This chiral primary nucleation is the origin of the known spontaneous resolutions, which will occur only if the racemate is a conglomerate in the solid state.[15]

An unusual enantiomeric resolution by recrystallization of a racemate has been recently disclosed by Japanese authors.[16] Compounds susceptible to this preferential enrichment were a series of racemic sulfonium sulfonates, and the flow diagram of Scheme 2 highlights its particular features. Thus, repeated recrystallization of the racemate results in an alternating enrichment of the two enantiomers in the mother liquors (up to 100% ee!) and at the same time when crystals with low ee are recrystallized, the deposited crystals have invariably the opposite handedness.

As might be expected, the authors were able to identify by X-ray diffraction analysis the presence of a racemic conglomerate composed of a regular packing of the *R* and *S* enantiomers in the crystal lattice, whereas compounds existing as disordered mixed crystals in which sites are occupied by the *R* and *S* enantiomers cannot be resolved.

Spontaneous resolution in fluid systems (*e.g.* liquid crystals) is rather unusual due to thermal fluctuations and molecular



Scheme 2 Preferential enrichment by recrystallization.

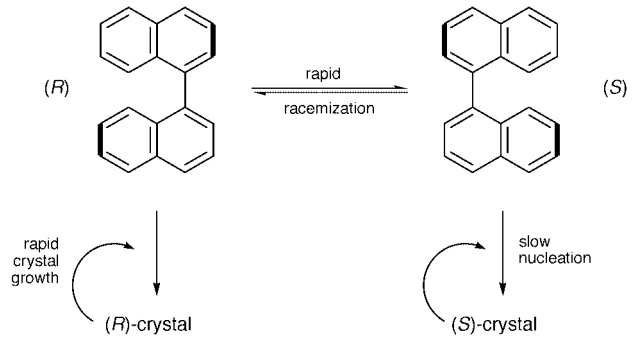
diffusion. Nevertheless, Mikami and his associates have described a spontaneous enantiomeric resolution in a fluid smectic phase of a racemate.[17] Similarly, a racemic liquid crystalline substance may be resolved on a crystalline graphite surface.[18]

Autocatalytic secondary nucleation

Chiral amplification by spontaneous nucleation may in practice be ineffective. Thus, sodium chlorate, which is an achiral molecule, may form left- and right-handed crystals by crystallization from a supersaturated solution. A statistically equal number of (+)- and (–)-$NaClO_3$ crystals are obtained from an unstirred solution, but if the solution is rapidly stirred, a large excess of either left- or right-handed crystals results.[19] It should be noted that the direction of stirring had no effect on the handedness of the crystals. The experiment was reproducible and could even be videotaped by McBride and Carter,[20] who noted that the process began with a single crystal and massive crystallization took place when the single crystal first contacted the stir bar. The overall process is called *secondary nucleation*, which involves the formation of new crystals by breaking up the dendritic structures that are constructed on the parent growing crystal. Presumably, stirring contributes to spread these secondary nuclei around the solution. Remarkably, the process is a chiral autocatalysis because the crystal nuclei generated have the same handedness as the mother crystal (compare with *primary nucleation* operating in the spontaneous resolutions mentioned above). In other words, all of the microcrystals were homochiral to the parent crystal. Both the stirring rate and the size of the nucleating crystal are critical parameters on the distribution of enantiomeric excess.[21]

The mechanism of secondary nucleation is not fully understood, even though a theory has been recently proposed.[22] Be that as it may, the phenomenon is thought-provoking, as natural crystals might have experienced this chiral nucleation under geological conditions.

Spontaneous resolution through stirring can be observed not only in solution but also in crystallization of a melt. When a large number of 0.20 g samples of 1,1′-binaphthyl are heated at 180 °C and the melt is then cooled from 180 to 150 °C and allowed to crystallize (mp is 158 °C) without any intervention, a statistically equal number of (*R*)-(−)- and (*S*)-(+)-crystals (*i.e.* a Gaussian-like distribution of optical activity centered around zero) are formed.[23] Alternatively, crystallization carried out with *constant stirring* gives rise to large ees (averaging 80%) in almost every crystallization,[24] though *R* or *S* enantiomers were randomly created (Scheme 3). Apparently, stirring suppresses the slow process of primary nucleation, thereby favoring the formation of secondary crystals with the same homochirality. In



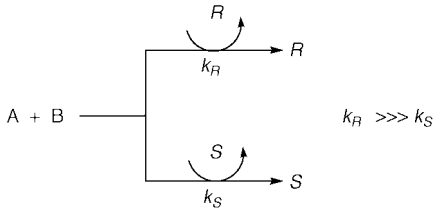
Scheme 3 Chirally autocatalytic spontaneous resolution.

addition, owing to stirring, the heat released will increase the temperature slightly, a factor that will also decrease the primary nucleation rate.

The authors have likewise studied the effect of seeding 1,1′-binaphthyl melts with (*R*)-(+)- or (*S*)-(−)-1,1′-bi-2-naphthol. Thus, a racemic sample of 1,1′-binaphthyl was cooled from 180 to 150 °C and a small amount of (*R*)-(+)- or (*S*)-(−)-1,1′-bi-2-naphthol was added, and the melt was stirred until all of it crystallized. There was a strong chiral influence of the added seed since (*R*)-(−)-1,1′-binaphthyl is isomorphous with (*R*)-(+)-1,1′-bi-2-naphthol. All of the samples seeded with (*R*)-(+)-1,1′-bi-2-naphthol presented a high value of optical rotation and close to 100% ee. Similarly, high ees were obtained for the samples seeded with (*S*)-(−)-1,1′-bi-2-naphthol.

Autocatalytic asymmetric reactions

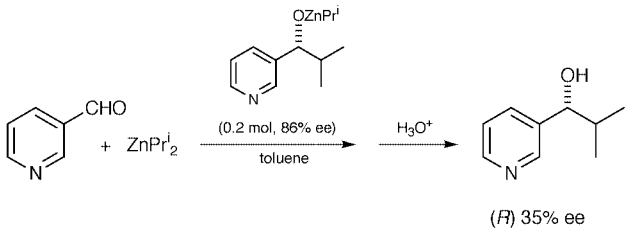
In the early fifties Frank proposed a mathematical model of chiral autocatalysis in which each enantiomer catalyzes its own formation and suppresses the production of the opposite enantiomer.[25] Owing to statistical fluctuations, a very small ee in an early stage can be amplified as the reaction proceeds (Scheme 4).



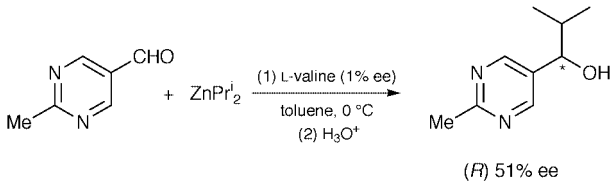
Scheme 4 Frank's hypothesis for chiral autocatalysis.

Autocatalysis implies the growth of the amount of catalyst, thereby modifying the initial *R/S* enantiomeric ratio. However, it can easily be demonstrated that an iterative autocatalytic process starting from a chiral catalyst with 100% ee and assuming a very high kinetic ratio k_R/k_S will inevitably end up with a lower ee unless nonclassical mechanisms such as a mutual inhibition of enantiomers are present.[4a] Furthermore, the use of catalysts of low optical purity may result in unpractical ees. Anyhow, a group of Japanese researchers led by Kenso Soai have found remarkable autocatalytic systems in the addition reactions of dialkylzincs to aromatic aldehydes.[26] Thus, a pyridyl alcohol of (*R*)-configuration with 86% ee catalyzes its own formation, although with a rather modest enantioselection (35% ee after subtracting the contribution of the catalyst, Scheme 5).

Better results were obtained by treating pyrimidine-5-carbaldehyde with diisopropylzinc in the presence of a pyrimidine alcohol with 2% ee, which gave the same chiral alcohol with up to 88% ee.[26d] In an extension of the latter autocatalysis, Soai *et al.* have recently reported that α-amino acids (*e.g.* leucine or valine) with 1–2% ee can serve as chiral initiators for the same addition reaction (Scheme 6). The configuration of the product



Scheme 5 Asymmetric autocatalysis in the reaction of pyridyl aldehydes with organozinc reagents.

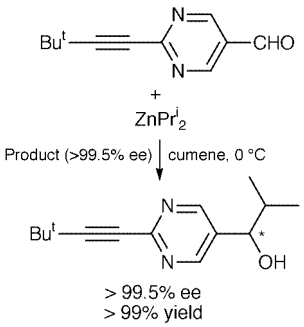


Scheme 6 Chiral autocatalysis promoted by nonracemic initiators.

is dependent on the configuration of chiral initiators. For example, L-leucine with 2% ee gives rise to an alcohol highly enriched in the *R* enantiomer, whereas addition of D-leucine causes the formation of the *S* alcohol in high ee.[27]

Improved results could be obtained with other chiral initiators such as (*R*)- or (*S*)-methyl mandelate and (*R*)- or (*S*)-butan-2-ol, even with 0.1% ee. The importance of this work lies in the fact that these initiators can be resolved by the action of CPL, thereby establishing a link between the influence of an external chiral force and autocatalysis. As mentioned, a process involving organometallic species in toluene is far from prebiotic conditions. Likewise, it would also be interesting if the same results could be obtained by irradiating with CPL the autocatalytic reaction in the presence of racemic initiators. In fact, this experiment will be attempted by these authors.[28]

An almost perfect asymmetric autocatalysis, in terms of enantioselectivity (> 99.5% ee), has been achieved in the addition of diisopropylzinc to 2-alkynylpyrimidine-5-carbaldehydes, albeit the autocatalytic alcohol had to be used with > 99.5% ee (Scheme 7).[29] The enantioselectivity was also

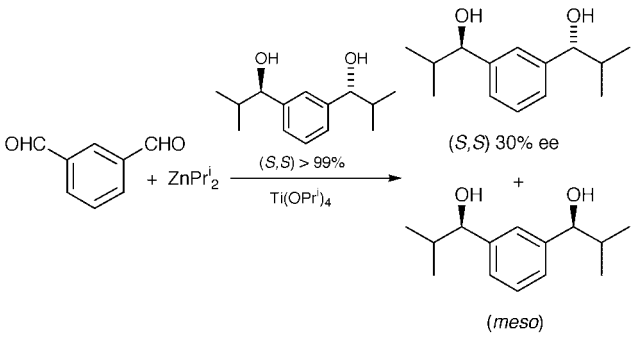


Scheme 7 Chiral self-replication of pyrimidyl alkanols.

dependent on both structural factors and reaction conditions. A rapid screening of 2-alkynylpyrimidyl alkanols revealed that a moderate electron-withdrawing alkynyl group along with a suitable bulkiness of the entire alkyne moiety are required. Accordingly, 1-(2-*tert*-butylethynyl-5-pyrimidyl)-2-methylpropan-1-ol was found to be an excellent autocatalyst. On the other hand, small differences in enantioselectivity were found when cumene was used instead of toluene, or better yet when a cumene solution of the organozinc reagent was used. It should be noted that either (*R*)- or (*S*)-pyrimidyl alkanols gave asymmetric autocatalysis with > 99.5% ee and in almost quantitative yields. If the reaction is performed consecutively with the product of one run serving as the autocatalytic reagent for the next entry, large multiplicative factors (10^3–10^7) are observed after a few rounds. An additional importance of these

chiral 5-pyrimidyl alkanols, which are obtained as single products, is their easy conversion into other important building blocks such as nonracemic α-hydroxycarboxylic acids.

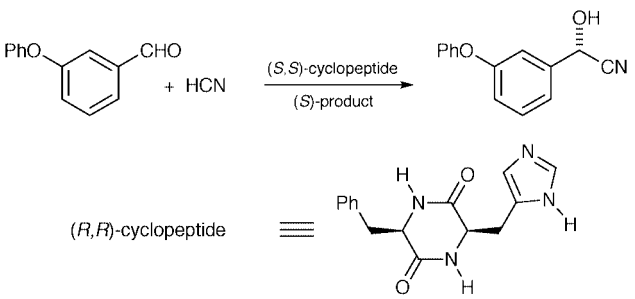
Besides asymmetric autocatalysis, a related process called *asymmetric autoinduction* may also amplify a small ee.[4] From a conceptual viewpoint, however, the term autoinduction implies a certain degree of interaction between the product and a chiral autocatalyst, which may be different or the same substance. There must be cooperativity between the two components through diastereomeric interactions, which anticipates any type of nonlinear effect. An enantioselective autoinduction has also been reported by Soai and his group in the addition of diisopropylzinc to aromatic dialdehydes.[30] The catalyst is a chiral titanium complex derived from $Ti(OPr^i)_4$ with the chiral diol (Scheme 8). This catalyst is different from



Scheme 8 Autoinductive addition of organometallic reagents to aromatic aldehydes.

the chiral zinc alkoxide which should be the actual intermediate, and this consideration justifies the term autoinduction rather than autocatalysis. Unfortunately, the product is obtained in only 30% ee along with a large amount of *meso* diol, starting from a catalytic diol with > 99% ee.

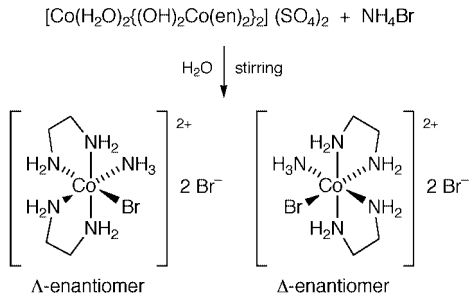
One of the most salient examples of chiral autoinduction has been reported by Danda *et al*. in the addition of HCN to aromatic aldehydes in the presence of small amounts of cyclopeptides.[31] The authors suggested that the catalyst arose from an *in situ* combination of the cyclic dipeptide with the resulting cyanohydrin. This hypothesis could be confirmed by adding a small amount of (*S*)-cyanohydrin with high ee to the cyclic dipeptide, either enantiopure or of low ee, at the beginning of the reaction (Scheme 9). Thus, catalyst with 2% ee



Scheme 9 Cyclopeptide-mediated asymmetric autoinduction.

gave product in 43% yield and 82% ee. Nevertheless, a catalyst prepared from the cyclic dipeptide in 67% ee plus (*S*)-cyanohydrin in 92% ee gave product in 89% yield and 96% ee, which is higher than the ee of both components of the catalyst. This does mean that the enantiomeric purity of cyanohydrin constitutes a key stereocontrolling factor on the catalytic cycle.

A very interesting autocatalytic reaction involving the formation of chiral coordination compounds in an aqueous environnement has been devised by Asakura and his associates.[32] The chiral octahedral cobalt complex *cis*-$[CoBr(NH_3)(en)_2]Br_2$ can be prepared by reaction of a diaquacobalt(II) complex, $[Co(H_2O)_2\{(OH)_2Co(en)_2\}_2](SO_4)_2$, with ammonium bromide in water. Despite the fact that all the reactants are optically inactive, when the reaction is stirred at room temperature for 1 min or at 50 °C for 5 min, crystalline optically active complexes are obtained in almost all runs. The ee, however, fluctuates randomly (Scheme 10).



Scheme 10 Autocatalytic nucleation of enantiomeric crystals of coordination compounds.

The chiral complex crystallizes as a conglomerate in which each crystal consists of either Λ- or Δ-enantiomers. In a stirring system, a crystal of a particular enantiomer can be self-replicated through secondary nucleation, thereby catalyzing its own formation. Again, the ee of the product was largely dependent on the stirring rate. In addition, when the stirred reactions were carried out in the presence of a tiny amount of crystals of one enantiomer, that enantiomer was preferentially produced. If an enantiomer is added in dissolution, such a preference is not observed. This does mean that an autocatalytic reaction operating *via* secondary nucleation *requires the presence of crystals* to induce symmetry breaking.

Prospects: symmetry breaking and evolution

If an aspect of chiral amplification dominates molecular evolution, it must surely be the formation of macromolecules, since enzymes, nucleic acids, and other biopolymers have acquired a definite handedness. More than four decades ago, Wald suggested that the regular secondary structure of peptides would have resulted from the helical sense preferred by the major enantiomeric amino acid whose handedness also permitted its own selection and growth.[33] Shortly afterwards, this hypothesis was verified on polypeptides derived from nearly an equal population of enantiomeric amino acids and on regularly isotactic vinyl polymers prepared by Ziegler–Natta polymerization.[21b,34]

Detailed studies and an in-depth interpretation of this so-called 'Majority Rule', which arises from the excess energy of the opposite helicity, has been recently carried out by Green, Selinger and their co-workers.[35,36] Thus, chiroptical measurements reveal that a polymer made of 98.4% achiral units and 1.6% chiral units, with an ee of only 2.8% among these chiral monomers, has the same optical activity as a polymer of just the chiral units with the same ee. Notably, the theory allows prediction of the helical sense ratio for any ee and, within certain limits, it is also possible to reduce the chiral component without affecting the optical purity.[36b,e,f] In the latter case, the circular dichroism (CD) spectrum does not show any variation until the composition of monomers reaches 99.2% achiral and 0.8% chiral.[36a] It seems that cooperative interactions in helical systems may lead to an important chiral amplification.[37]

Homochiral crystals of helical coordination polymers from achiral components have been obtained by Aoyama and his

group by treating an achiral pyrimidine derivative with cadmium nitrate in aqueous ethanol.[38] The achiral precursor itself, orthogonal 9-(5-pyrimidyl)anthracene, forms achiral $P2_1/n$ crystals with $Cd(NO_3)_2$ in methanol and without forming helical chains. However, the slow cooling (~ 6 h) of a hot (80 °C) ethanol–water solution of this compound and $Cd(NO_3)_2$ to room temperature afforded an adduct which crystallizes in chiral space group $P2_1$. The metal ion is hexacoordinated with two pyrimidine ligands, two nitrate ions, ethanol and water. The crystal structure contains an alternate arrangement of pyrimidine–metal helical layers and anthracene layers. The chirality results from a twist of the two pyrimidine rings and the overall helicity of the pyrimidine–metal array is maintained in the crystal by interstrand hydrogen bonding between the nitrate anions and water.

That the crystallization is homochiral is evidenced by the fact that all the crystals isolated from one crystallization show the same CD sign and hence the same helicity. Remarkably, chirality of this helical coordination polymer can be controlled by seeding. Thus, an achiral adduct can be converted into *P* or *M* helices at will, when the former is coground with a small amount of *P* or *M* adducts, respectively, and then exposed to vapors of ethanol.

In principle, the formation of chiral crystals from achiral building blocks is not surprising since achiral molecules can crystallize in chiral space groups.[15,39] However, these substances are obtained either as an in-crystal racemate or as a mixture of self-resolved enantiomeric chiral crystals.[40] The work by Aoyama and coworkers provides evidence for homochiral crystallization, by which achiral molecules afford spontaneously crystals with the same chirality, which can also be related to the concept of secondary nucleation mentioned above.

As long as a polymer can replicate, perhaps to perform a biological function, it could serve as the seed molecule. Its autocatalytic 'nucleation' would continue in an enantiomerically pure fashion. Thus, the number of copies of the selected homochiral polymer will become greater and greater while the number of competing stereoisomers will become fewer and fewer. The slight enantiomeric imbalance would have provided the driving force for such a selection, regardless of the appropriateness of structures or shapes.[3] Recent works by Eschenmoser *et al*. reinforce the idea that the choices of Nature were a question of availability. Pyranosyl-RNA has been found to be not only a stronger pairing system than furanosyl-RNA (and DNA as well), but also such a pairing is more selective and Watson–Crick purine–pyrimidine pairing in strictly antiparallel orientation was obtained.[41] Base sequences of pyranosyl-RNA can be copied with high regioselectivity and chiroselectivity. In general, the copying proceeds slower when one of the D-ribopyranosyl units of a homochiral tetramer-2′,3′-cyclophosphate is replaced by the corresponding L-unit.

Nevertheless, a general problem associated with the stereocontrol of self-assembly is the fact that the large number of random sequences from a mixture of right- and left-handed libraries will hinder the formation of regular cycles with specific-ordered sequences. At the molecular level effective self-replication may adopt the form of a hypercycle,[42] a type of nonlinear autocatalysis in which cross-catalysis superposes onto autocatalytic replication. These processes would have played a key role in the transition from inanimate to living systems, and hypercyclic peptide networks have been studied in detail. Thus, Reza Ghadiri and his associates have recently described two peptide autocatalysts that not only accelerate their own formation but also behave as cross-catalysts, each speeding up the production of the other more efficiently than its own duplication.[43]

At a discrete molecular level, only a few autocatalytic chemical systems contain vestiges of hypercylic organization.[44] Still, chiral hypercycles need to be disclosed and understood, but the above-mentioned transformations by Soai *et al*. constitute a good toehold for promising developments.

Conclusions

The ultimate origin of asymmetry in the universe is an unanswered question. During the last decade, however, a series of rather simple experiments have demonstrated the feasibility of producing optically active compounds from achiral materials. Crystallization processes, not involving spontaneous resolutions, and a few asymmetric reactions have established a direct linkage with the inherent handedness of prebiotic molecules and the biopolymers thereof. While we have seen the triumph of reductionism in explaining life in molecular terms, with stunning revelations of self-replication and regulation, still the large gap between molecular chirality and molecular evolution has become painfully clear. As noted by Avetisov and Goldanskii,[1d] this emerges from the lack of knowledge about the interrelations between the asymmetry of chemical processes involving simple organics and the chiral specificity of biological polymers. Accordingly, only a few assertions can be formulated about the role of symmetry breaking at the chemical stage of evolution, even though homochirality was forced by the initiation of enantiospecific functions in living systems. In any event, other recent studies, especially concerning oligonucleotide systems, suggest mirror symmetry breaking before replication.[39] This also supports the idea of autocatalytic processes capable of propagating the homochirality from an initial statistical mixture of chiral molecules. The interesting findings of enantiomeric excesses in extraterrestrial samples do not answer definitely the question of the generation of asymmetry, nor do they conflict with the statistical arguments.[14]

There will come a time, perhaps ten years from now, perhaps sooner, when we would not be able to discuss evolution at any finer level of detail without claiming the origin of enantiomeric homogeneity. That's what life is all about.

Acknowledgments

One of us (P. C.) thanks a group of talented colleagues: K. Asakura, D. G. Blackmond, A. Eschenmoser, H. B. Kagan, J. V. Selinger, J. Siegel, K. Soai and R. Tamura, for kindly providing copies and preprints of their contributions, and for helpful discussions. The Ministry of Education and Culture (PB95-0259) and the Junta de Extremadura-Fondo Social Europeo (IPR98-C040) supported this work.

40 A particular case of spontaneous resolution involves achiral compounds having chiral conformations, which may be 'frozen' in the solid state or in solution at low temperature. Thus, enantiomeric crystals of an *N*-methylbenzamide, which correspond to a stable *anti* conformer, could be distinguished morphologically as in Pasteur's experiments. Moreover, slow crystallization may lead to homochiral crystals. All four molecules in the unit cell of the chiral crystal have the same chirality. See for instance: I. Azumaya, I. Okamoto, S. Nakayama, A. Tanatani, K. Yamaguchi, K. Shudo and H. Kagechika, *Tetrahedron*, 1999, **55**, 11 237.

Received (in Cambridge, UK) 20th March 2000, Accepted 14th April 2000

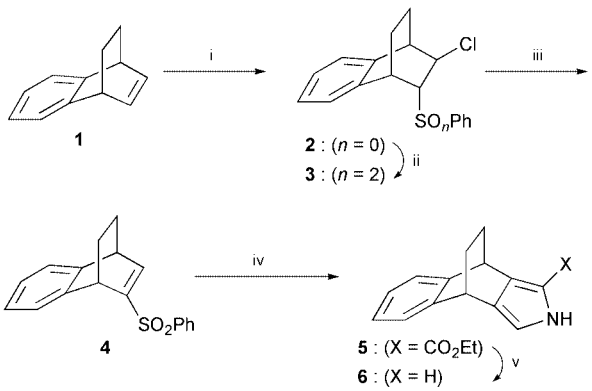
A new synthesis of [2,3]naphthoporphyrins using 4,9-ethano-*2H*-benz[*f*]isoindole as a synthon of *2H*-benz[*f*]-isoindole is described; soluble precursors of [2,3]naphthoporphyrins are converted into insoluble [2,3]naphthoporphyrins by simply heating at 290 °C.

Highly conjugated porphyrins have attracted attention as conducting materials, near-IR dyes, nonlinear optical materials,[1] or photosensitizers for photodynamic therapy (PDT) of cancer tissues on *in vivo* studies.[2] We and Lash *et al*. have reported syntheses of various highly conjugated porphyrins using pyrroles fused with polycyclic aromatic rings.[3] The requisite pyrroles are prepared by the reaction of polycyclic aromatic nitro compounds with ethyl isocyanoacetate. However, this method has a severe limitation. The reaction of nitrobenzene and nitronaphthalene with ethyl isocyanoacetate does not give the desired isoindole[4] and benz[*f*]isoindole.[5] In general, such isoindole derivatives are very difficult to prepare owing to their instability. In addition, highly conjugated porphyrins and their metal complexes are very difficult to purify, since they are insoluble in most organic solvents.[6] We have reported a simple solution of these problems using 4,7-dihydro-4,7-ethano-*2H*-isoindole as a synthon of isoindole for benzoporphyrin synthesis.[7,8] Thus, heating porphyrins fused with bicyclo[2.2.2]octadiene rings at 200–230 °C results in clean formation of benzoporphyrins *via* retro Diels–Alder reaction; the products are pure and do not require further purification. Here, we report a new synthesis of [2,3]naphthoporphyrins using a similar strategy, in which 4,9-ethano-*2H*-benz[*f*]isoindole is used as a synthon of *2H*-benz[*f*]isoindole.

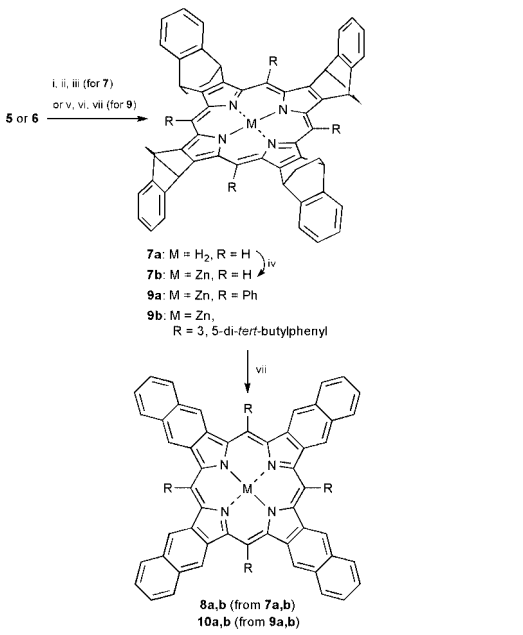
The synthesis of 4,9-dihydro-4,9-ethano-*2H*-benz[*f*]isoindole **6** is summarized in Scheme 1.† 1,4-Dihydro-1,4-ethanonaphthalene **1** was converted into sulfide **2** by reaction with PhSCl. Oxidation of **2** with *m*-CPBA followed by treatment with DBU gave α,β-unsaturated sulfone **4**. The pyrrole **5** was prepared in good yield by treatment of **4** with ethyl isocyanoacetate in the presence of 2.0 equivalents of Bu^{t}OK.[9] Deethoxycarbonylation upon heating **5** with KOH in ethylene glycol at 165 °C gave 4,9-dihydro-4,9-ethano-*2H*-benz[*f*]-isoindole **6** in 83% yield.

Porphyrin **7a** was prepared from pyrrole **5** by reduction with $LiAlH_4$ at 0 °C followed by subsequent tetramerization and oxidation. Various metals can be introduced into **7a** by the usual method using metal acetates. Porphyrins **7a**,**b** were purified by column chromatography (alumina, $CHCl_3$) followed by washing the resulting powder with MeOH–H_2O (*ca.* 1:1). Porphyrins **7a**,**b** were converted into pure tetranaphtho[2,3-*b*;2′,3′-*g*;2″,3″-*l*;2‴,3‴-*q*]porphyrins **8a**,**b** in 100% yield by heating at 290 °C under vacuum (10 mm Hg) for 10 min. Thus, porphyrins **7a**,**b** can be regarded as soluble equivalents of the corresponding tetra[2,3]naphthoporphyrins **8a**,**b**. The reaction of **6** with benzaldehydes in the presence of $BF_3{\cdot}OEt_2$ followed by oxidation and metallation gave *meso*-tetraarylated porphyrin zinc complexes **9a**,**b**. They were also converted into the corresponding *meso*-tetraarylnaphtho[2,3-*b*;2′,3′-*g*;2″,3″-*l*;2‴,3‴-*q*]porphyrin zinc complexes **10a**,**b** in 100% yield by heating at 290 °C *in vacuo* for 10 min (Scheme 2).

Mono[2,3-*b*]naphthoporphyrin **13** was also prepared in 100% yield by heating porphyrin **12** at 290 °C (Scheme 3).† Porphyrin **12** was prepared by the well established 3 + 1 approach consisting of the reaction of tripyrrane **11** with 3,4-diethylpyrrole-2,5-dicarbaldehyde followed by oxidation.[10] The requisite **11** was prepared by the reaction of **6** with 2.0 equivalents of *tert*-butyl 5-acetoxymethyl-4-butyl-3-methyl-1*H*-pyrrole-2-carboxylate in Pr^{i}OH–AcOH.



Scheme 1 *Reagents and conditions*: i, PhSCl, CH_2Cl_2, −78 °C, 1 h, 99%; ii, *m*-CPBA, $CHCl_3$, room temp., 2 h, 99%; iii, DBU, THF, 0 °C, 30 min, 99%; iv, ethyl isocyanoacetate, Bu^{t}OK, THF, 0 °C, 3 h, 91%; v, KOH, $HO(CH_2)_2OH$, 165 °C, 1.5 h, 83%.



Scheme 2 *Reagents and conditions*: i, $LiAlH_4$, THF, 0 °C, 1 h; ii, *p*-TsOH, $CHCl_3$, room temp., 15 h; iii, *p*-chloranil, room temp., 24 h, 20% (three steps from **5**); iv, Zn(OAc), $CHCl_3$–MeOH (9:1), room temp., 30 min, 95%; v, ArCHO, $BF_3{\cdot}OEt_2$, $CHCl_3$, room temp., 4 h; vi, *p*-chloranil, room temp., 4 h; vii, $Zn(OAc)_2$, $CHCl_3$–MeOH (9:1), room temp., 30 min (**9a** = 39%; **9b** = 16%, for three steps from **6**); viii, 290 °C, 10 min, 100%.

Table 1 Selected UV–VIS data for [2,3]naphthoporphyrins and their precursors

Porphyrin	λ_{max} ($CHCl_3$)/nm ($\log_{10}\varepsilon$)
7a	392 (5.20), 495 (4.14), 527 (3.66), 563 (3.69), 615 (3.12)
8a[a]	359 (0.34), 419 (0.50), 464 (1.00), 697 (0.13), 773 (0.87)
9a	349 (3.29), 426 (5.43), 549 (4.17)
10a	487 (4.96), 662 (3.73), 723 (4.87)
12	399 (5.17), 497 (4.12), 531 (3.86), 566 (3.73), 619 (3.49)
13	419 (5.34), 519 (3.92), 551 (4.53), 587 (3.75), 643 (4.34)

[a] In 5% TFA–$CHCl_3$; here relative intensities are given in parentheses.

Absorption spectrum data of [2,3]naphthoporphyrins and their precursors are summarized in Table 1. As porphyrin **8a** was insoluble in most solvents, its absorption spectrum was measured in 5% TFA-$CHCl_3$. The Soret and Q bands of the dication **8a** were observed at 464, 697 and 773 nm, respectively. The absorbance at 773 nm is unusually intense (0.87 × that of Soret band), showing behaviour reminiscent of phthalocyanines. *meso*-Tetraphenyltetra[2,3]napthoporphyrin **10a** was moderately soluble in organic solvents such as CH_2Cl_2 or $CHCl_3$. The Soret band of **10a** was rather weak compared to that of other porphyrins, owing to steric hindrance between *meso*-Ph and fused [2,3]naphthalene rings. By contrast, the intensity of the absorption at 723 nm is very strong ($\log_{10}\varepsilon$ = 4.87), this value is considerably larger than that of known π-extended *meso*-tetraphenylporphyrins.[3] The UV–VIS spectrum of **13** is rhodo-type (Q band: III > I > IV > II) which is typical for monobenzoporphyrins.[7]

In conclusion, we have succeeded in developing a new strategy for the preparation of [2,3]naphthoporphyrins using 4,9-ethano-2*H*-benz[*f*]isoindole as a synthetic equivalent of 2*H*-benz[*f*]isoindole. This strategy may extend to the synthesis of other π-extended molecules such as polypyrroles or pyrrole oligomers, which are fused with naphthalene rings.

The work was partly supported by Grants-in Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan. We are also grateful to Dr Y. Takahashi (JEOL) for recording the FAB mass spectra of porphyrins (**8a** and **10a**).

Selective 1:1 complex formation of a square quartet of 9-ethylguanine with small alkali metal cations (Li^+, Na^+) was detected by electrospray mass spectrometry

The guanine base is unique as a pair of hydrogen-donating groups (NH and NH_2) and a pair of hydrogen-accepting groups (C=O and N) are arranged on adjacent edges of the molecule [Fig. 1(a)]. Thus, a guanine base can form a self-complementary, hydrogen-bonded square quartet [Fig. 1(b)], which has been widely found in gels of guanosine derivatives **1**[1,2] and in parallel[3] and antiparallel[4] quadruple strands of guanine-rich oligonucleotides such as telomeric DNA.

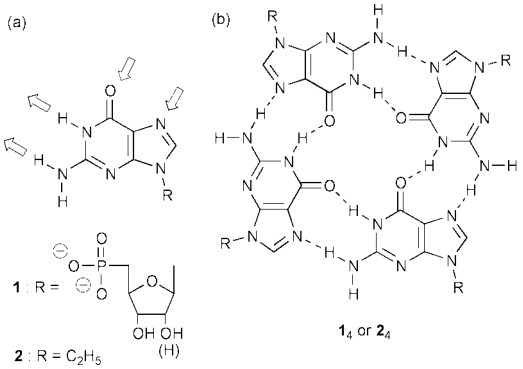

Fig. 1 (a) Guanosine-5′-monophosphate **1** and 9-ethylguanine **2**, (b) guanine quartet ($\mathbf{1}_4$ and $\mathbf{2}_4$).

Pinnavaia *et al.* and Laszlo and coworkers have independently reported that the aggregate of guanosine-5′-monophosphate (5′-GMP) in the presence of K^+ is a 2:1 complex (a sandwich complex) composed of two stacked $\mathbf{1}_4$ and one K^+ ion [Fig. 2(a)].[5] In order to stabilize the sandwich structure, chelation of cations with phosphate groups is essential,[5b,c] although stacking interactions between guanine bases and ion–dipole interaction between K^+ and carbonyl groups may also be important. In contrast to 5′-GMP, 9-alkylguanines do not have the ability to show such chelation. In this work, we have detected a 1:1 complex of guanine quartets with alkali metal cations by electrospray ionization mass spectrometry (ESI-MS)[6] in the system of 9-ethylguanine **2**.†

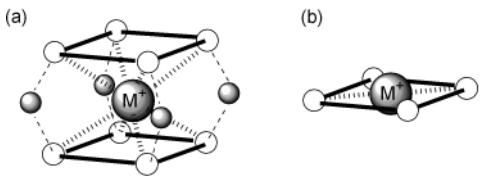

Fig. 2 Schematic representations of (a) a 2:1 complex (a sandwich complex) and (b) a 1:1 complex of a guanine quartet with alkali metal cations: ○, guanine base; (⋯⋯), interaction between alkali metal cation (M^+) and carbonyl group; (—), hydrogen bonding between guanine bases; (-----), chelation of alkali metal cation (◍) with phosphate groups.

The ESI-MS spectrum of **2** [Fig. 3(a)] shows prominent peaks at *m/z* 202, 381 and 739, corresponding to $[\mathbf{2} + Na]^+$, $[\mathbf{2}_2 + Na]^+$ and $[\mathbf{2}_4 + Na]^+$ in the presence of 0.1 mM $NaClO_4$. Other $[\mathbf{2}_n + Na]^+$ ($n = 3$ and $n \geqslant 5$) complexes were scarcely observed under these conditions. When the concentration of Na^+ was reduced to 0.01 mM [Fig. 3(b)], only the $[\mathbf{2}_4 + Na]^+$ ion was observed. The above results indicate that the 1:1 complex of the guanine quartet ($\mathbf{2}_4$) with sodium cation, $[\mathbf{2}_4 + Na]^+$, is remarkably stable.

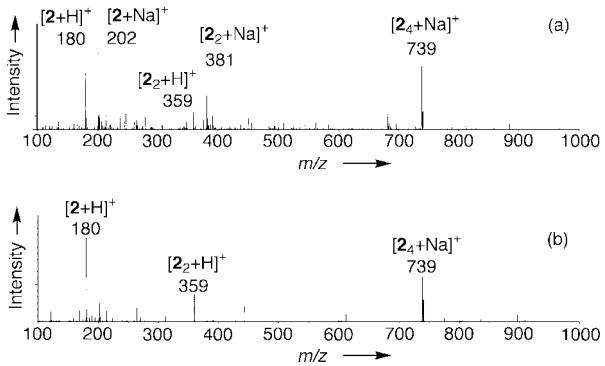

Fig. 3 ESI-MS spectra of 9-ethylguanine **2**: in the presence of (a) 0.1 mM and (b) 0.01 mM $NaClO_4$.

Similarly, **2** also gave the corresponding $[\mathbf{2}_4 + M]^+$ along with $[\mathbf{2} + M]^+$ and $[\mathbf{2}_2 + M]^+$ in the presence of 0.1 mM of other alkali metal cations (Li^+, K^+, Rb^+ and Cs^+) (Fig. 4). The peak intensity ratios of $[\mathbf{2}_4 + M]^+/[\mathbf{2} + M]^+$ for Li^+ and Na^+ (Li^+, 0.69 and Na^+, 0.80) are considerably higher than those of the other alkali

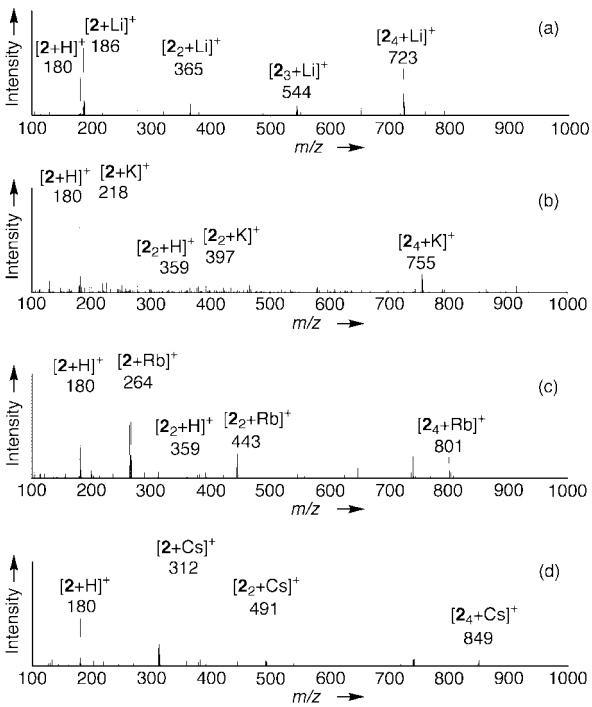

Fig. 4 ESI-MS spectra of 9-ethylguanine **2** in the presence of 0.1 mM $MClO_4$: (a) M = Li, (b) M = K, (c) M = Rb and (d) M = Cs.

DOI: 10.1039/b002235g

metals (K^+, 0.20; Rb^+, 0.20; and Cs^+, 0.16), suggesting that Li^+ as well as Na^+ form a stable $[\mathbf{2}_4 + M]^+$ complex. To confirm this tendency, ESI-MS measurements were performed in the presence of a pair of cations both 0.1 mM (Na^+–Li^+, Li^+–K^+, K^+–Rb^+, or Rb^+–Cs^+). The relative peak intensities of $[\mathbf{2}_4 + M]^+$ increased as $Na^+ > Li^+ > K^+ \gg Rb^+, Cs^+$.

NMR studies of 2:1 complexes $[(\mathbf{1}_4)_2 + M]^+$ showed that the stability increases in the order $K^+ > Na^+, Rb^+ \gg Li^+, Cs^+$.[5a] The K^+-selectivity in the 2:1 complex shows that size of the cavity between two 5′-GMP quartets ($\mathbf{1}_4$) is appropriate to accommodate K^+ [Fig. 2(a)].[5c] On the other hand, our results indicate that Li^+ and Na^+ bind with $\mathbf{2}_4$ more strongly than does K^+.[7] The selectivity for Na^+ and Li^+ is possibly explained by a correspondence between the size of M^+ and that of the central cavity of $\mathbf{2}_4$. Average distances from the center of $\mathbf{2}_4$ to carbonyl oxygens are estimated to be 2.41 Å by molecular orbital calculation,[8,9] close to the experimentally observed Na–O distance (2.34 ± 0.02 Å) by X-ray analysis.[4c] Accordingly, Na^+ can fit exactly in the central cavity of $\mathbf{2}_4$. Li^+ (Li–O, 2.04–2.24 Å[10]) may also be located inside the cavity. On the other hand, K^+, Rb^+ and Cs^+ (K–O, 2.75–2.81 Å;[11] Rb–O, 2.88–2.93 Å;[11] and Cs–O, 3.06–3.18 Å[12]) are too large to fit in the central cavity of $\mathbf{2}_4$ and would be located out-of-plane.

In conclusion, we have observed 1:1 complexes of $\mathbf{2}_4$ with alkali metal cations in the systems of 9-ethylguanine **2** using ESI–MS. The sodium complex $[\mathbf{2}_4 + Na]^+$ was the most stable, in contrast to the K^+-selective 2:1 complex of $\mathbf{1}_4$. The differences in the composition and in the cation selectivity between $[(\mathbf{1}_4)_2 + M]^+$ and $[\mathbf{2}_4 + M]^+$ may be ascribed to the difference in stacking ability of $\mathbf{1}_4$ and $\mathbf{2}_4$. For $\mathbf{2}_4$, the absence of phosphate groups may significantly reduce the stacking interaction in comparison with $\mathbf{1}_4$. Therefore, the stability of $[\mathbf{2}_4 + M]^+$ depends on the size of M^+ which is located in the central cavity of $\mathbf{2}_4$.

Notes and references

† *General procedure*. 9-ethylguanine **2** was purchased from Sigma and purified by reverse phase HPLC. The column (150 mm × 4.6 mm i.d.) packed with TSKgel ODS-120T (5 μm particle size) (Tosoh) was used in the LC-MS system. The solvents used in the LC-MS system were MeOH–H_2O (1:9, v/v) containing $MClO_4$ (M = Li, Na, K, Rb or Cs). 100 μl of 1.0 mM of an aqueous solution of **2** was applied to the HPLC. The flow rate was 1.0 ml min^{-1}. Mass spectra of the 9-ethylguanine fraction were obtained by introducing the effluent into the ESI-MS apparatus, a Hitachi M–1200HS mass spectrometer, just before the peak was eluted. The flow-rate of the pump was kept at 50 μl min^{-1} while the effluent was introduced into the ESI-MS apparatus.

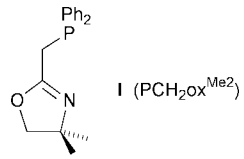
Received (in Basel, Switzerland) 29th March 2000, Accepted 11th April 2000
Published on the Web 9th May 2000

A new class of anionic, hybrid chelating ligands is reported which contain a phosphine moiety covalently linked to an oxazoline of which the nitrogen atom formally carries a partly delocalized negative charge; the first metal complex, a ruthenium derivative, has been characterized by X-ray diffraction and shown to be active in catalytic transfer hydrogenation.

The numerous synthetic pathways to oxazolines make them versatile synthons for ligand design[1] and their availability in enantiomeric pure forms accounts for the increasing use over the last 10 years of oxazoline-based ligands for asymmetric reactions catalyzed by transition metal complexes.[2] We have recently investigated the synthesis of Pd and Ru complexes with the neutral *P,N*-type ligand (oxazolinylmethyl)diphenylphosphine **I** (abreviated PCH_2ox^{Me2}) and studied their catalytic properties for ethylene/CO copolymerization and asymmetric transfer hydrogenation of ketones, respectively.[3]



I (PCH_2ox^{Me2})

We then felt it would be of interest to isolate Ru hydrido complexes of potential catalytic relevance but reactions of $[Ru(H)Cl(PPh_3)_3]$ or $[Ru(H)(OAc)(PPh_3)_3]$ with **I** were not selective and although hydrido species were observed by ^1H NMR spectroscopy, no pure complexes could be isolated. We then reacted $[Ru(OAc)(PCH_2ox^{Me2})_2]Cl$ **1**,† prepared from $[RuCl_2(PCH_2ox^{Me2})_2]$[3b] and Tl(OAc), with CsF in acetone in order to prepare a monofluoride derivative that could be subsequently cleanly transformed into a hydride complex.[4] The $^{31}P\{^1H\}$ NMR spectrum of the only product formed, **2**, exhibited an AB spin system at δ 46.8 and 58.3 with ^2J(PP) 35.8 Hz which, surprinsingly, showed no coupling with a ^{19}F nucleus. The reaction of $[RuCl_2(PCH_2ox^{Me2})_2]$ itself with CsF was found to be less selective and not further investigated. An X-ray diffraction study‡ established the ligand arrangement in **2** and the fact that one of the *P,N*-ligands had unexpectedly been deprotonated. The crystals contain two crystallographically independent, but almost identical, molecules (A and B). A view of the structure of one of them (A) is shown in Fig. 1. Both ligands (excepting for the substituents) are roughly planar, but in the deprotonated one the N(1)C(14)C(13)P(1) moiety is practically planar. The two Ru–N bond distances in the octahedral complexes differ remarkably and the shorter, 2.102(3) Å in (A) and 2.111(3) Å in (B), involves the N(1) atom bearing the partial negative charge. Whereas the double bond is mainly localized on the C–N bond in the PCH_2ox^{Me2} ligand [bond distance 1.281(4) Å in both A and B], electronic delocalization occurs within the N(1)C(14)C(13)P(1) moiety of $PCHox^{Me2}$, as indicated by the values of the C–C [1.370(5) Å in (A) and 1.371(5) Å in (B)], C–N [1.328(4) Å in (A) and 1.317(4) Å in (B)] and P–C [1.753(3) Å in (A) and 1.754(4) Å in (B)] bond distances. Consistently, the IR spectrum of **2** contains two bands at 1618 and 1535 cm^{-1} assigned to the C=N and C⋯N vibrations of PCH_2ox^{Me2} and $PCHox^{Me2}$, respectively. In the ^1H NMR spectrum, each proton in PCH_2ox^{Me2} and $PCHox^{Me2}$ appears as a single resonance in agreement with the lack of any symmetry element in the molecule.

The selective synthesis of **2** was unexpected and found to depend on the nature of the cation associated with the fluoride anion. Thus, reaction of **1** with LiF only afforded a low yield of **2**. A more rational and general access to the anionic chelate in **2** consisted in the reaction of **1** with Bu^tOK in THF and selective deprotonation of only one PCH_2 group was observed [eqn. (1)].

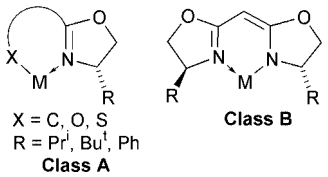
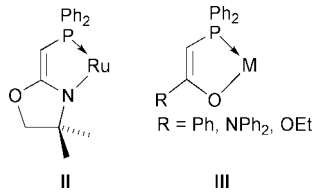
1 2 (1)

Anionic ligands incorporating an oxazoline ring are few compared to their neutral analogs and they belong to two main families. In class **A**, the anionic charge is carried by an exocyclic atom (C^-,[5] O^-,[6] S^- [7]) and the nitrogen atom of the oxazoline formally remains a neutral donor.



Some of their complexes are catalysts for, *e.g.* ethylene polymerization,[6a] sulfide oxidation,[8] alkyl- and phenyl-zincation of aldehydes[6b,c] and conjugate addition to enones.[7] In the second class of ligands, **B**, the anionic charge is partly localized on the nitrogen atom of the oxazoline but only one representative is known which has led to efficient Ti,[9] Cu,[10] Zn[11] or Mg[12] catalysts for several asymmetric reactions, *e.g.* reduction of ketones,[9b] cyclopropanation of olefins,[10] allylzincation,[11] and hydrocyanation of aldehydes.[12] Although there are two reported X-ray crystal structures of Cu[13] and Rh complexes,[14] the precatalysts were usually prepared *in situ* and not isolated (Zn, Mg, Ti).



The new ligand system in **II** provides an interesting extension to *anionic* four-electron donor phosphino enolate ligands of type **III** currently much investigated. These and related phosphorus/oxygen chelates confer special reactivity to their complexes, as found, *e.g.* in reactions with various organic or inorganic electrophiles[15] or in the highly selective convertion of ethylene into linear α-olefins.[16] The anionic ligand $PCHox^{Me2}$ found in **2** is therefore the first representative of a new class of hybrid ligands which combine some of the aspects of systems **B** and **III** and its chemistry therefore offers considerable potential. Preliminary catalytic studies with complex **2** have been performed for the transfer hydrogenation of aryl alkyl and dialkyl ketones by propan-2-ol, a reaction of current interest.[17] Under standard conditions ([Ru]/[ketone]/[PrⁱONa] = 1:200:5, [ketone] = 0.1 M, T = 82 °C), **2** exhibits very high to high activity for hydrogenation of acetophenone (98% yield in 5 min) and cyclohexylmethyl ketone (91% in 5 h) respectively.§

Access to complexes containing this new anionic *P,N*-ligand can be generalized, as shown with Pd since reaction of [Pd(dmba)Cl(PCH_2ox)] with BuᵗOK in THF afforded [Pd(dmba)(PCHox)] **3** in 84% yield.

§ *Catalytic transfer hydrogenation*: Typical procedure for the catalytic transfer hydrogenation of acetophenone: **2** (0.0052 g, 0.0068 mmol) was dissolved in 13 mL PrⁱOH in a 50 mL two-neck round bottom flask fitted with a reflux condenser. Acetophenone (0.158 mL, 1.36 mmol) was added and the yellow solution was brought to reflux. The solution was stirred for 10 min and 0.36 mL (0.034 mmol) of a solution of PrⁱONa in PrⁱOH (0.1 M) was added. The volume of PrⁱOH was adjusted so that all catalytic runs were performed with an initial concentration in acetophenone of 0.1 M. The addition of PrⁱONa was considered as the starting time of the reaction. Conversion was determined by gas chromatography using a Lipodex A 25 m × 0.25 mm column.

Published on the Web 9th May 2000

A new template synthesis of triphosphorus macrocycles has been developed based upon the intramolecular hydrophosphination of allylphosphine coordinated to the (η^5-cyclopentadienyl)iron(II) cation; the resulting tri-secondary macrocycle 1,5,9-triphosphacyclododecane is readily alkylated with ethene to give (η^3-1,5,9-[12]aneP_3Et_3)Fe(η^5-Cp)$^+$ which is in turn liberated as the free ligand stereospecifically as the *syn–syn* isomer; related reactions with phenyl(allyl)phosphine lead directly to the triphenyl macrocycle (1,5,9-[12]aneP_3Ph_3) which is also liberated stereospecifically.

The first examples of C_3 symmetrical triphosphamacrocycles were those based upon the 1,5,9-[12]aneP_3 core prepared by a stereoselective metal template assisted synthesis using a $Mo(CO)_3$ template.[1,2] Early results confirm that they support relatively very stable facially capped complexes for a range of transition metals,[3] they may also impose unusual structural distortions on metal centres (*e.g.* for metals that prefer square planar geometries).[4] These observations highlight distinct differences in comparison to the behaviour of analogous nitrogen or sulfur ligands or of related tripodal phosphines. In view of their influences on structure and reactivity and their ability to stabilise low oxidation states, the study of their complexes is of substantial interest.

The current and only route to this class of ligands, by radical initiated hydrophosphination, does however have significant preparative limitations. The tris-allylphosphine precursor complexes required for this route are very sensitive to oxygen, moisture and large scale reactions require fastidious care in order to be reproducible. Of greater significance is that this method is currently limited to a minimum ring size of twelve atoms. We have previously commented upon the inability of the $Mo(CO)_3$ template, and its smaller chromium analogue, to support the cyclisation of vinyl phosphines in attempts to achieve smaller ring sizes.[5] These templates lack any possible steric control over the *trans*-coordinated precursor phosphines precluding any freedom to force the ring closure of vinyl phosphines by compression of the non-bonded P–P distances. In order to address these problems and to develop a more reliable synthetic route to tri-phosphines of this nature, we have undertaken a study of alternative methods. For these reasons we have chosen to investigate the [(η^5-Cp)Fe(η^6-arene)]$^+$ class of complexes which readily form tris-phosphine adducts[6] including those of acyclic triphosphines (linear[6b] and tripodal[6c]) and of primary phosphines,[6d] all of which are of course restricted to *facial* coordination by the η^5-Cp group. This approach has led us to an entirely new template method for the stereoselective synthesis of 1,5,9-[12]aneP_3R_3 triphosphorus macrocycles; preliminary results of which are presented herein.

The photolytically activated substitution of the aryl ligand in [(η^5-C_5H_5)Fe(η^6-C_6H_6)]$^+$ (**1**) in the presence of allylphosphine gives the tris-primary phosphine complex [(η^5-C_5H_5)Fe($H_2PC_3H_5$)$_3$]$^+$ **2**, as the hexafluorophosphate salt, in quantitative yield (Scheme 1). In the IR spectrum, a peak due to ν_{P-H} is observed (2318 cm^{-1}). The microcrystalline solid is indefinitely air-stable, although in CH_2Cl_2 solution the complex decomposes over several days to give a green, NMR silent and presumably paramagnetic species of undetermined composition. Complex **2** is readily soluble in most polar solvents, such as THF and CH_2Cl_2, but insoluble in hydrocarbons and other non-polar solvents. The ^{31}P {^{1}H} NMR and ^{31}P NMR spectra consist of a singlet and triplet, respectively (δ −9.0, $^1J_{P-H}$ 328 Hz), consistent with magnetically equivalent coordinated allylphosphine ligands (*cf.* for free allylphosphine, δ−134.4, $^1J_{P-H}$ 195 Hz).

Cyclotrimerisation of **2** has been attempted in tetrahydrofuran (THF), chlorobenzene and anisole, using AIBN [azobis(isobutyronitrile)] as radical initiator (*ca.* 1–2% mol equivalents). In THF, both the cyclisation intermediates and final macrocyclic product slowly precipitate during the reaction which remains incomplete as a result, unless performed in dilute solution. Attempts to separate and characterise these intermediates have not been successful.

In chlorobenzene the cyclisation is more efficient, forming [(η^5-C_5H_5)Fe(η^3-1,5,9-[12]aneP_3H_3)]$^+$[PF_6]$^-$ **3**, in moderate yield. Complex **3** has a band due to the P–H stretch in its IR spectrum (ν_{P-H} 2303 cm^{-1}) and a doublet in the ^{31}P NMR spectrum (δ 12.7, $^1J_{P-H}$ 336 Hz) assigned to phosphorus atoms in the coordinated macrocycle. This increase in chemical shift ($\Delta\delta$ 21.8 ppm) and coupling constant is similar to that observed in the analogous Mo(0) complexes, ($H_2PC_3H_5$)$_3$Mo(CO)$_3$ and (η^3-1,5,9-[12]aneP_3H_3)Mo(CO)$_3$, ($\Delta\delta$ 27.0 ppm, for the latter $^1J_{P-H}$ 318 Hz).

Hydrophosphination of ethene by **3** gives the tris-ethylated macrocyclic complex [(η^5-C_5H_5)Fe(η^3-1,5,9-[12]aneP_3Et_3)]$^+$[PF_6]$^-$ **4** which is characterised by a singlet in the ^{31}P

DOI: 10.1039/b002174l

{^{1}H} NMR spectrum (δ 38.1) and the absence of a band due to ν_{P-H} in its IR spectrum. The identity of **4** is further supported by its preparation in THF directly from the template precursor complex **1** by addition of free 1,5,9-[12]aneP_3Et_3 obtained by our previously reported route.[2] The products obtained by either method have identical spectroscopic, analytical and physical properties. This independent confirmation of the nature of **4**, in turn confirms the characterisation of **3** as the secondary phosphine macrocycle complex. Both **3** and **4** are air stable for extended periods in both solution and the solid state.

The reaction of $[(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-}C_6H_6)]^+$ with phenyl-(allyl)phosphine in a manner similar to that for the formation of **2a**, leads to the tri-secondary phosphine complex, **2b**, in excellent yield (99%). Complex **2b** is characterised by its ^{31}P{^{1}H} NMR spectrum which has two multiplets from the presence of both diastereomers and enantiomers arising from the three chiral phosphines in **2b** (δ 55.8). The radical induced cyclisation of the coordinated secondary phosphines in **2b** proceeds to the tri-tertiary phosphine macrocycle complex, **4b**. Intermediates which do not readily cyclise are also observed after extended reaction times; these are readily separated from **4b** upon work up. The resistance of these intermediates to cyclisation is presumably dependant upon the relative chirality at adjacent phosphines. Although we have recently reported the synthesis of the triphenyl macrocycle, **5b**,[7] this is the first example of the cyclotrimerisation of a secondary phosphine to a tri-tertiary triphosphorus macrocycle and may offer direct routes to tri-tertiary phosphines which might otherwise be difficult to obtain.

The macrocycle complexes, **4a** and **4b**, are digested by sodium in liquid ammonia resulting in the high yield liberation of the free macrocyclic ligands **5a** and **5b** stereoselectively as the *syn–syn* isomers. The identities and stereochemistries of both the triphosphines **5a** and **5b**, are confirmed by singlets in their ^{31}P {^{1}H} NMR spectra (δ −31.7 and −34.6, respectively); their spectra are identical to those previously reported.[2,7] In all cases analytical, conductivity, ^{1}H and ^{13}C{^{1}H} NMR data are consistent with the formulations.[8]. In addition to the ^{31}P NMR data discussed above, a resonance due to PF_6^- is also observed in each case (δ −144.0, $^1J_{P-F}$ 711 Hz).

This new route to the coordinated secondary phosphine ligands, the facile alkylation of the secondary phosphine macrocycle complex **3** to the corresponding tertiary phosphines and the successful and stereospecific liberation of the free ligands offers an alternative preparation based upon a more readily accessible template than the sole current literature route and *via* relatively air-stable precursor and intermediate complexes. We are currently investigating the influences of variations in substituents on the Cp ring upon the course of the macrocyclisation reactions. We are also investigating the application of this method to the cyclisation of alternative phosphine precursors in order to achieve both different ring sizes as well as different 'backbone' bridging functions; preliminary results are encouraging.

We thank the EPSRC for a studentship (A. J. P.).

Gram-scale quantities of microcrystalline powdered CeO_2–ZrO_2 solid solutions can be produced continuously in a near-critical water flow reactor at *ca.* 300 °C and 25 MPa; rapid hydrothermal co-precipitation leads to nano-particulate $Ce_{1-x}Zr_xO_2$ (x = 0 to 1), the composition of which is merely determined by the initial concentrations of Ce^{4+} and Zr^{4+} ions in the starting solution.

The synthesis of ceria-containing materials has long been of considerable scientific interest for applications as diverse as UV absorbers and solid oxide fuel cells.[1] Mixed CeO_2–ZrO_2 systems show improved oxygen storage capacity and greater thermal stability compared to CeO_2 itself,[2–4] which is particularly important for three-way exhaust catalysts. $Ce_{1-x}Zr_xO_2$ is prepared conventionally using various methods including high temperature solid-state reactions,[5] use of micro-emulsions,[6] high energy ball milling,[7,8] the sol–gel method,[9,10] and ageing of solutions.[11] However, many of these techniques are quite time consuming (involving multi-step syntheses or ageing), energy intensive and/or environmentally unfriendly. When extremely small particle sizes are needed, the complexity (and sometimes the cost) of manufacture increases further.

Arai and coworkers[12,13] have recently shown that particulate CeO_2 and ZrO_2 can be made continuously by decomposition of the corresponding metal nitrates in super-critical water, scH_2O. The reaction is believed to proceed *via hydrolysis* to the hydroxides, followed by *dehydration* to the oxides. Here, we show for the first time that the *mixed oxide* $Ce_{1-x}Zr_xO_2$ can be obtained continuously by hydrolysis of mixtures of $[NH_4]_2[Ce(NO_3)_6]$ (CAN) and $[Zr(ac)_4]$† in near-critical water, ncH_2O, in the appropriate ratios. The reactor shown in Fig. 1 gave single phase $Ce_{1-x}Zr_xO_2$ at rates close to 10 g h^{-1}. The high diffusivity of the reactants and the fast dehydration reaction in ncH_2O and scH_2O result in very high hydrolysis and dehydration reaction rates. Thus, residence times at the mixing point of only a few seconds were sufficient. In most cases, decomposition of the metal precursors appeared to be virtually complete. The composition in $Ce_{1-x}Zr_xO_2$ mixed oxides could be *changed* from x = 0.2 to 0.9 merely by *varying* the Ce : Zr ratios in the metal feed solution. Pure CeO_2 and ZrO_2 oxides could also be synthesised by using just one of the precursors.‡

The samples of $Ce_{1-x}Zr_xO_2$ were characterised by powder X-ray diffraction (PXD), Raman spectroscopy, BET surface area measurements and, in selected cases, TEM. The PXD patterns of the materials indicated the formation of CeO_2–ZrO_2 solid solutions (Fig. 2). The individual solid phases were identified by combining PXD and Raman data. A crude estimate of the apparent particle size was obtained by application of the Scherrer equation to the PXD line-widths (Fig. 3). For selected cases, the particle size was also investigated by TEM. For the 1 : 1 mixture (*i.e.* $Ce_{0.5}Zr_{0.5}O_2$), the TEM image showed particles with well-defined edges, well dispersed, between 3 and 5 nm in size, values which agree with the estimates from the Scherrer equation (4.6 nm). Diffraction rings (TEM) confirmed

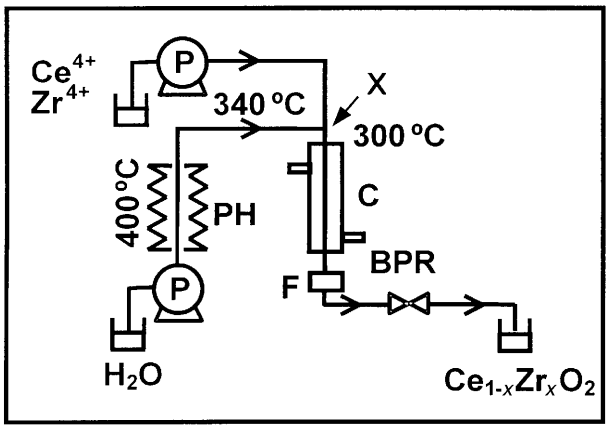

Fig. 1 Diagram of the flow reactor for the synthesis of metal oxide powders and solid solutions in ncH_2O. A solution of Ce^{4+} and Zr^{4+} salts at room temperature is mixed with a stream of H_2O heated up to 400 °C by the preheater (PH). The mixture is cooled immediately after the mixing point (X) by a water cooling (C) and is then passed through the filter (F) (to remove any large aggregates) and the back-pressure regulator (BPR). Particles are then collected as a suspension. P denotes pumps.

the crystallinity of the materials obtained. For pure ZrO_2, TEM showed a fluffy 'cloud-like' image with nano-particles of *ca.* 5 nm (5.6 nm by PXD). All materials have medium to high surface areas as measured by BET, S_{BET} (Fig. 3). It is also clear from Fig. 3 that there is a correlation between S_{BET} values and the apparent particle size. S_{BET} values for the samples appear to reach a maximum for the oxides with higher zirconium content (181, 184 and 183 m^2 g^{-1} for the 1 : 4 and 1 : 9 Ce–Zr materials and pure ZrO_2, respectively).

CeO_2 and $Ce_{1-x}Zr_xO_2$ (x = 0–0.5) showed cubic fluorite PXD patterns. Increasing Zr content in the solid solutions resulted in a decrease in the lattice parameter, owing to the incorporation of smaller Zr^{4+} ions into the fluorite (mainly

Ce^{4+}) lattice. For the samples of Ce : Zr ratios 1 : 4 and 1 : 9, a tetragonal phase was assigned.§ For pure ZrO_2, PXD and Raman data revealed a mixture of monoclinic and tetragonal phases. Considering the relative intensities of the most intense reflection in the PXD of both phases, the ratio of monoclinic to tetragonal phases was estimated to be 40 : 60.

The precise phase assignment is slightly different from that reported in the literature.[3,14] One possible explanation is that the Zr content in the solid solutions is lower than the expected. However, this would not explain why our samples of pure ZrO_2 contained a mixture of monoclinic and tetragonal phases rather than the monoclinic (thermodynamically stable) phase reported in the literature.[14] Therefore is likely that the differences are due to the small particle sizes of the materials produced. Fornasiero *et al*.[3] have reported that below a critical crystalline size, the tetragonal phase is favoured over the monoclinic and, with extremely small particles, the cubic phase is favoured over the tetragonal, which is consistent with our phase assignment. As discussed before, the extremely small particle sizes may be as a result of the rapid precipitation and relatively low synthesis temperature. All samples were studied by TGA. In each case, there was a weight loss (2–12%) at ⩽100 °C, presumably due to adsorbed water. Some samples showed smaller weight losses (4–7%) around 250 and 310 °C; IR spectra suggest that theses losses may be associated with residual nitrate and acetate.

In conclusion, we have reported a new and extremely rapid one-step synthesis of ceria–zirconia solid solutions (at the concentrations and flow rates employed in the experiments, between *ca.* 8 and 11 g h^{-1}, depending on the composition of $Ce_{1-x}Zr_xO_2$, can be produced continuously). The chemistry is simple and clean. The reaction does not require the addition of organic solvents, modifiers (to control pH) or prolonged reaction times. The temperatures are low (300 °C) compared to those used in conventional techniques. Most importantly, the composition of $Ce_{1-x}Zr_xO_2$ can be tuned simply by varying the amounts of precursors in the starting solution. The products are completely homogenous. The particles are highly crystalline (TEM) despite the relatively low temperatures of formation, and the primary particle sizes are extremely small imparting relatively high surface areas of up to *ca.* 180 $m^2\ g^{-1}$ for the materials. Currently we are exploring the potential of our technique for synthesising other solid solutions.

