In conclusion, treatment of *N*-benzyl tertiary amines with CAN results in smooth *N*-debenzylation to afford the corresponding secondary amines with complete chemoselectivity. While some *N*-debenzylations may be achieved under hydrogenolytic conditions in acid,[10] this novel debenzylation under oxidative conditions adds considerable versatility to *N*-benzylation protection–deprotection methodology and to regeneration of polymer supports in combinatorial chemistry. Investigations are currently underway to determine the reaction mechanism of this transformation.

Received (in Cambridge, UK) 2nd December 1999, Accepted 25th January 2000

A new methodology to fabricate solid-contact ion-selective electrodes (SC-ISEs) using SAMs of a lipophilic redox-active compound to facilitate the charge transfer across the interface leads to improved potential stability and prevents redox or O_2 interference of valinomycin-based SC-ISEs.

In conventional solvent polymeric ion-selective electrodes (ISEs), the membrane is in electrical contact with the internal reference electrode through an inner solution. This arrangement provides stable potentials at the membrane/solution and solution/internal electrode interfaces.[1] For an ISE whose membrane is in direct contact with the inner electrode (coated wire electrodes),[2] however, the potential stability is generally not satisfactory owing to poorly defined redox reactions at the metal surface and formation of a thin aqueous layer between this metal and the membrane.[3a–c] ISFETs with an immobilized buffered hydrogel layer between the PVC membrane and the SiO_2 surface showed improved stability[3d] but since the need for an inner solution impedes true miniaturization of ISEs, several approaches to improve the EMF stability of solid-contact electrodes have been suggested.[3b,4,5]

Here, we introduce a novel approach to prepare SC-ISEs using redox-active self-assembled monolayers (SAMs). A lipophilic and redox-active compound (a fullerene **1** or tetrathiafulvalene, (TTF) **2** derivative, Fig. 1) is attached by self-assembly to the inner gold electrode (gold film or gold bead), and a conventional ion-selective membrane (with polyurethane matrix) is deposited on the modified solid substrate. The redox properties of the SAMs guarantee a stable potential, while their lipophilicities prevent the formation of an aqueous layer between the membrane and the metal electrode. Two new compounds were designed in view of their easy reduction (of fullerene in **1**) or oxidation (of TTF in **2**).

Compound **1** was synthesized by converting 8-chlorooctanol to the *S*-acetyl protected 8-mercaptooctanol[6] and then into the malonate derivative, which was added in a modified Bingel reaction to C_{60}.[7] Acidic deprotection of the monoadduct yielded **1**. The synthesis of **2** is described in the literature.[8–10] Detailed procedures, spectroscopic and voltammetric data are included in the electronic supplementary information.†

SAMs of **1** and **2** were formed by dipping freshly evaporated Au films (2000 Å, vacuum-deposited on glass slides with a buffer layer of 60 Å Cr) or glass-sealed ultra-clean spherical Au bead (diameter of exposed area *ca.*1 mm) electrodes into a 1 mM CH_2Cl_2 solution of the respective compound for 24 h, followed by rinsing with large amounts of CH_2Cl_2 and drying under Ar.[10] The resulting modified surfaces were characterized by contact-angle measurements, ellipsometry and IR spectroscopy (for Au films) or voltammetry (for Au films and beads).

† Electronic supplementary information (ESI) available: synthetic and spectroscopic data for **1** and **2** is available from the RSC web site: http://www.rsc.org/suppdata/a9/a909532b/

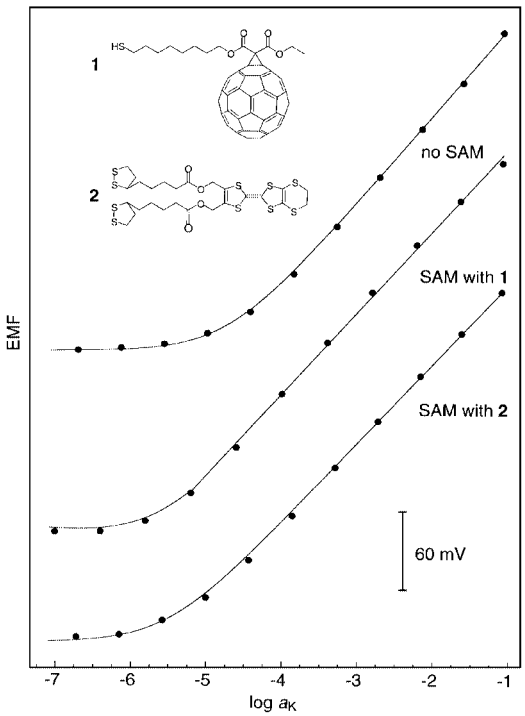

Fig. 1 K^+-Calibration curves of a valinomycin-based SC-ISE membrane with no SAM, and with a SAM of the fullerene derivative **1** or TTF derivative **2** (curves offset for clarity).

The cyclic voltammograms (CVs) recorded in a solution of 0.1 M NBu_4PF_6 in CH_2Cl_2 show a linear increase of the peak current related to the fullerene-based first reduction (for **1**) or TTF-based first oxidation (for **2**) with the scan rate, indicative of a surface-confined behavior (Fig. 2).[11] This was also confirmed by the small potential difference between the anodic and cathodic peaks: 22 mV for the fullerene reduction at $E_{1/2}$ = −680 mV and 35 mV for the TTF oxidation at $E_{1/2}$ = +575 mV (*vs.* an aqueous Ag/AgCl reference electrode at a scan rate of 1 V s^{-1}; Fig. 2). The SAMs derived from compounds **1** and **2** proved to be stable, exhibiting almost the same current responses after several scan cycles. The surface coverages[12] were found to be 3.9×10^{-10} and 1.9×10^{-10} mol cm^{-2} (estimated values for a monolayer: 1.9×10^{-10} and 3.6×10^{-10} mol cm^{-2})[13] for **1** and **2**, respectively.[8,14] The advancing contact angles of water revealed a higher lipophilicity (71 ± 2° for **1** and 70 ± 2° for **2**)[15] compared to that of the unmodified Au electrode, but a lower one than reported for highly hydrophobic surfaces (> 100°),[16] which apparently reflects the aromatic character of the terminal fullerene and TTF groups.

Both SAM-modified Au films and beads were used as internal electrodes for the potentiometric measurements[17] with

DOI: 10.1039/a909532b

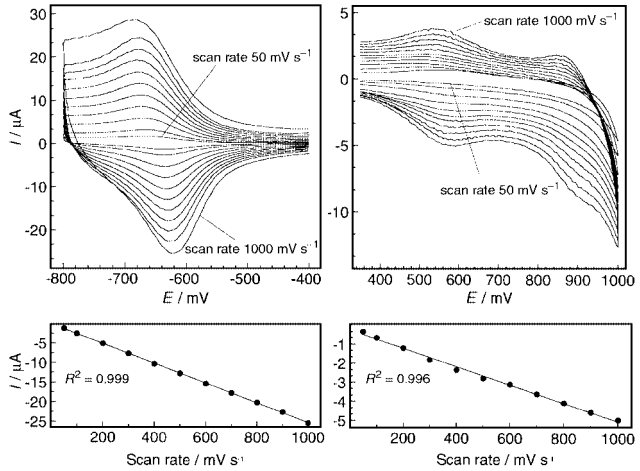

Fig. 2 Cyclic voltammograms of a SAM of **1** (left) or **2** (right) on a gold bead recorded in 0.1 M NBu_4PF_6 in CH_2Cl_2 with scan rates between 1000 (first scan) and 50 mV s^{-1} (last scan). All measurements were started at 0 mV.

K^+ selective polyurethane membranes.[18] Fig. 1 shows calibration curves for the SC-ISEs with different interfaces after conditioning in a 10^{-3} M KCl solution for 12 h. The SC-ISEs with SAMs exhibit linear responses down to 10^{-5} M K^+ with Nernstian slopes (the lower detection limit is due to H^+ interference[17]). Since the membrane composition for these SC-ISEs is the same as for conventional liquid-contact ISEs, the selectivity coefficients are also the same within experimental error. The EMF values of these SC-ISEs are more stable (long term drifts over 100 h 85 μV h^{-1} as compared to 220 μV h^{-1} without SAM) and not influenced by changes in the ratio of Fe(III)/Fe(II) in solutions of constant ionic strength (0.1 M KCl) and constant total amount of the redox couple (10^{-2} M $FeCl_3$/$FeCl_2$). In the absence of the redox-active SAM, the linear response range was reduced by about an order of magnitude (Fig. 1, the lower detection limit is no more due to H^+ inteference) and strongly drifting signals (> 5 mV min^{-1}) were observed when interfering ions were measured. Both of these effects can be explained by the presence of an aqueous layer between the polyurethane membrane and the gold surface. The composition of this layer changes upon contact of the SC-ISE with interfering sample ions and thereby affects both the phase boundary potential at the interface of the membrane and the aqueous layer as well as the interfacial potential at the metal surface, which is apparently determined by the reaction of O_2.[3b] The strong influence of O_2 on the EMF of coated wire electrodes[3b,5a] Fig. 3, top curve) is effectively reduced by the SAMs of **1**, **2** or *n*-$C_8H_{17}SH$ (Fig. 3), indicative of the absence of an aqueous layer. However, no Nernstian response could be obtained with the latter monolayer, corroborating the need for the redox active SAM.

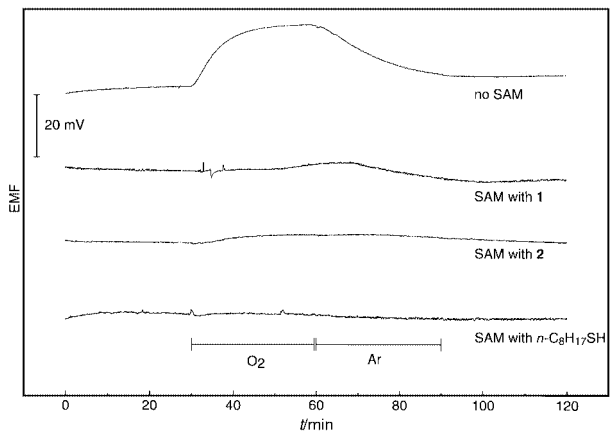

Fig. 3 EMF response of various SC-ISEs on introducing O_2 or Ar into a 10^{-3} M KCl solution (curves offset for clarity).

In summary, we have developed a new methodology to fabricate solid-contact ion-selective electrodes using SAMs of redox-active compounds. All the valinomycin-based SC-ISEs studied show Nernstian responses down to 10^{-5} M K^+, with improved stability, and no redox or O_2 interference.

The authors thank ETH Zurich for an internal research grant, Orion Research Inc. (Beverly, MA) for financial support, Dr M. Hirayama, H. Persson and Professor U. W. Sutter for their help in surface characterization, and Dr D. Wegmann for careful reading of the manuscript. L. E., S.-G. L., and K. B. wish to thank the US National Science Foundation (CHE-9816503 and DMR-9803088) and F. D. the Swiss National Science Foundation for financial support.

Received (in Cambridge) 10th November 1999, Accepted 26th January 2000

Exclusively *cis*-protonation occurs at axial N-atoms of chair shaped P_3N_9 ring cores in the protolysis of the lithium salt of hexaanionic cyclotriphosphazenate $[(CyN)_6P_3N_3]^{6-}$ with three equivalents of butan-1-ol and *cis*-deprotonation takes place at the hexaprotic cyclotriphosphazene $(PhNH)_6P_3N_3$ with three equivalents of Bu^nLi, respectively, yielding both times lithium salts of *cis*-trihydrogen cyclotriphosphazenates $[(RNH)_3(RN)_3P_3N_3]^{3-}$.

The formal replacement of oxy and hydroxy units (=O, –OH) by isoelectronic imino and amino groups (=NR, –NHR), respectively, has led to novel compounds with unusual properties, due to both the increased electron donating capability of the nitrogen centre and the steric demand of the lipophilic organic substituent.[1] Imino analogues of the classic oxy-anions $[SO_3]^{2-}$,[2] $[SO_4]^{2-}$,[3] $[PO_4]^{3-}$ [4] and the kinetically unstable $[PO_3]^-$ [5] exist as molecular aggregates and are highly soluble in aprotic organic solvents. However, little is known about multistep protonation pathways between corresponding acid–base pairs. Recently, we have discovered that cyclophosphazenes carrying RNH groups act as multiprotic acids in the presence of strong bases yielding multianionic phosphazenates, a novel class of highly charged ligand systems.[6] The hexaprotic cyclotriphosphazene $(CyNH)_6P_3N_3$ **1a** is fully deprotonated by Bu^nLi generating the lithium salt of the hexaanionic cyclotriphosphazenate $[(CyN)_6P_3N_3]^{6-}$ **3a** which is highly soluble in non-polar aprotic solvents.[6a] Its central P_3N_9 core is electronically related to the cyclotrisilicate ion $[Si_3O_9]^{6-}$. We have now revealed protonation and deprotonation pathways between hexaprotic phosphazenes and hexaanionic phosphazenates by monitoring reactions using ^{31}P NMR spectroscopy and determining crystal structures of trianionic intermediates.

Stepwise addition of Bu^nLi to a solution of **1a** (14.9 ppm) in thf leads to a complex signal pattern in the ^{31}P NMR spectrum (Fig. 1) which finally gives a single peak at 25.3 ppm due to the formation of fully deprotonated **3a**. However, stepwise protolysis of **3a** with Bu^nOH gives a single peak at 16.2 ppm after addition of three equivalents of Bu^nOH indicating the existence of the trianionic intermediate $[(CyNH)_3(CyN)_3P_3N_3]^{3-}$ **2a**. In contrast, the hexaanilino derivative $(PhNH)_6P_3N_3$ **1b** (3.2 ppm) gives directly $[(PhNH)_3(PhN)_3P_3N_3]^{3-}$ **2b** upon addition of three equivalents of Bu^nLi as indicated by the appearance of a single peak at 5.0 ppm. Addition of six equivalents to **1b** results in one signal at 16.2 ppm which can be attributed to hexaanionic $[(PhN)_6P_3N_3]^{6-}$ **3b**. In both cases tri- and hexa-anionic species are levelled by excess of Bu^nOH yielding **1** and exist only in aprotic non-acidic media or very weakly protic solvents such as cyclohexylamine.

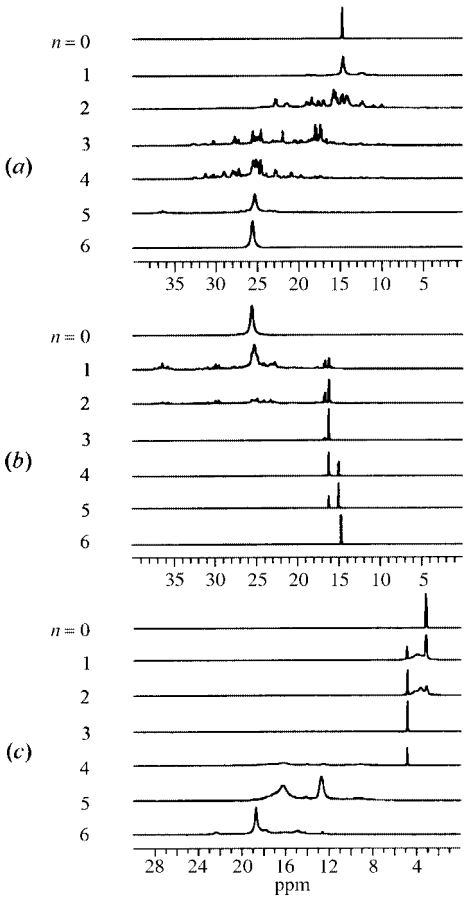

Fig. 1 ^{31}P NMR spectra (ppm) (161 MHz, thf, 25 °C) of stepwise reactions (a) **1a** + *n* Bu^nLi, (b) **3a** + *n* Bu^nOH and (c) **1b** + *n* Bu^nLi.

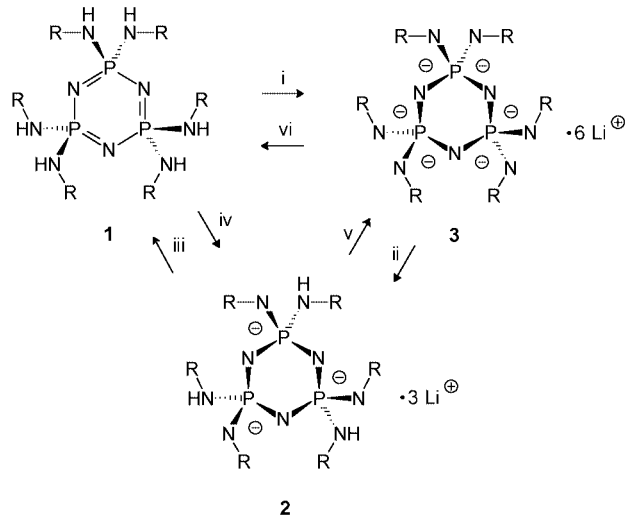

Scheme 1 *Reagents and conditions*: for **a** (R = Cy): i, Bu^nLi (6 equiv.), thf; ii, Bu^nOH (3 equiv.); iii, Bu^nOH (3 equiv.); for **b** (R = Ph): iv, Bu^nLi (3 equiv.), thf; v, Bu^nLi (3 equiv.), thf.

The X-ray structure† of **2a** reveals that exclusively axial N-atoms at the chair shaped P_3N_3 ring have been protonated (Fig. 2). The dimeric complex of **2a** is closely related to that of hexaanionic **3a** containing a centrally arranged polyhedral cage comprising six lithium cations which are encapsulated by two trianions. Each lithium cation is chelated by a bidentate N(eq)–P–N(ring) site of one of the anions and additionally coordinated by an equatorial N-atom of the other anion. The geometry of the central P_3N_9 core in **2a** is midway between those observed in **1a**

DOI: 10.1039/a908954c

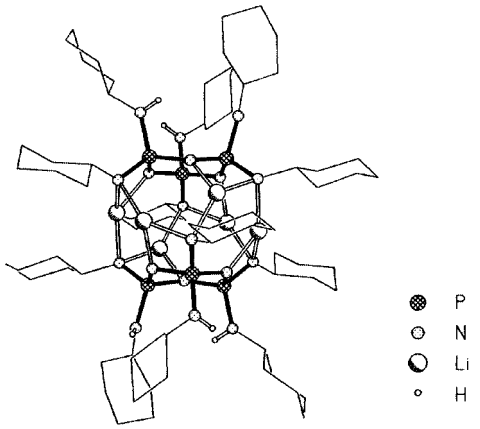

Fig. 2 Crystal structure of **2a**. Average bond lengths (Å) and angles (°): P–N(ring) 1.635, P–N(eq) 1.614, P–N(ax) 1.665, Li–N(ring) 1.99, Li–N(eq) 2.04, Li–N(eq) of the other trianion 2.03, N(ring)–P–N(ring) 112.3, N(eq)–P–N(ax) 111.3, P–N(ring)–P 121.9, av. P_3N_3 ring torsion = 33.2°.

and **3a**: torsion angles within the P_3N_3 ring show that the degree of ring puckering increases in the order **1a** (av. 3.6° ~planar), **2a** (av. 33.2°) and **3a** (av. 43.7°). The P–N ring stretching frequency in the IR-spectra undergoes a considerable red shift from **1a** (1194 cm^{-1}), **2a** (1095 cm^{-1}) to **3a** (1031 cm^{-1}) suggesting a decrease in bond order, also shown by the increase in P–N(ring) bond lengths from 1.598 (**1a**), 1.635 (**2a**) to 1.660 Å (**3a**) and decrease in N–P–N(ring) angles [116.3° (**1a**), 112.3° (**2a**), 109.7° (**3a**)] causing puckering of the central six-membered ring. The difference in exocyclic P–N bond lengths in **2a** [P–N(eq) 1.614, P–NH(ax) 1.665 Å] indicates that multiple bond character is partly transferred from ring onto equatorial P–N bonds.

2b exists as the monomeric C_3-symmetric complex $[(thf)_6Li_3$ *cis*-$(PhNH)_3(PhN)_3P_3N_3]$ in the solid state. Each lithium cation is chelated by an N(eq)–P–N(ring) site of the ligand and in addition coordinated by two thf molecules. Structural parameters of the P_3N_9 core in **2b** resemble those in **2a** (Fig. 3) and

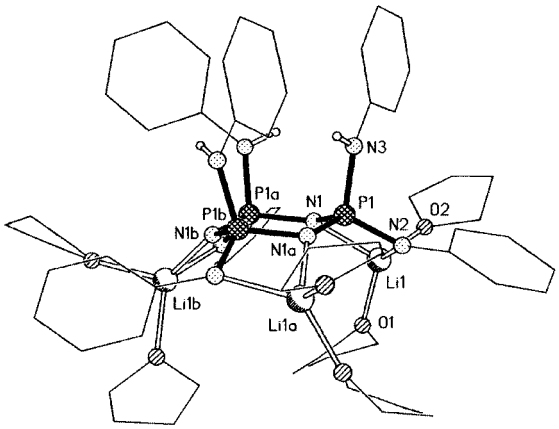

Fig. 3 Crystal structure of **2b**. Selected bond lengths (Å) and angles (°): P1–N1 1.621(3), P1–N1a 1.614(3), P1–N2 1.592(3), P1–N3 1.708(4), N1–Li1 2.054(8), N2–Li1 2.038(8); N1–P1–N1a 114.7(2), N2–P1–N3 112.3(2), P1–N1–P1a 119.8(2); P_3N_3 ring torsion = 32.3(4)°. Non-coordinated thf molecules have been omitted for clarity.

deprotonation also occurred in *cis* fashion at equatorial N-atoms. The difference in P–N bond lengths (P–N(ring) 1.617 (av.), P–N(eq) 1.592(3), P–NH(ax) = 1.708(4) Å) shows the same tendency as **2a**. The *cis*-arrangement in both structures can be rationalised as follows: charge repulsion within the P_3N_9 core forces the six-membered ring into a chair conformation, due to distribution of charge over ring and equatorial N atoms. This leaves axial sites protonated and provides three N(ring)–P–N(eq) chelates complexing the lithium cations on the opposite side of the trianion.

The successive protonation pattern of the above described $\{(RNH)_6P_3N_3/[(RNH)_3(RN)_3P_3N_3]^{3-}/[(RN)_6P_3N_3]^{6-}\}$ systems resembles that of mononuclear polyprotic oxy acids. It is, however, shifted towards the far basic region of the acidity scale and ion pairing seems to play a significant role. In contrast, condensed oxy acids lack corresponding acid–base reactions due to backbone cleavage in the presence of strong bases and related acidic oxy-anions such as $[H_3Si_3O_9]^{3-}$ are unknown. Another interesting feature of **2** is the site selective protonation pattern which is to our knowledge the first selective *cis*-trifunctionalisation of a cyclotriphosphazene.[7] This could lead to novel ligand systems equipped with a hexadentate coordination surface on one side and a non-polar surface on the other side of the molecule similar to calixarenes.

This work was supported by the EPSRC, the Royal Society and the Nuffield Foundation.

Synthesis and chloride binding properties of a Lewis acidic tetratin(IV) calixarene

Michael T. Blanda* and Michael A. Herren

Department of Chemistry, Southwest Texas State University, San Marcos, TX 78666, USA. E-mail: mb29@swt.edu

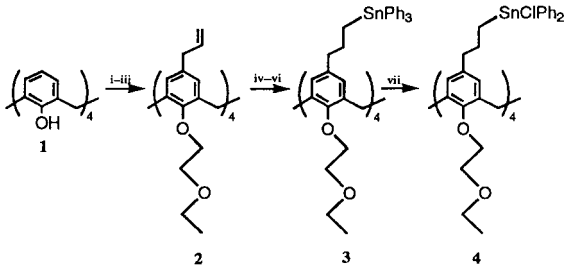
Received (in Columbia, MO, USA) 6th August 1999, Revised 9th December 1999, Accepted 9th December 1999

The Lewis acidic calix[4]arene with four covalently attached diphenylmonochlorotin(IV) centers was synthesized and its stannate complex with chloride was studied by ^{119}Sn NMR.

The supramolecular chemistry of anions including their detection, sequestration and transportation by calixarenes is an emerging area of research involving this versatile class of receptor molecules.[1] Compared to their positively charged counterparts, anions are inherently more difficult to bind due to their relatively larger ionic radii, higher solvation energies and diverse topologies.[2] Even with these formidable obstacles, calixarenes with incorporated hydrogen bond donors (*e.g.* ureas, amides and alcohols)[3] or electron-deficient metal centers (*e.g.* metallocenes and metal complexes)[4] have been synthesized which selectively bind different types of anions. Recently, there has been an increased interest in designing heteroditopic ligands for the simultaneous complexation of anions and cations suitable for extraction or transportation of metal salts. Since calixarenes can be functionalized on both their upper and lower rims, they are attractive molecular scaffolds for constructing heteroditopic hosts. Common design features of previously reported bifunctional calixarenes are hydrogen bond donors for anion complexation and crown ether or ester groups for cation recognition.[5] In this context, we report the synthesis and chloride-binding properties of a neutral, heteroditopic calixarene containing covalently attached Lewis acidic tin atoms for anion binding and ether oxygens for cation binding.

Incorporation of main group metals, particularly tin, represents a relatively unexplored area of calixarene chemistry. Two of the reported three examples are actually complexes containing mono- and ditin(II) centers wherein the calixarenes served as oxoligands.[6a,b] The lone example of a covalently attached tin(IV)-containing calixarene utilizes the tin atoms as the bridge between adjacent aromatic rings.[6c] The relatively longer C–Sn bonds allowed this compound to adopt a nearly planar geometry, thereby destroying the chalice-like structure.

The neutral Lewis acidic tetrastannacalix[4]arene host **4** was synthesized as outlined in Scheme 1.†‡ The principal starting material for the synthesis was the de-*tert*-butylated calix[4]arene **1**, which was readily obtained in multigram batches from literature procedures.[7] The dealkylated calixarene was used so that the Lewis acidic tin atoms could be appended to the upper rim. Alkylation of the lower rim of **1** with allyl bromide yielded the tetraallyl ether (85%), which when heated to 215 °C underwent a Claisen rearrangement that transferred the allyl groups to the upper rim (71%).[7]



Scheme 1 *Reagents and conditions*: i, NaH, allyl bromide; ii, *N*,*N*-diethylaniline, heat; iii, NaH, 2-bromoethylethyl ether; iv, 9-BBN, H_2O_2, NaOH; v, Ph_3P, CCl_4; vi, $Ph_3SnSnPh_3$, Li; vii, HCl, CH_2Cl_2.

The cone conformation in the calix[4]arene framework of **2** was then fixed by appending ethoxyethyl groups on to the lower rim of the rearranged tetraallyltetrahydroxycalixarene (58%).[8] These ether groups were used to create a prototypical cation binding site for three reasons: (i) they were inert to the conditions of the subsequent reactions, (ii) their cation-binding properties were already known[9] and (iii) their conformational influence on the calixarene was predictable. Hydroboration of the double bonds in **2** with 9-BBN produced the tetraol (28%) which was converted to the corresponding tetrachloride by treatment with Ph_3P/CCl_4 (82%). The tetratin compound **3** was obtained by reacting the tetrachloride with Ph_3SnLi (40%).[10] The ^{119}Sn NMR spectrum of **3** contained only one signal at δ −101.27, which indicated that the four tins were equivalent in solution. Without the inductive effects of an electron withdrawing group, the tin atoms are not acidic enough to complex chloride ions, thus host **4** was obtained after careful treatment of **3** with anhydrous HCl at −78 °C (90%). The ^{119}Sn NMR spectrum of **4** also contained just a single signal at δ +14.75 which is within the range of typical Ph_2RSnCl species.[11a] What ultimately motivated us to employ the 3-carbon spacer group on the upper rim was the fact that the order of reactivity in this reaction is Ph > Bn > R.[11b] This meant that at least a 2-carbon spacer had to separate the tin atoms from the aromatic rings on which they were attached so that regiochemical control could be achieved in the chlorination reaction.

The chloride complexing properties of **4** were investigated in $CDCl_3$ by using ^{119}Sn NMR to observe the change from the tetravalent uncomplexed, stannane species to the pentavalent geometry of the stannate complex.[11b,12] Initial binding studies were restricted to chloride binding in order to eliminate complications introduced by ligand exchange at the tin atoms. The stoichiometry of the complex was determined by the method of continuous variation (Job plot).[13] This method is particularly useful for systems under rapid exchange conditions and can be adapted easily to ^{119}Sn NMR data.[12] The experiment required analysis of several solutions of **4** and Bu_4NCl prepared such that the mole fractions changed, but the concentration was constant. A plot of $(\Delta\delta X_H)$ *vs.* X_H, where $\Delta\delta = (\delta_{obs} - \delta_H)$, produced a parabolic curve that maximized at $X_H = 0.25$, indicating that each tin atom acted independently in the formation of a 4:1 (Cl:**4**) stannate complex. This result is not surprising, since the tin atoms are not structurally preorganized in a well-defined binding site that would facilitate cooperative binding.

Chloride association constants for **4** were determined by the Benesi–Hildebrand method as adapted to ^{119}Sn NMR data as shown in eqn. (1).[12]

$$(\delta_{obs} - \delta_H)^{-1} = (\delta_C - \delta_H)^{-1} + (K_{eq}(\delta_C - \delta_H))^{-1}[Cl^-] \quad (1)$$

The rate of exchange between the free host and complex was rapid on the NMR time scale, over the temperature range of −20 to +50 °C, as evidenced by a single weighted-average signal that was observed to shift from its initial value for the free host (δ +14.35) to higher field strengths upon the addition of

DOI: 10.1039/b000522n

chloride. For example, the signal for Cl^-/host = 4 was observed at δ −171.93 and continued to shift slightly further upfield with the addition of 8, 12, 16 and 20 equiv. of Cl^-. The total displacement ($\delta_{obs} - \delta_{host}$) was 207 ppm, with 90% displacement occurring at the addition 4 equiv. of Cl^-. This behavior is characteristic of weak binding, which was confirmed by the small K_{eq} values that ranged from a high of 52 M^{-1} at 253 K to a low of 13 M^{-1} at 328 K, with intermediate values of 25 and 33 M^{-1} at 295 and 273 K, respectively. Not only are these values similar to acyclic ditin model compounds,[14] they were anticipated since the tin atoms in **4** lack any preorganization and cooperative binding.

We are currently investigating the simultaneous ion pair complexing properties of **4** with NaCl as the metal salt. These studies are based on previous results that demonstrated that the ethoxyethyl ether groups were selective for sodium ions even though the percent extraction is relatively low.[9]

M. T. B. would like to thank the Robert A. Welch Foundation for financial support and Dr Norman Dean for assistance in acquisition of the ^{119}Sn NMR data.

Notes and references

† All new compounds were characterized by ^{1}H (400 MHz), ^{13}C (100 MHz) and ^{119}Sn (149 MHz) NMR spectroscopy and elemental analysis. Internal standards for NMR spectra were tetramethylsilane (^{1}H and ^{13}C) and tetramethyltin (^{119}Sn).

^{119}Sn Job plot experiments: Aliquots from 0.1 M stock $CDCl_3$ solutions of **4** and Bu_4NCl were mixed so that the mole fractions of each changed, but the total concentration of all species in solution remained constant. Spectra were acquired at 295 K (149 MHz) on samples containing mole fractions of **4** ranging from 0.1 to 0.8.

Binding constants: Equilibrium constants were determined by the Benesi–Hildebrand method, wherein a large excess of guest species was present relative to the amount of host. In these experiments, aliquots of a 1.72 M solution of Bu_4NCl were added to 0.780 ml (0.071 mmol) of a 0.091 M solution of **4** in 1 ml volumetric flasks. The solutions were mixed thoroughly and transferred to an NMR tube. Binding constants were determined at 328, 295, 273 and 253 K.

Synthesis of a hydrophilic phosphonic acid monomer for dental materials

Liyuan Mou,[a] Gurdial Singh*[a] and John W. Nicholson[b]

[a] *Department of Chemistry, University of Sunderland, Sunderland, UK SR1 3SD. E-mail: gurdial.singh@sunderland.ac.uk*

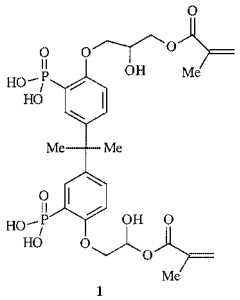
[b] *Dental Biomaterials Department, GKT Dental Institute, Kings College, University of London, London, UK SE1 9RT*

Received (in Liverpool, UK) 16th December 1999, Accepted 25th January 2000

A novel phosphonic acid monomer for use in dental composites was prepared by the base-catalysed rearrangement of the corresponding diethyl arylphosphonate.

In general dentistry may be described as a profession that is engaged with the repair and treatment of the teeth in order to restore proper function and good aesthetics. One of the major problems encountered in the treatment of teeth is dental caries, which is a preventable condition but one that is widespread and is possibly the most common disease in the world.[1] The onset of dental caries is due to metabolic activity by the bacteria of the plaque leading to production of acids from sugar in the diet, resulting in a localised attack on the enamel and dentine of the tooth.[2] The infection caused by caries can lead to other more serious conditions and can be fatal in the case of endocarditis,[3] and as a consequence dental repair can be seen as important. Repair materials have been the subject of considerable research, with recent emphasis on aesthetic materials that are capable of bonding to the cleaned tooth surface.

In the present work, we have sought to prepare an acid-functional monomer for use in dental restorative materials. There are existing filling materials that contain acid-functional monomers, but they are aliphatic, and the resulting materials have relatively poor mechanical properties.[4] We anticipate that aromatic monomers, such as **1**, will yield materials with



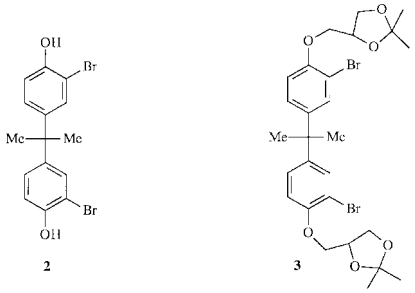
1

improved mechanical properties, because of the similarity with the aromatic dimethacrylate monomers currently used extensively in dentistry.

We also reasoned that the incorporation of a phosphonic function into monomer structures would result in increased biocompatability and adhesion to the tooth due to chelation with calcium ions in the tooth surface.

Here we report on the synthesis of the novel monomer **1** in which we have incorporated a phosphonic acid residue in both aromatic rings as well as incorporating a methylmethacrylate function that is capable of ionic or radical polymerisation.

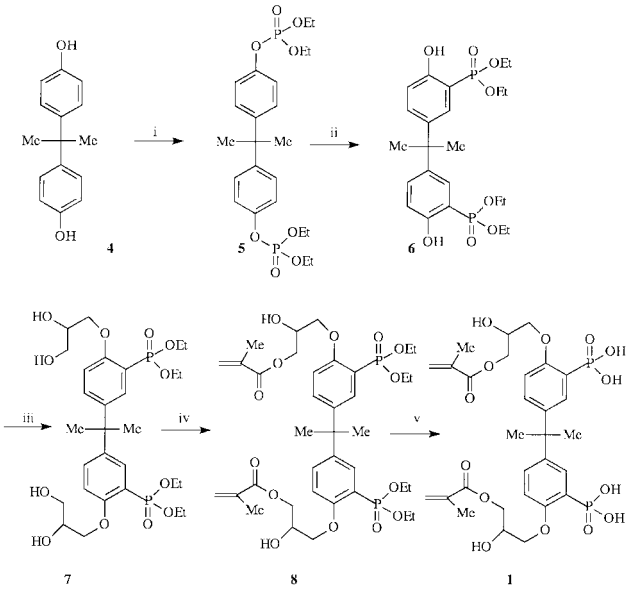
At the outset we investigated the formation of the aryl phosphonate **6** employing Michaelis–Arbuzov reaction with the 2,2′-dibromobisphenol **2** and triethyl phosphite and with *O*-dimethoxy analogues under a wide range of conditions,[5] and all of these attempts proved to be unfruitful. As a result of these findings we explored the chemistry of the di-*O*-isopropylidene protected dibromoaryl ether **3** employing Michaelis–Arbuzov conditions and also the Hirao modification.[6] Once again these attempts at the introduction of the phosphonate group proved to



2 **3**

be unfruitful. The alternative strategy of lithio anion formation.[7] followed by subsequent trapping led to complex mixtures that contained a small amount of the desired product, as evidenced by NMR.

Our successful approach to the synthesis of **1** is detailed in reaction Scheme 1. Bisphenol **4** was treated with NaH and chlorodiethylphosphite and afforded the di-*O*-phosphate **5** in 50% yield.† An improved yield (75%) of **5** was obtained if the reaction was conducted using diethyl phosphite in the presence of CCl_4 and triethylamine.[8] With the diphosphate **5** in hand we examined its rearrangement to the C-phosphonate as similar processes had been reported by Melvin at Pfizer[9] for simpler systems.[10] Thus treatment of the diaryl phosphate **5** with a 2.5 fold excess of lithium diisopropylamide at −78 °C resulted in the clean rearrangement to the diarylphosphonate **6** in 86% isolated yield after recrystallisation. That the rearrangement had occurred to give **6** was strongly supported by its spectral properties, in particular the ^1H, ^{13}C and ^{31}P NMR were most



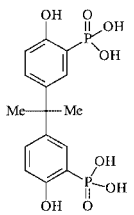
Scheme 1 *Reagents and conditions*: i, NEt_3 (2 equiv.), diethyl phosphite (2 equiv.), CCl_4, room temp., 30 h; ii, LDA (5 equiv.), THF, −78 °C, 1 h, then 3 h at room temp.; iii, glycidol (5 equiv.), cat. NEt_3, heat, 3 h; iv, Py, methacrylic anhydride (3.5 equiv.), cat. DMAP, room temp., 18 h; v, TMSBr (9 equiv.), room temp., 18 h, followed by aq. MeOH.

informative. In the ^{1}H NMR there was significant ^{1}H–^{31}P coupling to the *ortho* and *meta* protons (J_{P-H} 11.2 and 7.2 Hz) of the aromatic rings; this coupling was absent in **5**. In the ^{13}C NMR, coupling of ^{13}C–^{31}P was observed for the aromatic resonances (J_{C-P} 179.6, 13.5 Hz). The ^{31}P NMR also provided convincing support for the assignment, as the resonance due to the phosphonate was observed at δ −21.54 for **6** whilst in the phosphate **5** the resonance was found to be at δ −7.21.

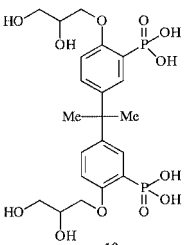
This type of rearrangement reaction most likely proceeds *via ortho*-directed metallation of the aromatic ring followed by migration of the phosphorus to the cabanion centre, resulting in the formation of the phenolic phosphate. During the course of these studies we examined this rearrangement using ^{31}P NMR but we were unable to detect any intermediates during this process. We believe that this is the first example of this type of double phosphate rearrangement to provide the diphosphonate **6**.

Having the desired arylphosphonate **6** in hand alkylation of both the phenolic functions was accomplished with glycidol in the presence of triethylamine to afford **7** in 50% yield. Selective methacrylation of the primary hydroxy functions at both termini was accomplished with either methacroyl chloride in the presence of pyridine or with methacrylic anhydride in the presence of a catalytic amount of DMAP. The latter sequence was preferred as it gave rise to the desired product **8** in 50% yield as compared to 29% for the former reaction procedure. In both of these esterification reactions we observed the formation of doubly and singly esterifed products that were separated by column chromatography. The mono ester thus obtained could be converted to the diester on further treatment with either of the two acylating agents.

At this juncture it remained for us to selectively remove the ethyl ester protecting group of the phosphinates in **8**. We examined a range of procedures, including acid and base hydrolysis, and all of these methods proved to be unfruitful, with many resulting in C–O bond cleavage and removal of the methacroyl group. As a result of this we undertook model deprotection experiments with both the phosphonates **5** and **7** using trimethylsilyl bromide.[11] This treatment resulted in the formation of the respective phosphonic acids **9** and **10** as



9



10

dicyclohexylammonium salts, after hydrolysis, in yields of 55 and 96%. As a result of these findings we used trimethylsilyl bromide followed by hydrolysis with aqueous methanol to undertake the removal of the phosphonate ester groups and gratifyingly this afforded the desired acid monomer **1** in 60%. Alternatively, it could be isolated as its dicyclohexylammonium salt.

In summary, we have successfully developed the synthesis of the phosphonic acids **1** employing a double phosphate rearrangement reaction in excellent overall yield.

Polymerisation studies of **1** will be reported elsewhere. To date preliminary biocompatability studies are showing promise and these are ongoing.

We thank the EPSRC for support of this work and for access to central facilities for high resolution mass spectrometric data at the University of Wales, Swansea.

Received (in Cambridge, UK) 2nd December 1999, Accepted 26th January 2000

Catalysed alkene hydroboration proceeds in supercritical CO_2 with several rhodium(I) complexes using tunable fluorinated ligands and shows higher regioselectivity relative to tetrahydrofuran or perfluoromethylcyclohexane.

The power of homogeneous transition metal catalysis rests in chemists' ability to fine-tune the steric and electronic properties of the metal coordination environment and to optimize activity and selectivity by judicious choice of the reaction medium.[1] While a number of studies have employed fluorinated ligands [2–4] to conduct a variety of metal-catalysed reactions[5] in environmentally benign supercritical carbon dioxide ($scCO_2$), little work has been reported on catalyst tunability. Recently reported phosphines PR_2R_F[3,6,7] and phosphinites $PR_2(OR_F)$[6,7] (R_F = $CH_2CH_2C_6F_{13}$) are easily prepared and offer the ability not only to enhance catalyst solubility, but to control the stereoelectronic environment of catalysts in $scCO_2$. We chose to investigate Rh^I-catalysed alkene hydroboration[8,9] due to the importance of boronate ester products in synthetic organic chemistry, medicinal chemistry, materials science and molecular recognition. The catalyzed reaction exhibits higher rates and complementary regioselectivity compared to the uncatalysed reaction, and efficient chirality transfer has been demonstrated in the asymmetric variant.[9] We now report the first demonstration of catalysed alkene hydroboration in $scCO_2$, the ability to tune both regio- and chemo-selectivity, and the discovery of much higher selectivity in $scCO_2$ compared to perfluoromethylcyclohexane ($CF_3C_6F_{11}$).

Catalyzed hydroboration of styrene derivatives with catecholatoborane (HBcat) was carried out in $scCO_2$ at 40 °C and 2800 psi for 5 h with a rhodium catalyst precursor and added phosphorus ligands using magnetically-stirred, high-pressure reactors with sapphire view windows that have been described elsewhere.[10] Addition of HBcat to vinylanisole using only the hexafluoroacetylacetonate (hfacac) rhodium complex (hfacac)$Rh(coe)_2$ **1** (coe = cyclooctene) as catalyst precursor[2] led to a homogeneous solution and, after 5 h, high conversion to a mixture of alkylboronate esters **A** and **B**, alkenylboronate ester **C**, and 4-ethylanisole **D** (Scheme 1, Table 1). Products **C** and **D** result from a competing dehydrogenative borylation pathway which is favoured by phosphine-free rhodium catalysts.[11] Addition of triphenylphosphine to **1** gave turbid solutions due to poor ligand and/or catalyst solubility in $scCO_2$. The fluorinated ligands, including **5**–**8** led to homogeneous solutions demonstrating that a single fluorinated substituent is sufficient to impart high solubility in $scCO_2$. As shown in Table 1, added ligands dramatically influence the regioselectivity of hydroboration. Triphenylphosphine, its 3,5-bis(trifluoromethyl)phenyl analog, and $P(R_F)_3$ all greatly increased hydroboration regiochemistry, but chemoselectivity was improved only marginally. Alkylboronate ester **A** was formed exclusively with cyclohexyl-substituted phosphine **8** (L:Rh ratio = 2:1), demonstrating the ability to control regioselectivity and chemoselectivity by tuning the solubility and stereoelectronic properties of ligands and metal catalysts in $scCO_2$.

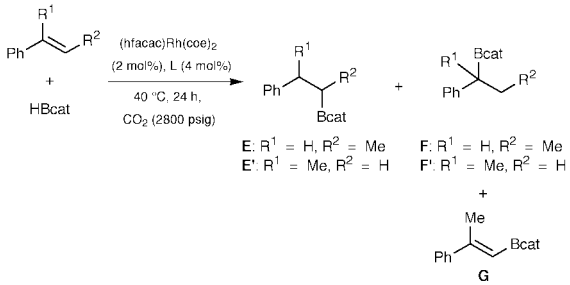
8	Cy_2PR_F (**8**)[b]	100	100	—	—	—

[a] (hfacac)$Rh(coe)_2$ **1** (0.02 mmol), ligand L (0.04 mmol) and substrate (1.0 mmol). Conversion and product selectivity were determined by ^1H and ^{11}B NMR using hexamethyldisiloxane standard. [b] R_F = $CH_2CH_2C_6F_{13}$. [c] Some polymeric material was observed in this reaction.



Scheme 2

In several studies of rhodium-catalyzed hydroboration of disubstituted alkenes, such as α- and β-methylstyrenes, monodentate ligands have been found to give poor selectivity to the desired Markovnikov addition product.[8] While conversions were low in some cases, the ability to control regiochemistry through tunable fluorinated ligands in $scCO_2$ is further illustrated in Scheme 2 and Table 2. For β-methylstyrene, the tris[3,5-bis(trifluoromethyl)phenyl]phosphine **3** and cyclohexyl-substituted ligands **6, 8** gave the highest activity, but with only fair regiocontrol. Ligands **4**, **5** and **7** gave alkylboronate ester **E** exclusively. The advantage of ligand tunability is also demonstrated for the reaction of α-methylstyrene and HBcat, as changing from cyclohexyl **6** to phenylphosphinite ligand **5** yields only the Markovnikov addition product **E′**.

Solvent effects play an important role in determining the selectivity of catalytic hydroboration reactions.[12] Gladysz and

[a] Reactions in organic solvents were run in NMR tubes using 0.002 mmol **1**, 0.004 mmol ligand, and 0.1 mmol vinylanisole. Conversion and selectivity were determined by ^1H NMR. [b] Some polymeric material was observed in this reaction.

Horvath[13] reported an elegant study of alkene hydroboration in fluorous biphasic media using $RhCl[P(R_F)_3]_3$ derived from **4**; however, the regioselectivity for styrene derivatives was low. Comparing the reaction of vinylanisole and HBcat in $scCO_2$ to that in perfluoromethylcyclohexane led to some surprising results. Catalyst precursor **1** and ligand **4** showed significantly greater regiocontrol in $scCO_2$ (Table 3, entry 1). This trend held for ligands **5**–**8** and was particularly striking for Cy_2PR_F (entry 5) which afforded a single product in $scCO_2$. Remarkably, the selectivity in $scCO_2$ for **4**–**8** was also considerably higher than that observed in THF. Ligand **4** is not soluble in THF; however, partially fluorinated ligands **5**–**8** and their rhodium complexes are fully soluble under the reaction conditions. In THF, product selectivity using the nonfluorinated analog of ligand **8** (*i.e.* $Cy_2PC_8H_{17}$) was found to be similar to that observed for ligand **8**, confirming the insulating effect of the two methylene spacers in the R_F group.† There are several reports[4,5,14,15] of enhanced selectivity of catalysed reactions in $scCO_2$ compared to conventional organic solvents. Except for a few cases where density is controlled through pressure changes,[16] we are unaware of any examples presenting such a dramatic effect as that shown here. The origin of the higher selectivities for hydroborations is not clear. Since ligand-free rhodium complexes result in poor hydroboration selectivity,[11] stability and lability of the catalysts (*i.e.* keeping the ligand on the metal), which are likely solvent dependent, may play an important role. It is also possible that a Rh–η^3-benzyl intermediate[17] that would lead to **A** could be stabilized in $scCO_2$ relative to the η^1-regioisomer that would yield **B**.

In summary, we have demonstrated that catalysed alkene hydroboration can proceed in supercritical CO_2 without any difficulty from B–H reactivity with the solvent. Regiocontrol can be achieved using tunable ligands of the form R_2PR_F and R_2POR_F. Furthermore, significantly higher regioselectivities can be obtained for these ligands in $scCO_2$, relative to fluorocarbons and even THF. Given further advancements in catalyst separations and recovery in $scCO_2$,[18] catalysis in this medium can complement fluorous phase approaches. We are currently assessing the effects of pressure (solvent density) on selectivity, monitoring reactive species by *in situ* NMR spectroscopy, and studying stoichiometric reactions of isolable 16 electron rhodium–boryl complexes.[19]

This work was supported as part of the Los Alamos Catalysis Initiative by the Department of Energy through Laboratory Directed Research and Development (LDRD) funding and by the Department of Energy (DE-FG02-98ER45732) for work performed at UNO. We would like to thank Drs Chris Haar and Dale Smith (UNO) for providing ligands and Professor John Gladysz for a generous donation of $P(CH_2CH_2C_6F_{13})_3$.

Notes and references

† Triphenylphosphine and catalyst precursor **1** (3:1) or Wilkinson's catalyst (ref. 9) lead to high selectivity > 95% to **A** in THF; however, these catalysts are not effective for methylstyrenes (ref. 19).

Design of a nucleobase-conjugated peptide that recognizes HIV-1 RRE IIB RNA with high affinity and specificity

Tsuyoshi Takahashi,[a] Keita Hamasaki,[a] Ichiro Kumagai,[a] Akihiko Ueno[a] and Hisakazu Mihara*[ab]

[a] *Department of Bioengineering, Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, Nagatsuta, Yokohama 226-8501, Japan. E-mail: hmihara@bio.titech.ac.jp*

[b] *Form and Function, PRESTO, Japan Science and Technology Corporation, Tokyo Institute of Technology, Nagatsuta, Yokohama 226-8501, Japan*

Received (in Cambridge) 6th December 1999, Accepted 26th January 2000

A nucleobase-conjugated peptide, derived from HIV-1 Rev, was designed and synthesized, and the peptide which contained the cytosine moiety at the L-α-amino acid side chain bound RRE IIB RNA with high affinity and high specificity.

RNA–protein interactions play important roles in nature. Many cellular functions, including transcription, RNA splicing and translation, depend on the specific interaction of proteins and RNA. RNA-binding proteins seldom target fully double-stranded tracts for recognition, but interact with secondary structural domains such as hairpin loops, internal loops, and bulges of RNA.[1] In most cases, an RNA-binding domain of a protein forms a suitable conformation such as an α-helix or a β-strand to recognize a structured RNA, and amino acids orientated exactly in the protein structure make specific contacts to the RNA backbone and bases, resulting in high affinity and high specificity in the RNA binding. The study of the design and synthesis of novel molecules that recognize the structure of RNA might lead to drugs targeting RNA.

Peptide nucleic acid (PNA) is a DNA mimic with the nucleobases on a pseudopeptide backbone composed of *N*-(2-aminoethyl)glycine units.[2] A PNA molecule has the ability to efficiently and sequence-specifically bind both single-stranded DNA and RNA as well as double-stranded DNA. However, a simple PNA molecule itself may not recognize highly structured RNA with high specificity, because PNA alone would not have the ability to form the various conformations that proteins or peptides do. We have attempted to design peptides containing nucleobases that combine the advantages of peptides (formation of rigid structure such as α-helices) and nucleobases (specific recognition of a base in RNA). For this purpose, we have utilized an artificial L-α-amino acid, with a nucleobase at the side chain, in peptides for keeping the peptide conformation.

In order to demonstrate the applicability of a nucleobase amino acid (NBA) in peptides, we have chosen the regulatory protein of virion expression (Rev) of human immunodeficiency virus type-1 (HIV-1)[3–6] from among the enormous range of examples of proteins which bind RNA specifically. The Rev protein binds the corresponding response region of HIV-1 mRNA (RRE), and this protein–RNA interaction plays a key role in HIV-1 virus replication. The arginine-rich domain (34–50) of the Rev protein binds specifically the stem-loop IIB region of RRE RNA (Fig. 1) by forming an α-helix conformation.[7] The α-helix potential of the $Rev_{34–50}$ peptide affects the binding affinity and specificity of the peptide to RRE IIB RNA.[7,8] Moreover, it has been proposed that the Gln36 residue in the $Rev_{34–50}$ peptide is placed close to the guanine-48 base in the internal loop region of the RRE IIB RNA by NMR structural analyses.[9]

On the basis of these informations, we designed and synthesized the nucleobase-conjugated peptide, $Q36C_{NBA}$, in which L-α-amino γ-cytosine butanoic acid (cytosine nucleobase amino acid: C_{NBA}) was introduced instead of Gln36 in $Rev_{34–50}$ (Fig. 1), and examined the effect of the introduction of the C_{NBA} unit on the peptide conformation and the RNA-binding affinity. It was expected that the cytosine base in $Q36C_{NBA}$ could interact with the guanine-48 base in RRE IIB RNA and that the interaction may lead to an increase in affinity and specificity of the peptide for the RNA. Furthermore, the chiral C_{NBA} unit possibly gives a rigid conformation in the peptide. For the elucidation of the structural importance of $Q36C_{NBA}$, $Q36C_{PNA}$, in which Gln36 and Ala37 were replaced by Nielsen type cytosine PNA (C_{PNA}),[2] was also designed (Fig. 1). The two amino acids were replaced by C_{PNA}, because a PNA monomer has the length equivalent of two amino acids in the main chain. Q36A and Q36GG were used to evaluate the effect of introduction of the cytosine moiety in $Q36C_{NBA}$ and $Q36C_{PNA}$, respectively (Fig. 1). To increase the stability of the α-helix structure, the N-terminal amino and C-terminal carboxy groups of the peptides were succinylated and amidated, respectively.[7,8] To introduce the C_{NBA} unit in the peptide, (2*S*)-4-(*N*^{4}-benzyloxycarbonylcytosin-1-yl)-2-(fluoren-9-ylmethoxycarbonyl)aminobutanoic acid [Fmoc-C_{NBA}(Z)-OH] was synthesized according to the method in ref. 10 with some modifications. Peptides were synthesized by the solid phase method using an Fmoc-strategy[11] and purified by HPLC with high purity (> 98% on analytical HPLC). The peptides $Q36C_{NBA}$ and $Q36C_{PNA}$ gave a molecular ion peak at *m/z* 2602.3 [$(M + H)^+$] (calc. = 2603.9) and 2588.6 [$(M + H)^+$] (calc. = 2589.9), respectively, by matrix assisted laser desorption ionization time-of-flight mass spectrometry. RRE IIB RNA was prepared by *in vitro* transcription from a synthetic DNA template using T7 RNA polymerase and purified by polyacrylamide gel electrophoresis.[12]

Circular dichroism studies revealed that none of the peptides including $Rev_{34–50}$ had a rigid structure in aqueous buffer (pH

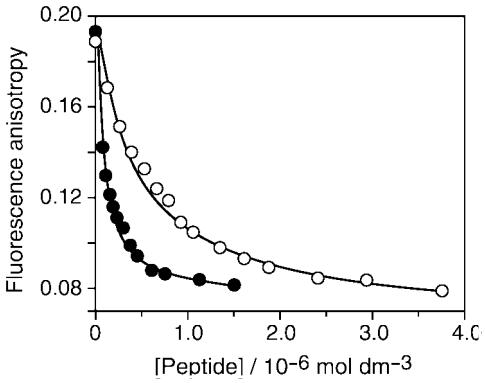

Fig. 2 Fluorescence anisotropy of Rhod-Rev containing RRE IIB RNA as a function of $Q36C_{NBA}$ (●) and $Q36C_{PNA}$ (○) concentration in 1.0×10^{-2} mol dm^{-3} Tris·HCl buffer (pH 7.5) containing 1.0×10^{-1} mol dm^{-3} KCl, 1.0×10^{-3} mol dm^{-3} $MgCl_2$, and 5.0×10^{-4} mol dm^{-3} EDTA at 25 °C. [Rhod-Rev] = 1.0×10^{-8} mol dm^{-3} and [RRE IIB] = 2.5×10^{-8} mol dm^{-3}.

7.5). On the contrary, in TFE, which is known to be an α-helix forming solvent,[13] the peptides showed an α-helix CD pattern. The α-helicity[14] (Table 1) of $Q36C_{NBA}$ was 60%, similar to that of $Rev_{34–50}$ (59%), suggesting that the C_{NBA} unit had a similar potential to the Gln36 residue in the Rev peptide for forming an α-helix structure. However, the α-helicity of $Q36C_{PNA}$ was decreased to 41% despite it being in TFE solution. These results indicate that the α-helix structure is disturbed by the flexible and achiral PNA unit, but not by the rigid and chiral C_{NBA}.

The binding properties of the peptides with RRE IIB RNA were evaluated by competition assay[15] using the Rev peptide modified with 5-carboxytetramethylrhodamine at the N-terminal (Rhod-Rev) as a fluorescence tracer. The dissociation constant (2.1×10^{-9} mol dm^{-3}) of Rhod-Rev with RRE IIB RNA was calculated from the anisotropy increase of the tracer upon the addition of the RNA using an equation with 1:1 stoichiometry.[15] In the mixture of Rhod-Rev (1.0×10^{-8} mol dm^{-3}) and RRE IIB RNA (2.5×10^{-8} mol dm^{-3}), fluorescence anisotropy values were decreased by the addition of the designed peptides as a competitor, affording the free Rhod-Rev (Fig. 2). This competition assay revealed that Rev_{34-50} bound RRE IIB RNA strongly with a dissociation constant (K_d) of 3.4 x 10^{-9} mol dm^{-3} (Table 1). Interestingly, $Q36C_{NBA}$ showed a K_d value of 1.7×10^{-9} mol dm^{-3}. Even though $Q36C_{NBA}$ has almost the same α-helix potential as $Rev_{34–50}$, it could bind RRE IIB RNA 2.0-fold stronger than $Rev_{34–50}$. These results suggest that the cytosine moiety of $Q36C_{NBA}$ contributes to the interaction of the peptide with the RNA by making a contact such as a hydrogen bond to a nucleobase of the RNA. Q36A showed the same affinity for the RNA ($K_d = 3.4 \times 10^{-9}$ mol dm^{-3}) as $Rev_{34–50}$. This result indicates that the higher α-helix content (76% in TFE) of Q36A enables it to maintain the same binding affinity as the $Rev_{34–50}$. On the other hand, the binding affinity of $Q36C_{PNA}$ for the RNA was significantly decreased ($K_d = 10.9 \times 10^{-9}$ mol dm^{-3}) to a level similar to Q36GG ($K_d = 9.9 \times 10^{-9}$ mol dm^{-3}), even if it has the same base in its sequence. These findings suggest that the introduction of the C_{PNA} residue at the Gln36 position does not improve the binding affinity with RNA. Furthermore, the decrease of the binding affinity is also attributed to the lower α-helix potential of $Q36C_{PNA}$ (41% in TFE).

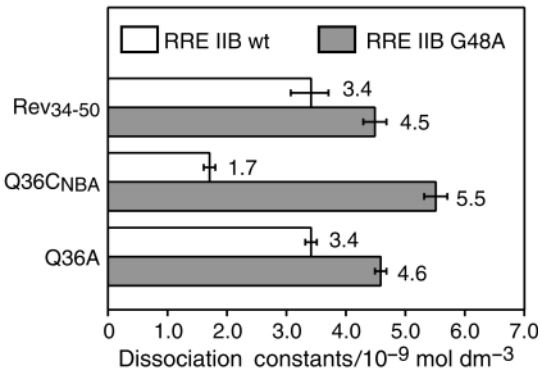

Fig. 3 Comparison of dissociation constants of the peptides with the wild-type and the mutant RNA.

In order to elucidate the selectivity of the designed peptide $Q36C_{NBA}$ for RRE IIB RNA, a mutant RNA (G48A), in which the guanine-48 base of RRE IIB RNA was replaced by adenine, was also prepared. $Rev_{34–50}$ bound G48A RNA with a dissociation constant of 4.5×10^{-9} mol dm^{-3}, comparable to that of the wild-type RRE IIB RNA (1.3-fold decrease) (Fig. 3). Q36A bound the mutant RNA with an affinity similar to $Rev_{34–50}$ ($K_d = 4.6 \times 10^{-9}$ mol dm^{-3}). $Q36C_{NBA}$ bound the mutant RNA with $K_d = 5.5 \times 10^{-9}$ mol dm^{-3}, 3.2-fold weaker than that of the wild-type RNA, that is, the affinity of $Q36C_{NBA}$ to the mutant RNA was lower than that of the $Rev_{34–50}$ and Q36A peptides. It seems that the cytosine base in $Q36C_{NBA}$ may interact with the guanine-48 moiety in RRE IIB RNA, and the interaction enhances the binding specificity to RRE IIB RNA more than Gln36 in $Rev_{34–50}$ does.

In conclusion, the nucleobase-conjugated peptide, $Q36C_{NBA}$, derived from HIV-1 Rev was successfully designed and synthesized. Introduction of the cytosine moiety as an artificial L-α-amino acid to the $Rev_{34–50}$ peptide increased the binding affinity and specificity to RRE IIB RNA, without changing the conformational properties of the peptide. This study should lead to a new strategy applicable to the construction of molecules that recognize a specific structure of an RNA molecule using various nucleobase amino acids.

Enhanced radical delivery from aldoxime esters for EPR and ring closure applications

Andrew J. McCarroll and John C. Walton*

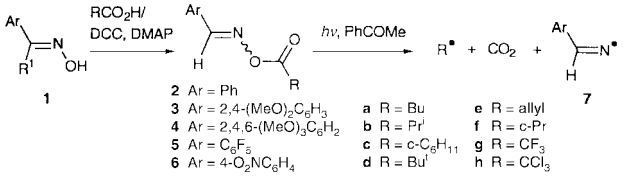
University of St. Andrews, School of Chemistry, St. Andrews, Fife UK KY16 9ST. E-mail: jcw@st-and.ac.uk

Received (in Cambridge, UK) 24th December 1999, Accepted 26th January 2000

Arylmethaniminyl and alkyl radicals were generated from di- and tri-methoxyphenyl aldoxime esters, by photolysis in the presence of 4-methoxyacetophenone, and were detected by EPR spectroscopy: good yields of cyclised products were isolated from suitably unsaturated alkyl substituents.

Molecules suitable for direct photochemical or thermal generation of free radicals, other than peroxides and azo compounds, are quite limited, and therefore potential alternative types are of special interest. Oxime esters **2** are easily made from aldehyde (or ketone) oximes **1** and carboxylic acids (or acyl halides) (Scheme 1) and are much easier to handle and characterise than peroxides or azo compounds. These esters, which contain weak N–O bonds, appear to be a category of precursors for carbon-centred and iminyl radicals (**7**) with promise of considerable generality, but so far exploitation has been minimal. Thus, benzophenone oxime esters [$Ph_2C{=}NOC(O)R$] were shown to function as photolytic sources of alkyl and diphenylmethaniminyl radicals and used in preparations of alkyl aromatics,[1,2] alkyl chlorides,[2] and alkanes.[2] Radical induced homolysis of oxime benzoates by tributylstannane was found to be a useful method for generating iminyl radicals,[3,4] which were also produced, without the need for toxic organotin compounds, by use of Ni powder and acetic acid.[5,6]

Aldoxime esters **2** (Ar = Ph) displayed strong UV absorption bands at 208 and 254 nm. Inclusion of methoxy substituents in the aryl group (**3**, **4**) induced additional strong absorption bands at longer wavelengths (λ_{max} = 273, 312 nm) and this implied that photo-dissociation to radicals might be more efficient. We tested this prospect by monitoring solution phase photolyses of oxime esters containing a range of aromatic and alkyl substituents by means of 9 GHz EPR spectroscopy. No observable spectra were obtained from photolysis (500 W Hg arc, unfiltered) of degassed solutions of oxime esters **2** to **6** in *tert*-butylbenzene solution in the temperature range 200 to 320 K, except for a very weak spectrum of the allyl radical from **2e**. However, on addition of 4-methoxyacetophenone to the solutions as a photosensitiser (≥0.1 equiv.), good quality EPR spectra were obtained, especially from methoxy-substituted oxime esters of types **3** and **4**, but not from types **5** and **6** containing electron-withdrawing substituents. In the sensitised photolyses of **2d**, **3d** and **4d**, for example, the EPR spectra consisted of a superposition of two radicals [see Fig. 1(*a*), (*b*)]. The most prominent signals were due to the *tert*-butyl radical, with EPR parameters identical to those reported in the literature.[7] Two widely spaced groups of nitrogen triplets could also be discerned in the wings of the spectra [from **7** (Ar = Ph): a(H) = 80.5, a(N) = 10.0 G, g = 2.0034 at 250 K]. The exceptionally large a(H) values, as well as the other EPR parameters, are the signatures of rarely observed arylmethaniminyl radicals,[8] *i.e.* **7**. Fig. 1(*b*) shows the well-resolved second-order structure of the individual lines of the *tert*-butyl radical and the partly resolved long range splitting from ring hydrogens in iminyl radical **7** (Ar = Ph). The ratio of the concentrations of the alkyl and iminyl radicals depended on temperature and on the nature of R. For example, from **3e** (R = allyl) very intense spectra mainly of allyl were obtained, particularly for lower power and low modulation amplitude [Fig. 2(*a*), whereas for **4a** (R = Bu) the spectra were dominated by iminyl signals [Fig. 2(*b*)] and in general primary alkyls were difficult to detect. These differences in the concentrations of the two radicals were probably due to minor differences in the rates of their termination reactions. For highly reactive σ-radicals, *e.g.* cyclopropyl, generated from **4f** and trifluoromethyl generated from **4g**, the EPR spectra showed only the 2,4,6-trimethoxy-



Scheme 1

Table 1 Results of irradiation of oxime esters

Oxime ester	Ar[a]	Solvent	MAP/equiv.	Product (%)[b]
8a	Ph	$PhCH_3$	—	**9** (6)
8a	Ph	$PhCH_3$	1	**9** (28)
8b	DMP	$PhCH_3$	—	**9** (39)
8b	DMP	$PhCH_3$	1	**9** (77)
8c	TMP	CCl_4	1	**10** (60)
11c	TMP	$PhCH_3$	1	**12** (34)
13c	TMP	CH_2Cl_2	1	**14** (72)

[a] DMP = 2,4-dimethoxyphenyl, TMP = 2,4,6-trimethoxyphenyl. [b] Yields determined by NMR.

phenylmethaniminyl radical [**7**, Ar = 2,4,5-$(MeO)_3C_6H_2$] except at low temperatures [< *ca.* 220 K], where cyclohexadienyl radicals from addition of cyclopropyl (or CF_3) to the *tert*-butylbenzene solvent were also visible.[9]

The large doublet H-hfs and comparatively few lines of the methaniminyl radicals provide a 'window' of *ca.* 60 G in the centre of the EPR spectrum which minimises overlap with the co-radical. Furthermore, the iminyl spectra act as useful standards with known *g*-factors so that spectral analysis of the co-radical is facilitated. Thus, these oxime esters constitute a convenient new class of radical precursors suitable for spectroscopic studies. Unlike the alternative diacyl peroxides, reagents **2** are innocuous and convenient to handle.

The EPR spectral results indicated that use of di- and trimethoxy oxime esters, in conjunction with a photosensitiser, could enhance their efficiency in preparative reactions. Accordingly, several ring closure reactions of oxime esters **8**, **11** and **13** were investigated. (Scheme 2).

Solutions of individual oxime esters (*ca.* 0.13 mol dm^{-3}) in a hydrogen donor solvent ($PhCH_3$, CH_2Cl_2) were photolysed with light from a 400 W medium pressure Hg lamp for *ca.* 3 h. Table 1 shows that for **8a** yields of the cyclised product, methylenecyclopentane (**9**), were low, but improved on inclusion of photosensitiser. Best yields of **9** were, however, obtained from the dimethoxy oxime ester **8b** when photosensitiser was included. Variation of the photosensitiser concentration showed that as little 0.1 equiv. could be used before serious loss of efficiency was experienced. The bicyclic ether **14** was obtained in good yield from photolysis of the trimethoxy oxime ester **13**, but the yield of 1-isopropyl-3-methylcyclopentane (**12**) from **11** was moderate, possibly because of poor hydrogen donation to the tertiary cyclised radical by the solvent.[10] No uncyclised products from direct reduction of the initial unsaturated alkyl radicals were detected. This is an advantage in that by-products are minimised, but indicates that, as expected, hydrogen donation is slow. An advantage of the method is that halogen-donor solvents can also be used for the preparation of functionalised rings. For example, photolysis of **8c** in CCl_4 afforded a good yield of chloromethylenecyclopentane (**10**). The main products derived from the iminyl radicals were the corresponding aldehydes, probably formed from intermediate imines, ArCH=NH, which are known to be highly susceptible to hydrolysis.

These results demonstrate that di- and tri-methoxy substitution of aryl oxime esters enhances their performance as photolytic sources of carbon-centred and iminyl radicals and that further improvement can be achieved by inclusion of a photosensitiser. These compounds are promising radical precursors of use in spectroscopic studies and as 'cleaner' tin-free reagents for preparative decarboxylative cyclisations of unsaturated carboxylic acids.

We thank the EPSRC (grant GR/L49185) for financial support.

9 EPR experiments with **2g** were also carried out in liquid cyclopropane which enables lower temperatures to be accessed. However, due partly to poor solubility at low temperatures, only weak spectra of **7** (Ar = 2,4,6-$(MeO)_3C_6H_2$ were observed.
10 For example: oxime ester **13c** (0.25 g, 0.69 mmol) and MAP (0.12 g, 0.8 mmol) in CH_2Cl_2 (5 cm^3) were photolysed in a quartz tube for 3 h at 50 °C with light from a 400 W medium pressure Hg lamp. The solvent was evaporated and the solid remaining was extracted several times with Et_2O. Concentration and microdistillation at ambient temperature/0.01 Torr gave bicyclic ether **14** (ref. 11) (0.01 g, 12%) (ref. 12), δ_H(300 MHz, $CDCl_3$) 1.15–1.30 (2H, m), 1.39–1.68 (6H, m), 1.83–2.04 (3H, m), 3.77–3.87 (2H, m), 3.96 (1H, q, *J* 8).

Received (in Liverpool, UK) 28th October 1999, Accepted 24th January 2000

Amphiphilic cationic polyenic push–pull chromophores which offer interesting supramolecular possibilities for second harmonic generation have been synthesised and their optical non-linearities studied for the first time by electric field induced second harmonic (EFISH) generation in solution.

Molecular nonlinear optics (NLO) has attracted increasing interest over the past ten years.[1] NLO materials are highly promising for applications in various fields including telecommunications, optical data storage and processing, optical power limitation *etc*. NLO phenomena also present interesting opportunities for probing and imaging purposes. For instance, second harmonic generation (SHG) has been successfully used for probing asymmetrical systems (such as interfaces)[2] or high resolution imaging of biological cells.[3]

Within this context, we have investigated a strategy based on the design of amphiphilic push–pull chromophores [*i.e.* molecules combining an electron-donating group (D) and an electron-withdrawing group (A) connected by a conjugated system] with enhanced quadratic molecular response (*i.e.* hyperpolarizability β) and prone to interact in an asymmetrical way with a lipid membrane. Such characteristics provide an interesting way to induce the asymmetry required for quadratic NLO phenomena both at the molecular and macroscopic levels, by taking advantage of specific interactions with hydrophilic–hydrophobic interfaces. Hereafter, we present the design and synthesis of amphiphilic cationic polyenic chromophores showing large nonlinearities. Their quadratic nonlinearities have been studied for the first time by electric field induced second harmonic (EFISH) generation in solution, a technique usually precluded for ionic species.

Stilbazolium dyes have been the topic of many studies in the field of NLO. They have led to highly SHG efficient crystals.[4] In addition, they are interesting candidates for designing NLO micro- and nanostructures. For examples, derivatives bearing an elongated alkyl chain have been deposited into Langmuir–Blodgett films showing SHG activity[5] and amphiphilic derivatives have been shown to be of interest for the design of optical probes for membrane potentials.[6] Our choice has been to investigate amphiphilic vinylogous derivatives of stilbazolium dyes (Fig. 1). The presence of two butyl hydrophobic tails grafted on the donor end group and of the positively-charged hydrophilic acceptor moiety confers an amphiphilic character to these push–pull chromophores and should facilitate their interaction with a lipidic membrane while avoiding deleterious detergent effects. Increasing the polyenic chain length is expected to lead to a marked increase of β as already known for other push–pull polyenic systems.[7–9] Similarly, by substituting the pyridinium acceptor end group by a quinolinium end group, larger nonlinearities are expected.

Stilbazolium dyes and analogous chromophores are usually prepared using Konevenagel condensation (Scheme 1).[6] However, this simple strategy proved ineffective in the case of polyenic analogues ($n > 1$) bearing long alkyl chains. It leads to both poor yields and purification problems due to the side formation of shorter homologues. To ensure satisfactory preparation yields, we have implemented an alternative synthetic scheme based on the Wittig–Horner condensation of a pyridine moiety[10] on a polyenal bearing the donating end group (Scheme 1). This allows for the preparation in medium to good yield of compounds of series **4** from polyenals of series **1** using solid–liquid phase transfer conditions. Polyenals of series **1** can be obtained in high yields from the generic molecule **1**[0] using a sequential vinylic homologation.[9] Molecules of series **4** were obtained as pure all-*E* isomers (as shown by NMR spectra and elemental analyses) after catalytic isomerisation and column chromatography ($n = 1$, 2) or recrystallisation ($n > 2$). Alkylation of molecules of series **4** in neat MeI readily afforded pure amphiphilic push–pull polyenic chromophores of series **2**.

The electric field induced second harmonic (EFISH) generation technique[11] is a useful method to derive the quadratic nonlinearity (and more precisely the projection of the dipolar part of the β tensor on the dipole moment μ) of dipolar chromophores. It is in principle precluded in the case of ionic species. Yet, we have been able to implement the EFISH technique for the determination of the $\mu\beta$ values of ionic amphiphilic chromophores **2** and **3** by operating in a solvent of low polarity thanks to the formation of close ion pairs. The EFISH experiments were carried out in chloroform ($\varepsilon_r = 4.7$) and at 1.907 μm in order to avoid absorption of the second harmonic. The $\mu\beta$ values and the wavelength of the maximum absorption (λ_{max}) are collected in Table 1. The static $\mu\beta(0)$ values extrapolated at zero frequency by using the two-level dispersion model for β[11] (valid in the case of 1-D intramolecular charge transfer only) are also included.

As clearly observed from Table 1, amphiphilic salts of series **2**[*n*] and **3**[1] show large $\mu\beta$ values. Lengthening the polyenic chain induces both a bathrochromic shift and a significant increase of the quadratic nonlinearity, although the effect seems to slow down for the longest derivatives. This leads to a $\mu\beta(0)$

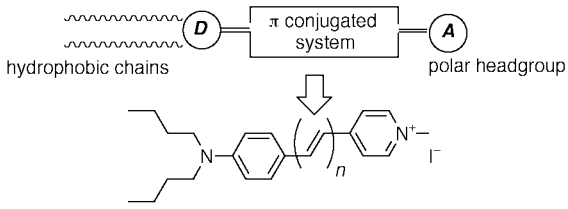

Fig. 1 Molecular engineering of amphiphilic push–pull chromophores.

Table 1 Linear and nonlinear optical properties of amphiphilic push–pull chromophores **2**[1–5] and **3**[1] in chloroform; $\mu\beta$ values were derived from EFISH measurements at 1.907 μm

Compound	$\mu\beta(2\omega)^a/10^{-48}$ esu	λ_{max}/nm	$\mu\beta(0)/10^{-48}$ esu
2[1]	840	517	550
2[2]	2230	558	1340
2[3]	2700	581	1540
2[4]	3380	589	1890
2[5]	3690	598	2020
3[1]	1380	603	745

[a] The β values are defined using the X convention (ref. 15).

value as high as 2000×10^{-48} esu for the **2**[5] ion pair, which is more than four times larger than the corresponding experimental value (450×10^{-48} esu) determined in similar conditions for the benchmark *dipolar* chromophore Disperse Red 1. Compound **3**[1], which bears the stronger heterocyclic acceptor, shows a $\mu\beta(0)$ value about 50% larger than that of compound **2**[1], but at the expense of a much reduced transparency. Compound **2**[3] exhibits a $\mu\beta(0)$ value twice as large as that for compound **3**[1] for a similar molecular weight while remaining significantly blue-shifted. Elongation of the polyenic chain of derivatives of series **2** is thus preferable—in terms of nonlinearity–transparency trade-off—to turning to a stronger acceptor moiety.

Finally, cationic polyenic push–pull chromophores have been synthesised and their optical non-linearities studied for the first time by electric field induced second harmonic generation in solution, owing to the formation of ion pairs in a solvent of low relative permittivity. Their quadratic nonlinearities can be enhanced by increasing the polyenic chain length and/or adjusting the charged heterocyclic acceptor. Recent second harmonic generation and two-photon excited fluorescence experiments reported in ref. 12 provide evidence that chromophores of type **2** are incorporated in the outer leaflet of model bilayer lipid membranes and orientated perpendicular to the membrane surface. These amphiphilic chromophores hold promise as sensitive probes for SHG imaging of membrane potentials.[3,13] In addition, incorporation of the chromophores in the lipid bilayer is expected to significantly influence the molecular nonlinear responses, as shown recently for the inclusion of a stilbazolium dye in a supramolecular complex.[14]

The Délégation Générale pour l'Armement (DGA) is acknowledged for a fellowship to V.A. We thank Idrissa Njabira for his participation in EFISH measurements.

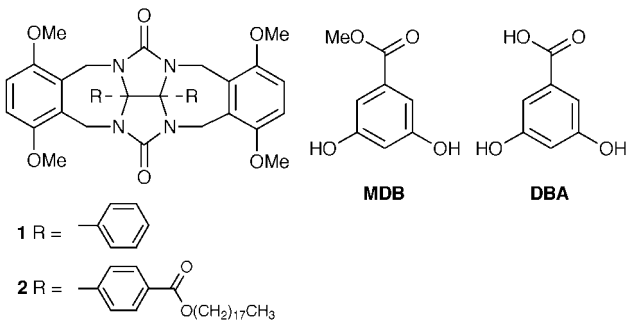
Received (in Liverpool, UK) 23rd November 1999, Accepted 19th January 2000

Molecular clip receptors with long hydrocarbon tails self-assemble and form lamellar thin solid films, the architecture and properties of which can be fine-tuned by complexation of guest molecules

The generation of ordered thin films of organic materials is of fundamental importance to future molecular electronic applications.[1] A variety of methods have been utilized in the formation of these films, generally the sequential build-up of multilayers through procedures such as Langmuir–Blodgett film deposition,[2] the Sagiv method of thin film self-assembly,[3] alkanethiol binding to gold surfaces,[4] anionic–cationic polyelectrolyte alternation[5] and thermal evaporation *in vacuo*.[6] However the ideal route to the self-assembly of thin organic films would involve a system that spontaneously self-orders upon either being cast from solution or cooled from the melt—essentially a one-step process involving the minimum of experimental input. To date the only systems approaching this ideal are microphase separated block copolymers[7] and liquid-crystalline materials.[8]

Over the past years our group has studied a class of host compounds commonly referred to as 'molecular clips'.[9] These molecules of type **1** possess a rigid, U-shaped cavity in which



dihydroxybenzene guests can selectively be bound through hydrogen bonding, π–π stacking and cavity filling effects.[10] Recently it has been demonstrated that molecular clips also exhibit self-recognition and ultimately self-assembly properties: they can form dimers in organic solvents as well as in the solid state, in which the cavity of one molecule is filled by one of the side-walls of its dimeric partner and *vice versa*.[11] In aqueous solution clips with water-soluble functions can assemble to form well-defined nano-arrays.[12]

Here we describe a clip (**2**) which is derivatised at its convex side with two long aliphatic tails. This molecule was designed to generate liquid crystalline phases: upon dimerisation, it can adopt a structure analogous to that of a typical 'rod-like' mesogen [Fig. 1(*a*)]. It turned out, however, that it formed solid films, the structure of which can be tuned by adding guest molecules.

Clip **2** was prepared according to standard procedures.[13] The compound melted at 195.4 °C, and upon recrystallisation from the melt it displayed a birefringent platelet texture under the polarising optical microscope (PM), similar to that shown by classic smectic mesogens.[8] In addition, the material turned out to be highly malleable upon the application of pressure to the covering slide, again similar to that expected for a liquid crystalline substance. Below 84 °C, the texture was retained but the material was now completely solid. The enthalpy (ΔH = 21.3 kJ mol^{-1}) involved with the final isotropisation transition upon heating the sample, as measured by differential scanning calorimetry (DSC), was, however, far larger than would have been expected for a typical mesophase to isotropic liquid transition. X-Ray powder diffraction (XRPD) analysis suggested that the material was actually crystalline at all temperatures below 195.4 °C.† It showed a set of equally spaced peaks in the low-angle region of the diffraction pattern, corresponding to 1st, 2nd, 3rd *etc*. order reflections, indicating a layered structure. We attribute the origin of this lamellar structure to the dimerisation of the molecular clips *via* cavity filling in conjunction with π–π stacking interactions occurring between adjacent clip dimers, giving rise to 'bilayers' of molecular clips separated by aliphatic tails which display varying degrees of interdigitation depending on the temperature (Fig. 2). Evidence for this comes from the observed *d*-spacing of 28.4 Å at 20 °C, calculated from the low-angle reflections, which increases to 42 Å at 175 °C. These values correspond to the length of a tilted bilayer of dimerised clip molecules.‡ The solid state ^{13}C CPMAS NMR spectrum of **2** confirmed the decreased interdigitation of the aliphatic tails at higher temperatures, which followed from the downfield shifts of the resonances of the $CH_2CH_2CH_3$ termini of the hydrocarbon tails. In addition, the resonances of the main chain CH_2 protons significantly sharpened, indicative of increased mobility. A more detailed NMR study will be published elsewhere.[13]

We believe that strong π–π interactions between the dimeric units prevent the material from being truly liquid crystalline, and attribute its malleability at higher temperatures to a lessening of the interdigitation and an increased mobility of the aliphatic tails, so that the layers of clips can more readily slide over one another.

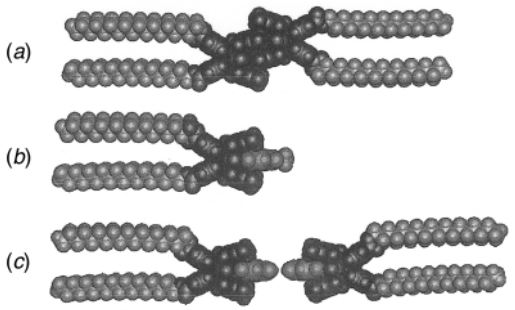


Fig. 1 Computer generated models of (*a*) a dimer of **2**, based on the X-ray structure of an analogue containing methyl instead of octadecyl ester groups, (*b*) the 1:1 complex of **2** and **MDB**, and (*c*) the 1:1 complex of **2** and **DBA**.

DOI: 10.1039/a909309e

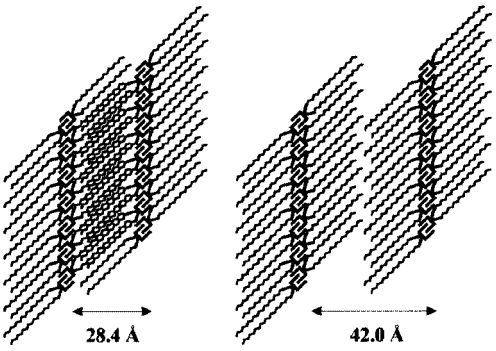

Fig. 2 Schematic representation of the proposed lamellar ordering of the molecules of **2** at 20 °C (left) and at 175 °C (right).

If, as postulated, the lamellar nature of **2** is a result of dimerisation *via* cavity filling, then addition of a guest molecule that can strongly bind in the cavity, such as methyl dihydroxybenzoate (**MDB**) [Fig. 1(*b*)], should result in the disruption of the bilayer structure and thus in the lamellar arrangement of the molecules.§ The 1 : 1 **2**:**MDB** complex was prepared by co-evaporation of an equimolar mixture of solutions of the two components in MeOH–$CHCl_3$ (1 : 4, v/v), followed by heating the mixture and recrystallisation of the complex from the isotropic melt. The complex recrystallised at 53 °C, displaying a white microcrystalline texture by polarised optical microscopy, typical of a crystalline organic material. Repeated heating and cooling runs were identical, and DSC analysis indicated the presence of only the 1:1 complex and no free clip or guest components.¶ The material showed no malleability under applied pressure, and XRPD revealed a unique diffraction pattern with no observable reflections corresponding to lamellar ordering.

Since complexation of **2** with **MDB** disrupts the lamellar arrangement of the molecules in the material, it was reasoned that complexation of **2** with 3,5-dihydroxybenzoic acid (**DBA**) might have the effect of 'stitching' together the bilayers of the clips, because the carboxylic acid groups of two guests can form a dimer without interfering with the bonding of the 3,5-dihydroxyaromatic parts to the clips. This then would result in the reimposition of the lamellar ordering. The 1 : 1 **2**:**DBA** complex was prepared in an identical manner to the 1 : 1 **2**:**MDB** complex. Upon cooling from the isotropic melt, the complex crystallised, displaying a clear 2D spherulitic morphology at 137 °C, indicative of a lamellar crystalline packing. As with free **2**, the complex proved to be malleable under applied pressure. XRPD measurements showed a set of equally spaced reflections yielding an interlayer spacing of 57.8 Å. This value is in line with an 'extended dimer' structure of the building blocks achieved through two independent molecular recognition processes, *viz.* host–guest binding and guest dimerisation [Fig. 1(*c*)]. Further evidence for this comes from infrared analysis, which confirmed that the C = O stretching vibration at 1690 cm^{-1}, due to benzoic acid dimerisation, was present in the material.

The ability of **2** to form highly ordered lamellar structures from the melt and the possibility to fine-tune this structure by adding guest molecules opens the way to design new functional materials that are easily melt-processed. Current research is focussed on the incorporation of functional guests, such as porphyrins and metal-coordination complexes, into these lamellar films.

Notes and references

† Compounds in the smectic mesophase in principle can still display Bragg lines in their XRPD patterns.

‡ When the clip dimers are tilted at an angle of *ca*. 40°, the width of the bilayer is *ca*. 42 Å. Strong evidence for such a tilting comes from the crystal structure of the methyl ester analogue of **2**, in which the clip dimers are packed with a similar tilt of 40° as a result of interdimer π–π stacking.

§ Binding of **MDB** by **2** in $CDCl_3$ solution was found to be several orders of magnitude stronger ($K_a > 10^4\ M^{-1}$) than dimerisation of **2** ($K_{dimer} = 18\ M^{-1}$).

¶ Complexation of the guest in the cavity of **2** was also supported by shifts in the C=O stretching vibration of the glycoluril urea functions of **2** and in the OH stretching vibration of **MDB** in the solid-state FTIR spectra.

Significant room temperature oxygen storage over 0.58% $Pt/Ce_{0.68}Zr_{0.32}O_2$ when H_2 is used as a reducing agent

N. Hickey,[a] P. Fornasiero,[a] J. Kašpar,*[a] M. Graziani,[a] G. Blanco[b] and S. Bernal[b]

Received (in Oxford, UK) 13th December 1999, Accepted 27th January 2000

The investigation of the oxygen storage/release capacity (OSC) of 0.58 wt% $Pt/Ce_{0.68}Zr_{0.32}O_2$ catalyst by oscillating the feed-stream between reducing and oxidising conditions showed that a high OSC could be measured at room temperature, even for redox-aged sample, by using H_2 as the reducing agent.

The so-called oxygen storage/release capacity (OSC) of a three-way catalyst (TWC) is the ability to attenuate the negative effects of rich/lean oscillations of exhaust gas composition. By maintaining a stoichiometric composition at the catalyst, the highest conversion efficiency of the exhaust is attained. OSC, which in the modern TWCs is achieved by adding a CeO_2–ZrO_2 mixed oxide component, is usually discussed in terms of the ability to regulate the oxygen partial pressure in the exhaust through the Ce^{3+}/Ce^{4+} redox couple [eqn. (1)]:

$$CeO_2 \underset{H_2O-CO_2}{\overset{H_2-CO}{\rightleftharpoons}} CeO_{2-x} + x/2O_2 \quad (1)$$

Formation of vacancies is therefore either implied or assumed. Following the pioneering work of Yao and Yu-Yao,[1] dynamic-OSC measurement involves alternately pulsing the chosen reducing agent (usually CO but sometimes H_2) and O_2 over the material under investigation. More recently the oxygen buffering capacity (OBC) technique has been developed by Bernal *et. al.*[2] In this method O_2 is pulsed over the sample in a flow of inert gas, which effectively corresponds to oscillations between mildly reducing and oxidising conditions.

Here, we demonstrate that it is possible, using H_2 as reducing agent, to measure significant dynamic-OSC over $Pt/Ce_{0.68}Zr_{0.32}O_2$ under conditions where vacancy creation is unlikely (room temperature, r.t.). Such high r.t. OSC is not observed when either CO is used as reductant or when the OBC method is employed. The evidence suggests that this dynamic-OSC may be associated with the phenomenon of spillover. This opens the possibility that spilled-over H_2 can be a contributing factor to OSC measurements even at higher temperatures. The presence of H_2 in exhaust effluent in a ratio of *ca.* 1:3 with respect to CO[3] makes this finding a potentially important piece of information.

0.58 wt% $Pt/Ce_{0.68}Zr_{0.32}O_2$ and 0.53 wt% Pt/CeO_2 were prepared and supplied by RHODIA as part of the CEZIR-ENCAT network.[4] 0.5 wt% Pt/γ-Al_2O_3 (γ-Al_2O_3: Alfa products) was prepared using $Pt(NH_3)_2(NO_2)_2$ as precursor. An *in situ* oxidising cleaning procedure[5] (heating in flow of O_2 at 823 K for 1 h) was applied before all experiments, giving a sample designated as fresh. Redox-aged sample was prepared as follows: reduction up to 1273 K in 5 % H_2 in Ar (25 ml min^{-1}), holding at 1273 for 15 min, flushing in Ar at 1273 K; slow cooling to 700 K; re-oxidation at 700 K and cooling to 423 K in 5% O_2 in Ar; and, finally, cooling to r.t. in Ar (60 ml min^{-1}). Quantitative dynamic-OSC measurements were performed by increasing the temperature in a stepwise manner and, during the isothermal steps (60 min), alternately pulsing every 70 s H_2 (500 or 100 μl, H_2-OSC) or CO (100 μl, CO-OSC) and O_2 (250 or 100 μl) over the sample (20 mg, maintained in a flow of Ar of 25 ml min^{-1}). OSC was measured using a thermal conductivity detector as the uptake of O_2 from the O_2 pulse. Steady-state values are reported. When CO was used as the reducing agent, the evolved CO and CO_2 were separated on a Porapak Q column. TPR-MS profiles were obtained up to 1273 K as above reported for redox-ageing. OBC measurements were carried out as reported previously.[2] Hydrogen chemisorption measurements were conducted at 298 and 195 K.[6]

The redox behaviour was first investigated by means of the TPR-MS technique. The TPR profiles (not reported) of fresh and redox-aged $Pt/Ce_{0.68}Zr_{0.32}O_2$ showed single reduction features centred around 500 and 400 K, respectively. This behaviour is fairly consistent with a recent report[6] and is attributed to an initial reduction of supported PtO, which in turn results in support reduction through spillover of hydrogen species. The degree of reduction, *i.e.* the overall transferable oxygen, was measured by O_2 uptake at 700 K after the TPR experiment as previously reported.[6] An O_2 uptake of 20 ml g^{-1} was obtained for both fresh and redox-aged samples.

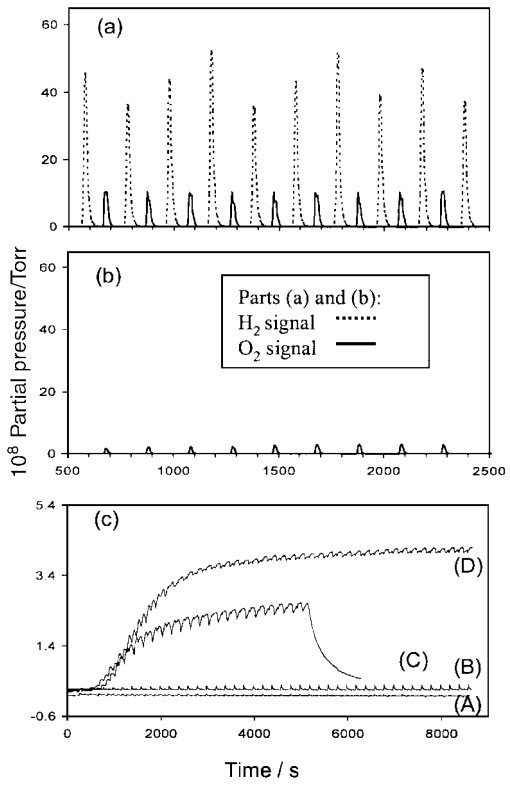

Fig. 1 H_2-OSC measured at r.t. H_2 (*m/z* = 2) and O_2 (*m/e* = 32) profiles over fresh/reduced at 500 K Pt/Al_2O_3 (for clarity this trace is displaced) (a) and $Pt/Ce_{0.68}Zr_{0.32}O_2$ (b), and water production (*m/e* = 18) (c) over: (A) fresh/reduced 500 K Pt/Al_2O_3, (B) fresh $Pt/Ce_{0.68}Zr_{0.32}O_2$; (C) redox-aged $Pt/Ce_{0.68}Zr_{0.32}O_2$, reaction stopped at 5000 s; (D) fresh/reduced 500 K $Pt/Ce_{0.68}Zr_{0.32}O_2$. MS was tuned to enhance the sensitivity to H_2 compared to O_2. 200 mg of sample and loop volumes of 1 ml were employed.

[a] Quantitative analysis using TCD, standard deviation ± 0.4 ml O_2 g^{-1}. Steady state values measured as O_2 uptake (ml g^{-1}). For CO / O_2 experiments, an OSC of 2.6 ml O_2 g^{-1} corresponds to a maximum O_2 uptake using the experimental setup described in the text. [b] OBC (%): [100 $(A_{NA} - A_A)/A_{NA}$]; A_{NA}: area under non-attenuated pulse; A_A: area under the attenuated pulse. Pulse volume 0.25 ml of 5% O_2 in He. [c] Sample reduced at 500 K for 1 h, followed by evacuation at 673 K for 4 h. A range of H_2 pressure of 2 –20 Torr was employed. Adsorbed volumes were determined by extrapolation to zero pressure of the linear part of the adsorption isotherm (0 Torr). Cumulative H_2 adsorption at p = 20 torr is also given. [d] Using loop volumes of 100 μl for H_2 and O_2 a full O_2 uptake, *i.e.* 2.6 ml O_2 g^{-1}, was observed in all experiments.

Fig. 1 compares the H_2-OSC behaviour at r.t. of $Pt/Ce_{0.68}Zr_{0.32}O_2$ and Pt/Al_2O_3. Table 1 summarises quantitative OSC measurements and also some characterisation data. Fresh/reduced Pt/Al_2O_3 does not exhibit appreciable H_2-OSC at r.t. In contrast, a very high consumption of both H_2 and O_2 is observed over fresh/reduced $Pt/Ce_{0.68}Zr_{0.32}O_2$, indicating the crucial role of the $Ce_{0.68}Zr_{0.32}O_2$ in providing sites for the storage process. Water evolution is also observed in the latter case [Fig. 1(c), trace D], ruling out any kind of chromatographic effect. Negligible water production is observed over the fresh $Pt/Ce_{0.68}Zr_{0.32}O_2$, [Fig. 1(c), trace B], indicating that reduced Pt is necessary to promote hydrogen activation. In an attempt to establish the origin of this high r.t. H_2-OSC, H_2 chemisorption measurements were carried out on the $Pt/Ce_{0.68}Zr_{0.32}O_2$ at 193 and 298 K. Spilling of H_2 at 193 K is negligible allowing determination of H/Pt ratios.[7] 0.31 ml H_2 g^{-1} are adsorbed at 193 K which correspond to a dispersion of 94% upon assumption of H : Pt = 1 : 1 stoichiometry. The low H_2 uptake indicates that titration of hydrogen/oxygen adsorbed on the metal cannot be responsible for the observed H_2-OSC. Conversely, the amount of H_2 adsorbed/spilled over the support at 298 K is of the same order of magnitude of the values of H_2-OSC, suggesting a relevant role of the spillover phenomena in the oxygen storage. A higher relative pressure of H_2 during the H_2 pulse and presence of H_2O could account for the high values of O_2 uptake compared to the spilt H_2 detected in the chemisorption measurement. In fact, H_2 and O_2 consumption close to stoichoimetry is measured in the H_2-OSC experiment. Redox-ageing decreases both the surface area and the amount of adsorbed H_2 at 298 K by a factor of three. The H_2-OSC decreases by a factor of two. The important role of hydrogen spillover in giving high H_2-OSC at r.t. is supported by the data reported for Pt/Al_2O_3 and Pt/CeO_2. In particular, very small r.t. H_2-OSC is observed for the latter catalyst after redox-ageing, when spillover is negligible.

The comparison with CO as reducing agent and the OBC measurements is striking. Irrespectively of the pre-treatment, fresh/reduced or recycled, significant CO-OSC is observed only at and above 473 K, while OBC starts being significant at 673 K. In both these experiments, the reduction process may be envisaged as a measure of the oxygen diffusion towards the surface where it is removed either by interaction with CO or simple desorption, provided that surface processes are not rate limiting.[8] The very high H_2-OSC clearly points to a crucial role of H_2 in affecting the redox properties of these systems at low temperatures.

In conclusion, there is a dramatic dependence of the results obtained on the nature of the reducing environment with significantly high dynamic-OSC particularly apparent at low temperatures using H_2. At r.t. spillover phenomena seem to be a dominant factor. The implications of these findings need to be carefully considered when the results of such measurements are extended to the extremely complicated conditions encountered in three-way catalysis.

The present work has received financial support from the TMR Program of the European Commission (Contract FMRX-CT-96-0060). Financial support from University of Trieste, the Ministero dell'Ambiente (Roma), contract n. DG 164/SCOC/97, Regione Friuli Venezia-Giulia, 'Fondo regionale per la ricerca', the CICYT (Contract No.: MAT96-0931) and the Junta de Andalucía are also acknowledged.

Encapsulation of two aromatics by a carcerand-like capsule of nanometre-scale dimensions†

Leonard R. MacGillivray,* Peter R. Diamente, Jennifer L. Reid and John A. Ripmeester

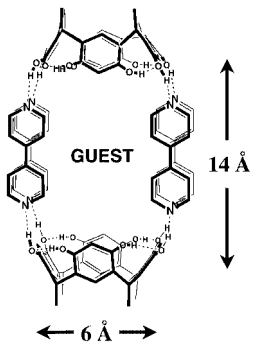
Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6. E-mail: lmacgil@ned1.sims.nrc.ca

Received (in Columbia, MO, USA) 10th November 1999, Accepted 7th January 2000

Co-crystallization of *C*-methylcalix[4]resorcinarene 1 with 4,4′-bipyridine 2 in the presence of nitrobenzene 3 yields a six-component carcerand-like capsule, 2(1)·4(2), held together by 16 hydrogen bonds, in which two molecules of 3 are aligned within the interior of the complex in a head-to-head fashion.

Using a modular approach to molecular self-assembly, it has been shown that co-crystallization of *C*-methylcalix[4]resorcinarene **1** with 4,4′-bipyridine **2** typically yields a one-dimensional (1D) host–guest wave-like polymer, **1**·2(**2**), in which the cavity of **1** is deepened supramolecularly, interacting with two stacking pyridine units of **2** by way of four O–H···N hydrogen bonds.[1] The cavity created by the five molecules, which may be induced to form by way of guest template effects,[2] is remarkably flexible, being able to accommodate either single[3] or multiple guests,[4] many of which are too large to fit within the parent receptor **1**,[2] by way of a conformational change of the network.

During experiments aimed at attempts to isolate multiple guests within **1**·2(**2**), we have discovered the ability of the components of the wave-like framework to undergo a structural reorganization to form a discrete, six-component carcerand-like capsule,[5] 2(**1**)·4(**2**), held together by 16 hydrogen bonds (Fig. 1). The capsule, which is a supramolecular isomer[6] of the parent 1D material **1**·2(**2**), assembles in the solid state such that the cavity of the host, which is of nanometre-scale dimensions,[7] encapsulates two identical aromatic guests aligned within the complex in a head-to-head fashion. Whereas **1** has been shown to form multi-component capsules based upon protic solvent molecules (*e.g.* H_2O, PrOH, EtOH),[8–10] 2(**1**)·4(**2**) represents, to the best of our knowledge, the first example of a hydrogen-bonded capsule, based upon **1**, formed using an aromatic spacer as a 'bridging unit'. Our observations also confirm the ability of nano-sized capsules to accommodate more than one guest,[7] where understanding the spatial relationships displayed by the guests of such multi-guest host systems is of much current interest.[11]



2(**1**)·4(**2**)

Fig. 1 Structure of 2(**1**)·4(**2**).

† Published as NRCC No. 43828.

Addition of **1** (0.021 g) to a boiling aliquot of THF (0.5 ml) and EtOH (1.0 ml) in the presence of **2** (0.012 g) and nitrobenzene **3** (3.0 ml) yielded, upon slow cooling, dark yellow crystals of **1**·2(**2**)·2(**3**) suitable for X-ray analysis. The formulation of **1**·2(**2**)·2(**3**) was confirmed by ^{1}H NMR spectroscopy and single-crystal X-ray diffraction.‡

An ORTEP perspective of 2(**1**)·4(**2**), along with a space-filling view, is shown in Fig. 2. As in the case of the wave-like framework **1**·2(**2**),[1–4] the components of 2(**1**)·4(**2**) have assembled in the solid state such that four pyridine units of **2**, in the form of two stacked dimers, interact with two opposite resorcinol units of **1** by way of four O–H···N hydrogen bonds [O···N separations (Å): O(1)···N(1) 2.75(1), O(2)···N(3) 2.71(1), O(5)···N(2) 2.74(1), O(6)···N(4) 2.68(1)]. The remaining hydroxy groups of **1** form four O–H···O hydrogen bonds [O···O separations (Å): O(3)···O(2) 2.76(1), O(4)···O(5) 2.79(1), O(7)···O(6) 2.79(1), O(8)···O(1) 2.71(1)] along the wider rim of **1** such that the macrocycle, as in **1**·2(**2**), adopts a bowl-like conformation with approximate C_{2v} symmetry. Unlike **1**·2(**2**), however, the four bipyridines of 2(**1**)·4(**2**), which act as bifunctional hydrogen bond acceptors, serve to bridge two, rather than three, molecules of **1**. This, in turn, gives rise to a discrete, six-component assembly held together by eight intermolecular O–H···N and eight intramolecular O–H···O hydrogen bonds, for a total of 16 structure-directing O–H···X (X = N, O) forces. In this arrangement, the cavities of **1**, which sit around a crystallographic center of inversion, are aligned in a head-to-head fashion such that the wider rims of the macrocycles, along with **2**, define a cylindrical cavity, of idealized D_{2h} symmetry, with dimensions ~6.0 × 14.2 Å. Indeed, the structure of 2(**1**)·4(**2**) is reminiscent of a carcerand[5] in which the eight covalent bonds that typically connect four spacer units to two molecules of **1** have been replaced by eight O–H···N forces.

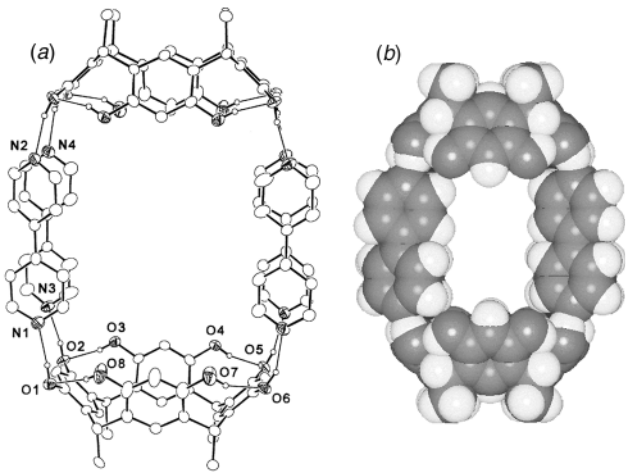


Fig. 2 (*a*) ORTEP perspective of the six-component capsule 2(**1**)·4(**2**), and (*b*) space-filling view. Selected interatomic distances (Å): O(1)···N(1) 2.75(1), O(2)···N(3) 2.71(1), O(5)···N(2) 2.74(1), O(6)···N(4) 2.68(1), O(3)···O(2) 2.76(1), O(4)···O(5) 2.79(1), O(7)···O(6) 2.79(1), O(8)···O(1) 2.71(1).

DOI: 10.1039/a909339g

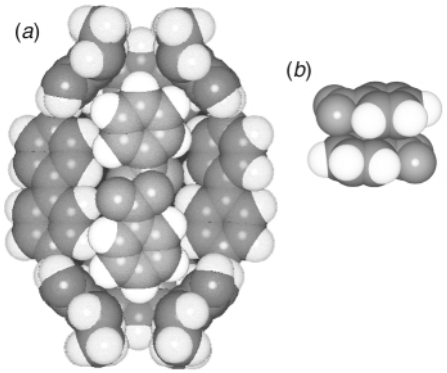

Fig. 3 Space-filling views of the guests of **1**·2(**2**)·2(**3**): (*a*) cut-away view of 2(**1**)·4(**2**)·2(**3**) displaying the two encapsulated aromatics (one occupied site is shown for clarity), and (*b*) the anti-parallel arrangement adopted by the guests exterior to 2(**1**)·4(**2**)·2(**3**).

A cut-away space-filling view depicting the guests of 2(**1**)·4(**2**) is shown in Fig. 3(*a*). Two molecules of **3**, which are disordered across two independent sites (75 : 25 occupancy), have assembled within the six-component complex in a head-to-head fashion such that the aromatic rings of the guests are directed into separate ends of the capsule,[7,11] each interacting with the interior of **1** by way of C–H···π interactions.[15] In these orientations, the phenyl groups of the guests of the major and minor occupied positions, in a way similar to **1**·2(**2**)·*p*-chlorotoluene,[2] lie approximately 20 and 27° off-axis to the principal rotation axis of the host and are rotated, in contrast to **1**·2(**2**)·*p*-chlorotoluene,[2] by approximately 78 and 21° along the symmetry axis of **1**, respectively.§ The nitro groups of the two encapsulated molecules are then observed to fill the center of the capsule, being separated by a distance of 3.6 Å. Interestingly, the organization displayed by the two molecules of **3** within 2(**1**)·4(**2**), in which two highly electron withdrawing substituents are oriented in close proximity,[11] contrasts that of pure **3** which self-assembles in the solid state, by way of C–H···O forces, to form antiparallel dimers.[16] Moreover, such observations confirm the ability of nano-sized capsules to encapsulate multiple guests where the cavities of such systems have been shown to impose spatial arrangements of guests not typically encountered in the free molecules.[7,11]¶

The capsule 2(**1**)·4(**2**) assembles in the solid state, in a tail-to-tail manner, to form 1D columnar arrays, which lie off-set and form a 2D layered architecture, in which two molecules of **3** are sandwiched between adjacent host–guest complexes. As shown in Fig. 3(*b*), in contrast to the two encapsulated guests, the aromatics located exterior to the host–guest complex assemble by way of face-to-face π–π interactions such that they form, in a way similar to pure **3**, antiparallel dimers (plane-to-plane separation: 3.35 Å).[16] Thus, **1**·2(**2**)·2(**3**) is an inclusion compound that possesses two different cavities, both of which accommodate two copies of the same guest in which the guests assemble in specific ways to meet the electronic and steric demands of each cavity.

In this report, we have revealed the ability of **1** to assemble with **2**, in the presence of a suitable guest, to form a six-component carcerand-like capsule, that is a supramolecular isomer of an extended 1D framework, held together by 16 hydrogen bonds.‖ The capsule, which is of nano-metre scale dimensions, features a cavity that hosts two identical aromatics as guests. With such observations realized, we are now investigating whether this system may be used to encapsulate additional guests where it may be possible to isolate two different molecules within the cavity of the assembly.[11] We are also investigating whether it is possible to lengthen 2(**1**)·4(**2**)[3] such that further analogies, in terms of structure and function, between discrete[8] and infinite[1–4] host–guest frameworks based upon **1** may be realized.

We are grateful for funding from the Natural Sciences and Engineering Research Council of Canada (graduate scholarship, J. L. R.; research grant, J. A. R.).

Enhancement in helicity of an oligopeptide by its organization onto a dendrimer template

Nobuyuki Higashi,* Tomoyuki Koga, Norio Niwa and Masazo Niwa*

Received (in Cambridge, UK) 6th December 1999, Accepted 27th January 2000

An oligopeptide comprised of γ-benzyl-L-glutamic acid has been successfully assembled on an amido amine dendrimer surface by graft polymerization and the resultant dendrimer has shown drastic enhancement in helicity of the peptide segment.

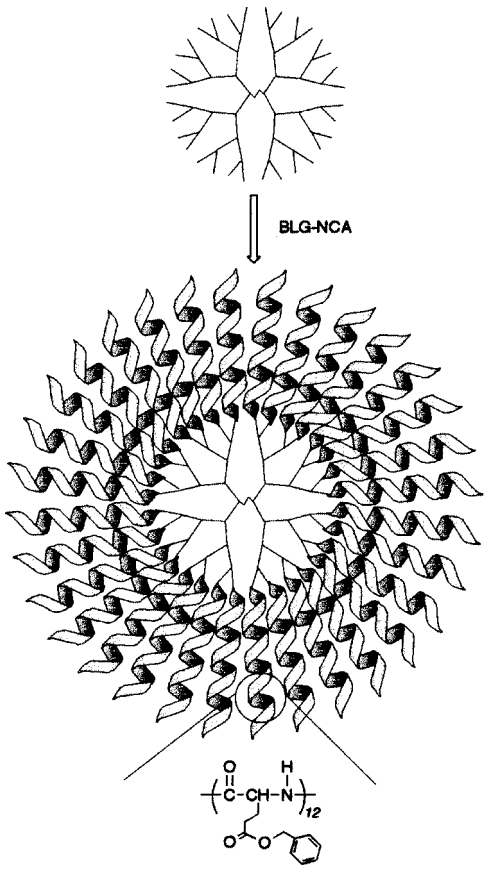
Here we describe the assembly of an oligopeptide onto the surface of an amine-terminated, poly(amido amine) (PAMAM) dendrimer and the enhancement in helicity of the oligopeptide.

Much effort has been dedicated to the molecular design and synthesis of model proteins to define interactions involved in protein folding[1,2] and to develop protein-based materials.[3] Protein tertiary structures can be looked upon as assemblies of secondary structural elements (α-helix, β-strand, reverse turn). This model has been the basis for the design of artificial proteins. A recent approach to protein design is to use a rigid template molecule.[4] Many artificial proteins have been prepared in aqueous solutions by attaching peptide blocks to templates that direct the component helices into a protein-like packing arrangement, *e.g.* a bundle structure of α-helices.[5] The amphiphilic properties of the helical blocks seem to be essential to stabilize such a bundle structure. We have devised a strategy in which purely synthetic polypeptides are aligned on two-dimensional media[6] such as on water and on Au surfaces. Poly(L-glutamic acid) has been chosen as a structural element because of its ease of synthesis and well-defined conformational characteristics in water. We now describe that complete surface modification of a three-dimensional dendrimer with an oligopeptide can be accomplished by graft polymerization of γ-benzyl-L-glutamate *N*-carboxy anhydride (BLG-NCA) and the resulting graft chains show interesting conformational properties.

Dendrimers are known to be hyperbranched macromolecules possessing a very high concentration of surface functional groups.[7] A variety of dendrimers have been developed by introducing functionalities into these terminal groups. For example, dendrimers terminated with an amino acid,[8] a sugar,[9] and a perfuluoroalky[10] or alkyl[11] chain show encapsulation functions for guest molecules. The other structural feature of dendrimers is the high degree of control over molecular weight and shape. The diameters of the spherical dendrimers range from 3 to 10 nm.[12] Taking account of these features in shape, the oligopeptide-attached dendrimer in this study may be a relevant candidate for model proteins.

The third-generation, amine-terminated PAMAM dentrimer (G3-NH_2) with branches and an ethylenediamine core was used as a template for assembly and an initiator for graft polymerization. As shown in Scheme 1, BLG-NCA (3.8 mmol) was polymerized with G3-NH_2 ([NH_2] = 0.30 mmol) in $CHCl_3$ at room temperature. A relatively short chain length of the peptide segment (degree of polymerization, n = 10–15) was employed because the number of amino acid units is appropriate for both characterization of the resultant dendrimer and elucidation of the effect of assembly. After stirring for 30 min, the reaction mixture was poured into a large excess of Et_2O and then purified and dried, giving a white powdery product (G3-PBLG) with a yield of 97%. The M_w/M_n value† determined by size exclusion chromatography was reasonably narrow (M_w/M_n = 1.06), indicating the absence of the polymerization catalyzed by the tertiary amine of the inner part of PAMAM dendrimer that produces a homopolymer of BLG-NCA with a broad molecular weight distribution.[9] ^{1}H and ^{13}C NMR spectroscopies (data not shown) supported the structure of G3-PBLG. In the ^{13}C NMR spectrum of G3-PBLG, no peaks assigned to the α- and β-carbons of the unreacted terminal amino groups of PAMAM dendrimer were observed, while those of G3-NH_2 appeared at δ_c 41 and 42, respectively. This means that the graft polymerization proceeded for all of the terminal amino groups located at the G3-NH_2 dendrimer surface. The n value of the grafted peptide segment was evaluated to be 12 on the basis of ^{1}H NMR analysis.‡

The secondary structure of G3-PBLG was investigated by means of circular dichroism (CD) and ^{1}H NMR spectroscopy. For comparison, Pr-PBLG, which possesses a propyl group at the C-terminus of the PBLG chain, was prepared by polymerization of BLG-NCA initiated with propylamine instead of G3-NH_2. The ^{1}H NMR analysis of Pr-PBLG showed that n for the PBLG segment was also 12. In the CD spectrum of this CH_2Cl_2 solution ([glutamate unit] = 1.0 mM), a trough appears at *ca.* 222 nm, indicating the exsitence of a right-handed α-helix



Scheme 1

DOI: 10.1039/a909586a

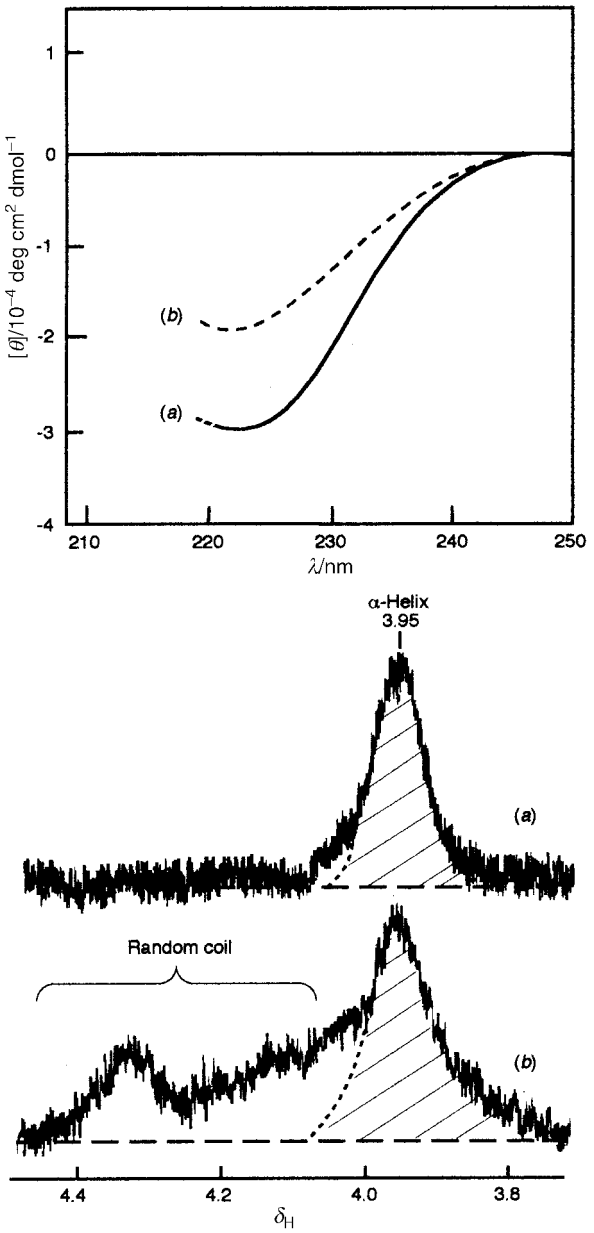


Fig. 1 CD and ^{1}H NMR spectra of G3-PBLG (*a*) and Pr-PBLG (*b*) in CH_2Cl_2 (for CD) or CD_2Cl_2 (for NMR) at 25 °C; [glutamate unit] = 1.0×10^{-3} M.

conformation (Fig. 1). The helix content of the Pr-PBLG solution is calculated to be 53% from the observed molar ellipticity $[\Theta]$ at 222 nm ($[\Theta] = 1.8 \times 10^{-4}$ deg cm^2 dmol^{-1}).§ This helix content is reasonable taking account of such a short segment length as $n = 12$.[13] On the other hand, the molar ellipticity of the G3-PBLG solution is found to be enhanced drastically, compared with that of the Pr-PBLG solution. Surprisingly, the helix content goes up to 92%. To obtain more quantitative information on the secondary structure, ^{1}H NMR spectra were measured in CD_2Cl_2 under the same conditions (Fig. 1). The α-C*H* resonance signal of the PBLG main chain was known to give a peak at δ_H 3.95 ascribed to the α-helix conformation, while giving an apparent lowfield shift on going from the helix to the random coil form.[14] From signal areas based on α-helix and random coil forms, the helix contents were evaluated to be 93 and 57% for G3-PBLG and Pr-PBLG, respectively. These values are consistent with those obtained by CD analysis. FTIR spectra (data not shown), in particular in amide II band region of the main chain, showed that β-sheet structures were absent for both PBLGs. It is clear from these spectral data that transfer and aggregation of the PBLG segment onto the dendrimer surface from bulk solution would cause such an enhancement in helicity since the PBLG segment lengths (*n*) of Pr-PBLG and G3-PBLG are the same. The enhancement of helicity due to aggregation of helices has sometimes been observed in aqueous solutions when a helix-bundle structure is formed by assembling with a template.[5] In those cases, it has been demonstrated that the hydrophobic effects among the side chain groups play an important role in stabilizing the helical conformation. Presumably, in our case, the driving force for causing such enhancement in helicity must also be the hydrophobic effect, resulting from the characteristic shape of the spherical dendrimer surface, at which the peptide segments are forced to assemble densely, which will require further exploration.

Notes and references

† M_w and M_n denote weight-average molecular weight and number-average molecular weight, respectively, determined by means of size exclusion chromatography, and the ratio of M_w/M_n is the polydispersity of the polypeptides prepared by polymerization of NCA. Size exclusion chromatography was performed in DMSO at 30 °C, with a Shimazu Model LC-5A high performance liquid-chromatograph apparatus (column, Shodex KD803 and 804).

‡ The *n* value was calculated by using the area ratio of the signal of CH_2 (benzyl) in the PBLG segment to that of CH_2 in the PAMAM dendrimer, observed in the ^{1}H NMR spectrum of G3-PBLG.

§ The helix content was calculated by using the following equation: helix content (%) = $([\Theta]_{222}/[\Theta]_h) \times 100$, where $[\Theta]_{222}$ and $[\Theta]_h$ are the molar ellipticity at 222 nm and −34 000 (deg cm^2 dmol^{-1} (ref. 15), respectively.

The self-assembly of benzyl alcohol derived deep-cavity cavitands: a new, highly efficient moiety for irreversible assemblies?†

Corinne L. D. Gibb, Edwin D. Stevens and Bruce C. Gibb*

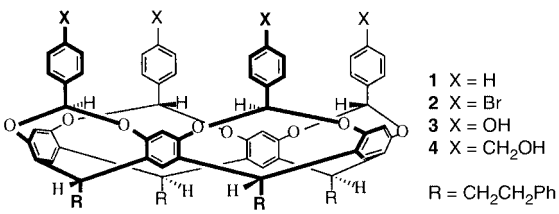
Department of Chemistry, University of New Orleans, New Orleans, LA 70148, USA. E-mail: bgibb@uno.edu

Received (in Columbia, MO, USA) 7th October 1999, Accepted 29th November 1999

In the absence of an apparent (single) molecular template, the irreversible self-assembly of benzyl alcohol substituted, deep-cavity cavitands is shown to be a highly efficient process.

With aspirations to improve our understanding of self-assembly, chemists have begun to focus on systems where the convergence of the molecular subunits is not promoted by a single molecular template,[1–4] but rather where assembly occurs around multiple 'templates'.[5] When considering the nano-scale products which such manifold species 'templations' result in, two options are available. First, scientists have considered self-correcting systems as a means to product formation, an approach that utilizes thermodynamics to maximize the yield of the target.[6,7] Alternatively, using a (normally less efficient) irreversible process allows the potential isolation of intermediates, and hence a more detailed picture of the assembly process in question. In this latter paradigm, considerable work has been carried out in systems requiring a single template. Thus, extending the original work of Cram,[8–10] Sherman *et al.* have demonstrated how carceplex formation is governed by the topology of the molecular template so essential for their synthesis.[11] In contrast, probing irreversible self-assemblies that require manifold species 'templation' has been relatively unexplored, primarily because of a lack of suitable supramolecular motifs[12] that can effectively drive such assemblies. Thus in the formation of a number of large, cavity-containing molecules, it has been noted that when using phenol groups to form the supramolecular motif, yields have tended to decrease toward statistical or worse.[10,13,14] We report here on an irreversible assembly in which the subunit utilizes benzyl alcohol groups in its supramolecular motif. Although the assembly occurs in the absence of a single molecular template, and the eight new covalent bonds created in the process are formed in a non-correcting manner, each is formed with an efficiency greater than 97%. As a result therefore, the synthesis of the nanoscale host is highly efficient.

We recently demonstrated the stereoselective bridging of resorcinarenes with benzal bromide, a process which provided access to a new series of deep-cavity cavitands (DCCs) epitomized by structure **1**.[15] More recently, we have noted that this reaction can be applied to a range of benzal bromides to form a series of DCCs whose 'upper row' of aromatic rings may be substituted at the *o*, *m* or *p* position.[16] We chose one example of these, the *p*-Br derivative **2** as an entry point for the synthesis of DCCs **3** and **4** whose architecture should allow them to undergo an assembly process analogous to the carceplex reaction.[10,11] Our initial attempts to perform this 'dimerization' of DCCs centered around the tetrakis(4-hydroxyphenyl) derivative **3**. However, our studies showed that **3** was insufficiently stable in either acidic or basic conditions, a result we attribute to the ability of the electrons on the OH groups to conjugate through to the acetal bridges. Consequently, we synthesized DCC **4** whose essential nucleophilic centers possess slightly less preorganization, but are 'insulated' from the benzal bridging-carbon by the benzyl methylene group.



Our initial studies focused on the covalent joining of two molecules of **4** with the bis-electrophile CH_2BrCl (Scheme 1) in the absence of a large templating molecule. Our early results with a range of aprotic solvents[17] gave poor yields of **5**, the bulk of **4** being transformed into intractable polymeric material and trace quantities of DCC–solvent conjugates. DMSO on the other hand led to a considerable improvement, with a highly efficient[18] 80% yield of **5** being obtained under dilute conditions, a remarkable yield for an irreversible process.[19] Yields decreased at concentrations > *ca.* 2 mmolar, presumably because of the highly concentration-dependent formation of the superbase, methylsulfinyl carbanion.[20] However at these concentrations, yields could be increased by the addition of small quantities of water to generate the less basic hydroxide[21] and inhibit[20] the superbase formation.

Definitive formation of **5** came from an X-ray crystallographic determination (Fig. 1).[22] In the solid state, both hemispheres of **5** are rotated slightly with respect to each other, while the linker groups each display the anomeric effect with *gauche–gauche* conformations for the $CH_2OCH_2OCH_2$ units. A consideration of the salient inter-carbon atom distances indicates that the cavity of **5** is approximately 19 × 15 Å, while the portals are roughly 9.5 × 11.5 Å. Not surprisingly, disordered solvent molecules within the cavity precluded an accurate determination of its composition.

Although the assembly is highly efficient, DCC **4** is too large to fit within the cavity of the product. Thus, there is no suitable, single template to promote the formation of **5** over and above

DOI: 10.1039/a908144e

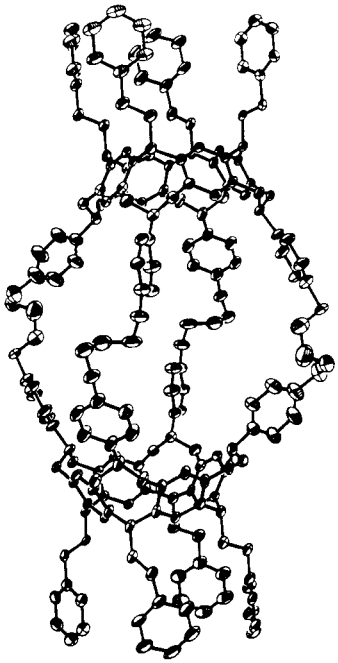

Fig. 1 ORTEP diagram of DCC dimer **5**. Hydrogen atoms have been omitted for clarity.

random polymer. As it seems entropically unlikely that several species in solution organize themselves into a multiple species template; we surmise that this efficient assembly process is occurring 'around' bulk solvent.

What lies behind this efficient assembly? In normal cavitands, the supramolecular motif that drives the reaction is constructed with the phenol group, a moiety that in the presence of base can form a charged hydrogen bond (CHB) with its conjugate base.[23] As yet, we have been unable to definitively ascertain if an analogous process is occurring in the assembly of **4**. However, variations in the base utilized for the reaction tentatively support this hypothesis.[24] Furthermore, work by Kolthoff[25]—who demonstrated that weakly acid phenols formed stronger CHBs with their conjugate bases than their more acidic counterparts—suggests that the poorly acidic benzyl alcohol group[21*a*] should form very strong CHBs.

In summary, we have demonstrated an efficient, irreversible self-assembly that occurs in the absence of a single, molecular template. Investigations into the use of the benzyl alcohol group in other molecular subunits are currently underway.

We are grateful to Richard B. Cole of the New Orleans Center for Mass Spectrometry Research for mass analysis of the deep-cavity cavitands. This work was partially supported by the Louisiana Board of Regents Support fund (1997-00)-RD-A-23, a Research Innovation Award from the Research Corporation, and the Donors of the Petroleum Research Fund, administered by the American Chemical Society.

5 Although templation has been defined in a variety of publications (refs. 1–4), to the best of the authors' knowledge there has been no attempt in the supramolecular chemistry field to precisely delineate between the terms 'templation' and 'solvation'. The few examples (using two or more templating molecules) (refs. 6, 7, 10, 13, 14) that lie in the 'gray area' between these two terms have either not raised this semantic problem, or have referred to the process at hand as templation. Thus, we will refer to the described process as being 'templated' by bulk solvent, although 'solvated' may be an equally applicable term.

12 We define here the term 'supramolecular motif' as the repeating pattern of functional groups that contribute significantly to the overall enthalpy (orentropy) change during assembly. We note that the term 'function groups' fails to differentiate between those moieties that drive the assembly process, and those that do not. The term 'functional groups' also invokes images of well-defined areas in a molecule that contain elements other than C and H, but ignores large tracts of hydrocarbon surface that are often important in the self-assembly of proteins.

18 As a measure of the efficiency of these assemblies, we define the term 'assembly number' (AN) as the ratio of the isolated yield of a compound over its theoretical yield (derived by assuming 100% efficiency for each of the possible reaction options available to the *isolated* self-assembly components which appear in the product). Such a derivation (see the supplementary data for a full description) provides a semi-quantitative guide to these (and other similar) assemblies: AN < 1 not an assembly process, AN > 1 (the higher the better), an assembly process. For **5**, AN = 4.04 for optimal carceplex formation (ref. 11), AN = 1.45; for extended hemicarcerands [ref. 14(*b*)], AN = 1.62.

24 No reaction was observed when $KHCO_3$, K_2CO_3 or DBU were used as base. Stronger bases (the following pK_a values are noted in DMSO), KOMe (pK_a = 29.0) [ref. 21(*a*)], KOEt (pK_a = 29.8) [ref. 21(*b*)], KOH (pK_a = 31.2) [ref. 21(*a*)] gave poor results compared to Bu^{t}OK (pK_a = 32.2) [ref. 21(*a*)]. In these cases, the bulk of the product was polymeric. Using KOH and Bu^{t}OH did not give a high yield of **5**, a fact that, in conjunction with our observation that the reaction gave only polymer with < 8 equiv. of base, may be attributed to the slow dissolution of KOH.

Optical resolution of sulfoxides by inclusion in host dehydrocholic acid

Olga Bortolini, Giancarlo Fantin,* Marco Fogagnolo, Alessandro Medici and Paola Pedrini

Università di Ferrara, Dipartimento di Chimica, via Borsari 46, 44100 Ferrara, Italy. E-mail: fnn@dns.unife.it

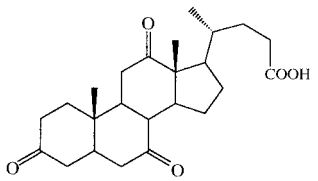
Received (in Liverpool, UK) 12th November 1999, Accepted 18th January 2000

Dehydrocholic acid serves as an effective chiral host molecule for the optical resolution of aryl alkyl sulfoxides by inclusion.

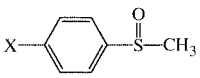
The optical resolution of different classes of organic substrates by lattice inclusion compounds is receiving significant attention on account of its high efficiency and simplicity.[1] Bile acids have often been used as host molecules both in the direct resolution of a guest racemate[2,3] and in enantioselective transformation of an inclusion compound.[4] The resolution of aliphatic alcohols with cholanamide (3,7,12-trihydroxy-5-cholan-24-amide)[2] and that of lactones in the presence of cholic and deoxycholic acid[3] are examples of the former case.

Chiral sulfoxides are finding increasing use as auxiliaries in asymmetric synthesis[5] and as intermediates in the pharmaceutical industry.[6] Beside the classical resolution methods,[7] new strategies have been developed mainly based on the oxidation of prochiral sulfides by titanium peroxo species bearing chiral C_2 symmetric diols[8–10] (*e.g.* tartaric esters) or C_3 symmetric trialkanolamines.[11] However, the limited turnover numbers characterizing most of these oxidation procedures and the kinetic resolution *via* oxidation involving the sulfoxides so produced[12] prompted us to reconsider the resolution method to obtain enantiomerically pure sulfoxides.

Described here is the novel observation that dehydrocholic acid (3,7,12-triketo-5-cholan-24-oic acid) **1**, a bile acid derivative lacking steroidal hydroxy groups can serve as a host molecule to form inclusion compounds with different aryl alkyl sulfoxides **2**–**6**, leading to the effective optical resolution of this class of compounds.



1



2 X = H,
3 X = CH_3
4 X = CH_3O
5 X = Cl
6 X = Br

The inclusion compounds of **1** with sulfoxides were obtained by two different methods based on direct absorption of the melted (method A) or solvent dissolved (method B) sulfoxide. The choice depends on the sulfoxide. In the former case the solid dehydrocholic acid is directly added to the melted sulfoxide in the absence of any solvent, whereas in the latter procedure **2**–**6** were dissolved in the minimum amount of Et_2O, and poured onto solid **1**. As shown in Table 1, both processes are equally effective, affording sulfoxides in good to high ees in the range 36–99%.

A view of the overall process is given in Scheme 1. On standing at room temperature for 48–72 h, dehydrocholic acid and the selected sulfoxide formed crystals[13] that were washed with Et_2O. The ethereal layer was separated from the solid phase and evaporated to give the crude sulfoxide in predominant (*S*) configuration. On the other hand, included sulfoxides were easily obtained in quantitative yields in (*R*) for **3**–**5** and (*S*) configuration for **2**, respectively, by dissolving the crystals with aqueous $NaHCO_3$ followed by extraction with Et_2O.[14] Furthermore, almost complete recovery of dehydrocholic acid can be obtained upon treatment of the aqueous basic layer with dilute mineral acid. No significant differences in optical and chemical yields were observed when recycled dehydrocholic acid was used.

The relative amount of the sulfoxide with respect to **1**, in the inclusion process, was expected to play an important role. Accordingly, a 3-fold excess of **2**–**6** over the bile acid favored high optical purities of the sulfoxides that are included in **1**, as shown from the data of Table 1, whereas a one-to-one stoichiometry increased the ees of the non-guest sulfoxides obtained from the Et_2O solution. As an example, when **6** is added in equimolar amounts to the bile acid, (*S*)-**6** is recovered from the solution and (*R*)-**6** is obtained from crystals in ees of about 70%. When a 3-fold excess of **6** is used the optical purity of (*R*)-**6** increased to 84% (Table 1).

Compared to **1** the efficiency of the well-known host cholic acid (3,7,12-trihydroxy-5-cholan-24-oic acid) is lower, affording sulfoxides with optical purities in the range 2–47%, depending on the sulfoxide. This is an example of the excellent ability of dehydrocholic acid, a non-naturally occurring steroid lacking hydroxy groups, to recognize sulfoxides according to

Covalent capture of dynamic hydrogen-bonded assemblies

F. Cardullo,[a] M. Crego Calama,[a] B. H. M. Snellink-Ruël,[a] J.-L. Weidmann,[a] A. Bielejewska,[a] R. Fokkens,[b] N. M. M. Nibbering,[b] P. Timmerman*[a] and D. N. Reinhoudt*[a]

Received (in Liverpool, UK) 26th November 1999, Accepted 18th January 2000

Covalent linkage of the three calix[4]arene units in hydrogen-bonded assemblies $\mathbf{1}_3$•$(DEB)_6$ *via* a threefold ring closing metathesis (RCM) reaction quantitatively converts the dynamic assemblies into covalent systems (123-membered macrocycles) that can be easily characterized using MALDI-TOF MS and HPLC.

Dynamic combinatorial libraries have recently attracted a great deal of attention in the rapidly expanding field of combinatorial chemistry.[1] Such libraries have the potential to amplify the formation of the strongest binder as a result of a templating effect exerted by an added host or guest molecule.[2–7] Most literature examples involve dynamic systems based on the reversible formation of *covalent* bonds[2–5] or coordinative bonds.[6,7] Dynamic libraries based on the reversible formation of weak noncovalent interactions, like multiple hydrogen-bonding, have so far not received a great deal of attention, most likely because of severe characterization problems. Our group has reported the synthesis and characterization of a 4-membered dynamic library of hydrogen-bonded assemblies and recently we have shown that guest-templating effects are also applicable to these systems.[8,9] Increasing the structural diversity in these systems is easy and can be performed simply by mixing the appropriate number of individual components under thermodynamically controlled conditions. However, the serious lack of suitable characterization techniques currently limits the size of the libraries that can be made.

Here we describe the covalent capture of dynamic libraries of hydrogen-bonded assemblies $\mathbf{1}_3$•$(DEB)_6$, which converts these dynamic libraries into covalent analogues that can be readily characterized using conventional techniques like mass spectrometry and HPLC. We used the ring-closing metathesis (RCM) reaction,[10] because it is compatible with the hydrogen-bonded network in assembly $\mathbf{1}_3$•$(DEB)_6$. Moreover, it has been used previously for the cyclization of cyclic peptides,[11] catenane formation,[12,13] and post-modification of dendrimers.[14]

Reaction of assembly $\mathbf{1a}_3$•$(DEB)_6$ (R = H, n = 6),[15] carrying oct-7-enyl side chains, with Grubbs catalyst in CD_2Cl_2 resulted in the covalent linkage of the three calix[4]arene units **1a** (Fig. 1) *via* a threefold metathesis reaction giving the 123-membered macrocycle **2a** as the corresponding hydrogen-bonded assembly **2a**•$(DEB)_6$ in 96% yield (Fig. 2).† Monitoring the reaction by ^{1}H NMR spectroscopy (Fig. 3) clearly showed that the reaction occurs without destroying the assembly. The signals for the terminal vinylic protons at δ 5.8 and 4.9 gradually disappear during the reaction and a new signal at δ 5.47 for the internal vinylic protons in **2a**•$(DEB)_6$ is observed [Fig. 3(*b*)].‡ HPLC analysis of the reaction mixture (at different time intervals) showed that **1a** is rapidly consumed (> 95% after 36 min) upon addition of the Ru catalyst, initially giving intermediate products (linear dimer and trimer) that are slowly converted into the final product **2a**.§ The clean formation of assembly **2a**•$(DEB)_6$ (detected as **2a** after loss of DEB under the MS conditions) was confirmed by MALDI-TOF MS (observed m/z = 3100 for $[\mathbf{2a} + H]^+$ containing the most abundant natural isotopes; calc. for $C_{180}H_{240}N_{36}O_{12}$ = 3100; Fig. 4). Both HPLC and MALDI-TOF MS clearly showed that the cyclic monomer **3a** (calc. m/z for $C_{60}H_{80}N_{12}O_4$ = 1032) is not formed, which emphasizes the high degree of preorganization of the reactive double bonds within the assembly.

The clean formation of assembly **2a**•$(DEB)_6$ was only observed under conditions where assembly $\mathbf{1a}_3$•$(DEB)_6$ is present. Not a single trace of **2a** was formed when **1a** was reacted with the Ru catalyst either in the absence of DEB or in the presence of 4 equiv. of *N*-propyl-5,5-diethylbarbituric acid (PDB), a substitute for DEB that cannot form an assembly similar to $\mathbf{1a}_3$•$(DEB)_6$. Moreover, RCM reactions carried out at $[\mathbf{1a}_3$•$(DEB)_6]_{t=0}$ = 0.01 mM (250-fold dilution) gave the cyclic monomer **3a** as the major product due to extensive dissociation of the assembly at this concentration.

The presence of bromo or iodo substituents at position R in assembly $\mathbf{1}_3$•$(DEB)_6$ significantly decreases the yields of the corresponding cyclic trimers **2b** (21%) and **2c** (16%) (Fig. 2). When the covalent capture was carried out in CD_2Cl_2 significant amounts of the cyclic monomers **3b** (12%) and **3c** (28%) were formed.¶ In toluene-d_8 formation of the cyclic monomers **3b** and **3c** was not observed, but still the yields of the cyclic trimers **2b** (37%) and **2c** (10%) were low in comparison to that of **2a** under the same conditions (100%). These results clearly indicate that the bromo and iodo substituents at position R significantly reduce the thermodynamic stability of the

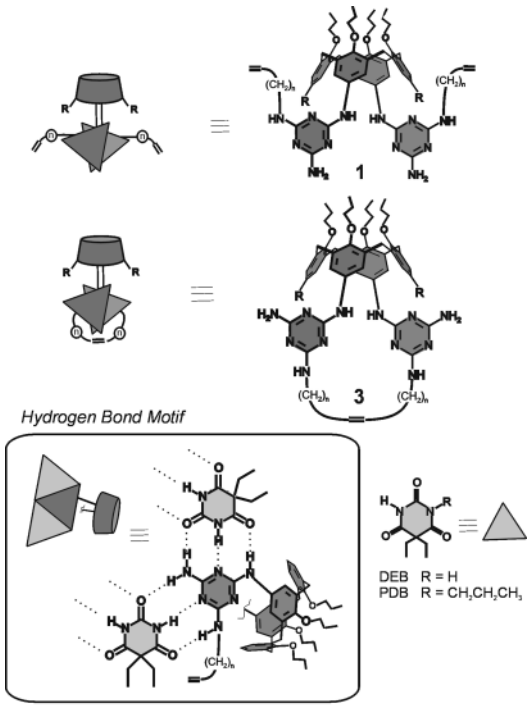

Fig. 1 Molecular structures and schematic representations of calix[4]arene dimelamine **1**, cyclic monomer **3** and barbituric acid derivatives DEB and PDB.

DOI: 10.1039/a909459h

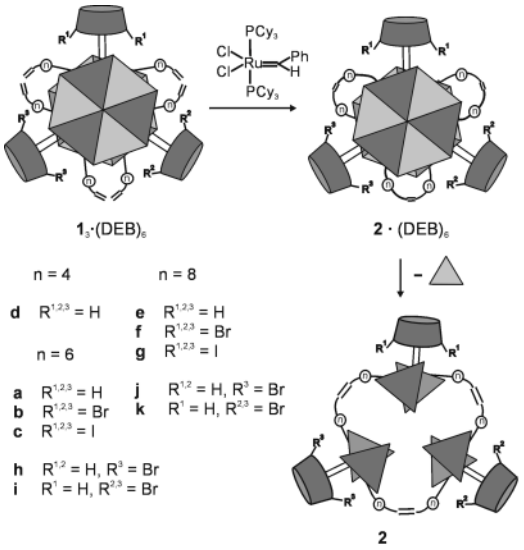

Fig. 2 Schematic representation of the covalent capture of hydrogen-bonded assemblies $\mathbf{1}_3$•$(DEB)_6$.

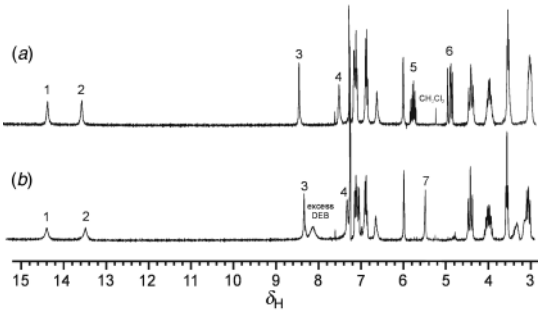

Fig. 3 ^{1}H NMR spectra of (*a*) assembly $\mathbf{1a}_3$•$(DEB)_6$ and (*b*) assembly **2a**•$(DEB)_6$ after reaction of assembly $\mathbf{1a}_3$•$(DEB)_6$ with Grubbs catalyst. Peak designations: NH_{barb} protons (1 and 2), NH_{Ar} protons (3), NH_{CH2} protons (4), terminal (5,6) and internal (7) vinylic protons. Spectra were recorded in $CDCl_3$ on a 300 MHz spectrometer.

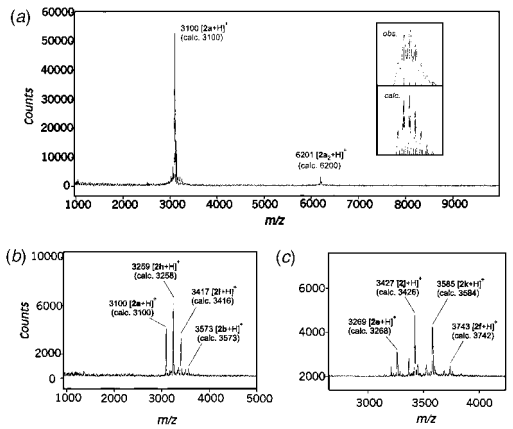

Fig. 4 MALDI-TOF mass spectra of the crude reaction mixtures of the covalent capture of (*a*) assembly $\mathbf{1a}_3$•$(DEB)_6$ (observed and calculated isotopic patterns for $[\mathbf{2a}+H]^+$ are given as inserts); (*b*) dynamic library $\mathbf{1a}_{3-x}\mathbf{1b}_x$•$(DEB)_6$ (x = 0–3, R = H, Br, n = 6); (*c*) dynamic library $\mathbf{1e}_{3-x}\mathbf{1f}_x$•$(DEB)_6$ (x = 0–3, R = H, Br, n = 8).

assemblies[15] and strongly hinder the reaction of the two alkene units, leading to competitive polymerization of the assemblies and/or intermediates.

Substitution of the oct-7-enyl chains in **1a** for hex-5-enyl chains, as in **1d**, completely inhibits the covalent capture of the corresponding assembly $\mathbf{1d}_3$•$(DEB)_6$ and formation of cyclic trimer **2d** does not occur to a significant extent either in CD_2Cl_2 or in toluene-d_8. The effect of an increase in the alkenyl chain length is much less pronounced. Covalent capture of assembly $\mathbf{1e}_3$•$(DEB)_6$, carrying dec-9-enyl side chains, in toluene-d_8 gave assembly **2e**•$(DEB)_6$ in 71% yield. The introduction of bromo substituents at positions R in these assemblies seems to decrease the yield of the corresponing assembly **2**•$(DEB)_6$ to a much smaller extent. For example, covalent capture of assembly $\mathbf{1f}_3$•$(DEB)_6$ (R = Br, n = 8) in toluene-d_8 gave assembly **2f**•$(DEB)_6$ in 61% yield.

Covalent capture of the 4-component dynamic libraries[8] $\mathbf{1a}_{3-x}\mathbf{1b}_x$•$(DEB)_6$ (x = 0–3, R = H, Br, n = 6), and $\mathbf{1e}_{3-x}\mathbf{1f}_x$•$(DEB)_6$ (x = 0–3, R = H, Br, n = 8) under standard RCM conditions in toluene-d_8 clearly showed the formation of all four possible trimers **2a**, **2b**, **2h** and **2i** (Fig. 4, relative ratio 20:43:30:7 determined by HPLC) and **2e**, **2f**, **2j** and **2k** (relative ratio 10:38:40:12 determined by HPLC), respectively. The product distribution for the library with oct-7-enyl side chains is slightly different from statistical (*i.e.* 12:38:38:12), due the lower stability of the Br-containing assemblies.

In conclusion we can state that the covalent capture of hydrogen-bonded assemblies $\mathbf{1}_3$•$(DEB)_6$ occurs with high efficiency and provides a new tool for the characterization of dynamic libraries using conventional techniques like HPLC and mass spectrometry.

We thank the EC for the Marie Curie Research Training Grant to Dr F. Cardullo (No. ERBFMBICT 972555) and Dr M. Crego Calama (No. ERBFMBICT 961445) as part of the TMR Programme.

Notes and refences

† Reaction conditions for RCM reactions: (*a*) CD_2Cl_2, room temp., 40 h; $[\mathbf{1}]_{t=0}$ = 9.0 mM; $[DEB]/[\mathbf{1}]_{t=0}$ = 2.5; $[Ru\ cat]_{t=0}$ = 20 mol%, additional 10 mol% at t = 18 h. (*b*) toluene-d_8, room temp., 48 h; $[\mathbf{1}]_{t=0}$ = 6.0 mM; $[DEB]/[\mathbf{2}]_{t=0}$ = 2.5; $[Ru\ cat]_{t=0}$ = 20 mol%, additional 10 mol% at t = 18 and 24 h. Reactions were quenched by extensive bubbling with oxygen.

‡ A mixture of *cis* (*c*) and *trans* (*t*) isomers is most probably formed (the HPLC analysis of assembly **3a**•$(DEB)_6$ shows two shoulders), but the different isomers (*ccc*, *cct*, *ctt*, *ttt*) were not resolved even in a 600 MHz ^{1}H NMR spectrum.

§ HPLC analysis was performed on crude reaction mixtures (no intermediate workup). Eluent: 95% CH_2Cl_2–4.75% MeOH–0.25% NH_3 (25% in H_2O); Column: Resolve Silica 90 Å 5 μm 3.9 × 150 mm. Yields were determined using DEB as an internal standard.

¶ In all reactions that show the formation of cyclic monomer **3** by MS and HPLC, precipitation of significant amounts of the monomer was observed, resulting in overall yields being much lower than 100%.

Selectin ligands: 2,3,4-tri-*O*-acetyl-6-*O*-(2-naphthyl)methyl (NAP) α-D-galactopyranosyl imidate as a novel glycosyl donor for the efficient total synthesis of branched mucin core 2-structure containing the NeuAcα2,3(SO_3Na-6)Galβ1,3GalNAcα sequence

Wensheng Liao, Robert D. Locke and Khushi L. Matta*

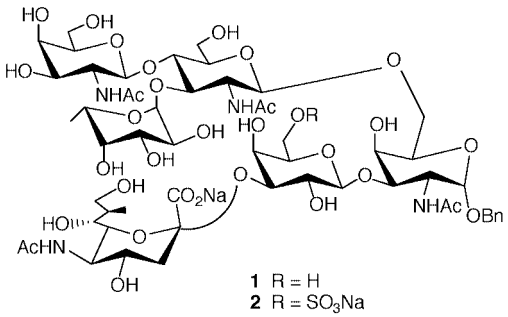
Received (in Corvallis, OR, USA) 21st October 1999, Accepted 10th January 2000

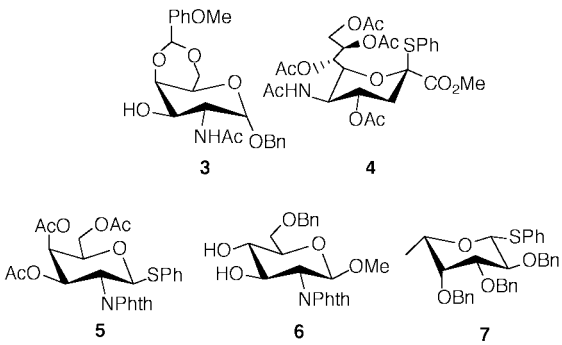
The stereo- and regioselective total synthesis of branched mucin core 2-structure 2, which contains the NeuAcα-2,3(SO_3Na-6)Galβ1,3GalNAcα sequence, is accomplished through the use of the key glycosyl donor 19.

Our recent study has shown that a core 2-branched sequence can enhance L- and P-selectin binding, *e.g.* our synthetic compound GalNAcβ1,4(Fucα1,3)GlcNAcβ1,6(NeuAcα2,3Galβ1,3)GalNAcαOMe **1** was found to be 5- to 6-fold better at inhibiting L- and P-selectins than sialyl Lewis^x-OMe.[1] It is now well established that natural selectin ligands, such as CD34, MadCAM-1, PSGL-1 and GlyCAM-1, are mucin type glycoproteins.[1] Both PSGL-1 and GlyCAM-1 contain the NeuAc2,3Galβ1,3GalNAcα sequence. In GlyCAM-1 it has been demonstrated that, in addition to sialylation and fucosylation, sulfation of the saccharide chains is important for high affinity binding to L-selectin.[2] Based upon this, we became interested in the synthesis of sulfated analogs of our previously reported **1** as



1 R = H
2 R = SO_3Na

potential ligands. Moreover, the sequences (SO_3Na-6)Galβ-1,3GalNAcα and especially NeuAcα2,3(SO_3Na-6)Galβ1,3GalNAcα have been found to be part of *O*-linked glycoproteins.[3] Thus, we turned our attention to the synthesis of our target molecule **2**, which contains the NeuAcα2,3(SO_3Na-6)Galβ-1,3GalNAcα sequence, as a potential ligand.

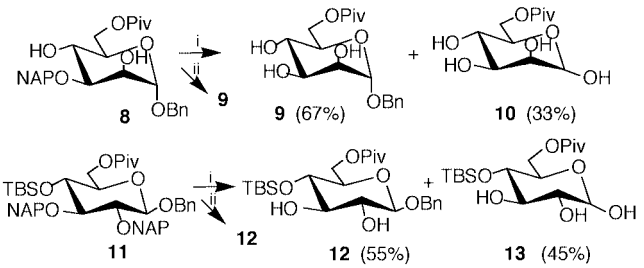


3 **4** **5** **6** **7**

Our present approach is based upon the use of imidate **19** bearing a 6-*O*-(2-naphthyl)methyl (NAP) group as a valuable glycosyl donor. Recently Spencer *et al.*[4] reported selective cleavage of the NAP group by hydrogenolysis (10% Pd/C, ethanol) even in the presence of benzyl groups. However, when we applied this method to the synthesis of oligosaccharides, our pilot experiments showed that the hydrogenation reactions went very slowly and the benzyl groups were also partially cleaved (Scheme 1). Meanwhile, in our lab we have found that DDQ can smoothly remove the NAP group and other usual protecting groups (such as Ac, pivaloyl, TBS, phthalimido, Bn and benzylidene) can still survive.[5] The donor **19** was prepared as shown in Scheme 2. On alkylation with 2-(bromomethyl)naphthalene, the readily accessible **14** provided **15** in quantitative yield. Deacetonation followed by acetylation furnished compound **17** (α:β 2:3). Selective removal of the anomeric *O*-acetyl group from **17** gave, in 87% yield, **18** which on treatment with CCl_3CN–DBU (−10 °C) afforded a 90% yield of trichloroacetimidate **19** as the pure α-anomer.

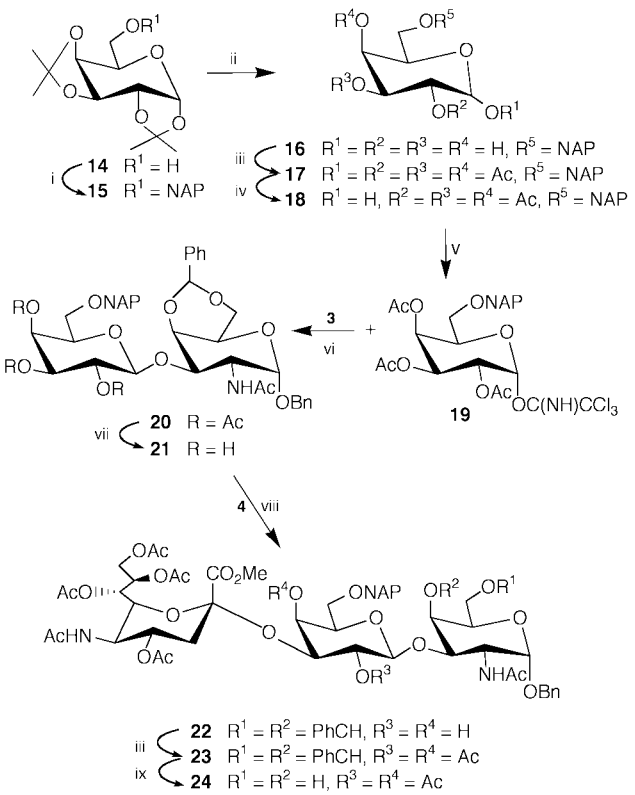
Glycosidation of alcohol **3** with imidate **19** was performed under Schmidt's 'inverse procedure'.[6] The β-linked disaccharide **20** was obtained in 74% yield, which was then *O*-deacetylated to furnish triol **21**. The sialylation of **21** with the sialic acid donor **4** under NIS–TfOH catalysis at −30 °C gave the trisaccharide **22** in 78% yield. Compound **22** was then acetylated to give **23**. The ^{1}H NMR spectrum of **23** displayed characteristic signals at δ 5.07 (dd, 1H, $J_{1',2'}$ 8.0, $J_{2',3'}$ 10.4 Hz, H-2′), 4.96 (d, 1H, $J_{3',4'}$ 2.8 Hz, H-4′), 5.27 (dd, 1H, $J_{6'',7''}$ 2.8, $J_{7'',8''}$ 9.6 Hz, H-7″) and 2.59 (dd, 1H, J_{gem} 12.8, $J_{3''eq,4''}$ 4.9 Hz, H-3″e) which confirmed an α(2 → 3) glycosidic linkage. Removal of the 4,6-benzylidene group in **23** (50% HOAc, 55 °C) afforded the trisaccharide diol **24** (90%).

Although preparation of the key GalNAc Le^x glycosyl donor **29** has been reported,[1] a simplified procedure based on employing diol **6** as an acceptor was developed (Scheme 3). Thus, regioselective condensation of phenylthio donor **5** and diol **6** under NIS–TfOH conditions (−65 °C) afforded the β(1 → 4) linked disaccharide **25** in 73% yield. Selectfluor–BF_3·Et_2O promoted[7] α-L-fucosylation of **25** with donor **7** in CH_3CN (0 °C) gave trisaccharide **27** in 75% yield. Hydrogenolysis of **27**, followed by acetylation and then acetolysis

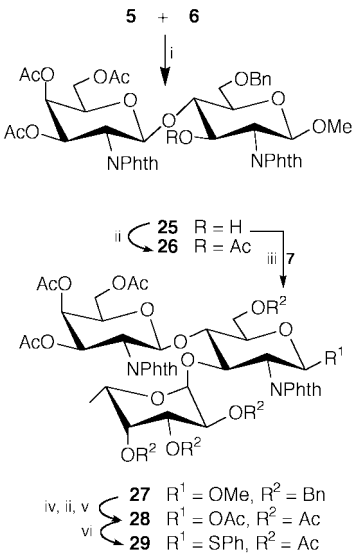


Scheme 1 *Reagents and conditions*: i, 10% Pd/C, HOAc–MeOH, 16 h; ii, DDQ (2.5 equiv. for **8**, 5 equiv. for **11**), CH_2Cl_2–H_2O (15:2), 3 h, quant.

DOI: 10.1039/a908511d

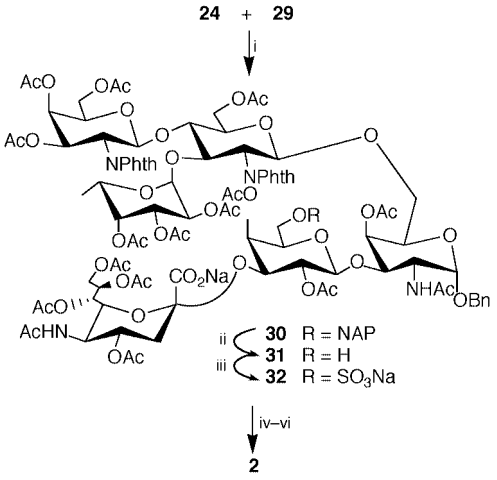


Scheme 2 *Reagents and conditions*: i, 2-(bromomethyl)naphthalene, KOH, 18-crown-6, THF, 2 h; ii, 80% AcOH, 75 °C, 95%; iii, pyridine–Ac_2O, DMAP; iv, hydrazine acetate, DMF, 2 h, 87%; v, CCl_3CN–DBU, CH_2Cl_2, −10 °C, 90%; vi, **19** (1.5 equiv.), TESOTf, 4 Å molecular sieves, CH_2Cl_2, room temp., 73%; vii, MeOH–Et_3N–H_2O, 4 °C; viii, **4** (2.0 equiv.), NIS–TfOH, 3 Å molecular sieves, CH_3CN–CH_2Cl_2, −30 °C, 3 h, 78%; ix, 50% AcOH, 55 °C, 4 h, 90%.



Scheme 3 *Reagents and conditions*: i, **5** (1.2 equiv.), NIS–TfOH, CH_2Cl_2, 4 Å molecular sieves, −65 °C; ii, pyridine–Ac_2O, DMAP; iii, **7** (3.0 equiv.), Selectfluor, $BF_3{\cdot}Et_2O$, 3 Å molecular sieves, CH_3CN, 0 °C, 75%; iv, 10% Pd/C, HOAc–MeOH; v, Ac_2O–HOAc–H_2SO_4, 70%; vi, PhSH, $BF_3{\cdot}Et_2O$, CH_2Cl_2, 73%.

with Ac_2O–HOAc–H_2SO_4 provided the fully acetylated trisaccharide **28**. Treatment of **28** with PhSH–$BF_3{\cdot}Et_2O$ furnished GalNAc Le^x glycosyl donor **29** in 73% yield.



Scheme 4 *Reagents and conditions*: i, **29** (1.5 equiv.), NIS–TfOH, CH_2Cl_2, 4 Å molecular sieves, −60 °C, 2 h, 70%; ii, DDQ (2.5 equiv.), CH_2Cl_2–H_2O, 3 h, quant.; iii, SO_3·pyridine complex (5 equiv.), DMF, 0 °C, 3 h, 95%; iv, LiI (40 equiv.), pyridine, 110 °C, overnight, 90%; v, hydrazine hydrate–MeOH (1:4), 80 °C, 6 h; vi, MeOH–CH_2Cl_2 (1:1), Ac_2O, 0 °C, 1 h; Na^+ resin.

Glycosylation of **29** with diol **24** (NIS–TfOH, −60 °C) gave the expected hexasaccharide **30** in 70% yield (Scheme 4). Removal of the NAP group in the β-galactopyranosyl residue by DDQ in CH_2Cl_2–H_2O afforded **31**, which was further treated with 5 equiv. of sulfur trioxide–pyridine complex in DMF at 0 °C to give the sulfated compound **32**. Finally, **32** was converted to the target compound **2** in three successive steps: (i) LiI–pyridine at 110 °C (methyl ester to free acid); (ii) 4:1 MeOH–hydrazine hydrate at 80 °C (removal of the phthalimido and acetyl groups); (iii) 5:5:3 MeOH–CH_2Cl_2–Ac_2O (*N*-acetylation). The structure of **2** was confirmed by ^1H, ^{13}C NMR and FAB mass spectroscopy.†

Received (in Cambridge, UK) 6th December 1999, Accepted 31st January 2000

The partial oxidation of methane in the gas phase reaction of CH_4–O_2–NO_2 was enhanced with the addition of a small amount of methanol; the selectivity of methanol at the same level of CH_4 conversion was enhanced in the presence of methanol which showed this effect exclusively in the presence of NO_2.

Methanol is a desirable product in the partial oxidation of methane. Recently, we found high yield methanol formation at 808 K under atmospheric pressure in the gas phase reaction of CH_4–O_2 upon the addition of a small amount of NO_x (x = 1,2).[1,2] The transition barrier energy of hydrogen atom abstraction from CH_4 by NO_2 was lower than that by O_2.[3,4] This brought about the enhancement effect of NO_2 on the reactivity of methane in CH_4–O_2–NO_2. Since successive oxidation of the produced methanol has been reported at high temperatures for the CH_4–O_2 gas phase reaction,[5,6] the successive oxidation of methanol could also occur in the CH_4–O_2–NO_x gas phase reaction. The initial hydrogen atom abstraction is the first step of successive oxidation of methanol that probably initiates radical chain reactions to enhance methane partial oxidation, since Burch and co-workers[5] reported that the addition of C_2H_6 lowered the reaction temperature by *ca.* 50 K at the same conversion of CH_4 for the gas phase reaction of CH_4–O_2. On the other hand, it was found in our previous study that the selectivity of the produced methanol was scarcely affected by a change of space velocity at a given temperature.[1,2,4] This indicates that methanol could be a fairly stabilized product in the gas phase. In addition, gaseous additives have been examined under high pressure so far,[7–9] but an enhancement effect of methanol was not found. Therefore it is important to clarify the behavior of methanol in the gas phase reaction of CH_4–O_2–NO_2. In this study, a small amount of methanol was added to the CH_4–O_2–NO_2 system to investigate its effects on the partial oxidation of methanol in the gas phase.

The reaction was carried out with using a test gas (CH_4: 28%, O_2: 14%, NO_2: 0.5%, He: 57.3 or 57.5%, CH_3OH: 0 or 0.16%). A quartz tube (7 mm i.d.) was used as a reactor and the length of heated reaction zone was 200 mm. The temperature was measured with a thermocouple attached on the outside of the reactor. Products were analyzed with two gas chromatographs. The carbon balance before and after the reaction exceeded 98%. Each reaction was performed for 30 min under each of the conditions and then the products were analyzed. All experimental data shown here were shown to be reproducible. Conversion and selectivities were calculated as follows (unit is mol): CH_4 conversion = (initial CH_4 − final CH_4)/initial CH_4; selectivity of a product = product/reacted CH_4; selectivity of methanol = total methanol/reacted CH_4.

Fig. 1 shows CH_4 conversion in each different reaction gas mixture as a function of reaction temperature. The temperature at the level of 10% CH_4 conversion is lowered by *ca.* 30 K (827 K) with addition of methanol (0.16%) to CH_4–O_2–NO_2. CH_4 conversion was scarcely observed at 827 K for both CH_4–O_2 and CH_4–O_2–CH_3OH systems. These differences indicate that the decrease of reaction temperature is derived from the presence of both CH_3OH and NO_2 in the reaction mixture. The enhancement effects of CH_3OH are clearly seen on an ON–OFF experiment for the supply of methanol (Fig. 2). An increase of reaction temperature after the addition of methanol was observed but amounted to < 3 K in the center of the reactor.

On varying the methanol concentration, it was found that 0.016% CH_3OH was the lower limit for which CH_4 conversion was enhanced.

The selectivity of CH_3OH for the reaction in the presence of methanol is higher than that without methanol in the lower conversion region (Table 1). The selectivity of CH_2O in the system CH_4–O_2–NO_2–CH_3OH had somewhat smaller values in the same region. The selectivity of CH_3OH in the presence of methanol exceeded that in the absence of CH_3OH for the regions of CH_4 conversion shown in Table 1.

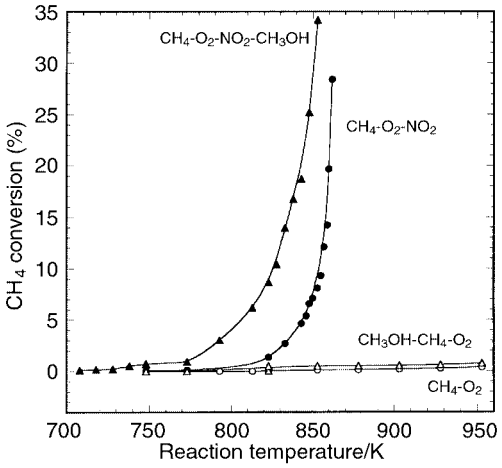

Fig. 1 CH_4 conversion *vs.* reaction temperature. Reaction gas: CH_4(28%)–O_2(14%)–NO_2(0.5%)–He(57.3%)–CH_3OH(0.16%) (▲), CH_4(28%)–O_2(14%)–NO_2(0.5%)–He(57.5%) (●), CH_4(28%)–O_2(14%)–He(57.8%)–CH_3OH(0.16%) (△), CH_4(28%)–O_2(14%)–He(58%) (○).

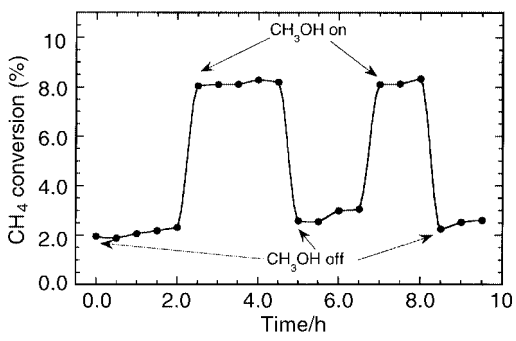

Fig. 2 The enhancement effect of CH_3OH on CH_4 conversion in CH_4–O_2–NO_2. 0.16% CH_3OH was fed into the reaction gas consisting of CH_4(28%)–O_2(14%)–NO_2(0.5%)–He(57.5%).

DOI: 10.1039/a909587j

Table 1 The effects of methanol addition on methane partial oxidation in the presence of NO_2[a]

			Selectivity (%)				
	T/K	CH_4 conversion (%)	HCHO	CH_3OH	CH_3NO_2	CO	CO_2
Without CH_3OH	831	2.3	38.0	11.7	10.8	33.5	6.0
	846	5.6	27.3	13.1	8.2	48.2	3.2
	851	8.1	19.8	13.1	8.0	55.9	3.1
	857	12.1	11.3	11.9	6.2	66.7	3.9
With CH_3OH	788	2.3 (0.3)[b]	29.1	18.8	11.7	35.1	5.3
	810	5.6 (0.7)[b]	25.0	17.1	11.9	42.3	3.7
	820	8.1 (2.3)[b]	19.6	15.7	11.1	50.4	3.2
	830	12.1 (5.6)[b]	14.0	14.0	7.4	60.7	3.9

[a] Reaction gas: CH_4(28.0%)–O_2(14.0%)–NO_2(0.5%)–He(57.3 ~ 57.5%), with or without 0.16% CH_3OH. [b] Values in parentheses are CH_4 conversion before CH_3OH addition.

It is of note that > 99% methanol was oxidized to CO and CO_2 in the CH_3OH–O_2–NO_2 system in the absence of methane below 750 K. Since all of the added methanol was completely oxidized up to 750 K, the obtained methanol in the CH_4–O_2–NO_2–CH_3OH system was assumed to be produced through the partial oxidation of methane. This indicates that the enhancement of reactivity of CH_4 in CH_4–O_2–NO_2–CH_3OH above 750 K was caused by reaction between NO_2 and CH_3OH.

In previous papers, we suggested reaction pathways to form C_1-oxygenates in the gas phase reaction of CH_4–O_2–NO_2.[1–4] The rate-determining step is hydrogen abstraction from methane with an activation energy of 37.6 kcal mol^{-1} at 800 K. The lowering of the initial reaction temperature upon CH_3OH addition indicated the presence of other lower barrier reaction pathways for the dissociation of methane. Furthermore, the enhancement of CH_4 conversion indicated the presence of radical chain reactions. We considered the most probable reaction between CH_3OH and NO_2 [eqn. (1)]:

$$CH_3OH + NO_2 \rightarrow CH_2OH + HNO_2 \quad (1)$$

Our theoretically obtained value for the activation energy of eqn. (1) was 28.4 kcal mol^{-1} at 800 K calculated using the Gaussian94 *ab initio* program package and was close to that reported by Bromly *et al.*[10] The produced CH_2OH was assumed to react easily with O_2 to produce formaldehyde [eqn. (2)]:

$$CH_2OH + O_2 \rightarrow CH_2O + HO_2 \quad (2)$$

This HO_2 could then react with CH_4 [eqn. (3)]:

$$CH_4 + HO_2 \rightarrow CH_3 + H_2O_2 \quad (3)$$

Since the reported[10] activation energy of eqn. (3) was 24.6 kcal mol^{-1} and is lower than 37.6 kcal mol^{-1} for the activation energy of hydrogen abstraction from methane, we considered that this difference lowered the commencement temperature of CH_4 conversion.

The higher selectivity of produced methanol is explained by assuming that the subsequent oxidation of methanol is retarded under the reaction conditions.

Charge-transfer in a π-stacked fullerene porphyrin dyad: evidence for back electron transfer in the 'Marcus-inverted' region

Dirk M. Guldi,*[a] Chuping Luo,[a] Maurizio Prato,*[b] Elke Dietel[c] and Andreas Hirsch*[c]

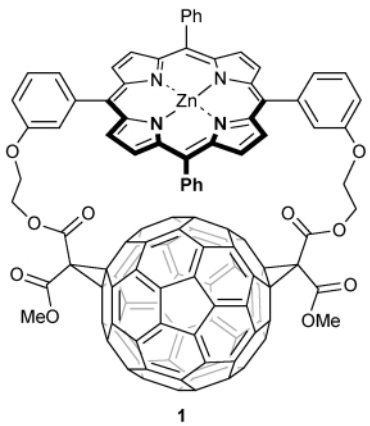
Received (in Cambridge, UK) 18th Decmeber 1999, Accepted 2nd February 2000

The 'Marcus-inverted' region for BET in a π–π stacked fullerene–porphyrin dyad was determined based on (i) the photoactivation of an intramolecular ET in a variety of solvents and (ii) the formation of a highly energetic charge-separated state

Photoinduced electron transfer (ET) to fullerenes is a subject of current interest.[1] Specifically, the moderate first reduction potentials of fullerenes[2] and their small reorganization energies in ET reactions[3] make them excellent building blocks for the design of novel donor–acceptor systems. According to the Marcus theory, electron transfer rates (k_{ET}) are expected to exhibit a parabolic dependence on the free energy gap of the electron transfer ($-\Delta G°_{ET}$).[4] In particular, k_{ET} decreases as the reaction becomes more exergonic, especially at large $-\Delta G°_{ET}$. The maximum of the theoretically expected bell-shaped energy gap dependence (*i.e.* $-\Delta G° \approx \lambda$, [$\lambda$ = reorganization energy (Marcus theory)]) is largely controlled by the nuclear reorganization energy including the solvent reorganization associated with the ET. Surprisingly, experimental support to ET kinetics clearly occurring in the inverted region, is limited to charge recombination processes in geminate radical pairs[5] and a few examples of non fullerene-containing donor–acceptor dyads.[6] In order to optimise the stability of a charge-separated state (*i.e.* retarding charge recombination) it is desirable to reach the thermodynamic maximum at small $-\Delta G°$ values and, thus, to push the exergonic back electron transfer (BET) into the 'Marcus-inverted' region. The small reorganization energy of the rigid C_{60} cage should be an ideal prerequisite to shift the maximum of the 'Marcus parabola' to smaller values and BET in fullerene-based donor–acceptor arrays is proposed to be decelerated compared with two-dimensional electron acceptors. Here, we present the first experimental evidence for an electron transfer within a C_{60} based compound in the 'Marcus-inverted' region.

The model compound that we used in this study is the π–π stacked C_{60}–ZnTPP dyad **1** involving a *trans*-2 addition pattern,[7] which we reported recently.[8] The fluorescence quantum yield of **1**, is strongly quenched ($\Phi = 1.26 \times 10^{-4}$) relative to a ZnTPP reference complex ($\Phi = 0.04$) even in a non-polar toluene solution. Similarly low fluorescence quantum yields were found in tetrahydrofuran ($\Phi = 1.16 \times 10^{-4}$), dichloroethane ($\Phi = 1.37 \times 10^{-4}$) and benzonitrile ($\Phi = 1.37 \times 10^{-4}$). This points to a very efficient electronic communication between the two moieties in the excited state. Significantly, the texture of the ZnTPP fluorescence is still preserved. Assuming that the lifetime of the ZnTPP singlet excited state is 2700 ps, the lifetime of the chromophore in dyad **1** can be estimated to be *ca.* 8.5 ps corresponding to an intramolecular rate constant of 1.18×10^{11} s^{-1}. The new emission band,[7] centered around 820 nm, was found exclusively in toluene solutions and is missing in the other solutions. To characterize this emission band, the phosphorescence of a ZnTPP reference compound was probed. The resemblance of the ZnTPP phosphorescence with the emission band of **1** in toluene suggests the spin-forbidden phosphorescence of the ZnTPP chromophore. The lifetime of the 820 nm emission band (τ = 2.84 ns)[7] matches nicely the proposed energy transfer rate measured by picosecond-resolved transient absorption spectroscopy (see below).



1

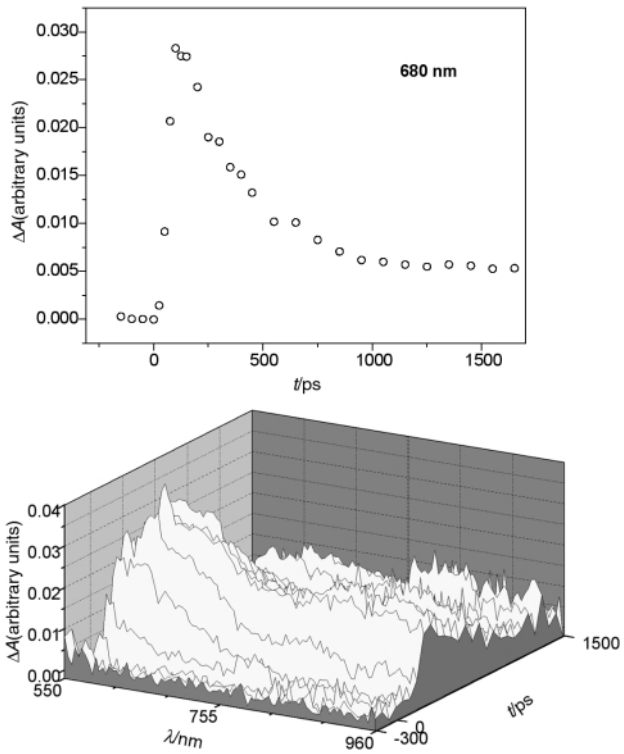


Fig. 1 (a) Differential absorption spectra obtained upon picosecond flash photolysis (532 nm) of *ca.* 10^{-5} M solutions of dyad **1** in nitrogen saturated toluene with time delays between −300 and 1500 ps. (b) Time-absorption profiles at 680 nm (*i.e.* maximum of the $ZnP^{\bullet+}$ absorption).

Table 1 Photophysical properties of dyad **1** in various solvents

Solvent	ε^a	$10^4\ \Phi$ (fluorescence)	τ (radical pair)/ps	$\Delta G_{CR}°$/eV	$\Delta G_{ET}°$/eV	Product
Toluene	2.38	1.26	619	1.536	0.524	Triplet excited state
Tetrahydrofuran	7.6	1.16	385	1.452	0.608	Singlet ground state
Dichloromethane	9.08		121	1.445	0.615	Singlet ground state
Dichloroethane	10.19	1.37	66	1.441	0.619	Singlet ground state
Benzonitrile	24.8	1.37	38	1.424	0.636	Singlet ground state

[a] Dielectric constant.

In order to measure the absolute quenching rate constants and to unravel the underlying mechanism, **1** was studied in various solvents by means of picosecond-resolved transient absorption spectroscopy. In all solvents used, **1** gives rise to the rapid formation of the ZnTPP π-radical cation absorption between 670 and 680 nm (Fig. 1). However the rise time, representing the actual forward ET process, is masked by the instrument response time. Thus, we can only provide an upper limit of the ZnTPP lifetime, for example, in a toluene solution of ~35 ps. Despite this inaccuracy, the estimate is in reasonably good agreement with the steady-state emission study.

Taking into account the strong fluorescence quenching and the formation of $ZnTPP^{\bullet+}$, we can conclude that electron transfer prevails in the deactivation of the ZnTPP singlet excited state, to yield the $C_{60}^{\bullet-}$–$ZnTPP^{\bullet+}$ pair. In line with the spectral identification of the $C_{60}^{\bullet-}$–$ZnTPP^{\bullet+}$ pair is the assumption, which is based on the thermodynamic driving force ($-\Delta G_{ET}°$) for an intramolecular electron transfer from the photoexcited ZnTPP. The $\Delta G_{ET}°$ values are approximated by:

$$\Delta G_{ET}° = -[E^*_{0\text{–}0} + \Delta G_{CR}°] \quad (\text{with } \Delta G_{CR}° = -[\Delta E° + e^2/d\varepsilon_S]) \quad (1)$$

and summarized in Table 1.

The fact that ET rather than energy transfer events govern the fate of the photoexcited ZnTPP chromophore, can be rationalized by the close packing of the two moieties. This clearly reflects the higher efficiency of an electron exchange mechanism compared with a dipole–dipole energy transfer mechanism.

As determined by transient absorption spectroscopy the product of the charge-recombination is the singlet ground state in any solvent [eqn. 2(a)]. The only exception is toluene [eqn. 2(b)]: Nanosecond-resolved photolysis confirmed the

$$C_{60}^{\bullet-} - ZnTPP^{\bullet+} \xrightarrow{\text{BET}} C_{60} - ZnTPP \quad (2a)$$

$$C_{60}^{\bullet-} - ZnTPP^{\bullet+} \xrightarrow{\text{BET}} C_{60} - {}^3{*}ZnTPP \xrightarrow{\text{EnergyT}} {}^3{*}C_{60} - ZnTPP \quad (2b)$$

formation of the fullerene triplet excited state with an overall quantum efficiency of 0.196. To shed further light onto the exact formation mechanism, we reinvestigated the dynamics of **1** in toluene on the picosecond time scale. Here, the radical pair (1.54 eV) decays *via* a transient intermediate, before the fullerene triplet excited state evolves (τ = 3970 ps). Based on the close spectral reminiscence with the ZnTPP triplet excited state we propose the formation of the latter state as an intermediate step towards the fullerene triplet excited state. Its excited state energy (1.53 eV) is then a sufficient promoter to activate an intramolecular triplet–triplet energy transfer to the lower lying fullerene triplet (1.50 eV).

In more polar solvents the energy of the radical pair state is decreased (< 1.45 eV; see Table 1) and, as a consequence, charge recombination, yielding the porphyrin or fullerene triplet excited state is thermodynamically hindered. Instead, direct generation of the singlet ground state takes place [eqn. 2(a)].

The clean decay kinetics of the π-radical cation absorption allowed us to measure the lifetime of the radical pair as a function of solvent polarity. The lifetime is subject to an interesting trend: The lifetimes in tetrahydrofuran (τ = 385 ps) and dichloromethane (τ = 122 ps) are markedly increased relative to the more polar solvents dichloroethane (τ = 61 ps) and benzonitrile (τ = 38 ps) (Table 1). This dependency prompts to an important conclusion: The rates of the back electron transfer processes, from the $C_{60}^{\bullet-}$–$ZnTPP^{\bullet+}$ state to the ground state, are clearly in the 'Marcus-inverted' region [*e.g.* a region in which larger free energy changes ($-\Delta G°_{ET}$) lead to slower electron transfer rates (k_{ET})].

Since the correct choice of intermolecular separation is essential to the efficiency of light-driven electron transfer, especially in light of guaranteeing $-\Delta G° > \lambda$, a comparison of **1** with non-fullerene systems, that have similar van der Waals contacts, was deemed necessary. In these systems,[6e,g] the inverted BET reactions are activated only at values exceeding 1.9 eV, while in **1** the 'Marcus-inverted' region was established even at values smaller than 1.5 eV. This underlines the unique role of [60]fullerene, possessing a smaller reorganization energy than two-dimensional acceptor moieties, as a novel electron acceptor.

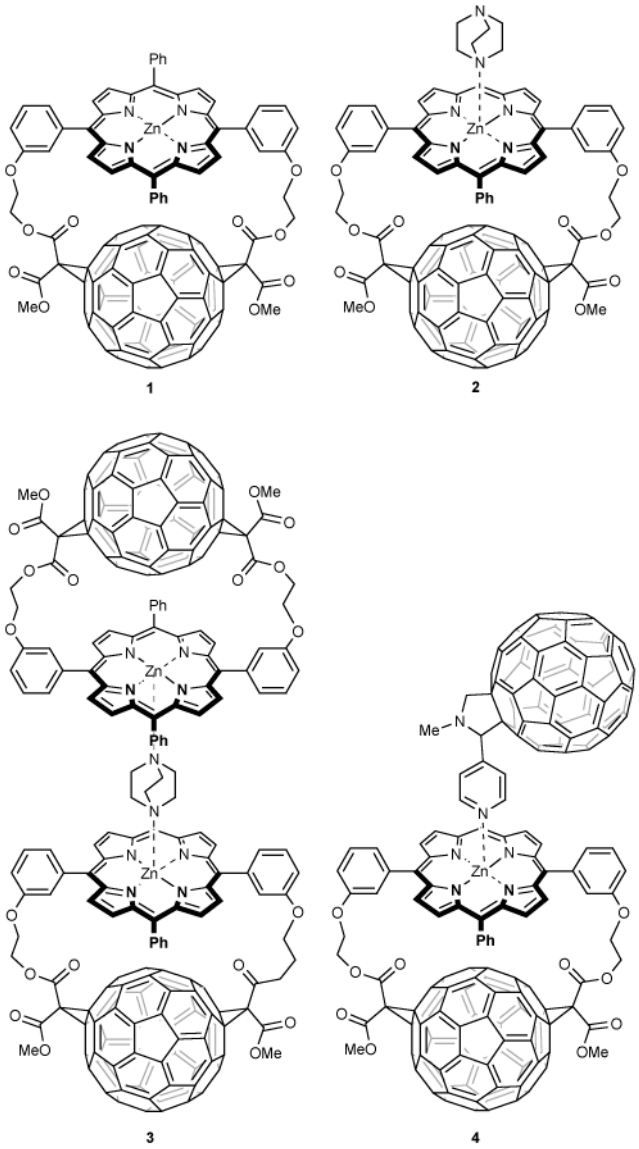
Received (in Cambridge, UK) 8th December 1999, Accepted 2nd February 2000

The kinetics of photoinduced electron transfer in new multicomponent arrays of a π-stacked fullerene porphyrin dyad and diazabicyclooctane or a fulleropyrrolidine ligand have been determined and depend on the molecular architecture

Owing to the importance of converting sunlight into electric current, suitable models are needed for the mimicry of the primary events in natural photosynthesis. A viable approach to artificial photosynthesis is to organize the donor–acceptor couple *via* covalent linkage and, thereby, controlling the separation and electronic coupling. To optimize the performance of such artificial systems, incorporation of secondary electron donor or acceptor moieties into multicomponent arrays (triads, tetrads, pentads *etc.*) has attracted considerable attention. Recently, different alternatives to address the critical issue of organizing the donor–acceptor couples has been forwarded, for example the assembly of individual molecules, linked by weak intermolecular interactions such as van der Waals' forces, hydrogen bonding, salt bridges or by complexation with metals.[1] In this contribution we present the formation and photophysical properties of new rigid electroactive arrays that evolve from complexation of a π–π stacked C_{60}-based ZnTPP dyad **1**[2] with diazabicyclooctane (DABCO) or a pyridine–fullerene ligand.[3]

The facile and selective formation of triad **2** or pentad **3** is based on the pronounced concentration dependence of ZnTTPs to form either square pyramidal 1:1- or 2:1 complexes with diazabicyclooctane (DABCO), respectively.[4] In analogy to related fullerene free TPPs[4] at low concentrations (*e.g.* 10^{-6} M) the exclusive formation of **2** was observed as shown, for example, with the titration experiment depicted in Fig. 1. Owing to the complexation the absorptions of the TPP moiety undergo a bathochromic shift of 9–10 nm which is very characteristic for a 1:1 complex.[4] The bathochromic shifts in 2:1 complexes are less pronounced (5–6 nm).[4] At higher concentrations the formation of the pentad **3** prevails. Titration of a 4.3×10^{-2} M solution of **1** in $CDCl_3$ with DABCO under ^{1}H NMR control showed the immediate appearance of one signal only for the 12 methylene protons of the axial ligand at δ −4.5 clearly demonstrating that exclusively **3** is formed. After the addition of 0.5 equiv. of DABCO only **3** can be detected in the NMR spectrum and all of free **1** is consumed. Upon formation of **3** the signals of the ZnTPP protons undergo an up-field shift of up to 0.5 ppm. Up-field shifts of up to 1 ppm for the ZnTPP C atoms and of 8.23 ppm for the C atoms of DABCO are observed in the ^{13}C NMR spectrum of **3**. Addition of more DABCO results in the formation of **2** being in an equilibrium with **3** as demonstrated by the appearance of a second signal for the DABCO ligand at δ −2.50 belonging to the three outer methylene groups of **2**. Similarly, triad **4** was prepared by mixing equimolar solutions of **1** and the corresponding fulleropyrrolidine.[3,5,6] The reversible formation of the complex was followed by visible and by ^{1}H NMR spectroscopies. In the former technique, a bathochromic shift of the porphyrin bands



was observed, in analogy to **2**, whereas in the proton NMR a considerable upfield shift of the pyridine *2*-protons confirmed the presence of an equilibrium between **1** and the fulleropyrrolidine.[5]

Picosecond excitation of triad **2** resulted in the rapid transformation of the ZnTPP singlet excited state into a new transient, which displays a broad absorption maximum around 680 nm. Since the absorption spectrum is in close agreement with that of dyad **1**, we conclude that a rapid intramolecular electron transfer to yield a charge-separated radical pair follows the initial excitation event. The lifetime of the charge-separated

DOI: 10.1039/a909659k

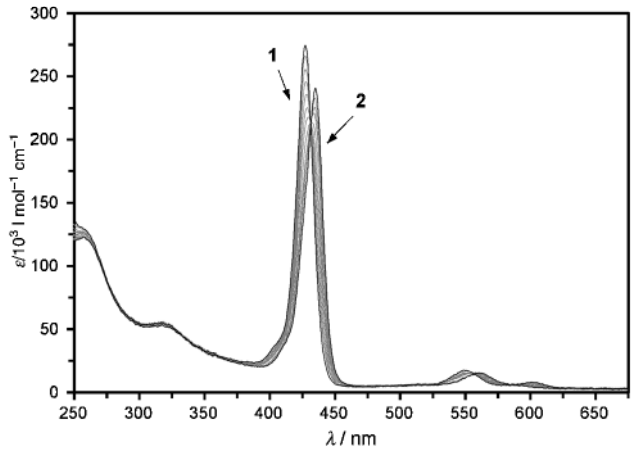


Fig. 1 Titration of **1** with DABCO in CH_2Cl_2: The appearance of **2** and disappearance of **1** is monitored by UV–VIS-spectroscopy.

state in triad **2** (1980 ± 30 ps) gives rise to a significant enhancement over dyad **1** (619 ps). Interestingly, the transient absorption spectra still revealed the characteristics of the ZnTPP π-radical cation. A reasonable rationalization for this observation implements the close energy of the $C_{60}^{\bullet-}$–$ZnTPP^{\bullet+}$–DABCO and $C_{60}^{\bullet-}$–ZnTPP–$DABCO^{\bullet+}$ states, as estimated by the oxidation potentials of the ZnTPP and DABCO electron donors. This leads to the assumption that the positively charge may be distributed over both moieties. In line with this assumption is the fact that the fullerene triplet quantum yield (*e.g.* the product of charge-recombination) did not change upon addition of the secondary electron donor (*i.e.* dyad **1** *cf.* triad **2**).

A qualitative similar picture was obtained with pentad **3**. Immediately after excitation of **3** in toluene the increase of absorbance between 600 and 800 nm is consistent with the formation of the radical pair, observed for dyad **1** and triad **2**. The kinetics of charge-recombination, as monitored around 660 nm, followed again first order kinetics, with a lifetime of 2280 ps.

As a viable alternative to DABCO (*e.g.* electron donor), addition of a fullerene derivative bearing a pyridine functionality (*e.g.* electron acceptor) to a toluene solution of dyad **1** was probed. In this context, the strong fluorescence quenching of **1** should be taken into account. Thus, addition of variable concentrations of the fullerene ligand ($0.5–5.0 \times 10^{-5}$ M) failed to show any meaningful effects on the fluorescence quantum yield of the resulting triad **4**. Photolysis (532 nm) of triad **4** in toluene or benzonitrile did not lead to any noticeable changes, relative to those described for dyad **1**. Owing to the rapid electron transfer occurring between the ZnTPP chromophore and the π–π stacked fullerene, the competing electron transfer route to the coordinated fullerene ligand is too slow that the latter reaction may contribute to the overall deactivation of the ZnTPP singlet excited state. Dramatic changes were, however, noted upon generating the fullerene singlet excited state (excitation at 337 nm). Now photoinduced electron transfer can be activated from both fullerene moieties, namely, the covalently linked one, which is still very fast (*e.g.* within the time-resolution of the apparatus) and the coordinatively one. Since benzonitrile is used as a solvent, its ability to coordinate to the zinc center and, therefore, interference with the fullerene–ligand complexation equilibrium between dyad **1** and triad **4** should be considered. This divides a reaction between the photoexcited fullerene and the ZnTPP into two processes. In particular, a fast intramolecular reaction (*ca.* 10^{10} s^{-1}) between the fullerene singlet excited state in the coordinated complex (triad **4**) is followed by a much slower intermolecular reaction (1.7×10^{10} $M^{-1}s^{-1}$) between the fullerene triplet excited state and the free dyad **1**. Spectroscopic evidence for this mechanism stems from the fact that the differential absorption changes reveal a two step formation of the $C_{60}^{\bullet-}/ZnTPP^{\bullet+}$ radical pair grow-in around 1010 and 680 nm, respectively.

In conclusion, we have shown that the reversible complexation of diazabicyclooctane or a fulleropyrrolidine ligand by a π–π stacked C_{60}–ZnTPP dyad **1** is a viable concept to construct novel supramolecular architectures. Rapid photoinduced electron transfer reactions in these multicomponent assemblies lead to charge-separated states, whose lifetimes are markedly improved relative to dyad **1**.

Synthesis, resolution and crystallographic characterization of a new C_2-symmetric planar-chiral bipyridine ligand: application to the catalytic enantioselective cyclopropanation of olefins

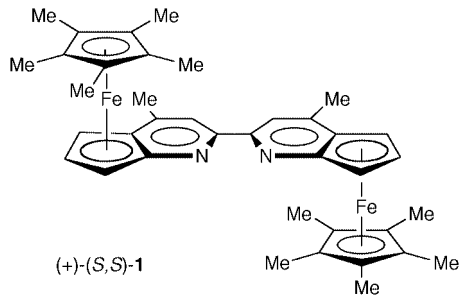
Ramon Rios, Jack Liang, Michael M.-C. Lo and Gregory C. Fu*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA. E-mail: gcf@mit.edu

Received (in Corvallis, OR, USA) 29th November 1999, Accepted 26th January 2000

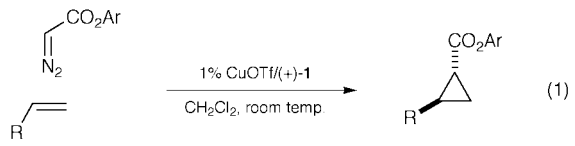
The synthesis of a new C_2-symmetric planar-chiral bipyridine ligand is described, as well as its application to the enantioselective Cu^I-catalyzed cyclopropanation of olefins.

As Togni and Venanzi have recently documented, the use of transition metal catalysts that employ nitrogen-donor ligands is expanding rapidly.[1] With respect to neutral, bidentate, nitrogen donors, 2,2′-bipyridine is one of the most widely used.[2,3] As a consequence, the development of an effective chiral derivative of bipyridine is a challenge of considerable importance.[4,5] We have recently been exploring the application of planar-chiral heterocycles in asymmetric catalysis, both as enantioselective nucleophilic catalysts[6] and as chiral ligands for transition metals.[7] Here we describe our first investigation in the area of chiral bipyridine chemistry, specifically, the synthesis, resolution and crystallographic characterization of C_2-symmetric planar-chiral ferrocene derivative **1**. To benchmark this new



(+)-(*S*,*S*)-**1**

ligand, we have chosen to follow the lead of others by examining its utility in the Cu^I-catalyzed cyclopropanation of olefins [eqn. (1)].[8–10]



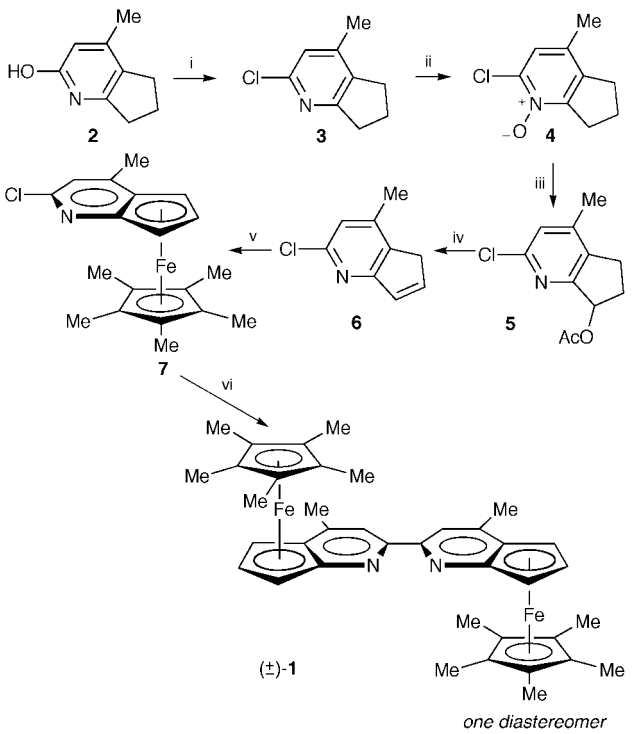
R = aryl, alkyl, silyl *up to 94% ee*

Our synthesis of ligand **1** begins with previously reported pyridine derivative **2**,[11] which is available in one step from commercially available materials (Scheme 1). Chlorination with $POCl_3$ affords compound **3** in 74% yield, and a standard sequence of oxidation, acetoxylation and elimination then furnishes pyrindine **6**.[6a] The five-membered ring of **6** is complexed to iron through reaction of its lithium salt with $(Cp^*FeCl)_n$ (59%),[6a] and the resulting ferrocene derivative is then reductively coupled with $NiBr_2(PPh_3)_2$/Zn/Et_4NI,[12] thereby providing racemic **1** as a single diastereomer in 58% yield. This route is amenable to the synthesis of multi-gram quantities of this new C_2-symmetric, planar-chiral bipyridine ligand.

The enantiomers of ligand **1** can be separated by chiral HPLC (Regis Whelk-O column). We have established the absolute configuration of (+)-**1** through X-ray crystallography.

In order to validate our ligand design, we chose to investigate the application of bipyridine **1** to the Cu^I-catalyzed cyclopropanation of olefins, a reaction that has previously been used to benchmark new chiral bipyridine designs.[8] We were pleased to observe that with the 2,6-di-*tert*-butyl-4-methylphenyl ester of diazoacetic acid as the carbene source, we can cyclopropanate an array of olefins with high stereoselectivity (Table 1). For example, treatment of styrene with 1% CuOTf, 1.2% (+)-**1**, and 2 equiv. of diazo ester in CH_2Cl_2 at room temperature furnishes the *trans*-cyclopropane in very good diastereomeric and enantiomeric excess (94% de, 87% ee; Table 1, entry 1). The stereoselection remains unchanged even at a very low catalyst loading (0.25%), although the yield drops somewhat (60%). It is worth noting that, in contrast to many previously reported Cu^I-catalyzed cyclopropanations wherein the diazo ester is the limiting reagent, our conditions employ the olefin as the limiting reagent. Among the copper sources and the solvents that we have examined, CuOTf and CH_2Cl_2 appear to be optimal.

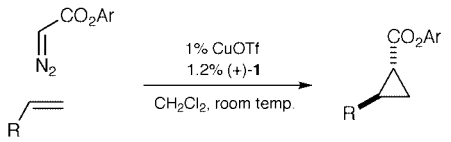
In the presence of CuOTf/**1**, we can effect the catalytic enantioselective cyclopropanation of an array of olefins (Table



Scheme 1 *Reagents and conditions*: i, $POCl_3$, 74%; ii, H_2O_2, AcOH, 88%; iii, Ac_2O, 58%; iv, H_2SO_4, 79%; v, BuLi, then $(Cp^*FeCl)_n$, 58%; vi, 30% $NiBr_2(PPh_3)_2$, Zn, Et_4NI, 58%.

DOI: 10.1039/a909457a

Table 1 Scope of the Cu^{I}/**1**-catalyzed enantioselective cyclopropanation of olefins[a]



Entry	R	*trans*:*cis*	Ee (%) (*trans*)	Yield (%)
1	Ph	97:3	87	78
2	*p*-(MeO)C_6H_4	95:5	75	71
3	*p*-(F_3C)C_6H_4	94:6	94	83
4	*n*-Hexyl	94:6	78	78
5	Et_3Si	96:4	80	60

[a] All data represent the average of two runs.

1). For styrene derivatives, we have made the interesting observation that whereas the electronic nature of the aromatic ring has only a modest effect on *trans*:*cis* diastereoselectivity, it exerts a very significant impact on enantioselectivity (entries 1–3). Thus, reaction of electron-rich 4-methoxystyrene proceeds with relatively moderate ee (75%, entry 2), whereas reaction of electron-poor 4-trifluoromethylstyrene occurs with quite high ee (94%, entry 3). Alkyl-substituted olefins (entry 4) and vinylsilanes (entry 5) undergo cyclopropanation with excellent diastereoselectivity and good enantioselectivity.

An examination of the X-ray crystal structure of [Cu((−)-**1**)(styrene)]PF_6† clearly shows that bidentate complexation of ligand **1** to copper furnishes a well-defined C_2-symmetric binding pocket [Fig. 1(*a*)]. The styrene is bound to copper in an orientation that is predictable on the basis of minimizing steric interactions with ligand **1** [Fig. 1(*b*)].

In summary, we have described the synthesis, resolution and crystallographic characterization of a new class of C_2-symmetric planar-chiral bipyridine ligands, and we have demonstrated the effectiveness of our ligand design through a study of Cu^{I}-catalyzed cyclopropanations of olefins. The chiral environment afforded by this family of bidentate ligands should be readily tunable, both through a change in the metal fragment (*e.g.* FeCp* → FeC_5Ph_5[6b]) and through the incorporation of substituents in the 7 and 7′ positions. The large number of processes known to be catalyzed by bipyridine–metal complexes provides a wealth of opportunities for applications of these ligands in asymmetric catalysis.

Support has been provided by the Alfred P. Sloan Foundation, the American Cancer Society, Bristol-Myers Squibb, the Camille and Henry Dreyfus Foundation, Merck, the National Science Foundation, Novartis, Pfizer, Pharmacia & Upjohn, Procter & Gamble, the Spanish Ministry of Education, and Union Carbide.

Received (in Cambridge, UK) 11th January 2000, Accepted 2nd February 2000

Zirconium complexes of two dianionic amine bis(phenolate) ligands have been synthesized, their X-ray structures solved, and their activity as hex-1-ene polymerization catalysts studied; upon treatment with $B(C_6F_5)_3$, an octahedral $[ONNO]Zr(CH_2Ph)_2$ complex, having an extra N-donor group on a side arm, shows exceptionally high polymerization activity and yields a high molecular weight poly(hex-1-ene), whereas a related pentacoordinate $[ONO]Zr(CH_2Ph)_2$ complex, having no extra donor group, shows only poor activity as a polymerization catalyst.

The increased interest in development of novel catalysts for polymerization of α-olefins has resulted in the introduction of a variety of non-metallocene group 4 metal complexes.[1] Most interest was drawn to pre-catalysts based on chelating di(amido) ligands,[2] while di(alkoxo) based pre-catalysts have attracted more limited attention.[3] Recently, we introduced the amine bis(phenolate) family of ligands to group 4 transition metal chemistry.[4] Here, we report on the synthesis, structure and hex-1-ene polymerization activity of two zirconium dibenzyl complexes of related amine bis(phenolate) ligands: a tetradentate $[ONNO]^{2-}$ ligand and a tridentate $[ONO]^{2-}$ ligand.

The ligand precursor $[ONNO]H_2$ **1** reacted cleanly with 1 mol equiv. of tetrabenzylzirconium at 65 °C yielding the dibenzyl complex $[ONNO]Zr(CH_2Ph)_2$ **2**, quantitatively, as a yellow crystalline solid (Scheme 1).† The spectral data of **2** indicate the formation of a rigid C_s symmetrical complex having symmetry related phenolate rings and two different benzyl groups.

The X-ray structure of **2** (Fig. 1)‡ features a complex having a slightly distorted octahedral geometry, in which the two oxygen atoms of the phenolate rings are in a *trans* configuration. Most importantly, the *cis* configuration of the two benzyl groups, expected from the arrangement of the donor atoms in this $[ONNO]^{2-}$ tetradentate ligand, is evident from the narrow C–Zr–C angle of 93.7°. A narrow angle between the active positions may facilitate the formation of a metallacyclobutane, in the rate determining step of the polymerization of α-olefins.[5]

The tridentate ligand precursor $[ONO]H_2$ **3**, having identical phenolate groups but lacking the extra donor group on the side arm, also reacted cleanly with 1 mol equiv. of tetrabenzylzirconium at 65 °C yielding the formally penta-coordinate dibenzyl complex $[ONO]Zr(CH_2Ph)_2$ **4**, quantitatively, as a yellow crystalline solid (Scheme 2).†

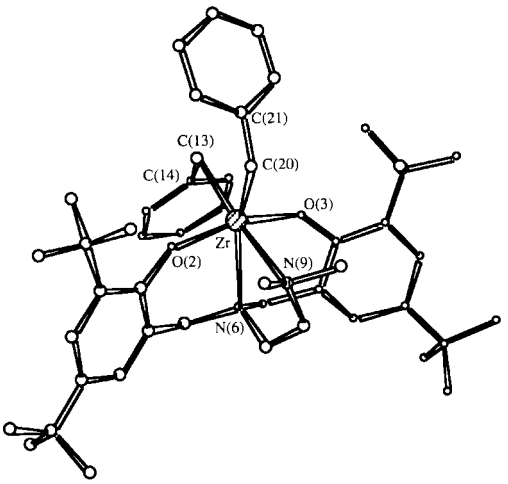

Fig. 1 Molecular structure of **2**. Selected bond lengths (Å) and angles (°): Zr–O(2) 1.995(5), Zr–O(3) 1.994(5), Zr–N(6) 2.446(6), Zr–N(9) 2.594(6), Zr–C(13) 2.305(7), Zr–C(20) 2.250(6); O(2)–Zr–O(3) 160.3 (2), N(6)–Zr–N(9) 69.7(2), C(13)–Zr–C(20) 93.7(2), Zr–C(13)–C(14) 104.9(5), Zr–C(20)–C(21) 115.8(5).