† Zirconium acetate/dilute acetic acid solution with a 15% Zr content as supplied by Aldrich.

‡ **CAUTION:** this experiment involves high pressure and temperature and requires appropriate apparatus.

The total concentration of the metal solution (Ce + Zr) was kept constant and equal to 0.21 M. The flow rates of the metal salt and water streams were 5.0 and 10.0 mL min^{-1}, respectively. Pressure was kept constant at 25 ± 1 MPa and the H_2O inlet temperature was *ca.* 360 °C. At the mixing point, the temperature was close to 300 °C. The resulting coloured suspensions of metal oxides were separated from the clear aqueous phase by decantation, and the solids were dried at 100 °C after washing with water.

§ Although the characteristic tetragonal splittings of the reflections (200), (220), (311) and (400) in the fluorite structure (Fig. 2) were not visible owing to the broadness of the PXD peaks, the appearance of bands at 625, 460 and 315 cm^{-1} in the Raman spectra of the fresh materials (not illustrated) suggests a tetragonal phase.[8]

Octylsilane-grafted hexagonal mesoporous silica removed low-concentrated nonylphenol, an endocrine disrupter, in water with high efficiency comparable to that of activated carbon, while the adsorbent showed no detectable uptake of phenol.

Mesoporous materials such as MCM-41[1] and FSM-16[2] have been extensively studied as catalyst supports and adsorbents. They have advantages for the adsorption of large molecules because of their large pore size and high surface areas. It has been reported that an as-synthesised surfactant–silica mesophase effectively absorbs 4-chlorophenol into its confined 'micelles' from aqueous solution.[3] Functionalization of the inner wall by grafting organic or organometallic groups is a promising strategy in designing the nature of pore spaces at the molecular levels.[4–8] Considering that grafted alkyl groups provide hydrophobic regions confined within the ionic surface of the inorganic phase, it is expected that control of the hydrophobicity would improve the performance of the absorbent for organic moelcules having both hydrophilic hydrophobic regions.

Alkylphenolic chemicals such as nonylphenol, which are biodegradaion products of alkylphenol polyethoxylate resin, have been found to be the major oestrogenic contaminants to induce feminising effects in fish.[9–11] The minimum effective concentration of nonylphenol was estimated *in vitro* to be in the range of 10 nM–10 μM (2.2–2200 ppb).[11] For the removal of a pollutant by adsorption with such a low concentration in sewage disposal plants, the adsorbent should have a very high molecular selectivity, otherwise many coexisting compounds with higher concentrations would saturate the capacity of the adsorbent.

Here we report that the grafting of alkylsilanes with intermediate chain lengths provides mesoporous silica with a high molecular selectivity. Octylsilane-grafted mesoporous silica effectively removed nonylphenol from water, while it showed no detectable adsorption of phenol. The capacity of the adsorbent for nonylphenol was comparable to that of an activated carbon which is currently used in sewage disposal plants and water purification plants.

Hexagonal mesoporous silica (MPS) was prepared by the following procedure: 0.011 mol of octadecyltrimethylammonium chloride was dissolved in 25 ml hydrochrolic acid (12.5 wt%) at 328 K. Then 0.011 mol of tetraethoxysilane was added with stirring to immediately give a white precipitate. After filtration, the obtained mesophase was dehydrated at 473 K for 2 h and then calcined at 813 K in air for 6 h to obtain MPS. For synthesis of alkylsilane-grafted MPS, 0.32 g of the MPS was refluxed in fresh distilled toluene with 9.6×10^{-3} mol of *n*-octyltriethoxysilane or *n*-dodecyltriethoxysilane for 48 h. Prior to the silylation, MPS was dried at 473 K for 2 h *in vacuo*. After the silylation, the samples were washed with distilled toluene and then with anhydrous methanol. During these procedures, the materials were treated in a glove-box filled with dry Ar (H_2O was monitored to be < 1 ppm). In typical adsorption experiments, 1 mg of the adsorbent was added to 10 g of an aqueous solution of nonylphenol (2100 ppb). After the adsorption with stirring for a given time, the supernatant solution was separated by centrifugation and the residual nonylphenol was analysed with an ultraviolet (UV) spectrometer at 278 nm. Blank experiments confirmed that the adsorption of nonylphenol on the flask wall was low ($< 10\%$). The data were corrected using the results of the blank tests. Adsorption of phenol in water (2000 ppb) was also measured in the same way. For comparison, an activated carbon (Calgon F-400, surface area *ca.* 1000 $m^2\ g^{-1}$) was used.

Fig. 1 shows the N_2 adsorption isotherm for the samples synthesised in this study. The pristine MPS showed a curve with no hysteresis, which is typical for materials having cylindrical regulated pores like MCM-41. For the octylsilane-grafted MPS (C_8-MPS), the amounts of N_2 adsorption at relative pressures above 0.4 were *ca.* one third of that for MPS and the isotherm showed no hysteresis. The dodecylsilane-grafted MPS (C_{12}-MPS) gave a similar curve. This demonstrates that the alkylsilanes were grafted successfully onto the inner walls of the mesopores. Since the lengths of grafted alkylchains are shorter than the template used for the synthesis of MPS, it is expected that there are spaces at the centre of the pores. An α_s plot[12] on the basis of the N_2 isotherms of C_8-MPS (not shown) gave a shape similar to that of MPS, where the condensation of nitrogen was observed at lower α_s (*ca.* 0.6) for C_8-MPS than for MPS (α_s = *ca.* 0.8). These results demonstrated that the pores are narrower than the original ones. These spaces however, can still provide pathways for effective molecular diffusion. The inset in Fig. 1 shows the powder X-ray diffraction (XRD) pattern of C_8-MPS. This pattern shows that the mesostructure of silica (d_{100} = 35 Å) was maintained after grafting with the *n*-alkylsilane. Thermogravimetry and differential thermal analysis (TG-DTA) of C_8 and C_{12}-MPS gave exothermic weight losses due to the decomposition of alkyl groups at *ca.* 493–573 K (not shown). The molar ratios of the alkyl group to Si were

Circles, squares and triangles correspond to MPS, C_8-MPS and C_{12}-MPS, respectively. The inset shows the powder X-ray diffraction pattern of C_8-MPS.

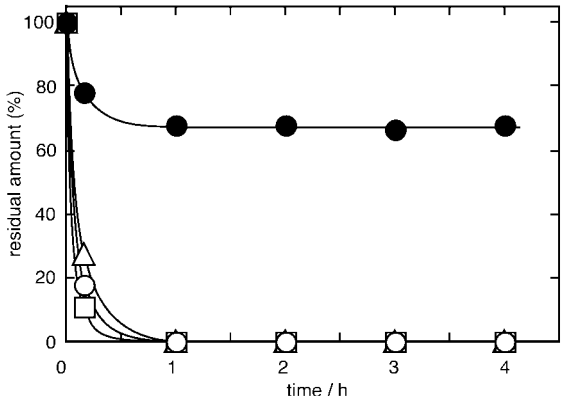

Fig. 2 Time courses of concentration of nonylphenol in water. 1 mg of adsorbent was used for 10 g of solution with an initial concentration of nonylphenol of 2100 ppb. Filled circles, open circles, open squares and open triangles correspond to MPS, C_8-MPS, C_{12}-MPS and activated carbon, respectively.

calculated from the TG data to be *ca.* 0.18 and 0.14 for C_8-MPS and C_{12}-MPS, respectively. These values are much smaller than the ratio of surfactant to Si for the as-synthesised mesophase (0.23), indicating that the materials have adequate space for molecular adsorption between the grafted alkyl groups in the mesopores.

Fig. 2 shows the time course of the concentration of nonylphenol during the adsorption. For the pristine MPS, *ca.* 30% of nonylphenol was removed. On the other hand, C_8-MPS removed nonylphenol totally within 1 h, showing that the grafting of alkyl groups is very effective in improving the performance of MPS. C_{12}-MPS and activated carbon also completely adsorbed nonylphenol within 1 h under the same conditions. A comparison between the alkyl-grafted MPSs and the activated carbon was carried out under much more severe conditions: 2 mg of the adsorbents were used for 200 g of the solution (1700–2100 ppb). The amounts of nonylphenol adsorbed at equilibrium are listed in Table 1. It was found that C_8-MPS showed a superior performance to the activated carbon. In addition, C_8-MPS was highly superior to C_{12}-MPS, while the differences of their surface areas and pore volumes were small. This indicates that the hydrophobicity of the dodecyl group is too strong while the moderate hydrophobicity of the octyl group is suitable for the effective adsorption of nonylphenol.

Table 1 Amounts of nonylphenol adsorbed on various adsorbents

Adsorbent	Concentration of nonylphenol/ppb	Amount of adsorbed nonylphenol/mol g^{-1}
C_8-MPS	6.2×10^2	6.5×10^{-4}
C_{12}-MPS	9.8×10^2	2.3×10^{-4}
MPS	1.3×10^3	9×10^{-5}
Activated carbon	6.2×10^2	5.3×10^{-4}

For comparison, adsorption of phenol in water (2000 ppb) was examined. 1 mg of absorbents were used for 10 g of solution. The activated carbon adsorbed 95% of phenol while MPS showed an uptake of 6%. On the other hand, C_8-MPS showed no detectable adsorption of phenol, while nonylphenol (2100 ppb) was completely removed under the same conditions. C_{12}-MPS gave the same results as C_8-MPS. Clearly, the grafting of alkyl group on the mesoporous silica provides a high molecular selectivity of nonylphenol against phenol.

In conclusion, MPS was made more hydorphobic by grafting alkyl chains on the inner surface of the mesopores and the resulting materials showed a high adsorption capacity for nonylphenol, an endocrine disrupter, comparable to that of activated carbon. The C_8-MPS adsorbent showed high molecular selectivity, distinguishing the hydrophobicity of molecules. These results indicate that the introduction of tuned hydrophobic regions in inorganic nanospaces is an effective strategy to design molecular selective adsorbents.

Rotaxane-encapsulated cyanine dyes: enhanced fluorescence efficiency and photostability

Jonathan E. H. Buston, James R. Young and Harry L. Anderson*

Department of Chemistry, University of Oxford, Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY. E-mail: harry.anderson@chem.ox.ac.uk

Received (in Liverpool, UK) 6th March 2000, Accepted 17th April 2000
Published on the Web 9th May 2000

Two isomers of a cyanine dye α-cyclodextrin rotaxane have been synthesised in aqueous solution, and structurally characterised by 2D NMR spectroscopy; they exhibit enhanced fluorescence and photostability, compared with the free dye.

Cyanine dyes are used as photographic sensitisers, laser dyes and biological fluorescence probes, and in optical data recording.[1,2] Their main limitation is low photochemical stability.[3] Here we report the first synthesis of a cyanine dye rotaxane, in which the chromophore is locked inside the cavity of a cyclodextrin.[4] Two diastereomers of the rotaxane have been isolated; one of these isomers exhibits substantially enhanced fluorescence quantum yield and photostability, in oxygen-saturated dioxane, relative to the unencapsulated dye.

Many dyes form inclusion complexes with cyclodextrins in aqueous solution, due to hydrophobic binding. These complexes often exhibit enhanced fluorescence[5] and photostability,[5g,6] but they can only be studied in water, in the presence of excess cyclodextrin, because they readily dissociate; the equilibrium constants are typically 10^2–10^3 M^{-1} in water, and much lower in other solvents. Rotaxane-encapsulated dyes[7] are similar to inclusion complexes except that they cannot dissociate, because the ends of the dye are too bulky to pass through the macrocycle, so they can be studied in a wide range of solvents.

Our strategy for preparing these rotaxanes is to synthesise a dumbbell-shaped dye in water, in the presence of a macrocycle; hydrophobic binding between the dye-precursors and the macrocycle results in rotaxane formation.[7] Cyanine dyes are not usually synthesised in aqueous solution, but we have found that reaction of 3-(9-julolidinyl)prop-2-en-1-al[8] **1** with *N*-(1-adamantyl)-4-methylpyridinium chloride[9] **2** and α-cyclodextrin in aqueous sodium hydroxide gives cyanine dye rotaxanes **3a** and **3b** as well as the free dye **4** (Scheme 1).† α-Cyclodextrin is cone-shaped; it has a narrow 6-rim (with primary OH groups) and a wide 2,3-rim (with secondary OH groups). So there are two possible orientations of the cyclodextrin unit, giving rise to the two stereoisomers **3a** and **3b**. The yield of **3a** and **3b** is low (6%, based on re-isolated aldehyde **1**), which is not surprising since the reaction involves dehydration in aqueous solution. ^{1}H NMR showed that this product was a 1:2 mixture of two stereoisomers **3a** and **3b**, which were separated by reverse phase chromatography. There is only one previous report of the separation of rotaxane stereoisomers of this type.[10]

The two pure cyanine dye rotaxanes **3a** and **3b** were both thoroughly authenticated by ^{1}H and ^{13}C NMR spectroscopy, and mass spectrometry, and their ^{1}H NMR spectra were fully assigned using 2D techniques. The vicinal ^{1}H–^{1}H coupling constants across each alkene unit in **3a** and **3b** (H_E–H_F and H_G–H_H) are in the range 15.1–15.4 Hz, proving that both isomers have the *trans–trans* geometry. NOESY experiments confirmed that the isomers have different orientations of the cyclodextrin unit. In rotaxane **3a**, NOEs were observed from H3 of the cyclodextrin (the wide rim) to both the aromatic and benzylic julolidine signals (H_C and H_D), and from H5 (near the narrow rim) to H_I at the other end of the dye. The opposite pattern of NOEs was observed in **3b**: from H3 to H_I and H_J; from H5 to H_D and from H6 to H_C. These NOE measurements not only elucidate the isomerism in **3a** and **3b**, but also show that the cyclodextrin is sitting round the reactive polymethine region in both rotaxanes. In both cases the NOEs are not consistent with a single static position of the cyclodextrin, showing that each isomer is dynamic in solution.

Encapsulation results in a bathochromic shift in the electronic absorption and emission spectra of both rotaxanes (for **3a**, **3b** and **4** in water λ_{max}(abs.) = 525, 535 and 477 nm; λ_{max}(em.) = 710, 718 and 678 nm respectively). The relative fluorescence quantum yields[11] of these three compounds in water, and a range of other solvents, are listed in Table 1. In water, the fluorescence quantum yields of both of the rotaxanes are lower than that of the free dye,[12] whereas in other solvents, especially dioxane, rotaxane **3b** is spectacularly more fluorescent. The fluorescence behaviour of the two isomers **3a** and **3b** are surprisingly different, with **3a** behaving more like the free dye **4**.

The higher fluorescence efficiency of **3b** in dioxane is not consistent with several common explanations for enhanced

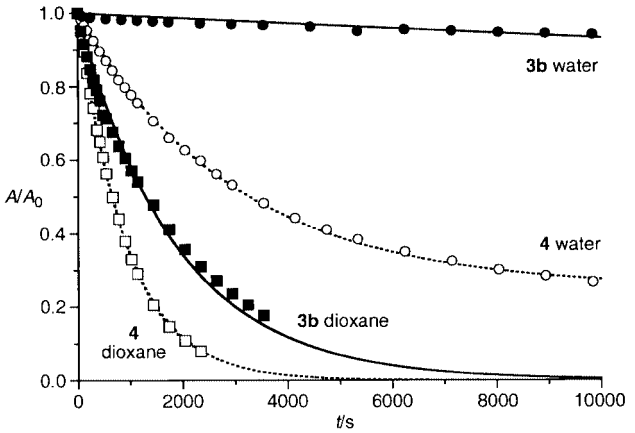

Fig. 1 Photo-bleaching curves for rotaxane **3b** in water, free dye **4** in water, **3b** in dioxane and **4** in dioxane, fitted to first-order decay curves with rate constants of 7.1×10^{-6}, 3.3×10^{-4}, 5.4×10^{-4} and 1.1×10^{-3} s^{-1}, respectively. Photolyses were carried out in 10 mm quartz cuvettes and O_2-saturated solvents with light from a tungsten filament bulb, using a 35 mm slide projector; A is the absorbance at time t and A_0 is the initial absorbance.

fluorescence in aqueous cyclodextrin–dye inclusion complexes, such as the exclusion of water from the dye surface and the changes in polarity around the dye when it enters the cyclodextrin.[5b,e,f] Here the fluorescence is enhanced in a range of non-aqueous solvents, and especially in dioxane which has a similar polarity to the cyclodextrin cavity. Cyclodextrin-encapsulation has been viewed as a way of reducing the quenching effect of an aqueous environment, whereas here encapsulation dramatically increases the fluorescence efficiency in a solvent in which the dye is already highly fluorescent. The enhanced fluorescence of **3a** and **3b**, compared to **4**, in dioxane is probably due to the reduced flexibility of the encapsulated chromophore.[5i] The possibility that this fluorescence enhancement is due to reduced aggregation[5c,d,i] can be discounted since **4** shows no sign of aggregation under these conditions.

The photostability of rotaxane **3b** was compared with that of the free dye **4**, in both water and dioxane, by monitoring the decrease in absorbance during irradiation of oxygen-saturated solutions with visible white light.[3c,6] Pseudo first order photo-bleaching curves were obtained in all cases, as shown in Fig. 1 (see caption for rate constants). The rotaxane **3b** exhibits higher photostability in both solvents (40-fold in water and 2-fold in dioxane, compared to the free dye **4**), and both compounds fade much faster in dioxane than in water. The mechanism of photo-bleaching has not yet been elucidated, but whatever process is involved, the faster bleaching in dioxane is probably related to the stronger fluorescence in this solvent, since a lower rate of quenching allows excited states to undergo more photo-chemistry. Matsuzawa *et al.*[6a] have shown that inclusion of cyanine dyes in β-cyclodextrin can enhance the photostability both by reducing the rate of singlet oxygen formation and by reducing the rate of reaction between singlet oxygen and the dye; both these factors may be involved here. It is remarkable that, in dioxane, **3b** exhibits a 5-fold fluorescence enhancement simultaneously with a 2-fold photostability enhancement.

The discovery that cyclodextrin encapsulation can increase the fluorescence and photostability of dyes under solvent conditions which already favour fluorescence indicates that this may be a valuable way of improving the stability and brightness of luminescent and electro-luminescent materials.

We are grateful to Dr T. D. W. Claridge for valuable assistance with NOE spectroscopy, and to Dr P. Gaffney for advice on reverse phase chromatography. This work was supported by the EPSRC.

Notes and references

† *Experimental:* 3-(9-Julolidinyl)prop-2-en-1-al **1** (1.0 mmol, 0.22 g), *N*-(1-adamantyl)-4-methylpyridinium chloride **2** (1.0 mmol, 0.26 g), α-cyclodextrin (4 mmol, 3.9 g) and aqueous NaOH (0.1 M, 20 ml) were stirred under N_2 at 95 °C for 24 h. The mixture was extracted with CH_2Cl_2, from which unreacted **1** (0.15 g, 67%) was recovered, together with **4** (14 mg, 2.9%). The aqueous phase was chromatographed (Sephadex CM25, eluting with NH_4HCO_3 aq) and lyophilized to yield 29 mg (6% based on re-isolated **1**) of a mixture of **3a** and **3b**. These isomers were separated by reverse-phase C18 silica chromatography, eluting with Pr^iOH–H_2O–0.01 M NH_4HCO_3 1:3:1, to give, in order of elution, rotaxanes **3a** and **3b**. Each fraction was anion-exchanged to the chloride and dried to give a purple powder.

Solutions 0.2–0.4 mol dm^{-1} in Ge^{II} and 6 mol dm^{-1} in HCl, generated by reaction of Ge^{IV} with H_3PO_2, are stable for more than three weeks and can be diluted 200-fold with dilute HCl to give $GeCl_4^{2-}$ preparations that may be handled by conventional techniques; kinetic profiles for the reduction of Fe^{III} by Ge^{II}, as catalyzed by Cu^{II} in this medium, implicate, for the first time, the odd-electron intermediate Ge^{III}, which is formed from Cu^{II} and Ge^{II} (k = 30 M^{-1} s^{-1} in 0.50 M HCl) and is consumed by reaction with Fe^{III} (k = 6 × 10^2 M^{-1} s^{-1}).

Only a few accounts decribing the preparation and reactions of germanium(II) species in aqueous solution are at hand,[1–4] and no systematic redox studies of this unusual donor have yet appeared. This oxidation state ($E^o_{IV,II}$ = −0.22 V at pH 0) is described as unstable in aqueous media in the absence of halide.[5]

We here report the prepartion of aqueous germanium(II) solutions which may be handled using conventional techniques. These have been used to compare the rates at which Ge(II) reacts with several oxidants in chloride media.

In a modification of the procedure of Jolly and Latimer,[1] all operations were carried out under high purity (99.99%) argon. 1.0 g of GeO_2 was dissolved in 5 ml of conc. NaOH, then reprecipitated and redissolved by adding 20 ml of 6 M HCl. The resulting Ge^{IV} solution was reduced with 7.5 ml of 50% H_3PO_2 at 100 °C for 5–6 h [eqn. (1)].

$$Ge^{IV} + H_2O + H_3PO_2 \rightarrow H_3PO_3 + Ge^{II} + 2H^+ \quad (1)$$

Germanium(II) hydroxide was precipitated from the cooled solution by addition of conc. NH_3, washed twice with 1 M HCl, then dissolved in 6 M HCl. Alternatively, crystalline $GeCl_2$ may separate slowly from the reduced solution and can be dissolved directly in 6 M HCl. Solutions 0.2–0.4 M in Ge(II) in 6 M HCl were unchanged after several weeks, but diluted solutions ([Ge^{II}] = 10^{-3} M, [Cl^-] = 0.08 M, [H^+] = 0.3 M) decomposed slowly ($t_{½}$ = 60 min). Germanium(II) hydroxide is not appreciably soluble in 4 M $HClO_4$. In analogy with the behavior of Sn(II),[6] Ge(II) may be taken to exist predominantly as $GeCl_4^{2-}$ at Cl^- concentrations > 0.3 M.

† Present address: Department of Chemistry, BITS, Pilani, Rajasthan 333031, India.

Solutions of Ge(II) rapidly reduce I_3^-, $IrCl_6^{2-}$, and the quinoxalinium cation, QH^+,[7] first to its radical, $QH^\bullet$, and thence to its dihydro derivative, QH_2:

$$Ge^{II} + I_3^- \rightarrow Ge^{IV} + 3I^- \quad k_{24\,°C}\ M^{-1}\ s^{-1} > 5 \times 10^6\ (0.5\ M\ Cl^-) \quad (2)$$

$$Ge^{II} + 2IrCl_6^{2-} \rightarrow Ge^{IV} + 2IrCl_6^{3-} \quad 2 \times 10^4\ (0.2\ M\ Cl^-) \quad (3)$$

$$Ge^{II} + 2QH^+ \rightarrow Ge^{IV} + 2QH^\bullet \quad 1.3 \times 10^2\ (1.0\ M\ Cl^-) \quad (4)$$

$$Ge^{II} + 2QH^\bullet \xrightarrow{2H^+} Ge^{IV} + 2QH_2 \quad 3 \times 10\ (1.0\ M\ Cl^-) \quad (5)$$

The very slow reduction of Fe(III) by Ge(II) is catalyzed markedly by Cu(II), even at the 10^{-7} M level. With [Cl^-] < 0.2 M, rates are proportional to [Ge^{II}] and [Cu^{II}] but are *independent* of [Fe^{III}], pointing to a slow formation of one or more active intermediates, the faster reactions of which are kinetically silent. At higher [Cl^-] and [Ge^{II}], the linear profiles become curved, most perceptibly near the end of the conversions, indicating that the initial catalytic act and the loss of Fe^{III} proceed at more nearly equal rates. Such patterns strongly support the sequence (6)–(8)

$$Ge^{II} + Cu^{II} \rightarrow Ge^{III} + Cu^{I} \quad k_6 \quad (6)$$

$$Fe^{III} + Ge^{III} \rightarrow Ge^{IV} + Fe^{II} \quad k_7 \quad (7)$$

$$Fe^{III} + Cu^{I} \rightarrow Fe^{II} + Cu^{II} \quad k_8 \quad (8)$$

Expression of this sequence as a trio of differential equations, and numerical integration using the program KINSIM[8] led, after slight adjustment for the slow unimolecular loss of Ge^{II} (k = 2 × 10^{-4} s^{-1}) to bimolecular rate constants k_6 and k_7 listed in Table 1. Values for k_8 (the Cu^I–Fe^{III} reaction) have been shown by Orth and Liddell[9] to vary with both [H^+] and [Cl^-] and have been taken from the report of these workers. A curved calculated in this manner is compared to a representative profile in Fig. 1. The constants k_6 and k_7, pertaining to the formation and oxidation of Ge^{III}, appear to be the first reported kinetic parameters associated with this odd-electron state. Within the ranges examined, the rate of formation of Ge^{III}, but not its oxidation, is proportional to [Cl^-]; neither rate is acid-dependent.

At [Cl^-] = 0.8–1.0 M and [Ge^{II}] > 3 × 10^{-3} M, decay curves become exponential, and the unimolecular loss of Ge^{II} is negligible. Combinations of parameters k_7, k_6 and k_8 (the latter two adjusted for [Cl^-]-dependence)[9] fit the observed curves

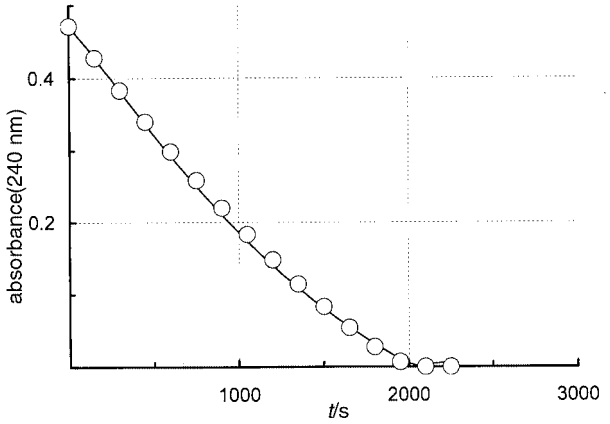

Fig. 1 Kinetic profile at 240 nm for the reduction of Fe(III) (1.0×10^{-4} M) by Ge(II) (6.6×10^{-4} M), as catalyzed by Cu(II) (5×10^{-6} M) in 0.20 M Cl^- at 24 °C; $[H^+]$ = 1.0 M. The solid line represents the experimental curve whereas the circles denote absorbances calculated from numerical integration of differential equations based on reaction sequence (6)–(8), taking k_6 as 9.8 M^{-1} s^{-1}, k_7 as 6×10^2 M^{-1} s^{-1}, and k_8 = 1.25×10^5 M^{-1} s^{-1} (ref. 9). The extinction coefficient used for Fe(III) is 4.7×10^3 M^{-1} cm^{-1}, and other species were considered to be negligibly absorbent. Optical path length = 1.00 cm.

only if an additional term (0.66 M^{-1} s^{-1}), pertaining to the uncatalyzed Ge^{II}–Fe^{III} reaction, is included in the treatment. This non-complementary redox change very probably passes through Ge^{III} as well. As expected, the initial step is much slower than the Fe(III)–Ge(III) reaction ($k_7 = 6 \times 10^2$ M^{-1} s^{-1}). In analogy to the In(I,III) system,[10] the odd-electron s^1 intermediate should be much more strongly reducing than the parent s^2 cation.

We are grateful to the National Science Foundation for the support of this work; to Dr Shawn Swavey and Dr Ksenija Namjesnik-Dejanovic for help in experimental procedures, and to Mrs Arla McPherson for technical assistance.

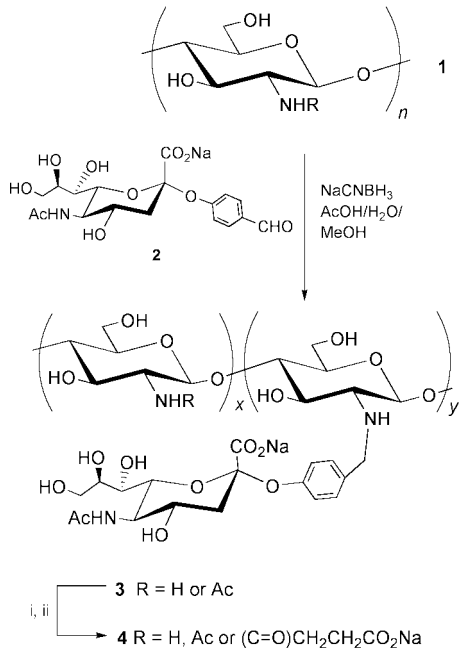
Water soluble hybrids of chitosan and sialic acid were prepared in good yields *via* reductive *N*-alkylation of *p*-formylphenyl α-sialoside 2 onto chitosan amine functionalities.

Chitosan **1** is a polysaccharide mainly composed of the β(1-4)-2-amino-2-deoxy-D-glucopyranose (D-glucosamine) repeating unit and includes a small amount (< 20%) of *N*-acetyl-D-glucosamine (GlcNAc) residues. At present, several interesting biological properties have been reported for chitosan alone, such as wound healing,[1] immunological activity,[2] and antibacterial effects.[3] Moreover, chitosan itself is non-toxic. Therefore, chitosan is an appealing bioactive polymer for further development. Additionally, sialic acid-containing polymers[4] have been shown to be potent inhibitors of hemagglutinination of human erythrocytes by *influenza* viruses.[4–6] *N*-Acetylneuraminic acid (Neu5Ac) is the most ubiquitous member of the sialic acid family of derivatives present on mammalian cell surface glycolipids and glycoproteins and is the key epitope recognized as being essential for a number of pathogenic infections.[7] We are now investigating the preparation and biological properties of sialic acid-bound chitosan (chitosan–sialic acid hybrid) as a new family of sialic acid-containing polymers. A noteworthy point is the effect of chitosan as a backbone polymer for investigating the biological properties of sialic acid, especially against infection by the *influenza* virus and for its immunological activity. We report herein the first preparation and chemical aspects of chitosan–sialic acid hybrids.

Reductive *N*-alkylation[8,9] of chitosan with aldehydes is a very convenient method for its chemical modification. Therefore, we attempted the direct reductive *N*-alkylation of chitosan with *p*-formylphenyl α-sialoside **2**.[10] Scheme 1 shows the preparation of the chitosan–sialic acid hybrid **3**† by reductive *N*-alkylation using sodium cyanoborohydride ($NaCNBH_3$). The degree of substitution (DS) of Neu5Ac can be controlled by increasing the amount of aldehyde **2** in the reaction mixture (Table 1). The reactivity level of **2** to chitosan was found to vary in the range 25–48%, which was caused by the simultaneous reduction of some of the aldehyde groups of **2** under the acidic reaction conditions. Water soluble material was obtained only at high DS (DS = 0.53) due to the high level of charged carboxyl groups.

Hybrids **3** of low DS were insoluble in neutral water and thus would not be useful for biological evaluation. To improve the solubility, the remaining amino groups of the hybrids were transformed by succinylation with succinic anhydride (AcOH, H_2O, MeOH, room. temp., 1 day, neutralized with aq. NaOH then dialyzed and lyophilized) to give hybrids **4** in 90–100% yields. Under these mild aqueous conditions and basic workup, no lactones or cyclic imides were formed.[9] The chemical structures of the succinylated hybrids **4** are summarized in Table 2. Despite using a large excess of succinic anhydride, some unreactive amino groups (DS = 0.07–0.17) still remained. Complete succinylation was difficult owing to increasing steric hindrance of the polymer. High field ^1H NMR spectra also indicated that no succinylation had occurred at the *N*-glycosylation sites (δ H-1 of GclN-Neu5Ac). All succinylated products **4** were soluble in water. The protein binding properties of the novel sialylated polysaccharides were initially evaluated with wheat germ agglutinin (WGA: *Triticum vulgaris*) which is a plant lectin specific toward GlcNAc and Neu5Ac residues. Strong immunodiffusion bands were observed for water soluble hybrids **3** and **4** when compared to a negative control (*N*-succinylated chitosan), thus demonstrating the specificity of the binding of the Neu5Ac epitope in the hybrid to WGA lectin. The



Scheme 1 *Reagents and conditions*: (i) succinic anhydride (0.2 g, 2 mmol), AcOH (50 mg, 0.83 mmol), H_2O (8 mL), MeOH (32 mL); (ii) 1% aq. NaOH (20 mL), room temp., 2 h.

—[b]	0	0.50	0.46	0.04	30000	±

[a] ++, strong band; ±, very faint band. [b] *N*-succinylated chitosan.

very faint band shown in *N*-succinylated chitosan could be due to the small amount of GlcNAc residues already present in the initial polymer chain (DS = 96% GlcN; 4% GlcNAc).

In conclusion, water soluble and lectin binding chitosan–sialic acid hybrids have been successfully prepared. Further biological evaluation of these promising compounds will be investigated.

We are indebted to Nippon Gaishi Co., Japan for generously supplying sialic acid.

Notes and references

† *Materials and methods:* chitosan **1** [DS = 96% GlcN, 4% GlcNAc, DP = 140; molecular weight (MW) 23061] was used in this study. The degree of polymerization (DP) of the initial chitosan **1** was determined by GPC using pullulan as standard. The DS of the hybrids was determined by ^{1}H NMR spectroscopy (Bruker 500 MHz AMX). The remaining unmodified primary amino groups of the hybrids were quantitated by colorimetric determination using ninhydrin at 570 nm.

Typical procedure for the preparation of hybrid **3**: Chitosan (50 mg, 0.24 mmol NH_2) was dissolved in H_2O (8 mL) and MeOH (32 mL) containing AcOH (50 mg, 0.83 mmol). Various amounts of **2** (Table 1) were added to the solution which was stirred at room temperature. After 1 h, $NaCNBH_3$ (100 mg, 1.6 mmol) was added and after 1 day, the reaction mixture was quenched by precipitation with 5% aq. NaOH (2 mL, 2.5 mmol) and acetone (80 mL). The precipitate was collected by filtration, dispersed with H_2O containing NaOH (100 mg), dialyzed and lyophilized.

Selected data for **3** (DS = 0.53)**:** ^{1}H NMR (0.2 M DCl in D_2O) δ 1.88 (t, 0.53 H, $J_{3ax–4eq}$ 12.1 Hz, H-3_{ax} of NeuNAc), 2.06 (m, 1.71 H, NHAc of Neu5Ac and GlcNAc in chitosan), 2.32 (dd, 0.53 H, $J_{3eq–4eq}$ = 5.0 Hz, H-3_{eq} of Neu5Ac), 3.20 (br, 0.96 H, H-2 of GlcN and *N*-alkylated GlcN), 3.55–4.10 (m, H-4,5,6,7,8,9 of Neu5Ac, H-2 of GlcNAc, H-3,4,5,6 of GlcN and GlcNAc), 6.97 (d, 1.06 H, J = 7.44 Hz, H-3 and H-5 of –OPh), 7.27 (d, 1.06 H, *J* 7.44 Hz, H-2 and H-6 of –OPh); ^{13}C NMR δ 25.0 (NAc), 41.7 (C-3 of Neu5Ac), 53.3 (CH_2Ph), 55.0 (C-5 of Neu5Ac), 58.8 (C-2 of GlcN), 63.0 (C-6 of GlcN), 66.1 (C-9 of Neu5Ac), 69.5 (C-4 of Neu5Ac), 71.2 (C-7 of Neu5Ac), 73.2 (C-8 of Neu5Ac), 73.4 (C-6 of Neu5Ac), 77.7 (C-3 and C-5 of GlcN), 79.4 (C-4 of GlcN), 98.1 (C-2 of Neu5Ac), 100.4 (C-1 of GlcN), 119.0 (C-2 and C-6 of Ph), 125.0 (C-4 of Ph), 135.0 (C-3 and C-5 of Ph), 159.8 (C-1 of Ph), 175.9 (NHCO), 177.9 (CO_2H of Neu5Ac).

Succinylation of hybrid was performed as described previously.[9]

Agar gel diffusion experiments were performed in 1% agarose (BDH) containing 2% poly(ethylene glycol) (MW = 8000, Sigma) in phosphate-buffered saline (PBS) according to the method of Ouchterlony and Nilsson.[11] The concentration of conjugate **3** was 1 mg mL^{-1} in PBS, and that of WGA lectin was 2 mg mL^{-1}. The precipitation bands were allowed to form overnight at 4 °C in a humid chamber.

The structure of the decamethylborocenium cation: the most tightly-squeezed metallocene?

Andreas Voigt, Silvia Filipponi, Charles L. B. Macdonald, John D. Gorden and Alan H. Cowley*

X-Ray crystallographic analysis along with DFT calculations on the decamethylborocenium cation provide definitive structural and electronic information about this most tightly-squeezed main group metallocene—the first to adopt the elusive σ/π geometry in the solid state.

The unusual structure of beryllocene, $Be(Cp)_2$ **1**, has attracted the attention of chemists for several years.[1] In both the solid and vapour states **1** adopts a 'slip-sandwich' structure in which the parallel Cp rings are attached to beryllium in an $\eta^1(\pi)/\eta^5$ fashion.[2] In solution **1** is fluxional owing to rapid changes in ring hapticities.[3] The observed structure contrasts with the $\eta^1(\sigma)/\eta^5$ structure predicted on the basis of numerous theoretical calculations.[3,4]

The borocenium cation $[B(Cp)_2]^+$, which is isoelectronic with **1**, is not known and unlikely to be stable at ambient temperature. Although the decamethylborocenium cation $[B(Cp^*)_2]^+$ **2** has been characterized by ^1H and ^{11}B NMR spectroscopy,[5] such data cannot be used to distinguish between $\eta^1(\pi)/\eta^5$ and $\eta^1(\sigma)/\eta^5$ structures. It was therefore necessary to perform an X-ray analysis of a suitable salt of **2**.

It was found that a variety of salts of **2** can be generated by treatment of $(Cp^*)_2BCl$[5] with *e.g.* $LiB(C_6F_5)_4$, $Ga(C_6F_5)_3$, $GaCl_3$ or $AlCl_3$. However, from the standpoint of single crystal growth, the best reaction was that between equimolar quantities of $(Cp^*)_2BCl$ and $AlCl_3$ in CH_2Cl_2–C_6D_6 solution which afforded an 86% yield of **2**$[AlCl_4]$ [mp *ca.* 60 °C (decomp.)].[6] The solid state structure of **2**$[AlCl_4]$ consists of an array of two independent cations and anions.† There are no unusually short interionic contacts and the metrical parameters for the independent cations are very similar and hence only one set of data is discussed here. The decamethylborocenium cation **2** (Fig. 1) features one η^5-bonded and one $\eta^1(\sigma)$-bonded Cp* substituent, both of which feature, within experimental error, planar C_5 rings. Such an arrangement for a main group metallocene has been predicted (*vide supra*) but never observed experimentally in the solid state. The boron–carbon distance for the η^1-bonded Cp* ring, B(1)–C(1) [1.582(6) Å] is considerably longer than the boron–η^5-Cp* ring centroid distance [1.269(5) Å] and the C(1)–B(1)–Cp* ring centroid arrangement is nearly lienar [177.9(5)°]. In contrast to beryllocene, which has an η^1/η^5 parallel-ring structure in the solid state,[7] the Cp* rings of **2** are non-parallel as indicated, for example, by the 114.4(5)° tilt angle between the B(1)–C(1) bond and the least squares plane of the η^1-Cp* ring. A further differentiating feature is that the η^1-attached ring of **2** exhibits a typical localized structure with average C_α–C_β and C_β–C_β bond distances of 1.339(5) and 1.476(6) Å, respectively.

The structure of **2** also contrasts with that of the isovalent decamethylaluminocenium cation, which adopts a staggered bis(η^5-Cp*) ferrocene-like geometry.[8] To provide insight into the reason(s) for this structural difference, DFT calculations were performed on $[B(Cp^*)_2]^+$, $[B(Cp)_2]^+$ and $[Al(Cp)_2]^+$. Geometry optimization of **2** at the BP86/A level of theory[9] provides excellent agreement with the experimental structure. Thus, the global minimum is the observed η^1/η^5 structure with B(1)–C(1) and B(1)–η^5-Cp* ring centroid distances of 1.593 and 1.291 Å, respectively, a C(1)–B(1)–Cp* ring centroid angle of 179°, and an η^1-Cp* ring tilt angle of 123°. Moreover, calculation of the ^{11}B chemical shift for this structure using the GIAO method[10] (δ −43.1) is in excellent agreement with the experimental value (δ −41.5).[5,6] The staggered bis-η^5 (D_{5d}) structure of **2** is computed to be 48.95 kcal mol^{-1} higher in energy than the η^5/η^1 structure, thus confirming that the observed geometry is not caused by crystal packing forces. Examination of space-filling models reveals the existence of pronounced steric congestion in $[(\eta^5\text{-}Cp^*)_2B]^+$ which is relieved somewhat in proceeding to the η^1/η^5 structure. However, traditional steric effects are not responsible for the observed geometry of **2** since DFT calculations on the unsubstituted borocenium cation, $[(Cp)_2B]^+$ reveal that the ground state geometry is also η^1/η^5 and remarkably similar to that of **2**. More importantly, the difference in energy between the η^1/η^5 and bis-η^5 structures is essentially the same for both the Cp*- and Cp-substituted cations (45.39 kcal mol^{-1} for the latter). Surprisingly, the D_{5d} $[(Cp)_2B]^+$ structure is not even a true minimum (N_{imag} = 4) on the potential energy surface (PES). Conversely, no η^1/η^5 minimum is found for $[(Cp)_2Al]^+$; geometry optimization on the C_s symmetry PES proceeds smoothly to the D_{5h} bis-η^5 structure instead. The difference in bonding modes is attributable to the higher electronegativity of boron and greater strength (and lower ionicity) of B–C *vs.* Al–C bonding. The smaller size and greater effective nuclear charge of boron is also important, expecially in comparison to Cp_2Be,

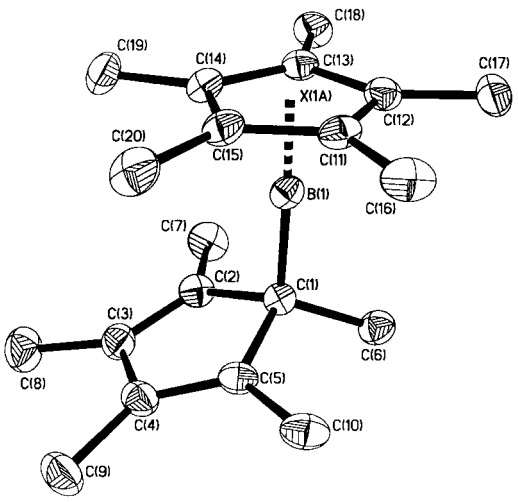

Fig. 1 ORTEP drawing of $[B(\eta^5\text{-}C_5Me_5)(\eta^1\text{-}C_5Me_5)]^+$ **2**. There are two independent cations: the bond distances (Å) and bond angles (°) for the second cation are shown in square brackets: B(1)–C(1) 1.583(5) [1.586(5)], B(1)–X(1A) (ring centroid) 1.290(5) [1.282(5)], B(1)–C(11) 1.782(6) [1.770(5)], B(1)–C(12) 1.775(5) [1.769(5)], B(1)–C(13) 1.782(5) [1.753(5)], B(1)–C(14) 1.757(5) [1.774(5)], B(1)–C(15) 1.757(5) [1.756(5)], C(1)–C(2) 1.515(5) [1.520(5)], C(2)–C(3) 1.343(5) [1.348(6)], C(3)–C(4) 1.473(6) [1.465(6)], C(4)–C(5) 1.340(5) [1.339(6)], C(1)–C(5) 1.523(5) [1.521(5)], C(1)–B(1)–X(1A) 177.9(5) [177.2(5)], B(1)–C(1)-least-squares-plane of (η^1-Cp*) 114.4(5) [112.4(5)], B(1)–C(1)–C(6) 112.4(3) [112.9(3)].

DOI: 10.1039/b001271h

because the putative D_{5d} structure is rendered much less stable owing to the increased repulsion between the π-clouds on the Cp ligands. Adoption of the $\eta^1(\pi)/\eta^5$ 'slipped-sandwich' structure by Cp_2Be relieves this strain sufficiently, but the closer ligand proximity in $[(Cp)_2B]^+$ mandates the non-parallel, π-localized $\eta^1(\sigma)/\eta^5$ alternative. In effect, the change from Be to B^+ results in a much steeper PES which more clearly favours the $\eta^1(\sigma)/\eta^5$ structure.

In conclusion, we have elucidated the structure of, and bonding in, the first authentic example of an $\eta^1(\sigma)/\eta^5$ metallocene. Because of the small size, combined with the high effective nuclear charge of the cationic boron(III) centre, we do not anticipate the isolation of a more tightly squeezed metallocene. Investigations of the reactivity of salts of **2** are currently underway.

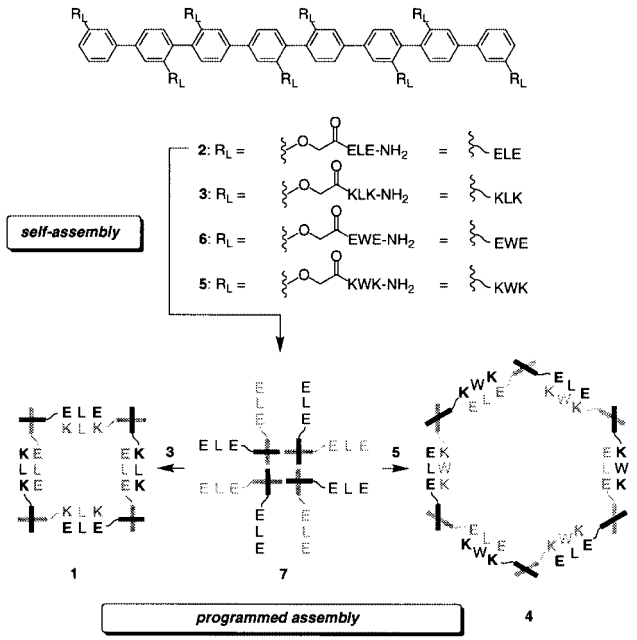
Received (in Cambridge, UK) 15th March 2000, Accepted 26th April 2000

A simple strategy for (a) expansion and (b) variation of the internal chemical nature of rigid-rod β-barrels is reported, and the importance of supramolecular preorganization for their programmed assembly is discussed.

In nature, barrel-like folds[1] serve to recognize antigens[2] and secondary metabolites,[3,4] to mediate transport across biomembranes,[5] to catalyze enolate chemistry,[2,6] and to let jellyfish fluoresce.[7] In view of this functional diversity in nature, it is surprising to note that the design of artificial barrels has attracted little scientific attention. According to Fujita and coworkers, the assembly of nanotubes[8–11] with precisely defined length but flexible diameter in isotropic media, *i.e.* 'nanobarrels', was achieved last year for the first time.[12,13]† More recently, we have used the unique properties of rigid-rod molecules to create tetrameric barrel **1** in detergent-free water by programmed assembly of the complementary tripeptide-rods **2** and **3** (Scheme 1).[14] Rigid-rod β-barrel **1** is characterized by a length of 3.4 nm and an internal diameter of *ca.* 0.8 nm.[14] Constructive electrostatic interactions between lysine and glutamate residues account for the hydrophilicity of the barrel surface, while leucine residues produce a hydrophobic interior that can accommodate planarized β-carotene.[14] Several design strategies for further expansion of rigid-rod β-barrels are conceivable.[15] Here we report programmed assembly of the hexameric rigid-rod β-barrel **4** in detergent-free water. In this case, barrel expansion was accomplished by partial replacement of the internal leucine residues in tetramer **1** by the more bulky tryptophan residues in hexamer **4** (Fig. 1). We further provide experimental support that supramolecular preorganization may play an important general role in the programmed assembly of rigid-rod β-barrels in water (Scheme 1).



Scheme 1 Programmed assembly of rigid-rod β-barrels **1** and **4** by supramolecular preorganization with pinwheel **7** in water, pH 6.4. One-letter abbreviations for amino acids are used (E: glutamate, K: lysine, W: tryptophan, L: leucine). All supramolecules are displayed schematically in axial view with the benzene rings as bold lines. The first 'layer' of arene-tripeptides is in black, the second in grey, and the following six not shown for clarity. Amino acids with residues located at the outer barrel surface are in bold, those at the inner surface not.

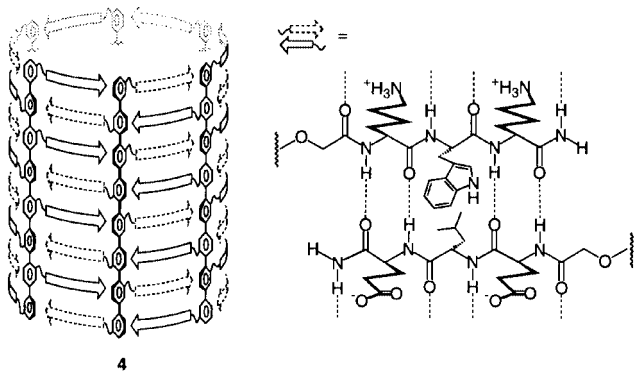


Fig. 1 Structure of hexameric rigid-rod β-barrel **4**. Amino acid residues located at the outer barrel surface are in bold, those at the inner surface not.

For programmed assembly of expanded rigid-rod β-barrels, we synthesized and characterized the complementary KWK-rod **5** and EWE-rod **6** following the experimental procedure for ELE-rod **2** and KLK-rod **3** that has been published in detail.[14] Size exclusion chromatogram (SEC) and circular dichroism (CD) spectrum of KWK-rod **5** in detergent-free water, pH 6.4, supported the previous observation with KLK-rod **3**[14] that cationic tripeptide-rods are monomeric under these conditions (Fig. 2, dashed line). Increasing amounts of ELE rod **2** converted the CD spectrum of KWK-rod **5** into that typical for rigid-rod β-barrels,[13–15] *i.e.* **4** (Fig. 2, continuous line). Namely, low energy negative (341 nm, $\Delta\varepsilon$ −5.8) and positive (294 nm, $\Delta\varepsilon$ +2.0) CD Cotton effects (CEs) centered around the octa(*p*-phenylene) ^{1}L transitions (319 nm, ε 28.6 mM^{-1} cm^{-1}) are followed by weaker negative and 'positive' CD CEs (253 nm, $\Delta\varepsilon$ −4.0; 242 nm, $\Delta\varepsilon$ −0.5) and two strong high energy CD CEs (232 nm, $\Delta\varepsilon$ −12.5; 216 nm, $\Delta\varepsilon$ +8.8; not shown). The circular dichroic absorption at 341 nm increased with decreasing mole fraction x = [**5**]/([**5**] + [**2**]) until a maximal $\Delta\varepsilon$ of −5.8 was reached at x = 0.5 [Fig. 2, inset (a)]. This corroborated the expected 1 : 1 stoichiometry of rigid-rod β-barrel **4**. An identical CD spectrum at x = 0.5 was obtained by addition of KWK-rod **5** to ELE-rod **2** [Fig. 2, inset (b)]. The nonlinear mixing curve suggested that β-barrel formation is inhibited at $x < 0.33$ [Fig. 2, inset (b)]. Addition of ELE-rods **2** to preformed barrel **4** (x = 0.5) did not, however, cause barrel deconstruction at $x < 0.33$ [Fig. 2, inset (c)].

In water, ELE-rods **2** self-assemble into the tetrameric pinwheel **7** (Scheme 1).[16] These supramolecules are composed

DOI: 10.1039/b002113j

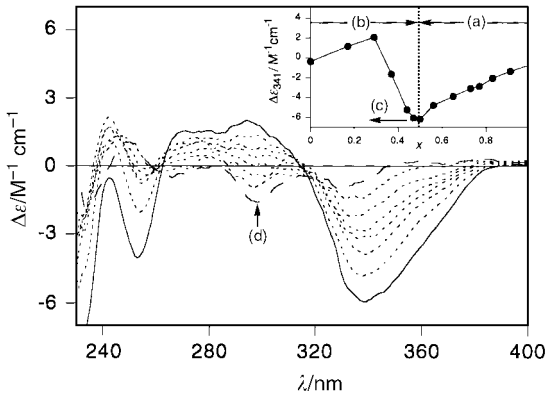

Fig. 2 Circular dichroism spectra of KWK-rod **5** (----) in the presence of increasing (····) and equimolar amounts of ELE-rod **2** (—). Inset: mixing curve for β-barrel **4**; x = [**5**]/([**5**] + [**2**]). (a) Addition of ELE-rod **2** (= pinwheel **7**) to KWK-rod **5** (identical with the displayed curves). (b) Addition of KWK-rod **5** to ELE-rod **2** (= pinwheel **7**). (c) Addition of ELE-rod **2** (= pinwheel **7**) to KWK-rod **5** (= barrel **4**) did not significantly change the initial CD spectrum (—). (d) The Cotton effect at 298 nm ($\Delta\varepsilon$ −1.1) was not observed in other peptide-rods[13–15] and is expected to originate from the L_a transition of the indoles in KWK-rod **5**. All experiments were performed in phosphate buffer (10 mM) at pH 6.4 with oligo(*p*-phenylene) concentrations around 10 μM, using a JASCO-710 spectropolarimeter. $\Delta\varepsilon$ values refer to the respective total octa(*p*-phenylene) concentration.

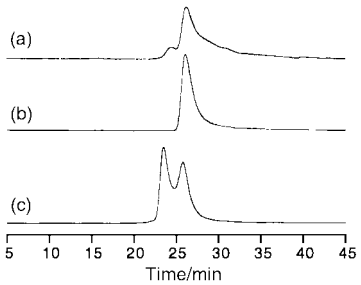

Fig. 3 Size exclusion chromatograms of (a) EWE-rod **6**, (b) ELE-rod **2** (= pinwheel **7**) and (c) β-barrel **4** (x = 1.0) with subsequently added ELE-rod **2** (= pinwheel **7**, final concentrations: [**2**]/[**5**] = 1.5/1.0). Chromatogram (b) displays new experiments that qualitatively reproduce previously reported data.[16] All experiments were performed in phosphate buffer (10 mM) at pH 6.4 with oligo(*p*-phenylene) concentrations around 10 μM, using a Superdex® 75 HR 10/30 prepacked column from Pharmacia Biotech (MW 70 000–3000, 1 mL buffer min^{-1}) coupled with a Jasco PU-980 pump and a Jasco UV-970 UV–VIS detector.

of a core of (presumably) edge-to-face π,π-stacked oligo(*p*-phenylene)s that is surrounded by anionic peptide strands in random-coil conformation.[16] The sharp peak of pinwheel **7** at R_t = 25.8 min [Fig. 3(b)] was used as a reliable internal standard for the determination of the molecular weight of barrels **4** by SEC [Fig. 3(c)]. Comparison of oligo(*p*-phenylene) and tryptophan absorption maxima at 319 nm and 282 nm,[17] respectively, confirmed that only the peak at R_t = 23.5 min [Fig. 3(c)] contained KWK-rod **5**. Rigid-rod β-barrel **4** is thus a hexamer under these conditions.

Programmed assembly of rigid-rod β-barrels using EWE-rod **6** instead of ELE-rod **2** was unsuccessful. Mixing of EWE-rod **6** with KWK-rod **5** resulted in immediate precipitation, and mixing with KLK-rod **3** did not result in clearly detectable supramolecular organization. The latter finding was of interest, because this non-forming barrel (composed of EWE-rods **6** and KLK-rods **3**) is the structural isomer of hexamer **4** (composed of ELE-rods **2** and KWK-rods **5**). This counter-intuitive result thus suggested that the (presumably) perpendicularly zigzagged preorientation of the lateral tripeptide strands of **2** in pinwheel **7** may significantly support the programmed assembly of rigid-rod β-barrels in water (Scheme 1). We further noted that the apparently reduced supramolecular preorganization in self-assembled EWE-rods **6** [Fig. 3(a) *cf.* ELE-rods **2** in Fig. 3(b)] and the capacity of pinwheel **7** to bind two KWK-rods **5** without significant suprastructural transformation [Fig. 2, inset (b), x = 0.33] are consistent with this view.

In summary, we have described the design and synthesis of expanded rigid-rod β-barrel **4** and obtained experimental support for the importance of supramolecular preorganization for programmed barrel assembly in detergent-free water. Compared to tetramer **1**,[14] hexamer **4** is of particular interest with regard to its enlarged hydrophobic interior (d > 2.0 nm in molecular models) and tryptophan residues at the inner barrel surface. We are currently interested in the influence of these 24 intratoroidal indoles in hexamer **4** on encapsulated chromophores of biological relevance.[3,4,7,18]

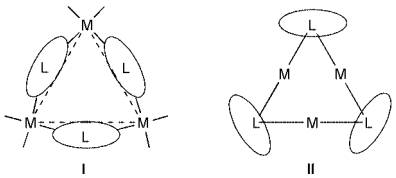
Received (in Basel, Switzerland) 4th February 2000, Accepted 20th April 2000

A strain free platinotriangle has been produced using 1,2-phenylene diisocyanide as the ligand determining 60° angles at the vertices, and *trans*-Pt(C_6F_5)$_2$ as the linear link building the sides.

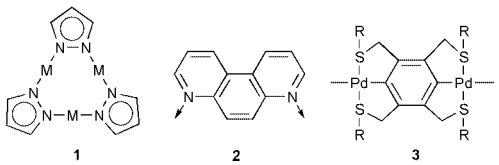
Compared to the number of metallosquares and metallorectangles reported, where the metal occupies either the vertices of the polygon (affording two *cis* coordination positions at 90°), the sides (affording two *trans* coordination positions at 180°), or both, reports on metallotriangles are surprisingly scarce.[1] Moreover, the majority of metallotriangles reported are of class **I**, with metal fragments offering two *cis* coordination positions



I II

at 90° occupying the vertices of a distorted equilateral triangle.[2] Curiously there are fewer of the apparently more favorable type **II** structure, where ligands imposing hexagonally based bonds at 60° should yield strain free triangles.

A well known family of triangles based on **II**, is that of [M(μ-pz)]$_3$ (pz = pyrazole or substituted pyrazole; M = Au, Ag) compounds **1**, even though the bonding angle determined by the

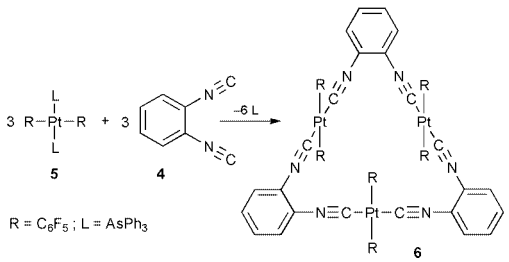


1 2 3

two pz nitrogens in a pentagonal ring is too open (*ca.* 72°).[3] Such triangles have been used to make hexagonal columnar liquid crystals.[4] Some years ago a number of complexes with iminoacyl, [M(CER$_n$=NR′)]$_3$ (M = Au, Ag; ER$_n$ = OR, NR$_2$),[5] or with 2-pyridyl, [Au(C_5H_4N)]$_3$,[6] as bridging groups were reported. These make triangles of the same small size as pyrazolate, and determine M···M distances of 3.3–3.5 Å. For trimeric mercury derivatives with *o*-phenylene, *o*-perfluorophenylene, or 1,2-$C_2B_{10}H_{10}$ at the corners these distances are 3.5–3.7 Å.[7] Only very recently a larger triangle has been reported, in which 4,7-phenanthroline **2** occupies the corners and the dipalladium fragment **3** makes the sides of the triangle.[8]

Isocyanides are known to bind strongly to many different transition metals. Diisocyanides have been used in the building of coordination polymers, and mixed donors 1,3- and 1,4-cyanoisocyanoarenes have afforded interesting mixed Pd–Cu polymers.[9] So far the only discrete metallapolygon reported involves 1,4-phenylene diisocyanide, making part of a very large tetragold rectangular ring.[10] On the other hand, Takahashi and coworkers have reported the metallosquare [Pd(PEt_3)$_2${μ-C_6H_4(C≡C)$_2$}]$_4$, with *o*-diethynylbenzene at the corners. Although the 60° angles determined by the two ethynyl groups are ideal for an equilateral triangle, steric repulsion of the PEt_3 ligands forces a strained square instead.[11]

1,2-Phenylene diisocyanide **4** is a neutral ligand geometrically equivalent to the dianionic *o*-diethynylbenzene used by Takahashi and coworkers.[12] We have tested its ability to make metallotriangles by reacting it with *trans*-[Pt(C_6F_5)$_2$($AsPh_3$)$_2$] **5**.[13] The pentafluorophenyl derivative **5** was chosen because it is quite inert towards isomerization, keeping its *trans* arrangement in substitution reactions. The reaction takes place very easily in CH_2Cl_2 at room temp., leading to the formation of [Pt(C_6F_5)$_2${μ-C_6H_4(NC)$_2$}]$_3$ **6** in high yield (Scheme 1).†



Scheme 1

The molecular structure of **6** is shown in Fig. 1.‡ There is a Pt atom at the center of each side of an equilateral triangle determined by the centers of the aryl rings of the diisocyanide ligands. The non-bonding Pt···Pt distances are *ca.* 5.65 Å. The coordination around the Pt atoms is square planar, with two *trans* isonitriles and two *trans* C_6F_5 groups. It is noteworthy that the metal atom is bonded only to C-donor ligands. The C_6F_5 groups are situated perpendicular to the planar triangle and their planes are more or less coplanar for each Pt(C_6F_5)$_2$ fragment. This can be better seen in Fig. 2, a space filling representation

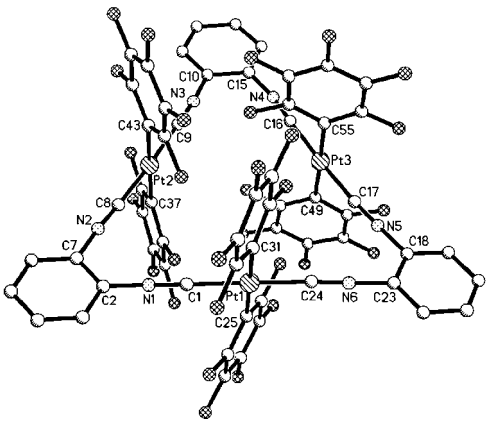


Fig. 1 Molecular structure of **6**. Phenylene hydrogens have been omitted for clarity. Selected distances (Å) and angles (°): Pt(1)–C(1) 1.918(10), Pt(1)–C(24) 1.925(10), Pt(1)–C(25) 2.057(9), Pt(1)–C(31) 2.076(10), C(1)–N(1) 1.170(11), C(2)–N(1) 1.402(11), C(2)–C(7) 1.380(12), C(1)–Pt(1)–C(24) 179.3(4), C(1)–Pt(1)–C(25) 90.9(4), C(1)–Pt(1)–C(31) 88.6(4), C(24)–Pt(1)–C(25) 89.4(4), C(24)–Pt(1)–C(31) 91.0(4), C(25)–Pt(1)–C(31) 178.6(4), Pt(1)–C(1)–N(1) 176.5(8), C(7)–C(2)–N(1) 121.6(8), C(1)–N(1)–C(2) 178.6(9).

DOI: 10.1039/b001027h

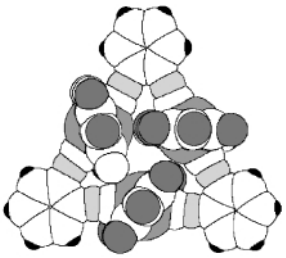

Fig. 2 Space filling structure of **6** viewed perpendicular to the plane of the triangle, showing the orientation of the C_6F_5 rings.

viewed perpendicular to the plane containing the triangle, where the C_6F_5 groups above and below this plane are eclipsing each other almost perfectly. The usual arrangement found for aryl ligands in square planar complexes has the aryl plane perpendicular to the metal coordination plane (torsion angle 90°).[14] In the triangle, this would cause them to clash in the center of the triangle. This is relieved by twisting the pentafluorophenyls about the Pt–C_6F_5 bond (we define twist as 0° for the perpendicular arrangement, thus torsion angle + twist angle = 90°). The average torsion angle around the Pt–C_{ipso} bonds is 54°. The maximum torsion is for C(24)–Pt(1)–C(31)–C_{ortho} = 63°, and the minimum is for C(9)–Pt(2)–C(37)–C_{ortho} = 46°. In addition there is some variation in the torsion angle along the Pt···C_{ipso} (phenylene) vectors. These angles give an idea of how orthogonal are the Pt–C_{ipso} (pentafluorophenyl) bonds to the 'plane' of the triangle. They vary between 103.0° [for C(31)–Pt(1)–C(23)–C(18)] and 77.4° for C(55)–Pt(3)–C(18)–C(23), and their average is close to 90°. van der Waals distances of the order 3.1–3.3 Å are found between the internal F_m or F_o of each ring and the closest carbons of another ring (C_m or C_p for F_m; C_o or C_{ipso} for F_o).[15]

In the C_{3h} symmetry found in the solid state structure, the F atoms inside and outside the triangle, as well as the four H atoms in each phenylene ring, should be diastereotopic (5 F signals and 4 H signals are expected). However only one signal is observed for each type of fluorine (F_o, F_m or F_p) in the ^{19}F NMR spectrum, and the hydrogens display an AA′XX′ pattern. This reveals fast rotation or tilting of the C_6F_5 groups.

A further structural feature worth commenting upon is the Pt–C_6F_5 distances: they range from 2.051 to 2.076 Å (average 2.061 Å), similar to other Pt–C_6F_5 distances and not particularly long. This suggests that the π back donation, which is sometimes invoked as a further source of stability for M–C_6F_5 compared to M–C_6H_5,[16] either is not very important in this case, or is not very much affected by the tilting.

The structural type found for **6** interesting for further elaboration. Both the diisocyanide and the R groups on the Pt can be easily modified to introduce other characteristics. For instance, *p*-substituted fluorinated rings have been used to produce metallomesogens.[17] We are currently pursuing these ideas.