Interestingly, a homoleptic complex of the type $[ONO]_2Zr$, was not formed, apparently due to the steric effect of the *tert*-butyl groups in the *ortho* position of the phenolate rings.[4] In analogy to **2**, the spectral data of **4** also indicated the formation of a rigid C_s symmetrical complex having symmetry related phenolate rings and two different benzyl groups. However, the X-ray crystal structure of **4** indicated several differences between it and **2** (Fig. 2).‡

The structure features a complex having a pseudo-trigonal bipyramidal geometry, with axial O atoms and equatorial N, C, C atoms, as evident from an O–Zr–O angle of 157.3°, and sum of angles between the equatorial substituents around the zirconium of 360°. The angle between the two benzyl groups in **4** is much wider than in **2**, at 117.4°. An acute Zr–CH_2–C(Ar) angle of 89.4° as well as a short Zr–C(Ar) distance of 2.71 Å, for one of the benzyl groups, indicate that the π-system interacts with the metal, *i.e.* there is a non-classical η^2 binding of this group to the Zr atom.[6] The η^2 binding in **4** may reflect the

electron deficiency of this complex relative to **2**, or may simply result from the lower crowding around the metal, allowing the bending of one of the benzyl groups. It is noteworthy that the central nitrogen and the two phenolate rings bind very similarly in **2** and **4**, despite the additional donor in **2**, and difference in benzyl hapticities.

Which of these systems is expected to lead to a better catalyst for polymerization of α-olefins? Since additional donor groups have been reported to increase the reactivity in certain systems[7] and reduce the reactivity in other systems,[8] this prediction is not straightforward. **2** proved to be an extremely reactive catalyst in the presence of tris(pentafluorophenyl)borane: adding 0.01 mmol of **2** and 1 mol equiv. of $B(C_6F_5)_3$ to 10 mL of neat hex-1-ene at room temperature, initiated a fast polymerization reaction accompanied by heat release, causing boiling of the hex-1-ene.§ The monomer reacted almost completely within 2 min giving an activity of 15 500 g $mmol_{cat}^{-1}$ h^{-1}. To the best of our knowledge, this is the highest reactivity reported for polymerization of hex-1-ene under such mild conditions, namely a dibenzyl complex[9] activated by the mild Lewis acid tris(pentafluorophenyl)borane.[2a,10] In order to restrain the polymerization, the monomer was diluted in an inert solvent, and the quantity of catalyst was reduced. Thus, adding 0.005 mmol of **2** and 1 mol equiv. of $B(C_6F_5)_3$ to 3 mL of hex-1-ene in 7 mL of heptane resulted in a slower evolution of heat, and linear consumption of the monomer for 8 min, after which time 80% had reacted. The polymer obtained had a molecular weight of M_w = 170 000 and PDI M_w/M_n = 2.2, indicating that the catalytic system is homogeneous.

In contrast, **4** yielded a poor hex-1-ene polymerization catalyst: adding 0.01 mmol of **4** and 1 mol equiv. of $B(C_6F_5)_3$ to 2 mL of neat hex-1-ene at room temperature, yielded only oligo(hex-1-ene) chains (30 mg), giving a low activity of 23 g $mmol_{cat}^{-1}$ h^{-1}. Olefinic termination groups were observed in the ^1H NMR spectra, integration of which indicated an average of < 20 units of monomer per chain.

In summary, of the two amine bis(phenolate) zirconium complexes that were introduced, that having an extra donor arm was about three orders of magnitude more reactive than its counterpart. We therefore propose that the side arm nitrogen of the $[ONNO]^{2-}$ ligand remains attached to the metal in the reactive catalyst. Since the extra donor is supposed to *lower* the electrophilicity of the zirconium complex, it seems that, at least for these systems, electrophilicity does not play a major role in determining the polymerization activity.[11] The extreme reactivity of the catalyst derived from the $[ONNO]^{2-}$ ligand may result from steric effects, *e.g.* a narrow angle between the growing polymer chain and a coordinated olefin, as well as electronic effects induced by the N-donors being *trans* to the active positions. The synthesis of related systems and their application as polymerization catalysts is currently under way.

This research was supported in part by the Israel Science Foundation founded by the Israel Academy of Sciences and Humanities. We thank Sima Alfi (BIU) for technical assistance.

High turnover number of γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$ for oxygenation of cyclohexane with 1 atm molecular oxygen†

Tetsuya Hayashi, Asako Kishida and Noritaka Mizuno*

Department of Applied Chemistry, Graduate School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: tmizuno@mail.ecc.u-tokyo.ac.jp

Received (in Cambridge, UK) 24th December 1999, Accepted 3rd February 2000

An all-inorganic oxo-bridged dimanganese-containing silicotungstate, γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$, showed the highest turnover number of 789 among various metal-substituted silicotungstates for the oxygenation of cyclohexane with 1 atm molecular oxygen; this is the highest level when compared with other catalysts reported so far.

Catalytic oxygenation of alkanes has attracted much attention. The utilization of molecular oxygen for catalytic oxygenation is a rewarding goal because among oxidants molecular oxygen has the highest content of active oxygen and forms no by-products.[1–7] Reducing reagents or radical initiators have been added for in an attempt to facilitate reaction lowering the reaction temperature and resulting in the suppression of overoxidation of oxygenated products.[8–13] However, there are only a few examples of ideal homogeneous oxygenation systems for alkanes with molecular oxygen in the absence of reducing reagents or radical initiators because of catalyst deactivation and difficulty of C–H bond/oxygen activation.[1–24] The oxidation of cyclohexane has been industrialized by using a cobalt catalyst with pressurized molecular oxygen above 423 K, low conversions, however, are a drawback in suppressing overoxidation of the products.[5,25,26] It is clearly desirable if oxygenation can be carried out with higher turnover numbers under milder conditions. Fe(DPA) (DPA = 2,6-dicarboxylatopyridine), $K[Ru^{III}(saloph)Cl_2]$ [saloph = *N*,*N*′-*o*-phenylenebis(salicylideneaminato)] $PW_9O_{37}\{Fe_{3-x}Ni_x(OAc)_3\}^{(9+x)-}$ (*x*) = predominantly 1) and γ-$SiW_{10}\{Fe^{III}(OH_2)\}_2O_{38}^{6-}$ are examples of catalysts for cyclohexane oxygenation with 1 atm molecular oxygen.[14–16,20]‡ Cobalt-containing aluminophosphate and $[Co(NCMe)_4](PF_6)_2$ have also been reported to be active for oxygenation of cyclohexane with pressurized molecular oxygen.[21–24] However, the turnover numbers are low at < 180.

Little is known of the structures of the active manganese centers for the oxygenation of cyclohexane with molecular oxygen. Here, we report that the oxo-bridged dimanganese-containing silicotungstate, γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$, can efficiently catalyze the oxygenation of cyclohexane with 1 atm molecular oxygen.

Cyclohexane was distilled and treated with activated alumina to remove impurities and cyclohexyl hydroperoxide. The other reagents were commercially obtained and used as received. The reaction was carried out in a glass vial containing a magnetic stir bar as described previously.[27] The reaction solution was periodically sampled and analyzed by gas chromatography on TC-WAX capillary columns. The oxidation of cyclohexane did not proceed without catalyst under the present conditions.

Cyclohexanol and cyclohexanone were mainly formed after an induction period for the catalytic oxygenation of cyclohexane with 1 atm molecular oxygen catalyzed by γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$ at 365 K. Only small amounts of dicyclohexyl and cyclohexyl hydroperoxide were observed and neither acids, oxoesters nor carbon oxides were observed. The selectivities changed little with time. The conversion was 6.4%, and the turnover number of γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$ reached 789 after 96 h, much higher than values reported for the oxygenation of cyclohexane catalyzed by Fe(DPA)/O_2(1 atm),[14] $K[Ru(saloph)Cl_2]/O_2$ (1 atm),[15] γ-$SiW_{10}\{Fe^{III}(OH_2)\}_2O_{38}^{6-}/O_2$ (1 atm),[20] $[Co(NCMe)_4](PF_6)_2/O_2$ (3 atm)[21] or cobalt-containing aluminophosphate/O_2 (15 atm).[23] In addition, the value was higher than those of 130, 90, 5 and 3 reported for $Mn(acac)_2$/NHPI (NHPI = *N*-hydroxyphthalimide),[11] $Co(acac)_2$/NHPI,[13] $[\{Fe(HBpz_3)(hfacac)\}_2O]$-/Zn ($HBpz_3$ = hydrotris(1-pyrazolyl)borate, hfacac = 1,1,1,5,5,5-hexafluoroacetylacetone)[28] and $[R_fMn(R_fTACN)]^{2+}$/TBHP (R_fTACN = tris-*N*-(4,4,5,5,6,6,7,7,8,8,9,9,10,10,11,11,11-heptadecafluoroundecyl)-1,4,7-triazacyclononane; R_f = C_8F_{17})[12] systems, respectively, which work in the presence of reducing reagents or radical initiators with 1 atm molecular oxygen.

The oxygenation of cyclohexane with 1 atm molecular oxygen proceeded catalytically even at 305 K,§ whilst no oxygenation was observed for γ-$SiW_{10}\{Fe^{III}(OH_2)\}_2O_{38}^{6-}$ at the same temperature. It has been reported that the commercial catalyst, $Co(oct)_2$ (oct = 2-ethylhexyl octanoate), was inactive at 348 K with 3 atm molecular oxygen.[21] All these results demonstrate that γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$ can catalyze the selective oxygenation of cyclohexane with high turnover number and under mild conditions.

Table 1 compares turnover numbers for cyclohexane oxygenation with molecular oxygen catalyzed by manganese-substituted silicotungstates. The turnover numbers for manganese-substituted silicotungstates decreased in the order γ-$SiW_{10}\{Mn^{III}(OH_2)\}_2O_{38}^{6-}$ > α-$SiW_{11}\{Mn^{III}(OH_2)\}O_{39}^{5-}$ > α-$SiW_9\{Mn^{III}(OH_2)\}_3O_{37}^{7-}$ ≈ α-$SiW_{12}O_{40}^{4-}$ ≈ 0. No oxygenation proceeded for γ-$SiW_{10}\{Mn^{II}(OH_2)\}_2O_{38}^{8-}$ in which the oxidation state of manganese is +2. In addition, among *mono*-transition metal-substituted silicotungstates, α-$SiW_{11}\{M^{n+}(OH_2)\}O_{39}^{(8-3n)-}$ (M = Mn^{3+}, Fe^{3+}, Cu^{2+}), the order of turnover numbers was Mn^{3+} > Fe^{3+} > Cu^{2+}. These facts show that manganese is an effective element for catalysis and that a dimanganese site with the oxidation state of +3 is the most effective for the oxygenation of cyclohexane with molecular oxygen.

Small amounts of dicyclohexyl, which is formed by the reaction of two cyclohexyl radicals, and cyclohexyl hydroperoxide were observed. The addition of an alkyl-radical scavenger, *p*-*tert*-butylcatechol, led to complete inhibition. These facts suggest that the reaction includes a radical-chain mechanism. Further mechanistic work is in progress.

We acknowledge Dr C. Nozaki for the preliminary experiments of this work. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan.

Received (in Cambridge) 9th December 1999, Accepted 7th February 2000

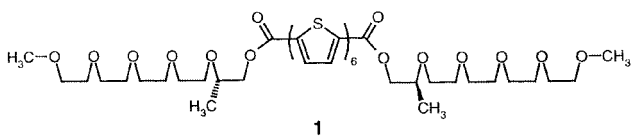
Nanospray FT-ICR mass spectroscopy provides unambiguous evidence for solvent-dependent aggregation of a substituted sexithiophene.

We report evidence for the solvent-dependent aggregation of an α,ω-disubstituted sexithiophene, obtained by nanospray Fourier-transform ion cyclotron resonance (FT-ICR) mass spectrometry[1–6] of solutions of varying polarity. Electrospray ionisation (ESI),[3] of which nanospray[4–6] is a variant, has been used for studying aggregation of proteins.[7,8] In this work, we used FT-ICR coupled with ESI (nanospray) to probe aggregation of an oligomer; high resolution was important in order to resolve overlapping signals due to differently sized aggregates.

Aggregation in solution is well known for α-oligothiophenes and poly(thiophenes).[9–11] Evidence for aggregation of such chromophores has been deduced from shifts in UV–VIS spectra, quenching of photoluminescence, broadening of linewidths in NMR or observation of a circular dichroism spectrum for aggregates of chiral chromophores.[12,13] Whereas these techniques give indirect evidence for aggregation, we have established direct evidence for solvent-dependent aggregation by FT-ICR mass spectrometry.

We have established a synthesis for 2,2′:5′,2″:5″,2‴:5‴,2⁗:5⁗,2⁗′:5⁗′-sexithiophene-5,5⁗′-dicarboxylic acid (2*S*)-2-methyl-3,6,9,12,15-pentaoxahexadecyl ester **1** (Fig. 1) and UV (absorption and emission) and CD spectroscopic evidence for its temperature dependent chiral aggregation in solution.[13] Compound **1** appears to aggregate in polar protic solvents such as THF–water mixtures and to be molecularly dissolved in organic solvents such as pure THF or $CHCl_3$. We have used nanospray FT-ICR mass spectrometry to investigate **1** in THF and THF–water mixtures. The nanospray technique provided the possibility of ionising the oligomer **1**, and its suspected aggregates, without fragmentation.

Experiments were performed using nanospray on a Bruker BioApex FT-ICR mass spectrometer equipped with a shielded 9.4 T magnet (Magnex Scientific Ltd., Abingdon, UK), a 6 cm diameter cylindrical infinity cell and electrospray ionisation source (Analytica of Branford, Branford, USA).[14,15] Low capillary and skimmer potentials were used to minimise any possibility of the non-covalent bonds of the aggregate being disrupted in the source. Solutions were made up using THF and a polar solvent mixture (PSM) containing equal volumes of ammonium acetate solution (10 mM, pH 6.0) and methanol, and 2% v/v concentrated acetic acid.



1

Fig. 1 2,2′:5′,2″:5″,2‴:5‴,2⁗:5⁗,2⁗′:5⁗′-sexithiophene-5,5⁗′-dicarboxylic acid (2*S*)-2-methyl-3,6,9,12,15-pentaoxahexadecyl ester **1**.

In agreement with our previous observations from UV–VIS and photoluminescence spectroscopy, the results from nanospray FT-ICR indicated that **1** did not aggregate in predominantly aprotic solution. Fig. 2 shows the mass spectrum obtained from a solution of **1** in 90% THF–10% PSM. The neutral oligomer is designated as 6T in the spectrum. Intense signals due to the ammonium and sodium ion adducts of the monomeric compound can be seen in Fig. 2. The experimental isotope patterns matched the theoretical, confirming that each cluster of peaks represented a single species. The measured mass-to-charge (*m*/*z*) ratios agreed with those calculated to within 1 ppm in all cases (all-^{12}C $[6T+NH_4]^+$, measured mass 1096.2811 *cf.* calc. 1096.2802; all-^{12}C $[6T+Na]^+$, measured mass 1101.2342 *cf*. calc. 1101.2356). There was no evidence for aggregation. Nanospray from a more polar solution of **1**, (75% THF–25% PSM), again gave mainly monomeric ammonium and sodium ion adducts but also a weak signal due to the dimeric diammonium ion adduct (Fig. 3). Peaks from the doubly charged dimer can lie underneath those from the singly charged monomer or appear between the singly charged monomer peaks. Thus, the all-^{12}C monomer peak and the all-^{12}C dimer peak both theoretically fall at *m*/*z* 1096.2802. The one-^{13}C monomer peak falls at *m*/*z* 1097.2836 but the one-^{13}C dimer peak falls between these two peaks at *m*/*z* 1096.7822 and is detected as a weak peak. The spectrum (Fig. 3) establishes that the bonding in the dimer between the constituent monomers is non-covalent, because the measured mass of the dimer is exactly twice that of the monomer. If the bonding had been covalent, loss of two hydrogen atoms might have been expected; there is no possibility of simple addition dimerisation of **1**. In the case of loss of two hydrogen atoms, there would have been a detectable peak at *m*/*z* 1095.2724 due to the doubly-charged all-^{12}C dimer, there was no peak at this *m*/*z*.

The diammonium ion adduct of the tetramer (Fig. 4), the diammonium ion adduct of the pentamer (Fig. 5) and the

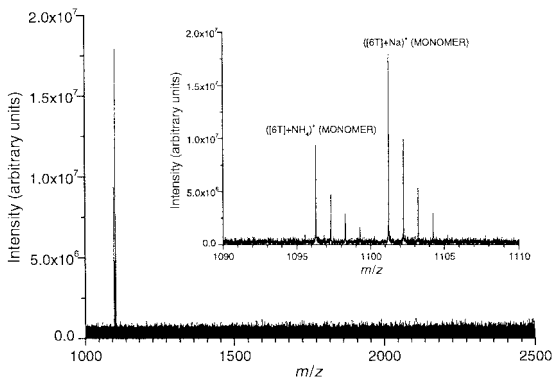


Fig. 2 Compound **1** (50 μM) in THF–PSM (90 : 10 v : v). Only monomeric species can be observed. The inset shows the isotope patterns of the ammonium adduct ion, $([6T]+NH_4)^+$ and of the sodium adduct ion, $([6T]+Na)^+$. 6T is a designation used for the neutral compound **1**.

DOI: 10.1039/a909686h

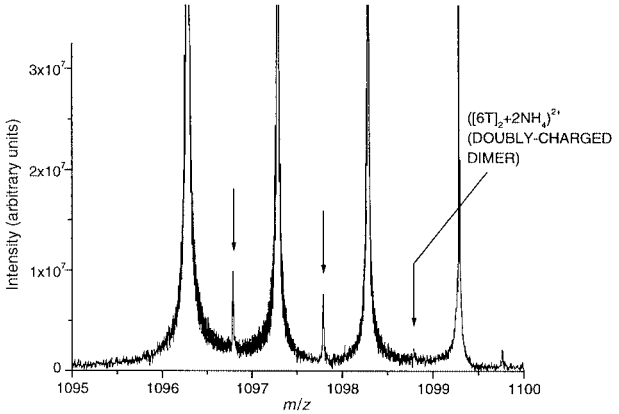

Fig. 3 Compound **1** (150 μM) in THF–PSM (75 : 25 v : v). The monomeric ammonium adduct ion (see also Fig. 2) and the dimeric diammonium adduct ion, $([6T]_2+2NH_4)^{2+}$ (see arrows) are observed.

triammonium ion adduct of the hexamer were observed when a solution of compound **1** in 50% THF–50% polar solvent mixture was investigated.

The diammonium adduct of the tetramer overlays the ammonium adduct of the dimer (Fig. 4). That the isotope distributions of the two ions were directly coincident indicates that the mass of the tetrameric species was exactly twice that of the dimer, *i.e.* bonding was non-covalent in the tetramer. The most intense peak in the isotope distribution of the diammonium pentamer adduct (Fig. 5) corresponds to the six-^{13}C species; the all-^{12}C isotopomer cannot be discerned in Fig. 5. The cluster of peaks shown in Fig. 6 represent isotopes of three species: the singly charged ammonium adduct of the dimer $([6T]_2+NH_4)^+$, the doubly-charged diammonium tetramer adduct

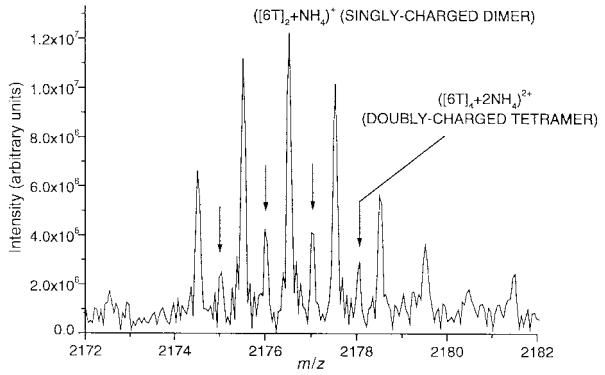

Fig. 4 Compound **1** (50 μM) in THF–PSM (50 : 50 v : v). Peaks due to the ammonium ion adduct of the dimer, $([6T]_2+NH_4)^+$, and the diammonium adduct ion of the tetramer, $([6T]_4+2NH_4)^{2+}$, are superimposed.

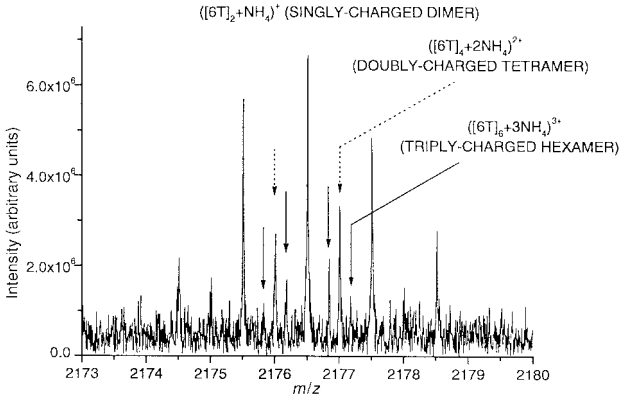

Fig. 6 Compound **1** (100 μM) in THF–PSM (50 : 50 v : v). Peaks due to the ammonium adduct ion of the dimer, $([6T]_2+NH_4)^+$, the diammonium adduct ion of the tetramer, $([6T]_4+2NH_4)^{2+}$ (dotted arrows) and the triammonium ion adduct of the hexamer, $([6T]_6+3NH_4)^{3+}$ (straight arrows) are overlaid.

$([6T]_4+2NH_4)^{2+}$ and the triply charged triammonium hexamer adduct $([6T]_6+3NH_4)^{3+}$.

The size of detectable aggregates is currently limited by the instrument configuration and the relationship between behaviour in solution and in the mass spectrometer source[16] is a matter for continuing study. However, we conclude that oligomeric aggregates of compound **1**, from the dimer to the hexamer have been observed by nanospray FT-ICR mass spectrometry when sprayed from polar solution, whereas the monomer alone was observed when sprayed from THF solution. Taken together these results constitute unambiguous evidence for the aggregation of **1** in solution, a process which intensifies with increasing solution polarity.

We thank Luc Brunsveld for the chiral penta(ethylene glycol), the European Commission Training and Mobility of Researchers Network SELOA (contract number ERBFMRX-CT960083) and the Royal Dutch Academy of Arts and Sciences. The FT-ICR laboratory at the University of Warwick is an EPSRC National Facility.

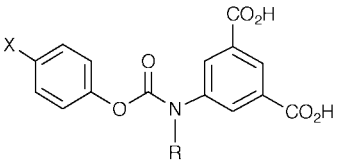
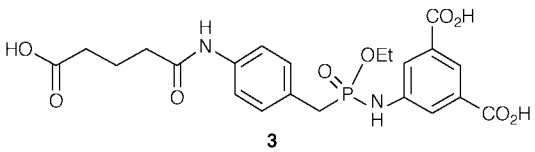
Received (in Corvallis, OR, USA) 23rd December 1999, Accepted 21st January 2000

The first example of antibody-catalyzed hydrolysis of an *N*-methylcarbamate, a highly challenging reaction for antibody catalysis, was achieved by raising a monoclonal antibody to a phosphoramidate transition state analogue.

The vast majority of antibody-catalyzed hydrolyses of carbonyl derivatives, such as esters, amides and carbamates, have been performed using substrates that are amenable to hydrolysis: half-lives for the spontaneous reactions usually range from hours to a few months under the assay conditions.[1] Antibody catalysis of more energetically demanding hydrolytic reactions of carbonyl derivatives in which the half-life for the spontaneous reaction is measured in years, rather than hours to months, is rare.[2a–f] As part of a project related to antibody-catalyzed 'remote' prodrug activation,[3] we became interested in examining the possibility of generating antibodies capable of catalyzing the hydrolysis of *N*-methylcarbamates. *N*-methylcarbamates are very resistant to hydrolysis[4] and there has yet to be a report describing an antibody capable of catalyzing this reaction. Several papers have appeared describing antibodies capable of catalyzing the hydrolysis of N–H carbamates.[2e,5] Of particular note is the work of Wentworth *et al.*[2e] These researchers obtained an antibody, DF8-D5, that catalyzes the hydrolysis of N–H carbamates of type **1** by raising antibodies to



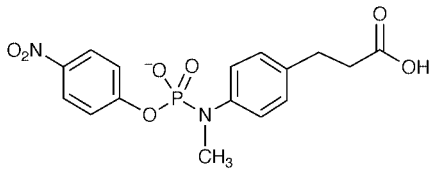
1 R = H, X = NO_2, Br, F, H, OMe
2 R = CH_3, X = NO_2



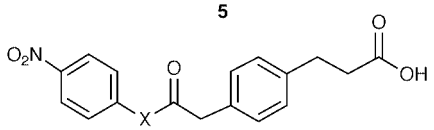
3

the phosphonamidate transition state analogue (TSA) **3**. Although this antibody did not hydrolyze *N*-alkylcarbamates such as **2**, the significantly smaller Hammett ρ value (ρ = + 0.53) obtained for the antibody-catalyzed reaction compared to that obtained for the uncatalyzed reaction (ρ = +2.68) suggested that the antibody reaction proceeded *via* the highly disfavoured $B_{Ac}2$ mechanism rather than the more favoured $E1_cB$ process found for the uncatalyzed reaction.[2e] These results suggest that antibodies raised to an appropriately designed TSA of the $B_{Ac}2$ process for *N*-methylcarbamate hydrolysis might be capable of catalyzing the hydrolysis of these stable compounds. Here we report the first example of antibody-catalyzed hydrolysis of an *N*-methylcarbamate, a highly challenging reaction for antibody catalysis.

Carbamate **4** was chosen as a model substrate for the antibody-catalyzed reaction (Scheme 1). Although this carbamate contains a *p*-nitrophenol leaving group, it is fairly resistant to hydrolysis, exhibiting a half life of approximately 5.7 years at pH 9.0.[4a,6] In the TSA used by Wentworth *et al.*,[2e] the phenolic oxygen of the substrate was replaced with a methylene unit. This was done to promote the $B_{Ac}2$ mechanism over the $E1_cB$ mechanism by minimizing recognition of the phenolate anion, an important feature of the $E1_cB$ transition state.[2e] However, during *N*-methylcarbamate hydrolysis, there is no competing $E1_cB$ mechanism. Consequently, we chose to employ a phosphoramidate TSA (hapten **5**), reasoning that a phosphoramidate should be a better mimic of the $B_{Ac}2$ transition state than a phosphonamidate.



5



6 X = NH
7 X = O

Hapten **5** was constructed† and conjugated to Bovine Serum Albumin (BSA) and Keyhole Limpet Hemocyanin (KLH) *via* its *N*-hydroxysulfosuccinimide ester, which was prepared *in situ via* reaction of **5** with *N*-hydroxysulfosuccinimide in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC). The degree of conjugation to the carrier protein was determined using the trinitrobenzene sulfonic acid (TNBS) assay of Habeeb.[7] Balb/c mice were hyperimmunized with the KLH conjugate and monoclonal antibodies were obtained using hybridoma technology.[8]†

Thirty-two monoclonal antibodies were screened for catalytic activity by removing aliquots from a solution containing antibody (~ 4 μM) and substrate **4** (1 mM) in 50 mM bicine, 5% DMSO, pH 9.0, at various time intervals, and then examining the aliquots for *p*-nitrophenol using HPLC. Under these conditions, we were unable to detect any hydrolysis of **4** in the absence of antibody after 40 h. Several of the antibodies

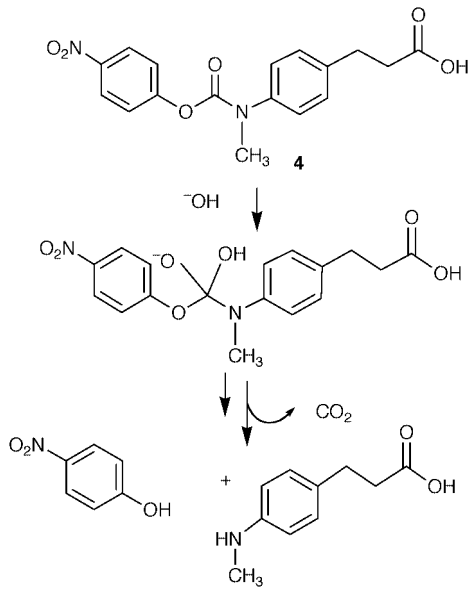

Scheme 1

exhibited catalytic activity. The most active antibody, ST51, was selected for a more detailed kinetic analysis. The ST51-catalyzed reaction obeys saturation kinetics and at pH 9.0 exhibited a $k_{cat} = 9.1 \times 10^{-2}$ h^{-1}, a $K_m = 2.6 \times 10^2$ μM, and $k_{cat}/K_m = 3.5 \times 10^{-4}$ μM^{-1} h^{-1}. The rate enhancement obtained for the reaction (k_{cat}/k_{uncat}) is 6.5×10^3, which is in the range of the average rate enhancement obtained for other antibody-catalyzed hydrolytic reactions of carbonyl derivatives such as esters, amides and carbamates.[1] The rate enhancement obtained with **4** and ST51 (6.5×10^3) is approximately 20 times greater than that obtained by Wentworth *et al.*[2e] for the hydrolysis of **1** when X = NO_2 with DF8-D5 (k_{cat}/k_{uncat} = 300). However, when DF8-D5 is assayed with other substrates (**1**, X = Br, F and OMe), it exhibits greater rate enhancements than that obtained with ST51 and substrate **4**.[2e]

That catalysis is indeed a result of the abzyme and not a contaminating protease or esterase is supported by the following results. First, the reaction is completely inhibited by stoichiometric quantities of the TSA. Second, pure ST51 Fab[10] exhibited the same catalytic activity as pure ST51 mAb. Finally, ST51 did not catalyze the hydrolysis of amide **6** *or even ester* **7**, two compounds that should be readily hydrolyzed by proteases or esterases and both of which undergo spontaneous hydrolysis under the assay conditions more readily than **4**.[11,12] The fact that ST51 does not hydrolyze **6** and **7** also indicates that ST51 is a remarkably selective abzyme compared to other abzymes that catalyze the hydrolysis of amides[2a] or carbamates.[5a]

Although ST51 is also active at pH 10.0 and exhibits a higher k_{cat} (2.5×10^{-1} h^{-1}) at pH 10.0 than at pH 9.0, it exhibits a considerably higher K_m (1.3 mM), and lower rate enhancement (1.8×10^3) at pH 10. ST51 is a robust abzyme, as evidenced by the fact that it can be stored at room temperature at pH 10.0 over several days without any loss of catalytic activity. In addition, ST51 is capable of multiple turnover, indicating that it is not subject to strong product inhibition as is often the case for hydrolase abzymes.[13] This may be due to the fact that carbamate hydrolysis yields CO_2, as opposed to a negatively charged carboxylic acid found with ester or amide hydrolysis, which should experience minimal charge interactions with positively-charged residues in the active site generated in response to the negatively-charged TSA.[13]

In summary, this work represents the first example of antibody-catalyzed hydrolysis of an *N*-methylcarbamate, a highly challenging reaction for antibody catalysis. This was achieved by raising antibodies to a phosphoramidate TSA. Studies concerning the application of this antibody to 'remote' prodrug activation[3] are in progress. In addition, X-ray crystallographic analyses to determine the structure of ST51 Fab are also in progress.[14] The results of the X-ray analysis and further kinetic studies will be used to elucidate the mechanism of this interesting abzyme.

We thank the Medical Research Council (MRC) of Canada and the Natural Sciences and Engineering Research Council (NSERC) of Canada (post-graduate scholarship for A. Nicole Dinaut) for financial support of this work. We would also like to thank Katherine Majewska for assistance in synthesizing compounds **6** and **7**, and Melanie Lea for assistence with hybridoma production.

Temperature programmed desorption of argon for evaluation of surface acidity of solid superacids

Hiromi Matsuhashi* and Kazushi Arata

Department of Science, Hokkaido University of Education, 1-2 Hachiman-cho, Hakodate 040-8567, Japan. E-mail: matsuhas@cc.hokkyodai.ac.jp

Received (in Cambridge, UK) 15th December 1999, Accepted 13th January 2000

The activation energy of Ar desorption from solid acids is determined by temperature programmed desorption (TPD) using Ar as 9.3, 7.6 and 6.0–6.7 kJ mol^{-1} for sulfated ZrO_2, $Cs_{2.5}H_{0.5}PW_{12}O_{40}$ and zeolites, respectively; the data indicate that Ar TPD is applicable to evaluation of the relative acid strengths of solid superacids.

Temperature programmed desorption (TPD) using ammonia is the most useful technique to evaluate relative acid strengths and the amount of acid sites on solid acids.[1–3] However, there are several problems when this technique is applied to solid acids with high acidity such as sulfated zirconia and zeolites. For instance, the ammonia desorption temperature is elevated owing to the strong interaction of ammonia with strong acid sites, and thus the acid sites may be decomposed by reaction with the adsorbents at such temperatures. Sikabwe *et al.* reported that Fe, Mn and Ni promoted sulfated zirconias were partially or completely decomposed in the temperature range 700–900 K when ammonia, pyridine or benzene were adsorbed.[4] An interaction of ammonia with both the acidic OH group and the basic oxygen site next to the acid site is another problem.[5] Therefore, accurate acid strengths of solid superacids can not be evaluated by TPD using probes such as ammonia or pyridine. To solve these problems, an inert molecule with lower basicity must be used as the probe molecule.

Argon is completely inert towards superacids, but shows an acid–base like interaction with acid sites at low temperature.[6] Argon has an induced dipole when it interacts with a strong dipole. The most polarized site on the solid acids must be the acid sites, and argon would be adsorbed on such sites in a polarized state. The strength of the interaction between Ar and acid sites would be expected to depend on the acid strength. Wakabayashi *et al.* reported that inert gases including Ar showed an interaction with acidic OH sites on zeolites giving 1 : 1 hydrogen-bonded complexes at low temperatures, and there was a linear correlation between the strength of the interaction and the proton affinities of the gases.[6,7] From their results, it is expected that the relative acid strength of solid superacids can be evaluated by TPD using Ar as a probe. Here, Ar TPD was applied to silica–alumina, several types of zeolites, sulfated zirconia and a Cs substituted heteropoly acid; the results clearly showed that Ar TPD was applicable for the evaluation of acid strength of solid superacids.

Silica–alumina and zeolites used in this study were supplied by the Catalysis Society of Japan as reference catalysis. Sulfated zirconia (SO_4^{2-}/ZrO_2) was prepared by the reported method,[8] and the heteropoly acid ($Cs_{2.5}H_{0.5}PW_{12}O_{40}$) was supplied by Professor T. Okuhara, Hokkaido University.[9] Both of these materials can convert *n*-butane into isobutane at room temperature. The solid acid (*ca.* 15–40 mg) was placed in a glass sample tube and pretreated in vacuum at 773 K (SiO_2–Al_2O_3 and zeolites) or 473 K (sulfated zirconia and heteropoly acid) for 2 h. After the pretreatment, the sample was exposed to 6.7 kPa of Ar at room temperature, then cooled to 113 K by N_2 gas which was bubbled out of liquid N_2. The sample cooling system is shown in Fig. 1. The adsorption of Ar was carried out at 113 K for 10 min. Then excess Ar was removed by evacuation at the same temperature. The final pressure of the system was $< 5.0 \times 10^{-3}$ Pa. Ar TPD was performed in the temperature range 113–223 K at a programmed rate of 2–5 K min^{-1}. The sample tube was heated by an electric heater regulated by a temperature controller. Argon desorbed from the surface of solid acid was detected by a mass spectrometer and an ionization gauge connected to the vacuum system.

Ar TPD profiles of solid acids are summarized in Fig. 2. The signal response (m/z = 40) was normalized by the weight of the samples. All the samples showed an Ar desorption peak at *ca.* 120–170 K, *i.e.* much higher than the boiling point of Ar (87.45 K). There was no relation between the BET surface area and the relative amounts of desorbed Ar. The profiles thus show evidence of interaction of Ar with the acid sites on the surface.

For zeolites, an acid site is constructed from Al^{3+} in the framework and the amount of Ar desorbed from the surface is expected to depend on the quantity of Al^{3+}. The amount of Ar desorbed from H-mordenite was much larger than that of H-ZSM-5 reflecting the higher content of Al^{3+} in H-mordenite (Table 1). However, the amount of Ar desorption from H-Y was much smaller than that expected from the Al^{3+} content. Only a small fraction of the acid sites on H-Y or SiO_2–Al_2O_3 appear to show an acid–base interaction with Ar.

An apparent activation energy of Ar desorption was calculated by applying eqn. (1).[10]

$$2\ln T_m - \ln\beta = E_d/RT_m + \text{const.} \quad (1)$$

Here, T_m is the peak temperature, β is the rate of temperature increase and E_d is the activation energy of desorption. E_d values are obtained from plots of $(2\ln T_m - \ln\beta)$ *vs.* $1/T_m$. For the

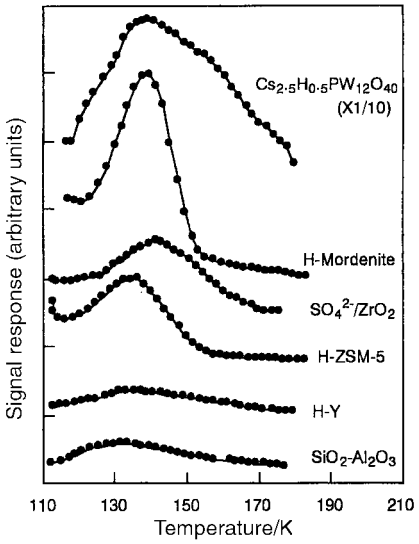

Fig. 2 Ar TPD profiles of solid acids; temperature programmed rate: 2 K min^{-1}.

Table 1 Solid acids and activation energies of Ar desorption

Solid acid	Surface area/ $m^2\ g^{-1}$	Al_2O_3 content (wt%)	Activation energy/ kJ mol^{-1}
SiO_2–Al_2O_3 (JRC-SAH-1)	511	28.61	5.5
H-Y (JRC-Z-HY-5.6)	650	22.0	6.0
H-ZSM-5 (JRC-Z5-70H)		1.99	6.6
H-Mordenite (JRC-Z-HM20)	399	7.76	6.7
SO_4^{2-}/ZrO_2	137		9.3
$Cs_{2.5}H_{0.5}PW_{12}O_{40}$	135		7.6

examples shown in Fig. 2, the estimated values of T_m were 131.5, 132.8, 136.0, 139.8, 139.5 and 138.9 K for SiO_2–Al_2O_3, H-Y, H-ZSM-5, SO_4^{2-}/ZrO_2, H-mordenite and $Cs_{2.5}H_{0.5}PW_{12}O_{40}$, respectively. The calculated activation energies of Ar desorption are summarized in Table 1. The order of the activation energies is as follows:

$$SO_4^{2-}/ZrO_2 \gg Cs_{2.5}H_{0.5}PW_{12}O_{40} \gg \text{H-mordenite} \geqslant \text{H-ZSM-5} > \text{H-Y} > SiO_2\text{–}Al_2O_3$$

The termination temperature of Ar desorption also followed this order, *viz.* 159.0, 158.7, 153.8, 153.9, 151.8 and 149.6 K for SO_4^{2-}/ZrO_2, $Cs_{2.5}H_{0.5}PW_{12}O_{40}$, H-mordenite, H-ZSM-5, H-Y and SiO_2–Al_2O_3, respectively. The polarization of the Ar molecule is induced by the polarized sites. The interaction between Ar and acid sites should be strong when Ar is adsorbed on strong acid sites because of higher polarization of Ar molecules on the more polarized acid sites. Therefore, the order of the activation energy reflects the acid strength of the solid acid sites. The strength order of zeolites evaluated in this study was consistent with previous reports.[11] From these results, it can be concluded that Ar TPD is applicable to the evaluation of relative acid strengths of solid acids of high acidity on the surface.

The energy of Ar desorption form the solid superacid of sulfated zirconia was 9.3 kJ mol^{-1} the highest among the tested catalysts. The highest acid strength of this sample ($H_0 \leqslant -16.04$) is reflected by the highest value of the desorption energy.[12] The Cs substituted heteropoly acid had a desorption energy (7.6 kJ mol^{-1}) which was higher than for the zeolites. Consequently, it can be stated that the heteropoly acid is a solid superacid.

In summary, the catalysis of solid superacids is characterized by activities for acid-catalyzed reactions at low temperatue and reactions are carried out below room temperature in many cases. The acidity of solid superacids should thus be evaluated at such lower temperatures. TPD using Ar can be performed in the temperature range 113–223 K, close to the reaction temperatures used. Destruction of acid sites can be avoided at these temperatures for themally sensitive sites as found, for example, in Cs-substituted heteropoly acids. In conclusion, TPD using Ar is a very useful technique to evaluate the acidity of solid superacids.

We thank Professor Toshio Okuhara, Hokkaido University, for his kindness in providing the Cs substituted-heteropoly acid.

Temperature-dependent helix–helix transition of an optically active poly(diarylsilylene)†

Julian R. Koe,[ab] Michiya Fujiki,*[ab] Masao Motonaga[b] and Hiroshi Nakashima[ab]

[a] *NTT Basic Research Laboratories, 3-1 Wakamiya, Morinosato, Atsugi, Kanagawa 243-0198, Japan. E-mail: jrkoe@with.brl.ntt.co.jp*

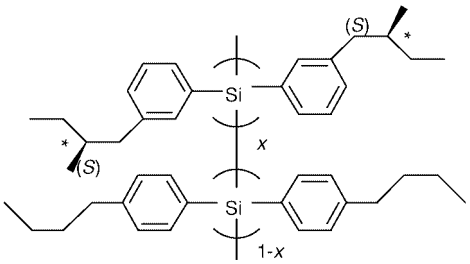
[b] *CREST-JST, 3-1 Wakamiya, Morinosato, Atsugi, Kanagawa 243-0198, Japan. E-mail: jrkoe@with.brl.ntt.co.jp*

Received (in Cambridge, UK) 26th November 1999, Accepted 28th January 2000

The poly(diarylsilylene) copolymer mainchain helix in $(Ar^*_2Si)_x(Ar_2Si)_{1-x}$ [Ar* = 3-(*S*)-2-methylbutylphenyl, Ar = 4-butylphenyl, x = 0.2] undergoes a thermally driven inversion of helical screw sense with a transition temperature of −10 °C.

Functional organic and polymeric materials with potential for application in devices in capacities such as switches, data storage, transmission and displays are attracting much attention owing to their relatively low cost, ease of fabrication of large area thin films, processability, and chemical tunability of optoelectronic properties through choice of substituents,[1] and particularly those with physical responses to stimuli, arising from higher order structural regularity.[2] Polymers adopting a preferential screw sense helical backbone conformation offer the possibility of a two state, switchable material if the opposite screw sense is energetically accessible and the helix–helix transition reversible.[3] Such helical inversions are rare and for discrete molecules in dilute solution responding to a change in temperature, have been reported only twice, first for a polypeptide, poly(β-propyl-L-aspartate)[4a] and very recently for a polyisocyanate, poly[3-{(*S*)-*sec*-butoxycarbonyl}phenylisocyanate].[4b] There is one example of a solid state helix inversion, for a polypeptide,[5] and change of sign of optical activity upon aggregation of other polyisocyanates,[6] polypeptides[7] and polythiophenes[3,8] is known.

Recently we showed using circular dichroism (CD) spectroscopy that poly(diarylsilylene)s (of significance owing to their electroluminescence (EL) properties)[9] with enantiopure chiral sidechains adopt preferential helical screw sense backbone conformations in solution.[10] Incorporation of the (*S*)-2-methylbutylphenyl group in polymers of the type $[(Ar')(Ar'')Si]_n$ (Ar′, Ar″ = 4-butylphenyl, 4-(*S*)-2-methylbutylphenyl or 3-(*S*)-2-methylbutylphenyl) afforded optically active materials with positive or negative Cotton effects in the CD spectra (solution state) for polymers with one or two chiral centres per silicon, respectively. We then set out to find poly(diarylsilylene)s which could exhibit either positive or negative Cotton effects, dependent upon the application of an external stimulus. Such materials could potentially find application in a polymer-based chiroptical photonic device (*e.g.* circularly polarised EL device or semiconducting small molecule chirality sensor). Now we report our preliminary findings that the copolymer, poly[{bis-3-(*S*)-2-methylbutylphenyl}$_{0.2}$-*co*-(bis-4-butylphenyl)$_{0.8}$silylene] **1** undergoes a reversible, thermally driven helix–helix transition in solution with a transition point at −10 °C.



1: $x = 0.2$
2: $x = 0.5$
3: $x = 0.8$

Poly(diarylsilylene) copolymers **1**–**3** were obtained by the Wurtz coupling of the appropriate dichlorosilane monomer mixtures in toluene at 70 °C and the compositions, as verified by ^{13}C NMR spectroscopy, corresponded to the nominal addition ratios (for preparative and NMR details see ESI†). Polymerisation and spectroscopic data are given in Table 1.

The polymers show relatively narrow ($\Delta\nu_{1/2}$ *ca.* 16 nm) UV absorptions (peak maximum *ca.* 396 nm) due to the conjugated Si backbone σ–σ* transition, mirror image fluorescence emission spectra, small Stokes' shifts (*ca.* 13 nm) and fluorescence anisotropies in the range 0.20–0.38, indicating regular, semi-flexible polymer molecules with long segment lengths.[10] The CD and UV spectra of **1** are shown in Fig. 1. A negatively signed Cotton effect is evident in the CD spectrum at −70 °C, coincident with the absorption due to the Si σ–σ* transition, whereas at 50 °C, the effect is positive and at −10 °C the signal is approximately zero. This indicates a change in the

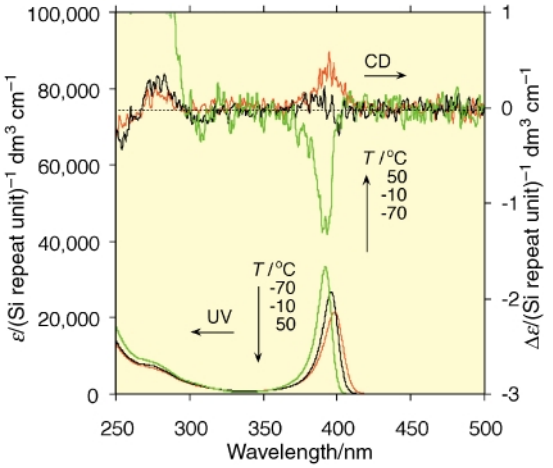

Fig. 1 CD and UV spectra of **1** at −70, −10 and 50 °C.

backbone from one prevailing helical screw sense to the other. The disymmetric ratio,[11] g_{abs}, defined as the ratio of CD and UV molar absorptivities, $\Delta\varepsilon/\varepsilon$ (and thus more appropriate as a gauge of helicity than simply $\Delta\varepsilon$), is small for **1** at the temperature listed in Table 1 (20 °C), since this is close to the transition temperature. However, at −70 °C, g_{abs} is −0.38, greater than that for **2** (−0.27), but less than that for **3** (−1.57). By comparison, g_{abs} for the related homopolymer, poly[bis{3-(*S*)-2-methylbutylphenyl}silylene],[10] at 20 °C is −2.00. The lower disymmetric ratios for **1**–**3**, therefore, are most probably the consequence of the coexistence of both helical screw senses in **1**–**3**, at all temperatures.

Consistent with the above suggestion, at −10 °C, the CD spectrum of **1** actually has a small negative component at *ca.* 401 nm in addition to the small positive peak at 390 nm. We ascribe these two bands to the two different screw senses, which should be characterised by different screw pitches.[12] It is not possible, however, in the present case to associate a particular screw sense with the sign of the Cotton effect.

The maximum magnitude of the positive Cotton effect for **1** occurs around 50 °C, but it is less than the maximum negative magnitude, as may be seen from the plot of CD intensity $\Delta\varepsilon$ *vs.* *T* in Fig. 2. Above 50 °C, the CD signal intensity decreases again, a feature in common with the poly(diarylpolysilylene) homopolymers in our earlier study,[10] which we attribute to thermal population of the higher energy screw sense state, but additionally, though to a much lesser degree, to thermal broadening of the bands as a result of slight bond length increase (the molar absorptivities for UV and CD spectra decrease with increasing temperature).

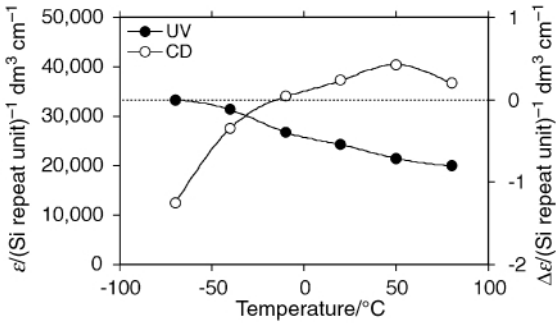

Fig. 2 Plots of CD ($\Delta\varepsilon$) and UV (ε) molar absorptivities per Si repeat unit *vs.* temperature for **1** (cubic spline fitting).

The corollary of this is an increase in $\Delta\varepsilon$ with decrease in temperature (in the absence of helical inversion), which has also been observed by other workers.[4b,13,14] Green *et al.* proposed that the optical activity of poly(alkyl isocyanate)s increases with decreasing temperature due to a diminishing number of helix reversals, allowing greater cooperation of backbone units.[14b]

A temperature cycling experiment comprising three cycles of −70/50 °C with CD and UV spectra recorded at each temperature for **1** indicated that the transition is reversible, negative and positive Cotton effects being observed, respectively. Excluding CD results, the data for polymer **2**, with a ratio of enantiopure chiral monomer to achiral monomer of 0.5 : 0.5, are similar to those of **1**. Polymer **3** (chiral : achiral = 0.8 : 0.2) with lower M_w (owing to lower solubility during synthesis) has slightly lower UV molar absorptivity but is otherwise also comparable to **1**, indicating similar polymer structures for **1**–**3**. The CD data, however, are markedly different: whereas **1** shows negative Cotton effects at low temperature and positive at high temperature indicating a transition from one helical screw sense to the other, **2**, **3** and the above mentioned related homopolymer, poly[bis{3-(*S*)-2-methylbutylphenyl}silylene],[10] show only negative Cotton effects at all temperatures and thus do not exhibit this phenomenon; *i.e.* this function is specific to **1**. It is apparent, therefore, that a subtle interplay of factors permits such a helix–helix transition, presumably as a result of the enthalpy and entropy terms in the Gibbs free energy equation being of the same sign, such that the free energy difference changes sign as a function of temperature, as was proposed in discussions of helix–helix transitions for certain polyisocyanates.[4b,15]

In conclusion, we have demonstrated a structure-specific, reversible, temperature-dependent helical screw sense inversion for a hybrid organic–inorganic chromophoric and fluorophoric polymer. Further investigation of poly(diarylsilylene) systems is in progress.

Cadmium- and zinc-directed assembly of nano-sized, resorcarene-based host architectures which strongly bind C_{60}†

Received (in Cambridge) 17th January 2000, Accepted 3rd February 2000

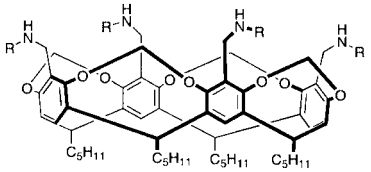
Nano-sized molecular loops based on a trimer of resorcarene ligands assembled by six cadmium or zinc ions are shown to strongly bind the spherically shaped fullerene C_{60} in toluene and benzene solutions.

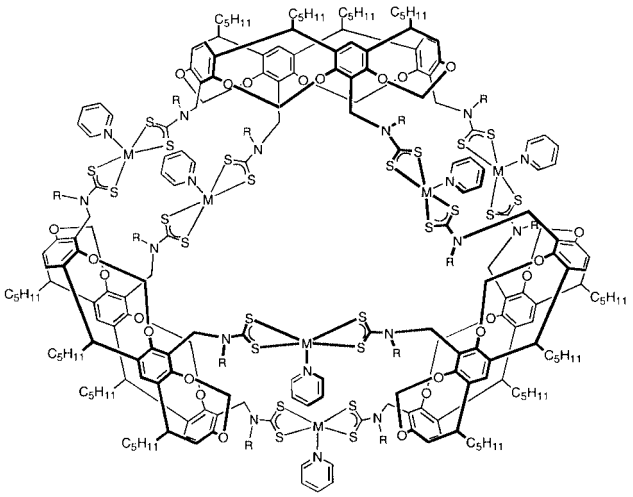
The chalice-shaped molecules, calixarenes, serve as excellent hosts for the binding of organic guest molecules through non-covalent interactions.[1] Pathways to multiple calixarene hosts employing self-assembly techniques that utilise numerous metal–ligand or hydrogen bonding interactions have been described recently.[2,3] The potential to exploit these and other nano-sized hosts as molecular receptors or containers in which large or multiple substrate molecules can be bound, stored, transported or even reacted upon has generated much recent interest in both their synthesis and properties.[4] Herein, we demonstrate the cadmium(II)- and zinc(II)-directed assembly of nano-sized host architectures based on a trimer of dithiocarbamate (dtc)-functionalised resorcarene ligands and show these loop-shaped hosts strongly bind buckminsterfullerene, C_{60}, in solution.

The C_4 symmetric resorcarenes are particularly suited for the generation of metal-assembled nano-hosts being easy to functionalise with a range of coordinating moieties. Reaction of tetra(bromomethyl)resorcarene with neat propylamine or butylamine yields tetrakis(alkylaminomethyl)resorcarenes **Am$_1$**, **Am$_2$**.† From these secondary amines, the dithiocarbamate cadmium(II) and zinc(II) resorcarene assemblies **1**–**4** were prepared in a one-pot synthesis from potassium hydroxide, carbon disulfide and metal(II) acetate and isolated as cream coloured powders. Recrystallisation from pyridine–water solutions afforded the pyridine adducts of the hexametallic hosts as pale yellow, prismatic crystals. All four compounds have been characterised by X-ray crystallography; three of the structures (**1**, **2** and **3**) are presented here (Fig. 1 and Table 1)‡ and **4** is described elsewhere.[2]

Metal complexes **1**–**4** are isomorphous and consist of three resorcarene cups linked by six divalent metal ions (all of which are crystallographically equivalent). The cup-shaped resorcarene ligands provide the corners of an equilateral molecular triangle whose sides are *ca*. 19–20 Å in length. In **1**, **2** and **3** the six metal(II) ions are five-coordinate with sulfur atoms of the bidentate dtc unit forming a square-plane [Cd–S 2.590(5)–2.635(5) **1**, 2.603(5)–2.641(5) **2**, Zn–S 2.444(4)–2.495(4) Å **3**]. Axial coordination *via* a pyridine molecule [Cd–N 2.35(2) **1**; 2.32(2) **2**, Zn–N 2.124(9) Å **3**] causes a pyramidal distortion which raises the metal ion slightly above the square plane [Cd 0.50 **1**, 0.49 **2**; Zn 0.53 Å **3**]. The trimeric loop-shaped assembly is formed by two parallel running sets of dtc–M(II)–dtc units on each side of the resorcarene bowl connecting to an adjacent resorcarene bowl.

Previously, calixarene and CTV macrocycles have been shown to bind fullerenes through favourable interactions between the π-electron system of the calixarene aromatics and the surface of the carbon sphere.[5–7].





Purple solutions of C_{60} in toluene or benzene turn red–brown on addition of colourless hosts **1**–**4**. Such a colour change is

Table 2 Association constants (log K_{ass}) for host structures **1**–**4** and guest C_{60} (T = 295 K)

Solvent	**1**	**2**	**3**	**4**
Benzene	4.7 ± 0.3	> 6[a]	4.41 ± 0.03	4.07 ± 0.03
Toluene	4.3 ± 0.2	5.1 ± 0.1	3.70 ± 0.05	3.47 ± 0.03

[a] Owing to the strength of binding a satisfactory convergence in the fitting program could not be reached.

indicative of a binding interaction between the host and the guest.[8] To determine the stoichiometry of this interaction, UV–VIS absorption spectra of mixtures of known concentrations of host and guest species in toluene were examined using a method of continuous variance, commonly known as Job's method.[9] Maxima in the curve of the Job's plot were observed at 1:1 concentration ratios of host and guest for all four compounds. The strength of binding was probed further by standard UV–VIS titration experiments of host and guest. Equivalents of host solutions **1**–**4** were added to a C_{60} solution (in benzene or toluene) and the absorbance in the UV–VIS spectrum monitored. From this data, binding constants for the host–C_{60} complexes in both toluene and benzene solutions were calculated using the computer programme Specfit. Table 2 shows all the host–guest stability constants are of substantial magnitudes and the binding is significantly stronger in benzene. It is noteworthy that the cadmium complexes **1** and **2** bind C_{60} much more strongly than the zinc complexes **3** and **4**, although the cavity dimensions are very similar. The association constants determined for cadmium hosts **1** and **2** exceed those reported by Fukazawa and coworkers who employed mono- and bis-calix[5]arene derivatives[7] and are comparable in magnitude with a bisporphyrin system reported most recently by Tashiro *et al.*[10]

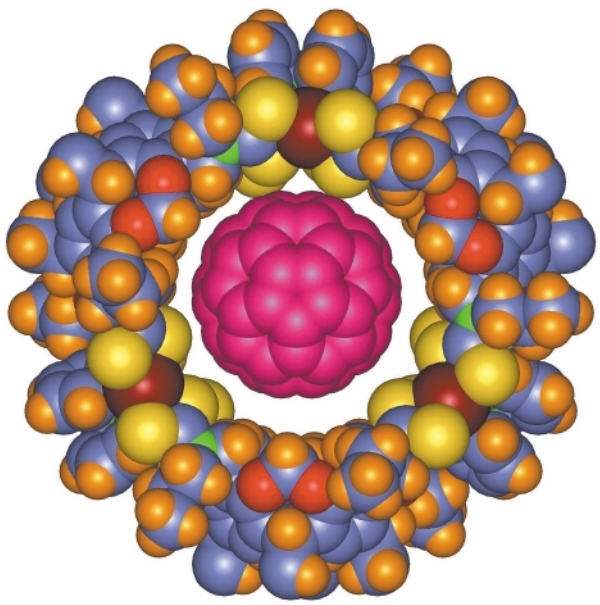

Fig. 2 Space filling model of host–C_{60} complex showing the proposed mode of fullerene binding by loop-shaped hosts **1**–**4**. For clarity, *n*-butyl chains at the base of the resorcarenes have been removed.

Space-filling CPK representations based on the crystal structures of **1**–**4** show that the cavity is circular with a diameter of *ca.* 16–17 Å and therefore suitable for the binding of spherically shaped molecules such as C_{60} (Fig. 2). The interatomic distances and molecular dimensions in **1**–**4** are all very similar (Table 1). Thus, it is unlikely that the modest differences in host size and shape can reasonably account for the large variation in binding constants observed. Molecular models of C_{60} inside hosts **1**–**4** indicate that a possible mode of receptor–guest binding is through the sulfur atoms of the dtc moieties;[11] the C_{60} resting in a cup-shaped cavity formed by sixteen sulfur atoms and the resorcarene bowl. It is the position and electronic nature of these donor atoms, which, affected by the choice of metal ion, may dictate the strength of binding to the electron-deficient fullerene guest species. Studies are in progress to elucidate further details of these binding interactions.

Oxidative *N*-demethylation of *N*,*N*-dimethylanilines catalysed by lignin peroxidase: a mechanistic insight by a kinetic deuterium isotope effect study

Enrico Baciocchi,*[a] Maria Francesca Gerini,[b] Osvaldo Lanzalunga,[b] Andrea Lapi,[b] Simona Mancinelli[b] and Paolo Mencarelli[b]

[b] *Dipartimento di Chimica and Centro CNR di Studio sui Meccanismi di Reazione, Università 'La Sapienza', P.le A. Moro 5, 00185, Rome, Italy*

Received (in Liverpool, UK) 18th October 1999, Accepted 13th January 2000

Lignin peroxidase can catalyse the *N*-demethylation of *N*,*N*-dimethylanilines by an electron transfer mechanism, where the deprotonation of the intermediate radical cation is also an enzymatic process.

Lignin peroxidase (LiP), a heme-containing glycoprotein isolated from the ligninolytic cultures of the white-rot fungus *Phanerochaete chrysosporium*, is a very important enzyme capable of performing the oxidative depolymerization of lignin with hydrogen peroxide.[1] For this reason, studies of this enzyme have been focused so far on the oxidation of non-phenolic electron rich aromatic lignin model compounds,[1c,d,2] while less information is available about the catalytic activity of LiP in the H_2O_2-promoted oxidation of other substrates.[3]

Here we report on the ability of LiP to catalyse the oxidative *N*-demethylation of *N*,*N*-dimethylanilines, a process of great biological importance. We also provide some information about the mechanism of this reaction *via* a kinetic deuterium isotope effect (KDIE) study.

4-X-Substituted *N*,*N*-dimethylanilines were reacted with an equimolar amount of hydrogen peroxide in the presence of LiP (purified from the *Phanerochaete chrysosporium* culture medium according to the literature method[4]) in an argon-degassed 50 mM sodium tartrate buffered solution at pH 4. A clean *N*-demethylation reaction was observed, but only when X is an electron withdrawing group (X = Br, CF_3, CN and NO_2). The yields are reported in Table 1. *N*,*N*-Dimethylaniline and anilines with electron donating substituents exhibited no reactivity, probably due to the fact that they were almost completely protonated at the low pH value necessary for the enzyme catalysis. In all cases, beside the demethylated products, formaldehyde was also formed, which was detected by GC-MS after conversion into the dimedone adduct.

The capacity of LiP to catalyse the oxidation of electron rich aromatics ($E° \leqslant 1.25$ V *vs.* SCE in water) by an electron transfer (ET) mechanism is well documented.[2c,3d] Therefore, it is reasonable to suggest that an ET mechanism also occurs in the *N*-demethylation reaction, as a value as low as 1.1 V *vs.* SCE[5] has been estimated for the redox potential of *N*,*N*-dimethyl-4-nitroaniline, the least oxidizable aniline in Table 1. This mechanism is also consistent with the absence of reactivity observed when the aniline is in the protonated form. Moreover, an ET mechanism has been proposed for the *N*-demethylation of *N*,*N*-dimethylaniline by other peroxidases.[7]

According to this mechanism (Scheme 1), an ET occurs between the substrate and the porphyrinato iron–oxo complex (Compound I), which is the active oxidant formed by reaction of the native form of LiP with H_2O_2. An anilinium radical cation and the reduced form of Compound I (Compound II) are obtained. The anilinium radical cation then undergoes deprotonation to give an α-amino carbon radical and it has been suggested by Guengerich and his associates that this process can either involve the enzyme or take place by a non-enzymatic pathway, depending on the nature of the peroxidase.[7b] In the former case [path (b) in Scheme 1], Compound II is suggested to be the proton abstracting base. The α-amino carbon radical then undergoes oxygen rebound to form a carbinolamine that is eventually converted to the *N*-demethylated product. In the second case, the deprotonation is promoted [path (a)] by the medium (H_2O). The α-amino carbon radical (a very easily oxidizable species) is oxidized to a carbocation which is then converted into a carbinolamine by reaction with H_2O.

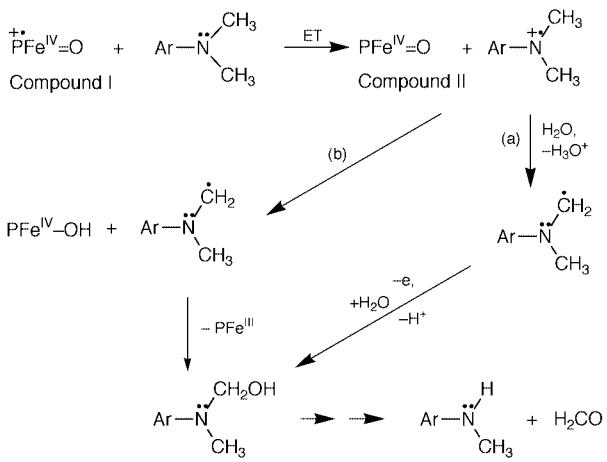
Guengerich also suggested, on the basis of intramolecular KDIE values, that chloroperoxidase followed the enzymatic path, while horseradish peroxidase followed the non-enzymatic one, probably due to the difficult accessibility of the ferryl oxygen in the latter enzyme.[7b]

In the case of LiP, the size of the substrate-access channel to the heme is still smaller than in HRP so that the substrate should have access only to the heme edge, where the electron transfer

Table 1 Products and yields in the reaction of 4-substituted *N*,*N*-dimethylanilines with hydrogen peroxide catalyzed by LiP[a]

Substrate (4-substituent)	Product yield ArNHMe (%)	Material balance[b] (%)
Br	16	> 99
CF_3	28[c]	75
CN	62	86
NO_2	20	87

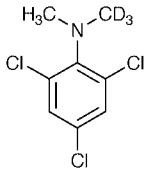
[a] Experimental procedures are as follows: the oxidant (10 μmol) was added, over a period of 1 h by an infusion pump, to a stirred degassed solution of the substrate (10 μmol), LiP (0.96 units, 1.16 nmol) and MeCN (50 μl) as the co-solvent, in 3 ml of Na–tartrate buffer (50 mM, pH 4) at 25 °C. Products analysis were performed by GC and GC-MS. [b] The sum of the moles of unreacted substrate and reaction product relative to the initial moles of substrate. [c] In this case 4-trifluoromethylaniline (5%) was also observed.



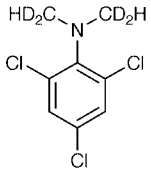
Scheme 1

DOI: 10.1039/a908394d

process can still take place, but not the deprotonation of the radical cation by the ferryl oxygen.[8] One would therefore predict a non-enzymatic pathway for the deprotonation of the radical cation in the LiP-catalysed *N*-demethylation reactions. However, strong evidence in favour of a deprotonation promoted by the enzyme has been provided by the complete masking [k_H/k_D = 1.04 (± 0.06)] of the intramolecular KDIE observed for the *N*-demethylation of *N*-methyl-*N*-trideuteromethyl-2,4,6-trichloroaniline **1** catalysed by LiP (25% yield).[9,10]



1



2

In this system, due to the steric effect of the two *ortho*-chlorine atoms, the two *N*-methyl groups are forced to stay one above and the other below the plane of aromatic ring as confirmed by theoretical calculations based on the Density Functional approach (DFT), carried out on the radical cation of *N*,*N*-dimethyl-2,6-dichloroaniline, a model compound for **1**.[11] These calculations moreover show that there is a quite large barrier (33.5 kJ mol^{-1}) to the rotation around the C(aromatic)–N bond.[12] Thus, the absence of a deuterium isotope effect for this substrate strongly suggests that deprotonation has to take place in the enzyme pocket, being significantly faster than rotation of CH_3 and CD_3 groups around the C(aromatic)–N bond.[13] Under these conditions, the loss of hydrogen or deuterium will only depend on which one of the two methyl groups in the radical cation is oriented towards the proton abstracting center and reasonably there is the same probability that this group is CH_3 or CD_3. Thus, the intramolecular KDIE with this substrate should be completely masked, as is actually observed. This interpretation is confirmed by the significant value of intramolecular KDIE (3.36 ± 0.07) found instead in the oxidation of *N*,*N*-bis(dideuteromethyl)-2,4,6-trichloroaniline **2** (27 % yield), where deuterium and hydrogen are bonded to the same carbon.[14] In **2**, the KDIE is no longer influenced by the hindered rotation mentioned before. Further support also comes from the high intramolecular KDIE value (7.0 ± 0.8) measured in the oxidation of *N*-methyl-*N*-trideuteromethyl-3,4,5-trichloroaniline, where the absence of *ortho*-substituents allows the two methyl groups to freely interchange within the enzyme pocket.

In conclusion, our data clearly show that LiP can catalyse the oxidative *N*-demethylation of aromatic tertiary amines with fairly good efficiency. Moreover, the intramolecular KDIEs measured with **1** and **2** indicate that the aminium radical cation is deprotonated by the enzyme. Concerning the basic center, Compound II seems unlikely, in the light of the already mentioned current views about the accessibility of the heme in this enzyme.[8] Another hypothesis is that the deprotonation of the radical cation is promoted by some specific amino acid residue located in or very close to the active site. Histidine 82 might be a suitable candidate in this respect. An additional possibility might be a medium induced deprotonation of an enzyme complexed radical cation.[15]

This work was carried out with the financial support of the Ministero dell'Università e della Ricerca Scientifica Tecnologica (MURST) and the Consiglio Nazionale delle Ricerche (CNR). We also thank Professor Pietro Tagliatesta, University of 'Tor Vergata', Rome, Italy, for cyclic voltammetry measurements.

9 All the KDIE values reported in this work were determined by GC-MS analysis of the formaldehyde–dimedone adduct, and they are an average of at least three independent determinations.

10 Compound **1** was prepared by reacting 2,4,6-trichloroaniline with MeI and then with CD_3I.

11 (*a*) The calculations were carried out, with the GAUSSIAN 94 package [ref. 11(*b*)], by using the DFT approach at the B3LYP/6-311+G(d,p) level of theory. Spin contamination due to states of multiplicity higher than the doublet state was negligible, in that the $< S^2 >$ parameter was, in all cases, well within 10% of the expectation value for a doublet (0.75). (*b*) M. J. Frisch, G. W. Trucks, H. B. Schlegel, P. M. W. Gill, B. G. Johnson, M. A. Robb, J. R. Cheeseman, T. Keith, G. A. Petersson, J. A. Montgomery, K. Raghavachari, M. A. Al-Laham, V. G. Zakrzewski, J. V. Ortiz, J. B. Foresman, J. Cioslowski, B. B. Stefanov, A. Nanayakkara, M. Challacombe, C. Y. Peng, P. Y. Ayala, W. Chen, M. W. Wong, J. L. Andres, E. S. Replogle, R. Gomperts, R. L. Martin, D. J. Fox, J. S. Binkley, D. J. Defrees, J. Baker, J. P. Stewart, M. Head-Gordon, C. Gonzalez and J. A. Pople, GAUSSIAN 94, Revision D.2, Gaussian, Inc., Pittsburgh PA, 1995.

12 This can also be argued by the oxidation peak potential (E_p) measured for **1** (1.34 V *vs.* SCE) [ref. 5(*b*)] which is significantly higher than that measured for its isomer *N*,*N*-dimethyl-3,4,5-trichloroaniline (E_p = 1.16 V *vs.* SCE) [ref. 5(*b*)].

13 Even assuming that the barrier to rotation does not increase in the enzyme pocket, a deprotonation faster than rotation around the C(aromatic)–N bond is plausible, as an activation enthalpy less than 33.5 kJ mol^{-1} is possible for the former reaction [ref. 5(*a*)].

14 Compound **2** was prepared by reacting 2,4,6-trichloroaniline with CD_2O and $NaBH_4$ (S. B. Karki, J. P. Dinnocenzo, J. P. Jones and K. R. Korzekwa, *J. Am. Chem. Soc.*, 1995, **117**, 3657).

15 We thank one of the referees for this suggestion.

A convenient synthesis of porphodimethenes and their conversion to *trans*-porphyrins with two functionalized *meso*-naphthyl substituents

Michael Harmjanz and Michael J. Scott

Department of Chemistry, University of Florida, Gainesville, FL 32611-7200, USA. E-mail: mjscott@chem.ufl.edu

Received (in Bloomington, IN, USA) 4th October 1999, Accepted 20th January 2000

The Mac Donald-type 2 + 2 condensation of the readily available 5-mesityldipyrromethane with acenaphthenequinone leads to the *trans* (*syn* and *anti*) porphodimethenes, respectively, which, after treatment with KOH or NaOMe in THF and subsequent oxidation with air, yield the corresponding *trans*-8-carboxynaphthylporphyrins or their esters.

meso-Substituted porphyrins with rigid anthracene, biphenylene or naphthalene spacers have been widely used to determine the distance dependency of photo-induced electron transfer[1] as well as to prepare and examine cofacial diporphyrins[2] or other bridged porphyrins with well defined separations and varying relative arrangements of the porphyrin rings.[3] Porphyrins with a functionalized anthracene or naphthalene group have also found utility as building blocks for the synthesis of molecular receptors and for the design of dinuclear complexes.[4] Despite the numerous potential applications for these types of complexes, their development has been severely hampered by the inability to prepare large quantities of the porphyrin precursors. The syntheses, in general, require complex procedures for the preparation of the aromatic side arm and/or a multistep procedure for the porphyrin backbone. Chang *et al*.[5] and Therien and coworkers[6] have reported the preparation of porphyrins attached to the 1-position of an 8-functionalized naphthalene but to the best of our knowledge, a straightforward synthetic procedure for the synthesis of *trans* αα/αβ porphyrins bearing two 8-functionalized naphthalene derivatives has yet to be reported.

As part of our building block approach towards the preparation of new di- and tri-nuclear porphyrin based complexes, a general two-step synthesis, starting from 5-mesityldipyrromethane, has been developed to provide convenient amounts of the desired porphyrins. Reaction of commercially available acenaphthenequinone with 5-mesityldipyrromethane in the presence of catalytic amounts of $BF_3{\cdot}OEt_2$[7] gives, after oxidation with DDQ and subsequent filtration through neutral alumina, a mixture of the corresponding porphodimethene isomers in 26% yield. Separation by column chromatography yields the two isomers [**1** (*syn*), **2** (*anti*)] in an almost 1:2 ratio.†

The porphodimethenes **1** and **2** are air-stable, bright orange solids and they exhibit a characteristic absorption maxima in the visible region at λ_{max}/nm (log ε) 440(4.97) (**1**) and 438(4.93) (**2**), which when compared to previously described octaalkylporphodimethenes (414–426 nm) are bathochromically shifted.[8] The N–H and C=O stretch frequencies can be found, respectively, in the IR at 3345, 1732 cm^{-1} for **1** and 3279, 1720 cm^{-1} for **2**. The absolute configuration has been determined by ^{1}H NMR and by an X-ray structure analysis of the metallated (Zn^{2+}) porphodimethene **2b**. Although the X-ray structure analysis of **2** reveals a strong roof-like folded structure of the porphodimethene core,[9] only one type of acenaphtheneoyl can be identified in the ^{1}H NMR spectra of both **1** and **2**, suggesting a fast up and down motion of the acenaphtheneoyl groups together with a flexing of the two dipyrromethane units along a line joining the two saturated *meso* carbons. Even at 223 K, only minor changes were evident in the NMR spectra of **2**. Owing to the lack of aromaticity in the macrocycle, the signal of the N–H protons appears downfield at δ 13.92 (**1**) and 14.00 (**2**), respectively, characteristic of porphodimethenes.[8,10] Metal insertion has been demonstrated by reaction of **2** with $Zn(OAc)_2{\cdot}2H_2O$ in refluxing $CHCl_3$–MeOH. Complex formation can be easily monitored by UV–VIS-spectroscopy [Fig. 1, λ_{max} (log ε) 475 nm (5.17) (**2b**)]. As shown in Fig. 2, the Zn^{2+} in **2b** is complexed by a nearly planar, C_2 symmetric, tetrapyrrole macrocycle, although the metal is disordered over two positions in the solid-state structure. The

DOI: 10.1039/a907992k

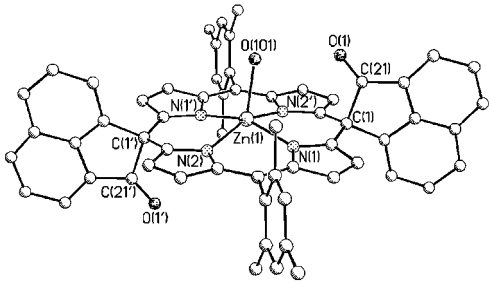

Fig. 2 Diagram of **2b**; the porphodimethene resides on inversion symmetry position, relating the prime and unprimed atoms. The zinc atom is disordered over two positions and the symmetry equivalent Zn(1′) and O(101′) atoms as well as all hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Zn(1)–N(1) 2.116(4), Zn(1)–N(2) 2.197(4), Zn(1)–N(1′) 2.038(4), Zn(1)–N(2′) 2.063(4), Zn(1)–O(101) 2.175(7), N(1)–Zn(1)–N(2) 85.2(1), N(1)–Zn(1)–N(2′) 88.6(1), N(1′)–Zn(1)–N(2) 87.0(1), N(1′)–Zn(1)–N(2′) 90.7(1), N(1)–Zn(1)–O(101) 97.9(2), N(2)–Zn(1)–O(101) 107.4(2), N(1′)–Zn(1)–O(101) 104.9(2), N(2′)–Zn(1)–O(101) 94.3(2).

largest out of plane displacements are observed for the saturated *meso* carbon atoms (0.11 Å) which are part of the five-membered rings of the two 1-acenaphthenone moieties aligned in an *anti* position. The Zn atom, coordinated by the four pyrrole nitrogens and an axial water molecule, resides 0.404 Å above the plane defined by the nitrogen donor set. The Zn–N bond lengths vary considerably from 2.038(4) to 2.197(4) Å, but the average distance of 2.10 Å is significantly larger than the corresponding linkage in tetra *meso*-aryl substituted porphyrins [mean: 2.036(6) Å; ZnTPP].[11]

Refluxing the porphodimethenes **1** and **2** in THF in the presence of 30% KOH results in ring opening and formation of the respective porphyrins without further oxidation by DDQ. Subsequent protonation with 6 M HCl gives the free acids (**3**, **4**) in high yields. While the αα isomer **3** is soluble in $CHCl_3$, the αβ atropisomer is virtually insoluble in most common organic solvents, possibly owing to strong intermolecular hydrogen-bonding interactions between the carboxylic acid groups. Accordingly, the αβ atropisomer has been fully characterized as the dipotassium salt.

Porphyrin formation has also been accomplished by reaction of **1** or **2** with NaOMe in THF–MeOH at room temp. After bubbling air through the reaction mixture, the corresponding esters (**5**, **6**) were isolated in moderate yields.‡ All of the porphyrins exhibit a characteristic Soret band between 425 and 432 nm in the UV–VIS spectra and they have been characterized by IR, NMR and MS. In addition, the αβ atropisomer **6** has been characterized by an X-ray structural analysis (Fig. 3), and although most of the structural parameters of the porphyrin core are indistinguishable from other *meso*-aryl substituted porphyrins, a few particular details are worth noting. The two mesityl residues are oriented nearly perpendicular to the porphyrin plane (85.3°) while the naphthalene moieties exhibit a twist of 61.8° relative to the macrocyclic ring. Owing to the electronic repulsion of the ester group and the electron rich porphyrin plane, the functionalized naphthalene groups are slightly inclined back away from the porphyrin, lifting the two oxygen atoms above the plane of the macrocycle by 2.667 Å [O(2)] and 3.087 Å [O(1)], respectively.

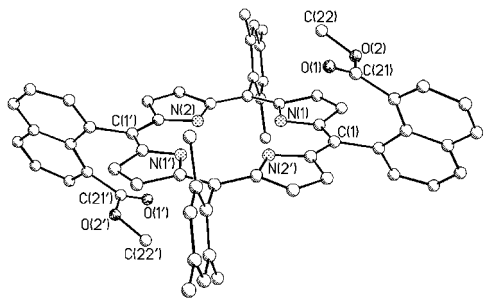

Fig. 3 Diagram of the structure of **6** outlining the atom numbering scheme. Primed and unprimed atoms are related by a center of inversion. The hydrogen atoms have been omitted for clarity.

In summary, we have demonstrated that acenaphthenone substituted porphodimethenes can be generated from 5-mesityldipyrromethane and acenaphthenequinone. Ring cleavage gives the desired porphyrins bearing two 8-functionalized naphthalene groups. Work is in progress to extend this reaction to other vicinale diketones. Other ring opening reactions are also under investigation.

TEMPO free radical derived β-aminoalkoxyketolactones: substrates for base-, acid- and radical-induced fragmentation reactions

Arthur G. Schultz† and Xuqing Zhang*

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, NY 12180-3590, USA. E-mail: zhangx4@rpi.edu

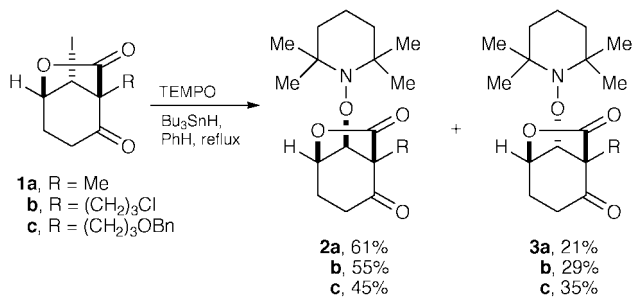
Received (in Corvallis, OR, USA) 10th December 1999, Accepted 2nd February 2000

β-Aminoalkoxyketolactones 2 and 3 obtained from the TEMPO free radical substitution of iodolactones 1 undergo fragmentations under basic, acidic and free radical conditions.

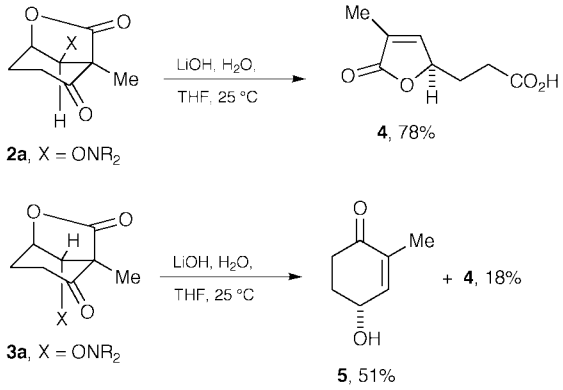
Fragmentation reactions of iodoketolactones of general structure **1**, available as single enantiomers,[1] with LiOH under aqueous conditions afford butenolide carboxylic acids and 4-hydroxy-2-cyclohexenones by way of competing additions of hydroxide ion to the ketone and lactone carbonyl groups.[2] The bicyclo[3.2.1] ring system in **1** locks the conformation of the two carbonyl groups with respect to the iodo substituent. To examine the importance of stereoelectronic factors[3] in these fragmentation processes it was desirable to have access to not only the axial iodo substituent in **1** but also an equatorial leaving group. We have found that it is possible to carry out an exchange of iodide in **1** with 2,2,6,6-tetramethyl-1-piperidinyloxy free radical (TEMPO) to provide both the axial and equatorial substituted β-aminoalkoxyketolactones **2** and **3** (Scheme 1).[4] Herein we describe the fragmentation reactions of **2** and **3** under basic, acidic and free radical conditions.

Mixtures of β-aminoalkoxyketolactones **2** and **3** were produced from **1** and were separated by flash chromatography on silica gel. Treatment of **2a** with 2 equiv. of LiOH in a 5:1 mixture of THF and water gave butenolide carboxylic acid **4** in 78% isolated yield with no trace of the 4-hydroxycyclohexenone **5** (Scheme 2). Addition of aqueous LiOH to the isomer **3a** with an axial aminoalkoxy group gave mainly the 4-hydroxycyclohexenone **5** along with 18% of **4** (Scheme 2).

That **2a** undergoes fragmentation to give **4** rather than **5** is a result of the antiperiplanar relationship of the leaving group X and the cyclohexanone C–C bond in the tetrahedral intermediate generated by addition of hydroxide ion to the ketone carbonyl group. The formation of **5** is explained by addition of hydroxide ion to the lactone carbonyl group of **3a** followed by a relatively fast fragmentation of the lactone C–C bond along with elimination of the antiperiplanar aminoalkoxy group. A competing fragmentation of **3a** occurs by addition of hydroxide ion to the ketone carbonyl group followed by a relatively slow cleavage of the cyclohexanone C–C bond to give a lactone enolate; elimination of the poorly oriented aminoalkoxy group is probably not in concert with C–C bond cleavage, but must await a conformational adjustment in the enolate to bring orbitals into proper alignment.[3] It is noteworthy that iodolactone **1a** also gave a mixture of **4** and **5** on treatment with aqueous LiOH.[4]



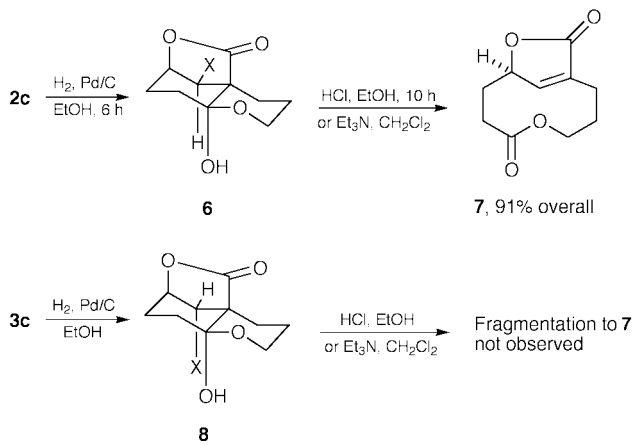
Scheme 1



Scheme 2

We were interested in the development of fragmentation processes initiated by intramolecular carbonyl addition reactions. Hydrogenolysis of the benzyl ether **2c** in the presence of dilute hydrochloric or acetic acids provided the hemiketal **6**, and treatment of **6** with moderately concentrated HCl in ethanol at 25 °C resulted in fragmentation to give the medium ring lactone-butenolide **7** in 90% yield (Scheme 3).[5] Hemiketal **6** also was converted to **7** (88%) by fragmentation under basic reaction conditions (Et_3N in CH_2Cl_2, 25 °C). By contrast, hemiketal **8** obtained from hydrogenolysis of the isomeric benzyl ether **3c** did not undergo fragmentation to **7** under comparable acidic or basic reaction conditions (Scheme 3).

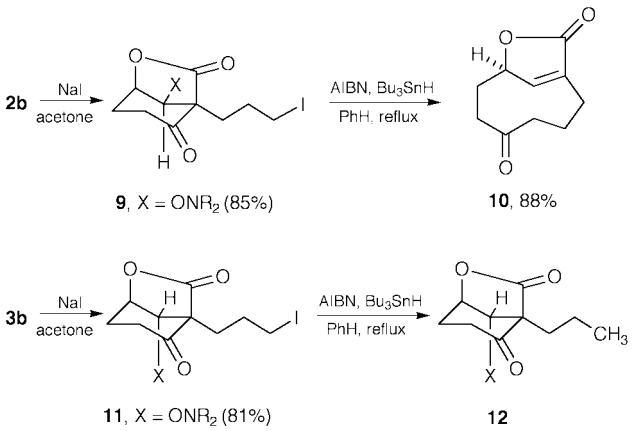
The utilization of aminoalkoxy substituents to initiate acid-catalyzed fragmentation reactions appears to be without precedent in the chemical literature. It is thought that fragmentation of **6** occurs from the *N*-protonated aminoalkoxy substituent to provide the oxide of a *sec*-amine as the leaving group; the amine oxide would be expected to rearrange to 1-hydroxy-



Scheme 3

† Deceased January 20th, 2000.

DOI: 10.1039/a909750c



Scheme 4

2,2,6,6-tetramethylpiperidine.[6] Ionization of the protonated axial aminoalkoxy substituent in **8** does not occur because of the synclinal relationship of the C–ONR_2 bond and the cyclohexane C–C bond.[7] Fragmentation of **6** with Et_3N occurs by deprotonation of the hemiketal with concomitant elimination of R_2NO^-.

Perhaps the most interesting application of the aminoalkoxy substituent as a regulator of fragmentation reactions is in the area of free radical-mediated ring expansions.[8] Treatment of the alkyl iodide **9** with AIBN and Bu_3SnH (added over 6 h) in refluxing benzene gave the nine-membered-ring ketone **10** in 77% yield (88% based on recovered **9**) (Scheme 4).[9] However, the isomer **11** with an axial aminoalkoxy substituent gave the *n*-propyl derivative **12** with no trace of **10** (Scheme 4).

These data suggest that the primary alkyl radical generated from **9** undergoes addition to the ketone carbonyl group, followed by a relatively fast alkoxy radical-induced fragmentation to give **10** and the TEMPO free radical. The primary radical generated from **11** probably also undergoes addition to the ketone carbonyl group (reversible), but without proper alignment of the aminoalkoxy substituent this addition is nonproductive; reversion to the alkyl radical and eventual reduction with Bu_3SnH gives the *n*-propyl derivative **12**. It should be noted that alkyl radical addition to the lactone carbonyl group and fragmentation to a 2,4-lactone fused-2-cyclohexenone (structure not shown; *cf.* **3a** → **5**) is not competitive with reduction of the alkyl radical with Bu_3SnH.

In summary, the 2,2,6,6-tetramethyl-1-piperidinyloxy group has been found to be an effective leaving group in fragmentation reactions performed under basic, acidic and free radical conditions. It is important to note that elimination of 2,2,6,6-tetramethylpiperidine from **2** or **3** to give the corresponding β-diketone did not occur under any of these reaction conditions.[10] The availability of β-aminoalkoxyketolactones **2** and **3** as single enantiomers[1] suggests that these fragmentation reactions ought to have substantial utility in organic synthesis; the development of methods to selectively generate **2** and **3** and related substrates are under investigation.

We thank Dr P. R. Guzzo and Dr L. Pettus for early contributions to this project and the National Institutes of Health (GM 26568) for generous financial support.

Development of a novel oxidatively removable and recyclable linker for combinatorial solid phase synthesis

Wen-Ren Li,* Nai-Mu Hsu, Hsueh-Hsuan Chou, Sung Tsai Lin and Yu-Sheng Lin

Department of Chemistry, National Central University, Chung-Li, Taiwan 32054, ROC.
E-mail: wenrenli@rs250.ncu.edu.tw

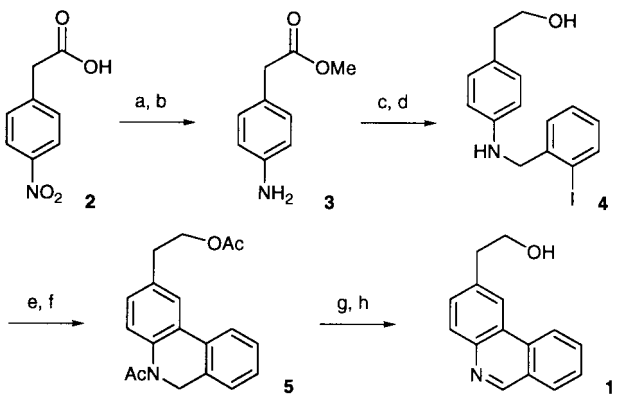
Received (in Cambridge, UK) 23rd November 1999, Accepted 28th January 2000

An appropriately derivatized phenanthridine is shown to behave as a novel, reusable linker which is based on a disubstituted amide anchorage and forms an acid group on oxidative cleavage, but tolerates exposure to acidic, basic and reductive reaction conditions.

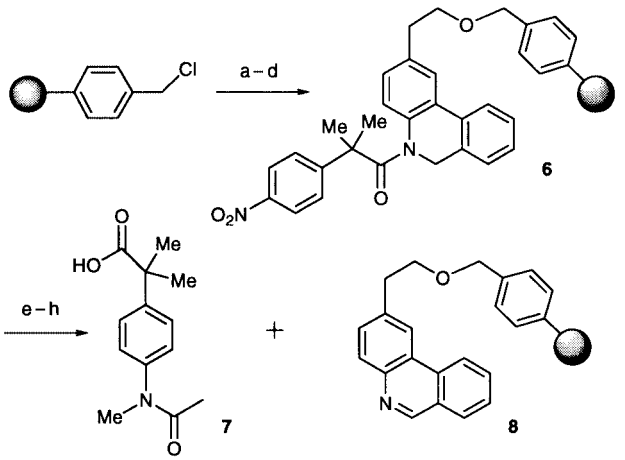
Recently, a considerable amount of attention has been focused on the use of the combinatorial library approach for the discovery of new molecules with desired properties.[1] Up to now, syntheses of a variety of classes of chemical libraries have been constructed employing solid phase methods.[2,3] Many linkers have, therefore, been developed for anchoring and selectively removing the desired target molecule from polymer supports.[4–8] As far as we are aware, none of the available linkers used for carboxylic functions survive through a series of acidic, basic and reductive reactions and are also stable to *N*-alkylation conditions.[9–11] This void led us to devise a new type of recyclable phenanthridine linker for the synthesis of acids, which possesses greater stability under the above reaction processes and the capability to be removed by a mild oxidative reagent. In addition, it can be recycled.

The synthesis of an appropriately functionalized phenanthridine **1** is detailed in Scheme 1. The synthesis was initiated with protection of the acid group of 4-nitrophenylacetic acid as its methyl ester using $SOCl_2$ and MeOH. Reduction of the nitro group of the methyl ester was rapidly accomplished by catalytic transfer hydrogenation with NH_4HCO_2 as the hydrogen donor over a Pd/C catalyst.[12] Coupling of amine **3** with 2-iodobenzoic acid was followed by reduction using $NaBH_4$ and $BF_3{\cdot}OEt_2$ to form the secondary amine **4** in 73% yield for four steps from 4-nitrophenylacetic acid. Attempts to perform an internal biaryl cyclization of the aryl substituted amide, before $NaBH_4$ reduction, gave an undesired intermolecular coupling dimer. Acylation of the amino and hydroxy group of compound **4** with AcBr, followed by intramolecular Heck type cyclization[13] employing $Pd(OAc)_2$, PPh_3 and Ag_2CO_3 in MeCN led to the amide **5** in 70% yield. Oxidative cleavage of the resulting amide **5** with cerium ammonium nitrate (CAN) and subsequent hydrolysis of the acetate with LiOH afforded the amine-masked phenanthridine handle **1** as a crystalline compound. Of particular note is that the synthesis of all intermediates in Scheme 1 can be carried out on a preparative scale to afford ample quantities of the desired compound in roughly 40% overall yield.

The suitability for reductive processing and alkylation of the new linker and its applicability to peptide chemistry were demonstrated by the synthesis a trimethylated derivative of actarit,[14] an immunomodulating agent, and a *N*-acylated dipeptide on the Merrifield resin as shown in Schemes 2 and 3. The phenanthridine derivatized solid support **8** (Scheme 2) can readily be prepared by treating chloromethylpolystyrene with the sodium salt of phenanthridine in dry DMF at room temperature for 16 h. In this form the phenanthridine resin is stable and can be stored for long periods without loss of activity. Reduction of this functionalized resin furnished the resin-bound secondary amine, which was first derivatized with 4-nitrophenylacetic acid and then subjected to enolate alkylation by employing commonly used bases such as NaH or LDA.[15] Reduction of the nitro group of resin **6** with $SnCl_2$ in DMF afforded, after acetylation and *N*-alkylation, the trimethylated acid-bound resin. Treatment of the resulting resin with 2 equiv. of CAN in MeCN and water for 10 min resulted in complete cleavage of the desired acid from the solid support. After removal of the MeCN, the crude product was dissolved in EtOAc, washed successively with water and aqueous HCl and purified to give the trimethylated actarit derivative **7** in 57% overall yield for eight steps. The regenerated phenanthridine resin **8** could be reused for another synthetic sequence with only a slight loss in activity. The yields after one and two recycles are 90 and 84%, respectively. The resin-bound amides in Scheme 2 are stable under either basic or acidic hydrolytic conditions.



Scheme 1 *Reagents and conditions*: (a) $SOCl_2$, MeOH, 97%; (b) 10% Pd/C, HCO_2NH_4, MeOH, 97%; (c) 2-iodobenzoic acid, DIC, MeCN, 84%; (d) $NaBH_4/BF_3{\cdot}OEt_2$, THF, 93%; (e) AcBr, Et_3N, MeCN, 87%; (f) PPh_3, $Pd(OAc)_2$, Ag_2CO_3, MeCN, 70%; (g) CAN, MeCN, H_2O, 95%; (h) LiOH, THF, H_2O, 95%.†



Scheme 2 *Reagents and conditions*: (a) NaH, DMF, linker **1**; (b) $NaBH_4$, $BH_3{\cdot}THF$, EtOH, 71%; (c) 4-nitrophenylacetic acid, DIC, CH_2Cl_2; (d) NaH, MeI, DMF or LDA, HMPA, THF, MeI; (e) $SnCl_2$, DMF, 88%; (f) Ac_2O, Et_3N, CH_2Cl_2; (g) NaH, MeI, DMF; (h) CAN, THF, H_2O, 92%.†

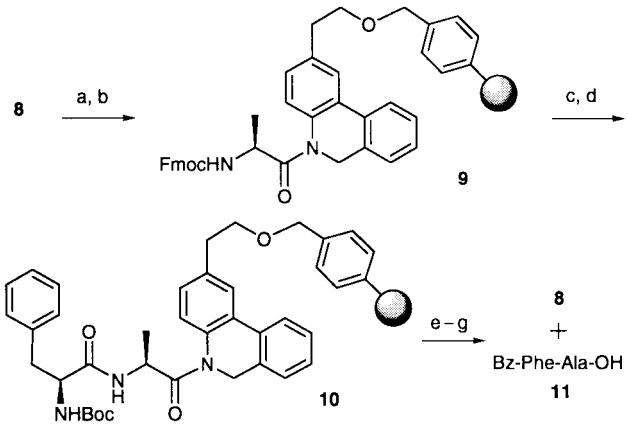

Scheme 3 *Reagents and conditions*: (a) $NaBH_4$, BH_3·THF, EtOH; (b) DIC, Fmoc-L-Ala-OH, CH_2Cl_2; (c) 20% piperidine, DMF, 89%; (d) HBTU, Pr^i_2NEt, Boc-L-Phe-OH, DMF; (e) TFA, CH_2Cl_2, 94%; (f) BzCl, Pr^i_2NEt, CH_2Cl_2; (g) CAN, THF, H_2O, 91%.

These amides were not hydrolyzed upon treatment with 1 M HCl or NaOH in THF–H_2O solution over 24 h. The further utility of this linker has been shown by synthesizing an *N*-acylated dipeptide **11** (Scheme 3). Similar results were achieved using a similar strategy to that employed for the previous syntheses. After *N*-Fmoc-L-alanine was coupled to the phenanthridine linker the resin was submitted to the peptide synthetic sequence to provide the desired dipeptide **11** in a nonoptimized yield of 76%, as shown in Scheme 3. At each step, the coupling efficiency was about 86–95% yield as monitored by photometric Fmoc determination and the ninhydrin method. Controls during these syntheses proved that the above reaction milieu did not cause either any premature cleavage or damage of the linker.

In conclusion, we have developed a new linker for solid phase organic synthesis of carboxylic acids and have successfully demonstrated its application. The advantages of this linker are: (i) it is orthogonal to the Fmoc/Boc and Boc/Bn protecting group strategies; (ii) it can be prepared in both large quantity and high purity; (iii) its attachment to the solid support is straightforward; (iv) it is anchored to the C-terminal residue by a disubstituted amide and not an ester bond, ensuring stability to *N*-alkylation and avoidance of diketopiperazine formation at the dipeptide stage; (v) the linker is rapidly cleaved under mild oxidative conditions and the reaction is very clean; (vi) the phenanthridine resin is sufficiently robust to be recovered and recycled through the reaction sequence. Therefore, the phenanthridine linker should find broad application in the field of solid phase combinatorial synthesis where orthogonal methods of release are required. Currently, we are investigating non-aqueous oxidative cleavage conditions which will afford the corresponding esters and are exploring the length and attachment position of the alkoxyacyl spacer that is needed to link the appropriate phenanthridine handle to aminated resins such as MBHA or BHA resin through an amide bond.

Preparation of synthetic steamcracker feed from cycloalkanes (or aromatics) on zeolite catalysts

Jens Weitkamp,*[a] Andreas Raichle,[a] Yvonne Traa,[a] Martin Rupp[b] and Franz Fuder[b]

[a] *Institute of Chemical Technology, University of Stuttgart, D-70550 Stuttgart, Germany. E-mail: jens.weitkamp@po.uni-stuttgart.de*

Received (in Cambridge, UK) 23rd December 1999, Accepted 4th February 2000

Methylcyclohexane is converted into a high-quality steamcracker feed over acidic zeolites with appropriate pore systems, thereby opening a new route for the utilisation of surplus aromatics.

Steamcrackers[1] are widely employed for the production of ethylene and propylene from naphtha,[2] ethane or similar light hydrocarbons. One of the by-products of steamcracking is pyrolysis gasoline which is rich in aromatics. Given the forecasted growth in the worldwide demand of ethylene[3] and propylene[4] from, respectively, 57×10^6 and 30×10^6 tonne yr^{-1} in 1990 to *ca.* 140×10^6 and 75×10^6 tonne yr^{-1} in 2010, the production of pyrolysis gasoline will necessarily increase as well. Up till now, pyrolysis gasoline has been used as an aromatics-rich and, hence, high-octane petrol component. With the so-called Auto Oil Programme of the European Community, the aromatics content of petrol has to be diminished from 45 to < 42 vol% until the year 2000, and to < 35 vol% until 2005.[5] Therefore, new outlets for surplus aromatics are urgently needed. We report here on a novel catalytic chemistry by which cycloalkanes (or aromatics, since these can easily be hydrogenated into cycloalkanes by state-of-the-art processes) are converted predominantly into light linear alkanes (ethane, propane, *n*-butane and *n*-pentane) the mixture of which is a premium steamcracker feedstock for high ethylene and propylene yields.[6]

Previous work on ring opening of cycloalkanes mostly relies on hydrogenolysis over noble metal catalysts designed predominantly to yield branched alkanes.[7–9] Such hydrocarbons are, however, less suitable as a steamcracker feed, since large amounts of undesired methane will be formed. Only few reports deal with cracking of cyclic hydrocarbons over acidic zeolites in an excess of hydrogen,[10–12] and yields of *n*-alkanes during the conversion of cycloalkanes or aromatics with seven or more carbon atoms are reported to be low.

On zeolite H-ZSM-5 at 400 °C, methylcyclohexane is converted[13] with a yield of 70.6% into ethane (9.4%), propane (47.7%), *n*-butane (12.4%) and *n*-pentane (1.1%), see Fig. 1 and Table 1, whereas on zeolite H-Y, much lower yields (42.8%) of these desirable products are obtained. On H-ZSM-5, the most important by-products are branched alkanes, *viz.* 17.6% isobutane, 6.2% isopentane and 0.6% isohexanes. Whereas on H-ZSM-5 virtually no aromatics are found, the total yield of aromatics on H-Y amounts to 15.9% (benzene 2.2%, toluene 6.4%, C_8-aromatics 5.6% and C_9-aromatics 1.7%). We tentatively attribute this difference to the lower activity of the larger-pore zeolite for cleavage of endocyclic carbon–carbon bonds.[14] The difference in selectivities becomes even more pronounced at lower conversions (Fig. 2) or at high times-on-stream (Table 1, entry 7). The deactivation observed on zeolite H-Y correlates qualitatively with the mass ratio of carbon in the coke formed on the catalyst[15] and in the methylcyclohexane fed (Table 1, entry 8).

The pronounced differences in the catalytic behaviour of both zeolites can be accounted for by introducing the so-called cracking mechanism ratio,[16] $\mathrm{CMR} \equiv (Y_{\mathrm{methane}} + Y_{\mathrm{C_2\ hydrocarbons}})/Y_{\mathrm{isobutane}}$ (Table 1, entry 9 and Fig. 3), which is considered as a quantitative measure for the relative contributions of monomolecular Haag–Dessau cracking[17] *versus* conventional bimolecular cracking. In the narrower pores of zeolite ZSM-5 and with increasing temperature, Haag–Dessau cracking, which produces large amounts of ethane and propane, is favoured over the spatially more demanding bimolecular mechanism which leads predominantly to isobutane. In line with this interpretation, much more hydrogen is incorporated into the cracked products on H-ZSM-5 than on H–Y (Table 1, entry 10): Clearly, H_2 can be activated on acidic zeolites, as demonstrated previously.[12,18,19]

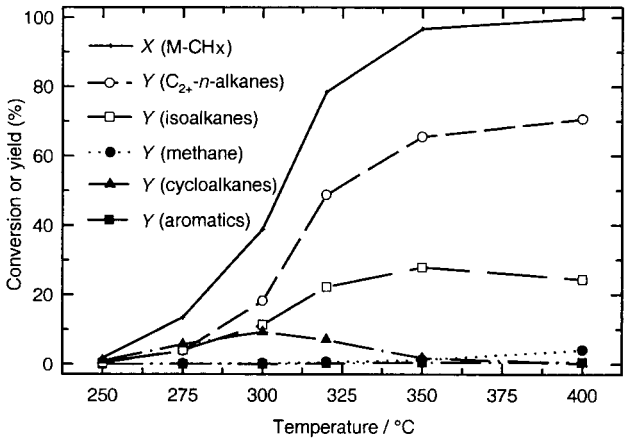

Fig. 1 Conversion of methylcyclohexane on H-ZSM-5 at various temperatures.

In conclusion, methylcyclohexane can be converted over acidic zeolites with suitable pore systems into a high-quality synthetic steamcracker feed consisting predominantly of eth-

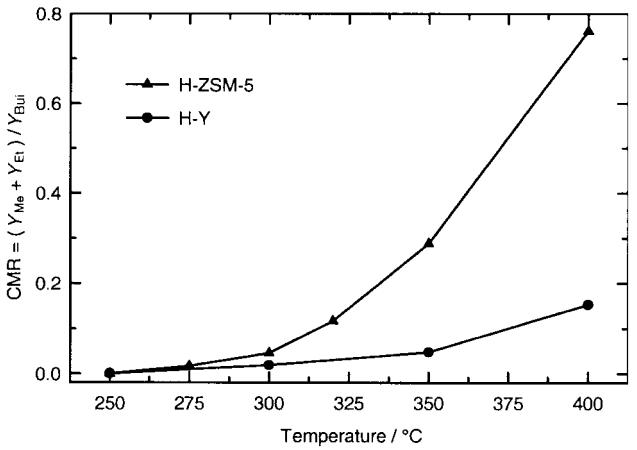

Fig. 3 Cracking mechanism ratio (CMR) after 30 min TOS as a function of temperature during the conversion of methylcyclohexane.

ane, propane and *n*-butane, thereby opening a new route for the utilisation of surplus aromatics. Instead of hydrogenating the aromatics to cycloalkanes and converting the latter into light *n*-alkanes separately, one can use a bifunctional form of the zeolite, such as Pd/H-ZSM-5 or Pt/H-ZSM-5, and produce light *n*-alkanes directly from aromatics in a single reactor. Such work is under way in our laboratories.

ChemComm

The catalytic hydrolysis of CCl_4 to HCl and CO_2 over magnesium oxide

Ulrike Weiss, Michael P. Rosynek and Jack Lunsford*

Department of Chemistry, Texas A&M University, College Station, Texas 77843, USA.
E-mail: lundsford@mail.chem.tamu.edu

Received (in Cambridge, UK) 29th November 1999, Accepted 1st February 2000

At temperatures > 400 °C, CCl_4 reacts with H_2O over a MgO catalyst to yield HCl and CO_2.

The destruction of carbon tetrachloride found in ground water and in effluent streams is typically carried out by using incineration[1] or catalytic oxidation.[2] We describe here the catalytic reaction of CCl_4 with H_2O to form CO_2 and HCl, which has not been previously reported except for a brief comment in the patent literature.[3] The kinetics of the corresponding uncatalyzed reaction in water was studied by Fells and Moelwyn-Hughes,[4] who observed a rather small second order rate constant (with respect to CCl_4) of $k = 1.21 \times 10^{-3}$ L mol^{-1} s^{-1} at 373 K for an initial CCl_4 concentration of 0.903 mmol L^{-1}. The rate was unaffected by proton, hydroxide or chloride ion concentration.

The use of an alkaline earth oxide catalyst is based on a non-catalytic cycle in which CCl_4 was first reacted with BaO to form $BaCl_2$.[5] The $BaCl_2$ was subsequently reacted with aqueous CO_3^{2-} to produce $BaCO_3$ and aqueous HCl. The $BaCO_3$ could be converted to BaO at elevated temperatures (600 °C), and the process could then be repeated. However when CCl_4 and H_2O were passed over BaO at 500°C, the catalytic reaction [eqn. (1)]

$$CCl_4 + 2H_2O \rightarrow 4HCl + CO_2 \quad \Delta G^{o}_{500\,^{\circ}C} = -390\ \text{kJ mol}^{-1} \qquad (1)$$

did not occur. Magnesium oxide, however, is an effective catalyst for this reaction, in part because magnesium chloride is not extensively formed, and, more importantly, magnesium carbonate decomposes at temperatures near 400 °C.

The catalyst was prepared by the decomposition of $Mg(OH)_2$ obtained by stirring a slurry of MgO (Fisher, light) and water at 80 °C for 24 h. The $Mg(OH)_2$ (20–40 mesh size) was decomposed at 400 °C in flowing O_2 (100 mL min^{-1}). The reaction of CCl_4 with H_2O was carried out in a plug flow reactor at a total flow rate of 80 mL min^{-1} with He as the diluent. Gas chromatography was used to analyze for CCl_4, CO_2 and H_2O, while HCl was trapped in water and subsequently titrated with $AgNO_3$ (aq). X-Ray photoelectron spectra (XPS) were acquired using a Perkin-Elmer (PHI) model 5500 spectrometer.

The conversions of CCl_4 and H_2O are shown in Fig. 1 for the reaction carried out at 500 °C over 0.58 g MgO with $P(CCl_4)$ = 2 Torr and $P(H_2O)$ = 4 Torr. Under these conditions, the initial conversion of 88% decreased to *ca.* 74% during the first hour, but thereafter the conversion remained nearly constant. After 24 h on stream, the conversion was 68%. The surface area of the catalyst decreased from 90 to 38 m^2 g^{-1}, with most of the decrease occurring during the first hour. At the same partial pressures of CCl_4 and H_2O, but with 1.72 g MgO at 525 °C, the conversion was > 99% (no remaining CCl_4 was detected) for 72 h. Thus, nearly complete removal of CCl_4 can be achieved over a long period.

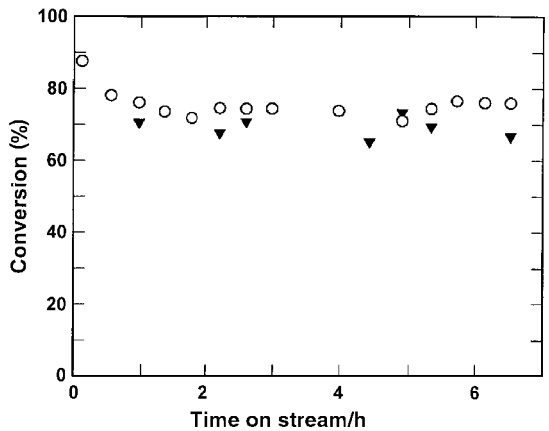

Fig. 1 Conversion of CCl_4 (○) and H_2O (▼) over 0.58 g MgO at 500 °C with $P(CCl_4)$ = 2 Torr and $P(H_2O)$ = 4 Torr.

Kinetic results were obtained under differential reaction conditions, which were achieved either by using a smaller amount of catalyst or by operating at lower temperatures. Over the temperature range 400–500 °C with 2 Torr CCl_4 and 4 Torr H_2O, the apparent activation energy was 85 kJ mol^{-1}. At the same initial pressures and at 450 °C, the specific activity was 0.167 μmol (g s)$^{-1}$ or 4.1 nmol (m^2 s)$^{-1}$ for a catalyst having a surface area of 38 m^2. The reaction orders with respect to CCl_4 and H_2O are given in Fig. 2. The reaction order with respect to H_2O at 400 °C was slightly dependent on the partial pressure of CCl_4 and increased to n = 0.16 at 6 Torr of CCl_4.

The amount of chloride in the sample after reaction was 4 wt%, which corresponds to a Cl/Mg ratio of 0.047. This value may be compared with a near-surface Cl/Mg ratio of 0.12 (as determined from XPS spectra), which was nearly the same for samples that had been on stream for 1 h at 500 °C or for 70 h at 525 °C. After steady state was attained, there was nearly a 100% chlorine balance between CCl_4 reacted and HCl formed.

The results are consistent with the mechanism described in Scheme 1, which is adapted from an earlier one that was proposed by Hooker and Klabunde[6] for the destructive adsorption of CCl_4. Although phosgene is a potential intermediate, none was detected in the gas phase by IR spectroscopy. The rate limiting step is believed to be the dissociative adsorption of CCl_4, although this is inhibited by the presence of chloride ions on the surface, which is consistent with the fact

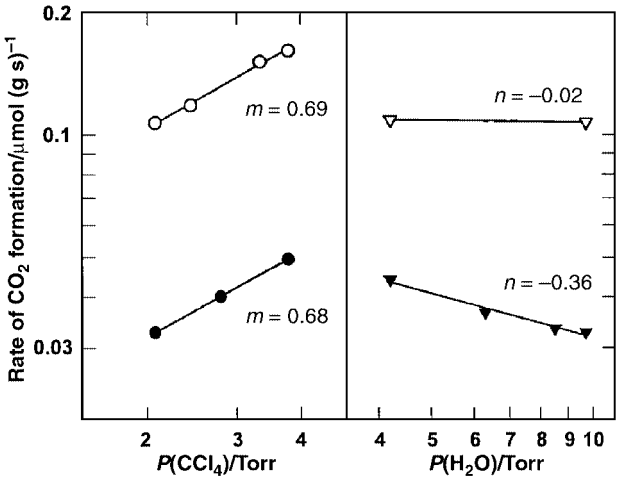

Fig. 2 Effect of CCl_4 and H_2O partial pressures on the rate of CO_2 formation over 0.40 g MgO: variation in CCl_4 pressure at 400 °C (●) and at 450 °C (○) with $P(H_2O)$ = 9.7 Torr; variation in H_2O pressure at 400 ° C (▼) and at 450 °C (▽) with $P(CCl_4)$ = 2.1 Torr.

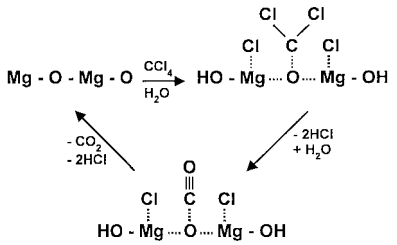
DOI: 10.1039/a909552g



Scheme 1

that the reaction order with respect to CCl_4 is less than unity. The dissociative adsorption of H_2O to form hydroxide ions is very rapid at the reaction temperatures used. One might expect that the formation of carbonate ions, derived from CO_2, would inhibit the reaction, but this is not the case since the addition of CO_2 to the feed, in a 30-fold excess of that produced during the reaction, did not influence the reaction rate. The presence of chloride ions may decrease the basicity of the surface[7] and thereby minimize the formation of surface carbonates on MgO (see below).

The results described to this point were obtained using Fisher MgO (Ca < 1%, Fe < 0.05%); however, one experiment was carried out with Puratronic MgO (99.998%), and at comparable conditions the activity was the same, indicating that impurities such as iron do not play a role. By contrast, CaO and, as noted above, BaO were not active as catalysts. Both of these oxides are more effective than MgO for the activation of CCl_4 to form the metal chloride at 425 °C,[5] therefore, the first step in the reaction mechanism would readily occur. Moreover, the replacement of Cl^- ions by CO_3^{2-} ions on $BaO/BaCl_2$ can even take place at 25 °C, albeit slowly. It appears that the formation of stable carbonates on CaO and BaO inhibits the catalytic reaction over the temperature range employed in this study. At a pressure of 2 Torr CO_2, the decomposition temperatures of $MgCO_3$, $CaCO_3$ and $BaCO_3$ are 430, 600 and 970 °C, respectively.[8]

In summary, it has been found that MgO is a catalyst that promotes the reaction of CCl_4 with H_2O to yield CO_2 and HCl. For environmental purposes, the HCl could be easily removed from an effluent stream.

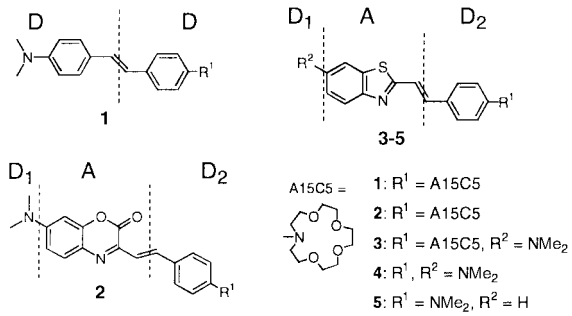
Received (in Liverpool, UK) 16th December 1999, Accepted 4th February 2000

Upon cation complexation, donor–acceptor–donor–substituted intrinsic fluoroionophore 3 shows red-shifted emission spectra accompanied by an extraordinarily high fluorescence enhancement.

Ionically controlling the fluorescence of molecular systems which contain an ion-sensitive receptor as an integral part of their signal generating fluorophore is of particular interest in fluorometric analysis.[1] These so-called intrinsic fluoroionophores usually combine an electron rich donor (D) as the ion-sensitive receptor and an electron acceptor unit (A) in a π-conjugated D–A arrangement.[2] Many such compounds are known including, *e.g.* styryl or stilbene dyes.[3] In highly polar solvents often encountered in sensing applications, the spectroscopic behaviour of such dyes is usually governed by an intramolecular charge transfer (ICT) process which leads to broad, structureless, and largely Stokes-shifted absorption and emission bands.[2,3] Upon cation binding to the receptor (= donor, R_D), strong hypsochromic shifts in absorption are found but the corresponding effects in emission are rather small.[2,3] The latter behaviour has been attributed to a decoordination reaction in the excited complex as a consequence of the ICT process, where a shift of negative charge from R_D to A leads to electrostatic repulsion between cation and formally positively charged donor.[4] Owing to complexation-induced fluorescence intensity changes as well as spectral shifts, these dyes are advantageous in terms of spectral discrimination as compared to PET (photoinduced electron transfer) systems[5] with electronically decoupled fluorophore and receptor. However, besides small shifts in emission the main disadvantage of intrinsic fluoroionophores is the relatively small change in fluorescence intensity (usually factors ≤5) upon ion binding.

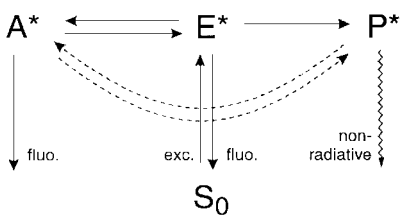
In order to circumvent the problem of cation decoordination in the excited state and thus to achieve stronger shifts in emission, other design concepts were realized including D–D-substituted sensor molecules (*e.g.* **1**) as well as compounds with a D–A–D arrangement (*e.g.* **2**). Unfortunately, cation complexation to **1** resulted in fluorescence quenching[3c] unfavourable in terms of a high signal output and complex specific fluorescence lifetimes and **2** is already moderately fluorescent (ϕ_f = 0.33) in the uncomplexed state.[3a] As was shown in various mechanistical studies of such dyes,[6] the excited state reaction mechanism involves several emissive and non-emissive conformers, closely related to the theory of so-called twisted intramolecular charge transfer (TICT) and biradicaloid states.[7] Upon complexation, the change in fluorescence yield critically depends on the change of the relative energetic positions of the excited species involved and thus on the rate constants of the competing reactions from planar emissive locally excited E* to a highly polar single-bond-twisted species



A* or to a non-emissive and weakly polar double-bond-twisted conformer P* of biradicaloid nature (three-state-model, Scheme 1).[6,7] Since for **2**, efficient formation of an emissive A* state is responsible for the moderate fluorescence in the uncomplexed dye in polar solvents,[3a,6a] reducing the acceptor strength promised to decrease the energy gap between emissive A* and quenching P* state and thus promised to lead to higher cation-induced fluorescence enhancement. With this in mind we designed the D–A–D fluoroionophore **3**.

Introduction of the electron donating dimethylamino group to the benzothiazole acceptor leads to slight shifts in both absorption (bathochromic) and emission (hypsochromic) accompanied by an increase in fluorescence quantum yield and lifetime (**4** *cf.* **5**, Table 1). A similar behaviour has been previously found for 4,4′-bis(dimethylamino)stilbene[6b] and corresponding 4-(dimethylamino)stilbene[6c] and quantum chemical calculations performed in analogy to those reported in ref. 6(*b*) support the validity of this model for **4** and **5**.[8] Based on the differences in bulkiness and donor strength of the two alkylated amino substituents, **3** and **4** show very similar spectroscopic properties and a slightly higher fluorescence yield in the case of **3** (Table 1).

Upon cation addition, the absorption band is slightly blue-shifted (Fig. 1) and the isosbestic points found in a titration indicate the formation of 1 : 1 complexes. This is supported by the fits of the titration data yielding complex stability constants in a range characteristic for neutral ICT fluoroionophores.[2,3] Concerning the cation-induced effects in fluorescence, **3** combines a red shift of the emission spectrum (Fig. 1) with extraordinarily high fluorescence enhancement factors (FEF),



Scheme 1 Three-state-model involving multiple emissive states (A*, E*). E* is the planar conformer, A* corresponds to the different single-bond-twisted conformers and P* to the double-bond-twisted conformers.

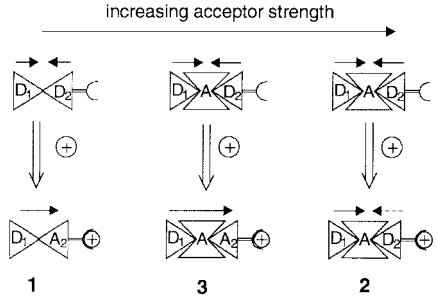
normally only found for electronically decoupled PET systems,[5] and cation specific fluorescence lifetimes (Table 1).

These analytically favourable effects can be understood on the basis of the three-state-model introduced above. For **1**, the D–D substitution pattern is turned into a D–A pattern upon ion binding (Scheme 2), exemplified by a red shift in emission, and the decrease in fluorescence yield in the order of **1** > **1** ⊂ Ca^{II} > 4-dimethylamino-4′-cyanostilbene,[9] correlates with the increase in acceptor strength and should mainly be related to the relative energetic positions of E*, A* and P*.[6b,9] As follows from the blue-shifted emission band of **2** ⊂ Ca^{II}, complexation to **2** decreases the strength of D_2 (Scheme 2) slowing down the formation of (probably less) emissive A* and leads to enhanced emission owing to more efficient formation of an ICT state of planar conformation involving partial charge transfer from D_1 to A.[6a] This was also observed for highly fluorescent D–A(–A) benzoxazinone dyes with R^1 = H[6a] or CHO.[10] Accordingly, for **3** ⊂ $M^{I/II}$ the bathochromic shift in emission suggests the conversion of D_2 into an acceptor yielding a D_1–A–A_2 pattern (Scheme 2) and radiative deactivation of such a highly emissive



Scheme 2 Change of donor and acceptor strength upon complexation (arrows indicate CT interactions).

CT species successfully competes with any quenching channel (P*) restoring the fluorescence as a function of the charge density of the metal ion bound.

In summary, we have shown for the first time that efficient complexation-induced 'switching on' of the fluorescence can be achieved for simple intrinsic fluoroionophores by careful tuning of the donor–acceptor substitution pattern.

We gratefully acknowledge the financial support by the Deutsche Forschungsgemeinschaft.

Synthesis of optically active *N*-hydroxylamines by asymmetric hydrogenation of nitrones with iridium catalysts

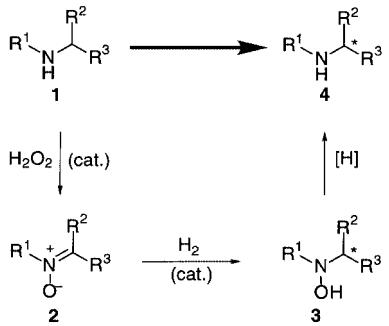
Shun-Ichi Murahashi,* Teturou Tsuji and Shuichi Ito

Department of Chemistry, Graduate School of Engineering Science, Osaka University, 1-3 Machikaneyama, Toyonaka, Osaka 560-8531, Japan. E-mail: mura@chem.es.osaka-u.ac.jp

Received (in Cambridge, UK) 21st December 1999, Accepted 2nd February 2000

Asymmetric hydrogenation of nitrones with the iridium catalyst system, prepared from $[IrCl(cod)]_2$, (*S*)-BINAP, and $NBu^n_4BH_4$, gives the corresponding *N*-hydroxylamines, which are important as biologically active compounds and precursors of amines, with high enantioselectivity (up to 86% ee).

Optically active *N*-hydroxylamines are of interest as biologically active compounds,[1] naturally occurring compounds,[2] and precursors of chiral amino compounds. A catalytic method for synthesis of these compounds is limited to the ruthenium-catalyzed asymmetric hydrosilylation of nitrones.[3] To explore more convenient and economical methods, we pursued the catalytic hydrogenation of nitrones which are obtained readily by catalytic oxidation of secondary amines with hydrogen peroxide.[4] We report herein asymmetric hydrogenation of nitrones with iridium catalysts to give optically active *N*-hydroxylamines. As shown in Scheme 1, catalytic oxidation of amines **1**, followed by catalytic asymmetric hydrogenation of nitrones **2** thus formed provides an efficient and useful route for synthesis of optically active *N*-hydroxylamines **3**. Furthermore, optically active secondary amines **4** can be prepared upon catalytic reduction of **3**.



Scheme 1 Catalytic asymmetric synthesis of chiral amino compounds.

This method is particularly convenient and useful because of the configurational stability of nitrones, ease of handling, and readiness of preparation. Although asymmetric hydrogenation of imines with homogeneous catalysts has been studied extensively,[5] neither asymmetric nor simple hydrogenation of nitrones with homogeneous catalysts are, to our knowledge, known.

We examined the catalytic activity of metal complexes for the hydrogenation of configurationally pure (*E*)-*N*-[1-(4-chlorophenyl)ethylidene]methylamine *N*-oxide **5a**, whose stereochemistry was determined by NOE experiments [eqn. (1)]. When ruthenium complexes were used as catalysts, no hydrogenation occurred. This may be due to the strong affinity of nitrones for ruthernium complexes. Iridium and rhodium complexes, however, showed catalytic activity.

Metal complex catalysts bearing the BINAP [2,2′-bis(diphenylphosphino)-1,1′-binaphthyl] ligand[6] were examined for asymmetric hydrogenation and results are summarized in Table 1. Enantioselectivity was not observed with rhodium catalysts such as $[RhCl(cod)]_2$/(*S*)-BINAP or [Rh{(*S*)-BINAP}(cod)]-ClO_4 (entries 1 and 2). The cationic iridium catalyst, 2.0 mol% [Ir{*R*)-BINAP}(cod)]BF_4 is less reactive, and the enantioselectivity obtained was 27% ee (entry 3). The neutral iridium catalyst, 1.0 mol% $[IrCl(cod)]_2$/(*S*)-BINAP (1.0 : 2.2 mol/mol) gave *N*-hydroxylamine (*R*)-**6a** in 69% yield with 40% ee (entry 4).

These results indicate that iridium catalysts are promising and the ligand coordinated to the iridium plays an important role in the face discrimination of nitrones. A systematic study of neutral iridium catalysts revealed that catalyst systems obtained by treatment of the $[IrCl(cod)]_2$/(*S*)-BINAP complex with hydride sources such as $NBu^n_4BH_4$ or $NaBH_4$ gave higher reactivity and enantioselectivity. The highest enantioselectivity was obtained, when the iridium catalyst system, prepared from 1.0 mol% $[IrCl(cod)]_2$/(*S*)-BINAP/$NBu^n_4BH_4$ (1.0 : 2.2 : 2.0 mol/mol) *in situ*, was used at 0 °C (*R*)-**6a**, 82%, 83% ee, entry 5).† The absolute configuration of **6a** was determined to be *R* by comparison of the optical rotation of the secondary amine derived from **6a** with the reported data.[7] The opposite enantiomer (*S*)-**6a** was obtained, when (*R*)-BINAP was used as a ligand. In this reaction, hydrogen pressure did not affect the enantioselectivity in the range 1–80 kg cm^{-2}. The effect of the solvent on the enantioselectivity is dramatic with THF found to

[d] The optical yields were determined by HPLC analyses using chiral columns. **5a**, **c**–**f**: CHIRALPAK AD, **5b**: CHIRALCEL OD-H, **5g**: CHIRALCEL OJ. [e] See text. [f] Reaction carried out at 22 °C

be best.† Toluene led to moderate enantioselectivity while methanol and dichloromethane gave poor results.

Various nitrones can be hydrogenated enantioselectively with the $[IrCl(cod)]_2$/(*S*)-BINAP/$NBu^n_4BH_4$ catalyst system (Table 2). In the reaction of (*E*)-*N*-1-(arylethylidene)methylamine *N*-oxides, the reactivity and enantioselectivity are increased noticeably by introduction of an electron-withdrawing group on the aryl group. The hydrogenation of nitrones bearing *para*- and *meta*-halogens, **5c** and **5d**, proceeded smoothly to give the corresponding *N*-hydroxylamines with enantioselectivity of 86 and 81% ee, respectively (entries 3 and 4). However, the hydrogenation of *ortho*-chlorinated compound **5e** proceeded slowly (entry 5). The hydrogenation of nitrone **5f** bearing a naphthyl group at the α-position of nitrogen gave the corresponding *N*-hydroxylamine with 80% ee (entry 6). The *N*-benzyl substituted nitrone **5g** was hydrogenated with 75% ee (entry 7). The absolute configurations of **6b**[7] and **6g**[5j] were determined to be *R*.

We prepared $[IrH(\eta^1,\eta^3\text{-}C_8H_{12})\{(S)\text{-BINAP}\}]$ **7** in 59% yield from $[IrCl(cod)]_2$, (*S*)-BINAP and KOH in methanol–benzene (1 : 1). Under the conditions of hydrogenation, the C_8H_{12} group of **7** is reduced to cyclooctane, and complex **7** would be converted to $[IrH\{(S)\text{-BINAP}\}(THF)_n]$. Using complex **7** as a catalyst for the hydrogenation of **5a** led to *N*-hydroxylamine **6a** with 86% ee (*R*). This result is comparable to the 83% ee (*R*) obtained with the $[IrCl(cod)]_2$/(*S*)-BINAP/$NBu^n_4BH_4$ catalyst system above, indicating that iridium–hydride species appear to form from $[IrCl(cod)]_2$/(*S*)-BINAP/$NBu^n_4BH_4$ mixtures and lead to high enantioselectivity for asymmetric hydrogenation of nitrones.

This work was supported by Research for the Future program, the Japan Society for the Promotion of Science.

Notes and references

† *Typical experimental procedure*: a Schlenk flask was charged with $[Ir(cod)Cl]_2$ (3.4 mg, 0.0050 mmol), (*S*)-BINAP (6.8 mg, 0.011 mmol), $NBu^n_4BH_4$ (2.6 mg, 0.010 mmol) and degassed THF (2.5 mL) under argon atmosphere and the mixture stirred for 15 min at room temperature. The solution of the catalyst was transferred to an autoclave, and (*E*)-*N*-[1-(4-chlorophenyl)ethylidene]methylamine *N*-oxide **5a** (92.2 mg, 0.50 mmol) added under argon. The argon gas in the autoclave was replaced by hydrogen in three cycles (20 kg cm^{-2}) and finally pressurized with hydrogen to 80 kg cm^{-2}. The mixture was stirred at 0 °C for 18 h. After the autoclave was vented and opened, the reaction mixture was transferred to a flask. The solvent was evaporated under reduced pressure. The product was purified by SiO_2 column chromatography (**6a**; 76.1 mg, 0.41 mmol, 82% yield). The enantiomeric excess was determined to be 83% by HPLC using a DAICEL CHIRALPAK AD. Optically pure *N*-hydroxylamine **6a** was obtained by recrystallization from acetone {**6a**, mp 97.5–98 °C, $[\alpha]_D$ +50.0 (c = 1.00, EtOH)}. The corresponding optically pure secondary amine was obtained by treatment of optically pure **6a** with molecular hydrogen over a palladium catalyst or by treatment with zinc/HCl.

Model studies towards carbohydrate–base pair recognition. Relevance of hydrogen–bonding cooperativity

Manuela López de la Paz,[a] Carlos González[b] and Cristina Vicent*[a]

[a] *Departamento de Química Orgánica Biológica, Instituto de Química Orgánica, CSIC, Juan de la Cierva 3, E-28006 Madrid, Spain. E-mail: iqocv18@iqog.csic.es*

[b] *Instituto de Estructura de la Materia, CSIC, Serrano 119, 28006 Madrid, Spain*

Received (in Cambridge, UK) 16th December 1999, Accepted 3rd February 2000

The importance of intramolecular OH···OH hydrogen-bonds (H-bonds) in the effective molecular recognition of carbohydrates is highlighted; specifically, the 1,3-*cis*-diaxial H-bonded OH groups of 1 are shown to provide an efficient binding motif for bidentate coordination of the amino-carbonyl Hoogsteen site of the CG base-pair through the formation of two cooperative intermolecular H-bonds; this result suggests that intramolecularly H-bonded carbohydrate OH groups may be considered as multidentate units able to H-bond cooperatively.

Deoxygenated oligosaccharides which are present in natural products[1] and aminoglycoside antibiotics[2] are known to directly interact with a number of DNA and RNA sequences, respectively. However there is limited structural information on the molecular basis of such a saccharide–nucleic acid recognition in solution.[3]

The design of many low molecular weight nucleic acid ligands has been based on hydrogen-bonding (H-bonding) recognition of the Hoogsteen sites of the B-DNA grooves.[4] One of the most important characteristics of multiple H-bonded complexes is the non-additivity of the H-bonds therein; this property has given rise to the concept of cooperativity.[5] As part of a general project to study H-bonding cooperativity and its implications in the molecular recognition of carbohydrates, we present here our initial effort to use H-bonding cooperativity to efficiently bind sugars in the grooves of B-DNA.

Carbohydrate 1,2- and 1,3-diol motifs are present in many DNA and RNA binders.[1] We have previously demonstrated that the hydroxy groups of the 1,3-*cis*-diaxial diol **1** are intramolecularly H-bonded (OH-2→OH-4); the presence of this H-bond polarizes the σ O-H bonds and enhances the donor ability of OH-4 and acceptor ability of OH-2 [Fig. 1(a)].[6]

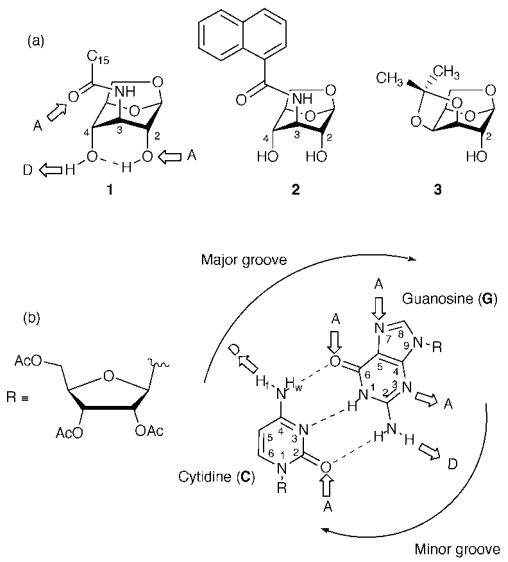

Fig. 1 Carbohydrate-derivatives and **CG** base-pair used in the binding studies.

Molecular modelling studies of the carbohydrate-derivative **1** and the cytidine–guanosine (**CG**) base-pair indicate that the hydroxy groups of **1** are suitably positioned to bridge both amino-carbonyl Hoogsteen binding sites of **CG** in a bidentate fashion [Fig. 1(b)]. A sugar–**CG** complex† could potentially be stabilized by two cooperative intermolecular H-bonds (Fig. 2); this would provide the first example of H-bonding cooperativity in carbohydrate-base pair recognition.

For the reasons outlined above, the binding of **1** to **CG** has been investigated.‡ Binding studies were performed by titrating **1** (0.08 mM) with an equimolar mixture of tri-*O*-acetylguanosine (**G**) and tri-*O*-acetylcytidine (**C**) (2 mM).[7]§ Under these experimental conditions only a 1 : 1 complex of the diol **1** and **CG** could be expected. The titration data were fitted to a 1 : 1 binding model, taking into account the dimerization of **CG** (Table 1).[8]¶ The measured association constant‖ for the **1–CG** complex was 1491 M^{-1}. The binding of the aromatic diol **2** to **CG** was also studied in the same way with the expectation of observing induced chemical shifts of the naphthyl proton resonances and thereby obtaining more data for model fitting. $\Delta G°$ values for the **1–CG** (-4.4 ± 0.1 kcal mol^{-1}) and **2–CG** (-4.2 ± 0.1 kcal mol^{-1}) complexes were greater than expected for a complex stabilized by a single H-bond, or two isolated H-bonds. This result implies the interplay of cooperative H-bonding in **1–CG** and **2–CG** recognition.

To quantify the effect of H-bonding cooperativity on the stabilization of the **1–CG** complex, it is necessary to know the number of intermolecular H-bonds formed between **1** and **CG**. ^{1}H NMR variable temperature experiments, NOESY, and deuterium exchange experiments were carried out with the aim of determining structural information.

The hydroxy proton resonances of **1** were deshielded upon complexation with **CG**, which indicates that the binding process is mediated by H-bonding of both OH groups of the carbohydrate (Table 2). In contrast, the amide proton (NH-3) of diol **1**

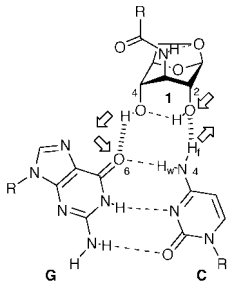

Fig. 2 Schematic representation of the complex formed by the carbohydrate **1** and the **CG** base-pair.

Table 1 Stability parameters of the interaction between the **CG** base-pair and the carbohydrate derivatives **1**–**3** (299 K, $CDCl_3$)

Compound	**1**	**2**	**3**
K_a/M^{-1}	1491	1091	6.7
$\Delta G°$/kcal mol^{-1}	-4.4 ± 0.1	-4.2 ± 0.1	-1.1 ± 0.1

Table 2 $\Delta\delta/\Delta T$ of the exchangeable resonances of **1** in the free and bound state to the **CG** base-pair[a]

Resonance of **1**	$\Delta\delta/\Delta T$ (**1**)[b]/ppb K^{-1}	$\Delta\delta/\Delta T$ (**1–CG**)[c]/ppb K^{-1}
OH-4	−5.2	−13.2
OH-2	−2.8	−6.8
NH-3	−2.9	−4.5

[a] Measured between 293–318 K. [b] [**1**] = 1.1 × 10^{-4} M. [c] [**1**] = 1.1 × 10^{-4} M; [**CG**] = 1.5 × 10^{-3} M (**1**:**CG** = 1:13).

showed minimal displacement on complexation. According to previous reports,[6a,9] comparison of $\Delta\delta/\Delta T$ of the OH resonances of the free ligand **1** and the **1–CG** complex also implies that both OH groups are involved in intermolecular H-bonds (Table 2).

NOESY spectra of mixed samples of **1** and **CG** in different ratios** revealed cross peaks between the OH proton resonances of **1** and the exchangeable protons of **CG**; these could not unambiguously be attributed to chemical exchange or intermolecular NOEs. However, the same experiments showed that the **C**(N^4–H)$_f$ proton resonates at lower field in the presence of a higher concentration of diol **1**, which further suggests its involvement in H-bonding with **1**.

Additional evidence for the preferred complexation site of **CG** was obtained by deuterium exchange experiments. An equal quantity of deuterated diol **1** (**1**–D) was added to separate samples of **CG** (experiment A: **CG** 2 mM) and **1**:**CG** in a 2:1 ratio (experiment B: **1**:**CG** 4 mM:2 mM), to facilitate the formation of the hypothetical 1:2 **CG**:**1** complex. In each case a control experiment was carried out (experiment A: **CG** 2 mM; experiment B: **1**:**CG** 4 mM:2 mM). ^{1}H-NMR spectra were acquired at t = 0 and 17 days. Both samples containing **1**–D showed complete H–D exchange of the **C** amino protons after 17 days, while the amino protons of **G** were only partially deuterated after the same period of time. In the control experiments a small and comparable decrease in the signal intensity of all the exchangeable **CG** protons was observed. From this result we infer that on average the **C**-amino group is in contact with the deuterated hydroxy groups of **1**–D for longer than the amino protons of **G**, and that a 1:1 **1–CG** complex is favoured over a 2:1 **1–CG** complex, which is in agreement with the Job plot determined stoichiometry.¶

Molecular modelling[11] of the **1–CG** complex supported the results of our ^{1}H-NMR experiments and confirmed that the carbonyl group **G**(C^6-O) is the H-bond acceptor best located to form a second H-bond to OH-4 of **1** .†† The calculated **1–CG** structure also showed that the non-exchangeable protons of the **1–CG** complex are very distant from each other, which could explain why only ambiguous intermolecular NOEs were detected.

To quantify the influence of the intramolecular OH-2→OH-4 H-bond on the formation of intermolecular H-bonds between **1** and **CG**, the complexation of monoalcohol **3** with **CG** was studied.‡‡ The K_a for the **3–CG** complex is 7 M^{-1} (Table 1); the formation of one H-bond between the monoalcohol **3** and the **CG** base-pair thus corresponds to a $\Delta G°$ value of −1.1 kcal mol^{-1}, while the $\Delta G°$ for two intermolecular H-bonds in the **1–CG** complex is more than four times greater than this value. This demonstrates that the formation of H-bonds between **1** and **CG** is non-additive (cooperative); furthermore the importance of intramolecular OH···OH H-bonds in the effective molecular recognition of carbohydrates is highlighted.

Our work has shown that in the future we may consider the intramolecularly H-bonded OH groups of carbohydrates as multidentate units capable of H-bonding cooperatively. Specifically, the 1,3-*cis*-diaxial relative configuration of carbohydrate OH groups serves in apolar medium as an efficient binding motif for bidentate coordination of the **C**(N^4–H)$_f$/**G**(C^6–O) site of **CG** through formation of two cooperative intermolecular H-bonds.

Hunter (University of Sheffield) for kindly providing the fitting program and Dr Joanne Hawley for critical reading of the manuscript.

Notes and references

† **C** (2',3',5'-tri-*O*-acetylcytidine) and **G** (2',3',5'-tri-*O*-acetylguanosine) were purchased (Sigma) and used without further purification. Carbohydrate-derivatives **1**, **2** and **3** were synthesized.[10] **1**–D was prepared by repeatedly dissolving **1** (1.4 mg, 3.5 mmol) in CD_3OD (5 × 0.5 mL) and evaporating to dryness. The deuterated residue (**1**–D) was dried under high vacuum and heated at 40 °C in the presence of P_2O_5 and dissolved in $CDCl_3$ (2 mL) to give a solution of concentration 1.8 mM.

‡ All binding studies were performed at 299 K using freshly prepared solutions in $CDCl_3$ which were always passed through basic alumina and collected over 4 Å molecular sieves prior to use; the alumina and molecular sieves employed were freshly activated by heating at 600 °C under high vacuum. Each experiment was carried out at least two times and $\Delta G°$ values were reproducible within ±0.1 kcal mol^{-1}.

§ The feasibility of this titration experiment relied on the high stability of the **CG** base-pair[7] in chloroform (K_a = 10^4–10^5 M^{-1}). The imino proton **G**(N^1–H) experienced minimal chemical shift displacement (upfield) upon complexation with **1** ($\Delta\delta$ < 0.1 ppm), which is consistent with the **CG** complex remaining intact during the titrations.[8a]

¶ The 1:1 stoichiometry of the complex **1**:**CG** was determined by a Job plot based on the chemical induced shifts of the hydroxy resonances. The **CG** base-pair dimerizes in chloroform.[8a] We have measured a dimerization constant of 55 M^{-1}.

‖ Reverse titration experiments (**CG** *vs.* **1**) were also performed. Fitting of the induced chemical shifts of the C(C^5–H) proton resonance to a 1:1 complexation model gave a value of K_a (1460 M^{-1}) which was in good agreement with the value determined experimentally from the **1** *vs.* **CG** titrations.

** NOESY spectra (500 ms, 278 K, 600 MHz) were recorded for two samples of different **1**:**CG** molar ratio: (i) **1**:**CG** 1:3, [**1**] = 6.7 × 10^{-4} M; [**CG**] = 2 × 10^{-3} M; (ii) **1**:**CG** 3:1, [**1**] = 6 × 10^{-3} M; [**CG**] = 2 × 10^{-3} M.

†† Molecular mechanics calculations were carried out using MM2[11a] (carbohydrates) and AMBER[11b] (nucleosides, CG base-pair and carbohydrate–CG complexes) with the GB/SA solvent model for chloroform.[11c] Molecular modelling of the complex involing the **C**(C=O) and **G**(N–N) of **CG** (minor groove of the base-pair) indicated that such a complex is not stable. This could be explained on the basis of steric hindrance of the acetylated ribose moieties.

‡‡ The use of **3** allowed us to evaluate the effect of a second OH in a 1,3-*cis*-diaxial relative configuration on the energetics of the recognition process between **1** and **CG**.

Chiral inclusion crystallization of tetra(*p*-bromophenyl)ethylene by exposure to the vapor of achiral guest molecules: a novel racemic-to-chiral transformation through gas–solid reaction

Koichi Tanaka,*[a] Daisuke Fujimoto,[a] Thomas Oeser,[b] Hermann Irngartinger[b] and Fumio Toda[c]

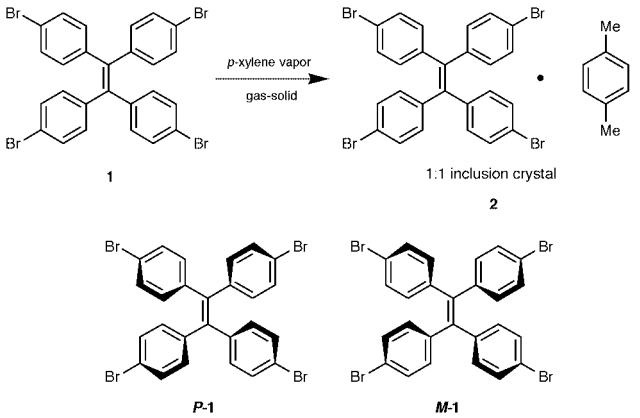
Received (in Cambridge, UK) 14th December 1999, Accepted 7th February 2000

Racemic crystalline tetra(*p*-bromophenyl)ethylene was converted into chiral inclusion crystals in the solid state by contact with gaseous achiral guest compounds.

Chiral crystallization of achiral molecules in the absence of any external chiral source is of special interest not only for "so-called" absolute asymmetric synthesis[1] but also for its relationship to the prebiotic origin of chirality.[2] Such chiral crystals have been obtained previously during crystallization of achiral substrates from their solutions. We have now found that chiral inclusion crystals can be obtained by treatment of a racemic host compound with the vapor of achiral guest compounds. This is the first example of the formation of chiral inclusion crystals from achiral components through gas–solid inclusion complexation.



Recently, we have found that tetra(*p*-bromophenyl)ethylene **1**[3] forms chiral inclusion compounds with various kinds of achiral guest molecules. For example, recrystallization of **1** from *p*-xylene gave 1:1 inclusion crystals (**2**). The chiral arrangement of **1** molecules in **2** was easily detected by measurement of CD spectra of its Nujol mull. Hence, one single crystal of **2** showed a positive Cotton effect while another showed a negative Cotton effect (Fig. 1). The host compound **1** also formed chiral inclusion crystals with acetone (1:1), dioxane (1:1) and benzene (1:1), whereas it formed racemic inclusion crystals with cyclohexanone (1:1), THF (1:2), β-picoline (1:1) and toluene (1:1), by recrystallization (Table 1).

Very interestingly, however, when exposed to *p*-xylene vapor at room temperature for 24 h, a single crystal of pure **1** prepared by recrystallization from *m*-xylene was gradually changed into the chiral polycrystalline 1:1 inclusion complex (**2**) of **1** with *p*-xylene. The inclusion complex (**2**) thus obtained showed the same CD spectrum as that obtained by the recrystallization

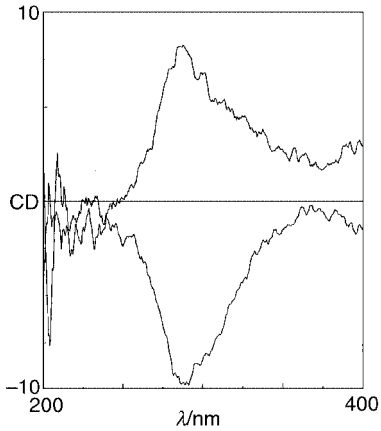


Fig. 1 CD spectra of the enantiomeric 1:1 inclusion crystals of **1** with *p*-xylene in Nujol mulls.

Table 1 Inclusion complexation of **1** with some guest compounds

	Inclusion complex				
	By recrystallization		By gas–solid reaction		
Guest	host:guest		host:guest		*t*/h
Acetone	chiral	1:2	—	—[a]	168
Cyclohexanone	*rac*	1:1	—	—[a]	168
THF	*rac*	1:2	chiral	1:2	2
1,4-Dioxane	chiral	1:1	chiral	1:1	24

Toluene	*rac*	1:1	—	—[a]	168
p-Xylene	chiral	1:1	chiral	1:1	24
β-Picoline	*rac*	1:1	chiral	1:1	168

[a] No complexation occurred.

method, and its X-ray powder pattern was similar to that obtained by recrystallization (Fig. 2) Gas-solid reaction of **1** with THF, dioxane, benzene and β-picoline also produced their inclusion complexes with the same host–guest ratios as those obtained by recrystallization (Table 1). It is also remarkable that the inclusion crystals of **1** with THF and β-picoline obtained by gas–solid reaction were chiral, whereas those obtained by recrystallization were racemic. Gas–solid inclusion complexation did not occur, however, in the cases of acetone, cyclohexanone and toluene (Table 1). The chiral crystalline lattice formed by chiral arrangement of **1** molecules is very stable and still exists after removal of the guest molecules *via* heating compound **2** under reduced pressure. The chiral crystalline powder left after removal of the guest from **2** showed a very similar X-ray powder diffraction pattern to that of **2**. By

DOI: 10.1039/a909782a

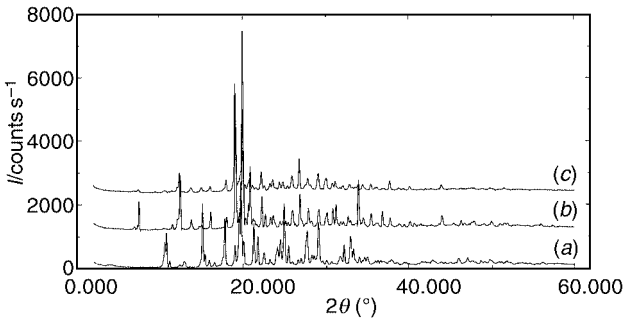

Fig. 2 The X-ray powder patterns of (*a*) *rac*-crystals of pure **1**, (*b*) chiral crystals of **2** prepared by recrystallization and (*c*) chiral crystals of **2** prepared by gas–solid reaction.

exposure to xylene vapor, this chiral crystalline powder was easily converted to the 1 : 1 inclusion crystals **2** with the same chirality.

X-Ray analysis of the *rac*-crystal of **1** showed that two halves of crystallographically independent molecules of *P*-**1** and *M*-**1** exist in the asymmetric unit (space group: *Pccn*). (Fig. 3)† Molecular layers of *P*-**1** and *M*-**1** are arranged perpendicular to the *a*-axis and within these layers the molecules are connected by Br··Br contacts along the *c*-direction. The *P*-**1** molecule has a right-handed and the *M*-**1** molecule has a left-handed propeller structure, respectively (Fig. 4).

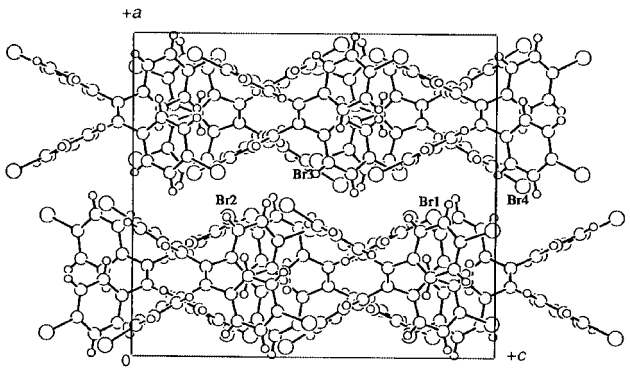

Fig. 3 Crystal structure of **1** viewed along the *b*-axis.

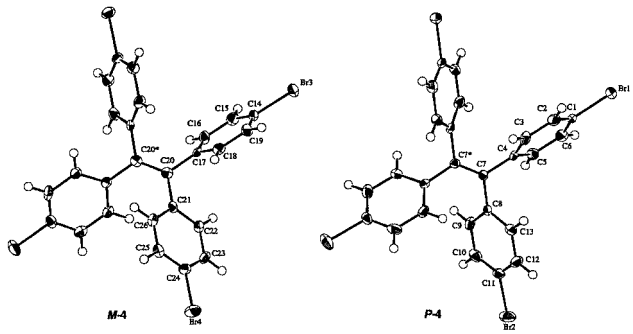

Fig. 4 Molecular structure of *P*-**1** (right molecule) and *M*-**1** (left molecule) in the crystal of **1**. Thermal ellipsoids are drawn at the 50% probability level.

The molecules in **2** occupied the chiral space group $P2_12_12_1$.‡ The *p*-xylene molecules are included in chiral cavities formed by the bromophenyl rings (Fig. 5) In **2**, molecular layers are arranged perpendicular to the *a*-axis, and within these layers the

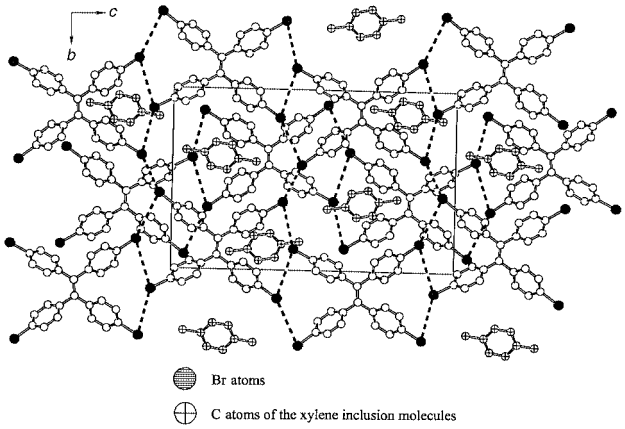

Fig. 5 Crystal structure of **2** viewed along the *a*-axis.

molecules are connected by Br··Br contacts along the *b* direction. It has been found that halogen··halogen contacts act as attractive interactions and the inclusion complex is stabilized by the Br··Br interactions between host molecules.[4] This is the first example of the construction of a chiral inclusion crystalline lattice by a Br··Br interaction network among achiral host molecules.

In conclusion, we have found a unique example of racemic-to-chiral transformation by exposing racemic crystalline material to the vapor of an achiral guest compound. This provides not only a new strategy for construction of chiral crystals but also a new model for studying the mechanism of generation of chirality in crystals.

The authors thank Dr M. Shiro of the Rigaku X-ray research laboratory for determining the X-ray structure of **1**.

A new redox-denitration reaction of aromatic nitro compounds

Charles W. Rees*[a] and Siu C. Tsoi[b]

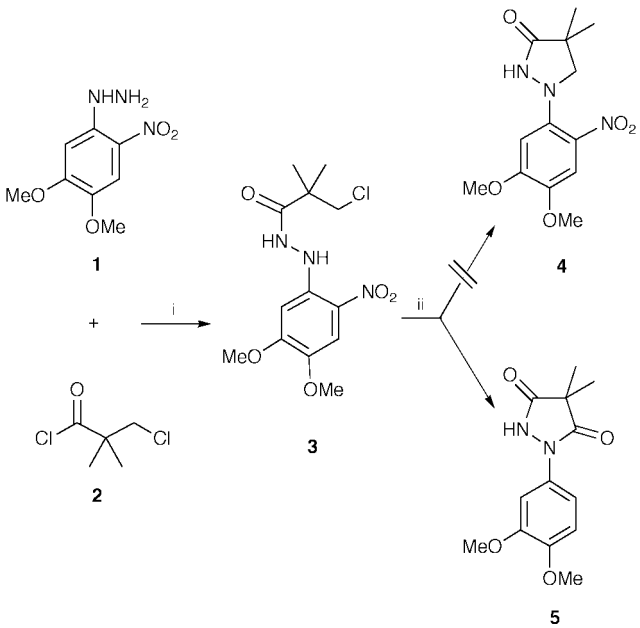
[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY. E-mail: c.rees@ic.ac.uk*

[b] *Kodak European Research and Development, Headstone Drive, Harrow, Middlesex, UK HA1 4TY*

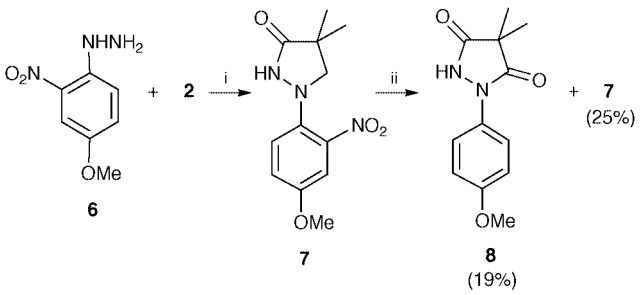
Received (in Liverpool, UK) 23rd December 1999, Accepted 3rd February 2000

When 4,4-dimethyl-1-(2-nitrophenyl)pyrazolidin-3-one 9 is heated in pyridine containing pyridine hydrochloride it is transformed into 4,4-dimethyl-1-phenylpyrazolidin-3,5-dione 10 in which the methylene group has been oxidised and the nitro group has disappeared; two further examples of the same reaction, of pyrazolidinones 4 and 7, are reported together with a mechanistic rationalisation of this curious reaction.

New reactions of aromatic nitro groups are rare. We recently discovered one during an unsuccessful attempt to synthesise the 1-arylpyrazolidin-3-one **4** from 4,5-dimethoxy-2-nitrophenylhydrazine **1** and 3-chloropivaloyl chloride **2**. After an initial reaction in cold pyridine which gave **3**,† mp 163 °C (isolable in 90% yield), the reaction mixture was heated under reflux for 24 h. From this complex reaction we could not isolate any **4**, but only a rather low yield of the 1-arylpyrazolidin-3,5-dione **5**,† mp 189–191 °C (23%), in which the nitro group has been replaced by hydrogen and the pyrazolidinone methylene group oxidised to a carbonyl group (Scheme 1). Compound **5** was synthesised independently from 3,4-dimethoxyphenylhydrazine and dimethylmalonyl dichloride. We assume that **1** and **2** are converted *via* **3** into the desired pyrazolidinone **4**, but this has reacted further to give **5**. On heating preformed **3** in pyridine for 20 h, **5** was again formed as the major product. This unexpected conversion of **4** into **5** is a novel redox reaction in which the nitro group has presumably oxidised the adjacent methylene group and has undergone, most unusually, complete cleavage from the aromatic ring with overall loss of the elements of nitroxyl, HNO.



Scheme 1 *Reagents and conditions*: i, pyridine, 5 °C, N_2, 1 h; ii, pyridine, 115 °C, N_2, 24 h.

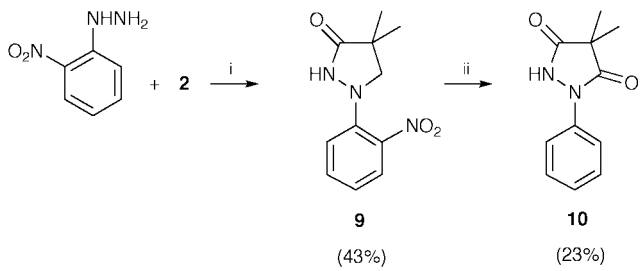


Scheme 2 *Reagents and conditions*: i, pyridine, 5 °C, N_2, 1 h, then room temp., 1 h, then 115 °C, 2 h, ii; pyridine 115 °C, N_2, 20 h.

We performed the same reaction (Scheme 2) with the monomethoxyphenylhydrazine **6** and acid chloride **2** in cold pyridine, to give the acylic hydrazide intermediate (TLC), followed by brief heating (2 h) to give the expected 1-arylpyrazolidin-3-one **7** as the major product. After extended heating (20 h) a mixture of **7** (25%) and the denitrated pyrazolidin-3,5-dione **8** (19%) was isolated. The formation of the monomethoxy product **8** is distinctly slower than for the dimethoxy product **5**.

Finally we treated 2-nitrophenylhydrazine with acid chloride **2** in cold pyridine and then at 90 °C for 11 h to give the nitrophenylpyrazolidin-3-one **9**,† mp 196–198 °C (43%) (Scheme 3). When pure compound **9** was heated in pyridine for up to 5 days there was very little reaction,‡ but when heated in pyridine containing pyridine hydrochloride (1 equiv.) to simulate the conditions of the reactions of **1** and **6**, the overall loss of HNO again occurred to give 1-phenylpyrazolidin-3,5-dione **10** (mp 180 °C, lit.[1] 180–182 °C) (23%) after 20 h. Product **10** was also synthesised from phenylhydrazine and dimethylmalonyl dichloride.

This new acid-catalysed redox-denitration reaction could thus be general for the conversion of 1-(2-nitroaryl)pyrazolidin-3-ones, like **4**, **7** and **9**, into 1-arylpyrazolidin-3,5-diones, like **5**, **8** and **10**. A possible mechanism is outlined in Scheme 4, for the simplest case. Aromatic nitro groups are well known to interact in thermal, photolytic and catalysed reactions with a range of *ortho* substituents,[2] often being reduced to nitroso, azo, azoxy or amino groups, but very rarely with concomitant cleavage of the aryl–nitrogen bond.[3] Since the methylene group would be activated towards oxidation by the adjacent pyrazolidinone



Scheme 3 *Reagents and conditions*: i, pyridine, 50 °C, N_2, 1 h, then 90 °C, 11 h; ii, pyridine, py·HCl (1 equiv.), 115 °C, N_2, 20 h.

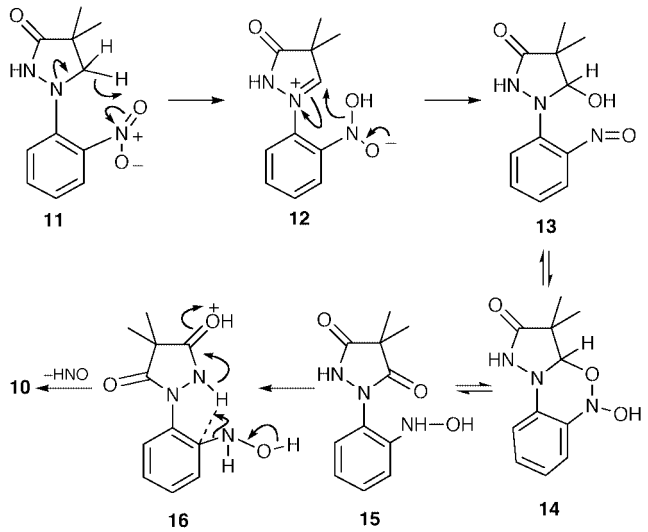

Scheme 4

nitrogen atom, it seems likely that the first step would be an intramolecular hydride transfer to the nitro group (arrows in **11**). This is exactly analogous to that proposed for tertiary amines, when the amine replaces our heterocyclic ring (the *tert*-amino effect).[4] This would give the iminium ion **12** which could collapse to the nitroso compound **13** or its tricyclic tautomer **14**; **13** and **14** would be in equilibrium with each other and with the hydroxylamine **15**.

The final and most unusual step would then be the loss of nitroxyl, HNO,[5] from **15** to give the isolated product **10**; this outcome may depend critically upon the particular structural features of the starting pyrazolidinones. Since protonation at the benzene 2-position must presumably be involved, the reaction should be acid-catalysed (as observed), inter- or intra-molecularly. It could occur, for example, in the conjugate acid **16** of **15** as shown (arrows in **16**). In this mechanism (Scheme 4) various steps would be facilitated by the electron releasing groups in the mono- and di-methoxy compounds, in accord with the observed relative rates of reaction. Further work is required to establish the scope and mechanism of this new reaction.

We are grateful to Kodak Ltd. for permission to publish this work and to Dr N. E. Milner for support and encouragement.

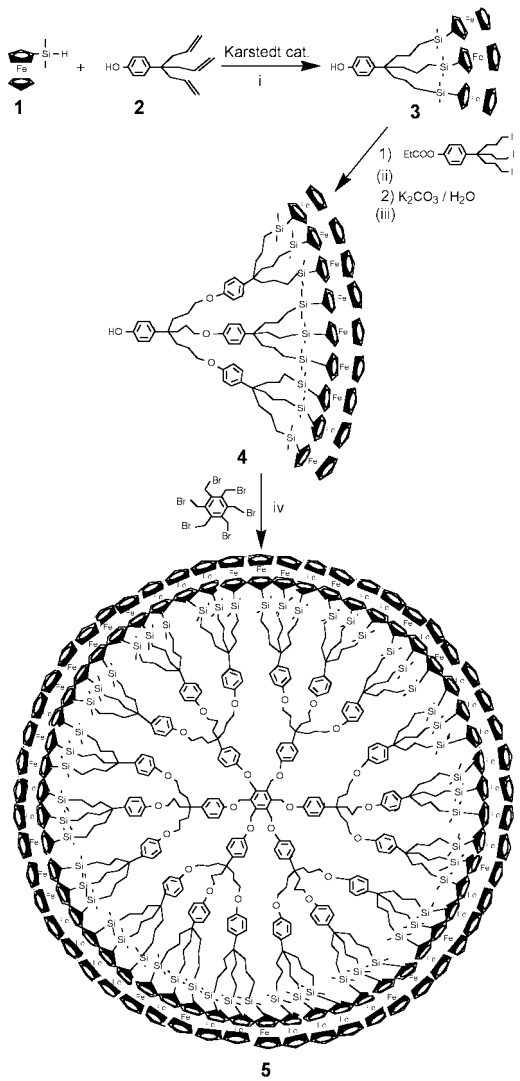
Received (in Cambridge, UK) 4th November 1999, Accepted 4th February 2000

A 54-ferrocene dendrimer is synthesized by a convergent route and can be used to modify a Pt electrode in CH_2Cl_2; it can be reversibly oxidized in DMF in a single 54-electron wave (and with NO^+).

The redox activity of nanoscopic materials,[1,2] in particular that of dendrimers,[3] is of promise in considering applications as materials devices. Ferrocene dendrimers[4] illustrate the potential access to precise redox active nanoscopic molecules with original properties. We now report the ferrocenylsilylation of dendrons and a fast convergent route[5] to *redox stable* dendrimers using ferrocenyldimethylsilane **1**.[6] Hydrosilylation has already been used as an excellent synthetic route to dendrimers.[4e,7] and ferrocenylsilylation has been successfully carried out by Jutzi *et al*. with decaallylferrocene.[4e]

The ferrocenylsilylation of the phenoltriallyl dendron **2**[8] using **1** is achieved with Karstedt's catalyst[9] in the absence of air without protection of the phenol function (Scheme 1). After chromatographic separation, the triferrocenylsilane dendron **3**† is obtained in 90% yield. ^{1}H and ^{13}C NMR spectra indicate the absence of regioisomers, the analytical data are excellent, and the MALDI TOF mass spectrum shows the molecular peak at *m/z* 960.41 (calc. 960.91). A convergent route was developed for the synthesis of the nonaferrocene dendron. The protected dendron *p*-$EtO_2CC_6H_4C(CH_2CH_2I)_3$[8] reacts with **3** in DMF in the presence of K_2CO_3 to give **4**† in 60% yield after deprotection and chromatography. The MALDI TOF mass spectrum of **4** shows an excellent degree of purity, the molecular peak being largely dominant at *m/z* 3110.44 (calc. molecule 3111.09). Dendron **4** reacts with the core hexa(bromomethyl)benzene in EtOH in the presence of K_2CO_3 at 80 °C over two weeks to give the 54-ferrocene dendrimer **5**† in 20% yield after chromatographic separation (C analysis within 0.3%).

Cyclic voltammograms (CVs) of the ferrocenyl dendrons **3** and **4** and the ferrocenyl dendrimer **5** were recorded on a Pt anode in dichloromethane and dimethylformamide (DMF).[10] Dendrons **3** and **4** show a reversible oxidation wave in a diffusion process (no adsorption, as indicated by ΔE_p = 60 mV at 20 °C) in both solvents. The number of electrons involved in this ferrocene oxidation wave was determined using Bard's equation[11] and decamethylferrocene as the internal reference. The experimental number of electrons was found to be in full agreement within 5% with the actual number of dendritic branches. In DMF, the CV of **5** also gives a single reversible wave corresponding to the oxidation of the 54 ferrocene redox centers in a pure diffusion process as indicated by ΔE_p = 60 mV at 20 °C as for the decamethylferrocene reference. The number of redox centers determined experimentally as above is 54 ± 3. In dichloromethane, the CV of **5** shows a mixture of diffusion and adsorption as indicated by a value of ΔE_p = 30 mV at a scan rate of 0.1 V s^{-1}. Modified electrodes[12] with **5** could be prepared by cyclic scanning between the ferrocene and ferrocenium regions of potentials on a Pt electrode in dichloromethane solution, washing with dichloromethane and drying in air. Cycling about twenty times is necessary before observation of a constant curve. When such a derivatized electrode is used in a new dendrimer-free solution containing only the electrolyte, the cyclic voltammogram of the adsorbed dendrimers are obtained with ΔE_p = 0 and a linear relationship between the scan rate and the intensity, both features being characteristic of derivatized electrodes with ferrocene polymers[12] and dendrimers[4g] (Fig. 1). The orange–red dendrimer **5** can be instantaneously oxidized by $NOPF_6$ in dichloromethane, and the blue PF_6^- salt of the 54-ferrocenium dendrimer $\mathbf{5}^{54+}$ obtained as a precipitate can be reduced back to the 54-ferro-



Scheme 1 *Reagents and conditions*: i, toluene, 40 °C, 1 d; ii, DMF, room temp., 2 d; iii, 40 °C, 2 d; iv, EtOH, K_2CO_3, reflux, 14 d.

cene dendrimer **5** using the monoelectronic reducing agent decamethylferrocene. No decomposition of the dendrimer occurs during these redox processes as indicated by the indentity of the ^{1}H NMR spectra before and after the reactions.

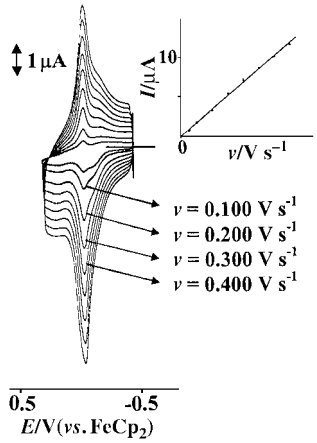

Fig. 1 Cyclic voltammogram of a Pt electrode modified with a film of the 54-ferrocene dendrimer **5**; CH_2Cl_2, 0.1 M $NBu^n_4PF_6$. Inset: plot of the peak intensity *vs.* sweep rate.

Whereas the mechanism of electron transfer in DNA is highly controversial,[13] that in multi-redox dendrimers is also of interest. The present study concerns a large dendrimer approaching a globular shape. The electrochemical reversibility observed for the oxidation of **5** indicates that the structural rearrangement between **5** and $\mathbf{5}^{54+}$ is small. Since the repulsion between the positively charged ferrocenium units in $\mathbf{5}^{54+}$ requires that they be at the periphery of the dendrimer with maximum space expansion, the shape of **5** is relatively closely related to that of $\mathbf{5}^{54+}$. The fact that a single reversible wave is observed is due to fast rotation of the dendrimer compared to the electrochemical timescale, so that all the redox centres come close to the electrode within this timescale.[14*b*] In addition, a kind of *relay*-mechanism from a ferrocene site to the next (hopping electron transfer or *via* π-stacking[14] of the ferrocene units or *via* the σ bonds between ferrocene units) may eventually occur. Otherwise, the heterogeneous electron transfer between the electrode and the most remote redox sites of the globular dendrimer would be slow, as it is when the redox site is isolated at the center of the dendrimer.[4*l*,*m*,15] This type of stable polyredox dendrimer in which the redox centers are all active and fully chemically and electrochemically reversible at about the same potential could find use in the future as molecular batteries and sensors.

Panoscopic materials: synthesis over 'all' length scales

Geoffrey A. Ozin

Materials Chemistry Research Group, Chemistry Department, 80 St. George Street, University of Toronto, Toronto, Ontario, Canada M5S 3H6. E-mail: gozin@alchemy.chem.utoronto.ca

Received (in Cambridge, UK) 25th June 1999, Accepted 23rd August 1999

For the latter half of the 'Solid State 20th Century' materials science has been the engine that propelled technology. As we enter the 'Materials 21st Century' it is abundantly clear that the insatiable demand for new materials for emerging technologies is driving materials synthesis and change. Materials chemistry will play a central role in this endeavor through the creation of materials with structures and properties able to meet the demands required by up-and-coming technologies. In this paper a far-sighted and innovative materials chemistry strategy is proposed. It takes solid state chemistry beyond fifty years of thermodynamic phases and microscale structures, to a new era of self-assembly chemistry focused on metastable phases and mesoscale structures, with accessible surfaces and well defined interfaces that determine function and utility. It is an interdisciplinary approach that combines synthesis, solid state architecture and functional hierarchy to create an innovative strategy for materials chemistry in the new millennium. The attractive feature of the approach is the ability to assemble complex structures rationally from modular components and integrate them into self-assembling constructions for a range of perceived applications. By creating a series of purposeful design strategies it is believed that truly revolutionary advances in materials science and technology can result from this approach.

Room at the top and bottom

Not so long ago in materials chemistry it seemed that there was only 'room at the bottom'.[1] The trend was to synthesize and organize nanoscopic materials. As we enter the new millennium it is becoming abundantly clear that there is also 'room at the top'.[2] What has changed and why is this important? In this brief essay I will make the case that the paradigmatic shift comes from the realization that self-assembly, templating, patterning, capping, layering and molding methods have expanded the materials chemists tool box to include synthesis and organization of materials at 'all' length scales. Hierarchy has been introduced into materials chemistry and purely synthetic integrated chemical systems that are designed to achieve a particular function are becoming a reality. This augurs well for the development of materials, composites and systems with novel properties, new functions and perceived value in a range of applications in the biomedical, pharmaceutical, aerospace, automotive, construction, energy, electronics and photonics user sectors.

Self-assembling materials

This story is about interfaces between organics and inorganics and how they can be controlled synthetically at the molecular level to produce composite materials in which structure is prescribed from angstrom to centimeter length scales. The construction kit consists of complementary organics and inorganics that spontaneously assemble through lock-and-key intermolecular interactions. The driving forces for molecular organization are quite varied and as summarized in Scheme 1 can be based upon ionic, covalent, hydrogen, non-covalent, metal–ligand and colloidal bonding interactions, which may result in structures and properties not found in the individual components.

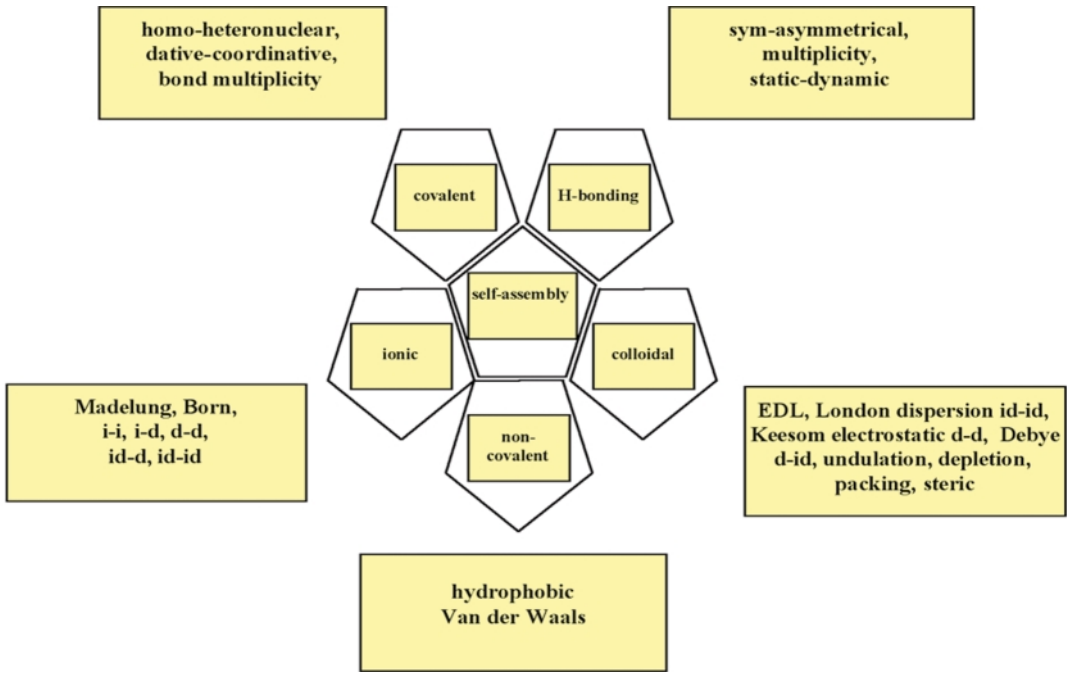
In this context, self-assembly may be viewed in terms of a map of bonding forces that operate between building blocks and over different length scales. In a self-organizing system, basic construction-units spontaneously associate to form a particular structure, the architecture of which is solely determined by the bonding properties and shapes of the individual components. The system proceeds towards a state of lower free energy and greater structural stability. Self-assembly is usually entropically driven in an aqueous system, where association of modules is accompanied by exclusion of ordered water molecules.

Hierarchy

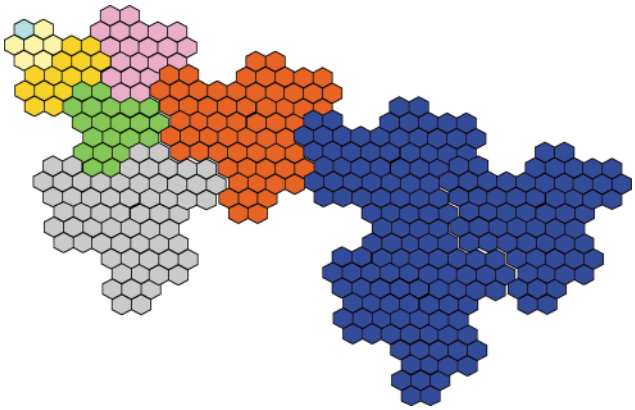
A feature of self-assembly is hierarchy, where primary building blocks associate into more complex secondary structures that are integrated into the next size level in the hierarchy. This organizational scheme, which is illustrated in Scheme 2, continues until the highest level in the hierarchy is reached. These hierarchical constructions may exhibit unique properties that are not found in the individual components. Hierarchy is a characteristic of many self-assembling biological structures and is beginning to emerge as a hallmark of supramolecular materials. Self-assembly is considered to be distinct from template-directed assembly, which involves structure-directing additives, often organics or polymers, in addition to the constituent building-units, which may be inorganics. The

Geoffrey A. Ozin, born 23rd August 1943 in London, England, received his BSc degree in Chemistry from Kings College, University of London in 1965, and his DPhil degree in Inorganic Chemistry from Oriel College, Oxford University in 1967. He was an ICI Fellow at the University of Southampton from 1967–69 before joining the University of Toronto in 1969 where he is currently Professor of Chemistry. Recently he was a Canada Council Isaac Walton Killam Research Fellow and inducted into the Royal Society of Canada. He is a materials chemist and the current work of his group focuses on micro-, meso- and macro-structured materials and composites. The research exploits molecular recognition and self-assembly, to organize inorganic and organic building-units into materials with structural features that span angstrom to centimeter length scales. The methodology embraces concepts in supramolecular, host–guest inclusion, and biomimetic chemistry. Self-assembling mesostructures emerging from the research may find utility in areas such as electrically tunable membranes and chemical delivery systems, chemoselective sensors and solar cells, batteries and fuel cells, bone implants and photonics, nanocomposites and environmental clean-up of toxic waste.

DOI: 10.1039/a905090f



Scheme 1



Scheme 2

template can serve to fill space, balance charge and direct the formation of a specific structure. In this definition, template assembly is synonymous with co-assembly and distinct from self-assembly.

Self-assembling materials over multiple length scales

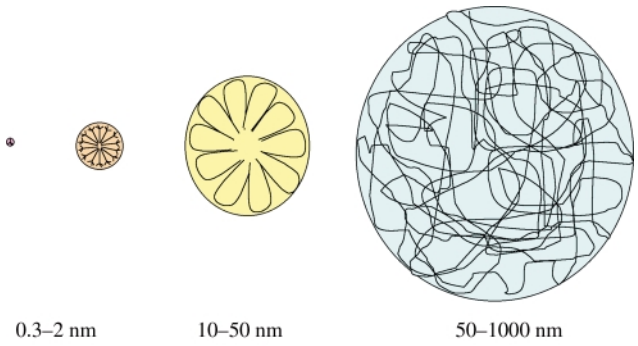
Simple, elegant and robust attributes of self-assembly are now being combined with the powerful methods of inorganic and solid state chemistry to create supramolecular materials with unprecedented structures, compositions and morphologies. The paradigmatic shift of utilizing organics for templating,[3] capping,[4], layering,[5,6] wiring,[7] patterning[8] and molding[9] inorganics is having a revolutionary effect on the field of materials research. This is because it enables, for the first time, self-assembly of most elemental compositions of the periodic table but without the usual restriction of the dimension of structural components. This is facilitating purely synthetic approaches to hierarchical systems with the construction pieces integrated over micro-, meso- and macro-scopic length scales. This kind of 'panoscopic' synthesis, so to speak, has up until very recently been unparalleled in the field of solid state and materials chemistry. By combining the methodologies of self-assembly and microfabrication it has become feasible to assume the challenge of self-organizing and interconnecting functional organic, bio-organic, inorganic and polymeric chemical components into integrated electronic, photonic, mechanical, analytical and chemical systems for future 'panoscale' (panoscale: of any sizes, pano, L) devices.[10] Part of the motivation stems from the notion that the architecture of complex macrosystems in biology and engineering physics are generally based on hierarchical building principles, that is, smaller units are assembled into larger ones, which in turn are organized at a higher dimension. This construction process is continued until the highest level of structural complexity in the hierarchy has been attained.

The hallmark of an integrated chemical, physical or biological system is the assembly of components into a particular architecture that performs a certain function.[11] In the cell of a higher green plant the photosynthetic chloroplast and oxidative phosphorylation mitochondrion machines are perhaps two of the most impressive examples of functional integrated biological systems. Within the body of a computer the atoms are assembled into insulators, semiconductors and metals, dopants, junctions, metal leads and contacts. These are the building blocks that constitute the transistors, diodes and capacitors of the integrated circuits, which comprise circuit boards and subassemblies of an integrated microelectronic system. Familiar integrated chemical systems include heterogeneous catalysts, photoelectrochemical cells, solid state lithium batteries, hydrogen–oxygen fuel cells, instant color photographic film, sensors and chromatographic stationary phases.

The ability to self-assemble diverse kinds of materials over 'all' length scales and spatial dimensions has taken synthetic chemistry to a new level of structural complexity that begins to match those found in biology and engineering physics. It is now feasible to devise strategies for organizing, patterning and linking chemical components into functional architectures that were not previously accessible purely through synthesis. Representative examples taken from the recent literature include, layer-by-layer assembly of a thin film Zerner diode from conducting polymers and monodispersed capped semiconductor nanoclusters,[12] a metal–insulator–metal nanocluster–insulator–metal (MINIM) single electron transistor (SET),[13] a multicolor pixel voltage-controllable semiconductor cluster–luminescent polymer light emitting diode (LED)[14] an all-plastic field effect transistor driven light emitting diode (FET-LED),[15] and a high density rechargeable ultrathin graphite oxide

nanoplatelet–polyelectrolyte lithium ion battery.[16] These few examples serve to demonstrate the power and versatility of a self-assembly materials chemistry approach to 'panostructured' integrated chemical systems that perform a specific function.

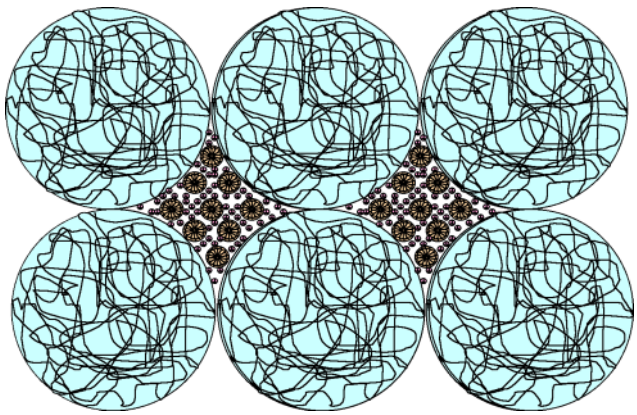
'Panoscopic' synthesis can be viewed in terms of molecular level control of interfaces between organics and inorganics. As illustrated in Scheme 3, this allows one to embrace molecular,[17]



Scheme 3

supramolecular,[18] macromolecular,[19] and colloidal crystalline[20] assemblies under the umbrella of organic template-based assembly, facilitating the synthesis of inorganic materials over multiple length scales, with structural features that may span angstroms to microns.

Through a creative fusion of organic templating, inorganic chemistry, soft lithographic patterning and micromolding methodologies it is feasible to create functional hierarchical materials of the type sketched in Scheme 4. Entirely through



Scheme 4

chemistry one can plan how to synthesize, self-organize and interconnect different kinds of materials over 'all' length scales to create an integrated chemical system with single or multiple functions. In the following, I will briefly expand upon this theme by examining some case studies taken from our recent research to illustrate where 'panoscale' synthesis may find 'room at the bottom as well as the top' of the new materials world.

Faux diatoms and radiolaria

Interest in the synthesis of 'panascopic' materials may be traced to a report in 1995 of surfactant-templated mesolamellar aluminophosphates whose 'natural form' bore a striking resemblance to those of the lace-like siliceous microskeletons produced by the single cell marine organisms known as the diatoms and radiolarians.[21] When looking at scanning electron microscope (SEM) images of these purely synthetic forms it is sometimes difficult to distinguish them from the real thing, Fig. 1. This turned out to be the first synthesis that created a hybrid inorganic–organic material with a shape that mimicked an entire biomineralized skeleton found in the natural world.

Fig. 2 Transmission electron microscopy image of the mesolamellar aluminophosphate material from which the synthetic diatoms and radiolaria mimics are built.

Multianalytical characterization of these synthetic natural forms revealed a hierarchical structure based upon a layered aluminophosphate.[21–25] The lamellae were well ordered at the mesoscale and glassy at the microscale, Fig. 2. Observed morphologies that emerged from a synthesis exhibited micron scale

patterns on millimeter sized solid and hollow spheres of a kind that are usually associated with the filigree microskeletons of diatoms and radiolaria. These aesthetically sculpted biological minerals continue to be admired in Ernst Haekel's *Art Forms in Nature*[26] and avidly read in D'Arcy Wentworth Thompson's *On Growth and Form*.[27]

How was such morphosynthesis possible in a laboratory setting? The template used to produce such shapes was dodecylamine, which in the presence of 85 wt% phosphoric acid formed dodecylammonium dihydrogen phosphate (DDP). Single crystal X-ray diffraction (SCXRD) established an interdigitated bilayer structure for DDP in which the ammonium head group was intricately hydrogen-bonded to the dihydrogen phosphate counter anion, Fig. 3. Powder X-ray diffraction (PXRD) and differential scanning calorimetry (DSC) showed that DDP transforms, under the reaction conditions that generate the patterned sphere shapes, to a thermotropic smectic liquid crystal phase. When observed between crossed-polarizers in a hot stage optical microscope (POM), as a film supported on a glass slide, the mesophase displayed the focal conic texture expected for a smectic liquid crystal,[22] Fig. 4. The optical birefringence pattern appeared even more pronounced when the DDP mesophase was formed in tetraethyleneglycol (TEG), which was the non-aqueous solvent used in the synthesis to create the patterned sphere shapes. The patterns seemed to be diagnostic of a microemulsion in which contiguous assemblies of phase separated water droplets were coated with a layer of the phosphate liquid crystal, Fig. 5. These observations suggested that the texture of the mesophase was 'fossilized' as a lamellar aluminophosphate by a POH + HOAl $\rightarrow$ P–O–Al + H_2O condensation–polymerization reaction of the dihydrogen phosphate anion with an aluminium(III) glycolate precursor located in the microphase separated domains of the DDP–TEG–H_2O liquid crystal microemulsion. This provided an appealing explanation for the origin of the micron-sized patterns observed on the surface of the mesolamellar aluminophosphate sphere shapes.

It was the recognition that inorganic liquid crystals could be used to synthesize inorganic materials with complex form and structures spanning multiple length scales that raised the possibility of a purely synthetic approach to functional hierarchical materials such as bone mimics.

Synthetic bone implant materials

Synthetic analogues of bone are being actively pursued for biomedical applications in the field of bone replacement,

augmentation and repair.[28] Numerous stringent criteria have to be satisfied for a biomaterial to be acceptable as a bone implant, including the ability to integrate into bone and not cause any side effects. We recently described a biomimetic strategy to a new type of bone analogue material.[29,30] Bone consists of *ca.* 70% hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$, (OHAp), embedded in an organic matrix consisting mainly of the proteinaceous triple helix, collagen. Needle or plate-like morphologies of hydroxyapatite crystallize at regular intervals along the collagen fibers with the long *c*-axes oriented parallel to the fibrils. The presence of HPO_4^{2-} groups in bone apatites suggests that octacalcium phosphate $Ca_8(PO_4)_4(HPO_4)_2{\cdot}5H_2O$, (OCP), is a precursor to hydroxyapatite formation in bone. The OCP serves to establish the final morphology, composition, solubility and interfacial energy of apatitic materials, as well as controlling the nucleation and growth of OHAp. These result from the fact that OCP and OHAp have similar crystal structures and are able to epitaxially grow together.[31] A prime consideration in the preparation and performance of a bone implant material is the selection of a surface that is able to induce nucleation of OCP and growth of new bone.

With this background in mind we set out to synthesize an analogue of bone that comprised a porous hydroxyapatite–octacalcium phosphate–calcium dodecylphosphate (CDDP) composite film grown on a titania–titanium substrate. It has the hierarchical construction illustrated in Fig. 6. A macroporous

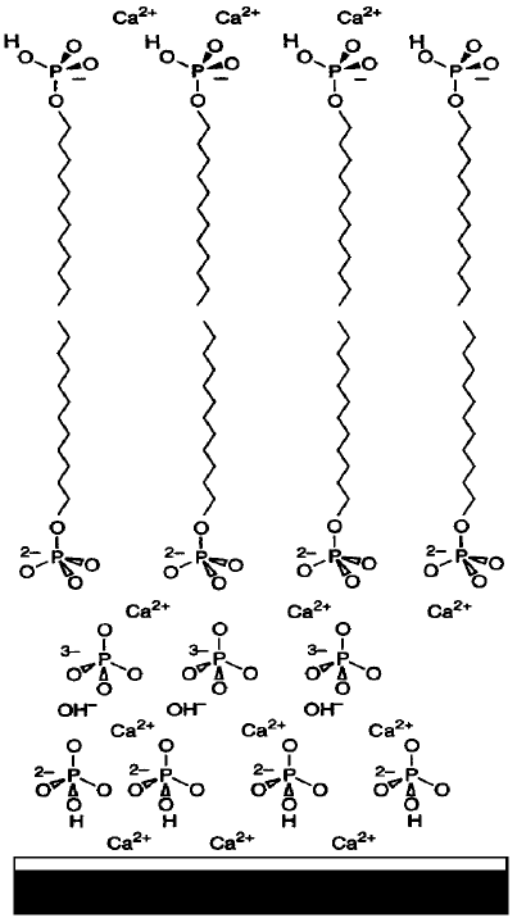

Fig. 6 Hierarchical construction of macroporous hydroxyapatite–octacalcium phosphate–calcium dodecylphosphate composite film grown on a titania–titanium substrate.

and oriented OHAp–OCP mineral phase was found to nucleate and grow, under physiological conditions, from TiOH Brønsted acid and base anchoring sites on the surface of a sputter-deposited titania film as seen in Fig. 7. The mesolamellar CaDDP phase was co-assembled with the OHAp phase in a 'mesoepitaxial' fashion as seen in Fig. 8. It is envisioned that if

materials of this genre can integrate into bone they may be able to deliver bioeffectors and drugs, from the hydrophobic region of the CaDDP mesolamellar phase, to stimulate bone growth and combat disease. Notably, the macroporous structure of the material would facilitate the influx of cells and blood vessels to the site of the bone implant.

Tin sulfide mesh mesophase

The discovery of phosphate liquid crystals raised the possibility that other inorganic liquid crystals should exist and exhibit equally fascinating chemical and physical properties. Materials of this type are rare, they are anticipated to combine the fluidity of organic liquid crystals with for instance, the charge transport and optical properties of inorganic materials. This thinking led to the synthesis of a new class of tin sulfide liquid crystals with a novel structure based on a mesh mesophase.[32,33] The preparation involved the reaction of tin(IV) chloride with hexadecylamine and ammonium sulfide in aqueous ammonium hydroxide. The stoichiometry of the product, $HDA_{2{\cdot}67}SnS_{2{\cdot}05}$, suggested that the material had a structure with a very large void volume. In fact, it was found to have a structure based on regularly perforated layers of tin sulfide sandwiched between a bilayer of partially protonated and charge-balancing hexadecylamine. The room temperature phase was shown to be crystalline with well ordered inorganic and organic layers. The illustration depicts the structure of the as-synthesized crystalline tin(IV) sulfide mesoporous layers at room temperature (top), its semi-liquid crystalline form at 45 °C (middle) and its liquid

crystalline form at 85 °C (bottom), Fig. 9. Tapping mode atomic force microscopy (AFM) images of the material at room temperature revealed well ordered mesopores and mesola-

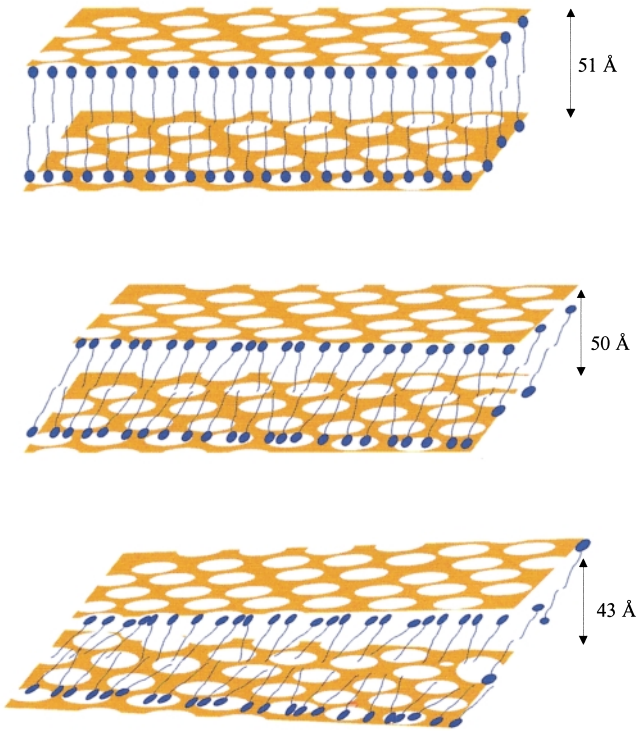

Fig. 9 Illustration of the structure of the tin sulfide mesh crystalline (top), semi-liquid crystalline (middle) and liquid crystalline (bottom) phase.

mellae, which was consistent with the results of powder X-ray diffraction (PXRD) and transmission electron microscopy (TEM), Fig. 10. The structure appeared to be best described as a tin sulfide replica of a mesh mesophase. A film of the room temperature crystalline phase had an electrical conductivity of 5.3×10^{-8} Ω^{-1} cm^{-1}. This increased by >1000 times on transforming to the liquid crystalline phase where it behaved as a semiconducting metallogen. Mesh type tin(IV) sulfide was found to be optically transparent and readily formed electrically conducting crystalline, semicrystalline or liquid crystalline thin films. Furthermore, it reversibly adsorbed molecules like H_2O and CO_2 with a concomitant and measurable electrical response. These observations bode well for the use of this new class of hybrid inorganic–organic semiconducting liquid crystals for display and chemical sensing applications.

Modular mesostructures

The work with tin sulfide liquid crystals suggested that metal sulfide cluster-based liquid crystals might be synthetically accessible and could provide a new and interesting way of assembling mesostructured metal sulfides from well defined building blocks. Earlier work involving the organic molecule templated assembly of adamantanoid $Ge_4S_{10}^{4-}$ clusters into crystalline microporous metal germanium sulfides showed that the integrity of the $Ge_4S_{10}^{4-}$ remained intact.[34] This suggested that cluster liquid crystals based on $Ge_4S_{10}^{4-}$ might be a good starting point to attempt the synthesis of mesostructured metal germanium sulfides. $TMA_4Ge_4S_{10}$ was readily accessible and could be ion exchanged for cationic surfactants like cetyltrimethylammonium chloride to form a lamellar germanium sulfide cluster mesophase $CTA_4Ge_4S_{10}$, Fig. 11. This appeared to be an attractive precursor for the assembly of mesostructured metal germanium sulfides, however the material was found to be insoluble in water, which prevented the formation of a lyotropic mesophase.

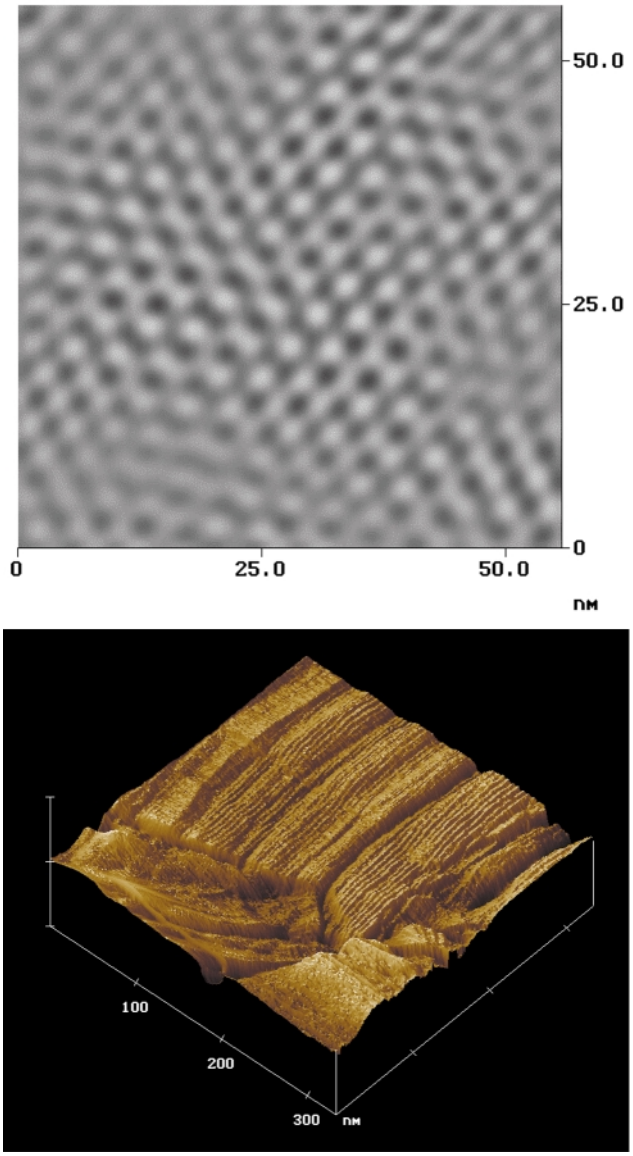

Fig. 10 Tapping mode atomic force microscopy images of the mesopores (top) and mesolamellae (bottom) in the crystalline tin sulfide mesh phase.

The solution to the problem, illustrated in Scheme 5, was found by using the interesting solvent formamide, $HCONH_2$, in which $CTA_4Ge_4S_{10}$ is soluble and self-assembles into a germanium cluster lyotropic liquid crystal.[35] Formamide is a strongly hydrogen-bonded solvent with a dielectric constant and boiling point higher than water. Moreover, the phase diagram of surfactants in formamide resembled that of surfactants in water. Using this knowledge it was discovered that adamantanoid $Ge_4S_{10}^{4-}$ clusters could be linked by divalent M^{2+} transition metal ions around a liquid crystal surfactant assembly in formamide to give exceptionally well ordered mesostructured metal germanium sulfide materials. Elemental analysis established the stoichiometry $CTA_2M_2Ge_4S_{10}$, which together with Raman spectroscopy of the precursor $CTA_4Ge_4S_{10}$ and microporous $TMA_2MGe_4S_{10}$ analogue proved that the cluster integrity remained intact, Fig. 12. These materials represented the first examples of 'coordination mesostructures', a new family of solids in which the $Ge_4S_{10}^{4-}$ cluster functions as a tetradentate ligand by coordinating through its four terminal sulfurs to transition metal ions like Co^{2+}, Ni^{2+}, Cu^{+}, Zn^{2+}.[35] By co-assembling the clusters and transition metal ions in this way, it proved possible to obtain a hexagonal mesostructure with metal linked adamantanoid clusters comprising the channel wall, Fig. 13. In the case of Cu^{+} compound the clusters were linked by Cu_2^{2+} dimers to create $CTA_2Cu_4Ge_4S_{10}$, an unusual example of a mesostructured material that contained a metal–

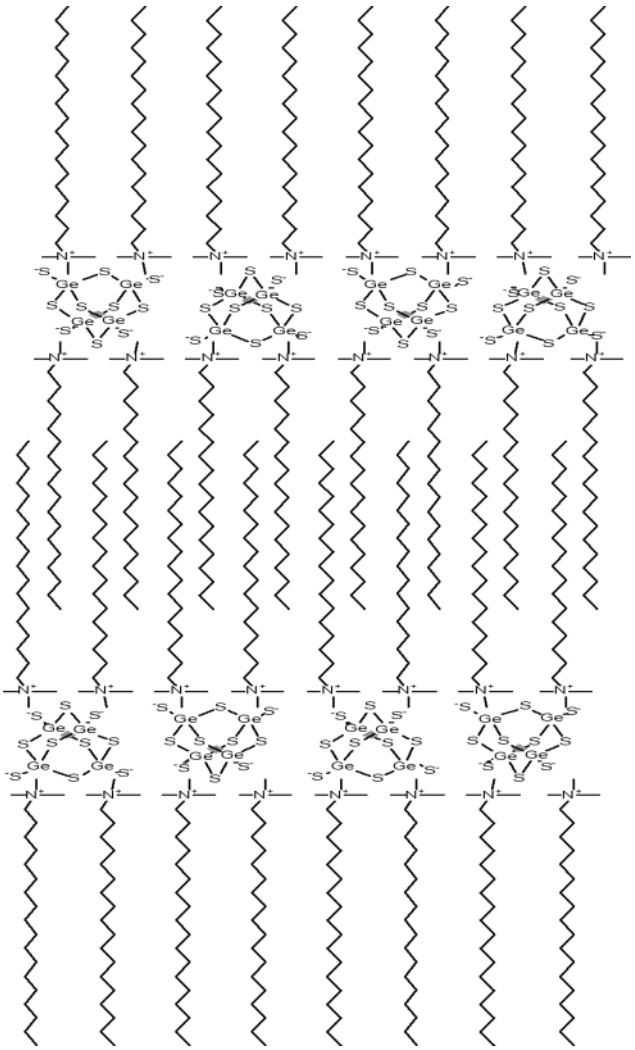

Fig. 11 Illustration of the lamellar adamantanoid germanium sulfide cluster crystalline phase.