Electrochemical reduction of different spiromethanofullerenes leads to adduct removal, opening the way to new protecting–deprotecting groups in fullerene chemistry.

The Bingel reaction has been used as a synthetic tool for the addition of di(alkoxycarbonyl)methano bridges to fullerenes for several years.[1] The resulting Bingel adducts are relatively stable thermally[2] and under a variety of chemical environments. However, Diederich and Echegoyen recently reported the retro-Bingel reaction, an electrochemical reduction reaction which efficiently removes the cyclopropane ring adduct, resulting in the formation of the parent C_{60}.[3] This electrochemical reduction reaction has also been employed successfully on other fullerene systems.[4,5] Before the work reported here, to our knowledge the only fullerene adducts that were removable *via* electrochemical reduction were the Bingel adducts.

Fullerenes substituted with electron-donating and electron-accepting addends have been studied extensively, mainly within the context of developing optically and electronically active systems for potential applications.[6] Previously, Wudl and coworkers described the electrochemical properties of the methanofullerenes **1** and **2**, which bear quinone type addends (Fig. 1).[7] These compounds exhibit irreversible electrochemistry, presumably resulting from the cleavage of one of the cyclopropane bonds connecting the addend to C_{60} upon reduction.[8] These observations, coupled with those of the retro-Bingel reaction, motivated the work reported here, to observe the behavior of compounds **1**–**4** under controlled potential electrolysis (CPE) for potential adduct removal. Compound **3** is similar to the Bingel adduct owing to the presence of the two carbonyls α to the methano bridge carbon. **4** is structurally and electronically very different from the others, and was used mainly for comparison.

The synthesis of the spiromethanofullerenes **1** and **2** was carried out according to the method previously reported in the literature.[9] Compound **3** was synthesized in two steps from indan-1,3-dione which was transformed into 2-diazoindan-1,3-dione by reaction with tosyl azide under basic conditions. Further reaction of 2-diazoindan-1,3-dione with C_{60} in ODCB (*o*-dichlorobenzene) at 120 °C for 4 h afforded spiromethanofullerene **3**[10] in 33% yield (62% based on consumed C_{60}). Compound **3** showed the presence of the carbonyl groups as a single signal at δ 191.7 in the ^{13}C NMR spectrum, which shows the presence of 17 signals, suggesting a C_{2v} symmetry. Spiromethanofullerene **4** was obtained from diphenylcyclopropenone in two steps, by formation of the tosylhydrazone and further *in situ* generation of the intermediate diazo compound under basic conditions,[11] which reacted with C_{60} by heating in ODCB to lead to **4** in 20% yield (46% based on consumed C_{60}). Spiromethanofullerene **4** shows a characteristic signal in the FTIR spectrum at 1712 cm^{-1} due to the cyclopropene double bond.

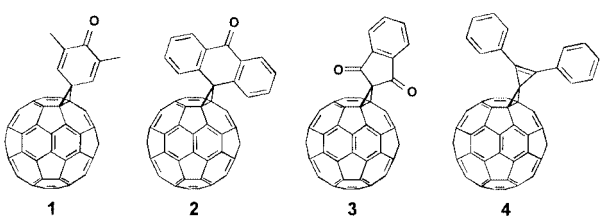

Fig. 1 Novel spiromethanofullerenes for reductive electrochemistry.

The electrochemistry of **1**–**4** in dichloromethane was studied by cyclic voltammetry (CV) and Osteryoung square wave voltammetry (OSWV) (Fig. 2 and Table 1).[12,13] The methanofullerenes **1** and **2** both exhibit, besides several reversible electrochemical processes, an irreversible electrochemical reduction wave between the first and third reductions. Compound **3** undergoes a two-electron reduction, followed by two one-

DOI: 10.1039/b001428l

electron reductions. By contrast, the reference methanofullerene **4**, which bears no electron accepting addends, has three reversible redox waves.

Typically 2–5 mg of each compound were subjected to CPE. CPE of **1** was performed at a potential *ca.* 100–150 mV more cathodic than the second, irreversible, reduction wave (Fig. 2, arrow 1). This electrolysis consumed *ca.* 3.9 electrons molecule^{-1} and induced clear changes in the CV and OSWV, indicating that a chemical reaction had taken place. Subsequent reoxidation at 0 V and purification of the product mixture by column chromatography (eluent toluene) yielded fullerene products in *ca.* 60% yield. Analysis of this mixture by HPLC, UV–VIS spectroscopy and MALDI-TOF spectrometry showed the complete disappearance of the starting material, but no C_{60} was isolated. Unfortunately, the structure of the products could not be assigned.[14]

CPE of methanofullerene **2** was initially performed after the first reduction wave in order to completely dissolve methanofullerene **2** in CH_2Cl_2 (arrow 3, Fig. 2; 1.0 electron molecule^{-1}). No changes in the CV or OSWV were observed after electrolysis. Subsequent electrolysis after the third reduction wave (arrow 4, Fig. 2) consumed *ca.* 3.7 electrons molecule^{-1}. At that point the cyclic voltammogram had completely changed. This voltammogram exhibited three reversible electrochemical waves. After reoxidation and purification, analysis of the reaction mixture by HPLC and UV–VIS clearly proved the formation of C_{60} in a 65% yield. Thus electrolysis leads to the clean and efficient removal of the spiroanthraquinone adduct.

Electrolysis of methanofullerene **3** was performed after the first, two-electron, reduction (arrow 5, Fig. 2; 2.3 electrons molecule^{-1}). CV and OSWV clearly showed that chemical processes accompanied the electrochemical reductions.

Reoxidation, purification and subsequent analysis showed the formation of the parent C_{60} in a 58% yield.[15]

CPE of methanofullerene **4** after the second reduction (arrow 6, Fig. 2) consumed 2.0 electrons molecule^{-1} and is fully reversible: no changes in the cyclic or OSWV voltammogram were observed. Electrolysis after the third reduction wave (arrow 7, Fig. 2; 7.3 electrons molecule^{-1}) leads to passivation of the working electrode and to the formation of insoluble and intractable products.

In conclusion, the electrochemical measurements described above show that for all 'quinone' type methanofullerenes **1**–**3**, a chemical reaction occurs after reduction. This reaction leads to the parent C_{60} for compounds **2** and **3**, in a 'retro-Bingel' like reaction. Thus the range of fullerene adducts that can be removed *via* electrochemical reduction is here extended beyond the Bingel adducts.

Financial support for this work from the National Science Foundation through grant CHE-9816503, the Netherlands Organization for Scientific Research (NWO, talent stipendium, M. B.) and the DGESIC of Spain (PB98-0818) is greatly appreciated. We also acknowledge the Fullbright Foundation (Project 99125) for financial support.

14 HPLC measurements indicated that the polarity of the products is in the range of that for the parent C_{60}, rather than around that of the starting methanofullerene **1**. UV–VIS spectroscopy measurements showed a broad band around 450 nm. Furthermore, the main peak in the MALDI-TOF mass-spectrum of the reaction mixture is at *m/z* 890. A separate electrolysis experiment performed after the third reduction potential of methanofullerene **1** (Fig. 2, arrow 2; 4.3 electrons molecule^{-1}), leads to a similar result: yield = 65%, main peak in the MALDI-TOF is at *m/z* 890.
15 Besides the retro-Bingel product C_{60}, 22% of starting material, methanofullerene **3** was also isolated.

Persistent carbenes containing acetylenes: 4,5-dialkynylimidazol-2-ylidene

A nucleophilic imidazole carbene featuring acetylene substituents in the 4- and 5-positions is prepared in three steps from dialkynyl diimines and is characterised by low temperature NMR spectroscopy and trapping reactions with MeI, CS_2 and $HgCl_2$.

The remarkable renaissance of nucleophilic carbenes, triggered by the isolation of the first crystalline imidazol-2-ylidene by Arduengo *et al.*,[1] is witnessed by recent syntheses of a variety of derivatives of this class of compounds[2] and has culminated in the development of imidazol-2-ylidenes as versatile ligands in transition metal complexes for use in catalysis applications.[3] In the course of these investigations it emerged that the variation of the 4,5-imidazole substituents can have striking effects on the stability of the corresponding carbenes. For example, the notion that a CC double bond between these positions is a crucial prerequisite for the generation of isolable carbenes could not be maintained after the preparation of a stable imidazolidine carbene.[4] Furthermore, a 4,5-dichloroimidazol-2-ylidene proved to be the first heterocyclic carbene stable to the air,[5] and an analogous 4,5-bistrifluoromethyl derivative could even be subjected to bulb-to-bulb distillations.[6]

We were intrigued by the challenge to introduce seemingly carbene-incompatible alkynyl groups into the 4,5-positions of imidazol-2-ylidenes as in **1** (Fig. 1), and are driven by the prospect to use the acetylene substituents as delocalising linkages able to connect several carbene sites within one molecular framework (**2**). Monomolecular multi-carbene arrays like **2** are deemed to be of particular interest with respect to metal coordination and to the exploitation of synergistic metal cooperativity. We report here the synthesis of a 4,5-dialkynyl imidazol-2-ylidene as the first representative of this class of compounds.

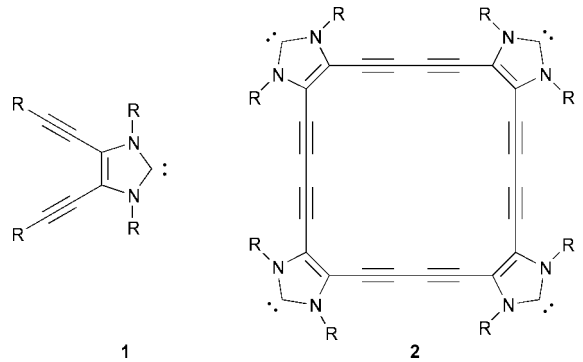

Fig. 1

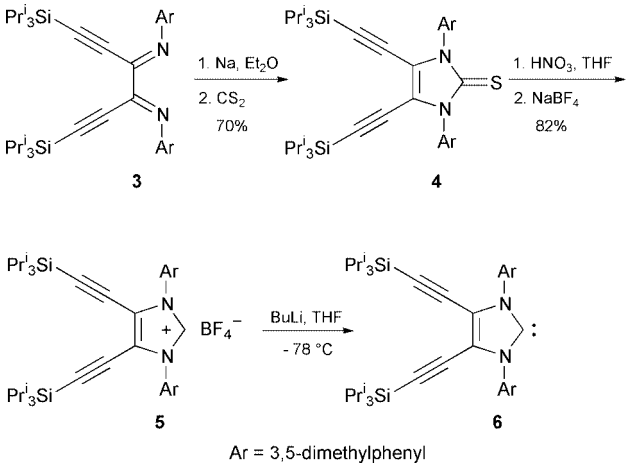
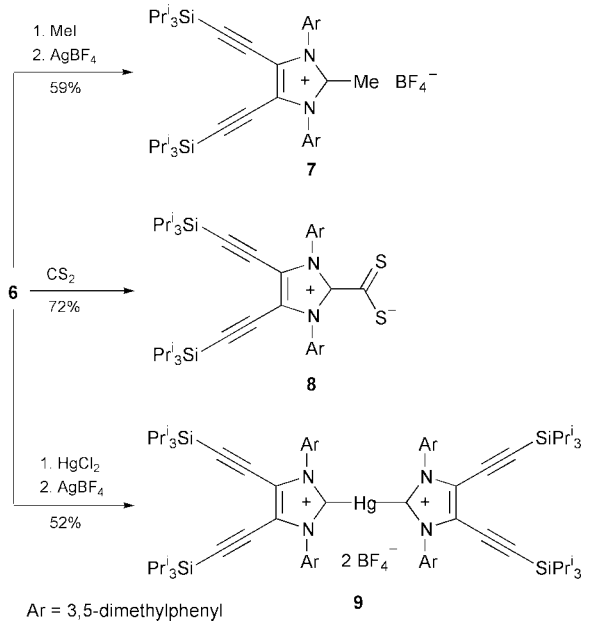
We have recently reported two complementary pathways to dialkynyldiimines such as **3** (Scheme 1) from oxalyl chloride and bisimidoyl chlorides, respectively.[7,8] These building blocks were deemed to be convenient starting materials for the rapid assembly of the 4,5-diacetylenyl imidazole core, since ring closure to the corresponding imidazole-2-thiones can be



Scheme 1

effected by quenching diimine dianions with CS_2.[9] Imidazole-2-thiones in turn are precursors to Arduengo-type carbenes which can be obtained either directly by alkali metal reduction of the thiones[10] or *via* deprotonation of an intermediate imidazolium salt derived from them.[1] Hence, stirring **3** together with sodium in dry diethyl ether at room temperature furnished an initially deep blue solution which slowly turned orange-red to indicate the formation of the dianion of **3**. Treatment of this solution with CS_2 led to the imidazole-2-thione **4** in 70% yield. Attempts to isolate an acetylenic carbene directly from **4** by a potassium-mediated reductive desulfurisation were unsuccessful and led only to the decomposition of the starting material. We therefore prepared the dialkynyl imidazolium salt **5** by oxidative desulfurisation of **4** with dilute nitric acid in THF followed by anion exchange with sodium tetrafluoroborate. Gratifyingly, deprotonation of **5** could be effected with BuLi in THF at −78 °C and resulted in a yellow-coloured solution of 4,5-dialkynyl imidazol-2-ylidene **6**. Interestingly, carbene **6** could only be generated from **5** using BuLi or LDA in THF. With potassium *tert*-butanolate, sodium or potassium hydride in either THF or DMSO on the other hand, only decomposition products were observed even at temperatures as low as −100 °C.

The acetylenic carbene **6** was clearly identified in the low temperature ^{13}C NMR spectrum (90.56 MHz, THF with external D_2O-lock, −78 °C) featuring a diagnostic signal for the ylidene carbon at 214.3 ppm.[11] However, and in contrast to many non-acetylenic imidazol-2-ylidenes, we were unable to isolate **6** in neat or in crystalline form. THF solutions of **6** could be kept at −78 °C for several hours without change, but allowing the solutions to gradually warm to −40 °C led to brown, unidentified decomposition products. Apparently, a 4,5-diacetylene substitution appears to have a detrimental effect on the thermal stability of the imidazol-2-ylidene. While this finding is somewhat unexpected in light of the remarkable persistence of 4,5-dichloroimidazol-2-ylidene[5] and the elec-



Scheme 2

tron-withdrawing properties of alkynyl substituents, it should be noted that nucleophilic carbenes are known to react with activated acetylenes[12] and that **6** therefore may be susceptible to intermolecular cycloaddition reactions.

The reactivity of **6** even at low temperature prompted us to further establish its identity by trapping reactions with various electrophiles (Scheme 2). Hence, treatment of a solution of **6** in THF with methyl iodide furnished, after anion exchange, the corresponding 2-methylimidazolium ion **7** in 58% yield. Similarly, the zwitterionic imidazolium dithiocarboxylate **8** could be obtained from the reaction of **6** with CS_2. Lastly, a further indirect proof of the intermediacy of carbene **6** was assembled by performing one of Wanzlick's original experiments,[13,14] namely the reaction of **6** with mercury dichloride. The reaction furnished, after anion exchange, the diimidazol-2-yl-mercurium salt **9** as a colourless solid. All adducts of **6** are fully characterised by spectroscopic data and elemental analyses. In addition, a qualitative X-ray diffraction study performed on crystals of **9** confirmed the presence of a bridging mercury atom between two imidazole ring structures. Unfortunately, severe disorder in the crystals caused by the anions and the floppy triisopropylsilyl groups prevented a refinement of the observed data below an *R*-value of 15%.

This work has demonstrated the feasibility of introducing alkynyl groups into the structural framework of nucleophilic carbenes and has therefore opened the way for the exploration of the metal coordination behaviour of these species and for the assembly of acetylene-linked, multinuclear metal-carbene complexes. Developments along those lines are currently underway.

We acknowledge the generous support from Professor Dr R. Neidlein, Pharmazeutisch-Chemisches Institut of the University of Heidelberg, Germany and from the Fonds der chemischen Industrie, Germany.

Received (in Irvine, CA, USA) 5th January 2000, Accepted 18th April 2000

A novel complex $[Fe^{III}_2(\mu\text{-}O)\{\mu\text{-}OC(NH_2)NH\}(tpa)_2](ClO_4)_3$ [tpa = tris(2-pyridylmethyl)amine] has been synthesized and fully characterized; its formation from urea and the $[Fe^{III}_2(\mu\text{-}O)(tpa)_2(OH)(H_2O)]^{3+}$ precursor in aqueous acetonitrile is a reversible multistep process.

Dinuclear metallohydrolases have been recognized as a wide class of enzymes which utilize two metal cations (Zn, Mg, Mn, Fe, Co, Ni) for the activation of different organic substrates for hydrolysis.[1] Urease, which catalyses urea hydrolysis, is probably the best known enzyme in this class. Ureases isolated from various species of plants, fungi and bacteria have invariably contained two Ni^{II} ions in their active site.[1,2] However, relevant substrates such as ethylurethane can be hydrolyzed by enzymes utilizing other metals. A urethanase with four Fe^{III} ions per molecule has been reported.[3]

The mechanism of urease action remains under debate. Initially it was proposed that urea binds monodentately to one Ni^{II} ion and is attacked by a hydroxide which is attached to the second Ni^{II} ion.[1,2,4] A new proposal for the urease mechanism suggests that both urea and hydroxide initially form bidentate bridges between the Ni^{II} atoms.[5] Two model nickel compounds with bridging urea anions have been recently characterized.[6] Here, we report the first dinuclear iron complex with bridging ureate having distinct metal sites.

Our approach was based on the rich chemistry of diiron oxo-bridged complexes with tris(2-pyridylmethyl)amine (tpa).[7] The $[Fe^{III}_2(\mu\text{-}O)(tpa)_2(OH)(H_2O)]^{3+}$ precursor **1** reacts with various ligands HL to form $[Fe^{III}_2(\mu\text{-}O)(\mu\text{-}L)(tpa)_2]^{n+}$ complexes.[7c,d,8] Compound **1** can also activate acetonitrile for hydrolysis.[7c,d]

The complex $[Fe_2(\mu\text{-}O)\{\mu\text{-}OC(NH_2)NH\}(tpa)_2]^{3+}$ **2** can be prepared either from **1** and urea in MeCN solution or directly from $Fe(ClO_4)_3$, tpa, urea and Et_3N in MeOH.‡ The spectral characteristics of **2** obtained by either method are identical.† The UV–VIS and ^1H NMR spectra of **2** are similar to those of relevant acetamidate and acetate bridging complexes, $[Fe^{III}_2(\mu\text{-}O)\{\mu\text{-}OC(Me)NH\}(tpa)_2]^{3+}$ and $[Fe^{III}_2(\mu\text{-}O)(\mu\text{-}MeCO_2)(tpa)_2]^{3+}$.[7] A detailed mass spectrometric study allowed the unambiguous assignment of **2** as a ureate complex. The peak with *m/z* 965 {corresponding to $[\mathbf{2}(ClO_4)_2]^+$} is the most prominent in both the $ESMS^+$ and FAB^+ spectra. The peak is shifted to *m/z* 967 in the spectra of the sample of $\mathbf{2}(ClO_4)_3$ prepared from urea-$^{15}N_2$. Satellite peak intensities and exact mass determinations confirm the compositions of the *m/z* 965 and 967 ions as $[\mathbf{2}(ClO_4)_2]^+$ and $[(\mathbf{2}\text{-}^{15}N_2)(ClO_4)_2]^+$, respectively.

Two different solvated complexes, $\mathbf{2}(ClO_4)_3\cdot 2H_2O$ and $\mathbf{2}(ClO_4)_3\cdot 0.75CO(NH_2)_2\cdot 0.25H_2O$, were crystallized and characterized by X-ray diffraction. The molecular dimensions of the complex dinuclear cation **2** in both are very similar (Fig. 1). Bond distances and angles in the asymmetric (tpa)Fe–O–Fe(tpa) unit of **2** are close to those in the relevant carboxylate bridged $[Fe_2(\mu\text{-}O)(\mu\text{-}RCO_2)(tpa)_2]^{3+}$ complexes [α(Fe–O–Fe) = 130(1)°],[7] which is in agreement with the isoelectronic nature and similar sizes of the delocalized carboxylate ($-CO_2^-$) and amidate groups ($-CONH^-$). The structural parameters of the planar ureate anion in **2** [*d*(C–O) = 1.238(12), *d*(C–NH) = 1.311(13), *d*(C–NH_2) = 1.439(15) Å] are close to those found in the $[Ni^{II}_4\{\mu_3\text{-}OC(NH)NH_2\}(L)_2]^{4+}$ complex [*d*(C–O) = 1.254, *d*(C–NH) = 1.311, *d*(C–NH_2) = 1.427 Å][6b] and those calculated by an *ab initio* method for $OC(NH_2)NH^-$ [*d*(C–O) = 1.260, *d*(C–NH) = 1.324, *d*(C–NH_2) = 1.488 Å].[9] The bent (tpa)Fe–O–Fe(tpa) core has two non-equivalent vacant positions at the potentially hexacoordinate Fe^{III} atoms, one with a tertiary aliphatic N atom and the other with a pyridine N atom as *trans* donors. The ureate anion in **2** coordinates with its oxygen atom *trans* to the pyridine N atom, which apparently allows for a stronger π-interaction along the O_{ureate}–Fe–N_{pyr} axis *versus* the possible N_{ureate}–Fe–N_{pyr} alignment.[10]

The equilibrium and kinetics of formation of **2** from the precursor **1** and urea were studied in aqueous acetonitrile (0.05–1.3 M H_2O) at 25 °C. In the presence of excess urea, **2** is stable in these solutions for weeks.

Spectrophotometric titrations gave the equilibrium constant $K = 650 \pm 100$ M for reaction (1) confirming the release of two molecules of water.

$$\mathbf{1} + CO(NH_2)_2 \rightleftarrows \mathbf{2} + 2H_2O \qquad (1)$$

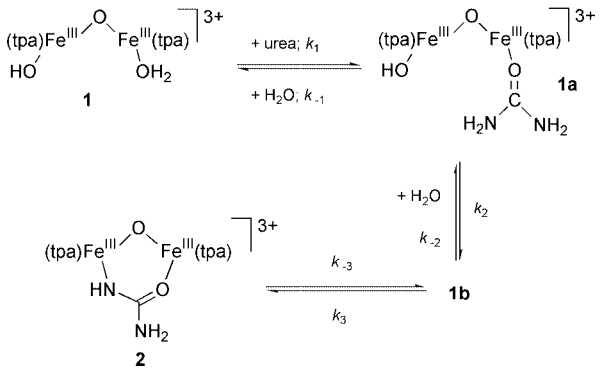
† Electronic supplementary information (ESI) available: selected data for **2** kinetic data and rotatable 3-D crystal structure diagram in CHIME format. See http://www.rsc.org/suppdata/cc/b0/b000286k/

DOI: 10.1039/b000286k

The kinetics of reaction (1) were studied by a stopped-flow technique under concentration conditions, which made the formation of **2** almost irreversible (yield > 96%). The excess of urea (8–60 fold) and water (> 100 fold) also provided pseudo-first order conditions. Two distinct steps are observed in reaction (1). In the first step, there is a nearly instantaneous (within the mixing time of the stopped-flow instrument, 1–2 ms) change in the optical spectrum when the solutions of **1** and urea are mixed. The dependence of this initial absorbance change on $[H_2O]$ and $[CO(NH_2)_2]$ corresponds to the formation of intermediate **1a** in a preequilibrium with $K_1 = 9 \pm 3$ (Scheme 1). It has been shown that the O-bonded urea is usually the first kinetic product of complex formation.[11] Thus, **1a** is most likely the $[Fe_2(\mu\text{-}O)(tpa)_2(OH)\{\eta_1\text{-}OC(NH_2)_2\}]^{3+}$ complex.



Scheme 1

The following step is observed as a nearly single exponential change of optical absorbance with the rate constant k_{obs} (0.1–1.8 s^{-1} under our experimental conditions) and corresponds to the formation of **2** from the preequilibrium mixture of **1** and **1a**. The process is accelerated by urea and decelerated by water. The simplest model that can account for the concentration dependences is shown in Scheme 1 and eqn. (2) (see also ESI).†

$$k_{obs} = \frac{k_2(k_3/k_{-2})}{(k_3/k_{-2})+[H_2O]} \cdot \frac{K_1[CO(NH_2)_2]}{K_1[CO(NH_2)_2]+[H_2O]} \qquad (2)$$

Optimization of this model by non-linear least squares methods gave the parameters $K_1 = k_1/k_{-1} = 8.9$, $k_2 = 2.6\ s^{-1}$ and $k_3/k_{-2} = 0.185$ M. Combination of the kinetic data with the equilibrium constant $K = 650$ M for the overall process (1) gave $k_{-3} = 6.6 \times 10^{-3}\ s^{-1}$ (Scheme 1).

The results of this study help us to understand the potential advantages and drawbacks of the new bidentate mechanism of urease activity[5] when compared to the previously accepted monodentate mechanism.[2,4] It is believed that the hydrolytic stability of the urea molecule is due to high resonance stabilization energy, which may be reduced on coordination to metal ion(s).[2,12] Bidentate N,O-coordination of urea leads to partial loss of resonance as witnessed by a significant elongation of the C–NH_2 bond in the μ-$OC(NH_2)NH^-$ ligand of **2** [d(C–NH_2) = 1.44 Å] *versus* uncoordinated urea [d(C–NH_2) = 1.34 Å].[13] In the neutral μ-$OC(NH_2)NH_2$ ligand both C–NH_2 bonds are elongated [$d(C–NH_2)_{endo}$ = 1.42, $d(C–NH_2)_{exo}$ = 1.37 Å] as was found in a Co^{II} complex.[14] In contrast, monodentate coordination of urea (typically *via* the O atom) is known to preserve its metric parameters [d(C–NH_2) = 1.34(1) Å].[15] Thus, the loss of resonance stabilization on bidentate N,O-coordination might be a key factor in urea activation by two metal ions in urease.

The protonation state of the bridging urea ligand is another important issue which was overlooked in the bidentate mechanism of urease action.[5] In the monodentate mechanism it did not arise,[2,4] because monodentate O-coordinated urea in model complexes has almost the same high pK_a as the free ligand (13 *cf.* 13.5).[16] However, N-coordination (which can be achieved in kinetically inert model complexes) is known to change the acidity of urea protons dramatically, down to pK_a = 3(1) in aqueous solution.[16] Quantitative formation of ureate complex **2** in the Et_3N/Et_3NH^+ buffer in MeOH confirms the enhanced acidity of urea on bidentate N,O-coordination. Because of the lower polarizing power of the Ni^{II} ions, a μ-$OC(NH_2)NH_2$ ligand coordinated to them will probably be less acidic than that coordinated to Fe^{III}. However, formation of a bridging urea anion still should be considered in urease under its optimal pH 4–8.[4] Relatively slow formation of the bidentate ureate and its hydrolytic stability as seen in complex **2** suggest that μ-$OC(NH_2)NH^-$ is unlikely to be the actual activated form of urea in the enzyme. An alternative possibility is that urease modulates the pK_a of the μ-$OC(NH_2)NH_2$ ligand to avoid its premature deprotonation.

Notes and references

‡ Precursor **1**$(ClO_4)_3$ was prepared by a published procedure.[7d]

Synthesis of **2**: urea (0.03 g, 0.5 mmol), tpa (0.29 g, 1 mmol) and Et_3N (0.152 g, 1.5 mmol) were dissolved in 40 ml of MeOH and added to a solution of $Fe(ClO_4)_3{\cdot}9H_2O$ (0.516 g, 1 mmol) in 10 ml of MeOH. Compound **2**$(ClO_4)_3{\cdot}H_2O$ crystallized as a brown solid from the resulting yellow solution on standing overnight in a refrigerator. Elemental analysis: calc. for $C_{37}H_{43}Cl_3Fe_2N_{10}O_{16}$: C, 40.33; H, 3.93; N, 12.71; Fe, 10.14. Found: C, 40.27; H, 3.55; N, 12.46; Fe, 10.37%. Single crystals of **2**$(ClO_4)_3{\cdot}2H_2O$ formed on recrystallization from MeCN. When the recrystallization was carried out in the presence of an added excess of urea, single crystals of **2**$(ClO_4)_3{\cdot}0.75CO(NH_2)_2{\cdot}0.25H_2O$ were obtained.

Crystal data for **2** $(ClO_4)_3{\cdot}2H_2O$: $C_{37}H_{43}Cl_3Fe_2N_{10}O_{16}$, M_w = 1101.86, monoclinic, space group $P2_1/c$, a = 12.178(3), b = 10.329(5), c = 39.179(10) Å, β = 94.65(2)°, V = 4912(3) Å^3, Z = 4, μ(Mo-Kα) = 0.829, T = 293(2) K, 5489 reflections measured, $R1[I > 2\sigma(I)]$ = 0.070, $wR2$ = 0.28 for all reflections. For **2**$(ClO_4)_3{\cdot}0.75CO(NH_2)_2{\cdot}0.25H_2O$: $C_{37.5}H_{42.5}Cl_3Fe_2N_{11.5}O_{15}$, M_w = 1115.38, monoclinic space group $P2_1/c$, a = 12.1610(15), b = 10.4451(17), c = 38.758(10) Å, β = 97.137(16)°, V = 4885.1(16) Å^3, Z = 4, μ(Mo-Kα) = 0.834, T = 293(2) K, 6383 reflections measured, $R1[I > 2\sigma(I)]$ = 0.067, $wR2$ = 0.206 for all reflections. A novel heptacyclic C_{37} alkane presenting a regular polyprenoid structure has been isolated from a biodegraded bituminous rock and identified by NMR; this hydrocarbon is the most highly cyclized polyprenoid alkane ever completely identified; the absence of specific methyl groups give clues to unprecedented biological precursor lipids resulting from the extensive cyclization of regular octaprenoids.

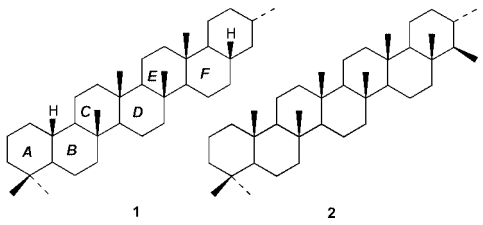
Polycyclic hydrocarbons of high molecular weight (> C_{30}) with a regular polyprenic skeleton identified in sediments and petroleum were for a long time restricted to tricyclopolyprenanes.[1] Recently, the structures and the occurrence of highly cyclized compounds based on regular polyprenoid skeletons could be established in various sediments; they were essentially identified as monoaromatic hydrocarbons[2,3] and sulfides.[4] Their regular polyprenoid structure strongly suggests that the biological precursors from which these molecular fossils originate, most likely derive from proton-induced enzymatic cyclization of all-*trans* regular isoprenoids. Biological precursors have not been observed until now in living organisms and so these molecular fossils would appear to belong to a new class of biolipids whose origin and function remain unclear. More recently, investigation of the saturated hydrocarbon fraction of sediments from various origins revealed the occurrence of new sedimentary polycyclic alkanes (four to seven rings) which were suggested to have a complete regular polyprenoid structure according to mass spectral data.[2,5] We report here on the first unambiguous identification of a heptacyclic alkane **1**, which is related to this new series of saturated hydrocarbons.



1 **2**

The studied sample was collected from a quarry (Maestu, Spain) which consisted of a calcareous reservoir rock of Campanian age impregnated by a heavy, partially biodegraded, petroleum.[5a] The crushed rock sample was extensively extracted with $CHCl_3$–CH_3OH (1/1, v:v) and the resulting extract chromatographed (SiO_2 / hexane) yielding the saturated hydrocarbon fraction. The major part of the low molecular weight constituents of the alkane fraction was removed by precipitating successively the heavy saturated hydrocarbons, including the polycyclic polyprenoid hydrocarbons, with acetone. Consecutive reverse-phase HPLC fractionation performed on the precipitated fraction led to the isolation of *ca.* 1 mg of the heptacyclic compound **1** with a purity of 91% (GC).

The EIMS spectrum of product **1**‡ exhibits a molecular ion at *m/z* 506 corresponding to the formula $C_{37}H_{62}$. Two characteristic fragmentation patterns composed of two sets of major fragments regularly shifted by 68 Da (one isoprene unit) were observed (*m/z* 177, 245, 313 and *m/z* 135, 203, 271) and were consistent with a polycyclic polyterpenoid structure.

1D- and 2D-NMR studies including homonuclear (^{1}H–^{1}H, COSY and NOESY) and heteronuclear (^{1}H–^{13}C, HMQC and HMBC) correlation experiments allowed us to assign the signals of all the protons and all the carbon atoms (ESI)† and to establish unequivocally the structure of the isolated compound.

The ^{13}C NMR spectrum of **1** shows 37 resonances, resolved into 7 methyl, 16 methylene, 9 methine and 5 quaternary carbon signals (as deduced from DEPT spectra and ^{1}H–^{13}C correlation experiments). The ^{1}H NMR spectrum also reveals 7 methyl signals, including 6 singlets and one doublet. A part of the carbon skeleton [Fig. 1(b)] could be established using ^{1}H–^{13}C long-range ($^{2,3}J$) couplings, the most intense of which are observed from the methyl groups. Two of the methyls exhibit remote connections ($^{2,3}J$) to each other as well as to the same quaternary, methine and methylene carbons, which implies that they must be geminal. The sector formed by these geminal methyl groups (*i.e.* atoms 26, 30, 32 and 32′) appears to be isolated from the rest of the molecule. Indeed, C-26 does not show remote connections with any remaining methyl groups, thus suggesting the absence of the Me-28′ at C-27. The nuclear Overhauser effects (NOE) observed between H-27 and protons of both 32′- and 24′-methyl groups [Fig. 1(a)] confirm the presence of a hydrogen atom at C-27 instead of a methyl group.

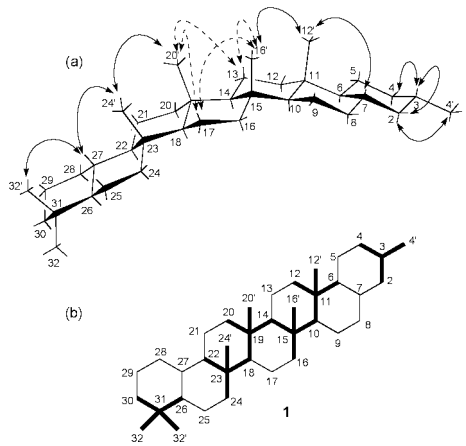


Fig. 1 (a) Spatial representation of **1** showing the most important NOEs observed. (b) Carbon sequence (bold) established from inverse long-range ^{1}H–^{13}C correlation experiment. Numbering is based on that of an acyclic octaprenol. The absolute configuration of compound **1** is not known and has been chosen arbitrarily.

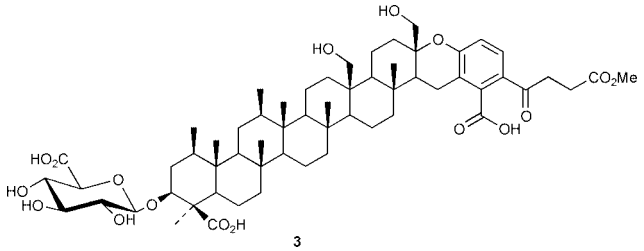
† Electronic supplementary information (ESI) available: ^{13}C and ^{1}H NMR data for hydrocarbon **1**. See http://www.rsc.org.suppdata/cc/b0/b001804j/

The central part of the molecule is constituted by the 12′, 16′, 20′ and 24′ methyl groups which are linked two by two to each other through one remote connection (^3J) with a methine (C-10, C-14 and C-18).

The remote connections of the last methyl group 4′ with the methylene (C-2 and C-4) and the methine (C-3) carbons confirm the position of substitution for this ring. This sequence Me-4′, C-2, C-3, C-4 also forms an isolated sector as demonstrated by the ^{1}H–^{13}C long-distance correlation experiment. However, linkage of this sector to the main structure, as well as final assignment of all remaining ^{1}H and ^{13}C chemical shifts was made possible through the COSY and NOESY experiments. Thus, the NOE observed between the proton H-7 and the protons of the 12′-methyl group demonstrates the lack of a methyl group (replaced by a H atom) on the ring junction at C-7. The ^{1}H–^{1}H COSY connectivities between H-7 and the protons of the methylene carbon C-2 confirm the sequence Me-4′, C-2, C-3, C-4 on the skeleton.

Stereochemical assignments can be made from the NOESY data: the NOEs observed between Me-32′/H-27, H-27/Me-24′, Me-24′/Me-20′, Me-16′/Me-12′, Me-12′/H-7 afford evidence that Me-32′, H-27, Me-24′, Me-20′ on one hand and Me-16′, Me-12′, H-7 on the other hand are on the same side of the molecule. Moreover, as no correlation between protons 7, 12′, 16′, 20′, 24′, 27 and protons 6, 10, 14, 18, 22, 26 could be detected on the NOESY spectrum, all the ring junctions are likely to be *trans* along the whole structure. As a result of all the NOEs reported in Fig. 1(a), both sectors comprising, respectively, Me-32′, H-27, Me-24′, Me-20′ and Me-16′, Me-12′, H-7, H-3 present *trans–transoid–trans* stereochemistries. Unfortunately, the determination of the global relative stereochemistry is hindered by the superposition of ^{1}H and ^{13}C chemical shifts of Me-16′ and Me-20′, as well as those of methylene groups C-13 and C-17. Thus, NOEs are indeed observed between the group of overlapping axial protons from methylene groups C-13 and/or C-17 and the overlapping methyl groups C-20′/C-16′ [indicated by dashed arrows on Fig. 1(a)] but individual interactions cannot be distinguished. This feature is not surprising in the case of highly symmetrical polycyclized regular polyprenoids since methyls 16′ and 20′, as well as methylenes 13 and 17, located in the 'middle' of the structure (*i.e.* far from demethylated positions which induce dissymmetry) have almost identical environments. The uncertainty concerning the global relative stereochemistry which arose from the interpretation of the NOESY spectrum could, however, be cleared by interpreting the chemical shift values. A *trans–transoid–trans* stereochemistry along the whole structure of compound **1** is indeed strongly supported by the underscoring of γ-*gauche* effects reflected by the chemical shifts of ^{1}H and ^{13}C proton and carbon signals.[6] In particular, the resonances of axial methylene protons Hβ-13 and Hβ-17 appear at high field (δ_H 1.35) and those of their related carbons at very low field (δ_C 17.4). This is concordant with triple γ-*gauche* interactions with the methyl groups. Furthermore, the strong deshielding of the methine carbon C-14 (δ_C 61.7), as well as the shielding of the corresponding proton (δ_H 0.73) can be taken as firm evidence for an absence of γ-*gauche* effects and thereby confirm the global relative stereochemistry with all the ring-junction axial methyl groups on the same side of the molecule. An equatorial position can reasonably be envisaged for methyl 4′ given the NOE between protons of Me-4′ and the axial proton located on C-2 and those between H-3 and H-4β, H-3 and H-2β.

From its structure, it appears that the new hydrocarbon **1**, which represents the most highly cyclized polyprenoid alkane ever identified, is likely to result from the diagenetic transformation of polycyclic polyprenoid precursors formed by proton induced cyclization of regular all-*trans* octaprenoids.[2] Indeed, the isolated compound definitely corresponds to a demethylated counterpart of a complete polycyclic octaprenoid hydrocarbon such as **2**. Until now, only one example of a polycyclic biological lipid **3** with more than four rings has been



3

identified in a living organism (bacterium *Streptomyces argenteolus*).[7] This bacterium can probably not account solely for the large sedimentary record of highly cyclized polyprenoid structures.[2,4,5] Therefore, the biological organisms able to biosynthesize the precursors of **1** still remain to be discovered. A wider survey of the occurrence of these new polyprenoid hydrocarbons in sediments could eventually pin-point the type of actual natural environments likely to contain their source-organism(s) and orient further research for their discovery.

Some structural features of the unknown biological precursors can, however, already be inferred from the structure of the molecular fossil **1**. Thus, the absence of three methyl groups compared to a complete octaprenoid hydrocarbon suggests either that these methyl groups were absent within the biological precursor or, that these positions were functionalized (*e.g.* **3**) and susceptible to various diagenetic processes (*e.g.* by decarboxylation). It can, however, not be excluded, that functionalization of methyl groups on the precursor polyprenoid was induced by microbial oxidation processes occurring at the earliest stages of diagenesis.[8]

The synthesis of kermesic acid by acetylation-aided tautomerism of 6-chloro-2,5,8-trihydroxynaphtho-1,4-quinone

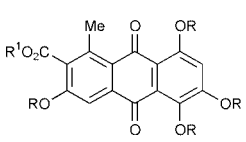
Steve J. Bingham and John H. P. Tyman*

Department of Chemistry, Brunel University, Uxbridge, Middlesex, UK UB8 3PH. E-mail: john.tyman@brunel.ac.uk
Laboratories of European Colour plc, Nathan Way, London, UK SE18

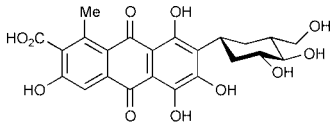
Received (in Cambridge, UK) 14th March 2000, Accepted 20th April 2000

6-Chloro-2,5,8-trihydroxynaphtho-1,4-quinone does not undergo cycloaddition reactions but the 1,2-diacetate, 2-chloro-5,6-diacetoxy-8-hydroxynaphtho-1,4-quinone, formed by acetylation-aided tautomerism added (*E*)- and (*Z*)-3-alkoxycarbonyl-2,4-bis(trimethylsiyloxy)penta-1,3-diene to afford kermesic acid after hydrolysis.

Kermesic acid **1a**, the red colourant component of kermes, a dyestuff of great antiquity and probably the earliest of which



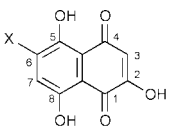
1a R = R^1 = H
b R = H; R^1 = Me
c R = R^1 = Me



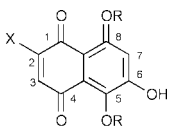
2

there is a record,[1] is also the aglycone of carminic acid[2] **2**, the colourant principle of cochineal.

Although carminic acid historically, through its brilliant range of red hues, superseded kermesic acid, dyeing with kermes is still active.[3] Nevertheless, the natural source of kermesic acid, for example from the wingless insect *Kermes illicis* which infects the kermes oak, is not abundant, and it was of interest to devise a synthetic approach that could provide an intermediate from which, by different strategies, either kermesic or carminic acid could be obtained. It was desirable to avoid penultimate tricyclic intermediates having an halogeno group requiring difficult hydrolysis[4,5] to the required hydroxy group and in another method[6] the simultaneous formation of isokermesic acid. Therefore, effort was focused on the preparation of 2-halogeno-5,6,8-trihydroxynaphtho-1,4-quinone **3**,



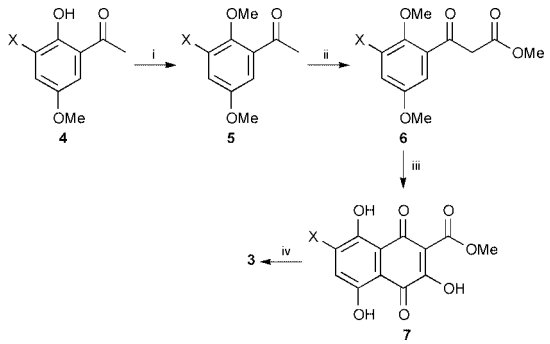
3 (form 1)



3 (form 2)

(form 2) which, as with naphthazarins generally, could be expected to exist as the 6-halogeno-2,5,8-trihydroxynaphtho-1,4-quinone tautomer **3** (form 1) where the halogeno atom is required to aid subsequent cycloaddition.

The starting point of the synthesis (Scheme 1) was 3-bromo-2-hydroxy-5-methoxyacetophenone[7] **4** (X = Br), and its chloro-analogue **4** (X = Cl), prepared in 80% yield by selective chlorination of 2-hydroxy-5-methoxyacetophenone with *N*-chlorosuccinimide (NCS) in acetic acid containing $Mg(OAc)_2$. Methylation of **4** with DMS in acetone containing K_2CO_3 afforded **5** (X = Br) 82% and **5** (X = Cl) 81%. Reaction of each with dimethyl carbonate in methanolic sodium methoxide gave the β-ketoesters **6** (X = Br, Cl), both in quantitative yield which by treatment with oxalyl chloride in nitromethane containing anhydrous aluminium chloride, a process used to prepare



4 **5** **6** **7**

Scheme 1 *Reagents and conditions*: **4** (X = Cl) from **4** (X = H), NCS, HOAc, $Mg(OAc)_2$ r.t., 24 h: i, DMS, Me_2CO, K_2CO_3, heat, 24 h; ii, NaOMe, MeOH, $(MeO)_2CO$, hear; iii, $(COCl)_2$, $MeNO_2$, $AlCl_3$, 0 to 80 °C, 3 h; iv, 10% conc. HCl–HOAc, 100 °C, 5 h.

unhalogenated naphthoquinones,[8] afforded the two 3-carbonylmethoxy-6-halogeno-2,5,8-trihydroxynaphth-1,4-quinones **7** (X = Br) 48% and **7** (X = Cl) 56% together with some partially demethylated quinones. Hydrolysis of the trihydroxyquinone esters with either aqueous sodium hydroxide followed by acidification, or with hot acetic acid containing hydrochloric acid (the preferred method) then gave the parent compounds **3** (X = Br) 69% and **3** (X = Cl) 53%.

Under a variety of conditions **3** (X = Cl) failed to undergo Diels–Alder cycloaddition with the dienes (*E*)- and (*Z*)-3-methoxycarbonyl-2,4-bis(trimethylsilyloxy)penta-1,3-diene[2] **8a**. This was attributed primarily to the intramolecular hydrogen bonding[9] of the 2-OH group thus inhibiting the normal tautomerism of the naphthazarin system and locking the structure in form 1. Further support for this exclusive structure was provided by an X-ray structure determination (Fig. 1)† and that, under mild conditions, **3** (X = Cl) readily underwent: (a) Michael addition at the 3-position and (b) selective O-methylation in 77% yield at the 2-OH with BF_3·MeOH which then removed the impediment to tautomerism and was expected to assist cycloaddition.

Acetylation of **3** (X = Cl) in dichloromethane with pyridine–acetic anhydride afforded the triacetoxy-compound in 91% yield as a 2:1 mixture (confirmed by NMR) of 6-chloro-2,5,8-triacetoxynaphtho-1,4-quinone and 2-chloro-5,6,8-triacetoxynaphtho-1,4-quinone. However, upon heating **3** (X = Cl) in acetic anhydride alone at 100 °C the 2-chloro-5,6-diacetoxy

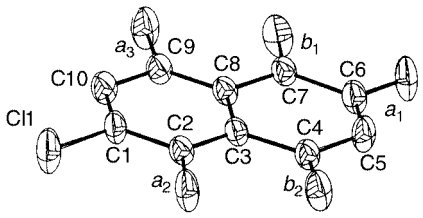


Fig. 1 X-Ray crystal structure of 6-chloro-2,5,8-trihydroxynaphtho-1,4-quinone; C–OH: a_1, a_2, a_3 = 1.33, 1.34, 1.35 Å; C=O: b_1, b_2 = 1.22, 1.24 Å.

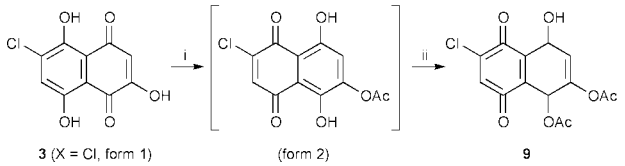
DOI: 10.1039/b002591g



Scheme 2 *Reagents and conditions*: i, ii, Ac_2O, 100 °C, 3 h; vac. to dryness.

compound **9** resulted quantitatively. It is believed (Scheme 2) that acetylation of the 2-OH occurs first allowing tautomerism to form 2 to take place and is then followed by acetylation at the 5-position which locks the structure as form 2. It is conjectural that since hydrogen-bonded OH groups are more difficult to acetylate, migration of the 6-acetyl group to the 5-position may possibly occur enabling the more susceptible 6-OH group to then react. This tentative notion may explain the non-acetylation of the hydrogen-bonded 8-OH although we have no distinct evidence to support this pathway. X-Ray crystallography provided confirmation of the structure of the 5,6-diacetoxy compounds (Fig. 2).†

The diacetyl compound **9** readily underwent cycloaddition with (*E*)- and (*Z*)-3-methoxycarbonyl-2,4-bis(trimethylsilyloxy)penta-1,3-diene **8a** followed by aromatisation in boiling toluene to afford **10**, methyl 5,6-diacetoxy-3,8-dihydroxy-1-methylanthra-9,10-quinone-2-carboxylate in 87% yield after column chromatography, with definitive proof of structure being provided by an X-ray study (Fig. 3).† The isopropyl analogue **8b** reacted similarly in 64% yield.

2-Chloro-6-methoxy-5,8-dihydroxynaphtho-1,4-quinone **11**, in which normal naphthazarin tautomerism is able to operate, although the structure is not locked as with the diacetate, also underwent cycloaddition with the diene **8a** in boiling toluene to afford after work-up, methyl 6-methoxy-3,5,8-trihydroxy-1-methylanthra-9,10-quinone-2-carboxylate **12** in 42% yield. Possibly both forms 1 and 2 are present owing to the fact that there is no locking of the structure in this compound. Hydrolysis of **10** in 1% methanolic sodium carbonate followed by acidification gave methyl kermesate **1b** quantitatively and thence by refluxing in acetic acid containing hydrochloric acid, kermesic acid **1a** was obtained (Scheme 3). Methylation of

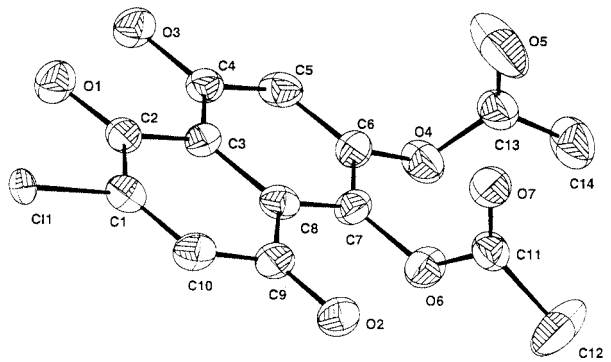


Fig. 2 X-Ray crystal structure of 2-chloro-5,6-diacetoxy-8-hydroxynaphtho-1,4-quinone.

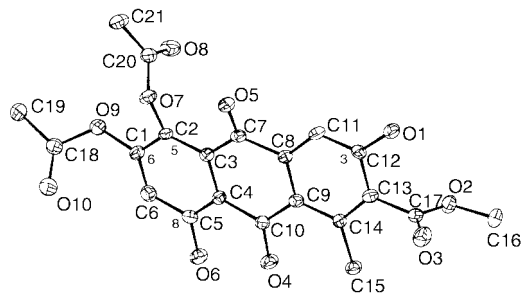

Fig. 3 X-Ray crystal structure of methyl 5,6-diacetoxy-3,8-dihydroxy-1-methylanthra-9,10-quinone-2-carboxylate.

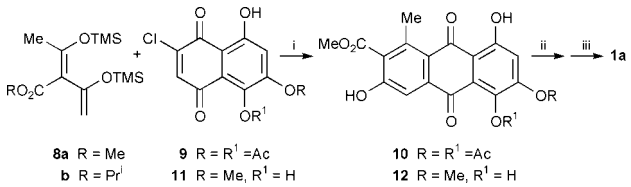
methyl kermesate **1b** with DMS in acetone solution containing potassium carbonate gave methyl 3,5,6,8-tetramethoxy-1-methylanthra-9,10-quinone-2-carboxylate **1c**, which was identical with an authentic sample[4] kindly made available by Paul Brassard. Correct spectroscopic, elemental analysis and mass spectral data were obtained for all compounds.



Scheme 3 *Reagents and conditions*: i, **9**, toluene, **8**, heat, 24 h; col chrom. SiO_2, ii, MeOH, 1% Na_2CO_3; iii, HOAc–HCl, heat; iv, **1b**, DMS, Me_2CO, K_2CO_3, heat **11** from **3** with BF_3·MeOH; toluene, **8**, heat; col. chrom. SiO_2.

Finally, it is believed that **3** (X = Cl) also has the potential utility to facilitate efficient access to carminic acid and work is continuing in this approach.[10]

Financial support is acknowledged from the SPUR initiative (DTI) and Mr G. Marshall (European Colour) is thanked for critical comments. We thank Professor S. Roberts (Exeter University) for facilitating and Professor M. Hursthouse (University of Wales, Cardiff) for effecting X-ray structure determinations.

9 The 2-, 5- and 8-OH groups in **3** (form 1) are hydrogen bonded, as seen in the ^{1}H NMR spectrum, with δ (DMSO-d_6) at 12.75 (br, s), 11.70, 13.35 ppm, respectively, *cf.* δ ($CDCl_3$) (Sadtler 19857) 10.34 for lawsone (2-hydroxynaphtho-1,4-quinone) and δ (Me_2CO) (Sadtler 3230) 8.35 for 2-naphthol. No NMR data for the 2-OH are given in ref. 8. In F. Farina, R. Martinez-Utrilla and M. C. Paredes, *Synthesis*, 1981, 300, the authors do not list the 2-OH group in data for 2-hydroxy-5,8-dimethoxynaphtho-1,4-quinone).
10 For this **3** (form 1) appears to be an ideal candidate from initial work on Michael addition and enamine reactions. Chemical approaches to using kermesic acid itself as an intermediate to carminic acid have not so far been successful although this or xanthokermesic acid are the likely biosynthetic precursors.

Theoretical investigation of the pathway for reductive cleavage of dinitrogen by a vanadium diamidoamine complex

Received (in Cambridge, UK) 30th March 2000, Accepted 19th April 2000

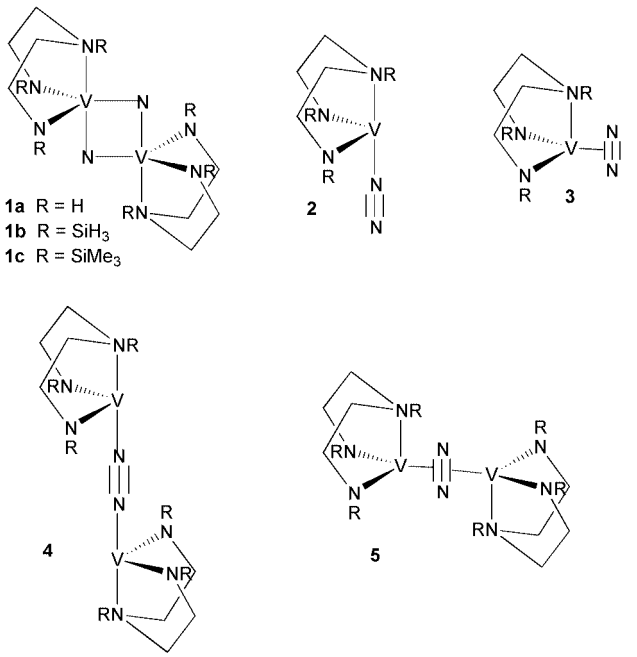
Density functional calculations show that $[HN(CH_2CH_2NH)_2V]$ will bind N_2 in a sideways fashion; further reaction with another molecule of $[HN(CH_2CH_2NH)_2V]$ leads to reductive cleavage of the N_2 moiety to form a bridged nitrido dimer, $[HN(CH_2CH_2NH)_2V(\mu\text{-}N)]_2$; this study provides a model for the formation of $[RN(CH_2CH_2NR)_2V(\mu\text{-}N)]_2$ (R = $SiMe_3$) by reduction of $[RN(CH_2CH_2NR)_2V(\mu\text{-}Cl)]_2$ under an N_2 atmosphere.

Examples of well-defined molecular systems which completely reductively cleave the dinitrogen molecule are extremely rare. The original case is the neutral Mo(III)–tris(anilide) complex of Laplaza and Cummins which yields a Mo(VI) terminal nitride upon reaction with N_2;[1] a comprehensive study has demonstrated that the mechanism of formation of the latter involves formation of a binuclear complex containing a linear μ-dinitrogen ligand which subsequently cleaves symmetrically *via* a transition state in which the μ-dinitrogen ligand is bound in a zigzag fashion.[2] Subsequently Floriani and coworkers reported an anionic Nb(III)–calixarene dinitrogen complex which affords an anionic nitrido-bridged dimer on further reduction.[3] The very recent report that reduction of the V(III) complex $[V(N\{N''\}_2)Cl]_2$, where $N\{N''\}_2$ = $(Me_3Si)N\{CH_2CH_2N(SiMe_3)\}_2$, under a dinitrogen atmosphere completely cleaves the N≡N bond to afford the doubly nitrido-bridged V(V)–V(V) dimer $[V(N\{N''\}_2)(\mu\text{-}N)]_2$,[4] has prompted us to investigate a possible pathway for this unusual reaction using density functional methods.[5]

Use of a mixture of $^{14}N_2$ and $^{15}N_2$ shows that both nitrido bridging atoms in the dimer molecule originate from the same dinitrogen molecule. If the reduction is carried out under argon and N_2 is subsequently introduced the nitrido-bridged dimer is not isolated. On the assumption that reaction of $[V(N\{N''\}_2)Cl]_2$ with potassium graphite in toluene results in the V(II) species $[V(N\{N''\}_2)]$, a possible route is given by eqn. (1). The V(II) species first binds dinitrogen and then reacts with a further V(II) species to give the product.

$$[V(N(N'')_2)(\mu\text{-}Cl)]_2 \xrightarrow{KC_8} 2[V(N(N'')_2)] \xrightarrow{N_2} [V(N(N'')_2)](N_2) + [V(N(N'')_2)] \rightarrow [V(N(N'')_2)(\mu\text{-}N)]_2 \quad (1)$$

We first tested whether theoretical calculations produced a good model of $[V(N\{N''\}_2)(\mu\text{-}N)]_2$, and whether the structural features could be reproduced with the $SiMe_3$ groups being replaced by SiH_3 and by H. Geometry optimization of these three dimers, **1a**, **1b** and **1c** reproduced the trigonal bipyramidal coordination found for $[V(N\{N''\}_2)(\mu\text{-}N)]_2$, and gave the V–N distances listed in Table 1. Frequency calculations showed **1a** to be a local minimum. Good agreement with the experimental distances (Table 1) was found for **1c**, and the only significant change on substitution was the magnitude of the long V–N (amino) distance which was calculated to be reduced by 0.3 Å on replacing $SiMe_3$ by the smaller H atom. We thus felt justified in modeling possible intermediates with the simpler $[HN(CH_2CH_2NH)_2]$ ligand (denoted L).



A search for stable $[LV(N_2)]$ intermediates yielded two promising candidates, **2** and **3**. Structure **2** had the N_2 moiety bound in an end on fashion in the axial site of a trigonal bipyramid and the quartet spin state was found to be lower in energy than a doublet for this intermediate. In **3** the N_2 was bound sideways in an equatorial site and in this case a doublet spin state was lower in energy. V–N and N–N distances for **2** and **3** are listed in Table 2 together with the energy of the various spin states relative to [LV] and N_2. Frequency calculations showed both **2** and **3** to be local minima. It should be noted that both $[LVN_2]$ intermediates show substantial binding energies for the N_2 molecule and also that **3** is predicted to be marginally more stable than **2** and to have a longer N–N

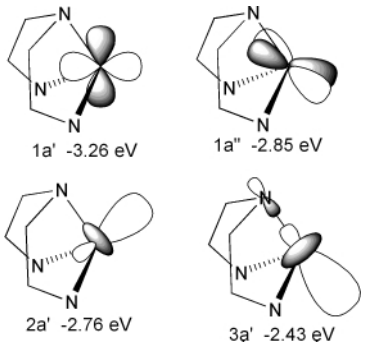

Fig. 1 Frontier orbital*S* of the [HN(CH_2CH_2NH)$_2$V] (LV) fragment.

distance. As the N_2 unit in **3** lies close to the substituent on the amino N we were concerned that this binding mode might be sterically hindered. However, geometry optimization of the fully trimethylsilylated analogue resulted in a similar structure with the N_2 only slightly displaced away from the amino substituent. The V–N (amino) distance was also lengthened by 0.061 Å.

Attachment of a second [LV] unit to **2** yielded the minimum energy structure **4** which had a triplet as the lowest spin state. The N–N bond was lengthened further (Table 2).

Attachment of a further [LV] fragment to **3** and geometry optimization of a triplet state led to **5**. This was more stable than **4** and had a considerably stretched N–N distance of 1.41 Å (Table 2) indicative of a bond order of 2 between the N atoms. The two half filled orbitals of **5** lay very close in energy and were of a_u and b_u symmetry. This closeness in energy led to problems with SCF convergence for geometry optimization of the singlet state. However, when the configuration was fixed with both electrons occupying the b_u orbital, the molecule optimized to a structure in which the N–N bond was broken and which was indistinguishable from **1a**.

Inspection of the frontier orbitals (Fig. 1) of the [LV] fragment neatly explains the two different coordination modes and sites for the N_2 molecule in **2** and **3**. The 2a′ and 3a′ orbitals are those that form σ bonds in a trigonal bipyramidal geometry, 2a′ providing equatorial coordination and the higher lying 3a′ axial coordination. In **2**, with the quartet ground state, the end on axially coordinated [LV(N_2)] intermediate, 3a′ is the acceptor orbital and 1a′ and 1a″ back donate in a π fashion to the antibonding π_g orbitals of the nitrogen molecule. Both of the back-donation MOs are singly occupied. The third unpaired electron occupies the 2a′ orbital. In **3**, the doublet ground state, the side-on bound [LV(N_2)] intermediate, the 2a′ orbital accepts electron density from the bonding π_u orbital and back donates in a π fashion from the 1a′ orbital (doubly occupied) and in δ fashion from the 1a″ orbital (singly occupied). The 3a′ orbital is unoccupied. Thus in **3,** more electrons are involved in back-donation to the N_2 unit. This results in a longer N–N distance.

In **4** additional back donation ensues from the π type orbitals, which are doubly occupied, and further lengthening of the N–N bond results. However, two unpaired electrons still occupy non-bonding orbitals of 2a′ origin.

The a_u and b_u half-occupied orbitals of **5** are shown in Fig. 2. The b_u orbital has N–N σ_u character and its partial occupancy results in further lengthening of the N–N bond. When it is

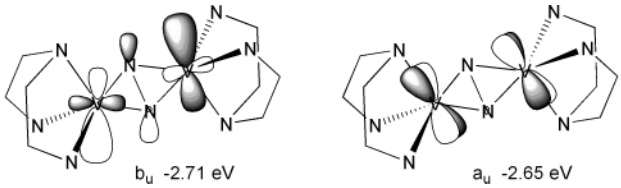

Fig. 2 Representation*S* of the b_u and a_u half-occupied orbital*S* of **5**.

doubly occupied, in the singlet state, all three N–N antibonding orbitals are receiving maximum input from the electron-rich vanadium centres and rupture of the N–N bond is achieved.

In essence, cleavage of the N_2 unit requires not only donation into its π_g orbitals but also into the antibonding σ_u orbital. This can only be sensibly achieved by sideways bonding of the N_2 unit where the acceptor function of the metal fragment is spatially separated from the interaction with the σ_u N_2 orbital. There are parallels between the N_2 cleavage discussed here and the relative stabilities of (μ-η^2:η^2-peroxo)dicopper(II) and bis(μ-oxo)dicopper(III) complexes, where donation into the σ_u* orbitals of O_2 is a key step in breaking the O–O bond.[11,12]

In conclusion a promising pathway for N_2 cleavage by [V(N{N″}$_2$)] to give [V(N{N″}$_2$)(μ-N)]$_2$, is side-on binding of N_2 by [V(N{N″}$_2$)] followed by association of a further molecule of [V(N{N″}$_2$)]. In a singlet state the N–N bond in the resultant sideways dinitrogen-bridged dimer will break and the nitrido bridged dimer is formed.

We thank EPSRC (ROPA) for support. Results were obtained using the resources of the Oxford Supercomputing Centre.

Synthesis and structural characterization of adaptable shape-persistent building blocks

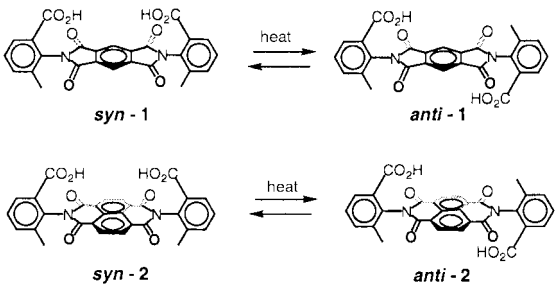
Charles Degenhardt III, David Brian Shortell, Richard D. Adams and Ken D. Shimizu*

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208 USA. E-mail: shimizu@mail.chem.sc.edu

Received (in Columbia, MO, USA) 8th March 2000, Accepted 5th April 2000

The rigid *syn*- and *anti*-atropisomers of diacids 1 and 2 were synthesized and assigned by symmetry-based methods and X-ray crystallography.

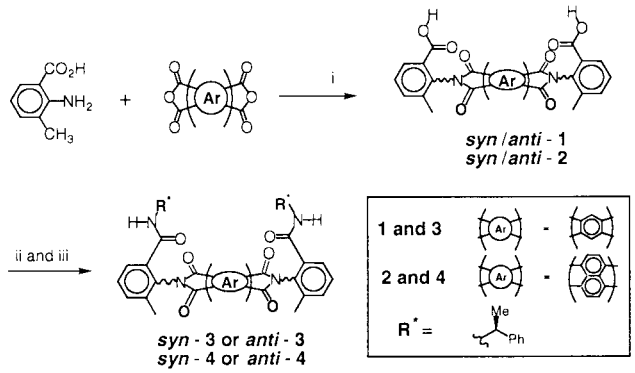
Rigid difunctional molecules are key components in synthetic molecular receptors and shape-persistent molecular polymers.[1,2] Reported herein are the syntheses and structures of two new diacid building blocks **1** and **2**. Both maintain highly rigid



and coherent conformations due to aromatic components and restricted rotation about two linking N_{imide}–C_{aryl} bonds.[3] The resulting *syn*- and *anti*-atropisomers are stable at room temperature but interconvert on heating.