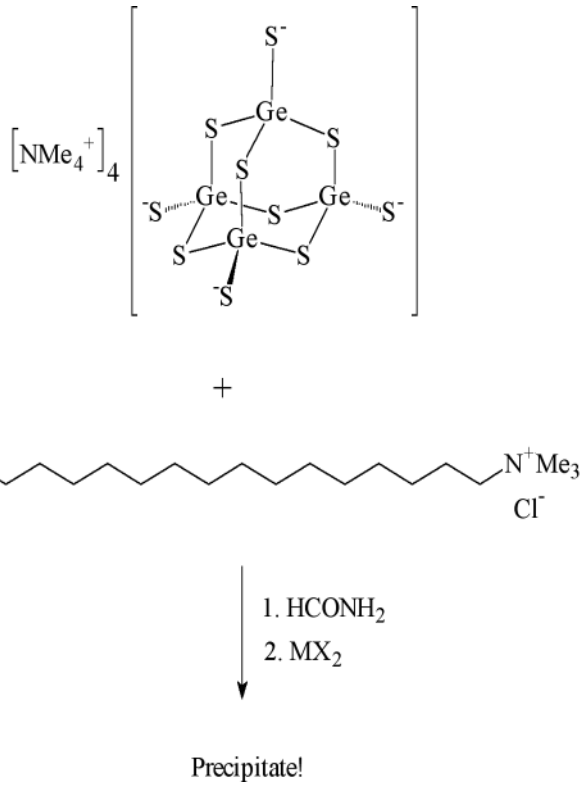
metal bond like its microporous counterpart $TMA_2Cu_2Ge_4S_{10}$.[34,35] The supramolecular assembly of mesostructured materials from the linking of clusters was unprecedented. From consideration of the architecture and composition of mesostructured metal sulfide materials it is envisioned that they could prove effective in diverse applications, such as detoxification of heavy metals in polluted water streams, sensing of sulfurous vapors and semiconductor quantum anti-dot devices.

Sol–Gel mesophase

Continuing with the theme of inorganic liquid crystals that can mineralize into mesostructured inorganic replicas of the templating mesosphase, raised the possibility that a generalized non-aqueous synthesis of main group and transition metal oxide mesostructures could be developed based upon the hydrolytic condensation–polymerization of a sol–gel mesophase. This led to the discovery of glycosilicate and glycometallate surfactants that self-assemble into a hydrolyzable lamellar mesophase.[36,37] The surfactant was cationic and the glycometallate functioned as the charge compensating counter anion, Fig. 14. The main advantage of hydrolyzable glycometallate surfactants was found to be the control that could be exerted over the condensation–polymerization of source reagents like silicates, titanates, zirconates and niobates. This proved pivotal to the successful incorporation of two or more metals into the framework of binary or ternary mesoporous metal oxide materials. Glycometallate precursors may be considered as



Scheme 5

bidentate metal alkoxides. They provide better command over differential rates of hydrolysis of binary combinations compared to traditional monodentate metal alkoxides or bulk metal oxide source materials.

Hydrolysis of Si(IV), Ti(IV), Zr(IV) and Nb(V) glycometallates was found to produce well-ordered mesoporous metal oxides, Fig. 15. Following treatment with metal alkoxides or disilane coupling reagents the surfactant template could be removed to create high surface area narrow pore size distribution mesoporous binary metal oxides. The glycosilicate mesophase showed a well defined lamellar to hexagonal structural transition, which appeared to originate from polymerization induced size and charge density changes in the headgroup region of surfactant. Binary silica–transition metal oxide, mesoporous materials that are rich in either the silica or metal component have been synthesized from a mesophase comprised of mixed glycometallates.

Glycometallate surfactants provide a facile synthetic entry to electroactive and photoactive mesoporous metal oxide materials. They are anticipated to function as electrodes, electrolytes and plasticisers in solid state batteries, fuel cells, solar energy conversion devices, and large molecule chemical sensors.

Mesostructured solid electrolytes

Inorganic liquid crystals again played a central role in the synthesis of a new class of solid electrolytes coined 'salted mesostructures'.[38] In a one-pot synthesis, a lithium triflate–silicate–oligo(ethylene oxide) surfactant mesophase was found to undergo an acid catalyzed polymerization to generate a lithium triflate–oligo(ethylene oxide) surfactant–mesoporous silica nanocomposite film. The optical birefringence fan texture observed for the film was that expected for a silicified version of the hexagonal symmetry mesophase, Fig. 16. $LiCF_3SO_3$ was found, by NMR and Raman spectroscopy, to be dissociated into free lithium (small solid black circle) and triflate (large hatched circle) ions, which were contained in the oligo(ethylene oxide) head group region of the surfactant assembly (thin black lines), all imbibed within the channels (thick black line) of the

mesoporous silica, Fig. 17. Nanocomposite materials of this genre have been found by ac impedance spectroscopy to behave as fast lithium ion conductors at room temperature, which bodes well for them finding utility in the important field of polymer electrolyte, plasticiser and battery technology.

Polymer–mesoporous silica nanocomposites

The ability to control the morphology and mesostructure of surfactant-templated silica as fibers, films, spheres, gyroids, discoids, spirals and soft lithographically defined micron scale patterns depends on the integration of chemical and physical concepts in surfactant, sol–gel, liquid crystal, surface, colloid and crystal growth science.[39,40] This entailed command over topological defects, director fields, surface charge, nucleation

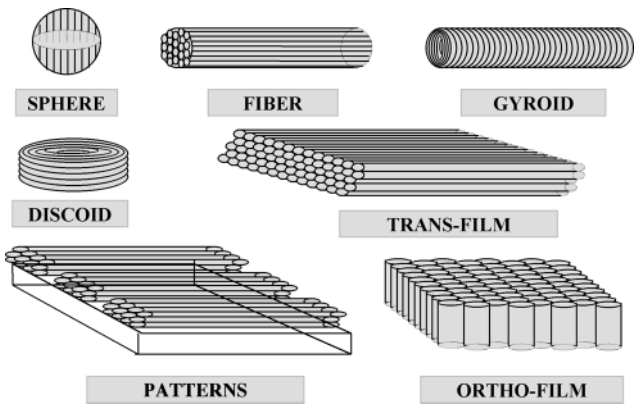
and growth of polymerizable silicate micelles and liquid crystals. The availability of shaped forms of hexagonal mesoporous silica, like those illustrated in Scheme 6, raised the interesting possibility of using host–guest inclusion chemistry to synthesize a range of nanocomposites, nanowires and nanoclusters, which may possess unique electrical, optical and mechanical properties. Spatially self-limiting synthesis of this genre has enabled the production of polymer nanocomposites. Subsequent etching of the silica host was able to provide a route to polymer mesofibres with the same diameter as the channels of the host.



Scheme 6

To amplify, phenol and formaldehyde were introduced into the channels of hexagonal mesoporous silica. Exposure to gaseous hydrogen chloride induced a condensation polymerization of the monomer precursors in the channels to form a cross linked poly(phenolformaldehyde)–mesoporous silica nanocomposite material.[41] Proof for the formation of intrachannel poly(phenolformaldehyde) in mesoporous silica was obtained by TEM imaging of aqueous HF extracted fibers. They were found to have a diameter of *ca.* 20–30 Å and aspect ratios as high as 10^4, Fig. 18. Depending on the details of the HF extraction process the polymer could be formed as either individual strands or bundles of fibers.

Fig. 18 Transmission electron microscopy image of poly(phenolformaldehyde) mesofibers extracted from poly(phenolformaldehyde)–mesoporous silica composite. Scale bar = 10 nm.

Inorganic polymer–mesoporous silica nanocomposites

This paradigm has been effectively used to synthesize a poly(ferrocenylsilane)–mesoporous silica composite, Fig. 19, by the ring opening polymerization of a silaferrocenophane within the channels of hexagonal mesoporous silica.[42] Temperature controlled heating in the range 500–1000 °C caused the encapsulated polymer fibers to pyrolyze and form a well ordered, superparamagnetic ceramic–silica nanocomposite, Fig. 20. The composite materials were shown to contain monodisperse superparamagnetic iron nanoparticles embedded in a SiC/C matrix, housed within the channels of the mesoporous silica host.

Silicon–silica nanocomposite film

Work of a related kind concerns the synthesis of silicon nanoclusters in hexagonal mesoporous silica film that displays bright visible photoluminescence and nanosecond lifetimes.[43] This is notably distinct to the longer millisecond and microsecond emission lifetimes usually observed for nanocrystalline and bulk forms of silicon.[44–46] The process of creating the luminescent silicon–silica nanocomposite film is purely synthetic and works well under very mild conditions. It is simple to execute, low cost, may be integrated into existing silicon technology and could be suitable for mass production. The methodology may be useful for the fabrication of silicon-based light emitting diodes, optical interconnections, displays and chemical sensors.

To amplify, chemical vapor deposition (CVD) of disilane Si_2H_6 at 140 °C and 30 Torr in free standing, oriented hexagonal mesoporous silica film, yielded photoluminescent silicon nanoclusters. This mild CVD process necessitated the use of an incompletely polymerized mesoporous silica film that contained a high population of hydroxy SiOH wall sites as well as

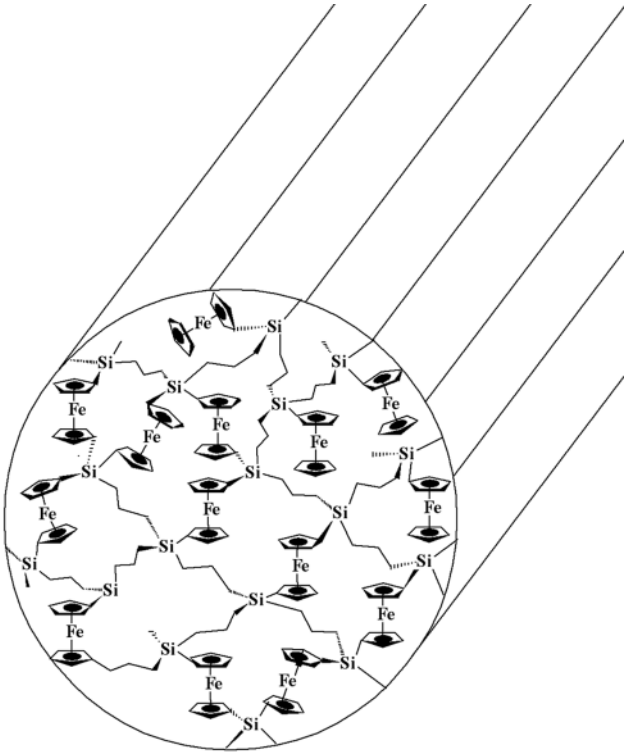


Fig. 19 Illustration of channel architecture of poly(ferrocenylsilane)–mesoporous silica composite.

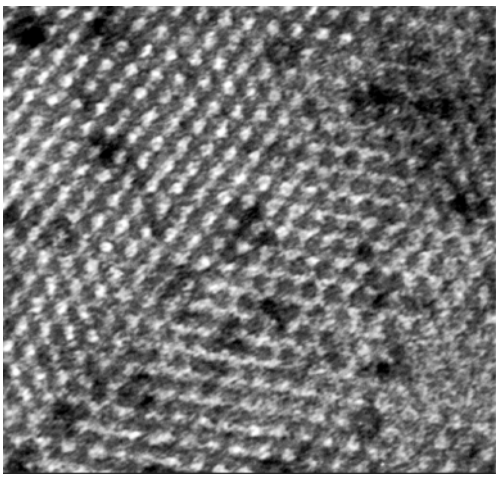

Fig. 20 Transmission electron microscopy image of superparamagnetic iron clusters in a silicon carbide–carbon matrix housed within the channels of a mesoporous silica host.

the surfactant template, required to make the film, within the channels. Exposure of the film to gaseous Si_2H_6 led to a silicon–silica nanocomposite film that displayed bright luminescence in the visible spectrum. Adsorption of Si_2H_6 into the film appeared to be facilitated by the surfactant imbibed within the channels. Anchoring of Si_2H_6 in the film occured at reactive SiOH sites located in the silica channel wall. Thermally induced hydrogen-elimination from anchored $Si_2H_6 \cdots SiOH$ and aggregation of silicon proceeded in the channel spaces of the film. This process restricted the growth of silicon clusters to the dimensions of the mesoscale channels. Raman, solid state NMR and luminescence spectroscopic techniques indicated that the size of the encapsulated silicon nanoclusters was *ca.* 1–2 nm and in this range they exhibited distinct structural and electronic properties compared to larger silicon nanocrystallites and bulk silicon, Fig. 21. This is believed to be the origin of the observed nanosecond lifetimes of the photoluminescence from the silicon–silica nanocomposite film.

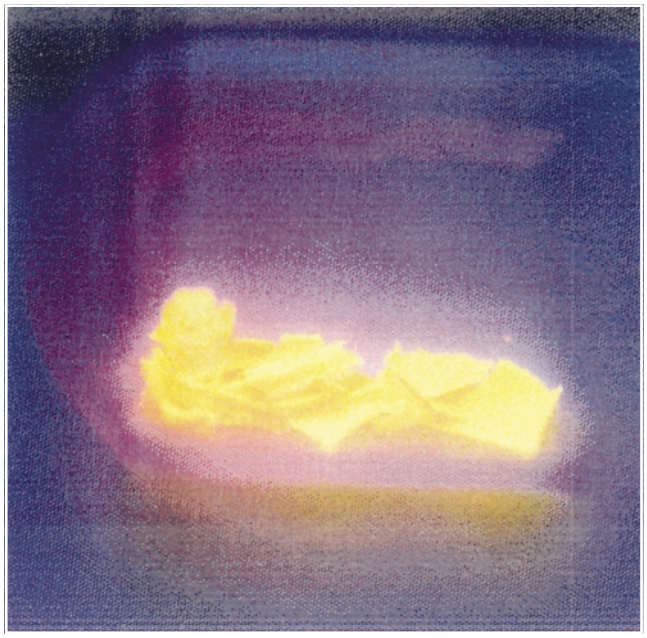

Fig. 21 Photoluminescence from 1–2 nm diameter silicon nanoclusters housed within the channels of hexagonal mesoporous silica film.

Buckling silicate liquid crystals

Morphosynthetic control of the nucleation, growth and polymerization of a lyotropic silicate liquid crystal has enabled sculpting of fiber, film and sphere shapes out of hexagonal mesoporous silica.[39,40] While topological defects (*e.g.* disclinations and dislocations) and colloidal interactions (*e.g.* electrical double layer, van der Waals) play a dominant role in the genesis of a particular form of mesoporous silica, more subtle elastic and compressive forces have been found to be responsible for the creation of radial patterns and twisted shapes like those shown in Fig. 22.

Patterning

Intriguing designs have been found on the surface of mesoporous silica shapes.[47] Radial patterns observed on discoid morphologies are particularly impressive, as judged by Fig. 23. While the relation between bulk and surface mesostructure, optical birefringence and morphology provided a useful insight into morphogenesis of curved mesoporous silica shapes, the origin of surface patterns remained an enigma and a challenge for materials chemistry. Analysis of the radial patterns of a large number of discoids showed the nodal frequency spans from zero to over a hundred with no obvious trend in the observed values. To gain an insight into the morphogenesis of radial patterns in mesoporous silica discoid shapes, the theory of elasticity for nematics with some modification was considered a logical starting point. The equilibrium shape of a hexagonal silicate mesophase confined to a regular discoid geometry (concentric co-axial director field, 2π line disclination) was obtained by integrating the free energy density over the volume of the liquid crystal, taking into account the surface tension term. It was found that the minimum energy of a regular discoid mesophase is attained by an elastic deformation to create a discoid with a radial pattern that was similar to those observed on mesoporous silica discoid shapes.

Although calculations predicted that radial patterns could appear on a planar discoid, it was found experimentally that radial patterns often occur on corrugated and/or sunken discoid shapes, Fig. 23. Clearly, some other distortion was operative in the silicate discoid mesophase besides just spontaneous elastic deformation and that had not been taken into account in the free energy calculations. The missing contribution to the growth process was believed to originate from longitudinal and radial

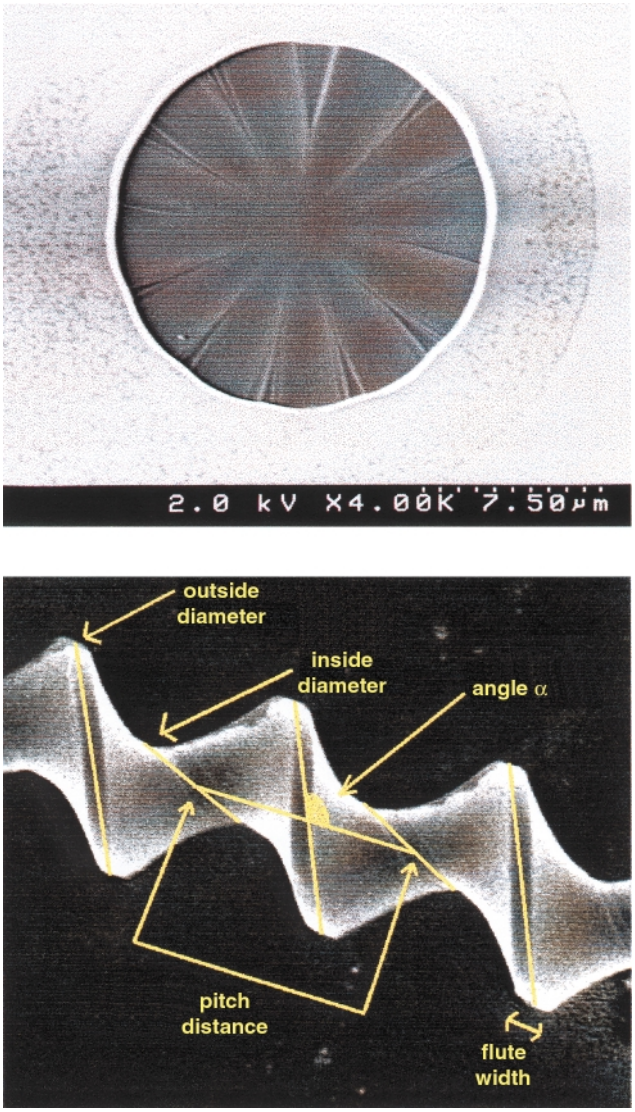

Fig. 22 Scanning electron microscope images of radially patterned discoid (top) and of hollow Archimedian screw (bottom) shapes both made of hexagonal mesoporous silica.

differential contraction of micelle rods that comprised the liquid crystal discoid and that was induced by polymerization of silicate to silica. Because growth of a discoid was imagined to occur from the center and radially outwards, the inner portion of the discoid was expected to be more polymerized than the outer region. The outcome of including polymerization induced differential contraction effects into the calculation of the shape of the radially patterned mesoporous silica discoid was to create sunken discoid shapes like those shown in Fig. 23.

Supramolecular origami

Similar kinds of polymerization induced differential contraction but now confined to a patch of hexagonal mesoporous silica film were found to be responsible for the morphogenesis of hollow helicoids of mesoporous silica.[48] It was found that a low acidity and high ionic strength medium favored a slow rate of silicification in a patch of mesoporous silica film. Hence polymerization-induced differential contraction of silicate micelle rods became influential in the formation of hollow helicoids rather than the formation of a mesoporous silica film. PXRD clearly defined the materials as hexagonal mesoporous silica and SEM images revealed shapes that resembled an Archimedian screw, Fig. 22. TEM images recorded for whole-mounted helicoids revealed that they were hollow with *ca.* 1 μm thick 'shell'. The shell was found to be composed of

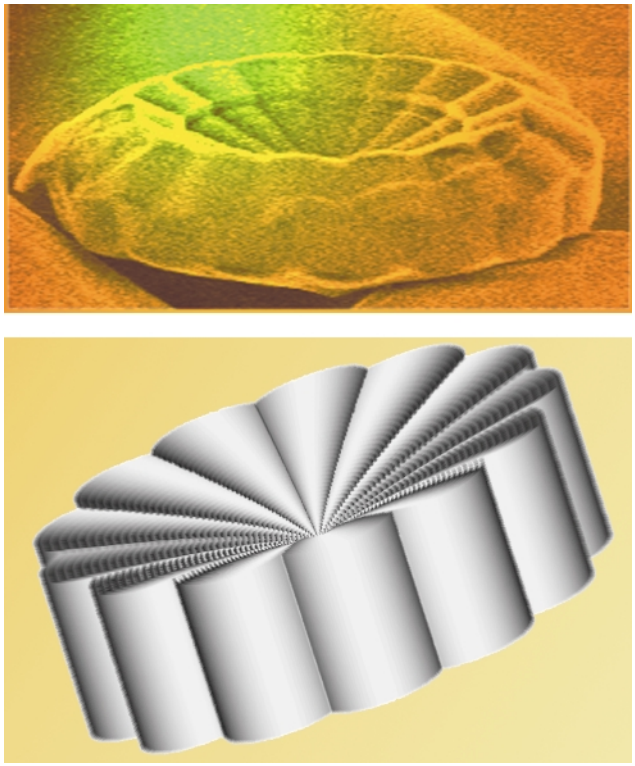

Fig. 23 Observed and calculated sunken and radially patterned hexagonal mesoporous silica discoid.

hexagonally close-packed *ca.* 5 nm diameter channels, which had a *ca.* 1 nm thick silica wall and appeared to spiral around the major axis of the helicoid. The dimensions of a significant collection of hollow helicoids were analyzed by measurements of SEM images. It was striking that diagnostic dimensions of the screw, namely pitch width and angle, flute width, and inside and outside diameter, were found to span a rather narrow range. Notably, the pitch angle α was centered at 70 and 110°, which, respectively, corresponded to left and right handed helices that occurred in essentially equal numbers within the same synthesis batch. From the collective evidence it was concluded that hollow helical cylinders originated from polymerization induced differential contraction of a hexagonal silicate liquid crystal 'patch', which contracted further into hollow helicoids made of hexagonal mesoporous silica, Fig. 24.

The folding mechanism illustrated in Fig. 24 is based upon both radial and longitudinal contractions across and parallel to the rods/channels, respectively, induced by polymerization of a hexagonal silicate mesophase to mesoporous silica. As the patch grows in area and thickness, older rods must undergo more polymerization and contraction than younger ones. Provided radial and longitudinal differential contractions in thickness are considered, they lead to diagonal bending of the patch because these two contractions act in mutually orthogonal directions. Within this diagonally folded patch, the volume of the micelle rods changes solely by contraction but not deformation. Therefore, the folded patch is stress-free, that is in an energetically favorable configuration.

Synthetic shape

The understanding that emerged from these studies has revealed new ways of controlling the growth and form of composite inorganic–organic mesostructured materials with novel topologies. Siliceous hollow helicoids with spiraling channels may find utility for separating viral or bacterial particles, in the synthesis of chiral macromolecules, and as micromolds for the fabrication of magnetically activated screws in microelectromechanical, microfluidic and microanalytical devices. The ability to intentionally synthesize micron-sized shaped objects

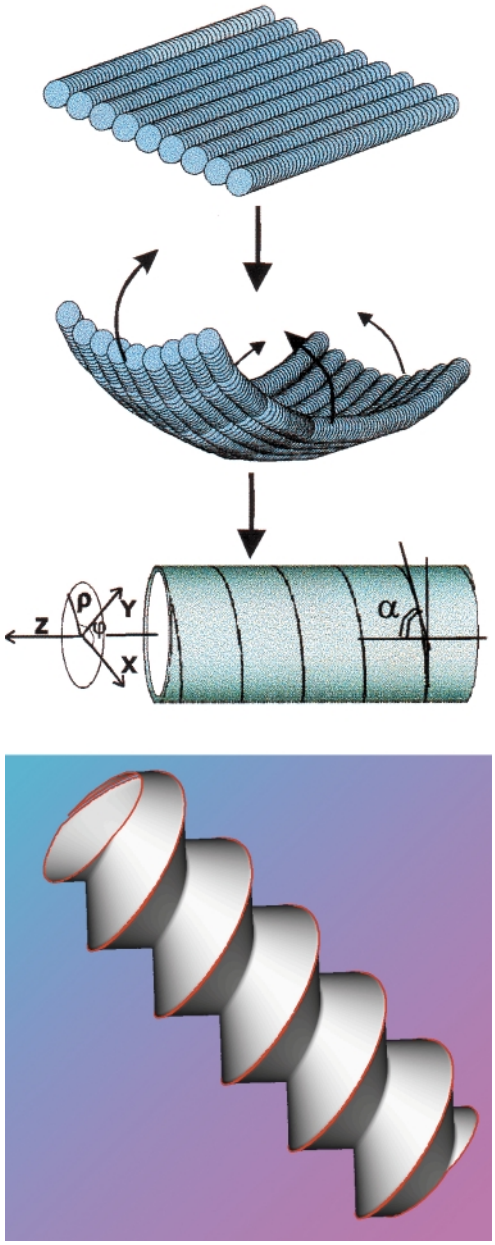

Fig. 24 Supramolecular origami: polymerization induced differential contraction and folding of a patch of hexagonal silicate liquid crystal film to give a mesoporous silica hollow cylinder (top) which further contracts to a hollow helicoid (bottom).

begins to point the way to self-assembling 'synthetic' micro-electro-mechanical machines (SMEMS), like the one imagined in Fig. 25. One might be able to employ this approach as an alternative or adjunct to currently employed MEMS techniques, which rely on the fabrication of components. This paradigm raises some intriguing possibilities for future 'panoscale' research aimed at the organization and integration of synthetically shaped materials for functional devices.

New nanocomposites: a fusion of synthetic organic and solid state materials chemistry

A brand new class of self-assembling nanocomposite materials called periodic mesoporous organosilica materials (PMOs) has recently been discovered.[49–53] What is so special about these nanocomposites is that for the first time organic functionality has been chemically integrated 'within' the framework of a solid state inorganic structure.

These organic–inorganic hybrids are prepared through the surfactant-templated hydrolytic polycondensation of bis(triethoxysilyl)organo precursors, $(EtO)_3SiRSi(OEt)_3$, in which

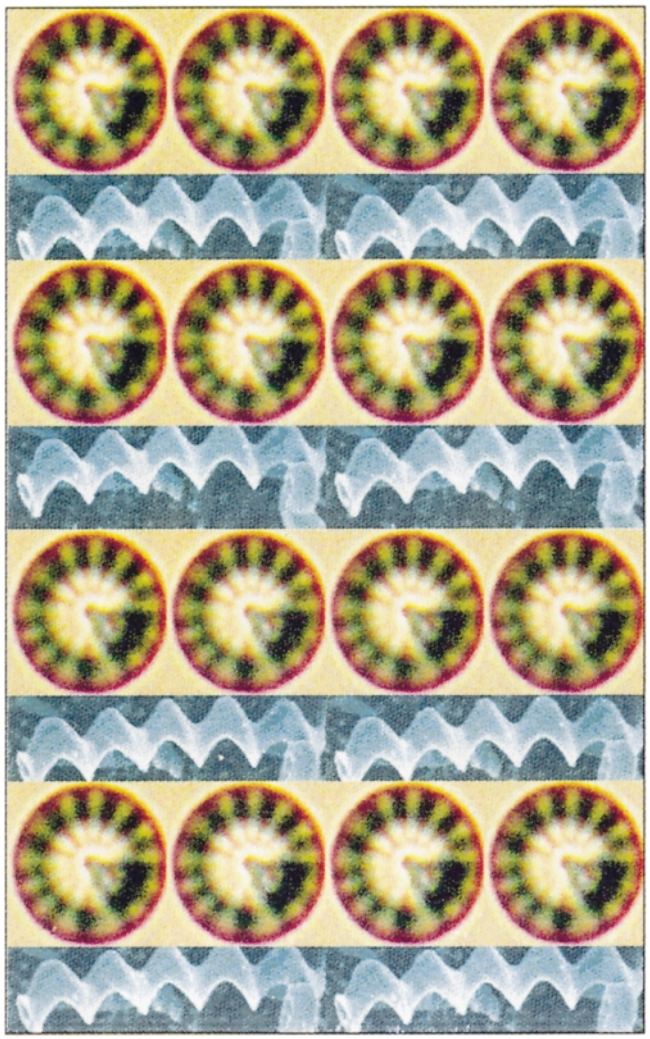

Fig. 25 Concept of futuristic synthetic microelectromechanical machines, SMEMS.

two sol–gel moieties are connected by an organic group R. Bridging organic groups that have been successfully integrated into the silica framework include ethane, ethene, methylene, benzene, thiophene, ferrocene and acetylene.[49–53] Significantly, the methodology also enables the synthesis of controlled morphology PMOs in the form of optically transparent monoliths and films (see Fig. 26).[54] This approach extends the realm of periodic mesoporous materials to 'chemistry of the channel walls' rather than limiting the 'chemistry to the channel space', which had been the situation until these reports.

The synthesis of PMOs fuses methodologies in organic synthesis, sol–gel chemistry and supramolecular assembly, to create a new class of nanocomposites in which the interface between the organic and inorganic components is under molecular scale control. What is so appealing about PMOs is the 'designed integration' of organic functionality 'inside' the actual framework of a solid state inorganic material, which exhibits crystalline mesoporosity. This is considered a breakthrough for several reasons. It allows the composition, hydrophobicity–hydrophilicity, and chemical properties of the mesoporous host to be tuned using chemistry. There is potential to chemically change the mesoporous material to modify the physical and mechanical properties of the mesoporous host—no other material designed thus far can claim this possibility. The functional groups do not hinder space inside the channels, as do terminally grafted organic groups. It permits a greater fraction (100% loading) of organic species to be placed in the framework of the material than other synthetic routes, which put organic groups inside the channel voids and are restricted to 25% loading before all order is lost. Also, it ensures a

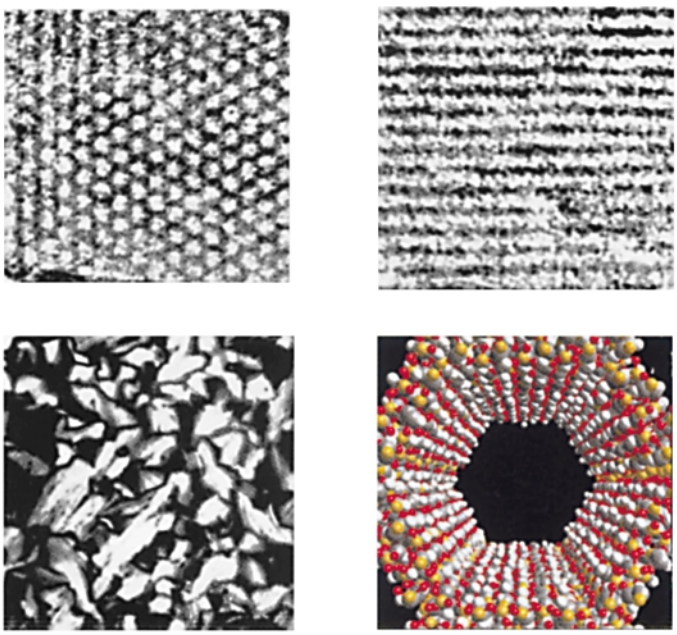

Fig. 26 Transmission electron micrograph (top left and right) and polarization optical microscope (bottom left) images and graphical representation of a single channel (bottom right) of optically transparent oriented hexagonal mesoporous ethenesilica film.[54]

homogeneous distribution of organic groups inside the walls of the materials.

Having reactive organic groups chemically integrated 'inside' the channel wall of periodic mesoporous silicas, rather than simply grafted to and hanging in the channel spaces, may prove to be advantageous for many applications. Moreover, there are additional advantages that may arise from the incorporation of organics into the 'backbone' of the material. Owing to the flexibility of organic spacers, PMO film and monolithic samples may be less prone to cracking, a problem that has always plagued research involving controlled morphology mesoporous silica materials. Moreover, the hardness and density of the bulk mesoporous organosilica may be tuned by changing the organic groups. This provides a new route to lightweight periodic mesoporous materials. Clearly, many opportunities abound for periodic mesoporous organosilicas with appropriately designed functional organics 'inside' the framework.

Value of panoscopic materials

Ultimately, the scientific and technological impact of any new class of materials depends on the ability to control the size, morphology and aggregate structure of primary particles. Self-assembling 'panoscopic' materials are no exception in this respect. They introduce hierarchy into materials chemistry and bode well for the development of materials and composites with novel properties, new functions and perceived utility in a range of applications in the biomedical, pharmaceutical, aerospace, automotive, construction, energy, electronics and photonics sectors. Possibilities for 'panostructured' materials include large molecule catalysis, membrane separation and sensing, battery electrolytes, low dielectric electronics packaging, chiral separation stationary phases, bone implants, chemical delivery vehicles, and toxic clean-up of water streams, The future looks very bright for self-assembling 'panoscopic' materials.

Acknowledgements

The research described in this personal account has profoundly influenced my way of thinking about materials chemistry. Chemical concepts in self-assembly, length scales, hierarchy, integration and topology have been introduced that hopefully will make a difference to the way materials research evolves in the new millennium. None of this would have been possible without the contributions of my talented coworkers whose names are listed in the references and who challenged me every day with important, insightful and creative ideas and suggestions. Dr Charles Kresge of Mobil, Dr Robert Bedard of UOP and Dr Juan Garces of Dow have championed the research in the U of T materials chemistry group for many years and were regular visitors in Toronto for many memorable brainstorming sessions, both in the laboratory and at great restaurants. During this exciting period of research, G. A. O. was awarded an Isaac Walton Killam Memorial Fellowship from the Canada Council. G. A. O. is also grateful to the Natural Sciences and Engineering Research Council (NSERC) of Canada for financial support of this work. Support and encouragement from the Chairman of the chemistry department, Dr Martin Moskovits, is appreciated. And last but not least I wish to express my gratitude to my best friend Linda Ozin who tries to make my writing more lucid.

Aggregate formation from 3-alkylindoles: amphiphilic models for interfacial helix anchoring groups

Received (in Columbia, MO, USA) 30th November 1999, Accepted 9th December 1999, Published on the Web, 29th February 2000

Indole can function as an amphiphile headgroup, but the counter-intuitive observation that 3-substituted indoles form less stable aggregates than the *N*-substituted isomers has been addressed by use of a Langmuir–Blodgett trough.

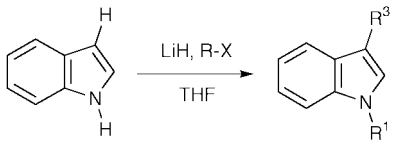
Many proteins that control the passage of cations and small molecules across membrane boundaries are thought to involve multiple α-helical strands that organize into a pore.[1] In most cases, this notion is based on a combination of sequence analysis and hydrophobicity plots[2] but firm structural data has come to hand recently for the K*sc*A channel of *Streptomyces lividans*[3] and the mechanosensitive ion channel homologue from *Mycobacterium tuberculosis.*[4] In many cases, the α-helices are thought to be connected by 'loops' that do not enforce rigid structural arrangements on the transmembrane segments. It has been postulated, for example, that the tryptophan residues of gramicidin serve as anchors at the membrane boundary to stabilize the single-strand, head-to-head dimer structure.[5] The interesting recent controversy over the active channel structure of gramicidin[6] has been argued partly in terms of indole position within the phospholipid bilayer.[7] It has also been noted 'that Trp and Leu are equally hydrophobic in character and able to embed in a bilayer membrane'.[8]

If transmembrane proteins require alignment of multiple α-helical segments for effective function, tryptophan is a reasonable candidate to serve that purpose. Indeed, the known solvatochromism[9] of the indole sidechain and tryptophan-rich[10] and highly conserved periplasmic loops[11] suggest an anchoring function. In the first stage of the present work, the strategy was to determine if vesicles could be formed from single-strand alkanes[12] terminated with a headgroup corresponding to the tryptophan sidechain.

One measure of a group's 'anchoring potential'[13] could be obtained by evaluating amphiphiles in which indole served as headgroup.[14] We felt that the loss of the NH residue resulting from *N*-alkylation of indole constituted a stringent test of the potential for this group to function as an anchor. We thus prepared several *N*-alkylindoles and assessed their ability to form aggregates. When the alkyl chains were of sufficient length, *N*-alkylindoles formed stable aggregates that were characterized by laser light scattering, electron microscopy, and dye entrapment.[15] We report here that the isomeric 3-alkylindoles form aggregates as well but their behavior is quite different.

3-Methylindole **1** was obtained commercially. Compounds **2**–**6** were obtained by treatment of indole with LiH in THF followed by addition of the alkylating agent (Scheme 1). Yields were modest (20–40%); the major by-products were the *N*-substituted isomer and/or the disubstituted compound. The previously unknown materials **2**–**6** were obtained either as oils or low-melting solids.[16]

Aggregates were formed from aqueous suspensions of the amphiphiles reported here by using the lipid hydration[17] vesicle preparation method.[18] Aggregate size was assessed by using a standard laser light scattering instrument[19] and negative stain electron microscopy. Aggregates were not observed for **1** or **2**, which have 3-methyl and 3-hexyl sidechains, respectively.



1 R^1 = H, R^3 = CH_3
2 R^1 = H, R^3 = $(CH_2)_5CH_3$
3 R^1 = H, R^3 = $(CH_2)_9CH_3$
4 R^1 = H, R^3 = $(CH_2)_{17}CH_3$
5 R^1 = $(CH_2)_{17}CH_3$, R^3 = H
6 R^1 = R^3 = $(CH_2)_{17}CH_3$

Scheme 1

Large aggregates (340 ± 93 nm) were observed for **3** (R′ = *n*-decyl) and when the 3-sidechain was *n*-octadecyl (**4**), the aggregate diameter was 142 ± 34 nm. The latter value compared with 138 nm (narrow size distribution) observed when the octadecyl chain was attached to indole at the 1-position. When both the 1- and 3-positions of indole were substituted by *n*-octadecyl groups, light scattering showed that the liposomes had an average diameter of 210 nm (size distribution was broad). Aggregates were further characterized by electron microscopy. Aggregates formed from **3** are shown in the accompanying photomicrograph (Fig. 1). These aggregates proved to be too fragile to stain with 0.2% uranyl acetate, converting into large, ill-defined structures. Previous studies with the corresponding *N*-alkylindoles suggested that the aggregates formed from those isomers were robust. Moreover, when an aqueous suspension of *N*-*n*-decylindole was maintained at ambient temperature in the dark for one week, the unimodal diameter increased from 272 ± 43 to 373 ± 130 nm. No other alteration in the system could be detected. In contrast, an aqueous suspension of the isomer **3** was monitored weekly

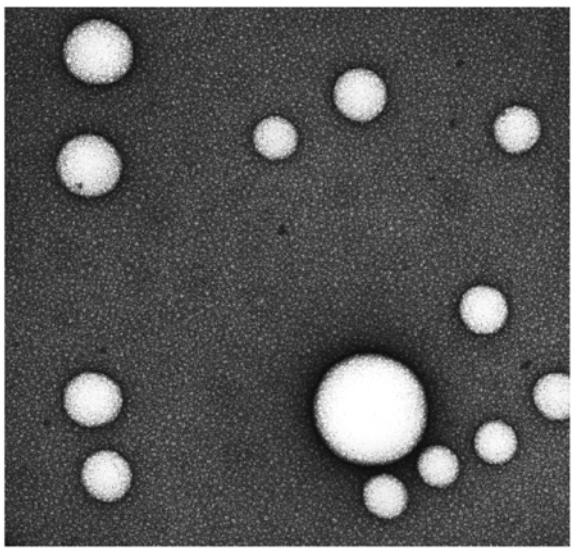


Fig. 1 Photomicrograph of **3** (field of view = 2000 × 2000 nm).

DOI: 10.1039/a909527f

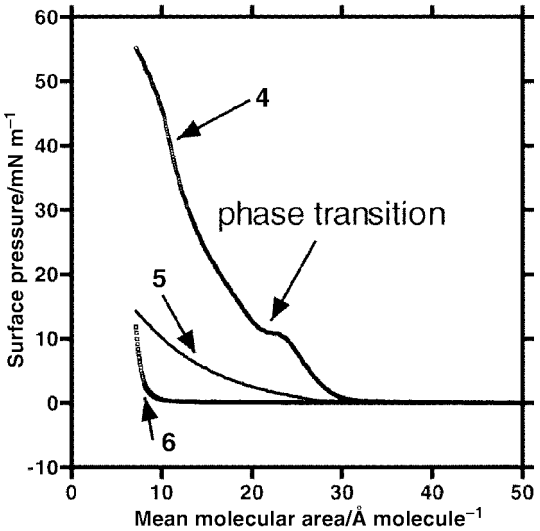

Fig. 2 Pressure–area isotherms for **4**–**6**.

during one month. The size observed for the aggregates, 340 ± 93 nm, remained constant. However, a foamy residue was observed to deposit on the walls of the vessel during this period and the amount of very large particles[20] detected by the laser light scattering instrument increased from 0% to 7%. It thus appears that some fusion[21] and precipitation have occurred.

A dye entrapment study conducted on vesicles formed from *N*-decylindole using the fluorescent dye carboxyfluorescein (1 and 100 mM) found inclusion to be 8%.[15] When such a study was undertaken with **3**, the observed aggregate size tripled from 340 to ~1000 nm. The inclusion was calculated to be 3.5% but the variation in aggregate size makes the meaning of the inclusion volume unclear. Alternative attempts to entrap other dyes, methylumbellyferyl-D-glucopyranose, or Na^{125}I also proved to be equivocal. The fragility of vesicles formed from 3-alkylindoles, which retain a free NH, compared to the stability of the *N*-substituted indoles, was remarkable. This seemed counter-intuitive as the free NH was expected to make the indole more capable of hydrogen bonding and thus interacting with water.

When the alkyl group is attached at indole's 3-position, the indolyl NH remains free and available to interact with proximate water. Hydrogen bonding could, in principle, compete with the organizational force[22] available from π-stacking.[23] When vesicles form, association of the lipid tails help to stabilize the overall structure. When there is no NH residue available for H-bonding, the hydrophobic forces are expected to dominate vesicular organization. The experimentally-determined pressure–area isotherm π–A curves (π = surface pressure, Langmuir–Blodgett trough) for compounds **4**–**6** at 20 °C are shown in Fig. 2. The *N*-alkylated indoles **5** and **6** gave no significant isotherm. 3-Octadecylindole **4** revealed a transition (20 °C) from expanded to condensed phase (surface pressure of the condensed phase, π_c, of ~12 mN m^{-1}) typical of many known amphiphiles when the monolayer is below its critical temperature.[24] The mean molecular area of the expanded phase at this pressure was 22.5 Å^2 molecule^{-1}. The area of the condensed phase was obtained by extrapolating the condensed isotherm **($\pi = \pi_c$).** The corresponding value is ~20.5 Å^2 molecule^{-1}. Unlike various other monolayer systems known in the literature,[25] the monolayers formed from **4**, which has an accessible NH functional group, did not collapse. Instead, the surface pressure rose until the trough barriers could not further compress the layer.

An important conclusion of the present work is that indole is capable of serving as a head group in the formation of stable aggregates, whether the alkyl chain is attached at the 1-(*N*) or 3-position. As expected for a typical amphiphile, aggregates are observed only when the alkyl chains are sufficiently long. These aggregates were characterized by standard methods. The difference in behavior for the isomeric indole amphiphiles may be understood in terms of hydrogen bonding. The Langmuir–Blodgett trough work suggests that lipid–lipid and headgroup stacking interactions control the formation of aggregates. When the NH residue is free (3-alkylindoles), the interaction with water becomes dominant, altering the stability of the aggregates. The multiple indolyl (Trp) headgroups in membrane-inserted gramicidin are focused to the aqueous boundary and stabilize the position of the structure. The present results demonstrate that indole may function generally as an organizing element in membrane-bound peptide[26] and protein structures.

We thank the NIH for grants (GM-36262 to G. W. G.) and (GM-47969 to D. F. C.) that supported this work.

Thin layer chromatography as a tool for reaction optimisation in microwave assisted synthesis

Lorenzo Williams

SINTEF Applied Chemistry, P.O. Box 124 Blindern, N-0314 Oslo, Norway.
E-mail: Lorenzo.Williams@chem.sintef.no

Received (in Liverpool, UK) 23rd November 1999, Accepted 18th January 2000,
Published on the Web, 1st March 2000

Reaction parameters for the microwave assisted synthesis of N′-substituted arylpiperazines were optimised *via* their rapid synthesis on thin layer chromatography (TLC) plates.

Piperazines form the backbone of many biologically interesting molecules.[1] Their incorporation into biologically active molecules has even been associated with an increase in potency.[2] Recent examples of piperazine-containing molecules include many fluoroquinolone antibiotics, the HIV protease inhibitor Crixivan™ and the PDE-5 inhibitor Viagra™, used for male erectile dysfunction. As part of a program dedicated to the development of new techniques for combinatorial chemistry,[3] we describe herein a simple procedure for reaction optimisation in microwave assisted synthesis.[4] This procedure is exemplified by the rapid derivatisation of a number of monoarylpiperazines.

Previously we synthesised several 2-iodobenzylamines as radical precursors for an investigation of the α-alkylation of amines *via* a 1,5-hydrogen shift.[5] During the synthesis of these precursors it was observed that, in some cases, amines would react partially with benzyl halides when co-spotted on a TLC plate.[6] After elution a new spot was sometimes seen that corresponded to that of the expected benzylated amine product. Product conversion was often poor since considerable amounts of unreacted starting materials were usually present. We were able to utilise this information in the design of methodology toward the rapid and efficient synthesis of the arylpiperazine derivatives shown in Table 1.†‡

Initial observations for the co-spotting of an arylpiperazine and an electrophile, either neat or as dilute solutions in CH_2Cl_2, onto a TLC plate confirmed the above in that reactions occurred sporadically if at all, and without complete consumption of the starting material. It was anticipated that the reactions could be accelerated by microwave irradiation of the reagents on a glass-backed TLC plate prior to elution, since the TLC plate would act as a support without the silica gel absorbing or restricting the transmission of microwaves. TLC plates (Merck silica gel 60 F254) with preadsorped reagents were irradiated in a domestic microwave oven with varying power outputs and at various time intervals. Method of application, loading and stoichiometry of the reagents were varied as an array on plates in order to discover the optimum conditions for the reaction. After cooling, the plates were eluted and viewed under UV light (254 nm) and by development with either I_2 or ninhydrin. The most convenient method involved the application of reagents in solution (at a concentration of *ca*. 1 mg in 1 ml CH_2Cl_2) in 5 μl aliquots onto a plate with a 0.2 mm layer of SiO_2. Complete consumption of one or other of the reagents occurred after irradiation for 5 min at an output of 585 watts. Reactions were complete under these conditions, regardless of the stoichiometry of the reagents. Only one product spot was seen, the R_f value of which was consistent with that of the expected product. Confirmation was later afforded through direct synthesis (*vide infra*). A rather serendipitous discovery was made in that excesses of sulfonyl chlorides appeared to degrade under these conditions to a product with a polar baseline spot, presumably the corresponding sulfonic acid. Fortunately the degradation appeared to occur rather more slowly than the desired transformation, and the reactions remained unaffected since the arylpiperazine component was completely consumed to yield the desired product.

Upon identification of the optimum reaction parameters, the reactions were scaled up to several hundred milligrams in size. Reagents were dissolved in a minimum amount of CH_2Cl_2 and adsorbed onto silica gel (230–400 mesh). After removal of solvent the mixture was irradiated for 5 min. The silica gel was allowed to cool and was then washed with CH_2Cl_2 and the washings filtered through a Celite pad. Evaporation of the solvent *in vacuo* yielded the desired product in high yield and purity. Although unnecessary, it was often advantageous to use a slight excess of the amine component to drive the reaction to completion and facilitate isolation of the final product in pure form, without the need to resort to chromatography. Reactions involving equimolar amounts of reagents worked equally as

Table 1 Arylpiperazine derivatives formed *via* microwave assisted synthesis

well, though occasionally the purity of the final product was compromised due to the presence of small amounts of unreacted halides. Fortuitously, reactions involving an equimolar amount or excess of sulfonyl halides were unaffected since the unreacted material degraded under the reaction conditions (*vide supra*). Interestingly, all reactions were high yielding and afforded *N′*-substituted products in high purity. The presence of electron-withdrawing groups on the arylpiperazine, *e.g.* 1-(4-nitrophenyl)piperazine in entries 3, 5, and 9, didn't appear to impede reaction. It has been reported previously that the presence of electron-withdrawing groups in the aryl ring of arylpiperazines diminishes the nucleophilicity of the secondary amine.[7]

Reactions on silica gel were performed without incident and somewhat surprisingly without salt formation. It is thought that silica gel scavenges any HCl formed in the reaction, thereby negating salt formation. When reactions were performed in the absence of silica gel or by using finely ground glass as the support none of the desired products were isolated. TLC analysis of these reactions indicated the absence of product. However, the presence of a new and more polar baseline spot was seen, presumably the corresponding amine salt formed in the presence of HCl generated *in situ*.

In summary, reactions performed on a TLC plate are a powerful tool for rapid reaction optimisation. The method is suitable in particular for microwave assisted reactions since the plate can be used as an inert support. The technique is applicable to combinatorial chemistry where reactions often have to be optimised prior to library synthesis. Moreover it is possible to combine this technique with bioautographical screening and analytical methods.[8] Use of this technology for the synthesis and screening of combinatorial libraries will be described in due course.

Aud Bouzga and Ole Saastad are gratefully acknowledged for NMR and GCMS analysis.

† All compounds gave satisfactory spectral data.

‡ *Typical procedure*: 1-(α,α,α-trifluoro-*m*-tolyl)piperazine (0.25 g, 1.1 mmol) in CH_2Cl_2 (1 ml) and 2-nitrobenzenesulfonyl chloride (0.24 g, 1.1 mmol) in CH_2Cl_2 (1 ml) were mixed thoroughly with silica gel (Merck 230–400 mesh, 1 g) in a glass vial and the solvent removed under reduced pressure. The mixture was then irradiated in a domestic microwave oven (Electrolux NF4884) at an output of 585 watts for 5 min. Water (50 ml) was placed in another vessel and irradiated simultaneously. After cooling to room temperature the product was dissolved in CH_2Cl_2 (*ca.* 5 ml) and filtered through a Celite pad. The solvent was removed under reduced pressure to afford the corresponding sulfonamide as a yellow solid (0.41 g, 91%, > 98% pure by HPLC); R_f 0.55 (MeOH–CH_2Cl_2, 5%); δ_H($CHCl_3$, 300 MHz) 8.01 (1H, d, *J* 9.3), 7.72 (2H, m), 7.63 (1H, m), 7.37 (1H, t, *J* 7.7), 7.14 (3H, m), 3.51 (4H, m), 3.31 (4H, m).

Synthesis and ring enlargement of 2-ethoxycarbonyl-1-silacyclobutanes

Gerhard Maas* and Susanne Bender

Division of Organic Chemistry I, University of Ulm, Albert-Einstein-Allee 11, D-89081 Ulm, Germany. E-mail: gerhard.maas@chemie.uni-ulm.de

Received (in Liverpool, UK) 23rd November 1999, Accepted 4th February 2000, Published on the Web, 3rd March 2000

2-Ethoxycarbonyl-1-silacyclobutanes were synthesized by intramolecular C–H insertion of carbenes generated photochemically from α-(di-*tert*-butylsilyl)-α-diazoacetates; they undergo smooth thermal ring-expansion by a 1,3(C → O) silyl shift to form 6-ethoxy-1-oxa-2-silacyclohex-5-enes.

Silacyclobutanes are useful precursors for other organosilicon compounds (*e.g.* larger silaheterocycles by ring expansion,[1,2] silaethenes by cycloreversion,[3] organosilicon polymers by ring opening[4]) and can be employed in C–C bond forming processes, such as the aldol reaction,[5] allylation of carbonyl compounds,[1,6] and metal-catalyzed cross-coupling reactions.[7] Much of this chemistry has been carried out with silacyclobutanes functionalized only at the silicon atom, and the synthesis of these compounds begins typically with a Wurtz-type cylisation reaction of γ-halopropyl(chloro)silanes.[8] Silacyclobutanes bearing functional groups at the ring carbon atoms appear to be rare; some notable exceptions are 3-alkenylsilacyclobutanes[9] and 3-(alkoxycarbonyl)methyl-1-silacyclobutanes.[10]

During our investigations into the chemistry of silicon-substituted carbenes,[11] it occured to us that the intramolecular 1,4-C,H insertion of these reactive intermediates might offer a novel route to silacyclobutanes. While the 1,5-C,H insertion of silylcarbenes or silylcarbenoids under thermal,[12] photochemical,[13] and transition-metal catalyzed[14] conditions is well documented, the formation of a 1-oxa-2-silacyclobutane from trimethoxysilylcarbene in an argon matrix[15] represents so far the only reported 1,4-C,H insertion involving a silicon-attached substituent in a silylcarbene.

We report now that photolysis of α-(di-*tert*-butylsilyl)-α-diazoacetates **1** provides convenient access to 2-alkoxycarbonyl-1-silacyclobutanes **2**. When solutions of **1a**–**d**[16] in toluene were irradiated with 300 nm light, silacyclobutanes **2a**–**d** were formed (Scheme 1).† From the photolysis of **1a** and **1c**, silacyclobutanes **2a** and **2c**, respectively, were obtained as the only produts and in high yield. In both cases, only one diastereomer was detected by NMR. In the absence of spectroscopic evidence for its configuration (irradiation into the Bu^t resonance did not provide a NOE effect with the ring-CH proton), a *trans*-relationship between the Bu^t and ester groups is assumed for steric reasons. Photolysis of **1b**,**d** led to an unseparable mixture of the expected silacyclobutanes **2b**,**d**, formed again as single diastereomers, and the isomeric 1-oxa-2-silacyclohex-5-enes **3b**,**d**. We reasoned that the latter compounds are ring-expansion products of **2**, and in fact, conversion of **2** into **3** was achieved when these product mixtures as well as the isolated silacyclobutanes **2a**,**c** were heated at *ca*. 85 °C in toluene.‡ The constitution of the cyclic *O*-silylketene acetals **3** was indicated by some characteristic NMR signals [δ(=CH) 3.70–3.81; δ(C_{olefin}) 154.4 ± 0.3 and 72.0 ± 0.3] as well as by strong IR absorptions at 1650–1680 cm^{-1} which are assigned to the C=C stretching mode (Table 1).

The 4 → 6 ring expansion of silacyclobutanes **2** proceeds by a 1,3(C → O) silyl shift. Monitoring of the isomerisation **2c** → **3c** by ^{1}H NMR spectroscopy indicated a first-order reaction with k = 1.25 × 10^{-4} s^{-1} at 70 °C in [D_6]benzene, corresponding to a half-life time of 92.7 min. Compounds **3** constitute cyclic *O*-silyl ketene acetals, and it should be recalled that acyclic compounds of this type undergo reverse thermal isomerisation, *i.e.* they rearrange to form α-silylcarboxylates.[17] Certainly, the smooth ring-expansion of silacyclobutane-2-carboxylates is due largely to the relief of ring-strain[18] for this four-membered ring.

The cyclic ketene acetals **3** appear not to be storable for a long time, and signs of decomposition were detected by ^{1}H NMR after just a few days. Nevertheless, the different functional groups in these molecules should allow some useful transformations. As an example, we treated **3a**,**d** with an excess of $LiAlH_4$ and obtained 3-(hydroxybutyl)silane **4** in yields of 39 and 61% (Scheme 2).§ The IR absorptions at ν_{max} 2110, 922 and 848 cm^{-1} are in the ranges expected for dialkylsilanes.[19]

In summary, we have reported a novel synthesis of silacyclobutanes, namely by intramolecular 1,4-insertion of a carbene center into the C–H bond of a Si–Bu^t group. It appears that the presence of a $SiBu^t_2X$ group in (silyl)diazoacetates **1** is

Table 1 UV-irradiation of diazoacetates **1a**–**d** in toluene and conversion of silacyclobutanes **2** into 1-oxa-2-silacyclohex-5-enes **3**

Diazoacetate	X	Product(s) and relative Yields[a] (%)	Yield of **3**[b] (%)
1a	Cl	**2a** (100)	36
1b	N_3	**2b** (46), **3b** (54)	45
1c	N=C=O	**2c** (100)	39

a favorable case for this type of C,H insertion which has not been reported so far for closely related α-silyl-α-diazoacetates with a β-C–H bond in the silyl group. For example, UV irradiation of the $SiEt_3$ and $SiPr^i_3$ substituted diazoacetates in benzene was unspecific while their copper- or rhodium-catalysed decomposition gave products derived from other carbene-type reactions.[20] α-Alkoxy(diisopropyl)silyl-α-diazoacetates, on the other hand, underwent a photochemical 1,5-C–H insertion of the carbene at the alkoxy chain but no 1,4-C,H insertion at the isopropyl substituents.[13] In spite of these apparent structural limitations, it is obvious that the transformation **1** → **2** represents an easy entry to silacyclobutanes with functionalities at both the silicon and the α-position of the ring which offer opportunities for further synthetic transformations.

This work was supported financially by the Deutsche Forschungsgemeinschaft.

***Ab initio* calculations and experimental oxidation and reduction potentials show that the functionalization of thiophene to the corresponding *S*-oxide leads to only a minor change in ionization potential but to a dramatic increase in the electron affinity.**

Owing to their electrical and optical properties, α-conjugated oligo- and poly-thiophenes are currently the subject of intense research activity in the field of organic materials. There is great interest in finding functionalization capable of decreasing the energy of the LUMO orbital of these compounds. Indeed, easily reducible compounds are useful for application in a variety of electrochemical and electrooptical devices.[1]

Unsubstituted thiophene *S*-oxide has not yet been isolated; however, new oxidation methods have recently been developed that make it possible to obtain stable substituted thiophene *S*-oxides.[2] Thus, following our research line on thiophene *S,S*-dioxides,[3] we have commenced a study aimed at elucidating how the functionalization of the thienyl sulfur of thiophene-based materials to the corresponding *S*-oxide affects the orbital energies and the electrochemical properties of these compounds.

Here, we report *ab initio* theoretical calculations performed on the thiophene *S*-oxide and compare the results with related physical properties for 2,5- and 3,4-disubstituted counterparts. The results on thiophene and thiophene *S,S*-dioxide analogues are also reported for comparison.

MP2/6-31G* *ab initio* calculations[4] indicate a non-planar structure for thiophene *S*-oxide with the sulfur atom lying outside the plane formed by the other four atoms by 0.26 Å (Scheme 1).

	I	II

>*bc*	110.6	106.9
>*cc'*	90.7	98.3
>*cd*	116.3	130.8
>*bab'*	0.0	0.0
>*abc*	9.8	0.0
>*bcd*	-132.9	180.0

Scheme 1 Selected bond lengths (Å) and angles (°) of the MP2/6-31G* ground state (**I**) and transition state (**II**) structures of thiophene *S*-oxide.

The results are in agreement with previous *ab initio* calculations at a lower level of theory[5] and with the X-ray structure reported for 2,5-diphenyl[2a] and 3,4-di-*tert*-butyl[2c] derivatives.

The non-planar geometry implies that thiophene *S*-oxide should be less aromatic than unmodified thiophene. Indeed, using this geometry, we calculated the aromaticity Bird index[6a] to be 37.4, which is much lower than that reported for thiophene (66)[6a] and similar to that of phosphole (35.5).[6b]

MP2/6-31G* calculations also show that inversion at the pyramidal sulfur proceeds through a fully planar transition state (Scheme 1) with a calculated energy barrier of 13.5 kcal mol^{-1}, in good agreement with the experimental value of 14.8 kcal mol^{-1} reported for 2,5-di-*tert*-octylthiophene *S*-oxide,[7] but much lower than the energy inversion barriers reported for sulfoxides (37–42 kcal mol^{-1}).[8] Clearly, in thiophene *S*-oxide the increased π-conjugation makes the planar transition state more aromatic than the ground state (the Bird index calculated for this planar geometry is 90.8) and furnishes extra stabilization that accounts for the lower value of the inversion barrier.

Table 1 reports the *ab initio* calculated frontier orbital energies of thiophene, thiophene *S*-oxide and thiophene *S,S*-dioxide (**1**–**3**) together with the oxidation and reduction potentials of the corresponding 2,5-disilylated derivatives (**4**–**6**) and of 3,4-di-*tert*-butylthiophene *S*-oxide **7**, measured by cyclic voltammetry (CV); UV maxima and optical edges for **4**–**7** are also reported.†

[a] CV in MeCN–NEt_4BF_4 0.2 M at 100 mV s^{-1}. [b] CV in propylene carbonate–NEt_4BF_4 0.2 M at 100 mV s^{-1}.

The calculations show that the frontier orbitals of **1**–**3** are all π in character. The LUMO orbital of thiophene is spread over all five atoms of the ring, while the LUMO orbitals of **2** and **3** and the HOMO orbitals of **1**–**3** are essentially confined to the four carbon atoms. This indicates that it is the LUMO orbital that is most affected by the functionalization of thienyl sulfur to the *S*-oxide and that it is the first oxidation step that mostly affects the frontier orbitals. The trend of the electrochemical potentials of **4**–**7** is in agreement with the trend shown by the calculated frontier orbital energies. It appears that the functionalization of the thienyl sulfur to *S*-oxide affects the reduction potential to a greater extent than the oxidation potential strongly

DOI: 10.1039/a909390g

increasing the electroaffinity and bringing about much greater variation than the functionalization of the *S*-oxide to the corresponding *S*,*S*-dioxide. It is interesting that the potential values of sulfoxides **5** and **7** indicate that these compounds are both oxidizable and reducible at moderate potential values, in contrast to thiophene (which is easily oxidized and difficult to reduce) and thiophene *S*,*S*-dioxide (which is easily reduced but difficult to oxidize).

Examining the optical data, it is seen that the first functionalization to *S*-oxide leads to two distinct maxima, at 256 and 324 nm, the latter showing a strong bathochromic shift with respect to the parent thiophene **4**, and to a substantially smaller optical edge. Literature data for to 2,5-di-*tert*-butylthiophene and the corresponding *S*-oxide and *S*,*S*-dioxide show an analogous trend.[7] Similar λ_{max} and ΔE_{edge} values were found for compounds **5** and **7** which have different substituents and substitution pattern. Taking into account also the similarity of the oxidation and reduction potentials of **5** and **7**, it appears that it is the type of functionalization of the sulfur atom which is the main factor affecting the frontier orbitals energies.

A 4 × 4 singly excited CI ZINDO/S//PM3 analysis[9] performed on **1**–**3** shows that the low wavelength absorption in thiophene *S*-oxide and in thiophene *S*,*S*-dioxide is due to the mixing of transitions involving both S–O and π orbitals, while in all the compounds the highest wavelength absorption is due to the HOMO–LUMO π–π* transition. It is of note that in both **2** and **3** the lone pairs of the oxygen atoms are not involved in the HOMO–LUMO transition.

In conclusion, theoretical calculations and electrochemical data show that the functionalization of thiophene to the corresponding *S*-oxide produces a dramatic increase in the electron affinity, without requiring complete de-aromatization of the molecule as in the case of the *S*,*S*-dioxide. In addition, there is only a minor variation in the oxidation potential. Therefore, this type of functionalization of thiophene-based compounds could lead to a novel class of materials with new and interesting properties.

Unnatural natural triterpenes produced by altering isoleucine into alanine at position 261 in hopene synthase and the importance of having the appropriate bulk size at this position for directing the stereochemical destiny during the polycyclization cascade†

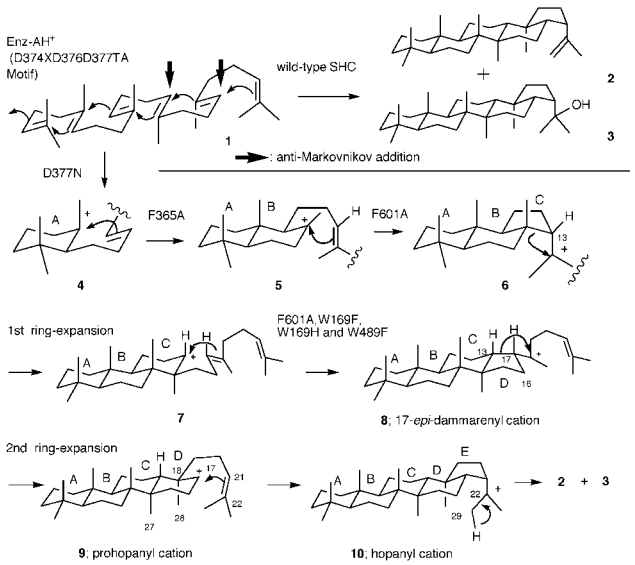
Received (in Cambridge, UK) 24th January 2000, Accepted 8th February 2000, Published on the Web, 29th February 2000

Incubation of squalene with the site-directed mutant of Ile261Ala of squalene-hopene cyclase from *Alicyclobacillus acidocaldarius* afforded multiple triterpenes consisting of tri-, tetra- and penta-cyclic skeletons, together with a final product of hopene, among which the previously unknown 6/6/6/6-fused tetracyclic skeletal compounds, denoted pro-hopene A and B, are included.

Squalene-hopene cyclase (SHC) catalyses the cyclization reaction of squalene **1** into pentacyclic triterpenes, hopene **2** and hopanol **3**, under a fine regio- and stereo-chemical specificity. The reaction has been believed to proceed through all *pre*-chair conformation,[1] but recent studies on the site-directed mutagenesis have indicated that the reaction proceeds *via* two expansion steps from the 5-membered C- and D-ring intermediates, which had been previously formed under Markovnikov closure, into the corresponding 6-membered rings (anti-Markovnikov adduct), as shown in Scheme 1.[2a,b] The ring-expansion processes have been further supported by trapping experiments of the 6/6/5-fused tricyclic intermediate **6** and the 6/6/6/5-fused tetracyclic intermediate **8** (Markovnikov adducts) using the substrate analogues having a highly nucleophilic hydroxyl group.[2a,b] The stereochemistry of 13H in **6** and 17H in **8** have been established to be of β-configuration; no enzymic products having the α-configurations have been obtained in the trapping experiments. Recently, we and Poralla's group have reported the isolation of the enzymatic products derived from the carbocation intermediates of mono- **4**,[3] bi- **5**,[4a,c] tri- **6**,[2b,4c] and tetra-cyclic **8**;[2a,b,4b,c] these discrete cationic intermediates were produced by a single amino acid replacement of D377N (D377C), F365A, Y420A, F601A, W169F, W169 H or W489F in *A. acidocaldarius* SHC (Scheme 1). The abortive cyclization products formed by each point mutation have revealed not only the catalytic function of given amino acids but also the cyclization mechanism for **1**; the cyclization is triggered by the DXDDTA motif;[3] D377 stabilises monocyclic cation **4** probably *via* the carboxylate anion; and both F365[4a] and F601[2b] stabilise the transient carbocations at each cyclization stage **5** → **8** possibly *via* a cation–π interaction. The aromatic residues of W169, W489 and Y420 are likely to play a significant role for folding the substrate **1**.[2a,4c] In a series of the site-directed mutagenesis experiments, we have focused on Ile261 as a next experiment, which is highly conserved among all the known SHCs and oxidosqualene cyclases. The mutated SHCs of I261A produced the unknown 6/6/6/6-fused tetracyclic **14** and **15** ('unnatural' natural products) together with the known **11**, **12**, **13** and **16**.[5] The stereochemistry at 13- and 17-positions of premature products **11** and **12** was of α-configuration and in contrast to those of true intermediates **6** and **8**. We report here, that the appropriate bulk size and shape at position 261 has a critical role in directing the steric control for constructing the hopane skeleton.



Scheme 1

† Electronic supplementary information (ESI) available: EIMS and NMR assignments. See http://www.rsc.org/suppdata/cc/b0/b000711k/

With the cell-free homogenates (150 ml), prepared from a 3 L culture of *E. coli* clone encoding I261A SHC, 100 mg of **1** was incubated for 15 h at optimum catalytic conditions (pH 6 and 55 °C). The GC analysis (30 m DB1, capillary column) showed six new enzymic products other than **2** in a hexane-extract of the reaction mixture.

Column chromatography over SiO_2 eluting with hexane afforded five fractions in the following order: **16**, **2** + **13**, **12** + **14** + **15**, **11** and the recovered **1**. The complete separation of each product was achieved by reverse-phase HPLC (C18) with THF–H_2O (6 : 4). The yields of each product, estimated by GC, were as follows: 4.0, 19.0, 4.1, 4.1, 3.7, 3.2, 48.6 and 3.1 mg for **11**, **12**, **13**, **14**, **15**, **16**, **2** and **3**, respectively, and 0.6 mg for the recovered **1**. No other products were observed in a detectable amount.

Structures of all the isolated compounds were determined as shown in Fig. 1 by EIMS and NMR spectra (H–H COSY 45, HOHAHA, NOESY, DEPT, HMQC and HMBC).† The EIMS, ^1H and ^{13}C NMR spectra of **11** were identical to those of the authentic (17*E*)-(13αH)-malabarica-14(27),17,21-triene,[2b] the stereochemistry of H13 being further confirmed to be of α-configuration by a strong NOE between H9 and H13. The epimer of **11**, (13βH)-malabaricatriene **11′**[2b] with a longer retention time (rt) on the GC than **11**, was never detected in the reaction mixture. The fragmentation pattern of **12** in the EIMS spectrum was superimposable to that of 17-*epi*-dammara-20(21),24-diene **12′**,[2a] but the rt of **12** on the GC is shorter than that of **12′**, and the NOE between 30-Me and H17 was found, thus proving the α-orientation of H17 in **12**. The double bond of **13** was $\Delta^{13,17}$ by HMBC correlation both from 30-Me to C13

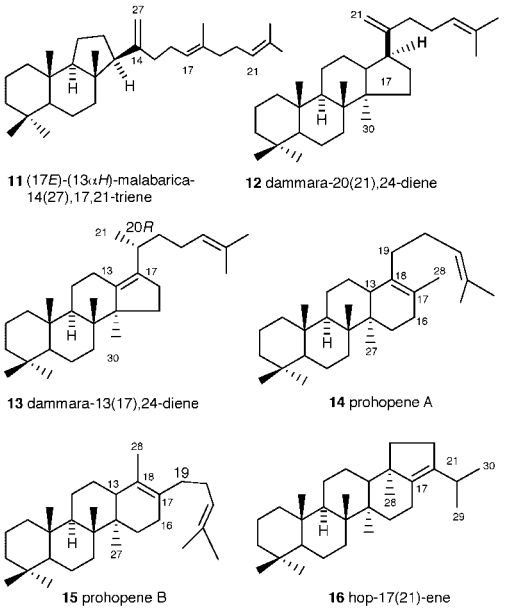


Fig. 1 Structures of the enzymatic products by the mutated I261A SHC.

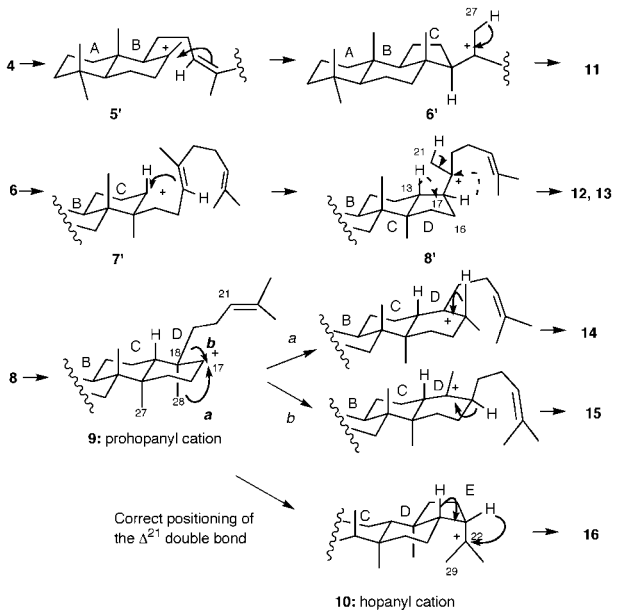
and from 21-Me for C17. The proton chemical shift of 21-Me was 0.919 ppm (*J* 6.7 Hz) in $CDCl_3$, which allowed the assignment of 20*R*-stereochemistry.[6] The EIMS spectrum of **14** was essentially the same as that of **15**. The 6/6/6/6-fused tetracyclic skeletons of **14** and **15** were revealed by NMR analyses. An HMBC correlation between 28-Me and C13 was observed for **15**, but not for **14**. A strong NOE was observed between H16 and H19 for **15**, while no NOE was seen for **14**. Product **16** differed from **2** only in the double bond position, which was determined by the HMBC cross peaks of 28-Me/C17, 29-Me/C21 and 30-Me/C2l.

Tricyclic **11** could be produced *via* **6′** and two tetracyclics **12** and **13**, *via* **8′** (Scheme 2). Proton elimination from 21-Me of **8′** could give **12**, but a hydride shift to C18 of **8′** followed by deprotonation of the 13H could afford **13**. Formation of tri- and tetra-cyclic skeletons **11**–**13** may have occurred owing to the local change, especially near the site(s) responsible for the C/D-ring formation; the mutated SHC replaced by a smaller bulk size of Ala could not perfectly fit with **1**.[7] Compounds **11**–**13** were accumulated, while the corresponding epimers **11′** and **12′** from **6** and **8** were not detected. This suggests that **6′** and **8′** cannot undergo further cyclizations, whereas the intermediates **6** and **8**, which had been produced by this mutated SHC, could undergo



Scheme 2

subsequent cyclizations to yield **2**. Therefore, it is likely that the (13βH)- and (17βH)-configurations in 6/6/5- and 6/6/6/5-ring systems are required for the completion of two ring-expansion processes to give **9**. This hypothesis agrees well with the previous results[2a,b] that only **6** and **8** were trapped when the squalene analogues having a hydroxy group were incubated with the native SHC, but that **6′** and **8′** were not. The secondary cation **9** has been assumed as an intermediate in hopene biosynthesis, but no experimental evidence has been given. Formation of **14** and **15** gave definitive evidence for the involvement of intermediate **9**. The 1,2-shift of 28-Me to the C17 cation could give **14** (path *a* in Scheme 2), whereas rearrangement of the isoprenoid side chain to the cation could afford **15** (path *b*). Triterpenes **14** and **15** have never been reported before. We propose to denote the prohopane skeleton for **9**, prohopene A for **14** and prohopene B for **15**. It is noteworthy that **8′** is the biosynthetic intermediate of some plant triterpenes.[1] A looser binding near the C/D-ring could also perturb the correct positioning of the Δ^{21} double bond in **9**, thus leading to the accumulation of **14** and **15**; the appropriate arrangement of the double bond could allow a further cyclization to give **10** through the nucleophilic attack of the double bond toward cation **9**. Product **16** could be formed perhaps due to the erroneous positioning of the deprotonation site for introducing the $\Delta^{22,29}$ double bond of **2**, which may have also occurred concomitantly with the local change near the C/D-rings.

With respect to the mutated I261V SHC, no abortive cyclization product was found and the kinetic data were almost the same as that of the wild-type SHC,[7] but the mutant I261A gave a looser affinity and a slower velocity for hopene biosynthesis.[7] Site-directed mutagenesis not only helps to understand the fundamental issue of the reaction mechanism (molecular recognition and catalytic function), but also generates the previously unknown 'unnatural' natural products,[8a] as represented by **14** and **15**. The rational genetic engineering of the active and/or recognition sites is a promising tool for the creation of novel natural products.[4a,8b]

7 Optimum catalysis was found at 55 °C for the mutants I261A, but at 60 °C for the wild-type and I261V. Kinetic values of K_m and V_{max} were determined at 55 °C and pH 6.0 from Lineweaver–Burk plots as follows; K_m: 25.8, 34.7 and 178 μM; V_{max}: 3.87, 3.57 and 0.43 nmol min^{-1} μg^{-1}, respectively, for the wild-type, I261V, and I261A. The I261G mutant, having the smallest size, also produced **11**–**13** in twice the quantity than I261A, despite the cyclase activity being significantly decreased (the amount of **2** was 17% of that of I261A), which further supports the importance of a bulk size at 261 position for the stereoselective cyclization reactions.

Dendrimers based on multiple 1,4,7-triazacyclononane derivatives

Paul D. Beer* and De Gao

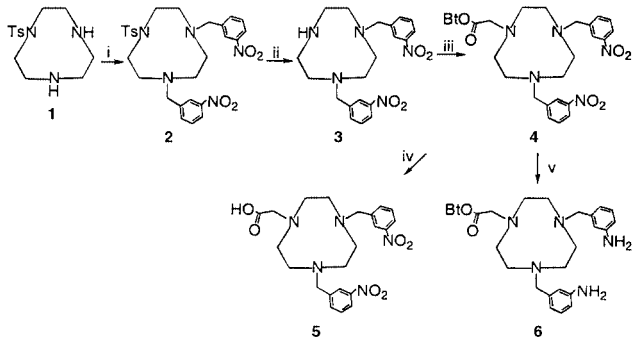
Department of Chemistry, Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR. E-mail: paul.beer@chem.ox.ac.uk

Received (in Cambridge, UK) 2nd December 1999, Accepted 9th February 2000, Published on the Web, 29th February 2000

New first and second generation dendritic poly-1,4,7-triazacyclononane molecules have been prepared and shown to coordinate multiple Cu(II) and Ni(II) metal cations.

The last decade has witnessed an enormous growth in the field of dendrimer chemistry with current interest being stimulated by the discovery of specific functions and novel properties that are a direct consequence of the dendritic architecture.[1] Metallodendrimers[2] in particular have been shown to exhibit novel electrochemical and photophysical properties. With a view to creating new efficient extraction and membrane transporting reagents for transition metals[3] and for the preparation of metal nanoclusters[4,7] we report here, the first examples of dendrimers containing the well established transition metal coordinating ligand, 1,4,7-triazacyclononane.[5]

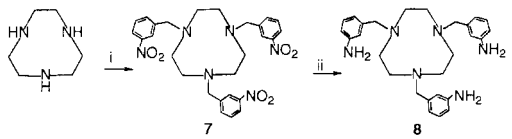
The new key asymmetric functionalised triazacyclononane branching synthons **5** and **6** required for convergent and divergent syntheses of the target dendritic macrocyclic molecules were prepared as shown in Scheme 1. The reaction of **1**[5] with 2 equiv. of 3-nitrobenzyl chloride in the presence of K_2CO_3 in MeCN solution gave **2** in 90% yield. Detosylation of **2** using sulfuric acid produced **3** in 50% yield. Refluxing **3** with 1 equiv. of butyl bromoacetate in the presence of K_2CO_3 afforded **4** as a pale yellow solid in 82% yield. Hydrolysis of **4** with formic acid gave **5** in 80% yield and reduction of **4** using hydrogen and Raney Ni produced the diamine **6** quantitatively (Scheme 1).



Scheme 1 *Reagents and conditions*: i, 2 equiv. 3-nitrobenzyl chloride, K_2CO_3, MeCN, reflux; ii, conc. H_2SO_4, 150 °C; iii, butyl bromoacetate, K_2CO_3, MeCN, reflux; iv, formic acid, reflux; v, H_2, Raney Ni, MeOH–THF, 55 °C.

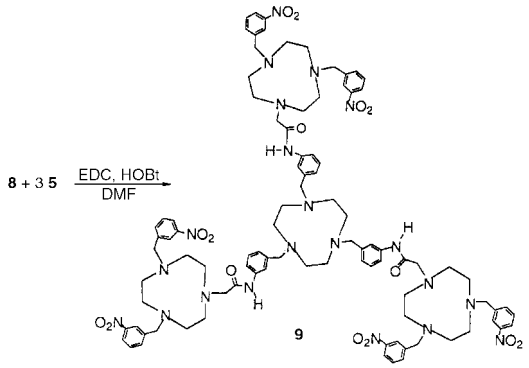
The dendritic core triazacyclononane derivative **8** was synthesised *via* reaction of 1,4,7-triazacyclononane with 3 equiv. of 3-nitrobenzyl chloride to give **7** followed by reduction with Raney Ni and H_2 (Scheme 2).

Using a divergent synthetic procedure the first generation dendrimer compound **9** was synthesised *via* a condensation

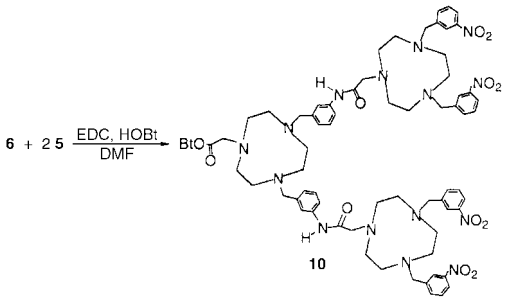


Scheme 2 *Reagents and conditions*: i, 3 equiv. 3-nitrobenzyl chloride, K_2CO_3, MeCN, reflux; ii, H_2, Raney Ni, MeOH–THF, 55 °C.

reaction of **8** with 3 equiv. of **5** in DMF in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) and 1-hydroxybenzotriazole hydrate (HOBt) (Scheme 3). After column chromatography using alumina and CH_2Cl_2, **9** was isolated as a yellow solid in 90% yield. The convergent preparative approach is illustrated with the synthesis of **10** from **6** and 2 equiv. of **5** using a similar condensation reaction (Scheme 4).



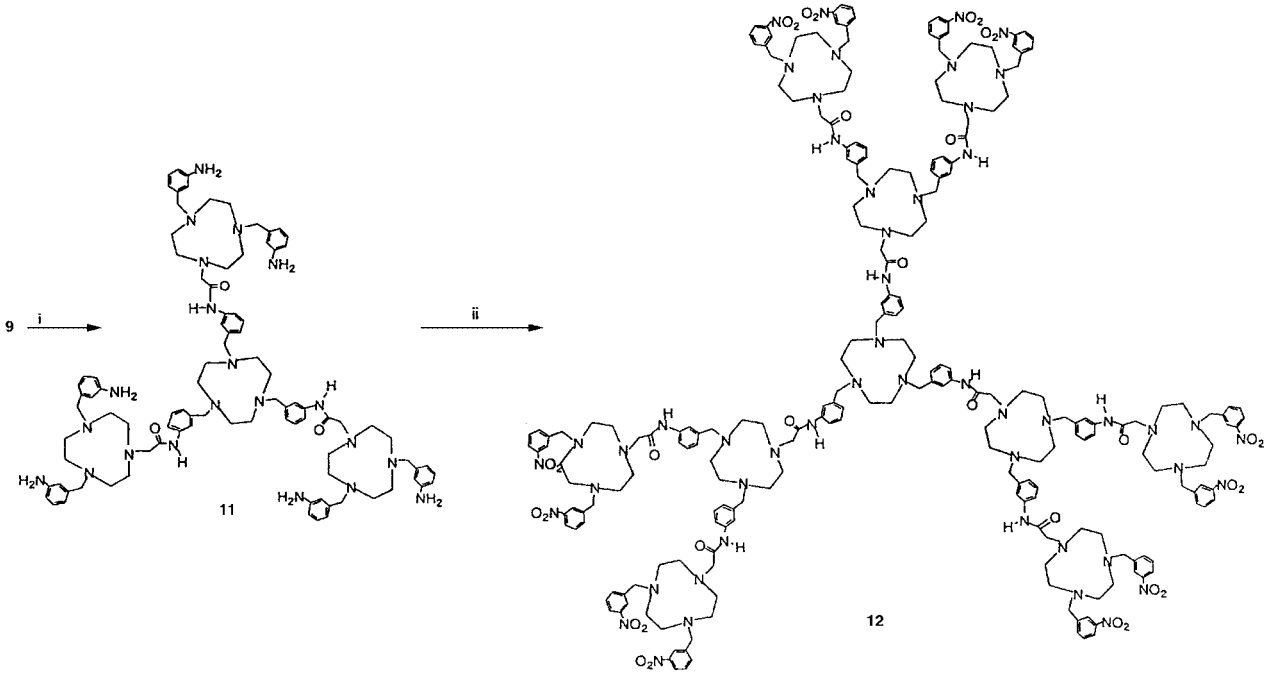
Scheme 3 *Reagents and conditions*: EDC, HOBt, DMF, room temp.



Scheme 4 *Reagents and conditions*: EDC, HOBt, DMF, room temp.

Raney Ni/H_2 reduction of **9** and reaction of the corresponding amine **11** with 6 equiv. of **5** in DMF gave the second generation dendrimer **12** in 60% yield (Scheme 5).†

Preliminary transition metal coordination investigations of dendrimers **9** and **12** with Cu(II) and Ni(II) metal cations have been undertaken using UV–VIS spectrophotometric titration experiments. In the absence of dendrimer, MeCN and DMF solutions of copper(II) acetate exhibit a broad d–d absorption at 710 nm. The addition of dendrimers **9** or **12** causes λ_{max} to undergo a blue shift to 646 nm which is characteristic of Cu(II) being bound by amine ligands.[5] The spectrophotometric titration curves (Fig. 1) suggest **9** binds four, and **12** ten Cu(II) metal cations, one Cu is coordinates to each triazacyclononane macrocyclic ligand of the respective dendrimer, suggesting the transition metal is complexed at the core, branches and surface dendritic recognition sites.‡ This result contrasts with PAMAM dendrimers which are thought to bind most Cu cations at the outermost tertiary amine donor sites of the dendrimer structure.[7] With Ni(II) preliminary spectrophotometric titration results with the first generation dendrimer **9** indicate as with Cu(II), each



Scheme 5 *Reagents and conditions*: i, H_2, Raney Ni, MeOH–THF, 55 °C; ii, 6 equiv. **5**, EDC, HOBt, DMF, room temp.

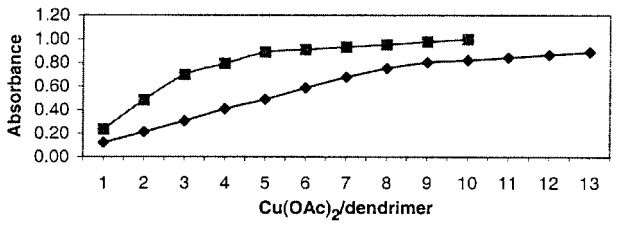


Fig. 1 Spectrophotometric titration of **8** (■) (3 mM) with $Cu(OAc)_2$ in acetonitrile, absorbance at 646 nm and of **12** (◆) (0.5 mM) with $Cu(OAc)_2$ in DMF, absorbance at 600 nm.

triazacyclononane ligand complexes one Ni(II) cation resulting in 4 Ni^{2+}: **9** solution stoichiometry.

Further transition metal coordination chemistry investigations with these novel dendritic poly-triazacyclononane-molecules are in progress.

We thank the Royal Society for a K. C. Wong Fellowship (D. G.) and the EPSRC mass spectrometry service at the University of Wales, Swansea.

Highly fluorescent and electroactive molecular squares containing perylene bisimide ligands

Frank Würthner* and Armin Sautter

Abteilung Organische Chemie II, Universität Ulm, Albert-Einstein-Allee 11, 89081 Ulm, Germany. E-mail: frank.wuerthner@chemie.uni-ulm.de

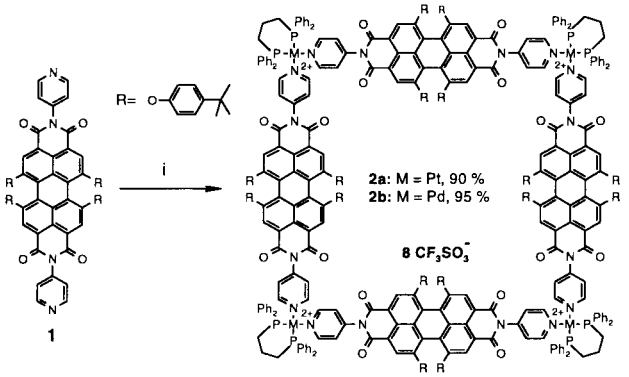
Received (in Cambridge, UK) 16th December 1999, Accepted 7th February 2000, Published on the Web, 29th February 2000

Large functional molecular squares have been assembled with ditopic perylene bisimide bridging ligands and Pt(II) and Pd(II) phosphine corner units and their optical, electrochemical and spectroelectrochemical properties have been studied.

Interest in functional supramolecular assemblies[1] has been triggered by examples from nature like the light harvesting system (LHS) in purple bacteria.[2] The supramolecular functionality of this natural assembly is realized by chlorophyll molecules organized in cyclic arrangements which control the electronic coupling of the dye molecules and allow accommodation of the reaction center of photosynthesis within the largest ring of LHS.[2] A straightforward access to cyclic structures in high yields was introduced by Fujita and Ogura[3] and Stang and Olenyuk[4] *via* the concept of molecular squares using ditopic bridging ligands and *cis*-coordinating square planar Pt(II) or Pd(II) corners. Some very interesting examples have been reported based on pyridyl-substituted porphyrin ligands,[5] where functionality is introduced by the ligand but porphyrin fluorescence is quenched upon metal complexation. Here, we report on a new ligand based on perylene tetracarboxylic acid bisimides[6,7] which exhibits fluorescence quantum yields Φ_F near 100%[6] as well as redox activity[8] and which conserves these properties in the metal-assembled state: a giant photo- and redox-active molecular square (metal–metal diagonal *ca*. 3.4 nm).

The perylene ligand **1** was synthesized in 66% yield by condensation of the corresponding perylene bisanhydride[7] with 4-aminopyridine in quinoline with catalytic amounts of zinc(II) acetate. The ligand exhibits an intense absorption band at λ_{max} = 585 nm and red fluorescence at λ_{max} = 618 nm with Φ_F = 0.94 for **1** in chloroform.[9]

Equimolar mixing of ditopic perylene ligand **1** with dpppM$(OTf)_2$ [M = Pt(II) or Pd(II), dppp = 1,3-bis(diphenylphosphino)propane; OTf = $CF_3SO_3^-$] in CH_2Cl_2 leads exclusively to the formation of molecular squares **2a**,**b** in 90 and 95% isolated yield, respectively (Scheme 1). The squares were characterized by elemental analysis, ^{1}H and ^{31}P{^{1}H} NMR spectroscopy and electrospray mass spectrometry (ESI–MS) (**2a**).† In the ^{31}P{^{1}H} NMR spectra of **2a**,**b** only one singlet is observed owing to the high symmetry of the squares, additionally there are Pt-satellites resulting from ^{195}Pt–^{31}P spin–spin coupling in the spectrum of **2a**. A typical change in chemical shifts of the phosphorus nuclei of *ca*. 10 ppm results upon complexation with **1**.[10] The ^{1}H NMR spectra show only a single set of signals for the ligand **1** and the dppp moiety with significant changes in the chemical shifts of the α- and β-pyridyl protons (*ca*. 0.3 ppm) owing to metal complexation.[10] In the ESI–MS of **2a** (acetone solution) we observed signals at *m/z* 2575.0 which we assign to the M−3OTf species with +3 charge state (separation of peaks by 1/3 mass unit) which corresponds to a molecular mass of 7725 for the square minus three triflate anions in excellent agreement with the calculated mass of 7724.89 ($C_{409}H_{360}N_{16}O_{47}F_{15}P_8S_5Pt_4$). Furthermore, we observed signals at *m/z* 1894, 1485 and 1213 which we assign to $(M-4OTf)^{4+}$, $(M-5OTf)^{5+}$ and $(M-6OTf)^{6+}$ species (THF–ethyl acetate solution). The less stable corresponding Pd-square



Scheme 1 *Reagents and conditions:* i, dpppM$(OTf)_2$, CH_2Cl_2, 24 h, 20 °C.

2b has not, as yet, been characterized by the ESI–MS technique.

The optical and electrochemical properties of the perylene ligand **1** remain almost unchanged upon formation of the complexes **2**. We ascribe this to the fact that in perylene tetracarboxylic acid bisimides, the imide substituents have only a small electronic coupling to the HOMO and LUMO of the perylene chromophore.[8,11] Therefore, the chromophoric perylene unit is largely decoupled of the binding site and only small bathochromic shifts of $\Delta\lambda$ = 5–7 nm in the absorption and emission spectra are observed upon complexation. The absorption maximum of **2a** is located at λ_{max} = 591 nm, the emission occurs at 625 nm. An even more important consequence is negligible quenching of the perylene fluorescence in these complexes with Φ_F (**2a**, $CHCl_3$) = 0.88.[9]

The ligand **1** and platinum complex **2a** exhibit reversible electrochemistry which was investigated by cyclic voltammetry in CH_2Cl_2. **1** displays two, reversible reductions at potentials of −1.08 and −1.23 V (*vs.* Fc/Fc$^+$), but oxidation is irreversible causing adsorption of **1** on the platinum electrode. The molecular square **2a** shows two reversible waves in the reductive cycle at similar potentials (−1.01, −1.14 V *vs.* Fc/Fc$^+$) but the oxidative cycle, in contrast to **1** shows a reversible wave at +0.93 V, probably as a consequence of the pyridyl nitrogen lone pairs which are now blocked by platinum-complexation (Fig. 1). The electrochemical studies of the palladium complex **2b** revealed a more complicated behavior displaying an irreversible reduction at $E < -1.15$ V which we attribute to electron transfer processes involving the Pd(II) corners.

A closer insight into the electrochemical processes was gained by spectroelectrochemical investigations of **2a** and **1**. By increasing the potential in a stepwise manner to the first reduction wave of **2a** (−1.01 V) the absorption bands of the perylene bisimide chromophores at 591 nm decrease while three bands in the UV–VIS–NIR appear with a maximum absorption at 791 nm [Fig. 2(a)]. Based on identical spectroscopic changes observed for the free perylene bisimide ligand **1**, we assign these optical transitions to perylene bisimide radical anionic species. After a further increase of the potential to the second reduction

DOI: 10.1039/a909892e

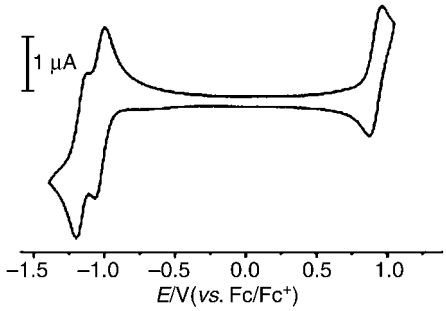


Fig. 1 Cyclic voltammogram of perylene–platinum square **2a** in CH_2Cl_2; scan rate 100 mV s^{-1}. Working electrode: Pt disc, auxiliary electrode: Pt wire, reference electrode: Ag/AgCl; concentration **2a** = 2.5×10^{-4} M; supporting electrolyte NBu_4PF_6 (0.1 M).

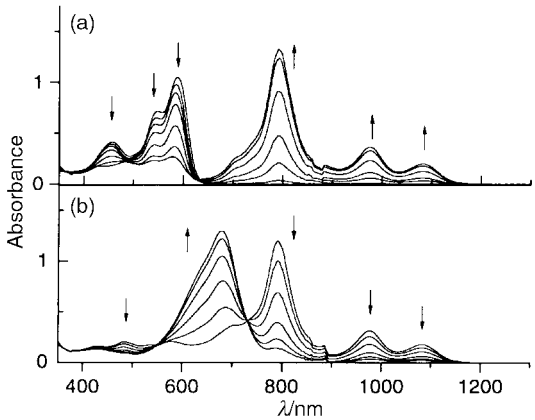

Fig. 2 Spectroelectrograms of perylene–platinum square **2a** in CH_2Cl_2 with NBu_4PF_6 (0.1 M) as supporting electrolyte. Working electrode: Pt disc; auxiliary electrode: Pt wire; reference electrode: Ag/AgCl; concentration **2a** = 1.4×10^{-4} M. Stepwise increase of the applied potential to radical anionic perylene species (a) and to dianionic perylene species (b).

wave of **2a** (−1.14 V) the perylene radical anion bands disappear completely whereas a broad and intense band appears, with a maximum absorption at 679 nm [Fig. 2(b)], corresponding to dianionic perylene bisimides. Oxidation to the radical cationic state results in less pronounced spectral changes in the visible but new broad bands appear in the NIR at 809, 908 and 1225 nm. The distinct isosbestic points in the absorption spectra for all redox couples confirm the reversibility of all oxidation and reduction processes. Therefore, we conclude that (i) the redox processes take place exclusively at the perylene ligands with the Pt(II) corner units being inert in the applied potential range and acting solely as structural building blocks, (ii) the perylene ligands assembled in the square do not interact with one another even in a charged state, and (iii) each perylene ligand in the square is reduced and oxidized at the same time at the given potentials.[12]

In summary, we report on a new functional ditopic perylene ligand **1** which has been used to construct nanosized molecular squares **2** with Pt(II) and Pd(II) phosphine corner units. The optical and electrical properties of the ligands are conserved in the metal-assembled state **2a** which shows a fluorescence quantum yield of almost unity and multiple, fully reversible redox couples. The giant inner volume of nanosquares **2** seems ideal to accommodate large functional guest molecules for studies on redox and photocatalytic processes.

Kinetic trapping of host–guest complexes in a polymeric matrix

Faysal Ilhan, Laura Diamondis, Leigh Gautreau and Vincent M. Rotello*

Department of Chemistry, University of Massachusetts, Amherst, MA 01003, USA. E-mail: rotello@chem.umass.edu

Received (in Columbia, MO, USA) 29th November 1999, Accepted 4th February 2000, Published on the Web, 29th February 2000

Diaminotriazine–flavin host–guest complexes are kinetically trapped in spin-cast polystyrene films.

Self-assembly is a powerful tool for the creation of nanoscale constructs. These non-covalently assembled host–guest complexes have been used to fabricate many molecular-scale components such as wires,[1] switches[2] and computers.[3] Central to the pragmatic utilization of these constructs, however, are the issues of immobilization and isolation. These attributes allow the utilization of molecular components to fabricate useful devices from the disorganized ensemble of components present in the solution phase.

Polymer matrix isolation is an effective technique for the isolation and immobilization of molecules.[4] Application of this methodology to the isolation of host–guest assemblies is hampered by issues of competition and aggregation. Matrix formation from polar polymers creates a competitive environment, disrupting the desired interactions such as hydrogen bonding. Conversely, creation of matrices using non-polar polymers can cause aggregation and concomitant phase separation of polar host–guest complexes. To overcome the issue of phase separation in non-polar polar matrices, we have explored methods of trapping host–guest complexes. We report here, the kinetic isolation of individual hosts and host–guest complexes in a highly non-polar polystyrene matrix through spin-casting of polymer solutions.

In preliminary investigations, we explored the fluorescence behavior of flavin **1** in different volumes of polystyrene films. The polymer-doped films were prepared by spin-casting[5] from solutions of 0.41, 0.87 and 1.75% w/w polystyrene ($M_n = 1{,}1 \times 10^5$, PDI = 2.3) and varying quantities of flavin **1**[6] in $CHCl_3$ on SiO_2 surfaces.[7] The optical transparency of these films[8] allowed direct observations of flavin **1** fluorescence behavior.[9] Addition of more equivalents of flavin **1** resulted in an increased quenching of fluorescence emission for the films prepared from solutions of 0.41 and 0.87% w/w polystyrene in $CHCl_3$ (Fig. 1).[10] This behavior is diagnostic of self-aggregation of flavin **1**. For films prepared from a solution of 1.75% w/w polystyrene in $CHCl_3$, increasing concentrations of flavin **1** resulted in a linear increase in fluorescence emission, demonstrating that self aggregation was effectively suppressed (Fig. 2). Heating of these films to temperatures higher than the T_g of the polystyrene (*ca.* 398 K) resulted in marked reduction in fluorescence and curvature of the fluorescence *vs.* concentration plot, both behaviors diagnostic of flavin aggregation.

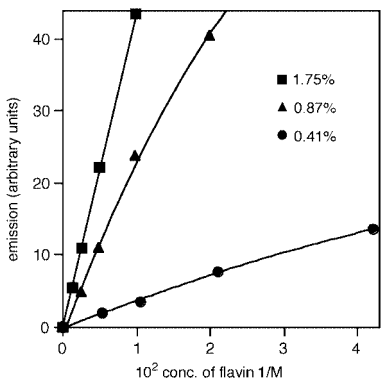

Fig. 1 Plot of fluorescence emission *vs.* concentration of flavin **1** in films prepared from solutions of 0.41, 0.87 and 1.75% w/w polystyrene in $CHCl_3$. Excitation: 445 nm, emission: 525 nm.

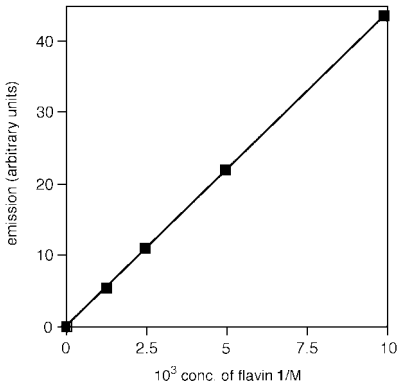

Fig. 2 Plot of fluorescence emission *vs.* concentration of flavin **1** in films prepared from a solution of 1.75% w/w polystyrene in $CHCl_3$. Excitation: 445 nm, emission: 525 nm.

To explore the complexation of flavin **1** *via* hydrogen bonding in the non-polar polystyrene matrix, films containing flavin **1** and complementary diaminotriazine-based[11] guest **2** were prepared. As shown in Fig. 3, increasing quantities of guest **2** resulted in only slightly decreased flavin **1** fluorescence emission for films prepared from solution of 0.41% w/w polystyrene in $CHCl_3$. This is consistent with non-specific aggregation between flavin **1** and triazine **2**. In contrast, titrations with 1.75% w/w polystyrene films showed marked decreases in fluorescence of flavin **1** with increasing concentrations of receptor **2**, reaching a limiting value. This is concordant with solution based investigations, where we established that hydrogen bonding between flavin **1** and guest **2** effectively quenches flavin fluorescence (Fig. 4).[12] Control experiments utilizing N(3)-methyl flavin **3** (Fig. 5), a molecule not capable

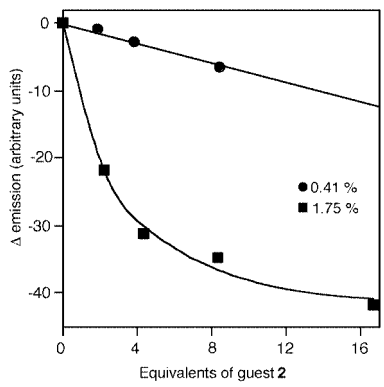

Fig. 3 Fluorescence emission changes of flavin **1** upon addition of triazine **2** in films prepared from solutions of 0.41 and 1.75% w/w polystyrene in $CHCl_3$. Excitation: 445 nm, emission: 525 nm. The curve for the titration performed with 1.75% w/w polystyrene films represents the best fit to the 1:1 binding isotherm. The line for the titration performed with 0.41% w/w polystyrene is a linear fit to the data points, and is intended only as a guide to the eye.

DOI: 10.1039/a909454g

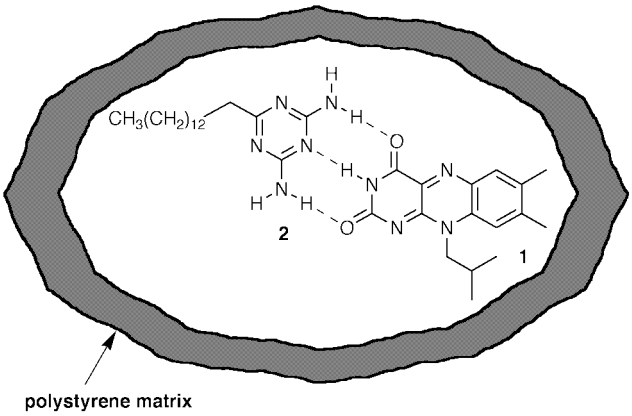

Fig. 4 Schematic illustration of isolated flavin **1**–triazine **2** host–guest complexes in a polystyrene matrix.

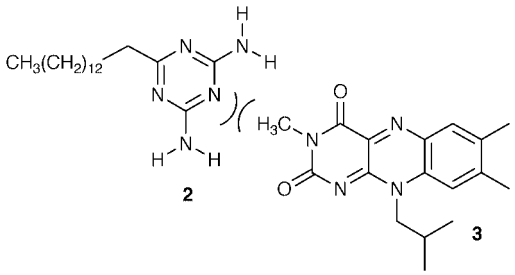

Fig. 5 N(3)-methyl flavin **3**–guest **2**.

of complementary binding through hydrogen bonding, in place of host **1** did not demonstrate any measurable complexation with guest **2**.

After calculating the volume of polymer matrices, the apparent association constants for flavin **1**–triazine **2** complexation were estimated by fitting the data to 1 : 1 binding isotherms for each different titration set of films. We did not observe any quantifiable recognition between flavin **1** and triazine **2** in films prepared from 0.41% w/w polystyrene solution, as a result of flavin **1** aggregation. For the films prepared from 1.75% w/w polystyrene solution, an estimated binding constant of 53 ± 12 M^{-1} was obtained.[13] This is considerably lower than the binding constant of 555 ± 8 M^{-1} which was obtained for the same host–guest complex formation in $CHCl_3$,[14] despite the non-competitive nature of the forming polystyrene matrix. This reduction in binding constant can be attributed to both the development of stress during polymer film formation[15] and the polymer entanglement during the deposition process, issues that we are currently exploring.

In summary, we have demonstrated the kinetic isolation of individual host flavin **1** and host flavin **1**–guest triazine **2** complexes in a highly non-polar polystyrene matrix through spin-casting of polymer solutions. Self-aggregation of polar flavin **1** in these non-polar polymer films was prevented by adjusting the ratio between polystyrene and flavin **1** in solution prior to spin casting. Fundamental and applied studies of this approach are underway and will be reported in due course.

7 Films were spin-cast at 4500 rpm onto 22 mm square SiO_2 slides , using 200 μL of polymer/flavin solution in $CHCl_3$. Prior to coating, the slides were sonicated for 10 min sequentially in 1,1;2,2-tetrachloroethane, acetone and isopropyl alcohol. The slides were then dried for 2 h at 120 °C, and allowed to cool to ambient temperature in a $CaSO_4$ dessicator. After casting, films were dried *in vacuo* for 16 h prior to spectroscopic observations.

8 The polymer-doped films were highly transparent. For example, the film of 1.75% w/w polystyrene containing 1×10^{-2} M flavin **1** showed 96% transmittance at 445 nm.

9 Fluorescence measurements were performed using a machined slide holder. The slides were vertically set, with the polymer coated surface at an angle of 60° to the excitation beam.

10 The spin-coated films were homogeneous, indicating the lack of macroscopic phase separation.

Electrosynthesis of cyclic carbamates from aziridines and carbon dioxide

Patricia Tascedda and Elisabet Duñach*

Laboratoire de Chimie Bioorganique, Associé au CNRS, Université de Nice-Sophia Antipolis, 06108 Nice Cedex 2, France. E-mail: dunach@unice.fr

Received (in Cambridge, UK) 23rd December 1999, Accepted 2nd February 2000, Published on the Web, 1st March 2000

A new and selective synthesis of five-membered ring cyclic carbamates involving nickel-catalyzed CO_2 incorporation into aziridines under mild electrochemical conditions was carried out in good yields.

Within our ongoing interest in carbon dioxide incorporation into small heterocyclic ring systems,[1,2] we present here our results on carbon dioxide incorporation into aziridines for the synthesis of 2-oxazolidones. 2-Oxazolidones are an important class of heterocyclic five-membered ring compounds.[3] These cyclic carbamates show good antibacterial properties[4,5] and are widely used in pharmaceutical chemistry.[6]

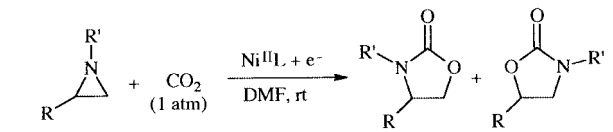
Their synthesis generally proceeds through the condensation of 1,2-aminoalcohols with toxic carbonyl derivatives such as phosgene[7] or cyanic acid (from urea decomposition).[8] The direct addition of CO_2 to β-amino alcohols at high pressure and temperature has been described in the patent literature.[9] Other methods of synthesis of 2-oxazolidones include the reaction of epoxides with cyanuric acid[10] or isocyanates[11] or the reaction of alkenes with *N*-bromosuccinimide and isocyanates.[12] 2-Oxazolidones can also be obtained from α-ketols and isocyanates or chloroformates.[13]

The direct functionalization of aziridines to cyclic carbamates has been reported *via* flash vacuum pyrolysis at 600 °C in the presence of ethyl chlorocarbonate[14] and by reaction with CO_2 at high pressure (50 atm, 60 °C) in the presence of tetraphenylantimony halides.[15]

We describe now a new and selective method of 2-oxazolidone synthesis using a simple electrochemical procedure, by which the cyclic carbamates **2** and **3** can be obtained in good yields from the direct reaction of substituted aziridines **1** with CO_2. Carbon dioxide insertion into the C–N bond of the aziridine ring takes place under very mild conditions, at room temperature and with atmospheric carbon dioxide pressure (Scheme 1). This new carboxylation reaction widens the field of utilization of CO_2 as a C-1 building block for organic chemicals.[16]

The reaction was catalyzed by a Ni(II) complex (10 mol%) and was carried out in a single-compartment cell fitted with a consumable magnesium anode and an inert cathode (*e.g.* stainless steel). Electrolyses were conducted at constant intensity in DMF as the solvent, and $[Ni(bipy)_3][BF_4]_2$ (bipy = 2,2′-bipyridine) was shown to be an efficient catalyst for this carboxylation. This same Ni(II)–bipy complex has already been used as a catalyst in other carbon dioxide incorporation reactions (*e.g.* into alkynes[17] or diynes[18]).

The electrochemical carboxylation of the *N*-Boc protected aziridine **1a**[19] led to the cyclic carbamates as a 60 : 40 mixture of two regioisomers **2a** and **3a** in 83% yield and 60% aziridine conversion (Table 1, entry 1). The major isomer corresponds to the incorporation of CO_2 at the less hindered side of the monosubstituted aziridine. No reaction occurred in the absence of current and in the absence of the nickel catalyst a very low yield of cyclic carbamates was obtained (< 10%).



1a R = Et, R′ = Boc
b R = *n*-C_8H_{17}, R′ = Boc
c R = Ph, R′ = Boc
d R = *n*-$BuOCH_2$, R′ = Boc
e R = Ph, R′ = H

Scheme 1

From a mechanistic point of view, oxidation of the magnesium rod to Mg^{2+} ions in solution takes place at the anode. At the cathode, the reduction of the Ni(II) complex to Ni(0) occurs reversibly at −1.2 V *vs.* SCE. Cyclic voltammetry showed that upon addition of **1a** to the Ni(II)–bipy solution, the reduction peak of the Ni(II)/Ni(0) transition at −1.2 V became irreversible. This was taken to indicate that the electrogenerated Ni(0) reacted with **1a** by a possible insertion into the C–N bond of the aziridine ring. The oxidative addition of Ni(0) complexes to oxirane rings has already been reported.[20]

Table 1 Ni-catalyzed electrochemical CO_2 incorporation into aziridines[a]

Entry	Aziridine	Catalyst[b]	Conditions[c]	Conversion (%)	Carbamate yield[d] (%)	Ratio **2**:**3**
1	**1a**	Ni–bipy	Mg/st. steel KBr	60	83	60:40
2	**1a**	Ni–bipy	Mg/Ni KBr	20	100	75:25
3	**1a**	Ni–bpy	Mg/C KBr	45	88	50:50
4	**1a**	Ni–bipy	Al/st. steel KBr	30	50	66:34
5	**1a**	Ni–bipy	Mg/st. steel NBu_4BF_4	30	85	76:24
6	**1a**	Ni–bipy	Mg/st. steel KCl	45	75	73:27
7	**1a**	Ni–cyclam	Mg/st. steel KBr	85	94	75:25
8	**1b**	Ni–cyclam	Mg/st. steel KBr	65	93	67:33
9	**1c**	Ni–cyclam	Mg/st. steel KBr	99	94	78:22
10	**1d**	Ni–cyclam	Mg/st. steel KBr	99	100	86:14
11	**1e**	Ni–cyclam	Mg/st. steel KBr	63	100	84:16

[a] *General electrochemical conditions*: into a single-compartment cell[21] of *ca.* 50 mL capacity fitted with the corresponding couple of electrodes, 40 mL of freshly distilled DMF, the supporting electrolyte (2×10^{-2} M), the Ni(II) catalyst (0.3 mmol) and aziridine **1** (3 mmol) were introduced. The solution was stirred at room temperature and CO_2 was bubbled into it at atmospheric pressure. The electrodes were connected to a stabilized constant current supply (Sodilec, EDL 36.07) and electrolyzed at 60 mA (corresponding to a current density of *ca.* 0.3 A dm^{-2}) for 7 h, until the consumption of **1** was negligible. The reaction mixture was then stirred at 50 °C overnight, hydrolyzed with aqueous HCl and extracted with ethyl acetate. The crude product was analyzed by GC, NMR and mass spectrometry, purified by column chromatography on silica gel and the identity of the carbamate products compared to the known compounds. [b] Ni–bipy = $[Ni(bipy)_3][BF_4]_2$, Ni–cyclam = $[Ni(cyclam)]Br_2$; both are 10 mol% with respect to the aziridine **1**. [c] The experimental conditions relate to the anode/cathode couple of electrodes and the supporting electrolyte (2×10^{-2} M). [d] The carbamate yields of **2** + **3** are calculated on the basis of converted aziridine.

DOI: 10.1039/a910285j

On the other hand, electrogenerated Ni–bipy complexes are also known to catalytically react with CO_2 to form its radical anion,[17,22] which, under the reaction conditions, undergoes reductive dimerization to oxalate.

In the electrocarboxylation of aziridines (Scheme 1), there is a competition for the electrogenerated Ni(0) complexes between two processes: (i) Ni(0) insertion into the aziridine ring followed by further CO_2 uptake and ring closure to the carbamate and (ii) CO_2 reduction to oxalate. This competition, which was very dependent on the reaction conditions, accounts for the limited aziridine conversion rates in some cases.

The influence of several factors such as the nature of the electrodes, the supporting electrolyte and of the ligand(s) attached to nickel were examined in the electrocarboxylation of **1a**. As regards the electrode, a magnesium/stainless steel couple afforded the best results, as compared to the use of carbon fiber or nickel foam as cathodes (compare Table 1, entries 1–3). When an aluminium anode was used (with several cathode materials) low aziridine conversions and low carbamate yields (*e.g.* Table 1, entry 4) were observed, with CO_2 electroreduction being favored. Among supporting electrolytes, KBr, KCl and NBu_4BF_4 were tested with Mg/stainless steel electrodes. The use of NBu_4BF_4 (Table 1, entry 5) afforded a good yield of carbamate but a low conversion of **1a** while KCl led to a conversion of 45% (Table 1, entry 6); KBr afforded the best results (Table 1, entry 1).

In the related CO_2 incorporation into oxirane rings for the synthesis of cyclic carbonates,[2] we showed that both 2,2′-bipy and cyclam ligands on nickel (cyclam = 1,4,8,11-tetraazacyclotetradecane) were effective for the CO_2 insertion reaction. In the electrocarboxylation of **1a**, the use of [Ni(cyclam)]Br_2 as the catalyst afforded **2a** and **3a** in 94% yield with 85% aziridine conversion (Table 1, entry 7). With the Ni–cyclam catalytic system the electroreduction of carbon dioxide was almost completely inhibited, in favor of aziridine carboxylation. The observed regioselectivity **2a**:**3a** was 75:25.

The reaction was then extended to the carboxylation of several monosubstituted aziridines **1b**–**e** with [Ni(cyclam)]Br_2 as the catalyst. Thus, aliphatic, aromatic or ether substituted *N*-Boc aziridines (Table 1, entries 8–10) led regioselectively to the corresponding carbamates in good yields and excellent conversions (Table 1, entries 9, 10). The electrocarboxylation of the non-protected N–H aziridine **1e** was also efficient and led to a 84:16 regioisomeric ratio of **2e**:**3e** in quantitative yield and with a 63% conversion (Table 1, entry 11).

In conclusion, a novel catalytic system for incorporation of CO_2 into aziridines for the synthesis of cyclic carbamates was developed. Use of stable and readily available Ni(II) complexes of cyclam or bipyridine ligands and application of simple preparative electrochemical conditions, led to efficient catalytic insertion of the carbon dioxide into the C–N bond of aziridines with regioselectivities of 60–86%.

The electrochemical method described here employs very mild experimental conditions (CO_2 pressure of 1 atm, 20 °C), as compared to existing methods, which require harsh conditions or the use of toxic starting materials such as phosgene. It is also worth noting that this reported method utilizes carbon dioxide as the starting C-1 carbon source, and constitutes a new example in the field of green and catalytic chemistry.

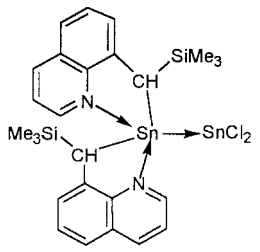
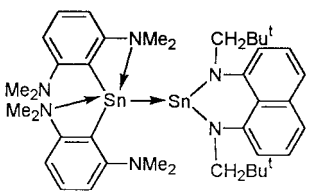
The reaction of dilithium complex [{1,2-[N(Bu^t)C(SiMe$_3$)C(H)]$_2$C$_6$H$_4$}{Li$_2$(TMEDA)$_2$}] 1 with SnCl$_2$ yielded an unusual asymmetric distannene [{1-[N(Bu^t)C(SiMe$_3$)C(H)]-2-[N(Bu^t)(SiMe$_3$)CC(H)]C$_6$H$_4$}Sn→Sn{1,2-[N(Bu^t)(SiMe$_3$)CC(H)]$_2$C$_6$H$_4$}] 2 resulting from intramolecular self-rearrangements of the ligands; 2 has a tin–tin bond distance of 3.0087(3) Å.

Ethene analogues of tin containing homoleptic ligands such as [SnR$_2$]$_2$ have been an interesting topic of research. The first crystallographically characterized distannene [Sn{CH(SiMe$_3$)$_2$}$_2$]$_2$ [Sn–Sn 2.768(1) Å] was reported in 1976 by Lappert and coworkers.[1] Nearly two decades later, solid-state structures of three thermally stable compounds [Sn{Si(SiMe$_3$)$_3$}$_2$]$_2$,[2] [Sn{2,4,6-(CF$_3$)$_3$C$_6$H$_2$}$_2$]$_2$[3] and [Sn(4,5,6-Me$_3$-2-Bu^{t}C$_6$H)$_2$]$_2$[4] having tin–tin bonds [Sn–Sn 2.825(1), 3.64, 2.910(1) Å, respectively] were reported. These compounds were either partially or completely dissociated to the monomers SnR$_2$ in toluene or methylcyclohexane. There have been evidences for formation of an unstable dimer [Sn(2,4,6-Pr$^i_3$C$_6$H$_2$)$_2$]$_2$ from the photolysis of corresponding cyclotrimer [Sn(2,4,6-Pr$^i_3$C$_6$H$_2$)$_2$]$_3$ in methylcyclohexane at 205 K.[5] However, the dimer had not been structurally characterized owing to its complete reversion to the cyclotrimer at room temperature. To our knowledge, only two examples of structurally characterized bivalent tin complexes containing different ligands attached to each tin atom having a tin–tin bond have been reported. One of them reported by our group was a thermally labile compound [{8-(CHSiMe$_3$)C$_9$H$_6$N}$_2$Sn→SnCl$_2$] **I** with an Sn–Sn distance of 2.961(1) Å,[6] and the other compound [{2,6-(Me$_2$N)$_2$C$_6$H$_3$}$_2$Sn→Sn{1,8-(NCHBu^t)$_2$C$_{10}$H$_6$}] **II** [Sn–Sn 3.087(2) Å] reported recently by Lappert and coworkers.[7] These two complexes were obtained from the reactions of two tin(II) complexes, where each of the tin complexes either acts as a Lewis acid or a base. Here, we report a rare example of an asymmetric distannene having chelating ligands bonded in different modes to the tin metals resulted from intramolecular self-rearrangements within the binuclear tin(II) compound.

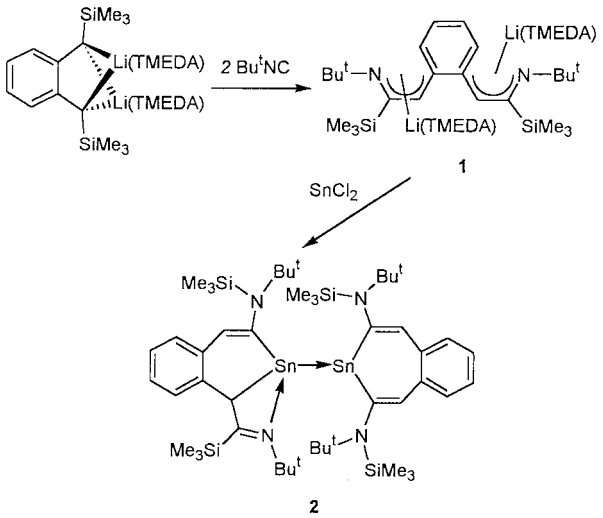


I



II

This novel distannene [{1-[N(Bu^t)C(SiMe$_3$)C(H)]-2-[N(Bu^t)(SiMe$_3$)CC(H)]C$_6$H$_4$}Sn→Sn{1,2-[N(Bu^t)(SiMe$_3$)CC(H)]$_2$C$_6$H$_4$}] **2** was prepared from the reaction of the bis(1-azaallyl) dilithium compound [{1,2-[N(Bu^t)C(SiMe$_3$)C(H)]$_2$-C$_6$H$_4$}{Li$_2$(TMEDA)$_2$}] **1** with SnCl$_2$ (Scheme 1). Dilithium compound **1** was prepared by the addition of isocyanide Bu^{t}NC to a diethyl ether solution of the dilithium dialkyl compound [{1,2-(CHSiMe$_3$)$_2$C$_6$H$_4$}{Li$_2$(TMEDA)$_2$}]. In this reaction, the isocyanide inserts into the Li–C bond followed by a 1,2-shift of the trimethylsilyl group along the carbon chains. Similar reaction with organonitrile Bu^{t}CN has been reported earlier.[8] Compound **1** has been characterized by ^{1}H and ^{13}C NMR spectroscopy, EI-MS spectrometry and elemental analysis.‡ The X-ray structure of **1** has been determined.



Scheme 1 Synthesis of complexes **1** and **2**.

Subsequent treatment of **1** with a slight excess of SnCl$_2$ led to the formation of **2** in 64.9% yield. By X-ray structure analysis of the product, it has found that the ligands bonded to the two tin(II) atoms undertake different rearrangements. One of the ligands undergoes two 1,2-shifts of the SiMe$_3$ group from C to N, and both of the 1-azaallyl arms are bonded to the tin(II) atom *via* the carbon atoms. The ligand attached to the other tin(II) core undergoes a 1,2-silyl migration. This rearrangement results in the two 1-azaallyl arms bonded to the tin atom in an η^1-C and η^2-C,N bonding mode, respectively. Compound **2** is soluble in toluene, Et$_2$O and THF, and slowly decomposes to tin metal in solution. It has been characterized by EI-MS spectrometry, ^{1}H, ^{13}C, ^{119}Sn NMR spectroscopy, elemental analysis‡ and X-ray structure analysis.§ The ^{1}H and ^{13}C NMR spectra of **2** in C$_6$D$_6$–C$_5$D$_4$N (4 : 1) showed only one set of signals corresponding to the ligand at ambient temperature. The ^{119}Sn NMR spectrum displayed a broad singlet at δ 333.04.

Compound **2** crystallized from a solvent mixture of THF and toluene (1 : 10) as a THF solvate (Fig. 1). It is comprised of two

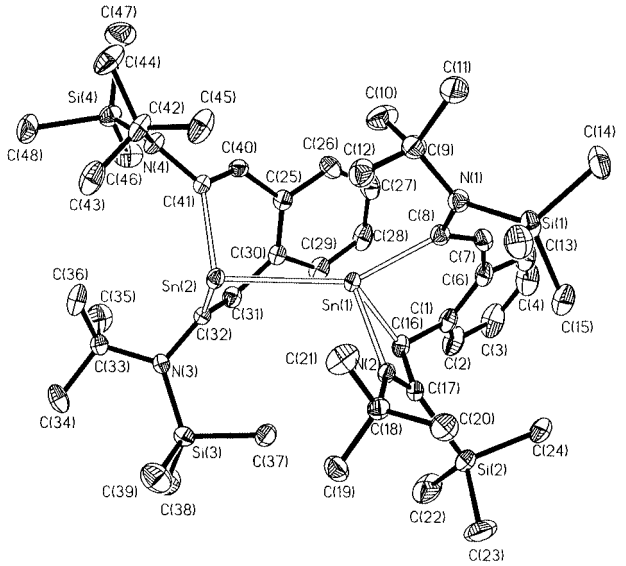

Fig. 1 Molecular structure of [{1-[N(Bu^t)C(SiMe$_3$)C(H)]-2-[N(Bu^t)(SiMe$_3$)CC(H)]C$_6$H$_4$}Sn→Sn{1,2-[N(Bu^t)(SiMe$_3$)CC(H)]$_2$C$_6$H$_4$}] **2**. Hydrogen atoms and solvent molecule have been omitted for clarity. Selected bond distances (Å) and angles (°): Sn(1)–Sn(2) 3.0087(3), Sn(1)–C(8) 2.208(2), Sn(1)–C(16) 2.219(2), Sn(1)–N(2) 2.266(1), Sn(2)–C(32) 2.209(2), Sn(2)–C(41) 2.255(2); C(8)–Sn(1)–C(16) 89.53(7), C(8)–Sn(1)–N(2) 91.32(6), C(16)–Sn(1)–N(2) 61.70(6), C(8)–Sn(1)–Sn(2) 144.21(4), C(16)–Sn(1)–Sn(2) 126.22(5), N(2)–Sn(1)–Sn(2) 106.25(4), C(32)–Sn(2)–C(41) 90.05(6), C(32)–Sn(2)–Sn(1) 93.42(4), C(41)–Sn(2)–Sn(1) 97.18(4).

independent stannylene moieties linked by a tin–tin bond at a distance of 3.0087(3) Å. The coordination geometries at the tin atoms are different. The Sn(1) centre adopts a distorted tetrahedron with the Sn(1)–Sn(2) vector residing on one of the vertices. The 1-azaallyl ligand attached to the Sn(1) atom undergoes a further 1,2-shift of the SiMe$_3$ group, resulting in a C(7)–C(8) double bond [1.352(2) Å] and C(8)–N(1) single bond [1.431(2) Å]. The other 1-azaallyl skeleton of the same ligand links to the Sn(1) atom in an η^2-C,N coordination mode, with an Sn(1)–C(16) bond distance of 2.219(2) Å and an Sn(1)–N(2) bond distance of 2.266(1) Å. The Sn(1)–N(2) bond distance is somewhat longer than the average Sn–N(amido) distances of 2.092 Å in [Sn{N(SiMe$_3$)$_2$}$_2$],[9] and 2.085 Å in **II**,[7] and comparable to the Sn–N distances of 2.153(4) and 2.288(4) Å in [Sn{C(SiMe$_3$)$_2$C(Ph)N(SiMe$_3$)}$_2$].[10] Unlike most 1-azaallyl complexes, no distinctive electron delocalization was found within the C(16)C(17)N(2) part. The C(16)–C(17) bond [1.539(3) Å] is a normal C–C single bond and the C(17)–N(2) bond distance [1.279(2) Å] coincides with the C–N double bond. The angle sum around N(2) is 359.97°, indicative of an sp^2 hybridization. Sn(2) adopts a trigonal pyramidal environment with an angle sum of 280.65° at Sn(2). This value is comparable to similar angles in **I** and **II**. In **I**, SnCl$_2$ acts as a Lewis acid, and the angle sum around Sn is 282.6°.[6] In **II**, the three-coordinate Sn core behaves as an acceptor with an angle sum of 279.4°.[7] The Sn(2) moiety in **2** can be viewed as an acceptor, and the Sn(1) fragment as a donor. Both of the 1-azaallyl ligands of Sn(2), undergo a 1,2-SiMe$_3$ migration, and are bonded to the Sn(2) atom in an η^1-C bonding mode. The Sn–C bond distances of 2.255(2) and 2.209(2) Å in **2** are shorter than those in [Sn{2-C(SiMe$_3$)$_2$C$_5$H$_3$N}$_2$] [2.334(6), 2.346(6), 2.377(7) Å],[11] and [Sn{2-C(SiMe$_3$)(Ph)C$_5$H$_3$N}$_2$] [2.329(4), 2.333(4) Å],[12] and comparable to the corresponding Sn–C distances in **I** [2.200(8), 2.203(8) Å],[6] and **II** [2.186(6), 2.196(7) Å].[7]

Synthesis and molecular structure of an unusual –Ga–Ga–Ga– linked organometallic

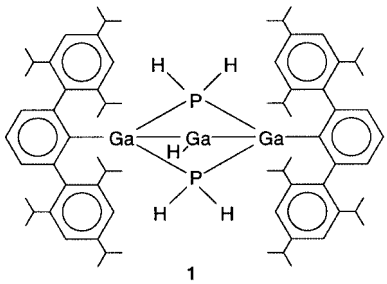
Xiao-Wang Li, Pingrong Wei, Brent C. Beck, Yaoming Xie, Henry F. Schaefer III, Jianrui Su and Gregory H. Robinson*

Department of Chemistry and the Center for Computational Quantum Chemistry, The University of Georgia, Athens, GA 30602-2556 USA. E-mail: robinson@sunchem.chem.uga.edu

Received (in Columbia, MO, USA) 24th November 1999, Accepted 5th February 2000, Published on the Web, 1st March 2000

Reaction of $[(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$ with $P(SiMe_3)_3$ affords the unusual organometallic compound $[(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3]Ga\{H_2PGa(H)PH_2\}Ga[C_6H_3(C_6H_2\text{-}Pr^i_3\text{-}2,4,6)_2]$ 1 characterized by multinuclear NMR, complete (C, H, Ga and P) elemental analyses, IR spectroscopy and single crystal X-ray diffraction; 1 is significant as it contains a rare Ga–Ga–Ga [2.5145(13) and 2.7778(14) Å] linkage even as its formation is facilitated by the unusual stripping of the sterically demanding *m*-terphenyl ligand from the central gallium atom.

One of the most extensively studied reactions in organo-group 13 chemistry of the past decade has been that of organometallic moieties with various phosphines.[1] The preference for tris-(trimethylsilyl)phosphine, $P(SiMe_3)_3$, as a phosphorus source may largely be traced to the considerable steric demands (*i.e.* large cone angle) of this compound coupled with the robust nature of the trimethylsilyl leaving groups.[2] Herein, we report the synthesis[3] and molecular structure[4] of $[(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3]Ga\{H_2PGa(H)PH_2\}Ga[C_6H_3(C_6H_2\text{-}Pr^i_3\text{-}2,4,6)_2]$ **1** isolated from reaction of $[(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$[5] with $P(SiMe_3)_3$. Compound **1**, characterized by



1

multinuclear NMR, complete elemental (C, H, Ga and P) analyses IR spectroscopy, and single crystal X-ray diffraction, is significant as it contains a rare –Ga–Ga–Ga– linkage even as its formation is facilitated by the unusual stripping of the sterically demanding *m*-terphenyl ligand from the central gallium atom.

The laboratory has had an interest in the organogallium chemistry of $P(SiMe_3)_3$ for some time having previously reported the synthesis and molecular structure of the phosphinogallane dimer $[Me_2Ga\text{–}P(SiMe_3)_2]_2$, isolated from reaction of $GaMe_3$ with $P(SiMe_3)_3$.[6] This compound contained a planar Ga_2P_2 four-membered ring with an independent Ga–P bond distance of 2.456(1) Å. Reaction of the Lewis acid–base adduct $Me_3Ga\text{–}PMe_3$ [Ga–P 2.455(4) Å] with $P(SiMe_3)_3$ was shown by this laboratory to afford $[(Me_3Si)_2P\{Me_2Ga\}_2PMe]_2$ – a novel bicyclic phosphinogallane consisting of two fused Ga_2P_3 five-membered rings sharing a common P–P base at a distance of 2.25(3) Å with a mean Ga–P bond distance of 2.44(4) Å.[7] Relative to sterically demanding ligands the *m*-terphenyl moiety $(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3$ has been most prominently utilized in the stabilization of $Na_2[\{(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3\}\text{–}Ga{\equiv}Ga\text{–}\{C_6H_3(C_6H_2Pr^i_3\text{-}2,4,6)_2\}]$, a novel gallyne possessing a short Ga–Ga bond distance of 2.319(3) Å.[8–10] Thus, as described herein, we endeavored to examine the organogallium chemistry of this ligand as a function of $P(SiMe_3)_3$.

The formation of **1** is at once both surprising and interesting. Although the stripping of a large organic moiety from a gallium center, as with the central gallium atom of **1**, is noteworthy, it is not unprecedented as a $Pr^i_3C_6H_2$ ligand has been shown to be stripped from a gallium atom.[11] While it may be reasonable to consider the five hydrogen atoms, two on each of the two phosphorus atoms and one on the central gallium atom, as having originated from the stripped *m*-terphenyl ligand, there are other possibilities. It is also possible, for example, that the ligand stripping may have initiated hydride abstraction from the solvent (or *vice versa*). It is noteworthy that the title compound has been repeatedly isolated in this laboratory under a number of conditions.[3] The phosphine hydrogen atoms and the gallium hydride are prominently manifest in IR and NMR spectroscopy. IR spectroscopic data for **1** indicate the presence of phosphine hydrogen atoms with bands at 2371 cm^{-1} [ν_{P-H} (m)] and 2337 cm^{-1} [ν_{P-H} (m)]. These values compare well to 2314 cm^{-1} [ν_{P-H} (m)] for $\{[Me_2Ga]_4[(\mu\text{-}PH)_2(C_6H_4)]_2\}$[12] and to 2343 cm^{-1} [ν_{P-H} (sym)] and 2335 cm^{-1} [ν_{P-H} (asym)] for the phosphinogallane trimer $[Bu^t_2Ga(\mu\text{-}PH_2)]_3$.[13] The gallium hydride IR bands at 1801 cm^{-1} [ν_{Ga-H} (vw)] and 1849 cm^{-1} [ν_{Ga-H} (vw)] of **1** are comparable to previously reported gallium hydride IR bands: $Me_2N\text{–}GaH_3$,[14] 1829 cm^{-1} [ν_{Ga-H} (vw)]; $[(PhCH_2(Me)_2NGaH_3]$,[15] 1835 cm^{-1} (ν_{Ga-H}) and $(Et_2O)_2Li[\mu\text{-}As(SiMe_3)_2]_2GaH_2$,[16] 1834 cm^{-1}. Similar to **1** which exhibits two Ga–H IR bands, the organometallic (mono)hydride $K[Ga(H)(CH_2SiMe_3)_3]$ also exhibits two Ga–H IR bands at 1915 cm^{-1} [ν_{Ga-H} (vw)] and 1840 cm^{-1} [ν_{Ga-H} (vw)].[17] It is important to note that our calculated IR spectrum agrees well with the experimental results of **1** reported herein.[18] A theoretical study of the model molecule $CH_3Ga\{H_2PGa(H)\text{-}PH_2\}GaCH_3$ at the DZP B3LYP level of theory in this laboratory reveals harmonic vibrational frequencies corresponding to P–H stretches of 2441, 2441, 2418 and 2415 cm^{-1}. Moreover, the calculated Ga–H IR band appears at 1882 cm^{-1}. In sum, these theoretical predictions are in good agreement (within 5%) with the experimentally observed IR spectrum. Although the Ga–H bond could not be unambiguously assigned in the ^1H NMR spectrum, P–H was clearly observed as a multiplet at δ 3.25; moreover the integration is indicative of two hydrogen atoms on each of the two phosphorus atoms. Consistent with its diamagnetic nature, the title compound did not prove to be EPR active.

A number of points are noteworthy relative to structure (Fig. 1) and bonding in the title compound. Compound **1** may be considered as a Ga_3P_2 trigonal bipyramidal core bridging the two *m*-terphenyl ligands. The Ga–C bonds in **1** of 1.969(6) and 1.982(6) Å are longer than the value reported for $[(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3]GaCl_2$ [1.949(8) Å] and yet are considerably shorter than that reported for the $Na_2[\{(2,4,6\text{-}Pr^i_3C_6H_2)_2C_6H_3\}\text{–}Ga{\equiv}Ga\text{–}\{C_6H_3(C_6H_2Pr^i_3\text{-}2,4,6)_2\}]$ gallyne (2.06 Å). The angles about the {–P–Ga–P–} core connecting the

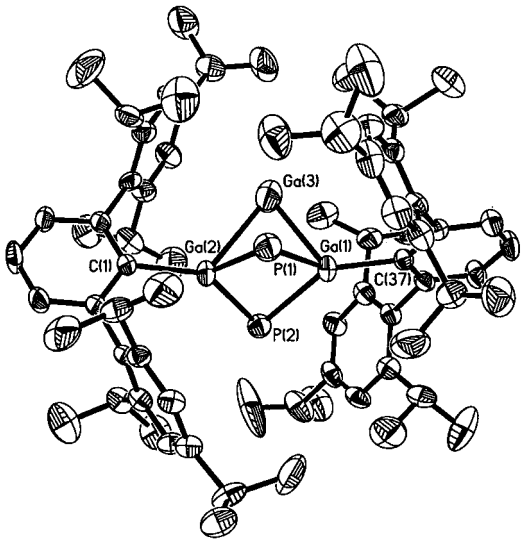


Fig. 1 Molecular structure of **1** (all hydrogen atoms, including that on Ga(3) and the two each on P(1) and P(2), have been omitted for clarity and only one position for each disordered phosphorus atoms is shown. Ellipsoids are shown at the 30% probability level): Bond distances (Å) and angles (°): Ga(1)–C(37) 1.969(6), Ga(2)–C(1) 1.982(6), Ga(1)–P(2) 2.564(5), Ga(1)–P(1) 2.660(6), Ga(1)–Ga(3) 2.5145(13), Ga(2)–P(1) 2.449(5), Ga(2)–P(2) 2.455(4), Ga(2)–Ga(3) 2.7778(14), Ga(1)···Ga(2) 3.031, Ga(3)···P(1) 3.327, Ga(3)···P(2) 3.314, P(1)···P(2) 3.930; C(37)–Ga(1)–P(2) 129.98(19), C(37)–Ga(1)–P(1) 130.3(2), P(2)–Ga(1)–P(1) 97.58(10), C(37)–Ga(1)–Ga(3) 115.97(18), P(2)–Ga(1)–Ga(3) 81.48(15), P(1)–Ga(1)–Ga(3) 79.96(18), C(1)–Ga(2)–P(1) 124.0(2), C(1)–Ga(2)–P(2) 128.1(2), P(1)–Ga(2)–P(2) 106.5(3), C(1)–Ga(2)–Ga(3) 119.69(18), P(1)–Ga(2)–Ga(3) 78.78(15), P(2)–Ga(2)–Ga(3) 78.33(13), Ga(1)–Ga(3)–Ga(2) 69.68(4), Ga(2)–P(1)–Ga(1) 72.65(17), Ga(2)–P(2)–Ga(1) 74.27(14).

two [(2,4,6-$Pr^i_3C_6H_2)_2C_6H_3$]Ga fragments are particularly acute at angles of 69.68(4), 72.65 and 74.27° for Ga(1)–Ga(3)–Ga(2), Ga(1)–P(1)–Ga(2) and Ga(1)–P(2)–Ga(2), respectively. The Ga(1)–Ga(3)–Ga(2) linkage is asymmetric at distances of 2.5145(13) and 2.7778(14) Å for Ga(1)–Ga(3) and Ga(2)–Ga(3), respectively. It should be noted, however, that compound **1** is not governed by a plane of symmetry or a twofold axis which would demand a symmetrical –Ga–Ga–Ga– linkage. Even though these Ga–Ga distances in **1** are rather long, they compare with a Ga–Ga range of 2.678–2.702 Å for the Ga_4-tetrahedral based [Ga{$C(SiMe_3)_3$}]$_4$.[19] Indeed, the Ga–Ga bond distances of **1** compare favorably with the Ga–Ga distances of 2.440(1) and 2.790(1) Å for the recently reported 'silicon-capped' Ga_4Si trigonal bipyramidal anion.[20]

The mean Ga–P distance in **1** is 2.461 Å. With Ga···P contacts of 3.327 and 3.314 Å for Ga(3)···P(1) and Ga(3)···P(2), respectively, the possibility of meaningful gallium–phosphorus interactions would appear to be remote. Likewise, the P(1)···P(2) approach of 3.930 Å is far beyond the realm of a phosphorus–phosphorus bond as typical P–P single bond distances are normally in the range 2.25(3)–2.35 Å.[21] Lastly, the Ga(1)···Ga(2) approach of 3.031 Å virtually rules out significant metal–metal interaction.

We are grateful to the National Science Foundation (H. F. S.: CHE-9815397; G. H. R.: CHE-9520162) and to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for support of this work.

3 Compound **1** was prepared by a number of methods under a variety of conditions. All syntheses afforded **1** in comparable yields. *Method A*: inside a drybox (M Braun LabMaster 130), a Schlenk flask was charged with [(2,4,6-$Pr^i_3C_6H_2)_2C_6H_3$]$GaCl_2$ (1.30 g, 2.08 mmol), diethyl ether (40 mL) and a stirring bar. The resulting colorless solution was cooled to −78 °C. To this flask a solution of $P(SiMe_3)_3$ (0.52 g, 2.08 mmol) in diethyl ether (30 mL) was added *via* syringe over a period of 10 min. The solution was allowed to stir for 3 h at low temperature, after which it was allowed to slowly warm to room temperature and continued to stir for 72 h resulting in a slightly yellow solution. After filtration, the volume of the solution was reduced to *ca.* 20 mL *in vacuo*. Cooling the solution to −25 °C for one week gave colorless crystals of **1** (0.25 g, 0.20 mmol). Yield: 30%. mp: 191 °C (decomp.). Anal. Calc. (found) for $C_{72}H_{103}P_2Ga_3$ (E + R Microanalytical Laboratory, Corona, NY): C, 69.80 (70.30); H, 8.40 (8.19); Ga, 16.90 (16.88); P, 5.00 (4.86%). ^{1}H NMR (300 MHz, 298 K, C_6D_6): δ 0.87–1.31 [m, 72H, CH(CH_3)$_2$], 2.92 [m, 12H, –CH(CH_3)$_2$], 3.25 (m, 4H, PH_2), 7.10–7.21 [m, 14H, CH (aromatic)]. ^{13}C NMR (300 MHz, 298 K, THF-d_8): δ 23.5, 31.3, 35.4 (isopropyl); 120.0, 121.5, 128.8, 129.3, 140.6, 146.9, 148.0, 149.6 (aromatic carbon atoms). ^{31}P{^{1}H} NMR (300 MHz, 298 K, THF-d_8): δ −167.95 (s). Compound **1** was EPR inactive, thereby confirming its diamagnetic nature. IR (Perkin Elmer Paragon 1000PC FT-IR Spectrometer) (Nujol mull): 2371 [ν_{P-H} (m)], 2337 [ν_{P-H} (m)], 1801 [ν_{Ga-H} (vw)], 1849 cm^{-1} [ν_{Ga-H} (vw)].

4 A number of crystals of **1** were mounted and sealed in a glass capillaries under an atmosphere of nitrogen inside the drybox. The X-ray intensity data on an appropriate sample were collected at room temperature on a Bruker SMART TM CCD-based X-ray diffractometer system with graphite-monochromated Mo-Kα radiation (λ = 0.710 73 Å) using the ω-scan technique to a maximum 2θ value of 46.7°. *Crystallographic data*: $C_{72}H_{103}P_2Ga_3$: monoclinic, space group $P2_1/n$ (no. 14), a = 18.7040(16), b = 18.4955(16), c = 20.3393(17) Å, β = 92.588(2)°, V = 7029.0(10) Å^3, Z = 4, M = 1239.64, μ = 1.224 mm^{-1}, D_c = 1.171 g cm^{-3}. Of the 9812 independent reflections collected, 4427 were observed [$I > 2\sigma(I)$]. A routine absorption correction was applied by using SADABS and any decay correction was made with the SAINT program. The structure was solved by direct methods using the SHELXTL 5.1 Software Package. Each of the two bridging phosphorus atoms was found to be disordered over two adjacent positions with a refined occupancy factor of 0.50 for each position. The non-hydrogen atoms (except for the disordered phosphorus atoms) were refined anisotropically while hydrogen atoms were placed in ideal positions with their coordinates and thermal parameters riding on the attached carbon atoms (C–H 0.98 Å), the phosphorus atoms (P–H 1.50 Å) and the bridging gallium atom (Ga–H 1.50 Å). The final residual values based on 695 variable parameters and 4427 observed reflections [$I > 2\sigma(I)$] and $R1$ = 0.0637, $wR2$ = 0.1359 and those for all 9812 unique reflections are $R1$ = 0.1665, $wR2$ = 0.1711. When the hydrolysis of substituted benzoyl chlorides is carried out in a water/oil (w/o) microemulsion, the point in the substituent σ^+/lg *k* plot at which the mechanism changes from associative to dissociative depends on the water content of the microemulsion.

Water-in-oil (w/o) microemulsions[1] can be considered as consisting of three compartments in which small solutes may be located: the aqueous core of the droplets; the continuous non-polar phase; and the intervening micellar interface made up of surfactant molecules with their polar head groups facing the aqueous core.[2] They are extensively used for foods, cleaning products, drug delivery, tertiary oil recovery,[1] and as media for chemical reactions.[3] This latter application derives largely from their ability to catalyse reactions by bringing water-soluble reagents dissolved in the aqueous compartment into contact, at the micellar interface, with water-insoluble organic reagents dissolved in the non-polar compartment; microemulsion catalysis is an alternative to phase-transfer catalysis[4] and other techniques for favouring reaction between water-soluble and water-insoluble compounds. In addition, however, microemulsions can also bring about catalysis simply by concentrating water-soluble reagents in the aqueous droplet core and at the interface, the droplets thus acting as 'microreactors'.[5] Furthermore, reaction rates can be influenced by the altered properties of the water in droplets with very low water contents.[6,7]

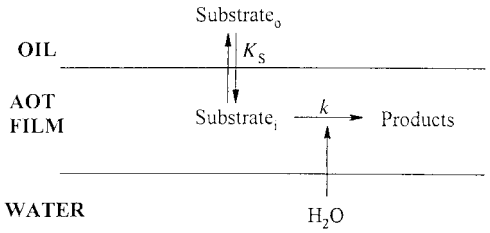
In this work, we found that the altered properties of microemulsion water can affect not only reaction rates, but also the mechanism by which certain reactions take place. The specific class of reactions investigated was the hydrolysis of substituted benzoyl chlorides in water/AOT/isooctane microemulsions [AOT = sodium bis(2-ethylhexyl)sulfosuccinate] with water contents $W = [H_2O]/[AOT]$ ranging from 2 to 50.

The kinetics of the hydrolysis of benzoyl chlorides in microemulsions can be investigated using our extended pseudophase model of the latter.[8] Specifically, since the poor solubility of benzoyl chlorides in water makes it safe to assume that the amount of substrate dissolved in the aqueous compartment is negligible, we applied the model shown in Scheme 1, where K_S {$K_S = ([\text{Substrate}]_i Z)/[\text{Substrate}]_o$} governs the partition of substrate between the organic phase and the interface, the only region in which the reaction occurs. For the observed rate constant k_{obs}, this model affords eqn. (1), in which *k* is the

$$k_{obs} = \frac{kK_S}{K_S + Z} \quad (1)$$

pseudo first-order rate constant for the reaction in the interface and Z = [isooctane]/[AOT] is the ratio of the molar concentrations of the non-polar solvent and the surfactant.

As predicted by eqn. (1), plots of $1/k_{obs}$ *vs.* Z are linear in all cases studied (errors are always < 10–12% for the intercepts and *ca.* 1–2% for the slopes). Fig. 1 shows these results for some of the benzoyl chlorides used. For each value of *W*, the values of *k* (errors are always < 15%) so obtained were used to construct the corresponding Hammett plot. Fig. 2 shows the results for $W = 2$ and 50.



Scheme 1

Mechanistically, the solvolysis of benzoyl chlorides can proceed *via* either of two phenomenologically distinct kinds of mechanism: one in which the rate-limiting step includes a transition state with little or no cleavage of the bond binding the leaving group [an associative mechanism, Scheme 2(a)], and one in which it shows well advanced cleavage of the leaving group bond [a dissociative mechanism, Scheme 2(b)].[9,10] A positive ρ^+ value provides evidence for an associative transition state that involves bimolecular attack of water on the acyl chloride with little or no bond-breaking to the leaving group in the rate-limiting step. This corresponds to the initial step of an addition–elimination mechanism, but we do not know if there is an intermediate with a significant lifetime on the reaction path. An 'uncoupled concerted' reaction pathway may occur, in which there is no intermediate, but in which bond formation and bond cleavage are not balanced; *i.e.* bond-making and bond-breaking have not occurred to the same extent at the same time.[9]

The mechanism of a given reaction depends on the nature of the substituent and the solvent in which the reaction takes place.[9] The slope of a Hammett plot for solvolysis of benzoyl chlorides in water changes from negative (indicative of dissociative reactions, $\rho^+ = -3.0$[9]) to positive values (indicative of associative reactions) somewhere between the points corresponding to 3-(trifluoromethyl)benzoyl chloride and 4-ni-

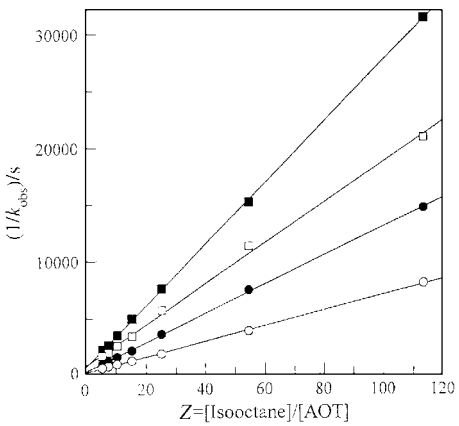


Fig. 1 Plots of $1/k_{obs}$ *vs.* Z = [isooctane]/[AOT] [see eqn. (1)] for the hydrolysis of substituted benzoyl chlorides at 25 °C in AOT/isooctane/water microemulsions with $W = 18$. (■) 4-Cl, (□) 4-H, (●) 4-Me, (○) 4-CF_3.

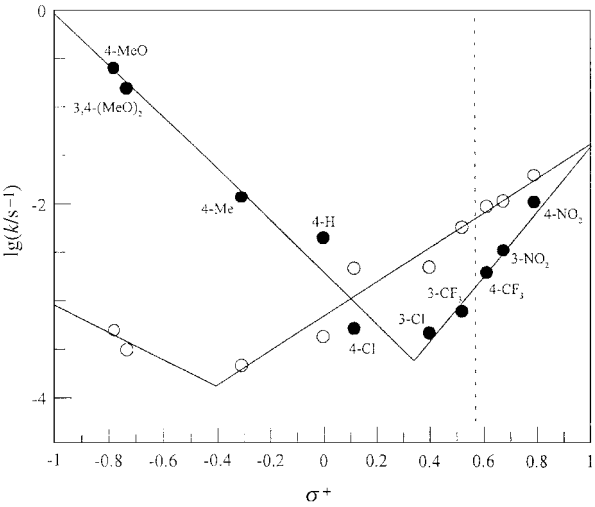

Fig. 2 Hammett plots for the hydrolysis of substituted benzoyl chlorides in AOT/isooctane/water microemulsions with different water contents: (●) W = 50 and (○) W = 2 at 25 °C. The dashed line indicates the point at which a similar plot for the reaction in water changes from negative to positive slope (ref. 9).

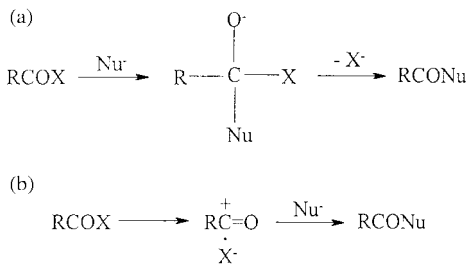

Scheme 2

trobenzoyl chloride, the latter of which reacts faster than the former.[9]

Fig. 2 shows that in microemulsions, as in water, there is indeed a switch from the dissociative to the associative mechanism. For the microemulsion with W = 50 this occurs at σ^+ *ca.* 0.3, between the points for 4-chlorobenzoyl chloride and 3-chlorobenzoyl chloride: for $\sigma^+ > 0.3$ there is very good Hammett correlation with a slope of $\rho^+ = 3.5 \pm 0.3$, whereas the least-squares line through the results for substituents with $\sigma^+ < 0.3$ has a slope of $\rho^+ = -2.7 \pm 0.3$, close to the value of −3.0 observed for reaction in pure water.[9] For the microemulsion with W = 2, the switch occurs at σ^+ *ca.* −0.4, just below the point for 4-methylbenzoyl chloride, with a Hammett slope of $\rho^+ = 1.8 \pm 0.2$ for $\sigma^+ > -0.4$ (the number of substrates with more negative σ^+ values was too few for accurate calculation of a Hammett slope for the dissociative branch).

As the water content of the medium falls, so too does the σ^+ value at which the mechanism switch occurs (see Fig. 2, in which the value at which the switch occurs in bulk water is shown by a dotted line). This can be attributed to the change in the properties of micelle-borne water.[11,12] The change from a dissociative to an associative reaction path with increasingly electron-withdrawing substituents occurs much later in water than in AOT/isooctane/water microemulsions with W = 50. The rate of the associative reaction is independent of the leaving group, while the dissociative reaction is strongly dependent on the nature of the leaving group and on its solvation.[9] For large values of W, water at the centre of the aqueous micelle core is similar in nature to that of bulk water, but water in or adjacent to the interface is devoted to solvating the surfactant head groups[12] and, hence, has a limited ability to assist the leaving group; in microemulsions with W = 2, all water is of this latter kind. Consequently, lowering W favours the associative pathway, with the result that the change in mechanism occurs at lower σ^+ values; in the microemulsion with W = 2, even 4-methylbenzoyl chloride, with its electron-donating substituent, is hydrolysed *via* the associative mechanism.

In conclusion, in this work we found that carrying out the hydrolysis of benzoyl chlorides in microemulsions allows not only the reaction rate but also the reaction mechanism to be controlled by modifying the quantitative composition of the microemulsion. The effect on the mechanism can be attributed to the dependence of the properties of micelle-borne water on the value of W = [H_2O]/[surfactant]. We envisage that this phenomenon may prove to be of use for investigation of other reaction mechanisms.

Received (in Columbia, MO, USA) 7th October 1999, Accepted 2nd February 2000, Published on the Web, 1st March 2000

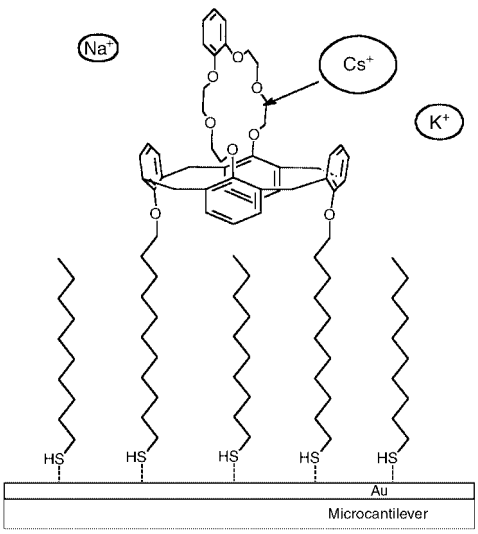
We report a new sensor concept based on an ion-selective SAM modified microcantilever which can detect caesium ion concentrations *in situ* in the range 10^{-11}–10^{-7} M and shows potential for use in developing a new family of real time *in situ* metal ion sensors with high sensitivity/selectivity and low cost, for chemical and biological applications.

Research in the area of sensor development for metal ion detection in chemical and biological applications has received considerable attention in recent years.[1–3] In particular, the application of host–guest chemistry to sensor development has proved to be a very useful detection method.[4] Many different receptors (hosts) including crown ethers, cryptands and calixarenes have been synthesized as molecular recognition agents for the binding of various metal ions (guests).[5–7] Recent results from our laboratory on microcantilever based sensors have revealed that adsorption-induced stress on microcantilevers can be used to detect low concentrations (ppb) of chemical vapors.[8] This adsorption-induced stress can be detected by the change in bending[9] or resonance frequency[10] caused by changes in the cantilever surface. We have shown that microcantilevers can operate in both the gas and liquid phase for chemical sensing applications.[8,9] In liquid environments, the preferable mode of detection appears to be adsorbate induced cantilever bending. Chemical selectivity for inorganic ions can be obtained by coating an ion-selective polymer film or modified SAM containing ion selective binding sites.

Here we report the first example of a selective caesium ion sensor based on an ion-selective SAM coated microcantilever capable of detecting caesium ions in the presence of high concentrations of potassium of sodium ions. Our data shows that the sensitivity of this cantilever based sensor for *in situ* measurements is several orders of magnitude better than the currently available ion selective electrodes (ISE).

The caesium recognition agent used in this work was 1,3-alternate 25,27-bis(11-mercapto-1-undecanoxy)-26,28-calix[4]benzocrown-6 **1**, bound to a gold coated microcantilever. The crown cavity of the 1,3-alternate conformation of calix[4]benzocrown-6 has been shown to be very suitable for accommodating caesium ions with Cs/Na and Cs/K selectivity ratios in excess of 10^4 and 10^2, respectively, by a solvent extraction technique.[11] Binding constant values of 10, 2×10^4 and 2.5×10^6 have also been determined by a fluorescence technique for Na^+, K^+ and Cs^+ in MeOH–CH_2Cl_2 (1:1) solution.[12] Based on the high selectivity exhibited by these compounds, receptor molecule **1** was designed and anchored onto the gold surface of the microcantilever by standard techniques.[13] Decane-1-thiol was co-absorbed onto the gold surface in a 2:1 ratio to fill the gaps present between the two alkyl thiol arms of **1** and the adjacent molecules (Scheme 1) and to enhance the aqueous stability of the SAM.

The experiments were performed in a flow-through glass cell where the SAM coated V-shaped microcantilever was immersed in distilled water at a flow rate of 10 mL min^{-1}. Electrolyte solutions (Cs, K or Na nitrate) were introduced using a syringe pump by switching the syringe delivering pure water to the syringe containing the desired electrolyte solution. The volume of the glass cell was selected to be small enough (4 mL) to insure fast replacement of the liquid in contact with cantilever. The bending of the cantilever was measured by monitoring the position of a laser beam reflected off the top of the microcantilever onto a four-quadrant photodiode. The microcantilever was initially immersed into the cell exposed to a constant flow of distilled water and its deflection (bending) was measured as the background and set to 0 nm. Approximately 30 s later, the flow of distilled water was replaced with caesium ion solution. As the Cs^+ ions diffuse to the SAM coated microcantilever, the bending response of the cantilever changes reaching an equilibrium within 70–80 s (Fig. 1). Based on the large complexation constant calculated (*vida infra*) for caesium and 1,3-alternate calix[4]benzocrown-6, it is reasonable to assume that the initial rapid increase in bending response depends on the concentration of caesium in solution. Fig. 2 shows the observed change in bending response of the microcantilever as the concentration of caesium ions is varied. It is clear from the plot in Fig. 2 that the most dramatic response is exhibited when the concentration of caesium is in the range 10^{-7}–10^{-11} M. In contrast, the cantilever response to potassium ions (the most prevalent interfering ion) in the same concentration range is very small (*e.g.* 20 nm deflection for 1×10^{-8} M solution of K^+ compared to 330 nm deflection for caesium at the same concentration, Fig. 2). For Cs^+ ion concentrations $> 10^{-6}$ M, the bending response at equilibrium reaches its maximum value at *ca.* 330 nm (Fig. 2). A blank test performed on a gold coated silicon nitride cantilever without the SAM revealed that



Scheme 1 Schematic representation of the molecular structure of receptor molecule 1,3-alternate 25,27-bis(11-mercapto-1-undecanoxy)-26,28-calix[4]benzocrown-6 (**1**) co-absorbed with decane-1-thiol on the gold surface of microcantilever by the SAM technique. The synthetic procedure for preparation of the thiol derivative of 1,3-alternate calix[4]arene **1** used in this work will be published elsewhere. The microcantilever is commercially available and has the following dimensions: 200 μm long, 40 μm base and 0.7 μm thick (Park Scientific Instruments, CA). The maximum number of molecules of **1** that can adsorb on the surface of cantilever is $\leqslant 2 \times 10^{10}$. The sensitivity of detection is 10.58 mV nm^{-1}

DOI: 10.1039/a908143g

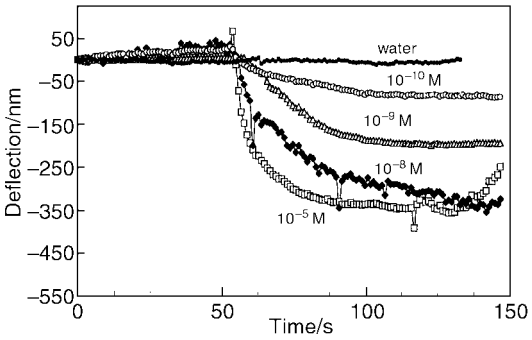


Fig. 1 Bending deflection response of the SAM coated microcantilever as a function of time, *t*, before and after exposure to different concentrations of Cs^+ ions in solution at room temperature. For the *y*-axis, the voltage has been converted to nm using the conversion factor 10.58 mV nm^{-1}.

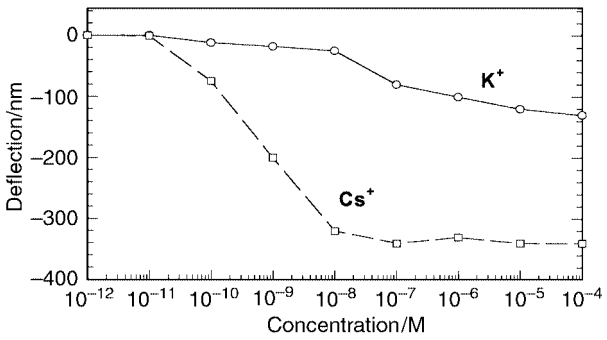

Fig. 2 Bending deflection response of the SAM coated microcantilever as a function of the change in concentration of Cs^+ and K^+ ions. For the *y*-axis, the voltage has been converted to nm using the conversion factor 10.58 mV nm^{-1}.

even at high Cs^+ ion concentration (*e.g.* 10^{-3} M) the bending response was unaffected (same as pure water). Such a finding clearly rules out any contribution to the cantilever bending response by the caesium ions in the absence of receptor molecule, and substantiates the role of molecular recognition agent (receptor) in inducing the observed change in bending response.

The relationship between the cantilever displacement, *z*, and the differential surface stress can be expressed by eqn. (1).

$$z = \left(\frac{3(1-\nu)L^2}{t^2E}\right)\delta s \quad (1)$$

where *L* is the length of the cantilever, *v* is Poisson's ratio, *E* is Young's modulus for the substrate, *t* is the thickness of the cantilever, and δs is the adsorption-induced differential surface stress. Since δs is directly proportional to ion absorption by the microcantilever, eqn. (1) can be re-arranged to eqn. (2) where *b* is a constant, *K* is the complexation constant between the ion receptor and the ions present in solution (1 : 1 stoichiometry), [M] is the concentration of ions in solution, and R_0 is the no of mol of ion receptor present on cantilever before complexation.

$$z = b\left(\frac{3(1-\nu)L^2}{t^2E}\right)\left(\frac{K[\mathrm{M}]R_0}{1+K[\mathrm{M}]}\right) \quad (2)$$

Since the change in concentration of ions present in solution after absorption by the receptor is essentially unchanged in a continuous flow system, the value of [M] will be the same as the initial concentration of ions. The complexation constants determined from the plot of 1/*z vs.* 1/[M] for caesium (K_{Cs}) and potassium (K_K) using eqn. (2) are 2×10^9 M^{-1} and 1.6×10^7 M^{-1}, respectively. These values are much higher (three orders of magnitude) than the corresponding values observed for the derivatives of similar compounds in MeOH–CH_2Cl_2 (1 : 1) solution[12] but the ratio of K_{Cs}/K_K is essentially the same. Similar enhancements in the association constant values for other SAM systems (relative to the free molecule) have also been reported.[14,15] The large value of association constant observed for Cs^+ ions indicates that binding is essentially irreversible. This notion is further supported by our experimental results that showed cycling pure water through the system (to rinse the SAM coated microcantilever containing Cs^+ ions) for several hours failed to regenerate the initial reading (water curve in Fig. 1).

The bending response of the SAM coated microcantilever upon Cs^+, K^+ and Na^+ complexation was also compared for the same concentration of each ion (10^{-5} M). The results indicated that SAM coated microcantilever was much more selective towards Cs^+ ions compared to K^+ and Na^+ ions (not shown). In fact, Na^+ ions have a minimal effect (if any) on the bending response while K^+ ions exhibit enough sensitivity to interfere (as a perturbing ion when present) in the detection of caesium ions.

In summary, our study has shown that the concept of ion-selective-SAM coated cantilever can be applied successfully to detect trace amounts (ppb) of caesium ions (*in situ*) in the presence of high concentrations of interfering potassium ions with remarkable sensitivity. This methodology can be applied to the detection of a wide variety of metal ions of chemical and biological importance. For example, we envision construction of a compact device capable of measuring low levels of metal ions in the blood stream *in situ* using this technique. This concept can be further expanded by constructing a multi-panel array device based on an SAM coated microcantilever for *in situ* detection of different metal ions present in solution or biological fluids. Along these lines, we are currently synthesizing molecular recognition agents containing different size cavities capable of complexing different metal ions.

This research was funded by the Environmental Management Science Program, Office of Environmental Management, US Department of Energy and in part by an appointment sponsored by the Oak Ridge National Laboratory Postdoctoral Research Associates Program administered jointly by the Oak Ridge Institute for Science and Education and Oak Ridge National Laboratory. Oak Ridge National Laboratory is operated by Lockheed Martin Energy Research Corporation for the US Department of Energy under contract number DE-AC05-96OR22464.

Synthesis of optically active amino sugar derivatives using catalytic enantioselective hetero-Diels–Alder reactions

Wei Zhuang, Jacob Thorhauge and Karl Anker Jørgensen*

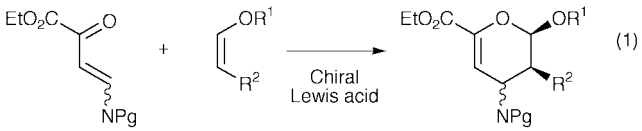
Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark. E-mail: kaj@kemi.aau.dk

Received (in Cambridge, UK) 17th November 1999, Accepted 5th February 2000, Published on the Web, 2nd March 2000

A new synthetic method for the formation of optically active amino sugars using catalytic enantioselective inverse-electron demand hetero-Diels–Alder reactions of γ-amino-protected β,γ-unsaturated α-keto esters with vinyl ethers is presented; the catalytic reactions proceed in good yield with high diastereo- and enantioselectivity and fully control of the stereochemistry at the amino-carbon center.

Sugars containing nitrogen atoms have a variety of different biological activities; they are, *e.g.* among the largest group of carbohydrate mimetics and belong to the strongest known inhibitors of glycosidases found.[1] Furthermore amino sugars are also applied as pharmaceuticals such as for treatment of diabetes[2] and promising drugs against influenza.[3]

The synthesis of optically active amino sugars normally takes its starting point from naturally occurring carbohydrates.[4] or amino acids.[5] A simple and convenient procedure for the formation of optically active amino sugars and their derivatives (**3**) could be the catalytic enantioselective inverse-electron demand hetero-Diels–Alder (HDA) reaction of γ-amino-protected β,γ-unsaturated α-keto esters **1** with vinyl ethers **2** [eqn. (1)]. This approach has previously been used in diastereoselective reactions.[6]



1 **2** **3**

Here, we present the first catalytic enantioselective synthesis of amino sugars **3** by inverse-electron demand HDA reactions using C_2-bisoxazoline-Lewis acid complexes as catalysts.[7,8]† The reaction has been developed for two different protected γ-amino β,γ-unsaturated α-keto esters **1a**, **b** which have the protected γ-amino substituent, *trans* or *cis*, respectively, as these by reaction, *e.g.* ethyl vinyl ether **2a**, will give the two different diastereomers of the optically active amino sugars **3a** and **4a**, respectively [eqn. (2)]. The (*S*)-Bu^t-BOX-Cu(OTf)$_2$ [(*S*)-**5a**] and (*R*)-Ph-BOX-Zn(OTf)$_2$ [(*R*)-**5b**] complexes are found to be good catalysts for the reaction among different C_2-bisoxazoline–Lewis acid complexes tested.

Table 1 Reaction of γ-amino-protected β,γ-unsaturated α-keto esters **1a**, **b** with ethyl vinyl ether **2a** in the presence of (*S*)-Bu^t-BOX-Cu(OTf)$_2$ [(*R*)-**5a**] and (*R*)-Ph-BOX-Zn(OTf)$_2$ [(*S*)-**5b**] at room temperature (r.t.)

Entry	Substrate	Cat./mol%	Yield[a] (%)	*endo*-de[b] (%)	Ee[c] (%)
1	**1a**	(*S*)-**5a**/10[e]	**3a**/98	88	98
2	**1a**	(*S*)-**5a**/5[e]	**3a**/67	95	> 99
3	**1a**	(*S*)-**5a**/10[e,f]	**3a**/94	90	> 99
4	**1a**	(*S*)-**5a**/10[g]	**3a**/82	29	99
5	**1b**	(*S*)-**5a**/10[g]	**4a**/96	74	94[d]
6	**1b**	(*R*)-**5b**/10[e]	**4a**/99	70	70[d]

[a] Isolated yield. [b] Diastereomeric excess measured by ^{1}H NMR. [c] Enantiomeric excess measured by chiral HPLC using a Daicel Chiralpak OJ column. [d] Enantiomeric excess measured by chiral GC using a Chrompack ChiralsilDex CB column. [e] Et_2O as solvent. [f] Reaction temperature 0 °C [g] THF as solvent.

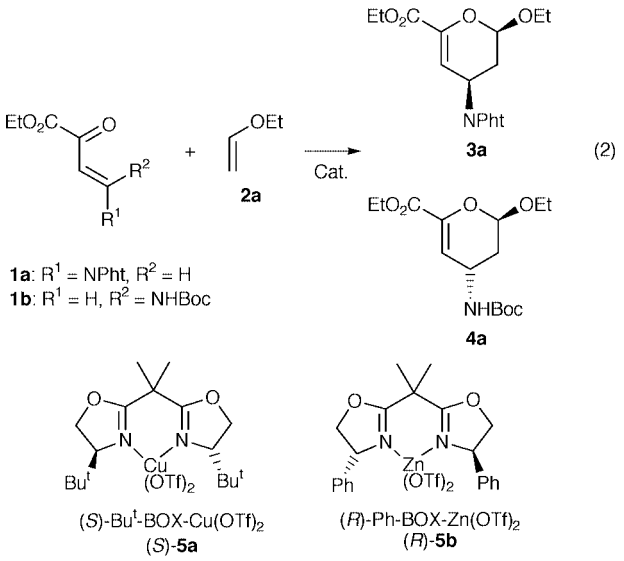


Table 1 presents some results obtained for the reaction of **1a**, **b** with **2a**. It appears that the γ-amino-protected β,γ-unsaturated α-keto esters **1a**, **b** react with ethyl vinyl ether **2a** in the presence of the (*S*)-**5a** catalyst giving the protected amino sugars **3a** and **4a**, respectively, in high yield, diastereo (de) and enantiomeric excess (ee) at room temperature. The reaction of **1a** with **2a** can proceed with 5 mol% of the catalyst with very high diastereoselectivity giving only one detectable enantiomer by chiral HPLC of **3a** (entry 2). The reaction can take place in several solvents and high yield, de and ee are obtained in, *e.g.* Et_2O and THF (entries 1, 4). However, it is notable that the de is reduced when THF is the solvent compared with Et_2O, and that the reaction performed in CH_2Cl_2 gives the *exo*-diastereomer as the major diastereomer (de_{exo} 43% and with 90% ee_{exo}). The reaction of **1b** leads to the other diastereomer of the protected amino sugar (**4a**) and this reaction proceeds also with high yield, de and ee using (*S*)-**5a** as the catalyst and **4a** is obtained in 96% yield, 74% de and 94% ee (entry 5). The yield of **4a** is slightly improved in the presence of (*R*)-**5b** as the catalyst, while the de is the same and the ee is reduced compared to (*S*)-**5a** as the catalyst (entry 6). The absolute configuration of a related series of compounds has been determined previously.[8e]

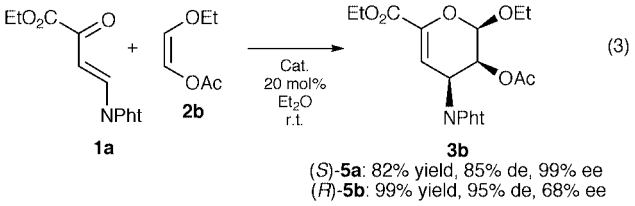
The application of this catalytic enantioselective approach for the preparation of various types of different amino sugar derivatives is shown in the following equations. In eqn. (3) the reaction of **1a** with *cis*-1-acetoxy-2-ethoxyethene **2b** in the presence of (*S*)-**5a** and (*R*)-**5b** as the catalysts is presented. The reaction proceeds in a highly regio-, diastereo- and enantioselective manner giving **3b** in 82% yield, 85% de and 99% ee when (*S*)-**5a** is the catalyst and an improvement in yield, and reduction in ee when (*R*)-**5b** is the catalyst. The reaction in eqn. (3) shows that it is possible to introduce two different

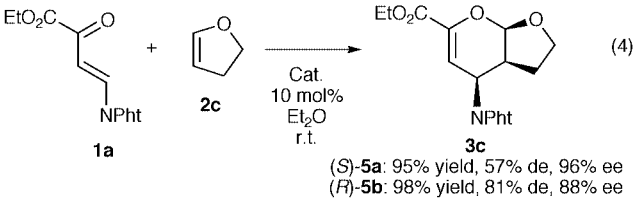
DOI: 10.1039/a909115g



(3)

protected hydroxy functionalities in the amino sugar fragment by this reaction.

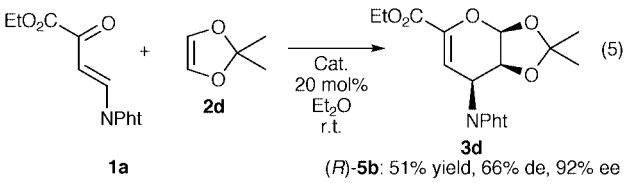
The results for the reaction of **1a** with 2,3-dihydrofuran **2c** is presented in eqn. (4). Both catalysts give good yield of the



(4)

amino sugar **3c**; the (*S*)-**5a** catalyst gives the highest ee (96%) of the major diastereomer, formed with a de of 57%, while (*R*)-**5b** leads to the highest de (81%), and with only a slight reduction to 88% ee. It is notable that the same enantiomer of **3b** and **3c** in eqns. (3) and (4) are obtained using the (*S*)-**5a** and (*R*)-**5b** catalysts.

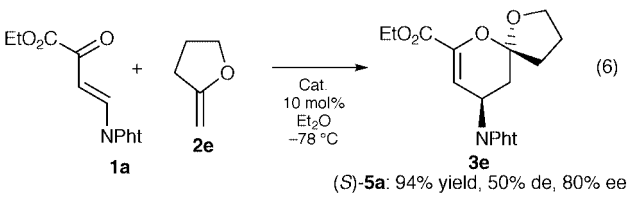
The catalytic enantioselective reaction of the activated cyclic alkene **2d** with **1a** gives **3d** in moderate yield (51%) and de (66%), and with high ee (92%) [eqn. (5)]. The highest yield of



(5)

3d is obtained with the chiral zinc(II) catalyst (*R*)-**5b**, while catalyst (*S*)-**5a** only gives 12% isolated yield of **3d**, but formed in a highly enantioselective manner as 97% ee is obtained.

The catalytic enantioselective HDA reaction can also be used for the preparation of optically active spiro-amino sugars. The spiroacetal functionality is found in natural products such as pheromones, steroidal compounds, anti-parasitic agents and polyether antibiotics[9] and eqn. (6) shows how the reaction of



(6)

1a with the exo-cyclic vinyl ether **2e** catalyzed by (*S*)-**5a** leads to high yield, de and ee of the spiro-amino sugar **3e**.

The present work has shown a new development in catalytic enantioselective HDA reactions for the preparation of optically active amino sugars. It is demonstrated that the approach can be used for the synthesis of a series of different types of protected amino sugars in good yield with control of both the diastereo- and enantioselectivity. The new synthetic procedure introduces a new approach for the formation important amino sugars from simple substrates. Furthermore, can the products obtained also be considered as cyclic γ-amino acid esters. Further work is in progress in developing optically active highly functionalized molecules using this approach.

Stable single-wall carbon nanotube (SWCNT) colloids in polar solvents, such as water, ethanol, acetone and DMF, have been prepared and the third-order optical nonlinearity of the SWCNTs measured using the femtosecond optical Kerr effect.

Owing to their novel structural, electronic and mechanical properties, single-wall carbon nanotubes (SWNTs) are likely to possess many potential applications.[1,2] However, it is difficult to study their chemical behavior and properties because of their insolubility in solvents. Chen *et al*.[3,4] obtained an SWCNT derivative which was soluble in organic solvents obtained from shortened SWCNTs[5] and studied the solution-phase EPR of such SWCNTs.[6] Liu *et al*.[7] successfully deposited individual short SWCNT segments on chemically functionalized nanolithographic templates from a 0.1 mg ml^{-1} carboxylated SWCNT suspension of DMF. Here, we report the preparation of stable SWCNT colloids by dispersing carboxylated SWCNTs in several polar solvents, which will facilitate the study of chemical properties and the engineering of electronic devices based upon SWCNTs. The third-order optical nonlinearity of colloidal SWCNTs in DMF was measured. The high third-order optical nonlinearity susceptibility obtained indicate potential applications of SWCNTs in optical information processes.

SWCNTs were produced by the dc arc-discharge method[8] and purified to > 90%.[9] The SWCNTs had a diameter of *ca*. 1.3 nm and existed as SWCNT bundles both in the raw-soot and purified samples. The SWCNT bundles had a diameter of 20–30 nm in the raw-soot and 50–60 nm in the purified sample with lengths of > 10 μm.[9] The preparation of aqueous colloids was carried out by dissolving 100 mg purified SWCNTs in 120 ml 98% H_2SO_4–70% HNO_3 (3 : 1) and subjecting to ultrasonication for 8 h. The obtained solution was diluted with deionized water to 500 ml and left to stand over night. After decanting the solution, 50 ml of deionized water was added to the residue which was allowed to stand for one day. After discarding the supernatant, 25 ml of deionized water was added to the residue to form a colloidal solution of SWCNTs in water. The pH value of the colloidal solution was *ca*. 3 for a concentration of 1.77 mg ml^{-1}. The colloid solution remained very stable for > 1 year.

In order to remove the residual acids, the colloid solution was passed through a PTFE membrane disc Filter (Gelman, 1 μm pore size) under vacuum followed by washing several times with deionized water. The SWCNTs on the membrane disc were readily dispersed in water, ethanol, acetone and DMF after ultrasonication for a few minutes to form black colloids in the absence of surfactants. The saturated concentration of SWCNTs in water, ethanol, acetone and DMF were 1.16, 0.5, 1.06 and 2.0 mg ml^{-1}, respectively, and the pH value of the colloid solution of SWCNTs in water was 5.5.

In our experiments, the saturated concentration of SWCNTs in water largely depended on the acidity of the solution. At pH < 1.5, SWCNTs in water precipitate in 1 or 2 h after standing while pH at 2.4, 1.97 mg SWCNTs can be dispersed in 1 ml of water to form a stable colloid. At a pH of 5.5 the saturated concentration of SWCNTs is reduced to 1.16 mg ml^{-1}. Thus, the pH range 2–3 is favorable for the formation and existence of stable colloids of SWCNTs in water.

The observation of stable colloids suggests the presence of carboxylic groups at open ends of the SWCNTs, which was verified by the characteristic stretching band ($\nu_{C=O}$) at 1710 cm^{-1} in the FTIR spectrum.[4] The structure of the SWCNTs was established by Raman spectroscopy. As shown in Fig. 1, no obvious change occurs in the Raman spectra of SWCNTs before or after treatment with mixed acids except for a decreasing peak ratio G : D, which implied that the SWCNTs were shortened after acid treatment. Compared to Liu's results for relatively longer nanotubes,[5] it can be anticipiated that SWCNTs should exist in a non-aggregated state in the various colloid solutions.

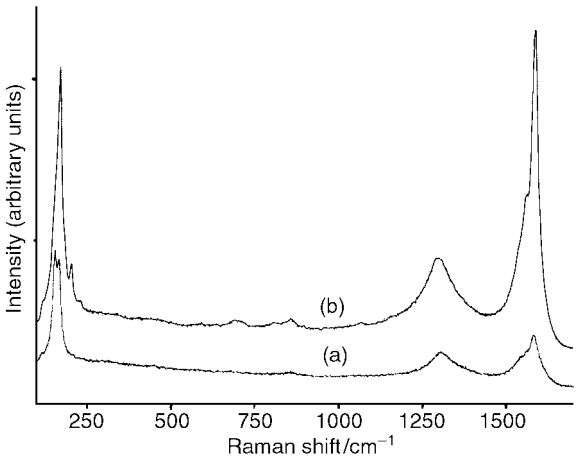

Fig. 1 Raman spectra of purified (b) and carboxylated (a) SWCNTs at 783 nm.

The tube length distribution of SWCNTs in solvents can be approximately estimated by the hydrodynamic radius *via* laser-scattering characterization. SWCNTs in water have a hydrodynamic radius in the range 23–300 nm with a mean of 81.1 nm (Fig. 2). In other words, the length of the SWCNTs ranges from 50 to 600 nm with a mean of *ca*. 160 nm. The length distribution is shorter than that reported by Liu *et al*.[5]

The successful preparation of the colloids made it possible to measure the third-order optical nonlinearity of the SWCNTs. Nonlinear optics (NLO) measurements were performed using the femtosecond optical Kerr technique[10] with a Ti:sapphire laser (Mira 900F, Coherent Co. Ltd., USA). The operating wavelength was centered at 820 nm, where the sample shows no absorption. In our experiments, three SWCNTs colloid solutions of 0.33, 0.22 or 0.13 mg ml^{-1}, in DMF were used and the sample cell thickness was 1 mm. The zero delay point was determined with a BBO crystal (0.3 mm thick) and the pulse duration was set at 120 fs.

The ultrafast NLO response of the SWCNT colloids is shown in Fig. 3 together with that for the reference sample of CS_2 under the same conditions. The instantaneous response proves that the NLO signal is attributed to conjugated π-electrons. The

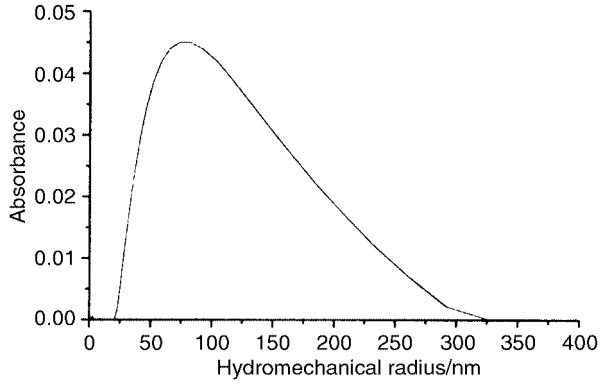

Fig. 2 Hydrodynamic radius distribution of an aqueous colloid of SWCNT measured using 514.5 nm laser-scattering.

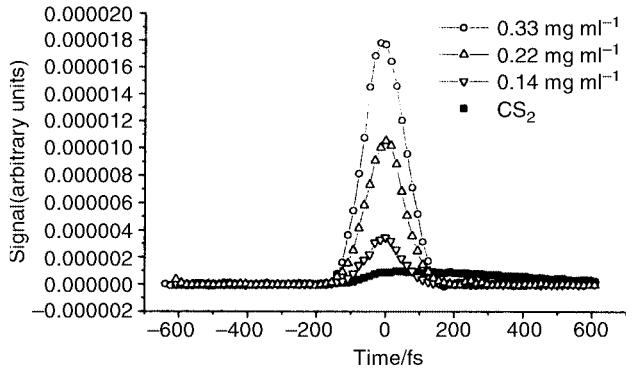

Fig. 3 Ultrafast OKE signals of SWCNT colloids in DMF together with a reference sample of CS_2.

signal caused by colloids at different concentrations indicates a square dependence of the signal on the concentration. The third-order optical nonlinearity susceptibility, $\chi^{(3)}$, of the colloid at a given concentration can be calculated[11] and a value of 4×10^{-13} esu was obtained for the 0.33 mg ml^{-1} SWCNT colloid in DMF. In this measurement, the contribution of DMF (*ca.* 1×10^{-14} esu) is reasonably neglected as the $\chi^{(3)}$ value for DMF is nearly ten times smaller than that of CS_2[12] (1×10^{-13} esu).[13] Furthermore, the magnitude of the second-order hyperpolarizabilities, γ_c, for each carbon atom can be calculated as 7.7×10^{-33} esu, which is much higher than those of C_{60} and multiwall carbon nanotubes,[14] and close to the value expected from theoretical calculation.[15] This is a remarkably large non-resonant and instantaneous NLO response for π-conjugated molecules, which indicates that SCWNTs may be useful as nonlinear optical materials.

In conclusion, stable SWCNTs colloid solutions in polar solvents, such as water, ethanol, acetone and DMF, have been prepared with purified SWCNTs and using a sulfuric acid–nitric acid mixture. This opens the possibility for template assembly or functionalization of SWCNTs in polar solvents. For colloids of SWCNTs in DMF, the third-order optical non-linearity of SWCNTs was measured and a large nonresonant and instantaneous NLO response was obtained, indicating the potential applications of SWCNTs in optical information process.

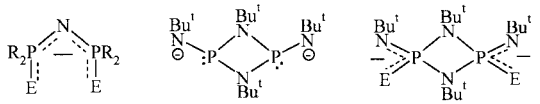
Received (in Cambridge, UK), 13th January 2000, Accepted 28th January 2000, Published on the Web, 2nd March 2000

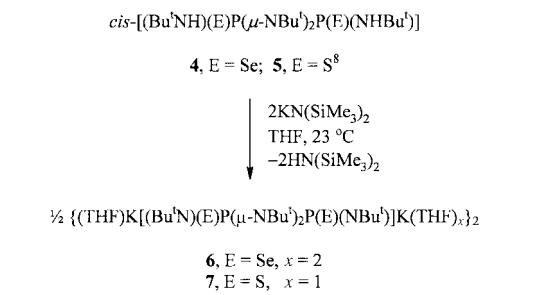
The partially THF-solvated dipotassium salt of the novel bis-chelating dianion $[Bu^tN(Se)P(\mu\text{-}NBu^t)_2P(Se)NBu^t]^{2-}$ forms an infinite network of twenty-membered $K_6Se_6P_4N_4$ rings involving two types of K···Se interactions.

The coordination chemistry of monoanions of the type $[R_2P(E)NP(E)R_2]^-$ **1** is a very active area of investigation.[1] The interest in metal complexes of these acetylacetonate analogues includes their use in catalysis[2] or as lanthanide shift reagents,[3] as well as the stabilization of unusual geometries at main group metal centres.[4] The dianionic bis(amido) P(III) ligand **2** has also been studied recently for possible applications in catalysis[5] and as a ligand for main group metals.[6] Bischalcogenido derivatives of **2** are unknown. Such dianionic P(V) ligands **3** would be especially interesting in view of the possibility of (a) selective chelation of different metals *via* S,S′ or Se,Se′ (soft) and N,N′ (hard) centres or (b) generation of metal-containing polymers *via* bis-chelation. Here, we describe the synthesis and X-ray structures of the first alkali metal derivatives of **3a** and **3b**.



1 (E = O, S, Se) **2** **3a**, E = Se; **3b**, E = S

The dianions **3a** and **3b** are obtained as their dipotassium salts **6** and **7** in good yields *via* the deprotonation reaction depicted in Scheme 1.† The ^1H and ^{13}P $\{^1H\}$ NMR spectra of **6** and **7** are consistent with symmetrical bis-chelation of the dianions to two K^+ ions, but these spectroscopic data do not distinguish between two possible bonding modes: (a) bis-(N,E) chelation or (b) N,N′ and E,E′ chelation. The ^{31}P $\{^1H\}$ NMR spectrum of the diprotonated precursor **4** shows two pairs of ^{77}Se satellites attributable to the AA′X spin system of the isotopomer containing one ^{77}Se ($I = \frac{1}{2}$, 7.6%) atom.†[7] The value of $^1J(^{31}P–^{77}Se)$ is reduced from 880 to 684 Hz upon deprotonation consistent with a decrease in P–Se bond order (*cf.* 786 and 687 Hz for $Ph_2P(Se)NHP(Se)Ph_2$ and its K^+ salt).[7] The A–A′ $[^2J(^{31}P–^{31}P)]$ coupling is 25 Hz in **4**, but it is unresolved for **6**. A reliable estimate of the number of THF ligands per K^+ ion by integration of the ^1H NMR spectra of **6** and **7** could not be obtained owing to the facile loss of THF from the crystals.



cis-$[(Bu^tNH)(E)P(\mu\text{-}NBu^t)_2P(E)(NHBu^t)]$

4, E = Se; **5**, E = S[8]

↓ $2KN(SiMe_3)_2$, THF, 23 °C, $-2HN(SiMe_3)_2$

7, E = S, $x = 1$

Scheme 1

The X-ray structural analysis of **6** (Fig. 1)‡ reveals that bis-chelation occurs at the 'top' and 'bottom' of the dianion (Se,Se′ and N,N′) in preference to 'side-on' bis(N,Se) chelation. Presumably the formation of six-membered KNPNPN and KSePNPSe rings is preferred over the known four-membered KNPSe ring[9] for the relatively large K^+ ion. The mean K–Se distance in the monomeric unit is 3.312 Å, *cf.* 3.377 Å for $(K[Ph_2P(Se)NSiMe_3]\cdot THF)_2$.[9] Fig. 2 shows that dimerization occurs *via* two K···Se interactions (3.418(3) Å) to give a central K_2Se_2 ring as observed for $(K[Ph_2P(Se)NSiMe_3]\cdot THF)_2$.[9] For **6**, however, the K^+ ions involved in these four-membered rings are bis-solvated (five-coordinate). The X-ray crystal structure of the sulfur analogue **7** is similar to that of **6** except that both K^+ ions are monosolvated.[10] The dimeric units in **6** associate further *via* weak···Se interactions (3.644(3) Å) involving the monosolvated K^+ ions and the two-coordinate Se atoms to give an extended structure. Extended ladder structures involving K···E interactions have been reported previously for the unsolvated complexes $K[Ph_2P(E)NP(E)Ph_2]$ (E = S,[11a] Se[11b]). For **6** the

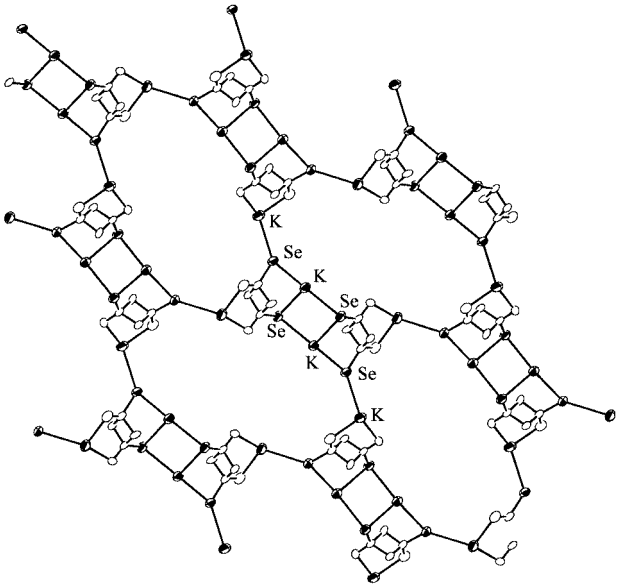

Fig. 2 The extended structure of **6** showing the two types of K···Se interactions. For clarity Bu^t groups and THF are omitted.

presence of two K^+ ions per monomeric building block allows the formation of an extended network of twenty-membered ($K_6Se_6P_4N_4$) rings (Fig. 2). The sulfur analogue **7** forms a similar extended structure.[10] By contrast, we note that the sodium salt of **3a**, $(THF)_2Na[Bu^tN(Se)P(\mu\text{-}NBu^t)_2P(Se)(NBu^t)]Na(THF)_2$ **8**, in which *both* Na^+ ions are bis-solvated, has a monomeric structure similar to that depicted in Fig. 1.[10] The ^{31}P {^1H} NMR parameters for **8** in d_8-THF are δ +3.9, $^1J(^{31}P–^{77}Se)$ = 678 Hz and $^2J(^{31}P–^{31}P)$ = 6.1 Hz.

Investigations of the formation of metal-containing coordination polymers involving the novel bis-chelating dianions **3a** and **3b** are in progress. Details of the structural characterization of **7** and **8** will be provided in the full account of this work.

We thank the NSERC (Canada) for financial support.

† *Synthesis* of **6**: *cis*-[(Bu^{t}NH)(Se)P(μ-NBu^t)$_2$P(Se)(NHBu^t)] **4** was obtained in *ca.* 80% yield from the reaction of [(Bu^{t}NH)P(μ-NBu^t)P(NHBu^t)] with elemental selenium in boiling toluene for 18 h. NMR (d_8-THF): ^1H, δ 4.56 (s, 2H, NH), 1.68 (s, 18H, Bu^t), 1.46 (s, 18H, Bu^t); ^{31}P {^1H}, δ 26.7 (s, $^1J(^{31}P–^{77}Se)$ 880, $^2J(^{31}P–^{31}P)$ 25 Hz; ^{77}Se, δ −128.4 (d, $J(^{31}P–^{77}Se)$ 877 Hz). IR (cm^{-1}): 3383 [ν(N–H)], 581 [ν(PSe)].

A solution of $KN(SiMe_3)_2$ (1.66 g, 7.90 mmol) in THF (10 mL) was added slowly to a stirred solution of **4** (2.00 g, 3.95 mmol) in THF at 23 °C. After 2 h solvent was removed under vacuum and the product was washed with hexane (2 × 10 mL) to give **6** (2.07 g, 2.59 mmol) as a yellow powder. X-Ray quality crystals were obtained from THF–hexane (1 : 1) solution at 23 °C. NMR (d_8-THF): ^1H, δ 3.58 (m, OCH_2CH_2), 1.74 (m, OCH_2CH_2), 1.66 (s, 18H, Bu^t), 1.33 (s, 18H, Bu^t); ^{31}P {^1H}, δ −0.03 (s, $^1J(^{31}P–^{77}Se)$ 686 Hz); ^{77}Se, δ 13.2 (d, $J(^{31}P–^{77}Se)$ 684 Hz). IR (cm^{-1}): 514 [ν(PSe)].

Synthesis of **7**: complex **7** was obtained in 81% yield as a yellow powder from $KN(SiMe_3)_2$ (5.00 mmol) and **5**[7] (2.50 mmol) in THF (20 mL) by a procedure similar to that described above for **6**. NMR (d_8-THF): ^1H, δ 3.58 (m, OCH_2CH_2), 1.75 (m, OCH_2CH_2), 1.60 (s, 18H, Bu^t), 1.31 (s, 18H, Bu^t); ^{31}P {^1H}, δ 26.6 (s), IR (cm^{-1}): 551 [ν(PS)].

‡ *Crystal data* for **6**: $C_{28}H_{60}N_4K_2O_3P_2Se_2$, M = 798.87, monoclinic, space group $P2_1/n$ (no. 14), a = 10.733(11), b = 14.085(10), c = 26.138(9) Å, β = 90.99(5)°, V = 3951(5) Å^3, Z = 4, D_c = 1.343 g cm^{-3}, μ(Mo-Kα) = 21.94 cm^{-1}. Crystal dimensions 0.50 × 0.30 × 0.20 mm. Data were measured on a Rigaku AFC6S diffractometer with graphite-monochromated Mo-Kα radiation using ω scans. The structure was solved by direct methods and refined anisotropically using data that were corrected for absorption. Three carbon atoms of a THF molecule (C18, C19 and C20) had large thermal displacement parameters. 2135 of the 6958 unique reflections has $I \geqslant 2.00\sigma(I)$. The final agreement factors were R = 0.0640, R_w = 0.1652.

The synthesis of (+)-nemorensic acid

Timothy J. Donohoe,*[a] Jean-Baptiste Guillermin,[a] Christopher Frampton[b]† and Daryl S. Walter[b]

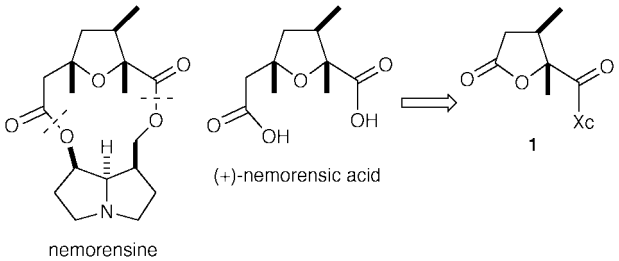
Received (in Liverpool, UK) 19th January 2000, Accepted 8th February 2000, Published on the Web, 2nd March 2000

The synthesis of (+)-nemorensic acid in nine steps is described; key steps in the route were the stereoselective Birch reduction of a substituted furan, and addition of allyltrimethylsilane to an oxonium ion at C-5; an X-ray crystal structure of (−)-nemorensic acid provided proof of the relative stereochemistry of the target.

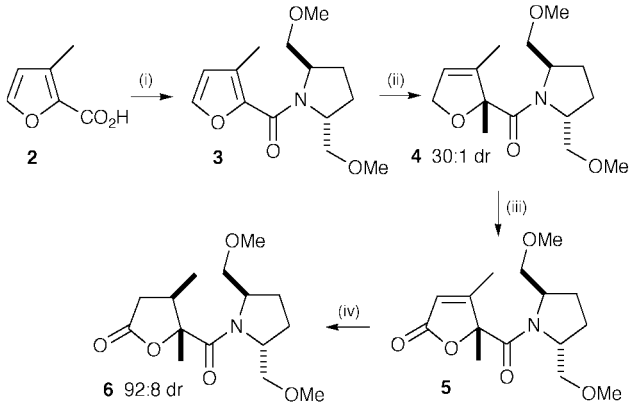
We have recently initiated a research programme aimed at synthesising the pyrrolizidine alkaloids.[1] These alkaloids are a diverse series of compounds, isolated from the *Senecio* family of plants, which display a wide range of biological activities such as hepatotoxicity and carcinogenic activity; some of these alkaloids have the ability to cross-link DNA at specific points.[2] In particular we were drawn to pyrrolizidine alkaloids containing a macrocyclic bislactone. Hydrolysis of these bislactone alkaloids yields a diol (necine base) and a diacid (necic acid). While the synthesis of necine bases is well established, the necic acid moiety has received relatively little attention; indeed it is variation in this part of the molecule that is responsible for much of the diversity of these plant alkaloids. We now report our studies on the synthesis of nemorensic acid, which is obtained from hydrolysis of nemorensine (Scheme 1).[3] A survey of the literature reveals that nemorensic acid has been synthesised by the groups of Klein (±),[4] White (+),[5] Mascareñas (±)[6] and Honda (+).[7] Our retrosynthetic analysis of nemorensic acid identified the lactone **1** as a viable precursor for the target; we know from previous studies that **1** can be prepared from the commercially available 3-methyl-2-furoic acid *via* a Birch reduction on a chiral auxiliary (Xc) laden furan.[8]

Our synthesis began with **2**, which was coupled to (*R*,*R*)-(−)-bismethoxymethylpyrrolidine in excellent yield. We have already reported that the reductive methylation of **3** proceeds in high yield and with ⩾30:1 diastereoselectivity.[8] Subsequent Jones (allylic) oxidation gave **5** and hydrogenation with palladium provided **6** in good overall yield, and with high selectivity for the isomer shown (Scheme 2).[9]

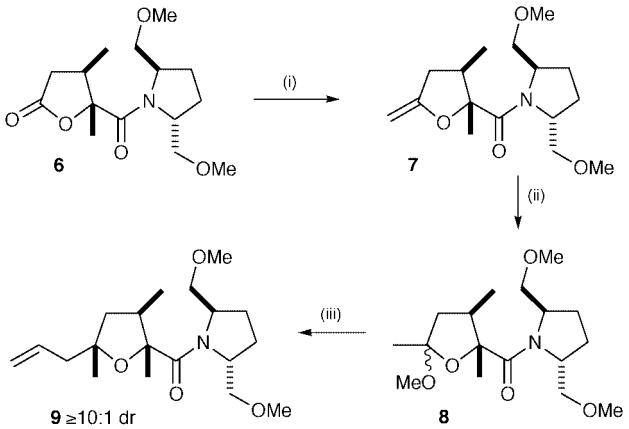
The lactone **6** (structure proven by X-ray crystallography) was treated with 'Cp_2TiMe_2' which was freshly prepared from Cp_2TiCl_2 and MeLi, according to Petasis (Scheme 3).[10] The resulting enol ether **7** was rather sensitive to hydrolysis and was, therefore, converted immediately into the acetal **8** (1:1 mixture of epimers) with acidic methanol (72% overall yield). Introduction of carbon functionality at C-5 was accomplished by



Scheme 1



Scheme 2 *Reagents and conditions*: i, $SOCl_2$, then (*R*,*R*)-bismethoxymethylpyrrolidine, NaOH, 95%; ii, Na, NH_3, THF, −78 °C then MeI, 93%; iii, CrO_3, H_2SO_4, 89%; iv, H_2, Pd-C, EtOH, AcOH, 87% (pure *cis*).



Scheme 3 *Reagents and conditions*: i, Cp_2TiCl_2, MeLi; ii, MeOH, HCl, 72% (two steps); iii, allyltrimethylsilane, $TiCl_4$, CH_2Cl_2, −78 °C, 79%.

reaction of the epimeric mixture of acetals with titanium tetrachloride and allyltrimethylsilane. The allylated compound **9** that resulted from this reaction was formed as a single diastereoisomer according to ^1H NMR analysis of the crude reaction mixture. We could assign the stereochemistry of the product with the aid of NOE experiments which showed a strong (and reciprocal) enhancement between the allylic methylene protons and the (*cis*) methine proton at C-3 (Fig. 1).

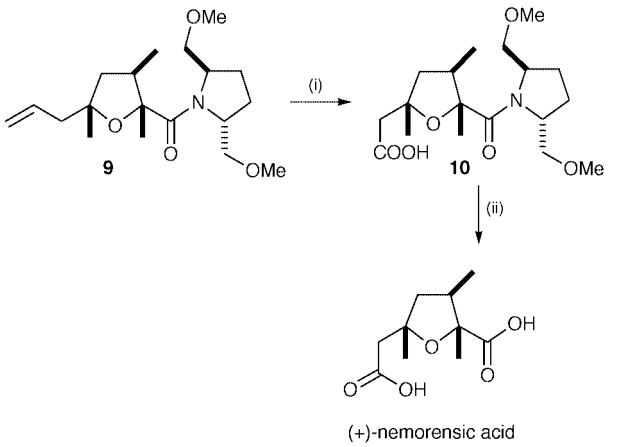
DOI: 10.1039/b000565g



Scheme 4 *Reagents and conditions*: i, $RuCl_3$ (cat.) $NaIO_4$; ii, 6 M HCl, Δ, 65% (two steps).

The sense of diastereoselectivity displayed during the allylsilane addition to acetal **8** is interesting and is consistent with a recent observation by Woerpel *et al.* on related systems.[11] According to this model, geminal substitution at C-2 is crucial for high levels of selectivity, and the main reason for addition to the lower face of the oxonium ion derived from **8** is steric interaction with the pseudoaxial methyl group at C-2 (Fig. 1).

The synthesis was completed by oxidative cleavage of the alkene unit with catalytic ruthenium tetroxide; the acid **10** was immediately treated with aqueous acid to cleave the auxiliary and liberate nemorensic acid, (65% yield from **9**) (Scheme 4). The relative stereochemistry of the product was confirmed by X-ray crystallographic analysis (Fig. 2).‡

Nemorensic acid produced by this sequence had spectroscopic data (^1H, ^{13}C NMR) that were identical with those reported in the literature. Its melting point was 171–173 °C (lit.[3] 174–177 °C) and its optical rotation was $[\alpha]_D$ +84 (*c* 0.18, EtOH) (lit.[3] $[\alpha]_D$ +87 (*c* 0.84, EtOH)).

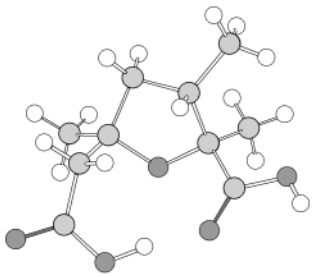


Fig. 2 Nemorensic acid.

To conclude, we have prepared (+)-nemorensic acid in nine steps and 25% overall yield using the Birch reduction of furan as the key step. This synthesis is particularly efficient and is amenable to the preparation of ample amounts of material.

We thank the EPSRC and Roche Pharmaceuticals for financial support. Clare Stevenson is thanked for some preliminary experiments.

High isolated yields in thermodynamically controlled peptide synthesis in toluene catalysed by thermolysin adsorbed on Celite R-640

Alessandra Basso, Luigi De Martin, Cynthia Ebert, Lucia Gardossi* and Paolo Linda

Dipartimento di Scienze Farmaceutiche, Università degli Studi, Piazzale Europa 1, 34127 Trieste, Italy. E-mail: gardossi@univ.trieste.it

Received (in Liverpool, UK) 27th January 2000, Accepted 14th February 2000, Published on the Web, 2nd March 2000

An innovative immobilisation method that allows peptide synthesis to be performed even at equimolar concentrations, by controlling water activity, is reported.

Enzymes have proved to be an attractive alternative to chemical methods in peptide synthesis since several proteases effect peptide bond formation under mild conditions, with minimum side-chain protection, and avoiding racemization. In spite of these benefits, enzymatic methods are not routinely employed, partly because they suffer from unfavourable thermodynamics in water.

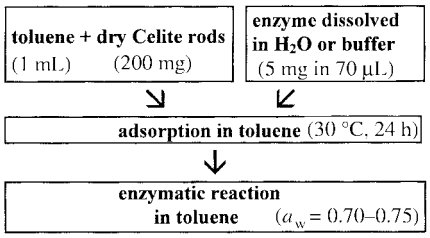
There are two distinct mechanisms for protease-catalysed peptide synthesis: thermodynamically and kinetically controlled synthesis. In principle, replacing water with organic solvents as a reaction medium should be beneficial for both types of reaction. However, water is essential for proteases such as thermolysin and α-chymotrypsin, and various studies confirmed that these enzymes display no activity when insufficiently hydrated.[1] Unfortunately, water/solvent mixtures are not optimal media for peptidases since high percentages of co-solvents reduce the activity of the enzyme dramatically.

Owing to these two opposite roles of water in enzymatic peptide synthesis, various approaches have been developed in order to search for compromises. These include kinetically controlled syntheses in solvents containing low percentages of water [2] or methods to reverse the equilibrium towards synthesis, such as using an excess of the amino component and extracting/precipitating the product.[3]

Kitaguchi and Klibanov[1a] have given an alternative solution to the problem by demonstrating that water can be replaced partially by water mimics such as formamide, maintaining the activity of the enzyme in the organic solvent while minimising hydrolytic reactions. Finally, promising results have been obtained by Halling and coworkers by controlling the hydration of thermolysin in kinetically controlled peptide synthesis in hexane[4] and, more recently, by developing solid-to-solid peptide synthesis in the presence of minimum amounts of water.[1b]

Aiming to overcome the above drawbacks to a larger application of enzymes in peptide synthesis, the present work describes a novel approach for the non-covalent immobilisation of thermolysin in toluene and its application to thermodynamically controlled peptide synthesis at controlled water activity (a_w). The method exploits the ability of Celite R-640 rods (Fluka) to adsorb large amounts of water (> 90% of its weight) and to maintain the a_w constant in a reaction system within wide defined ranges of water concentrations.[5,6] Thermolysin was adsorbed on dry Celite R-640 according to an innovative and practical technique illustrated in Scheme 1. The enzymatic aqueous solution was added to the hydrophobic solvent containing the dry support. Owing to the presence of the hydrophobic solvent, a uniform coating of the aqueous phase formed around the Celite rods and the enzymatic solution was adsorbed on the Celite within 24 h.

The immobilised catalyst suspended in toluene gave, after equilibration, a_w values between 0.70 and 0.75. Enzymatic reactions can be carried out simply by adding the reactants to the toluene used for the adsorption and storage of the enzymes. The use of the hydrophobic organic solvent makes the leakage of the enzyme negligible so that the biocatalyst can be recycled. The hydrophobic solvent leads to further remarkable advantages in terms of stability, especially if compared to the detrimental effects of the water miscible solvents largely reported.[7] For instance, the hydrolases immobilised on Celite R-640 in toluene were stored in the same solvent at a controlled degree of hydration without any appreciable decrease of activity for at least 4 weeks. The same immobilisation technique can also be employed for the immobilisation of α-chymotrypsin and penicillin G amidase (PGA), which were shown to be effective in catalysing amino acid esterification and protection of amino groups, respectively. Table 1 reports some examples of syntheses catalysed by the three immobilised enzymes in toluene at controlled a_w. The water adsorbed by the porous support provides the enzymes with the hydration necessary to display their catalytic activity.[2–4] It should be noted that no reaction was observed when the three native enzymes were employed in dry toluene or acetonitrile in accordance with our observation that PGA is also active in organic solvents only when sufficiently hydrated (a_w > 0.4).[5]



Scheme 1

Table 1 Enzymatic synthesis performed in toluene at a_w between 0.70 and 0.75 at 30 °C

Enzyme[a]	CO_2H donor[b]	Nucleophile[b]	Final conversion[c] (%)	*t*/h
Thermolysin/Celite	Z-L-Phe–CO_2H	L-Phe–OEt	98	48
Thermolysin/Celite	Z-L-Phe–CO_2H	L-Tyr–OEt	97	144
Thermolysin[d]/Celite	Z-L-Phe–CO_2H	L-Leu–NH_2[d]	95	96
PGA[e]/Celite	$PhCH_2CO_2Me$	L-Tyr–OEt	98	24
α-Chymotrypsin[e]/Celite	Z-L-Phe–CO_2H	MeOH	97	60

[a] Enzyme dissolved in buffer and adsorbed on 200 mg of Celite rods according to Scheme 1. [b] Equimolar concentrations of reactants (80 μmol) were employed in all reactions. An excess of MeOH (250 μmol) was used only in the esterification of Z-L-Phe-CO_2H. [c] Conversions calculated by means of RP-HPLC using an internal standard. Isolated yields of Z-L-Phe-L-Phe–OEt, Z-L-Phe-L-Tyr–OEt and Z-L-Phe-L-Leu–NH_2 were 93, 90 and 76%, respectively. Reactions catalysed by α-chymotrypsin and thermolysin were monitored also by titrating the Z-L-Phe–CO_2H with 0.1 M NaOH solution. [d] The enzyme was dissolved in 35 μL of buffer, adsorbed on the Celite rods and equilibrated for 24 h. Afterwards, a buffer solution (35 μL) containing L-Leu–NH_2 was added to the thermolysin/Celite system and equilibrated for 3 h. [e] The enzyme was dissolved in water before adsorption.

DOI: 10.1039/b000797h

The use of Celite R-640 as a support for thermolysin and α-chymotrypsin enables peptide bond synthesis and esterification to be performed using free carboxylic acids since the water produced during the reaction is adsorbed by the Celite rods. Therefore a_w was maintained sufficiently low and hydrolytic reactions were prevented so that nearly quantitative conversions were achieved even when employing equimolar concentrations of non-activated, and thus less expensive, substrates. It must be noted that when native thermolysin was employed in water–acetonitrile (13% v/v)† in the synthesis of Z-L-Phe-L-Tyr–OEt, a maximum of 22% of conversion was obtained in 6 h but during the reaction course a_w exceeded 0.90 so that hydrolytic reactions prevailed, causing a very low final conversion (11%).

Despite the fact that the poor solubility of peptides has often been viewed as a restriction for enzymatic reactions in organic solvents, results in Table 1 indicate that thermodynamically controlled peptide enzymatic synthesis in hydrophobic solvents can be carried out employing substrates having very low solubility and which are present in the reaction medium mainly as a suspension. This observation is in accord with previous studies concerning kinetically controlled peptide synthesis[4] and the solid-to-solid synthesis.[1b,c]

The dipeptide Z-L-Phe-L-Leu–NH_2 was synthesised following an alternative strategy since the poorly soluble L-Leu–NH_2 was previously dissolved in an aqueous buffer and then adsorbed on the Celite rods where thermolysin had been already immobilised. However, this second method led to lower isolated yields (76%) probably owing to some adsorption of the product on the Celite rods.

The time required to achieve complete conversion is mainly affected by the fact that equimolar concentrations of the reactants were used in all peptide synthesis, so that the reaction rate slows down dramatically at the end of the reaction when the concentrations of the two reactants become extremely low. Complete conversions are achievable in shorter times using a two fold excess of the amino component (> 98% yield of Z-L-Phe-L-Tyr–OEt in 48 h). Nevertheless, employing equimolar concentrations of reactants is advisable since this enables the recovery and isolation of the products very simply and, most importantly, avoiding any purification step.‡ As a consequence, remarkably high isolated yields (93 and 90%) are achievable. This is a factor of major importance in peptide synthesis, especially when various subsequent synthetic steps are required.

Reactions reported in Table 1 catalysed by α-chymotrypsin and PGA are also of practical use in peptide synthesis since they are potentially useful for the preparation and protection of activated amino acids suitable for kinetically controlled peptide synthesis. It is noteworthy that α-chymotrypsin catalysed the complete esterification of Z-L-Phe, despite it being previously reported that the enzyme accepts preferentially the *N*-acetyl amino acids,[1d] which, however, are deprotected with difficulty.

The novelty of our method lies not only in the synthetic results obtained but also in the immobilisation technique developed. The use of Celite R-640 allows control of the water activity, rather than water concentration, during the whole process, thus controlling effectively both the enzyme activity and the reaction equilibrium. No devices, such as hydrated salts,[8] equilibration with the atmosphere at known relative humidity,[9] or more complex methods[10] for adjusting the a_w of the system are required; also there is no need to remove the water produced during the process.[11] Furthermore, the immobilisation method fulfils the fundamental requirements for a larger application to biotransformations since the procedure is simple and inexpensive, it provides very high reproducibility in terms of enzyme and water content so leading to reproducible activity and quantitative adsorption yields. Detrimental effects caused by the removal of water under vacuum or with polar solvents[12–14] are avoided. Moreover, microbial contaminations are prevented, the support material is stable under the reaction conditions, and possesses no swelling capacity.

In conclusion, the present work describes the first example, to the best of our knowledge, of thermodynamically controlled enzymatic peptide synthesis performed in organic solvent leading to complete conversions and very high isolated yields even when equimolar concentrations of the reactants are employed.

Since it has been already demonstrated that peptidases catalyse the formation of the bond between oligopeptide fragments in organic solvents and that PGA is able to remove phenylacetic groups selectively from amino acids, we are currently investigating the application of this technique to a totally enzymatic approach for peptide synthesis competing with chemical routes.

We thank CNR and MURST (Roma) for financial support to P. Linda.

† 13% v/v of H_2O enables operation at $a_w \approx 0.73$[12d] in MeCN.

‡ The three synthesised dipeptides precipitated upon formation owing to their low solubility in toluene. The toluene was removed and the solid residue was washed with MeCN. The organic solutions were combined, filtered and taken to dryness obtaining products having > 98% purity by HPLC. Products of reactions catalysed by PGA and α-chymotrypsin are soluble in toluene and were isolated by removing the organic phase and evaporating the solvent.

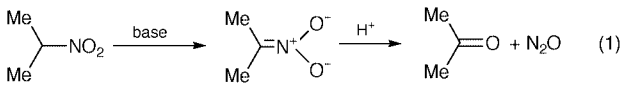
Received (in Basel, Switzerland) 1st January 2000, Accepted 10th February 2000, Published on the Web, 2nd March 2000

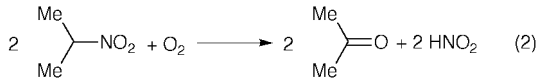
Iron(III) chloride reacts with potassium 2-propanenitronate to give the homoleptic tris(2-propanenitronato-*O*,*O*)iron(III) complex which in ethanol transfoms to an ethoxy-bridged diiron(III) 2-propanenitronate complex.

The conversion of nitro compounds to aldehydes and ketones is one of the most important functional group transformations.[1] It can be achieved conveniently by the Nef reaction, where conjugate bases of nitro compounds are treated with sulfuric acid leading to the hydrolysis of the C=N bond [eqn. (1)].[2]



(1)

Alternative oxidative methods also exist for this reaction in the literature resulting in better yields and fewer side reactions.[3] Biological organisms can also transform aliphatic nitro compounds to the corresponding oxo species and nitrite ion [eqn. (2)]. Oxygenated flavoenzyme species,[4] glucose oxidase, D- and



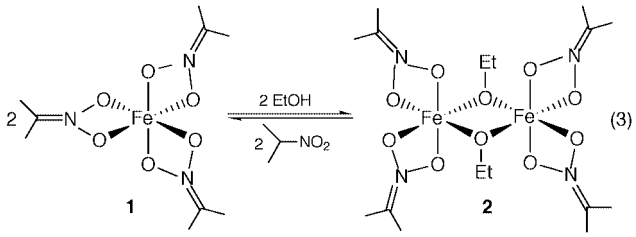
(2)

L-amino acid oxidase,[5] extracts of *Neurospora crassa*[6] pea seedlings and those from the hyphae of a nitrifying strain of *Aspergillus flavus*[7] and the intracellular enzyme 2-nitropropane dioxygenase of *Hansenula mraki*[8] oxidatively degrade nitroalkanes. The latter is believed to contain iron ions at its active center. Recently we demonstrated the facile copper-assisted oxygenation of nitroalkanes according to eqn. (2) and proposed a mechanism for the reaction.[3,9]

In order to understand the coordination of alkanenitronates to iron and their conversion to oxo compounds, we now describe the first fully characterised 2-propanenitronato-*O*,*O*–Fe(III) complexes and their oxygenation reaction.

Treatment of $FeCl_3$ with an equimolar amount of potassium 2-propanenitronate in benzene at room temperature for 4 h yielded the red–brown crystalline complex $[Fe(C_3H_6NO_2)_3]$ **1** in 24% yield.† If the reaction was carried out in a mixture of benzene and ethanol or **1** was recrystallised from ethanol the red crystalline complex $[Fe_2(C_3H_6NO_2)_4(C_2H_5O)_2]$ **2** was obtained in 27% yield.† In ethanol complex **1** undergoes ligand exchange, ethanolate displaces the nitronate ligand and bridges the two iron(III) ions to form **2** in an equilibrium [eqn. (3)].

The IR spectra of **1** and **2**, obtained as KBr pellets, reveal a particularly diagnostic absorption [ν(C=N)] at 1639 and 1644 cm^{-1}, respectively. The relative intensity of this absorption suggests a similar mode of coordination for both complexes and implies considerable carbon–nitrogen double bond character.[10] Magnetic measurements gave values of μ_B = 5.87 per Fe(III) for **1** and 7.29 per 2Fe(III) for **2** accord with high spin Fe(III) centers,



(3)

with a slight antiferromagnetic interaction in complex **2**. The Mössbauer spectra, recorded at 80 K, reflect the different coordination of Fe(III) in complexes **1** and **2**. Although the identical isomer shift values (δ_1 = 0.48 mm s^{-1} and δ_2 = 0.48 mm s^{-1}) reveal the same electron density on the iron in both compounds, the quadrupole splittings (Δ_1 = 0.90 mm s^{-1} and Δ_2 = 0.53 mm s^{-1}) differ significantly owing to different ligand contributions to the electric field gradient (EFG). The trigonal distortion of complex **1** makes the EFG rather large; however, this is considerably reduced upon dimerisation, when the local environment of the iron becomes closer to octahedral.

The crystal structure of **1**,‡ shown in Fig. 1 together with selected data, shows a distorted octahedral geometry around the

Displacement ellipsoids are shown at 50% probability level.

iron atom, with all coordination sites being occupied by the bidentate 2-nitropropanate ligands. The Fe–O bond distances are in the range 2.013(3)–2.026(3) Å and the bite-angles of the ligands lie in the range 109.8(3)–110.3(3)°. **1** exhibits a propeller-like structure with the iron atom being 0.007 Å out of the plane of the three N atoms of the three ligands. The crystal structure of **2**,‡ shown in Fig. 2 together with selected data, shows that there are two very similar ethoxy-bridged diiron molecules with slightly different bond distances and angles. The geometry around the iron atoms is aproximately octahedral, the six coordination sites being occupied by two ethoxy groups and two bidentate 2-propanenitronate ligands. The average Fe–O (bridging) bond distance is 1.966 Å with an Fe···Fe separation of 3.07 Å. The dimer lies on a crystallographic inversion center, the bridging Fe_2O_2 is perfectly planar with Fe–O–Fe and O–Fe–O angles of 102.35(8), 102.58(10) and 77.65(8), 77.43(10)°, respectively. The Fe–O bond lengths of the nitronato ligands are in the range 2.021(2)–2.053(2) Å while the N–O bond distances average 1.337 Å, only slightly shorter than the N–O single bond and larger than the N=O double bond (N–O 1.40 Å, N=O, 1.21 Å).[11] The carbon–nitrogen bonds in both complexes (1.283–1.291 Å) are essentially double bond in character (C–N 1.47 Å, C=N 1.27 Å).[11]

Complex **1** is very sensitive towards dioxygen and moisture while **2** is reasonably stable to both in the solid state. Preliminary oxygenation reactions of 2-nitropropane in the presence of **1** and **2** in pyridine at 90 °C resulted in the formation of acetone and HNO_2. Conversions of *ca.* 80% could be achieved at substrate : catalyst ratios of 20–40 : 1 during 20 h. The conversion–time profiles of the catalytic reactions were very similar for complexes **1** and **2** indicating that **2** transforms to **1** if an excess of 2-nitropropane is present. To our knowledge, these reactions represent the first examples of iron-catalysed oxygenation of 2-nitropropane resembling enzyme action, and indicating the possible role of iron ion as a cofactor. Further work is in progress for the elucidation of the mechanism of the reaction.

Received (in Liverpool, UK) 21st October 1999, Accepted 25th January 2000, Published on the Web, 2nd March 2000

Novel piperidine lactones 1 and 2, which represent direct precursors to the new C-6 homologues of 1-deoxynojirimycin (3) and 1-deoxy-L-idonojirimycin 4, were prepared by key Pd^{II}-catalysed aminocarbonylation of protected aminoalkene 10.

The inhibitors of glycosidases, enzymes involved in many crucial biochemical pathways,[1] could be very valuable in the treatment of serious human diseases such as diabetes,[2] cancer[3] and viral infections including AIDS.[4] The prominent members of this class of compounds are polyhydroxylated piperidines (often referred to as 'azasugars'). There has been an enormous effort put toward their efficient syntheses as well as toward the preparation of their various derivatives over the last decade. However, only a few of the already published synthetic strategies deal with the preparation of C-6 homologues of azasugars.[5–8] Here we report on the synthesis of new homologues of 1-deoxynojirimycin (**3**) and 1-deoxy-L-idonojirimycin (**4**), (Fig. 1).

Our synthetic plan relies on the successful $PdCl_2$-catalysed aminocarbonylation of the benzyl protected aminoalkene **10** yielding the desired lactones **1** and **2**. Generally, aminocarbonylation of 3-hydroxypent-4-enylamines giving pyrrolidine lactones proceeds easily,[9,10] which is in contrast to 4-hydroxy-hex-5-enylamines producing the corresponding piperidine lactones (Scheme 1).

To the best of our knowledge, there are only a few papers in the literature which deal with such a transformation on similar but simpler substrates.[10,11] However, reported yields are fairly low and no further synthetic elaboration of the prepared piperidine lactones has been reported. The common feature of almost all published amino-/amido-carbonylations (either producing pyrrolidine or piperidine lactones) is the use of electron-withdrawing protecting groups (tosyl, CO_2Me, CO_2Bn, CONHMe, CONHPh, CONHBn) on the NH function of the aminoalkenes. However, properties of such protecting groups (introduction, deprotection, chemical inertness and stability) were not suitable for our proposed plan for the total synthesis. Therefore, we decided to explore the applicability of the benzyl protecting group in the aminocarbonylation producing the piperidine lactones. We report here the above-mentioned strategy in the total synthesis of new C-6 homologues of 1-deoxynojirimycin (**3**) and 1-deoxy-L-idonojirimycin (**4**).

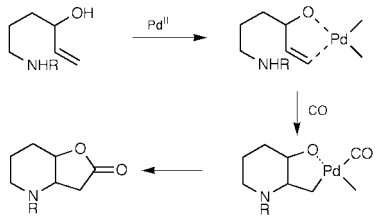

Scheme 1

Thus, the key substrate **10** was prepared by analogy with the known procedure according to the literature:[12] benzylidenation of the starting methyl-α-D-glucoside **5** afforded the diol **6**, which was subsequently benzylated to a fully-protected compound **7**. Acidic hydrolysis of **7** and nucleophilic displacement of the primary hydroxy function of **8** yielded bromide **9**, the latter being finally converted to the desired (2*S*,3*S*,4*R*)-*N*-benzyl-2,3-di-*O*-benzyl-2,3,4-trihydroxyhex-5-enylamine **10**.

First attempts to cyclise **10** under standard carbonylation conditions[11a] (1 atm CO, 0.1 equiv. $PdCl_2$, 3 equiv. $CuCl_2$, 3 equiv. AcONa, AcOH, conditions A) at room temperature failed and always the starting material was isolated. Gratifyingly, simply raising of temperature to 50 °C led to the complete consumption of aminoalkene **10** while the colour of the reaction mixture changed from dark green to ochre. However, aminocarbonylation of **10** yielded a complex mixture of compounds from which desired lactones **1** and **2** were isolated in the ratio 1 : 4.8 as main products. The major by-product of the reaction turned out to be *N*-benzyl-2,3-di-*O*-benzyl-6-chloro-1,6-dideoxy-L-idonojirimycin **11**‡ (Scheme 2).

We then searched for reaction conditions that would produce more of lactone **1** than **2** and suppress the formation of the side product **11**. We were pleased to find that a catalytic system consisting of 0.1 equiv. $PdCl_2$, 1 equiv. *p*-benzoquinone, 2 equiv. LiCl, 2 equiv. AcONa in THF under 1 atm CO at room temperature (conditions B) afforded a mixture of lactones **1** and **2** in the ratio 3.7 : 1 with no formation of **11**. Our suspicion that $CuCl_2$ (used in excess as reoxidant) might be responsible for the formation of undesired **11** was thus proved. The definitive confirmation came from the experiment in which aminoalkene **10** was subjected to conditions A but with exclusion of CO atmosphere. The only product we were able to isolate was the chloroderivate **11**§ (Scheme 3).

The separation and purification of **1** and **2** by FLC and subsequent reduction of both lactone rings gave the piperidine

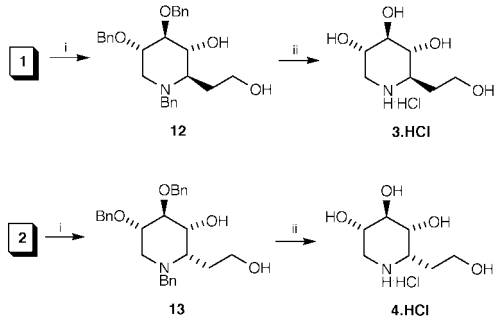
diols **12** [mp = 97–98 °C; $[\alpha]_D^{31}$ −19.4 (*c* 0.29, CH_2Cl_2); *m/z* 417 (M − $CH_2OH)^+$] and **13** [$[\alpha]_D^{31}$ −1.32 (*c* 0.34, CH_2Cl_2); *m/z* 447 (M − $1)^+$]. Final catalytic debenzylation of both tetraols afforded the desired (2*R*,3*R*,4*R*,5*S*)-2-(2-hydroxyethyl)-3,4,5-trihydroxypiperidine **3** [mp 177–179 °C; $[\alpha]_D^{26}$ +30 (*c* 0.55, MeOH); *m/z* 177 (M − $HCl)^+$] and (2*S*,3*R*,4*R*,5*S*)-2-(2-hydroxyethyl)-3,4,5-trihydroxypiperidine **4** (mp 202–203 °C; $[\alpha]_D^{32}$ +20.2 (*c* 0.42, MeOH); *m/z* 177 (M − $HCl)^+$] as hydrochlorides (Scheme 4).¶



Scheme 4 *Reagents and conditions*: i, $LiBH_4$, THF, room temp., 64–65% ii, H_2, 10% Pd/C, MeOH, HCl, room temp., DOWEX (H^+), 82–90%.

In conclusion, we have performed the first successful Pd^{II}-catalysed aminocarbonylation of highly substituted 4-hydroxyhex-5-enylamine that contains a Bn-protected amine group.‖ In contrast to the literature precedents,[10,11] we observed the formation of both diastereoisomeric *cis*- and *trans*-fused piperidine lactones. Their ratio depended on the reaction conditions and these compounds represent direct precursors for the synthesis of new derivatives of polyhydroxylated piperidines. The applicability of this methodology has been demonstrated in the total synthesis of new C-6 homologues of 1-deoxynojirimycin (**3**) and 1-deoxy-L-idonojirimycin (**4**).

In addition, we have observed an interesting type of $PdCl_2$/$CuCl_2$ catalysed chloroaminocyclisation of substituted 4-hydroxyhex-5-enylamine producing the corresponding piperidine derivative **11** which could be useful in the synthesis of various piperidine and azepine alkaloids.[13] Investigation of the scope and limitations of the presented methodology is under progress and will be reported in due course.

We are grateful to Professor V. Jäger (Stuttgart) for very helpful ideas, discussions and unlimited support. This research was supported by VW Stiftung (Hannover) and The Slovak Grant Agency. We thank TauChem Ltd. (Bratislava) for providing us with carbon monoxide and to Dr Zálupsky for language corrections.

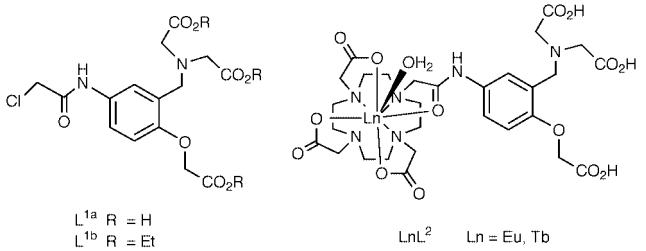
Received (in Cambridge, UK) 10th January 2000, Accepted 16th February 2000, Published on the Web, 2nd March 2000

Luminescence enhancement of terbium emission accompanies zinc ion binding at pH 7.4 with an apparent dissociation constant of 0.6 μM in a competitive ionic background.

Responsive luminescent lanthanide complexes have been defined recently in which the concentration variation of certain analytes has been signalled by changes in emission intensity,[1] lifetime[1,2] or polarisation.[3] For this purpose, kinetically robust complexes of Eu and Tb have been studied in particular and systems that respond to changes in pH,[4] pO_2[2,5] and pX[6] in water have been reported. We set out to prepare analogous complexes which respond sensitively and selectively to changes in metal ion concentration, in competitive aqueous media at physiological pH. The signalling of zinc ion concentration is of particular interest in this respect. Although total [Zn^{2+}] have long been established to be *ca.* 12 μM in serum,[7] there is considerable interest in defining the concentration of 'available' Zn^{2+}—both in the extracellular and intracellular environments. Different approaches have been adopted,[8,9] of which the most advanced involve the use of fluorescent 8-tosylamide-quinoline derivatives.[10,11] In seeking to prepare a suitable complex, the requirement for selectivity over Na^+, K^+ and more particularly Mg^{2+} (*ca.* 0.9 mM) and Ca^{2+} (1.2 mM extracellular; < 0.1 μM intracellular) was evident. Accordingly, we resolved to prepare the ligand L^{1a} and explore the complexation behaviour of the Eu and Tb complexes in the macrocyclic derivative L^2, as model systems for selective zinc binding.



Stepwise alkylation of *o*-aminomethylphenol ($BrCH_2CO_2Et$, 5% KI, Na_2HPO_4; *O*-alkylation with $BrCH_2CO_2Et$, KI, K_2CO_3) followed by mild nitration (HNO_3–HOAc; −20 °C) yielded an intermediate nitro-ester which was reduced (H_2/Pd–C/MeOH) and acylated with chloroacetyl chloride (Et_3N, DEE) to yield the triethyl ester L^{1b}. Basic hydrolysis of L^{1b} (pH 12, 20 °C, aq. NaOH) afforded the amino acid L^{1a} which was purified by ion-exchange chromatography. Reaction of L^{1b} with 1,4,7-tris(*tert*-butoxycarbonylmethyl)-1,4,7,10-tetraazacyclododecane (MeCN, K_2CO_3) followed by treatment with CF_3CO_2H–CH_2Cl_2 and complexation with $Ln(NO_3)_3{\cdot}5H_2O$ (Ln = Eu, Tb; pH 5.5; 20 °C) gave the neutral lanthanide complexes; successive treatment with aqueous sodium hydroxide and then strong-acid cation exchange resin afforded the desired lanthanide complexes, [LnL^2].[12] Measurements of the rate constants for decay of the Eu or Tb excited state were made in H_2O and D_2O in the absence and presence of 10 mM $ZnCl_2$. Values for [EuL^2] (k_{H_2O} = 1.61, k_{D_2O} = 0.45 ms^{-1}; *q* (Ln hydration state) = 1.0[13]) were unchanged in the presence of zinc and data for [TbL^2] (k_{H_2O} = 0.55, k_{D_2O} = 0.29; *q* = 1.0) were similarly unaffected by addition of $ZnCl_2$ or $CaCl_2$.

Addition of $ZnCl_2$ to L^{1a} or [LnL^2] was monitored by changes in absorption, fluorescence and lanthanide emission at pH 7.4. The ligand L^{1a} absorbed at 248 nm and no change to the position and intensity of this band occurred on ion binding, suggesting that the aryl ether oxygen was not participating in ion binding. For [TbL^2], a small blue-shift was observed in absorption (λ_{max} 255 → 250 nm); in fluorescence emission two bands were observed at 440 nm and a second, half as intense at 365 nm, which may be ascribed to internal charge transfer and locally excited states, respectively. On binding zinc, the former band shifted (442 → 430 nm) and reduced in intensity, while the latter did not shift but increased in intensity. Zinc binding was also characterised by a small increase in absorbance ($\lambda_{max.}$ = 250 nm) and with a larger enhancement of lanthanide emission intensity, following excitation at the isosbestic wavelength (262 nm). Smaller changes in absorption and emission spectra were obtained following addition of $CaCl_2$ (*e.g.* < 3 nm shift in absorption $\lambda_{max.}$) and no significant variations in absorption wavelength were observed following $MgCl_2$ addition, consistent with reduced or insignificant aryl ether oxygen donation, in these cases. The enhancement of Tb (and Eu) emission intensity (26 and 42%, respectively) upon Zn^{2+} binding is likely to be related to suppression of a photo-induced electron transfer from the benzylic nitrogen to the intermediate aryl singlet excited state.[1,2] In addition for [EuL^2], the metal based emission and ligand based fluorescence intensity was *ca.* 20 times lower than for [TbL^2], owing to quenching of the intermediate singlet state by the Eu^{3+} ion.

Such spectral changes allowed titrations to be carried out, monitoring absorption and luminescence intensity variations as a function of added metal salt concentration. The data obtained reveal a consistent selectivity pattern (Table 1), with Zn^{2+} bound more strongly than Ca^{2+} or Mg^{2+} ions. Two other general features emerged from this analysis: metal ion complexation of the linking amide carbonyl enhanced the ion-binding affinity of the potentially pentadentate ligand and a slightly higher apparent affinity was also found in the excited state for the lanthanide complexes, *i.e.* when observing ligand or lanthanide emission intensity variations. The lanthanide ion may serve to promote intramolecular charge transfer involving conjugation of the ether oxygen lone pair in the ground and excited states, *via* a through-ring electron withdrawing effect. This may also lead to a better orientation of the oxygen lone pair, in those cases (*e.g.* Zn^{2+} binding) where chelation of the benzylic N and the aryl ether O occurs. Such behaviour allowed zinc concentrations to be monitored in the sub-micromolar range, even in a simulated extracellular environment, *i.e.* the presence of 0.9 mM $MgCl_2$, 1.26 mM $CaCl_2$, 140 mM NaCl and 4 mM KCl, with an apparent dissociation constant of 0.6 μmol (pH 7.4, 295 K). The observed zinc ion sensitivity and selectivity with [TbL^2] augur well for the development of practicable signalling

† Electronic supplementary information (ESI) available: representative examples of spectral changes and of data analysis. See http://www.rsc.org/suppdata/cc/b0/b000283f/

DOI: 10.1039/b000283f

Table 1 Affinity constants (log β_{ML}) for cation binding, based on modulation[c] of absorption (S_0) or lanthanide (Ln*) luminescence[d] (295 K, 10 mM HEPES, 20 mM NaCl, 115 mM KCl, pH 7.4[a])

Ligand/complex (parameter)	Zn^{2+}	Ca^{2+}	Mg^{2+}
$L^1(S_0)$	5.04	3.91	2.1
$[TbL^2](S_0)$	5.48	3.84	2.0
$[TbL^2]$(Tb*)	6.35[b]	4.03	2.5
$[EuL^2](S_0)$	5.38	3.90	2.1
$[EuL^2]$(Eu*)	5.99	4.06	1.9

[a] Potentiometric titration of L^1 (298 K, I = 0.1 M NMe_4NO_3) revealed a pK_a for N-protonation of 7.35, echoed by the pH variation of ligand absorption; for binding constant measurements, the pH was adjusted to 7.4 by addition of 'Tris' base and was also monitored at the end of the titration. [b] In a simulated extracellular environment (Na, K, Mg, Ca), the apparent binding affinity for $[TbL^2]$, based on Tb emission intensity changes, was 6.22. [c] Binding constants were obtained by iterative least-squares fitting to a 1:1 model and showed reasonably good agreement to Hill plot analysis. [d] Excitation of the Ln complexes was effected at the isosbestic wavelength (λ_{exc} = 262 nm), while absorption spectral changes were monitored at 240 or 250 nm (294 nm for L^1). Excitation was also performed in the tail at 320 nm and emission variation as a function of $[M^{2+}]$ gave slightly higher binding affinities, *e.g.* for Ca^{2+}; 4.37 with $[TbL^2]$ and 4.67 with $[EuL^2]$ with a luminescence enhancement of 20%.

systems, in which longer wavelength excitation is of course required and where changes in the form of the lanthanide emission are desirable.

Intramolecular Diels–Alder reactions of masked *p*-benzoquinones: a novel methodology for the synthesis of highly functionalized *cis*-decalins

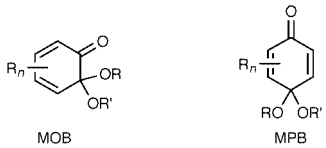
Yow-Fu Tsai, Rama Krishna Peddinti and Chun-Chen Liao*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 300. E-mail: ccliao@mx.nthu.edu.tw

Received (in Cambridge, UK) 4th January 2000, Accepted 25th January 2000, Published on the Web, 2nd March 2000

Tethering of dienols to hydroquinones under Mitsunobu conditions followed by oxidation with diacetoxyiodobenzene in methanol resulted in the development of highly functionalized *cis*-decalins *via* intramolecular Diels–Alder reactions of *in situ* generated masked *p*-benzoquinones.

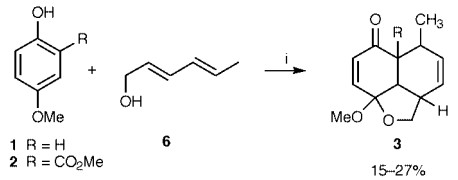
Because of their widespread occurrence in a large variety of natural products of biological importance, decalins remain a focus of attention for synthetic organic chemists.[1–3] Functionalized decalins with proper stereochemistry are possible intermediates for several terpenoids possessing biological activity. Not surprisingly, there has been a great deal of interest in developing methodologies for their synthesis, as evidenced by the growing number of reports in this area.[4–8] Most recently, we have shown that masked *o*-benzoquinones (MOBs), *i.e.*



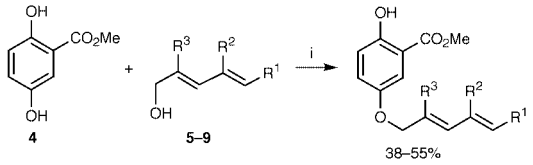
6,6-dialkoxycyclohexa-2,4-dienones, are efficient intermediates for the stereoselective synthesis of highly functionalized *cis*-decalins.[9] Herein, we report a novel method for the synthesis of highly functionalized decalins *via* the intramolecular Diels–Alder (IMDA) reactions of *in situ* generated masked *p*-benzoquinones (MPBs), a class of cross-conjugated cyclohexadienones. To the best of our knowledge this is the first detailed study of IMDA reactions of MPBs.[10]

Over the past ten years we have been investigating the inter- and intra-molecular Diels–Alder reactions of MOBs[11] and their synthetic potential has been exploited.[12] In contrast to the case of MOBs, the Diels–Alder chemistry of MPBs is less explored.[13] This may be due to the fact that the lesser reactivity of MPBs often requires harsh reaction conditions like high pressure[13*a*] or high temperature[13*c*,*d*] with prolonged reaction times. We envisioned that this problem could possibly be overcome by performing these reactions in an intramolecular fashion[14] *via* the *in situ* generation of MPBs by oxidizing *p*-methoxyphenols with diacetoxyiodobenzene (DAIB) in the presence of a dienol in a tandem oxidative acetalization process that would furnish stereoselective and highly functionalized *cis*-decalins.

As a prelude to this objective, we have carried out the reactions of *p*-methoxyphenols **1** and **2** with 10 equiv. of sorbic alcohol (**6**) in the presence of DAIB in different solvents, such as THF, CF_3CH_2OH and CH_2Cl_2. We have isolated the adducts **3** formed *via* IMDA reaction of *in situ* generated MPBs in rather poor yields (Scheme 1). Although the reasons for the lower reactivity of **1** and **2** with **6** are not known at this point, it is apparent that, unlike 2-methoxyphenols,[11*b*] 4-methoxyphenols cannot undergo facile tandem IMDA reactions. Consequently, we have switched our attention to tethering[15] the diene moiety to the hydroquinones *via* Mitsunobu reaction with dienols prior to oxidation by DAIB. For this purpose, we have performed the reactions of hydroquinone **4** and dienols **5**–**6** under Mitsunobu conditions to obtain the products in 38–55% yields (Scheme 2).



Scheme 1 *Reagents and conditions*: i, DAIB, solvent, room temp., 2 h.

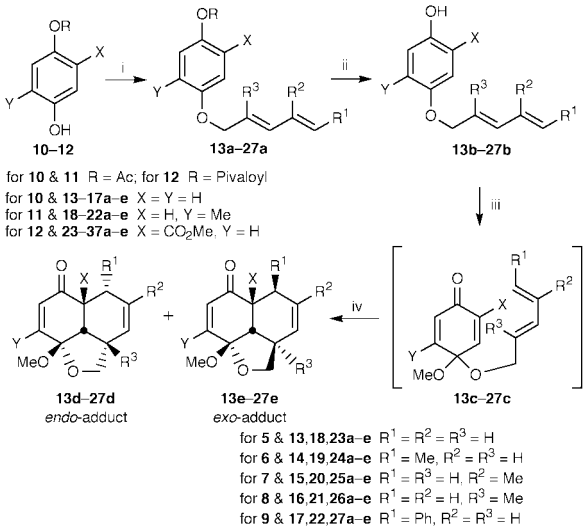


Scheme 2 *Reagents and conditions*: i, PPh_3, DEAD, THF.

Attempts to improve the yields by changing the reaction conditions were not successful. The use of DIAD in place of DEAD produced slightly better yields. However, we have conveniently produced the required phenols **13b**–**27b** by choosing selectively protected hydroquinones **10**–**12** as starting materials for Mitsunobu reaction followed by saponification in very good yields (Scheme 3, Table 1).

Masked *p*-benzoquinones **13c**–**27c** generated *via* oxidation of phenols **13b**–**27b** (0.5 mM) in MeOH (50 ml) using DAIB (0.75 mM) as oxidant underwent intramolecular cyclization at room temperature (Method A), or at reflux temperature in benzene (Method B) or in toluene (Method C) to afford the cycloadducts **13d**,**e**–**27d**,**e** in 78–90% yield (Scheme 3). Table 2 illustrates typical results of the IMDA reactions of MPBs.

The gross structures of all the IMDA adducts were determined by their IR, ^{1}H and ^{13}C NMR, DEPT, low- and high-resolution mass spectral analyses. The stereochemistries of



Scheme 3 *Reagents and conditions*: i, PPh_3, DIAD, THF, **5**–**9**; ii, K_2CO_3, MeOH, 0 °C; iii, DAIB, MeOH; iv, Methods A–C.

[a] All MPBs were generated at 0 °C and after usual workup, the crude residue was used as such for Methods B and C. Method A: room temp., 15 min; Method B: benzene, reflux, 4 h; Method C: toluene, reflux, 40 h. [b] Determined by ^{1}H NMR. [c] Reaction time: 18 h.

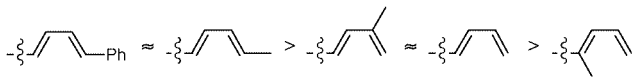

Fig. 1 Reactivity series for the diene moiety.

endo-adducts **14d**, **16d**, **17d**, **19d**, **21d**, **22d** and **26d** were established by NOE studies. The *endo*-adduct **25d** and the *exo*-adduct **25e** were separated from their mixture **25d** + **e** by recrystallizing from hexane–Et_2O to afford the former as an oil and the latter as crystals, and their stereochemistry was deduced from NOE studies. The stereochemistry of **25e** was further confirmed from its single crystal X-ray structure.[16] The *endo* and *exo* ratios of cycloadducts from entries 1, 3, 6, 8, 11–13 and 15 were determined from their ^{1}H NMR (400 MHz) spectra.

In the IMDA reactions of unsymmetrical MPBs **18c**–**22c** and **23c**–**27c**, the double bond with less electron density, *i.e.* the unsubstituted double bond in **18c**–**22c** and the CO_2Me-substituted double bond in **23c**–**27c**, behaved as a dienophile. The IMDA reactions of MPBs **23c**–**27c** bearing an additional electron-withdrawing group (CO_2Me) (entries 11–15) are faster than those of **13c**–**22c** (entries 1–10), where such a group is not present. The two sets of MPBs **13c**–**22c** and **23c**–**27c** show comparable reactivities. It appears that the reactivity pattern mainly depends on the tethered diene unit and could be explained on the basis of the position of the substituents attached to the diene moiety,[17] as shown in Fig. 1.

In most of the cases studied, the *endo*-adduct was obtained as either the sole product or the predominant product. The

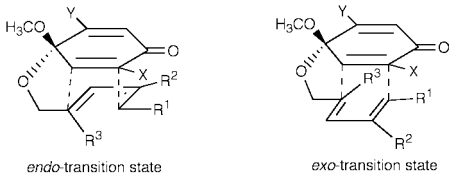

Fig. 2 Diels–Alder transition states.

transformation of transoid to cisoid conformation of the diene units in MPBs **16c**, **21c** and **26c** (R^1 = R^2 = H, R^3 = Me) required for Diels–Alder reaction needs more energy as reflected by the reaction conditions employed (entries 4, 9 and 14). Owing to the disfavored interactions in their *exo*-transition states (Fig. 2), *endo*-adducts **16d**, **21d** and **26d** were formed exclusively in these reactions.

In summary, we have shown for the first time that masked *p*-benzoquinones tethered to a diene moiety undergo efficient intramolecular cyclization to produce highly functionalized *cis*-decalins in very good yields. Our methodology provides an easy access to a series of stereoselective *cis*-decalins attached to five-membered oxygen heterocycles which may otherwise be difficult to synthesize. Further applications of MPBs in organic synthesis are under investigation in our laboratory.

We thank the National Science Council (NSC) of the Republic of China for financial support. R. K. P. thanks the NSC for a post-doctoral fellowship.

Received (in Cambridge, UK) 2nd December 1999, Accepted 14th February 2000

Monolithic mesoporous silica samples of *ca.* 2 × 2 × 1 mm in dimension with large surface areas (> 900 m² g⁻¹) and pore volumes (> 0.80 cm³ g⁻¹) have been readily prepared *via* a sol–gel process in the presence of hydroxy-carboxylic acid compounds as non-surfactant templates, and their pore structure was observed directly by means of atomic force microscopy (AFM).

The synthesis and applications of mesoporous materials prepared using surfactants as templates have attracted great attention since the discovery of the M41S family of mesoporous molecular sieves by scientists at the Mobil Corporation.[1,2] So far, most synthetic methods typically yield products in the form of fine powders resulting from uncontrolled precipitation during the sol–gel synthesis or template removal. Such powder forms hamper their use in catalysis and separation technologies. For example, for potential use in membrane separation, it is important to be able to process mesoporous structures in the form of defect-free, oriented films. Mesostructured silica films with ordered or disordered mesopore channel arrangements have been prepared using surfactants as templates under very carefully controlled conditions.[3–6] Mesoporous silica materials with diverse and remarkable morphologies[7–9] have been prepared under some extreme synthetic conditions to prevent uncontrolled precipitation of the mesostructured silicates. However, the dimensions of the products which occur as hollow spheres, tubules or other shapes is still microscopic. Emulsion biphase chemistry has been demonstrated to yield hollow or hard mesoporous macroscale spheres.[10,11] Recently, Wei *et al.*[12,13] reported a non-surfactant templating route to mesoporous silica materials *via* a sol–gel process. Because of the mild conditions, this process facilitates the preparation of mesoporous silica bulk objects. Here, we present the synthesis of mesoporous silica samples of large size (*e.g.* 2 mm) *via* a non-surfactant sol–gel route with hydroxy-carboxylic acids as templates.

The synthetic procedure was similar to that in the literature.[12] The preparation of colourless, transparent disks (*ca.* 3 cm in diameter) of the template-containing silicas was achieved by HCl-catalyzed sol–gel reactions of tetraethyl orthosilicate (TEOS) in the presence of organic hydroxy-carboxylic acid compounds, *i.e.* citric acid (CA), lactic acid (LA), malic acid (MA) and tartaric acid (TA). In general, TEOS (Acros Organics, 98%) was prehydrolyzed with deionized water in ethanol using HCl as catalyst (at TEOS : HCl : H_2O : EtOH molar ratios of 1 : 0.01 : 4 : 3) at about 70 °C for 5–6 hours. Upon cooling to room temperature, the prehydrolyzed solution (*e.g.* 10.6 ml) was added to a designed volume of aqueous solution (*e.g.* 3 ml of 0.45 g ml⁻¹) of hydroxy-carboxylic acid compound under stirring. The transparent and monolithic template-containing silica disks were obtained after the gel formed and dried within about two months at room temperature. The template-containing silica disks were then broken into smaller pieces instead of being ground into fine powders as reported in the literature.[12] The transparent and monolithic mesoporous silica samples were readily obtained by removing the templates *via* Soxhlet

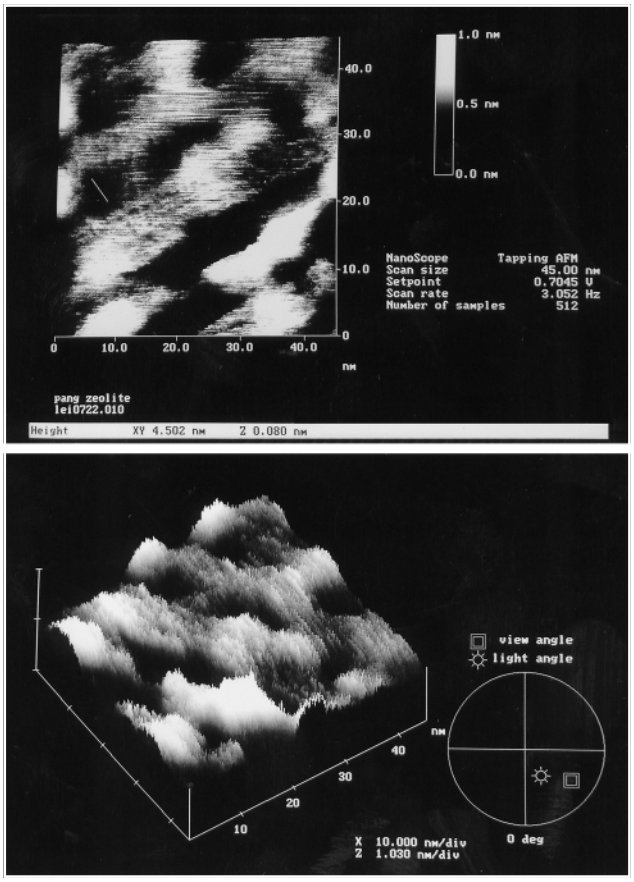

Fig. 2 AFM images of the surface of the sample Si-LA-50 (the scale bar in the top-view image is 4.50 nm).

extraction with ethanol for 3–4 days followed by drying. The samples before and after extraction were monitored by FTIR using a Bruker Vector22 FTIR spectrometer. Disappearance of the characteristic absorption band at *ca.* 1734 cm^{-1} for the carbonyl of the hydroxy-carboxylic acids indicated the completion of template removal. The Brunauer–Emmett–Teller (BET) surface area and pore parameters of the samples as small pieces after the removal of templates were determined by nitrogen adsorption–desorption isotherm measurements at 77 K on a Micromeritics ASAP2100 analyzer. Mesopore size distributions were calculated from the desorption branch of the isotherm by the Barrett–Joyner–Halenda (BJH) method using the Halsey equation. The AFM images were obtained on a Digital Instruments Nanoscope IIIa SPM by tapping mode AFM.

The BET surface area data and pore parameters of the silica samples after the removal of the templates are summarized in Table 1. Mesoporous materials with large surface areas (> 900 $m^2\ g^{-1}$) and pore volumes (> 0.80 $cm^3\ g^{-1}$) were obtained with CA, LA, MA or TA as template. As shown in the MA-templated synthesis, the pore diameter and volume tend to increase with the MA concentration. From the t-plot analysis with the Harkins–Jura equation, we conclude that the contributions from micropores to the measured surface areas and pore volumes are negligible.

The nitrogen adsorption–desorption isotherms of all the samples exhibit type IV-like isotherms with a sharp inflection at $P/P_0 \approx 0.5$ (type H2 hysteresis), as shown in Fig. 1. The pore size distributions are quite narrow in all the samples. As shown in the inset of Fig. 1, the pore size distribution has a peak pore diameter at *ca.* 4.3 nm with a peak width of *ca.* 0.6 nm at half-maximum. In contrast, the silica sample prepared in the absence of template under otherwise identical conditions shows a type I isotherm and a BET surface area of *ca.* 50 $m^2\ g^{-1}$.

Most reported mesoporous materials have been characterized with established techniques, such as transmission electron microscopy (TEM) or scanning electron microscopy (SEM).[1,2] Atomic force microscopy (AFM) enables resolution at the atomic level[14] and can be used to obtain nanoscale images of the surface of bulk materials and recently, AFM images of nanoporous ceramic films have appeared in a report.[15] The mesoporous silica samples obtained in this work are relatively easily characterized by AFM, as long as a smooth surface on freshly prepared samples could be identified. Fig. 2 shows AFM images (top-view and topographic view) of the sample Si-LA-50. From the images, we can readily identify the mesopores of *ca.* 4.5 nm diameter. Some channels are vertical to the observed surface and two are slanted to the surface, suggesting that the channel axes are largely disordered and three-dimensionally interconnected as reported in the literatures using TEM.[12] Although the images only reflect the surface pattern of the mesoporous materials, the inner mesostructures can be inferred from the large surface area, large pore volume and narrow pore size distribution as measured with the BET method.

Enantioselective deprotonation reactions using a novel homochiral magnesium amide base

Kenneth W. Henderson,* William J. Kerr* and Jennifer H. Moir

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, Scotland, UK G1 1XL. E-mail: cbas69@strath.ac.uk

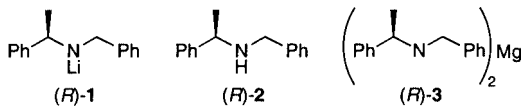
Received (in Liverpool, UK) 11th January 2000, Accepted 7th February 2000

A novel homochiral magnesium bisamide base system has been prepared and reacted with a series of prochiral ketones in the presence of TMSCl to give efficient formation of the corresponding enol ethers in enantiomeric ratios of up to 95:5.

Optically pure lithium amide bases have proven to be versatile tools in modern asymmetric synthesis. Indeed, highly enantioselective deprotonation reactions have been accomplished for several sets of substrates, including conformationally locked ketones, epoxides, and tricarbonyl (η^6-arene)chromium complexes.[1] In turn, many of the more recent advances in this area have been accomplished by the development of new homochiral ligands and the tuning of reaction conditions to improve the selectivity of these lithium-mediated deprotonations.[2] In contrast to the Li-based strategies, magnesium reagents have received relatively little attention for use in asymmetric synthesis[3] and, in particular, as mediators of enantioselective deprotonation processes.

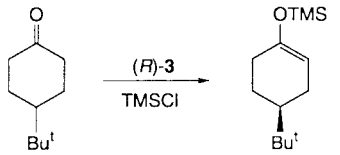
More recently, studies within our laboratories have shown how, in a racemic sense, magnesium amides can be employed as alternatives to their more widely used lithium counterparts in both enolisation and aldol addition reactions.[4] Indeed, advantages of the Mg-bases over the Li-analogues which have already been noted include their greater thermal stability (which, for example, allows aldol reactions between ketones to be promoted[4b]) and, in some instances, higher levels of more general reaction selectivity.[5] Consequently, with a view to developing asymmetric Mg-based protocols we considered that these observations, as well as the ability to formally bond two (chiral) ligands to the Mg centre, would allow good levels of stereoselectivity in organic transformations to be achieved. Herein, we report the first use of homochiral magnesium amide bases as reagents in the enantioselective deprotonation of conformationally locked ketones.

At the outset of this programme, and based on our recently reported structural study of the Li-amide (*R*)-**1**,[6] we chose to utilise readily available (*R*)-*N*-benzyl-α-methylbenzylamine, (*R*)-**2**. In due course, the Mg-amide base was readily prepared by the addition of dibutylmagnesium to 2 equiv. of the amine (*R*)-**2** in hexane solution, followed by heating to reflux for 90 min.† Analysis of the reaction mixture by ^{1}H NMR spectroscopy showed complete amination to the bisamide (*R*)-**3**.[7]



Subsequently, and based on extensive studies as reported in the chemical literature,[1] ketone **4a** was the substrate on which we chose to perform our initial deprotonation attempts. As shown in Table 1, a range of solvents, with and without HMPA as an additive,‡ were employed at −78 °C; from entries 1–5 it is clear that THF in the presence of 1 mol equiv. of HMPA provided good conversion to the silyl enol ether **5**.§ Furthermore and to our delight, even this simple Mg-amide base system displayed high levels of enantioselectivity for the (*S*)-silyl enol ether, (*S*)-**5a**.¶ Subsequent reaction optimisation (entries 5–8) showed that the use of only 0.5 mol equiv. of HMPA (entry 7) delivered a good reaction conversion and, at least as importantly, provided an enhanced level of enantioselection with a 91:9 enantiomeric ratio (82% ee) of (*S*)-**5a** over its optical isomer.‖ It should also be noted that reaction at −98 °C in THF, again with 0.5 mol equiv. of HMPA, gave a similar conversion (80%) and the same e.r. of 91:9, whereas reactions at more elevated temperatures with (*R*)-**3** led to a general reduction in enantioselectivity.

Table 1 Enantioselective deprotonations of **4a** and formation of silyl enol ether **5a**[a]



4a (*S*)-**5a**

Solvent	HMPA (mol equiv.)	Conversion (%)[b]	Enantiomeric ratio (e.r.)[b] (*S*):(*R*)
Et_2O	0	0	—
Et_2O	1	83	80:20
CH_2Cl_2	1	40	72:28
THF	0	33	90:10
THF	1	94	86:14
THF	2	26	84:16
THF	0.5	82	91:9
THF	0.1	53	91:9

[a] All reactions were performed at −78 °C for a period of 6 h. [b] Conversions and enantiomeric ratios were determined by separate GC analysis; see footnote ‖.

With these initial studies in hand and in order to investigate the wider applicability of this Mg-based strategy, a range of substituted cyclohexanones were subjected to our optimised reaction conditions. As can be seen from Table 2, using ketones **4a**–**e** the developed protocol with (*R*)-**3** was shown to consistently deliver the corresponding enol ethers **5a**–**e** with good efficiency and enantioselection, up to an excellent e.r. of 95:5 for **5d**.

To further extend our studies, as shown in Scheme 1, the less reactive 2,6-dimethyl ketone **4f** (82:18 *cis*:*trans* mixture; *trans*-ketone 50:50 e.r.) was also transformed with appreciable asymmetric induction (e.r. 90:10) to enol ether **5f** with the (*R*)-enantiomer in excess (55% conversion).** Notably, upon reaction completion the ratio of the returned ketone **4f** displayed a relatively unchanged 80:20 *cis*:*trans* ratio. However, the final enantiomeric ratio of the the *trans*-isomer of the starting ketone was 37:63. These latter observations and the elevated enantiomeric ratio for enol ether **5f** affirm that the Mg-amide base (*R*)-**3** had mediated a kinetic resolution process with the *trans*-ketone, as well as efficient asymmetric deprotonation with the *cis*-isomer.

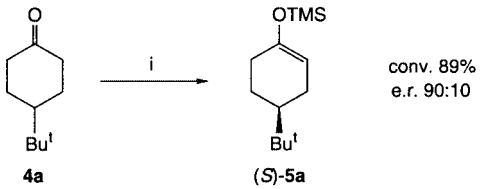
4f (*R*)-**5f**

Scheme 1 *Reagents and conditions*: i, (*R*)-**3**, HMPA (0.5 equiv.), TMSCl (4 equiv.), THF, −78 °C, 65 h.

Finally, in attempts to find a more practically acceptable additive to replace HMPA, equivalent quantities of DMPU were introduced to reactions of **4a** with (*R*)-**3**. In THF solvent at −78 °C, when 0.5 mol equiv. of DMPU were used, pleasingly an enantiomeric ratio of 90:10 in favour of (*S*)-**5a** was achieved in 89% conversion (Scheme 2); use of 1 mol equiv. of DMPU led to comparable conversion (93%) and e.r. (86:14).



4a (*S*)-**5a**

Scheme 2 *Reagents and conditions*: i, (*R*)-**3**, DMPU (0.5 equiv.), TMSCl (4 equiv.), THF, −78 °C, 6 h.

In conclusion, having prepared a novel homochiral magnesium bisamide system, we have demonstrated, for the first time, that such bases can successfully mediate enantioselective deprotonation reactions. Indeed, significant levels of selection in these asymmetric processes have been realised, and to an extent that they are already approaching the optimum enantiomeric ratios achievable by more complex Li-base systems.[1] Furthermore, and more importantly for the widespread use of the Mg-based approach, this efficient enantioselection has been achieved using a reagent which is easily prepared from a simple, readily available, and inexpensive amine. The application of further Mg-bisamide systems and the development of related methodology is currently under investigation and will be reported in due course.

We gratefully acknowledge The Carnegie Trust for the Universities of Scotland for a postgraduate studentship (J. H. M.) and The Royal Society for a University Research Fellowship (K. W. H.). We also thank AstraZeneca Pharmaceuticals, Alderley Park for generous funding of our research endeavours *via* Strategic Research Funding, and the EPSRC Mass Spectrometry Service, University of Wales, Swansea for analyses.

Notes and references

† *Preparation* of Mg-amide base (*R*)-**3**: a Schlenk flask was charged with a solution of amine (*R*)-**2** (0.42 mL, 2 mmol) in dry hexane (8 mL) under N_2. To this stirred solution, dibutylmagnesium (0.85 mL of a 1.1 M solution in heptane, 1 mmol) was added dropwise and the mixture heated to reflux for 90 min. The reaction solution was then allowed to cool followed by removal of all solvent *in vacuo* and replacement by the solvent of choice for the subsequent deprotonation reaction. ^{1}H NMR spectroscopic analysis of the resultant yellow oil, after removal of the reaction solvent, is consistent with the formation of the bisamide (*R*)-**3**: (400 MHz, C_6D_6, 25 °C): δ 7.22–7.02 (m, 10H, Ph), 3.57–3.48 (m, 2H, 2 × CH), 3.40–3.35 (m, 1H, CH), 1.11 (d, *J* 6.6 Hz, 3H, CH_3).

‡ The beneficial use of HMPA as a co-solvent has been reported previously for various Li-mediated enantioselective reactions.[1a,c]

§ From the 94% conversion (by GC) shown as entry 5 in Table 1, following alumina column chromatography, an isolated yield of 64% was obtained for **5a** with a 90% recovery of the starting amine (*R*)-**2**.

¶ Formation of the (*S*)-silyl enol ether, (*S*)-**5a**, is consistent with the selectivity of the analogous Li-base (*R*)-**1**.[8] Additionally, GC analysis, by comparison with that of Knochel and co-workers[2b] allowed confirmation of the assignment of absolute stereochemistry for the enol ether **5a**.

‖ The typical procedure for the enantioselective deprotonation reactions is illustrated by a preparation of **5a**: a Schlenk flask containing base (*R*)-**3** (1 mmol) suspended in THF (10 mL) was cooled to −78 °C under N_2. The flask was then charged with TMSCl (0.5 mL, 4 mmol) and HMPA (0.09 mL, 0.5 mmol). After stirring for 20 min at −78 °C, 4-*tert*-butylcyclohexanone (123 mg, 1 mmol) was added as a solution in THF (2 mL) over 1 h using a syringe pump. The reaction was allowed to stir at −78 °C for a further 5 h and then quenched by the addition of saturated aqueous $NaHCO_3$ (5 mL). After warming to room temperature the reaction mixture was extracted with diethyl ether (50 mL) and washed with saturated aqueous $NaHCO_3$ (2 × 20 mL). The combined aqueous phase was extracted with diethyl ether (2 × 20 mL), the combined organic phase was then dried over Na_2SO_4, followed by removal of solvent *in vacuo*. The reaction conversion was determined as 82% by GC analysis [DB 179 fused silica capillary column, carrier gas H_2 (80 kPa), 60–190 °C; temperature gradient: 45 °C min^{-1}, t_r = 3.1 min (**4a**), t_R = 3.3 min (**5a**)]. The resultant yellow oil was then filtered through a silica plug and washed with a light petroleum–diethyl ether solution (9:1). This afforded **5a** as a colourless oil. The enantiomeric ratio was determined by GC analysis as 91:9 [Chirasil-DEX CB capillary column, carrier gas H_2 (30 kPa), 80 °C (1 min)–120 °C; temperature gradient: 1.5 °C min^{-1}, t_R = 32.2 min [(*S*)-**5a**], t_R = 32.8 min [(*R*)-**5a**)]].

** Enantiomeric ratios were determined by GC analysis. Additionally, the absolute configuration of the major and minor enantiomers for **5b**, **5c**, **5d** and **5f** were assigned by correlation of optical rotation measurements with those of Koga and coworkers;[9] for **5e** the major and minor isomer configurations were tentatively assigned by comparison with **5a–d**. Furthermore, all compounds exhibited satisfactory analytical and spectral data.

The first hafnium methandiide complexes: the assembly of an entire triad of group 4 metal 'pincer' bis(phosphinimine) complexes possessing the M=C carbene–ylide structure

Ruppa P. Kamalesh Babu,[a] Robert McDonald[b] and Ronald G. Cavell*[a]

[a] *Department of Chemistry, University of Alberta, Edmonton, AB, Canada T6G 2G2. E-mail:Ron.Cavell@Ualberta.ca*
[b] *Structure Determination Laboratory, University of Alberta, Edmonton, AB, Canada T6G 2G2*

Received (in Cambridge, UK) 8th December 1999, Accepted 14th February 2000

Dichlorobis[bis(trimethylsilylamido)]hafnium(IV) reacts with $(R_2P{=}NSiMe_3)_2CH_2$ (R = Cy, Ph) cleaving the C–H bonds of the P–C–P backbone methylene group and eliminating 2 mol of hexamethyldisilazane to yield the hafnium methandiide (carbene) complexes 3 and 4, thus completing the triad of group 4 metal complexes containing the M=C moiety.

Although extensive systems of group 5, 6 and 7 carbene complexes are known,[1] similar group 4 carbene complexes are rare[2] being limited to a few titanium,[3] and zirconium alkylidene complexes[4] and some zirconium Fischer carbene complexes.[5] In particular, carbene complexes of hafnium have long eluded isolation. Whereas hafnium alkylidene species have been implicated as intermediates in stoichiometric reactions, attempted isolation gave orthometallated[6] or dimeric products.[7] We now report a novel, high yield synthesis of the first examples of hafnium bis(iminophosphorano)methandiide complexes which have a hafnium–carbon bond with multiple (hence carbene) character supported by phosphinimine substituents in a "pincer" structure. With these hafnium complexes we now complete the triad of group 4 metal complexes with similar structural features.[8]

The reaction of $[HfCl_2\{N(SiMe_3)_2\}_2]$[9] with $CH_2(R_2P{=}NSiMe_3)_2$ [R = Cy **1** (prepared by heating $(Cy_2P)_2CH_2$[10] with N_3SiMe_3), or Ph **2**[11]] in refluxing toluene (Scheme 1) gave the electron deficient methandiide complexes, $[HfCl_2\{C(R_2P{=}NSiMe_3)_2\text{-}\kappa^3C,N,N'\}]$ (R = Cy **3** or Ph **4**), as the result of a facile C–H bond cleavage process whereby the protons of the methylene group in the backbone of the ligand are removed;† 2 mol of hexamethyldisilazane were eliminated. This hafnium precursor reacts much more rapidly with the phenyl substituted bis(iminophosphorano)methane ligand, **2**, compared to the cyclohexyl analog, **1**, which we attribute to the higher acidity of the methylene protons in the former. Under similar conditions $[ZrCl_2\{N(SiMe_3)_2\}_2]$[9] reacts with **1** and **2** to yield the zirconium methandiide analogs, $[ZrCl_2\{C(R_2P{=}NSiMe_3)_2\text{-}\kappa^3C,N,N'\}$, prepared previously[8] by a different route. The hafnium methandiide complexes have a relatively high thermal stability, as do the Ti and Zr complexes,[8] which can be attributed to the steric protection of the carbene center by the formation of the tridentate chelate "pincer" structure.

The ^{31}P NMR spectra of complexes **3** and **4** consist of one sharp singlet showing that the two phosphorus nuclei are equivalent. The carbene resonances (δ 66.6 for **3**, 84.6 for **4**) appear as triplet signals because of coupling to two equivalent phosphorus atoms. The unusual upfield carbon chemical shift values for these carbene complexes relative to the general range exhibited by group 4 carbene complexes[2] may arise from the electronic influence of the phosphorus substituents, the presence of conjugated phosphinimine structures or because of the constrained geometry of the encapsulated carbene center.[12] We note that these shift values are similar to those of the previously reported carbodiphosphorane complexes of W[13] and Re[14] which show definitive M=C character. These latter complexes have neither the pincer nor the cyclic ring structure, thus the NMR properties probably devolve from the nature of the phosphorus–carbon interaction.

The molecular structure of $[HfCl_2\{C(Cy_2P{=}NSiMe_3)_2\text{-}\kappa^3C,N,N'\}]$ **3**,‡ shown in Fig. 1,[15] is similar to that of the zirconium analog.[8] The key structural feature of the complex is the relatively short Hf–C(1) bond length [2.162(6) Å] which is shorter than the Hf–C bonds in other hafnium hydrocarbyl complexes (mean Hf–CH_2C 2.300 Å, Hf–CHC_2 2.387 Å[16,17]). The two four-membered ring systems defined by the common Hf=C bond are nearly coplanar with a dihedral angle of 5.4(4)°. The C(1) atom lies above the least square plane defined by P(1), P(2), N(1), N(2) and Hf by 0.108(7) Å. The structure is consistent with a considerable degree of multiple bond character between the metal and the carbene center. A closer look at the bond lengths within the six-membered frame shows that the Hf–N bonds [mean 2.167(5) Å] are slightly shorter than values typical of neutral amine complexes but longer than values typical of amide complexes.[18] If we compare the P–C and P–N bond lengths in the complex to those of the free ligand,[19] we see that the endocyclic P–C bonds [mean 1.665(7) Å] of the P–C–P backbone are shorter and the P–N [mean 1.637(5) Å] bonds are

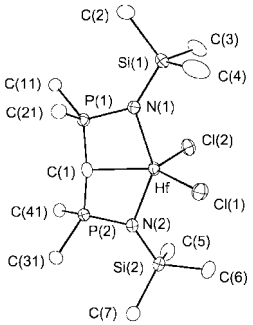

Fig. 1 An ORTEP[15] view of $[HfCl_2\{C(Cy_2P{=}NSiMe_3)_2\text{-}\kappa^3C,N,N'\}]$ **3** showing the atom labeling scheme. All cyclohexyl (except the *ipso*) carbon atoms and all hydrogen atoms have been removed for clarity. The remaining atoms are represented by Gaussian ellipsoids at the 20% probability level. Selected interatomic lengths (Å) and angles (°) Hf–Cl(1) 2.377(2), Hf–Cl(2) 2.389(2), Hf–C(1) 2.162(6), Hf–N(1) 2.164(5), Hf–N(2) 2.170(5), P(1)–N(1) 1.639(5), P(2)–N(2) 1.635(5), P(1)–C(1) 1.662(7), P(2)–C(1) 1.668(7), P(1)–C(11) 1.834(6), P(2)–C(31) 1.825(6), P(1)–C(1)–P(2) 169.9(4), Hf–C(1)–P(1) 93.5(3), Hf–C(1)–P(2) 93.6(3), N(1)–Hf–N(2) 143.3(2), N(1)–P(1)–C(1) 100.5(3), N(2)–P(2)–C(1) 100.3(3).

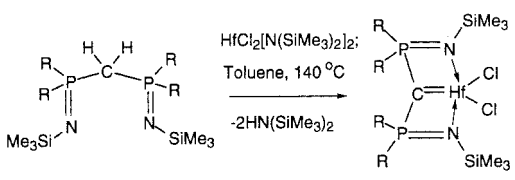

Scheme 1

longer which implies delocalization of π-electron density in the four-membered planes which would arise from the conjugation of the P=N and the M=C bonds,[20] as delineated in Scheme 2. The central carbon NMR shifts in complexes **3** and **4** suggest that a tautomeric ylide–carbene formulation may be an appropriate description.

Scheme 2

Having assembled a complete triad of Ti, Zr and Hf complexes with the same chemical structures we are now in a position to conduct a comparison of the similarities and differences in reaction behaviour which derive from the metal alone. Such comparative reactivity studies are now in progress.

We thank the Natural Sciences and Engineering Research Council of Canada, NOVA Chemicals Corporation and the University of Alberta for financial support.

Notes and references

† *Preparation* of **3**: all experimental manipulations were performed under rigorously anaerobic conditions using Schlenk techniques or an argon-filled glovebox. The complex, $[HfCl_2\{N(SiMe_3)_2\}_2]$ (0.2 g, 0.35 mmol) was dissolved in 10 mL of toluene. Solid $CH_2(Cy_2P{=}NSiMe_3)_2$ **1** (0.204 g, 0.35 mmol) was added to this solution with stirring and the colorless solution was heated at 140 °C for seven days. The resultant pale yellow solution was concentrated and cooled to −15 °C for 24 h to obtain colorless crystals which were isolated by filtration (yield: 0.21 g, 72.1%). IR (Nujol mull): 1447s, 1404w, 1377w, 1356w, 1320s, 1297w, 1260s, 1246s, 1202w, 1192w, 1176w, 1168w, 1112m, 1024s br, 915w, 887m, 836s br, 783m, 771s, 754s, 747s, 707w, 679m, 654s, 635m, 615s, 552s, 542m, 495m, 485m, 464w. ^{1}H NMR (400.1 MHz, C_6D_6, 298 K): δ 2.1–1.1 (br m, 40 H, methylene-Cy and 4 H, methine-Cy), 0.47 (s, 18 H, $SiMe_3$). ^{13}C{^{1}H} NMR (100.6 MHz, C_6D_6, 298 K): δ 66.6 (t, $^1J_{PC}$ 158.0 Hz, 1 C, quaternary C-PCP), 40.7 (m, 4 C, methine-Cy), 26.8 (m, 8 C, *ortho* methylene-Cy), 26.6 (s, 4 C, *para* methylene-Cy), 26.4 (s, 4 C, *meta* methylene-Cy), 26.3 (s, 4 C, *meta* methylene-Cy), 3.5 (s, 6 C, $SiMe_3$). ^{31}P{^{1}H} NMR (161.9 MHz, C_6D_6, 298 K): δ 32.6 (2 P). Anal. Calc. for $C_{31}H_{62}Cl_2HfN_2P_2Si_2$: C, 44.84; H, 7.53; N, 3.37. Found: C, 45.04; H, 7.98; N, 3.29%.

Preparation of **4:** in a similar fashion, $[HfCl_2\{N(SiMe_3)_2\}_2]$ (0.104 g, 0.18 mmol) in toluene solution was treated with solid $CH_2(Ph_2P{=}NSiMe_3)_2$ **2** (0.102 g, 0.18 mmol) and heated at 140 °C for 3 d. The solution was reduced to a small volume and layered with hexane. After 2 days at ambient temperature, colorless crystals were deposited which were isolated by filtration (yield: 0.11 g, 74.8%). IR (Nujol mull): 1589w, 1574w, 1480w, 1463m, 1436s, 1378m, 1311s, 1251s, 1181w, 1156w, 1111s, 1070m, 1057s, 1037s, 999m, 843s, 787s, 772m, 754m, 738m, 716s, 696s, 654s, 631m, 622s, 615m, 576m, 524s. ^{1}H NMR (400.1 MHz, C_6D_6, 298 K): δ 7.63 (m, Ph), 6.97 (m, Ph), 6.91 (m, Ph), 0.22 (s, 18 H, $SiMe_3$). ^{13}C{^{1}H} NMR (100.6 MHz, C_6D_6, 298 K): δ 134.7 (m, 4 C, *ipso* Ph), 131.5 (t, $^2J_{PC}$ 6.0 Hz, 8 C, *ortho* Ph), 131.0 (s, 4 C, *para* Ph), 128.5 (t, $^3J_{PC}$ 5.6 Hz, 8 C, *meta* Ph), 84.6 (t, $^1J_{PC}$ 145.0 Hz, 1 C, quaternary C-PCP), 2.6 (s, 6 C, $SiMe_3$). ^{31}P{^{1}H} NMR (161.9 MHz, C_6D_6, 298 K): δ 12.2 (2 P). Anal. Calc. for $HfCl_2\{C(Ph_2P{=}NSiMe_3)_2$-$\kappa^3C,N,N'\}\cdot 0.5C_6H_5Me$, $C_{34.5}H_{42}Cl_2HfN_2P_2Si_2$: C, 48.62; H, 4.97; N, 3.29. Found: C, 48.24; H, 5.21; N, 3.34%.

‡ *Crystal data* for $[HfCl_2\{C(Cy_2P{=}NSiMe_3)_2$-$\kappa^3C,N,N'\}]$ **3**: monoclinic, space group, $P2_1/c$ (no. 14), a = 10.3572(7), b = 20.8156(10), c = 17.8865(10) Å, β = 93.226(5)°, V = 3850.1(4) Å^3, Z = 4, D_c = 1.433 g cm^{-3}, μ = 7.829 mm^{-1} (Cu-Kα, λ = 1.54178 Å), T = 213 K; the structure was solved by direct methods and refined by full matrix least squares procedures: R_1 = 0.0432 and 0.0495, (wR_2 = 0.1100 and 0.1148) for 4864 reflections with $F_o^2 > 2\sigma(F_o^2)$ and all data respectively.

$2C_{60}·3CS_2$: orientational ordering accompanies the reversible phase transition at 168 K

Marilyn M. Olmstead,* Feilong Jiang and Alan L. Balch

Department of Chemistry, University of California, Davis, CA 95616, USA. E-mail: olmstead@indigo.ucdavis.edu

Received (in Columbia, MO, USA) 7th October 1999, Accepted 2nd February 2000

At 168 K crystals of $2C_{60}·3CS_2$ undergo a reversible phase transition (from orthorhombic to monoclinic), which is accompanied by orientational ordering of both C_{60} molecules in the asymmetric unit.

Carbon disulfide and aromatic hydrocarbons are widely used as good solvents for C_{60} and for the higher fullerenes. Both carbon disulfide and benzene solutions of C_{60} form crystalline solvates when they are allowed to evaporate to dryness. The structure of $C_{60}·4C_6H_6$ has been reported[1–3] and shown to contain van der Waals interactions of the types: benzene–benzene, benzene–C_{60}, and C_{60}–C_{60}. In spite of numerous intermolecular interactions, the C_{60} molecule is disordered with two orientations of the molecules occupying a common site at 104 K. Solutions of C_{60} in carbon disulfide produce brown crystals of $2C_{60}·3CS_2$.[4–6] Crystallographic studies at room temperature have identified the space group as either orthorhombic,[5] *Pbnm*, a = 24.97(6), b = 25.52(3), c = 9.98(1) Å or as orthorhombic,[6] $Pn2_1a$, a = 25.588(2), b = 9.984(2), c = 24.997(2) Å. The latter study reported a complete structure determination and showed the gross packing of molecules. However the resulting R value was high (0.18), and each of the two independent C_{60} molecules was modeled with four different orientations of the C_{60} molecule at each of the two independent sites. Additionally, the carbon disulfide molecules were disordered with two orientations at each of the three sites, and the structure could only be refined using a set of bond constraints. In this report we examine the structure of $2C_{60}·3CS_2$ at low temperatures and show that a reversible phase transition occurs at 168 K.

The structure of $2C_{60}·3CS_2$, obtained by evaporation of a carbon disulfide solution, was determined at 90 K. At this temperature the crystals belong to the monoclinic space group $P2_1/n$, with a = 9.8722(12), b = 25.466(3), c = 24.671(3) Å, β = 90.047(3)°.† The crystal was treated as a pseudo-merohedral twin. Refinement proceeded satisfactorily with a model that included two fully ordered C_{60} molecules and three ordered carbon disulfide molecules in the asymmetric unit. The average values and average deviations for the low temperature form are: fullerene; C–C bond distance (5:6 ring junctions) = 1.382(11) Å; C–C (6:6 ring junctions) = 1.450(11) Å; carbon disulfide; C–S bond distance = 1.544(6) Å; S–C–S bond angle = 179.0(4)°. A stereoview of the monoclinic structure perpendicular to the shortest axis is given in Fig. 1. In this structure, the set of three CS_2 molecules approach one another end-on to form a triangle with non-bonded S··S contacts of 3.696, 3.697 and 3.808 Å (Fig. 2). The closest contact between any sulfur atom and C_{60} is 3.460 Å (between S6 and C59), and the next shortest (3.468 Å) involves S3 and C1. The twenty shortest contacts between sulfur atoms and fullerene carbon atoms have an average value of 3.602 Å. Interestingly, one of the sulfur atoms, S5, has no contacts in this group; its shortest contact to a fullerene carbon is 3.834 Å. The shortest contact between the central carbon of CS_2 and C_{60} is 3.278 Å.

In view of the similarities of the orthorhombic and monoclinic cell parameters, the structure at room temperature was reexamined, and we confirmed that at room temperature $2C_{60}·3CS_2$ has an orthorhombic cell with a = 24.988(9), b = 25.602(8), c = 9.984(3) Å. We also confirmed that the structure

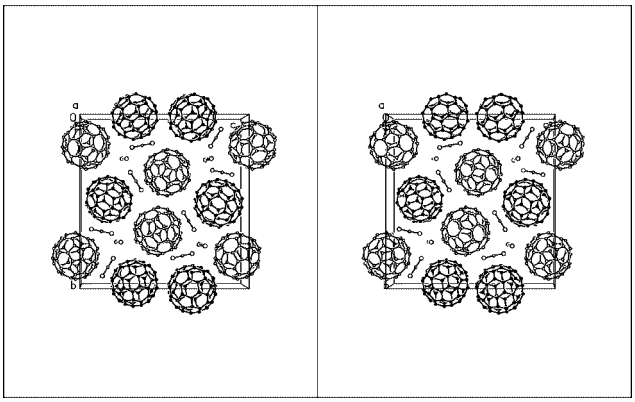

Fig. 1 A stereoview down the short (9.872 Å) axis of the monoclinic structure of $2C_{60}·3CS_2$. The two fullerene molecules are differentiated by using open circles for one and shaded circles for the other.

cannot be solved in the centrosymmetric space group, *Pbnm*. After two days of data collection a 25% reduction in the intensity of check reflections had occurred, presumably as a result of loss of CS_2.

In order to understand the relationship between the two crystallographically distinct forms of $2C_{60}·3CS_2$, variable temperature crystallographic studies were conducted. The orthorhombic setting for the high temperature form will match the monoclinic B setting of the low temperature form if it is described in the space group $P2_1nb$, the *cab* setting of $Pna2_1$, (no. 33). In this space group the symmetry elements differ from $P2_1/n$ by the addition of a b glide, and by a 2_1 screw axis that lies along the a-axis instead of the b-axis. Although the presence of

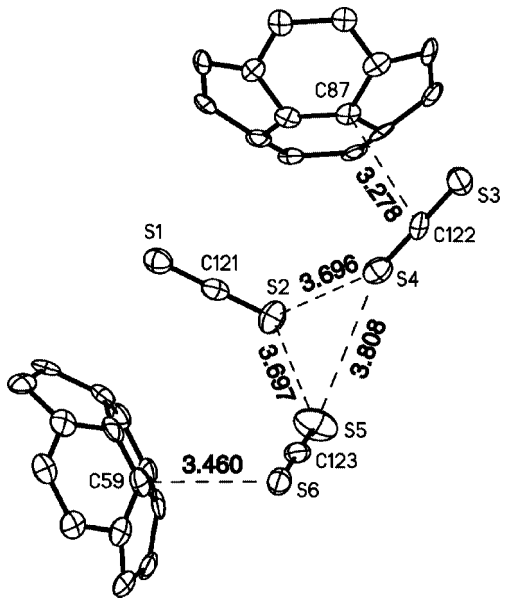

Fig. 2 A drawing showing selected intermolecular contacts associated with the CS_2 molecules in the monoclinic form.

DOI: 10.1039/a908147j

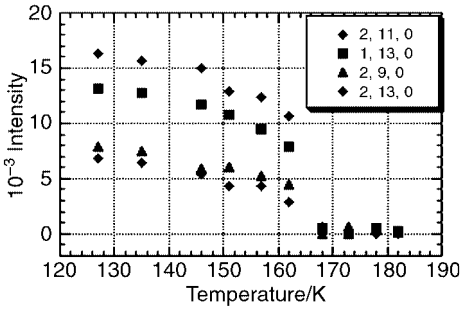

Fig. 3 A plot of the reflection intensity as a function of temperature for four selected *hk*0 reflections of $2C_{60}{\cdot}3CS_2$.

the screw axis does not confer any extra conditions; the presence of the *b* glide in the orthorhombic form leads to the condition, *hk*0, $k = 2n$, which is distinct from that of the monoclinic form, for which *hk*0 has no conditions.

A set of ten strong reflections in the set of *hk*0, $k = 2n + 1$ were identified in the low temperature form. A small data set was collected on these reflections at selected temperatures between 127 and 183 K. Without exception, extinction was observed at 168(2) K. This can be seen in the plot of the intensities of four of these reflections as a function of temperature shown in Fig. 3. The temperature was raised and lowered three times through the above range, and no loss in intensity of the benchmark reflections was observed.

Since the high temperature, orthorhombic, and low temperature, monoclinic, structures are interconvertible without loss of crystallinity, it is not surprising that they contain similar arrays of molecules. Each form has two distinct C_{60} sites and three CS_2 sites. The pattern of packing of these constituents is exactly the same, and the orientation of the CS_2 molecules matches. The orthorhombic space group has an additional glide plane, but the principal difference is that in the high temperature form there are four different orientations of the C_{60} molecules and two different orientations of the CS_2 molecules at sites which themselves contain no crystallographic symmetry. However, as a consequence of the higher orthorhombic symmetry, there would be higher order in the high temperature form if the disorder did not occur. Thus, the phase transition results in an increased disorder upon warming and is entropically driven.

Some compression of the structure at low temperature would be expected due to the reduction in temperature, and this is clearly seen by a comparison of the average center-to-center distances. For the orthorhombic form (298 K), the average value is 10.051 Å, while for the monoclinic form (90 K), the average value is 9.961 Å. An accurate comparison of the individual bond distances and angles cannot be made due to the disorder at room temperature. Likewise, comparison of temperature-dependent changes in the contact distances between C_{60} and CS_2 is flawed by the same inaccuracies due to the disorder, but, based upon the packing, no remarkable differences are expected.

Despite the ordering observed in this crystallographic study, the fullerene molecules in $2C_{60}{\cdot}3CS_2$ still undergo dynamic reorientation at low temperatures. Crystalline $2C_{60}{\cdot}3CS_2$ has been studied previously by solid state ^{13}C NMR spectroscopy.[7] Over the temperature range 125 to 263 K, the spectrum consists of a single narrow line which exhibits a minimum in the spin–lattice relaxation time, T_1 at 170 K. Those results were interpreted to indicate that an orientational ordering transition occurs and that the fullerene molecules jump between equivalent orientations with a correlation time of $< 10^{-5}$ s. The nature of the interactions between C_{60} and CS_2 has been examined by quantum mechanical calculations.[8]

Reversible phase transitions in molecular crystals are relatively rare occurrences. More commonly, molecular crystals undergo cooling without phase change or fragment upon cooling owing to irreversible phase changes which generally make determination of the structure of the low temperature phase inaccessible. Reversible phase changes in molecular crystals are likely to involve an aspect of increased molecular order at low temperature owing to a reorganization process such as the molecular ordering seen for $2C_{60}{\cdot}3CS_2$ or the side chain ordering and molecular reorientation observed in cholesterol.[9] Since orientational disorder is common in fullerenes, it is likely that other reversible phase changes will be seen in the large number of crystals in which a fullerene co-crystallizes with one or two other molecules. The present study emphasizes the value of examining fullerene structures at the lowest experimentally obtainable temperature.

Notes and references

† The crystal used was a dark brown lath of size $0.065 \times 0.13 \times 0.36$ mm. Data for the structure determination was collected on a Bruker SMART 1000 equipped with a CRYO Industries low-temperature apparatus. Selection of the monoclinic space group, $P2_1/n$, followed directly from the observation of systematic absences. The unit cell was based upon a least-squares fit of 5907 reflections with $2.3 < \theta < 24.3°$. Solution of the structure was achieved with some difficulty from direct methods and subsequent refinement and difference maps. Refinement of the structure stopped with an *R*1 of 0.28, yet there was no indication in the difference maps of another, rotationally disordered, C_{60} molecule. At this stage a twin law was introduced because there were two strong indicators of pseudo-merohedral twinning.[10] One was a mean $|E^2 - 1| = 0.749$, a value near to that expected for a non-centrosymmetric structure rather than a centrosymmetric one, and the other was the β angle very near 90°. A twin law [1 0 0 0 −1 0 0 0 −1] and twin component of 0.5 were introduced, which led to a 20% reduction in the value of *R*1. Another 2% reduction in the *R*1 value was achieved by the introduction of anisotropic thermal parameters for all atoms, leading to an *R*1 of 0.0579 computed for 8239 observed data [$> 2\sigma(I)$] and 1162 parameters. The twin component converged to 0.5032(10) and was subsequently set to 0.5000. The largest difference map peak had a value of 0.42 e Å^{-3}.

Crystal data for $2C_{60}{\cdot}3CS_2$, $M = 1669.59$, monoclinic, space group $P2_1/n$, $a = 9.8722(12)$, $b = 25.466(3)$, $c = 24.671(3)$ Å, $\beta = 90.047(3)°$, $U = 6202.5(7)$ Å^3, μ(Mo-Kα) = 0.297 mm^{-1}, $Z = 4$, $T = 90$ K, 60760 reflections collected, 14233 unique ($R_{int} = 0.115$), $wR(F^2)$ was 0.1224 (all data). CCDC 182/1546. See http://www.rsc.org/suppdata/cc/a9/a908147j/ for crystallographic files in .cif format.

A Siemens P4 diffractometer equipped with a rotating Cu anode and LT-2 low temperature apparatus was used for the study of the phase change. The temperature at the crystal and calibration of the readout were determined by a separate study of the phase transition (at 123 K) of potassium dihydrogen phosphate. The Bruker SMART diffractometer was funded in part by NSF grant CHE-9808259.

1,3-Dipolar cycloaddition of 2-azetidinone-tethered azomethine ylides. Application to the rapid, stereocontrolled synthesis of optically pure highly functionalised pyrrolizidine systems

Benito Alcaide,* Pedro Almendros, Jose M. Alonso and Moustafa F. Aly†

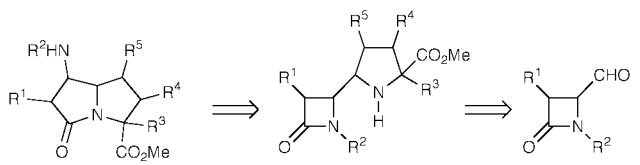
Received (in Liverpool, UK) 4th January 2000, Accepted 14th February 2000

A new straightforward methodology to prepare polyfunctionalised enantiopure pyrrolizidine systems, based on the 1,3-dipolar cycloaddition of 2-azetidinone-tethered azomethine ylides as the key reaction, is presented.

1,3-Dipolar cycloaddition employing azomethine ylides is an important process in organic synthesis, acquiring a prominent place of synthetic strategy for a variety of targets, including natural products such as azasugars and alkaloids.[1] Pyrrolizidine alkaloids occur in many natural products of potential use in medicine and agriculture.[2] In view of their potent and various biological activities, pyrrolizidine alkaloids as well as structurally related unnatural compounds are continuosly stimulating new synthetic approaches.[3] On the other hand, the importance of 2-azetidinones as synthetic intermediates has been widely recognized in organic synthesis. This usefulness is based on the impressive variety of transformations which can be derived from this system.[4] The application of β-lactams in stereoselective synthesis may be divided into two groups, namely, those processes based on transformation of the 2-azetidinone by external reagents and those based on rearrangements of the four-membered ring. The first type of reactivity is exemplified by the β-lactam synthon method.[5] The second group of reactions is based on the building of a conveniently functionalised 2-azetidinone to produce different types of, usually cyclic, compounds by selective bond breakage and rearrangement.[6] Despite the versatility of the 2-azetidinone ring, there is little information available on the use of β-lactams as chiral synthons for the synthesis of pyrrolizidine alkaloids, just the groups of Reuschling[7] and Palomo[8] have reported β-lactam routes to simple pyrrolizidines. Our interest in the use of 4-oxoazetidine-2-carbaldehydes as substrates for addition reactions and cyclization processes,[9] prompted us to evaluate the combination of the 1,3-dipolar cycloaddition of alanine (glycine) derived iminoester ylides with rearrangement reactions on the 2-azetidinone ring as a route to complex pyrrolizidine alkaloids (Scheme 1). We report here, a straightforward asymmetric synthesis of different kinds of highly fuctionalised bi- and tri-cyclic pyrrolizidine systems using β-lactams as chiral building blocks.

Cyclization precursors, 4-oxoazetidine-2-carbaldehydes **1**, were prepared both in the racemic form and in optically pure form using standard methodology.[9–12] Treatment of aldehydes **1** with various α-aminoesters in the presence of molecular sieves provided the corresponding aliphatic aldimines **2**. Imines **2** were obtained in quantitative yields and were used for next step without further purification



Scheme 1

We sought to explore the reactivity of 2-azetidinone-tethered azomethine ylides with cyclic and acyclic dienophiles such as *N*-phenyl maleimide and methyl acrylate.‡ The 1,3-dipolar cycloaddition was achieved *via* metal ion catalysis at room temperature. Treatment of aldimines **2** with the appropriate dienophile in the presence of $AgOAc–Et_3N$ in toluene at room temp. for 40 h gave with reasonable diastereoselectivity mixtures of cycloadducts **3** and **4** (Table 1) in moderate to excellent yields (45–90%).§ Fortunately, in all cases the diastereomeric cycloadducts were easily separated by flash chromatography. Furthermore, the reaction with an unsymmetric monoactivated alkene, methyl acrylate, proceeded with total regioselectivity. The steric properties of the C3 substituent on the 2-azetidinone ring influence the stereoselectivity of the cycloaddition, sterically less demanding groups increasing the diastereoisomeric ratio (Table 1). Next, our aim was to find an expedient transformation of the cycloadducts into pyrrolizidine systems. First we tested sodium methoxide as reagent for the conversion of adducts **3** or **4** into the framework of pyrrolizidine alkaloids. In the event, the pyrrolizidine skeleton was obtained. Sodium methoxide works well in maleimide derived cycloadducts, however epimerization was observed in adducts coming from methyl acrylate. This preliminary result encouraged us to find a more convenient reagent for this transformation. To our delight, when the reaction was conducted in a saturated solution of HCl(g) in isopropanol at room temperature for 36 h, optically pure pyrrolizidine systems **5** and **6** were obtained in moderate to good yields and without by-products (Scheme 2).¶ However, bicycle (−)-**6b** was more efficiently obtained in a saturated methanolic solution of HCl(g), with some isopropyl transesterification being observed when adduct (+)-**4d** was treated with HCl(g) in isopropanol. The reaction of (+)-**3d** in a saturated solution of HCl(g) in methanol for 36 h gave a quantitative yield of the monocyclic pyrrolidine (+)-**7**, which requires 2 h of heating in toluene under PTSA catalysis to give the expected tricyclic system (+)-**5b**.‖ The formation of pyrrolizidinones **5** and **6** involves a selective C–N bond cleavage of the four-membered ring, followed by a rearrangement under the reaction conditions. The relative *anti*-disposition of the ester and amine moieties in bicycles **6** must be responsible for the failure of the third cyclization to occur, preventing the formation of a highly strained tricyclic system. The polycyclic structures (by DEPT, HETCOR and COSY) and the stereochemistry (by vicinal proton couplings and NOE experiments) of compounds **5** and **6** were established by one- and two-dimensional NMR techniques.** Taking into account that separated diastereomeric cycloadducts **3** and **4** could be obtained and cyclized, the stereochemistry for compounds **3** and **4** was inmediately deduced by comparison with the NOE results of the polycyclic systems. Also, the *cis*-stereochemistry of the four-membered ring is set during the cyclization step to form the 2-azetidinone ring and it is transferred unaltered during the further synthetic steps.

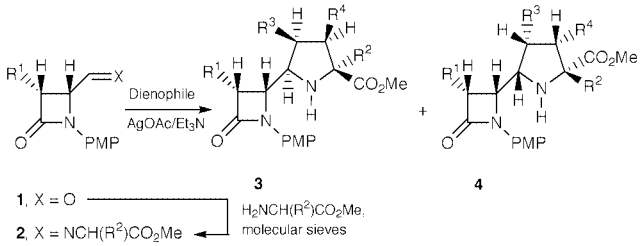
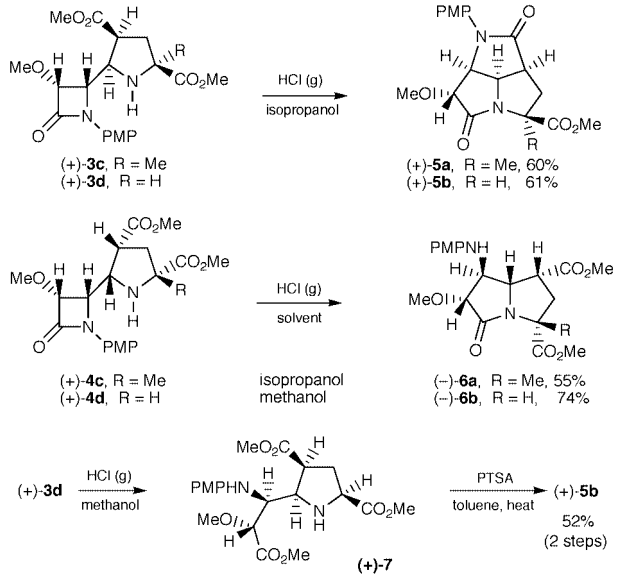
Table 1 1,3-Dipolar cycloaddition of 2-azetidinone-tethered azomethine ylides



Entry	Aldehyde	R^1	R^2	R^3	R^4	Products	**3**:**4** ratio[a]	**3**:**4** yield[b]
1	**1a**	H	Me	CO_2Me	H	**3a**[c]	—[c]	48[d]
2	**1b**	Vinyl	H	CO_2Me	H	**3b**/**4b**	95:5	43/2
3	(+)-**1c**	MeO	Me	CO_2Me	H	(+)-**3c**/(+)-**4c**	65:35	39/21
4	(+)-**1c**	MeO	H	CO_2Me	H	(+)-**3d**/(+)-**4d**	70:30[e]	46/20

[a] The ratio was determined by integration of well resolved signals in the ^{1}H NMR spectra of the crude reaction mixtures before purification. PMP = 4-$MeOC_6H_4$. [b] Yield of pure, isolated product with correct analytical and spectral data. [c] The ^{1}H NMR spectrum of the crude mixture showed mainly **3a** togheter with unmeasurable traces of two other isomers. [d] Additional fractions containing the major cycloadduct together with traces of the minor isomers were isolated after column chromatography, accounting for an overall 80% yield. [e] Two additional diastereoisomeric cycloadducts were detected in the ^{1}H NMR spectra of the crude reaction mixture accounting, respectively, for 7 and 4% of the products formed.



Scheme 2

In summary, we have demonstrated that the combination of 1,3-dipolar cycloaddition of 2-azetidinone-tethered azomethine ylides with rearrangement reactions on the 2-azetidinone ring is a powerful, hitherto unknown, strategy for the asymmetric synthesis of different types of highly functionalised pyrrolizidine systems. In addition, this methodology is very versatile offering the possibility of obtaining a variety of complex pyrrolizidine derivatives just by changing the substituents in readily available 4-oxoazetidine-2-carbaldehydes, α-amino-esters or dipholarophiles.

Notes and references

‡ During the evaluation of this manuscript a report appeared describing the 1,3-dipolar cycloaddition of closely related β-lactam azomethine ylides: R. Grigg, M. Thornton-Pett and L.-H. Xu, *Tetrahedron*, 1999, **55**, 13 841.

§ When DBU was used instead of Et_3N, complex mixtures of unidentified products were obtained, whereas pyridine gave erratic results. Perfoming the reaction in acetonitrile afforded poor yields of cycloadducts.

¶ *Representative experimental procedure* for the synthesis of pyrrolizidine systems: HCl(g) was bubbled, during 1 h, through an unstirred solution of the appropriate cycloadduct **3** or **4** (0.4 mmol) in isopropyl alcohol (6 ml) and the reaction solution left to stand in a sealed vessel for 36 h. The reaction mixture was concentrated under reduced pressure, diluted with dichloromethane (10 ml), washed with saturated aqueous sodium hydrogen carbonate and brine, dried ($MgSO_4$) and concentrated under reduced pressure. After purification by flash chromatography, pyrrolizidinones **5** and **6** were obtained in analytically pure form.

‖ Tricycle (+)-**5b** was alternatively obtained *via* heating overnight the adduct (+)-**3d** in methanol using 37% aqueous hydrochloric acid as a catalyst.

** All new compounds were fully characterised by spectroscopic methods and microanalysis and/or HRMS.

Aragonite $CaCO_3$ thin-film formation by cooperation of Mg^{2+} and organic polymer matrices

Ayae Sugawara and Takashi Kato*

Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. E-mail: kato@chiral.t.u-tokyo.ac.jp

Received (in Cambridge, UK) 3rd December 1999, Accepted 15th February 2000

Aragonite thin films of calcium carbonate have been deposited on chitosan matrices by cooperation of chitosan, poly(aspartate) and $MgCl_2$ in $CaCO_3$ solution, and their double layered composite structures are obtained by the alternate operations of chitosan coating and thin-film crystallization.

Living organisms produce a great diversity of organic/inorganic composite materials by using interactions between biopolymers and inorganic substances. The nacre of mollusc shell, one of the most studied, has a laminated composite structure of $CaCO_3$ crystals in the aragonite polymorph and biological macromolecules such as chitin and silk-fibroin-like protein, which provides high mechanical strength and unusual optical properties.[1] Aragonite crystals are considered to enhance mechanical properties of the nacre owing to the absence of cleavage planes.[2] Polymorph control for aragonite crystals has been performed by the use of proteins extracted from shells,[3] synthetic polymers[4] and LB films.[5] A biofabrication method involving a biosystem, the mantle and shell of red abalone, led to the formation of flat aragonite films.[6] However, to our knowledge, no aragonite thin film has been formed by the use of simple polymers *in vitro*. Here, we report a synthetic approach to the fabrication of aragonite thin films which resemble a part of lamellar sheets in the nacre by using a cooperative effect of Mg^{2+} and organic polymers with simple repeating units.

For calcite and vaterite syntheses, thin films could be obtained on organic matrices such as polysaccharides[7,8] and aggregated amphiphilic molecules[9] in the presence of acid-rich macromolecules. In the present study, we selected poly(aspartate) (pAsp) as an organic additive. It was reported that aspartate-rich proteins are responsible for the controlled crystallization of $CaCO_3$ layers of shells.[1]

$CaCO_3$ was crystallized on chitosan matrices spin coated on glass substrates from supersaturated calcium hydrogen carbonate aqueous solution by slow evaporation of CO_2.† In the absence of additives, rhombohedral calcite crystals of size 10 μm were deposited, which suggests that the chitosan matrix does not solely exert any effects on the crystallization. In contrast, the addition of pAsp to the solution induced the deposition of thin film states of crystals with a homogeneous thickness, as shown in Fig. 1(a), for concentrations of pAsp between 4.4×10^{-4} and 1.0×10^{-2} wt%. The thickness of these films is *ca.* 1 μm. These thin films show circular symmetry around the center of nucleation. X-Ray diffraction patterns show that these crystals are mixtures of calcite, aragonite and vaterite [Fig. 2(a)]. The fraction of aragonite as well as vaterite increases with the concentration of pAsp.

To prepare thin films of high aragonite content, we added $MgCl_2$ ($Mg^{2+}/Ca^{2+} = 6$) to the solution in addition to pAsp as Mg^{2+} is known to induce aragonite formation.[10] Thin film crystals have also been deposited [Fig. 1(b)], although the appropriate concentration of pAsp is limited to *ca.* 4.4×10^{-4} wt%. The surface of the films is smoother than that without $MgCl_2$. X-Ray diffraction studies reveal that the fraction of aragonite in the films is 95 wt% or higher, and vaterite is absent [Fig. 2(b)]. By contrast, aragonite crystals with needle morphology were grown on chitosan matrices by the addition of $MgCl_2$

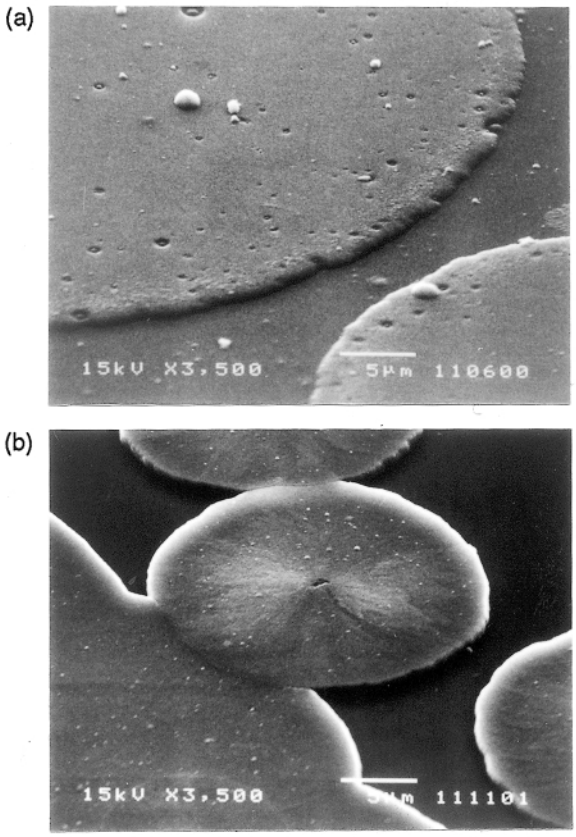

Fig. 1 Scanning electron micrographs of $CaCO_3$ thin films grown on chitosan matrices in the presence of pAsp (4.4×10^{-4} wt%): (a) in the absence of $MgCl_2$ and (b) in the presence of $MgCl_2$ ($Mg^{2+}/Ca^{2+} = 6$).

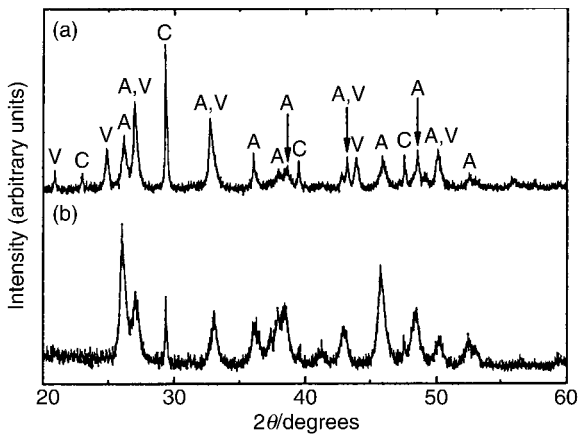

Fig. 2 X-Ray diffraction patterns of $CaCO_3$ thin films grown on chitosan matrices in the presence of pAsp (4.4×10^{-4} wt%): (a) in the absence of $MgCl_2$ and (b) in the presence of $MgCl_2$ ($Mg^{2+}/Ca^{2+} = 6$); aragonite (A), calcite (C) and vaterite (V).

DOI: 10.1039/a909566g

in the absence of pAsp. These results show that selective aragonite deposition by the addition of $MgCl_2$ and the formation of thin film crystals by chitosan and pAsp are compatible for aragonite thin-film formation. Furthermore, the stability of the film was so high that no flaking was observed upon microwave irradiation while needle-like aragonite crystals obtained with $MgCl_2$ in the absence of pAsp were observed to detach under such conditions.‡

By alternate operations of chitosan spin coating and aragonite crystallization,§ we could prepare double layered composite films of aragonite and chitosan. Fig. 3 shows an example of such a film; the upper aragonite layer has successfully grown on the underlying layer. It is expected that multi-layered composite materials resembling the nacreous structure can be prepared if adequate control is provided.

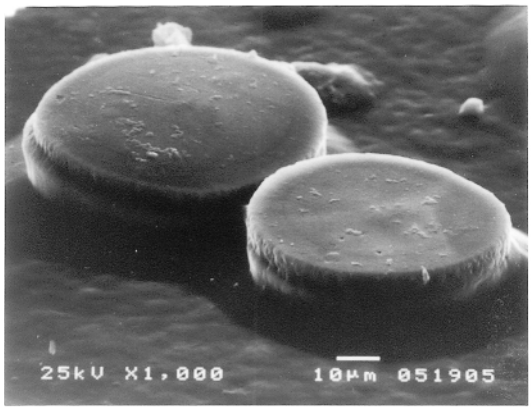

Fig. 3 Scanning electron micrograph of double layered aragonite thin films grown on a chitosan matrix in the presence of pAsp (4.4×10^{-4} wt%) and $MgCl_2$ ($Mg^{2+}/Ca^{2+} = 6$) by alternate spin coating and crystallization.

In summary, we have succeeded, for the first time, in the formation of aragonite thin films with a controlled homogeneous thickness. Double layer films have also been fabricated by the cooperative effect of $MgCl_2$ and functionalized organic polymers. These results offer potential for the design of high-performance organic/inorganic composite materials by simple synthetic procedures.

Partial financial support of a Grant-in-Aid for Scientific Research (No. 10875188) from the Ministry of Education, Science, Sports, and Culture is gratefully acknowledged.

Notes and references

† Crystals were grown from supersaturated calcium hydrogen carbonate solution in the presence of poly-L-(aspartic acid) sodium salt (DP = 360) (pAsp) and/or $MgCl_2$ at 30 °C. The detailed synthetic procedure has been described previously.[7] Polymorphs of $CaCO_3$ were studied by X-ray diffraction measurements. The fraction of aragonite in the crystals was calculated from the diffraction peak areas using a calibration curve obtained from crystal mixtures with known ratios of the polymorphs.

‡ The stability of the crystals formed on the matrix polymers was tested by microwave irradiation at 140 W for 30 min for the films placed in water.

§ After preparation of the aragonite thin films, chitosan was spin coated on them, and then $CaCO_3$ was subsequently crystallized.

Unusual stability of the coordinated triethylborohydride anion in an alkaline-earth metal complex: crystallographic characterization of $[Ca(HBEt_3)\{1,2,4\text{-}C_5(SiMe_3)_3H_2\}(thf)_2]$

Received (in Bloomington, IN, USA) 1st November 1999, Accepted 11th February 2000

The triethylborohydride anion $[HBEt_3]^-$ transfers intact from $Na[HBEt_3]$ to a calcium center to form the monomeric organocalcium complex $[Ca(HBEt_3)\{1,2,4\text{-}C_5(SiMe_3)_3H_2\}(thf)_2]$, which is stable in solution and the solid state; the $[HBEt_3]^-$ anion is coordinated in a multidentate fashion to the metal, which likely contributes to the failure of attempts to abstract the triethylborane moiety from the compound.

Owing to its exceptional nucleophilicity and selectivity, the triethylborohydride anion ($[HBEt_3]^-$) has found extensive use in organic, organometallic, and materials chemistry as a reducing agent and hydride source.[1–5] Study of the structure and bonding of the $[HBEt_3]^-$ anion itself is complicated by its high reactivity; it is usually encountered only in the form of its Group 1 (Li–K) salts, and is rarely incorporated into complexes containing other metals.[6–8] When the latter is the case, the stability of the resulting compounds may not be high; the organolanthanide species $[Sm(C_5H_4Bu^t)_2(HBEt_3)(thf)_2]$[7] and $[Nd(C_5H_4Bu^t)_2(HBEt_3)]$,[8] for example, cannot be removed from solution without decomposing. We have been interested in the $[HBEt_3]^-$ anion as a synthon for molecular main-group element hydrides, and in the course of this work discovered the unusual stability and structural features of the triethylborohydride anion in a Group 2 complex.

Parallels between the structure and reactions of the heavier Group 2 and divalent lanthanide elements[9] suggest that an alkaline-earth mono(cyclopentadienyl) halide might serve as a precursor to an organometallic hydride by metathetical reaction with an appropriate hydride source.[10,11] To examine this possibility, the iodide-bridged dimer $\{Ca(\mu\text{-}I)[1,2,4\text{-}C_5(SiMe_3)_3H_2](thf)\}_2$[12] was allowed to react in toluene with $Na[HBEt_3]$; removal of the NaI precipitate and evaporation of the filtrate left an air- and moisture-sensitive white solid that could be recrystallized from thf and was characterized as the triethylborohydride complex $[Ca(HBEt_3)\{1,2,4\text{-}C_5(SiMe_3)_3H_2\}(thf)_2]$ **1**.†

Spectroscopic evidence indicates that the $[HBEt_3]^-$ anion in **1**, which has transferred intact from Na^+, is involved in a bridging $Ca\cdot\cdot H\cdot\cdot BEt_3$ interaction. A prominent B–H stretch occurs at 1935 cm^{-1} (KBr) in the IR spectrum, in the region associated with μ-BH bonds.[13] This vicinity is where ν(BH) appears in $M[HBEt_3]$ salts [1870, 1835 and 1950 cm^{-1} for M = Li (KBr), Na (cyclohexane) and K (toluene), respectively].[14] The ^{11}B NMR resonance (δ −13.3 in C_6D_6; J_{B-H} 50 Hz) of **1** is characteristic of a bridging BH contact (*cf.* 60–90 Hz for J_{B-H_b} in transition metal examples),[15] and is also similar to that of $Na[HBEt_3]$ (δ −12.5; J_{B-H} 50 Hz).[16]

An X-ray diffraction study of **1** provided the first details of the bonding of the triethylborohydride anion to an element other than a Group 1 metal.‡ The compound crystallizes from thf as a monomer, with the calcium center surrounded by a $[\eta^5\text{–}C_5(SiMe_3)_3H_2]^-$ ring, two thf molecules and the $[HBEt_3]^-$ ligand (Fig. 1). The average Ca–C(ring) and Ca–ring centroid distances of 2.707(9) and 2.42 Å in **1** are comparable to those in $\{Ca(C_5Pr^i_4H)[C{\equiv}CPh](thf)\}_2$ [2.713(15) and 2.43 Å, respectively],[17] which contains a formally seven-coordinate Ca^{2+} center.

In **1**, the calcium–carbon distances reflect the multidentate ligation of the triethylborohydride anion to the metal. The hydrogen atom on B(1) was located from difference maps and successfully refined, with B(1)–H(1) and Ca(1)–H(1) distances of 1.13(4) and 2.21(4) Å, respectively, and a Ca(1)–H(1)–B(1) angle of 110(2)°. These values are similar to those observed for the $[HBEt_3]^-$ anion in, for example, the dimeric complex $[Nb_2(hexahydropyrimido\{1,2\text{-}a\}pyrimidinate)_4\bullet NaHBEt_3]$ (B–H 1.24, Na···H(B) 2.17 Å; Na–H–B 108°).[18] In **1**, the niobium dimer, and in related compounds such as $[Pd_2(dippp)_2\text{-}H_2]\bullet[(Li,Na)(BEt_4)]$ [dippp = 1,3-bis(diisopropylphosphino)-propane][19] and $[TaH_5(dmpe)_2]\bullet[LiBEt_4]$,[20] there is a close contact between the metal center and a methylene hydrogen on one or more ethyl groups. In **1**, the methylene hydrogen positions are calculated from the carbon atom locations, so the Ca···H(α-C) distance is not as reliable as is the Ca···H(B) separation. Even so, the Ca···H(25a) contact in **1** (2.41 Å)

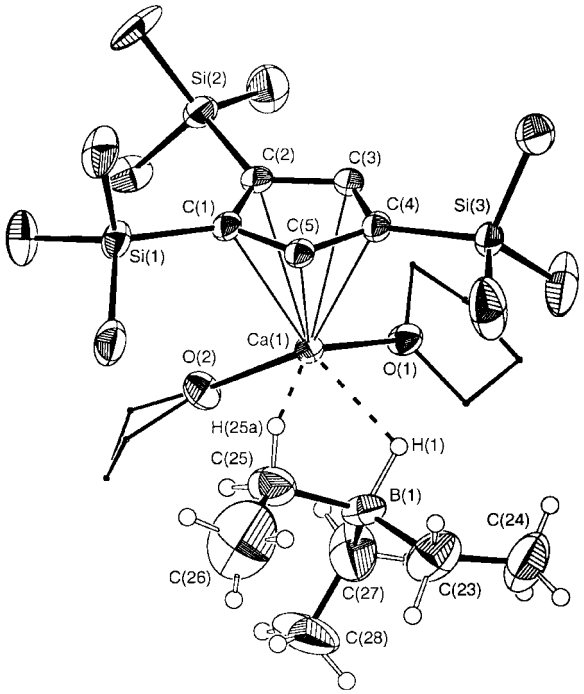

Fig. 1 ORTEP diagram of $[Ca(HBEt_3)\{1,2,4\text{-}C_5(SiMe_3)_3H_2\}(thf)_2]$ **1**. The trimethylsilyl groups on C(1) and C(2) were found to be disordered; for clarity, only one conformation for each is shown. Selected bond distances (Å) and angles (°): Ca(1)–C(1) 2.733(4), Ca(1)–C(2) 2.764(4), Ca(1)–C(3) 2.685(4), Ca(1)–C(4) 2.676(4), Ca(1)–C(5) 2.679(4), Ca(1)–C(19) 2.84(2), Ca(1)–O(1) 2.386(3), Ca(1)–O(2) 2.367(3), B(1)–C(23) 1.629(9), B(1)–C(25) 1.629(8), B(1)–C(27) 1.610(8), B(1)–H(1) 1.13(4); O(1)–Ca(1)–O(2) 86.3(1), Ca(1)–H(1)–B(1), 110(2).

DOI: 10.1039/a908674i

appears to be structurally significant, and the triethylborohydride group should be regarded as binding through both H(1) and H(25a).

The triethylborohydride anion in **1** proves to be remarkably robust, and several approaches to removing the BEt_3 moiety from **1** have been unsuccessful. For example, no reaction is observed with the competing base PMe_3 in toluene, and refluxing a solution of **1** in toluene leads to decomposition and the formation of the metallocene [Ca{η^5-1,2,4-C_5(SiMe_3)$_3H_2$}].[21] The bidentate bonding of the $[HBEt_3]^-$ anion to the calcium evidently strengthens the attachment of the BEt_3 fragment.

Several features of the complex are worth noting. (i) The similarity of the bonding arrangement of the triethylborohydride anion in **1** to complexes of the alkali metals may indicate that this is its typical ligation geometry to highly electropositive metals. The structure of **1** may thus serve as a model for the triethylborohydride complexes of the lanthanide elements, which have yet to be structurally characterized.[6–8]

(ii) The resistance of the BEt_3 moiety to removal from **1** may stem from several factors. Heavy organoalkaline-earth complexes containing the bulky 1,2,4-tris(trimethylsilyl)cyclopentadienyl ligand are kinetically stabilized against ligand redistribution,[12] and the presence of the thf ligands enables **1** to remain coordinately saturated without having to oligomerise. These structural features combined with the bidentate ligation of the $[HBEt_3]^-$ ion probably leave it without a facile pathway for decomposition. Knowledge of these bonding requirements may help in the use of the triethylborohydride anion with other metals.

Pyrrole as an NMR probe molecule to characterise zeolite basicity

Manuel Sánchez-Sánchez and Teresa Blasco*

Instituto de Tecnología Química (UPV-CSIC), Avenida de los Naranjos s/n 46022-Valencia, Spain. E-mail: tblasco@itq.upv.es

Received (in Cambridge, UK) 21st January 2000, Accepted 10th February 2000

The ^{1}H NMR chemical shift of the N–H group of pyrrole adsorbed on alkali metal ion exchanged FAU-type zeolites depends on the zeolite intrinsic basicity, while, as shown for zeolite LiY, the NMR of alkali metal nuclei reflects the interaction of the aromatic cycle with the cations at sites SII.

Zeolite molecular sieves have been extensively investigated mainly due to their application as acidic catalysts in the chemical and petrochemical industry. The large social and economical impact of such processes when compared with those using base catalysts can explain why much less attention has been paid to zeolite basicity. Only recently it has been realized that basic zeolites can also be successfully used as catalysts and have gained a growing interest in the last decade.[1,2]

Basic zeolites are, by definition, non-protonic, and the negative charge created by the presence of aluminium atoms into the network are compensated by extraframework usually monovalent metal cations. The zeolite oxygen atoms act as Lewis basic sites, while the compensating cations act as Lewis acid sites, forming an acid–base pair. The so-called intrinsic zeolite basicity increases with the negative charge on the oxygens, which is determined by their framework structure and chemical composition. The basic strength of zeolites is strongly enhanced by increasing the framework aluminium content, and for a given Si/Al molar ratio, when the electronegativity of the compensating cation decreases. These results can be understood in terms of the average charges over oxygen atoms calculated using the Sanderson principle of equalization of electronegativities based on the zeolite chemical composition.[3] whereas the effect of the crystalline structure was quantified by the more sophisticated electronegativity equalization method (EEM).[4]

The most used method to characterize zeolite basicity uses pyrrole as an IR probe molecule and is based on the shift to lower frequencies of the pyrrole N–H stretching band when the framework basicity increases.[1] Pyrrole is an amphoteric molecule which can interact with zeolite basic sites forming hydrogen bonds between the N–H group and framework oxygen atoms, and with cationic acid sites by donation of charge from its aromatic five-membered heterocycle. Hydrogen bonding is clearly shown by the shift of the IR N–H stretching frequency, while the pyrrole–cation interaction is only suggested from the IR CH out of plane deformation bands[5,6] and by theoretical calculation,[6,7] however, no direct experimental evidence has been reported so far. Here, we show that the ^{1}H NMR chemical shift of the N–H group of pyrrole adsorbed over basic zeolites is a very sensitive probe to measure the average intrinsic basicity, with the advantage that the NMR spectra of alkali metal nuclei provides direct information about the pyrrole–cation interaction, as illustrated for zeolite LiY.

The chemical composition of the zeolites X and Y used here were described previously.[8] Zeolites LiY, KY, CsY and LiX, KX also contains Na^+ as compensating cation owing to incomplete exchange. Samples were heated under dynamic vacuum at 673 K for 12 h up to a final pressure of $< 10^{-5}$ kPa, then contacted with the vapor pressure of pyrrole at room temperature for 5 min and subsequently evacuated at 338 K for 30 min to eliminate physisorbed pyrrole.

The ^{1}H NMR spectra of adsorbed pyrrole (Fig. 1), shows three peaks of relative intensity 1:2:2 corresponding to the three types of protons in the molecule. The less intense peak is due to the N–H group, whereas the other two are from the four C–H protons in the five-membered heterocycle; the two C–H groups in α and the two in β positions give rise to the intermediate and high field resonances, respectively. The N–H peak of liquid pyrrole appears at δ 7.1 and shifts to higher frequency when it is adsorbed on alkali zeolites X and Y, to an extent that depends on the sample. From the chemical composition and the characterization performed by other methods, the intrinsic basicity of the zeolites used here increases in the order LiY < NaY < KY < LiX < CsY < NaX < KX.[8] Therefore, the N–H proton resonance shifts to higher frequency when the framework basicity increases, giving differences of up to 3 ppm between LiY and KX (Fig. 1). This shift can be understood by the higher polarization of the N–H bond, which forms hydrogen bonds with the framework oxygen atoms, when the intrinsic zeolite basicity increases.

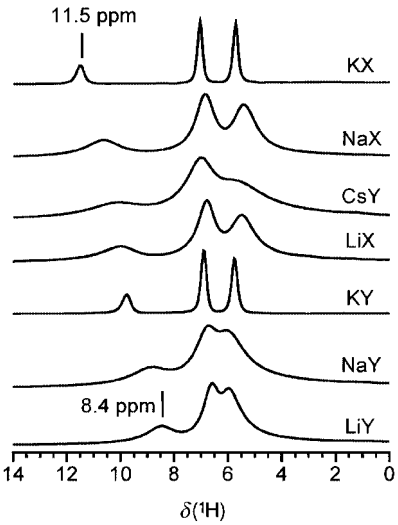

Fig. 1 ^{1}H magic angle spinning (MAS) NMR spectra of pyrrole adsorbed over the zeolites indicated. The samples were prepared by the method described in the text and transferred into the rotors in a glove box. The spectra were recorded at room temperature with a Varian VXR-S 400-WB spectrometer at 399.9 MHz, using a VT CP/MAS Varian probe with 5 mm silicon nitride rotors spinning at 13 kHz. $\pi/2$ rad pulses of 6 μs and a recycle delay of 5 s were used.

At the same time, solid state NMR of alkali metal cations reveals their interaction with the guest molecules as illustrated in Fig. 2 for zeolite LiY, where the degassing temperature after the pyrrole adsorption was varied. Very recently, an upfield shift of the ^{7}Li resonance has been reported to occur after the adsorption of benzene over Li-ZSM-5 as a result of 1:1 π-complexation between Li^+ and benzene, as confirmed by *ab initio* calculation of ^{7}Li chemical shifts.[9] Fig. 2(a) shows the ^{7}Li NMR spectrum of bare LiY, consisting of a peak formed by two

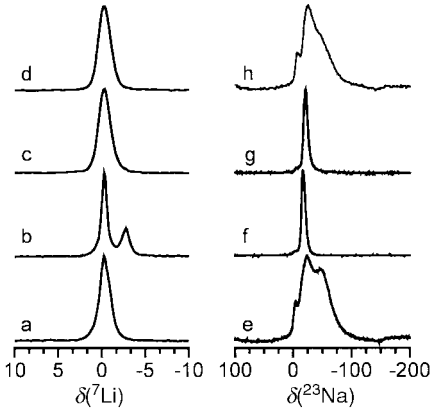

Fig. 2 ^{7}Li and ^{23}Na magic angle spinning (MAS) NMR spectra of: (a) and (e) bare zeolite LiY. Sample LiY after the adsorption of pyrrole at room temperature and evacuation at: (b) and (f) 338 K; (c) and (g) 423 K; (d) and (h) 473 K. The ^{7}Li and ^{23}Na spectra were recorded at room temperature with a Varian VXR-S 400-WB spectrometer at 155.4 and 105.8 MHz, respectively, using a VT CP/MAS Varian probe with 5 mm silicon nitride rotors spinning at 13 kHz. To record both ^{7}Li and ^{23}Na MAS NMR spectra, pulses of 1.5 μs to flip the magnetization π/8 rad and a recycle delay of 1 s were applied. ^{7}Li and ^{23}Na chemical shifts are referred to 0.1 M solutions of LiCl and NaCl, respectively.

overlapping signals at δ −0.2 and −1.0 which can be assigned to lithium atoms in front of six-ring windows at sites SI′ and SII in the sodalite and super-cages, respectively, of the faujasite structure, in agreement with published results for LiX.[10] From chemical analysis and NMR results the site occupancy per unit cell in zeolite LiY is 24 Li^+ at site SI′ and 10 at SII positions. As shown in Fig. 2(b), after pyrrole adsorption and subsequent evacuation at 338 K, the peak from ^{7}Li cations at sites SI′ remains at the same position, while the resonance from ^{7}Li atoms at sites SII shifts to δ −2.8 indicating the direct interaction of accessible Li cations with the π electrons of the pyrrole ring. As is apparent from Fig. 2(c), these pyrrole species are desorbed at 423 K and the original ^{7}Li spectrum is recovered. The corresponding ^{23}Na MAS NMR spectra are shown in Fig. 2(e)–(h). The ^{23}Na spectrum of bare LiY [Fig. 2(e)] shows a peak at δ −3 for cations within the hexagonal prism at site SI, and two broad bands from quadrupolar signals of sodium at sites SI′ and SII.[11] The site population per unit cell is *ca.* 0.8 Na^+ at SI and 20 Na^+ atoms at sites SII and SI′ (with a higher population of SII). After the adsorption of pyrrole, the signal from Na^+ at sites SI remains unchanged while the quadrupole coupling constant (QCC) of sodium atoms at sites SII and SI′ strongly decreases, as shown in Fig. 2(f). Consistent with the results for ^{7}Li, the modification of the ^{23}Na NMR signal of cations at sites SII must be attributed to direct interaction with the aromatic system of the pyrrole molecules. The changes observed for the ^{23}Na signal of Na^+ at site SI′, which are inaccessible to pyrrole molecules, could be attributed to the influence of pyrrole adsorption on nearby oxygen atoms, or interpreted in terms of cation migration to accessible positions.[12] The ^{23}Na spectrum of bare LiY zeolite is almost recovered and only some residual pyrrole is evident after evacuation at 473 K [Figs. 2(f)–(h)]. Simultaneously, the ^{1}H resonance of the pyrrole N–H group progressively shifts to higher frequency (up to 0.5 ppm) when the degassing temperature is increased to 473 K, indicating that pyrrole species at more basic sites remain.

The results reported here confirm the model proposed for the adsorption of pyrrole over alkali metal exchanged zeolites of FAU-type structure based on theoretical calculations.[6,7] Pyrrole adsorbs on zeolites Y at cations at sites SII by interaction of its aromatic ring, and the N–H group points towards framework basic oxygen sites forming hydrogen bonds.[6,7] For zeolite LiY, basic centres involving SII sites occupied by Na^+ are more basic than those occupied by Li^+, although the overall intrinsic zeolite basicity is also modified by the type of compensating cation. Heterogeneity of the basic sites is directly observed by the appearance of several components in the N–H stretching band of pyrrole adsorbed over basic zeolites,[1,13] which are not reflected in the ^{1}H MAS NMR spectra because of the different time scale of both spectroscopic techniques. However, the interpretation of the IR spectra is still controversial,[7,13] and the use of solid state NMR can shed some light in the knowledge of the host–guest interactions between the probe molecules and basic zeolites and the nature of the adsorbed species.

Financial support by the CICYT (Project MAT 97-1016-C02-01) is gratefully acknowledged.

Using a large calixarene as a polyalkoxide ligand: *tert*-butylcalix[12]arene and its complex with the uranyl cation

Pascal C. Leverd,*[a] Isabelle Dumazet-Bonnamour,[b] Roger Lamartine[b] and Martine Nierlich[a]

Received (in Basel, Switzerland) 31st January 2000, Accepted 16th February 2000

***tert*-Butylcalix[12]arene ($H_{12}L$) encompasses two uranyl bimetallic units inside its cavity to form $[HNEt_3]_2[\{(UO_2)_2(NO_3)(py)\}_2(H_4L)]$ 1, the first metal complex of a large calixarene; the comparison of the crystal structures of 1 and $H_{12}L$ shows a relatively limited influence of metal coordination on the conformation of the macrocycle.**

The coordination chemistry of the calixarenes exclusively concerns calix[4,5,6,7 and 8]arenes and their various derivatives.[1,2] Working with the large calix[$n > 8$]arenes is considered a challenge and very little organic and physical chemistry has been reported for this class of molecules.[3] The calixarene with the highest number of phenolic units for which structural information is currently available is calix[8]arene.[4] The major interest of the calix[$n > 8$]arenes in coordination chemistry is that these large and flexible polyalkoxide ligands have the potential to assemble several metallic units inside their cavity and could lead to new molecular architectures. In an attempt to widen the use of calixarenes in coordination chemistry, we set out to study *tert*-butylcalix[12]arene ($H_{12}L$)[3a,b] as a ligand for the uranyl cation. We report herein, the crystal structure of $H_{12}L\cdot10py$, the first of a large calixarene, and comparison with that of $[HNEt_3]_2[\{(UO_2)_2(NO_3)(py)\}_2(H_4L)]$ **1**, the first metal complex with a ligand of this class. To the best of our knowledge, **1** is a unique example of an organic macrocycle binding two bimetallic species inside its cavity.

Crystals of $H_{12}L$ suitable for X-ray crystallography were obtained from pyridine–acetonitrile (1:1) (0.050 g $H_{12}L$ in 10 ml) that was slowly evaporated at 290(1) K over 180 days.†‡ The structure was solved and revealed $H_{12}L\cdot10py$ a pyridine solvate of the fully protonated macrocycle (Fig. 1). In the solid state, $H_{12}L$ is located around a crystallographic centre of inversion. All its phenolic groups engage in strong H-bonding. Four successive intramolecular H-bonds are formed between O(4), O(3), O(2), O(1) and O(6) while O(5) and O(6) bind to pyridine molecules. The all-in conformation of the calixarene is at first reminiscent of that described for *tert*-butylcalix[8]arene.[5] However, a closer look at the dihedral angles between the adjacent phenolic faces indicates that the conformation cannot be described as a pleated loop or a cone.[6,7] In order to define the overall shape of the macrocycle, attention was paid to the relative positions of the phenolic rings [the centroid of the ring bearing O(n) is denoted X(n)]. X(2), X(5) and their two symmetry equivalents define a perfect plane above which are located X(3) and X(4) (+1.37 and +2.50 Å, respectively) and below which are positioned X(1) and X(6) (−4.70 and −3.90 Å, respectively). With this work, $H_{12}L$ becomes the first large calixarene to have its solid state conformation determined by X-ray crystallography.

When $UO_2(NO_3)_2\cdot6H_2O$ was treated with $H_{12}L$ in the presence of NEt_3 in pyridine, a red solution typical of a phenolate complex of uranyl was immediately obtained. The solution was allowed to stand and after a few days a red microcrystalline powder of **1** was obtained as the sole reaction product in 46% yield.†

The synthesis was repeated in a crystallisation vessel (10 mL) which was allowed to stand at 290(1) K. After 180 days, very small crystals suitable for X-ray crystallography were isolated from the same mixture of solvent as for $H_{12}L$.‡ The structure was solved and revealed a complex in which four uranyl cations are encompassed by the macrocyclic ligand (Fig. 2).

As for $H_{12}L$, **1** is located around a centre of symmetry in the solid state. The four uranyl dications form two symmetry related bimetallic units in which the two metal cations are bound by a tridentate nitrate ligand. Such a bis-chelating binding mode of $[NO_3]^-$ is not unusual for solid state polymers, however, it is more rarely found for discrete metal complexes.[8,9] The bimetallic units are bound to the macrocycle through five of its oxygen atoms, four of which are deprotonated [O(1), O(2), O(4) and O(5)]. The resulting short U–O distances (*ca.* 2.2 Å) are typical of uranyl phenolate complexes while the longer U(1)–O(3) distance [2.62(3) Å] corresponds to the dative bond

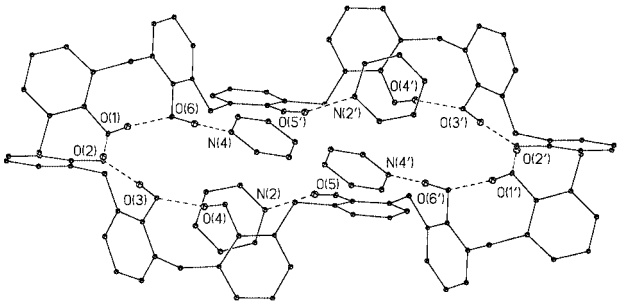

Fig. 1 Crystal structure of compound $H_{12}L$ (5% probability). All Bu^t groups and H atoms or solvent molecules not participating in H-bonding have been omitted for clarity. H-bond donor–acceptor distances (Å): O(1)–O(6) 2.57(3), O(2)–O(1) 2.63(3), O(3)–O(2) 2.61(3), O(4)–O(3) 2.66(3), O(5)–N(2) 2.82(4), O(6)–N(4) 2.56(4).

Selected bond lengths (Å): U(1)–O(1) 2.21(3), U(1)–O(2) 2.23(3), U(1)–O(3) 2.62(3), U(1)–O(11) 2.47(3), U(1)–O(21) 2.49(2), U(2)–O(4) 2.32(3), U(2)–O(5) 2.15(3), U(2)–O(11) 2.41(3), U(2)–O(31) 2.46(3), U(2)–N(1A) 2.58(2).

DOI: 10.1039/b000909l

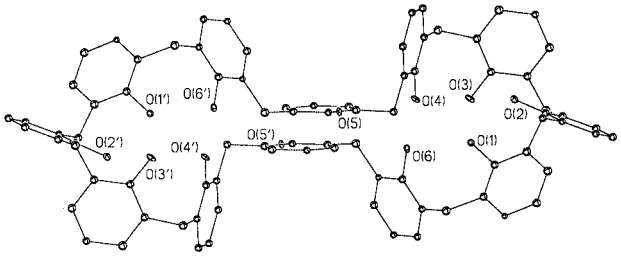

Fig. 3 Side view of the calixarene core in **1**.

formed by a phenolic group.[10] The geometry around the uranyl ion is five-coordinate pentagonal with one of the uranium atoms completing its coordination sphere with the nitrogen atom of a pyridine molecule.

Interestingly, the arrangement of the metallic species in **1** is reminiscent of that reported for the uranyl complex of an acyclic hexaphenol where the six oxygen atoms of the ligand are coordinated to the $[(UO_2)_2(NO_3)]^{3+}$ core.[9] The latter was presented as an open analogue of calix[6]arene but can also be viewed as the half of a calix[12]arene. The macrocyclic geometry of $H_{12}L$ does not enable such flexibility and is probably the cause of the unprecedented arrangement of the donor atoms observed for the metallic species of **1**, in which one of the cations is coordinated by five oxygen atoms and the other by only four, plus a nitrogen atom. To the best of our knowledge, **1** is the first example of an organic macrocycle carrying two bimetallic units inside its cavity. The isolation of **1** reinforces the notion that large polyalkoxide ligands such as calixarenes can be considered as potential 'cluster-keepers'.[3]

$H_{12}L$ acts as a double pentadentate ligand. As indicated by the stoichiometry and the U–O bond distances, only O(3) and O(6) have been able to retain their acidic proton. The calixarene is thus deprotonated eight times, with the negative charges evenly distributed around the macrocycle.[11] The conformation of the macrocycle is a regular succession of distorted pleated-loops and cones.[12] Although its structure appears different from that of $H_{12}L$, it essentially only differs by the positive sign of the fourth dihedral angle ϕ which is negative for the free macrocycle (−4.8°). Had the latter been positive, the conformation of $H_{12}L$ and **1** would have been similar.[13] This result follows Gutsche's postulate that flexible calixarenes seek conformations which possess as much cone and/or pleated loop character as their geometry permits.[1]

A good indication of the effect of metal coordination on the ligand is obtained by comparison of some intramolecular distances in $H_{12}L$ and **1**. The longest distance for the oxygen atoms of the phenolic groups in $H_{12}L$ is 17.815 Å between O(1) and O(1′) while the shortest is 4.66 Å between O(5) and O(5′). In **1**, these two distances are 15.68 Å between O(2) and O(2′) and 9.94 Å between O(5) and O(5′). Whereas the free ligand is a thin and elongated molecule, **1** is a shorter and wider compound. The macrocycle is stretched open by metal coordination inside its cavity, but retains its global geometry. The side view of the calixarene core (Fig. 3) emphasises best the shape of the macrocycle in **1** and its resemblance to that of the free ligand.

In conclusion, the encompassing of two metal dimers into one macrocycle has a surprisingly limited influence on the conformation of what was considered a very flexible molecule. The use of a large polyalkoxide ligand leads to a new combination of donor atoms around the uranyl cation and seems highly appropriate for the design of new metal complex architectures. Work is in progress to study other large calixarenes.

Notes and references

† *General*: $H_{12}L$ was prepared by the method described in ref. 3(*a*).

Synthesis of $[HNEt_3]_2[\{(UO_2)_2(NO_3)(py)\}_2(H_4L)]$ **1** : $UO_2(NO_3)_2{\cdot}6H_2O$ (0.052 g, 1.04×10^{-4} mol) was treated with $H_{12}L$ (0.050 g, 2.6×10^{-5} mol) and NEt_3 (0.021 g, 2.08×10^{-4} mol) in pyridine (2.5 mL) at 313 K for 2 h. After allowing the red solution to stand for 7 days at room temperature, a red microcrystalline powder of **1** was separated by decanting, washed twice with acetonitrile (2 mL) and dried for 2 h to afford $[HNEt_3]_2[\{(UO_2)_2(NO_3)(py)\}_2(H_4L)]{\cdot}py$ (0.045 g, 1.2 10^{-5} mol, 46%). $C_{159}H_{207}N_7O_{26}U_4$: Calc. C, 53.28; H, 5.78; N, 2.74. Found: C, 53.36; H, 5.35; N, 2.61%.

‡ *Crystal data*: for $H_{12}L{\cdot}10py$: $C_{182}H_{218}N_{10}O_{12}$, M = 2737.66, 0.12 × 0.03 × 0.03 mm, triclinic, $P\bar{1}$, Z = 1, a = 12.232(2), b = 16.072(3), c = 20.841(4) Å, α = 98.25(3), β = 103.53(3), γ = 91.77(3)°, V = 3933(2) Å^3, D_c = 1.156 g cm^{-3}, $F(000)$ = 1476, $2\theta_{max}$ = 49.34°, μ(Mo-Kα) = 0.072 cm^{-1}, T = 100 K. The structure was solved by direct methods[14] and refined on F^2.[15] Of the 23623 reflections measured, 12327 were found to be independent (R_{int} = 0.247), 3687 of which were considered as observed [$I > 2\sigma(I)$] and were used in the refinement of the 439 parameters, leading to a final R_1 of 0.1212 and a R_{all} of 0.3481. wR_{obs} and wR_2 were 0.2145 and 0.3373, respectively. All hydrogen atoms were introduced in the calculation as riding on calculated positions except those of the phenolic groups which were located on the Fourier map. The goodness-of-fit parameter S was 0.989 and the maximum residual density 0.308 e Å^{-3}.

For **1**·9py: $C_{199}H_{247}N_{15}O_{26}U_4$, M = 4217.22, 0.06 × 0.04 × 0.03 mm, triclinic, $P\bar{1}$, Z = 1, a = 10.099(2), b = 22.133(4), c = 25.109(5) Å, α = 114.39(3), β = 94.07(3), γ= 97.50(3)°, V = 5019(2) Å^3, D_c = 1.395 g cm^{-3}, $F(000)$ = 2120, $2\theta_{max}$ = 41.26°, μ(Mo-Kα) = 3.283 cm^{-1}, T = 100 K. The structure was solved and refined as above. Of the 16796 reflections measured, 9436 were found to be independent (R_{int} = 0.214), 3687 of which were considered as observed [$I > 2\sigma(I)$] and were used in the refinement of the 375 parameters, leading to a final R_1 of 0.1397 and a R_{all} of 0.3007. wR_{obs} and wR_2 were 0.2578 and 0.3604 respectively. Hydrogen atoms were introduced in the calculation as riding on calculated positions. The goodness-of-fit parameter S was 1.228 and the maximum residual density 0.988 e Å^{-3}. CCDC 182/1545. Enantiopure epoxidation of electrophilic alkenes

Otto Meth-Cohn,*[a] David J. Williams[b] and Yi Chen[a]

[a] *Chemistry Department, University of Sunderland, Sunderland, UK SR1 3SD. E-mail: otto.meth-cohn@sunderland.ac.uk*

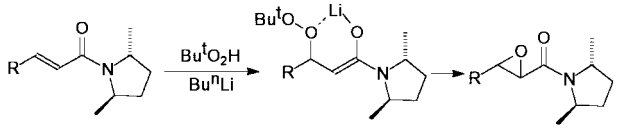
[b] *Chemistry Department, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*

Received (in Liverpool, UK) 18th January 2000, Accepted 14th February 2000

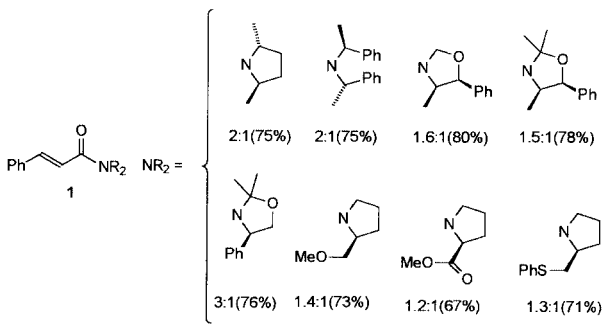
Cinnamamides derived from prolinols (*e.g.* –CH_2OH and –CPh_2OH) and from proline amides (*e.g.* prolineanilide) are epoxidised with total retention of the alkene configuration, to give either epoxides or bicyclic derivatives thereof, essentially enantiopure, using *tert*-butyl hydroperoxide and butyllithium.

Recently we disclosed[1] that our general method for the stereocontrolled epoxidation of electrophilic alkenes using lithium *tert*-butylhydroperoxide[2] was capable of homochiral application using α,β-unsaturated amides derived from homochiral secondary amines (Scheme 1). However, the method produced two diastereomers, albeit easily separable, that could then be further converted into, for example, α,β-unsaturated ketones with organolithium derivatives. It would be much more elegant and extremely useful synthetically, if the epoxidation could be conducted to give solely one or other enantiopure diastereomer in a predictable manner. This would be especially worthwhile if the chiral auxiliary were cheap, easily available as both enantiomers and was recyclable. We herein present our recent endeavours to achieve these goals.

The first requirement in this search was to understand the basis of the diastereomeric selection that operates in this reaction. On the basis of a very large body of work by ourselves and numerous others, the reaction proceeds with total retention of the alkene configuration of the epoxide. We have already proposed[2] that this stereocontrol of the epoxidation derives from the potent 'lithium bonding' which ensures a chelate control of the epoxidation process (Scheme 1). For diastereocontrol of the process, a mechanism whereby a similar fixation of the geometry of the transition state is required. In order to achieve optimum diastereoselection we examined a series of homochiral secondary amines from which were made cinnamamides **1** (Scheme 2). These alkenes proved universally disappointing, giving diastereomeric ratios between 1.2 : 1 and 3 : 1 (Scheme 2). Clearly, the usual steric or geometric factors alone were not sufficient to generate a high diastereomeric excess (de).

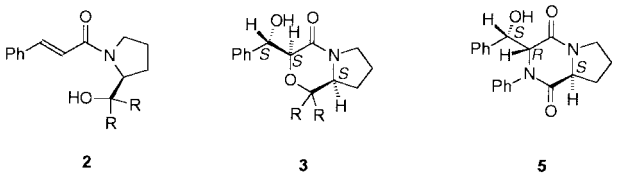


Scheme 1



Scheme 2 Diastereomeric ratios and yields from epoxidation of homochiral cinnamamides.

We next examined the (*S*)-prolinol-derived cinnamamides **2**. These compounds reacted very rapidly and generated essentially enantiopure products in reasonable yield. However, the products were not the expected epoxides but the pyrrolidinooxazinones **3**. The structures were confirmed both by spectroscopy and by X-ray crystallography (Fig. 1)† which showed that the product had the (*S*,*S*,*S*)-configuration.



2 a, R = H; b, R = Ph

3 a; de >99:1, 65%; b, de >99:1, 61%

5

We then made a series of cinnamamides **4** based on (*S*)-proline, with the proline side-chain being varied. Using proline itself or prolinamide, epoxidation of the cinnamamide (**4**, R = H) gave complex mixtures, and thus derivatives were studied. Some remarkable variations in diastereomeric ratio were uncovered, the more surprising in that closely similar systems proved to be either highly effective or of little value (Scheme 3). In general, the de of the epoxidation increased with the steric bulk of the group R on the proline side-chain. However, spectacular ratios were observed using prolineanilide (> 99 : 1), the epoxide always being accompanied by an interesting bicyclic product. Spectroscopy and ultimately X-ray crystallography (Fig. 2)† confirmed that the product was the pyrrolidinopiperazinedione **5** but surprisingly with (*S*,*R*,*S*)-configuration.

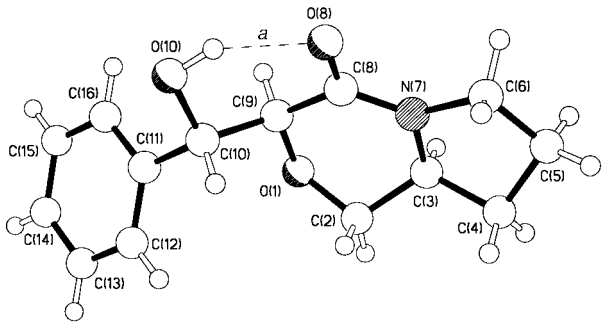


Fig. 1 The molecular structure of **3**. The hydrogen bonding geometry, (*a*) is O···O, H···O 2.66, 1.84 Å; O–H···O 149°.

DOI: 10.1039/b000520g

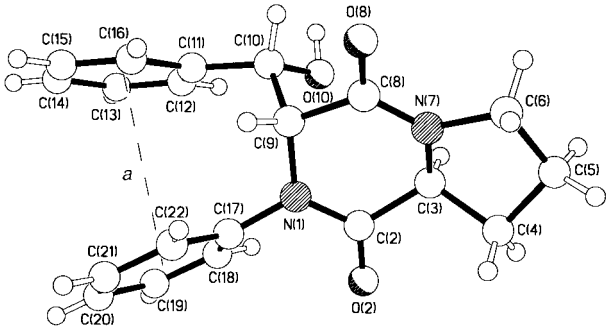

Fig. 2 The molecular structure of **5**. The ring-centroid ring-centroid separation (*a*) is 3.75 Å.

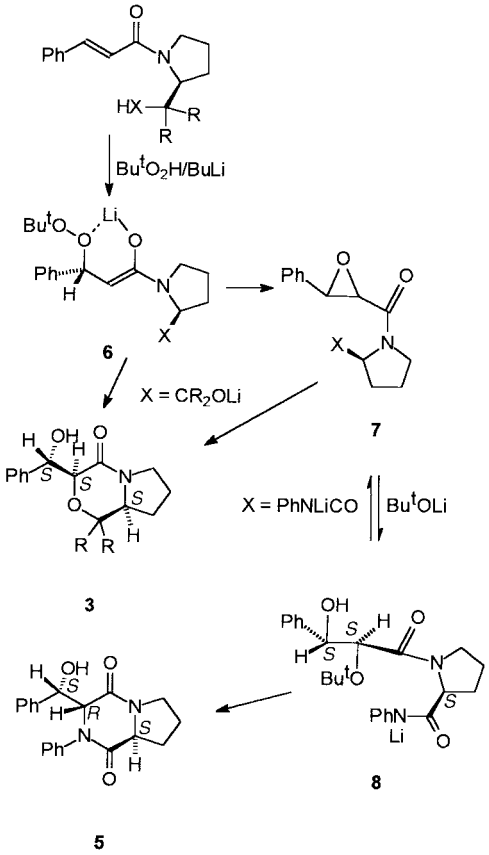

Scheme 4

Short reaction times gave primarily the epoxide (61%) while longer reaction time resulted in the sole formation of the potentially useful pyrrolidinopyrazinedione **5** (45%), both in >99% de. The related *p*-chloro-, *p*-cyano- and *p*-methoxy-anilides gave solely the bicyclic analogue of **5**, again essentially enantiopure (41–45%), while proline-*N*-methylanilide (CONMePh) gave only the corresponding epoxide **7** though with poor diastereo-discrimination (1.4:1, 68%). Both of these cyclic derivatives **3** and **5** are of considerable interest *per se*, being potential sources of novel homochiral amino acids and dihydroxy acids respectively. It should be underlined that while the *oxazine* derivative **3** shows (*S,S,S*)-stereochemistry the *piperazine* **5** is (*S,R,S*)!

A possible explanation for this stereochemical surprise is presented in Scheme 4. The prolinol-derived system **4** could arise either by direct interception of the hydroperoxide intermediate **6** *en route* to the epoxide **7** or by ring-opening of the epoxide **7**, in both cases by the pendant OLi group, both processes being highly enantioselective. The stereochemical inversion involved in the generation of the compound **5** suggests that a double inversion at the central chiral centre occurs. Thus, the *trans*-epoxide **7** is opened rapidly (and probably reversibly; this reversibility is probably a general, though degenerate process in all such epoxidations) firstly by LiOBu^t, the by-product of the epoxidation, followed by a slow attack by the considerably less nucleophilic CONPhLi side-chain. This would explain (a) the comparatively slow formation of this product compared to the oxygen analogue **3** and (b) the fact that brief reaction gives the epoxide while prolonged reaction generates the bicyclic product **5**. Treatment of the isolated epoxide **7** (X = CONHPh) with butyllithium does not yield the piperazine **5**.

As regards the remarkable diastereospecificity observed in the epoxidation of prolinol and prolineanilide derivatives (not in the case of NMePh, and other NHR derivatives of proline) we propose: (a) The preferred conformation of the cinnamamides prior to epoxidation is as shown (*e.g.* Scheme 4) to backside attack by the Bu^{t}O$_2$Li. This backside attack is further favoured by side-chain OLi or NLi 'lithium bonding' to the carbonyl oxygen. (b) As shown in the X-ray crystallographic study (Fig. 2) a π–π interaction between the two benzenoid rings of the prolinamide is favoured; this effect also tends to lock the preferred conformation for backside attack in the epoxidation, enhancing the otherwise weaker 'lithium bonding' between an NLi and the carbonyl oxygen. Presumably, this interaction is weakened by steric factors (*e.g.* as with the 2,4,6-trimethylanilide).

A fuller explanation of the specificities and mechanisms is clearly necessary and the application of these epoxidations and their the interesting downstream derivatives is under active study.

We thank the EPSRC for a grant that made this work possible.

The *N,N′*-bis(trimethylsilyl)pentafluorobenzamidinate ligand: enhanced ethene oligomerisation with a neutral V(III) bis(benzamidinate) alkyl catalyst†‡

Edward A. C. Brussee, Auke Meetsma, Bart Hessen* and Jan H. Teuben

Received (in Basel, Switzerland) 20th December 1999, Accepted 18th February 2000

The pentafluorobenzamidinate ligand $[C_6F_5C(NSiMe_3)_2]^-$ is reported, together with its bis(benzamidinate) vanadium(III) methyl derivative; the latter is considerably more active in catalytic ethene oligomerisation than its non-fluorinated analogue.

Fluorination of ancillary ligands attched to catalytically active transition-metal centres leads in many cases to a significant improvement in catalytic properties relative to the non-fluorinated analogues. Examples of this can be found in the metathesis catalysts $[(CF_3)_nMe_{3-n}CO]_2W(CHCMe_3)(NAr)$ (n = 0, 1 2; Ar = 2,6-diisopropylphenyl)[1] and in the olefin polymerisation catalysts based on [2-pyridyl–$C(CF_3)_2O]_2Zr(CH_2Ph)_2$.[2] The electron withdrawing properties of the fluorinated ligand renders the metal centre more electrophilic and, for many reaction types, more reactive. In this contribution we present the synthesis of a new fluorinated derivative of a well known ancillary ligand, *N,N′*-bis(trimethylsilyl)benzamidinate, and show that this leads to a significant improvement in the catalytic performance of an ethene oligomerisation catalyst, bis(benzamidinate)vanadium alkyl.

The *N,N′*-bis(trimethylsilyl)benzamidinate monoanionic ancillary ligand, $[PhC(NSiMe_3)_2]^-$, is widely used in transition-metal chemistry and catalysis,[3] for example in the olefin polymerisation catalysts $[PhC(NSiMe_3)_2]_2MCl_2$/MAO (M = Ti, Zr, Hf; MAO = methylaluminoxane)[4] and Cp*M[PhC(NSi-$Me_3)_2]Cl_2$/MAO (M = Ti, Zr, Hf).[5] We recently reported the neutral paramagnetic (S = 1) 12-electron bis(benzamidinate)-vanadium(III) alkyls $[PhC(NSiMe_3)_2]_2VR$ (R = Me, Et).[6] This neutral alkyl system catalyses the oligomerisation of ethene to linear alkenes without the need for added cocatalysts. The productivity of the catalyst system is modest, which is likely to be due to the relatively low electrophilicity of the metal centre. We therefore sought to increase this electrophilicity by preparing a benzamidinate with a more electron-withdrawing aryl group, pentafluorophenyl, on the ligand backbone.

Lithium *N,N′*-bis(trimethylsilyl)benzamidinate is readily prepared by reacting benzonitrile with the bis(trimethylsilyl)amide $LiN(SiMe_3)_2$.[7] The reaction of pentafluorobenzonitrile with $LiN(SiMe_3)_2$ in THF was recently reported to lead to C–F activation of the nitrile rather than to formation of the pentafluorobenzamidinate $[C_6F_5C(NSiMe_3)_2]Li$.[8] We observed that changing the solvent from THF to diethyl ether suppresses this tendency towards C–F activation. Thus, addition of 1 equivalent of C_6F_5CN to a suspension of $Li[N(SiMe_3)_2]$ in diethyl ether at −40 °C and gradual warming to ambient temperature yields a clear, pale yellow solution of the desired pentafluorobenzamidinate that is ready for further use (Scheme 1). For spectroscopic analysis, small solid samples were obtained by simply evaporating the solvent from an aliquot of the solution. NMR spectroscopy (^1H, ^{13}C and ^{19}F)[9] showed clean formation of a single product with apparent composition $[C_6F_5C(NSiMe_3)_2]Li\cdot0.5Et_2O$ and IR spectroscopy showed no residual nitrile bands.

Reaction of 2 equivalents of $[C_6F_5C(NSiMe_3)_2]Li$ with $VCl_3(THF)_3$ in THF resulted in formation of the green bis(amidinate) complex $[C_6F_5C(NSiMe_3)_2]_2VCl(THF)$ **1** (Scheme 1), which was isolated in 58% yield. Removal of THF by heating solid **1** *in vacuo* at 120 °C for 5 h yields the orange base-free chloride $[C_6F_5C(NSiMe_3)_2]_2VCl$ **2**. The ^{19}F NMR spectrum of paramagnetic **2** shows a strong downfield shift of the *o*-F resonance (δ −106.8, $\Delta\nu_{1/2}$ 380 Hz), and less pronounced shifts for the *p*-F (δ −144.1, $\Delta\nu_{1/2}$ 85 Hz) and *m*-F (δ −155.3, $\Delta\nu_{1/2}$ 45 Hz) resonances.

It proved to be difficult to obtain single crystals of **2** that were suitable for X-ray diffraction. For structural characterisation the benzonitrile adduct $[C_6F_5C(NSiMe_3)_2]_2VCl(NCPh)$ **3a** was prepared by addition of benzonitrile to a pentane solution of **2** followed by recrystallisation from diethyl ether. Its molecular structure§ is shown in Fig. 1. For comparison a structure determination of the non-fluorinated analogue **3b** was also performed.§ This compound is essentially isostructural, and its

DOI: 10.1039/b000397m

molecular structure is not shown here. The metal centre in **3a** has a distorted octahedral geometry, with two bidentate amidinate ligands and with the chloride and benzonitrile ligands being *cis* relative to each other. The pentafluorobenzamidinate exhibits a normal bidentate coordination mode, and the aryl substituent is perpendicular to the ligand NCN plane. In this respect it does not differ significantly from the non-fluorinated ligand in **3b**. The largest differences between the structures of the two complexes are found in the V–Cl distance and the Cl–V–N(5) and N(1)–V–N(4) angles [2.306(1) Å, 91.33(3) and 164.63(7)°, respectively, in **3a**; 2.350(1) Å, 86.01(8) and 168.6(1)° in non-fluorinated **3b**].

Unlike with the non-fluorinated analogue,[6] reaction of **1** with MeMgCl in THF followed by crystallisation from pentane yields a stable THF adduct of the methyl complex, $[C_6F_5C(NSiMe_3)_2]_2VMe(THF)$ **4** (Scheme 1). The stability of this adduct is an indication of the enhanced electrophilicity of the metal centre in the fluorinated benzamidinate complexes. Reaction of the base-free chloride **2** with MeLi in diethyl ether, followed by extraction with and crystallisation from pentane, affords the orange 12-electron methyl complex $[C_6F_5C(NSiMe_3)_2]_2VMe$ **5a** in 52% isolated yield. NMR spectra indicate that this alkyl compound (without β hydrogens) is thermally robust in benzene solution at 80 °C (no noticeable decomposition after 18 h).

To illustrate the effect of the fluorination of the amidinate ligand on the reactivity of the metal complexes, we compared the catalytic conversion of ethene by the neutral alkyl **5a** and its non-fluorinated analogue **5b**. Reactions on NMR tube scale had already shown that at 80 °C **5b** converts ethene to linear alkenes.[6] Initially, linear alk-1-enes are formed which are isomerised to internal alkenes when the system is starved of ethene. Autoclave experiments (80 °C, toluene, 4 or 8 bar ethene pressure) were performed using **5a** and **5b** as catalysts. Under these conditions, **5b** produces a Flory–Schultz distribution of linear alk-1-enes (>99% by GC) with $[C_{n+2}]/[C_n]$ = 0.87(2) over the range C_8–C_{32}, that is practically invariant with ethene pressure. The catalyst productivity for **5b** (as determined from isolated material precipitated with methanol) at 8 bar ethene (4 h run time) is 1.5 kg (mol V)$^{-1}$ h^{-1} of a material with M_n = 850 (by NMR). Under the same conditions, the fluorinated catalyst **5a** shows a productivity that is more than five times higher, 8.1 kg (mol V)$^{-1}$ h^{-1} giving a material with higher molecular weight (M_n = 1780, M_w/M_n = 2.3 by GPC).

A series of experiments with **5a** at 4 bar ethene pressure and run times of 2, 4 and 16 h shows that catalyst deactivation occurs, as the observed overall productivity drops from 7.4 to 4.5 and 1.3 kg (mol V)$^{-1}$ h^{-1}, respectively. As vanadium-based polymerisation catalysts are generally considered to deactivate through reduction of the metal centre to V(II),[10] it is likely that the electron-withdrawing nature of the fluorinated ligand accellerates this process.

In conclusion, we have prepared the new *N*,*N*′-bis(trimethylsilyl)pentafluorobenzamidinate ligand in a convenient manner, and have shown that the fluorination of the aryl substituent has a significant effect in the reactive properties of the metal centre in complexes with this ligand. Presently we are extending the chemistry of this ligand to other catalytically active metal centres. We are also using the synthesis route to prepare pentafluoro-derivatives of other trimethylsilylbenzamidinates (such as the amidinate–amine ligands reported recently by us[11]).

This investigation was carried out in connection with NIOK, the Netherlands Institute for Catalysis Research, and supported by the Department of Economic Affairs of the Netherlands.

Radical-chain deoxygenation of tertiary alcohols, protected as their methoxymethyl (MOM) ethers, using thiols as polarity-reversal catalysts

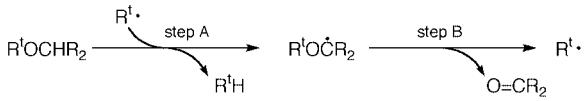
Hai-Shan Dang, Paola Franchi† and Brian P. Roberts*

Christopher Ingold Laboratories, Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ. E-mail: b.p.roberts@ucl.ac.uk

Received (in Liverpool, UK) 19th January 2000, Accepted 14th February 2000

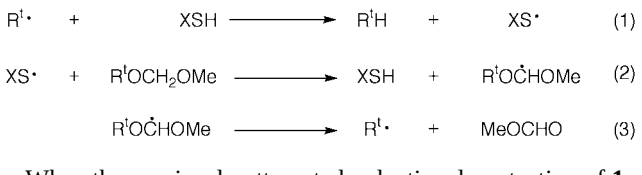
The deoxygenation of tertiary alcohols can be accomplished by heating their MOM ethers in the presence of a peroxide initiator and a thiol catalyst: the proposed radical-chain mechanism is supported by EPR spectroscopic studies.

Several free-radical based procedures are available for the deoxygenation of secondary alcohols (R^sOH). In particular, methods that involve radical-chain reactions of thiocarbonyl derivatives $R^sOC(=S)X$ with tributyltin hydride have found wide application in organic synthesis.[1] However, because of the thermal instability of many corresponding thiocarbonyl derivatives of tertiary alcohols, the number of methods available for the deoxygenation of the latter is more limited.[1] Conversion to an ether is commonly used to protect the alcohol functionality during chemical manipulations[2] and it would be convenient if appropriate ether derivatives of tertiary alcohols (generalised as R^tOCHR_2) could be induced to undergo radical-chain deprotection and deoxygenation in a single step to yield the deoxy compound R^tH, as shown in Scheme 1. Although the β-scission

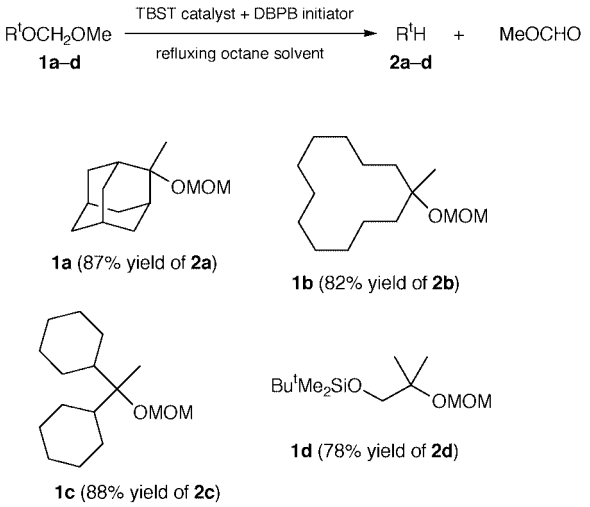


Scheme 1

step B is expected to be rapid above room temperature,[3] the hydrogen transfer step A will be close to thermoneutral and also suffer from adverse polar effects in the transition state (a nucleophilic radical R^t· is required to abstract hydrogen to give another nucleophilic radical $R^tO\dot{C}R_2$), making it a relatively slow process at moderate temperatures.[4] Consonant with this analysis, no 2-methyladamantane **2a** was formed after heating the methoxymethyl (MOM) ether of 2-methyl-2-adamantanol **1a** in refluxing octane for 2 h in the presence of the 2,2-di-*tert*-butylperoxybutane (DBPB, 2 × 3 mol%) as a thermal source of initiating alkoxyl radicals. We reasoned that step A should be subject to polarity-reversal catalysis[4] by a protic catalyst such as a thiol when, in the case of a MOM ether, it would be replaced by the cycle of polarity-matched reactions (1) and (2). Coupled with the β-scission reaction (3), this sequence would then provide a pathway for the thiol-catalysed deprotection and deoxygenation of the MOM ethers of tertiary alcohols to give R^tH and methyl formate.



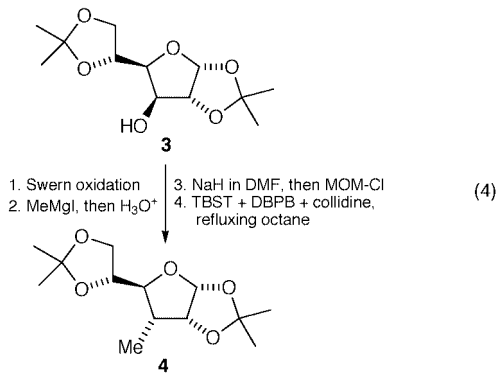
When the previously-attempted reductive deprotection of **1a** was repeated in the presence of tri-*tert*-butoxysilanethiol[5] (TBST; 2 × 3 mol%), the reaction now proceeded smoothly and 2-methyladamantane was isolated in 87% yield. Similar treatment of the tertiary alkyl MOM ethers **1b–d** gave the



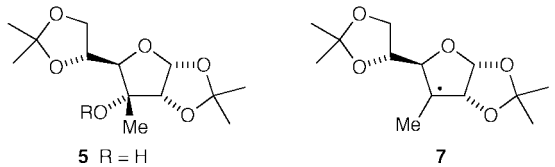
Scheme 2

corresponding deoxy compounds **2b–d** in good yields (Scheme 2); only traces of R^tH were formed in the absence of the thiol catalyst and most of the MOM ether could be recovered unchanged.‡

In order to explore its applicability to more complex systems, we made use of the procedure in the conversion of diacetone D-glucose **3** to 3-deoxy-1,2:5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose **4** [eqn. (4)]. Swern oxidation followed by



treatment of the derived ketone with methylmagnesium iodide afforded the tertiary alcohol **5**,[7] which was converted to the corresponding MOM ether **6**. The latter was heated under reflux in octane in the presence of TBST (3 × 3 mol%), DBPB (3 × 3 mol%) and 2,4,6-trimethylpyridine§ (collidine, 1 ×



† On study leave from the University of Bologna, Italy.

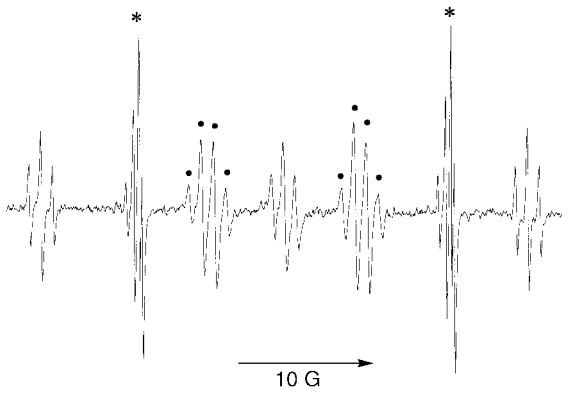


Fig. 1 EPR spectrum recorded during UV irradiation of a fluorobenzene solution containing Bu^tOCH_2OMe and di-*tert*-butyl peroxide at −61 °C. The two central 'lines' (showing second-order fine structure) from the *tert*-butyl radical are indicated by asterisks and the doublet of quartets from **8** by filled circles; the remaining lines arise from **9**. At −61 °C, the splitting constants for **8** (g = 2.0031) are 11.3 G (1 H_α) and 0.91 G (3 H_γ); for **9** (g = 2.0032) they are 18.0 G (2 $H_\alpha^{average}$) and 0.87 G (2 H_t). The central multiplet in the spectrum of **9** is broadened because rotation about the C_α–O bond is occurring at an intermediate rate on the EPR timescale.

10 mol%), to afford, after chromatography, a 91 : 9 mixture of **4**[9] and its C-3 epimer in a total isolated yield of 90%. The predominance of **4** in the epimeric product mixture is evidently a result of the preferential attack by TBST at the *exo*-face of the intermediate radical **7**.

In order to gain further insight into the mechanism of this redox process, the reaction of Bu^tOCH_2OMe with *tert*-butoxyl radicals was investigated by EPR spectroscopy. UV irradiation of a fluorobenzene solution containing Bu^tOCH_2OMe (1.4 M) and di-*tert*-butyl peroxide (*ca*. 20% v/v) at −61 °C, while the sample was in the microwave cavity of the spectrometer,[10] afforded the EPR spectrum shown in Fig. 1. The three radicals $Bu^tOCHOMe$ **8**, $Bu^tOCH_2OCH_2$ **9** and $Bu^{t\cdot}$ are present at this temperature, while above *ca*. −35 °C only the spectra of the last two were detectable. The rate constant (k_β) for β-scission of **8** to give *tert*-butyl radicals was determined relative to the rate constant ($2k_t$) for self-reaction of the latter, using the established 'steady-state' EPR method,[11] and the Arrhenius relation obtained from measurements in the temperature range −70 to −40 °C is given in eqn. (5), where $\theta = 2.303RT$ kJ mol^{-1}.¶

$$\log_{10}(k_\beta/s^{-1}) = (12.0 \pm 0.5) - (33.8 \pm 1.5)/\theta \qquad (5)$$

The value of k_β extrapolated to 126 °C (the boiling point of octane) is 3.8×10^7 s^{-1}. Even at +20 °C, there was no EPR evidence for the β-scission of **9** to give Bu^tOCH_2 although, because of line overlap, the latter radical could be difficult to detect in the presence of a higher concentration of the former. However, in similar experiments with $MeOCH_2OMe$, only the spectra of $MeOCHOMe$ and $MeOCH_2OCH_2$ were observed up to +72 °C; in particular $MeOCH_2$ was not detected, supporting the conclusion that β-scission of **9** to give Bu^tOCH_2 and formaldehyde must be *very* much slower than the cleavage of **8** to give $Bu^{t\cdot}$ and methyl formate. Although the selectivity of $Bu^tO^\cdot$ in hydrogen-atom abstraction from Bu^tOCH_2OMe will differ quantitatively from that of $(Bu^tO)_3SiS^\cdot$,‖ both radicals are electrophilic and it is probable that the thiyl radical would also abstract hydrogen to some extent from the *O*-methyl group of the mixed acetal. However, for the tertiary alkyl MOM ethers examined in this work, the major fate of any radicals of the type $R^tOCH_2OCH_2$ (or of radicals which might possibly be formed by abstraction of hydrogen from the R^t group)** must be 'repair' by hydrogen-atom transfer from the thiol to regenerate the starting MOM ether.

Financial support for this work was provided by the EPSRC. We thank Professors K. J. Hale and W. B. Motherwell for helpful discussions and we are grateful to Peroxid-Chemie GmbH for a gift of 2,2-di-*tert*-butylperoxybutane.

Notes and references

‡ *Representative procedure*: a solution containing the MOM ether **1a** (210 mg, 1.0 mmol), TBST (9 mg, 3 mol%) and DBPB (18 μl of a 50% w/w solution in mineral oil, 3 mol%) in dry octane (1.2 cm^3) was stirred and heated under gentle reflux (bath temperature 130 °C, pre-heated) under an atmosphere of argon. After 40 min, more initiator and thiol (3 mol% of each) were added and heating was continued for a further 2 h. The solvent was removed by evaporation under reduced pressure and the residue was subjected to flash chromatography on silica gel (hexane eluent) to give 2-methyladamantane **2a** (131 mg, 87%), mp 146–147 °C (lit.[6] mp 146–148 °C).

§ The yield was improved in the presence of collidine, probably because this acts as a scavenger of acid resulting from reactions between the initiator and the thiol.[8] Collidine was also present during the reductive deprotection of **1d** (Scheme 2).

¶ The value of ($k_\beta/2k_t$) at a given temperature is equal to ([$Bu^{t\cdot}$]/[**8**])\{[$Bu^{t\cdot}$] + [**8**] + [**9**]\}.[11] The Arrhenius relation for the self-reaction of *tert*-butyl radicals in fluorobenzene was taken[12] to be $\log_{10}(2k_t/M^{-1}\ s^{-1}) = 11.6 - 10.2/\theta$ and the rate constants for the diffusion-controlled reactions of $Bu^{t\cdot}$ with **8** and with **9** are assumed to be equal to $2k_t$.

‖ The relative molar rate constants (k_8/k_9) for hydrogen abstraction by $Bu^tO^\cdot$ from Bu^tOCH_2OMe to give **8** and **9** were determined by measuring relative radical concentrations in the temperature range −70 to −20 °C.[13] The value of k_8/k_9 is given by \{[**8**] + [$Bu^{t\cdot}$]\}/[**9**] and was shown to conform to the Arrhenius relation $\log_{10}(k_8/k_9) = -0.59 + 4.4/\theta$; the extrapolated value of k_8/k_9 at 126 °C is 0.97.

** Epimerisation[8] at C-5 did not compete with the reductive deprotection reaction of **6** to give **4**.

Important sedimentary sesterterpenoids from the diatom *Pleurosigma intermedium*

Simon T. Belt,*[a] Guy Allard,[a] Guillaume Massé,[ab] Jean-Michel Robert[b] and Steve Rowland[a]

[a] *Petroleum and Environmental Geochemistry Group, Department of Environmental Sciences, University of Plymouth, Drake Circus, Plymouth, UK PL4 8AA. E-mail: sbelt@plymouth.ac.uk*

[b] *ISOMer, Faculté des Sciences et des Techniques, Université de Nantes, 2 Rue de la Houssinière, 44027 Nantes Cedex 3, France*

Received (in Liverpool, UK) 8th December 1999, Accepted 16th February 2000

The new sesterterpenoids (5*E*,8*E*/*Z*)-3,9,13-trimethyl-6-(1,5-dimethylhex-4-enyl)tetradeca-1,5,8,12-tetraene have been isolated from the diatom *Pleurosigma intermedium* and characterised structurally by NMR spectroscopy.

Highly branched isoprenoid (HBI) C_{25} and C_{30} hydrocarbons are ubiquitous chemicals found in environmental matrices ranging from recent sediments to ancient oils.[1] The parent structures of these geochemicals (**1** and **2**, Fig. 1) were established by synthesis[1,2] during the 1980s, but it was not until 1994, that Volkman *et al.*[3] reported their occurrence in the diatoms *Haslea ostrearia* (C_{25}) and *Rhizosolenia setigera* (C_{30}) thus revealing the only known source organisms for these compounds. In our own studies, we have reported on the structures of the compounds in *H. ostrearia*, together with descriptions of some of the controls governing their unsaturation.[4–7] The most common HBIs possess between two and six double bonds, though pentaenes and hexaenes are relatively rare in *H. ostrearia*[5] (*e.g.* structures **3** and **4**, Fig. 1). In a recent report, *Rhizosolenia setigera* was shown to produce a C_{25} HBI pentaene rather than C_{30} compounds,[8] but to date, no further species or genus of diatoms have been shown to produce this class of widespread organic geochemicals. In terms of stereochemistry, HBIs exist as single geometric isomers in all cases (*E* where appropriate), though they are often reported as mixtures of configurational diastereoisomers.[4,9,10]

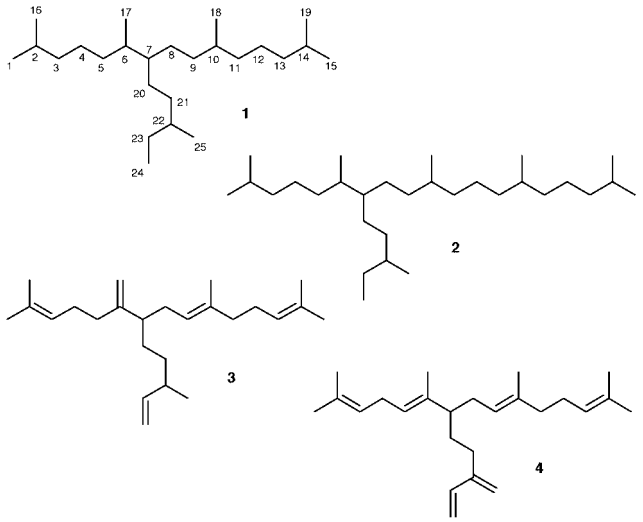

Fig. 1 C_{25} and C_{30} HBI parent structures and typical alkenes.

Here, we report the identification of an entirely different genus of diatom which biosynthesises C_{25} HBIs of a previously unreported structural type, which nonetheless appears to be common in sediments.

Pleurosigma intermedium is a benthic diatom measuring *ca.* 130 × 20 μm that is commonly found in estuarine muds. After large scale (400 L) culture of this species (Bay of Bourgneuf, France) followed by harvesting, centrifugation and freeze drying, we isolated a lipid fraction by extraction with hexane. Subsequent saponification (to remove triglyceride esters of fatty acids) and extraction (hexane) yielded a hydrocarbon fraction that was analysed by GC and GC–MS. Analysis of these chromatograms revealed the presence of *n*-$C_{21:5}$, *n*-$C_{21:6}$, squalene and eight compounds possessing related but different properties to previously reported HBIs.[4,5,7] Thus, hydrogenation of this mixture resulted in the formation of a single compound having identical GC–MS characteristics[1] to that of the authentic C_{25} alkane **1**. Following purification by column chromatography (SiO_2/hexane) and re-examination by GC–MS, the two major components (> 55%) of the hydrocarbon fraction were assigned as new HBI pentaenes ($C_{25:5}$, M^+ 342, RI 2126,2172 $_{HP\text{-}5}$; 2112,2159 $_{HP\text{-}1}$, relative abundance 1.6 : 1). The mass spectra of the two compounds were virtually identical, suggesting that that they were stereoisomers rather than positional isomers. Examination of the ^1H and ^{13}C NMR spectra† revealed the presence of four trisubstituted alkene moieties, together with a vinyl group, a structural feature common to all known HBIs. For all of these previously reported HBIs, the main branch point is at C-7, probably as the result of a biosynthetic coupling of geranyl and farnesyl type precursors.[9] However, for these new sesterterpenoids isolated from *Pleurosigma intermedium*, C-7 is unsaturated with a double bond between C-7 and C-20 (note: the numbering scheme for NMR assignments is shown for parent alkane **1**). The determination of this double bond position (C7–C20) and of the other trisubstituted double bonds was established using 2-D NMR methods (COSY, HMQC, HMBC) resulting in structures **5** and **6** (Fig. 2), namely 3,9,13-trimethyl-6-(1,5-dimethylhex-4-enyl)tetradeca-1,5,8,12-tetraene. Of particular note is the absence of any ^{13}C resonances in the 40–50 ppm region indicative of saturated, branched positions (C-7) observed for all previously reported HBIs.[4–10] Instead, alkenic C-7 resonates at δ 142.8 and 142.4 for **6** and **5**, respectively. To date, we have not been successful in separating the two $C_{25:5}$ isomers using further chromatography including argentation TLC. However, both spectroscopic (^{13}C NMR) and chromatographic (GC) separations of these compounds are most consistent with the presence of two geometric isomers (C9–C10). The mixed double bond stereochemistry of C9–C10 (and not C7–C20) was determined by careful examination of the NMR data. Specifi-

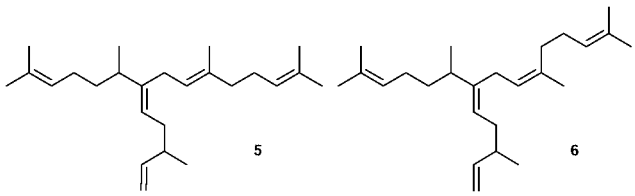

Fig. 2 Structures of C_{25} pentaenes isolated from *Pleurosigma intermedium.*

DOI: 10.1039/a909670a

cally, unique ^{1}H and ^{13}C (CH_3) resonances at δ 1.55, 1.69 (H-18) and δ 15.8, 23.4 (C-18) were observed for **5** and **6** (with **6** being the major isomer). Two further ^{13}C resonances for C-11, each of which correlated with the corresponding H-18 protons in the HMBC spectrum were also observed. Since the alternative position for geometric isomerism (C7–C20) does not possess a CH_3 substituent, the position of *E/Z* isomerism is limited to C9–C10. In order to determine the stereochemistry of the C7–C20 double bond, NOE data were obtained for **5** and **6**. Significantly, NOEs were observed between H-6 and H-20, indicating an *E* configuration. The remaining six HBIs consisted of two trienes ($C_{25:3}$) and four tetraenes ($C_{25:4}$) on the basis of their mass spectra (M^+ 346 and 344, respectively), though insufficient quantities of these compounds were present in the culture to allow for comprehensive NMR analysis.

HBIs in general have been proposed as potential biomarkers or palaeoenvironmental indicators.[11] However, to date, the environmental record of these compounds does not correlate well with those compounds structurally characterised from previous large scale cultures of diatoms including *Haslea ostrearia* and *Rhizosolenia setigera*.[4–10] The reason for this may be that HBIs from these two species undergo relatively mild diagenetic reactions (*e.g.* alkene isomerisation) but since the products of laboratory simulations of these processes do not produce the sedimentary isomers,[12] a more attractive explanation is that other diatoms such as *Pleurosigma intermedium* are the producers of many of the common sedimentary HBIs. To address this more fully, we now intend to isolate and characterise all of the HBIs produced by *Pleurosigma intermedium* under different culture conditions and to compare the mass spectra and chromatographic data (retention indices) of these with the numerous geochemical reports.[13] A preliminary investigation of this type indicates that two of the C_{25} pentaenes (RI 2124, 2169 $_{DB\text{-}5}$) reported from the Todos os Santos Bay, Brazil,[14] are HBIs **5** and **6**.

We would like to acknowledge the British Council (ALLIANCE program) and the University of Plymouth for funding (G. A. and G. M.).

A new synthetic approach to 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acid (Tic) derivatives *via* enyne metathesis and the Diels–Alder reaction

Sambasivarao Kotha* and Nampally Sreenivasachary

Department of Chemistry, Indian Institute of Technology-Bombay, Mumbai, 400 076, India.
E-mail: srk@ether.chem.iitb.ernet.in

Received (in Cambridge, UK) 20th December 1999, Accepted 7th February 2000

Various subtituted 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acid (Tic) derivatives are synthesized *via* enyne metathesis and the Diels–Alder reaction.

1,2,3,4-Tetrahydroisoquinoline-3-carboxylic acid (Tic) is a phenylalanine analogue in which the dihedral angle χ is limited to a very small range because of its bicyclic nature.[1] In connection with the design of topographically constrained peptides Tic has been utilized in several instances as a replacement of phenylalanine or tyrosine.[2] Moreover, the tetrahydroisoquinoline unit is an important structural element in several important alkaloids and other medicinally useful products.[3] Availability of synthetic methods for the preparation of various Tic derivatives with varying degrees of steric/electronic and hydrophobic properties are useful in receptor mapping and also in designing meaningful QSAR studies.[4] In connection with our building block approach for the preparation of constrained amino acid derivatives[5] we sought a Diels–Alder strategy to prepare various unknown Tic derivatives **1**–**3**. Most of the known methods such as Bischler–Napieralski[6a] Picter–Spengler[6b] and among others[6c] for Tic preparation starts with the preformed benzene derivatives while our methodology involves generation of a benzene ring *via* the cycloaddition reaction as a key step. Consequently, the present methodology provides a unique opportunity to efficiently enhance the molecular complexity of inaccessible Tic derivatives. Here, we report our preliminary results for the preparation of various Tic derivatives using enyne metathesis and the Diels–Alder reaction as key steps.

Retrosynthetic routes for various Tic derivatives *via* Diels–Alder strategy as a key step are shown in Fig. 1. Pathways a and b in Fig. 1 lead to angularly substituted and pathway c to linearly substituted Tic derivatives. In exploring the synthesis of inner–outer ring dienes such as **4** and **5** containing a dehydropipicolinic acid moiety, we conceived a relatively less explored enyne metathesis reaction as a viable option. Conceptually, cycloiosomerization of a suitably functionalised 1,7-enyne building block is expected to deliver the 4,5-dimethylene pipicolinic acid derivative (*e.g.* **6**).

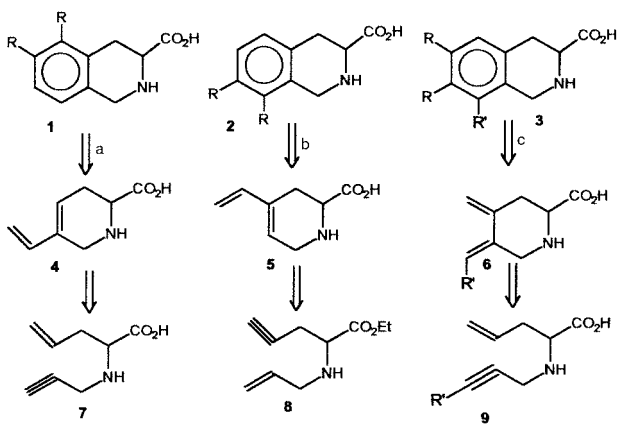

Fig. 1

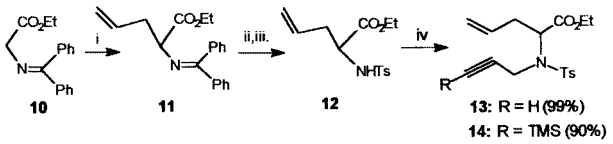
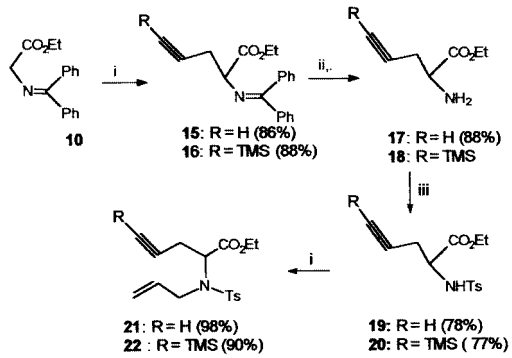
Realization of the strategies shown in Fig. 1 require the preparation of key building blocks **7**, **8** and **9**. In this regard, ethyl *N*-(diphenylmethylene)glycinate **10**[7] was treated with allyl bromide in the presence of K_2CO_3 to give allylated product **11** (82%, Scheme 1). Hydrolysis of **11** with 1 M HCl in diethyl ether gave the amino ester which upon treatment with tosyl chloride in presence of triethylamine gave **12** in 78% yield [mp 43–44 °C, ^{13}C NMR ($CDCl_3$, 75 MHz) δ 170.7, 143.1, 137.4, 131.5, 129.5, 127.4, 119.6, 61.4, 55.2, 37.7, 21.6, 14.0]. Reaction of **12** with propargyl bromide in the presence of K_2CO_3 gave **13** in quantitative yield. Under similar reaction conditions, enyne **14** was prepared in 90% yield.



Scheme 1 *Reagents and conditions*: i, allyl bromide, K_2CO_3, MeCN, 82%; ii, 1 M HCl, diethyl ether, 85%; iii, TsCl, Et_3N, CH_2Cl_2, 78%; iv, K_2CO_3, RC≡CCH_2Br, MeCN.

Towards the preparation of building blocks related to **8**, sequential reaction of ethyl *N*-(diphenylmethylene)glycinate **10** with propargyl bromide and 3-bromo-1-trimethylsilylprop-1-yne in the presence of K_2CO_3 in acetonitrile gave **15** (86%) and **16** (88%) respectively (Scheme 2). Hydrolysis of **15** with 1 M HCl in diethyl ether gave amino ester **17** (88%) which was protected as a tosyl derivative using tosyl chloride/triethylamine in dichloromethane at room temperature to give **19** (mp 48–49 °C). The structure of **19** is established by ^{1}H and ^{13}C NMR spectral data. During the hydrolysis of compound **16**, a minor amount of desilylated product was obtained which was separated (11%) after a protection sequence. The required compound **20** was obtained in 77% yield. Then allylation of compounds **19** and **20** in the presence of K_2CO_3 with allyl bromide gave **21** and **22** in 98 and 90% yields, respectively.



Scheme 2 *Reagents and conditions*: i, RC≡CCH_2Br, K_2CO_3, MeCN; ii, 1 M HCl, diethyl ether; iii, TsCl, Et_3N, CH_2Cl_2, 78%.

Having accomplished a high yielding synthesis of enyne building blocks **13** and **21**, we then focussed our attention towards the preparation of inner–outer ring dienes **24** and **25**.

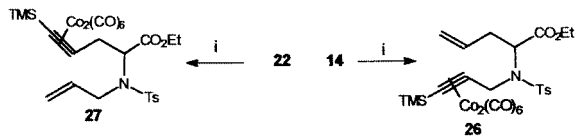
DOI: 10.1039/a910217p

Table 1

Enyne	13	21	26	27
Reagents/ conditions	$(Cy_3P)Cl_2Ru{=}CHPh$/ 36 h	$(Cy_3P)Cl_2Ru{=}CHPh$/ 36 h	toluene/reflux	toluene/reflux
Diene	 24 65%	 25 70%	 28 53% +  29 11%	 30 78% +  31 7%

Thus, treatment of **13** with Grubb's catalyst[8] in refluxing toluene gave **24** in 65% isolated yield after column chromatography. Under similar reaction conditions diene **25** was prepared (70%) from enyne **21** (Table 1). Attempts to convert enynes **14** and **22** to the corresponding dienes by enyne metathesis conditions were not rewarding.

Next we turned our attention towards the preparation of silylated dienes **28** and **30**. Towards this goal, enyne **14** was treated with dicobalt octacarbonyl in diethyl ether to give compound **26** in 83% yield.[9] Similarly, enyne **27** was prepared in 84% yield (Scheme 3).



Scheme 3 *Reagents and conditions*: $Co_2(CO)_8$, diethyl ether, room temp.

Refluxing of enyne **26** in toluene followed by oxidative decomposition with *N*-methylmorpholine *N*-oxide yielded the 4,5-dimethylene pipicolinic acid derivative **28** in 53% yield along with a minor amount of Pauson–Khand product **29** (11%). The other diene **30** was obtained under similar reaction conditions in 78% yield along with the enone **31** (7%). It is worth mentioning that compound **31** is a useful precursor for tecomanine alkaloid.[10]

Having the dienes **24**, **25**, **28** and **30** in hand, we then examined their Diels–Alder chemistry with the readily available dienophiles (Table 2). The reaction of dienes **24** and **25** with different dienophiles and subsequent oxidation of Diels–Alder adducts with DDQ[11] gave angularly substituted Tic derivatives (**32**–**35**). Similarly, the Diels–Alder reaction of dienes **28** (or **30**) with dimethyl acetylenedicarboxylate (DMAD) and oxidation with DDQ gave desilylated product **36**.

In conclusion, for the first time we have demonstrated an exceptionally simple and versatile method for the synthesis of several Tic derivatives using enyne metathesis and the Diels–Alder reaction as key steps.

We gratefully acknowledge the DST for financial support and RSIC Mumbai, Professor A. Srikrishna for recording the spectral data. NS thanks CSIR, New Delhi for the award of research fellowship.

Table 2

Entry	Diene	Dienophile	DDQ product	Yield[a] (%)
1	 24		 32	93
2	 24		 33	52
3	 25		 34	85
4	 25		 35	45
5	 28		 36	69
6	 30		 36	65

[a]Yields refer to combined isolated yields for both the Diels–Alder reaction and DDQ oxidation.

Received (in Columbia, MO) 7th October 1999, Accepted 30th November 1999

Ru(II) diimine complexes having phosphonic acid substituents adsorb to TiO_2 modified ITO electrodes and exhibit electrogenerated chemiluminescence when potentiostated at positive voltages in the presence of oxalate in buffered aqueous solutions.

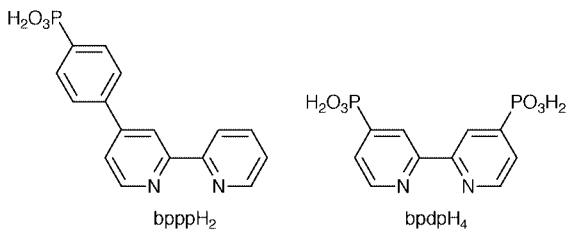
Luminescence is often observed from chromophores excited by highly exoergic redox reactions that generate excited states without direct photonic excitation.[1] When the redox reaction is driven electrochemically the process (electrogenerated chemiluminescence, ECL) has several potential applications including electroactive display development and trace analysis.[2] Many potential applications of ECL can be optimized by using luminescent electroactive species that are immobilized at an electrode surface. A number of approaches to surface modification for ECL have been developed including (a) covalent or ionic attachment of the chromophore to a surface bound polymer,[3] (b) formation of thin polymer films from a monomer containing an ECL active chromophore,[4] (c) attachment of a chromophore to a substrate capable of binding to the surface *via* specific molecular recognition (*i.e.* antibody/antigen interaction)[5] and (d) direct incorporation of the redox active species into the electrode material.[6,7] For many applications it is desirable for the ECL active chromophore to be bound to a highly robust support which is also porous enough to allow for rapid ion and substrate uptake. This report describes ECL of Ru(II) diimine complexes adsorbed onto mesoporous TiO_2 films on optically transparent ITO electrode supports.

Among the chromophores most commonly used for ECL are Ru(II) diimine complexes.[8] They are stable upon one-electron oxidation and reduction and annihilation of the radical ions leads to formation of a metal-to-ligand (MLCT) charge transfer excited state. Electrogenerated luminescence can also be obtained from these complexes by reducing the complex in the presence of a species which can be reduced to produce a strong oxidizing agent (such as $S_2O_8^{2-}/SO_4^{\cdot -}$)[9] or oxidizing the complex in the presence of a species which can be oxidized to produce a strong reductant (such as $C_2O_4^{2-}/CO_2^{\cdot -}$).[10]

Several examples exist of ECL from surface bound Ru(II) diimine complexes[2–7] and recent work has shown the potential of these complexes in electroluminescent displays.[11] The most chemically flexible and durable of the modified surface ECL systems consists of ITO with a thin film of Nafion into which the Ru(II) diimine complex is adsorbed. This system involves a polymer support for which the porosity, solubility and ion transport characteristics are intimately dependent on the medium. The development of porous, insoluble, inert supports for ECL would expand the opportunities for applications of ECL in sensing and display development. Very recently Sykora and Meyer reported ECL from a polymer/SiO_2 sol–gel composite, which has the potential to meet the above criteria.[12] We report here, the observation of ECL from Ru(II) diimine complexes adsorbed onto mesoporous TiO_2 films deposited on ITO optically transparent electrodes. The TiO_2 films provide an inert, robust support for the ECL active Ru(II) complex. Gratzel and coworkers have recently observed ECL in a similar system involving reduction of $S_2O_8^{2-}$ in DMF at ITO/TiO_2 surfaces having an adsorbed Ru(II) diimine complex; the $SO_4^{\cdot -}$ radical ion produced oxidizes surface bound Ru(II) which then annihilates with conduction band electrons to yield luminescence.[7]

TiO_2 modified ITO electrodes were initially prepared as a means of increasing the photoactive surface area of electrodes used in dye sensitized photoelectrochemical cells.[13] Films are prepared by deposition of a colloidal suspension of TiO_2 onto ITO surfaces, evaporation and sintering of the subsequent film.[14] Surfaces prepared in this way are typically 1–10 μm thick and appear by SEM and AFM as packed spherical particles of the order of 20–50 nm in diameter.[15] The films are known to adsorb dyes having negatively charged substituents (carboxylates, phosphonates, *etc.*). In two electrode cells consisting of the dye modified ITO/TiO_2 electrode and a noble metal counter electrode excitation of particular dyes results in charge injection into the TiO_2 with high efficiency.[8] However, other dyes often exhibit strong photoluminescence when adsorbed.[16,17] The observation of luminescence from Ru(II) diimine complexes on ITO/TiO_2 photoelectrodes is believed to result from either (a) complex which has desorbed from the surface[16*b*] or (b) complex adsorbed to surfaces for which charge injection is thermodynamically unfavorable.[17]

The Ru(II) complex dyes used in this work are adsorbed to the surface through interaction of phosphonic acid moieties on 2,2′-bipyridyl ligands. The ligands used are $bpppH_2$ and $bpdpH_4$. The complexes prepared from these ligands are $[(bpy)_2Ru(bpppH_2)]^{2+}$, $[(bpy)_2Ru(bpdpH_4)]^{2+}$ and $[Ru(bpppH_2)_3]^{2+}$, having one, two and three phosphonic acid substituents, respectively. The ligand and complex syntheses are reported elsewhere.[18] The complexes were deposited on ITO/TiO_2 surfaces by immersion of electrodes in DMSO–H_2O (90 : 10) solutions of the complex for 12 h.



Observation of ECL from the dye modified ITO/TiO_2 surfaces requires that three conditions are met: (a) the adsorbed Ru(II) complex is oxidized by the electrode, (b) oxidation of the oxalate occurs in the film and (c) emission is observed from the adsorbed Ru(II) complex following reaction of Ru(III) with $CO_2^{\cdot -}$. Fig. 1 shows an oxidative cyclic voltammogram for a ITO/TiO_2/$[Ru(bpppH_2)_3]^{2+}$ modified electrode in aqueous pH 7 buffer. There is a large difference in peak potential between the oxidative and reductive waves reflecting limitations to charge transport in the thin film.[19,20]

Spectroelectrochemical studies indicate that nearly complete oxidation of the complexes in the film can be affected by potentiostating at voltages more positive than the one-electron oxidation potential; in addition, the process is reversible. However, complete oxidation of the complex in the films is extremely slow ($t_{1/2} \geqslant 15$ min). The implication is that only Ru(II) centers adsorbed near the ITO/TiO_2 interface are readily

DOI: 10.1039/a908148h

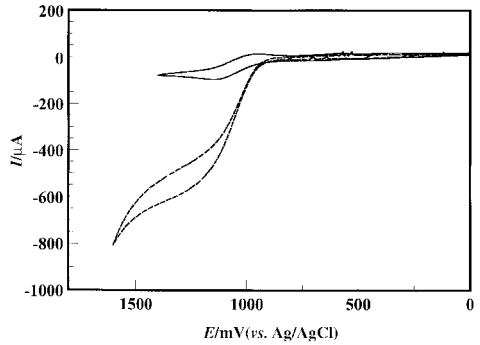


Fig. 1 Cyclic voltammogram of (—) $[Ru(bpppH_2)_3]^{2+}$ modified ITO/TiO_2 electrode in pH 7 buffer solution (0.1 M) and (----) the same modified electrode in the presence of sodium oxalate (0.002 M).

oxidized; oxidation of Ru(II) sites adsorbed away from the interfacial area must be affected by migration of Ru(III) in the TiO_2 thin film or, for films with high complex loading, charge percolation.[8] Cyclic voltammograms obtained following addition of oxalate exhibit a significant increase in current associated with the oxidative wave (Fig. 1). The process is completely irreversible, reflecting the decomposition of the oxidized oxalate. The result illustrates that oxalate is able to permeate the porous TiO_2 film and is oxidized on the cyclic voltammetric time scale [either directly at the electrode surface or by Ru(III) mediated oxidation].

When modified surfaces are potentiostated at > 0.9 V *vs.* Ag/AgCl in stirred solutions containing oxalate (0.02 M), luminescence is observed from all the Ru(II) complex modified electrodes.[21] No emission is observed in the absence of oxalate. The ECL spectrum of $[Ru(bpppH_2)_3]^{2+}$, shown in Fig. 2, is identical to that of the Ru(II) complex in aqueous buffer. The luminescence intensity increases with increasing potential until a maximum is reached at +1.25 V and falls off slightly at potentials above +1.4 V (inset). Thus, luminescence arises from the MLCT excited state of the complexes and the intensity is proportional to the relative steady state concentration of Ru(III) in the films. Whether luminescence arises in these systems from desorbed complex or from complex adsorbed to sites where charge injection is not thermodynamically favorable is not clear.

When the electrode potential is held at a potential positive relative to $E°[Ru(III/II)]$ in a stirred solution containing oxalate, the ECL intensity decreases with time. Both $[(bpy)_2Ru(bpppH_2)]^{2+}$ and $[(bpy)_2Ru(bpdpH_4)]^{2+}$ desorb from the TiO_2 support and dissolve in the buffer solution. Only the complex having three phosphonic acid substituents, $[Ru(bpppH_2)_3]^{2+}$, shows no evidence for desorption from the surface. However, even this complex exhibits a decrease in ECL intensity with time. The decrease in intensity is not related to depletion of oxalate in the solution. We are presently investigating the behavior of the $[Ru(bpppH_2)_3]^{2+}$ complex in greater detail, but preliminary results suggest that the oxidized form of the complex migrates in the film *via* desorption and readsorption processes which lead ultimately to depletion of the complex at the electrode surface.

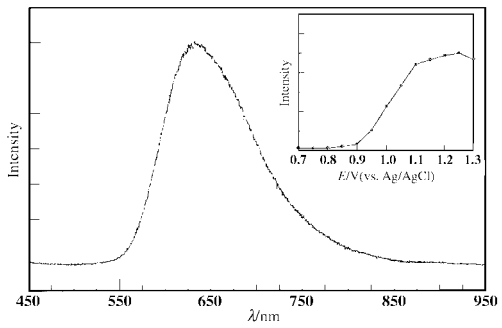

Fig. 2 Dispersed emission from a $[Ru(bpppH_2)_3]^{2+}$ modified ITO/TiO_2 electrode in pH 7 buffer containing sodium oxalate (0.02 M); 5 s exposure. Inset: integrated emission intensity as a function of applied potential.

In summary, ITO optically transparent electrodes modified with a clear ceramic thin film of mesoporous TiO_2 can serve as solid supports for generation of ECL from adsorbed Ru(II) diimine complexes. The Ru(II) complex dyes adsorb *via* interaction of phosphonic acid substituents on the diimine ligands with the surface sites on the TiO_2. Initial results suggest that the stability of the modified surfaces for generation of sustained ECL is dependent on the number of phosphonic acid substituents per chromophore. We are currently exploring covalent attachment of ECL active dyes to these robust, mesoporous thin film electrodes as a potential approach to making sensing devices with improved longevity.

We wish to thank the Department of Energy, Office of Basic Energy Sciences (Grant DE-FG-02-96ER14617) for support of this work. D. M. is grateful to the Louisiana Alliance for Minority Participation (LAMP) for a summer fellowship. The authors would like to thank Mr Jim Mellott of the D. K. Schwartz research group for AFM studies of ITO/TiO_2 surfaces.

21 The modified electrode is typically a 1 × 3 cm piece of ITO with the TiO_2 thin film containing the Ru(II) complex covering a 1 × 2 cm area. The electrode is mounted in the sample compartment of a SPEX fluorolog spectrofluorimeter at 45° relative to the emission collection optics. Emission spectra are observed using a spectrograph/CCD with 5–10 s exposure times. ECL is observed by potentiostating the ITO electrode at potentials more positive than 0.9 V in stirred solutions containing oxalate.

Received (in Cambridge, UK) 18th January 2000, Accepted 15th February 2000

Electroactive conjugated polymers have been synthesized by electropolymerisation of increasing generations of dendrimers derivatized by peripheral bithiophene groups.

Dendrimer chemistry is a rapidly expanding field for both basic and applicative reasons.[1] Recently, the synthesis of dendrimers with conjugated oligomers introduced either at the periphery of the molecule,[2] or as a central rigid core,[3] has been reported by several groups. An interesting further development in this area involves the attachment of electropolymerisable groups at the periphery of a dendrimer taking advantage of the electropolymerisation process[4] to prepare electrodes modified by electroactive poly(dendrimers).