Diacids **1** and **2** were synthesized in high yields by condensation of the corresponding arylamine and aromatic dianhydrides (Scheme 1).[4] In each case, the presence of restricted rotation was immediately evident by the isolation of two spectroscopically similar molecules that interconverted on heating. The stable atropisomers were readily separated by flash chromatography and could be derivatized without isomerization. To further demonstrate their stability, the individual *syn*- and *anti*-isomers of diamides **3** and **4** were synthesized from the corresponding isomers of diacids **1** and **2**.

The rotational barrier of the C_{aryl}–N_{imide} bonds was measured in diamides **3** and **4**. Rotational barriers of $\Delta G^{\ddagger}$ = 29.4 kcal mol^{-1} ($t_{1/2}$ = 35 h at 77 °C) for **3** and $\Delta G^{\ddagger}$ = 34.0 kcal mol^{-1}



Scheme 1 *Reagents and conditions*: i, DMF, reflux, 8 h, (80% yield) or neat, *in vacuo*, 150 °C, 12 h, (95% yield); ii, oxalyl chloride, cat. DMF, CH_2Cl_2, reflux 2 h; iii, (*S*)-α-methylbenzylamine, triethylamine, CH_2Cl_2, 1 h, (70–80% yield for steps ii and iii).

($t_{1/2}$ = 4.1 h at 152 °C) for **4** were determined from the equilibration rates in DMSO. The higher rotational barrier of naphthalene diimide **4** appears to be due to increased steric effects in the six-membered cyclic imides. Molecular modeling calculations correctly predicted the magnitude and ordering of this trend.[5]

For diacids **1** and **2**, 1D and NOE NMR experiments could not lead to assignment of the atropisomers owing to their high symmetries. Instead, symmetry-based characterization methods were applied which efficiently identified the *syn*- and *anti*-isomers without the necessity of X-ray crystallography.[6] Derivatization of the diacids with a chiral auxiliary reduced the symmetry of the corresponding isomers in a predictable manner that yielded characteristic ^{1}H NMR spectra. This was achieved experimentally by reaction of the individual *syn*- and *anti*-isomers of the diacid chlorides of **1** and **2** with (*S*)-α-methylbenzylamine to yield the *syn*- and *anti*-isomers of diamides **3** and **4**. The chiral auxiliary accentuates the differences in symmetry of the *syn*- and *anti*-isomers and allowed assignment based on the chemical equivalence or inequivalence of the protons of the diimide spacer. For example, the two protons of the benzene diimide spacer in **3** are chemically equivalent in the *syn*-isomer and inequivalent in the *anti*-isomer (Fig. 1). A similar analysis of diamide **4** predicts that adjacent protons in *anti*-**4** and diagonal protons in *syn*-**4** are chemically equivalent. The corresponding ^{1}H NMR spectra of *anti*- and *syn*-**4** exhibited two singlets and two doublets, respectively.

Corroboration for the symmetry-based assignments was provided by polarity-based arguments and an X-ray crystal

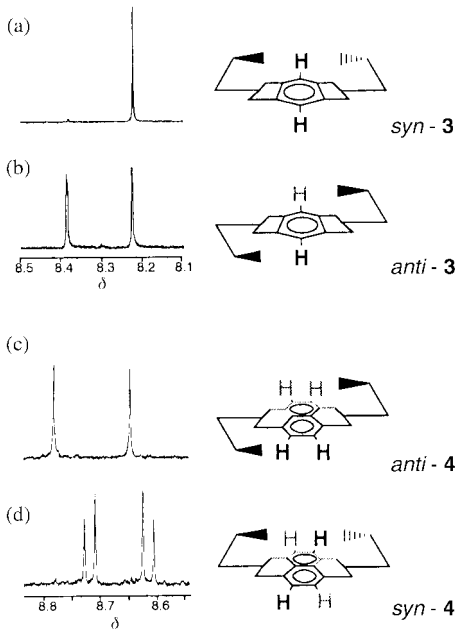


Fig. 1 Proton NMR spectra (DMSO-d_6, 400 MHz) of chiral diamides **3** and **4** and schematic representations showing the symmetry present in each rotamer; (a) *syn*-**3**, (b) *anti*-**3**, (c) *anti*-**4**, (d) *syn*-**4**.

DOI: 10.1039/b002085k

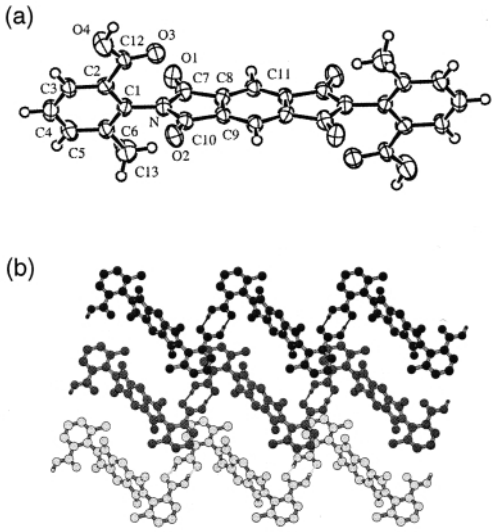

Fig. 2 (a) X-Ray structure of *anti*-**1** and (b) extended hydrogen-bonded ribbon structure of **1**. Solvent molecules and non-carboxylic acid hydrogens have been omitted for viewing clarity.

structure of *anti*-**1**. Initially, the atropisomers were tentatively identified based on polarity as measured by thin layer chromatography on silica gel. The *anti*-conformer was expected to be the less polar (higher R_f) owing to its inversion symmetry.[7] For all of the *N*,*N*′-diarylimide atropisomers examined thus far, the symmetry- and polarity-based assignments have been in agreement. In the case of diacid **1**, further evidence for the correct assignment was provided by an X-ray crystal structure [Fig. 2(a)] of the *anti*-isomer, which was crystallized from $MeCO_2H$–CH_2Cl_2.† The *anti*-configuration was immediately evident from the inversion symmetry of the space group ($P\bar{1}$) coupled with the small unit cell that contained approximately half of the atoms in diacid-**1**.

The structure also revealed interesting information about the molecular and extended structures. The positions of the non-hydrogen atoms of *anti*-**1** were well defined and revealed a structure with the *N*-aryl rings rotated 73° out of the plane of the diimide spacer. In the extended structure [Fig. 2(b)] *anti*-diacid **1** forms a hydrogen-bonded ribbon polymer with channels along the *a*-axis filled with disordered acetic acid dimers which was the source of the relatively high *R*-value for the structure.

This work was supported by grants from the NSF (DMR-9807470) and the Research Corporation (RI0081).

5 The barriers of rotation were calculated using MM2 as implemented in MacroModel v5.5 (F. Mohamadi, N. G. J. Richards, W. C. Cuida, R. Liskamp, M. Lipton, C. Caufield, G. Chang, T. Hendrickson and W. C. Still, *J. Comput. Chem.*, 1990, **11**, 440). The rotational barrier varied greatly with the step angle of the dihedral driver. Accurate values were attained only for small step angles of < 1°. Larger step angles would jump over the barrier and predict considerably smaller rotational barriers.

Received (in Basel, Switzerland) 16th March 2000, Accepted 17th April 2000

***C,O*-Chelated tetracarbonyl[*o*-methoxyphenyl(methoxy)-carbene] complexes of molybdenum(0) and tungsten(0) react with tin tetrahalides SnX_4 (X = Cl, Br, I) by oxidative decarbonylation and incorporation of two halides to form novel chelated hepta-coordinated Fischer-type tricarbonyl-(bishalogeno)carbene molybdenum(II) and tungsten(II) complexes**

Heteroatom-stabilized Fischer-type transition-metal carbene complexes are important stoichiometric or catalytic reagents for the transformation of organic substrates and for the synthesis of organometallic compounds.[1] For instance, the carbene complexes $[(CO)_5M{=}C(OR)R']$ (M = Cr, Mo, W; R = Me, Et; R′ = alkyl, aryl, ...) react with boron trihalides BX_3 by abstraction of OR^- and substitution of a halide ion for a CO ligand to give carbyne complexes, *trans*-$[X(CO)_4M{\equiv}CR']$ (Scheme 1).[2] Apart from boron trihalides, other Lewis acids such as aluminium or gallium trihalides[3,4] or ethyl aluminium dichloride[4] have also been employed in the synthesis of carbyne complexes.[5]

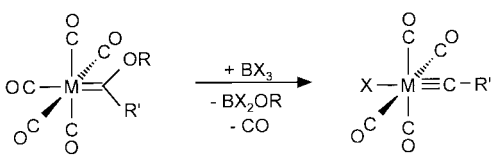
We now observed that the reactions of chelated alkoxy-carbene complexes of molybdenum and tungsten with the Lewis acids SnX_4 deviate from this carbene → carbyne transformation pattern and report (i) on the facile oxidation of the central metal in these complexes and (ii) on the formation of novel hepta-coordinated group 6 metal(II) carbene complexes.

Addition of a solution of $SnCl_4$ to the *C,O* carbene chelate complex **1a**[6] in CH_2Cl_2 led to an immediate gas evolution. The originally brown solution turned red and a white precipitate formed. From the position and the intensity ratio of the ν(CO) absorptions (2049s and 1974vs cm^{-1}) in the IR spectrum† of the reaction solution it followed that very likely a carbyne complex[7] had not been formed. The conclusion was confirmed by the ^{1}H NMR spectrum of the new complex (Scheme 2, **2a**). The spectrum exhibited, in addition to signals for four aromatic protons, two singlets at δ 4.49 and 4.94 (ratio 4 : 3 : 3) indicating that both MeO groups of **1a** were still present in the new complex. The mass spectrum indicated that two chloride atoms had been incorporated into the complex.

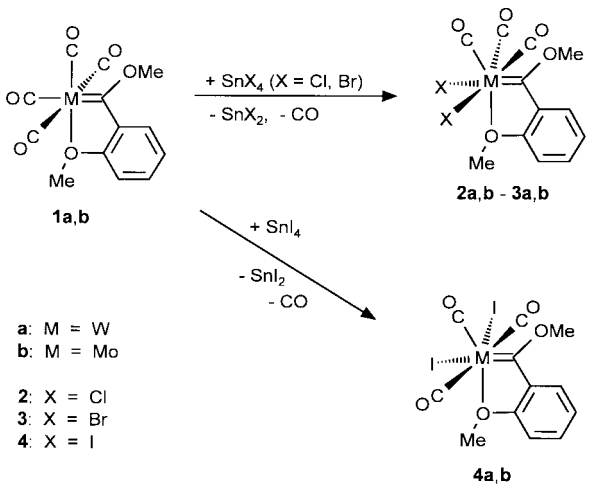
Finally, from pentane–CH_2Cl_2, crystals suitable for an X-ray analysis were grown.‡ The structure of **2a** is shown in Fig. 1. The metal is hepta-coordinated and the complex is C_s-symmetric. The mirror plane formed by the *C,O*-chelating carbene ligand, the tungsten atom and one CO ligand bisects the Cl–W–Cl angle and one OC–W–CO angle.

Obviously, $SnCl_4$ had not induced the abstraction of the methoxide substituent from the carbene carbon atom to give a tungsten(0) carbyne complex but rather acted as an oxidizing agent to give a tungsten(II) carbene complex.

The conversion of **1a** into **2a** is quantitative as could be shown by following the reaction of **1a** with $SnCl_4$ in $CDCl_3$ by



Scheme 1



Scheme 2

^{1}H NMR spectroscopy. Analogously to $SnCl_4$, treatment of **1a** with $SbCl_5$ or $TiCl_4$ also afforded complex **2a**. In contrast, when $AlCl_3$ was added to a solution of **1a** only rapid decomposition of the complex was observed.

The related tungsten(II) dibromo carbene chelate complex **3a** and the corresponding molybdenum(II) complexes **2b** and **3b** (Scheme 2) were obtained by reaction of **1a** with $SnBr_4$ and of **1b**[5] with $SnCl_4$ and $SnBr_4$, respectively. The IR spectra of the resulting complexes were similar to that of **2a** indicating a similar structure.

In contrast, the diiodo carbene chelate complex **4a** (Scheme 2), formed when **1a** was treated with SnI_4, exhibited three rather than two ν(CO) absorptions and three CO resonances in the ^{13}C NMR spectrum, as compared to two for **2a**,**b** and **3a**,**b**. These observations indicated that the structure of **4a**,**b** deviates from

Fig. 1 Molecular structure of **2a**. Scheme 3

that of **2a**. Presumably, the structure of **4a** is derived from that of **2a** by a mutual halide/CO exchange of two ligands outside the mirror-plane. The reaction of the molybdenum complex also proceeded rapidly, however, the resulting compound **4b** turned out to be very labile and could not be isolated. Its formation could only be established by IR spectroscopy.

Deviating from the tungsten and molybdenum complexes **1a**,**b** the corresponding chromium complex did not react with $SnCl_4$. Within several hours in solution in the presence of $SnCl_4$, as well as in its absence, only a slow decomposition of the carbene complex and formation of $[Cr(CO)_6]$ was observed.

From these observations it was concluded that an energetically high-lying HOMO at the metal is required for the oxidative decarbonylation of **1a**,**b** by SnX_4. The assumption is supported by the absence of a reaction between $SnCl_4$ and the non-chelated *o*-anisylcarbene(pentacarbonyl) complex $[(CO)_5W{=}C(OMe)C_6H_4OMe\text{-}o]$. After several hours at room temperature in CH_2Cl_2 only small amounts of **2a** could be detected, presumably formed *via* CO elimination to form **1a** which then rapidly reacts with $SnCl_4$. In contrast, the reaction of the phenylcarbene complex $[(CO)_5W{=}C(OMe)Ph]$ with excess $SnCl_4$ afforded among other compounds a carbyne complex.

However, chelation of the carbene ligand is not a prerequisite for the oxidative decarbonylation as is shown by the reaction of **1a** with PMe_3. Ring-opening of the metallacycle in **1a** by PMe_3 afforded the *cis*-carbene(tetracarbonyl)phosphine complex **5** which subsequently was transformed by $SnCl_4$ into the chelated tungsten(II) carbene complex **6** (Scheme 3).

Tungsten(II) complexes of the type $(CO)_3(L)_2(X)_2W$ have been shown to catalyze the ring-opening polymerization of norbornene.[8] Likewise, complexes **2**–**4** are active ROMP catalysts for norbornene even at room temperature. The highest catalytic activity was observed with the molybdenum complex **2b** which even at room temperature readily induces without a cocatalyst (i) the ring-opening polymerization of norbornene and norbornadiene and (albeit slowly) of cyclopentene, (ii) the polymerization of phenylacetylene, and (iii) the isomerization of pent-1-ene into pent-2-ene.

Hepta-coordinated Fischer-type Mo(II) and W(II) carbene complexes are exceedingly rare. Usually, Fischer-type carbene complexes react with oxidizing agents by oxidative decomplexation of the *carbene* ligand.[1a] Until now, the oxidative decarbonylation of group 6 carbonyl–carbene complexes has only been observed in the reactions of Br_2 with some Lappert-type carbene complexes in which the electron density at the central metal is increased by cyclic strongly electron-donating bisaminocarbene ligands $=C[N(R)–CH_2–]_2$.[9] Our results indicate that Fischer-type Mo(II) and W(II) carbene complexes are readily accessible by oxidation of Mo(0) and W(0) carbene complexes as soon as their oxidation potential is reduced by substitution of a suitable strong donor for a CO ligand.

Financial support of this work by the Fonds der Chemischen Industrie is gratefully acknowledged.

Palladium catalysed cyclisation-Barbier-type allylation cascades

Usman Anwar, Ronald Grigg* and Visuvanathar Sridharan

Molecular Innovation, Diversity and Automated Synthesis (MIDAS) Centre, School of Chemistry, Leeds University, Leeds, UK LS2 9JT. E-mail: r.grigg@chem.leeds.ac.uk

Received (in Cambridge, UK) 5th April 2000, Accepted 18th April 2000

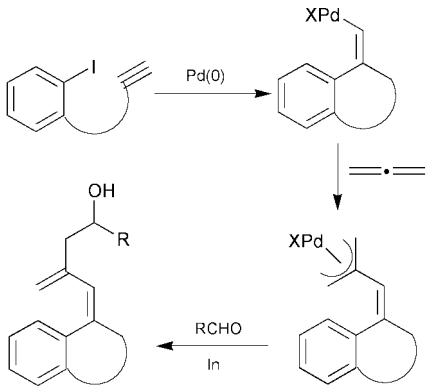
Pd(0) catalysed termolecular queuing processes involving cyclisation of aryl halides onto proximate alkynes, allene (1 bar) insertion, transmetallation of the resulting π-allylpalladium(II) species with indium and addition to an aldehyde affords heterocyclic and carbocyclic dienes.

Our ongoing development of palladium catalysed polycomponent cyclisation-queuing processes has provided powerful methodology for the construction of carbocyclic and heterocyclic rings with accompanying substantial increases in molecular complexity.[1]

Recently we reported the palladium–indium mediated Barbier-type allylation of aldehydes with allenes[2] and identified four synthetic variants of this Pd–In mediated reaction depending on whether the Pd or In step was *intra*- or *inter*-molecular.

We now describe the incorporation of this reaction into a palladium catalysed cyclisation-termolecular queuing cascade. This cascade involves palladium catalysed cyclisation of an aryl iodide moiety onto proximate alkynes followed by allene insertion.[3] The resulting π-allylpalladium(II) species then undergoes transmetallation with indium metal generating an allylindium species which subsequently adds to the aldehyde component, affording heterocyclic and carbocyclic dienes (Scheme 1). Marshall and Grant have described transmetallation of allenylpalladium(II) species (sp^2-C–Pd) with indium salts[4] and very recently a report of the transmetallation of conventionally generated π-allylpalladium(II) species with In(I) and In(III) halides has appeared.[5]

Reaction (DMF, 84 °C, 8–16 h, Schlenk tube) of alkynes **1a**–**c** (1.0 mmol) with allene (1 bar), aldehydes (1.0 mmol) and indium powder (1.6 mmol) in the presence of a catalytic system comprising 10 mol% $Pd(OAc)_2$ and 20 mol% tris(2-furyl)-phosphine afforded the expected six- and seven-membered



Scheme 1

Table 2

Alkyne	Aldehyde	Product	Yield(%)
 **1d**	 **2a**	 **6a**	43
 **1e**	 **2e**	 **6b**	43

carbo- and hetero-cyclic products with aromatic, hetero-aromatic and aliphatic aldehydes. Products of alkene isomerisation were not detected under these conditions (Table 1).

We next turned our attention to alkynes **1d** and **1e** (Table 2). When these compounds were subjected to the same reaction conditions as **1a**–**c** the expected cascade ensued but the resulting products, **6a** and **6b**, were the isomeric conjugated dienes.

A possible mechanism, which explains the formation of **6a** and **6b**, is shown in Scheme 2. The driving force for the proposed 1,5-H shift is the developing aromaticity in the rearrangement transition state. This latter factor is absent in **3a**–**d**, **4** and **5a**–**c**.

These reactions further emphasise the versatility of the palladium–indium cascade process. There is clearly considerable scope for variation of the carbonyl and allene components and further developments are in hand.

Deliberate combination of coordination polymers and hydrogen bonds in a supramolecular design strategy for inorganic/organic hybrid networks

Christer B. Aakeröy, Alicia M. Beatty, Destin S. Leinen and Keith R. Lorimer

Department of Chemistry, Kansas State University, Manhattan, KS, USA. E-mail: aakeroy@ksu.edu

Received (in Columbia, MO, USA) 1st February 2000, Accepted 20th April 2000

Two crystal structures containing infinite CuI chains connected into 2-D layers by non-covalent interactions demonstrate how coordinate covalent bonds and hydrogen bonds can be combined in the design of new inorganic/organic hybrid materials.

Crystal engineering of inorganic/organic hybrid materials is typically based on a modular approach, where discrete building blocks are linked into larger networks.[1] The construction of these metal-containing networks has, so far, been achieved using two different design philosophies: adjacent transition-metal complexes are linked either through (i) coordinate covalent bonds[2] or (ii) weaker intermolecular forces (*e.g.* hydrogen bonds, aryl–aryl interactions, *etc.*).[3] Both methods have enjoyed considerable success, but there have been few *planned* attempts at using a combination of these approaches to build lamellar or 3-D architectures. Here we present two crystal structures based on copper(I) iodide and an auxiliary hydrogen-bonding ligand that demonstrate how the two philosophies can be forged into a supramolecular tool that has not yet been employed in a systematic manner.

One of the main challenges in crystal engineering is to control the assembly and solid state structures in three dimensions. This task is complicated by the fact that ionic/molecular building blocks are capable of adopting a vast number of orientations in the crystal, thus making predictions of the resulting structure very difficult. Coordination polymers, however, are typically very robust and the topology of such networks can often be predicted with the aid of well known principles of coordination chemistry.[4] Thus, by using an infinite coordination polymer with known topology instead of a discrete complex as a synthetic module, the resulting assembly process will have fewer degrees of freedom, which facilitates intermolecular synthesis. Why then use anything but coordination polymers in the design of hybrid materials? Weaker intermolecular forces can impart properties to solids that sometimes offer advantages over 'pure' coordination polymers. Materials held together by hydrogen bonds tend to be more readily soluble, which is desirable for reasons ranging from ease of synthetic modification and manipulation to crystal growth and structural characterization.[5] In addition, unlike the more rigid frameworks of coordination polymers, a network generated through hydrogen bonds[6] can 'flex' to accommodate changes in its environment, and may therefore lend itself to host–guest applications that are less accessible in a rigid framework.[7]

Copper(I) complexes with monodentate ligands, $(CuXL)_\infty$ (where L is a pyridine derivative and X is a halide), are known to form robust halogen-bridged 1-D step, stair or chain structures,[8] and several 2-D coordination polymers based on 'pre-formed' 1-D copper(I) iodide chains and cross-linking bidentate ligands have recently been reported.[9–11]

In order to change network strength and flexibility without making significant changes to the *topology* of the structure, we have replaced the bidentate bridging ligand (*e.g.* pyrazine or 4,4′-bipyridine) with a supramolecular linker capable of simultaneous metal coordination and self-complementary hydrogen bonding. To this end, we report the syntheses† and crystal structures‡ of $[CuI(3\text{-pyridinealdoxime})]_\infty$ **1** and $[CuI(\text{isonicotinamide})]_\infty$ **2**.

The crystal structure of **1** contains 3-pyridinealdoxime ligands coordinated to a polymeric 'staircase' of CuI. Each tetrahedral Cu(I) ion is coordinated to three μ_3-I ligands to generate an infinite 1-D motif. The 3-pyridinealdoxime ligand is attached to each Cu(I) ion through the pyridine nitrogen atom [Cu(1)–N(1) 2.059(3) Å], to complete the coordination sphere. The oxime ligands are staggered ($N_{py}\cdots N_{py}$ internuclear distance *ca.* 4.1 Å) along the polymeric CuI chain and protrude outward. Adjacent oxime moieties are connected *via* O–H···N hydrogen bonds [O(7)···N(7), 2.841(3) Å], in a catemer-like fashion, to propagate the 1-D polymeric chains into an infinite 2-D sheet (Fig. 1). The sheets are non-interpenetrating resulting in a lamellar structure. There are no short contacts or noteworthy aryl–aryl interactions between adjacent chains, or between neighboring sheets.

The crystal structure of **2** is very similar to **1** and also contains infinite polymeric Cu(I) chains. The isonicotinamide ligand occupies the fourth coordination site of the Cu(I) center by coordination through the pyridine nitrogen atom [Cu(1)–N(1) 2.02(2) Å].

Adjacent isonicotinamide molecules form two self-complementary N–H···O hydrogen bonds [N(8)···O(9) 2.87(3) Å] to yield a head-to-head amide–amide dimer. Through this intermolecular interaction, the carboxamide functionalities act as linear, bridging linkers between CuI 'staircases' to generate two-dimensional infinite sheets almost identical to those displayed by **1**, Fig. 2.

The structures of **1** and **2** are very similar to copper(I) iodide architectures where copper–halide staircases are interconnected through covalent bonds by bridging bidentate ligands.[10] In general, these staircases are normally aligned parallel to each other along the short axis of the unit cell. The length of this axis (which also corresponds to the Cu···Cu separation within a staircase) is *ca.* 4.1–4.4 Å for CuI,[9,10] 3.95–3.98 Å for CuBr, and 3.75–3.78 Å for CuCl containing motifs. The precise orientation and separation of neighbouring ribbons is determined by the specific geometry of the ligand(s). Variations in

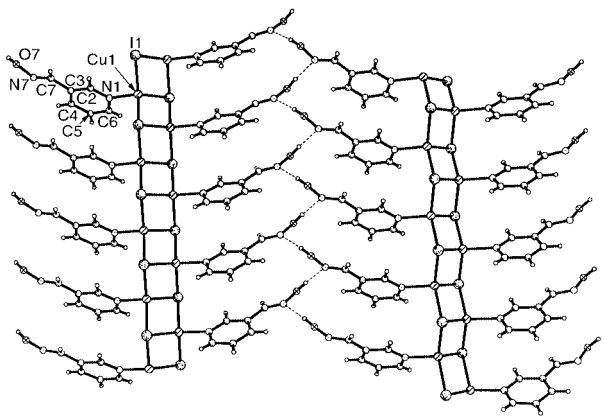

Fig. 1 Infinite 2-D sheets of $[CuI(3\text{-pyridinealdoxime})]_\infty$ **1**. Adjacent oxime moieties bridge polymeric 'staircases' of CuI *via* catemeric hydrogen bonds.

DOI: 10.1039/b001001o

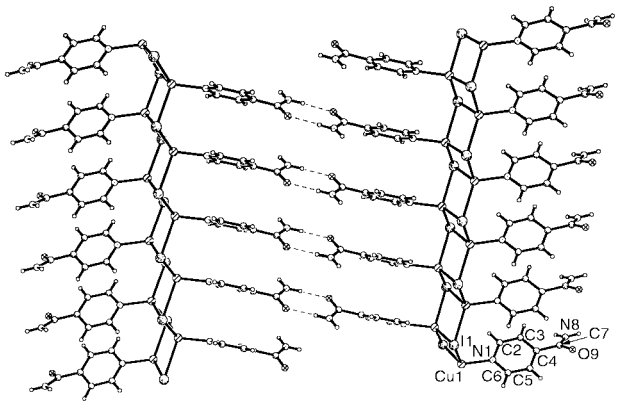

Fig. 2 Infinite 2-D sheets of $[CuI(isonicotinamide)]_\infty$ **2**. Head-to-head amide–amide interactions between isonicotinamide ligands cross-link CuI 'staircases'.

the size and substituent position(s) of the ligand also lead to modifications of the resulting layer (*e.g.* planar *vs.* undulating).

Although the chemical properties of the hydrogen-bonding moieties on the two pyridine-based ligands in **1** and **2** are different, their structural influence is very similar: network topologies and unit cell dimensions are nearly identical.[12] This, of course, is a benefit of using 1-D polymeric chains as building blocks; they are structurally reliable and therefore reduce the task of prediction and control to a much simpler problem. By extending this combined coordination polymer/hydrogen-bond design strategy, one can envisage using a 'pre-formed' 2-D coordination polymer in combination with suitable organic hydrogen-bonding linkers to obtain custom-built porous solids for host–guest applications, *e.g.* separation and catalysis. Further development and applications of this design principle are currently underway in our laboratories.

We acknowledge financial support from Kansas State University and DuPont.

Notes and references

† All starting materials were purchased from Aldrich and used as received. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. In both cases, yields were *ca.* 70–75%.

$[CuI(3\text{-pyridinealdoxime})]_\infty$, **1**: 3-pyridinealdoxime (0.10 g, 0.82 mmol) in the minimum amount of diethyl ether was layered on top of CuI (0.16 g, 0.84 mmol) in acetonitrile. The layered solution was covered and allowed to stand in ambient air. After 1–2 days, yellow rods of **1** were obtained. Mp > 210 °C (decomp.).

$[CuI(isonicotinamide)]_\infty$, **2**: acetonitrile was carefully layered over a solution of isonicotinamide in THF. A saturated solution of CuI in acetonitrile was then added dropwise to the acetonitrile layer. The layered solution was allowed to stand in ambient air. Slow diffusion produced yellow rods of **2** in 1–2 days. Mp > 270 °C (decomp.).

‡ *X-Ray crystallography*: crystalline samples of **1** and **2** were placed in inert oil, mounted on a glass pin, and transferred to the cold gas stream of the diffractometer. Crystal data were collected and integrated using a Bruker SMART 1000 system with graphite monochromated Mo-Kα (λ = 0.71073 Å) radiation at 173 K. The structures were solved using heavy-atom methods using SHELXS-97 and refined using SHELXL-97 (G. M. Sheldrick, University of Göttingen). Non-hydrogen atoms were found by successive full matrix least squares refinement on F^2 and refined with anisotropic thermal parameters. Hydrogen atoms for **1** were located on the difference map, and those for **2** were placed at calculated positions. All hydrogen atoms were then refined using a riding model with fixed thermal parameters [U_{ij} = 1.2 U_{ij}(eq) for the atom to which they are bonded] for subsequent refinements.

Crystal data: for **1**: $C_6H_6N_2OCuI$, M = 312.57, monoclinic, space group $P2_1/c$, a = 13.544(1), b = 4.1098(4), c = 15.094(1) Å, β = 105.583(2)°, U = 809.3(1) Å^3, Z = 4, D_c = 2.565 g cm^{-3}, T = 173(2) K, μ(Mo-Kα) = 6.452 mm^{-1}, wR_2 = 0.0665 (1859 reflections collected, 1752 unique), R = 0.0253 [$I > 2\sigma(I)$].

For **2**: $C_6H_6N_2OCuI$, M = 312.57, monoclinic, space group $P2_1/c$, a = 13.459(2), b = 4.0960(6), c = 16.649(3) Å, β = 109.617(3)°, U = 864.6(2) Å^3, Z = 4, D_c = 2.401 g cm^{-3}, T = 173(2) K, μ(Mo-Kα) = 6.040 mm^{-1}, wR_2 = 0.3177 (1997 reflections collected, 1768 unique), R = 0.0868 [$I > 2\sigma(I)$].

ChemComm

Facile dynamical intramolecular exchange of a phosphine ligand between two different metal atoms†

Richard D. Adams,* Burjor Captain, Wei Fu and Perry J. Pellechia

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, USA. E-mail: Adams@mail.chem.sc.edu

Received (in Irvine, CA, USA) 8th February 2000, Accepted 5th April 2000

The cluster complex $PtRu_5(CO)_{15}(PMe_2Ph)(\mu_6\text{-}C)$ has been shown to exhibit facile intramolecular exchange of the phosphine ligand between a platinum and ruthenium atom that is rapid on the NMR timescale at 160 °C.

The ability of polynuclear metal complexes to rearrange their ligand frameworks is central to understanding their reactivity.[1] Today, there are many examples of dynamical exchange of ligands between metal atoms in polynuclear metal complexes.[1,2] CO, CNR and NO ligands are the most common examples of ligands that undergo these exchange processes intramolecularly. Although there is evidence that phosphine ligands may change sites between metal atoms in polynuclear metal complexes,[3] there has heretofore been only one demonstrated example of the *intramolecular* exchange of phosphine ligand between two metal atoms that is rapid on the NMR timescale.[4] Here, we report the first example of facile intramolecular exchange of a phosphine ligand between two different metal atoms in a heteronuclear metal cluster complex.

Reaction of the complex $PtRu_5(CO)_{16}(\mu_6\text{-}C)$ **1**[5] with PMe_2Ph at 25 °C has yielded two new complexes, $PtRu_5(CO)_{15}(PMe_2Ph)(\mu_6\text{-}C)$ **2** (36% yield) and $PtRu_5(CO)_{14}(PMe_2Ph)_2(\mu_6\text{-}C)$ **3** (45% yield).‡ Compounds **2** and **3** were characterized by a combination of IR,§ NMR§ and single-crystal X-ray diffraction analyses.¶ The molecular structures of **2** and **3** are shown in Figs. 1 and 2, respectively. Both compounds are structurally similar to that of **1** and consist of an octahedral cluster containing one platinum and five ruthenium atoms and a single carbon atom in the center. The PMe_2Ph ligand is terminally coordinated to the platinum atom in **2**, while in compound **3** the two PMe_2Ph ligands are both coordinated to ruthenium atoms on opposite sides of the cluster. In both compounds there is a bridging carbonyl ligand between the platinum atom and one of the ruthenium atoms.

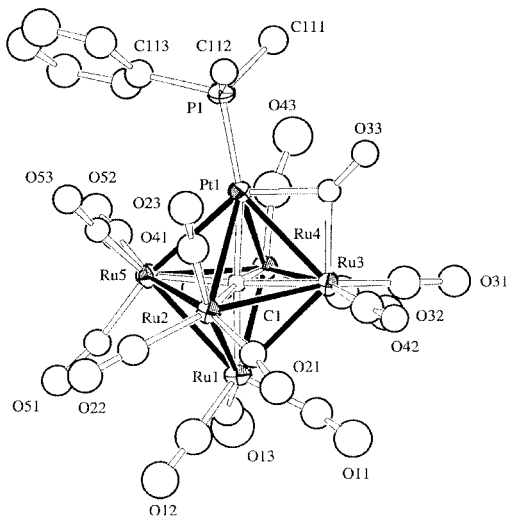

Fig. 1 An ORTEP diagram of the molecular structure of $PtRu_5(CO)_{15}(PMe_2Ph)(\mu_6\text{-}C)$, **2** showing 40% probability thermal ellipsoids. Selected bond distances (Å) and angles (°): Pt(1)–P(1) 2.26(1), Pt(2)–P(2) 2.27(1); Ru(3)–Pt(1)–P(1) 144.5(3), Ru(5)–Pt(1)–P(1) 123.5(3), Ru(10)–Pt(2)–P(2) 145.4(4), Ru(8)–Pt(2)–P(2) 123.6(3).

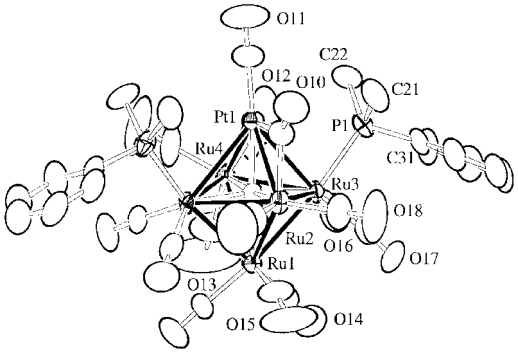

Fig. 2 An ORTEP diagram of the molecular structure of $PtRu_5(CO)_{14}(PMe_2Ph)_2(\mu_6\text{-}C)$ **3** showing 40% probability thermal ellipsoids. Selected bond distances (Å) and angles (°): Ru(3)–P(1) 2.344(2); Pt(1)–Ru(3)–P(1) 81.60(6).

The ^{31}P NMR spectrum of **2** indicates that it exists in solution as a mixture of two isomers in a 7:3 ratio at 25 °C. The resonance of the major isomer, δ −10.52, shows large coupling ($^1J_{PtP}$ 6084 Hz) to the platinum atom indicating that the P and Pt atoms are mutually bonded. By contrast, a small coupling ($^2J_{PtP}$ 115 Hz) to the ^{195}Pt in the phosphorus resonance of the minor isomer, δ 9.51, indicates that the phosphorus atom is coordinated to one of the neighboring ruthenium atoms. This is supported by the ^{31}P NMR spectrum of compound **3** which shows that **3** exists as a mixture of three isomers in solution. One isomer (40% abundance) shows only a single phosphorus resonance with a small ^{195}Pt–^{31}P coupling of 139 Hz. This is assigned to the isomer as found in the solid state that has equivalent phosphine ligands on separate ruthenium atoms. The major isomer (50% abundance) and the minor isomer (10% abundance) both show two phosphorus resonances. For both isomers there is one resonance with large ^{195}Pt –^{31}P coupling, $^1J_{PtP}$ 5999 Hz (major) and $^1J_{PtP}$ 6111 Hz (minor), and one resonance with small coupling, ^{195}Pt–^{31}P, $^2J_{PtP}$ 63 Hz for the major isomer (in the minor isomer the ^{195}Pt–^{31}P coupling was too small to measure). It is proposed that one PMe_2Ph ligand is coordinated to the platinum atom and one PMe_2Ph ligand is coordinated to a ruthenium atom in these two isomers.

^1H NMR spectra of the methyl resonances of **2** at various temperatures are shown in Fig. 3.‖ At 25 °C, two resonances are observed: δ 1.78 (d, 6H, CH_3, $^2J_{PH}$ 10, $^3J_{PH}$ = 53 Hz) (major isomer) and δ 1.98 (d, 6H, CH_3, $^2J_{PH}$ 10 Hz) (minor isomer). The major isomer shows significant ^{195}Pt–^1H coupling. No ^{195}Pt–^1H coupling was observed for the minor isomer. This is consistent with our interpretation of the ^{31}P NMR spectra of **2**. It was observed that the resonances of both isomers broaden and coalesce, reversibly, as the temperature is raised, and most importantly, ^{195}Pt satellites are observed on the resonances in

DOI: 10.1039/b001080o

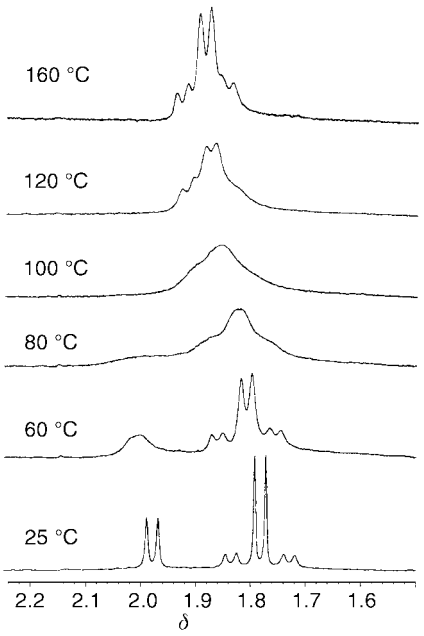

Fig. 3 ^{1}H NMR spectra of compound **2** at various temperatures in 1,2-$C_6D_4Cl_2$ solvent.

the averaged spectrum at 160 °C. The ^{195}Pt–^{1}H coupling of 41 Hz observed at 160 °C is a weighted average of the ^{195}Pt–^{1}H coupling of the two isomers.** These spectra confirm the existence of a dynamical isomerization process by which the phosphine ligand interchanges coordination sites between the platinum atom and one of the ruthenium atoms in **2**, and the observation of the ^{195}Pt–H coupling in the averaged spectra confirms that the process is intramolecular.[6] The exchange broadened spectra were simulated by line shape calculations‖ that have provided exchange rates and in turn activation parameters for the process, $\Delta H^{\ddagger}$ = 15.1(3) kcal mol^{-1} and $\Delta S^{\ddagger}$ = −7.7(9) cal K^{-1} mol^{-1} for the transformation of the major isomer to the minor isomer, and $\Delta H^{\ddagger}$ = 14.5(3) kcal mol^{-1} and $\Delta S^{\ddagger}$ = −11.4(9) cal K^{-1} mol^{-1} for the transformation of the minor isomer to the major isomer.**

A mechanism to explain these observations is shown in Fig. 4. The structure of the major isomer is represented in diagram **2a**. The proposed structure of the minor isomer is represented in diagram **2b**. The dynamical isomerization between **2a** and **2b** can be explained by a shift of the phosphine ligand from the platinum atom to one of the neighboring ruthenium atoms. It is proposed that the phosphine ligand is shifted to the ruthenium atom positioned opposite to that containing the bridging carbonyl ligand. The process may be initiated by a series of CO ligand shifts that traverse the intermediate **A**. To form **A** from **2a**, the bridging CO ligand is shifted to a terminal position on the platinum atom and two terminal CO ligands on ruthenium atoms are shifted to bridging positions across two adjacent Ru–Ru bonds. The structure of **A** is analogous to that of the compound $PtRu_5(CO)_{14}(PPh_2CH_2CH_2PPh_2)(\mu_6\text{-}C)$ **4** recently reported by Lee and Shapley in which both phosphorus atoms of the chelating ligand are coordinated to the platinum atom.[7] The exchange process is completed by a shift of the phosphine ligand from the platinum atom to the ruthenium atom. The bridging CO ligands are shifted to terminal positions as indicated by the arrows in **A** and a terminal CO ligand is moved into a bridging position across the same Pt–Ru bond that contained the bridging CO ligand in **2a**.

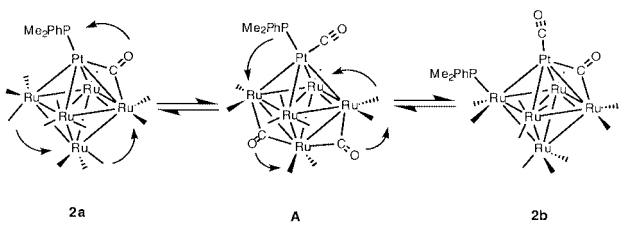

Fig. 4 A proposed mechanism for the isomerization of two isomers of compound **2** by intramolecular shifts of the phosphine and carbonyl ligands between the metal atoms. The carbon atom in the center of the cluster is omitted for clarity.

This research was supported by the Division of Chemical Sciences of the Office of Basic Energy Sciences of the U. S. Dept. of Energy.

¶ *Crystal data*: for **2**: $PtRu_5PO_{15}C_{24}H_{11}$, M_r = 1270.76, orthorhombic, space group $Pna2_1$, a = 44.897(5), b = 14.590(2), c = 10.208(2) Å, V = 6687(2) Å^3, T = 20 °C, μ = 6.47 mm^{-1}, R_1 = 0.050, R_2 = 0.080. Two structurally similar independent molecules in the asymmetric crystal unit; anisotropic refinement on Pt, Ru and P only.

For **3**: $PtRu_5P_2O_{14}C_{37}H_{28}$, M_r = 1459.01, monoclinic, space group $P2_1/m$, a = 9.407(1), b = 25.955(7), c = 9.980(1) Å, β = 113.41(1)°, V = 2236.0(7) Å^3, T = 20 °C, μ = 4.88 mm^{-1}, R_1 = 0.034, R_2 = 0.046. Compound **2** has mirror symmetry in the solid state; anisotropic refinement of all non-hydrogen atoms.

CCDC 182/1610. See http://www.rsc.org/suppdata/cc/b0/b001080o/ for crystallographic files in .cif format.

‖ Lineshape simulations of spectra in the exchange broadened region were preformed by using the program EXCHANGE written by R. E. D. McClung, Dept. of Chemistry, University of Alberta, Edmonton, Alberta, Canada. Variable temperature ^{1}H NMR spectra of compound **3** show that it is also undergoing dynamical processes indicative of rapid phosphine ligand exchanges.

** A plot of the temperature dependence of the equilibrium, minor isomer to major isomer, provided the thermodynamic parameters $\Delta H°$ = 0.58(8) kcal mol^{-1} and $\Delta S°$ = 3.7(3) cal K^{-1} mol^{-1}. From these parameters the ratio of the major isomer/minor isomer is calculated to be 3.3:1 at 160 °C. From this ratio, the weighted average of the ^{195}Pt–^{31}P coupling constant is calculated to be 40.7 Hz.

Proquinoid acceptors as building blocks for the design of efficient π-conjugated fluorophores with high electron affinity

Jean-Manuel Raimundo, Philippe Blanchard, Hugues Brisset, Said Akoudad and Jean Roncali*

Ingénierie Moléculaire et Matériaux Organiques, CNRS UMR 6501, Université d'Angers, 2 Bd Lavoisier, 49045 Angers Cedex, France. E-mail: jean.roncali@univ-angers.fr

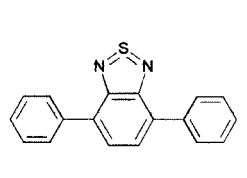
Received (in Cambridge, UK) 24th March 2000, Accepted 17th April 2000

The association of aromatic electron donor groups with proquinoid acceptors leads to π-conjugated fluorophores combining tunable emission wavelength at constant geometry, high fluorescence efficiency and high electron affinity.

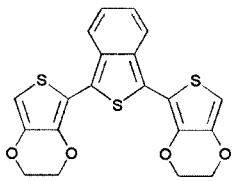
Conjugated fluorophores usable as active materials for light emitting diodes (LEDs) should ideally combine high emission quantum yields, tunable emission spectra and high electron affinity in order to allow electron injection from stable metal cathodes.[1]

The difficulty of meeting these various prerequisites with a single compound has given rise to specific synthetic approaches. Thus, control of the emission wavelength has been realized by adjusting the conjugation length of the fluorophore,[1,2] while increases in electron affinity have been achieved by incorporation of electron deficient groups, such as *e.g.* cyano or oxadiazole, in the π-conjugated system.[1,3]

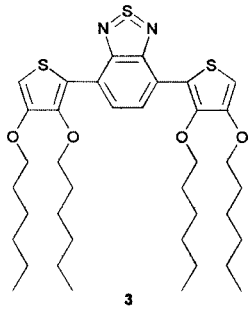
It has been shown that the association of five-membered heterocycles with electron-deficient systems such as thienopyrazine or benzo[*c*]thiadiazole (BTD) which have a strong propensity to impose a quinoid geometry on the ground state of the conjugated system, leads to polymers with small intrinsic band gaps.[4] As part of our continuing interest in band gap engineering,[5] we have synthesized a new series of tricyclic π-conjugated systems **1**–**4** based on this approach. Besides their



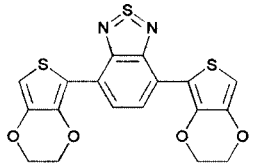
1



2



3



4

use as precursors for low band gap polymers,[6] these compounds exhibit original electronic and optical properties which make them potentially interesting for the design of photoluminescent materials for LEDs.

Compounds **1**, **3** and **4** were synthesized from 4,7-dibromo-2,1,3-benzothiadiazole.[7] Compound **1** was obtained by Suzuki coupling with phenyl boronic acid and compounds **3** and **4** were prepared by Stille coupling with the tributylstannyl derivatives of 3,4-dihexyloxythiophene[8] and 3,4-ethylenedioxythiophene, respectively (Scheme 1). Compound **2** was prepared using a procedure already described for the synthesis of 2,5-dithienylbenzo[*c*]thiophene.[9] Reaction of phthaloyl chloride with 2-mercaptopyridine led to 1,2-bis[*S*-(2-pyridyl)]benzenedithioate **6** which was then reacted with 3,4-ethylenedioxy-2-thienylmagnesium bromide to give diketone **5**. Compound **2** was then obtained by ring closure with the Lawesson reagent (L.R.). Compounds **1**–**4** have been characterized by ^{1}H and ^{13}C NMR spectroscopy, mass spectrometry and elemental analysis.†

Table 1 lists the cyclic voltammetric (CV) and optical data for compounds **1**–**4**. Literature data for terphenyls (**3P**) and terthienyl (**3T**) have been included for comparison. Compounds **1**–**4** are reversibly reduced to their anion radicals and irreversibly oxidized owing to electropolymerisation. The values of the absorption maximum (λ_{max}) and HOMO–LUMO gap, ΔE (estimated from the absorption edge), for **3P** and **1** show that replacement of the median phenyl ring by the BTD group produces a 100 nm red shift of λ_{max} and a 1.10 eV decrease in ΔE. Comparison of the anodic peak potentials (E_{pa}) for **3P** and **1** shows that the BTD group scarcely affects the oxidation

[a] In 0.1 M NBu_4PF_6–MeCN, ref. SCE, 100 mV s^{-1}. [b] In CH_2Cl_2. [c] *vs.* Ag/AgCl (ref. 11). [d] In NBu_4Br–DMA (ref. 11). [e] In cyclohexane (ref. 12). [f] In NBu_4–DMF (ref. 13). [g] In dioxane (ref. 14).

potential but produces a positive shift of the reduction peak potential (E_{pr}) by more than 1.30 V, indicating a considerable increase in electron affinity.

As expected, thiophene-based compounds exhibit smaller ΔE values than **1** owing to the lower resonance energy of thiophene and the electron releasing effect of the alkoxy groups.[5]

Comparison of the optical data for **3T** and **2** shows that the combined effects of replacement of the median thiophene by benzo[*c*]thiophene and electron-releasing ethylenedioxy substituents produce a *ca.* 100 nm red shift of λ_{max} associated with a 0.70 eV decrease in ΔE. On the other hand, the 0.54 V decrease in E_{pa} and the 0.20 V positive shift of E_{pr}, indicated by the CV data, show that the gap reduction is essentially related to raising of the HOMO level.

Further replacement of the benzo[*c*]thiophene in **2** by the BTD group (**3** and **4**) produces a 6–31 nm red shift of λ_{max} and a small decrease in ΔE. However, the 0.40–0.50 V parallel positive shift of both E_{pa} and E_{pr} shows that the BTD group induces major changes in the HOMO and LUMO levels, with again a large enhancement of electron affinity. The small decrease in ΔE from **3** to **4** and the slight negative shift of E_{pa} reflects the stronger electron-donating effect of the ethylenedioxy bridge compared to dialkoxy chains.[8]

The fluorescence properties of compounds **1**–**4** have been analyzed in CH_2Cl_2 and the emission quantum yields (ϕ_f) have been determined against anthracene in 95% EtOH for **1**, and perylene in 95% EtOH for **2**–**4**. Introduction of BTD in the **3P** system produces a 150 nm red shift of the emission maximum (λ_{em}) and a 50 nm increase in the Stokes shift. Whereas the effect of BTD on ϕ_f is difficult to evaluate due to the different experimental conditions, the measured value of 0.80 for **1** shows that ϕ_f remains high.

Comparison of the data for **3T** and **2**–**4** reveals a large red shift of λ_{em} (up to 200 nm for **4**) and a 70–80 nm increase in the Stokes shift for **2** and **4**. Furthermore, the three compounds exhibit a considerable increase in ϕ_f which reaches a value as high as 0.92 for **2**. The significant increase in ϕ_f compared to the analog of **2** based on unsubstituted thiophene (ϕ_f = 0.67),[10] underlines the strong effect of the ethylenedioxy substituents on the fluorescence efficiency.

To summarize, we have shown that the insertion of proquinoid acceptor groups in short-chain π-conjugated oligomers leads to fluorophores with a unique combination of enhanced electron affinity, high fluorescence efficiency and ready control of the emission wavelength at constant chain length. In addition to the intrinsic interest of these compounds as a new class of efficient fluorophores, the above synthetic strategy could open interesting perspectives for the design of active molecular or polymeric materials for LEDs.

Received (in Bloomington, IN, USA) 3rd September 1999, Revised manuscript received 15th December 1999, Accepted 15th March 2000

Hydrogenation of arenes, including the lignin model compound 2-methoxy-4-propylphenol, has been effected using a Rh colloid in biphasic aqueous/supercritical ethane reaction media; this is the first successful example of an unsupported colloid-catalysed hydrogenation of a substrate in a supercritical fluid; the same reaction does not proceed in aqueous/supercritical carbon dioxide or ionic liquid/supercritical fluid media.

Catalysis performed in aqueous/organic biphasic media, with the catalyst in the aqueous phase and hydrophobic substrates and products in the organic phase, is appealing for industry because the products can be separated cleanly and easily from the catalyst with negligible loss of catalyst.[1] However, given the ability of water to retain high levels of organic solvent residues, the disposal of the aqueous phase can be problematic. A more environmentally benign alternative is to use aqueous/supercritical fluid (SCF) biphasic media for catalysis. In such a scheme the catalyst resides in the aqueous phase and the non-polar SCF phase dissolves and transports the substrates, reagent gases (if any) and products. The advantages of using SCFs such as carbon dioxide ($scCO_2$) or ethane (scC_2H_6) over liquid organic solvents include lower environmental impact, enhanced diffusion rates of H_2, ease of recycling, and facile removal of the SCF solvent from the product and from the aqueous phase.[2] Aqueous/SCF biphasic media have been found to be effective for several types of catalysts, including enzymes,[3] antibodies,[4] and water-soluble homogeneous catalysts.[5,6] We now report the use of aqueous/SCF biphasic media for arene hydrogenation with a colloidal catalyst.

Hydrogenation of arenes, an important chemical process in the synthesis of fine chemicals,[7] can be catalysed by Raney nickel, supported palladium or nickel catalysts, homogeneous catalysts or colloidal catalysts. Many of the "homogeneous" catalysts that have been reported for arene hydrogenation are in fact catalytically active colloidal metal particles.[8] Such particles are known to be quite active and are usually prepared *in situ* in biphasic aqueous/organic reaction media.[9] Hydrogenations with this type of catalyst can be achieved at room temperature and low hydrogen pressure.[10,11]

Colloid-catalysed reactions in SCFs or aqueous/SCF biphasic media have not been much studied in the past. Zemanian *et al.* reported minimal conversion (0.25–1%) in the hydrogenation of naphthalene to tetralin using a colloidal $CoMoO_3$ catalyst in reverse micelles in supercritical butane at 135–155 °C.[12] In our laboratory we have tested the hydrogenation of a series of arenes in a biphasic, aqueous/SCF using Rh colloids generated *in situ* from the complex $[RhCl(cod)]_2$.

The first tests in this series were of the hydrogenation of 2-methoxy-4-propylphenol. This compound was selected because results published earlier[13] showed it to be particularly difficult to hydrogenate and because it is a model for the phenolic groups in lignin; the hydrogenation of the aromatic rings in lignin has been proposed as a method of preventing the yellowing of mechanical pulps.[13,14] The reactions were performed in 1.5 mL aqueous buffer and 29.5 mL of supercritical fluid, with the catalyst precursor, surfactant (tetrabutylammonium hydrogen sulfate, THS) and arene typically in a Rh : THS : arene ratio of 1 : 3 : 50.

The hydrogenation did not proceed in aqueous/$scCO_2$ biphasic media (Table 1); the likely reason being the low pH due to the dissolution of CO_2 in the aqueous phase (see ESI†). Rh colloidal catalysts are particularly sensitive to pH, with optimum activity at pH 7.4–7.6.[10] In order to bypass the pH problem, attempts were made to use a non-aqueous polar solvent in place of the water.‡ For example, the ionic liquid $[bmim]BF_4$ (bmim = 1-butyl-3-methylimidazolium cation) is insoluble[15] in $scCO_2$ and therefore is an appropriate substitute. Unfortunately, the colloidal catalyst in the present experiments was not active for hydrogenation in $[bmim]BF_4/scCO_2$, $[bmim]BF_4/scC_2H_6$, or $[bmim]BF_4$/pentane mixtures. The catalyst may have been inactivated by the ionic liquid itself or by trace chloride ions[16] remaining from the preparation of the ionic liquid.

In an aqueous/supercritical ethane (scC_2H_6) biphasic medium, excellent results were obtained (Scheme 1 and Table 1). At a substrate : Rh ratio of 10 : 1, complete conversion was obtained, while at 50 : 1, the reaction was 88% complete (Table 1). This is the first successful example of the use of an aqueous-phase colloidal catalyst for the hydrogenation of a substrate in a supercritical phase. Hydrogenations using liquid C_2H_6 as the non-polar phase were also achieved. In all cases, the major

Table 1 Reaction conditions for the hydrogenation of 2-methoxy-4-propylphenol[a]

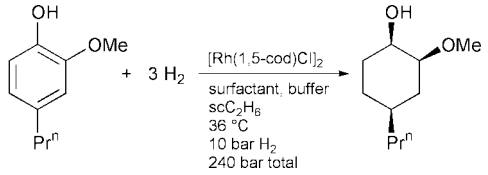
[a] The catalyst precursor $[RhCl(1,5\text{-cod})]_2$ was used for all reactions. The buffer is 0.1 M Na_3PO_4, 0.05 M citric acid, and 0.2 M boric acid except where noted. The buffer pH refers to the pH at room pressure. [b] Substrate / rhodium mole ratio. [c] 1 M AOT, conversion determined by GC. [d] 0.5 M Na_3PO_4, 0.05 M citric acid and 0.2 M boric acid. [e] 1 M MOPS solution.

† Electronic supplementary information (ESI) available: experimental details, description of the effect of changing the buffer, plot of pH of aqueous buffers under 10 atm H_2 and varying pressures of CO_2. See http://www.rsc.org/suppdata/cc/a9/a907193h/



Scheme 1

product was *cis*-2-methoxy-*cis*-4-propylcyclohexanol. The minor product, which had been observed in small amounts in earlier studies, was *cis*-2-methoxy-*trans*-4-propylcyclohexanol. The ratio of products was 8 : 1 in all runs, regardless of whether scC_2H_6 or an organic liquid was used. This high selectivity indicates that the hydrogenation of the arene ring takes place without the partially-hydrogenated substrate dissociating from the catalyst.[14]

Switching the surfactant from THS (0.04 M) to AOT (dioctylsulfosuccinate, sodium salt, 1 M), which has been used previously for the preparation of aqueous/scC_2H_6 emulsions,[17–20] resulted in a dramatic drop in the catalytic activity.§

The extension of the method to the hydrogenation of simpler arenes was also explored (Table 2). In these experiments, an even higher substrate : Rh ratio of 100 : 1 was used. Conversions were high in all cases. The hydrogenation of 4-phenylbutanone was essentially complete and highly selective for hydrogenation at the arene ring only. *p*-Xylene was primarily converted to *cis*-1,4-dimethylcyclohexane, although it is interesting that the selectivity for hydrogenation on a single face was greater for 2-methoxy-4-propylphenol than xylene. One could speculate that the hydroxy and methoxy groups help anchor the substrate to the metal surface.

Catalytic activity in this system may be related to the solubility of the substrates. The range of arenes tested encompasses hydrophilic and hydrophobic arenes. Phenol, which is very soluble in water and essentially insoluble in alkanes, was completely hydrogenated. It is tempting to conclude that solubility in water is a requirement for efficient hydrogenation by this method, but the conversion of *p*-xylene, which is far more soluble in alkanes than it is in water, was still fair. Unfortunately, the literature does not contain solubility data for these arenes in scC_2H_6, but the solubility is expected to be similar to that in $scCO_2$. Xylene[21] and anisole[22] are completely miscible with $scCO_2$ but benzyl alcohol[23] and phenol[24] have limited solubilities of 1–2 mol% at 36–40 °C and elevated pressures (above 140 bar). Despite this wide range of solubilities, the extent of hydrogenation was satisfactory for all substrates.

Table 2 The hydrogenation of other arenes in H_2O/scC_2H_6[a]

Substrate	TON	Products (%)
	100	 (100%)
	110[b]	 (73%)
	99	 (97%) (2%)
	77	 (77%)
	79	 (53%) (26%)
	96	 (96%)

[a] Conditions: 36 °C, 62 h, 31 mL vessel, 240 bar total pressure (10 bar H_2, balance ethane), 9.5 μmol $[RhCl(1,5\text{-cod})]_2$, 76 μmol THS, and 1.9 mmol arene (arene : Rh ratio of 100 : 1) were used for all reactions. The buffer is 0.1 M Na_3PO_4, 0.05 M citric acid and 0.2 M boric acid (buffer volume 1.7 mL, pH at atmospheric pressure 7.5). TON = turnover number = mol product per mol Rh. [b] Arene : Rh ratio of 150 : 1.

In conclusion, arene hydrogenation is catalysed by Rh colloids with high conversion in an aqueous/scC_2H_6 biphasic medium. The same reaction in aqueous/$scCO_2$ biphasic medium does not proceed, probably due to pH problems which could not be alleviated by the use of buffers. These results are new examples of transition-metal catalysed reactions in aqueous/SCF biphasic solvent mixtures.

We acknowledge experimental assistance from Miss Denise Nakawatase and Mr Christopher Ablan, valuable discussions with Dr Joan Brennecke (University of Notre Dame), and funding from the University of California.

Notes and references

‡ This is complicated by the fact that most polar organic solvents are quite soluble in $scCO_2$. For example, using a methanol or methoxyethanol solution of the Rh catalyst precursor gave no conversion, presumably because the organic solvent entirely dissolved in the supercritical phase.
§ The effect of applying shear to create an emulsion was not tested.

Received (in Oxford, UK) 9th March 2000, Accepted 26th April 2000

A new open-framework fluorinated gallium phosphate (MIL-31) containing the $Ga_9(PO_4)_9(H_2O)(OH)(OH,F)_4^{5-}$ anion was hydrothermally synthesized by using long alkyl chain diamines (C_9 and C_{10}) as structure-directing agents; its crystal structure is built up from hexameric units and exhibits large one-dimensional hexagonal channels delimited by 18-rings.

The search for new large pore materials has received much attention because of their potential applications in catalysis, ion exchange or molecular sieving. Historically, most of the porous solids are zeolite aluminosilicates and metal phosphates. Since the discovery of $AlPO_4$-*n*[1] in 1982, the syntheses of a large diversity of new open-framework structures[2] have been reported, many incorporating other elements such as B, Be, Ga, In, Sn, Sb or transition metals as well as oxyfluorides, sulfides, phosphonates, carboxylates, *etc*. Phosphate-based three-dimensional architectures contain pores larger than those usually observed in aluminosilicates. Whereas the pore size limit encountered in silicates corresponds to 14-membered rings (UTD-1[3]), some phosphates are characterized by extra large pore open-frameworks with 16-ring (Ga-ULM-5,[4] Ga-ULM-16,[5] Fe-ULM-15[6]), 18-ring (Al-VPI-5[7]), 20-ring (Al-JDF-20,[8] Ga-cloverite,[9] FePO,[10] GaPO[11]) and very recently 24-ring channels (Ni-VSB-1,[12] Zn-ND-1[13]). We now report here a new fluorinated gallium phosphate exhibiting a three-dimensional open-framework with 18-ring channels.

The MIL-31 compounds were synthezised under mild hydrothermal conditions by using either 1,9-diaminonane (DAN) or 1,10-diaminodecane (DAD) as structure-directing agents. There were prepared (180 °C, 3 days, autogenous pressure) from a mixture of gallium oxyhydroxide [GaO(OH), prepared from the reaction of gallium metal (4N, Rhône-Poulenc) with water at 200 °C for 24 h), phosphoric acid (H_3PO_4, 85%, Prolabo), hydrofluoric acid (HF, 48%, Prolabo), tripropylamine [NPr^n_3 (TPA), 98% Aldrich], 1,9-diaminononane [$H_2N(CH_2)_9NH_2$, 98% Aldrich] or 1,10-diaminodecane [$H_2N(CH_2)_{10}NH_2$, 97% Aldrich] and deionized water. Typically, the molar ratio was 1 Ga (0.356 g) : 1 P (0.16 ml) : 0.5 F (0.06 ml) : 80 H_2O (5 ml) : 0.4 TPA (0.25 ml) : 0.25 DAN (0.137 g) or 0.25 DAD (0.149 g). TPA was added in order to fix the reaction pH to between 3 and 4. Without TPA, only dense quartz-type $GaPO_4$ is formed. The resulting white thin needle-like crystals were filtered off, washed with water and dried at room temperature. The XRD patterns of both powdered samples were new and identical. With DAN, the compound was obtained with a yield of 90% together with a small amount of unreacted GaO(OH) whereas the yield is lower (70%) using DAD. However, only single crystals of the phase using DAD were suitable for X-ray structure determination† after hydrothermal treatment for one month. With DAN, the crystals were too small (even after a long reaction time). Only cell parameters can be extracted by using a conventional X-ray source diffractometer.‡

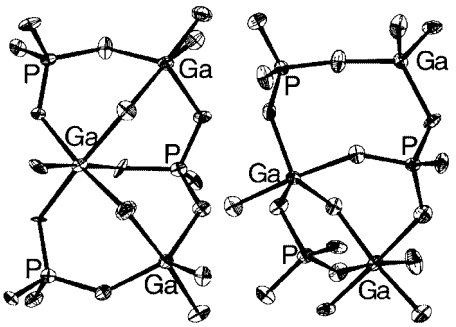

Fig. 1 Hexameric building units of MIL-31: $Ga_3(PO_4)_3(OH,F)_2$ of type I (left) and $Ga_3(PO_4)_3(OH)(H_2O)$ or type II (right).

The structure of MIL-31 consists of the connection of three crystallographically distinct building units (BU) composed of three phosphate groups and three gallium polyhedra (Fig. 1). Two of them are identical to that already observed in the ULM-*n* series[13] (denoted type I) built up from three PO_4 tetrahedra corner-sharing with one $GaO_4(OH,F)_2$ octahedron and two $GaO_4(OH,F)$ trigonal bipyramids. Within these hexameric units, the octahedron is in a central position and linked to the two $GaO_4(OH,F)$ trigonal bipyramids by corner-sharing *via* fluorine or hydroxy groups. These hexameric blocks are connected to each other whilst conserving strict Ga–P alternation in order to generate a sheet of composition $[Ga_6(PO_4)_6(OH,F)_4]$ in the *ab* plane (Fig. 2). In this layer, two adjacent units have opposite orientation, as already encountered in the 3D framework of ULM-16[5] or the 2D solid ULM-8.[14]

These hexameric-based layers are connected through a second type of BU (type II) with Ga_3P_3 stoichiometry. In this entity, the three phosphate groups share corners with three gallium polyhedra which exhibit three different coordinations:

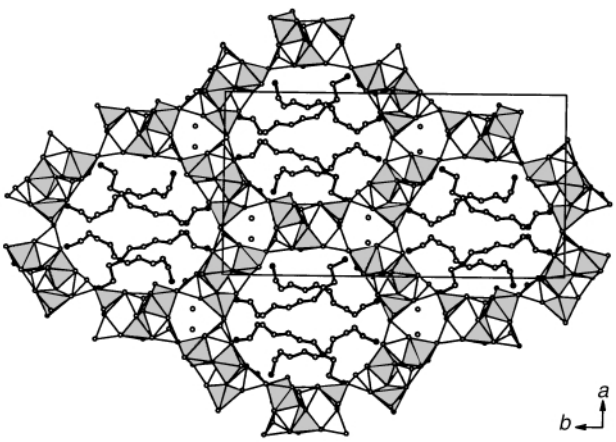

Fig. 2 View of the structure of MIL-31 along the 18-ring channels (along the *c* axis).