As a first step in this direction, we describe here the synthesis and electropolymerisation of dendrimers with peripheral bithiophene (BT) groups. The target structures are based on the association of neutral phosphorus containing dendrimers,[5] with bithiophenes having a linking site at an internal β-position. Such precursors are known for their better polymerisability compared to monomers in terms of applied potential, concentration and steric demand.[6]

Dendrimers with 3, 6, 12, 24 and 48 peripheral bithiophenes (**G_0b**–**G_4b**) were synthesized in 80–97% isolated yield† by a Wittig reaction between dendrimers with carbaldehyde end groups (**G_0a**–**G_4a**)[5] and the phosphonium salt derived from 3-(bromohexyl)-2,2′-bithiophene.[6c] All compounds were characterized by ^{1}H, ^{31}P and ^{13}C NMR and elemental analysis.

A single potential scan applied to solutions of **G_0b**–**G_4b** in 0.10 M $NBu^n_4PF_6$–CH_2Cl_2 shows an irreversible oxidation peak at 1.25 V typical for 3-alkyl-substituted BTs.[6] Upon application of recurrent potential scans, a broad redox system corresponding to the doping/undoping process of the growing polymer progressively develops in the region 0.50–1.10 V. The steady increase in the intensity of the waves with the number of scans indicates straighforward polymerisation, as confirmed by the formation of a dark blue film on the anode surface. A constant concentration of substrate (0.5 mM) leads to a steep increase in the intensity of the cyclic voltammetric (CV) waves

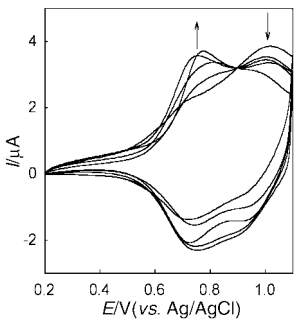

Fig. 1 Cyclic voltammograms of poly(**G_nb**) in 0.10 M NBu_4PF_6–MeCN, Pt electrodes, reference Ag/AgCl, scan rate 100 mV s^{-1}. The arrows indicate increasing generation number.

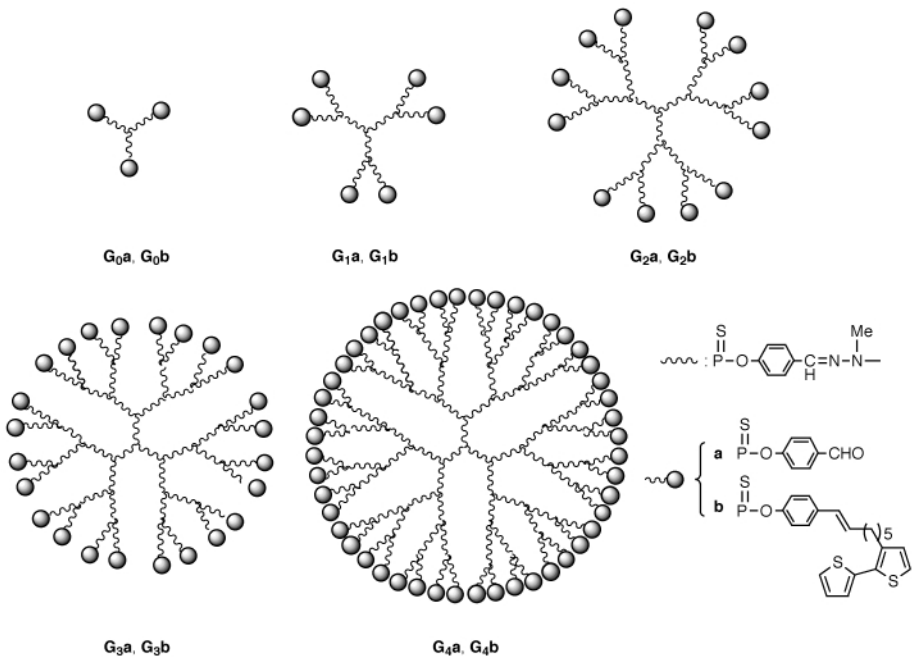

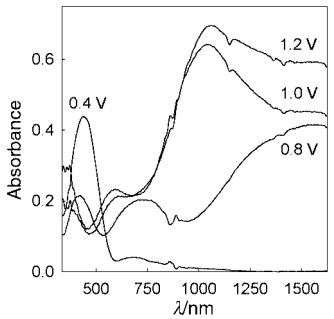

Fig. 2 Electronic absorption spectra of poly(**G_4b**) recorded *in situ* in 0.10 M NBu_4PF_6–MeCN, at various applied potentials.

with the generation number (**G_n**) owing to the rapid increase in the number of BT groups. Conversely, CV waves of similar intensity are obtained for all generations when using a constant BT concentration (1×10^{-2} M). Fig. 1 shows the CV of the five polymers in a precursor-free electrolyte. In each case two anodic waves occur around +0.75 and +1.00 V. Increasing **G_n** produces a slight negative shift of both waves and an intensification of the wave at 0.75 V to the detriment of the second one. This result suggests that raising **G_n** increases the number of longer conjugated segments in the polymer thus enhancing the effective conjugation. Such an evolution of the polymer structure could be related to the increasing probability of intra-dendrimer couplings of the BT units as **G_n** augments. Thus, whereas poly(**G_0b**) and poly(**G_1b**) essentially contain inter-dendrimer linkages subject to steric hindrance to planarity, the higher content of intra-dendrimer linkages in polymers of higher **G_n**, should limit intermolecular steric interactions in the poly(BT) chains. Consequently, the effective conjugation would approach an hypothetical limit determined by the bending imposed on the conjugated chains by the spherical shape of the underlying dendritic scaffolding.

The electrochemical behavior of the polymers has been analysed in more detail on films deposited potentiostatically under the same conditions (1×10^{-2} M equivalent BT, 1.30 V, deposition charge $Q_d = 50$ mC cm^{-2}). Under these conditions, the electroactivity expressed by the ratio Q_r/Q_d (where Q_r is the amount of charge reversibly exchanged upon cycling) increases from 5.2% for poly(**G_0b**) to 10.3% for poly(**G_4b**). While an increase in the doping level of the polymer cannot be totally excluded, these results strongly suggest a greater electropolymerization efficiency for high **G_n** precursors. This phenomenon could reflect the increasing proximity of the polymerizable BT groups.

The aqueous electroactivity of the polymers has been analysed in 0.10 M $LiClO_4$–H_2O. Whereas poly(BT) is almost inactive in this case, all poly(**G_n**) are highly electroactive in aqueous media. The electroactivity increases from 80% of its value in MeCN for poly(**G_0b**) to practically 100% for poly(**G_4b**). This enhancement may be related to the decrease in the relative weight of hydrophobic BT groups [and hence poly(BT) chains] from 45% for **G_0** to 30% for **G_4**.

Fig. 2 shows the *in situ* electronic absorption spectra of poly(**G_4**) at various applied potentials. The spectrum of the neutral polymer shows a broad band with λ_{max} around 450 nm. The 20–50 nm blue shift of λ_{max} compared to some highly conjugated functionalized poly(BTs),[6] indicates a less extended effective conjugation. Application of increasing potentials produces a gradual decrease of the π–π* absorption while two polaronic transitions develop around 700 and 1500 nm. At potentials higher than 1.00 V, these two bands merge into a broad band centered around 1050 nm assigned to the formation of bipolarons.

Attempts to solubilize the neutral polymers of higher **G_n** in CH_2Cl_2, THF or chlorobenzene remained unsuccesful. This behavior which contrasts with the good solubility of the starting dendrimers suggests that the outer poly(BT) chains form a barrier hindering the penetration of solvent molecules inside the dendrimer cavities.

While the formation, structure and properties of these new electroactive materials pose many complex problems requiring further investigation, these first examples of electrogenerated poly(dendrimers) open interesting perspectives in the field of modified electrodes for electrocatalysis or electroanalysis. A particularly exciting topic concerns the entrapment of guest molecules[7] during the electropolymerization process with possible electrochemical controlled release *via* the redox state of the poly(thiophene) outer layer. Work in this direction is now underway and will be reported in future publications.

On-column derivatization of oligodeoxynucleotides with ferrocene†

Amy E. Beilstein and Mark W. Grinstaff*

Department of Chemistry, Paul M. Gross Chemical Laboratory, Duke University, Durham, North Carolina 27708, USA. E-mail: mwg@chem.duke.edu

Received (in Bloomington, IN, USA) 16th September 1999, Accepted 21st January 2000

The solid-phase synthesis and characteristics of ferrocenoyl propargylamide (FPA)-labeled oligodeoxynucleotides are described.

Site-specifically labeled DNA is of interest for hybridization assays, artificial nucleases, anticancer therapies, and DNA-mediated charge-transfer studies.[1–16] Current oligodeoxynucleotide (ODN) labels range from metal complexes[12,17] to organic dyes[10,11,18] that are covalently attached to DNA either at the ribose,[19] phosphate[20–22] or nucleobase[4–6,23–26] moieties. While synthetic strategies such as oligodeoxynucleotide post-modification and labeled nucleoside phosphoramidites afford modified ODNs, these methods are often hampered by extensive purification, side reactions and low yields. Furthermore, many of these approaches do not allow for systematic studies to be performed, as labeling is limited to the 3′- or 5′-terminus. Here, we report the *on-column derivatization* of ODNs with ferrocene at the nucleobase using a newly developed synthetic procedure in combination with standard automated DNA synthesis.[27] This site-specific on-column procedure requires an alkyne-terminated ferrocene and a halo-substituted nucleobase for Pd(0) cross-coupling.

Ferrocene was selected as the ODN label as it possesses high stability as well as reversible and tunable electrochemical and spectroscopic properties. In addition, ferrocene has been attached previously to other biomolecules of interest, including terminal-phosphate-labeled DNA oligomers,[3,28] as well as peptide nucleic acids[29] and amino acids.[30]

The ferrocene precursor for on-column derivatization (ferrocenoyl propargylamide or FPA) (Fig. 1) was synthesized by coupling ferrocene monocarboxylic acid to propargylamine hydrochloride in the presence of dicyclohexylcarbodiimide (94% yield). To further evaluate the physical properties of these novel FPA-modified ODNs, we also synthesized the corresponding FPA-labeled nucleobase, 3′,5′-dibenzoyl-5-(ferrocenoyl propargylamide) uridine, FPAU (Fig. 1). FPAU was synthesized by Pd(0) cross-coupling[31] FPA with 3′,5′-dibenzoyloxy-5-iodouridine. FPA displayed a reversible one-electron oxidation in the cyclic voltammogram, with $E_{\frac{1}{2}}$ = 0.243 V *vs.* Ag/Ag^+ (1.0 mM compound in $CDCl_3$, 0.1 M NBu_4PF_6), compared to 0.103 V for ferrocene. After attachment to uridine, $E_{\frac{1}{2}}$ shifts to 0.262 V *vs.* Ag/Ag^+.[30] The spectroscopic properties of ferrocene, FPA and FPAU were similar: all exhibited the characteristic weak (d–d) band at 444 mm.

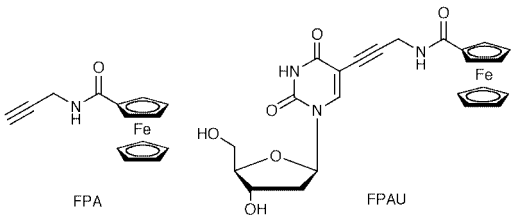

Fig. 1 Ferrocenoyl propargylamide (FPA) and 3′,5′-dibenzoyl-5-(ferrocenoyl propargylamide) uridine (FPAU).

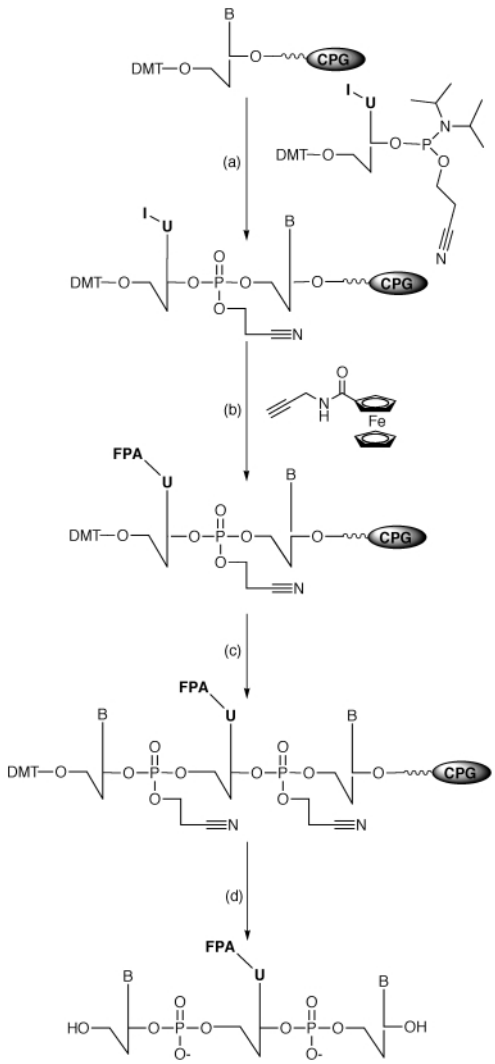
† Electronic supplementary information (ESI) available: experimental procedures, melting profiles and CD spectra for the duplexes. See http://www.rsc.org/suppdata/cc/a9/a907568b/

The on-column derivatization method was used to site-specifically label an oligodeoxynucleotides with FPA at the nucleobase. As shown in Scheme 1, automated ODN synthesis was performed on an ABI 395 DNA synthesizer using a standard protocol. 5-Iodo-2′-deoxyuridine (5-IdU) phosphoramidite (Glen Research) was incorporated at the desired position on the ODN. Phosphoramidite couplings for the standard bases; dA, dC, dG and dT; as well as 5-IdU were > 95%. Synthesis was then paused,[32] and the column was removed from the synthesizer and dried by flushing with argon. The ferrocene precursor, FPA (20 mg), $Pd(PPh_3)_4$ (10 mg) and CuI (1 mg) were added to the column, which was then filled



Scheme 1 Key: (a) Incorporation of 5-iodo-2′-deoxyuridine phosphoramidite (5-IdU) during standard ODN synthesis (B = A, C, G or T); (b) Pd(0) cross-coupling of FPA and the column-bound iodouridine; (c) normal ODN synthesis is resumed; (d) the synthesized site-specifically FPA-labeled ODN is cleaved from the column and protecting groups are removed by incubation in ammonia at 55 °C for 16 h.

Table 1 Melting temperatures for FPA-labeled and unlabeled duplexes

Duplex		T_m/°C
1	5′-TGC TAC AAA CTG T**U**^{FPA}G A-3′	
4	5′-TCA ACA GTT TGT AGC A-3′	49.6 ± 0.1
2	5′-TGC TAC AAA C**U**^{FPA}G TTG A-3′	
4	5′-TCA ACA GTT TGT AGC A-3′	48.2 ± 0.2
3	5′-TGC TAC AAA CTG TTG A-3′	
4	5′-TCA ACA GTT TGT AGC A-3′	50.8 ± 0.3
5	5′-TGC TAC AAA C**U**^{FPA}G-3′	
7	5′-CAG TTT GTA GCA-3′	42.6 ± 0.3
6	5′-TGC TAC AAA CTG-3′	
7	5′-CAG TTT GTA GCA-3′	41.4 ± 0.4

(**U**^{FPA}) indicates the FPA-labeled uridine

with DMF–TEA (9:1). The column was shaken at room temperature for 6 h. It was then rinsed with DMF–TEA, dried and replaced on the synthesizer. Routine synthesis was resumed until the desired oligodeoxynucleotide was synthesized. A series of FPA-labeled ODNs were synthesized in this manner (Table 1). FPA-modified oligodeoxynucleotides were purified *via* reverse-phase HPLC; retention times for labeled and unlabeled ODNs differed by several minutes (18.8 *cf.* 14.8 min). Isolated yields of the labeled ODNs were typically 50%.[33]

The stabilities of FPA-labeled duplexes are evaluated by thermal denaturation of the duplexes.[34] Table 1 lists the melting temperatures of several FPA-labeled and unmodified duplexes. FPA-modified duplex **1**:**4** which is labeled at the third base from the 3′-terminus, exhibits similar stability to duplex **2**:**4**, labeled at the sixth base. These melting temperatures are only slightly lower than the T_m for the unmodified duplex, **3**:**4**. Duplex **5**:**7**, a dodecamer labeled at the second base, has a T_m of 42.6 *cf.* 41.4 °C for the analogous unmodified duplex **6**:**7**. The small changes in the melting temperatures of the labeled duplexes compared with the unmodified duplexes indicate that FPA derivatization causes minimal disruption of duplex structure. These data are consistent with previous reports that the 5-position of uridine tolerates a variety of modifications without disrupting the duplex.[26] CD spectra of the duplexes also indicate that the FPA-labeled duplexes retain the B-form DNA structure found in the unlabeled duplexes.

In summary, novel ODNs labeled with ferrocene are synthesized by solid-phase coupling of a ferrocene derivative to an ODN containing 5-iodouridine. This facile synthesis provides a simple method for labeling ODNs at the nucleobase with a spectroscopic or redox label in good yields, with minimal purification of the labeled ODN product. Melting profiles and CD spectra (see ESI) show that the FPA-labeled duplexes are stable at room temperature and have B-form DNA structure similar to unlabeled duplexes.

Received (in Cambridge, UK) 30th November 1999, Accepted 18th February 2000

A photosensitive ultrathin film with G1.5 PAMAM dendrimers (carboxylate salts) as polyanions and NDR (nitro-containing diazoresin) as polycations was fabricated *via* sequential deposition and subsequent UV irradiation which causes the linkage between the layers to change from ionic to covalent.

The large size and globular shape of PAMAM dendrimers make them suitable building blocks for self-assembled monolayer or multilayer ultrathin films. Watenabe and Regen[1] used the procedure of repeated deposition of amine terminated PAMAM dendrimers onto a Pt^{2+} bearing surface, followed by reactivation with K_2PtCl_4, which yielded multilayer films. Wells and Crooks[2] reported the first covalently bound dendrimer monolayer, which resulted from linking PAMAM dendrimers to a mercaptoundecanoic acid self-assembled monolayer *via* amide bond formation. Tsukruk's group fabricated composite molecular films by self-assembly of dendritic macromolecules of two adjacent generations using electrostatic layer-by-layer deposition.[3] All these examples showed the potential application of mono- or multi-layer films as chemical sensors,[4] size selective heterogeneous catalysts or a basis for optical filters and optical devices.[5–7] Recently, Cao and coworkers reported the formation of a stable ultra-thin multilayer film by converting hydrogen or ionic bonds to covalent bonds under ultraviolet irradiation.[8,9] This conversion of the bonding increases the resistance of films to etching by polar solvents.

Here, we describe, for the first time, the preparation of multilayer films constructed from poly(amidoamine) dendrimers (PAMAM) and nitro-containing diazoresin (NDR) *via* a layer-by-layer technique and the conversion of the linkage bonds under UV irradiation.

The PAMAM dendrimers were synthesized according to the literature.[10] The methyl-ester-terminated dendrimer (G = 1.5) was hydrolyzed with stoichiometric amounts of KOH in methanol to obtain external carboxylate groups associated with potassium ions. NDR was prepared according to the method described in ref. 11. Surface-negatively charged mica was used as the substrate. The freshly cleaved mica was immersed in an aqueous solution of 2 mg ml^{-1} NDR for 5 min, rinsed with deionized water and then dried under a stream of air. After being totally dried, the mica was dipped into an aqueous solution of 2 mg ml^{-1} hydrolyzed G1.5 PAMAM dendrimer for 5 min, followed by rinsing and drying. Repetition of this procedure six times yielded a 12-bilayer self-assembled ultrathin film. All stages of growth were carried out at room temperature in the dark.

The absorbance of NDR on mica after each cyclic deposition was recorded using a UV–VIS scanning spectrophotometer (Shimadazu UV-2101 PC) to monitor the self-assembly process (Fig. 1). The peak at 383 nm is assigned to the absorption of the diazonium group of NDR and increases linearly with increasing bilayer number. From Fig. 1, it can be seen that the absorbance increases by *ca.* 0.016 every two bilayers, indicating smooth step-by-step deposition.

The twelve bilayer film was then irradiated with UV light for different times and the resulting absorbances determined (Fig. 2). From the inset plot it can be seen that the photodecomposition of the film follows the kinetics of a first-order reaction,

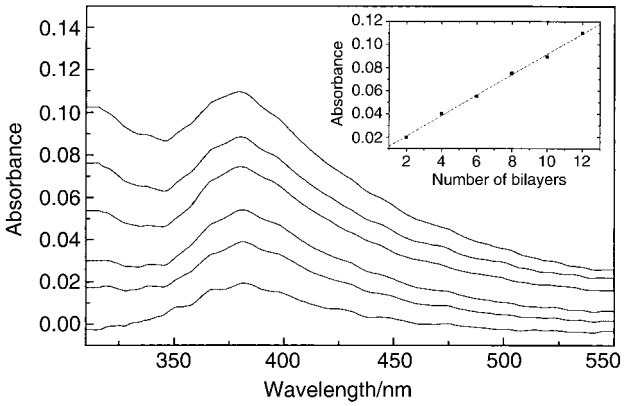

Fig. 1 Absorbance of multilayer films with different numbers of bilayers. Bilayer numbers (bottom to top): 0, 2, 4, 6, 8, 10 and 12. Inset: Relationship between the absorbance at 383 nm and the bilayer number.

where A_0 and A_t represent the absorbance of the film before and after irradiation for different times t, respectively. The absorbance at 383 nm (N_2^+ group absorption) decreases with irradiation, which indicates the formation of a covalent linkage. The conversion of the ionic bonds to covalent bonds is shown in Scheme 1. Before irradiation, the multilayer film is formed *via* electrostatic attraction between the diazonium groups and carboxyl groups. Under UV-irradiation, the diazonium groups decompose leading to phenyl cations, which combine with the carboxyl groups to produce covalent linkages.

The formation of covalent bonds was further verified by comparing the FTIR spectrum of the self-assembled film before and after irradiation. Distinct changes were the disappearance of the absorbances at 2162 and 1580 cm^{-1}, assigned to the stretching vibrations of the diazonium group and the carboxyl group, respectively. At the same time, the absorbance at 1738 cm^{-1} assigned to the carboxyl group of an ester bond increases.

From AFM measurements, the four-bilayer film (Fig. 3) is rather flat and the mean roughness only 1.4 nm which indicates

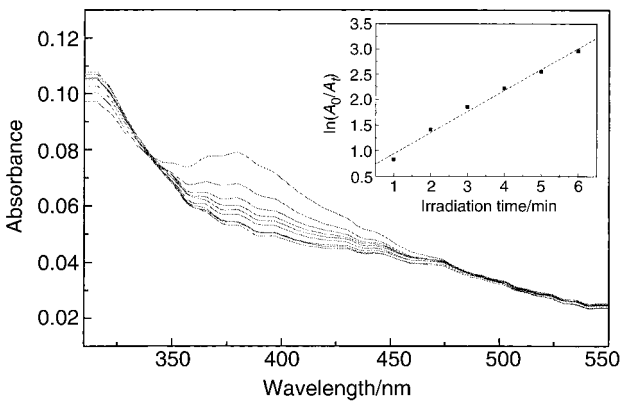

Fig. 2 UV–VIS spectra of a 12-bilayer film irradiated for different times. Irradiation intensity (360 nm): 230 μW cm^{-2}, irradiation time (top to bottom) 1, 2, 3, 4, 5, 6, 10, 20 and 30 min.

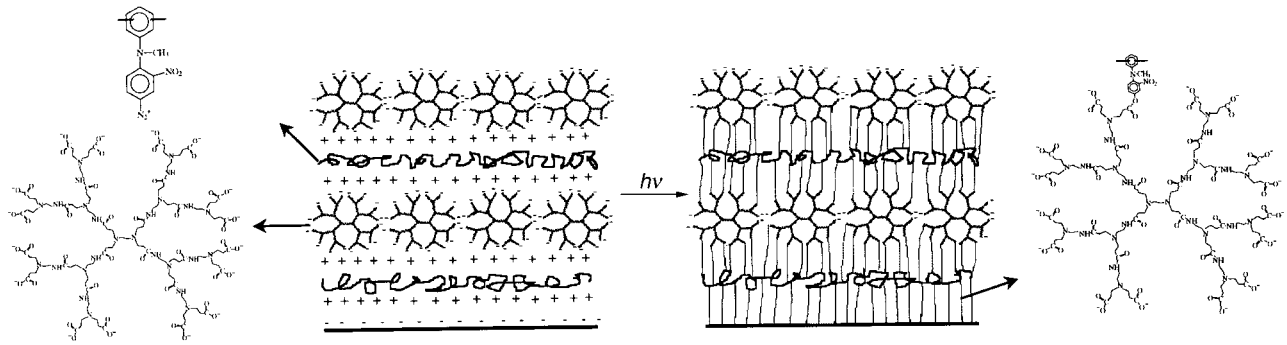
DOI: 10.1039/a909441e



Scheme 1 The conversion of the linkage bonds from ionic to covalent in multilayer films fabricated from PAMAM and NDR.

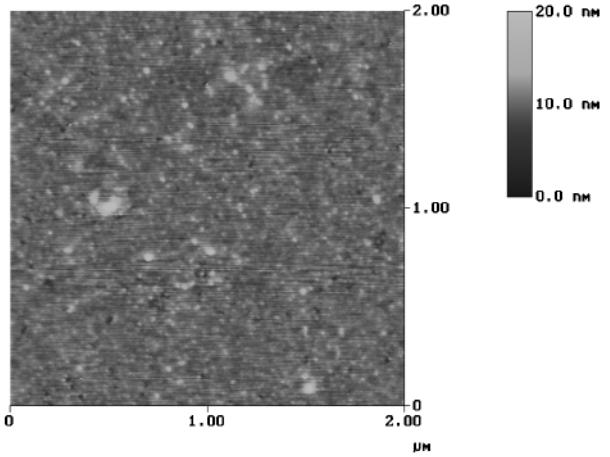


Fig. 3 Morphology of the 4-bilayer film fabricated from PAMAM and NDR. Mean roughness 1.4 nm.

the formation of a uniform multilayer film from PAMAM and NDR through the step-by-step technique.

The effect of UV irradiation on the stability of the film to polar solvents was also investigated. The absorbance of the unirradiated film decreases significantly after etching for 30 min in DMF, while the irradiated film showed no etching under the same conditions. This shows that the stability of the film towards polar solvents increases significantly after UV irradiation.

In order to determine the film thickness, X-ray diffraction measurements were performed on a Rigaku DMAX 2400 X-ray diffractometer. X-Ray data were collected within a scattering angle range of 1–8° using Cu-Kα radiation. A peak occurs at 2θ = 2.500 and 2.660 for the film before and after irradiation, respectively and suggests the film can be viewed as being ordered. According to the Bragg equation, the layer thickness of the film before and after irradiation is 3.5 and 3.3 nm, respectively. This change corresponds to the alteration in the bonding since the layers will become more compact when covalent bonds form.

In conclusion, an ultrathin multilayer film was fabricated from PAMAM dendrimers and NDR by a self-assembly technique. Under UV irradiation, the linkages change from ionic to covalent.

Studies in progress will focus on fabrication of the multilayer films by using different generation PAMAM dendrimers. We are also studying the characteristics of these unique films.

Organometallic models of catalytic hydrodesulfurization: $Re_2(CO)_{10}$-promoted cleavage of C–S bonds in benzothiophene

Michael A. Reynolds,[a] Ilia A. Guzei[b] and Robert J. Angelici*[a]

[a] *Ames Laboratory and the Department of Chemistry, Iowa State University, Ames, IA 50011, USA. E-mail: Angelici@iastate.edu.*

[b] *Molecular Structure Laboratory, Iowa State University, Ames, IA 50011, USA.*

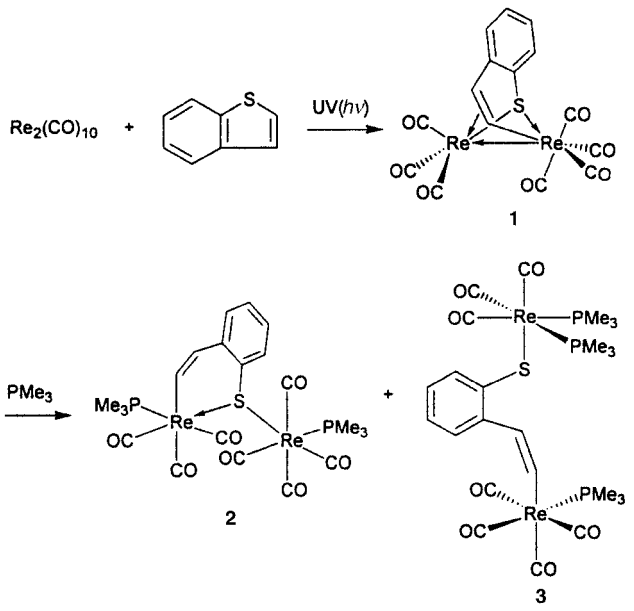
Received (in Bloomington, IN, USA) 17th November 1999, Accepted 15th February 2000

Ultraviolet photolysis of hexanes solutions containing $Re_2(CO)_{10}$ and benzothiophene (BT) give the C–S cleavage product $Re_2(CO)_7[\eta^2(C2,C3)\text{-}\mu_2(C2,S)\text{-BT}]$ 1 which reacts with PMe_3 at room temperature to yield two phosphine-substituted products, 2 and 3, in which the fragmented BT ligand is partially displaced from the metals; molecular structures of 1, 2 and 3 are models for possible intermediates in the HDS of BT on catalyst surfaces.

Heterogeneous catalytic hydrodesulfurization (HDS), the commercial process used for the removal of sulfur from organosulfur compounds present in petroleum-based feedstocks, is important in industry and for the environment.[1,2] Typically, the sulfur in crude petroleum is present in the form of organic thiols, sulfides, disulfides and thiophenes. It is the thiophenic molecules, however, such as benzothiophene (BT) that are the most difficult to desulfurize under current hydrotreating conditions.[3] In order to improve the efficiency of current HDS catalytic systems, much needs to be learned about intermediates that are present on transition-metal sulfide-based catalysts during the HDS of benzothiophene.

The present paper reports preliminary results of reactivity studies of $Re_2(CO)_{10}$ with BT under mild conditions to produce the C–S cleavage product **1** containing a Re–Re backbone. Upon addition of PMe_3 to **1**, two unexpected phosphine substitution products are formed (**2** and **3**) in which both the C–S and Re–Re bonds have been cleaved (Scheme 1).

Complex **1** was prepared by UV photolysis (Hanovia 450 W, medium pressure Hg lamp) of a stirred hexanes solution containing $Re_2(CO)_{10}$ and 2 equiv. of BT in a quartz reaction vessel under nitrogen for 24–36 h at 10 °C. The progress of the reaction was monitored by IR spectroscopy of samples taken during the reaction. The IR bands corresponding to $Re_2(CO)_{10}$ [ν_{CO} (hexanes): 2071w, 2015s, 1977m cm^{-1}][4] were gradually replaced by those of **1** [ν_{CO} (hexanes): 2099m, 2043s, 2027s, 1981s, 1977s, 1957m, 1947s cm^{-1}]. Solvent removal, followed by extraction with CH_2Cl_2 and column chromatography on silica gel packed in hexanes, produced orange **1** in 30–45% yield.†‡



Scheme 1

The molecular structure of **1** was confirmed by single crystal X-ray structure analysis (Fig. 1). It contains a bridging BT ligand in which the vinylic C–S bond of the BT has been cleaved, and three CO ligands have been displaced from the $Re_2(CO)_{10}$. The sulfur bridges both Re atoms asymmetrically with distances of 2.506(2) Å for Re(1)–S and 2.431(3) Å for Re(2)–S. The vinyl carbon also bridges the two Re atoms asymmetrically acting as a η^1-ligand to Re(1) and η^2 to Re(2) with distances of 2.142(10) Å for Re(1)–C(8) and 2.208(10) Å for Re(2)–C(8). The Re–Re distance [2.8945(7) Å] is shorter than that in $Re_2(CO)_{10}$ [3.0413(11) Å].[5] Other previously reported dinuclear complexes, prepared by quite different methods, that contain a similar bridging BT ligand are $Fe_2(CO)_5(PPh_3)(C_8H_6S)$[6] and $[Cp^*Co]_2(\mu\text{-}C_8H_6S)$.[7]

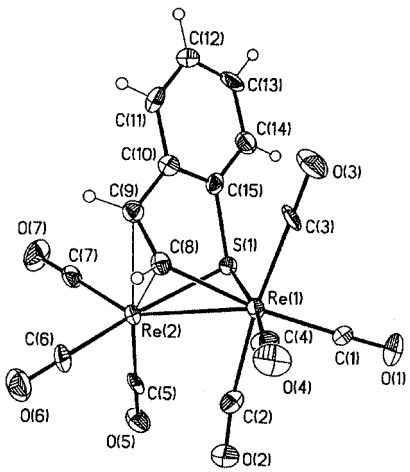


Fig. 1 Molecular structure of **1** in the solid state. Selected bond lengths (Å) and angles (°): Re(1)–Re(2) 2.8945(7), Re(1)–S, 2.506(2), Re(2)–S 2.431(3), Re(1)–C(8) 2.142(10), Re(2)–C(8) 2.208(10), Re(2)–C(9) 2.413(11), C(8)–C(9) 1.370(14), S–C(15) 1.805(11), Re(2)–S–Re(1) 71.77(7), Re(1)–C(8)–Re(2) 83.4(3), C(8)–Re(2)–S 82.8(3), C(8)–Re(1)–S 82.3(3), C(8)–C(9)–C(10) 126.6(10).

The addition of PMe_3 (1–5 equiv.) (1 M in toluene) to a toluene solution of **1** at room temperature causes an immediate change from orange to pale yellow with no evolution of CO. Solvent removal, extraction with CH_2Cl_2, and fractional crystallization of the crude residue produced yellow crystals of **2** and white **3**. Both complexes have been characterized spectroscopically‡ and by X-ray structure analysis of their single crystals.

DOI: 10.1039/a909161k

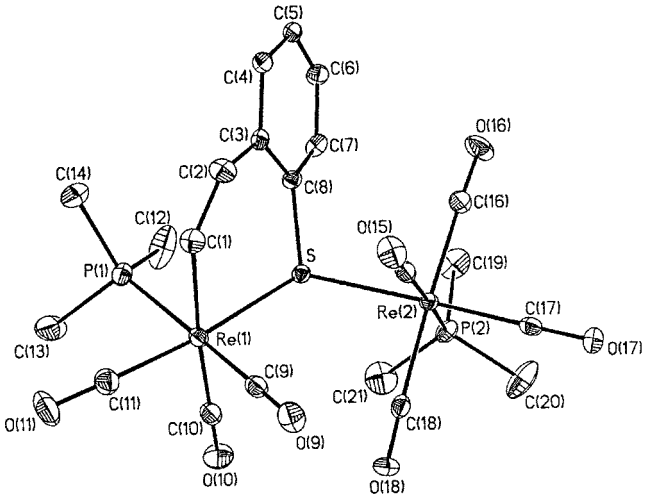

Fig. 2 Molecular structure of **2** in the solid state. Selected bond lengths (Å) and angles (°): Re(1)··Re(2) 4.2874(3), Re(1)–S 2.5027(9), Re(2)–S 2.5320(9), C(8)–S 1.796(3), Re(1)–C(1) 2.169(3), C(1)–C(2) 1.343(5), Re(1)–S–Re(2) 116.76(3), C(1)–Re(1)–S 86.51(10), Re(1)–S–C(8) 109.94(12), Re(2)–S–C(8) 105.40(12), P(1)–Re(1)–S 87.24(3), P(2)–Re(2)–S 88.04(3).

The X-ray structure of **2** (Fig. 2) shows that the C(1)–C(2) double bond is no longer η^2-coordinated and the Re–Re bond has been cleaved. Both Re atoms are pseudo-octahedral and each contains a PMe_3 ligand. The S bridges both Re atoms almost symmetrically with distances of 2.5027(9) Å for Re(1)–S and 2.5320(9) Å for Re(2)–S.

A single crystal X-ray analysis of **3** (Fig. 3) shows that there are no single atom bridges between the two Re centers nor is there a metal–metal bond. The Re centers are pseudo-octahedral with respect to the C–Re–C angles between Re and adjacent CO ligands. The Re(1)–C(1) distance is 2.205(3) Å which is longer than that in either **1** or **2**. The Re(2)–S distance is 2.5086(9) Å which is similar to those in both **1** and **2**.

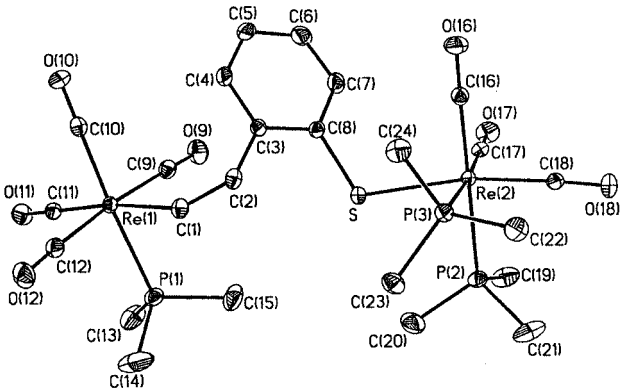

Fig. 3 Molecular structure of **3** in the solid state. Selected bond lengths (Å) and angles (°). Re(1)–C(1) 2.205(3), Re(2)–S 2.5086(9), C(1)–C(2) 1.327(4), S–C(8) 1.769(3), C(2)–C(3) 1.479(4), Re(1)–C(1)–C(2) 134.8(3), C(8)–S–Re(2) 113.18(12), P(2)–Re(2)–S 84.54(3), C(1)–C(2)–C(3) 129.8(3), C(1)–Re(1)–P(1) 82.44(8).

In the reaction (Scheme 1) of **1** with PMe_3, the relative amounts of **2** and **3** formed are the same whether 1 or 5 equiv. of PMe_3 are used. This means that the tri-phosphine product **3** is not formed from the bis-phosphine product **2** even in the presence of an excess of PMe_3. Therefore **2** and **3** must form by independent pathways. The structures of **2** and **3** are also fundamentally different from each other because the terminal vinyl carbon is bound to the $Re(CO)_3$ unit in **2** whereas in **3** it is coordinated to the $Re(CO)_4$ group. The formation of these products may be understood in terms of a mechanism that involves two forms of **1** resulting (Scheme 2) either from a "flip-flop" of the vinyl group from one Re to the other, as proposed for related bridging thiophene complexes $\{Fe_2(CO)_6(C_8H_6S)$,[6] $[(C_5Me_5)Co]_2(\mu\text{-}C_4H_4S)$[8] and $[(dippe)Ni]_2(\mu\text{-}C_8H_6S)$[9]}, or the migration of a CO group from one Re to the other.

1 **1′**

Scheme 2

The reaction of isomer **1′** with 2 equiv. of PMe_3 would lead to product **2** in which the olefin is displaced and the Re–Re bond is cleaved, leaving the terminal vinyl carbon coordinated to the $Re(CO)_3$ unit. On the other hand, the reaction of isomer **1** with 3 equiv. of PMe_3 would lead to product **3** with the vinyl carbon bonded to the $Re(CO)_4$ moiety while undergoing Re–olefin, Re–S and Re–Re bond cleavages. An attempt to detect the two isomers of **1** by low temperature (−50 °C, CD_2Cl_2 solvent) ^{1}H NMR spectroscopy showed only the same isomer that is present in the room temperature spectrum.‡ However, variable temperature ^{13}C NMR spectra of **1** (−50 °C to +20 °C) showed that the CO ligands are fluxional. Thus, while the two isomers are not detected by the NMR studies, a low concentration of the highly reactive **1′** would reasonably account for the formation of **2**.

The reactions in Scheme 1 are of special interest because they indicate the variety of ways that a bridging, C,S-cleaved BT ligand can bind to two metal centers. Were C–S cleavage to occur on a HDS catalyst, all three forms of BT represented in compounds **1**–**3** would be potential modes of BT adsorption on the catalyst surface.

The authors thank the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Chemical Sciences Division, under contract W-7405-Eng-82 with Iowa State University for financial support.

Synthetic dephosphorylation reagents: rate enhancement of phosphate monoester hydrolysis by Cu(II)-metallated adenine nucleobase polymers

S. G. Srivatsan and Sandeep Verma*

Department of Chemistry, Indian Institute of Technology-Kanpur, Kanpur-208016 (UP), India, E-mail: sverma@iitk.ac.in

Received (in Cambridge, UK) 11th January 2000, Accepted 17th February 2000

Significant rate enhancement of *p*-nitrophenyl phosphate hydrolysis, catalyst turnover and recycling has been observed for metallated, 9-allyladenine-containing cross-linked polymers.

Nucleic acids can coordinate to metal ions through the participation of base keto oxygen atoms, heterocyclic ring nitrogen atoms, sugar hydroxy groups and phosphate oxygen atoms.[1] The importance of metal ion binding is not simply limited to phosphate charge neutralization, but is also essential for stabilization of the nucleic acid structure and for RNA catalysis.[2,3] The design of our dephosphorylation agents has drawn inspiration from nucleic acids[4a–c] and we have invoked metal-ion coordination ability of purine nucleosides and nucleotides,[5a–h] for the synthesis of metallated, cross-linked nucleobase polymers. These polymeric molecules have been utilized for the hydrolysis of a model phosphate monoester and the kinetic parameters have also been determined.

Phosphate ester hydrolysis plays an important role in energy metabolism and in a variety of cellular signal transduction pathways in biological systems.[6a,b] The design of synthetic models of this reaction has been an attractive area of research and consequently, a wealth of information regarding artificial phosphatases and nucleases is available in literature.[7a–d] Most of these models utilize ligand bound transition and inner-transition metal ions for the catalysis of phosphate ester hydrolysis.[8a–k] It is assumed that metal ions play an important role in hydrolysis through the formation of metal–aqua complexes and by providing electrostatic neutralization of the negative charge on the phosphate group, thus making it more susceptible to nucleophilic attack.[8c] Owing to polarization effects, water molecules coordinated to metal ions can be substantially more acidic compared to free water molecules.[9]

The synthesis of our metallated nucleobase polymers involve AIBN-initiated polymerization of 9-allyladenine[10] with a cross-linking agent such as 1,4-divinylbenzene (DVB) or ethylene glycol dimethacrylate (EGDMA), in the presence of added metal ions. Adenine derivatives have been shown to coordinate to metal ions such as Cu^{2+}, Mn^{2+}, Zn^{2+} and Co^{2+}, predominantly through purine ring nitrogens.[5a–h] Keeping this fact in mind, we have prepared a polymeric matrix containing multiple adenine rings for extensive metal ion coordination. The metallated polymers so obtained were insoluble in common solvents and thus the present study is an example of heterogeneous catalysis of phosphate monoester hydrolysis. Atomic absorption spectroscopy and inductively coupled plasma analysis were used to estimate the amount of Cu(II) incorporated within the polymeric matrix (Table 1). It was found that incorporation of Cu(II) in EGDMA cross-linked polymer was 2.5 times that when compared to the DVB polymer. A much higher loading could be explained due to the presence of oxygen atoms in EGDMA, which can provide additional sites for metal ion coordination. Preliminary EPR studies have also been performed with these polymers.[11]

We have employed *p*-nitrophenyl phosphate (pNPP), a routinely used model monophosphate ester substrate, to evaluate the phosphatase activity of our adenine polymers and time-dependent release of *p*-nitrophenolate anion ($\varepsilon_{400} = 1.65 \times 10^4$ M^{-1} cm^{-1}) was used to determine kinetic constants. Remarkable rate enhancement was observed for pNPP hydrolysis in the presence of metallated polymers. The pseudo-first order rate constants (k_{obs}) were determined and it was found that polymers **1** and **2** displayed *ca.* 2,700- and 11,000-fold rate enhancement for pNPP hydrolysis (Table 1), respectively, as compared to the uncatalyzed reaction (4.92×10^{-7} min^{-1}, pH 7 at 25 °C[8h]). These observations prompted us to perform a more thorough kinetic evaluation and therefore, the Michaelis–Menten kinetic parameters for metallated adenine nucleobase polymers **1** and **2** were determined. Lineweaver–Burk plots (1/V *vs.* 1/[S], Fig. 1) were used to calculate Michaelis constants (K_m) and maximal velocities (V_{max}). For polymer **1**, containing DVB cross-linker, the K_m and V_{max} values were found to be 1.01 mM and 2.55×10^{-5} mM min^{-1}, respectively. While for polymer **2**, containing EGDMA cross-linker, the corresponding K_m and V_{max} values were found to be 0.21 mM and 4.6×10^{-5} mM min^{-1}, respectively (Table 2, Fig. 1).

Table 1 Estimated copper-loading and pseudo-first-order rate constants for pNPP hydrolysis in the presence of polymers **1** and **2**[a]

Polymer[b]	9-Allyladenine: cross-linker: Cu(II)	Mg of Cu(II) (g polymer)$^{-1}$ [c]	k_{obs}/min^{-1}	k_{rel}
1	DVB, 1:3:1	63.60	1.32×10^{-3}	2.7×10^3
2	EGDMA, 1:4:1	160.00	5.47×10^{-3}	1.1×10^4

[a] All hydrolytic reactions were performed in duplicate in 3 mL of 0.01 M *N*-ethylmorpholine buffer in 50% aqueous methanol (pH 8.0, 30 °C). [b] Polymer weights were 1 mg in 3mL of buffer, corresponding to 0.33 and 0.84 mM of Cu^{2+}, if polymers **1** and **2** were completely soluble in buffer and substrate concentrations were 3.3 and 8.4 mM, respectively. [c] Determined by AAS (AAS-300 Analyst, Perkin Elmer) and ICP (Integra XL, GBC) measurements.

We have also evaluated polymer **2** under turnover conditions[12e] by increasing the substrate concentration, while keeping the amount of polymer constant. Pseudo-first-order rates were determined and it was found that polymer **2** displayed efficient catalysis even in the presence of a 10-fold excess concentration of pNPP (Table 3). A unique feature of our

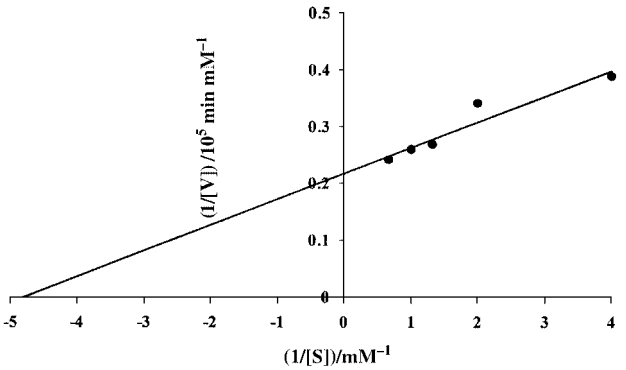

Fig. 1 Lineweaver–Burk plot of Cu(II)-metallated EGDMA cross-linked adenine nucleobase polymer **2**.

Table 2 Michaelis constants and maximal velocities of Cu(II)-containing adenine polymers for pNPP hydrolysis[a]

Polymer[b]	K_m/mM	V_{max}/mM min^{-1}
1	1.01	2.55×10^{-5}
2	0.21	4.6×10^{-5}

[a] All hydrolytic reactions were performed in duplicate in 5 mL of 0.01 M *N*-ethylmorpholine buffer in 50% aqueous methanol (pH 8.0, 30 °C), pNPP concentrations, [S]: 0.5–2.0 mM and 0.25–1.5 mM (for polymers **1** and **2**, respectively). [b] Polymer weights were 1 mg in 5 mL of buffer, corresponding to 0.2 and 0.5 mM of Cu^{2+}, for polymers **1** and **2** respectively, if the polymers were completely soluble in buffer.

Table 3 Turnover experiments[a]

Molar ratio of Cu(II) present in EGDMA adenine polymer[b]: pNPP	Pseudo-first-order rate constant k_{obs}/ min^{-1}
1:1	1.69×10^{-3}
1:3	2.39×10^{-3}
1:10	5.47×10^{-3}

[a] All hydrolytic reactions were performed in duplicate in 3 mL of 0.01 M *N*-ethylmorpholine buffer in 50% aqueous methanol (pH 8.0, 30 °C); [b] Polymer weights were 1 mg in 3 mL of buffer, corresponding to 0.84 mM of Cu^{2+}, if polymer **2** was completely soluble in buffer.

polymers is that they could be easily recycled. In a typical procedure, after pNPP hydrolysis, the reaction mixtures were centrifuged; polymers were filtered off and washed with copious volumes of 50% aqueous methanol. Washed and dried polymers were then reused for the catalysis of a subsequent hydrolytic reaction. Both of the polymers were reused thrice and the initial velocities, depending on the release of *p*-nitrophenolate anion, were found to be similar to the values obtained by using fresh polymeric catalysts (data not shown).

It is tempting to attribute a differential rate enhancement between the two polymers to the high loading of Cu(II) in polymer **2**. Unmetallated, cross-linked adenine polymers failed to catalyze pNPP hydrolysis over an extended period of time (data not shown), thereby indicating a crucial role of coordinated metal ion in accelerating the hydrolytic reaction. There are some literature reports that describe polymer-based, non-enzymatic hydrolysis of activated phosphate esters and RNA.[4c,12a–f] We have also introduced a novel matrix of cross-linked nucleobase polymers and have exploited metal coordination capability of adenine nucleobase for phosphate monoester hydrolysis. Turnover and recycling experiments indicate that these molecules are robust, possess high catalytic efficiency, and are amenable to recycling. Importantly, the heterogeneous nature of our catalyst can be utilized for its convenient removal at the completion of reaction.

The precise mechanism of monophosphate ester hydrolysis by metallated nucleobase polymers is unclear at the present time. Experiments are underway to elucidate the mechanism and to evaluate the catalytic assistance of these polymers for the hydrolysis of amides, esters, dinucleotides and nucleic acids. Moreover, we are also in the process of developing soluble, nucleobase containing polymeric matrices for effecting homogeneous catalysis of the above mentioned reactions.

We would like to thank Mr D. Saran for his contribution to the initial phase of this project and FEAT Lab, IIT-Kanpur, for AAS/ICP measurements. Financial support from the Council of Scientific and Industrial Research (CSIR) is gratefully acknowledged.

Entrapment of ferrocenes within supramolecular, deep-cavity resorcin[4]arenes†

Leonard R. MacGillivray,* Heather A. Spinney, Jennifer L. Reid and John A. Ripmeester

Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, Canada, K1A 0R6. E-mail: lmacgil@ned1.sims.nrc.ca

Received (in Columbia, MO) 8th December 1999, Accepted 14th February 2000

Using a template-based method to molecular self-assembly, the ability of ferrocene (FcH) and two of its acetylated derivatives [FcAc, 1,1′-Fc(Ac)$_2$] to induce formation of a supramolecular deep cavity based upon *C*-methylcalix[4]resorcinarene 1 and 4,4′-bipyridine 2, 1·2(2), 3, is revealed; equatorial inclusion of 1,1′-Fc(Ac)$_2$ within 3 promotes a change in conformation of the guest.

Ferrocenes are attractive guests for studies involving facets of second sphere coordination in which molecular receptors serve as hosts.[1,2] The cyclopentadienyl (Cp) rings of such complexes can be readily derivatized and, upon interacting with the surface of a receptor, may adopt a conformation not exhibited by the free molecule which, in turn, may influence properties of the guest (*e.g.* reactivity).[3] Despite this realization, it is surprising that little structure information exists concerning the interaction of ferrocene (FcH) with most receptors designed to date, an observation likely related to the relatively large size of the complex. α-Cyclodextrin was the first receptor shown to assemble with FcH in the solid state, in the form of a 2:1 assembly [2(α-CD)·FcH],[4] while a hemicarcerand has been recently illustrated to encapsulate the molecule in a 1:1 host–guest complex (HC·FcH).[5] In each case, the included FcH is located within a symmetric cavity such that the Cp rings of the molecule are surrounded by identical chemical environments, which, in effect, prohibits any degree of discrimination, in terms of recognition, among the rings.[6]

Our approach to the construction of a host able to recognize FcH, and its derivatives (FcR), involves the use of a supramolecular cavity based upon Högberg's resorcin[4]arenes.[7] In particular, extensive work has demonstrated that co-crystallization of *C*-methylcalix[4]resorcinarene **1** with 4,4′-bipyridine **2** typically yields a one-dimensional, wave-like polymer, **1**·2(**2**), **3**, in which the cavity of **1** is deepened supramolecularly,[8] interacting with four stacking pyridine units of **2** by way of four O–H···N hydrogen bonds.[9] The cavity created by the five molecules, which may be induced to form by way of guest templation,[10] is flexible, being able to accommodate either single or multiple guests by way of a conformational reorganization of the network **3**.[9]

With the observation that hemicarcerands recognize FcH realized,[5] we sought to determine whether **3** may be exploited in a similar manner. In contrast to the cavities cited above, the cavity of **3** is polar and, therefore, may be used to control the orientation, and possibly the conformation, of a ferrocene guest in which the structure of the guest is dictated by the electron-rich, bowl-shaped cavity of **1**.[6] Here, we reveal the ability of **3** to serve as a host for FcR. In particular, using a template-based method to molecular self-assembly,[10] we demonstrate the ability of FcH in **3**·FcH, and its mono- (FcAc) and 1,1′-diacetylated [Fc(Ac)$_2$] derivatives in **3**·FcAc and **3**·Fc(Ac)$_2$, respectively, to assemble within **3** such that each FcH guest interacts with the cavity of **1** in a 'side-on', or equatorial fashion. For **3**·Fc(Ac)$_2$, the Cp rings of the complex adopt a 1,1′-eclipsed conformation[11] which contrasts a 1,3′-staggered structure for the free molecule.[12] To our knowledge, **3**·FcH, **3**·FcAc and **3**·Fc(Ac)$_2$ represent the first examples in which metallocenes have been isolated within a resorcin[4]arene in the solid state.‡

Addition of FcH (0.020 g) to a boiling aliquot of EtOH (5 mL) in the presence of an equimolar amount of **1** (0.058 g) and two molar equivalents of **2** (0.033 g) yielded, upon slow cooling, a microcrystalline powder with yellow–orange crystals of **3**·FcH suitable for X-ray analysis within a day. The formulation of **3**·FcH was confirmed by single crystal X-ray analysis§ and ^{1}H NMR spectroscopy.

A space-filling view of the X-ray crystal structure of **3**·FcH is shown in Fig. 1. The FcH guest, which lies across a crystallographic mirror plane, has assembled within the wave-like framework **3** [polymer wavelength (λ) 25.4 Å; amplitude (ampl.) 19.3 Å],[9] which is propagated along the crystallographic *b*-axis [O···N separations (Å): O(1)···N(1) 2.74(11), O(2)···N(2) 2.68(13)], such that the sandwich complex interacts with **1** in an equatorial fashion. In this arrangement, the Cp–Fe–Cp axis of the iron complex is pointed in a direction that runs approximately parallel to the direction of the hydrogen bonds of **3** such that the Cp ligands of the guest, which adopt an approximate eclipsed D_{5h} conformation,[13] interact with **1** and **2** by way of C–H···π interactions.[14] Notably, the fit displayed by **1** and FcH markedly contrasts that of HC·FcH in which the sandwich complex is included axially,[5] the principal rotation axes of host and guest being approximately coincident. In both 2(α-CD)·FcH[4] and HC·FcH,[5] the Cp rings of the FcH guest adopt a staggered D_{5d} conformation.[13]

The observation that **3** may host FcH in the solid state suggested that **3** may be used to host derivatives of the complex. Indeed, **3** has been shown to accommodate guests of various size by modifying the relative orientations of the components of the host which results in a conformational change of the network.[9] If achieved, we anticipated that it may be possible to control stereochemical features of a ferrocene guest in which the substituents of the Cp ligands, owing to their electronic nature, may be directed either in or out of the cavity of **1**.[6]

To test this hypothesis, **1** (0.040 g) was co-crystallized with two molar equivalents of **2** (0.023 g) from a boiling aliquot of EtOH (5 mL) in the presence of a molar equivalent of either

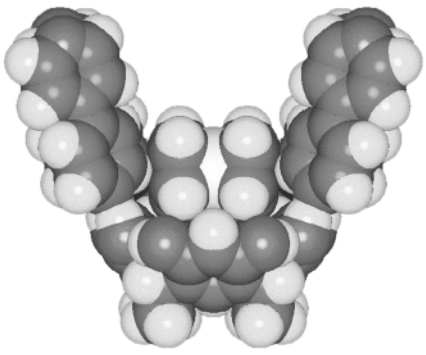

Fig. 1 Space-filling view of guest inclusion in the X-ray crystal structure of **3**·FcH.

† Published as NRCC no. 43832.

DOI: 10.1039/a909745g

FcAc or $Fc(Ac)_2$. Yellow and red crystals of **3**·FcAc and **3**·$Fc(Ac)_2$, respectively, suitable for X-ray analysis grew within a day. The formulations of **3**·FcAc and **3**·$Fc(Ac)_2$ were confirmed by single crystal X-ray analysis§ and ^{1}H NMR spectroscopy.

An ORTEP perspective of the X-ray crystal structure **3**·$Fc(Ac)_2$ is shown in Fig. 2(a). In a similar way to **3**·FcH, the guests have assembled within **3** such that both complexes lie within **1** in an equatorial fashion and the Cp rings of the guests, which run in a direction parallel to the hydrogen bonds of **3** [O···N separations for **3**·FcAc and **3**·$Fc(Ac)_2$ (Å): O(1)···N(1) 2.660(3), 2.705(3), O(2)···N(3) 2.710(3), 2.683(3), O(5)···N(2) 2.649(3), 2.762(3), O(6)···N(4) 2.758(3), 2.633(3), respectively], interact with **1** and **2** by way of C–H···π forces [**3**·FcAc and **3**·$Fc(Ac)_2$: polymer λ (Å): 27.0, 26.6; ampl. (Å): 18.4, 18.5, respectively]. In this arrangement, the electron-rich carbonyl substituents of the guests are directed away from the cavity of **1** such that the substituents, which, as in the free molecules,[12,18] are approximately co-planar with the Cp rings, lie above the wider rim of **1**. For **3**·$Fc(Ac)_2$, the acetyl groups of the disubstituted complex, in contrast to free $Fc(Ac)_2$ and most 1,1′-disubstituted ferrocenes which tend to crystallize in a 1,3′-conformation,[19] adopt a 1,1′-conformation such that the substituents are eclipsed [Fig. 2b].¶ Indeed, this latter observation may be attributed, in part, to the electron-rich nature of the cavity of **3** which, upon maximizing attractive non-covalent forces between host and guest, has induced the molecule, by way of second sphere coordination,[1,2] to adopt a structure of a less preferred conformer.[12,19]

In this report, we have revealed the ability of **1**, with a cavity deepened supramolecularly,[8] to entrap FcH, and two of its acetylated derivatives, in the solid state. Owing to the ability of **1** to interact with the complex in an equatorial fashion, we have shown that it is possible to effect the conformation of a ferrocene guest such that, for $Fc(Ac)_2$, the substituents of the complex lie eclipsed. With such observations realized, we plan to determine if more reactive derivatives of FcH may be entrapped within **3** such that the substituents of the Cp rings may undergo reaction in the solid state.[20] We are also investigating whether **3** may be used as a host for other transition-metal-based complexes in which the structure behaviours of such organic–organometallic host–guest materials are expected to be governed by the supramolecular properties of **3** by way of second-sphere coordination.[1,2]

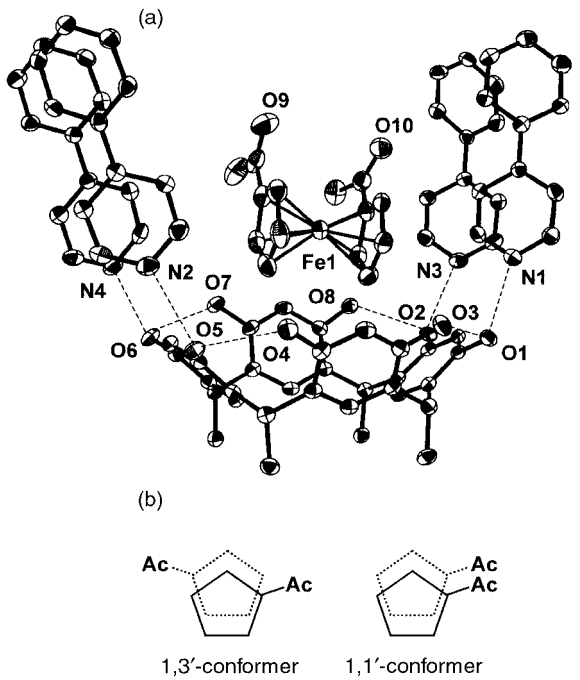

Fig. 2 (a) ORTEP perspective of the X-ray crystal structure of **3**·$Fc(Ac)_2$ and (b) schematic representation illustrating the conformation of $Fc(Ac)_2$ within the cavity of **3**. The guest adopts a 1,1′-conformation.

We are grateful for funding from the National Research Council of Canada (WES undergraduate scholarship, H. A. S.) and the Natural Sciences and Engineering Research Council of Canada (graduate scholarship, J. L. R.).

Notes and references

‡ To our knowledge, a metallocene has not been observed to assemble within a calix[4]arene in the solid state.

§ *Crystal data*: for **3**·FcH: monoclinic, space group, $P2_1/m$, a = 9.730(1), b = 25.440(3), c = 10.825(1) Å, β = 110.710(3)°, V = 2506.4(6) Å^3, D_c = 1.38 g cm^{-3}, Mo-Kα radiation (λ = 0.71070 Å) for Z = 2. Least-squares refinement based on 1527 reflections with $I_{net} > 2.0\sigma(I_{net})$ (out of 3370 unique reflections) led to a final value of R = 0.089.

For **3**·FcAc: monoclinic, space group, $P2_1/n$, a = 18.477(1), b = 11.742(1), c = 26.086(1) Å, β = 107.794(1)°, V = 5389.0(4) Å^3, D_c = 1.34 g cm^{-3}, Mo-Kα radiation (λ = 0.71070 Å) for Z = 2. Least-squares refinement based on 5416 reflections with $I_{net} > 2.0\sigma(I_{net})$ (out of 7041 unique reflections) led to a final value of R = 0.034.

For **3**·$Fc(Ac)_2$: monoclinic, space group, $P2_1/n$, a = 18.808(1), b = 11.948(1), c = 25.595(1) Å, β = 108.306(1)°, V = 5460.4(4) Å^3, D_c = 1.37 g cm^{-3}, Mo-Kα radiation (λ = 0.71070 Å) for Z = 2. Least-squares refinement based on 5676 reflections with $I_{net} > 2.0\sigma(I_{net})$ (out of 7141 unique reflections) led to a final value of R = 0.044. Intensity data for **3**·FcH, **3**·FcAc and **3**·$Fc(Ac)_2$ were collected at 173 K using the SMART system. Aromatic, methine, methyl and hydroxy hydrogen atoms were placed by modelling the moieties as rigid groups with idealised geometry, maximizing the sum of the electron density at the calculated hydrogen positions.

Structure solutions were accomplished using SHELXS-86[15] and refinements were conducted using SHELXL93[16] locally implemented on a pentium-based IBM compatible computer. Structure refinements and production of figures were accomplished with the aide of RES2INS.[17]

CCDC 182/1550. See http://www.rsc.org/suppdata/cc/a9/a909745g/ for crystallographic files in .cif format.

¶ We also note that the acetyl groups of free and entrapped $Fc(Ac)_2$ display *transoid* and *cisoid* relationships, respectively, while the Cp ligands in both complexes are eclipsed.

Recent applications of olefin metathesis and related reactions in carbohydrate chemistry

René Roy* and Sanjoy Kumar Das

Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5. E-mail: rroy@science.uottawa.ca

Received (in Cambridge, UK) 23rd September 1999, Accepted 4th November 1999
Published on the Web 1st March 2000

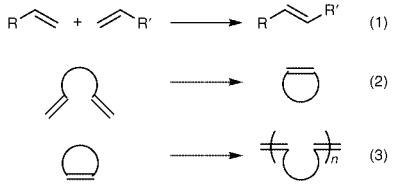
The potential use of olefin metathesis reactions in carbohydrate chemistry is discussed. In recent years, the use of olefin metathesis reactions for the construction of carbon–-carbon bonds has significantly expanded with the development of efficient and well-defined catalytic systems (1–7). These catalytic systems have found extensive use through cross-metathesis, ring-closing metathesis and ring-opening metathesis reactions for the syntheses of many carbohydrate-containing natural products. In some cases it has been shown that carbohydrate molecules can be synthesized from non-carbohydrate precursors using this simple but efficient procedure.

Professor René Roy was born in Sherbrooke, Québec, Canada in 1952. He received his Ph.D. degree in medicinal chemistry with Professor Stephen Hanessian in 1980 at the University of Montreal. He then obtained an NRC fellowship from 1980–1985 and worked in the Biological Sciences Division of the National Research Council in Ottawa, Ontario where he conducted immunological studies with Dr H. J. Jennings on bacterial polysaccharide vaccines. From 1985 onward, he joined the Department of Chemistry of the University of Ottawa were he moved to the rank of full Professor in 1995. During that time he also became adjunct Professor to the Department of Microbiology and Immunology. His research interests are centered around neoglycoconjugate syntheses and their applications in carbohydrate–protein interactions related to cancer vaccines and flu virus infections. He developed the first syntheses of glycodendrimers as potential antiadhesins. He made several contributions towards glycopolymer synthesis and their applications as coating antigens in ELISA assays. His recent interests lie in transition metal catalyzed reactions and phytomedicines. He has received the Hoffmann-La Roche Limited award in 1997.

Dr Sanjoy Kumar Das was born in Raiganj, India, in October 1967. He received his M.Sc. degree in Organic Chemistry from North Bengal University in 1991. After completing his Ph.D. degree under the supervision of Dr Mukund K. Gurjar at the Indian Institute of Chemical Technology, Hyderabad, India in 1996, he joined Professor Pierre Sinaÿ's laboratory at École Normale Supérieure, Paris as a postdoctoral fellow. After spending two years in Paris, he moved to Professor Roy's laboratory where currently he is working as a postdoctoral fellow. He is the recepient of several awards (awarded medals in B.Sc. and M.Sc. Exams. and selected as a best research scholar during his Ph.D. in 1995) including the most prestigious, Council of Scientific and Industrial Research, New Delhi, award. His research interests include the transition-metal catalyzed syntheses of neoglycoconjugates and the development of new methodologies in carbohydrate chemistry.

Introduction

The use of olefin metathesis in organic synthesis has grown considerably in recent years.[1,2] This simple procedure does not require the use of any additional reagents except for a catalytic amount of metal carbene, and the only by-product that forms is volatile ethylene gas. The importance of this carbon–carbon bond construction method is evident from the huge number of publications that have appeared within a short span of time.[3–5] Olefin metathesis can be categorized into three different sections: (1) cross-metathesis, in which two different alkenes undergo an intermolecular transformation to form a new olefinic product (eqn. 1); (2) ring-closing metathesis, a procedure which is useful for the formation of cyclic compounds (eqn. 2); and (3) ring-opening metathesis polymerization, which involves the metathetic opening of strained cyclic olefins to give polymeric compounds (eqn. 3).

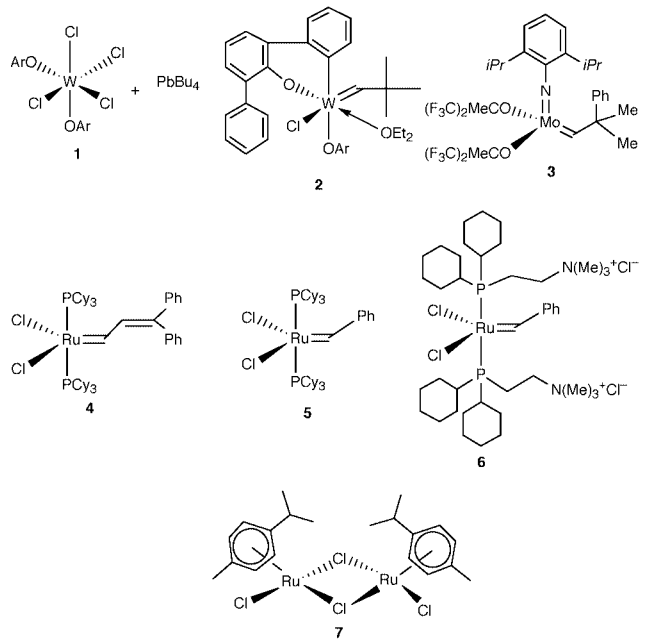


Although many examples of cross-metathesis, ring-closing metathesis and ring-opening metathesis reactions are available in the literature, only carbohydrate-related applications reported up to September 1999 will be discussed herein. Some interesting discoveries (cyclotrimerization, isomerization) from our laboratory using Grubbs' catalyst will also be discussed.

Catalyst development

The early examples of olefin metathesis employed classical catalysts which usually included a tungsten chloride or oxychloride and an alkyl metal species. These catalysts were less reactive to olefins due to their increased stability and yields were generally found to be low.[6–8] The other established catalyst is dichlorobis(2,6-dibromophenoxy)oxotungsten, $Cl_2(ArO)_2W{=}O$.[9] Although this system shows good functional group tolerance and has been used for many syntheses, it is considered to be unsuitable for industrial applications owing to its complexity and cost. Olefin metathesis began to receive more attention in 1993, when Basset and co-workers developed and applied the tungsten catalysts **1** and **2** for cross-metathesis reactions.[10,11] To date, these have been successfully shown to be remarkably tolerant to heteroatoms, including sulfur, silicon, phosphorus, and tin. Since the use of this catalyst is limited because of its steric demand toward shorter alkenes, such as allyl groups, researchers have searched for alternative catalytic systems for olefin metathesis reactions. One of the most useful catalysts for olefin metathesis reactions is the molybdenum catalyst (**3**) developed by Schrock *et al.*[12] Although the major advantage of **3** is its high reactivity towards a broad range of substrates with a variety of functional groups, this catalyst also

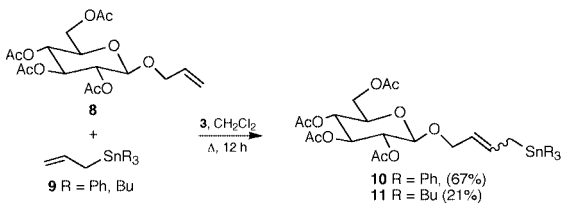
DOI: 10.1039/a907712j



has some limitations. Its major drawbacks are that it is air sensitive and has moderate to poor functional group tolerance. Much work on the development of catalytic systems has been done by Grubbs and co-workers using two very important ruthenium-based catalysts, **4**[13] and **5**.[14] Although both catalysts benefit from the same impressive tolerance to air, moisture and various functional groups, catalyst **5** provides improved initiation rates and can be prepared easily. In addition to the catalytic systems discussed above, a few other transition metal catalysts have been prepared for olefin metathesis reactions. Among them, the water soluble ruthenium catalyst **6**,[15] also developed by Grubbs and co-workers, and a photoinducible dichloro(*p*-cymene)ruthenium(II) dimer (**7**), developed by Fürstner and Ackermann,[16] are noteworthy. Many applications of these catalysts have been recently reported in the literature. Although several metal carbenes have been mentioned, we have endeavoured to cover only the catalytic systems which have been used in carbohydrate chemistry.

Cross-metathesis

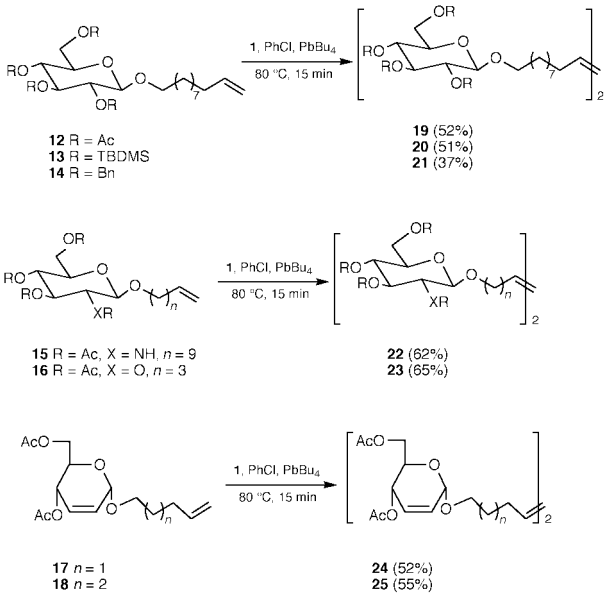
The cross-metathesis reaction, in which two different alkenes are used to form a new alkene, is shown in eqn. 1. This method has not found widespread application because of the fact that general conditions which give rise to high yields and stereoselectivity have not yet been discovered. With the development of new, well-defined metal alkylidenes and a better understanding of the nature of the reaction mechanisms involving these catalysts, some examples of selective cross-metathesis reactions have recently appeared in the literature. Thus, Blechert *et al.*[17] have shown that allyltributyl or allyltriphenyl stannane can undergo selective cross-metathesis reactions with allyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**8**) using Schrock's catalyst **3** (Scheme 1). The cross-metathesized



Scheme 1

product **10** could be very useful for nucleophilic additions to electrophilic carbon centres and for radical reactions.

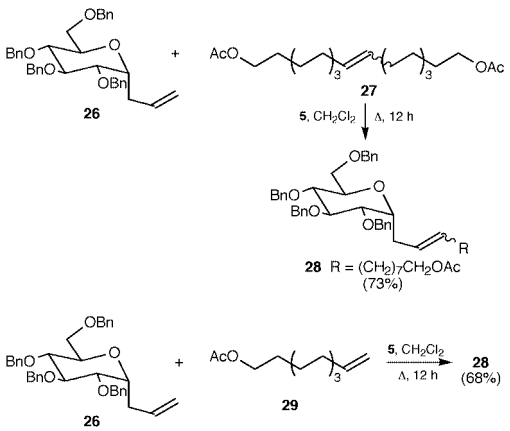
Descotes *et al.*[18] have chosen this procedure as the most efficient method for the preparation of sugar bolaamphiphiles (**19**–**25**) in good yields (Scheme 2). Glucosides protected as



Scheme 2

acetates (**12**) or silyl ethers (**13**) were found to be superior substrates to benzyl-protected carbohydrates (**14**) in metathesis reactions. The same group has also successfully extended this methodology to the *N*-acetyl aminosugar **15**. Catalysts **1** and **2** were found to be active with pentenyl glycosides, whereas allyl glycosides did not afford any metathesis products; again the catalysts were deactivated by competitive coordination of the ether oxygen to the metallocarbenes. Metathesized products were synthesized in good yields, but the *cis*:*trans* ratios were not determined.

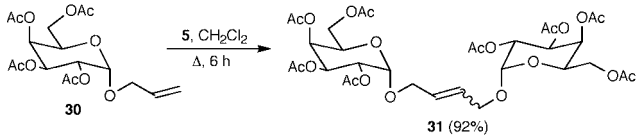
Recently, Grubbs *et al.*[19] have used the cross-metathesis reaction between *C*-allyl α-D-glucopyranoside and disubstituted olefins to supress the formation of self-metathesis products (Scheme 3). Homodimer **27** was subsequently used to function-



Scheme 3

alize *C*-allylglycoside (**26**) in 73% yield as a mixture of *cis* and *trans* isomers in a 3:1 ratio. In order to compare the yield and isomeric ratios, they performed the reaction with 4 equiv. of the terminal olefin **29**. The cross-metathesized product **28** was isolated in a marginally lower yield with slightly lower *trans*-selectivity (68%, 2.2:1 *E*:*Z*).

We have shown that peracetylated *O*-allyl β-galactoside (**30**) can be easily homodimerized in the presence of Grubbs' or Schrock's catalyst (Scheme 4).[20] Since, in both cases, the yields were found to be more or less the same, catalyst **5** was preferred



Scheme 4

because of its operational simplicity. Various other homodimers were synthesized using the same catalyst **5** (Table 1).

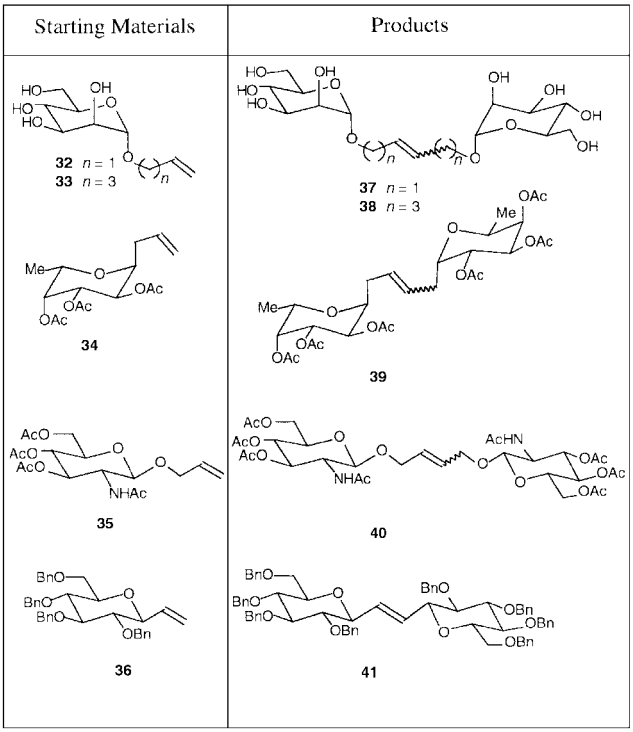
Table 1 Olefin self-metathesis of alkenyl *O*- and *C*-glycopyranosides

R	Product (*E*:*Z*)	Yield (%)
	(5:1)	92
	(4:1)	95
	(5:1)	85
	(4:1)	89
	(2:1)	82
	(1:1)	75
	(3:1)	76

In order to investigate the influence of unprotected glycosides in metathesis reactions, we have shown[21] that the reaction proceeds smoothly with catalyst **5** at room temperature rather than under refluxing conditions, where *O*-allyl (**32**) and *O*-pentenyl mannopyranosides (**33**) gave homodimers **37** and **38** in good yields. Compounds **34** and **35** also provided homodimers, **39** and **40** in 95 and 66% yields, respectively (Scheme 5). The sterically more demanding C-vinyl glycoside (**36**) can undergo olefin metathesis reaction at elevated temperatures (70 °C) albeit slowly (Table 2).

Olefin metathesis has also been used for the synthesis of divalent sialoside derivatives.[22] Treatment of allyl *O*-α-sialoside (**42**) with 5 mol% of Grubbs' catalyst (**5**) in refluxing dichloromethane gave homodimer **44** in 82% yield. The corresponding thio-analogue, **43**, gave homodimer **45** in only 26% yield. Undoubtedly, the lower yield was due to catalyst-poisoning by the sulfide moiety (Scheme 6).

Synthesis of *O*- and *C*-glycosides **30** and **46** with differently functionalized spacers in the aglycon moiety was also carried out by cross-metathesis reactions from *O*-allyl and *C*-allyl glycosides in good yields (Table 3).[23] These extended glycosides can be further transformed by known methods into useful neoglycoconjugates including glycodendrimers and polymers. An interesting application of this reaction was the synthesis of



Scheme 5

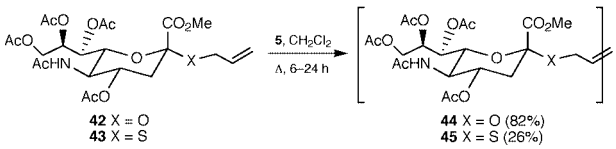

Scheme 6

C-linked pseudodisaccharides, which can be synthesized by the cross-metathesis between two different sugar moieties, using a head to tail condensation procedure (Scheme 7 and Table 4).

The cross-metathesis of *O*- or *C*-allyl glycosides and *N*-alkenyl-containing oligosaccharide derivatives (peptoids) has been reported by Hu and Roy.[24] The treatment of a GlcNAc derivative (**35**) with *N*-allylamine in the presence of Grubbs' catalyst (**5**) gave no cross-metathesis product, but dimerization of **35** was achieved in 30% yield. Alternatively, the use of amine **61** in the cross-metathesis reaction with **35** gave **62** in 41% yield. This was a surprising result, since free carboxylic acids are not considered to be good substrates for olefin metathesis reactions (Scheme 8).

The cross-metathesis reaction involving polymer-bound olefins has more potential benefits because product isolation should be easier. In an interesting application of the cross-metathesis reaction on a solid support, Blechert *et al.*[25] have

Table 3 Isolated yields and *E*:*Z* ratios of ruthenium catalyzed cross-metathesis of **30** with alkenes **47–54** to provide extended glycosides

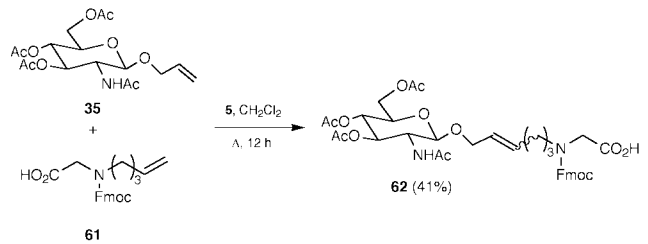
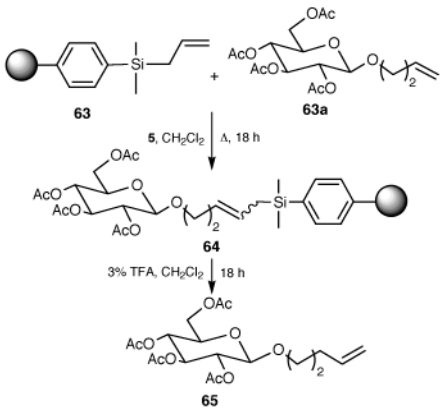


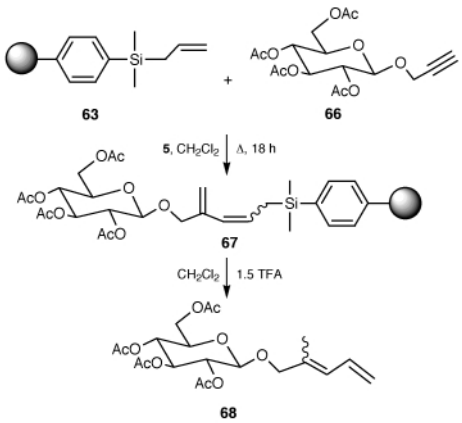
Scheme 8

reported the metathesis reaction between immobilized allyl silane **63** with various olefins (*e.g.*, **63a**) to give new immobilized olefins. Product **64** could be cleaved under acidic conditions to provide the homologated derivative **65** (Scheme 9).



Scheme 9

In another solid-support application, Schuster and Blechert[26] have reported a catalytic cross-coupling reaction between the functionalized terminal alkynes **66** and allylsilyl polystyrene, **63**, *via* a more selective ruthenium-catalyzed crossed yne–ene metathesis reaction. Upon cleavage of **67** by 1.5% TFA, the procedure afforded the 1,3-diene **68** (Scheme 10).



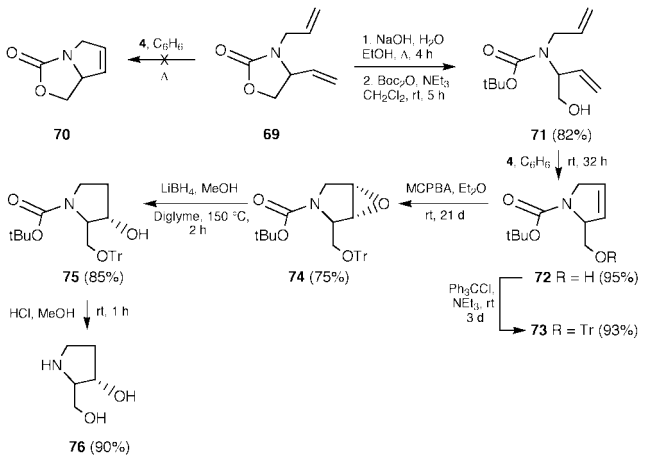
Scheme 10

Ring-closing metathesis

Among all the categories, ring-closing metathesis (RCM) reactions, which lead to cyclic products, have found the widest application in synthesis. With the advent of well-defined molybdenum- and ruthenium-based catalysts, high yielding

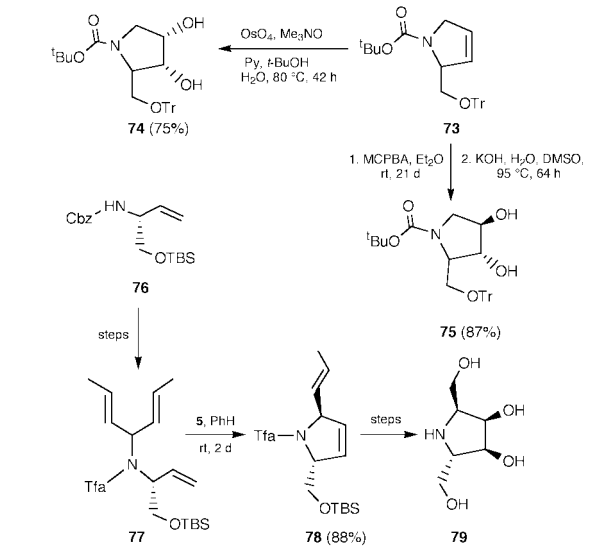
RCM of smaller ring systems was realized. It has been successfully used for the synthesis of a variety of carbo- and heterocyclic products and has also proven to be the key step for many total syntheses.

Huwe and Blechert[27] have chosen this novel strategy for the synthesis of azasugars from vinyl glycine methyl ester using catalyst **4**. They have shown that compound **69** is not suitable for olefin metathesis reactions (Scheme 11). Hydrolysis of **69** with NaOH in aqueous ethanol and subsequent treatment with di-*tert*-butyldicarbonate [$(Boc)_2O$] gave **71**. Olefin metathesis of **71** with 4 mol% of catalyst **4** gave a good yield of the RCM product **72** (95%). Compound **72**, on subsequent epoxidation and hydride opening of the epoxide, gave the 1,2-dideoxy sugar **76**.



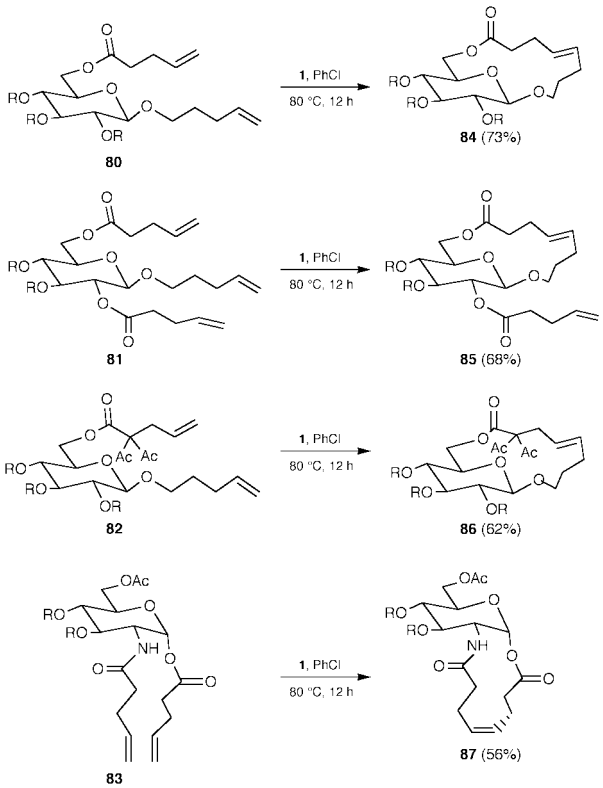
Scheme 11

In an another application, the same group[28] applied the Sharpless dihydroxylation method to obtain 1-deoxy azasugars (*e.g.*, **74** and **75**). They also used an analogous strategy toward the synthesis of the homoazasugar **79** from vinyl glycine methyl ester (Scheme 12).



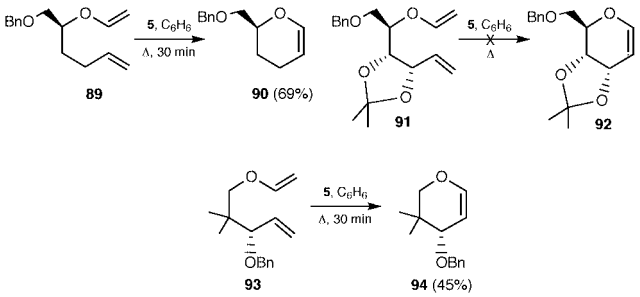
Scheme 12

Descotes *et al.*[29] have used catalysts **1** and **2** for an intramolecular carbohydrate macrocyclization. Thus, diluted solutions of the unsaturated substrates **80**–**83** in chlorobenzene when treated with 7 mol% of catalyst **1** at 80–85 °C afforded the cyclic products **84**–**87** in reasonable yields (56–73%). It has been observed that homodimerization of the starting material did not occur during the metathesis reaction. The results of the metathesis reaction are summarized in Scheme 13. The cyclization took place between the substituents at C1 and C6 which are in a *cis*-configuration. Thus, the chemoselectivity of the reaction could be controlled by the anomeric configuration.



Scheme 13

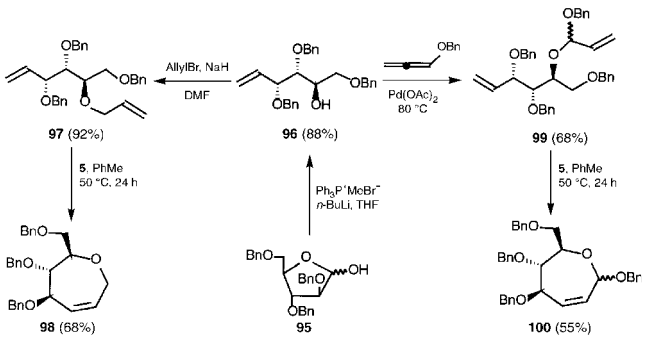
Sturino and Wong[30] have made some interesting observations. They have reported the ring-closing metathesis of the vinyl ethers **89**, **91** and **93** with Grubbs' catalyst (**5**) (Scheme 14). Although compound **89** gave the cyclic product **90** in 69% yield, compound **91** was inert. They concluded that the presence of an allylic alkoxy substituent has a negative influence on the RCM reaction. As an exception to this finding, it was shown that compound **93** can give **94** due to the Thorpe–Ingold effect of the *gem*-dimethyl substituents.



Scheme 14

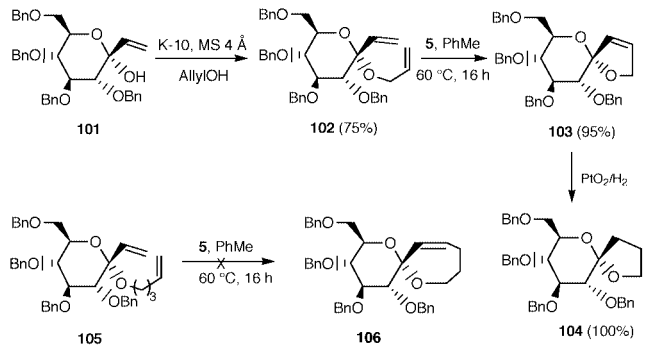
A novel and versatile route to highly functionalized chiral oxepines, which is based on RCM of differently protected glycofuranoses,[31] has been developed by van Boom *et al.* Thus, treatment of **97**, which can be easily prepared from 2,3,5-tri-*O*-benzyl-D-arabinofuranose (**95**), with 5 mol% of the Ru-catalyst **5** in toluene at 50 °C for 24 h gave the expected cyclized product, **98** (Scheme 15). The success of this smooth cyclization of the vinyl-*O*-allyl derivatives encouraged this group to prepare interesting oxepanes, such as **100**. The RCM of **99** led to the formation of **100** as a mixture of diastereoisomers (1:1) in 55% yield. These compounds are potentially useful synthons for the construction of higher carbon sugars.

Recently, it has been shown[32] that the RCM reaction can be used as a highly stereoselective route to unsaturated spiroacetals



Scheme 15

starting from a terminal alkene–*O*–alkene arrangement at the anomeric centre of a sugar. Thus, the reaction of **102** in the presence of Grubbs' catalyst (**5**) (6 mol%) at 60 °C for 16 h gave the 1,6-dioxa-(5*R*)-spiro(4,5)dec-3-ene derivative **103** in excellent yield (95%) (Scheme 16). Interestingly, it has also been



Scheme 16

shown that similar treatment of diene **105** did not lead to the expected spiro compound, **106**. Instead, a dimeric product was isolated. The formation of this dimer could not be prevented by lowering the concentration of the substrate with a larger amount of catalyst. It has been concluded that the RCM reaction depends on the site of the ring closure rather than the ring size.

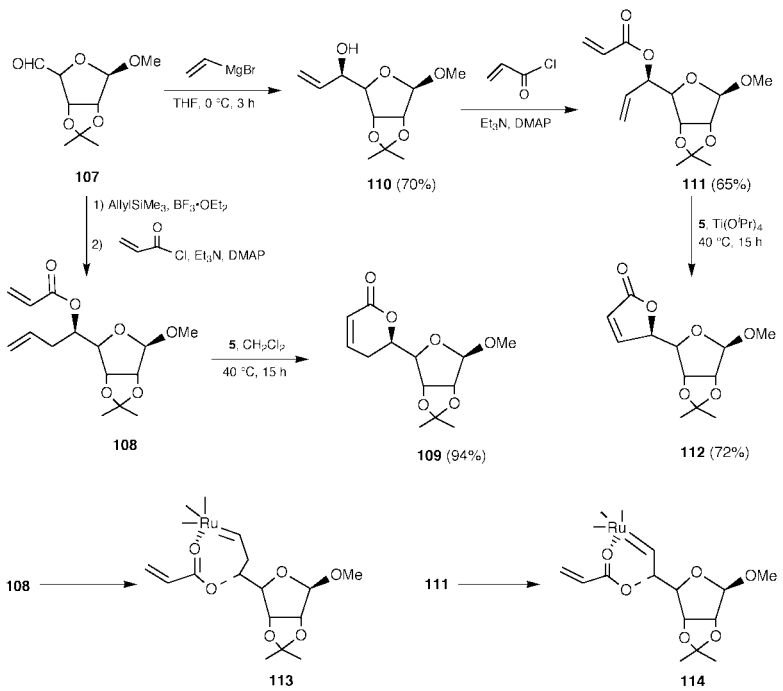
The ring-closing metathesis of the acryloylated derivatives **111** and **108**, derived from allylic and homoallylic alcohols, appeared conveniently poised to provide five or six-membered α,β-unsaturated lactones (**109** and **112**). Unfortunately, this scenario did not happen to be operational. It could be postulated that this is due to the formation of unproductive six- (**114**) and seven-membered (**113**) metal chelates, formed between the ester carbonyl and the intermediate carbene species. These intermediates were apparently too stable for the subsequent olefin metathesis reactions to occur.[33]. However, Ghosh and his co-workers[34] have successfully overcome this problem by adding the external Lewis acid [Ti(^{i}OPr)$_4$], which can disrupt such inactive complexes and can provide effective cyclization. These methods provide convenient access to α,β-unsaturated, γ and δ-lactones (**109** and **112**) in good yields (Scheme 17).

The RCM reaction is an important method for the preparation of carbohydrate derivatives. Recently, Evans and Murthy[35] have developed an interesting silicon-tethered ring-closing metathesis procedure for the synthesis of C_2-symmetrical 1,4-diols (**115**) (Scheme 18). Dihydroxylation of the cyclic alkene by the Sharpless-protocol and removal of the protecting groups afforded the reduced carbohydrate D-altritol (**118**).

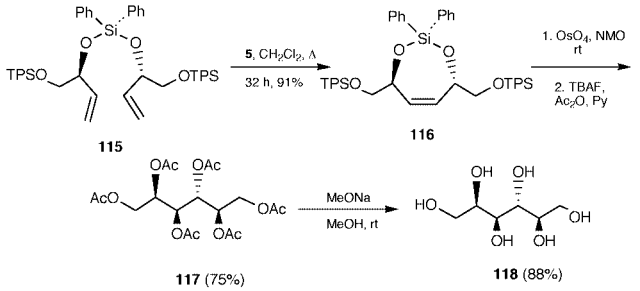
Overkleeft *et al*.[36] reported an efficient synthesis of pyrrolizidine (**121**) and quinolizidine (**125**) azasugar derivatives by using catalyst **4** or **5**. When γ-lactam **120**, derived from aldehyde **119** by Wittig olefination, was subjected to an RCM reaction with catalyst **4**, the expected 5/5 bicyclic pyrrolizidine azasugar (**121**) was formed (Scheme 19). Although the reaction required prolonged reaction time and elevated temperature (50 °C), compound **121** was still isolated in 66% yield. In other examples, the quinolizidine derivative **125** could be derived from either **122a** or **122b** using catalyst **4** or **5**.

The same group[37] has reported a formal total synthesis of the important glucosidase inhibitor castanospermine **130** using olefin metathesis as a key step. It is noteworthy that the cyclization of diene **126**, which contains an α,β-unsaturated ester (not usually suitable for metathesis reactions), reacted with catalyst **4** to give the bicyclic lactam **127** in 70% yield (Scheme 20).

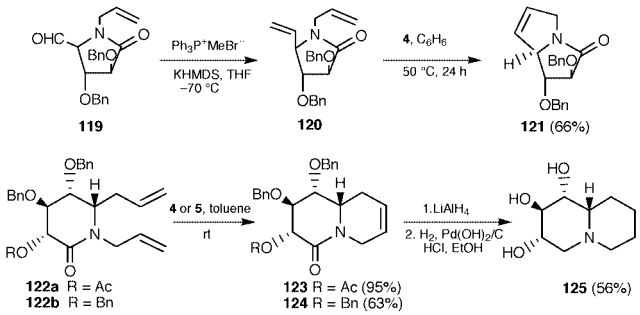
In the synthesis of *C*-aryl glycosides, Schmidt and Sattelkau[38] have used the RCM strategy as the key step (Scheme 21). An interesting feature of their approach was that protecting



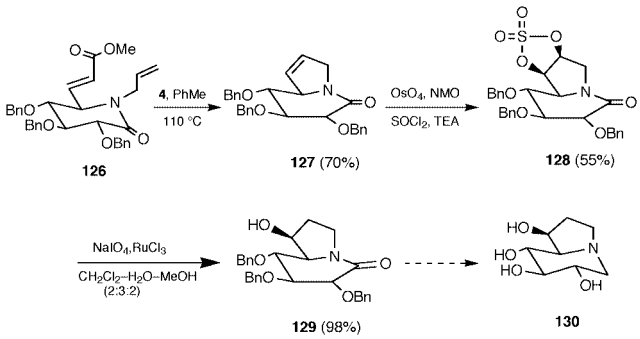
Scheme 17



Scheme 18

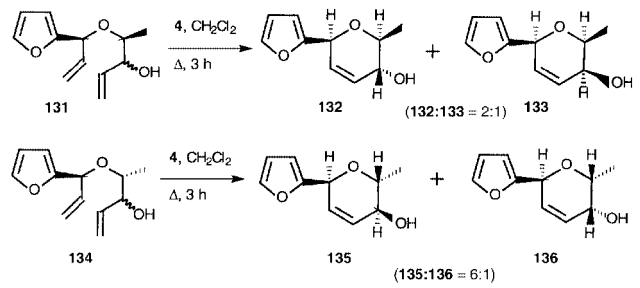


Scheme 19



Scheme 20

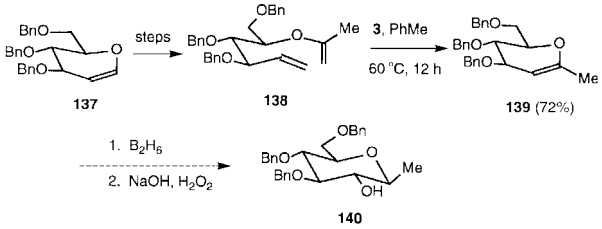
groups, normally necessary for *C*-glycoside synthesis, were not required for the success of the reaction.



Scheme 21

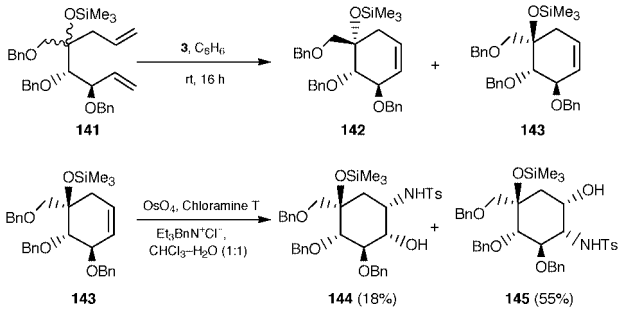
Another approach toward the synthesis of *C*-glycosides was reported by Calimente and Postema,[39] in which RCM was employed as a key step for the intramolecular cyclization. The starting material, **138**, was prepared from the corresponding glycal, **137**, in a few steps. Exposure of the acyclic enol ether **138** to catalyst **3** in toluene solution produced the *C*-linked glycal **139** in 72% yield. It was further suggested by the authors[39] that glycal **139** could then be easily converted into a *C*-glycoside (**140**) by an oxidative hydroboration (Scheme 22).

An efficient and practical method for the preparation of valiolamine has been described.[40] The starting material, **141**, was easily prepared from a D-arabinose derivative and the ring-



Scheme 22

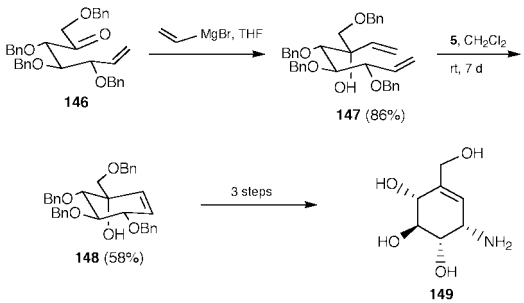
closing metathesis reaction proceeded smoothly (92% crude yield) to provide the substituted cyclohexene derivatives **142** and **143** as a 7:3 mixture of stereoisomers that could be separated by HPLC (Scheme 23). Interestingly, when the



Scheme 23

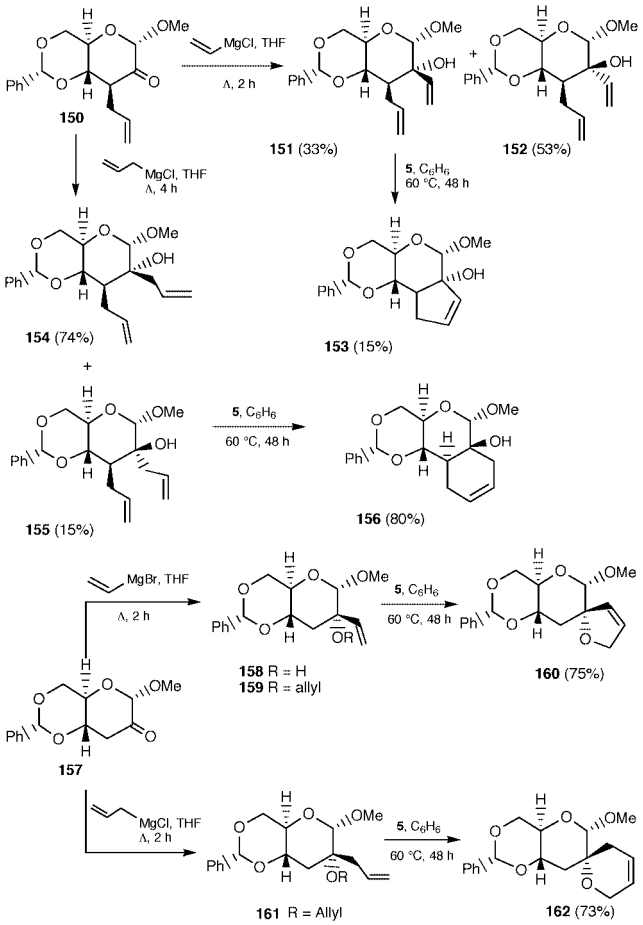
reaction was subjected to the RCM conditions using Grubbs' catalyst, the reaction failed, but proceeded effectively using Schrock's catalyst at room temperature. After separation of both isomers, compound **143** was subjected to a *cis*-aminohydroxylation toward the synthesis of valiolamine (**144**) and its isomer (**145**).

An efficient synthesis of (+)-valienamine from commercially available D-glucose has been reported by Vasella *et al.*[41] using a ring-closing metathesis reaction as a key step. The ring-closing metathesis of **147**, derived by vinylation of ketone **146**, was performed in refluxing CH_2Cl_2 using catalyst **5**. Compound **148** was then converted into (+)-valienamine in three steps with a 47% overall yield (Scheme 24).



Scheme 24

Five-, six- and eight-membered annulated sugars along with spiro systems can also be prepared in good yields.[42] The Grignard reaction between **150** and vinylmagnesium chloride gave two stereoisomers, **151** and **152** (Scheme 25). The ring closing metathesis reaction of **151** with catalyst **5** gave the five-membered annulated sugar **153** in only 15% yield, due to the steric hindrance from the *trans*-fused 5-6 ring system in the product. For six-membered ring annulation, the starting materials (**154** and **155**) were prepared by the Grignard reaction of **150** with allylmagnesium chloride. Thus, the reaction of **155** and **5** involved ring-closing metathesis to produce the annulated sugar derivatives **156** in 80% yield. The structures were unambiguously determined by X-ray crystallography. Clearly, there was no steric impediment to the formation of the *cis* and *trans* 6-6



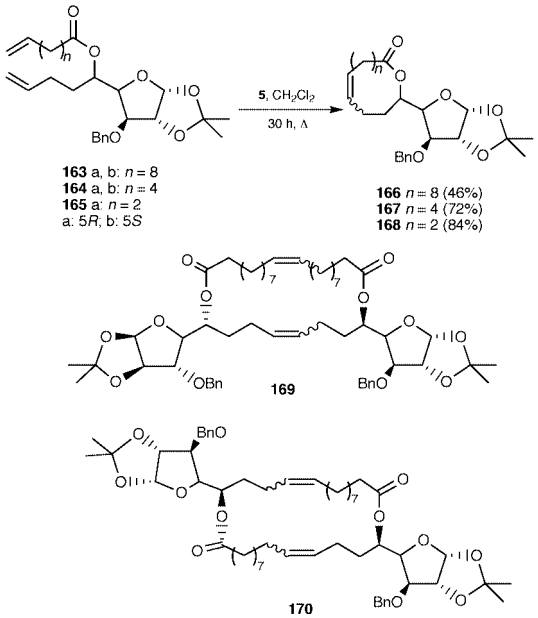
Scheme 25

ring system in both structures. Analogously, spiro-fused dihydropyran derivatives, such as **160** and **162** (Scheme 25) could also be obtained by efficient intramolecular ring-closing metathesis reactions involving allylic ethers **159** and **161**. Both derivatives were obtained from the same progenitor ketone (**157**) following the strategy described for **150** above.

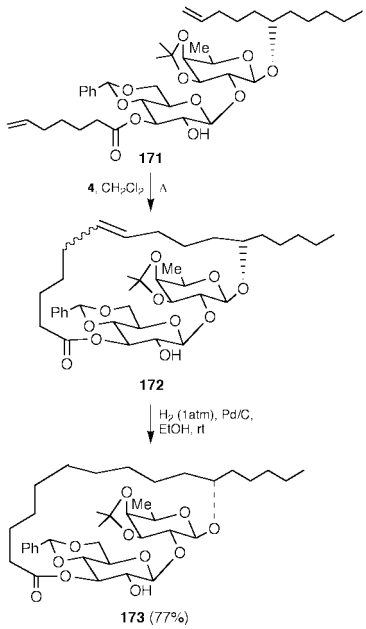
In connection with the synthesis of annonaceous acetogenins and their analogs, ring-closing metathesis of unsaturated esters (**163**–**165**) has been used toward the synthesis of 9- to 15-membered-ring lactones (**166**–**168**) in moderate to good yields (Scheme 26).[43] The RCM reaction proceeded slowly and the corresponding lactones were isolated together with *ca.* 10% of the corresponding dimers. The yield was high in the case of **168** because of the formation of a 9-membered-ring lactone. Due to polymerization, the isolated yields of the 11- and 15-membered-ring lactones were moderate. When slow syringe pump addition was carried out, the yields were slightly better, but the formation of the corresponding dimers (**169** and **170**) was not prevented.

Recently, Fürstner and Muller[44] have synthesized the disaccharide fragment of tricolorin A (**173**) *via* ring-closing metathesis as the key step (Scheme 27). Tricolorin A exhibits significant cytotoxic properties against cultured P-388 and human breast cancer cell lines. The key intermediate was prepared *via* a multistep process. When disaccharide **171** was treated with catalyst **4**, the cyclized product **172** was formed. The free hydroxy group in the substrate did not interfere with the RCM, thus illustrating again the excellent compatibility and selectivity of Grubbs' catalyst. Hydrogenation of the crude 19-membered cycloalkene (*E*/*Z* mixture) afforded the desired cyclic disaccharide **173** in 77% yield (two steps) and completed the formal synthesis of tricolorin A.

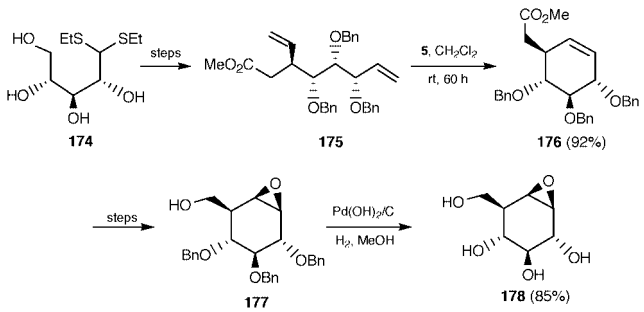
Ziegler and Wang[45] completed the direct synthesis of (+)-cyclophellitol from a carbohydrate precursor, D-xylose (Scheme 28). Ru-catalyzed ring-closing metathesis of the diene



Scheme 26



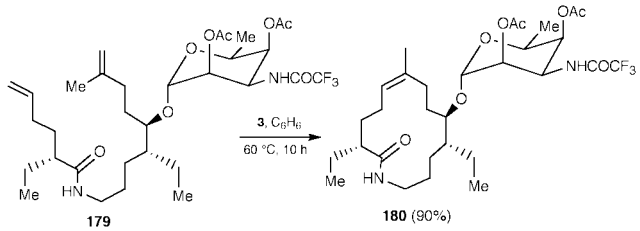
Scheme 27



Scheme 28

175 led to the efficient formation of the cyclohexene **176** in 92% yield. Compound **176** was converted to the final target (+)-cyclophellitol **178** in a few further steps.

In the enantioselective total synthesis of the antifungal agent Sch 38516 (**180**), Houri *et al.*[46] have again used the RCM reaction as the crucial step (Scheme 29). The glycoside **179** was treated with Schrock's catalyst (**3**) to provide **180** as a single cycloalkene in 90% yield.

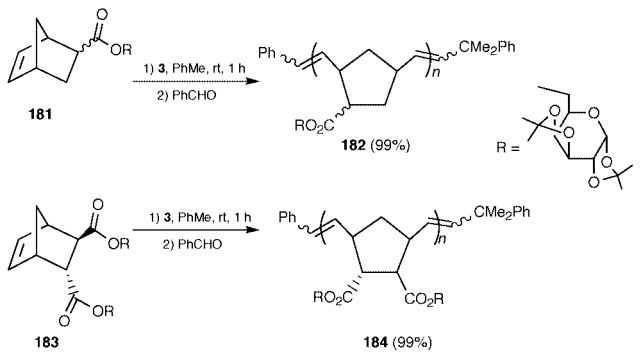


Scheme 29

Ring-opening metathesis

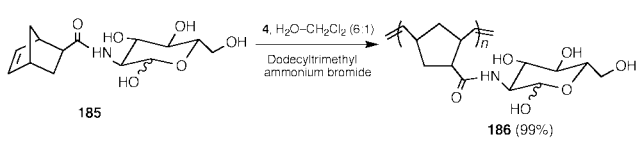
The ring-opening metathesis (ROM) reaction is a variation of the cross-metathesis reaction, where one of the olefin partners is a cyclic alkene and the driving force is the strain in the starting material that is released during the process (eqn. 3). Although this reaction is very useful in synthetic organic chemistry, the poor chemo-, stereo- and regio-selectivity have limited the synthetic utility of this reaction and, to the best our knowledge, there is no example of ROM in carbohydrate chemistry. On the other hand, in the absence of a second open-chain olefin, the metal-carbene intermediate formed by the reaction between the cyclic olefin and the catalyst can react with a series of cyclic olefins to give polymers. The application of this method (ROMP) has been greatly expanded by highly active and well-defined catalysts. Some examples of this method have appeared in the literature. A key advantage of the ROMP reaction is that the polymerization can be living, that is, the elongation can proceed more rapidly than termination or chain transfer. This living polymerization method offers new opportunities for oligomer synthesis.

Nomura and Schrock[47] have shown the formation of various kinds of norbornene-based homopolymers and multiblock copolymers (**182**, **184**) that contain protected sugars by ring-opening metathesis polymerizations of **181** and **183** using the Mo-catalyst **3**. The acetal groups in polymers containing 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose residues can be hydrolyzed rapidly under acidic conditions to afford useful water-soluble 'sugar-coated' polymers (Scheme 30).



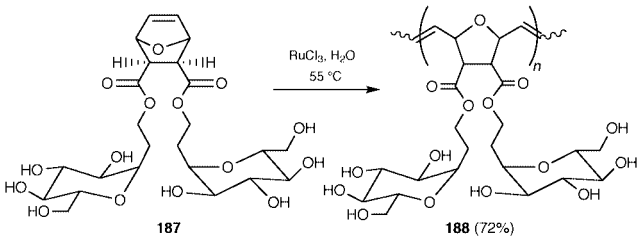
Scheme 30

The polymerization of an unprotected norbornene *N*-acylglucosamine derivative **185** has been reported in an aqueous–organic two phase system by Grubbs and Fraser[48] using catalyst **4**, since this catalyst is not sensitive to alcohol functionality (Scheme 31).



Scheme 31

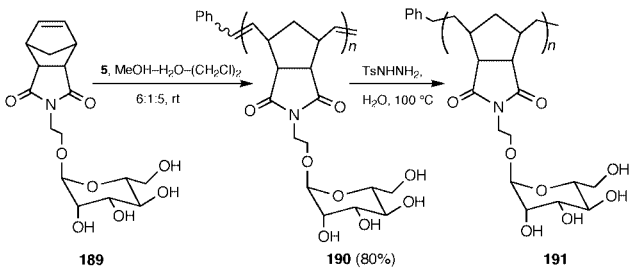
Recently, Kiessling and co-workers[49] have shown that the ROMP reaction can be used to create a polyvalent carbohydrate-bearing polymer that can block protein-initiated cell agglutination. Thus, the treatment of **187** with $RuCl_3 \cdot H_2O$ in H_2O afforded a good yield of the glycopolymer **188** (Scheme 32). This novel application of ROMP to the synthesis of



Scheme 32

polyvalent carbohydrate polymers offers new opportunities for the design of materials for modulation of cell adhesion, immobilization of particular cell types, and study of multivalency in extracellular interactions.

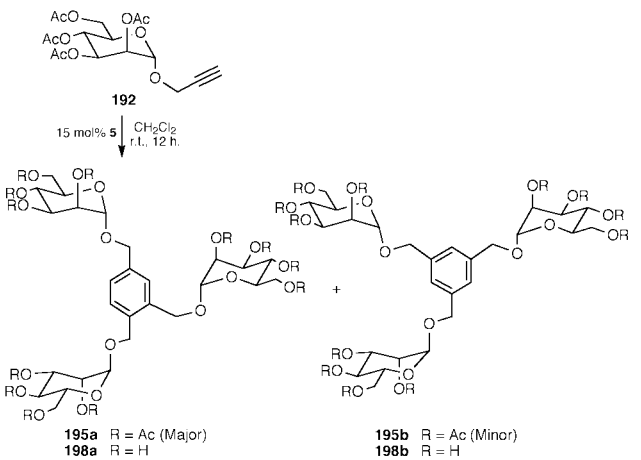
In an another application, Kiessling *et al.*[50] described ring-opening metathesis polymerization to generate collections of multivalent saccharide displays in which the number of repeat units within a set was systematically varied (Scheme 33).



Scheme 33

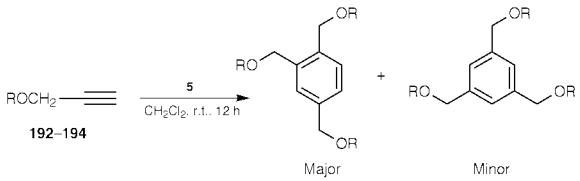
Acetylene metathesis

We have recently found that 2-propynyl glycosides can undergo a cyclotrimerization reaction in the presence of Grubbs' catalyst to give a mixture of regioisomeric aryl glycosides (Scheme 34, Table 5).[51] As oligosaccharide mimetics, such molecules may find biological utility as 'cluster-type ligands' and may help to elucidate binding specificity in multiple carbohydrate–protein interactions.



Scheme 34

Table 5 Cyclotrimerization of 2-propynyl derivatives

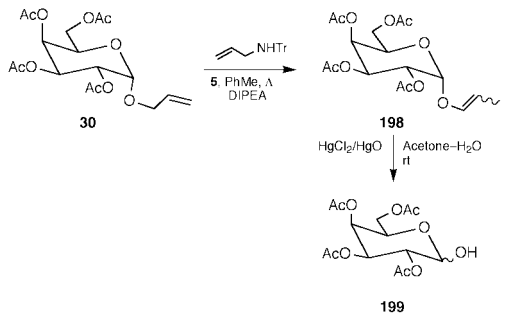


195–197

Entry	Substrate	R	Product	Yield (%)	Isomer Ratios
1	**192**		**195**	75	90 : 10
2	**193**		**196**	72	90 : 10
3	**194**		**197**	66	90 : 10

Isomerization

An unexpected[52] isomerization product, **198**, was isolated in 30% yield, instead of the anticipated cross-metathesis compound, when the cross-metathesis reaction between *N*-allyltritylamine and allyl 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside **30** was carried out with catalyst **5**. Furthermore, neither a sugar nor a *N*-allyltritylamine dimer could be detected. Treatment of **30** with 1,4-diazabicyclo[2,2,2]octane (DABCO) in the presence of Grubbs' catalyst (**5**) afforded only 4% of the isomerized product, **198**, together with 40% of allyl α-D-galactopyranoside homodimer. Similar results were obtained when triethylamine was used as base. Neither isomerization nor metathesis products were detected when diethylamine or pyridine were used. The isomerized product **198** was obtained with the highest yield when **30** was treated with diisopropylethylamine (DIPEA) in the presence of Grubbs' catalyst (**5**). However, all the isomerization yields of these reactions were still very low in the absence of *N*-allyltritylamine. When both *N*-allyltritylamine and 1 eq. of DIPEA were simultaneously used in the reaction, the isomerization yield was improved dramatically to 80%. Furthermore, no self-metathesis product could be detected. The new catalytic system offers a novel procedure for the cleavage of allyl ethers/acetals to provide reducing sugars such as **199** (Scheme 35).



Scheme 35

Conclusions

The results outlined herein show that olefin metathesis has already proven to be an efficient method in synthetic organic chemistry. With the development of well-defined catalytic systems (**1**–**7**) and a better understanding of the nature of these catalysts, selective cross-metathesis, ring-closing metathesis and ring-opening metathesis reactions have started to appear in the literature. It has been shown that this efficient reaction provides diverse types of new alkenes, including some total syntheses of carbohydrate-containing natural products which can not be readily obtained by other known procedures, especially involving closure of large rings (macrocycles). While this review was under preparation, several other examples appeared in the literature[53–64] and we apologise to those investigators whose work could not be summarized herein. Ongoing work to search for even more active and tolerant metal complexes promises further interesting and useful work ahead.

The hydroxylation and amidation of equilenin acetate catalyzed by chloro[5,10,15,20-tetrakis(pentafluorophenyl)porphyrinato]manganese(III)

Jerry Yang, Richard Weinberg and Ronald Breslow*

Department of Chemistry, Columbia University, New York, NY 10027, USA. E-mail: rb33@columbia.edu

Received (in Corvallis, OR, USA) 11th January 2000, Accepted 14th February 2000
Published on the Web 13th March 2000

The aromatic steroid equilenin acetate undergoes regioselective and stereoselective hydroxylation and amidation catalyzed by a manganese porphyrin using iodosobenzene (PhIO) and *N*-tosyliminophenyliodinane (PhINTs) as the oxygen and nitrogen donor, respectively.

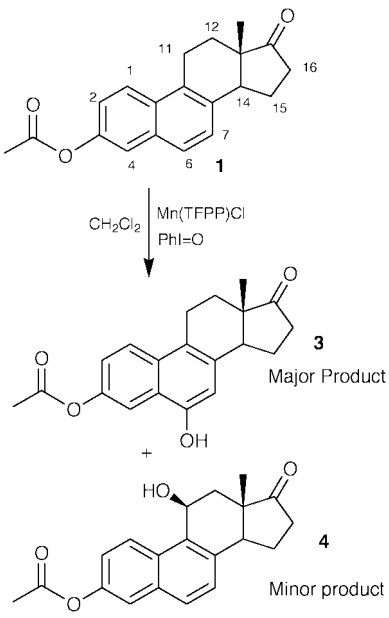
It is important to develop chemical methods for the regiospecific oxidation of natural products such as steroids to replace microbial fermentations that are currently used.[1] Biochemically, such oxidations are normally performed by the heme-containing cytochrome P-450 class of enzymes, and metalloporphyrins have been studied as models for these enzymes.[2] We have recently reported the regiospecific catalytic hydroxylation of steroids, using a water soluble porphyrin carrying hydrophobic binding units, that performs efficient and specific oxidations directed by the well defined geometry between the catalyst and substrates.[3–5] Herein, we report that the aromatic steroid equilenin acetate **1** can be hydroxylated and amidated at very specific positions with good catalytic turnover by iodosobenzene (PhI=O) and *N*-tosyliminophenyliodinane (PhI = NTs),[6] catalyzed by chloro[5,10,15,20-tetrakis(pentafluorophenyl)porphyrinato]manganese (III) **2**.

The metalloporphyrin-catalyzed oxidation of substituted arenes with several oxidants has been studied by the groups of Baciocchi[7] and Meunier.[8] Both groups found that quinones were the dominant products produced from these reactions, especially in the case of substituted naphthalenes. However, when we treated a 54 mM solution of equilenin acetate **1** with 270 mM PhI=O in the presence of 54 mM chloro[5,10,15,20-tetrakis(pentafluorophenyl)porphyrinato] manganese(III) **2**, no quinones were produced after 12 h. Instead, the major product isolated was the 6-hydroxylated product **3**, along with a smaller amount of the 11β-OH product **4** (Scheme 1). No starting material was recovered. Analytical HPLC studies using a catalyst:substrate:oxidant mole ratio of 1:50:250 (CH_2Cl_2, 23 °C, 12 h) resulted in a 57% conversion of **1** to 42% of **3** and 15% of **4**, indicating *ca*. 25 catalytic turnovers (Scheme 1).†

The products were characterized by MS and NMR spectra. Compound **3** had a ^{1}H NMR spectrum with one less aromatic proton than the starting material. COSY spectroscopy confirmed coupling between the 1, 2, and 4 protons as well as the allylic coupling between the 7 and 14 protons, indicating that hydroxylation occurred at C-6.

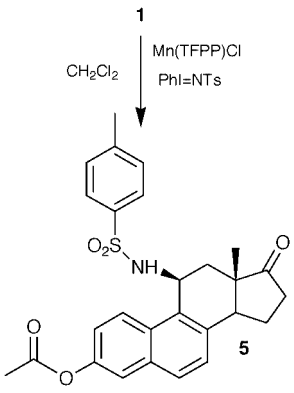
Compound **4** lacked the original C-11 benzylic methylene group signal at 3.3–3.4 ppm, and had a new peak at 5.77 ppm as expected for a downshifted C-11. The C-11 proton showed coupling to a methylene group with no other neighbors (C-12), and also showed NOE coupling to the C-1 proton. This coupling indicates that the H on C-11 is equatorial, so the OH is on the β face. This 11-β OH assignment is also consistent with an upfield shift of the angular methyl group from 0.80 ppm in **1** to 0.72 ppm in **4**. The remaining C-14, C-15, C-16 coupled protons and the aromatic protons were still present.

We first reported the metalloporphyrin catalyzed amidation of organic compounds in 1982.[9] Most recently, Che and coworkers reported the asymmetric amidation of substituted naphthalenes using chiral ruthenium and manganese porphyrins.[10] We find that such an amidation can also be performed on the equilenin steroid substrate **1** with good selectivity. A 60 mM solution of **1** was stirred for 12 h under argon in 1 ml of distilled CH_2Cl_2 containing metalloporphyrin **2** (60 mM), PhI=NTs (300 mM) and molecular sieves to produce the 11β-amidation product **5** and trace amounts of **3** and **4**, with complete conversion of starting material (Scheme 2).† In contrast to hydroxylation, the amidation reaction went completely to the 11β position of the steroid without any detectable amidation at the 6 position. A mole ratio of 1:50:250 catalyst:substrate:PhI=NTs afforded an 82% conversion of **1** to 30% **3**, 5% **4** and 47% **5**, as determined by HPLC assay, so there are *ca*. 40 turnovers.



Scheme 1

Compound **5** had the expected MS, and again a downfield shifted C-11 proton at 5.43 ppm was coupled to the C-12 methylene and showed NOE coupling to the C-1 proton. Thus the tosylamide group is attached at the 11-β position. The



Scheme 2

DOI: 10.1039/b000463o

angular methyl group shifts strongly upfield from 0.80 ppm in **1** to 0.55 ppm in **5**.

The hydroxylation products **3** and **4** reflect hydrolysis of the Mn=NTs intermediate by traces of water in the small scale analytical runs, and they are minimally present in larger preparative scales. In previous work, we had found that the enzyme cytochrome P-450 could aminate cyclohexane with PhI=NTs, but that some hydroxylation also occurred in the water solution.[11] Since the relative amount of hydroxylation depended on the particular isoform of the enzyme used, hydrolysis of the metalloporphyrin intermediate was the most likely explanation. The finding that benzylic substitution in compounds **4** and **5** occurs on the beta face of the steroid must reflect the stereoelectronic control of the flat conjugated benzylic radical intermediate in these reactions.

The readily available manganese porphyrin **2** is able to catalyze the hydroxylation and amidation of an aromatic steroid. These reactions are especially interesting for their apparent differences in regiospecific oxidations. Although not explicitly stated in the literature, metalloporphyrin catalyzed oxidations of substituted naphthalene compounds have been reported to afford mostly quinones after aromatic ring hydroxylation in the presence of oxygen donors, whereas they tend to produce only amides at previously saturated carbon positions in the presence of PhINTs as the nitrogen donor.[7–10]

Apparently the oxidations involve preferential oxygen atom donation to the aromatic ring before hydrogen loss, while the tosylamidations involve initial hydrogen removal from a benzylic position. Perhaps aromatic ring addition is more sterically demanding, and thus more available to a small oxygen atom than to a large tosylamide group. We see that this difference generally holds true in the case of equilenin acetate and provides a method by which steroids of this class can be functionalized at different positions. Furthermore, the amidation of a steroid substrate can lead to the development of a novel class of nitrogen containing steroids that may have useful biological properties.

Notes and references

† Equilenin acetate was synthesized by acylation of equilenin (Steraloids, Inc.) with acetic anhydride in pyridine using standard procedures. All products were isolated by column chromatography and characterized by ^{1}H-NMR, COSY, NOESY and CI-MS.

3: ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.86 (1H,d, C4-H), 7.82 (1H, d, C1-H), 7.41 (1H, dd, C2-H), 6.29 (1H, d, C7-H), 3.38 (1H, ddd, C14-H), 2.34 (3H, s, acetate Me), 0.76 (3H, s, C18-Me), 2.8–1.9 (8H, steroid envelope). CI-MS: m/z = 342 (M + 1 + NH_3), 323 (negative, M − 1). Product **3** in its ^{1}H NMR spectrum showed one less aromatic proton as compared to the starting material. COSY spectroscopy confirmed coupling between the 1, 2 and 4 protons as well as the allylic coupling between the 7 and 14 protons. All remaining aliphatic protons were identified by COSY, also confirming the identity of the product as C6-hydroxylated equilenin acetate.

4: ^{1}H NMR ($CDCl_3$, 500 MHz): δ 8.38 (1H, d, C1-H), 7.83 (1H, d, C6-H), 7.60 (1H, d, C4-H), 7.37–7.28 (2H, m, C7-H and C2-H), 5.77 (1H, br m, C11α-H), 3.43 (1H, m, C14-H), 2.39 (3H, s, acetate Me), 0.72 (3H, s, C18-Me), 2.83–1.91 (6H, steroid envelope). CI-MS: m/z 342 (M + 1 + NH_3). Product **4** COSY indicated coupling of both C15 hydrogens to the easily identifiable C14 proton at 3.43 ppm. The C15 protons were coupled to the C16 protons, indicating that oxidation must have occurred on the C11 or C12 steroid position. The C11 protons, originally at 3.3-3.4 ppm in **2**, were not present in product **4** and a new C*H*–OH appeared at 5.7 ppm, consistent with a benzylic oxidation. The relatively large upfield shift of the angular C18 methyl is inconsistent with C12 oxidation and is furthermore consistent only with oxidation occurring on the beta face of the last remaining steroid carbon position at C11 (most C11 α hydroxlations occur with large downfield shifts of the C18 methyl). Lastly, strong NOE coupling between the C1-H and the C11α-H indicated that compound **4** was indeed the 11β hydroxylated product.

In the analytical runs, the formation of products relative to starting material were monitored with 2-methoxynaphthalene as an internal standard, comparing NMR ratios and HPLC responses to calibrate the relative absorption coefficients of the products and starting material in the UV-VIS HPLC detector.

5: ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.81 (1H, d, C1-H), 7.77 (1H, dd, C6-H), 7.72 (2H, d, toluenesulfonamide), 7.52 (1H, d, C4-H), 7.31 (1H, dd, C7-H), 7.29(2H, d, toluenesulfonamide), 7.09 (1H, dd, C2-H), 5.43 (1H, ddd, C11α-H), 4.45 (1H, d, N–H), 3.36 (1H, m, C14-H), 2.45 (3H, s, toluene Me), 2.36 (3H, s, acetate Me), 0.55 (3H, s, C18-Me), 2.66–1.96 (6H, steroid envelope). CI-MS: m/z 495 (M + 1 + NH_3). The same COSY pattern was present as with product **4**. The C14 hydrogen was coupled to both C15 hydrogens, which in turn were coupled to both C16 hydrogens indicating oxidation at C11 or C12. Again, there was a large upfield shift of the angular C18 methyl, and the new CH-NH at 5.43 ppm is consistent with a benzylic oxidation. Also, strong NOE coupling between the C1-H and the C11α-H confirmed **5** as the 11β amidated product.

Templated silicate molecular sieves exhibiting templated super-micropores in the range 1.0–2.0 nm and interesting pore symmetries bearing similarity to the Lα, SBA-2 (*P6*$_3$/*mmc*) and Mα (*cmm*) phases have been prepared by exploiting the novel aggregation properties of a new family of ω-hydroxyalkylammonium bolaform surfactants.

Recently, a series of papers have described the formation of mesostructured silicates[1–3] and microporous transition metals oxides by exploiting the aggregation properties of bifunctional 'bolaform' surfactants.[4–8] These new templating systems have produced pillared-lamellar and M41S type mesostructures and most recently, an intermediate phase possessing the *cmm* space group. Unlike earlier work which focused on known surfactant systems,[1] Stucky and coworkers[6] exploited new design in surfactant molecular structure. Indeed mesostructures have been prepared that do not mimic any known surfactant liquid crystal phases.[6,9]

One of the synthetic goals identified early in the development of this field was the formation of materials possessing regular pores in the range 1.2–2.0 nm, that would allow shape selective catalysis of organic molecules too large to be accessed by zeolites. It is clear that while normal M41S materials exhibit great promise in the processing of long-chain and bulky hydrocarbons, they do not possess desirable shape selectivity.[2] The elegant preparation of extra-large pore crystalline aluminosilicate zeolite compositions such as UTD-1,[10] the PCH materials,[11] recent efforts at post-synthesis pore-mouth modification of MCM-41[12] and the ubiquitous pillared-clays[13] are among the somewhat few successful efforts at accessing the super-microporous region.

Here, we report preliminary results of the exploitation of a new family of ω-hydroxy-bolaform surfactants.[14,15] These surfactants have permitted the *a priori* design of templated super-microporous silicate structures. Primarily, the ω-hydroxy-bolaform surfactants form micelles in aqueous solution with low aggregation numbers and diameters approximately half those of the parent alkylammonium halide surfactants.[15] Secondly, it is implicit from the geometry of the aggregates that the polar ω-hydroxy groups be located near the micelle surface. Thus, the hydroxy group could conceivably be involved in additional H-bonding at the organic/water/inorganic interface thus modifying the effective surfactant headgroup area and thus the micelle packing and subsequent pore symmetries.

The bolaform surfactants $HO(CH_2)_{16}NR_3^+Br^-$ (R = Me or Et), were evaluated as potential templates. The materials we describe herein were prepared by substituting the new templates directly into existing M41S synthesis methods[16] from the following gel compositions: 4.0 SiO_2: *x* $HO(CH_2)_{16}NEt_3^+Br^-$: 3.0 NaCl : 2.0 NaOH : 0.34 $NH_3{\cdot}H_2O$: 236 H_2O (*x* = 0.40, 0.55, 0.70, 0.85). The high Krafft temperature, 63 °C,[16] of the trimethylammonium derivative precluded its use owing to poor solubility during the preliminary stages of the reaction. The triethyl surfactant has a much lower Krafft temperature, around room temperature, and hence an acceptable solubility.

Powder X-ray diffraction (XRD) patterns of selected samples prepared with different Si : surfactant ratios are presented in Fig. 1. The pattern in Fig. 1 of the as-prepared sample **A** (see Table 1), appears to describe a lamellar (Lα) phase, exhibiting strong d_{100} and weak d_{200} reflections. This material does not completely collapse upon calcination which suggests that a porous structure not based on a layered motif has been retained. The calcined material **B** (Fig. 1) produces a multireflection pattern that may possibly be indexed to a 3-D cubic (*P6*$_3$/*mmc*) array.[7] The XRD pattern of the calcined sample **C** (Fig. 1) is very similar to that described for the hexagonal Mα (*cmm*) liquid crystal phase.[18] The major Bragg reflections from all the materials formed were found at higher angles than those reported for M41S or SBA-8 type materials.[1,6] This is the first evidence that the repeat units formed are smaller than those of 'typical' mesostructured materials.

The formation of super-micropores was further supported by N_2 sorption isotherms (Fig. 2). Neither the Langmuir nor the

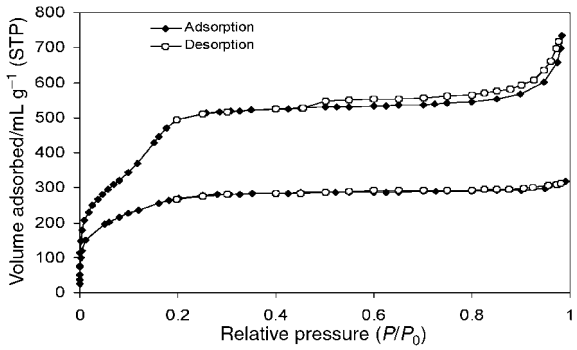

Fig. 2 Nitrogen adsorption–desorption isotherms of calcined samples corresponding to samples **B** (upper) and **E** (lower) in Table 1. Isotherm **B** has been offset along the Y axis for clarity.

BET model plots from the isotherms of these materials were linear thereby suggesting incompatabilities of the models with pores in this size regime. The BET model however, remains the most accessible and has thus been used here for indicative surface area determination. Surface areas and pore volumes (Table 1) of a selection of the materials prepared are relatively high, indicating that the pore structures of the new materials are well ordered and accessible. The isotherms of the most well defined materials *e.g.* **B** in Fig. 2 are typical reversible type IV curves[19] with small hysteresis of the desorption branch. The most interesting feature is the clear capillary condensation step at very low relative pressure (P/P_0 = 0.15). This is lower than any previously reported templated mesostructured material. The presence of an adsorption upturn at high partial pressures is suggestive of textural or indeed other non-specific meso-porosity. Pore diameters as calculated by the BJH method[19] centre around 1.6 nm, while HK calculations[19] centre around 2.0 nm (Table 1). However, the reliability of these common methods for pore size determination when applied to templated mesostructured materials has recently been questioned.[20]

Particle morphologies as determined by scanning electron micrographs (SEM) show particles of *ca*. 100 μm diameter that appear to be agglomerations of primary particles. Transmission electron micrographs (TEM) of micro-sectioned samples (Fig. 3) confirm the existence of pores of below 2.0 nm diameter. The TEM images are ambiguous with respect to the rigorous determination of pore symmetry and diameter, but do suggest the presence of hexagonal or similar symmetry among a generally disordered pore system. TEM data also indicated that the particles were not 'solid' but have highly open internal structures. This would explain the upturn in adsorption at higher nitrogen relative pressures. The reason for the formation of these particle morphologies however, is not known at this time.

We have been moderately successful, at this stage, in forming Al and Ti substituted materials with the goal of introducing catalytic function. As is often observed in M41S syntheses, the Al substituted materials were less ordered than the pure silica analogues and possessed smaller pore diameters as is evidenced in the type I nitrogen isotherm (sample **E**, Table 1, Fig. 2). The

preparation of further novel super-microporous compositions from $HO(CH_2)_nNR_3^+Br^-$ surfactants where n = 12 or 14 and R = propyl and pyridyl is also continuing. It is anticipated that the reduction in the length of the alkyl chain of the surfactant from C_{16} will further reduce the pore diameters into the 1.2–1.5 nm region, although the increased solubility of these shorter surfactants may introduce new synthetic challenges. Indeed, early results indicate that ω-$HO(CH_2)_{12}NEt_3Br$ templated silicates do have pores in the range 1.0–1.2 nm, but are poorly ordered owing to the high solubility of the template. Further increasing the head group size will change the pore symmetries that are obtained due to packing parameter modification.

This work has been performed as part of a research contract with the New Zealand Foundation for Science Research and Technology, contract number CO 8512.7. We thank Karen Reader of the Victoria University of Wellington Electron Microscopy Facility for expert electron microscopic analysis, and Karl Lindsay of Otago University for preparation of surfactant samples.

Received (in Liverpool, UK) 9th February 2000, Accepted 25th February 2000
Published on the Web 15th March 2000

Intermolecular radical addition of a xanthyl phosphonoacetate to a γ,δ-enone gives rise to an adduct suitable for a base induced Horner–Emmons ring closure to a cyclohexene derivative, optionally after the reductive removal of the xanthate group.

The construction of rings often hinges on the ability to attach together two reacting partners, which are then made to undergo an intramolecular combination under suitable conditions.[1] In some cases, such as in the classical Robinson annelation, both the attachment and cyclisation require similar reaction conditions and can sometimes be accomplished concomittantly. This, however, imposes various constraints in terms of selectivity that must be addressed.[1b] More frequently, one or both of the reacting functions have to be protected and then unmasked just before the cyclisation step. A more concise approach would be to combine an intermolecular assembly process with a ring closure proceeding through two different mechanisms and operating under orthogonal sets of conditions: the two reacting units are thus rapidly brought together whilst avoiding cumbersome protection–deprotection steps. In view of the importance of ring structures in essentially all classes of natural products, numerous combinations of reactions have therefore been exploited to construct mono- and poly-cyclic derivatives.[1] Here, we describe the use of an intermolecular radical addition to an unactivated olefin in conjunction with an intramolecular Horner–Emmons reaction to rapidly access various cyclohexene containing architectures.

Unlike intermolecular C–C bond formation involving radical additions to activated (usually electrophilic) olefins, clean bimolecular additions to simple alkenes are not generally easy to accomplish using common radical processes.[2] The rate of the addition step is often too slow to allow it to compete successfully with other pathways open to the radical intermediate. In stannane based chemistry for example, premature hydrogen abstraction from the organotin hydride is difficult to avoid.[3] This limitation may be lifted to a large extent by using the dithiocarbonate (xanthate) transfer reaction we have developed over the past few years.[4] The main competing pathway is degenerate: the intermediate radicals acquire an extended effective lifetime and are thus able to interact with comparatively unreactive traps. For our present purpose, the reaction of xanthate **1**[5] derived from triethyl phosphonoacetate with a γ,δ-enone would provide in one step the desired combination of functionality for a subsequent intramolecular Horner–Emmons ring closure (Scheme 1). Indeed, heating 2-allyl-2-methylcyclohexanone **2a** (1.08 mmol) with xanthate **1** (2.17 mmol) in refluxing 1,2-dichloroethane (2 mL) in the presence of a small amount of lauroyl peroxide (16 mol%) as initiator under an inert atmosphere delivered the expected adduct **3a** in (80%) yield (Scheme 1). Reductive removal of the xanthate group with tributylstannane and base-induced (NaH/THF) cyclisation finally gave bicyclic derivative **5a** in high overall yield. The Horner–Emmons reaction may, if desired, be performed whilst keeping the xanthate group. In this way, **3a** was efficiently converted into **5b** by exposure to a combination of potassium carbonate and 18-crown-6 in toluene.[6] The initial NaH/THF system did not prove suitable in this case. The xanthate group in the final product represents a very useful handle since it provides an entry into the exceptionally rich chemistry of sulfur. The ring size of the starting cyclic ketone may of course be modified as illustrated by the conversion of cycloheptanone **2d** into bicyclo [5.4.0] derivative **5c**. Fused 6–7 ring systems are found in some terpene families, such as the sandresolides, the tiglianes (*e.g.* phorbol), and the daphnanes.[7]

One important feature of this approach is that the unsaturated ketone precursors are readily available, either by direct allylation of the corresponding enolate or through the powerful Claisen rearrangement. The latter route is especially interesting, since it can provide substituted substrates with controlled relative (and sometimes absolute) sterochemistry of adjacent chiral centres.[8] Compound **2d** was thus obtained by heating together 1-methoxy-2-methylcyclohexene and crotyl alcohol in the presence of trifluoroacetic acid.[8] Application of the same sequence gave **5d** with a defined relative stereochemistry, again in good overall yield (Scheme 1).

If a 2-allyl cyclopentanedione component is employed, the sequence now provides a ready access to the ubiquitous hydrindane backbone. This is illustrated by the conversion of **2e**, prepared by allylation of 2-methylcyclopentane-1,3-dione with allyl bromide[9] followed by ketalisation of one of the ketone groups, into **5e**, as outlined in Scheme 2. This route is significantly shorter than that previously reported for an analogue of **5e**.[10] The presence of the olefin allows access to the *trans*-hydrindane system through catalytic reduction.[10] For the ethyl derivative **2f**, the Horner–Emmons reaction was performed after acid mediated cleavage of the ketal group but

without removal of the xanthate. Ring closure took place only on the ketone group leading to the least congested isomer, **5f**, with the xanthate in the equatorial orientation and in a location corresponding to the important C-11 position in steroids. There are several clinically useful steroid drugs with the unnatural C-13 ethyl group and some, such as the third-generation contraceptive Desogestrel, also contain a substituent at C-11.[11] Surprisingly, a Robinson-type annulation to construct the C-ring in this series was recently reported to fail.[12]

Finally, the possibility of performing a non-classical Horner–Emmons reaction[13] on an imide may be exploited as an entry to indolizidine and quinolizidine alkaloids. An example of the latter is displayed in Scheme 3. Addition of xanthate **1** to *N*-allylglutarimide followed by removal of the xanthate group using lauroyl peroxide/isopropyl alcohol gave the requisite adduct **4g** in 42% overall yield. We have previously described the use of this reagent combination as a an economical and ecologically more acceptable alternative to organotin hydides for reductively removing xanthates and related groups.[14] Treatment of **4g** with NaH/THF induced ring closure to furnish **5g** in 43% yield. This compound is in principle an immediate precursor of lupinine.[15] The moderate yield in the cyclisation step must be contrasted with the sole literature precedent of a Wittig–Horner-type cyclisation on a glutarimide motif, reported to proceed in only 19%.[16]

In summary, we have described a new, short and flexible strategy for accessing cyclohexenes and related structures. The key radical addition to the unactivated terminal olefin occurs under mild, *neutral* conditions, that are compatible with most functional groups encountered in modern synthesis.

We thank Dr Philippe Mackiewicz (Aventis, Romainville, France) for a generous gift of 2-ethylcyclopentane-1,3-dione.

Received (in Cambridge, UK) 17th December 1999, Accepted 24th February 2000
Published on the Web 15th March 2000

In acetone and at ambient temperature, the dinuclear manganese complex of TPTN is able to catalyse the oxidation of several alkenes to the corresponding epoxides with high turnovers numbers (up to 900) using H_2O_2 as oxidant.

Selective oxidation of alcohols to aldehydes and the formation of epoxides from olefins are among the key reactions in organic chemistry. In the ongoing pursuit to develop environmentally benign synthetic methodology there is currently great interest in new and more efficient catalytic versions of these oxidations. Compared to catalytic methods that require oxidants like NaOCl and ammonium periodates the use of H_2O_2 offers the advantage that it is a cheap, environmentally friendly and a readily available reagent. Since water is the only expected byproduct, synthetic applications of this reagent are undoubtedly appealing provided efficient catalysis is accomplished.

Recently a number of metal complexes have been found to be suitable catalysts for selective epoxidation reactions with H_2O_2 as oxidant.[1–4] Noyori and coworkers reported a catalytic system based on Na_2WO_4 dihydrate for the epoxidation of terminal olefins and turnovers numbers (TON) were found in the range 150–200 per W atom by using 150 mol% H_2O_2 and 0.2–2 mol% of the catalyst.[1] Methyltrioxorhenium (MTO) is also emerging as a highly suitable epoxidation catalyst.[2] A remarkable acceleration effect on the epoxidation rate was found by Sharpless and coworkers by using pyridine and pyridine derivatives for the MTO catalysed epoxidation of terminal and internal olefins.[3] The Jacobsen catalyst[5] and the related Katsuki catalyst[6] are commonly applied for asymmetric epoxidation reactions of *cis*-olefins. However, with a few exceptions[7] NaOCl is used as oxidant for which TON values in the range of 35–40 were found. Recently it was found that a manganese(IV) complex based on the *N*,*N*′,*N*″-1,4,7-trimethyl-1,4,7-triazacyclononane (MeTACN) ligand is a highly active oxidation catalyst.[4]

This dinuclear manganese complex **1** is capable of the epoxidation of alkenes with TON usually below 100[8,9] but in some cases up to 1000 have been reported using H_2O_2 as oxidant.[10]‡ This complex was also shown by us to be a highly active and selective catalyst for the oxidation of benzyl alcohols to benzaldehydes (TON up to 1000).[11] Synthesis and modifications of the MeTACN ligand are, however, not easily accomplished due to lengthy and tedious preparation whereas the sensitivity of the corresponding metal complexes to changes in the MeTACN structure often leads to completely inactive Mn-complexes. Therefore a challenge is the design of novel dinucleating ligands featuring the three N-donor set for each Mn-site and retaining the high oxidation activity. We present here, high catalytic epoxidation activity for the manganese complex **2** based on the ligand TPTN† using H_2O_2 as oxidant.

3

Advantages of this type of ligands are the accessibility and the possibility for ligand modification. The ligands and manganese complexes examined here were synthesised following literature procedures and complexes **2** (and **3**) have been reported as mimics for the photosystem II (PS II).[12–15] Preliminary screening in a number of different catalytic epoxidations showed that complex **3** based on TPEN,† featuring a two-carbon spacer between the three N-donor sets in the ligand, was unreactive in epoxidation reactions.§ In sharp contrast, complex **2**, based on TPTN with a three-carbon spacer, is able to catalyse the oxidation of various alkenes to the corresponding epoxides, with H_2O_2 as oxidant in acetone and at ambient temperature (Scheme 1).

Catalytic reactions were performed under a nitrogen atmosphere using 1 equiv. of complex **2**, 1000 equiv. substrate and H_2O_2 was used as oxidant (1 ml of 30% aqueous H_2O_2, 9.8 mM, 8 equiv. with respect to substrate).¶ During the oxidation reaction in acetone at room temperature gas bubbles developed rapidly when the excess of oxidant was added. As for the reactions using **1**[4,11] part of the H_2O_2 disproportionates to O_2. An increase of the catalyst TON was obtained by performing the

[a] Experimental conditions, see text. [b] All products were identical to independent samples and identified by GC (HP 6890, column HP1 15 × 0.3 mm × 2.65 μm, polydimethylsiloxane) and ^{1}H NMR. [c] Turnover number = mol product per mol catalyst, 8 equiv. H_2O_2 with respect to substrate. [d] 16 equiv. H_2O_2 with respect to substrate.

catalytic reactions in acetone at 0 °C suppressing H_2O_2 decomposition. For the selected olefins generally up to 300 TONs were found. Addition of a further 1 ml of H_2O_2 (30% aqueous solution in water, 9.8 mmol, 8 equiv. with respect to substrate) resulted in an considerable increase in epoxide yield after 4 h (total TON up to 900, for cyclohexene). These results indicate that the catalyst is very robust under the conditions used. High selectivity is observed and it should be emphasized that in the epoxidation reaction of cyclic alkenes (especially for cyclohexene), besides the epoxides, no allylic oxidation products were found. In control experiments replacing $Mn_2O(OAc)_2$(TPTN) **2** with $Mn(OAc)_3{\cdot}3H_2O$, strong peroxide decomposition and no epoxide formation was found. Data for the conversion of various alkenes to the corresponding epoxides are compiled in Table 1. Styrene epoxidation is accompanied by the formation of a small amount of benzaldehyde; a feature commonly observed with epoxidation of this substrate. Cinnamyl alcohol also showed some cleavage and alcohol oxidation leading to benzaldehyde and cinnamyl aldehyde, respectively. A substantial amount of *trans*-epoxide is obtained in the reaction of *cis*-β-methylstyrene with H_2O_2 in the presence of catalyst **2** which is usually attributed to the formation of a radical intermediate with a lifetime sufficient for internal rotation before ring closure.[16] Excellent results were also found for internal alkenes *e.g.* entries 5 and 6 whereas slightly lower yields were found for terminal linear alkenes.

In conclusion, we have demonstrated that the manganese complex **2** based on TPTN is a promising catalyst in catalytic epoxidation procedures using H_2O_2 as the terminal oxidant. Main advantages of the new catalytic system are the facile synthesis and possibility for ligand modification. In acetone and at ambient temperature the manganese complex of TPTN is able to catalyse the selective oxidation of various alkenes to the corresponding epoxides, with H_2O_2 as oxidant. Further studies towards the elucidation of the mechanism and introduction of chirality in the ligand are in progress.

‡ Very recently a co-ligand effect was reported by the groups of De Vos and Berkessel, see: D. E. De Vos, B. F. Sels, M. Reynaers, S. Rao and P. A. Jacobs, *Tetrahedron Lett.*, 1998, **39**, 3221; A. Berkessel and C. A. Sklorz, *Tetrahedron Lett.*, 1999, **40**, 7965

§ L. Fraisse, J. J. Girerd, F. Perie, A. Rabion, D. Tetard, J. B. Verlhac and A. Nivorozhkin, PCT WO 97/18035 Elf-Aquitaine. Oxidation catalysis with various Mn and Fe complexes based on amine-heteroaromatic ligands has been claimed recently (*e.g.* cyclohexane oxidation, polyaromatic oxidation). No epoxidation activity was given however.

¶ Catalytic reactions were started by mixing 1.0 ml of a 1.2 μM stock solution of the manganese complex in acetone and 1.0 ml of a 1.2 mM stock solution of substrate at 25 °C under a nitrogen atmosphere. As an internal standard, bromobenzene or 1,2- dichlorobenzene (in the case of cyclooctene) were used. After stirring for 2 min, an excess of hydrogen peroxide (1.0 ml of 30% aqueous H_2O_2, 9.8 mM, 8 eq. with respect to substrate) was added. The progress of the reaction was monitored by GC, by removing small samples of the reaction mixture and filtering over a short column of silica. To establish the identity of the epoxides and other products unequivocally, the retention times and spectral data were compared to those of commercially available and independently synthesised compounds.

Neutron powder and *ab initio* structure of *ortho*-xylene: the influence of crystal packing on phenyl ring geometry at 2 K†

Richard M. Ibberson,*[a] Carole Morrison[b] and Michael Prager[c]

[a] *ISIS Facility, CCLRC-Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire, UK OX11 0QX. E-mail: rmi@isisa.rl.ac.uk*

[b] *Department of Chemistry, The University of Edinburgh, King's Buildings, West Mains Road, Edinburgh, UK EH9 3JJ*

[c] *Institut für Festköperforschung, Forschungszentrum Jülich, 52425 Jülich, Germany*

Received (in Oxford, UK) 27th October 1999, Accepted 24th February 2000
Published on the Web 15th March 2000

Crystal packing effects in the previously unknown structure of *ortho*-xylene are found to induce a high degree of strain to the phenyl ring which is not observed in high-level *ab initio* structure calculations or in the crystal structures of the *para* and *meta* isomers; the potential for aromatic hydrogen bonding in the structure is discussed.

One motive for performing crystallographic studies on simple model systems is to reveal structural motifs that may be applicable to whole classes of compound. The wealth and understanding of these crystallographic data has led to the development of crystal engineering[1] which is of increasing interest to organic and physical chemists. In addition such studies can be used in the derivation and testing of model potentials[2,3] which is the background to the present study. Though the three isomers of xylene are familiar laboratory compounds, until recently little was known about their structure in the solid state.[2,4,5] We now describe the crystal structure of *o*-xylene at low temperature which, in contrast to the other isomers, exhibits a strained ring conformation which we suggest may be attributed to weak intermolecular forces.

A 2 g powder sample of perdeuterated *o*-xylene was prepared by the method described in ref. 6 and neutron powder diffraction data‡ were collected at 2 K on the High Resolution Powder Diffractometer, HRPD, at the ISIS pulsed-neutron source, UK. The structure was solved§ routinely from the powder data using direct methods to reveal a monoclinic phase of cell volume 634 Å^3; space group $P2_1/a$. The four molecules in the unit cell are arranged in columns running along the unit cell *a* axis in a herring-bone configuration with D··Đ contact distances of *ca.* 2.4–2.8 Å.

Examination of the refined molecular conformation (Fig. 1) reveals the determination of bond lengths and bond angles to be both precise and accurate as is expected from a high-resolution study on a structure of this limited complexity. The conformation shows small but significant deviations from C_{2v} symmetry, but most striking is the deformation of the carbon skeleton of the phenyl ring between the two substituted carbon atoms C(1) and C(2). The observed bond length of 1.433(3) Å is considerably in excess of the distance expected on consideration of steric repulsion of the eclipsed methyl groups and possible conjugation effects due to the substituent methyl groups. This finding is in contrast to the minor ring deformation observed in the crystal structures of the *meta* and *para* isomers[5] determined from neutron powder diffraction data and, for example, the negligible deformation seen in the X-ray single crystal study of *ortho*-dinitrobenzene,[11] all of which are found to be in accord with expected conjugation effects. Accordingly, a series of high-level *ab initio* calculations¶ were undertaken in order to establish the minimum energy conformation of the *ortho, meta* and *para* isomers.

† Electronic supplementary information (ESI) available: neutron diffraction data and comparison of bond parameters from neutron and *ab initio* data. See http://www.rsc.org/suppdata/cc/a9/a908599h/

Calculations for *o*-xylene (Fig. 1), assuming overall ideal C_{2v} symmetry, show a significantly reduced distortion to the ring. In particular the C(1)–C(2) bond length is calculated at 1.412 Å—a discrepancy of 0.22 Å (> 7 standard deviations) as compared with the refined solid-state structure. Note, calculations were also made without the C_{2v} symmetry constraint and starting from the crystal structure coordinates, but the same minimum was obtained. Subsequent refinement of a model assuming C_{2v} symmetry against the neutron powder data, although resulting in a degraded fit to the pattern, was found to retain this discrepancy between the minimum-energy and solid-state conformation. Crystal packing effects in the structure of *o*-xylene thus appear to play a significant role in defining the molecular conformation.

In contrast, the calculated and experimentally determined solid-state conformations of the remaining isomers show excellent agreement. For *m*-xylene the discrepancies in bond lengths determined in each case were typically 0.004 Å (1 standard deviation) with a maximum discrepancy for one phenyl-ring bond of 0.007 Å. For *p*-xylene the discrepancies in

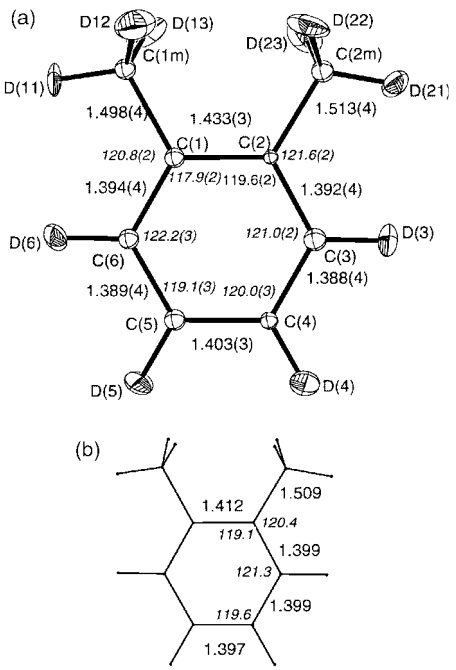

Fig. 1 (a) ORTEP[17] diagram of the molecular conformation of *o*-xylene at 2 K; thermal ellipsoids are drawn at the 50% probability level. Bond length (Å) and bond angle (°) values are shown with estimated standard deviations in parentheses determined from the neutron powder diffraction data. (b) Bond length (Å) and bond angle (°) values calculated *ab initio* using the MP2/6-311G* basis set. (Average values for bond lengths and bond angles around the methyl groups are: for C(1m) 1.093(3) Å, 110.85(3)°; for C(2m) 1.075(3) Å, 111.86(3) and from *ab initio* calculation 1.095 Å, 111.27°.)

DOI: 10.1039/a908599h

bond lengths determined in each case were typically 0.008 Å (2 standard deviations) with a maximum discrepancy for one phenyl-ring bond of 0.012 Å. The most significant differences in each case were observed for the torsions of the methyl groups. Rotations of 6 and 23° compared to the minimum-energy conformation are observed for *m*-xylene, and 6° (one clockwise, one anticlockwise) for *p*-xylene. However, as the vibrational frequencies calculated (b3pw91/6-31G*) for these low energy torsional modes are only 21 and 24 cm^{-1}, respectively, it is not surprising that crystal packing forces have distorted the ring substituents from their idealised torsional values.

The *o*-xylene crystal structure has, on inspection of the intermolecular contacts (Fig. 2), the potential for 'aromatic hydrogen bonding' (see for example ref. 12). The closest contact from the midpoint of the phenyl ring to a methyl, D(21), atom of a neighbouring molecule is 2.816(4) Å. The distances of this D(21) atom to the six individual C atoms lie in a broad range of 2.849–3.422 Å. The two shortest contacts with the C(1) and C(2) atoms are 2.849(4) and 2.908(5) Å, respectively, which is significantly less that the sum of the van der Waals radii at 3.05 Å, and, most notably the distance from the C(1)–C(2) bond midpoint to D(21) is only 2.789(4) Å, making an angle of 152.6(3)° with the methyl group C–D bond. No other significant contacts are made to C(1) and C(2), in contrast with the remaining four phenyl C atoms which typically have three or more contacts in the range 2.86–3.1 Å. The contact is made off-centre to the phenyl ring and in general would be regarded as less favourable for an interaction, however, in this case it is the apparent directional (as opposed to isotropic) nature of the contact which correlates well with the observed molecular conformation. It is this strong directional nature of the contact that leads us to suppose it to be a significant interaction.

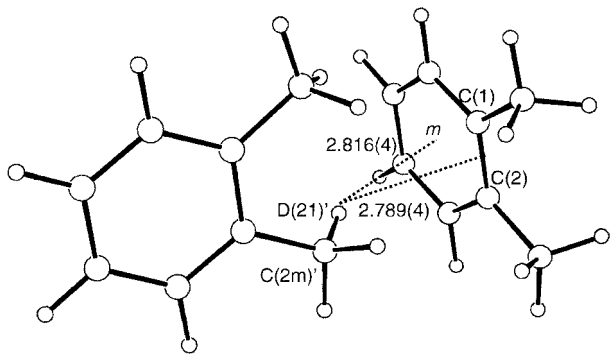

Fig. 2 Geometry of the aromatic ring–methyl group interactions. (Primed atoms denote symmetry code $\frac{1}{2}-x, -\frac{1}{2}+y, -z$; *m* denotes the midpoint of the phenyl ring.)

It is now generally recognised that C–H groups can act as weak hydrogen bond donors[13–16] and there is a growing literature on the subject particularly in the context of crystal engineering cited earlier. The documentation and characterization of these weak interactions is well advanced only in the case for bonds formed between C–H donors and oxygen acceptors. The interactions between other weak donor–acceptor combinations, especially as in the present case of such a weakly polarized donor group as Me with a π-acceptor, is considerably less well characterized. Nevertheless, electron donation from a Me group of a neighbouring molecule into an antibonding aromatic orbital seems the most plausible explanation for the unusual lengthening of the disubstituted C–C bond in the solid-state structure of *o*-xylene.

We thank Dr C. C. Wilson for helpful discussions during the course of this work. Acknowledgement is made to the EPSRC for the provision of beam time at the ISIS Facility and for the Edinburgh *ab initio* facilities (grant GR/K/04194).

Notes and references

‡ Data were recorded using a vanadium-tailed helium-flow 'orange' cryostat over a time-of-flight range of 30–230 ms corresponding to a *d*-spacing range of 0.6–4.6 Å at backscattering ($<2\theta>$ = 168°). Lower angle (90 and 30°) detector banks enabled *d*-spacings of, in this case, up to 6.0 Å to be recorded, albeit at lower resolution, for the purposes of unit cell indexing.

§ *Crystal data* for *ortho*-xylene: C_8D_{10}, M = 116.23, monoclinic, space group $P2_1/a$ (no.14), a = 12.5114(1), b = 6.0714(1), c = 8.8157(1) Å, β = 108.6847(4)°, U = 634.36(1) $Å^3$, T = 2 K, Z = 4. The unit cell was determined automatically from 36 low-order reflections $2.4 < d < 6.0$ Å using program ITO.[7] The structure was solved by direct methods (MITHRIL)[8] and refined without the use of bond length or bond angle constraints using the Rietveld method[9] implemented by program TF12LS.[10] Only the D atoms were refined anisotropically. R_e = 1.62%, R_p = 3.38%, R_{wp} = 3.90%, χ^2 = 3.63 for 6579 observations and 145 basic variables.

¶ All *ab initio* calculations were performed on a DEC Alpha APX 1000 workstation using the GAUSSIAN 94 program.[18] A graded series of calculations were undertaken for all three compounds using the standard gradient techniques at the SCF and b3pw91 levels of theory using the 6-31G* basis set. Vibrational frequencies calculated from analytic second derivatives at the b3pw91/6-31G* level confirmed the C_{2v} symmetry grouping for *o*-xylene, C_s for *m*-xylene and C_i for *p*-xylene as minimum on their respective potential energy surfaces. Further calculations were then undertaken for *o*-xylene: firstly, to confirm the C_{2v} structure as the global minimum an optimisation was performed (b3pw91/6-31G*) starting from the crystal structure coordinates with no symmetry constraints. From an observation of the absolute energies obtained it was clear that removal of the symmetry constraints resulted in exactly the same minima being obtained in the optimisation. Finally, for direct comparison with the crystal structure parameters one further higher level calculation (MP2/6-311G*) was undertaken. At this level all geometric parameters were observed to be effectively converged within the series of calculations performed, with *e.g.* C–C bond distances varying by <0.3 pm and all angles by $<0.2°$ for improvements in basis set at the MP2 level. It can therefore be concluded that any further higher level calculations are unlikely to result in significant changes in molecular geometry.

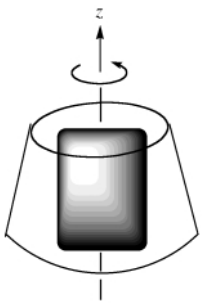
Significant restriction of the rotation of an intermolecular guest upon binding into a distorted cyclodextrin cavity has been observed for the first time.

Most enzymes bind substrates in their hydrophobic pockets and promote the reaction of bound substrates in a strictly controlled manner. It is not rare that enzymes control multiple reactants so exactly as to give only one isomeric product during the formation of multiple chiral centers. In the last three decades, bioorganic chemists have been investigating the main factors that predominate in enzyme reactions and have created artificial enzymes by mimicking the enzyme actions with synthetic model compounds.[1–3] In this endeavour, cyclodextrins (CDs) are the first and also the most profoundly studied class of apoenzyme mimics.[4,5] Cyclodextrins have a closed-up belt-type structure usually composed of 6–8 glucopyranose units. Their cavity can accommodate a variety of guest molecules of suitable size and shape, mainly *via* hydrophobic interactions. Since the hydrophobic binding force is non-directional, the C_n symmetry of the CD cavity leaves appreciable freedom for the bound substrates to rotate around the *z* axis (Scheme 1).[6] However, this rotation should be properly controlled in order to develop more efficient and sophisticated enzyme mimics. However, this problem has been essentially ignored up to now. The only work dealing with this problem appeared ten years ago, concluding that the hosts having larger binding constants restrict the molecular motion of guests more significantly.[7] Since the binding site of an enzyme is usually unsymmetrical rather than symmetrical, a cyclooligosaccharide with a distorted hydrophobic cavity may serve as a better model for enzymes than a C_n symmetrical CD. We found that distorting the hydrophobic cavity of β-CD remarkably reduces the rotation of bound 2-naphthalenesulfonate, but does not necessarily increase the binding strength. Herein, we describe NMR evidence for this first example of cavity-based restriction of guest rotation.



Scheme 1 In principle, a guest in a CD cavity has appreciable freedom to rotate around the *z* axis.

One glucose of β-CD can be readily converted to altrose.[8] The resultant mono-*altro*-β-CD **1** shows distinct NMR signals (Fig. 1, bottom) for all its protons. Though it no longer has C_n symmetry, the difference between the glucose units is not very significant. As a result, the signals of all the non-anomeric C–H protons are crowded in the narrow range of δ 3.9–3.5. However, significant changes occur in the NMR spectrum of **1** upon complexation with sodium 2-naphthalenesulfonate (Na–Nas). By following the spectral change upon addition of Na–Nas to the host solution, a binding constant of 176 M^{-1} can be derived, slightly smaller than that of β-CD–Nas.[9] In the NMR spectrum of 90% **1**–Nas complex and 10% **1** (Fig. 1), the originally overlapped signals in the range δ 3.9–3.5 are more widely dispersed over the range δ 4.2–2.69, and all the H-1 protons are clearly separated. Obviously, the guest Nas exercises a very strong anisotropic effect on each sugar unit of the host.

In order to further understand this phenomenon, the NMR spectrum of the complex has been assigned in detail with the aid of various techniques (the assignment is partially depicted in Fig. 1). As is clear from Fig. 1, inclusion complexation causes significant shifts for the inner-directed H-3 and H-5 protons. The drastic upfield shifts of protons 3C, 5C, 3D, 5D, 3G and 5G

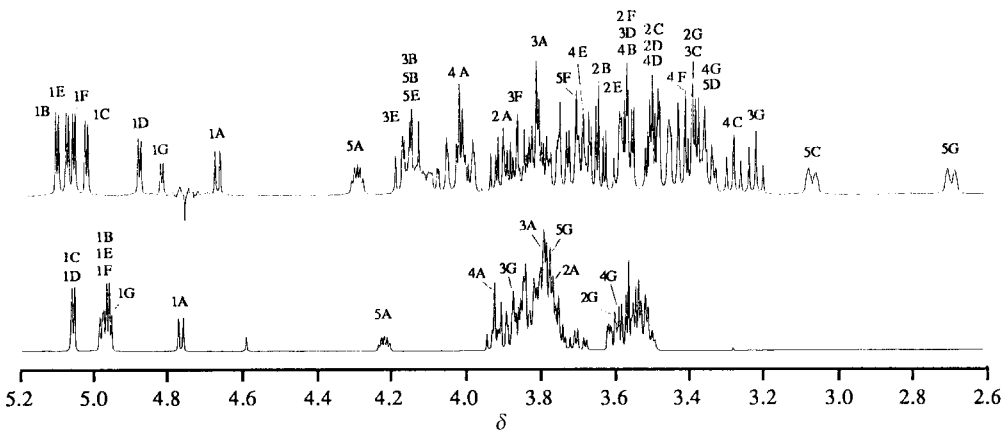


Fig. 1 500 MHz ^{1}H NMR spectra of mono-*altro*-β-CD **1** (bottom) and of its 2-naphthalenesulfonate inclusion complex **2** (top, 90% binding) in D_2O, assigned based on 1D TOCSY, 2D COSY, HMBC and NOE experiments. The sugar units are labeled clockwise A–G (viewed from the primary hydroxy side), starting from the altrose unit. The numbers denote the positions to which the corresponding protons are attached.

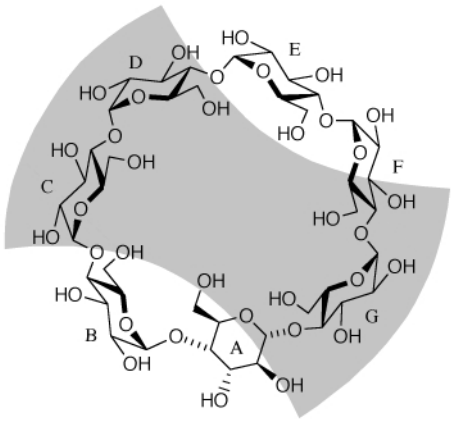
Scheme 3 Mono-*altro*-β-CD **1** and its inclusion complex with sodium 2-naphthalenesulfonate. **2** is a sketch (view from the 6-OH side) for the proposed structure of the **1**–Nas complex: the cylinders denote pyranosides while the plate represents Nas.



Scheme 2 The anisotropic effect that **1** experiences in the complex: the shaded region denotes a shielding field while the unshaded region represents a deshielding field.

imply that the sugar units C, D and G are under a strong shielding effect from Nas, while the large downfield shifts of protons 3B, 5B, 3E and 5E are indicative of a strong deshielding effect. Careful examination of the NMR data thus reveals that the host molecule in the complex is under an extremely unusual anisotropic effect, as represented in Scheme 2. The protons in the shaded region are shifted upfield while those in the non-shaded region are shifted downfield. Sugar G is located in the center of the lower right half of the shielding region and is subjected to the strongest shielding effect and the largest upfield shifts are for H-3 and H-5 of sugar G ($\Delta\delta$ −0.77 and −1.18 ppm, respectively). The effect becomes much weaker for the neighboring sugar units A and F, and gradually becomes deshielding when crossing the two units. On the opposite side of G, both C and D lie in the upper left half of the shielding region. Accordingly, protons H-4C and H-1D, although outward-directed, exhibit a remarkable upfield shift. The inward-directed H-3 and H-5 protons of the two sugar residues are still strongly shielded, but obviously to a smaller extent than the corresponding protons of sugar G. The shielding effect is weak for H-4D and H-1C and becomes deshielding for H-1E and H-4B. Both the sugar units B and E are fully under a deshielding effect with their inward-directed protons H-3 and H-5 being significantly shifted downfield. As a result, each pyranoside in the inclusion complex experience different anisotropic effects, which represents, to the best of our knowledge, an unprecedented strongly anisotropic effect of an intermolecular guest within a cyclooligosaccharide host.

Based on the above result, the structure of the complex (**2**) can be visualized as shown in Scheme 3. The pyranose G and disaccharide C–D are situated on either side of and nearly parallel to the naphthalene ring, while the naphthalene species directs its 1-9-8 and 4-10-5 rims towards between the sugar units B and A or E and F but much closer to the B and E units. Although Scheme 3 represents a static situation rather than a dynamic one, it probably represents the most probable rotamer, if indeed there is any rotation of the guest in the CD cavity, outweighing any others for the complex to a very large extent. Were mono-*altro*-β-CD not restricting the guest rotation, as in the case of β-CD, the ring-current effect of the guest would be averaged so that each sugar unit would be subjected to a similar shielding effect rather than the observed anisotropic effect, and the inward-oriented protons of all the sugar units would give NOE on irradiation at the naphthalene protons. Irradiation at the 1-H of the guest gave cross peaks at the frequencies corresponding to protons H-3 and H-5 of B and E whereas no cross peaks correlating with the protons of C, D and G were observed, which supports the above assertion.

It is not surprising that the rotation of the bound guest is substantially restricted as the host adopts a distorted conformation and **2** is the complex structure expected from the host conformation. The altrose portion of **1** is an equilibrium of the $^0S_2$ and $^1C_4$ conformers with an approximate 2 : 1 preponderance of the latter (Scheme 3).[10] The $^0S_2$ makes the overall shape of **1** closely resemble that of β-CD, while the $^1C_4$ conformer straightens the A–G disaccharide but bends the A–B disaccharide, and leads to a mussel-shaped ellipse shape for the cavity with its longer axis passing through residues B and E. It is reasonable to deduce that $^1C_4$ is the preferential conformer enabling the host to accommodate the flat guest Nas, by accommodating the guest plane along its longer axis. Indeed, the binding of Nas into the cavity of **1** increased the coupling constants $J_{1,2}$ and $J_{2,3}$ of the altroside, suggesting a significant enrichment of the $^1C_4$ conformer upon inclusion.

In conclusion, the introduction of an altrose unit to β-CD narrows the hydrophobic cavity and enables it to substantially reduce the rotation of the bound flat Nas guest. In this sense, the binding of mono-*altro*-β-CD **1** is more like an enzyme process than that of normal CDs.

We thank Japan Maize Products Co. Ltd. for a generous gift of CDs. D.-Q. Y. thanks the NSFC (project 29772023) and the State Education Ministry of China (project 380).

Received (in Basel, Switzerland) 25th October 1999, Accepted 17th December 1999
Published on the Web 15th March 2000

$RuH_2(H_2)_2(PCy_3)_2$, the first reported stable bis (dihydrogen) complex crystallizes in the *P*1 space group; the two dihydrogen ligands lie in the equatorial plane in a mutual *cis* position and are located *trans* to the hydride ligands; the H–H distances are *ca.* 0.85 Å, in agreement with the presence of unstretched dihydrogen ligands; these results are compared with previous theoretical calculations using density functional theory.

The chemistry of dihydrogen complexes has developed considerably since the first discovery of dihydrogen coordination without dissociation in 1984.[1] Many different compounds have now been isolated, characterized, in particular by X-ray crystallography, and have given rise to reactivity studies.[2]

The number of complexes containing more than one dihydrogen ligand remains, however, very limited.[3] No tris(dihydrogen) complex is known and only a few bis(dihydrogen) complexes have been isolated, namely $RuH_2(H_2)_2(PCy_3)_2$ **1**[4] and $LRuH(H_2)_2$ [L = hydridotris(3,5-dimethylpyrazolyl)borate, Tp*; L = hydridotris(3-isopropyl-4-bromopyrazolyl)borate, Tp'].[5] $RuH_2(H_2)_2(P^iPr_3)_2$ has been observed in solution following the same procedure as that used for preparing **1**[6] and recently isolated by Morris using a different procedure.[7] $Cr(CO)_4(H_2)_2$ has been observed in an argon matrix or in liquid xenon and characterized by IR spectroscopy.[8] Crabtree *et al.* have characterized the bis(dihydrogen) complex $[IrH_2(H_2)_2(PCy_3)_2]$+ in solution upon protonation of the neutral precursor $IrH_5(PCy_3)_2$.[9] Finally Caulton and coworkers have characterized a bis(dihydrogen) osmium derivative $[Os(H_2)_2(NCMe)_2(PPr^i_3)_2]^{2+}$ by protonation of $[OsH_3(NCMe)_2(P^iPr_3)_2]^+$.[10] A number of unstable bis(dihydrogen) ruthenium complexes have also been prepared when studying the reactivity of $RuH_2(H_2)_2(PCy_3)_2$.[11]

In a recent paper, we described the spectroscopic properties of $RuH_2(H_2)_2(PCy_3)_2$, in particular INS spectra demonstrating the presence of a low rotation barrier for the dihydrogen ligands and the results of DFT calculations showing that the most stable structure involved the presence of two mutually *cis* hydrides each of which was located *trans* to a dihydrogen ligand.[12] Complex **1** has proven to be important in ruthenium chemistry and has found applications as a starting material for a great variety of ruthenium dihydrogen complexes,[11,13,14] and complexes containing two σ-bonds.[15] It has also been used as a catalyst precursor for hydrogenation[13, 16] and silylation reactions[17] and as a precursor for carbene derivatives used in metathesis of alkenes, particularly ring closing metathesis.[18] Our synthesis involves the hydrogenation of Ru(cod)(cot) in the presence of the phosphine ligand PCy_3. This synthesis has proven over the years to be a high yield one, to be reproducible and to yield a very pure product.[4,13] An alternative synthesis has recently been proposed which is claimed to lead to a better yield but which produces a yellow complex, probably because of the presence of impurities mixed with **1**.[18]

We now describe the crystal structure of **1**, the first of a bis(dihydrogen) complex, including the location and refinement of all hydrogen atoms.

$RuH_2(H_2)_2(PCy_3)_2$ **1** was prepared as previously reported[13] by reacting a pentane solution of Ru(cod)(cot) and PCy_3 with dihydrogen (3 bar). After filtration, the white precipitate was dissolved in a minimum quantity of toluene by gentle warming under dihydrogen, concentrated in a dihydrogen stream and left standing at room temperature under a dihydrogen atmosphere. The resulting crystals were then mounted on a STOE diffractometer operating at 160 K under dinitrogen.†

The complex crystallizes in the *P*1 space group and the molecular structure is shown in Fig. 1. The environment of ruthenium consists of two phosphines located *trans* to each other [P–Ru–P 179.79(11)°] and displaying normal Ru–P distances (*ca.* 2.35 Å). In addition, two hydrides and two dihydrogen ligands are present in the equatorial plane. All Ru–H distances are within the range expected for such Ru–H and Ru–H_2 bonds (1.5–1.7 Å). The H–H distances within the

DOI: 10.1039/a908567j

dihydrogen molecules are found to be *ca.* 0.85 Å, indicating the presence of an unstretched dihydrogen ligand (even taking into account the standard deviations, the H–H distances remain below 1 Å; see legend to Fig. 1)[2] and consistent with previous spectroscopic and theoretical studies carried out on this compound.[1,2] All the hydrogen atoms whether belonging to the hydride or dihydrogen ligands lie in the equatorial plane with no significant deviation from this plane. The distances between one hydride and the proton of the next dihydrogen molecule (*e.g.*; H6 ··H1 and H5··H4) are both > 2 Å and rule out the presence of any *cis*-interaction.[22] These data are consistent with the low rotation barrier found for the dihydrogen ligands in this complex by INS. However, it is interesting that the distance between the two dihydrogen ligands [H2··H3 1.405(65) Å] is relatively short, which may explain the structures found in the INS spectra, the origin of which was proposed to be the concerted rotation of both dihydrogen ligands.[1,2]

All these data are in complete agreement with previous DFT/B3LYP calculations.[1,2] In particular, the overall geometry of the complex, namely mutually *cis* disposition of the hydride and dihydrogen ligands, their coplanarity and the *trans* arrangement of the phosphines are well reproduced by the calculation. The Ru–P distances [2.311 Å by DFT/B3LYP calculations for the optimized most stable geometry *cf.* the experimental values of 2.329(2) and 2.347(2) Å] are very satisfactorily reproduced although the calculation was performed using PH_3 as a model for PCy_3. Steric interactions are presumably not important in this complex. The H–H distances within the dihydrogen molecule are also satisfactorily reproduced [0.853 Å by DFT/B3LYP; 0.848(37), 0.864(38) Å experimentally]. The only difference concerns the Ru–H distances which are found to be larger for the dihydrogen ligands than in the hydrides by X-ray diffraction, contrary to calculations. However, it is noteworthy that the X-ray technique only detects the electron density around the atoms. This density may be polarized towards ruthenium for these unstretched dihydrogen ligands which have a partially protonic character, much more than in the hydride ligands and may contribute to the present observation.

In conclusion, we report the first X-ray crystal structure of a bis(dihydrogen) complex with $RuH_2(H_2)_2(PCy_3)_2$ being first reported stable bis(dihydrogen) complex. It was originally formulated as a hexahydride and then correctly reformulated in 1988. Since its original preparation in 1982, this complex has proven to be very important in the chemistry of ruthenium. The confirmation of its structure by X-ray crystallography should induce a new interest for this bis(dihydrogen) complex and will provide renewed impetus for reactivity studies in our group.

The authors thank CNRS and the Polish Academy of Science/CNRS exchange program (CNRS/PAN/Projet 2722) for support.

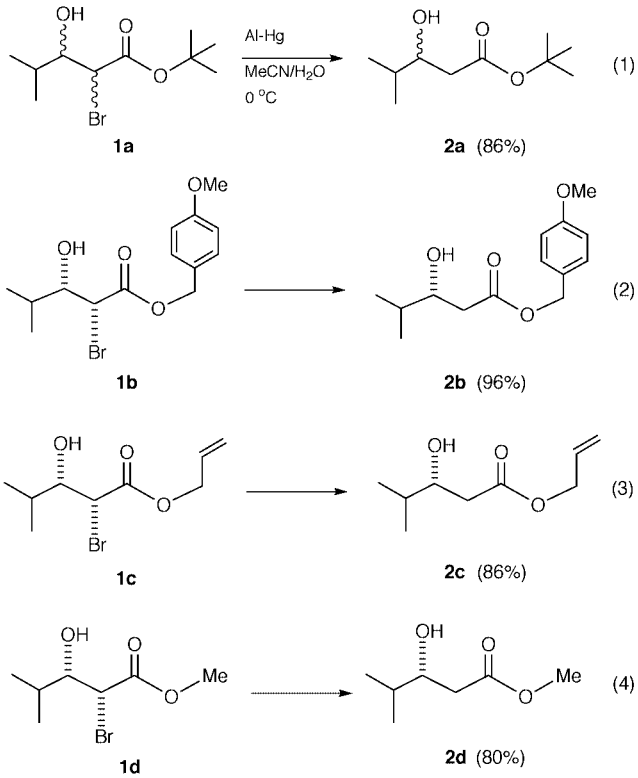
Al–Hg mediated chemoselective cleavage of the carbon–halogen bond of α-halocarboxylates allows for a facile and clean transformation of halohydrin aldol adducts into β-hydroxy acid derivatives with no evidence of dehydroxyhalogenation.

Chemoselective transformations of halohydrin aldol adducts into β-hydroxy acid derivatives are very important owing to the ready availability of the chiral starting materials[1] and the significance of the products as building blocks in the synthesis of drugs and natural products.[2] The recently reported catalytic hydrogenolysis (H_2/Pd–C) of α-bromo-β-hydroxy esters and tri-*n*-butyltin hydride mediated radical cleavage of carbon–bromo bonds provided β-hydroxy acid derivatives with the added benefit of good to excellent yields.[3]

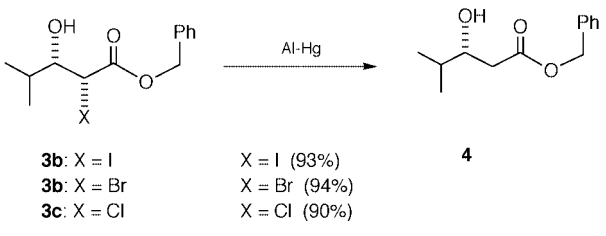
However, their utilization is not unproblematic. Chemoselective hydrogenolysis of the C–Br bond in the presence of C=C double bonds is not possible while tributyltin hydride is relatively unstable, toxic and expensive. Furthermore, the tin byproducts are not always easy to separate. The invention and development of a new chemoselective procedure for removing the halogen from halohydrin aldol adducts would be of great synthetic value. A promising solution to this problem appeared to be metal-promoted reductive cleavage of carbon–halogen bonds. Although this process has been used in reductive elimination reactions such as zinc-mediated dehydroxybromination[4] and aluminium amalgam-mediated deacetoxybromination,[5] they leave open the question of whether these methodologies can be applied to the chemoselective cleavage of carbon–halogen bonds of halohydrin aldol adducts without concurrent elimination of the β-hydroxy group. We were attracted to the Al–Hg mediated process because of the mild neutral conditions.

Initial work centered on the debromination of various α-bromo-β-hydroxy esters **1** derived from aldolizations of bromoacetate enolates with isobutyraldehyde.[1] Treatment of *tert*-butyl ester **1a** with 3–5 equiv. of Al–Hg (mercury content *ca*. 2.5%) in aqueous acetonitrile (1:10) at 0 °C led to clean debromination within 30 min to give **2a** in 86% isolated yield [eqn. (1)]. Dehydroxybromination does not appear to compete with carbon–hydrogen bond formation, although products arising from elimination of hydroxy groups would not be isolable owing to their volatility. To quantify the potentially small degree of elimination that may be occurring, we chose to explore the related reductive cleavage of the C–Br bond using *p*-methoxybenzyl α-bromo-β-hydroxy ester **1b** derived from the transesterification of thioimide aldol.[6] The chemoselective debromination proceeded efficiently yielding the corresponding β-hydroxy ester **2b**† in excellent yield (96%) [eqn. (2)]. We were unable to detect any 4-methyl-2-pentenoate, a product of elimination, under careful analysis of the crude reaction mixture. In addition, allyl ester **1c**, which is particularly prone to hydrogenolysis, can also be cleanly converted to the correspopnding β-hydroxy ester **2c** under our standard conditions [eqn. (3)]. Switching the bromo ester from allyl to methyl had little effect. The debromination product **2d** was obtained in 80% isolated yield [eqn. (4)].



Variation of the halogen was briefly explored. Halohydrin aldols such as iodohydrin **3a**, bromohydrin **3b** and chlorohydrin **3c** were utilized to test the feasibility of Al–Hg promoted reductive cleavage. On exposure to an excess of Al–Hg in aqueous CH_2Cl_2 (1:10) at 0 °C for 2 min, the C–I bond in **3a** was completely cleaved (Scheme 1) while the same conditions effected complete debromination of **3b** within 30 min to afford β-hydroxy ester **4** in 94% isolated yield. Switching the halohydrin from bromo to chloro had a rate retardation effect while maintaining excellent yield. Thus, after 1 h at 0–25 °C, **3c** was cleanly converted to the ester **4** in 90% isolated yield with no evidence of dehydroxychlorination to the α,β-unsaturated ester.

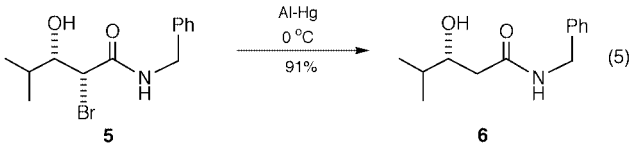
Extension of these observations to other carboxylic acid derivatives confirms the generality of this procedure. We were



Scheme 1

DOI: 10.1039/b000335m

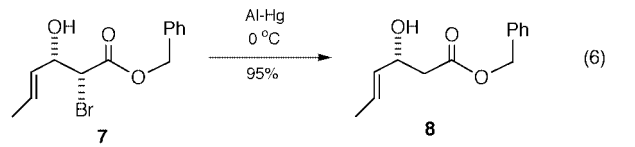
pleased to find that switching the α-bromo-β-hydroxy acid derivative from ester **3** to amide **5** had little effect. The debromination product **6** was obtained in 91% yield under the usual conditions in 30 min [eqn. (5)].



(5)

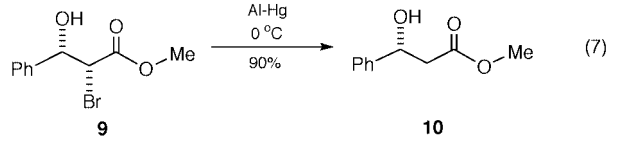
5 **6**

The broad scope of the reaction is illustrated by the additional examples provided below. A particularly interesting example illustrating the chemoselectivity of this process is the debromination of chiral bromohydrin aldol adduct **7**, which by virture of the sensitivity of allyl-type alcohol requires very mild methods. Using these standard reduction conditions, only reductive cleavage of the C–Br bond to give β-hydroxy ester **8** is observed, without concurrent reductive cleavage of the C–OH bond or dehydroxybromination [eqn. (6)]. Using an α-bromo ester bearing a benzyl-type alcohol **9**, the identical reaction gave the corresponding methyl β-hydroxy ester **10** in 90% isolated yield [eqn. (7)].[7]



(6)

7 **8**



(7)

9 **10**

This Al–Hg mediated reductive cleavage of carbon–halogen bonds represents an extremely simple, practical and efficient elaboration of various halohydrin compounds into α-unsubstituted β-hydroxy acid derivatives. Its use in the reduction of halohydrin aldols to β-hydroxy acid derivatives compares very favorably with other methods such as catalytic hydrogenolysis or reduction with tri-*n*-butyltin hydride. Further studies on the reductive cleavage of isolated halohydrins and other α,β-difunctional aldol adducts such as α,β-epoxy esters and amides are currently underway and will be reported in due course.

We thank the National Science Council of the Republic of China for support of this work. (NSC 89-2113-M-005-003).

A metal complex was designed to bind to the protein carbonic anhydrase strongly and selectively in aqueous medium.

Strong and selective binding to a pre-determined protein by synthetic receptors is of paramount importance for drug design,[1] protein purification[2] and protein sensing.[3] The recognition of active sites of enzymes leading to very effective inhibitors has been developed to a high level of sophistication. [4] Recognition of protein surface patterns by polypeptides has been used as a model system for studying protein–protein interactions[5] or to design enzyme inhibitors.[6] These studies employed multiple hydrogen bonding or ionic interactions as the basis of recognition. Herein, we report our results on selective recognition of a protein, carbonic anhydrase (CA, bovine erythrocyte) based on its *surface histidine pattern*, employing Cu^{2+}–histidine interactions in water (25 mM HEPES buffer, pH 7.0, 25 °C). To our knowledge, this is the first report of protein surface recognition using the surface histidine pattern of the protein. Metal–histidine interactions have been used for protein purification using immobilized metal affinity chromatography (IMAC).[2] However, in IMAC, the proteins are distinguished based on their surface histidine contents.

Metal–ligand interactions have several advantages in recognition compared to hydrogen bonding, ion-pair or other weak interactions. Metal–ligand interactions are stronger especially in aqueous media.[7] A variety of transition metal ions are available and are used by nature in biological systems for molecular recognition and catalysis.[8] This allows fine tuning of each of the interactions and opens the possibility of catalysis, following recognition. The spectroscopic properties of the metal ions can be utilized to monitor the binding process and to get structural information about the resultant complex.[9]

CA has five histidines (3, 10, 15, 17, 64) exposed on the surface (determined using the modeling software insight-II and discover, version 98.0, Molecular Simulations Inc., Burlington, MA).[10] The distance amongst the histidines 3, 10, 17 (or 15) are *ca*. 16 Å. This pattern was mapped into the pattern of Cu^{2+} ions by the tris–Cu^{2+} complex **2**. Another shorter tris–Cu^{2+} complex **3** (distance amongst the Cu^{2+} ions: *ca*. 12 Å) was synthesized for comparative studies. A mono-Cu^{2+} complex **1** served as the control for the recognition studies. Structures of the metal complexes **1**, **2** and **3** are shown in Fig. 1. These complexes were modeled using the software Spartan (version 5.0.3, Wavefunction Inc., Irvine) employing the Merck molecular mechanics force field. After energy minization, the resultant structures were subjected to systematic conformational searches to identify the lowest energy structures.

Two other proteins with different surface histidine patterns were used as controls for these studies, chicken egg albumin (CEA) and chicken egg lysozyme. CEA has six histidines on the surface (22, 23, 329, 332, 363, 371); lysozyme (chicken egg) has only one histidine (15) exposed to surface.[10] All of these three proteins are known to interact with transition metal ions through the surface exposed histidines.[11] CEA has a higher number of surface exposed histidines than the target protein (CA) but their distributions are different. If the recognition is based on the *contents* of surface exposed histidine residues (*e.g*. IMAC), then CEA is expected to bind more strongly compared to CA. Since the studies reported here rely on the histidine pattern, CEA was chosen as a control protein.

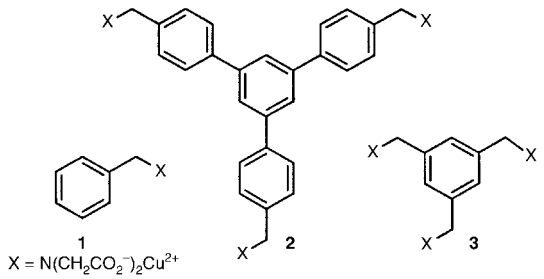

Fig. 1 Structures of the tris–Cu^{2+} complexes **2**, **3** and the control **1** used for recognition of carbonic anhydrase.

Complexes **2** and **3** were synthesized from the corresponding bromides and diethyl iminodicetate, using K_2CO_3 as the base in acetonitrile solvent. The ester groups were hydrolyzed by LiOH in methanol–water at 25 °C.[12] The complexes were found to be stable in aqueous buffer solution (25 mM HEPES buffer, pH 7.0), at room temperature, in air for more than a month. It is reported in the literature that the IDA–Cu^{2+} complex binds to proteins (pH 7.0) primarily through the surface exposed histidine residues of proteins. Primary amino groups and carboxylate residues on the protein surface only play weak, secondary roles.[13]

Binding studies were conducted in water (25 mM HEPES buffer, pH 7.0; [protein] = 100 μM, [**1**] = 0–1.2 mM; [**2**] or [**3**] = 0–500 μM, 25.0 °C) and were followed by isothermal titration microcalorimetry[14] (ITC-4200, Calorimetry Scientific Corporation, Provo, UT). The software provided by the instrument manufacturer (Bindworks 3.0) was used for data and error analysis. The raw data were corrected for the heat of dilution of the appropriate Cu^{2+}-complex before the curve fitting process (data for titrations are available as electronic supplementary information†).

Results for the binding experiments (stoichiometry, binding constant and enthalpy) are shown in Table 1. The control **1** showed low affinity ($K < 4000\ M^{-1}$) for the proteins tested. With the complex **2**, CA was found to bind tightly ($K \approx 300\,000\ M^{-1}$). CEA showed weak binding with complex **2** ($K < 1000\ M^{-1}$) under the experimental conditions. Lysozyme was found to precipitate when [**2**] > 25 μM. With the shorter complex **3**, the affinity for CA was found to decrease ($K \approx 75\,000\ M^{-1}$) compared to that of **2**. Both lysozyme and CEA bound weakly to complex **3** (no precipitation). Complex **2** bound CA more strongly compared to the control **1** (90 : 1) or the shorter tris–Cu^{2+} complex **3** (4 : 1). This slight selectivity of CA for **2** (over **3**) may be due to greater strain in binding for **3** ($\Delta H = -15.1$ kcal mol^{-1} for **2**; -12.2 kcal mol^{-1} for **3**) to the protein. Complex **2** also showed very good selectivity for CA when compared to CEA (300 : 1).

In order to demonstrate selective binding of **2** to CA, a mixture of the protein and the control **1** ([CA] = 100 μM; [**1**] = 100 μM) was titrated with **2** ([**2**] = 0–500 μM). No change in the binding constant of **2** with CA was observed. When a

mixture of **2** and CA ([CA] = 100 μM; [**2**] = 100 μM) was titrated with control **1** ([**1**] = 0–1 mM), no binding was observed. Similar results were obtained with the complex **3**. When a mixture of the three tested proteins (100 μM each) was titrated with complex **2**, the binding constant remained unchanged (280 000 ± 30 000). If carbonic anhydrase was not included in the mixture (*i.e*. CEA and lysozyme, 100 μM each), very weak affinity (< 1000) was detected. The binding selectivity reported here (for complex **2**) is distinctly different compared to that observed with a random distribution of copper(II) ions (on chelating Sepharose fast flow with iminodiacetate–Cu^{2+}, pH 7.0, 22 °C, either in equilibrium binding experiments or in chromatograhy).[15]

To demonstrate the role of Cu^{2+}–histidine interactions in the recognition process, we have studied the binding between CA and complex **2** by EPR spectroscopy in the solution phase (9.4 GHz, [CA] = 1.2 mM; [**2**] = 600 μM, 25.0 °C). Upon addition of the protein, the $g_{\|}$ value of Cu^{2+} ions of **2** decreased from 2.290 to 2.261. These values match well with the reported $g_{\|}$ values of the iminodiacetate–Cu^{2+} complex, free and bound to myoglobin through the histidine residues (2.288 and 2.264, respectively).[16] Also ITC titrations failed to detect any binding between the metal-free ligands (for **1**, **2** and **3**) and the proteins.

The binding of CA with the metal complexes **2** and **3** were followed by UV–VIS spectrometry. Upon addition of CA to a solution **2** (or **3**, [**2** or **3**] = 0.5 mM; [CA] = 0.8 mM, 25 mM HEPES buffer, pH 7.0, 25 °C, 10 × 100 μL additions), the absorption maxima progressively shifted from 727 to 660 nm. This indicated the coordination of one imidazole group (of histidine residues) per copper(II) ion of the complexes.[17] Analyses[18] of the resultant titration curves corroborated the ITC results. Circular dichroism studies (80 μM protein, 0–500 μM of **2** or **3**, 25 mM phosphate buffer, pH 7.0, 23.0 °C) indicated that the proteins were not unfolding in presence of the control **1** or receptors **2** or **3**.

Thus these studies demonstrate that the tris–Cu^{2+}complex **2** binds carbonic anhydrase strongly and with good selectivity compared to two other proteins with different histidine patterns on the surface. It should be noted that the reported method of protein recognition is applicable to proteins of known structures possessing histidine residues on the surface. With rapidly increasing number of solved protein structures, the method has wide applicability.

This work was supported by NSF-CAREER award (CHE-9896083) and an NIGMS - AREA grant (1R15 59594-01, NIH). The microcalorimeter was purchased through an NSF-EPSCoR award to North Dakota. We thank Professor Kenton Rodgers for help with the EPR experiments.

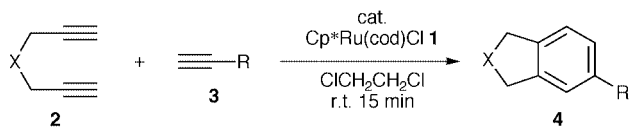
Ru(II)-catalyzed cycloaddition of unsymmetrical 1,6-diynes gives the desired cycloadducts in high yields with a regioselectivity *meta*:*ortho* = 88:12–98:2.

Transition-metal catalyzed [2 + 2 + 2] cyclotrimerizations of alkynes has been recognized as a straightforward route to substituted benzenes.[1] The control of both the chemo- and regio-chemistries in the cyclotrimerization of two or three different alkyne components, however, have been a crucial problem. Although the selective cyclocotrimerization of three different alkynes was achieved using stoichiometric zirconocene reagent,[2] the regiochemistry problem has remained unsolved. In addition, catalytic reactions are ideal from both the environmental and economical points of view. The intramolecular cyclization of triynes was pioneered as a completely chemo- and regio-selective process by Vollhardt in work on the catalytic reactions of $CpCo(CO)_2$,[3] and subsequently, many triyne cyclizations have been applied for the syntheses of complex polycyclic systems.[4] Intermolecular couplings between a diyne and a monoalkyne have also been realized as a successful method to construct bicyclic frameworks.[3,5] At the expense of the complete regio- and chemo-selections, this partially intermolecular approach becomes more advantageous than the triyne methodology, because a wide variety of readily accessible or commercially available diynes and monoalkynes could directly be used. The chemoselectivity can be improved using an excess amount of a monoalkyne, although a satisfactory level of regiocontrol has not been achieved in previous diyne–monoalkyne couplings. Herein, we report the first Ru-catalyzed regioselective cycloaddition between unsymmetrical 1,6-diynes and monoalkynes.

Recently, we have found that Cp*Ru(cod)Cl **1**: (Cp* = pentamethylcyclopentadienyl, cod = cycloocta-1,5-diene) effectively catalyzes the selective intermolecular coupling of 1,6-heptadiynes with 2,5-dihydrofuran.[6] In order to extend the catalytic utility of the ruthenium complex **1**, we further explored the catalyzed cross-cyclotrimerization of 1,6-diynes with monoalkynes. To the best of our knowledge, ruthenium-catalyzed [2 + 2 + 2] cyclotrimerizations of monoalkynes has scarcely been investigated so far,[7] and no example of co-cyclotrimerization of different alkynes was found in previous reports.[1,8] At the outset, dimethyl dipropargylmalonate **2a** [X = $C(CO_2Me)_2$] and 2 equiv. of hex-1-yne **3a** (R = Bu) were treated with 1 mol% of **1** in 1,2-dichloroethane at *ambient* temperature (Scheme 1). The



Scheme 1

† Electronic supplementary information (ESI) available: experimental procedures and analytical data for **4** and **6**. See http://www.rsc.org/suppdata/cc/b0/b000466i/

starting diyne **2a** was completely consumed within 15 min, and silica-gel column chromatography of the crude reaction mixture gave the desired indan derivative **4a** in 89% yield (TOF = 356 h^{-1}; Table 1, entry 1). The undesired competitive dimerization and trimerization of **2a** were effectively suppressed (11%), and the cyclotrimerization of **3a** was not detected in the crude reaction mixture by ^1H NMR spectroscopy. The yield and the selectivity were slightly improved using 4 equiv. of **3a** (entry 2). The reaction of phenyl acetylene **3b** (R = Ph) required a longer reaction time (14 h) even using 3 mol% of **1a** (entry 3). A biphenyl derivative **4b** was obtained in 74% yield. In contrast to these results, a terminal alkyne possessing a bulky substituent, *tert*-butyl acetylene **3c** (R = Bu^t) gave the corresponding cycloadduct **4c** only in low yield (entry 4). In this case, substantial amounts of the dimer and the trimer of **2a** were formed. In addition to terminal alkynes, the parent acetylene **3d** (R = H) was found to be an effective monoalkyne component for our catalyzed cycloaddition. The diyne **2a** was treated with **1** at 0 °C for 1 h under acetylene gas (balloon) to afford **4d** in 84% yield (entry 5).

Table 1 Cp*Ru(cod)Cl-catalyzed cycloaddition of 1,6-diynes **2a–c** with terminal alkynes **3**[a]

					Yield[b] (%)	
Entry	X	R	Catalyst (mol%)	*t*	**4**	Dimer + trimer
1	$C(CO_2Me)_2$	Bu	1	15 min	**4a**, 89	11
2	$C(CO_2Me)_2$	Bu[c]	1	15 min	**4a**, 94	5
3	$C(CO_2Me)_2$	Ph	3	14 h	**4b**, 74	21
4	$C(CO_2Me)_2$	Bu^t	1	30 min	**4c**, 21	53
5	$C(CO_2Me)_2$	H[d]	1	1 h	**4d**, 84	9
6	NTs	Bu	1	10 min	**4e**, 80	—
7	O	Bu	1	12 h	**4f**, 68	18

[a] All reactions were carried out with a terminal alkyne (2 equiv.) in 1,2-dichloroethane at r.t. [b] Isolated yield. [c] 4 equiv. [d] Under acetylene gas (balloon) at 0 °C.

Furthermore, this novel protocol using the Ru(II)-catalyst was successfully applied to other heterocyclic species. The cycloaddition of *N*,*N*-dipropargyl tosylamide **2b** (X = NTs) with hex-1-yne **3a** was complete within 10 min at ambient temperature to afford an isoindoline derivative **4e** as the sole product in 80% yield (entry 6). A phthalan derivative **4f** was obtained in 68% yield along with the dimer and trimer of **2c** (entry 7).

We next investigated the regiochemistry in the cycloaddition of a series of unsymmetrical 1,6-diynes **5** (Scheme 2). The regiochemistry of the cyclotrimerization key steps have been examined only to a limited degree: a few examples of regioselective cycloaddition using $ClRh(PPh_3)_3$ have been reported, but these were limited to alkynes possessing a hydroxyl group.[5f,k] In fact, the reaction of a malonate derivative **5a** [X = $C(CO_2Me)_2$, R^1 = Me] with hexyne **3a** at 60 °C for 3 days using 5 mol% $ClRh(PPh_3)_3$ gave a 5,7-disubstituted indan derivative *meta*-**6a** and its 5,6-disubstituted isomer *ortho*-**6a** in

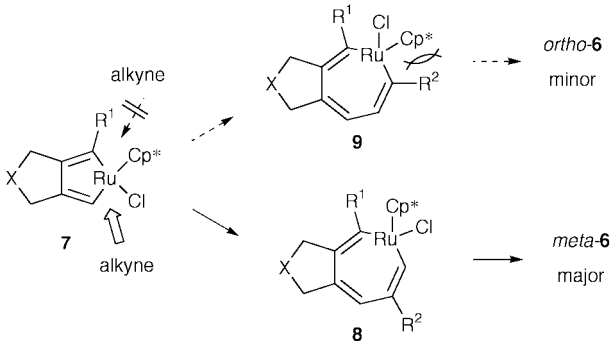
Table 2 Cp*Ru(cod)Cl-catalyzed cycloaddition of 1,6-diynes **5a–c** with terminal alkynes **3**[a]

Entry	X	R^1	R^2	Catalyst (mol%)	Yield[b] (%) t	(*meta*:*ortho*)[c]
1	$C(CO_2Me)_2$	Me	Bu	1	1 h	**6a**, 85 (93:7)
2	$C(CO_2Me)_2$	Me	Me[d]	3	18 h	**6b**, 80 (94:6)
3	$C(CO_2Me)_2$	Me	CH_2OMe	1	3 h	**6c**, 86 (94:6)
4	$C(CO_2Me)_2$	Me	Ph	3	24 h	**6d**, 82 (88:12)
5	$C(CO_2Me)_2$	Ph	Bu	10	24 h	**6e**, 80 (95:5)
6	$C(CO_2Me)_2$	$SiMe_3$	Bu	5	7 h	**6f**, 94 (98:2)
7	NTs	Me	Bu	1	10 min	**6g**, 82 (93:7)
8	O	Me	Bu	1	30 min	**6h**, 75 (95:5)

[a] All reactions were carried out with a terminal alkyne (2 equiv.) in 1,2-dichloroethane at r.t. [b] Isolated yield. [c] Ratios in parentheses were determined by GC analyses of isolated products. [d] Under propyne gas (balloon).

61% total yield with a low regioselectivity *meta*:*ortho* = 65:35. In our hands, **5a** regioselectively reacted with 2 equiv. of **3a** in the presence of the catalyst **1** (1 mol%) to afford *meta*-**6a** and *ortho*-**6a** in 85% total yield with an excellent regioselectivity *meta*:*ortho* = 93:7 (Table 2, entry 1). The importance of the bulky Cp* ligand of **1** was clearly demonstrated by the fact that the reaction of **5a** and **3a** conducted using CpRu(cod)Cl bearing a smaller Cp ligand gave cycloadduct **6a** in 76% yield with lower selectivity (*meta*:*ortho* = 87:13). Similarly, the reaction of **5a** with propyne gas **3e** (R^2 = H; balloon) or propargyl methyl ether **3f** (R^2 = CH_2OMe) gave **6b** and **6c** in 80 and 86% yields, respectively with high *meta*-selectivities (entries 2 and 3). The ether functionality at the propargylic position in **3f** did not decrease both the yield and regioselectivity. Cycloaddition with the less reactive aromatic alkyne, phenylacetylene **3b**, was conducted using an increased amount of the catalyst, and biphenyl derivatives **6d** were obtained in a comparable total yield (82%) with somewhat lower selectivity (entry 4). Similar biphenyl derivatives **6e** were also obtained from the reaction of a 1,6-diyne possessing a phenyl group as a terminal substituent **5b** (entry 5). In this case, the increased amount of the catalyst (10 mol%) was again found to be effective. The highest yield and regioselectivity were achieved in the reaction of a diyne **5c** having a bulky trimethylsilyl substituent at the terminal position with **3a** (entry 6). The corresponding indan derivatives **6f** were obtained in 94% total yield with an isomer ratio of *meta*:*ortho* = 98:2. The regioselective syntheses of highly substituted heterocycles were also realized using nitrogen- or oxygen-tethered unsymmetrical diynes **5d** and **5e**. An isoindoline derivative **6g** and a phthalan derivative **6h** were obtained in 82 and 75% yields, respectively, with high *meta*-selectivities (entries 7 and 8).

The origin of the high *meta*-selectivity can be explained by the insertion mechanism depicted in Scheme 3. A ruthenacyclopentadiene **7** formed from **1** and **5** can be proposed as a key intermediate.[9] In order to avoid the steric interaction with the terminal substituent R^1, a monoalkyne **3** is selectively inserted into the less substituted Ru–C single bond to form ruthenacycloheptatriene intermediates **8** or **9**. At this stage, the bulky Cp* ligand directs formation of **8** because the steric repulsion between Cp* and R^2 is obviously greater in **9** and reductive elimination from **8** gives a *meta*-isomer *meta*-**6** as the major product.



Scheme 3

In conclusion, an Ru(II) complex possessing a bulky planar ligand, Cp*Ru(cod)Cl, catalyzed the cycloaddition of 1,6-diynes with terminal alkynes at or below room temperature. Satisfactory chemoselectivity can be achieved using 2 equiv. of a monoalkyne. Excellent *meta*-selectivity was observed for the reaction of unsymmetrical diynes.

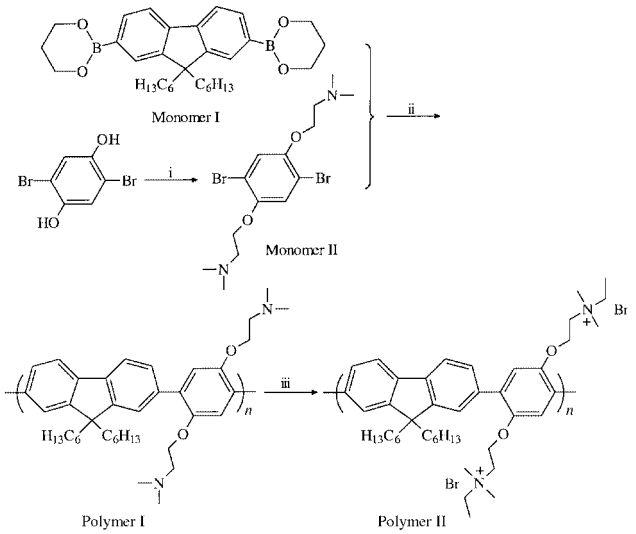
Received (in Cambridge, UK) 24th January 2000, Accepted 23rd February 2000
Published on the Web 17th March 2000

A novel cationic conjugated polymer, poly[(9,9-dihexyl-2,7-fluorene)-*alt-co*-(2,5-bis{3-[(*N*,*N*-dimethyl)-*N*-ethylammonium]-1-oxapropyl}-1,4-phenylene)] dibromide, which is water-soluble and emits bright blue fluorescence both in solutions and as films, is synthesized through Suzuki coupling reaction and a post-polymerization treatment.

Water-solubility of conjugated polymers may offer many new application opportunities. Potential applications of water-soluble conjugated polymers include the construction of active layers in organic light-emitting diodes through a layer-by-layer self-assembly approach,[1] as buffer layer and emissive layer materials in inkjet printing fabricated organic LEDs,[2] and as highly sensitive fluorescent sensory materials in living bodies.[3] Such applications generally favor high molecular weights and high photoluminescence (PL) efficiencies and require different ionic types. Water-solubility of semiconducting conjugated polymers was first demonstrated in 3-substituted polythiophenes[4,5] and was then extended to poly(*para*-phenylene vinylene) (PPV)-based[6] and poly(*para*-phenylene) (PPP)-based polymers.[7,8] The water-solubility in such polymers was achieved by functionalizing the substituted side chains with terminal carboxylate or sulfonate groups. These polymers are, therefore, anionic polyelectrolytes. Until the most recent report on the synthesis of ammonium-functionalized PPPs from Reynolds' group,[9] there are no cationic water-soluble conjugated polymers available. Fluorene-based conjugated polymers have received considerable attention in the past few years for the high efficiencies both in PL and in electroluminescence (EL).[10] Moreover, we recently demonstrated that conjugated polymers based on alternating fluorene and phenylene backbones are promising efficient and stable blue luminescent materials.[11] This work presents the successful effort in developing a cationic water-soluble conjugated polymer based on the alternating fluorene and phenylene backbone, which represents the first example of fluorene-based water-soluble conjugated polymer and exhibits efficient blue light emission.

The chemical structure of the new water-soluble conjugated polymer, poly[(9,9-dihexyl-2,7-fluorene)-*alt-co*-(2,5-bis{3-[(*N*,*N*-dimethyl)-*N*-ethylammonium]-1-oxapropyl}-1,4-phenylene)] dibromide (PFP-NMe_2EtBr) and the synthetic route are depicted in Scheme 1. Monomer I, 9,9-dihexylfluorene-2,7-bis(trimethylene boronate), was synthesized from 2,7-dibromofluorene as the starting material.[11] Monomer II, 2,5-bis[3-(*N*,*N*-dimethylamino)-1-oxapropyl)-1,4-dibromobenzene], was prepared from 2,5-dibromohydroquinone by reaction with 2-chloroethyldimethylamine in refluxing acetone in the presence of an excess of anhydrous potassium carbonate.[9] The polymerization was carried out in a mixture of toluene and aqueous potassium carbonate solution (2 M) containing 1 mol% $Pd(PPh_3)_4$ under vigorous stirring at 85–90 °C for three days. The neutral polymer, polymer I, was obtained as a fibrous white solid with a yield of *ca*. 70% after purification and drying. Conversion of the neutral polymer to the final water-soluble polymer was achieved by treatment with bromoethane in dimethyl sulfoxide (DMSO) and tetrahydrofuran (THF) (1 : 4).



Scheme 1 Chemical structures and synthetic route towards the polymers. *Reagents and conditions*: i, 2-chlorotrimethylamine hydrochloride, anhydrous potassium carbonate, acetone, reflux, 3 days; ii, toluene/aqueous potassium carbonate solution (2 M), $Pd(PPh_3)_4$, 85–90 °C, 3 days; iii, bromoethane, DMSO–THF (1 : 4), 50 °C, 3 days.

The structures of both the neutral and the final water-soluble polymers were confirmed by NMR and elemental analysis.†

The characterization of molecular weight is often a problem for water-soluble conjugated polymers. The post-polymerization approach for the realization of water-solubility allows us to characterize the molecular weight at the stage of the neutral polymer. The neutral polymer, polymer I, can be readily dissolved in $CHCl_3$, THF, toluene and aqueous acid, but is insoluble in DMSO, methanol and water. Gel-permeation chromatography (GPC) measurement using THF as eluent and polystyrenes as the standards indicated the weight average molecular weight to be 47 000, with a polydispersity of 1.61. Another advantage of the post-polymerization approach is that the quaternization degree can be controlled and thus the water-solubility of the resultant polymer is tunable. The tunable solubility is useful for the application of such materials as buffer layers in inkjet printing fabrication of LEDs.[2] The degree of quaternization could be determined by ^{1}H NMR spectra. As shown in Fig. 1, the neutral polymer exhibits three peaks in the region δ 7.8–7.6 arising from the aromatic protons in fluorene and one peak at δ 7.15 due to the protons in the phenylene ring. The well resolved peaks at δ 4.09, 2.67 and 2.30 correspond to methylene groups adjacent to the oxygen ($-OCH_2-$) and nitrogen ($-CH_2N-$) atoms and the methylamino groups ($-NCH_3$), respectively. After the treatment with bromoethane, the peaks in the aromatic region remain almost unchanged, whereas all the signals corresponding to $-OCH_2-$, $-CH_2N-$, and $-NCH_3$ split into two peaks, which arise from the quaternarized (lower field) and un-quaternized components, respectively. The

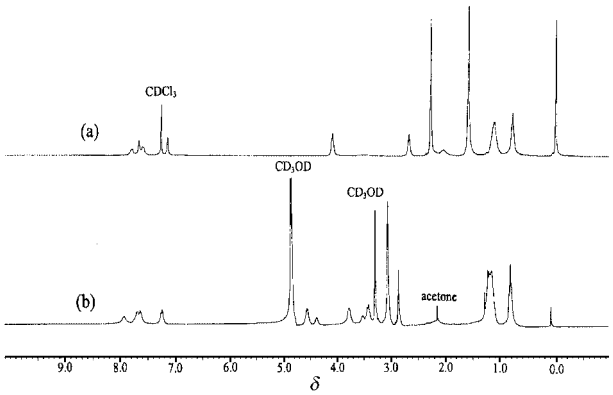


Fig. 1 ^{1}H NMR spectra of polymers I (a) and II (b).

relative integrals of each pair of the split peaks can thus be used to estimate the degree of quaternization. The highest degree of quaternization obtained in our experiments is *ca*. 80%. With this degree of quaternization, the resulting polymer shows solubility characteristics opposite to that of polymer I, being completely soluble in DMSO, methanol, and water but insoluble in $CHCl_3$ and THF.

Polymer II also possesses good thermal stability. The onset degradation temperature of this polymer is 300 °C in nitrogen, whereas it starts to decompose above 230 °C in air, with a small amount of water loss at lower temperatures. In air, no residue remained after heating to 800 °C.

The UV–VIS absorption spectra of polymer I in chloroform solution and as a film (on quartz plate, spin-cast from chloroform solution) are almost identical with the same maximum absorption at 366 nm. The PL spectrum of the polymer solution peaks at 414 nm, whereas the polymer film exhibits an emission maximum at 424 nm with a vibronic shoulder around 444 nm. The emission spectral feature of the polymer in the film state is very similar to that of the polymer having the same backbone structure and substitution on fluorene unit but without the terminal amino group in the phenylene side chains.[11] This implies that the terminal amino groups are unlikely to affect the conformation of the backbone in the film state. For the quaternized sample with the highest degree of quaternization (*ca*. 80%), the electronic spectra are remarkably dependent on the solvent, showing a bathochromic shift with a decrease in solvent polarity. As displayed in Fig. 2, the polymer shows absorption maxima at 343, 354 and 367 nm in water, methanol and DMSO, respectively. The corresponding PL maxima appear at 409, 409 and 419 nm, respectively. Uniform and transparent films of the polymer on quartz plates were prepared by spin-casting its aqueous solution. The UV–VIS absorption and PL spectra of the polymer film are also shown in Fig. 2. The absorption and emission peaks appear at 359 and 416 nm, respectively.

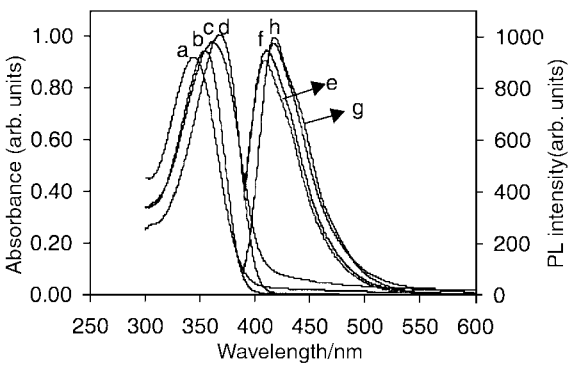

Fig. 2 UV–VIS absorption and photoluminescence spectra of polymer II in solutions and as films. (a) UV in aqueous solution, (b) UV in MeOH, (c) UV in film, (d) UV in DMSO, (e) PL in MeOH, (f) PL in aqueous solution, (g) PL as film and (h) PL in DMSO.

From the application point of view, one of the most attractive properties of the polymers is the relatively high PL quantum yield (Φ_{pl}). Both the neutral polymer and the quaternized polymers display strong blue fluorescence either in solutions or as films upon exposure to UV light. The Φ_{fl} of the neutral polymer (polymer I) is as high as 97% as measured from its dilute solution in chloroform.‡ For polymer II (with a degree of quaternization of 80%), the Φ_{pl} was measured to be 86% from its dilute solution in methanol. When the measurement was conducted in aqueous solution, the corresponding value of Φ_{pl} is 25%. The decrease of PL efficiency may be attributed to the aggregation of the polymer in aqueous solution. This was supported by a further reduced PL efficiency measured in the solid state (films on quartz plate cast from methanol solution), which is 4% compared with 9,10-diphenylanthracene as standard (dispersed in PMMA films with a concentration lower than 1×10^{-3} M, assuming a PL efficiency of 83%).[12]

In summary, we have synthesized a new cationic water-soluble conjugated polymer based on the alternating fluorene and phenylene backbone structure through a facile post-polymerization approach, which permits a full structural characterization of the polymer and control of the degree of cation formation. The polymer emits intense blue fluorescence both in solutions and in film states. The good water-solubility and high fluorescence quantum yield make it attractive for applications in fabricating organic LED devices and as fluorescent bio-sensory materials.

The work was partially supported by the National University of Singapore through a research grant (RP970610).

Received (in Cambridge, UK) 18th January 2000, Accepted 23rd February 2000
Published on the Web 17th March 2000

Diastereoselective and regioselective [1,5]-C,H insertion reactions of 2′-deoxy-3′-diazomalonate nucleosides afforded τ-butyrolactones of nucleosides as chiral synthons for the preparation of 2′-*C*-branched nucleosides.

Since oxetanocin[1] was isolated and turned out to show potent antiviral activity such as inhibition of HIV-1 antigens and infectivity, *C*-branched nucleosides bearing carbon–carbon bonds at the furanose rings have attracted considerable attention as clinically useful chemotherapeutic agents.[2] Moreover, the discovery of a positive correlation between inhibitory activity against ribonucleotide reductase and antitumor activity,[3] has led to rational drug design to find potent antitumor agents having C–C bonds at the 2′-positions.[4] The key step in the synthesis of *C*-branched nucleosides is stereocontrolled C–C bond formation at the branching site of the ribofuranose ring. However, it is especially difficult to construct C–C bonds at the 2′-position of nucleosides. Intramolecular cyclization is a facile and useful strategy for stereo- and regio-controlled C–C bond formation to provide γ-butyrolactones of nucleosides as a useful chiral synthon for the synthesis of *C*-branched nucleosides.[5] The γ-butyrolactones of nucleosides are important key intermediates to manipulate various 2′-*C*-branched nucleoside analogues. Recently Camarasa and coworkers reported that γ-butyrolactones of nucleosides were prepared by intramolecular radical cyclization in good diastereoselectivities but low yields[6] which might result from reductive deoxygenation, which is a feature of free radical cyclizations. Intramolecular [1,5]-C,H insertion reactions of α-diazocarbonyl compounds have been among the most attractive and effective methods for the construction of functionalized five membered rings.[7] Substrates can be smoothly cyclized without difficulty by dirhodium(II)-catalyzed C,H-insertion reactions. However, surprisingly, no successful C,H-insertion reactions in the modification of ribofuranose ring of nucleosides have been reported. Efficient construction of a C–C bond at the branching point has been a difficult task especially at the 2′-position of nucleosides by currently available methods. Here, we describe diastereoselective intramolecular C,H-insertion of 2′-deoxy-3′-α-diazoacetates of nucleosides in the presence of a catalytic amount of dirhodium tetraacetate to [3.3.0] fused lactones (γ-butyrolactones) of a series of nucleosides having a new chiral center at an off-template site of the ribofuranose ring, in high yields, as shown in Scheme 1.

For the synthesis of the fused γ-butyrolactones of nucleosides we chose 2′-deoxy-3′-diazoacetates of nucleosides (R^1 = H, MeCO, MeO_2C, EtO_2C) as templates for [1,5]-C,H insertion reactions. The general strategy is shown in Scheme 2.

The 5′-position of 2′-deoxynucleosides were protected with *tert*-butyldiphenylsilyl chloride in dried pyridine at room temperature. These 5′-*O*-protected-2′-deoxynucleoside derivatives **10a**–**e** undergo transesterification[8] by reaction with the corresponding methyl ester to give 3′-*O*-acetoacetyl-2′-deoxy-

nucleosides and 2′-deoxy-3′-*O*-α-(methoxycarbonyl)acetylnucleosides in moderate yields. Diazo transfer of these esters with methanesulfonyl azide and triethylamine in acetonitrile[9] afforded the corresponding 3′-diazoester derivatives **1a**–**4a** and **1b**–**4b** in poor yields (*ca.* 50%). These low yields might be due to steric hindrance by furanose rings. It was found, however, that the satisfactory yields (84–96%) of **1a**–**4a** and **1b**–**4b** could be smoothly obtained using methyl α-diazoacetate derivatives instead of methylacetate ones, and α-ethoxycarbonylacetates of nucleosides **1c** and **2c** were not formed by this procedure. The desired products **1c** and **2c** could be obtained by a coupling reaction of 5′-*O*-protected-2′-deoxynucleosides **10a**,**b** with monoethyl malonate followed by diazo transfer in moderate yields (56–71%), while 2′-deoxy-3′-α-diazoacetates of nucleosides **1d** and **2d** could be obtained in good yields (78–90%) using the modified House–Blankey procedure.[11]

Our initial studies on stereocontrolled C,H-insertion of 2′-deoxy-3′-α-diazoacetates of nucleosides were performed in the presence of dirhodium tetraacetate (1.0 mol%) in dichloromethane at room temperature. However, only a trace amount of product was obtained and starting material was recovered. To improve the yields, when the reaction mixture was refluxed, high yields of γ-butyrolactones of nucleosides **5**–**8** were obtained and results obtained are summarized in Table 1.

Moreover, the C,H-insertion of 2′-deoxy-3′-α-diazoacetates of nucleosides **1**–**4** afforded the γ-butyrolactones of nucleosides **5**–**8** with high diastereoselectivities. Through the J_{H-H} coupling constant ($J_{1''-2'}$ 8.8 Hz) between 1″-hydrogen and 2′-hydrogen of **6b**, the stereochemistry of 1″-position of γ-butyrolactone of nucleoside **6b** was determined as *exo*. Irradiation of the anomeric proton of **6b** caused enhancement of the signal for H-1″ (8%), indicating that the configuration at C-1″ of **6b** was (*S*). A possible mechanism for the stereochemical outcomes of γ-

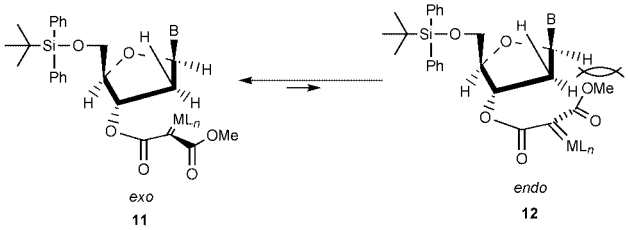


Scheme 3

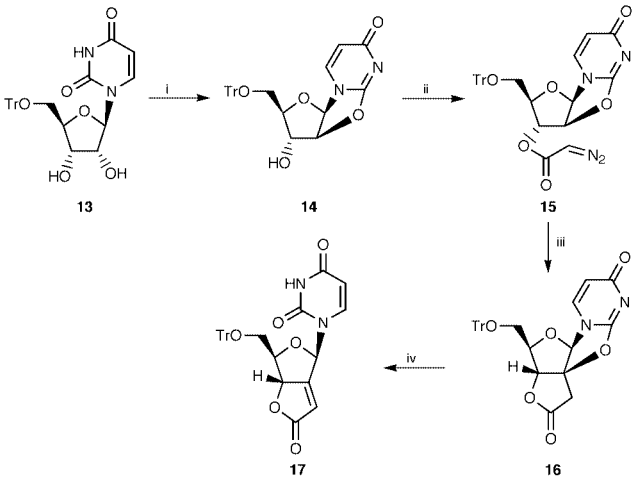
butyrolactones of nucleosides **5**–**8** is proposed as shown in Scheme 3.

The unfavorable steric hindrance between the anomeric proton and the methyl ester in *endo* transition state **12** drives the equilibrium to the left to the *exo* transition state **11**, which gives the (*S*) conformer (*exo* adduct, **5**–**8**) stereoselectively. When pure **6b** was refluxed in CH_2Cl_2 for 10 h, no epimerization occurred.

The γ-butyrolactones of the nucleosides described above can be considered as useful chiral synthons for the synthesis of *C*-branched nucleosides. In connection with biologically interesting nucleosides containing the 2′-methylene moiety, for instance (*E*)-FMC[3] and (*E*)-2′-deoxy-2′-(carboxymethylene)-5′-*O*-trityluridine-3′,2′-γ-lactone **17**,[12] the synthesis of **17** was attempted by employing C,H-insertion of the 2′,5′-cyclouridine derivative **14** as shown in Scheme 4.

Cyclization of 5′-*O*-trityluridine **13** by basic diphenylcarbonate gave the 2′,5′-cyclouridine **14** in 81% yield. Exposure of **14** to the House–Blankey protocol afforded the corresponding diazo compound **15**, which could be converted to the γ-butyrolactone of uridine **16** in 65% yield. Product **17** could be smoothly obtained by an elimination reaction with sodium hydride in 85% yield.

In conclusion, we have achieved the new stereoselective syntheses of α-substituted-γ-butyrolactones of nucleosides *via* [1,5]-C,H insertion reactions of α-diazo-γ-butyrolactones of nucleosides.



Scheme 4 *Reagents and conditions*: i, $(PhO)_2CO$, $NaHCO_3$, DMF; ii, TsHNN=CHCOCl, Et_3N, MeCN; iii, $Rh_2(OAc)_4$, CH_2Cl_2, reflux; iv, NaH, MeCN.

Furthermore, this reaction can be applied to the synthesis of (*E*)-2′-deoxy-2′-(carboxymethylene)-5′-*O*-trityluridine-3′,2′-γ-lactone **17**, a chiral synthon in the synthesis of 2′-*C*-branched nucleosides.

Received (in Liverpool, UK) 12th January 2000, Accepted 22nd February 2000
Published on the Web 17th March 2000

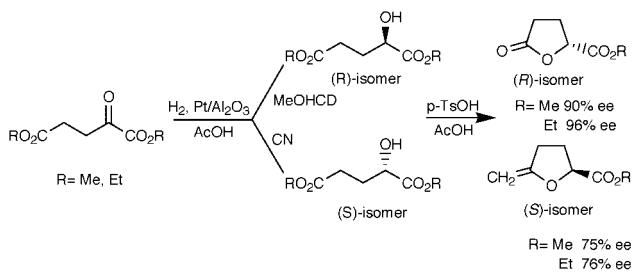
The first direct asymmetric synthesis of chiral alkyl 5-oxotetrahydrofuran-2-carboxylates (up to 96% ee), which are important building blocks in the synthesis of natural products by heterogeneous cinchona-modified Pt-catalyzed hydrogenation of α-ketoglutaric acid esters and subsequent cyclization of hydroxy esters is described.

The growing interest in the synthesis of important chiral compounds provides significant impetus for asymmetric synthesis. Owing to the recent environmental considerations and safety concerns, the use of heterogeneous asymmetric methods such as enantioselective hydrogenation are especially preferable.[1] One of those, the cinchona alkaloid-modified platinum catalyst system, was found to be especially effective in the hydrogenation of α-ketoesters and ketoacids[1] and ketoacetals.[2] The most prominent substrates are ethyl pyruvate,[3] pyruvaldehyde dimethyl acetal,[2] ketopantolactone[4] and 1-ethyl-4,4-dimethylpirrolidine-2,3,5-trione,[5] which can all be hydrogenated with excellent enantioselectivity (91–98%) over cinchona-modified Pt/Al_2O_3 catalysts.

Here, we report a new successful enantioselective synthesis of alkyl (*R*)-5-oxotetrahydrofuran-2-carboxylates, *via* the asymmetric hydrogenation of α-ketoglutaric acid esters over cinchona-modified Pt/Al_2O_3 catalyst.

The target chiral esters are very frequently used synthons in the synthesis of natural products.[6] In addition, their utilization in the free acid form as chiral derivatizing agents[7] or as a template for acyclic stereoselection through asymmetric synthesis[8] is also well known. The enantioselective hydrogenation of dialkyl 2-ketoglutarates and the subsequent cyclization to alkyl 5-oxotetrahydrofuran-2-carboxylates are shown in Scheme 1.

The existing process for the preparation of the target compounds is a template synthesis based on the deamination of enantiopure glutamic acid.[9] Asymmetric pathways to their perparation are enzymatic resolution of the racemic mixtures or direct bioreduction of ketoglutaric acid esters.[10] The former process provides high enantiomeric excess, however, the yield is obviously does not exceed 50% in the best case. The bioreduction, however, is not an efficient method for the preparation of enantiomers of high purity, since the ee values (up to 67%) vary considerably and significant decarboxylation and byproduct formation may be observed. Heterogeneous hydrogenation carried out on camphor-modified Raney Ni was also inefficient (24% ee).[11] As a consequence, to the best of our knowledge, no satisfactory enantioselective reduction of α-ketoglutaric acid derivatives has been developed.



Scheme 1

In this study two well known Pt/Al_2O_3 reference catalysts (Engelhard 4759, denoted E4759 and Johnson Matthey 94, denoted JMC94) were used while the two modifiers [cinchonidine (CD) and cinchonine (CN)] and 2-ketoglutaric acid were all Fluka products. 9-Methoxy-10,11-dihydrocinchonidine (MeOHCD) was kindly donated by Dr Martin Studer (Novartis, Basel, Switzerland). The dimethyl and diethyl α-ketoglutaric acid esters were prepared on the basis of a literature procedure.[10] The hydrogenations were performed in an atmospheric batch reactor or in a Berghof Bar 45 autoclave at 20 °C as described previously.[2,3] After hydrogenation, the hydroxyester obtained was subjected to a cyclization reaction with *p*-toluenesulfonic acid according to the literature procedure.[10] During the reaction no racemization or inversion occured, as a result the ee of the cyclic products corresponded to that of the open chain hydroxy esters. Product identification was carried out by GC–MS (HP5890 GC-HP5970 MSD) and ^{1}H NMR spectroscopy (Bruker AM500), while the enantiomeric excesses $\{ee\% (|[R] - [S]|) \times 100/([R] + [S])\}$ were monitored by chiral gas chromatography [HP 5890 GC-FID, 30 m long Cyclodex-B (J&W Scientific) capillary column, carrier gas: He, 15 psi, 125 °C, retention time for (*S*)-isomer: 31.8 min, for (*R*)-isomer: 32.5 min]. The ee values were reproducible within 2%.

According to earlier findings[1–5] two well known 5% Pt/Al_2O_3 references catalysts (E4759 and JMC94) were highly efficient in the enantioselective hydrogenation of activated α-oxo-compounds. As a result, these samples were selected for the enantioselective hydrogenation of diethyl α-ketoglutarate. Taking into account that in the literature, toluene and acetic acid have mainly been applied as solvents in these systems, both of them were tested first to find the most suitable medium, catalyst and modifier for the hydrogenation. Although the enantioselectivity in toluene is only moderate (up to 63% ee), using acetic acid as solvent, the results are excellent (up to 93% ee) and comparable or even slightly higher than those obtained with ethyl pyruvate.[1,2] As generally found,[12] the ee was always higher with the CD modifier than with the CN modifier. The results obtained in the two solvents, including reaction rates and optical yields, are tabulated in Table 1.

In the light of the results shown in Table 1 it can be concluded that the JMC catalyst exhibited a slight but clear increase in both reaction rates and optical yields (5–6% ee increase) compared to E4759. It seems also clear that MeOHCD is the best modifier for the reaction, the ee values obtained mostly exceed by *ca.* 10% those achieved with cinchonidine.

Since the enantioselective hydrogenation of α-ketoesters over the Pt-cinchona catalyst system generally shows better performance (higher reaction rates and optical yields) under elevated hydrogen pressures, the effect of hydrogen pressure, on the present system was also studied. According to the literature[1] a wide hydrogen pressure (1–100 bar) was studied with acetic acid as solvent using the JMC94 catalyst and MeOHCD modifier.

7	AcOH	E4759	MeOHCD	0.55	(*R*)	87
8	AcOH	E4759	—	0.12	Racemic	—
9	AcOH	JMC94	CD	0.75	(*R*)	83
10	AcOH	JMC94	CN	0.46	(*S*)	66
11	AcOH	JMC94	MeOHCD	1.41	(*R*)	93
12	AcOH	JMC94	—	0.34	Racemic	—
13	Toluene	JMC94	MeOHCD	0.75	(*R*)	63

[a] CD = cinchonidine, CN = cinchonine, MeOHCD = 9-methoxy-10,11-dihydrocinchonidine.

The ee data indicate that the enantioselectivity of the reaction shows a slight hydrogen pressure dependence. Starting from 93% ee (1 bar H_2) the optical yields increased as a function of hydrogen pressure up to 96% ee. However, at 20 bar hydrogen pressure the enantiomeric excess seems to reach its maximum, and any further increase in hydrogen pressure does not result in higher optical yields. Under the same conditions (JMC94, MeOHCD, 20 bar) using dimethyl ester, the product was obtained in 90% ee. The (*S*)-isomer can also be prepared in 76% optical purity in the presence of CN-modified JMC94 catalyst at elevated hydrogen pressures (20–40 bar). Although the study currently is of an experimental nature, the kinetic data (Table 1)indicate that the mechanism is most likely similar to that proposed for ethyl pyruvate and other α-ketoesters. The cinchona-modified reactions all take place at higher rates than the modifier-free runs, resulting in a racemic product mixture. This phenomenon unambiguously indicates a ligand accelerated mechanism.[13] As a result, the highest enantioselectivity was obtained at the highest reaction rate (entry 11, Table 1).

Taking into account the practical importance of the products, one of them was prepared and isolated in preparative scale. Starting from 1.5 g of diethyl 2-ketoglutarate after the hydrogenation (20 bar) and cyclization, ethyl (*R*)-5-oxotetrahydrofuran-2-carboxylate was isolated in 80% yield and 94% ee optical purity.

In conclusion, the cinchona-modified Pt/Al_2O_3 catalytic system was found to be effective in the highly enantioselective hydrogenation of α-ketoglutaric acid esters providing the first satisfactory asymmetric synthetic route for the preparation of chiral alkyl 5-oxotetrahydrofuran-2-carboxylates which are frequently used as chiral building blocks. In addition, this work provides an opportunity to widen further the practical applications and potential of the Pt–cinchona catalytic system.

Received (in Cambridge, UK) 12th January 2000, Accepted 23rd February 2000
Published on the Web 17th March 2000

We report the first successful production and isolation of a new C_{80} isomer together with ^{13}C NMR structural and UV–VIS–NIR spectroscopic studies of the purified sample; ^{13}C NMR results unambiguously suggest that the new C_{80} isomer has an ellipsoidal structure with D_{5d} symmetry.

C_{80} has seven structural isomers satisfying the isolated pentagon rule (IPR).[1,2] However, owing to its extremely low abundance in arc-burning soot, this fullerene has long been known as one of the three 'missing' fullerenes[3] between C_{70} and C_{96} (the other two fullerenes are C_{72} and C_{74}).[3] It was not until recently that a small quantity of $C_{80}(D_2)$ was isolated by Henrich *et al.*[4] Here, we report the production, isolation and ^{13}C NMR structural analysis of a new C_{80} isomer.

Fullerene soot containing C_{80} was produced by the dc arc discharge method. Graphite/iron composite rods (12.5 × 12.5 × 300 mm, 0.7 atom% Fe/C, Toyo Tanso Co.Ltd.) were used for the arc discharge at 350 A and 23 V under a 12 l min^{-1} He flow (90–100 Torr). The resulting soot was succesively extracted with carbon disulfide and pyridine for 20 h. The separation of C_{80} was achieved by a multi-stage HPLC method[5,6] using a Buckyprep column (nacalai Cosmosil, 25 × 250 mm, toluene eluent) at 16.5 ml min^{-1} flow rate and a Buckyclutcher column (Regis, 20 × 300 mm) at 10 ml min^{-1} flow rate. The first stage was performed on the Buckyprep column which roughly separates C_{80}(I) and C_{80}(II) from other fullerenes by collecting the corresponding C_{80}-containing fractions. In the second stage, the HPLC fractions collected in stage 1 were re-injected into a 5PYE column (nacalai Cosmosil, 25 × 250 mm, toluene eluent) and recycling HPLC was performed. The third stage was again a recycling HPLC process on the Buckyclutcher column which can finally isolate C_{80}(I) and C_{80}(II) obtained from stage 2. The purity of the isolated samples [C_{80}(I): > 98%, *ca.* 5 mg; C_{80}(II): > 98%, *ca.* 2 mg] was determined by both positive and negative laser-desorption time-of-flight (LD-TOF) mass spectrometry.

On the 5PYE column, the C_{80} isomers I and II have different HPLC retention times. C_{80}(I) appears immediately after C_{78}. A ^{13}C NMR spectrum of this fullerene has already been reported by Henrich *et al.*[4] to have 20 near-equal signals, suggesting D_2 symmetry. C_{80}(II) has a much longer retention time than C_{80}(I) and appeared after C_{86}. The relative abundance of C_{80}(I) to C_{80}(II) is *ca.* 30 : 1. C_{80}(II) is light green in carbon disulfide solution. Fig. 1 shows the VIS–NIR absorption spectra of C_{80}(II) together with that of $C_{80}(D_2)$ for comparison. Aside from the relative intensity, the band positions in the two absorption spectra are similar. The characteristic peaks of $C_{80}(D_2)$ are seen at 420(sh), 466(sh), 596, 775, 860, and 882 nm, whereas for C_{80}(II) the main peaks are observed at 446(sh), 484(sh), 589, 606, 845 and 880 nm. C_{80}(II) shows a strong absorption band at *ca.* 600 nm which accounts for the greenish color of this fullerene in CS_2 solution.

Fig. 2 shows a ^{13}C NMR spectrum of C_{80}(II) in carbon disulfide solution with chromium(III) tris(acetylacetonate) as a relaxant and benzene-d_6 as the internal lock. The spectrum consists of a series of three distinct lines of near-equal intensity (lines 1,2,3) and two additional lines at half the intensity (lines 4* and 5*). The position of line 1 (δ 128.9) is very close to that of benzene-d_6 (δ 128.5). However, its characteristic fullerene linewidth (*ca.* 0.02 ppm) unambiguously distinguishes it from other solvent signals (linewidth > 0.1 ppm). We also performed ^{13}C NMR measurements by using acetone-d_6 instead of benzene-d_6 as an internal lock. The results confirm the five NMR lines and show that no C_{80} resonant lines were hidden by the benzene signals. The five signals cover a wide chemical shift range (δ 128.9–163.9), suggesting that C_{80}(II) has an ellipsoidal shape. C_{80} has seven IPR isomers (D_2, D_{5d}, C_{2v}, C_{2v}', D_3, D_{5h} and I_h)[2,4]. The present ^{13}C NMR result unambiguously assigns C_{80}(II) as the D_{5d} isomer (3 × 20; 2×10), where (a × b) indicates (number of NMR lines × relative intensity).

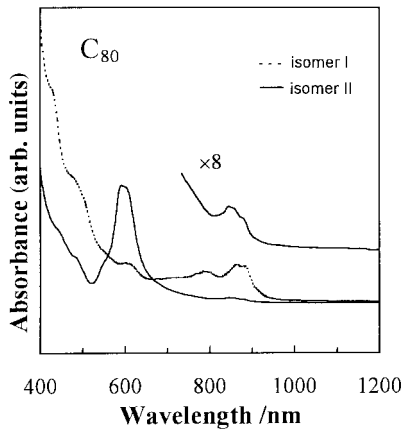

Fig. 1 VIS–NIR absorption spectra of C_{80}(I) and C_{80}(II) in CS_2 solution.

The most stable structure of C_{80} as D_{5d} is inferred from theoretical optimization by a nonlocal density function B3LYP/3-21G calculation using the Gaussian 98W program.[7] As shown in Fig. 3, $C_{80}(D_{5d})$ has an ellipsoidal structure with an aspect ratio (long axis/short axis) of *ca.*1.3. $C_{80}(D_{5d})$ can easily be obtained by adding one C_{10} ring on a half cap of $C_{70}(D_{5h})$ (*i.e.*, C_{30} or C_{40}) or adding two C_{10} rings successively on a $C_{60}(I_h)$ hemisphere (*i.e.*, C_{30}). As proposed by Curl,[8] $C_{70}(D_{5h})$ is formed by dissecting C_{60} into two C_{30} hemispheres along a suitable orientation (rotating one hemisphere 36° with respect to another hemisphere), and then by adding a ring of 10 carbon

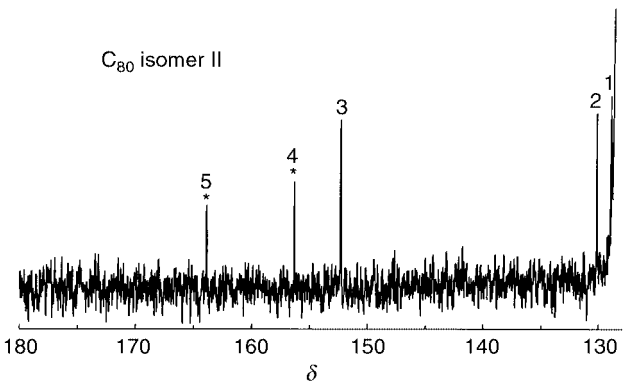

Fig. 2 ^{13}C NMR spectrum of purified C_{80}(II). The spectrum consists of five signals: 1(128.9, 13.9), 2(130.2, 12.7), 3(152.4, 12.2), 4*(156.3, 7.6), 5*(163.9, 6.0), in which (δ, I_{rel}) represent measured chemical shifts δ and relative intensity I_{rel}, and where lines indicated by * are half-intensity lines.

DOI: 10.1039/b000387p

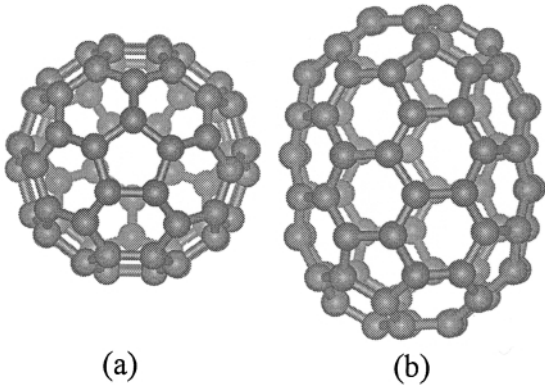

Fig. 3 The optimized structure of the $C_{80}(D_{5d})$ isomer based on *ab initio* calculation at the B3LYP/3-21G level by Gaussian 98W. (a) Top view along the main C_5 axis and (b) side view. The short/long axis ratio (a)/(b) is *ca.* 1/1.3.

atoms at the equator to combine the two hemispheres. The $C_{80}(D_{5d})$ fullerene is formed in a similar way by adding two C_{10} ring successively at the equator of C_{60} (*i.e.*, $C_{30} + C_{10} + C_{10} + C_{30}$). On going from $C_{60}(I_h)$ to $C_{70}(D_{5h})$ to $C_{80}(D_{5d})$, the fullerene structure, therefore, progressively acquires tubular and cap (hemisphere) parts, which leads to ^{13}C NMR lines spread over a wide range of chemical shift values.

The calculated energy ordering of the seven C_{80} isomers at the HF/Am1 level is: $D_5(D_{5d}) < D_2[+2.3] << C_{2v}[+23.6] < C_3(D_3)[+36] < C_s(C_{2v'})[+38.5] < C_s(D_{5h})[+49.9] << D_2(I_h)[+102$ kcal mol^{-1}], where the stabilization energies are given relative to the most stable $D_5(D_{5d})$ isomer.[4,9] The $D_5(D_{5d})$-C_{80} and D_2-C_{80} isomers are nearly isoenergetic and their relative energies are much smaller than those of the other five isomers. The currently isolated $C_{80}(D_{5d})$ is one of the most ellipsoidal fullerenes so far produced and isolated.

Published on the Web 17th March 2000

Through molecular dynamics and quantum mechanical/molecular mechanical calculations we found that differential charge distributions due to the enzyme and to the different solvents can determine the reactivity of subtilisin in different media.

The possibility to use enzymes in organic media[1,2] has widened the range of applicability of proteins to almost all synthetic organic reactions. In these media, the absence of a continuous aqueous layer around the enzyme makes it possible for it to interact directly with the non-aqueous solvent, which results in modifications of the properties of the enzyme in terms of stability, activity and specificity/selectivity:[2] thus, enzymes like hydrolases and proteases can catalyse esterification and transesterification readily and with high product yields.[1] Serine proteases like subtilisin have also been the subject of many computational studies involving either the investigation of their structure–activity relationships[3–5] or of their catalytic mechanism using different theoretical approaches.[6–8] In a previous paper[9] we have examined the origin of enantioselectivity of the serine protease subtilisin in DMF through the use of molecular dynamics (MD) and free energy perturbation (FEP) simulations. As a model reaction we studied the resolution of a racemic mixture of *sec*-phenethyl alcohol by transesterification reaction with the acylating agent vinyl acetate in organic solvents (Scheme 1, ESI data†). The transition state (in which enantioselectivity is determined) leading to the ester formation in organic solvents is the same as the one leading to ester hydrolysis in water, and is represented by the tetrahedral intermediates (Figs. 1 and 2). A critical aspect of our previous study was the determination of the charge distribution on the two (*R* and *S*) tetrahedral intermediates and on the residues of the catalytic triad through the use of a combined quantum mechanical/molecular mechanical (QM/MM) electrostatic potential (ESP) fitting methodology. Our approach could reproduce the experimental $\Delta\Delta G^*_{(S-R)}$ value very well thanks to the application of a flexible charge model for the two diastereomeric intermediates. The experimental $\Delta\Delta G^*_{(S-R)}$ resulted 0.4 kcal mol^{-1}, while the calculated value was *ca.* 1 kcal mol^{-1}.[9]

We now extend the QM/MM treatment to other two solvents: water and hexane. The program ROAR 1.0[10] was used to carry out all the calculations, with all-atom AMBER parameters for the protein,[11] OPLS parameters for the organic solvents[12] and TIP3P parameters for water.[13] The QM region for QM/MM ESP calculations comprised the substrate and the residues involved in catalysis (Ser 221, Asp 32, His 64, Asn 155). The PM3[14,15] Hamiltonian was used for the minimisation stage, while MNDO[14,15] was used for the ESP stage. We used the MNDO Hamiltonian for ESP fitting because MNDO has been shown to give ESP fitted charges that are well correlated to HF/6-31G* ESP derived charges, while PM3 does not.[14,15] The systems (*R* and *S* complex in the three different environments) were MD equilibrated for 300 ps, and the structures for QM/MM calculations were saved every 15 ps over the last 180 ps of MD.

Two enantiomers in an achiral environment have the same physico-chemical properties, and hence, the same charge distribution on the corresponding atoms. The same enantiomeric substances bound or complexed to the enzyme, however, experience a chiral environment, which gives rise to two diastereoisomeric complexes. Lipkovitz *et al.*[16] pointed out that chiral auxiliaries can induce a desymmetrization of the frontier orbitals at the reaction site, making them chiral as well. This desymmetrization will be reflected in the electron (*i.e.* charge) distributions. In the tetrahedral complexes we have studied, the two substrates are perturbed by the chiral environment determined by the enzyme and thus by differential electrostatic fields, giving rise to differential charge distributions on analogous atoms of the substrate in the complex.

The concept of 'electrostatic stereodifferentiation',[9] together with steric factors, can be important in the determination of the energy difference between the two transition states leading to selectivity. The availability of QM/MM electrostatic potential fitting methods allows us to carefully take this aspect into consideration, by explicitly considering polarization and charge transfer effects due to the solvents (water, DMF, hexane).

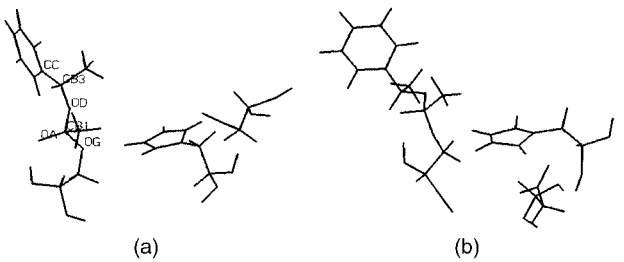

Fig. 1 Representation of the equilibrated *S* (a) and *R* (b) tetrahedral intermediates in organic solvents.

† Electronic supplementary information (ESI) available: average charge values for the reactive intermediate of Scheme 1. See http://www.rsc.org/suppdata/cc/a9/a909680i/

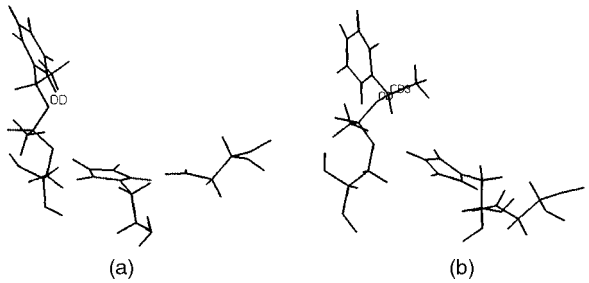

Fig. 2 Representation of the equilibrated *S* (a) and *R* (b) tetrahedral intermediates in water.

DOI: 10.1039/a909680i

The steric factors in the two organic solvents resulted very similar. Once the complex is equilibrated the phenyl group of the *S*-substrate fits very nicely into a hydrophobic pocket defined by residues 126, 127, 128 and Asn 155, in both DMF and hexane [Fig. 1(a)]. For the *R*-enantiomer [Fig. 1(b)] the phenyl ring is oriented towards the surrounding solvent, giving rise to favourable hydrophobic solvation interactions with the organic environment. The methyl group of the alcoholic moiety of the *R*-complex is now pointing into the hydrophobic pocket, and in total, these rearrangements contribute to disrupt the catalytically essential H-bonds (OD to HE2). We will show later on that this can have important consequences in terms of charge distribution.

In water, the phenyl ring tends to be removed from the unfavourable contact with the polar hydrogen bonding solvent, and resides in the hydrophobic pocket for both *R* and *S*-complexes. The methyl groups point towards the solvent. The difference in the two structures can be found in the conformation around the OD–CB3 bond. In the *S*-complex, the phenyl ring is in *anti*-conformation with respect to the rest of the bulky tetrahedral intermediate, while, for the *R*-complex, it assumes a more hindered and unfavourable *gauche*-conformation. The energetically unfavourable conformation of the *R*-complex will be a factor in depressing the reactivity of this enantiomer. The diastereoisomeric arrangement that determines the steric differences will be reflected in the charge distributions on the atoms which are directly involved in the formation (organic solvents) or disruption (water) of the tetrahedral intermediate (Table 1, ESI data†). Moreover, not only do we notice differences between enantiomers, but also on the same atoms of the same enantiomer in different solvents. In particular this is true for the stereogenic center CB3 and the atoms forming its environment. In fact, CB3 shows a charge value for the *S*-complex in water which is lower than in the two organic solvents. The same consideration applies also to CB3 in the *R*-complex, even if the charge differential among the solvents is less pronounced in this case. The case of CC (phenyl atom directly bound to the stereocenter) is also representative of this solvent effect for the *S*-complex: the charge on CC has a value of 0.11 in water and is negative for both hexane and DMF. For the *R*-complex the charges for this atom are very similar. Small but noticeable differences due to solvent effect can be noticed in HB3, as well. We believe that all these effects involving the differentiation of charges on analogous atoms of the same enantiomer in different solvents is mainly due to the differential polarising characteristics of the solvents.

When the same solvent environment is considered, the most dramatic differences between analogous atoms of the two enantiomers can still be noticed on the stereogenic (CB3) center and in the atoms around this center. This factor can be ascribed to the stereodifferentiating environment determined by the enzyme. In particular, we notice that the alcoholic OD has a higher charge concentration (*i.e.* more negative charge) in all solvents for the *S*-complex. On the other hand, a higher concentration of positive charge is localized on the tetrahedral carbon (CB1) in the *S*-complex in all solvents. This makes the CB1–OD bond (the one formed in organic solvents and cleaved in water) more highly polarised in the transition state leading to the *S*-product. A higher concentration of negative charge on the nucleophilic atom, coupled with a higher positive charge on the electrophilic carbon (CB1), will favour the approach between the alcoholic moiety and the acyl enzyme in the absence of other nucleophiles. Moreover, the higher negative charge concentration on OD will favour the formation of a stable hydrogen bond between OD and the acidic HE2 hydrogen on His 64 for the *S*-complex (the average distance between OD @Ser 221–HE2 @His 64 in this case is 2.6 ± 0.6). On the other hand, in the *R*-complex, the catalytically essential hydrogen bond is disrupted because of both steric and charge factors: OD is, in fact, less negative than in the *S*-complex case. These observations suggest that, in the transesterification reaction the *R*-alcohol cannot readily donate its proton to the catalytic residue His 64, which is essential for catalysis.[17] For hydrolysis this very factor will favour the cleavage of the reactive bond, by concentrating more negative charge on the more electronegative carbon (OD), in the tetrahedral intermediate for *S*-complex. A smaller polarization is found for the CB1–OD bond in the *R*-complex in all solvents. This will slow down the corresponding reaction leading to the preferential synthesis or hydrolysis of the compounds with *S* absolute configuration. By considering the charge distribution, we can garner deeper insights into how the electrostatically stereodifferentiating environment imposed by the enzyme can influence reactivity and selectivity. Our results are in agreement with, and help us rationalize, the experimental observation of reactivity in several environments.[18]

Summarising, we showed that steric and electrostatic factors play an important role in determining asymmetric induction and selectivity for enzymes in different environments. The application of QM/MM simulation techniques can be of valuable help in identifying the residues near the active site and of the binding pocket which are important for catalysis. The steric differentiation between two bound enantiomers can thus be magnified by mutating non-bulky residues of this region to sterically demanding ones. Maximising the charge differential between the two tetrahedral intermediates through mutations of non-polar to polar residues, which are involved in recognition, can also improve selectivity. Finally, focussing on the solvation patterns of the two simulated bound intermediates can help us find solvents which could better solvate the exposed parts of one of the two enantiomers.

We thank the Biotechnology Programme of the European Commission and the National Research Council of Italy (CNR) Target Project on Biotechnology for funding.

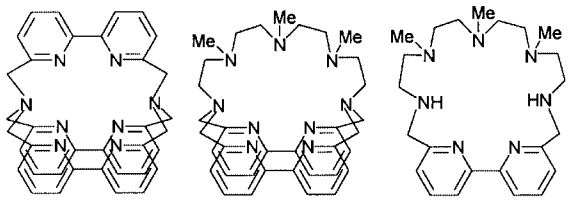
Received (in Cambridge, UK) 6th December 1999, Accepted 22nd February 2000
Published on the Web 17th March 2000

The luminescence emission of a new dipyridyl-containing Eu(III) cryptate complex is modulated by pH, due to protonation of the polyamine chain strategically inserted within the ligand backbone.

The use of europium and terbium complexes as luminescent labels in fluoroimmunoassay is limited by the fact that they have extremely low absorption coefficients.[1] This drawback can be overcome through encapsulation of the metal inside the cavity of phenanthroline or dipyridyl-containing cryptands.[2] These moieties contain two nitrogen donors which act as binding sites for the metal cation and can efficiently protect the metal from the solvent, especially in aqueous solution where metal-bound water molecules may act as quencher of the emission. In addition, these efficient chromophore units allow the collection and transfer of electronic energy to the metal.[1] A further development of this study is the design of water-soluble cryptate complexes whose fluorescence emission can be modulated by pH. To this purpose we have synthesized the new cryptand **L**.



1 **L** **2**

The major difference from previously reported dipyridyl-containing cryptands, such as **1**,[1,2] is the strategic insertion in **L** of a polyamine chain within the ligand backbone, which connects the two dipyridyl chromophore units. We hoped that this ligand could be able to lead to a stable Eu(III) cryptate complex in aqueous solution. At the same time, the aliphatic amine groups, which are more basic than heteroaromatic nitrogens,[3] may be protonated, leading to protonated cryptate complexes.

Ligand **L** was obtained, as the sodium complex, [Na⊂**L**]ClO_4, by reaction of 2,2′-bis(bromomethyl)dipyridyl[4] with the macrocyclic precursor **2** (MeCN, Na_2CO_3, reflux). The latter was obtained by condensation of 2,2′-bis(bromomethyl)dipyridyl with 1,13-ditosyl-4,7,10-trimethyl-1,4,7,10,13-pentaazatridecane,[5] by using the procedure of Richman and Atkins.[6] Reaction of [Na⊂**L**]ClO_4 with $EuCl_3$ (1:1 molar ratio) in aqueous solution (pH 3, 100 °C, 24 h) affords the protonated complex [$EuCl_3$⊂$\mathbf{L}H_2$]$(ClO_4)_2 \cdot 4H_2O$ in 64% yield.†

The crystal structure of $[EuCl_3 \subset \mathbf{L}H_2]^{2+}$ **3** (Fig. 1)‡ shows the metal enclosed within the cryptand cavity, coordinated by the dipyridyl nitrogens N(2), N(3), N(5) and N(6) and by the two bridgehead amine groups N(1) and N(4). The polyamine chain N(7)–N(8)–N(9) is not coordinated, due to binding of the two acidic protons within this triamine subunit. The Eu(III) cation completes its coordination environment by binding three chloride anions. The coordination geometry is best described as a distorted tricapped trigonal prism, the two basal planes being defined by N(5), N(6) and Cl(1) and N(2), N(3) and Cl(2), respectively. The capped positions are occupied by the N(1), N(4) and Cl(3) donors. It is also of interest that, although the metal is lodged inside the cryptand cavity, the protonated ligand leaves free binding sites at the metal, available for the binding of exogenous species, such as chloride anions in the present structure. Most likely, water molecules replace these anions in aqueous solutions in the absence of chloride.

The Eu(III) cryptate complex can be obtained in aqueous solution by addition of $Eu(ClO_4)_3$ to [Na⊂**L**]ClO_4 (1:1 molar ratio, 60 °C, 12 h at pH 7); the luminescence spectrum of the europium cryptate in aqueous solution shows the characteristic visible emission of the complexed metal (λ_{max} = 617 nm) which mainly arises from intramolecular transfer to the metal ion from the highest energy triplet state of the cryptand.§ The

DOI: 10.1039/a909581k

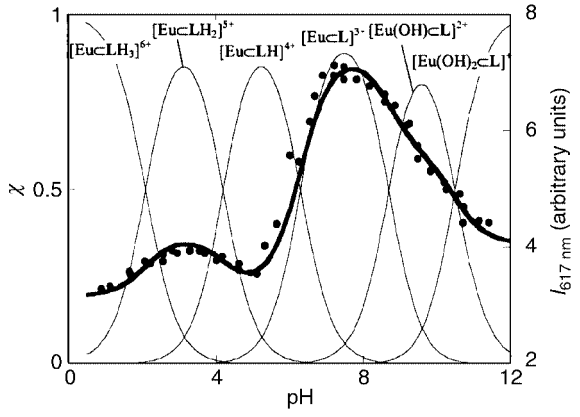

Fig. 2 Luminescence emission (●) of the Eu(III) complex with **L** (λ_{exc} = 260 nm; λ_{em} = 617 nm, [**L**] = [Eu^{3+}] = 5×10^{-5} M, T = 300 K) and calculated molar fractions of the Eu(III) complexes (——) as a function of pH.

luminescence emission, however, is strongly affected by pH, displaying a maximum at neutral pH and significant decreases both at acidic and alkaline pH, as shown in Fig. 2. pK_a values of 2.1, 4.2, 6.3, 8.7 and 10.5 for the Eu(III) complex can be derived from the titration curve in Fig. 2 by least-squares analysis using the bracketing technique.[7]¶ Most likely, the first three constants correspond to protonation of the complex to give [Eu⊂**L**H$_n$]$^{(n+3)+}$ (n = 1–3) species at acidic pH. This process involves the aliphatic polyamine chain, as strongly supported by the crystal structure of the [EuCl$_3$⊂**L**H$_2$]$^{2+}$ cation. Protonation does not allow the amine groups to bind to the Eu(III) cation, and, therefore, the ligand donors do not fulfill the coordination sphere of the metal. The resulting free binding sites at the metal are occupied by water molecules, which can quench the luminescence of the complex. This hypothesis is confirmed by the analysis of the lifetimes (τ) of the Eu(III) cryptate at different pH values in H_2O and D_2O at 300 K. For instance, at pH 2, τ = 0.39 ms in H_2O and 1.4 ms in D_2O, while, at pH 6.8, τ = 0.52 and 1.34 ms in H_2O and D_2O, respectively. These data account for the coordination of *ca*. two water molecules at pH 2 and just one at pH 6.8.[8] Binding of amine groups in the unprotonated [Eu⊂**L**]$^{3+}$ complex gives a more 'protected' metal cation from the solvent molecules, thus enhancing the luminescence emission, with a maximum at pH 7.2. Finally, the observed decrease of the emission at alkaline pH is due to the formation of the hydroxylated species [Eu(OH)⊂**L**]$^{2+}$ and [Eu(OH)$_2$⊂**L**]$^+$, with pK_a values of 8.7 and 10.5, respectively. Binding of hydroxide anions to Eu(III) gives rise to a quenching of the emission.

The spectral features of the present complex are similar to those reported for other dipyridyl-containing Eu(III) cryptate complexes.[1,2,9] At pH 6.8, the quantum yield (Φ = 0.014 at 300 K), the radiative rate constant (k_r = 746 s^{-1}), the non-radiative temperature independent rate constant due to the coupling with the high-energy O–H oscillators [k_{nr}(OH) = 1177 s^{-1}], and the temperature dependent decay rate constant [$k_{nr}(T) \cong 0$], are somewhat lower than those found for [Eu⊂**1**]$^{3+}$, as expected considering the replacement of a dipyridyl chromophore unit of **1** by an aliphatic polyamine chain in **L**. The present complex, however, still remains an efficient luminescent system. At the same time, the pH dependence of the emission intensity is a novel characteristic of our cryptate complex, which can be defined a 'pH modulated antenna device'.

§ Fluorescence emission spectra at different pH values were recorded on solutions with [**L**] = [Eu^{3+}] = 5×10^{-5} M using a SPEX F111 Fluorolog spectrofluorimeter.

¶ The total emission intensity at each pH value is given by $\Sigma_i c_i \chi_i$, where c_i is a constant proportional to the quantum yield and χ_i the molar fraction of the ith species. The c_i and χ_i values were calculated by least squares fitting of the emission data collected at different pH values. The pK_a values were then derived from the calculated χ_i. The fitting was carried out by using the emission intensity at 617 nm with an excitation wavelength of 260 nm. Absolute quantum yields were calculated by least squares fitting of the integrals of the emission spectra at each pH value, using the fluorescence emission of [Ru(bpy)$_3$]$^{2+}$ as reference: [Eu⊂**L**H$_3$]$^{6+}$, 0.0022; [Eu⊂**L**H$_2$]$^{5+}$, 0.0098; [Eu⊂**L**H]$^{4+}$, 0.00014; [Eu⊂**L**]$^{3+}$, 0.014; [Eu(OH)⊂**L**]$^{2+}$, 0.011; [Eu(OH)$_2$⊂**L**]$^+$, 0.0014.

A novel alkoxide bridging motif between boron trifluoride and copper(II) in a crown thioether complex

Liam R. Sutton, Alexander J. Blake, Paul A. Cooke and Martin Schröder*

School of Chemistry, The University of Nottingham, Nottingham, UK NG7 2RD.

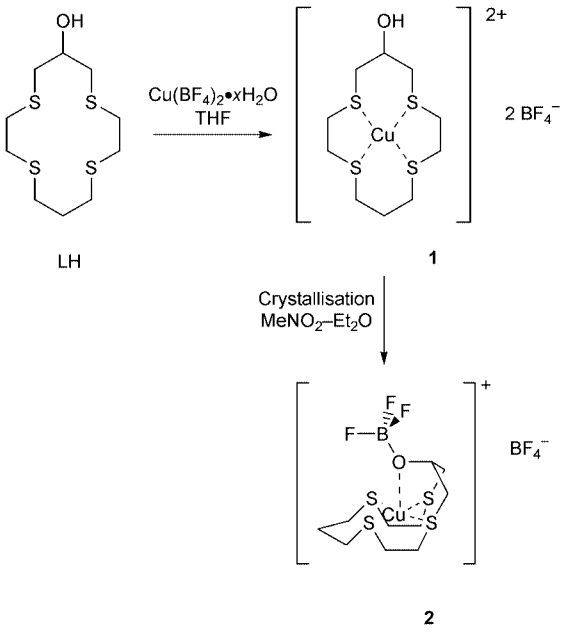
Received (in Cambridge, UK) 3rd November 1999, Accepted 19th January 2000

Reaction of 6-hydroxy-1,4,8,11-tetrathiacyclotetradecane (LH) with $Cu(BF_4)_2$ in THF yields $[Cu(LH)](BF_4)_2$; crystallisation of the complex from $MeNO_2/Et_2O$ gives brown crystals of $[Cu(LBF_3)](BF_4)$, the first example of alkoxide bridging between BF_3 and a metal centre.

The synthesis and coordination chemistry of crown thioethers has become well established over the past two decades[1] with many complexes of the transition metals, from titanium to mercury, having been reported.[2] We have been interested in the functionalisation of thioether crowns[3] in order to couple their coordination behaviour to desirable physical and/or chemical properties, with a particular interest in developing macrocyclic metallomesogens.[4] Because such modification must take place on the carbon backbone we have been studying the organic and coordination chemistry of a number of functionalised crown thioethers including 6-hydroxy-1,4,8,11-tetrathiacyclotetradecane (LH)[5] so that we might better understand the interplay between the macrocyclic core and the pendant functionality.

Addition of a colourless solution of LH in THF to a pale green solution of a slight excess of $Cu(BF_4)_2$ hydrate in THF immediately affords a fine dark green precipitate which was isolated in 85% yield (Scheme 1). IR spectroscopic, FAB mass spectrometric and microanalytical data for this product are in accord with the stoichiometry $[Cu(LH)](BF_4)_2$, **1**.† Compound **1** appears to be unstable in MeCN and $MeNO_2$ to give very dark brown solutions. Deep brown crystals suitable for X-ray diffraction were formed over several days by the diffusion of Et_2O vapour into a solution of **1** in $MeNO_2$ and a single crystal structural determination‡ was undertaken in order to confirm the structure of the product. The single crystal X-ray structure determination (Fig. 1) confirms the formation of $[Cu(LBF_3)]BF_4$, **2**, in which one of the BF_4^- anions from **1** has condensed with the $[Cu(LH)]^{2+}$ cation, eliminating HF. Presumably, HF goes on to combine with the glass walls of the vials used for crystallisation forming Si–F bonds which provide the thermodynamic driving force for the reaction. Interestingly, attempted crystallisation of $Ni(BF_4)_2$ with LH from MeOH–Et_2O resulted in the quantitative formation of $[Ni(MeOH)_6]SiF_6$ (confirmed by single crystal X-ray structural analysis) supporting the mechanism postulated.



Scheme 1

Microanalytical data obtained from the sample of **2** from which the crystal was drawn, in concert with the difference in colour of **1** and **2**, indicate that conversion of **1** to **2** occurs quantitatively.§ Further evidence that **1** is different to **2** is provided by the powder X-ray diffraction pattern (Fig. 2) obtained from **1**, which is different to that calculated for **2**. Compound **2** is unstable in air, with hydrolysis *via* atmospheric moisture affording a product tentatively assigned as $[Cu(LH)](BF_4)(BF_3OH)$, which exhibits a similar electronic spectrum to **1**.

The monocation $[Cu(LBF_3)]^+$ in **2** adopts a square-pyramidal geometry at Cu(II) which is somewhat distorted by the steric restrictions imposed by the macrocyclic ligand, with Cu, B(1), O(6), C(6) and C(13) lying on a crystallographic mirror plane. The Cu–S distances of 2.2677(15) and 2.3312(15) Å in **2** are similar to those observed[6] in $[Cu([14]aneS_4)]^{2+}$, with the Cu–O(6) distance of 2.311(5) Å in the five coordinate complex **2**

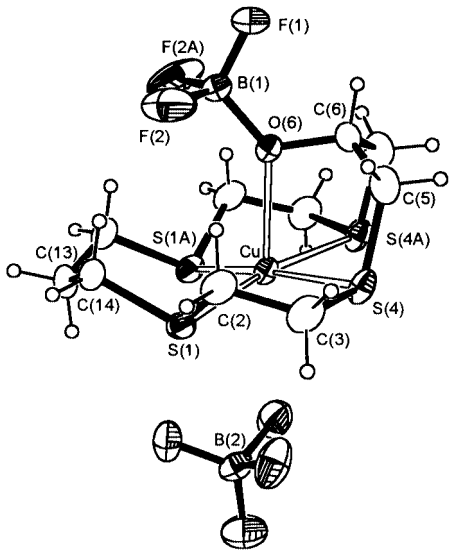


Fig. 1 View of the structure of **2** with numbering scheme adopted. Selected bond distances (Å) and angles (°): Cu–S(1) 2.2677(15), Cu–S(4) 2.3312(15), Cu–O(6) 2.311(5), B(1)–O(6) 1.441(10), O(6)–C(6) 1.419(9); S(1)–Cu–S(1A) 95.32(8), S(1)–Cu–S(4) 88.58(6), S(4)–Cu–S(4A) 86.43(8), S(1)–Cu–O(6) 103.29(9), S(4)–Cu–O(6) 83.71(10), Cu–O(6)–B(1) 139.2(4), Cu–O(6)–C(6) 100.0(4), B(1)–O(6)–C(6) 120.8(6). Minor parts of disorder omitted for clarity. Atoms carrying the suffix A are related to the corresponding unsuffixed atoms across a crystallographic mirror plane by $x, -y + 3/2, z$.

DOI: 10.1039/a908778h

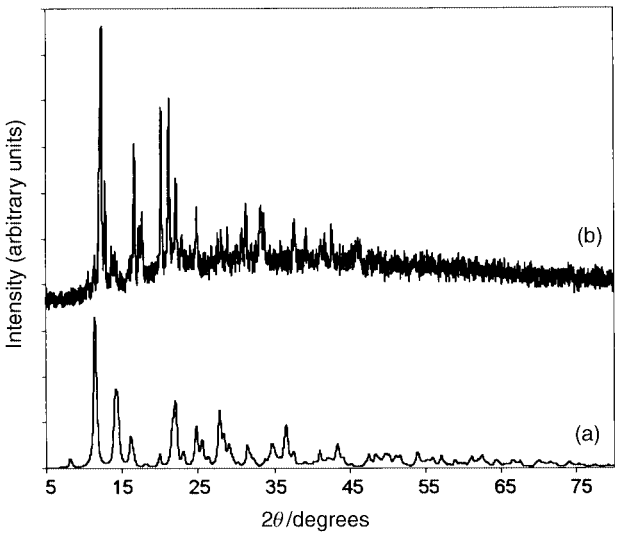

Fig. 2 Powder X-ray diffraction patterns: (a) calculated for **2** from crystal data[13] and (b) recorded for **1** (Philips X-pert diffractometer; PW3710 diffractometer control unit; Cu-*K*α radiation source at 40kV/40mA; step size 0.02° (0.4 s per step); 2θ range 5–80°; divergence slit 1° and receiving slit 2°).

some 0.131 Å shorter than in the related [Cu(*trans*-6,13-dihydroxy[14]aneS$_4$)](ClO$_4$)$_2$ where O atoms occupy the two axial sites of a Jahn–Teller distorted octahedral Cu(II) centre.[7] This reflects the greater electrostatic interaction expected for the five coordinate Cu(II) centre in **2** with an apical alkoxide ligand compared to the six coordinate analogue. The apical O-donor in **2** bridges to a disordered BF_3 moiety, O(6)–B(1) 1.441(10) Å which exhibits a rigorously planar geometry. The unconstrained B(1)–O(6)–C(6) angle of 120.8(6)° and the fact that the relevant atoms lie on a crystallographic mirror plane indicate sp^2 hybridisation at O(6), supporting the designation of this oxygen as a bridging alkoxide.[8]

Significantly, the structure of **2** represents the first example of an alkoxide bridge between BF_3 and a metal ion to be confirmed crystallographically. Hydrolysis of BF_4^- to give $BF_3(OH)^-$ is not uncommon and several examples of coordination of this anion *via* bridging hydroxide have been reported.[9] Alcoholysis has also been observed yielding, for example, the $BF_3(OEt)^-$ anion, which has not been seen to coordinate further.[10] A small number of adducts of BF_3 and carbonyl compounds have been isolated[11] due to the interest in the use of Lewis acids to activate such compounds. However, examples of trigonal oxygen in BF_3–alcohol adducts such as the MeOH·BF_3 are rare,[12] and the structure of **2** represents, to our knowledge, the first example of alkoxide bridging between BF_3 and a metal centre.

The short Cu–O(6) distance in **2** affords boat conformation for the Cu–S(4)–C(5)–C(6)–C(5A)–S(4A) chelate ring. We conclude that the stereochemistry and conformation of the complexed macrocycle is a key factor governing the formation of the novel bridging motif observed in **2**, the macrocyclic core allowing O(6) to adopt a position where stabilising interactions with both BF_3 and Cu(II) are possible. The crown thioether macrocycle, therefore, provides a covalently attached S_4-donor set which supports the close approach of Cu(II) to the alkoxytrifluoroborate O-centre, resulting in the unusual structure observed.

We thank the EPSRC for support and Dr David Rees for assistance with X-ray powder diffraction.

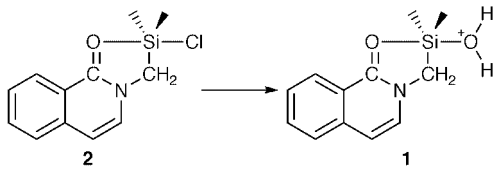
Received (in Basel, Switzerland) 29th November 1999, Accepted 23rd February 2000
Published on the Web 17th March 2000

Careful hydrolysis of a pentacoordinate chlorosilane gives a pentacoordinate protonated silanol that resembles the intermediate in the aqueous hydrolysis of silanes.

One of the key areas of organosilicon chemistry is the study of the mechanism of nucleophilic substitution and in particular the mechanism of hydrolysis of chlorosilanes.[1] Application of crystal structure correlation has shown that formation of the nucleophile–silicon bond is accompanied by lengthening of the silicon-leaving group bond and formation of a trigonal bipyramidal structure with the non-participating groups equatorial.[2] Many model pentacoordinate silicon species have now been prepared and characterised using X-ray crystallography.[1c,3] Although a range of ligands have been used to form hypervalent silicon species, we are unaware of any that contain a water molecule as a coordinating ligand. Such elusive species are highly desirable since they mimic the intermediate and/or activated complex for the hydrolysis of silanes.

Here we report the preparation and characterisation of a protonated hypervalent silanol, **1**. Careful hydrolysis of the quinoline derivative **2**[4] in acetonitrile followed by slow, partial evaporation of the solvent led to colourless, needle-like crystals of **1** (Scheme 1).



Scheme 1

The crystal structure (Fig. 1) shows that there is chloride in the crystal, but it is not bonded directly to the silicon.[5] The closest contact between the silicon and the chlorine atoms is 4.39 Å. By comparison, a typical Si–Cl bond distance is 2.03 Å and the sum of the van der Waals radii for Si and Cl is 3.85 Å. The Si–O bond length corresponding to the protonated silanol is 1.9114(14) Å. An additional oxygen atom (O3) is also present in the unit cell. The closest silicon atom to O3 is 3.97 Å away while a typical Si–O distance is 1.63 Å[6] and the sum of the van der Waals radii for Si and O is 3.62 Å.

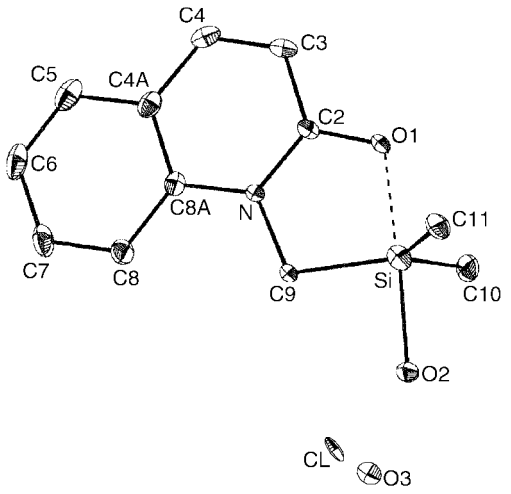


Fig. 1 Structure of **1** in the crystal. Selected bond distances (Å) and bond angles (°): Si–O1 1.9604(14), Si–O2 1.9114(14), Si–C9 1.8726(19), Si–C10 1.856(2), Si–C11 1.867(2), O1–Si–O2 174.62(7), N–C9–Si 106.54(13), O1–Si–C9 86.53(8), O2–Si–C9 88.14(8), C9–Si–C10 118.62(10), C9–Si–C11 119.43(10), C10–Si–C11 121.85(9).

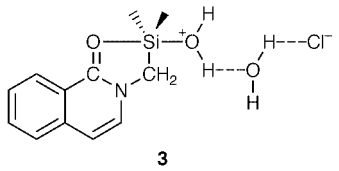
The X-ray analysis revealed the positions of all the hydrogen atoms which show that O2 is part of a water molecule which is bonded to the silicon. This water molecule is hydrogen bonded to a second water molecule containing O3, which in turn is hydrogen bonded to a chloride ion, as shown in **3**. The other



3

alternative involving a molecule of hydrogen chloride hydrogen bonded to a water molecule which in turn is hydrogen bonded to a hypervalent silanol is ruled out by the bond distances. The covalent O–H bond distances in **3** are between 0.82 and 0.99 Å, and the O···H hydrogen bond distances are between 2.6 and 3.1 Å.

Solid state silanol structures which do not involve any hydrogen bonding are known but are comparatively rare.[7] Thus, intermolecular hydrogen bonding in silanols has been extensively studied and shown to take many forms.[8] For example, diisopropylsilanediol,[9] exists as hydrogen bonded dimers which are linked together in ladder chains by further hydrogen bonds, and tris(trimethylsilyl)silylsilanetriol[10] forms hexameric cages of hydrogen bonds. As expected, there is extensive intermolecular hydrogen bonding throughout the crystal of **1**. Each of the hydrogen atoms associated with the two water molecules are involved in hydrogen bonding and each chlorine is hydrogen bonded to three hydrogens, as shown in Fig. 2. Effectively there are ladders of hydrogen bonding running through the structures.

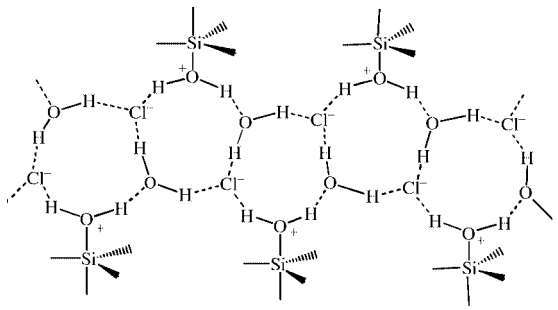


Fig. 2 The arrangement of hydrogen bonding within a crystal of **1**.

DOI: 10.1039/a909504g

These are made of puckered, fused 10-membered rings with hydrogen atoms in alternate positions. The chains extend indefinitely in parallel along the *y*-axis repeating every 7.22 Å. Along the *z* axis the chains stack one above the other in an 'AB' fashion, repeating every 21.45 Å. In the *x* direction the chains stack side by side in a repeating 'AA' manner every 9.13 Å. Hydrogen bonding is confined to within a chain.

The Si–O2 distance observed, [1.9114(14) Å] is, as expected, somewhat longer than that for a traditional Si–O bond. Reed and coworkers have recently reported the crystal structure of a protonated tetracoordinated silanol complex, $[Bu^t_3Si(OH_2)]^+[Br_6CB_{11}H_6]^-$[11]. The Si–O distance in this compound is 1.78 Å, which is longer than that of a standard Si–O bond, reflecting the fact that the silanol is protonated. The Si–O2 bond distance in the hypervalent species **1** is greater than that observed for the protonated silanol as a result of the axial bond length distortion that is expected in five-coordinate silicon complexes.[2]

The Si–O1 bond distance in **1** is 1.9604(14) Å, similar to that for Si-O2. This suggests that the structure resembles a point on the reaction profile where the extent of bond formation is equivalent to that of bond breaking. In the absence of ring strain the structure should be perfectly trigonal pipyramidal. This is confirmed by the fact that the three equatorial substituents and the silicon atom effectively all lie in the same plane. The sum of the three C_{eq}–Si–C_{eq} bond angles, 359.9°, is very close to the 360° expected. The sum of the C–Si–C bond angles in Reed's protonated silanol was 348°, that is, significantly distorted from a trigonal bipyramidal structure and moving towards a tetrahedral species. The larger value observed by Reed and coworkers suggests that the protonated silanol has some characteristics reminiscent of a silyl cation complexed by a water molecule.[12] In this context **1** has some of the features of a silyl cation complexed by two oxygen atoms, but is better described as a covalently bonded trigonal bipyramidal molecule.

Macharashvili and coworkers have used a series of pentacoordinate silicon species involving amide ligands to map nucleophilic substitution at silicon.[2b] The maximum extent of pentacoordination was observed for the chloride derivative where the carbonyl oxygen–silicon bond distance was *ca.* 1.95 Å. This is very close to the Si–O1 bond distance in **1**, confirming that maximum pentacoordination is achieved with two equivalent axial Si–O bond distances.

We thank the EPSRC for financial support for D. J. P.

The vitamin C route to the ciguatoxins: enantioselective synthesis of a ring F building block

Silas Bond and Patrick Perlmutter*

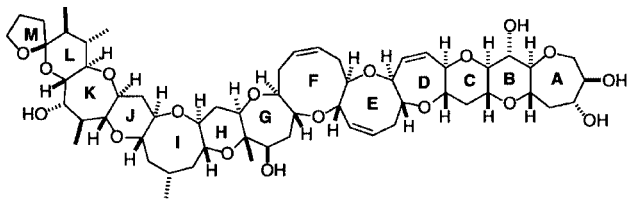
Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia.
E-mail: Patrick.Perlmutter@sci.monash.edu.au

Received (in Cambridge, UK) 21st December 1999, Accepted 2nd February 2000
Published on the Web 17th March 2000

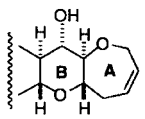
A ten-step enantioselective synthesis of an F ring lactone for CTX antibody assay development, employing vitamin C as a starting material, is described.

Ciguatera, a disease caused by consumption of ciguateric fish (*i.e.* those fish which have accumulated ciguatoxins (CTXs) in their flesh as a result of ingesting *Gambierdiscus toxicus*, a benthic dinoflagellate which synthesizes these toxins) is endemic throughout the tropics.[1] Consequently there is a need to develop a simple assay for the presence of these toxins in fish. Because of the very low concentrations (<0.1 ppb) of ciguatoxins in fish such an assay will need to be highly sensitive, such as an immunoassay.[2] Hence as part of a program[3] directed towards the synthesis of immunogenic domains of the CTXs, we report here, the enantioselective synthesis of a ring F building block.[4]

From a synthetic point of view, the ciguatoxins constitute one of the most synthetically challenging classes of naturally occurring marine toxins.[5] Each of these toxins consists of thirteen contiguous, fused cyclic ethers ranging in size from five to nine members. The structures of two potential targets, the Pacific ciguatoxins 2,3-dihydroxy-P-CTX-3C **1a**[6] and P-CTX-3C **1b**[7] are shown in Fig. 1.



1a 2*R*,3*R*-Dihydroxy-P-CTX-3C



1b P-CTX-3C

Fig. 1 The structures of two Pacific ciguatoxins: P-CTX-3C and 2,3-dihydroxy-P-CTX-3C.

We envisaged the ring F target to be of general structure **4** (Fig. 2). This nine-membered lactone has the correct relative and absolute stereochemistry in place as well as a reactive lactone carbonyl. Related oxoninones have been shown to be valuable intermediates in natural product synthesis.[8–10] In principle **4** should be accessible from vitamin C **2** *via* bicyclic lactone **3** (Fig. 2). Indeed an intermediate bicyclic *ether*, similar to **3**, has recently been reported by Hirama's group to be a very useful intermediate in CTX synthesis.[11]

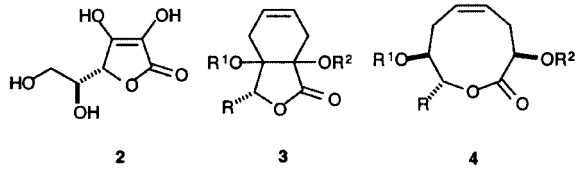


Fig. 2 The structures of vitamin C **2** and two key synthetic targets.

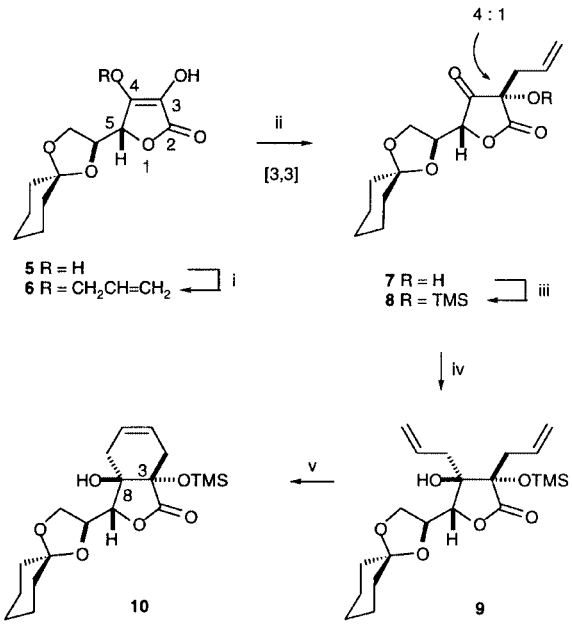
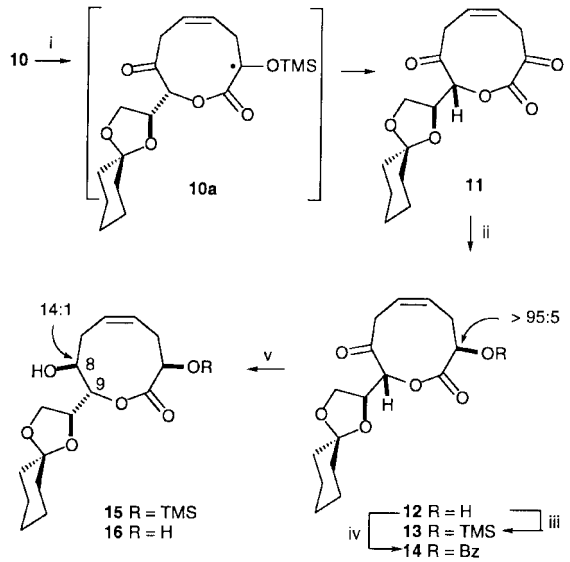
The synthesis of **4** is shown in the Schemes and begins with the cyclohexylidene acetal **5** of vitamin C (Scheme 1). (The corresponding acetonide[12] was employed initially, however it proved to be insufficiently robust in subsequent transformations). Selective *O*-allylation of the C4 hydroxyl of **5** in preference of the hydroxyl at C3, using potassium carbonate/THF–DMSO/allyl bromide, has been reported for vitamin C acetonide.[12] Unfortunately under these conditions we were not able to obtain **6** sufficiently pure for further reactions. Selective C4 *O*-allylation of **5** was ultimately achieved by treatment with allyl bromide in aqueous THF maintaining neutral to slightly alkaline pH. The corresponding *C*-allyl derivative **7** was obtained as a 4 : 1 mixture of diastereomers by heating a toluene solution of **6** at reflux for 6 h. Next it was necessary to generate a diene from **7** which could be closed under ring closing metathesis conditions. Addition of a variety of allyl nucleophiles to **7** gave mixtures of diastereomers which proved very difficult to purify. After considerable experimentation it was found that addition of allylzinc bromide to the *O*-trimethylsilyl derivative **8** (obtainable as a single diastereomer, after purification, by silylation of crude **7**) gave pure diene **9** in excellent yield and complete diastereoselectivity. The preference for attack from the *Si*-face at C4 is probably due to a combination of steric hindrance from the C3 allyl group and coordination to the oxygens at C3 and/or those contained in the side chain acetal. Although the stereochemistry at C3 and C4 is lost later it



Scheme 1 *Reagents and conditions*: i, K_2CO_3, allyl bromide, DMSO–THF, r.t., 6 h or allyl bromide, 1 M NaOH–THF pH 7–8, r.t., 24 h; ii, toluene, reflux, 6 h; iii, TMSCl, imidazole, THF, r.t., 2 h, 20% as a single isomer from **5**; iv, allylzinc bromide, THF, r.t., 30 min, 94%; v, RuCHPh(P-$Cy_3)_2Cl_2$, toluene, 60–70 °C, 24 h, 69%.

DOI: 10.1039/a910163m



Scheme 2 *Reagents and conditions*: i, HgO, I_2, benzene, *hν*, reflux, 8 h; ii, $NaCNBH_3$, AcOH, *ca.* 13 °C, 20 min, 43% from **10**; iii, TMSCl, imidazole, THF, r.t., 12 h, 99%; iv, $(PhCO)_2O$, Et_3N, DMAP, THF, r.t., 2 h, 99%; v, 1 M LiB[CHMe(Et)]$_3$H, THF, *ca.* −130 °C, 30 min, 73%.

proved operationally more practicable to handle a single stereoisomer through the next sequence of reactions. Thus ring closing metathesis[13] of **9** gave bicyclic lactone **10** in excellent yield. This crystalline product was subjected to single crystal X-ray analysis and the relative stereochemistry of the new stereogenic centres at C3 and C8 was confirmed to be as shown.

Oxidative ring opening of **10**, following adaptations of the conditions of O'Dell *et al.*[14] and Ito *et al.*[15] yielded oxonintrione **11** in good yield (Scheme 2). We assumed that an intermediate such as **10a** would be generated under these conditions. Such intermediates have been proposed before for the oxidative cleavage of silyl ethers.[15] With the nine-membered lactone in hand it remained to reduce the two ketone carbonyls. We found that this was best achieved in a stepwise manner. Thus treatment with sodium cyanoborohydride regio- and stereo-selectively reduced **11** to alcohol **12**. The (*R*)-stereochemistry of the new centre was confirmed by single crystal X-ray analysis of the corresponding benzoate (**14**, R = benzoyl in Scheme 2 and Fig. 3).

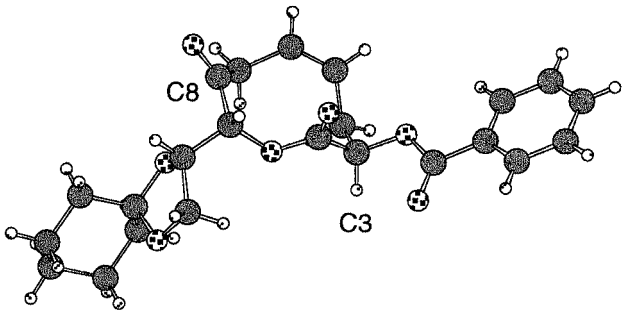


Fig. 3 Single crystals of $C_{23}H_{26}O_7$ **14** were recrystallised from diethyl ether–hexanes, mounted in inert oil and transferred to the cold gas stream of the diffractometer. *Crystal data*: $C_{23}H_{26}O_7$, M = 414.44, monoclinic, space group $P2_1$ (no. 4), a = 10.1336(2), b = 9.5207(2), c = 11.1957(2) Å, β = 104.750(1)°, U = 1044.55(4) Å^3, T = 123 K, Z = 2, μ(Mo-K) = 0.097 mm^{-1}, 14784 reflections measured, 4923 unique (R_{int} = 0.023) which were used in all calculations. The final $wR(F^2)$ was 0.074 (all data), and flack parameter χ = 0.1(6). CCDC 182/1556. See http://www.rsc.org/suppdata/cc/a9/a910163m/ for crystallograpic files in .cif format.

Treatment of **13** with L-selectride {LiB[CHMe(Et)]$_3$H} at −78 °C gave **15** as a 6:1 mixture of diastereomers. Lowering the reaction temperature to *ca.* −130 °C improved the selectivity to 14:1 in favour of the desired isomer. Reduction of **11** with 2 equivalents of L-selectride at *ca.* −130 °C resulted in a mixture of products consisting of 60% **16** and a 1:1:1 mixture of the other three possible diastereomers. The relative stereochemistry of **15** was established by examination of the coupling between H8 and H9 ($J_{8,9}$ 8.7 Hz). For closely related nine-membered cyclic ethers, typical coupling constants are J_{trans} 8.5 Hz, J_{cis} 2.2 Hz.[11] The reasons for the remarkably high diastereoselectivity in the first reduction remain unclear as initial molecular mechanics modelling failed to reveal a low-energy conformation likely to lead to the observed stereochemistry at C3. However, the source of the selectivity in the second reduction appears to be a folded conformation for **13** similar to that shown in Fig. 3 for crystalline **14**. If this conformation is maintained in solution then attack at the *Si* face of the ketone is clearly favoured, generating the observed sterochemistry at C8.

In conclusion, we have demonstrated the usefulness of vitamin C as an enantiomerically pure starting material for the synthesis of oxonins. Key steps included (i) a ring closing metathesis/oxidative cleavage sequence to form the nine-membered ring and (ii) a sequence of two highly diastereoselective reductions. Compounds such as oxonin **15** represent valuable intermediates for the synthesis of F-ring containing CTX domains as well as other naturally occurring oxonins such as obtusenyne and other nine-membered cyclic ethers of marine origin.[16]

We are grateful to Dr Gary D. Fallon for determining the X-ray structures of **10** and **15**. P. P. is grateful to the Australian Research Council for financial support. S. B. is grateful to the Australian Government for an Australian Postgraduate Award scholarship.

Total synthesis of (+)-streptazolin

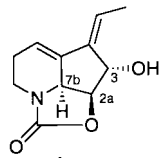
Shenlin Huang and Daniel L. Comins*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695-8204, USA. E-mail: daniel_comins@ncsu.edu

Received (in Cambridge, UK) 21st February 2000, Accepted 28th February 2000
Published on the Web 17th March 2000

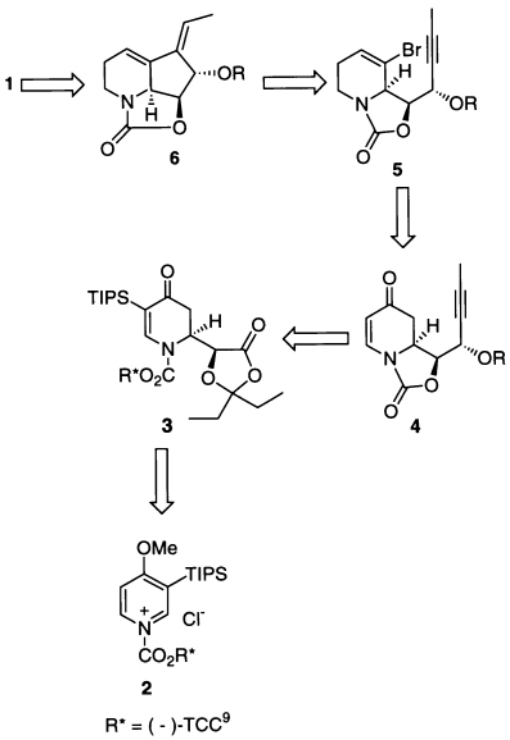
The first chiral auxiliary mediated asymmetric synthesis of (+)-streptazolin has been accomplished in 13 steps and with a high degree of stereocontrol.

Streptazolin **1** was first isolated from cultures of *Streptomyces viridochromogenes* by Drautz *et al.* in 1981.[1] Streptazolin and a derivative, 3,9-dihydrostreptazolin, were found to exhibit antibacterial and antifungal properties.[1,2] Some naphthoquinone Diels–Alder adducts of **1** have been reported to have



1
(+)-streptazolin

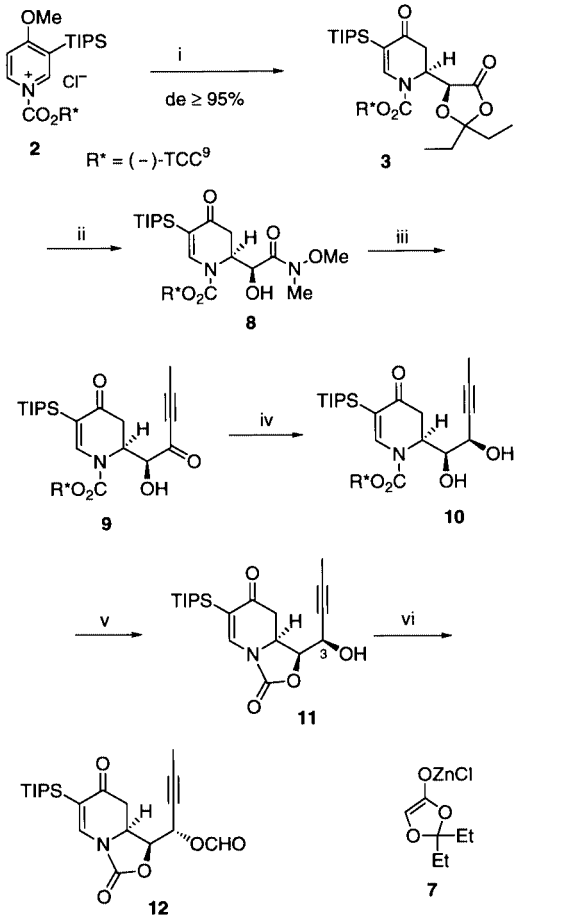
striking bactericidal, fungicidal and protozoacidal activities, as well as antitumor activity similar to adriamycin on leukemia L1210 cells.[3] The unique structure of the natural product, and its interesting biological activities, have stimulated synthetic efforts that resulted in three total syntheses. Kozikowski and Park[4] reported a racemic synthesis of **1**, and Flann and Overman[5] completed an enantioselective synthesis starting from L-tartaric acid. Recently, Kibayashi and coworkers[6] reported a total synthesis of (+)-streptazolin also starting from L-tartaric acid.



Scheme 1 Retrosynthetic analysis.

As part of a program directed at synthesizing alkaloids using enantiopure *N*-acyldihydropyridones as chiral building blocks,[7] we developed a strategy for the first chiral auxiliary mediated asymmetric synthesis of (+)-streptazolin. In addition to effectively installing the required stereocenters, the direct incorporation of the diene system of **1** in a regio- and stereo-controlled manner was given high priority. Metallo-enolate addition to chiral 1-acylpyridinium salts is a useful method for the enantioselective synthesis of 2-substituted piperidines containing functionality and stereocenters in the C-2 side chain[8] The piperidine core of streptazolin, with its highly functionalized cyclopentane apendage, seemed to be an attractive target for this recently developed methodology. We now report a concise and highly stereocontrolled asymmetric synthesis of **1**.

Our synthesis plan was based on the retrosynthetic analysis depicted in Scheme 1. The enantiopure *N*-acyldihydropyridone **3**, prepared from chiral pyridinium salt **2**, would be converted to bicyclic carbamate **4**. Through a bromination/reduction/elim-

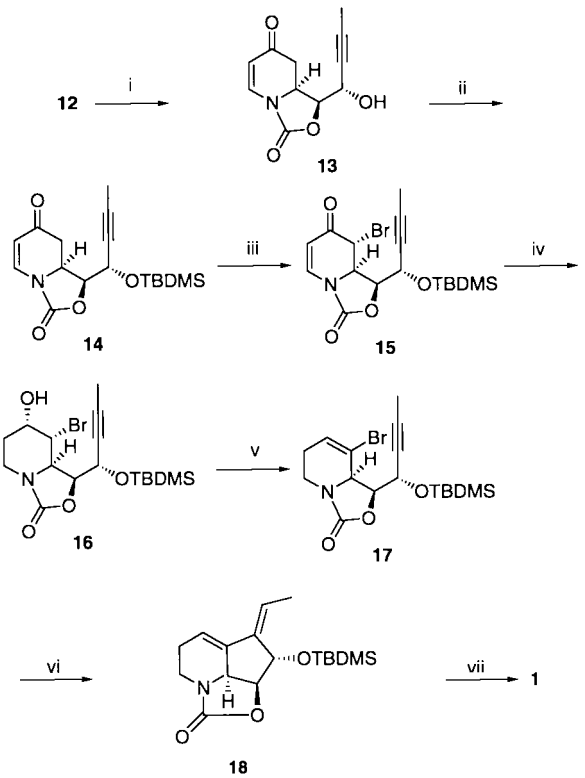


Scheme 2 *Reagents and conditions*: i, **7** (3 equiv.), THF, −78 °C, 3 h, then 10% HCl, 76%; ii, MeONHMe–HCl, $AlMe_3$, CH_2Cl_2, 25 °C, 1 h, 95%; iii, prop-1-ynyllithium (2.5 equiv.), THF, −78 → −15 °C, 1 h, 84%; iv, $NaBH_4/CeCl_3$, MeOH, −50 °C, 95%; v, NaH (2.2 equiv.), THF, 25 °C, 6 h, 81%; vi, formic acid, DEAD, PPh_3, THF, 64%.

DOI: 10.1039/b001425g

ination sequence, vinyl bromide **5** would be prepared from **4**. At this stage, an intramolecular palladium-catalyzed cyclization would be used to give streptazolin precursor **6**, which contains the diene in the proper position and with the required stereochemistry. Removal of the alcohol protecting group would provide **1**.

The 1-acylpyridinium salt **2**[9] was treated with zinc enolate **7**[8] to afford dihydropyridone **3** in 76% yield (Scheme 2).† Conversion of **3** to Weinreb's amide **8** proceeded in excellent yield using standard conditions.[8,10] Addition of propynyllithium[11] (2.5 equiv.) to **8** provided ketone **9**, which was reduced under Luche conditions to afford diol **10** (> 95% de) in high yield.[12] The presence of the bulky C-5 TIPS group allowed the previous three steps to be carried out without serious side reactions at the enone functionality. Treatment of **10** with sodium hydride (2.2 equiv.) effected cyclization to give bicyclic carbamate **11** with concomitant release of the chiral auxiliary, (−)-TCC[13] (93% recovery). The C-3 secondary alcohol in **11** has the wrong stereochemistry for the natural product. This stereogenic center was inverted using the Mitsunobu reaction to provide formate ester **12**. The key intermediate **14** was prepared in good yield from **12** in three steps by removing the TIPS group through protodesilylation using formic acid, cleaving the formate ester with refluxing methanol, and reprotecting the hydroxyl as its TBDMS ether (Scheme 3). At this stage, conversion of dihydropyridone **14** to vinyl bromide **17** was needed. Bromination of the lithium enolate of **14** with NBS gave exclusively the desired *trans*-bromide **15**. Reduction of the enone moiety with K-Selectride (2 equiv.) provided the *cis*-bromohydrin **16** *via* a one-pot reaction.[14] After considerable effort, conditions were found to convert **16** into vinyl bromide **17**. This was carried out by first forming the corresponding triflate and then effecting a regioselective anti-elimination *in situ* with DBU to afford a good yield of **17** as the only vinyl bromide isolated.[15] This intermediate contains three contiguous stereocenters with the correct configuration for the natural product, and the alkyne and vinyl bromide are properly positioned for a palladium-catalyzed cyclization. Subjection of **17** to Grigg's conditions[16] effected ring closure to give the desired diene **18**. Cleavage of the silyl protecting group with fluoride provided the labile natural (+)-streptazolin **1** in near quantitative yield. Our synthetic **1** exhibited spectral data in agreement with reported data for authentic material.[6] The optical rotation, $[\alpha]_D^{22}$ = + 20.6 (*c* = 0.15, $CHCl_3$), is also in agreement with the literature value, $[\alpha]_D^{23}$ = + 22 (*c* = 2.8, $CHCl_3$).[6]



Scheme 3 *Reagents and conditions*: i, formic acid, reflux, 2 h, then MeOH, reflux, 3 d, 88%; ii, TBDMSCl, imidazole, DMF, 83%; iii, LiHMDS (1.1 equiv.), THF, −78 → −40 °C, NBS (1.1 equiv.), 84%; iv, K-Selectride (2 equiv.), THF, −78 °C, 30 min., 58%; v, Tf_2O (1.1 equiv.), CH_2Cl_2, pyridine (5 equiv.), 25 °C, 4 h, then DBU (5 equiv.), 25 °C, 10 h, 79%; vi, $Pd(OAc)_2$/TPP (cat.), sodium formate, THF, 130 °C (sealed tube), 20 h, 50%; vii, TBAF, THF, 0 °C, 30 min., 95%.

In summary, the first chiral auxiliary mediated asymmetric synthesis of (+)-streptazolin **1** has been accomplished in 13 steps and with a high degree of stereocontrol. The piperidine ring and two of the required stereocenters were introduced in one step using a metallo-enolate addition to chiral pyridinium salt **2**. Other key features are the use of a TIPS group to protect an enone moiety, and the regio- and stereo-specific construction of the diene system using a palladium-catalyzed vinyl bromide/alkyne cyclization.

We are grateful to the National Institutes of Health (GM-34442) for financial support of this research and to Dr C. Kabayashi for 400 MHz ^1H NMR and ^{13}C NMR spectra of streptazolin.

Published on the Web 17th March 2000

Polyelectrolyte multilayers have been prepared using both the neutral and oxidised forms of a poly(alkoxythiophene) derivative with pendant sulfonate groups and it is shown that the oxidation state of the polymer affects multilayer formation.

The fabrication of polyelectrolyte multilayers by consecutive adsorption of polyanions and polycations on a charged surface is a facile method for the preparation of stable multicomposite thin films.[1] The strongly interpenetrating layers are held together principally by electrostatic interactions between multiple ion pairs in the oppositely charged chains. Multilayers of simple polyelectrolytes have been studied in detail but electrochemically active polyelectrolytes have received considerably less attention.[2,3] In particular, multilayers of conducting polymers carrying pendant ionic groups have scarcely been characterised at all,[4] although multilayers have been prepared using oxidised conducting polymers as polycations.[5] Owing to their special electrical and optical properties the polyelectrolyte films containing conducting polymers can have potential applications in the fields of, *e.g.*, sensors, electrooptics and LED technology.[1,6]

With weak polyelectrolytes the charge density can be controlled by pH with profound effects on the multilayer formation.[7] Analogously, the charge density of conducting polymers can be controlled by the oxidation state. We report here the formation and preliminary characterisation of multilayers prepared from the neutral or oxidised (referring to the polymer backbone) sodium salt of poly-3-(3′-thienyloxy)propanesulfonate (P3TOPS) as polyanion and poly(allylamine hydrochloride) (PAH, M_w = 5–6.5 × 10^4, Aldrich) or poly(diallyldimethylammonium chloride) (PDADMAC, M_w = 4–5 × 10^5, Aldrich) as polycation. The water-soluble polythiophene P3TOPS was prepared by iron(III) chloride oxidation of the monomer† in chloroform.[8] The crude polymer was fractionated with a Sephadex G-50 F column using water as eluent and the highest molecular weight fraction collected.[9] The neutral polymer is blue with λ_{max} at 620 nm and the oxidised form is bluish grey. The oxidation potential of P3TOPS is *ca.* +0.2 V *vs.* SSCE (sodium saturated calomel electrode) and it is easily oxidised by oxygen. In solution the polymer stays in the neutral state only by addition of a strong reducing agent, *e.g.*, hydrazine or $Na_2S_2O_4$. Polyelectrolyte adsorption was carried out from dilute polyelectrolyte solutions (1 or 10 mM with P3TOPS or PAH and PDADMAC, respectively) for 30 min followed by washing with water (3 × 1 min). The substrates were primed with a layer of physisorbed polycation, polyethyleneimine (PEI, M_w = 25 000, Aldrich; quartz and indium–tin oxide ITO), or chemisorbed 2-mercaptoethanesulfonic acid (MESA, Aldrich; gold). The ionic strength was set to 0.6 M with 0.2 M Na_2SO_4 or $Na_2S_2O_4$.

Neutral P3TOPS is a polyanion with one negative charge per monomer unit. Oxidation of the polymer introduces positive charges in the thiophene backbone and reduces the charge density. However, both forms can be used for the fabrication of polyelectrolyte multilayers. Fig. 1 shows the sequential build-up of P3TOPS/PAH bilayers on quartz. A linear increase of absorbance indicates a regular increase of adsorbed polymer. If the charge density of the oxidised polymer is too low multilayer formation would be hindered. However, oxidation of polythiophenes gives rise to a positive charge of *ca.* 0.25–0.4 per monomer unit, which itself is enough to render oxidised conducting polymers useful as polycations in multilayer fabrication.[5] The spectra of P3TOPS/PDADMAC multilayers on ITO are shown in Fig. 2. The film, which is electroactive owing to efficient interpenetration of the layers, displays behaviour similar to electrodeposited polythiophene films. As the potential is made more anodic, the π–π* transition of the neutral form decreases, and the absorbance increases above 800 nm. At high anodic potentials the absorbance at 900 nm again decreases and a new transition forms in the NIR region above 1000 nm. This implies that these multilayers can be oxidised to the metallic state in aqueous solutions.

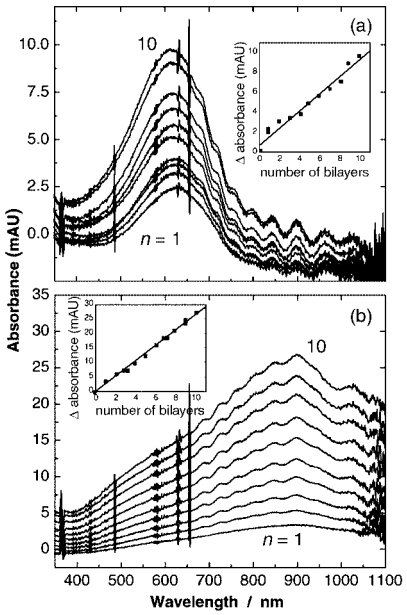

Fig. 1 Polyelectrolyte multilayer formation on quartz. Quartz/PEI/(P3TOPS/PDADMAC)$_n$ using (a) neutral (hydrazine added) and (b) oxidised P3TOPS. Insets show the increase of absorbance at 600 and 900 nm. [Ordinate values in milliabsorbance units (mAU).]

Sequential multilayer fabrication with the neutral and oxidised P3TOPS was carried out also on gold using a quartz crystal microbalance (QCM, Fig. 3). In the first case, the polyanion and polycation (PDADMAC) were adsorbed from 0.2 M $Na_2S_2O_4$ solutions in order to keep polythiophene in the neutral state. With oxidised P3TOPS, oxygen saturated 0.2 M Na_2SO_4 solutions were used. A regular build-up was observed after 2–4 bilayers, a common feature with polyelectrolyte

DOI: 10.1039/b000769m

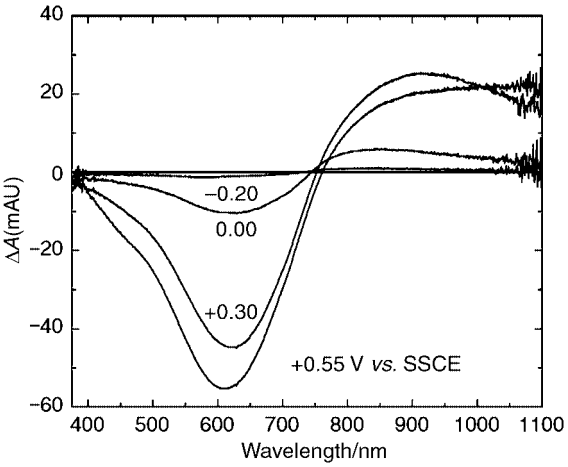

Fig. 2 Difference spectra of ITO/PEI/(P3TOPS/PDADMAC)$_5$ multilayers at potentials indicated (in 0.6 M $NaNO_3$; adsorbed using oxidised P3TOPS). Spectrum at –0.40 V *vs*. SSCE taken as reference.

multilayers.[1,2] QCM studies on polyelectrolyte layers have shown that viscoelastic properties are not important and data can be treated in a gravimetric manner.[10]

With oxidised P3TOPS the average mass increase per PDADMAC/P3TOPS bilayer was approximately half of that observed with neutral polymer, showing the effect of the charge density on multilayer formation. However, contrary to expectations, lower charge density results in the adsorption of less material. Lowering the charge density of weak polyelectrolytes by adjusting the pH of the adsorption solution yields thicker films because more polymer is needed to compensate the surface charge.[7] Closer inspection of Fig. 3 reveals a more complex behaviour with P3TOPS. Although irregular growth persists longer for the neutral (*cf.* also insets of Fig. 1; the more regular growth in that case can be attributed to the PEI underlayer) mass increase ($\Delta f < 0$) or decrease ($\Delta f > 0$) is observed after 3–4 bilayers upon addition of PDADMAC or

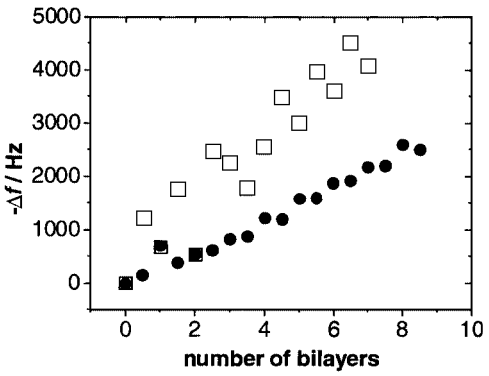

Fig. 3 QCM frequency changes (film side in contact with water) upon multilayer formation in the Au/MESA/(PDADMAC/P3TOPS)$_n$ system. Open and filled symbols refer to neutral and oxidised P3TOPS, respectively.

neutral P3TOPS, respectively. By contrast, the adsorption of oxidised P3TOPS leads to a mass increase and the mass stays constant when PDADMAC is added. Evidently, neutral P3TOPS, with high charge density, is able to remove some of the previously adsorbed polycation whereas PDADMAC does not adhere well to the surface of oxidised P3TOPS having low *surface* charge density. Therefore, even though more material is deposited when neutral P3TOPS is used, more electroactive polymer is adsorbed for the oxidised material. This conclusion is supported by electrochemical experiments, which show that the film oxidation current increases more rapidly with oxidised P3TOPS as the polyanion.

In summary, we have shown for the first time that electroactive polyelectrolyte multilayers can be prepared from ionically substituted polythiophenes using both neutral and oxidised polymer as a polyanion. The oxidation state changes the charge density of the polyanion and has a marked effect on multilayer formation. This behaviour is analogous to that of weak polyelectrolytes as a function of pH.

Financial support from the Academy of Finland (Grant no. 30579) is gratefully acknowledged.

Notes and references

† 3-(3-Bromo)propoxythiophene was synthesised from 3-methoxythiophene and 3-bromopropanol analogously as described in ref. 8. ^{1}H NMR ($CDCl_3$): δ 7.18 (1H, dd), 6.75 (1H, dd), 6.27 (1H, dd), 4.10 (2H, t), 3.58 (2H, t), 2.30 (2H, td). The product was refluxed with Na_2SO_3 in acetone–water (2:1), evaporated to dryness and the crude product dissolved in ethanol. Recrystallisation from ethanol yielded white crystals of sodium 3-(3′-thienyloxy)propanesulfonate. ^{1}H NMR (D_2O): δ 7.19 (1H, dd), 6.67 (1H, dd), 6.40 (1H, dd), 4.00 (2H, t), 2.90 (2H, t), 2.03 (2H, td).

Molybdenum η^2-imine complex formation and the reductive coupling of imines†

Tom M. Cameron,[a] Carlos G. Ortiz,[a] Khalil A. Abboud,[a] James M. Boncella,*[a] R. Tom Baker[b] and Brian L. Scott[b]

[a] *Department of Chemistry, University of Florida, Gainesville, FL 32611, USA. E-mail: boncella@chem.ufl.edu*

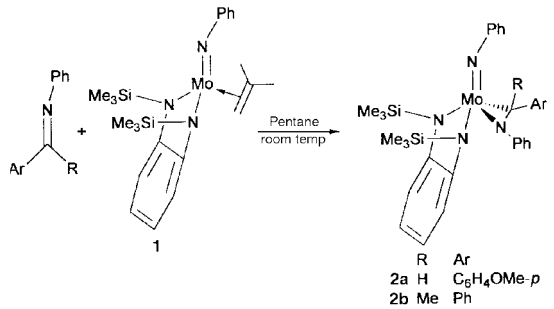
Received (in Bloomington, IN, USA) 5th January 2000, Accepted 25th February 2000
Published on the Web 17th March 2000

Addition of imine PhN=C(Ar)R (Ar = Ph, R = Me; *p*-$MeOC_6H_4$, R = H) to (PhN)Mo(TMS-*o*-pda)(CH_2=CMe_2) 1 [TMS-*o*-pda = bis(trimethylsilyl)-*o*-phenylenediamide] affords the corresponding η^2-imine complexes (PhN)Mo(TMS-*o*-pda)[PhN=C(Ar)R] 2a and 2b; analogous reactions with aldimines RN=C(H)Ar (Ar = *p*-$MeOC_6H_4$, R = CH_2Ph, Et) afford products (PhN)Mo(TMS-*o*-pda)-[RNC(H)ArC(H)ArNR] 3a and 3b resulting from reductive imine coupling, providing the first example of facile and general Mo(IV) η^2-imine complex formation.

Current synthetic methodologies affording η^2-imine complexes (azametallacyclopropanes) consist of C–H activation from methylmetallocene amides,[1,2] rearrangements of iminoacyl complexes,[3] reaction between $Cp^*_2ZrH_2$ and ArNC,[4] reduction of a low-valent complex with phosphaazaallene,[5] and various *in situ* methods of η^2-imine complex formation.[6] Isolation and characterization of η^2-imine complexes generated by direct reaction of imines with metal reductants has for the most part been unsuccessful, and although two recent reports detail the isolation and characterization of ytterbium[6] and tantalum[7] η^2-imine complexes *via* such direct methods, examples with other early transition metals are, to our knowledge, non-existent. We report herein structural characterization and direct synthesis of molybdenum(IV) η^2-imine complexes obtained by treatment of the molybdenum(IV) olefin complex (PhN)Mo(TMS-*o*-pda)(CH_2=CMe_2) **1**[8] with appropriate aldimines and ketimines. Furthermore, aldimine reductive coupling products are isolated for less sterically demanding aldimines.

Reaction of the aryl amine derived aldimine PhN=C(H)Ar or ketimine PhN=C(Me)Ph with **1** affords the η^2-imine complexes **2a** and **2b**, respectively, as green crystals in 70% isolated yield (Scheme 1).‡ The molecular structure of **2b** was determined by an X-ray crystallographic study, and selected bond distances and angles for **2b** are shown in Fig. 1.§

Complex **2b** adopts a five-coordinate square pyramidal geometry with the imido ligand occupying the apical position.



Scheme 1 The generation of molybdenum(IV) η^2-imine complexes.

† Electronic supplementary information (ESI) available: spectroscopic data for **1**, **2a**, **2b**, **3a** and **3b**. See http://www.rsc.org/suppdata/cc/b0/b000355g/

The short imido Mo(1)–N(3) bond length of 1.736(2) Å is typical of a Mo–N triple bond interaction.[9] The Mo(1)–N(4), Mo(1)–N(2) and Mo(1)–N(1) bond lengths of 1.944(2), 2.009(2) and 1.996(2) Å, respectively, are all consistent with Mo–N single bonds.[10] The C(31)-centered bond angles of the imine fragment are all < 120° and support a considerable amount of azametallacyclopropane character in **2b** as does the N(4)–C(31) bond length of 1.414(3) Å.[11]

Complete conversion of **2a** to the corresponding organic amine ($PhNHCH_2Ar$) was observed by ^{1}H NMR upon exposure of a solution of **2a** to an atmosphere of 15 psi H_2 at room temperature over a 1 week period.[12] Unfortunately no catalytic activity was observed upon treatment of **2a** with excess imine under low pressures (*ca.* 15 psi) of H_2 gas.

The reaction of aldimines derived from less hindered primary amines with **1** affords molybdenum(VI) bisdiamide imido complexes **3a** and **3b** from reductive imine coupling (Scheme 2).‡ Complexes **3a** and **3b** were isolated in 75% yield from cold pentane–toluene solutions. Interestingly, only the *rac*-coupled form of the metal complexes is isolated as ascertained from ^{1}H and ^{13}C NMR spectroscopy. An X-ray crystallographic study was performed on a single crystal of **3b**.

The molecular structure and selected bond lengths and angles are shown in Fig. 2.§ The complex adopts a distorted square pyramidal geometry around molybdenum with the imido ligand

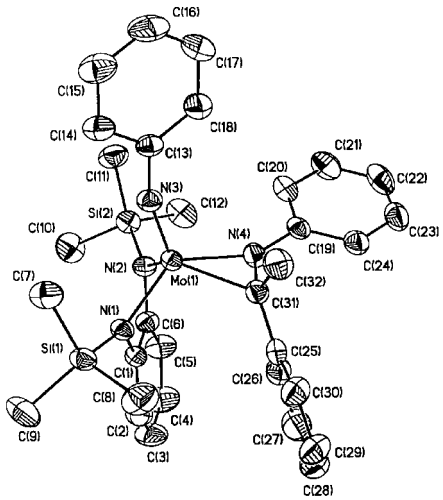


Fig. 1 Thermal ellipsoid plot of **2b**. Selected bond lengths (Å) and angles (°): Mo(1)–N(1) 1.996(2), Mo(1)–N(2) 2.009(2), Mo(1)–N(3) 1.736(2), Mo(1)–N(4) 1.944(2), Mo(1)–C(31) 2.200(3), N(3)–C(13) 1.409(3), N(4)–C(31) 1.414(3), C(31)–C(32) 1.518(4); Mo(1)–N(3)–C(13) 163.0(2), N(2)–Mo(1)–N(1) 85.28(9), N(4)–Mo(1)–C(31) 39.29(9), N(2)–Mo(1)–N(4) 100.09(9), N(1)–Mo(1)–C(31) 99.20(9), N(4)–C(31)–Mo(1) 60.55(13), N(4)–C(31)–C(32) 116.9(2), N(4)–C(31)–C(25) 116.6(2), C(32)–C(31)–C(25) 116.2(2).

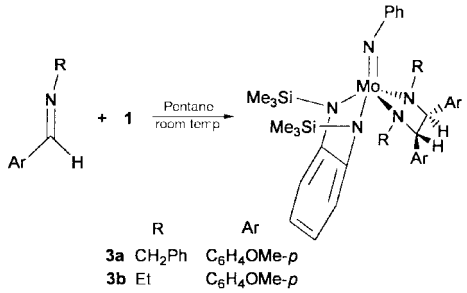
DOI: 10.1039/b000355g



Scheme 2 The reductive coupling of imines.

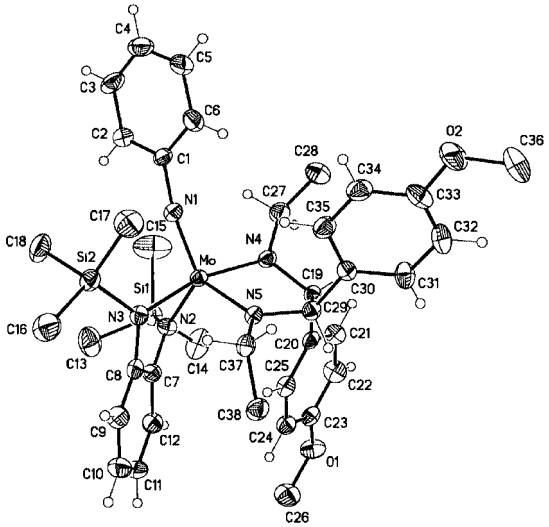


Fig. 2 Thermal ellipsoid plot of **3b** with 50% probability ellipsoids. Selected bond lengths (Å) and angles (°): Mo–N(1) 1.754(3), Mo–N(2) 2.008(3), Mo–N(3) 2.065(3), Mo–N(4) 1.996(3), Mo–N(5) 2.021(3), N(4)–C(19) 1.476(5), N(5)–C(29) 1.468(5), C(19)–C(29) 1.514(5); Mo–N(1)–C(1) 166.6(3), N(2)–Mo–N(3) 80.65(14), N(3)–Mo–N(5) 85.75(12), N(5)–Mo–N(4) 77.46(12), N(2)–Mo–N(4) 102.59(12).

occupying the apical position. The Mo–N(1) bond length of 1.754(3) Å is consistent with a molybdenum nitrogen triple bond interaction.[9] The Mo–N(2), N(3), N(4) and N(5) amide bond lengths of 2.008(3), 2.065(3), 1.996(3) and 2.021(3) Å, respectively, are within the range expected for Mo–N single bonds.[10] The hydrogen atoms located on the backbone of the newly formed diamide ligand are related by an H–C(19)–C(29)–H torsion angle of 90°. Consistent with this torsion angle there is no observed coupling between these protons in the solution ^{1}H NMR spectrum at 300 MHz. Complex **3a** displays similar characteristics in its ^{1}H NMR spectrum.

In summary, we have demonstrated that chelate-supported Mo(IV) η^2-imine complexes can be easily prepared *via* displacement of olefin from **1** upon reaction with *N*-aryl imines. In contrast, imine reductive coupling products were observed for sterically less demanding imines. We are currently investigating the reactivity of these η^2-imine complexes with unsaturated organic molecules.

Notes and references

‡ All reactions and manipulations were carried out using standard Schlenk techniques or a dry box under atmospheres of nitrogen and argon. *Synthesis* of **2a** and **2b**: to a green solution of **1** (0.50 g, 1.05 mmol) in pentane at room temperature was added a pentane solution of the appropriate imine (0.20 g, 1.05 mmol). After stirring for 12 h the pentane solution was concentrated *in vacuo* and cooled, affording the appropriate metal complexes. The synthesis of **3a** and **3b** was similar but required the addition of 2 equivalents of the appropriate imine.

§ *Crystal data*: for **2b**: $C_{32}H_{40}N_4Si_2Mo$, M = 632.80, a = 9.8565(5), b = 18.8443(8), c = 17.9089(8) Å, β = 104.6520(1)°, V = 3218.2(3) Å^3, monoclinic, space group $P2_1/c$, Z = 4, T = 203(2) K, final $R1$ = 0.0431, $wR2$ = 0.0831, GOF (on F^2) = 1.225.

For **3b**: $C_{38}H_{53}MoN_5O_2Si_2$, M = 763.97, a = 9.9600(5), b = 19.0705(9), c = 10.2628(5) Å, β = 97.351(1)°, V = 1933.3(2) Å^3, monoclinic, space group $P2_1$, Z = 2, T = 173(2) K, final $R1$ = 0.0420, $wR2$ = 0.0775, GOF (on F^2) = 1.021.

Both structures were solved using the direct methods option of SHELXS. Full-matrix least-squares refinements based on F^2 were subsequently performed using SHELXL 97.[13] All non-hydrogen atoms were assigned anisotropic temperature factors, with corresponding hydrogen atoms included in calculated positions.

Published on the Web 17th March 2000

Highly ordered, hydrothermally stable, caged cubic mesoporous silica structures ($Im\bar{3}m$) with unusually large pore size (120 Å) have been synthesized by using hydrophobic poly(butylene oxide) containing triblock PEO–PBO–PEO copolymer as a structure-directing agent.

Ordered large pore materials are in great demand because of their potential applications for catalysis, separation of large molecules, medical implants, semiconductors, magnetoelectric devices, *etc.*[1–8] Using triblock poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) (PEO–PPO–PEO) copolymers as structure-directing agents, we have previously reported the synthesis of highly ordered hexagonal mesoporous silica structures (SBA-15) with large pore sizes of 50–300 Å.[2] Three-dimensional cubic mesoporous structures, such as MCM-48 ($Ia\bar{3}d$),[1] SBA-1 ($Pm\bar{3}n$)[7] and SBA-16 ($Im\bar{3}m$),[2] show advantages compared to hexagonal mesoporous structures with one-dimensional channels. However, such cubic structures could be synthesized only under strict conditions. Calcined SBA-16 synthesized with PEO–PPO–PEO triblock copolymers has the largest pore size (54 Å) among these cubic silica structures, but can only be synthesized with large PEO segment amphiphilic PEO–PPO–PEO block copolymers, such as F127 ($EO_{106}PO_{70}EO_{106}$) in a narrow range of reaction compositions at room temperature.[2b] The small differences of hydrophilicity/hydrophobicity between PEO and PPO chains at room temperature might be one of the reasons leading to such a small pore size.

Here, we report the synthesis of a highly ordered, ultra hydrothermally stable caged cubic mesoporous silica structure (FDU-1, $Im\bar{3}m$) with large, uniform pore size (120 Å) by using the more hydrophobic poly(butylene oxide) containing triblock copolymer PEO–PBO–PEO as the structure-directing agent.

Cubic mesoporous silica FDU-1 samples were synthesized by using the triblock copolymer $EO_{39}BO_{47}EO_{39}$ [B50-6600 (Dow) $\overline{M}_n$ = 6800] as the structure-directing agent under acidic conditions. In a typical experiment, 0.5 g of B50-6600 was dissolved in 30 g of 2 M HCl. To this homogeneous solution, 2.08 g (0.01 mol) of tetraethylorthosilicate (TEOS) was added with vigorous stirring for 24 h. The resulting solid was then aged at 100 °C for a further 24 h. The solid product was filtered off, washed, and dried *in vacuo* at room temperature. Calcination was carried out in an oven at 550 °C for 6 h in air.

Small angle X-ray diffraction (XRD) patterns of as-synthesized and calcined FDU-1 are shown in Fig. 1. As-synthesized FDU-1 shows a well resolved XRD pattern and the first diffraction peak appears at a low angle (2θ = 0.68). After calcination the first diffraction peak is shifted slightly (2θ = 0.73) due to shrinkage. Calcined FDU-1 shows nine well resolved Bragg peaks. Combined with TEM analysis (see below) we can index the diffraction peaks to 110, 200, 211, 220, 310, 222, 400, 411 and 420 reflections for space group $Im\bar{3}m$ (Q^{229}), respectively. The relative intensity of these observed peaks follows the trend reported in previous literature reports for surfactant–water systems.[9,10] The values of the cubic cell lattice parameter, *a*, are calculated to be 183 and 171 Å for as-synthesized and calcined FDU-1, respectively.

Transmission electron micrographs (TEM) of calcined FDU-1 are shown in Fig. 2. Although both simple (P) and centerd (I) cubic structures show a square lattice along the [100] direction and a hexagonal lattice along the [111] direction, the value of d_{100} relative to d_{111} is equal to 0.866 (I) and 1.224 (P), respectively, from geometrical calculations. From bright/dark TEM images [Fig. 2(a) and (b)] for calcined FDU-1, the value of d_{100}/d_{111} is estimated as 0.88, giving further evidence that the mesostructure is centered cubic with $Im\bar{3}m$ space group. The cell parameter, *a*, is estimated as 170 Å from TEM images, in good agreement with the value determined from the XRD data. Moreover, TEM measurements also reveal that all areas for calcined FDU-1 have well ordered mesoscopic arrays and a three-dimensional caged structure can be observed along the edge of the sample [Fig. 2(b)], indicating that calcined FDU-1 has a high quality caged cubic mesostructure.

Calcined cubic mesoporous silica FDU-1 synthesized using B50-6600 yields a type IV isotherm with a large type-H_1 hysteresis loop (Fig. 3).[11] A narrow pore-size distribution (FWHM *ca.* 10 Å) with a mean value of 120 Å (BJH model) is also obtained from the adsorption branch, indicating that FDU-1 has well defined uniform pore dimensions. The calcined cubic mesoporous silica has a pore volume of 0.77 $cm^3\ g^{-1}$ and a BET surface area of 740 $m^2\ g^{-1}$. Although the cell parameter for FDU-1 is similar to that of SBA-16 (176 Å), the pore size and pore volume for FDU-1 are much larger than those (54 Å, 0.45 $cm^3\ g^{-1}$, respectively) for SBA-16,[2b], suggesting that the pore size is very dependent on hydrophobic domains. More hydrophobic PBO segments relative to PPO segments yields a larger

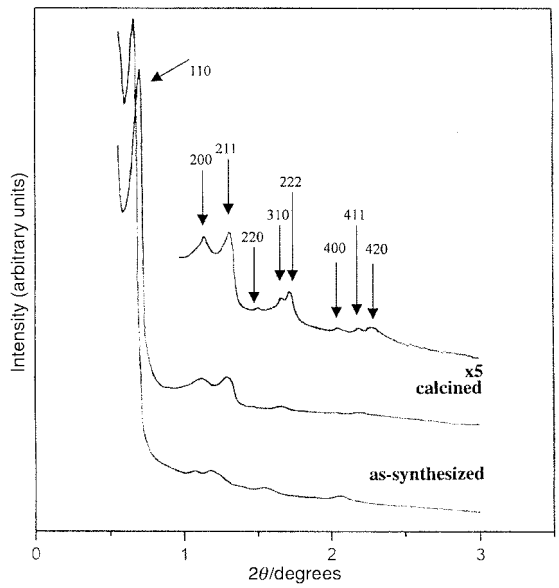

Fig. 1 XRD patterns of as-synthesized and calcined cubic mesoporous siica FDU-1 prepared using $EO_{39}BO_{47}EO_{39}$ triblock copolymer as the structure-directing agent at room temperature. XRD patterns were recorded with a Rigaku D/Max-IIA using Cu-Kα radiation.

DOI: 10.1039/b000603n

mesopore size. To the best of our knowledge, FDU-1 has the largest pore sizes among all reported cubic silica structures.

Cubic mesoporous silica can be synthesized over a relatively wide range of reaction mixture compositions at temperatures of 0–60 °C. At room temperature, the cubic structure can be synthesized over a range of PEO–PBO–PEO concentrations (0.6–2.4 wt%), with cell parameters (*a*) in the range 200 to 178 Å. Moreover, a low temperature such as 0 °C yields a large cell parameter (*a* up to 220 Å), but may lead to slight disorder for FDU-1 according to XRD and TEM. At higher temperatures, the cell parameter and crystalline quality for FDU-1 remain almost unchanged. Addition of swelling agents, such as 1,3,5-trimethylbenzene (TBM), can slightly enlarge the cell parameter (up to 220 Å) with a highly ordered mesostructure. Fig. 2(d) shows a TEM image of calcined FDU-1 obtained with TMB. The cell parameter is estimated as 220 Å, in agreement with that determined from XRD.

Despite of such large lattice dimensions, calcined cubic FDU-1 is hydrothermally stable. After calcined FDU-1 was heated in boiling water for more than 9 days, at least five diffraction peaks can be observed in the XRD pattern and the intensity for the (110) reflection was even increased after the treatment, indicating that large pore mesoporous FDU-1 is hydrothermally stable.

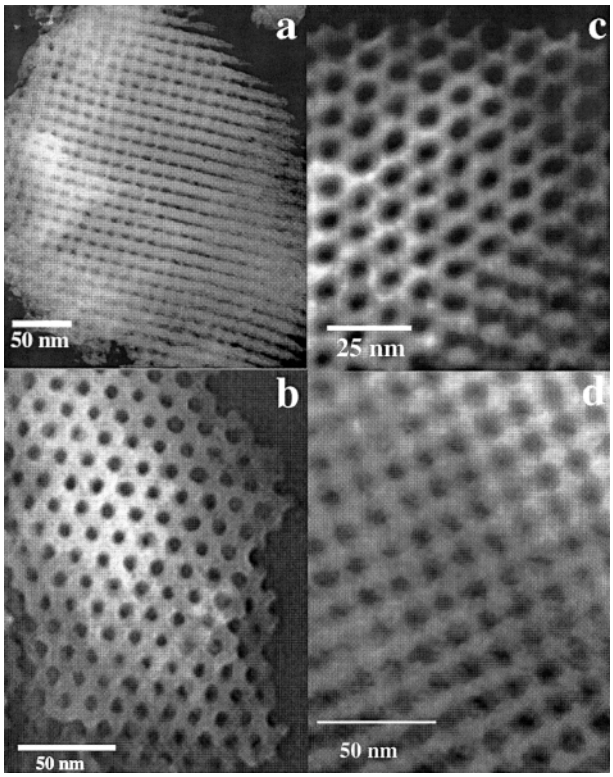

Fig. 2 TEM images of calcined cubic FDU-1 synthesized using $EO_{39}BO_{47}EO_{39}$ triblock copolymer without TMB at room temperature: (a) along the [100] direction, (b) along the [111] direction and (c) along the [110] direction; (d) calcined cubic FDU-1 synthesized with TMB as the swelling agent. TEM photographs were obtained with a JEM-1200EX microscope operated at 80 kV. For TEM measurements, the samples were ground, embedded in epoxy resin, and ultramicrotomed except the sample in Fig. 2(a), which was prepared by dispersing the powder products as a slurry in acetone and subsequently deposited and dried on a holey carbon film on a Cu grid.

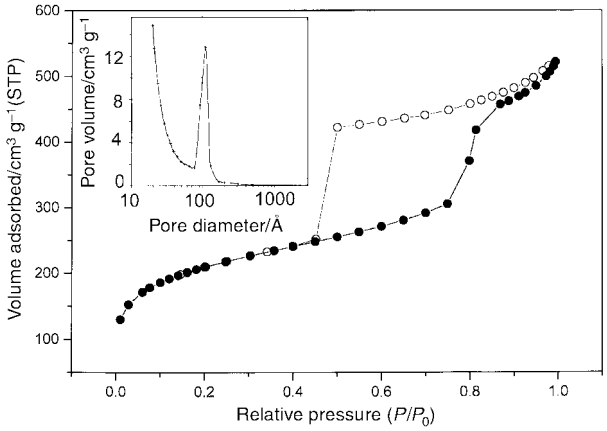

Fig. 3 Nitrogen adsorption–desorption isotherm plots and pore size distribution curve of calcined mesoporous silica FDU-1. N_2 adsorption measurements were performed at 77 K using a Micromeritics ASAP 2000 analyzer utilizing Barrett–Emmett–Teller (BET) calculations for surface area and Barrett–Joyner–Halanda (BJH) calculations for pore volume and pore size distributions for the adsorption branch of the isotherm.

In summary, highly ordered, large cage-structured cubic mesoporous silica FDU-1 has been synthesized with the hydrophobic PBO containing triblock PEO–PBO–PEO copolymer as a template. The new large cage structure and high hydrothermal stability for the resulting cubic mesoporous silica are expected to be of great value in electrochemistry, catalysis and separation for large moleculars.

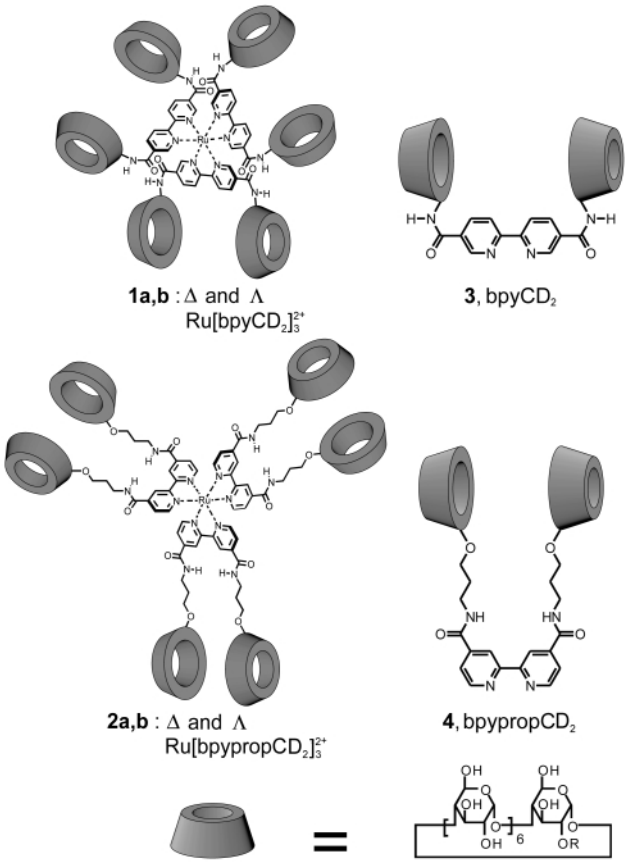
Received (in London, UK) 5th January 2000, Accepted 28th February 2000

A luminescent ruthenium(II) complex with six cyclodextrin binding sites is shown to switch off its emission upon binding of *N,N′*-dinonyl-4,4′-bipyridinium bromide and to recover luminescence upon displacement of the bipyridinium ion by a steroid.

The design of luminescent cyclodextrin sensor systems which are able to detect neutral organic compounds, *e.g.* steroids by a change in emission properties is an area which has attracted much interest over the last decade.[1] Most of these systems rely on a decrease in fluorescence intensity when a covalently linked fluorophore is displaced from the cyclodextrin cavity by a guest. Few systems exist in which the detection of a guest is accompanied by an increase in emission intensity.[2,3] Here, we describe the sensor properties of two novel cyclodextrin-based sensor compounds, containing a central luminescent tris(bipyridyl) ruthenium(II) complex,[4] to which six cyclodextrins are attached. One of these compounds (**2**) is able to detect steroids by first turning off the emission of the ruthenium complex by the binding of a quenching viologen in its cyclodextrin cavities, and then switching on the original luminescence by displacement of the viologen by the steroid.

The orange ruthenium complexes **1** and **2** were synthesised by reaction of $RuCl_3$ with 3 equivalents of the dimers **3**[5] and **4**,‡ respectively, in boiling water. The resulting mixtures were poured into acetone to precipitate the complexes as their chloride salts.‡ The UV–VIS spectra of **1** and **2** showed a characteristic metal-to-ligand charge transfer (MLCT) absorption centered at 465 nm and an intense ligand centered (LC) absorption around 300 nm. No quenching of the emission by oxygen was observed for either compound probably because the ruthenium centers are shielded by the cyclodextrins.[6]

Compound **1** was only weakly luminescent (95% less intense than **2**), probably because the bulky cyclodextrins prevent optimal coordination of the bipyridyl ligands to the ruthenium centers. Compound **2** displayed a bright luminescence, twice as intense as the reference compound $Ru(bpy)_3^{2+}$ (bpy = 2,2′-bipyridine). Compound **2** was, therefore, selected for binding studies with organic guest molecules. When ursodeoxycholic acid, lithocholic acid, cholesterol or 1-adamantanecarboxylic acid were added to a solution of **2** in water no change in the emission spectrum of **2** was observed. This means that there is no direct or indirect communication between the ruthenium complex and these guest molecules when they are bound. Since it is known[7] that covalently linked viologens (*N,N′*-dialkyl-4,4′-bipyridiniums) are able to quench the emission intensity of tris(bipyridyl)ruthenium(II) complexes very efficiently *via* an electron transfer process, we chose *N,N′*-dinonyl-4,4′-bipyridinium bromide as a guest molecule. The two long alkyl chains were attached to this molecule to increase its binding to the cyclodextrins.[8] Upon addition of the bipyridinium compound to an aqueous solution of **2** the emission intensity gradually dropped, resulting in 92% quenching at saturation (Fig. 1). Most importantly, when this guest was added to the reference compound $Ru(bpy)_3^{2+}$ under the same conditions (aereated solution, same concentrations) only a linear decrease of 15% in luminescence was observed. This implies that the bipyridinium compound is bound in the cyclodextrin cavities and thereby facilitates electron transfer.



Analysis of the complex stoichiometry by constructing a Job-plot (see ESI†) suggested that a 1:1 complex was formed between **2** and the bipyridinium guest. The observed binding curve could be fitted to a 1:1 binding model and gave an apparent association constant (K_a) of 2.8×10^5 M^{-1}.

A microcalorimetric titration study of the binding of the bipyridinium guest in **2** revealed a different picture (Fig. 2). This time the observed titration curve could not be fitted to a 1:1 model, instead a second (**2**:bipyridinium = 1:2) equilibrium was needed to give a satisfactory fit (Fig. 2, inset). The data from this study are collected in Table 1. As can be seen the binding constant for the 1:1 complex matches within experimental error (15%) the observed value from the fluorimetric determination. Apparently, with the latter method, only the

† Electronic supplementary information (ESI) available: characterisation of compounds **2** and **4**, and a Job-plot for the binding of the *N,N′*-dinonyl-4,4′-bipyridinium bromide to **2**. See http://www.rsc.org/suppdata/cc/b0/b000271m/

DOI: 10.1039/b000271m

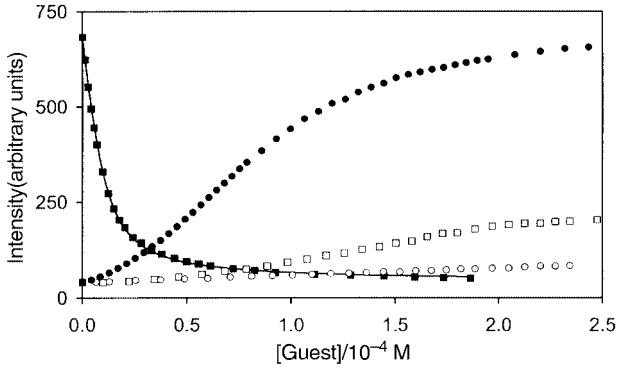


Fig. 1 Fluorimetric titration of (■) *N*,*N*′-dinonyl-4,4′-bipyridinium to **2** (1.0×10^{-5} M). The solid line shows the fitted curve assuming a 1:1 host(**2**):guest complex. Similar titration plots of (●) ursodeoxycholic acid, (□) lithocholic acid and (○) cholesterol to **2** (1.0×10^{-5} M) in the presence of 5.7×10^{-4} M of *N*,*N*′-dinonyl-4,4′-bipyridinium bromide. All titrations were performed in an aqueous 0.1 M Tris–HCl buffer at pH 7.0.

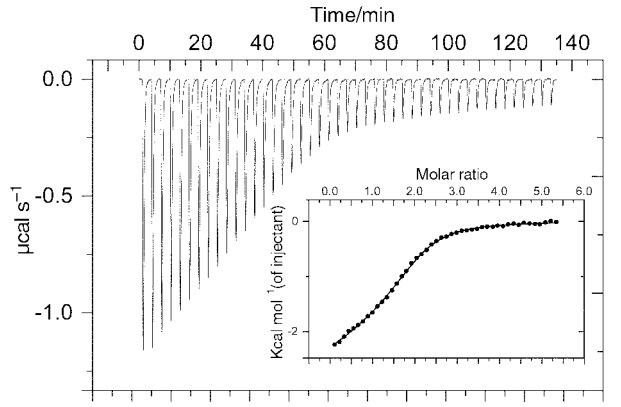

Fig. 2 Microcalorimetric titration of *N*,*N*′-dinonyl-4,4′-bipyridinium to **2** (1.0×10^{-4} M). For conditions see Table 1. The solid line (inset) shows the fitted curve according to a 1:2 (**2**:bipyridinium) model.

formation of the 1:1 complex can be detected. This implies that the binding of the first bipyridinium center results in almost complete quenching of the luminescence of **2** and that the second bipyridium unit has no effect on the luminescence.

Table 1 shows that $-T\Delta S$ of binding is the same for the 1:1 and the 1:2 complex. This parameter is probably related to the break up of solvent shells around the alkyl tails of the bipyridinium guest, which will be the same for the first and the second bipyridinium unit. By contrast ΔH of binding is different, being 1 kcal mol^{-1} smaller for the second step. We propose that two cyclodextrin moieties are involved in the complexation of a long chain bipyridinium guest.[8] Apparently, the binding of a second guest in **2** is disfavoured and the binding of a third guest completely absent, probably owing to a negative allosteric effect. Further studies are underway to substantiate this.

Having observed that bipyridinium compounds can quench the emission of **2** efficiently, we used this property to detect organic compounds. Displacement of the bipyridinium compound by other guests such as steroids should inhibit the quenching process and recover the luminescence of **2**. This would then give a sensor system which emits light when a guest is added. From a technological point of view this is an advantage since, in contrast to conventional systems, a luminescent signal is produced against a dark background, allowing a more sensitive detection in for instance a diagnostic test. When ursodeoxycholic acid was added to an aqueous solution of **2** and the bipyridinium ion, full recovery of the luminescence was observed (Fig. 1). A similar titration curve was recorded for lithocholic acid and cholesterol, showing the general applicability of the procedure. The curves for lithocholic acid and ursodeoxycholic acid displayed a sigmoidal shape suggesting that these steroids first displace one bipyridinium which will not result in a significant increase of the luminescence (*vide supra*), and only when the second bipyridinium ion becomes displaced the luminescence will be recovered.§

All steroids must have a binding constant of the same magnitude as the bipyridinium salt, *i.e.* 10^5 M^{-1} or slightly higher, in order for displacement in **2** to occur. The binding of ursodeoxycholic acid is strong enough to completely displace the bipyridinium salt and recover the full luminescence. Lithocholic acid only restores 30% of the emission, probably due to a weaker binding. The binding of cholesterol is too weak to even show a sigmoidal binding curve. Nevertheless, at a concentration of 2.3×10^{-4} M of cholesterol the luminescence has already doubled. Lithocholic acid shows a 5-fold increase at the same concentration, while for ursodeoxycholic acid the increase is 15-fold. This means that this sensor system is able to differentiate between different steroids which is a prerequisite for a selective diagnostic test. More detailed studies on this new sensor system are underway.

We thank the Netherlands Technology Foundation (STW) for financial support and M. R. de Jong and Dr J. Huskens (University of Twente) for stimulating discussions and their help with the microcalorimetry experiments.

Table 1 Thermodynamic data for the complexation of *N*,*N*′-dinonyl-4,4′ bipyridinium bromide in **2**[a]

Host–guest complex	K_a/M^{-1}	ΔH/kcal mol^{-1}	$-T\Delta S$/kcal mol^{-1}
1:1	2.4×10^5	−2.4	−4.8
1:2	4.0×10^5	−1.4	−4.9

[a] Obtained from a microcalorimetric titration of the bipyridinium guest with **2**. The data points were fitted assuming a two step (**2**:guest = 1:1 and 1:2) equilibrium. The titration was performed at 25.0 °C in an aqueous 0.1 M Tris–HCl buffer of pH 7.0, by adding small aliquots of a solution of the bipyridinium salt (3.09×10^{-3} M) to a solution of **2** (1.00×10^{-4} M). The data were corrected for the dilution heat of the bipyridinium ion.

Notes and References

‡ Compounds **1**, **2** and **4** were fully characterised by ^{1}H NMR, MS and elemental analysis.

§ In addition to compound **2** we also prepared a ruthenium complex with two unsubstituted bipyridines and one molecule of **4** as ligands. This mixed complex has only one binding site for the bipyridinium guest and therefore a single competition event should take place. The emission properties of this complex turned out to be much weaker than those of **2**, and, therefore, were not further investigated.

A novel dodecanuclear chromium(III) cage: structural control by choice of leaving group

Published on the Web 17th March 2000

The synthesis and structural characterisation of a novel metal polyhedron is reported, involving chromium(III) and isobutyrate; comparison of this product with those obtained using different carboxylates suggests that the leaving group—which can be carboxylate, water or both—strongly influences the structure found.

Recent research on paramagnetic cages has been stimulated by the discovery of 'single molecule magnetism',[1,4] *i.e.* cages which have an energy barrier to reorientation of their magnetisation which is sufficiently high that at low temperature magnetisation is lost slowly when an external magnetic field is removed. We have been looking at new routes to high nuclearity cages, and found that heating small cages to high temperatures in an inert atmosphere can lead to oligomerisation.[5–7] Here we report a further reaction which gives a quite new metal polyhedron, but also which indicates that choice of carboxylate can control the structure of the resulting cage.

Reaction of $Cr(NO_3)_3{\cdot}9H_2O$ (0.050 mol) with $K(O_2CCHMe_2)$ (0.175 mol) in H_2O (100 cm^3) at *ca.* 80 °C gives a blue precipitate (> 90% yield) which is soluble in Pr^iOH. Analysis of this solid suggests formation of an oxo-centred chromium triangle, $[Cr_3O(O_2CCHMe_2)_6(H_2O)_3](NO_3)$ **1**.† Heating this precipitate at 400 °C under a stream of N_2 for 5 min gives a dark green solid which can be recrystallised from a mixture of Pr^nOH–CH_2Cl_2 to give green blocks suitable for X-ray study in 7 days. The yield of crude material is 84%. IR spectroscopy and elemental analysis confirm the crude and recrystallised compounds are identical.

Structural analysis‡ reveals a cage of stoichiometry $[Cr_{12}O_8(OH)_4(O_2CCHMe_2)_{16}(HO_2CCHMe_2)_4]$ **2** (Fig. 1). The cage consists of three face-sharing Cr_4O_4 heterocubanes, with the two terminal cubanes capped by further chromium centres attached to the external μ_4-oxides. The central cubane, containing Cr(3), Cr(4), Cr(5) and Cr(6), is held together exclusively through four μ_4-oxides [O(3), O(4), O(5) and O(6)]. These oxides have an unusual geometry, with one Cr–O–Cr angle *ca.* 164°, and five further Cr–O–Cr angles at between 90 and 101°. Therefore these four-coordinate oxygens have a 'saw-horse' geometry, rather than tetrahedral. This geometry may be found

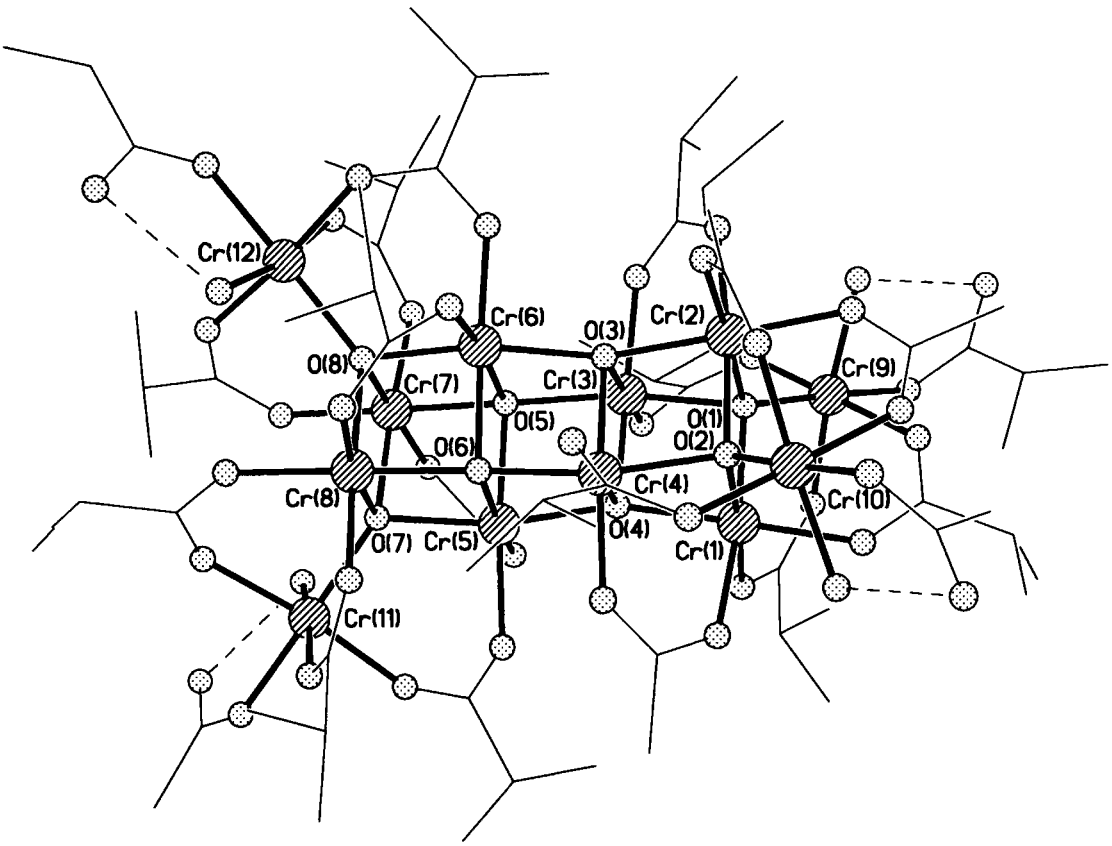

Fig. 1 The structure of **1**. The H-bonds between OH and protonated carboxylates are shown as dashed lines (see text). Bond length ranges: Cr–O(μ_4-O) 1.947–2.050, Cr–O(O_2CR) 1.943–1.997, Cr–O(OH) 1.966–1.986 Å. Av. esd. 0.008 Å. Bond angle ranges: *cis* O(μ_4-O)–Cr–O(μ_4-O) 78.8–89.3, *trans* O(μ_4-O)–Cr–O(μ_4-O) 163.7–166.1, *cis* O(μ_4-O)–Cr–O(O_2CR) 89.1–103.0, *trans* O(μ_4-O)–Cr–O(O_2CR) 169.6–179.2, *cis* O(O_2CR)–Cr–O(O_2CR) 81.7–90.8, *trans* O(O_2CR)–Cr–O(O_2CR) 173.0–173.9, *cis* O(OH)–Cr–O(μ_4-O) 92.6–93.4, *cis* O(OH)–Cr–O(O_2CR) 87.5–91.5, *trans* O(OH)–Cr–O(O_2CR) 170.1–171.4°. Av. esd. 0.4°.

DOI: 10.1039/b001140l

because this central Cr_8O_8 fragment can be considered to be a fragment of the NaCl structure.

The μ_4-oxides involved in the external heterocubanes have a more regular geometry, approximating to tetrahedral. The two Cr atoms in the face that is shared with the central heterocubane are each bridged to one of the two external Cr atoms [either Cr(1) and Cr(2) or Cr(7) and Cr(8)] by 1,3-bridging carboxylates. The final four Cr atoms [Cr(9), Cr(10), Cr(11) and Cr(12)] are found attached to the μ_4-oxides, and these are each further attached to the centre triple-cubane by bridging carboxylates. Two of these carboxylates bridge to Cr centres at the exterior of the triple-cubane [*e.g.* between Cr(9) and Cr(1)], and one bridges to a Cr centre in the shared-face [*e.g.* between Cr(9) and Cr(5)].

The chromium sites therefore fall into three groups. All are six-coordinate with regular octahedral geometries, but they vary in the groups attached to them. The Cr sites in the central cubane are each bound to four μ_4-oxides and two oxygen donors from carboxylate bridges. The Cr sites at the exterior of the triple-cubane are each bound to three μ_4-oxides and three O-atoms from carboxylates. The Cr sites capping the tricubane are each bound to one μ_4-oxide, three oxygens from bridging carboxylates and two terminal groups that can be described as a hydroxide and a HO_2CCHMe_2 group, or a water molecule and a $^-O_2CCHMe_2$. As there is a strong H-bond (O···O 2.47 to 2.53 Å) between these two groups, the exact description is perhaps unimportant.

The structure of **2** is new, but related to previous cages built of cubanes. The nearest relation is an octanuclear triple-cubane of cobalt(III), reported by Christou and coworkers,[10] which lacks the final four capping atoms. Three octanuclear cages, featuring Cr,[6] Fe[11] and Co,[12] contain a heterocubane capped on the μ_4-oxides. **2** combines features from both these previous structural types. There are also some similarities between **2** and Ni_{11} and Mn_{18} cages we have reported previously, which also feature face-sharing heterocubanes.[13]

It appears that the structure of **2** is largely maintained in solution. Two peaks, due to mono- and di-cationic species, dominate the electrospray mass spectrum.§ The mono-cationic species, at *m/z* 2351.4, can be assigned as ($\mathbf{2} - 2\ HO_2CCHMe_2 - 2H_2O)^+$ (calc. 2353.7), while the dication at *m/z* 1160.1 matches ($\mathbf{2} - 2\ HO_2CCHMe_2 - 2OH - 2H_2O)^{2+}$ (calc. 1159.8). Remaining peaks in the spectrum have less than 10% of the intensity of these peaks.

The reaction to form **2** gives quite different cages if the carboxylate present is benzoate[6] or pivalate (trimethylacetate).[7] As the yields are very good (approaching 90%) for all cages, it is worth discussing the difference in these three examples. For benzoate, assuming a stoichiometric reaction, a balanced equation for the reaction at 400 °C would give:

$$8\ [Cr_3O(O_2CPh)_6(H_2O)_2(OH)] \rightarrow 3\ [Cr_8(\mu_4\text{-}O)_4(O_2CPh)_{16}] + 20\ H_2O$$

This implies exclusive loss of water on heating. A balanced equation for the reaction involving pivalate is:

$$4[Cr_3O(O_2CCMe_3)_6(H_2O)_2(OH)] \rightarrow [Cr_{12}(\mu_4\text{-}O)_9(\mu_3\text{-}OH)_3(O_2CCMe_3)_{15}] + 9\ HO_2CCMe_3 + 4H_2O$$

This is mainly loss of carboxylic acid on heating, with some loss of water. The reaction which gives **2**, is intermediate between these two extremes:

$$4[Cr_3O(O_2CCHMe_2)_6(H_2O)_2(OH)] \rightarrow [Cr_{12}(\mu_4\text{-}O)_8(OH)_4(O_2CCHMe_2)_{16}(HO_2CCHMe_2)_4] + 4H_2O + 4HO_2CCHMe_2$$

It is noticeable that for benzoate, which has the lowest pK_a (4.19) of the three carboxylates, water is lost and the carboxylate is retained, while for both pivalate (pK_a 5.03) and isobutyric acid (pK_a 4.84) a mixture of acid and water are lost. This gives us a hypothesis to examine to see if further chromium cages with new metal polyhedra can be made from this simple route. It also implies an unusual means of influencing the structure of a cage by the pK_a of the leaving group.

Magnetic studies of **2** are disappointing.¶ The room temperature value of χ_mT (where χ_m is the molar magnetic susceptibility) of 18.1 emu K mol^{-1}, is below that expected for 12 non-interacting Cr^{III} centres (22.3 emu K mol^{-1}, for g = 1.99). This value indicates moderately strong antiferromagnetic exchange between metal centres. This is confirmed by the steady fall in χ_mT down to 25 K, where the value is 7.2 emu K mol^{-1}. Below 25 K the fall is more rapid, and at the lowest temperature studied (1.8 K) the cage is almost diamagnetic.

We thank the EPSRC(UK) for funding for a diffractometer, electrospray mass spectrometer and SQUID susceptometer, and for a studentship (to A. A. S.)

Notes and references

† Satisfactory elemental analyses were obtained for all compounds reported.

‡ *Crystal data* for $C_{80}H_{148}Cr_{12}O_{53}\cdot 3.5CH_2Cl_2$. **2**: triclinic, $P\bar{1}$, a = 16.770(5), b = 17.049(6), c = 24.405(9) Å, α = 88.12(3), β = 85.11(3), γ = 69.756(15)°, V = 6523(4) Å^3, M = 2755.15, Z = 2, T = 150.0(2) K, $R1$ = 0.0975. Data collection, structure solution and refinement were performed using programs DIRDIF[8] and SHELXL-97.[9] Only Cr and O atoms were refined anisotropically, and there is a disordered solvent region in the structure. CCDC 182/1559. See http://www.rsc.org/suppdata/cc/b0/b001140l/ for crystallographic files in .cif format.

§ Electrospray mass spectra were obtained on a Finnegan LCQ spectometer with the sample dissolved in CH_2Cl_2 which was added to MeOH prior to injection into the spectrometer.

¶ Variable-temperature magnetic measurements on **2** in the region 1.8–325 K were made using a SQUID magnetometer (Quantum Design) with samples sealed in gelatine capsules. Diamagnetic corrections for sample holders and samples were applied to the data.

Chemistry of M(allyl)$_3$ (M = Rh, Ir) compounds: structural characterization of tris(allyl)iridium complexes with phosphorus ligands†

Kevin D. John,[a] Kenneth V. Salazar,[b] Brian L. Scott,[a] R. Thomas Baker*[a] and Alfred P. Sattelberger*[a]

[a] *Los Alamos Catalysis Initiative, Chemical Science and Technology Division, Los Alamos National Laboratory, MS J514, Los Alamos, NM 87545, USA. E-mail: weg@lanl.gov; sattelberger@lanl.gov*

[b] *Materials Science and Technology Division, Los Alamos National Laboratory, MS E549, Los Alamos, NM 87545, USA*

Received (in Bloomington, IN, USA) 21st December 1999, Accepted 22nd February 2000

While addition of phosphorus ligands such as P(OPh)$_3$ to Rh(allyl)$_3$ gives monovalent Rh(allyl)L$_2$, the iridium analog gives stable mixed σ/π-tris(allyl) complexes, as evidenced by the structural characterization of mono-, bi-, and tri-dentate ligand complexes.

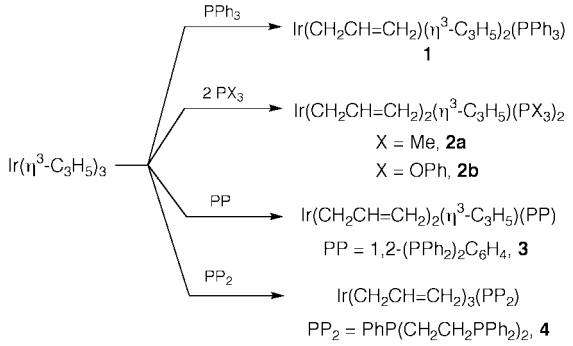
Recent efforts aimed at preparing and characterizing 'single-site' catalysts consisting of well defined, metal–oxide surface-bound, ligated transition metals have yielded exciting new catalytic systems for alkane metathesis and polyolefin depolymerization.[1,2] One particularly well-characterized class of such sites is derived from reactions of tris(allyl)rhodium, Rh(C$_3$H$_5$)$_3$, with carefully prepared, high-purity metal oxides.[3–5] The use of these systems for catalysis, however, is hampered by weak Rh–O bonds to the metal oxide surface and the proclivity of trivalent rhodium intermediates to undergo reductive elimination.[6] We are investigating the use of tris(allyl)iridium to prepare single-site catalysts with better thermal and reductive stability. In expanding the relatively unexplored[7] ligand addition chemistry of M(allyl)$_3$ compounds, we have developed an improved synthesis of the iridium analog and demonstrated that its reactions with a variety of phosphorus ligands all afford trivalent products, including a stable tris(σ-allyl) adduct.

The literature procedure[8] for preparing Ir(allyl)$_3$ from Ir(acac)$_3$ (acac = acetylacetonate) and (allyl)MgCl affords the desired product in *ca*. 20% yield. Ir(acac)$_3$ is itself prepared in *ca*. 10% yield from commercially available IrCl$_3$·*x*H$_2$O. We have found that the crystalline yellow tetrahydrothiophene adduct, IrCl$_3$(tht)$_3$, can be prepared from IrCl$_3$·*x*H$_2$O in *ca*. 90% yield *via* a slight modification of the original synthesis.[9] Reaction of IrCl$_3$(tht)$_3$ with allyllithium in benzene provides Ir(allyl)$_3$ in > 90% NMR yield [eqn 1)].[10]

$$IrCl_3(tht)_3 + 3\ LiC_3H_5 \xrightarrow[25\ °C]{\text{benzene}} Ir(C_3H_5)_3 + 3\ LiCl + 3\ tht \quad (1)$$

Removal of the solvent *in vacuo* followed by hexane extraction, filtration, solvent removal and sublimation of the brown residue affords colorless, microcrystalline Ir(allyl)$_3$ in *ca*. 45% yield. Treatment of isolated Ir(allyl)$_3$ with PPh$_3$ in toluene gives the 1:1 adduct Ir(σ-allyl)(π-allyl)$_2$(PPh$_3$) **1** in high yield (Scheme 1).‡ Alternatively, the hexane filtrate from the synthesis of Ir(allyl)$_3$ can be used directly to prepare **1** with comparable efficiency. Although complex **1** did not react further with excess PPh$_3$, even at 100 °C, smaller phosphorus ligands such as PMe$_3$ and P(OPh)$_3$ yielded 1:2 adducts Ir(σ-allyl)$_2$(π-allyl)L$_2$ **2a**,**b**. The chelating bis(phosphine) 1,2-(PPh$_2$)$_2$C$_6$H$_4$ gave a similar product **3**. Addition of the tridentate phosphine PhP(CH$_2$CH$_2$PPh$_2$)$_2$ to Ir(allyl)$_3$ gave the tris(σ-allyl) complex **4**. Complexes **2**–**4** were prepared in > 90% yield.

† Electronic supplementary information (ESI) available: preparative details and NMR data for **1**–**6** and crystallographic data for **1**, **3** and **4**. See http://www.rsc.org/suppdata/cc/a9/a910164k/



Scheme 1

The tris(allyl)iridium ligand adducts **1**–**4** were characterized by elemental analysis, NMR and IR spectroscopy, and, for **1**, **3** and **4** by single crystal X-ray diffraction (Fig. 1).§ IR analysis revealed that all phosphine adducts possess a characteristic C=C stretch in the region 1600–1610 cm^{-1}. ^{1}H and ^{13}C NMR spectra of **1** confirmed the presence of one σ-allyl and two *inequivalent* π-allyl groups, even at 100 °C. The PPh$_3$ ligand is located *trans* to a methylene group of one of the π-allyl groups, as evidenced by the large P–C coupling constant ($^2J_{PC}$ 38 Hz). Room temperature spectroscopic characterization of complexes **2a**,**b** was also consistent with an unsymmetrical structure, but a dynamic process leads to equivalent phosphorus ligands *and* σ-allyl groups at 40 °C. The P–C coupling constants for **2a**,**b** ($^2J_{PC}$ 32.6, 47.5 Hz, respectively) indicate that the phosphines are *trans* to the methylenes of the π-allyl group and the σ-allyls are thus mutually *trans*. By contrast, complex **3** has inequivalent σ-allyl groups, even at 100 °C, with the two phosphorus donors *trans* to one methylene of the π-allyl ($^2J_{PC}$ 39.4 Hz) and to one of the σ-allyl groups ($^2J_{PC}$ 79.5 Hz), respectively (Fig. 2). Adduct **4** has two sets of σ-allyl groups in a 1:2 ratio, consistent with C_s symmetry.

For compound **1**, the π-allyl ligand *trans* to P is symmetrically bound with typical Ir–C bond distances[11] (Ir–CH 2.143[5], Ir–CH$_2$ 2.201[5] Å). The other π-allyl ligand is unsymmetrically bound as a result of the *trans* influence of the σ-allyl {C(1)–Ir–C(7) 161.6[2]°; Ir–C(7) 2.268[4] *cf*. Ir–C(9) 2.196[4] Å}. A similar effect is seen in **3** {C(1)–Ir–C(7) 162.1(1)°; Ir–C(7) 2.270(2) *cf*. Ir–C(9) 2.202(3) Å}.

Reaction of Rh(allyl)$_3$[12] with PMe$_3$ afforded the 1:2 adduct **5** similar to **2a**. With triphenylphosphine[12] or better π-accepting ligands such as P(OPh)$_3$, however, only monovalent complexes, Rh(π-allyl)L$_2$ **6a**,**b** were obtained. Analogous complexes have been reported previously *via* alternative preparative routes.[11,13] The reaction leading to **6b** was accompanied by formation of the C$_6$ hydrocarbons *n*-hexane, hex-1-ene and 2-methylpentane.¶

In summary, our improved preparation of tris(allyl)iridium has enabled us to demonstrate that, in contrast to its rhodium analog, addition of a range of phosphorus ligands gives stable trivalent adducts which show no tendency to undergo hydro-

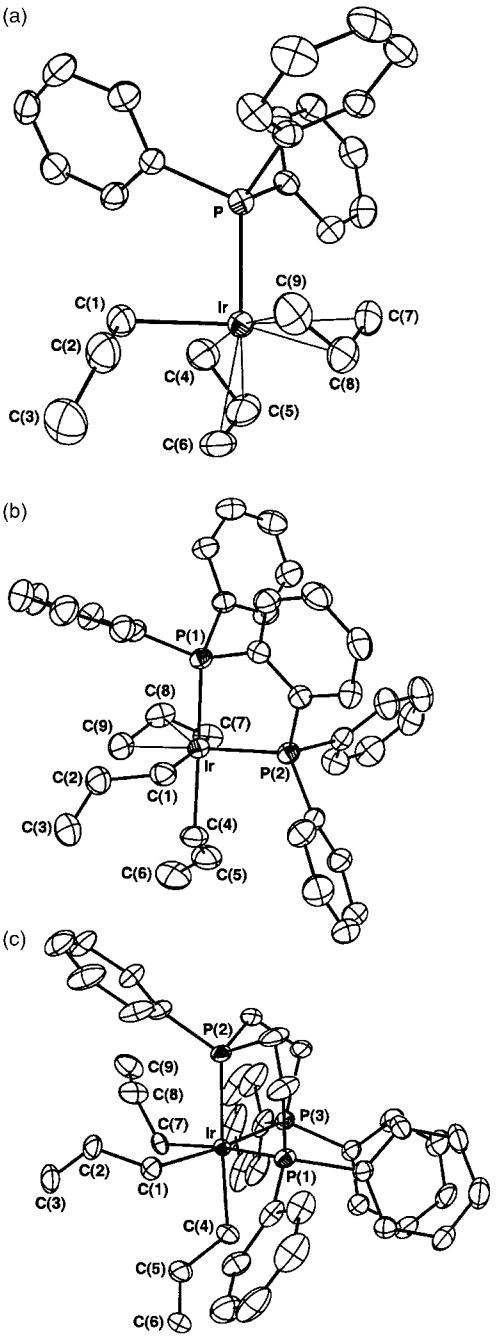


Fig. 1 Thermal ellipsoid representation of (a) **1**, (b) **3** and (c) **4** shown at the 50% probability level. For **1**, only one of the two molecules in the asymmetric unit is shown. For **1** and **4**, only one orientation of the disordered allyl group is shown.§ Hydrogen atoms have been omitted for clarity.

carbon elimination reactions. We are currently extending these findings to prepare trivalent, ligated iridium moieties on metal oxide surfaces for use in hydrocarbon functionalization.

We thank the Department of Energy's Laboratory Directed Research and Development (LDRD) program for financial support and Dr David Smith for preliminary experiments. This paper is dedicated to Professor John P. Fackler, Jr. on the occasion of his 65th birthday.

Notes and references

‡ *Preparation* of Ir(σ-allyl)(π-allyl)$_2$(PPh$_3$): to a room temperature solution of Ir(allyl)$_3$ (0.100 g, 0.32 mmol) in toluene (10 mL) was added triphenylphosphine (0.083 g, 0.32 mmol). The reaction mixture was stirred for 2 h and then filtered. The filtrate was concentrated to *ca*. 2 mL and allowed to sit at room temperature for 24 h to yield **1** as colorless crystals in 92.7% yield (0.170 g, 0.24 mmol). This procedure is representative of the syntheses of all of the phosphine complexes with the caveat that the preparation of **3** and **4** required brief heating (80 °C, 10 min) in order to dissolve the ligand.

§ CCDC 182/1552. See http://www.rsc.org/suppdata/cc/a9/a910164k/ for crystallographic files in .cif format.

¶ *Preparation* of Rh(π-allyl)[P(OPh)$_3$]$_2$: to a room temperature solution of Rh(allyl)$_3$ (0.031 g, 0.14 mmol) in toluene (5 mL) was added triphenyl phosphite (0.086 g, 0.28 mmol) with stirring. Approximately 30 min after the phosphite addition, a brilliant yellow precipitate was observed. The reaction mixture was stirred for an additional 2 h during which time the precipitate dissolved. The filtrate was then concentrated to *ca*. 2 mL and allowed to stand at −35 °C for 24 h to yield **2b** as yellow crystals in 96.7% yield (0.102 g, 0.13 mmol). GC–MS analysis of a portion of this reaction revealed that the organic products were *n*-hexane, 2-methylpentane and hex-1-ene.

Received (in Cambridge, UK) 9th December 1999, Accepted 10th February 2000

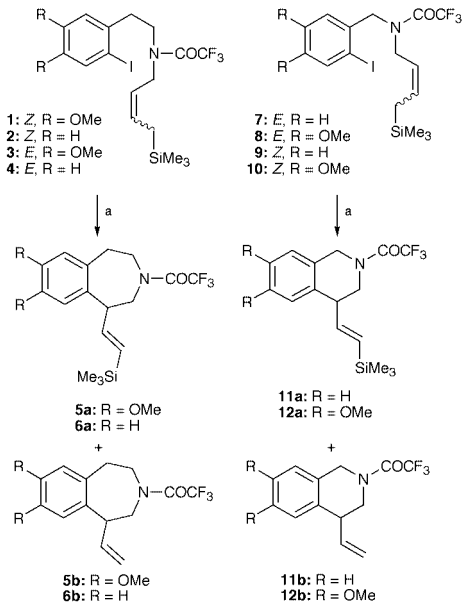
The intramolecular Heck reaction of the iodoaryl compound 1 with a (*Z*)-allyl silane moiety in the presence of the chiral ligand (+)-TMBTP 13 leads to the benzazepine 5b with 92% ee, whereas 3 with an (*E*)-allyl silane moiety in the presence of the chiral ligand (*R*)-BITIANP 14 gives 5a with 91% ee; in a similar way, 9 and 10 were transformed in the presence of 13 into the tetrahydroisoquinolines 11b and 12b with 86 and 84% ee, respectively.

The Heck reaction,[1] the Pd(0) catalyzed coupling of an aryl or alkenyl halide or triflate with an alkene, is nowadays one of the most important C–C bond forming transformations and has been used in numerous syntheses of natural products;[2] extensive work has also been done in the enantioselective series.[3] Here, we describe the enantioselective intramolecular silane terminated Heck reaction[3g–i] of the substrates **1**–**4** and **7**–**10** with the novel chiral ligands (+)-4,4′-bis(diphenylphosphino)-2,2′,5,5′-tetramethyl-3,3′-bithiophene [(+)-TMBTP] **13**[4a] and (*R*)-(+)-2,2′-bis(diphenylphosphino)-3,3′-bibenzo[*b*]thiophene [(*R*)-BITIANP] **14**[4b] as well as, for comparison, also with the well known and widely used ligands (*R*)-MeO-BIPHEP **15**[5] and (*R*)-BINAP **16**,[6] to give the substituted benzazepines **5a**/**b** and **6a**/**b** and the tetrahydroisoquinolines **11a**/**b** and **12a**/**b** (Scheme 1). In addition, we have used phosphinooxazolines[3c,e] as chiral ligands, however, in our systems these ligands show low reactivity.

We have recently shown that one of the main disadvantages of the Heck reaction, namely the low selectivity in the elimination of the L_nPd–H species to form the double bond as the last step in the catalytic cycle, can be overcome by using allyl silanes as terminating alkenes.[3g–i] This allowed the selective formation of tertiary stereogenic centers starting from acyclic alkenes for the first time. However, the use of this procedure for the synthesis of chiral heterocyclic compounds such as benzazepines and tetrahydroisoquinolines with **16** as ligand was rather disappointing owing to its low enantioselectivity.[3i] By contrast, employing the novel chiral ligands **13** and **14** (Scheme 2) we are now able to synthesize these heterocycles with up to 92% ee.

13 had not been used successfully previously for enantioselective transformations, whereas **14** was employed with great success in the hydrogenation of C–C and C–O double bonds[4b] and in intermolecular Heck reactions.[3a] In our investigations we used (*E*)- and (*Z*)-allyl silanes as substrates, which not only gave different enantioselectivities using the various ligands, but also allowed us to control the formation of the different side chains in the products, namely a vinyl or a trimethylsilylvinyl group.

The selective formation of the (*Z*)-allyl silanes **1**, **2** and **9**, **10**, respectively, was performed by a Ni catalyzed hydrogenation of the corresponding propargyl silanes **17**–**20**. For the synthesis of the (*E*)-compounds **3**, **4** and **7**, **8**, respectively, the propargyl amine **21** was reduced with $LiAlH_4$, the obtained allyl amine **22** alkylated with **23**, **24**, **25** or **26** and finally treated with trifluoroacetyl anhydride (Scheme 3).



Scheme 1 Syntheses of benzazepines **5** and **6** and tetrahydroisoquinolines **11** and **12** by silane terminated enantioselective Heck reaction. *Reagents* a, $Pd_2dba_3{\cdot}CHCl_3$, ligand, Ag_3PO_4 (1.1 eq.), DMF.

The Heck reaction of the (*Z*)-allyl silane **1** in the presence of triphenylphosphane gave nearly exclusively the benzazepine **5b** with a vinyl side chain (Table 1, entry 1); using the chiral ligands **15** (entry 2) and **14** (entry 3), **5b** again was the main product, however, the enantioselectivity was < 50% ee; with (*S*)-BINAP *ent*-**16** (entry 4), **5b** was formed with 64% ee. In contrast, using **13**, the product **5b** could be obtained in good yield, with complete regioselectivity and 92% ee (entry 5). Similar results were found with the (*Z*)-allyl silane **2**, but here the highest ee value using **13** as chiral ligand was only 70% ee (entry 9). This could probably be ascribed to the lower ligand Pd ratio, which was necessary owing to the low reactivity using higher ratios. This, however, is a general problem in enantioselective Heck reactions.

Employing the (*E*)-allyl silane **3** again an excellent enantioselectivity of 91% ee was obtained (entry 10). For the first time in the enantioselective silane terminated Heck reation, **5a** with a

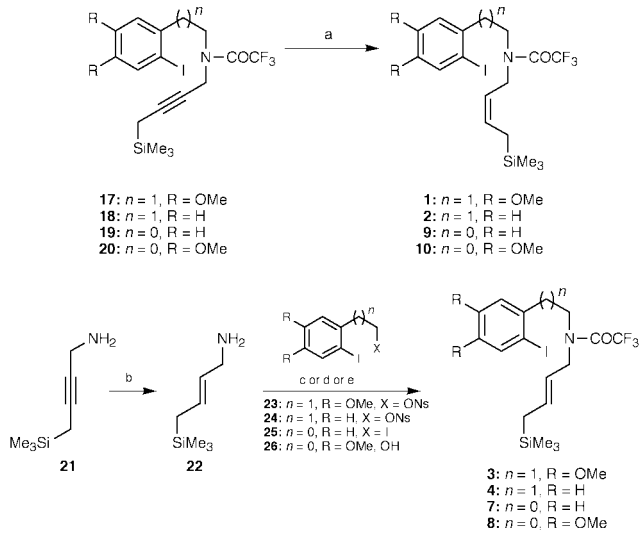
[a] Determined by chiral HPLC (Baker CHIRALCEL OD-R). [b] $Pd(OAc)_2$ was used instead of $Pd_2dba_3{\cdot}CHCl_3$. [c] KOAc (4 eq.) and NPr_4Br (1 eq.) were used instead of Ag_3PO_4. [d] Not determined.



Scheme 3 Syntheses of the (*E*)- and (*Z*)-allyl silane precursors. *Reagents and conditions*: a, H_2, $Ni(OAc)_2$, $NaBH_4$, ethylenediamine, EtOH; **1**: 65%, **2**: 90%, **9**: 88%, **10**: 60%; b, $LiAlH_4$, THF, heat; 50%; c, 1. Pr^i_2NEt, MeCN–MeOH, 50 °C; 2. $(CF_3CO)_2O$, NEt_3, THF, 0 °C → r.t.; **3**: 42%, **4**: 40%; d, 1. $(CF_3CO)_2O$, NEt_3, THF, 0 °C → r.t.; 2. NaH, DMF, 0 °C → r.t.; **7**: 75%; e, 1. $(CF_3CO)_2O$, NEt_3, THF, 0 °C → r.t.; 2. MsCl, NEt_3, CH_2Cl_2, 0 °C → r.t.; NaH, DMF, 0 °C → r.t.; **8**: 39%.

trimethylsilylvinyl side chain is the main product, with **14** as the best ligand; thus, **13** gave **5a** with only 8% ee (entry 11). Interestingly, in the Heck reaction of the (*Z*)- and the (*E*)-allyl silanes with **14** and **13** the opposite enantiomers of **6b** were formed, whereas in the presence of **16** the double bond configuration had virtually no influence on the facial selectivity.

Astoundingly, the Heck reactions of the (*E*)-allyl silanes **7** and **8** were only marginally successful. Here the regio- and enantio-selectivity were rather low. However, the (*Z*)-compounds **9** and **10** gave much better results. Using **13** as chiral ligand, the vinyl substituted tetrahydroisoquinolines **11b** and **12b** were obtained with high enantioselectivities of 86 and 84% ee, and complete regioselectivity (entries 20 and 22).

These results together with the investigations of intermolecular Heck reactions[3a] clearly show that the novel ligands **13** and **14** are superior to known ligands, at least in the investigated transformations.

This work has been supported by the Fonds der Chemischen Industrie. We thank the Degussa AG for a generous gift of precious metals and the Hoffmann-La Roche AG for ligand **15**. We are also greatly indebted to Dr S. Console (Chemi SpA) for providing the new ligands.

New effective synthons for supramolecular self-assembly of *meso*-carboxyphenylporphyrins

Yael Diskin-Posner, Sanjay Dahal and Israel Goldberg*

School of Chemistry, Sackler Faculty of Exact Sciences, Tel-Aviv University, 69978 Ramat-Aviv, Tel-Aviv, Israel. E-mail: goldberg@post.tau.ac.il

Received (in Oxford, UK) 10th February 2000, Accepted 28th February 2000

Tesselation of new supramolecular motifs of the tetra(4-carboxyphenyl)porphyrin building blocks by metal ion templates has been demonstrated in crystals, characterizing the square-planar $[Na^{+}\cdot(-COOH)_4\cdot X^{-}]$ and the tetrahedral $[Zn^{2+}\cdot(-COOH)_2\cdot(-COO^{-})_2]$ molecular recognition elements for effective multiporphyrin assembly.

The *meso*-tetra(4-carboxyphenyl)porphyrin (TCPP) framework turned out to be an extremely versatile building block for effective supramolecular self-assembly and fabrication of new materials.[1–4] We have reported previously the formation of interpenetrating as well as non-penetrating two-dimensional arrays of TCPP with large interporphyrin voids through cooperative hydrogen-bonding between the terminal carboxylic groups of adjacent porphyrin entities.[2,3] Noteworthy is a unique and remarkably stable molecular sieve structure with nanosized (15 Å wide) channels.[4] Here, we communicate the first formulations of extended TCPP networks sustained by metal ion templates through multiple coordination to the carboxylic substituents.[5] Such templates may provide higher enthalpic driving force for the self-assembly process than the soft hydrogen bonding interactions alone, by adding ion-pairing attractions between the assembling entities. They could be thus more helpful in efforts to tailor porous solids based on robust multiporphyrin architectures.

Mononuclear and binuclear metallo-carboxylic/carboxylate assemblies are quite abundant in crystallographic databases. Yet, these synthons have not been used thus far in the context of porphyrin supramolecular chemistry. The large and rigid TCPP is in fact an excellent building block to this aim containing four coordination sites, each one pointing in a different direction. Here, we describe two representative examples of TCPP networks tesselated by metal ion auxiliaries which provide the supramolecular organizing force by multiply coordinating to the carboxylic functions (compounds **1** and **2**).† The self-assembly process of the free-base TCPP in the presence of NaCl and benzoic acid leads to the formation of two-dimensional multiporphyrin arrays sustained by sodium ions. The resulting motif of the supramolecular organization, involving TCPP and sodium benzoate (associated with deprotonation of the benzoic acid and expulsion of HCl) is illustrated in Fig. 1. It charaterizes the $Na^{+}(-COOH)_4$ synthon (see also Fig. 3) in which every alkali metal cation is coordinated (at 2.318–2.360 Å) to the carboxylic groups of four surrounding porphyrin moieties. The O(=C) binding sites involved in these interactions form an approximate square planar arrangement around the central cation. The coordination sphere around each cation is supplemented on one side by a coordinating molecule of the ethyl benzoate solvent (at $Na^{+}\cdots O$ 2.261 Å). The benzoate anion provides another enforcement to the layered porphyrin structure by approaching the sodium cation from the opposite side, its carboxylate oxygens acting as effective proton acceptors for the four carboxylic groups of the converging porphyrins (this forces all O–H proton donors to point in the same direction, inducing a chiral polar structure in space group $P2_1$). The corresponding O···(H)O distances of these hydrogen bonds are within 2.57–2.68 Å, reflecting on a relatively strong

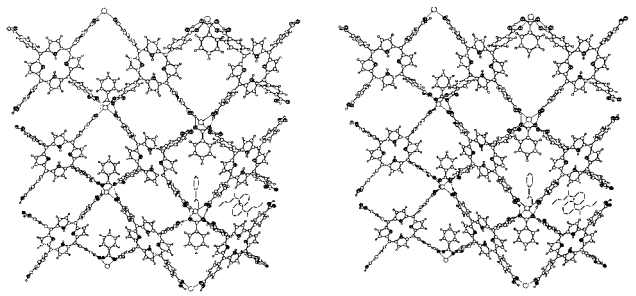

Fig. 1 Stereoview of the TCPP 'wavy' open networks formed in **1**, which are assembled by multiple coordination of the porphyrin units to the sodium benzoate template (*b* is horizontal and *a*–*c* is vertical). These layers stack tightly in the crystal along *a* + *c*. The interporphyrin channels thus formed are accommodated by molecules of the ethyl benzoate solvent (one of them coordinating to the sodium ion as well), as illustrated for clarity only in the lower right corner. The sodium ion is represented by a large uncrossed circle.

attraction. Every TCPP unit associates in this way with four different sodium benzoate entities (through four partly charged hydrogen bonds and four coordinative bonds to sodium), thus yielding a rather robust coordination polymer in two dimensions. Geometric optimization of these interactions results in the formation of corrugated ('wavy') porphyrin layers, adjacent units being related to each other either by pure lattice translation or by screw axis symmetry. van der Waals stacking of such layers one on top of the other in the normal direction (along *a* + *c*), at an average distance of *ca.* 4.21 Å between the corresponding porphyrin sections, composes the three-dimensional crystal structure. Additional molecules of the ethyl benzoate solvent fill effectively the channel voids which propagate in the lattice between the porphyrin columns of the stacked layers (Fig. 1).

The formation of the multiporphyrin networks in **2** is associated (in the absence of other acidic species in the crystallization environment) with double deprotonation of ZnTCPP to preserve neutrality. The observed assembly of the anionic porphyrin arrays templated by zinc ions is shown in Fig. 2. As commonly observed, the zinc ion residing within the porphyrin core is five-coordinated deviating outward from the porphyrin plane and attracting one molecule of the ethylene glycol solvent as an axial ligand. The external zinc cation is rather strongly coordinated (at 1.948–1.967 Å) to four different ZnTCPP units, maintaining an approximate tetrahedral geometry of coordination around it; it represents the $[Zn^{2+}\cdot(-COOH)_2\cdot(-COO^{-})_2]$ synthon (Fig. 3). This assembly mechanism *via* ion-pairing forces is assisted by additional intermolecular hydrogen bonding between the converging ZnTCPP units (involving the ethylene glycol axial ligand as well). Further coordination of any given ZnTCPP moiety to four different cations yields continuous diamondoid arrays consisting of chain-segments of nearly coplanar porphyrins which propagate in an alternating manner roughly in perpendicular directions. The resulting robust arrays thus extend in three dimensions, and the only way to pack them in a condensed

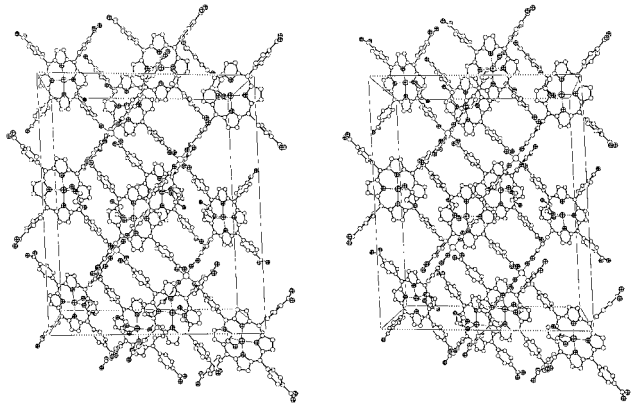

Fig. 2 Crystal structure of **2** (stereoview approximately down the *b*-axis; *a* is horizontal). It shows the diamondoid networks of $ZnTCPP^{2-}$ units templated by external Zn^{2+} cations, and the way they interpenetrate into one another. Large channel voids (*ca*. 7.5 Å in vdW diameter) centered at ($\frac{1}{2}$, 0, *z*) and (0, $\frac{1}{2}$, *z*) extend in the crystal along the *c*-axis between the concave surfaces of the porphyrin bands, explaining the large solvent content of this lattice. The zinc-ion template is represented by a large uncrossed circle. Hydrogen atoms are omitted for clarity.

crystalline phase must involve interpenetration.[6] Fig. 2 illustrates this feature, confirming that this is indeed the case. In the observed interwoven structure overlapping porphyrin bands of adjacent networks lie parallel to each other (at 4.33 and 4.62 Å) in the commonly observed offset stacked manner. The glycol–$ZnTCPP^{2-}$–Zn^{2+} networks occupy only about 40% of the crystal volume, reflecting on the geometric rigidity of this structure. Hexagonally shaped channels, which extend between the interpenetrating arrays, account for most of the remaining space. These channels propagate along the *c*-axis of the crystal between the concave surfaces of the porphyrin moieties, are centered at ($\frac{1}{2}$, 0, *z*) and (0, $\frac{1}{2}$, *z*), and have an average van der Waals diameter of 7.5 Å. They are filled in a diffused manner with numerous molecules (about 100 per unit cell) of the glycol solvent, which preserves the crystallinity of this open lattice.

The high significance of the metal ion templates to the formulation of TCPP-based networks with high structural rigidity has been demonstrated most recently by a successful crystal engineering of a stable metalloporphyrin zeolite analogue.[7] The latter represents three-dimensionally structured open arrays of interlinked $(ZnTCPP)^{2-}$ and 4,4′-bipyridyl units sustained by binuclear $[(Na^+)_2{\cdot}(-COOH)_6{\cdot}(-COO^-)_2]$ synthons (Fig. 3). It has been shown previously that cooperative hydrogen-bonding and coordination forces are sufficiently robust to direct concerted intermolecular organization and formation of stable nanostructures in solution as well.[5b,8]

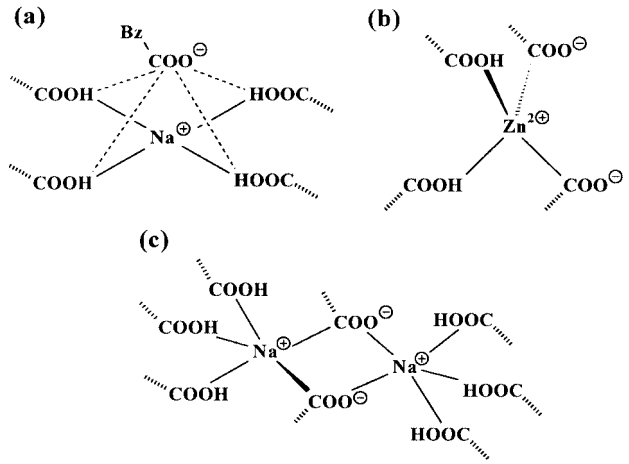

Fig. 3 The tesselation modes of TCPP supramolecular networks *via* metal ion templates in (a) **1**, (b) **2** and (c) the zeolite analogue reported in ref. 7. Every carboxylic or carboxylate group displayed here belongs to a different TCPP/ZnTCPP building block of the supramolecular aggregate.

Correspondingly, the above described molecular recognition algorithms can be also useful in the synthesis of *discrete* porphyrin-based supramolecular domains for the formulation of biomimetic photonic models and other molecular devices.[9]

This research was supported in part by the Israel Science Foundation administered by Israel Academy of Sciences and Humanities.

Notes and references

† Crystals of **1** were obtained by dissolving TCPP in a mixture of methanol, ethyl benzoate and benzoic acid in the presence of NaCl; those of **2**, by dissolving ZnTCPP in a hot mixture of methanol and ethylene glycol in the presence of $Zn(OAc)_2$. Both crystals turned out to contain a considerable amount of solvent in interporphyrin channels (see below).

Crystal data: **1,** $[(C_{48}H_{30}N_4O_8){\cdot}3(C_9H_{10}O_2){\cdot}(C_7H_5O_2)^-{\cdot}Na^+]$: M = 1385.4, monoclinic, space group $P2_1$, a = 9.854(1), b = 32.338(1), c = 11.358(1) Å, β = 110.52(1)°, V = 3389.6(2) Å^3, Z = 2, T = 110 K, D_c = 1.357 g cm^{-3}, μ(Mo-Kα) = 1.00 mm^{-1}, 10388 unique reflections ($2\theta_{max}$ = 51.5°). The final $R1$ = 0.065 for 7865 observations with $F_o > 4\sigma(F_o)$, $R1$ = 0.095 ($wR2$ = 0.178) for all unique data, $|\Delta\rho| \leqslant 0.74$ e Å^{-3}.

2, $[(C_{48}H_{26}N_4O_8Zn)^{2-}{\cdot}Zn^{2+}{\cdot}(C_2H_6O_2)_x]$: monoclinic, space group $C2/c$, a = 27.694(1), b = 19.510(1), c = 32.598(1) Å, β = 92.72(1)°, V = 17593.1(2) Å^3, Z = 8, T = 115 K, 13909 unique reflections ($2\theta_{max}$ = 50.0°). For x = 13 (see below) M = 1724.2, D_c = 1.302 g cm^{-3}, μ(Mo-Kα) = 0.63 mm^{-1}. This crystallographic refinement converged at $R1$ = 0.175 for 6785 reflections with $F > 4\sigma(F)$, $R1$ = 0.30 and $wR2$ = 0.42 for all the data. One molecule of ethylene glycol is coordinated to the five-coordinate zinc ion residing in the porphyrin center. The remaining solvent molecules incorporated the interporphyrin voids of the crystal lattice were found to be heavily disordered, and their structure could not be modeled. The contribution of the diffused solvent was thus subtracted from the diffraction pattern by the 'Squeeze' method.[10] This refinement converged smoothly at final $R1$ = 0.076 for 5931 observations with $F_o > 4\sigma(F_o)$, $R1$ = 0.150 ($wR2$ = 0.165) for all unique data, $|\Delta\rho| \leqslant 0.27$ e Å^{-3}. The integrated total residual electron density accounted for the presence of at least twelve additional molecules of ethylene glycol, or a corresponding combination of ethylene glycol and methanol (which represents about 45% of the overall electron count), in the asymmetric unit of this structure. Covalent coupling of an phospholipid monolayer on the surface of ceramic materials

Yikang Wang, Tsueu Ju Su, Rebecca Green, Yiqing Tang, Dmitrii Styrkas, Timothy N. Danks, Roger Bolton and Jian R. Lu*

Department of Chemistry, University of Surrey, Guildford, UK GU2 5XH. E-mail: j.lu@surrey.ac.uk

Received (in Oxford, UK) 13th January 2000, Accepted 28th February 2000

A new synthetic route to the covalent bonding of an organic monolayer bearing terminal phosphorylcholine (PC) groups onto the surface of silicon oxide is reported; such monolayers prohibit the deposition of enzymes and proteins and can be used to improve surface biocompatibility.

Phospholipids are a group of molecules with double acyl chains and zwitterionic head groups. Their existence in membrane walls is primarily responsible for creating a biocompatible environment so that proteins, enzymes and platelets in blood do not foul the surface of blood cells. The dominant phospholipids on the outer surface of membrane walls have phosphorylcholine (PC) head groups. The biocompatibility is therefore rendered by these lipid heads. The role played by these phospholipids has been known for decades and a great deal of endeavour has been made to mimic the natural behaviour of these phospholipids. Most of the activities have focused on creating polymeric materials containing pendent PC groups[1–3] although a great deal of work has explored other types of biocompatible polymers, *e.g.* polyurethane and polymethacrylate grafted with polyethylene oxide.[4] Literature results have shown that PC polymers are superior to other types of polymers in reducing protein deposition and the subsequent biological consequences.[1–5] Surfaces coated with PC polymers also show much better performance against thrombosis than heparin derivatized surfaces.[4]

An alternative approach to the coating of PC polymers is *via* covalent bonding of an organic monolayer bearing terminal PC groups onto a solid substrate. We report here, a new synthetic route to the construction of a PC monolayer onto silicon oxide. Covalent bonding of a PC monolayer should fulfil the same anti-fouling function as PC-incorporated polymers, and bring a number of improved features over polymer coating. First, although the coated layer is thin, its thickness can be reliably controlled to an accuracy around a few Å. Second, the coverage of the PC groups can be directly manipulated. The delicate chemical environment supporting the PC groups can also be engineered effectively. Third, the chemically grafted monolayer is robust and can withstand very harsh conditions. Leaching is therefore not a problem. These features are critical to a number of applications where small coating agents are desired. These include coating the surfaces of the inner pores of ceramic membranes and dialysis films. As the dimension of the inner pores within these membranes is usually between 1 and 100 nm and is comparable to the size of polymers, it is difficult to coat such pore surfaces with PC polymers. The incorporation of silyl groups in PC polymers can further intensify the blockage on the outer surface of membranes. For membranes with larger pore diameters, it is difficult to control the thickness of the coated films and the final dimensions of the coated pores will be poorly defined.

To our knowledge there is no literature work concerning the formation of a covalently bound PC monolayer on the surface of silicon oxide. The work of Hayward *et al.*[6,7] has demonstrated the potential of the formation of PC monolayers, but in their case the attached alkyl chain bearing terminal PC group is unstable as a result of the presence of an oxygen between carbon and silicon. The resulting alkyl silicate structure readily hydrolyses, with loss of the alkyl chain and its PC functionality. Our approach is similar to that of Hayward *et al.*, but we sought direct chemical bonding between the carbon and silicon so that stable chemical grafting is obtained. Because silica has a surface layer of hydroxide, a layer of organic compound can be grafted through silane cross-linking. In comparison with C–O–Si bonding, the formation of Si–O–Si connections at the end of the organic monolayer is much more stable. In fact, this part of the layer is identical to the structure of the underlying silica layer. The PC groups can be attached through reaction with hydroxy or amine groups in the outer surface of the organic layer. We show in the following a route (Scheme 1) *via* hydroxy groups as intermediate functionalities. Although different alkyl chain lengths can be used we choose the covalent binding of pentadecanol as an example.

The synthesis starts with 1,12-dibromododecane to which an allyl group is attached to one end and a silane group on the other *via* Grignard chemistry, resulting in the formation of 14-pentadecenyl trichlorosilane. The freshly cleaned silicon surfaces were treated with 1 mmol of 15-pentadecenyl trichlorosilane in dichloromethane–hexadecane (1 : 4, v/v) at 11 °C for 1.5 h. A number of studies have shown that the coverage and uniformity of the attached layer are strongly affected by temperature. Higher temperature tends to lower the surface coverage, possibly as a result of the thermal motions within the anchored layer.[8,9] In addition, the reaction time is also crucial; while insufficient time may not allow enough coating to proceed, immersion of the silicon surface in the solution for too long a period may lead to the formation of an inhomogeneous layer. The reaction conditions were optimised through a number of trial experiments, using spectroscopic ellipsometry to examine the quality of the coated surface layers. The advancing contact angle of the alkene surface was found to be 93 ± 2°, consistent with the value expected for an organic surface with double bond end groups. Structural information about the coated organic layer was obtained by fitting a uniform layer model to the two ellipsometric angles, Ψ and Δ measured at the air/solid interface, where Ψ measures the change in the amplitude of the

beam before and after reflection and Δ measures the change in phases. In principle, the fitting directly leads to the thickness (τ) and volume fraction of the layer (ϕ). However, for such thin surface layers, there is little resolution to decouple τ and ϕ although the ellipsometric measurement is sensitive to the product of the two. For the layer coated under the optimised conditions, the fitting suggests a thickness of 17 ± 3 Å if the density of the layer is taken to be the same as liquid pentadecene. Thinner layers were detected when shorter reaction times were used. Under prolonged reaction conditions (*e.g.* a few days), layers were found to be well over 30 Å, suggesting the formation of multilayers. In contrast, the thickness of 17 ± 3 Å is a good indication of monolayer coating. The conversion of the double bond into the primary alcohol functions was achieved by reacting the grafted pentadecenes with BH_3·THF for 10 min, followed by alkaline hydrogen peroxide for 1 h.[9] This treatment did not alter the layer thickness within the quoted experimental error, as expected, but the contact angle was found to drop to 54 ± 3°, consistent with the presence of an organic layer containing terminal hydroxy groups on silicon oxide.