DOI: 10.1039/b001948h

GaO_4 tetrahedra, $GaO_4(OH)$ trigonal bipyramids and $GaO_4(OH)(H_2O)$ octahedra. The gallium bipyramidal unit is in the central position and has one common hydroxy group with the gallium octahedral unit. This BU is derived from TO_4-based 4-ring units (T = tetrahedral Ga or P species) forming infinite double-crankshaft chains as found in ULM-16.[5] In MIL-31, additional $GaO_4(OH)(H_2O)$ and PO_4 groups are connected to the 4-ring unit. This induces a change of the coordination of one of the GaO_4 tetrahedra to give a $GaO_4(OH)$ bipyramid. All the vertices of the gallium polyhedra are shared with the PO_4 polyhedra, except the terminal water molecule attached to the $GaO_4(OH)(H_2O)$ octahedron [Ga–OH_2 2.115(7) Å] pointing towards the channel centre. Such a situation was previously observed for the aluminophosphate VPI-5[15] in which one of the aluminium sites has an octahedral surrounding. This aluminium atom is at the center of the Al_3P_3 hexameric unit and is coordinated to four PO_4 groups and to two terminal water molecules.

Fluorine chemical analysis gave three fluorine atoms per $Ga_9(PO_4)_9$ unit which implies a statistical OH/F occupancy for the five observed Ga–X–Ga (X = OH or F) bridging positions. The ^{19}F NMR spectrum indicates only one signal at δ −93.8 (ref. $CFCl_3$) characteristic of bridging fluorine, but the spectral resolution precludes any assignment. However, in BU II the Ga–X distance (< Ga–X > = 1.93 Å) is smaller than in BU I (< Ga–X > = 2.00 Å). As only one peak is visible by ^{19}F NMR spectroscopy and given the measured fluorine content in the material, we can assume that the bridging site in BU II is only occupied by a hydroxy group and the fluorine would thus be located on the other bridging sites of the BU I.

The connection of these different building units generates a three-dimensional framework $[Ga_9(PO_4)_9(OH,F)_4(OH)(H_2O)]^{5-}$ composed of large hexagonal-shaped tunnels with 18- and 6-membered rings running along the *c* axis (Fig. 2). Two diprotonated diamines are inserted within the larger channels whereas two water molecules are trapped in the 6-ring channels. Each terminal ammonium group of the organic template interacts with anions of the framework *via* hydrogen bonds, with distances in the range 2.8–3.1 Å. These interactions occur between fluorine or hydroxy anions and one of the terminal ammonium groups of the template as already found in other phases of the ULM-*n* series.[14] The water molecules in the 6-ring channels interact with the ammonium groups *via* hydrogen bonding.

Besides the four positive charges from the organic molecules, an additional positive charge is required for the electroneutrality of the structure and might come from one H_3O^+ residing within the pore system. The pore opening diameter is *ca.* 12 Å but the presence of the terminal water of the gallium octahedron reduces thus to 10 Å along the *b* axis. The framework density calculated from the number of cations per 1000 Å^3 is 12.6 for MIL-*n* and is comparable to that found in the faujasite[16] structure (12.7) but lower than that observed in VPI-5 (14.2) which is also of 18-ring based topology.

The thermal behaviour of the DAN phase was characterized by X-ray diffraction and thermogravimetric analyses. The TG curve (Fig. 3) shows three major events. The first step (30–150 °C) is related to the removal of water (exptl: 4.30%; calc: 1.84%). The difference between the values would be due to the departure of five water molecules (calc: 4.50%) per $Ga_9(PO_4)_9$ unit, two found in the crystal structure analysis and three corresponding to adsorbed water. The second event (300–500 °C) can be assigned to the departure of the alkyldiamine and the observed experimental weight loss shows that the organic template is partly removed from the framework (exptl: 10.51%; calc: 16.51%). Above 600 °C, the weight loss is continuous and corresponds to 6.61% at 1000 °C. The XRD diagrams show clearly that the resulting structure is collapsed and transforms into dense $GaPO_4$ (high cristobalite). The weight loss can be assigned by assuming the removal of hydroxy groups and fluorine (exptl: 6.61%; calc: 4.67%) and additional organic template.

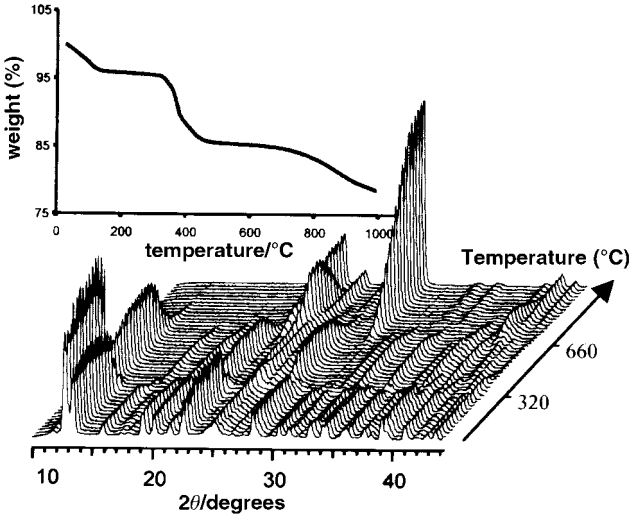

Fig. 3 Evolution of X-ray diffraction powder patterns as a function of temperature (30–1000 °C under air) and TG curve of MIL-31 (2 °C min^{-1} under N_2).

Di- and oligo-nuclear nickel complexes with oxalic amidinato bridging ligands: syntheses, structures and catalytic reactions†

Thomas Döhler, Helmar Görls and Dirk Walther*

Institut für Anorganische und Analytische Chemie der Friedrich-Schiller-Universität, D-07743 Jena, Germany. E-mail: cdw@rz.uni-jena.de

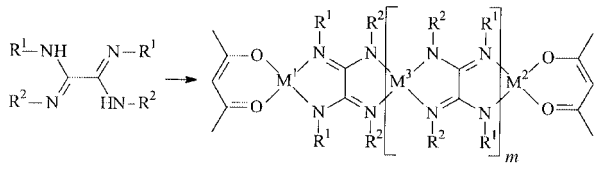
Received (in Basel, Switzerland) 21st January 2000, Accepted 26th April 2000

A new family of di-, tri- and tetra-nuclear Ni(II) complexes containing oxalic amidinates as bridging ligands is described in which both peripheral Ni centres are catalytically active in the oligomerization or polymerization of ethylene or in the selective cross coupling of Ar–X with Ar′–MgX.

Di- or oligo-nuclear metal complexes of late d metals connected *via* the conjugated π-system of oxalic amidinato ligands ('oxam') are attractive candidates for catalytic reactions, because the ligands are easily accessible and their steric and electronic properties can be easily modified. Furthermore, systems with different metals in peripheral positions enable catalysts to be designed in which either one or two metals are catalytically active. In addition, the metal coordinated at the opposite side of an active metal centre may be used for fine tuning the catalytic activity.

Since oxalic amidinato ligands tend to form ill-defined polymers with metal salts[1,2] their coordination chemistry is very limited.[3–6] Neither dinuclear d^8 metal complexes nor tri- or oligo-metallic complexes are known. Furthermore, catalytic C–C-linking reactions are also unknown.

Surprisingly, the Ni(II) complexes **1**–**4** (Scheme 1, $m = 0$) are obtained by reacting $Ni(acac)_2$ in toluene or THF with a variety of oxalamidines. Recrystallisation from toluene resulted in red–brown diamagnetic crystalline complexes in 35–60% yields. According to ^{1}H NMR spectroscopy on **1**–**5** the ratio of acac to oxalic amidine ligand was 2:1 supporting dimeric structures (Scheme 1).‡



1 $m = 0$, R^1, R^2 = phenyl, M^1, M^2 = Ni
2 $m = 0$, R^1, R^2 = tolyl, M^1, M^2 = Ni
3 $m = 0$, R^1, R^2 = mesityl, M^1, M^2 = Ni
4 $m = 0$, R^1 = tolyl, R^2 = mesityl, M^1, M^2 = Ni
5 $m = 0$, R^1, R^2 = mesityl, M^1 = Ni, M^2 = Zn
6 $m = 1$, R^1, R^2 = mesityl, M^1, M^2 = Ni, M^3 = Zn

Scheme 1

The solid state structure of the key complex **4** was determined by X-ray diffraction and Fig. 1 displays its molecular structure.§

As expected, the oxalamidinate acts as bridging ligand connecting two (acac)Ni(II) fragments with both metal centres essentially planar. Although **4**, containing different N-substituents, may exist as two isomers, to our surprise only one isomer was observed, in which both metal centres have different coordination environments: one metal is surrounded by two mesityl–N groups, the other by two *p*-tolyl–N groups. The aromatic substituents are oriented to the ligand plane at an angle of 90°. The ^{1}H NMR spectrum confirms the presence of only one isomer in solution. Complexes **1**–**5** can be considered as the first members of a series of oxalamidinato complexes of general composition $L_nM^1(oxam)[M^3(oxam)]_mM^2L_n$ ($m = 0$).

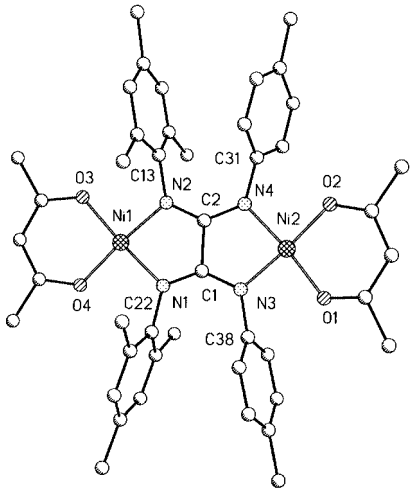


Fig. 1 Molecular structure of **4**. Selected bond distances (Å) and bond angles (°): Ni1–N1 1.880(8), Ni2–N2 1.886(8), Ni1–O3 1.841(7), Ni1–O4 1.843(7), Ni2–N3 1.879(8), Ni2–N4 1.902(8), Ni2–O1 1.845(7), Ni2–O2 1.854(7), C1–C2 1.518(13), N1–C1 1.304(12), N2–C2 1.311(12), N3–C1 1.316(13), N4–C2 1.334(12); O4–Ni1–N1 90.3(3), O3–Ni1–N2 90.9(3), N2–Ni1–N1 83.9(3), O3–Ni1–O4 94.8(3), O1–Ni2–N3 89.7(3), O2–Ni2–N4 91.4(3), N3–Ni2–N4 84.5(4), O1–Ni2–O2 94.4(3).

The trimetallic complex [(acac)Ni(oxam)Zn(oxam)Ni(acac)] **6** is the first example of the next generation of this series (m = 1, M^1, M^2 = Ni; M^3 = Zn, oxam = tetramesityloxalamidine) which was prepared by reacting of 2 equiv. of oxam with $ZnEt_2$ in toluene , followed by addition of 2 equiv. of $Ni(acac)_2$ in good yields.

The Ni_2Zn_2 complex **7** is the first example of a tetrametallic complex of the above-mentioned range prepared from 2 equiv. of $ZnEt_2$ and 3 equiv. of bis(mesityl)bis(*p*-tolyl)oxalamidine in THF, followed by reaction with 2 equiv. of $Ni(acac)_2$. Red crystalline complex **7** was isolated upon recrystallisation of the product from toluene. Elemental analyses, mass spectra, and the ^{1}H NMR spectrum confirm its composition. Its X-ray structure (Fig. 2) shows that both peripheral Ni centres have the same planar environment as in **4**, while the two central Zn atoms are tetrahedrally coordinated.

Table 1 shows that all the complexes are catalytically active towards ethylene when activated with MAO or Et_3Al. In contrast to the well established Ni catalysts for the SHOP process,[7] in which negatively charged P–O ligands support the oligomerization of ethylene, we observed both oligomerization and polymerization of ethylene (Table 1).

A comparison of **2** (runs 1 and 2 in Table 1) and **3** (runs 5 and 6 in Table 1) clearly shows that the *p*-tolyl groups in **2** promote the oligomerization of ethylene; however, substitution by

[a] *General conditions:* 0.031 mmol catalyst, 10 bar ethylene, 20 ml toluene, 16 h reaction time, room temperature; run 9: most of the polymer was insoluble, only the molecular weight of the soluble fraction was determined.

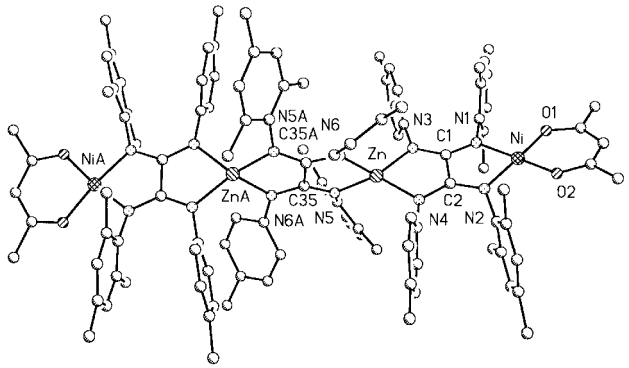

Fig. 2 Molecular structure of **7.** Selected bond distances (Å) and angles (°): Ni–O1 1.840(4), Ni–O2 1.864(4), Ni–N1 1.897(4), Ni–N2 1.885(4), Zn–N3 2.002(4), Zn–N4 2.007(4), Zn–N5 1.996(5), Zn–N6 2.000(5), C1–N1 1.309(6), C1–N3 1.334(7), C2–N2 1.312(7), C2–N4 1.344(7), C1–C2 1.524(8), C35–N5 1.343(7), C35–N6A 1.338(7), C35–C35A 1.518(12), dihedral angle between planes (Ni–O1–O2)/(Ni–N1–N2) 6.9(2), (Zn–N2–N4)/(Zn–N5–N6) 100.8(2). Symmetry transformations used to generated equivalent atoms: A $-x + 3/2, y, -z + 1$.

mesityl groups (in **3**) results in the formation of a selective polymerization catalyst. In contrast to recently described 1.2-diimine or salicylaldiminato complexes of d^8 metals, where very bulky substituents have to be used for selective polymerization,[8–11] in the oxalic amidinato complexes only two additional *ortho*-methyl groups are necessary to switch the reaction from oligomerization to polymerization of ethylene. Since both oligomerization and the polymerization of ethylene occur using **4** as catalyst which contains two different coordination spheres, we can conclude that *both* metals are catalytically active (runs 3 and 4 in Table 1). If the reaction with **3** was carried out heating the reaction mixture from room temperature to 69 °C within 10 min (50 bar ethylene) then 3.7 g of polyethylene was produced giving a TOF of 102 000 h^{-1}.

The catalytic reaction of **6**/MAO with ethylene shows that the Zn moiety in the middle of **6** increases the selectivity towards polymerization compared with **3** (Table 1, runs 5 and 9). This demonstrates the possibility for fine tuning the catalytic activity by using different metals. The tetranuclear complex **7**, however, is a dimerization catalyst when activated with MAO. The complexes can also be used as catalysts in other C–C coupling reactions such as the polymerization of styrene (*e.g.*: **3**/300 equiv. MAO/4000 equiv. styrene yielded 94% polystyrene) or cross coupling, *e.g.* of mesitylmagnesium bromide (500 equiv.) with *p*-tolyl bromide (500 equiv.) to give mesityl–4-tolyl in 99% selectivity and an overall yield of 95% when **4** in THF at ambient temperature was used.

In conclusion, we have shown that di-, tri- and tetra-nuclear complexes of late d metals with oxalamidinates can easily be prepared and used in a number of catalytic C–C-linking reactions. Both peripheral Ni centres are catalytically active in these complexes.

New FeS clusters with NO: associative formation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$, and larger clusters†

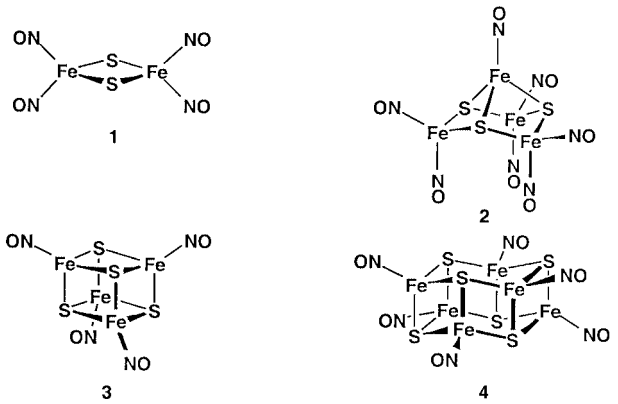
Mark Lewin, Keith Fisher and Ian Dance*

School of Chemistry, University of New South Wales, Sydney 2052, Australia. E-mail: I.Dance@unsw.edu.au

Received (in Cambridge) 3rd March 2000, Accepted 20th April 2000

Solutions of $[Fe_2S_2(NO)_4]^{2-}$ or $[Fe_4S_3(NO)_7]^-$ undergo facile aggregation to new clusters $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$, but do not form the known species $[Fe_4S_4(NO)_4]^z$ and $[Fe_6S_6(NO)_6]^{2-}$; reactivities and reactions in solution and gas phases were monitored by electrospray Fourier transform ion cyclotron resonance mass spectrometry, and the probable structures of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ were determined by density functional calculations.

In 1858 Roussin reported salts of $[Fe_2S_2(NO)_4]^{2-}$ **1** and $[Fe_4S_3(NO)_7]^-$ **2**.[1] Since then there have been numerous publications on derivatives of **1** and **2**,[2–6] but $[Fe_4S_4(NO)_4]^z$ (z = 0, −1) **3**[7–9] and $[Fe_6S_6(NO)_6]^{2-}$, **4**[10] are the only other



known iron sulfide clusters containing only NO ligands. We report here the formation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ by a facile aggregation process, which also yields other larger clusters.

Negative ion electrospray mass spectrometry (ESMS) of a solution of $Na_2[Fe_2S_2(NO)_4]$ in methanol immediately after preparation shows $[Fe_2S_2(NO)_4H]^-$, which rapidly (*ca.* 15 min at 10^{-4} M concentration, 25 °C) converts to a species of *m/z* 647.† By accurate mass analysis of the isotopomer pattern, and collision induced dissociation of NO, this species was confirmed as $[Fe_5S_4(NO)_8]^-$. Subsequently (40 min), $[Fe_5S_4(NO)_8]^-$ in this methanol solution converts to a mixture of $[Fe_4S_3(NO)_7]^-$ and a new species with *m/z* 883, which is confirmed to be $[Fe_7S_6(NO)_{10}]^-$. A solution of $Na_2[Fe_2S_2(NO)_4]$ in acetonitrile also shows the formation of $[Fe_4S_3(NO)_7]^-$ and $[Fe_5S_4(NO)_8]^-$, and eventually $[Fe_7S_6(NO)_{10}]^-$, together with transitory low intensity species at *m/z* 412, 478, only during the early stages.† Solutions of $Na[Fe_4S_3(NO)_7]$ in methanol also show the formation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$, although generated more slowly (7 to 14 d at 10^{-4} M and 25 °C).

These spectra are significant also for the species that are absent. There is no evidence of $[Fe_4S_4(NO)_4]^{z-}$ or $[Fe_6S_6(NO)_6]^{z-}$ (z = 1 or 2) in any of the numerous spectra recorded.† Apart from the strong peaks for $[Fe_4S_3(NO)_7]^-$, $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ the spectra are devoid of peaks in the mass range 500–900. Additional high mass peaks above *m/z* 900 have been observed, but not identified unambiguously.

With ESMS there is a fundamental question whether the observed species exist in the electrosprayed solution or are artefacts of the energetic ES desolvation process. The dependence of the spectra on the history of the solutions is strong evidence for the transformations in solution. Further, we have adjusted the ES capillary potential to effect controlled fragmentation, which involves only NO dissociation and occurs well above the threshold capillary voltage for observation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$.† It is significant that induced fragmentation does not disrupt the FeS cores. The stability and coordinative saturation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ are demonstrated by their inertness to reactive $NO_{2\,(g)}$ in the FTICR cell. After controlled partial dissociation of NO from $[Fe_5S_4(NO)_8]^-$ or $[Fe_7S_6(NO)_{10}]^-$ they do react with NO_2, by oxygen addition.

We have not yet been able to crystallise the new species, but have investigated their structures by validated density functional calculations,[11] evaluating the minimised energies of postulated structures. For $[Fe_5S_4(NO)_8]^-$ eight structure types were investigated, and Fig. 1 shows the best structure found, **548A**, which is a flattened FeS_4 tetrahedron with four edge-bridging $Fe(NO)_2$, and a spin doublet ground state (HOMO–LUMO gap of 1.1 eV). This is 22 kcal mol^{-1} more stable than the next best structure, **548B** (Fig. 1). For $[Fe_7S_6(NO)_{10}]^-$, 29 postulated structures were investigated. The most probable structure, **7610A** (Fig. 2), contains two of the Fe_4S_3 cores fused at one Fe: structures **7610B** and **7610E** are configurational isomers with Fe_4S_3 cores linked by Fe–S bonds; **7610C** also contains the Fe_4S_3 core; while **7610D** is $[Fe_2S_2(NO)_4]$ linked to **548A**. These four isomers are not strongly differentiated in total energy (see Fig. 2). One of the isomers for $[Fe_7S_6(NO)_{10}]^-$ is **5**,

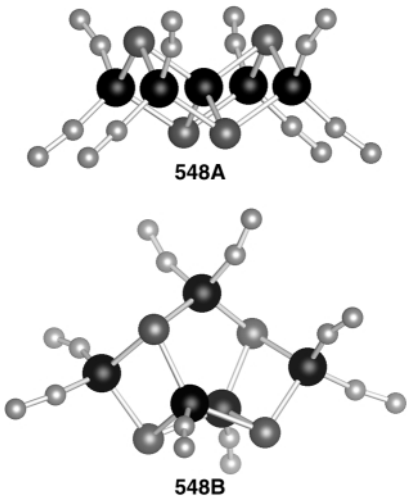


Fig. 1 The optimised structures of isomers **548A** (symmetry D_{2d}) and **548B** (symmetry C_2) of $[Fe_5S_4(NO)_8]^-$: Fe black; S grey, intermediate size; N, O small. The energy of **548B** relative to **548A** is +22 kcal mol^{-1}.

DOI: 10.1039/b001738h

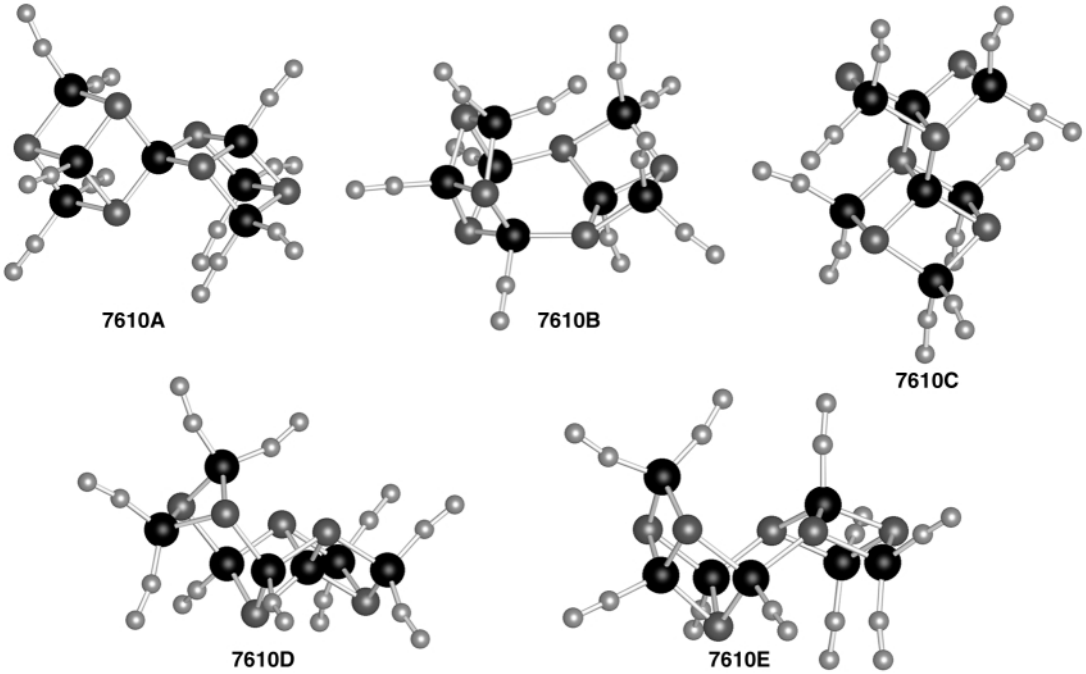

Fig. 2 The optimised structures of the five best isomers of $[Fe_7S_6(NO)_{10}]^-$: Fe black; S grey, intermediate size; N, O small. The symmetries and relative energies (kcal mol^{-1}) are: **7610A**, C_2, 0; **7610B**, C_s, +15; **7610C**, C_s, +18; **7610D**, C_s, +19; **7610E**, C_s, +22.

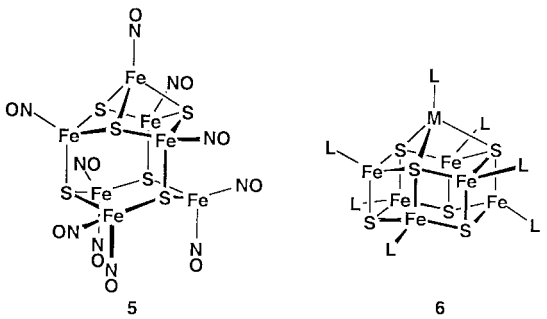

5

6

which is a logical extension of **2**, and is related to the established metal sulfide cluster type **6**,[12] but **5** is 38 kcal mol^{-1} less stable than **7610A**. We believe that our geometry searches have canvassed all reasonable possibilities.

The comparatively fast formation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ suggests facile mechanisms, with uncomplicated connectivity changes between the precursors and the proposed structures. The general absence of observable intermediates during the formation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ indicates that the mechanisms are associative. We can propose a facile mechanism for the assembly of **548A** from three $[Fe_2S_2(NO)_4]$, involving the breaking of only three Fe–S bonds and dissociation of two Fe–NO, with reformation of five Fe–S bonds [stoichiometry eqn. (1)]. For the assembly of **7610A** from $[Fe_5S_4(NO)_8]^-$ in solution according to eqn. (2) we can propose a mechanism involving the breaking of a total of only eight Fe–S bonds in concert with transfer of two NO ligands, and reformation of eight Fe–S bonds.

$$3\,[Fe_2S_2(NO)_4] \rightarrow [Fe_5S_4(NO)_8] + [FeS_2(NO)_2] + 2\,NO \quad (1)$$

$$3\,[Fe_5S_4(NO)_8] \rightarrow [Fe_7S_6(NO)_{10}] + 2\,[Fe_4S_3(NO)_7] \quad (2)$$

An important feature of the reactions observed is that they occur at ambient temperature and low concentration. This is associative cluster formation which is thermodynamically favourable and kinetically facile. In contrast, the formation of **4** (and its precursors) required extended reactions at elevated temperatures.[10] The difference is in the degree of NO dissociation: the Fe–S–NO clusters easily formed by association in solution retain $Fe(NO)_2$ groups, while other established Fe–S cluster cores have at most one terminal ligand per Fe.

The facility of the associative formation of Fe–S aggregates described here could be relevant to the biosynthesis of Fe–S cofactors.[13–15]

The resources used in this research were provided by the Australian Research Council and the University of NSW.

Engineering the surface chemical properties of semiconductor nanoparticles: surfactant-encapsulated CdTe-clusters

Dirk G. Kurth,* Pit Lehmann and Constanze Lesser

Max-Planck-Institute of Colloids and Interfaces, D-14424 Potsdam, Germany. E-mail: kurth@mpikg-golm.mpg.de

Received (in Cambridge, UK) 25th February 2000, Accepted 26th April 2000

Self-assembly of CdTe-nanoparticles and alkylammonium surfactants gives stable, hydrophobic surfactant-encapsulated CdTe-clusters that can be isolated as solid materials which dissolve in common organic solvents, spread at the air–water interface, and show enhanced photochemical stability.

Nanoparticles of semiconductors are at the focus of materials research owing to the novel electronic, catalytic and optical properties of these materials. The unusual properties can be attributed to two main factors: the high surface area to volume ratio and the spatial confinement of electronic states. The confinement results in discrete transitions with highly polarizable excited states that are tunable with particle size.[1]

The synthesis, purification and isolation of stable, discrete nanoparticles preferentially with a narrow size distribution and tailored surface chemical properties represents a considerable challenge because the large surface energy promotes aggregation to minimize the surface area. A successful synthesis should, therefore, result in monodisperse nanoparticles with robust surface passivation. Essentially, there are three methods to achieve these goals with varying success.[2] A common approach relies on decomposition of organometallic precursors, where surface passivation is achieved by coordination of solvent molecules, such as alkylphosphine oxides, to the cluster surface *in situ*.[3] In a second method, particle growth is restricted in confined media, such as polymer micelles.[4] Finally, nanoparticles can be synthesized *via* colloid chemistry where the particles are capped by suitable stabilizing molecules, such as thiocarboxylic acids.[5]

Following our recent work on encapsulated polyoxometalate clusters,[6] we present here, the synthesis and isolation of stable surfactant encapsulated CdTe-clusters (SECs). This self-assembly strategy relies on an ion exchange process of the cluster counter ions with surfactants. This approach has been applied to a variety of particles,[7] including gold colloids,[8] metal[9] and metal oxide clusters.[10] The advantage of our approach is that the preparation of the parent CdTe-clusters rests on well established experimental procedures.[11] The synthesis of CdTe-SECs is achieved in a second independent step by treating aqueous CdTe-solutions with the surfactant dimethyldioctadecylammonium bromide (DODABr). Encapsulation of the CdTe-clusters with surfactants results in hydrophobic SECs, which are readily isolated as solid powder. These semiconductor clusters possess many interesting properties and are, therefore, of considerable technological interest.[12]

The CdTe-clusters were synthesized by treating a demineralized aqueous solution containing thioglycolic acid and $Cd(ClO_4)_2 \cdot 6H_2O$ (0.013 M) at pH 11 with NaHTe in an inert gas atmosphere,[5,11] leading to particles of diameter *ca*. 4 nm.[13] A 4.5 ml aliquot of this solution was diluted to 100 ml with water and the pH was adjusted to 6 by addition of HCl. 50 mg of DODABr was then added and the resulting CdTe-SEC was extracted with chloroform. Quantitative transfer of the CdTe-clusters into the organic phase was observed by visual inspection after 20 min: the chloroform phase turned yellow–brown, while the aqueous phase became colourless. The organic phase was separated, dried and evaporated to yield the CdTe-SEC material as a brown–yellow solid, which readily dissolved in common organic solvents. The solubility properties imply that the surfactant molecules form a closed, hydrophobic shell around the CdTe-core with the positive head groups of the surfactant molecules binding to the surface carboxylates.

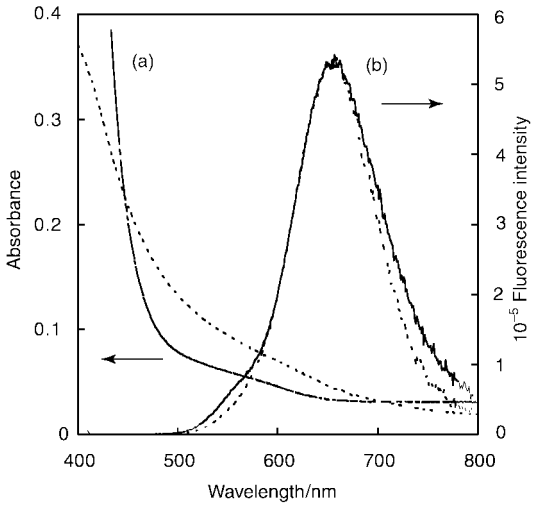

Fig. 1 UV–VIS spectra (a) and fluorescence spectra (b) of CdTe-clusters (——) and CdTe-SECs (- - - -). The fluorescence spectra are normalized for better comparison (excitation wavelength 400 nm). The spectra of the CdTe-clusters and the CdTe-SECs are nearly identical, indicating the structural integrity of the CdTe-clusters within the surfactant encapsulated clusters.

UV–VIS and fluorescence spectroscopy demonstrate that the CdTe-clusters maintain their structural integrity upon encapsulation. The absorbance spectra of the parent CdTe-clusters and the CdTe-SECs are fairly similar (Fig. 1) with both samples showing characteristic shoulders at *ca*. 400 and 600 nm. The fluorescence spectra have similar band positions and widths, indicating that the particle size distributions of the two samples are similar. It is interesting that the apparent fluorescence intensity for the CdTe-SECs is larger by almost a factor of two. These observations demonstrate how sensitive the photophysical properties of the CdTe-nanoparticles are to surface derivatization and local field effects.[14]

A comparison of the long-term development of the fluorescence intensity is shown in Fig. 2. The parent CdTe-clusters show a decay of the fluorescence intensity by an order of magnitude within 4 h. Also shown is the UV–VIS absorbance as a function of time. A decrease in absorbance indicates a loss of material from within the probe beam volume. Although the use of thioglycolic acid for adjusting the pH of the aqueous solution extends the photochemical stability of the CdTe-clusters, the particles are completely decomposed after seven days with the fluorescence intensity and the absorbance falling close to zero. Because CdTe-solutions stored in the dark are stable over extended periods of time, we conclude that a light induced reaction occurs, which eventually results in precipitation of the CdTe-clusters. In contrast, the CdTe-SECs show a steady fluorescence intensity under the same experimental conditions (Fig. 2).† Even after seven days of illumination, the CdTe-SECs maintain most of their initial fluorescence. Clearly, the

DOI: 10.1039/b001563f

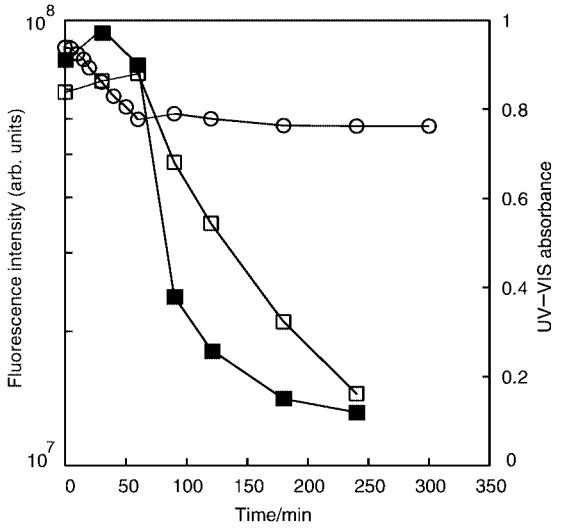

Fig. 2 Fluorescence intensity of CdTe-clusters (□) and CdTe-SECs (○) as a function of time. The CdTe-SECs show a nearly constant fluorescence intensity under irradiation at the excitation wavelength (400 nm). By contrast, the fluorescence intensity of parent CdTe-clusters decays under identical conditions. Also shown is the UV–VIS absorbance at 400 nm of the CdTe-clusters (■). The diminution with time corresponds to a loss of material within the probe beam volume (precipitation) which causes the decrease of fluorescence intensity.

surfactant shell effectively protects the CdTe-core from photo-induced decomposition and precipitation.

The hydrophobic nature of the CdTe-SECs is shown by the fact that they form stable Langmuir monolayers at the air–water interface‡ and Fig. 3 shows a representative compression isotherm which are very reproducible. The area per SEC cannot be obtained from the isotherm because the molecular mass of the CdTe-SECs is, as yet, not known. The isotherm does not show well defined phase transitions, but only a slight shoulder at 20 mN m^{-1} while the collapse pressure is *ca*. 42 mN m^{-1}. Upon expansion a slight hysteresis is visible. The collapse pressure is relatively high, which indicates a good stability of the monolayer. This behavior is similar to that of structurally related surfactant encapsulated polyoxometalate clusters.[6]

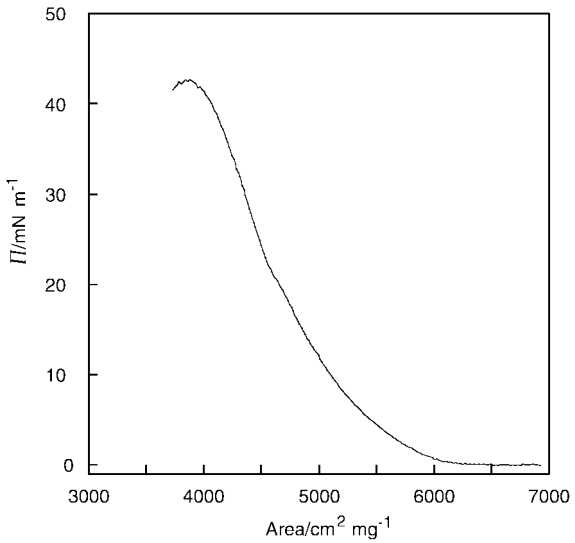

Fig. 3 Representative compression isotherm of a CdTe-SEC at the air–water interface. The Langmuir monolayers are quite stable as indicated by the high collapse pressure of *ca*. 42 mN m^{-1}.

In summary, we have presented a facile non-covalent strategy to tailor the surface chemical properties of semiconductor nanoparticles, including solubility and surface activity. The nanoparticles have been synthesized according to an established experimental procedure. Self-assembly of the charged clusters and dialkylammonium surfactants results in encapsulation and formation of discrete, hydrophobically encapsulated CdTe-clusters. Encapsulation enhances the fluorescence intensity and photochemical stability of the CdTe-nanoparticles.

The study was supported by the Max-Planck Society. Helmuth Möhwald and Stefan Kirstein are acknowledged for valuable discussions.

Notes and references

† Samples were directly irradiated at an excitation wavelength of 400 nm in the spectrometer (Spex Fluorolog 1680 Double Spectrometer) with fully opened slits with fluorescence intensity recorded periodically. UV–VIS spectra were recorded with a Varian Cary 50 Spectrophotometer. After 4 h the samples where removed from the spectrophotometer and stored under daylight. CdTe-SECs were dissolved in chloroform while the CdTe-clusters were investigated in aqueous solution.

‡ Langmuir isotherms were measured with a Lauda film balance (Lauda GmbH&Co KG, Königshofen, Germany) at 20 °C. 2.69 mg of the solid CdTe-SEC were dissolved in 2 ml chloroform and 100 μL of the solution were spread on Milli-Q water (resistance > 18.2 MΩ cm).

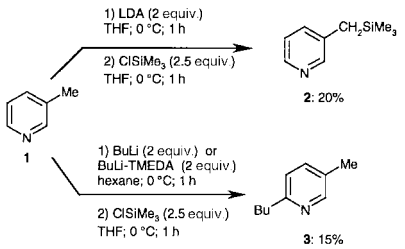
Received (in Liverpool, UK) 28th February 2000, Accepted 13th April 2000

BuLi–$Me_2N(CH_2)_2OLi$ (BuLi–LiDMAE) promoted the clean C-6 functionalisation of 3-picoline *via* a methyl to C-6 lithium shift.

The selective lithiation-functionalisation of 3-picoline **1** remains a synthetic challenge since the potential electrophilicity of the azomethine bond towards alkyllithium reagents as well as a competitivity between acidic protons of the methyl group and those of the heteroaromatic ring must be considered. In fact, a survey of the literature revealed that major studies concern the abstraction of side-chain protons[1] while the selective lithiation of the pyridinic ring has been performed only *via* halogen–metal exchange on the corresponding brominated derivatives.[2] To our knowledge, direct lithiation of the cheap and easily available parent **1** has not yet been described.

Recently, we have reported the usefulness of BuLi–$Me_2N(CH_2)_2OLi$ (denoted BuLi–LiDMAE) for the metallation of pyridine derivatives in apolar solvents. This new reagent prevented the classical nucleophilic addition of BuLi while promoting the regioselective lithiation at C-α of the pyridinic ring.[3] Herein, we describe our investigations on the selective metallation of 3-picoline **1** with BuLi–LiDMAE and its efficiency for the synthesis of 2-substituted-5-methylpyridines.

All our initial attempts to metallate the pyridinic ring of **1** with classical lithium reagents failed (Scheme 1). Reaction with LDA affected exclusively the methyl group[1] giving **2** while BuLi or BuLi–TMEDA led to complex mixtures containing the nucleophilic addition product **3**.



Scheme 1

In contrast, when **1** was treated with BuLi–LiDMAE (3 equiv.),[4] after subsequent quenching with $ClSiMe_3$, neither silylation of the methyl group nor addition products were detected. Moreover, exclusive C-6 silylation of the pyridinic ring occurred and **4a** was isolated in 90% yield. The versatility of this unprecedented reaction was further nicely illustrated by condensation of representative electrophiles[5] (Table 1).†

As shown, clean C-6 functionalisation was observed and products **4b**–**h** were isolated in good to very good yields. Note that the derivatives **4g**–**j** are of particular interest as potentially reactive precursors for further chemical modifications.

Our attention then focused on the interpretation of the obtained regioselectivity. At first we felt that owing to the known higher acidity of side-chain protons,[6] lithiation at the methyl group could be considered as the initial step of the reaction pathway. Thus, we attempted the metallation of

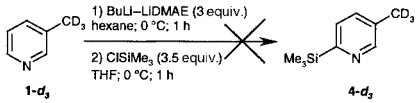
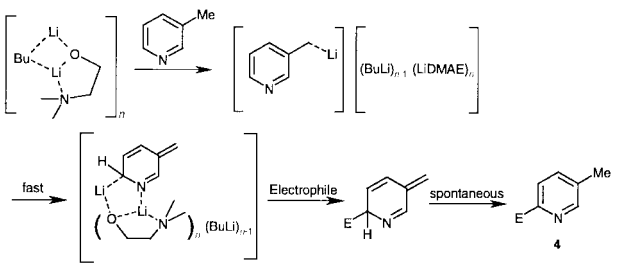


Scheme 2

3-(methyl-d_3)pyridine **1**-d_3 with BuLi–LiDMAE. Deuterium was here expected to act as a carbon protecting group preventing methyl proton abstraction owing to a kinetic isotope effect (KIE).[7] As shown in Scheme 2, no silylated product **4**-d_3 was detected.

This strong KIE clearly indicated that the availability of methyl protons was critical to ensure functionalisation of the pyridinic ring. An eventual direct metallation at C-6 was thus excluded and the reaction pathway probably involves a fast lithium migration from the side chain to the 6 position. According to our previous observations,[3] this unusual shift is assumed to be favoured by a strong complexation of BuLi–LiDMAE aggregates in the neighbourhood of the pyridine nitrogen atom. Subsequent electrophilic quenching followed by



Scheme 3

DOI: 10.1039/b001690j

spontaneous aromatisation[8] would then afford product **4** (Scheme 3).

In summary, we have shown that BuLi–LiDMAE promoted the unprecedented regioselective C-6 functionalisation of 3-picoline. This efficient method was found to be a direct and simple route to functional picolinic derivatives which constitute the key structure of many biologically active compounds.

Notes and references

† All compounds gave satisfactory spectral data (^{1}H, ^{13}C NMR) and new compounds gave satisfactory elemental analyses. The preparation of **4a** is given as a typical procedure. To a solution of 2-dimethylaminoethanol (1.07 g; 12 mmol) in hexane (5 mL) cooled at 0 °C, was added dropwise BuLi (24 mmol; 15 mL of a 1.6 M solution in hexanes). After 15 min, a solution of 3-picoline (0.37 g; 4 mmol) in hexane (5 mL) was added dropwise and the orange solution stirred for 1 h at 0 °C. After cooling at −78 °C, a solution of TMSCl (1.55 g, 14 mmol) in THF (25 mL) was added dropwise. The reaction mixture was maintained at −78 °C for 1 h and then allowed to warm to room temperature. Hydrolysis at 0 °C with water (15 mL) was followed by extraction with diethyl ether (20 mL) and drying over $MgSO_4$. After evaporation of solvents, the crude product was purified by flash-chromatography using hexane–AcOEt (85:15) as eluent. **4a** was obtained as an oil (0.59 g, 90%). δ_H($CDCl_3$, TMS), 0.32 (s, 9H), 2.31 (s, 3H); 7.41 (s, 1H), 7.42 (s, 1H), 8.62 (s, 1H). δ_C($CDCl_3$, TMS), −1.3, 18.95, 128.7, 132.7, 135.0, 151.2, 164.8. *m/z* (EI): 165 (M^+, 59%), 164 (54%), 150 (100%), 93 (18%), 73 (36%), 65 (47%).

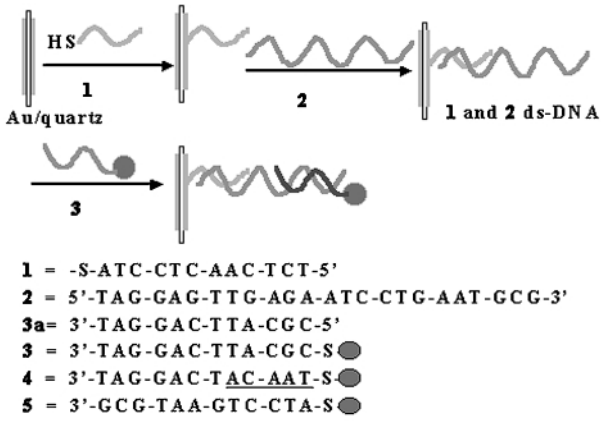
Received (in Cambridge, UK) 3rd March 2000, Accepted 26th April 2000

A novel microgravimetric gene sensing system has been developed using an oligonucleotide anchored on the gold electrode of a quartz crystal microbalance and an Au nanoparticle modified oligonucleotide, both of which formed a sandwich-type ternary complex with the target DNA to give an amplified frequency response.

The microgravimetric quartz crystal microbalance (QCM) is a promising candidate for biosensor applications, and its potential for the detection of DNA hybridization has been demonstrated recently.[1–6] Although the QCM has a high inherent sensitivity (capable of measuring sub-nanogram levels of mass changes), methods for improving the detection limit of this device are being sought to enable wide application of the technique for DNA hybridization detection. A detection limit of *ca*. 10^{-18} M, which corresponds to *ca*. 10^{-12} g (depending on the number of DNA base pairs) of target DNA is required for many applications. The sensitivity can in some cases be improved by using QCM crystals of higher frequencies[7] or by amplification of the nucleic acids to increase the concentration of the analyte DNA by polymerase chain reaction (PCR).[8] These two methods, however, have practical limitations, particularly in the development of automated biosensor systems for genetic detection: QCM devices of higher frequencies (> *ca*. 10 MHz) are often difficult to operate in liquids because of frequency stability problems, while use of PCR can be laborious and time consuming and requires a number of manipulations. Amplifications of QCM gene sensors by adsorption of an anti-ds-DNA antibody to the formed ds-DNA complex[9] or using dendritic nucleic acid as sensing probes[10] have been reported, but the sensitivities are not good enough.

Here we describe a novel microgravimetric technique for gene detection in which a sandwich-type ternary complex consisting of an oligodeoxynucleotide (ODN) immobilized on a QCM electrode, the target DNA and a Au nanoparticle modified oligonucleotide is formed to give an amplified frequency signal (Scheme 1). Because the mass of each nanoparticle is relatively large in comparison to the masses of the binding pair members themselves, the mass coupling of the nanoparticles to the oscillator surface effectively amplifies the mass increase. As a result, this method provides an amplified frequency shift and substantially extends the limits of sensitivity of the QCM detection system.



Scheme 1 Schematic illustration of the sensing and amplified system based on the formation of a complementary sandwich-type complex.

All ODNs used in this study were prepared on a fully automated DNA synthesizer (GENSET CA). The 12-mer oligonucleotide **1**, which includes a hexanethiol residue linked to the 3′-terminus, has a sequence that is complementary to part of the target DNA **2**. Oligonucleotide **1** was immobilized *via* self-assembly on a cleaned Au electrode of the QCM (AT-cut, 10 MHz, ICM Co., 0.204 cm^{-2} area Au electrode; the detection limit of the QCM instrument in liquid = 1 Hz) from a 10 μg mL^{-1} solution of **1** (0.05 M HEPES buffer, pH 7.5) for 1 h. The immobilized amount of the probe was estimated to be 7.4 ± 1 pmol cm^{-2} from the frequency change of 6 Hz (in air), which corresponds to *ca*. 11% coverage of single strand nucleotide (area per molecule *ca*. 2.2 nm^2) on the electrode.

Gold nanoparticle modified ODN probes **3**, **4** and **5** were synthesized by derivatizing 1 mL of aqueous 13 nm diameter Au nanoparticle solution (≅17 nM)[11] with 10.5 μg of (alkanethiol) oligonucleotide. After standing for 16 h, the solution was adjusted to buffer conditions (0.1 M NaCl, 0.05 M HEPES buffer, pH 7.5) and allowed to stand for 40 h, followed by centrifugation to remove excess reagents. After removal of the supernatant, the red oily precipitate was washed twice with 0.5 mL of 0.1 M NaCl, 0.05 M HEPES buffer solution, recentrifuged, and redispersed in 0.5 mL of 0.05 M HEPES buffer (containing 0.1 M NaCl, 0.01% azide) as stock solution.

The **1**-functionalized QCM was reacted with target DNA **2** at different concentrations to form **1** and **2** ds-DNA complex. The frequency decrease resulting from the interaction of the **1**-functionalized crystal with **2** is enhanced as the bulk concentration of **2** increases. This is consistent with the increased surface coverage of the sensing interface by **2**. At a bulk concentration of **2** corresponding to 3.2×10^{-8} M, the crystal frequency decreases by 12 Hz and levels off to a constant value after 300 s exposure. Interaction of the monolayer-functionalized crystal with higher concentrations of **2** does not increase the crystal frequency change. This implies that the **1**-monolayer interface is saturated as a result of the formation of the ds-DNA complex. At a bulk concentration of **2** corresponding to 1.7×10^{-9} M, a frequency change of only 3 Hz is observed after 300 s exposure. This seems to be the sensitivity limit according to the IUPAC 3:1 signal to noise guideline.

Fig. 1 illustrates the amplification of the sensing signal by interaction of the resultant **1** and **2** ds-DNA interface (formed by interaction of the **1**-functionalized crystal with **2** at 1.7×10^{-9} M) with the Au nanoparticle modified oligonucleotide **3**. The resulting frequency decrease is enhanced as the bulk concentration of **3** increases, up to 1.3×10^{-7} M where the largest frequency decrease Δf = 67 Hz is observed [Fig. 1(*a*), (*b*) and (*c*)]. Interaction of the **1** and **2** ds-DNA with oligonucleotide **3a** at 3.5×10^{-7} M which is not modified with

DOI: 10.1039/b001737j

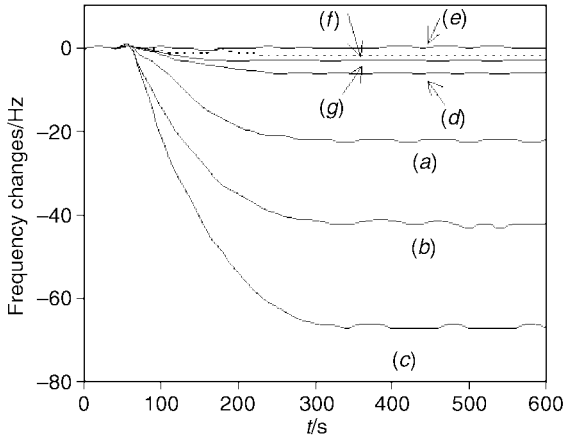


Fig. 1 Response of the **1** and **2** ds-DNA functionalized QCM upon addition of (*a*) Au nanoparticle labeled DNA probe **3,** 2.2×10^{-8} M; (*b*) probe **3,** 6.7×10^{-8} M; (*c*) probe **3,** 1.3×10^{-7} M; (*d*) **3a,** 3.5×10^{-7} M; (*e*) pure Au nanoparticle solution; (*f*) probe **5**, 7.6×10^{-8} M and (*g*) probe **4**, 6.7×10^{-8} M.

Au nanoparticles results in low frequency changes, $\Delta f = -(6 \pm 1)$ Hz, [Fig. 1(*d*)]. Increasing the oligonucleotide **3a** concentration further does not change the frequency further. The frequency change of $\Delta f = -(6 \pm 1)$ Hz at saturated adsorption for oligonucleotide **3a** is consistent with the estimated 100% hybridization of the **1** and **2** ds-DNA interface. The similar time dependency of the frequency changes (*i.e*. the attainment of steady-state signals within 300 s) observed for Au nanoparticle modified oligonucleotide **3** as compared with conventional oligonucleotide **3a** indicates that the Au nanoparticle does not compromise the hybridization kinetics. Control experiments reveal that the **1** and **2** ds-DNA interface is unaffected upon interaction with pure Au nanoparticle solution, $\Delta f = -(1 \pm 1)$ Hz, [Fig. 1(*e*)]. Furthermore, treatment of the **1** and **2** ds-DNA interface with Au nanoparticle modified oligonucleotide **5** at 7.6×10^{-8} M, does not yield any significant change in the frequency response, $\Delta f = -(2 \pm 1)$ Hz, [Fig. 1(*f*)].

Note that the oligonucleotide **5** is essentially complementary to **3**. Thus, the lack of frequency change upon interaction of the **1** and **2** ds-DNA interface with **5** indicates that non-specific oligonucleotide binding is negligible on the interface. The specificity of the sensing interface with oligonucleotide mutants was also investigated. Fig. 1(*g*) shows the interaction of the **1** and **2** ds-DNA with the Au nanoparticle labeled 12-mer oligonucleotide **4** (6.7×10^{-8} M), which has a five-base mutation in the base order compared to **2**. No detectable frequency decrease is observed, indicating that the removal of the five-base pair recognition between the sensing interface and **5** is sufficient to eliminate significant binding interactions. Note that with a fully Au nanoparticle labeled complementary oligonucleotide **3**, a frequency change of −67 Hz was observed at this bulk concentration. Therefore, the oligonucleotides modified with Au nanoparticles still preserve the specificity as that observed on QCM gene sensors with normal oligonucleotide probes.[9,10]

The results show that Au nanoparticle modified oligonucleotides can be applied to detect target DNA at sub-nanomolar concentration. The frequency changes after treatment with different concentrations of the analyte **2** followed by the Au nanoparticle modified DNA probe **3** were investigated. When the concentration of analyte **2** $> 5 \times 10^{-9}$ M, a constant frequency change was observed, implying saturation of the sensing surface. When the analyte **2** is in the concentration range of 3.2×10^{-11} M to 5×10^{-9} M, the frequency changes show a linear behavior. The crystal frequency changes from $\Delta f = -3$ Hz at 3.2×10^{-11} M of **2** to $\Delta f = -160$ Hz at 5×10^{-9} M. The linear regression line was $\Delta f(\text{Hz}) = 0.33C + 3.1$ (with C in units of 10^{-11} M) with $R^2 = 0.98$. A detection limit of *ca*. 3.2×10^{-11} M of the target DNA **2** has been estimated from the response of the QCM signal according to the IUPAC 3 : 1 signal to noise guideline. The significant sensitivity enhancement achieved with the Au nanoparticle modified oligonucleotides compared to the conventional detection system (detection limit of 1.7×10^{-9} M) is attributed to the high density of the Au nanoparticles which are capped to the DNA probes.

In conclusion, we have demonstrated a novel approach for highly sensitive detection of DNA using Au nanoparticle modified oligonucleotides as amplifying probes. The sensing process also showed specificity. This method exhibits extraordinary sensitivity and provides a simple means for rapid detection of a target oligonucleotide at sub-nanomolar concentration. Although the reported sensitivity is impressive, the sensitivity of the system may be further enhanced by using oligonucleotides modified with much smaller Au nanoparticles.

Received (in Cambridge, UK) 24th January 2000, Accepted 27th April 2000

Surfactant derivatives of [9]aneN$_3$ and [12]aneN$_3$ are prepared; micelles are formed at low concentrations in water while at higher concentrations lyotropic hexagonal, cubic and lamellar phases are characterised.

The study of surfactant materials is very well established,[1] the materials being used on a vast scale worldwide and in a number of settings such as soaps, detergents and emulsifiers. Surfactants are also important in a number of other areas, for example in cell membranes[2] and in the preparation of mesoporous silicates.[3] Similarly, the study of macrocyclic materials is also a mature area of investigation, especially in the development of sensors for selective cation and anion binding, host–guest chemistry and in supramolecular chemistry.[4]

We have become interested in the synthesis and properties of liquid-crystalline macrocycles with a view to establishing and understanding their structure/property relationships and to combine the substrate binding ability of macrocycles with their known properties as liquid crystals.[5] Previously, Neve has studied difunctionalised derivatives of [18]aneN$_2$S$_4$ which were treated with AgOTf and AgPF$_6$ to give the corresponding Ag^{I} complexes.[6] In the anhydrous state, these complexes showed a viscous, birefringent mesophase which was investigated by X-ray scattering which implied an undulating, bilayer mesophase in which the metal-containing cations describe a 'U'-shaped motif. The same materials were also found to show lyotropic mesomorphism in acetonitrile at concentrations between 15 and 35 wt% complex, giving a lamellar ripple phase (*i.e.* again, a modulated phase). Later, Fallis[7] reported a related system in which [9]aneN$_3$ was functionalised with a long-chain secondary alcohol and then complexed to Ni(II) and Cu(II) centres. In this case, the neutral macrocycle was poorly soluble in water and surfactant properties were reported only for the cationic complexes. As part of our own work in this area,[5] we have begun to investigate surfactant derivatives of simple, uncomplexed aza macrocycles and report herein the synthesis of new surfactants derived from [9]aneN$_3$ and [12]aneN$_3$.

A general model for a surfactant consists of a polar head group bound to a non-polar chain and so initially we confined ourselves to systems bearing one alkyl chain. We argued that the simplest way of accessing such systems was *via* orthoamide protection of the triazamacrocycles (Fig. 1). These are obtained after a multistep synthesis for the [9]aneN$_3$ derivative[8] (**1**) or after a one-step synthesis for the [12]aneN$_3$ derivative (**2**).[9] Once obtained, these orthoamides can be reacted with, for example, a haloalkane which opens up the orthoamide to give a cationic, *N*-alkylated macrocycle with two nitrogens still protected by a bridgehead carbon.[10] Our initial attempts focused on functionalisation using a C_{12} chain which ought to be sufficiently long to give rise to surfactant behaviour. However, following reaction of 1-bromododecane with the orthoamide of [12]aneN$_3$ in acetonitrile, we were unable to recover a pure, alkylated macrocycle. This is most likely due to quaternisation at nitrogen followed by Hoffmann elimination to give ring-opened products.

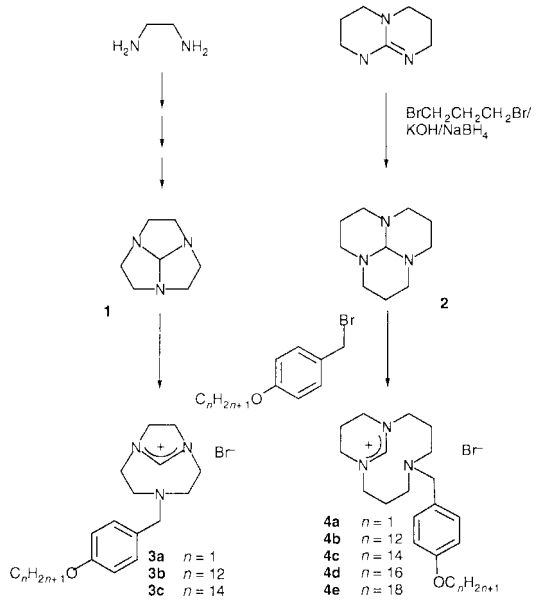

Fig. 1 Synthesis of the surfactant derivatives of [9]aneN$_3$ and [12]aneN$_3$.

However, we were more successful using 4-alkoxybenzyl bromides which reacted smoothly with the orthoamide derivatives of [9]aneN$_3$ and [12]aneN$_3$ to give the desired products (**3** and **4**) which were isolated in near quantitative yields (Fig. 1).[11] For the methoxy derivative of [12]aneN$_3$ (**4a**) we were able to obtain single crystals, and the molecular structure resulting from the X-ray diffraction study‡ is shown in Fig. 2. The structure confirms the substitution at the macrocyclic core with the bridgehead still in place, forming a 6-membered ring within the macrocycle in an envelope conformation, with the two N–C bonds [N(2)–C(4) and N(3)–C(4)] being virtually identical in length [1.308(3) and 1.312(3) Å respectively]. The conformation of the flexible [12]aneN$_3$ ring is distorted considerably by the formation of the bridgehead, shown by a comparison of the torsion angles in the bridge ring [C(3)–N(2)–C(5)–C(6) and C(6)–C(7)–N(3)–C(8) = 172.0(2) and 174.9(3)° respectively] with those in the conformationally more flexible region of the macrocycle [C(9)–C(10)–N(1)–C(1) and C(2)–C(1)–N(1)–C(10) = 152.0(2) and 143.5(2)° respectively]. An additional indicator of the strain induced in the macrocycle by the formation of a 6-membered ring is the observed shortening of the non-bonded N···N distance about the bridge [N(1)–N(2), N(1)–N(3) and N(2)–N(3) = 3.11(3), 3.10(3) and 2.33(4)° respectively]. Further, the structure reveals that the bromide counter anion is reasonably close to the head group, the average N–Br distance being 4.3(3) Å.

Thus far, we have synthesised three derivatives of [9]aneN$_3$, **3a**–**c**, and five derivatives of [12]aneN$_3$, **4a**–**e** (Fig. 1) and evaluation of their critical micelle concentration in water was undertaken using an automated tensiometer. The trend in cmc

† Electronic supplementary information (ESI) available: Fig, S1. See http://www.rsc.org/suppdata/cc/b0/b003368p/

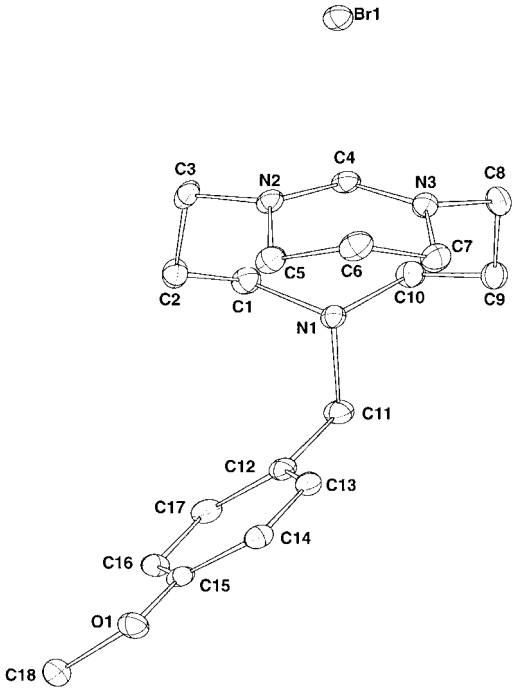

Fig. 2 Molecular structure of compound **4a**.

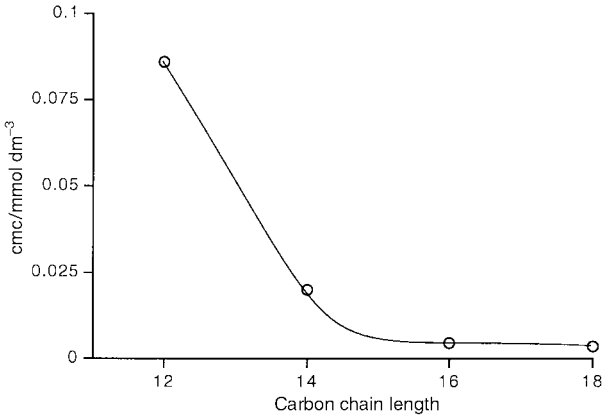

Fig. 3 Plot of cmc *vs* chain length for compounds **4**.

values for the [12]aneN$_3$ derivatives is shown in Fig. 3 and reveals the expected decrease in cmc with increasing chain length on account of the increasing hydrophobicity of the chain. While it is perhaps surprising that the cmc of the two longest-chain derivatives are very similar, we have repeated these measurements and found them to be reproducible. We did not attempt to measure the cmc of **3a** and **4a** which were synthesised for the purpose of single crystal structural analysis.

Absolute and relative values of the cmc for these materials deserve some comment. In general, the cmc values for simple monocationic surfactants are of the order of 10^{-3} mol dm^{-3} while those of neutral surfactants are up to two orders of magnitude lower.[12] The reason for this difference is accounted for by the greater dirving force required to push together head groups of like charge. However, the cmc is also affected by the hydrophobicity of the headgroup and as, in these examples, this contains not only the macrocyclic ring but a benzyl group, too, then the fact that the cmc values are $< 10^{-4}$ mol dm^{-3} is not entirely unexpected. For such an argument to hold, we would predict that the cmc values for the [9]aneN$_3$ derivatives would be higher for the [12]aneN$_3$ derivatives since the head group in this system is smaller, less hydrophobic and more charge-dense. This prediction appeared to be borne out by initial experiments which indicated that the cmc value of surfactant **3b** was approximately three times higher than that of **4b**. Similar arguments had been advanced by Fallis *et al.* to explain lower-than-expected cmc values in their cationic surfactant complexes.[7] However, subsequently we found that the [9]aneN$_3$ derivatives were unstable in water and NMR studies in D_2O implied that between 5–10% decomposed over 24 h. The nature of the decomposition was not clear, but we suspect that the instability of compounds **3** was due to the greater ring strain present when compared to **4**. Thus, we cannot say anything conclusive about the relative cmc values of **3** and **4**.

We have studied the properties of one of the surfactants in more concentrated solution to see whether lyotropic liquid crystal phases can be observed. Using the Lawrence penetration method,[13] we studied **4b** and found that at temperatures of 40 °C a normal hexagonal (H_1) phase was observed, while at 50 °C, a bicontinuous cubic (V_1) phase was also observed (Fig. S1a†). At much higher temperatures, a lamellar (L_α) phase was observed (Fig. S1b†). Thus, we have the possibility of organising and tuning the behaviour of these macrocyclic materials in a predetermined fashion.

The present study has shown that rather simple, functionalised triazamacrocycles can lead to materials which aggregate on a local (micelle) or extended (mesophase) scale. These bridgehead-protected materials will not complex to metal cations and so we are now investigating free-base derivatives with respect to both solution behaviour and to metal complexation chemistry. Details of these studies will be reported in due course.

We thank the EPSRC, Leverhulme Trust and the Royal Society for financial support.