The subsequent connection of PC groups was achieved by reaction of the bound organic hydroxy groups with $POCl_3$ in the presence of triethylamine, leading to the attachment of phosphoric chloride systems, followed by a reaction with $HOCH_2CH_2NMe_3^+OAc^-$. A similar process using $HOCH_2CH_2NH_2$ in the final step, resulted in the formation of phosphorylamine (PA) groups. The ellipsometric measurement showed an increase in layer thickness by some 6 ± 3 Å after PC groups were attached and the contact angle with *ca.* 37 ± 2°. For PA, the layer was found to be thickened by some 8 ± 3 Å and the contract angle was 41 ± 2°. One would expect that the attachment of PC groups produces a thicker head group layer than that of PA groups, but the difference is within the experimental error.

The successful attachment of PC groups has been further confirmed using time-of-flight secondary ion mass spectrometry (TOF-SIMS). The results listed in Table 1 show the presence of a number of mass units (*e.g.* NMe_3^+, $CH_2NMe_3^+$) that match the characteristic fragments disintegrated from the PC monolayer. These fragments were not observed from the measurements on the surface coated with pentadecanol. Parallel SIMS experiments were also performed using the thin films of dipalmitoylglycerylphosphorylcholine (DPPC) and synthetic polymers grafted with PC head groups;[10–12] the results showed identical mass fragments characteristic of PC head groups, further confirming the presence of PC groups in the coated monolayer. Finally, the effectiveness of our C_{15}PC monolayer as a protein repellant interface has been characterised by performing ellipsometry measurement at the solid/solution interface at 25 °C. At a lysozyme concentration of 1 g dm^{-3} and at pH 7, the surface excess of lysozyme was found to be 0.5 ± 0.3 mg m^{-2}, as compared with 3.6 ± 0.3 mg m^{-2} at the bare silicon oxide/water interface.[13] The residual amount of lysozyme adsorption at the C_{15}PC surface is comparable to the values obtained on the surfaces of two PC polymers,[10–12] showing that the surfaces coated with PC monolayers are as effective as the PC polymers in their resistance to protein fouling.

We thank the EPSRC for a grant under the ROPA Scheme.

Oxazole–Carbonyl photocycloadditions: selectivity pattern and synthetic route to *erythro* α-amino, β-hydroxy ketones†

Axel G. Griesbeck,* Maren Fiege and Johann Lex

Institute of Organic Chemistry, University of Cologne, Greinstr. 4, D-50939 Köln, Germany. E-mail: griesbeck@uni-koeln.de

Received (in Liverpool, UK) 20th January 2000, Accepted 23rd February 2000

The photocycloaddition of aliphatic and aromatic aldehydes with 2,4,5-trimethyloxazole proceeds highly regio- and diastereoselectively to give bicyclic oxetanes; hydrolytic cleavage of these adducts gives selectively *erythro* α-amino, β-hydroxy methyl ketones.

The photocycloaddition of electronically excited carbonyl compounds to alkenes (Paternò–Büchi reaction, PBR) is *the* important synthetic route to oxetanes which can be subsequently transformed into polyfunctionalized products.[1] Concerning the regio- and especially diastereoselectivity of the PBR, recent experimental and theoretical work brought a remarkable increase in our understanding of triplet 1,4-biradical behaviour[2] which also improved the synthetic significance of this reaction.[3]

The regioselectivity of the PBR with unsymmetrically substituted cycloalkenes is only moderate but can be substantially increased by using cyclic enol ethers[4] and enamines,[5] respectively. The majority of these substrates show moderate simple diastereoselectivities with distinct preference for *endo*-products. This selectivity pattern is completely inverted for carbo- and heterocyclic 1,3-dienes. With respect to regio- and simple diastereoselectivity, furans have been most extensively investigated and *exo*/*endo*-selectivities of 212 : 1 (benzaldehyde addition to furan)[6] to 363 : 1 (mesitaldehyde addition to furan)[7] were determined. Similar reactivities and selectivities have been reported for pyrroles, thiophenes, thiazoles, imidazoles and pyrazoles as alkene components in Paternò–Büchi reactions.[8]

To the best of our knowledge, oxazoles have not been investigated until now. This class of heterocycles can be viewed as masked α-amino ketones or aldehydes (Fig. 1). Analogous to the furan–carbonyl photocycloaddition which equals a photo-Aldol process,[9] the oxazole-carbonyl process results in masked α-amino, β-hydroxy carbonyl compounds.

A similar concept has been evaluated already by the groups of Sekretar[10] and Scharf.[11] They used 2(3*H*)-oxazolones and 2,3-dihydrooxazoles, respectively, as alkene components and investigated the photocycloaddition with ketones and α-keto carboxylates. The simple stereoselectivity of these reactions was high, however, the regioselectivity was low with preferential formation of the 2-amino-substituted oxetanes in the case of 2,3-dihydrooxazoles. With phenylglyoxylic esters, the photocycloaddition proceeded efficiently and *endo*-phenyl (> 95%) selectively.[12]

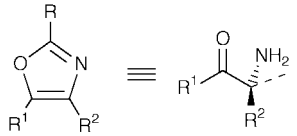

Fig. 1

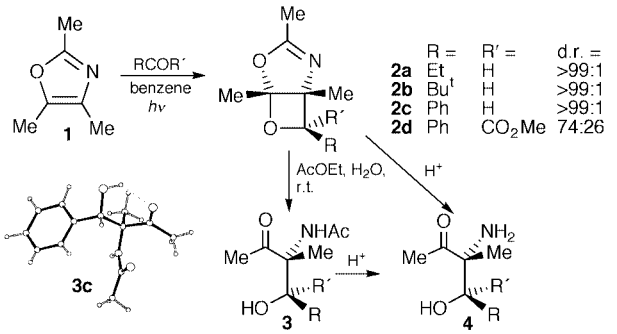
† Regarded as Part 10 of the series 'Stereoselectivity of Triplet Photocycloadditions', Part 9: A. G. Griesbeck and M. Fiege, in *Molecular and Supramolecular Photochemistry*, ed. V. Ramamurthy and K. S. Schanze, Marcel Dekker, New York, 2000, vol. 6, in press.

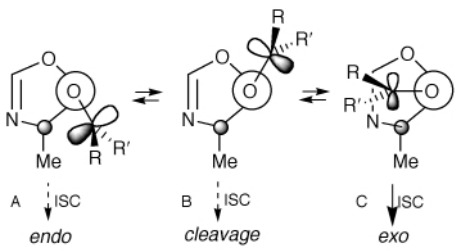
We photolyzed 2,4,5-trimethyloxazole **1** together with several aliphatic and aromatic aldehydes. In all cases, only the regioisomers **2** were formed with very high (*exo*) diastereoselectivity (> 99 : 1) in near quantitative yields (Scheme 1).



Scheme 1

Both regio- and diastereoselectivity are in accord with the rules reported by us for the carbonyl–furan photocycloaddition reaction,[6] but unusual for the oxazole derivatives mentioned above. The stereoselectivity decreased for the methyl ester of phenylglyoxylic acid: a 3 : 1 mixture of *exo*/*endo*-phenyl substituted oxetanes **2d** was isolated, however, still with high regioselectivity. This result is remarkable because not only has the stereoselectivity decreased in comparison with the results described by Scharf and coworkers,[12] but also the direction of stereocontrol was inverted. The resulting bicyclic oxetanes are thermally as well as hydrolytically labile products and were ring-opened during chromatography on silica or upon standing after several days at room temperature in moist solvents. For the benzaldehyde-derived *N*-acylated β-aminoalcohol **3c**, the primary product of this processes starting with **2c**, the *erythro* configuration was proven by means of an X-ray crystal structure determination.‡ The unprotected β-amino alcohols can be directly synthesized *via* treatment of the oxetanes **2** with trifluoroacetic acid or under milder conditions with acetic acid and conventional work-up.

From a mechanistic point of view, the stereoselectivity of the PBR with trimethyloxazole results from a combination of two factors: (1) the spin–orbit coupling controlled ISC-geometries favourable for spin inversion and transition to closed-shell products[2] and (2) the methyl-group effect which we have discovered for cyclic monoalkenes.[13] The three projections shown in Scheme 2 correspond to the three ISC-reactive



Scheme 2

DOI: 10.1039/b000578i

conformations which lead to cleavage reaction, *endo*- and *exo*-product formation, respectively.

Aldehydes (R′ = H) show strong preference for bond formation *via* structure **C** and thus give *exo* oxetanes with high stereoselectivities. For the unsubstituted furan, ketoesters (R = alkyl, aryl; R′ = CO_2R'') prefer structure **A** and give preferentially the *endo* diastereoisomers. If, however, the ring terminus of the triplet biradical is methyl substituted, additional steric interactions disfavor structure **A**. Methyl phenylglyoxylate addition to trimethyloxazole corresponds to such a case and a 3:1 *exo*/*endo* (with respect to the position of the phenyl group) mixture resulted.

In summary, we have shown that the oxazole–carbonyl photocycloaddition serves as an excellent method for the regio- and diastereoselective preparation of *erythro* β-amino alcohols from aldehydes and keto esters, respectively.

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Communication b000578i

The first X-ray structurally characterized M_3L_2 cage-like complex with tetrahedral metal centres and its encapsulation of a neutral guest molecule

Hong-Ke Liu,[a] Wei-Yin Sun,*[a] De-Jian Ma,[a] Kai-Bei Yu[b] and Wen-Xia Tang[a]

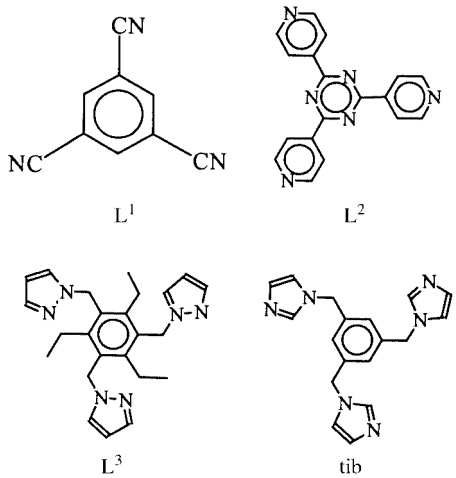
[a] *Coordination Chemistry Institute, State Key Laboratory of Coordination Chemistry, Nanjing University, Nanjing 210093, China. E-mail: sunwy@netra.nju.edu.cn*

[b] *Analysis Center, Chengdu Branch of Chinese Academy of Science, Chengdu 610041, China*

Received (in Cambridge, UK) 4th January 2000, Accepted 28th February 2000

The first X-ray structurally characterized M_3L_2 cage-like complex with tetrahedral metal centres $[Zn_3(tib)_2(OAc)_6]\cdot xH_2O$ [tib = 1,3,5-tris(imidazol-1-ylmethyl)benzene, $x \approx 4$] obtained by reaction of zinc(II) acetate with the tripodal ligand tib exhibits guest inclusion properties of neutral molecule such as synthetic camphor in aqueous solution.

Metal-directed assembly has been proved to be a useful methodology in supramolecular chemistry.[1] Frameworks with specific topologies such as honeycomb grids and cages have been obtained by assembly of suitable metal ions with rationally designed tripodal ligands such as L[1], L[2] and L[3].[2–4] Among



these, cage-like complexes have attracted much attention owing to their interesting properties and possible applications, *e.g.* molecular and chiral recognition.[5] The groups of Fujita, Steel, Robson, Stang and Raymond have performed outstanding work in the construction of cage-like complexes.[3–8] Most recently, an $M_{12}L_8$ type cage was obtained by assembly of a tri-bidentate ligand with Cu(II),[8] and larger cages with four organic moieties and eight-coordinate copper(III) centres have been reported by Beer's group.[9] However up to now, to our knowledge, no M_3L_2 cages have been isolated and characterized by X-ray structural analysis, although a guest-induced Pd_3L_2 cage-like complex [L = 1,3,5-tris(4-pyridylmethyl)benzene] and analogous cages have been reported.[6] Moreover, in reported M_6L_4 cage-like complexes, the metal ions are essentially square planar, *e.g.* Pd(II), Pt(II) or octahedral *e.g.* Ga(III), Fe(III),[3,4,6,7,10] with no case of the metal ion being tetrahedral being reported. Herein we report the assembly and X-ray crystal structure of an M_3L_2 cage-like complex formed between a novel tripodal ligand, 1,3,5-tris(imidazol-1-ylmethyl)benzene (tib), and zinc ion, which has tetrahedral configuration. The complex shows the interesting property of guest inclusion in aqueous solution.

The tib ligand was prepared from 1,3,5-tris(bromomethyl)benzene and imidazole in a molar ratio of 1 : 3 in dimethyl sulfoxide under strong alkali (KOH) conditions.† Its trinuclear zinc(II) complex $[Zn_3(tib)_2(OAc)_6]\cdot xH_2O$ ($x \approx 4$), was synthesized by self-assembly of the tib ligand with zinc acetate dihydrate in ethanol solution.‡ An X-ray crystal structural analysis provides direct evidence that the complex is an M_3L_2 cage.§ As shown in Fig. 1, two tib ligands that are both in *cis, cis, cis*-conformations adopt a face-to-face orientation and are joined together by three zinc atoms to generate an individual three-dimensional cage. Highly disordered water molecules may present in the cage as suggested by elemental analysis.‡ Each zinc atom is four-coordinate with two oxygen atoms from two acetate anions and two nitrogen atoms of imidazole from two different tib ligands. The coordination geometry of the zinc atoms is distorted tetrahedral with coordination angles ranging from 101.5(4) to 123.3(7)°. The distance between the zinc atoms are 9.10 Å and the two benzene ring planes are strictly parallel with each other with a separation of 9.49 Å.

It is clear from the X-ray structural analysis that the title complex has a large cavity inside the cage and therefore is

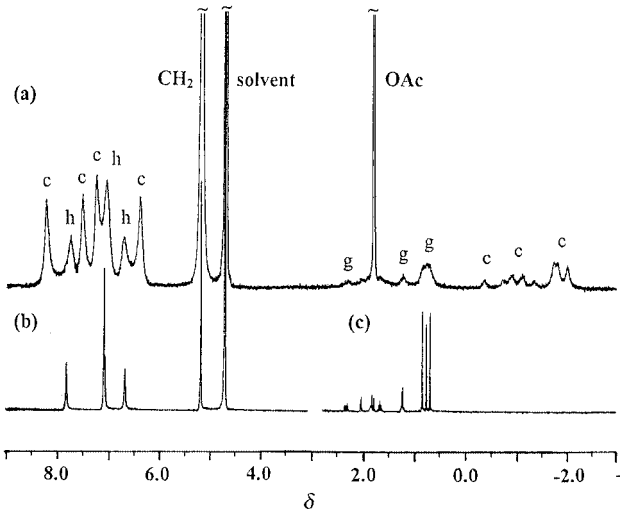

Fig. 2 ^{1}H NMR spectra in D_2O at 293 K: (a) camphor (3.0 mM) + $[Zn_3(tib)_2(OAc)_6]$ (3.0 mM); (b) downfield region for $[Zn_3(tib)_2(OAc)_6]$ (3.0 mM); (c) camphor (3.0 mM). c refers to complexed species; h to host species and g to guest species.

expected to have the ability to encapsulate guest molecules.[6] Thus we observed remarkable ability of the complex to encapsulate neutral molecules in its aqueous solution. It has been reported that ^{1}H NMR spectroscopy is a powerful method for investigation of host–guest complexation.[6,11] Fig. 2(a) shows the ^{1}H NMR spectrum of the complexation of the $[Zn_3(tib)_2(OAc)_6]$ with camphor in deuterated aqueous solution. Two kinds of signal were observed for both the host and guest species when the guest camphor was added to a D_2O solution of $[Zn_3(tib)_2(OAc)_6]$. One set remains unshifted compared with the corresponding signals of the host [Fig. 2(b)] and of the guest [Fig. 2(c)], *i.e.* the unshifted signals originate from uncomplexed species. The other set of upfield shifted signals are from the guest camphor molecules, while for the signals of the host molecule, both up- and down-field shifts were observed. These up- and down-field shifted signals for the host and guest species arise from complexed species.[11] The integration ratio of the host and guest signals in the ^{1}H NMR spectrum confirmed the 1 : 1 stoichiometry for the complexation between the cage complex and camphor and indicated that *ca.* 60% of the camphor was complexed [Fig. 2(a)]. The results indicate that the camphor molecule, which has a diameter of *ca.* 6 Å, is large enough so that species inside and outside of the cavity of the complex can be distinguished on the NMR time scale. The broadening of the signals as observed in Fig. 2(a) is due to slow exchange between the free and complexed species, since the signals become much broader when the temperature is raised. The kinetic process of the complexation of the cage with camphor was investigated by two-dimensional exchange spectroscopy (2D EXSY).¶ The rate constants for the forward (complexation) and reverse (decomplexation) process are 3.9×10^3 M^{-1} s^{-1} and 32.9 s^{-1}, respectively, giving an equilibrium constant of 117.6 M^{-1}. For chain-like molecules such as ethanol, ethyl acetate, diethyl ether or *n*-butyl alcohol, no complexation was observed.

In conclusion, the present study shows that an M_3L_2 cage is assembled from five small component molecules by the rational design of a suitable tripodal ligand and metal ions, and provides example of supramolecules with interesting properties such as guest inclusion.

We are grateful for funding from the National Nature Science Foundation of China for financial support of this work.

Do interstrand hydrogen bonds contribute to β-hairpin peptide stability in solution? IR analysis of peptide folding in water

Christopher S. Colley, Samuel R. Griffiths-Jones, Michael W. George* and Mark S. Searle*

Received (in Cambridge, UK) 14th January 2000, Accepted 24th February 2000

The amide I carbonyl stretch in the IR spectrum, together with ^{1}H NMR Hα chemical shifts, have been used to investigate the folding of a 16-residue β-hairpin peptide in water: while Hα shifts are consistent with a significant population of the folded state (*ca.* 40%), we see no features in the IR spectrum in the amide I region to suggest a significant contribution from interstrand hydrogen bonds, although at high peptide concentration (≥10 mM) the appearance of a new band at 1616 cm^{-1} is consistent with the onset of irreversible peptide aggregation.

The question of how the compact, biologically active state of a protein can assemble reversibly from a relatively disordered polypeptide chain remains a cornerstone to our understanding of the relationship between amino acid sequence and three dimensional structure. One possible mechanism for the folding process proposes that short range interactions within the polypeptide chain are responsible for transient formation of elements of secondary structure (α-helix or β-sheet) which can subsequently act as nucleation sites for further collapse to the native folded state.[1] Protein fragments or designed peptides have proved useful in modelling these nucleation events. While α-helical peptides have been well studied,[2] short peptides that form β-structures, in particular β-hairpins, have been described only relatively recently.[3] There is still some debate as to which are the dominant factors in stabilising these model β-sheet structures, with contrasting opinions on the relative importance of interstrand hydrogen bonding interactions, hydrophobic burial of sides chains and amino acid conformational preferences arising from local steric interactions.[4] Although it is widely regarded that the hydrophobic effect contributes significantly to the folding of globular proteins,[5] thermodynamic evidence from simpler model systems is more difficult to obtain.

In several recent studies, we have investigated in detail the reversible temperature-dependent changes in the ^{1}H NMR Hα chemical shifts that accompany the folding of β-hairpin peptide **1** (Fig. 1) in aqueous solution.[4,6,7] Changes in Hα chemical shift deviations from random coil values indicate that the β-hairpin unfolds at temperatures both above and below *ca.* 298 K. A thermodynamic analysis of temperature-dependent effects on Hα chemical shifts shows that folding is entropy-driven at 298 K with a corresponding negative change in heat capacity.[4,6] Both of these thermodynamic signatures, including the observation of 'cold denaturation', point to the hydrophobic effect providing a key driving force for folding, at least in this model system. However, the contribution interstrand hydrogen bonding interactions make to the stability of the folded state is unclear.

The sensitivity of vibrational spectroscopy to protein structure is well documented, particularly the use of the amide I carbonyl stretch to monitor hydrogen bonding and secondary structure formation.[8–10] Variable temperature IR spectroscopy has been used to probe protein secondary structure in a model α-helix,[11] in β-sheet rich proteins,[12] other β-hairpin systems,[10] in intermolecular β-sheet formation,[13] and even in monitoring peptide aggregation and the onset of amyloid formation.[14,15] For the model α-helix, temperature-dependent changes in the IR spectrum show evidence for unfolding above 298 K with loss of intramolecular hydrogen bonding. Previous studies of β-hairpin peptides[10] have reported a characteristic amide I band at *ca.* 1617 cm^{-1} in aqueous solution at a significantly lower wavenumber than corresponding bands for unstructured random coil peptides.

We have investigated by FTIR spectroscopy the conformation in aqueous solution of the β-hairpin peptide **1**, and a truncated eight residue analogue **2** (Fig. 1). The latter represents the isolated C-terminal β-strand of the hairpin which we use as a reference state. FTIR spectra of peptide **2** at 2 mM concentration show an envelope of strong amide I bands centred around 1640 and 1670 cm^{-1} [Fig. 2(a)], which exhibit little temperature-dependence in the range 278–330 K, consistent with a monomeric, disordered 'random coil' conformation.[10]

Surprisingly, a 2 mM solution of β-hairpin peptide **1** gives a remarkably similar FTIR spectrum to peptide **2** [Fig. 2(b)]. These spectral features again show little temperature-dependence. Resolution enhancement techniques (derivative spectroscopy and Fourier self-deconvolution) reveal a very weak band at 1616 cm^{-1}, representing only a few percent of the total intensity of the amide I envelope. The temperature-dependent changes in the IR spectrum are very small and reversible, which we interpret in terms of temperature variation in band shape and position. To check the extent to which the hairpin is folded in aqueous solution we have repeated ^{1}H NMR experiments on the *exact same* sample used for FTIR analysis. Deviations of Hα chemical shifts from random coil values (ΔδHα values) are shown in Fig. 3 for both peptides **1** and **2**. While ΔδHα values for peptide **2** are very small, again supporting a random coil conformation, reasonably large deviations are apparent for peptide **1**, showing the characteristic pattern for a folded β-hairpin peptide, and ΔδHα values virtually identical to those previously described.[4]

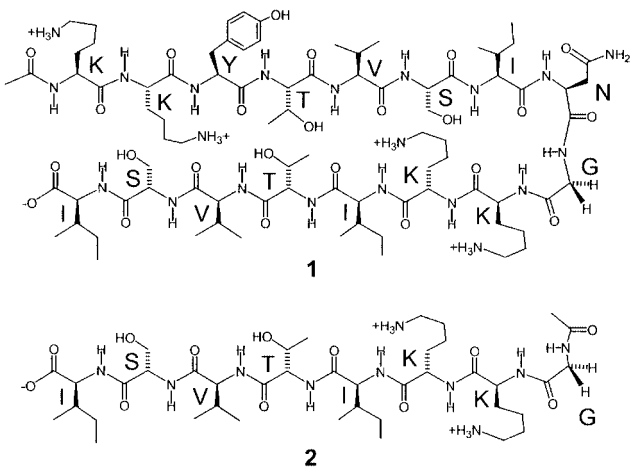

Fig. 1 Schematic representation of the amino acid sequences of peptides **1** and **2**, using the one letter amino acid code. The backbone alignment of the two strands of the β-hairpin peptide are shown to indicate the position of putative interstrand hydrogen bonding interactions.

DOI: 10.1039/b000426j

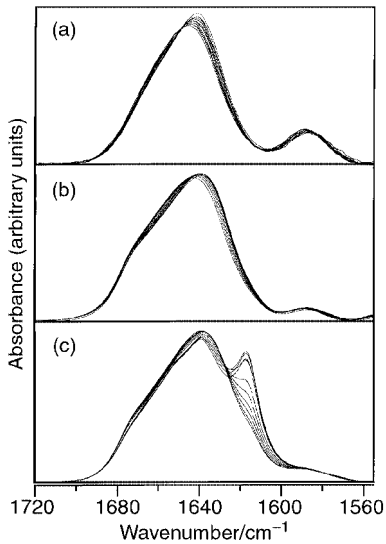

Fig. 2 Variable temperature FTIR spectra of (a) 2 mM aqueous solution of peptide **2**; (b) 2 mM solution of β-hairpin peptide **1**; (c) 10 mM solution of peptide **1**, all in the temperature range 278–330 K. FTIR spectra were collected using a Nicolet Nexus 670 FTIR spectrometer equipped with MCT detector. Circulating water bath controlled temperatures were measured with a J-type thermocouple inside the cell. All peptide solutions were made up in D_2O and the pH (uncorrected for the deuterium isotope effect) adjusted to 5.0 using D_2O solutions of NaOD and DCl. Typically IR spectra were collected as 1000 scans with a resolution of 2 cm^{-1} using a 100 μm cell with calcium fluoride windows. In (a) and (b), the signal intensity at 1640 cm^{-1} increases with increasing temperature, but in (c) decreases with increasing temperature in the range 278–330 K.

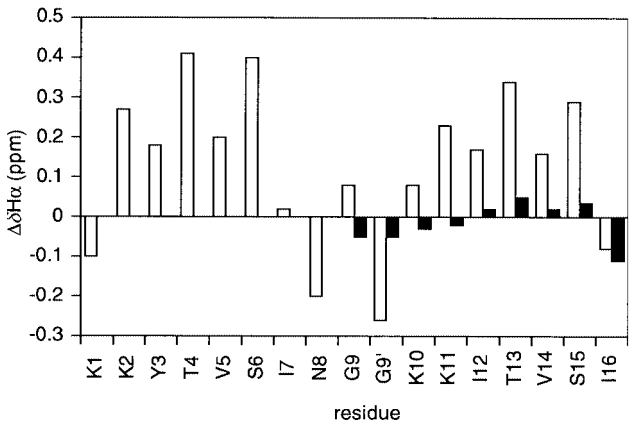

Fig. 3 Deviations of Hα chemical shifts from random coil values[18] (ΔδHα values) for β-hairpin peptide **1** and 8-mer peptide **2** (black bars) at 298 K. NMR data were collected at 500 MHz using reported procedures.[4]

Increasing the concentration of β-hairpin peptide **1** from 2 to 10 mM results in the appearance of a new band in the FTIR spectrum at *ca.* 1616 cm^{-1} [Fig. 2(c)], which is highly and irreversibly temperature-dependent, increasing in intensity initially as the temperature is increased. Integration of this band suggests that at its maximum intensity it corresponds to *ca.* 20% of the total concentration of the peptide. We readily attribute these concentration-dependent changes to irreversible peptide aggregation as reported for a number of model peptides,[10] and partially unfolded proteins that undergo amyloid formation.[14]

Despite previous IR studies of isolated β-hairpin peptides, that identify and assign an amide I band at *ca.* 1617 cm^{-1} to hydrogen bonding across the β-sheet,[10] such features are not a characteristic of the current system. The thermodynamic profile for the folding of peptide **1** has already indicated that hydrophobic contributions from the burial of non-polar side chains play an important part in stabilising the folded conformation.[4,6] The results presented in this study from FTIR analysis in aqueous solution suggest that direct interstrand hydrogen bonding plays, at best, a rather minor role in hairpin stabilisation, and that water molecules appear to compete effectively for hydrogen bonding sites. Significant effects on the amide I band only become apparent in the aggregated state at high concentrations, where arrays of intermolecular hydrogen bonds are co-operatively stabilised. There is, however, still some disagreement regarding the relative importance of the various contributions to the observed changes in the amide I band; hydrogen bonding interactions and other mechanisms involving adjacent oscillators coupled through the covalent framework, have already been discussed.[8,13,16,17]

Although hydrophobic side chains appear to be able to interact sufficiently to populate the folded state of the monomeric peptide, as evident from extensive NOE measurements,[4,6] the hydrophilic peptide backbone appears to remain sufficiently solvated that we can detect no significant changes in the amide I band between the single stranded reference peptide **2** and the folded hairpin **1**. Precise details of the nature of the 'folded state' remain unclear,[6] but explicit consideration of the role of solvent molecules in such models appears to be a necessity, with the possibility of water intercalated between the amide groups of opposing strands. Weakly stabilised β-hairpins ($\Delta G \approx 0$) undoubtedly adopt dynamic conformations in solution. Molecular dynamics simulations show that hydrophobic contacts between strands can be achieved without greatly restricting the orientation of the peptide backbone, while retaining some degree of solvent accessibility.[6] Measurements of backbone $^3J_{NH-H\alpha}$ values for peptides **1** and **2** demonstrate that the peptide backbone is no more ordered in the folded hairpin than in the reference peptide,[4] suggesting that the amino acid sequence predisposes the β-strand residues to adopt an extended conformation, with β-hairpin folding arising from coalescence of the two β-strand arms.

We are grateful to the EPSRC for studentships to C. S. C. and S. R. G.-J. and to Roche Discovery, Welwyn, UK for a CASE award to S. R. G.-J. We thank the Department of Chemistry for financial contributions to this work and John Keyte in the School of Biomedical Sciences for peptide synthesis.

Received (in Oxford, UK) 18th January 2000, Accepted 3rd March 2000

We report the synthesis and structure, obtained through Rietveld analysis of powder synchrotron X-ray diffraction data, of zinc oxide clusters encapsulated in zeolite LTA.

There is currently considerable interest in the study of zinc oxide nanoparticles and clusters formed within zeolite crystallites, which is based on potential applications in optics, electronics, sensors and photocatalysis.[1–4] Recent work has concentrated on the characterisation of the materials by spectroscopic methods such as UV–VIS and diffuse reflectance IR spectroscopy,[1–3] but to date there is no crystallographic information on the structure and location of such clusters. A variety of different synthetic routes have been used for the preparation of zinc oxide clusters in zeolites.[1–4] On account of our longstanding interest in metal-zeolite reactions,[5,6] we have adopted the method of Lee *et al.*,[3] who synthesised zinc oxide clusters in zeolite Y through oxidation of the zinc-loaded zeolite, and have applied it to a range of zeolites. As a first step we decided to examine the zinc-loaded zeolites prior to oxidation, and report that in zeolite A (LTA) oxygen-containing clusters are already present at this stage of the synthesis.

The zinc ion-exchanged form of zeolite A (Zn-A) was prepared from as-synthesised Na-A by conventional ion-exchange methods.[7] The zinc-loaded material was prepared through the reaction of dehydrated Zn-A (12 h, 500 °C under vacuum) with Zn powder in a sealed, evacuated (1×10^{-5} mbar) quartz tube. A homogeneous yellow powder was obtained after reaction for 7 days at 500 °C, with a small excess of zinc metal deposited on the ends of the tube. For structural studies to be carried out, a small amount of the sample was placed in a 0.7 mm diameter glass capillary and sealed with epoxy resin in an argon-filled glovebox. X-Ray powder diffraction data were collected at room temperature at station X3B1 at the National Synchrotron Light Source, Brookhaven National Laboratory, USA. The wavelength of the radiation (0.69884 Å) was chosen to minimise any sample absorption problems.

Least squares refinement of our structural model was carried out with the GSAS suite of programs.[8] The starting model was based on the framework coordinates for dehydrated Zn-A obtained by McCusker and Seff,[9] who used the primitive cubic space group $Pm\bar{3}m$ with a lattice constant of *ca*. 12.2 Å. A detailed justification for the use of $Pm\bar{3}m$ in the analysis of X-ray diffraction data from zeolite A has been given by Cruz *et al.*[10] There was no evidence in our data to suggest the need to use a doubled unit cell. After refinement of the background (automated linear interpolation), lattice parameter, peak profiles and framework atomic positions, difference Fourier maps were used to find the positions of three zinc sites. These sites were located at the centre of the sodalite cage (0, 0, 0), in the 6-ring (just inside the sodalite cage) (0.18, 0.18, 0.18) and inside the sodalite cage along the body diagonal (0.13, 0.13, 0.13). Refinement of the fractional occupancies of these sites gave a total zinc content of approximately nine ions per unit cell, three more than necessary to balance the negative charge of the framework.

Difference Fourier maps were used to check for any residual electron density. One peak was found inside the sodalite cage at (0, 0, 0.17). Examination of the bond distances between this site and the zinc site at the centre of the sodalite cage suggested that this new site was actually occupied by oxygen as the bond length of 2.08 Å would be much too short for a Zn–Zn interaction. No sites were found in the α-cage. After further refinement of atomic positions, isotropic thermal parameters and further fitting peak profiles, final difference Fourier maps were again calculated and showed no electron density due to further atomic positions. This refinement (labelled A) converged with $\chi^2 = 2.71$, $R_{wp} = 7.53\%$, $R_p = 5.83\%$, $D_{wd} = 0.807$ and $R_{F^2} = 8.41\%$. Owing to the pronounced asymmetry and large intensity of the first peak the refinement was carried out again with this peak excluded, to avoid excessive bias. This second refinement (B) converged with $\chi^2 = 1.83$, $R_{wp} = 7.32\%$, $R_p = 5.37\%$, $D_{wd} = 1.080$ and $R_{F^2} = 8.86\%$. There was little difference in the structural models obtained from each refinement; the atomic positions, fractional occupancies and isotropic thermal parameters were all within two standard deviations, except for the fractional occupancy of O(4) which was within four standard deviations. Final atomic coordinates, fractional occupancies and isotropic thermal parameters for refinement A are given in Table 1. Observed, calculated and difference plots are shown in Fig. 1. A close visual inspection indicates the main features in the difference plot can be attributed to imperfect modelling of the peak shapes, rather than a mismatch in intensities.

The presence of a non-framework oxygen site implies that a cluster comprising only zinc atoms has not been formed. McCusker and Seff[9] also found non-framework oxygen in Zn-A dehydrated at 600 °C, which was ascribed to water molecules coordinated to Zn^{2+}. In the present work the average unit cell composition[11] is approximately $Zn_{2.75}O_{2.7}/Zn_6[Al_{12}Si_{12}O_{48}]$. It

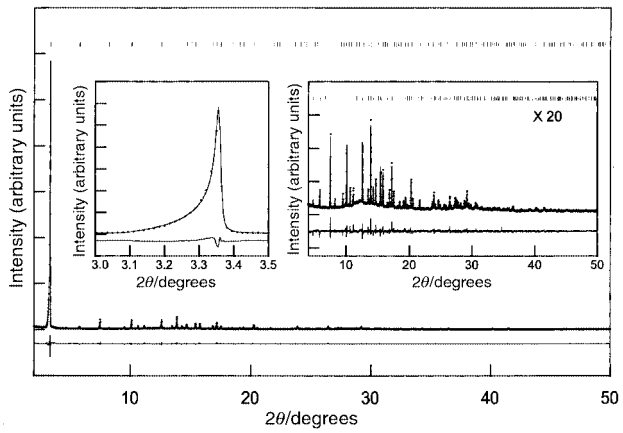

Fig. 1 Final Rietveld fits for refinement A (first peak included) showing observed (dots), calculated (solid line) and difference plots.

is unlikely the extra framework oxygens in this case are due to residual water molecules as the oxidation state of the added zinc atoms would then be close to zero. Likewise, if hydroxy groups were present, the oxidation state of the extra zinc atoms would be approximately +1. If O(4) is considered as O^{2-}, however, the extra zinc atoms can then be considered to be Zn^{2+}. Rittner *et al.*[12] have shown that zinc vapour reacts readily with zeolite H-Y to form a Zn^{2+}-exchanged product. For these reasons we propose that zinc oxide clusters have been formed as a result of the reaction of zinc metal with residual water molecules that remain coordinated to zinc ions within the zeolite after dehydration at 500 °C.

The model obtained from this refinement shows that clusters are formed in the sodalite cage of zeolite A (Fig. 2) as opposed to the larger α-cage as recently proposed by Lee *et al.*[3] The sum of the fractional occupancies of Zn(1) and Zn(3) is approximately unity, without the use of constraints. This is an expected consequence of the distance between the two sites, which is too short for both to be occupied simultaneously. Relatively short Zn–O bond distances supplemented by bond valence sum calculations[12] suggest that Zn(3), located at the centre of the 6-ring, can be considered as Zn^{2+} coordinated only to the oxygen atoms which form the 6-ring. McCusker and Seff[9] found a zinc site in approximately the same position in dehydrated Zn-A. In addition, the fractional occupancies of Zn(1) and Zn(2) are approximately equal, suggesting that each atom at Zn(2) is surrounded by eight at Zn(1). It seems logical to conclude that zinc atoms occupy Zn(1), recessed into the sodalite cage, only when bonded to O(4) atoms. We therefore propose that clusters are formed from Zn(1), Zn(2) and O(4) in approximately 75% of the sodalite cages, and the remaining 25% contain eight Zn^{2+} ions at Zn(3) coordinated to the 6-rings. As there is no evidence of a superstructure, the occupancy of the sodalite cages by the clusters must be random.

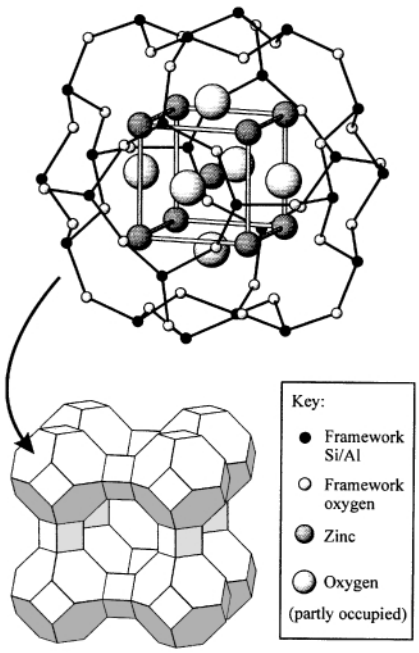

Fig. 2 Structure of zeolite LTA showing the proposed cluster arrangement in the sodalite cage. The oxygen sites are partially occupied.

The proposed cluster is illustrated in Fig. 2 with a zinc atom at the centre of the sodalite cage [Zn(2)] surrounded by eight zinc atoms [Zn(1)] at a distance of 2.78 Å. By symmetry there are six possible oxygen sites each at a distance of 2.08 Å from Zn(2) and 2.32 Å from four atoms at Zn(1). As the results indicate an average of three to four oxygen atoms per cluster, the exact geometry remains unknown. Although the difference between the extra zinc and oxygen contents obtained from the refinement is not significant, there is a possibility that the clusters are slightly oxygen deficient and this may account for the yellow colour of the compound. It is possible that the oxygen content is limited by the small number of water molecules remaining in the zeolite after high temperature dehydration.[9] Experiments aimed at varying the oxygen content are in progress.

One further interesting feature of the structure is that at 11.906 Å, the lattice parameter for this sample is one of the smallest reported for zeolite A. Depmeier has related the lattice parameters of a wide range of zeolite A samples to a framework distortion resulting in the O(3) atoms of the 6-ring being drawn into the sodalite cage and an approximately linear T–O(1)–T angle.[14] It is likely, therefore, that a range of unusual crystallographic parameters, such as the small lattice parameter and the T–O(1)–T angle of 178.5°, observed in this compound result from a framework distortion occasioned in part by cluster formation in the sodalite cage.

We would like to thank Peter Stephens for the synchrotron X-ray diffraction time at Brookhaven, USA.[15] We would also like to thank the Royal Society for the award of a University Research Fellowship (P. A. A.) and EPSRC (J. E. R.) for funding.

Artificial metallopeptidases: regioselective cleavage of lysozyme†

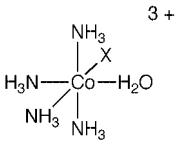
Challa V. Kumar,* Apinya Buranaprapuk, Abraham Cho and Anita Chaudhari

Department of Chemistry, U-60, University of Connecticut, Storrs, CT 06269-3060, USA. E-mail: C.V.Kumar@uconn.edu

Received (in Columbia, MO, USA) 10th September 1999, Accepted 30th October 1999

Pentammineaquocobalt(III) chloride and tetramminediaquocobalt(III) chloride cleave chicken hen egg lysozyme between Ala 110 and Trp 111 at neutral pH and 37 °C.

Metal complexes that can cleave proteins with a high specificity under mild conditions will be useful for structure–activity studies of proteins, investigation of protein structural domains, and in converting large proteins into smaller fragments that are more amenable for sequencing.[1–8] Such reagents are also useful for the chemical modification of proteins, or for heavy atom labeling.[2–3] Metal complexes have been attached to specific sites on proteins and subsequent activation resulted in protein fragmentation *via* oxidative or hydrolytic chemistry. Hydrolytic chemistry is preferred over oxidative chemistry as the latter can potentially damage the protein side chains and the resulting fragments may not be amenable to sequencing. Exopeptidase activities of pentammineaquocobalt(III) (CoPA) and tetramminediaquocobalt(III) (CoTA) ions (Scheme 1), under mild conditions, is demonstrated here for the first time.



Scheme 1 Structure of the cobalt(III) metal complexes used to cleave lysozyme with high specificity. X = NH_3 for CoPA and H_2O for CoTA.

Metal complexes with labile ligands may bind to the side chains of amino acid residues such as Cys, His, Trp, Asp and Lys and such coordination may function as an anchor to position the reagent for the controlled hydrolysis of protein backbone.[2,3] In this context, Cu, Pt and Pd complexes showed significant artificial metallopeptidase activities.[3] Co(III) complexes are known to induce N-terminal hydrolysis of peptides (endopeptidase activity)[9,10] but the exopeptidase activity of Co(III) is not known. Hydrolysis of N-4(1-pyrenyl)butyroylphenylalanine by CoPA (hydrolysis occurs at the C-terminus) prompted us to investigate the catalytic hydrolysis of proteins by Co(III) complexes.[11] Chicken hen egg lysozyme was chosen for the current studies because lysozyme can bind a number of metal ions,[12] its three-dimensional structure is known[13] and catalytic activity of lysozyme provides a convenient handle to test if the protein cleavage results in the loss of activity.

Incubation of lysozyme (15 μM) with CoPA or CoTA (1 mM) at 37 °C for 21–26 h resulted in facile cleavage of the protein into two fragments as demonstrated in SDS PAGE experiments (6% acrylamide, 0.4% bisacrylamide, 13% glycerol; pH 8.4).[14] Two new bands with molecular weights of *ca.* 12 and 2 kDa are clearly visible in Fig. 1(a) (lanes 4 and 6). If the protein cleavage were to be random, one would have observed a smear in these lanes. Occasionally, the 2 kDa band was difficult to see in the gels (lane 2). The rate of protein cleavage increases with the concentration of CoTA (0.2, 0.5 and 1 mM) and similar activity was observed with CoPA [Fig. 1(b)].

† Electronic supplementary information (ESI) available: self cleavage of lysozyme at room temperature and 37 °C. See http://www.rsc.org/suppdata/cc/a9/a907477e/

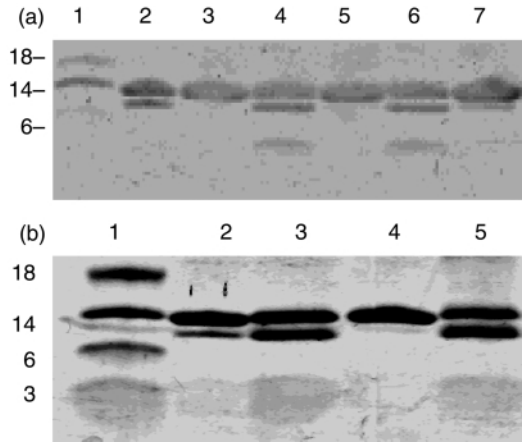


Fig. 1 (a) Lysozyme cleavage by CoTA at 37 °C. Lane 1 contains molecular weight markers at 18, 14 and 6 kDa. Lanes 2–7 contain lysozyme (15 μM) and increasing concentrations of CoTA (lanes 2, 3 contain 0.2 mM, lanes 4, 5 contain 0.5 mM and lanes 6, 7 contain, 1 mM CoTA, respectively). Lanes 2, 4 and 6 were kept at 37 °C (26 h) while lanes 3, 5, 7 were kept at room temperature (26 h). Two new bands corresponding to lower molecular weights than the native protein are indicated in lanes 4 and 6. (b) Lane 1 contains molecular weight markers at 18, 14, 6 and 3 kDa. Lanes 2–5 contain lysozyme (15 μM). Lane 2 contains protein treated with CoTA (1 mM, 22 °C); lane 3, CoTA (1 mM, 37 °C); lane 4, CoPA (1 mM, 22 °C) and lane 5, CoPA, 1 mM, 37 °C). Facile cleavage of lysozyme at 37 °C (26 h) by the aquo complexes is evident. In addition to the major new band in lanes 3, and 5, a faint band with a molecular weight around 2000 Da is also present.

No cleavage was observed when the protein was incubated with CoPA at room temperature (26 h, lane 4) while CoTA induced weak but detectable cleavage even at room temperaure (lane 2, 6%). The ratio of the major product band intensity to the sum of the intensities of the major product and the starting material in lanes 3 and 5 are 45 and 35%, respectively.

Even though the reaction does not proceed at room temperature with CoPA [Fig. 1(b), lane 4] and the reaction is very weak with CoTA [Fig. 1(b), lane 2] self cleavage of lysozyme at room temperature and at 37 °C was examined in the absence of the metal complexes (ESI†). No reaction occurs at 37 °C, 26 h (lane 3) or at room temperature (lane 2) indicating that the reaction is mediated by the metal complexes.

By contrast, no reaction was observed with the *cis* or *trans* isomers of bisethylenediaminediaquocobalt(III) bromide (Fig. 2, lanes 4, 5). Other cobalt complexes such as chloropentamminecobalt(III), chlorotetramminecobalt(III) or chlorotetramminecarbonatocobalt(III) also induced protein cleavage, although, at much slower rates (data not shown). These metal complexes can undergo hydrolysis under the reaction conditions to give rise to the corresponding aquo complexes which are active. Hexamminecobalt(III) chloride did not induce protein cleavage suggesting that the Co(III) center with one or more aquo ligands are needed for activity.

The reaction rate is accelerated with temperature and protein cleavage products could be detected within 5 h at 45 and 55 °C. The protein cleavage was optimal at pH 7 and was slowed down

DOI: 10.1039/a907477e

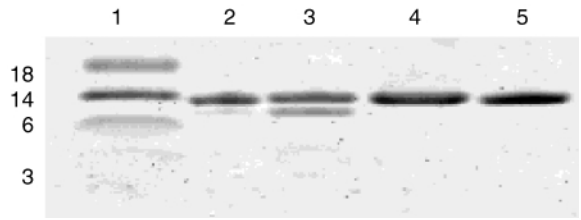

Fig. 2 Lane 1 contains molecular weight markers at 18, 14, 6 and 3 kDa. Lanes 2, 3, 4 and 5 contain lysozyme (15 μM) treated with the metal complexes (1 mM) under different conditions. Lane 2 contains CoTA at 25 °C; lane 3 contains CoTA at 37 °C; lane 4 contains *trans*-$[Co(en)_2Br_2]Br$ at 37 °C and lane 5 contains *cis*-$[Co(en)_2Br_2]Br$ (37 °C). An intense product band is evident in lane 3, and another faint band at 2000 Da is also present in this lane. No products were formed with the *cis*- or *trans*-ethylenediammine complexes treated at 37 °C or at 22 °C even after 21 h.

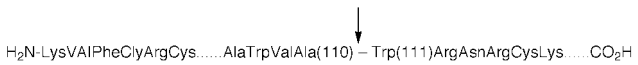
at pH 4.5 or 9. Protein cleavage proceeded smoothly when Tris–HCl buffer was replaced by acetate or phosphate.

The peptide fragments from the gels were isolated and their molecular weights have been determined from electrospray ionization mass spectrometry. The larger fragment had a molecular weight of 11998 Da while the smaller fragment had a molecular weight of 2343 Da. N-terminal sequencing by Edman degradation method revealed that the 12 kDa fragment had the sequence KVFGRCELAAAM, the known N-terminal sequence of lysozyme (Scheme 2). The N-terminus of the smaller fragment had the sequence, WRNRCK, a sequence internal to lysozyme. The cleavage thus occurs between Ala 110 and Trp 111, as inferred from the known sequence of lysozyme.[13] A minor product (< 3%) of molecular weight 3 kDa had the N-terminal sequence KVFGRCELAAAM, suggesting cleavage of lysozyme at a secondary site, in addition to the major cleavage site described above.



Scheme 2 Lysozyme sequence that has been targeted by the metal complex at neutral pH.

Catalytic activity of lysozyme was examined before and after the cleavage by CoTA, using glycol chitin as the substrate.[5b] The enzyme activity was unaffected by the protein cleavage reaction, and this observation is consistent with the location of the active site in the 12 kDa fragment. The major fragment thus retains the active site with little or no damage to the key residues involved in the enzyme catalysis. Preliminary ^{1}H NMR studies of lysozyme–CoPA solutions (2.9 mM lysozyme, 18 mM CoPA) indicate a number of shifts when compared to those of the protein (3 mM) in the absence of the metal complex. Further studies are needed to assign these changes but the resonances due to Trp 108 appears to have undergone significant changes. The known three-dimensional structure of lysozyme[13] indicates that Trp 108 is accessible to the aqueous medium and Trp108 could anchor the Co(III) reagent. Such coordination could position the metal complex proximate to the Ala 110 and Trp 111 peptide bond where the cleavage was observed.

The mechanism for protein cleavage by Co(III) is expected to be similar to that reported for amide hydrolysis by CoTA and CoPA.[15,16] The amide hydrolysis rates were higher for complexes with two open coordination sites.[15] Water molecules bound to the metal ion may participate in acid–base catalysis at the metal binding site, facilitating peptide bond cleavage. Size is also important as larger size may preclude the metal complex from reaching the peptide back bone (ethylenediamine complexes are not active). Current results demonstrate that Co(III) complexes can cleave internal peptide bonds, possibly *via* a hydrolytic mechanism. Chemical proteases derived from inorganic materials may prove to be useful as tools in molecular biology.

Financial support from the University of Connecticut Research Foundation, ACS Petroleum Research Fund and the Naional Science Foundation is gratefully acknowledged. We are grateful to Mary Moyer and William Burkhart of Glaxo Wellcome Inc., for the sequencing and mass spectral data.

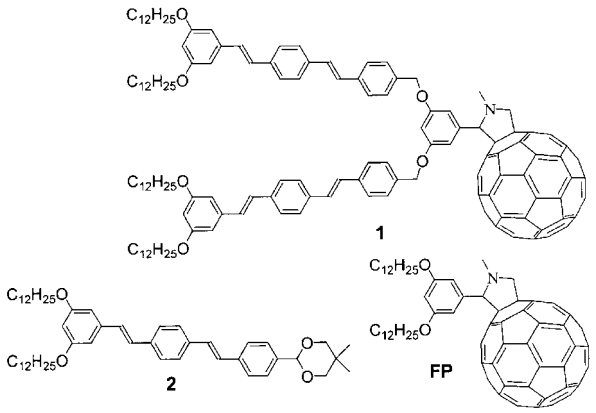
Received (in Cambridge, UK) 19th January 2000, Accepted 25th February 2000

A fullerene derivative in which two oligophenylenevinylene (OPV) groups are attached to C_{60} through a pyrrolidine ring has been prepared and photophysical studies in CH_2Cl_2 solution show that photoinduced energy transfer from the OPV moieties to C_{60} occurs, and not electron transfer.

Following the observation of electron transfer from conducting oligomers and/or polymers derived from poly(phenylenevinylene) or poly(thiophene),[1] and the successful preparation of photovoltaic cells from such bulk heterojunction materials,[2] several examples of covalent fullerene derivatives bearing a conjugated oligomer substituent have been synthesized in the past few years.[3,4] As a part of this research, we have recently shown that such hybrid compounds can be incorporated in photovoltaic devices.[4] Whereas the synthesis and applications of such hybrid compounds have been investigated, their electronic properties have been probed to a much lesser degree.

In this paper, we report on the preparation and the electronic properties of fullerene derivative **1** in which two OPV groups are attached to C_{60} through a pyrrolidine ring using the related OPV derivative **2** and the fulleropyrrolidine **FP**[4] as reference compounds. Interestingly, the photophysical studies of **1** in solution show that photoinduced energy transfer from the OPV moiety to C_{60} is the main pathway and not electron transfer.



The synthesis of **1** is depicted in Fig. 1 and the functionalisation of C_{60} is based on the 1,3-dipolar cycloaddition[5] of the azomethine ylide generated *in situ* from aldehyde **7**.

The electrochemical properties of **1**, **2** and **FP** were investigated by cyclic voltammetry (CV) in CH_2Cl_2–0.1 M Bu_4NPF_6 solutions (Table 1). In the cathodic region, **1** shows three reversible one-electron processes followed by a bielectronic peak (IV_{red}), visible only at low temperature. A comparison of the $E_{1/2}$ potentials of **1** and **FP** clearly shows that the first three waves correspond to fullerene-centred reductions and the slightly negative shift observed for **1** compared to **FP** could be the result of a small interaction between the electron-accepting C_{60} unit and the electron-donating OPV groups. The fourth reduction process seen for **1** appears to be difficult to assign unambiguously as either fullerene- or OPV-based. In the anodic region, **1** presents two chemically irreversible and ill-defined peaks, corresponding to the transfer of three electrons. They can likely be attributed to the simultaneous oxidation of the two OPV groups and the bridging dialkyloxybenzene unit,[6] since these groups present in both model compounds **2** and **FP** are irreversibly oxidized in the same potential region.

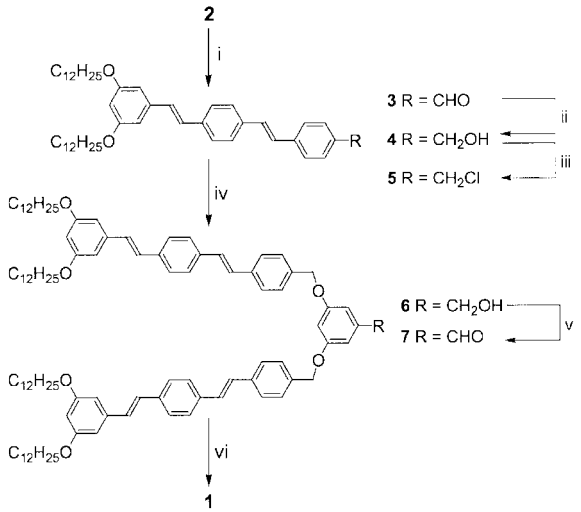


Fig. 1 *Reagents and conditions*: i, CF_3CO_2H, CH_2Cl_2, H_2O, room temp., 4 h (96%); ii, DIBAL-H, CH_2Cl_2, 0 °C, 1 h (90%); iii, TsCl, LiCl, DMAP, CH_2Cl_2, 0 °C to room temp., 12 h (80%); iv, 3,5-dihydroxybenzyl alcohol, K_2CO_3, KBr, 18-crown-6, acetone, Δ, 24 h (69%); v, MnO_2, CH_2Cl_2, room temp., 2 h (95%); vi, C_{60}, *N*-methylglycine, toluene, Δ, 16 h (40%).

The ground state electronic absorption spectrum of **1** is reported in Fig. 2 and, within the experimental error, it matches the profile obtained by summation of the spectra of the component units **FP** and **2**. Importantly, on each moiety of **1**, a fairly good excitation selectivity can be achieved. Indeed, at $\lambda >$

† Electronic supplementary information (ESI) available: CV curves for **1**, **2** and **FP**, and calculation of energy transfer rate constants. See http://www.rsc.org/suppdata/cc/b0/b000564i/

DOI: 10.1039/b000564i

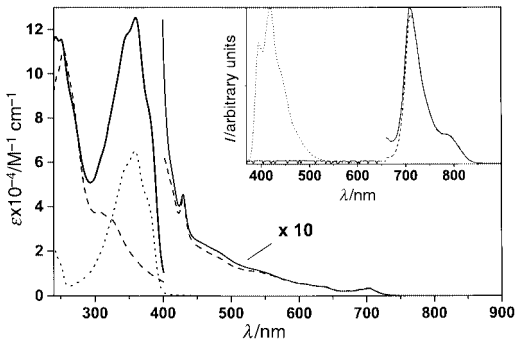

Fig. 2 Absorption spectra of **1** (full line), **FP** (dashed line) and **2** (dotted line) in CH_2Cl_2 at 298 K; above 400 nm a multiplying factor of 10 is used. Inset: fluorescence spectra of solutions of **2**, **FP** and **1** (for all samples, optical density = 0.50 at λ_{exc} = 360 nm). Above 660 nm the spectrofluorimeter sensitivity is increased by three orders of magnitude, due to the weakness of the **FP** fluorescence relative to that of **2**.

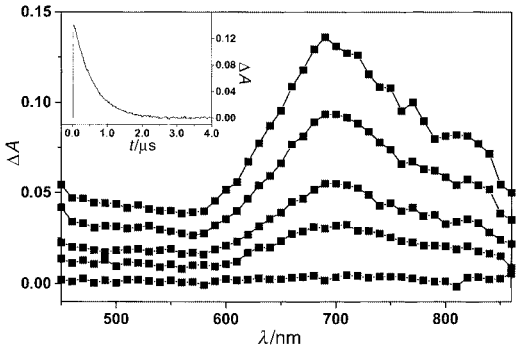

Fig. 3 Sensitized fullerene triplet–triplet transient absorption spectrum of **1** at 298 K in CH_2Cl_2 air equilibrated solution, upon laser excitation at 355 nm (energy = 5 mJ pulse^{-1}). The spectra were recorded at delays of 100, 300, 600, 900, 2000 ns following excitation (from top to bottom). The inset shows the time profile of ΔA (690 nm) from which the spectral kinetic data were obtained; the fitting is monoexponential and gives a lifetime of 540 ns.

530 nm light is exclusively directed to the fullerene fragment, whereas at λ = 360 nm at least 85% of the incident light is absorbed by the OPV moieties.

Upon selective excitation of **1** on the fullerene fragment, the typical fulleropyrrolidine fluorescence and triplet–triplet transient absorption spectra are observed.[6,7] This indicates that the excited state properties of the C_{60} fragment are not affected by the presence of the nearby OPV moieties. On the other hand, when excitation is directed to the latter (*e.g.* at λ = 360 nm, see above), intercomponent processes are evidenced. Under such conditions, the intense fluorescence band characteristic of the OPV moiety (Φ_{em} = 1.0, τ = 1.0 ns) is not observed (Fig. 2), whereas the typical fluorescence band of the fulleropyrrolidine fragment (λ_{max} = 710 nm, τ = 1.3 ns) is detected; in addition, the fullerene fluorescence quantum yields of **1** and **FP** obtained at λ_{exc} = 360 nm are identical (Φ_{em} = 5.5 × 10^{-4}), although in the former at least 85% of the incident light is absorbed by the OPV fragments. The excitation spectrum of **1**, taken at λ_{em} = 715 nm, matches the absorption profile throughout the UV–VIS, range including the diagnostic band of the OPV moieties around 360 nm. These findings are consistent with quantitative occurrence of singlet–singlet energy transfer from the OPV unit to the fullerene in the multicomponent array **1**.

In order to monitor the fate of the lowest triplet state centred on the fullerene moiety, following excitation of the OPV counterpart, we performed a series of transient absorption experiments by setting the excitation wavelength of an Nd:YAG laser to 355 nm. The reference compound **FP** displays a triplet–triplet transient absorption spectrum with λ_{max} = 690 nm and τ = 0.54 μs in air-equilibrated solution, which becomes 31 μs in deaerated solution due to the suppression of the well-known, very efficient quenching of fullerenes by dioxygen.[7,8] A quite similar behaviour is observed for **1**, which displays a fullerene triplet yield formation equal to that of **FP** and the same triplet lifetimes. In other words, preferential excitation of the OPV moieties (> 85%) quantitatively sensitizes the formation of the lowest fullerene singlet state, which then populates the lower lying triplet level (Fig. 3) *via* intersystem crossing.

From the electrochemical data one can place the energy of the charge separated state[9] of **1** at about 2 eV, *i.e.* well below the energy of the lowest singlet excited state of the OPV moieties (3.1 eV, as derived from the 77 K fluorescence spectrum). However, even if the population of the charge separated state following photoexcitation of the OPV units is thermodynamically allowed, this process is not evidenced in CH_2Cl_2 solution. The use of polar solvents does not change the observed pattern; for instance, quantitative evidence for OPV→C_{60} singlet–singlet energy transfer is also observed in benzonitrile solution. We have performed model calculations on the OPV→C_{60} singlet–singlet energy transfer step by following both the dipole–dipole and double-electron exchange approaches (for details, see supplementary data).† The spectral overlap between the luminescence spectrum of the donor OPV unit and the absorption spectrum of the fulleropyrrolidine acceptor unit allows calculation of the overlap integrals J^F = 1.4 × 10^{-14} cm^6 mol^{-1} and J^D = 1.4 × 10^{-4} cm for the two approaches, and results in estimated rate constants, k_{en}^F; $k_{en}^D \gg 10^{12}$ s^{-1} up to 10 Å of intercenter separation. These estimates suggest that the energy transfer step is so fast that the competing charge separation path is not effective.

In conclusion, **1** appears to be a multicomponent array containing a fullerene unit as a terminal receptor of excitation energy.[10] These results suggest the possibility of building up more complex arrays where a larger number of OPV fragments allow an even more pronounced excitation selectivity with an antenna effect, and the attachment of a suitable electron donor to the C_{60} unit would result in multicomponent artificial photosynthetic systems where light energy harvesting is followed by charge separation.[11]

Received (in Basel, Switzerland) 29th September 1999, Revised manuscript received 1st January 2000, Accepted 23rd February 2000

Reaction of the amidate ligand *N*-{2-[(2-pyridylmethylene)amino]phenyl}pyridine-2-carboxamide (Hcapca) with $[VOCl_2(thf)_2]$ and MeONa in 1:1:1 molar ratio in MeCN affords the compound *trans*-[VOCl(capca)] 1, while reaction of 1 with NEt_4NCS, $MeCO_2NHEt_3$ and imidazole yields the complexes *trans*-[VO(NCS)(capca)] 2, *trans*-[VO(MeCO$_2$)(capca)] 3 and *trans*-[VO(im)(capca)]$^-$ 4 respectively; the X-ray crystal structure of 1 is reported; Cw EPR studies of compounds 1–3 reveal a novel phenomenon of the reduction of their A_z components by *ca*. 10% compared to N_4 reference compounds.

The oxovanadium(IV) cation, $V^{IV}O^{2+}$, has been successfully employed as a spin probe in EPR[1] and electron spin echo envelope modulation (ESEEM)[1] studies of naturally occurring vanadoproteins and in proteins where the divalent cations (Mg^{2+}, Ca^{2+}, *etc*.) have been substituted by $V^{IV}O^{2+}$. More specifically, the *z*-component of the ^{51}V(I = 7/2) hyperfine coupling tensor $\boldsymbol{A}$, has been extensively employed as a benchmark for the identification of the equatorial donor atom sets in oxovanadium(IV) complexes.[1a,2]

Oxovanadium(IV) compounds have usually square pyramidal or octahedral geometry with a weak sixth ligand in axial position. To the best of our knowledge, there are only two other structurally characterized $V^{IV}O^{2+}$ species with a monoanionic ligand (Cl^-)[3] in axial position and obviously the effect of the charged axial ligand on ^{51}V hyperfine coupling constants has not been systematically studied. The potentially tetradentate amidate ligand, *N*-{2-[(2-pyridylmethylene)amino]phenyl}pyridine-2-carboxamide (Hcapca), was chosen in an effort to force axial ligation of anionic as well as of neutral ligands. In this report, we describe the synthesis, the cw EPR, and ESEEM spectra of the oxovanadium(IV) compounds of the general formula *trans*-$[V^{IV}OX(capca)]^{0/+}$ (X = Cl^- **1**, SCN^- **2**, $MeCO_2^-$ **3** and imidazole **4**) as well as the X-ray crystal structure of **1**·MeOH with the view to studying the effect of the charged axial ligands on the ^{51}V-hyperfine coupling constants and in particular on the parallel component, A_z.

The mononuclear brick-red compound *trans*-[VOCl(capca)] **1** was prepared by refluxing an MeCN solution containing $[VOCl_2(thf)_2]$ (3 mmol), Hcapca (3 mmol) and MeONa (3 mmol) for *ca*. 24 h [eqn. (1)]. The brick-red precipitate was Soxhlet extracted (CH_2Cl_2) to remove NaCl and to obtain **1**·CH_2Cl_2.‡

$$[VOCl_2(thf)_2] + Hcapca + MeONa \rightarrow \textit{trans}\text{-}[VOCl(capca)] + MeOH + NaCl + 2thf \quad (1)$$

Crystals of **1**·$MeOH^+$ suitable for X-ray structure analysis§ were obtained by vapour diffusion of diethyl ether into a concentrated MeOH solution (at 4 °C) of the complex. **2**, **3** and **4** were prepared according to Scheme 1.‡

The continuous wave (cw) EPR parameters of the four oxovanadium(IV) compounds (Table 1) were determined by computer simulation of the experimental cw EPR spectra. The cw EPR spectrum of **1**·MeOH is typical of a monomeric oxovanadium(IV) ($S = \frac{1}{2}$, I = 7/2) species with no evidence for

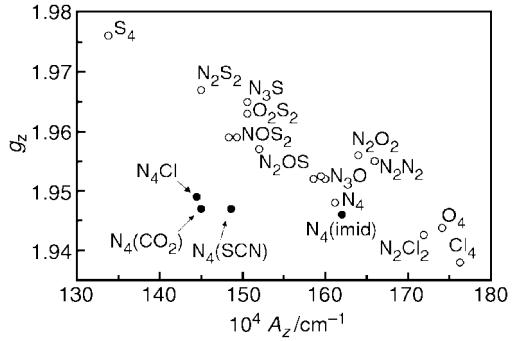

Fig. 1 A correlation plot of A_z *vs.* g_z for the $V^{IV}O^{2+}$ compounds **1**·MeOH and **2**–**4** (●) and a series of oxovanadium(IV) compounds (○) with various equatorial donor atoms.[2]

magnetic couplings between electron spins, *i.e.* line-broadening or splittings in the spectral features. $^{51}V(S = \frac{1}{2}, I = 7/2)$ EPR spectra of the oxovanadium(IV) compounds **2**, **3** and **4** are also typical of monomeric $V^{IV}O^{2+}$ compounds. The $\boldsymbol{g}$ and $\boldsymbol{A}$ tensors of **1**·MeOH and **2**–**4** were found to be rhombic (Table 1).

Fig. 1 (open circles) displays a correlation plot of g_z *vs.* A_z, for a series of known oxovanadium(IV) compounds with various equatorial donor atom sets.[2] The data lie approximately on a straight line with negative slope. This anti-correlation between g_z and A_z is well known and simply indicates that increased in-plane π- and σ-bonding results in decreased A_z values and increased g_z values.[2] Addition of the g_z and A_z values for compounds **1**·MeOH and **2**–**4** (filled circles) on the plot reveals that: (i) the points for compounds **1**·MeOH, **2** and **3** deviate substantially from the locus of the reference data. More specifically, compound **1**·MeOH[4] has an A_z value of 145 × 10^{-4} cm^{-1}, *ca.* 10% lower than the expected value of *ca.* 162 × 10^{-4} cm^{-1} for reference compounds[5] with an N_4 equatorial donor atom set. A similar reduction of the A_z values by *ca.* 8–10% is also observed for compounds **2** and **3**, (ii) in all cases, the g_z values seem to be unaltered, (iii) the A_z value for compound **4**, with imidazole in axial position, falls on the main locus as expected. The shift of the points for **1**·MeOH, **2** and **3** relative to **4**, as well as relative to the reference data, implies that the physical mechanism which determines the A_z values in compounds **1**·MeOH, **2** and **3** is not the same as in the reference compounds. In the same context, it is noted that the $A_{x,y}$ values (Table 1) in compounds **1**·MeOH, **2** and **3** are also lower than those of compound **4**.

The equatorial ligands in compounds **1**·MeOH and **2**–**4** were studied by electron spin echo envelope modulation (ESEEM) spectroscopy.[6] ESEEM is a pulsed EPR technique, eminently suited for measuring weak hyperfine couplings.[6] Orientation-selective ESEEM spectra recorded across the EPR spectrum of compound **1**·MeOH, were dominated by two sets of sharp features at 3–5 and 7–9.5 MHz. According to numerical simulations, performed as described in ref. 7, the ESEEM spectra are assigned to $^{14}N(I = 1)$-nuclei coupled to the electron spin $S = 1/2$. Two classes of almost isotropic ^{14}N-hyperfine couplings were resolved, with A_{iso} values of 5.2 and 6.1 MHz, respectively. These couplings are typical for $^{14}N(I = 1)$ atoms equatorially coordinated to $V^{IV}O^{2+}$.[1d,e] The ESEEM spectra recorded for **2**–**4** are comparable to those for **1**·MeOH, and this indicates that the equatorial coordination environment for compounds **2**–**4** is similar to the equatorial environment of **1**·MeOH, *i.e.* an N_4 donor-atom set for all complexes. Moreover, the ESEEM spectra show that in all four cases the $^{14}N(I = 1)$ hyperfine couplings are comparable, and this means that the bonding properties of the equatorial ligands in compounds **1**·MeOH and **2**–**4** are similar. Thus, the ESEEM spectra of compounds **1**·MeOH, **2** and **3** indicate that the reduction in their A_z values compared to N_4 reference complexes is not related to the nature of the equatorial ligands, but is rather due to the nature of the axial ligands.

In conclusion, a series of octahedral oxovanadium(IV) compounds, containing charged or neutral axial ligands, with the amidate molecule Hcapca was synthesized and structurally (**1**·MeOH) and spectroscopically characterized. The main effect of the monoanionic axial ligands on the A_z values of $V^{IV}O^{2+}$ compounds is their reduction by almost 10% compared to N_4 reference complexes. Thus, the present data reveal a novel phenomenon which bears strong relevance to the use of the A_z value as a predictive tool, in vanadoproteins, or $V^{IV}O^{2+}$ substituted proteins, *etc*. We are currently exploring analogous phenomena in $V^{IV}O^{2+}$-compounds with various combinations of symmetries/charges of the ligands.

4 There are two compounds in the literature (ref. 3) containing the unit *trans*-[V(=O)Cl] and having N_4 equatorial donor atom sets, namely: $[VOCl(1\text{-vinylimidazole})_4)]^+$ and $[VOCl(pyrazole)_4]^+$ with A_z values of 162 and 176 × 10^{-4} cm^{-1}, respectively. The A_z value for compound $[VOCl(pyrazole)_4]^+$ is characteristic of an equatorial donor set dominated by oxygens, most likely indicating decomposition of the complex in the solvent system (water–glycerine) used. The A_z value for $[VOCl(1\text{-vinylimidazole})_4)]^+$ is in the expected range for an N_4 equatorial donor atom system.[5]

Received (in Cambridge, UK) 17th January 2000, Accepted 2nd March 2000

A high quality NaA zeolite membrane, which shows a H_2/n-C_4H_{10} permselectivity of 106, has been synthesized on a seeded α-Al_2O_3 support by a multistage synthesis method.

The synthesis of zeolite membranes and their application in separation and catalysis have attracted great interest in recent years.[1,2] For gas separation, most studies have concentrated on MFI type (silicalite-1 and ZSM-5) zeolite membranes. Although high separation factors were obtained for mixtures of organic gases,[3–6] MFI zeolite membranes do not show good separation performance for permanent gases or permanent gas/organic gas mixtures because of the large pore size and hydrophobic nature of the zeolite. Thus the investigation of zeolite membranes with small pore size has attracted much attention.[7–9] NaA zeolite has a smaller pore size (0.41 nm) than that of MFI zeolite (*ca.* 0.55 nm). However, most studies on NaA zeolite membranes focused on the dehydration of liquid mixtures by pervaporation[10,11] and few gas permeation results were reported.[9,12] Furthermore, it was shown, from the gas permeation results,[9,12] that the quality of these NaA zeolite membranes was poor. Here, a high quality NaA zeolite membrane has been synthesized on a seeded α-Al_2O_3 support by a multistage synthesis method.

A self-made porous α-Al_2O_3 disk (30 mm in diameter, 3 mm in thickness, 0.1–0.3 μm pore radius, *ca.* 50% porosity) was used as the support. Before synthesis, one side of the support was coated with NaA zeolite crystals as nucleation seeds by dipping the support in a 0.5 wt% NaA zeolite suspension in a single step for 30 s. The 0.5 wt% NaA zeolite suspension was prepared by peptizing 0.5 g NaA zeolite in 100 ml deionized water. In order to form a thin and uniform NaA zeolite membrane on the support surface and to inhibit the formation of zeolite in the pores of the support, a uniformly sized NaA zeolite of dimensions *ca.* 1 μm, larger than those of the pores of the support, was used as the seed. The synthesis mixture was prepared by mixing sodium aluminate, water glass, sodium hydroxide and water. The molar ratio of the resultant gel mixture was $3Na_2O:2SiO_2:Al_2O_3:200H_2O$. The synthesis was carried out at 90 °C for 24 h in a stainless steel autoclave with the seeded support held vertically in the synthesis mixture by a Teflon holder. After the synthesis, the composite membrane was washed several times with water until the pH of the washings was neutral, then dried at 150 °C for 3 h. In order to obtain a high quality NaA zeolite membrane, the synthesis was repeated twice more (in all, a three-stage synthesis). The as-synthesized membrane was characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM) and gas permeation studies. The permeances of the gases were measured at different temperatures by a soap-film flowmeter under a pressure difference of 0.10 MPa. The permselectivity of A/B is defined as the permeance ratio of gas A to gas B.

The XRD pattern of the as-synthesized membrane prepared by the three-stage synthesis is shown in Fig. 1. The diffraction pattern of the as-synthesized membrane is represented by the sum of the peaks of the α-Al_2O_3 support and the NaA zeolite, which indicated that the membrane formed on the α-Al_2O_3 support is an NaA zeolite membrane. The variation of the intensity of the diffraction patterns of the NaA zeolite is possibly caused by the orientation of the zeolite crystals on the support surface. From the SEM images (Fig. 2), it can be seen that the surface of the α-Al_2O_3 support is completely covered with NaA zeolite crystals and the crystals are highly intergrown. A continuous membrane was formed on the support surface and the thickness of the zeolite membrane is *ca.* 18 μm. In addition, the zeolite membrane remained firmly bonded to the support surface even after 15 min of vigorous ultrasonic vibration. However, XRD and SEM characterization can only indicate

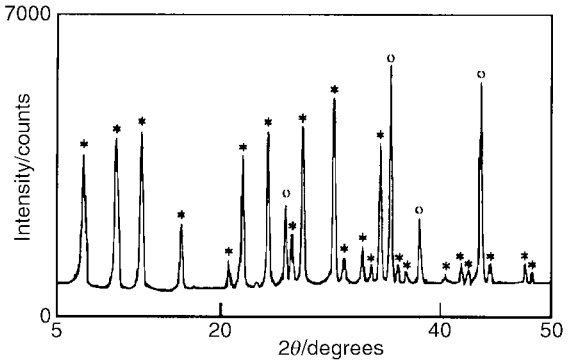

Fig. 1 XRD pattern of the NaA zeolite membrane: (○) α-Al_2O_3, (∗) NaA zeolite.

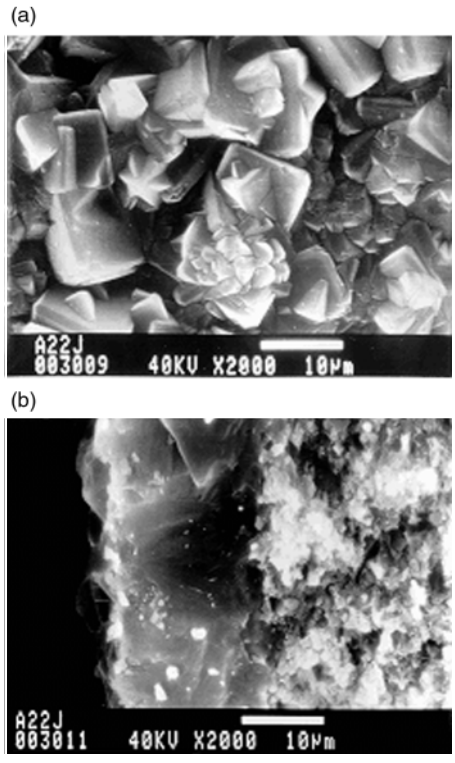

Fig. 2 SEM images of the NaA zeolite membrane: (a) top view, (b) cross-section.

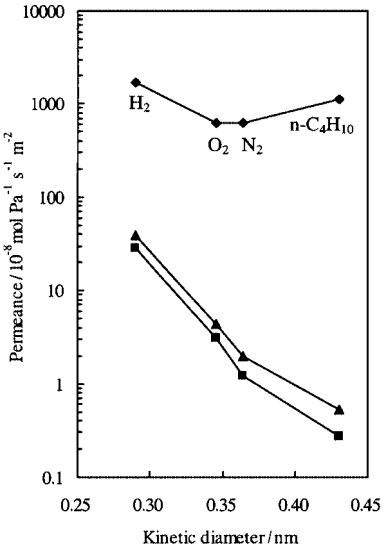

Fig. 3 Gas permeation properties of the seeded α-Al_2O_3 support (◆), the NaA zeolite membrane at 298 K (■) and the NaA zeolite membrane at 423 K (▲).

whether a continuous membrane is formed on the support, and can not confirm whether a defect-free zeolite membrane is formed. Such a property of the zeolite membrane can only be evaluated by gas permeation.[5] Taking into the consideration the opening pore size of the NaA zeolite channels and the hydrophilic nature of the NaA zeolite, the permselectivities of H_2/n-C_4H_{10} and O_2/N_2 were selected as the yardstick of the quality of the NaA zeolite membrane. Since the kinetic diameter of n-C_4H_{10} (0.43 nm) is larger than the pore size of the NaA zeolite (0.41 nm), n-C_4H_{10} should not permeate through a defect-free NaA zeolite membrane; the higher the permselectivity of H_2/n-C_4H_{10}, the more perfect is the NaA zeolite membrane. If the permselectivity of H_2/n-C_4H_{10} is near to or smaller than the Knudsen diffusion ratio of 5.39, large defects must be present in the NaA zeolite membrane. Since the kinetic diameter of O_2 (0.346 nm) is smaller than that of N_2 (0.364 nm), the permeance of O_2 should be higher than that of N_2 through a defect-free NaA zeolite membrane which is the reverse of the Knudsen diffusion ratio of 0.96 for a mesoporous membrane. Fig. 3 shows the gas permeation results of the NaA zeolite membrane. The permeances of H_2, N_2 and O_2 of the supported NaA zeolite membrane decreased by two orders of magnitude compared with those of the α-Al_2O_3 support, which indicated that a compact zeolite membrane was formed on the porous α-Al_2O_3 support. With an increase of the molecular kinetic diameter, the permeances of the gases decreased, which showed the molecular sieving effect of the NaA zeolite. At 298 K, the permeance of O_2 was 2.61 times higher than that of N_2, which is the reverse of that of the Knudsen diffusion ratio of 0.96. The permselectivity of H_2/n-C_4H_{10} was 106, a value much higher than that of the Knudsen diffusion ratio of 5.39, which indicated that a high quality NaA zeolite membrane was formed on the support surface. Compared with the gas permeation results of NaA zeolite membranes in the literature,[9,12] the NaA zeolite membrane synthesized in this study showed a very high H_2/n-C_4H_{10} permselectivity. The reason for the formation of the high quality NaA zeolite membrane may arise from the use of uniformly sized seeds and is still under investigation. With an increase of the permeation temperature, the permeance of the gases increased. However, the permselectivity of H_2/n-C_4H_{10} and O_2/N_2 at 423 K decreased to 73.2 and 2.22, respectively.

In conclusion, a high quality NaA zeolite membrane was successfully synthesized on a seeded α-Al_2O_3 support by a multistage synthesis method. The permeation of n-C_4H_{10} indicated that the NaA zeolite membrane had intercrystalline pores larger than those of the NaA zeolite channels. The permeance of the NaA zeolite membrane was also relatively low. Methods for the preparation of high permeance or virtually perfect NaA zeolite membranes are under investigation.

A novel immobilised cobalt(III) oxidation catalyst†

Birinchi K. Das‡ and James H. Clark*

Clean Technology Centre, Department of Chemistry, University of York, York, UK YO10 5DD. E-mail: jhc1@york.ac.uk

Received (in Liverpool, UK) 19th January 2000, Accepted 25th February 2000

A complex form of cobalt(III) has been successfully immobilised on a chemically modified silica and proven to be an active catalyst for the selective oxidation of alkylaromatics using air as the source of oxygen and in the absence of solvent.

Cobalt salts are widely used as catalysts in the liquid phase oxidation of alkylaromatics.[1] Reactions are normally carried out in acetic acid as solvent and in the presence of a promoter such as a bromide. It has been reported that under such reaction conditions, the aerial oxidation of Co(II) to Co(III) is a slow process[2] although this can be accelerated by the addition of bases such as pyridine which stabilises the higher oxidation state of the metal.[3] The heterogenisation of catalysts and their use in the oxidation of neat substrates are subjects of considerable interest especially in these environmentally conscious days when solvent losses and catalyst losses on separation can lead to unacceptable levels of waste.[4] Several heterogeneous metal catalysts have been designed for aerial oxidation reactions[5] but limited activities and questionable stabilities[6] have delayed their commercial exploitation. It seemed to us that if we could design a heterogeneous system that favours and stabilises Co(III), this should enhance rates of reaction where the Co(II) to Co(III) step was rate limiting and should increase catalyst stability owing to the relative substitutional inertness of Co(III). Here, we report our preliminary results from designing such a catalyst that can indeed be successfully used to catalyse the aerial oxidation of alkylaromatics in the absence of solvents.

The novel catalyst is based on a chemically modified porous silica.[7,8] Cyanoethyl-silica was prepared from the sol–gel reaction of tetraethylorthosilicate (196 mmol) and cyanoethyltriethoxysilane (98 mmol) in aqueous ethanol in the presence of *N*-dodecylamine as the templating agent. The resulting precipitate was washed with boiling ethanol to remove the template and then treated with hot aqueous H_2SO_4 so as to hydrolyse the CN group to CO_2H.[9] The resulting silica-$(CH_2)_2CO_2H$ material was washed with water and ethanol and then dried at 110 °C before use as a support for the Co(III) complex. Pyridine (40 mmol) was added dropwise to a mixture of the silica material (5g), $Co(NO_3)_2{\cdot}6H_2O$ (20 mmol), and sodium acetate (40 mmol) in water (100 ml). Complexation of the cobalt to the support only occurs on addition of the pyridine as witnessed by the purple colour of the solid particles. After adding more water (50 ml), the mixture was heated to boiling and dilute hydrogen peroxide (80 mmol) was slowly added over 8 h. This resulted in the apparent oxidation of the immobilised cobalt with a change in colour of the solid particles from purple to olive green. It is necessary to treat the supported metal complex with peroxide so as to form the immobilised Co(III). This solid was separated by filtration, thoroughly washed with water and acetone and then dried at 110 °C.

While the precise structure of the surface-bound cobalt complex is as yet unknown we have carried out a number of analytical studies to gain information on the cobalt loading and distribution, the material structure and the surface species (Table 1). Atomic absorption analysis of the digested material gives a cobalt loading of 0.68 mmol g^{-1}. Optical and scanning electron microscopic studies on the material reveal a homogeneous mass with elemental analysis (EDAX) carried out at randomly selected spots showing a consistent Co : Si ratio of *ca.* 1 : 7. This suggests an evenly distributed cobalt complex rather than a simple mixture of a cobalt complex with the silica. The BET isotherms for the supported Co(III) complex and the intermediate silica-$(CH_2)_2CO_2H$ material have almost identical appearances and suggest a mixture of micropores and mesopores. The BJH pore size distributions of these materials show *ca.* 65 and 80%, respectively, of the pore volumes are due to pores with diameters of < 6 nm. The surface area is also reduced on going from the intermediate supported carboxylic acid to the final supported metal complex (from 1041 to 528 $m^2\ g^{-1}$) although it is still very high compared to more traditional supported reagents.[10,11] These results are consistent with a reasonably homogeneous build-up in the surface species as the metal complex is formed. The powder X-ray diffraction pattern of the supported Co(III) material shows a weak peak at < 2° with the strongest peak at 2θ *ca.* 22.5° consistent with a lack of long range order as expected for materials of this type.[8,10] Diffuse reflectance FTIR (DRIFTS) of the final material reveals bands characteristic of surface bound CO_2^-, pyridine and acetate. The difference in the wavenumbers of the symmetric and asymmetric stretching vibrations of the acetato ligand carboxyl group (125 cm^{-1}) is consistent with these ligands bonding in a bridging fashion. The diffuse reflectance UV–VIS spectrum of the final material shows an ill-defined absorption maximum at *ca.* 580 nm in contrast to the strong band at 545 nm for the material before treatment with hydrogen peroxide. This is consistent with a change from Co(II) to Co(III) on peroxide treatment. Furthermore, by carrying out a similar complex preparation but in the absence of the support material, the final cobalt complex, believed to contain the cation $[Co_3(\mu_3\text{-}O)(\mu\text{-}O_2CR)_6(py)_3]^+$ [12] (ClO_4^- as counter anion) gives an olive green complex with a very similar UV–VIS spectrum. The measured C : N ratio of 12 : 1 in the final material is consistent with the presence of a similar complex rather than a simple species containing two pyridines and two carboxylato ligands per cobalt atom (for which the C : N ratio would be 7 : 1)

Table 1 Physical data for the supported Co(III) complex

	HMS–Co(III) complex	HMS–CO_2H
BET surface area/$m^2\ g^{-1}$	528	1041
Pore volume/$cm^3\ g^{-1}$	0.315	0.688
Co : Si ratio (EDAX)	1 : 7	—
Co loading (AAS)/mmol g^{-1}	0.68	0
λ_{max}(UV–VIS)/nm	580	—

The supported cobalt(III) reagent was tested as a catalyst in the aerial oxidation of neat ethylbenzene, chlorotoluene and toluene as representative alkylbenzenes (Table 2). Reactions were carried out at atmospheric pressure with 400 ml of substrate and 0.8 g of the catalyst in a baffled glass reactor with a overhead stirrer operating at 700 rpm, an air feed at 400 ml min^{-1}, chilled water condensers and twin Dean–Stark separators to remove the water produced during the reactions. Reactions could be monitored both by the amount of water

Table 2 Catalytic oxidations of alkylaromatics using the supported Co(III) complex (0.8 g) in neat substrate (400 ml) at atmospheric pressure for 22 h

Substrate	*T*/°C	Product (isolated yield%)[a]
PhEt	130	PhCOMe (70)
4-ClC_6H_4Me	130	4-$ClC_6H_4CO_2H$ (25)
PhMe[b]	100	$PhCO_2H$ (6)

[a] Purified (> 99%) product. [b] 1% added PhCHO which remains constant.

produced and by GC/GC–MS. Ethylbenzene was converted to acetophenone at a rate of *ca*. 4% h^{-1} at 130 °C, and with no induction period (in contrast to other reports of heterogeneously catalysed aerial oxidations[13]). The absence of an induction period may be due to the metal existing in its higher oxidation state at the beginning of the reaction. After 22 h a remarkable 76% of the ethylbenzene had been oxidised with selectivity to acetophenone of 94%, the remainder being benzoic acid. An isolated yield of 70% acetophenone can be obtained. We believe that this is the highest reported yield of acetophenone obtained from a heterogeneous oxidation of ethylbenzene.[5,14] Previous reports have shown that conversions of > 60% are very difficult to achieve with neat substrate and this has been linked to the rate limiting adsorption of the relatively non-polar ethylbenzene from an increasingly acetophenone-rich mixture.[5,13] Here the rate of oxidation is almost linear up to *ca*. 70% conversion and this may be a result of the relatively organophilic surface of the new catalyst facilitating the adsorption–desorption processes. Under the same conditions a 25% isolated yield of pure 4-chlorobenzoic acid was obtained from the oxidation of neat 4-chlorotoluene after 22 h simply by filtering the solid product from the cooled final reaction mixture and washing it with light petroleum. No other products were observed. This oxidation occurred at over twice the rate of comparable reactions reported elsewhere.[5,13] We were also able to achieve a small but significant rate of oxidation for toluene itself. At 100 °C and in the presence of a small amount of benzaldehyde (1% by volume) as a promoter,[5] we obtained an isolated yield of recrystallised benzoic acid of 6% after 22 h reaction (the 1% benzaldehyde remains almost constant throughout the reaction). This is again a marked improvement in reaction rate compared to similar systems.[5] In none of these reactions was leached cobalt detectable by atomic absorption spectroscopy in the organic liquors and the amount of cobalt measured in the catalyst (after digestion) was always unchanged. However, our first attempts to reuse the catalysts failed. Closer analysis of the used catalysts showed that there had been a complete loss of pyridine during reaction although the cobalt was still present. By adding a small amount of pyridine (0.48 g) to any of the substrate–used catalyst reaction systems, or by treatment of recovered catalyst with pyridine, the rate of reaction returned to close to the original value and very similar levels of substrate oxidation and conversions to product were achieved. The facile loss of pyridine from the catalyst at elevated temperatures was confirmed from thermal analysis on the material under nitrogen which shows loss of pyridine at *ca*. 150–200 °C with decomposition of the remaining catalyst structure starting at > 300 °C. We are now investigating methods for stabilising the catalyst notably the replacement of pyridine by a less volatile nitrogen base.

We gratefully acknowledge the support of the Commonwealth Institute for a Fellowship to B. K. D. and the RAEng.-EPSRC for a Clean Technology Fellowship to J. H. C., as well as the support and advice of the York Green Chemistry group.

Rapid syntheses of difluorinated dihydropyrans

Jonathan M. Percy* and Stéphane Pintat

School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT.
E-mail: jmpercy@chemistry.bham.ac.uk

Received (in Liverpool, UK) 4th January 2000, Accepted 15th February 2000

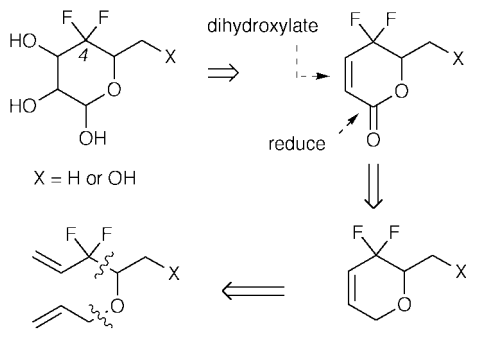
A very short reaction sequence opens with metal-mediated addition of commercial bromodifluoropropene to aldehydes; allylation under phase transfer catalysed conditions sets the stage for a ring closing metathesis (RCM) in the presence of commercial Grubbs' catalyst to afford potentially useful difluorinated dihydropyrans.

Difluorinated carbohydrate analogues are normally prepared by DAST [(diethylamino)sulfur trifluoride] difluorination of highly protected precursors in which a ketonic carbonyl group has been isolated, chemistry which is highly vulnerable to stereoelectronic effects as demonstrated many times by Castillón and coworkers.[1] Even when such difficulties have been overcome, the hazardous nature of the DAST reagent precludes scale-up, while safer versions of the reagent sacrifice reactivity in the cause of thermal stability.[2] Building block chemistry then appears most attractive and the Reformatsky reaction of ethyl bromodifluoroacetate with aldehydes and other electrophiles is a well-worked and productive theme.[3] Our own approaches have relied on metallated difluoroenol derivatives fashioned *in situ* from trifluoroethanol but we were struck by the simplicity of a possible RCM-based approach.[4] Scheme 1 shows the analysis; the route closely follows that published recently by Carda *et al.*[5] but forms the first instance where RCM technology has been used for the synthesis of ring-fluorinated heterocycles.

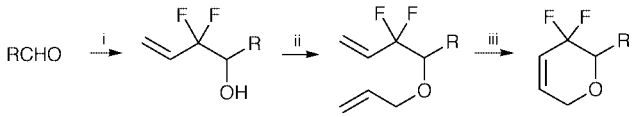
Initially, we were interested in the reproducibility of the allylindium chemistry described by Momose and coworkers[6] in which bromodifluoropropene adds very smoothly to aldehydes. With the homoallyl alcohols in hand, we would perform an allylation and then expose the allyl homoallyl ether to an RCM catalyst. Both alkenes are made less electron rich by electron-withdrawing substitutents at the allyl position and we were concerned that the overall cycle would be slow and that metallo-[2 + 2] cycloaddition in the fluorinated allyl system could result in β-fluoride elimination with concomitant formation of a strong metal–fluorine bond destroying the catalyst.

In the event, our fears were groundless. The allylindium chemistry was highly reproducible and homoallyl alcohols **2a**–**d** were synthesised in moderate to high (57–80%) yield (Scheme 2).

The reactions worked best when the suspensions were shaken or sonicated, and purification was facile.[7] We also explored the replacement of the indium metal with 325-mesh zinc under the conditions described by Wilson and Guazzaroni (saturated NH_4Cl, THF).[8] The zinc-mediated reaction[9] was much more effective in the case of benzaldehyde, affording the homoallyl alcohol **2b** in 84% yield, but less effective (37%) when the more interesting and electrophilic benzyloxyacetaldehyde **1d** was present, despite our observation of an extremely clean ^{19}F NMR spectrum from the crude material. Pinacol coupling of the aldehyde may be responsible for the low yield though we did not isolate any products of this type.



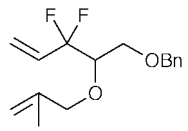
Scheme 1



1a, R = Bu^n	**2a** 57%	**3a** 98%	**4a** 56%
1b, R = Ph	**2b** 57%	**3b** 99%	**4b** 57%
1c, R = 2-furyl	**2c** 77%	**3c** 99%	**4c** 81%
1d, R = CH_2OBn	**2d** 80%	**3d** 99%	**4d** 97%

Scheme 2 *Reagents and conditions*: i, $H_2C{=}CHCF_2Br$, In, DMF, sonication, room temp.; ii, $H_2C{=}CHCH_2Br$, NaOH, CH_2Cl_2, Bu_4NHSO_4, room temp.; iii, 5 mol% Grubbs' catalyst, CH_2Cl_2, rt, 24 h.

Allylation[10] was trouble-free as was the RCM reaction[11] at room temperature in dichloromethane, though reaction times of 24 h were required to consume the starting material entirely.



5

The methallyl ether **5** prepared by an analogous sequence failed to cyclise at all under these conditions suggesting that the additional steric hindrance imposed by a methyl group is enough to prevent coordination and stop the cycle. Dihydropyran **4d**, formed in a particularly high isolated and purified yield is of the type identified in the analysis, while **4c** is potentially interesting for the synthesis of higher sugars and related species; we are continuing to explore the scope of the reaction more fully. This short study clearly shows how potentially important oxygen heterocycles can be assembled in an extremely concise manner using off-the-shelf reagents.

We wish to thank the EPSRC (GR/K84882) and the University of Birmingham for financial support and Dr Philip Walker (Fluorochem Ltd.) for a generous gift of 1-bromo-1,1-difluoropropene.

Synthesis and spectroscopic characterisation of *all* the intermediates in the Pd-catalysed methoxycarbonylation of ethene

Graham R. Eastham,[a] Brian T. Heaton,*[b] Jonathan A. Iggo,[b] Robert P. Tooze,[a] Robin Whyman[b] and Stefano Zacchini[b]

[a] *Ineos Acrylics, PO Box 90, Wilton, Middlesborough, Cleveland, UK TS90 8JE*
[b] *Chemistry Department, University of Liverpool, Liverpool, UK L69 7ZD. E-mail: amf@liv.ac.uk*

Received (in Cambridge, UK) 14th January 2000, Accepted 28th February 2000

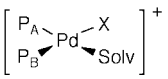
The pathway of the palladium catalysed methoxycarbonylation of ethene to methyl propanoate has been shown to occur *via* a hydride rather than a methoxycarbonyl cycle and *all* the intermediates in this cycle have been unambiguously identified by multinuclear NMR spectroscopy and ^{13}C-labelling.

The alkoxycarbonylation of alkenes is of increasing scientific and technological importance. This reaction can give rise to a broad spectrum of products; for ethene, this can range from high melting thermoplastic polymers—the so called 'polyketones' to low boiling liquids such as methyl propanoate. The former materials have attracted more attention in the literature as they have been developed into commercial products.[1] Our work focuses on methyl propanoate, a key intermediate in the manufacture of methyl methacrylate, an important monomer produced annually on a multi-million tonne scale world wide.[2]

A new catalyst for the production of methyl propanoate (MeP) *via* the palladium catalysed methoxycarbonylation of ethene has recently been reported.[3] The catalyst, generated *in situ via* the reaction of [Pd(L–L)(dba)] [L–L = 1,2-$(CH_2PBu^t_2)_2C_6H_4$; dba = *trans*,*trans*-$(PhCH{=}CH)_2CO$] with *e.g.* methanesulfonic acid, gives MeP with a selectivity of 99.98% at a production rate of 50 000 mol product (mol Pd)$^{-1}$ h^{-1} under very mild conditions (353 K and 10 atm pressure of CO–C_2H_4). Two alternative mechanistic pathways have been proposed for this type of reaction, *i.e.* a hydride or a methoxy cycle (**A** and **B** respectively in Scheme 1).[1] Here, we report an investigation which provides unambiguous spectroscopic evidence for *all* the intermediates in the *hydride* catalytic cycle (**A** in Scheme 1).

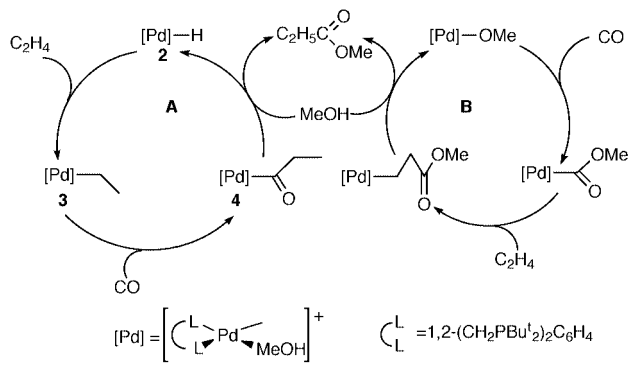
The complex [Pd(L–L)(dba)] reacts in MeOH with HBF_4 or CF_3SO_3H in the presence of oxygen or benzoquinone (BQ) to give selectively a new compound, which can be formulated as either the neutral complex [Pd(L–L)HX] {X = $[BF_4]^-$ **1a**, X = $[CF_3SO_3]^-$ **1b**} or the solvento-cation [Pd(L–L)H(MeOH)]X {X = $[BF_4]^-$ **2a**, X = $[CF_3SO_3]^-$, **2b**}. We prefer the cationic formulation **2** since variable temperature ^{31}P and ^{1}H NMR spectra of the products resulting from the reaction with HBF_4 do not show any coupling to fluorine. Furthermore, the ^{31}P{^{1}H}, ^{31}P and ^{1}H NMR spectra of **2b** at room temperature in MeOH are very similar to those of **2a** and are entirely consistent with the proposed structure in which the anion is present only as a non-coordinating counter ion. Thus, the ^{31}P{^{1}H} NMR spectrum of **2b** consists of two resonances due to the inequivalent *cis*-P-atoms [δ 25.8 and 77.5; $^2J(P_A–P_B)$ 17 Hz] and the resonance at δ 25.8 is assigned to P_B since it shows additional coupling to the *trans*-hydride [$^2J(P_B–H)$ 179 Hz]. In order to avoid H/D exchange, the ^{1}H NMR spectrum was recorded in MeOH using the ^{1}H/^{31}P correlations measured *via* zero and double quantum coherences.[4] The hydride resonance consists of a doublet of doublets at δ −10 [^2J(P–H) 179 and 14 Hz], due to the *trans*- and *cis*-couplings respectively).

On carrying out the above reaction in CD_3OD, the new deuterides [Pd(L–L)D(CD_3OD)]X {X = $[BF_4]^-$ **2c**, X = $[CF_3SO_3]^-$ **2d**} can be isolated and their ^{31}P{^{1}H} NMR spectra are exactly in accord with their formulation; the resonance at δ 25.8 due to P_B is clearly a sextet [$^2J(P_A–P_B)$ 17 Hz and $^2J(P_B–D)$ 27 Hz].



X	Solv	
H or D	MeOH	**2**
Et	MeOH	**3**
COEt	MeOH, THF	**4**

The hydride complex **2** reacts *immediately* with ethene at room temperature. Thus, addition of 1 equivalent of ethene to **2** results in the complete formation of the cationic complex [Pd(L–L)Et(MeOH)]X {X = $[BF_4]^-$ **3a**, X = $[CF_3SO_3]^-$ **3b**} and there is no further reaction on addition of more ethene. The ^{31}P{^{1}H} NMR spectra of **3a** and 3**b** in MeOH at 193 K consist of two doublets [δ 36.1 and 68.0; $^2J(P_A–P_B)$, 31 Hz] and $^2J(P_B–H)$ has completely disappeared. In order to confirm the formulation of **3**, the reaction of **2b** was repeated with $^{13}CH_2{=}CH_2$. In this case, there is a doublet at δ 68 [$^2J(P_A–P_B)$, 31 Hz] in the ^{31}P{^{1}H} NMR spectrum (at 193 K) and a more complicated multiplet at δ 36.1 (Fig. 1). As a result of using $^{13}CH_2{=}CH_2$, a 1 : 1 mixture of two isotopomers of **3b** is formed, *i.e.* [Pd(L–L)($CH_2{}^{13}CH_3$)(MeOH)]$^+$ **3c** and [Pd(L–L)($^{13}CH_2CH_3$)(MeOH)]$^+$ **3d**. For **3c**, the phosphorus *trans* to the ethyl group (P_B) couples only with the *cis*-phosphorus P_A [$^2J(P_A–P_B)$ 31 Hz] whereas in **3d**, P_B couples with both P_A and the *trans* carbon atom [$^2J(P_B–C)$ 38 Hz], resulting in a doublet of doublets (Fig. 1). The ^{13}C{^{1}H} NMR spectrum of the 1 : 1 mixture of the two isotopomers **3c** and **3d** at 193 K consists of a singlet at δ 8 (CH_3) and a doublet of doublets at δ 31 due to the CH_2 group [$^2J(P_A–C)$ 5 Hz, $^2J(P_B–C)$ 38 Hz]; the proton coupled ^{13}C NMR spectrum at 193 K shows the expected couplings due to the CH_3 and CH_2 groups [^1J(C–H) 124 and 158 Hz, respectively].



Scheme 1 Alternative reactive functional groups in the methoxycarbonylation of ethene (**A**, hydride cycle; **B**, methoxycarbonyl cycle).

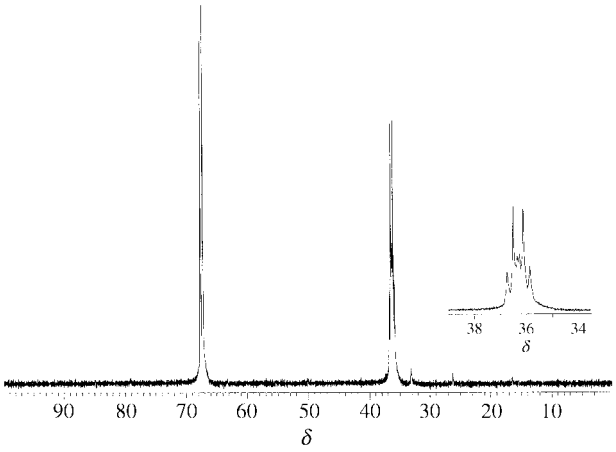


Fig. 1 ^{31}P NMR spectrum at 193 K of the two isotopomers **3c** and **3d** formed on reaction of $^{13}CH_2{=}^{12}CH_2$ with [Pd(L–L)H(MeOH)]$^+$ **2**, in MeOH.

The ethyl complex **3** is also quite stable in THF at low temperature. In this solvent the species [Pd(L–L)Et(THF)]$^+$ **3e** is present [in THF at 193 K, $\delta(P_A)$ 67.9, $\delta(P_B)$ 37.1; $^2J(P_A–P_B)$ 31.5 Hz]. On adding 1 equivalent of CO to **3e** in THF, [Pd(L–L)(COEt)(THF)]$^+$ **4** is formed *immediately* and the $^{31}P\{^1H\}$ NMR spectrum at 193 K consists of two doublets [δ 79.9 and 32.5; $^2J(P_A–P_B)$ 40 Hz]. On using ^{13}CO, both ^{31}P resonances become doublets of doublets owing to additional couplings [$^2J(P_B–C)$ 82.9 Hz, $^2J(P_A–C)$ 18.2 Hz] and, in the $^{13}C\{^1H\}$ NMR spectrum at 193 K, the $^{13}C(O)C_2H_5$ group is clearly identified at δ 232 as a doublet of doublets due to *cis* and *trans* $^2J(P–C)$.

On addition of a trace of MeOH to a THF solution of **4**, even at low temperature, there is an immediate reaction to regenerate the palladium hydride complex **2** with the formation of $EtCO_2Me$ (MeP). In methanol solution, **3** reacts immediately, even at low temperatures, with CO to give **2** and MeP, presumably *via* an acyl intermediate analogous to **4**.

The synthesis and reactivity of **2** provides important information on the mechanism involved in the methoxycarbonylation of ethene promoted by this particular class of catalyst. The nature of *all* the intermediates (**2**, **3** and **4**) involved in the hydride catalytic cycle (**A** in Scheme 1) has been determined and the chemical connections between these intermediates demonstrated.

It has been previously claimed that both the catalytic cycles, *i.e.* **A** and **B** in Scheme 1, are involved for the catalysts used for the synthesis of polyketones.[1,5] Moreover, it has been suggested that the methoxy cycle is the dominant cycle in the presence of oxidants (*e.g.* BQ).[1] These data have always been explained on the basis of the fact that Pd–hydrides are usually oxidised to give Pd–methoxy complexes in MeOH in the presence of oxidants.[1,6] However, we find that **2** is very stable in the presence of oxidants; oxygen can be bubbled through a methanol solution of **2** for 20–30 min at temperatures as high as 353 K without reaction; **2** is also stable in the presence of an excess of BQ (< 7 equivalents) on the timescale of the catalysis. In all cases, the only reaction observed on addition of further BQ is the metallation of the phosphine ligands[3] and there is no evidence for the formation of any methoxy complex. Hence, all the above data provide strong evidence in support of the hypothesis that the methoxycarbonylation of ethene promoted by [Pd(L–L)(dba)] follows the hydride catalytic cycle (**A** in Scheme 1).

We thank EPSRC for a CASE award (to S.Z.) and for funding the NMR equipment.

Mechanistic studies on ruthenium-catalyzed hydrogen transfer reactions

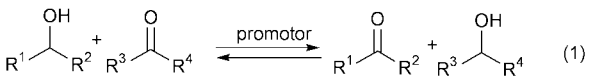
Y. R. Santosh Laxmi and Jan-E. Bäckvall*

Department of Organic Chemistry, Arrhenius Laboratory, Stockholm University, SE-106 91 Stockholm, Sweden. E-mail: jeb@organ.su.se

Received (in Cambridge, UK) 19th January 2000, Accepted 1st March 2000

Ruthenium-catalyzed hydrogen transfer from (*S*)-α-deuterio-α-phenylethanol [(*S*)-1] to acetophenone with catalyst 3 occurs with retention of deuterium at the α-carbon of the alcohol product whereas H/D scrambling occurs with catalyst 2.

Hydrogen transfer reactions in which hydrogen is transferred from one organic molecule to another is of great importance in organic synthesis since one can avoid the use of molecular hydrogen.[1,2] In particular the reaction in which one equivalent of hydrogen is transferred from an alcohol to a ketone [eqn. (1)]



(1)

has become useful. This transformation has been known since 1925[3,4] and in the original version an aluminium alkoxide was employed as promotor [Meerwein–Ponndorf–Verley (MPV) reduction and Oppenauer oxidation].[1] In these reactions a direct transfer of a hydride is supposed to take place (Fig. 1, A).[5]

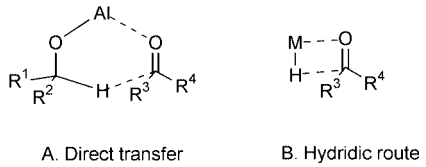


Fig. 1

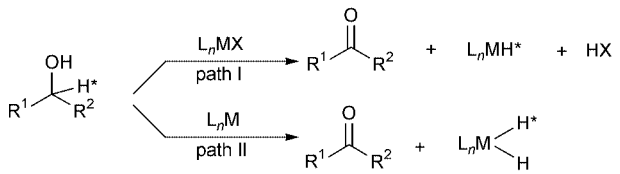
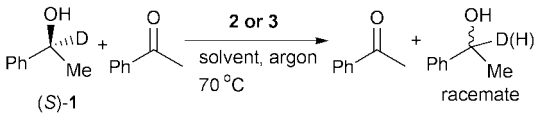
More recently, transition metal-catalyzed versions of these reactions have been developed.[6,7] The latter reactions are supposed to involve metal hydride intermediates[7,8] (Fig. 1, B) and recently hydride intermediates were isolated from ruthenium–catalyzed hydrogen transfer reactions.[9,10] An interesting question is whether the metal hydride arises purely from the α-hydrogen of the secondary alcohol (path I, Scheme 1) or if hydride on the metal also originates from the OH group (path II, Scheme 1).



Scheme 1

To answer this question and to gain further insight into the mechanism of hydrogen transfer reactions we have studied the ruthenium-catalyzed hydrogen transfer from (*S*)-α-deuterated α-phenylethanol [(*S*)-**1**)] to acetophenone [eqn. (2)].

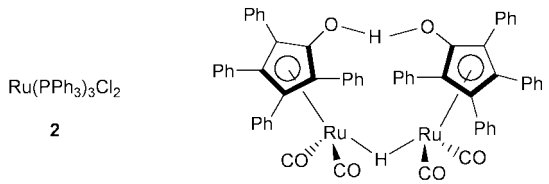


(2)

(*S*)-**1**

The use of enantiomerically pure α-deuterated alcohol (*S*)-**1** makes it possible to monitor the progress of the reaction since the hydrogen transfer catalyzed by the achiral catalyst should lead to racemization. The alcohol (*S*)-**1** is readily obtained from the enzymatic resolution of the corresponding racemic alcohol.[11] The latter was in turn obtained from $LiAlD_4$ reduction of acetophenone.

Ruthenium-catalyzed reaction of (*S*)-**1** with acetophenone resulted in moderate to slow racemization of the alcohol. Two different catalysts **2** and **3** were used in the present study. The



2

3

important question is to what extent deuterium is retained in the racemized alcohol. The racemization of (*S*)-**1** with both catalysts was carried out in aprotic as well as in protic solvents (Table 1). The reaction of (*S*)-**1** with **2** as the catalyst in THF in the presence of base and 0.5% of water resulted in complete racemization within 4 h (Table 1, entry 1). ^{1}H NMR and MS analyses showed that a significant loss of the deuterium had occurred and the deuterium content in the α-position was only 37%. In contrast, when **3** was employed as catalyst in the racemization of (*S*)-**1**, which took 24 h, essentially all of the deuterium was maintained in the α-position of the alcohol (entry 2). When the racemization experiment was carried out in a protic solvent (Bu^{t}OH) catalyst **2** gave a dramatic drop in the deuterium content to 15% (entry 3), whereas with catalyst **3** a high α-deuterium content was still maintained (91% D, entry 4). Interestingly, when catalyst **3** was employed in toluene, (*S*)-**1** gave a racemized product with 82% deuterium in the α-position. This suggests that slow aromatic activation of toluene by the active catalyst takes place leading to some H/D exchange.

The results from the racemization of (*S*)-**1**† suggest that catalysts **2** and **3** operate by two different mechanisms. With catalyst **2** it is evident that the hydride on the metal arises both from the α-position and the OH group of the alcohol (path II, Scheme 1), whereas with catalyst **3** the hydride arises only from the α-position (path I, Scheme 1). The former mechanism (path

Table 1 Racemization of (*S*)-**1** *via* Ru-catalyzed hydrogen transfer[a]

Entry	Catalyst	Base	Solvent	Water (%)	*t*/h	Result[b]
1	**2**	NaOH	THF	0.5	4	37% D
2	**3**	—	THF	—	24	95% D
3	**3**	—	Bu^{t}OH	0.5	72	91% D
4	**2**	NaOH	Bu^{t}OH	0.5	4	15% D
5	**3**	—	Toluene	—	24	82% D

[a] 2 mol% of the catalyst was employed together with 1 equiv. of acetophenone at 70 °C. [b] The deuterium content was determined by ^{1}H NMR and also by mass spectrometry and refers to the amount in the α-position.

DOI: 10.1039/b000530o

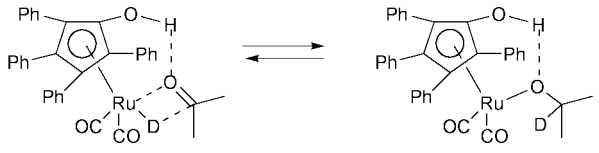


Fig. 2

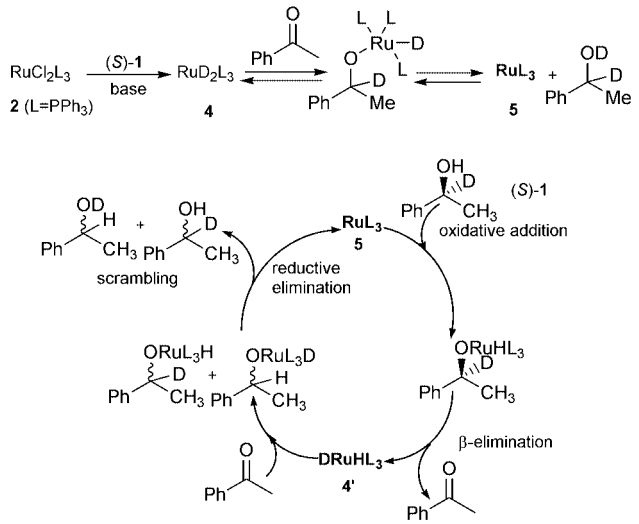
II) is expected to give a H/D ratio of 50/50 in the α-position of the racemized alcohol from (*S*)-**1**. With path I (Scheme 1), (*S*)-**1** would give only ruthenium deuteride and as a result the α-position would be 100% deuterated in the racemized product.

The mechanism for catalyst **3**, which follows path 1, probably involves an intermediate in which the hydrogen transferred to the carbonyl carbon comes from the metal and the hydrogen transferred to the ketone oxygen arises from the OH group of the catalyst (Fig. 2). This may involve insertion of the ketone into a Ru–D bond followed by protonation of the ruthenium alkoxide by the OH group. In the reversed reaction a β-elimination from the alkoxide gives the ruthenium deuteride. This is in line with the mechanism proposed in our previous studies on ruthenium-catalyzed hydrogen transfer reactions with catalyst **3**.[12]

In the hydrogen transfer reaction with catalyst **2** it is known that the chlorides are eliminated under the formation of a ruthenium dihydride species.[9] With substrate (*S*)-**1** a di-deuterated complex **4** would be formed, which can react with the ketone to give a ruthenium(0) complex RuL_3 **5** after reductive elimination (Scheme 2). The latter complex should be in equilibrium with **4**.



Scheme 2 Hydrogen transfer with catalyst **2**.

In the catalytic cycle (Scheme 2) oxidative addition of (*S*)-**1** to **5** would give a ruthenium alkoxide, which on β-elimination produces acetophenone and $DRuHL_3$ **4′**. The mixed hydride-deuteride species **4′** can now add to acetophenone, and after reductive elimination, the alcohol obtained would have deuterium scrambled between the α- and oxygen-positions. Any exchange with protons in the medium (*e.g.* a protic solvent) at this stage will lower the deuterium content of **1** by exchange of deuterium in the oxygen-position (*cf.* entry 4, Table 1). This is in contrast to catalyst **3** for which there will be no such H/D exchange since the hydride on the metal only arises from the α-position of the alcohol.

In conclusion, the results presented here show that quite different mechanisms may operate in ruthenium-catalyzed hydrogen transfer. Evidence is provided that catalyst **2** does not distinguish between the α-hydrogen and the OH hydrogen in hydrogen transfer from an alcohol to a ketone. In contrast, catalyst **3** selectively transfers the α-hydrogen to the carbonyl group and the OH hydrogen to the keto oxygen in the corresponding hydrogen transfer.

Financial support from the Swedish Natural Science Research Council and the Swedish Foundation for Strategic Research is gratefully acknowledged.

Notes and references

† *Typical procedure* for racemization of (*S*)-**1**: the ruthenium catalyst (2 mol%) and the base (10 mol%) were placed in a Schlenk tube, which was evacuated and filled with argon. Argon was bubbled through a solution of (*S*)-**1** (123 mg, 1 mmol) and acetophenone (120 mg, 1 mmol) in 1.25 ml of the appropriate solvent and transferred *via* a canula to the Schlenk tube containing the catalyst. The reaction mixture was heated to 70 °C (when THF was used as the solvent, the Schlenk tube was sealed with the help of a stopcock). The reaction was followed by chiral GC, worked up by filtration through a bed of Celite and purified by column chromatography. The racemized alcohol obtained was analyzed by ^{1}H NMR and MS for the deuterium content in the α-position.

Catalytic α-hydroxy carbon radical generation and addition. Synthesis of α-hydroxy-γ-lactones from alcohols, α,β-unsaturated esters and dioxygen

Takahiro Iwahama, Satoshi Sakaguchi and Yasutaka Ishii*

Department of Applied Chemistry, Faculty of Engineering & High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan. E-mail: ishii@ipcku.kansai-u.ac.jp

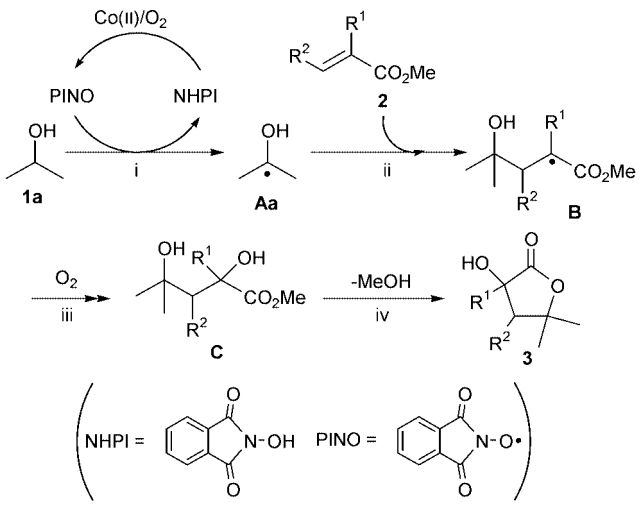
Received (in Cambridge) 24th January 2000, Accepted 28th February 2000

A catalytic method for α-hydroxy carbon radical generation from alcohols has been developed and a convenient and synthetically useful approach to α-hydroxy-γ-lactones constructed.

Free radical reactions have attracted much attention in the synthesis of organic compounds because of their many advantages over ionic reactions, and therefore a variety of methodologies have been developed for the generation of carbon radicals.[1] To our knowledge, however, a limited number of methods, *e.g.* peroxide-[1,2] and photo-[1,3] initiated techniques and redox systems using metal ions,[1,4] have been used for the generation of carbon radicals from alcohols. Therefore, we believe that the catalytic carbon radical formation from alcohols and its use in organic synthesis are of interest and very useful as a synthetic tool. However, such a method has, as yet, not been realized.

Recently, we have shown that phthalimide *N*-oxyl (PINO), generated from *N*-hydroxyphthalimide (NHPI) and dioxygen, can abstract the hydrogen atom from alkanes to form alkyl radicals which are readily captured by O_2 to give oxygenated compounds such as alcohols, ketones and carboxylic acids.[5] As an application of this procedure, we report here, the first successful catalytic α-hydroxy carbon radical generation from alcohols using NHPI combined with cobalt species as the catalyst under O_2 (1 atm) and trapping the resulting α-hydroxy radicals by α,β-unsaturated esters leading to α-hydroxy-γ-lactones which are very difficult to obtain by conventional methods. Such lactones are very attractive as valuable synthetic precursors for species such as α,β-butenolides which have potent biological activity[6] as well as fine chemicals which are expected to be widely used in chemical industry.[7]

An outline of our approach is shown in Scheme 1: (i) *in situ* generation of an α-hydroxy carbon radical **Aa** from an alcohol assisted by NHPI/Co(II) under O_2; (ii) the addition of the radical **Aa** to an α,β-unsaturated ester; (iii) trapping of the radical **B** by O_2; (iv) the intramolecular cyclization of the resulting 1,3-diol **C** to yield α-hydroxy-γ-lactone **3**.



Scheme 1

Initially, the generation of an α-hydroxy carbon radical from isopropyl alcohol **1a** and the trapping of this radical by methyl acrylate **2a** were examined by the use of three different combined catalytic systems: NHPI/$Co(OAc)_2$ **I**, NHPI/$Co(acac)_3$ **II** and NHPI/$Co(OAc)_2$/$Co(acac)_3$ **III** under O_2 (1 atm) at 60 °C, leading to α-hydroxy-γ,γ-dimethyl-γ-butyrolactone **3a** in 27–78% yields (Fig. 1).† Inspection of Fig. 1 indicates that the reaction *via* catalyst **I** is terminated at an early stage and that catalyst **II** gives a higher yield of **3a**, although an induction period of 3 h was observed. The Co(III) ion is well known to be gradually reduced to Co(II) by organic substrates *via* a one-electron transfer process.[8] Therefore, it is thought that the induction period observed in the catalytic system **II** would correspond to the time required for the generation of Co(II) during the reaction. In order to shorten the induction period, we carried out the above reaction by adding a small amount of Co(II) ion [as $Co(OAc)_2$] to the NHPI/Co(III) system. As expected, a reduction of the induction period of the reaction was observed, and the best yield of **3a** (78%) was obtained by the use of the catalytic system **III**. On the basis of these results, a variety of alkenes were treated with **1a** under O_2 using the NHPI/$Co(OAc)_2$/$Co(acac)_3$ system (Table 1).

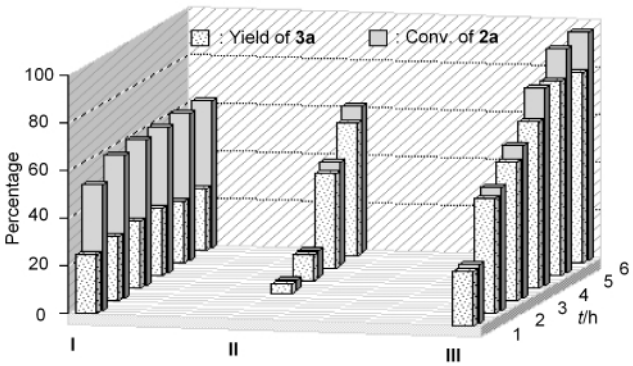


Fig. 1 Time dependence for the reaction of isopropyl alcohol **1a** with methyl acrylate **2a** to give **3a** under O_2 (1 atm) using NHPI/$Co(OAc)_2$ **I**, NHPI/$Co(acac)_3$ **II** and NHPI/$Co(OAc)_2$/$Co(acac)_3$ **III**. **2a** (3 mmol) was reacted with **1a** (10 equiv.) in the presence of NHPI (10 mol%) under O_2 (1 atm), 60 °C in MeCN (0.5 mL). **I**: $Co(OAc)_2$ (1 mol%), **II**: $Co(acac)_3$ (1 mol%), **III**: $Co(OAc)_2$ (0.1 mol%) and $Co(acac)_3$ (1 mol%).

5		**1i**	8		**3i** (80)
6		**1j**	5		**3j** (41) [56/44][c]

[a] **2a** (3 mmol) was reacted with **1** (5 equiv.) in the presence of NHPI (10 mol%), $Co(OAc)_2$ (0.1 mol%) and $Co(acac)_3$ (1 mol%) under O_2 (1 atm) in MeCN (0.5 mL). [b] Isolated yield. [c] *trans/cis* ratio by GLC. [d] **1d** (3 equiv.) used.

From α- and β-methyl substituted acrylates, methacrylate **2b** and crotonate **2c**, the corresponding α-hydroxy-γ-lactones, **3b** and **3c**, were obtained in 71 and 14% yields, respectively. The lower reactivity of **2c** may be due to the β-CH_3 group which exerts steric hindrance towards the attacking radical **Aa**.[9] Reactions with methyl maleate **2d** and methyl fumarate **2e** proceeded smoothly even at 25 °C to afford α-hydroxy-β-carbomethoxy-γ-lactone **3d** in excellent yields, respectively. It is known that the incorporation of an electron-withdrawing substituent into the alkene decreases the SOMO–LUMO energy difference, and thus increases the rate of addition of alkyl radicals which possess nucleophilic reactivity.[9]

This new method for the construction of α-hydroxy-γ-lactones was quite general for a variety of alcohols (Table 2).‡ From cyclic alcohols, α-hydroxy-γ-spirolactones, which so far have been very difficult to synthesize, were obtained in high yields. Like secondary alcohols, the primary alcohol, hexa-1-nol **1j**, was found to generate the 1-hydroxyhexyl radical which then adds to **2a**, giving the corresponding γ-lactone **3j** (41%).

From viewpoints of low cost material, reaction efficiency and reaction simplicity, the present reaction is an innovative approach for the synthesis of α-hydroxy-γ-lactones which have considerable industrial potential.[10]

To gain further insight into the role of the cobalt species in the present reaction, the reaction of **1a** with **2a** by the NHPI/Co(II) system at room temperature was compared with that by the NHPI/Co(III) system [eqn. (1)]. The reaction *via* the NHPI/Co(II) system occurred at room temperature to give **3a** in excellent selectivity (92%) at 37% conversion, while the same reaction with the NHPI/Co(III) system was not observed even after 24 h. These results indicate that the presence of Co(II) is important to initiate the reaction. In a previous paper, we reported that a Co(III)–dioxygen complex derived from Co(II) species and O_2 accelerates the generation of PINO from NHPI.[5] Efforts to expand this method and to elucidate the reaction mechanisms are currently in progress.

Heterogeneous asymmetric epoxidation of alkenes catalysed by a polymer-bound (pyrrolidine salen)manganese(III) complex

Choong Eui Song,*[a] Eun Joo Roh,[a] Byoung Mook Yu,[b] Dae Yoon Chi,[b] Su Chang Kim[c] and Kee-Jung Lee[c]

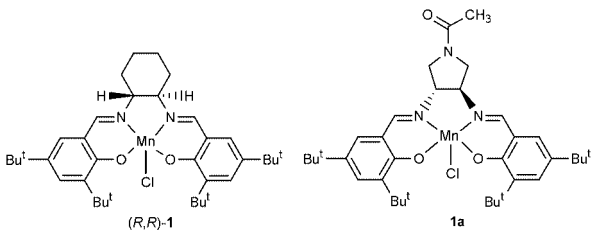
Received (in Cambridge, UK) 1st February 2000, Accepted 6th March 2000

Excellent enantioselectivity (*e.g.* 92% ee for 2,2-dimethylchromene) has been achieved in heterogeneous asymmetric epoxidation using a polymer-bound (pyrrolidine salen)-manganese(III) complex; however, this polymeric catalyst underwent partial decomposition under epoxidation conditions.

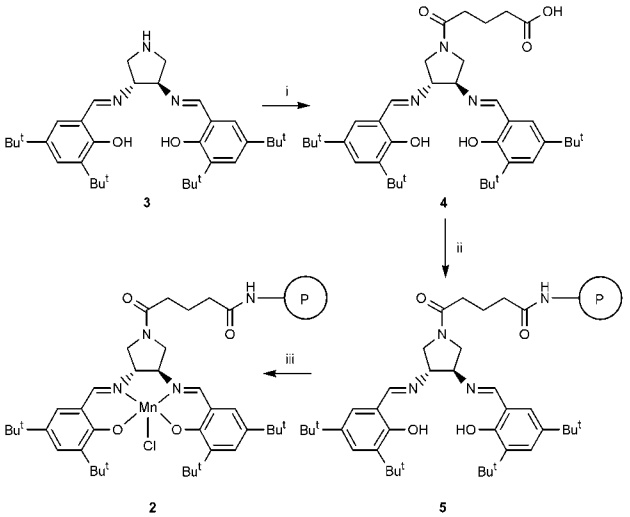
Catalytic asymmetric epoxidation of alkenes presents a powerful strategy for the synthesis of enantiomerically enriched epoxides. Among several catalytic methods, the asymmetric epoxidation of unfuntionalised alkenes catalysed by chiral salen manganese complexes, *e.g.* the compound **1** developed by Jacobsen *et al*. is one of the most relevant methods.[1]



Recently, several attempts to build heterogeneous systems by the covalent attachment of Jacobsen-type catalysts to insoluble solid supports have been made.[2,3] Facilitation of catalyst separation, catalyst reuse and an increase in stability of the catalyst [*e.g.* minimisation of the possibility of formation of inactive μ-oxo-manganese(IV) species[4]] are the main objectives of such research. However, the results obtained so far are rather disappointing. This is perhaps not surprising since most of approaches have been focussed on copolymerisation of bis-styryl derivatives of chiral salen ligands.[2a–f] Such systems may show steric restriction for complex formation. Recently, Sherrington and coworkers[2g] have reported a series of polymer supported chiral (salen)Mn complexes, where the chiral catalytic unit was immobilised in a pendant fashion by only one of its aromatic rings to polymer supports to minimise local steric restriction. In one case, a very high ee (91%) was achieved in the epoxidation of 1-phenylcyclohexene, although the yield of the corresponding epoxide was relatively low (49%).

We now report the synthesis and application of a polymer-bound chiral (pyrrolidine salen)manganese(III) complex **2**, in which the (pyrrolidine salen)Mn moiety is attached by a single flexible linkage *via* the N-atom of the pyrrolidine moiety to the polymer support.

The dark brown polymeric complex **2** was prepared as shown in Scheme 1 by the reaction of NovaSyn® TG amino resin LL[5] with the chiral pyrrolidine salen derivative **4**, followed by treatment with $Mn(OAc)_2 \cdot 4H_2O$ in the presence of an excess of NaCl. In order to remove soluble (salen)Mn species which could interfere with the catalysis, the polymeric catalyst **2** was extracted in a Soxhlet device with MeOH for 24 h. Manganese analysis of **2** indicated that 0.11 mmol g^{-1} of the (salen)Mn complex was incorporated. The chiral pyrrolidine salen derivative **4** was readily prepared in 86% yield by the reaction of **3**[6] with glutaric anhydride in the presence of triethylamine and DMAP (CH_2Cl_2, 12 h, room temp.). To compare the catalytic efficiency in homogeneous and heterogeneous reactions, the homogeneous analogue **1a** was also prepared by a similar procedure.



Scheme 1 *Reagents and conditions*: i, glutaric anhydride, NEt_3, DMAP, CH_2Cl_2, room temp., 12 h; ii, NovaSyn® TG amino resin LL (ref. 5), 1-hydroxybenzotriazole hydrate, $NEtPr^i_2$, 1.3-diisopropylcarbodiimide, DMF–CH_2Cl_2, room temp., 15 h; iii, $Mn(OAc)_2 \cdot 4H_2O$, EtOH–toluene, 85 °C, air, 12 h, then NaCl(aq).

Catalytic asymmetric epoxidations were carried out in the presence of 4 mol% of catalyst using NaOCl–PPNO (4-phenylpyridine *N*-oxide) or MCPBA–NMO as the oxidant system. The conditions were typical of those reported in the use of the soluble Jacobsen catalyst **1**[7] and the results obtained are shown in Table 1.

As a control experiment, we first investigated the catalytic efficiency (activity and enantioselectivity) of the monomeric analogue **1a** of the polymeric catalyst **2**. We were pleased to find that this catalyst was nearly as effective as Jacobsen's catalyst **1** (Table 1, entries 1 and 2). This result means that the chiral pyrrolidine salen moiety appears to be an appropriate chiral scaffold for the asymmetric epoxidation catalyst. With these results in hand, we turned to studying polymer-bound catalyst **2**. As shown in Table 1, the polymer-bound catalyst **2** exhibited quite satisfactory results, although the activity and enantioselectivity were still slightly lower than those obtained with its homogeneous analogue **1a**. In general, the reaction with MCPBA as the oxidant proceeded much faster than with NaOCl and afforded higher ee values. For example, the epoxidation of 2,2-dimethylchromene with MCPBA was completed in 1.5 h, affording the corresponding oxide with very high ee (92% ee, entry 4). On the other hand, the same reaction with NaOCl,

8	**2**		MCPBA –NMO	2	76	68

[a] See footnote†. [b] Isolated yields. [c] Determined by chiral GC or chiral HPLC: see footnote† and ref. 7(*b*); major enantiomers: (3*R*,4*R*)-3,4-epoxy-2,2-dimethylchroman, (3*R*,4*R*)-3,4-epoxy-6-cyano-2,2-dimethylchroman and (1*R*,2*S*)-1-phenylcyclohexene oxide.

which was carried out under two-phase conditions, required 24 h for a comparable degree of conversion and gave the epoxide with 87% ee (entry 3). The polymeric catalyst **2** could be simply recovered by filtration so enabling catalyst recycling. However, the polymer-bound catalyst **2** underwent partial decomposition under epoxidation condition. The initially dark brown resin was more or less decolourised after the reaction. When MCPBA was used as oxidant, much more severe decolourisation was observed than when NaOCl was used. This result is in accord with results of Skarzewski *et al*., who also observed a fairly high resistance to degradation when NaOCl is used as an oxidant for salen complexes with *tert*-butyl groups at the 5- and 5′-positions.[8] This tendency of salen manganese catalysts to undergo decomposition under epoxidation conditions could limit successful recycling of immobilised catalyst.[9]

In summary, we have prepared a promising class of polymer-bound catalyst for heterogeneous asymmetric epoxidation of alkenes. Our results showed that polymeric catalyst **2** showed a comparable degree of enantioselectivity (92% ee for 2,2-dimethylchromene) in asymmetric epoxidation of alkenes to that obtained with its homogeneous analogue **1a**. However, the activity and enantioselectivity of the polymeric catalyst **2** are highly dependent on epoxidation conditions, and, moreover, the degree of decomposition of catalyst also seems to be highly influenced by oxidation conditions. Therefore, to carry out heterogeneous asymmetric epoxidation successfully, not only the design of supported catalysts, but also the selection of appropriate oxidation conditions are very important. More detailed studies concerning the optimisation of both catalyst structure (to increase activity and enantioselectivity by modifying the spacer length and resin morphology, *etc*.) and reaction conditions (to minimise catalyst decomposition) are currently in progress.

This research was supported by a grant from Ministry of Science and Technology in Korea.

Notes and references

† Asymmetric epoxidation using polymer-bound catalyst **2**.

Using NaOCl as the oxidant: resin beads of **2** (202 mg) were stirred in CH_2Cl_2 (2 mL) for 1 h. Alkene (0.54 mmol) and 4-phenylpyridine *N*-oxide (18.5 mg, 0.108 mmol) were then added and the mixture was cooled to 0 °C. To this mixture buffered NaOCl (0.81 mmol, pH = 11.3) was added and the reaction was stirred at 0 °C. At the end of the reaction, the suspension was filtered off and resin beads were washed with CH_2Cl_2. The filtrate was washed with brine and dried ($MgSO_4$). After removal of the solvent under reduced pressure, the residue was purified by column chromatography.

Using MCPBA as the oxidant: resin beads of **2** (202 mg) were poured into a solution containing 2.7 mmol (316 mg) of *N*-methylmorpholine *N*-oxide dissolved in CH_2Cl_2 (4 mL). Alkene (0.54 mmol) was then added and the mixture was cooled to −78 °C. Solid MCPBA (1.08 mmol, 186 mg) was then added as a solid in four roughly equal portions over a 2 min period. The reaction mixture was stirred at −78 °C and the progress of the reaction was monitored by TLC. At the end of the reaction, the suspension was filtered off and resin beads were washed with CH_2Cl_2. The filtrate was washed with 1 M NaOH, brine and dried. After removal of the solvent under reduced pressure, the residue was purified by column chromatography.

The ee values of products were determined by chiral HPLC or chiral GC: For 3,4-epoxy-2,2-dimethylchroman: Daicel Chiralpak AD, propan-2-ol–hexane (5:95), 0.8 mL min^{-1}; 9.30 min (3*R*,4*R*), 10.63 min (3*S*,4*S*); for 3,4-epoxy-6-cyano-2,2-dimethylchroman: Daicel Chiralcel OJ, propan-2-ol–hexane (30:70), 1 mL min^{-1}; 13.95 min (3*R*,4*R*), 26.88 min (3*S*,4*S*); for 1-phenylcyclohexene oxide: see ref. 7(*b*).

Triply-bridged diphos disilver helical complexes $[Ag_2(\mu_2\text{-dppa-}P,P')_3(anion)_2]$ [dppa = bis(diphenylphosphino)acetylene]

Stuart L. James,* Elvira Lozano and Mark Nieuwenhuyzen

School of Chemistry, The Queen's University of Belfast, David Keir Building, Stranmillis Road, Belfast, Northern Ireland, UK BT9 6EQ. E-mail: s.james@qub.ac.uk

Received (in Basel, Switzerland) 6th December 1999, Accepted 18th February 2000

Triply-bridged disilver complexes $[Ag_2(\mu_2\text{-dppa-}P,P')_3(anion)_2]$ form selectively and are stabilised by many aromatic interactions.

Multimetallic 'coordination clusters' which assemble from metal ions and multidentate bridging ligands currently attract much interest.[1] In most cases, their structures can be predicted from the geometries of the rigid bridging ligand and the metal ion used (*e.g.* square planar or octahedral). By contrast, silver(I)–phosphine complexes exhibit varying coordination numbers, and often dissociative equilibria. Therefore more subtle 'secondary' factors might control product selectivity in the formation of a multisilver complex with bridging phosphines. Some known multisilver and -copper complexes with bridging phosphines[2] are shown in Fig. 1. Some of these have quite unexpected structures, *e.g.* the hexanuclear adamantanoid triphos cages **b**.[2j] With flexible diphosphines $Ph_2P(CH_2)_nPPh_2$, silver(I) or copper(I) salts with oxo-anions selectively form dinuclear (2:2) macrocycles, *e.g.* **a**. The larger rings of this type (up to 18-membered) are stabilised by bridging oxo anions. This stabilisation is enabled by the flexibility of the diphosphine, which allows the P lone pairs to point inwards, setting up the metals for anion bridging.

Bis(diphenylphosphino)acetylene ($Ph_2P–C\equiv C–PPh_2$, dppa), by contrast, cannot have inwardly pointing lone pairs owing to its rigidity. We were therefore interested to discover what type of stable non-dissociating structure, if any, this ligand would cause to form.

At room temperature, solutions of equimolar mixtures of dppa and AgX (X = SbF_6 or OTf) in $CDCl_3$–$MeNO_2$ (2:1) gave ^{31}P NMR spectra (121 MHz) which were broad and did not show Ag–P coupling, suggesting dissociation of the Ag–P bonds on the NMR timescale. At −60 °C, this process is slow on the NMR timescale and only sharp lines characteristic of coupling to ^{107}Ag and ^{109}Ag were seen. 95% of the spectral intensity was due to a mixture of three species, each with distinctly different coupling constants corresponding to AgP (767 Hz), AgP_2 (505 Hz) and AgP_3 (377 Hz) coordination centres.[3] The lowest nuclearity structures which could account for these coordination centres are indicated in Scheme 1. Therefore the rigid dppa ligand does not selectively produce a 2:2 macrocycle **2**, but instead favours some disproportionation to the 1:2 and 3:2 structures **1** and **3**.

We therefore investigated the selective formation of triply-bridged complex **3**, at the appropriate 3:2 ligand to metal ratio. The reaction of 3 equivalents of dppa with 2 equivalents of $AgSbF_6$ did indeed lead quantitatively to this product. This behaviour was further found to be general to the salts AgX (X = BF_4 **3a**, SbF_6 **3b** NO_3 **3c**, OTf **3d**).† Unusually for silver-phosphine complexes, **3a–d** show no evidence of Ag–P dissociation at room temperature on the NMR timescale (at 121 MHz). A $^{19}F\{^1H\}$-HOESY spectrum[4] in $CDCl_3$ reveals an interionic contact between the BF_4^- and the dppa *ortho* protons (of < 4.5–5 Å), showing that complex **3** exists as a tight ion-pair in this solvent.

Crystals obtained from chloroform–nitromethane–diethyl ether had the composition $[Ag_2(\mu_2\text{-dppa-}P,P')_3(BF_4)_2]\cdot 0.5CHCl_3\cdot 1.5MeNO_2$ as established by single crystal X-ray crystallography (Fig. 2).‡ Consistent with the NMR data, there is trigonal geometry at silver, although with pyramidal distortion toward the BF_4 anions (distances of Ag1 and Ag2 from their P_3 planes are 0.55 and 0.54 Å, respectively). The two Ag(I) centres are linked by three bridging dppa ligands with outwardly bent P–C≡C–P backbones, and C≡C–P angles lying in the range 171.3(4)–175.1(4)°. This strain results from the mismatch between distorted tetrahedral geometry at phosphorus and pseudo-cofacial silver coordination centres, and is partially alleviated by the pyramidal distortion at silver. There is a helical twist of *ca.* 27°, about the Ag···Ag axis, taken as the average of the torsion angles P(1)–Ag(1)–Ag(2)–P(2), P(3)–Ag(1)–Ag(2)–P(4) and P(5)–Ag(1)–Ag(2)–P(6). The crystalline material is achiral however, each unit cell containing two molecules of each enantiomer. There is small void at the centre (dimensions: Ag to molecular centroid 2.83 Å, typical C≡C centroid to molecular centroid 2.48 Å).

Perhaps importantly, there are sixteen intramolecular aromatic contacts of both stacking and C–H···π types in the range

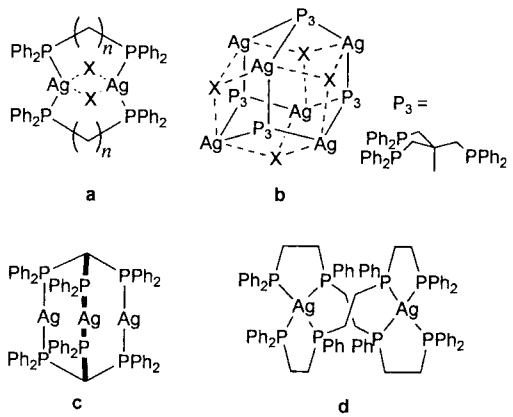

Fig. 1 Multisilver complexes with bridging multidentate phosphines: diphos macrocycles (**a**), triphosphine cages (**b** and **c**), and a tetraphosphine helicate (**d**).

DOI: 10.1039/a909683c

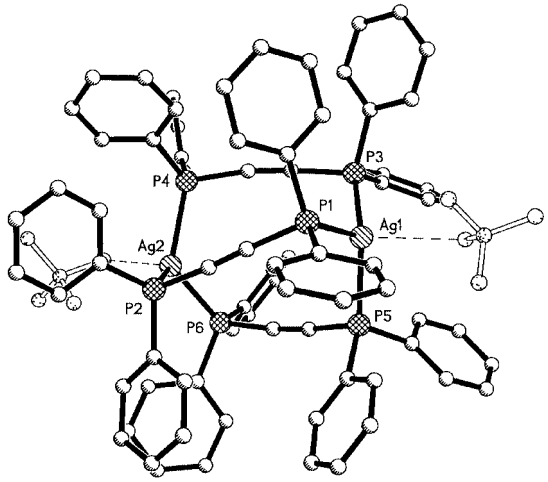

Fig. 2 The structure of complex **3a** in the solid state with H-atoms omitted.

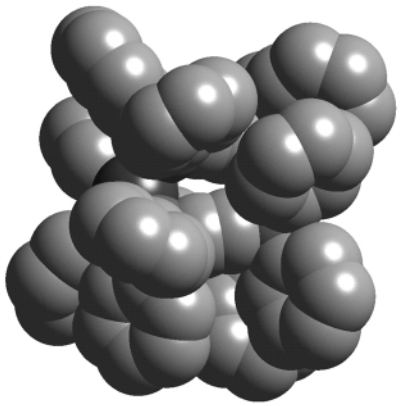

Fig. 3 Space-filling representation of complex **3a** to show the clustering of aromatic groups (H-atoms omitted).

3.5–3.8 Å (C–C distance) between the twelve phenyl groups. An impression of the clustering of aromatic groups can be gained from Fig. 3. Though individually weak, in combination these contacts may contribute significantly to the observed stability of complexes **3** in solution. Multiple aromatic interactions also occur in the triphos cage complexes $[Ag_6(triphos)_4(oxo\text{-}anion)]^{2+}$, and furthermore, may be responsible for their unexpected structure.[2j] The ^{1}H NMR spectrum of **3a** (−60 °C, 500 MHz) shows only one type of phenyl group suggesting that in solution it is either not helical or rapidly interconverts between enantiomers. Much interest has been shown in triple helicates,[4] and most are based on tris-chelate metal centres. Relevant exceptions are the Cu_3L_3 complex of Potts *et al.*[5a] with trigonal coordination, and the Ag_3L_3 toroidal triple helix with two-coordination at silver reported by Williams *et al*.[5b] We note with interest that the related dppa complexes $[(CO)_3Mo(\mu_2\text{-dppa-}P,P')_3Mo(CO)_3]$[6a] and [BuTeCu($\mu_2$-dppa-$P,P')_3$CuTeBu][6b] are also helical. In contrast to complex **3a**, as a consequence of their higher coordination numbers and correspondingly smaller P–M–P angles, these complexes have longer, narrower central voids (Mo–Mo distance 7.38 Å, Cu–Cu distance 6.40 Å).

In conclusion, complexes **3a**–**d** are a novel type of stable disilver complex with triply-bridging diphosphines. They assemble selectively from a 3:2 ligand to metal ratio, and unusually their Ag–P bonds do not dissociate on the NMR timescale at room temperature. Interesting structural features are the many intramolecular aromatic interactions, the central void and helical twist. The aromatic interactions may explain their selective assembly and stability in solution. This has implications for coordination-based self-assembly with flexible ligands or where the metal has no clearly preferred coordination number.

We are grateful to Dr Graham Saunders and Dr Graeme Hogarth for valuable discussions.

Notes and references

† To a solution of AgX (0.44 mmol) in nitromethane–acetonitrile or acetonitrile (8 ml) was added a solution of dppa (263 mg, 0.66 mmol) in $CHCl_3$ (10 ml). Layering with diethyl ether gave colourless prisms in > 90% yield. **3a** (X = BF_4) δ_P 19.4, $^1J(^{109}Ag^{31}P)$ 377 Hz, **3b** (X = SbF_6) $^1J(^{109}Ag^{31}P)$ 360 Hz, **3c** (X = NO_3) $^1J(^{109}Ag^{31}P)$ 336 Hz, **3d** (X = OTf) $^1J(^{109}Ag^{31}P)$ 336 Hz. $\delta_H(CDCl_3)$: **1a** (X = BF_4) 7.56 (m, 24H, H_{ortho}), 7.27 (t, 1.8 Hz, 12H, H_{para}), 7.10 (t, 1.8 Hz, 24H, H_{meta}).

‡ *Crystal data* for **3a**. $C_{80}H_{60}Ag_2B_2Cl_{1.50}F_8N_{1.50}O_3P_6$, M = 1718.65, monoclinic, space group $P2_1/n$ (no. 14), a = 22.1929(16), b = 14.8355(18), c = 23.8561(13) Å, β = 99.460(6)°, V = 7747.6(12) Å^3, Z = 4, D_c = 1.473 g cm^{-3}, μ = 0.749 mm^{-1}. Data collection ($2.21 \leqslant \theta \geqslant 25.00$) was performed at 153 K on a Bruker SMART diffractometer (Mo-Kα, λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-97)[7] and refined with full matrix least squares to a final R_1 value of 0.0674, for 929 parameters and 13639 unique reflections with $I \geqslant 2\sigma(I)$ and wR_2 of 0.1067 for all 14014 reflections. The BF_4 anions are each disordered over two sites with occupancies of 65 and 60% for the major component of each anion. There are short fluorine contacts to the silver(I) centres and to some *ortho*-hydrogen atoms. For the major components, contacts shorter than the sum of the van der Waals radii (2.67 Å) between fluorine and hydrogen are F11–H62A 2.593, F21–H12B 2.589 and F22–H36B 2.507 Å. To the Ag centres, contacts shorter than the combined van der Waals radii (3.19 Å) are F21–Ag1 2.933(9), F22–Ag1 2.751(7), F11–Ag2 2.861(9) and F12–Ag2 2.656(9) Å. CCDC 182/1549. Received (in Liverpool, UK) 17th January 2000, Accepted 12th February 2000

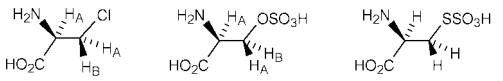
L-Aspartate aminotransferase, a member of the α-family of PLP mediated enzymes, which normally catalyses transamination, has been used to catalyse the β-substitution reaction of stereospecifically labelled samples of the enzyme inhibitor β-chloro-L-alanine with 2-mercaptoethanol; the stereochemistry of the products was assigned by independent synthesis, showing that the abnormal substitution reaction proceeds with overall retention of stereochemistry, the usual stereochemical consequence of reactions catalysed by enzymes of the β-family of PLP mediated enzymes which have low homology with enzymes of the α-family.

Pyridoxal phosphate (PLP) dependent enzymes catalyse a wide variety of different reactions, mainly involving amino acids. Early theories[1–3] to generalise and explain the chemical basis for these widely differing reactions have largely been confirmed. Dunathan and Voet[4] proposed that PLP-dependent enzymes evolved from a common ancestor protein, and there is evidence[5] that this is true for one of the three families of PLP mediated enzymes, the α-family, which contains a predominant number of enzymes. Homology studies have recently suggested that the α- and γ-families of enzymes may be distantly related but that enzymes of the β-family are not closely related to either of these families.[5]

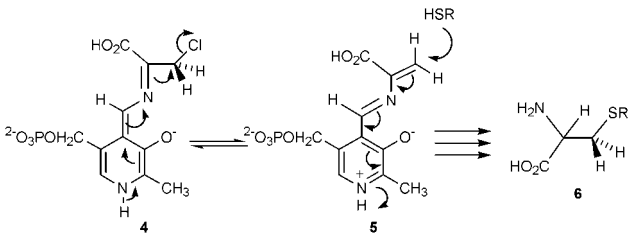
L-Aspartate aminotransferase (EC 2.6.1.1) is an enzyme of the α-family, catalysing the transamination of L-aspartic acid to α-ketoglutaric acid giving oxaloacetic and glutamic acids. β-Chloro-L-alanine **1**[6,7] has been shown not only to inhibit this enzyme, but also to be converted to pyruvic acid by it. It has also been observed that introduction of thiosulfate during the inactivation of L-aspartate aminotransferase by L-serine-*O*-sulfate **2** reversed inhibition and caused production of L-cysteine-*S*-sulfonate **3**.[8] Further, inhibition of D-amino acid



1 **2** **3**

aminotransferase by β-bromo-D-alanine was reversed by addition of thiols and, when β-mercaptoethylamine was used, *S*-(β-aminoethyl)-D-cysteine and Δ^1-thiomorpholine-2-carboxylic acid were products.[9] Thus these enzymes have catalysed β-substitution reactions typical of enzymes of the β-family, rather than transamination which is typical of α-family enzymes. This would suggest that the quinonoid form **4**, formed in the 'normal' reaction, instead of protonation at C-4′ by Lys258, converted to **5** in the inhibition reaction. This may be processed to pyruvate or an inhibitor complex in the absence of a thiol. In the presence of a thiol, however, the reaction presumably proceeds as shown in Scheme 1 eventually to give the final cysteine derivative **6**.

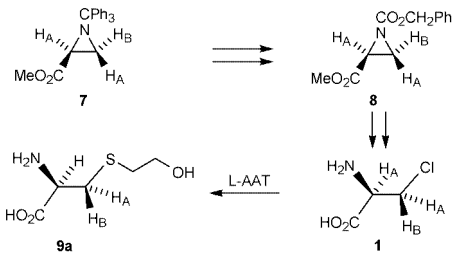
The change in role from catalyst for transamination to catalyst for β-substitution exhibited by aspartate aminotransferase on change of substrate from L-aspartate to β-chloro-L-alanine **1** was intriguing and we decided to examine the overall stereochemistry of the β-substitution reaction in the presence of thiol to see whether it was in keeping with the retention generally shown by reactions catalysed by the enzymes whose



4 **5** **6**

Scheme 1

normal role this was.[10] We therefore prepared samples of β-chloro-L-alanine **1** which were stereospecifically labelled at C-3. This was achieved by first converting the labelled samples of methyl (2*S*)-*N*-tritylaziridine-2-carboxylate **7**(H_B = ^2H)[11] and **7**(H_A = ^2H)[11] to the corresponding urethanes **8**† by reaction with trifluoroacetic acid in chloroform to remove the trityl group, followed immediately by reaction with benzyl chloroformate under Schotten Baumann conditions (Scheme 2). β-Substitution with chloride ion was achieved by reaction with $TiCl_4$ in CH_2Cl_2–$CHCl_3$, and deprotection in refluxing 4 M H_2SO_4 then gave the enzyme inhibitors **1**.† The ^1H and ^2H NMR spectra indicated that the inhibitors **1** were unique diastereoisomers and, since substitution is accompanied by inversion of stereochemistry at the labelled β-position, these were assigned as (2*R*,3*S*)-[3-$^2H_1$]- and (2*R*,3*R*)-[2,3-$^2H_2$]-β-chloroalanine, **1**(H_B = ^2H) and **1**(H_A = ^2H), respectively.



7 **8** **9a** **1**

Scheme 2

The enzyme L-aspartate aminotransferase (EC 2.6.1.1) was isolated by a standard purification protocol[12] from *E. coli* TY103[13] which was transformed with plasmid pKDHE19/AspC.[14] It had specific activity of 36.57 units mg^{-1} and appeared as one major band of molecular weight 43000 Da on SDS-PAGE. Incubation with (2*R*,3*R*)-[2,3-$^2H_2$]-β-chloroalanine **1**(H_A = ^2H) in the presence of a variety of thiols and under various conditions was now undertaken. The best results were obtained at pH 8.4 when mercaptoethanol was employed‡ and samples of labelled 3-(2-hydroxyethyl)cysteine **9a** were obtained in which the α-deuterium atom had exchanged as expected from the mechanism in Scheme 1. The β-deuterium atom also exchanged on prolonged incubation, an effect which had been previously noted in reactions with this enzyme.[15,16] However, when the incubation was stopped after 3 h, a sample of (2*R*)-3-(2-hydroxyethyl)cysteine **9a** was obtained with a ^1H NMR spectrum which showed that there was stereospecific

DOI: 10.1039/b000442l

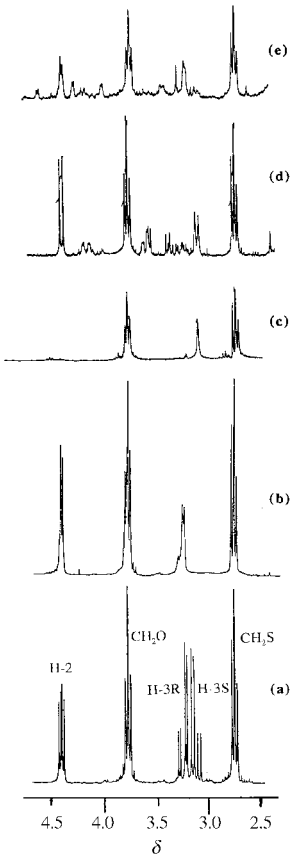


Fig. 1 ^{1}H NMR spectra in 10% ^{2}HCl–^2H_2O of (a) synthetic (2*R*)-3-(2-hydroxyethyl)cysteine **9**, (b) synthetic (2*R*,3*S*)-[3-$^2H_1$]-3-(2-hydroxyethyl)cysteine **9b**(H_B = ^{2}H), (c) synthetic (2*R*,3*R*)-[2,3-$^2H_2$]-3-(2-hydroxyethyl)cysteine **9b**(H_A = ^{2}H), (d) product from incubation of (2*R*,3*R*)-[2,3-$^2H_2$]-β-chloroalanine **1**(H_A = ^{2}H) with L-aspartate aminotransferase and (e) product from incubation of (2*R*,3*S*)-[3-$^2H_1$]-β-chloroalanine **1**(H_B = ^{2}H) with L-aspartate aminotransferase.

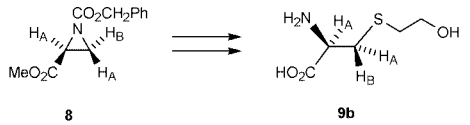
labelling at C-3 [Fig. 1(d)]. (2*R*,3*S*)-[3-$^2H_1$]-3-β-Chloroalanine **1**(H_B = ^{2}H) was therefore incubated for the same time when the ^{1}H NMR spectrum [Fig. 1(e)] of the product **9a** indicated that it was the C-3 epimer.

The trapping reaction was evidently stereospecific and it was now necessary to determine the absolute stereochemistry of the overall reaction. This was achieved by independent synthesis of samples of (2*R*)-3-(2-hydroxyethyl)cysteine **9b** which were labelled stereospecifically with deuterium at C-3 in an unambiguous manner. This is shown in Scheme 3, the labelled carbobenzyloxyaziridines **8** being reacted with mercaptoethanol containing a catalytic quantity of boron trifluoride etherate. Inversion of stereochemistry at the labelled atom, C-3, is expected and ^{1}H and ^{2}H NMR spectra showed that the labelled products† were single diastereoisomers. Hydrolysis in refluxing 4 M H_2SO_4 then gave the free amino acids **9b**.



8 **9b**

Scheme 3

The ^{1}H NMR spectra of the synthetic samples of (2*R*,3*S*)-[3-$^2H_1$]-3-(2-hydroxyethyl)cysteine **9b**(H_B = ^{2}H)† [Fig. 1(b)] and (2*R*,3*R*)-[2,3-$^2H_2$]-3-(2-hydroxyethyl)cysteine **9b**(H_A = ^{2}H)† [Fig. 1(c)] allowed the 3-*pro-S* and 3-*pro-R* protons in the spectrum of 3-(2-hydroxyethyl)cysteine **9** to be assigned and therefore the absolute stereochemistry of the incubation products to be deduced. It was evident that the product from the incubation using (2*R*,3*S*)-[3-$^2H_1$]-3-β-chloroalanine **1**(H_B = ^{2}H) was (2*R*,3*S*)-[3-$^2H_1$]-3-(2-hydroxyethyl)cysteine **9a**(H_B = ^{2}H) [Fig. 1(e)] and that the product when (2*R*,3*R*)-[2,3-$^2H_2$]-3-β-chloroalanine **1**(H_B = ^{2}H) was used was (2*R*,3*R*)-[3-$^2H_1$]-3-(2-hydroxyethyl)cysteine **9a**(H_A = ^{2}H) [Fig. 1(e)].

These results imply that the β-replacement reaction, which in this case is catalysed by an enzyme of the α-family whose normal function is transamination, occurs with overall retention of stereochemistry. This is the general expectation[10] for the PLP-mediated enzymes of the β-family where β-replacement reactions are the norm and may imply a closer relationship between families than homology[5] suggests. Although X-ray structures are available for aspartate aminotransferase[17] and other α-family enzymes, tryptophan synthase (EC 4.2.1.20) is one of the few enzymes of the β-family whose tertiary structure has been defined by X-ray cystallography.[18] It is interesting that, in the presence of thiols, tryptophan synthase has been shown to catalyse transamination and β-replacement of L-serine by mercaptoethanol.[19] Further, the Lys87Thr mutant of tryptophan synthase will not turn over the natural substrate serine in the absence of NH_4^+ but it will turn over β-chloro-L-alanine.[20]

We thank the BBSRC (K. J. M. B.) and the Leukaemia Research Fund (B. A.) for fellowships and the EPSRC for a studentship (S. M. W.), Mr C. Dadswell for NMR experiments, the EPSRC National Mass Spectrometry Service, Swansea for accurate mass measurements and Professor H. Kagamiyama for *E. coli* TY103 and plasmid pKDHE19/AspC.

Molecular beacons attached to glass beads fluoresce upon hybridisation to target DNA

Lynda J. Brown,[a] Jon Cummins,[b] Alan Hamilton[b] and Tom Brown*[a]

[a] *Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ*
[b] *Nycomed Amersham, Amersham Laboratories, White Lion Road, Amersham, UK HP7 9LL*

Received (in Liverpool, UK) 13th January 2000, Accepted 1st March 2000

Molecular beacons attached to glass beads have been synthesised which are non-fluorescent until exposed to a complementary target nucleic acid, whereupon they fluoresce, indicating hybridisation.

Tyagi and Kramer[1] have described a novel technology for the detection of specific nucleic acids in homogeneous solution. These probes, denoted 'molecular beacons', fluoresce upon hybridisation to their complementary DNA target. The essential feature of the probes is their stem–loop structure. The loop portion is an oligodeoxynucleotide probe for a complementary target nucleic acid. The stem is constructed of two short oligodeoxynucleotide arms, one which is terminally labelled with a fluorophore and the other with a quencher. Annealing of the arms causes intramolecular energy transfer from the fluorophore to the quencher. In this 'closed' conformation the probe is non-fluorescent. Hybridisation of the loop to its target causes the stem to open, the fluorophore and quencher are no longer in close proximity and fluorescence is emitted (Fig. 1).

Molecular beacons have been used in the detection of specific complementary sequences,[2–7] and the simultaneous detection of different pathogenic retroviruses has been reported.[8] Molecular beacons are able to distinguish between wild-type and single point mutations[3,9] and in real-time monitoring of the polymerase chain reaction (PCR) amplicon-specific probes lead to an increase in fluorescence intensity with increasing copy number of target DNA.

We have developed a modification of this technology that involves supporting the molecular beacons on solid glass particles (Fig. 2) and we have shown that glass-bound beacons exhibit similar properties to their soluble analogues. This technology could be harnessed in nucleic acid screening as hybridisation of CPG-bound beacons to target DNA or RNA generates fluorescent beads that can be isolated and analysed.

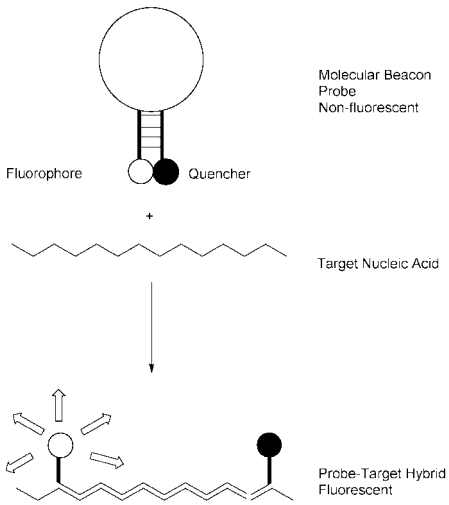

Fig. 1 Mechanism of action of molecular beacons in the presence of a complementary target nucleic acid.

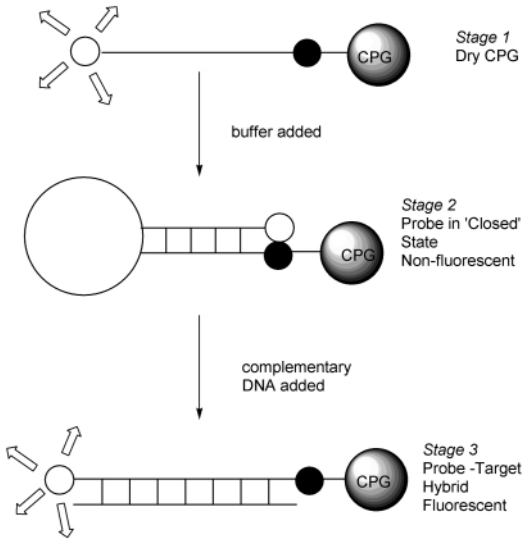

Fig. 2 Stages in assay of CPG-bound beacons.

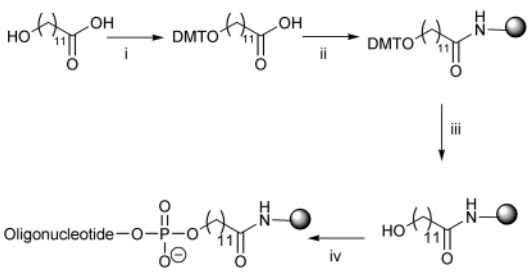
Long chain alkyl amino-controlled pore glass (LCAA-CPG) was derivatised with a polyalkyl linker as shown in Scheme 1: first, the primary hydroxy group of 12-hydroxydodecanoic acid was protected as a 4,4′-dimethoxytrityl (DMT) ether.[10] Then, the carboxylic acid moiety was coupled to free amino groups on the CPG using DIC/HOBT (DIC = 1,3-diisopropylcarbodiimide, HOBT = 1-hydroxybenzotriazole) in 1% DIPEA–CH_2CCl_2 (DIPEA = *N*,*N*-diisopropylethylamine) to create a stable amide bond between the linker and CPG. The loading of the linker on the CPG was determined by acid-catalysed detritylation followed by quantitation at 495 nm using a UV–VIS spectrometer. The appropriate amount of CPG was used for 0.2 mmol scale oligonucleotide synthesis on a ABI 394 DNA synthesiser. Coupling efficiencies of > 98.5% were achieved by extending the coupling time from 45 s to 10 min.

In order to establish suitable conditions for the hybridisation of CPG-bound oligonucleotides to solution nucleic acids, an oligonucleotide, CGAGATACGGTTTTCACAGC (OG1), was assembled† on the LCAA-CPG. The CPG was heated (60 °C) in



Scheme 1 Derivitisation of LCAA-CPG with a polyalkyl linker and oligonucleotide synthesis. *Reagents and conditions*: i, DMTCl, pyridine, room temp.; ii, LCAA-CPG, DIC, HOBT, DIPEA, CH_2Cl_2; iii, 5% CCl_3CO_2H, CH_2Cl_2; iv standard automated DNA synthesis.

DOI: 10.1039/b000389l

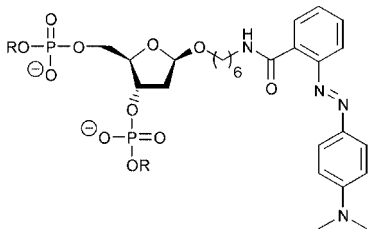


Fig. 3 Methyl Red phosphoramidite, the quencher used at the 3′ ends of CPG-bound probes.

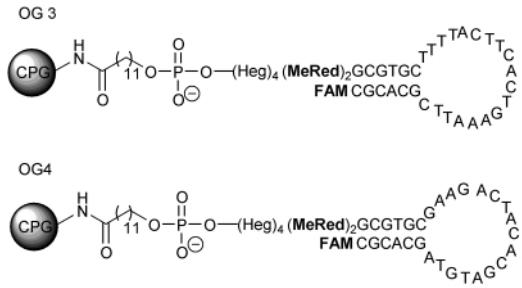

Fig. 4 Chemical structure of the CPG-bound molecular beacon probes.

conc. aqueous ammonia–ethanol (4 : 1 v/v) for 4 h and washed thoroughly with anhydrous CH_2Cl_2, to remove the cleaved protecting groups. An oligonucleotide GCTGTGAAAACCG-TATCTCG (OG2) of complementary sequence to the CPG-bound oligonucleotide (OG1) was synthesised and purified using standard methods. OG2 (0.22 OD) was mixed with the CPG-oligonucleotide (OG1) in 30 μL of an aqueous buffer of sodium hydrogenphosphate (10 mmol), EDTA (1 mmol) and NaCl (1 M) at pH 7.0, such that the CPG-bound oligonucleotide was in fourfold excess. The heterogeneous mixture was allowed to stand at room temperature for 3 h after which the absorbance (260 nm) of the CPG solution gave a reading of 0.035. This corresponds to a reduction of 84% of oligonucleotide in free solution. UV melting of the mixture gave a smooth transition as the oligonucleotide was released from the CPG into solution (T_m = 83.6 °C).

Two molecular beacons were assembled by solid phase DNA synthesis on the polyalkylamide LCAA-CPG previously described (Scheme 1). Both oligonucleotides were labelled at the 5′ end with fluorescein (FAM);

CGCACGCTTAAAGTCACTTCATTTTCGTGCG (OG3)

CGCACGATGTAGCACATCAGAAGCGTGCG (OG4).

Four hexaethylene glycol (Heg) spacers were incorporated between the CPG and the methyl red quencher (MeRed) to minimise steric interference from the solid support (Figs. 3, 4). Two complementary solution oligonucleotides were synthesised;

AAAATGAAGTGACTTTAAG (OG5), CTTCTGATGTGC-TACAT (OG6).

The molecular beacon-functionalised CPGs were heated (60 °C) in conc. aqueous ammonia–ethanol (4 : 1 v/v) for 4 h, to deprotect the oligonucleotides. Both solutions became fluorescent during this period implying loss of oligonucleotide from the CPG (*ca.* 70% loss of oligonucleotide from the resin). However subsequent thorough washing of the CPG afforded glass beads that remained fluorescent, indicating that some of the oligonucleotide was still present on the beads. Cleavage of a proportion of the silicon–oxygen bonds within the glass is inevitable under these strongly basic conditions. Alternative deprotection conditions or CPG material may be beneficial for future applications.

The heterogeneous beacon assay was carried out in two stages. First, the CPGs (OG3 and OG4, 2 mg) were placed in an aqueous buffer of sodium hydrogenphosphate (10 mmol), EDTA (1 mmol) and NaCl (1 M) at pH 7.0 to facilitate annealing. Then, the complementary oligonucleotides (OG5 and OG6) were added and after 2 h at room temperature any increase in fluorescence due to hybridisation (stem dissociation) was noted. Fluorescence was monitored under a fluorescence microscope (LEITZ DM IL) and photographed (ASHAI PENTAX K1000).

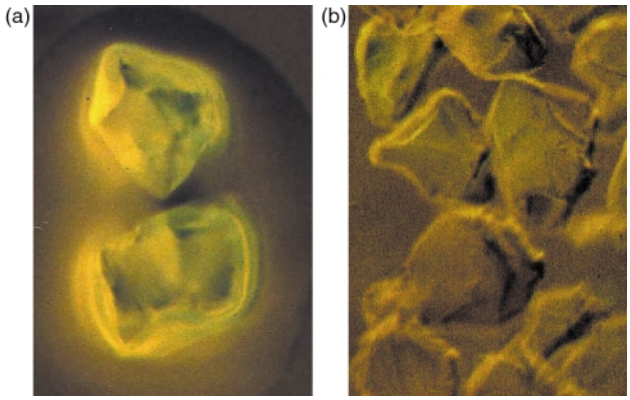

Fig. 5 (a) CPG-beacon in buffer and (b) CPG-beacon in buffer and complementary target nucleic acid.

Addition of a suitable annealing buffer causes the beads to become non-fluorescent [Fig. 5(a)], indicating the presence of a hairpin loop. Introduction of a complementary oligonucleotide in solution causes a significant increase in the fluorescence of the beads, due to the loop portion of the probe annealing to its target, allowing the solid-supported molecular beacons to exist in the fluorescent 'open' state [Fig. 5(b)]. Exposure of the CPG-beacons to a non-complementary oligonucleotide in the same buffer did not increase the level of fluorescence on the beads.

In summary, we have synthesised CPG-bound molecular beacon probes. These single-stranded probes have been shown to detect the presence of their target nucleic acids. At present, we are investigating the properties of alternative resins that have more uniform and spherical structures and we are applying the CPG-bound probes to the differentiation of nucleic acid sequences by variation of the fluorophore.

We thank the BBSRC and Nycomed Amersham for financial support of this work.

Formation of platinum nanosheets between graphite layers

Masayuki Shirai,* Koichi Igeta and Masahiko Arai

Institute for Chemical Reaction Science, Tohoku University, Katahira, Aoba, Sendai, 980-8577, Japan.
E-mail: mshirai@icrs.tohoku.ac.jp

Received (in Cambridge, UK) 13th August 1999, Accepted 3rd March 2000

Platinum nanosheets with thickness 2–3 nm containing hexagonal holes were formed between graphite layers by hydrogen reduction of platinum chloride–graphite intercalation compounds.

The size and shape of metal particles formed in a matrix are determined by its structural features. Platinum nanowires are formed in the mesotubes of FSM-16[1,2] and nanorods and nanoparticles are produced in the channels of carbon nanotubes.[3–6] Graphite has a layered structure, and each layer is a regular hexagonal net of carbon atoms. The interlayer spacing is equal to 0.335 nm with the layers interacting *via* van der Waals forces. Because the interaction between graphite layers is fairly weak, a variety of chemical substances can be inserted into the interlayer space to produce graphite intercalated compounds (GICs). Transition metal particles intercalated in graphite layers (M–GICs) are formed *via* the insertion of transition metal chlorides into graphite and subsequent reduction.[7–9] Commercially available M–GICs (Graphimet)[10] have numerous applications for catalytic reactions.[11–16] Graphimets are obtained by treating the graphite–metal chloride with lithium biphenyl at 223 K under a helium atmosphere and small metal particles (1–10 nm) were observed by HRTEM observations.[17] In the present work using different preparation procedures, we report the formation of platinum metal nanosheets containing hexagonal holes, intercalated within graphite layers.

Platinum(IV) chloride and graphite (KS6, Lonza) were mixed in a thick walled Pyrex reactor under nitrogen atmosphere and dried *in vacuo* at 423 K for 2 h. The intercalation reaction was performed in the reactor at 723 K for 2 weeks under 0.3 MPa of chlorine (Takachiho, 99.999%), to obtain the platinum chloride intercalated compounds ($PtCl_4$–GIC). The $PtCl_4$–GIC samples were reduced at 573 K for 1 h under 40 kPa hydrogen to produce the platinum metal intercalated compounds (Pt–GIC).

The XRD pattern of 5 wt% $PtCl_4$–GIC (platinum loading: 5 wt%) shows new peaks at 2θ = 10.0, 14.6 and 20.3°.† The peaks ascribed to platinum chloride disappeared and the (002) diffraction peak of graphite at 2θ = 26.57° was weakened after the reaction under chlorine atmosphere. The three new peaks remained unaltered after 12 days exposure to air, indicating that $PtCl_4$–GIC is stable in air. Peaks ascribed to platinum chloride and graphite were observed on XRD patterns of a reference mixture of platinum chloride and graphite [$PtCl_4$/G (mix)]. The platinum chloride peaks of $PtCl_4$/G(mix) changed after a few days exposure to air because of the hygroscopicity of platinum chloride. The diffraction peak positions calculated for (002), (003) and (004) reflections for $PtCl_4$–GIC of the repeat distance along the *c* axis (*c* = 1.76 nm) were 10.0, 15.1 and 20.2°, respectively, in good agreement with the experimental peaks. The distance of 1.76 nm corresponds to the sum of three graphite layers and one intercalated layer (0.75 nm). This result shows that platinum chloride is intercalated in every three graphite layers (stage three structure) in the 5 wt% $PtCl_4$–GIC sample. With an increasing amount of platinum chloride inserted from 1 to 15 wt% Pt loadings, the three peaks increased and the diffraction for (002) of graphite decreased. No other peaks except for the three peaks and graphite peaks were observed. The XRD results indicate that platinum chloride is intercalated in graphite layers with the stage three structure for 1–15 wt% Pt loading. The maximum amount of platinum chloride that can be intercalated is *ca.* 38 wt%, and thus platinum chloride intercalated compounds with the stage three structure are mixed with the graphite matrix at low platinum chloride loadings under our experimental conditions. EXAFS analysis showed the existence of Pt–Cl–Pt bonds in the 5 wt% $PtCl_4$–GIC sample, indicating that some platinum chloride molecules aggregate with each other within graphite layers at low platinum loadings.

Fig. 1(a) shows TEM image of 5 wt% Pt–GIC reduced at 573 K. This image reveals large sheets with a number of hexagonal holes with the edge angles of the large sheets being 120°. X-Ray microanalysis (XMA) results confirmed the dark images to be

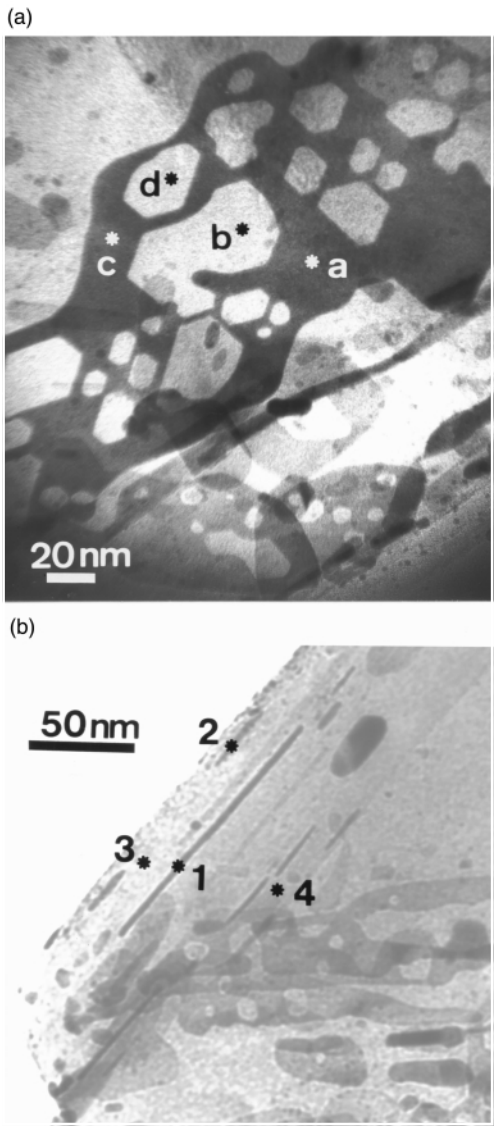

Fig. 1 TEM images of 5 wt% Pt–GIC showing Pt nanosheets; (a) top view and (b) side view.

DOI: 10.1039/a906596b

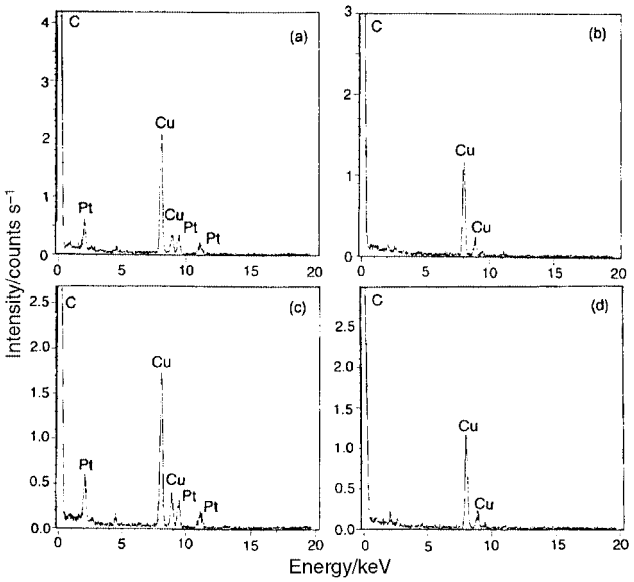

Fig. 2 XMA results of 5 wt% Pt–GIC at points a, b, c and d as indicated in Fig. 1(a).

platinum metal (Fig. 2).‡ Fig. 1(b) shows the presence of dark images in a parallel rod-like arrangement. XMA scans obtained from regions 1 and 2 showed that the dark material corresponded to platinum metal while XMA scans obtained from regions 3 and 4 indicated the absence of platinum metal, indicating that the dark features correspond to platinum layers. The TEM images show the structure of the platinum nanosheets, which are 2–3 nm thick and 5–300 nm wide. The observation of a number of sheets in parallel presumably indicates that platinum sheets exist between graphite layers. Platinum chloride can aggregate only two dimensionally between graphite layers during reduction because of the steric hindrance of graphite layers, so that the resulting platinum metal particles of Pt–GIC have two-dimensional structures. Platinum chloride molecules are reduced in a small area to produce small particles (1–10 nm) and do not move between graphite layers upon low temperature reduction at 223 K.[14,15,17] On the other hand, platinum atoms and/or platinum chloride molecules can migrate along a regular hexagonal net of carbon atoms during hydrogen reduction at 573 K. Movement during the reduction will determine the morphology of the resulting platinum nanosheets which have hexagonal holes. A number of nanosheets with hexagonal holes were also observed in TEM images of the 5 wt% Pt–GIC sample reduced at 773 K for 1 h after reduction at 573 K for 1 h. Large spherical particles still were not observed because the platinum nanosheets are still prevented from moving freely between graphite layers. For comparison, the mixture 5 wt% $PtCl_4$/G(mix) upon reduction at 573 K [Pt/G(mix)] led to spherical platinum particles according to TEM (Fig. 3).§ For $PtCl_4$/G(mix) samples platinum chloride molecules on the graphite surface can aggregate in a three dimensional manner and there is no interfering factor for the growth of metal particles, and so large platinum particles are formed.

In conclusion, platinum nanosheets can be prepared between graphite layers for Pt–GIC sample and such complex materials may show interesting properties owing to their structural features and metal–graphite interactions.

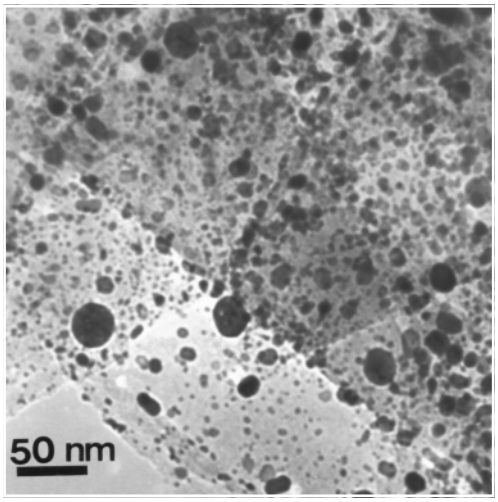

Fig. 3 TEM image of 5 wt% Pt/G(mix).

We thank Dr E. Aoyagi and Dr Y. Hayasaka (High Voltage Electron Microscope Laboratory of Tohoku University) for the TEM and XMA analysis.

Iridium-catalyzed aziridination of aliphatic aldehydes, aliphatic amines and ethyl diazoacetate

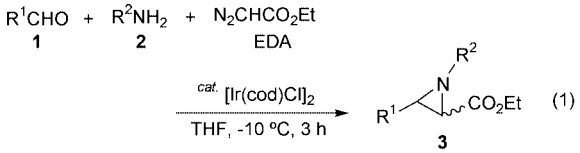
Takashi Kubo, Satoshi Sakaguchi and Yasutaka Ishii*

Department of Applied Chemistry, Faculty of Engineering and High Technology Research Center, Kansai University, Suita, Osaka 564-8680, Japan. E-mail: ishii@ipcku.kansai-u.ac.jp

Received (in Cambridge, UK) 18th January 2000, Accepted 6th March 2000

Three-component coupling reactions of aliphatic aldehydes, aliphatic amines and ethyl diazoacetate to the corresponding aziridine derivatives has been achieved by the use of $[Ir(cod)Cl]_2$ as a catalyst under mild conditions; for instance, the reaction of *n*-butyraldehyde, *tert*-butylamine and ethyl diazoacetate in the presence of a catalytic amount of $[Ir(cod)Cl]_2$ in THF at −10 °C gave 1-*tert*-butyl-2-ethoxycarbonyl-3-propylaziridine in 85% yield in high stereoselectivity (*cis* : *trans* = 96 : 4).

Aziridines are versatile compounds as precursors for the synthesis of various types of nitrogen-containing compounds, which are biologically important, such as amino acids, amino alcohols and β-lactams, *etc.*[1] There are many reports on the synthesis of aziridines, *e.g.* trapping of nitrenes and carbenes by alkenes[2] and imines,[3] respectively, and Lewis acid-catalyzed reaction of imines with ethyl diazoacetate (EDA).[4] These methods are suitable for the synthesis of aziridines derived from aromatic imines and diazo compounds; however, aziridine synthesis from aliphatic imines and EDA has not yet been established. Recently, Nagayama and Kobayashi have reported a three-component coupling reaction of aldehydes, amines and EDA in the presence of $Ln(OTf)_3$, although 5 Å molecular sieves must be added to the reaction system.[5] Now we have found that the three-component coupling reaction of aliphatic aldehydes, aliphatic amines and EDA to aziridine derivatives proceeds smoothly using an iridium complex as a catalyst and without any dehydrating agents [eqn. (1)].



To a solution of $[Ir(cod)Cl]_2$ in THF was added *n*-butyraldehyde **1a** and *n*-butylamine **2a**. After stirring for 10 min, EDA was added and then the mixture was stirred at −10 °C for 3 h (standard conditions).† The reaction produced 1-butyl-2-ethoxycarbonyl-3-propylaziridine **3aa**‡ which consists of a *ca.* 1 : 1 stereoisomeric mixture of *cis*-**3aa** and *trans*-**3aa** in 71% yield (Table 1, run 1). Table 1 summarizes the results for various three-component coupling reactions of aldehydes, amines and EDA under selected reaction conditions. $[Ir(cyclooctene)_2Cl]_2$ also catalyzed the coupling reaction to form **3aa** in 75% yield, while $IrCl_3$ was inert (runs 2 and 3). Various solvents could be employed for this reaction. (runs 4–6).

On the basis of these results, the reaction of aldehydes, amines and EDA was examined in the presence of a catalytic amount of $[Ir(cod)Cl]_2$ in THF under standard conditions. The reaction led to the corresponding aziridines in fair to good yields (runs 7–11). Interestingly, the stereoselectivity of the resulting aziridines was found to be improved by the use of a bulky amine such as *tert*-butylamine **2f**. For instance, the reaction of **1a**, **2e** with EDA afforded 1-*tert*-butyl-2-ethoxycarbonyl-3-propylaziridine **3af** in 83% yield in excellent stereoselectivity (*cis* : *trans* = 96 : 4) (run 11).§ In this reaction, ethanol was also suitable as a solvent, and **3af** was obtained in almost the same yield and stereoselectivity as those in THF (run 12). No aziridine was detected in the reaction of benzaldehyde **1d**, aniline **2g**, and EDA under these reaction conditions (run 13). These results will be discussed later.

Table 1 Three-component coupling reaction of aldehyde **1**, amine **2** and EDA[a]

Run	Aldehyde	Amine	Adirizine	Yield (%)[b]	
1	 **1a**	 **2a**	**3aa**	71	(63/37)
2[c]	**1a**	**2a**	**3aa**	75	(52/48)

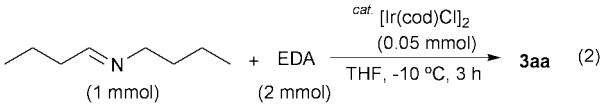
13	Ph—CHO **1d**	Ph—NH_2 **2g**	**3dg**	No reaction	

[a] Aldehyde (1 mmol), amine (1 mmol) and EDA (2 mmol) were allowed to react in the presence of $[Ir(cod)Cl]_2$ (0.05 mmol) in THF (1 mL) at −10 °C for 3 h under Ar atmosphere. [b] Parentheses indicate *cis*/*trans* ratio. [c] $[Ir(cyclooctene)_2Cl]_2$ (0.05 mmol) used as catalyst. [d] $IrCl_3$ (0.05 mmol) used as catalyst. [e] Dichloromethane (1 mL) used as solvent. [f] *n*-Hexane (1 mL) used as solvent. [g] Ethanol (1 mL) used as solvent.

The present Ir-catalyzed three-component coupling reaction seems to proceed *via* the formation of imine which then reacts with EDA. Indeed, *N*-butylidene-*n*-butylamine **4aa** prepared independently from **1a** and **2a** was allowed to react with EDA under standard conditions to form **3aa** (73%) as expected [eqn. (2)]. Although the $La(OTf)_3$-catalyzed three-component coupling reaction requires the presence of 5 Å molecular sieves,[5] the present three-component coupling reaction was performed without any dehydrating agents. It is noteworthy that the Ir-

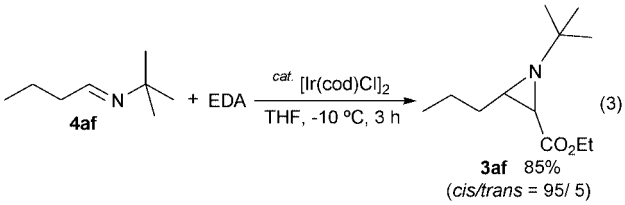
DOI: 10.1039/b000518p

catalyzed aziridination was not affected by water in the reaction system. When the reaction of imine **4aa** with EDA was carried out in the presence of a small amount of water, **3aa** was obtained in almost the same yield as the reaction in the absence of water [(eqn. (2)].



Additive	Yield (%)
–	73
H_2O (1 mmol)	69

Furthermore, the reaction of *N*-butylidene-*tert*-butylamine **4af** with EDA took place in high stereoselectivity, giving **3af** in 85% yield (*cis*:*trans* = 95:5) [(eqn. (3)]. For the reaction of *N*-benzylideneaniline **4dg** with EDA, however, diethyl maleate **5** and diethyl fumarate **6** were formed in 46% yield, and **4dg** was recovered unchanged.



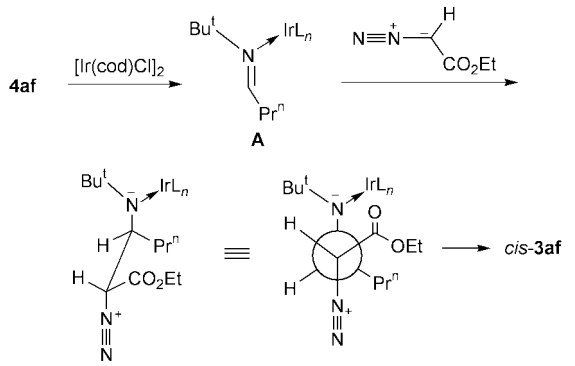
Addtionally, the reaction of a ketimine such as *N*-(1-ethylpropylidene)-*n*-butylamine with EDA led to 1-butyl-3,3-diethyl-2-ethoxycarbonylaziridine in 54% yield.

From the mechanistic point of view, it is of note that the selectivity of aziridine is affected by the order of the addition of substrates to the catalyst solution. When 1.0 mmol of imine **4aa** was added to a THF solution containing $[Ir(cod)Cl]_2$ (0.05 mmol) at −10 °C, the solution changed immediately from orange–red to light yellow, and EDA (2 mmol) was added to this solution to form aziridine **3aa** (73%). However, the addition of EDA (2.0 mmol) to a THF solution of $[Ir(cod)Cl]_2$ resulted in a change from orange–red to dark purple, and then **4aa** (1.0 mmol) was added to produce **3aa** in lower yield (59%) along with a homocoupling product of EDA, **5** and **6** (13%), the formation of which may be explained by *in situ* generation of carbene from EDA by the action of an Ir complex. Hence, it is probable that the present Ir-catalyzed aziridine synthesis proceeds *via* the formation of an Ir–imine complex rather than an Ir–carbene complex.

In addition, when imine **4dg** was added to a THF solution of $[Ir(cod)Cl]_2$, no color change was observed, and the aziridine expected was not obtained and instead, dimers of EDA, **5** and **6** as shown above. Therefore, it is reasonable to presume that the reaction of **4dg** with EDA is difficult to occur owing to the difficulty of the complexation of **4dg** with the Ir-complex.

The high stereoselectivity of the reaction of **1a**, **2f** and EDA (Table 1, run 11) may be explained by assuming a similar reaction path suggested in the $Yb(OTf)_3$-catalyzed reaction of *N*-benzylidene-*tert*-butylamine with EDA (Scheme 1).[4f] It is probable that the Ir complex $[Ir(cod)Cl]_2$ coordinates to imine **4af** to lead to a complex **A**.¶ The nucleophilic attack of EDA to the resulting complex **A** would take place from the direction to reduce the steric repulsion between the ester moiety of the incoming EDA and the *tert*-butyl group of the imine to form *cis*-**3af**.

In summary, various types of aziridine derivatives, which are difficult to prepare by the conventional methods, have been prepared by the three-component coupling reaction of aliphatic aldehydes, aliphatic amines and EDA, catalyzed by $[Ir(cod)Cl]_2$. High stereoselectivity was attained by the reaction of aldehyde, tertiary amine and EDA.



Scheme 1 A possible reaction pathway for reaction of **4af** with EDA.

Notes and references

† *Typical reaction procedure*: to a THF solution (1.0 mL) of dichlorobis(cycloocta-1,5-diene)diirdium {$[Ir(cod)Cl]_2$} (0.05 mmol) was added aldehyde (1.0 mmol) and amine (1.0 mmol) at −10 °C under Ar. After stirring for 10 min, EDA (2.0 mmol) was added, and then the reaction mixture was stirred at −10 °C for 3 h. The reaction was quenched with wet diethyl ether, and products were isolated by column chromatography [(230–400 mesh silica gel, ethyl acetate–hexane (1:12) eluent].

‡ *Spectral data* for **3aa**: ^{1}H NMR δ 4.25–4.15 (m, 2H), 2.42–2.06 (m, 2H), 2.09 (d, *J* 6.6 Hz, 1H), 1.72–1.69 (m, 1H), 1.60–1.30 (m, 6H), 1.31 (q, *J* 7.3 Hz, 2H), 1.27 (t, *J* 7.3 Hz, 3H), 0.92 (t, *J* 7.3 Hz, 3H), 0.90 (t, *J* 7.3 Hz, 3H); ^{13}C NMR δ 170.0, 60.8, 60.7, 46.6, 42.6, 31.4, 29.7, 20.6, 20.3, 14.3, 13.9, 13.7; IR (neat) 2959, 1747, 1183 cm^{-1}; MS, *m/z* = 213 (M^+), 198, 140, 84; Anal. Calc. for $C_{12}H_{23}NO_2$: C, 67.57; H, 10.87; N, 6.57. Found: C, 67.25, H, 10.52; N, 6.62%.

§ The stereochemistry of **3af** was determined by comparison of the coupling constant obtained from ^{1}H NMR spectral data for **3af** with that of 2-ethoxylcarbonyl-1,3-diphenylaziridine reported in the literature.[4a,f]

¶ NMR observation showed the formation of the complex **A** from $[Ir(cod)Cl]_2$ and imine; *i.e.* when $[Ir(cod)Cl]_2$ was added to 1.0 equiv. of **4af** in a NMR tube, the ^{13}C NMR signals at δ 164.5 (–CH=N–) and 61.0 (=NCH_2–) of **4af** were shifted to δ 171.6 and 63.6, respectively.

The role of neighbouring group participation in TTF-mediated 'radical-polar crossover' reactions: trapping of aliphatic radicals by $TTF^{+\bullet}$

Nadeem Bashir and John A. Murphy*

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL. E-mail: John.Murphy@strath.ac.uk

Received (in Cambridge, UK) 26th January 2000, Accepted 18th February 2000

Trapping of secondary alkyl radicals with tetrathiafulvalenium tetrafluoroborate ($TTF^{+\bullet}BF_4^-$) leads to *S*-alkyltetrathiafulvalenium tetrafluoroborate salts; the solvolysis of such salts is critically dependent on the presence of appropriately sited neighbouring groups.

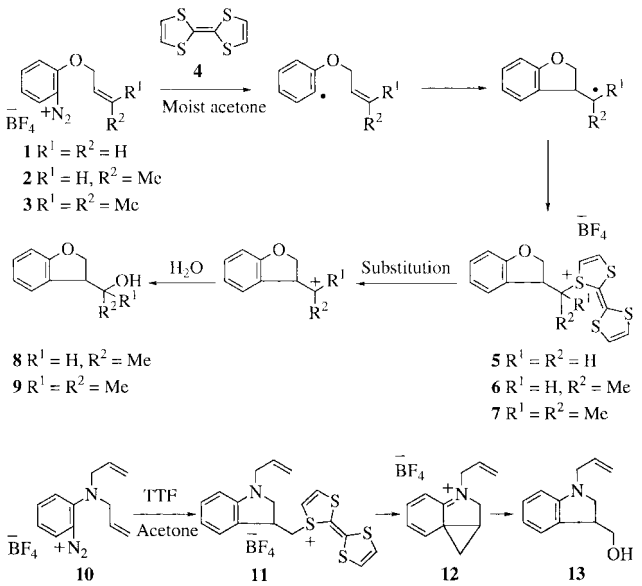
The radical-polar crossover reaction[1] (Scheme 1) features a unique sequence of radical and polar steps in one pot. Tetrathiafulvalene (TTF) transfers an electron to an arenediazonium salt, dinitrogen is lost and the resulting radical can then cyclise before being trapped by the radical-cation of TTF to afford a sulfonium salt and terminate the radical chemistry. In the polar crossover step, solvolysis of the sulfonium salt occurs affording a useful functionalisation at the site of the ultimate radical. The reaction has recently been used as the key step in a novel route to (±)-aspidospermidine.[2]

The substitution (solvolysis) step is of particular interest. Whereas alcohols **8** and **9** were formed on treatment of diazonium salts **2** and **3** with tetrathiafulvalene **4** in undried acetone at room temperature, diazonium salt **1** proceeded only up to the tetrathiafulvalenium salt stage **5**. This strongly suggested that the solvolysis step involved an S_N1 substitution; solvolysis of the salt **5** would not be possible since it would require the intermediacy of a primary carbocation, while sulfonium salts **6** and **7** undergo solvolysis without difficulty. More recently, attempts to force the substitution of the sulfonium group of **5** uncovered a range of novel fragmentation reactions.[3]

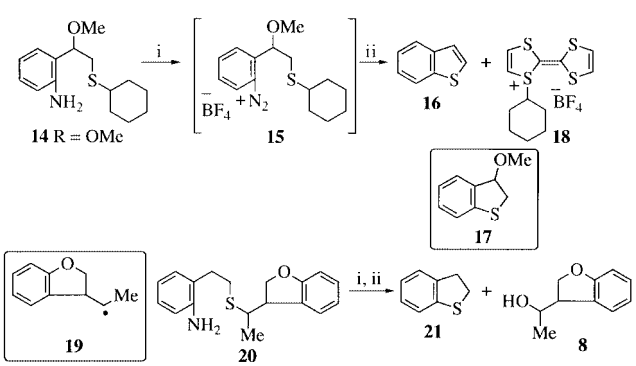
Although **5** is resistant to solvolysis, the conversion[4] of the diallylamino diazonium salt **10** to the alcohol **13** suggested that matters could be more complex. Here, the powerful electron donating effect of the *ortho*-amino group must act through the aromatic ring to assist the departure of the TTF molecule from **11** *via* a cyclopropane intermediate **12**. However, the inability of the *ortho*-alkoxy group to trigger the solvolysis of **5** shows that there are strict demands for solvolysis at a primary carbon.[5] However, almost all examples of the radical-polar crossover reaction have involved substitution at secondary carbon. This paper provides experimental evidence that neighbouring group participation is mandatory for solvolysis at secondary carbon under our usual conditions and reveals the requirements for substrate structure in order for solvolysis to be observed.

To investigate whether solvolysis could occur at a secondary carbon in the absence of neighbouring groups, an alkyl radical free of other functionalities was required to be generated under radical-polar crossover conditions. This was achieved using intramolecular radical displacement at sulfur. This reaction has been investigated by the groups of Kampmeier,[6] Beckwith[7] and Schiesser.[8] More recently, Crich *et al.* have used this method to generate acyl radicals both from iodide[9] and diazonium salt[10] precursors. Accordingly, the cyclohexyl substrate **14** was prepared (all amines were prepared by reduction of the corresponding nitro compounds), diazotised and subjected to the radical-polar crossover conditions (Scheme 2). This afforded benzothiophene **16** (48%), (arising from facile elimination of methanol from methoxydihydrobenzothiophene **17** together with the salt **18** (32%) as major products. The S-coupled salt **18** was completely resistant to solvolysis under our conditions (room temperature, 2% water in acetone, 48 h), showing that a tetrathiafulvalenium salt linked *via* a secondary carbon could not of itself undergo solvolysis under these conditions.

Because the outcome of the experiment on the cyclohexyl radical differed from results found with all previously studied secondary radicals, there was some concern that the sulfur substitution reaction conditions might in some way have prevented the normal radical-polar crossover process from occurring. To test this, the intramolecular sulfur displacement reaction was used to generate a radical which had been previously studied under radical-polar conditions, namely **19**, the intermediate in the reaction of **2**. The required substrate, **20**, was prepared, diazotised and subjected to the radical-polar crossover reaction and afforded both dihydrobenzothiophene **21**



Scheme 1



Scheme 2 *Reagents*: i, $NOBF_4$, CH_2Cl_2; ii, TTF, acetone, H_2O.

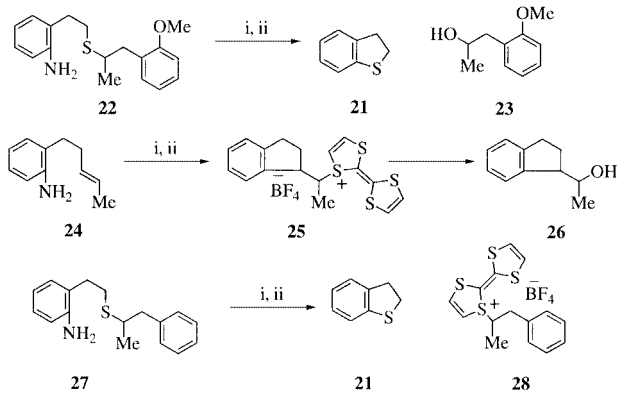


Scheme 3 *Reagents*: i, $NOBF_4$, CH_2Cl_2; ii, TTF, acetone, H_2O.

(52%) and the alcohol **8** (58%), showing that the radical **19** generated under these conditions was behaving exactly as it had in the reaction of **2**.

The contrast between cyclohexyl TTF salt **18** and salt **6** indicated that a solvolysis of a secondary TTF salt could not occur without some assistance from neighbouring groups. The nature and extent of the assistance were now probed directly. First, to investigate whether some special effect resulted from the dihydrobenzofuran ring system, amine **22** was prepared and diazotised to afford a diazonium salt analogue of **2** (Scheme 3). This duly cyclised to form dihydrobenzothiophene **21** (52%) and the alcohol **23** (53%). No TTF salts were detected after the solvolysis.

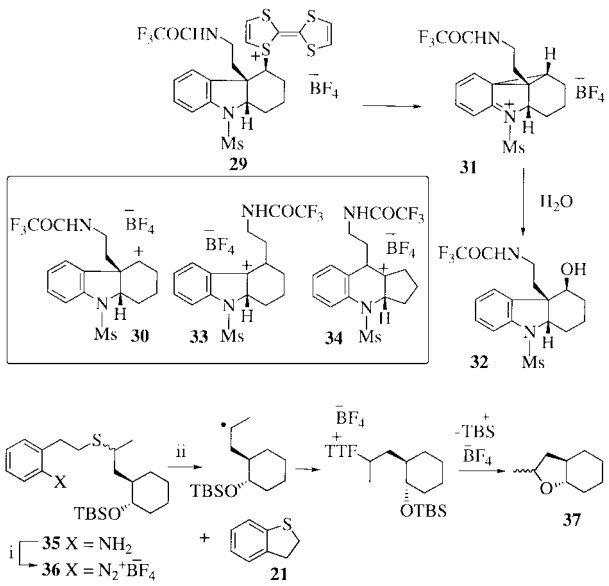
Next, amine **24**, lacking the electron-donating oxygen atom, was prepared and diazotised affording **25**. Surprisingly, the compound also afforded an alcohol product, *i.e.* **26** (24%), indicating that the oxygen atom is not essential for solvolysis.