Preparation of mordenite membranes on α-alumina tubular supports for pervaporation of water–isopropyl alcohol mixtures

X. Lin, E. Kikuchi and M. Matsukata*

Department of Applied Chemistry, Waseda University, 3-4-1 Okubo, Shinjuku, Tokyo 169-8555, Japan. E-mail: mmatsu@mn.waseda.ac.jp

Received (in Cambridge, UK) 15th December 1999, Accepted 20th April 2000

Mordenite membranes prepared on α-alumina tubular supports by *in situ* hydrothermal synthesis using organic template-free media showed high water permselectivity for pervaporation of water–isopropyl alcohol mixtures.

Zeolite membranes have been widely studied in recent years because of their great potential applications in separations, membrane reactors and sensors. A continuous zeolite layer can be grown on various supports, including α-alumina and stainless steel generally by *in situ* hydrothermal synthesis. Different types of zeolites such as MFI, zeolite A, zeolite Y, mordenite and ferrierite have been synthesized on flat and tubular supports. Research has so far mainly focused on MFI (silicalite and ZSM-5) membranes for gas separation because their pore sizes, which are close to the sizes of gas molecules, allow separation of molecules based on their size. In addition, MFI crystals are easily grown on a support with structure-directing agents (SDAs). Some MFI membranes showing good separation of hydrocarbon isomers such as *n*-butane–isobutane have been reported by several groups.[1–3]

With respect to pervaporation separation, not only the pore sizes of zeolites, but also their surface properties (hydrophobicity and hydrophilicity) play an important role. Hydrophobic MFI membranes exhibit preferential alcohol permeation for pervaporation of a water–alcohol mixture although the molecular size of water is smaller than that of the alcohol.[4] In contrast, water permeated much faster than alcohols through hydrophilic zeolite A and Y membranes.[5,6] Since mordenite zeolite with large channels of 0.67 × 0.7 nm and small channels of 0.26 × 0.56 nm is hydrophilic, mordenite membranes would be selective for permeating water against alcohols.

In 1990, Suzuki *et al.*[7] first claimed the synthesis of a zeolite membrane (mordenite) onto a porous silica–alumina plate using an *in situ* hydrothermal synthesis method. Their membrane, synthesized at 160 °C for 2 days, exhibited Knudsen-diffusion behavior. Matsukata and coworkers[8] applied the vapor-phase transport method to obtain a mordenite membrane on a porous α-alumina disk. Their membranes showed a good separation factor of 160 for pervaporation of a benzene–*p*-xylene mixture. Very recently, Santamaría and coworkers[9,10] synthesized mordenite membranes onto a tubular support by *in situ* hydrothermal synthesis using TEAOH and reported the formation of composite mordenite/ZSM-5/chabazite membranes. They studied the separation of a water–n-propanol mixture through their composite membranes by a sweep gas method. Permeance ratios as high as 70 to 140 for water and *n*-propanol were achieved through their membranes. To our knowledge, the synthesis of mordenite membranes under SDA-free conditions on tubular supports has not been reported. Here we report the synthesis of a mordenite membrane onto a tubular support for pervaporation of a water–isopropyl alcohol mixture.

Mordenite membranes were synthesized on porous 6 cm long α-alumina tubes (NGK, Ltd.) with 0.1 μm diameter pores by *in situ* hydrothermal synthesis. The parent aluminosilicate gel was prepared as follows. An appropriate amount of alumina sulfate (Wako Pure Chem. Ind. Co. Ltd.) was added to a NaOH solution and stirred at room temperature until it dissolved. Colloidal silica containing 30–31 wt% of SiO_2 and 0.6 wt% of Na_2O ST-S, Nissan Chem. Ind. Ltd.) was then added to this solution and stirred vigorously for 1 h to give a gel of molar composition $0.38Na_2O:SiO_2:0.025Al_2O_3:40H_2O$.[7] The tubular support was washed, coated with a water slurry of seed crystals of zeolite mordenite (HSZ600, 70A, Tosoh Co.), SiO_2/Al_2O_3 ratio = 10.2), and then dried at 100 °C for 15 min. The support was then vertically immersed in the gel. Crystallization was carried out at 180 °C for a given period. After the crystallization, the sample was removed, washed carefully with distilled water, and then dried at 100 °C.

The membranes obtained were characterized by X-ray diffraction (XRD) with Cu-Kα radiation (Rigaku RINT2000). Fig. 1 shows the XRD patterns for the products crystallized at 180 °C for 8 and 24 h together with that for the seed powder. These XRD patterns were consistent with the mordenite structure. The XRD patterns of the membranes crystallized for different periods of crystallization showed that the (150) reflection intensity at 22.24°, became dominant with increasing crystallization time. Thus, mordenite crystals appear to grow randomly in the early stages of crystallization, and further crystal growth occurred mainly with the (150) face parallel to the support surface. Mordenite crystals were also grown on an unseeded support and gave almost the same XRD pattern as those on the seeded supports.

The morphology of the mordenite membranes was studied by scanning electron microscopy (SEM) (Hitachi S2150) and Fig. 2 shows SEM images for the surface and cross section of the mordenite membrane crystallized at 180 °C for 24 h. A continuous, intergrown layer fully covers the surface of support. The crystal sizes are *ca.* 6–7 μm, and the thickness of crystal

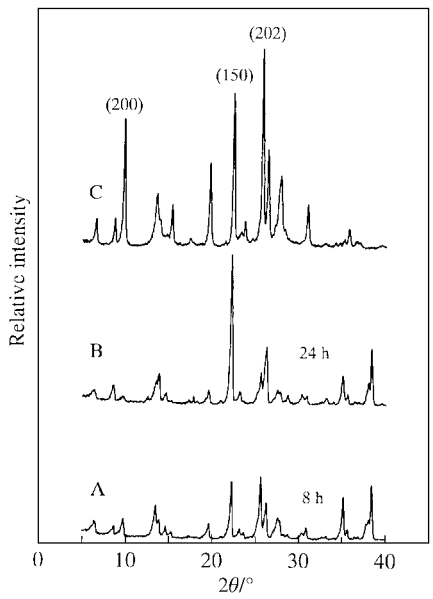

Fig. 1 XRD patterns for mordenite membranes crystallized at 180 °C for (A) 8 and (B) 24 h, and (C) mordenite seed powder.

DOI: 10.1039/a909867d

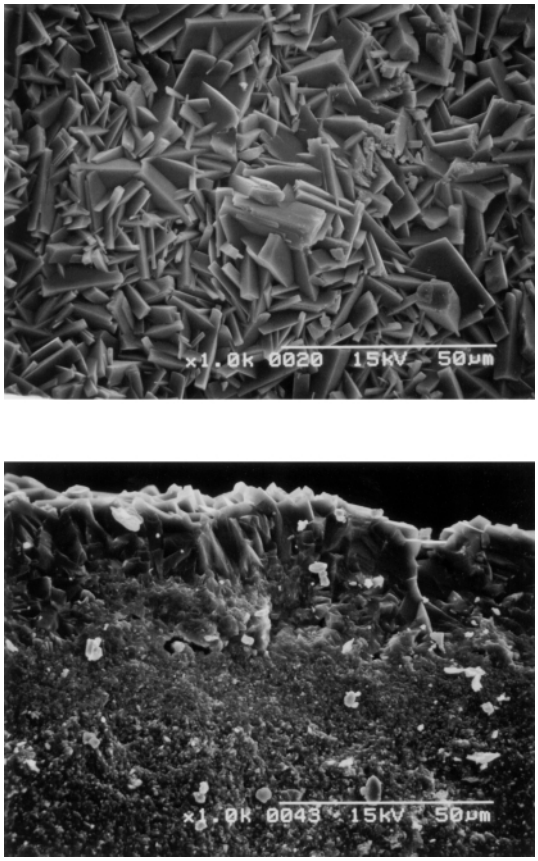

Fig. 2 SEM images for the surface and cross section of the mordenite membrane synthesized at 180 °C for 24 h.

layer is *ca.* 35 μm. The SiO_2/Al_2O_3 ratio of the mordenite zeolites determined by EDAX was *ca.* 12. In addition, the mordenite crystals have a rectangular form.

The pervaporation (PV) tests for water–isopropyl alcohol, and water–n-propanol mixtures were carried out at 75 °C using the pervaporation experimental apparatus described elsewhere.[8] The effective membrane area was *ca.* 15 cm^2 and the permeation side was kept under vacuum. The flux was calculated by weighing the condensed permeate. The separation factor was determined as $\alpha_{A/B} = (Y_A/Y_B)/X_A/X_B)$, where X_A, X_B, Y_A and Y_B denote the mass fractions of components A and B in the feed and permeate sides. The pervaporation results through the mordenite membranes crystallized at 180 °C for 24 h are listed in Table 1 and clearly show that water preferentially permeated through the mordenite membranes. The membrane synthesized on the seeded support exhibited a very high separation factor of 3360 for the water–isopropyl alcohol mixture compared with that of the unseeded support (192). We propose that the seed crystals increased the density of mordenite crystals on the support, resulting in a pinhole-free structure in contrast to the membrane formed on the unseeded support.

Table 1 Pervaporation results through mordenite membranes

Membrane[a]	Feed solution (A/B) (wt% of A)	Separation factor (A/B)[b]	Flux/ kg m^{-2}
M1	Water–n-propanol (10)	1782	0.2
M2	Water–isopropyl alcohol (10)	3360	0.1
M3[c]	Water–isopropyl alcohol (10)	192	0.2

[a] Membranes were crystallized at 180 °C for 24 h; [b] PV carried out at 75 °C. [c] Prepared without seeds.

Mordenite is formed for Si/Al ratios of *ca.* 5–6, higher than those for LTA (Si/Al = 1) and Y (Si/Al ratio = *ca.* 2.5). Thus, in comparison with LTA and Y, mordenite has potential application in acidic solutions under which esterification can occur. In addition, it is known that the effective pore size of mordenite can be precisely controlled in the range of *ca.* 0.3–0.6 nm by ion exchange, possibly leading to a wide variety of applications such as hydrocarbon separation and use as membrane reactors.

Electrophilic fluorination at saturated sites

Richard D. Chambers,*[a] Mandy Parsons,[a] Graham Sandford*[a] and Roy Bowden[b]

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE. E-mail: graham.sandford@durham.ac.uk*

[b] *F2 Chemicals Ltd., Lea Lane, Lea Town, Preston, UK PR4 0RZ*

Received (in Liverpool, UK) 23rd February 2000, Accepted 20th April 2000

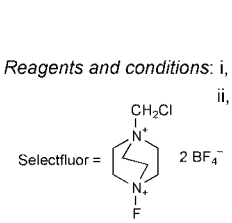
Transformation of carbon–hydrogen bonds to carbon–fluorine bonds at saturated secondary and tertiary carbon sites by electrophilic aliphatic substitution processes is possible using either elemental fluorine or fluorinating reagents of the N–F class.

The development of effective methodology for the selective introduction of fluorine atoms into organic molecules has received much attention recently because of the significant effects on the physical, chemical and biological properties that incorporation of one or several fluorine atoms into a substrate can impart.[1] These sometimes unique effects are especially important in the life-science industries and there are now many pharmaceuticals and plant-protection agents that are commercially available which owe their biological activity to the presence of fluorine in their structures.

Synthetic procedures for the selective transformation of carbon–hydrogen bonds to carbon–fluorine bonds offer, in principle, efficient, direct processes for introducing fluorine atoms into organic molecules. In this context, during the last few years we, and others,[2] have been able to demonstrate that elemental fluorine is a viable reagent for selective introduction of fluorine into organic compounds, including aromatic systems[3] and a wide range of carbon sites that are nucleophilic, *e.g.* dicarbonyl compounds,[4] diesters,[5] *etc.* Fluorination of unactivated sp^3 hybridised carbon–hydrogen sites offers significant opportunities for the incorporation of fluorine into an even wider range of hydrocarbon derivatives. However, selective direct fluorination at saturated carbon sites is largely limited to the work of Rozen and co-workers[6] who demonstrated that tertiary C–H sites could be fluorinated using elemental fluorine in a reaction medium of $CHCl_3/CFCl_3$ at −78 °C. These reaction conditions are clearly limiting, especially for scale-up, and therefore we have explored other systems.

We have now established that acetonitrile as a solvent is highly beneficial over a variety of other media that we have investigated. Reactions are conveniently carried out by passing fluorine gas, diluted to a 10% solution (*v/v*) in nitrogen, through a mixture consisting of the substrate and acetonitrile, cooled to 0 °C, and efficient, selective fluorination of a variety of systems has now been achieved this way (see Table 1). Both secondary C–H (**1a** to **2a**) and tertiary C–H sites (*e.g.* **1b** to **2b**) were transformed to C–F bonds using these convenient reaction conditions. Fluorination of cyclohexane **1a**, *trans*-decalin **1b** and norbornane **1c** gave a single mono-fluorinated isomer in each case whereas fluorination of decane **1d** led to a mixture of four mono-fluorinated positional isomers **2f** in similar amounts, indicating that fluorine substitution had occurred at all possible secondary sites of the alkyl chain. In contrast, fluorination of ester **1e** gave a mixture consisting of four mono-fluorinated isomers in a ratio of 5.8:3.9:3.2:1 which were identified by NMR studies to be the 6-, 5-, 4- and 3-fluoroheptanoate derivatives respectively. Therefore, fluorination occurs preferentially at secondary sites that are furthest removed from the electron withdrawing ester group. In all cases the yields quoted are based upon analysis of the crude product obtained after separation from the acetonitrile reaction medium (*i.e.* after washing with water and extraction into dichloromethane). All reactions were clean, in that no tar formation was observed. Additional products contained in the crude product were present in very low concentration and too minor to be identified. Inevitably handling losses on the scale used (*ca.* 5 g of starting material) are relatively high, especially in the cases of very volatile substrates, but would obviously be reduced by an increase in scale.

Table 1 Selective fluorination of saturated systems



Substrate	Conditions	Product(s)	Yield (Conv.%)
 **1a**	i	 **2a**	63 (53)
1a	ii	**2a**	22 (100)
 **1b**	i	 **2b**	54 (68)
1b	ii	 **2c** **2d**	23 (81)
 **1c**	i	 *exo* : *endo* = 5 : 1 **2e**	41 (60)
 **1d**	i	 and 3-, 4- and 5-fluorodecane **2f** (2.6 : 1.2 : 1.1 : 1.0)	63 (61)
1d	ii	**2f** (2.4 : 1.3 : 1.1 : 1.0)	58 (84)
 **1e**	i	 and methyl 4-, 5- and 6-fluoroheptanoate **2g** (5.9 : 3.9 : 3.2 : 1.0)	49 (42)
1e	ii	**2g** (3.7 : 1.3 : 1.3 : 1.0)	48 (57)

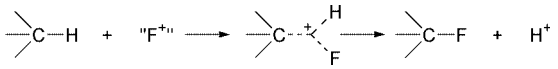
The question of the mechanism of direct fluorination processes arises and the obvious difficulty of distinguishing between electrophilic and radical substitution presents a

DOI: 10.1039/b001624l

problem. Consequently, we have explored corresponding reactions between these hydrocarbon systems and Selectfluor™ (available from Air Products), an easily handled, commercially available fluorinating reagent of the N–F class.[7,8] Selectfluor™ and structurally related N–F reagents have themselves been characterised as electrophilic reagents in mechanistic studies by Wong[9] and Differding[10,11] because no evidence of radical intermediates or products arising from one-electron transfer processes were obtained in radical-clock experiments.

Fluorinations of **1** were achieved by heating a mixture consisting of the substrate, Selectfluor™ and acetonitrile at reflux temperature and, for most of the systems that we have investigated, nearly parallel results to those observed using fluorine were obtained. For example, fluorination of decane **1d** using Selectfluor™ led to a similar product distribution to that obtained when fluorine was used. In the case of decalin, however, fluorine gave products arising from substitution at the tertiary site whereas, in contrast, Selectfluor™ gave fluorine substitution exclusively at the CH_2 sites. We attribute this difference simply to the greater steric requirements of the Selectfluor™ reagent. Therefore, the general similarity in product distribution obtained upon fluorination of saturated systems with both fluorine or Selectfluor™, suggests that these transformations of C–H bonds to C–F bonds may be considered to proceed *via* relatively uncommon aliphatic electrophilic substitution reactions at saturated sites (S_E2) involving 3 centre–2 electron bond transition states[12] (see Scheme 1). Addition of nitrobenzene, a free-radical scavenger, to the direct fluorination reaction medium does not affect product distribution or yield, further supporting an electrophilic process.

In the light of the intense interest in electrophilic N–F reagents[8,13] it is surprising that substitution at saturated sites has been so little developed because the examples shown in Table 1 demonstrate that it is a quite general process. However, Zupan[14] and co-workers have reported unusual fluorinations of methyl groups in tertiary alcohol systems but a mechanism is not advanced for the process.



Scheme 1

In summary, we are confident in describing the reactions of elemental fluorine, shown here, as electrophilic rather than fluorine atom processes. Indeed, the electrophilic fluorination of saturated sites shown here, using either fluorine or N–F fluorinating reagents, are surprisingly efficient, convenient processes.

We thank F2 Chemicals (Studentship to M. P.) for funding and the Royal Society (University Research Fellowship to G. S.).

Biarylphosphonites: a class of monodentate phosphorus(III) ligands that outperform their chelating analogues in asymmetric hydrogenation catalysis

Carmen Claver,[b] Elena Fernandez,[b] Amy Gillon,[a] Katie Heslop,[a] David J. Hyett,[a] Aina Martorell,[a] A. Guy Orpen*[a] and Paul G. Pringle*[a]

[a] *School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS. E-mail: paul.pringle@bristol.ac.uk*

[b] *Universitat Rovira i Virgili, Department de Química Fisica Inorgànica, Plaça Imperial Tàrraco, 1, Tarragona, Spain*

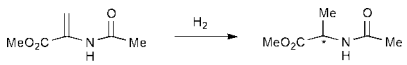
Received (in Cambridge, UK) 29th February 2000, Accepted 17th April 2000

Rhodium(I) complexes of monodentate phosphonites derived from 2,2′-binaphthol and 9,9′-biphenanthrol are compared with diphosphonite chelate analogues as catalysts for asymmetric hydrogenation; the high ee's (up to 92%) obtained with the monodentate systems and the observation that they are sometimes superior to the chelate analogues are discussed.

The enantioselective hydrogenation of prochiral alkenes is perhaps the most important application of asymmetric catalysis with synthetic catalysts and is decidedly the most studied and best understood. In 1972 Kagan *et al.*[1] were the first to show that a diphosphine was more efficient as an ancillary ligand for asymmetric hydrogenation than corresponding monophosphines. Since then, it has been found[2] that complexes of bidentate ligands consistently give higher asymmetric inductions in hydrogenation. This has been rationalised in terms of the chirality of the phosphorus substituents whose retention is enforced by the chelate ring. We report here, hydrogenation catalysis that challenges this received wisdom in that monodentate phosphonite species show, in some cases, higher enantioselectivity than the analogous bidentate phosphonites.

The resolved monodentate biarylphosphonites **1a–c** and **2a–c** and the related diphosphonites **3** and **4** are afforded by the routes shown in Scheme 1. The corresponding rhodium(I)–monophosphonite complexes **5a–f** and rhodium(I)–diphosphonite complexes **6a**,**b** have been isolated and characterised by a combination of elemental analysis, ^{31}P, ^{1}H and ^{13}C NMR spectroscopy; the monophosphonite **2b** has been previously reported[3] and while this work was in progress[4] Reetz *et al.*,[5] reported the preparation of **3**.

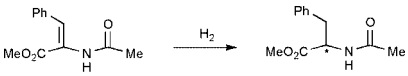
The results for the asymmetric hydrogenation of methyl-2-acetamido acrylate [eqn. (1)] catalysed by our rhodium



(1)

phosphonite complexes are given in Table 1. The monophosphonite complexes give remarkably high enantioselectivities, up to 92% ee with **5c** (entry 3). Furthermore the monophosphonite complexes **5e** and **5f**, derived from biphenanthrol are much more selective than the corresponding diphosphonite **6b**.

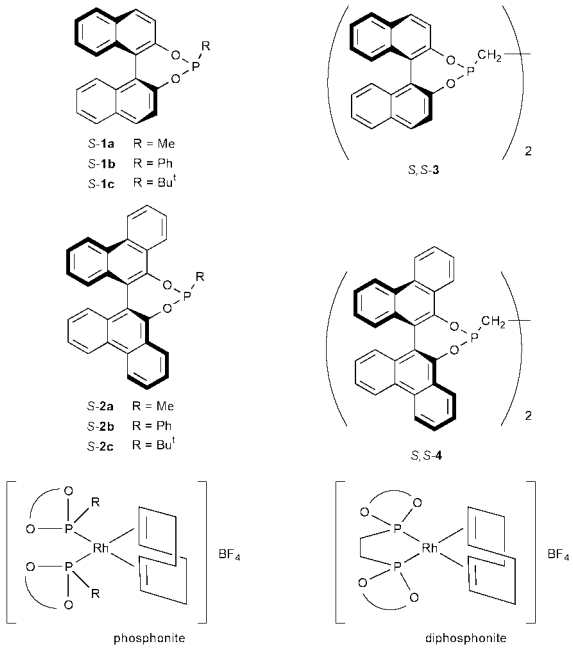
The results for the asymmetric hydrogenation of methyl-2-acetamido cinnamate [eqn. (2)] are also given in Table 1. For



(2)

this reaction, the diphosphonite complexes **6a** and **6b** both give poor (< 20% ee) enantioselectivities (entries 15 and 16) and in several cases (see entries 9, 10, 13 and 14) the monophosphonite analogues give superior enantioselectivities (ee up to 80%).

The phosphonite ligands reported here are therefore an apparent exception to the rule in enantioselective hydrogenation that catalysts based on bidentate phosphorus(III) ligands are



superior to their monodentate analogues. This dogma is based on the idea that the conformational control in metallochelates provides efficient stereocontrol that is not possible with monodentate ligands because of a low energy barrier to M–P bond rotation in the latter case. The most effective monophosphine for asymmetric hydrogenation to date (up to 90% ee) is PMePh(C_6H_4OMe-2);[6] however this ligand may form a hemilabile chelate *via* coordination of the *o*-methoxy group and moreover the bidentate analogue (dipamp) gives a much more enantioselective hydrogenation catalyst.[7]

The solution ^{31}P NMR behaviour of the rhodium complexes **5b** and **5e** was unexceptional. In each case a single sharp doublet was observed at +25 °C which remained essentially unaltered down to −90 °C. This is consistent with rapid M–P bond rotation and/or the presence of predominantly one rotamer.

We have been unable to obtain crystals of salts of the rhodium(I) complexes suitable for X-ray crystallography but the crystal structures of [$PtCl_2$(*R*-**2b**)$_2$] *R*,*R*-**7** (an analogue of the enantiomer of **5e**) and [$PtCl_2$(*S*,*S*-**4**)$_2$] *S*,*S*-**8** (an analogue of **6b**)

[a] Reaction conditions: methyl-2-acetamido acrylate or cinnamate (3.5 mmol), catalyst (0.0073 mmol) and CH_2Cl_2 (7.5 cm^3) were placed in a stainless steel autoclave, which was then pressurised to 1.5 atm with hydrogen and the reaction mixture was stirred at 25 °C for 3 h (acrylate) or 20 h (cinnamate). Conversions and ee's were determined by GC using a Hewlett-Packard 5800 A with a L-Chirasil-Val column. [b] This ee agrees with the literature report[5] but we unambiguously assign the opposite configuration to the major enantiomer.[c] In MeOH.

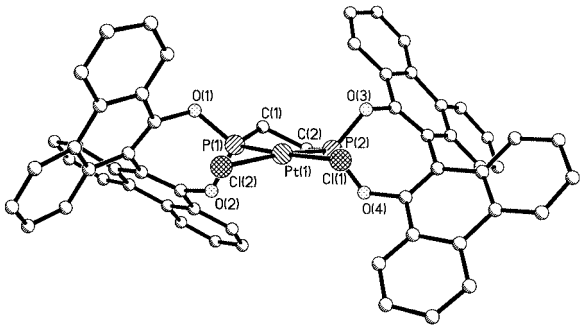

Fig. 2 Molecular structure of *S*,*S*-**8**. Important bond lengths (Å) and angles (°) include: Pt(1)–P(1) 2.189(2), Pt(1)–P(2) 2.183(3), Pt(1)–Cl(1) 2.351(2), Pt(1)–Cl(2) 2.337(3); P(1)–Pt(1)–P(2) 85.93(9). Hydrogen atoms have been omitted for clarity.

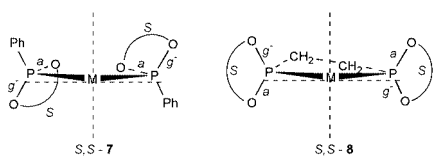

Scheme 2

as solvates† have been obtained. The structures of the *mirror image* of *R*,*R*-**7,** *i.e*. *S*,*S*-**7** (for ease of comparison) and *S*,*S*-**8** are shown in Figs. 1 and 2. In both cases the conformation about the P–O bonds is of note. In *S*,*S*-**7**, both P(1) and P(2) show *a* and g^- Pt–P–O–C conformations [*i.e*. *anti* (*a*, Pt–P–O–C torsion angle *ca*. 180°) and *gauche* negative (g^-, Pt–P–O–C torsion angle *ca*. −80°)] at the P–O bonds as counted clockwise from the P–C bond, viewed down the M–P bond, see Scheme 2. Identical behaviour is observed for *S*,*S*-**8** and a range of > 20 phosphonites and phosphites in which the phosphorus is incorporated in a seven-membered POC_4O ring containing a biaryl unit.[8] The implication of this observation is that the absolute stereochemistry of the biaryl unit controls the conformations of the P–O bonds at the phosphorus in such species (enforcing ag^- conformations for *S* and g^+a for *R* biaryls).

The *anti* arm of the phosphonites in **7** and **8** has the attached phenanthryl group far from the metal and the *gauche* arm phenanthryl closer to it. This arrangement provides a highly asymmetric ligand profile. Models suggest that as a result, rotation about the M–P bond in **7** is not possible and that the observed conformation (with the two *anti* arm oxygens essentially in the coordination plane, see Fig. 1 and Scheme 2) is the only likely rotamer. Similar conclusions seem likely to hold for other cases where the carbon substituent is significantly more bulky than the *anti* arm of the phosphonite (and less bulky than the *gauche* arm). Quadrant diagrams for *S*,*S*-**7** and *S*,*S*-**8** based on this analysis are shown in Scheme 2. It is notable that in the chelate species, **8**, the quadrant occupied by the *gauche* arm of the phosphonite is altered as compared with **7**. Hence, in this instance, it seems the primary effect of chelation is to *change* the preferred rotamer rather than to stop rotation about the M–P bond. Furthermore the rotamer favoured in the chelate form (as in **8** or **6b**) has the *gauche* arm phenanthryl group essentially face-on to the coordination plane whereas the rotamer favoured in the monodentate case (as in **7** or **5e**) has the *gauche* arm phenanthryl edge-on (see Figs. 1 and 2). The implication of the higher ee's observed for **5e** as compared with **6b** is that the edge-on phenanthryl in the former causes greater asymmetric induction.

In conclusion, the asymmetric ligand profile caused by the biaryl backbone in these phosphonites has three consequences: (i) rotation about the M–P bond in monodentate phosphonites is prevented; (ii) a different rotamer from that in the chelate analogues is favoured; (iii) the favoured rotamer causes more effective chiral induction in the hydogenation catalyses. The results presented here challenge the view that chelating ligands are essential for high stereocontrol and open the possibility that chiral monodentate phosphorus ligands may be designed that can equal or better their bidentate analogues for hydrogenation.

Received (in Basel, Switzerland) 3rd March 2000, Accepted 14th April 2000

Neutral heterobinuclear triazenide-bridged complexes are oxidised to paramagnetic monocations; the electron distribution in the σ* metal–metal orbital of rhodium–iridium complexes may be controlled by the ancillary ligands at the two metals.

Systematic carbonyl substitution reactions[1–3] of the redox-active $[Rh_2]^{2+}$ complex $[Rh(CO)_2(\mu\text{-RNNNR})_2Rh(CO)_2]$ (R = C_6H_4Me-*p* throughout) have led to the stabilisation of the core oxidation levels $[Rh_2]^{3+}$ {*e.g.* in $[Rh(CO)(PPh_3)(\mu\text{-RNNNR})_2Rh(CO)(PPh_3)]^+$}[1] and $[Rh_2]^{4+}$ {*e.g.* in $[RhCl(CO)(PPh_3)(\mu\text{-RNNNR})_2Rh(bipy)]^+$ (bipy = 2,2′-bipyridine)}.[2] Moreover, detailed structural and EPR spectroscopic studies have shown the SOMO of the $[Rh_2]^{3+}$ complexes to be σ* with respect to the Rh–Rh bond.[4] We now describe the synthesis, characterisation and redox properties of novel *hetero*binuclear triazenide-bridged analogues, with RhM (M = Ir or Pd) cores, and show how the electron distribution in the Rh–Ir bond of paramagnetic $[RhIr]^{3+}$ complexes is remarkably dependent on the ancillary ligands at the two linked metals.

Mixing CH_2Cl_2 solutions of the neutral triazene complexes $[RhCl(CO)_2\{N(H)RNNR\}]$ [ν(CO) 2095 and 2025 cm^{-1}] and $[IrCl(\eta^4\text{-cod})\{N(H)RNNR\}]$ (formed from the triazene and $[\{Rh(\mu\text{-Cl})(CO)_2\}_2]$ or $[\{Ir(\mu\text{-Cl})(\eta^4\text{-cod})\}_2]$, respectively) resulted in ligand exchange to give a mixture of $[IrCl(CO)_2\{N(H)RNNR\}]$ [ν(CO) 2082 and 2004 cm^{-1}][5] and $[RhCl(\eta^4\text{-cod})\{N(H)RNNR\}]$. Subsequent addition of NEt_3 to the mixture then gave a dark red solution containing $[Rh(\eta^4\text{-cod})(\mu\text{-RNNNR})_2Ir(CO)_2]$ **1** which was separated (from the homobinuclear dimer $[Ir(CO)_2(\mu\text{-RNNNR})_2Ir(CO)_2]$[5]) by column chromatography (Table 1).† A comparison of the IR carbonyl spectrum of **1** with those of $[M(\eta^4\text{-cod})(\mu\text{-RNNNR})_2M(CO)_2]$ [M = Rh, ν(CO) 2064vs and 2002s; M = Ir, ν(CO) 2049vs and 1986s cm^{-1}] suggested the presence of an $Ir(CO)_2$ unit {rather than $Rh(CO)_2$}, supported by the observation of two doublet ^{13}C resonances at δ 31.2 and 31.0 [$J(^{103}Rh^{13}C)$ 15 Hz], for the pairs of inequivalent rhodium-bound alkenic carbons of the cod ligand and confirmed by the X-ray crystal structure (Fig. 1).‡

Passing CO gas through a CH_2Cl_2 solution of **1** yielded $[Rh(CO)_2(\mu\text{-RNNNR})_2Ir(CO)_2]$ **2** which reacted with P-donor ligands to give the heterobinuclear complexes $[Rh(CO)(PPh_3)(\mu\text{-RNNNR})_2Ir(CO)_2]$ **3** and $[Rh(CO)L(\mu\text{-RNNNR})_2Ir(CO)L]$ [L = PPh_3 **4** or $P(OMe)_3$ **5**]. A comparison of the ^{31}P NMR spectra of **3** {δ 38.9 [d $J(^{103}Rh^{31}P)$ 151 Hz]} and **4** {δ 39.2 [d, $J(^{103}Rh^{31}P)$ 154 Hz], 14.3, s} confirms sequential phosphine substitution at Rh and then Ir. The preference for the $Ir(CO)_2$ isomers of **1** and **3** and the lower ν(CO) wavenumbers for $Ir(CO)_2$ than for $Rh(CO)_2$ in $[Rh(\eta^4\text{-cod})(\mu\text{-RNNNR})_2M(CO)_2]$ are consistent with the Ir centre being somewhat more electron rich than the Rh centre in cases such as **2**, *i.e.* Ir orbital energies are slightly higher than Rh, other things, such as ancillary ligands, being equal.

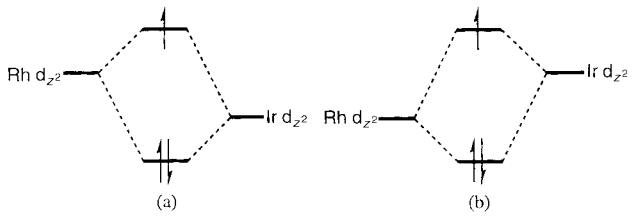
[a] High field feature only; A in 10^{-4} cm^{-1}.

Cyclic voltammetry in CH_2Cl_2 shows that **1**–**5** undergo two one-electron oxidation processes (Table 1) the first of which is fully reversible in all cases (the second is also reversible for **1** and **4**). Treatment of the neutral complexes **1** and **4** with $AgPF_6$ and $[Fe(\eta\text{-}C_5H_5)_2][PF_6]$ respectively gave near quantitative yields of the paramagnetic $[RhIr]^{3+}$-containing cations $\mathbf{1}^+$ and $\mathbf{4}^+$ (as their $[PF_6]^-$ salts). X-Ray structural studies on the redox-related pair **4** and $\mathbf{4}^+$ show a shortening of the Rh–Ir distance on oxidation, from 2.945(2) to 2.7131(9) Å, consistent with removal of an electron from a σ* metal–metal orbital derived from the interaction of d_{z^2} orbitals, and the formation of a three-electron metal–metal bond. A similar structural difference was observed with the homobinuclear redox pair $[Rh(CO)(PPh_3)(\mu\text{-}RNNNR)_2Rh(CO)(PPh_3)]^z$ (z = 0 and 1).[4]

Cations $\mathbf{1}^+$ and $\mathbf{4}^+$, and also $\mathbf{3}^+$ and $\mathbf{5}^+$ (generated *in situ* by treatment of **3** and **5** with $[Fe(\eta\text{-}C_5H_4COMe)(\eta\text{-}C_5H_5)][PF_6]$ and $[Fe(\eta^5\text{-}C_5H_5)_2][PF_6]$, respectively) show well resolved EPR spectra in CH_2Cl_2–thf (1:2); those of $\mathbf{1}^+$ and $\mathbf{4}^+$ at 100 K are shown in Fig. 2. The spectra show hyperfine coupling to ^{103}Rh (I = 1/2) and to ^{191,193}Ir (I = 3/2), but are complicated by Ir quadrupole coupling.[6] The high-field g-feature is generally well resolved; the corresponding parameters are given in Table 2. These parameters clearly indicate that the distribution of unpaired electron density in the three-electron Rh–Ir bond is strongly dependent on the nature of the terminal ligands at each metal. Thus, Rh makes the major contribution to the SOMO of $\mathbf{1}^+$ and $\mathbf{3}^+$, whereas Ir makes the major contribution in $\mathbf{4}^+$ and $\mathbf{5}^+$.



Scheme 1 Schematic orbital interactions in the three-electron metal–metal bond of species such as (a) $\mathbf{1}^+$ and (b) $\mathbf{4}^+$ in which the ancillary ligand sets are asymmetric and symmetric, respectively.

In a first-order semi-quantitative analysis the spin density is *ca.* 75% on Ir in the species $\mathbf{4}^+$ and $\mathbf{5}^+$ in which the ancillary ligand sets at Ir and Rh are the same. When the iridium centre carries more electron withdrawing ligands (as in $\mathbf{1}^+$ and $\mathbf{3}^+$) *ca.* 80% of the spin density is located at the rhodium centre. This is consistent with the carbonyl ligands of the $Ir(CO)_2$ unit reducing the Ir d_{z^2} energy below that of the Rh d_{z^2} (*i.e.* the reverse of their order in $\mathbf{1}^+$ and $\mathbf{3}^+$, for example) leading to an inversion of the dominant contributions to the SOMO (Scheme 1). We therefore conclude that asymmetry of the ancillary ligand set can overturn the inherent metal orbital energy difference (as noted above) and reverse spin localisation in these species.

The preparative route to complexes **1**–**5** can also be applied to the synthesis of redox-active rhodium–palladium complexes $[Rh(CO)_2(\mu\text{-}RNNNR)_2PdL_n]$ [L_n = η³-allyl **6**, L_n = $Cl(PPh_3)$ **7**], *i.e.* by reacting $[RhCl(CO)_2\{N(H)RNNR\}]$ with $[PdCl(\eta^3\text{-allyl})\{N(H)RNNR\}]$ and $[PdCl_2(PPh_3)\{N(H)RNNR\}]$, respectively (again prepared *in situ* from the triazene and the corresponding halide-bridge dimer). Subsequent treatment of **7** with $ONMe_3$ in MeCN gave the highly asymmetric complex $[Rh(CO)(NCMe)(\mu\text{-}RNNNR)_2PdCl(PPh_3)]$ **8** in which four different terminal ligands are selectively distributed between the two different metals.

In summary, the new preparative route described leads to novel redox-active heterobinuclear species which are oxidised to paramagnetic complexes in which the distribution of unpaired electron density in a metal–metal bond can be tuned by systematic ligand variation.

We thank the Royal Thai Government and the EPSRC for Studentships (to P. K. and O. D. H., respectively).

The arched four-rung ladder structure of the unsolvated dilithium salt of *N,N′*-bis(trimethylsilyl)-2-aminobenzylamine, and its structural deformation on THF complexation

Régis M. Gauvin,[a] Nathalie Kyritsakas,[b] Jean Fischer[b] and Jacky Kress*[a]

[b] *Laboratoire de Cristallochimie et de Chimie Structurale, UMR 7513, Université Louis Pasteur, Institut Le Bel, 4 rue Blaise Pascal, 67070 Strasbourg Cedex, France*

Received (in Basel, Switzerland) 9th March 2000, Accepted 2nd May 2000

The X-ray crystal structures of 2-Li($SiMe_3$)$NC_6H_4CH_2N(SiMe_3)$Li 1 and 2-Li($SiMe_3$)$NC_6H_4CH_2N(SiMe_3)$Li·THF 2 show that both compounds exist in the solid state as discrete dimers that display an analogous four-rung ladder core, allowing us to analyse the effect of THF coordination.

The aggregation of lithium amides *via* so-called ring-laddering processes is now well documented, and a wide variety of architectures has been described in the literature.[1] In the absence of coordinating Lewis bases, these compounds generally adopt polymeric infinite ladder structure, but examples of shorter arrangements have been reported. On exposure to solvating ligands, these structures are often broken down to smaller entities which can however still be assembled into oligomeric ladders of limited length if only partial solvation has taken place.[1] Here, we present the first structural characterization of a heteroditopic dilithium diamide, both in its unsolvated and THF monoadduct forms. The unsolvated compound 2-Li($SiMe_3$)$NC_6H_4CH_2N(SiMe_3)$Li **1** is dimeric and exhibits an arched four-rung ladder structure which had not been observed previously for an uncomplexed amidolithium compound. Coordination of THF to give 2-Li($SiMe_3$)$NC_6H_4CH_2N(SiMe_3)$Li·THF **2** changes the structural parameters of this edifice, but alters neither its dimeric nature nor its conformation, providing the opportunity to analyse the fundamental bond modifications upon lithium complexation in such ladder frameworks.

Compound **1**† was obtained as colourless crystals through double deprotonation of the diamine 2-NH($SiMe_3$)$C_6H_4CH_2NH(SiMe_3)$[2] by Bu^nLi in pentane, followed by concentrating the reaction mixture under reduced pressure and cooling the resulting solution to −20 °C. Its high solubility in hydrocarbons restricted the isolated yield to 58%. Its molecular structure was established by X-ray diffraction analysis‡ (Fig. 1). The three fused $(NLi)_2$ rings that build the four-rung ladder are strictly planar and significantly twisted with respect to each other, as shown by the average value of the two N–Li–N–Li edge dihedral angles (51.1°). The chelating 2-benzyl linkages bridge the nitrogen atoms along each edge and are located on the same face of the ladder, which imposes the arch-like folding, the nearly parallel orientation of the two aromatic rings (which is not the result of π-stacking, the two ring planes being staggered and distant by *ca.* 4 Å), and the cisoid configuration of the four $SiMe_3$ substituents.

The four-coordinate anilinic nitrogens are located in the outer rungs, while the five-coordinate benzylic nitrogens occupy the inner positions, leading to a 'head-to-tail' arrangement. Although the molecule shows only approximate and not crystallographic C_2 symmetry, the discussion of its dimensional parameters can be restricted to one half of the dimer.

Interestingly, the two outer lithium atoms are only two-coordinate with respect to nitrogen ligation and hence highly electron-deficient, which results in short outer rungs [Li(1)–N(4) 1.964(4) Å] and close contacts with carbons of the neighbouring aromatic rings [Li(1)–C(5) 2.350(5) Å, Li(1)–C(10) 2.627(5) Å]. These relatively strong lithium–carbon interactions are certainly at the origin of the limited length of this unsolvated ladder (together with the steric hindrance of the $SiMe_3$ substituents at the ladder ends), and of its folding down into an arch. On the other hand, the inner lithium atoms are three-coordinate with respect to nitrogen ligation and pyramidal. Although less unsaturated, they interact similarly with the benzylic carbons [Li(2)–C(4) 2.484(4) Å], tying the 2-benzyl framework even closer to the $(NLi)_4$ core, accounting further for the severely folded structure of the ladder [Li(1)–N(1)–Li(2) 106.00(2)°, N(1)–Li(2)–N(2) 108.8(2)°], and leading to inner Li–N edges that are relatively shorter than the inner rungs [Li(2)–N(1) 2.025(4) Å, Li(4)–N(1) 2.113(4) Å]. ^1H NMR spectra† suggest that this dimeric structure is maintained in benzene solution, and show that the molecule is fluxional.

It should be pointed out that lithium amides exhibiting a four-rung ladder structure have been described previously, but are either solvated at the terminal lithium centers[3] (as **2**, *vide infra*) or folded into stairs.[4] Both of these characteristics are found together in a few compounds.[5] The example of unsolvated dimeric $[Li(Dipp)NCH_2CH_2N(Dipp)Li]_2$[4] (Dipp = 2,6-diisopropylphenyl) is of particular interest owing to its close analogy with **1**. It similarly contains strong lithium–carbon interactions, but exists as a stepped four-rung ladder.[4] We presume this different geometry arises from the fact that the Li–C inter-

actions in this latter compound do not involve the edge-hugging chelating bridges as in **1**, but the other nitrogen substituent of the secondary amides (Dipp in that case).

Compound **2**† was obtained serendipitously by the reaction of **1** with 0.5 equiv. $ZrCl_4(THF)_2$ in toluene.[6] A single-crystal X-ray structure determination‡ showed that its molecular structure is in all respects similar to that of **1**, and the same numbering scheme was thus used for the sake of clarity (Fig. 2). Coordination of THF occurs at the outer lithium atoms which become three-coordinate, but the four-rung ladder core of **1** is not broken down in **2** and its peculiar geometry is furthermore retained. However, the $(NLi)_4$ arch is significantly flattened, as shown by the increased distance between the two outer rungs [from 3.653 Å in **1** to 4.337 Å in **2** for Li(1)–N(2) for instance], the more obtuse edge angles Li(1)–N(1)–Li(2) and N(1)–Li(2)–N(2) (+10.7 and +5.5°, respectively), and the less pyramidal inner lithium atoms, whose average summed angles vary from 323.3° in **1** to 333.6° in **2**. Moreover, the ladder framework is more severely twisted in **2**, the N–Li–N–Li edge dihedral angles increasing to 67° (average value), and, most importantly, the 2-benzyl aromatic rings are considerably withdrawn from the outer lithium atoms [Li(1)–C(5) 2.762 Å, Li(1)–C(10) 2.906 Å]. Undoubtedly, the outer lithium atoms have become less electron deficient on complexation by THF, and the above structural modifications are the consequence of subsequent weakening of their interactions with the aromatic ring of the 2-benzyl bridges.

The Li–N bond distances within the ladder core are also modified accordingly, both edges and rungs involving the outer lithiums being lengthened by an average value of 0.078 Å. The electrons of the four nitrogen atoms become thereby more available for the inner lithium atoms, leading to the strengthening of the corresponding Li–N bonds and to their average shortening by *ca.* 0.045 Å, with the notable exception of the two inner edges Li(2)–N(1) and Li(4)–N(3). These indeed are slightly longer in **2** than in **1**, [+0.026 Å for Li(2)–N(1) for instance], as are the lithium–carbon distances between the inner lithium atoms and the benzylic carbons [+0.062 Å for Li(2)–C(4)]. THF complexation of the outer lithium atoms hence also results in higher electron density on the inner ones. This weakens the lithium–methylene interactions that squeezed the inner Li–N edges in **1**, to such an extent that also these latter bonds are lengthened in **2**.

We dedicate this paper to the memory of Professor John A. Osborn. We thank the CNRS and the Ministère de l'Education Nationale, de la Recherche et de la Technologie for funding this work.

Chemo- and regio-selective synthesis of functionalized 3(2*H*)-furanones by the first cyclization reactions of 1,3-bis(trimethylsiloxy)buta-1,3-dienes with α-chlorocarboxylic acid chlorides

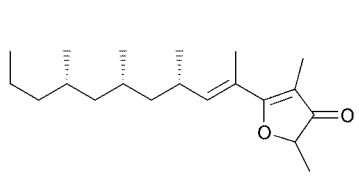
Peter Langer* and Thilo Krummel

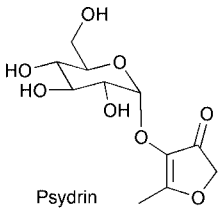
Institut für Organische Chemie der Georg-August-Universität Göttingen, Tammannstr. 2, 37077 Göttingen, Germany. E-mail: planger@gwdg.de

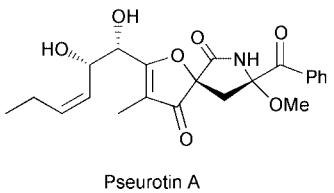
Received (in Cambridge, UK) 24th February 2000, Accepted 20th April 2000

Reaction of 1,3-bis(trimethylsiloxy)buta-1,3-dienes with α-chlorocarboxylic acid chlorides resulted in chemo- and regio-selective formation of 6-chloro-3,5-dioxoesters which were regioselectively converted into functionalized 3(2*H*)-furanones.

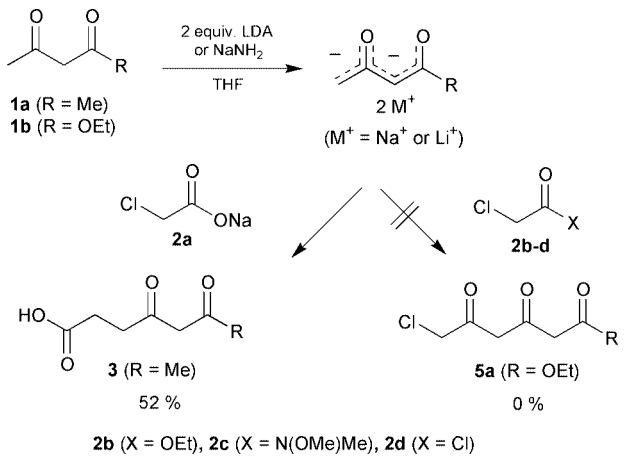
Domino and consecutive reactions are of great interest in organic chemistry since they enable the rapid assembly of complex products in a one-pot process.[1] Surprisingly, despite the simplicity of the idea, only few domino and consecutive reactions of 1,3-dianions[2] with 1,2-dielectrophiles have been reported so far.[3] Several drawbacks are possible for these reactions: on the one hand, dianions are highly reactive compounds which can react both as a nucleophile and a base; on the other hand, 1,2-dielectrophiles often represent rather labile compounds. Therefore, previous attention in dianion chemistry has been mainly focused on reactions with monofunctional electrophiles after which the resultant monoanion is simply quenched with water following the initial reaction. We have recently reported the first domino reactions of 1,3-dianion synthons with oxalic acid dielectrophiles to give γ-alkylidene-butenolides.[4,5] Herein, to the best of our knowledge, we report the first cyclization reactions of 1,3-dianion synthons with α-chlorocarboxylic acid chlorides. These reactions provide a convenient, chemo- and regio-selective access to a variety of functionalized 3(2*H*)-furanones. A large number of natural products and pharmacologically important compounds belong to the group of 3(2*H*)-furanones: prominent examples include polyketides from *siphonaria pectinata*,[6a] the antitumor active trachyspic acid,[6b] antiallergic 4,5-dihydro-4-oxo-2-amino-3-furancarboxylic acids,[6c] the mutagenic furaneols,[6d] pseurotin A,[6e] the antitumor active sesquiterpenes eremantholide A-C,[6f] lychnophorolide A,[6g] ciliarin,[6h] and the recently reported metabolite longianone.[6i,j]





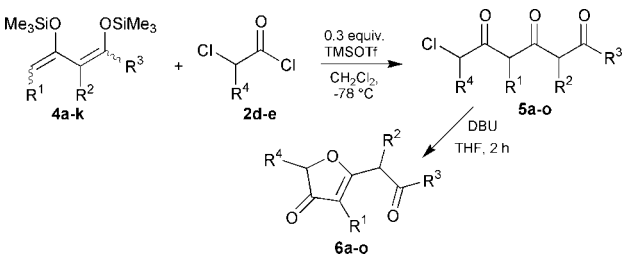


A variety of products are, in principle, possible in the reaction of 1,3-dicarbonyl dianions with α-chloroacetic acid derivatives. Both the initial attack of the dianion onto the dielectrophile and the subsequent cyclization can proceed with different chemo- and regio-selectivities. Reaction of the disodium salt of acetylacetone **1a** with the sodium salt of chloroacetic acid **2a** was reported to give 4,6-dioxoheptanoic acid **3** by attack of the terminal carbon of the dianion onto the carbon attached to the chlorine atom.[7] Unfortunately, our first attempts to induce a chemoselective attack of 1,3-dicarbonyl dianions onto the carbonyl group of chloroacetic acid derivatives in order to prepare the ester **5a** were unsuccessful: reaction of the dianion of ethyl acetoacetate **1b** with ethyl chloroacetate **2b**, *N*-methyl-*N*-methoxy-chloroacetic acid amide **2c** or chloroacetyl chloride **2d** resulted in formation of complex mixtures only (Scheme 1).



Scheme 1

In order to overcome these problems, we decided to study the Lewis-acid catalyzed reaction of 1,3-bis-(trimethylsiloxy)buta-1,3-dienes, synthons of 1,3-dicarbonyl dianions,[8] with chloroacetyl chloride **2d**. Our initial attempts to realize this concept were unsuccessful. Reaction of **2d** with the diene **4a** in the presence of stoichiometric amounts of $BF_3{\cdot}OEt_2$ or $TiCl_4$ resulted in formation of complex mixtures. Much to our satisfaction, the use of catalytic amounts of TMSOTf resulted in chemo- and regio-selective formation of the desired 6-chloro-3,5-dioxoester **5a** (Scheme 2).† Optimal yields (up to 71%) were obtained when the reaction was started at −78 °C and slowly warmed to ambient during 12 h. Treatment of **5a** with base resulted in regioselective cyclization[9] *via* the oxygen atom



Scheme 2

DOI: 10.1039/b001529f

to give the 3(2*H*)-furanone **6a**.† The use of KOBu^t resulted in the formation of a complex mixture from which **6a** could be isolated in only 23% yield. Eventually, we found that optimal yields (up to 91%) were obtained when 2 equivalents of DBU were used as the base. It is noteworthy that isolation of **5a** was not necessary: the crude product of **5a** could be directly transformed into **6a** which was isolated in 65% overall yield (from **4a**).

In order to study the preparative scope of the new methodology for the synthesis of 3(2*H*)-furanones the substituents of the 1,3-bis(trimethylsiloxy)-1,3-dienes were systematically varied (Table 1). Reaction of chloroacetyl chloride **2d** with the diene derived from methyl acetoacetate and subsequent cyclization afforded the 3(2*H*)-furanone **6b** in 70% overall yield. Reaction of **2d** with 1,3-bis(trimethylsiloxy)-1,3-dienes **4c**–**g**, containing methyl, ethyl, butyl, benzyl, and allyl groups, respectively at the terminal carbon atom, afforded the 4-alkyl-3(2*H*)-furanones **6c**–**g** in good yields and with very good chemo- and regio-selectivities.

Table 1

6	R^1	R^2	R^3	R^4	Yield[a] (%)
a	H	H	OEt	H	65

l	H	H	OEt	Me	56
m	Me	H	OMe	Me	40
n	Et	H	OEt	Me	32
o	$CH_2CH_2CH_2$		OEt	Me	26

[a] Isolated yields of **6a**–**o** over two steps from **4a**–**k** and **2d**–**e**.

A variety of naturally occuring 3(2*H*)-furanones contain an oxygen atom at carbon C-4.[10] The synthesis of 3(2*H*)-furanone **6h**, containing a methoxy group at carbon C-4, was therefore of special interest. Dianions cannot be used for the synthesis of **6h** since, besides the severe selectivity problems discussed above, dianions of methyl 4-methoxyacetoacetate and related substrates cannot be generated. This is presumably due to the fact that the dianion is destabilized by lone pair–lone pair interactions and by the π-donor effect of the oxygen atom.[11] Much to our satisfaction, reaction of **2d** with 4-methoxy-1,3-bis(trimethylsiloxy)-1,3-diene **4h**[12] afforded the 4-methoxy-3(2*H*)-furanone **6h** in good yield and with very good chemo- and regio-selectivity. Starting with the 1,3-bis(trimethylsiloxy)-1,3-dienes **4i**–**j**, which are substituted at the central carbon atoms, the 3(2*H*)-furanones **6i**,**j** were isolated in good yields. Reaction of **2d** with the cyclic diene **4k**, which is derived from ethyl cyclohexanone-2-carboxylate, afforded the interesting bicyclic 3(2*H*)-furanone **6k** in good yield.

Variation of the substituents of the dielectrophile was then studied. Reaction of diene **4a** with 2-chloropropionyl chloride **2e** afforded the 6-chloro-3,5-dioxoester **5l** which was transformed into the 2-methyl-3(2*H*)-furanone **6l**. Reaction of 2-chloropropionyl chloride with the methyl- and ethyl-substituted dienes **4b** and **4c** afforded the 2-methyl-3(2*H*)-furanones **6m** and **6n** in good yields and with very good chemo- and regioselectivities, respectively. Reaction of **2e** with the diene derived from ethyl cyclohexanone-2-carboxylate afforded the bicyclic 2-methyl-3(2*H*)-furanone **6o** as a 1:1 mixture of diastereomers.

In conclusion, we have developed a new approach for the synthesis of a wide range of functionalized 3(2*H*)-furanones which are of pharmacological relevance and of interest for the synthesis of natural products.

P. L. thanks Professor A. de Meijere for his support. Financial support from the Fonds der Chemischen Industrie e. V. (Liebig-scholarship and funds for P. L.) is gratefully acknowledged.

Notes and references

† *General procedure* for the preparation of **6a**–**o**: to a CH_2Cl_2 solution (70 ml) of **2d** (5.5 mmol, 0.62 g) and of **4a** (5.5 mmol, 1.5 g) was added TMSOTf (1.65 mmol, 0.35 g) at −78 °C. The temperature of the reaction mixture was allowed to rise to 20 °C during 12 h. After stirring for 2 h at 20 °C a saturated solution of $NaHCO_3$ was added, the organic layer was separated and the aqueous layer was repeatedly extracted with diethyl ether. The combined organic extracts were dried ($MgSO_4$), filtered and the solvent of the filtrate was removed *in vacuo*. The residue was purified by column chromatography [silica gel, ether–petroleum (bp 40–70 °C)] to give **5a** as a colourless oil (805 mg, 71%). To a THF solution (5 ml) of **5a** (0.64 mmol, 122 mg) was added DBU (1.28 mmol, 195 mg). After stirring for 2.5 h, glacial acetic acid (0.4 ml) was added. The solvent was removed *in vacuo* and the residue was purified by chromatography to give **6a** as a colourless oil (100 mg, 91%): δ_H($CDCl_3$, 250 MHz): 1.22 (t, 8 Hz, 3 H, CH_3), 3.55 (s, 2 H, CH_2), 4.18 (q, 8 Hz, 2 H, OCH_2CH_3), 4.48 (s, 2 H, OCH_2), 5.66 (s, 1 H, CH). δ_C($CDCl_3$, 62.5 MHz): 13.79, 36.46, 61.57, 75.10, 106.13, 166.39, 185.95, 202.15. MS (70 eV) *m*/*z* 170 (M^+, 20). Anal. Calc. for $C_8H_{10}O_4$: C, 56.47; H, 5.92. Found: C, 56.35; H, 6.08%. All new compounds gave satisfactory spectroscopic and analytical and/or high resolution mass data.

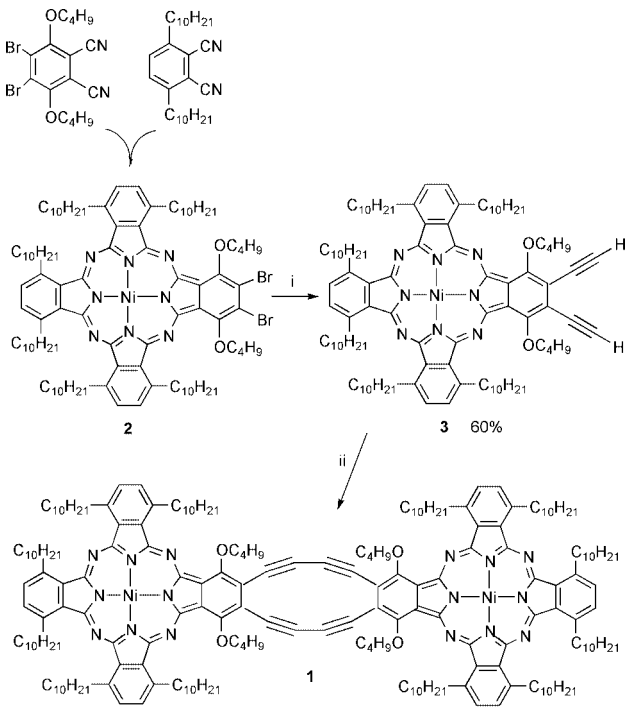
Received (in Cambridge, UK) 6th March 2000, Accepted 11th April 2000

A diphthalocyanino-dehydro[12]annulene, synthesised by oxidative coupling of a dialkynylphthalocyanine, has been characterised by mass spectrometry and UV–VIS spectroscopy and shown to undergo thermal oligomerisation.

Phthalocyanines (Pcs) are important functional materials, their 18π electron system providing the basis for their characteristic photophysical, optoelectronic and conductiometric properties.[1] More complex structures such as covalently linked binuclear Pc structures are attracting attention because of interesting effects arising from the further extension of the π conjugation.[2] Formally planar structures in which two Pc cores share a common benzene ring have been characterised satisfactorily[3] and applications of palladium coupling reactions have provided access to alkynyl Pcs[4–6] of which some monoalkynyl derivatives[6] have been coupled to give both ethynyl and butadiynyl linked Pcs. These coupling methods are here applied to the synthesis of the first example of a diphthalocyanino-dehydroannulene **1** which is highly substituted to promote solubility in organic solvents. A report that annulenes are polymerisable at a diyne unit[7] indicates that phthalocyanino-dehydroannulenes could act as useful precursors for the synthesis of novel phthalocyanine network polymers. Preliminary studies of the thermolysis of **1** are described.

The synthesis of **1** is summarised in Scheme 1. The principal features are that the dehydroannulene ring is constructed in the last stage, requiring a non-uniformly substituted Pc as precursor. The latter is the dibromo derivative **2**,† obtained by a conventional mixed condensation of 3,6-didecylphthalonitrile[8] and 3,6-dibutoxy-4,5-dibromophthalonitrile[9] (ratio 6 : 1). Stille coupling,[10] converted **2** into **3**.† The conversion of **3** into **1** was achieved by copper(II) acetate mediated oxidative coupling in dry THF–pyridine–methanol (1 : 1 : 0.25). The reaction was investigated under various conditions, its progress monitored by visible region spectroscopy. Fig. 1 (top) shows the spectrum of **3**, line (a), with the visible region (Q-band) absorptions at 698 and 729 nm. The spectrum of the reaction mixture after 20 min at 50 °C under an argon atmosphere shows a broadened spectrum, line (b), with prominent peaks at λ_{max} 701 and 756 nm. After further time, there is a gradual appearance of a new peak at 822 nm, whose intensity maximises after 48 h. This same absorption band envelope was also obtained in a separate coupling reaction of **3** (39 mg) after 8 h at 80 °C, Fig. 1 (top), line (c). The crude reaction products were filtered through silica (eluent: light petroleum (bp 40–60 °C)–THF, 9 : 1) to remove copper salts and polymeric material. MALDI-TOF MS of the filtrate gave a base peak corresponding to **1** with smaller peaks attributable to a cyclic trimer and cyclic tetramer. Size exclusion chromatography failed to separate the mixture. However, purification by repeated column chromatography over silica (eluent: light petroleum (bp 40–60 °C)–THF, 19 : 1) afforded **1** as the major fraction (9.5 mg); MALDI-TOF showed an isotopic cluster at *m*/*z* 3206 corresponding to a singularly charged molecular ion. Scanning to higher mass gave no indication of higher molecular weight species. The high resolution FT-ICR MS of **1** using electrospray ionisation in THF confirmed the structure. The base signal corresponds to the doubly charged M^{2+} ion at *m*/*z* 1601.1211 (requires 1601.1235),



Scheme 1 *Reagents and conditions*: i, $Bu_3SnC{\equiv}CH$, $Pd(PPh_3)_2Cl_2$/$Pd(PPh_3)_4$; ii, $Cu(OAc)_2$, THF–pyridine–MeOH.

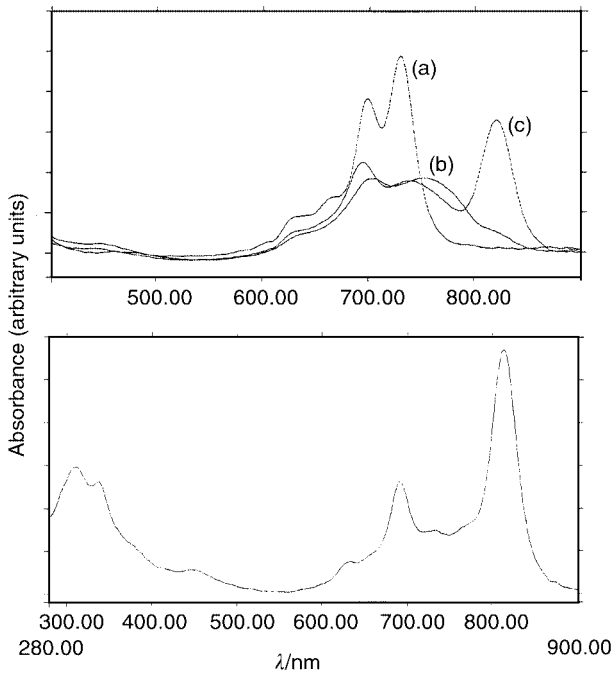


Fig. 1 UV–VIS spectra: (top) line (a), compound **3** as a solution in toluene; line (b), spectrum (toluene) of oxidative cross-coupling product from **3** after 20 min at 50 °C; line (c), the oxidative cross-coupling product from **3** after 8 h at 80 °C. (Bottom) spectrum of **1** as a solution in cyclohexane, showing the split Q-band. There is also evidence of splitting of the Soret band in the UV region.

DOI: 10.1039/b001783n

isotopic distribution showing a mass difference between each peak of 0.5 u. Signals are also present for M^+ at *m*/*z ca*. 3206 (poorly resolved) and M^{3+}, *m*/*z* 1067.4227 (requires 1067.4157). The spectrum also indicates the presence of aggregated structures. A peak cluster at *m*/*z ca*. 2138 corresponds to a triply charged two molecule aggregate of **1** and a very weak peak at *m*/*z ca*. 2400 corresponds to a quadruply charged trimeric aggregate.

Aggregation is also apparent from the ^{1}H NMR spectrum. Thus unlike the spectra of **2** and **3**, the spectrum of **1** (4.5 mg per 0.5 ml benzene-d_6) shows broadening of the signals for the aromatic protons, and the $-OCH_2$ and benzylic protons. Addition of pyridine-d_5 failed to inhibit aggregation at this concentration. Aggregation of **1** implies the possibility that π–π interactions lead to a supramolecular structure involving Pc units stacking to encapsulate a π electron rich channel formed by the dihydroannulene units. At higher dilution, (*ca*. 0.9 mg per 0.5 ml benzene-d_6), and at 40 °C the ^{1}H NMR spectrum is better resolved. Apart from aliphatic protons, there are overlapping signals for the aromatic protons, an 8 proton triplet at δ 4.91 (OCH_2 protons), a multiplet for 8 benzylic protons at δ 4.76 and a 16 proton multiplet for the remaining benzylic protons at δ 4.62.

The Q-band absorption for **1** is split, λ_{max} 822 and 691 nm, Fig. 1 (bottom). This is expected for metallated macrocycles of lower symmetry than D_{4h}[11] and is indeed observed for compounds **2** and **3.** However, the splitting is much more significant for compound **1**. A sample of **1** was heated on a hotstage and analysed by visible region spectroscopy. After heating for 5 min at 220 °C, the solution phase spectrum of the material shows reduction in absorbance of the two main components of the Q-band and growth of a broad band between them. Continued heating gives a sample whose spectrum shows an irreversible disappearance of the original bands and a featureless band envelope in the region 680–820 nm. The MALDI-TOF spectrum of the product shows broadened high molecular mass clusters corresponding to multiples of *m*/*z* 3206, the highest centered at *m*/*z ca*. 19200. This provides a clear indication that oligomerisation has occurred. The potential for developing large and potentially well organised phthalocyanine networks from these and related materials is under investigation.

We thank EPSRC for a studentship (M. J. H.), the EPSRC Mass Spectrometry Service at Swansea for FAB mass spectra, Ms V. Boote at University of Manchester for running MALDI-TOF mass spectra, and Dr Helen Cooper at Warwick University for providing FT-ICR mass spectra.