In contrast, when the diazonium salt derived from **27** was subjected to the radical-polar crossover reaction, **21** was produced (45%) as well as the sulfur-coupled TTF salt **28** (21%). Intriguingly, this sulfur-coupled salt was stable to solvolysis. We deduce that there is a sharp demarcation between substrates that undergo solvolysis in acetone and those that do not. Salt **25** features an *ortho*-dialkylarene and so should be more electron-rich than the monosubstituted arene in **28**; hence it should more effectively promote neighbouring group participation.

The observation of neighbouring group assistance suggests an answer to one of the key questions on the mechanism of these reactions. Until now, solvolysis of TTF salts such as **29** (Scheme 4) was thought to involve intermediates such as the open secondary cation **30**. This cation should easily undergo rearrangement and/or fragmentation (*e.g.* to products **33** and **34**), but this was not observed. With neighbouring group participation, the delocalised cation **31** can be proposed as the true intermediate, and this involvement by the aryl ring can decelerate rearrangements by stabilising the cation and altering the orbital alignment from that required for rearrangement. (The delocalised cation could also control the stereochemistry of attack by the nucleophile water.)

The question now arose about whether groups other than an aromatic ring could assist the solvolysis step. An immediate answer was obtained from diazotisation of the silyl ether **35** and subjection of the product diazonium salt to reaction with TTF (Scheme 4). This afforded the perhydrobenzofuran **37** (23% from amine **35**) indicating that a side-chain oxygen can participate. Dihydrobenzothiophene **21** (56% from amine **35**) was also isolated from this reaction.

Summarising the findings: (i) for the first time, radicals have been produced under TTF-induced radical-polar crossover



Scheme 4 *Reagents*: i, $NOBF_4$, CH_2Cl_2; ii, TTF, acetone, H_2O.

conditions which are totally aliphatic. Although we do not advocate the intramolecular sulfur displacement reaction as a synthetic route to aliphatic radicals, it allows us to determine the properties of such systems. The development of more powerful radical-polar crossover catalysts than TTF should lead to such products starting from *e.g.* alkyl and aryl halides, thus extending the scope of the reaction.

(ii) A TTF salt linked to a *secondary* carbon will undergo solvolysis with a little assistance from the arene—the arene needs to bear at least two alkyl functions to be sufficiently electron-rich to trigger the solvolysis in acetone under our conditions. This contrasts with the situation for *primary* carbon, where more powerful assistance is required. (The requirement for neighbouring group participation at a secondary carbon has important implications for stereochemical control.)

(iii) Groups other than arenes can participate in the solvolysis. This extends the scope of the radical-polar crossover reaction.

Synthesis of medium-ring lactones *via* tandem methylenation/Claisen rearrangement of cyclic carbonates

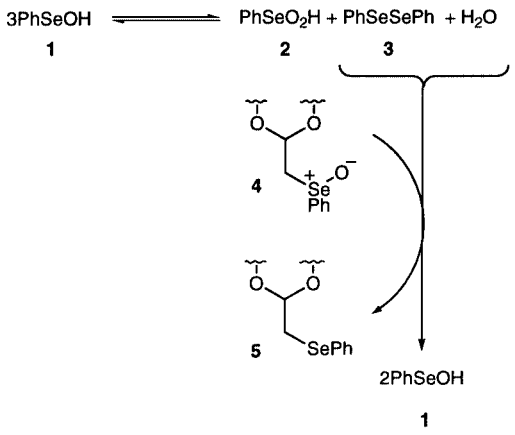
Received (in Cambridge, UK) 6th January 2000, Accepted 4th February 2000

Tandem methylenation/Claisen rearrangement of cyclic carbonates derived from vinyl-substituted 1,3- and 1,4-diols afforded eight and nine-membered unsaturated lactones respectively.

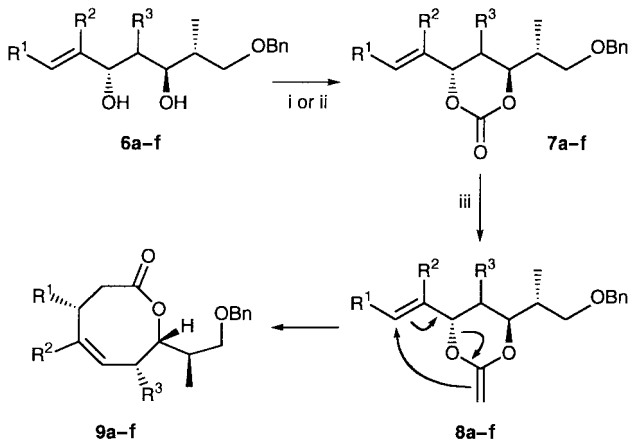
Medium-ring oxacycles form the core of many natural products such as obtusenyne[1,2] and (+)-laurencin.[3] Our approach to systems of this type has used the ring-expansion Claisen rearrangement of a vinyl-substituted ketene acetal, generated *in situ* from the thermal elimination of a selenoxide precursor (in turn derived from the oxidation of a selenoacetal) to form a medium-ring lactone.[4] Whilst this methodology provides efficient access to many medium ring lactones, several limitations became evident when the vinyl group carried electron rich substituents. In addition to the toxicity associated with selenium reagents, the formation of the selenoacetal from a 1,3- or a 1,4-diol requires somewhat harsh conditions (refluxing toluene, PPTS). This can be a problem in cases where the allylic hydroxy group of the diol is prone to β-elimination. The selenoxide elimination product, benzeneselenenic acid **1**, has been shown to disproportionate under the reaction conditions to benzeneseleninic acid **2** and diphenyl diselenide **3**.[5] The latter is postulated to act as a reducing agent, converting the selenoxide (ketene acetal precursor **4**) back into the selenoacetal **5** (Scheme 1).



Scheme 1

The disproportionation of benzeneselenenic acid can be suppressed by the use of non-nucleophilic bases and a nucleophilic silyl ketene acetal as a selenium scavenger.[6] Even under these optimal conditions, oxygen transfer from **4** to produce **5** can be a significant side reaction. Finally, selenoxide elimination and rearrangement require high temperatures (sealed tube, up to 185 °C). These conditions and the need for high dilution could make large scale preparations more troublesome. Here we report the methylenation of cyclic carbonates derived from vinyl-substituted diols using the Petasis reagent (dimethyltitanocene)[7–9] and the subsequent *in situ* Claisen rearrangement of the presumed ketene acetal intermediate.

Preparation of the 1,3-diols **6a–f** (Scheme 2, Table 1) was carried out according to the methods described previously.[4] The carbonates **7a**,**c–f** were synthesised from the diols using carbonyldiimidazole.† Alternatively, the carbonates **7a–c** were prepared using a modification of a procedure with triphosgene.[10] Dimethyltitanocene was synthesised by the reported procedure,[11] and could be stored in the freezer as a solution in toluene for several months without degradation. Treatment of the carbonates **7a–f** with dimethyltitanocene in refluxing toluene provided the Claisen rearrangement eight-membered lactone products **9a–f** as single diastereomers (^{1}H NMR), in reasonable to good yields (Scheme 2, Table 1), presumably *via* the ketene acetal intermediates **8a–f**. Comparison of the yields over two steps with the combined yields for the analogous selenium route shows this method to be superior to the selenoxide route in many cases.[4]



Scheme 2 *Reagents and conditions*: i, carbonyldiimidazole, toluene, reflux; ii, triphosgene, pyridine, Et_3N, −78 °C, 4 Å molecular sieves, CH_2Cl_2; iii, Cp_2TiMe_2, toluene, reflux in absence of light.

Nine-membered lactones may also be prepared. The 1,4-diols **10a–c** could be prepared from 2-deoxy-D-ribose in three steps. Treatment of the lactols derived from 2-deoxy-D-ribose by our previously reported route[12] with a variety of vinyl Grignard reagents provided mixtures of separable diastereomers of each of the diols **10a–c**. Exposure of the diols to triphosgene in dichloromethane and triethylamine–pyridine gave the carbonates **11a–c** which were converted into the lactones **13a–c**, as

DOI: 10.1039/b000299m

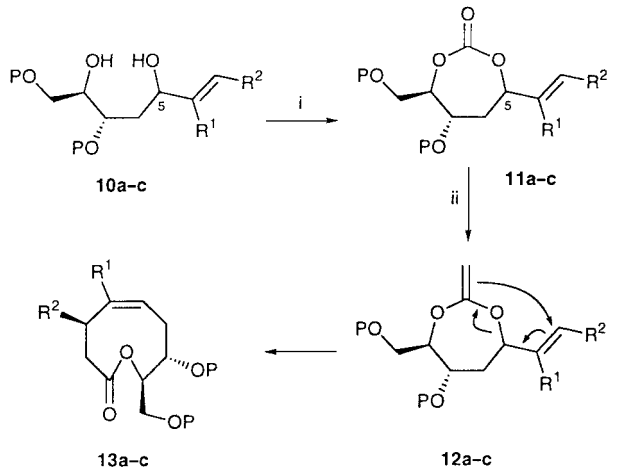

Scheme 3 *Reagents and conditions*: i, triphosgene, pyridine, Et_3N, −78 °C, 4 Å molecular sieves, CH_2Cl_2; ii, Cp_2TiMe_2, toluene, reflux in absence of light. P = TBDPS.

single diastereomers (^{1}H NMR), upon rearrangement of the *in situ* generated ketene acetals **12a–c** (Scheme 3, Table 2).

In summary, an alternative route to medium-sized lactones by a tandem methylenation/Claisen rearrangement has been developed. This milder route avoids the use of toxic selenium compounds and the problematic side reactions associated with certain selenoxides under elimination conditions. The application of this methodology to the synthesis of fused lactone derivatives is described in the following Communication.

Received (in Cambridge, UK) 6th January 2000, Accepted 4th February 2000

Fused bicyclic medium-ring lactones, carrying identical ring-fusion to that in the polyether toxins, are prepared by a Claisen rearrangement sequence.

The polyether neurotoxins have attracted enormous synthetic interest as a result of their unusual molecular architecture and biological activity.[1] Most recently Nicolaou *et al.* have described the total synthesis of brevetoxin A,[2,3] and there have been many contributions from others active in this field.[4] Here, we report the use of the Claisen rearrangement to prepare fused bicyclic medium-ring lactones having the precise structural features present in the medium-ring fused polyether segments of brevetoxin B and ciguatoxin.

Our approach to fused medium-ring lactones follows the methodology previously developed for the synthesis of obtusenyne[5,6] and (+)-laurencin.[7] Transformation of a 1,3-diol into a vinyl-substituted ketene acetal by selenoxide elimination or carbonate methylenation (see preceding Communication) provides the desired medium-ring fused bicyclic lactone after Claisen rearrangement.

Scheme 1† summarises the construction of the bicyclic lactone **1**. Methylenation (72%) of the monocyclic lactone **2**,‡ BOM deprotection (94%) and silylation with $(Me_2SiH)_2NH$ (100%) provided the silane **3**. Rhodium catalysed intra-

IBX = *o*-iodoxybenzoic acid.

DOI: 10.1039/b000303o

molecular hydrosilation[5,7] followed by oxidation yielded the diol **4** (86%) as a single diastereomer (^{1}H NMR). *p*-Methoxybenzylidene acetal formation (85%), reduction with DIBAL-H (79%) and IBX oxidation[8] furnished the labile aldehyde **5**. Exposure of **5** to vinylmagnesium bromide in the presence of cerium(III) chloride, according to the procedure of Imamoto,[9] provided the corresponding allylic alcohols (85%, 5:1 mixture of diastereomers, Felkin control). The major diastereomer was deprotected with TFA to furnish the diol **6** (90%). Heating a solution of **6** and phenylselenoacetaldehyde diethyl acetal in acidic toluene provided the selenides **7** (94%, mixture of diastereomers) which were oxidised to the corresponding selenoxides. Pyrolysis of the selenoxides in toluene at reflux yielded the desired *trans*-fused bicyclic lactone **1** (90%, single diastereomer, $J_{a,b}$ 9.7 Hz) presumably *via* the intermediate ketene acetal **8**. Alternatively the diol **6** could be converted into the corresponding carbonate **9** (89%), which on heating with dimethyltitanocene provided **1** (63%). Thus the conversion of a medium-ring lactone into the corresponding *trans*-fused bicyclic lactone has been achieved in 11 synthetic steps and 25% overall yield.

In a similar manner the lactones **9**‡ and **10**‡ were converted into the corresponding bicyclic lactones **11** and **12** (Scheme 2†). The silanes **13** and **14** were synthesised from the lactones **9** and **10** by an analogous route to that depicted in Scheme 1. Rhodium catalysed intramolecular hydrosilation converted **13** into the diols **15** (61% combined yield, 6:1 mixture of *cis*:*trans* diastereomers, major diastereomer shown) after oxidative work-up. Similarly exposure of the silane **14** to the hydrosilation conditions provided the diols **16** after work-up (57% combined yield, 1.33:1, mixture of *trans*:*cis* diastereomers, major diastereomer shown). Conversion of the major diastereomers *cis*-**15** and *trans*-**16** into the corresponding allylic alcohols **17** and **18** proceeded without incident. The *cis*-fused bicyclic lactone **11** ($J_{a,b}$ 2.4 Hz) was accessed from the diols **17** *via* both the selenoacetal route (58% for three steps) and the carbonate route (38% for two steps) thus demonstrating the versatility of this method for the synthesis of bicyclic lactones. It also proved possible to convert the diols **18** into the *trans*-fused bicyclic lactone **12** *via* initial conversion to the corresponding carbonates (90%) followed by heating in the presence of dimethyltitanocene (48%).

The synthesis of the 8,9-*trans*-fused bicyclic lactone **19** was achieved *via* elaboration of the known nine-membered lactone-aldehyde **20** (Scheme 3†).[10] Treatment of **20** with vinyl iodide in the presence of chromium(II) chloride in Me_2SO[11] provided the allylic alcohols **21** (59%, 2:1 mixture of diastereomers, Felkin control, major diastereomer shown). The allylic alcohol **21-maj** was deprotected (50–69%) and converted into the crystalline carbonate **22** {78%, mp 126–127 °C (from hexane)}. Treatment of **22** with dimethyltitanocene in toluene at reflux provided the crystalline *trans*-fused bicyclic lactone **19**§ [25% unoptimised, mp 109–111 °C (from hexane)] and recovered starting material (75%).

In summary, we have shown that the Claisen rearrangement and hydrosilation methodology, developed for the synthesis of medium-ring oxygen-containing heterocycles, can readily be extended to the synthesis of *cis*- or *trans*-fused bicyclic medium-ring lactones which form the basis for the synthesis of members of the polyether toxin family.

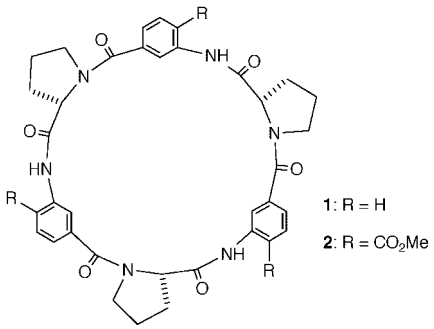
Received (in Liverpool, UK) 19th January 2000, Accepted 28th January 2000

Methoxycarbonyl groups in the 4-position of the aromatic subunits strongly influence the conformational behaviour and the receptor properties of cyclic peptides composed of alternating 3-aminobenzoic acid and L-proline

We recently showed that cyclic hexapeptides composed of alternating natural amino acids and 3-aminobenzoic acid subunits bind cations and anions with high affinity.[1,2] Cation–π interactions with the aromatic subunits of such cyclopeptides generally result in inclusion of cations into the shallow dish-shaped receptor cavity.[3] By contrast, anions are only bound when they are able to form hydrogen bonds to the peptide amide groups. This latter interaction induces a receptor conformation in which all NH groups of the peptide point towards the cavity centre.[4] In the absence of suitable anions, the amide groups are able to rotate more freely. We speculated that suitable substituents on the peptide subunits would also restrict amide rotation. Such an approach may have the additional advantage that the anion complexation could be completely prevented by locking the NH groups in an orientation unsuitable for interactions with these guests. Here we report our first results in this direction.

Inspired by the work of Hamilton and coworkers who have shown that methoxycarbonyl groups can be used for the conformational control in oligoanthranilamides,[5] we introduced these substituents at the 4-position of the aromatic subunits of **1**.



Methoxycarbonyl groups are able to form hydrogen bonds to adjacent NH protons and thus induce an amide orientation parallel to the aromatic rings. They also cause the NH protons to point away from the cavity centre and make the amides less available for anion complexation.

Peptide **2** was synthesised from the commercially available 2-aminoterephthalic acid 1-methyl ester by following a procedure similar to that used for **1**.[1] Whereas **1** possesses a simple ^{1}H NMR spectrum that represents an averaged C_3-symmetrical structure, the spectrum of **2** is more complicated [Fig. 1(a) and (c)]. Identical protons of **2** give two signals in most cases, and even the methyl ester signal is split. Since the spectrum is not significantly affected by varying the concentration of **2** in the region 2–0.2 mM, an intermolecular association of the peptide at these concentrations is unlikely. Instead, the spectrum more probably represents a non-symmetrical conformation of **2** or different slowly interconverting peptide conformers. Temperature-dependent ^{1}H NMR spectroscopy of **2** in $C_2D_2Cl_4$ shows that at 120 °C the flexibility of the peptide is still somewhat restricted. The rigidity of **2** is certainly caused by the effects of the additional methoxycarbonyl substituents. The unusually large downfield shift of the NH protons in the ^{1}H NMR spectrum of **2** in $CDCl_3$ at δ 11.1 [for **1** δ(NH) 9.2] and the strong N–H vibration band at 3303 cm^{-1} in the FTIR spectrum in $CDCl_3$ indicate that these groups are involved in hydrogen bonds. The crystal structure of **2** monohydrate (Fig. 2) shows that, as predicted, these hydrogen bonds are formed between the amide NH groups and the neighbouring methoxycarbonyl groups.‡ The overall peptide conformation in this structure is non-symmetrical, presumably caused by the water molecule, with one aromatic subunit tilted away from the others. As a result, one would expect a weak cation affinity of **2**.

Nevertheless, a significant upfield shift of the guest protons is observed upon addition of quaternary ammonium salts such as *n*-butyltrimethylammonium picrate (BTMA$^+$ picrate) to solutions of **2** in $CDCl_3$. This shift is generally interpreted in terms of an inclusion of the cation into a receptor cavity which brings the guest protons in close proximity to the aromatic subunits.[3] The spectrum of the peptide is also affected in the presence of the cation. On increasing the guest concentration, the spectrum becomes simpler until, after addition of 4 equivalents of BTMA$^+$ picrate to a 2 mM solution of **2** in $CDCl_3$, it represents a symmetrical conformation [Fig. 1(b)]. Complex formation

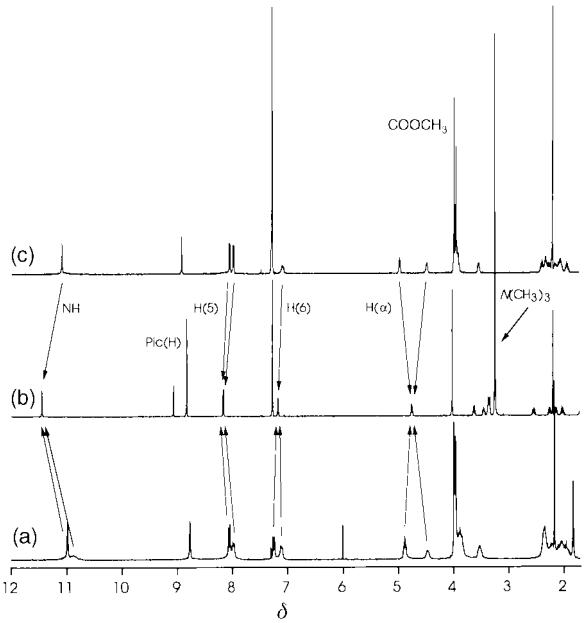


Fig. 1 ^{1}H NMR spectra of **2** (a) in $C_2D_2Cl_4$ (60 °C), (c) in $CDCl_3$ (25 °C) and (b) after addition of 4 equiv. of BTMA$^+$ picrate in $CDCl_3$ (25 °C).

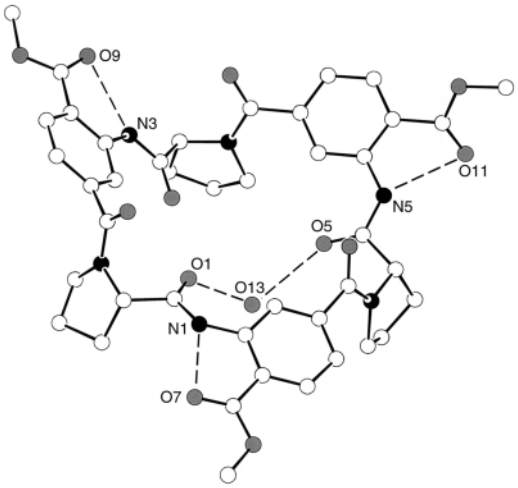

Fig. 2 Molecular structure of **2**·H_2O. Selected interatomic distances (Å): N1··O7 2.677(2), N3··O9 2.656(2), N5··O11 2.903(3).

obviously causes a shift of the conformational equilibrium of **2**. The NOESY NMR spectrum shows strong NOE effects between NH and H(α), which confirms that the NH groups are oriented towards the methoxycarbonyl substituents. As yet, we have not been able to obtain crystals of the **2**·BTMA$^+$ complex. However, **2** crystallises from acetone with one solvent molecule per peptide unit. X-Ray crystallography reveals that the solvent molecule is located inside the peptide cavity (Fig. 3). Moreover, the peptide conformation in this structure is more symmetrical than in **2**·H_2O. The three aromatic subunits are all tilted into the same direction with all hydrogen bonds between NH and the methoxycarbonyl substituents retained. These results indicate that suitable guest molecules can induce a symmetrical peptide conformation well suited for guest binding when they are included into the cavity of **2**. The NMR spectroscopic results demonstrate that certain cations induce a similar conformation in solution. This mechanism of complex formation is therefore consistent with an 'induced-fit'.

The upfield shift of the BTMA$^+$ protons in the presence of **2** can be used to quantitatively determine the complex stability by NMR titrations.[6] When the shifts of the cation protons of BTMA$^+$ picrate were followed in the titration, a stability constant K_a was obtained that is almost an order of magnitude larger than that of the corresponding complex of **1** (Table 1). This significant increase of cation complex stability can be attributed to the conformational rigidity of **2**.

Whereas a dramatic increase of the cation complex stability was observed for **1** with iodide or tosylate anions,[1] the BTMA$^+$

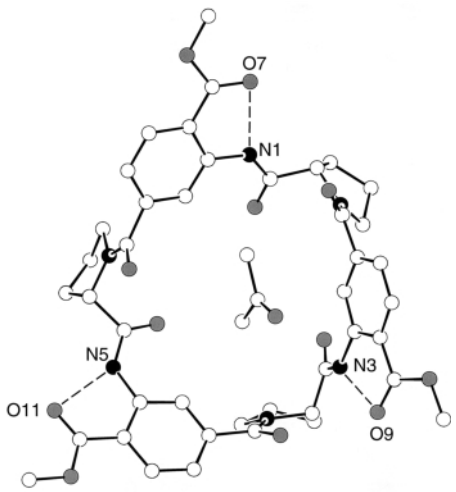

Fig. 3 Molecular structure of **2**·Me_2CO projected onto a plane through the three amide N atoms of **2** (tilt angles of the aromatic rings to this plane (°): at N1, +35; at N3, +57; at N5, +31). Selected interatomic distances (Å): N1··O7 2.668(3), N3··O9 2.692(3), N5··O11 2.678(2).

Table 1 BTMA$^+$ complex stabilities in $CDCl_3$ at 298 K (K_a = stability constant in M^{-1}, error limits of K_a < 20%; $\Delta\delta_{max}$ = maximum chemical shift in ppm; ΔG_H = Gibbs free energy of hydration of the anions in kJ mol^{-1})

	1		**2**		
Anion	K_a	$-\Delta\delta_{max}$	K_a	$-\Delta\delta_{max}$	$-\Delta G_H$
Picrate	1 260	0.70	10 800	0.54	197
Iodide	21 100	1.11	3 310	0.59	283
Tosylate	5 050 000	1.16	740	0.54	318

complex stabilities of **2** decrease when going from picrate to iodide and tosylate. A similar anion effect has also been reported for cation complexes of calixarenes.[7] Bartsch and coworkers have shown that the extraction efficiency of certain crown ether salt complexes correlates inversely with the hydration enthalpy of the anion.[8] In accordance with these findings, the stabilities of the BTMA$^+$ complexes of **2** decreases with increasing Gibbs free energy of hydration of the anion.[9] The dependence of the complex stabilities on the type of anion can therefore be attributed to an intrinsic property of the salts and not to possible peptide–anion interactions. Indeed, the FTIR spectrum of **2** is unaffected by the different anions, not even those that bind very strongly to **1**.

In summary, we have shown that the NH groups of **2** can be locked in a defined orientation by hydrogen bonds to methoxycarbonyl groups on the aromatic subunits. This results in a reduction of the conformational freedom of the cyclopeptide and in improved cation affinity as well as a complete loss of anion binding ability. Currently, we are investigating effects of other substituents. The fact that the conformation and hence the binding properties of these peptides can be influenced by non-covalent intramolecular interactions give them important advantages over many other artificial receptors.

S. K. thanks Professor G. Wulff, to whom this paper is dedicated on the occasion of his 65th birthday, for his generous support and Mrs D. Kubik for the preparative work.

Received (in Cambridge, UK) 20th December 1999, Accepted 6th March 2000

Topological analysis of experimental and theoretical charge densities in tetrasulfur tetranitride clarifies features of the intramolecular bonding; intermolecular charge concentrations reveal directional 'key–lock' interactions corresponding to molecular recognition in the solid state.

Tetrasulfur tetranitride, S_4N_4, is perhaps the most studied inorganic heterocycle, yet a full understanding of its bonding remains elusive. Thus, whilst S–S bonding interactions between *proximal* S atoms are established, the nature and extent of interaction remain unclear,[1–3] and the existence of *distal* S···S interactions is either claimed[1,4] or refuted.[2]

Two decades ago a low-temperature X-ray diffraction study provided the most accurate molecular geometry to date, and reported a preliminary analysis of the charge density distribution, $\rho(\boldsymbol{r})$, in S_4N_4.[1] With the subsequent advances in instrumentation, analytical methods and computing power, we have undertaken experimental and theoretical studies of $\rho(\boldsymbol{r})$ for S_4N_4[5] and a theoretical study of S_2N_2 for comparison. Our geometrical parameters for S_4N_4 are in good agreement with those of the earlier study.[1] We have clarified several inconsistencies still outstanding in the various bonding descriptions of S_4N_4, and observed distortions in the experimental charge density giving rise to directional *intermolecular* attractions corresponding to molecular recognition in the solid state.

Intramolecular bonding: in order to reveal both *gross* and *subtle* features of $\rho(\boldsymbol{r})$, we have analysed its Laplacian, $\nabla^2\rho(\boldsymbol{r})$, using the 'Atoms in Molecules' (AIM) approach of Bader.[6] By means of a topological analysis of $\rho(\boldsymbol{r})$, features such as bond critical points (CPs) and paths of maximum electron density can be used to construct a molecular graph representing the network of bond paths connecting linked atoms. As shown in Fig. 1(a), we find ten (3, −1) bond CPs,[6] corresponding to eight S–N and two S–S linkages, and four (3, +1) ring CPs,[6] in a tetrahedral array about a central (3, +3) cage CP.[6] These conclusions are in accord with an earlier theoretical study.[3] $\rho(\boldsymbol{r})$ at the cage CP is a minimum in all three dimensions, supporting the conclusions drawn from two theoretical deformation density studies,[2,7] and affording no evidence of significant distal S···S interactions. The value of ρ at the bond CPs, $\rho(\boldsymbol{r}_c)$, for the S–S bonds [$\rho(\boldsymbol{r}_c)_{av}$ = 0.37(1) e Å^{-3}; av = average] is significantly lower than that for the S–N linkages [$\rho(\boldsymbol{r}_c)_{av}$ = 1.54(1) e Å^{-3}], being about one-third that reported for an S–S single bond.[8] This, together with the long S–S distances[8] of 2.5995(2) and 2.5950(2) Å and a positive value of the Laplacian,[6] $\nabla^2\rho(\boldsymbol{r}_c)_{av}$ = 1.61(1) e Å^{-5}, may be interpreted in terms of a weak, closed-shell interaction between the two S atoms. However, analysis of both kinetic energy densities $G(\boldsymbol{r})$ and potential energy densities $V(\boldsymbol{r})$[10] of the electrons at the bond critical points suggests some covalent character for the S–S bond [$H(\boldsymbol{r}_c) = G(\boldsymbol{r}_c) + V(\boldsymbol{r}_c)$ = −0.116; $G(\boldsymbol{r}_c)$ = 0.228 hartree Å^{-3}].[9]

The shortness of the S–N bond [1.629(1) Å; on average] and its degree of ellipticity[6] [ε = 0.17; $\rho(\boldsymbol{r}_c)_{av}$ = 1.54(1) e Å^{-3}; $\nabla^2\rho(\boldsymbol{r}_c)_{av}$ = −10.60(3) e Å^{-5}] implies π-contributions. The bond paths are displaced, respectively, outwards and inwards for the S–S and S–N bonds, and the S–N bond CPs are located closer to the electropositive S atoms [Fig. 1(a)]. Calculated atomic charges[11] suggest transfer of *ca*. 1.3 electrons to N from S, although monopole charges based on the X-ray multipolar model suggest a lower figure of 0.3 electrons.

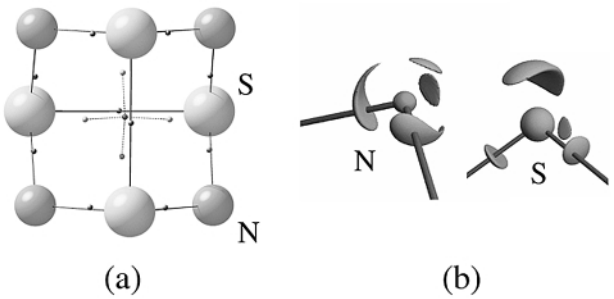

Fig. 1 (a) Location of the critical points denoted by closed circles in the S_4N_4 skeleton. The bond critical points along the S–N bonds are shifted towards the more electropositive sulfur atoms. Important distances (Å) and angles (°) (average values): S–N 1.629(1), S–S 2.598(1); N–S–N 104.5(1), S–N–S 112.7(1). (b) Isosurface maps at constant $-\nabla^2\rho(\boldsymbol{r})$ values indicating bonded and non-bonded charge concentrations on N(1) and S(2) [$-\nabla^2\rho(\boldsymbol{r})$ = 45 and 9 e Å^{-5}, respectively].

Intermolecular bonding. The solid-state structure of S_4N_4 consists of helical chains of molecular units along the crystallographic *b*-axis. The pronounced polarity of the S–N bonds orients neighbouring molecules such that electrostatic S···N contacts are formed [Fig. 2(a),(b)]. $\rho(\boldsymbol{r})$ at the intermolecular S···N bond CPs is rather small [$\rho(\boldsymbol{r}_c)_{av}$ = 0.085(1) e Å^{-3}], but is substantially greater than, for example, the S···S *intra*molecular interactions in 3,3,6,6-tetramethyl-*S*-tetrathiane [$\rho(\boldsymbol{r}_c)$ = 0.043(1) e Å^{-3}].[12] Despite the flatness of the $\rho(\boldsymbol{r})$ map, four *intermolecular* bond CPs, six ring CPs and one cage CP have been located; all experimental and theoretical topological parameters are in good agreement. A more detailed picture emerges from analysis of the Laplacian, $\nabla^2\rho(\boldsymbol{r}_c)$, in regions corresponding to these intermolecular bonding interactions. The results are depicted in Fig. 2 as contour plots for (a) the NNS′S′, and (b) the SNN′S′ interactions, respectively. Here maxima in $-\nabla^2\rho(\boldsymbol{r}_c)$ signal regions of local charge concentration and minima regions of local charge depletion. In accord with both the present and an earlier theoretical study,[3] we deduce that (i)

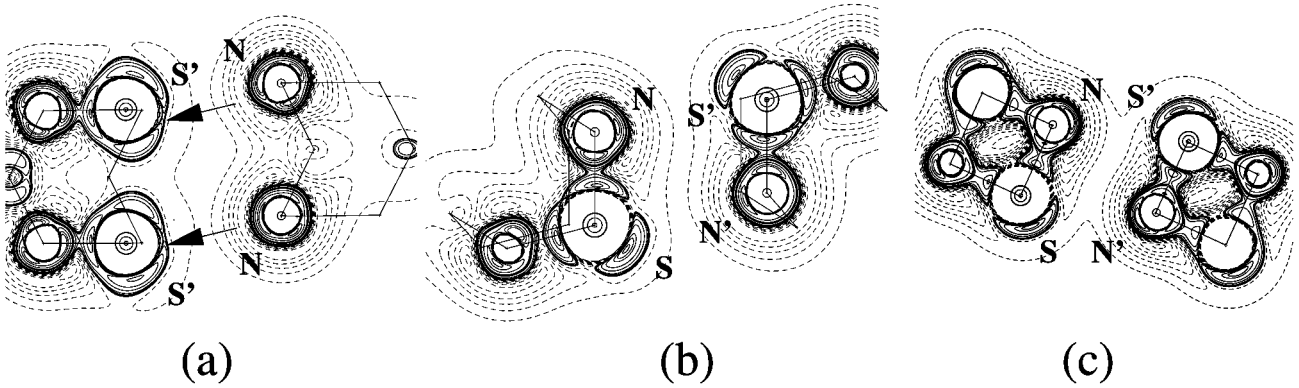

Fig. 2 Contour plots of charge concentrations determined experimentally and by calculation [B3LYP/6-311G(3df) level]. Negative values of $-\nabla^2\rho(\boldsymbol{r})$ are marked by broken lines. (a) $-\nabla^2\rho(\mathbf{r})_{exp}$ in the NNS′S′ plane and (b) $-\nabla^2\rho(\boldsymbol{r})_{exp}$ in the SNN′S′ plane. The relative orientations of the S_4N_4 molecules are indicated by solid lines. Salient distances (Å) and angles (°): S–N′ 3.0882(8); N–S···N′ 79.43(3); N···NS′ 100.00(3). (c) $-\nabla^2\rho(\boldsymbol{r})_{calc}$ in the SNN′S′ plane of the $(S_2N_2)_2$ dimer. In (a) the 'key–lock' interaction is marked by arrows.

two bonded and two non-bonded, and (ii) three bonded and one non-bonded charge concentrations, respectively, in the valence shells of the N and S atoms of S_4N_4 are retained in the solid state [Fig. 1(b)].

While the bonded charge concentrations constitute the intramolecular bonds, the *magnitude* and *location* of the non-bonded charge concentrations on the nitrogen and the local charge depletions on the sulfur atoms should be responsible for the orientation of the S_4N_4 molecules in the solid state.[3,13] According to a point charge model, optimal interaction should occur for closest contact of S···N′ pairs, giving a value of 90° for the NNS′ angle in the NNS′S′ plane. In fact, this angle is 100.00(3)° on account of the directionality of the interactions between the local charge concentrations in the valence shells of the N atom and the associated regions of charge depletion on the corresponding S′ atom. Fig. 2 clearly shows the resulting 'key–lock' principle of facing charge *concentrations* and charge *depletions* in the valence shells of the nitrogen and sulfur atoms in the intermolecular NNS′S′ plane of the $(S_4N_4)_2$ dimer. A similar pattern of charge tessellation is displayed by the Laplacian in the corresponding NSN′S′ plane of S_4N_4 and also in the structurally related model system $(S_2N_2)_2$,[12] as depicted in Fig. 2(c). For $(S_2N_2)_2$ the S···N′ contacts are significantly shorter than in $(S_4N_4)_2$ [2.890(1)[14] *cf.* 3.0882(8) Å], in accord with the proclivity of S_2N_2 to polymerise to $(SN)_x$ with the transformation of one S···N′ contact into a covalent S–N bond.

The 'key–lock' interaction based on the Laplacian goes beyond a point charge model which takes no account of the polarisation of the valence shell and the consequent formation of local charge concentrations and depletions. Whilst crystal architecture is often controlled by directional interactions like hydrogen bonding,[17] this appears to be the first experimental study to reveal a simple three-dimensional directional interaction involving facing charge concentrations and charge depletions as a transferable architectural principle in a molecular crystal. The transferability of the 'key–lock' pattern is remarkable since S_2N_2 and S_4N_4 display rather different geometries and electronic structures. These results suggest that similar architectural forces encoded in the Laplacian of the charge density may be more generally revealed by this type of experimental study. The ability to observe such intermolecular interactions is an important advance, for it demonstrates the response of the non-isolated molecule to its chemical environment, and so holds out the prospect of a better understanding not just of molecular structure, but of molecular *reactivity* and molecular *recognition* under appropriate conditions.

Reversible encapsulation is one of the more recent forms of molecular recognition. Small molecule targets are completely surrounded by larger molecular assemblies and steric barriers keep the guest from escaping the host. Calix[4]arenes make useful modules for capsule construction and the review traces their history. Applications in physical organic chemistry, materials science and spectroscopy are described.

Calixarenes are widely used modules in supramolecular chemistry but I was avoiding them. After all, there were (and still are) a good number of superbly capable research groups busy with these molecules. Their work has generated hundreds of original journal articles, extensive literature reviews and whole monographs; I did not intend to disappear in this avalanche of paper. But here I am, tossing another snowball on the heap, writing more about them. What changed my mind was the imagination and skill of a graduate student, Ken Shimizu. He presented me with an accomplished fact: a calixarene that formed an encapsulation complex. No one else could have arrived at the same molecules, we thought—but that was a colossal illusion.

Ken was working in aspects of molecular recognition chemistry involving cleft-like synthetic shapes and he possessed a keen eye for molecules with curvature. At that time more than half of the research group was involved in self-assembling systems, particularly hollow, pseudo-spherical structures, and he set out to invent his own version. Instead of carving up the sphere into a pattern of, say, a tennis ball, Ken felt that a simpler, hemispherical division would lead to a fertile formula for assembly. For this he needed a bowl-shaped molecule that could be usefully functionalized on its rim. He found it in calixarenes[1] when they are in the so-called 'cone' conformation (Fig. 1).

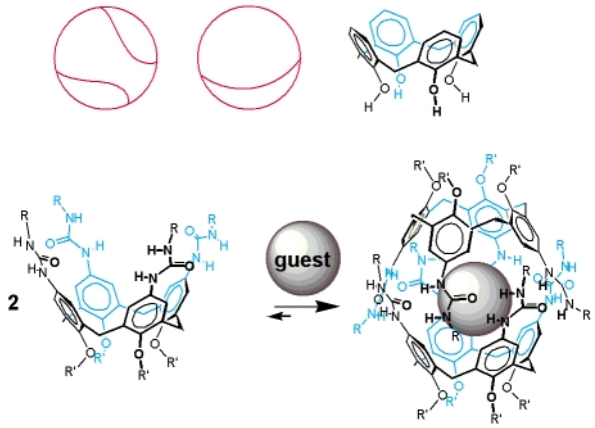

Fig. 1 *Top*. Ways of dividing a spherical surface and the curvature of a calix[4]arene in a cone conformation. *Bottom*. The calix[4]arene bearing ureas on the upper rim forms a dimeric capsule when an appropriate guest is present.

This conformation features a gentle curvature on its molecular surface that can be enforced and maintained by placing sizable groups on the lower rim, on the phenolic oxygens.[2] The cavity left by this shape is what matters; if the calixarene were constructed from CPK models then filled to the brim with, say, a quick-setting plaster,[3] then the hardened material, when removed, would resemble not so much a cone as it would (in miniature) the great pyramid at Giza. The cone descriptor was devised by Gutsche[1] whose heroic synthetic studies have resulted in calixarenes being articles of commerce. In addition, Böhmer,[4] Ungaro,[5] Shinkai,[6] de Mendoza[7] and others have worked out the synthetic protocols and the many conformational possibilities of calixarenes. I am grateful to the advantages their work gave us latecomers.

Shimizu's idea had been to bring two of these calixarenes together, rim-to-rim, and the enduring fashion in the group was to use hydrogen bonding patterns on self-complementary molecules to accomplish this. The moderate directionality and reversible formation of hydrogen bonds had been successful in other ongoing projects and Ken used the nature of ureas to nurture a seam of hydrogen bonds between the hemispheres. A circle of eight ureas, four from each hemisphere, assembled head-to-tail as shown in Fig. 1. This directionality leads to a reduction of symmetry (at least on the NMR timescale) and no planes of symmetry are present in the dimer: the two meta protons of the benzene units are now in different magnetic environments. It was the coupling constant between these protons that gave away the structure.

When I first lectured about this work at a conference in Jerusalem in the summer of 1995, I was disappointed to find that the calixarene capsule was greeted with some skepticism. Two other groups had already made molecules having all the functional aspects of Ken's, but had not recognized them to be dimeric capsules. Volker Böhmer proposed that we look for

Julius Rebek, Jr. was born in Hungary in 1944 and lived in Austria from 1945–49. He and his family then settled in the USA in Kansas. He received his undergraduate education at the University of Kansas in 1966, and obtained the PhD degree from the Massachusetts Institute of Technology (1970) for studies in peptide chemistry with Professor D. S. Kemp. As an Assistant Professor at the University of California at Los Angeles (1970–1976) he developed the 'three-phase test' for reactive intermediates. In 1976 he moved to the University of Pittsburgh where he rose to the rank of Professor of Chemistry and developed cleft-like structures for studies in molecular recognition. In 1989 he returned to the Massachusetts Institute of Technology, where he was the Camille Dreyfus Professor of Chemistry and devised synthetic, self-replicating molecules. In July of 1996, he moved his research group to The Scripps Research Institute to become the Director of The Skaggs Institute for Chemical Biology, where he continues to work in combinatorial chemistry and self-assembling systems.

DOI: 10.1039/a910339m

meta coupling in our systems, as predicted by a dimeric structure, and indeed, there was. Böhmer subsequently published his capsular system,[8] about which more later. David Reinhoudt favored a 'pinched cone' conformation but eventually described the cone conformation for anion detection with his urea and sulfonyl urea calixarenes.[9]

Even though the NMR spectra in solvents such as $CDCl_3$ were consistent with the formation of a dimeric capsule, it was not until Shimizu detected a guest inside the capsule that we were confident enough to publish this work.[10] First, it was necessary to solve the solvent problem and the solution was, well, in the solution. Still and Chapman[11] had shown that concave surfaces into which solvents do not fit tended to show high affinities for other small molecules that do. This scenario was staged by the use of solvents that are too large to be accommodated in the concavity, provided that they still dissolved the components of the system. These observations concerning solvent size *vs.* cavity size are generally applicable to encapsulation phenomena and we have used them extensively. For the case at hand, it meant that solvents such as $CDCl_3$ that are excellent guests for the cavities, are reluctant to leave the cavities to solutes. After all, the solvent at ~10 molar concentration has a seemingly insurmountable advantage. To make matters worse, trace impurities in the solvents can provide stoichiometric amounts of excellent guests. For example, a solvent like deuterated *p*-xylene, for which modeling suggested an uncomfortably tight fit, was easily displaced by simple aromatics. Benzene, for example, fits well and when it is added to such a solution a new resonance in the NMR spectrum appears, a sharp singlet at *ca.* 4 ppm. The benzene oozes into the cavity over the course of about an hour. But when the deuterated xylene solvent is subjected to fractional distillation to remove deuterated benzene contaminants, the added benzene guest enters rapidly.

A different approach to the dimeric nature of the capsule was provided by Böhmer. He showed that mixing two very similar calixarene dimers gave a heterodimeric system.[8] Shortly thereafter, Böhmer took all of the doubt out of things by providing an X-ray crystal structure[12] with the hydrogen bonds of the capsule clearly defined, and a benzene guest inside the capsule to boot.

Solubility is an ever-present issue for our self-assembling systems. For the calixarenes we enhanced it by attaching large groups, such as benzylic groups, to the lower rim and alkyl-substituted aromatics along the ureas of the upper rim. Nowadays, we use *p*-*n*-heptylphenyl, but in the early days the best peripherals were tolyl or even normal alkyl chains. Even with these appendages low solubility in our favorite (large) deuterated solvent, *p*-xylene and the pricey (largest) mesitylene often thwarted our encapsulation attempts. To this very day we suffer the neglect of commercial concerns for our need of larger, deuterated solvents.

Our studies centered around what types of guests could be ushered in. Because of the unusual shape of the cavity (two square pyramids rotated at 45° from each other) we tried some correspondingly exotic shapes (Fig. 2). Phil Eaton provided us with a generous sample of cubane and it proved to be an excellent guest. Halobenzenes, especially fluorobenzenes were also readily encapsulated and gave us some information about their orientation when trapped within. For example, in fluorobenzene the chemical shifts of the *ortho*, *meta* and *para* protons suggest a positioning in which the C–F bond and the *para* proton are along the equator (a polar microenvironment), directed at the seam of hydrogen bonds.[13] A semantically challenging situation arises in the description of these capsules since the 'poles' are not polar but the equator is! The resonance of the *para* proton of C_6H_5F was shifted only moderately upfield in the NMR spectrum, while the *ortho* and *meta* protons, directed at the eight aromatic faces in the poles of the cavity, experience the largest upfield shifts. Blake Hamann found that even the floppy pentane is encapsulated.[14] Its terminal methyl groups appear at higher field than −2 ppm. In any of these cases, it was possible to 'denature' the system, that is, by flooding the solution with competing ureas the hydrogen bonds were disrupted and the guest was liberated. Of course, the same result can be reached by adding a solvent such as DMSO that competes for the hydrogen bond acceptors. We will discuss those experiments in due course.

During this time, Christoph Schalley and Gary Siuzdak were intent on characterizing the capsules in the gas phase. Historically, it has not been easy to get evidence for hydrogen bonded assemblies through mass spectrometry, since the protic solvents required for protonation tend to disrupt the very hydrogen bonded aggregates that one wishes to detect. A number of static tactics have been used to overcome this problem: labeling with alkali ions by covalently attached crown ethers,[15] cation–π complexes with silver ions and suitably arranged aromatics,[16] and even anions[17] appended to the assemblies have been useful. Schalley tested various organic cations and found that the *N*-methylquinuclidinium ion was an excellent guest for the calixarene capsules, both in solution and in the gas phase. This ion acts simultaneously as a guest and an ion label. Moreover, this guest is one of the best for the calixarenes, it even competes with solvent chloroform for the interior of the capsule.[18] Cation–π interactions provide the driving force. Schalley used this ion in a number of contexts including heterodimerization experiments[19] and with a covalently bound capsule, discussed below.

A number of other functional groups were attached to the upper rims of the calixarenes then screened for capsule formation. One of these led to a discovery that had far-reaching consequences for our program. Ron Castellano and Professor Byeang Hyean Kim made a sulfonyl urea derivative,[20] similar to one earlier reported by Reinhoudt.[9] It was characterized as a capsule, but in the presence of a aryl urea capsule, disproportionation took place in an exclusive manner: only the heterodimeric system was observed by NMR! Probably the superior acidity of the sulfonyl urea finds its counterpart in the

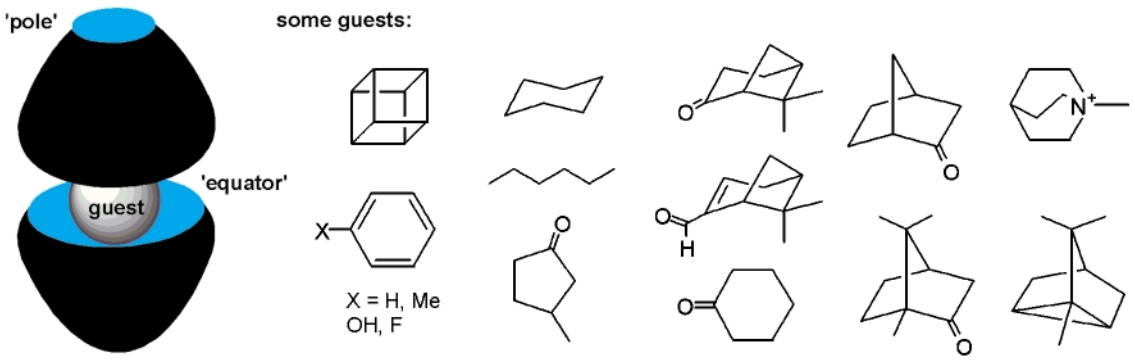

Fig. 2 *Left.* Cartoon representation of the calixarene capsules used elsewhere in this review. *Right*. Some of the many guests encapsulated by these dimers.

basicity of the aryl urea, but there must be other intermolecular forces involved since simple alkyl ureas do not show the same tendency to heterodimerize. Whatever the cause, this phenomenon helped us characterize a number of systems of increasing complexity (Fig. 3). For example, using a 1,3,5-trisubstituted aromatic spacer, we were able to observe an assembly in solution that was capped by three sulfonyl ureas.[21] This is one of the most complicated assemblies we have prepared to date; it consists of seven molecules – the centerpiece, three caps and three guests. It maintains its structure in solution and in the gas phase when quinuclidinium is the guest.

The calixarenes also allowed us to explore the practical differences between covalently bound molecules-within-molecules, carcerands[22] and reversibly formed capsules.[23] Independently, Sherman was pursuing this very line of inquiry using resorcinarene-based systems.[24] The question dealt with whether or not we could combine the best aspects of assembly—reversibility and stability—but side-step the worst aspects—lengthy syntheses and solubility problems—with capsules that were hybrids. In both approaches, the tactic was the same; to covalently attach two of the bowl-shaped molecules at their upper rims in such a way that they would still form a capsule. For the calixarenes, a tether was needed that was long enough to reverse the seemingly divergent directions, and yet short enough to minimize the problems posed by entropy. Marcus Brody arrived at the hexyl tether since it modeled well and provided the distance needed to span the two hemispheres without causing an undue amount of entropy loss from the methylenes of the chain. The synthesis was uneventful, following well-trodden paths.[25] Happily, he found enhanced stability for the new molecule (Fig. 4). It was loathe to miscengenate with other aryl substituted ureas at comparable concentrations; it neither dimerized nor polymerized, but it could be forced to heterodimerize with excess sulfonyl ureas. The product favored at equilibrium was a dumbbell-shaped assembly that featured five molecules. Again, it was characterized both in solution and in the gas phase as its quinuclidinium complex.

The capsule exists as a pair of enantiomers but we expected very little in the way of entantioselective recognition from such a system. After all, the chirality exists in the lining, in the seam of the hydrogen bonds, as a clockwise or counter-clockwise arrangement with respect to the tether. The tether is largely external and cannot reasonably be expected to influence binding events inside. The longer-term significance of this molecule is that the tether also provides a place for covalent attachment of an entire capsule-forming unit on, say, a solid surface. We have aims on a sensing device for appropriate guests, but this has not yet been brought to practice.

Polycaps

Self-complementary structures have fascinated us for some time as there is a certain economy, even dignity, in a molecule that recognizes itself in a predictable way. By predictable I include the contributions of crystal engineering,[26] but any molecule that enjoys a liquid or solid state does express some self-complementarity, intended or not. When the recognition surfaces are arranged in a way that all sites find their complements in a dimer, then additional possibilities arise: these self-complementary structures can give rise to the simplest molecular replicators.[27] Experiments in the Ghadiri lab have recently shown that trimeric peptide helix bundles are also capable of replication,[28] and there is no reason to exclude tetramers or higher order aggregates, even if no specific cases exist at this writing. What is certain is that recognition surfaces that diverge on self-complementary molecules lead to open-ended systems such as polymers. For some years we had been trying to realize this in the context of the capsular structures, and the calixarenes gave us the opening we were looking for.

Professor Dmitry Rudkevich and Ron Castellano used literature precedents to synthesize a calixarene tetraurea bearing

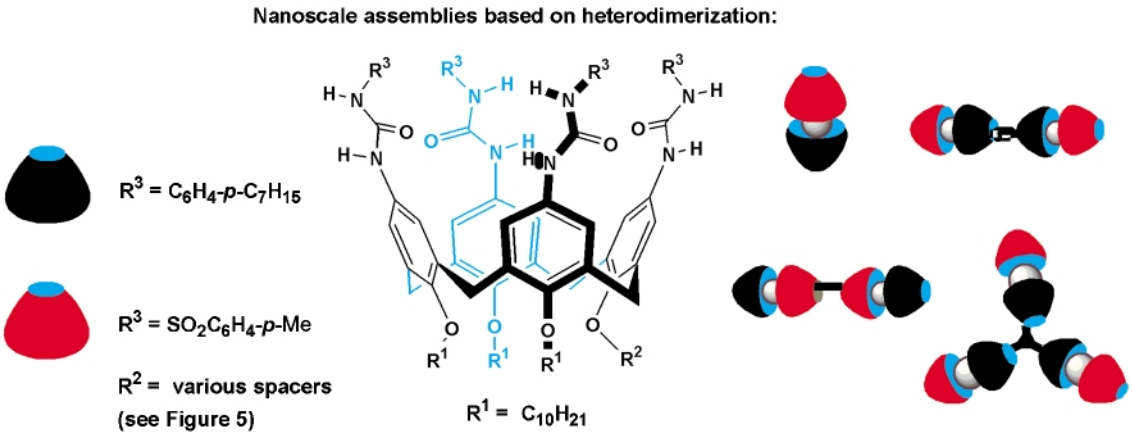

Fig. 3 Aryl and sulfonyl ureas further functionalized on their lower rims are converted into modules. Heterodimerization takes place exclusively to give predictable nanoscale assemblies.

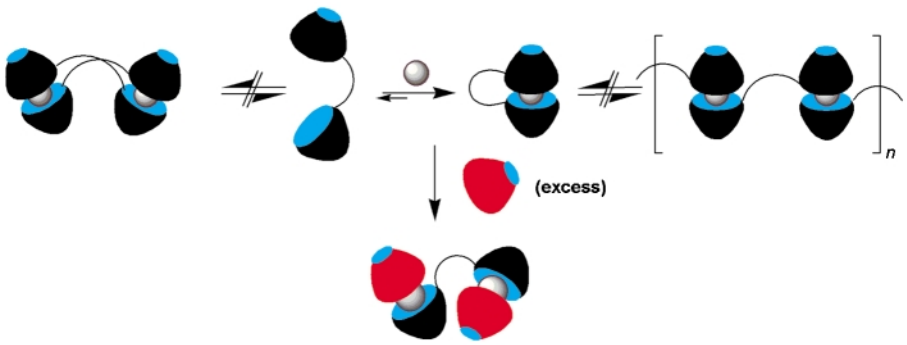

Fig. 4 Covalent connection of the two hemispheres at their upper rims now leads to capsules in an intramolecular sense. Neither 2+2 dimers (top left) nor polymers (top right) are formed. However, with excess sulfonyl functionalized calixarenes a dumbbell-like shape is favored (bottom).

a unique site for functionalization on the lower rim. This had already been accomplished elsewhere[29] to anchor alkali and alkaline earth ions to a calixarene platform. Dimerization of this molecule was as expected but gave us a taste of the complex flavors of isomerism that lay ahead. For example, two regioisomers of the capsules exist and there are unique environments for all 8 (downfield) N–H resonances in each! Nonetheless, they are not very different; these 16 urea resonances appear within 0.1 ppm of each other in the NMR spectrum. Two of the monomeric calixarenes were duly linked through amide bonds to relatively short spacers (Fig. 5).[30]

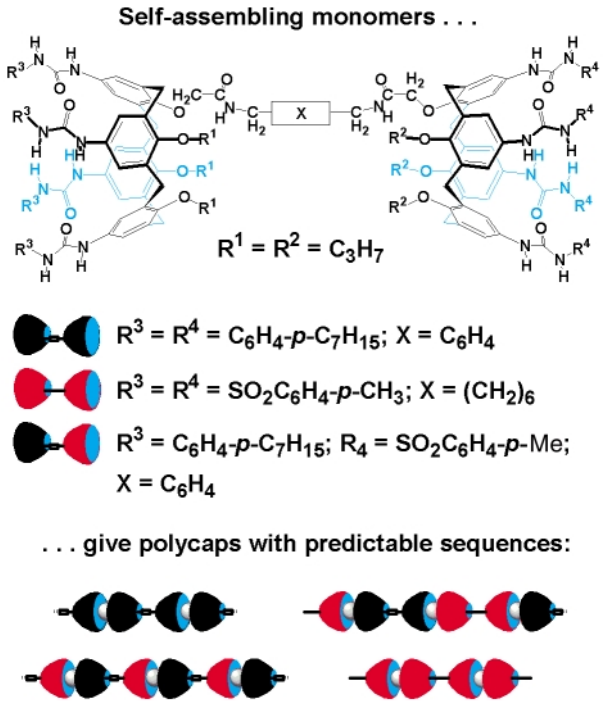

Fig. 5 Heterodimerization preferences lead to predictable polymer sequences from either complementary or self-complementary subunits.

Consider, now, the assembly of such a unit in a linear polymeric array. Capsules appear like beads on a string, and each site is at a characteristic distance from the end of the polymer. At first glance, one might think there is symmetry about the center of the supermolecule, but the two halves of each capsule are different, each cavity is chiral, that is, the head-to-tail arrangement of ureas is either clockwise or counterclockwise at each capsule. For a string of, say, 100 units the number of isomers due to chirality and regiochemistry approaches 4^{100}. This figure is many times greater than the total number of molecules in the sample (or on earth, for that matter). The symmetry must be broken as described by Eschenmoser.[31] That we were able to observe and interpret the signals for the polycaps and their encapsulated guests was a triumph of high resolution NMR.

The polymeric assemblies do show broadened NMR spectra but the positions of the resonances matched very closely those of simpler model (dimeric) capsules. Addition of guests resulted in the emergence of new signals, and the encapsulated species showed up right where we expected them. The reversibility of the polymerization was readily established: for example, a few % DMSO added to the $CDCl_3$ solvent gave a system that contained roughly equal amounts of monomer and polycap. When a good guest like *p*-difluorobenzene was then added, the growth of a new polycap species was evident at the expense of both the monomer and the original (solvent-filled) polycap.

A linear polymeric capsule can be of any length and we attempted to determine the length with size exclusion or gel-permeation chromatography. The polycaps proved to be at the limits of the sensitivity of our columns, and the technique, but we have been fortunate to recruit Professor George Benedek and Aleksey Lomakin to address some physical aspects of these systems. They are presently unraveling the complex questions regarding polymer length, individual association constants of the polycaps and their effect on reptation, that is, the entanglements often encountered in covalently bound polymers. The reversible formation of the polycaps may allow ideal, untangled arrangements to form. In the meantime, we note that there are not many examples of reversibly-formed, hydrogen bonded polymers.[32] The uniqueness of the systems at hand have to do with their ability to function as capsules as well as polymers.

The formation of heterodimeric systems was likewise explored by 'end capping' experiments. Specifically, the polycap rapidly broke down to a dumbbell-shaped assembly when treated with an excess of the simple dimeric capsule. The dumbbell featured a sharply resolved NMR spectrum that showed all of the expected resonances. A version capable of cross-linking was also prepared. This was based on a spacer derived from a symmetrical 1,3,5-trisubstituted benzene to which three of the monofunctionalized calixarenes described earlier[21] were attached. The polycap here was insoluble in all of the solvents in which it assembled, but the monomer proved useful in nucleating other complex assemblies.

Let me now describe the long-range order of these polycaps. Colin Nuckolls and Ron Castellano felt confident that the polycaps could be forced into increasing order, for example, into liquid crystalline phases, if the appropriate modifications were made on the surface of the structures. Accordingly, the monomers were outfitted with long alkyl chains that provided a liquid-like sheath around the polymer chains; this helps fill the space between the chains. The resulting polycaps (at high concentrations) showed birefringence patterns when viewed between crossed polarizers and gave typical Schlieren textures.[33] These textures reflect the morphology of the liquid crystals and were found to be a function of what guest was inside. Lyotropic, nematic liquid crystalline phases were generally observed with the polycaps. The characterization was done by our collaborators: Holger Eichhorn in Timothy Swager's lab at M.I.T. and Andrew Lovinger at the Bell Labs. Typically, molecules like difluorobenzene and nopinone were readily encapsulated in these liquid crystalline phases. Further characterization by X-ray diffraction patterns showed peaks at 2.4 and 1.6 nm that match well the repeat distances and the dimensions of the polycaps (Fig. 6).

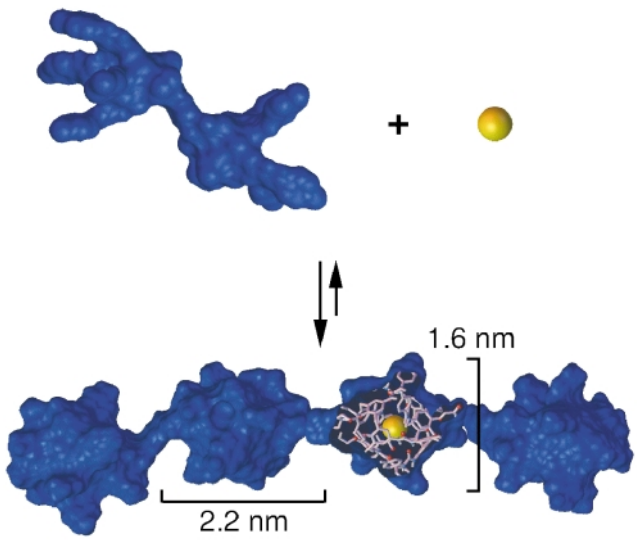

Fig. 6 Covalently-linked calixarenes form polycaps in the presence of a suitable guest.

It was also possible to show that external, mechanical forces can be used to further organize the liquid crystalline phases. For example, shearing gave fibers that showed a uniform width of about 6 μm when viewed through a confocal microscope. Macroscopic samples were also prepared. Specifically, fibers from liquid crystalline samples could be pulled to cm lengths. This ability to draw fiber structures from polymeric liquid crystals is also characteristic of other hydrogen bonded polymers.[34] In short, a hierarchical ordering of the molecules that ranges from the Å to the cm scale is at hand. Whether we are able to find applications for these liquid crystals that have encapsulated guests is not yet clear. After all, liquid crystals are a dime a dozen (or worse, a dime a pound) and our polymeric capsules cost a bit more.

While we started this discussion praising the virtues of self-complementarity, the heterodimerization that we discussed between the sulfonyl ureas and the aryl ureas took us a long way in ordering assemblies. There is another way heterodimerization became an advantage and that dealt with chiral derivatives. The calixarene tetraureas derived from norleucine in its optically active form showed a very high preference for forming heterodimers with the parent aryl urea. Within these the head-to-tail arrangement of the eight ureas appeared entirely to be oriented in one direction. In other words, the peripheral point chirality of the amino acid was being transmitted to the capsule's lining (Fig. 7). This heterodimerization was shown to

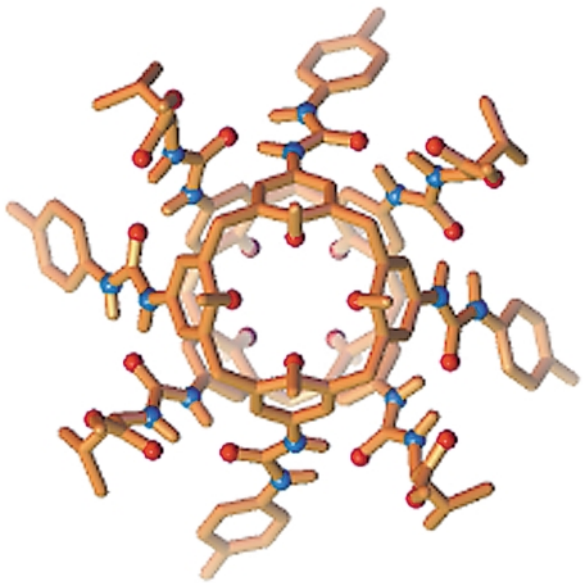

Fig. 7 The heterodimer formed between a tolyl urea and a chiral urea (L-valine) as viewed from one of its poles.

be exclusive with other amino acids that have β-branched side chains, like isoleucine and valine.[35] Circular dichroic spectroscopy was used to assign the absolute configuration of these capsules. The side chains of the amino acids provide contacts that are vital in the dimeric assembly and eventually lead to instruction of the clockwise or counter-clockwise arrangement of the ureas.

Do these asymmetric microenvironments distinguish between enantiomeric guests? They do, but to date only modestly. For example, with norcamphor as a racemic guest, the heterodimer shows two sets of assemblies and there is about a 15% excess of one diastereomeric complex. With smaller guests such as 3-methylcyclopentanone encapsulation occurs, but no enantioselective binding is observed. So the many asymmetric centers in these molecules do not necessarily translate into an outrageously chiral space. Rather, as is the case with cyclodextrins, the bumps and dimples of the lining of these capsules are smoothed over by the large number of their subunits. On the positive side, the heterodimerization systems that have emerged out of the studies of sulfonylureas and β-branched chiral ureas represent forms of molecular instruction. They have parallels in base pairing in double-stranded DNA. All of the bases can—and to some extent, do—homodimerize, but the appropriate heterodimers are far more stable.[36]

Polymeric systems based on heterodimerization capabilities of the capsules were also explored by Ron Castellano. For example, the alternating urea/sulfonyl urea polycap was made as was the system in which each subunit had one urea and one sulfonyl urea at each end. Both of these systems gave nearly the same NMR spectrum. The instructions for heterodimerization represent a vehicle for information in these systems, and it becomes possible to consider an informational polymer based on these molecules. For example, consider a backbone along which the calixarenes may be appended. One of the simplest constructs is an amino acid that has the calixarene as the side chain. Such a system was duly made[37] and is recognizable as a quite large amino acid (Fig. 8). The intent was to build a ladder-like polypeptide molecule capable of pairing, wherein the sequence of ureas and aryl ureas could be read by an opposite strand, very much like a sequence of a nucleic acid is read by the complementary strand. Would such a system show pairing? Our early characterization of the molecule answers this question in the affirmative. Specifically, the dipeptide analog was prepared and characterized as a self-complementary dimer, but the molecules have become so large that their characterization, even for the simplest cases, has become unmanageable by the conventional techniques we have at hand.

A third and independent means of establishing heterodimerization comes from Ron Castellano, Colin Nuckolls, and Stephen Craig's recent experiments with fluorescence resonance energy transfer, or FRET (Fig. 9). Two different dyes are placed on each of the lower rims of two different calixarenes and only when they are held in a heterodimeric capsule are the dyes close enough together to permit energy transfer.[38] Excitation of the donor ($h\nu$) results in two colors of emitted light: one fluorescence band at the donor emission wavelength ($h\nu'$), and a second at the acceptor emission wavelength ($h\nu''$) that signals the noncovalent union of three species—donor, acceptor and guest. By monitoring these wavelengths, assembly and dissociation processes can be observed in real time.

The FRET process allows for much more than just *detection* of the heterodimer; the kinetics and thermodynamics of the assembly can also be determined. We knew that a donor sulfonyl urea **1D** would heterodimerize exclusively with an acceptor aryl urea **2A** to give a predominance of the desired complex, **1D·2A**, capable of FRET. When these species are combined, the heterodimer **1D·2A** duly forms, FRET occurs, and the acceptor emission increases until essentially quantitative energy transfer is observed. By using different stoichiometries of donor and acceptor, as well as untagged derivatives, we were able to determine association and dissociation rates under pseudo first-order conditions. The corresponding K_A's are, as expected, high—just shy of 10^9 M^{-1} for **1D·2A** in benzene. By titrating these dimer solutions with a solvent that can effectively compete for the hydrogen bonds, such as DMSO, the assembly process can be reversed, and the donor emission is restored. We believe that energy transfer fluorescence techniques may be a general means to investigate the solution behavior of related assemblies wherein association constants are high and compound availability is low.

The assembly process shown in Fig. 9 can only occur in the presence of a suitable guest molecule. In our work published to date that role is played by the solvent itself, but when the solvent is not a viable guest, then the FRET system may be a sensitive method for small molecule detection. The analytes remain chemically unmodified because they are held in capsules by mechanical as well as intermolecular forces. In the sytem with heterodimers of calixarenes functionalized with aryl ureas and amino acid-derived ureas, our initial results are promising;

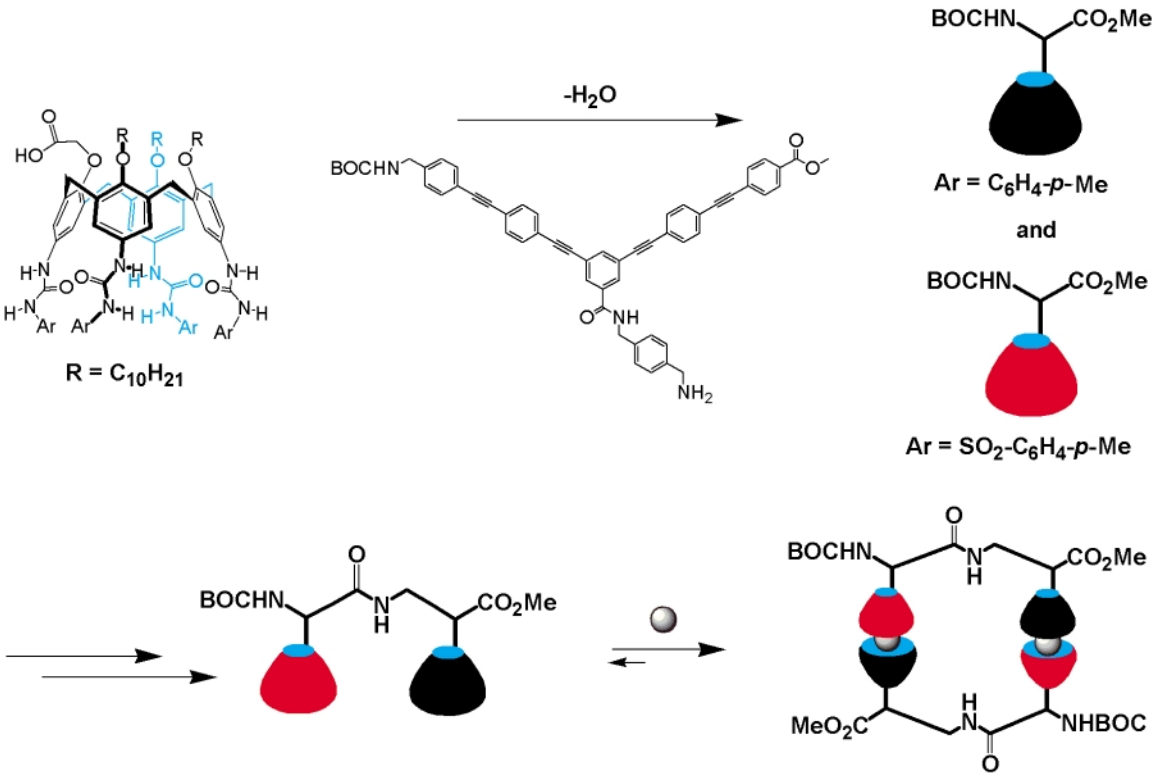

Fig. 8 A 'two bit' system. Hemispheres are placed on an extended amino acid. Heterodimerization preferences provide molecular instructions along the peptide backbone.

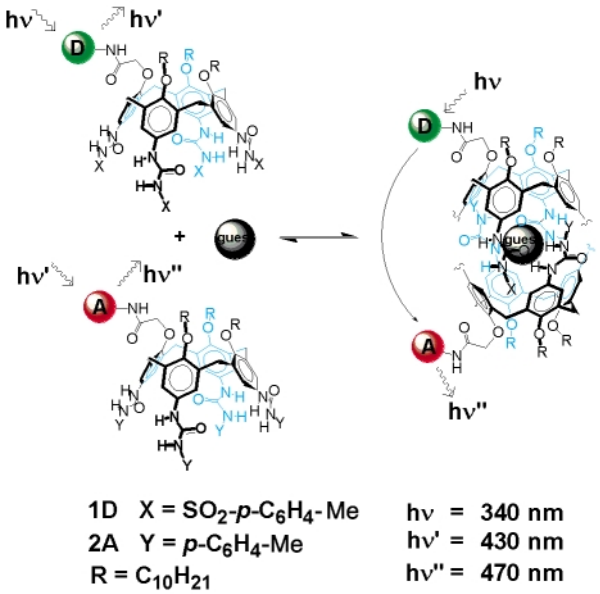

Fig. 9 The use of fluorescence resonance energy transfer (FRET) to monitor self-assembly. The two calixarene hemispheres are outfitted with energy transfer dyes; the presence of the guest nucleates the heterodimerization and allows the FRET to occur. Some ureas have been omitted for clarity.

energy transfer is observed only in the presence of the intended guest.

The molecular encounters described here are matters of timing and the timescales are huge. A normal diffusion complex lasts less than a billionth of a second, while molecules held within the carcerands[22] are confined for the lifetime of a covalent bond, typically a billion seconds. The reversible encapsulation complexes exist in the midrange of these extremes on a human-friendly timescale of 1 second, with three orders of magnitude on either side. Conventional kinetic studies concerning how guests get in and out of these capsules have been initiated and we have made some progress on the problem in the context of 'softballs'.[39] The calixarenes still pose a challenge that inspires our current efforts.

Palladium–indium mediated Barbier-type allylation of aldehydes with allenes

Usman Anwar, Ronald Grigg,* Marcello Rasparini, Vladimir Savic and Visuvanathar Sridharan

Molecular Innovation, Diversity and Automated Synthesis (MIDAS) Centre, School of Chemistry, Leeds University, Leeds, UK LS2 9JT. E-mail: R.Grigg@chem.leeds.ac.uk

Received (in Cambridge, UK) 22nd February 2000, Accepted 6th March 2000
Published on the Web 27th March 2000

A new allylation reaction of carbonyl compounds using allenes is described; homoallylic alcohols were obtained in moderate to good yields from aryl iodides, allenes and carbonyl compounds and an excellent diastereoselection was exhibited when 2-hydroxycyclohexanone was employed.

In the last decade indium has emerged as the metal of choice to mediate the allylation of carbonyl compounds because of its environmentally benign properties allied with a high degree of *chemo-*, *regio-* and *diastereo*-selectivity especially in aqueous media.[1] Furthermore the reaction requires no activation of the carbonyl group and produces few by-products.

The indium mediated allylation reaction is an aldol-type reaction where the nucleophile is an allylindium(I) species usually generated from an allylic halide and indium(0).[2]

Here, we describe the formation of allylindium species by transmetallation[3] of π-allylpalladium(II) complexes generated from aryl iodides and allenes. The resultant allylindium species subsequently add to the carbonyl compound affording homoallylic alcohols (Scheme 1).

There are four synthetic variants of this Pd–In mediated reaction depending on whether the Pd or the In step are *intra-* or *inter*-molecular.

A first set of examples (class 1 processes) where both the Pd and the In steps are intermolecular is presented in Table 1. Aryl/heteroaryl iodides (1.5 mmol) react (DMF, 80 °C, 18 h, Schlenk tube) with allene (1.0 bar) and aldehydes (1.0 mmol) in the presence of indium (100 mesh powder, 1.5 mmol), $Pd(OAc)_2$ (0.1 mmol) and tris(2-furyl)phosphine (0.2 mmol). The use of triphenylphosphine resulted in an incomplete conversion of the starting materials.

Encouraged by these results we employed a substituted allene, *n*-octylallene[4] (1.5 mmol) in the process. A reaction time of 24 h was necessary to achieve complete conversion of the aldehyde. In both the cases so far explored (Table 2) only one geometric isomer was produced and their structures were assigned from NOE data.

A class 2 process (intermolecular π-allyl formation—intramolecular allylation[5]) was explored next. The increased rigidity of the transition state of the aldol-like addition (sub-optimal approach trajectory) may explain the lower yield observed in entry 1. The six membered product was obtained in a better yield (Table 3). The catalytic system comprised $Pd(PPh_3)_4$ (10 mol%) (entry 1) or $Pd_2(dba)_3$ (5.0 mol%) and tris(2-furyl)phosphine (20.0 mol%) (entry 2).

A class 3 process requires an aryl/heteroaryl iodide bearing an allenic side chain. The Pd catalysed step is then intramolecular and is combined with an intermolecular In mediated reaction. Allenyl (2-iodobenzyl) ether[7] (1.0 mmol) was reacted (DMF, 90 °C, 14 h) with aldehydes (1.05 mmol) in the presence of $Pd(PPh_3)_4$ (0.10 mmol) (Scheme 2).

We have briefly studied the effect of chelating groups α to the carbonyl group, such as nitrogen,[8] hydroxyl[9] and alkoxy,[10] on the stereochemical outcome (Table 4) of the reaction of iodobenzene and allene following the protocol described above.

The preliminary results (Table 4) show that the palladium–indium mediated allylation of carbonyl compounds using allenes provides easy access to homoallylic alcohols and that chelation clearly controls its diastereoselectivity.

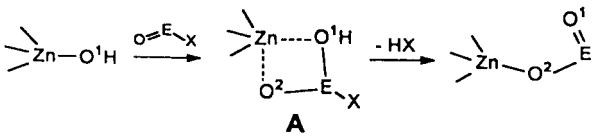
Received (in Basel, Switzerland) 10th February 2000, Accepted 7th March 2000
Published on the Web 27th March 2000

The reaction between L_3Zn–OH complexes (L = N_3 based ligand) and CS_2 which is an analogue of the carbonic anhydrase functionality was computed at the B3LYP/6-311 + G* level to proceed *via* stable four-center intermediates [L_3Zn–SC(S)OH or L_3Zn–SC(O)SH] to give L_3Zn–SH and COS; in agreement with these calculations, the chemical reaction of $Tp^{Ph,Me}Zn$–OH with CS_2 resulted in the quantitative formation of $Tp^{Ph,Me}Zn$–SH and COS; in the presence of 1 equivalent of MeOH the reaction yielded $Tp^{Ph,Me}Zn$–SC(S)OMe, thus also supporting the existence of the four-center intermediate L_3Zn–SC(S)OH.

It is now generally accepted that hydrolytic zinc enzymes (carbonic anhydrase, peptidases, phosphatases, esterases, nucleases) owe their high efficiency to their double functionality, in that they allow electrophilic activation by metal coordination to a substrate oxygen (C=O, P=O) and they provide the attacking nucleophile in the form of the Zn–OH unit.[1] When only one zinc ion is present as in carbonic anhydrase or in the many matrix metalloproteases it performs both functions. This means that during the catalytic turnover zinc changes its coordination number from four to five and then back to four, and the essential intermediate for the general case of O=E–X [E = CR, $P(OR)_2$; X = OR, NHR] hydrolysis is a four-center species like **A**. Several computational studies have considered the details of this process,[2–4] and one of us has recently published structural evidence for the corresponding reaction trajectory.[5]

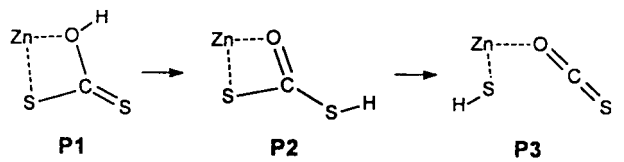


A

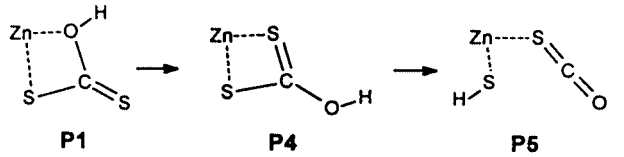
While one would assume that in passing through the intermediate **A**, the Zn–O^1 bond is broken and the Zn–O^2 bond is formed, *i.e.* hydroxide is the leaving group, experimental proof for this reaction course is still missing. Major obstacles to discerning O^1 and O^2 by isotopic labelling lie in the mobility of the OH proton, in the reversibility of the reactions, and in the high lability of zinc complexes, which for instance leads to rapid scrambling of ^{17}O from $C^{17}O_2$ over all positions in the TpZn–OH/CO_2 system [Tp = tris(pyrazolyl)borate].[6] It was therefore attractive to investigate a reaction system where homologous substitution, *i.e.* of O by S, renders distinguishable the atoms in question. We chose for this purpose the L_3Zn–OH/CS_2 system (L = N based ligand) based on previous experience in both the computational treatment of the L_3Zn–OH/CO_2 system[7] and reactivity studies of pyrazolylborate complexes TpZn–OH with CO_2 and similar heterocumulenes.[8] This has enabled us to present a case where the computational results came first and were only subsequently verified by the experiments.

The quantum chemical investigation on the B3LYP/6-311 + G* level of theory was carried out for the potential energy surface of the reaction system comprised of naked $[Zn–OH]^+$ and CS_2 (*cf.* Schemes 1 and 2). It confirmed what might have been expected from thermodynamic considerations, namely that the global energy minimum corresponds to $[Zn–SH]^+$ and COS, and it gave some insight into possible reaction mechanisms leading there. Scheme 1 presents the relevant intermediates of a reaction course which corresponds to the Lipscomb mechanism[9] of carbonic anhydrase action. It consists of subsequent proton transfers and implies that the oxygen of Zn–OH becomes part of O-bound COS (**P3**) which is then expelled. Scheme 2 shows a reaction sequence according to the Lindskog mechanism,[10] the essence of which is an internal rotation of the coordinated dithiocarbonate (**P1**) from the O,S- to the S,S-bound state without a proton transfer. A subsequent proton transfer then yields Zn–SH and COS which is now S-bound (**P5**) before it is expelled.

Our calculations have shown that both pathways are feasible because their steps have low to moderate activation barriers, and referred to the separated reactants the overall activation barrier is +2.4 (Scheme 2) or −3.9 (Scheme 1) kcal mol^{-1}. In order to corroborate the results obtained for this very simple model system we recalculated all minima of the potential energy surface for the two well accepted model systems $[(NH_3)_3ZnOH]^+$ and $[(Him)_3ZnOH]^+$ (Him = imidazole). A comparison of the relative energies of all three model complexes is given in Table 1. As expected, the inclusion of a complete ligand sphere levels the energy differences and yields no minimum for species like **P3** or **P5**. As compared with the results for the $[ZnOH]^+/CS_2$ system, the relative energies of the **P2**/**P4** intermediates change to a marked preference for the **P2** structures. Furthermore **P2** is now similar in energy to the separated reaction products L_3ZnSH and COS, as is **P1** to **P4**, supporting the notation that four-center intermediates like **P1**,



Scheme 1



Scheme 2

DOI: 10.1039/b001149p

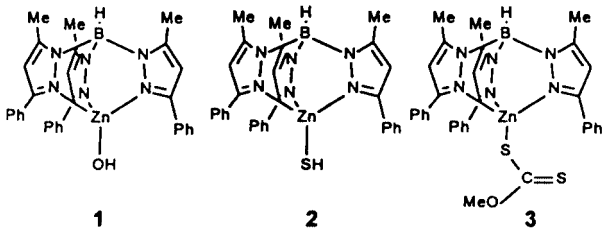
Table 1 Relative energies of the minima for the reaction of the three model complexes with CS_2 (energies in kcal mol^{-1})

	P1	P2	P4	Product(s)
$[ZnOH]^{+a}$	−28.49	−41.65	−46.87	−72.47/−69.90[c]
$[(NH_3)_3ZnOH]^{+a}$	−5.36	−20.61	−10.86	−21.82[d]
$[(Him)_3ZnOH]^{+b}$	−6.61	−20.84	−6.68	−24.80[d]

[a] B3LYP/6-311 + G*//B3LYP/6-311 + G*. [b] B3LYP/6-311 + G*//HF/6-311 + G*; Him = imidazole. [c] **P3**/**P5**. [d] L_3ZnSH + free COS.

P2 and **P4** are relevant entities in the reaction course for the CS_2 just like for the CO_2 reaction system.

The chemical investigation of this reaction system, carried out with the phenyl-substituted TpZn–OH complex **1**, resulted in full agreement between the calculated and observed reaction. In water-free dichloromethane **1** and a stoichiometric amount of



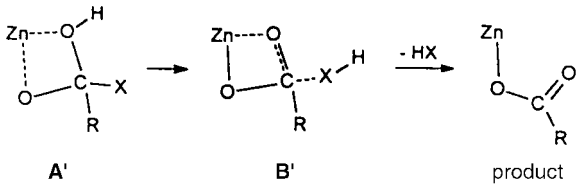
1 **2** **3**

CS_2 were converted quantitatively to the TpZn–SH complex **2** and COS within 12 h at room temperature.† The analysis of the gaseous reaction products† revealed that CO_2 had formed in addition to COS. This pointed to the fact that COS is capable of undergoing the same interconversion, as was verified subsequently by reacting **1** with COS.

An indication of possible reaction intermediates was found when MeOH was present accidentally in the reaction system: a 1:1:1 mixture of **1**, CS_2 and MeOH then yielded the xanthogenate complex **3**, again quantitatively.† The formation of **3** can be understood as a CS_2 addition to the methoxide complex TpZn–OMe (which can exist in very small quantities in equilibrium with **1** and methanol[11]), in analogy to the formation of alkali metal xanthogenates from alkali and CS_2. This proposal was verified by reacting TpZn–OMe, the methoxide derivative of **1**,[12] with CS_2 in dichloromethane, which produced **3** fast and quantitatively.† The corresponding intermediate, in analogy to **P1**, should be **P1a**. Alternatively, intermediate **P4** might be esterified with MeOH, yielding an intermediate **P4a**. We favor the insertion reaction *via* **P1a**,

P1a **P4a**

because we see no reason why **P4** should be esterified faster than being interconverted to **P5**. On the other hand, and in agreement with our calculations,[13] the methoxide in TpZn–OMe should be a stronger nucleophile than the hydroxide in TpZn–OH and hence capable of outracing the latter in the reaction with CS_2 even when present in much smaller



Scheme 3

concentrations. We have observed similar alcohol incorporations before when reacting the cumenyl substituted TpZn–OH with CO_2 and CS_2.[8]

The considerations applied and verified here for the CO_2/CS_2 system are applicable in the same way to the hydrolytic cleavage reactions of O=C(R)–X with intermediate **A** (Scheme 3). **A′** corresponds to **P1**, a conceivable proton transfer to X creates a possible intermediate **B′** corresponding to **P2**. Thereafter the course of events is different: HX is eliminated while HS in **P3** stays zinc-bound, and while OCS in **P3** leaves, its equivalent RCOO in **B′** becomes part of the reaction product, implying that the Zn–O^1 bond in **A** is broken. If one believes in the wisdom '*natura non facit saltus*' this means that the general pathway for all zinc-catalyzed hydrolytic reactions follows the mechanism in Scheme 1, *i.e.* the Lipscomb mechanism.

This work was supported by the Deutsche Forschungsgemeinschaft (Va 29/15 and GRK 307, Freiburg, and SFB 436, Jena) and by the Fonds der Chemischen Industrie. Financial support by the Thüringer Ministerium für Wissenschaft, Forschung und Kultur is gratefully acknowledged. Furthermore, we thank the Konrad-Zuse-Zentrum für Informationstechnik Berlin for generously providing us with computing time.

Notes and references

† The new complexes were characterized by elemental analyses, IR and NMR spectra in comparison with reference compounds.[8] COS and CO_2 were identified by GC–MS. An X-ray structure determination was carried out for **2**.

Fluoridation of heteroaromatic iodonium salts—experimental evidence supporting theoretical prediction of the selectivity of the process‡

Published on the Web 27th March 2000

Theoretical prediction, that the nucleophilic substitution of a range of arylheteroaryliodonium salts by fluoride ion is regioselective for the aryl ring with the exception of benzo[*b*]furan, are borne out by experimental observation.

Iodine, like the other halogens, is found typically existing in monovalent form (oxidation state: −1), however owing to its large size and polarisability it is able to form stable polycoordinate, multivalent compounds. Compounds of this type, containing hypervalent iodine, have been known for over a century and have received considerable attention. The ability of these compounds to act as both selective reagents and intermediates has formed the basis for this interest.[1–3]

Our interest in the most numerous member of this group, the diaryliodinium salts, arose as it has been demonstrated that they are suitable precursors for the formation of fluoroarenes by the action of fluoride ion.[4,5] We have extended this methodology to the introduction of the fluorine-18 label ($t_{\frac{1}{2}}$ = 109.7 min) in the form of [^{18}F]fluoride.[6,7] This reagent has distinct advantages over the standard electrophilic procedures, which employ molecular [^{18}F]F_2 and derived reagents, as it is produced in higher amounts and higher specific radioactivity by several orders of magnitude.[8] This is an important consideration as ^{18}F-labelled organics are required at very high specific radioactivity as receptor radioligands in clinical research. Positron emission tomography (PET) is an imaging technique for the absolute measurement, *in vivo*, of positron emitters,[9] enabling their pharmacokinetics and biodistribution to be elucidated by non-invasive means. It is a well established technique; for example, L-6-[^{18}F]fluoro-DOPA[10,11] is used for the study of brain dopaminergic neuron density in movement disorders such as Parkinson's disease.

The ability to control/predict the regiochemical outcome of the aromatic nucleophilic substitution process is of paramount importance. Experimental observations, by us[7,12] and others,[13,14] suggest that it is the interplay of steric demand (the so called '*ortho* effect') and/or the electron deficiency of the aromatic rings that determines the site of nucleophilic substitution. It has been proposed[13,14] that the trigonal bipyramidal iodine(III) intermediates (see Fig. 1) in this process are fluxional and that the observations can be explained by the 'reactive' ring occupying the equatorial position *syn* to the nucleophile. This simple model does account for a large number of the reported observations for the nucleophilic aromatic substitution process. However, there are a number of examples where the outcome is not as predicted using this approach.[4,15] For arylheteroaryl iodonium salts (RR′I$^+$, R = phenyl, R′ = hereroaryl), the model predicts that the product will always be fluorobenzene, resulting from substitution of the relatively electron-poor phenyl ring (*i.e.* as in the equilibrium in Fig. 1).

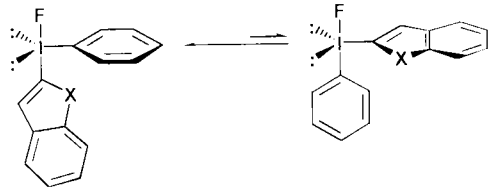

Fig. 1

We have recently applied computational modelling to the nucleophilic substitition of the structurally simpler dialkynyliodonium[16] and diphenyliodonium salts[15] in an attempt to gain a better understanding of the processes involved. This study established, *inter alia*, that the relative energies of the transition states for F–aryl extrusion, mediated by electron-withdrawing and electron-donating substituents, are the opposite of the axial/equatorial ground state equilibria, and that the latter cannot be reliably used to predict the regioselectivity of the process.

Here, we extend our model to the fluoridation of arylheteroaryliodonium salts in order to establish the method as a viable and accurate tool for predicting the outcome of such reactions. As before, quantitative models at the MNDO-d and at the Hartree-Fock *ab initio* level using the computationally efficient MIDI basis set (Table 1) were evaluated. Coordinate files for on-line viewing of the transition state models are available as ESI data.‡

The results reveal the phenyl group is more stable in the equatorial position for the ground state for all the pairs of isomers. Remarkably, the difference in energy grows along the heteroatom series N < S < O. However, the geometries and energies of the two possible transition states show significant variations from our original model. For the monocyclic systems, the transition state stability criterion is in the same sense as the ground state, which results in predicting fluorobenzene as the major product for all three heterocycles (Table 1, entries 1–3). The difference in energy between the two transition states grows in parallel with the aromaticity of the heterocycle. For the benzo-fused systems, all three ground states predict the phenyl group to be equatorial. At the transition state, however, we predict the 2-benzo[*b*]furyl group to be equatorial, resulting in 2-fluorobenzo[*b*]furan as the product. For benzo[*b*]thiophene this is reversed, and again fluorobenzene is predicted. For 1-methylindole, the energy differences are much smaller, and we predict a much less selective reaction, with fluoridation of both the phenyl and the indole rings.

As the prediction for the selectivity of the process did not appear to follow any simple trend, experimental data to assess the validity of the theoretical method was sought. Consequently, a range of arylheteroaryliodonium salts were prepared, in good yield, from the corresponding 2-trialkylstannyl derivatives by treatment with Koser's reagent [Ph(OH)OTs] (ESI‡)[17] (Scheme 1).

Fluoridation of the resultant iodonium tosylates was carried out by treatment with caesium fluoride in acetonitrile at 80 °C

overnight (Scheme 2) and the reaction mixture analysed by GC–MS (ESI‡).

The results from these reactions are summarised in Table 1. As expected the 2-substituted five-membered rings (Table 1, entries 1–3) gave fluorobenzene as the sole fluoroaromatic product. The small value for $E_{TS1} - E_{TS2}$ (−0.1, −2.6 kcal mol^{-1}) for the 2-furylphenyliodonium salt (Table 1, entry 1) suggests that 2-fluorofuran may also be a product. However, owing to the volatile nature of this material we are not able to discount its presence.

The fluoridation products from the reaction of the benzoheteroaromatics (Table 1, entries 4–6), with the exclusive formation of 2-fluorobenz[*b*]furan and the generation of 2-fluoro-1-methylindole, strikingly confirm our transition state model of stability, and not that adopted by the simple model[13,14] where the products should all be fluorobenzene.

We have also included predictions for the 3-substituted series of heteroaromatics (Table 1). In general, fluorobenzene is predicted as the product for all the systems. Specific differences from the 2-series include a much greater specificity predicted for the phenyl 3-(1-methylindolyl) system, and that the aromatic rings show little or no preference in the ground state for either the equatorial or axial position ($E_{GS1} - E_{GS2}$ values are small).

In summary, we have demonstrated, by the fluoridation of arylheteroaryliodonium salts, efficiency prepared from the corresponding aryltrialkylstannanes, that the computational techniques employed are a reliable way of predicting the outcome of the fluoridation process and that the process is therefore transition state and not ground state controlled.

We thank the EPSRC and the UROP scheme (C. D. C) for financial support. We also thank Mr J. Barton for GC–MS and Mr R. Sheppard for 2D NMR.

Superlattices, polymorphs and solid-state NMR spin–lattice relaxation (T_1) measurements of 2,6-di-*tert*-butylnaphthalene

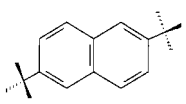
Two polymorphs of 2,6-di-*tert*-butylnaphthalene, which differ by a factor of twelve in the number of crystallographically independent *tert*-butyl group environments, have been characterized by a synergistic combination of low-frequency ^{1}H NMR spin–lattice relaxation rate measurements and conventional crystallographic structure determinations.

When molecular materials crystallize, the symmetry-independent portion of the crystal lattice may consist of an ensemble of molecules that collectively form the *asymmetric unit*. This occurs in about 7–8% of molecular crystals.[1] Most often, the ensemble's organization has no symmetry relationships among its members, even though order is often created by hydrogen bonds or other weak interactions. However, in cases where the number of independent molecules is greater than two, it often happens that the molecules are arranged in a manner that almost, but not precisely, mimics a periodic translation. When such pseudo-periodic relationships exist among molecules, the diffraction patterns are commonly dominated by a subset of the reflections;[2] only the very minor differences among molecules contribute to superlattice (actually, the *true* lattice) reflections. Thus, superlattice reflections may be one to two orders of magnitude weaker than sublattice data and may be undetected during routine data collections.

Failure to recognize the presence of a superlattice results in one or more unit-cell dimensions being only $1/n$ as long as it actually is, where typically n ranges from 2 to 6. Hence, the determined 'structure' of the molecule will be a more or less malformed composite of n molecules in slightly different orientations. Based on our experience, we now believe that many structures reported to have bond parameters substantially outside of anticipated ranges (occasionally accompanied by bizarre chemical claims) may result from unrecognized superlattices.

Our current interest in superlattices was aroused by unusual results obtained in a ^{1}H solid-state NMR spin–lattice relaxation[3] study of 2,6-di-*tert*-butylnaphthalene (2,6-DTN).†



2,6-DTN

A dynamic process producing a local fluctuating magnetic field causes nuclear spin–lattice relaxation. For the molecular solid state, the spin–lattice interactions arise from rotational, and sometimes translational, motions. For molecular solids like 2,6-DTN, the primary process involves alkyl-group reorientation, either the *tert*-butyl group as a whole, the methyl groups individually, or a synchronized motion of both. Whatever process dominates relaxation in 2,6-DTN, its C_{2h} (2/*m*) symmetry suggests that the two *tert*-butyl groups will behave identically. Therefore, it was anticipated that a variable-temperature study of the nuclear spin relaxation rate ($R_1 = T_1^{-1}$) for 2,6-DTN would have the usual Debye form for a ln R_1 *vs.* $1/T$ plot, as has been recorded previously for several alkyl-substituted aromatics.[5] Instead, the very complex plots at Larmor frequencies of 8.50 and 22.5 MHz in Fig. 1 (labeled 'polymorph **E**') were obtained and found to be a composite of several, partially resolvable Debye relaxation curves.‡

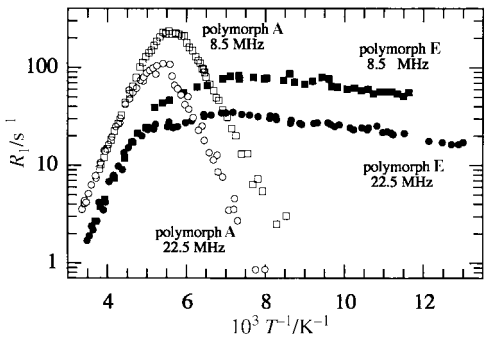


Fig. 1 Relaxation rate (R_1) *vs.* reciprocal temperature (T^{-1}) for **E** and **A** of 2,6-DTN at 8.5 and 22.5 MHz.

An X-ray diffraction study was initiated on a crystal of 2,6-DTN grown from ethanol (polymorph **E**).§ Using CCD detection, it was found that the reflection data contained a systematic weakness for $h \neq 3n$, with the $h = n$ set being approximately 20 times more intense. The unit-cell volume indicated that it contained 12 molecules ($Z = 12$). In the non-centrosymmetric space group, $P2_1$, the only symmetry operation is the 2_1 screw. There are, therefore, two equivalent positions in the unit cell and the asymmetric unit contains six independent molecules ($Z' = 6$). In the stereoview of the unit cell in Fig. 2(a), the arrangement of molecules appears to be repeated three times along the crystallographic *a* axis (horizontal), but if viewed from a perpendicular perspective [Fig. 2(b)], the aromatic planes of the three molecules are seen to be twisted by a few degrees along their long axis, one relative to the other. Fig. 2(b) also shows the herring-bone packing pattern formed by the 2,6-DTN molecules. These data for **E**, although very weak, were sufficient to explain the origin of the unusual relaxation data.

With $Z' = 6$, there are twelve symmetry independent *tert*-butyl groups and 36 independent methyl groups in **E**. Each slightly different environment has associated with it a different hindering potential and therefore a different mean reorientation rate. The localized pseudo-symmetry of the lattice suggests that similar environments might group into a smaller number of quasi-environments. The temperature dependence of ln R_1 at two Larmor frequencies for **E** can be fitted to a multiple-environment model, but the complexity of the curve makes a determination of the number of environments impossible. These environmentally sensitive relaxation studies confirm that the true repeat distance along *a* must be an integral multiple of some sublattice dimension, for only a large number of symmetry independent environments could account for the complex relaxation behavior observed.

DOI: 10.1039/a909449k

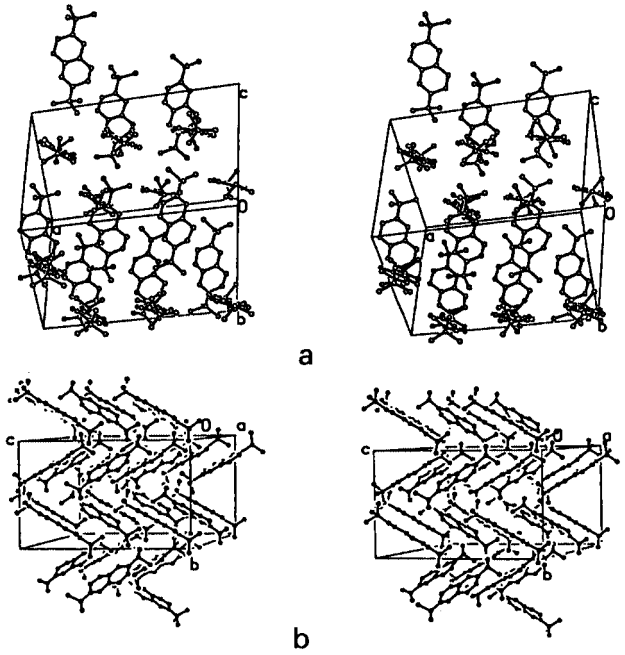

Fig. 2 Stereo drawings of the unit-cell packing for **E**. (a) As viewed with the *a* direction horizontal and (b) as rotated 90° with the *c* direction horizontal.

We then searched for other polymorphs of 2,6-DTN, assuming that the likelihood was strong that a more symmetrical form existed that would be thermodynamically favored at low temperature. Less symmetrical forms with more degrees of freedom may prevail at higher temperatures due to their higher vibrational entropies, but at lower temperatures denser packing arrangements with greater order commonly prevail.[7] Crystals were grown from 18 organic solvents and unit cells were obtained for each. **E** was recovered unchanged from 17 solvents, but a new polymorph (polymorph **A**) was obtained from acetone. It is *ca.* 4% denser, also monoclinic, and crystallizes in the centrosymmetric space group $P2_1/c$ with Z = 2 and Z' - 0.5. The unit-cell packing diagram for **A** is shown in Fig. 3. Thus, the asymmetric unit for **A** is half a molecule on a crystallographic inversion center, which requires all *tert*-butyl group environments to be chemically and crystallographically identical. As expected, the plot of ln R *vs.* $1/T$ plot for **A** Fig. 1) is the classical, single-environment Debye curve. When heated, samples of **A** irreversibly convert to **E** above 40 °C; no thermal events are seen on slowly lowering the temperature to 20 °C from above the transition temperature. The conversion is accompanied by a small, complex endotherm associated with the enthalpy of the conversion of **A** to **E**.

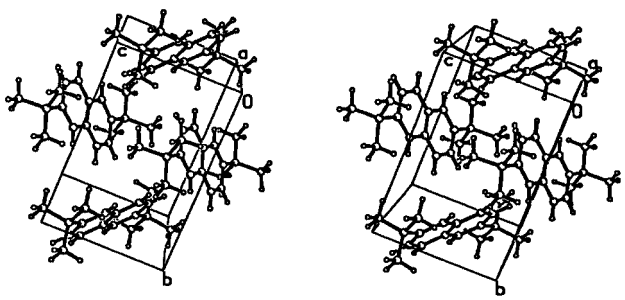

Fig. 3 Stereo drawing of the unit-cell packing for **A**.

That a single Debye process is observed in **A** (in marked contrast to **E**) shows that the motion is characterized by a single thermally activated correlation time τ_c (and only by a single τ_c). R_1 is given by $R_1 = A[J(\omega) + 4J(2\omega)]$, where $J(\omega) = 2\tau_c/(1 + \omega^2\tau_c^2)$ for Larmor frequency $\omega/2\pi$. The parameter A can be calculated from the geometry of a *tert*-butyl group and very reasonable assumptions about the motion.[8,9] The observation of a single Debye process coupled with the fitted value of A clearly shows that the *tert*-butyl groups and their methyl groups all reorient at the same rate τ_c, presumably due to some gearing process. The analysis shows, in addition, that there are no further motions on the NMR timescale.

^{13}C MAS NMR spectra for **E** and **A** reveal only small and random chemical shift differences of no more than 1.6 ppm at any site, and only minor differences in line width, despite the averaging of twelve *tert*-butyl group environments for **E**. Additionally, both agree closely with high-resolution solution chemical shift data.

Despite an obvious complementary relationship between the static, long-range information (translational order) available from X-ray diffraction data, and the dynamic, short-range information (especially spin–lattice relaxation rates, but also chemical shifts and coupling constants) available from solid-state NMR, surprisingly little effort has been made to exploit these potential synergies.[10] We have shown in this study of 2,6-DTN that crystallography and T_1 measurements can provide information essential to the complete understanding of the other, and that together they provide a very complete picture of both polymorphic and superlattice phenomena in these van der Waals molecular solids.

Notes and references

† 2,6-DTN was prepared by literature methods[4] and purified by sublimation.

‡ R_1 rates was measured at 8.50 and 22.5 MHz with Spin–Lock CPS-2 Solid-State NMR spectrometers, one for each frequency. Measurements used a standard π–t–π/2 pulse sequence[6] with a recycle delay of at least $8T_1$. Temperature was varied by a controlled flow of cold nitrogen gas and measured by a calibrated copper–constantin thermocouple. Low frequencies are required to place the maxima in R_1 (corresponding to the motional correlation time being similar to the inverse Larmor frequency) in a convenient temperature region.

§ *Crystal data*: Siemens P4/CCD, Mo-Kα radiation. **E**: $C_{18}H_{24}$, colorless block, monoclinic, space group $P2_1$, a = 19.6636(1), b = 12.6712(3), c = 19.7853(1) Å, β = 104.4322(1)°, V = 4774.17(11) Å^3, Z = 12, Z' = 6, T = 173(2) K, $R(F)$ = 0.137, $R(wF^2)$ = 0.369, N_o/N_v = 10.2. The high residuals are associated with the extreme weakness of all 'superlattice' reflections, and not a result of diffuse scattering, an alternative raised by a reviewer. Spot shapes in the CCD images were found to be identical for both sub- and super-lattice data.

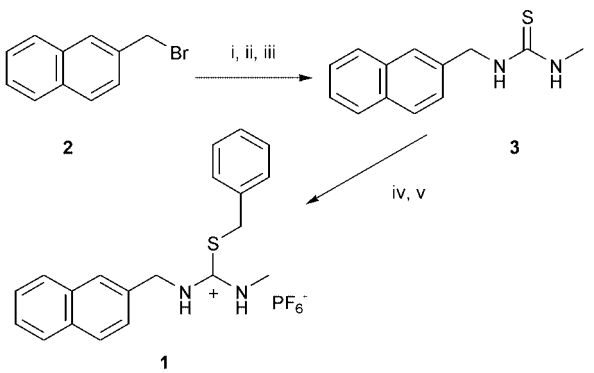
Received (in Cambridge, UK) 13th January 2000, Accepted 9th March 2000
Published on the Web 27th March 2000

A fluorescent-active molecular dyad comprising a naphthalene moiety covalently attached, *via* a methylene spacer, to a thiouronium receptor is described where selective anion-induced fluorescence changes make it of potential use as an anion chemosensor material.

Our ongoing program aimed at the synthesis of new easy-to-make optical sensors of biologically and/or chemically important anions leads us to explore a suitable anion-binding unit capable of efficient interaction with a built-in chromophore. A family of thiouronium salts, being known not only as synthetic intermediates for the conversion of alkyl halides to the corresponding mercaptans[1] but also as classical reagents for the identification of organic acids,[2] has potential as one of key functional groups for the purpose of molecular recognition of anion species in the area of supramolecular chemistry[3] because such groups would enhance the acidity of the NH moieties compared to the corresponding thiourea.[4] Indeed, quite recently, Yeo and Hong reported new thiouronium-derived systems for a carrier of 5′-AMP[5] and oxoanion recognition.[6] It occurred to us that a sophisticated combination of the above-mentioned functional entity and a suitable chromophore such as naphthalene would, therefore, allow production of a new type of chemosensor material. The design is mainly based on our idea that anion recognition events on the electron-deficient binding site of the thiouronium moiety would be efficiently communicated to the fluorescent property of naphthalene so that an easily detectable signalling effect would occur in the system. Surprisingly, to the best of our knowledge, although a number of optical read-out chemosensors of anions have been developed[7] a thiouronium-containing system towards this end is, as yet, unknown. Here, we report the intriguing aspects on the title system **1**.

The synthesis of **1** is shown in Scheme 1: 2-(bromomethyl)naphthalene **2** was converted to the corresponding thiourea **3** *via* amination using potassium phthalimide followed by $NH_2NH_2{\cdot}H_2O$, and then condensation with methyl isothiocyanate. Compound **3** was reacted with 1.1 equiv. of benzyl bromide followed by anion exchange treatment with $AgPF_6$. Purification by reversed phase column chromatography afforded the desired **1**† in excellent yield.



Scheme 1 *Reagents and conditions*: i, K^+ phthalamide$^-$ dry DMF; ii, $NH_2NH_2{\cdot}H_2O$, THF–EtOH; iii, MeNCS, $CHCl_3$; iv, benzyl bromide, dry EtOH; v, $AgPF_6$, dry EtOH.

System **1** showed very weak fluorescence in MeCN at 25 °C ([**1**] = 20 μM), the intensity of which was lower by a factor of 50 than that of 2-methylnaphthalene. This finding indicates that the electron-deficient thiouronium moiety acts as a quencher for the singlet state of the appended naphthalene. However, the addition of AcO^- as a putative response-induced anion was found to dramatically enhance the fluorescent intensity as illustrated in Fig. 1. Subsequently, 1 equiv. of AcO^- caused a remarkable intensity increase of up to *ca.* 350%. The acetate-induced signal effect is well explained by efficient emission retrieval upon an interaction between the anion and the thiouronium moiety of **1**. Further assessment of the receptor–anion complexation process came from a ^1H NMR titration; aliquots of the tetrabutylammonium salt of the anion were added to a CD_3CN solution of **1** (2 mM). Although NH resonances of the thiouronium moiety could not be detected in CD_3CN‡ because of the high acidity, significant upfield shifts (up to 0.2 ppm) of the resonances arising from two types of methylene (NaphCH_2NH– and PhCH_2S–) and methyl (–NHCH_3) protons, which are located in the periphery of the anion-binding site, were observed upon complexation with AcO^-. Judging from the titration, the strong binding of AcO^- allowed the mole ratio method[8] to be used in the determination of the binding stoichiometry, which was found to be 1 : 1 for the receptor–anion complex.

Fig. 2 shows the resulting titration curves for the fluorescent intensity when adding AcO^-, $(BuO)_2P(O)O^-$§ or Cl^- to an MeCN solution of **1** at 25 °C, supporting the formation of a 1 : 1 stoichiometry complex. The association constants (K_a)¶ could be calculated using nonlinear curve-fitting plots. As a result, interestingly, the fluorescent response of **1** was found to show a significant selectivity for the nature of anions in spite of the simple molecular system of **1** [K_a/M^{-1}: AcO^-, > 10^6; $(BuO)_2P(O)O^-$, 5.6 × 10^4; Cl^-, n.d.‖], being probably correlated with the guest basicity. Of particular note is that **1** shows not only a high susceptibility to AcO^- but also a

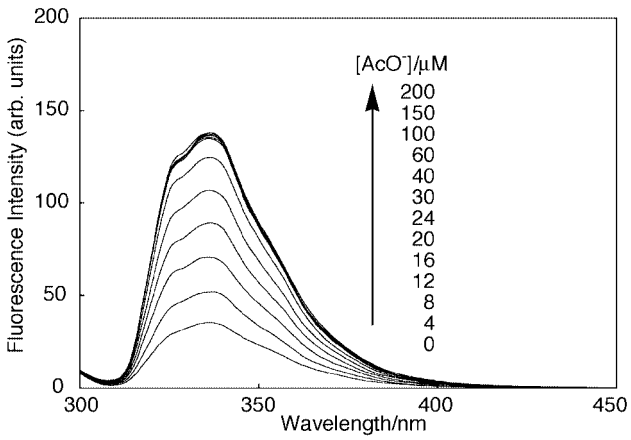


Fig. 1 Emission spectra of **1** (20 μM) in MeCN at 25 °C excited at 270 nm upon addition of AcO^- as a NBu_4 salt.

DOI: 10.1039/b000352m

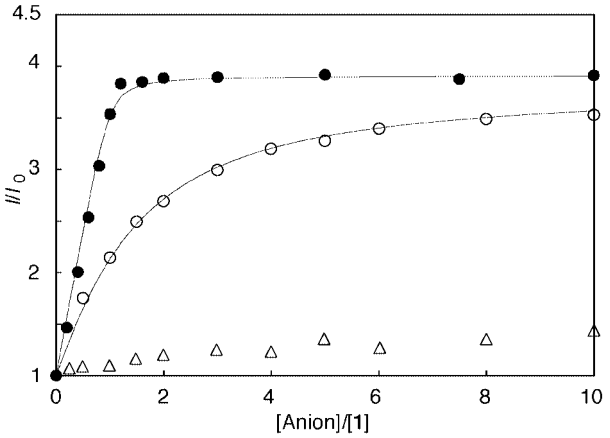

Fig. 2 Fluorescent intensity at 336 nm of **1** (20 μM) in MeCN at 25 °C excited at 270 nm as a function of anion concentration: (●) NBu_4OAc, (○) $NEt_4OP(O)(OBu)_2$, (Δ) NBu_4Cl.

discernible binding towards oxo-anions. Taken together, it could allow us to analyze AcO^- quantitatively[9] using an easy-to-detect fluorescent signal response. This would be most welcome to applications involving medical diagnostics.

As a control experiment, the interaction of AcO^- with 2-methylnaphthalene was investigated in the fluorescent spectra for which no change was observed. This insight supports the argument that the fluorescent enhancement of **1** induced by anions could be based on the significant change on the photoinduced charge transfer characteristics in system **1** where the anion binding event decreases the interaction between the naphthalene and thiouronium moieties.

We conclude that system **1** represents a simple, easy-to-make and hitherto unexplored class of luminescent chemosensors of anions. Owing to the unique sensing properties based on the naphthalene–thiouronium conjugate, the development of highly functional derivatives will represent an important synthetic challenge. Indeed, we are currently preparing more elaborate systems incorporating binaphthalene units.

Calc. for $C_{20}H_{21}N_2SPF_6$: C, 51.50; H, 4.54; N, 6.01. Found: C, 51.66; H, 4.53; N, 5.98%.

‡ The NH resonances were observed at δ 9.22–9.85 as a broad signal in d_6-DMSO.

§ The result of the titration by adding $H_2PO_4^-$ did not fit to curve based on a 1 : 1 host–guest stoichiometry complex, which may be due to a phosphate–phosphate dimerization.[7d,10]

¶ The K_a values were estimated by three individual fluorescent intensity titrations: λ_{max}(ex) = 270 nm, λ_{max}(em) = 336 nm in MeCN at 25 °C. The estimated error for the titration with $(BuO)_2P(O)O^-$ is < 3%.

‖ The response was too low to determine the K_a value.

The mild oxidation of $[NEt_4]_2[Ni_{15}Sb(CO)_{24}]$ in acetone solution with $SbCl_3$ in a *ca.* 3 : 1 molar ratio leads to the new high-nuclearity $[Ni_{31}Sb_4(CO)_{40}]^{6-}$ hexaanion, which displays two interstitial Ni and four semi-interstitial Sb atoms with unprecedented stereochemistries.

Several low-nuclearity Ni–Sb carbonyl clusters have been reported.[1–4] All adopt an icosahedral geometry which can be Sb-centred, *viz.* $[Ni_{15}(\mu_{12}\text{-Sb})(CO)_{24}]^{2-}$ $\mathbf{1}^{2-}$,[1] or Ni-centred, *viz.* $[Ni_{10}Sb_2(\mu_{12}\text{-Ni})(CO)_{18}]^{n-}$ $\mathbf{2}^{n-}$,[1] and $[Ni_{10}(Sb \rightarrow Ni(CO)_3)_2(\mu_{12}\text{-Ni})(CO)_{18}]^{n-}$ $\mathbf{3}^{n-}$, (n = 2–4),[2,3] as well as non-centred, *e.g.* $[Ni_{10}(SbR)_2(CO)_{18}]^{2-}$ $\mathbf{4}^{2-}$, (R = alkyl or aryl substituent).[4] Notably, only the Ni-centred $\mathbf{2}^{n-}$ and $\mathbf{3}^{n-}$ species are multivalent and display three stable oxidation states.[1–6] It has been later shown that the presence of interstitial or highly connected nickel or platinum atoms triggers multivalence in several carbonyl metal clusters.[5,6] Icosahedral species such as $\mathbf{1}^{2-}$, $\mathbf{2}^{n-}$ and $\mathbf{3}^{n-}$ are potential building blocks of poly-icosahedral *supra*-clusters,[7] related to $[Ag_{12}Au_{13}(PPh_3)_{10}Br_8]^-$,[8,9] $Ag_{20}Au_{18}[P(C_6H_4Me)_3]_{12}Cl_{14}$,[10] or $Pd_{59}(CO)_{32}(PMe_3)_{21}$.[11] The above consideration, as well as our interest in redox-active[5,6] and paramagnetic metal carbonyl clusters,[12] led us to investigate the chemical behaviour of $\mathbf{1}^{2-}$, $\mathbf{2}^{n-}$ and $\mathbf{3}^{n-}$ with the aim to synthesise polyicosahedral Ni–Sb carbonyl clusters of higher nuclearity. We now report our first result consisting in the synthesis and structural characterisation of the $[Ni_{31}Sb_4(CO)_{40}]^{6-}$ $\mathbf{5}^{6-}$, hexaanion, which displays unprecedented stereochemical features.

The $\mathbf{5}^{6-}$ salts were spectroscopically detected among the by-products of the synthesis of $\mathbf{1}^{2-}$ by reaction of $[Ni_6(CO)_{12}]^{2-}$ with $SbCl_3$. The best synthesis of $\mathbf{5}^{6-}$ consists in the mild oxidation of $[NEt_4]_2\mathbf{1}$ in acetone solution with $SbCl_3$ in a *ca.* 3 : 1 molar ratio. $[NEt_4]_6\mathbf{5}\cdot 2\,Me_2CO$ [ν_{CO} in acetonitrile at 2040vw, 2001s, 1980(sh), 1894m, 1861m, 1846m and 1812(sh) cm^{-1}; no hydride signal in the ^1H NMR spectrum in the range δ +25 to −50; diamagnetic] separates out from the reaction solution on standing as well shaped black crystals (yields up to 30% based on Sb) and has been characterised by X-ray diffraction studies.† The by-products of the above reaction are $[Ni(CO)_3Cl]^-$, $Ni(CO)_4$ and $[NEt_4]_3$ **3**. As shown by separated experiments, a mixture of $Ni(CO)_4$ and $[NEt_4]_3$ **3** also results from degradation of $\mathbf{5}^{6-}$ salts under a carbon monoxide atmosphere.

The overall structure of $\mathbf{5}^{6-}$ is shown in Fig. 1 and a formal reconstruction of its metal framework is given in Fig. 2(a). The central $Ni_{19}Sb_4$ moiety of the metal frame is based on two interpenetrating Ni-centred $Ni_{11}Sb_3(\mu_{14}\text{-Ni})$ 14-hedron displaying a distorted bicapped hexagonal antiprismatic geometry. One of the two 14-hedrons has been emphasised out with filled in bonds; its idealised C_6 axis is almost orthogonal to the plane of the paper and the in-plane idealised C_6 axis of the other moiety. Each of the two 14-coordinated nickel atoms behaves at the same time as an interstitial atom of one unit and as an *ortho* atom of the Ni_5Sb hexagonal ring of the second unit. The second hexagonal ring of the above 14-hedra displays a *para*-Sb_2Ni_4 geometry. The major deviation of the centred $Ni_{11}Sb_3(\mu_{14}\text{-Ni})$ 14-hedron from the idealised bicapped hexagonal antiprism is due to departure from the mid-point of the Sb–Sb diagonal of the Ni atoms capping the Ni_4Sb_2 hexa-rings. These caps become closer to one of the two pairs of nickel atoms and show Ni···Ni contacts with the second pair which are beyond the usually accepted limit for a Ni–Ni bond [3.350(2) and 3.426(2) Å].

The metal framework of $\mathbf{5}^{6-}$ is completed by condensing two Ni_6 moieties [Ni–Ni range 2.373(2)–2.944(2) Å], displaying a polytetrahedral metal arrangement having the architecture of the $Os_6(CO)_{18}$ prototype,[13,14] on two opposite sides of the central $Ni_{19}Sb_4$ kernel. These Ni_6 moieties bind to the two Sb and surrounding Ni atoms through their butterfly face. As

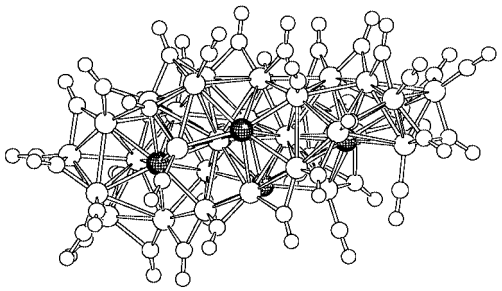

Fig. 1 The molecular structure of the $[Ni_{31}Sb_4(CO)_{12}(\mu\text{-}CO)_{24}(\mu_3\text{-}CO)_4]^{6-}$ $\mathbf{5}^{6-}$ ion. The Ni–Ni and Ni–Sb bonding interactions are spread over the ranges 2.357(1)–3.090(1) and 2.496(1)–2.782(1) Å respectively.

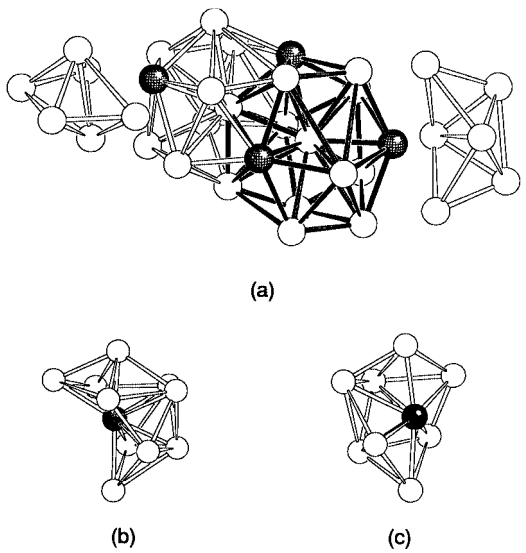

Fig. 2 Formal reconstruction of the metal framework of $\mathbf{5}^{6-}$ with omission of the bonds between the two outer Ni_6 moieties with the central $Ni_{19}Sb_4$ kernel (a) and the two coordination stereogeometries shown by the Sb atoms [(b) and (c)].

pointed out in Fig. 2(b) and (c), the four Sb atoms display two pairs of different stereogeometries, being semi-interstitially lodged in Ni_{10} and Ni_8 incomplete icosahedral moieties, which are related to the $[B_{10}H_{14}]^{2-}$ and B_8H_{14} *arachno*-boranes, respectively.[15,16] Semi-interstitial lodging of Sb atoms in a nickel cluster is not surprising because it has been shown that a Sb atom is oversized for a Ni_{12} icosahedral cage.[1] In contrast, the coordination of the two interstitial nickel atoms is more unexpected and unprecedented in molecular clusters. A metal coordination number of 14 has been found in intermetallic phases such as the Ni–V σ and Ni–Mo δ phases.[15] These alloys also involve 12-coordinated sites of icosahedral geometry, as partially displayed by $\mathbf{5}^{6-}$, as well as 15- and 16-coordinated sites. Besides, these intermetallic phases show a tendency to segregate the bulkiest metal atoms in the highest coordinated sites (14–16), while the other metal atoms occupy the 12- and 14-coordinated sites.[15] In this regard, an ideal 14-hedron having a bicapped hexagonal antiprismatic geometry provides two 6-fold vertices and the interstice as the most suitable sites for the bulkiest Sb atoms of a centred $Ni_{12}Sb_3$ moiety. Therefore, centring of the above by the least bulky nickel atom and segregation of Sb in the two hexagonal rings may appear odd. However, the segregation observed in $\mathbf{5}^{6-}$ could probably be due to its molecular nature and the need to accommodate the carbonyl ligand shell. The forty carbonyl ligands can be approximately classified as terminal (12), edge-bridging (24) and face-bridging (4).

In conclusion, the condensation of $\mathbf{1}^{2-}$ into $\mathbf{5}^{6-}$ does not lead to polyicosahedral *supra*-clusters, as for the Ag–Au system.[7–10] An alternative and unprecedented growth pathway has been observed, which shows that high nuclearity nickel carbonyl clusters can be stabilised not only by interstitially lodging small main group elements such as carbon, *e.g.* $[Ni_{32}C_6(CO)_{36}]^{6-}$ and $[Ni_{38}C_6(CO)_{42}]^{6-}$,[17] but also bulkier atoms such as antimony. Studies of the chemical and physical behaviour of $\mathbf{5}^{6-}$ are underway.

Novel room light-induced disproportionation reaction of organo-ditin and -dilead compounds with organic dichalcogenides: an efficient salt-free route to organo-tin and -lead chalcogenides

Farzad Mirzaei, Li-Biao Han and Masato Tanaka*

E-mail: mtanaka@home.nimc.go.jp

Received (in Cambridge, UK) 7th January 2000, Accepted 8th March 2000
Published on the Web 30th March 2000

Disproportionation of organo-ditin and -dilead compounds $(R_3M)_2$ (M = Sn, Pb) with organic dichalcogenides $(R'Z)_2$ (Z = S, Se, Te) is efficiently promoted by room light to produce the corresponding organo-tin and -lead chalcogenides R_3MZR' quantitatively.

Chalcogenides of heavier group 14 metals, R_3MZR' (M = heavier group 14 element; Z = chalcogen element) decompose upon heating to give composite metal chalcogenides which are useful for solar cells and other semiconductor applications.[1,2] They are also useful reagents in organic synthesis.[3] Conventional synthetic routes generally involve troublesome stoichiometric salt elimination reactions of R_3MX (X = halogen atom) with alkali metal chalcogenides.[3] However, the alkali metal salts concomitantly formed can be a serious contaminant that reduces the performance of the semiconductor materials derived *via* the MOCVD process of these metal chalcogenides as precursors.[2] Thus, an alternative, clean and salt-free route to R_3MZR' is highly desirable. During an extended research on the Pt-catalysed disproportionation of $(ArS)_2$ with $(SiCl_3)_2$[4] we accidentally came across a novel light-induced disproportionation.We disclose herein preliminary results of the light-induced disproportionation reaction of organic dichalcogenides $(R'Z)_2$ (Z = S, Se, Te; R′ = alkyl, aryl) with organo-ditin and -dilead compounds $(R_3M)_2$ (M = Sn, Pb) leading to R_3MZR' in excellent yields [eqn. (1)].[5]

$$(RZ)_2 + (R'_3M)_2 \xrightarrow{\text{room light}} 2RZMR'_3 \quad (1)$$

Z = S, Se, Te; M = Sn, Pb

In a typical experiment, an equimolar mixture of $(PhS)_2$ and $(Me_3Sn)_2$ in C_6D_6 (0.5 M) was placed in a Pyrex tube under nitrogen and exposed to room light at 35 °C.[6] As confirmed by ^{1}H NMR spectroscopy, the starting materials were completely consumed within 20 min and $PhSSnMe_3$ was obtained quantitatively as the sole product. Irradiation was essential for this disproportionation; a control experiment carried out in the dark under similar conditions did not lead to $PhSSnMe_3$ even after 2 h.[7,8] The reaction proceeded equally well in other solvents such as toluene and chloroform. Particularly noteworthy is that even in the *absence* of the solvent, the reaction took place as efficiently. Thus, a colourless liquid of analytically pure $PhSSnMe_3$ was obtained by simply stirring a heterogeneous mixture of 10 mmol of $(PhS)_2$ (2.18 g) and an equivalent amount of $(Me_3Sn)_2$ (3.28 g) for 1 h at 35 °C in room light.

Table 1 demonstrates the wide applicability of the present light-induced disproportionation reaction. Other aromatic disulfides such as $(4\text{-}MeC_6H_4S)_2$, $(4\text{-}ClC_6H_4S)_2$, $(2,4,5\text{-}Cl_3C_6H_2S)_2$ and $(2\text{-}pyS)_2$ all reacted efficiently with $(Me_3Sn)_2$ to afford the corresponding trimethyltin sulfides in quantitative yields. Primary aliphatic disulfides such as $(BuS)_2$ reacted similarly. However, as the alkyl group became bulkier,

17	$(PhSe)_2$	$(PbPh_3)_2$	1.5	$PhSePbPh_3$	96[c]
18	$(PhTe)_2$	$(SnMe_3)_2$	9	$PhTeSnMe_3$	93[c]
19[d]	$(PhTe)_2$	$(PbPh_3)_2$	3	$PhTePbPh_3$	98[c]

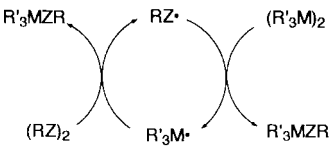
[a] Unless otherwise stated, the reaction was performed as follows: 0.03–0.5 M benzene solution in a Pyrex tube irradiated with a 40 W fluorescent lamp at 35 °C. [b] Yields in parentheses obtained after 7 h reaction time. [c] Traces of decomposition products were also formed. [d] Irradiation with a 200 W tungsten lamp at 50 °C.

DOI: 10.1039/b000309n

the reaction proceeded more slowly; the completion of the reaction between $(CyS)_2$ and $(Me_3Sn)_2$ required > 7 h and the formation of Bu^tSSnMe_3 in the reaction of $(Bu^tS)_2$ with $(Me_3Sn)_2$ under similar reaction conditions was only marginal. Although slower than $(Me_3Sn)_2$, $(Ph_3Sn)_2$ reacted with both aromatic and aliphatic disulfides to produce the corresponding triphenyltin sulfides in quantitative yields.

Similar disproportionation reactions did not take place with disilanes such as $(Me_3Si)_2$, $(MePh_2Si)_2$, $(Ph_3Si)_2$ or $(SiCl_3)_2$ under the same conditions. Digermanes such as $(Me_3Ge)_2$, $(ClMe_2Ge)_2$ and $(Ph_3Ge)_2$ did not react either. However, the reactions of $(Ph_3Pb)_2$ with $(PhS)_2$ and $(BuS)_2$ proceeded smoothly and quantitative yields of the products were obtained. $(PhSe)_2$ was as reactive as $(PhS)_2$ in the above disproportionation reactions. Similar reactions with $(PhTe)_2$ proceeded relatively slowly,[8] but ultimately afforded respectable yields.

$(Bu_3Sn)_2$ has no absorption maximum in the normal UV region. However, its λ_{max} at a wavelength < 215 nm displays strong end absorption that tails to 250–260 nm.[9] $(Ph_3Sn)_2$ and $(Ph_3Pb)_2$ display absorption maxima in the UV region (λ_{max} 248–260 nm for the former depending on the solvent and 294 nm for the latter).[9] Diphenyl dichalcogenides also have absorption maxima in the UV, near-UV or visible regions.[10] Because of these absorptions, various reactions involving ditins[11] or dichalcogenides[10] can very efficiently proceed under photolytic conditions by irradiation with a sunlamp through Pyrex.[12] With these precedents in mind, we envisioned that the present disproportionation reaction proceeds *via* a radical mechanism as shown in Scheme 1.[13] However, the initiation step is uncertain at the present time since precedents suggest that homolytic cleavage of both M–M[11] and Z–Z[10] bonds by light is possible to initiate the reaction. In agreement with the reactivity trends in other reactions of chalcogen-centered radicals (S > Se > Te),[10] the disproportionation of $(PhTe)_2$ proceeded most sluggishly. The decreasing trends in the reactivity of aliphatic disulfides, $(BuS)_2$ > $(CyS)_2$ > $(Bu^tS)_2$, appear to suggest that steric factors of the chalcogen-centered radicals also play an important role.[14]



Scheme 1

In summary, a clean and salt-free route to single source precursors for semiconductors has been presented and the process does not require the use of the volatile organic solvents. These features appear to meet the requirement for 'green' chemistry, which is of contemporary public concern.[15]

Financial support from the Japan Science and Technology Corporation (JST) through the CREST (Core Research for Evolutional Science and Technology) program and a post-doctoral fellowship to F. M. are gratefully acknowledged.

6 Special irradiation apparatus is not necessary for the disproportionation of $(ArS)_2$ with $(Me_3Sn)_2$. Usually, mixing the two reagents in a flask placed about 2 m under a 40 W fluorescent lamp at room temperature for a few minutes leads to quantitative formation of the products. Only when the reactivity was low, was irradiation with a 200 W tungsten lamp performed.

7 $PhSSnMe_3$ was found to be formed only in *ca.* 15% yield by heating a benzene solution of $(PhS)_2$ and $(Me_3Sn)_2$ at 80 °C for 2 h in the dark.

8 Neither $(PhS)_2$ nor $(Me_3Sn)_2$ was detected by ^1H NMR spectroscopy when pure $PhSSnMe_3$ in benzene was exposed to the room light at room temperature, indicating the irreversibility of the disproportionation reaction. Similar phenomena were observed for $PhSeSnMe_3$ and $PhTeSnMe_3$, although decomposition of $PhTeSnMe_3$ (conversion 30%) to Ph_2Te and $(Me_3Sn)_2Te$ was found to have occurred after prolonged irradiation (44 h) at room temperature.

10 UV absorption for $(PhZ)_2$: $(PhS)_2$, λ_{max} 250 nm; $(PhSe)_2$, λ_{max} 330 nm; $(PhTe)_2$, λ_{max} 406 nm. Radical additions of $(PhZ)_2$ to unsaturated carbon–carbon bonds under irradiation of visible light have been studied. For examples, see: A. Ogawa, I. Ogawa, R. Obayashi, K. Umezu, M. Doi and T. Hirao, *J. Org. Chem.*, 1999, **64**, 84; A. Ogawa, R. Obayashi, H. Ine, Y. Tsuboi, N. Sonoda and T. Hirao, *J. Org. Chem.*, 1998, **63**, 881; A. Ogawa, R. Obayashi, M. Doi, N. Sonoda and T. Hirao, *J. Org. Chem.*, 1998, **63**, 4277.

11 Irradiation with a sunlamp through Pyrex efficiently promotes $(Bu_3Sn)_2$-initiated radical chain reactions; see D. P. Curran, M.-H. Chen and D. Kim, *J. Am. Chem. Soc.*, 1989, **111**, 6265.

12 Curran *et al.* have reported that Pyrex shows 1–2.5% transmittance at 250–260 nm, which allows homolytic cleavage of $(Bu_3Sn)_2$. See ref. 11.

13 In agreement with the radical mechanism, heating an equimolar mixture of $(Me_3Sn)_2$ and $(PhS)_2$ in C_6D_6 at 80 °C in the dark in the presence of 10 mol% of AIBN led to 95% conversion after 2 h, whereas the same treatment in the absence of AIBN showed only 15% conversion.

14 $(BuS)_2$ is reported to be 14 times more reactive toward $Bu_3Sn^\cdot$ than $(Bu^tS)_2$, see: J. Spanswick and K. U. Ingold, *Int. J. Chem. Kinet.*, 1970, **2**, 157.

15 Note added at proof: We have found very recently that the December 20 issue of *Chemical Abstracts* has compiled a paper on a new method for the synthesis of stannyl selenides; see V. A. Potapov, S. V. Amosova, V. Svetlana, I. P. Beletskaya, A. A. Starkova, A. V. Martynov and L. Hevesi, *Sulfur Lett.*, 1999, **22**, 237; *Chem. Abstr.*, 1999, **131**, 337113u.

1,2,5-ortho esters of D-arabinose as versatile arabinofuranosidic building blocks. Concise synthesis of the tetrasaccharidic cap of the lipoarabinomannan of *Mycobacterium tuberculosis*

Published on the Web 31st March 2000

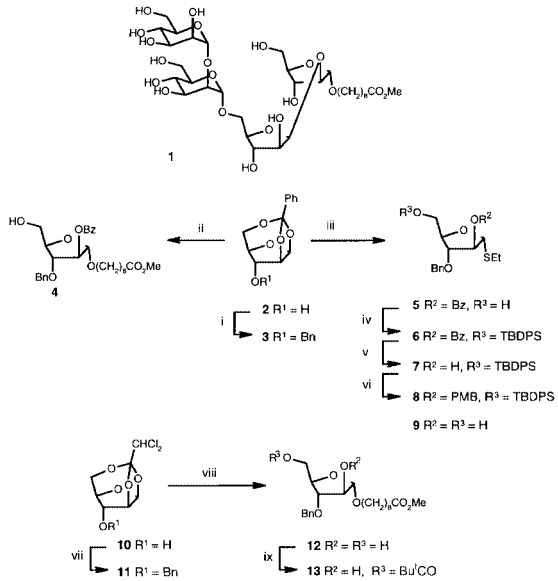
1,2,5-ortho esters of D-arabinose were found to be ideally suited building blocks for the stereoselective formation of α and β arabinofuranosidic linkages after nucleophilic opening of the orthoester with oxygen and sulfur nucleophiles; the tetrasaccharidic cap of the lipoarabinomannan of *Mycobacterium tuberculosis* was then synthesized in a highly convergent manner.

Lipoarabinomannans (LAMs) are highly antigenic polysaccharidic compounds isolated from the cell wall of various species of mycobacteria.[1] They share common structural features, a phosphatidyl *myo*-inositol anchor and a mannan core substituted by an arabinan domain, exclusively composed of D-arabinofuranosidic units.[1] At the ends of this arabinan domain, are found β-D-arabinofuranosides substituted on position 5 by small motifs, called caps, variable on the mycobacterial species.[2–5] Strong modulations of the biological properties of the LAMs were observed for LAMs isolated from different species of mycobacteria and these variations have been tentatively correlated to the structure of these caps.[2,4–8]

In light of the importance of these motifs for the biological properties of the LAMs in relation with the immunopathogenicity of *M. tuberculosis*, we now report the expeditious synthesis of **1** (Scheme 1) the major tetrasaccharide found at the ends of the LAMs of *M. tuberculosis* and *M. bovis* BCG in a form suitable for further conjugation with a protein.[9] Orthoesters **3** and **11** were found to be highly versatile precursors for the elaboration of the two different arabinofuranosidic rings and the construction of the crucial β-arabinofuranosidic linkage. The result is a rapid and convergent synthesis of **1**.

3-*O*-benzyl 1,2,5-benzylidene D-arabinofuranose **3** was readily obtained in 82% yield from the 1,2,5-benzylidene D-arabinofuranose **2** {$[\alpha]_D^{25}$ −28 (*c* 0.94, $CHCl_3$) lit.[10] +28 for the enantiomer} after treatment with benzyl bromide and sodium hydride in dimethylformamide (Scheme 1). $SnCl_4$ catalyzed opening of orthoester **3** with 5 equiv. of methyl 9-hydroxynonanoate[9] in CH_2Cl_2 gave the 2-*O*-benzoyl-α-D-arabinofuranoside **4** as the only isolated product in 76% yield. Complete regio- and stereo-selectivity were observed for the double orthoester opening[11] and none of the isomeric 5-*O*-benzoyl arabinofuranosidic compound was observed with this catalyst. In an analogous manner, ethyl 2-*O*-benzoyl-3-*O*-benzyl-1-thio-α-D-arabinofuranoside **5** was obtained in 80% yield from the opening of **3** with 1.1 equiv. of ethanethiol under $SnCl_4$ catalysis, once again with complete stereocontrol of the orthoester opening.[12,13] Unmasking of the hydroxy group on the 2-position of the arabinofuranosidic ring of thioglycoside **5** for later attachment of the *p*-methoxybenzyl tether[14] was carried out in two steps and gave alcohol **7** in 73% overall yield (Scheme 1).

We also looked at the reactions of 3-*O*-benzyl 1,2,5-dichloroethylidene D-arabinofuranose **11**, available in 90% yield (BnBr, NaH, DMF) from known compound **10**, prepared in only two steps from D-arabinose.[15] As was expected from electronic factors, nucleophilic opening of the orthoester function of **11**

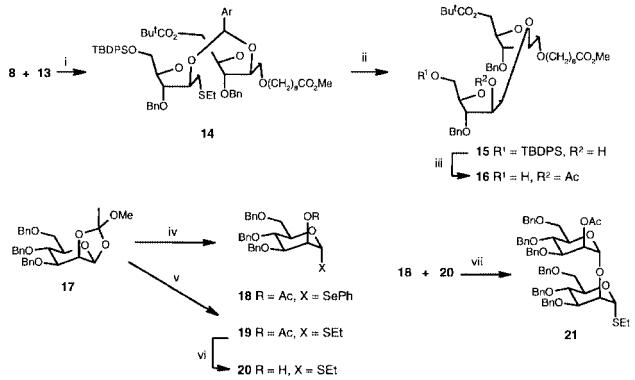


Scheme 1 *Reagents and conditions*: i, NaH, BnBr, DMF, room temp., 1 h, 82%; ii, 5 equiv. methyl 9-hydroxynonanoate, 0.1 equiv. $SnCl_4$, MS 4 Å, CH_2Cl_2, room temp., 15 min, 76%; iii, 1.1 equiv. EtSH, 0.1 equiv. $SnCl_4$, MS 4 Å, CH_2Cl_2, −18 °C, 30 min, 80%; iv, 1.5 equiv. Bu^tPh_2SiCl, 1.5 equiv. imidazole, DMF, room temp., 1 h, 92%; v, 0.1 equiv. MeONa, MeOH, room temp., 79%; vi, 2.5 equiv. BEMP, 2.5 equiv. *p*-MeOBnBr, MeCN, 0 °C to room temp., 1 h, 70%. vii, NaH, BnBr, DMF, room temp., 1 h, 90%; viii, 5 equiv. $HOCH_2(CH_2)_7C(O)OMe$, 2 equiv. $SnCl_4$, MS 4 Å, CH_2Cl_2, room temp., 3 h, then MeONa, MeOH, room temp., 1 h, 60%; ix, 1.5 equiv. Bu^tCOCl, 0.1 equiv. DMAP, pyridine, 0 °C, 1.5 h, 80%.

proved to be more difficult than for **3**. 2 Equiv. of $SnCl_4$ at room temperature were necessary to bring the reaction of **11** with methyl 9-hydroxynonanoate to completion and a mixture of 2-*O*- and 5-*O*-dichloroacetyl α-arabinofuranosides was obtained. α-Arabinofuranoside **12** was isolated in 60% yield after deacylation with sodium methoxide. Selective pivaloylation of the primary hydroxy group of **12** (0 °C, Bu^tCOCl, DMAP, pyridine) gave alcohol **13** ready for glycosylation (80%). Opening of **11** with ethanethiol was also obtained with 1.2 equiv. of EtSH and 0.2 equiv. $SnCl_4$ at 0 °C, deacylation of the mixture of dichloroacetates as above gave **9** in 64% overall yield from **11**. Selective silylation of the primary position of **9** with TBDPSCl and imidazole afforded 73% of the previously prepared **7**. Finally, the 4-methoxybenzyl group was introduced on the 2-position of **7** with 2.5 equiv. of 4-methoxybenzyl bromide[16] and 2.5 equiv. of 2-*tert*-butylimino-2-diethylamino-1,3-dimethylperhydro-1,3,2-diazaphosphorine[17] (BEMP) in acetonitrile to give thioarabinofuranoside **8** in 70% yield.

Coupling of the arabinofuranosidic units and elaboration of the β-arabinofuranosidic linkage were accomplished according to Ogawa's internal aglycon delivery approach.[14,18] Reaction of 1.1 equiv. of **8** with **13** and 1.5 equiv. of 2,3-dichloro-

DOI: 10.1039/b000873g

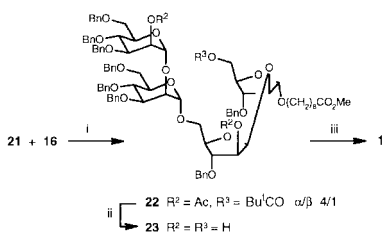


Scheme 2 *Reagents and conditions*: i, 1.1 equiv. **8**, 1 equiv. **13**, 1.5 equiv. DDQ, MS 4 Å, CH_2Cl_2, 0 °C to room temp., 2.5 h, 84%; ii, 1.2 equiv. IDCP, MS 4 Å, CH_2Cl_2, room temp., 1.5 h, 73%; iii, Ac_2O, pyridine, room temp., then 1.2 equiv. Bu^n_4NF, THF, room temp., 0.5 h, 75%, 2 steps; iv, 1.5 equiv. PhSeH, MS 4 Å, cat. $HgBr_2$, MeCN, room temp., 2 h, 75% ; v, 5.5 equiv. EtSH, MS 4 Å, cat. $HgBr_2$, MeCN, room temp., 48 h, 79% ; vi, MeONa, MeOH, room temp., 16 h, 91% ; vii, 1 equiv. **18**, 1.1 equiv. **20**, 1.1 equiv. NIS, 0.1 equiv. TMSOTf, MS 4 Å, CH_2Cl_2, −18 °C to room temp., 71%.

5,6-dicyano-1,4-benzoquinone in CH_2Cl_2 gave the mixed acetal **14** in 84% isolated yield after chromatography (Scheme 2). Intramolecular glycosylation was promoted with 1.2 equiv. of iodonium dicollidine perchlorate (IDCP)[19] in CH_2Cl_2 and gave a rewarding 73% yield of the β-linked disaccharide **15** as the only isolated product. The β-(D) configuration of the new anomeric center was firmly established from the ^1H and ^{13}C NMR data ($\delta_{H\text{-}1'}$ 5.15, $J_{H\text{-}1',H\text{-}2'}$ 4.5 Hz; $\delta_{C\text{-}1'}$ 101.48).[20] Acetylation (acetic anhydride, pyridine) and silyl ether deprotection with tetrabutylammonium fluoride in tetrahydrofuran gave the diarabinofuranoside **16** ready for further elongation (75% from **15**).

The dimannosidic glycosyl donor **21** was efficiently obtained from orthoester **17**[21] taking advantage of the higher reactivity of selenoglycosides over thioglycosides towards activation.[22,23] **17** was first opened with 1.5 equiv. of selenophenol[24] under $HgBr_2$ catalysis and gave (α-selenoglycoside **18** in 75% yield (Scheme 2). The known thioglycoside **19**,[25] obtained in 79% from **17** after $HgBr_2$-promoted ethanethiol opening, was deacetylated (MeONa, MeOH) to give glycosyl acceptor **20** in 91% yield. Selective activation of selenoglycoside **18** with 1.1 equiv. of *N*-iodosuccinimide (NIS) and 10% trimethylsilyl trifluoromethanesulfonate (TMSOTf),[26] and coupling with 1.1 equiv. of thioglycoside **20** in CH_2Cl_2 at −18 °C gave the expected α-linked dimannosidic compound **21** in 71% yield with complete control of the new anomeric center. **21** was isolated in slightly lower yield (64%) when the original silver trifluoromethanesulfonate/potassium carbonate combination[22] was used as promoter for the glycosylation of **20** with **18**.

Final coupling was done by glycosylation of disaccharide **16** with 1.5 equiv. of thiodisaccharide **21** under NIS/catalytic TMSOTf activation (Scheme 3). A 70% yield of tetrasaccharidic compounds **22** was obtained as a 4 : 1 α,β anomeric



Scheme 3 *Reagents and conditions*: i, 1 equiv. **16**, 1.5 equiv. **21**, 1.7 equiv. NIS, 0.15 equiv. TMSOTf, MS 4 Å, CH_2Cl_2, −15 °C, 1 h, 70%; ii, 0.5 M MeONa, MeOH, room temp., 5 h, 75%; iii, H_2, $Pd(OH)_2$/C, MeOH, room temp., 1 h, 65%.

mixture on the H-1″ anomeric center. This mixture could not be separated at this stage, so the ester groups were removed with 0.5 M sodium methoxide solution in methanol (75%) and the mixture of triols was chromatographed to give pure **23**. Hydrogenolysis of the benzyl groups [H_2, $Pd(OH)_2$/C, MeOH] gave the target compound **1**[27] in 65% yield.

In conclusion, orthoester derivatives of arabinose and mannose were used for the efficient synthesis of **1**, the tetrasaccharidic cap of the lipoarabinomannan of *M. tuberculosis*, *via* a convergent route using minimal protecting groups manipulation and selective anomeric activation. Both α- and β-arabinofuranosides were obtained with complete stereocontrol from 3-*O*-benzyl-1,2,5-orthoesters of D-arabinose. Extension of this methodology to the elaboration of other complex polyarabinofuranosidic structures and synthesis of neoantigens from **1** for biological evaluation are currently under way.

Received (in Cambridge, UK) 12th January 2000, Accepted 6th March 2000
Published on the Web 31st March 2000

Mixed self-assembled monolayers of pyrene and porphyrin have been prepared to mimic efficient energy transfer in the photosynthetic antenna complex.

X-Ray structural determination of the photosynthetic antenna complex[1] has stimulated many organic chemists to design covalently-linked multichromophores such as linear, circular and dendritic porphyrin oligomers for mimicry of efficient energy transfer (EN) process.[2,3] An alternative strategy involves molecular assembly of chromophores in organized media. Langmuir–Blodgett films and lipid bilayer membranes have been frequently employed to construct light-harvesting systems.[4–10] However, these systems seem to be inapplicable in terms of stability, uniformness and manipulation. In contrast, the use of self-assembled monolayers (SAMs)[11] may be a promising approach to organize chromophores on substrates because of their uniform and well ordered structures. Here, we report the first preparation of mixed SAMs of pyrene **1** and porphyrin **2** on a gold surface (Fig. 1) in which efficient singlet–singlet EN from **1** to **2** has been detected successfully.

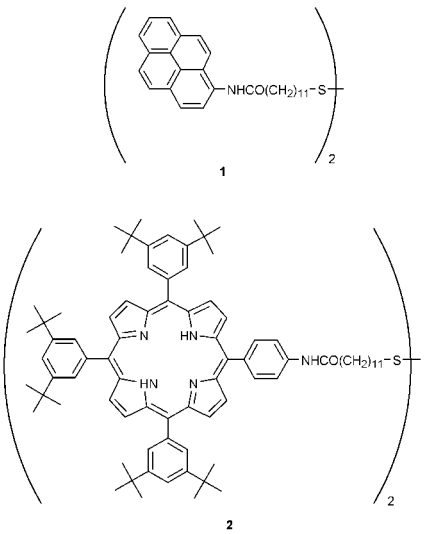

Fig. 1 Molecular structure of pyrene and porphyrin dimers **1** and **2**.

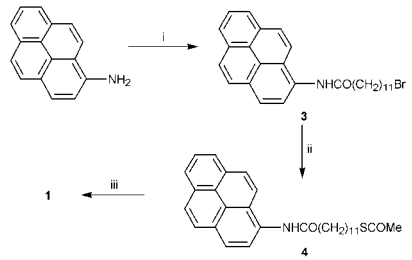
The synthetic route to **1** is shown in Scheme 1. Condensation of 1-aminopyrene with 12-bromododecanoic acid in the presence of 2-chloro-4,6-dimethoxy-1,3,5-triazine afforded **3** in 29% yield. Bromide **3** was converted to disulfide **1** *via* thioesterification with potassium thioacetate and subsequent base deprotection of **4**. Porphyrin disulfide **2** was prepared by following the same procedures as described previously.[12,13] The structures of **1** and **2** were verified by spectroscopic analyses including ^{1}H NMR and MALDI-TOF mass spectra.†



Scheme 1 *Reagents and conditions*: i, 12-bromododecanoic acid, 2-chloro-4,6-dimethoxy-1,3,5-triazine, THF, 29%; ii, potassium thioacetate,THF–EtOH, 52%; iii, KOH, THF–MeOH, 42%.

Monolayers of mixtures of **1** and **2** were formed by the coadsorption of **1** and **2** onto Au(111) mica substrates (denoted **1**–**2**/Au, where / represents an interface). The coadsorption onto the gold surface was carried out from CH_2Cl_2 solutions containing **1** and **2** with a total concentration of 10 μM [molar ratio of **1**:**2** = (a) 100:0, (b) 90:10, (c) 50:50, (d) 10:90, (e) 0:100] for 20 h to complete mixed SAM formation. After soaking, the gold substrate was washed well with CH_2Cl_2 and dried with a stream of argon. A cyclic voltammetric experiment using **1**–**2**/Au in CH_2Cl_2 containing 0.1 M $Bu^n_4NPF_6$ electrolyte with a sweep rate of 50 mV s^{-1} (electrode area, 0.48 cm^2) was performed to estimate the surface coverage (Fig. 2). The adsorbed amount of **1** and **2** on **1**/Au [**1**:**2** = (a) 100:0] and **2**/Au [**1**:**2** = (e) 0:100] was calculated from the charge of the anodic peak of the pyrene and the porphyrin moieties as 2.8×10^{-10} mol cm^{-2} (= 59 $Å^2$ $molecule^{-1}$)‡ and 1.5×10^{-10} mol cm^{-2} (= 110 $Å^2$ $molecule^{-1}$),[12] respectively. These values indicate the formation of the well packed structures of **1** and **2** on the gold surface. However, an attempt to determine the adsorbed amounts of **1** and **2** in the mixed SAMs was

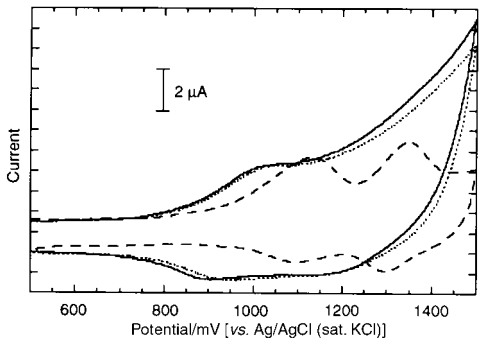


Fig. 2 Cyclic voltammograms of **1**/Au (—), **2**/Au (----), and a mixed SAM of **1** and **2** on a gold surface (·····) from CH_2Cl_2 solution using a molar ratio of 50:50.

unsuccessful because of the broad wave of the first oxidation due to the pyrene and porphyrin moieties.

Fig. 3 shows absorption spectra of **1** and **2** in CH_2Cl_2 and of **1**–**2**/Au [**1**:**2** = (c) 50:50] using the transmission mode in air.[12] The absorption band of **1** (λ_{max} = 337 nm) and **2** (λ_{max} = 424 nm) on the gold surface is blue- and red-shifted by 7 and 3 nm, respectively, as compared to that of **1** and **2** in CH_2Cl_2. Assuming that the relative ratio of the molar absorption coefficients of **1** and **2** in the mixed SAMs are the same as those in CH_2Cl_2 [**1**: 4.90×10^4 M^{-1} cm^{-1} (λ_{max} = 344 nm); **2**: 1.08×10^6 M^{-1} cm^{-1} (λ_{max} = 421 nm)], the relative ratios of **1**:**2** in the mixed SAMs are estimated as (a) 100:0, (b) 99:1, (c) 94:6, (d) 85:15 and (e) 0:100. The strong π–π interactions of the pyrene moieties compared with the relatively weak interaction between the porphyrin moieties (as a consequence of the bulky tert-butyl groups) may be responsible for the preference of adsorption of **1** over **2** on the gold surface. In addition, the fact that the pyrene molecules occupy about half the surface area of the porphyrins would lead to a thermodynamic preference for pyrene adsorption, since displacement of a porphyrin for two pyrenes results in an extra S–Au interaction.

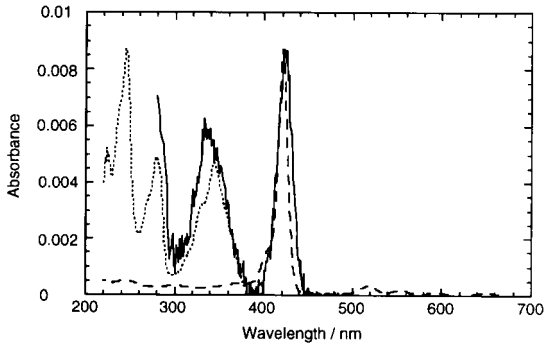

Fig. 3 Absorption spectra of **1** (⋯) and **2** (----) in CH_2Cl_2 and a mixed SAM of **1** and **2** on a gold surface (—) from CH_2Cl_2 solution using a molar ratio of 50:50. The spectra are normalized for comparison.

Steady-state corrected fluorescence spectra of **1** and **2** in CH_2Cl_2 were measured with the excitation wavelength at 340 and 427 nm, respectively, and were compared with those of **1**/Au and **2**/Au. The fluorescence spectrum of **2**/Au is essentially the same as that of **2** in CH_2Cl_2 as shown in Fig. 4.[12] Fluorescence emission of **1** in Fig. 4 overlaps well with absorption of **2** in Fig. 3. Thus, it is expected that excitation of the pyrene moiety as an antenna chromophore may lead to efficient singlet–singlet EN from the pyrene to the porphyrin in the SAMs. Unfortunately, however, the emission of **1**/Au was too weak to be detected. No detectable fluorescence from the pyrene or the porphyrin moiety was observed in **1**–**2**/Au under steady state irradiation. Then, time-resolved, single-photon counting fluorescence studies were made for **1**–**2**/Au§ [**1**:**2** = (a) 100:0, (b) 90:10, (c) 50:50, (d) 10:90, (e) 0:100) as well as for **1** and **2** in solutions with an excitation wavelength at 280 nm, where the light is mainly absorbed by the pyrene moiety. In each case the decay of the fluorescence intensity at 385 nm and/or 720 nm (due to the singlet excited states of the pyrene and the porphyrin, respectively) could be monitored. The decay curve could be fitted as single exponential except for **1** at 385 nm in CH_2Cl_2. The fluorescence lifetimes of **1**/Au at 385 nm (23 ps) and **2**/Au at 720 nm (40 ps) were much shorter than those of **1** [7.4 ns (30%), 3.2 ns (70%)] and **2** (8.1 ns) in CH_2Cl_2. This indicates that the excited singlet states of the pyrene and the porphyrin are quenched by the gold surface through EN, as reported previously.[12] The fluorescence lifetimes of the pyrene moiety in **1**–**2**/Au at 385 nm decreased with an increase in the relative ratio of the porphyrin to the pyrene [(a) 23 ps, (b) 20 ps, (c) 11 ps, (d) 8.8 ps].¶ The fluorescence lifetimes of the porphyrin moiety in **1**–**2**/Au at 720 nm also decreased with an increase in the relative ratio of the porphyrin to the pyrene [(b) 92 ps, (c) 88 ps, (d) 60 ps, (e) 40 ps]. A likely explanation for these observations is that efficient EN (> 62%) occurs from the excited singlet state of the pyrene to the porphyrin, followed by energy transfer among the porphyrins.[14]

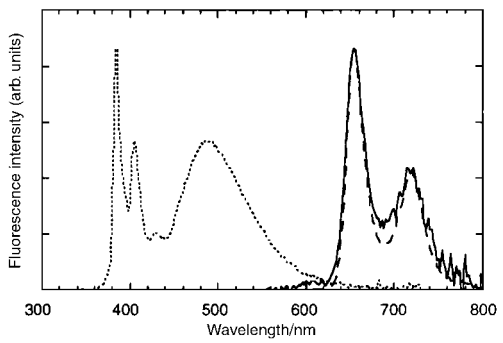

Fig. 4 Fluorescence spectra of **1** (⋯) and **2** (----) in CH_2Cl_2 and a SAM of **2** on a gold surface (—) with excitation at 340 nm for **1** and 427 nm for **2**. The spectra are normalized for comparison.

In conclusion, we have developed the first mixed self-assembled monolayers of pyrene and porphyrin in which efficient singlet–singlet EN takes place from the pyrene to the porphyrin. Further improvement on the ability of harvesting the light may be made by choosing a suitable couple of different chromophores which absorb visible light extensively.

† *Selected data* for **1**: δ_H(270 MHz; $CDCl_3$) 7.7–8.3 (m, 20H), 2.68 (t, *J* 8 Hz, 4H), 2.58 (t, *J* 8 Hz, 4H), 2.0–1.0 (m, 36H); *m/z* (MALDI-TOF; positive mode) 862 ($M + H^+$).

‡ Densely packed monolayer films are known to retard ion transport and electrochemical accessibility. Since pyrene is a planar aromatic molecule, the pyrene moiety of **1** may be densely packed owing to the strong π–π stacking in the monolayers. Thus, the real value of surface coverage may be larger, as compared to the estimated value using cyclic voltammetry.

§ For the time-resolved fluorescence measurements, gold substrates were prepared by a vacuum deposition technique with titanium (50–100 Å) and gold (200–1000 Å) in sequence onto a Si(100) wafer (Sumitomo Sitix Corp.).

¶ Monomer emission (*ca.* 400 nm) as well as excimer emission (*ca.* 500 nm) were observed for **1** in CH_2Cl_2, as shown in Fig. 4. The fluorescence lifetimes of **1**–**2**/Au at 500 nm also decreased with an increase in the relative ratio of the porphyrin to the pyrene.

The silica supported tantalum hydride $(\equiv SiO)_2Ta–H$ 1, catalyses the H/D exchange reaction between CH_4 and CD_4 at 150 °C producing the statistical distribution of all methane isotopomers.

Methane is the most thermodynamically stable alkane. Its activation necessarily requires the cleavage of a C–H bond and, for example, the H/D exchange reaction between CH_4 and a deuterium source (D_2, D_2O or a deuterated alkane or arene) is a typical process involving C–H bond activation.[1] Some of the first examples were observed in the 1930s and 1940s using metal surfaces.[2] Numerous examples have appeared since in heterogeneous catalysis,[3] while only few homogeneous systems are known to perform the catalytic H/D exchange with CH_4.[4]

Surface OrganoMetallic Chemistry (SOMC) lies at the interface between homogeneous and heterogeneous catalysis and consists in grafting a molecular organometallic complex onto an oxide or metal surface to generate ultimately single site catalysts.[5] This strategy has led to the synthesis and the characterization of a silica supported tantalum hydride, $(\equiv SiO)_2Ta–H$ **1**, a highly electrophilic complex (formally a eight electron complex).[6] It can activate the C–H bond of cyclic alkanes, to form a tantalum cycloalkyl species, $(\equiv SiO)_2Ta–C_nH_{2n-1}$.[7] It also catalyses both the low temperature hydrogenolysis of alkanes[8] and the new reaction of alkane metathesis,[9] which transforms acyclic alkanes into their higher and lower homologues. Here, we report that **1** also catalyses the H/D exchange reaction between CH_4 and CD_4, leading to the statistical formation of all possible isotopomers.

When a 55:45 mixture of CH_4/CD_4 was contacted with **1** at 150 °C for 10 h, it was converted into a mixture of all the isotopomers of methane as a statistical distribution (Fig. 1).† At low conversion, d_1- and d_3-methanes were formed faster than d_2-methane, suggesting that the H/D exchange was stepwise *via* the exchange of one H/D atom at a time [Fig. 1(a)]. This initial CH_4/CD_4 mixture gave a mixture of methane isotopomers, of which CD_2H_2 was the major product. If a 65:35 mixture of CH_4/CD_4 was contacted with **1** under identical conditions, the evolution toward a different statistical distribution of all isotopomers was observed. The composition of the equilibrated mixture according to GC–MS was 24, 40, 24, 12, 0% of d_0-, d_1-, d_2-, d_3- and d_4-methanes, respectively, in good agreement with the calculated statistical distribution (18, 38, 31, 11, 1.5%), which was no longer centered on CD_2H_2 since there was an excess of H- over D-atoms in the initial mixture.

The number of turnovers for this exchange reaction can be estimated according to eqn. (1) if considering that (a) the formation of CDH_3 and CD_3H requires at least one C–H(D) bond cleavage and formation from CH_4 and CD_4, respectively, and that (b) the formation of CD_2H_2 necessitates at least two C–H bond cleavages and formations from either CH_4 or CD_4

$$\text{TON} = [Q(CDH_3) + Q(CD_3H) + 2\,Q(CD_2H_2)]/Q(\text{Ta}) \quad (1)$$

Q(X) represents the amount (in mol) of the compound X.

The number of turnovers as defined in eqn. (1) is underestimated since it does not take into account degenerate processes such as the exchange of a D atom with another D atom. The calculated TON for the H/D exchange is therefore *ca.* 200 after 6 h of reaction. For a comparison, the metathesis of ethane catalysed by the same surface complex **1** under similar experimental conditions has reached a TON of *ca.* 4 after 6 h.[9] The higher activity of **1** for H/D exchange reaction is however not surprising since this process involves C–H in place of C–C bond cleavage for alkane metathesis.

A similar H/D-exchange also occurs between deuterated methane and hydrogen. When a 1:2 mixture of CD_4/H_2 (P_{tot} = 200 Torr) was contacted with **1** (52 mg, 5.2 wt% Ta) at 150 °C, the formation of d_0-, d_1-, d_2-, d_3-methanes could be detected after 40 min by IR spectroscopy. A new stable composition of the gas mixture, containing all the deuterated methanes, was reached after several hours, which corresponded to the statistical distribution of all H/D atoms (7.6, 15.8, 35.8, 26.6, 14.2% of d_0-, d_1-, d_2-, d_3- and d_4-methanes, respectively, *cf.* the calculated theoretical composition of 6, 25, 37.5, 25, 6%). The initial rates obtained in the exchange of CH_4/CD_4 and CD_4/H_2 do not appear to be significantly different, which is in agreement with the cleavage of the C–H bond being the rate-determining step for both transformations.

During the reaction with CH_4/CD_4 mixtures, the evolution of **1** could be followed by *in situ* IR spectroscopy. The addition at room temperature of a mixture of d_0- and d_4-methanes to **1** did not lead to a significant decrease in intensity of the ν(Ta–H) band, centered at 1825 cm^{-1}.[6] However, after 45 min at 150 °C, the ν(Ta–H) band was reduced to about half its initial intensity, and a new band at 1323 cm^{-1} was observed, which corre-

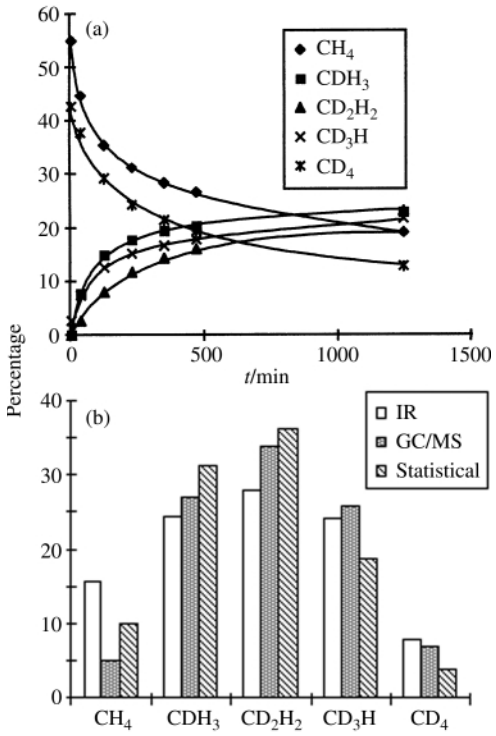

Fig. 1 CH_4/CD_4 exchange reaction (CH_4/CD_4 = 55:45; P_{tot} = 200 Torr; 150 °C, 36 mg of **1** (6.1 wt% Ta)). (a) Isotopomeric composition of the gas phase *vs.* time. (b) Distributions of the different isotopomers at the end of the reaction (2500 min).

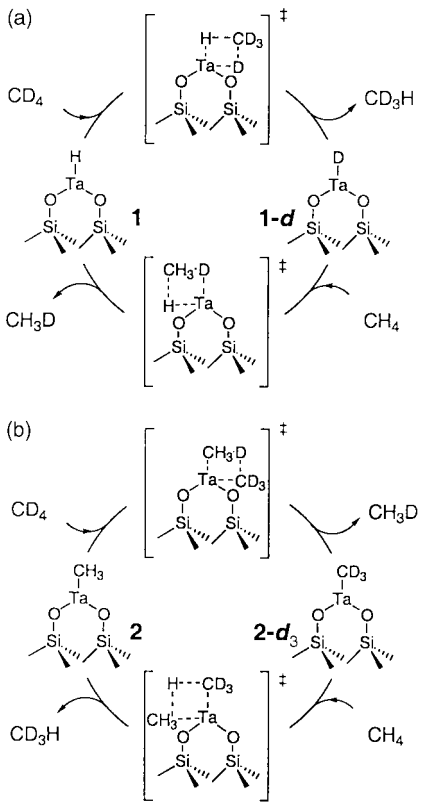
DOI: 10.1039/a910239f

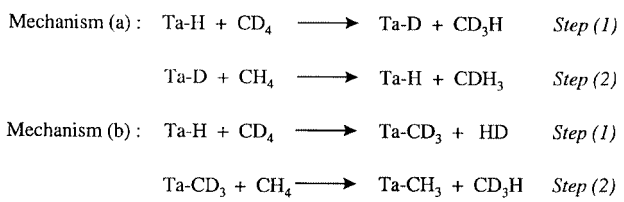
sponded to a ν(Ta–D) vibration.‡ No peaks associated with Ta–CH_3 or Ta–CD_3 were detected, but these types of surface species are usually difficult to observe by IR spectroscopy.[7] In fact, independent experiments showed that hydrolysing the surface species formed after reacting **1** with CH_4 (P = 200 Torr, T = 150 °C, 2 days) gave methane in the gas phase, which probably arose from the hydrolysis of a surface tantalum methyl, $(\equiv SiO)_2Ta–CH_3$ **2**. This consequently shows that **1** can be converted into **2** under the H/D exchange experimental conditions although the complete disappearance of both the Ta–H and Ta–D vibration bands has never been observed.

Two mechanisms for the H/D exchange reaction between CH_4 and CD_4 can be proposed. Both rely on a σ-bond metathesis C–H activation step and involve different active species, *i.e.* **1** or **2** (Scheme 1).



Scheme 1

A two-step experiment, in which **1** is first contacted with CD_4 (step 1) and then with CH_4 (step 2) under the same conditions, should provide a different isotopomeric distribution depending on the reaction mechanism (Scheme 2).



Scheme 2

Therefore, the reaction of CD_4 (30 Torr) with **1** at 150 °C for 3 h (step 1) led to the formation of CD_3H as the sole methane isotopomer in the gas phase. After removing the gas phase, the addition of 20 Torr of CH_4 (step 2) followed by a 3 h reaction at 150 °C gave CDH_3 as the only deuterated product present in the gas phase. This shows that despite the probable formation of Ta–CD_3 species in step 1 (*vide supra*), it does not participate efficiently in the H/D exchange process since CD_3H has not been observed [mechanism (b), step 2]. Consequently, mechanism (a) which only involves Ta–H bonds instead of Ta–C bonds [mechanism (b)] appears to be the most consistent to describe the H/D exchange between methanes. This observation also agrees with previous data relative to the stability of four-center intermediates, in which a carbon atom opposite to the metal [Scheme 1(a)] instead of a hydrogen/deuterium atom [Scheme 1(b)] is preferred.[4e]

In summary, the silica supported tantalum hydride **1** catalyses the H/D exchange reaction in CH_4/CD_4 mixtures. This reaction proceeds under mild conditions and leads to the formation of the statistical distribution of all isotopomers of methane. Its rate is approximately two orders of magnitude faster than that of the alkane metathesis reaction. A mechanism in which the tantalum hydride species is the active intermediate in the catalytic cycle rather than the Ta–CH_3 species is consistent with the experimental observations.

Notes and references

† A statistical distribution corresponds to a random distribution of all hydrogen and deuterium atoms among the five possible isotopomers of methane and can be calculated by the coefficients of the polynom: $(d_0 + d_4)^4$, where d_0 and d_4 represent the initial amount of non-deuterated and perdeuterated methane, respectively. The consumption of CH_4 and CD_4 as well as the formation of the different isotopomers of methane (d_1, d_2, d_3) were monitored by IR spectroscopy. CH_4, CDH_3, CD_2H_2, CD_3H and CD_4 show characteristic IR bands at 1347 cm^{-1} (CH_4), 1156 cm^{-1}, (CDH_3), 1090 cm^{-1} (CD_2H_2), 1034 cm^{-1} (CD_3H) and 994 cm^{-1} (CD_4). The isotopomeric composition of the gas phase was also measured by GC–MS at the end of the reaction. The determination of the isotopomeric distribution was evaluated by minimizing the sum of the square difference of the respective peaks of calculated theoretical and experimental spectra. The calculated theoretical spectra were generated by incrementing the selectivity of various relative amounts of d_0-, d_1-, d_2-, d_3- and d_4-methanes, which fragmentation patterns were taken from *Compilation of mass spectral data*, ed. A. Cornu and R. Massot, Heyden & Son Limited, London, 1966. The mass spectrum of a mixture of variously labelled methanes was considered according to a peak distribution in the range *m/z* 13–20.

‡ Changes in the intensity of the Ta–D vibration band are not easily observed since this band appears at the border of the spectral window of silica and is partially truncated.

Synthesis of a chiral adamantoid network— the role of solvent in the construction of new coordination networks with silver(I)

Alexander J. Blake, Neil R. Champness,* Paul A. Cooke and James E. B. Nicolson

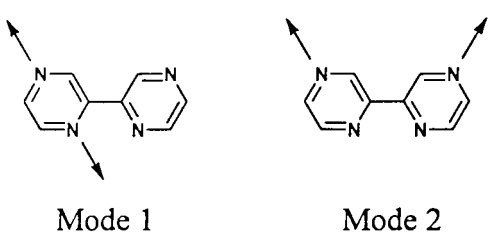
School of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD. E-mail: Neil.Champness@nottingham.ac.uk

Received (in Cambridge, UK) 15th December 1999, Accepted 6th March 2000
Published on the Web 3rd April 2000

Depending on the crystallisation solvent used, reaction of 2,2′-bipyrazine with $AgBF_4$ results in the formation of either a chiral three-dimensional adamantoid coordination network or a two-dimensional sheet incorporating five coordinate Ag(I) ions.

Inorganic supramolecular chemistry and in particular the construction of polymeric coordination networks is an extremely topical area of research.[1] Chiral coordination polymers are particularly intriguing as such systems have potential future applications as stereoselective hosts for the separation of racemic mixtures. One of the most obvious methods of introducing chirality into coordination polymers is to use polymeric helicates and this method has been exploited to generate one-dimensional polymers.[2–4] Some of these polymeric helices spontaneously resolve through weak π–π[3] or H-bonding[4] interactions to give chiral three-dimensional structures within a given crystal. Structures formed through stronger metal–ligand bonds are rare[5] and resolution often relies upon weaker interactions[6] to induce the chirality within the system. We are interested in developing a strategy for preparing three-dimensional coordination polymers in which the chirality of the system is introduced *via* these more robust metal–ligand interactions, an integral feature of the network itself. We have targeted one of the most commonly studied structural motifs in coordination polymer chemistry, namely the adamantoid or super-diamondoid structure.[7,8] Such compounds, formed by the reaction of tetrahedral metal ions [*e.g.* Cu(I) or Ag(I)] with linear connecting units (*e.g.* 4,4′-bipyridyl), may not, at first, be an obvious choice. However, although conventionally considered to be built from edge-sharing adamantane units, such networks may also be thought of in terms of fused 4_1 and 4_3 helices.[8] These helices display opposing hands so that the conventional adamantoid structure does not exhibit chirality.

Our strategy was to see whether we could perturb the balance of these helices in order to remove the racemic nature of their orientation. In an attempt to achieve this, we have targeted a ligand system [2,2′-bipyrazine (bpyz)] which provides two different modes by which it can bridge adjacent metal centres. This ligand provides not only two independent types of binding sites, the chelating bidentate site and the two monodentate N-donor sites, but also two possible modes for bridging metal centres (Scheme 1). These two bridging modes provide a possible mechanism for generating two independent helices when reacted with a suitable metal centre and thus, potentially, an asymmetric adamantoid network. Two ligands which have a similar combination of one bidentate and two monodentate donor sites, 2,2′-bi-1,6-napthyridine and 5,5′-dicyano-2,2′-bipyridine, have previously been shown to generate one-dimensional helical structures with Cu(I)[9] and Ag(I)[10] in the elegant work of Janiak and coworkers but no examples of three-dimensional helical structures were prepared.



Scheme 1 Two possible bridging modes demonstrated by 2,2′-bipyrazine.

Single crystals of $\{[Ag(bpyz)](BF_4)\}_\infty$ were prepared by slow mixing of solutions of $AgBF_4$ and the ligand in $MeNO_2$, followed by diffusion of diethyl ether vapour into the homogeneous reaction solution.† Single crystal X-ray diffraction experiments‡ revealed that $\{[Ag(bpyz)](BF_4)\}_\infty$ crystallises in the chiral tetragonal space group $P4_32_12$ and that the Ag(I) centre is coordinated by one chelating ligand and by two monodentate N-donors from two further bpyz ligands in a distorted tetrahedral geometry. Each Ag(I) centre is linked to four nearest-neighbour Ag(I) centres, two *via* the chelating ligand and two more through the two monodentate pyrazine-like donors forming a distorted adamantoid array. Inspection of the extended lattice viewed down the *c*-axis confirms that the structure forms two distinct channels (A and B) which represent different helices running through the network (Fig. 1). The square-shaped channel, A (*ca.* 4.9 Å cross-section), runs through a 4_3 helix in which each Ag(I) centre is linked to the next Ag(I) centre along the helix through a pyrazine unit (bridging mode 1, Scheme 1) [Fig. 2(a)]. In contrast, the rhomboid-shaped channel, B (*ca.* 3.5 Å cross-section), runs through a 2_1 helix in which adjacent Ag(I) centres are linked through bridging mode 2 (Scheme 1) *via* two monodentate N-donor ligands [Fig. 2(b)]. Whereas in a conventional adamantoid lattice, adjacent helices which have opposing hands are chemically identical, in $\{[Ag(bpyz)](BF_4)\}_\infty$ adjacent anti-parallel helices are chemically distinct, displaying different bridging modes and different pitches. Therefore the structure of $\{[Ag(bpyz)](BF_4)\}_\infty$ has an overall chirality and represents the

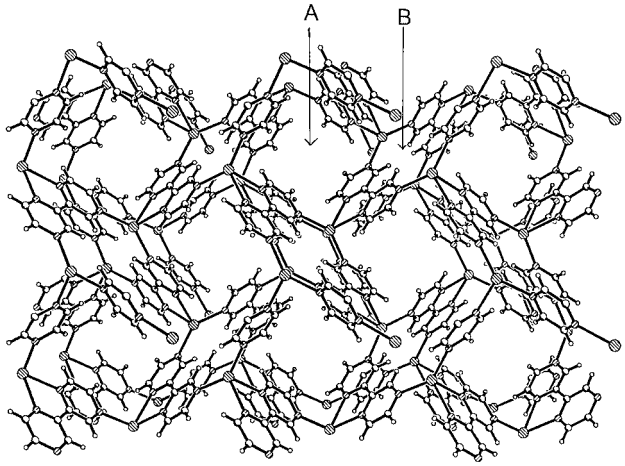


Fig. 1 View of the two different channels formed in $\{[Ag(bpyz)](BF_4)\}_\infty$. The square-shaped channels (A) are surrounded by the 4_3 helices and the rhomboid-shaped channels (B) by 2_1 helices (silver, left-hatch; nitrogen, right-hatch).

DOI: 10.1039/a909868b

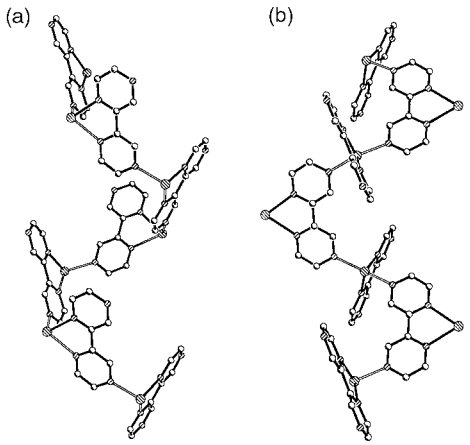

Fig. 2 (a) View, perpendicular to channel A, showing the 4_3 helix and illustrating the propagation of the channel periphery through bridging mode 1; (b) view, perpendicular to channel B, showing the 2_1 helix and illustrating propagation through bridging mode 2 (silver, left-hatch; nitrogen, right-hatch).

first example of a chiral adamantoid network. The channels are filled by BF_4^- counter-anions and $MeNO_2$ solvent molecules. Interestingly the BF_4^- anions sit exclusively in the channel generated by the 2_1 helix (channel B) leaving the more open channels generated by the 4_3 helix (channel A) open for solvent inclusion. This channel represents some 45.2%[11] of the total crystal volume and therefore this system appears promising for potential use as a chiral host material.

When single crystals were grown in an analogous manner but replacing non-coordinating $MeNO_2$ with the co-ordinating solvent MeCN, a different product, $\{[Ag(bpyz)(MeCN)](BF_4)\}_\infty$, was isolated. Single crystal X-ray diffraction experiments‡ show that this network adopts an entirely different structure. In this case, each Ag(I) centre coordinates a MeCN ligand leading to a distorted trigonal-bipyramidal Ag(I) environment. As with $\{[Ag(bpyz)](BF_4)\}_\infty$ each Ag(I) centre is coordinated by one chelating and two monodentate bpyz ligands resulting in each Ag(I) being linked to four nearest-neighbour Ag(I) junctions. However, in this case, the coordination of the MeCN ligand flattens the extended lattice to give a two-dimensional (4,4) sheet (Fig. 3). Each of these sheets undulates, with the MeCN ligands protruding from its surface resulting in interdigitation of adjacent $\{[Ag(bpyz)(MeCN)](BF_4)\}_\infty$ layers. The five-coordinate geometry observed here is rare for Ag(I), which prefers linear or tetrahedral coordination, and has only been observed three times before within coordination networks.[12]

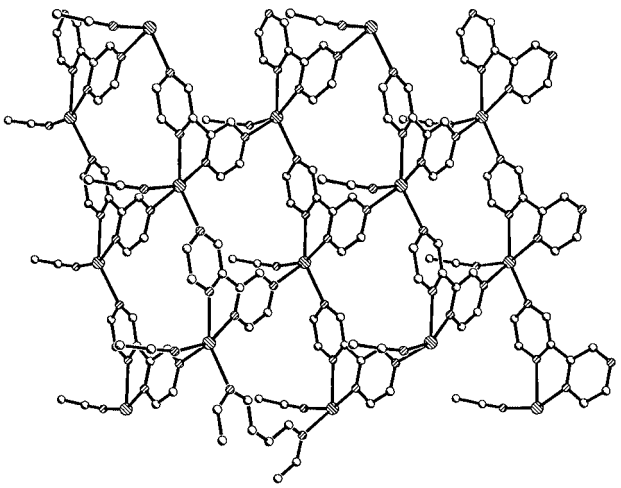

Fig. 3 View of the (4,4) two-dimensional sheet formed by $\{[Ag(bpyz)(MeCN)](BF_4)\}_\infty$ (silver, left-hatch; nitrogen, right-hatch).

In conclusion, we have shown that by using a ligand that can exhibit different bridging modes we can induce the formation of a chiral adamantoid network. The effect of solvent of crystallisation upon network structure has also been demonstrated by the formation of an extended two-dimensional lattice which incorporates five-coordinate Ag(I) centres. We are currently investigating whether the chirality of the adamantoid lattice can be controlled by the use of chiral anions.

We would like to thank the University of Nottingham (J. E. B. N.) and the EPSRC for support.

† *Experimental*: $\{[Ag(bpyz)](BF_4)\}_\infty$: a solution of $AgBF_4$ (10 mg, 0.05 mmol) in $MeNO_2$ (10 cm^3) was slowly diffused into a solution of 2,2′-bipyrazine {bpyz} (8 mg, 0.05 mmol) in $MeNO_2$ (10 cm^3) to give a homogeneous reaction solution. Diethyl ether was then diffused into the reaction solution affording colourless block crystals. Yield (8 mg, 44%). $\{[Ag(bpyz)(MeCN)](BF_4)\}_\infty$ was prepared analogously but replacing $MeNO_2$ with MeCN. Yield (54%). Satisfactory spectroscopic and analytical data were obtained.

‡ *X-Ray experimental, general procedures*: data for both compounds were collected on a Stoe Stadi-4 four-circle diffractometer using graphite monochromated Mo-Kα radiation (λ = 0.71073 Å). Hydrogen atoms were placed in geometrically calculated positions and allowed to ride on their parent atoms.

Received (in Cambridge, UK) 9th February 2000, Accepted 6th March 2000
Published on the Web 3rd April 2000

The reaction of $(C_6F_5)_2BCl$ with trimethylsilyl azide results in the formation of $(C_6F_5)_2BN_3$ 1; evaporation of the stabilizing solvent results in irreversible dimerization yielding $[(C_6F_5)_2BN_3]_2$ 1a as the first example of a dimeric boron azide; in the presence of pyridine a stable adduct $(C_6F_5)_2BN_3$·py 2 is isolated.

Extending the first report in boron azide chemistry by Wiberg and Michaud in 1954, Paetzold *et al*. has made remarkable contributions on this field.[1,2*a–e*] To our knowledge all of the liquid or solid boron azides reported in the literature are monomeric except for the trimeric boron dihalide azides $(BX_2N_3)_3$ (X = F, Cl, Br) and dimethylboron azide which shows a temperature dependent oligomerization.[3*a,b*] The structure of boron dichloride azide was determined by Müller in 1971, confirming the six-membered boron nitrogen heterocycle with diazo groups bound to nitrogen.[4] Here, we report on the synthesis and structural characterization of a novel dimeric boron azide, which can be considered as a *N*,*N*′-diazodiazadiboratacyclobutane.

Bis(pentafluorophenyl)boron chloride was reacted with trimethylsilyl azide in a toluene solution and the resulting mixture was monitored by NMR spectroscopy.† A single resonance was observed in the ^{11}B NMR spectrum at δ 43.9, in the region typical for three-coordinate boron. The ^{19}F NMR spectrum shows three signals for the pentafluorophenyl substituents at δ −131.4 (*o*-F), −146.4 (t, *p*-F, $^3J_{FF}$ 20.8 Hz) and −161.0 (*m*-F). In the ^{14}N NMR spectrum three resonances for covalent azide nitrogens are observed δ −144 (N_β), −160 (N_γ) and −322 (N_α).[5] The NMR data clearly indicate the formation of monomeric bis(pentafluorophenyl)boron azide **1**. After removal of the solvent, **1a** was obtained as a colorless solid which is insoluble in common organic solvents. For the NMR study of **1**, the reaction had to be performed in toluene or benzene as a solvent. In other solvents such as hexane, dichloromethane or chloroform, **1a** precipitated immediately.

The IR spectrum of solid **1a** shows a strong absorption at 2202 cm^{-1} which is the typical region for the asymmetric stretching vibration of azides.[6] However, in comparison to the corresponding asymmetric stretching vibration found for diphenylboron azide (2120 cm^{-1}), this vibration is significantly shifted to a higher wavenumber and is almost identical with that found for trimeric boron dichloride azide $(BCl_2N_3)_3$ (2210 cm^{-1}) which has bridging azides.[2*e*,7] In the Raman spectrum, $\nu_{as}(N_3)$ was found at 2209 cm^{-1} as a peak of medium intensity (Fig. 1).

A mass spectrum of **1a** recorded in the EI mode did not show a molecular ion peak M^+ and is therefore not expressive regarding a dimeric structure. The monomer **1** is visible, *m*/*z* = 387 (^{11}B), but N_2-abstraction of this fragment (**1** − N_2), typical for azides, is not observed.

The findings of the vibrational data indicate that **1a** is not monomeric in the solid state, which is in contrast to the structure of the starting material $(C_6F_5)_2BCl$ as determined by single X-ray diffraction techniques.[8] The solid state structure of **1a** (dimeric) has been determined by single crystal X-ray diffraction and confirmed the oligomeric skeleton proposed on the basis of vibrational (IR, Raman) spectroscopy (Fig. 2).‡

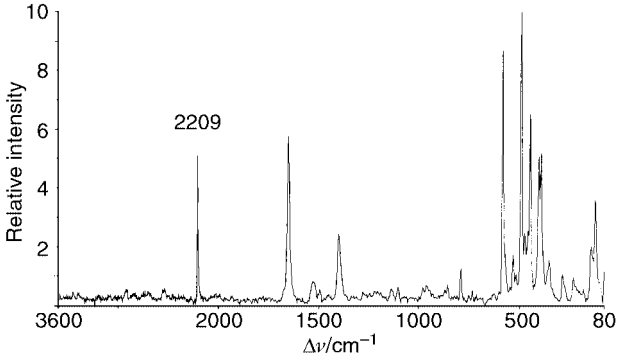

Fig. 1 Raman spectrum of **1a**.

Single crystals suitable for X-ray diffraction studies were obtained by cooling a concentrated solution of **1** in toluene. **1a** crystallized in the space group *C2/c* with four formula units in the unit cell. The B_2N_2 ring is planar with a B–N–B angle of 97.2(1)° and a N–B–N angle of 82.8(1)°. The B–N distances of 1.59/1.60 Å have typical B–N single bond character. The azide group is slightly bent with a N–N–N angle of 177.5(2)° which is in accord with the structures of other covalent boron azides previously determined.[2*b*,4,9*a,b*] The N1–N2 bond distance is 1.241(2) Å and comparable with the corresponding N–N distance found in $(BCl_2N_3)_3$ (1.25 Å); the N2–N3 distance is 1.113(3) Å indicating considerable triple bond character (N≡N 1.098 Å).[4,10*a–c*]

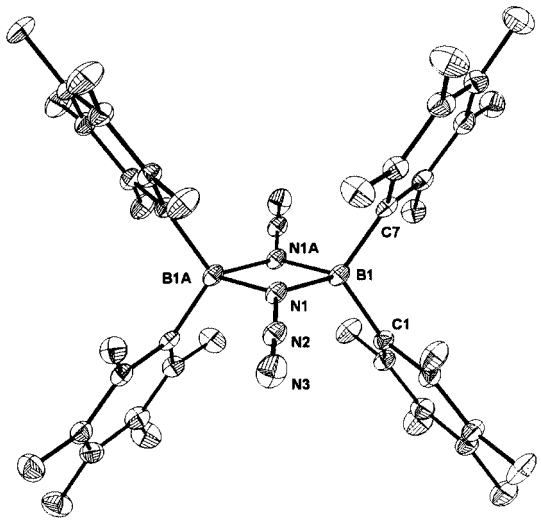

Fig. 2 ORTEP plot of the molecular structure of **1a** with thermal ellipsoids drawn at the 25% probability level. Selected bond lengths (Å) and angles (°): B(1)–N(1) 1.591(3), B(1A)–N(1) 1.601(2), N(1)–N(2) 1.241(2), N(2)–N(3) 1.113(3), B(1)–C(1) 1.607(3), C–F 1.33–1.35; N(1)–N(2)–N(3) 177.5(2), N(2)–N(1)–B(1) 130.3(2), N(1)–B(1)–N(1A) 82.8(1), B(1)–N(1)–B(1A) 97.2(1), C(7)–B(1)–C(1) 113.5(2), C(7)–B(1)–N(1) 115.2(2), C(1)–B(1)–N(1) 114.3(2), C(7)–B(1)–N(1A) 113.4(2).

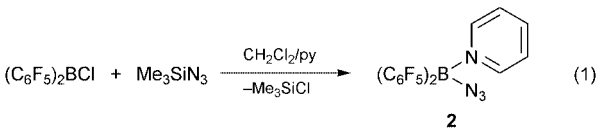
DOI: 10.1039/b001103g

The results of the X-ray analysis, Raman and IR spectroscopy prove **1a** as the first example of a *N*,*N*′-diazodiazadiboratacyclobutane. The dimerization can be explained by the electronic character of the boron atom in **1**. The electron-withdrawing pentafluorophenyl substituents create a highly electron deficient boron atom which stabilizes itself to a borate **1a** with the formation of a σ-bond to the α-nitrogen atom of another molecule **1**.

The reaction was also carried out in the presence of pyridine yielding the new adduct $(C_6F_5)_2BN_3$·py **2** as a colorless solid [eqn. (1)].†



(1)

2

This adduct **2** is soluble in toluene, dichloromethane, diethyl ether and chloroform but insoluble in hexane. The IR spectrum shows a very strong absorption at 2137 cm^{-1} and the Raman spectrum shows a weak peak at 2138 cm^{-1} which can be assigned to the asymmetric stretching vibration of the azide group, and is comparable with those found in other reported adducts of this type [Ph_2BN_3·py $\nu_{as}(N_3)$ = 2110 cm^{-1}].[2e] The NMR data and elemental analysis are consistent with the product proposed in eqn. (1). The chemical shift for **2** [$\delta(^{11}B)$ −0.5] is in the region of four-coordinate boron, the ^{14}N NMR shows four resonances at δ −144 (N_β), −159 (N-py), −204 (N_γ) and −308 (N_α).

Further investigations of the chemistry of pentafluorophenyl substituted boron azides are in progress and will be reported in a full paper.

Financial support of this work by the University of Munich and the Fonds der Chemischen Industrie is gratefully acknowledged.

Facile synthesis of α-amino phosphonates in water using a Lewis acid–surfactant-combined catalyst

Kei Manabe and Shū Kobayashi*

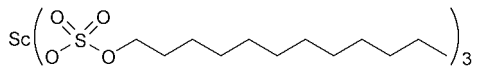
Graduate School of Pharmaceutical Sciences, The University of Tokyo, CREST, Japan Science and Technology Corporation (JST), Hongo, Bunkyo-ku, Tokyo 113-0033, Japan. E-mail: skobayas@mol.f.u-tokyo.ac.jp

Received (in Cambridge, UK) 7th January 2000, Accepted 6th March 2000
Published on the Web 30th March 2000

Three-component reactions of aldehydes, amines and triethyl phosphite were efficiently catalyzed by scandium tris(dodecyl sulfate) at ambient temperature in water to give various α-amino phosphonates in high yields.

α-Amino phosphonates constitute an important class of biologically active compounds, and their synthesis has been a focus of considerable attention in synthetic organic chemistry as well as in medicinal chemistry.[1] Most synthetic methods reported utilize reactions of imines with phosphorus nucleophiles. Recently, it has been shown that three-component reactions of aldehydes (or ketones), amines, and diethyl phosphite [HOP(OEt)$_2$] were efficiently promoted by catalytic amounts of Lewis acids such as ytterbium triflate[2] and indium chloride[3] in dichloromethane (CH_2Cl_2) or THF at ambient temperature. Although these procedures do not require the isolation of the unstable imines prior to the reactions, reaction times of longer than 10 h are necessary to obtain the desired products in good yields at room temperature. In addition, the use of harmful organic solvents such as CH_2Cl_2 is undesirable from the viewpoint of today's environmental consciousness.

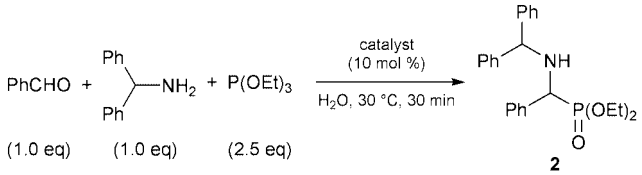
In the course of our investigations to develop environmentally friendly synthetic methods, we have found that surfactant-type Lewis acids function as effective catalysts for aldol reactions in water without using organic solvents.[4] The catalysts, which we denote Lewis acid–surfactant-combined catalysts (LASCs), consist of Lewis acidic metal cations such as scandium(III) and amphiphilic anions such as dodecyl sulfate, and form stable colloidal dispersions in the presence of organic substrates in water. Here we report that scandium tris(dodecyl sulfate) **1**, a representative LASC, effectively catalyzes three-component reactions of aldehydes, amines and triethyl phosphite [P(OEt)$_3$] in water to give α-amino phosphonates in high yields.



1

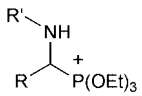
First, the reaction of benzaldehyde, benzhydrylamine and P(OEt)$_3$ was tested as a model reaction in the presence of various catalysts in water (Table 1). When LASC **1** was used as a catalyst, the reaction proceeded smoothly to afford the desired product **2** in good yield (entry 1). On the other hand, sodium dodecyl sulfate (SDS) or scandium triflate gave **2** in very low yields (entries 2 and 3). These results indicate that both the Lewis acidic cation and the anionic surfactant are indispensable for the efficient catalysis. LASC **1** was much superior to dodecylbenzenesulfonic acid (DBSA, entry 4), a surfactant-type Brønsted acid which has been successfully used for three-component Mannich-type reactions in water.[5] Furthermore, the reaction under neat conditions without any solvents proceeded slowly (entry 5), indicating that water as a solvent plays an essential role for acceleration of the reaction. It was interesting to find that a reaction with HOP(OEt)$_2$, which has been used as a phosphorus nucleophile in the Lewis acid-catalyzed synthesis of α-amino phosphonates in organic solvents,[2,3] scarcely proceeded (entry 6). Thus, the use of P(OEt)$_3$ instead of HOP(OEt)$_2$ is a characteristic of our system. Mechanistically, P(OEt)$_3$ attacks an imine, which is formed from an aldehyde and an amine *in situ* and then activated by the Lewis acid, to generate phosphonium intermediate **3**. In contrast to the reactions in organic solvents, hydrolysis of **3** to the corresponding phosphonate should occur rapidly in water without causing any side reactions. This rapid hydrolysis makes the use of P(OEt)$_3$ possible in the present catalytic system. Unfortunately, an excess of P(OEt)$_3$ is needed at the present stage, since it is gradually hydrolyzed to HOP(OEt)$_2$ in water. Under the same reaction conditions as those in entry 1, the reaction in the absence of the amine afforded only a trace amount of diethyl 1-hydroxy-1-phenylmethylphosphonate. This result indicates that imines are activated by **1** more effectively than aldehydes.

Table 1 Three-component synthesis of α-amino phosphonate **2** in water



Entry	Catalyst	Yield(%)
1	**1**	71
2	SDS (30 mol %)	8
3	Sc(OTf)$_3$	6
4	DBSA	18
5[a]	**1**	31
6[b]	**1**	Trace

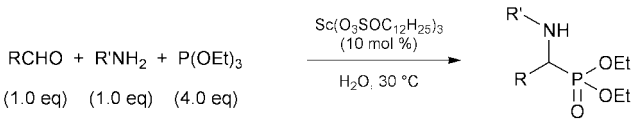
[a] Under neat conditons. [b] HOP(OEt)$_2$ (2.5 eq.) was used instead of P(OEt)$_3$.



3

The reactions of various aldehydes and amines with P(OEt)$_3$ in the presence of **1** in water gave the corresponding α-amino phosphonates in high yields as shown in Table 2.† Not only benzaldehyde (entries 1–6) but also other aromatic (entries 7 and 8), heteroaromatic (entry 9) and aliphatic aldehydes (entries 10 and 11) worked well to give the phosphonates in high yields, although α,β-unsaturated aldehydes such as cinnamaldehyde (entry 12) afforded the desired products in lower yields. A characteristic point of these reactions is the extremely short reaction time. When using aniline-type amines such as aniline

Table 2 Three-component synthesis of α-amino phosphonates in water



Entry	RCHO	R'NH$_2$	*t*/min	Yield (%)
1	PhCHO		60	83
2	PhCHO	PhNH$_2$	20	88
3	PhCHO		20	86
4	PhCHO		60	84
5	PhCHO		60	78[a]
6	PhCHO		60	80[b]
7		PhNH$_2$	30	85
8		PhNH$_2$	20	80
9			120	78
10			60	83
11			60	95
12			20	53

[a] 56% de. [b] 61% de.

and *o*-anisidine, the reaction proceeded rapidly, and > 80% yields of the products were attained in 20–30 min (entries 2, 3, 7, and 8). Thus, the turnover frequencies (TOFs) for these reactions are 17–26 h^{-1}, in contrast to the reported procedures in organic solvents, in which the TOFs are < 1 h^{-1}.[2,3] While several organic reactions in water have been developed so far,[6] most of them proceeded slowly in water compared with the corresponding synthetic methods in organic solvents. It is noted that the use of an LASC, a new type of Lewis acid, creates excellent hydrophobic reaction fields to realize the rapid three-component reactions in water. Use of chiral amines, (*R*)-1-phenylethylamine and (*R*)-1-(1-naphthyl)ethylamine, resulted in modest diastereoselectivities (entries 5 and 6).

In conclusion, three-component reactions of aldehydes, amines and triethyl phosphite were effectively catalyzed by LASC **1** to give various α-amino phosphonates in high yields. It should be noted that these high yields were obtained in water, at ambient temperature, and at high reaction rates. This reaction system not only provides a novel method for the synthesis of biologically important α-amino phosphonates but also extends the applicability of LASCs in organic synthesis in water to lead to environmentally friendly chemical processes.

Notes and references

† *General procedure* for the synthesis of α-amino phosphonates: an amine (0.25 mmol), an aldehyde (0.25 mmol) and $P(OEt)_3$ (1.0 mmol) were successively added to a mixture of LASC **1** (0.025 mmol, 10 mol%) in water (1.5 mL) at 30 °C. The mixture was stirred at the same temperature for 20–120 min, and then 1 M NaOH (5 mL) was added. After stirring at room temperature for 15–30 min, brine (5 mL) was added, the mixture extracted with ethyl acetate (30 mL), dried over Na_2SO_4, and concentrated. Purification by silica gel chromatography afforded the desired product.

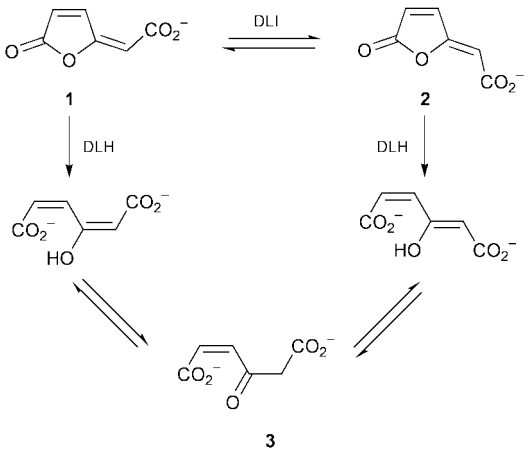
Replacing the active site Cys-123 of dienelactone hydrolase with Ser completely changes the catalysis displayed by the protein, from hydrolysis of the substrate *E*- and *Z*-dienelactones to maleylacetate by the native enzyme, to interconversion of the substrates by the mutant, dienelactone isomerase.

Dienelactone hydrolase (EC 3.1.1.45) from *Pseudomonas* sp. B13 (DLH Type III) catalyses the hydrolysis of the *E*- and *Z*-dienelactones **1** and **2** to give maleylacetate **3** (Scheme 1),[1] as part of the chlorocatechol branch of the β-ketoadipate pathway for the biodegradation of toxic aromatic compounds.[2] The activity of DLH derives from a catalytic triad of amino acids at its active site, comprising Cys-123 aligned for nucleophilic attack on the substrates by the adjacent His-202 and Asp-171 residues.[3,4] This triad is a hybrid of those found in cysteine (Cys-His-Asn)[5] and serine (Ser-His-Asp)[6] proteases, and has been observed in human and yeast ubiquitin *C*-terminal hydrolase[7] and engineered in mutant serine proteases such as thiol-subtilisin[8] and thiol-trypsin.[9] The mechanism of catalysis by DLH has been elucidated primarily through crystallographic analysis of both the native protein and several of its site specific mutants.[10] In one mutant (C123S), Cys-123 was replaced with Ser, to produce the catalytic triad found in serine proteases. We now report that this mutation completely changes the catalysis displayed by the protein, from hydrolysis of the substrates **1** and **2** by DLH to catalysis of their isomerisation by the mutant protein, dienelactone isomerase (DLI).



Scheme 1

The synthesis of the lactones **1** and **2**[11] and the procedures used to obtain the native and mutant proteins, DLH and DLI,[3,4,10] have been reported previously. The reactions of the proteins with the substrates **1** and **2** were examined in 0.02 mol dm^{-3} HEPES buffer containing 0.001 mol dm^{-3} EDTA, at pH 7.0 and 298 K. The products were characterised using HPLC and a diode array detector, thin layer chromatography and ^{1}H NMR spectrometry, by comparison with authentic samples. The kinetics of the reactions were studied by HPLC and by monitoring changes in absorbance at 280 nm by UV spectroscopy. The lactones **1** and **2** have λ_{max} values of 276 (ε 17200) and 277 (ε 17550 dm^3 mol^{-1} cm^{-1}) nm, and ε values of 17000 and 15625 dm^3 mol^{-1} cm^{-1} at 280 nm, respectively, while maleylacetate **3** shows negligible absorbance in this region.[1,12]