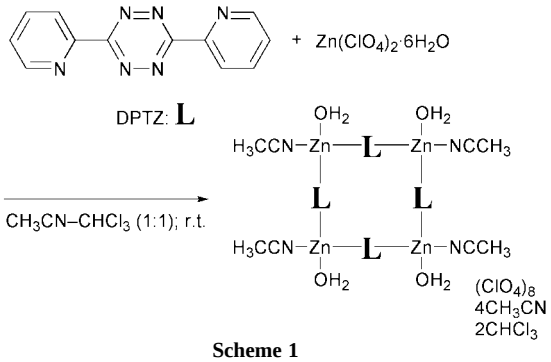
Received (in Columbia, MO, USA) 9th December 1999, Accepted 21st March 2000

A quantitative synthesis of a novel cyclic tetranuclear Zn^{II} complex with 3,6-di-2-pyridyl-1,2,4,5-tetrazine (DPTZ), which was spontaneously resolved as chiral crystals, has been developed.

The rational design of discrete self-assembling systems is one of the most challenging tasks in the exploitation of supramolecular synthons. In particular, the metal-assisted assembly of cyclic molecular arrays plays an integral part in the development of inclusion chemistry as well as 'engineering up' molecular architectures. To date, the groups of Fujita,[1] Stang,[2] and others[3] have been exploiting the coordination-based syntheses of molecular squares or rectangles with right angles at their corners, which are one of the simplest members of the polygon family. The creation of a new class of artificial *chiral* supramolecular species *via* spontaneous self-assembly has been one key to further development of this rapidly expanding field. Stang and coworkers have explored the syntheses of chiral Pt^{II}_4 or Pd^{II}_4 molecular squares by using either chiral chelating ligands or C_{2h}-symmetrical bridging ligands.[4] As described previously, there are several ways of creating chiral supramolecular architectures, of which use of an inherently chiral octahedral metal complex has been recognized as a promising strategy. Unlike the square-planar Pt^{II} or Pd^{II} complexes, octahedral metal complexes are inherently chiral[5] and therefore no chiral auxiliary ligands are required. Recently, Wang and coworkers have reported a Co^{II} molecular square complex that exhibits a chiral molecular structure in the solid state,[6] where no chiral auxiliary ligands were employed, and the individual single crystal was found to consist of one enantiomer only. However, the reaction yield was low and the solution behavior of the molecular square remains unsolved.

We report herein a *quantitative* preparation of a novel cyclic tetranuclear Zn^{II} complex that was *spontaneously resolved* as *chiral* crystals. The bridging ligand used in this study is 3,6-di-2-pyridyl-1,2,4,5-tetrazine (DPTZ). Although the two pyridyl groups of DPTZ can rotate around the C–C bonds between the pyridine rings and tetrazine ring, upon coordinating to metal ions the three aromatic rings can become almost coplanar to bridge two metal centers. We therefore anticipated that DPTZ would serve as a rigid multitopic spacer ligand and that a thermodynamically stable yet kinetically labile chiral assembly could be formed by the use of the Zn^{II} ion which is inherently chiral in an octahedral coordination geometry.[7]

The reaction of $Zn^{II}(ClO_4)_2{\cdot}6H_2O$ with an equimolar amount of DPTZ in chloroform–acetonitrile at ambient temperature produced orange prisms of $[Zn^{II}_4(DPTZ)_4(H_2O)_4(CH_3CN)_4](ClO_4)_8{\cdot}2CHCl_3{\cdot}4CH_3CN$ **1**, in 90% yield (Scheme 1). The structure of **1** was determined by a single-crystal X-ray diffraction analysis with a Siemens CCD X-ray diffractometer. Complex **1** crystallizes in the chiral space group $C222_1$.[8] As shown in Fig. 1, complex **1** has a crystallographically imposed



Scheme 1

D_2 symmetry with half of the molecule being in the asymmetric unit. As a consequence of the D_2symmetry, the four Zn^{II} centers have identical chirality, *i.e.* either all Δ or all Λ optical geometry. The Flack parameter was nearly zero, indicating *each* individual crystal of **1** consists of *a single* enantiomer.[9] Indeed, all four Zn^{II} centers of the single crystal used in this analysis have Λ geometry and therefore complex **1** is a chiral molecular box in the solid state.

Space-filling diagrams of the molecular box **1** are shown in Fig. 2. Each Zn^{II} ion of complex **1** has a typical octahedral coordination geometry with two DPTZ ligands bridging the other two Zn^{II} centers. The other two coordination sites of the Zn^{II} ion are occupied by one acetonitrile and one water molecule. It is noteworthy that there should be many possible structures in the four Zn^{II} centers if the acetonitrile and water molecules occupy their positions randomly. However, all the

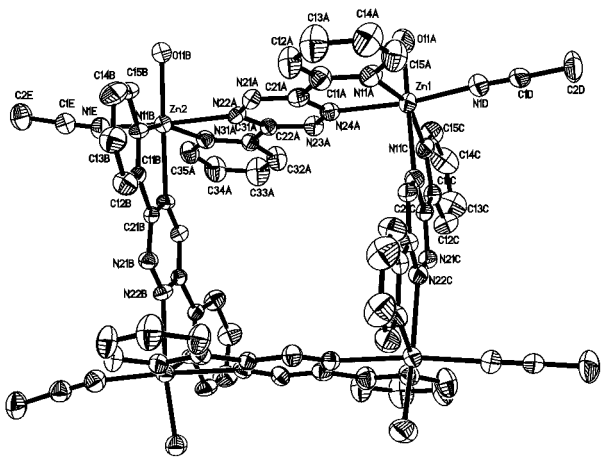


Fig. 1 ORTEP view of the molecular structure of **1** with 50% thermal ellipsoids and labeling scheme. Perchlorate anions and solvent molecules are omitted for clarity.

DOI: 10.1039/a909742b

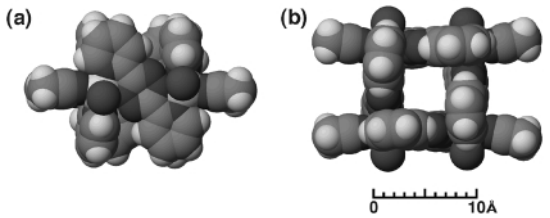

Fig. 2 Space-filling diagrams showing (a) a side-view and (b) a top-view of the box cavity of complex **1**.

four acetonitrile and four water molecules coordinate to Zn^{II} in a highly symmetrical manner, and the formation of a single diastereomer was observed. The $Zn^{II}\cdots Zn^{II}$ distances along the corners of the box are *ca.* 7.2 Å. The dimensions of the box cavity are estimated to be *ca.* 4 Å × 4 Å [Fig. 2(b)]. It is of interest that one perchlorate ion and two chloroform molecules are encapsulated within the box cavity of **1**, where the two chloroform molecules interpose the perchlorate ion like two caps to close the box. Such guest molecules may facilitate the cyclization and therefore stabilize the resulting cyclic box structure.

The ^{1}H NMR spectrum of **1** in CD_3CN showed one set of proton signals for the pyridine parts of DPTZ,[10] suggesting that the DPTZs are bridging ligands and are coordinated symmetrically between two Zn^{II} centers. The discrete tetrameric structure of **1** in acetonitrile was confirmed by ESI-TOF mass spectroscopy. The isotopically resolved ESI-TOF mass spectrum of this assembly is shown in Fig. 3. The signals of Zn^{II} tetrameric species for **1** are centered at *m/z* 2166.6, 1954.6, 1900.6 and 1664.6, which correspond to the +1 charged cationic species [Fig. 3(a)].[11] For example, the enlarged plot of the signal for *m/z* 1954.6 $[Zn^{II}_4(DPTZ)_4(H_2O)_3(CH_3CN)_2(OH)(ClO_4)_6]^+$ gave excellent agreement between the experimental and theoretical isotopic distributions, indicating the tetrameric character of **1** [Fig. 3(b) and 3(c)]. These results establish that the cyclic Zn^{II} tetramer is stable in solution.

A solution of complex **1** in acetonitrile exhibited an essentially zero optical rotation, indicating that the bulk of the crystals is a racemate. Although the single-crystal X-ray diffraction analysis demonstrated that each individual crystal of **1** consists of one enantiomer only, the question of whether the single enantiomer of **1** undergoes racemization in solution still remains unsolved because the individual chiral crystals of **1** are too small to allow any meaningful kinetic study and circular dichroism measurement. Attempts for preferential crystallization of either enantiomer Δ or Λ through seeding of the racemic supersaturated solution with a seed of one crystal were unsuccessful.

The present molecular box **1** is the first example of spontaneous resolution of a quantitatively self-assembled Zn^{II} molecular box.

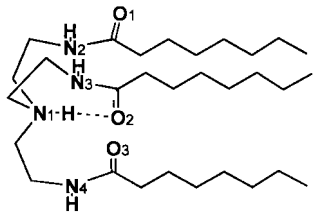
Received (in Columbia, MO, USA) 15th November 1999, Accepted 31st December 1999

The crystal structure of a protonated tripodal lipophilic amide, *N*-{2-[bis(2-octanoylaminoethyl)amino]ethyl}octanamide, identified an elegantly architected bilayer hydrogen bonded structure consisting of ladder-like cascades of the amide, with the rungs comprised of the lipophilic tails pointing inward and the poles made up of polar quaternary ammonium heads lining channels filled with nitrate ions.

In our investigation of the anion binding capabilities of a series of lipophilic amide receptors of varying chain length, we recently isolated the nitrate salt of a protonated triamide **1** with



1

three seven-carbon alkyl chains. The unanticipated structure shows a novel and elegant bilayer structure comprised of ladder-like cascades of the amide, with the rungs consisting of the lipophilic tails pointing inward and the polar heads lining channels filled with nitrate ions. Because of the high thermal motion usually exhibited by such chains, crystallographic determinations are limited. This most unusual structure thus provides solid state insights into the forces holding such frameworks together.

Anion complexation is a swiftly emerging field of chemistry with relevance to biology, the environment, and industry.[1] Of the oxo-anions, nitrate is important because of its prevalence in soil and groundwater as well as at nuclear waste facilities. Our interest in nitrate binding began several years ago with the isolation and structural characterization of the nitrate salt of an inclusion complex of nitrate with a polyammonium macromonocycle,[2] and more recently with a *di*nitrate inclusion complex within a tripodal bicyclic aza cryptand.[3] Drawbacks associated with polyammonium receptors, however, are their binding dependency on pH as well as high water solubilities, which limit their effectiveness in many applications. In this regard, receptors soluble in organic phases and capable of binding over a range of pH are desirable. Hence we, along with a number of other researchers, have begun to explore hosts containing amide functionalities, a logical choice considering that Nature employs such moieties in the biological binding and transport of anions.[4]

In our study of lipophilic receptors we have synthesized and characterized a series of tripodal amides with hydrocarbon tails based on the triamine building block, tren. In earlier work, Reinhoudt and coworkers examined related tren-based systems, and were successful in identifying several excellent neutral receptors for phosphate.[5] Only one hydrocarbon chain (with six carbons) was included in that study,which focussed on aromatic 'tails'. Potvin and Jairam also have employed similar types of ligands, but primarily for binding metal ions and especially as models for zinc enzymes.[6] Crystallographic characterization of such receptors with lipophilic tails tends to be very limited because of the floppy nature of the hydrocarbon chains, which generally results in poor crystallinity and in large thermal motion and very high *R* factors.[7] By contrast, the structure reported herein was 'well behaved', and, as such, provides a significant addition to the structural database of bilayers.

Synthesis of the tripodal amide receptor from tren and octanoic acid was found to proceed in high yield using triphenyl phosphite as a coupling agent.[8]† To purify the resulting triamide, the crude product was dissolved in DMSO and acidified with nitric acid to pH 1. The crystalline product, when recrystallized from a DMSO–water mixture, gave crystals suitable for X-ray diffraction.

The crystal structure shows the crystals to be the mononitrate salt of the amide, singly protonated at the apical nitrogen.‡ While it was initially disappointing to us that the nitrate was not encapsulated within the tren unit, the reason is apparent: one of the amide carbonyl oxygen atoms points into the cavity to hydrogen bond with the *endo*-oriented proton of the apical amine [O(2)···N(1) 2.74(1) Å], effectively 'closing' the cavity. The receptor packs in beautifully patterned three-dimensional arrays reminiscent of bilayer structures, with the hydrophilic tren 'heads' lining open channels for the nitrates [Fig. 1(a) and (b)]. The bilayer is held together by hydrogen bonding between pairs of cations, O(1)···N(3′) 2.816(9) and O(3)···N(2″) 2.800(9) Å, in adjacent unit cells. The distance between apical nitrogens through the bilayer is 25.3 Å, while the distance between apical nitrogens across the bilayer is 6.2 Å. The torsion angles in **1** indicate that the carbon chains are highly ordered. Within the polar head of the tripod, the $N_{apical}CCN_{amide}$ angles approximate the *gauche* conformation, while the hydrocarbon portion of the tail exhibits a consistent array of *trans* angles. One exception to this pattern occurs on the chain in which the amide oxygen points inward, to hydrogen bond with the apical nitrogen of the tren unit. In the latter case both the CCN(3)C(O) [−73.1(6)°] and N(3)CC(O)C angles [132.3(5)°] differ significantly from their $CN_{amide}C(O)C$ [−124.3(5) and −139.1(5)°] and $N_{amide}C(O)CC$ [176.6(5) and 177.1(6)°] counterparts on adjacent tails.

The closest nitrate–nitrate approach along the channels is 5.75 Å between nitrogen centers. Only the two disordered oxygen atoms on the nitrate are within strong hydrogen bonding range of one of the amide nitrogens, O(6)···N(4) 2.98(2) and O(7)···N(4) 2.96(3) Å. One of the two ordered oxygens, O(5) of the nitrate, lies within a 3.5 Å distance of both N(3) and N(4).

In conclusion, while **1** is not a selective receptor for nitrate, having rather similar K_{as} values for a series of ions,[9] this is one of the few crystallographically confirmed bilayer structures. A structure of 1,2-dilauroyl-DL-phosphatidylethanolamine with two chains forming the bilayer, in which the unweighted *R* factor was extremely high (0.28), would appear to be the only crystal structure closely related to **1**.[7] Thus the structure of the

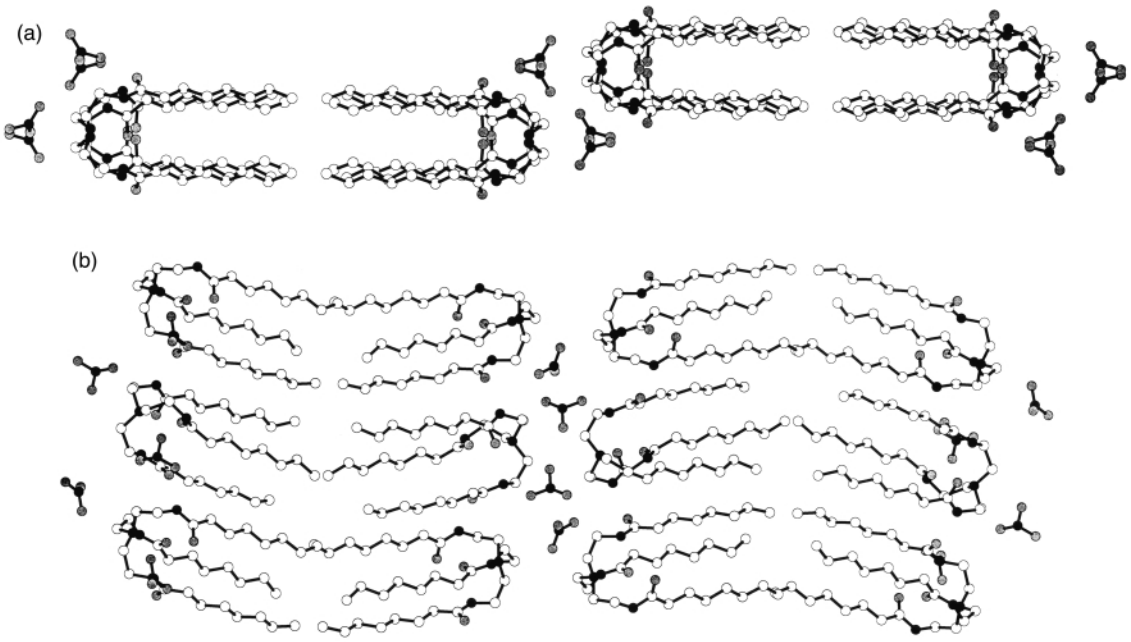


Fig. 1 (a) View of the *ab* plane (*b* along the horizontal axis) looking down *c*. (b) View of the *ac* plane (*b* along the horizontal axis) looking down *a*.

nitrate complex of **1** with its three-chain bilayer formation provides rare evidence of the elegant architectural pattern that is undoubtedly inherent in these systems in their biological habitats.

This research was supported by a grant from the Department of Energy DE-FG07-96ER62307. We are grateful for helpful discussions with Professor Nathaniel W. Alcock.

Synthesis of *O*-alkylhydroxylamines by electrophilic amination of alkoxides

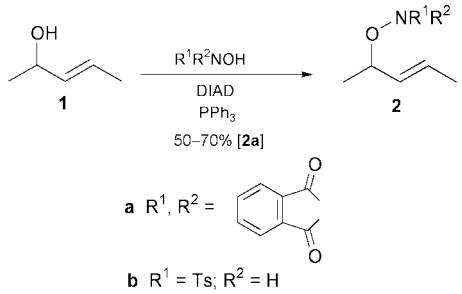
Oliver F. Foot and David W. Knight*

Chemistry Department, Cardiff University, PO Box 912, Cardiff, UK CF10 3TB. E-mail: knightdw@cf.ac.uk

Received (in Liverpool, UK) 21st March 2000, Accepted 27th April 2000

The 3-trichloromethyloxaziridine 7 reacts smoothly with lithium alkoxides, derived from a representative range of alcohols, transferring an NHBoc function to the oxygen to provide good to excellent yields of *N*-Boc-*O*-alkylhydroxylamines 8–16 by this new *O*-amination protocol.

In pursuance of our studies of various electrophile-driven 5-*endo* cyclisation processes,[1] we required access to the hydroxylamines represented by structures **2** and **6** and sought to obtain these by a Mitsunobu displacement[2] using the corresponding and readily available alcohols **1** and **5**, as this seemed the best of a relatively limited number of options.[3] Unfortunately, both approaches suffered from serious drawbacks. For the allylic alcohol **1**, the Mitsunobu method using *N*-hydroxyphthalimide,[4] under standard conditions delivered good yields of the required substrate **2a**; in contrast, when *N*-(4-toluenesulfonyl)hydroxylamine (TsNHOH)[5] was used as the nucleophile, yields were very poor (Scheme 1). However, when



Scheme 1

applied to unsymmetrical substrates, both the S_N2 and S_N2' pathways were followed (Fig. 1) to give both possible products

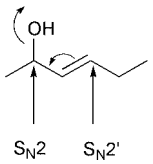


Fig. 1

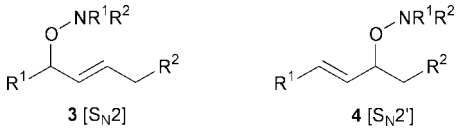
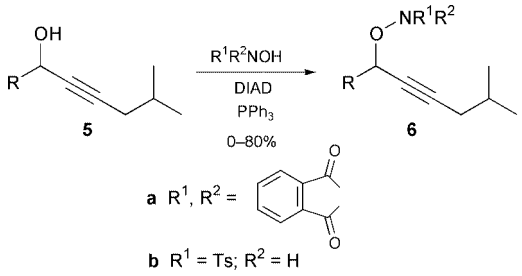
(*i.e.* hydroxylamines **3** and **4**). For propargylic alcohols **5**,

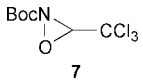


Mitsunobu displacement with either nucleophile (R^1R^2NOH) gave very variable, precursor dependent yields of the required products **6** (Scheme 2). Despite these problems, and the additional necessity of converting the phthalimides (*e.g.* **2a**, **6a**), into the corresponding *N*-tosylates (*e.g.* **2b**, **6b**)we were able to access the latter substrates in sufficient quantities to demonstrate that the projected 5-*endo*-trig and 5-*endo*-dig cyclisations generally work extremely well to provide a new entry into



Scheme 2

isoxazolidines and isoxazolines, respectively.[6] We were therefore prompted to find an alternative and more efficient approach to these classes of compounds (**2**–**4** and **6**), both for this reason and also because approaches to hydroxylamines in general are somewhat lacking.[7] We were attracted by recent reports from the Vidal–Collet group[8] that various electron-deficient oxaziridines could behave as positive nitrogen sources ($^+$NHBoc), rather than as the more familiar positive oxygen sources ($^+$OH), popularized by the work of Davis and his colleagues.[9] However, while such species were reported to react efficiently with various amines and enolates and both sulfur and phosphorus nucleophiles, there was no report of similar reactions with alcohols or the derived alkoxides.[8] Such a transformation has been achieved using chloramine, but only with a large excess of alkoxide and in relatively poor yields,[10] and it was not until a very recent report that 3,3′-di-*tert*-butyloxaziridine reacts with a range of potassium alkoxides in DMPU and in the presence of 18-crown-6 to provide *O*-alkylhydroxylamines in 10–86% yields that such a process had synthetic value.[11] We report herein, that the highly electron deficient oxaziridine **7** reacts

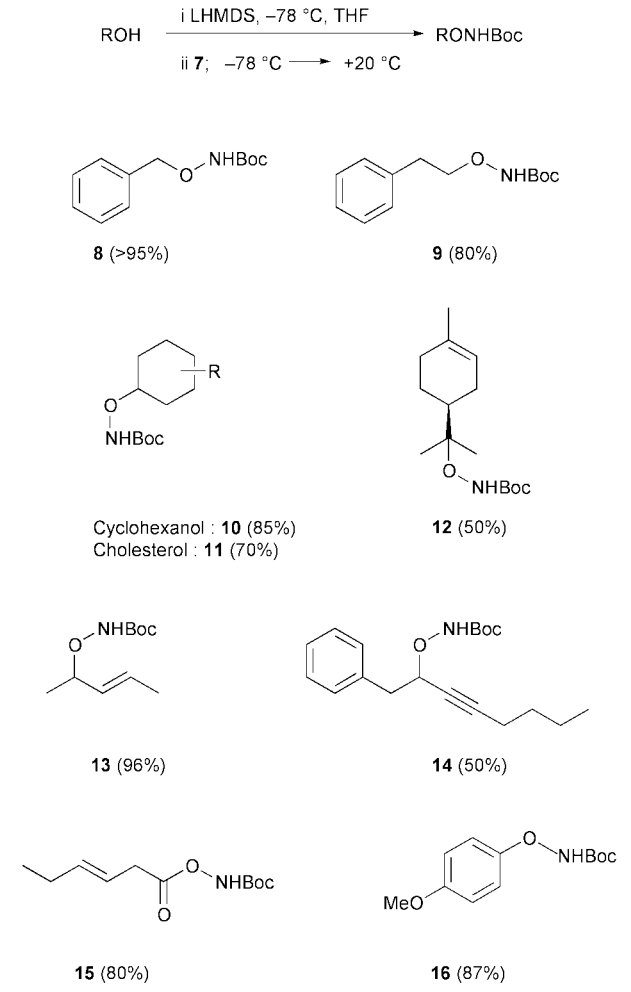


smoothly with lithium alkoxides using very practical conditions, despite our fears that it would simply act as a proton source for these basic species.

Oxaziridine **7** was prepared as previously described[8] starting from *tert*-butyl carbazate, diazotization of which provided *tert*-butyl azide. This potentially dangerous material was not isolated but only handled in solution and was immediately treated with triphenylphosphine in wet ether to give the imine Ph_3P=NBoc; subsequent aza-Wittig reaction with chloral and oxone® oxidation gave the oxaziridine **7**, as previously reported.[8] The compound was purified by column chromatography[8] and, in our hands, was sufficiently stable for use for *ca.* two months if stored below 0 °C, after which repurification was necessary. We were delighted to find that generation of the lithium alkoxide of benzyl alcohol using lithium hexamethyldisilazide (LHMDS) in tetrahydrofuran at −78 °C followed by the addition of oxaziridine **7** and slow warming to ambient temperature delivered an essentially quantitative yield of the *O*-benzyl-*N*-Boc-hydroxylamine **8** after a simple aqueous work-up.[8] Using the same method, we tested its viability with a range of other alcohols of varying structure and the results are collected in Table 1. A primary saturated alcohol, phenethanol,

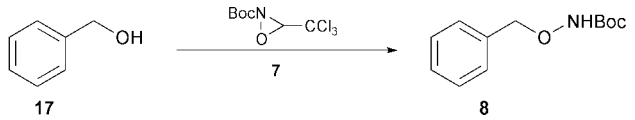
DOI: 10.1039/b002388o

Table 1



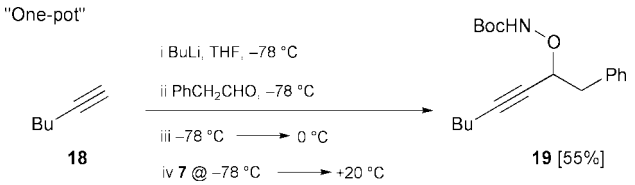
reacted slightly less efficiently giving the hydroxylamine derivative **9** in 80% yield. Two secondary alcohols, cyclohexanol and cholesterol, similarly gave the hydroxylamines **10** and **11** in 85 and 70% yields, respectively. Even the tertiary alcohol group in α-terpineol reacted reasonably efficiently to give the derivative **12** in 50% yield. This contrasts with the use of 3,3′-di-*tert*-butyloxaziridine,[11] which delivered only a 10% yield from a similar tertiary alcohol. However, it should be noted that this latter method leads directly to *O*-alkylhydroxylamines as the free bases, which could be useful in some contexts. Returning to our original substrates, we were glad to find that yields were again viable, the allylic alcohol derivative **13** being isolated in almost quantitative yield while the relatively sensitive propargylic derivative **14** was isolated in 50% yield, with the material balance being largely unreacted alcohol. Hence, it appears that the present method is especially efficient when applied to benzylic or allylic alcohols. Other oxygen-based nucleophiles also react successfully. Thus, under the same conditions, (*E*)-hex-3-enoic acid was converted into the *O*-acylhydroxylamine **15** and 4-methoxyphenol into the *O*-arylhydroxylamine **16**, both in excellent yields. In general, all of the foregoing derivatives appeared rather sensitive to chromatography over silica gel; Grade II alumina was more suitable but its use still often resulted in losses of some 10–20%[12] deprotection to give the corresponding *O*-alkylhydroxylamines (*i.e.* **2**, **6**; $R^1 = R^2 = H$) has ample literature precedent,[13] which we have confirmed during the present work, during which we have also been able to exchange the *N*-protecting group from Boc to TS (*e.g.* **13** → **2b**) in an efficient manner.

The ease with which alkoxides in general can be formed led us to briefly investigate some alternative protocols, using benzyl alcohol **17** as a test substrate. As outlined in Scheme 3, generation of the sodium alkoxide using sodium hydride in



Scheme 3 *Reagents and conditions*: NaH, Et_2O, 20 °C, > 95% yield *or* BuLi, THF, −78 °C for 1 h then warming to 20 °C, > 90% yield.

diethyl ether at ambient temperature followed by addition of the oxaziridine **7** again gave an excellent yield of the hydroxylamine **8** as did the use of butyllithium as base. Finally, we have succeeded in preparing suitable substrates for the 5-*endo*-dig cyclisations by a very direct, 'one-pot' method (Scheme 4). Thus, condensation of hex-1-yne **18**, after deprotonation using butyllithium, with phenylacetaldehyde, addition of the oxaziridine **7** to the resulting alkoxide and warming to ambient temperature gave a 55% yield of the desired hydroxylamine **19**. These results suggest that there could well be a number of (substrate-dependent) modifications which could usefully be applied to this type of chemistry. Further studies along these lines are underway, along with work on the 5-*endo* cyclisations, which is now viable in the light of the foregoing results.



Scheme 4

We are very grateful for some helpful referees comments and to the EPSRC mass Spectrometry Centre (University College, Swansea) for the provision of mass spectral data and to the EPSRC for financial support.

TiO_2 photocatalytic 2e$^-$-reduction of azobenzene to hydrazobenzene is found to occur at λ_{ex} > 300 nm while loading of nanometer-sized Pt particles on TiO_2 induces N=N bond cleavage *via* 4e$^-$-reduction; only photoisomerization occurs in the absence of TiO_2.

From the viewpoint of "green chemistry", it is important to develop new processes for synthesizing useful compounds or detoxifying harmful compounds utilizing solar energy. Heterogeneous photocatalytic oxidations derived from valence band holes (h^+_{vb}) are attracting a great deal of attention for application to environmental problems.[1,2] Much less interest has been shown in reductive photochemistry despite the fact that conduction band electrons (e^-_{cb}) have a potential to induce highly selective reduction because of their mild reducing power.[3–6] Most of the azo dyes used widely in textile industries are carcinogenic and resistant to bacterial degradation, thus requiring effective wastewater treatment. The groups of Kiwi[7] and Oliveira-Campos[8] have recently reported photocatalytic oxidation of azo dyes using TiO_2 and Fe_2O_3. On the other hand, to our knowledge, the present work is the first study on heterogeneous photocatalytic reduction of azo dyes. Particular emphasis is placed on the loading effect of Pt nanoparticles on a TiO_2-photocatalyst.

Anatase TiO_2 particles (average diameter = 180 nm, BET surface area = 9.0 $m^2\ g^{-1}$) were supplied from Tayca Co. (JA-1) and 0.1 wt% Pt was deposited on them by photodeposition (Pt/TiO_2).[9] The particles (20 mg) were suspended in a 1.0 × 10^{-4} M solution [50 mL, solvent H_2O–EtOH (9/1 v/v)] of azobenzene (AB, > 95%, Tokyo Kasei Co.) in a double-jacketed cell. After the suspension had been purged with N_2 for 15 min, irradiation (λ_{ex} > 300 nm) was carried out with a 400 W high-pressure mercury arc (H-400P, Toshiba); the light intensity integrated from 320 to 400 nm ($I_{320–400}$) was measured as 3.4 mW cm^{-2}. N_2 bubbling and magnetic stirring of the suspension were continued throughout the irradiation while the reaction temperature was maintained at 31 ± 1 °C by circulating thermostatted water around the cell through the outer jacket. Product analysis was performed by both UV–VIS spectroscopy and high performance liquid chromatography [HPLC measurement conditions: column = Fluofix INW425 4.6 × 250 mm (NEOS); mobile phase H_2O–MeOH (1/1 v/v); flow rate = 3 mL min^{-1}; λ = 230 nm].

High-resolution transmission electron micrograph (HRTEM) images of Pt/TiO_2 demonstrated that Pt particles of diameter 2–5 nm are dispersed on the surface of TiO_2. The degree of adsorption of AB increased with loading of Pt (4.3 × 10^{-7} mol g^{-1} for TiO_2 and 2.6 × 10^{-6} mol g^{-1} for Pt/TiO_2 at an equilibrium concentration of 4.0 × 10^{-5} M), whereas the degree of adsorption of EtOH was essentially invariant with Pt loading. This finding indicates that AB and EtOH preferentially adsorb on Pt and TiO_2 surfaces of Pt/TiO_2, respectively. The interaction between AB and Pt would involve both σ-bonding [π orbital (AB) → d orbital (Pt)] and π-backbonding [d orbitals (Pt) → π* orbital (AB)]. Aliphatic alcohols are known to adsorb strongly on the surface of TiO_2.[10]

The electronic absorption spectrum of AB showed two absorption bands at 423 and 321 nm assignable to the n→π* and π→π* transitions, respectively, for the *trans* isomer. The absorptivity of the π→π* band for the *trans* isomer is 3.3 times that for the *cis* isomer.[11] The visible absorption at λ > 400 nm vanishes when the N=N bond of AB is broken. Accordingly, the n→π* band is a good indication of the presence of the N=N bond. Without either TiO_2 (or Pt/TiO_2) or irradiation, the intensity of the n→π* band was almost invariant, while that of the π→π* band significantly decreased. This fact suggests that only *trans–cis* isomerization occurs under these conditions.[12] Also, Pt loading on TiO_2 increased the rate of isomerization in the dark. This is probably due to the decrease in the energy barrier for molecular rotation around the N=N bond with adsorption of AB on Pt surfaces. No products other than AB were detected from the irradiated solution by HPLC, which supports the above conclusion.

Fig. 1 shows the variation of the concentrations of AB and products in the presence of TiO_2 as a function of irradiation time (t). AB is slowly reduced to hydrazobenzene (HAB) with a selectivity of 97% at 0 < t < 3 h. Since the turnover frequency is calculated to be *ca*. 3 at t = 3 h, this reaction can be regarded as photocatalytic. In the absorption spectra, the n→π* band gradually weakened concurrently with a rapid decrease in the π→π* band intensity. Providing direct evidence for cleavage of the N=N bond.

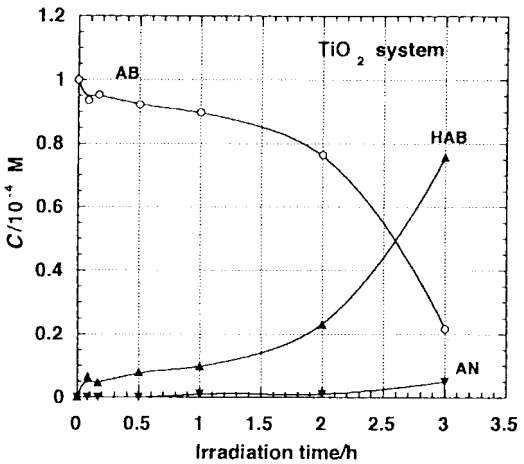

Fig. 1 TiO_2 photocatalytic reduction of AB at 31 ± 1 °C: initial pH = 6.4; TiO_2 20 mg/50 mL.

Fig. 2 shows time profiles of the concentrations of AB and products with irradiation in the presence of Pt/TiO_2. The rate of reduction of AB to HAB markedly increases with loading of Pt [conversion *ca*. 100%, selectivity (HAB) = 91% at t = 1 h]. Noticeably, further reduction of HAB to aniline (AN) occurs [selectivity(AN) = 19.2% at t = 3 h]. In the absorption spectra, the n→π* band of AB completely disappeared at t = 1 h and new absorption bands appeared at 280 and 230 nm at 3 h that are in accordance with the positions for the n→π* and π→π*

DOI: 10.1039/b001062f

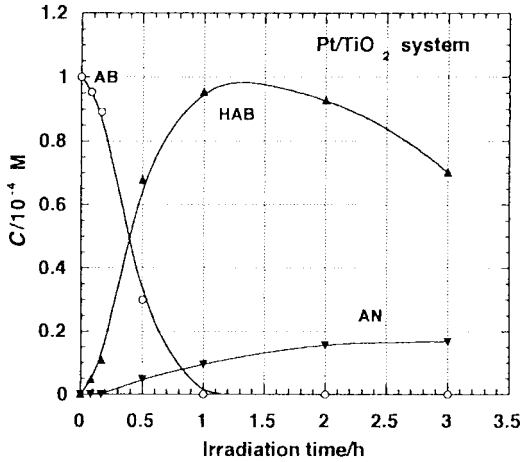

Fig. 2 Pt/TiO_2 photocatalytic reduction of AB at 31 ± 1 °C: initial pH = 6.5; Pt(0.10 wt%)/TiO_2.

bands, respectively, of AN. These facts are consistent with the results of Fig. 2. The pH of the Pt/TiO_2 system decreased from 6.5 (t = 0) to 5.6 (t = 1 h), while the corresponding change was very small for the unmodified TiO_2 system (Δ pH = 0.2). Product analysis by gas chromatography confirmed generation of MeCHO and CO_2 in each system. Evidently, EtOH acts as a reductant in the present photocatalytic reaction.[13] It has been established that EtOH exerts a current doubling effect in TiO_2 photocatalysis,[14] which would also be responsible for the reduction to proceed.

The results above clarified the two effects of Pt loading; one is to increase the rate of 2e$^-$-reduction (AB→HAB) and the other is to enable 4e$^-$-reduction (AB→AN). Pt loading enhances both the adsorption of AB (adsorption effect)[4] and the charge separation of $e^-_{cb}\cdots h^+_{vb}$ pairs (charge separation effect).[15] In addition, selective adsorption of the reactant (AB) on reduction sites (Pt) and the reductant (EtOH) on oxidation sites (TiO_2) is observed (reasonable delivery effect).[16] The remarkable increase in the reduction rate can be explained in terms of these effects. Also, inspection of Fig. 1 and comparison with Fig. 2 suggests that Pt loading leads to the absence of an induction period. Further the surface multi-electron transfer is thought to be assisted by an electron-pool effect of Pt with a large work function.

In conclusion, the 2e$^-$-reduction of AB to HAB proceeds selectively by using TiO_2 as a photocatalyst, whereas only photoisomerization occurs in the absence of TiO_2. Loading of Pt on TiO_2 not only accelerates the reduction but also enables the 4e$^-$-reduction of AB to AN. Our work thus represents a novel method for treating wastewater containing azo dyes *via* reductive cleavage of the N=N bonds.

We express sincere gratitude to Professor Masakuni Yoshihara (Kinki University) for permission to use HPLC and to Dr Tomoki Akita (Osaka National Research Institute) for the HRTEM measurements.

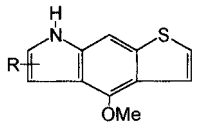
Received (in Cambridge, UK) 29th March 2000, Accepted 27th April 2000

An expedient synthesis of benz-1,2-oxazine derivatives involving nitrene insertion on a methoxy group is described.

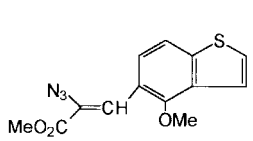
Our findings[1,2] in the course of synthesis of novel photoconducting materials consisting of electron donor and acceptor molecules linked by polymethylene spacers induced us to synthesize the linear tricyclic system **1**, which is expected to be



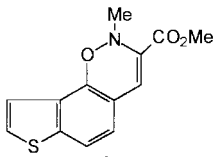
1

a good electron donor. This system can be conveniently accessed by annelation of a pyrrole ring to the 4-methoxy-1-benzothiophene core, through insertion of vinyl nitrene, incipiently liberated by thermolysis of the corresponding vinyl azide. We have previously used this methodology developed by Rees and coworkers[3] in the synthesis of angular thienoindoles.[4]

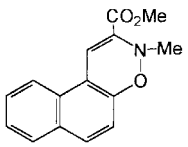
The vinyl azide **2** obtained from 4-methoxy-1-benzothiophene-5-carbaldehyde and methyl azido acetate, afforded upon heating for 2.5 h in xylene, a mixture of two compounds, separable by careful chromatography over silica gel. The desired 2-methoxycarbonylthieno[3,2-*f*]indole **1** (R = 2-CO_2Me) was eluted with light petroleum (bp 60–80 °C)–ethyl



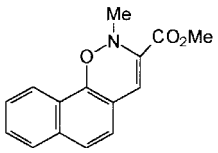
2



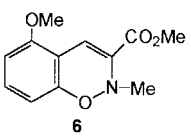
3



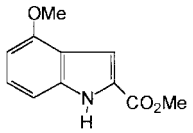
4



5



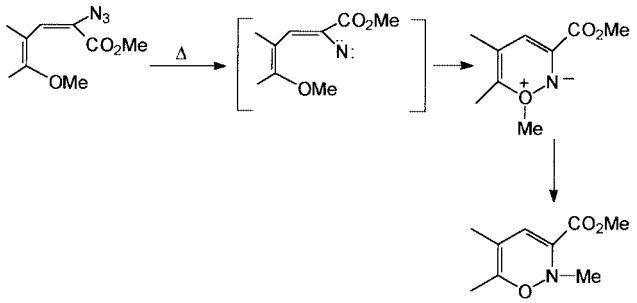
6



7

acetate (23 : 2) while the second compound, eluted with ethyl acetate–light petroleum (bp 60–80 °C) (1 : 9) was found to be 2-methyl-3-methoxycarbonylthieno[2,3-*h*]benz-1,2-oxazine **3** the structure of which was confirmed from elemental analysis and spectral data.†

Thermolysis of vinyl azides derived from 2-methoxy-1-naphthaldehyde, 1-methoxy-2-naphthaldehyde and 2,6-dimethoxybenzaldehyde afforded the corresponding condensed 1,2-oxazines **4**, **5** and **6**, respectively,† showing the general applicability of this methodology. However, the vinyl azide derived from 2-methoxybenzaldehyde afforded 2-carbomethoxy-4-methoxyindole **7**† as the exclusive product.



Scheme 1

Insertion of nitrene on to the adjacent methoxy group followed by rearrangement plausibly leads to benz-1,2-oxazine (Scheme 1).

The methyl migration most likely involves a radical pathway since a concerted pathway appears unlikely.[5]

In summary, a simple method is reported which accesses benzo-1,2-oxazines, little reported in the literature, presumably owing to the absence of expedient synthetic routes.[6] Further work is in progress to establish the general nature and mechanism of this reaction by thermolysis of vinyl azides derived from other *o*-methoxyarylaldehydes.

We thank Professor Charles W. Rees for helpful discussion. S. C. G. thanks the Council of Scientific and Industrial Research (New Delhi) for a Senior Research Fellowship.

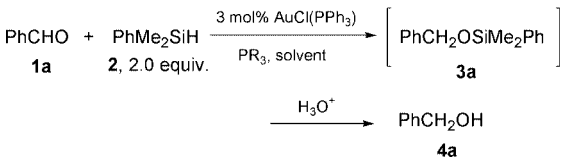
Received (in Cambridge, UK) 3rd March 2000, Accepted 20th April 2000

The first examples of the hydrosilylation of organic compounds such as aldehydes and an aldimine using a catalytic amount of a gold complex, which accomplished versatile regio- and chemo-selective reduction of carbonyl compounds, are described.

The exploration of catalytic reactions using soluble gold complexes has been a challenging area in organic synthesis.[1,2] The design of synthetic reactions using gold complex catalysts is still considered to be a difficult subject, though some successful systems have been reported. A considerable number of transition metal complexes have been employed as catalysts for the hydrosilylation of organic compounds.[3] However, to our knowledge, no examples of hydrosilylation catalyzed by gold complexes have been reported. Recently, we found a highly reactive catalysis by a gold complex for the dehydrogenative dimerization of a hydrostannane, offering new clues to the further development of gold complex-catalyzed reactions.[4] Here we describe the first example of the hydrosilylation of organic compounds using a gold complex as a catalyst. These results reveal the novel reactivity of the gold complex as well as its versatile selectivity in the reduction of organic compounds.

We first examined the hydrosilylation of benzaldehyde **1a** using a catalytic amount of chloro(triphenylphosphine)gold(I) alone [eqn. (1), Table 1, entry 1].[5] After the addition of



(1)

dimethylphenylsilane **2** (2.0 mmol), the colorless mixture of chloro(triphenylphosphine)gold(I) (0.03 mmol), benzaldehyde **1a** (1.0 mmol) and dry DMF (1.0 ml) changed to a deep-purple solution and precipitation of metallic gold was observed within 10 min at 70 °C.[6] No silylated product was found under these conditions. We next examined a combination of chloro(triphenylphosphine)gold(I) and triphenylphosphine as catalyst, which gave good results in our previous study of gold catalysis; however, here it gave a similar disappointing result (entry 2).[4] Use of tributylphosphine, which is more basic and is strongly coordinating, as an additive ligand to chloro(triphenylphosphine)gold(I) provided remarkable catalytic activity for the hydrosilylation of **1a** (entry 3). Compound **2** (2.0 mmol) was added to a mixture of chloro(triphenylphosphine)gold(I) (0.03 mmol), tributylphosphine (0.20 mmol), **1a** (1.0 mmol) and DMF (1.0 ml) under nitrogen. After stirring for 1.5 h at 70 °C, the quantitative formation of the corresponding silyl ether **3a**, the hydrosilylation product of **1a** and **2**, was observed by ^{1}H NMR spectroscopy, and alcohol **4a** was isolated in 90% yield after acidic hydrolysis.[7,8] In sharp contrast to the previous two

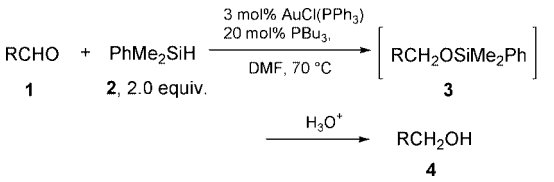
Table 1 Gold complex-catalyzed hydrosilylation of benzaldehyde **1a** under various conditions

Entry[a]	Additive/equiv.	Solvent	Conditions	Yield[b] of **4a** (%)
1	—	DMF	70 °C, 1.5 h	0
2	PPh_3, 0.2	DMF	70 °C, 1.5 h	0
3	PBu_3, 0.2	DMF	70 °C, 1.5 h	90
4	PBu_3, 0.2	Toluene	70 °C, 11 h	65
5	PBu_3, 0.2	THF	70 °C, 3.0 h	92
6	PBu_3, 0.2	MeCN	70 °C, 5.0 h	77

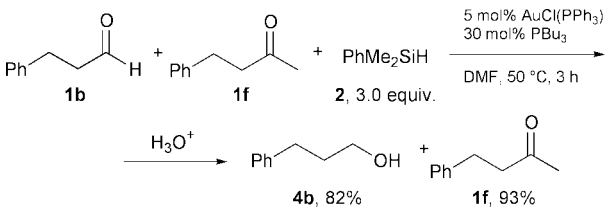
[a] To a solution of benzaldehyde **1a** (1.0 mmol), AuCl(PPh_3) (3 mol%, 0.03 mmol), and phosphine (0–20 mol%, 0–0.20 mmol) in dry DMF (1.0 ml) was added dimethylphenylsilane **2** (2.0 equiv., 2.0 mmol) under nitrogen. [b] Isolated yield after hydrolysis.

systems, the reaction mixture was colorless and a precipitate of metallic gold was not observed. Although this catalytic system was compatible with other solvents, DMF was found to be optimal (entries 4–6).[9] The generality of this gold complex-catalysed hydrosilylation was successfully demonstrated by reaction with various aldehydes [eqn. (2), Table 2]. In



(2)

particular, cinnamaldehyde, which contains a conjugated double bond, was converted to the 1,2-addition product with high selectivity, and the corresponding allyl alcohol **4c** was exclusively obtained in 94% yield after hydrolysis (entry 2).[3,10] When this catalytic system was applied to the reduction of ketone **1f**, no reduced product was obtained (entry 5). The versatile chemoselectivity of the catalyst was clearly shown by the selective reduction of the aldehyde **1b** irrespective of the presence of ketone **1f** under modified conditions [eqn. (3)].[3,10]



(3)

Reduction of an aldimine was also carried out with hydrosilane in the presence of the gold catalyst [eqn. (4)].

4	Cyclohexanecarboxaldehyde **1e**	70 °C, 11 h	**4e**, 78
5	4-Phenylbutanone **1f**	70 °C, 15 h	**4f**, 0[d]

[a] To a solution of carbonyl compound **1** (1.0 mmol), $AuCl(PPh_3)$ (3 mol%, 0.03 mmol) and tributylphosphine (20 mol%, 0.20 mmol) in dry DMF (1.0 ml) was added dimethylphenylsilane **2** (2.0 equiv., 2.0 mmol) under nitrogen. [b] Isolated yield after hydrolysis. [c] Only a 1,2-reduced product was detected. [d] The starting material was recovered in good yield (**1f**, 93%).

Although it took four days for the reaction to be complete, the corresponding reduced product **6** of aldimine **5** was obtained in good yield (83%).

The effect of the amount of the additional ligand on the reactivity is shown in Fig. 1. Monitoring of the reaction by ^{1}H NMR spectroscopy showed that the hydrosilylation product was formed continuously at 50 °C in the presence of 3 mol% of chloro(triphenylphosphine)gold(I) and 20 mol% of tributylphosphine with the reaction almost complete after 600 min (experiment **A**) during which the reaction mixture was colorless and transparent throughout. In experiment **B**, which was carried out with a lower amount of tributylphosphine (10 mol%) than in experiment **A**, considerable rate retardation was observed as the reaction time approached 400 min, though the initial reaction rate in experiment **B** was slightly higher than that of **A** within 200 min. A deep-purple coloration was observed immediately after adding the hydrosilane to reaction mixture and the slow precipitation of gold(0) was observed in experiment **B**. These results indicate that the role of the excess tributylphosphine is the prevention of catalyst decomposition rather than increasing the reaction rate.

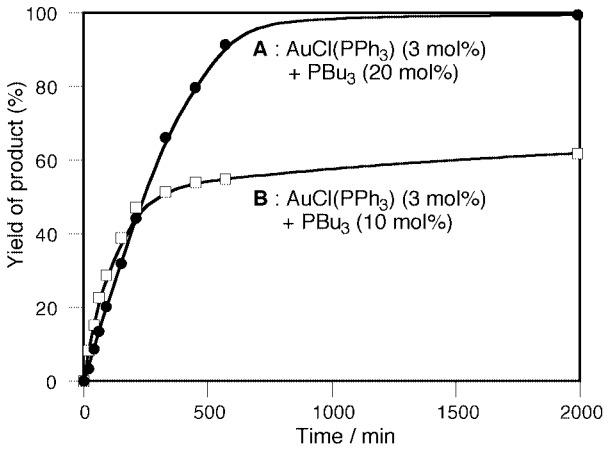

Fig. 1 Product formation *vs.* time for reactions carried out with benzaldehyde **1a** (1.0 mmol), dimethylphenylsilane **2** (2.0 mmol), 3 mol% of chloro(triphenylphosphine)gold(I) (0.03 mmol) and 20 mol% of tributylphosphine (0.2 mmol) (experiment **A**, ●) or 10 mol% of tributylphosphine (0.1 mmol) (experiment **B**, □) in DMF (1.0 ml) at 50 °C. Yields determined by ^{1}H NMR spectroscopy.

Although the active species of this catalyst is still unclear at this stage, we propose that colorless monomeric gold complexes stabilized by the excess tributylphosphines play an important role in this reaction and that the predominant deactivation process is the formation of gold clusters and metallic gold(0) upon reduction of gold(I).

In conclusion, we have described the unprecedented hydrosilylation of organic compounds by a gold complex catalyst with high chemoselectivity. The deactivation of the gold catalyst was suppressed in the presence of an additional ligand (tributylphosphine). These results provide an important principle for the design of gold complex-catalyzed systems.

Poly(ethylene glycol)-linked dimers of D-*myo*-inositol 1,4,5-trisphosphate

Andrew M. Riley and Barry V. L. Potter*

Wolfson Laboratory of Medicinal Chemistry, Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, UK BA2 7AY. E-mail: b.v.l.potter@bath.ac.uk

Received (in Cambridge, UK) 23rd March 2000, Accepted 27th April 2000

The first poly(ethylene glycol)-linked dimers of D-*myo*-inositol 1,4,5-trisphosphate have been synthesised as probes for multi-subunit binding proteins of this ubiquitous second messenger.

D-*myo*-inositol 1,4,5-trisphosphate [Ins(1,4,5)P_3] acts as an intracellular second messenger in almost all mammalian cells by evoking the release of Ca^{2+} ions from intracellular stores through Ins(1,4,5)P_3-gated ion channels[1] [Ins(1,4,5)P_3 receptors, IP_3Rs] located in the endoplasmic reticulum. IP_3Rs are tetramers, composed of four subunits, each with a single Ins(1,4,5)P_3 binding site, surrounding the central ion channel. This suggests the possibility of designing multivalent ligands for IP_3Rs, in which two or more copies of the natural ligand connected by a linker may be able to access multiple binding sites simultaneously, potentially giving enhanced potency, selectivity or other novel effects. To this end, a synthesis of bivalent and tetravalent analogues has been reported in which two or four molecules of a synthetic carbohydrate-based Ins(1,4,5)P_3 mimic were directly attached to a small hydrophobic hub.[2] As the IP_3R is large (12 nm width, estimated from electron microscopy[3]) and the locations of the Ins(1,4,5)P_3 binding sites are unknown, a more promising and versatile approach may be to use bivalent ligands with hydrophilic polymeric linkers in a realistic range of lengths. This strategy has been successfully employed, using very simple chemistry, to identify super-potent dimeric ligands for tetrameric cyclic nucleotide gated (CNG) channels of photoreceptor and olfactory neurones by using a series of dimers of the 8-thio derivative of the natural ligand (cGMP) linked by PEG chains.[4] These PEG-linked dimers of cGMP also showed partial agonist properties at photoreceptor CNG channels, and some were membrane-permeant.

Application of this approach to Ins(1,4,5)P_3 is, however, synthetically much more difficult. Nevertheless, studies have shown that bulky groups may be attached to the axial 2-oxygen atom of Ins(1,4,5)P_3 with minimal reduction in affinity for the IP_3R,[5] suggesting that at the Ins(1,4,5)P_3 binding sites of the IP_3R this area may be open to solvent. We therefore chose to synthesise Ins(1,4,5)P_3 dimers linked *via* the 2-position (Fig. 1). The synthetic strategy was first explored using a short PEG linker derived from hexa(ethylene glycol) (estimated[4] r.m.s. length 1.5 nm), and then three larger dimers were synthesised from PEGs with average molecular weights 1450, 3350 and 8000 (estimated rms lengths 3, 5 and 8 nm, respectively).

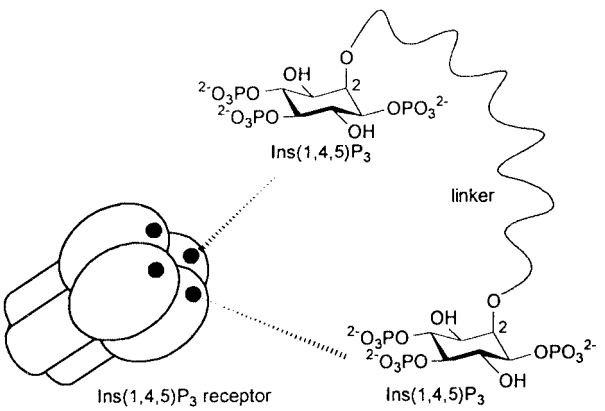

Fig. 1 Ins(1,4,5)P_3 dimers could target multiple receptor binding sites.

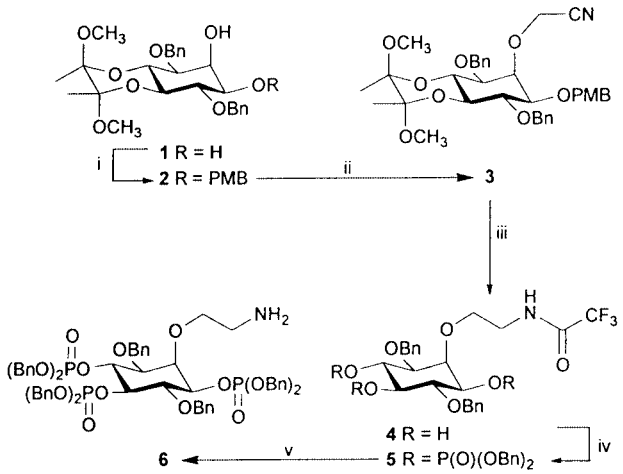
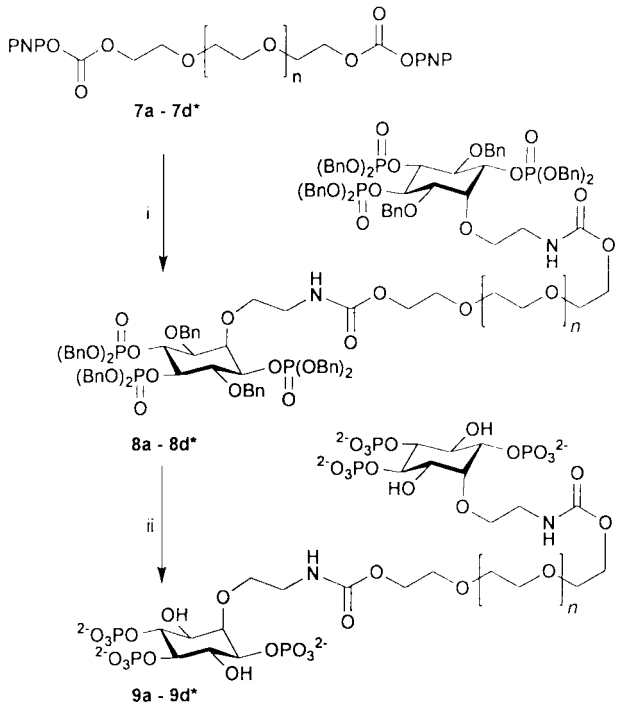
The synthesis begins with diol **1**[6] (Scheme 1). Stannylene-mediated regioselective alkylation of the equatorial 1-OH group with *p*-methoxybenzyl chloride in the presence of CsF gave the alcohol **2** in 80% yield. Alkylation of **2** with bromoacetonitrile and sodium hydride in acetonitrile at reduced temperatures[7] then gave the 2-*O*-cyanomethyl derivative **3** {mp 120–121 °C, $[\alpha]_D^{18}$ +56 (*c* 1, $CHCl_3$)} in 83% yield. The nitrile was smoothly reduced with LAH in THF to the primary amine, which was not isolated but temporarily protected as the trifluoroacetamide by reaction with ethyl trifluoroacetate in THF at room temperature.[8] Finally, the acid-labile butanediacetal (BDA) and PMB protecting groups were cleaved using TFA, exposing the hydroxy groups at positions 1, 4 and 5. The trifluoroacetyl protection was not affected under these conditions, and the triol **4** {mp 130–131 °C, $[\alpha]_D^{18}$ +3 (*c* 1, $CHCl_3$)} was obtained in 77% overall yield from **3**. Phosphitylation using bis(benzyloxy)(*N*,*N*-diisopropylamino)phosphine and 1*H*-tetrazole followed by *in situ* oxidation with MCPBA gave crystalline **5** {mp 85–87 °C, $[\alpha]_D^{20}$ −6 (*c* 1, $CHCl_3$)}.



Scheme 1 *Reagents and conditions*: i, (a) Bu_2SnO, MeOH, 4 Å sieves, Soxhlet, reflux, 16 h; (b) PMBCl, CsF, DMF, 50 °C, 5 h, 84%; ii, NaH, $BrCH_2CN$, CH_3CN, −20 to −40 °C 5 h then room temp., 16 h, 83%; iii, (a) LAH, THF, room temp, 1 h, (b) ethyl trifluoroacetate, THF, room temp., 1 h, (c) TFA–CH_2Cl_2–H_2O (19:20:1), room temp., 30 min, 77% from **3**; iv, $(BnO)_2PNPr^i_2$, 1 *H*-tetrazole, CH_2Cl_2, room temp., 1 h, then MCPBA, −78 °C to room temp., 30 min (96%); v, LiOH·H_2O (10 equiv.) in THF–MeOH–H_2O (2:2:1), room temp., 1 h, 91%. Bn = benzyl, PMB = *p*-methoxybenzyl.

It was now necessary to expose the primary amine by selective removal of the trifluoroacetyl group. Treatment of **5** with methanolic ammonia or K_2CO_3 in aqueous methanol was only partially successful; long reaction times were required, leading to the formation of various polar products, presumably from partial cleavage of benzylphosphate esters. However, it was found that the trifluoroacetyl group could cleanly be removed by treatment with LiOH in THF–MeOH–H_2O[9] for 1 h.

DOI: 10.1039/b002312o



Scheme 2 *Reagents and conditions*: i, **6** (3–4 equiv.), DMF, room temp., 24 h, 31–58%; ii, Pd–C, H_2, 50 psi, room temp., 24 h, 52–65%. Bn = benzyl, PNP = *p*-nitrophenyl. ***a**, n = 4; **b**, $n \approx 30$; **c**, $n \approx 75$; **d**, $n \approx 180$.

Within this time there was little effect on the benzylphosphate groups. The amine **6** was found to be unstable, and was therefore freshly prepared for each cross-linking reaction and used immediately.

Cross-linking of two molecules of **6** was first attempted using the bis(*p*-nitrophenylcarbonate) derivative† **7a** of hexa(ethylene glycol) (Scheme 2). Reaction of **7a** with 3 equivalents of **6** in DMF gave the protected PEG-linked dimer **8a**, which was isolated in moderate yield (58% based on **7a**) yield after purification by flash chromatography on silica gel. The ^{1}H NMR spectrum of **8a** confirmed that it was a dimer‡ and the ^{31}P NMR spectrum showed three signals, each corresponding to two equivalent phosphorus atoms in **8a**. Removal of all sixteen benzyl groups from **8a** was easily achieved by hydrogenation over Pd–C. Purification by ion-exchange chromatography on Q-Sepharose Fast Flow resin, eluting with a gradient of triethylammonium hydrogencarbonate buffer gave **9a** as the triethylammonium salt, which eluted between 0.7 and 0.9 mol dm^{-3} buffer. The structure of **9a** was confirmed by ^{1}H and ^{31}P NMR spectroscopy, and by negative ion FAB mass spectrometry§ before accurate quantification by total phosphate assay.[10] The larger protected dimers **8b**, **8c** and **8d** were then synthesised by reaction of **6** with bis(*p*-nitrophenylcarbonate)-PEGs **7b**, **7c** and **7d** under the conditions established for **7a**. In each case, the product was purified by flash chromatography and its dimeric structure was confirmed by ^{1}H NMR spectroscopy before deprotection as for **8a**. Finally, purification of each dimer by ion exchange chromatography as for **9a** gave **9b**, **9c** and **9d** as their triethylammonium salts, which were all freely soluble in water.

Thus we have demonstrated, for the first time, a viable synthetic route to high molecular weight bivalent ligands as potential pharmacological tools to probe the IP_3R. Other proteins are known to have multiple binding sites[11] for Ins(1,4,5)P_3 or phosphatidylinositol 4,5-bisphosphate and the Ins(1,4,5)P_3 dimers could also be used to investigate these. A particularly attractive application might be to use Ins(1,4,5)P_3 metabolising enzymes to convert Ins(1,4,5)P_3 dimers into dimers of other inositol phosphates, which may have their own intracellular targets proteins.

We thank the Wellcome Trust for Programme Grant support (045491) and Drs S. W. Garrett and I. S. Blagborough for valuable advice.

Notes and references

† **7a**: this was synthesised by reaction of hexa(ethylene glycol) with 6 equivalents of bis(*p*-nitrophenyl) carbonate in DMF in the presence of diisopropylethylamine, and was purified by flash chromatography on silica gel before use. **7b** and **7d** were synthesised in a similar way from PEGs with average molecular weights of 1450 and 8000, respectively. The bis(*p*-nitrophenyl carbonate)-PEG **7c**, derived from a PEG of average molecular weight 3350, is commercially available (Sigma).

Passerini multicomponent reaction of protected α-aminoaldehydes as a tool for combinatorial synthesis of enzyme inhibitors

Luca Banfi,* Giuseppe Guanti* and Renata Riva

Università di Genova, Dipartimento di Chimica e Chimica Industriale, and C.N.R., CSCCCA, via Dodecaneso 31, I-16146 Genova, Italy. E-mail: banriv@chimica.unige.it, guanti@chimica.unige.it

Received (in Liverpool, UK) 10th March 2000, Accepted 20th April 2000

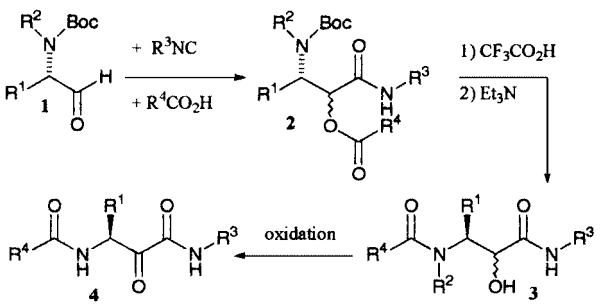
Three-component Passerini condensation of *N*-Boc-α-aminoaldehydes with various isocyanides and carboxylic acids leads, after Boc-deprotection/transacylation, to complex peptide-like structures containing an α-hydroxy-β-aminoacid unit or, after oxidation, an α-oxo-β-aminoacid unit.

Isocyanide employing multicomponent reactions have emerged as very powerful tools for the combinatorial synthesis of various pharmacologically important derivatives.[1] Of the two classical reactions belonging to this family, the Ugi condensation has been more widely studied and used in the generation of chemical libraries. On the other hand, the Passerini reaction, although older, has been employed less in combinatorial chemistry.[2] The reasons for this lower success are associated with the fact that a four-component condensation (Ugi) introduces a higher degree of diversity than a three-component one (Passerini). Moreover, the two amide bonds that link the components in Ugi adducts are more suitable for the synthesis of peptidomimetics, than the combination of one ester and one amide bond produced in the Passerini reaction. Finally, intramolecular variants declass the Passerini process to a two-component reaction, making it less suited for combinatorial chemistry.

In this work we show that, when protected α-aminoaldehydes are employed in Passerini condensation, a simple rearrangement of the reaction products allows an easy combinatorial entry to peptide-like structures, making this old methodology more valuable, particularly in the field of peptidomimetics and enzyme inhibitors.

The general strategy is depicted in Scheme 1 and involves condensation of *N*-Boc protected α-aminoaldehydes **1** with various isocyanides and various carboxylic acids, followed by one-pot Boc deprotection and acyl migration. This two step protocol gives rise to complex peptide-like substances **3** possessing a central α-hydroxy-β-aminoacid unit. This type of monomer has been widely used in the synthesis of enzyme inhibitors.[3] Moreover, a simple oxidation will produce oligopeptides **4** containing an α-oxo-β-aminoacid unit, which is an even more attractive structure, thanks to its similarity with protease transition state.[4]

Only two examples of Passerini reactions involving protected α-aminoaldehydes have been reported previously.[5] In one case, however,[5a] the carboxylic component was not retained during course of the synthesis; in the other case the yields were low and no further manipulation of the condensation adduct was attempted.[5b]



Scheme 1

The L-*N*-Boc protected α-aminoaldehydes employed in this work are all known[4c,6] and have been prepared either through $LiAlH_4$ reduction of Weinreb hydroxamates,[6b] or by Swern oxidation of the corresponding *N*-Boc aminoalcohols,[6d,e] in turn prepared by $BH_3{\cdot}Me_2S$ reduction of the *N*-Boc aminoacids.[6a] The latter are all commercially available compounds except for *O*-methyl-*N*-Boc-serine, which was prepared as previously described.[7]

Table 1 reports the results obtained in this two-step protocol for various combination of six *N*-Boc-α-aminoaldehydes, six isocyanides and ten carboxylic acids (including also protected aminoacids). In particular, isocyanides and carboxylic acids were chosen in order to check the effect of various kinds of side chains with different steric and electronic requirements. All isocyanides and carboxylic acids were commercially available, apart from benzyl 3-isocyanopropionate, which was prepared in two steps (1, BnOH, DCC, DMAP, 70%; 2, diphosgene, *N*-methylmorpholine, CH_2Cl_2, −15 °C, 67%) from known *N*-formyl-β-alanine.[8]

Although we did not perform all the 360 possible combinations, we think that the 20 examples shown represent a good 'statistical sample', which gives an idea of the generality of the presented methodology. In all cases, even when the reaction involved bulky substrates (*e.g.* entry 18), the yields of the Passerini condensation were satisfactory. Surprisingly, notwithstanding the wide variety of substrates employed, the stereoselectivity was at nearly the same level in all cases, being *ca.* 2:1. In view of combinatorial applications, the modest diastereoselection is not necessarily a drawback. Moreover, if the final targets are α-oxoamides **4**, diastereoselection at this level is unimportant.

When enantiomerically pure carboxylic acids were employed (entries 10–12, 14 and 15), only two diastereoisomers were detected by NMR spectroscopy, indicating that the starting α-aminoaldehydes do not undergo significant racemization under the reaction conditions. For entries 14 and 15 the diastereoisomeric mixtures were also checked by HPLC, which showed only 2–5% of isomers deriving from aldehyde racemization. This percentage was shown to depend on the method of preparation of the α-aminoaldehyde, the reduction–oxidation protocol turning out better from this point of view.

In most cases, treatment of the Passerini adducts **2** with CF_3CO_2H led to both Boc cleavage and *in situ* transacylation to give directly the oligopeptides **3**. However under these conditions, the acyl migration was not always complete and in some cases (entries 16–18) it did not take place at all. Thus the procedure of choice involves brief treatment with Et_3N in CH_2Cl_2 after CF_3CO_2H removal. For adducts deriving from Boc-protected aminoacids as the acid component (entries 12, 14 and 15) this procedure cleaved both Boc groups producing the expected transacylated compounds, whose identity was further confirmed by acylation with various reagents of the free amino group.

The overall yields of the sequence leading to **3** from **1** were in all cases > 50% and often > 70%.

[a] Transformation of **1** into **2** was carried out in CH_2Cl_2 at r.t. for 20–40 h, using 1.1 equiv. each of isocyanide and carboxylic acid. Isolated yields (after chromatography) reported. [b] Diastereoisomeric ratio, determined by ^1H NMR spectroscopy and/or HPLC. Relative configuration not determined. [c] Transformation of **2** into **3** was performed by: 1, CF_3CO_2H–CH_2Cl_2 (1:3 v/v), r.t., 1 h; 2, (after evaporation of CF_3CO_2H): Et_3N–CH_2Cl_2 (1:3 v/v), 1 h. Isolated yields are reported. [d] The ratio of the diastereoisomeric couples differentiated by the relative configuration between CH–N and CH–O is given.

It is worth noting that purification of Passerini adducts **2** could be performed quite simply by fast chromatography of the crude reaction solution on silica gel or alumina. The isocyanides (in excess) in all cases elute much faster than **2**, while the carboxylic acids, especially when alumina is used, remain adsorbed on the column. On the other hand the adducts **3** are usually pure enough to be used as such for further reactions (the only significant by-product being $Et_3NH^+CF_3CO_2^-$ which can be removed by extraction with H_2O). Thus several parallel preparations of compounds **3** can be run and processed in two days by a single operator even without the aid of automatic synthesizers.

Compounds **3** obtained as described in entries 10 and 11 of Table 1 were converted in high yields (NaOClO, KBr, cat. TEMPO$^{\cdot}$, 91 and 80%)[4c] into the corresponding α-ketoamides **4** (R^1 = Et, R^2 = H, R^4CO = (Z)-L-leucyl, R^3 = Bu^n or $CH_2CH_2CO_2Bn$), which are very similar to recently discovered potent calpain inhibitors (where R^3 = Et or Pr^n).[4a,c] This straightforward three-step synthesis of complex peptidomimetics is a clear example of the potentiality of this reported methodology. Accepting a wide variety of substrates, it appears ideally suited for the combinatorial synthesis of oligopeptides containing an α-hydroxy-β-aminoacid or α-oxo-β-aminoacid unit, which are of paramount interest as enzyme inhibitors.

We thank Dr Emiliano Calcagno for his important contribution to this work and CNR, University of Genova, and MURST (COFIN 98) for financial support.

Trifluoromethylthiodediazoniation: a simple, efficient route to trifluoromethyl aryl sulfides

Dave J. Adams, Andrew Goddard, James H. Clark* and Duncan J. Macquarrie

Clean Technology Centre, Chemistry Department, University of York, Heslington, York, UK YO10 5DD. E-mail: jhc1@york.ac.uk

Received (in Liverpool, UK) 15th February 2000, Accepted 28th April 2000

Copper(I) trifluoromethanethiolate reacts with a range of diazonium salts containing electron-withdrawing groups to give the corresponding trifluoromethyl aryl sulfides in high yield; it is also possible to carry out the diazotisation and trifluoromethylthiolation in one pot directly from the anilines.

Incorporation of a SCF_3 group into an aromatic molecule is of interest to the pharmaceutical and agrochemical industries, where the high lipophilicity and high electron-withdrawing ability of the group have important implications.[1] Current industrial methods for the formation of trifluoromethyl aryl sulfides generally involve multi-step processes which requires harsh conditions, restricting the nature of the other substituents on the ring as well as being environmentally damaging.[2] A simple, direct method for the formation of these compounds is thus highly desirable. One pot methods for preparing trifluoromethyl aryl sulfides have been reported but these are based on preformed thioaryl units (ArSCl and ArSCN) and require excess quantities of both of the expensive reagents CF_3SiMe_3 and Bu_4NF.[3] The Sandmeyer reaction is a well known method for the formation of chloro-, bromo- and cyanoarenes *via* reaction of the diazonium salts with copper(I) chloride, bromide or cyanide respectively.[4] However, despite copper(I) trifluoromethanethiolate ($CuSCF_3$) being used for the formation of trifluoromethyl aryl sulfides *via* reaction with iodobenzenes at high temperature[5] there are no reports of its reaction with diazonium salts. We have found that it is possible to form trifluoromethyl aryl sulfides from the corresponding diazonium tetrafluoroborates or directly in one pot from the anilines simply by reacting with $CuSCF_3$.

Addition of a solution of 2-nitrobenzenediazonium tetrafluoroborate **1a**[6] to an acetonitrile solution of $CuSCF_3$ at 50 °C[7] leads to rapid evolution of gas with concurrent formation of a deep yellow colour[8] ^{1}H NMR, ^{19}F NMR and GC of the solution all show that the major aromatic product is the 2-nitrophenyl trifluoromethylsulfide **2a**. Phenol, biphenyl or azo compounds, which are often observed as byproducts in diazonium reactions, were not formed in this system[9] although a small amount of nitrobenzene was detected.[10] At room temperature, the reaction is slower, but leads to a very similar product distribution. Other diazonium salts (Fig. 1) containing electron-withdrawing groups react similarily (Table 1). Halo, nitro and cyano groups

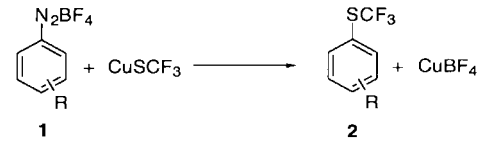

Fig. 1 Conversion of aryl diazonium tetrafluoroborates to trifluoromethyl aryl sulfides.

Table 1 Yields of $ArSCF_3$ from two-stage dediazoniations

1a	89 (83)	**1g**	60
1b	97	**1h**	95 (67)
1c	98 (76)	**1i**	91
1d	95	**1j**	17
1e	98	**1k**	7
1f	92	**1l**	3

[a] Yields calculated on the basis of GC area, unoptimised isolated yields in parentheses.

all survived the reaction. Steric factors do not appear to have an important effect: 2-, 3- and 4-nitrobenzenediazonium tetrafluoroborates all reacted immediately under the same conditions to give very similar product yields and impurity profiles, whereas it can be difficult to synthesise *ortho*-substituted derivatives by traditional means.[11]

Unfortunately, when electron-donating groups are present, the product yields are generally low (Table 1). This is due to a lack of reaction selectivity, thus while 2-diazobiphenyl tetrafluoroborate completely reacts the major product is the amide (Fig. 2). Such reactions have been reported to occur *via* reaction of a diazonium salt with acetonitrile.[12] In benzonitrile, no reaction of this substrate with $CuSCF_3$ was observed, with the only detected product being 2-hydroxybiphenyl. This was also the major product when the reaction was carried out in acetone. Methylbenzenediazonium tetrafluoroborates reacted similarily.

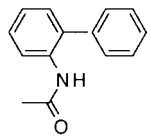

Fig. 2 Product from the reaction of 2-diazobiphenyl tetrafluoroborate with $CuSCF_3$.

In an effort to avoid the isolation of the diazonium intermediate, we investigated other diazotisation methods. Because $CuSCF_3$ reacts with acids to give $HSCF_3$, a non-protic system was required. Although, classically, diazotisation is achieved using sodium nitrite and a mineral acid, alternative methods do exist.[13] Doyle *et al.* have decribed the conversion of aryl amines to the corresponding halides in one-pot using *tert*-butyl nitrite and a copper(II) halide.[14] We have found that it is possible to effect a similar one-pot conversion of an aryl amine to a trifluoromethyl aryl sulfide (Fig. 3). Hence, when *tert*-butyl nitrite in acetonitrile was added to a pre-heated solution of 2-nitroaniline and $CuSCF_3$ in acetonitrile at 50 °C, the solution

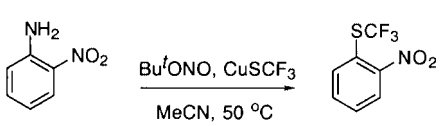

Fig. 3 One-pot synthesis of trifluoromethyl aryl sulfides from anilines.

DOI: 10.1039/b002560g

gradually became black. The formation of 2-nitrotrifluoromethylphenyl sulfide (29%) was detected, along with nitrobenzene (34%) and 2-nitrophenol (2%). It occurred to us that while it is not possible to use a Brønsted acid to improve the reaction, a Lewis acid may be beneficial. Repeating the one-pot reaction of 2-nitroaniline in the presence of BF_3 improved the selectivity to the 2-nitrotrifluoromethylphenyl sulfide to 45%. This method proved to be even more successful with 3-nitroaniline (72%) and 4-nitroaniline (66%), and moderately successful with other activated substrates and aniline itself (Table 2).[15] Substrates containing electron donating groups gave no appreciable yield of the desired trifluoromethyl aryl sulfide.

Table 2 Yields of $ArSCF_3$ from one-pot reactions of anilines

Aniline	GC yield of $ArSCF_3$ (%)
Aniline	42
2-Nitroaniline	45
3-Nitroaniline	72
4-Nitroaniline	66
3-Trifluoromethylaniline	46
3-Chloroaniline	18

In conclusion, we have demonstrated a new approach to trifluoromethyl aryl sulfides which is applicable to a wide range of substrates. This has advantages over current methodologies—the yields and product purity are high after a very simple work up procedure; the route is shorter than the traditional multi-step methods; and a wider range of functional groups is accessible owing to the mild conditions utilised. Unfortunately, this methodology is apparently restricted to substrates which are not electron-rich. It is also possible to form trifluoromethyl aryl sulfides in one pot directly from the anilines in a clean, safe and efficient direct route to these important compounds.

We gratefully acknowledge the support of the EPSRC (ROPA grant), the EPSRC/RAEng (Clean Technology Fellowship to J. H. C.) and the Royal Society (University Research Fellowship to D. J. M.). We would also like to thank Alec Taylor for helpful discussions.

Asymmetric functionalisation of tricarbonylchromium(0) complexes of arenes by non-racemic chiral bases

Susan E. Gibson (née Thomas)* and Ellian G. Reddington

Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS. E-mail: susan.gibson@kcl.ac.uk

Received (in Cambridge, UK) 15th November 1999, Accepted 22nd February 2000
Published on the Web 29th March 2000

Non-racemic chiral bases have been proven to be of significant use in the synthesis of a wide range of enantiomerically enriched *organic* molecules. Their use in the synthesis of *organometallic* reagents and catalysts, however, is still in its infancy. This article reviews one of the first areas of organometallic chemistry to be examined in this context, *i.e.* asymmetric functionalisation of tricarbonylchromium(0) complexes of arenes using non-racemic chiral bases.

Introduction

The use of chiral lithium amide bases[1] and alkyllithiums in conjunction with chiral ligands[2] to desymmetrise organic molecules began in earnest in the late 1980s and early 1990s. In view of the excitement generated by the pioneering studies in this area, it was clear that this approach to the synthesis of non-racemic chiral molecules would have applications in organometallic chemistry and, in particular, the study of organometallic complexes used in organic synthesis. Tricarbonylchromium(0) complexes of aromatic compounds have received much attention as building blocks for organic synthesis, partly because of the intriguing changes in reactivity that occur on complexation of an aromatic compound to the tricarbonylchromium(0) unit, and partly because of the inherent stereochemical properties of complexes of polysubstituted arenes. Two major changes that occur when an arene ring is complexed to a tricarbonylchromium(0) unit are: (i) an increase in the acidity of the hydrogens attached to the aromatic ring,[3] and (ii) an increase in the acidity of any benzylic hydrogens associated with the arene.[4] Thus, it is not too surprising that some of the first attempts to exploit chiral bases in organometallic chemistry focused on the introduction of chirality into tricarbonylchromium(0) complexes of arenes. This article reviews progress to date on the application of chiral bases to aromatic functionalisation and benzylic functionalisation of tricarbonylchromium(0) complexes of arenes.

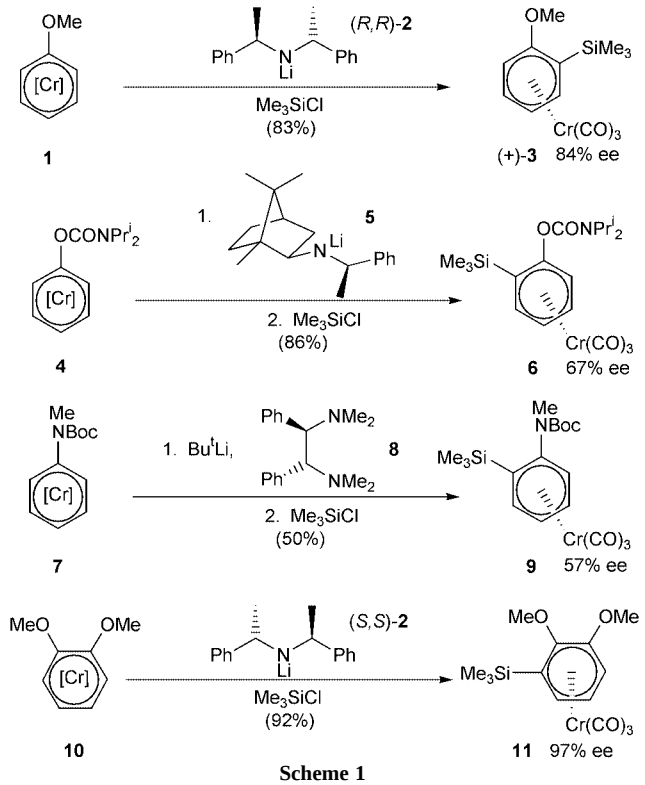
Sue Gibson did her first degree in Cambridge and her D. Phil. in Oxford under the supervision of Professor Steve Davies. She was then awarded a Royal Society European Fellowship to study at the ETH, Zürich with Professor Albert Eschenmoser. In 1985, she returned to the UK to a lectureship in organic chemistry at the University of Warwick, in 1990 she was appointed to a lectureship at Imperial College, London, and last year, she took up the Daniell Chair of Chemistry at King's College London. Her research interests revolve around the application of transition metals in organic synthesis. Current projects include the immobilisation of transition metal catalysts on solid supports, the biological and catalytic applications of conformationally constrained amino acids, and the application of chiral base chemistry and tricarbonylchromium(0) complexes of arenes to natural product synthesis and catalyst design.

Ellie Reddington attended school in North America, Asia and Europe. In 1996, she received her B.Sc. Hons. in Chemistry from Imperial College, London. She then started her Ph.D. on 'Chiral base-mediated asymmetric functionalisation of organometallic complexes' under the supervision of Sue Gibson. In 1999, she moved to King's College London with Professor Gibson where she completed her Ph.D.

Aromatic functionalisation

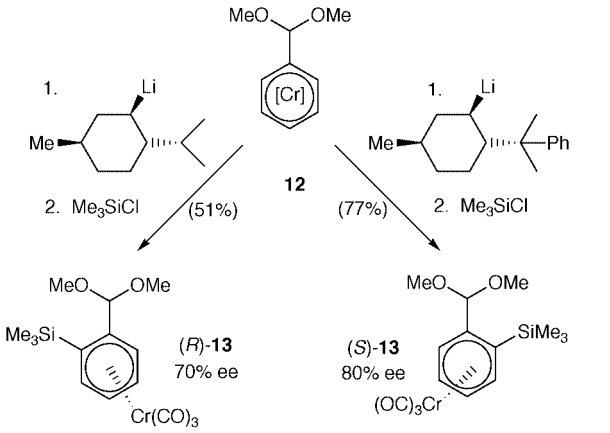
Aromatic functionalisation of tricarbonylchromium(0) complexes of arenes using a chiral amide base or an alkyllithium/chiral ligand combination was first reported in 1994. Indeed, there was a flurry of publications in this year from three groups, all of whom had identified and realised the potential of chiral bases in this area. Although the overall goal was the same, *i.e.* selective functionalisation of one of the *ortho* positions of a monofunctionalised arene complex, the methods of achieving this goal differed. Each group obtained success with a different directing group and a different chiral base or alkyllithium/chiral ligand combination. The introduction of a trimethylsilyl substituent was examined by each group and the result obtained was either typical or optimal. The Simpkins group successfully desymmetrised the tricarbonylchromium(0) complex of anisole **1** ([Cr] = tricarbonylchromium(0)) using chiral base (*R,R*)-**2** to give the planar chiral complex **3** in very good yield and enantiomeric excess,[5] the Kündig group successfully desymmetrised the prochiral carbamate complex **4** using chiral base **5** to give the trimethylsilyl derivative **6**,[6] and the Uemura group successfully desymmetrised the Boc-protected amine complex **7** using diamine **8** in conjunction with Bu^{t}Li to yield **9** (Scheme 1).[7] These results, and the many others described in these papers, demonstrated for the first time that planar chirality in (arene)tricarbonylchromium(0) complexes could be created using chiral bases. In parallel, the Schmalz group had been considering the possibility of using enantioselective *ortho*-deprotonation/silylation of 1,2-dimethoxyarene complexes in connection with their work on the synthesis of calamenen, pseudopterosin and helioporin. They discovered they were able to desymmetrise the disubstituted complex **10** using (*S,S*)-**2** to give the trisubstituted planar chiral complex **11** in excellent yield and enantiomeric excess.[8]

In the course of the studies described above, a problem was encountered with arguably one of the most synthetically useful classes of (arene)tricarbonylchromium(0) complexes, *i.e.* benzaldehyde acetal complexes; benzylic deprotonation often competed effectively with *ortho*-lithiation. This problem was addressed by the Green group using organolithium reagents derived from (1*R*)-menthyl chloride and (1*R*)-8-phenylmenthyl chloride. Reaction of these two reagents with the acetal complex **12** followed by addition of chlorotrimethylsilane afforded enantiomers (*R*)-**13** and (*S*)-**13**, respectively, in acceptable yield



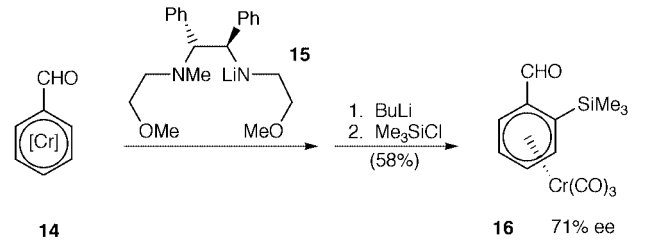
Scheme 1

and enantiomeric excess (Scheme 2).[9] A solution to the enantioselective functionalisation of (benzaldehyde)tricarbonylchromium(0) itself was provided by the Alexakis group,



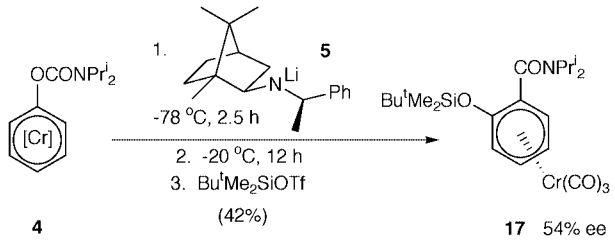
Scheme 2

which although strictly outside the scope of this review is nevertheless of interest in this context. In a typical example of their approach, reaction of complex **14** with **15** gave an amino alcoholate with an appended tertiary amine; subsequent addition of *n*-butyllithium followed by chlorotrimethylsilane gave complex **16** in notable enantiomeric excess (Scheme 3).[10]



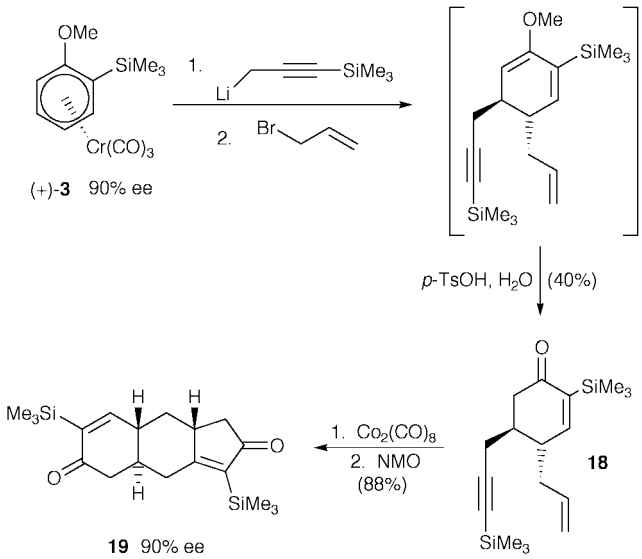
Scheme 3

Recently, the reaction of complex **4** with lithium amide **5** has been used to initiate an anionic *ortho*-Fries rearrangement. Warming the anion generated to −20 °C and stirring for 12 h induced the rearrangement; after quenching, product **17** was isolated and shown to be enantiomerically enriched (Scheme 4).[11]



Scheme 4

The chiral base approach to enantiomerically enriched (arene)tricarbonylchromium(0) complexes is starting to be applied in the synthetic arena. Thus complex **3**, made using the Simpkins method, has been used at the start of two synthetic studies. Kündig used a nucleophilic addition to (+)-**3** followed by an electrophilic quench and *in situ* hydrolysis to form the substituted cyclohexenone **18**. A subsequent Pauson–Khand reaction gave diastereomerically pure tricycle **19** in enantiomeric excess equal to that of (+)-**3** (Scheme 5).[12] Elaboration of



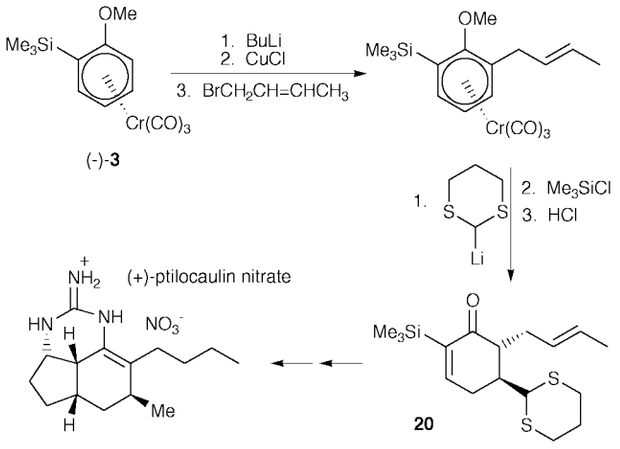
Scheme 5

(−)-**3** by the Schmalz group followed by nucleophilic addition and work-up gave substituted cyclohexenone **20**.[13] This was subsequently converted into (+)-ptilocaulin nitrate, an antimicrobial and cytotoxic metabolite of a Caribbean sponge (Scheme 6).[14] In both of these studies, the stereochemical information introduced using the chiral base is relayed first of all across the complexed arene ring to the chiral centre constructed on addition of the nucleophile. The stereochemistry of this chiral centre subsequently controls the formation of the remaining chiral centres in the product.

Benzylic functionalisation

Ethers: simple functionalisation

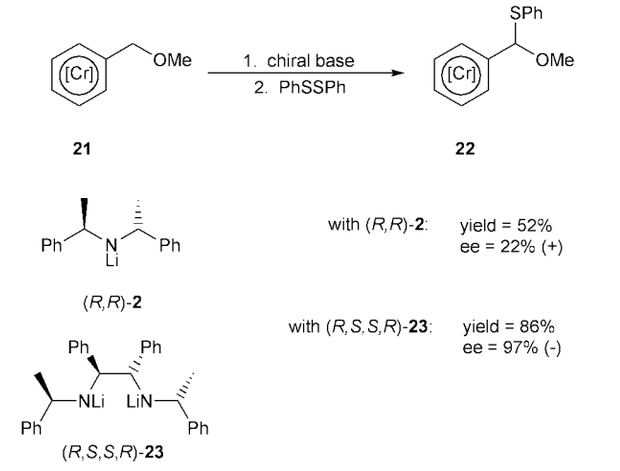
In 1996, we decided to examine the possibility of using chiral base methodology to asymmetrically functionalise the benzylic position of (arene)tricarbonylchromium(0) complexes. We selected the tricarbonylchromium(0) complex of benzyl methyl ether **21** as our test substrate as: (i) it was readily available and (ii) it had been demonstrated previously that it could be alkylated in good yield using *n*-butyllithium followed by quenching with a range of alkylating reagents.[15] That said, we



Scheme 6

were somewhat concerned that the high degree of conformational flexibility of complex **21**, compared to other substrates that had been successfully desymmetrised by chiral base technology, would render discrimination between its two benzylic sites difficult.

In an initial exploratory experiment, the well-established chiral base (*R*,*R*)-**2** was used to deprotonate **21** and diphenyl disulfide was used to quench the reaction. Workup provided the novel complex (+)-**22** in 52% yield. Complex **22** proved easy to analyse by chiral HPLC and its ee was found to be a moderate 22% (Scheme 7). In view of our reservations about the

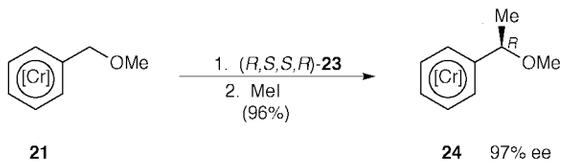


Scheme 7

conformational flexibility of **21**, we were highly encouraged by this seemingly modest result and decided to undertake further experiments with different bases. The next base used was the C_2-symmetric vicinal diamide **23**. A straightforward two-step synthesis of this base had been reported in 1994,[16] but its potential as a chiral base had not been explored in any detail. Using this base, the reaction of complex **21** to give the α-phenylsulfenyl derivative (−)-**22** proceeded in 86% yield and, to our delight, the ee of the product was found to be 97% (Scheme 7).[17]

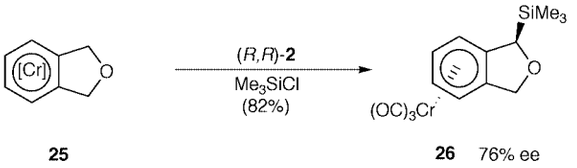
In order to glean information about the absolute stereochemistry of the products of this highly enantioselective system, the reaction between ether complex **21** and chiral base (*R*,*S*,*S*,*R*)-**23** was next quenched with iodomethane. This gave the α-methylbenzyl methyl ether complex **24** in 96% yield and 97% ee (Scheme 8). Comparison of the $[\alpha]_D$ of this material with literature data[18] revealed that the absolute configuration of **24** was *R*.

In parallel to our benzylic deprotonation studies on the acyclic ether **21**, the Simpkins group had been examining the effect of chiral bases on the cyclic ether complex **25**.[19] In a



Scheme 8

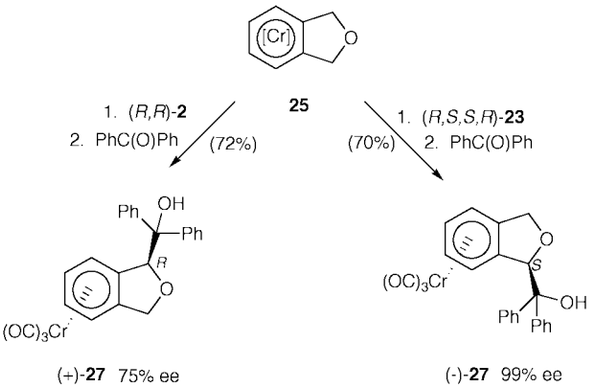
typical example from their work, (1,3-dihydroisobenzofuran)-tricarbonylchromium(0) **25** was treated with the monoamide base (*R*,*R*)-**2** in the presence of chlorotrimethylsilane. The product of benzylic functionalisation **26** was isolated in 82% yield and 76% ee (Scheme 9). Thus, in this case, in contrast to



Scheme 9

the acyclic ether case, the well-established monoamide base (*R*,*R*)-**2** led to good enantioselectivity. The absolute configuration of **26** was assigned by analogy with the product of methylation, the stereochemistry of which was rigorously determined by chemical correlation.

A little later, the reactions of the cyclic ether complex **25** with monoamide base (*R*,*R*)-**2** and the diamide base (*R*,*S*,*S*,*R*)-**23** followed by a benzophenone quench were reported by Simpkins.[20] Interestingly, switching from the monoamide base to the diamide base raised the enantioselectivity of this reaction from 75% to 99% (Scheme 10). Moreover, the absolute configuration



Scheme 10

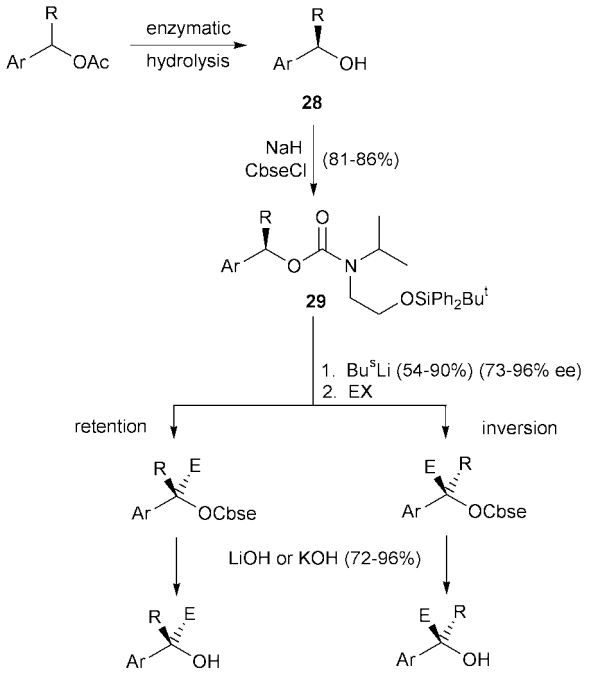
of the product **27** changed from *R* to *S* with the change of base, an observation reminiscent of the change from (+) to (−) observed with acyclic ether complex **21** in the production of sulfur derivative **22**.

Ethers: further elaboration

As a result of the studies described above, it was clear that asymmetric functionalisation of the benzylic position of ether complexes using the diamide base (*R*,*S*,*S*,*R*)-**23** was a high-yielding and highly enantioselective reaction. At this point, we decided to examine whether or not the reactivity discovered could be used as a basis for further elaboration of ether complexes and the generation of enantiomerically enriched products.

Synthesis of tertiary ethers. The synthesis of enantiomerically enriched tertiary alcohols is more challenging than their secondary counterparts, which are now readily available by a

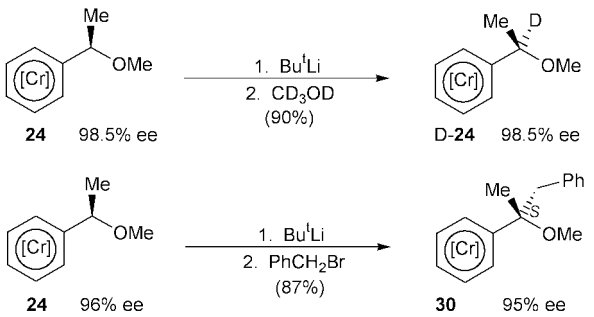
variety of reliable and versatile routes. In 1996, Hoppe and Dewing reported that enantiomerically enriched secondary alcohols **28**, derived from racemic mixtures by enzymatic hydrolysis, could be converted into enantiomerically enriched tertiary alcohols *via* deprotonation/electrophilic quench sequences on carbamate derivatives **29** (Scheme 11).[21] Some of



Scheme 11

the electrophilic quenches proceeded with retention of configuration, others with inversion. We thus decided to probe whether or not optically active complexes of secondary benzyl ethers. such as **24**, could be converted into optically active complexes of tertiary benzyl ethers by a deprotonation/electrophilic quench protocol. If so, it would be of interest to determine whether the reaction proceeded with retention or inversion of configuration.

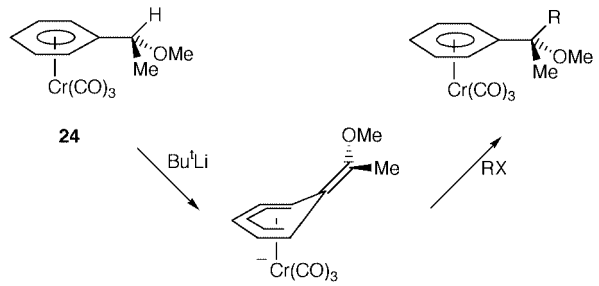
Complex **24** (98.5% ee and *R* configuration) was deprotonated with *tert*-butyllithium in THF at −78 °C, and, after 90 min at this temperature, the anion was quenched with deuteriomethanol. Work-up gave a 90% yield of complex D-**24** (91% D incorporation) which HPLC analysis revealed had an ee of 98.5% and was also of *R* configuration (Scheme 12). Thus the



Scheme 12

deprotonation/quench sequence had clearly proceeded with overall retention of configuration, presumably *via* a configurationally stable anion.[22]

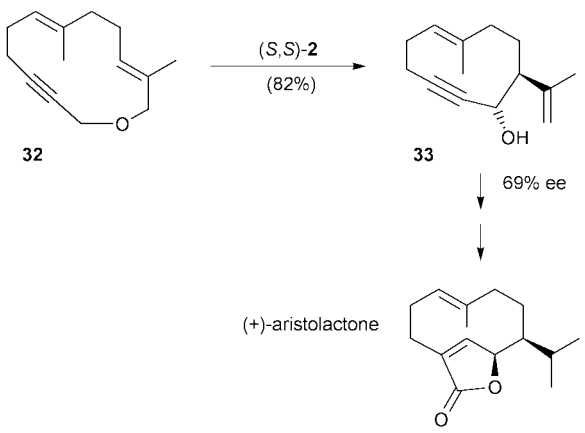
Having ascertained that the lithium anion of **24** is configurationally stable at −78 °C, our attention turned to synthetically more interesting electrophiles. Whilst deprotonation of (±)-**24** followed by quenching with iodomethane and chlorotrimethylsilane has been shown to proceed in yields of 93 and 53%, respectively, indicating that the formation of carbon–carbon and carbon–heteroatom bonds in this system is chemically feasible,[23] the stereochemical consequences and the synthetic scope of this type of process needed to be determined. We examined several systems varying both the benzylic substituent on the secondary ether and the electrophile used in the quench. In a typical example, complex **24** was deprotonated and quenched with benzyl bromide. Work-up led to the isolation of the novel complex **30** of essentially the same enantiomeric purity as its precursor in 87% yield (Scheme 12). An X-ray crystallographic analysis of this product revealed that its absolute configuration was *S*. Thus the deprotonation/benzylation of **24** proceeds with overall retention of configuration. This may be rationalised as follows: abstraction of the benzylic proton of **24** from a conformation that places it antiperiplanar to the tricarbonylchromium(0) unit gives the chromium-centred and configurationally-locked anion **31** (Scheme 13). The



Scheme 13

incoming electrophile then approaches the sterically less-hindered *exo*-face of the intermediate to give the observed product under excellent stereochemical control.

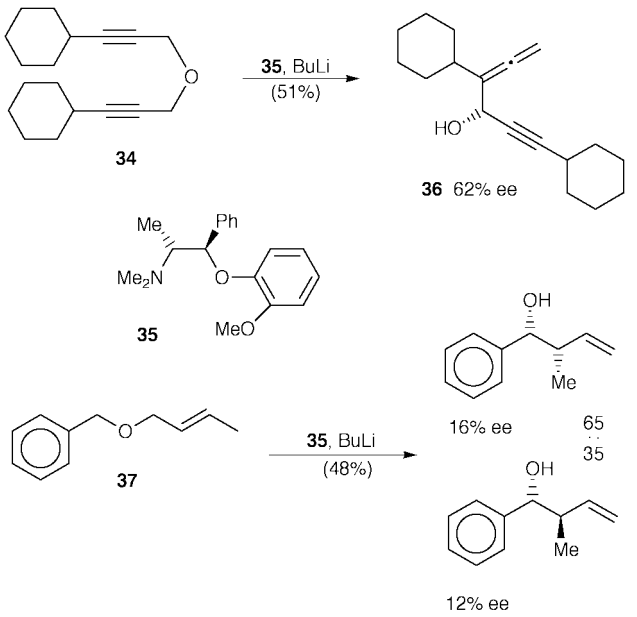
[2,3]-Wittig rearrangement. Our attention turned next to stereochemical control of the [2,3]-Wittig rearrangement. This is a useful carbon–carbon bond-forming reaction[24] and, as such, asymmetric versions of it are a desirable goal.[25] Research in recent years has produced several approaches, the greatest success being achieved using chiral auxiliaries.[26] Enantioselective versions of the [2,3]-Wittig rearrangement involving an achiral substrate and a chiral non-racemic base are synthetically more attractive, but this approach has been much less successful. The best result to date for a *cyclic* system is the conversion of the 13-membered ether **32** into the 10-membered alcohol **33** in 69% ee and 82% yield using (*S*,*S*)-**2** (Scheme 14).



Scheme 14

This success was attributed to special conformational effects as the same base gave a poorer result with a 17-membered homologue, and racemic products when applied to acyclic α-(allyloxy)acetic acids and amides.[27] Typical results to date for

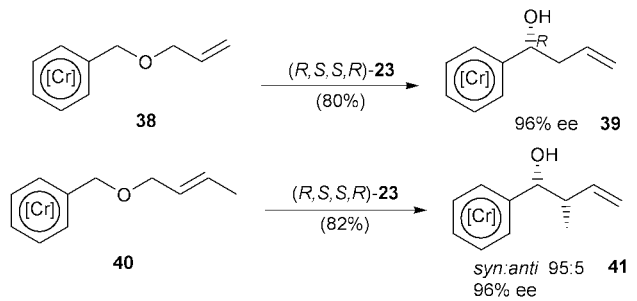
linear systems are exemplified by reactions carried out using a norpseudoephedrine/BuLi combination.[28] Thus Wittig rearrangement of dialkyne **34**, under the influence of **35**, produced alcohol **36** in moderate yield and ee, whilst rearrangement of unsaturated ether **37** gave a moderate yield of a diastereomeric mixture of alcohols each of poor optical purity (Scheme 15).



Scheme 15

In view of the high enantioselectivities and yields obtained for the asymmetric functionalisation of tricarbonylchromium(0) complexes of alkyl benzyl ethers, and earlier reports that tricarbonylchromium(0) complexes of allyl benzyl ethers undergo [2,3]-Wittig rearrangements,[29] we decided that it would be of interest to determine whether or not such Wittig rearrangements could be performed under good enantiomeric control using non-racemic chiral bases.

The first reaction to be examined was that of parent allyl benzyl ether complex **38** with diamide base (*R,S,S,R*)-**23**. This was found to proceed in good yield (80%) and excellent ee (96%) (Scheme 16).[30] In order to determine the absolute



Scheme 16

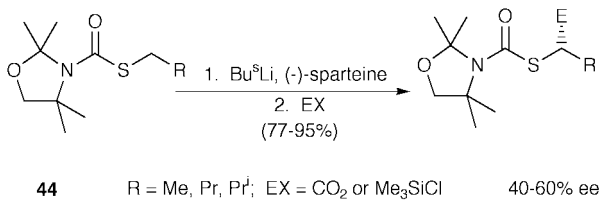
configuration of the product **39**, the tricarbonylchromium(0) unit was removed by photolysis and the $[\alpha]_D$ of the resulting alcohol compared with literature values.[31] This revealed that the absolute configuration of **39** was *R*, a result consistent with the sense of asymmetric induction observed for the functionalisation of complex **21** with external electrophiles.

A series of rearrangements were examined in order to determine the effect of substituents on chemical yields and enantioselectivities. In the first series of experiments, substituent patterns were chosen which would lead to products containing just one chiral centre. These experiments gave products of very good optical purity (84–94%), but the chemical yields ranged from good to poor (82–25%). Next the rearrangement of complex **40** was examined, as this gives rise to two chiral centres, raising the issue of diastereoselectivity. Pleasingly, the but-2-enyl complex **40** rearranged smoothly to give a good yield (82%) of alcohol **41** (Scheme 16). The diastereomeric ratio of the product complex was found to be 95 : 5 and the relative stereochemistry of the major isomer was identified as *syn* by comparison of its spectroscopic data and the data of its decomplexation product with literature values obtained from a racemic sample. HPLC analysis of **41** revealed that its ee was 96%. Thus the yield, diastereoselectivity and enantioselectivity observed for the rearrangement of **40** to **41** under the influence of base (*R,S,S,R*)-**23** compare well with the rearrangement of the non-complexed material **37** under the influence of the norpseudoephedrine/BuLi combination.

Thioethers

The configurational instability of α-sulfur substituted alkyllithium compounds **42**[32] and benzyllithium compounds **43**[33] is

well documented and attempts to use these species in asymmetric synthesis have met with little success to date. Indeed, the first examples of enantiomerically enriched α-sulfur substituted alkyllithium compounds, whose chirality is determined solely by the stereogenic carbon centre, were prepared only quite recently. Thus, generation of α-sulfur substituted alkyllithiums by deprotonation of **44** with Bu^{s}Li/(−)-sparteine and subsequent quenching with carbon dioxide or chlorotrimethylsilane gave products in 77–95% yield and 40–60% ee (Scheme 17).[32]

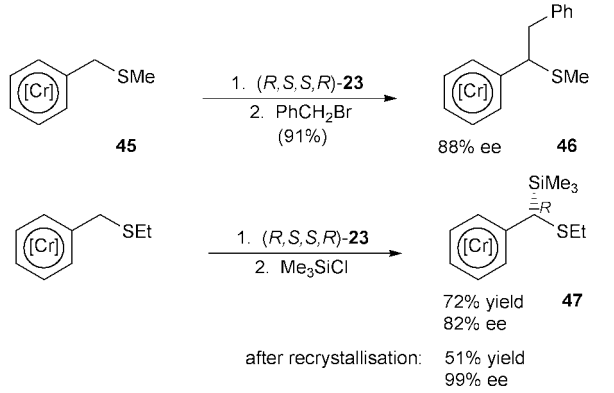


Scheme 17

In view of (i) the recognised instability of α-sulfur substituted lithium compounds, and (ii) the emerging potential of chiral sulfides as ligands in asymmetric synthesis,[34] we wanted to determine whether or not anions of tricarbonylchromium(0) complexes of alkyl/aryl benzyl sulfides would be sufficiently configurationally stable to undergo bond-forming reactions and produce enantiomerically enriched products.

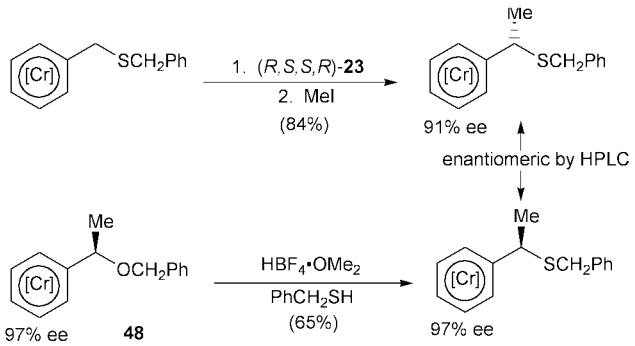
A series of thioether complexes was easily and efficiently prepared by reacting (benzyl alcohol)tricarbonylchromium(0) with a range of thiols in the presence of tetrafluoroboric acid.[15] After some experimentation, it emerged that enantioselectivity was a function of the thioether substituent and that methyl and benzyl substituents gave the best results. In a typical experiment, thioether complex **45** was reacted with (*R,S,S,R*)-**23** and quenched with benzyl bromide to give the benzylic substitution product **46** in 91% yield and 88% ee (Scheme 18).[35] In order to determine the absolute stereochemistry of the chiral sulfides generated by this new approach, we subjected the silyl substituted complex **47** (Scheme 18) to X-ray crystallographic analysis. To our surprise, this revealed that **47** was the opposite enantiomer to the one we had predicted based on the results obtained with the analogous ether complexes.

In order to probe this change in stereochemical outcome further, the ether complex **48** (97% ee) was reacted with benzyl



Scheme 18

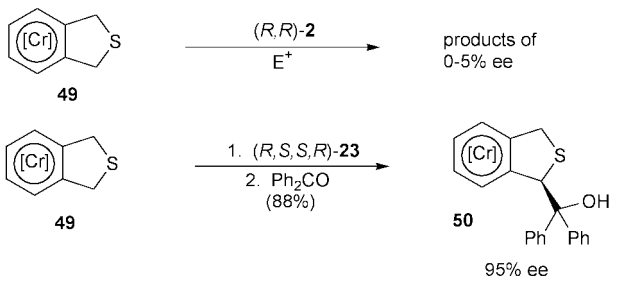
thiol in the presence of acid. Work-up gave a thioether complex in 65% yield and HPLC analysis of this material revealed that it was the opposite enantiomer to that obtained by the deprotonation/quench route (Scheme 19). As acid catalysed substitutions



Scheme 19

of this type are known to proceed with retention of configuration,[36] this result is stereochemically consistent with the X-ray crystallographic analysis of **47**. It thus appears that deprotonation of tricarbonylchromium(0) complexes of benzyl sulfides with the chiral base (*R*,*S*,*S*,*R*)-**23** proceeds in the opposite stereochemical sense to deprotonation of the corresponding ethers.

The Simpkins group also examined the effect of chiral bases on tricarbonylchromium(0) complexes of thioethers, but their focus was on the cyclic system **49**. Initially, **49** was reacted with the monoamide base (*R*,*R*)-**2** and subjected to a range of quenches, but these reactions gave products of very low ee (*ca.* 5%) (Scheme 20).[19] On re-examining the system with the



Scheme 20

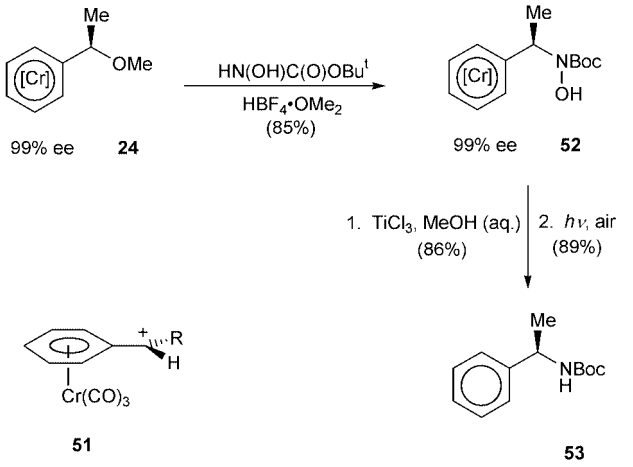
diamide base (*R*,*S*,*S*,*R*)-**23**, however, they were able to generate products in excellent yield and ee.[37] Addition of benzophenone to **49** using (*R*,*S*,*S*,*R*)-**23**, for example, generated **50** in 88% yield and 95% ee (Scheme 20). Interestingly, comparison of **50** with (−)-**27** obtained from the cyclic ether **25** indicates that the change in stereochemistry observed in the acyclic systems is not repeated here. This may be a function of the increased rigidity of the cyclic system.

In summary, diamide base (*R*,*S*,*S*,*R*)-**23** can be used to asymmetrically functionalise complexes of benzylic sulfides. Although the enantiomeric excesses observed in the acyclic system are slightly lower than those observed in the corresponding oxygen ether system, the relatively high selectivity compared to other α-sulfur substituted lithium systems suggests that the anion involved possesses unusually high stereochemical stability. This is attributed to the delocalisation of the negative charge onto chromium (and beyond onto the carbonyl ligands) which raises the energy barrier to rotation about the *ipso* carbon–benzylic carbon bond.

Amines

The efforts of our group and the Simpkins group to use chiral bases to asymmetrically functionalise tricarbonylchromium(0) complexes of benzylic amines, or their derivatives, have, to date, proved unsuccessful. Nevertheless, we have demonstrated that it is possible to access this important class of compounds using the reliable and robust ether chemistry.

Initial experiments were carried out using complex **24** of 99% ee. It was hoped that nucleophilic substitution of this complex using a nitrogen nucleophile would give us access to enantiomerically enriched amines. Literature precedent, however, was not encouraging: although substitution of α-oxygenated (arene)tricarbonylchromium(0) complexes with acid/nucleophile combinations *via* a chromium-stabilised carbocation intermediate **51** (Scheme 21) is well-established for carbon,

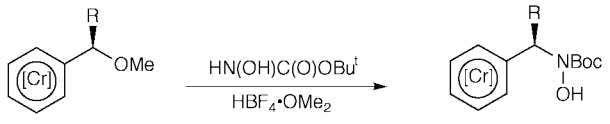


Scheme 21

hydrogen, and oxygen nucleophiles, the use of nitrogen nucleophiles is rare and inefficient. Thus, reactions of ammonia and primary and secondary amines with benzyl alcohol complexes in the presence of hexafluorophosphoric acid gives low yields of substitution products.[38] Indeed our initial reactions of complex **24** with a wide range of amines in the presence of tetrafluoroboric acid were disappointing, providing only very low levels of nitrogen incorporation and complex mixtures of products. In contrast, protonation of **24** at −40 °C with tetrafluoroboric acid followed by addition of commercially available *tert*-butyl-*N*-hydroxycarbamate gave the nitrogen substitution product **52** in 85% yield (Scheme 21). Moreover the ee of the novel complex **52** was measured by chiral HPLC and found to be 99%.[39]

The absolute configuration of the nitrogen substitution product **52** was determined by chemical correlation. Reduction of the nitrogen–oxygen bond using titanium trichloride in aqueous methanol proceeded smoothly. Subsequent oxidative removal of the tricarbonylchromium(0) unit gave carbamate **53** (Scheme 21), the optical rotation of which was essentially identical to a sample prepared from authentic (*R*)-α-methylbenzylamine. Thus the absolute configuration of **52** is *R* and the conversion of **24** to **52** proceeds with retention of configuration, presumably *via* a chromium stabilised carbocation **51**.

In order to probe the effect of increasing steric hindrance around the benzylic position on the nitrogen substitution reaction, complexes **54** and **55** bearing ethyl and *iso*-propyl groups, respectively, were prepared and reacted with *tert*-butyl-*N*-hydroxycarbamate. The reactions gave products **56** and **57** in moderate yield and 96 and 91% ee respectively (Scheme 22).



R	educt	ee (%)	product	ee (%)	yield (%)
Me	**24**	99	**52**	99	85
Et	**54**	96	**56**	96	53
i-Pr	**55**	98	**57**	91	43

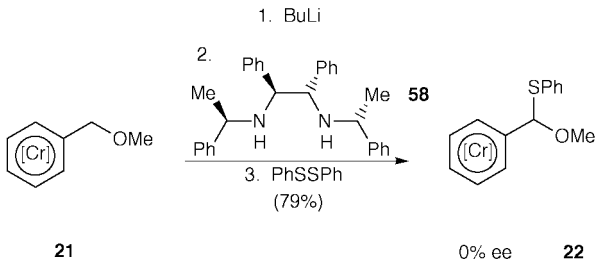
Scheme 22

Thus, increasing steric hindrance on going from methyl to *iso*-propyl leads to notable yield reduction and a small but significant stereochemical leakage. These effects are attributed to a reduced rate of addition of the nitrogen nucleophile to the intermediate carbocation, the increased lifetime of which leads to byproducts and rotation about the *ipso* carbon–benzylic carbon bond.

Mechanistic probes

Several studies have been carried out in order to probe the mechanism of the highly selective reactions described above.

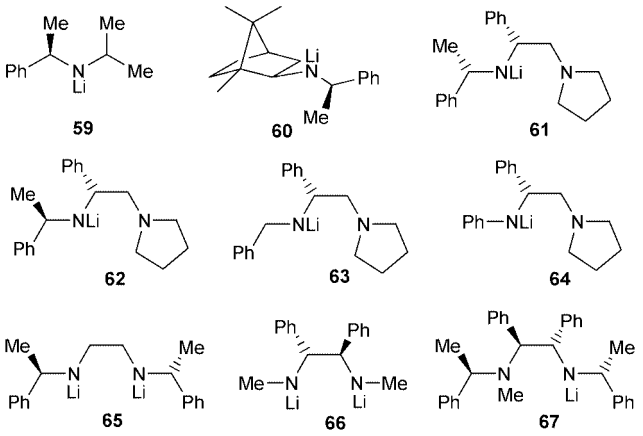
Addition of diamine after BuLi. In order to test whether the benzylic asymmetric functionalisations described in previous sections were due to asymmetric deprotonations or to asymmetric electrophilic quenches, we performed an experiment in which the substrate was deprotonated with the achiral base *n*-butyllithium and the chiral diamine was added afterwards.[40] Thus methyl ether complex **21** was treated with 1.1 equiv. of butylithium followed by 1.1 equiv. of diamine **58** (and 1 equiv. of lithium chloride). The reaction was subsequently quenched with 2 equiv. of diphenyl disulfide to give the expected product **22** in 79% yield (Scheme 23). The ee of **22** was measured and



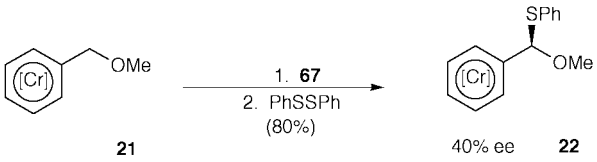
Scheme 23

found to be zero. Thus the racemic anion generated in this experiment did not undergo an asymmetric electrophilic quench under the control of the chiral diamine present in the reaction mixture. This result is consistent with the asymmetric control observed in the benzylic functionalisations originating in the deprotonation step rather than the quench step.

Effect of base structure. As diamide base (*R*,*S*,*S*,*R*)-**23** was only the second base we had examined in our initial studies on the functionalisation of oxygen ether **21**, we thought it prudent to screen other chiral bases to establish whether or not the high yields and ees obtained with (*R*,*S*,*S*,*R*)-**23** were unique to this structure. Amides **59**–**64** were used in the conversion of ether **21** to sulfur derivative **22** and found to give only moderate yields and enantioselectivities compared to (*R*,*S*,*S*,*R*)-**23**.[41] We also synthesised and tested bases **65** and **66** to probe whether all the features of (*R*,*S*,*S*,*R*)-**23** were essential to the high yields and



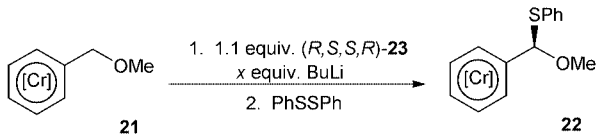
selectivities. These studies revealed that both the backbone and the side chain chirality were necessary for optimum results.[41] Finally, in order to ascertain whether the second lithium amide was necessary for success, base **67** was synthesised[42] and tested on substrate **21** (Scheme 24). This gave a good yield (80%) and



Scheme 24

moderate ee (40%) of the *R* enantiomer of **22**, a finding which was later used to explain results obtained by varying the equivalents of BuLi used in the reaction (*vide infra*).

Effect of BuLi stoichiometry. All the reactions described above were carried out using 2.2 equiv. of BuLi and 1.1 equiv. of diamine. In an effort to minimise the amount of BuLi required in these experiments, **21** was converted to **22** using 1.1 equiv. of BuLi and the effect on yield and ee determined. In order to determine the effect on ee of reducing the equivalents of BuLi used still further, reactions using 0.55 and 0.275 equiv. of BuLi were also performed (Scheme 25). Pleasingly, use of



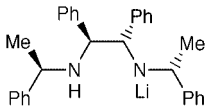
BuLi (equiv.) (*x*)	yield (%)	ee (%)	recovered substrate (%)
2.2	95	98	0
1.1	96	95	0
0.55	60	92	40
0.275	21	96	67

Scheme 25

1.1 equiv. of BuLi had negligible detrimental effect on yield and ee, producing **22** in 96% yield and 95% ee. It was interesting to note that although reduction of the equivalents of BuLi to 0.55 and 0.275 gave the expected drop in yield (60 and 21% respectively; an experimental error of ±5% in BuLi measurement accounts for the unreasonably high yield in the first case), the enantioselectivity of the reaction remained very high (92 and 96% respectively).

The results obtained by varying the equivalents of BuLi may be explained as follows. The dilithiated species (*R*,*S*,*S*,*R*)-**23** (or an aggregate thereof) is clearly a highly enantioselective

reagent. If we assume that the monolithiated species **68** is relatively unselective, a hypothesis supported to a degree by the low ee (40%) obtained with **67**, then it follows from the results obtained on reducing the number of BuLi equivalents that (i) there is a ready exchange of lithium cations between all the nitrogen sites in the system, and (ii) (*R*,*S*,*S*,*R*)-**23** is more reactive than **68** with respect to complex **21**. In conclusion, it



68

appears that all the deprotonation power of the BuLi is channelled through the highly selective diamide species rather than the relatively unselective monoamide species.

Conclusion

Studies carried out in the last five years have demonstrated that chiral bases provide an excellent entry into enantioenriched tricarbonylchromium(0) complexes of arenes. Moreover, the products of these studies are starting to be used in synthetic endeavours. It is anticipated that in the next few years, chiral bases will be used to generate a wide variety of enantioenriched organometallic complexes which will find uses both in synthesis and catalysis. Whilst the selectivities that can be achieved are impressive and useful, discovery of the origin of this selectivity in both the organometallic systems described here and the organic systems developed over the last fifteen years remains a significant challenge.

Published on the Web 22nd May 2000

Nickel and gold meshes having three-dimensional periodicity at optical wavelengths and nanoscale structural fidelity have been prepared by electrodeposition within close-packed silica sphere arrays.

There is major current interest in the fabrication of nanoporous metal arrays.[1–4] Routine access to such materials could impact a variety of areas including photonics, magnetics, catalysis, electrochemical applications and thermoelectrics. Recent reports have described the formation of 3-D metal meshes within colloidal silica or polymer membranes through the use of molten metal infiltration, nanoparticle infiltration and electroless methods.[4–6] Though metal electrodeposition methods have been effectively used for membranes with one-dimensional pore structures,[7] the extension of this technique to three-dimensional structures has not been reported. This electrochemical method has the major advantage of readily producing well defined metal meshes of materials melting at such high temperatures that melt infiltration is prohibited by template structural instability. Herein, we describe the use of this approach for the fabrication of nickel and gold arrays having three-dimensional periodicity at optical wavelengths.

Silica membranes (opal) were prepared by published methods.[8] Silica spheres with a diameter of *ca.* 300 nm diameter were initially prepared from tetraethylorthosilicate (TEOS). The spheres were then formed into close-packed lattices through a sedimentation process over several months. This precipitate was then sintered at 120 °C for two days and then 750 °C for 4 h, producing a robust opalescent piece that could be readily cut into smaller sections. Electrodes were formed from the opal (typically 7 × 10 × 1.5 mm) by first depositing *ca.* 0.5 μm thick copper films on one side of the piece by magnetron sputtering. A length of wire was attached to the copper backing with silver paste (Ted Pella, Inc.) and the copper/wire side of the electrode, as well as the edges, were sealed off with neoprene glue (Elmer's). For metal deposition, the electrodes were immersed into nickel or gold plating solutions (Technic, Inc.) with a platinum wire counter electrode. Electrodeposition was carried out by a constant current method over a 36 h period; a low current density (0.50 mA cm^{-2}) was used in an effort to achieve even deposition within the opal membrane. Low current densities such as that used here have been found to be effective in the growth of nanowires. After deposition, the opal was washed thoroughly with distilled water and the neoprene layer peeled off. To remove the silica matrix, the metal–opal pieces were soaked in a 2% HF solution for 24 h. This resulted in a dark opalescent metal membrane (*ca.* 100 μm thick). Scanning electron micrographs (SEM) were obtained on a JEOL JSM 5410 SEM. Magnetic measurements on the nickel mesh were performed on a Quantum Design MPMS-5S SQUID susceptometer. The mesh was fixed between two pieces of Kapton tape and placed in a commercially available soda straw. No correction for the diamagnetic contribution of the sample holder was taken into account because it was by at least three orders of magnitude smaller than the response generated from the Ni-mesh. The field dependence was studied at various temperatures (2, 10 and 300 K) in external fields up to ±5 T. The temperature dependence was measured in a zero-field cooled (zfc) and a field-cooled (fc) cycle at 1000 G.

This electrodeposition method produces well-defined metal meshes. Fig. 1(a) shows a cross-section of the closed-packed silica membrane (10 000× magnification). Stacking faults are present on (111) planes in the original opal, which will be replicated in the metal mesh. Electrodeposition fills the void space between the close-packed spheres. Fig. 1(b) shows a section of a nickel metal mesh (10 000×) after dissolution of the silica spheres. This image highlights the packing variation for these spheres. Different sections corresponding to (111), (100) and (110) orientations can be observed. Fig. 2(a) and (b) are views of predominately the (100) and the (110) planes, respectively. Fig. 2(c) is a higher magnification (50 000×) of the (100) plane. The square features are essentially cubes with concave sides that arise from filling the octahedral sites in the close-packed structure. Each cube is connected to eight other cubes through its vertices *via* tetrahedra [Fig. 2(d)]. The structure is akin to the fluorite structure (CaF_2) where the calcium ions, representing the cubes, are eight coordinate and the fluoride ions, representing the tetrahedra, are four coordinate. Based on the diameter of the closed-packed spheres of *ca.* 300 nm, one would predict minimum diameters of *ca.* 50, 70 and 120 nm for the interconnects, tetrahedra and cubes, respectively, as is observed. Since the metal mesh crystals are interpenetrating air- and metal-phase networks, they are

metallo-dielectric photonic crystals, which are predicted to have an unusual metallicity bandgap.[1]

Interestingly, the extended nickel metal arrays maintain their structure after removal of the silica membrane, while the gold arrays appear to collapse in on themselves. Fig. 3 shows a low magnification image (7500×) of gold. Some areas of the mesh appear spherical in what look like 'florets'; localized structural features, however, are still quite apparent between the regions. Though this effect may simply be due to incomplete filling during electrodeposition, it is also possible that it may be associated with the greater malleability of gold relative to that of nickel. A possibly related effect has recently been described by Jiang *et al.*,[6] who reported curling of gold films made by the electroless method.

Magnetic measurements on the nickel mesh show size effects due to the nanometer dimensions of the components. The material exhibited a coercive field (H_c) of 500 G at 2 K that decreased slightly with increasing temperature (H_c = 300 G at 300 K). This value is much higher than that found in bulk nickel, which is on the order of a few tens of G. Such an enhancement in the coercivity is well known for other size-constrained magnetic systems.[9] The presently observed coercive field is about four times smaller than reported for 53 nm diameter electrodeposited Ni wires[10] (2000 G at T = 5 K), which is possibly due to the absence of a 'true' quantum confinement and/or structural disorder. The temperature dependence of the magnetization (Fig. 4) shows a sharp inflection at 15 K, a broad inflection at 210 K and a merging of the fc and zfc curves at 330 K. It is not clear at this point how these features relate to the combined superparamagnetic effects of the components in the metal meshes, interconnects, tetrahedra and cubes. Micromagnetics calculations may give some insight into the response of these arrays.

It is demonstrated that in our atmosphere sulfur trioxide (SO_3) is hydrated rather than the much more abundant sulfur dioxide (SO_2), *i.e.* atmospheric oxidation precedes hydration.

In our atmosphere sulfur dioxide is converted to sulfuric acid, a major component of acid rain, and sulfates, which increase Earth's reflectance by forming nuclei for cloud condensation. The pathway of this conversion is constituted of both an oxidative and hydration step. Whether SO_2 is first oxidized, as proposed by Stockwell and Calvert,[1] or first hydrated is still not fully clear. The direct oxidation of SO_2 by the hydroxyl radical proceeds either without[2] or with a very small energy barrier.[3] Also the activation barrier for oxidation of 'hydrated SO_2' ($HOSO_2^-$) by H_2O_2[4,5] or O_2[6] is rather low. Vincent, Hillier and Palmer conjectured that in fact SO_2 and not the hydrogensulfite anion ($HOSO_2^-$) is oxidized.[5] These low barriers indicate that both oxidations are fast. In order to investigate which of the two possible hydrations is fast or slow, we have performed direct dynamics calculations on reactions (1) and (2)

$$SO_2 + nH_2O \rightleftharpoons SO_2{\cdot}nH_2O \rightleftharpoons \{H_2SO_3{\cdot}(n-1)H_2O\} \quad (1)$$

$$SO_3 + nH_2O \rightleftharpoons SO_3{\cdot}nH_2O \rightleftharpoons H_2SO_4{\cdot}(n-1)H_2O \quad (2)$$
